Endoreceptors with Convergent Phenanthroline Units: A Molecular Cavity for Six Guest Molecules**

By *Fritz Vögtle,** *Ingo Lüer, Vincenzo Balzani,* and *Nicola Armaroli*

The cagelike bridging of three 2,2′-bipyridine units has so far afforded ligands whose conformational flexibility allows the nitrogen donor centers to be twisted.[1] The use of 1,10-phenanthroline instead of 2,2′-bipyridine promised to increase the preorganization of the binding sites directed toward the interior of large molecular cavities, as *Lehn* et al.[2a] have described for smaller ligands. In this way, it should be

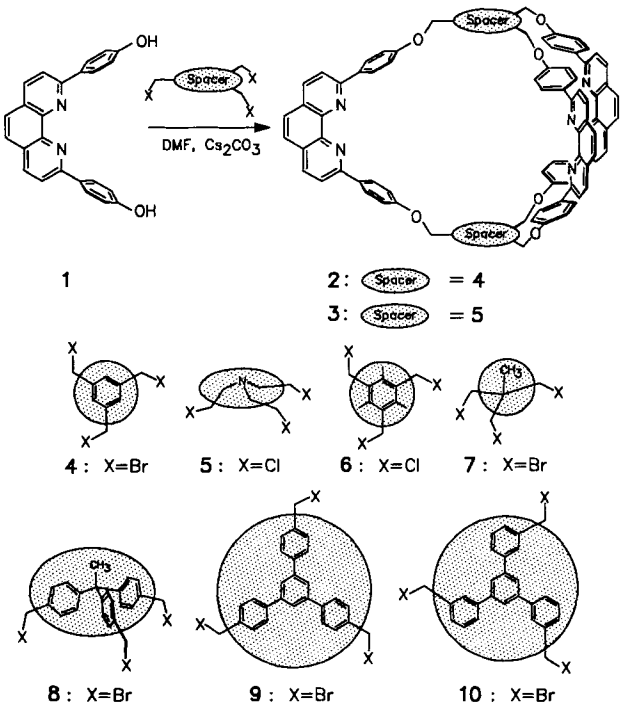
[**] This work was supported by the Bundesministerium für Forschung und Technologie (BMFT-0329120A). We thank Dr. *G. Eckhardt* and Dr. *S. Schuth*, Universität Bonn, for recording the FAB mass spectra and Prof. Dr. *E. Steckhan* and Dipl.-Chem. *M. Frede*, Universität Bonn, for recording and interpreting the cyclic voltammograms.

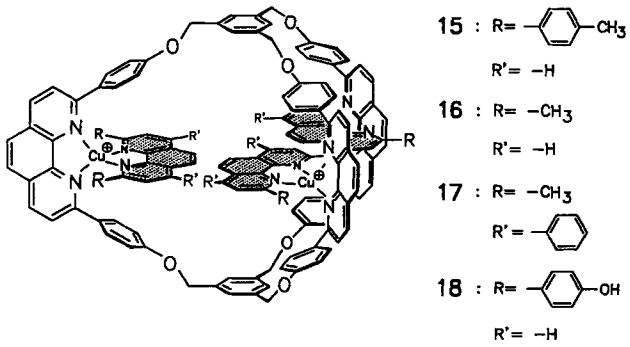
possible to confine several organic guest molecules in the interior of a *single* host molecule, thereby bringing them into close proximity—a prerequisite for controlled reactions in the cavities of tailored catalysts.

In the new endoreceptors[2b] **2** and **3**, the convergent arrangement of the donor centers realizes the desired extent of *endo* preorganization of the binding sites, while the conformational flexibility made possible by the ether bridges should result in little hindrance to the inclusion of guest molecules. The synthesis of **2** and **3** was accomplished in a one-step reaction of 2,9-bis(4-hydroxyphenyl)-1,10-phenanthroline (**1**), introduced by *Sauvage* et al.,[3] with **4**[4a] and **5**,[4b] respectively, in 11% und 2.3% yield. The ^{1}H NMR spectra, the FAB mass spectra, and the elemental analyses are consistent with the host structures proposed; the formation of the corresponding macrobicyclic hosts containing the spacers **6**–**10**[4c–e] was confirmed by FAB MS.

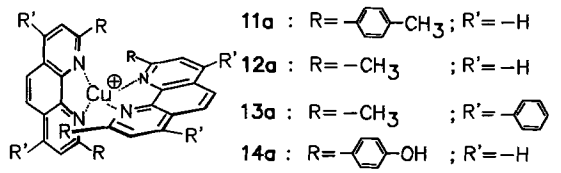


Like the bipyridine cavities described earlier,[1b] **2** and **3** were expected to form inclusion compounds with trihydroxybenzenes. However, attempts to complex 1,3,5-trihydroxybenzene were unsuccessful, as were efforts involving 1,3,5-tris(4-hydroxyphenyl)benzene, which fits better into the cavity. These results underline the demands of host/guest complementarity.

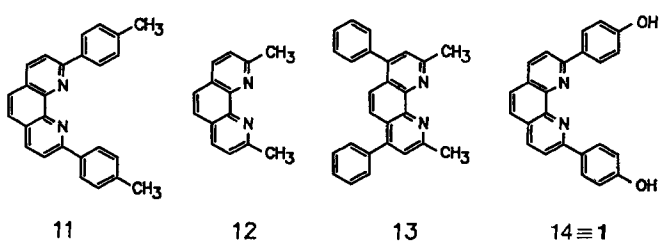
Surprisingly, however, inclusion of 2,9-disubstituted 1,10-phenanthrolines such as **11**–**14**, as their Cu^I complexes, takes place in the interior of the macrobicyclic host **2**. Treatment of a solution of **2** in dimethylformamide (DMF) with $[Cu(CH_3CN)_4]BF_4$ in CH_3CN, followed by addition of a solution of **11** or **12** in CH_2Cl_2, results in quantitative formation of complex **15** or **16**, respectively, both of which are stable in solution and to air. Elemental analysis gave the correct empirical formulas for $[\mathbf{15}(BF_4)_3] \cdot 3\,H_2O$ and $[\mathbf{16}(BF_4)_3] \cdot 3\,H_2O$ and FAB MS and ^{1}H NMR spectroscopy established the presence of *endo* complexes. FAB mass spectra confirmed the composition of **15** and **16**: peaks at *m/z* 2765 and *m/z* 2307 correspond to $[\mathbf{15}(BF_4)_2]^{\oplus}$ and $[\mathbf{16}(BF_4)_2]^{\oplus}$, respectively; further peaks correspond to the fragmentation products formed by stepwise loss of phenanthroline and $Cu^{\oplus}$. The ^{1}H NMR spectrum of **15** (5×10^{-3} M in CD_2Cl_2) indicates a symmetric arrangement of the guests in the cavity: the signals of the OCH_2 protons are shifted to higher field compared with those of the free ligand **2** by $\Delta\delta = 0.38$ to give a single, somewhat broad signal at $\delta = 5.00$. The signals of the mutually interacting phenylene groups of the bis(4-methylphenyl)phenanthroline (**11**) guest and the bis(oxyphenyl)phenanthroline unit of the ligand are both shifted to higher field.[3b] The signals of the methyl groups of the phenanthroline guest are shifted by $\Delta\delta = 0.06$ to higher field ($\delta = 1.90$) compared with those of the complex **11a**; the signal intensities are those expected for a complex with three $Cu^{\oplus}$ centers and three phenanthroline guests.



In complex **16**, the signals of the OCH_2 protons ($\delta = 4.78$) are shifted more strongly to higher field than those in **15** ($\Delta\delta = 0.6$). The inclusion of neocuproine (**12**) also causes high-field shifts of the signals for the phenylene protons of the bis(oxyphenyl)phenanthroline. The signals of the methyl groups of neocuproine are at higher field compared with those of complex **12a**[3b] by $\Delta\delta = 0.2$ and their intensity ratios are those expected. Accordingly, **2** is a true endoreceptor. The convergent arrangement of the donor centers forces the guest molecules to "dock" within the cavity. Steric factors prevent the guests from swinging freely.



The space available in the cavity of **2** is not unlimited, however. Whereas three 2,9-disubstituted phenanthroline molecules fit into the cavity, only two molecules of bathocuproine (**13**, R' = phenyl), which is larger, were found by FAB MS to undergo inclusion under analogous conditions.



Although host **2** is sparingly soluble in CH_2Cl_2, complexes **15** and **16**, obtained by inclusion of **11** and **12**, respectively, are readily soluble. Attempts to synthesize **18**, on the other hand, led to a substance that was sparingly soluble in CH_2Cl_2 and could not be purified any further. ^1H NMR spectra indicate the presence of a mixture of **18** and **14a**.

Table 1. Absorption and luminescence data for **11a**, **12a**, **15**, and **16** [a].

Complex	λ_{max}^{abs} [nm] [b]	λ_{max}^{em} [nm] [c]	$\varphi^{em} \times 10^3$ [d]	τ_{em} [ns] [e]
11a	440	720	1.70	237
12a [f]	457	750	0.40	73
15	437	730	0.70	170
16	443	760	0.08	50

[a] Room temperature, degassed CH_2Cl_2 solution. [b] Absorption maximum at the longest wavelength. [c] From corrected emission spectra; estimated error $\pm$ 5 nm. [d] Quantum yield; estimated error ca. 25 %. [e] Lifetime; estimated error $\leq$ 10 %. [f] See also [5b].

The absorption and luminescence data for **11a** and **12a** as well as for **15** and **16** are summarized in Table 1; the emission maxima are corrected. Figure 1 shows the absorption and (uncorrected) luminescence spectra of **15** and **16**. The photophysical properties of **12a** and similar complexes, including the Cu^I catenate, are well-investigated.[5] The intense absorp-

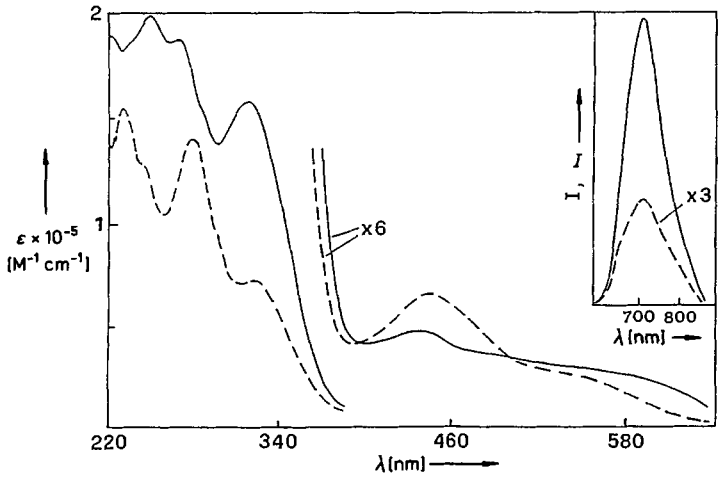


Fig. 1. Absorption and (superimposed) uncorrected luminescence spectra of **15** (——) and **16** (– – –) in CH_2Cl_2.

tion bands in the UV region are due to π–π^* ligand-centered transitions, while the bands appearing in the visible region are assigned to metal-to-ligand charge-transfer (MLCT) transitions. The three metal-containing chromophoric units of the trinuclear complexes **15** and **16** are equivalent. The luminescence bands of **15** and **16** should be assigned to an MLCT-excited state involving the ligands **11** and **12**, respectively. This assumption is based on the observed redshift of the luminescence bands of **15** and **16** with respect to those of **11a** and **12a**, respectively, which is expected on replacing a ligand in **11a** and **12a** by the more basic[5e] bis(anisyl)-phenanthroline unit of the macrobicyclic host. The tolyl substituents in **15** and **11a** protect the excited state against the formation of short-lived exciplexes and this is reflected in an increase in the luminescence intensity and lifetime compared to those of **16** and **12a**.[5d]

The stabilizing effect of tolyl substituents in the guest is also evident in the cyclic voltammetry measurements on **15** and **16**. Although adsorption effects at the glassy-carbon working electrode make the investigation of the complexes difficult, a chemically largely reversible reduction was detected for **15** and can be assigned to the formal transition $Cu^I \rightarrow Cu^0$. In contrast, **16** is reduced irreversibly.

The new type of complex offers the possibility of using the methods developed by *Sauvage* et al.[3d–e] to synthesize a previously unknown type of catenane in which **2** would be symmetrically interlaced with three crown ethers. The confinement and orientation of three guests in close proximity in a *single* cavity, achieved here for the first time, opens up new possibilities for the development of catalysts for selective reactions between several oriented guests within a molecular cavity.

Experimental Procedure

2: A solution of **1** (3.3 g, 9 mmol) in 250 mL of dry DMF and a solution of **4** (2.14 g, 6 mmol) in 250 mL of DMF were added simultaneously to a solution of $CsCO_3$ (8 g) in 1.2 L of DMF under argon at 70 °C over 15 h. The reaction mixture was then stirred for an additional 15 h at 70 °C. After removal of the solvent, the residue was extracted into $CHCl_3$ and purified by chromatography on silica gel (eluent: CH_2Cl_2/MeOH, 10 : 1) (R_f value: 0.63); m.p. 282–285 °C. ^1H NMR (200 MHz, $CDCl_3$/TFA): δ = 5.38 (s, 12 H), 7.35 (d, 12 H, ^3J = 9 Hz), 7.63 (s, 6 H), 8.08 (d, 12 H, ^3J = 9 Hz), 8.37 (s, 6 H), 8.5 (d, 6 H, ^3J = 8 Hz), 9.07 (d, 6 H, ^3J = 8 Hz). FAB-MS (matrix: *m*-nitrobenzyl alcohol): *m/z* 1321 ($M^{\oplus}$ + H). The extreme low solubility of **2** in pure $CDCl_3$ only allowed an ^1H NMR spectrum of unsatisfactory quality to be recorded; it is clearly evident, however, that the shift of the OCH_2 protons is unchanged with respect to the measurement in $CDCl_3$/TFA (δ = 5.39). the aromatic protons absorb at δ = 7.17–8.33.

3: Synthesized analogously to **2**. The product was obtained by column chromatography on silica gel (eluent: CH_2Cl_2/MeOH, 40 : 1) (R_f value: 0.27); m.p. 263 °C. ^1H NMR (90 MHz, CD_2Cl_2): δ = 3.2 (t, 12 H, ^3J = 5 Hz), 4.26 (t, 12 H, ^3J = 5 Hz), 7.06 (d, 12 H, ^3J = 9 Hz), 7.55 (s, 6 H), 7.82 (d, 6 H, ^3J = 8 Hz), 8.04 (d, 6 H, ^3J = 8 Hz), 8.26 (d, 12 H, ^3J = 9 Hz). FAB-MS (matrix: dithioerythritol/dithiothreitol + 2 N HCl): *m/z* 1283 (100 %), ($M^{\oplus}$ + H), 1256 (17 %).

15–17: $[Cu(CH_3CN)_4BF_4$ (95 mg, 0.3 mmol) [6] in 15 mL of degassed CH_3CN was added to **2** (132 mg, 0.1 mmol) in 20 mL of degassed DMF with stirring under argon. The solution turned red-brown. It was stirred for a further 10 min, after which the phenanthroline guest (0.3 mmol), dissolved in 15 mL of degassed CH_2Cl_2, was added continuously over 1 h. After 3 h, the reaction mixture was evaporated to dryness and the residue dissolved in CH_2Cl_2. The product was isolated by preparative layer chromatography (PLC) (eluent: CH_2Cl_2/methanol, 10 : 1) and recrystallized from CH_2Cl_2/benzene. [**15**$(BF_4)_3$] · 3 H_2O: Fp = 302–303 °C; [**16**$(BF_4)_3$] · 3 H_2O: Fp = 285–287 °C. **11a**, **13a**, **14a**: Synthesized analogously to **12a** [3b].

The absorption spectra were recorded with a Perkin-Elmer λ6 spectrophotometer; the luminescence spectra were obtained with a Perkin-Elmer 650-40 spectrofluorimeter. The emission lifetimes were measured with an Edinburgh single photon counting apparatus. The quantum yields were determined with $[Os(bpy)_3]^{2\oplus}$ as standard ($\Phi = 5 \times 10^{-3}$ in CH_3CN at room temperature) [7].

[3 + 2] Cycloadditions with Azirine Radical Cations: A New Synthesis of *N*-Substituted Imidazoles**

By *Felix Müller* and *Jochen Mattay**

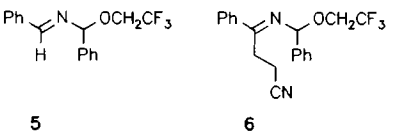
Dedicated to Professor Kurt Schaffner on the occasion of his 60th birthday

Recently, much attention has been focused on the investigation of reactions involving photoinduced electron transfer (PET), especially the PET-catalyzed ring opening of highly strained carbo- and heterocycles.[1] Here we report on the reactions of azirines, a group of compounds frequently used in 1,3-dipolar cycloaddition reactions,[2] under photosensitized (electron-transfer) irradiation conditions.

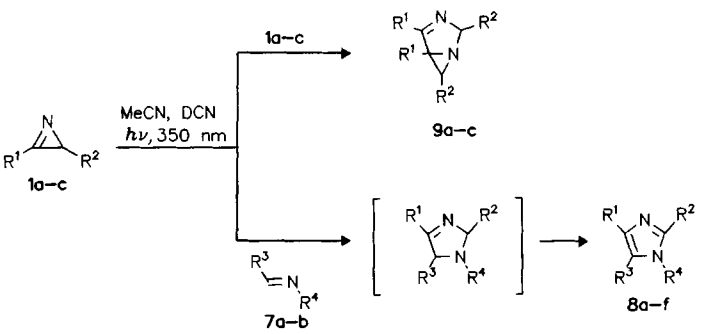
Photochemical irradiation usually results in energy transfer to a substrate either by direct excitation or through a triplet sensitizer. PET, however, generally proceeds by the irradiation of an electron acceptor. For this purpose cyanoarenes such as 1,4-napthalenedicarbonitrile (DCN) are very useful.

Since the n–π^* transition of azirines such as **1a** occurs at a wavelength of 280 nm,[2] irradiation with light of 350-nm wavelength does not lead to the direct excitation of the substrate. However, DCN is excited and abstracts an electron from the azirine.[3] As observed for direct excitation,[2] the C–C bond of azirine is thereby broken. We regard the formation of the 2-azaallenyl radical cation **2** as an intermediate. This species reacts with acrylonitrile under ring closure and back electron transfer to give the five-membered ring **4**. The addition thus proceeds via a two-step mechanism. The photoinduced 1,3-dipolar cycloaddition of azirines described by *Padwa* et al.[4] leads to a very high diastereoselectivity. Compound **4b** is formed in a yield of 90%, whereas that of **4a** is just 10%. In contrast, we found a product ratio of 50:50 when DCN catalysis was used.

Scavenging with 2,2,2-trifluoroethanol resulted in **5** and **6** as products.[5] Compound **5** is the trapped product of the 2-azaallenyl radical cation **2**. The formation of **6** is easily explained by the trapping of **3a/3b**, which were formed through reaction of **2** with acrylonitrile. Thus, dihydropyrroles **4** are not formed via a concerted [3 + 2] cycloaddition, as is the case for direct irradiation.[4]



The reaction does not proceed upon 350-nm irradiation in the absence of DCN or in the presence of a triplet sensitizer (benzophenone). When we compared the reactivity of **2** with nitrile ylides generated by direct irradiation, we noted that the reaction is favored for olefins substituted with electron-withdrawing groups; for instance, the reaction with vinyl ethers does not lead to five-membered rings. If there is no suitable reaction partner, azirines will dimerize, via [3 + 2] cycloaddition[4,6] to give **9**. Both nitrile ylides and 2-azaallenyl radical cations react with aldehydes and ketones to form 3-dihydrooxazoles.[6]



Scheme 2. **1a**, $R^1 = R^2$ = phenyl; **1b**, R^1 = phenyl, R^2 = H; **1c**, R^1 = *n*-butyl, R^2 = H; **7a**, R^3 = phenyl, R^4 = *n*-propyl, **7b**, $R^3 = R^4$ = *n*-propyl.

[**] Radical Ions and Photochemical Charge-Transfer Phenomena (Series A), Part 31, and Cycloadditions (Series B), Part 35. This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and the state of Nordrhein-Westfalen. We also thank Bayer AG for generous gifts of materials. *F. M.* would like to thank the Studienstiftung des deutschen Volkes for a predoctoral grant. Series A, Part 30: J. Mattay, M. Vondenhof, *Top. Curr. Chem. 159* (1991) 219. Series B, Part 34: M. Conrads, J. Mattay, *Chem. Ber. 124* (1991) 1425.

The radical cation **2** is also able to attack the C–N double bond in imines in an intermolecular fashion, a reaction not possible for photochemical 1,3-dipolar cycloaddition.[6] The reaction of azirines with imines leads to the formation of the *N*-substituted imidazoles.

The course of the reaction is as follows: Addition of the radical cation **2** to the imine is followed by ring closure to form a dihydroimidazole. Under these reaction conditions the dihydroimidazole is not stable and undergoes subsequent aromatization, so that, even in the crude product, no dihydroimidazole is detected. *Huisgen*[7] did not find a dihydroimidazole under comparable conditions either. The reaction of azirines with imines offers a ready approach for the synthesis of *N*-substituted imidazoles with a wide variety of substituents.

Since the C–N double bonds of the imine and the azirine compete for reaction, the yields of imidazoles vary rather widely (Table 1). The remaining products are the azirine dimers. Nevertheless, compared to classical procedures,[8] the yields of this direct synthesis are quite high. Furthermore, the ready availability of starting materials offers plenty of new synthetic opportunities.

Table 1. Yields of the new imidazoles **8**.

Compd	R^1	R^2	R^3	R^4	Yield
8a	phenyl	phenyl	phenyl	*n*-propyl	87% [8] [a]
8b	phenyl	H	phenyl	*n*-propyl	12% [b]
8c	*n*-butyl	H	phenyl	*n*-propyl	3% [c]
8d	phenyl	phenyl	*n*-propyl	*n*-propyl	25% [d]
8e	phenyl	H	*n*-propyl	*n*-propyl	35% [e]
8f	*n*-butyl	H	*n*-propyl	*n*-propyl	40% [f]

[a] **9a**, 12%; [b] **9b**, 85%; [c] **9c**, 95%; [d] **9a**, 74%; [e] **9b**, 60%; [f] **9c**, 57%.

Experimental Procedure

The azirines were prepared according to [9], the imines according to [10]. The synthesis of DCN is described in [11]. A solution of the azirine (0.3 mmol) and the imine (1.0 mmol, in 10 mL of acetonitrile was poured into a Pyrex tube. 1,4-Naphthalenedicarbonitrile (0.1 mmol, 18 mg) was added, the reaction solution deoxygenated by argon bubbling, and the tube sealed. Irradiation was carried out by means of a Rayonet photochemical reactor and 350-nm radiation lamps. Irradiation was maintained for 6–10 hours. The solvent was then evaporated and the residue separated by flash chromatography on alumina (Merck Neutral Act. I) using diethyl ether as eluent. The new compounds gave satisfactory ^{1}H NMR, ^{13}C NMR, and mass spectroscopic data, which are similar to the data of comparable compounds [12].

Laser Flash Photolysis Generation, Spectra, and Lifetimes of Phenylcarbenium Ions in Trifluoroethanol and Hexafluoroisopropyl Alcohol. On the UV Spectrum of the Benzyl Cation**

By *Robert A. McClelland,* Christopher Chan, Frances Cozens, Agnieszka Modro*, and *Steen Steenken* *

Dorfman and co-workers have reported reactivities of $Ph_3C^{\oplus}$, $Ph_2CH^{\oplus}$, and $PhCH_2^{\oplus}$ with various nucleophiles in chlorinated hydrocarbon solvents.[1–3] The experiments were performed using the pulse radiolysis technique, with the cations obtained upon fragmentation of the initially formed radical cations. In the case of $Ph_3C^{\oplus}$ and $Ph_2CH^{\oplus}$, there were excellent matches of spectra of the transients observed in the pulse radiolysis experiments with ones obtained for solutions of authentic cations in concentrated acid and there

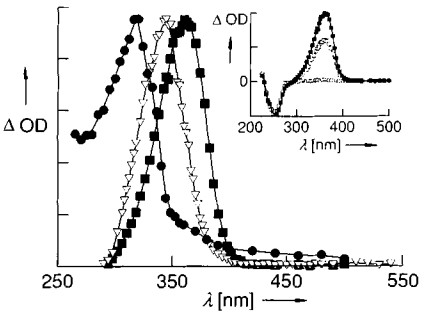

Fig. 1. Absorption spectra of the *p*-methoxycumyl cation (in TFE, ■), the *p*-methoxyphenethyl cation (in TFE, △), and the *p*-methoxybenzyl cation (in HFIP, ●). The precursors *p*-methoxy-α-methylstyrene, *p*-methoxystryrene, and *p*-methoxybenzyltrimethylammonium tetrafluoroborate were photolyzed at 248 nm with 20-ns pulses. Spectra were recorded 50–100 ns after the pulse. The insert shows the formation and decay of the cation and the (permanent) depletion of parent in the experiment with *p*-methoxy-α-methylstyrene, at 100 ns, 45 μs, and 500 μs after the pulse.

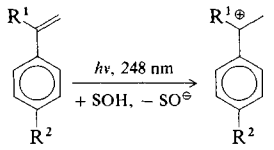
can be no question that the particular cations were being studied. With $PhCH_2^{\oplus}$, however, no spectrum from a "classical" source is available. The transient that was observed had an absorption maximum at 363 nm. Arguments that this represented $PhCH_2^{\oplus}$ were based upon the analogy with the other two systems, the observation of the same transient with different precursors, and the characteristic quenching by nucleophiles.[1] Using nanosecond laser flash photolysis ($\lambda = 248$ nm) we now have observed a number of substituted benzyl cations in trifluoroethanol (TFE) and hexafluoroisopropyl alcohol (HFIP). Our results lead to the conclusion that the 363-nm transient is unlikely to have been the benzyl cation.

The λ_{max} and rate constant data for the benzyl cations are summarized in Table 1, and spectra are shown in Figures 1 and 2 for the parent and *p*-methoxy series. In the case of the cumyl (**2**, R^1 = Me) and arylethyl (**2**, R^1 = H) cations, the styrenes **1** (R^1 = Me, H) were the precursors, with cation generation involving protonation of the electronically excited styrene by the solvent SOH [Eq. (a)]. This process, which



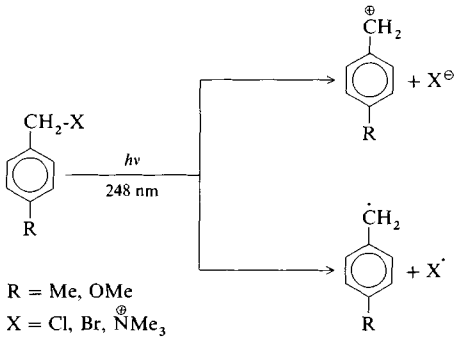
(a)

1 **2**

R^1 = H, Me; R^2 = H, Me, MeO; S = CF_3CH_2, $(CF_3)_2CH$

has previously been described for *p*-methoxystyrene in TFE,[4, 5] has now proved to be a general one for styrenes in these fluorinated alcohols, HFIP being particularly efficient. This weakly nucleophilic solvent[6] also permits the observation of the more reactive cations.

The benzyl cations were generated by photoheterolysis of appropriate precursors, *p*-methoxybenzyl from *p*-methoxybenzyltrimethylammonium fluoroborate[7, 8] and *p*-methoxybenzyl chloride and *p*-methylbenzyl from *p*-methylbenzyl chloride and bromide [Eq. (b)]. In these cases radicals arising from a competing photohomolysis[4, 7, 8] were also observed [Eq. (c)].



(b)

(c)

R = Me, OMe
X = Cl, Br, $\overset{\oplus}{N}Me_3$

Identification of transients as benzylic cations took several forms. (1) They were quenched in a manner characteristic of carbenium ions, with large rate accelerations upon addition of methanol and bromide (see insert to Figure 2 and Table 1 for the rate constants). Oxygen, on the other hand, had no effect. (2) The cations were formed in monophotonic processes, which shows that they are not derived from cation radicals, which could only be generated via biphotonic processes.[9] (3) The appropriate products were observed, for example, *p*-methoxybenzyl trifluoroethyl ether upon photolysis of $4\text{-}MeOC_6H_4CH_2N(CH_3)_3 \cdot BF_4$ in TFE, and the Markovnikov adducts of both styrene and α-methylstyrene with the solvent HFIP. (4) For the *p*-methylbenzyl cation, which decays in HFIP with $k_s = 2 \times 10^6\ s^{-1}$, a rate constant of $1.0 \times 10^{10}\ M^{-1}\,s^{-1}$ was measured for reaction with bromide (added as the $nBu_4N^{\oplus}$ salt, Table 1), giving $k_{Br^{\ominus}}/k_s = 5 \times 10^3\ M^{-1}$. The solvolysis of *p*-methylbenzyl bromide in HFIP containing nBu_4NBr showed pronounced common ion inhibition, from which the $k_{Br^{\ominus}}/k_s$ ratio was calculated to be $5 \times 10^3\ M^{-1}$, identical with the number obtained from observation of the cation. (5) For the parent cumyl cation, the spectrum of the transient in HFIP is virtually identical to that reported by *Olah* et al. for the same cation in SO_2–SbF_5–FSO_3H ($\lambda_{max} = 390$ nm, $\varepsilon = 1400$; $\lambda_{max} = 326$, $\varepsilon = 11\,000$).[10] With the latter extinction coefficient, the quantum yield for formation of the cumyl cation upon irradiation of α-methylstyrene in HFIP was calculated, using a previously described technique,[11] as 0.08.

Table 1. λ_{max} [nm] and rate constants (20 °C) for reaction of derivatives of benzyl cations with solvent (k_s) and with $Br^{\ominus}$ ($k_{Br^{\ominus}}$) and MeOH (k_{MeOH}) in TFE and HFIP. The cations were generated by 248-nm laser flash photolysis according to Equations (a) and (b).

Cation	Cumyl	Phenethyl	Benzyl
4-Methoxy			
λ_{max}	360	340	320, ~360 [a]
k_s (TFE) [b]	1.6×10^4	3.9×10^5	4.3×10^6 (9×10^6) [c]
k_s (HFIP) [b]	$<10^2$	$<10^2$	3.2×10^2
$k_{Br^{\ominus}}$ [d]	1.1×10^8 (TFE) [e]	4.5×10^9 (TFE)	4.8×10^9 (HFIP)
k_{MeOH} [d]	9.1×10^5 (TFE)	5.6×10^6 (TFE)	5.8×10^5 (HFIP)
4-Methyl			
λ_{max}	340, ~380 [a]	325, ~390 [f]	310 [g]
k_s (TFE) [b]	1×10^7	$>5 \times 10^7$	$>5 \times 10^7$
k_s (HFIP) [b]	6×10^2	5×10^4 [h]	2×10^6
$k_{Br^{\ominus}}$ (HFIP) [d]	1.3×10^9	7.2×10^9	1.0×10^{10}
k_{MeOH} (HFIP) [d]	3.4×10^5 [j]	1.1×10^7	6.5×10^7
4-H			
λ_{max}	325, ~410 [f]	315, ~430 [f]	
k_s (HFIP) [b]	9×10^3	6×10^5 [h]	
$k_{Br^{\ominus}}$ (HFIP) [d]	6.7×10^9	8.2×10^9	
k_{MeOH} (HFIP) [d]	4.1×10^6	4.3×10^7	

[a] Shoulder. [b] Units s^{-1}. [c] The rate constant $9 \times 10^6\ s^{-1}$ was obtained in 1:1 TFE/acetonitrile with both $4\text{-}MeOC_6H_4CH_2N(CH_3)_3 \cdot BF_4$ and $4\text{-}MeOC_6H_4CH_2Cl$ as precursors. In 100% TFE and 100% HFIP, the choride undergoes rapid thermal solvolysis. [d] Units $M^{-1}s^{-1}$. [e] The reaction is reversible (F. Cozens, to be published). [f] λ_{max} approximate, peak is about 10% of major one (see Fig. 2). [g] Weak absorbance also at higher λ, but this is obscured by other weak transient(s). [h] Extrapolated to zero styrene concentration. These cations also react with excess styrene remaining after photolysis. [j] The k_{obsd} vs. [MeOH] plot is curved upwards. The number indicated is from a linear fit in the [MeOH] range 0.1 to 0.35 M.

These experiments establish that simple benzyl cations such as cumyl and phenethyl do exist as free ions in HFIP. However, the benzyl cation itself was not observed in this solvent when precursors such as benzyl halides were used. We estimate its lifetime to be in the range 2–20 ns, just beyond the limit of detection of our apparatus. The spectra of the other eight cations have a major peak with λ_{max} in the range 310–360 nm, with the trend λ_{max} (4-MeO) > λ_{max} (4-Me) > λ_{max} (H) for a given type of cation (as is also observed for $Ar_3C^{\oplus}$ and $Ar_2CH^{\oplus}$),[11, 12] while for a given *para* substituent, λ_{max}(cumyl) > λ_{max}(phenethyl) > λ_{max}(benzyl). There is also absorbance at higher wavelengths that is associated with the cation, as concluded from the identity of the decay and quenching characteristics with those of the major peak, and as observed in strong acids with the cumyl cation.[10] This absorbance appears as a shoulder or weak peak with

most of the cations, the exceptions being *p*-methoxycumyl and *p*-methoxyphenethyl. The dependence of λ_{max} on structure is less precisely defined because of the weakness of this absorbance, but it appears to be exactly opposite to that seen in the stronger peaks at lower wavelength. Examination of the trends in both bands leads to the prediction that the parent benzyl cation has a strong band with λ_{max} 300–310 nm and a weak peak (about 10% of the strong band) at 430–460 nm. In contrast, the transient observed in the pulse radiolysis experiments by *Dorfman* et al.[1] was a single broad peak with λ_{max} at 363 nm and weak absorbance at 320 and 420 nm (see Figure 2 of Ref. [1]). We conclude that this was not the benzyl cation. One possibility is that the transient observed was due to a cyclohexadienyl cation arising from coupling of an initially generated cation or cation radical with unreacted precursor. Cyclohexadienyl cations of this type would absorb in this region.[3] Consistent with a bimolecular mechanism for its formation, the amplitude of the 363-nm transient was larger at higher concentrations of precursor.[1]

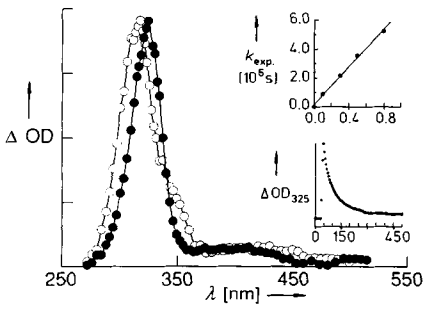


Fig. 2. Absorption spectra of the cumyl cation (•) and the phenethyl cation (○) in HFIP, obtained on photolysis of α-methylstyrene and styrene, respectively, recorded at ≈ 100 ns after the pulse. The inserts show the decay of the cumyl cation at 325 nm (time scale in [μs]), and first-order rates for decay of cation measured in the presence of Bu_4NBr [mM]; the slope of the line yields the rate constant 6.7×10^9 $M^{-1} s^{-1}$ for the reaction cumyl$^{\oplus}$ + $Br^{\ominus}$.

From an analysis of reactivities with alkenes, *Mayr* et al. have recently arrived at a similar conclusion; that is, the rate constants for the 363-nm transient are not consistent with it being the benzyl cation.[14] In addition there is a recent example showing that the technique of pulse radiolysis to produce cations is not a general one, particularly for less stable cations. The radical cation of 9-chlorofluorene[15] does not fragment to the 9-fluorenyl cation.[6]

ACRL Toxin I: Convergent Total Synthesis of Its 3-Methyl Enol Ether from D-Glucose**

By *Frieder W. Lichtenthaler,** *Jürgen Dinges*, and *Yoshimasa Fukuda*

A pathogenic type of the fungus *Alternaria citri*, found host-specifically on rough lemon and Rangpur lime citrus species, produces a number of toxins, which cause a rapidly spreading, harvest-threatening necrosis (brown spot disease) on the leaves and fruits of infected plants.[1] The main component of this mixture of toxins and, at the same time, the substance with the highest biological activity is ACRL Toxin I (**1a**), which, after laborious isolation, was characterized as a light orange oil.[2, 3a] Since it is present as a mixture of keto and enol tautomers (^{1}H NMR) and, moreover, readily undergoes decarboxylation, **1a** is converted for convenience into the stable methyl enol ether **1b**. Intensive CD and NMR spectroscopic investigation of **1b**, together with X-ray structure analysis of the decarboxylation product, established its constitution and absolute configuration.[3]

Our strategy for the total synthesis of **1b** involves the preparation of enantiopure,[4] connective segments from D-glucose. The key feature of the retrosynthetic analysis was the expectation that the dihydro-α-pyrone ring could be introduced via a suitable acetoacetic ester derivative. Thus, the molecule was dissected into the segments **A**, **B**, and **C** (Scheme 1). The advantage of this segmentation is the possibility of carrying out a convergent reaction sequence, since both the twofold methyl-branched C_6 chain of synthon **A** and the adipaldehyde building block **B** are derivable—each in the correct absolute configuration—from the 1,2-acetonide of 3-deoxy-3-*C*-methyl-α-D-allofuranose (**2**), which, in turn, is accessible from D-glucose by a known route.

In order to synthesize the key starting material **2** on a scale of 50–100 grams, the diacetone glucose **3** was first oxidized with pyridinium dichromate/acetic anhydride.[5] The resulting ulose **5**, formed in practically quantitative yield, was converted into **4** by reaction with methyl(triphenyl)phosphonium bromide. Hydrogenation of **4** over Pd/C followed by

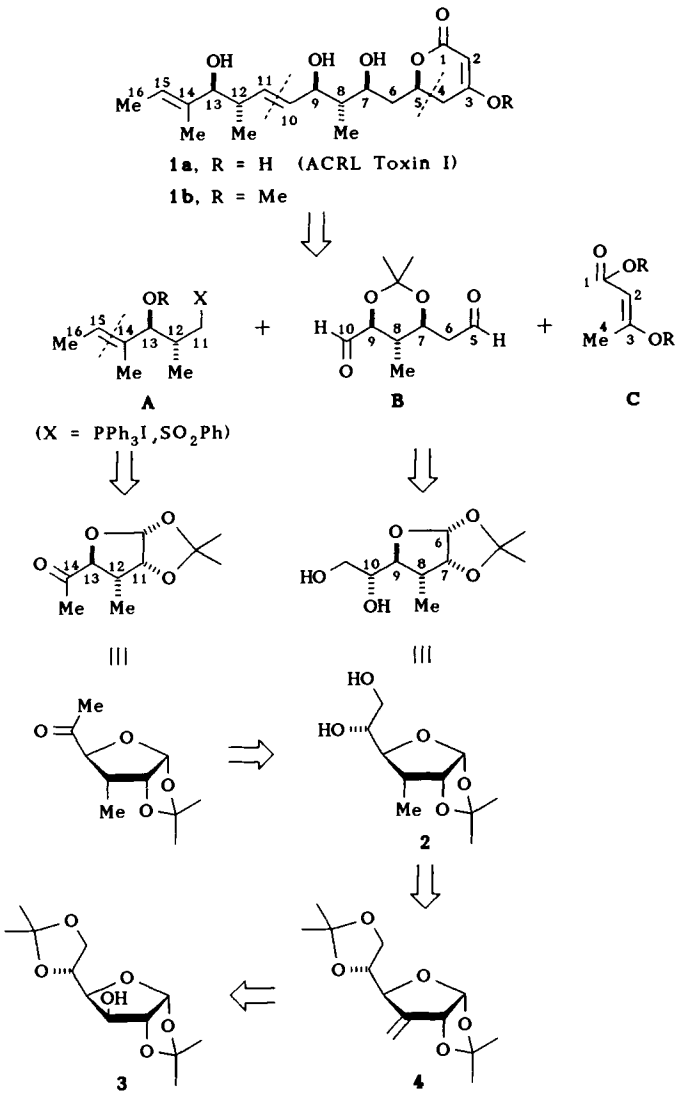
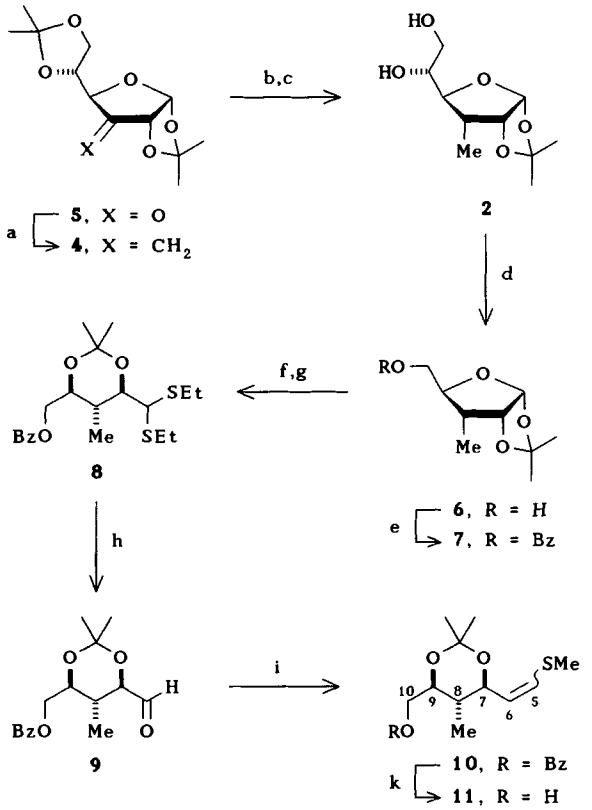
[**] Enantiopure [4] Building Blocks from Sugars, Part 13. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. Part 12: F. W. Lichtenthaler, *Zuckerindustrie (Berlin) 115* (1990) 762.



Scheme 1. Retrosynthetic analysis of the ACRL toxin I (**1a**) to D-glucose.

acid cleavage of the 5,6-isopropylidene group gave **2** (Scheme 2). This four-step process, optimized with respect to reaction conditions and procedure, affords an overall yield of 58% (previously 22%[6]).

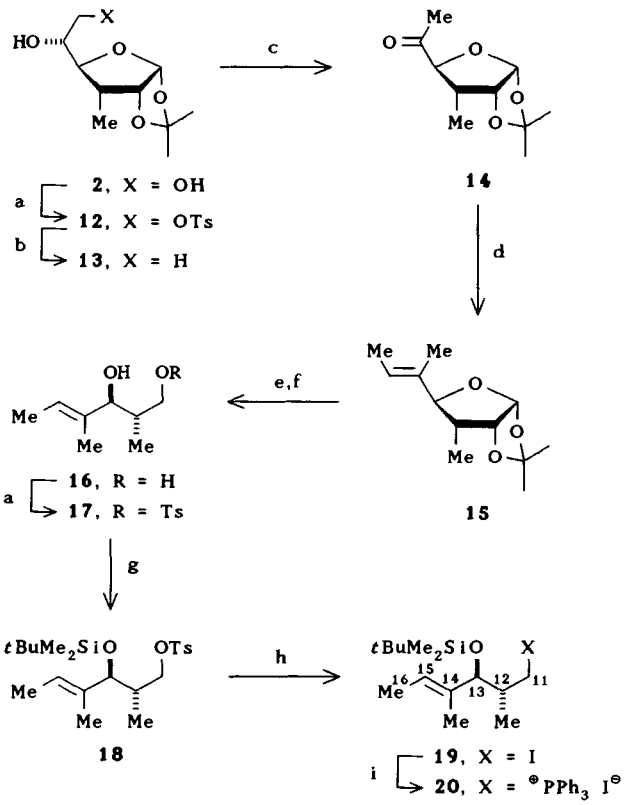
The synthesis of the C_5–C_{10} building block **B** in an OH-protected form suitable for coupling at either end starts with the periodate oxidation of **2** followed by hydride reduction to give 3-deoxy-3-*C*-methyl-D-ribose (**6**), which was converted by benzoylation into the well-crystallizing **7**[7]—in contrast to **2** and **6**, characterizable only as syrups. The unmasking of the aldehyde group in **7** and its protection as the dithio acetal was smoothly accomplished with ethanethiol/conc. HCl at 0°C. The 1,3-diol thereby formed was immediately protected: acid-catalyzed acetonation smoothly led to the *O,O*-isopropylidene-blocked *S,S*-acetal **8** (syrup, $[\alpha]_D^{20}$ 13, $CHCl_3$, 92%). Alkylating hydrolysis of the *S,S*-acetal **8** by the methyl iodide/cadmium carbonate variant,[8] in this case, proved to be preparatively satisfactory (93%) for unmasking the aldehyde group to yield the suitably *O*-protected 3-*C*-methyl-3-deoxy-*aldehydo*-D-ribose **9**.[7] The C_1 extension required for conversion of **9** to the desired C_5–C_{10} segment **11** was accomplished by reaction with methylthiomethyl(triphenyl)phosphonium chloride/sodium amide to give the thio enol ether **10**, which was obtained as a 1:1 *E*/*Z* mixture and could be desulfurized in the presence of mercury salts. The synthesis of compound **11**[7] thus makes accessible the C_5–C_{10} fragment of ACRL Toxin I in a suitably functionalized, enantiopure form. Steps **2** → **6** and **7** → **8** can be carried out in a one-pot reaction, the overall yield for the eight-step synthesis of **11** being 33%.



Scheme 2. a) $MePPh_3Br$, *n*BuLi, THF, 22°C, 2 h, 84%; b) H_2, 10% Pd/C, Et_3N, MeOH, 22°C, 5 h, 85%; c) 0.1 N H_2SO_4, MeOH, 22°C, 5 h, 84%; d) $NaIO_4$, C_2H_5OH/H_2O (2:1), 5°C, 30 min, then $NaBH_4$, 5°C, 30 min, 81%; e) BzCl, pyridine, 22°C, 2 h, 88%; f) conc. HCl, C_2H_5SH, 0°C, 6 h, 79%; g) *p*-TsOH, acetone/$Me_2C(OMe)_2$ (4:1), 22°C, 2 h, 92%; h) MeI, $CdCO_3$, acetone/H_2O (4:1), 22°C, 24 h, 93%; i) $MeSCH_2PPh_3$, $NaNH_2$, THF, 22°C, 2 h, 71%; k) 0.1 N NaOH, MeOH, 22°C, 3 h, 83%.

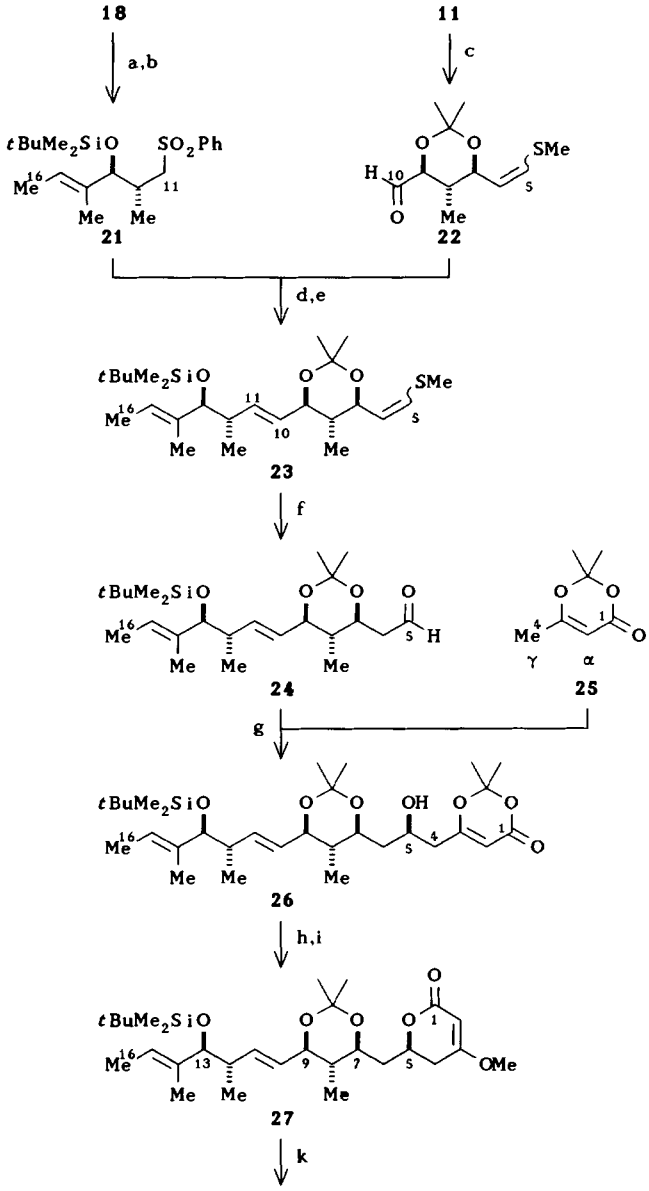
The C_{11}–C_{16} building block **B** (Scheme 1) can also be obtained from **2** in a suitably functionalized form (Scheme 3). Tosylation[9] of the primary hydroxyl group in **2** was accomplished in a highly regioselective fashion (93%). Subsequent hydride reduction (**12** → **13**) and oxidation with pyridium chlorochromate (PCC) on aluminum oxide[10] afforded **14** in a yield of 76% over the three steps. Olefination of the carbonyl group in **14** with ethyl(triphenyl)phosphonium bromide/butyllithium led to **15** as a 4.1:1 mixture of the *Z*/*E* isomers,[11] a ratio that can be shifted towards the *E* compound (→ 1:6.6) by light-induced diphenyl sulfide-aided isomerization. Thus, **15** was obtained as the pure *E* isomer (m.p. 35°C; $[\alpha]_D^{20}$ 26, $CHCl_3$) in 67% yield (based on **14**). Acid hydrolysis of the isopropylidene protecting group in **15**, subsequent periodate oxidation, hydride reduction of the aldehyde, and saponification of the resulting 3-formyl ester of **16** were performed in one continuous operation and afforded 2,4-dimethylhex-4-ene-1,3-diol (**6**)[7] in an overall yield of 77%. Compound **6** has the *S,S* configuration required for the C_{11}–C_{16} segment. Differentiation between the hydroxyl groups in **16** was accomplished by virtually re-

giospecific tosylation of the primary OH group (→ **17**) and protection of the secondary OH group as the *tert*-butyl dimethylsilyl ether **18**. Substitution of the tosyloxy group by iodine proceeded smoothly upon heating **18** with sodium iodide in butanone to give the distillable iodide **19** (b.p. 125 °C/0.04 Torr; 94%), which, on reaction with triphenylphosphane, afforded the C_{11}–C_{16} building block **20**,[7] suitable for subsequent Wittig reaction.



Scheme 3. a) *p*-TsCl, pyridine, 22 °C, 20 h, 93%; b) $LiAlH_4$, Et_2O, 35 °C, 3 h, 88%; c) PCC/Al_2O_3, NaOAc, CH_2Cl_2, 22 °C, 24 h, 93%; d) $C_2H_5PPh_3Br$, *n*BuLi, THF, 22 °C, 2 h, then $(PhS)_2$, *hv*, benzene, 22 °C, 30 min, 67%; e) 1.4 N H_2SO_4, dioxane, 22 °C, 2 d, 76%; f) $NaIO_4$, dioxane/H_2O (1:1), 5 °C, 2 h, then $NaBH_4$, dioxane, 0 °C, 2 h, and saponification of the formyl ester by $KHCO_3$, MeOH, 22 °C, 2 d, 77%; g) *t*$BuMe_2SiCl$, DMF, imidazole, 22 °C, 15 h, 92%; h) NaI, butanone, reflux, 8 h, 94%; i) PPh_3, 80 °C, 25 h, 65%.

The expectation that the phosphonium salt **20** would couple with the aldehyde **22** prepared from **11** by oxidation proved to be delusive. The ylide generated by treatment of **20** with butyllithium reacted with **22** as well as with a number of simple model aldehydes to give disappointingly complex mixtures. Even extensive variation of the reaction conditions did not improve the preparative outlook.[12] Since the Julia coupling[13] has proved itself superior to the Wittig reaction in a variety of cases,[14] the C_{11}–C_{16} fragment was generated as its phenylsulfone **21** by reaction of the tosylate **18** with thiophenol followed by oxidation. The coupling of the lithium derivative of **21** with model aldehydes, as well as with the C_5–C_{10} aldehyde **22**, proceeded smoothly; the diastereomeric β-acetoxysulfones initially formed after acetylation were transformed by subsequent sodium amalgam reduction into a 4:1 *E*/*Z* mixture (^{1}H NMR) of the two C_{10}–C_{11} olefins, from which the *trans E* isomer **23** (syrup, $[\alpha]_D^{20}$ 19, $CHCl_3$) could be separated in 70% yield (based on sulfone **21**) (Scheme 4).



Scheme 4. a) PhSH, KO*t*Bu, DMF, 45 °C, 1 h, 75%; b) $(PhSe)_2$, H_2O_2, 15% CH_2Cl_2/Et_2O, 22 °C, 4 h, 89%; c) DMSO, $(COCl)_2$, CH_2Cl_2, −78 °C, 15 min, then Et*N*i-Pr_2, 90%; d) *n*BuLi, THF, −78 °C, 1 h, then Ac_2O, 22 °C, 90 min; e) 6% Na/Hg, MeOH/EtOAc (2:1), −30 °C, 17 h, 87% (for d + e); f) $HgCl_2$, HgO, acetone/H_2O, (2:1), 50 °C, 16 h, 65%; g) LDA, THF, −78 °C, 2 h, 35%, h) 0.1 N NaOH, MeOH, 22 °C, 2 h, then 2 N HCl to pH 5; i) $(MeO)_2SO_2$, K_2CO_3, acetone, 22 °C, 1 h, 24% (for h + i); k) 0.1 N H_2SO_4, EtOAc, 22 °C, 6 d, 71%.

For annelation of the C_1–C_4 unit as an acetoacetic ester derivative (building block **C** in Scheme 1), several standard methods were tested with respect to the diastereoselectivity of the addition to the carbonyl group of **24** as well as the α,γ regioselectivity in the acetoacetic ester. The obvious use of the acetoacetic ester dianion[15] under otherwise successful conditions[16] led, in the case of **24**, to complex mixtures; the same holds for attempts to add the bistrimethylsilyl enol ether[17] of acetoacetate to **24** in a $TiCl_4$-induced reaction. Likewise, extensive variations of reaction conditions successfully employed in other systems[18] led nowhere. At long last, in order to form the dihydro-α-pyrone ring, the inexpensive[19] trimethyl-1,3-dioxinone (**25**) was evaluated. Al-

though **25** has not been used previously for aldol additions, in two cases (pentyl iodide[20a] and chloroacetyl chloride[20b]) it gave terminal alkylation products. Reaction of **24** with the lithium enolate generated by deprotonation of **25** with lithium diisopropylamide (LDA) in THF at $-78\,^{\circ}C$ led to a mixture of the C_5-epimeric (ca. 2:1 in favor of **26**) γ and α adducts (3.5:1 according to ^1H NMR); the desired product **26** (syrup; $[\alpha]_D^{20} = -18$, $CHCl_3$) is surprisingly simple to obtain by chromatography in a yield of 45% (based on **24**). Although the aldol addition step **24** → **26** is still not preparatively satisfactory, current investigations with the menthone-protected, enantiopure acetoacetic ester analogues of **25**[21] indicate that better results are attainable with respect to the diastereoselectivity of carbonyl addition as well as the α, γ regioselectivity at the acetoacetic ester.

Alkaline saponification of the ester group in **26**, which, on acidification, spontaneously lactonizes, and standard methylation afforded a 64% yield of the 3-methyl enol ether **27** (Scheme 4), crystallizing as long needles. Compound **27** differs from **1b** only in two protecting functions. The X-ray structure analysis[22] (Fig. 1) established unequivocally the

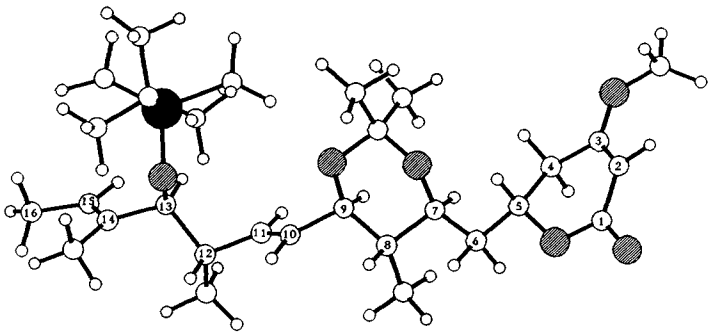


Fig. 1. Structure of the protected ACRL toxin **27** [22]. The O-1 atom and the C-5 atom lie 0.2 Å and 0.8 Å from the four-atom ring plane (C-1 to C-4) and thus the conformation of the dihydropyranone ring is between a boat ($B_{0,5}$) and an envelope (E_5).

structural and configurational integrity of the compound. Subsequent deprotection of **27**, cleavage of the silyl moiety, and hydrolysis of the acetal group was accomplished in one step by treatment with 0.1 N sulfuric acid at room temperature. The 3-methyl enol ether of ACRL toxin I (**1b**) was thereby obtained in 71% yield in crystalline form with an $[\alpha]_D^{20}$ value of -42 ($c = 1$, MeOH). The identity of synthetic **1b** with that obtained from the ACRL Toxin **1a**, characterized so far only as a syrup of $[\alpha]_D^{20} = -26$ ($c = 1$, MeOH),[3b] was established by ^1H and ^{13}C NMR spectroscopic and CD data;[3, 7] the higher optical rotation measured for the synthetic sample is undoubtedly due to its higher purity, which also induced the substance to crystallize.

Conclusion: A convergent synthesis has been developed for ACRL Toxin I as its stable enol ether **1b**; the C_5–C_{10} and C_{11}–C_{16} segments are prepared in an enantiopure form, suitable for coupling, from D-glucose, in both cases via the acetonide of 3-*C*-methyl-D-allose. The outcome of the synthesis is quite satisfactory: 16% overall yield for the thirteen steps from diacetone glucose to the C_5–C_{10} building block (as C_5 aldehyde) and 10% for the preparation of the C_{11}–C_{16} segment (as C_{11} sulfone) from the same starting material. The C_1–C_4 unit was introduced through an acetoacetic ester derivative; the connective steps were effected through Julia and aldol coupling, requiring another seven steps (15%) to the target molecule **1b**. This synthesis represents the first preparatively variable route to structures of type **1** and now enables the synthesis of analogues for the study of the largely unexplained toxin activity. Also noteworthy is an observation made during the synthesis: alkyl(triphenyl)phosphonium salts with a 3-alkoxy-4-ene group in the aliphatic portion of the molecule deprotonate abnormally and thus are unsuitable for a Wittig reaction, whereas the analogous phenylsulfones in the Julia coupling are not subject to this limitation.

[11] The isomeric ratio was determined by ^{1}H NMR spectroscopy by integration of the 4-H signals ($\delta_{4\text{-H,Z}} = 4.70$, $\delta_{4\text{-H,E}} = 4.04$) and their assignment was confirmed by NOE experiments.

[12] a) An approach to explaining these difficulties is provided by the finding that, on treatment with butyllithium in hexamethylphosphoramide (HMPA) or THF/HMPA at −78 °C in the absence of a carbonyl component, **20** affords the diphenylphosphane oxide (i) (m.p. = 92 °C, $[\alpha]_D^{20}$ − 5 ($CHCl_3$); 53%). This abnormal course of a phosphonium salt deprotonation, which has not been previously documented, is possibly due to the fact that deprotonation does not occur in a position α to phosphorus, but rather at the allylic C atom bearing the alkoxy group. This, together with participation of the 4,5 double bond, seemingly results in formation of the cyclic intermediate (ii); the subsequent elimination of benzene, without precedent at pentavalent phosphorus [12b], then leads, after aqueous workup, to the hydroxyphosphorane (iii), which undergoes cleavage of the P–C bond to give (i), thereby forming the best resonance-stabilized moiety [12c]. The abnormal course of the deprotonation seems to be limited to alkenyl(triphenyl)phosphonium salts with a 3-alkoxy-4-ene group in the aliphatic moiety. Compounds without 3-alkoxy groups undergo normal deprotonation and smoothly afford the desired olefination products [12d]; b) D. Seyferth, J. K. Heeren, W. B. Hughes Jr., *J. Am. Chem. mer-[Cr(CO)$_3$(η^4-norbornadiene)(η^2-ethene)]: A Key Compound in Understanding the Mechanism of the Photocatalytic Diene Hydrogenation with Chromium Carbonyl Complexes**

By *Dietmar Chmielewski, Friedrich-Wilhelm Grevels,* Jürgen Jacke,* and *Kurt Schaffner*

Dedicated to Professor Horst Prinzbach on the occasion of his 60th birthday

The photocatalytic hydrogenation of norbornadiene (NBD) with [Cr(CO)$_6$] or [Cr(CO)$_4$ (η^4-nbd)] as precursor of the catalytically active species[1–4] affords norbornene (NBN) and nortricyclene (NTC) in a ratio of about 1 : 3 (Scheme 1). Conjugated dienes undergo selective *cis* 1,4-hydrogenation.[5–8] Much work has addressed questions about the photochemical activation as well as the subsequent course of the reaction. The most recent IR spectroscopic results,[9,10] obtained both by conventional spectroscopy at low temperature in noble-gas matrices and in liquid noble gases and by time-resolved spectroscopy at room temperature, indicate that [Cr(CO)$_4$(η^4-nbd)] is transformed into *fac*- and *mer*-[Cr(CO)$_3$(η^4-nbd)] by photolytic detachment of CO. Both complex fragments[11] add hydrogen,[10] which is subsequently transferred to the norbornadiene ligand. This provides a plausible explanation for the formation of the two hydrogenation products (*mer* isomer, 1,2-hydrogenation → NBN; *fac* isomer, *homo* 1,4-hydrogenation → NTC; Scheme 2).

Scheme 1. Norbornene (NBN) and nortricyclene (NTC) are formed in a ratio of approximately 1 : 3. Norbornadiene = NBD.

Scheme 2.

We describe here the photochemical synthesis and the use of the thermally labile complex *mer*-[Cr(CO)$_3$(η^4-nbd)(η^2-ethene)] (**1**), whose ethene ligand is readily exchanged. Thus, **1** offers a potential source of the reactive [Cr(CO)$_3$ (η^4-nbd)] fragment, which, in turn, obviates the photochemical induc-

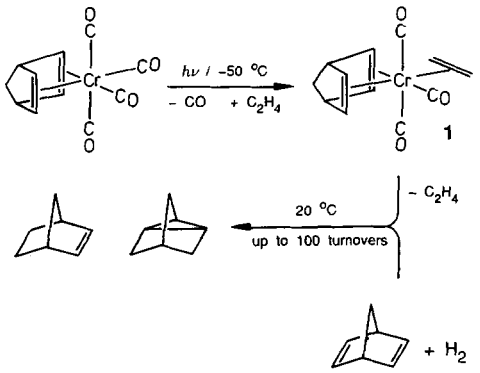
[**] This work was supported by the Commission of the European Community (contract SCI-0007-C, EDB).

tion step. The catalytic hydrogenation of norbornadiene can then be carried out in the dark, thus affording deeper insight into the reaction mechanism.

Complex **1** is obtained in crystalline, analytically pure form by irradiation of $[Cr(CO)_4(\eta^4\text{-nbd})]$ in ethene-saturated solution at $-50\,^{\circ}C$, followed by workup below $-30\,^{\circ}C$ (Scheme 3). The structural assignment is supported by a comparison of the spectroscopic data with those of the analogous tungsten complex,[12] which was investigated by X-ray analysis. Solid **1** is stable for a limited period of time even at room temperature. Its lability is revealed in solution, where it decomposes above $-10\,^{\circ}C$ to give insoluble products and $[Cr(CO)_4(\eta^4\text{-nbd})]$. If other ligands are present (L = trimethylphosphite, *E*-cyclooctene, CO, ^{13}CO), they smoothly displace the coordinated ethene to form $[Cr(CO)_3(\eta^4\text{-nbd})(L)]$.

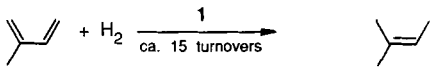


Scheme 3. Product distribution after catalysis: NBN : NTC = 1 : 3.2.

In H_2-saturated solution, **1** catalyzes the hydrogenation of norbornadiene present in excess. Without irradiation, roughly 100 turnovers take place for a substrate-to-catalyst ratio of 200 : 1, until catalysis ceases after about 2 h. The product distribution (NBN : NTC = 1 : 3.2) is nearly identical to that obtained in the photoinduced catalysis with $[Cr(CO)_4(\eta^4\text{-nbd})]$. Detachment of ethene from **1** seems to be the rate-determining step, since the gradual loss of catalytic activity parallels the decrease in concentration of **1** observable by IR spectroscopy. Complex **1** decomposes with formation of $[Cr(CO)_4(\eta^4\text{-nbd})]$ together with traces of $[Cr(CO)_6]$, both of which are catalytically inactive in the dark. When the reaction is performed with D_2 instead of H_2, *endo*-[D_2]NBN and [D_2]NTC are formed in a ratio of 1 : 2.2. Both this H/D isotope effect and the selective *endo* deuteration are consistent with the results of the photoinduced catalysis with $[Cr(CO)_4(\eta^4\text{-nbd})]$, which was carried out earlier by others[11] and was repeated by us.

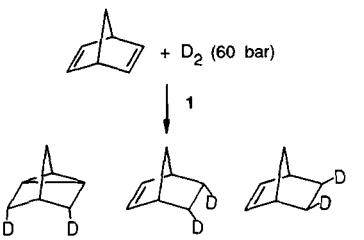
Our results indicate that photolytic CO detachment from $[Cr(CO)_4(\eta^4\text{-nbd})]$ and loss of ethene from **1** generate the same catalyst system. Earlier suggestions that *cis*-vacant $[Cr(CO)_4$ (*endo*-η^2-nbd)] is the active species[2-4] in the formation of norbornene (NBN) are not supported by our results. Moreover, we have obtained no evidence that the *mer*-$[Cr(CO)_3]$ structure of **1** is retained in the active catalyst and thus could favor even transiently the 1,2-hydrogenation ($\rightarrow$ NBN). Instead, a rapid *mer*/*fac* rearrangement of the $[Cr(CO)_3(\eta^4\text{-nbd})]$ fragment presumably occurs, so that the catalysis affords the two products, NBN and NTC, in a constant ratio from the very beginning. It is unlikely, therefore, that the product ratio will be controllable by selective photochemical generation of *mer*- or *fac*-$[Cr(CO)_3(\eta^4\text{-nbd})]$.

Analogous conclusions apply to the hydrogenation of conjugated dienes,[5-8] as shown by catalytic experiments with **1** in which, instead of norbornadiene, isoprene was used as the substrate (Scheme 4). After displacement or hydrogenative release of the NBD ligand ($\rightarrow$ NBN : NTC = 1 : 3 to 1 : 3.5), the $[Cr(CO)_3]$ unit is available for hydrogenation of isopropene. Without irradiation, up to 15 turnovers took place. As observed in the photoinduced catalysis,[6] isoprene almost selectively undergoes 1,4-hydrogenation ($\rightarrow$ 2-methyl-2-butene), despite the *mer* structure of the $[Cr(CO)_3]$ skeleton in complex **1**. From this we conclude that the stereoselective photolytic formation of the *fac*-$[Cr(CO)_3(\eta^4$-1,3-diene)] fragment[13] is not a necessary condition for the photocatalytic selective 1,4-hydrogenation of conjugated dienes.



Scheme 4. The NBD contained in **1** is partly hydrogenated (NBD: NTC ≈ 1:3), partly displaced without hydrogenation.

With respect to the pressure dependence of the NBD hydrogenation,[4] the use of **1** also provides new insight. First of all, it should be noted that, by analogy with the photoinduced catalysis,[4] a high pressure of H_2 also favors the formation of norbornene when the reaction is carried out in the dark with **1** as catalyst (NBN : NTC = 1 : 1.4 under 50 bar H_2; a small amount of norbornane is also formed). When D_2 is used, the ratio of products formed under high pressure is likewise shifted in favor of 1,2-addition ([D_2]NBN : [D_2]NTC = 1 : 1.1 under 60 bar D_2; Scheme 5).



Scheme 5. [D_2]NTC *endo*-[D_2]NBN *exo*-[D_2]NBN

Surprisingly, however, the ^1H NMR spectrum of [D_2]NBN, isolated by preparative gas chromatography, reveals that exclusive *endo* 1,2-deuteration has not taken place here. Instead, a mixture of 52 % *endo* and 48 % *exo* 1,2-deuterated norbornene is present. This finding clearly shows that the increased formation of NBN under high pressure is not due to a favoring of the *mer*-$[Cr(CO)_3$ (η^4-nbd)] species over the *fac* species, but rather to an additional reaction path involving *exo* η^2-coordinated norbornadiene. Owing to the absence of the stabilizing chelate effect, an intermediate of this kind should have an considerably shorter lifetime compared with the above-mentioned species with η^4-NBD, in consequence of which this hydrogenation path becomes kinetically important only at higher H_2 or D_2 pressures.

The *mer*-$[M(CO)_3(\eta^4\text{-nbd})(\eta^2\text{-olefin})]$ complexes are generally more stable than the corresponding *fac* isomers because of the *trans*-orthogonal orientation of the olefin with respect to one of the C=C bonds of norbornadiene.[12] Identification of the *fac* isomer in the case of chromium complexes was achieved only with *E*-cyclooctene (ECO),

which has elsewhere[14] manifested a special coordination ability. Irradiation ($\lambda = 289$ nm) of [Cr(CO)$_4$(η^4-nbd)] and ECO in 2-methylpentane at $-40\,^\circ$C affords *mer*- and *fac*-[Cr(CO)$_3$(η^4-nbd)(η^2-eco)], which are easily distinguished on the basis of their CO stretching bands (*mer* complex, $\tilde{\nu}$[cm^{-1}] = 1997(m), 1925 (sst); *fac* complex $\tilde{\nu}$[cm^{-1}] = 1968, 1904, 1876). The *mer* complex, which is more stable, is the only observed product at room temperature. In order to determine the quantum yield ($\Phi = 0.18$ at 300 nm, 0.11 at 365 nm), its formation was followed quantitatively by IR spectroscopy. If this reaction is assumed to serve as a model for the generation of the catalytically active [Cr(CO)$_3$] complex (Φ_{ind}), then the relation $\Phi_{cat} = \Phi_{ind} \times$ (turnovers) gives a rough estimate of 10 to 20 for the quantum yield of the photocatalytic hydrogenation of norbornadiene (Φ_{cat}). The experimentally determined values (1.9,[2] ca. 0.3[4]) are considerably lower, probably because the active [Cr(CO)$_3$] complex generated in situ is rapidly transformed into inactive [Cr(CO)$_4$(η^4-nbd)] by the CO still present in the system.

The stability of [M(CO)$_3$(η^4-nbd)(η^2-olefin)] complexes increases markedly in the series Cr $\ll$ Mo $<$ W. As a result, the catalytically active species is trapped by excess substrate (NBD) as [M(CO)$_3$ (η^4-nbd)(η^2-nbd)] in the cases of tungsten and molybdenum.[10] The analogous chromium complex, by contrast, has not yet been detected. Thus, the drastic decrease in the catalytic activity in the series Cr $\gg$ Mo $>$ W[3] is readily explained.

In analogy to the hydrogenation, norbornadiene can also be hydrosilylated with silanes (R_3SiH), both photocatalytically with [Cr(CO)$_4$ (η^4-nbd)] and in the dark with **1**. As we will report in detail elsewhere, both variants afford *endo* 1,2-, *exo* 1,2-, and *homo* 1,4-adducts with comparable product distributions.

Experimental Procedure

Preparation of **1**: [Cr(CO)$_4$(η^4-nbd)] (1.00 g, 3.9 mmol) was irradiated in 200 mL of ethene-saturated pentane at $-50\,^\circ$C in an immersion lamp apparatus (Solidex glass, $\lambda \geq 280$ nm; Philips HPK 125-W Hg lamp) for about 3 h, until the starting material ($\tilde{\nu}_{CO}$ [cm^{-1}] = 2043, 1961, 1946, 1917) had largely reacted. The temperature was maintained at $\leq -30\,^\circ$C during workup. After addition of about 2 g of silica gel (to absorb readily decomposable by-products), the solution was stirred for several minutes and then evaporated to dryness under vacuum. The residue was extracted into 3 × 10 mL of ethene-saturated pentane, transferred to a column (silica gel 60, Merck; 2 × 15 cm), and eluted with additional solvent. The first of the two yellow fractions was concentrated under vacuum to about 50 mL and cooled to $-78\,^\circ$C, whereupon pure *mer*-[Cr(CO)$_3$(η^4-nbd)(η^2-ethene)] (0.46 g, 46%) crystallized out. M.p. = 46 °C; correct elemental analysis (C, H, Cr); IR (*n*-hexane): $\tilde{\nu}$[cm^{-1}] = 2005(m), 1933 (sst) (CO). ^{1}H NMR (400 MHz, C_7D_8, 243 K): $\delta = 0.85$ (m, 2 H), 1.85 (s, br, 4 H, ethene), 3.00 (s, br, 2 H), 3.16 (s, br, 2 H), 3.89 (s, br, 2 H). ^{13}C NMR (100.6 MHz, C_7D_8, 243 K): $\delta = 47.41$ (CH), 52.78 (ethene), 55.66 (CH), 59.95 (CH_2), 79.47 (CH), 229.45 (CO), 232.62 (2 CO). The second yellow fraction of the chromatographic run contained residual, unreacted starting material.

Catalytic hydrogenations with **1**: A solution of **1** (4–6 mM) and NBN (0.2–0.8 M) or isoprene in *n*-hexane (with addition of *n*-octane as internal standard) was prepared at $-35\,^\circ$C and hydrogen was admitted to the solution, which was warmed to room temperature and then stirred in the dark. Samples were treated with aqueous cerium(IV) ammonium nitrate solution to destroy the complex and then analyzed by gas chromatography. In pressure experiments, the precooled solution was sucked rapidly into a previously evacuated autoclave and H_2 or D_2 was admitted.

The Mechanism of Interaction of Triplet 3-Methylcyclohex-2-en-1-one with Maleo- and fumarodinitrile: Evidence for Direct Formation of Triplet 1,4-Biradicals in [2 + 2] Photocycloadditions without the Intermediacy of Exciplexes**

By *David I. Schuster,* George E. Heibel, and Jan Woning*

Dedicated to Professor Kurt Schaffner on the occasion of his 60th birthday

The mechanism of [2 + 2] photocycloaddition reactions between cyclic enones and alkenes continues to be of interest.[1] There seems to be general agreement that triplet 1,4-biradicals are intermediates in these reactions.[1–5] However, the question of whether exciplexes of enone triplet excited states (T_1) and alkenes are precursors to the 1,4-biradicals remains unresolved.[6,7]

In acetonitrile, the high-energy triplets of acetophenone ($E_T = 73.8$ kcal mol^{-1}),[8] benzophenone ($E_T = 68.6$ kcal mol^{-1}),[8] and bicyclo[4.3.0]non-1(6)-en-2-one (BNEN, $E_T = 74$ kcal mol^{-1})[9] interact with maleo- (MN) or fumarodinitrile (FN, $E_T = 48$ kcal mol^{-1})[10] exclusively by energy transfer. Thus, in acetonitrile the T_1 state of BNEN is quenched by both FN and MN at the diffusion-controlled rate ($k_q = (4.5 \pm 0.7) \times 10^9$ M^{-1} s^{-1}).[11] Irradiation of these ketones in the presence of FN leads exclusively to *cis–trans* isomerization of the alkene. The MN:FN photostationary state ratios are 49:51, 48:52, and 44:56, respectively. No [2 + 2] cycloadducts could be detected in these systems. On

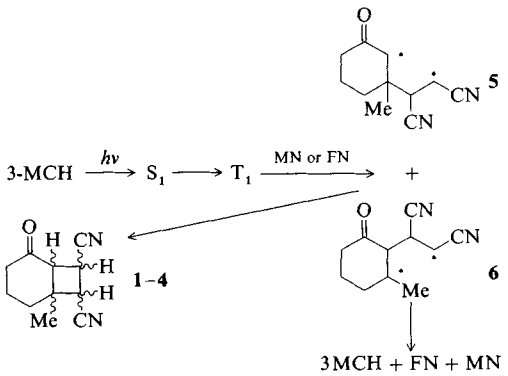
the other hand, irradiation of conformationally flexible cyclohexenones ($E_T = 63-69$ kcal mol^{-1})[12] or cyclopentenone[12] in the presence of FN or MN gives rise to both *cis–trans* isomerization of the alkene and the formation of [2 + 2] cycloadducts.

We previously reported[6] that the rate constants for quenching of enone triplets by alkenes are higher for electron-poor than for electron-rich alkenes. This is inconsistent with the hypothesis of *Corey*[4] and *de Mayo*[5,13] that donor–acceptor complexes, with the alkene acting as the donor and the enone as the acceptor, are involved in the reaction. Such exciplexes have been invoked even in reactions involving electron-deficient alkenes.[1,4,5] However, the possibility that triplet energy transfer might be responsible for the high quenching rates observed with electron-poor alkenes could not be previously ruled out. Here we report new evidence that triplet 3-methylcyclohex-2-en-1-one (3-MCH) reacts with MN and FN to yield triplet 1,4-biradicals directly and that exciplexes of the type proposed by *Corey*[4] and *de Mayo*[5,13] are not involved in this system.

Irradiation of 3-MCH in the presence of either MN or FN gives four [2 + 2] cycloadducts, **1**–**4** (Scheme 1).[14] The



Scheme 1.

yields of these adducts increase linearly with the irradiation time (Fig. 1), while their ratio (**1**:**2**:**3**:**4** = 29:15:21:35) is

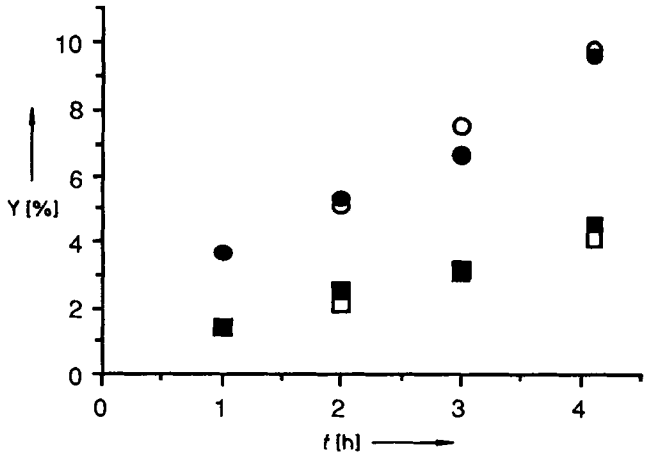


Fig. 1. Yield (Y) vs. time curves (GC) for **2** (squares) and **4** (circles) obtained from irradiations (300 nm, merry-go-round, max. 28% conversion) of 3-MCH (0.087 M) in the presence of stoichiometric quantities of FN (closed plot symbols) and MN (open plot symbols). Similar curves for **1** and **3** have been omitted for clarity.

independent of the conversion of the alkene (FN or MN) used. This indicates that the stereochemistry on the alkene moiety is completely lost in the course of the reaction. The loss of stereochemistry is also evident from the crystal structure (Fig. 2)[15] of the major [2 + 2] cycloadduct **4** originating from irradiation of 3-MCH and FN, which unambiguously establishes a *cis* configuration for the two CN groups.

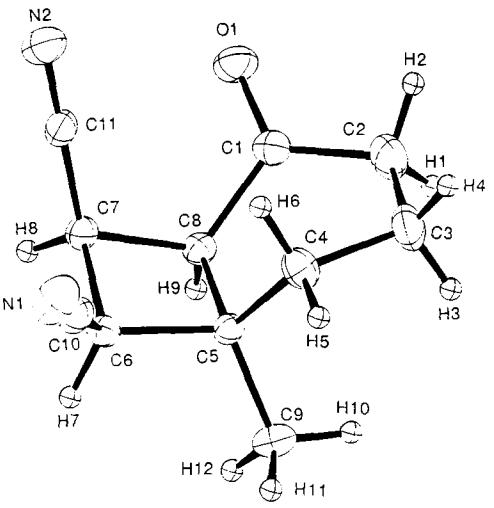

Fig. 2. The molecular structure of [2 + 2] cycloadduct **4** [15].

The quantum yields for adduct formation (Φ_{prod}) and alkene isomerization (Φ_{iso}) from 3-MCH in the presence of MN or FN are presented in Table 1.

Table 1. Rate constants (k_q) or quenching of 3-MCH by alkene and quantum yields [a] of **1**–**4** (Φ_{prod}), alkene isomerization (Φ_{iso}), and triplet capture (Φ_{tc}) from irradiation of 3-MCH and MN or FN in acetonitrile.

Alkene	k_q [M^{-1}s^{-1}]	Φ_{prod}	Φ_{iso}	Φ_{tc}	$\Phi_{tc} - \Phi_{prod}$
FN	$(5 \pm 1) \times 10^8$	0.28 ± 0.05	0.19 ± 0.04	0.95	0.67
MN	$(7 \pm 1) \times 10^8$	0.36 ± 0.06	0.42 ± 0.08	0.96	0.60

[a] Concentrations: 0.015 M (3-MCH), 0.5 M (alkene). Irradiation wavelength: 313 nm. Apparatus: PTI QUANTACOUNT, calibrated using the photochemical transformation of valerophenone (*n*-butyl phenyl ketone) into acetophenone in benzene ($\Phi = 0.33$).

The rate constants (k_q) for quenching of the 3-MCH triplet ($\tau_T = 75$ ns) by MN and FN in acetonitrile, determined by transient absorption spectroscopy,[16] are 7×10^8 and 5×10^8 M^{-1}s^{-1}, respectively. The quantum yields Φ_{tc} for

$$\Phi_{tc} = k_q[\text{alkene}] \times (\tau_T^{-1} + k_q[\text{alkene}])^{-1} \quad \text{(a)}$$

capture of 3-MCH triplets by MN and FN under the conditions stated in Table 1 are 0.96 and 0.95. The quantity Φ_{tc} is the sum of the quantum yields Φ_{bir} for formation of the 1,4-biradical intermediate and Φ_{et} for triplet energy transfer from the 3-MCH triplet. In addition to energy transfer from triplet 3-MCH, alkene isomerization can arise from reversion of the intermediate 1,4-biradicals **5** and **6** to ground-state 3-MCH and MN or FN. Depending on the extent of

this reversion, $\Phi_{prod} \leq \Phi_{bir}$. Therefore, the minimum value of Φ_{et} is zero and the maximum value is $\Phi_{tc} - \Phi_{prod}$.

The maximum quantum yields for biradical reversion to 3-MCH, FN, and MN equal $\Phi_{tc} - \Phi_{prod}$ and are collected in Table 1. These quantities would be reduced to the extent that concomitant alkene isomerization by triplet energy transfer occurs. From these data one can also calculate the minimum fraction F of intermediates (triplet adduct 1,4-biradicals or perpendicular 1,2-dicyanoethene triplets) which revert to FN. From the values of Φ_{iso} and $\Phi_{tc} - \Phi_{prod}$ given in Table 1 these fractions F are calculated to be 0.70 ($\Phi_{iso}/[\Phi_{tc} - \Phi_{prod}]$) and 0.72 ($[\Phi_{tc} - \Phi_{iso} - \Phi_{prod}]/[\Phi_{tc} - \Phi_{prod}]$) for the addition of MN and FN, respectively, to the 3-MCH triplet. The excellent agreement between these two values, and their deviation from the *cis–trans* decay ratio of ca. 1:1 for triplet-sensitized FN and MN isomerizations, provide strong evidence for the direct formation of a common set of rotationally equilibrated triplet 1,4-biradicals (**5** and **6**) in the photoreactions of 3-MCH with MN and FN. The fact that the stereochemistry on the alkene moiety is entirely lost in the course of formation of the cycloadducts **1**–**4** indicates that rotational equilibration in the intermediate triplet 1,4-biradicals is complete. This supports the conclusion that alkene isomerization predominantly, if not exclusively, arises from reversion of the biradicals **5** and **6**.

If one were to assume, for the sake of argument, that the isomerization of MN and FN induced by 3-MCH triplets occurs entirely by energy transfer, despite the large discrepancy observed in the *cis–trans* decay ratios, minimum rate constants $k_{add} = k_q \Phi_{prod}$ of 2.5×10^8 and 1.4×10^8 s^{-1} are derived for the addition of MN and FN, respectively, to triplet 3-MCH. These lower limits to k_{add} are two orders of magnitude larger than the rate constants[6] for interception of the T_1 states of 3-MCH and other enones by typical electron-rich alkenes. This finding is clearly inconsistent with the Corey–de Mayo exciplex hypothesis, according to which higher rate constants for the interception of enone triplets should be expected for the more electron-rich alkenes. In the present system the possible involvement of a reverse exciplex, with the electron-deficient enone triplet acting as the donor toward MN or FN, is improbable, but not rigorously ruled out by the experimental data. However, the high rate constants observed for addition of MN and FN to the 3-MCH triplet are completely consistent with formation of stabilized (by the neighboring CN group) triplet 1,4-biradicals **5** or **6** directly from the enone triplet. The fact that triplet energy transfer from 3-MCH to FN or MN does not occur despite the favorable energetics of this process remains puzzling. This could be an example of inefficiency in triplet energy transfer[17] due to twisting of the π system of the triplet donor 3-MCH,[9,18] since planar enone triplets such as BNEN are quenched by MN and FN at a diffusion-controlled rate by an energy-transfer mechanism.[11]

As stated previously,[2,6] direct physical evidence for the involvement of exciplexes in the mechanism of [2 + 2] photocycloaddition reactions of enones has not been forthcoming from studies using transient absorption spectroscopy[18] and time-resolved photoacoustic calorimetry.[9] In the present case and earlier studies,[6] photophysical data do not support the intermediacy of donor–acceptor enone–alkene exciplexes of the type repeatedly invoked in the literature concerning enone photocycloaddition to alkenes.[1,4,5] Although we do not dispute the heuristic value of the Corey–de Mayo exciplex hypothesis in rationalizing product ratios in such reactions, we note that all efforts to directly observe enone–alkene triplet exciplexes have failed thus far. Hence, the exciplex hypothesis should, in our opinion, be regarded with skepticism, at least until compelling experimental evidence supporting its validity is presented.

Experimental Procedure

1–**4**: A deaerated solution of 3-MCH (1.103 g, 10.0 mmol) and FN (782 mg, 10.0 mmol) in acetonitrile (50 mL) was irradiated (300 nm, Pyrex) to > 98% conversion. The solvent was evaporated and traces of 3-MCH, FN, and MN were thoroughly removed under vacuum. Purification of the remaining residue by column chromatography (silica gel, EtOAc–cyclohexane 1:3) afforded isomer **1** (250 mg, GC purity 99.3%) and two fractions containing **2** and **3** (1:2 ratio) and **3** and **4** (1:2 ratio), respectively. Slow evaporation of the solvent from the latter fraction afforded crystals (300 mg), which, upon repeated fractional crystallization from EtOAc–cyclohexane 4:1, gave single crystals of **4** containing < 6% of **3**.

6-Deoxy-6-*N*-histamino-β-cyclodextrin Copper(II) Complex, a New Enantioselective Receptor for Aromatic Amino Acids**

By *Giuseppe Impellizzeri, Giuseppe Maccarrone, Enrico Rizzarelli,* Graziella Vecchio, Roberto Corradini,* and *Rosangela Marchelli**

Cyclodextrins have been widely used as chiral discriminating agents in gas[1] and liquid[2] chromatography, either covalently bound to the stationary phase or as chiral additives to the eluent. Recently, β-cyclodextrins with both positive and negative charges on the C6 carbons of two adjacent glucose rings have shown enantioselective recognition of L- and D-tryptophan based on a three-point interaction (two polar sites and the hydrophobic cavity).[3]

However, other types of interactions, such as those occurring in ligand exchange chromatography (LEC),[4] can be exploited by chemically modifying the cyclodextrin structure. Accordingly, we have synthesized[5] 6-deoxy-6-*N*-histamino-β-cyclodextrin (β-CDhm), which was opportunely designed in order to coordinate transition-metal ions. β-CDhm was shown to form a 1:1 complex with a copper(II) ion,[5] giving rise to an ideal receptor site for the enantiomeric recognition of aromatic amino acids.

Here we report the direct HPLC enantiomeric resolution of D,L-tryptophan by using the copper(II) complex of β-CDhm as additive to the mobile aqueous phase in combination with a conventional achiral reversed-phase (RP-18) column. To obtain quantitative information about the interactions responsible for the chiral recognition, we have investigated the formation and the stability of the ternary complexes between copper(II), β-CDhm, and L- and D-trptophan, respectively, in aqueous solution by means of potentiometric and spectroscopic measurements (CD).

Indeed, baseline separation of D- and L-Trp was obtained by eluting with H_2O:MeOH (80:20) at pH 7.5 in the presence of Cu^{II} (β-CDhm), with an enantioselectivity factor $\alpha = 1.41$ (elution order $k'_D < k'_L$). In contrast, D,L-alanine was eluted much faster and was not separated. This can be regarded as the first example of mixed inclusion-ligand exchange chromatography for the separation of optical isomers. When β-CDhm was used in the mobile phase without the addition of copper(II) at pH 7.5, the reversed elution order was observed, suggesting that both inclusion and complexation at the metal ion were effective in the former case.

Furthermore, this seems to be one of the few examples in which the discrimination process occurs in the aqueous mobile phase, with the more strongly bound enantiomer eluting first. It is thus possible to approach the problem of enantioselectivity on the basis of molecular thermodynamics in aqueous solution.

Potentiometric titrations were carried out in aqueous solution with β-CDhm (L), Cu^{II}, and two amino acids (A), D- and L-Trp or D- and L-Ala, as a function of pH; three mixed species were detected: $[CuLAH_2]^{3\oplus}$, $[CuLAH]^{2\oplus}$, and $[CuLA]^{\oplus}$, whose stability constants are listed in Table 1. No

Table 1. Logarithm of the overall stability constants (lg β) [a] for the ternary complexes containing Cu^{II}, β-CDhm (L), and D- and L-amino acids (A) at 25 °C and $I = 0.1$ M (KNO_3).

$A^{\ominus}$	$[CuLAH_2]^{3\oplus}$	$[CuLAH]^{2\oplus}$	[CuLA]
L-Trp$^{\ominus}$	25.03(1)	20.78(1)	16.12(1)
D-Trp$^{\ominus}$	25.02(3)	20.82(2)	16.47(2)
L-Ala$^{\ominus}$	25.12(4)	20.68(3)	15.53(4)
D-Ala$^{\ominus}$	25.12(5)	20.67(5)	15.51(2)

[a] The generalized reaction for formation of the complexes is given by the following equation:

$$m\mathrm{Cu} + l\mathrm{L} + a\mathrm{A}^{\ominus} + h\mathrm{H}^{\oplus} \overset{\beta_{mlah}}{\rightleftharpoons} [\mathrm{Cu}_m\mathrm{L}_l\mathrm{A}_a\mathrm{H}_h]^{(m+h-a)\oplus}.$$

The stability constants for the simple complex with protons or copper(II) have been reported elsewere [5, 6] lg $K_{HL^{\oplus}} = 8.01$, lg $K_{H_2L^{2\oplus}} = 5.81$, lg $K_{AlaH} = 9.69$, lg $K_{AlaH_2^{\oplus}} = 2.44$, lg $K_{TrpH} = 9.37$, lg $K_{TrpH_2^{\oplus}} = 2.41$, lg $K_{CuL^{2\oplus}} = 7.26$, lg $K_{Cu(Ala)^{\oplus}} = 8.17$, lg $K_{Cu(Ala)_2} = 6.77$, lg $K_{Cu(Trp)^{\oplus}} = 8.29$, lg $K_{Cu(Trp)_2} = 7.13$.

enantioselectivity was observed for the $[CuLAH_2]^{3\oplus}$ and $[CuLAH]^{2\oplus}$ species for both amino acids, whereas a significant difference in the stability of the two mixed species was shown to occur only with tryptophan in the case of the $[CuLA]^{\oplus}$ species. In the last complex, both tryptophan and β-CDhm act as bidentate ligands, with the two amino groups most likely arranged in the *cis* position, as generally observed in the ternary complexes formed by histamine and other amino acids.[6] The relative stability is governed by the position of the aromatic side chain of tryptophan relative to the cyclodextrin cavity, so that inclusion may be allowed only for D-Trp and not for L-Trp (Fig. 1). In fact, the small bulk of the alanine side chain is irrelevant to the size of the cavity, so that there is neither discrimination in HPLC nor enantioselectivity in the ternary complex formation.

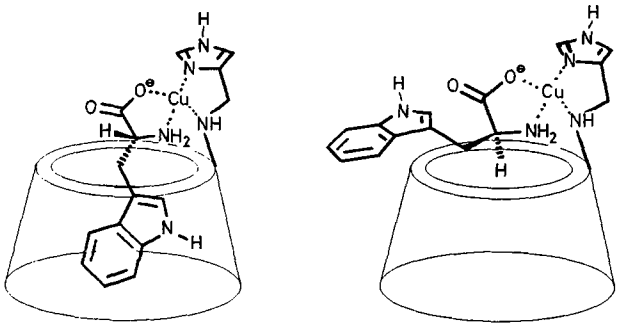

Fig. 1. Schematic model for the ternary complexes $[CuLA)^{\ominus}$ containing D- (left) and L-tryptophan (right).

Indeed, the D-Trp side chain experiences a more highly asymmetric environment than the L-Trp moiety, as evidenced by circular dichroism spectroscopy, both in the UV and in the visible regions (Fig. 2): at pH 7.5, both chromophores (Cu^{II} and the tryptophan aromatic side chain) showed an abnormal CD intensity enhancement for the ternary complex containing D-Trp, whereas much weaker effects were observed in the case of the L-Trp diastereomeric complex. The more favorable interaction of the D-Trp aromatic side chain with the cavity also drags the copper ion inside, thus enhancing the CD intensity of the d–d transitions compared to the corresponding ones in the binary $[Cu(\beta\text{-CDhm})]^{2\oplus}$ complex.

On the basis of these results, other experiments for estimating the different contributions to the process, as well as

for determining whether the method can be extended to other amino acids, are warranted.

Experimental Procedure

β-CDhm was prepared from dried 6-*O*-(p-tosyl)-β-cyclodextrin [7] (1 g, 0.77 mmol), converted into the iodo derivative by reaction with NaI (10-fold excess) in anhydrous DMF (40 mL) at 90 °C for 5 h under stirring, then allowed to reacted with histamine (10-fold excess) in DMF at 60° for 24 h under nitrogen. After purification on CM-Sephadex C-25, β-CDhm was obtained with a total yield of 40%. β-CDhm was characterized by ^1H and ^{13}C NMR and by elemental analysis [5].

Chromatographic separations were performed on a Waters model 6000A HPLC pump, using a Radialpak C_{18} cartridge (10 × 0.8 cm) and a model 440 UV detector, set at 280 nm. The mobile phase was prepared as described previously [4c]. β-CDhm can be subsequently recovered from the eluent, after precipitation of copper(II) as CuS, by filtration and HPLC purification using a Technosphere 5 Amino (30 × 0.4 cm) column and a mixture of CH_3CN and water (1/1) as eluent.

Potentiometric titrations were carried out in aqueous solution by means of two fully automated computer-controlled meters (Metrohm E654) using a combined glass electrode (Metrohm 125). All potentiometric data were handled by the program SUPERQUAD [8].

CD Measurements were performed on a JASCO J-500A spectropolarimeter equipped with a DP-500N data processor.

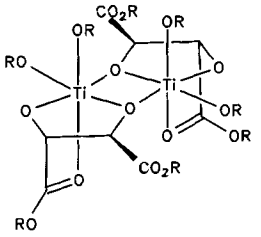
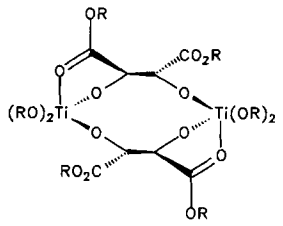
Competing Occurrence of Isomeric (Dialkyltartrato)zirconocene Dimers with Dimetallatricyclic and Ten-Membered Dimetallamonocyclic Frameworks**

By *Gerhard Erker,** *Stefan Dehnicke, Mathias Rump, Carl Krüger, Stefan Werner,* and *Matthias Nolte*

Dinuclear (dialkyltartrato)titanium alkoxides are starting substances for the generation of important enantioselective catalysts.[1] It is still an open question, however, whether the catalytically active species is derived only from the dimetallatricyclic structure type **1** found in the solid state[2, 3] or whether the isomeric ten-membered dimetallamonocyclic structure **2**[4] is also present in equilibrium. We have investigated the structure and dynamic behavior of (dialkyltartrato)zirconocenes as catalytically inactive model systems for **1**/**2** and have made a surprising observation.



1



2

Reaction of (2*R*, 3*R*)-(+)-diisopropyl tartrate (**4a**) with dimethylzirconocene (**3**) results in loss of methane and dimerization to give the dimetallatricyclic complex **5a**. The dimetallatricyclic structure is confirmed in the solid state by the crystal structure analysis (Fig. 1) and in solution by the symmetry properties of the complex revealed by the low-temperature NMR spectra. For example, the ^1H NMR spec-

trum (4.7 T) of **5a** at 233 K in CD_2Cl_2 shows two sets of signals for the methine protons of the isopropoxy groups at $\delta = 5.2$ and 4.9 in a ratio of 1:1; the framework methine protons (the protons of the CH(E)CH(E) unit, E = $-CO_2CHMe_2$) appear as an AX system at $\delta = 4.67$ and 4.17 ($^3J = 8.3$ Hz). When the monitoring temperature is raised, pairwise coalescence of the signals of the ester groups, as well as those of the framework methine protons, is observed. Above the coalescence temperature of 255 K, the framework methine protons appear as a singlet. An activation barrier of $\Delta G^{\neq} = 12 \pm 1$ kcal mol^{-1} at 255 K was estimated for the underlying exchange process from the temperature-dependent ^{1}H NMR spectra (C*H*(E) coalescence).

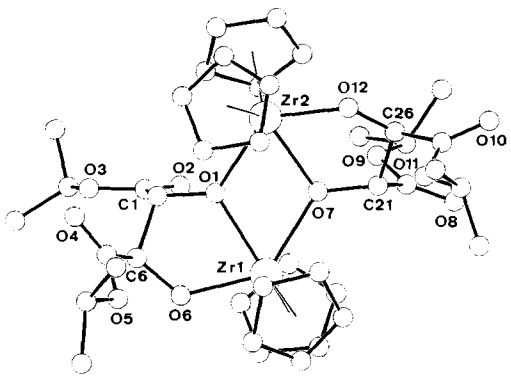

Fig. 1. Molecular structure of the dimetallatricyclic complex **5a**. Selected bond distances [Å] and angles [°]: Zr1-O1 2.239(5), Zr1-O6 2.066(6), Zr1-O7 2.268(5), Zr2-O1 2.244(6), Zr2-O7 2.258(5), Zr2-O12 2.032(6); C1-O1-Zr2 127.8(5), Zr1-O1-Zr2 113.7(2), Zr1-O1-C1 118.2(5), C21-O7-Zr1 127.2(5), Zr1-O7-Zr2 112.1(2), Zr2-O7-C21 116.8(5). Folding of the central Zr_2O_2 four-membered ring, 157°; angle of the Cp centroids with Zr1 and Zr2, 122.5 and 121.2°, respectively.

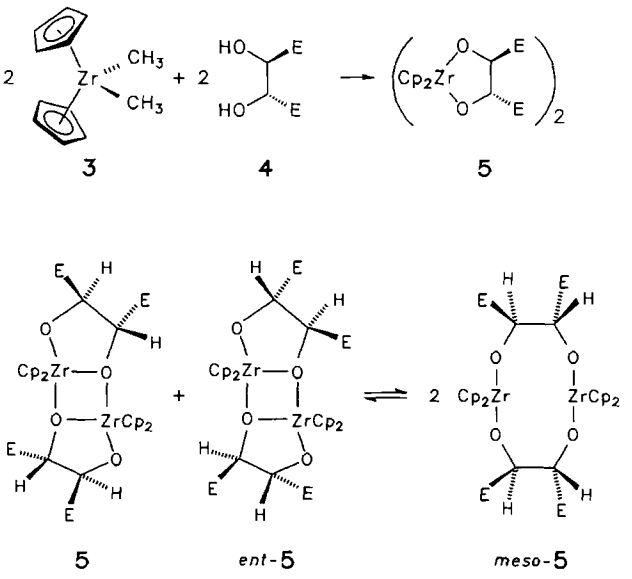
A quite analogous dynamic behavior in solution has long been known for the "Sharpless system" **1** ($\Delta G^{\neq} \approx 15$ kcal mol^{-1}).[2a, b] As in the case of our zirconocenes, it is also an open question there whether an inter- or an intramolecular equilibration is involved. Therefore, we allowed dimethylzirconocene to react with (2*S*, 3*S*)-(−)-diisopropyl tartrate to give *ent*-**5a**. ^{1}H NMR spectroscopy can be easily used to follow and to analyze kinetically the intermolecular exchange reaction of the monomeric five-membered metallacyclic complex *trans*-$Cp_2\overline{ZrOCH(E)CH(E)O}$, starting from the racemate prepared from the components **5a** and *ent*-**5a**, by monitoring the appearance of, for example, the singlet of the framework methine protons of the complex *meso*-**5a** at 268 K in CD_2Cl_2 (equilibrium *rac*-**5a**/*meso*-**5a** ≈ 1:1, $\Delta G^{\neq} = 21 \pm 1$ kcal mol^{-1} at 268 K).[5]

The products of the reaction of dimethyl tartrate (**4b**) with dimethylzirconocene behave analogously. At 233 K, the ^{1}H NMR spectrum of the optically active (dimethyltartrato)zirconocene dimer **5b** displays an AX spin system ($\delta = 4.81$, 4.11, $^3J = 9.5$ Hz) for the framework methine protons, which coalesces above 255 K to a singlet ($\Delta G^{\neq}_{intra} = 12 \pm 1$ kcal mol^{-1} at 262 K). The intermolecular exchange reaction **5b** + *ent*-**5b** ⇌ *meso*-**5b** proceeds about seven orders of magnitude slower ($\Delta G^{\neq}_{inter} = 20 \pm 2$ kcal mol^{-1} at 268 K).

The chiral (*rac*-**5a**, *rac*-**5b**) and achiral (*meso*-**5a**, *meso*-**5b**) diastereomeric (tartrato)zirconocene dimers show very different dynamic behavior. In the case of the racemic compounds (see above), the singlet of the framework methine protons ($\delta = 4.45$, *rac*-**5a**; $\delta = 4.56$, *rac*-**5b**) is split into an AX spin system on cooling, whereas, in the case of *meso*-**5a** and *meso*-**5b**, a corresponding intramolecular exchange process cannot be frozen out on the NMR time scale. Down to the lowest temperature attainable, the signals of the framework methine protons of the *meso* diastereomers remain unchanged ($\delta = 4.39$ (202 K), *meso*-**5a**; $\delta = 4.49$ (213 K), *meso*-**5b**). This simple stereochemical variation results, at least for the dimeric (dialkyltartrato)zirconocenes, in a dramatic change in the activation barrier for the intramolecular equilibration process; possibly, the diastereomers *rac*-**5** and *meso*-**5** have completely different structures. The NMR spectra of these *meso* compounds are fully consistent with a ten-membered dimetallacylic structure.



4,5: E = $-CO_2CHMe_2$ (a) ; $-CO_2CH_3$ (b)

For the chiral compound **5b**, obtained by reaction of dimethylzirconocene with (2*R*, 3*R*)-(+)-dimethyl tartrate, we demonstrated that external effects alone could cause a change in the preferred dimeric structure. The NMR spectra (see above) of **5b** indicate a C_2-symmetric dimetallatricyclic structure in solution (CD_2Cl_2). In the solid state, on the other hand, the ten-membered dimetallamonocyclic structure is favored, as shown by the crystal structure analysis of **5b** (Fig. 2, crystals from CH_2Cl_2).

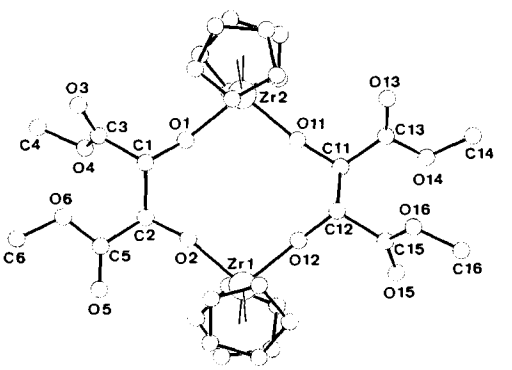


Fig. 2. Molecular structure of the ten-membered dimetallacyclic complex **5b**. Selected bond angles [°]: O2-Zr1-O12 99.4(2), O1-Zr2-O11 100.8(2)°. Angle of the Cp centroids with Zr1 and Zr2 126.7 and 127.4°, respectively.

In the crystal, **5b** displays a crown-shaped ten-membered ring framework. The ester groups are arranged pairwise in a nearly C_2-symmetric fashion. For both pairs, the Zr–O (carbonyl) distances are too large for an interaction (Zr1-O5, 3.88; Zr2-O3 4.48, Zr1-O15 4.18, Zr2-O13 4.00 Å). Noteworthy are the short bonds of the zirconium atoms to the ring oxygen atoms (Zr1-O2 1.952(3), Zr1-O12 1.952(8), Zr2-O11 1.941(3), Zr2-O1 1.974(6) Å) and the substantially increased Zr–O–C angles in the metallacycle (Zr1-O2-C2 152.9(2), Zr1-O12-C12 158.8(3), Zr2-O1-C1 148.2(2), Zr2-O11-C11 169.9(4)°). Accordingly, the formation of energetically favorable metal–oxygen π interactions can compensate for the energy difference between a ten-membered dimetallacyclic and the commonly observed dimetallatricyclic structure.[6]

If it is equally facile to effect the change between a ten-membered dimetallacyclic and a dimetallatricyclic structure through external influences in the case of the dinuclear (dialkyltartrato)titanium catalysts,[2, 3] then the question of the detailed structure of the active species in these important enantioselective catalyst systems is again open. Since, in such a case, it is problematic to draw conclusions about the structural parameters from direct observation, we are trying to obtain this information on modified catalyst systems in which stereochemical probes are incorporated.

Experimental Procedure

5a: Reaction of **3** (1.52 g, 6.04 mmol) with **4a** (1.39 g, 5.92 mmol) ($[\alpha]_D^{25}$ = + 17.0) in 80 mL of CH_2Cl_2 gave, after removal of the solvent and recrystallization twice from toluene, 2.50 g (93 %) of **5a**; m.p. 146–153 °C (dec.). $[\alpha]_D^{25}$ = + 28.0 (c = 0.82, CH_2Cl_2). Correct C, H analysis. ^{1}H NMR (200 MHz, CD_2Cl_2, 300 K): δ = 6.25 (s, 20 H; Cp), 5.09 (sept, 4H; $CHMe_2$), 4.45 (s, 4H; CH(metallacycle), 1.36 (d, 12 H; CH_3), 1.34 (d, 12 H; CH_3).

Crystal structure analysis of **5a**: $C_{40}H_{52}O_{12}Zr_2$, crystal size, 0.25 × 0.36 × 0.29 mm; M = 907.3, a = 9.692(1), b = 9.784(1), c = 21.105(2) Å, β = 93.88(1)°, V = 1996.9 Å^3, ϱ_{calcd} = 1.51 g cm^{-3}, μ = 5.71 cm^{-1}, Z = 2, space group $P2_1$, λ = 0.71069 Å, Enraf-Nonius CAD4 diffractometer, 4933 measured reflections ($\pm h, +k, +l$), $[(\sin\theta)/\lambda]_{max}$ = 0.65 Å^{-1}, 4803 independent and 4439 observed reflections ($I > 2\sigma(I)$), 487 refined parameters, R = 0.053, R_w = 0.062, residual electron density 1.82 e Å^{-3}.

ent-**5a**: Reaction of **3** (1.72 g, 6.84 mmol) and *ent*-**4a** (1.60 g, 6.84 mmol) ($[\alpha]_D^{25}$ = − 16.5) gave 2.72 g (88 %) of *ent*-**5a**; m.p. 149–151 °C (dec.); $[\alpha]_D^{25}$ = − 28.2 (c = 0.93, CH_2Cl_2). Correct C, H analysis.

5b: Reaction of **3** (2.14 g, 8.51 mmol) and **4b** (1.52 g, 8.51 mmol) ($[\alpha]_D^{25}$ = + 21) gave 3.08 g (91%) of **5b**; m.p. 149 °C (dec.); $[\alpha]_D^{25}$ = +6.5 (c = 1.11, CH_2Cl_2). Correct C, H analysis. ^{1}H NMR (200 MHz, 300 K, CD_2Cl_2): δ = 6.24 (s, 20 H; Cp), 4.56 (s, 4 H; CH) 3.71 (s, 12 H; CH_3) ^{13}C NMR (50 MHz, 300 K, CD_2Cl_2): δ = 173.9 (C=O), 112.9 (Cp), 84.8 (CH), 52.0 (OCH_3). Crystal structure analysis of **5b**: $C_{32}H_{36}O_{12}Zr_2$; crystal size, 0.39 × 0.49 × 0.49 mm, M = 795.1, a = 8.222(1), b = 18.842(2), c = 11.240(1) Å, β = 107.85(1)°, V = 1657.4 Å^3, ϱ_{calcd} = 1.59 g cm^{-3}, μ = 6.76 cm^{-1}, Z = 2, space group $P2_1$, λ = 0.71069 Å, Enraf-Nonius CAD4 diffractometer, 4092 measured reflections ($\pm h, +k, +l$), $[(\sin\theta)/\lambda]_{max}$ = 0.65 Å^{-1}, 3892 independent and 3805 observed reflections ($I > 2\sigma(I)$), 416 refined parameters, R = 0.022, R_w = 0.029, residual electron density 0.22 e Å^{-3}. Further details of the crystal structure investigations are available on request from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, W-7514 Eggenstein-Leopoldshafen 2, (FRG) on quoting the depository number CSD-55411, the names of the authors, and the journal citation.

ent-**5b**: Reaction of **3** (1.34 g, 5.34 mmol) and *ent*-**4b** (0.95 g, 5.34 mmol) ($[\alpha]_D^{25}$ = − 21) gave 2.12 g (quant.) of *ent*-**5b**; correct C, H analysis; m.p. 149 °C (dec.); $[\alpha]_D^{25}$ = − 6.1 (c = 0.95, CH_2Cl_2).

Bis(hydroperoxy)naphthaldiimide as a "Photo-Fenton Reagent": Sequence-Specific Photocleavage of DNA

By *Seiichi Matsugo, Shosuke Kawanishi, Koji Yamamoto, Hiroshi Sugiyama, Teruo Matsuura,* and *Isao Saito**

Dedicated to Professor Kurt Schaffner on the occasion of his 60th birthday

In view of the high level of interest in the role of the hydroxyl radical (HO•) in biological systems,[1] several approaches toward the development of efficient methods for HO• generation without using transition-metal ions and hydrogen peroxide have been investigated.[2, 3] Our objectives are to design an efficient organic precursor that generates pure HO• by low-energy irradiation, such as long-wavelength UV (>350 nm) or visible light irradiation. Such molecules, referred to as "photo-Fenton reagents", are particularly attractive as a controllable and mechanistically less complicated HO• source for applications in a number of biologically important reactions such as cross-linking of biopolymers[4] and cleavage of DNA[5] and proteins.[6] The design criteria include the ease of synthesis, stability at ambient temperature, solubility in aqueous solvents, and ability to produce free HO• by irradiation with long-wavelength light. Our initial studies have indicated that hydroperoxyphthalimides can photogenerate HO• upon irradiation at λ > 280 nm.[3] In the present work, a naphthaldiimide derivative bearing a symmetrical bis-hydroperoxy group was designed in order to improve the efficiency of HO• generation per molecule and to enhance the absorption at longer-wavelengths. It acts as an effective photogenerator of HO• and can induce sequence-specific cleavage of duplex DNA at the 5′ site of 5′-GG-3′ sequences.

Bis(hydroperoxide) **1** was prepared from the corresponding dimethyl ketal **2** by treatment with excess ethereal hydro-

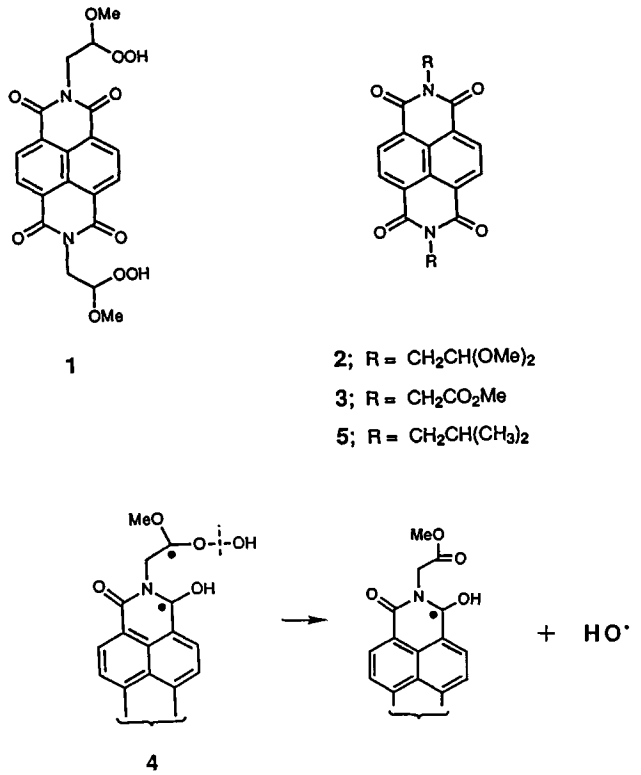
gen peroxide in the presence of triflic acid (1 equivalent) in dichloromethane at 0°C followed by recrystallization (67%). The thermally stable hydroperoxide **1**[7] was soluble in aqueous organic solvents (up to 0.25 mM in acetonitrile–water 8:92) and exhibited a strong absorption at 377 nm (lg $\varepsilon = 4.45$).

Photolysis of **1** in acetonitrile at 366 nm under nitrogen proceeded rapidly to give the ester **3** quantitatively with a quantum yield of $\Phi = 0.18$.[8] In the presence of adamantane (5 equivalents) as HO• acceptor, 1-adamantanol, 2-adamantanol, and adamantanone were obtained in 30, 15, and 6% yields, respectively, based on **1**, and their formation was inhibited by addition of an HO• scavenger such as dimethyl sulfoxide. Generation of HO• during this photodecomposition was confirmed by an ESR spin trapping method using 4,5-dihydro-5,5-dimethyl-3*H*-pyrrole-*N*-oxide (DMPO).[3] Upon brief exposure of a solution of **1** (100 μM) and DMPO (1.5 mM) in sodium cacodylate buffer (pH 7.0) to 366-nm light, intense ESR signals (1:2:2:1 four-line pattern, $a_N = a_H = 14.8$ G, $g = 2.0058$) characteristic of a hydroxyl radical–DMPO adduct[9] were detected. Exclusive formation of **3** accompanied by HO• generation is consistent with a mechanism involving γ-hydrogen abstraction by the naphthalimide carbonyl followed by β cleavage of the labile O–O bond of the biradical **4**,[10] and cannot be explained by direct homolysis of the O–O bond initiated by intramolecular energy transfer from the photoexcited naphthaldiimide chromophore.[3]



We have examined the strand scission of DNA in the presence of **1** by using supercoiled circular φX174RFI DNA (form I). Single-strand breaks and a small amount of double-strand breaks at higher conversion were observed, as evidenced by the production of form II and form III DNA, respectively (Table 1). Addition of sodium benzoate as HO• scavenger to the reaction system considerably inhibited the DNA cleavage.[11] The base and sequence specificity of

Table 1. Cleavage of supercoiled circular ØX 174 RFI DNA (form I) into nicked circular (form II) and linear DNA (form III) by photoirradiation of **1** [a].

Conc. of **1** [μM]	% form I[b]	% form II[b]	% form III[b]
100	–	88.0	12.0
10	23.8	72.4	3.8
1	69.5	28.4	2.1
0 [c]	83.1	16.9	–

[a] The reaction mixtures containing 25 μM DNA (form I) and varying concentrations of **1** in 50 mM sodium cacodylate buffer (pH 7.0) were irradiated at a distance of 10 cm from the light source at 0°C for 20 min and analyzed by agarose gel electrophoresis. [b] The values were determined by densitometry reading after ethidium staining. [c] The DNA used contained a small amount of form II DNA.

DNA cleavage was analyzed by using ^{32}P-end-labeled DNA fragments obtained from human c-Ha-*ras*-1 protooncogene[12] (Fig. 1). Hydroperoxide **1** induced DNA strand cleavage preferentially at the 5′ site of 5′-GG-3′ sequences after piperidine treatment. No cleavage was observed at other sites, including single G residues. This is in marked contrast to the photocleavage of DNA mediated by singlet oxygen, where the cleavage occures equally at each G residue after piperidine treatment.[13] In control experiments, photoirradiation of the related naphthaldiimide derivatives **2** and **5** did not induce DNA cleavage, even after piperidine treatment. These results indicate the crucial role of the hydroperoxy group of **1** in the specific photocleavage and clearly eliminate the possibility of oxidative DNA cleavage with singlet oxygen generated from the photoexcited naphthaldiimide.

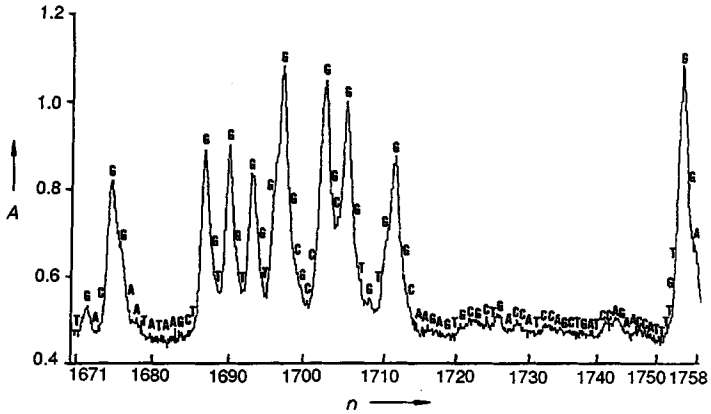


Fig. 1. Site specificity of the DNA cleavage in the photoirradiation of **1**. A solution containing the ^{32}P-5′-end-labeled 261-bp fragment (*Ava*I *1645-*Xba*I 1905) of human c-Ha-*ras*-1 protooncogene[12] and 10 μM of **1** in 50 mM sodium cacodylate buffer (pH 7.0) was photoirradiated for 20 min under the conditions shown in Table 1. After piperidine treatment (1 M, 90°C, 20 min) the DNA fragments were separated by electrophoresis on an 8% polyacrylamide/8 M urea gel. The relative amounts of oligonucleotides produced by the photoreaction and following piperidine treatment were measured by a laser densitometer. The horizontal axis shows the nucleotide number of the DNA fragment (from left to right, 5′ → 3′). *A* = absorption.

The DNA cleavage was enhanced approximately 10-fold upon treatment with piperidine at 90°C, suggesting that HO• reacts preferentially with the DNA base, particularly with the guanine base rather than the sugar backbone.[5c, d, e, 14] The cleavage of double-stranded DNA by HO• with piperidine treatment usually occurs at every nucleotide position with some preference for G and T.[5c, 15b] We therefore propose that the observed specific cleavage is a consequence of the selective binding of **1** to 5′-GG-3′ sequences.[16]

This method of HO• generation is very efficient and could be quite attractive for the use in applications requiring HO• in a number of other biological systems.

The Interaction of Tri-*tert*-butylgallium with White Phosphorus: Isolation of an Unusual Gallium Phosphorus Cluster**

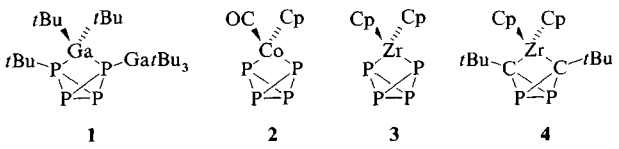
By *Michael B. Power* and *Andrew R. Barron**

Despite the vast quantity of literature concerning compounds containing both group 13 and 15 elements, and their proposed relevance to electronic materials,[1] there has been surprisingly little variation in the chemistry of these compounds since they were first reported nearly 30 years ago.[2] Thus, the vast majority of the compounds fall into one of two classes of compound, i.e., $[MR_x(ER'_2)_{3-x}]_n$ (x = 0, 1, 2 and n = 1, 2, 3)[3] and $(RMER)_n$ (n = 2 → ∞)[4] where M is a group 13 metal, Al, Ga, or In and E is one of the group 15 elements N, P, As, or Sb. Two notable exceptions are the unusual gallium-arsenic and gallium-phosphorus clusters reported by the groups of *Wells* et al.[5] and *Power* et al.,[6] $[(GaR_2)(GaR)_4(AsHPh)(AsPh)_6]$ and $[Ga(GaR)_3(PR')_4(PHR')]$ (R = CH_2SiMe_3, R' = 1-adamantyl, Ar = 2,4,6-$iPr_3C_6H_2$).

In an effort to develop new classes of mixed 13/15 compounds we have investigated the reaction of group 13 alkyls with elemental phosphorus. The results for $GatBu_3$ are presented herein.

The reaction of white phosphorus, P_4, with two molar equivalents of $GatBu_3$,[7] in pentane at room temperature, affords a colorless solid with a composition corresponding to $Ga_2P_4tBu_6$ **1**. The medium-resolution mass spectrum (70 eV, CI, NH_3) of **1** exhibits a fragmentation pattern m/z consistent with loss of tBu (m/z = 566) and $GatBu_3$ (m/z = 365).

The ^{1}H and ^{13}C-{^{1}H}-NMR spectra of **1**[8] indicate the presence of three different *tert*-butyl environments with an integrated ratio of 3:2:1, the latter showing coupling to a single phosphorus atom. The ^{31}P-{^{1}H}-NMR spectrum of **1**[8] consists of three signals which exhibit P–P one-bond coupling to give two triplets and a doublet of doublets. The one-bond connectivity of the phosphorus atoms is confirmed by the homonuclear 2D-^{31}P-NMR-COSY[9] spectrum. The shift of the downfield triplet (δ = −50.73) is close to that observed for "tBuP" fragments in the polycyclodiphosphanes tBu_6P_8 (δ = −45),[10] while the two upfield signals (δ = −226.81 and −327.43) are indicative of a tetrahedrane type phosphorus environment, and may be compared with those for the transition metal complexes **2** (δ = −258.2, −335.9, and −376.9),[11] **3** (δ = 166.1 and −206.5),[12] and **4** (δ = −247.0).[13]



1 **2** **3** **4**

The similarity of the ^{31}P-NMR spectrum for **1** to that of **2** suggests that they are structurally related, however, since the structure of **1** could not be established unequivocally from NMR spectroscopy, an X-ray crystal structure analysis was performed,[14] the result of which is presented in Figure 1. The X-ray structure is entirely consistent with analytical and spectroscopic data. All the P–P distances [2.197(2)–2.214(2) Å] are consistent with that of a P–P single bond. The Ga(1)–P(1) and Ga(1)–P(4) distances, 2.515(2) and 2.476(2) Å respectively, are towards the long end of the range previously observed for Ga–P bonds, 2.370(3)–2.475(4) Å,[6, 15] consistent with the strain imposed by the small P(1)–Ga(1)–P(4) angle, 68.8(1)°. The dative P(4)–Ga(2) bond [2.619(2) Å] is significantly longer than those associated with the P–Ga–P bridge, and is presumably a result of the steric crowding at Ga(2) due to the three *tert*-butyl ligands.

Since little is known about ring opening reactions of white phosphorus with Lewis acids we can, at present, only speculate as to how **1** is formed. Presumably the initial reaction

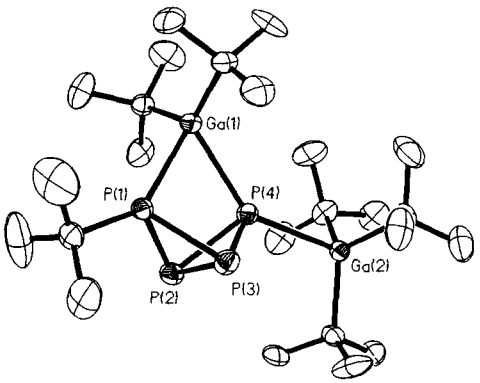

Fig. 1. Structure of **1** in the crystal (ORTEP). Important bond lengths and angles, see text.

involves the addition of a Ga–C bond across one of the P–P bonds in P_4 since a related addition of alkyllithium reagent across P_4 has previously been described.[16] Finally, we note that thermolysis (75–80 °C in C_6D_6) of **1** results in the liberation of $GatBu_3$ and the decomposition of the remaining GaP_4tBu_3 moiety.

Experimental Procedure

1: $GatBu_3$ (3.89 g, 16.13 mmol) in pentane (40 mL) was stirred for 3 to 4 h with P_4 (1.0 g, 8.07 mmol) at room temperature under nitrogen. After all the P_4 had been visibly consumed by the reaction a pale yellow solution resulted. Some solvent was then removed under vacuum (ca. 10 mL), and the resulting solution set aside in the freezer overnight (−25 °C). A large mass of white crystalline material was deposited, which was filtered and dried under vacuum. More crystalline material was obtained from the filtrate. Yield: 4.10 g, 84%. m.p. 120–121 °C.

A Simple Way to Predict the Products of Topochemical Photoreactions on the Basis of Force Field Calculations

By *Klaus Angermund,* Ingo Klopp, Carl Krüger,* and *Matthias Nolte*

Dedicated to Professor Kurt Schaffner on the occasion of his 60th birthday

Photoreactions in organic solids are for the most part highly selective and, in many cases, enable access to unusual compounds.[1] For the interpretation of such solid-state reactions the relationship between the packing of the molecules in the crystal and the resulting photoproducts is very important. These relationships were first studied systematically by *Schmidt* et al.[2] on substituted *trans*-cinammic acids. The investigations led to the establishment of the topochemical postulate, according to which "reactions in organic crystals take place with minimal atomic and molecular movement".

Recently, however, reactions have also been observed which take place with considerable reorganization of the molecules in the crystal lattice.[1, 3] They can be described in terms of an extension of the topochemical postulate proposed by *Cohen*.[4] According to this *reaction cavity principle*, "lattice-controlled reactions proceed with minimal distortion of the surface of the reaction cavity". The reaction cavity is the space which is formed by the molecules surrounding the transition state of the reaction complex in the lattice.

If several reaction products are conceivable a prediction of the products on the basis of force field calculations or theoretical methods should be possible via a determination of the cavity deformation. The result of such calculations, however, crucially depends on the formulation of the transition state and on the size of the crystal lattice section ("thickness of cavity wall") used in describing the reaction cavity, and thus significantly limits the practical application of this principle.

We have therefore modified the Cohen model to the effect that the deformation of the cavity by the transition state of

[*] Dr. K. Angermund, Prof. Dr. C. Krüger, Dipl.-Chem. M. Nolte

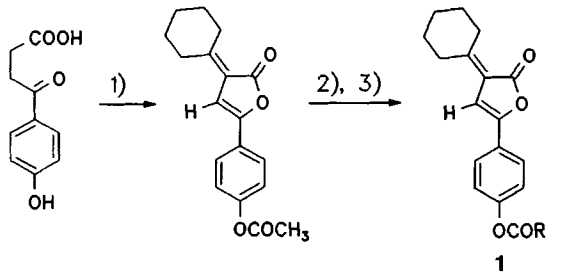
Stiftstrasse 34–36, W-4330 Mülheim an der Ruhr (FRG)

the reaction complex is approximated as deformation of the product in the reaction cavity assumed to be rigid. This leads to some essential advantages in the practical application of the concept: The smallest crystal lattice section to be set as reaction cavity is unequivocally given by the nearest neighbors of the starting compounds in the crystal. Inclusion of further parts of the crystal lattice has no significant influence on the result. The computational effort required is comparatively small because only the deformation of the potential products instead of that of the whole reaction cavity, as in the classical Cohen model, has to be determined. The energy difference $\Delta E = E_K - E_G$ between the potential energy of the most stable conformation of the product in the cavity (E_K) and that of the isolated molecule (E_G) serves as a relative measurement. It is obtainable by known methods of molecular modeling.[5] For topochemically-controlled reactions before the recrystallization, ΔE is a measure of the solid-state solubility (stabilization) of the products in the reacting crystal. A comparison of the ΔE values should afford information about the expected reaction products, which exceeds the prediction by topochemical considerations.

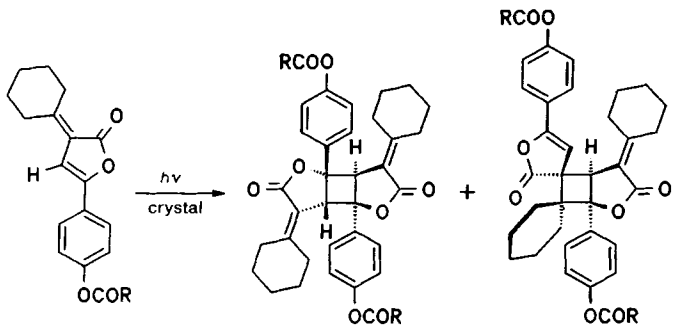
In the class of compounds including the 3-cyclohexylidene-5-phenyl-2(3*H*)furanones, lattice-controlled photoreactions are known which cannot be explained by the topochemical rules[6] and are therefore especially suitable for checking the predictions made by using our approach. For this purpose the homologous esters **1a** and **1b** were chosen and prepared from *p*-hydroxy-substituted β-benzoylpropionic acids by a method analogous to the Erlenmeyer azalactone synthesis (Scheme 1).[6, 7]



1

Scheme 1. Synthesis of the esters **1** [6, 7]. 1) Cyclohexanone, Ac_2O, lead(II) acetate, 4 h at 150 °C; 2) $Al(OiPr)_3$, CH_2Cl_2, MeOH, 2 h reflux; 3) acid chloride RCOCl, triethylamine, CH_2Cl_2.

The crystalline esters were then irradiated with UV light (λ = 360 nm) and the product distribution was determined NMR spectroscopically.[6] Whereas the propionate **1a** forms only the symmetrical [2 + 2]-photoproduct **2a**, the homologous butyrate **1b** forms the corresponding product **2b** in similar yields together with the unsymmetrical [2 + 2]-dimer **3b** (Scheme 2).



1a : R = C_2H_5 **2a** (21.2%) **3a** (−/−)

1b : R = C_3H_7 **2b** (20.4%) **3b** (16.6%)

Scheme 2. Photoreactions of the crystalline esters **1a** and **1b**.

To find an explanation for the different reaction behavior, the X-ray crystal structures of **1a** and **1b** were determined.[8] The packing of the two compounds in the crystal reveals two different arrangements of monomers around the inversion centers from which the reactions could take place (Fig. 1).

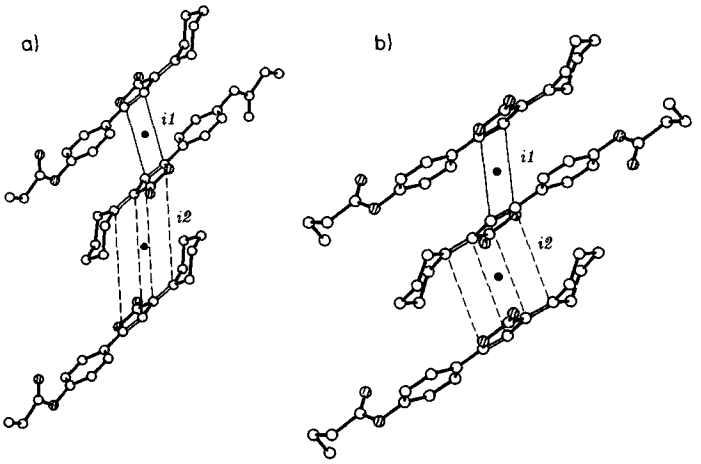


Fig. 1. Sections from the crystal structures of the butenolides **1a** (a) and **1b** (b). investigated. C: white spheres; O: shaded spheres; inversion centers: black spheres. The potential reaction routes leading to the symmetrical *endo* dimers are indicated by unbroken lines, those to the unsymmetrical dimers **3** by broken lines, via the corresponding inversion centers *i1* and *i2*, respectively. Coordinates of the inversion centers: a) $i1 = (0, \frac{1}{2}, \frac{1}{2})$, $i2 = (0, 0, \frac{1}{2})$; b) $i1 = (\frac{1}{2}, \frac{1}{2}, 1)$, $i2 = (\frac{1}{2}, \frac{1}{2}, \frac{1}{2})$. Distances of the midpoints of the double bonds from a) *i1* 3.88(1) Å, *i2* 6.25(1) Å; b) *i1* 3.88(1) Å, *i2* 4.92(1) Å. Distances between the planes of the π-systems a) *i1* 3.52(1) Å, *i2* 4.82(1) Å; b) *i1* 3.43(1) Å, *i2* 4.50(1) Å.

According to the topochemical rules, the reaction leading to the symmetrical *endo*-dimers **2a** and **2b** is allowed at inversion center 1 (*i1*) but forbidden at inversion center 2 (*i2*).[2] A formation of the unsymmetrical dimers **3a** and **3b** is similarly topochemically forbidden, since bonds over distances of more than 4.9 Å would have to be coupled for a reaction at both inversion centers (Fig. 1). The deviating reaction behavior of **1b** should, however, be understandable in terms of the reaction cavity concept and, in principle, should be predictable according to our method.

The most stable of all potential dimers were determined using the program SYBYL,[9] and the relevant energy values E_K and E_G were calculated (Table 1).

As can be seen from Table 1, the symmetrical dimers **2a** and **2b** are stabilized by the crystal assembly in a reaction at

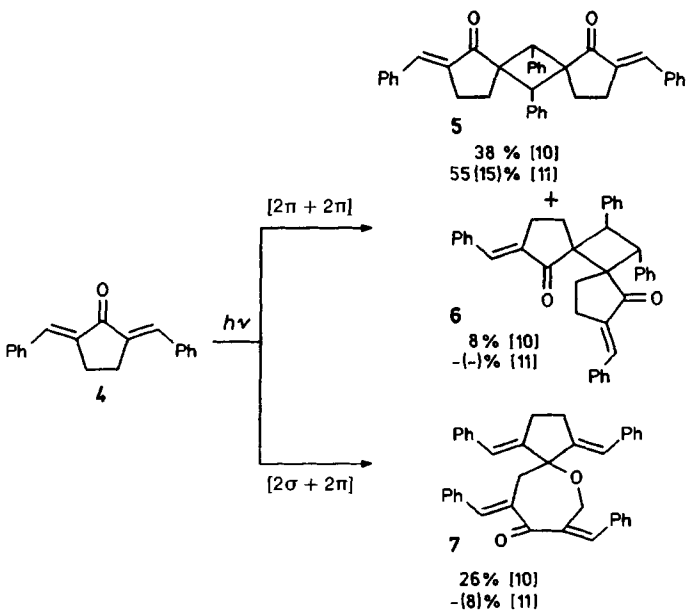
Table 1. Potential energies [kcal mol^{-1}] of the possible dimers of **1** and **4** in the reaction cavity (E_K) and as isolated molecules (E_G).

Reaction at	Product	E_K	E_G	ΔE	Product	E_K	E_G	ΔE
i1	**2a**	−15	50	−65	**2b**	−26	49	−75
	3a	57	51	6	**3b**	56	51	5
i2	**2a**	211	50	161	**2b**	70	49	21
	3a	53	51	2	**3b**	17	51	−34
	5	9	68	−59	**6**	166	58	108
	7	65	32	33				

i1 (ΔE negative). A conceivable reaction at the inversion center *i2*, on the other hand, leads to a destabilization (ΔE positive) of the products in the cavity. The energy differences between the two routes indicate that the dimerization to the symmetrical product should proceed at *i1*, which is consistent with the results of the topochemical consideration. In the case of the dimer **3a**, both formations at *i1* as well as at *i2* are associated with a slight destabilization. Since an energetically much more favorable reaction route exists with the formation of **2a** at *i1*, **3a** should not be formed, or only in very small amounts.

For the formation of the dimer **3b** at the inversion center *i2*, however, we found a stabilization by the crystal lattice. Hence, the reaction leading to the unsymmetrical dimer **3b** should also be possible in the case of the butyrate **1b**, but, due to the greater stabilization by the cavity, **2b** should be formed preferentially. Thus, a qualitatively correct prediction of the photoproducts is possible with the modified Cohen model also in the case of the topochemically forbidden reactions leading to **3a** and **3b**.

The limited application of this purely energetic approach is manifested in the photodimerization of crystalline 2,5-dibenzylidenecyclopentanone **4** (Scheme 3).[10, 11] Whereas



Scheme 3. Photoreactions of crystalline **4**. The yields quoted in brackets refer to 25% conversion.

the results of the simulation correlate with the experimental findings of the $[2\pi + 2\pi]$ cycloaddition leading to **5** and **6**,[10, 11] **7** formed by radical $[2\sigma + 2\pi]$ addition[10] is significantly stabilized by the crystal assembly (see Table 1). Its high ΔE value, together with the experimental finding that **7** could only be isolated at incomplete (25%) conversion,[11] points to a kinetically controlled reaction for which the modified Cohen model is of limited application. Reversal of the product distribution upon carrying out the reaction in solution[10, 11]—a kinetic inhibition of the formation of **7** presupposed[10]—follows from a comparison of the E_G-values of **5** and **6**, in agreement with the experiment (Table 1).

That only two energy values are necessary per potential product molecule in the method presented here enables a simpler calculation, with generally accessible force-field programs, compared to the classical Cohen model. This possibility of predicting products, is together with the simulation of molecular packings, an important step on the way to a rational design of organic solid-state reactions and thus also to their application in synthetic chemistry.

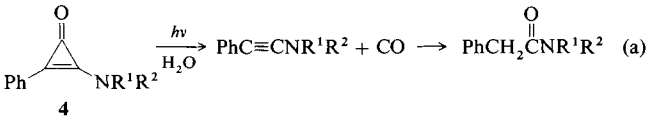
[**] This work was supported by the Natural Sciences and Engineering Research Council of Canada, the Donors of the Petroleum Research Fund, administered by the American Chemical Society, the National Institutes of Health, and the Swiss National Science Foundation (Project No. 2000-5.515)

of their facile isomerization to ketenimines, have heretofore been observed only in the gas phase or in low-temperature matrices.[2, 3] We wish to report that we have now developed a method for generating all three classes of ynamines in aqueous solution and have begun to study their chemistry in that medium.

$RC{\equiv}CNR_2$ (1) $RC{\equiv}CNH_2$ (2) $RC{\equiv}CNHR$ (3)

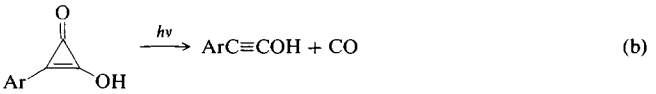
We have found that flash photolysis[4] of phenylaminocyclopropenones **4** in aqueous solution gives carboxylic acid amides as the ultimate reaction products [Eq. (a)], via short-lived transient intermediates with strong absorbance in the region $\lambda = 270-290$ nm, which, from their behavior as well as by analogy with our previous flash photolytic generation



$$\xrightarrow[H_2O]{h\nu} PhC{\equiv}CNR^1R^2 + CO \longrightarrow PhCH_2\overset{O}{\overset{\|}{C}}NR^1R^2 \quad (a)$$

4

a: $R^1 = R^2 = H$; **b**: $R^1 = R^2 = C_6H_5$; **c**: $R^1 = H$, $R^2 = C_6F_5$; **d**: $R^1 = H$, $R^2 = C_6H_{11}$; **e**: $R^1 = H$, $R^2 = CH(CH_3)_2$; **f**: $R^1/R^2 = (CH_2)_5$; **g**: $R^1/R^2 = [(CH_2)_2]_2O$; **h**: $R^1/R^2 = C(N(CH_3)_2)_2$.



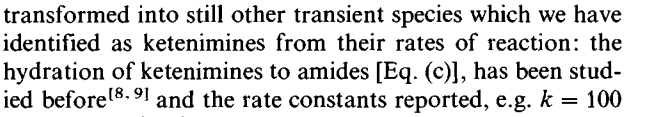
$$\xrightarrow{h\nu} ArC{\equiv}COH + CO \quad (b)$$

of ynols from arylhydroxycyclopropenones,[5] [Eq. (b)], we conclude are ynamines.[6] Ynamines produced in this way with at least one hydrogen substituent on amine nitrogen are transformed into still other transient species which we have identified as ketenimines from their rates of reaction: the hydration of ketenimines to amides [Eq. (c)], has been studied before[8, 9] and the rate constants reported, e.g. $k = 100$ and 2200 $M^{-1}s^{-1}$ for the hydrogen-ion catalyzed reactions

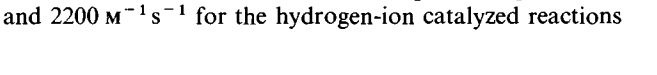
$$PhCH{=}C{=}NR \xrightarrow{H_2O} PhCH_2\overset{O}{\overset{\|}{C}}NHR \quad (c)$$

of phenylketene-*N*-phenylimine and phenylketene-*N*-isopropylimine respectively, are in good agreement with our values, $k = 98$ and 2190 $M^{-1}s^{-1}$. Ynamines without amino hydrogen, i.e. tertiary ynamines, cannot isomerize to ketenimines, but their direct hydration has also been studied before,[11] and again the rates we measure are consistent with those reported, e.g. $k = 1.03\ s^{-1}$ for the "uncatalyzed" reaction of phenylpiperidinoacetylene in 8.6% dioxane-water vs. our $k = 1.84\ s^{-1}$ for wholly aqueous solution.

These reactions of primary, secondary, and teriary ynamines are acid catalyzed, and the conversion of primary and secondary ynamines into ketenimines is base catalyzed, as well. The acid-catalyzed reactions show general catalysis and give sizeable kinetic isotope effects, e.g. $k_{H_2PO_4^\ominus}/k_{D_2PO_4^\ominus} = 5.9$ for phenylpiperidinoacetylene. This is classic evidence for rate-determining proton transfer to carbon and suggests that the reaction is initiated by electrophilic addition of a proton to acetylenic carbon, as shown in [Eq. (d)]. Such a mechanism is further supported by the correlation illustrated in Figure 1, which shows that the rate of reaction increases with increasing basicity, and therefore cation stabilizing ability, of the amino portion of the substrate. This step in the case of tertiary ynamines is then followed by hydration of the cation and amide formation, as shown in [Eq. (e)], and in the case of primary and secondary ynamines, by loss of a proton from nitrogen, [Eq. (f)]. The fact that primary, secondary,



$$PhCH{=}CNR_2^\oplus \xrightarrow[-H^\oplus]{H_2O} PhCH{=}\overset{OH}{\overset{|}{C}}NR_2 \longrightarrow PhCH_2\overset{O}{\overset{\|}{C}}NR_2 \quad (e)$$



$$PhCH{=}CNHR^\oplus \longrightarrow PhCH{=}C{=}NR + H^\oplus \quad (f)$$

and tertiary ynamines obey the same correlation (Fig. 1) implies that this proton loss from nitrogen is not concerted with proton addition to carbon, for such proton loss cannot occur in the case of tertiary ynamines. The slope of the correlation is 0.34, which suggests an early transition state consistent with the rapid nature of these reactions.

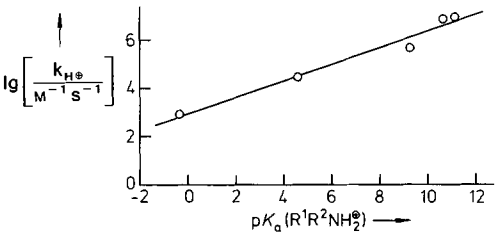


Fig. 1. Relationship between rate constants for the reaction of ynamines with hydronium ion in aqueous solution at 25 °C and acid dissociation constants of the conjugate acids of amines corresponding to the amino portion of the ynamines; from left to right: $R^1 = H$, $R^2 = C_6F_5$; $R^1 = H$, $R^2 = C_6H_5$; $R^1 = R^2 = H$; $R^1 = H$, $R^2 = C_6H_{11}$, and $R^1R^2 = (CH_2)_5$.

In sufficiently acidic solutions, ynamines can be expected to experience reversible protonation on nitrogen in addition to rate-detemining proton transfer to carbon [Eq. (g)]. The *N*-protonated species will be much less susceptible to elec-

$$PhC{\equiv}CNHR_2^\oplus \overset{K_a}{\rightleftharpoons} PhC{\equiv}CNR_2 + H^\oplus \xrightarrow{[a]} PhCH{=}CNR_2^\oplus \quad (g)$$

[a] rate determining

trophilic attack on carbon, and carbon protonation will consequently be inhibited. We detected no such inhibition up to the most acidic solutions we examined, e.g. $[H^\oplus] = 0.5$ M for phenylcyclohexylaminoacetylene. This sets an upper limit of $pK_a < 0.3$, i.e. $-\lg 0.5$, for the conjugate acid of this ynamine, and that makes the ynamine more than ten orders of magnitude less basic than cyclohexylamine ($pK_a(BH^\oplus) = 10.6$). This strong base-weakening effect of the acetylenic group parallels the remarkable acid-strengthening effect which we found in the case of ynols,[5, 12] and which is also evident in the ionization of ynamines as acids (*vide infra*).

The base-catalyzed isomerization of primary and secondary ynamines to ketenimines shows only specific hydroxide-ion catalysis. This suggests a mechanism, shown in [Eq. (h)],

$$PhC{\equiv}CNHR + HO^\ominus \overset{K}{\rightleftharpoons} PhC{\equiv}CNR^\ominus + H_2O \xrightarrow{k[a]} PhCH{=}C{=}NR + HO^\ominus \quad (h)$$

[a] rate-determining

$$PhC{\equiv}CNR_2 + HA \longrightarrow PhCH{=}CNR_2^\oplus + A^\ominus \quad (d)$$

consisting of proton transfer from the substrate to base in a rapid and reversible reaction, whose position of equilibrium is governed by the hydroxide ion concentration, followed by an "uncatalyzed" rate-determining protonation at carbon by water. The hydroxide-ion catalytic coefficient for such a process is equal to the equilibrium constant for the first step times the rate constant for the second: $k_{HO}^{\ominus} = Kk$. This equilibrium constant is also equal to the acidity constant of the ynamine ionizing as an acid divided by the autoprotolysis constant of water, $K = K_a/K_w$. Use of $k = 10^{11}\ s^{-1}$ as an upper limit for this rate constant[13] combined with the experimentally determined value of $k_{HO^{\ominus}} = 6.5 \times 10^6\ M^{-1}s^{-1}$ for phenylaminoacetylene then gives $pK_a \leq 18.0$ as an upper limit for the acid dissociation of this ynamine [Eq. (i)]. This

$$PhC{\equiv}CNH_2 \overset{K_a}{\rightleftharpoons} PhC{\equiv}CNH^{\ominus} + H^{\oplus} \qquad \text{(i)}$$

makes phenylaminoacetylene at least 17 pK units more acidic than ammonia ($pK_a = 35$[15]) and provides another example of the dramatic acidifying effect of the acetylenic group.

[9] Although ketenimines substituted at nitrogen are hydrated to amides directly[8], we have found that phenylketenimine, whose nitrogen substituent is hydrogen, is first converted into the corresponding nitrile; i.e., the cationic intermediate formed by protonation of the ketenimine at carbon loses a proton from nitrogen more rapidly than it reacts with water:

$$PhCH{=}C{=}NH \xrightarrow[-A^-]{HA} PhCH_2C{\equiv}NH^{\oplus} \xrightarrow{-H^{\oplus}} PhCH_2CN$$

This is consistent with the generally accepted mechanism for acid catalyzed hydrolysis of nitriles in which rapid and reversible protonation on nitrogen is followed by rate-determining reaction of the *N*-protonated intermediate with water[10].

Solvent Dependence of Photoinduced Intramolecular Electron Transfer: Criteria for the Design of Systems with Rapid, Solvent-Independent Charge Separation**

By *Jan Kroon, Jan W. Verhoeven,* Michael N. Paddon-Row,** and *Anna M. Oliver*

Dedicated to Professor Kurt Schaffner on the occasion of his 60th birthday

Photoinduced electron transfer constitutes one of the most versatile and potentially efficient methods for converting light energy into useful (electro)chemical energy, as unequivocally demonstrated by its successful implementation in the photosynthetic apparatus. The ongoing extensive investigations[1] of such processes have made clear that, e.g., in synthetic D(onor)-bridge-A(cceptor) systems very large charge separation distances can be realized but at the same time it has become evident that the success is critically dependent upon a number of factors relating to the structure of the system itself as well as that of its environment. We and others have addressed, via both experimental and theoretical methods, the structural requirements to be met by the "bridge" in order to sustain sufficient electronic coupling over long distances.[2–9] During these studies we have also occasionally noted the remarkable difference in solvent sensitivity that the rate of charge separation may show in structurally quite closely related D-bridge-A systems and we have pointed out the decisive role that the interdependence of solvent stabilization and solvent reorganization may play.[5, 10] In the present paper this important point is quantified by comparison of the solvent effect on the rate of photoinduced charge separation in the fully rigid and structurally related systems **1a** and **1b** (Scheme 1), for which kinetic data could be collected in a wide variety of solvents. Furthermore, as will be shown, consideration of the interplay between solvent stabilization and solvent reorganization leads to the formulation

of design criteria for systems capable of undergoing virtually medium-independent charge separation at the maximum rate feasible for a particular D/A distance.

As shown by *Rehm* and *Weller*[11, 12] the standard Gibbs free energy change ("driving force") for photoinduced electron transfer between neutral D and A species in a medium with static dielectric constant ε_s can be estimated via Equation (1),

$$\Delta G = e[E_{ox}(D) - E_{red}(A)] - E_{00} - \frac{e^2}{\varepsilon_s R_c} - \frac{e^2}{r}\left(\frac{1}{37} - \frac{1}{\varepsilon_s}\right) \quad (1)$$

which we can rewrite in the form of Eq. (2):

$$\Delta G = P - \frac{e^2}{\varepsilon_s R_c} - \frac{e^2}{r}\left(\frac{1}{37} - \frac{1}{\varepsilon_s}\right) \quad (2)$$

The parameter P ("polar driving force") represents the limiting value of ΔG for charge separation across an infinite distance in polar media and is readily accessible from the independently determined redox potentials and excitation energies (E_{00}) of the separate D and A units.

Oxidation potentials (measured in acetonitrile relative to SCE) and excitation energies for relevant model D systems **2a** and **2b** as well as the reduction potential of the model A system **3** are given in Scheme 1. Applying $R_c = 11.4$ Å for the center-to-center distance[13] and $r = 4.5$ Å for the average ionic radius,[5] the plots of ΔG versus ε_s in Figure 1 were constructed. From these plots it is evident that photoinduced charge separation in **1a** should be thermodynamically feasible in virtually all solvents, including saturated hydrocarbons ($\varepsilon_s \approx 2$), while for **1b** additional solvent stabilization ($\varepsilon_s \geq 3$) is required.

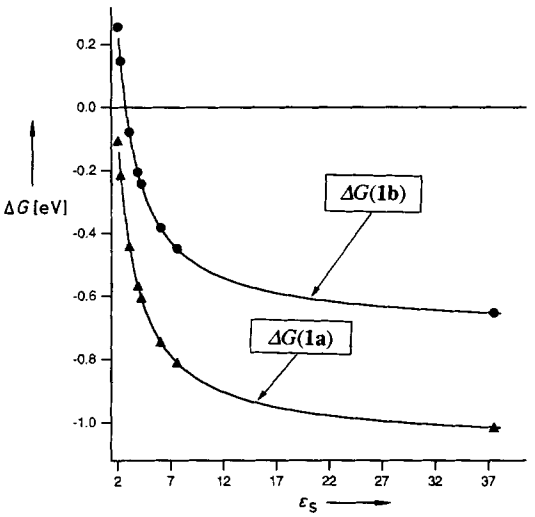

Fig. 1. Standard Gibbs free energy change (ΔG) for photoinduced charge separation in **1a** and **1b** as a function of the solvent dielectric constant (ε_s). Markers (▲ for **1a**, ● for **1b**) correspond to the solvents employed (see Table 1).

Our experimental results (see Table 1) are in line with this prediction. Thus, for **1a**, as reported earlier,[5] photoinduced charge separation occurs with a high rate (k_{et}) in all solvents investigated, but for **1b** we now find that it can only be detected if $\varepsilon_s > 3.1$, with the exception of benzene ($\varepsilon_s = 2.28$). The latter is obviously due to specific solvation effects that cannot be accounted for by Equation (1), but the overall

Table 1. Rate data (k_{et}) for photoinduced charge separation in **1a** and **1b** as calculated from fluorescence lifetimes in various solvents.

Solvent	ε_s	n^2	**1a** $10^{-7} \times k_{et}$ [s^{-1}] [a]	**1b** $10^{-7} \times k_{et}$ [s^{-1}] [b]
cyclohexane	2.02	2.03	2100	<0.1
benzene	2.28	2.25	5200	1.4
di-*n*-butyl ether	3.10	1.96	4700	<0.1
diisopropyl ether	3.88	1.87	–	0.5
diethyl ether	4.20	1.83	4700	1.4
ethyl acetate	6.02	1.88	4500	3.9
tetrahydrofuran	7.58	1.98	6700	6.5
acetonitrile	37.5	1.81	3000	11

[a] Data from Ref. [5]. [b] Analogous to the procedure used for **1a** (Ref. [5]), rates for **1b** were calculated from comparison of the naphthalene fluorescence lifetimes of **1b** and **2b** as k_{et} (**1b**) = $(\tau(\mathbf{1b}))^{-1} - (\tau(\mathbf{2b}))^{-1}$. Compound **2b** shows little solvent dependence of its fluorescence lifetime (59 ± 3 ns) over the range of solvents investigated while the lifetime of **1b** decreases from 60 ns in cyclohexane to 8 ns in acetonitrile.

data once more underline[14] the remarkable usefulness of this equation for estimating ΔG.

Closer inspection of the data in the Table reveals a dramatic difference in solvent dependence of k_{et} for **1a** and **1b** in the region where ΔG is negative for both molecules. While k_{et} in **1a** shows very minor ε_s dependence over the whole range of solvents, in **1b** it increases by more than an order of magnitude in response to a tenfold increase of ε_s (i.e. from diisopropyl ether to acetonitrile). Even more strikingly, under conditions of virtually identical ΔG, such as constituted by comparison of **1a** in di-*n*-butyl ether ($\Delta G = -0.44$ eV) and **1b** in tetrahydrofuran ($\Delta G = -0.45$ eV), the rate in **1a** is almost three orders of magnitude higher than in **1b**.

This observation leads to the important generalization that while a lower intrinsic driving force (ΔG), such as that in **1b** as compared to **1a**, can be compensated by use of a solvent with high ε_s, this evidently does not proportionally decrease the barrier ($\Delta G^{\neq}$) to electron transfer.

We have presented earlier[10] a rationalization of a similar difference in solvent sensitivity between two other rigid D-bridge-A systems via qualitative energy surface intersection diagrams. We now pursue this aspect more quantitatively in terms of the Marcus[15] expression for $\Delta G^{\neq}$ [Eq. (3)], which quantifies the relation between $\Delta G^{\neq}$, ΔG, and the overall reorganization energy, λ. The latter can be written as the sum of an internal part and a solvent dependent part ($\lambda = \lambda_{in} + \lambda_s$). Using approximations similar to those used in deriving Equation (1) above, the solvent reorganization energy, λ_s,[16] can be expressed by Equation (4), where n is the solvent refractive index.

$$\Delta G^{\neq} = \frac{(\Delta G + \lambda)^2}{4\lambda} \quad (3)$$

$$\lambda_s = e^2\left(\frac{1}{r} - \frac{1}{R_c}\right)\left(\frac{1}{n^2} - \frac{1}{\varepsilon_s}\right) \quad (4)$$

In Figure 2, the $\Delta G^{\neq}$ values for **1a** and **1b**, which were calculated from Equations (1)–(4), are plotted for the solvents experimentally employed (see Table 1) and also as a continuous function of ε_s at a fixed value of $n^2 = 2$, which is a reasonable approximation for most (organic) solvents. In calculating the $\Delta G^{\neq}$ values, the previously determined[5] λ_{in} value of 0.6 eV for **1a**, was used.

In agreement with experiment $\Delta G^{\neq}$ for **1a** is predicted to be low for all values of ε_s. In contrast, $\Delta G^{\neq}$ for **1b** initially

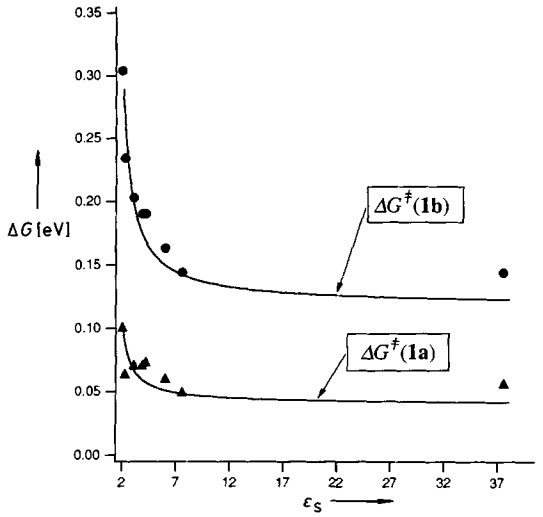

Fig. 2. Activation barrier for photoinduced charge separation in **1a** (▲) and **1b** (●) in various solvents as calculated from Equations (1)–(4). Continuous lines were calculated for $n^2 = 2$.

falls sharply with increasing ε_s, but it soon reaches a constant value of ca. 0.14 eV, owing to the compensating effects of changes in λ_s and ΔG. Thus, in (very) polar solvents the difference between **1a** and **1b** approaches 0.1 eV, implying a ratio $k_{et}(\mathbf{1a})/k_{et}(\mathbf{1b}) = 50$, thereby accounting for the major part of the experimental ratio, which amounts to about 300 (see Table 1). The latter would imply a barrier difference of 0.15 eV, but it should be borne in mind, that part of the discrepancy may in fact be due to a difference between **1a** and **1b** in electronic coupling as a result of different orbital-coefficients and/or -symmetry at the donor site.[17] The latter point is currently under further study.

From the experimental and theoretical results presented above it can be concluded that the same design criteria with regard to $E_{ox}(D)$, $E_{red}(A)$ and E_{00} that allow a system to undergo optimally fast photoinduced charge separation also make this rate virtually solvent independent. Thus, a check for solvent (in)dependence also provides a convenient experimental method to test whether optimization with respect to the rate of charge separation has been achieved. This intriguing interdependence between the degree of sensitivity of the electron transfer rate to solvent polarity and the extent by which the rate deviates from its optimal value is visualized in Figure 3, which plots the energy barrier for electron transfer in systems with the geometrical properties of **1a** and **1b** (i.e. $R_c = 11.4$ and $r = 4.5$ Å) as a function of both ε_s and the polar driving force P. The $\Delta G^{\neq}$ plots in Figure 2 represent sections through the three dimensional plot of Figure 3 at two specific values of P (i.e. $P = -0.98$ eV for **1a** and $P = -0.62$ eV for **1b**).

The observation that a unique valley, running parallel to the ε_s axis, occurs with $\Delta G^{\neq} = 0$ in Figure 3 demonstrates that a single P value ($= P_{opt}$) can be found at which both optimally fast electron transfer and virtual solvent independence of the rate of this process can be achieved. From the equations given above, together with the condition that $\Delta G^{\neq} = 0$, expression (5) can be derived:

$$P_{opt} = -\lambda_{in} - \frac{e^2}{n^2}\left(\frac{1}{r} - \frac{1}{R_c}\right) + \frac{e^2}{37r} \approx -\lambda_{in} - \frac{e^2}{n^2}\left(\frac{1}{r} - \frac{1}{R_c}\right) \quad (5)$$

This demonstrates that P_{opt} is independent of the solvent dielectric constant, but depends on the charge separation distance. On the other hand, since λ_{in} and the average ionic radius r are mainly determined by the structure of the D and A units employed while n varies only marginally with solvent, this also implies that for any given D/A combination the condition defined by Equation (5) can only be fulfilled at a single charge separation distance R_c, irrespective of the solvent employed. In fact at the distance $R_c = 11.4$ Å dictated by the structure of compounds **1a** and **1b** a $P_{opt} = -1.57$ eV (see Fig. 3) would be required (assuming the same λ_{in} and r) to make electron transfer barrierless in all solvents. Clearly, **1a** ($P = -0.98$ eV) comes closer to meeting this requirement than does **1b** ($P = -0.62$ eV), which is in agreement with our experimental results. Interestingly, Equation (5) also allows definition of the P_{opt} for very large charge separation ($R_c \gg r$), leading to $P_{opt}(R_c \rightarrow \infty) = -\lambda_{in} - e^2/n^2 r$ which amounts to 2.2 eV for the present type of D/A combinations.

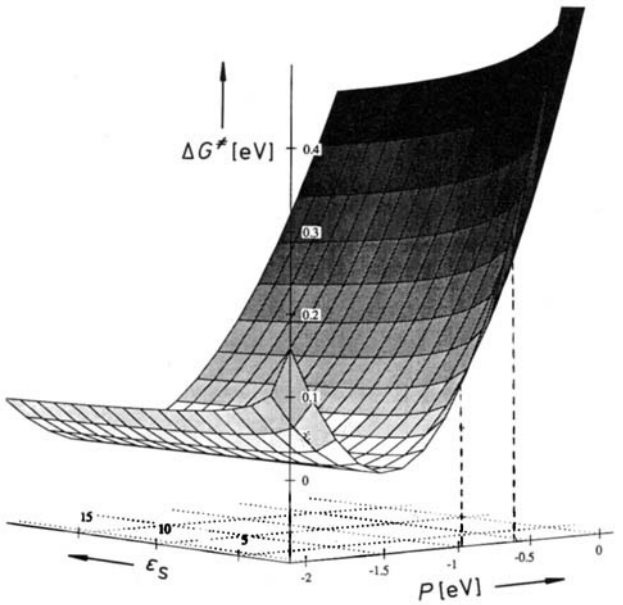

Fig. 3. Activation barrier, $\Delta G^{\neq}$ (in eV), of photoinduced charge separation for systems with $\lambda_{in} = 0.6$ eV, $R_c = 11.4$ Å and $r = 4.5$ Å as a function of the solvent dielectric constant ε_s and the "polar driving force" P [eV], at a fixed value of the refractive index ($n^2 = 2$). Vertical dashed lines indicate P values for **1a** (-0.98 eV) and **1b** (-0.62 eV).

In conclusion we propose that application of Equation 5 provides useful design criteria for systems intended to display optimally fast charge separation across a given distance that is also virtually independent of both medium effects and temperature, since under the barrierless conditions existing at P_{opt} the reorganization energy exerts only a weak ($\lambda^{-0.5}$) influence on the rate, via the pre-exponential component, and so does the temperature. Since in such systems the transition state for charge separation can be reached without solvent reorientation, it may be predicted that for systems designed to work at P_{opt}, the viscosity and dielectric relaxation rate of the medium are of minor importance.[18–20]

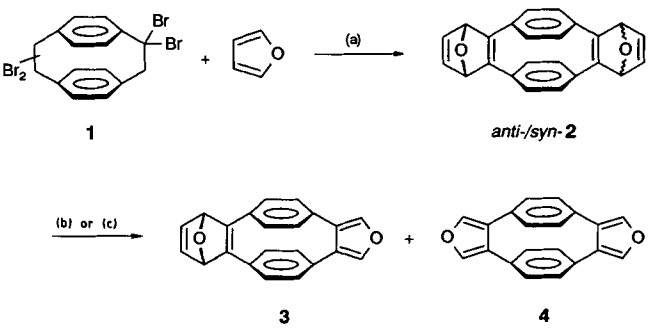
A General Entry to Rigid Systems with Alternatingly Orthogonal Arene Units via Diels-Alder Reactions**

By *Burkhard König, Jürgen Heinze, Klaus Meerholz,* and *Armin de Meijere**

Dedicated to Professor Horst Prinzbach on the occasion of his 60th birthday

Unconventional materials with novel features are of interest worldwide,[1] and new and unusual properties can be expected for polycyclic aromatic systems with alternatingly orthogonal subunits. One basic system of this sort is realized in 1:2,9:10-dibenzo[2.2]paracyclophane-1,9-diene.[1] In fact di- and tetraphenyl derivatives of dibenzo[2.2]paracyclophanediene do exhibit uncommon features in that the odd electrons in their radical anions and dianions reside in the annelated biphenyl units and are isolated from each other by the intersecting [2.2]paracyclophane moiety.[2] Consequently, the triplet diradical dianions of these systems appear to be energetically favored over the singlet states. Our recently reported octaphenyldibenzo[2.2]paracyclophane-1,9-diene can be reversibly reduced to its hexaanion.[3] Extended systems containing several dibenzo[2.2]paracyclophanediene units linked through electroactive arene groups can be envisaged to accept an even larger number of charges which would be partitioned in groups by the intersecting orthogonal units. We therefore wanted to develop a versatile methodology that makes such molecules accessible from relatively simple starting materials.

The mixture of 1,1,9,9- and 1,1,10,10-tetrabromo[2.2]-paracyclophane **1** can readily be obtained in virtually quantitative yield from commercially available [2.2]paracyclophane.[4] Fourfold dehydrobromination of **1** with potassium *tert*-butoxide in tetrahydrofuran leads to the stepwise generation of two triple bonds in the bridges of the molecule which rapidly add to dienes present.[3] Furan readily cycloadds to the reactive intermediates to give a mixture of *anti*- and *syn*-isomeric bisendooxides *anti*/*syn*-**2** in 23% yield (Scheme 1). Flash vacuum pyrolysis (FVP) at 240 °C (2 mbar) via double *retro Diels-Alder*-reaction with evolution of ethyne afforded 1:2,9:10-bis-(3,4-furano)[2.2]paracyclophane **4** in 60% yield. When the pyrolysis was carried out at lower pressure (0.01 mbar), corresponding to a shorter contact time in the hot tube, a mixture of **2** (20%), **4** (34%) and 1:2-(1,4-epoxybenzo)-9:10-(3,4-furano)[2.2]paracyclophan-1-ene **3** (27%) was obtained. The starting material **2** and two products **3**/**4** can be separated by column chromatography on silica gel (dichloromethane/hexane 1:1).[5] This two-step procedure starting from **1** easily affords mono- and difurano-annelated [2.2]paracyclophanes **3** and **4** on a gram scale. The new compounds are stable, crystalline solids, and can be stored without noticeable alteration for months.



Scheme 1. a) KO*t*Bu, THF, room temperature, 23%. b) FVP, 240 °C, 0.01 mbar; 20% *anti*/*syn*-**2**, 27% **3**, 34% **4**. c) FVP, 240 °C, 2 mbar; 60% **4**.

Both **3** and **4** were allowed to react with a variety of dehydroarenes and bisdehydroarenes generated in situ from the corresponding vicinal dibromoarenes with *n*-butyllithium in close analogy to procedures described in the literature (Scheme 2, Table 1).[6–8] Treatment of a mixture of **3** (1 equiv.) and 1,2,4,5-tetrabromo-3,6-di-*n*-hexylbenzene **5**[9] (0.5 equiv.) with 1.1 equivalents of *n*-butyllithium at low temperatures gave, after warming to room temperature, a complex mixture of isomeric cycloadducts. This mixture was deoxygenated with low-valent titanium ($TiCl_4/LiAlH_4$)[11] without further purification to give bis-2:3,6:7-[1:2-benzo[2.2]paracyclophane-1,9-dieno]-9,10-di-*n*-hexylanthracene **6** (overall yield 25%). In solution, **6** adds oxygen, when exposed to light and air at room temperature; the corresponding 9,10-endoperoxide is formed in quantitative yield. As a solid, "bisphane" **6** can be stored indefinitely without any change.

Upon reaction of 1,2,3,4-tetrabromo-5,6-dimethylbenzene **7** (0.5 equiv.) with *n*-butyllithium (1.1 equiv.) in the presence of **3** (1 equiv.) and subsequent deoxygenation with $TiCl_4/LiAlH_4$, 2:3,6:7-bis[1:2-benzo[2.2]paracyclophane-1,9-dieno]-1,2-dimethylphenanthrene **8** was obtained (15%). As in all these cases, it was not necessary to separate the

3	1,2,3,4-tetrabromo-5,6-dimethylbenzene **7**	1) 0.5 equiv. **7**, 1.1 equiv. *n*BuLi, toluene, −90 °C → 25 °C, 6 h 2) $TiCl_4$, Zn, NEt_3, THF, 25 °C, 1 h	**8** (> 290)	15
3	1,2,4,5-tetrabromo-3,6-di-*n*-hexylbenzene **5**	1) 1.0 equiv. **5**, 1.1 equiv., *n*BuLi, −90 °C → 25 °C, 6 h 2) $TiCl_4$, $LiAlH_4$, NEt_3, THF, 25 °C, 1 h	**9** (> 290)	40
4	**9**	1) 2.5 equiv. **9**, 2.7 equiv. *n*BuLi, toluene, −90 °C → 25 °C, 6 h 2) $TiCl_4$, $LiAlH_4$, NEt_3, THF, 25 °C, 1 h	**10** (> 290)	18

[a] *Anti*- and *syn*-isomers were not separated in the first step. Where applicable, the ratio of isomers was about 1 : 1. [b] Isolation of the pure Diels Alder adducts is not necessary for the deoxygenation step.

stereoisomeric endooxides before the reductive deoxygenation.

In order to obtain the one-sided cycloadduct **9**, a 1 : 1 mixture of **3** and **5** was treated with 1.1 equivalents of *n*-butyllithium at low temperature and the mixture warmed to room temperature. Reductive deoxygenation of the crude mixture of *anti*- and *syn*-isomers without affecting the bromine substituents was achieved with $TiCl_4$ and zinc in refluxing tetrahydrofuran according to a procedure described by *Hart* et al.[6] 1:2-Benzo-9:10-(1,4-di-*n*-hexyl-2,3-dibromo-6,7-naphtho)[2.2]paracyclophane-1,9-diene **9** was isolated as a crystalline compound with an overall yield of 40%. According to its substitution pattern, **9** can be used to generate an aryne again. Thus, reaction of **9** with 1.1 equivalents of *n*-butyllithium in the presence of **4** at low temperature afforded a mixture of two isomeric cycloadducts (*anti*/*syn*), from which the extended "trisphane" hydrocarbon **10** was obtained in 18% yield by reductive deoxygenation with $TiCl_4/LiAlH_4$. In solution, **10** exhibits the same reactivity toward oxygen and light as the anthracene derivative **6**.

All the new hydrocarbons are white crystalline solids with melting points higher than 290 °C. In solution, the "bisphane" **6** and the "trisphane" **10** show intense fluorescence. Compared with the spectra of anthracene,[10] bathochromic shifts of 25 to 34 nm are observed for all bands in the UV spectra, and shifts of 37 to 42 nm as well as remarkable increases in quantum yields to $\Phi = 0.8$ (excitation wave length 388 nm) in the fluorescence spectra.[5]

The cyclic voltammogram of the "bisphane" **6** shows four reversible one-electron reduction waves at $E^0 = -1.93$, -2.43, -3.03 and -3.10 V, when measured in dimethylamine with 0.1 M tetrabutylammonium bromide[11] versus Ag/AgCl.[12] Since anthracene can only be reduced to a dianion in the accessible region, this means that **6** accepts two electrons in the central anthracene moiety and one each in its two phane units. In spite of its four *n*-hexyl groups, the 38 Å long "trisphane" **10** caused severe solubility problems. Nevertheless, two reversible one-electron and one reversible two-electron reduction waves were detected in the cyclic voltammogram of **10** at $E^0 = -1.93$, -2.06 and -2.41 V. A slight rise in the current at the limit of the supporting electrolyte reduction indicates a further charge-transfer step below -3.19 V. Obviously, the two anthracene units are again reduced to their dianionic redox states. The fifth redox step then leads to the charging of the phane units, which occurs at extremely negative potentials due to the strong Coulombic repulsion of the already existing excess charges.

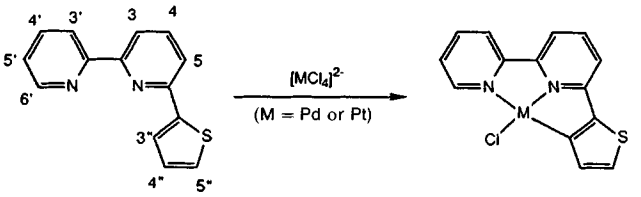
Metal-Ion Dependent Regioselectivity in Cyclometalation Reactions**

By *Edwin C. Constable,* Roland P. G. Henney, Paul R. Raithby,* and *Lynn R. Sousa*

Cyclometalated compounds contain chelated ligands in which one of the donor sites is an anionic carbon center.[1] Recently, there has been particular interest in species in which the carbon center is formally an aryl anion,[2] and we have been investigating the features which favor the formation of such compounds.[3,4] The ligand 6-(2-thienyl)-2,2′-bipyridine (HL) has proved to be of particular interest, and forms complexes in which it behaves as an N-, N,N-, N,N,S- or N,N,C-donor ligand.[3,4] In this communication we wish to describe the behavior of HL with d^8 metal centers, and correct an earlier misassignment of the structure of a gold(III) complex.[4]

The reaction of HL with $K_2[MCl_4]$ (M = Pd or Pt) in aqueous acetonitrile at room temperature results in the direct and near-quantitative formation of the cyclometalated complexes [MLCl] **1** as yellow-brown microcrystalline solids. Each compound exhibits peaks assigned to $[ML]^+$ and $[MLCl]^+$ in their FAB mass spectra (3-nitrobenzyl alcohol matrix). The ^1H-NMR spectra of CD_2Cl_2 solutions of the complexes are sharp and well-resolved, and may be fully assigned using a double quantum filtered phase-sensitive COSY experiment. In each case only two resonances, a pair of doublets, are assigned to H4″ and H5″ of the metalated thienyl ring. In the platinum complex H4″ and H5″ also exhibit satellites due to coupling with ^{195}Pt of 20 Hz and 8 Hz respectively. The $^3J_{H\text{-}H}$ coupling constant of 4.8 Hz establishes the site of metalation as C3′, because in thiophenes $^3J_{2,3}$ ($\equiv {}^3J_{4,5}$) lies in the range 4.90–5.80 Hz, whereas $^3J_{3,4}$ is in the range 2.45–4.35 Hz.[5]



HL **1**

In contrast to the above, the reaction of $Na[AuCl_4]$ with HL in aqueous acetonitrile results in the precipitation of a non-metalated complex $[Au(HL)Cl_3]$ **2** as an orange microcrystalline solid in 95 % yield. The ^1H-NMR spectrum of this complex clearly exhibits three resonances assigned to the non-metalated thienyl ring. We believe the compound to be similar in structure to $[Au(bipy)Cl_3]$.[6]

The reaction of HL with $Na[AuCl_4]$ at 90 °C in aqueous acetonitrile results in the formation of a red-brown crystalline product **3**; the same compound is obtained by heating **2** under similar conditions. Microanalysis indicates a formulation $[AuLCl_2]$ to be appropriate, and the ^1H-NMR spectrum confirms the presence of a metalated thienyl ring showing only two doublet resonances (CD_2Cl_2, $\delta = 7.06$, 7.44, $^3J_{HH}$ 3.9 Hz). A detailed analysis of the ^1H-NMR spectrum of **3** suggested that only the terminal pyridine ring was coordinated, whilst the central pyridine was not. Furthermore, the coupling constants within the metalated ring (3.9 Hz) are indicative of a compound containing H3″ and H4″ rather than one which is metalated at the expected 3″-position. These observations are at odds with our previous belief that the complex was analogous to those formed with palladium(II) and platinum(II), and in order to clarify the position we have determined the crystal and molecular structure of **3**.[7] It proved to be extremely difficult to grow crystals of **3**, but eventually one poor quality crystal was obtained.

[**] This work was supported by the U.K. Science and Engineering Research Council (Studentship for *R.P.G.H.*). We also thank the Royal Society of Great Britain for assistance in the purchase of spectrometers and Johnson Matthey p.l.c. for support and the loan of precious metal salts.

The crystal and molecular structure of **3** is shown in Figure 1. The compound is dimeric and contains two crystallographically non-equivalent $[AuLCl_2]$ units. Each thiophene is metalated at the 5″-position; the C–Au distances 1.95(3) and 2.00(4) Å are unremarkable and typical of gold(III) organometallic compounds. The two gold centers are approximately square-planar (the greatest deviation of any atom from each of the square planes is 0.1 Å), with the coordination sphere being completed by two *trans* chlorines and the nitrogen of the terminal pyridine ring of the second ligand. The gold–chlorine and gold–nitrogen distances are typical for gold(III) complexes. Each ligand acts as a bridging C,N-donor to two gold centers; the ligands are metalated but not *cyclo*metalated. The central pyridine ring of each ligand is noncoordinated. The dimeric structure is achieved by twisting the molecule about the internuclear C–C bonds between the pyridyl (33.4°, 41.5°) and the pyridyl and thienyl rings (14.8°, 4.4°).

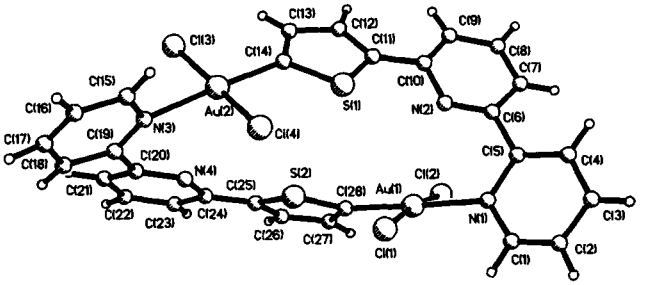

Fig. 1. The crystal and molecular structure of **3** showing the numbering scheme adopted. Important bond lengths [pm] and angles [°]: Au(1)-Cl(1) 227.9(14), Au(1)-Cl(2) 2279(12), Au(1)-N(1) 206.3(26), Au(1)-C(28) 195.3(29), Au(2)-Cl(3) 225.4(12), Au(2)-Cl(4) 227.9(12), Au(2)-C(14) 200.0(39), Au(2)-N(3) 211.1(34), Cl(1)-Au(1)-Cl(2) 172.5(5), Cl(1)-Au(1)-N(1) 90.2(10), Cl(2)-Au(1)-N(1) 88.3(9), Cl(1)-Au(1)-C(28) 88.8(13), Cl(2)-Au(1)-C(28) 93.0(12), N(1)-Au(1)-C(28) 177.7(17), Cl(3)-Au(2)-Cl(4) 173.7(4), Cl(4)-Au(2)-C(14) 92.3(12), Cl(4)-Au(2)-N(3) 89.6(10), Cl(3)-Au(2)-C(14) 91.2(12), Cl(3)-Au(2)-N(3) 87.2(10), C(14)-Au(2)-N(3) 176.2(16)

We have no evidence for the formation of 5″-metalated complexes with palladium(II) or platinum(II) compounds, or of 3″-metalated compounds with gold(III). Significantly, reactions of 2-(2′-thienyl)pyridine (HL′) appear to parallel this behavior; reaction with palladium(II) acetate or with $Li_2[PdCl_4]$ results in clean metalation at C3″ ($^3J_{4,5}$ 4.9 Hz), whereas reaction with $Na[AuCl_4]$ results in the formation of the non-metalated compound $[Au(HL')Cl_3]$ **4**.[8, 9] Upon heating **4** to 90 °C in aqueous acetonitrile a mixture of products derived from a range of reactions (chlorination, oxidative dimerization *etc.*) at C5″ are obtained in low yield. This is compatible with the formation of the non-strained chelated cyclometalated ring in the case of the metal(II) centers, and reflects the inability of the Au^{II} center to form either a complex cyclometalated at C3″ or a dimer in this case.

It has previously been noted that 2-(2′-thienyl)-pyridine forms a kinetic 3-lithio and a thermodynamic 5-lithio derivative.[10] In the case of the HL ligand, we believe that all of the metalated products are obtained under thermodynamic control; there is no evidence for the formation of other metalated species. We suggest that the differences in reactivity with isoelectronic d^8 ions result from the interplay between the differing sizes of the metal ions and the fixed 'bite' of the cyclometalated N,C donor mode. We are currently investigating the photochemical and photophysical properties of these unusual gold(III) complexes.

Experimental Procedure

The gold complexes **2** and **3** and the ligand HL were prepared as reported previously [4]. X-ray quality crystals of **3** were obtained by the diffusion of diethyl ether vapor into a solution of **3** in *N,N*-dimethylformamide.

1 (M = Pd): A solution of HL (0.016 g, 0.066 mmol) in acetonitrile (1.5 mL) was added to an aqueous solution of $K_2[PdCl_4]$ (0.022 g, 0.066 mmol in 1 mL water). The resulting solution was heated to 60 °C for 2 h., whereupon a yellow solid precipitated. This was collected by filtration to give **1** (M = Pd) [Yield 0.026 g, 99 %]. Correct C, H, N, Cl analysis. ^{1}H NMR (CD_3SOCD_3) δ = 8.62 (m, $^3J(5,6)$ = 5.1 Hz; H 6′, 7.80 (dd, $^3J(5,6)$ = 5.1, $^3J(5,4)$ = 7.6 Hz; H 5′), 8.28 (dd, $^3J(4,5)$ = 7.6, $^3J(3,4)$ = 7.9 Hz; H 4″), 8.49 (d, $^3J(3,4)$ = 7.9 Hz; H 3′) 8.05 (m, $^3J(x,4)$ = 7.9 Hz; H 4 and H 3 or H 5), 7.60 (d, $^3J(x,4)$ = 7.9 Hz; H 3 or H 5) 7.07 (d, $^3J(4,5)$ = 4.8 Hz; H 4″) 7.67 (d, $^3J(4,5)$ = 4.8 Hz; H 5″); FAB-MS (3-nitrobenzyl alcohol matrix) m/z = 378, 380 (PdLCl), 343 (PdL).

1 (M = Pt): A solution of HL (0.050 g, 0.21 mmol) in acetontrile (3 mL) was added to an aqueous solution of $K_2[PtCl_4]$ (0.085 g, 0.205 mmol in 4 mL water). The resulting solution was heated to reflux for 20 h., whereupon a brown solid precipitated. This was collected by filtration to give **1** (M = Pt) [Yield 0.086 g, 97 %]. Correct C, H, N, Cl analysis. ^{1}H NMR (CD_3SOCD_3) δ = 8.85 (m, $^3J(5,6)$ = 5.2 Hz; H 6′), 7.91 (dd, $^3J(5,6)$ = 5.2, $^3J(5,4)$ = 7.8 Hz; H 5′), 8.35 (t, $^3J(4,5)$ = 7.8, $^3J(3,4)$ = 7.8 Hz; H 4′), 8.47 (d, $^3J(3,4)$ = 7.8 Hz; H 3′), 7.98 (m, $^3J(x,4)$ = 7.9 Hz; H 4 and H 3 or H 5), 7.56 (d, $^3J(x,4)$ = 7.9 Hz; H 3 or H 5), 6.97 (d, $^3J(4,5)$ = 4.7 Hz; H 4″), 7.83 (d, $^3J(4,5)$ = 4.7 Hz; H 5″); FAB-MS (3-nitrobenzyl alcohol matrix) m/z = 468, 470 (PtLCl + H), 432 (PtL).

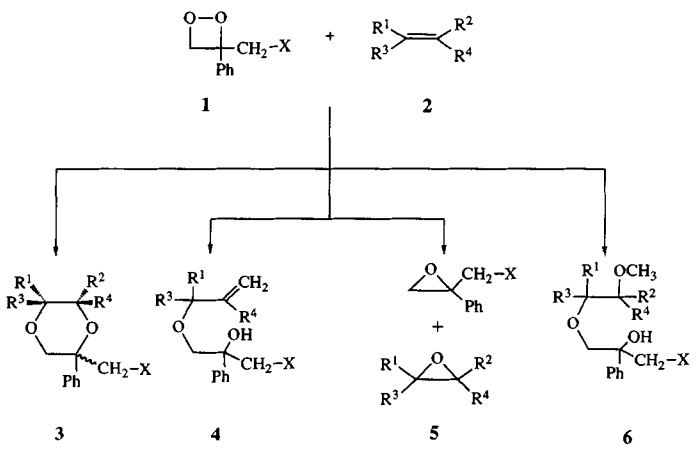
Novel Reactions of Disubstituted 1,2-Dioxetanes with Olefins as π-Nucleophiles: Cycloadditions via 1,6-Dipoles**

By *Waldemar Adam,** *Simone Andler,* and *Markus Heil*

In view of their ability to serve as an efficient source of excited carbonyl products, 1,2-dioxetanes have been the subject of intensive investigation for almost twenty years.[1] However, aside from unimolecular fragmentations in excited carbonyl compounds, only little was hitherto known about the chemical transformations of these strained peroxides. One of the first reactions of 1,2-dioxetanes with heteroatomic nucleophiles to be reported was their deoxygenation by phosphanes.[2] Biphylic insertion into the peroxide bond first yields a pentacovalent intermediate, which, after thermal elimination of phosphane oxide affords the epoxide. Also the reaction of dioxetanes with sulfides[3] generates epoxides, whereas lithium aluminum hydride,[4] thiols[5] and biologically relevant reductants,[6] such as ascorbic acid or NADH, reduce 1,2-dioxetanes to 1,2-diols. Moreover, although reactions of cyclic acyl peroxides[7] with π-nucleophiles, e.g. olefins, are quite common, such transformations do not appear to be known in the case of dioxetanes. In this communication we report the cycloaddition of 3,3-disubstituted 1,2-dioxetanes **1** with electron-rich olefins **2** to afford unusual products, whose structure depend on the type of olefin and solvent employed (Scheme 1, Table 1).



Scheme 1. **1a**: X = H; **1b**: X = Cl; **1c**: X = Br; **2a**: $R^1 = R^2 = R^3 = R^4 = OEt$; **2b**: $R^1 + R^2 = -OCH_2CH_2O-$, $R^3 = R^4 = H$; **2c**: $R^1 = R^2 = CH_3$, $R^3 + R^4 = o\text{-}OC_6H_4O$; **2d**: $R^1 = R^2 = CH_3$, $R^3 + R^4 = (CH_2)_3$; **2e**: $R^1 = R^2 = R^3 = R^4 = CH_3$; **3a**: $R^1 = R^2 = R^3 = R^4 = OEt$, X = Br; **3b**: $R^1 + R^2 = -OCH_2CH_2O-$, $R^3 = R^4 = H$, X = Br; **4a**: $R^1 = CH_3$, $R^3 + R^4 = o\text{-}OC_6H_4O$, X = Br; **4b**: $R^1 = CH_3$, $R^3 + R^4 = (CH_2)_3$, X = Br; **4c**: $R^1 = R^3 = R^4 = CH_3$, X = Br; **4d**: $R^1 = R^3 = R^4 = CH_3$, X = H; **4e**: $R^1 = R^3 = R^4 = CH_3$; X = Cl; **5a**: $R^1 = R^2 = CH_3$, $R^3 + R^4 = (CH_2)_3$; **5b**: $R^1 = R^2 = R^3 = R^4 = CH_3$; **6**: $R^1 = R^2 = R^3 = R^4 = CH_3$; X = Br.

The dioxetane **1a** was synthesized as described in the literature.[8] The previously unknown halogen-substituted derivatives **1b** and **1c**[9] were prepared from the corresponding β-bromohydroperoxides according to the usual Kopecky method.[4]

[*] Prof. Dr. W. Adam, S. Andler, Dipl.-Chem. M. Heil
Institut für Organische Chemie der Universität
Am Hubland, W-8700 Würzburg (FRG)

[**] This work was supported by the Deutsche Forschungsgemeinschaft (SFB 172 "Molekulare Mechanismen kanzerogener Primärveränderungen") and the Wilhelm-Sander-Stiftung. We are grateful to Prof. Dr. *R. Saalfrank*, Erlangen, for a sample of tetraethoxyethene.

The reaction of dioxetane **1c** with tetraethoxyethene **2a** and 1,4-dioxene **2b**, electron-rich olefins without allylic hydrogen, afforded the dioxane derivatives **3** in good yields; cleavage of the dioxetane into carbonyl fragments occurred only to a small extent (Table 1), and deoxygenation to epoxides was not observed. The moisture-sensitive orthoester product **3a** (m.p. 47–48 °C) showed characteristic singlets at $\delta = 108.8$ and 109.4 in the ^{13}C-NMR spectrum ($CDCl_3$, 63 MHz) for the orthoester carbon atoms. The cycloadduct **3b** formed from dioxetane **1c** and 1,4-dioxene **2b**, was established as its *cis* isomer (coupling between the acetal protons: $J = 1.6$ Hz) and was isolated as the diastereomeric mixture (52:48).

Table 1. Reaction of dioxetane **1c** [a] with olefins **2**.

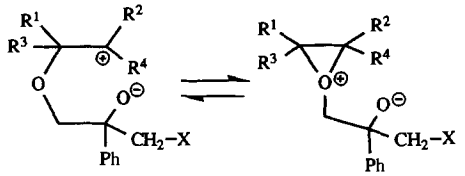
Olefin	Reaction Conditions: solvent	T [°C]	t [h]	Product Distribution [%] [b]: Adduct [c]	Epoxide [d]	Ketone [e]
2a	CH_2Cl_2	−30	0.5	**3a**: 83 (74)	0	17
2b	CH_2Cl_2	−20	1	**3b**: 78 (59) (*dr* = 52:48)	0	22
2c	CH_2Cl_2	−20	2	**4a**: 78 (38) (*dr* = 59:41)	0	22
2d	CH_2Cl_2	−20	8	**4b**: 80 (65) (*dr* = 77:23)	4	16
2e	CH_2Cl_2	−10	2	**4c**: 73 (58)	6	21
2e	CH_3OH	−20	1	**4c**: 10 **6**: 84 (73)	0	6

[a] For the reaction of **1a**, **b** with 2,3-dimethyl-2-butene cf. Ref. [13]. [b] Determined by ^{1}H-NMR spectroscopy (250 MHz) and yields refer to 100% dioxetane consumption; mass balance > 90%. [c] The adducts were isolated by column chromatography and the yields are given in parenthesis; *dr* = diastereomeric ratio. [d] 2-Bromomethyl-2-phenyloxirane and [e] ω-Bromoacetophenone were not isolated but identified by means of their characteristic ^{1}H-NMR signals.

In contrast, reaction of the 2,3-dimethylbenzo-1,4-dioxene **2c** with dioxetane **1c** furnished the ene product **4a** as the main product (two diastereomers, 59:41), together with appreciable amounts of ω-bromoacetophenone as cleavage product from dioxetane **1c** (Table 1). Epoxides or cycloadducts **3** were not observed. In a similar way, 1,2-dimethylcyclopentene **2d** and 2,3-dimethyl-2-butene **2e** gave with dioxetane **1c** the corresponding ene products, namely the β-methylene-β′-hydroxy ethers **4b**, **c**; two diasteromers (77:23) were found for the ene product derived from olefin **2d**. No cycloadducts **3** were detected, but cleavage into carbonyl products and deoxygenation of the dioxetane **1c** leading to 2-bromomethyl-2-phenyloxirane, together with the corresponding oxygen transfer products 1,2-dimethyl-1,2-epoxycyclopentane **5a**[11a] and 2,3-dimethyl-2,3-epoxybutane[11b] **5b**, were observed. Likewise, reaction of the dioxetanes **1a**, **b** with 2,3-dimethyl-2-butene **2e** resulted mainly in the formation of the ene products **4d**, **e** and small amounts of the corresponding epoxides,[12] besides considerable quantities of ketones from dioxetane cleavage. When the reaction of olefin **2e** and dioxetane **1c** was carried out in methanol, hydroxy ether **6** was obtained as the main product, the ene product **4c** was formed in only ca. 10% yield.

The two-step character of the reaction between dioxetanes **1** and olefins is evident from the observation of the cycloadducts **3**, the ene products **4**, and the methanol adduct **6**. The 1,6-dipole **7**, which is formed by attack of the π-nucleophile on the peroxide bond of the dioxetane, and is stabilized by the epoxide valence-isomeric structure **7′**, presumably operates as bona fide intermediate. All products can be convincingly explained via this dipolar intermediate. When the car-

bocation center does not bear methyl groups (olefins **2b**, **c**), the 1,6-dipole **7** cyclizes to the cycloadducts **3** (Scheme 1). Methyl groups at the carbocation center (olefins **2c**, **e**) lead exclusively to the ene product **4** by hydrogen atom abstraction. In presence of methanol, the 1,6-dipole is trapped as the hydroxy ether **6**.

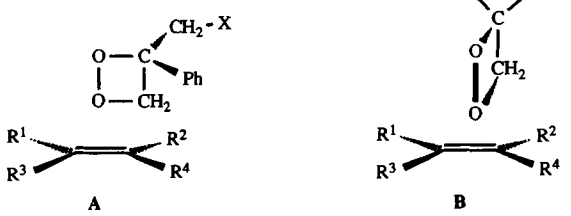


7 **7′**

In the case of the halogen-substituted dioxetanes **1b** and **1c**, instead of proton abstraction to afford the corresponding ene product, the 1,6-dipole might have also extruded halogen to give a terminal epoxide, but we did not detect it. From the point of view of energy, halogen elimination seems unfavorable compared with deprotonation, because in the former case an ion pair is formed, whereas in the latter case the charges of dipole **7** are annihilated in one step and the stable ene product **4** is formed.

It remains to explain the formation of the side products. Epoxide **5** and the expoxide derived from the dioxetane are formed by nucleophilic attack of the alkoxide center on the methylenic carbon of the dioxetane moiety of the epoxide-like 1,6-dipole **7′**. The carbonyl fragmentation products ω-bromoacetophenone and formaldehyde suggest a catalytic decomposition of the dioxetane **1**, which might arise by fragmentation of the 1,6-dipole **7** with regeneration of the olefin.

To summarize, we have found that 3,3-disubstituted 1,2-dioxetanes are quite different from the tetrasubstituted derivatives in their reactivity towards π-electron donors. For example, the reaction of tetramethyldioxetane with electron-rich olefins leads exclusively to fragmentation into carbonyl compounds instead of cycloaddition (Scheme 1). This difference in behavior is rationalized in terms of the transition states **A** or **B**. We postulate these in the attack of the 3,3-di-



A **B**

substituted dioxetane on the olefin, but for steric reasons they are unlikely in the case of tetrasubstituted dioxetanes. Of the two possibilites, again on steric grounds, transition state **A** should be preferred. A comprehensive theoretical study of these novel reactions is necessary.

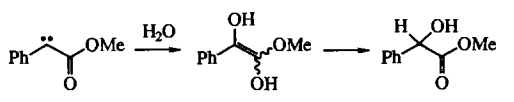
[13] Reaction of the dioxetane **1a** with 2,3-dimethyl-2-butene in CH_2Cl_2 at −20 °C gave the ene product **4d** (44%), 2-methyl-2-phenyloxirane (20%), and acetophenone (36%), while dioxetane **1b** led under these conditions to ene product **4e** (72%), 2-chloromethyl-2-phenyloxirane (1%), and ω-chloroacetophenone (28%).

The Mechanism of Acylcarbene Insertion into O–H Bonds—Direct Observation of the Enol of a Carboxylic Acid Ester in Aqueous Solution**

By *Yvonne Chiang, A. Jerry Kresge,* Przemyslaw Pruszynski, Norman P. Schepp,** and *Jakob Wirz*

One of the most common reactions of carbenes is their insertion into X–H bonds,[1] especially into the O–H bonds of alcohols and water.[2] A number of different mechanisms have been proposed for the O–H insertion reaction,[2, 3] all of which involve direct and exclusive attack of the alcohol or water at the carbene carbon atom. We wish to report that we have observed the formation of an enol intermediate in the reaction of phenylcarbomethoxycarbene **1**[4] with water, and have been able to demonstrate that "insertion" in this case involves the carbonyl group as well [Eq. (a)]; the process



1 **2** **3** (a)

may therefore be more accurately described as conjugate addition of water across the entire acylcarbene function. The enol intermediate observed is the enol tautomer **2** of methyl mandelate **3**, and our detection of this species constitutes the

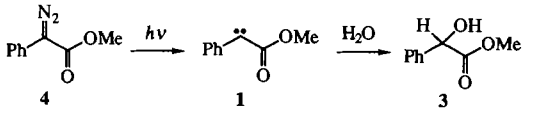
first direct observation of a carboxylic acid ester enol in aqueous solution.

We generated the carbene **1** by photolysis of methyl phenyldiazoacetate **4**,[5] [Eq. (b)]. The product **3** expected



(b)

from the insertion of **1** into the O–H bond of water was the only material produced by photolysis in aqueous solution over the pH range from 1 to 13. When the photolysis was conducted in ^{18}O-enriched water, the isotopic label appeared exclusively in the α-hydroxy group of **3**, thus confirming the occurrence of an O–H "insertion" reaction.

Laser flash photolysis of **4** in aqueous solution produces two transient species (Fig. 1). The longer-lived transient

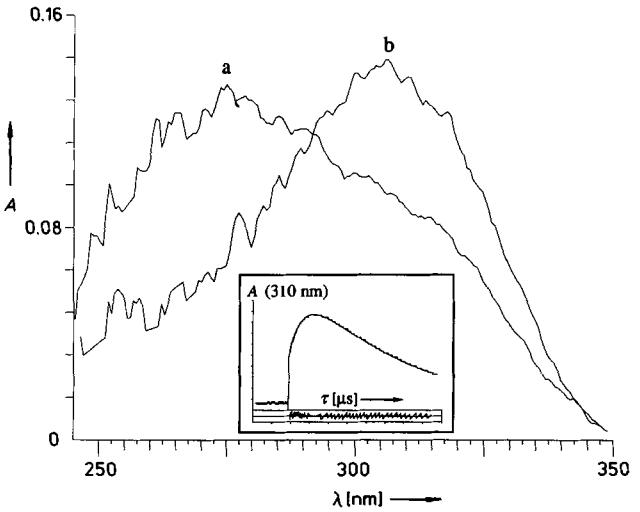


Fig. 1. Absorption spectra of the transients generated upon flash photolysis of **4** in ca. 0.0001 M NaOH at 25 °C (I = 0.10 M) using an excitation pulse from a KrF-excimer-laser (λ_{exc} = 248 nm, 20 ns pulse width, 100 mJ per pulse). Curve a represents the absorption immediately after the laser pulse; curve b represents the absorption 1 μs after the pulse. The inset shows the time-dependent absorbance changes at λ = 310 nm; the bottom trace shows residuals from a least squares fit of the data to a double exponential expression which gives the rate constants $k_{formation} = 2.3 \times 10^6\ s^{-1}$ and $k_{decay} = 4.3 \times 10^5 s^{-1}$.

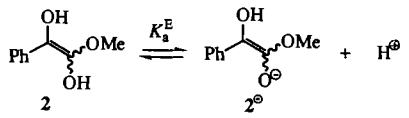
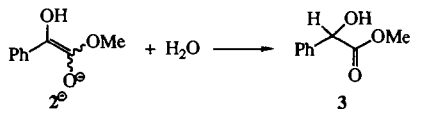
shows an absorption band with $\lambda_{max} \approx 280$ nm in acidic solution which shifts to $\lambda_{max} \approx 310$ nm in basic solution (Fig. 1., curve b), as expected for conversion of an enol into its enolate ion.[6] Decay of this transient is catalyzed by both acids and bases, showing general catalysis in both cases, and it gives the rate dependence on the concentration of the solvent-related species, $H^{\oplus}$ and $OH^{\ominus}$, depicted by curve a in Figure 2. Such behavior is typical for the ketonization of enols,[7] and in particular the rate profile is closely similar, both in shape and in magnitude of rate constants, to that for the ketonization of the enol of mandelic acid.[8] The saturation of the base catalysis observed between $[H^{\oplus}] = 10^{-6}$ and 10^{-7} M is the result of the ionization of enol **2** as an oxygen acid [Eq. (c)] to give the enolate ion $\mathbf{2}^{\ominus}$, and the kinetic data obtained in this region plus a spectrophotometric titration curve[9] lead to the acidity constant, $pK_a^E = 6.45 \pm 0.14$; this value is similar to that obtained for the first ionization of the



(c)

enol of mandelic acid ($pK_a^E = 6.62 \pm 0.07$).[8] The flat portion of the rate profile at $[H^{\oplus}] < 10^{-7}$ M represents ketonization through reaction of the anion $\mathbf{2}^{\ominus}$ with water [Eq. (d)]. A comparison of the rates of reaction in this region measured in H_2O with those measured in D_2O gives the isotope effect $k_H/k_D = 7.5$, which is consistent with expectation for this kind of reaction and similar again to values obtained for other enols: $k_H/k_D = 6.9$ (mandelic acid enol)[9] and $k_H/k_D = 7.5$ (isobutyrophenone enol).[10]



(d)

These observations indicate that the longer-lived transient species observed upon flash photolysis of **4** in aqueous solution is the enol **2** of methyl mandelate **3**. This assignment then suggests that the shorter-lived transient is the carbene **1**. The absorption spectrum of this transient in aqueous solution, $\lambda_{max} \approx 275$ nm (Fig. 1, curve a), is similar to that previously reported for **1** in Freon 113.[4] However, unlike in the previous study, we did not observe any influence of oxygen concentration on the rate of decay of **1**, nor did we detect the presence of the carbonyl oxide produced by reaction of **1** with oxygen.[4] This change upon going from Freon 113 to aqueous solutions may be attributed to the low solubility of oxygen in water, or to a shift of the carbene singlet-triplet equilibrium more to the side of the singlet carbene in water.[11]

Hydration of the carbene **1** to the enol **2** is catalyzed by both acids and bases, and both catalyses are once again general in type. The rate profile for reaction through solvent-related species is shown by curve b in Figure 2. The catalytic

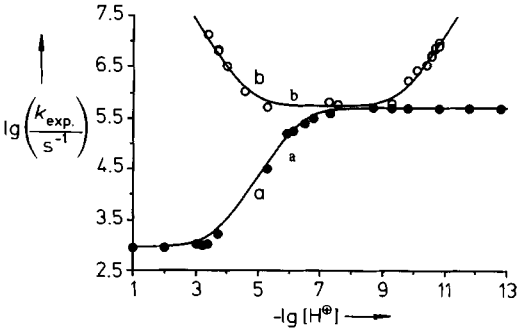


Fig. 2. Rate profile for a) the ketonization of **2** and b) the hydration of **1** in aqueous solution at 25 °C, I = 0.10 M. Data for the pH range 4–11 were obtained from measurements in HOAc, $H_2PO_4^{\ominus}$, $NH_4^{\oplus}$, $HCO_3^{\ominus}$ and $Et_3NH^{\oplus}$ buffers extrapolated to zero buffer concentration.

coefficients for general base catalysts give a shallow Brønsted relation with the exponent $\beta = 0.2$, and the isotope effect for catalysis by hydronium ions in H_2O and $D_3O^{\oplus}$ in D_2O is $k_H/k_D = 1.3$. These results are similar to those obtained for the hydration of simple carbonyl compounds,[12] and thus

imply a not unexpected mechanistic similarity between these two hydration reactions. A more detailed investigation of this carbene hydration is presently underway.

In unsaturated alcohols so constructed that a single chiral center is present and features conducive to the independent induction of π-facial selectivity are lacking, the resulting transition state structures will differ energetically only by virtue of oxido-group orientation. Furthermore, if the alcohol is geometrically and optically pure, oxido-group orientation in the transition state can be directly inferred from the absolute configuration of the newly created stereogenic center in the product. These criteria are met by **2** and **6** (Scheme 1).

Importance of Oxyanion Orientation to the Stereochemical Control of Anionic Oxy-Cope Rearrangements**

By *Leo A. Paquette** and *George D. Maynard*

Dedicated to Professor Horst Prinzbach on the occasion of his 60th birthday

The anionically-accelerated oxy-Cope rearrangement[1] is widely recognized to proceed via a highly dissociative transition state having a substantially weakened C3–C4 bond.[2] Where possible, chair conformations are preferred,[3] although structural constraints that demand passage through a boat geometry do not arrest [3,3] sigmatropy.[4] Despite extensive synthetic application of this useful reaction,[5] little is known about the factors that determine the orientation of the oxido-groups in the associated transition states[6] and the importance of this orientation to chirality transfer.[6, 7] Several well-documented cases have been reported in which chair-like transition states having both pseudoequatorial[6a, 8] and pseudoaxial oxyanion substituents[9] are involved. However, analysis of the relative importance of the oxido-group orientation to stereochemical control requires that other steric demands on the particular system be absent or at least well defined.

Base-promoted condensation of racemic 3-buten-2-ol with allyl bromide followed by [2,3]-Wittig rearrangement provided (*E*)-1,5-heptadien-3-ol (**1**) admixed with 2–5% of the (*Z*)-isomer.[10] Subsequent kinetic resolution according to *Sharpless* et al.[11] gave optically pure **2** ($[\alpha]_D^{25} = +3.4°$ ($c = 3.4$, $CHCl_3$)), as determined by analysis of the Mosher ester.[12] The most efficient route to **5** involved allylic stannylation of 3-(phenylsulfonyl)-1-butene **3** under free radical conditions,[13] followed by coupling of **4** with acrolein in the presence of 2.5 equiv. of di-*n*-butyltin dichloride. Optically pure **6** free from detectable isomeric contamination ($[\alpha]_D^{25} = +2.0°$ ($c = 3.4$, $CHCl_3$)), was obtained by analogous kinetic resolution.

The action of KH and [18]crown-6 on **2** and **6** at 50 °C in THF or DME promoted efficient oxy-Cope rearrangement provided that quenching was carried out with methanol at −78 °C. Although the pure (*R*)- and (*S*)-enantiomers of 4-methyl-5-hexenal have been described earlier,[14] their optical rotations have never been reported. Accordingly, pure (*S*)-**8** ($[\alpha]_D^{25} = +14.4°$ ($c = 3.6$, $CHCl_3$)) was prepared from (*S*)-(+)-citronellene **7** as shown (Scheme 2, above). This information permitted ready calculation of the distribution of pathways followed by the potassium alkoxides of **2** and **6**. Independent verification of these data was realized by hydride reduction of the aldehydes so obtained,[15] hydrogenation of the unsaturated alcohols, and Mosher ester analyses of the products **9** (Scheme 2, below). The agreement between the two forms of measurement is very good (Table 1).

Several relevant control experiments were also undertaken. In order to eliminate from consideration the possibility that the intermediate potassium enolates experience partial racemization by reversible allylic proton abstraction (per-

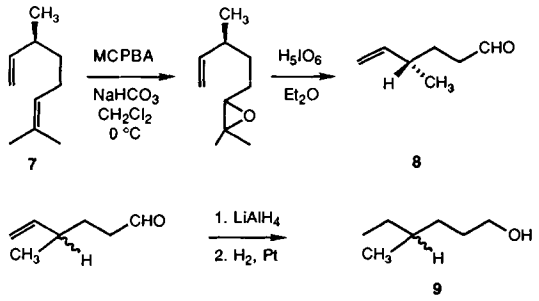
[**] Grateful acknowledgement is made to the National Science Foundation for support of this research. *G. D. M.* has served as an Ohio State University Fellow (1986–1987), National Need Fellow (1988–1989) and American Chemical Society Organic Division Fellow (1989–1990).

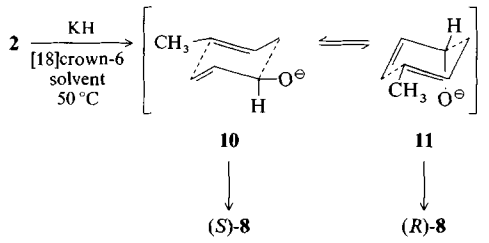


Scheme 2. MCPBA = *meta*-chlorobenzoic acid.

haps accelerated by the neighboring oxido group), (*S*)-**8** was heated with KH (8 equiv.) and [18]crown-6 (3 equiv.) in dry THF under argon at 50 °C for 8 h, isolated as before, and converted into **9**. Since the optical purity of this sample was unchanged relative to a reference sample formed directly from untreated **8**, the enantiomer ratios are *not* lowered by adventitious epimerization of this type.

The operational assumption of chairlike transition states to the exclusion of boat conformations for [3,3]-sigmatropic rearrangements in *acyclic* systems has become routine[6c, 16] because of the widely disparate energy differences involved.[17] Although no ambiguities are expected for **2** and **6**, their associated chair transition states **10**–**13** do lead to pairs of (*E*)- and (*Z*)-enolates, respectively, that differ mutually in absolute configuration and should be enantiomerically pure if no subsequent isomerization of the stereogenic center or enolate double bond takes place. Knowledge of the absolute configuration and (*E*/*Z*)-enolate geometry, if these are unperturbed, would serve to dismiss unequivocally boat conformations from consideration. When **2** was rearranged and treated with *tert*-butyldimethylsilyl chloride (−78 °C to 0 °C), a 64:36 mixture of *cis* (J = 5.9 Hz) and *trans* (J = 11.9 Hz) silylenol ethers was obtained (71%). Hydrogenation of each pure isomer ($H_2/PtO_2/CH_2Cl_2/CH_3OH$) gave samples of **9** identically enriched (60%) in the (*R*)-enantiomer (Mosher ester analysis). These results establish that enolate geometry is not preserved following oxy-Cope rearrangement and unilateral use of this method probing the mechanism is therefore not recommended. Nevertheless, the intimate consequences of transition state geometry depicted in Table 1 are consistent with all available facts.

Table 1. Data for the anionic oxy-Cope rearrangement of **2** and **6**.



10 → (*S*)-**8**; **11** → (*R*)-**8**

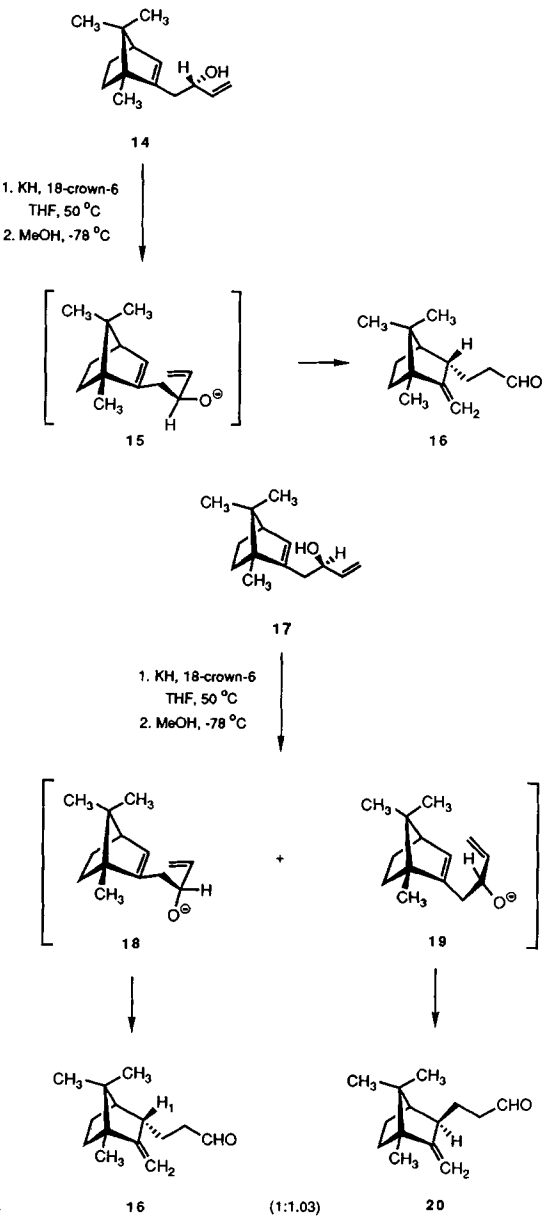
[a] GC analysis values as averaged over two experiments. [b] Samples purified by preparative GC before measurement.



Scheme 3.

The $[\alpha]_D$ values of the products are seen to remain relatively constant irrespective of solvent. Significantly, both stereoisomeric alcohols show a preference for electronic reorganization via that chairlike species where the oxido-group is equatorially disposed. However, the extent of this bias is not especially dramatic. One possible explanation for the low selectivity is that a positive stereoelectronic contribution

from the axial C–O$^{\ominus}$ bond to the LUMO of the system offsets to some degree the steric advantages enjoyed by its equatorial C–O counterpart.

Whatever the actual underlying cause(s) in these *acyclic* examples, related studies have shown that the steric demand of the oxido-group can gain considerably greater importance when *cyclic* systems are involved. Thus, alcohol **14**[18] isomerizes by way of **15** to **16**, avoiding in the process that transition state option involving *exo* C–C bond formation with axial oxido-group orientation. In contrast, stereoisomer **17**[18] must project the alkoxide group axially as in **18** to arrive at **16**. This less favorable state of affairs allows for the competitive formation of **20** via **19**. Therefore, a change in relative carbinol configuration can have significant impact on product distribution.

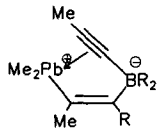
[18] The alcohols **14** and **17** were prepared by subjecting (1*R*)-(+)-camphor trishydrazone to the Shapiro reaction and condensing the resultant vinyl anion with butadiene monoxide. After chromatographic enrichment of the (α*R*,1 *R*,4 *S*) and (α*R*, 1 *S*, 4 *R*) diastereomers, pure samples of the individual alcohols were obtained by appropriate Sharpless epoxidation to remove the unwanted minor constituent.

π-Coordination of Diorganotin Dications**

By *Bernd Wrackmeyer,* Gerald Kehr,* and *Roland Boese*

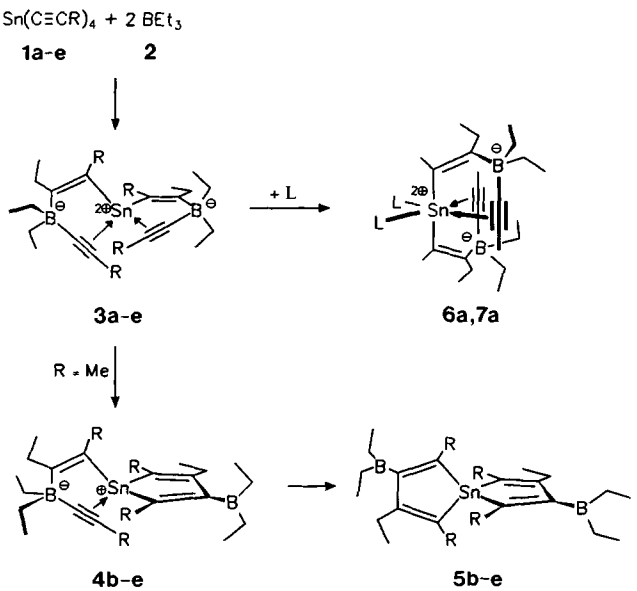
Alkynyl groups have fascinating properties, both as bridging ligands of transition metals[1] as well as of main group elements.[2] During the organoboration of alkynylmetal compounds,[3] intermediates are presumed to occur in which an alkyne moiety bridges metal and boron atom. Thus, we recently found in the case of **A** the first example of the π-coordination of a C≡C bond of an alkynyl borate moiety to a triorganolead cation.[4] Tin compounds analogous to **A**



A (R = *i*Pr)

could, however, only be postulated on the basis of NMR spectroscopic data.[5] We report here on a new type of compound **3**, in which a diorganotin dication is stabilized by π-coordination to two C≡C bonds. These compounds are of special interest for gaining insight into the mechanisms of organoboration.

The reaction of tetraalkynylstannanes **1** with triethylborane **2** affords the *spiro*-compounds **5b–e** in high yields[6, 7] (Scheme 1). Monitoring of the reaction of **1** and **2** by ^{119}Sn-



Scheme 1. **a**: R = Me, **b**: R = Et, **c**: R = Pr, **d**: R = *i*Pr, **e**: R = Bu. **6**, **7**: L = py, bipy.

NMR spectroscopy in the temperature range −78 to 25 °C provided the first indications of the formation of intermediates **3** and **4** (cf. Table 1). The compound **3a** can be isolated as a crystalline, colorless solid,[8] which decomposes above

− 20 °C. The compounds **3b–e**[9] are also present in the mixture at 0 °C together with **1**, **2** and **4**, but are finally converted into **5** without signs of decomposition.

Owing to the ready decomposition of **3a**, both in solution as well as in the solid state, the preparation of crystals was carried out in a vessel[10] specially designed for the purpose of performing an X-ray structure analysis at 115 K (Fig. 1).[11]

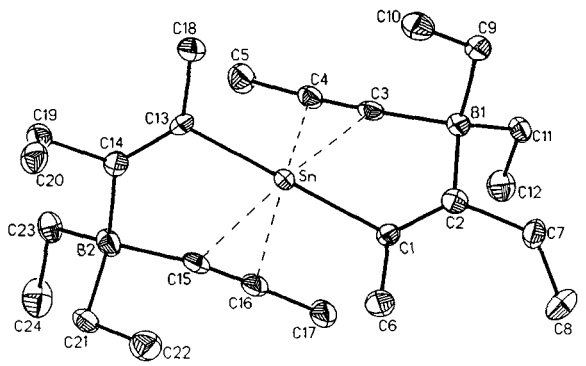

Fig. 1. Structure of **3a** in the crystal, ellipsoids drawn at the 50% probability level. Important bond lengths [Å] and angles [°]: Sn-C1 2.117(3), Sn-C3 2.355(3), Sn-C4 2.511(3), Sn-C13 2.122(3), Sn-C15 2.351(3), Sn-C16 2.535(3), B1-C2 1.634(5), B1-C3 1.643(5), B2-C14 1.630(5), B2-C15 1.647(5), C1-C2 1.337(4), C3-C4 1.227(5), C4-C5 1.459(5), C13-C14 1.347(4), C13-C18 1.509(4), C15-C16 1.222(5), C16-C17 1.479(5); C1-Sn-C3 84.0(1), C1-Sn-C4 111.5(1), C3-Sn-C4 29.0(1), C1-Sn-C13 140.9(1), C3-Sn-C13 118.8(1), C4-Sn-C13 99.1(1), C1-Sn-C15 115.7(1), C3-Sn-C15 114.9(1), C4-Sn-C15 93.8(1), C13-Sn-C15 84.8(1), C1-Sn-C16 95.0(1), C3-Sn-C16 94.6(1), C4-Sn-C16 83.3(1), C13-Sn-C16 112.8(1), C15-Sn-C16 28.7(1), C2-B1-C3 108.6(3), C14-B2-C15 109.5(3), Sn-C1-C2 113.5(2), B1-C2-C1 125.5(3), Sn-C3-B1 104.4(2), B1-C3-C4 172.7(3), C3-C4-C5 175.8(3), Sn-C13-C14 112.3(2), B2-C14-C13 126.6(3), Sn-C15-B2 104.9(2), B2-C15-C16 171.0(3), C15-C16-C17 177.2(3).

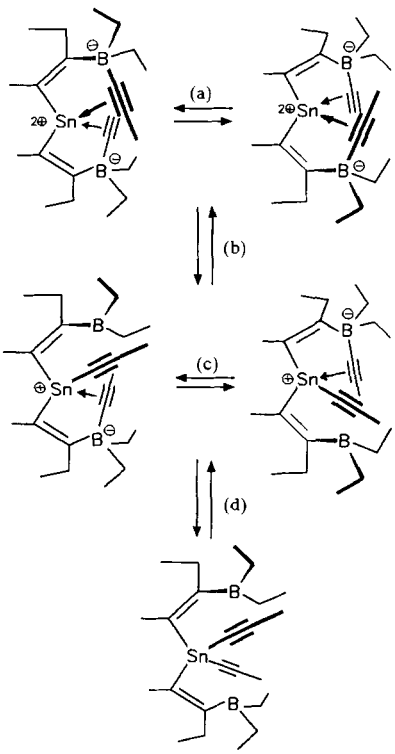
In addition, the ^{13}C- and ^{119}Sn-CP/MAS-NMR spectra of crystalline **3a** were recorded at − 30 °C.[12] The agreement of the NMR data in solution with $\delta(^{13}C)$ and $\delta(^{119}Sn)$ values obtained from the solid-state NMR measurements confirmed that the π-coordination at the $R_2Sn^{2\oplus}$ dication remains intact in solution. The double set of ^{13}C resonance signals in the case of solid **3a** is consistent with the result of the X-ray structure analysis,[11] according to which there are slight differences in the bond lengths and angles in the two halves of the molecule.

For a free diorganotin dication, the bond angle at the tin should be 180°. But the angle measured for C(1)–Sn–C(13) is 140.9°, which is unprecedented for organotin compounds. The coordination of the tin to the C≡C bond is unsymmetrical with the distance to the boron-bound alkyne carbons being on average 0.17 Å shorter. Even these distances are significantly longer than all known tin–carbon single bond lengths. With $d_{C\equiv C}$ distances of 1.227 and 1.222 Å and almost linear geometry at the alkyne carbon atoms, the C≡C bond is little influenced by the coordination to the tin atom. Remarkably, the distances B1–C3 and B2–C15 for the ≡C–B bonds are even greater than the B–C(sp^2) and B–C(sp^3) bond lengths. This weakening of the B-C(sp) bond is in accord with the observed exchange of the propynyl moiety of **3a** in solution (see below). The unexpectedly large B–C–C angles, with an average value of 116.5(5)°, are consistent with quantum mechanical calculations and the experimental results of other structural analyses with B-C-C fragments.[13]



Scheme 2. Dynamic processes in **3** (**3a** as example). a) Ring inversion, b)–d) exchange of the propynyl groups.

^1H-NMR spectra of **3a** between − 20 °C and − 90 °C indicate dynamic behavior of the compound in solution. Two processes are discernable, namely exchange of the propynyl group between the tin and the boron atoms, and, at lower temperature, ring inversion (Scheme 2).

Slow exchange of the propynyl groups leads to diastereotropism of the B–CH_2 protons (below − 35 °C), and hindered inversion finally results in nonequivalence of the Et_2B methyl groups and the diastereotopism of the C=C–CH_2 protons (below −60 °C and −90 °C, respectively).

The electrophilic character of tin in the new compounds **3** is manifested in reactions with nucleophiles.[14] With pyridine and with 2,2'-bipyridyl, **3a** forms the adducts **6a** and **7a**,[15] in which the tin atom is coordinatively saturated (cf. Table 1, ^{119}Sn resonance signals at high field). As in the case of **3a**, dynamic processes can also be demonstrated for **6a** and **7a** by ^{1}H- and ^{13}C-NMR spectroscopy. The structure for the intermediates **4** is based on consistent sets of NMR data (cf. Table 1 for **4b**) and is confirmed by the isolation of the final product **5**. The results suggest that the formation of compounds **4** and **5** from **3** and **4** respectively proceeds via an Sn-Substituted vinyl cation **8**.

[6] a) Only in the case of tetra-1-propynylstannane **1a** and triethylborane **2** and upon using the pure intermediate **3a** could no well-defined products be obtained. Various solutions of **3a** [concentration between 0.5 M down to 0.001 M (in order to suppress intermolecular reactions) in CH_2Cl_2, THF, hexane or toluene at $-78\,^{\circ}C$ afford elemental tin and red, highly viscous oils on warming to room temperature. The large number of broad ^{13}C- and ^{1}H-resonances point to complex mixtures with polymeric constituents. Separation into pure components could not be achieved by distillation. An analogous behavior was observed upon heating the compounds **6a** and **7a**.—b) In contrast, spiro compounds analogous to **5** are formed smoothly from tetra-1-propynylsilane or -germane and excess triethylborane: R. Köster, G. Seidel, MPI für Kohlenforschung, Mülheim a.d. Ruhr (FRG), private communication.

[7] **5b**: A solution of **1b** (3.10 g, 9.37 mmol) in toluene (20 mL) was cooled to $-78\,^{\circ}C$, treated with **2** (3.00 mL, 21.3 mmol), and the stirred mixture was slowly warmed to room temperature. After heating to 60 °C for 24 h the solvent and unchanged **2** were removed in vacuo. Kugelrohr distillation of the residue afforded 3.85 g (78%) of **5b** (b.p. 175–180 °C/10^{-3} torr). **5c** (180–190 °C/10^{-3} torr), **5d** (b.p. 200 °C/10^{-3} torr), and **5e** (b.p. 185–190 °C/10^{-3} torr) were obtained analogously. ^{1}H- and ^{13}C-NMR data are consistent with the proposed structures. ^{119}Sn/^{11}B-NMR (111.9 MHz, CD_2Cl_2, 298 K): (^{119}Sn)/(^{11}B) = − 19.7/83.0 (**5b**), − 13.7/84.3 (**5c**), − 48.3/86.3 (**5d**), − 15.7/85.2 (**5e**).

[8] **3a**: A solution of **1a** (3.2 g, 11.6 mmol) in toluene (40 mL) was cooled to $-78\,^{\circ}C$, treated with 4 mL (28 mmol) of **2** and the stirred mixture warmed to 0 °C. After ca. 30 min the solvent and excess **2** were removed in vacuo. The remaining yellow solid was crystallized from pentane at $-78\,^{\circ}C$; 3.8 g (69%); decomp. above − 20 °C. **3a**: ^{1}H NMR (300 MHz, C_7D_8, 243 K): $\delta(^{1}H)[^{n}J(^{119}Sn^{1}H)] \approx 0.80$ m, 1.10 t (20H; BEt_2) 2.22 q, 0.96 t (10H; =CEt), 1.42[7.3] s(6H; ≡CMe), 1.81[107.6] s(6H; =CMe).

[9] **3b**, **3c**, **3d**, **3e**: relevant ^{1}H- and ^{13}C NMR data correspond to the values for **3a**. ^{119}Sn/^{11}B NMR (CD_2Cl_2, 298 K): $\delta(^{119}Sn)/\delta(^{11}B)$ = + 207.5/−4.9 (**3b**); + 203.1/−4.5 (**3c**); + 223.2/−4.3 (**3d**); + 202.1/−4.4 (**3e**).

[14] A report of the reaction of **3a** with ammonia, amines, and alcohols will be reported elsewhere.

[15] **6a**: A solution of **3a** (0.5 g, 1.1 mmol) in toluene (ca. 20 mL) was treated with pyridine (0.3 mL, 3.7 mmol) at $-78\,^{\circ}C$. After removal of solvent and excess pyridine in vacuo at 0 °C their remained 0.6 g (95%) of a colorless solid (> 20 °C, decomp.). **7a** was obtained analogously as a yellow solid (> 40 °C, decomp.), whereby **3a** already reacts at $-78\,^{\circ}C$.

Stable Phosphazenium Ions in Synthesis—an Easily Accessible, Extremely Reactive "Naked" Fluoride Salt**

By *Reinhard Schwesinger,* Reinhard Link, Gerhard Thiele, Heinz Rotter, Dieter Honert, Hans-Heinrich Limbach,* and *Ferdinand Männle*

Dedicated to Professor Horst Prinzbach on the occasion of his 60th birthday

Lipophilic organic cations are of exceptional importance in preparative organic chemistry; however, their breadth of application has hitherto been limited owing to their modest stability towards bases and nucleophiles.[1] This is especially true in the case of organic fluoride salts,[2] efficient auxiliary bases and indispensable reagents in organosilicon chemistry. The only unsolvated organic ("naked") fluoride salt that has proven reliable[3] is tetramethylammonium fluoride,[6] certainly the most reactive source of fluoride known so far.[7] However, it is only sparingly soluble, and the cation is particularly unstable towards strong nucleophiles. We now report on the stable, easily accessible phosphazenium fluoride **1**-F, a source for THF solutions of naked fluoride ions.

In connection with our studies on the preparation of novel, extremely basic polyaminophosphazenes we found that peralkylated cations such as **1** and particularly **2** are many orders of magnitude more stable than conventional organic cations towards nucleophiles.[8, 9] In the meantime we have been able to simplify the synthesis of **1**[8, 10] considerably: reaction of PCl_5 with NH_4Cl and subsequently with

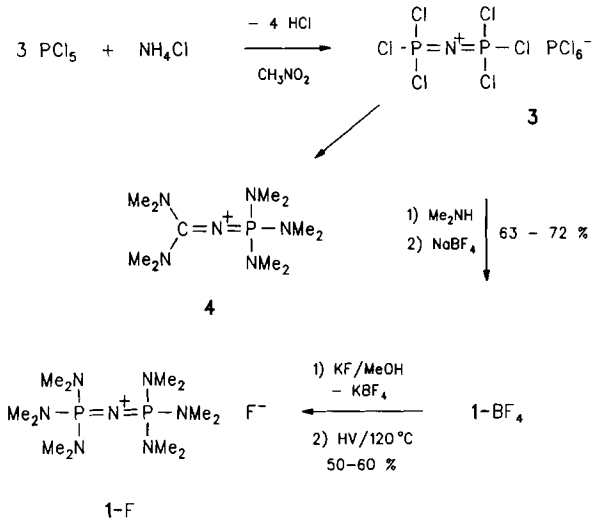
2

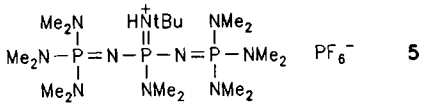
dimethylamine and $NaBF_4$ to give **1**-BF_4 via **3**[11] can be carried out in a one-pot process; hexamethylphosphoric triamide (HMPA) and salts of **4** are formed as by-products via complex routes from the aminolysis product of PCl_6^- and CH_3NO_2 (Scheme 1).



Scheme 1. HV = high vacuum.

On attempting to obtain **1**-F by double reaction of **1**-BF_4 with KF in methanol/water and drying in a vacuum, partial hydrolysis of the cation and formation of **1**-FHF was observed. However, on using anhydrous methanol a product was obtained from which the solvent could be largely removed at 120 °C. After washing with THF, colorless, extremely hydroscopic **1**-F was obtained in 50–60% yield and could be recrystallized from THF.

According to the X-ray structure analysis,[12] the very first of an organic unsolvated fluoride salt, **1**-F crystallizes with FeS_2-(in the broadest sense NaCl-)type structure, hitherto unprecedented for organic compounds, with discrete phosphazenium and fluoride ions. The cation–anion distance (6.3 Å) is the largest observed in any known solvent-free fluoride salt (KF 2.67 Å, CsF 3.01 Å, NMe_4F presumably 4.2 Å[6]), which immediately allows conclusions to be drawn about the solubilities and reactivities of the ion pairs or ion aggregates. Six P–N bonds point almost exactly (P1–N2–F = 178°) to a fluoride ion, which is surrounded approximately icosahedrally by one proton each of the twelve methyl groups. The F–H distances (2.37 and 2.57 Å), however, are in the region of the sum of the van-der-Waals radii and are too large for hydrogen bridges, i.e. the fluoride ion here (in agreement with IR data) can be regarded as "naked". The cation has crystallographic C_{3i} (S_6) symmetry, its conformation is almost the same as that of the isoelectronic oxa compound[14] and, with respect to the linearity of the bridge, also that of the carba compound.[15] The PNP bridges in the cation of **5**[8] are indeed bent (141 and 143°[16]), but in the case of **1** there is no evidence of disordered bent conformers, for example the P–N1 distance is very similar to the P–N distances in the bridges of **5** (1.55–1.58 Å), and the standard deviation is small. The dimethylamino groups are turned through about 39° from the N1–P–N2 plane, their six N atoms staggered with respect to the P–N1–P bridge and slightly pyramidal (sum of angles 358.2°).



5

Crystalline **1**-F is stable indefinitely at room temperature in the absence of moisture, and is stable to a limited extent on heating; above 144 °C, however, it melts with decomposition and formation of **1**-FHF.

At 20 °C, **1**-F dissolves in THF to give an approximately 2 mM solution, which rapidly becomes inactive in the absence of the corresponding solid phase, even in fired glass vessels; at boiling temperature it is markedly more soluble and, for a few hours, is stable except for the reaction with the glass surface. The solutions of **1**-F are more basic than the corresponding solutions of previously known phosphazene bases.[8] Triphenylmethane-containing, deep-red solutions of **1**-F (with solid phase) are decolorized within a minute already at −55 °C upon treatment with an excess of tetrabutylammonium hexafluorophosphate; this suggests that "naked tetrabutylammonium fluoride" was no more than a myth.[2b]

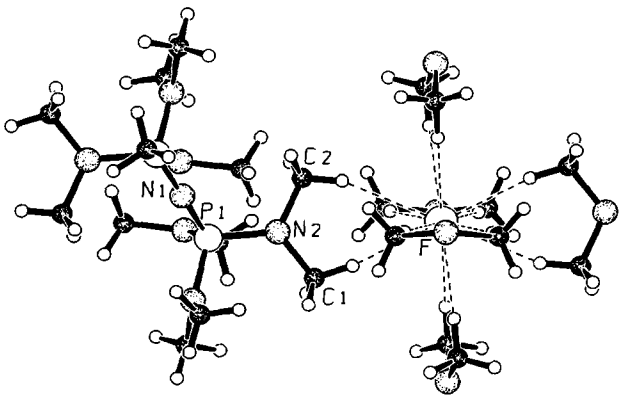


Fig. 1. Structure of **1**-F in the crystal [17]. Bond lengths [Å] and angles [°]: P–N1 1.536(2), P–N2 1.644(5), N2–C1 1.471(9), N2–C2 1.483(8); N1–P–N2 110.8(2), P–N2–C1 122.3(4), P–N2–C2 118.9(4).

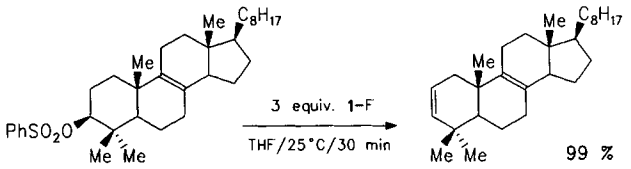
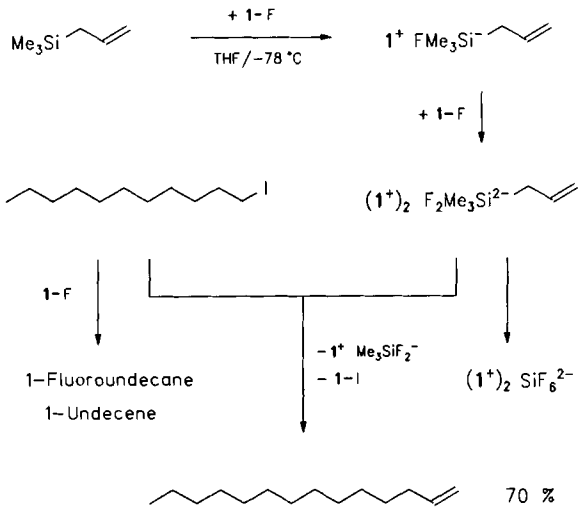
Compared with solvated fluorides,[2a] potassium *tert*-butoxide[18] or phosphazene bases,[8] the fluoride ion in **1**-F shows unique E2 reactivity (with formation of **1**-FHF) with comparatively unusually low nucleophilicity, and is excellently suitable for the generation of 1-alkenes from 1-halides; e.g., three equivalents of **1**-F react with 1-iodoundecane already at −70 °C to give a 9:1 mixture of 1-undecene and 1-fluoroundecane. The benzenesulfonate of lanost-8(9)-en-3β-ol reacts in THF within 30 minutes at room temperature

to give lanosta-2,8(9)-diene exclusively, a reaction which with potassium *tert*-butoxide in dimethyl sulfoxide/THF (1:1) furnishes the diene in only 75% yield after four days at 80 °C.[19]



1-F enables, for the first time, the alkylation of an allyl anion species generated from allyltrimethylsilane. The addition of one equivalent of a 1:1 mixture of allyltrimethylsilane and 1-iodoundecane to 2.2 equivalents of **1**-F at −78 °C leads (not optimized) to **1**-tetradecene in 70% yield; only the aforementioned reaction of **1**-F with alkyl halide competes to any significant extent.

No extensive conversion can be achieved with one equivalent of **1**-F; the difluorotrimethylsilicate monoanion[21] formed after alkyl transfer (presumably from the allyldifluorotrimethylsilicate dianion[20]) is here apparently neither sufficiently reactive as source of fluoride nor as source of methyl anions; in the absence of electrophiles, however, even the methyl groups of the silane are transferred to other compounds, as recognizable by the formation of a precipitate of



$(\mathbf{1})_2$-SiF_6; the supernatant orange solution decolorizes on thawing and **1** can be recovered from the mixture almost quantitatively as tetrafluoroborate by aqueous work-up. Further studies will be concerned with elucidating the mechanisms of the reactions involved ("naked" allyl anion or hypervalent Si species), exploring the scope of application of this alkylation (and analogous reactions of other silanes) particularly in cyclization reactions, and investigating, in general, the possible use of "naked" phosphazenium salts for the anion-activation of main group organometallic compounds.

Experimental

1-BF_4: A suspension of PCl_5 (208.5 g, 1.00 mol) and NH_4Cl (17.83 g, 0.333 mol) in anhydrous CH_3NO_2 (330 mL) under N_2 was slowly heated to 100 °C. After evolution of HCl had ceased (ca. 1 h), the mixture was cooled to − 10 °C (dry-ice bath, **3** crystallized as pale yellow, robust needles). Dimethylamine (330 g, 7.33 mol, free of primary amines) was then passed (after drying over Na_2O) into the mixture at − 10 °C (delivery tube above solution). After storage at 20 °C for 2 d the mixture, which had turned yellow-orange, was treated with a solution of $NaBF_4$ (73 g, 0.67 mol) in water (330 mL) and stirred vigorously. The mixture was then adjusted to pH 8 by addition of H_3PO_4. The heavier, organic phase was separated off, the aqueous phase extracted once with a little CH_3NO_2, and the combined organic phases washed once with water (170 mL). The organic phase was then evaporated down in vacuo and dried in a high vacuum. The orange-brown, partly crystalline residue (Caution! contains ca. 0.2 mol HMPA) was treated with a 5% $NaBF_4$ solution (330 mL), and the mixture stirred vigorously, cooled to − 5 °C for 30 min, and finally filtered. The colorless crystals were then washed with ice-cooled 5% $NaBF_4$ solution (170 mL) and with a little ice-water. For the further reaction to give **1**-F, the crude crystals of **1**-BF_4 were recrystallized from THF (800 mL) and dried in a high vacuum. Yield 90–102 g (63–72%); m.p. 260 °C (decomp). Correct elemental analysis (C,H,N). ^{1}H NMR (250 MHz, $CDCl_3$, 30 °C, TMS): $\delta = 2.69$ (m).

1-F: A solution of **1**-BF_4 (25.63 g, 60.00 mmol) in MeOH (60 mL, < 50 ppm water) was treated with a solution of KF (3.486 g, 60.00 mmol, dried for 12 h at 240 °C in a high vacuum) in MeOH (40 mL) under N_2. After removal of KBF_4 by suction, the majority of MeOH was removed by evaporation in vacuo at room temperature. The residue was dried in a high vacuum for 1 h at 100 °C (initially with stirring until the contents of the flask became solid, no Teflon used, vacuum apparatus with 10-mm flow cross-section) and 1–2 h at 120 °C bath temperature (until constant weight, if necessary with ^{1}H-NMR monitoring of MeOH), and finally digested and washed with THF (distilled over Na/K/anthracene). After drying in a high vacuum at room temperature, 11–13 g (50–60%) of almost colorless crystals were obtained; according to titration (with HPF_6 salt of 1,8-bis(dimethylamino)naphthalene against *N*-ethyl-4-nitroaniline in THF) at least 88–93% in strongly basic fluoride; ca. 20% **1**-BF_4 could still be recovered from the mother liquor. The crude product was sufficiently pure for most reactions, but could be recrystallized from THF, whereupon the titer increased. M.p. 144 °C (decomp.). IR [perfluorokerosine]: $\tilde{\nu}$ [cm^{-1}] = 2978, 2910, 2886, 2850, 2798, 2478, 2386, 2340, 2214, 1866, 1806, 1736, 1464. ^{19}F-NMR (282 MHz, HMPA, 77 °C, polyethylene ampule in NMR-tube, CCl_3F external): $\delta = -81$ (s, $\nu_{1/2} = 97$ Hz) [22].

1-Tetradecene from allyltrimethylsilane and 1-iodoundecane: A suspension of crude **1**-F (832 mg, at least 2.05 mmol of strongly basic fluoride, see above) in anhydrous THF (3.5 mL) was degassed by removal of 0.5 mL of solvent in a high vacuum. The degassed solution was cooled to − 80 °C, treated dropwise with a mixture of 1-iodoundecane (296 mg, 242 µL, 1.05 mmol) and allyltrimethylsilane (120 mg, 168 µL, 1.05 mmol), and the mixture warmed to room temperature. After addition of water (10 mL), the mixture was extracted with 4 × 5 mL of pentane, the combined pentane extracts washed four times with water, dried over Na_2SO_4, and then the solvent was removed in vacuo. Yield: 208 mg of crude product, according to GC and ^{1}H-NMR analysis consisting of 144 mg of 1-tetradecene (70% yield), 1-iodoundecane (2%), trimethylsilanes (ca. 2%), 1-undecene (22%), and 1-fluoroundecane (2–3%).

[3] Salts of naked fluoride ions have already been reported which apparently were obtained from acetonitrile solutions [4] or extracted into $CDCl_3$ [5]. The very high basicity already found for the tetramethylammonium fluoride, however, indicates that naked fluoride ions could not be capable of existing in such acidic solvents [6].

Complexation of Transition Metal Ions with Substituted Aza Macrocycles: Induction of Columnar Mesophases by Molecular Recognition

By *Andrea Liebmann, Carlo Mertesdorf, Thomas Plesnivy, Helmut Ringsdorf,** and *Joachim H. Wendorff*

Coronands, as for example [18]crown-6, readily complex metal ions. Whereas crown ethers can incorporate both alkali-metal ions and alkaline-earth-metal ions with high complexation constants, the nitrogen analogues show special affinity for transition metal ions.[1] Furthermore, the aza macrocycles can be converted by substitution at the nitrogen atom into discoid compounds, which in the case of acylated compounds can form discotic liquid crystal phases;[2] however, their complexing ability is only modest. The results presented in this contribution show that both of these aspects of coronand chemistry can be combined, namely the formation of host/guest complexes and their self-assembly to liquid crystalline phases.

At temperatures between 106 and 136 °C, hexa(*p*-tetradecyloxybenzoyl)hexacyclene **1** forms a columnar discotic mesophase (D_{hd}),[3] which, owing to the central cavity in the columns, has been described by *Malthête* et al. as tubular.[2] With the help of gas-volumetrically calibrated solutions of AlH_3 in THF it was possible to carry out the reduction of **1** to the *non*liquid crystalline amine **2** in high yields (83%) (Scheme 1).[4]

The cyclam derivatives **4** and **6**[5] were prepared analogously from the acylated tetraaza macrocycles **3**[3] and **5**[6] respectively (Scheme 1), of which only the derivative **5** bearing eight wing groups forms a mesophase.

With exception of compound **6**, complexation of transition metal salts by the highly flexible cyclic amines induces a liquid crystalline phase which is absent for the free amines. We attribute this phenomenon in part to a stiffening of the macrocycle. This interpretation is consistent with the fact that the stiffer, structurally analogous amides can form mesophases. The phase behavior of the metal complexes is given in Table 1.

Table 1. Phase behavior of the transition metal complexes [a].

Complex	Ratio host/guest	Phase T [°C]
2 · $Co(NO_3)_2$	2:1 [7]	c 30 N_c 60 [b] i
2 · $Ni(NO_3)_2$	1:1	c 29 lc 95 i
4 · $Cu(NO_3)_2$	1:1	c 18 lc [c]
6 · $Cu(NO_3)_2$	1:1	g 67 i

[a] Abbreviations: c = crystalline; N_c = nematic-columnar; i = isotropic; lc = liquid crystalline; g = glassy. [b] First cooling curve of the DSC thermogram. [c] Decomposition above 160 °C.

In the following communication we shall deal more closely with the 1:2 $Co(NO_3)_2$/amine **2** system, which has been characterized as liquid crystalline by polarization microscopy, differential calorimetry, and X-ray diffraction analysis. Upon heating under the polarization microscope the birefringence of the enantiotropic liquid crystal phase is visible up to a temperature of about 53 °C. Initially, no specific texture is recognizable, but tempering at ca. 40 °C leads after 3 h to the formation of characteristic schlieren. The texture depicted in Figure 1 shows the singularities of $s = -1/2$ and $s = -1$ typical for a nematic phase. The enthalpy for the transition between the liquid crystalline and isotropic phase, which is obtainable from the cooling curve of the DSC thermogram is of an order of magnitude that is consistent with a transition into a slightly ordered nematic phase. A macroscopic planar orientation of the mesophase can easily be achieved by mechanical shearing. Under crossed polarizers it

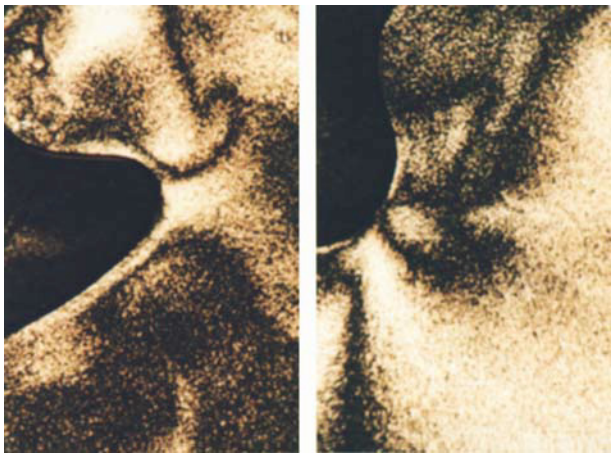

Fig. 1. Nematic schlieren texture of the **2** · $Co(NO_3)_2$ complex with singularities of s = −1/2 (left) and s = −1 (right).

is characterized by extinction perpendicular to and parallel to the direction of stress.

The X-ray scattering diagram of the complex shows a diffuse reflection at small angles and a halo in the wide angle region. The distance of 4.5 Å corresponding to the halo in the wide angle region compares with the typical scattering behavior of paraffin chains in liquid crystals and liquids. The reflection at 39.0 Å can be assigned to the average distance between the disk-shaped mesogens. Formally, the scattering behavior of the liquid crystal would thus suggest a discotic nematic ordering (N_D) of the complexed aza macrocycles, whereas the planar orientation of the highly viscous mesophase observable under the polarizing microscope, which is readily achievable by mechanical shearing, would suggest a columnar ordering. The diffuse reflection at 39.0 Å would then correspond to the average distance between the columns. There is no scattering reflection which can be attributed to the distance between the macrocycles in the columns. On the one hand, this could be indicative of a general disordering of the mesogenic units in the columns, which would correspond to a new nematic-columnar phase (N_{Cd}). Equally interesting

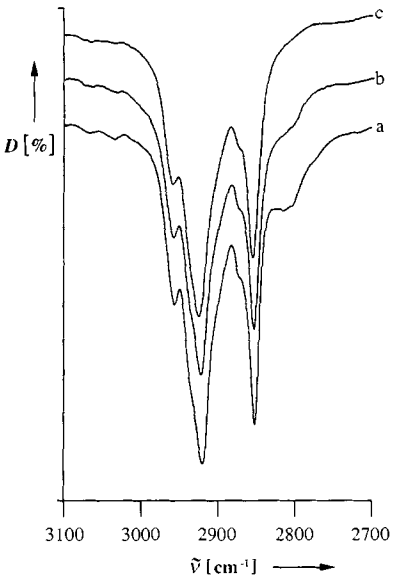

Fig. 2. FT-IR spectra of pure ligand **2** (a) and the complexes **2** · $Co(NO_3)_2$ (3:1) (b), and **2** · $Co(NO_3)_2$ (2:1) (c).

is the possibility of a jumping of the metal cations between the ligand molecules, which has already been proposed for the oxygen coronands in solution.[8]

In this connection the absence of the C–H stretching vibration of the methylene groups neighboring the donor centers (compare the IR spectra of amine **2** and amine **2**/$Co(NO_3)_2$ system) indicates that the ligand is completely complexed (cf. Fig. 2). This could be a result of the previously mentioned dynamic process.[9] In comparison, in the case of a 3:1 mixture the shoulder observable for the free ligand reappears. In principle, this observation could be explained by the formation of a sandwich complex. However, due to the absence of a scattering reflection which would result from the distance between the cobalt ions in such a structure, this possibility seems unlikely; hence the single macrocycle must be regarded as the repeat unit of the liquid crystal.[10]

Further spectroscopic investigations are needed to completely determine the molecular structure of this system. The process of phase induction and a possible supermolecular structure of the complex in the mesophase is shown schematically in Figure 3.

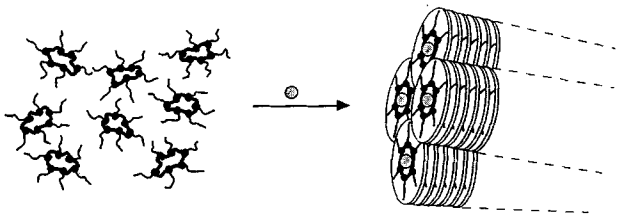

Fig. 3. Schematic representation of the induction of a columnar discotic mesophase by complexation of transition metal ions with substituted aza macrocycles.

A comparison of the substituted hexacyclenes **1** and **2** clearly reveals the influence of molecular dynamics on phase properties and provides an insight into the causes of the phase induction described here. As a result of the partial double bond character of the exocyclic C–N bond in the amide **1**, rotation about this bond axis is considerably restricted, and the macrocycle thus has an essentially rigid conformation. In comparison, in the case of the amine **2** a rapid change of conformation is possible due to the unhindered rotation of the wing groups and to the nitrogen inversion vibration.[11] Converting the amine into the complex decisively influences these dynamics; by coordination to the cobalt ion, the hexacyclene framework experiences substantial conformational rigidification and in this way forms the constitutional unit of the liquid crystal. Herein, this system differs fundamentally from the phthalocyanines, which, even as free ligands, are rigid and form liquid crystalline phases.

However, the occurrence of a broad mesophase in the case of the Cu^{II} complex of the amine **4**,[12] whose parent amide **3** is not liquid crystalline due to an insufficient space filling of the peripheral alkyl chains also demonstrates that the described induction of a mesomorphic phase is not only an effect of the conformational rigidification. Possibly, in this case the interaction between the central units is sufficiently large to compensate for the disadvantage of a smaller packing density of the alkyl chains. Preliminary susceptibility measurements on this system would seem to indicate a possible electronic coupling between the metal ions. The multifarious possibilities of variation with regard to ring size and substitution pattern of the aza macrocycles on the one hand,

and of the central ions and counterions on the other, open up a broad spectrum of novel metallomesogens.[13]

[4] N. M. Yoon, H. C. Brown, *J. Am. Chem. Soc. 90* (1968) 2927. *Procedure* for **2**: A solution of **1** (216 mg, 0.10 mmol) in THF (2 mL) was slowly added dropwise under nitrogen to a 0.35 M solution of aluminum hydride in THF (2.20 mL) cooled to 0 °C; the mixture was then stirred for 2 h at 0 °C. The reaction was terminated by addition of 0.5 mL THF/water (1:1). By addition of a small amount of dilute caustic soda, the reaction product could be filtered much more easily from the aluminum hydroxide precipitate. The hydroxide precipitate was thoroughly washed with cloroform, the filtrate dried with sodium sulfate, and the solvent finally removed by evaporation. The almost pure product obtained in this way was then recrystallized twice from ethyl acetate. Yield 172 mg (83%) of a white crystalline powder; m.p. 96 °C; elemental analysis in agreement with the calculated values. ^{1}H NMR (200 MHz, $CDCl_3$): $\delta = 0.86$ (t, 18H; CH_3), 1.20–1.50 (m, 132H; $(CH_2)_{11}$), 1.76 (m, 12H; O-CH_2-CH_2), 2.56 (s, 24H; CH_2-N-CH_2), 3.37 (s, 12H; N-CH_2), 3.91 (t, 12H; CH_2-O), 6.75 (d, 12H; aromat. 3,5), 7.04 (d, 12H; aromat. 2,6); IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 1250 (ν, C-O), 1514, 1613 (ν, C = C).
[5] *Procedure* for **4**: The reaction was conducted in the same way as in the synthesis of **2**. The purification of the crude product, after washing the hydroxide precipitate with THF, ether, and chloroform, combination of the organic phases, drying with sodium sulfate and removal of the solvent in a rotary evaporater was carried out by flash chromatography (chloroform/methanol, 80:1) and recrystallization from ethyl acetate. Yield: 61.5%; m.p. 105 °C (DSC; 20 °C per min); R_f (chloroform/methanol, 10:1) = 0.52; elemental analysis compared favorably with the calculated values. ^{1}H NMR (200 MHz, $CDCl_3$): $\delta = 0.86$ (t, 12H; CH_3), 1.10–1.50 (m, 88H; $(CH_2)_{11}$), 1.78 (m, 12H, O-CH_2-CH_2 + N-CH_2-CH_2), 2.47, 2.56 (m, 16H; N-CH_2-CH_2-CH_2-N + N-CH_2-CH_2-N), 3.36 (s, 8H; N-CH_2), 3.86 (t, 8H; CH_2-O), 6.77 (d, 8H; aromat.), 7.13 (d, 8H; aromat.); IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 1257 (ν, C-O), 1513, 1612 (ν, C = C).
Procedure for **6**: Reaction and work-up were carried out as in the synthesis of **4**. The purification of the crude product was accomplished by flash chromatography (chloroform/methanol, 80:1) and subsequent recrystallization from acetone. Yield 72.8%; m.p. 52 °C (DSC; 20 °C per min); R_f (chloroform/methanol, 10:1) = 0.52; elemental analysis consistent with calculated values.
^{1}H NMR (200 MHz, $CDCl_3$): $\delta = 0.86$ (t, 24H; CH_3), 1.10–1.55 (m, 112H; $(CH_2)_7$), 1.74 (m, 20H; O-CH_2-CH_2 + N-CH_2-CH_2), 2.41, 2.51 (m, 16H; N-CH_2-CH_2-CH_2-N + N-CH_2-CH_2-N), 3.26 (s, 8H;N-CH_2), 3.78 (t, 8H; CH_2-O), 3.91 (t, 8H; CH_2-O), 6.69 (s, 8H; aromat. 2,5), 6.93 (s, 4H; aromat. 6); IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 1261 (ν, C-O), 1516, 1590 (ν, C = C).
[6] G. Lattermann, *Liq. Cryst. 6* (1989) 619. According to *G. Lattermann* further phase transitions occur in the case of the cyclam derivative **5**, the nature of which is still unclear: S. Schmidt, G. Lattermann, 19th Freiburger Working Conference on Liquid Crystals, April 4–6, 1990.
[7] The complexation of the transition metal ions with the amines was accomplished by dissolution of the appropriate equivalents of ligand and metal salt in dry THF and two days' stirring at room temperature in the case of amine **2** and one hours' stirring in the case of cyclam derivatives. After removal of the solvent in a rotary evaporator and drying under oil-pump vacuum the **2**-complexes precipitated as brownish ($Co(NO_3)_2$) or pale-green ($Ni(NO_3)_2$) substances. In the case of the tetraaza macrocycles an immediate change in color of the initially blue $Cu(NO_3)_2$ solution to green could be observed upon addition of the ligand; this is associated with the occurrence of a charge transfer band in the UV/VIS spectrum. The solid complexes are likewise intense green. In the case of the $Co(NO_3)_2$-complex an oxidation of the central ion by atmospheric oxygen occurs during the complexation, which is of decisive importance for the phase induction. Upon complete exclusion of atmospheric oxygen, and thus of any oxidation, no color change could be observed; nor could any signs of a complexation be recognized in the IR spectrum. The solid precipitating after removal of the solvent in a rotary evaporator showed merely a melting point depression as compared to the pure ligand, and no formation of a mesophase.
[8] F. L. Dickert, W. Gmeiner, W. Gumbrecht, H. Meissner, *Angew. Chem. 99* (1987) 238; *Angew. Chem. Int. Ed. Engl. 26* (1987) 228.
[9] In addition, the IR spectrum of the complex shows an intense band at 1384 cm^{-1}, which can be assigned to the twofold degenerate stretching vibration of ionically coordinated nitrate. Cf. also N. F. Curtis, Y. M. Curtis, *Inorg. Chem. 4* (1965) 804.
[10] Cf. for example the investigations on the bis(octaalkoxyphthalocyaninato)lutetium coordination compounds that form discotic mesophases in which sandwich complexes are the repeat units of the liquid crystal: C. Piechocki, J. Simon, J. J. Andre, D. Guillon, P. Petit, A. Skoulios, P. Weber, *Chem. Phys. Lett. 122* (1985) 124.
[11] This difference in the molecular dynamics of amide and amine is immediately apparent on comparing the ^{1}H-NMR spectra recorded in solution. In the case of the acylated hexacyclene **1** the aromatic protons as well as the methylene protons of the macrocycle show extremely broad signals at room temperature, whereas in the case of the amine sharp bands occur as a result of the rapid change of conformation, which in the case of the amide can first be observed at elevated temperature. A description of the coalescence phenomena occurring in benzoyl-substituted hexacyclenes is given in: D. Tatarsky, K. Banerjee, W. T. Ford, *Chem. Mater. 2* (1990) 138.
[12] Preliminary X-ray scattering measurements indicate a D_{hd} phase.

Azarhoda-*closo*-dodecaborane **

By *Hans-Peter Hansen, Jens Müller, Ulrich Englert,* and *Peter Paetzold**

Of the heteroboranes with nitrogen as heteroatom in the cluster framework, the compounds *arachno*-$N_2B_8H_{12}$,[1] *nido*-$NB_{10}H_{13}$ **1**,[2] and *closo*-$NB_{11}H_{12}$,[3] derive structurally from an icosahedron as the corresponding *closo*-polyhedron. The N atom in these azaboranes is four-, five- and six-coordinate, respectively; consequently classical two-center, two-electron bonds do not suffice for a description of the bonding of the N atom in the *nido*- and the *closo*-compound. We now report on the first representative of an azametallaborane from the series of icosahedra. Following *Hawthorne*'s classical route to the *closo*-dicarbametallaboranes from *nido*-$C_2B_9H_{11}^{2-}$ and suitable transition-metal compounds,[4] we first deprotonated **1** according to Equation (a) (tmeda = 1,2-bis(dimethylamino)ethane) to give the anion $NB_{10}H_{12}^-$, whose structure with C_s symmetry follows unequivocally from the 2D-^{11}B-^{11}B-NMR spectrum. The NH group detectable ^{1}H-NMR and IR spectroscopically is especially informative, since it indicates that a bridge proton and not an *N*-bound proton is cleaved from **1**. The remaining non-terminal H atom shows a correlation with B9 and B10 in the 2D-^{11}B-^{1}H experiment, that is either bridges B9 and B10, or undergoes, as *endo*-H-atom, a rapid exchange equilibrium between the degenerate isomers with a BH_2 group in the 9 or 10 position. A broad ^{1}H-NMR signal at $\delta = -3.59$ suggests a bridge position on the mirror plane of $NB_{10}H_{12}^-$. The position of the corresponding H atom in the isoelectronic anion $C_2B_9H_{12}^-$ could recently be established unequivocally as *endo*, i.e. this anion contains a BH_2 group on its symmetry plane.[5] A renewed deprotonation of **2** to give the dianion $NB_{10}H_{11}^{2-}$ isoelectronic with the dianion $C_2B_9H_{11}^{2-}$ can indeed be accomplished unproblematically with $LiBHEt_3$, but is unnecessary for the synthesis of the target molecule **3**, since **3** is formed directly from **2** when the latter is allowed to react

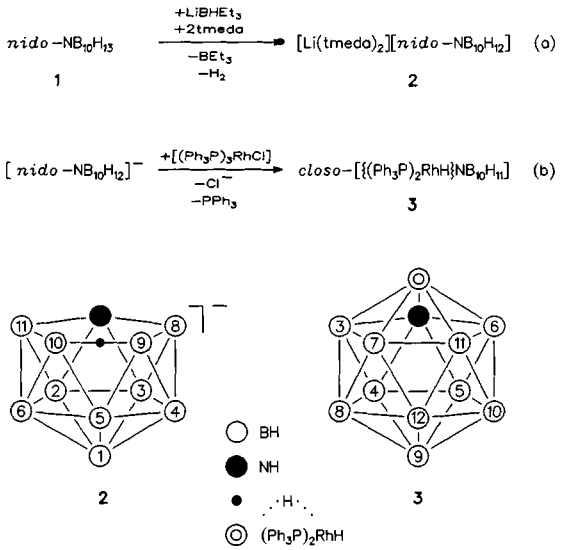
[**] This work was supported by the Deutsche Forschungsgemeinschaft.

with $[(Ph_3P)_3RhCl]$ according to Equation (b). The nonterminal H atom of **2** is bound, in **3**, terminally to Rh as hydrido ligand. The anion $NB_{10}H_{12}^-$ thus behaves like the anion $C_2B_9H_{12}^-$, which reacts directly with $[(Ph_3P)_3RhCl]$ analogous to reaction (b) to give *closo*-$[\{(Ph_3P)_2RhH\}C_2B_9H_{11}]$ **4**.[6]



An X-ray structure analysis was carried out on crystals which still contained 1 mol of CH_2Cl_2 and 0.5 mol of pentane per mol of **3**.[7] The central structural unit of **3** consists of a distorted $RhNB_{10}$ icosahedron (Fig. 1). The Rh atom, because of its size, lies well outside the ideal icosahedral position, and consequently the angles subtended by the five triangles apexing at the Rh atom are significantly smaller than 60° (41.8–47.3°). For electronic reasons the smaller N atom is obviously more distant from the Rh atom (2.40 Å) than the four larger B atoms neighboring the Rh atom (2.23–2.26 Å). The planarity of the pentagon, which is capped by the Rh atom with formation of a pentagonal pyramid, is thereby lost (angle between the planes through B3–N–B6 and B3–B7–B11–B6 13.2°). In contrast to the Rh atom, the N atom, because of its smallness, lies more central than would correspond to the ideal position, so that the angles subtended by the five triangles apexing at the N atom are greater than 60° (62.8–64.3°). The pentagonal pyramid capped by the atom B9 opposite the Rh atom more closely approaches the ideal icosahedral geometry and has an almost planar base (angle between the planes B8–B12–B10 and B8–B4–B5–B10: 3.7°). With exception of the triangles B3–B4–B8 and B5–B6–B10 the ten remaining triangles formed by B atoms deviate only slightly from the regular geometry. The structure of **3** is related with that of **4** and, in the icosahedral region, also with that of $[\{(C_5Me_5)Rh\}C_2B_9H_{11}]$.[8]

3 is a cluster compound of the *closo* type with a six-coordinate N atom. With the elucidation of the structure of **3**, also the *nido* structure of **1** which we previously deduced from 2D-NMR spectra is indirectly confirmed.[2] The orange solid **3**, which can be handled at least briefly whilst exposed to air, is stable up to 100 °C.

Fig. 1. Structure of 3 in the crystal. Experimental

2: A solution of **1** [2] (66 mg) in THF (3 mL) was treated at −78 °C with 0.49 mL of 1 M $Li[BHEt_3]$ in THF. After 5 minutes' stirring at room temperature, all volatile components were removed in vacuo; the residue was taken up in 3 mL of THF and the resulting solution treated with 0.38 g of tmeda. After evaporation to dryness the residue was washed three times with pentane, and, after drying, contained 0.180 g (99%) of **2**.—NMR spectra in $[D_8]$THF at 25 °C; ^{1}H NMR (299.95 MHz, TMS): δ = −3.59 (br, μ-H), 0.16 (H1), 0.53 (H9/10), 0.75 (H5), 1.34 (H4/6), 1.70 (H2/3), 1.85 (H8/11) (measurement and assignment of the BH signals as cross peaks in the 2D-^{11}B-^{1}H-NMR spectrum), 2.15 and 2.31 (2s in the ratio 3:1, tmeda), 4.08 (br, NH); ^{11}B NMR (96.23 MHz, $Et_2O \cdot BF_3$): δ = −42.8 (d, J = 147 Hz, B1 (B5, B2/3, B4/6)), −25.0 (d, J = 147 Hz, B9/10 (B5, B4/6, B8/11)), −22.8 (d, J = 147 Hz, B5 (B1, B9/10, B4/6)), −17.6 (d, J = 171 Hz, B2/3 (B1, B6/4)), −15.4 (d, J = 146 Hz, B4/6 (B1, B9/10, B5, B3/2, B8/11)), −10.9 (d, J = 147 Hz, B8/11 (B9/10, B4/6)) (in brackets, the B atoms correlated in the 2D-^{11}B-^{11}B-NMR spectrum pulse, sequence COSY 45; as expected [2], no cross peak is observable between B2/3 and B11/8 due to the common neighborhood of the N atom). IR(CH_2Cl_2): $\tilde{\nu}$ [cm^{-1}] = 3365 (NH), 2522 (BH).

3: Starting with a solution of **1** (0.24 g) in THF (4 mL), the same procedure was followed as in the preparation of **2** except that, instead of treatment with tmeda, the product taken up in THF (5 mL) was added dropwise at −78 °C to a suspension of $[(Ph_3P)_3RhCl]$ (1.62 g) in toluene (10 mL). The mixture was stirred for 3 h at room temperature, filtered, and the orange solid washed with toluene (2 × 5 mL). After column chromatographic purification in CH_2Cl_2 on silica gel the solution was evaporated down to 20 mL and layered with 20 mL of pentane. At −40 °C there crystallized 0.83 g (54%) of $3 \cdot CH_2Cl_2 \cdot 0.5C_5H_{12}$.—NMR spectra of **3** in CD_2Cl_2 at 25 °C; ^{1}H NMR (299.9 MHz, TMS): δ = −14.70 (d/t, ^1J(Rh,H) = 29 Hz, ^2J(P,H) = 20 Hz, 1H; RhH), 1.19–3.02 (10H; BH), 3.05 (s, 1H; NH), 7.06–7.26 (30H; Ph); ^{11}B NMR (96.23 Hz, $Et_2O \cdot BF_3$): δ = −19.21 and −15.01 (d, J = 146 Hz, and s resp., br, 4B), −2.59 and 1.86 (m and d resp., J = 146 Hz, 6B). IR (CH_2Cl_2): $\tilde{\nu}$ [cm^{-1}] = 3318 (NH).

Surface Fractality of Dendrimers**

By *Dina Farin* and *David Avnir**

We provide evidence that a conjecture made in this journal on the fractal nature of the surface of polymeric dendrimer molecules[1] is correct. The chemistry and physical properties of dendritic polymers (starburst dendrimers) have been the topic of intensive recent research activity in several laboratories[2] and were reviewed recently in this journal by *Tomalia* et al.[1]. These macromolecules are constructed from various initiator cores upon which radially branched layers, termed generations, are covalently attached, thus yielding a three-dimensional highly ordered polymeric compound. The final exterior layer may be further modified chemically to provide a variety of terminal functionalities. The interest in starburst dendrimers is due to an ever-rising demand for materials with special properties, a demand which can be approached through the controlled hierarchical molecular architecture, layer after layer, of these novel polymers.

Since most of the specific applications of starburst dendrimers involve interaction with their outer exposed surface, their full characterization is of prime importance, as indeed stressed by *Tomalia* et al.[1] In particular, these authors drew attention to the importance of the *morphological* characteristics of the surface of dendrimers. The hierarchical self-similarity suggested to them that this morphology may be fractal in its nature. We now provide direct evidence that *Tomalia* et al. were right in their intuition and that the highly clefted surfaces of starburst dendrimers are indeed fractal. This finding is in accordance with the evidence accumulated over the past decade that the complex morphologies of surfaces of both man-made and natural materials are, by and large, describable by fractal geometry.[3,4] Of particular relevance is the evidence that the surfaces of many enzymes and proteins are fractal;[5] we recall that one of the potential applications of starburst dendrimers is to mimic these biomolecules.[1]

We have applied two different fractal analyses. The first method[6] is based on Equation (a), where A is the surface

$$A \sim \sigma^{(2-D)/2} \qquad (a)$$

area accessible to probe spheres of cross-sectional area σ. The degree of surface irregularity is quantified through D, the surface fractal dimension. For a smooth surface ($D = 2$), A becomes independent of the size of the yardstick used to measure it, but for $D > 2$ surface accessibility to external spheres does depend on their size.

The second method[6] is based on Equation (b), in which

$$A \sim d^D \qquad (b)$$

the surface area of an object, as determined with a fixed yardstick (sphere), is measured as a function of the object size, d. For objects with surfaces which are mainly external, the D values from both equations coincide. Many materials[5g] obey Equations (a) and (b), not only in terms of surface area but also in terms of the effective area which participates in a reaction.[3,5g]

Of the starburst dendrimers described in Ref. [1], starburst polyamidoamine (PAMAM) is accompanied by data which allow a comparative fractal analysis based on Equations (a) and (b). Figure 27 in Ref. [1] describes the relation between the (square root of the) solvent-accessible surface-area of PAMAM and the size of probe spheres (Fig. 1). For the larger

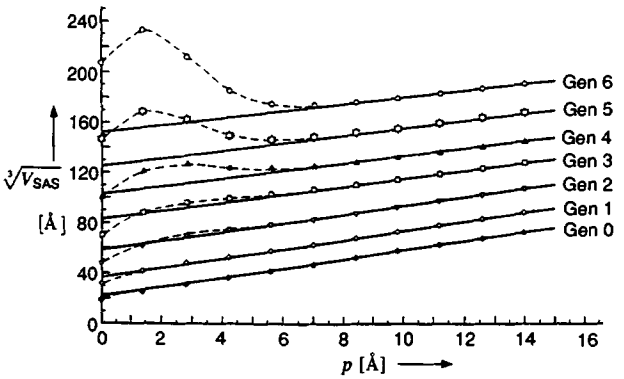

Fig. 1. Relationship between the solvent-accessible surface area and the probe-sphere diameter p (Figure 27 in [1]).

spheres (those with cross-sectional areas much larger than the size of a surface atom), there is a smooth weak increase in surface area with probe size, which actually reflects the increase in the area of enveloping contours with probe size. The fine details of the surface are probed by the smaller probes, and here it is clearly seen, for instance for the highest (sixth) generation, that the area *decreases* with increase in probe size, as is indeed expected for a rough surface. Using the data for the highest generation over the area-yardstick range of 7–158 Å^2 (radii of 1.5–7.0 Å), one finds that Equation (a) is obeyed nicely (Fig. 2a) with $D = 2.41 \pm 0.04$ (correlation coefficient 0.988). The authenticity of this result is corroborated by applying now the second method [Eq. (b)].

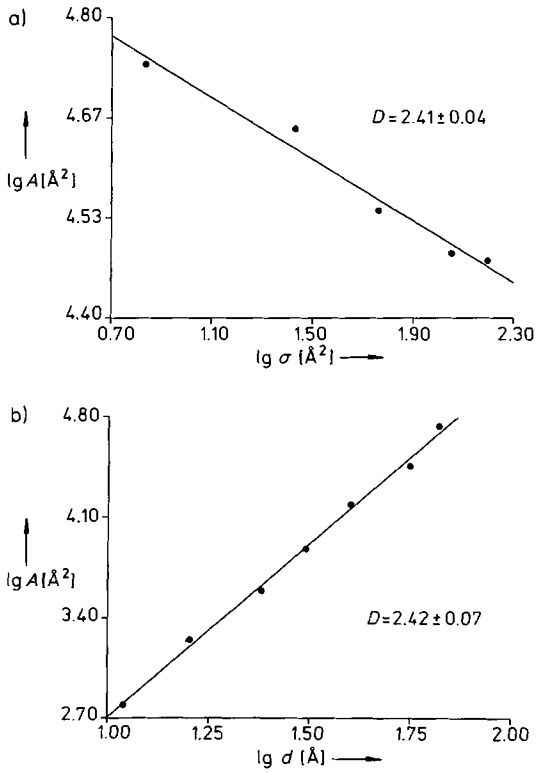

Fig. 2. Solvent-accessible surface area A of PAMAM dendrimers (a) as a function of probe cross-sectional area σ [Eq. (a)] and (b) as a function of dendrimer diameter d [Eq. (b)].

Figure 1 provides also the change in area with the generation number, and Table 6 in Ref. [1] links the generation number with the size, d (d_{exp} in the table). As explained elsewhere,[5] it is more accurate to use the smallest available yardstick, which, in our case, is a sphere with a cross-sectional area of 7 Å^2 (radius of 1.5 Å). We find that this data obeys Equation (b) (Fig. 2b) with $D = 2.42 \pm 0.07$ (correlation coefficient 0.998), practically the same value obained by the first method. Interestingly, *Lewis* and *Rees* obtained $D = 2.4$ as a general value for the surfaces of various enzymes.[5b]

Similar data is available for polyether dendrimers (Fig. 28 in Ref. [1]), but the range is too limited (four generations compared with six for PAMAM). Nevertheless, it is interesting to notice that the different apparent D value obtained from this limited data, namely, $D = 1.96 \pm 0.02$ (correlation coefficient 0.999), is in agreement with the difference in the structural properties between the two types of dendrimers as described in Ref. [1] (p. 155): "The polyether system quickly becomes congested and has little in the way of internal cavities," while the "PAMAM dendrimers have a great deal of internal surface area and solvent-filled volume"; that is, the latter have a porous structure leading to a rough surface, whereas the former is densely compact with much smoother surface cavities.

The demonstrated ability to quantify the surface roughness of starburst dendrimers in terms of their surface fractal dimension opens the possibility of applying several theoretical approaches that have been developed for the physical-chemistry properties of such surfaces. Examples include adsorption[7a, b] and diffusion[7c] on fractal surfaces, their derivatization,[7d] and their catalytic[7e] and noncatalytic[7f] reactivity.

Acronyms and Abbreviations in Molecular Spectroscopy. An Encyclopedic Dictionary. By *D. A. W. Wendisch*. Springer, Berlin 1990. 314 pp., hardcover DM 98.00.—ISBN 3-540-51348-5

This book entitled "Acronyms and Abbreviations in Molecular Spectroscopy: An Encyclopedic Dictionary" by *D. A. W. Wendisch* is a comprehensive collection of the jargon used by spectroscopists, which is rich in abbreviations. Of the approximately 500 entries, an overwhelming majority are concerned with abbreviations used in NMR spectroscopy; other spectroscopy methods such as ESR, NQR, IR, Raman, optical spectroscopy, and polarized light methods receive only minor coverage. To that extent, therefore, the description "Molecular Spectroscopy" in the title promises more than is contained in the book.

Each entry includes an explanation varying in length from a few lines to several pages. At the end of each section there are relevant literature references, mostly to recent publications. The choice of keywords is very comprehensive for the field of NMR, but is rather limited for the other areas of spectroscopy. Of the NMR keywords that occurred to this reviewer, not a single one had been omitted. On the other hand, though, many terms that are not normally abbreviated have been forced to fit into the procrustean bed of abbreviations and acronyms, and have thereby been altered out of recognition in some cases. Thus, POF stands for "product operator formalism", WST for "water suppression technique", and CDRE for "convolution difference resolution enhancement". I have not previously encountered the abbreviation POF in any publication, but have certainly seen "product operator formalism" for which there is no entry in this encyclopedia. This shortcoming detracts a little from the book's value as a reference source.

The explanations vary greatly in their extent and depth. For example, under CYCLOPS I would expect to find not only that it provides a way of avoiding instrumental errors in data acquisition, but also an additional line of text giving the phase cycle. WALTZ is described as a pulse sequence for heteronuclear decoupling, but again the pulse sequence is not given. Some rather unimportant sequences such as UPT are given the rare distinction of a detailed description with a diagram of the pulse sequence, whereas important sequences such as HMQC or DEPT are described by text alone; only four lines are devoted to DEPT, the most important of all editing sequences! This very uneven treatment of different entries does not appear to follow any kind of system, and it is regrettable that there is no correlation with the relative importance of the entries.

Apart from these imbalances in the descriptions, which could give non-specialists a wrong impression of the relative importance of the various techniques, the explanations are in general accurate and provide a good starting point, not least through the literature references given. However, it would be unreasonable to expect a complete coverage of all the important publications relevant to a given entry.

A further positive feature is the references that are given to software packages for the analysis or simulation of NMR spectra, such as LAOCOON, DAISY, SPHINX, or SMART; on the other hand, commercial programs such as Felix or the nmri products are not mentioned.

An index of keywords at the end of the book allows one to quickly assign each term to the relevant area of spectroscopy. Here the extreme bias of the encyclopedia towards NMR becomes obvious, even if it has not been noticed earlier. The book is printed on glossy paper with a hard cover. The printing error on the cover is not typical of the rest of the book. The figures are of good quality.

Despite the weaknesses mentioned above, the book can be recommended as a work of reference for NMR spectroscopists. It provides an alternative to the recently published book "A Handbook of Nuclear Magnetic Resonance" by *R. Freeman*; although the explanations in the latter are more detailed and well-balanced, the number of terms included is much smaller.

Challenges in Synthetic Organic Chemistry. By *T. Mukaiyama*. Oxford University Press, Oxford 1990. 225 pp., hardcover £ 27.50.—ISBN 0-19-855644-6

To mark his 60th birthday *Teruaki Mukaiyama* wrote a comprehensive review of his research efforts during the last forty years. He describes all his research achievements chronologically. Thanks to *J. E. Baldwin*, who has written a fitting foreword, we can now read this fine book in English.

The importance of *Mukaiyama*'s contributions becomes immediately clear just by browsing through the book. The development of the oxidation–reduction condensation was a real breakthrough in the development of organic synthetic methods. Many macrolide syntheses still rely on the use of the combination of triphenylphosphine and dipyridyl disulfide for the ring closure. The *Mitsunobu* reaction, developed by a former collaborator of *Mukaiyama*, is one of the most reliable transformations to obtain a carbon–heteroatom bond with inversion. Finally 2-halopyridinium salts as reagents for esterification and macrolactonization have been widely used in organic synthesis. The titanium(IV) chloride catalyzed crossed aldol reaction between silyl enol ethers and acetals is one of the most important C–C bond-forming reactions in organic chemistry. Since the first pioneering reports of *Mukaiyama*'s group an enormous number of applications of titanium(IV) chloride have been reported. The use of Lewis acids for the aldol reaction made it possible to achieve high and synthetically useful stereoselectivities. At least as important are the contributions of *Mukaiyama*'s group to the development of the tin and boron enolates. Finally, the

use of proline-derived chiral auxiliaries for the stereoselective reduction of ketones and for the stereoselective addition of organometallic reagents to carbonyl compounds is yet another achievement of *Mukaiyama*'s group.

That the author succeeds in accurately and impartially describing all these results and many more which have been accomplished in his laboratories is an astonishing achievement. Personal views intrude only rarely, and the results are reported in essentially chronological order. Only in the prologue and in the epilogue does *Mukaiyama* allow himself some personal remarks. In the first, poetic sentence of his prologue he proclaims the importance of purely exploratory experimentation. He advocates the importance of the unpredictable as a tool to achieve major breakthroughs in chemical research. One of the most fascinating parts of his book is the well-documented change of *Mukaiyama*'s interest from mechanistic questions to the development of synthetic methods. A series of unexpected results led him to develop the oxidation–reduction condensation. In spite of the clear distinction made between the different research projects described in the individual chapters, a Western reader is surprised to find how all the innumerable experimental results seem to be connected by an invisible network of associations. The fact that most of *Mukaiyama*'s inventions of new reactions can be traced to the concept of "dehydration" may be astonishing for Western chemists, but perhaps reflects some of the Japanese traditions.

Keeping this in mind, the book is not only a source book for the synthetic chemist about the results of one of the most successful research groups in Japan, but also affords some insights into the Japanese way of doing research.

Reinhard Neier [NB 1163 IE]

Atomic and Molecular Clusters. Edited by *E. R. Bernstein*. Elsevier, Amsterdam 1990. 806 pp., hardcover DFl 495.00.—ISBN 0-444-88193-X

Although research on clusters is still a relatively young field, its close connections with atomic and molecular physics, solid state physics, and not least with chemistry, have resulted in it already becoming an extensive field of study in its own right. This book does not attempt to present a superficial review of all the different areas of cluster physics. Instead some of the most important aspects of cluster physics have been selected and described in detail in eight independent chapters. Each chapter is carefully constructed and thoughtfully worked out, presenting valuable information in a clearly comprehensible style.

The first chapter, by *R. E. Smalley*, gives a comprehensive 62-page review of studies on clusters of carbon atoms. Special attention is devoted to the cluster C_{60}, which according to the author will possibly "come to be recognized as one of the most abundant and most important molecules in the universe". If this raises some doubts in the reader's mind, he or she will presumably feel a need to read this fascinating chapter.

The next chapter is a comprehensive and well-written account of clusters of main group elements. In preparing this the authors, *M. L. Mandich, W. D. Reents, Jr.* and *V. E. Bondybey*, have performed an important service for the clusters research community. This substantial 290-page review is packed with useful information, and contains nearly 500 literature references. It is the only such report in the clusters literature, and is enough in itself to make the book a worthwhile purchase.

Chapter 3 is devoted to a specialist topic, the structures of weakly bound complexes. In this 34-page article *S. E. Novick, K. R. Leopold*, and *W. Klemperer* have tabulated the most important properties of 144 complexes.

In Chapter 4 *R. O. Watts* reports on recent advances in the IR spectroscopy of van der Waals clusters. Reducing the temperature of such clusters by adiabatic expansion and laser cooling makes it possible to obtain IR spectra of previously unattainable resolution.

The following chapter is also concerned with van der Waals clusters, though in this case with a special class, namely clusters made up of inert gas atoms and halogen atoms. *K. C. Janda* and *C. R. Bieler* describe how such clusters exhibit a wealth of interesting effects, including the so-called "rotational rainbows" and quantum interference effects associated with vibrational predissociation.

In Chapter 6 *A. W. Castlemann, Jr.* and *R. G. Keese* describe a number of important techniques for observing clusters in a cluster beam, together with the interpretation of the results from such measurements. Special attention is given to the technique of resonance enhanced multiphoton ionization of clusters followed by detection in a time-of-flight mass spectrometer.

Chapter 7 represents another substantial contribution by this book. In this 200-page article the editor, *E. R. Bernstein*, describes the properties of a special class of molecular clusters consisting of two or more different molecular species, usually organic, one of which is spectroscopically active. By applying absorption and emission spectroscopy to molecular clusters of this type, together with computer simulations, one can investigate the ground and excited states.

The eighth and final chapter is a well-written review by *R. L. Whetten* and *M. Y. Hahn* of the spectroscopy of large molecular clusters. It includes discussions of the liquid drop model, the elementary excitations, and the liquid-solid transition in molecular clusters.

This book succeeds in the aim of filling the gap between international conference reports and general reviews. The wealth of information that it contains should make it a welcome addition to the library of every cluster physicist.

Quasicrystals, Networks, and Molecules of Fivefold Symmetry. By *I. Hargittai*. VCH Verlagsgesellschaft, Weinheim/ VCH Publishers, New York 1990. xiii, 314 pp., hardcover, DM 148.00.—ISBN 3-527-27927-X/0-89573-723-X

The discovery by *Shechtman* et al. in 1984 of a material that exhibited the diffraction properties of an ordinary crystal (Bragg peaks) and yet seemed to display perfect fivefold rotational symmetry has brought on a surge of activity in solid state chemistry and physics. The output of the scientific community in this area has been very large indeed, and the need for monographs, both as introductions to the field and as overviews, is obvious. The present book is therefore timely (although not unique, as a fair number of monographs on the subject have already appeared).

The book covers an area ranging from pure mathematics to organic chemistry, thus providing a good overview to newcomers and experts alike. Like any monograph consisting of a number of papers by different authors, it suffers

from a certain amount of disjointedness, but this is well counterbalanced by the thus widened scope of the book.

In the first chapter *Mackay* reviews the history of fivefold symmetry in crystallography and discusses its philosophical implications. The chapter is a good introduction to the general problem of the meaning of the terms order and disorder in flat and curved spaces of different dimensionalities. *Senechal* discusses the impact of the one-dimensional quasicrystal, pointing out that even this, the simplest of cases, is very incompletely elucidated, and that our understanding of noncrystallographic symmetry is indeed rather poor. In the excellent second chapter current knowledge of the one-dimensional case is summarized in a clear and thorough way. Chapter 3 is an account of the connections between stochastic web mappings and quasicrystalline symmetry. The authors *Sagdeev* and *Zaslavsky* exploit the connections between the chaotic behavior of self-similar fractals and the self-similarity of quasicrystalline systems.

Chapters 4 to 6 deal more closely with experimental chemistry. High resolution electron microscopic (HREM) images of quasicrystals have been published by many authors, and to build models of the atomic arrangement in these materials based on the information from HREM images has been the method of choice for many. In Chapter 4 *Lin* and *Bursill* show how computer-simulated images of clusters of different sizes can be compared to experimental images. The other major method to get structural information from quasicrystals is by X-ray diffraction studies. This is used on a single crystal by *Dénoyer* et al. in Chapter 5 to characterize a slowly cooled icosahedral alloy and on a powder by *Dunlap* et al. in Chapter 6 to distinguish between the cubic crystal model and the quasicrystal model for aluminum based samples.

There exist a number of different ways of generating quasilattices. One of these is to use a set of substitution rules on a finite lattice that generates the infinite lattice. This procedure is well known for the Fibonacci sequence, and it has recently been generalized to higher dimensions. In Chapter 7 *Allouche* and *Salon* prove that such a 2-D substitution can generate the Robinson tiling. Chapters 8 to 10 deal with the connection between quasilattices and higher space. *Whittaker* and *Whittaker* give a general overview of symmetry in higher space; *Baake* et al. discuss 2-D quasilattices as projections from regular 4-D root lattices; and *McMullen* deals with nondiscrete regular apeirotopes. The grid method is discussed by *Nissen* in Chapter 11 and *Stampfli* in Chapter 12.

The rest of the articles in the monograph deal with fivefold symmetry in a rather different concept. Potential energy hypersurfaces have been studied extensively by *Mezey*, and in Chapter 13 he discusses the impact of fivefold symmetry on these structures.

The last six chapters are devoted to the C_{60} carbon cluster found by *Kroto* et al. in laser vaporized graphite and christened buckminsterfullerene, a somewhat more manageable name than that which IUPAC nomenclature would require. This molecule, which takes the form of a truncated icosahedron, has prompted an avalanche of theoretical papers and further experimental work. In this volume *Klein* and *Schmalz* give an introductory overview.

As early as 1910, astronomers analyzing light received from stars found diffuse absorption bands whose origin was later proved to be interstellar. The source of these bands has long been a matter of controversy, and *Léger* et al. argue here in favor of buckminsterfullerene as a possible source.

The buckminsterfullerene molecule poses some rather interesting theoretical problems. In the present volume *Brendsdal* et al. analyze its Hückel energy levels, *Elser* et al. study the Kekulé structures (there are exactly 12500 of them), and *Brendsdal* et al. discuss the vibrational spectrum of the molecule. The last chapter is devoted to the subject of polyindans, organic systems of fused five-membered rings. The author, *Kuck*, discusses several different features of the centropolyindans: classification, synthesis, and structural aspects.

In all the present monograph covers a very wide scope indeed, and it prompts the reader to go far beyond the narrower interests of one's own field. The book should be a valuable addition to the library of anyone with an interest in the implications of fivefoldedness.

Basic One- and Two-Dimensional NMR Spectroscopy. By *H. Friebolin*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York 1991. xxi, 344 pp., hardcover DM 58.00—ISBN 3-527-28108-8/0-89573-972-0

This book is intended to provide a simple introduction to the world of one- and two-dimensional NMR spectroscopy, taking the reader from a limited knowledge base to a general understanding of the NMR methods and applications available today. There are fourteen chapters ranging from a general introduction, through spectral parameters, relaxation, simple pulsed methods, and the nuclear Overhauser effect (NOE) to finally medical applications.

The general introduction discusses the basic theory and principles behind the NMR phenomenon and briefly introduces the spectral parameters of shift and scalar coupling. This, as always, is important groundwork to cover initially. Some of the figures in this section are less than adequate. In particular the resolution in the spectra in some cases is so poor that it is difficult to decide whether the discrepancies in peak heights are due to this or to potential strong coupling effects. As with other introductory texts, a more detailed description of the rotating frame transformation and its consequences would be beneficial. Certainly, it seems that those people learning this subject for the first time have a good deal of difficulty in grasping the impact of this point.

Chapters 2 and 3 dealing with chemical shift and spin–spin coupling respectively follow on well from Chapter 1. Throughout Chapter 2 there are an unusually large number of excellent examples, and substituent effects and stereochemical aspects are covered in precise detail. Chapter 3 continues along the same lines with many useful tables of coupling constants. A particularly useful inclusion is the in-depth description of dihedral angle effects and Karplus curves, vital in much structure determination work. The section on the "theory" of coupling would, however, have been much better suited at the beginning of this chapter than at the end. A useful chapter on spectral analysis (two, three, and four spin systems) is followed by Chapter 5 outlining double resonance procedures. Homonuclear spin decoupling is covered, but it should be noted that this technology has been all but eclipsed by the ease and speed of running COSY-type spectra. Most importantly, proton decoupling in carbon experiments is addressed. Chapter 6 deals with the assignments of proton and carbon shifts and the prediction of shifts by empirical methods.

Chapter 7, covering relaxation processes, appears to be directed almost exclusively towards the study of carbon-13

nuclei. It is never completely clear, especially to a novice audience, that methods such as inversion-recovery and Carr-Purcell-Meiboom-Gill experiments are general methods for observing general phenomena. One-dimensional experiments using pulse sequences are covered in Chapter 8. Spin-echoes are covered well, and the treatment of the INEPT and refocussed INEPT experiments is particularly good. Unfortunately, several vector pictures in this chapter are extremely confusing and detract from the lucid description in the text. It is important to remember that trying to oversimplify problems often results in overloading the reader with too much information at one time. Two-dimensional NMR experiments are covered in Chapter 9. Particularly good here is the slow development of the heteronuclear correlation experiment, taking the method from its intuitive beginnings through to a usable pulse sequence. Descriptions of spectral widths as related to the incrementable delay period and phase sensitive spectra would make a useful addition here. Only basic two-dimensional experiments are covered, and many of the recent and powerful two-dimensional methods are not presented.

Chapter 10, developing the idea of the NOE, is well explained and very understandable and leads nicely into Chapter 11 on dynamic NMR. This section, including lineshape analysis and coalescence, is packed with informative examples. Rotations about bonds, ring inversion, tautomerism, and exchange effects are all described with clarity. Bringing the book to a close are chapters on shift reagents, macromolecular applications (synthetic polymers) and, surprisingly, medical applications including in vivo studies and magnetic resonance tomography.

In summary, this text provides a reasonably successful introduction to basic NMR ideas. Its greatest asset is that it is written at a level that is accessible to students across a wide range of disciplines and consequently would make a useful basis for an introductory teaching course. The reservations that exist include the lack of clarity and accuracy in some of the figures and the fact that the enormous power of two-dimensional NMR is not conveyed to an appropriate extent.

Computational Chemistry Using the PC. By *D. W. Rogers*. VCH Verlagsgesellschaft, Weinheim 1990. viii, 224 pp., hardcover DM 98.00. – ISBN 3-527-27937-7

The term "computational chemistry" does not have a very precise definition. In the title of this book it essentially means molecular mechanics and molecular orbital calculations and the numerical methods on which these are based. In contrast to the numerous monographs dealing with the theory of molecular and quantum mechanics, this book aims to give an introduction to programming such methods and applying them. This seems a very sensible approach, and the book succeeds in its aims. Most "computer chemists" have become involved in this field in an unplanned way through modifying already existing programs to perform new tasks, and have had to acquire the necessary expertise in numerical mathematics from a variety of sources. This book now offers a systematic introduction, ranging from the basic numerical methods to working with ready-made HMO and SCF programs. Each chapter includes many exercise problems, for which solutions are provided in most cases. The book also includes "computer projects", a form of learning aid which is an innovation, at least in the context of a textbook. Each one consists of a set of guidelines for solving a physical chemical problem using a computer program. The programs, most of which are written in BASIC, are supplied with the book on a $5^1/_4$-inch diskette suitable for running on any IBM-compatible PC operating under DOS.

The book is divided into two parts. The first six chapters present the basic principles of programming numerical methods. Iterative methods and numerical integration methods are explained with the help of examples from physical chemistry (e.g. the van der Waals equation, Wien's law, and the Maxwell–Boltzmann distribution). These are followed by matrix operations and curve-fitting. The last seven chapters of the book are concerned with molecular orbital calculations, molecular mechanics, and molecular graphics. In the treatment of MO theory, if not even earlier, the author encounters a basic difficulty that is inherent in the task he has undertaken, namely whether to introduce the reader to quantum theory (and thereby make the book considerably more bulky), or to assume this knowledge. He decides in favor of a middle road. The theoretical introductions are short and very condensed. Consequently, if the book is to be used as a self-study text one must already be familiar with the main fundamentals, or must use it in conjunction with a textbook of theoretical or physical chemistry. Subject to these preconditions, the chapters on molecular mechanics and MO methods (Hückel, EHT, PPP, MNDO, ab initio, etc.) provide a deeper insight into how these programs function.

The book fills an important gap that has existed between those (very few) books dealing with the application of the most popular molecular mechanics and MO programs to chemical problems (e.g. *T. Clark*'s "Handbook of Computational Chemistry") and the actual textbooks of theoretical chemistry. It is shown here that as a result of the present state of development of PCs, the excellent programs already available can now be usefully run on cheap hardware that nearly all students can afford. The high price of the book is in marked contrast to this, but on the other hand the perfect typography that is typical of the publishers, VCH, is a delight to the eye. The book is outstandingly suitable as a self-study text for lecturers and students of graduate level and beyond. It is especially recommended for users of black box program systems such as GAUSS or MOPAC who would like (and indeed ought) to gain a somewhat better understanding of what they are calculating.

Rainer Herges [NB 1132 IE]
Institut für Organische Chemie
der Universität Erlangen-Nürnberg (FRG)

Metals and Ligand Reactivity. By *E. C. Constable*. Ellis Horwood, New York 1990. xii, 246 pp., hardcover $54.50. – ISBN 0-13-577222-2

The rapid development from about 1960 onwards of the new organometallic chemistry with its sometimes exotic structures and bonding situations, temporarily pushed the study of classical coordination compounds into the background. During the 1950s the latter were at the center of attention in molecular inorganic chemistry as a result of the successful combination of spectroscopy, reactivity studies, and ligand field theory. Now their importance is gradually

becoming generally appreciated once again, especially through the rise of bioinorganic chemistry as a new field of research. However, even leaving aside the remarkable catalytic capabilities of the metal centers in enzymes, many organic chemical transformations that are made possible or are catalyzed by non-organometallic coordination compounds are indispensable in laboratory synthesis and technological processes. Whether one already has an interest in the subject or has previously regarded classical coordination chemistry as boring, weighed down with theory, and irrelevant, it will be found that Constable's account is a thoroughly readable one that offers an agreeable way of catching up on developments. The main emphasis in this monograph is on using (transition) metal centers to influence the reactivities of organic compounds that have coordination sites formed by heteroatom donors.

The particular features that make this an easy book to read are its emphasis on synthetically useful reactions and the absence of lists of physico-chemical data and literature citations in the main text. References for further reading are collected at the end of the book under topic headings—where the author gives more detailed information.

Constable begins with a very brief introduction to the orbital models needed. Regrettably, however, the qualitative description of chemical reactivity does not include catalytic aspects. Coordinative bonding, both with and without π interaction, is described from the standpoint of electrostatic interactions and geometry in a clearly understandable way. The descriptions of examples begin with the chapters on attack by nucleophiles, including H_2O and $OH^{\ominus}$, on metal-coordinated carbonyl compounds and their derivatives (nitriles, imines), on sulfur compounds, and on phosphoric acid esters. These are followed by a chapter discussing electrophilic attack on metal-stabilized anions such as enolates or thiolates and on neutral bases (e.g. metal-induced amine–imine transformations).

Another chapter describes template reactions that lead to ring closure, with a general discussion of the special characteristics of macrocyclic systems with regard to stability, resistance to attack, metal selectivity, and geometric strains caused by imperfectly matching metal ions. Supramolecular structures, including knotted molecules, continue to be a source of fascination. The special characteristics of aromatic substrates are discussed, with particular emphasis on the substitution reactions of metal-coordinated *N*-heterocycles of the pyridine type. The description of redox processes is limited to transition metal catalyzed reactions with O_2, which are of practical importance, but whose mechanisms are not always as they seem at first sight. It is pleasing to note that here, at last, a clear distinction has been made between the processes of electron transfer, dehydrogenation, and oxygen transfer. The final chapter, entitled "Envoi", contains a very brief, and consequently rather simplified account of the search for an overall rationalization of the catalytic capabilities of coordinated metal ions in enzymes.

The contents of the book are clearly arranged and well presented, matching the author's excellent lecturing style. The many formulas are well prepared, except for a few ring systems and the inconsistent use of arrows for coordinative bonds. The popular structure diagrams as reproduced from X-ray diffraction studies are few in number so that the reader obtains a rather limited appreciation of the complex geometries. On the other hand, the summaries given at the end of each chapter and the pithy critical evaluations scattered throughout the text are especially useful. Thus, for the reader who, for a relatively small cost in time and money, wishes to acquire as much practical, useful knowledge of coordination chemistry as possible, this book is recommended unreservedly.

Wolfgang Kaim [NB 1131 IE]
Institut für Anorganische Chemie
der Universität Stuttgart (FRG)

Sonochemistry: The Uses of Ultrasound in Chemistry. Edited by *T. J. Mason*. The Royal Society of Chemistry, London 1990. 151 pp., paperback \$ 89.25.—ISBN 0-85186-293-4

Chemical applications of ultrasonic waves, often referred to as sonochemistry, enjoyed a renaissance in the eighties. These books are introductory in nature, intended for the chemist with a potential interest in the field. The first is more general, while the second will be of more interest to synthetic chemists.

There are nine contributors covering an important range of topics in eleven chapters: *T. J. Mason* provides an overview of the field in the first chapter (8 pages, 10 references) dealing with historical aspects, non-chemical uses of ultrasound (diagnostics), power ultrasound, and specific examples of ultrasound enhanced chemical reactions. The incorrect attribution of *Regen*'s work on dichlorocarbene to *Repic* is unfortunate. Chapter 2 ("Sonochemistry, the General Principles", *J. P. Lorimer*, 18 pages, 5 references) offers a lucid discussion of wave propagation, particle displacement due to a longitudinal wave, factors affecting cavitation, and the fate of a bubble in a sound field. It is one of the best chapters in the book, marred only by the conspicuous absence of a discussion of the "hot spot" theory and *Suslick*'s vapor shell.

The third chapter ("Ultrasound in Diagnosis, Inspection, and Monitoring", *C. S. Gartside* and *M. M. Robins*, 20 pages, 6 references) is simply out of place and dilutes the effort of such a small book. Chapter 4, ("Power Ultrasound", *J. P. Perkins*, 13 pages, 5 references) deals with some important fundamental concepts such as monitoring acoustic input and output, construction of the transducer, cavitation phenomena, health and safety aspects, and large scale applications, but would be more effective if blended efficiently with topics in Chapters 2 (see above), 5 ("A Survey of Commercially Available Sources of Ultrasound Suitable for Sonochemistry", *T. J. Mason*, 9 pages, no references), 10 ("The Uses of Ultrasound in Chemical Technology", *T. J. Mason*, 6 pages, 13 references), and 11 ("Scale-up Considerations", *T. J. Goodwin*, 14 pages, 4 references). There is a good deal that is useful in these chapters but the fragmentation of information and unnecessary repetition detract from them.

Chapters 6 ("Ultrasound in Organic Synthesis", *R. S. Davidson*, 17 pages, 38 references), 7 ("Free Radical Reactions under Sonochemical Conditions", *J.-L. Luche*, 15 pages, no references) and 8 ("Ultrasound in Heterogeneous Catalysis", *J. Lindley*, 8 pages, 89 references) discuss much of the important literature of interest to synthetic chemists. It is distracting that a number of the references in Chapters 6 and 8 are simply incorrect and others have an author's name misspelled.

There is overlap among the chapters that a small book can ill afford. As examples, precious space is wasted on two discussions with schemes by *Davidson* and *Luche*, of *Luche*'s free radical ring closure of benzamide and of his elegant preparation of dialkylzinc compounds. Likewise, *Davidson*'s treatment of continuous ultrasonic hydrogenation of soy-

bean oil and platinum catalyzed hydrosilation belong only in *Lindley*'s chapter where they are also discussed. Chapter 9 ("Ultrasound in Polymer Chemistry", *J. P. Lorimer*, 20 pages, 10 references) covers theory of high frequency waves (>1 MHz) as well as applications in providing information on relaxation phenomena. Uses of low frequency waves (polymerization/depolymerization) are also given.

Ultrasound in Synthesis. By *S. V. Ley* and *C. M. Low*. Springer, Berlin 1989. 133 pp., hardcover, $ 79.50.— ISBN 0-387-51023.

Following a very brief introductory chapter (1 page), Chapter 2 ("The Physical Basis of Sonochemistry", 27 pages) provides a qualitative discussion of the origin of and the factors influencing sonochemical reactivity. The current thinking on the cavitation process and the roles of frequency, intensity, temperature, and cell and probe design are presented, along with a discussion of methods of measuring ultrasonic intensity. This chapter will be useful to the novice in the field.

The remainder of the book summarizes applications of ultrasonic waves to synthesis, and covers organic, inorganic and organometallic examples. The chapter titles and page count illustrate the organization of the book. The treatment is broad with only the highlights in each area covered: Chapter 3 ("Aqueous Sonochemistry", 4 pages); Chapter 4 ("Preparation of Activated Magnesium", 6 pages); Chapter 5 ("Preparation of Organoaluminum Compounds", 1 page); Chapter 6 ("Application of Ultrasound to the Preparation of Organolithiums", 11 pages); Chapter 7 ("Reactions with Other Alkali Metals", 11 pages); Chapter 8 ("Organozinc Reagents", 16 pages); Chapter 9 ("Intercalation Reactions", 1 page); Chapter 10 ("The Effects of Ultrasound on Enzyme-Catalyzed Reactions", $1\frac{1}{4}$ pages); Chapter 11 ("Ultrasonic Acceleration of Organic Reactions", 19 pages); Chapter 12 ("Ultrasonic Acceleration of Redox Reactions", 6 pages); Chapter 13 ("The Effects of Ultrasound on Transition Metal Catalysts", 2 pages); Chapter 14 ("Transition Metal Carbonyls and Ultrasound", 15 pages).

Chapters 11 and 12 emphasize homogeneous phase-transfer and nonmetal reactions, although there is some overlap with metal-based reactions. Perhaps a different organization of material would have avoided this and the need for the one- and two-page chapters (5, 9, 10 and 13). Considering the hefty price tag, a more judicious use of space is required for good value. For example, the diagrams and schemes are too large for a book this size, as are the spaces allotted for chapter headings, leading to far too much white space. The aim of this book is to familiarize a wider audience with the background of chemical applications of ultrasound. This is accomplished at the "acquaintance" level.

Chemistry and Biology of the Enediyne Anticancer Antibiotics

By K. C. Nicolaou* and W.-M. Dai

Novel, biologically active substances from nature often provide excitement, stimulation, challenges, and opportunities for the scientific and medical communities. Experience and wisdom dictate investigation of their chemistry and pursuit of their chemical synthesis for more often than not, the rewards for both chemistry and medicine are great. The enediyne anticancer antibiotics are a rapidly emerging class of such compounds derived from bacterial sources. Combining unprecedented and highly unusual molecular architecture, phenomenal biological activities and fascinating modes of action, these DNA cleaving compounds burst onto the scene in the latter half of the 1980s when their structures became known, and they rapidly moved to center stage. Today the enediyne family includes the neocarzinostatin chromophore, the calicheamicins, the esperamicins, and the dynemicins, and soon the number of family members is certain to increase. These molecules elicited extensive research activities in chemical, biological, and biomedical circles and inspired the design of a number of novel molecular assemblies to probe and mimic their chemical and biological actions. A new body of synthetic technology and several novel synthetic strategies have already been devised to address the challenges posed by these molecules, and several new DNA cleaving agents have been designed and synthesized. This article summarizes the chemistry and biology of the enediynes and discusses mechanistic, synthetic, molecular design, and DNA cleavage aspects associated with the field.

1. Introduction

In 1985 *Edo* et al.[1] disclosed the structure of neocarzinostatin chromophore **1** (Scheme 1) possessing a novel bicyclo[7.3.0]dodecadiynene system. This seminal contribution received little attention until 1987 when the structures of two other novel families of natural products, the calicheamicins (**2**: calicheamicin γ_1^I, Scheme 1) and the esperamicins (**3**: esperamicin A_1, Scheme 1) possessing an enediyne moiety, were reported by scientists from the Lederle Laboratories[2] and Bristol-Myers,[3] respectively. In 1989 a fourth novel structure, dynemicin A (**4**, Scheme 1) was reported by Bristol-Myers, Japan.[4] Thus began the story of this rapidly emerging class of anticancer antibiotics known today as the enediynes. The apparent failure of neocarzinostatin chromophore to immediately spark the interest of the synthetic community despite its structural novelty may be partially explained by the absence of an X-ray crystallographic analysis that left unresolved a number of stereochemical issues, not to mention suspicions about its, at the time, seemingly unlikely structure. Today, however, all these novel compounds and their relatives are in the forefront of chemical, biological and medical research.

The excitement surrounding these molecules lies in their novel molecular architecture, their important biological activity, and their fascinating mode of action. All four types of compounds mentioned above exert their biological action by virtue of their ability to cleave DNA. Furthermore, their DNA

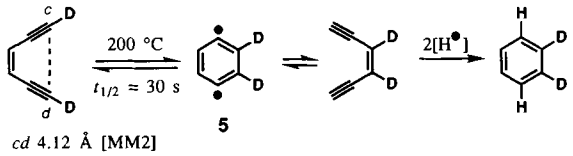
cleaving properties are derived from their common ability to generate sp^2 carbon-centered radicals upon suitable activation. It has been widely recognized that these molecules are equipped with at least three important functional domains: a) a "warhead" destined to "explode" upon suitable activation, thus providing the fragments that damage DNA; b) a "delivery system" which apparently delivers the warhead to its target, DNA; and c) a triggering device, which upon suitable activation, initiates the cascade of reactions that leads to the generation of the damaging radicals.

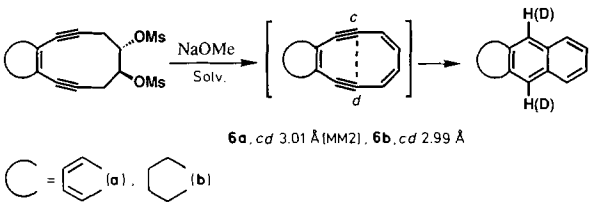
Before discussing the chemistry of these remarkable antibiotics, it is perhaps appropriate to review some interesting observations made in the 1960s and 1970s by a number of investigators pursuing research in the area of physical organic chemistry and theoretically interesting molecules. Thus, in 1972 *Bergman*[5] reported his elegantly designed studies with model enediynes, showing clearly their cycloaromatization via 1,4-benzenoid diradicals (e.g. structure **5**, Scheme 2).



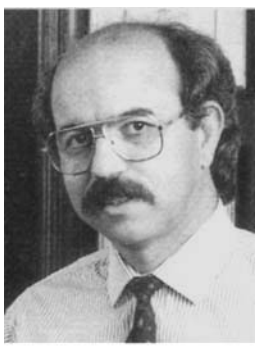
5

Scheme 2. The Bergman cyclization (1972). The distance between the centers *c* and *d* in the educt calculated by MM2 is 4.12 Å.

This is precisely the reaction that nature is apparently using as the crucial process to generate the fragments that inflict the lethal blows on DNA. Prior to *Bergman*'s studies, *Masamune* et al.[6] described the conversion of the two cyclic enediynes **6** (Scheme 3) into benzenoid systems, but without



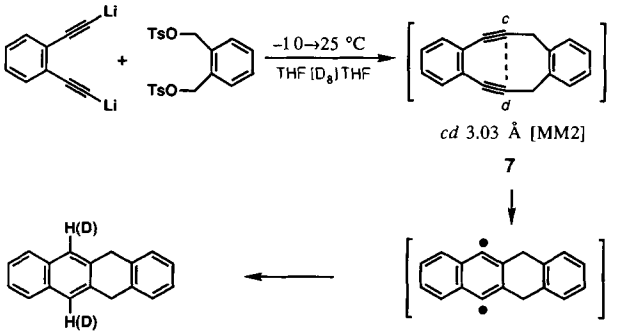
Scheme 3. Observations by *Masamune* et al. (1971). Ms = mesyl.



K. C. Nicolaou was born in Cyprus in 1946 and received his Ph.D. degree from the University of London under Professors F. Sondheimer and P. Garratt. After postdoctoral work at Columbia University with Professor T. Katz and at Harvard University with Professor E. J. Corey, in 1976 he joined the faculty at the University of Pennsylvania, where he was promoted to Rhodes-Thompson Professor of Chemistry. He moved to La Jolla in 1989 to fill an unprecedented joint appointment as a Professor of Chemistry at the University of California San Diego and as the Darlene Shiley Professor of Chemistry and Chairman of the Department of Chemistry at the Scripps Research Institute. The recipient of numerous awards, including the Alfred P. Sloan Award, a Guggenheim Fellowship, and a Humboldt Senior American Scientist Award, Nicolaou has been involved with the development of new ways of synthesizing complex organic molecules of natural or nonnatural origin. He is the author or co-author of over 250 publications, 16 patents, and one book. His hobbies include walking on the beach and playing tennis.

W.-M. Dai was born in 1957 in Ninghai, China. He received his B. S. in 1982 from Hangzhou University (China) and then moved to the Shanghai Institute of Organic Chemistry, Academia Sinica for his graduate studies with Professor W.-S. Zhou, receiving his M. S. in 1984. In 1985 he joined Professor Y. Nagao's group at Kyoto University (Japan) where he worked in the area of asymmetric synthesis utilizing chiral Tin(II) enolates and applying this chemistry to the total synthesis of alkaloids. After gaining his Ph.D. degree from Kyoto University in 1990 he joined Professor Nicolaou's group in La Jolla, California where he is currently a Research Associate. His research interests include the development of novel asymmetric reactions and the synthesis of natural products and biomedically interesting molecules. He is currently engaged in the design, synthesis, and study of novel enediynes. W.-M. Dai speaks fluent Chinese, Japanese, and English, and his hobbies include chinese cooking and reading the literature.

mentioning the involvement of a diradical intermediate. Subsequent to these studies and prior to the discovery of the naturally occurring enediynes, *Wong* and *Sondheimer*[7] had also observed the cycloaromatization of in situ generated strained cyclic enediynes such as **7** (Scheme 4) and postulated benzenoid 1,4-diradicals as intermediates. This process is now widely known as the Bergman cyclization reaction. Even earlier (1966) *Mayer* and *Sondheimer*[8] described a rearrangement (Scheme 5) which most likely involved a similar type of cyclization reaction of **8** and a diradical intermediate.



Scheme 4. Observations by *Wong* and *Sondheimer* (1980). Ts = tosyl.

Although it was known for some time that reactive benzenoid diradicals are formed from enediynes, no one took up the challenge to engineer this chemistry for the design of molecules with potential biological and medical significance. It took nature once again to show us the way to what now, of course, looks so obvious! This recognition should serve as

a constant reminder to those who do not have, or have lost their appreciation for natural products chemistry: This discipline continues, and will continue for a long time, to uncover invaluable leads and knowledge from nature that become the guiding lights in our search for new scientific ventures and wonder drugs of tomorrow. At the same time we should also salute the discipline of physical organic chemistry and those who champion its course, for they often open pathways for others to follow, or should follow, in related disciplines such as synthetic and bioorganic chemistry. Let us now return to the fascinating chemistry and biology of the enediynes.

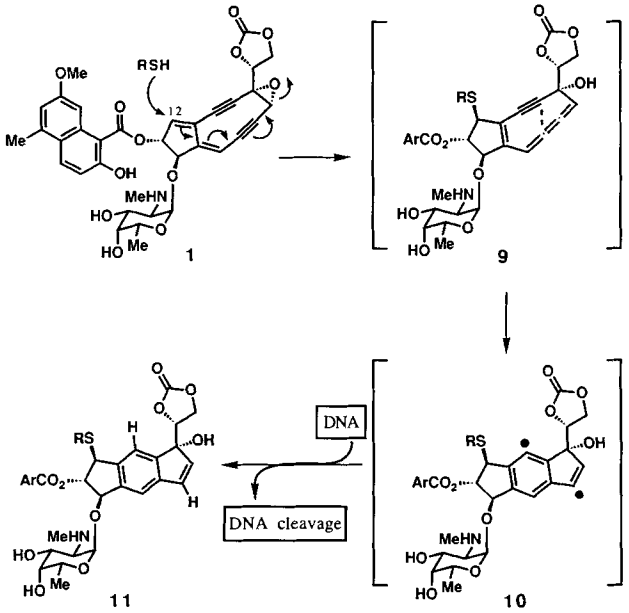
2. Isolation, Biological Properties, Structures, and Mechanisms of Action of the Enediyne Anticancer Antibiotics

The announcement of the structures of the calicheamicins[2] and esperamicins[3] in 1987 aroused a great deal of interest in chemical and biological circles. The newly discovered compounds combined unprecedented and intriguing molecular structures with striking biological activities. At the same time, mechanistically intriguing proposals relating to their mode of action were put forward by the authors.[2, 3] Synthetic chemists throughout the world became immediately interested in these structures. Furthermore, the neocarzinostatin chromophore[1] that had earlier failed to fully capture the chemist's imagination was now viewed with renewed interest because of its structural and biological similarities with the newly discovered enediynes.

2.1. Neocarzinostatin

Neocarzinostatin (NCS) is a naturally occurring antibiotic complex consisting of a 1:1 mixture of a protein component (NCS apoprotein) and a chromophoric molecule (NCS chromophore) isolated from *Streptomyces carzinostaticus* Var. F-41. First reported in 1965 by *Ishida* et al.,[9] this antibiotic complex was later resolved into its components, NCS apoprotein and NCS chromophore.[10, 11] It was soon recognized that essentially all the biological activity of NCS resides in its chromophoric moiety and that the protein component plays an important role in transporting and stabilizing the drug.[12, 13] NCS apoprotein binds tightly and specifically to NCS chromophore ($K_D = 1 \times 10^{-10}$ M)[14] and delivers the active chromophore to its target, DNA, by controlled release.[15] The biological activities of NCS include potent antitumor and antibacterial actions and they are exerted via DNA cleavage. The DNA damaging activity of the labile, free NCS chromophore, results primarily in single strand cuts and proceeds via an oxygen-dependent reaction.[16] Thiols[17] and ultraviolet radiation[18] greatly enhance the DNA cleaving properties of NCS chromophore.

The novel structural skeleton of NCS chromophore was first proposed by *Edo* et al. in 1985.[1] The first proposal for



Scheme 6. Mechanism of DNA cleavage by **1**. RSH = thionucleophile, Ar = naphthyl substituent.

the mechanism of action of NCS chromophore was put forward by *Myers* in 1987.[19] According to this elegant hypothesis (Scheme 6) the cascade of reactions leading to DNA damage is initiated by stereospecific nucleophilic attack at C12, probably assisted by the basic nitrogen of the carbohydrate moiety of the agent. This triggering event is accompanied by rearrangement of the ring skeleton with epoxide opening and formation of cumulene **9** as shown in Scheme 6. The highly strained and labile intermediate **9** then suffers rapid cycloaromatization to form diradical **10** which proceeds to attack DNA by hydrogen atom abstraction resulting in **11**. This scenario has been demonstrated in the laboratory using $HSCH_2COOMe$[19–22] and $NaBH_4$[22] as nucleophiles, and the cumulene intermediate **9** has been observed at low temperature by ^1H NMR spectroscopy.[21] Furthermore, the methyl thioglycolate adducts of NCS chromophore have been isolated and fully characterized, leading to complete structural elucidation of the molecule including the absolute configuration.[20]

It is now accepted that NCS chromophore intercalates into DNA via its naphthoate group and positions the rest of the molecule in the minor groove[23–25] ready for activation (Fig. 1). Triggering is thought to occur upon nitrogen-assisted nucleophilic attack[26] by thiol at C12 of the chromophore as discussed above. The NCS chromophore preferentially attacks at adenine and thymine sites.[27]

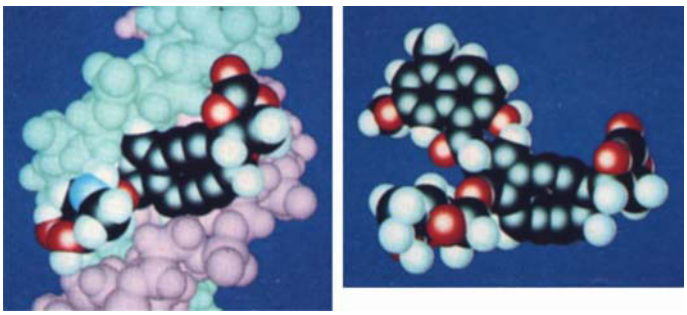


Fig. 1. Computer-generated space-filling models of free **1** (right) and DNA-bound **1** (left).—These and the following pictures in this article were obtained as follows: Molecular models were elicited using Sybyl Version 5.4 (Tripos Associates, Inc.) on a Personal Iris 40/25 Super Turbo (Silicon Graphics) computer terminal. The files were then submitted to a Stardent ST 1040 (Stardent) terminal and visualized using Stardent AVS (Version 3.0). The models were then photographed from the screen.

It has been demonstrated that at least 80% of the DNA cleavage by NCS chromophore leads to the 5′-aldehyde of the A and T residues selectively.[27] The chemistry leading to these breaks involves hydrogen atom abstraction from C5′ by the diradical species **10** and oxygen atom transfer from molecular oxygen to the resulting DNA radical and eventually, the aldehyde residues are formed according to the pathway shown in Scheme 7. Less than 20% of the strand breaks result from pathways initiated by hydrogen atom abstraction from C4′ (Scheme 8)[28–32] and C1′ (Scheme 9).[29]

Biosynthetic studies[33] with neocarzinostatin chromophore showed that the C_{14} dienediyne ring skeleton incorporates six intact acetate units and two terminal acetate units which suffer C–C bond cleavage, and suggested that the C_{14} chain is derived from degradation of oleate via the oleate-crepenylate pathway for polyacetylenes. Similar proposals have been made for the C_{15} ring skeleton of the calicheamicin/esperamicin families.[33]

Interesting synthetic studies and designed molecules inspired by NCS chromophore will be discussed in Section 3.1.

2.2. Calicheamicins

The calicheamicins (Table 1) are a family of enediyne antibiotics isolated from *Micromonospora echinospora* ssp. calichensis. Their structures were first reported in 1987 by *Lee* et al.[2] and revised (one stereochemical center) in 1989.[34] Calicheamicin γ_1^I **2** is the most prominent member of this class of compounds.[34] The iodine-containing

Calicheamicin	X	R_1	R_2	R_3
Calicheamicin β_1^{Br}	Br	Rha	Ami	$CHMe_2$
Calicheamicin γ_1^{Br}	Br	Rha	Ami	Et
Calicheamicin α_2^I	I	H	Ami	Et
Calicheamicin α_3^I	I	Rha	H	–
Calicheamicin β_1^I	I	Rha	Ami	$CHMe_2$
Calicheamicin γ_1^I **2**	I	Rha	Ami	Et
Calicheamicin δ_1^I	I	Rha	Ami	Me

calicheamicins were discovered when sodium iodide was added to the fermentation medium, resulting not only in the new compounds containing iodine rather than bromine, but also in much improved fermentation yields.[34] The calicheamicins are active[2, 34] in the biochemical prophage induction assay at concentrations below 1 pg mL^{-1}, extremely active against Gram-positive bacteria, and highly active against Gram-negative bacteria. Most importantly, they exhibit extraordinary potency[2, 34] against murine tumors such as P338 and L1210 leukemias and solid neoplasms such as colon 26 and B-16 melanoma with optimum doses of 0.15–5 μg/kg. These compounds are thought to exert their biological activities by damaging DNA. Indeed, the calicheamicins are highly potent DNA cleaving agents giving rise primarily to sequence specific double strand cuts.[35, 36]

The molecule of calicheamicin γ_1^I **2** is a masterpiece of "natural" ingenuity. Its structure can be roughly divided into three components: a) the enediyne system with its potential power to wreak havoc on any biological target, but cleverly locked in place until activated; b) the oligosaccharide fragment which is thought to serve as a delivery system to bring the lethal warhead to its intended target, DNA; and c) the trisulfide moiety, which acts as a triggering device allowing the initiation of the crucial chemical events which lead to the generation of highly aggressive species that cause fatal damage to the genetic material. But the beauty of this molecule must extend beyond this simplistic picture, for we still marvel at its biological actions without fully understanding its precise mode of action. How does binding to DNA, for example, initiate activation, and how does the producing organism protect itself from such a dangerous molecule?

Nevertheless, from the information gathered so far, the following scenario[2, 3] accounts for its damaging action on DNA. Calicheamicin γ_1^I **2** binds to the minor groove of

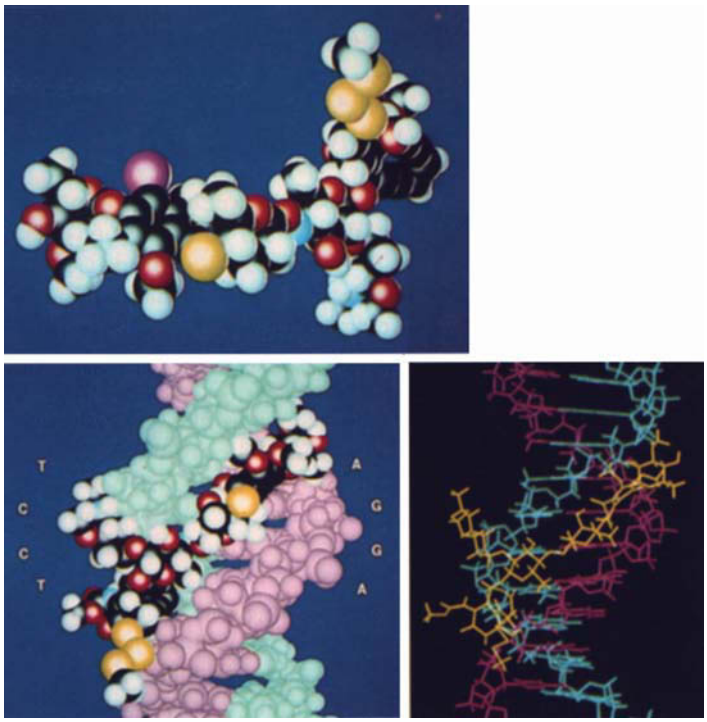

Fig. 2. Computer-generated models of free **2** (top) and DNA-bound **2** (bottom).

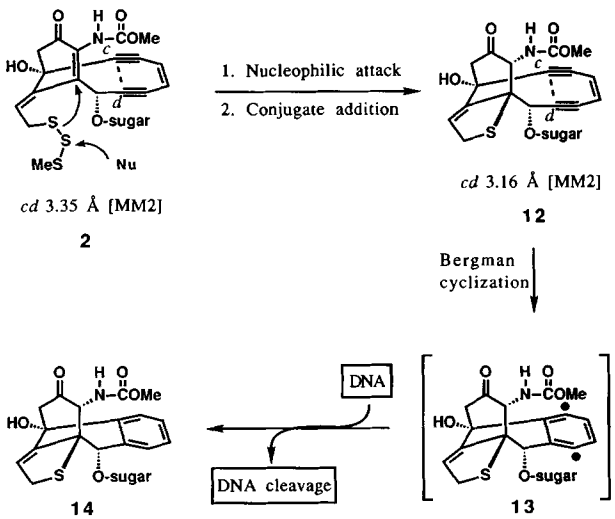
double helical DNA specifically at TCCT sites and by orienting its oligosaccharide tail towards the 3′-ends of DNA fragments (Fig. 2).[37] The oligosaccharide fragment is thought to be the molecule's main recognition and binding moiety.[38, 39] A nucleophile (e.g. glutathione), probably activated by an internal basic nitrogen, then attacks the central sulfur atom[2, 40] of the trisulfide group, causing the formation of a thiolate (bioreduction) which finds itself in a perfect position, due to the proper geometry of the allylic double bond, to attack intramolecularly the α,β-unsaturated ketone embedded in the adjacent six-membered ring to give compound **12** (Scheme 10). This reaction, converting the sp^2 carbon atom at the point of attack to an sp^3 carbon paves the



Scheme 10. Mechanism of DNA cleavage by **2**.

way for a Bergman cyclization reaction, leading to the benzenoid diradical **13**. It is interesting to note that the distance between the *c* and *d* carbon atoms (Scheme 10) is significantly shortened in going from calicheamicin γ_1^I **2** [3.35 Å, MM2] to the highly strained intermediate **12** [3.16 Å, MM2].[41] The reactive diradical **13** is capable, and well positioned, to abstract two hydrogen atoms, one from the C5′ position of deoxycytidine (C) and the other from a ribose position of the opposing strand.[37, 42] The DNA radicals so generated then proceed to react with molecular oxygen leading to double strand cleavages according to the mechanism depicted in Scheme 7.[37] Carefully designed experiments led to observation of the proposed intermediate **12** (estimated half-life at 37 °C ca. 4.5 s).[43] Furthermore, it was shown that the majority of the cleavage within the T *C*CT recognition sequence is initiated by hydrogen abstraction from the C5′ position of deoxycytidine (*C*) and transfer to the C4′ position (site nearest to the oligosaccharide segment) of the cycloaromatized calicheamicin γ_1^I molecule.[37] Other experiments confirmed the requirements of thiols for the high potency of calicheamicin γ_1^I **2** in DNA cleavage and the crucial role of the ethyl amino group on the terminal carbohydrate unit.[34]

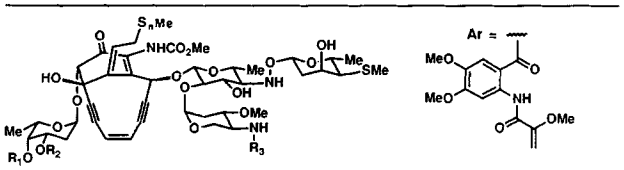
Although the natural calicheamicins exhibit unacceptable delayed organ toxicity in animals,[44] antibody conjugates of modified derivatives show exceptional promise as drug candidates. Thus, calicheamicin γ_1^I derivatives attached to tumor-selective monoclonal antibodies are currently under development for clinical use, having shown high potency against tumors with low toxicity.[44]

Much synthetic work has been inspired by calicheamicin γ_1^I **2**. A number of novel strategies and model systems will be discussed in Section 3.2.

2.3. Esperamicins

The esperamicins are a subclass of naturally occurring enediynes with extremely high activities as broad spectrum antibiotics and antitumor agents. These compounds were isolated[45] from cultures of *Actinomadura verrucosospora* and their molecular structures were elucidated in 1987 (Table 2).[3, 46] The similarities between the esperamicins and the calicheamicins are quite striking, extending over structure, biological activity, and mode of action. Thus, like the calicheamicins, the esperamicins contain in their structure a bicyclo[7.3.1]tridecadiynene ring system, an allylic trisulfide, (or tetrasulfide), a 1,5-diyn-3-ene moiety as part of the ring system, and an α,β-unsaturated ketone in which the double bond is at the bridgehead of the bicyclic core. The absolute configuration of esperamicin A_1 **3** and its relatives has been determined.[47–49] The esperamicins, together with the calicheamicins, are amongst the most potent anticancer agents known, exhibiting powerful activity[47] against a number of murine tumor models such as P388, B16, M5076 at injected doses in the 100 ng/kg range.[3] Like calicheamicins, the esperamicins are thought to exert their biological action by damaging DNA. The mechanism of the DNA cleavage by esperamicin A_1 **3** is identical to that of the cleavage by calicheamicin γ_1^I **2** (see Scheme 10), as proposed simultaneously by the Lederle[2] and Bristol-Myers[3] groups. Esperamicin A_1 **3**, however, exhibits less sequence selectivity[50, 51] than calicheamicin γ_1^I **2** and shows[50, 51] preference for T > C > A > G. As in the case of calicheamicin γ_1^I **2**, the activity of esperamicin A_1 **3** towards DNA is significantly enhanced by thiols such as dithiothreitol[50, 51] and results in both single and double strand cuts. The carbohydrate fragments are thought to assist in the binding of the drug to the minor groove of DNA[50, 51] (Fig. 3), as in the case of calicheamicin γ_1^I **2**. Light-induced DNA cleavage by esperamicin A_1 **3** has also been demonstrated.[18]

Table 2. The esperamicin family.



Esperamicin	n	R_1	R_2	R_3
Esperamicin A_1 **3**	3	H	Ar	$CHMe_2$
Esperamicin A_{1b}	3	H	Ar	Et
Esperamicin A_{1c}	3	H	Ar	Me
Esperamicin P	4	H	Ar	$CHMe_2$
Esperamicin A_2	3	Ar	H	$CHMe_2$
Esperamicin A_{2b}	3	Ar	H	Et
Esperamicin A_{2c}	3	Ar	H	Me

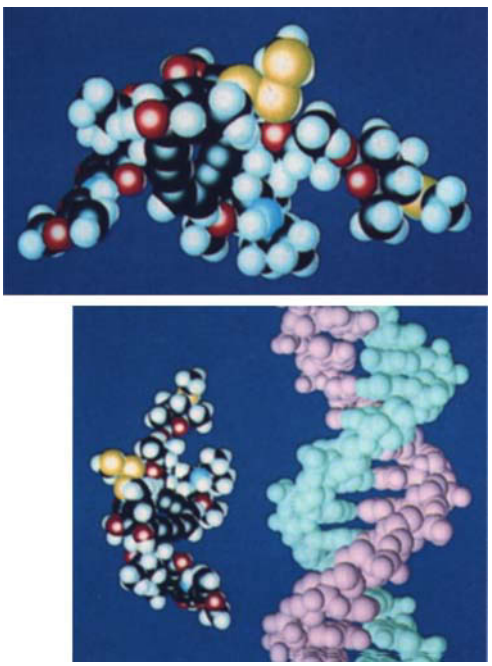


Fig. 3. Computer-generated models of free **3** (top) and of **3** on approaching DNA (bottom).

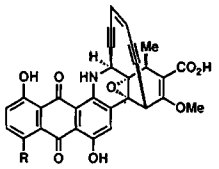
Despite a number of side effects, esperamicin A_1 has successfully passed phase I[47, 51] and is currently in phase II clinical trials.[52]

2.4. Dynemicins

The first member of this subclass of enediynes, dynemicin A **4**, was reported in 1989.[4] This novel, violet-colored anticancer antibiotic was discovered in the fermentation broth of

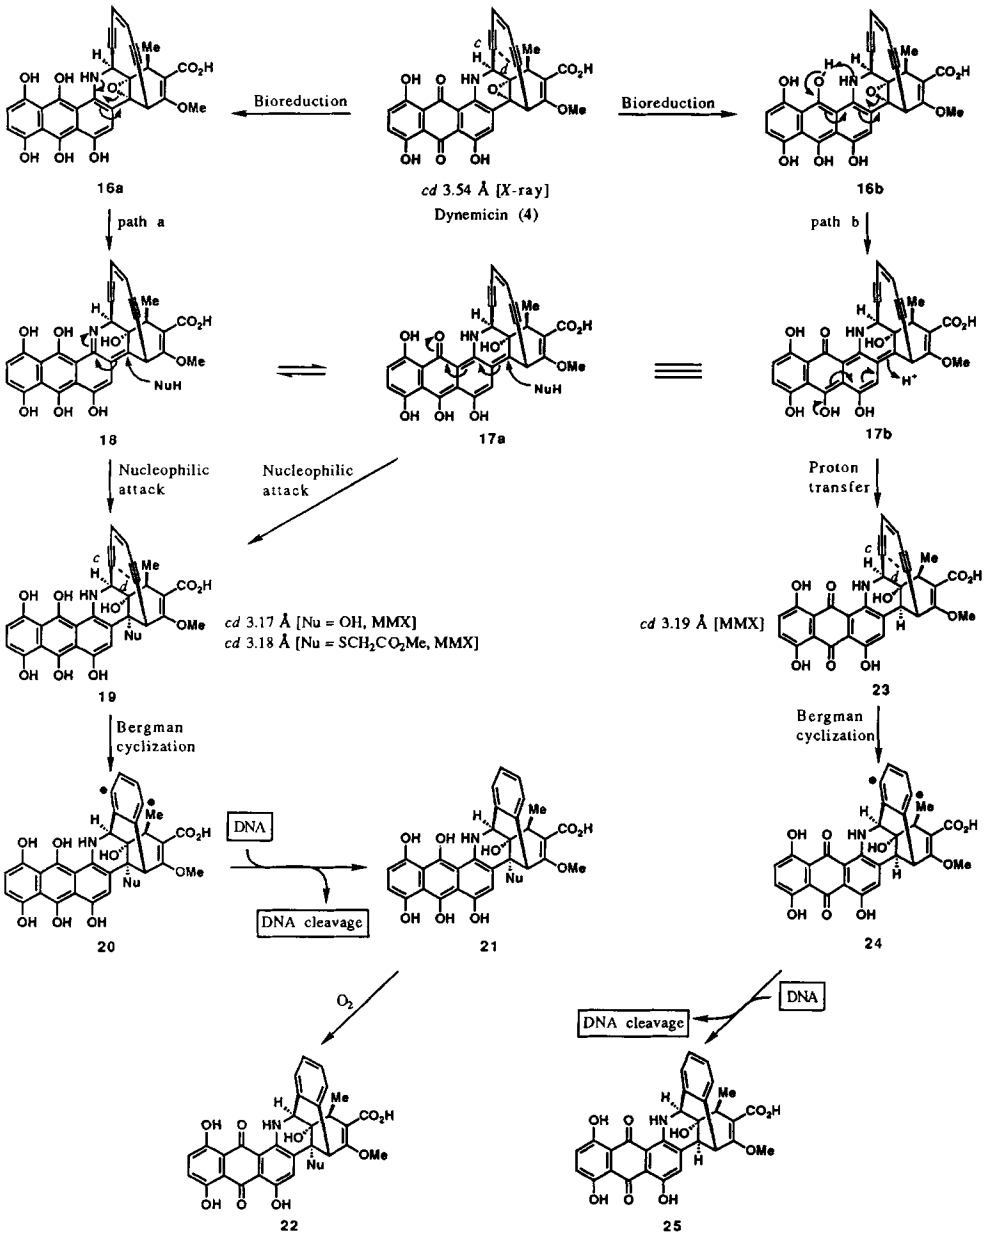
Table 3. The dynemicin family.



Compound No.	Name	R
4	Dynemicin A	OH
15	Deoxydynemicin A	H

Micromonospora chersina.[4] Its molecular structure, with exception of the absolute configuration, was fully determined by spectroscopic and X-ray crystallographic analysis.[53] Dynemicin A **4** exhibits very potent activity against a variety of cancer cell lines and prolongs significantly the life span of mice inoculated with P388 leukemia and B16 melanoma cells.[53] Furthermore, dynemicin A **4** and its derivatives exhibit promising in vivo antibacterial activity with low toxicity.[4] More recently, a second member of this family, deoxydynemicin A **15** (Table 3), a bioactive compound with similar biological profile to dynemicin A **4**, was isolated from *Micromonospora globosa* MG331-hF6.[54] Like the calicheamicins and esperamicins, the dynemicins include in their molecular structures a ten-membered ring with a 1,5-diyn-3-ene bridge. They are, however, distinctly unique in combining the enediyne unit with the anthraquinone chromophore of the anthracycline[55] anticancer antibiotics.

It has been shown that dynemicin A **4** cleaves double-stranded DNA, causing both single and double strand cuts.[56, 57] The potency of the drug as a DNA cleaving agent is significantly enhanced by thiols[56] and by visible light irradiation.[57] Dynemicin A **4** preferably attacks the 3′ side of purine bases such as 5′-AG, 5′-GC, 5′-GT and 5′-AT with



Scheme 11. Proposed mechanism of DNA cleavage by **4**.

clear selection for G and to a lesser extent A.[56, 58] Intercalators and minor groove binders interfere with DNA cleavage by dynemicin A **4**, suggesting both intercalation and minor groove binding for this agent.[56] A mechanism of action of dynemicin A **4** involving several pathways has been suggested (Scheme 11).[56–61] This mechanism combines features of the modes of action of the enediyne and the anthracycline antibiotics.

The hypothesis for the mode of action of dynemicin A **4** postulates minor groove binding and intercalation (Fig. 4), bioreduction, epoxide opening, trapping of generated intermediates, cycloaromatization with benzenoid diradical formation, and hydrogen atom abstraction from DNA. This

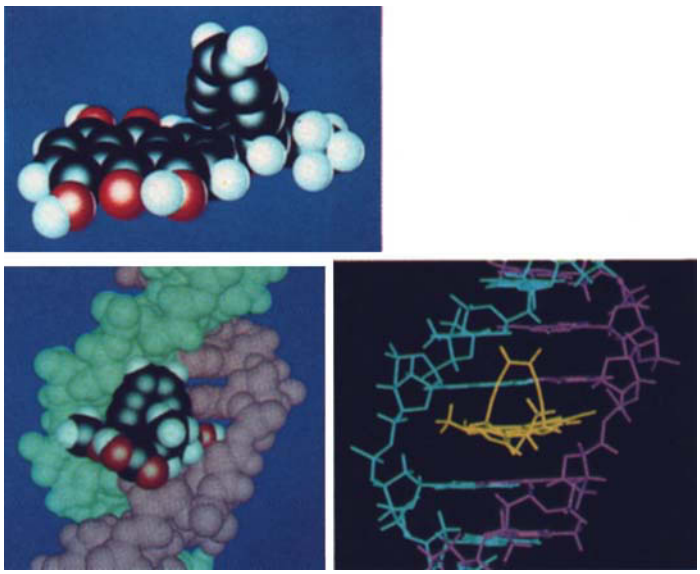


Fig. 4. Computer-generated models of free **4** (top) and DNA-bound **4** (bottom).

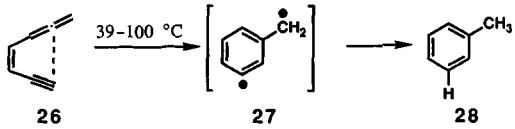
remarkable chemical cascade (Scheme 11) is triggered by a reduction process (**4** → **16**) which unleashes two lone pairs of electrons, one on nitrogen and one on oxygen (structures **16a** and **16b**) providing two alternative pathways for epoxide opening (path a and path b). Path a leads to the conjugated quinone methide intermediate **17** which may suffer nucleophilic attack (structure **17a**) or proton transfer (structure **17b**) to form intermediates **19** and **23**, respectively. Molecular mechanics calculations on **19** and **23** revealed considerable shortening of the $c \cdots d$ distance (3.17–3.19 Å) compared to the X-ray crystallographically determined valued 3.54 Å for **4**,[4] suggesting and explaining their rapid collapse to benzenoid diradicals, **20** and **24**, respectively, via Bergman cyclization. Alternatively, path b may lead to the *ortho*-iminoquinone methide **18** (tautomeric with **17**), which could suffer nucleophilic attack (or proton shift) via intermediate **19** (or **23** after tautomerization). The benzenoid diradicals generated are thought to be responsible for initiating DNA rupture by hydrogen abstraction, although direct alkylation of DNA by intermediates **17** and/or **18** may also contribute to DNA damage.[56, 60, 61] Compound **21** may suffer spontaneous oxidation to **22**. Both compounds **22** (Nu = OH, SCH_2CO_2Me) and **25** were isolated as final products of this cascade.[53, 56, 57, 61]

Synthetic studies in the area of the dynemicins as well as other enediyne antibiotics are discussed in Section 3.3.

3. Synthesis of Enediyne Antibiotics

3.1. Neocarzinostatin Chromophore Model Systems

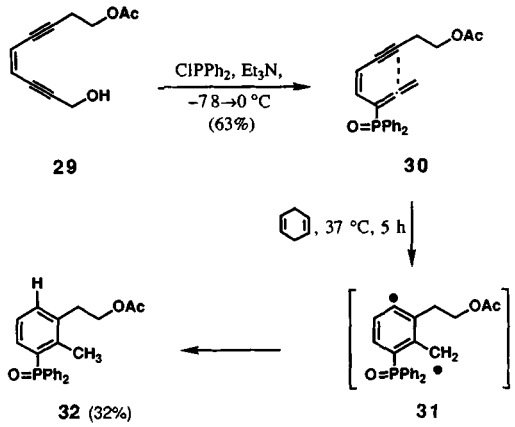
The basic reaction[19] involved in the generation of radicals from neocarzinostatin chromophore was demonstrated with the parent system (*Z*)-1,2,4-heptatrien-6-yne **26**, (Scheme 12) by *Myers* et al.[62] in 1989. This cycloaromatiza-



Scheme 12. The Myers cyclization (1989).

tion, now recognized as the Myers reaction, proceeds via α,3-didehydrotoluene **27** and leads to toluene **28** upon hydrogen atom abstraction (Scheme 12). In his elegant studies,[62] *Myers* determined the following activation parameters for this process: $\Delta H^{\neq} = 21.8 \pm 0.5$ kcal mol^{-1}, $\Delta S^{\neq} = -11.6 \pm 1.5$ cal K^{-1} mol^{-1} ($E_a = 22.5$ kcal mol^{-1}, lg $A = 10.7$).

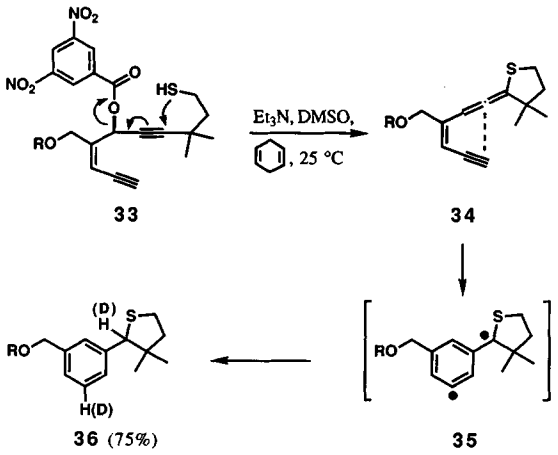
Saito et al.[63, 64] demonstrated the chemistry shown in Scheme 13 as well as DNA cleaving properties for compound **30** and its phenylsulfoxide.[64]



Scheme 13. Neocarzinostatin chromophore related studies by *Saito* et al. (1989).

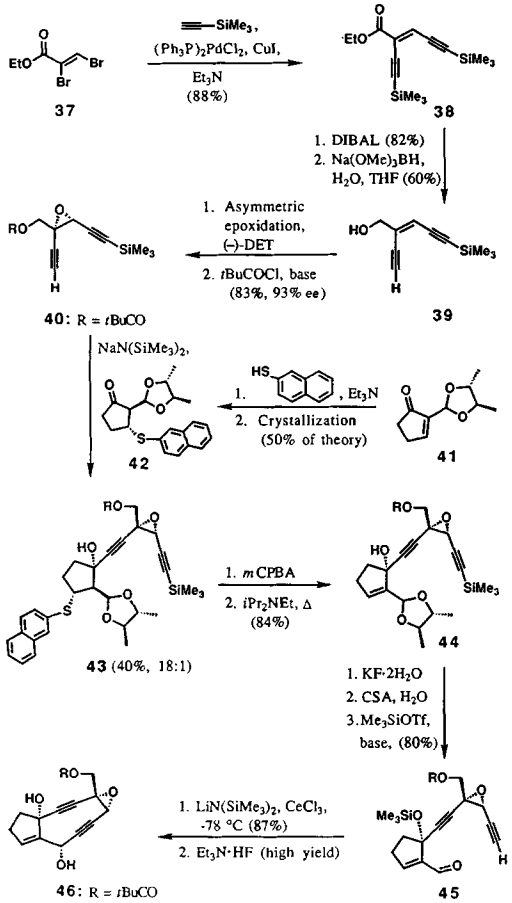
A very imaginative and skilfull choice of model compound by *Myers* and *Dragovich*[65] resulted in the chemistry depicted in Scheme 14. Compound **33** was triggered under basic conditions to form the (*Z*)-1,2,4-heptatrien-6-yne derivative **34**, which was observed to decay below room temperature, forming, in the presence of cyclohexadiene, aromatized derivative **36** via diradical **35**.

The *Myers* group has also reported[66] an enantioselective synthesis of the epoxy diyne core of the neocarzinostatin chromophore (**46**, Scheme 15). Key features in this synthesis include Pd^0/Cu-catalyzed construction of the enediyne moiety (**37** → **38**), Sharpless asymmetric epoxidation (**39** → **40**), dia-



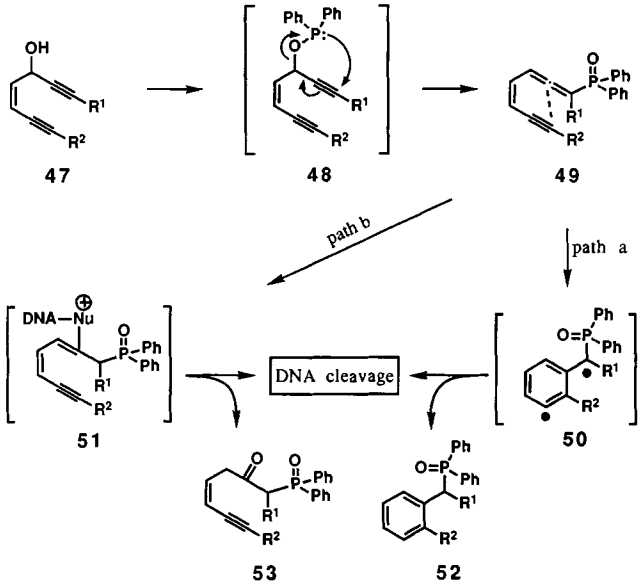
Scheme 14. Model studies related to neocarzinostatin chromophore by *Myers* et al. (1989). R = Si*t*BuPh$_2$.

stereomeric resolution by crystallization (**42**, obtained from **41**) and intramolecular acetylide addition to an aldehyde (**45** → **46**) to close the nine-membered ring.



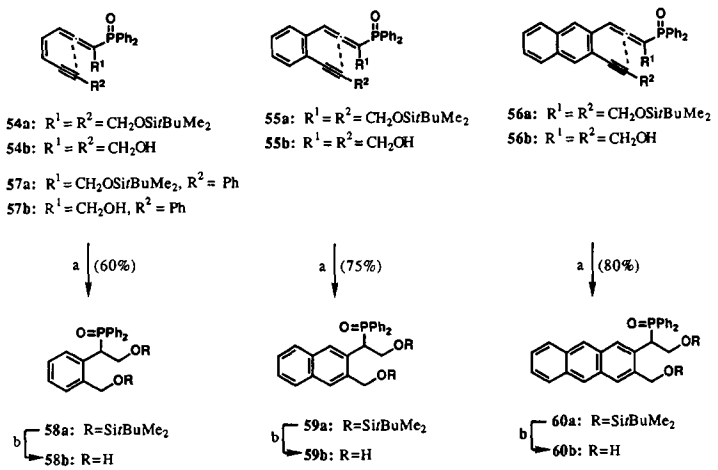
Scheme 15. Synthesis of the epoxy diyne core **46** of neocarzinostatin chromophore by *Myers* et al. (1991). DIBAL = diisobutylaluminum hydride, DET = diethyl tartrate, *m*CPBA = *meta*-chloroperbenzoic acid, CSA = camphorsulfonic acid, Tf = trifluoromethanesulfonate; R = *t*BuCO.

Our work[67] in this area focused on the design of DNA-cleaving molecules which react both by way of a radical mechanism as well as by way of an alkylation mechanism (Scheme 16). This mechanistically supported reaction cascade starts from **47** and incorporates a [3,2]sigmatropic rearrangement (**48** → **49**) and a Myers cyclization reaction[62] leading to a diradical (**49** → **50**), or to a nucleophilic attack of a DNA base at the allene system (**49** → **51**). The by-products of the DNA cleavage are then **52** and **53**, respectively.



Scheme 16. Design of DNA-cleaving molecules with dual mode of action: a) radical mechanism; b) alkylation mechanism (*Nicolaou* et al., 1990).

Scheme 17 shows a number of synthesized compounds and their cyclizations to aromatic systems with half-lives ranging from 8 h to 117 h at 37 °C. Experiments with supercoiled



Scheme 17. Cycloaromatization of conjugated phosphane oxide allene-eneynes synthesized by *Nicolaou* et al. (1990). a) 0.01 M in 1,4-cyclohexadiene, 37 °C; **54a**, $t_{1/2}$ = 8 h; **55a**, $t_{1/2}$ = 23 h; **56a**, $t_{1/2}$ = 117 h, b) 48 % aq. HF, CH_3CN, 20 °C, 100 %.

ΦX174DNA (form I) demonstrated thermally-induced DNA cleavage by these compounds (Fig. 5)[67] and mechanistic studies[67] confirmed their dual mode of action. Figure 6 shows computer-generated space-filling models of compound **54b** and of **54b** approaching double helical DNA.

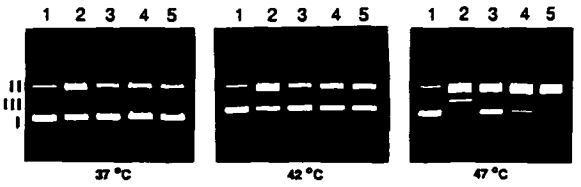


Fig. 5. DNA cleavage by the compounds **54**–**57**. ΦX174 form I DNA (50 μM/base pair) was incubated for 48 h at the specified temperatures with various compounds (1 mM in 20% ethanol in phosphate buffer, pH 8.5, 50 mM) and analyzed by gel electrophoresis (1 % agarose, ethidium bromide stain). Lane 1, DNA alone; lanes 2–5, DNA with compounds **54b**, **55b**, **56b**, and **57b**, respectively. Forms I, II, and III used in this article correspond to supercoiled, relaxed, and linear DNA, respectively.

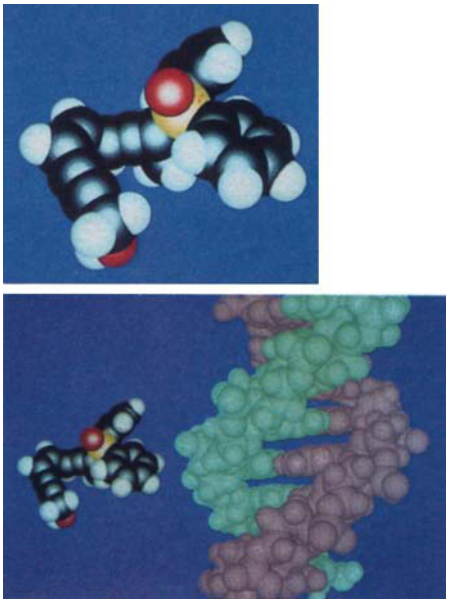

Fig. 6. Computer-generated models of free **54b** (top) and of **54b** on approaching DNA (bottom).

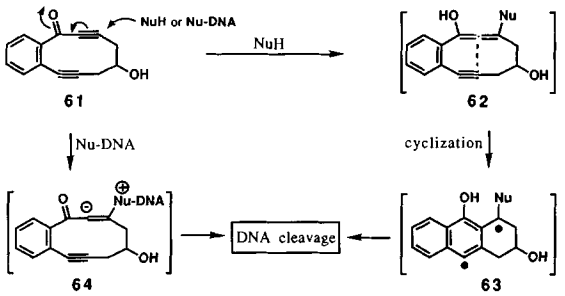
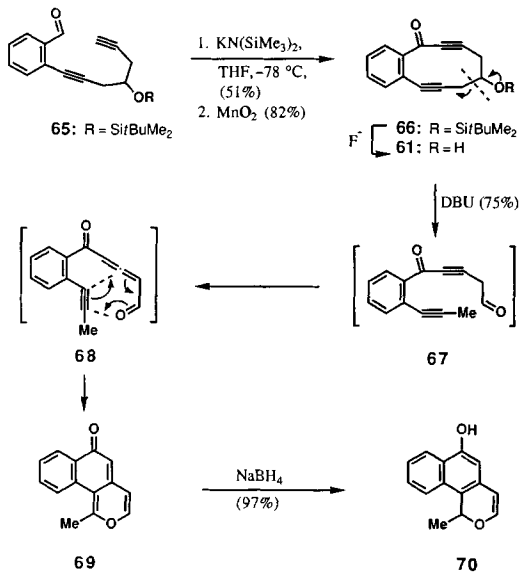
Golfomycin A **61** is a novel, designed molecule reported from our laboratories with DNA-cleaving properties and antitumor activity.[68] Two mechanistic rationales, shown in Scheme 18, led to the design of this intriguing molecule. The



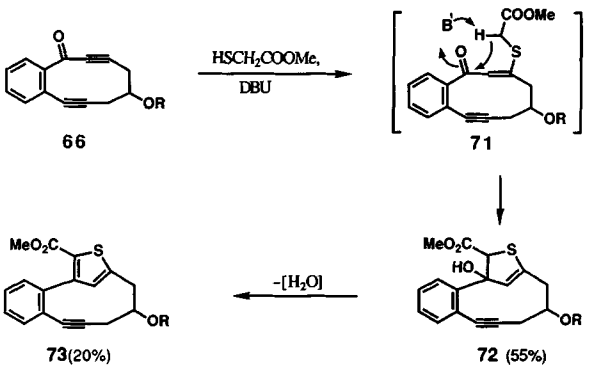
Scheme 18. Mechanism-based design of golfomycin A **61** (*Nicolaou* et al., 1990).

neocarzinostatin chromophore-inspired rationale (**61** → **62** → **63**) postulated a Myers type[62] cyclization, whereas the nucleophilic attack (**61** → **64**) had plenty of examples.[69] The construction of golfomycin A **61** (Scheme 19) involved base-induced intramolecular C–C bond formation within **65**, followed by mild oxidation (**65** → **66**) and deprotection (**66** → **61**).[68]



Scheme 19. Synthesis and reactions of **61** (*Nicolaou* et al., 1990). DBU = diazabicyclo[5.4.0]undecene.

Golfomycin A **61** and its protected precursor **66** exhibit unusual chemistry[68] upon treatment with base and methyl thioglycolate, respectively. Thus, upon treatment with DBU, **61** entered into the cascade shown in Scheme 19 (**61** → **67** → **68** → **69**) with **69** isolated as the final product and **67** detected by ^{1}H NMR spectroscopy. The structure of **69** was confirmed by its reaction with sodium borohydride to give **70**, whose *p*-bromobenzoate was characterized X-ray crystallographically. On the other hand, derivative **66** reacts with DBU and methyl thioglycolate to give the unusual thiophene derivatives **72** and **73**, presumably via intermediate **71** (Scheme 20).



Scheme 20. Reaction of the golfomycin A precursor **66** with methyl thioglycolate (*Nicolaou* et al., 1990). R = Si*t*BuMe$_2$.

Figure 7 shows space-filling models of golfomycin A **61**, whereas Figure 8 depicts the molecule's DNA-cleaving activity against supercoiled DNA at various pH's.[68] Preliminary results with golfomycin A indicated growth inhibition of MB49 murine bladder carcinoma cells with an IC_{50} of

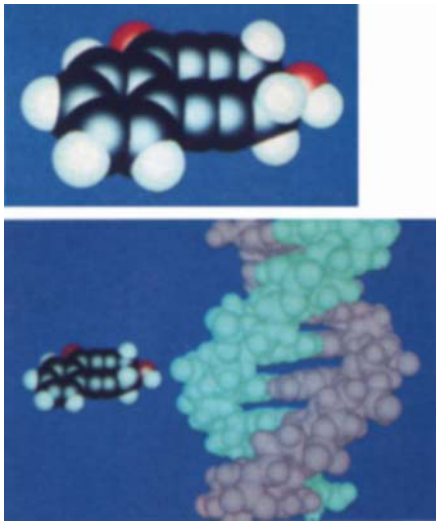


Fig. 7. Computer-generated models of free **61** (top) and of **61** on approaching DNA (bottom).

3.4 μmol L^{-1} during 4 days of exposure.[68] These properties fulfilled the expectations of the molecular design and elevated the compound to a significant lead for further developments.

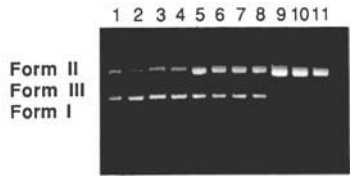

Fig. 8. DNA cleavage by golfomycin A **61** at various pH values. ΦX174 form I DNA (50 μM/base pair) was incubated for 20 h at 37 °C with **61** (1000 μM) in various pH buffers and analyzed by electrophoresis (1 % agarose gel, ethidium bromide stain). Lane 1, DNA alone at pH 8.5; lanes 2–11 correspond to pH 5.0, 6.0, 7.0, 7.4, 8.0, 8.5, 9.0, 9.5, 10.0, and 10.7, respectively. Control experiments at the above pH's in the absence of agent demonstrated no DNA cleavage.

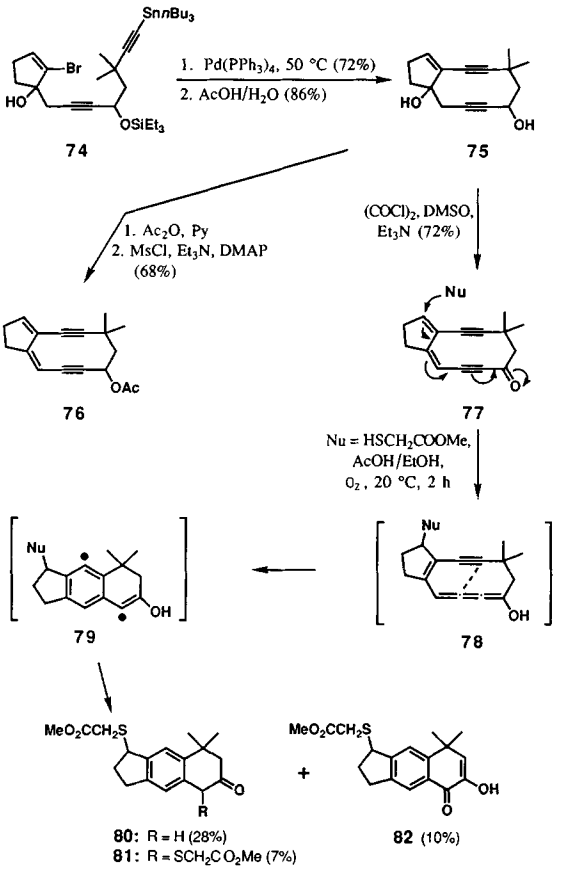
Elegant studies by the *Hirama* group[70] culminated in the synthesis of neocarzinostatin chromophore-related model systems **76** and **77** (Scheme 21). Key to the success of this scheme was an intramolecular, Pd^0-catalyzed coupling of a vinyl bromide with an acetylenic stannane. The reaction of ketone **77** with methyl thioglycolate in AcOH/EtOH under aerobic conditions proved to be quite fascinating, leading to compounds **80**–**82**, presumably via intermediates **78** and **79** (Scheme 21). The acetate **76** (Scheme 22) reacted similarly under the same conditions to afford compounds **85a** and **85b** via the postulated intermediates **83** and **84** (Scheme 22). Under anaerobic conditions, compounds **88a–d** were isolated in the indicated yields (Scheme 22). Compounds **88a–c** are presumably formed via pathway **76b** → **86** → **87** as shown in Scheme 22. The regioisomeric ketone **89** (Scheme 23) was also synthesized by *Hirama* et al.[71] and its reaction with methyl thioglycolate explored under aerobic and anaerobic conditions, leading to compounds **91a–c** (aerobic, path a via **90**) and **94a–c** (anaerobic, path b via **92** and **93**) as shown in Scheme 23.

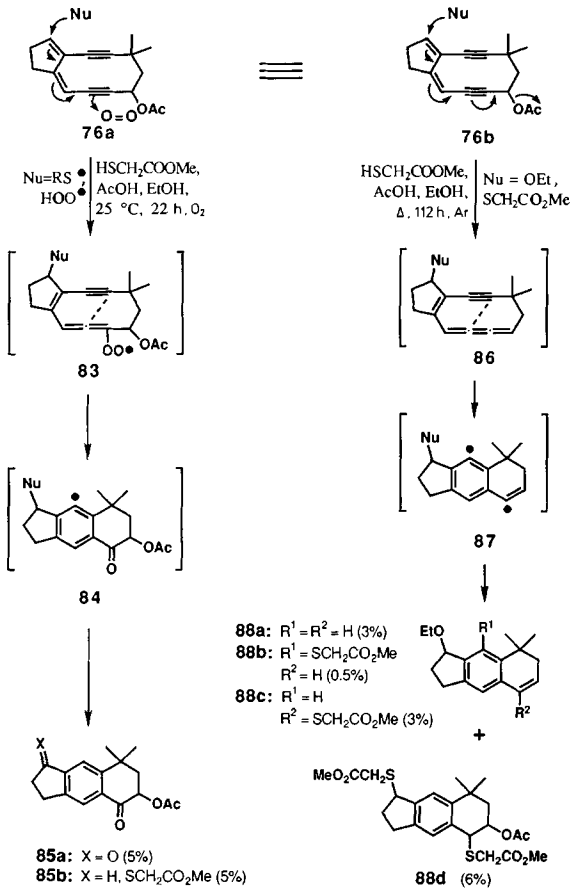


Scheme 21. Neocarzinostatin chromophore related model studies by *Hirama* et al. (1989). Synthesis and cycloaromatization of the ketone **77**. Py = pyridine, DMAP = dimethylaminopyridine.

The interesting enyne[3]cumulene **96** was synthesized by *Hirama* et al.[72] as shown in Scheme 24 (**95** → **96**). This compound exhibited the expected reactivity towards a Myers-type cyclization,[62] leading to **98** via **97** as well as forming compound **100**. The latter compound is thought to be formed via the indicated pathway (Scheme 24) initiated by a formal [2 + 2] intramolecular cycloaddition (**96b** → **99** → **100**). The half-life of **96** at 80 °C was found to be 1.1 h.[72, 73]

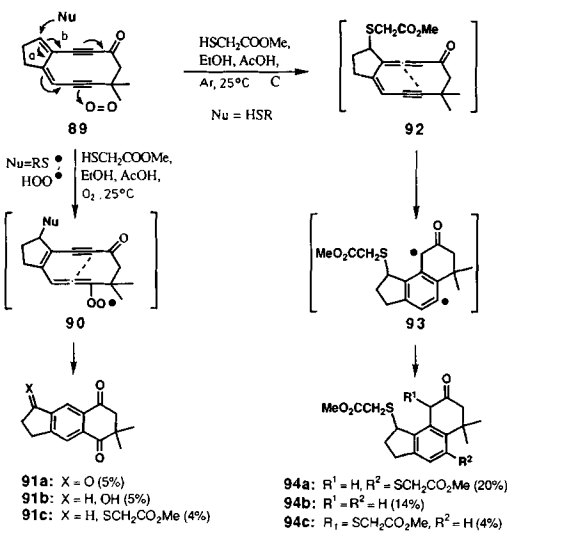
The team led by *Toshima* and *Tatsuta* recently reported[74] an interesting ten-membered sulfur-containing ring system (**102**, Scheme 25) with Myers-type reactivity reminiscent of the chemistry of neocarzinostatin chromophore. Thus, deprotection and dehydration of **101**[75] led to the stable crystalline compound **102** in high yield, which upon reaction with basic methanol furnished compound **104** via the postulated intermediate **103a** and the presumed polar mechanism shown in Scheme 25. On the other hand, DBU-induced isomerization of **102** in the presence of CCl_4 and oxygen furnished compounds **106**–**109**, presumably via **103b** and the diradical **105**.

The parent hydrocarbon representing the carbocyclic framework of neocarzinostatin chromophore (**115**, Scheme 26) was synthesized by *Wender* et al. in 1988.[76] In these studies,[76] the Wender group demonstrated the viability of a number of reactions (**111** → **112** → **113** → **114** → **115**) for the synthesis of such systems. Compound **115** was found to be rather labile ($t_{1/2}$ = 48 h at room temperature), suffering polymerization upon removal of solvent.[76] In a more recent

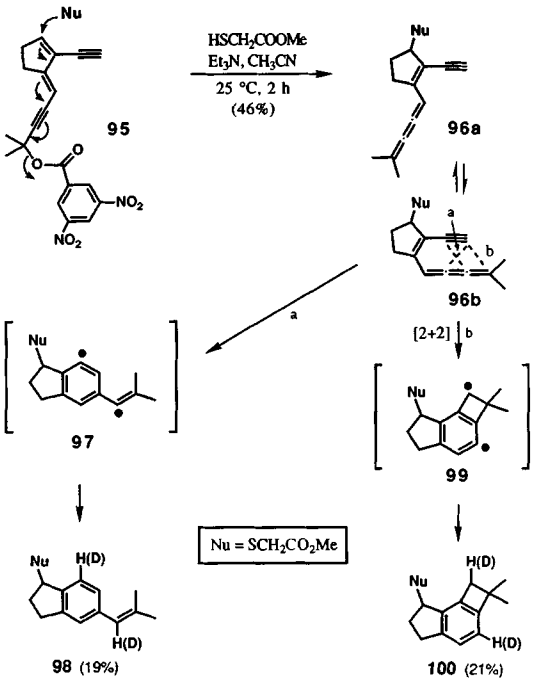


Scheme 22. Neocarzinostatin chromophore related model studies by *Hirama* et al. (1989). Cycloaromatization of compound **76** under aerobic and anaerobic conditions.

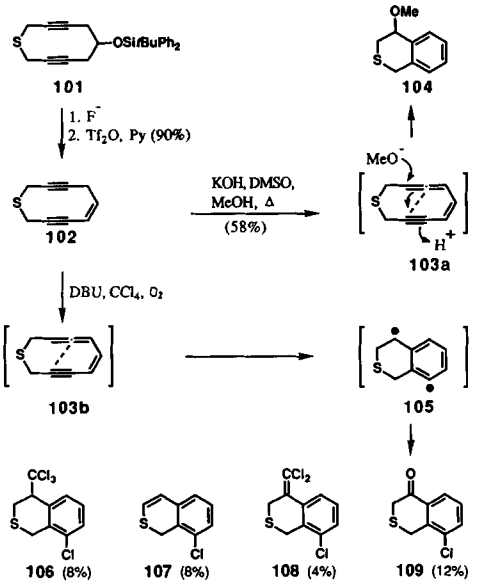
study[77] the same group demonstrated the utilization of a chromium-induced intramolecular condensation[78] (**116** → **117**, Scheme 27) and a ring contraction strategy based on the Wittig rearrangement[79] (**119** → **117**, Scheme 27). Selective acetylation of **117** followed by dehydration resulted in the formation of the model compound **120**.



Scheme 23. Neocarzinostatin chromophore related model studies by *Hirama* et al. (1990). Cycloaromatization of ketone **89**.



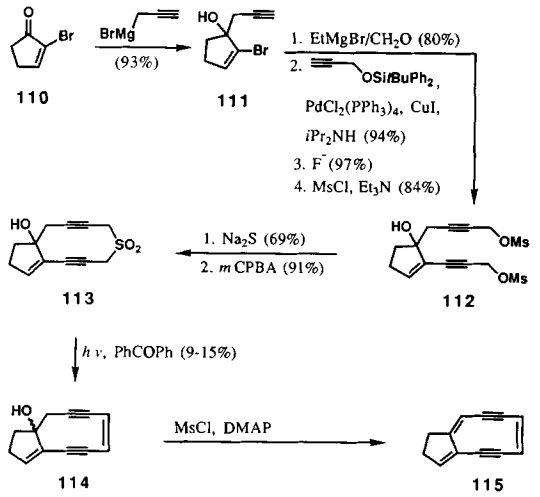
Scheme 24. Synthesis and cycloaromatization of enyne[3]cumulene **96** (*Hirama* et al., 1991).



Scheme 25. Neocarzinostatin chromophore related model studies by *Toshima, Tatsuta* et al. (1991).

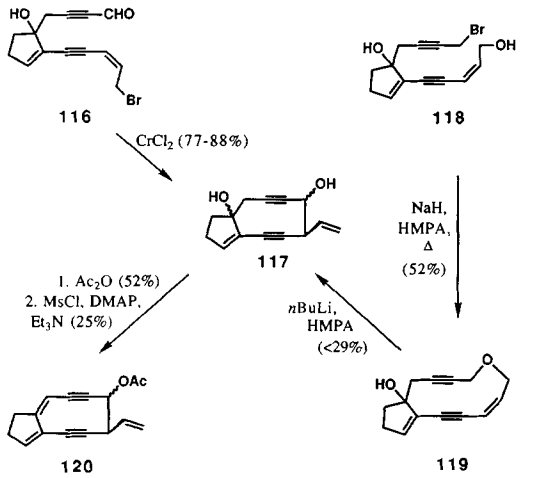
The *Takahashi* group[80] has also cleverly utilized the Wittig rearrangement reaction to contract the macrocyclic rings **121** to the smaller rings **122** (Scheme 28), which served as precursors to the neocarzinostatin related model systems **123** and **124**. The enediyne **123** underwent smooth Bergman-type[5] cyclization to afford compounds **126** via diradical **125**, whereas compound **124** was triggered by methyl thioglycolate to undergo a Myers-type[62] ring closure affording **129** via **127** and **128**.

The synthesis of the twelve-membered macrocyclic ether **131** from **130** was also reported by *Krebs* et al.[81] (Scheme



Scheme 26. Synthesis of the parent carbocycle **115** of the neocarzinostatin chromophore by *Wender* et al. (1988).

29). The same group also reported[82] the synthesis of the interesting neocarzinostatin chromophore related systems **133** and **135** from **132** employing intramolecular aldol-type ring closures by the routes outlined in Scheme 29.



Scheme 27. Neocarzinostatin chromophore related model studies by *Wender* et al. (1990). HMPA = Hexamethylphosphoric acid triamide.

An intramolecular allylsilane-aldehyde cyclization was successfully employed by *Suffert*[83] to synthesize compound **137** (1:1 mixture of diastereoisomers from compound **136** (Scheme 30). The acyclic neocarzinostatin chromophore-related derivatives **138** and **139** (Scheme 31) were synthesized by *Terashima* et al.[84] Interestingly, the (*Z*)-isomer **138** exhibited stronger cytotoxicity against P388 leukemia cells than the (*E*)-isomer **139**.[84]

Scheme 32 summarizes recent studies by *Magnus* et al.[85] with neocarzinostatin models in which an intramolecular aldol-type addition was used to convert the organocobalt compound **140** into the nine-membered ring enediyne precursor **141**. In situ generation of **142** resulted in Bergman cyclization and trapping as tricyclic system **143**.[85]

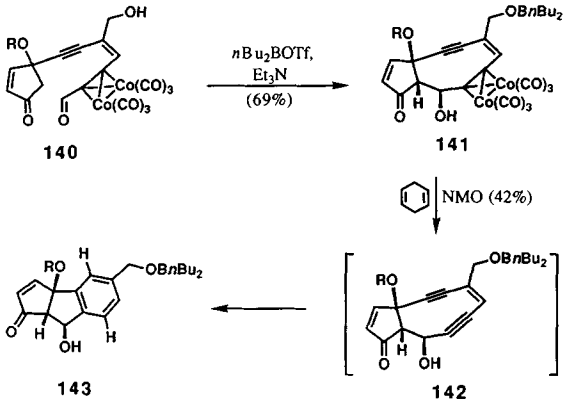


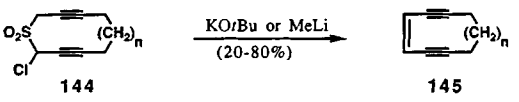
Scheme 32. Intramolecular aldol-based construction of a model system related to neocarzinostatin by *Magnus* et al. (1991). NMO = *N*-methylmorpholine *N*-oxide; R = $SiBuMe_2$.

Two syntheses of the naphthalene moiety of neocarzinostatin chromophore have been reported.[86]

3.2. Calicheamicin/Esperamicin Model Systems

3.2.1. Enediyne Systems

Intrigued by the novel molecular architecture and fascinating mode of action of the calicheamicin/esperamicin enediyne antiobiotics, we initiated in 1987 a program directed toward their total synthesis, an understanding of their chemistry, and the design of novel mimics of their biological actions. Our initial studies focused on monocyclic conjugated enediynes[41] of the type present in these naturally occurring substances. Thus, a series of compounds with formula **145** were synthesized by the Ramberg–Backlund reaction (Scheme 33) and studied. Table 4 lists a number of such compounds together with some other related systems and summarizes selected parameters and properties.



Scheme 33. Synthesis of monocyclic enediynes **145** via Ramberg–Backlund reaction (*Nicolaou* et al., 1988).

On the basis of these data it was surmised that, as a general rule at least in monocyclic systems, the distance between the remote acetylenic carbons ($c \cdots d$ distance, see Table 4 and some Schemes) provides a useful guide for determining the ease of cyclization, since it correlates with the strain energy (see Section 4). It must be emphasized, however, that this hypothesis is based on first approximations and is meant for simple systems, and that exceptions, particularly in bicyclic systems with complex frameworks and centers, do exist.[87] The rule works well for a large number of examples and it has been useful in molecular design and in making predictions regarding the stability of certain members of a given series of compounds. As expected from inspection of Table 4, enediyne **145** (n = 2) cyclized smoothly at 37 °C in the presence of cyclohexadiene via the diradical **149** to give the tetralin **150** (Scheme 34) (and two isomeric adducts with cyclo-

Table 4. Calculated $c \cdots d$ distances and stabilities of conjugated enediynes.

Entry	Compound	Ring size	$c \cdots d$ Distance [Å]	Stability	Ref.

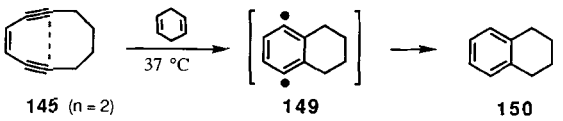
2	**145** (n = 2)	10	3.25	$t_{1/2}$ = 18 h at 37 °C	[41]
3	 **146**	10	3.20	$t_{1/2}$ = 11.8 h at 37 °C	[90]
4	 **7**	10	3.03	cyclized at 25 °C	[7]
5	 **6a**	10	3.01	cyclized < 25 °C	[6]
6	 **6b**	10	2.99	cyclized < 25 °C	[6]
7	 **147**	10	3.40 [a]	$t_{1/2}$ = 52 h at 37 °C	[88a]
8	**145** (n = 3)	11	3.61	stable at 25 °C	[41]
9	 **148**	12	3.77	stable at 25 °C	[88b]
10		–	4.12	stable at 25 °C; $t_{1/2}$ = 30 s at 200 °C	[5a]
11		–	3.94	stable at 25 °C; $k_{obs} = 6.4 \times 10^{-4}\,s^{-1}$ at 156 °C	[5c]

[a] For *trans* conformer, see Ref. [88a].



Scheme 34. Bergman-type cyclization of enediyne **145** (n = 2) (*Nicolaou* et al., 1988). $t_{1/2}$ = 18 h, E_a = 23.8 kcal mol^{-1}.

hexadiene). The oxaenediyne system **147** (Table 4, entry 7) also cyclizes at 37 °C, as reported recently by *Just* et al.[88a]

The eleven-membered ring (**145**, $n = 3$), again as anticipated from a $c \cdots d$ distance of 3.61 Å (Table 4, entry 8), was found to be quite stable at ambient temperature and, furthermore, it crystallized nicely from pentane. An X-ray crystallographic analysis of **145** (n = 3) revealed an interesting conformation (Fig. 9) and a $c \cdots d$ distance of 3.66 Å, agreeing

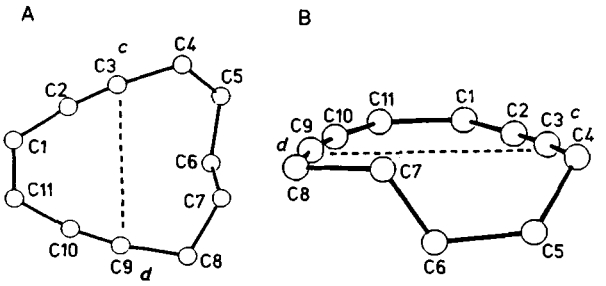


Fig. 9. ORTEP drawing of **145** (n = 3): A) top view, B) side view. $c \cdots d$ distance = 3.661(5) Å.

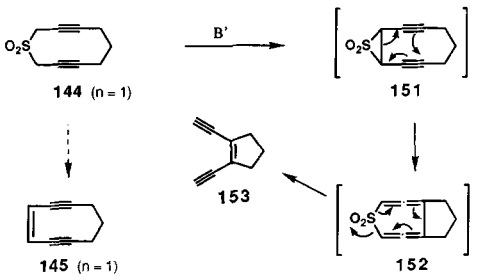
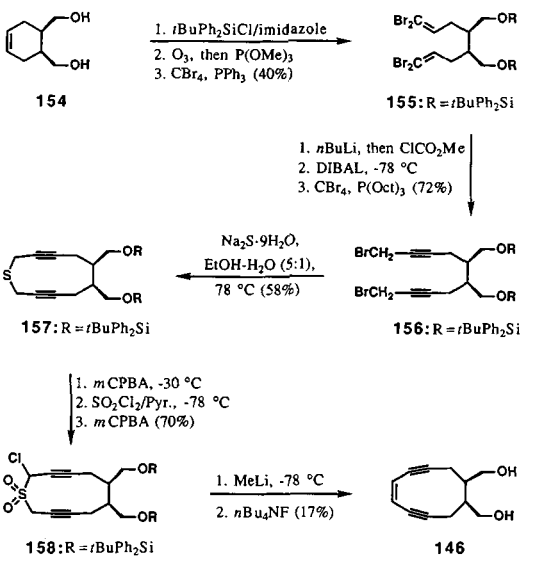
remarkably well with the calculated value and thus boosting our confidence in such calculations. Interestingly the nine-membered ring **145** (n = 1) could not be synthesized; instead, the diacetylene **153** was isolated. The latter compound presumably arose from the unusual pathway shown in Scheme 35.[89]

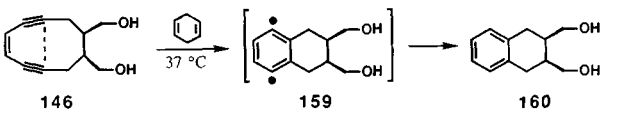


Scheme 35. Attempted synthesis of **145** (n = 1). Formation of compound **153** (*Nicolaou* et al., 1988).

On the basis of the studies described above, the conjugated cyclodecenediyne **146** was designed as a potential DNA-cleaving agent.[90] Its synthesis proceeded along the lines presented in Scheme 36. The compound **146** was sufficiently stable for handling but decayed at 37 °C in the presence of cyclohexadiene into the benzenoid product **160** via diradical **159** (Scheme 37) with a half-life of 11.8 h (E_a = 23.6 kcal mol^{-1}). Most significantly, enediyne **146** demonstrated marked temperature- and time-dependent DNA cleaving properties, re-



Scheme 36. Synthesis of the enediyne **146** (*Nicolaou* et al., 1988). Oct = octyl; R = Si*t*BuPh$_2$.



Scheme 37. Bergman-type cyclization of the enediyne **146** (*Nicolaou* et al., 1988).

sulting in both single and double strand DNA cuts (Fig. 10).[90] Figure 11 shows computer-generated space-filling models of enediyne **146** and its target, DNA.

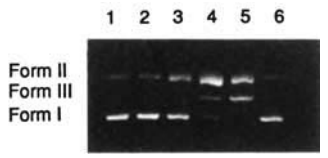


Fig. 10. DNA cleavage by **146** and **160**. ΦX174 form I DNA (50 μM/base pair) was incubated with **146** or **160** in Tris-acetate buffer (pH 8.5, 50 mM) at 37 °C for 12 h and analyzed by agarose gel electrophoresis. Lane 1, DNA alone; lanes 2–5, DNA + 1.0, 10, 100, and 500 μM **146**, respectively; lane 6, DNA + 2 mM **160**.

These results provided the first confirmation for the proposed mode of action of calicheamicins and esperamicins and supported our previous hypothesis[41] that simple cyclic conjugated enediynes should spontaneously cleave DNA in the absence of any cofactors such as metals or thiols, and should therefore serve as "warheads" for designed systems against preselected targets such as specific DNA segments and tumor cells. The incorporation of structures of the type **146** into larger molecular assemblies equipped with delivery systems may, therefore, be worthwhile and may result in powerful biotechnological tools and useful therapeutic agents.

Encouraged by the results with the model ten-membered ring enediynes and inspired by chemistry previously discovered by *Garratt*[91] and *Braverman*,[92] we proceeded to de-

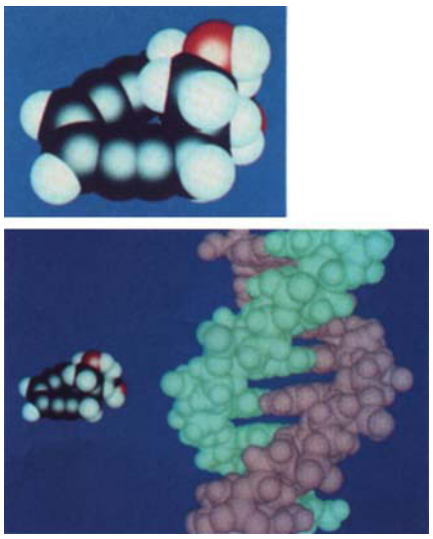

Fig. 11. Computer-generated models of free **146** (top) and of **146** on approaching DNA (bottom).

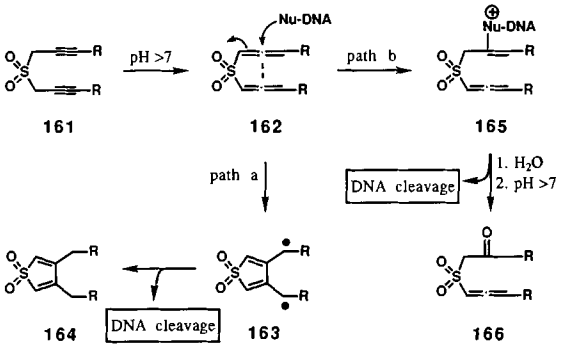
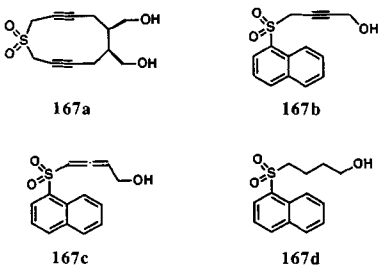
sign a new class of DNA-cleaving molecules containing propargylic or allenic sulfone moieties.[75] Scheme 38 shows the mechanistic rationale, which led to the design of this class of compounds. Specifically, it was hypothesized that the



Scheme 38. Mechanistic rationale for the design of DNA-cleaving molecules of the propargylic and allenic sulfone type (*Nicolaou* et al., 1989).

Garratt–Braverman cascade would proceed in aqueous solution at pH > 7, converting a bis(propargylic) sulfone **161** first into a bis(allenic) sulfone **162** and subsequently into a diradical species **163** (path a) which might cause DNA damage (→ **164**). Alternatively, it was reasoned that nucleophilic attack (path b) by DNA on the conjugated allenic

Table 5. Structures of propargylic and allenic sulfones **167a–d**.



acceptor **162** may lead to structures such as **165** which were then expected to undergo Maxam–Gilbert[69] type reactions (→ **166**) causing DNA rupture as shown in Scheme 38.

Table 5 presents the structures of some of the most interesting molecules of this series, whereas Figure 12 outlines DNA-cleaving action with these molecules.[93] Exploring

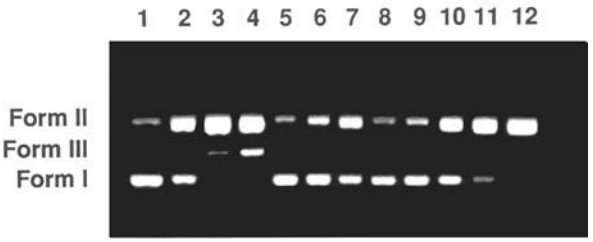


Fig. 12. DNA cleavage by **167**. ΦX174 form I DNA (50 μM/base pair) was incubated for 24 h at 37 °C with **167a–c** in buffer solution (50 mM Tris/HCl, pH 8.5) and analyzed by electrophoresis (1% agarose gel, ethidium bromide stain). Lane 1: DNA control; lane 2: DNA + 100 μM **167a**; lane 3: DNA + 5 μM **167b**; lane 4: DNA + 5 μM **167c**; lane 5: DNA + 10 mM **167d**; lane 6: DNA + 100 μM ethidium bromide; lane 7: DNA + 100 μM **167a** + 100 μM ethidium bromide; lane 8: DNA + 5 μM **167b** + 5 μM ethidium bromide; lane 9: DNA + 5 μM **167c** + 5 μM ethidium bromide; lane 10: DNA + 100 μM **167a** + 10 mM **167d**; lane 11: DNA + 5 μM **167b** + 10 mM **167d**; lane 12: DNA + 5 μM **167c** + 10 mM **167d**.

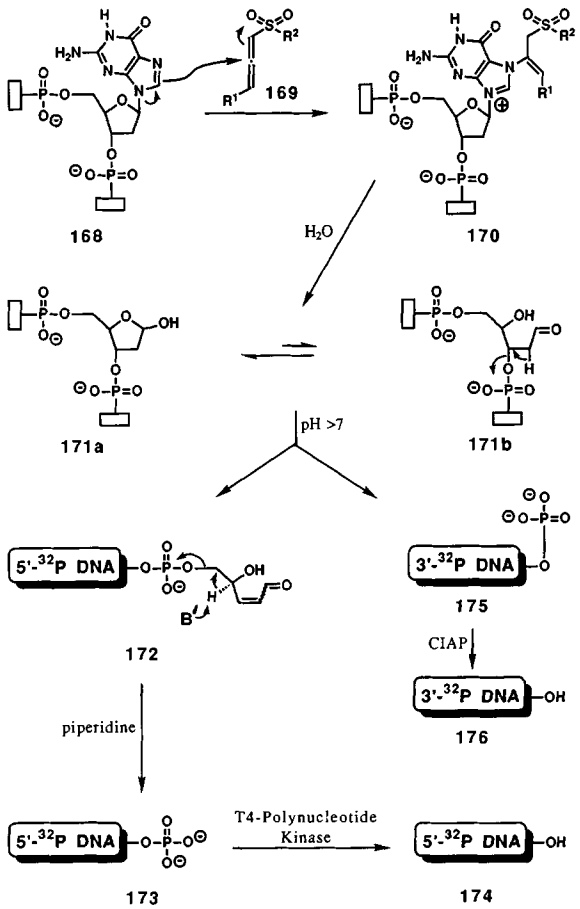
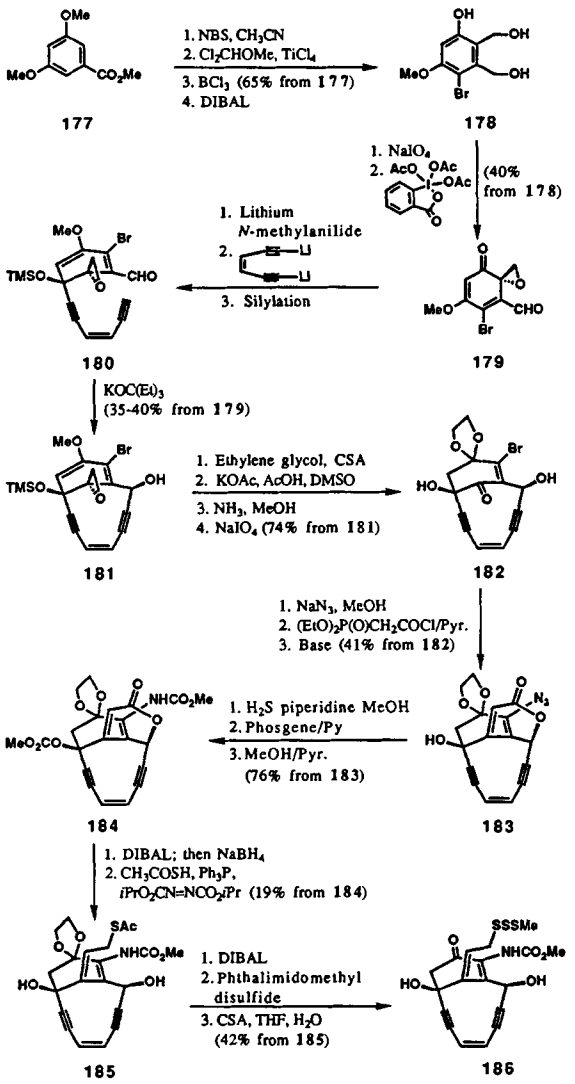
structure–activity relationships, base and sequence selectivity, and other mechanistic aspects, led to the conclusion that the most likely mechanism for the mode of action of these com-



Scheme 39. Mechanism of DNA cleavage by propargyl and allenic sulfones (e.g. **169**) (*Nicolaou* et al., 1989). CIAP = calf intestine alkaline phosphatase.

pounds is the alkylation pathway (**168**–**176**) depicted in some detail in Scheme 39.[93] Furthermore, it was established that compound **167a** (Table 5) shows preferential attack at guanine sites and, significantly, high selectivity for 5′-GCA, 5′-GCG, and 5′-GCC sequences.[93] These results render these types of compounds quite attractive as "warheads" for further manipulation and development.

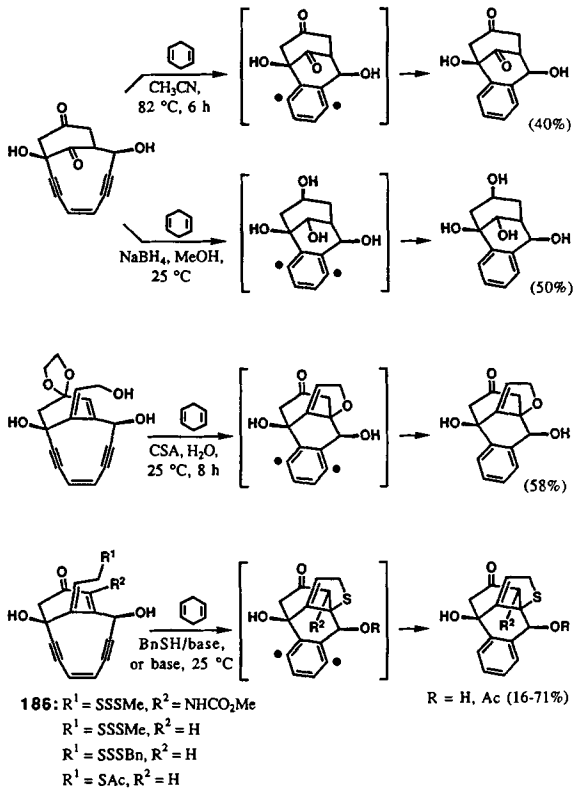
The *Danishefsky* group has been very active in the calicheamicin/esperamicin area.[94–98] Their synthesis of calicheamicinone **186** shown in Scheme 40[94] represents the first arrival at this target and a major achievement in the field.



Scheme 40. *Danishefsky*'s synthesis of calicheamicinone **186** (1990). NBS = *N*-bromosuccinimide.

Key steps in this sequence, which begins with **177**, are: a) the formation of the quinone epoxide **179** from **178**; b) the regioselective addition of dilithioenediyne to ketoaldehyde **179**; c) the intramolecular acetylide addition to the aldehyde group of **180** to give **181**; and d) the intramolecular Emmons condensation (**182** → **183**) to keep the allylic functionality in the correct configuration for **186**.

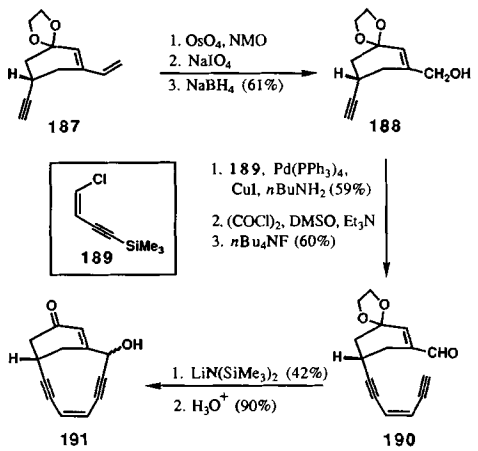
Simulation of the calicheamicin/esperamicin cascade has been amply demonstrated by *Danishefsky* et al. with a variety of compounds (Scheme 41).[95, 97] Furthermore, comparisons of calicheamicin γ_1^I **2** and calicheamicinone **186** in DNA cleavage experiments pointed to the importance of the carbohydrate fragment of the natural product in the molecular recognition of its target sequence.[39]



Scheme 41. Bergman cyclization of calicheamicinone **186** and related analogues (*Danishefsky* et al., 1989–1990). Bn = benzyl.

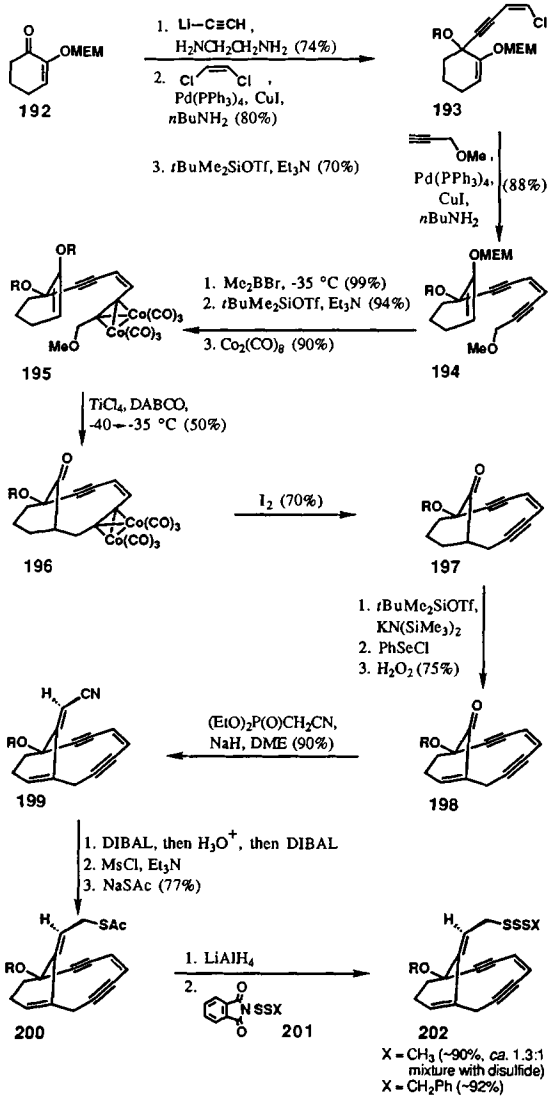
Kende and *Smith*[99] also utilized the intramolecular acetylide/aldehyde condensation (**190** → **191**, Scheme 42) to construct an enediyne model system (**191**) related to the calicheamicin/esperamicin core from **187**.

Magnus's approach to the enediyne model of the calicheamicin/esperamicin core cleverly exploited some intriguing



Scheme 42. The Kende synthesis of the calicheamicin/esperamicin related model system **191** as 3:1 mixture of epimers (*Kende* et al., 1988).

organocobalt chemistry to construct the ten-membered ring.[100-104] Schemes 43 and 44 show the synthesis of the model compounds **202** (from **192**)[100,101] and **205** (from **203**)[102] utilizing a $TiCl_4$/DABCO-induced ring closure of methoxy precursor **195** to give **196** and an intramolecular aldol reaction of the keto aldehyde **203** to give **204**, respectively. The *Magnus* group was the first[103a] to demonstrate

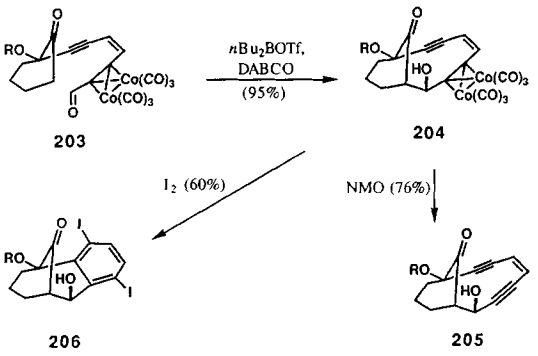


Scheme 43. Synthesis of calicheamicin/esperamicin related models by *Magnus* et al. (1988–1989). DABCO = diazabicyclooctane, DME = dimethoxyethane; R = Si*t*BuMe$_2$.

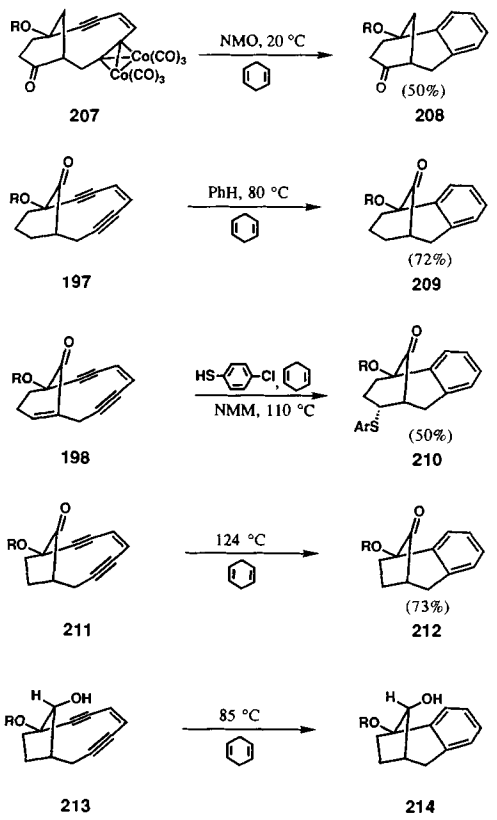
the construction of the trisulfide moiety in such systems using reagents of type **201** (Scheme 43). The same group also synthesized a number of other model systems such as **207**,[101] **211**,[87] and **213**[87] (Scheme 45) and demonstrated the cycloaromatization of a series of these compounds as shown in Schemes 44 (**204** → **206**)[102] and 45 (**207** → **208**;[101] **197** → **209**;[100] **198** → **210**;[104] **211** → **212**;[87] and **213** → **214**[87]).

The same approach towards for the synthesis of **197** has been reported by *Tomioka* et al.[105]

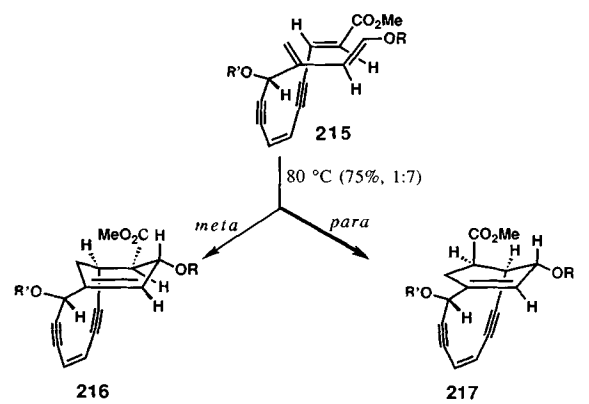
Schreiber's entry to the calicheamicin/esperamicin enediyne studies was based on an intramolecular Diels–Alder reac-



Scheme 44. Intramolecular aldol-based construction of a model system related to calicheamicin/esperamicin by *Magnus* et al. (1990). R = Si*t*BuMe$_2$.

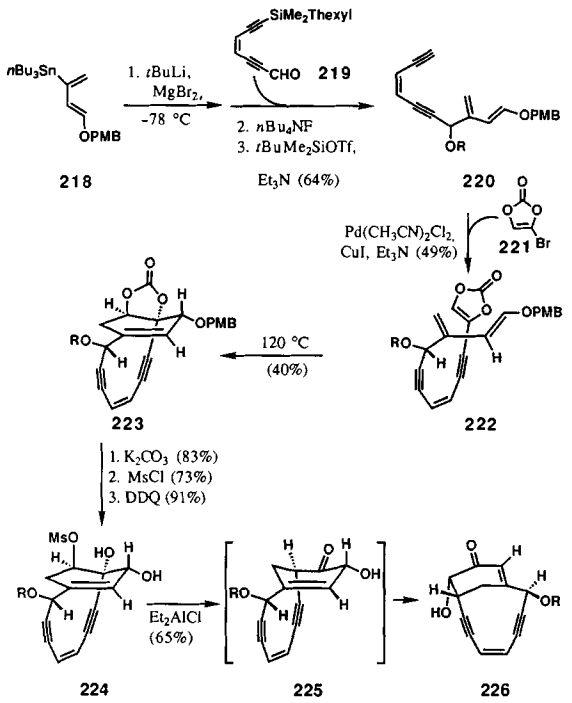


Scheme 45. Calicheamicin/esperamicin related systems synthesized and studied by *Magnus* et al. (1988–1990). NMM = *N*-methylmorpholine; R = Si*t*BuMe$_2$.



Scheme 46. The synthesis of the calicheamicin/esperamicin enediyne core skeleton by intramolecular Diels–Alder reaction according to *Schreiber* et al. (1988–1989). R = Si*t*BuMe$_2$. **216** present only as by-product.

tion. This approach initally met with a disappointing regiochemical outcome, as indicated in Scheme 46.[106, 107] Thus, heating the polyunsaturated substrate **215** to 80 °C resulted in the unfavorable ratio of 1:7 for the *meta*- and *para*-products (**215** → **216** + **217**). This outcome, however, was swiftly corrected in subsequent work[108] by a clever maneuver involving a Tsuchihashi pinacol rearrangement[109] with con-



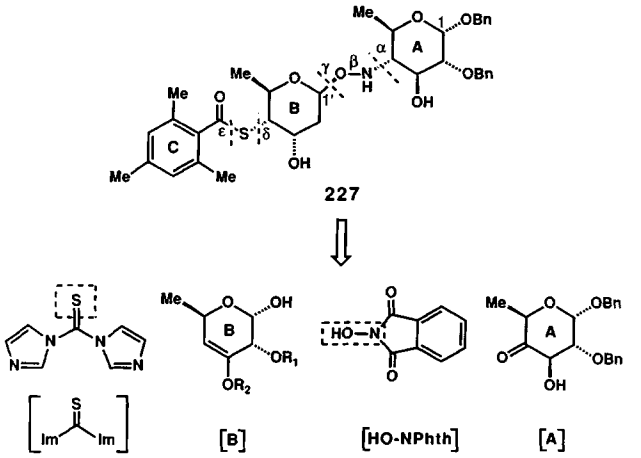
Scheme 47. The intramolecular Diels–Alder approach to the calicheamicin/esperamicin enediyne model **226** by *Schreiber* et al. (1989). Thexyl = Me_2CH-CMe_2, PMB = *para*-methoxybenzyl, DDQ = dichlorodicyanobenzoquinone; R = Si*t*BuMe$_2$.

comitant diastereoselective acyloin shift to secure the desired ring skeleton (**224** → **225** → **226**, Scheme 47).

3.2.2. *Carbohydrate Fragments*

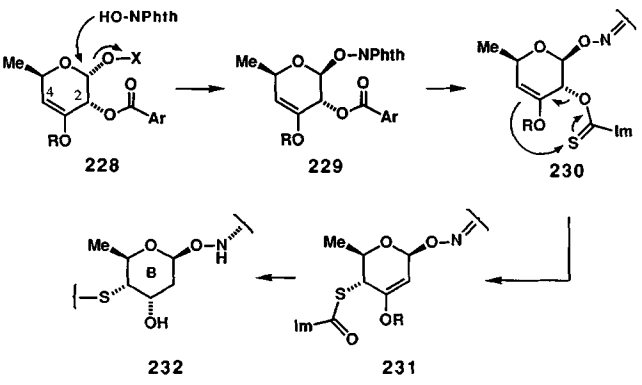
The implication of the calicheamicin γ_1^I oligosaccharide segment as a minor groove binder and recognition element for sequence specificity in DNA cleavage coupled with the challenge of the calicheamicin γ_1^I total synthesis prompted us to undertake its construction.[110–114] Focusing on the oligosaccharide fragment of calicheamicin γ_1^I, we identified the following novel and challenging structural features shown in model **227** (Scheme 48)[110, 111]: a) the unusual alkoxylamine bond (β) linking carbohydrate units A and B through bonds α and γ; b) the *β*-configuration of the glycoside bond γ, which, taken in combination with the 2-deoxy nature of saccharide B, presents a unique challenge to synthetic construction; c) the sulfur bridge, linking carbohydrate unit B with the fully substituted aromatic ring via bonds δ and ε; and d) the α-configuration of the N- and S-bearing stereogenic centers of carbohydrate units A and B, respectively.

Targeting model system **227** (Scheme 48) provided rather novel solutions to all the above synthetic challenges. The synthetic design for this construction was based on the retrosynthetic disconnections indicated in structure **227** (Scheme 48) which led to diimidazolylthioketone (Im_2C=S) as the sulfur source, *N*-hydroxyphthalimide (HO–NPhth) as the ori-



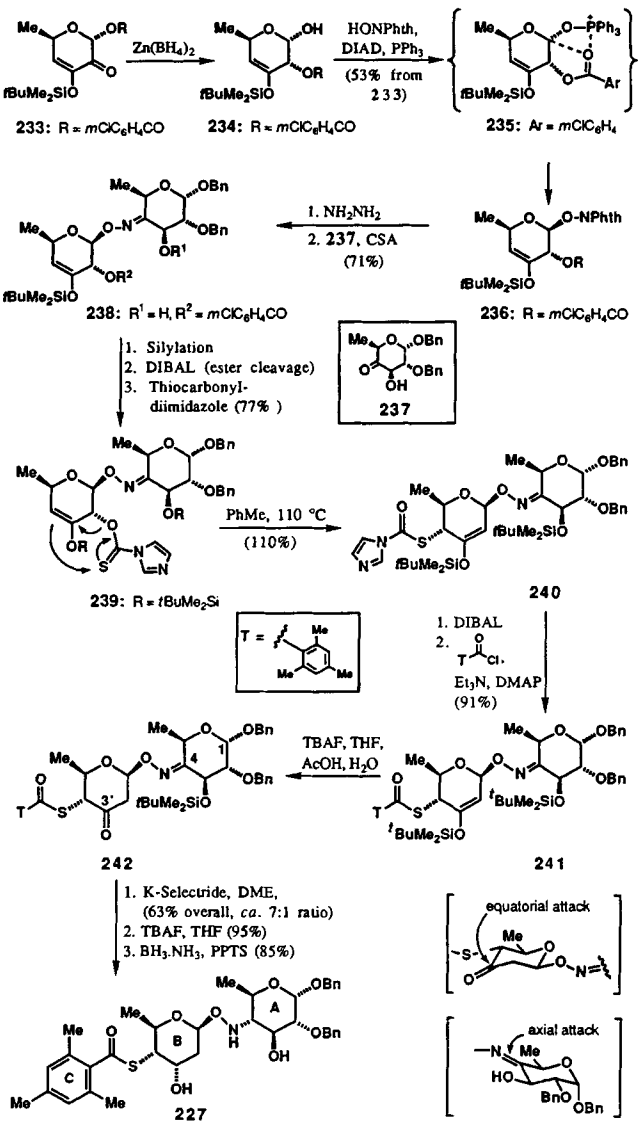
Scheme 48. Retrosynthetic analysis of the ABC model fragment **227** of the calicheamicin γ_1^I oligosaccharide moiety (*Nicolaou* et al., 1990).

gin of the alkoxyamino group, and precursors to rings A, B, and C as potential starting materials. Scheme 49 outlines the strategy utilized in this synthesis as designed from the above analysis and which, in addition to solving the above mentioned problems, avoids a potentially difficult deoxygenation step to generate the desired methylene group of the B ring. Thus, intermediate **228** was designed with an ester group at position 2 to assure the desired stereochemical outcome of the glycosidation reaction (**228** → **229**, *β*-configuration) as well as to serve as a device to stereoselectively deliver the sulfur atom at position 4 via a sigmatropic rearrangement (**229** → **230** → **231**). Compound **231** was then expected to serve as a



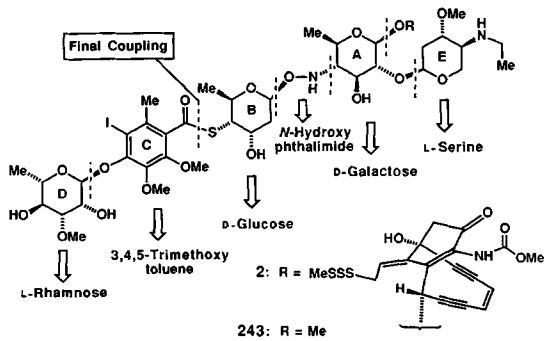
Scheme 49. Synthetic strategy for the construction of the central ring region **232** of the calicheamicin γ_1^I oligosaccharide moiety (*Nicolaou* et al., 1990).

precursor to **232**. The execution of the synthesis proceeded as planned (Scheme 50). In addition to the above mentioned highlights, the synthesis featured stereoselective reductions of both the C=O and the C=N bonds (**242** → **227**) to afford the desired product in high overall yield.[110, 111]

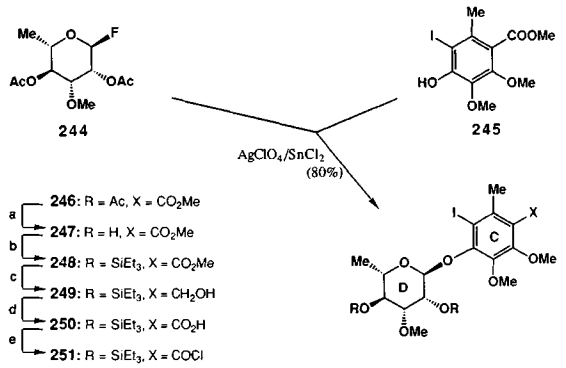


Scheme 50. Synthesis of the calicheamicin γ_1^I oligosaccharide model system **227** (*Nicolaou* et al., 1990). DIAD = diisopropylazodicarboxylate, TBAF = tetrabutylammonium fluoride, PPTS = pyridinium *p*-toluenesulfonate.

Application of this synthetic technology featuring the novel [3,3]sigmatropic rearrangement to the construction of the natural calicheamicin γ_1^I oligosaccharide methyl glycoside **243** followed swiftly. Designated on structure **243** (Scheme 51) are the strategic bond disconnections that allowed the tracing of the requisite intermediates to the readily available

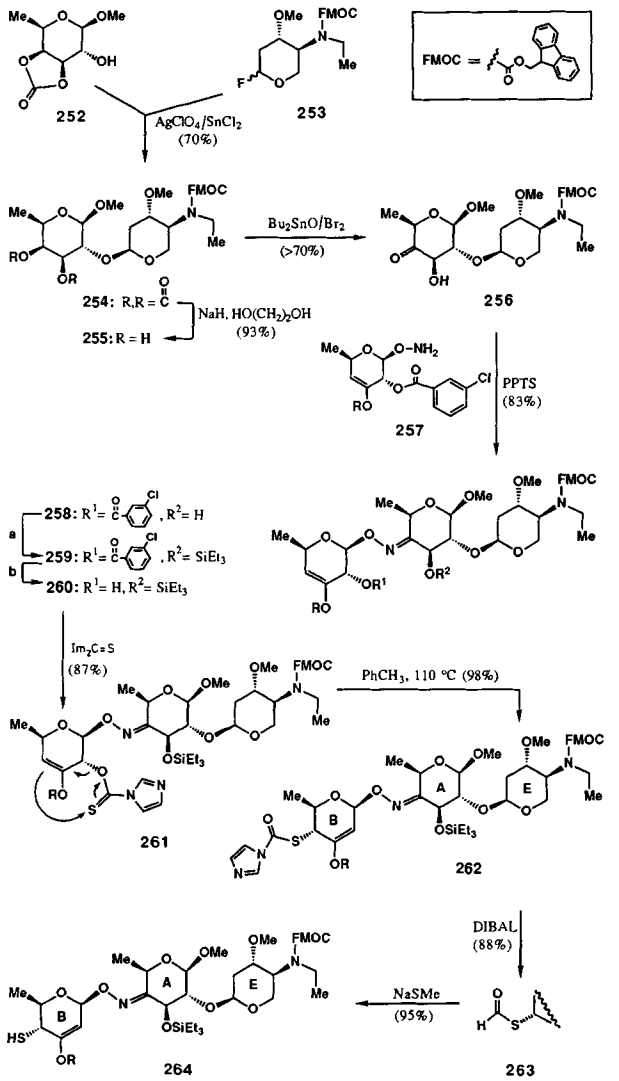


Scheme 51. Strategic bond disconnections and retrosynthetic analysis of the calicheamicin γ_1^I oligosaccharide derivative **243** (*Nicolaou* et al., 1990).



Scheme 52. Synthesis of the DC ring system **251** of the calicheamicin γ_1^I oligosaccharide moiety (*Nicolaou* et al., 1990). a: K_2CO_3, MeOH (100 %); b: Et_3SiOTf, 2,6-lutidine (92 %); c: DIBAL (90 %); d: $RuCl_3 \cdot H_2O$, $NaIO_4$, $CCl_4/CH_3CN/H_2O$ (2/2/3) (75 %); e: $(COCl)_2$ (95 %).

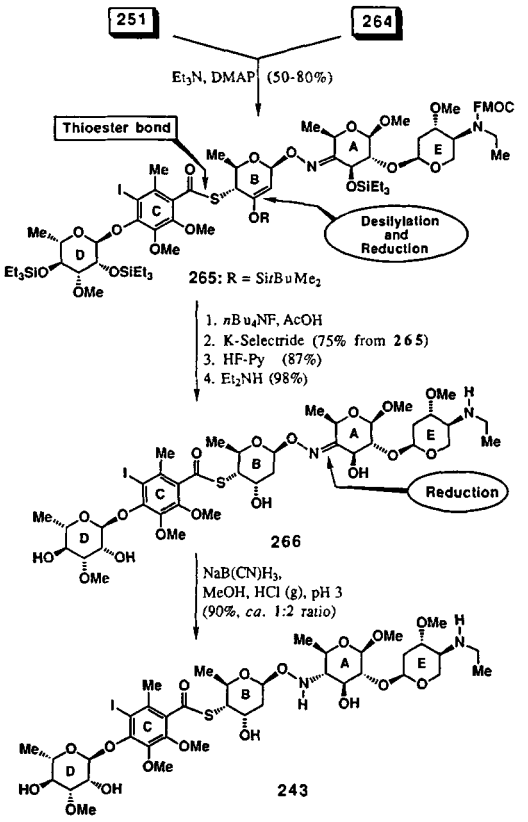
starting materials: L-rhamnose (ring D); 3,4,5-trimethoxytoluene (ring C); D-glucose (ring B); *N*-hydroxypthalimide (O–NH group); D-galactose (ring A); and L-serine (ring E). The thioester linkage (CO–S) was reserved as the key bond for the final coupling reaction. Schemes 52–54 summarize



Scheme 53. Synthesis of EAB ring systems **263** and **264** of the calicheamicin γ_1^I oligosaccharide moiety (*Nicolaou* et al., 1990). a: Et_3SiOTf, 2,6-lutidine (100 %); b: DIBAL (91 %). R = *Si*BuMe$_2$.

the total synthesis of **243** with the intermediates **244**, **245**, **252**, **253** and **257** as key building blocks. Despite the encouraging results with model system **227**, the final reduction of the C=N bond in **266** proceeded with rather low stereoselectivity to afford a mixture of products (1:2 in favor of the wrong isomer). Efforts to improve this outcome are continuing.

Molecular recognition studies involving **243** *and DNA* segments are now possible and so are projected total syntheses of calicheamicin γ_1^I **2** and other hybrid structures.

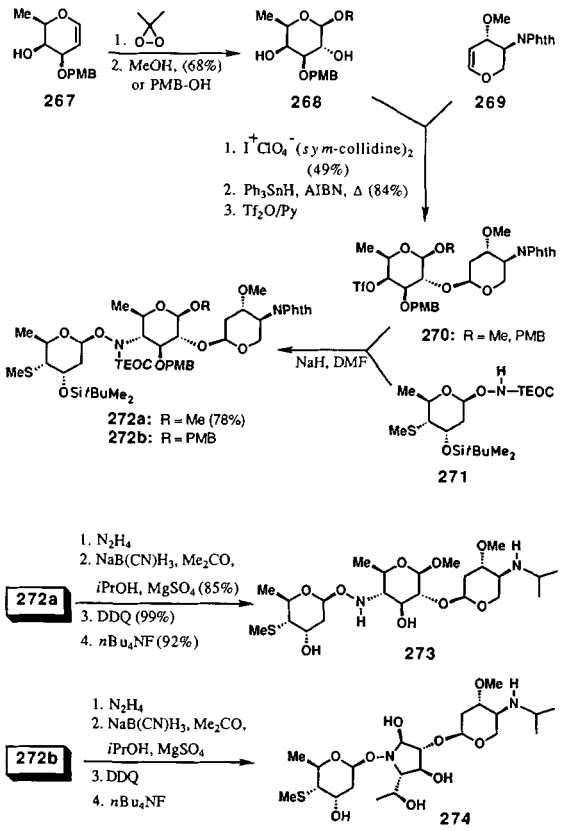


Scheme 54. Total synthesis of the calicheamicin γ_1^I oligosaccharide compound **243** (*Nicolaou* et al., 1990).

A synthesis of the trisaccharide segment **273** of esperamicin A_1 **3**, was recently completed by *Danishefsky* et al.[115, 116] as summarized in Scheme 55. Highlights of this construction include: a) the utilization of glycals in glycosidation reactions, and b) the use of a urethane anion to construct the crucial C–N bond (**270** + **271** → **272a, b**), as demonstrated by the *Kahne* group.[117] An interesting observation in the *Danishefsky* work[115] was the rearrangement of the central pyranose ring to a five-membered nitrogen-containing ring system (**272b** → **274**) upon liberation of both the anomeric and the NH–O position of the central sugar unit.[48]

The *Kahne* group was the first to publish a synthesis of the 4-ethylamino sugar (ring E) of calicheamicin γ_1^I **2** and to assign its absolute configuration.[118] The same group has recently reported a new method for the construction of N–O linkages for oligosaccharides based on urethane anion chemistry and applied it to the construction of the calicheamicin/esperamicin core trisaccharide **281** as shown in Scheme 56.[117]

Subunits of the calicheamicin γ_1^I oligosaccharide were also synthesized by *Laak* and *Scharf*.[119]



Scheme 55. The Danishefsky synthesis of the core trisaccharide fragment **273** of esperamicin (1991). AIBN = azodiisobutyronitrile. TEOC = $Me_3Si(CH_2)_2OC(O)$–

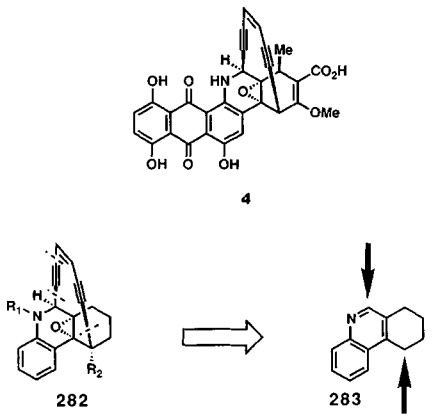
3.3. Dynemicin A Model Systems

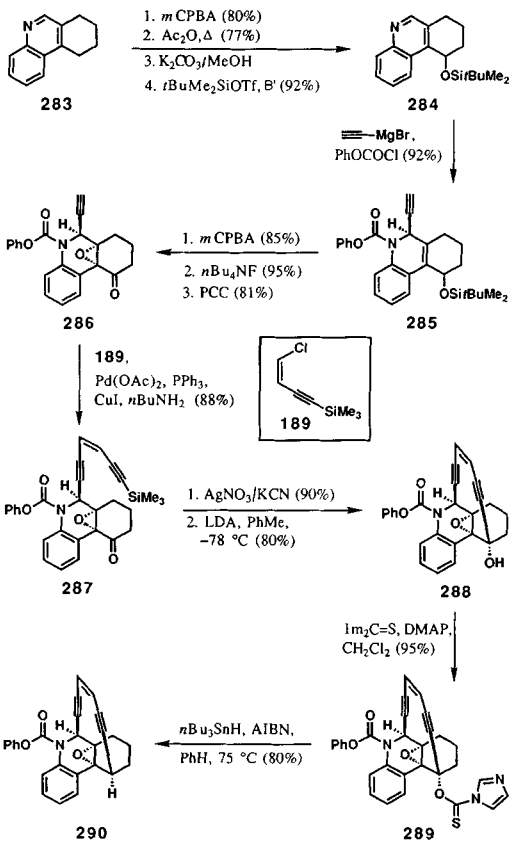
The elegance and challenging nature of the dynemicin A structure combined with its potent antitumor and antibiotic

activity prompted immediate response from the synthetic chemistry community. We decided to pursue the design, synthesis, and study of models for dynemicin A in order to gain further insight into the mechanism of action of this fascinating molecule and to pave the way for an eventual total synthesis as well as to lay the foundations for the development of biotechnological tools and therapeutic agents.

The model system **282** was initially designed[120, 121] for its simplicity and flexibility to generate a library of related structures. It was traced retrosynthetically as outlined in Scheme 57, to tetrahydrophenanthridine **283.** The synthetic strategy



Scheme 57. Strategic bond disconnections and retrosynthetic analysis of the dynemicin model compounds **282** (*Nicolaou* et al., 1990). The positions to be activated in **283** are indicated by arrows.



Scheme 58. Synthesis of dynemicin A model systems **288**–**290** (*Nicolaou* et al., 1990). PCC = pyridinium chlorochromate, LDA = lithium diisopropylamide.

for its construction is summarized in Scheme 58.[120, 121] Highlights of this synthesis include: a) the functionalization of the tetrahydrophenanthridine ring (**283** → **284** and **284** → **285**); b) the palladium-catalyzed construction of the enediyne moiety (**286** → **287**); c) the intramolecular acetylide–ketone condensation to close the ten-membered ring; and d) the radical-induced deoxygenation step (**289** → **290**). The structures of both **288** and **290** were confirmed by X-ray crystallographic analysis revealing interesting geometrical parameters. Figure 13 shows the ORTEP drawing of **290** and lists some of these

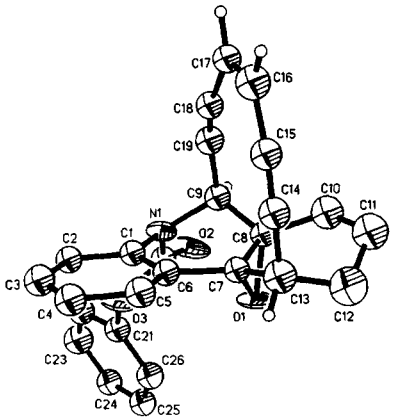


Fig. 13. Structure of **290** in the crystal. $c \cdots d$ distance ($r_{C_{14}-C_{19}}$) = 3.59 Å. Angles at the sp carbon atoms: C14 163.7, C15 170.1, C18 170.2, C19 162.0°.

parameters. Figure 14 shows computer-generated space-filling models of compounds **290** and its target, DNA.

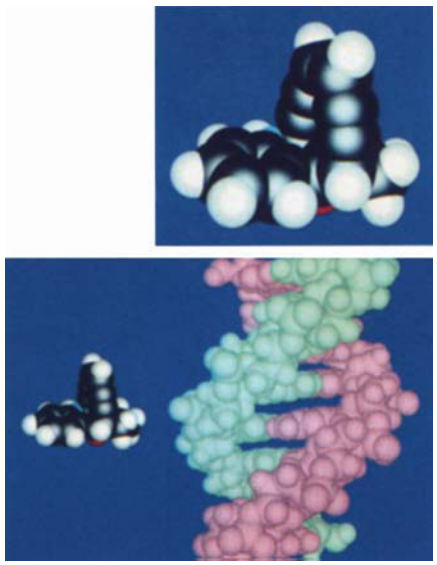

Fig. 14. Computer-generated models of free **290** (top) and of **290** on approaching DNA (bottom).

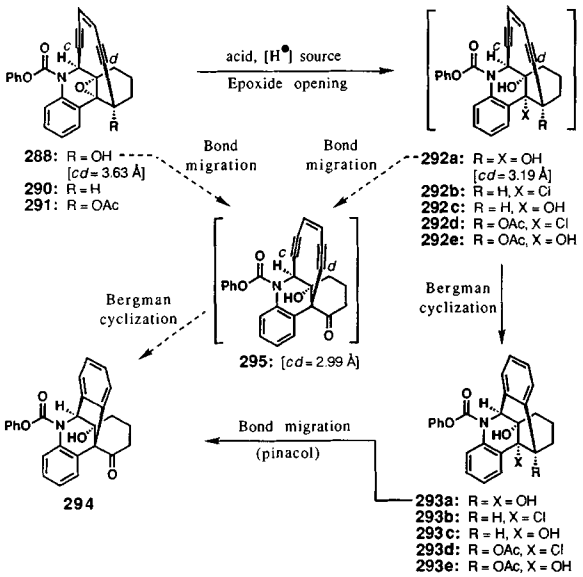
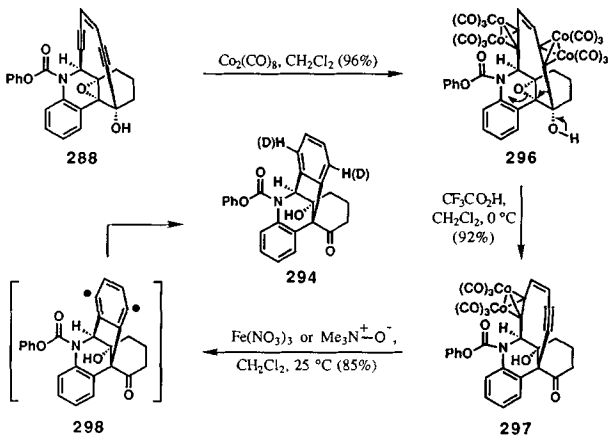
The chemistry of these dynemicin A model systems proved to be quite fascinating.[120, 121] Thus, upon triggering with acid, the hydroxy compound **288** entered the reaction cascade shown in Scheme 59, involving: a) epoxide opening leading to **292a** [calculated $c \cdots d$ distance = 3.19 Å]; b) Berg-

man cycloaromatization to give **293**; and c) spontaneous pinacol rearrangement under the reaction conditions furnishing ketone **294**. It is interesting to speculate about the timing of the bond migration leading to ring construction, in relation to the cascade coordinate, and whether the sequence includes structure **295**. Blocking the final rearrangement step (R = H or OAc) results in the isolation of structures **293b–e** (Scheme 59).[120, 121]



Scheme 59. Chemistry of dynemicin A model systems. Triggering the Bergman cyclization/pinacol rearrangement cascade (*Nicolaou* et al., 1990–1991).

An organometallic-based mode of triggering the dynemicin A cascade was devised as shown in Scheme 60.[121] This pathway was designed so as to prevent the enediyne unit from spontaneously collapsing to a benzenoid diradical upon epoxide opening and allow isolation of the postulated resulting *cis*-diol in the form of its cobalt complex. Accordingly, the cobalt complex **296** was prepared from **288**.[121] Surprisingly, acid treatment of **296** led to the highly strained compound **297** in which epoxide opening had apparently



Scheme 60. Synthesis and chemistry of cobalt complexes of dynemicin A model systems. Triggering of Bergman cyclization by decomplexation (*Nicolaou* et al., 1991).

been accompanied by bond migration–ring contraction and regiospecific loss of one of the cobalt groups.[121] Structure **297** was supported by X-ray crystallographic analysis of its acetate derivative which revealed some interesting topological data (Fig. 15). As expected, oxidative decomplexation of

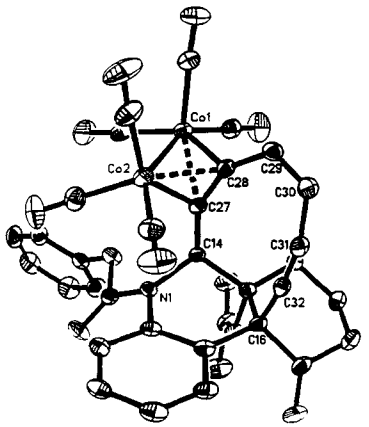


Fig. 15. Structure of the acetyl derivative of **297** in the crystal. Hydrogen atoms are omitted for clarity. $c \cdots d$ distance ($r_{C_{27}-C_{32}}$) = 3.08 Å. Angles at the sp carbon atoms: C27 151.7, C28 151.1, C31 158.3, C32 166.8°.

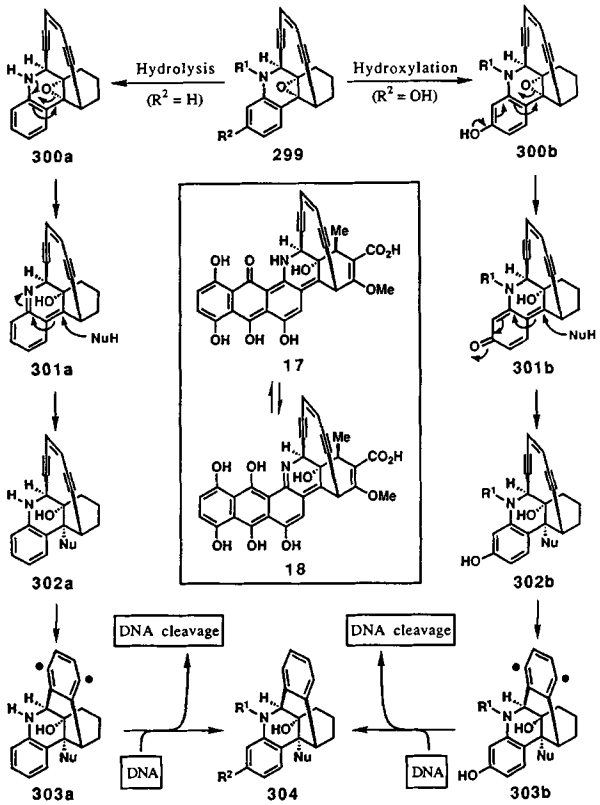
297 precipitated spontaneous Bergman cyclization leading to product **294** via the presumed nine-membered enediyne **295** (Scheme 59) and diradical **298** (Scheme 60).[121]

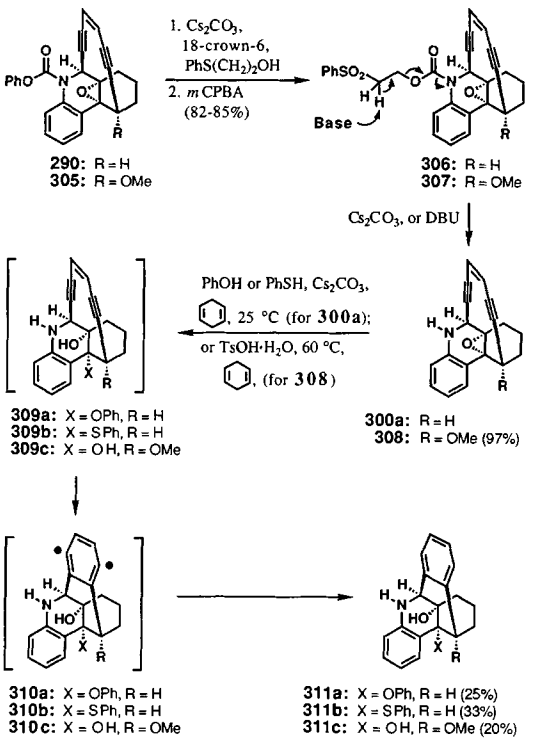
Recent work from our laboratories[60] resulted in a number of second generation enediyne systems of the dynemicin type, equipped with acid-, base-, and photo-sensitive trigger-



Scheme 61. Simulation of the dynemicin cascade by model compounds (*Nicolaou* et al., 1991).

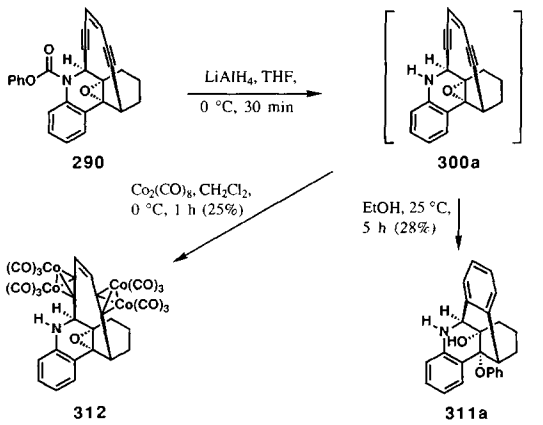
ing devices. The designed structures (**299**) were considered as candidates for laboratory simulation of the two cascade scenarios shown in Scheme 61 under mild conditions. These two sequences involving iminoquinone methide species **301 a** (related to the dynemicin-derived species **18**, Schemes 11 and 61) or quinone methide species **301 b** (related to the dynemicin-derived species **17**, Schemes 11 and 61) may, in fact be initiated in vivo by enzymatic action and are, therefore, of value in the design of potential prodrugs.

The enediyne system **306** was designed so as to allow easy access to the parent compound **300 a**. Its preparation and conversion to **300 a** are shown in Scheme 62.[60] The parent



Scheme 62. Chemistry of dynemicin A model systems. Triggering the dynemicin cascade with base or acid (*Nicolaou* et al., 1991).

enediyne **300 a** proved too labile for isolation but its reactivity and ability to cleave DNA (see Figs. 17 and 18) support the notion of the involvement of path a (Scheme 11) and the



Scheme 63. Chemistry of dynemicin A model systems. Triggering the dynemicin cascade by reduction (*Nicolaou* et al., 1991).

participation of an *ortho*-iminoquinone methide species in the dynemicin A cascade at least as a partially contributing pathway. The structure of **300 a**, which was also generated in solution by LAH reduction of **290** (Scheme 63), was deduced from a number of trapping experiments as summarized in Schemes 62[60] and 63.[121] In contrast to **300 a**, the methoxy compound **308** (Scheme 62) proved to be a stable, crystalline solid. Its structure was confirmed by X-ray crystallographic analysis (Fig. 16) and under acidic conditions **308** followed the expected dynemicin-type cascade (Scheme 62).

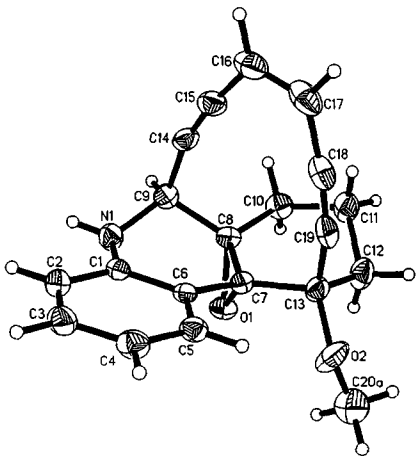


Fig. 16. Structure of **308** in the crystal. $c \cdots d$ distance ($r_{C_{14}-C_{19}}$) = 3.63 Å. Angles at sp carbon atoms: C14 163.2, C15 173.0, C18 169.3, C19 160.5°.

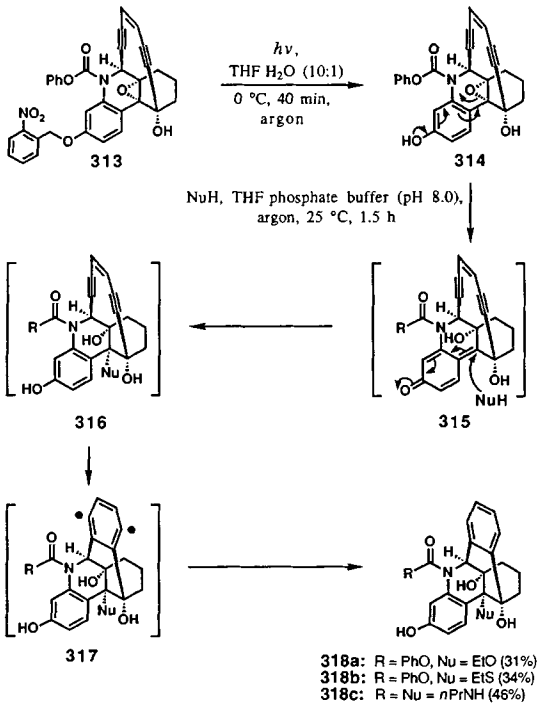
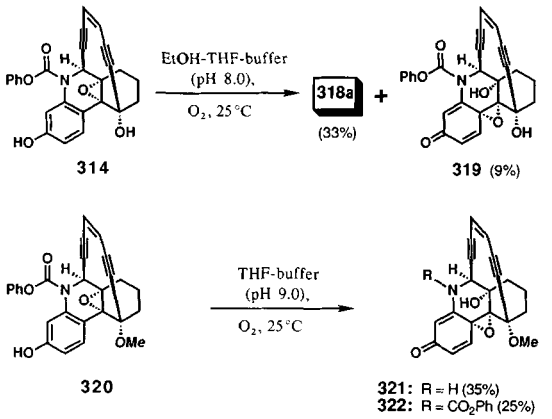
The enediyne model system **313** (Scheme 64) was designed and synthesized[60] for its potential to generate species **314** upon photolysis. Indeed, irradiation of **313** resulted in its clean conversion to **314** as detected by TLC and ^1H NMR spec-



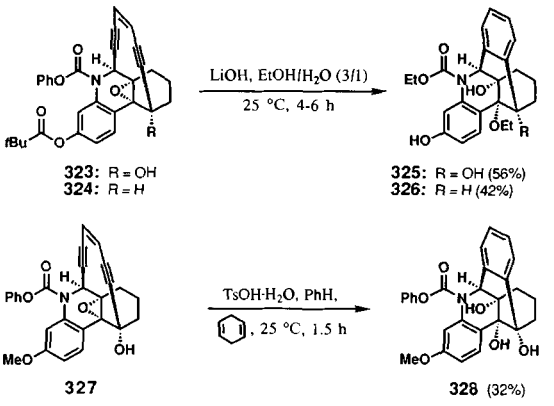
Scheme 64. Chemistry of dynemicin A model systems. Triggering the dynemicin cascade by photo-deprotection (*Nicolaou* et al., 1991).

troscopy. Attempted isolation of **314** led to decomposition, whereas treatment of crude **314** with nucleophiles (e.g. EtOH, EtSH, nPrNH$_2$) furnished the aromatized products **318a–c** as shown in Scheme 64. Interesting observations in these experiments include the isolation of the novel quinone–epoxide structure **319** (Scheme 65) from the reaction with ethanol in air (along with **318a**) as a sensitive but stable molecule under neutral conditions. The isolation of **319** provides support for the intermediacy of quinone methide **315** (Scheme 64), which when trapped with oxygen could provide **319**. Equally remarkable was the isolation of **321** and **322** as stable molecules upon treatment of **320** with O_2 (Scheme 65).



Scheme 65. Chemistry of dynemicin A model systems. Trapping quinone methide intermediates by molecular oxygen (*Nicolaou* et al., 1991).

The pivaloate protected enediyne systems **323** and **324** (Scheme 66) were also synthesized[60] for their potential to liberate phenolic species under basic conditions, thus presenting yet another triggering mechanism to initiate the dynemicin A cascade. Not surprisingly, exposure of **323** and **324**



Scheme 66. Chemistry of dynemicin A model systems. Triggering the dynemicin cascade with base or acid (*Nicolaou* et al., 1991).

to lithium hydroxide in aqueous ethanol resulted in the formation of compounds **325** and **326**, respectively, via benzenoid diradicals and concomitant carbamate exchange (PhO → EtO, Scheme 64). The methoxy compound **327** was found to be reasonably stable under neutral and basic conditions but cyclized rapidly under acidic conditions to give aromatized product **328** (Scheme 66) as expected.

Molecules **300a**, **314**, and **319** caused significant DNA cleavage when incubated with supercoiled ΦX174 DNA (Fig. 17 and 18).[60, 121] Noteworthy in these experiments is the

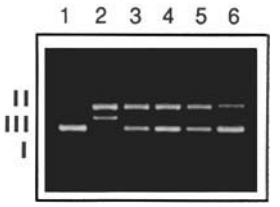


Fig. 17. DNA cleavage by **300a**. ΦX174 form I DNA (50 μM/base pair) was incubated for 12 h at 37 °C with **300a** (in 20% THF in phosphate buffer, pH 7.4, 50 μM) and analyzed by electrophoresis (1% agarose gel, ethidium bromide stain). Lane 1: DNA control; lanes 2–6: DNA + 5000, 2000, 1000, 500, and 100 μM of **300a**, respectively.

observation of both single and double strand cuts, as is the case with dynemicin A.[50, 51] As expected from their chemical profiles, the methoxy compounds **308**, **320**, **321**, and **322** exhibited diminished activity against DNA.[60] The potency of these DNA-cleaving molecules is expected to increase by attaching them to suitable DNA-binding moieties.

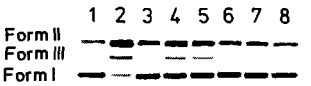

Fig. 18. DNA cleavage by dynemicin A model compounds. ΦX174 form I DNA (50 μM/base pair) was incubated for 24 h at 37 °C with **300a**, **308**, **314**, **319**, **320**, **321**, or **322** in buffer (50 mM Tris/HCl, pH 8.0) and analyzed by electrophoresis (1% agarose gel, ethidium bromide stain). Lane 1: DNA control; lane 2: DNA + 5 mM **300a**; lane 3: DNA + 5 mM **308**; lane 4: DNA + 5 mM **314**; lane 5: DNA + 5 mM **319**; lane 6: DNA + 5 mM **320**; lane 7: DNA + 5 mM **321**; lane 8: DNA + 5 mM **322**.

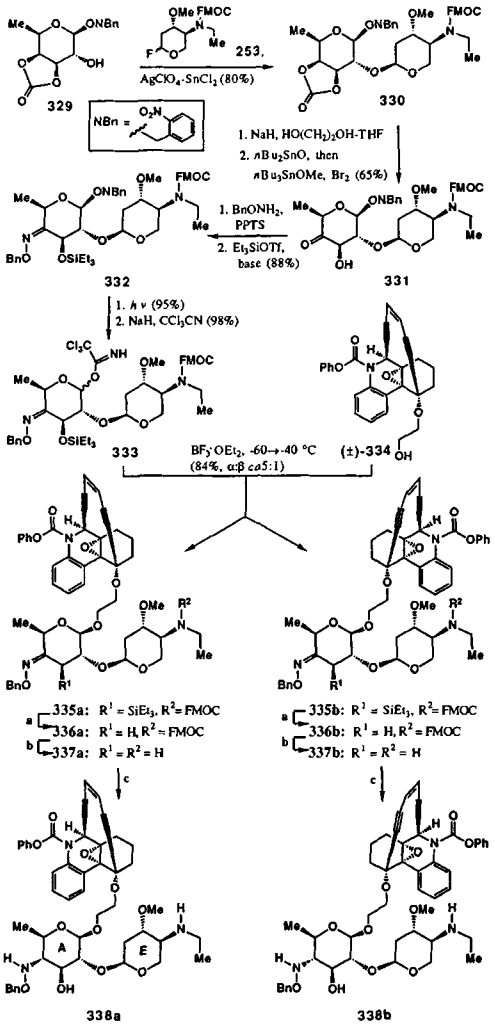
These studies provided support for the viability of both paths a and b of Schemes 11 and 61 as triggering mechanisms for the dynemicin A cascade by demonstrating that a lone pair of electrons on a heteroatom (nitrogen or oxygen) strategically positioned on the aromatic ring in relation to the epoxide moiety serves well to initiate the Bergman cyclization reaction. Such reactive species may be generated within cells from natural or designed molecules of the enediyne type, or as discussed above, be released from suitable precursors in the laboratory under mild conditions. Furthermore, the observation and relative stability of certain intermediates in these studies is intriguing in that it allows for the possibility of bioreduction prior to intercalation as well as a nucleophilic attack by a DNA base on a quinone methide and/or an *ortho*-iminoquinone methide species such as **17** and/or **18** (tautomeric structures, see Scheme 11). Thus, the proposition[51] that dynemicin A **4** may be interacting with DNA by a dual mechanism (nucleophilic and radical) appears attractive, not only because of the observed preference[50, 51] for cleavage at adenine and guanine but also in light of the chemistry of **314** (Scheme 64).[60]

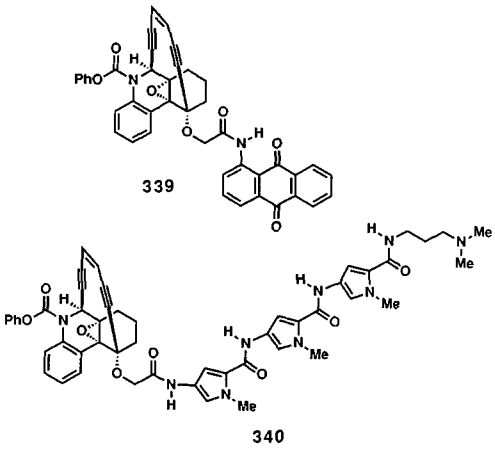
A number of hybrid molecules between the dynemicin A model system **334** (Scheme 67) and potential DNA binding moieties were recently synthesized in our laboratories.[122] Scheme 67 summarizes the construction[122] of the two diastereomeric, enatiomerically pure hybrids **338a** and **338b** containing a dynemicin A enediyne model system and the AE disaccharide segment of calicheamicin γ_1^I **2**. The highlights of this technology include a stereoselective glycosidation using Schmidt's trichloroacetimidate method[123] (**333** + **334** → **335a, b**, Scheme 67) and a highly efficient and stereoselec-



Scheme 67. Synthesis of calicheamicin–dynemicin model hybrid structures (*Nicolaou* et al., 1991). a: HF · Py (98 %); b: Et_2NH (98 %); c: $Ti(OiPr)_4$, Ph_2SiH_2 (90 %).

tive reduction of the C=N bond with $Ti(OiPr)_4/Ph_2SiH_2$ (**337a, b** → **338a, b**, Scheme 67).[122] In addition to providing these novel compounds, this chemistry demonstrated potential synthetic technology for the coupling of the carbohydrate and aglycone fragments of the calicheamicins and esperamicins.

Aiming for higher binding constants, we designed and synthesized hybrid structures **339** and **340** (Scheme 68).[124] These molecules, containing anthraquinone and distamycin units as respective intercalating and minor groove binding moieties, as well as the oligosaccharide-containing hybrids



Scheme 68. Hybrid structures of dynemicin A model compound and DNA binding molecules (*Nicolaou* et al., 1990).

discussed above and other recently synthesized molecules are currently under investigation in our laboratories with regard to their biological activity and molecular recognition profiles. Figure 19 shows computer-generated space-filling models of these compounds and their target, DNA.

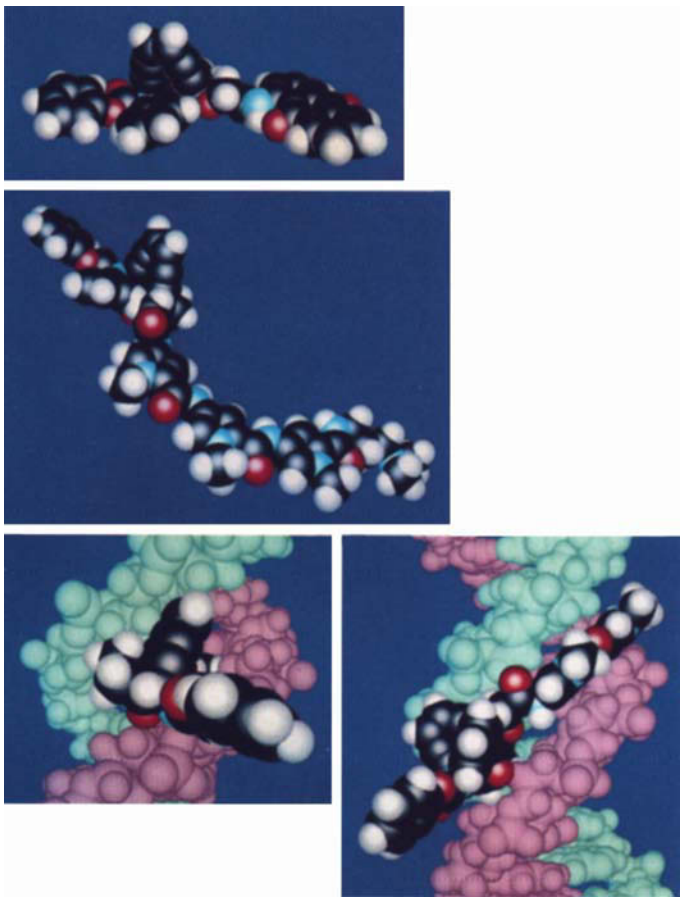


Fig. 19. Computer-generated models of the compounds **339** (top) and **340** (center) and DNA-bound **339** (bottom right) and **340** (bottom left).

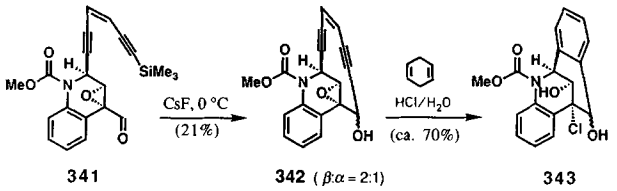
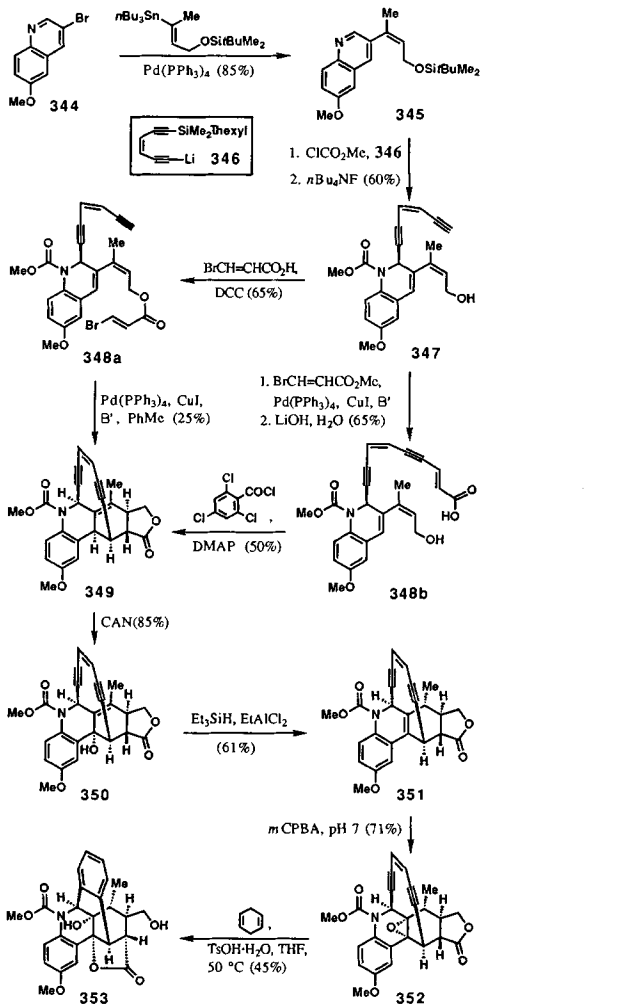
Wender's group has recently published[125] the dynemicin A model studies summarized in Scheme 69.



Scheme 69. The Wender synthesis of dynemicin A model compounds (1991).

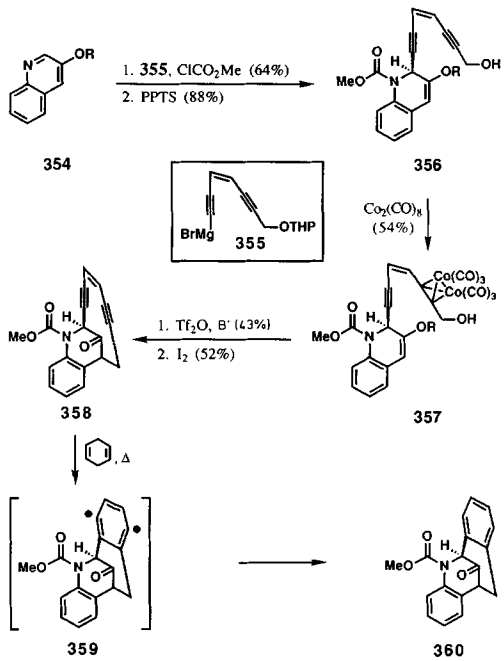
Schreiber et al.[126] have been able to apply their enediyne intramolecular Diels–Alder approach to the synthesis of the dynemicin A model system **352** (Scheme 70). In addition to the ring skeleton assembly, interesting points in this elegant synthesis include: a) a regioselective allylic oxidation (**349** → **350**); b) a stereospecific hydride delivery with concomitant S_N2' displacement of a hydroxyl group (**350** → **351**); and c) a chemoselective epoxidation (**351** → **352**). *Schreiber*'s group has also recently reported[127] a synthesis of an anthraquinone subunit of dynemicin A.



Scheme 70. The Schreiber synthesis of dynemicin A model compounds (1990). DCC = dicyclohexylcarbodiimide, CAN = cerium ammonium nitrate.

Magnus et al. synthesized[128] and studied the core tetrahydroquinoline diynene structure **358** utilizing a cobalt acetylene complex as a precursor as summarized in Scheme 71.

Model studies by *Isobe* et al.[129] with open enediynes related to dynemicin A have recently been published.



Scheme 71. The Magnus synthesis of dynemicin A model compound **358** (1991). THP = tetrahydropyranyl; R = $SiBuMe_2$.

4. Theoretical Studies

The fascinating enediyne structures did not fail to attract the attention of theorists. Extending the initial, first approximation attempts to correlate the distance between the remote acetylenic carbons and reactivity in simple acyclic and monocyclic enediynes, *Snyder*[130] carried out broader calculations linking reactivity in monocyclic and polycyclic enediynes with molecular strain in the ground and transition states. *Snyder* also described a quantum mechanical model for the cycloaromatization of a number of calicheamicin/esperamicin models[131] and evaluated two distinct pathways of dynemicin A activation involving acid-catalyzed epoxide opening and quinone methide formation.[132] *Semmelhack* et al. also reported[59] on the mechanism of action of dynemicin A with supportive calculations on $c \cdots d$ distances.

Koga and *Morokuma*[133] compared the energetics of the Bergman (enediyne) and Myers (enyne–allene) cyclizations and found that the enyne–allene reaction is more exothermic and is associated with a lower activation energy than the enediyne process, consistent with experimental data.

It is certain that these systems will stimulate many more theoretical studies in the years to come.

5. Concluding Remarks

With their unprecented molecular stuctures, fascinating mode of action, and phenomenal biological activities, the enediyne anticancer antibiotics have excited the creative im-

pulses and imagination of many researchers and thus established a vibrant field of investigations. Research in this rapidly evolving field spans areas from computational chemistry, molecular design, chemical synthesis, molecular recognition, DNA chemistry, and medicine.

Rarely before has a newly discovered class of natural products created such stimulation and excitement in chemistry, biology, and medicine as the enediynes. Equally rare is the beauty and fascination associated with the molecular architecture and mode of action of these naturally occurring substances. The opportunities they offer for challenging and creative scientific endeavors may be overshadowed only by their potential therapeutic and biotechnological applications. It is, therefore, not surprising that so much exciting science could be written in this first comprehensive review of the subject, even though the field is only about four years old. Judging from the present momentum driven by their promise as targets of opportunity, these structures are sure to occupy the minds of an increasing number of investigators in academia and industry. It is certain that shortly a number of these formidable synthetic targets will be conquered and that some of them or their analogs may even be in the hands of clinicians before too long. No doubt many more pages will be needed to cover the entire field a few years from now.

A comparison of the enediynes with the β-lactams, the macrolides, and the polyether antibiotics may well be appropriate. In terms of their chemistry, the enediynes compare well with the very best nature has shown us so far. With regard to medical applications, an affirmative prediction may seem at present too daring. But one should remember that fertile ground combined with persistent cultivation often bring forth a good harvest.

Finally, this topic serves as a reminder to us of the beauty of the natural products and their value in opening up new fields of investigation. Who can deny in this instance, nature's "pioneering" role in this area of research even though, in principle, man could have done it all! The molecules of nature are still serving as initiating sparks and guiding lights, which when followed with wisdom and modern ideas may result in highly satisfying and rewarding scientific endeavors. Natural products synthesis and related chemistry, when pursued wisely with the proper perspective and with the right blend of originality and imagination, will remain a valid and exciting practice for a long time to come.

Addendum (October 1, 1991)

After submission of the original manuscript several articles have appeared in the literature. These works are briefly mentioned below under the appropriate sections where they should be inserted.

Section 2.1.:

A review article on the mechanism of action of the neocarzinostatin chromophore has recently appeared.[134] The protein/chromophore complex of neocarzinostatin was examined by 2D-NMR spectroscopy.[135]

Section 2.2.:

A review article on all aspects of calicheamicins has recently appeared.[136] Hydrophobic interaction of calicheamicin γ_1^I with DNA has been suggested and studied using inorganic salts and temperature variations to probe the rate of DNA cleavage and binding.[137] DNA cleavage by esperamicins, calicheamicin γ_1^I, and DNase I has been compared showing that single strand action predominates in the case of esperamicin A_1 and DNase, whereas esperamicin C and calicheamicin γ_1^I operate mainly through double-strand cleavage.[138] The action of calicheamicin γ_1^I on the ataxia-telangiectasia derived cell lines has been studied.[139]

Section 2.3.:

Based on energy minimizations and molecular dynamics techniques, a model for dynemicin A has been proposed and and its absolute stereochemistry was deduced from this model [2*S*, 3*S*, 4*S*, 7*R*, 8*R*].[140]

Section 3.1.:

Seco dienediyne compounds related to the neocarzinostatin chromophore have been prepared via Pd(0)–Cu(I) mediated coupling reactions of bis(enoltriflate) intermediates with alkynes.[141, 142]

Section 3.2.:

A Cr(II)–Ni(II) mediated ring closure reaction was utilized to construct simple 10- and 11-membered ring enediynes.[143] A sulfur-containing 10-membered ring enediyne has been synthesized and studied.[144] An oxidative formation of an enediyne unit from a 1,5-diyne precursor demonstrating a new triggering device for the in situ generation of the enediyne moiety has been published.[145]

Section 3.3.:

Two new dynemicin A model systems have been reported.[146]

We wish to thank our many talented and motivated collaborators without the contributions of whom this article could not have been written: A. L. Smith, C.-K. Hwang, P. Maligres, G. Skokotas, S. V. Wendeborn, R. D. Groneberg, N. A. Stylianides, W. Stahl, E. P. Schreiner, S. Furuya, T. Miyazaki, G. Zuccarello, Y. Ogawa, K. Toshima, Y. Torisawa, J. Shin, E. De Leon, D. Rideout, H. Suemune, E. J. Schweiger, D. C. Nicolaou. We thank Janise Petrey for her speedy typing and patience, and Professors Reza Ghadiri, C.-H. Wong and Richard Lerner for useful discussions. Thanks are also due to Professors S. J. Danishefsky (Yale), P. Magnus (Texas) and D. Kahne (Princeton) for kindly providing us with some of their results prior to publication. In acknowledging financial support for the work described in this article we extend our gratitude and many thanks to the following: The National Institutes of Health (USA), the National Science Foundation (USA), Merck Sharp & Dohme (USA), Smith Kline Beecham (USA), Hoffmann-LaRoche (USA), Glaxo (USA), Lederle Laboratories (USA), Takeda Co. (Japan), Ono Pharmaceutical Co. (Japan), Sanraku Co. (Japan), Johnson & Johnson (USA), the Humboldt Foundation (FRG), the SERC-NATO (UK), and the Fonds der Chemischen Industrie (FRG).

Mechanisms of Molecular Recognition: Investigations of Organic Host–Guest Complexes

By Hans-Jörg Schneider*

Dedicated to Professor Michael Hanack on the occasion of his 60th birthday

Noncovalent interactions constitute the basis for information transfer between molecules in living systems as well as in synthetic supramolecular structures. Despite ever more accurate descriptions of biological systems and a dramatically increasing diversity of synthetic host–guest complexes, a systematic and general understanding of the underlying intermolecular forces is still in its infancy. Organic chemistry makes possible the targeted construction of infinitely variable host compounds with multiple centers interacting in complementary ways. This in turn opens the door to systematic experimental analyses based on binding increments, which can be shown to have a high degree of additivity. Even in the case of relatively simple ion pairs, several mechanisms are at work simultaneously, and either entropy or enthalpy contributions may prove to be decisive. Nevertheless, it is possible to identify individual interactions and then use them to practical advantage in ways analogous to the free-energy relationships of physical organic chemistry. Contributions due to solvophobic effects, to interactions with permanent and induced dipoles, and to hydrogen bonds lend themselves to a high degree of empirical quantification on the basis of classical physical-chemical principles. Water as a solvent plays a special role due to its low polarizability, apart from hydrophobic effects. Quantification of pairwise interactions and ultimate control over them through manipulation of the microenvironment should prove useful not only in the design of new synthetic host–guest complexes but also, for example, in the rational development of biologically active substances, molecular switches (e.g., for sensor technology), and catalysts that function analogously to enzymes. The results should also assist in the planning and analysis of biochemical experiments including techniques of genetic engineering.

1. Introduction, Goals, and Methods

The growing significance of supramolecular chemistry is already documented in a number of monographs,[1–20] with the early emphasis more on the complexation of inorganic ions.[17–19] For further orientation with respect to the vigorous development of this highly interdisciplinary subject the reader is referred to more recent review articles and the original literature.[21–76] Noncovalent interactions between host and guest molecules lie at the heart not only of synthetic supramolecular complexes but also much of biomimetic and biological chemistry too.[6, 7, 51, 77–93] Elucidation of these interactions is also the basis of promising new approaches in pharmacy, medicine, chemical analysis,[15, 55–58, 82, 86–93] and chromatography,[94] as well as catalysis[22b, 23a, 24, 28c, 29a, c, 35d, 75b, 95] and materials science.[55–58, 96] The principal advantage of synthetic host–guest chemistry is that it permits targeted construction of supramolecular complexes with infinitely variable noncovalent interactions arranged in conformationally defined ways. To analyze and to plan, for example, the genetically engineered exchange of amino acids in a protein is obviously a more difficult problem given the complexity and flexibility of typical biopolymers. With respect to interaction analyses in biological systems we cite only a few illustrative references.[81–84]

Despite the large (and exponentially increasing) number of known synthetic host–guest systems, systematic description of the underlying mechanisms has so far developed only to roughly the point reached by the mechanistic chemistry of covalent bonds decades ago. The goal of this overview is to classify as completely as possible the most important interactions found in organic host–guest complexes, and more particularly to quantify these interactions. Parameters that can be established in this way are applicable not only in a host of biological and industrial contexts (cf. Table 1), but also to the process of designing and synthesizing new supramolecular complexes with structures and energy contents that are predictable. Our methodology is aimed primarily at characterizing as far as possible pairwise interactions by targeted variation of the experimental systems. A model for this approach exists in the semiempirical methods of physical-organic chemistry, where analogous free-energy relationships play a major heuristic and practical role.

Table 1. A few potential applications arising from the studies of interaction mechanisms in organic host–guest complexes.

1) Synthetic planning for supramolecular complexes
2) Quantification for systems of biological or medicinal interest: enzymes, pharmacological receptors, immunoglobulins, antigen–antibody systems, nucleic acids
3) Genetic engineering/modification of proteins
4) Drug design
5) New analytical and diagnostic procedures
6) Selective phases for affinity chromatography
7) Development of molecular sensors, switches, etc.
8) Enzyme-analogous catalysis in water as solvent

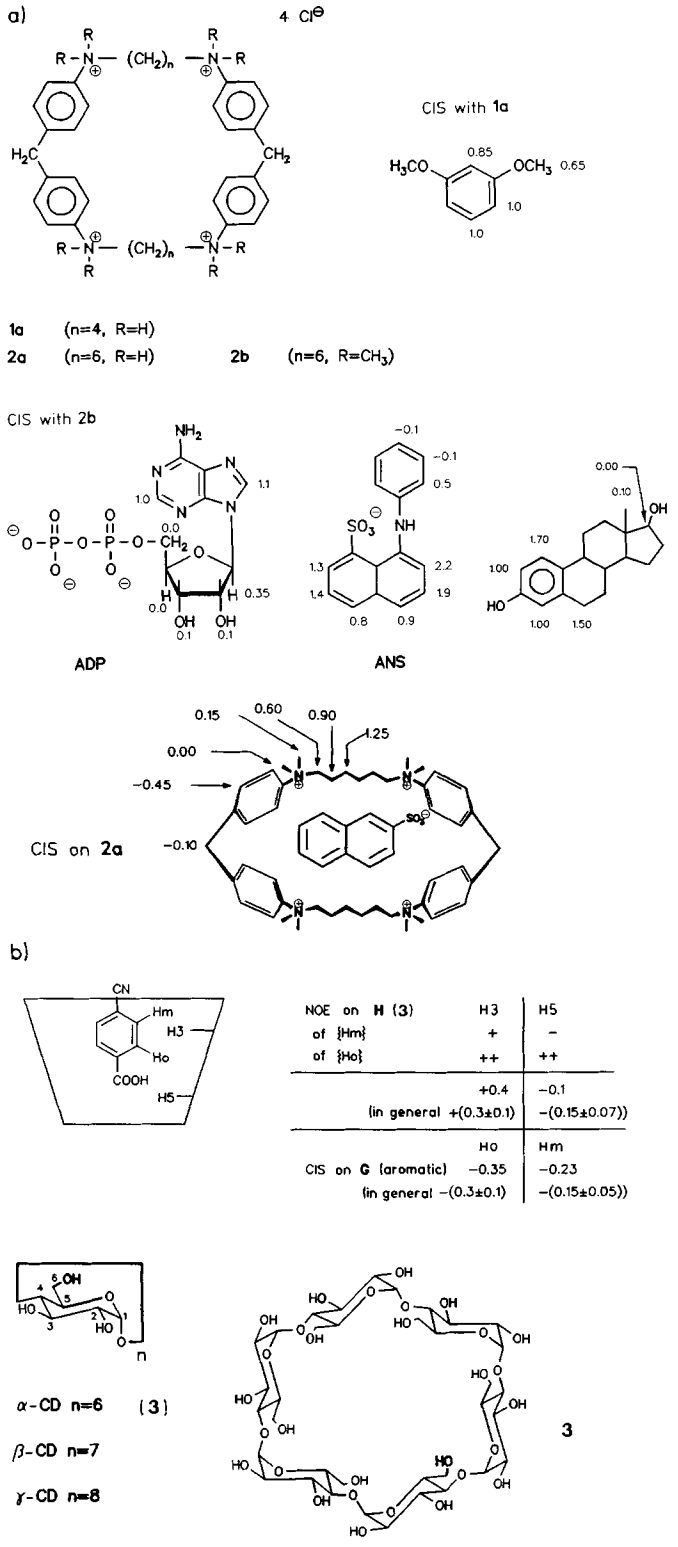
The physicochemical basis of intermolecular interactions is treated in a number of classical monographs;[97-100] nevertheless, exact description is possible, even today, only in the case of relatively small systems.[101, 102] Recent dramatic advances in computer technology and the application of semiempirical molecular-mechanics (MM) methods now offer the prospect of quantitative simulations of larger molecular systems as well, including biopolymers.[103-115] Especially in the case of relatively small metal complexes of crown ethers and cryptands,[112] satisfactory agreement already exists between calculated and experimental *structures*. Quite recently this has also come to be true for larger systems, in some cases ones containing organic substrates.[112-114] The introduction of molecular dynamics (MD) and Monte Carlo (MC) methods has led here to significant advances.[103-111] The application of statistical perturbation theory (SPT or FEP)[92b, 111a] makes it possible to calculate *changes in free energy* (ΔG) between similar states. Statistical mechanics is used here to provide a description of the substrate and receptor or the solvent separately, which then constitutes a reference state, and associations are treated as a perturbed state. This approach requires extensive calculation even for relatively small complexes, and comparisons should be restricted to similar molecules. On the basis of appropriate thermodynamic cycles, and with the inclusion of discretely describable solvent molecules and the free energy of desolvation of host and guest molecules (**H** and **G**), the method becomes applicable to systems in *solution*.

In this overview we limit ourselves to noting only a few of the—often overlooked—problems that arise during the simulation of complex molecules. The extremely high degree of freedom associated with multiparticle systems, even ones of limited size, imposes limitations with respect to the localization of optimal geometries in terms of energy minima, even if one is willing to devote massive amounts of computational effort to the problem.[116] For example, 262 discrete minima with ΔH differences $< 13\ kJ\,mol^{-1}$ were found for cycloheptadecane ($C_{17}H_{34}$),[116c] and a nine-membered lactam gave as many as 39 minima,[116d] 12 of them falling within only $< 13\ kJ\,mol^{-1}$ of each other. Equally serious—and often underestimated, even in comparisons between two simple conformations—are shortcomings in the potentials assigned to individual interactions, which constitute the basis for all such calculations. Thus, descriptions of electrostatic or van der Waals interactions are to some extent quite arbitrary (cf. Sections 5–7), and induction of di- or polypoles, without which the binding of aromatic substrates would often be impossible (cf. Section 7), is not taken into account by the force fields in use, particularly those available commercially. Such inductions are difficult to include in the calculations, in part due to the anisotropy of polarizability.[115] Different force fields sometimes lead to widely diverging energies even for the same structure;[114] for example, ΔH values computed for the *cis* and *trans* amide conformations in the above-mentioned lactam differ by more than $10\ kJ\,mol^{-1}$, depending on the method used.[116d] It is to be hoped that systematic measurements with organic host–guest complexes will contribute to some improvement and extension in the force-field potentials for noncovalent binding.

Results presented in this review relate primarily to host–guest complexes in solution, although the many analyses of corresponding crystal structures reported in conjunction with supramolecular solid-state chemistry[1a, b, 11, 25-27] naturally represent essential starting points with respect to the geometric boundary conditions for complex formation. The many *functions* of synthetic and biological supramolecular systems often require a dissolved or "mobile" state. Information regarding energy changes during complex formation or, for example, in allosteric phenomena (for molecular switches, etc.) is accessible in any event only from the solution state. Furthermore, a liquid medium is often required to establish a solvophobic driving force for association between host and guest molecules, and it opens the way to a large degree of control over the complexation process.

To obtain reliable results on host–guest complexes in solutions it is necessary to employ suitable methods of measurement. At this point we limit our comments to a few brief observations. Spectroscopic titrations[117] are preferable for establishing equilibrium constants and the corresponding values of ΔG. Compared to UV/VIS and fluorescence spectroscopy (which are also utilized),[117b] NMR methods offer the advantage of supplying several independent signals for the determination of a single constant K.[41b, 118] This often leads to the discovery that a particular solution actually contains more than simply one type of 1:1 complex, a conclusion that may be subject to verification by optical methods with data collected at several wavelengths.[117-119] Typical complexation constants tend to be smaller than those for biochemical systems, which limits the applicability of standard biochemical methods. In working with titration curves it is usually necessary that one first optimize the experimental conditions and then apply nonlinear curve-fitting techniques in order to obtain complexation constants and intrinsic spec-

Hans-Jörg Schneider was born in Stuttgart, Germany in 1935. He studied chemistry in Tübingen, Munich, and Berlin and received his Ph.D. under Michael Hanack at the Tübingen Institut Walter Hückels in 1967. After conducting postdoctoral research at the University of California, San Diego (1967–1969) he worked on his habilitation and other research until 1971 in the laboratory of Walter Hückel. In 1971 he completed his habilitation in Saarbrücken and since 1973 he has been Professor of Organic Chemistry at the Universität des Saarlandes. His areas of interest include: conformational analyses, quantitative structure–reactivity relationships for aliphatic compounds, including steroids, NMR spectroscopic methods with an emphasis on ^{13}C and ^{1}H NMR shielding parameters, selective functionalization of paraffins, and in the last few years supramolecular receptor and enzyme models.



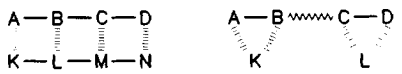
Scheme 1. Typical ^{1}H NMR CIS values in D_2O on complexation. (CIS > 0: upfield shift, CIS < 0: downfield shift). a) Complexation in azoniacyclophanes **1a**, **2a**, **2b**; b) complexation of 1,4-disubstituted aromatics in α-cyclodextrin **3**. NOE effects are indicated as + + (very strong), + (weaker), and − (absent). Hm = *meta*-H atoms and Ho = *ortho*-H atoms of the benzene ring, **H** = host, **G** = guest. ADP = adenosine diphosphate, ANS = 1-anilido-8-naphthylsulfonate, CD = cyclodextrin.

troscopic values x characteristic of the fully complexed system, a state that in most cases is not accessible experimentally.[41b, 117, 118] Scheme 1 includes a selection of typical NMR complexation-induced shifts (CIS values: + refers to upfield shifts, − to downfield shifts). Quantitative interpretation of such shifts requires explicit calculations, in particular of anisotropy and field effects.[43a, 120] These can only be parameterized on the basis of appropriate model investigations with geometrically fixed substrates such as steroids.[121] Spectral shifts can be analyzed with respect to both guest and host molecules, although the latter approach has often been neglected. CIS values obtained with curve-fitting methods (cf. Scheme 1) provide considerable information regarding whether (or to what extent) molecules **G** are actually complexed within an **H** cavity. Unfortunately, intermolecular NOE effects (NOE = *N*uclear *O*verhauser *E*nhancement) for organic host–guest systems at least in water usually fall between the positive NOE values (signal increases) for *intra*molecular interactions in smaller molecules and the numerically much larger negative NOEs of biopolymers.[122] Small NOE effects, caused by unfavorable relaxation times and by high magnetic fields, can be enhanced by application of such spin-lock techniques as ROESY,[122a] (ROESY = *R*otating frame nuclear *O*verhauser *E*ffect *S*pectroscop*y*) thereby permitting (with cyclodextrin complexes, for example) at least semiquantitative conclusions (Scheme 1). Taken together with CIS chemical shifts, these have led in the case of cyclodextrins to considerable modification of the lock-and-key principle.[43c, 119]

2. The Additivity of Noncovalent Binding Increments

Polytopic host compounds **H** and guest molecules **G** with multiple complementary centers A,B,C,... and K,L,M,..., respectively, for pairwise noncovalent binding A · · · K, B · · · L, etc., (Scheme 2) offer the important opportunity for

Scheme 2.



increasing to the nth power the effect of even weak individual interactions through incorporation of n such centers. The basis for this phenomenon is the additivity of the corresponding individual free energies [Eq. (1a)] and formation constants [Eq. (1b)] well known in inorganic coordination

$$\Delta G_{HG} = \Delta G_{AK} + \Delta G_{BL} + \Delta G_{CM} \cdots \quad (1a)$$

$$K_{HG} = K_{AK}\, K_{BL}\, K_{CM} \cdots \quad (1b)$$

chemistry as the "chelate effect". Incidentally, here no recourse to entropy arguments is necessary.[47] Organic substrates, too, are subject to the principle that multiple binding to natural or synthetic receptors leads to greater efficiency and selectivity in complexation. The familiar "lock-and-key" model of *Emil Fischer*, dealt with extensively elsewhere,[43c, 123] implies a close steric approach of the individual centers for optimal ΔG values. Conformational changes during the course of complexation can assist in the process ("induced fit"[124]) and can also result in allosteric systems, which are particularly interesting from a functional standpoint.

The use of host–guest systems containing at least two binding centers offers significant advantages in the experi-

mental determination of intrinsic interactions, which in turn facilitate the reverse process: predicting on the basis of Equations (1a) and (1b) previously unknown complexation strengths and selectivities. In addition to supplying an experimentally desirable increase in what might be an inconveniently small complexation constant in the presence of only one interaction, the incorporation of an additional center makes it possible to analyze the effects of that particular center more fully through systematic variation of substituents, assuming all other interactions and the solvent are left unchanged. In particular, this makes it easier to maintain a constant entropy effect. The reduction in translational freedom of **H** and **G** that accompanies formation of a complex **H** · **G** leads to a reduction in the entropy, with typical $T\Delta S$ values of 150 kJ mol^{-1}.[125] The entropy disadvantages accompanying the association of host and guest molecules with only one different interaction site can be kept quite similar, although rotatory degrees of freedom also influence complex formation.[125] With this strategy we in fact frequently observe a linear correlation between measured free energy of complexation ΔG_{HG} and the number n of analogous binding centers (see Sections 5–8). When this is the case, the slope of a best-fit line provides the intrinsic binding increment ΔG_i per interaction.

The principle of additive binding increments can be applied even in a case with only two centers, which makes it valuable for noncovalent interactions of a wide variety of types. It is important here to ensure that the primary interaction—the one held constant—is larger than the secondary interaction that is to be quantified on the basis of variation ($\Delta G_{AK} > \Delta G_{BL}$), in part to minimize possible entropy differences. The free energies of complexation ΔG_{HG} established for the azoniacyclophane **2b** with a series of substituted naphthalene derivatives (Scheme 3), for example, reveals a

	ΔG_{HG}
X = H, OH, NH_2	19
βX = $CO_2^{\ominus}$, $SO_3^{\ominus}$, $OPO_3H^{\ominus}$	22
αX = $CO_2^{\ominus}$	20
αX = $CH_2CO_2^{\ominus}$, $OPO_3H^{\ominus}$	22

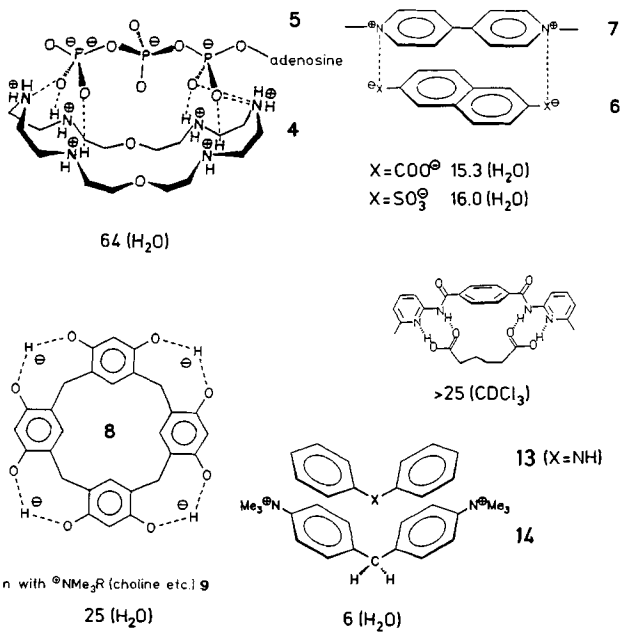
Scheme 3. Complexation of azoniacyclophane **2b** with naphthalene derivatives. ΔG_{HG} values in kJ mol^{-1}.

large contribution from the hydrocarbon residue that is held constant ($\Delta G_{AK} \approx 19$ kJ mol^{-1}), and for a variety of anionic substituents X at the β position a relatively constant electrostatic increment (cf. Section 5) of $\Delta\Delta G_{BL} \approx 3$ kJ mol^{-1}. These increments are significantly smaller for substituents in the α position ($\Delta\Delta G'_{BL} = 1-2$ kJ mol^{-1}); introduction of spacer elements (–O– or $-CH_2-$), however, leads to an increment similar to that observed for βX, since optimal contact is once again possible between $X^{\ominus}$ and the positively charged N atom of the receptor. This example illustrates a further prerequisite to the application of additive binding increments: the host–guest system must be so conceived that mutual disturbances of the individual interactions are minimized. Molecular-mechanics simulations can be helpful in controlling this factor, and permit, if necessary, numerical corrections for conformational strain energy changes.

The analysis of pairwise interactions led earlier already to the identification of specific types of interactions,[72] also in biologically significant complexes,[89–91] but it is subject particularly to influences related to differences between cavities (cf. Sections 4 and 8). Only the systematic application of constant binding increments under the conditions described above leads to comprehensive comparisons between experiment and prediction covering a large number of complexes of varying type. The value of this approach has already been demonstrated (cf. Sections 5–8) in the analysis of Coulombic interactions,[126] hydrogen bonding,[127] higher-order field (van der Waals) effects, and charge-transfer (CT) interactions,[128] the latter being mostly insignificant. The linear correlations that usually result are different from earlier Hammett correlations, as found, for example, by *Connors* et al.[129] for inclusion of phenyl derivatives in cyclodextrins. Here not only the substituents themselves but also the arenes whose π systems they modify participate in binding within the same cyclodextrin cavity. For this reason it becomes necessary also to introduce terms for molar refraction and dipole moments in order to obtain linear energy relationships.[129]

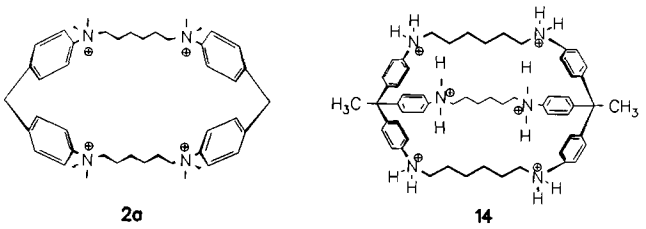
3. Receptor Structures: Open, Half-Open, and Closed

The examples[128, 130–133] in Scheme 4 show that multiplicative pairwise interactions can also lead to strong complexation at open, extended receptor surfaces. Contrary to



Scheme 4. Complexation on open, extended receptor surfaces. Numbers indicate ΔG_{HG} [kJ mol^{-1}] for the solvent given in parentheses.

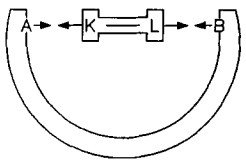
simplifying expectations,[42a] the provision of a more completely enclosed cavity does *not* necessarily lead to increased complex stability even in those cases where the interactions are primarily solvophobic. This is illustrated by a comparison of the monocyclic host compound **2a** with its bicyclic



2a + ANS $K = 2.0\times10^5\ M^{-1}$ **14** $K = 0.4\times10^5\ M^{-1}$

Scheme 5. Complexation of ANS (Scheme 1) in a mono- and a bicyclic receptor in D_2O at 300 K.

analogue **14**[134] (Scheme 5). What then are the prerequisites for increased effectiveness with concave or closed cavities? In addition to solvophobic effects (see below) it is important also to take into account the fact that spherical particles are subject, in a hemispherical cavity, to four times as much dispersive binding force (cf. Section 7) as on a planar surface, and that this factor increases to six with a cylindrical cavity and approximately eight with a fully encompassing spherical cavity.[135] Especially in the case of vectorially directed interactions (indicated by the arrows in Scheme 6) like those involved in hydrogen bonding, binding efficiencies are found to be particularly high when the binding is so arranged as to avoid linear attachment with parallel vectors, unlike, for example, the systems in Schemes 2 and 4. This principle underlies many of the so-called cleft-receptors[35h, 41c, 66b, 74, 136, 137] (Scheme 7), in which a convergent arrangement of binding centers at the same time hinders self-association of the host compound. Cavities that are more completely enclosed, as in the case of cyclodextrin **3** or many cyclophanes[28, 29, 33, 72, 118, 138] (Schemes 1 and 8), generally lead to significantly higher ΔG_{HG} values even in the absence of solvophobic forces, and with increasing encapsulation of the guest molecule the result may actually be immeasurably low levels of complex dissociation.[138]



Scheme 6. Vectoral interactions between substrate and the sites in the cavity of a hemispherical receptor.

The sections that follow introduce those host–guest complexes in which specific types of interaction mechanisms dominate. The treatment is intended to be illustrative rather than exhaustive.

4. Solvophobic Forces: Contributions from Both Enthalpy and Entropy

The most important host–guest interaction in aqueous solution consists of attraction between lipophilic regions in the host and guest molecules. The "classical"[79] hydrophobic effect[139, 140] is caused by a release of water molecules and a corresponding gain in entropy ΔS°. Prior to association of the lipophilic particles water solvates the particle surfaces in the form of highly organized solvation shells.[141] There can be no better example of the continuing state of uncertainty with respect to the physical principles that govern molecular recognition than the conflicting explanations offered for the behavior of lipophilic particles in water: in addition to (or

even in place of) the entropy factor already cited, claims are made for a purely enthalpic basis for the solvophobic effect (see below). In particular, some authors regard dispersive interactions (cf. Section 7) as entirely[142] or partially[143] sufficient to explain thermodynamic data obtained with noble gases or alkanes in water. On the other hand, even the most recent edition of a well-known monograph[139] on the hydrophobic effect barely mentions dispersive interactions. Without going further into the extensive and in some respects controversial literature on this subject,[79, 139, 140, 142] we note that in the case of complex formation with proteins[145] as well as, for example, cyclodextrins[146] in water, significantly positive ΔS° values have in fact frequently been observed—even overall losses in ΔH° (cf. Section 7). A further characteristic of such associations is a decrease in heat capacity ΔC_p,[143, 144] since the release of water of solvation leads to a reduction in the number of heat-absorbing bonds. One important consequence for supramolecular equilibria is that the corresponding $\Delta H^\circ/\Delta S^\circ$ values show significant dependence on the temperature, and like the changes in ΔCp such values can only be established by very precise measurements of equilibrium constants over a wide range of temperatures[147] or, better, by direct calorimetric studies.[146, 148]

The determination of individual thermodynamic parameters for organic host–guest complexes suffers from more than simply experimental difficulties (which are often underestimated!); interpretations are complicated further by the previously noted temperature dependency—including variable temperature coefficients for different interactions. Linear free-energy relationships (LFER) such as the Hammett correlation are subject to similar problems with respect to $\Delta H/\Delta S$ distinctions. For example, the observed pK values for substituted acids and bases owe their magnitudes at least as much to differences in entropy as in enthalpy. Despite this fact, it is the additivity of ΔG increments that is the basis of the practical success of LFER analyses. An analogous approach appears to be justified in the case of noncovalent binding, particularly since here there is also a tendency toward compensation between ΔH and ΔS;[146, 148b] a given molecular interaction frequently gives rise to enthalpy and entropy effects of the same sign, as for example with the solvophobic effect.

One model based on a gain in enthalpy ΔH° describes the solvophobic effect in terms of cohesive forces—usually hydrogen bonds—between solvent molecules, for which an experimental measure can be deduced from the surface tension.[149] The approach of two particles at a surface A, solvated before association by, for example, water, leads according to *Sinanoglu*[149] to a release of solvent molecules and creation of a single cavity in the water where before there were two. This in turn implies an increase in cohesive energy described by Equation (2)[149] where γ is the surface tension, M the number of solvent molecules per kg, and ϱ the solvent density.

$$\Delta H = 0.43\,\gamma A T^{-1} - 1.36\,M\varrho \qquad (2)$$

Investigations have already been carried out on the association of relatively nonpolar substrates as a function of solvent.[149, 150] Agreement in principle with this theory has been reported by *Diederich* et al.[151] for a large number of solvents ranging from water to benzene for the complex **19**, among others (Scheme 8). Thus, a roughly continuous increase is observed in the free energy of complexation ΔG_{HG} with the cohesive pressure of the solvent or the related Hildebrand–Scott parameter,[152] as well as with decreasing polarizability of the solvent. As is often observed with solvent effects, the best (linear) correlation of the ΔG_{HG} values for **19** was obtained with empirical parameters, in this particular case,[151] in fact, with the polarity factors E_T.[152a] It will continue to be necessary to use such empirical parameters as long as it remains impossible to carry out satisfactory calculations of, for example, even solvation enthalpies for simple halobenzenes, irrespective of whether one uses reaction field theory or the classical Kirkwood–Westheimer approach.[153]

What effect does *substrate structure* have on the magnitude of solvophobic effects? *Connors, Cohen* et al. found for associations between planar aromatic molecules an approximately linear relationship between ΔG_{HG} and the contact surface A linking **H** with **G**.[150a, b, 154] Even more definitive evidence of the dominance of cohesive forces in water comes from the slope of the observed linear correlation, which is reported to have a value of 64 dyn cm^{-1}, close to the macroscopic surface tension of water (72 dyn cm^{-1}).[154] The assumption that association is due almost entirely to desolvation of the individual particles (**H** and **G**) is supported by the absence of larger specific effects or dependence, for example, on whether the aromatic substrates are ionic or neutral: although there was considerable scatter, the value of ΔG_{cplx} for ca. 50 different association pairs appeared to be determined exclusively by the surface area A.[154] In the absence of substrate-specific solvation, therefore, the hydrophobic effect can be computed solely from the energy required to create a free surface of 1 Å^2 in water (γ = 72 mN m^{-1}); this amounts to 7.2×10^{-12} J or, after multiplication by Avogadro's number N, to 0.43 kJ Å^{-2}mol^{-1}.

Is there a specific effect dominated by hydrophobicity with respect to cavities? With the help of the host molecules **2b** and **12** shown in Scheme 9 it becomes possible for the first time to examine structurally equivalent receptors both in the presence and in the absence of cavities.[133] The results indi-

	2b		**12**
	ΔG_{HG}	$\Delta\Delta G$	ΔG_{HG}

	10.0	*7.3*	2.7

Scheme 9. Differences in the energy of complexation ΔG [kJ mol^{-1}] (in D_2O) between host compounds with cavities (**2b**) or without cavities (**12**). $\Delta\Delta G$ is on average 7.3 kJ mol^{-1}.

cate a surprisingly constant increase in ΔG_{HG} of $7 \pm 1\ kJ\,mol^{-1}$ for a wide variety of guest molecules **G** as a consequence of the cavity that is present only in **2b**. For the complexation of diiodomethane this value is significantly larger than the maximum increase $\Delta G_{HG} \leq 4\ kJ\,mol^{-1}$ that can be ascribed to total surface contact with the surface A through total inclusion of **G**. Simulations of the macrocyclic system **2b** in a water box with the aid of the CHARMm force field[108] suggest, as the possible cause of this special cavity effect, five water molecules located in or near the cavity (Fig. 1) that participate in an average of only two hydrogen bonds as opposed to the four typical for "free" water.[155] That a loss of water hydrogen bonds within a cavity might be a source of the hydrophobic effect gains support from crystal structure analyses of cyclodextrins[156] as well as peptides.[157] Dependence of the extent of the hydrophobic effect on the form of the cavity can lead to considerable divergence in comparisons of pairwise interactions[89-91] within biopolymers (cf. Section 8).

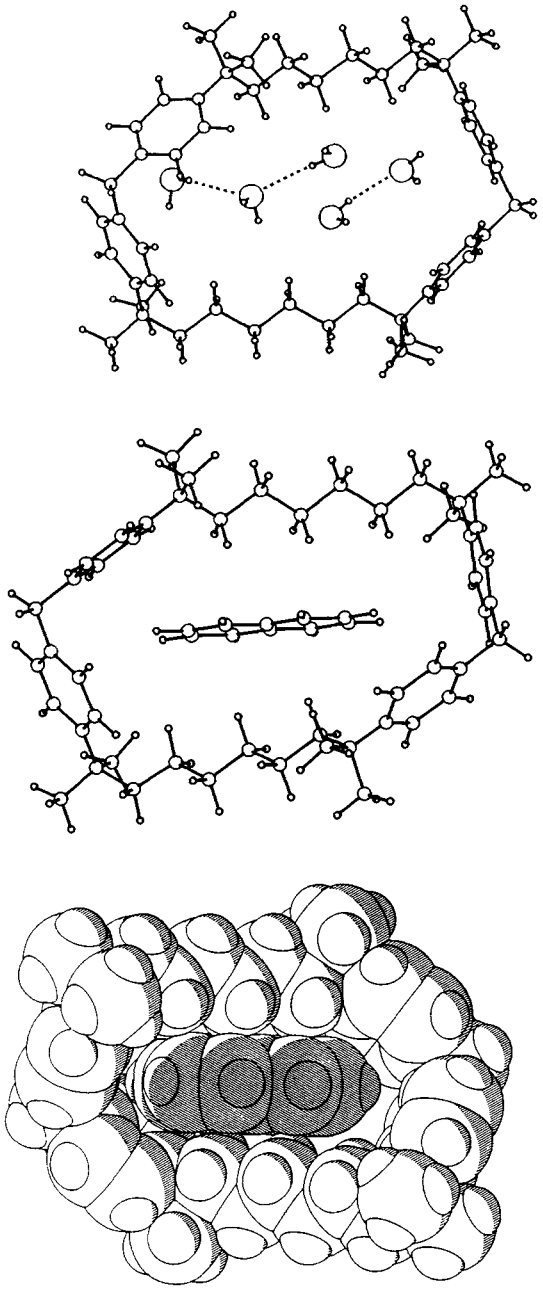

Fig. 1. Molecular graphics representation (CHARMm/QUANTA) of the azoniacyclophane **2b**; top: with 5 water molecules in or partially within the cavity; the (on average) two, rather than the normal four, hydrogen bonds are indicated by dotted lines [133]; for comparison (center and bottom): **2b** with naphthalene in its cavity.

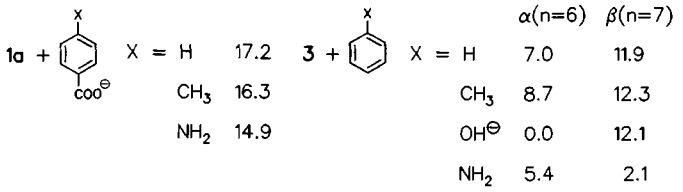
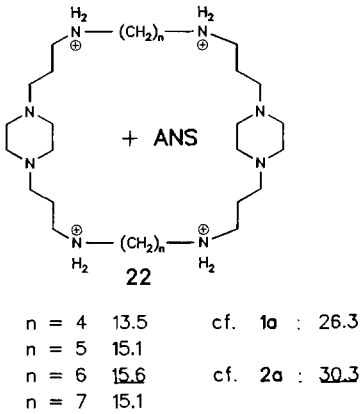


Scheme 10. Energies of complexation [$kJ\,mol^{-1}$] in H_2O or D_2O for the reaction of azoniocyclophane **1a** [158b] and of α-cyclodextrin **3** [159, 160] with arenes.

The limitations of a nonspecific model of cohesive solvent forces appear as soon as there are significant differences in the natures of the particles. Despite similar surface areas A and volumes, the various cyclophane[158] and cyclodextrin complexes[159, 160] in Scheme 10 display ΔG_{HG} values that differ markedly, sometimes opposing the anticipated trend. There is likewise no satisfactory correlation between stabilities of cyclodextrin complexes and either the water solubilities of the corresponding substrates or their distribution coefficients between water and lipophilic solvents,[129] as illustrated by a comparison of benzene derivatives (Scheme 10). These apparently substrate-specific interactions between **H** and **G** or between solvent and either **H** or **G** can be attributed largely to higher order electrical effects (cf. Section 7).

Despite cavities of geometrically similar size, complexes with **22**[161] (Scheme 11) are considerably weaker than those with **2a**. This means that desolvation of a cavity containing primarily hydrophilic N atoms requires especially large amounts of energy. Furthermore, bonding with cyclophanes can be affected by portions of the guest molecules **G** that extend beyond the cavities and are therefore unable to contribute to contact between **H** and **G**. This *extracavity* effect[162] is apparent, for example, in the regular increase in complexation constants K for **1a** in water from $K_{rel} =$



Scheme 11. Energy of complexation [$kJ\,mol^{-1}$] in H_2O for the reaction of the macrocycle **22** with ANS (see Scheme 1).

$1.0\ M^{-1}$ for benzene to $K_{rel} = 8.0\ M^{-1}$ for biphenyl.[162] Similar considerations apply to the association of steroids with **2b**, which bind more effectively than the corresponding tetralin derivatives.[163] Substituents like the phenyl group in the fluorescence dye ANS or the C- and D-rings in estradiol[163] definitely fall outside the cavity of **2b**, as shown not only by a study of models but also from observed NMR shifts (Scheme 1). The fact that such molecular fragments displaying no contact with the host can nonetheless cause complexation to increase by a factor of as much as ca. 30[162] is an indication of the important role played by entropy in the hydrophobic effect; it also illustrates the problems associated with the usual computer-generated geometric-fit predictions for host and guest molecules.

Better relative values for the extent of the hydrophobic contribution to ΔG_{HG} with various host–guest complexes can be anticipated from studying changes in ΔG_{HG} or K as a function of solvent composition, rather than relying solely on individual measurements in water.[150] The corresponding relationship (3)[118] is intended to characterize the sensitivity of contributions from hydrophobic interactions (in terms of the slope a), where S_p is an empirical parameter

$$\lg K_{HG} = a S_p + \lg K^\circ \qquad (3)$$

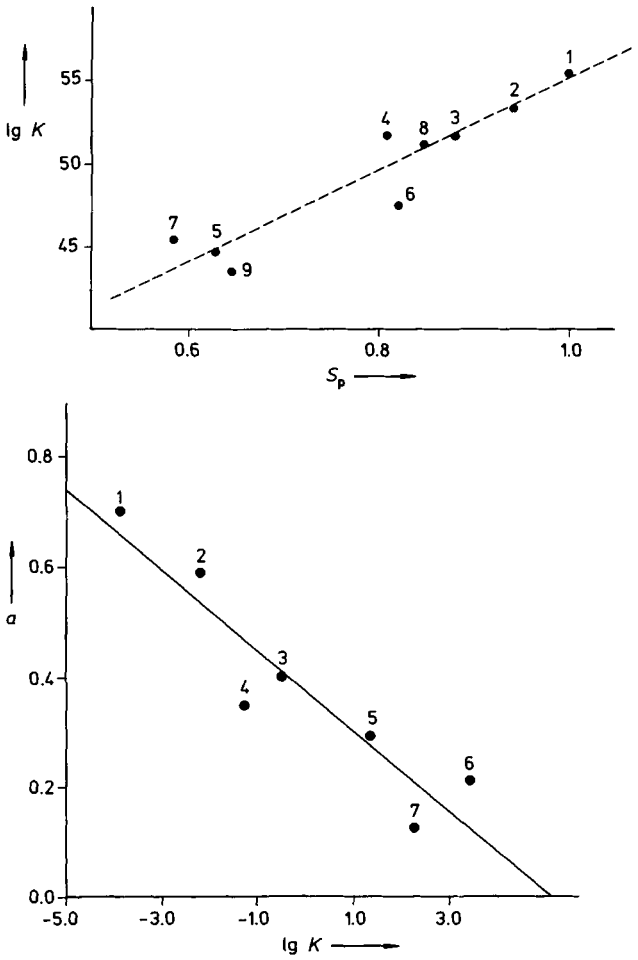


Fig. 2. Solvophobic effects on the association constants K; the numbers refer to complexes described in the literature, corresponding to Equation (3) [118]. Top: correlation for lg K vs. the solvophobicity parameter S_p for **2b** · ANS; bottom: correlation for the slope a (a measure of sensitivity) vs. lg K° (corresponding to complexation in hydrocarbon solvent, $S_p \equiv 0.0$).

describing the solvophobicity of the medium. Free energies of transfer ΔG_t for hydrocarbons for instance, from the gas phase into a particular medium[143a] and the related ΔG_t values from water to the same medium have been found on the basis of various investigations to constitute a suitable measure of S_p.[164, 127b] Using parameters ranging from $S_p \equiv 0.00$ for hexane as solvent to $S_p \equiv 1.00$ for water, we have obtained correlations with about ten complexes of **2b**, **3**, and **8** that are significantly more linear than with E_T parameters.[118] The slopes a provide a similarly satisfactory correlation with the intercepts lg K°, which correspond to extrapolations to the thus accessible complexation in a hexane medium (Fig. 2). As expected, complexes with **3** (cyclodextrin complexes), which have, for example, $a = 7.0$ and lg $K^\circ = -3.9$, represent one extreme, those with **8** (e.g., $a = 1.25$, lg $K^\circ = +2.3$) the other. The latter complex can in fact be described essentially as an ion pair (cf. Section 5).

While the solvophobic effects discussed above do increase the stability of supramolecular associations, they necessarily lead to a simultaneous reduction in the *selectivity* of interactions between host and guest molecules. Water as a medium brings about these entropic and/or cohesive hydrophobic effects largely through the desolvation of individual particles. At the same time, however, it also promotes complexation through induction of di- or polypoles as a result of its extremely low polarizability-forces that once again show relatively little directional character (cf. Sections 6 and 7). By contrast, highly directional and thus selective Coulombic effects, including hydrogen bonding (Sections 5 and 8), are *reduced* by water and other polar media, and *increased* by nonpolar media.

5. Electrostatic (Coulombic) Interactions with Permanent Charges

Electrostatic (ES) forces play a central role in molecular association not only with respect to inorganic systems but also in biological phenomena, for example in the case of nucleic acids and proteins. Such systems have been the subject of extensive investigation particularly by *Warshel*[109] and by *Williams* et al.[165] Electrostatic interactions have also been shown to provide a suitable basis for developing organic host–guest complexes that illustrate particularly efficient and straightforward approaches to molecular recognition. According to the Debye–Hückel theory in the classical point-charge model, the potential between two ions is a function of the separation r, the charge numbers z, the unit charge e_0, and the dielectric constant ε, which is assumed to be uniform [Eq. (4)]. The variable χ includes changes in the

$$\psi = z_i e_0 \frac{1}{\varepsilon r} e^{-\chi r} \qquad (4)$$

activity coefficient—and thus also the salt effect (see below)—by way of the ionic strength $I = \frac{1}{2}\sum c_i z_i^2$ [Eq. (5)].

$$\chi = \left[\frac{8\pi N e_0^2 \cdot I}{1000 \cdot \varepsilon k T} \sum c_i z_i^2\right]^{1/2} \qquad (5)$$

According to *Bjerrum* the association constant between spherical ions $A^{\oplus}$ and $B^{\oplus}$ can be described as a function of the charge product $z_A \cdot z_B$ and a mean effective distance a between $A^{\oplus}$ and $B^{\ominus}$, which in addition to z_A, z_B, and ε determines the magnitude of the factor $Q(b)$ [Eq. (6)]. For a

$$K = \frac{4\pi N}{1000}\left[\frac{|z_A z_B|}{\varepsilon k T}\right]^3 \cdot Q(b) \qquad (6)$$

mean separation a of 5–7 Å Equation (6) predicts a relatively linear dependence of $\lg K$ on $z_A z_B$, which is in agreement with experimental equilibrium constants for numerous inorganic complexes—for example, with $[A^{2\oplus}B^{2\oplus}]$ for which $z_A z_B = 4$, $K \approx 10^2\ M^{-1}$.[165] Associations involving different metal ions, such as $Ca^{2\oplus}$ and $Mg^{2\oplus}$, especially with complicated organic anions, show considerable deviations, however, and these can be explained only partially on the basis of known ionic radii.[165] Problems related to the selection of a mean ionic distance[165, 167e] are also encountered in the description of contact ion pairs according to *Fuoss*, *Eigen*, *Denison*, *Ramsey*, et al.[167] for which the simplified relationship of Equation (7) is applicable.[167a]

$$pK = -2.6 - 3\lg a - \frac{560|z_A z_B|}{a\varepsilon} \qquad (7)$$

Empirically determined stability constants K include the sum of the constants for contact (K_{CIP}) and solvent-separated (K_{SSIP}) ion pairs, which in some cases can be distinguished spectroscopically.[167a] Other limitations associated with the above-described models [Equations (4)–(7)] include neglect of specific interactions between ions and solvent molecules. Thermodynamic measurements reveal that ion-pair formation, especially in water, usually results in an increase in entropy and sometimes even in an unfavorable value of ΔH°.[167a] Similar to the situation with solvophobic effects (see above), association here is favored primarily by the release of highly ordered solvent molecules from solvation shells surrounding the separated ions. Other forces responsible for ion-pair formation include (in addition to the classical Coulombic interaction) those resulting from induced dipoles, especially with highly polarizable electron clouds.[167] Thorough analysis of ion association is further hampered by serious measurement and evaluation problems, for example with conductometric procedures. The result can be differences of 50–100% in experimental K values,[168a, 169] especially at high concentrations and in the presence of foreign salts.[168b]

In view of the difficulty of characterizing inorganic ion pairs, it is surprising to find that equilibrium constants for currently known organic ionic host–guest complexes turn out to be predictable on the basis of simple rules.[126a] With water as the solvent a plot of ΔG_{HG} versus the number n of possible ionic interactions or salt bridges results in a linear correlation [Fig. 3 and Eq. (8)]. The slope here corresponds

$$\Delta G_{HG(ES)}[kJ\,mol^{-1}] = (5 \pm 1)\,n \qquad (8)$$

roughly to the constant calculated according to Equation (6) or (7) for $a = 5$ to 7 Å,[165] for example in the region of $z_A = z_B = 2$, but is surprisingly independent of the sizes and

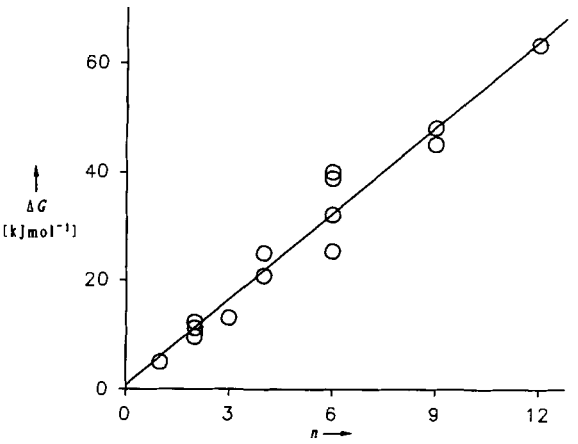

Fig. 3. Electrostatic interactions in ion pairs ($H^{x\oplus}G^{y\ominus}$); ΔG_{HG} vs. number of salt bridges n [Eq. (5)]; based on measurements in H_2O or D_2O at 300 K [126, 128].

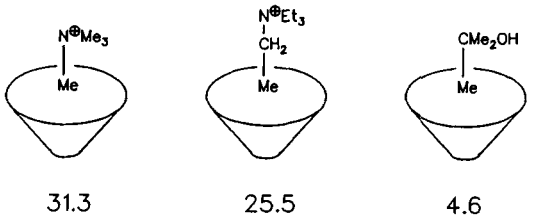
polarizabilities of the ions involved: the examples presented in Schemes 4 and 12 as well as Figure 3 include (among others) $R_2NH^{2\oplus}$, $R_4N^{\oplus}$, pyridinium-$N^{\oplus}$, $R_4P^{\oplus}$, $-COO^{\ominus}$, $-SO^{3\ominus}$, $-OPO(OH)O^{\ominus}$, $-OPOO_2^{2\ominus}$, and phenolate-$O^{\ominus}$. Organic ion pairs with flexible alkane chains, examined by *Tam* and *Williams*,[169] also fall into the linear correlation (Fig. 2), since contrary to the expectations of the authors[169] entropy effects do not result in deviations greater than the limits of experimental error. The fact that a regular difference of $\Delta G_{HG} = 3$ rather than 5 kJ mol^{-1} was observed in complexes of the azoniacyclophane **2b** with electrically neutral and anionic naphthalene derivatives (Scheme 3) can be explained by assuming that in these complexes the dominant hydrophobic contribution to binding is diminished by the hydrophilic anionic substituent X. The prerequisites to correlations on the basis of Equation (1) are that a) for the electrostatic part comparisons are made to electrically neutral partner molecules that are as nearly isosteric as possible (e.g., Me_3COH with $Me_4N_{\oplus}$ in **8**, Schemes 4 and 12), and b) that n will be limited to salt bridges, which are based on direct $A^{\oplus}/B^{\ominus}$ contacts.



Scheme 12. Energies of complexation ΔG_{HG} [kJ mol^{-1}] with host **8** in D_2O (cf. with choline: 30 kJ mol^{-1}).

For straightforward systems such as the ion pair **8** · $^{\oplus}NMe_3R$ ($R = H_3C(CH_2)_n$) (Scheme 12, left for $n = 0$) the expected decrease in ΔG_{HG} with distance r^{-1} for a simple Coulombic relationship [Eq. (9)] can be verified experimentally (Fig. 4). In this case the distance r between the charge centers $O^{\ominus}$ and $N^{\oplus}$ was established from model geometries.

$$\Delta G_{HG(ES)} = \frac{q_A q_B}{\varepsilon r} \qquad (9)$$

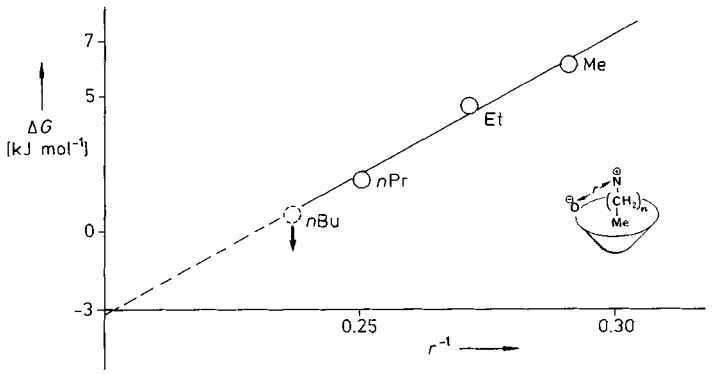


Fig. 4. Electrostatic interaction as a function of separation r in the ion-pair complex $\mathbf{8} \cdot {}^{\oplus}NR_4$ (R = $(CH_2)_nMe$) [131a] from data acquired in D_2O at 300 K.

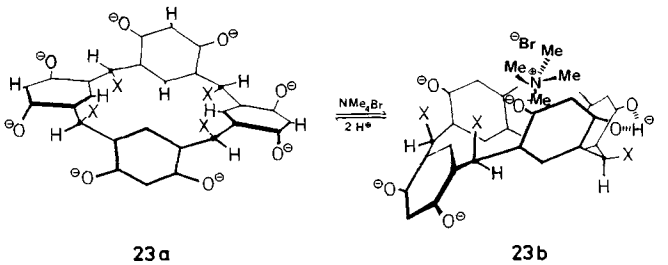
The slope of the line derived from experiments in water led to $\varepsilon = 30$, providing evidence that the concept is realistic.

Charge distribution within the ions, which in the case of alkylammonium ions, for example, implies considerable delocalization onto the C and H atoms, has little influence on the total Coulomb energy. This has been demonstrated by simulations with various point charges using MO calculations, as well as[128] by the observed relative lack of dependence of the empirical correlations in Equation (8) on the nature of the ionic groups.[126a]

The principle of multiple salt bridges between charges situated in a complementary way permits the construction of receptors like **4** or **8** (Scheme 4) that bind such species as $ATP^{4\ominus}$ ($K = 10^{11}\ M^{-1}$) or the singly charged choline ($K = 5 \times 10^{4}\ M^{-1}$). This approach can be exploited for both catalysis (as in the case of **4**)[23a, 130] and inhibition (with **8**)[170] in appropriate reactions of these substrates.

Allosteric systems containing the elements of a simple proton pump can be conceived provided 1) the creation of a charge (and therefore a salt bridge) through uptake or release of a proton can be controlled and is accompanied by conformational changes in the receptor caused by the corresponding salt bridges or hydrogen bonds, and 2) these conformational changes lead to association or dissociation of another guest molecule. The macrocyclic resorcinol derivative **23** (Scheme 13) features optimal conformational coupling between precisely such processes.[131a] Since only the half-open conformation **23b** is suitable for binding choline, for example, (more generally: any species $^{\oplus}NMeR^3$), addition of a substance like this to a solution of the corresponding octaphenolate (**23a**), the latter dominating for reasons of strain, leads to the creation of two hydrogen bonds in **23b** and to the uptake of two protons from the solution. In a reversal of the process, an increase in pH causes release of the positively charged guest molecule from complex **23b** into the solution. The phenomenon is completely reversible and can be characterized unambiguously by NMR spectroscopy as a result of the differing symmetries of the conformers.



23a 23b

Scheme 13.

What influence does the microenvironment exert upon the stability of organic ion pairs?[167] A decrease in solvent polarity causes a considerable increase in association constants due to the reduction in dielectric shielding: with tetraethylammonium bromide, for example, from $K \approx 10\ M^{-1}$ in methanol to $K \approx 1000\ M^{-1}$ in 2-butanone.[167f] The simple $1/\varepsilon$ (ε = dielectric constant) relationship predicted by Equations (4) through (7) is seldom observed, however, in part due to solvent-dependent changes in the effective ionic separation a as well as specific donor and acceptor characteristics of the solvent molecules.[167] On the other hand, salt effects do induce ΔG_{HG} changes that are predictable from Debye–Hückel Equations (4) and (5), even for complicated anisotropic complexes like those with **2b** or **8**.[118] The observed lg K values show a linear dependence on ionic strength consistent with Equation (5) and have slopes remarkably close to those calculated from the charge numbers z for isotropically spherical ions or cavities (Fig. 5). This is true even with

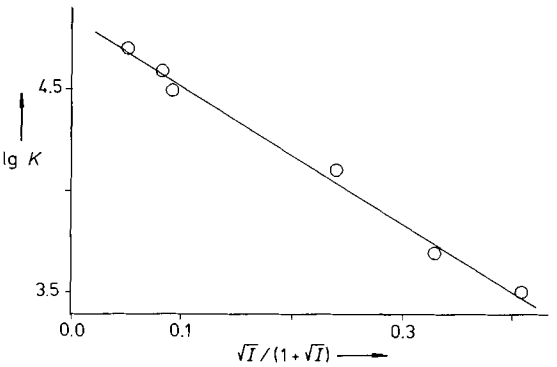


Fig. 5. Debye–Hückel plot of salt effects on the complex $\mathbf{8} \cdot {}^{\oplus}Et_4N$; slope: theoretical −4.07; observed −3.3. I = ionic strength [118].

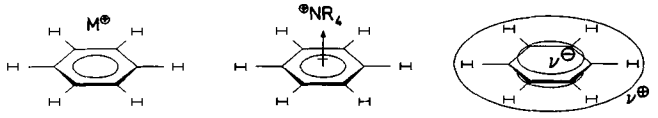
foreign salt concentrations up to 0.5 M provided the correspondingly modified Debye–Hückel equation is used. Specific salt effects outside these correlations arise if foreign salt ions associate selectively with the host compound. Thus, with 0.1 M glycine solution, which is often used as a buffer, reduction in the association constant by a factor of 70 is observed with **2b** · ANS (Scheme 1).[118] Consideration of the salt effect, especially when there are significant electrostatic contributions to the binding (under some circumstances even with complex titrations) is therefore required for the interpretation of supramolecular complexation constants. On the other hand, salt effects can make it possible to quantify ionic contributions to binding. In the presence of nonionic binding forces the effect of even high concentrations of foreign salts is quite limited.[166, 167a, c, f] For example, 1 M NaCl leads to only a 15% increase in the association constant for a cyclodextrin complex (**3** · *p*-nitrophenolate).[118]

Although the analysis of complex ion pairs in terms of additive salt-bridge increments appears straightforward, quantitative description of systems with *partial* charges and di- or polypoles has proven difficult, even with the aid of MC, MD, and, more recently, FEP methods[103-111] (cf. Section 1). The situation is complicated partly because of the underlying charge distribution. Treatment of the solvent as a dielectric continuum according to *Kirkwood* or *Tanford* is increasingly being displaced by an explicit consideration of discrete solvent molecules,[105, 106, 109, 111] and several suggestions have been made for reducing the degree of computational effort entailed.[171] The inherent difficulty of a theoretical approach for a secure assignment of significant noncovalent forces becomes apparent, for example, with cyclodextrin complexes,[48-50, 52, 53] which have been regarded as being dominated either by electrostatic[50, 172] or dispersive factors[173] (cf. Section 7). We limit ourselves here to a consideration of electrostatic interactions with aromatic rings in host–guest complexes.

The charge distribution in benzene is characterized by partial positive charges on the hydrogen atoms and partial negative charges on the carbon atoms, the latter residing primarily in the π system[174] (Scheme 14). This distribution has

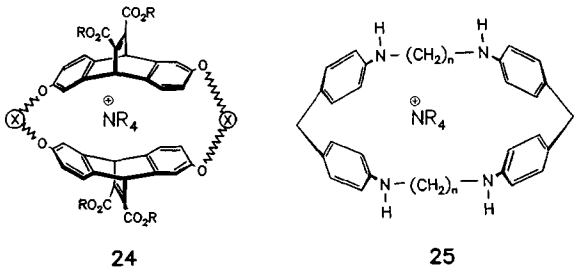


Scheme 14.

been quantified by means of various ab initio calculations[174, 175] and can be confirmed on the basis of the experimental quadrupole moment, whose direction lies in the C_6 symmetry axis z of the ring. The resulting Coulomb interactions are attractive for positively charged particles perpendicular to the plane of the ring and for negatively charged particles in the plane of the ring. Such interactions have been quantified[175, 176] with model calculations, and have also been measured, for example, for the association of potassium ion with benzene in the gas phase.[176a] Here again, entropy changes are responsible for much or all of the free energy of complexation.[176a] Model calculations[176a] for the energetically most favorable axial orientation of $K^{\oplus}$ over a benzene ring, once again using experimentally based parameters for charge and polarizability, reveal that interactions via induced dipoles (Section 6) play as large a role as Coulombic forces, and the role of dispersive forces (Section 7) is greater still.

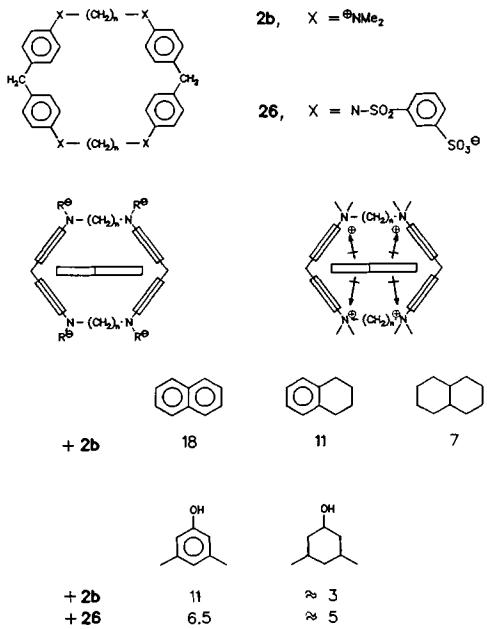
All known organic host–guest compounds with charges vis-a-vis π systems demonstrate, due to the polarizable solvents, much weaker complexation than in the previously described gas-phase associations.[176] They are nevertheless stabilized by both electrostatic and induced dipole interactions (see below). Positive *partial* charges are probably also capable of associating with the negatively charged π faces of arenes. The best-known example is the however still controversial "edge-to-face" dimer of benzene itself.[177] Because of their low charge content such complexes are significantly less stable even in the gas phase. For this reason no definitive examples yet exist of "edge-to-face" stabilization within host–guest complexes in solution. On the other hand, systematic analysis of crystal structures does reveal a statistically significant accumulation of preferred conformations of this type.[91] *Hunter, Sanders*, et al.[67] have predicted in the case of porphyrin complexes not only solid-state but also solution structures on the basis of simplified calculations of Coulombic energies. They emphasize that the inevitably repulsive π–π interactions between arenes in a centrosymmetric stack—a consequence, of course, of the known charge distribution (Scheme 14)[91, 174-176]—can be transformed into attractive interactions by geometric displacement of the ring planes, or through appropriate charge redistribution brought about by heteroatoms within the ring systems.

In supramolecular structures such as **2b** · naphthalene, **24**, and **25** (Scheme 15), ammonium ions are so situated with respect to the π systems that they experience electrostatic attraction and can at the same time induce dipoles in the arenes. Whereas in **24** (R = H)[68] it is possible to envision a



Scheme 15.

contribution from the potentially far-reaching Coulombic interaction[178] between the guest molecule and the external carboxylate group of the host, this cannot be the case with complexes such as **2b** · naphthalene or **25**. *Dougherty* et



Scheme 16. Energy of complexation ΔG_{HG} [kJ mol^{-1}] for the reaction of the macrocyclic hosts **2b** and **26** with arenes and completely or partially hydrogenated arenes.

al.[68] have established for complexes of the type **24** a dominant influence of special $N^{\oplus}\cdots\pi$ interactions through the observed increase in ΔG_{HG} with addition of supplementary arenes as spacers ⊗ in the host compounds, as well as by complexation of positively charged substrates with the neutral receptor **24** (R = CH_3) in chloroform rather than water as solvent.[179]

In contrast to the otherwise similar **2b**, cyclophane **26** (Scheme 16) possesses no $N^{\oplus}$ unit in its cavity. The cavity is thus considerably more lipophilic, despite which **26** is *less effective* at binding naphthalene in water than **2b** with its hydrophilic cavity![180a] Only with aliphatic guest molecules does lipophilicity lead to the anticipated reverse order.[180b] These results can only be explained through special $N^{\oplus}$–π interactions, the various ΔG_{HG} values for which (Scheme 16) permit estimation of an increment ($\Delta G_{N^{\oplus}/\pi}$) of about 2 kJ mol^{-1} as the cause of the interaction (in water). The relative contributions of the individual electrostatic and dipole-induced mechanisms to this interaction, however, need to be discussed further (Section 6).

6. Van der Waals Interactions: Induced Dipoles (IN Interactions)

The notion that complex stabilization through the interaction of charged particles is due largely to induction of dipoles in easily polarizable electron clouds is supported by more than empirically based calculations on gas-phase associations.[176] The azoniacyclophane **2b** in aqueous solution binds diiodomethane, but not dichloromethane (Scheme 17) even though the latter has a C–Hal dipole moment that is equally well suited to Coulombic attraction. Moreover, *negative* charges can also lead to attractions through dipole induction in π systems, as illustrated by **19b**[181] in Scheme 17. Observed NMR shifts indicate a geometry for the complex with **19a** similar to that of **19b**. In view of what are presumably repulsive electrostatic interactions in **19b** between X = $SO_3^{\ominus}$ and the π cloud the stability demonstrated by this complex is rather high, which together with the other observations supports the conclusion that the increments $\Delta G_{N^{\oplus}/\pi} \approx 2$ kJ mol^{-1} derived in Section 5 should be ascribed largely to induction of a dipole.

A similar increment for the interaction between charges and π systems emerges from the equilibria for association of di- and trications with corresponding di- and trianions containing varying numbers of benzene rings (for examples see Scheme 18).[128] The structures were selected in such a way that contact would always be possible between the cationic and anionic centers. Geometries were tested in some cases by molecular simulation with the CHARMm force field,[108] and the results agree qualitatively with observed NMR shieldings. Neglecting two complexes in which the conformational fits were inadequate, results obtained for nine ion pairs with various experimental techniques (NMR[128] and UV/VIS[128] spectroscopy, conductivity[168b]) showed not only the expected dependence of complex stability on the number *n* of salt bridges [Eq. (5)] but also a dependence on the number *m* of aromatic rings present in the ion pair. If one subtracts from the experimental ΔG_{HG} values the electrostatic increment $\Delta G_{ES} = 4.8$ kJ mol^{-1} per salt bridge *n* obtained by studying ion pairs lacking supplementary interactions (for example zinc sulfate, cf. Section 5), one then ob-

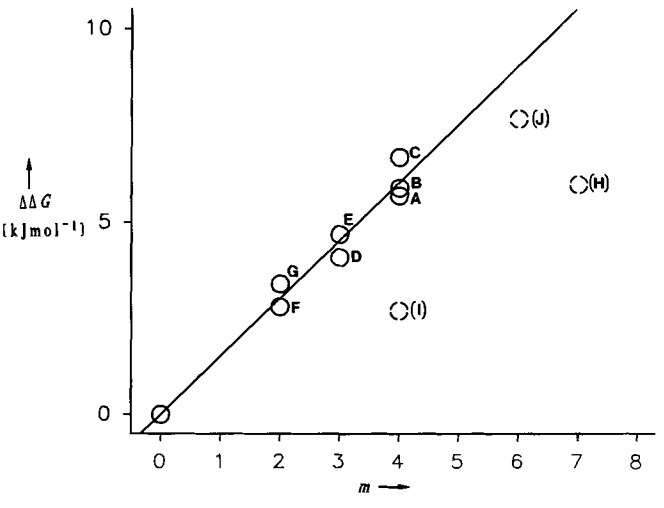

Fig. 6. Additional van der Waals interactions $\Delta\Delta G$ in aromatic ion-pair complexes (examples in Scheme 18) as a function of the number *m* of phenyl rings (based on measurements in H_2O/D_2O at 300 K, [128]); deviations in the case of *I*, *H*, *J* (not taken into account in the correlation): cf. text.

tains a linear correlation between the induced-dipole increment, $\Delta G_{IN} = (\Delta G_{HG(exp)} - 4.8n)$, and the number m (Figure 6).[128] The slope of the linear correlation that results from applying the principle of additive increments [Eq. (1)] corresponds to ca. 1.5 kJ mol^{-1} per arene, and it agrees once again reasonably well with the increments reported above even though these were obtained quite independently. The linear correlation implies that the small conformational shifts required for optimal attraction (i.e., shifts of the arenes relative to one another as well as to the available charges) are always achieved thanks to the flexibility of the complexes. This in turn explains why repulsive interactions such as those between centrosymmetrically arranged stacks of aromatic systems do not develop in supramolecular complexes, which are instead stablilized by a multitude of attractive interactions of the electrostatic and induced-dipole type.

Induced dipoles can also be identified as probable causes of the binding differences between different nucleosides and nucleotides in azoniacyclophanes such as **2b**, since complex stability increases with the polarizability of the nucleobase (Scheme 19).[181] Observed NMR shifts prove that, in con-

	A	G	U	C	T

Scheme 19. Energies of complexation ΔG_{HG} [kJ mol^{-1}] for nucleotides and nucleosides with **2b**.

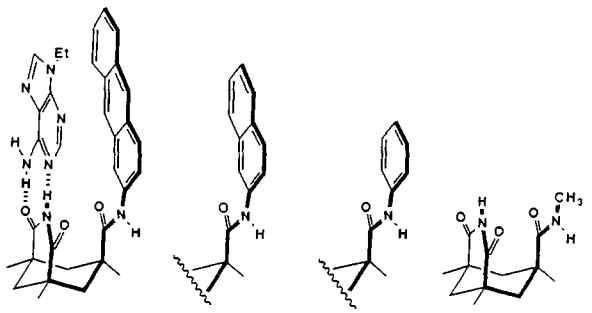
trast to the adenosine phosphate receptor **4** of *Lehn, Hosseini*, et al.,[23a] the nucleobases are bound by **2b** *within* the van der Waals cavity, whereas the hydrophilic sugar residues remain on the periphery of the cavity. It is remarkable in this context that the permethylated azoniacyclophane **2b** proves to be one of the strongest complexation agents of the polyamine type with respect to DNA, as shown by fluorescence titration with ethidium bromide as indicator.[181]

7. Van der Waals Interactions: Dispersive (DI) and Charge-Transfer (CT) Contributions; "Stacking"

Numerous studies of organic host–guest complexes make reference to electron donor–acceptor (EDA) interactions, although these actually represent nothing more than the sum of highly variable electrostatic (Coulombic and induced, Sections 5 and 6) and higher-order (e.g., dispersive and CT, see below) effects.[97, 182] Ab initio SCF calculations for simple EDA complexes suggest primarily electrostatic contributions in the case of "hard" Lewis acid–base complexes such as $H_3N \cdot BH_3$, but for "soft" combinations like $C_6H_6 \cdot Cl_2$ roughly comparable electrostatic, dispersive, and CT contributions. It should be noted that we are referring here to gas-phase calculations, and that partitioning of the energy is to some extent arbitrary.[182]

Charge-transfer (CT) complexes are stabilized by the transfer of electrons from high-lying occupied MOs into low-lying unoccupied MOs.[183] Increases in complexation constants have occasionally been observed as a result of alternating electron-withdrawing and electron-donating groups,[196] but these are presumably also due to electrostatic and induced-dipole contributions: even for the strongest CT complexes between 1,3,5-trinitrobenzene and, for example, hexamethylbenzene in CCl_4 solution ΔG_{HG} is only 4.6 kJ mol^{-1}, and with toluene in fact -2 kJ mol^{-1}[183]—that is to say, a negligible effect, especially in polar solvents. Complexation constants for various arene-containing ionic associations (Scheme 18) are subject to correlation *without* reference to CT contributions simply on the basis of electrostatic and induced-dipole increments (cf. Fig. 6), although the complexes, for example, with the unusually electron-poor species methylviologen (Scheme 4) do show typical CT bands in their electronic spectra.[128]

The π–π or "stacking" complexes are subject to stabilization from the three sources, namely electrostatic, induced dipole, and dispersive contributions, in addition to solvophobic effects. Various complexes with a face-to-face arrangement between host and guest—stable even in lipophilic media—have recently been described [Scheme 7 compound **17** and Scheme 8 compound **20**]. They suggest that there may be an increase in ΔG_{HG} with increasing surface of the π system, a significant observation with respect to DNA intercalations as well. The hydrogen bonds in *Rebek*'s complexes[35h] (Scheme 20) function in the sense of Equation (1) as a fixed interaction; each benzene unit then supplies a reasonably constant binding increment of $\Delta G_{\pi/\pi} = 1.8$ kJ mol^{-1}.



K	440	220	100	50
$\Delta\Delta G_{HG}$		1.72	1.96	1.72

Scheme 20. Complexation constants K [M^{-1}] and $\Delta\Delta G_{HG}$ values [kJ mol^{-1}] in $CDCl_3$ for associations of the derivatives of *Rebek*'s tricarbonic acids and 9-ethyladenine [35h].

Dispersive or London–Eisenschitz interactions result from attraction between fluctuating transient dipoles that also develop in nonpolar bonds. The dependence of such interactions upon the actual separation r relative to the van der Waals distance r_0 is usually given by the Lennard-Jones potential [Eq. (10a)] or the Buckingham equation [Eq. (10b)].

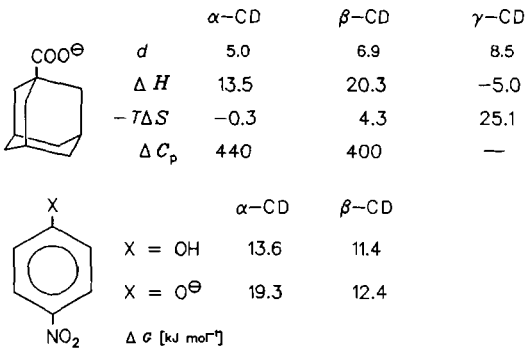
$$V = C\left[\left(\frac{r_0}{r}\right)^{12} - 2\left(\frac{r_0}{r}\right)^{6}\right] \quad (10a)$$

$$V = Ce^{-112.5\,r_0/r} - C'\left(\frac{r_0}{r}\right)^{6} \quad (10b)$$

The first terms in these equations represent repulsion due to approach closer than the distance r_0; the applicable constants (C and C') can be derived from polarizability parameters among other sources. The extent of the calculated gas-phase interaction between two relatively nonpolarizable C–H bonds amounts to only ca. 0.2 kcal mol^{-1} even at the optimal distance, but the cumulation in the case of organic molecules as a result of the large number of bonds present leads, for example, to 25 kJ mol^{-1} in the case of two *n*-hexane chains. Determinations of transfer energies for linear alkanes from the gas phase into water give average values $\Delta H = 1.5$ and $T\Delta S = 0.5$ kJ mol^{-1} for the hydrophobic contribution per CH_2 group, whereas CH_3 groups make equivalent contributions (1.4 kJ mol^{-1}) to both the enthalpy and the entropy terms. Despite their sometimes high ΔG values, dispersive forces contribute only slightly to *selectivity* in molecular recognition. Potentials (10a) and (10b) require only a single—though narrowly defined—contact distance between **H** and **G**, and are much less orientation-dependent than the other intermolecular forces discussed previously.

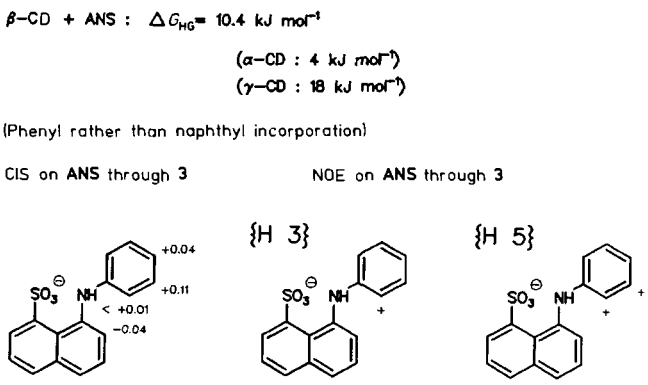
Intermolecular London–Eisenschitz interactions are not reduced as much in water as they are in organic solvents, which are much more polarizable. Complex formation with the cryptophanes of *Collet* et al.[33] is therefore observed only when the lipophilic solvent molecule is chosen so large that it cannot enter the cavity. The cleft compound **17** described by *Zimmerman* et al.[74] represents one of the rare examples to date of purely hydrophobic π–π complex formation in chloroform despite the fact that the cavity in this case permits the entry of solvent molecules.[74, 111c] Nevertheless, association is limited to species like tetranitrofluorenone, which is both polar and polarizable; with the less polar and polarizable adenine complexation requires the presence of a supplementary hydrogen bond:[74a] introduction of a carboxyl group into receptor **17** causes adenine binding in chloroform with the remarkably high complexation energy of 24 kJ mol^{-1}.[74a] A simple carboxylic acid function adds only $\Delta G_{HG} = 7$ kJ mol^{-1}, so the net gain in stacking energy for adenine is 17 kJ mol^{-1}, a value in good agreement with calculations based on perturbation theory.[111c]

Dispersive forces between **H** and **G** generally play a significant role only in aqueous medium due to the low polarizability of water. At the same time, these become difficult to distinguish from solvophobic effects (cf. Section 4). The literature on cyclodextrin complexes is almost impossible to summarize, but an attempt will nonetheless be made to demonstrate on the basis of a few examples the ways in which binding mechanisms can be distinguished in aqueous solution. Calorimetric measurements[185] suggest negligibly small entropy contributions for the complexes of α- and β-cyclodextrin (**3** and **4** respectively) with adamantane-1-carboxylate.[185a] In contrast to these results, association with γ-cyclodextrin (**5**) is favorable only because of entropy factors, (ΔH is in fact unfavorable; Scheme 21), since here the large size of the cavity relative to the α and β compounds makes it unsuitable for effective dispersive forces. Similar conclusions can be drawn from equilibrium studies with *p*-nitrophenol and its anion[159, 186] (Scheme 21); anion formation, with the resulting accumulation of a highly polarizable charge, is considerably more advantageous with the narrower α-cyclodextrin cavity, since here dispersive forces



Scheme 21. Energy of complexation [kJ mol^{-1}] and change in heat capacity ΔC_p [J mol^{-1}K^{-1}] in H_2O or D_2O for the complexation of cyclodextrins **2**, **3**, and **4** (α-, β-, and γ-CD respectively) with adamantane-1-carboxylate and nitrobenzene derivatives, from calorimetric measurements [185a].

which require a close contact predominate. These experiments show that at least two different mechanisms govern the formation of cyclodextrin complexes, but they do not allow secure predictions as to which cavity will be most effective for the complexation of a particular substrate. Competition experiments with guest molecules containing simultaneously larger and smaller residues (e.g. naphthyl and phenyl; cf. Scheme 22) show by NMR shifts and NOEs that, in general, binding within larger cavities is preferred over binding in those cavities that offer the best fit. This is consis-

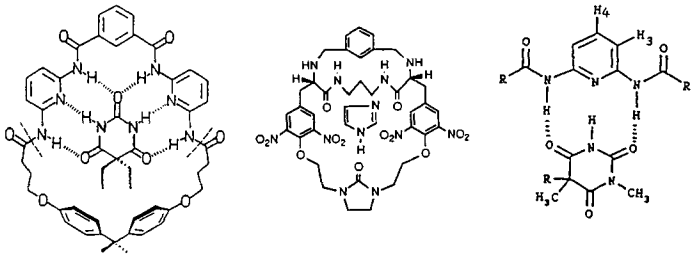


Scheme 22. **3** = α-CD.

tent with the observation that many monosubstituted benzene derivatives associate more strongly with β- than with α-cyclodextrin[159] (Scheme 10).

8. Hydrogen Bonds

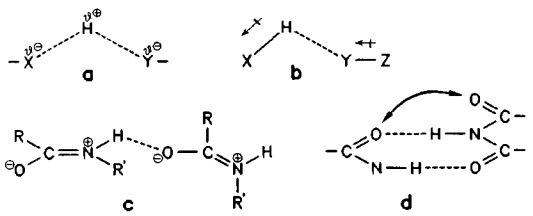
Similarly to EDA complexes, hydrogen-bonded associations[187] involve the participation of at least three interaction mechanisms: electrostatic (Coulombic), dispersive, and charge-transfer. The predominant role of Coulombic forces has become increasingly apparent through quantum-chemical calculations utilizing larger basis sets, and it is supported by experimental evidence of a stability dependence for appropriate complexation systems on the acidity of the donor X–H and the basicity of the acceptor Y.[189] For this reason, structures and energies of such complexes (Schemes 23 and



27 28 29

Scheme 23. Host–guest complexes with hydrogen bonds (see also **15** in Scheme 7).

24) are most often calculated on the basis of Coulomb potentials. Interactions of this type are relatively insensitive to changes in charge separation distance (cf. Section 5), but the central role of positively charged hydrogen leads to the highest directional specificity of all the interactions, as demonstrated by calculations based either on point charges (Scheme 24, model **a**) or on the presence of two dipoles (Scheme 24, model **b**). A significant factor in this directional specificity is anisotropy in the charge distribution at typical acceptor atoms Y (e.g., for lone pairs), a factor that is neglected in most force fields.



Scheme 24.

Due to their charge distributions, carboxylic acid amides are predestined for hydrogen bonding (Scheme 24). Such bonds dominate therefore not only in proteins[91] but also in the most successful known cases of selective binding in organic host–guest complexes. The groups of *Rebek*,[35] *Hamilton*,[39] and *Still*[76] (Schemes 4, 23) have been especially active in designing systems containing multiple complementary hydrogen donor–acceptor sites, which are also well suited for chiral recognition. The strength of a simple amide hydrogen bond[190] was until now derived, for example, from measurements with *N*-methylacetamide in carbon tetrachloride, with results that varied between 4[190b] and 7 kJ mol^{-1}[190c] depending upon the method. The principle of additive binding increments [Eq. (1)] makes it possible to establish a more reliable ΔG value,[127] one that is free of the problems associated with the stoichiometry and geometry of simple dimers.[190b,c] A plot of a large number of literature values for ΔG_{HG} determined in chloroform versus the number n of possible hydrogen bonds in each case leads to a straight line (Fig. 7), the slope of which provides the increment $\Delta G_{HB} = 5 \pm 1$ kJ mol^{-1}.[127a] The solvent chloroform itself associates with amides ($K \approx 1$ M^{-1}[190a]); therefore, experiments were also conducted in CCl_4 and carried out with reference to self-association using the simpler model **29** (Scheme 23), leading to an increment $\Delta G_{HB} \approx 10$ kJ mol^{-1}.[127] Addition of methanol leads in the case of **29** to a linear decrease in complexation, and with only 10% (v + v) CH_3OH in CCl_4 the complexation constants are reduced by a factor of about 100.[127b] In the presence of the even more efficient hydrogen-bonding component water only an extremely strong acid–base pair such as $FH\cdots F^{\ominus}$ ($K = 4$ M^{-1})[187,189] forms complexes of this type; there is a total absence of complexation under aqueous conditions in the case of amides.[79,111a,187] Were it not for supplemental contributions toward association from the entropy,[79,84] peptide fragments would be capable of forming hydrogen bonds only in the hydrophobic interiors of proteins. Possible interferences due to polar or polarizable amino acids, as well as cavity-dependent solvophobic effects, can lead here to variable incremental values per hydrogen bond. For this reason pairwise interactions determined experimentally with peptides and proteins vary between ca. 2[91,191] and ca. 20 kJ mol^{-1}[90c] per amide bridge!

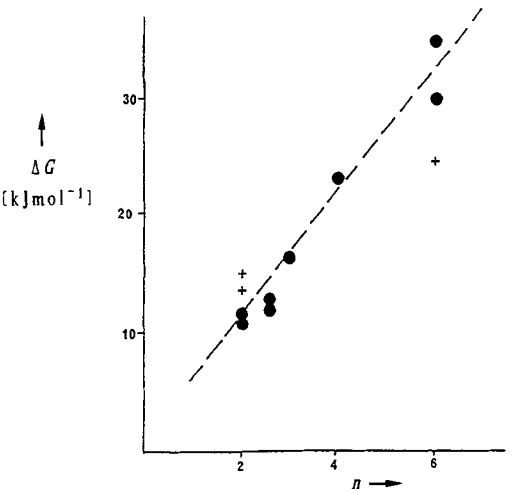


Fig. 7. Complexation energies ΔG for compounds containing the structure R–CONHR′– (mostly amides) in $CDCl_3$ as a function of the number n of hydrogen bonds [127]. The compounds indicated on the graph as + show additional stabilization through stacking or destabilization through entropy losses.

Linear correlation of ΔG_{HG} with n (Fig. 7) ignores such positive secondary interactions as the stacking effects that result from the presence of additional π systems,[35] as well as negative factors accompanying unusually large losses in entropy.[39] *Rebek* et al.[192] recently observed systematically higher association values for amide–amide and lactam–lactam bridges relative to imide–imide or imide–lactam bridges. Destabilization of the latter by about 1.5 kJ mol^{-1} (in $CDCl_3$) can be interpreted in terms of electrostatic repulsion by the additional carbonyl groups present in the imides (cf. **d** in Scheme 24) and can be reproduced quantitatively by MC–FEP calculations.[193]

In the case of interactions in nucleic acids, the distinction between Watson–Crick and Hoogsteen base pairs is of particular significance.[194] *Rebek* et al.[35h] have succeeded in demonstrating with the adenine receptors not only the Watson–Crick pairing illustrated in Scheme 20, but also (by varying the arenes involved in stacking in the host com-

pound) Hoogsteen complexation, as well as the simultaneous presence of both types of interaction with the cleft compound **15** (Scheme 7). Model systems of this sort should make it possible to achieve a clearer understanding of the distortion of the DNA double helix caused by intercalated substances, and eventually permit its exploitation for medicinal purposes.[195]

9. Conclusions and Prospects

The systematic investigation of organic host–guest compounds in solution permits positive identification of important noncovalent interactions. Departing from the crystalline state does have its price, however: one must be content with imprecise descriptions of aggregates equilibrating in solution. Similarly, the advantages connected with studying complicated associations in solution instead of simple complexes in the gas phase come at the expense of precise statements on the relevant mechanisms and their energy contributions (cf. Table 2). Even inorganic ion pairs, and even more so organic substrate–receptor complexes, owe their existence to a multitude of noncovalent forces; in solution it is the entropy term that often proves decisive. Nevertheless, synthetic complexes allow extensive and planned variation of functionalities and shape in controlled conformations, and are in principle better suited for the isolation and manipulation of individual mechanisms than biological systems. As in classical physical-organic chemistry, systematic variation of host and guest structures and their microenvironments in solution permits the identification of generalizable parameters that can subsequently be applied to problems of even greater complexity. The increments listed in Table 2 can be of assistance in the design of new supramolecular complexes, allowing one to make quantitative predictions on behavior, on the basis, for example, of salt bridges and hydrogen bonds between subunits and reflecting, at least in principle, infinite variability with respect to stability and function.

One important group of complexes has so far been ignored in this overview even though it represents a subject of increasing importance. The combination of metals with organic ligands has led not only to fascinating template-synthesis strategies[37, 70]—with promising technical, analytical, and pharmaceutical implications—but also to the construction, for example, of a fully synthetic double helix.[23f] Conformational coupling of metallic binding centers[196] with other

Table 2. Typical intermolecular interactions [a] in organic host–guest complexes.

Type		Geometric factor	Example	Medium	Typical ΔG_{HG} [kJ mol^{-1}]	Ref.

centers opens the way to the formation of allosteric systems possessing more effective cooperativity than that found in proteins. For example, we have recently synthesized various receptors containing coordination centers for transition-metal ions in the form of ethylene diamine or amino acid units in conjunction with a second lipophilic or polar binding center (Scheme 25, **30**–**32**).[197] System **30** displays the greatest degree of positive cooperativity between a polar and a lipophilic center yet recorded (Scheme 26),[197a] whereas **31** is characterized by somewhat less pronounced negative cooperativity, releasing a second ionically bound substrate upon binding, for example, a cadmium ion.[197c]

Finally, we touch upon the question of which of the interactions discussed will play a key role in the development of enzyme-analogous catalysts. In principle all of the mechanisms are capable of assisting in stabilization not only of the essential binary or ternary complexes but also of transition states for the reactions subject to catalysis, with multiple interactions again potentiating the efficiency consistent with Equation (1). It must be noted, however, that higher-order

interactions (Section 7) demand a particularly precise geometrical fit between catalyst and substrate due to the rapid decline of such forces with increasing intermolecular separation r (cf. Table 2). A close fit is especially difficult to achieve in the stabilization of short-lived transition states. Nature alone has succeeded in meeting this challenge through millions of years of evolution, taking advantage of cooperative interactions of all the various mechanisms. In particular, electrostatic interactions with their extremely long-range character are especially promising in the development of synthetic enzyme-analogous systems, which should also be suitable for more than just one specific substrate.

Our work in Saarbrücken was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and in part by the Volkswagen-Stiftung. I am particularly grateful for the efforts of all the co-workers cited in our publications. They have not only learned to apply, both intellectually and in practice, a wide diversity of methods, but in the course of overcoming a multitude of synthetic problems they have also provided the prerequisites without which the actual experiments and their subsequent interpretation would have been impossible.

Protease-Catalyzed Kinetically Controlled Peptide Synthesis

By Volker Schellenberger and Hans-Dieter Jakubke*

In spite of the enormous progress in the synthesis of peptides and proteins using commercial peptide synthesizers and the immense technological possibilities of recombinant DNA technology, a C-N ligase is an indispensable tool for the racemization-free fragment condensation of peptides. Since activation of the C-terminal α-carboxyl group of a peptide segment could cause partial racemization, chemical condensations of peptide fragments are prone to racemization. For the synthesis of the huge number of peptides and proteins, however, nature has only developed the ribosomal peptidyltransferase, which exhibits its full catalytic function independent of the side-chain functions of the amino acids being coupled. However, its function requires coordination with numerous other ribosomal factors. Besides the limited possibilities of using multienzyme complexes of bacterial peptide synthesis systems, the only alternatives to peptidyltransferase are proteases, which, based on their in vivo function as hydrolases, cannot act as ideal ligases. However, by exploiting the intrinsic reversibility of hydrolytic reactions and by adjusting appropriate physicochemical reaction parameters, the protease acitivity can be used in the direction of ligation. Undoubtedly, the course of kinetically controlled, serine and cysteine protease-catalyzed reactions can be more efficiently influenced than the equilibrium-controlled protease-catalyzed synthesis. This article describes the influence of the enzyme specificity on the efficiency of kinetically controlled synthesis and points the way toward a broad exploitation of serine and cysteine proteases for the catalysis of C–N bond formation.

1. Introduction

In principle, the use of enzymes for peptide bond formation offers great advantages over chemical procedures. Thus, because of the regiospecificity of enzymes, the reversible protection of side-chain functions of the amino acid building blocks is not necessary. The mild reaction conditions of the enzyme-catalyzed reactions guarantee racemization-free syntheses. Owing to the stereospecificity of enzymes, chirally homogeneous products are obtained even when racemic N-protected amino acid derivatives are used as starting material.

A prerequisite, however, is a C-N ligase which can be simply handled like a coupling reagent to form a peptide bond. Since such an ideal ligase is not available, even the proponents of this strategy do not regard the enzymatic approach as a real alternative to chemical procedures in peptide synthesis. There are, however, a number of convincing arguments which vigorously support the necessity for further basic research to find other—although certainly not so favorable—enzymes.

In spite of the high efficiency of the now virtually automatic solid-phase peptide synthesis and the development of coupling reagents that do not cause racemization in model syntheses, the high optical purity required of pharmaceutical products cannot be guaranteed by this approach. In particular, the danger of racemization is strongly dependent on the amino acid sequence adjacent to the residues undergoing peptide bond formation. Therefore, the standard racemization tests do not possess general validity. Chemical fragment condensations are specially at risk.[1] In the stepwise solid-phase synthesis using urethane-type protecting groups, moreover, the danger of partial racemization cannot be excluded and is often revealed by employing increasingly sensitive analytical methods.

The use of enzymes is above all necessary for (1) the coupling of fragments obtained from natural proteins in semisynthesis, (2) the condensation of peptide fragments synthesized by stepwise chemical procedures, and (3) the modification of products prepared by recombinant DNA technology.

The ribosomal peptidyltransferase is not suitable for practical use and also the multienzyme complexes involved in bacterial peptide synthesis do not seem to possess a general applicability at present. Consequently, only the proteases come into consideration. Their fundamental suitability for peptide synthesis is based on the principle of reversibility and was predicted by *van't Hoff* more than 90 years ago[2] and proved experimentally by *Bergmann* and *Fraenkel-Conrat* in 1937.[3]

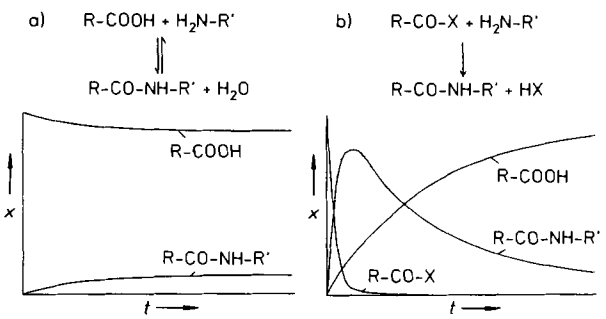

Fig. 1. Comparison of an equilibrium (a) and a kinetically controlled (b) peptide synthesis. In the kinetically controlled reaction, besides the product R-CO-NH-R', the acid R-COOH is formed.

[*] Prof. Dr. H.-D. Jakubke, Dr. V. Schellenberger

Talstrasse 33, O-7010 Leipzig (FRG)

[**] In this article the amino acid residues of the peptide substrate, *p,p'*, and the binding sites on the enzyme, *S, S'*, are abbreviated in italics to avoid confusion with S = substrate and P = product or leaving group (Scheme 1).

Two strategies for protease-catalyzed peptide synthesis are distinguished in the literature (cf. recent reviews[4-8]). While the equilibrium-controlled synthesis represents the direct reversal of the proteolysis, the kinetically controlled synthesis makes use of weakly activated carboxy components. Both methods are compared in Figure 1.

2. Is Protease-Catalyzed Kinetically Controlled Fragment Condensation Preferential to Other Methods?

The equilibrium-controlled peptide synthesis, as direct reversal of the protease-catalyzed hydrolysis of a peptide bond, has the advantage that all the proteases, independent of their catalytic mechanism, can be used. However, the high enzyme requirements and the low reaction velocity are disadvantages. Furthermore, high concentrations of organic solvents are usually required in order to suppress the ionization of the fragments being condensed. In spite of these limitations, this strategy proved to be worthwhile in the trypsin-catalyzed semisynthesis of human insulin as well as the aspartame synthesis using thermolysin (cf. reviews[4-8]). On the other hand, if one plans to carry out equilibrium-controlled reactions involving reactants with unprotected side-chain functions in aqueous media, then the specificity-determining C-terminal amino acid residue of the carboxy component should not occur once more in the fragments.

It has been known for a long time that, besides the hydrolysis of peptides and proteins, serine and cysteine proteases can also catalyze acyl transfer to various acceptors.[9, 10] This is a direct consequence of the reaction mechanism of these enzymes. The acyl-enzyme intermediate formed during catalysis can be deacylated competitively by water and also by other nucleophiles. The use of peptide esters for the acyl transfer to other peptide derivatives has special significance. This is described in the literature as kinetically controlled peptide synthesis. By using acylamino acid esters as the carboxy components, it is possible to achieve a temporary product accumulation lying far above the thermodynamically determined equilibrium concentration (see Fig. 1).

Kinetically controlled enzymatic fragment couplings with unprotected side-chain functions can be carried out in aqueous systems with a modest addition of organic solvents. This is due to the decisively improved solubility of the fragments in aqueous medium. Unfavorable conformational effects of the peptides, which occur during the chemical condensation of fully protected fragments, can thereby be avoided. The application of proteases to protein synthesis, however, necessitates a knowledge of the kinetics of the acyl-transfer reactions and the introduction of a few kinetic parameters to describe the reaction course. Methods for determining the individual parameters will be compared and their significance explained in the following discussion.

3. Survey of Protease-Catalyzed Acyl-Transfer Reactions

The first protease-catalyzed acyl-transfer experiments were mainly performed in order to investigate the mechanism of the catalysis.[11, 13] Since the middle of the 1970s the preparative use of such reactions has been the focus of interest.[14-20] The influence of reactant structure and reaction conditions on the yield of the peptide product has been investigated. However, the variable conditions (type and concentration of the employed solvents, pH, ionic strength, reactant concentration, and temperature) make it difficult to compare the results. In many investigations only the concentration of the peptide product at a fixed time is given, but not the initial relationship between the formation of aminolysis

Hans-Dieter Jakubke, born in 1933 in Mosau (Mark Brandenburg), studied chemistry at the Universität Halle-Wittenberg from 1952 to 1958. He received his Ph.D. in 1961 under W. Langenbeck for work on enzyme models and cyclic peptides. After doing research in Prague for one year with J. Rudinger, he completed his habilitation in 1968 on racemization-free peptide synthesis. In 1970 he was appointed lecturer at the Institut für Biochemie at the Universität Halle-Wittenberg and was appointed Ordinarius für Biochemie at the Universität Leipzig in 1977. Since 1990 Jakubke has been a member of the Council of the European Peptide Society. He is the coauthor of several books. The focus of his research is peptide chemistry, enzymatic peptide synthesis, and studies on the specificity of proteases.

Volker Schellenberger, born in 1960 in Leipzig, studied biochemistry from 1979 to 1983 at the Universität Leipzig and received his Ph.D. in 1986 under H.-D. Jakubke for work on protease-catalyzed peptide synthesis. After doing research with Yu. V. Mitin (Puschchino, USSR) and A. Aaviksaar (Tallinn, USSR) and working as an FEBS postdoctoral fellow with V. Kasche (Hamburg), he completed his habilitation in 1991 at the Universität Leipzig. After doing research with H.-J. Fritz (Göttingen), he began his current work with W. J. Rutter at the Hormone Research Institute (San Francisco, USA).

and hydrolysis products. Consequently, it is virtually impossible to draw conclusions about the enzyme specificity for the different amino components.

The nomenclature for protease specificity, which was introduced by *Schechter* and *Berger*,[21] is explained in Figure 2. A characterization of the *S'*-subsite specificity of the

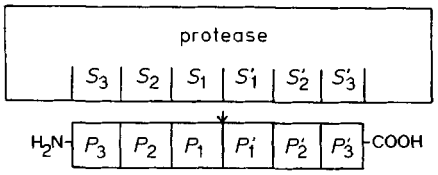

Fig. 2. Schematic representation of the nomenclature of protease specificity according to *Schechter* and *Berger* [21]. The amino acid residues are denoted by *P* and *P'*, respectively. They interact with the corresponding *S* and *S'* subsites of the enzyme active site, respectively. The arrow indicates the site of proteolytic cleavage. Starting at this site, *P* or *S* are numbered.

proteases requires a large series of acyl-transfer reactions, which must be investigated under standardized reaction conditions. The fundamental studies on the serine- and cysteine-protease-catalyzed acyl transfer are summarized in Table 1.

An extensive discussion of the results of these studies is beyond the scope of this article. Some generalizations, however, seem to be possible, although the individual experiments differ regarding the reaction conditions and analytical procedures.

The ratio between aminolysis and hydrolysis of the acyl-enzyme is generally more favorable for cysteine proteases than for serine proteases. This is in accordance with the finding that the ratio of the esterase to amidase activity of cysteine proteases is clearly less than that of serine proteases.[35]

In the class of serine proteases, the enzymes of the trypsin family show a higher acyltransferase efficiency than the enzymes of the subtilisin type, which generally constitute very good esterases.[36]

Hydrolysis of the initially formed acyl-enzyme–nucleophile complex (EAN, see Schema 1) has seldom been observed.[31, 37–39] This is of special significance in the trypsin-catalyzed reactions.[28] At present, most of the available

information concerns the acyl-transfer efficiency of chymotrypsin. These data will be discussed in Section 7.

4. Competitive Reactions during Acyl Transfer

Proteases are not perfect acyltransferases. Owing to their limited specificity, other reactions can take place parallel to acyl transfer (Fig. 3).

The acyl-enzyme formed in the course of the reaction can undergo hydrolysis. The resulting hydrolysis product possesses a very low acylation potential and consequently is not available for formation of the desired product. For this reason, the ratio between aminolysis and hydrolysis of the acyl-donor ester is of utmost importance in protease-catalyzed acyl-transfer reactions. It is essentially determined by the *S'*-subsite specificity of the enzyme. The peptide bond formed by acyl transfer corresponds to a cleavage site for the enzyme. In the literature, enzymatic attack on this bond is denoted as secondary hydrolysis.

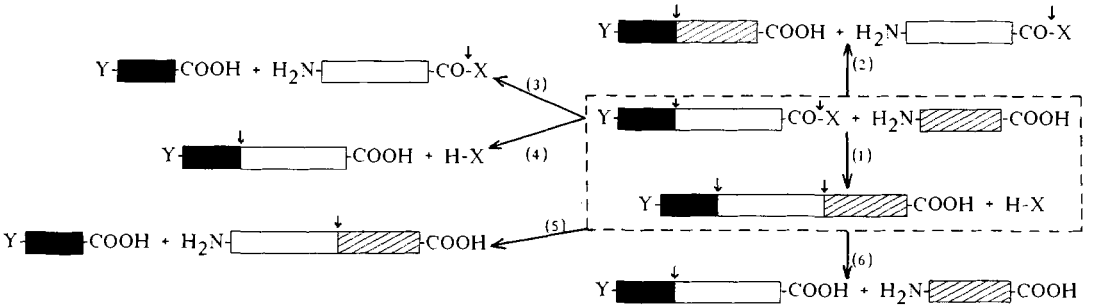

Fig. 3. Reaction paths of the protease-catalyzed acyl transfer. The peptide synthesis (1), starting from the acyl donor and amino component, is framed. Cleavage sites of the individual compounds are indicated by arrows. Parallel to the synthesis reaction (1), hydrolysis of the ester bond (CO-X) of the acyl donor also occurs (4). Besides the ester bond, the acyl donor is presumed to possess a further cleavage site in the acyl part. If the peptide bond of the acyl donor is attacked by the protease, then, besides hydrolysis (3), an acyl transfer (2) to the amino component can take place. The newly formed bond of the synthesized product may undergo a secondary hydrolysis (6); moreover, hydrolysis of another peptide bond is possible (5). Many of the depicted products can undergo further protease-catalyzed reactions because they contain cleavage sites for the enzyme; alternatively, owing to the presence of a free α-amino group, they can behave as a nucleophilic acceptor.

With increasing length of the peptide to be synthesized, the possibility grows that the sequence will contain further peptide bonds that meet the specificity of the protease employed. In the reaction shown in Figure 3, it was assumed that the acyl donor contains only one further cleavage site for the enzyme. It is obvious that there are a large number of reaction pathways, only a few of which are presented in Figure 3.

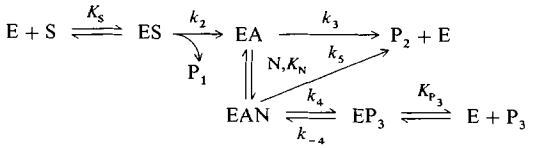
For the suppression of this kind of undesired side reaction, therefore, enzymatic attack at the ester bond of the acyl donor should be preferred over attack at all other bonds in the reactants and products. The crucial parameters of the enzyme specificity responsible for such side reactions will be discussed in Section 8.

5. Amino Component and Water Compete for the Acyl-Enzyme

5.1. Definition and Significance of the Partition Constant

As already mentioned, the ratio of the formation of aminolysis and hydrolysis products is of decisive importance in preparative peptide synthesis. Moreover, it allows conclusions to be drawn about the *S'*-subsite specificity of the protease. A parameter that describes the acyl-transfer efficiency of the protease must therefore be introduced.

The kinetics of protease-catalyzed acyl-transfer reactions can be described by Scheme 1. The nucleophilic amino component first binds to the acyl-enzyme. The resulting acyl-enzyme–nucleophile complex can undergo aminolysis as well as hydrolysis.[23] The ratio of the formation of aminolysis and hydrolysis products, which is also denoted as selectivity,[40] is determined by the acyl-transfer efficiency of the protease for the corresponding reactants.



Scheme 1. Protease-catalyzed acyl-transfer reaction. E = enzyme, S = acyl-donor ester (carboxy component), N = nucleophile (amino component), P_1 = leaving group of the acyl-donor ester, P_2 = hydrolysis product, P_3 = peptide product, EA = acyl-enzyme, EAN = acyl-enzyme–nucleophile complex.

In analogy to the definition of the Michaelis constant, we decided to introduce the partition constant p defined in Equation (1).[41] The partition constant corresponds to the

$$\frac{v_H}{v_A} = \frac{d[P_2]}{d[P_3]} = \frac{p}{[N]} \quad (1)$$

nucleophile concentration at which aminolysis and hydrolysis of the acyl-enzyme proceed with the same velocity. Such a definition of the partition constant has the advantage that it is not based on a particular kinetic scheme. Moreover, p allows a rapid estimation of the yield of the acyl-transfer reaction. Only if $[N] > p$ is valid can the peptide be produced in a high yield.

The partition constant is an empirically introduced measure. Its definite significance ensues from the kinetic pattern of the reaction. If an equilibrium is assumed between the acyl-enzyme and the acyl-enzyme–nucleophile complex, Equations (2) and (3) can be derived from Scheme 1 for the velocities of hydrolysis and aminolysis of the acyl-enzyme.

$$v_H = [EA]k_3 + [EA][N]\frac{k_5}{K_N} \quad (2)$$

$$v_A = [EA][N]\frac{k_4}{K_N} \quad (3)$$

By combining Equations (1)–(3), one obtains Equation (4).

$$p = \frac{[N]k_5}{k_4} + \frac{K_N k_3}{k_4} \quad (4)$$

Accordingly, Scheme 1 yields a linear correlation between the partition constant and the nucleophile concentration. The quotient k_5/k_4 corresponds to the ratio of hydrolysis to aminolysis of the EAN complex. The term $K_N k_3/k_4$ is a measure for the nucleophilic efficiency.

The concept of the partition constant has been accepted by several research groups.[42, 43] *Gololobov* et al.[44] have proposed the parameter β, which is the reciprocal of the partition constant. Other authors prefer to characterize the nucleophilic efficiency by means of quotients of different rate constants.[22, 26, 29, 31, 32] A disadvantage of the latter method is the lack of comparable results, since they depend on the particular kinetic pattern of each reaction.

5.2. Methods for Determining the Partition Constant

5.2.1. Product Ratio for an Excess of Nucleophile

According to Equation (1), the partition constant is determined by the ratio of the velocities of aminolysis and hydrolysis of the acyl-enzyme. If the reaction is carried out in the presence of a large excess of nucleophile, ($[N]_0 \gg [S]_0$), then the decrease of the nucleophile concentration during the reaction course can be ignored. Under these conditions the ratio is $v_H/v_A = [P_2]/[P_3]$. This relation allows a simple calculation of the partition constant according to Equation (5).

$$p = \frac{[P_2][N]}{[P_3]} \quad (5)$$

The determination of the product ratio is preferentially carried out by HPLC analysis.

By employing appropriate acyl-donor esters it is possible to establish the ratio of hydrolysis to aminolysis from the change of the absorption during the reaction course,[29, 37] provided that the absorption changes differ for the two reactions ($\varepsilon_{P_2} \neq \varepsilon_{P_3} - \varepsilon_N$).

5.2.2. Apparatus for the Determination of p

The determination of the partition constant p by means of HPLC analysis is a discontinuous method. Moreover, it is

necessary to adjust the separation conditions for each product mixture. In order to characterize the applicability of the proteases for peptide synthesis, however, it is necessary to perform extensive investigations on the acyl transfer. In this process a large number of acyl-donor esters and nucleophiles in various combinations have to be examined.

An apparatus was developed by us, especially for the broad screening of the S'-subsite specificity of proteases.[45] The velocity of hydrolysis is determined by titration. The aminolysis of the acyl-enzyme is indirectly determined by the decrease of the nucleophile concentration in the reaction mixture. For this purpose, the amino groups are allowed to react with *o*-phthalaldehyde and photometrically evaluated.[46]

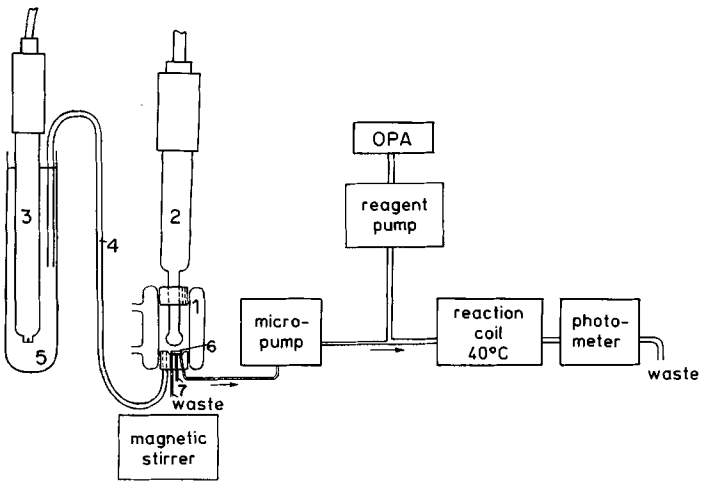


Fig. 4. Apparatus for the continuous monitoring of protease-catalyzed acyl-transfer reactions. The reactions are carried out in a thermostated vessel (1) equipped with a magnetic stirrer and a cannula for the titrant (7). The pH measurement is carried out using a miniature glass electrode (2). In order to keep the reactor volume small, the reference electrode (3) was connected via a salt bridge (4) to the vessel. The reference electrode and the polyethylene tube are inserted into a reagent glass filled with saturated potassium chloride solution (5). The reaction sample is continuously pumped from the reaction vessel and is mixed with *o*-phthalaldehyde solution by means of a second pump. The absorption of the mixture running through a reaction loop is continously recorded at 340 nm.

The apparatus schematically shown in Figure 4 was used to carry out numerous series of acyl-transfer reactions and to investigate the S'-subsite specificity of α-chymotrypsin and porcine pancreatic elastase.[27, 30]

5.2.3. *Acceleration of the Deacylation by the Nucleophile*

In the serine- and cysteine-protease–catalyzed hydrolysis of specific ester substrates, the deacylation of the acyl-enzyme generally constitutes the rate-limiting step (i.e., $k_2 \gg k_3$ and $k_{cat} = k_3$). Under these conditions, the catalytic constant $(k_{cat})_{app}$ increases in the presence of an added nucleophile according to Equation (6).

$$(k_{cat})_{app} = k_3\frac{K_N}{K_N + [N]} + (k_4 + k_5)\left(1 - \frac{K_N}{K_N + [N]}\right) \quad (6)$$

If $k_5 = k_3$ or $k_4 \gg k_3$ is valid, then it is possible to simplify Equation (6) to Equation (7).

$$(k_{cat})_{app} = k_3 + k_4\frac{K_N}{K_N + [N]} \quad (7)$$

If an acyl-donor ester with a chromogenic leaving group is used, then, from the k_{cat} increment due to the nucleophile addition, the efficiency of the employed nucleophile can be calculated. Applications of this method are described in a series of publications.[22, 24, 26, 32, 38] For nonspecific ester substrates it is possible to isolate the acyl-enzyme and to follow the deacylation directly.[25]

5.2.4. *Determination of p from the Integrated Rate Equation*

As mentioned in Section 3.2.1, an excess of the nucleophilic amino component over the acyl donor is used in the analysis of acyl-transfer reactions by HPLC. In the preparative use of acyl-transfer reactions, however, a large excess of the nucleophile is not useful because a complete turnover of both reactants is desired. For this reason, we developed a method which allows the partition constant to be determined from HPLC data, even when the nucleophile concentration significantly decreases during the reaction.[47]

For the initial nucleophile concentration Equation (8) is valid. By substituting Equations (8) and (4) into Equation (1) and subsequent integration, Equation (9) is obtained.

$$[N] = [N]_0 - [P_3] \quad (8)$$

$$\frac{[P_2]}{[P_3]} = \frac{k_5}{k_4} + K_N\frac{k_3}{k_4}\frac{\ln([N]_0/([N]_0 - [P_3]))}{[P_3]} \quad (9)$$

According to Equation (9), a plot of $[P_2]/[P_3]$ versus $\ln([N]_0/[N]_0 - [P_3]))/[P_3]$ gives a straight line with the slope $K_N k_3/k_4$ and an intercept with the y axis at k_5/k_4. Figure 5 shows a plot according to Equation (9) for the acyl-transfer reaction catalyzed by V8 proteinase.[47]

This method permits a determination of the partition constant under the conditions employed in a preparative peptide synthesis. Therefore, it should be especially useful for the optimization of the reaction conditions.

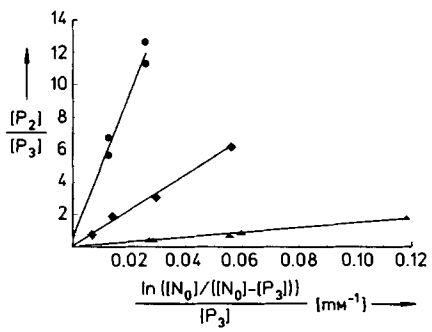

Fig. 5. Plot according to Equation (9) for the V8-protease-catalyzed acyl transfer using Z-Glu-OMe as the acyl donor. Nucleophiles: ▲, H-L-Leu-NH_2; ●, H-D-Leu-NH_2; ■, H-L-Val-NH_2.

It is a further advantage of this method that the reactions can be carried out in the presence of an excess of the acyl donor. This allows the analysis of reactions in which the peptide product is subjected to further protease-catalyzed reactions. For example, this type of reaction is known for the thiolprotease papain.[35,48] An excess of the acyl donor protects the peptide product from secondary hydrolysis by the enzyme and allows an exact determination of the partition constant.

6. The *S'*-Subsite Specificity for the Acyl Transfer and Peptide Hydrolysis Are Equal

Acylation of the enzyme by a peptide substrate represents the reversal of the aminolysis of the acyl-enzyme by the corresponding nucleophile. For the illustration of this case, the hydrolysis of two peptide substrates, YA and YB, will be compared [Eqs. (a) and (b)]. The course of the free energy for

$$E + YA \rightleftharpoons EY + A \rightleftharpoons E + Y + A \quad (a)$$

$$E + YB \rightleftharpoons EY + B \rightleftharpoons E + Y + B \quad (b)$$

both reactions is depicted in Figure 6. During the hydrolysis of both substrates the same acyl-enzyme EY is formed as an intermediate. Consequently, the free energy of the acyl-enzyme hydrolysis, ΔG_{deac}, is identical for both substrates.

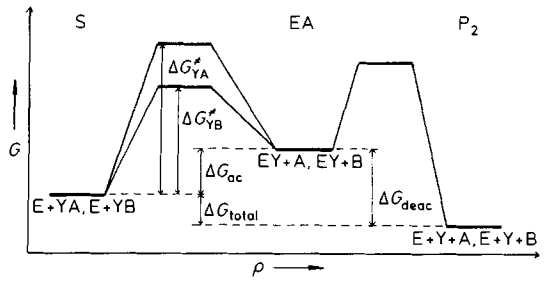

Fig. 6. Comparison of the reaction coordinates ρ for the enzymatic hydrolysis of the two peptide substrates YA and YB with the same acyl moiety. EA = acyl-enzyme, P_2 = hydrolysis product.

Fersht and *Requena*[49] carried out numerous investigations concerning the influence of the structure of peptides on the equilibrium constants of their hydrolysis. The results showed that the free energy of peptide hydrolysis is only minimally influenced by the structure of the amino acid side-chains, as long as the pK values of the amino acids released by hydrolysis do not differ significantly. This leads to the assumption that the free energy of hydrolysis of both substrates, ΔG_{total}, scarcely differs.

The free energy of the enzyme acylation by the substrate is obtained from Equation (10). ΔG_{ac} must be identical for

$$\Delta G_{ac} = \Delta G_{total} - \Delta G_{deac} \quad (10)$$

both substrates, because the substrates do not differ in ΔG_{total} and ΔG_{deac}. Furthermore, aminolysis of the acyl enzyme and peptide hydrolysis pass through the same transition state. Assuming the substrate YB possesses the higher specificity constant k_{cat}/K_M (i.e., $\Delta G^{\ddagger}_{YB} < \Delta G^{\ddagger}_{YA}$), then the nucleophilic efficiency of the leaving group B must lie above the efficiency of A by the same magnitude.

If only peptides whose free energies of hydrolysis do not differ significantly are compared, then there exists a strict relationship between the *S'*-subsite specificity of peptide hydrolysis and aminolysis of the acyl-enzyme. Therefore, it becomes possible to investigate the *S'*-subsite specificity of serine and cysteine proteases via acyl-transfer reactions. This is a significant point since analysis of the specificity of proteases in peptide hydrolysis encounters several problems. This type of measurement requires the preparation of numerous series of peptide substrates. Especially in large peptides, several peptide bonds in the sequence may be simultaneously cleaved. Moreover, peptide hydrolysis is not generally accompanied by an absorption change which can be spectrophotometrically measured. Since in the acyl-transfer reactions comparatively reactive esters are used as acyl donors, one can even determine the specificity for peptide sequences which are not hydrolyzed by the corresponding protease at detectable rates.[32]

7. Chymotrypsin-Catalyzed Acyl Transfer

α-Chymotrypsin is one of the most intensively investigated enzymes.[10] Its three-dimensional structure has been determined by X-ray crystallography.[50–52] α-Chymotrypsin is an endopeptidase with a distinct primary specificity for peptide substrates bearing aromatic amino acids in the P_1 position.[53]

The specificity of α-chymotrypsin for the leaving groups of the substrates has been intensively investigated. In these reactions substituted phenyl esters, anilides, or aliphatic alkyl esters of various structures have been employed.[54–58] However, there is a lack of information on the *S'*-subsite specificity of α-chymotrypsin in the hydrolysis of peptides. Investigations have so far been restricted to substrates with aromatic amino acids in the P_1 position and small hydrophobic amino acids in the P'_1 position.[17,18,59–62]

7.1. Specificity of the *S'* Subsites

A large number of chymotrypsin-catalyzed acyl-transfer reactions are described in the literature.[29,30–32,37] In accordance with the endopeptidase character of chymotrypsin, no acyl transfer to free amino acids has been ascertained.[29] Also, when H-β Ala-Gly-OH and D-amino acid derivatives are used as nucleophiles, aminolysis of the acyl-enzyme was barely observed[30,31] Obviously, efficient acyl transfer requires nucleophiles containing α-amino acids of the L configuration.

In order to characterize the specificity of the enzyme S'_1 subsite, a large number of amino acid amides were investigated as nucleophilic amino components. The results of these measurements are summarized in Table 2. The values demonstrate a preference of the S'_1 subsite for amino acids with hydrophobic side chains. An exception is H-Arg-NH_2, which clearly shows a higher efficiency than all the other amino acid amides. This is believed to be due to electrostatic

Table 2. Partition constants [mM] for the chymotrypsin-catalyzed acyl transfer to amino acid amides [a].

Nucleophile	Ac-Tyr-OEt [31]	Ac-Phe-ONp [32], [b]	Mal-Phe-OMe [30]	Mal-Leu-OBzl [30]
H-Met-NH_2	–	–	3.3	4.9
H-Tyr-NH_2	–	8.5	–	–
H-Trp-NH_2	–	22	–	–
H-Leu-NH_2	19 [c]	–	4.2	10
H-Val-NH_2	21 [c]	–	6.7	15
H-Ala-NH_2	23 [c]	23	9.3	18
H-Ser-NH_2	49	–	–	–
H-Gly-NH_2	104	87	44	90
H-Arg-NH_2	–	–	0.11	0.24
H-D-Ala-NH_2	5500	–	–	–

[a] The acyl-donor esters and the references are given in the table head. All acyl-transfer experiments were carried out under comparable conditions (25 °C; pH 9.0–10.0; solvent content < 5 %; ionic strength = 0.19–0.95). Mal = maleyl (3-carboxyacryloyl). [b] δ-Chymostrypsin was used. All the other reactions were carried out with α-chymotrypsin. [c] The partition constant is dependent on the nucleophile concentration (i.e., $k_3/k_4 > 0$).

interactions with the enzyme, which will be separately discussed in the following section.

The S'_1-subsite specificity of chymotrypsin can be explained in terms of the structure of complexes of the enzyme with protein inhibitors. These inhibitors constitute specific substrates for the proteases, whose hydrolysis proceeds reversibly owing to the structure of the inhibitor molecule.[63] The structures of such inhibitors and of enzyme–inhibitor complexes can serve as models for the interactions of proteases with peptide substrates.

From the model of the complex between bovine pancreatic trypsin inhibitor and chymotrypsin, it was deduced that the P'_1 side chain of the substrate is directed away from the enzyme.[64] Accordingly, larger amino acid side chains can also be bound. The same model also explains the low efficiency of H-D-Ala-NH_2.

Investigations on the acyl transfer to dipeptide amides revealed that additional interactions in the S'_2 binding site slightly influence the specificity of the S'_1 subsite.[30] A series of dipeptide nucleophiles with different residues in the P'_2 position showed that amino acids with hydrophobic side chains are preferred at this site.[29, 65]

7.2. Ionic Interaction in the S' Subsites

Nucleophiles containing charged groups clearly show a different behavior in the α-chymotrypsin-catalyzed acyl-transfer reactions when compared with uncharged compounds (see Table 3). Thus, for H-Arg-NH_2, the p values lie more than one order of magnitude lower than the values of the other amino acid amides. Also, the high partition constants of nucleophiles containing free carboxyl groups are conspicuous. We believe that the influence of the charged groups on the nucleophilic efficiency is due to a negative electrostatic potential at the S' subsites of the enzyme.[37]

A statistical analysis of proteolysis data confirmed that α-chymotrypsin possesses a specificity for peptide bonds bearing arginine or lysine in the P'_1 position.[66] Furthermore, the analysis showed that α-chymotrypsin cleaves Leu–Asp bonds of proteins considerably less frequently than one expects from the frequency of occurrence of this bond.

The X-ray crystallographic analysis of a chymotrypsin complex with a protease inhibitor from ovomucoid showed that a salt bridge is formed between the P'_3 arginine residue of the inhibitor and Asp-64 of the enzyme.[67]

A comparison of the oligoglycines in Table 3 shows the influence of the distance between the nucleophilic amino group and the charged carboxyl group. With increasing length of the nucleophile, the electrostatic interactions with the negatively charged residues of the α-chymotrypsin S' subsites are reduced. Favorable interactions of the nucleophiles with the S'_3 and S'_4 subsites cannot explain the influence of the nucleophile length on the p value, since for H-Gly-NH_2 a higher efficiency has been established than for H-Gly-Gly-Gly-Gly-OH (compare Tables 2 and 3).

Table 3. Influence of charged groups in the nucleophile on the aminolysis of Mal-Phe-α-chymotrpysin.

Nucleophile	p [mM]	Ref.
H-Arg-NH_2	0.11	[30]
H-Leu-NH_2	4.2	[30]
H-Arg-OMe	22 [a]	[37]
H-Leu-OMe	> 600	[37]
H-Ala-Ala-OH	58	[30]
H-Ala-Ala-NH_2	4.9	[30]
H-Gly-Gly-OH	214	[30]
H-Gly-Gly-Gly-OH	138	[30]
H-Gly-Gly-Gly-Gly-OH	103	[30]

[a] The partition constant is dependent on the nucleophile concentration.

For a series of model reactions, it could be shown that the nucleophilic efficiency of dipeptides with free carboxyl groups can be improved by more than one order of magnitude by adding inorganic salts to the reaction medium.[65] This is supposed to be due to the shielding of the unfavorable electrostatic interactions between the negatively charged carboxyl group of the nucleophile and the negative potential of the acyl-enzyme S' subsites. The interaction of the arginine residues in the nucleophile with the enzyme can similarly be influenced by the addition of various salts.[68]

All the above-mentioned examples prove that proteolysis, the binding of the inhibitors, and acyl transfer are governed by the same factors. Consequently, an understanding of the molecular interaction between the acyl-enzyme and the nucleophile allows an optimization of the acyl-transfer efficiency.

7.3. Influence of the Acyl-Donor Structure on the Partition Constant

For the planning of protease-catalyzed peptide syntheses, it is of importance to determine whether the nucleophilic specificity of a protease is influenced by the structure of the acyl donor. For this reason, we compared the α-chymotrypsin-catalyzed acyl transfer from two different acyl-donor esters to a series of nucleophiles.[30]

As Figure 7 shows, the partition constants for a particular nucleophile do not differ by more than one order of magnitude, whereas for different nucleophiles and the same acyl donor, differences of more than three orders of magnitude

are observed. The structure of the residues occupying the S subsites obviously has little influence on the binding of the nucleophile in the S' subsites. An investigation of the acyl transfer from fourteen acyl-donor esters to four different nucleophiles confirmed this conclusion.[30]

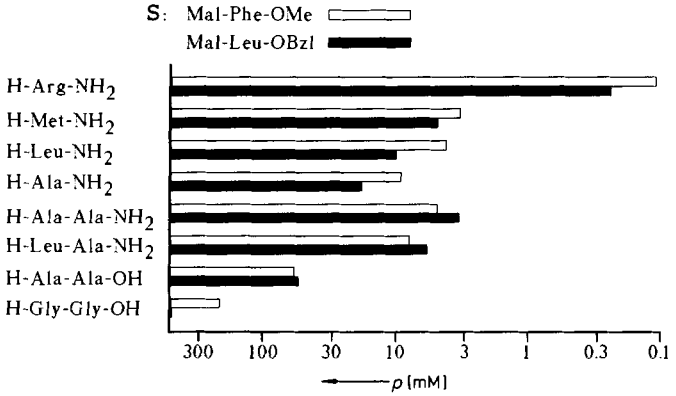

Fig. 7. Comparison of the partition constants for the α-chymotrypsin-catalyzed acyl transfer with two different acyl-donor esters [30].

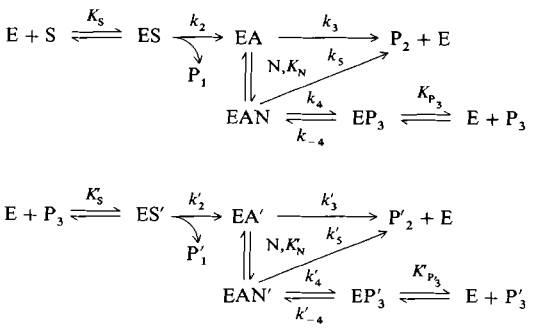
Accordingly, for the characterization of the S' subsite specificity of α-chymotrypsin, it is sufficient that a series of nucleophiles be allowed to react with a single acyl donor. The resulting data can be applied with an accuracy sufficient for preparative purposes to other acyl donor esters.

8. Competition for the Free Enzyme

Besides the hydrolysis of the acyl-enzyme, which was already discussed in detail, an attack of the enzyme on the peptide product has practical relevance (cf. Fig. 3). This process can result in secondary hydrolysis of the peptide bond formed. With increasing number of peptide bonds the probability grows that other peptide bonds in the product will meet the specificity of the enzyme. If in the course of the reaction a product containing a protease-labile bond is accumulated, then the desired product can undergo further enzymatic reaction. A kinetic analysis of this type of reaction is a prerequisite for the optimization of the peptide yield.

In considering the reactions that can occur subsequent to proteolysis, it is sufficient to assume that the peptide product possesses, besides the newly formed peptide bond, only one additional protease-labile peptide bond. The corresponding reaction mechanism is presented in Scheme 2. Despite the large number of velocity and equilibrium constants in Scheme 2, it is possible to discuss the kinetic relationships in a simple manner, provided that a small number of parameters for the enzyme specificity are introduced. All the kinetic parameters used and their significance are summarized in Table 4.



Scheme 2. Protease-catalyzed acyl-transfer and competitive reactions of the peptide product P_3. In the reaction of P_3 to EA', the bond cleaved is different from the one formed in the upper part of the scheme.

Table 4. Kinetic parameters for the description of protease-catalyzed acyltransfer reactions. Each parameter characterizes the competition between two reaction paths in Scheme 2. The quotients k_2/K_S, k'_2/K'_S, k_4/K_{P_3}, and k'_{-4}/K'_{P_3} correspond to the rate constants for the second-order reactions given in the last two columns of the table. They are therefore equal to the specificity constants k_{cat}/K_M of these reactions.

Parameter	Equation [a]	Competitive reactions	
p	$p = [N]\frac{k_5}{k_4} + K_N\frac{k_3}{k_4}$	EA ⟶ P_2	EA + N ⟶ P_3
p'	$p' = [N]\frac{k'_5}{k'_4} + K'_N\frac{k'_3}{k'_4}$	EA' ⟶ P'_2	EA' + N ⟶ P'_3
α	$\alpha = \frac{k_{-4}/K_{P_3}}{k_2/K_S}$	E + P_3 ⟶ EA	E + S ⟶ EA
α'	$\alpha' = \frac{k'_{-4}/K'_{P_3}}{k_2/K_S}$	E + P'_3 ⟶ EA	E + S ⟶ EA'
α_1	$\alpha_1 = \frac{k'_2/K'_S}{k_2/K_S}$	E + P_3 → EA'	E + S ⟶ EA

[a] The equation gives the parameter according to Scheme 2.

8.1. Parameter α of Secondary Hydrolysis

The attack of the enzyme on the newly formed peptide bond is the reversal of the aminolysis of the acyl-enzyme. Consequently, this side reaction may occur during every enzymatic peptide synthesis. For the understanding of the kinetics, it is important that the acyl donor employed and the resulting peptide compete for the free enzyme. Accordingly, the concentration ratio and the specificity constants, k_{cat}/K_M, determine which substance will be preferably attacked.

In kinetically controlled reactions, the tendency for the occurrence of a secondary hydrolysis is characterized by the parameter α[44] (see Table 4). A small value of α signifies a low risk of secondary hydrolysis.

If serine proteases are used for the synthesis, a secondary hydrolysis of the product should not generally be expected as long as a small concentration of the acyl-donor ester is still available in the reaction mixture. For these enzymes esters constitute much better substrates than peptides with the same acyl part. In the case of cysteine proteases, the preference for ester substrates is lower[35] and proteolytic side reactions are observed.[48]

8.2. Parameter α_1 of Specificity

If one compares the variety of peptide sequences to be synthesized with the limited number of proteases available for preparative purposes, it becomes clear that enzymes with an absolute specificity for the bond formation will not be available. Consequently, segment coupling must be feasible, although the peptide product possesses several cleavage sites for the enzyme.

For the reaction depicted in Scheme 2, it was assumed that the peptide product P_3, besides the newly formed bond, contains one further protease-labile bond. To explain the competition between this bond and the acyl donor for the free enzyme, we introduced the parameter α_1,[48] as shown in Table 4.

8.3. Calculation of the Reaction Course

By applying the steady-state principle and on the basis of the parameters in Table 4, Equations (11)–(16) can be

$$\frac{d[P_2]}{dt} = [E]\frac{k_2}{K_s}\frac{[S] + \alpha[P_3]}{1 + [N]/p} \tag{11}$$

$$\frac{d[P_3]}{dt} = [E]\frac{k_2}{K_s}\frac{[S][N]/p - (\alpha + \alpha_1 + \alpha_1[N]/p)[P_3]}{1 + [N]/p} \tag{12}$$

$$\frac{d[P'_2]}{dt} = [E]\frac{k_2}{K_s}\alpha_1\frac{[P_3] + \alpha'[P'_3]}{1 + [N]/p'} \tag{13}$$

$$\frac{d[P'_3]}{dt} = [E]\frac{k_2}{K_s}\alpha_1\frac{[P_3][N]/p' - \alpha'[P'_3]}{1 + [N]/p'} \tag{14}$$

$$[N] = [N]_0 - [P_3] - [P'_2] - 2[P'_3] \tag{15}$$

$$[S] = [S]_0 - [P_2] - [P_3] - [P'_2] - [P'_3] \tag{16}$$

derived. The numerical solution of this system of equations allows the yield of the peptide product to be calculated from a given set of initial conditions (concentration of the nucleophile and the acyl donor).

The term $[E]k_2/K_S$ appears in all four differential equations and, therefore, has no influence on the concentration ratios of the individual products. The enzyme concentration only influences the velocity of the reaction, but not its course and the yield of P_3.

In order to explain the significance of the individual parameters, it is helpful to consider the conditions at the product maximum, which is attained if $d[P_3]/dt = 0$ is valid. If one denotes the concentrations of the acyl donor and nucleophile at the time of the maximum product concentration with [S]* and [N]*, respectively, then Equation (12) gives Equation (17). In order to achieve high product yields,

$$[P_3]_{max} = \frac{[N]^*[S]^*}{p(\alpha + \alpha_1 + \alpha_1[N]^*/p)} \tag{17}$$

the following conditions must be fulfilled: $[N] > p$, $\alpha < 1$ and $\alpha_1 < 1$.

The procedure described above corresponds to the approach of *Gololobov* et al.[44], which has been extended to the analysis of subsequent reactions. Another approach to estimate the product concentration has been proposed by *Bratovanova* et al.[69]

8.4. Determination of the α Parameters

The formally simplest way to determine the individual α parameters follows from the equations given in Table 4. Accordingly, the hydrolysis kinetics of the acyl-donor ester and the peptide products P_3 and P'_3 must be investigated. In the hydrolysis of the peptide product, several cleavage sites can be attacked. These individual cleavage sites can be dealt with as competitive substrates; that is, the occurrence of cleavage is proportional to the specificity constants of the enzyme for the individual bonds.

It is easier to carry out an analysis of the product mixture at the time of the yield maximum. The α parameters can be calculated from the concentration ratios by using Equation (17). For the separate determination of α and α_1, several reactions with various nucleophile concentrations must be investigated.

8.5. Possibilities to Suppress Competitive Reactions

If undesired subsequent reactions are observed in a kinetically controlled protease-catalyzed synthesis, then it is of minor importance which bond is cleaved by the enzyme. These reactions merely show that the specificity of the enzyme for the acyl donor does not lie sufficiently above its specificity for the peptide product. Since structural changes in the amino acid building blocks of the reactants are ruled out, the leaving group of the acyl donor remains as the only variable to suppress these competitive reactions. *Leaving group variations at the carboxy components*, therefore, are of great importance in order to counteract undesired side reactions. For syntheses using carboxypeptidase Y[70] and papain,[71] the proper choice of the leaving groups of the carboxy component allowed the subsequent reactions to be suppressed.

We studied the chymotrypsin-catalyzed synthesis of the chromogenic chymotrypsin substrate Mal-Leu$\overset{\downarrow}{-}$Phe$\underset{\uparrow}{-}$pNA (the arrow from above shows the newly formed peptide bond) as a peptide model with a highly sensitive cleavage site. In this case the subsequent chymotryptic cleavage of the anilide bond (arrow from below) can be easily detected spectrophotometrically.[72] Table 5 shows the relationship between the specificity of the acyl donor ester and the yield of the synthesis. When Mal-Leu-OMe is employed as acyl donor, the velocity of the product cleavage reaches the velocity of its formation after a short time. By using more specific acyl-donor esters a clear product accumulation is attained. Only after almost complete consumption of Mal-Leu-ONb was there an indication that a reaction involving the product took place. This result proves that by choosing a specific leaving group for the acyl donor, protease-labile products can be obtained in good yield.

Table 5. Influence of the specificity of the acyl donor on the α-chymotrypsin-catalyzed synthesis of Mal-Leu-Phe-pNA [72].

Acyl donor	k_{cat}/K_M [$M^{-1}s^{-1}$]	Yield [%]
Mal-Leu-OMe	4.7×10	3
Mal-Leu-OBzl	3.2×10^3	65
Mal-Leu-ONb	1.5×10^4	80.5

The use of "inverse substrates" in trypsin-catalyzed peptide synthesis allows a still more effective suppression of the

subsequent reactions to be achieved. In inverse substrates[73] the positive charge required for the trypsin catalysis is not located in the P_1 position but on the leaving group. These acyl-donor esters allow a nearly irreversible trypsin-catalyzed peptide synthesis.[74] Of the acylamino acid esters with positively charged leaving groups synthesized so far, the *p*-guanidinophenyl esters proved to be especially suitable. The extremely low specificity of trypsin for the acyl part of such inverse substrates enables even the formation of peptide bonds with proline, which, in general, is not simple to achieve by protease catalysis. The concept of inverse substrates therefore allows the trypsin-catalyzed synthesis of peptides, independent of the side-chain groups in the P_1 position. Furthermore, the newly formed peptide bond is practically resistant toward secondary hydrolysis, with the exception of trypsin-labile Arg(Lys)–Xaa bonds. Whether this strategy can be developed into a standard method depends on further optimization of the synthesis of inverse substrates.

The reaction conditions influence the course of kinetically controlled synthesis in various ways. High pH values favor an increase of the nonprotonated form of the amino component and, consequently, enhance the efficiency of the aminolytic deacylation of the acyl-enzyme. Furthermore, high pH values may effect an increased proteolytic stability of the newly formed peptide bonds. In a papain-catalyzed synthesis, a temperature decrease from 40 °C to 5 °C led to a noticeable lowering of undesired subsequent reactions.[48]

The protease-catalyzed synthesis of peptides in frozen aqueous medium opens completely new possibilities.[75] At temperatures down to − 25 °C, a dramatically improved ratio between aminolysis and hydrolysis of the acyl-enzyme was observed, presumably resulting from a high local concentration of the nucleophile. This procedure even allowed the chymotrypsin-catalyzed coupling of free amino acids, which yield no detectable amount of product at 25 °C.

The possibility of protease-catalyzed peptide synthesis in organic solvents has been intensively investigated.[76] Chymotrypsin-catalyzed acyl-transfer reactions in nonpolar solvents in the presence of salt hydrates have been described.[77, 78] Besides a minimization of the undesired proteolytic side reactions and an improvement of the reactant solubility, the protease-catalyzed synthesis in monophasic organic solvent offers favorable conditions for adjusting the reaction media between the enzymatic and chemical synthetic steps. This is in accordance with the attempts to achieve an enzymo-chemical synthesis. Enzymatic syntheses in monophasic organic solvents are frequently described as reactions with "solvent-modified enzymes". Besides such apparent modifications, the proteases can be chemically modified to become soluble in organic solvents; examples include chymotrypsin[79, 80] and papain[81] modified with polyethylene glycol (PEG). Under these conditions, generally the proteolytic reactions can be completely eliminated. Reactions in monophasic organic systems also possess disadvantages, such as drastic lowering of the velocity of the catalyzed reaction, extensive loss of the regiospecificity and thus the necessity to protect the side-chain functions, and change of the substrate specificity, as well as the necessity for waste disposal of the organic solvents.

On the basis of elevated solvent tolerance and also owing to the lowered amidase and protease acitivity, chemically and genetically engineered proteases have been successfully used for synthetic purposes. The use of cyanomethyl esters and methylchymotrypsin[82] proved to be an advantageous synthesis variant, which, on the basis of the reduced esterolytic activity, also allows the coupling of amino components with C-terminal alkyl ester groups. Thiolsubtilisin[83] is active against specific ester substrates, but shows no amidase and peptidase activities. It proved to be useful for the synthesis of Leu-enkephalin and a partial-segment synthesis of ribonuclease T_1. Good results were also obtained in the synthesis of various L,D-dipeptides using [Met(O)^{192}]chymotrypsin as catalyst.[84] Using multiple site-directed mutagenesis, *Wong* et al.[85] converted subtilisin into so-called subtilisin 8350, which allows kinetically controlled syntheses to be performed in the presence of high concentrations of dimethylformamide. This development has certainly opened the way for a new phase of protease-catalyzed peptide synthesis.

Nonproteases are supposed to possess favorable prerequisites for the enzymatic peptide synthesis because undesired proteolytic cleavages in the reactants and products can be ruled out. Besides other hydrolases, several synthetases can be used as alternatives to proteases. Lipases that contain the catalytic triade typical of serine proteases[86, 87] seem to be especially suitable. Peptide derivatives have been synthesized using various lipases as well as pig liver esterase.[88–90] In accordance with the investigations of *Wong* and co-workers,[88, 89] acyl-donor esters with long-chain leaving groups such as glycerol or *n*-octanol are more suitable than simple alkyl esters. Lipases also accept D-amino acid derivatives as substrates. Thus, the dipeptide N^{α}-phenacetyl-L-cysteinyl-D-valine was synthesized by lipase catalysis.[89] It could be converted into penicillin G by a cyclase.[91]

The use of synthetases for peptide synthesis has the advantage that the formation of the peptide bond is practically irreversible. Besides the aminoacyl-tRNA-synthetase–aminoadenylate complex[92, 93] and the arginyl-tRNA:protein arginyltransferase,[94] further synthetase complexes have been tested for the C–N coupling, especially for the synthesis of microbiologically active peptides.[95] Enzymatic syntheses of cyclosporin and its analogues, gramicidin S, special β-lactam antibiotics, etc., support the increasing importance of such multienzyme complexes.

9. Planning and Optimization of Protease-Catalyzed Syntheses

In the synthesis of a peptide, enzymes can only make a meaningful contribution to a synthesis strategy if the full advantages of the enzymatic reactions can be utilized. To compare the stepwise protease-catalyzed assembly of a peptide chain with solid-phase peptide synthesis is a priori completely unrealistic. On the other hand, di- and tripeptides can be prepared enzymatically on a large scale, even in a continuous fashion.[96, 97] For the assembly of biologically active peptides of medium size, it has to be examined in each case whether the formation of peptide bonds, which are especially prone to racemization, is more amenable to enzymatic

procedures. From an ecological point of view, enzymatic steps should be included wherever possible in large-scale syntheses. Proteolysis studies, carried out in advance, can provide information about the specificity of the enzymes employed in the different coupling steps.

Of special interest are also protease-catalyzed acyl-transfer modification of peptide chains prepared by recombinant-DNA technology. For example, the knowledge of the S' specificity of α-chymotrypsin allows specific cleavage sites to be inserted into a peptide chain. As exemplified by a model peptide with a chymotrypsin-labile sequence, it can be shown experimentally that chymotrypsin-catalyzed modification of the C-terminus is possible via transpeptidation.[98]

Apart from the enzyme specificity, the solubility of the components being coupled also dramatically influences the application of enzymes. The spectrum of solvents ranges from water, the ideal medium, to monophasic organic solvents. The character of the peptide components as well as the protecting groups always determines the compromise adopted with regard to the choice of solvent.

The kinetic parameters for the course of an enzymatic synthesis are often not available. These parameters can at best be estimated from data for similar substrates or nucleophiles. Such estimates are usually sufficient for establishing an optimum synthesis strategy. The measures required for an optimization of the peptide yield are obtained by analyzing the reaction course of the acyl transfer. The concentration ratios of the reactants and products furnish the information necessary to decide which parameter limits the product yield. Here, the following rules have to be considered:

(1) In the initial phase of the reaction the product concentration is low. Accordingly, the subsequent reactions of the product can be ignored, and the partition constant can be calculated from the ratio of the peptide product P_3 to the hydrolysis product P_2. If $p > [N]_0$ is met, then a large part of the acyl donor is hydrolyzed. Thus, the nucleophile concentration has to be increased or the reaction conditions (temperature, addition of the solvents or inorganic salts) have to be optimized.

(2) Information about the occurrence of subsequent reactions is obtained from the analysis of the reaction mixture at the maximum recovery point for P_3. If at this point a high concentration of the acyl-donor ester is still present, then the specificity constant k_{cat}/K_M for the acyl donor is small. In this case, an improvement of the yield can be achieved by increasing the concentration of the acyl donor, or more favorably, by choosing a more specific leaving group of the acyl-donor ester.

(3) In enzymatic synthesis it is generally reasonable to use the acyl donor in excess. In the presence of the acyl donor the peptide product is largely protected against enzymatic attack. Furthermore, a certain loss of the acyl donor through hydrolysis is unavoidable.

The employment of this strategy allowed us to achieve a rapid optimization of the (D-Phe)^6-GnRH synthesis by means of a chymotrypsin-catalyzed (3 + 7) segment condensation.[99] By using a small amount of substance for the optimization of the process, we succeeded in finding reaction conditions that led to a yield of more than 97%. If a reaction is to be carried out on a large scale, then it seems reasonable to determine the fundamental kinetic parameters in advance. In order to facilitate an estimation of the expected yield on the basis of these parameters, we have calculated the diagram presented in Figure 8. If the parameters α_1 and p as well as the concentration of the amino component are given, then from the graph it can be determined what concentration of the acyl donor is required in order to obtain a peptide yield of 90%, based on the starting amino component.

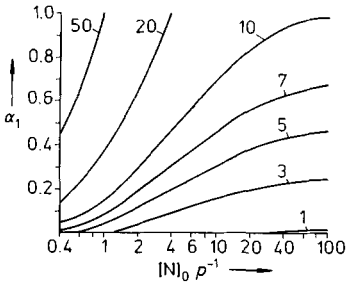


Fig. 8. Correlation between the kinetic parameters of the reaction and the reactant concentrations necessary for preparative peptide synthesis. If α_1, $[N]_0$, and p are given, the ratio $[S]_0/[N]_0$ for which a 90% yield of the peptide product is obtained, can be read from the diagram. The values are calculated from the system of equations in Section 8.3 by using numerical integration. For that, an iterative procedure described by to *Runge-Kutta* is employed [100]. Further kinetic parameters are obtained from Table 4 and are treated in the following way: A value of 0.001 is assumed for α. This value is consistent with the fact that in the majority of the kinetically controlled peptide syntheses the secondary hydrolysis of the formed bond takes place slowly (if this condition is not met, α_1 can be replaced in good approximation by $\alpha_{app} = (\alpha + \alpha_1 + \alpha_1 [N]_0/p)$). Furthermore, it is assumed that $p = p'$. As shown in Section 7.3., the partition constant is not significantly dependent on the structure of the transferred acyl component. The α' value is set to 1, since this parameter corresponds to the quotients of the specificity constants of a second peptide substrate with the same acyl part. The values of the parameters α', p' have a very small influence on the results of calculations. Changing these parameters by about one order of magnitude does not significantly alter the calculated peptide yield. This is understandable because both parameters describe the subsequent reactions of the peptide product. If a 90% yield is desired, the occurrence of these subsequent reactions must be minimized.

10. Outlook

Protease-catalyzed kinetically controlled peptide synthesis has a series of advantages which renders its use in peptide and protein chemistry attractive. Especially, the stereo- and regiospecificity of the proteases, which guarantee racemization-free fragment condensation and require only minimal side-chain protection, are of great significance for preparative purposes.

At present, model investigations on the synthesis of small peptides aim to characterize the enzyme specificity and the parameters which determine the reaction course. Further measurements, especially for the specificity of the S' subsites of the proteases, are required. For the future, it seems quite conceivable to adapt the specificity of the proteases, by means of site-directed mutagenesis, to the practical requirements of the synthesis. Another possibility is the use of catalytic antibodies whose specificity can be adapted to the synthesis objectives.

A further broad field of application for protease-catalyzed reactions ensues from the rapid development of recombinant-DNA techniques. These methods allow the preparation of long peptide sequences; however, they are limited to the 20 proteinogenic amino acids. A selective chemical modification of the genetically prepared peptides and proteins is barely possible due to the numerous unprotected side-chain functions. A combination of gene expression followed by protease conversion could represent an important method to prepare long-chain peptides in the future.

Helices, Supramolecular Chemistry, and Metal-directed Self-Assembly

By *Edwin C. Constable**

Chemists have been concerned with shape ever since the realization that molecules possess three-dimensional structure. An aspect of shape which has attracted recent attention is conveniently categorized under the title molecular topology and is concerned with the interlinking and intertwisting of molecular threads.[1] The spatial orientation of the molecular threads is critical and has been the subject of some very elegant organic chemistry. More recently, it has been recognized that the required pre-organisation of molecular threads may be achieved by utilization of the specific stereochemical requirements of transition metal ions. All that is required is the incorporation of suitable donor atoms into the molecular threads, and this approach has been exploited in the synthesis of many "exotic" molecular systems. The beauty of using transition metal ions as the templates for the spatial control of molecular threads lies in the fact that all of the stereochemical information is contained at the metal center. The result is that the chemist is then a *passive* observer of the assembly of the organized molecular system—a phenomenon termed spontaneous self-assembly.

The helical geometry is particularly appealing, and this structural motif appears in many important biological molecules. The metal-directed assembly of double helices has been established by a number of groups, and in a paper in this issue, *Williams* et al. report the extension of this methodology to the synthesis of a binuclear triple-helical complex.[2] The principle used for the assembly of the triple helix is very simple. A bis-bidentate ligand is allowed to react with a metal ion which favors six-coordinate octahedral geometry; each of two such metal ions coordinates to one bidentate grouping at each end of three such ligands (Fig. 1).

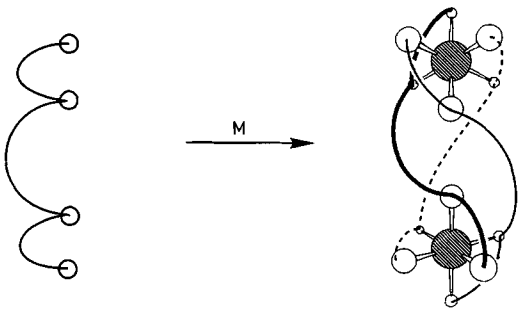

Fig. 1. The formation of a triple-helical complex by interaction of a bis-bidentate ligand with a six-coordinate metal center.

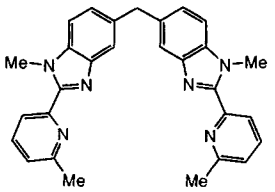
The key to assembling helicate structures lies in the design of a ligand with the correct linker groups between the metal-binding termini. *Williams, Piguet,* and *Bernardinelli*[2] have now shown that the relatively rigid bis-bidentate ligand **1**, consisting of two 2-(2′-pyridyl)benzimidazolyl units linked together, each of which can act as a bidentate N_2 donor, spontaneously forms a triple-helical complex cation $[Co_2(\mathbf{1})_3]^{4+}$ upon treatment with cobalt(II) salts. The X-ray crystal structure of the organge-red complex $[Co_2(\mathbf{1})_3][ClO_4]_4 \cdot 2.5$ MeCN reveals that the complex is indeed a triple helix. The two cobalt(II) centers are in slightly distorted octahedral environments, and the ligand-imposed geometry places the metals over 8 Å apart within the triple-helical array.

1



This paper is important for a number of reasons beyond the remarkable beauty of the resultant structure. *Williams* et al.[2] has demonstrated that new molecular topologies may be *designed* and *synthesized* by a logical combination of ligands and metals with specific donor and acceptor properties. The spontaneous manner in which the highly ordered structure assembles illustrates the efficacy and the remarkable potential of this approach. This is the first example of a triple-helical coordination compound, although *Shanzer* et al. have described a diiron triple helix resulting from the metal-controlled intermolecular twisting of a tripodal ligand[3] and *Lehn* et al. have mentioned in passing a diiron complex with a bis-bidentate ligand which may well possess this geometry.[4]

The synthesis of this triple-helical structure is a logical extension of investigations by a number of groups into the metal-controlled intertwisting of molecular threads to give double helical arrays. Although a considerable variety of ligands have been used for the preparation of double-helical coordination compounds, they all exhibit structural features

in common with **1**. The basic pattern consists of two or more polydentate ligands linked by spacer groups. Ligands which have been shown to give rise to double-helical structures include tetrapyrroles,[5] cyclohexane-1,2-diimines,[6] bishydrazones,[7] quater-,[8] quinque-,[9] and sexipyridines[10]. But the essential structural features are most simply seen in the linked oligobipyridines (**2**)[4, 11] and oligophenanthrolines[12]. In the same way that a triple helix is built up by coordination of bis-bidentate ligands to a six-coordinate metal center, a double helix is assembled by interaction with a four-coordinate (usually tetrahedral) one (Fig. 2).[12]

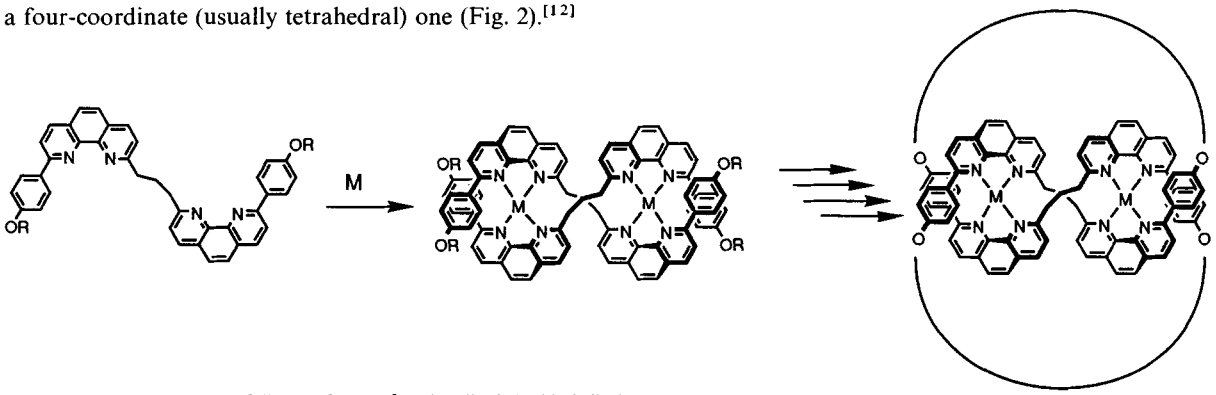

Fig. 3. The assembly of a trefoil knot from a functionalized double helical precursor. R = H, ∩ = $CH_2(CH_2OCH_2)_5CH_2$, M = Cu.

3

Why is there such interest in this esoteric activity? There are a number of answers to this question. Perhaps the simplest answer lies in the aesthetic beauty of the molecules which are obtained— helices and interlinked networks have long been associated with artistic works, and the molecular analogues are equally satisfying to the observer. A more serious reason to investigate these systems arises from some of the consequences of intertwisting molecular threads. *Sauvage* and *Dietrich-Buchecker* have demonstrated that the key intermediate for the synthesis of the trefoil knot **3** is a suitably functionalized double helix, and have used the metal-directed assembly of a double-helical complex as the key step in their elegant preparation of a molecular knot.[12] The important step is the formation of a double-helical dicopper(I) complex of a functionalized bis-1,10-phenanthroline ligand, followed by cyclization in a conventional macrocyclization step (Fig. 3).

The functionalization of helicate complexes offers another reason for their investigation. These are the first examples of a new class of chiral molecules, which may possess novel optical or electronic properties. *Lehn* et al. are investigating extrahelical interactions in which substituents on the external surface of a double-helical structure may interact with other molecules, of which helicate–nucleic acid interactions are an obvious area of interest.[13]

The future for metal-directed topological chemistry is very bright. The wide variety of coordination numbers and stereochemistries which are available offer a new "playground" for molecular chemists to prepare new structures in designed and high-yielding syntheses. A fusion of inorganic and organic chemistry is leading to an exciting and beautiful new interdisciplinary area.

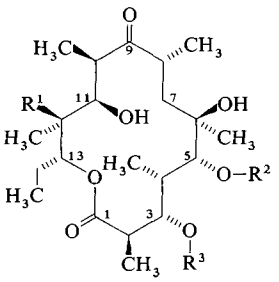
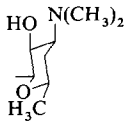
Erythromycin Synthesis—A Never-ending Story?

By *Johann Mulzer**

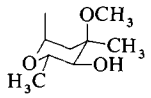
The synthesis of the macrolide antibiotics, erythromycin A (**1**) and B (**2**), which are highly effective against gram-positive pathogens, is probably the most extensive single project in the history of synthetic organic chemistry.[1] This phenomenon is not rational as **1** and **2** are accessible in large quantities from fermentation by the microorganism *Streptomyces erythreus*. It is the complexity of the molecule's structure, the plethora of stereocenters and functional groups, and the magic of the medium ring that has fascinated about 15 large research groups worldwide for more than a decade. All total syntheses followed the same pattern. They first aimed at the aglycons (erythronolides A and B, **3** and **4** respectively). The final glycosidation, and with it the synthesis of **1**, has been achieved only by the Woodward group.[2] The protected aglycons are formed by lactonization of the seco acids; for example, **3** is prepared from **5**–**7**, and **4** from **8**–**11**. The seco acids are constructed by coupling smaller chiral fragments that are obtained from the chiral pool, by optical resolution, or by enantioselective synthesis.



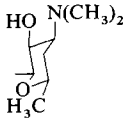
1, R^1 = OH, R^2 =



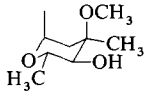
R^3 =



2, R^1 = H, R^2 =



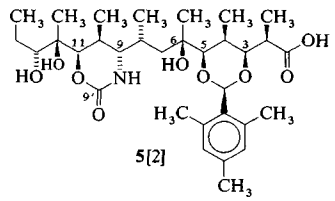
R^3 =



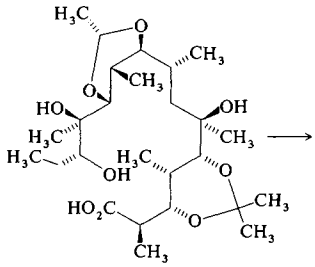
3, R^1 = OH, R^2 = R^3 = H

4, R^1 = R^2 = R^3 = H

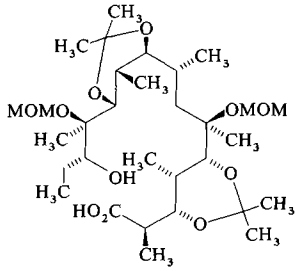
Over the years the priorities have shifted several times. Initially the attention focused on the seco acid fragments and therefore on the stereocontrolled construction of the often recurring β-hydroxycarbonyl and 1,3-diol units of **3**/**4**. The development of methods for enantio- and diastereomeric control (acyclic stereoselection[9]) proved to be unbelievably fruitful. Whereas the first syntheses of seco acids[2,6] required cyclic intermediates and optical resolution, and often resorted to "relay compounds" recovered from the degradation of the natural product, today in ca. 15 steps derivatives such as **10** and **11** can be constructed stereoisomerically pure in gram amounts.[7,8]



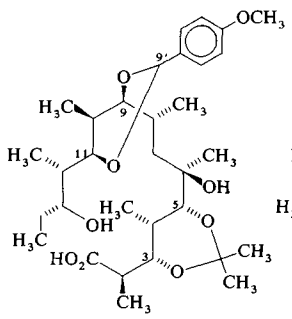
5[2]



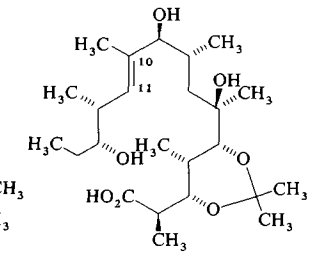
6[3]



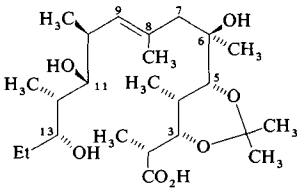
7[4]



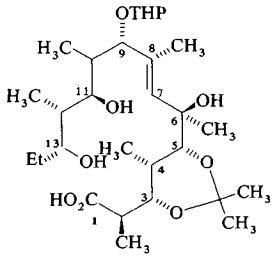
8[5]



9[6]



10[7]



11[8]

In the last two years the growing number of easily accessible seco acids shifted the attention more and more toward the lactonization step. In general this was carried out via an activated ester intermediate (**12**, Table 1). However, the formation of a 14-membered ring proved to be not straightforward; dimerization and polymerization are significant side reactions. The thiopyridyl activation (via the intermediates

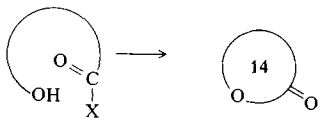
12a, b)[10] was the standard procedure for the macrolactonization for ten years, but has now been replaced by the Yamaguchi lactonization via the mixed anhydride **12c**. Next to activation the hydroxyl protecting groups play a central role. They not only suppress the formation of rings of unwanted size, but may also be used to induce conformations favorable for cyclization. Thus the 3,5-acetal or ketal unit in **5**–**11** locks the C2–C6 fragment of the molecule into a rigid, linear structure, due to the diequatorial arrangement around the 1,3-dioxane chair. In this case the 6-OH function may remain unprotected, because it can only be lactonized after flipping the acetonide to the diaxial conformation. The 9- and 11-hydroxyl groups are often protected by a cyclic acetal (as in **5**–**8**), which induces considerable transannular strain by the 9′-substituent. In fact, 9′-disubstituted derivatives such as **7** are substantially more difficult to cyclize than the corresponding 9′-monosubstituted seco acids **5**, **6**, and **8** (Table 1).[3,4] Moreover, the configuration at C9 is important: (9*S*) seco acids behave much more favorably than (9*R*)

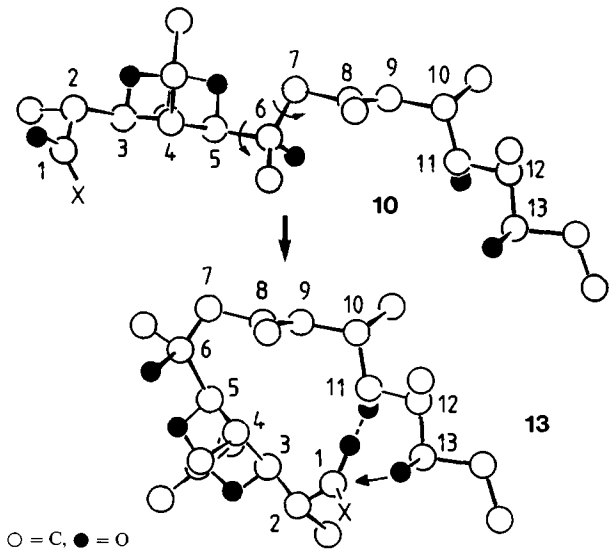


12

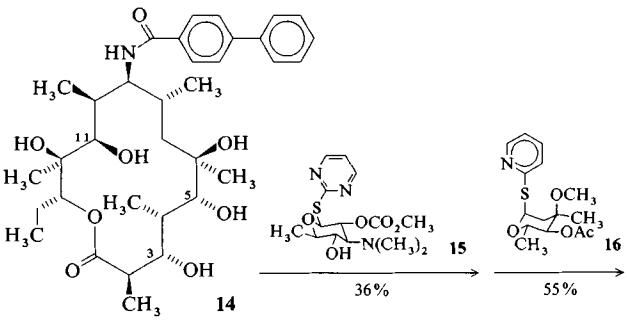
Table 1. Macrolactonization to form the 14-membered ring in the erythromycin synthesis.

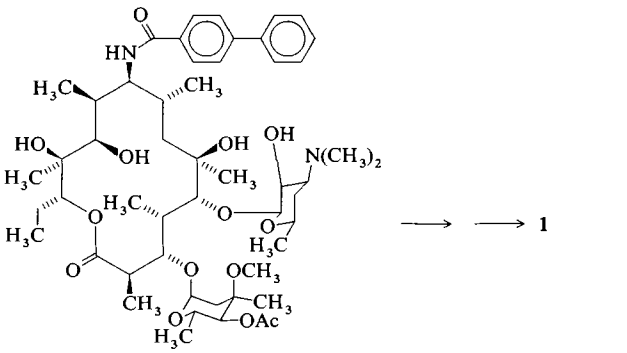
12	Activating group X	Product yield in [%]
a[10]		**5** (70)[2]
b[10]		**8** (65)[5], **9** (50)[6]
c[11]		**7** (27)[4], **10** (89)[7], **11**(>95)[8]

isomers.[2] Many of these hitches may be avoided by the introduction of a CC double bond in the critical region between C7 and C11 (see **9**–**11**). At least one OH function and its protecting group is then missing; in addition the two sp^2 centers on the periphery of the ring decrease the transannular ring strain. Trisubstituted olefins display the phenomenon of allylic 1,3 strain.[12] In seco acid **10** this leads to a sickle-like curve in the carbon chain at C7–C10. Thus simple rotations of the rigid C1–C6 fragments around the C5/6 and C6/7 axes lead to an optimal conformation for cyclization (**13**). The 11-OH group is out of reach of the carboxyl function and can remain free.[7]



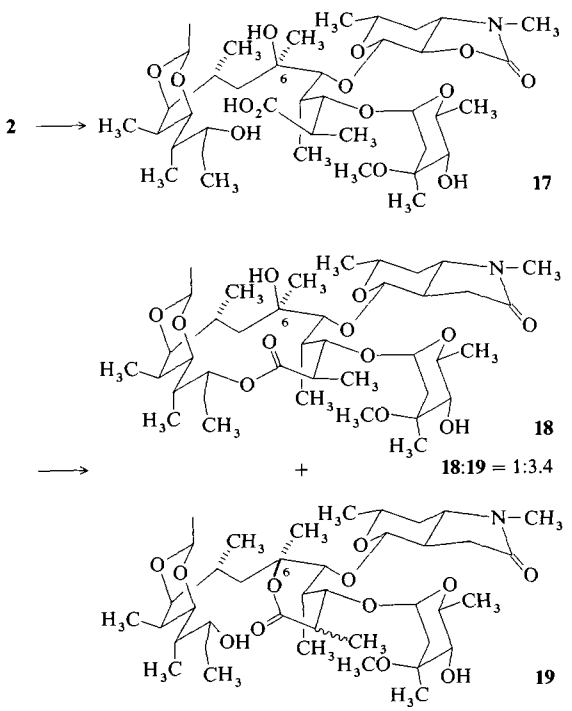
The high macrolactonization yields for **10**/**11** (Table 1) leave as the last aspect of the erythromycin synthesis to be solved the **3** → **1** and **4** → **2** glycosations, which are indispensible for the physiological activity. As was shown early by the Woodward group[2] both the monosaccharide blocks desosamine (**15**) and cladinose (**16**), in suitably protected and activated form, can be coupled to an almost "naked" aglycon (**14**). Only the 5- and the 3-OH groups can be glycosidated and the 5-OH group has a clear kinetic advantage over the 3-OH.





Recently in a remarkable experiment *S. F. Martin* and *M. Yamashita*[13] have broken with the accepted sequence of lactonization followed by glycosidation. In ten steps the diglycosidated seco acid **17** was prepared from **2** by *partial*

synthesis and subjected to the Yamaguchi conditions. However, the procedure afforded only small amounts of the desired macrolide **18**. The major products were seven-membered lactones **19** epimeric at C2. This is not surprising because the seven-membered ring is favored and can form readily, since the 6-OH function is not protected and also not blocked by a 3,5-ketal. As predicted, the Yamaguchi lactonization of the 6-OMe derivative of **17** (14 steps from **2**) affords exclusively the 6-OMe derivative of **18**, but in only 53% yield.



Have *Martin* and *Yamashita* solved the problem of erythromycin B synthesis? Hardly, because 1) the protecting groups of 6-OMe-**18** must still be removed and a mild 6-*O*-demethylation will probably be difficult, and 2) **17** is only partially synthesized; the necessary 3,5-differentiation for the total synthesis will be considerably more troublesome in the acyclic form than in the aglycon, where it occurs unaided.[2]

Therefore at the moment it seems more promising to stay with the traditional sequence and to optimize the glycosidation of **3**/**4** derivatives, perhaps by enzyme catalysis. After all, the biosynthesis follows this pathway: first **4**, and from it **2**.[14]

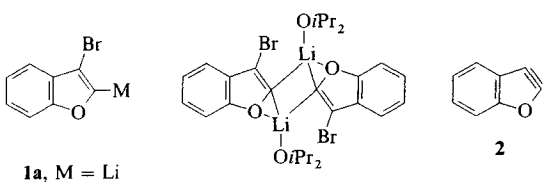
[3-Bromo-2-lithio-1-phenylsulfonylbenzofuran · Diisopropyl Ether]$_2$ and 3-Fluoro-2-lithio-1-phenylsulfonylbenzene · Pentamethyldiethylenetriamine: Crystal Structures of Compounds with Lithium and Halogen on Neighboring Carbon Atoms**

By *Ferdinand Bosold, Peter Zulauf, Michael Marsch, Klaus Harms, John Lohrenz,* and *Gernot Boche**

The elimination of a metal halide, MX (M = Li, Na, K, MgX, etc.; X = F, Cl, Br, I) from neighboring sp^3- or sp^2-hybridized carbon atoms (β-elimination) is a standard reaction for the preparation of (cyclo)olefins and (cyclo)acetylenes. A similar approach is used for the generation of arynes (dehydroaromatic compounds)[1] and heteroarynes.[2] As expected, the stability of the organometallic compound containing the α-halogen atom correlates with the instability of the corresponding unsaturated compound. This is observed, for example, on going from six-membered to five-membered ring compounds containing a "triple" bond.[1-3] It is of historical interest that 2,3-dehydrobenzofuran (**2**), which *Stoermer* and *Kahlert* formulated in 1902 as the reaction product of 3-bromo-2-sodio/potassiobenzofuran (**1b**), was the first (hetero)aryne to be postulated.[4] *Wittig* and *Kolb*[5], on the other hand, observed that 3-bromo-2-lithiobenzofuran (**1a**)—like other five-membered ring compounds of this structural type[6-9]—is stable at 20 °C. Trapping of **2** upon reaction of **1a, b** at higher temperature[4, 5] has been essentially ruled out in the meantime.[2]



The number of successful attempts to prepare dehydrobenzene and substituted dehydrobenzenes from the corresponding α-halogen-substituted organometallic benzene derivatives, in contrast, is legion. For instance, 1-fluoro-2-lithiobenzene decomposes at -60 °C to give LiF and dehydrobenzene.[1] A remarkable substituent effect is observed for 3-fluoro-2-lithio-1-phenylsulfonylbenzene (**3**), which only eliminates LiF on warming to $+60$ °C, affording phenylsulfonyl-substituted dehydrobenzene (**4**).[1, 10]

Here we report on the crystal structures of **1a**, which crystallizes from diisopropyl ether as [**1a** · O*i*Pr$_2$]$_2$, and **3** · PMDETA (Figs. 1 and 2, respectively).

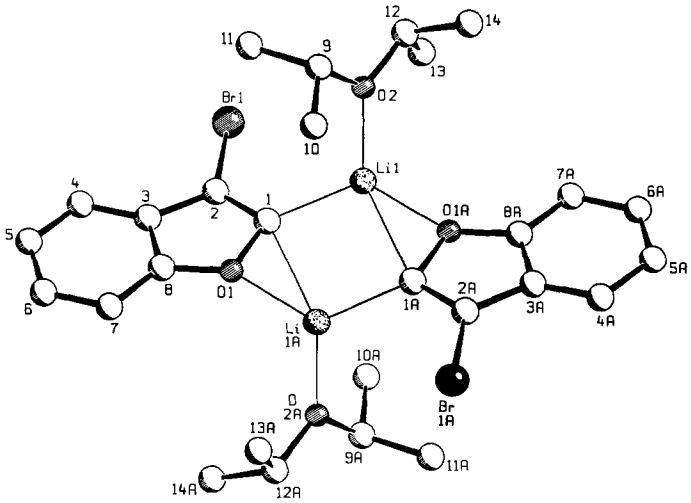


Fig. 1. Molecular structure of [**1a** · O*i*Pr$_2$]$_2$ [11, 13]. Selected bond lengths [pm] and angles [°]: Li1A-O1 195.4(6), O1-C1 147.0(4), C1-C2 134.9(4), C2-Br1 189.3(3), C1-Li1 212.2(7), C1-Li1A 250.2(6), Li1-O2 194.7(6), O1-C8 137.5(4), C2-C3 144.4(5), C3-C8 139.4(4), Li1-Br1 386.7(6), Li1A-Br1 533.3(6); C8-O1-C1 109.6, O1-C1-C2 102.9(3), C1-C2-C3 113.9(3), C1-C2-Br1 124.2(3), Li1-C1-C2 130.3(3), C1-O1-Li1A 92.8(2), O1-C1-Li1A 51.3(2); Li1-C1-C2-Br1 28.9(5), Li1A-C1-C2-Br1 $-151.5(4)$, O1-C1-C2-Br1 $-179.5(2)$, C2-C1-O1-Li1A 162.4(3).

As Figure 1 shows, [**1a** · O*i*Pr$_2$]$_2$ is present as a *trans* dimer whose anionic C atoms are bridged through lithium. C1-Li1 (212.2(7) pm) is markedly shorter than Li1-C1A (250.2(6) pm). The preferred tetracoordination of the Li atoms is achieved through one bond to the oxygen atom of the diisopropyl ether (Li1-O2 194.7(6) pm) as well as to the oxygen atom of the bromobenzofuranyl anion (Li1-O1A 195.4(6) pm). This *intra*molecular O–C bridging through Li is also found in [2-lithiobenzofuran · TMEDA]$_2$ for *one* of the two anions with pentacoordination of the bridging Li.[18, 19] The two bromobenzofuranyl anions of [**1a** · O*i*Pr$_2$]$_2$ lie in the same plane; the Li1–Li1A axis is bent out of this plane by an angle of 62.7°. The C1–O1 bond (147.0(4) pm) is relatively long—the O1–C8 bond is 137.5(4) pm long[20]—in accord with the situation for [2-lithiobenzofuran · TMEDA]$_2$ (145.3 pm)[18] and our observations for two other α-oxygen-substituted organolithium compounds.[21] A lengthening of this bond, as well as the bridging of O1 and the anionic C1 atom through Li, is in agreement with model calculations on $LiCH_2OH$.[22]

The stability of [**1a** · O*i*Pr$_2$]$_2$ toward β-elimination of LiBr (as well as the stability of other lithiated five-membered ring

[*] Prof. Dr. G. Boche, F. Bosold, Dipl.-Chem. P. Zulauf, M. Marsch, Dr. K. Harms, Dipl.-Chem. J. Lohrenz

[**] This work was supported by the Deutsche Forschungsgemeinschaft (SFB 260) and the Fonds der Chemischen Industrie.

compounds containing α-halogen atoms[1, 2, 6–9]) indicates that, as observed here, the structure is not favorable for elimination. Thus, the C2–Br1 bond length (189.3(3) pm) corresponds roughly to the C–Br distance found in nonlithiated 4-bromo-2-formylburan (189.9 and 190.3 pm).[23, 24] Furthermore, no close approach of Li and Br is evident, as revealed by the Br1–C2–C1 (124.2(3)°) and C2–C1–Li1 (130.1(3)°) angles and the Li1–Br1 (386.7(6) pm) and Li1A–Br1 (533.3(6) pm) distances. Li1 (Li1A) lies outside the Br1–C2–C1 plane, as shown by the Li1(Li1A)–C1–C2–Br1 torsion angle of 28.9(5)° (– 151.5(4)°).

The crystal structure of **3** · PMDETA (Fig. 2) shows that the greater ease of MX elimination is also reflected structurally. In **3** · PMDETA, which is present as a monomer, the

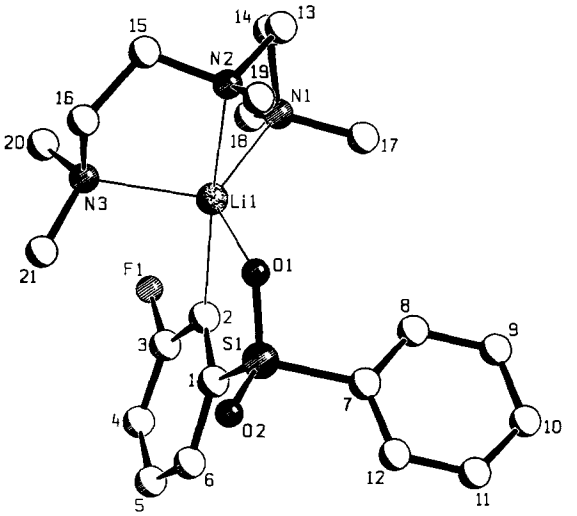

Fig. 2. Molecular structure of **3** · PMDETA [25, 26]. Selected bond lengths [pm] and angles [°]: Li1-N1 227.8(7), N2-Li1 228.6(8), N3-Li1 219.4(8), C1-C2 139.5(5), C2-C3 138.2(6), C3-C4 136.7(6), C4-C5 137.0(6), C5-C6 138.9(6), C1-C6 138.5(6), C1-S1 177.0(4), C7-S1 176.5(4), S1-O1 145.0(3), S1-O2 144.2(3), Li1-O1 217.0(8), C2-Li1 225.8(8), C3-F1 138.9(5), Li1-F1 367.2(7); F1-C3-C2 117.9(4), C3-C2-Li1 133.8(4), S1-C1-C2 116.3(3); F1-C3-C4-C5 – 179.3(4), Li1-C2-C3-F1 25.7(6), C2-C1-S1-O1 149.7(3).

Li1 atom exhibits, besides the three contacts to the N atoms of the amine ligand, an additional contact to the anionic C2 atom (Li1-C2 225.8(8) pm) and to the O1 atom of the sulfonyl group (O1-Li1 217.0(8) pm). Li1 lies outside the plane of C1 to C6 and F1: Li1-C2-C3-F1 25.7(6)°. We have previously observed a five-membered ring structure such as that formed by C2-C1-S1-O1-Li1.[28a] This complexation of lithium by the neighboring phenylsulfonyl group explains why the LiF elimination in **3** occurs only at + 60 °C.[1, 28b] Despite the very large Li1–F1 distance (367.2(7) pm), the C3–F1 distance (138.9(5) pm) is still lengthened compared to the average value of 160 C_{aryl}–F distances (135.4 pm; Cambridge Structural Database). Interestingly, another α-fluoro-substituted organometallic compound also exhibits a lengthened C–F distance: in bis(2-fluorophenyl)triphenylbismuth, this distance is 138.2 pm.[29] Accordingly, it is reasonable to assume that the observed LiF elimination from **3** in solution to give the aryne **4** is structurally reflected, in the sense of the correlation principle,[30] in the crystal structure of **3** · PMDETA, in total contrast to the situation found for [**1a** · O*i*Pr$_2$]$_2$ and **1a**.

[11] Preparation of [**1a** · O*i*Pr$_2$]$_2$: 2,3-Dibromobenzofuran (250 mg, 0.91 mmol) was dissolved in 3 mL of diisopropyl ether and treated at – 78 °C with 0.6 mL (0.96 mmol) of a 1.6 M solution of *n*BuLi in hexane. After 20 min, the solvent was removed from the precipitated Li compound and the solid was washed twice with 1 mL of hexane and then dissolved in 9 mL of diisopropyl ether at 50 °C. After 24 h at 4 °C, single crystals suitable for X-ray structure analysis had formed. ^{1}H NMR ([D$_8$]THF, 293 K): δ = 7.19 (d, J = 9 Hz, 1 H), 7.18 (d, J = 9 Hz, 1 H), 6.95 (t, J = 7 Hz, 1 H), 6.86 (t, J = 7 Hz, 1 H) (H5-H8), 3.69 (sept, J = 7 Hz, 2H; C*H*(CH$_3$)$_2$); 1.07 (d, J = 7 Hz, 12H; CH(C*H*$_3$)$_2$). ^{13}C-NMR ([D$_8$]THF, 173 K): δ = 218.4 (q, J(^{13}C,^{7}Li) = 40 Hz; C2), 160.5 (C9), 130.4 (C4), 111.6 (C3), 120.4, 119.6, 116.2, 109.9 (C5-C8), 67.4 (*C*H(CH$_3$)$_2$), 22.9 (CH(*C*H$_3$)$_2$). The quartet of the ^{13}C–^{7}Li coupling shows that only *one* C–Li bond is still present when [**1a** · O*i*Pr$_2$]$_2$ is dissolved in [D$_8$]THF and investigated by NMR spectroscopy at 173 K. We still do not know which C1–Li bond is broken or whether a dimer or monomer is present [12]. Note added in proof (September 24, 1991): A cryoscopic determination of the aggregation state of [**1a** · O*i*Pr$_2$]$_2$ in THF at – 108 °C revealed a monomeric **1a** (F. Haller, Universität Marburg 1991).
[12] For comparison: ^{13}C NMR spectrum of 3-bromobenzofuran ([D$_8$]THF, 173 K), δ = 155.1 (C9), 144.7 (C2), 127.6 (C4), 126.5, 124.5, 120.2, 112.6 (C5-C8), 98.5 (C3).
[13] Crystal structure data for [**1a** · O*i*Pr$_2$]$_2$: $C_{14}H_{18}BrLiO_2$, M = 305.14; forms triclinic crystals, space group $P\bar{1}$, a = 8.200(4), b = 8.916(5), c = 11.315(4) Å, α = 72.87(3), β = 69.01(3), γ = 74.97(4)°, Z = 2, ϱ_{ber} = 1.394 g cm^{-3}, μ = 2.788 mm^{-1}. 2761 reflections were measured on an Enraf-Nonius diffractometer (Mo$_{K\alpha}$ radiation, graphite monochromator, T = 179 K) of which 2563 were unique (R_{int} = 0.0194) und 2271 with $F_o > 4\sigma(F_o)$ were regarded as observed. Empirical absorption correction. Solution by direct methods (SHELXTL Plus), refinement (SHELXTL Plus) to R = 0.0314, wR = 0.0322, $w = 1/\sigma^2(F_o)$. Non-hydrogen atoms refined anisotropically, position of the hydrogen atoms determined and refined with groupwise common temperature factors. 221 parameters. All calculations were performed on a MicroVAX II [14–17].

[19] On the basis of model calculations on *intra*molecular solvation in *monomeric* 2-furanyllithium, *Harder* concluded that the O–C bridging through Li is considerably overestimated and is overcome by solvent molecules (three OH_2 on Li); I thank Dr. *S. Harder*, University of Utrecht, for sending us his dissertation (1990). This result, however, is not directly comparable with the crystal structures of the *dimeric* $[\mathbf{1a} \cdot O i Pr_2]_2$ and [2-lithiobenzofuran · TMEDA]$_2$ [18], since in the calculated monomer Li lies *in* the plane of the furan ring, while in the crystalline dimers the Li atoms lie *above* and *below* the planes of the benzofuran rings (private communication, *A. Harder*, September 7, 1991).

[20] The average value of the bond lengths corresponding to O1-C1 (O1-C8) is 138.5 (137.1) pm for 27 benzofurans (Cambridge Structural Database).

[24] Average value of C–Br for 1121 bromarenes: 189.7 pm (Cambridge Structural Database).

[25] Preparation of **3** · PMDETA: 3-(fluorophenyl)phenylsulfone (150 mg, 0.63 mmol) was dissolved in 0.5 mL tetrahydrofuran, deprotonated at −75 °C with 0.4 mL (0.64 mmol) of a 1.6 M solution of *n*BuLi in hexane, and then treated immediately with 0.2 mL of PMDETA. After 30 min, the reaction solution was warmed to 20 °C and 1 mL of hexane was added. After 6 h at 0 °C, crystals suitable for X-ray structural analysis were obtained. ^{1}H NMR ([D$_8$]THF, 258 K) δ = 7.92 (d, J = 7 Hz, 2H), 7.50 (m, 3H), 7.34 (dd, $J(^1H, ^1H)$ = 7 Hz, $J(^1H, ^{19}F)$ = 2.6 Hz), 6.98 (dt, $J(^1H, ^1H)$ = 7 Hz, $J(^1H, ^{19}F)$ = 7 Hz), 6.72 (d, J = 7 Hz, 1H), 2.53 (s, 4H; CH_2-PMDETA), 2.52 (s, 4H; CH_2-PMDETA), 2.44 (s, 3H, CH_3-PMDETA), 2.23 (s. 12H, CH_3-PMDETA). ^{13}C-NMR ([D$_8$]THF, 253 K) δ = 176.2 (d, ^2J(C,F) = 133.3 Hz; C2), 172.2 (d, ^1J(C,F) = 217.5 Hz; C3), 153.9 (d, ^3J(C,F) = 39.0 Hz; C1), 145.0 (C7), 132.6 (C10), 129.4 (C9-C11), 128.0 (C8-C12), 126.2 (d, ^3J(C,F) = 5.0 Hz; C5), 122.4 (d, ^4J(C,F) = 3.8 Hz; C6), 114.2 (d, ^2J(C,F) = 42.7 Hz; C4), 57.7, 55.1, 46.1, 44.4 (PMDETA). For comparison: ^{13}C NMR spectrum of 3-(fluorophenyl)phenylsulfone ([D$_8$]THF, 253 K): δ = 163.2 (d, ^1J(C,F) = 250.3 Hz; C3), 145.2 (d, ^3J(C,F) = 6.3 Hz; C1), 142.3 (C7), 134.4 (C10), 132.5 (d, ^3J(C,F) = 7.8 Hz; C5), 130.3 (C9-C11), 128.6 (C8-C12), 124.6 (d, ^4J(C,F) = 3.4 Hz; C6), 121.2 (d, ^2J(C,F) = 21.4 Hz; C4), 115.5 (d, ^2J(C,F) = 23.9 Hz, C2). Particularly noteworthy is the difference in the ^2J(C2,F) coupling in the "anion" **3** · PMDETA (133.3 Hz) and in the neutral compound 3-(fluorophenyl)phenylsulfone (23.9 Hz). *Harder*, in his dissertation [19], described this phenomenon for the first time in 1990 for several other fluorinated pairs of compounds and explained it in terms of a through-space interaction of fluorine with the "lone pair" of the C–Li bond. Related couplings have been explained in a similar way by *F. B. Mallory, C. W. Mallory* und *W. M. Ricker* (*J. Org. Chem. 50* (1985) 457). The ^3J(C1,F) coupling in the "anion" is also markedly larger (39.0 Hz) than in the neutral compound (6.3 Hz); not quite as large is the difference in the ^2J(C4,F) couplings: "anion", 42.7 Hz; neutral compound: 21.4 Hz. The C2–Li coupling could not be resolved in the temperature range 198–253 K, a result also found by *Harder* for 2-fluorophenyllithium at lower temperatures [19].

[26] Crystallographic data for **3** · PMDETA: $C_{21}H_{31}FLiN_3O_2S$, M = 415.5, monoclinic, space group $P2_1/n$, a = 889.4(3), b = 1997.2(2), c = 1304.6(4) pm, β = 101.34(1)°, Z = 4, $\varrho_{ber.}$ = 1.215 gcm^{-3}, μ($Cu_{K\alpha}$ radiation) = 14.62 cm^{-1}. Measurement carried out an Enraf-Nonius CAD4 diffractometer ($Cu_{K\alpha}$ radiation, λ = 1.54184 Å, graphite monochromator, T = 190 K); 3137 measured reflections, of which 2807 were unique (R_{int} = 0.0667) and 2579 with $F > 4\sigma(F)$ were regarded as observed. Solution by direct methods and refinement with the Siemen's SHELXTL-PLUS(VMS) program package, R = 0.0636, wR = 0.0693 ($w = 1/\sigma^2(F)$), all non-hydrogen atoms refined anisotropically, H atoms refined in a "riding" model with groupwise common isotropic temperature factors [15, 16]. The measurement data were corrected empirically with the program DIFABS [27]. Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, W-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-320305, the names of the authors, and the journal citation..

Extension of Free Energy Correlations to Gas-Phase Ionic Reactions. Competitive Alkylation of Substituted Benzonitriles by $(CH_3)_2Cl^+$ Ions**

By *Marina Attinà, Fulvio Cacace,** and *Andreina Ricci*

The study of structure–reactivity relationships is greatly complicated in solution by the effects of the reaction medium, which are quantitatively reflected in the Hammett equation and in other free energy correlations by the strong dependence of the reaction constant on the nature of the solvent.[1] The substantially reduced impact of such complicating factors in gaseous media is a strong incentive to extend the study to the gas phase, especially in the case of charged species whose reactivity is deeply affected and diversified by the effects of solvation, ion pairing, viscosity, etc.

So far, experimental approaches to the problem have met with considerable problems, since in the low-pressure range accessible to mass spectrometry operation of a unique "electrostatic activation" mechanism prevents ion–molecule reactions from obeying thermal kinetics, a necessary prerequisite for the construction of free energy correlations. In fact, without efficient collisional thermalization, the energy released by the electrostatic interaction of the reactants remains stored in the ion–molecule complex formed and is available to overcome the activation barrier of the reaction.[2, 3] This explains why most exothermic ion–molecule reactions have been found to proceed at the collision rate, often with *negative* temperature coefficients, when investigated by mass-spectrometric techniques.

Here we report the construction of a free energy correlation in a typical gas-phase ionic reaction by a different approach, based on the combination of mass-spectrometric and high-pressure radiolytic techniques successfully exploited in the study of thermal ion–molecule kinetics.[4]

Since it was deemed important to follow in the gas phase exactly the same procedure adopted in solution for the derivation of the original Hammett[5] equation, a suitable ionic process was sought, involving a side-chain reaction center bound to a *meta*- or *para*-substituted aromatic ring.

The reaction chosen [Eq. (a)], the counterpart of the Ritter reaction long known in solution[6] and previously investigat-

[**] This work was supported by the Italian Ministero dell'Università e della Ricerca Scientifica e Tecnologica (MURST) and the National Research Council (CNR).

ed in the gas phase,[7] involves *N*-alkylation of substituted benzonitriles by $(CH_3)_2Cl^+$ ions, obtained upon ionization of gaseous CH_3Cl according to a well-established[8] reaction sequence.

$$XC_6H_4CN + (CH_3)_2Cl^+ \longrightarrow \underset{\mathbf{1}}{XC_6H_4C{\equiv}\overset{+}{N}CH_3} + CH_3Cl \qquad (a)$$

Even in the absence of specific thermochemical data for all the substrates involved, it can be asserted with confidence that reaction (a) is generally exothermic (e.g., a ΔH° value of -163 kJ mol^{-1} can be estimated for X=H[9]). The nitrilium ions **1** can subsequently be captured by a gaseous nucleophile (e.g., water), eventually yielding the corresponding *N*-methylbenzamides [Eq. (b)].

$$\mathbf{1} \xrightarrow{+H_2O} XC_6H_4\overset{+}{C}(OH_2)NCH_3 \xrightarrow[-H^+]{} XC_6H_4\overset{+}{C}(OH)NHCH_3 \xrightarrow[-BH^+]{+B} XC_6H_4CONHCH_3 \qquad (b)$$

Chemical ionization (CI) mass spectrometry of appropriate gaseous mixtures demonstrates the occurrence of processes (a) and (b), in particular the CH_3Cl/CI spectra of benzonitriles diplay ions **1** as major charged adducts.

Whereas the CI experiments allow the mechanistically informative detection of the charged reactants and intermediates, they are not equally useful from the kinetic standpoint; that is, no meaningful selectivity data could be obtained from the competitive alkylation of nitriles under the conditions ($p(CH_3Cl) = 67$ Pa, $T = 330$ K) prevailing in the CI ion source.

The radiolytic experiments, representative examples of which are illustrated in Table 1, involved γ irradiation of CH_3Cl gas (100 kPa, 320 K) containing traces of the nitriles and of water, followed by analysis of the neutral end products by GC and GC/MS. The results show that indeed *N*-methylbenzamides are obtained in high yields, accounting for up to 30% of the radiolytically formed $(CH_3)_2Cl^+$ ions, depending on the composition of the irradiated systems, where the nitriles compete with other nucleophiles (e.g., the water vapor added to trap the nitrilium ions) for the $(CH_3)_2Cl^+$ ions. The ionic character of the alkylation is ensured by a large excess of an effective radical scavenger (O_2) and independently demonstrated by the depression of the yields upon addition of a gaseous base which intercepts the $(CH_3)_2Cl^+$ ions (see Table 1).

The results of the competition experiments conform to a Hammett-type equation, $\lg k/k_0 = \rho\sigma^+$, characterized by a reaction constant $\rho = -1.9$, a correlation of 0.98, and a zero intercept (Fig. 1). The quality of the correlation is quite reasonable if one considers that the σ^+ constants used are the ones derived from conventional solution kinetics[1] and their values may be somewhat different in a gaseous reaction medium. Furthermore, the largest deviation from linearity, observed for the OCF_3 substituent, may reflect, at least in part, the uncertainty of its σ^+ constant measured in solution.

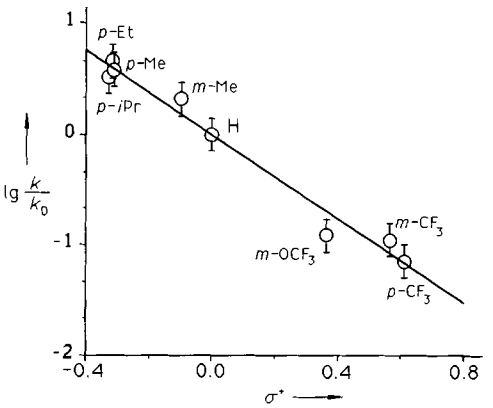

Fig. 1. Hammett-type plot of the relative reactivity of substituted benzonitriles, XC_6H_4CN, toward gaseous $(CH_3)_2Cl^+$ ions in CH_3Cl gas at 100 kPa, 320 K.

The selectivity of $(CH_3)_2Cl^+$ characterizes the gaseous reagent as a typical, if rather indiscriminate, electrophile, as shown by the small and negative value of its ρ constant.

As to the general problem addressed in this study, it seems fair to conclude that the results are definitely encouraging. In fact, a typical ion–molecule reaction, whose selectivity is inappreciable under mass-spectrometric conditions, when studied in a pressure domain where thermal kinetics are obeyed, lends itself to the construction of a free energy correlation analogous to those established in solution.

Extension of the approach outlined here to other reactants, and to different reference reactions, can be a useful step toward unified structure–reactivity relationships, unaffected by the complicating effects of the medium that influence ionic processes in solution, and hence amenable to direct correlation with theoretical results.

Table 1. Methylation of benzonitriles, XC_6H_4CN, by $(CH_3)_2Cl^+$ ions in CH_3Cl at 320 K, 100 kPa.

[a] All systems contained O_2 (1.33 kPa) as a radical scavenger. SF_6 (0.667 kPa) was used in certain irradiations as a thermal-electron scavenger. [b] Standard deviation ± 10%. [c] Not detectable.

Experimental Procedure

Pyrex ampules containing premixed gaseous systems of the desired composition, preheated for 22 h at 320 K to ensure complete evaporation of relatively involatile nitriles, were irradiated (9.6×10^3 Gy, 1.9×10^4 Gy h^{-1}) in a Gammacell (Nuclear Canada Ltd.), equipped with a thermostatic device, at 320 K, suitable blanks being run to rule out the occurrence of "dark" reactions. The products were analyzed by GC and GC/MS, using a HP 5970 B mass-selective detector and a TRIO 1/QMD 1000 (VG Micromass). The CI measurements were carried out in CH_3Cl at 67 Pa, 330 K, using a HP 5982 A quadrupole instrument or a VG Micromass ZAB-2F magnetic spectrometer.

Observation of a Direct Sn–Li Bond; The Crystal and Molecular Structure of Monomeric [$Ph_3SnLi \cdot PMDETA$] and the Detection of $^{119,117}Sn$–^7Li NMR Coupling in Solution**

By *David Reed, Dietmar Stalke*, and *Dominic S. Wright**

Stannyl-metal reagents (R_3SnM, R = alkyl or aryl; M = Li, Na, K, MgX, X = halogen) have been used widely by organic chemists for some years.[1] Such reagents have been prepared prior to use by low-temperature in situ reactions of organotin halides (R_3SnX), hexaorganoditins (R_3SnSnR_3), or organotin hydrides (R_3SnH) with the metals (M) or organometallics (RM).[2] They are particularly useful in the formation of tin–carbon bonds by stannylation of electrophilic substrates (e.g., ketones, epoxides, and vinyl halides) and many of these reactions occur with control of regio- and stereoisomerism.[2] However, despite such synthetic utility, even the simple and widely employed trialkyl and triaryl derivatives have not been systematically studied in solution and the solid state. Reflecting such lack of data on these species, there has been some controversy as to whether the lithium ion is bound to the tin or whether a solvent-separated ion pair is present.[2, 3] We describe here the synthesis of [$Ph_3SnLi \cdot$ PMDETA] (**1**; PMDETA = $(Me_2NCH_2CH_2)_2NMe$) from the metalation reaction of Ph_3SnH with *n*BuLi in the presence of PMDETA and its characterization in solution and in the solid state. In the crystal, **1** is monomeric (n = 1) and contains a Sn–Li bond between the pseudotetrahedral Ph_3Sn^- anion and the (PMDETA)Li^+ cation. This is the first simple triaryl- or trialkylstannyllithium reagent to be structurally characterized and the first clear identification of a Sn–Li bond, or indeed, we believe, of any bond between tin and an alkali metal or alkaline-earth metal. Cryoscopy measurements show that **1** is similarly monomeric in solution. The maintenance of Sn–Li bonding is proved by the first observation, in low-temperature ^7Li NMR studies, of direct $^{119,117}Sn$–^7Li coupling.

Addition of *n*BuLi to a chilled solution of Ph_3SnH and PMDETA in toluene (1:1:1 equivalents) leads to the formation of a white precipitate. This dissolves on heating and, from the clear yellow solution produced, colorless crystals of **1** were grown in good yield (see *Experimental Procedure*).

Crystals of **1**, mounted directly from the mother liquor, were investigated by X-ray diffraction.[4] The structure (Fig. 1) is that of a monomer, [$Ph_3SnLi \cdot$ PMDETA]. The two crystallographically independent molecules within the asymmetric unit differ essentially only in the stereochemistry of the coordinated tridentate amine ligand. The main feature

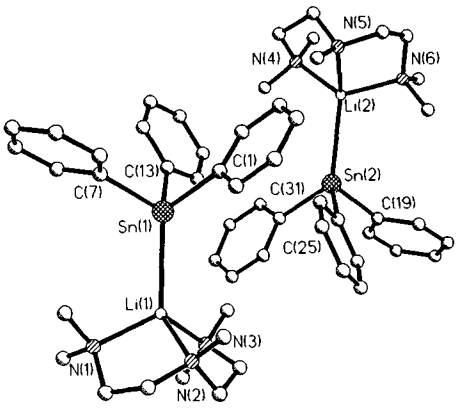

Fig. 1. The molecular structure of both monomer molecules of **1** in the asymmetric unit. Hydrogen atoms have been omitted for clarity. Selected distances [Å] and angles [°]: Li(1)-Sn(1) 2.861(7), Li(2)-Sn(2) 2.882(7), Sn(1)-C(1) 2.221(4), Sn(1)-C(7) 2.210(4), Sn(1)-C(13) 2.212(3), Sn(2)-C(19) 2.205(4), Sn(2)-C(25) 2.210(4), Sn(2)-C(31) 2.180(4); C-Sn-C 96.1(2) (average); Li-Sn-C 120.7(2) (average).

is the clear occurrence of a Sn–Li bond (Sn-Li, average 2.817(7) Å). This bond is only slightly longer than expected for pure covalent bonding (sum of covalent radii of Sn and Li, ca. 2.74 Å). Although a considerable number of alkali and alkaline-earth stannate complexes have been structurally characterized, *none* of these contain metal–Sn contacts; rather, these are ion-separated species or else bridging heteroatoms (e.g., O, P, Cl) hold the metal and Sn centers together. The closest analogue to **1** is the only other lithium triorganostannate thus far characterized in the solid, [Li(dioxane)$_4$]$^+$ [Sn(furyl)$_3$ · Li(furyl)$_3$Sn]$^-$ [furyl = $-\overline{C(CH)_3O}$], the anion of which consists of two pyramidal Sn(furyl)$_3^-$ ions linked via their furyl O atoms to a central six-coordinate Li center; there is no obvious Sn–Li contact.[3] Also, within the structure of the trialkoxystannate, [Li(μ-2,6-

$Ph_2C_6H_3O)_3Sn]$, μ_2-bridging of the three O atoms is probably responsible for the close approach of Li to Sn (Sn-Li, 2.784(4) Å).[5] However, the absence of further intermolecular association involving the donor-deficient and highly distorted pyramidal Li centers may, in the light of our current work, imply some degree of Sn–Li intramolecular bonding, rather than the hinted-at agostic aryl $\cdots$ Li interactions.[5] In marked contrast to the few hitherto known Sn–Li complexes, there are certainly no bridging phenyl $\cdots$ Li interactions in **1**. Indeed, the phenyl groups bend *away* from the Sn–Li contact (average Li-Sn-C 120.7(2)°), so that the average C–Sn–C angle (96.1(2)°) is well below that expected for pure tetrahedral geometry about the Sn center (cf. ca. 109° in $Ph_3SnSnPh_3$[6]). A similar pyramidal geometry has been observed for the "naked" Ph_3Sn^- ion in the solid-state structure of $[(18\text{-crown-6})K^+ \cdots SnPh_3^-]$ (closest K $\cdots$ Sn contact > 6 Å; average C-Sn-C 96.9(2)°).[7] This suggests that, within this ion (whether separated or, as in **1**, contacted), a high degree of p character is employed in Sn–C bonding. As a result, the lone pair on the Sn center has mainly s character. The trend towards planarity of the central atoms observed in the Ph_3C^- system[8] is not found here.

Finally, cryoscopic relative molecular mass measurements show that **1** is also monomeric in benzene (number of formula units 0.96 ± 0.05, $c = 0.013$ mol L^{-1}). Thus, the Sn–Li contact observed in the crystal structure is maintained. Evidencing this, low-temperature 139.96-MHz ^{7}Li NMR spectra of **1** in [D_8]toluene (-90 °C, $c \approx 0.020$ mol L^{-1}, PhLi external standard in [D_8]toluene) clearly show the presence of unresolved ^{119,117}Sn ($I = 1/2$)–^{7}Li coupling, as an apparent 1:1 doublet ($J \approx 412$ Hz[9]) (Fig. 2).[10] The integral ratio

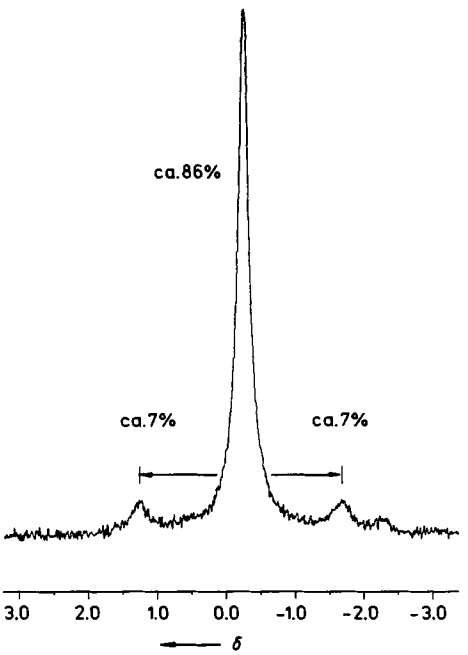

Fig. 2. The low-temperature 139.96-MHz ^{7}Li NMR spectrum of **1**. The average coupling constant $J(^{119,117}Sn\text{-}^7Li)$ is 412 Hz. For further details see text.

of these satellites to the central ^{118}Sn($I = 0$)–^{7}Li signal tallies with the natural abundance ratios of ^{119,117}Sn to ^{118}Sn (ca. 14:86). To our knowledge, this is the first observation of such direct coupling, although very weak long-range ^{119,117}Sn–^{7}Li coupling ($J = 6.2$ Hz) has been observed in the low-temperature ^{7}Li NMR spectrum of 6-substituted 3-trimethylstannylbicyclo[3.2.1]octa-2,6-dienyllithium in THF.[11]

We are now extending this initial work by similarly investigating a variety of alkali-metal (Li, Na, K, Rb, Cs) and alkaline-earth-metal (Mg, Ca, Sr, Ba) triphenylstannate complexes. The hope is to further elucidate the nature of these bonds between p-block metals and early-main-group metals and to assess the structural trends within these compounds.

Experimental Procedure

1: *n*BuLi (2.6 mmol, in hexanes) was added to a chilled solution (ca. -10 °C) of Ph_3SnH (0.91 g, 2.6 mmol) in toluene (12 mL) and PMDETA (0.55 mL, 2.6 mmol) under nitrogen. An exothermic reaction ensued as the reaction mixture warmed to 20 °C, giving a yellow solution and a white precipitate, which dissolved on heating to 70 °C. Slow cooling of the resulting yellow solution (12 h) gave air-sensitive, colorless crystals, identified as [$Ph_3SnLi \cdot$ PMDETA] (**1**). First batch yield 52%, m.p. 145 °C, dec. 230–235 °C to black oil ^{1}H NMR (C_6D_6): $\delta = 8.12$ (m, 5H; phenyl H), 7.30 (m, 10H; phenyl H), 1.86 (s, 3H; CH_3-N), 1.76 (s, 12H; $(CH_3)_2$N-), 1.50 (m, 8H; $(CH_2)_2$). Correct C, H analysis.

Investigation of the Light-Induced Charge Transfer between Covalently Linked Porphyrin and Quinone Units by Time-Resolved EPR Spectroscopy**

By *Friedhelm Lendzian,* Jenny Schlüpmann, Jörg von Gersdorff, Klaus Möbius,** and *Harry Kurreck**

The efficiency of the light-induced charge separation in the primary step of photosynthesis is governed by the molecular and electronic structure of the chlorophyll donor and the pheophytin and quinone acceptors and by their mutual separations and orientations. Covalently linked porphyrin quinones (P-Q's) have proven particularly suitable as model compounds for the investigation of these complex electron-transfer (ET) processes.[1] In liquid solvents at room temperature, these compounds generally show rapid ET from the optically excited singlet state of the porphyrin component to the quinone in a time range of several 10 to several 100 ps.[1] Current interest has focused increasingly on the influence of the static and dynamic properties of the surrounding medium on the ET rates. The reorientation of the polar solvent molecules (dielectric relaxation) as a result of Coulomb interaction on transition from ^{S}*P-Q to ^{S}($P^{\bullet+}$-$Q^{\bullet-}$) affects, according to Marcus theory,[2] the free energy ΔG^0 of the reaction and particularly the reorganization energy λ_0.[3] With increasing viscosity (decreasing temperature) the dielectric relaxation time τ_l of the solvent increases and can strongly decrease the rate of the ET reaction. The adiabaticity parameter[4] κ [Eq. (a)] is the decisive factor, where V is the

$$\kappa = 4\pi V^2 \tau_l/(\lambda_0 \hbar) \qquad \text{(a)}$$

electronic interaction between the initial state ^{S}*P-Q and the charge-separated state ^{S}($P^{\bullet+}$-$Q^{\bullet-}$) (Fig. 1) and τ_l is the longitudinal dielectric relaxation time[4] of the solvent. For $\kappa \ll 1$, a nonadiabatic ET results; this is usually assumed for P-Q's in low-viscosity solvent at around 300 K. For $\kappa \gg 1$, the reaction proceeds adiabatically. The ET rate is proportional to τ_l^{-1}[4] and therefore strongly temperature-dependent. Thus, the ET reaction from the excited singlet state of a P-Q could be sufficiently slowed down in a polar solvent at low temperature to observe the competing reaction via intersystem crossing (ISC) to the excited triplet state of the porphyrin component, followed by ET to the charge-separated triplet state of the radical pair ^{T}($P^{\bullet+}$-$Q^{\bullet-}$) (Fig. 1). Both triplet states could be detected for the first time in a P-Q by time-resolved EPR spectroscopy in the time range of several 100 ns to several 10 μs.[5]

A recent report discusses picosecond fluorescence spectroscopy of PQ's, covalently bridged by, among others, cyclohexylene units, in low-viscosity, liquid solution.[6] Under these conditions, the fluorescence lifetimes, are in the picosecond time range. Here we report on time-resolved EPR measurements on two P-Q's[7] in highly viscous solution with a continuous wave (cw) EPR spectrometer equipped for direct detection (without field modulation) of transient signals.[6, 8] The comparison of *trans*- and *cis*-cyclohexylene-linked P-Q's, **1** and **2**, respectively (Fig. 2), seemed especially attractive, since the arrangement of donor and acceptor differs despite the same number of bonds in the cyclohexylene bridges.[9]

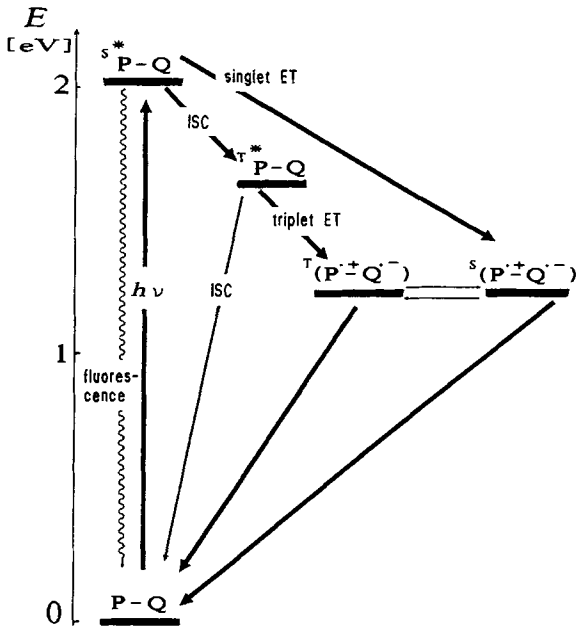

Fig. 1. Energy levels and ET reaction scheme for the P-Q's **1** and **2**. In low-viscosity solution at room temperature, the reaction pathway is "singlet ET"; in highly viscous solution at lower temperature, the favored pathway is "ISC" with subsequent "triplet ET" (see also text).

The ethanolic solutions of the P-Q's were irradiated at about 150 K in situ, that is, in the EPR resonator, with a pulsed dye laser at 584 nm. In the time range of 0.2 μs to several 10 μs after the laser pulse, both compounds show spin-polarized transient EPR spectra, which clearly reveal a broad signal of about 70-mT width (Fig. 2a) and a narrow group of signals of about 6-mT width (Fig. 2a and c). Whereas the intensity of the broad signal decreases in less than 1 μs, the inner group of signals increases, its polarization pattern changing with time.

These results can be interpreted in terms of the energy level and reaction scheme in Figure 1. Laser irradiation results in the initial generation of the (EPR-inactive) excited singlet state of the porphyrin quinone, ^{S}*P-Q, from which the charge-separated singlet-state radical pair ^{S}($P^{\bullet+}$-$Q^{\bullet-}$) is formed in low-viscosity solution at 300 K within several 10 ps.[6] In highly viscous solution at 150 K, a slower, adiabatic, solvent-controlled reaction is expected. An estimate based on Equation (a) with the values $\lambda_0 = 1$ eV,[6] $V = 2.4 \times 10^{-3}$ eV,[6] and $\tau_l \approx 5 \times 10^{-9}$ s (calculated from $\tau_l = (\varepsilon_\infty/\varepsilon_S)\tau_D$[4] with the values for ethanol at 150 K[10]) gives an adiabaticity parameter of $\kappa_{150K} \approx 5.5 \times 10^2$. At 150 K the ET reaction from the excited singlet state of the porphyrin moiety can no longer compete effectively with the temperature-independent singlet-triplet ISC, induced by spin-orbit coupling, to the triplet porphyrin ^{T}P-Q ($\tau_{ISC} = 1.9$ ns[11]). The triplet porphyrin undergoes subsequent ET reaction to give the charge-separated radical pair ^{T}($P^{\bullet+}$-$Q^{\bullet-}$) in its triplet state. If the values for V and λ_0 are assumed to be similar to those for the reaction from the excited singlet state, this reaction is likewise adiabatic. Both triplet species are in principle detectable by EPR spectroscopy. Indeed, the broad EPR signal (Fig. 2a) corresponds to the known EPR powder spectrum of the triplet state of zinc tetraphenylporphyrin (ZnTPP), where the z and y components happen to coincide at the outer edges of the

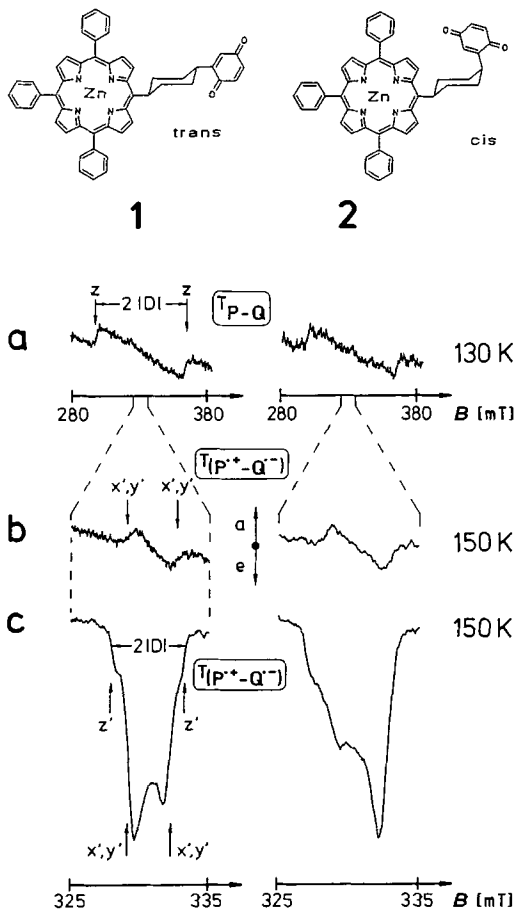

Fig. 2. Spin-polarized transient EPR spectra of the P-Q's **1** and **2** after pulsed laser excitation of the porphyrin moiety (10 ns, 584 nm, 8 mJ, repetition rate 20 Hz). a) Spectra of ^{T}P-Q; delay times: **1**, 0.2 μs; **2**, 0.4 μs; integration time, 0.5 μs. b) Early spectrum of $^{T}(P^{\bullet+}\text{-}Q^{\bullet-})$; delay time, 0.5 μs; integration time, 0.5 μs. c) Late spectrum of $^{T}(P^{\bullet+}\text{-}Q^{\bullet-})$: delay time, 5 μs; otherwise as in b). For interpretation see text. a = absorption, e = emission.

spectrum, while the x components (xyz is a coordinate system intrinsic to the molecule, the z axis lying perpendicular to the molecular plane; Fig. 3) coincide at the center of the spectrum but cannot be observed because they cancel each other owing to opposite polarization.[12] From the positions of the signals the electron dipole–dipole interaction can be determined in terms of the zero-field splitting parameters D and E, where E describes the nonequivalence of the x and y axes.[13] The D values obtained for *trans* and *cis* ^{T}P-Q, are equal within experimental error and agree with the data reported for ^{T}ZnTPP[12] (**1**, 32.6(4) mT; **2**, 32.8(4) mT with $|D| \approx 3|E|$).

The group of signals at the center (Fig. 2b, c) can be assigned to the charge-separated state $^{T}(P^{\bullet+}\text{-}Q^{\bullet-})$ formed by subsequent ET. The measured D values for the *trans* (2.65(5) mT) and *cis* compounds (3.75(5) mT) are significantly smaller than those for ^{T}P-Q and are of similar magnitude to those of another P-Q with comparable porphyrin–quinone separation.[5] The expected magnetic dipole–dipole interaction of $^{T}(P^{\bullet+}\text{-}Q^{\bullet-})$ was estimated using the point dipole model,[14] whereby the two electrons were assumed to be localized at the respective centers of gravity of the porphyrin and quinone moieties and the vector joining them forms the z′ axis of the radical pair (Fig. 3). Using the measured D values of $^{T}(P^{\bullet+}\text{-}Q^{\bullet-})$, electron separations of 10.2 Å are calculated for the radical pair of **1** and 9.1 Å for that of **2**, both values being in good agreement with the midpoint separations (10.7 Å and 8.8 Å, respectively) between porphyrin and quinone obtained with the molecular modeling program Alchemy II.

In addition to the detection of the ET reaction from the porphyrin triplet state by identification of the transient triplet species ^{T}P-Q and $^{T}(P^{\bullet+}\text{-}Q^{\bullet-})$ via the dipolar interactions, the observed spin polarization patterns are of particular interest. The pattern obtained for ^{T}P-Q (aaa eee, starting on the low-field side) agree well with spectra reported for the triplet state of ZnTPP,[12] which can be understood by assuming a spin-selective ISC resulting in exclusive population of the T_z level[12] (see Fig. 3). In the high-field limit, then, the T_0 level for BIIx and BIIy is not populated, whereas this level is predominantly populated for BIIz.

The polarization pattern (aa ee) appearing for the radical pair $^{T}(P^{\bullet+}\text{-}Q^{\bullet-})$ after a short delay time (ca. 0.5 μs, Fig. 2b) can be interpreted with the following assumptions: (1) During ET, the spin polarization in the porphyrin moiety ^{T}P-Q is transferred to the biradical formed. (2) The z′ principal axis is tilted by 90° with respect to the z axis (Fig. 3), whereby T_0 is empty for BIIz′ and overpopulated for BIIx′, y′. (3) $D < 0$, as expected for two separated, localized electrons (biradical)[13] (see Fig. 3).

The polarization effects described so far are similar to those observed previously for another P-Q with a conjugated bridge.[5] The essential structural difference of the systems investigated here is the aliphatic cyclohexylene bridge. In comparison to the P-Q with a conjugated bridge, therefore, the singlet–triplet splitting parameter (exchange energy) $|J|$ of the radical pair $^{T}(P^{\bullet+}\text{-}Q^{\bullet-})$ is appreciably smaller and is of the same order of magnitude as the Zeeman energy. This leads to a mixing of the radical-pair triplet states T_0, T_-, and T_+ with the radical-pair singlet state S (Fig. 3), whereby the respective admixture of singlet character depends on the energy separation between the radical-pair singlet state and the respective triplet sublevel.[15] Owing to their differing singlet character, the radical-pair states T_0 and T_- recombine with different rates to the singlet ground state P-Q (the recombination from the pure radical-pair triplet state is spin-forbidden). Thus, the initial spin polarization pattern in the EPR spectrum of the radical pair $^{T}(P^{\bullet+}\text{-}Q^{\bullet-})$ is governed by the

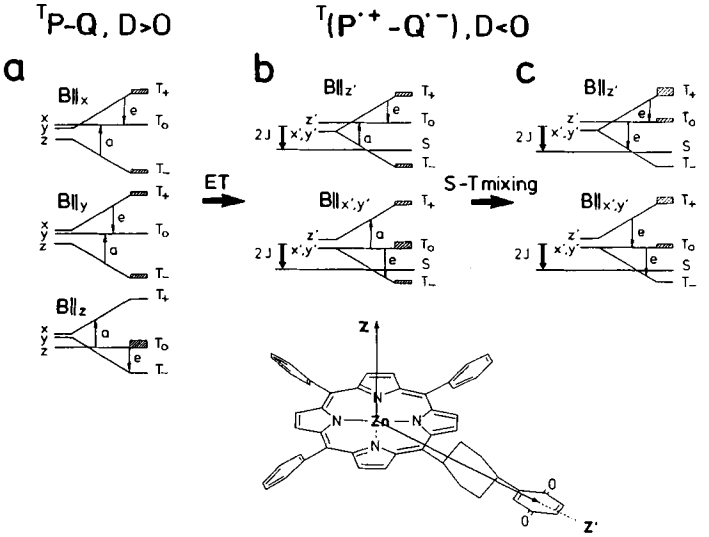

Fig. 3. Zeeman energy levels and excess spin populations for the three canonical orientations (B field in each case parallel to one of the three principal axes x, y, z of the zero-field splitting tensor) of the triplet states ^{T}P-Q ($D > 0$, $E \neq 0$) and $^{T}(P^{\bullet+}\text{-}Q^{\bullet-})$ ($D < 0$, $E = 0$). a) Starting high-field population of ^{T}P-Q due to spin-selective ISC [12]. b) Starting populations of the radical pair $^{T}(P^{\bullet+}\text{-}Q^{\bullet-})$. c) Later populations formed by different recombination rates to the ground state P-Q (see text).

polarization transfer from ^{T}P-Q, whereas after longer times spectra in pure emission develop owing to the differing recombination rates from the triplet sublevels (cf. Figs. 2 and 3). A more exact analysis of the amplitude ratios of the high-field and low-field x',y' signals of **1** and **2** reveals a stronger mixing of the singlet and T_- state in **2**, which, in turn, indicates a larger $|J|$ in comparison to **1**. This is likewise expected because of the smaller porphyrin–quinone distance in **2** compared to **1**.

The kinetics of primary ET reactions in covalently linked P-Q's have been investigated up to now almost exclusively by time-revolved optical spectroscopy.[1] Only in multistep complex donor–acceptor cascades have states with far-separated charges been found to be sufficiently long-lived for detection by time-resolved EPR spectroscopy.[16] The strong decrease of ET in polar solvents of high viscosity (ethanol, 150 K), however, also enables the observation of primary ET reactions in covalently linked, simple P-Q's from the excited triplet state of the porphyrin to the triplet state of the charge-separated radical pair $^{T}(P^{\bullet+}\text{-}Q^{\bullet-})$ by time-resolved EPR spectroscopy in the time range of 0.1 μs to several 10 μs.[5] Augmenting optical spectroscopy, EPR allows an unequivocal identification of both triplet species on the basis of the measured electron dipole–dipole interaction. The observed spin polarization in the transient radical pairs of these model compounds contains information about these interactions, which also determine the ET and spin dynamics of the transient radical pairs in photosynthetic organisms.[16]

Unique Reactivity of Heterodinuclear Pentacarbonyl(fulvalene)molybdenumruthenium with Alkynes: Fluxionality, Rearrangements, Structures, and First Reversible Conversion of a "Side-on"- to a Semi-Bridging Alkenylidene Ligand **

By *Roland Boese*,* *Mark A. Huffman*, and *K. Peter C. Vollhardt**

We report on the unique reactivity of the heterodinuclear fulvalene (Fv) cluster **1** with alkynes,[1] the dynamic behavior of the resulting alkyne complexes, the direct observation of alkyne–alkenylidene rearrangements mediated by a heterodinuclear core,[2] and the unprecedented reversible conversion of an alkenylidene ligand from the "side-on"- to the semi-bridging mode.[3]

Irradiation of $[(Fv)MoRu(CO)_5]$ (**1**)[4] in the presence of diphenylethyne (THF, 300 nm, 5.5 h) gave **2** (48%) and traces of **3**.[5,6] The former is readily carbonylated (CO,

in **3** and **6** rests on the ^1H and ^{13}C NMR spectra, which reveal the symmetrical patterns expected for **3** and the appropriate lack thereof for **6**. In contrast, the NMR spectra indicate that the four-electron donor alkynes in **2**, **4**, and the two (inseparable) isomers of **5** (assignments by NOE experiments at $-30\,^{\circ}C$, **5a**:**5b** = 7:1) adopt a terminal, perpendicular configuration, a conclusion corroborated by an X-ray structural analysis of **2** (Fig. 1).[5] Noteworthy (with respect to the observed isomer ratio for **5**) is the relatively unencumbered environment of the phenyl group *syn* to the Fv moiety, a location preferred by the more bulky silyl substituent in **5**.

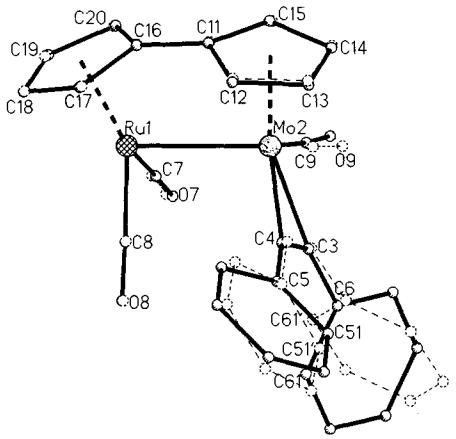

Fig. 1. Molecular structure of **2**, hydrogen atoms omitted. The two independent molecules are drawn superpositioned (fitted on the metal atoms and the fulvalene moiety), with the coordinates of the atoms of one molecule inverted (dashed lines). Atomic labeling is given for only two atoms of the phenyl rings. Selected bond lengths [Å] and angles [°] (interplanar angles defined as best planes of the given atomic positions in parentheses, separated by virgules): Ru1'–Mo2' 2.840(1), Ru1'–Mo2' 2.860(1), Mo2–C3 2.055(5), Mo2'–C3' 2.060(5), Mo2–C4 2.026(4), Mo2'–C4' 2.023(5), C3–C4 1.304(7), C3'–C4' 1.322(5), C3–C6 1.466(7), C3'–C6' 1.464(5), C11–C16 1.451(7), C11'–C16' 1.453(6); Mo2–Ru1–C7 92.0(2), Mo2'–Ru1'–C7' 93.8(2), Mo2–Ru1–C8 86.0(2), Mo2'–Ru1'–C8' 84.7(2), Ru1–Mo2–C9 90.2(1), Ru1'–Mo2'–C9' 93.8(1), Ru1–Mo2–C3 106.6(1), Ru1'–Mo2'–C3' 107.7(1), Ru1–Mo2–C4 105.4(1), Ru1'–Mo2'–C4' 107.7(1), C3–Mo2–C4 37.3(2), C3'–Mo2'–C4' 37.8(2), C3–C4–C5 141.3(4), C3'–C4'–C5' 138.7(5), C4–C3–C6 138.0(4), C4'–C3'–C6' 142.1(5), (C11–C15)/(C16–C20) 29.1, (C11'–C15')/(C16'–C20') 27.2, (C3,C4,C5,C6)/(C5,C51–C55) 147.5, (C3',C4',C5',C6')/(C5',C51'–C55') 14.9, (C3,C4,C5,C6)/(C6,C61–C65) 43.6, (C3',C4',C5',C6')/(C6',C61–C65) 56.5, C12–C11–C16–C17 0.7, C12'–C11'–C16'–C17' −2.4, C3–C4–C5–C51 −24.2, C3'–C4'–C5'–C51' 12.7, C4–C3–C6–C61 −36.8, C4'–C3'–C6'–C61' 123.0.

Interestingly, **2** and **4** exhibit fluxionality via two different processes, one that equilibrates the two sides of the Fv ligand (i.e., C(14,15,20,19) with C(13,12,17,18)) at the same rate as CO(9) with *one* of the Ru carbonyls (presumably CO(8); $\Delta G^{\ddagger}_{25\,^{\circ}C} = 15.5 \pm 0.1$ kcal mol^{-1}), a second ($\Delta G^{\ddagger}_{25\,^{\circ}C} = 17.6 \pm 1.0$ kcal mol^{-1}) that in addition reveals coalescence of the signals of the respective arylcarbyne halves of the alkynes. The most plausible mechanism for the first involves stereospecific access to a hitherto undetected doubly bridging carbonyl (e.g., CO(8) and CO(9)) intermediate containing a perpendicular terminal alkyne group, the second process being alkyne rotation. The latter should interconvert **5a** and **b**, an expectation verified through spin-saturation transfer experiments at 50 °C.

In contrast to the photosubstitution chemistry of **1** with internal alkynes which leaves the Ru center as a seemingly innocent spectator, their terminal analogues (e.g., PhC_2H and $(CH_3)_3SiC_2H$) provide the first heterodinuclear, side-on-bridging four-electron-donating alkenylidenes **7** and **8** (40–50%).[5] Unlike previous systems which were stereochemically biased,[2] they exist as (inseparable) mixtures of the two possible diastereomers (ratio: 3.5:1 for **7**, 4:1 for **8**; relative configuration undetermined). Both compounds are also available thermally from **2** by treatment with the corresponding alkynes (42–53%). The two respective isomers of **7** and **8** are in equilibrium, as indicated by line-broadening of their NMR spectra at 75 °C (**7**) or 23 °C (**8**) and ready crystallization in (presumably) one form, a finding that allowed the X-ray structural analysis of crystalline **7** (Fig. 2).[5]

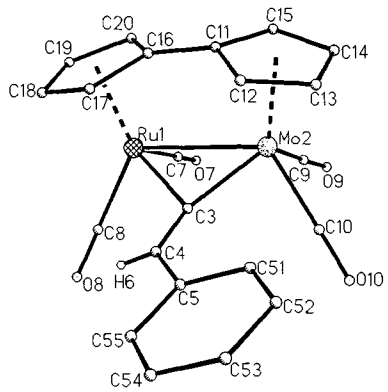

Fig. 2. Molecular structure of **7**, hydrogen atoms except H6 omitted. Selected bond lengths [Å] and angles [°] (interplanar angles given as in Fig. 1): Ru1–Mo2 2.847(1), Mo2–C3 1.918(4), Ru1–C3 2.091(4), C3–C4 1.388(5), C4–C5 1.478(5), C11–C16 1.452(6); Mo2–Ru1–C7 103.3(1), Ru1–Mo2–C9 88.9(1), Ru1–Mo2–C3 47.3(1), Mo2–Ru1–C3 42.4(1), Ru1–C3–Mo2 90.4(1), C3–C4–C5 123.6(4), (C11–C15)/(C16–C20) 26.7, (C3,C4,C5)/(C5,C51–C55) 1.5, (Ru1–Mo2–C3)/(C3–C4–C5) 69, C12–C11–C16–C17 −7.2, C3–C4–C5–C51 1.1.

To gain further insight into this isomerization process, it was desirable to scrutinize the dynamic behavior of the parent structure **9**, available by ready protodesilylation of **8a, b** (Bu_4NF, THF, 23 °C, 65%). On heating **9**, the ^1H NMR signals for the two vinylidene hydrogens ($\delta = 2.37, 2.84$, $J = 14$ Hz) suffer extensive line-broadening, while the Fv absorptions remain unchanged. The molecule's thermal sensitivity required spin-saturation transfer techniques to establish the occurrence of vinylidene H–H site exchange (20–60 °C; $\Delta H^{\ddagger} = 14.8 \pm 0.8$ kcal mol^{-1}; $\Delta S^{\ddagger} = -15.3 \pm 2.4$ cal K^{-1} mol^{-1}, $\Delta G^{\ddagger}_{25\,^{\circ}C} = 19.4 \pm 0.1$ kcal mol^{-1}). This observation is significant in light of the mechanism proposed for the similar fluxional behavior of $[Cp_2M_2(CO)_4(\mu\text{-}\eta^1\text{:}\eta^2\text{-}C{=}CMe_2)]$ (M = Mo, W),[7] the cornerstone of which is the intermediacy of a symmetrical μ_2-η^1-structure, insufficient to explain the dynamics of **9** because of the asymmetry imparted by the heterodinuclear backbone. Rather, vinylidene rotation has to be postulated, perhaps featuring a non-bridging isomer[8] or a dipolar semibridging form (see below).

That the precursors to **7** and **8** are most likely terminal alkyne complexes was indicated by protodesilylation of **5a, b** as above (7:1) at −78 °C to give first **10a** and **b** (not isolated) in varying ratios. ^1H NMR analysis at −57 °C revealed the composition **10a**:**10b** = 2:1, changing to the equilibrium ratio (1:5) at −40 °C. The diastereomer assignments are tentative, resting on the presumed steric preference of the phenyl group to be *syn* to the Fv unit. Remarkably, even at −40 °C, these compounds are unstable with respect to alkyne–alkenylidene isomerization (**7a, b** 3.5:1), a facility that is unprecedented.[2, 3a]

In analogy to side-on- and semi-bridging CO,[3] the corresponding alkenylidenes should be readily displaced by added ligands. Indeed, exposure of **7** to CO (5 atm, CH_3COCH_3,

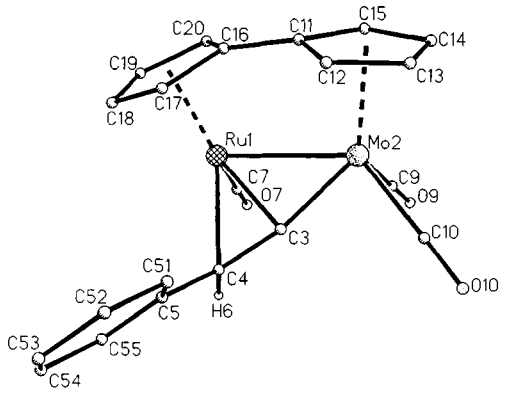

Fig. 3. Molecular structure of **11**, hydrogen atoms except H6 omitted. Selected bond lengths [Å] and angles [°] (interplanar angles given as in Fig. 1): Ru1–Mo2 2.906(1), Mo2–C3 2.053(2), Ru1–C3 2.191(3), C3–C4 1.340(4), C4–C5 1.478(4), C11–C16 1.452(5); Mo2–Ru1–C7 81.2(1), Mo2–Ru1–C8 116.3(1), Ru1–Mo2–C9 96.3(1), Ru1–Mo2–C3 48.8(1), Mo2–Ru1–C3 44.8(1), Ru1–C3–Mo2 86.3(1), Ru1–C3–C4 121.3(2), Mo2–C3–C4 148.3(3), C3–C4–C5 129.2(3), (C11–C15)/(C16–C20) 25.4, (C3,C4,C5)/(C5,C51–C55) 2.3, (Ru1–Mo2–C3)/(C3–C4–C5) 160, C12–C11–C16–C17 4.2, C3–C4–C5–C51 2.6.

75 °C, 20 h) effected monocarbonylation (60%) to isomerically pure **11**,[5] a process that is reversible under vacuum. The IR spectrum exhibited only terminal CO absorptions, suggesting the formation of a nonbridging structure containing a terminal, Mo-bound alkenylidene or alkyne ligand. However, the ^{13}C NMR data were inconsistent with either view. This ambiguity was resolved by an X-ray structural analysis revealing the presence of a semi-bridging Ph(H)CC moiety (Fig. 3).[5]

The most outstanding feature of the structure is its general resemblance to that of **7**, particularly with respect to the asymmetric disposition of the alkenylidene, C(3) being attached to Mo by a relatively short and to Ru by a correspondingly long bond. Moreover, C(4) is strongly tilted towards the Ru atom, while the carbonyls maintain their terminal coordination mode.[9] These similarities notwithstanding, there is a large change in the "twist" angle of the terminal methylene group relative to the metallacyclopropane core when going from **7** (69°) to **11** (160°). It is curious that, while both experience an unusually large distortion (typically only about 10°)[3, 9] from the "ideally" expected perpendicular and coplanar configurations, respectively, the net "rotation" is exactly that predicted: 90°. The equilibrium **7** ⇄ **11** is the first of its kind to be observed. Interestingly, **11** is also readily generated from **6** by protodesilylation.

In stark contrast to the chemistry of **1**, under the same conditions its homodinuclear analogues give rise to distinctly different products,[1, 6, 10] some exhibiting behavior[11] that is not unlike that of the related Cp_2M_2 (M = Ru, Mo) systems.[12]

1,2-Asymmetric Induction in the Ketene Claisen Rearrangement of Allyl Sulfides

By *Udo Nubbemeyer, Reinhold Öhrlein, Jozef Gonda, Beat Ernst,** and *Daniel Belluš**

The preparative potential of even such old reactions as the [3,3]-sigmatropic Claisen rearrangement[1] still seems far from exhausted. The stereochemical course of this intra-

[*] Prof. Dr. D. Belluš, Dr. B. Ernst, Dr. J. Gonda, Dr. U. Nubbemeyer, Dr. R. Öhrlein

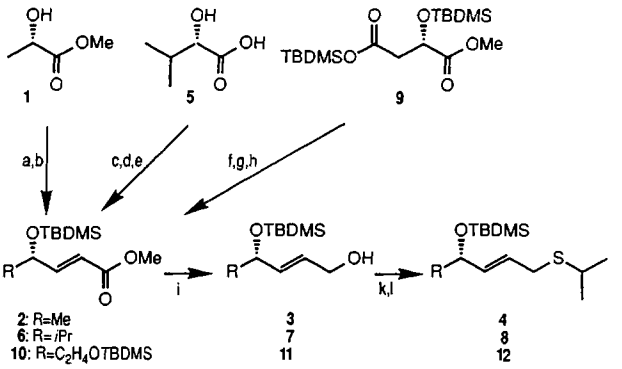
molecular reaction has been thoroughly investigated,[2] so that it can be incorporated into sophisticated synthetic sequences.[3] We recently showed that the ketene Claisen rearrangement of allyl sulfides (allyl thioethers),[4] a novel "intramolecular" variant of the [3,3]-sigmatropic rearrangement, proceeds chemoselectively (allyl thioether versus allyl ether) with excellent chirality transfer from a C–S to a C–C bond.[5] Here we report on the 1,2-asymmetric induction in this new type of reaction. We chose the optically active allyl thioethers **4**, **8**, and **12** (Scheme 1) as starting compounds for our investigations.



Scheme 1. Synthesis of allyl thioethers **4**, **8**, and **12**. **4**: a) TBDMSCl, imidazole, dimethylformamide (DMF), 20 °C (98%) [9]; b) DIBAH, hexane, −78 °C, 1 h [6], then $Ph_3P{=}CHCO_2Me$, THF, CH_2Cl_2, −78 °C to 20 °C, 1 h, 51% *E*, 7% *Z* [6b, c] (see *Experimental Procedure*); i) DIBAH, THF, 0 °C, 30 min (92%) [10]; k) AcSH, Ph_3P, diethyl azodicarboxylate (DEAD), THF, 0 °C (95%) [11] (see *Experimental Procedure*); l) NaOEt, EtOH, 20 °C, 1 h then *i*PrBr, 20 °C, 12 h (92%). **8**: c) TBDMSCl, imidazole, DMF, 20 °C (quant.) [12]; d) DIBAH, THF, −78 °C, 1 h (93%); e) $(COCl)_2$, dimethyl sulfoxide (DMSO), CH_2Cl_2, NEt_3, then $Ph_3P{=}CHCO_2Me$, −78 °C to 20 °C (81% *E*, 1% *Z*); i) (83%); k) (81%); l) (82%).

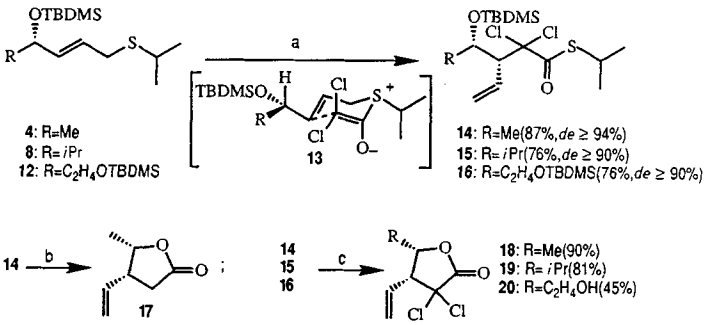
The methyl ester of L-(−)-lactic acid (**1**, *ee* ≥ 99%), after silylation with *tert*-butyldimethylsilyl chloride (TBDMSCl), was reduced with diisobutylaluminum hydride (DIBAH) to the known lactaldehyde[6a] and lengthened via in situ Wittig olefination[6b] to the α,β-unsaturated ester **2**.[6c] A second DIBAH reduction then led to the allyl alcohol **3**, whose corresponding Mosher ester[7] was used to determine its optical purity (*de* ≥ 94%).

Subsequently, **3** was converted into the thioacetate by reaction with thioacetic acid under Mitsunobu conditions. Saponification and in situ alkylation with isopropyl bromide afforded thioether **4**.[8]

An analogous reaction sequence, starting from L-(+)-hydroxyisovaleric acid (**5**, *ee* ≥ 98%), was used to synthesize the allyl alcohol **7**, whose Mosher ester showed *de* ≥ 90% according to the ^{1}H NMR spectrum. The thioether **8**[8] was then prepared as described above.

L-(−)-Malic acid (*ee* ≥ 99%) was first converted by a known procedure[13] into the 1-methyl ester **9** (Scheme 1). Mild hydrolysis resulted in selective cleavage of the silyl ester.[14] Reduction of the acid function with borane–dimethyl sulfide, silylation of the resulting alcohol, DIBAH reduction of the methyl ester function, and subsequent Wittig olefination then led to isolation of the disilyl ether **10**, from which the allyl alcohol **11** was obtained. The corresponding Mosher ester showed *de* ≥ 90% according to the ^{1}H NMR spectrum. The allyl alcohol **11** was finally transformed into the allyl thioether **12**.[8] The chiral allyl thioethers **4** (*ee* ≥ 94%), **8** (*ee* ≥ 90%), and **12** (*ee* ≥ 90%) were thus available for the ketene Claisen rearrangement. Dichloroketene, generated in situ by reductive elimination of chlorine from trichloroacetyl chloride upon treatment with activated zinc,[4] was allowed to react with the allyl thioethers **4**, **8**, and **12**. In all three cases, as expected,[5] the rearrangement proceeded with high chemoselectivity.

Compound **4** afforded thioester **14** (*de* ≥ 94%),[8] **8** gave **15** (*de* ≥ 90%),[8] and **12** yielded **16** (*de* ≥ 90%)[8] (Scheme 2). The retention of configuration in the ketene Claisen rearrangement was examined by ^{1}H NMR spectroscopy of γ-butyrolactone **17**, obtained by reduction of **14**. For racemic **17**, the methyl groups give rise to two signals in the presence of *R*-(−)-1-(9-anthryl)-2,2,2-trifluoroethanol. This splitting is not observed for **17**, so that the optical purity is ≥ 95%.

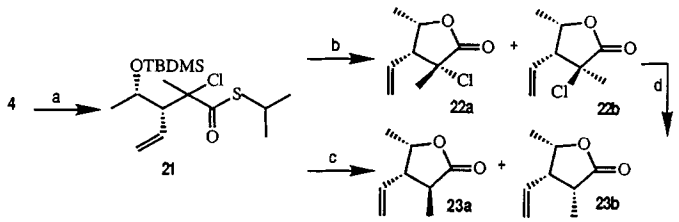


Scheme 2. Reaction of **4**, **8**, and **12** with dichloroketene via **13** and subsequent lactonization of the reaction products **14**–**16**. a) CCl_3COCl, Et_2O, Zn/Cu, 40 °C, 3–5 h; b) AcOH, Zn, 110 °C, 1 h; c) 48% HF, CH_3CN, 20 °C, 2 h.

In contrast, the intramolecular [3,3]-sigmatropic rearrangement of analogous silylketene acetals, prepared from L-lactaldehyde[16] or D-glyceraldehyde,[17] proceeds with diastereomeric excesses of only 50 and 13%, respectively, in favor of the *syn* product. In view of these results and the model for the steric and electronic course of [3,3]-sigmatropic reactions proposed by *Felkin* et al., *Houk* et al.[18] and *Kahn* and *Hehre*,[19] the rearrangement products **14**–**16** should have a *syn* structure, since the reaction should occur via transition state **13** with minimal 1,3-diaxial interactions. Examination of the postulated *syn* selectivity in the formation of ester **14** was carried out by ^{1}H NMR spectroscopic investigation of the corresponding cyclization product **17**.[20] Irradiation of the methyl protons in lactone **17** resulted in a positive NOE effect in the vinyl CH signal, which supports a *syn* selectivity in the formation of thioesters **14**–**16**.[21] Under nonreducing conditions, these esters afforded chlorolactones **18**–**20**, which likewise were *cis* isomers.

The less reactive chloromethylketene also reacted with thioether **4**. The resulting thioester **21**,[8] which possesses a further stereocenter in the α position to the carbonyl group, was obtained as an inseparable mixture of diastereomers (*de* ≈ 50%). After desilylation, the chromatographically separable lactones **22a** and **22b** were obtained in a ratio of 3:1 (Scheme 3).

The stereochemistry of these lactones could again be assigned by NOE measurements. Reduction of ester **21** in zinc/acetic acid yielded the chlorine-free lactones **23a** and **23b** in a ratio of 1:3.[22] This ratio was also obtained when either the diasteromeric mixture **22a**, **b** or either one of the pure isomers, **22a** or **22b**, was dehalogenated with zinc in acetic acid. The radical dechlorination of **22a** or **22b** with tributylzinc hydride at various temperatures led to the same ratio of lactones **23**.



Scheme 3. Reaction of **4** with chloromethylketene and subsequent lactonization. a) CH_3CCl_2COCl, Et_2O, Zn/Cu, 40 °C, 7 h (82%); b) 48% HF, CH_3CN, 20 °C, 2 h (**22a**: 65%, **22b**: 22%); c) AcOH, Zn, 110 °C, 1 h (**23a**: 19%, **23b**: 53%); d) nBu$_3$SnH, toluene, *hv*, −78 °C, 1.5 h (89%); for further conditions see text.

This novel, "intermolecular" ketene Claisen rearrangement is characterized not only by its excellent chemoselectivity but also by its excellent 1,2-*syn* selectivity (ca. 20:1). By choice of suitably substituted precursors, such as **8** or **12**, this reaction offers a route to optically active γ-butyrolactones, a class of substances of use in numerous natural product syntheses.[23]

Experimental Procedure

One-pot procedure for the synthesis of α,β-unsaturated esters **2** and **6** [6b]: The α-siloxy ester (60 mmol), dissolved in 60 mL of dry hexane at −78 °C, was treated dropwise over 30 min with 65 mL of a 1 M solution of DIBAH in hexane under argon. After 1 h, methoxycarbonylmethylene(triphenyl)phosphorane (60 mmol) in 40 mL of THF and 50 mL of CH_2Cl_2 was added. The reaction mixture was then allowed to warm over 1 h to room temperature, poured into ice water, and extracted with diethyl ether. The organic phase was washed with a saturated aqueous NaCl solution and the *E*/*Z* mixture separated by chromatography on silica gel.

Mitsunobu variant for the synthesis of the allyl thioacetate: Freshly distilled DEAD (20 mmol) was injected into a solution of triphenylphosphane (20 mmol) in 20 mL of dry THF at 0 °C under argon. After 40 min, allyl alcohol (10 mmol) and freshly distilled thioacetic acid (20 mmol), each dissolved in 5 mL of THF, were successively added dropwise. Monitoring by thin layer chromatography revealed that the reaction was over after about 1 h. Pentane was added and the mixture was filtered through silica gel with pentane/ether (1:1) as eluent. After removal of the solvent, the thioester was chromatographed or purified by distillation.

Ketene Claisen rearrangement of allyl thioether: Allyl thioether (1.5 mmol) and about 15 mmol of Zn/Cu alloy [4] were placed in 15 mL of vigorously stirred ether under argon and the mixture was heated to reflux. A solution of 3 mmol of freshly distilled trichloroacetyl chloride in 5 mL of ether was added dropwise to the solution over 4 h by means of a syringe pump (7 h infusion for the generation of chloromethylketene from 2,2-dichloropropionyl chloride). After cooling, the reaction solution was decanted from the residue. Purification of the thioester was accomplished by chromatography on silica gel.

Directed Synthesis of Peptides from α-Amino Acid Esters at Metal Centers**

By *Wolfgang Beck** and *Roland Krämer*

Dedicated to Professor Viktor Gutmann on the occasion of his 70th birthday

The first directed synthesis of peptides from nonactivated α-amino acid esters at a metal center was accomplished with cobalt(III) amine complexes.[1] The cobalt atom acts as an amino protecting group and, at the same time, activates the carboxyl group.[1] However, the preparation of oligopeptides by this route is relatively laborious, since the peptide has to be liberated from the metal and isolated before it is allowed to react with the next α-amino acid ester complex of cobalt.[2]

Several metal salts, particularly those of copper(II), catalyze the formation of peptides (up to tetrapeptides) from α-amino acid esters.[3] Different α-amino acid esters, however, cannot be linked in a defined sequence; instead, a mixture of the corresponding peptides is obtained.[3,4] An interesting model for the prebiotic formation of peptides is the recently described Cu^{II}-catalyzed synthesis of peptides from α-amino acids in aqueous NaCl solution.[5]

We have now found a way to extend metal-coordinated peptide esters from the amino terminus in a controlled manner. In the course of our work on chiral organometallic compounds containing α-amino acids,[6] we obtained the diglycine ester complexes **1** and **2**, in which the amide N atom is deprotonated.

These chelate complexes react with α-amino acid esters such as Gly-OEt, L-Ala-OMe, L-Leu-OMe, L-Asp-$(OMe)_2$, and L-Ser-OMe in the presence of triethylamine at 20 °C to give the corresponding tripeptide ester complexes **3** and **4**,

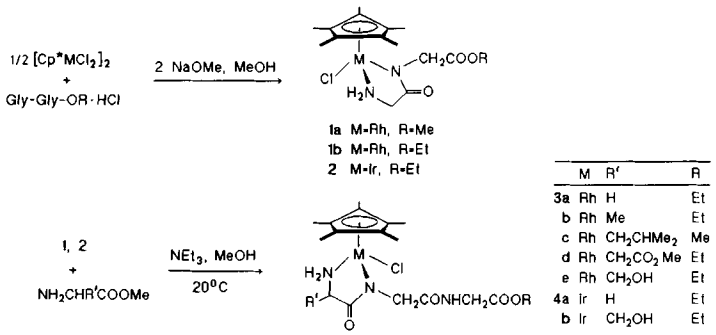
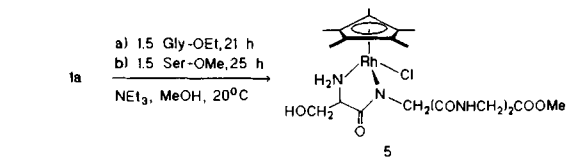
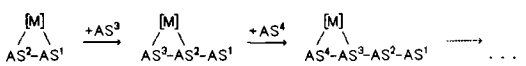
respectively, in yields of 70–90% (crystalline products).[7] Complex **3b** was also prepared in a one-pot reaction from $[\{Cp^*RhCl_2\}_2]$ ($Cp^* = \eta^5$-C_5Me_5), Gly-Gly-OMe · HCl, and Ala-OMe with Na_2CO_3 as base (80% yield). Treatment of complexes **3b, c** (see *Experimental Procedure*) with 0.2 N methanolic HCl solution liberated the tripeptide esters L-Ala-Gly-Gly-OMe · HCl and L-Leu-Gly-Gly-OEt · HCl, respectively, which were then isolated; $[\{Cp^*RhCl_2\}_2]$ was thereby re-formed. The tripeptides in **3b, c** are formed without almost any racemization. For comparison, **3a**, which cannot be isolated in pure form, was synthesized directly from Gly-Gly-Gly-OEt and $[\{Cp^*RhCl_2\}_2]$ and characterized by X-ray structure analysis.[8] The tetrapeptide ester complex **5** is formed via a triglycine methyl ester complex as intermediate when Gly-OEt and Ser-OMe are added successively to **1a**.



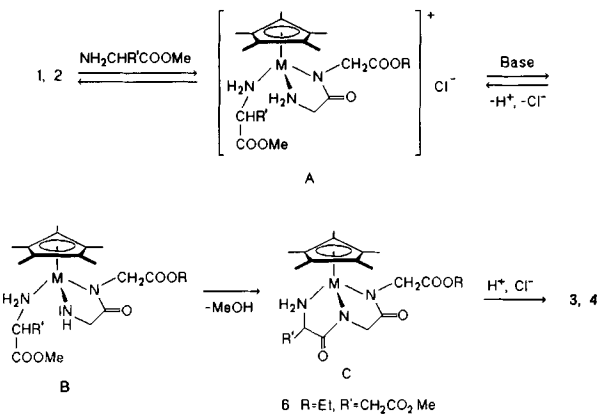


Further peptide ester complexes are formed as side products (ca. 15%) in these reactions. Independently, **5** was obtained from [Cp*(Cl)Rh(Gly-Gly-Gly-OMe − H^+)] and Ser-OMe in the presence of NEt_3 and its structure was determined by X-ray analysis.[9] The principle illustrated in Scheme 1 should allow still longer peptide chains to be constructed at the complex in a one-pot procedure.



Scheme 1. AS = α-amino acid building block, AS^1 = *C*-terminal amino acid, [M] = metal complex fragment.

A template reaction is plausible for the mechanism of peptide formation. The synthesis of the tripeptide at the metal center affords complexes with three accessible (here, facially arranged) coordination sites. The crucial step is a nucleophilic attack of the coordinated amino anion in **B** on the carbonyl group of the N-coordinated amino acid ester. *Yamada* et al. have suggested such a step for peptide formation at Cu^{II}.[3c] The base serves only as catalyst. The intermediacy of **C** (M = Rh, R = Et, R′ = CH_2CO_2Me) could be established by reaction of **1b** with asparagine dimethyl ester and sodium methoxide instead of NEt_3. The complex [Cp*Rh{L-Asp(β-OMe)-Gly-Gly-OEt − $2H^+$}] (**6**) was characterized by crystal structure analysis;[10] it contains an unusual structural element, a bridgehead peptide N atom surrounded in a pyramidal fashion (sum of angles at N atom: 346.1°).[11]



Of particular interest is the question whether optically active dipeptide ester complexes preferentially incorporate only one enantiomer of an α-amino acid ester present as a racemate. The reactions of [Cp*(Cl)Rh(L-Ala-Gly-OMe − H^+)] with D,L-Leu-OMe and D,L-Ser-OMe indicate that the tripeptide esters L-Leu-L-Ala-Gly-OMe and L-Ser-L-Ala-Gly-OMe are formed somewhat faster at the complex than the corresponding diastereoisomers D-Leu-L-Ala-Gly-OMe and D-Ser-L-Ala-Gly-OMe, respectively.

Experimental Procedure

NEt_3 (1.00 mmol, 139 μL) was added to a solution of **1a** (0.20 mmol, 84 mg; prepared from $[\{Cp^*RhCl_2\}_2]$[12], Gly-Gly-OMe · HCl, and two equivalents of NaOMe in methanol) and L-Leu-OMe (0.21 mmol, 32 μL) in 5 mL of absolute methanol. The reaction mixture was stirred for 15 h at 20°C and then concentrated to about 0.5 mL. Addition of 20 mL of ether and 30 mL of hexane resulted in precipitation of the orange complex. The isolated and dried complex **3c** (yield 92%) was dissolved in 5 mL of 0.2 N methanolic HCl and the solution was then concentrated to about 1.5 mL and kept at −78°C for 2 h. The precipitate of $[\{Cp^*RhCl_2\}_2]$ was filtered off and the filtrate was concentrated to about 0.5 mL and treated with 50 mL of ether. The resulting solution was cooled with liquid nitrogen until it began to solidify and then allowed to warm to room temperature with stirring. The precipitated tripeptide ester hydrochloride was centrifuged, washed with 30 mL of $CHCl_3$/hexane (1/1), and reprecipitated from methanol/ether (yield 61% based on **1a**). ^1H NMR of L-Leu-Gly-Gly-OMe · HCl [13] (400 MHz, CD_3OD, 22°C, TMS): δ = 3.92 (m, 1H, partly overlapped; Leu-Hα), 1.7 (m, 3H; CH-CH_2, $CH(CH_3)_2$), 1.01 (m, 6H; $CH(CH_3)_2$), 3.92, 4.05 (d, $^2J(H,H)$ = 16.3 Hz, 1H; $NHCOCH_2$, diastereotopic), 3.98 (s, 2H; $CH_2CO_2CH_3$), 3.72 (s, 3H; CO_2CH_3).

Amino acid analysis [14]: $Leu_{0.87}Gly_2$. TLC (*n*BuOH/glacial acetic acid/water 4/1/1; silica gel): R_f = 0.47. Gas-chromatographic racemate test [15]: 1.5% D-Leu-OMe. Racemate test for L-Ala-Gly-Gly-OEt · HCl isolated from **3b**: 1.0% D-Ala.

The reaction of [Cp*Rh(Cl)(L-Ala-Gly-OMe · HCl)] with D,L-Leu-OMe or D,L-Ser-OH was carried out analogously to the preparation **3c**. The reaction times were chosen so that only a small amount of the added amino acid ester reacted. After 3.5 and 2 h, respectively, the complexes were isolated and treated with 0.2 N methanolic HCl solution. In the liberated peptide esters (nonreacted serine methyl ester could not be separated quantitatively from the complex), amino acid ratios of $Leu_{0.15}Ala_{0.96}Gly_{1.00}$ and $Ser_{0.60}Ala_{0.98}Gly_{1.00}$, respectively, and L-proportions of L-Leu (52.3%)/L-Ala (99.1%) and L-Ser (61.3%)/L-Ala (99.1%), respectively, were determined.

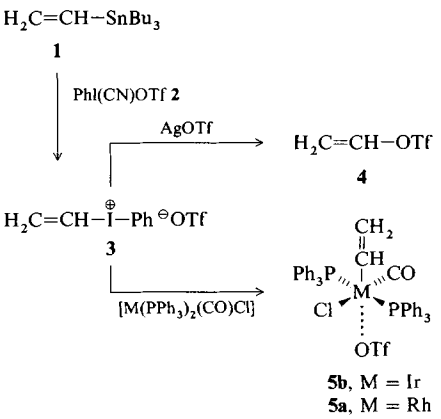
Synthesis of Ethenyl(phenyl)iodonium Triflate, $[H_2C{=}CHIPh][OSO_2CF_3]$, and Its Application as a Parent Vinyl Cation Equivalent**

By *Peter Stang** and *Jörg Ullmann*

Dedicated to Professor Michael Hanack on the occasion of his 60th birthday

Vinylations are well recognized and widely employed in organic chemistry. However, most known vinylating agents are nucleophilic, such as vinylmetals of the first and second main-group elements as well as vinylsilanes and -stannanes.[1] Vinylations have also been carried out with acetylene[2] and by metal-catalyzed processes.[3] However, there are only few examples for the electrophilic introduction of the parent vinyl moiety (e.g., vinyl ethers, acetates, and halides[1]).

Ethenyl(phenyl)iodonium triflate (**3**) is a novel electrophilic vinylating agent with promising applications in vinylation reactions that are not covered by the known reagents mentioned above. For example, **3** may be employed to synthesize the hitherto unknown parent vinyl triflate (**4**),[4] a possible precursor for the generation of the parent vinyl cation[5] as well as for metal-catalyzed vinylic couplings.[6] Compound **3** should also undergo oxidative addition to organometallic substrates, serving formally as a vinyl cation equivalent. Such a synthesis complements the more traditional methods for the introduction of the σ-bonded parent vinyl substituent into organometallic complexes, mainly the use of vinylmagnesium bromide in displacement reactions[7] and the equilibration of π-ethene complexes.[7a, 8]



Salt **3** was obtained from tri-*n*-butyl(vinyl)tin (**1**) and cyano(phenyl)iodonium triflate (**2**) in 75% isolated yield.[9, 10] The previously unknown parent vinyl triflate (**4**) was formed from **3** by cleavage of the C–I bond in the presence of catalytic amounts of silver triflate. Isolation of **4** was possible from benzonitrile by distilling **4** directly from the reaction mixture (15 to 20% yield). Compound **4** is fully characterized. Noteworthy is the ^{13}C NMR spectrum, where the signals of the vinyl carbons of **4** have changed positions with respect to **3** (**3**, $\delta_{CH_2} = 133.4$, $\delta_{CH} = 109.5$; **4**, $\delta_{CH_2} = 106.4$, $\delta_{CH} = 143.5$).

Iodonium salt **3** is also a strong electrophilic substrate in organometallic reactions. Treatment of Vaska's complex or its rhodium analogue with **3** yields the new octahedral hexacoordinate rhodium and iridium species **5a**, **b** in 84 and 75% yield, respectively. The IR spectrum reveals a strong CO vibration at $\tilde{\nu} = 2063\ cm^{-1}$ for **5a** and at $\tilde{\nu} = 2088\ cm^{-1}$ for **5b**. In the far-infrared region of **5a**, an Ir–Cl stretch at $\tilde{\nu} = 307\ cm^{-1}$ indicates a *trans* arrangement between the Cl and CO ligands.[12] Likewise, the *trans* relationship of the phosphane ligands and the octahedral symmetry is confirmed in the ^{31}P NMR spectrum by the typical high-field position of the Rh doublet ($\delta = 15.1$) for **5b** and the singlet ($\delta = -8.3$) for **5a**.

The introduction of the parent vinyl substituent into organometallic substrates via **3** constitutes a significant change in methodology. Rather than vinylmagnesium bromide reacting as a nuclephile due to the carbanionic character of the vinyl substituent, **3** shows an umpolung of the vinyl reactivity, making it employable as an electrophile in oxidative additions. Traditionally, oxidative additions are well established as a method for the introduction of alkyl substituents,[13] but could not be used for vinylations owing to the unreactivity of simple vinyl substrates.[14]

Other applications of **3** are under investigation (e.g., cycloadditions). Preliminary results show that **3** reacts with cyclopentadiene. Isolation of the expected product, however, is not possible owing to the thermal instability of alkyliodonium salts.

Experimental Procedure

3: Salt **2** [10] (0.60 g, 1.58 mmol), suspended in CH_2Cl_2 (30 mL) under N_2, was cooled to $-40\,^{\circ}C$. Compound **1** [15] (0.46 mL, 1.58 mmol), dissolved in CH_2Cl_2 (10 mL), was added dropwise. After the addition was complete, the cooling bath was removed and the heterogeneous mixture was allowed to warm to room temperature, turning into a clear, slightly yellow solution. By adding hexane under vigorous stirring, a yellowish oil separated out and was washed with hexane twice to remove tri-*n*-butyltin cyanide. Crystallization occurred by adding the oil, dissolved in a small amount of CH_2Cl_2, to vigorously stirring hexane. After decantation of the solvent, the precipitate was dried in vacuo, yielding 0.45 g (1.18 mmol; 75%) of white microcrystalline **3**. M.p. 32 °C. ^{1}H NMR (300 MHz, CD_2Cl_2): $\delta = 6.22$ (dd, $J_{H\text{-}1,H\text{-}2} = 5.2$, $J_{H\text{-}1,H\text{-}3} = 15.0$ Hz, 1H; H-1), 6.95 (dd, $J_{H\text{-}2,H\text{-}1} = 5.2$, $J_{H\text{-}2,H\text{-}3} = 6.8$ Hz, 1H; H-2, *trans* to I), 7.20 (dd, $J_{H\text{-}3,H\text{-}2} = 6.8$, $J_{H\text{-}3,H\text{-}1} = 15$ Hz, 1H; H-3, *cis* to I), 7.57 (t, $J = 7.8$ Hz, 2H; H_{meta}), 7.75 (*t*, $J = 7.3$ Hz, 1H; H_{para}), 7.99 (d, $J = 8.4$ Hz, 2H; H_{ortho}). ^{13}C NMR (75 MHz, CD_2Cl_2): $\delta = 109.5$ (s; =CH), 110.1 (s; C_{arom}), 120.5 (q, $J_{C,F} = 320$ Hz; CF_3), 132.5, 133.2, 136.6 (3s; CH_{arom}), 133.4 (s; $=CH_2$). IR [16]: $\tilde{\nu}$ [cm^{-1}] = 3087, 3072, 3004, 2946, 1588, 1568, 1474, 1446, 1379, 1253, 1223, 1165, 1156, 1025, 992, 733. MS(FAB): *m/z* 231 ($M^{\oplus}$). High-resolution MS: calcd for $C_9H_8F_3IO_3S^{\oplus}$, 230.96707; found, 230.96655.

4 [17]: To **3** (0.84 g, 2.21 mmol), dissolved in benzonitrile, was added 10 mol % of silver triflate (0.06 g). After the mixture was stirred for 3 d, colorless **4** (0.06 g, 0.34 mmol) was distilled off in 15% yield. B.p. 80 °C. ^{1}H NMR (300 MHz, CD_3CN): $\delta = 5.14$ (dd, $J_{H\text{-}2,H\text{-}3} = 3.7$, $J_{H\text{-}2,H\text{-}1} = 5.5$ Hz; H-2, *trans* to OTf), 5.36 (dd, $J_{H\text{-}3,H\text{-}2} = 3.7$, $J_{H\text{-}3,H\text{-}1} = 13.0$ Hz, 1H; H-3, *cis* to OTf), 6.84 (dd, $J_{H\text{-}1,H\text{-}2} = 5.5$, $J_{H\text{-}1,H\text{-}3} = 13.1$ Hz, 1H; H-1). ^{13}C NMR (75 MHz, CD_3CN): $\delta = 106.4$ (s; $=CH_2$), 119.4 (q, $J_{C,F} = 319$ Hz; CF_3), 143.5 (s; =CH). Fischer Carbene Complexes Facilitate the Intramolecular Pauson–Khand Reaction**

By *Francisco Camps, Josep M. Moretó,* Susagna Ricart,* and *Josep M. Viñas*

The $[Co_2(CO)_8]$-mediated carbonylative cycloaddition of acetylenes and olefins (Pauson–Khand reaction) is one of the most straightforward methods for preparation of cyclopentenone derivatives.[1] This procedure has been successfully applied to the synthesis of a variety of bioactive natural products.[2] Recently, the first efficient enantioselective synthesis of a hirsutene precursor has also been reported.[3]

However, there are still some unsolved drawbacks that limit the scope of application of the Pauson–Khand reaction. For example, low yields are often obtained owing to the high temperatures required to further activate the alkyne–$Co_2(CO)_6$ intermediate complex, which, in addition, may preclude the presence of certain thermally labile moieties in the starting reagents. To overcome these problems, different modifications have been put forth such as the use of silica gel,[4] nitrogen oxides,[5] sonication,[6] or UV irradiation.[7] Yields can be substantially improved in intramolecular reactions.[2–5, 7, 8] As an example of its potential practical importance, an efficient catalytic synthesis of jasmone by application of this reaction has been recently published.[9]

In connection with our current studies of the applications of Fischer carbene complexes to organic synthesis, we have proved, in agreement with results described by other authors,[10] that a triple bond conjugated to a transition-metal carbene moiety becomes highly polarized, resulting in easy

cycloadditions and Michael additions with a variety of substrates.[11] We anticipated that this approach might be used to facilitate the intramolecular Pauson–Khand reaction by activation of the corresponding acetylenic moiety in a similar strategy to that reported for analogous olefin complexes in Diels–Alder cycloadditions.[12]

When alkynyl allylamino carbene complexes **1a–d** were treated with one equivalent of $[Co_2(CO)_8]$ in dry THF *for a few hours at room temperature*, the expected cyclopentenone derivatives **2a–d** were obtained in 70–75% yields. Moderate yields of tricyclic derivative **2e** were obtained by performing the reaction with cyclohexenylamine complex **1e** (Table 1).

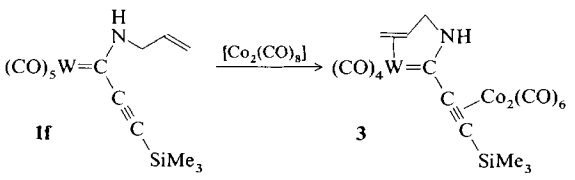
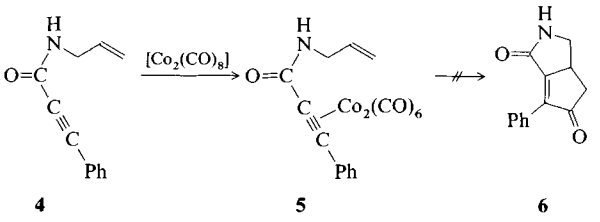
Surprisingly, unlike the report of previous authors on high yields of Pauson–Khand cycloadducts from trimethylsilylacetylenic derivatives,[13, 2b, c, g] carbene complex **1f** afforded only $[Co_2(CO)_6]$–alkyne complex **3** in good yields. We attribute this failure mainly to the steric encumbrance of the trimethylsilyl group, which should push the olefin moiety towards coordination with the transition metal of the carbene.

The activating role of the carbene-metal functionality was made clear by an independent experiment in which one equivalent of the enyne amide was stirred with one equivalent of $[Co_2(CO)_8]$ in dry THF for three days at room tem-



1f **3**



4 **5** **6**

perature and the $[Co_2(CO)_6]$–amide complex **5** was obtained instead of the expected cycloadduct **6**.

A few remarkable points deserve further comment. Good yields of cycloaddition products are obtained despite the fact that disubstituted acetylenes bearing electron-withdrawing substituents (the metal-carbene group may be considered to fall into this category) usually give mainly linear diene adducts and low yields of cycloadducts.[1, 13] Furthermore, the reaction occurs at room temperature with high stereoselectivity (in cases **2d** and **2e** the formation of only one stereoisomer was detected[14]). This stereoselectivity control might be expected from the defined coordination geometries around both metal centers.

In conclusion, we have proved that intramolecular Pauson–Khand reactions can be efficiently performed on a metal-carbene-activated enyne derivative in a stereoselective manner under very mild conditions. The resulting cycloadducts still bearing the Fischer carbene functionality may be used to carry out further reactions (such as benzannulation[15] or cyclopropanation[16]).

Experimental Procedure

$[Co_2(CO)_8]$ (1 mmol) was added to the allylamino carbene complex (1 mmol) in 25 mL of dry THF and the reaction mixture was left at room temperature for 2–12 h (Table 1). The reaction course was monitored by thin layer chromatography (hexane/ethyl acetate 2/1). After the starting product had completely disappeared, the solvent was removed and the residue passed through a flash chromatography column using the mentioned eluent. The cyclopentenone complexes crystallize upon concentration. All compounds (**2a–e, 3**) gave satisfactory spectroscopic data and elemental analysis. Those for **2d** and **2e** are given as representative: **2d**: IR ($CHCl_3$): $\tilde{\nu}$ [cm^{-1}] = 2058(m), 1989(w), 1943(vs), 1925(sh), 1755(m), 1725(m); ^1H NMR (300 MHz, $CDCl_3$): δ = 9.05 (br. s, 1H), 7.45 (m, 5H), 4.12 (ddd, J = 2.1, 8.4, 11.4 Hz, 1H), 3.53 (dd, J = 8.1, 11.4 Hz, 1H), 3.25 (ddd, J = 4.2, 8.4, 8.1 Hz, 1H), 2.54 (dq, J = 7.3, 4.2 Hz, 1H), 1.39 (d, J = 7.3 Hz, 3H); ^{13}C NMR (75.4 MHz, $CDCl_3$): δ = 232.9, 209.7, 202.7, 198.2, 178.1, 143.0, 131.9, 131.2, 131.1, 129.3, 128.5, 59.6, 51.4, 47.6, 13.7. **2e**: IR ($CHCl_3$): $\tilde{\nu}$ [cm^{-1}] = 2060(m), 1970(w), 1920(vs), 1705(m); ^1H NMR (80 MHz, $(CD_3)_2CO$): δ = 9.02 (br.s, 1H), 7.45 (m, 5H), 4.25 (dd, J = 8, 16 Hz, 1H), 3.5 (t, J = 8 Hz, 1H), 3.0 (dd, J = 8, 16 Hz, 1H), 1.1–2.8 (m, 6H); ^{13}C NMR (75.4 MHz, $CDCl_3$): δ = 363.3, 210.9, 201.9, 197.5, 174.9, 145.0, 130.3, 130.2, 129.5, 128.4, 63.8, 45.7, 43.1, 31.2, 25.8, 20.0.

[14] The structural assignment has been made on basis of NMR data as well as structural and mechanistic considerations. Particular significance has been given to the different coupling constants for **2d** and **2e** for the bridgehead proton with the vicinal α-ketonic proton. These values (J = 4.2 Hz for **2d** and J = 8 Hz for **2e**), although slightly higher than those reported by *Schore* et al. for related organic structures (N. E. Schore, M. J. Kundsen, *J. Org. Chem. 52* (1987) 569), are complementary and in the same order of assignment (the larger for the *cis*-vicinal coupling constant and the smaller for the corresponding *trans*). Furthermore, the stereoisomers thus obtained are those which are to be expected starting from a *trans* olefin (*E*-crotylamine) and a *cis* one (2-cyclohexenylamine) in a stereospecific process.

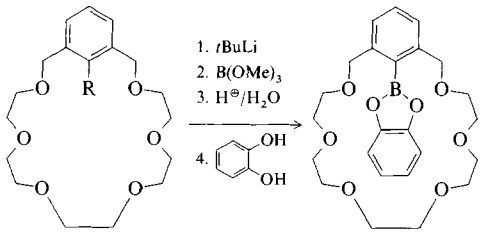
Crown Ethers with a Lewis Acidic Center: A New Class of Heterotopic Host Molecules**

By *Manfred T. Reetz,* Christof M. Niemeyer,* and *Klaus Harms*

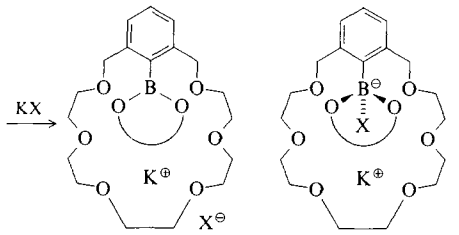
Many cation-selective crown ethers and cryptands are known,[1] but only a few host compounds bind anions selectively. Naturally, the latter are electronically inverse macrocycles that usually contain suitably positioned protonated or quaternary nitrogen functions.[2] Here we report a new class of anion-selective receptors, **2**, which in addition to a conventional crown ether moiety for complexation of cations, contain a σ-bonded Lewis acidic metal center—in this case, boron— for complexation of anions. Our concept is based on the expectation that, for example, potassium salts, KX (X = F, Cl, Br, I, SCN, CN, OCH_3) should be able to bind to the host **2** in either a monotopic (**3**) or a heterotopic (**4**) fashion. The selectivity would then be governed by quite diverse factors, such as the strength of the B–X bond in the ate complex **4**, the lattice energy of the salt KX, Coulomb and van der Waals interactions, and solvent effects.

Since potassium salts were to be investigated first, we chose the 21-membered crown ether **2**, which contains six oxygen atoms. The aryl bromide **1a** was used for its synthesis.[4] The corresponding aryllithium compound was borylated with $B(OCH_3)_3$ and the crude product was hydrolyzed to



1a, R = Br
1b, R = H

2



3 **4**

a, X = F; **b**, X = Cl; **c**, X = Br; **d**, X = I
e, X = SCN; **f**, X = CN; **g**, X = OCH_3;

give the arylboronic acid.[5] Treatment of the acid with catechol finally led to the target compound **2** (>95% overall yield), which is stable and easy to handle under an inert atmosphere.

In the first complexation experiment, host **2** was added to a suspension of dry KF (excess) in dichloromethane at room temperature. A stoichiometric amount of the otherwise insoluble salt dissolved within 4 h with quantitative formation of adduct **4a**. This is noteworthy since potassium-specific crown ethers such as [18]crown-6[6] or 1,3-xylyl[21]crown-6 (**1b**)[7] complex at most *catalytic* amounts of KF.[8] In the case of **4a**, the strength of the B–F bond[9] is decisive. The usual interaction between $K^{\oplus}$ and the oxygen atom of the crown ether acts synergistically, since a control experiment with KF and the catechol ester of phenylboronic acid afforded *no* adduct.[10, 11]

The host–guest compound **4a** was investigated in solution particularly by ^{11}B and ^{13}C NMR spectroscopy. The ^{11}B NMR spectrum (CD_2Cl_2) at room temperature with BF_3–ether as external standard shows a single signal at $\delta = 10.0$, which means a shift of $\Delta\delta = 20$ to higher field compared with the signal of the uncomplexed host **2** ($\delta = 30$). This is characteristic of compounds with tetracoordinated boron.[12] The participation of $K^{\oplus}$ as guest is shown by a comparison of the ^{13}C NMR spectra of the free host **2** and the adduct **4a** (Fig. 1). The low-field shift of the signals of the benzylic C atoms (C7 and C18) and the high-field shift of the other ether C atoms are definite indications of cation binding.[13] The fact that the spectra of mixtures of compounds **2** and **4a** exhibit sharp signals shows that, under these conditions, rapid exchange processes do not occur on the NMR time scale. The ^{19}F NMR ($\delta = -124.4$; $CFCl_3$ as external standard) and the ^1H NMR spectrum are also consistent with structure **4a**.

Figure 2 shows the result of an X-ray structure analysis of **4a**.[14] The inclusion of $K^{\oplus}$ and $F^{\ominus}$ is clearly evident (Fig. 2, top), as are intermolecular interactions between the units of the host–guest compound (Fig. 2, bottom). The "unsymmetrical" structure (Fig. 2, top) could be due to a crystal packing effect, since the ^{13}C NMR spectrum of **4a** in solution does *not* show a double set of signals in the range of 40 °C to −80 °C.

[**] This work was supported by the Deutsche Forschungsgemeinschaft (Leibniz-Program) and the Fonds der Chemischen Industrie.

The salts KCl and KBr do not undergo monotopic or heterotopic interactions with **2**, even after a reaction period of two weeks. This behavior corresponds to that of crown ether **1b**.[15] We ascribe this to the fact that $K^{\oplus}$ complexation is not sufficiently favored energetically and to the weaker B–Cl and B–Br bonds.[9] By contrast, monotopic binding is observed for KI and KSCN (formation of **3d** and **3e**, respectively). After two days, the respective ^{13}C NMR spectra show the signal shifts characteristic of $K^{\oplus}$ inclusion,[13] whereas the position of the ^{11}B NMR signal has hardly changed (**3d**, $\delta = 29.9$; **3e**, $\delta = 29.4$). The formation of the host–guest compound **3** is energetically favored in these cases by the usual $K^{\oplus}$ complexation.[16] This interpretation is consistent with the observation that the reaction of crown ether **1b** with KI or KSCN leads to inclusion of $K^{\oplus}$. In the reactions of host **2** with KCN (reaction time 2 d) and $KOCH_3$ (1 h), **4f**[17] and **4g**, respectively, are formed nearly quantitatively. The ^{11}B NMR spectra (**4f**, $\delta = 10.7$; **4g**, $\delta = 10.6$), as well as ^{13}C NMR signal shifts characteristic of $K^{\oplus}$ binding, confirm a heterotopic behavior.

The selectivity described here for the series of potassium salts KX has not been previously observed for any other receptor.[1–3] Selectivity in competition experiments is also possible. For example, if **2** is allowed to react with a mixture of KF, KCl, KBr, and KI the KF adduct **4a** is formed exclusively within two days. Host **2** is also capable of distinguishing between potassium salts leading to heterotopic host–guest compounds **4**. Thus, upon reacting the host **2** with a KF/KCN mixture for a sufficient length of time,[18] only **4a** is formed. The suitability of host compounds of type **2** with respect to synergistic effects in molecular recognition of organic compounds is the subject of further investigations.[19]

[3] *Schmidtchen* has synthesized heterotopic compounds that contain a crown ether moiety and an ammonium macrocycle: F. P. Schmidtchen, *Tetrahedron Lett. 25* (1984) 4361; F. P. Schmidtchen, *J. Org. Chem. 51* (1986) 5161.

[4] M. Newcomb, S. S. Moore, D. J. Cram, *J. Am. Chem. Soc. 99* (1977) 6405.

[5] *Reinhoudt* et al. have carried out a similar borylation and have oxidized the resulting, nonisolated boronic acid to the corresponding phenol: M. Skowronska-Ptasinska, V. M. L. J. Aarts, R. J. M. Egberink, J. van Eerden, S. Harkema, D. N. Reinhoudt, *J. Org. Chem. 53* (1988) 5484.

[6] According to *Liotta* et al., [18]crown-6 binds potassium fluoride (as a suspension in benzene or acetonitrile) only to the extent of 2–5%, which

is nonetheless sufficient to accelerate S_N2 reactions: C. L. Liotta, H. P. Harris, *J. Am. Chem. Soc. 96* (1974) 2250.
[7] D. N. Reinhoudt, R. T. Gray, *Tetrahedron Lett. 1975*, 2105.
[8] When the suspension of KF in CH_2Cl_2 is allowed to react with 1,3-xylyl[21]crown-6 **1b** for several days under ultrasonication, the ^1H and ^{13}C NMR spectra of the solution show no evidence of binding of $K^{\oplus}$ ions.
[9] Since dative bonds are formed in the ate complexes, the usual values of the bonding energies, which refer to diatomic molecules, cannot be used (cf. A. Haaland, *Angew. Chem. 101* (1989) 1017; *Angew. Chem. Int. Ed. Engl. 28* (1989) 1010). The usual trend toward weaker bonding in the order B-F > B-Cl > B-Br > B-I probably still holds, however.
[10] a) Tris(dimethylamino)sulfonium fluoride reacts with 1,8-naphthalenediylbis(dimethylborane) to form an adduct: H. E. Katz, *J. Org. Chem. 50* (1985) 5027; b) [18]crown-6 binds the counterion of pentacoordinated silicon compounds: J. L. Brefort, R. J. P. Corriu, B. J. L. Henner, W. W. C. W. Chi Man, *Organometallics 9* (1990) 2080.
[11] The mixture containing the catechol ester of phenylboronic acid and 1,3-xylyl[21]crown-6 (**1b**) also effects the dissolution of KF. The synergistic effect, however, is smaller. For example, if adduct **4a** is allowed to react with a 1:1 mixture containing **1b** and the catechol ester of phenylboronic acid, an equilibrium is established in favor of **4a** ($\approx$ 70:30).

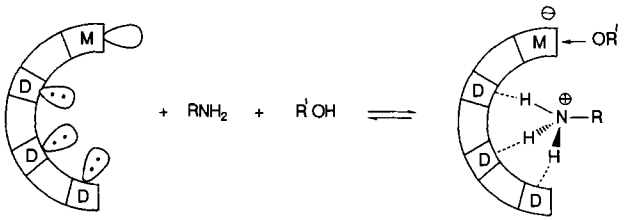
Heterotopic Host Molecules for Binding Two Different Guests **

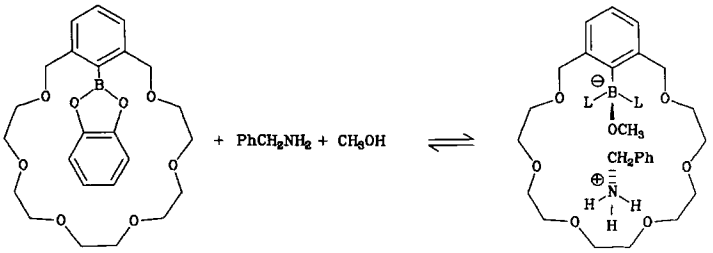
By *Manfred T. Reetz,* Christof M. Niemeyer,* and *Klaus Harms*

An important aspect of host/guest chemistry is the simulation of biological systems.[1] It is all the more surprising, therefore, that practically no host molecules capable of recognizing and binding *two different* organic guest molecules have been synthesized.[1–3] Here we describe a new concept of molecular recognition in which alcohols and amines are recognized simultaneously and selectively. This work was motivated by the hope that compounds with one acceptor site (e.g., a metal center[3]) and several donor sites (e.g., ether functions) might be potential hosts for alcohols *and* amines, because, after proton transfer, the alkoxide anion and the ammonium cation could bond through reversible dative and hydrogen bonds, respectively (Scheme 1). Such binding would therefore involve heterotopic host molecules whose Lewis acid/base property affects the equilibrium of the Brønsted acid/base pair (alcohol and amine; see Scheme 1).



Scheme 1. Simultaneous molecular recognition of amines and alcohols (M = metal center with empty orbital; D = donor site with occupied orbital).

In an initial experiment the boron-containing crown ether **1**[4] was allowed to react with a 1:1 mixture of methanol and benzylamine in dichloromethane. A spontaneous reaction ensued, leading to the formation of **2**. The assumption that methoxide bonds to boron and the ammonium ion to the crown ether moiety was supported by ^{11}B, ^1H, and ^{13}C NMR spectroscopy.[5]



1 **2**

The X-ray structure analysis[6] provided final confirmation and also brought to light some structural details. The ammonium ion is completely embedded in the crown ether moiety, as a space-filling picture reveals (Fig. 1b[7]). This structural element is unique, since ammonium ions are usually situated "outside" the crown ether and form hydrogen bonds to the ether oxygen atoms.[1, 8] In this case, however, the ammonium ion is drawn deeply into the host owing to the formation of a hydrogen bond to the methoxide. The N atom is located exactly in the average plane of the crown ether atoms, the maximum deviation of the ring atoms being ± 0.8 Å.[6] This type of communication between the two guests leads to a rotaxane-type structure.

To determine whether host **1** can distinguish between different alcohols and amines, we first carried out competition experiments involving benzylamine and, in each case, two alcohols.[9] The results summarized in Table 1 establish that steric factors are mainly responsible for the molecular recognition.[10] Thus, host **1** can distinguish between methanol and ethanol (73% in favor of the methanol adduct). Control

[**] This work was supported by the Deutsche Forschungsgemeinschaft (Leibniz Program) and the Fonds der Chemischen Industrie.

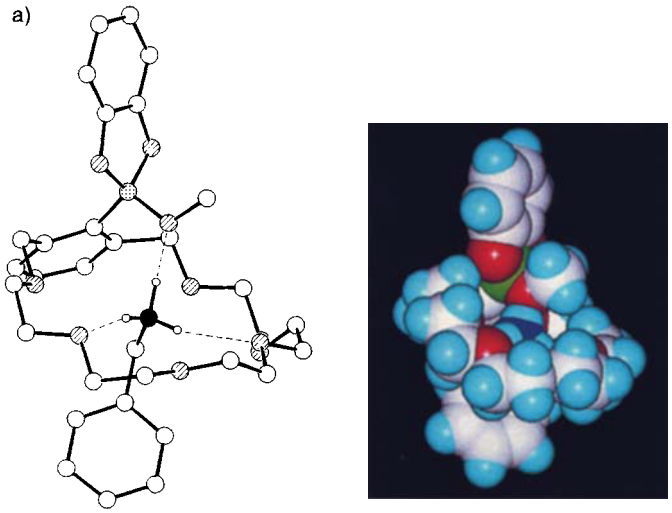

Fig. 1. a) Asymmetric unit of **2** in the crystal. Boron, dotted; carbon, white; oxygen, striped; nitrogen, black (H atoms only shown for ammonium ions). b) Space-filling representation of **2** [7]. Boron, green: carbon, white; oxygen, red; nitrogen, dark blue; hydrogen, light blue.

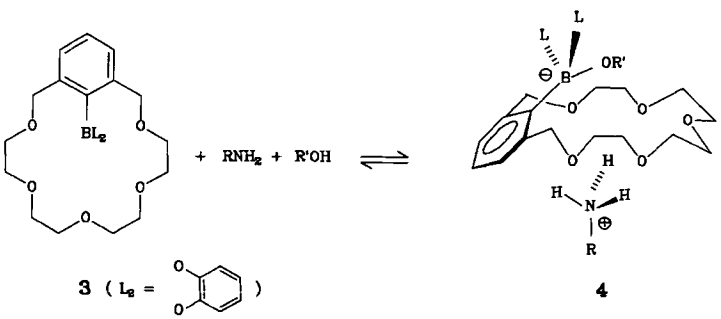
experiments show that the data were obtained under thermodynamic conditions. Although the exchange processes are reversible, they are slow on the NMR time scale, and two host/guest compounds can be detected simultaneously by NMR spectroscopy.

Table 1. Molecular recognition of alcohols by host **1** in the presence of benzylamine at room temperature [9].

R^1OH	R^2OH	Ratio of complex formation $R^1OH:R^2OH$
CH_3OH	CH_3CH_2OH	73:27
CH_3OH	$Ph(CH_3)CHCH_2OH$	86:14
CH_3OH	$(CH_3)_2CHOH$	93: 7
CH_3OH	$(CH_3)_3COH$	>97: <3
CH_3OH	PhOH	71:29
$PhCH_2OH$	CH_3CH_2OH	56:44
$PhCH_2OH$	$(CH_3)_2CHOH$	88:12

On the basis of the X-ray structure analysis of adduct **2** (Fig. 1), we expected a high degree of molecular recognition of amines. Indeed, competition experiments with the amine pair benzylamine/α-methylbenzylamine and one alcohol (methanol, ethanol, or isopropyl alcohol) show that, in each case, only *one* host/guest[1]/guest[2] combination is realized, namely, **1**/benzylamine/alcohol.

When similar competition experiments were performed with a smaller analogous host containing five oxygen atoms in the 18-membered ring,[11] the amine selectivity turned out to be significantly lower. In the case of methanol as the alcohol component, for example, benzylamine is favored over α-methylbenzylamine to the extent of only 80%. This has to do with the fact that the ammonium ions cannot penetrate as deeply into the smaller crown ether ring,[12] as shown by the result of the X-ray structure analysis of the ethanol/benzylamine adduct **4** (Fig. 2a).[13] Thus difference in steric interactions in the case of different amines is not as great as in the case of the host **1**. In contrast, alcohol selectivity is much higher. In the case of benzylamine as the amine component and methanol/ethanol as alcohols, methanol is complexed exclusively! The smaller ring induces more steric shielding of the boron (see Fig. 2b). Further investigations, involving



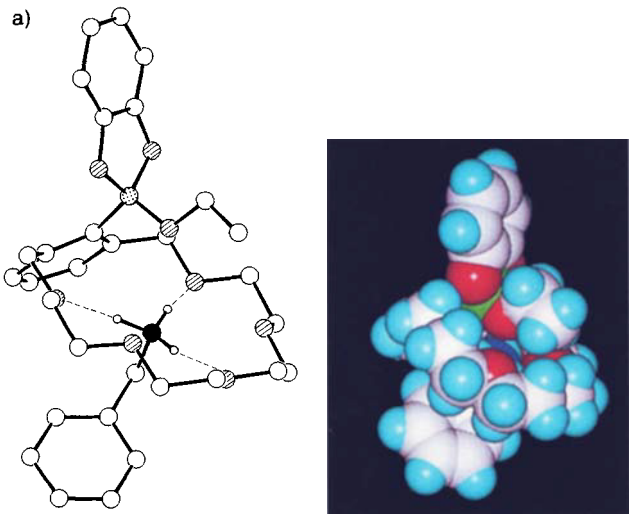


Fig. 2. a) Asymmetric unit of **4** (R = $PhCH_2$, R' = Et) in the crystal. b) Space-filling representation of **4** [7]. Same notation as in Fig. 1.

variation of the guests,[14] the ligands on boron, the topology of the cavity, and the metal, are in progress.

[2] Systems obtained by molecular biological techniques are not considered here. Several host compounds that bind organic molecules and metal cations simultaneously are known: F. Diederich, M. R. Hester, M. A. Uyeki, *Angew. Chem. 100* (1988) 1775; *Angew. Chem. Int. Ed. Engl. 27* (1988) 1705, and references cited therein; crystalline clathrate compounds with several guests, such as alcohols: E. Weber, M. Hecker, I. Csöregh, M. Czugler, *Mol. Cryst. Liq. Cryst. 187* (1990) 165; see also J. L. Atwood, J. E. D. Davies, D. D. MacNicol (Eds.): *Inclusion Compounds*, Vol. 1–3, Academic Press, London 1984.

[3] Host molecules with metal centers have been reported in recent years. Examples include the following: a) compounds with two zinc-containing porphyrin rings, which complex dipyridines and diamines: S. Kugimiya, *J.*

Chem. Soc. Chem. Commun. 1990, 432; H. L. Anderson, C. A. Hunter, M. N. Meak, J. K. M. Sanders, *J. Am. Chem. Soc. 112* (1990) 5780; b) metallomacrocycles, such as uranium-containing chelates, which form complexes with pyridines: A. R. van Doorn, M. Bos, S. Harkema, J. van Eerden, W. Verboom, D. N. Reinhoudt, *J. Org. Chem. 56* (1991) 2371; c) numerous multidentate Lewis acids that bind two molecules of the same kind, see, e.g.: B. Bachand, J. D. Wuest, *Organometallics 10* (1991) 2015, and references cited therein; d) Note added by the editorial staff: See also the communication by *F. Hawthorne* et al. in this issue, in which a host compound analogous to a [12]crown-4 with four Hg atoms is reported: X. Yang, C. B. Knobler, M. F. Hawthorne, *Angew. Chem. 103* (1991) 1519; *Angew. Chem. Int. Ed. Engl. 30* (1991) 1507.

[4] In the preceding communication we describe the synthesis of the host compound **1** as well as its ability to bind potassium salts, KX (X = F, Cl, Br, I, SCN, CN, OCH_3) selectively: M. T. Reetz, C. M. Niemeyer, K. Harms, *Angew. Chem. 103* (1991) 1515; *Angew. Chem. Int. Ed. Engl. 30* (1991) 1472.

[5] The ^{11}B NMR spectrum (CD_2Cl_2, BF_3-ether as external standard) of **2** shows one signal at $\delta = 9.0$, a reliable indication of the presence of a compound with tetracoordinated boron [4]. The ^1H and ^{13}C NMR spectra exhibit chemical shifts characteristic of cation inclusion [4].

[6] Crystallographic data for **2** · toluene ($C_{39}H_{52}BNO_9$, $M_r = 689.6$): triclinic, space group $P\bar{1}$, $a = 1093.8(1)$, $b = 1392.3(1)$, $c = 1447.7(2)$ pm, $\alpha = 101.16(1)$, $\beta = 109.52(1)$, $\gamma = 104.29(1)°$, $Z = 2$, $\varrho_{calcd} = 1.193\ g\,cm^{-3}$, $\mu(Cu_{K\alpha}) = 6.42\ cm^{-1}$. Measurement carried out on an Enraf-Nonius CAD4 diffractometer ($Cu_{K\alpha}$ radiation, $\lambda = 1.54184$ Å, graphite monochromator, $T = 190$ K); 4666 measured reflections, 4404 of which are independent ($R_{int.} = 0.0185$), 4081 with $F > 4\sigma(F)$ were regarded as observed. Solution by direct methods and refinement with the Siemens SHELXTL-PLUS(VMS) program package, $R = 0.0641$, $R_w = 0.0797$ ($\omega = 1/\sigma^2(F)$); all non-hydrogen atoms refined anisotropically; N- and O-bonded H atoms localized; the others "riding" with groupwise common isotropic temperature factors. Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, W-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-320298, the names of the authors, and the journal citation.

[7] In order to generate the space-filling representation, the X-ray data were processed on a Silicon graphics computer using the Sybyl program.

[8] See, e.g.: D. J. Cram, K. N. Trueblood, *Top. Curr. Chem. 98* (1981) 43; I. Goldberg in S. Patai, Z. Rappoport (Eds.): *Crown Ethers and Analogs*, Wiley, Chichester, England 1989, p. 359.

[9] In a typical experiment, 0.1 mmol of host **1** and 0.1 mmol of an amine were placed in 1 mL of dry CD_2Cl_2 at room temperature and treated with 0.2 mmol of each alcohol. The analysis was carried out by ^{13}C NMR spectroscopy at room temperature. When 1, 3, or 5 mmol of the methanol/ethanol pair was used, no change in the selectivity was observed. The selectivities thereby obtained (Table 1) provide no information concerning the absolute magnitudes of the binding constants, which are the subject of a more detailed investigation.

[10] The equilibrium constants for the reaction of boranes and amines to form borane/amine adducts were measured by *Brown* et al. and interpreted on the basis of front strain: H. C. Brown, R. B. Johannesen, *J. Am. Chem. Soc. 75* (1953) 16; H. C. Brown, *Rec. Chem. Prog. 14* (1953) 83; Related studies have recently been reported by *Yamamoto* et al. on this kind of molecular recognition in the complexation of ethers and carbonyl compounds by bulky aluminum compounds: K. Maruoka, S. Nahahara, H. Yamamoto, *J. Am. Chem. Soc. 112* (1990) 6115; K. Maruokoa, S. Nagahara, H. Yamamoto, *Tetrahedron Lett. 31* (1990) 5475.

[11] The host was prepared in the same way as **2** [4].

[12] An indication of the weaker complexation is the fact that rapid exchange processes are detectable by NMR spectroscopy for the ammonium components at room temperature. In this case the competition experiments were therefore carried out at $-40\,°C$.

[13] Crystallographic data for **4** ($C_{31}H_{42}BNO_8$, $M_r = 567.5$): monoclinic, space group $P2/n$, $a = 1535.9(3)$, $b = 994.4(2)$, $c = 2067.8(4)$ pm, $\beta = 105.55(3)°$, $Z = 4$, $\varrho_{calcd} = 1.239\ g\,cm^{-3}$, $\mu(Cu_{K\alpha}) = 6.82\ cm^{-1}$. Measurement carried out on an Enraf-Nonius CAD4 diffractometer ($Cu_{K\alpha}$ radiation, $\lambda = 1.54184$ Å, graphite monochromator, $T = 190$ K); 4290 measured reflections, 3830 of which were independent ($R_{int.} = 0.0660$); 2605 with $F > 4\sigma(F)$ were regarded as observed. Solution by direct methods and refinement in Siemens SHELXTL-PLUS(VMS) program system, $R = 0.0686$, $R_w = 0.0613$ ($\omega = 1/\sigma^2(F)$), all non-hydrogen atoms refined anisotropically; *N*-bonded H atoms localized; the others were refined using the riding model with groupwise common isotropic temperature factors. Further details of the crystal structure determination are available on request from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, W-7514 Eggenstein-Leopoldshafen 2, on quoting the depository number CSD-320335, the names of the authors, and the journal citation.

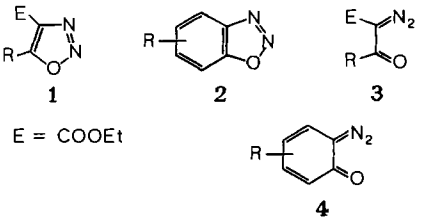
[14] For example, host **1** can bind water and benzylamine in the same way as **2**. Furthermore, preliminary experiments show that hosts form 1:1 inclusion complexes with amines and even ammonia.

Naphtho[2,3-*d*][1,2,3]oxadiazole**

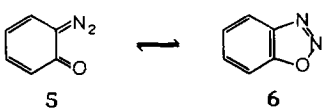
By *Achim Blocher* and *Klaus-Peter Zeller**

Dedicated to Professor Michael Hanack on the occasion of his 60th birthday

The early history of "diazoanhydrides", obtained on diazotization of α-amino β-keto esters and of *o*-aminophenols, is marked by controversy over the constitution of these compounds.[1] Much evidence initially favored the presence of 1,2,3-oxadiazoles of type **1** and **2**, respectively. In the end, however, the application of spectroscopic methods settled this structural discussion in favor of the isomeric α-diazo carbonyl compounds **3** and the *o*-quinonone diazides **4**, respectively.[2]



Only recently were *Schulz* and *Schweig*[3, 4] able to detect the formation of an equilibrium[5] between the parent compound, the *o*-quinone diazide **5**, and its valence isomer, the benzo[1,2,3]oxadiazole **6**, in the gas phase and in nonpolar solvents and thus provide the first experimental evidence for the existence of this five-membered heterocycle.



The *o*-quinone diazide **8**, expected on deprotonation of the diazonium tetrafluoroborate **7**, contains the *o*-quinone bismethide substructure A together with the *o*-quinonoid structural element B. On going to naphtho[2,3-*d*][1,2,3]oxadiazole (**9**), both of these energetically unfavorable structures should give way to the more stable naphthalene system. Thus, the cyclization to **9** should be particularly favored.

We have carried out the deprotonation of **7**[6] on basic alumina and sublimed the product (which is slightly colored owing to impurities) at about 10 °C under vacuum. The white to pale lemon yellow solid thereby obtained is stable for several days in the dark at $-20\,°C$. Its spectroscopic data

[**] This work was supported by the Fonds der Chemischen Industrie.

rule out both the *o*-quinone diazide structure **8** and the equally conceivable α-carbonyl diazirine structure **10**,[7] but are consistent with **9**. To the best of our knowledge, **9** is the first 1,2,3-oxadiazole to be isolated in pure form.

In the IR spectrum (KBr), the intense diazo and carbonyl bands typical of *o*-quinone diazides are absent. If the KBr disk is exposed to daylight for a few minutes and the IR spectrum recorded again, intense bands appear at 2090 (ν(C=N=N)) and 1627 cm^{-1} (ν(C=O)), indicative of the photochemical ring opening **9** → **8**. If the disk is kept in the dark for 30 min at 20 °C, the initial spectrum is obtained once again.

The ^1H and ^{13}C NMR spectra indicate that compound **9** is a 2,3-disubstituted naphthalene derivative; this structure is supported in particular by the lowest-field ^{13}C NMR signal ($\delta = 148.7$), which is at markedly higher field than that of a carbonyl C atom of *o*-quinone diazides, which usually show a chemical shift of $\delta = 180$.[8]

In the 70 eV mass spectrum (*m/z*, rel. int.), the molecular-ion peak, M^+ (170, 10%), is accompanied by intense peaks corresponding to the fragment ions $[M - N_2]$ (142, 100%) and $[M - N_2 - CO]^{\oplus}$ (114, 14%).

Table 1. Spectroscopic data for **9**.

IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 1626 (m), 1611 (m), 1594 (m), 1503 (m), 1464 (s), 1457 (s), 1443 (m), 1376 (m),...

After direct irradiation of the KBr disk with sunlight (filtered through a glass window) for 7 min [a]: $\tilde{\nu}$ [cm^{-1}] = 2090 (s), 1718 (s), 1700 (s), 1696 (s), 1684 (s), 1675 (m), 1627 (s), 1617 (m), 1601 (m), 1576 (m), 1565 (m), 1560 (m), 1499 (s), 1457 (s),...

^1H NMR (200 MHz, $CDCl_3$, −20 °C): $\delta = 8.58$ (s, 1H; H-9), 8.04–8.01 (d, 1H, $J = 8.3$ Hz; H-5 or H-8), 7.97–7.94 (d, 1H, $J = 8.5$ Hz; H-5 or H-8), 7.91 (s, 1H; H-4), 7.63–7.57 (t, 1H, $J = 7.6$ Hz; H-6 or H-7), 7.51–7.45 (t, 1H, $J = 7.6$ Hz; H-6 or H-7)

^{13}C NMR (200 MHz, $CDCl_3$, −20 °C): $\delta = 148.7$ (C-9a), 137.6 (C-3a), 135.7, 130.0 (C-4a, 8a), 129.4, 128.8, 128.0, 125.1 (C-5,6,7,8), 121.2 (C-4), 103.8 (C-9)

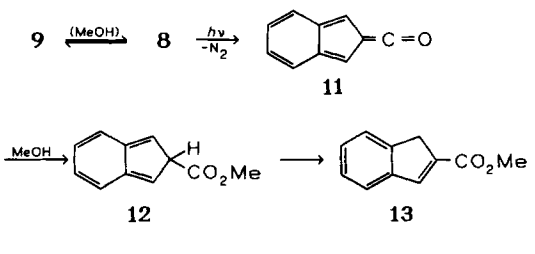
UV/VIS (*n*-heptane): λ_{max} (log ε) = 358 (3.37), 311 (4.00), 298 (3.84), 286 (3.56), 239 (4.54), 213 (4.54) nm

UV/VIS (95% methanol/5% *n*-heptane) [b]: λ_{max} (log ε) = 547 (3.07), 335 (3.70), 312 (3.76), 298 (3.73), 246 (4.43), 213 (4.33), 198 (4.03), 192 (3.98) nm

[a] Photochemical valence isomerization to **8**. [b] Formation of an equilibrium mixture between the valence isomers **8** and **9**.

The UV/VIS spectrum of **9** in *n*-heptane is similar in structure to that recorded for benzo[1,2,3]oxadiazole **6** in solution.[4] As expected, the positions of the bands are shifted to longer wavelengths. The spectrum of **9** in polar methanol is significantly different. We interpret this change as evidence of partial ring opening to give **8**, in analogy to the system **5** ⇌ **6**.[4] The absorption in the visible ($\lambda_{max} = 547$ nm, $\varepsilon_{max} = 1200$), in contrast to the short-wavelength absorptions, remains unchanged on going back to nonpolar *n*-heptane and is therefore presumably due to a secondary product of the ring-opened *o*-quinone diazide **8**.

Photolysis[9] of a 4.7×10^{-3} molar solution of **9** in methanol affords, as main product, 2-(methoxycarbonyl)indene (**13**) (59% yield).[10] As indicated by the UV/VIS spectrum, **9** forms an equilibrium with its valence isomer **8** in methanol.



In addition, as already noted, **8** can be formed photochemically from **9**. We assume that the observed loss of N_2 and the ring closure preceed as expected for a Wolff rearrangement[11] of an *o*-quinone diazide, via the ketene **11** and the ester **12**[12] as intermediates.

Experimental Procedure

9: A solution of **7** (100 mg, 0.388 mmol) in about 80 mL of methanol was concentrated to about 3 mL at ca. 20 °C and then transferred to a cooled column (ca. 10 °C) filled with 100 g of basic Al_2O_3 (Woelm B, activity 1) and immediately eluted (eluent: petroleum ether/ethyl acetate 1:1). Concentration of the eluate afforded 74 mg of crude product, which was dissolved in a small amount of dichloromethane and transferred to a sublimation apparatus. The sublimation was carried out in the dark (bath temperature ca. 10 °C, cold finger temperature −70 °C, 0.01 Torr). Yield: 14.3 mg (22%). The product could be stored in the dark at −20 °C for two days without any noticeable spectroscopic changes. At 20 °C, **9** gradually turns brown. Above 77 °C, it decomposes explosively.

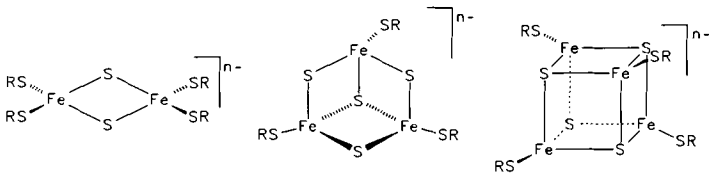
[**] 'S_4'$^{2-}$ = 2,2'-(ethylenedithio)dibenzenethiolate. Transition Metal Complexes with Sulfur-Containing Ligands, Part 77. This work was supported by the Deutsche Forschungsgemeinschaft, the Bundesministerium für Forschung und Technologie, and the Fonds der Chemischen Industrie. Part 76: D. Sellmann, S. Fünfgelder, F. Knoch, M. Moll, *Z. Naturforsch. 46b* (1991), in press.

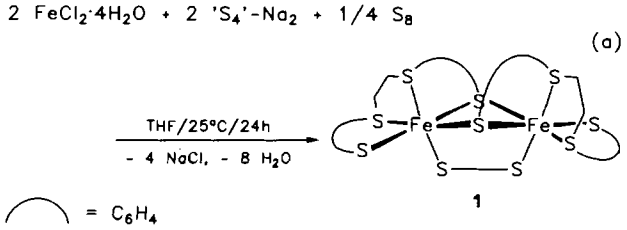
genases, and nitrogenases.[1] The structure of such centers has been determined unambiguously only in the case of a few ferredoxins. In these, iron is always surrounded tetrahedrally by thiolate and sulfide *S*-donors and forms [Fe–S] clusters of the type [2Fe–2S], [3Fe–4S], or [4Fe–4S] (**I**–**III**).[1] The SR ligands are cysteinates in the proteins, and thiolates such as $C_6H_5S^-$ in the synthetic analogues.



I **II** **III**

In most [Fe–S] enzymes, however, the structure of the active site is as yet undetermined. They possibly contain building blocks completely different from **I**–**III**. This assumption is supported by Mössbauer and EXAFS studies (EXAFS = *E*xtended *X*-ray *A*bsorption *F*ine *S*tructure). They indicate that, for instance, hydrogenases[2] and nitrogenases[3] contain [Fe–S] units that are fundamentally different from types **I**–**III**. Moreover, **I**–**III** interconvert very easily, and consequently no definite conclusions on the structure of the [Fe–S] sites in the native proteins can be drawn from extrusion experiments. Finally, the influence that the peptide chains and their cysteine residues exert on the formation and structure of [Fe–S] centers is still unknown.

It is therefore of basic interest that Fe^{2+} ions, elemental sulfur, and a multidentate thioether–thiolato ligand spontaneously form the novel [Fe–S] cluster $[\{Fe(\mu\text{-}'S_4')\}_2(\mu\text{-}S_2)]$ (**1**) under normal conditions in high yield according to Equation (a).



Complex **1** differs distinctly from types **I**–**III** and the organometallic clusters $[Cp_2Fe_2(\mu\text{-}S_2)(\mu\text{-}SR)_2]$ and $[Cp_2Fe_2(\eta^1\text{-}\mu\text{-}S_2)(\eta^2\text{-}\mu\text{-}S_2)]$[4] and has in many aspects prototype character.

The black-green **1** is diamagnetic and is soluble in dimethyl sulfoxide (DMSO), dimethylformamide (DMF), and CH_2Cl_2. The X-ray structure analysis[5] (Fig. 1) shows that both iron centers in **1** are pseudooctahedrally surrounded by six sulfur donors and are linked by two thiolato bridges of the 'S_4' ligands and one S_2 bridge. The Fe–thiolate and Fe–thioether distances of 225.2(4)–233.1(4) pm lie in the region typical for such complexes. The S_2 bridge has a S–S distance of 200.5(3) pm, which corresponds to a stretched interatomic distance in a neutral S_2 molecule (188.7 pm), and the Fe–Fe distance of 331.5 pm excludes a direct Fe–Fe bond. The [Fe1–S1–Fe2–S5] dihedral angle (148.3°) indicates that the four-membered ring is distinctly folded.

Complex **1** is chiral and contains two homochiral [Fe('S_4')] fragments linked through the thiolato-S atoms whose *ortho*

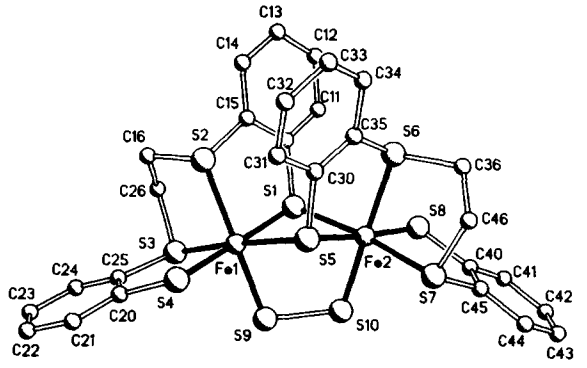


Fig. 1. Crystal structure of **1** (H atoms omitted). Important distances [pm] and angles [°]: Fe1-Fe2 331.5, Fe1-S1 228.3(3), Fe1-S2 229.5(4), Fe1-S3 225.5(4), Fe1-S4 228.2(3), Fe1-S5 233.1(4), Fe1-S9 215.9(5), Fe2-S1 232.1(4), Fe2-S5 228.6(3), Fe2-S6 227.3(5), Fe2-S7 225.2(4), Fe2-S8 231.3(4), Fe2-S10 213.1(5), S9-S10 200.3(5); Fe1-S1-Fe2 92.1(1), Fe1-S5-Fe2 91.8(1), S1-Fe1-S5 83.2(1), S1-Fe2-S5 83.3(1), S2-Fe1-S9 176.2(1), S6-Fe2-S10 178.8(2).

thioether-S atoms on the same benzene ring are *trans* to the μ-S_2 coligand. This α-bridging[6] is apparently electronically favored. The formation of **1** is thus also an interesting case of chiral recognition, since only homochiral fragments combine with one another from a racemic mixture of [Fe('S_4')] precursor complexes that form initially in the reaction represented in Equation (a).

The bonding in the $[\mu\text{-}S_2Fe_2]$ unit may be described as a delocalized 4-center 6-electron π system, formed from occupied Fe d orbitals and the π and π* orbitals of the μ-S_2 ligand. This model plausibly explains the S–S distance in the μ-S_2-bridge that is elongated with respect to uncomplexed S_2 molecules, and the short Fe–S distances in the FeS_2Fe unit (215.9 and 213.1 pm). Also the intense absorptions in the electronic spectrum of **1** (Fig. 2, left) may be attributed to the Fe···S···S···Fe bonding system. They extend into the near IR region and can be assigned to π–π* transitions.

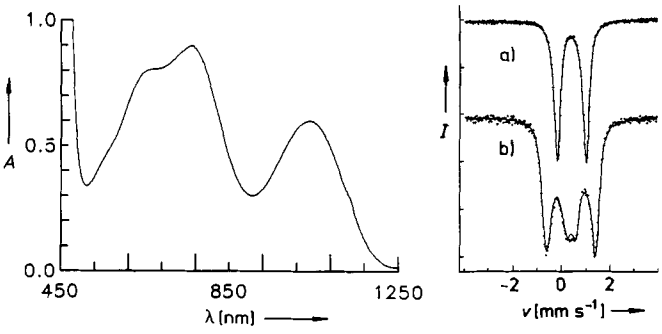

Fig. 2. Left: UV/VIS/near IR spectrum of **1** in CH_2Cl_2; λ_{max}[nm] (ε)[$M^{-1}cm^{-1}$]: 640(1950), 760(2100), 1050(1650); right: Mössbauer spectra of **1** at a) 4.2 K (δ = 0.367 and ΔE_Q = 1.161 mm s^{-1} with respect to metallic iron at 295 K and b) 4.2 K in a magnetic field (4 T) parallel to γ radiation. *I* = relative intensity.

The Mössbauer spectra (Fig. 2, right)[7] indicate that **1** contains low-spin Fe^{II} centers. This follows not only from the spectral parameters, but additionally from the agreement of experimental and calculated curves[8] on perturbation in an external magnetic field. The two Fe^{II} centers distinguish **1** from complexes of type **I**, that are accessible in Fe^{III}/Fe^{III} and Fe^{III}/Fe^{II} but not Fe^{II}/Fe^{II} oxidation states.[1]

Also the electrochemical properties of **1** are worth comment. In contrast to the [2Fe–2S] clusters of type **I**, complex **1** can take up or release several electrons and shows five redox waves in the cyclic voltammogram (Fig. 3).

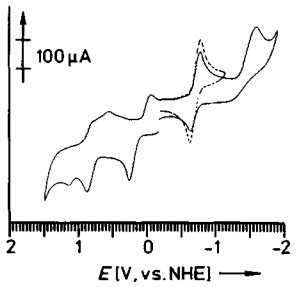

Fig. 3. Cyclic voltammogram of **1**; 10^{-3} mol L^{-1} in CH_2Cl_2, 0.1 mol L^{-1} $[N(C_4H_9)_4]ClO_4$, $v = 100$ mV s^{-1}, NHE = normal hydrogen electrode.

Complex **1** gives a positive methylene-blue reaction.[9] This interesting finding shows that μ-S_2 ligands apparently also undergo this reaction, which is a typical test for S^{2-} ligands. It is thus not surprising that the exact number of S^{2-} ligands in many [metal sulfide] proteins is unknown. The difficulties encountered when determining the S^{2-} content of such proteins were comprehensively reviewed recently.[10] Furthermore, similarly to the H clusters of Fe/Fe hydrogenases,[2] **1** reacts irreversibly with CO under normal conditions. $[\{Fe(CO)(\mu\text{-}'S_4')\}_2]$[6] forms from **1**, showing that the coordinatively saturated Fe centers of **1** are still reactive enough to coordinate CO with concomitant loss of the S_2 bridge.

These results are significant for a more detailed characterization of structurally unknown [Fe–S] sites of proteins, including in particular the M^N, P, and S clusters of nitrogenases and the H clusters of hydrogenases. For example, for the M^N clusters, which probably contain the Fe–Mo cofactor, Mössbauer parameters $\delta = 0.41$ and $\Delta E_Q = 0.8$ mm s^{-1} have been reported,[3] which correlate with octahedral low-spin Fe^{II} centers in sulfur-dominated coordination spheres as found in **1** or $[\{Fe(CO)(\mu\text{-}'S_4')\}_2]$ and $[Fe_2(CO)(NO)(\mu\text{-}'S_4')_2]$.[6] The H clusters of hydrogenases in the reduced form of the protein are diamagnetic in external magnetic fields up to 6.0 T, and EXAFS studies on them yield Fe–Fe distances of 3.3 Å.[2] Both properties agree with those of **1**, but are incompatible with the occurrence of conventional [Fe–S] clusters of type **I**–**III**.

Experimental Procedure

All operations were carried out in an inert atmosphere (N_2) with Schlenk techniques. To a stirred white suspension of 'S_4'-H_2 (2060 mg, 6.7 mmol) and NaOMe (728 mg, 13.4 mmol) in THF (100 mL) was added $FeCl_2 \cdot 4H_2O$ (1320 mg, 6.7 mmol). On subsequent addition of elemental sulfur (215 mg, 6.7 mmol), the red-brown reaction mixture gradually became black-green, and **1** was formed. Complex **1** was filtered off after 24 h, washed with CS_2 and thereafter MeOH, and dried. Yield: 80%; correct elemental analyses; MS(FD): m/z 792 (M^+). ^1H NMR (270 MHz): $\delta = 7.8$–6.8 (m, C_6H_4; in $[D_7]$DMF); 2.9 (m), 2.6 (m, C_2H_4; in CD_2Cl_2); $^{13}C\{^1H\}$ NMR spectra could not be recorded because of the low solubility of **1**.

The First Persistent β-Silyl-Substituted Vinyl Cation**

By *Hans-Ullrich Siehl*, Frank-Peter Kaufmann, Yitzhak Apeloig, Viviana Braude, David Danovich, Armin Berndt*, and *Nikolaos Stamatis*

Dedicated to Professor Michael Hanack on the occasion of his 60th birthday

The ability of silyl substituents to promote the formation of positive charge at the β-position (the "β-silyl effect") has attracted considerable experimental as well as theoretical interest in the last decade.[1] Gas-phase experiments,[2] solvolysis studies,[3] and high-level ab initio calculations[4] show that the β-silyl stabilization, attributed to strong σ–π interactions (hyperconjugation), is substantial—in the range of 18–22 kcal mol^{-1} (relative to hydrogen) for secondary carbenium ions.

However, attempts to observe β-silyl-substituted carbocations in solution have failed.[5] These failures have been attributed to the higher bond energy of Si–O and Si–halogen bonds compared to the Si–C bond, to the ease of forming five-coordinated silicon intermediates, and to the polar nature of the Si–C bond ($Si^{\delta+}$–$C^{\delta-}$) which makes the silicon prone to attack even by weakly nucleophilic anions of superacids, with subsequent cleavage of the Si–C bond.

In this communication we report the first successful observation of a stable β-silyl-substituted carbocation by ^{13}C NMR. Furthermore, the very efficient hyperconjugative stabilization by the β-silyl groups enables the first characterization by NMR of a vinyl cation which is not stabilized by π-conjugating groups, such as vinyl or aryl substituents.[6]

Protonation of tetrakis-(trimethylsilyl) allene **1**[7] with HSO_3F/SbF_5 under carefully controlled experimental condi-

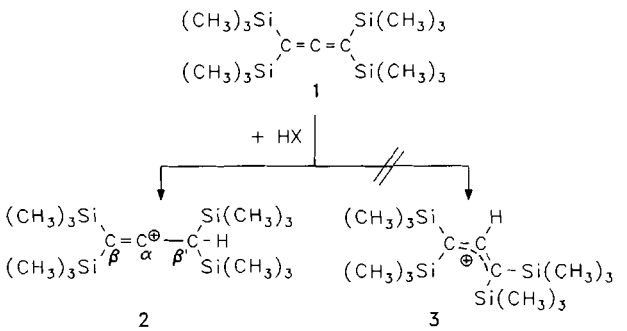
tions[8] gives the 1,1,3,3-tetrakis(trimetylsilyl)methylpropen-2-yl cation **2**.[9] The isomeric allyl cation **3** is not formed, as is evident from the ^1H and ^{13}C NMR data[9] (e.g. the chemical shifts, in particular of the β' proton signal at $\delta = 2.81$ ($-100\,^\circ C$), as well as the multiplicities and relative intensities of the carbon signals[9]). This contrasts with the protonation of 1,3-dimethyl, 1,1,3,3-tetramethyl, and 1,3,3-trimethyl 1-phenyl allene with HSO_3F/SbF_5, which yield the corresponding allyl cations.[10] The different reaction courses followed by the silyl- and alkyl-substituted allenes are fully consistent with the hyperconjugation model, which predicts that a β-silyl group is more stabilizing than a β-alkyl group,[2-4] and with previous conclusions[11] that α-silyl substitution as in **3** is destabilizing relative to α-methyl substitution. The larger spatial requirements of the trimethylsilyl groups may also contribute to the kinetic stability of **2**.



At $-100\,^\circ C$ the ^{13}C NMR spectrum of **2** shows five signals (Fig. 1). Assignments[9] are based on the ^1H-coupled ^{13}C NMR spectra and on comparison of chemical shifts with

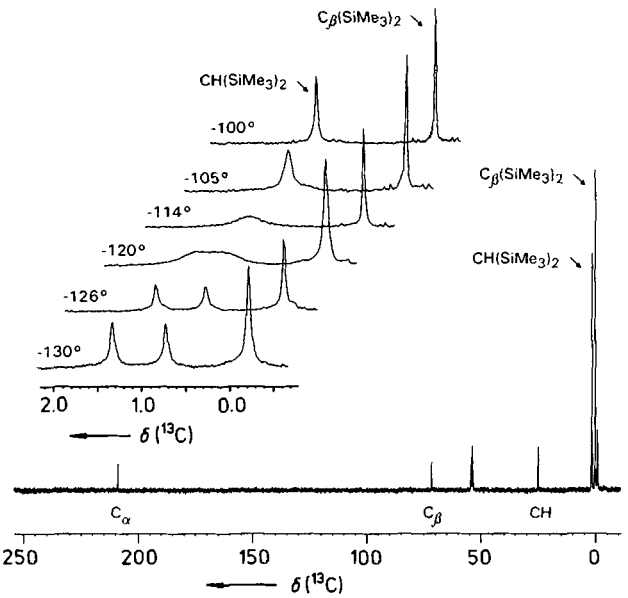


Fig. 1. 100.6 MHz ^{13}C NMR spectrum of **2** ($-100\,^\circ C$, $SO_2ClF/SO_2F_2/CD_2Cl_2$). The insert shows the temperature dependence (-130 to $-100\,^\circ C$) of the $(CH_3)_3Si$ signals.

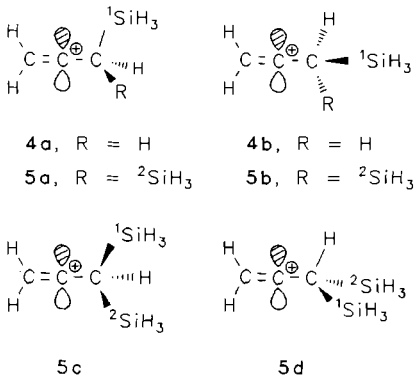
those of other β-silyl-substituted vinyl cations,[6d] as well as with IGLO chemical shift calculations[12] of model systems such as **4** and **5**. Comparison with NMR data of other vinyl cations, which were obtained in several types of acidic media and with different counterions,[6d] indicates that specific interactions (like ion pairing and fluoride ion complexation to the silicon atom) are not important for **2** under the conditions employed. The good agreement between the experimental and the calculated shifts for **2** (see below) also support this conclusion.

$H_2C=C^\oplus-CH_2(SiH_3)$ **4** $H_2C=C^\oplus-CH(SiH_3)_2$ **5**

The signal at $\delta = 208.7$ assigned to C_α of **2** is strongly shielded (by ca. 250, 198, 186, and 214 ppm) relative to the IGLO calculated shifts for C_α in the parent (nonbridged vinyl cation,[12a] in $H_2C=C^\oplus CH_3$, in $H_2C=C^\oplus CH_2CH_3$, and in $(H_3C)_2C=C^\oplus CH_3$, respectively. Comparable shieldings of C_α have been observed in vinyl cations stabilized by $2p-\pi$ conjugation or by hyperconjugation with cyclopropyl substituents.[6a] Calculations[12b] for model cations confirm the strong shielding effect of β-silyl substituents (Scheme 1).



Scheme 1. Conformers of **4** and **5** for which the ab initio and IGLO calculations were performed.

Thus, the calculated chemical shift for C_α in **5c** ($\delta = 331$) is 75 ppm upfield relative to C_α in $H_2C=C^\oplus CH_3$. The vinylic β-silyl groups cause even larger shielding of C_α (123 ppm in $(H_3Si)CH=C^\oplus CH_3$ and 158 ppm in $(H_3Si)_2C=C^\oplus CH_3$ relative to $H_2C=C^\oplus CH_3$). The calculated overall shielding of the four β- and β'-H_3Si groups in **5c** is 233 ppm (158 + 75), 18 ppm higher than the observed shielding of C_α in **2** compared with the IGLO value for C_α in $(H_3C)_2C=C^\oplus CH_3$. These strong shielding effects can be attributed mainly to hyperconjugative charge dispersal and not to the inductive effect of silicon. Thus, IGLO calculations show that C_α is shielded by 75 ppm in **4a** compared to **4b** and by 53 ppm in **5c** relative to **5d**, while in $H_2C=C^\oplus CH_2CH_3$ the difference between conformations analogous to **4a** and **4b** is only 10 ppm. Similar shielding effects attributed to hyperconjugation have been observed for analogous β-silyl methyleneboranes.[13a]

The chemical shift for C_β in **2** ($\delta = 71.39$) is not much different from that in other vinyl cations[6] or from the IGLO values for C_β in $H_2C=C^\oplus H$ ($\delta = 69$),[12a] $H_2C=C^\oplus CH_3$ (73), **5c** (74), or $H_3SiCH=C^\oplus CH_3$ (66). The chemical shift of the methine carbon C_β ($\delta = 25$) is also in line with the IGLO calculations; for example, $\delta = 30$ in $H_2C=C^\oplus CH_3$, 36 in **5c**, and 19 in $H_3SiCH=C^\oplus CH_3$.

At $-100\,^\circ C$ two signals at $\delta = 0.14$ and 1.59 are observed for the four trimethylsilyl groups. However, upon cooling (see insert in Fig. 1) the peak at $\delta = 1.59$ broadens, and below the coalescence temperature of ca. $-114\,^\circ C$ it splits into two peaks, which at $-130\,^\circ C$ are 0.67 ppm apart and have similar line widths to the other peaks at that temperature.

This allows the unequivocal assignment of the signal at $\delta = 0.14$ ($-100\,^{\circ}C$) to the β-$SiMe_3$ groups and the averaged peak at $\delta = 1.59$ ($-100\,^{\circ}C$) to the $CH(SiMe_3)_2$ groups. The free energy barrier for the dynamic process is $\Delta G^{\neq} = 7.5$ kcal mol^{-1} (31 kJ mol^{-1}) at $-114\,^{\circ}C$.

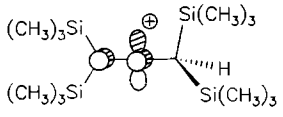
Ab initio calculations[14] on model cations **4**–**6** assist in the interpretation of the equilibration process that leads to the averaged signal.

$(H_3Si)_2C = C^{\oplus} - CH(SiH_3)_2$

6

As expected on the basis of the hyperconjugation concept[4], cation **4** prefers conformation **4a** in which hyperconjugation between the empty 2p orbital on $C^{\oplus}$ and the Si–C bond is maximized. The calculated rotation barrier around the $C^{\oplus}$–CH_2SiH_3 bond is 14.5 kcal mol^{-1} at MP 3/6–31 G*//6–31 G* (12.4 kcal mol^{-1} at 6–31 G*//6–31 G*); conformation **4b** is the highest point along the rotation path.

In the disilyl-substituted cation **5**, the most stable calculated conformation is **5c**, where each of the Si–C bonds forms a dihedral angle θ of ca. 30° with the empty 2p orbital on $C^{\oplus}$, each thus contributing 75 % of the full hyperconjugative stabilization of this group. (This estimation is based on the dependence of the hyperconjugative stabilization on $[1 + \cos 2(90 - \theta)]$,[15] where θ is the dihedral angle $HC_{\beta}C_{\beta'}Si$.) Conformation **5a**, in which the maximal interaction with the empty 2p orbital is possible for one silyl group ($^1SiH_3$) and 25 % for the other ($^2SiH_3$), is 3.1 kcal mol^{-1} (MP 3/6–31 G*//6–31 G*) higher in energy. However, a detailed analysis of the computational results leads us to predict that at higher levels of calculations **5a** is actually the most stable conformation of **5**.[16a] Thus, as a result of hyperconjugation the geometry in **5a** is strongly distorted toward a ^1Si-bridged species $\sphericalangle\, ^1Si{-}C_{\beta'}{-}C_{\alpha} = 102.4°$ and $d(C_{\beta'}{-}^1Si) = 203$ pm, compared to $\sphericalangle\, ^2Si{-}C_{\beta'}{-}C_{\alpha} = 117.1°$ and $d(C_{\beta'}{-}^2Si) = 196$ pm). It is therefore likely that energetically, **5a** will benefit more than **5c** from geometry optimizations at the MP2/6–31 G* level (which are beyond our computing capabilities) making it more stable than **5c**.[16b] MP2/6–31 G* geometry optimizations of **4a** indeed show stronger distortions toward silyl bridging than at 6–31 G*, and $\sphericalangle\, Si{-}C_{\beta'}{-}C_{\alpha}$ is reduced from 102° (6–31 G*) to 92°. In analogy to **5** we expect the most stable conformation of **2** to be **2a**, in which the $^1Si(CH_3)_3$ group is in the $H_2C{=}C^{\oplus}$ plane and strongly bent toward the cationic center.



2a

This conclusion is consistent with the experimental observation at $-130\,^{\circ}C$ of two ^{13}C NMR signals for the β'-silyl groups. Recent calculations on tricoordinated carbocations show analogous structural distortions accompanying hyperconjugation[17a] and the same preference for σ–π interaction with one of two seemingly equal β-C–H or β-C–C σ bonds.[17b] Similar distortions due to C–Si hyperconjugation have been observed experimentally in a substituted 1-bis(trimethylsilyl)methyl methyleneborane.[13b]

The calculated barrier to rotation around the $C^{\oplus}$–$CH(SiMe_3)_2$ bond in **5** is 13.6 kcal mol^{-1} (MP 3/6–31 G*//6–31 G*), **5d** being the highest energy conformer along the rotation path. Further stabilization of **5** by two β-silyl groups lowers the electronic demand on the β'-silyl groups and in **6** the calculated rotation barrier is only 5.9 kcal mol^{-1} (3–21 G*//3–21 G*). Computational experience with the smaller cations suggests that at MP 3/6–31 G*, the barrier to rotation in **6** would be higher by 1–2 kcal mol^{-1}. The calculated rotation barrier for **6** is close to the value of 7.5 kcal mol^{-1} determined experimentally for the equilibration of the two β'-$SiMe_3$ groups in **2**. However, this equilibration process can bypass the conformation analogous to **5d**.

In conclusion, we have prepared and observed by NMR spectroscopy the first persistent β-silyl-substituted carbocation and have shown by molecular orbital calculations that rotation around the $C^{\oplus}$–$CH(SiMe_3)_2$ bond is controlled by strong hyperconjugation with the β-silyl groups, and that IGLO calculations nicely account for the observed chemical shifts.

Inclusion of Metal Ions within a Tin–Oxygen Cage Stabilized by Organic Residues: Crystal Structure of $[(i\text{PrSn})_{12}O_4(OH)_{24}][Ag_7I_{11}]\cdot NaCl\cdot H_2O\cdot 10\,DMSO$**

By *Hans Reuter**

Dedicated to Professor Heinrich Puff on the occasion of his 70th birthday

As in the case of polyoxovanadates, where it was only recently observed that solvent molecules[1a] and also halide ions[1b] can reside within the vanadium–oxygen cavity, large cagelike units are found in the crystal structures of partially or completely hydrolyzed monoorganotin trichlorides,[2] carboxylates,[3] phosphinates,[3a,4] and phosphates,[3d] which can thus be considered as hosts for ions and small molecules. Although potential inclusion behavior has been long discussed in relation to the tin–oxygen cage,[3a] a preparative access to such supramolecular structures was hitherto unknown.

Only with difficulty could we imagine how a solvated or even a "naked" metal ion could penetrate the apolar organic shell to enter the relatively rigid tin–oxygen framework. We therefore tried to use the metal ion as template around which the tin–oxygen cage could be built.

Already the preliminary experiment in which an organotin compound was treated with sodium and silver ions as potential templates in the molar ratio 1:1:1.5 (see *Experimental Procedure*) proved the value of this strategy. Among the phases that crystallized from the solution over several weeks were compact, dark red crystals, which were shown by a single-crystal X-ray crystallographic analysis[5] to have the composition **1** and in which the sodium ion is included within the oligomeric organotin unit. The reaction can be represented formally by Equation (a).

$$12\,i\text{PrSn(OH)Cl}_2\cdot 3/4\,H_2O + 10\,AgI + NaI \xrightarrow{DMSO} [(i\text{PrSn})_{12}O_4(OH)_{24}][Ag_7I_{11}]\cdot NaCl\cdot H_2O\cdot 10\,DMSO + 5\,H_2O + 3\,AgCl + 8\,HCl \quad (a)$$

1

$[(i\text{PrSn})_{12}O_4(OH)_{24}]^{4+}$ **2** $[Ag_7I_{11}]^{4-}$ **3**

The solid-state structure of **1** (= **2**–**3**·NaCl·H_2O·10 DMSO) contains as novel structural elements cation **2** and anion **3**. The structure of **2** and the position of the encapsulated sodium ion is shown as ball-and-stick model in Figure 1, left. The ion has approximate C_s symmetry. It differs from the known hydrolysis products[2] of monoorganotin trichloride, in which five-coordinate, trigonal-pyramidal or square-planar tin atoms coexist with six-coordinate tin atoms, in that all 12 tin atoms have octahedral coordination. Further primary building units[6] are four oxygen atoms each bridging three tin atoms (the oxygen atoms form the apex of trigonal pyramids) and 24 hydroxyl groups each bridging two tin atoms.

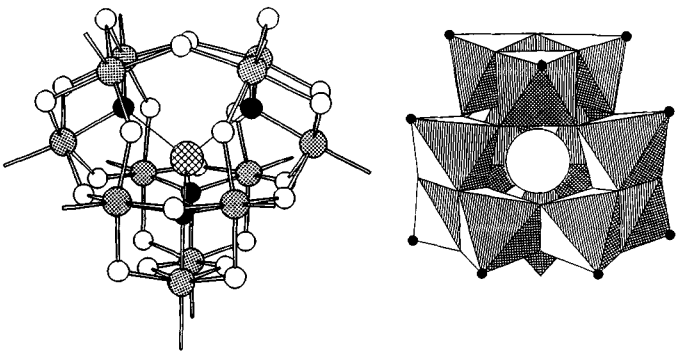

Fig. 1. Crystal structure of the $[(i\text{PrSn})_{12}O_4(OH)_{24}]^{4+}$ ion and the sodium ion encapsulated within it. Left: ball-and-stick model. Open circles = OH groups, filled circles = O atoms, dotted circles = Sn, hatched circle = Na^+ ion; for clarity the atoms of the isopropyl groups have been omitted, but their position relative to the Sn–O framework is indicated by a bonding stick. Observed distances [pm] and angles [°] (averaged values/no. of individual values in parentheses): Na-O 233.9–243.8 (240.2/4), O-Na-O = 104.0–113.6 (109.4/12); Sn-O = 204.3–218.5 (210.8/12), Sn-O-Sn = 101.7–108.9; Sn-OH = 199.1–221.9 (211.5/48), Sn-OH-Sn = 101.4–110.6 (105.3/14), 137.1–146.9 (141.6/10). Right: polyhedral type model. Black spheres = position of an organic residue, open spheres = Na^+ ion; view of the ten-membered Sn–O ring.

The cavity inside the tin–oxygen cage is edged by the four μ_3–O atoms tetrahedrally arranged around the sodium ion. The average O–Na distance is 240.2 pm, and the O-Na-O angle 109.5°. Such a low coordination number for sodium ion is unusual, but not impossible.[7] In this case it is probably forced on the ion by the topological requirements within the Sn–O cage.

Metal–oxygen cagelike clusters with twelve octahedrally coordinated metal atoms and a tetrahedrally coordinated metal or nonmetal ion at the center also occur in hetero- and isopolycations and -anions, to which the different Keggin structural types belong. The structural correspondence of **2** with these compounds becomes clear on considering the polyhedral type model in Figure 1, right. In both, the dodecameric ion comprises four trimeric building blocks. Every octahedral unit of the trimer shares two edges with both the other two.[8] In contrast to the heteropolyanion $[PW_{12}O_{40}]^{3-}$ ($\triangleq[(W^{oct}O)_{12}(\mu_3\text{-}O)_4(\mu_2\text{-}O)_{24}(P^{tetr})]^{3-}$) of the α-Keggin structural type,[9] in which one trimeric building block shares two corners with all three other trimers, and the isopolycation $[Al_{13}O_4(OH)_{24}(H_2O)_{12}]^{7+}$ ($\triangleq[(H_2O\text{-}Al^{oct})_{12}(\mu_3\text{-}O)_4(\mu_2$-

$OH)_{24}(Al^{tetr})]^{7+}$) analogous to the ε-Keggin structural type, in which each trimeric building block shares an edge with all other three,[10] one trimeric building block in this case shares corners with the three others, which in turn share edges. It is thus isostructural with the heteropolyanion $[PW_{10}V_2O_{40}]^{5-}$ ($\triangleq[(V^{oct}O)_2(W^{oct}O)_{10}(\mu_3\text{-}O)_4(\mu_2\text{-}O)_{24}(P^{tetr})]^{5-}$) of the γ-Keggin type.[11]

Ion **2** is bound to ten DMSO molecules by hydrogen bonds. All μ_2-OH groups, with few exceptions (see below), are involved, but in one case a single water molecule lies between the hydroxyl group and the solvent molecule. As can be seen in Figure 2, the apolar organic shell formed by the isopropyl groups is completed by these solvent molecules. The thus

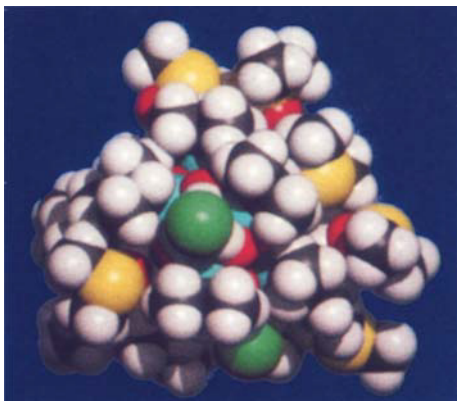

Fig. 2. Space-filling model of $[(i\text{PrSn})_{12}O_4(OH)_{24}]^{4+}$ ion and its immediate surroundings: tin = turquoise, oxygen = red, carbon = black, hydrogen = white, sulfur = yellow, chlorine = green; for a clearer picture of the function of the solvent molecule, the structural model has been extended to include the hydrogen atoms. Intermolecular distances [pm]: DMSO···HO- 246.1–298.6, DMSO···H_2O = 276.6, H_2O···HO- 248.0, Cl···HO- 324.2–345.1.

solvated cation is not isolated in the crystal, but is linked as a strongly puckered one-dimensional string via chloride ions. Also in this case the bonds are hydrogen bonds, which are, however, distinctly longer because of the larger ionic radius of the chloride ion and its weaker acceptor properties.

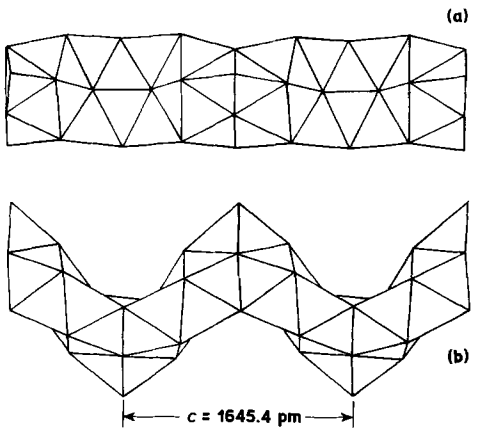

Fig. 3. Polyhedral type model of the $[Ag_7I_{11}]^{4-}$ ion from the top (a) and from the side (b); for clarity only the face-sharing tetrahedrons formed by the iodide ions are shown; the positions of all silver ions are within this one-dimensional double string; interatomic distances [pm] (average/number of individual values in parentheses): I···I 409.5–521.2 (470.6/41), Ag···I 234.8–330.0 (288.9/72); between the individual anion strings and between these and the solvated cation strings are no interactions that are stronger than normal van der Waals interactions.

The second remarkable structural feature of **1** in the crystal is the complex anion $Ag_7I_{11}^{4-}$ (**3**), which may be described as a one-dimensional, twisted double chain $^1_\infty[Ag_7I_{11}^{4-}]$ of face-sharing iodine tetrahedrons. This anion string lies in the *yz* plane (depicted in Fig. 3), strictly parallel to the cation string, although no forces stronger than van der Waals interactions are formed between the strings.

Although the positions of the iodine atoms could be determined very precisely, this was only partly possible for the Ag^+ ions.[12] In the structural model proposed here, 18 Ag^+ sites (occupancy factors from 1.00 to 0.15) were taken into account, some of which are situated at the center of the iodide tetrahedrons and some are displaced towards a shared tetrahedral face. Thus of the total of 19 crystallographically independent tetrahedrons per asymmetric unit, almost all are partly or completely occupied.

These structural characteristics of **3** fulfill the essential conditions for a solid-state electrolyte, and we anticipate that the compound will show a significant one-dimensional silver-ion conductivity.[13]

Experimental Procedure

First NaI (5.64 g, 37.6 mmol) was dissolved in 35 mL DMSO in a 100 mL Erlenmeyer flask. Much heat evolved, and after the solution cooled AgI (12.2 g, 52.0 mmol) was dissolved. Thereafter $i\text{PrSn(OH)}_2\text{Cl}\cdot 3/4\,H_2O$ [2a] (9.22 g, 37.7 mmol) was added. The suspension was stirred and heated to ca. 80 °C, during which time the organotin compound slowly dissolved. After two hours the small amount of undissolved substance was filtered from the hot solution and the clear, dark red solution left to stand open to air. Beside other not yet studied crystalline phases, **1** separated during the course of several weeks as large dark red crystals that slowly decomposed in air [14].

[6] Besides the almost planar four-membered Sn–O rings with acute angles at tin and wide angles at the oxygen atoms, which are characteristic for organotin oxygen compounds, and also the six-membered Sn–O rings in half-chair conformation [2b] the new hitherto unknown structural motifs of more or less strongly puckered, eight- and ten-membered Sn–O rings are found at secondary building units embedded in the molecular structure.

[14] Because of the very inhomogenous composition of the crystallized material, which is accompanied by a strong interpenetrating growth of individual phases, the X-ray crystallographic determination of the Sn, I, and Ag content of the single crystal used was confirmed by energy dispersive X-ray microanalysis (EDX). The ratio thus determined (1:1.02:0.55) agrees well, within the limits of precision of this method, with those calculated from electron densities. The formulation of anion **3** as $[Ag_7I_{11}]^{4-}$ implies that all oxygen atoms bridging two tin atoms in **2** are protonated and that the oxygen atom of the solvate must come from water. This agrees with the observed pattern of hydrogen bonds.

Ring Inversion in Sterically Hindered Arenes

By *Günther Maier,* Frank Fleischer, Hans-Otto Kalinowski,* and *Roland Boese*

Dedicated to Professor Horst Prinzbach on the occasion of his 60th birthday

The congestion of *tert*-butyl groups in a molecule favors the formation of spherical structures.[1] The most convincing example of this behavior is the "corset effect", which gives tetra-*tert*-butyltetrahedrane its surprisingly high stability.[2] We now report on another phenomenon which is likewise based on the repulsive interactions of neighboring *tert*-butyl groups and which came to our attention on examination of the ^{1}H NMR spectrum of 3,4,5-tri-*tert*-butyl-6-isopropylpyridazine (**1**).

Analogous to the tetra-*tert*-butyl derivative **2**[3], the pyridazine **1** is accessible in almost quantitative yield by heating (tri-*tert*-butyl-2-cyclopropen-1-yl)isopropyldiazomethane to 80 °C. The diazo compound itself is obtained in 12% yield by the reaction of lithiated isopropyldiazomethane with tri-*tert*-butylcyclopropenylium tetrafluoroborate.[4]

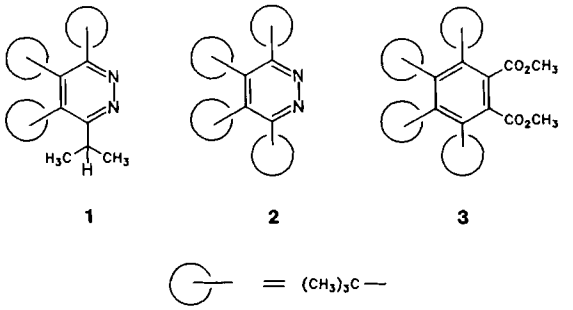
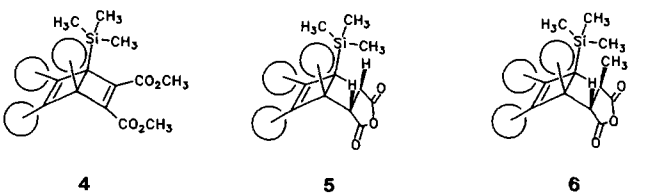
At room temperature the ^{1}H NMR signals of both methyl groups of the isopropyl substituent of **1**[5] appear as two separated doublets (J = 6.5 Hz) at δ = 1.26 and 1.55 and the corresponding ^{13}C NMR signals[5] at δ = 22.6 and 25.2. However, a single, sharp signal is observed for the methyl groups of each of the three *tert*-butyl substituents. On heating a sample of **1** in pentadeuterionitrobenzene or [D_{18}]cyclosilane (1,1,3,3,5,5-hexakis(trideuteriomethyl)-1,3,5-trisilacyclohexane), the previously separate doublets of the methyl groups of the isopropyl substituent broaden. At 181 °C (nitrobenzene) and 190 °C (cyclosilane) the coalescence point is reached. From the coalescence temperature and the difference in chemical shift of the separated signals at room temperature, an activation energy barrier of $\Delta G^{\neq}$ = 91.5 kJ mol^{-1} may be estimated for the observed dynamic process.



1 **2** **3**

It is tempting to attribute the occurrence of two signals for the methyl groups at room temperature to a hindered rotation of the isopropyl substituent. Such behavior is well known for rotation about C–C bonds.[6] So it is not too surprising, for example, that on cooling three signals appear in the ^{1}H NMR spectrum for the methyl groups of the *tert*-butyl substituents on the sp^3 atom of the adducts **4**, **5**, and **6** of tri-*tert*-butyl(trimethylsilyl)cyclobutadiene[7] and acetylenedicarboxylic acid ester, maleic anhydride, and citraconic anhydride. That steric hindrance, such as that confirmed by the low-temperature spectra of **4**–**6**, may also be observed for rotation about the considerably longer C–Si bond (in **5**, 188 pm) is, however, new. The coalescence temperatures for C–Si rotation are − 80 (**4**), − 93 (**5**), and − 23 °C (**6**). The corresponding free energies of activation derived for **4**–**6** are 35.3 (**4**), 32.5 (**5**), and 50.2 (**6**) kJ mol^{-1}.[8]



4 **5** **6**

A logical conclusion on the basis of this information would be that the aromatic ring in **1** is planar and the substituents favor a configuration in which the symmetry of the whole molecule is no longer C_s. In such a case, however, the signal for the *tert*-butyl group adjacent to the isopropyl group should also broaden. We therefore propose another explanation: As a result of the congestion of the four bulky groups, the six-membered ring is in a twisted configuration (the C4–C5 axis crosses the N1–N2 axis). The resultant lowering of the symmetry of the ring causes the two methyl groups of the isopropyl substituent to be diastereotropic and they give rise

to separate signals in the ^{1}H NMR spectrum. This should also be true at higher temperatures. If coalescence is nevertheless observed, it must result from inversion of the ring together with its substituents on heating. Above 180 °C this process occurs rapidly on the NMR timescale. Thus the time-averaged arene spectrum has the appearance of that of a planar and achiral ring.

The following findings support this hypothesis: Although the ^{1}H NMR spectrum of **1** does not change on addition of racemic Pirkle's reagent [1-(9-anthryl)-2,2,2-trifluoroethanol, **7**], all signals split again on addition of optically active (*S*)-(+)-**7**; pyridazine **1** is therefore chiral. This was also observed for tetra-*tert*-butylpyridazine **2**[3] (in the presence of (*S*)-(+)-**7** both ^{1}H NMR signals of the *tert*-butyl groups are doubled) and for dimethyl tetra-*tert*-butylphthalate **3**[9] (one of the two signals of the *tert*-butyl groups splits and line broadening for the ester methyl groups is noticeable).

The X-ray structure analysis—to our knowledge the first of an alkyl-substituted pyridazine—reveals the type and extent of the distortion of **1** (Fig. 1). The conformation has an

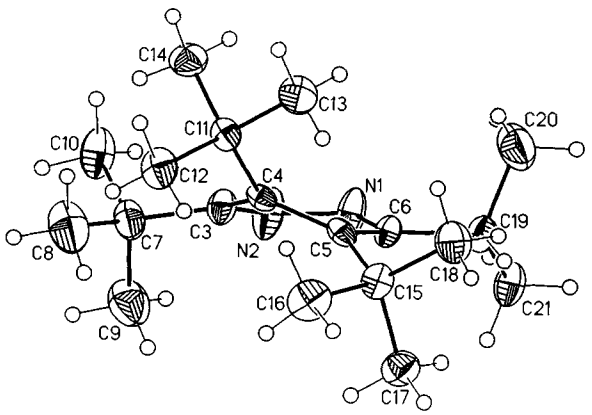


Fig. 1. Structure of **1** in the crystal (side view). Important distances [Å]: N1-N2 1.334(6), N1-C6 1.333(5), N2-C3 1.332(5), C3-C4 1.449(6), C4-C5 1.402(6), C5-C6 1.426(5), C3-C7 1.533(7), C4-C11 1.572(6), C5-C15 1.562(6), C6-C19 1.519(6) [11].

angle of 24.6° between the planes containing the N1, N2, C3, and C4 atoms and the C4, C5, C6, and N1 atoms.[10] Similar to the case for tetra-*tert*-butylcyclopentadienone,[1, 2] the ring C atoms are in an almost planar environment; the sum of the angles at C3, C4, C5, and C6 are 359.6, 358.2, 359.4, and 358.9°, respectively. It must have been easier to deform the ring system than to distort the planar environment of the ring C atoms. The intramolecular H···H contacts between the *tert*-butyl groups and the isopropyl groups lie between 1.75 and 2.16 Å. An additional distortion is observed particularly at the C7 and C19 atoms: angles C7-C3-N2 and C7-C3-C4 are 109.6 and 129.7°, respectively; angles C19-C6-N1 and C19-C6-C5 are 110.0 and 127.4°, respectively.

[FCNF]$^+$[AsF$_6$]$^-$, a Salt of the Linear 22-Valence Electron Cation [FCNF]$^+$ **

By *Inis C. Tornieporth-Oetting, Petra Gowik,* and *Thomas M. Klapötke**

New and very simple inorganic cations are still being found.[1, 2] Recently, *Pyykkö* and *Runeberg*[3] reported an ab initio study of the hitherto unknown 22-valence electron cation [FCNF]$^+$ and predicted a linear arrangement of its constituent atoms. This stimulated our interest in synthesizing an [FCNF]$^+$-salt. As starting material for the synthesis of such a salt we chose [HCNH]$^+$[AsF$_6$]$^-$ **1**, which was prepared according to Equation (a).[4]

The [HCNH]$^+$ cation appeared to be suitable as educt,[5] since, firstly, **1** reacts with KrF_2 in the ratio 1:1 with HF-elimination to give [HCNKrF]$^+$ [AsF$_6$]$^-$,[4] and, secondly, it could be estimated on the basis of a simple Born–Haber cycle that a reaction corresponding to Equation (b) should be thermodynamically allowed [ΔH°_{298} (b) = − 815 kJ mol^{-1}].[6]

[**] This work was supported by the Deutsche Forschungsgemeinschaft (KL-636/2-1), the Fonds der Chemischen Industrie, the Solvay Fluor und Derivate GmbH, and the Bundesminister für Bildung und Wissenschaft im Rahmen des Graduiertenkollegs "Synthese und Strukturaufklärung niedermolekularer Verbindungen". We thank Prof. Dr. *Pyykkö* for stimulating information [3] and Prof. Dr. *H. Bürger* for supplying a preprint [18]. We also thank Prof. Dr. *H. Willner* und Dipl.-Chem. *J. Schaebs* for providing facilities for and carrying out an ^{19}F NMR measurement, and Prof. Dr. *O. Glemser* for a gift of ClF_3.

$$HCN + HF + AsF_5 \xrightarrow{HF} \underset{\mathbf{1}}{[HCNH]^+[AsF_6]^-} \quad (a)$$

$$[HCNH]^+(g) + 2F_2(g) \longrightarrow [FCNF]^+(g) + 2HF(g) \quad (b)$$

Reaction of **1** with an excess of elemental fluorine in anhydrous hydrogen fluoride afforded $[FCNF]^+[AsF_6]^-$ **2**, which could be identified by vibration (IR, Raman[10]) and ^{19}F NMR spectroscopy.[11]

$$\mathbf{1} + 2F_2 \text{ (excess)} \xrightarrow{HF,\ 0\,^\circ C} \underset{\mathbf{2}}{[FCNF]^+[AsF_6]^-} + 2HF \quad (c)$$

Salt **2** is stable at $-196\,^\circ C$, and can be handled with ease at $-78\,^\circ C$; however, the neat substance already decomposes rapidly and irreversibly below room temperature with loss of AsF_5 (IR) to give a yellow oil.[12] The ^{19}F NMR spectrum of an HF solution of **2** shows, after warming to $+10\,^\circ C$, two further multiplets in an intensity ratio of about 3:1 at $\delta = -74$ and -90, which can be assigned to the salt $[CF_3NFH_2]^+[AsF_6]^-$ **3** (cf. the synthesis of **3** in HF from CF_2NF and AsF_5,[13] ^{19}F NMR: $\delta = -74.5$ (d), -92.2 (q)[13]). The formation of **3** as decomposition product in solution is consistent both with the cleavage of AsF_5 from neat **2** as well as with the fact that CF_2NF does not react with AsF_5 to give **2**, but in the absence of HF forms only a loose adduct[13] and can be formulated as in Equations (d) and (e).

$$\mathbf{2} \longrightarrow F_2C{=}NF + AsF_5 \quad (d)$$

$$F_2C{=}NF + AsF_5 \xrightarrow{HF} \underset{\mathbf{3}}{[CF_3\text{-}NFH_2]^+[AsF_6]^-} \quad (e)$$

The vibration spectrum of the $[FCNF]^+$ cation was calculated at the HF/6-31G* level;[3] the calculated, scaled,[14–16] and experimental data are compared in Table 1. From the reasonably good agreement of the calculated and experimental data, as well as from a comparison of the vibration spectrum with that of the very recently prepared isoelectronic difluoroacetylene[17, 18] and that of the $[N_2F]^+$ cation,[19] it can be concluded that the 22-valence electron cation $[FCNF]^+$ in **2** is linear as predicted, and the electronegative F atoms occupy the terminal positions of the heteronuclear species as expected.

Moreover, the appearance of two signals of almost equal intensity in the ^{19}F NMR spectrum of **2**,[11] which can be assigned to the cation, confirms the linear $C_{\infty v}$ structure of the $[FCNF]^+$ cation and, in agreement with the IR and Raman data, rules out a likewise conceivable C_{2v} structure $[F_2CN]^+$. The signals at $\delta = -99$ and -105 are, as expected, shifted substantially downfield compared to that of FCN ($\delta = 157$[20]), and are in good agreement with the value reported for the $[N_2F]^+$ cation. However, owing to the expectedly very similar resonance frequencies of the N–F and C–F fluorine atoms in **2** (cf. $FN{=}CF_2$: $\delta(NF) = -67$; $\delta(CF_2) = -60$[20]) and the unresolved couplings, an extensive assignment cannot be given.

Table 1. Calculated and observed vibration frequencies (relative intensities in brackets) of the $[FCNF]^+$ cation in **2** and, for comparison, of FCCF [18].

Raman [a]	IR [a]	Calcd. [b]	Scaled [c]	FCCF [d]	Assignment

Experimental

2: F_2 (5.69 mmol, 0.22 g) was condensed at $-196\,^\circ C$ onto a frozen solution of **1** (0.41 g, 1.90 mmol) in anhydrous HF (5 mL; dried over BiF_5) in a 15 mL Kel-F reaction vessel (deactivated with ClF_3). The stirred reaction mixture was warmed within 12 h to $0\,^\circ C$. After cooling to $-50\,^\circ C$, all volatile components (excess fluorine, HF) were removed in vacuum and **2** was isolated as a white solid and stored at $-196\,^\circ C$.

Warning: F_2, AsF_5, ClF_3, and N–F compounds are potentially explosive substances and are sensitive to phase transformations and fluctuations in temperature[21]. In another attempt at the synthesis of **2**, we irradiated (UV, 1 h, 254 nm, 900 W) a mixture of F_2, $(CN)_2$, and AsF_5 at $-196\,^\circ C$; the mixture exploded on warming to $-85\,^\circ C$!

A Metal-Ion- and Cofactor-independent Enzymatic Redox Reaction: Halogenation by Bacterial Nonheme Haloperoxidases**

By *Theodor Haag, Franz Lingens,* and *Karl-Heinz van Pée**

In memorium Richard Kuhn

Haloperoxidases are oxidoreductases, which, with the help of peroxides (e.g. H_2O_2) and halide ions (chloride or bromide) catalyze the halogenation of organic substrates [Eq. (a)]. The halogenation proceeds in two steps. In the first enzyme-catalyzed step the halide ions are oxidized by H_2O_2 or other peroxides. In the second step the Hal^+ species formed thereby attacks electrophilically at the organic substrate in a reaction that is not necessarily enzyme-catalyzed.

$$R\text{-}H + H_2O_2 + Hal^- + H^+ \rightarrow R\text{-}Hal + 2H_2O \qquad (a)$$
$$Hal = Br, Cl$$

In all previously investigated haloperoxidases the electron transfer from the halide ion to the peroxide proceeds via a prosthetic heme group[1] or the cofactor vanadium.[2] The bacterial nonheme haloperoxidases, on the other hand, contain neither a cofactor nor a prosthetic group.[3, 4] They thus differ both from the usual haloperoxidases as well as from all other oxidoreductases, since redox enzymes normally require a cofactor or a prosthetic group for electron transfer. As examples of bacterial nonheme haloperoxidases, two enzymes from antibiotic-producing bacterial strains were investigated: the chloroperoxidase from the pyrrolenitrin producer *Pseudomonas pyrrocinia*[3] and the bromoperoxidase from the 7-chlorotetracyclin-producing strain *Streptomyces aureofaciens*.[4] Since they contain neither a cofactor nor a prosthetic group, the electron transfer must take place from the halide ion to the H_2O_2 on an amino acid. The behavior of the bacterial nonheme haloperoxidases towards cyanide ions played an essential role in the identification of this amino acid.

The incubation of the bacterial nonheme haloperoxidases with cyanide in the presence of H_2O_2 and bromide, i.e. under reaction conditions,[5] led to inactivation of the enzymes by splitting of the proteins into two peptides. By electrophoretic separation of the two peptides it could be shown that they have the same molecular weight as two fragments formed by cleavage of the native enzymes with cyanogen bromide. Since both the enzyme reaction with cyanide as well as the cleavage with cyanogen bromide lead to the same products, the enzymes must be capable of producing cyanogen bromide.

Cyanogen bromide cleaves peptide chains after methionine. Since an excess of methionylglycine could not prevent the self-cleavage of the enzymes, it may be assumed that the reactive methionine is located in or near the active center of the enzyme. In this case the cyanogen bromide formed reacts immediately with the methionine of the enzyme before it can leave the active center. The assumption that this methionine lies in the active center was confirmed by the behavior of chloroperoxidase during the cyanogen bromide cleavage. Cleavage of the denatured chloroperoxidase with cyanogen bromide[7] leads to a large number of peptides, corresponding to the five methionine residues contained in the amino acid sequence. In contrast, cleavage of the native chloroperoxidase with cyanogen bromide leads to the two previously mentioned peptides, which are also formed in the reaction with cyanide and correspond to the cleavage of the enzyme after a single methionine residue (Fig. 1). Bromoperoxidase contains only one methionine residue.

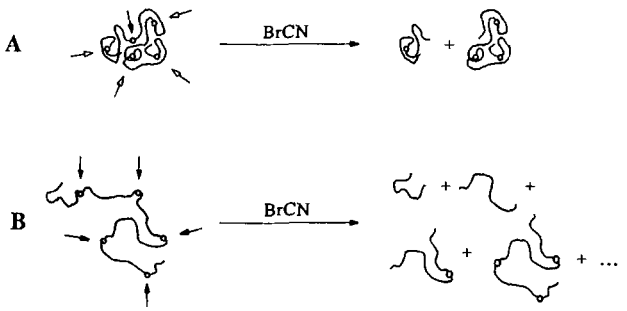

Fig. 1. Cleavage of native (A) and denaturated (B) chloroperoxidase with cyanogen bromide. o = methionine residue of the chloroperoxidase.

Methionine can be readily oxidized by H_2O_2 to methionine sulfoxide. Many enzymes lose their catalytic activity thereby.[8] Therefore, in an enzyme whose substrate is H_2O_2, methionine residues should be protected from the H_2O_2 molecule—and thus also from the similarly large cyanogen bromide molecule. Indeed, four of the five methionine residues of chloroperoxidase in the native enzyme are inaccessible for cyanogen bromide. The only accessible methionine is that after which the enzyme is cleaved by reaction with cyanide. This readily accessible methionine is oxidized to methionine sulfoxide by H_2O_2 under the reaction conditions.

Sulfoxides are reduced to sulfides in HBr solution in a chemical reaction,[9] and Br^- is oxidized by the sulfoxide to Br_2. An analogous reaction, via methionine sulfoxide, can be postulated for the enzymatic oxidation of Br^- to Br^+ by bacterial nonheme haloperoxidases (Scheme 1).

This model also explains the reaction of the haloperoxidases with cyanide: If the bromine atom in **4** is replaced by a cyano group, this leads to an intermediate which also occurs in the cleavage of proteins with cyanogen bromide. The substrate specificity of the chloroperoxidase for the chlorination—the chloroperoxidase can chlorinate substrates from the biosynthesis of pyrrolenitrin, whereas organic substrates such as 2-chloro-4,4-dimethyl-1,3-cyclohexanedione are only brominated[3]—can also be explained by this reaction scheme. The chemical oxidation of Cl^- to give Cl_2 (or HOCl) by sulfoxide is not possible under conditions in which the oxidation of Br^- to Br_2 is observed.[9] The reaction with Cl^- leads only to the intermediate **4**. Only substrates which find access to the active center—i.e. substrates from the pyrrolenitrin biosynthesis for which the enzyme has an affinity—and can react there with the intermediate **4**, are chlorinated. In other compounds the enzyme can only catalyze an unspecific bromination with free Br_2 via **4a**. This explains why the chloroperoxidase only catalyzes the bromination and not the chlorination of 2-chloro-4,4-dimethyl-1,3-cyclohexanedione.

If the enzymes are treated with H_2O_2, methionine is oxidized, and methionine sulfoxide **2** is detectable.[10] This reaction can be carried out quite easily with many enzymes. For the reduction of the resulting methionine sulfoxide back to methionine, reducing agents such as mercaptoethanol must usually be employed. In contrast, the reduction in the case of bacterial nonheme haloperoxidases according to the proposed mechanism with halide ions must take place, i.e. in the

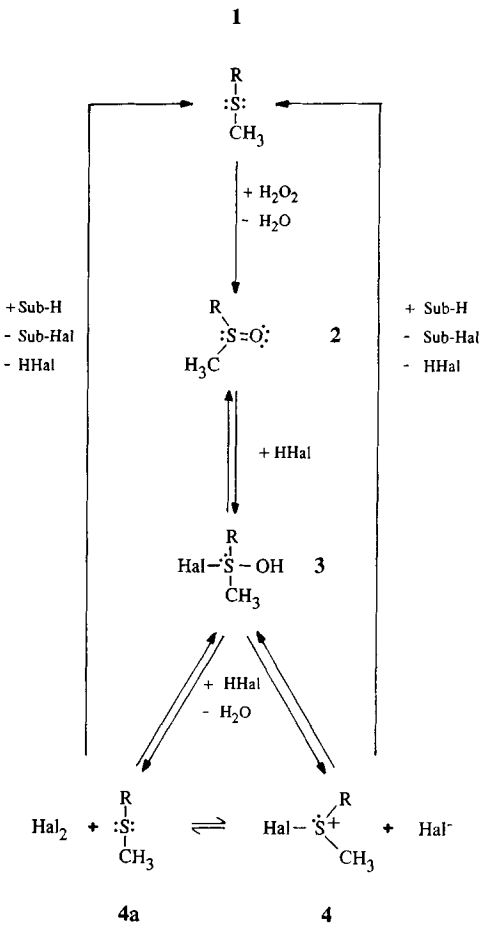

Scheme 1. Reaction cycle of bacterial nonheme haloperoxidases. R = $CH_2CH_2CH(NHR')(COR'')$ with R',R'' = peptide chain of the enzyme; Hal = Br or Cl; Sub-H = organic substrate; Sub-Hal = halogenated product. **4a** is formed only in the case of Hal = Br.

presence of bromide and the organic halogen acceptor (2-chloro-4,4-dimethyl-1,3-cyclohexanedione) in excess compared to H_2O_2, and the reaction cycle must stop at the stage of the methionine **1** after consumption of all of the H_2O_2. This could be confirmed by cleavage with cyanogen bromide and subsequent electrophoresis.[10]

The overall enzyme reaction is certainly much more complex than is depicted in this scheme. There must, for example, still be amino acids in the active center which induce the necessary polarization of the S–O bond during the reaction. These amino acids can be determined by elucidation of the structure of the active center by X-ray structural analysis. For this purpose the bromoperoxidase has already been crystallized, and the first structure investigations have been carried out on these crystals.[11]

Direct Observation of the Central Atom in $[C\{Au[P(C_6H_5)_2(p\text{-}C_6H_4NMe_2)]\}_6](BF_4)_2$ by ^{13}C NMR Spectroscopy**

By *Hubert Schmidbaur,** *Benno Brachthäuser*, and *Oliver Steigelmann*

Previous studies that led to the discovery of hexakis(phosphaneaurio)methanium(2+) cations of the type $[(LAu)_6C]^{2+}$ with a hypercoordinated central carbon atom teach us that direct detection of the interstitial atom is of utmost importance. When such a hexanuclear complex was formed by chance in earlier experiments with gold clusters, the presence of this carbon atom was overlooked and the product was formulated as $[(LAu)_6]^{2+}$.[2] However, since this stoichiometry should, according to theoretical predictions, lead to an edge-shared bi-tetrahedral and not to the octahedral geometry found in the experiment,[3] initial doubts were cast on the validity of the data, especially since the synthesis was not reproducible.[4] Further calculations revealed that C-centered octahedral clusters should be characterized by a particularly stable electron configuration.[5]

Following the successful, directed synthesis of $[(LAu_6)C]^{2+}$ dications with tertiary phosphanes as ligands L, the presence of the central atom could at first only be detected with certainty by high-resolution field desorption (FD) and fast atom bombardment (FAB) mass spectroscopy.[1] Although the X-ray diffraction patterns of all complexes investigated in the meantime[1,6–8] show the expected electron density in the center of the cluster, the information obtained from such diagrams is only of limited value in view of the six large surrounding atoms with their even larger ligand systems. The same is true for the IR/Raman and UV/VIS spectra and the diamagnetism, as well as the ^{197}Au-Mössbauer spectra.[1]

Thus, direct observation of the central C atom by NMR spectroscopy remained a challenge, not least because, in view of the unusual bonding situation of this atom, for which there is no precedent, no predictions were possible regarding the chemical shift and spin-spin coupling values. This prompted

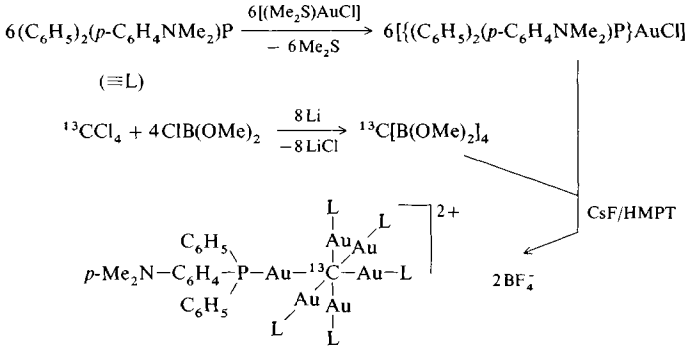
We thank Prof. *M. Taylor*, University of Auckland, New Zealand, for helpful discussions, Prof. *J. Shamir*, Hebrew University, Jerusalem and Prof. *W. Preetz*, Universität Kiel, for the first Raman spectroscopic measurements, as well as Dr. *S. Mronga* and Mr. *J. Balbach*, TU München, for high-field NMR measurements.

us to synthesize the title compound starting from ^{13}C-enriched $^{13}CCl_4$. Commercially available $^{13}CCl_4$[8] was diluted with CCl_4 with natural isotopic abundance, for cost reasons, to a ^{13}C-content of 20%, and converted as previously described[9] into $^{13}C[B(OCH_3)_2]_4$. NMR and MS monitoring of this product confirmed the expected ^{13}C-content at the central atom. As the second component required for the synthesis of the title compound the 1:1 complex of $(p\text{-}C_6H_4NMe_2)P(C_6H_5)_2$[10] and AuCl was prepared, the constitution of which was confirmed analytically and structurally (yield 97%, m.p. 218–220 °C (decomp.)[11] (Scheme 1). The *p*-dimethylamino-substituents are meant to improve the solubility and derivatizability in order to facilitate the detection. The reaction of the R_3PAuCl complex with $^{13}CCl_4/CCl_4$ in the presence of CsF in hexamethylphosphoric triamide (HMPT) furnished the title compound in 40% yield in the form of colorless crystals (m.p. 145–152 °C (decomp.)). The FAB mass spectrum (nitrobenzyl alcohol matrix) confirmed the (half) mass of the dication (m/z = 1521.1), the ^{197}Au-Mössbauer spectrum, the equivalence of the six gold atoms in the solid state (IS = 2.5 mms^{-1} and QS = 7.54 mms^{-1} at 4 K). The counterions are identified by a quintet signal in the ^{11}B NMR spectrum ($^1J_{BF}$ = 7.6 Hz).



Scheme 1.

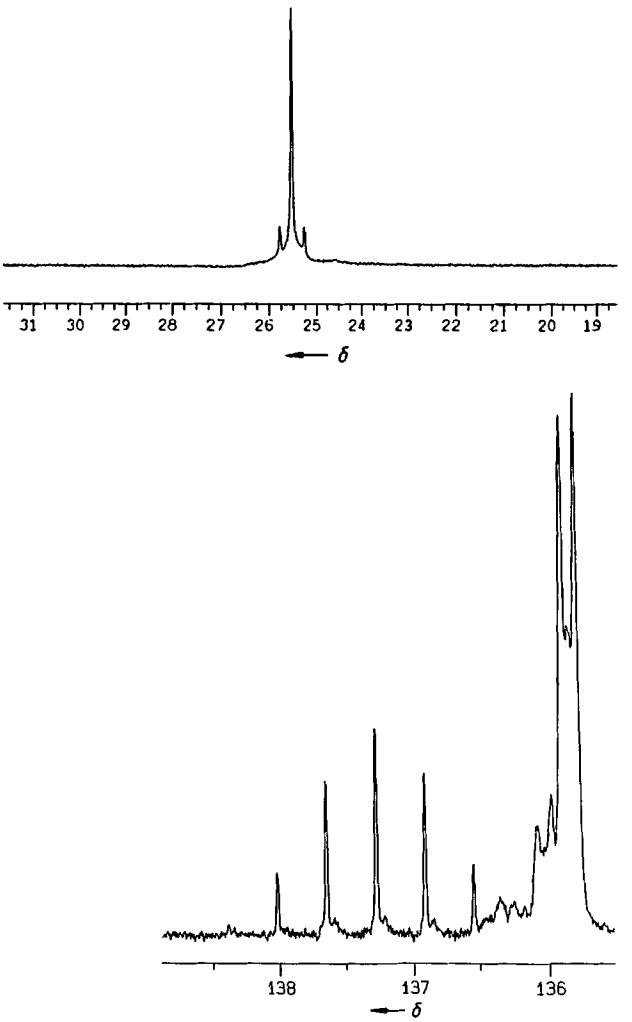


Fig. 1. Above: $^{31}P\{^1H\}$ NMR spectrum (161.84 MHz) of the title compound in CD_2Cl_2 at 300 K. Below: Section from the arene region of the $^{13}C\{^1H\}$-NMR spectrum (150.91 MHz) of the title compound in CD_2Cl_2 at 300 K.

In the ^{31}P NMR spectrum (161.84 MHz) of a solution of the product in CD_2Cl_2 at 300 K the satellite pair expected from the ^{31}P–^{13}C interaction appears symmetrically disposed to the singlet at δ = 25.50 in the intensity ratio 10:80:10 with the coupling constant ^2J = 56.1 Hz (Fig. 1, above). Only with a knowledge of this value could we unambiguously assign a septet signal *in the arene region* of the $^{13}C\{^1H\}$-NMR spectrum (600 MHz spectrometer, 150.91 MHz) at δ = 137.27 to the interstitial C-atom. Parts of this septet are already partly masked by the signals of the phenyl and *p*-dimethylaminophenyl groups in spectra recorded with a 400 MHz spectrometer, and are therefore difficult to locate. In the ^1H-coupled ^{13}C NMR spectrum the resonance of the central C atom experiences no further splitting, whereas the expected multiplicities are recorded for all the remaining signals. The same applies in the case of the ^1H NMR spectrum.[12]

The ^{13}C-resonance of the cluster C atom thus appears in a completely unexpected region, since one would have expected either a very strong or an extremely weak shielding upon coordination of metals, particularly with high coordination numbers. For example, the resonance of the central P atom in the related cluster dication $[(Ph_3PAu)_5P]^{2+}$ is observed at very high field,[13] whereas those of interstitial C atoms in typical carbonyl transition metal carbides appear at $\delta \approx 450$.[14] An explanation for these discrepancies is only to be expected from theoretical calculations, which, in the case of heavy metals—and especially in the case of gold—must take into account strong relativistic effects. The scalar value of the coupling constant $^2J_{PAuC}$ (without determination of sign), on the other hand, is less surprising, since values between 122.6 and 51.5 Hz have been found for organogold compounds such as $[(R_3P)AuCN]$, $[(R_3P)AuR]$, $[(R_3P)Au\{CH(SiR_3)_2\}]$, and $[(R_3P)Au\{C(SiR_3)_3\}]$.[15] The placement in the lower range is in keeping with the electron deficient character of the cluster and a formal hybridization of the interstitial atom with little s-character.[5]

Knowing the δ and J values for the title compound, the resonance of the cluster atom could also be found in the case of the non-^{13}C-enriched parent compound $[\{(Ph_3P)Au\}_6C](BF_4)_2$ (δ = 55.3, J = 54 Hz).

NMR spectroscopic evidence for the central N-atom in $[\{(Ph_3P)Au\}_4N]^+$ ions was obtained in the case of high-purity samples and suitable anions (BF_4^-) by observation of a 1:1:1 triplet splitting of the ^{31}P signal ($^2J_{^{31}P^{14}N}$ = 26 Hz).[16] Responsible for the success of the experiment here, as in the case of the title compound, is a zero-field gradient between the quadrupole nuclei of the gold atoms, determined by high point symmetry of the complex. Polarizing anions and impurities, which can induce exchange processes, lead to eradication of the coupling pattern. Enrichment with ^{15}N

should also enable direct observation of the central atom in the case of $[\{(Ph_3P)Au\}_4N]^+$.

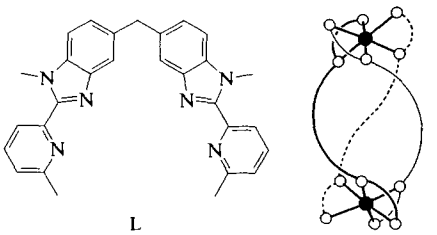
A Self-Assembling Triple-Helical Co_2^{II} Complex: Synthesis and Structure**

By *Alan F. Williams,* Claude Piguet,* and *Gérald Bernardinelli*

A theme of considerable interest in supramolecular chemistry is the selective and spontaneous assembly of supermolecules by the complexation of polydentate ligands around two or more metal ions.[1] Double-helical structures may be generated by two "oligobidentate" ligands complexing cations with a preference for tetrahedral coordination—the metal–metal axis is the helical axis about which the ligands are twisted. *Lehn* et al.[2] have synthesized a series of oligobipyridyl ligands which form double-helicates containing as many as five Cu^I ions, while *Sauvage* et al.[3] have used the double-helical complex formed by Cu^I with a ligand containing two phenanthroline units linked by a $(CH_2)_4$-bridge as a precursor for the synthesis of a molecular knot. Tetrahedral coordination of the metal is not an essential requirement for the formation of a helical structure, and we recently reported[4] a double-helical complex of Cu^I in which the ligand 2,6-bis(1-methylbenzimidazol-2-yl)pyridine (mbzimpy) acts essentially as a bis(monodentate) ligand, giving a linear coordination of the two copper ions.

A basic requirement for self-assembly around metal ions is that the coordinating possibilities of the ligands should match the stereochemical preference of the metal ion. We may therefore predict for ions with a preference for octahedral coordination the possible formation of double-helical complexes from bis(terdentate) ligands and of triple helices from bis(bidentate) ligands. The first possibility has recently been shown to occur in the complex $[Cd_2(sexipyridyl)_2]^{4\oplus}$ reported by *Constable*.[5] In this communication we report the crystal structure of a triple-helical complex which is formed on mixing stoichiometric amounts of the bis(bidentate) ligand bis[1-methyl-2-(6'-methyl-2'-pyridyl)benzimidazol-5-yl]methane (L) and cobalt(II) ions.



L

Scheme 1. Left: Structure of the ligand L. Right: Schematic representation of the helical complex formed from L and Co^{II} ions. Co atoms are shown as black spheres, N atoms as white spheres.

The ligand L has four coordination sites, but the rigidity of the aromatic rings prevents it from acting as a tetradentate ligand, and repulsion between the hydrogens in position 4 of the benzimidazoles destabilizes a planar structure. It is therefore ideally suited to act as a bis(bidentate) ligand. Reaction with cobalt(II) perchlorate leads to the isolation of orange salts with the composition $[Co_2L_3(ClO_4)_4]$; the rose-orange color of the crystals suggested a probable octahedral coordination of the cobalt, and the stoichiometry is in agreement with a triple-helical structure.

The X-ray crystal structure determination of $[Co_2L_3(ClO_4)_4 \cdot 2.5CH_3CN]$ confirms the existence of a triple-helical cation with approximate D_3 symmetry. Figure 1 shows an ORTEP[6] stereoview of the cation along one of the C_2 axes which passes through one of the methylene carbon atoms and the midpoint between the two cobalt atoms. Figure 2 gives computer-generated representations of the structure in which the different strands are shown in different colors. Figure 3 shows a projection down the Co–Co axis. The perchlorate anions and the acetonitrile molecules have been omitted; one of the perchlorates showed five positions for the oxygens, but the other three were relatively well ordered. Five solvent molecules were found, but the sites were not totally occupied, and they were refined with a population parameter of 0.5.

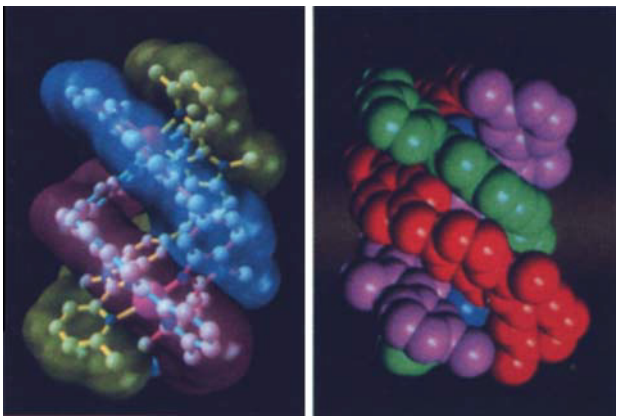

Fig. 2. Left: View [14] of the triple-helical cation $[Co_2L_3]^{4\oplus}$ with the ligands represented by a ball-and-stick model surrounded by a translucent Connolly surface [15]. Right: View [16] of the triple-helical cation $[Co_2L_3]^{4\oplus}$ with the non-hydrogen atoms represented as spheres with radii 80% of the van der Waals radius showing how the ligands wrap round the C_3 axis.

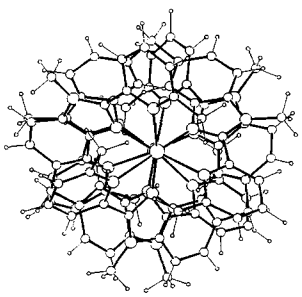

Fig. 3. View along the Co–Co axis showing the approximate C_3 symmetry.

The coordination sites of the two cobalt atoms are very similar, and in Table 1 we give the structural parameters obtained by averaging bond distances and angles related by pseudo D_3 symmetry. The cobalt coordination sphere may best be described as an octahedron flattened along a C_3 axis. The Co–N(benzimidazole) distance (2.07(2) Å) is shorter than the literature value of 2.103 Å[7] for high spin octahedral cobalt(II), but the Co–N(pyridine) distance 2.29(6) Å is longer than the standard value of 2.185 Å. We attribute this distortion to repulsion between the methyl groups on position 6 of the pyridine, since the distances between the carbon atoms of these methyls are quite short (average value 4.05(2) Å). This is supported by the observation that the average pyridine-Co-pyridine angle of 103° is significantly greater than the average benzimidazole-Co-benzimidazole angle (97°). The average ligand "bite angle" is 76.2°, and the cobalt–cobalt distance is 8.427(4) Å.

Table 1. Structural data for the cobalt coordination sphere, py = pyridine, bzim = benzimidazole.

	average [e.s.d.] [a]	minimum	maximum
$Co-N_{py}$	2.29(6)	2.24	2.40
$Co-N_{bzim}$	2.07(2)	2.04	2.10
ligand "bite angle"	76(2)	74.0	78.4
py–Co–py	103(4)	96.9	106.9
bzim–Co–bzim	97(2)	95.2	99.5
bzim–Co–py	172(2)	171.0	174.4
bzim–Co–bzim	84(3)	79.7	89.2

[a] Bond lengths [Å] and angles [°] are averaged assuming D_3 symmetry, and the quoted e.s.d. are obtained from the six values used to obtain the average. The experimental e.s.d are smaller.

The aromatic rings of the ligands are planar within experimental error, and the interplanar angles are given in Table 2. The average angle between the pyridine and the benzimidazole planes of a chelate ring is 22.7°, and between the two benzimidazole planes of one strand is 80°, but the spread of values is several degrees. Although the coordination sites of the cobalt ions are approximately related by D_3 symmetry, the complex as a whole deviates significantly from this high symmetry (Fig. 3). This deviation is essentially due to the spread in torsion angles which are not expected to be strongly constrained, and suggest that the molecule is fairly flexible. In support of this we note the absence of the strong stacking interactions observed[4] in $[Cu_2(mbzimpy)_2]^{2\oplus}$; in $[Co_2L_3]^{4\oplus}$ there is evidence of some slight stacking between benzimidazoles in different strands, but the planes are not parallel, and the distances between the benzimidazoles, calculated using those atoms which show the greatest overlap, lie in the range 4.2 to 4.6 Å compared with the 3.4 Å observed previously.[4] It therefore seems probable that the self

Table 2. Interplane angles [°] between aromatic rings.

Ring [a]	pA1	bA1	bA2	pA2	pB1	bB1	bB2	pB2	pC1	bC1	bC2
bA1	24.0										
bA2	86.6	79.1									
pA2	82.7	87.7	30.5								
pB1	75.1	52.6	52.9	81.3							
bB1	85.6	67.2	32.1	62.3	22.6						
bB2	58.0	70.2	50.5	27.9	87.9	76.3					
pB2	33.2	49.3	66.3	51.7	84.1	81.9	25.0				
pC1	80.7	82.5	22.6	8.6	72.7	53.9	30.8	52.2			
bC1	69.0	76.3	37.0	14.0	81.0	65.7	14.7	37.7	16.1		
bC2	56.3	32.4	68.3	91.3	22.5	43.0	87.3	74.6	83.2	85.9	
pC2	70.1	47.4	54.8	82.0	5.1	26.1	86.1	80.5	73.5	80.45	17.7

[a] The rings are denoted as pyridine p or benzimidazole b, belonging to ligand strand A, B, or C, and bound to Co1 or Co2. Thus pB2 is the pyridine of strand B that is bound to Co2. The error in the angles is typically 1°.

assembly is directed by the coordination requirements of the cation rather than by interligand interactions.

This is, to our knowledge, the first triple-helical coordination compound which has been characterized by X-ray crystallography. *Libman, Tor*, and *Shanzer*[8] reported a triple-helical dinuclear iron complex which was characterized by ^{1}H NMR and CD spectra, but in this case the tripodal nature of the ligand undoubtedly plays an important role in structuring the complex. Another Fe_2 complex composed of two Fe^{II} centers with octahedral coordination and three bidentate ligands was reported recently,[9] but in this case a triple-helical structure was not observed, presumably as a result of the greater flexibility of the ligands.

Experimental

The ligand L was obtained by a Phillips condensation of 3,3'-diamino-4,4'-bis(*N*-methylamino)diphenylmethane (prepared according to a modified literature procedure [10]) with 2-methylpyridine-6-carboxylic acid [11]. Crystals of $[Co_2L_3(ClO_4)_4 \cdot 2.5\,CH_3CN]$ were grown from acetonitrile solution at 40 °C. A red-orange crystal ($0.22 \times 0.32 \times 0.32$ mm^3) was sealed in a capillary tube with some of the supernatant liquid. $M_r = 1994$, triclinic $P\bar{1}$, $a = 14.403(2)$, $b = 16.558(3)$, $c = 21.328(3)$ Å, $\alpha = 78.15(1)°$, $\beta = 81.19(1)°$, $\gamma = 89.02(1)°$ based on 24 reflections ($16° < 2\theta < 31°$), $V = 4919(1)$ Å^3, $Z = 2$. Intensity data were collected at room temperature on an Enraf-Nonius CAD4 diffractometer with $Mo_{K\alpha}$ radiation ($\lambda = 0.71069$ Å), $4° < 2\theta < 38°$, 7877 unique reflections measured. Structure solved by direct methods [12], other calculations made using the XTAL system [13]. Full matrix refinement was performed successively on ligand 1 and cobalt, ligand 2, ligand 3 and perchlorate and solvent molecules (maximum of variables = 335). All atoms other than perchlorate oxygens and carbons of solvent molecules were refined with anisotropic thermal displacement parameters. Final R factor 11.0% ($R_w = 9.7\%$, $w = 1/\sigma^2(F_0)$), for 4980 observed reflections ($|F_0| > 4\sigma(F_0)$). Further details of the crystal structure investigation are available on request from the Director of the Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, GB-Cambridge, CB2 1EW (UK), on quoting the full journal citation.

Synthesis, Absolute Configuration and Specific Rotation of (+)- and (−)-Modhephene**

By *Lutz Fitjer,* Honorato Monzó Oltra,* and *Mathias Noltemeyer**

Dedicated to Professor Michael Hanack on the occasion of his 60th birthday

Since its discovery in *Isocoma wrightii*,[1] a plant toxic to sheep and cattle in the south west USA, (−)-modhephene (**5**) has been a popular goal of synthetic studies. Because of a growth-inhibiting function of derivatives,[2] related compounds have also been investigated. Twelve diastereoselective[3] and one enantioselective syntheses[4a–c] document an intense interest.

The only enantioselective synthesis[4a–c] assigns (−)-modhephene a (1*R*,5*S*,8*R*) configuration on the basis of the circular dichroism of a cyclopropyl ketone precursor. The

[**] Polyspiranes, Part 21. Rearrangement Cascades; Part 15. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. Part 20: L. Fitjer, K. Justus, P. Puder, M. Dittmer, C. Hassler, M. Noltemeyer, *Angew. Chem. 103* (1991) 431; *Angew. Chem. 30* (1991) 436; Part 16: L. Fitjer, A. Kanschik, M. Majewski, *NATO Adv. Study Inst. Ser. C 273*(1989) 431.

specific rotation ($[\alpha]_D$ − 5.2)[4c] corresponds to that of the natural product ($[\alpha]_D$ − 4.2),[1b, 4c] although the synthetic product (78% *ee*) was contaminated with 17% epimodhephene, whose specific rotation is unknown. A negligible specific rotation for epimodhephene could explain this observation. Contradictions cast doubt on the absolute configuration when a considerably different rotation ($[\alpha]_D$ − 20.5) was determined for modhephene isolated from *Otanthus maritimus*.[5] As there were no reliable criteria for purity, we synthesized both enantiomers and determined the absolute configuration and specific rotation anew.

Our synthesis (Scheme 1) is based on the stereospecificity of the rearrangement of (±)-**4** to (±)-modhephene (**5**)[6] and required separation of racemic (±)-**1**. According to the general method of *Johnson* et al.[7] we treated (±)-**1**[6] with lithiated (+)-(*S*)-*N*,*S*-dimethyl-*S*-phenylsulfoximine (97% *ee*, $[\alpha]_D$ + 178, *c* = 3, acetone; literature value[7] + 184, *c* = 3, acetone) and obtained a liquid and a solid β-hydroxysulfoximine. X-ray crystallography[8] showed the solid ($[\alpha]_D$ + 61, *c* = 1.34, $CHCl_3$) to be (S*S*,5*R*,6*S*,7*S*)-**2**[10] (Fig. 1); the liquid ($[\alpha]_D$ + 34, *c* = 1.39, $CHCl_3$) was therefore (S*S*,5*S*,6*R*,7*R*)-**3**.[10] Cleavage to form the corresponding

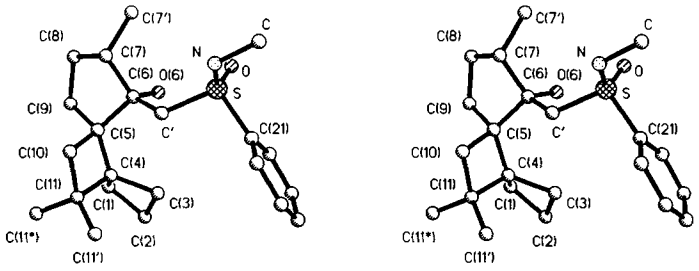

Fig. 1. Stereoscopic view of the crystal structure of (S*S*,5*R*,6*S*,7*S*)-**2** (hydrogen atoms omitted). Selected bond lengths [pm] and angles [°]: cyclobutane rings: C4–C11 158.3, other C–C 152.2–155.6, C-C-C 88.1–91.0; cyclopentane ring: C–C 151.1–154.3, C-C-C 101.5–106.6.

ketones (−)-(5*R*,7*S*)-**1**[10] ($[\alpha]_D$ − 39, *c* = 1.3, $CHCl_3$) and (+)-(5*S*,7*R*)-**1**[10] ($[\alpha]_D$ + 36, *c* = 0.9, $CHCl_3$) was achieved by thermal fragmentation (12 h/80 °C), and the stereospecific addition of methyllithium afforded finally the desired alcohols (+)-(5*R*,6*S*,7*S*)-**4**[10] ($[\alpha]_D$ + 58, *c* = 1.05, $CHCl_3$) and (−)-(5*S*,6*R*,7*R*)-**4**[10] ($[\alpha]_D$ − 57, *c* = 1.09, $CHCl_3$).

For the rearrangement, (+)-(5*R*,6*S*,7*S*)-**4** and (−)-(5*S*,6*R*,7*R*)-**4** were heated with equivalent quantities of a 0.075 M solution of dry *p*-toluenesulfonic acid in benzene for 25 min at 70 °C. Column chromatography on silica gel doped with 20% silver nitrate (eluant pentane/dichloromethane 95:5) afforded (+)-modhephene, (+)-(1*S*,5*R*,8*S*)-**5**,[10] ($[\alpha]_D$ + 16.5, *c* = 0.5, $CHCl_3$) from the rearrangement of (+)-(5*R*,6*S*,7*S*)-**4**, and (−)-modhephene, (−)-(1R,5*S*,8*R*)-**5**,[10] ($[\alpha]_D$ − 15.8, *c* = 1.08, $CHCl_3$) from the rearrangement of (−)-(5*S*,6*R*,7*R*)-**4**.

Since our optical rotation values contradicted every other earlier report, we have reisolated (−)-modhephene from *Othanthus maritimus*[5, 11], determined its specific rotation again ($[\alpha]_D$ − 16.5, *c* = 1.58, $CHCl_3$), and reexamined the chemical and optical purity of all natural and synthetic samples by capillary gas chromatography on permethylated β-cyclodextrin (Fig. 2).[12] With the exception of synthetic (−)-**5** (95% *ee*, $[\alpha]_D^{corr}$ − 16.6), all the samples were chemically and optically pure and therefore the rotation data are conclusive.

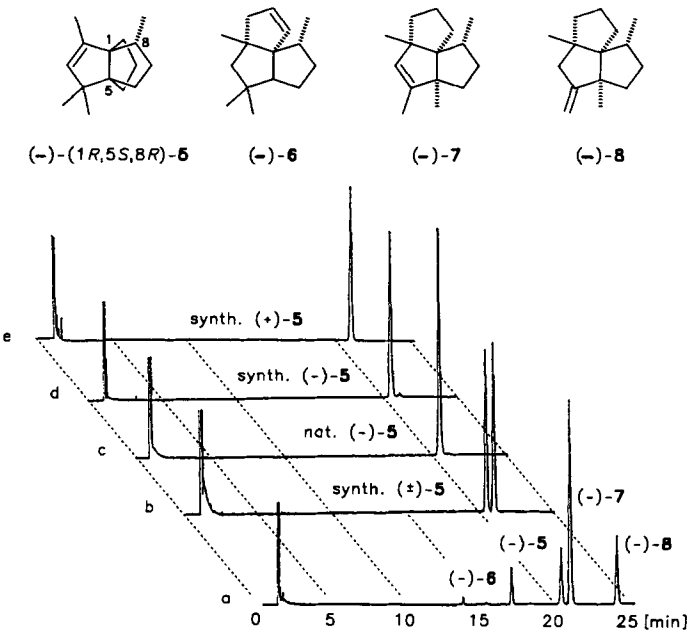

Fig. 2. Capillary chromatograms [25 m × 0.25 mm inner diameter, deactivated fused-silica capillary columns coated with heptakis(2,3,6-tri-*O*-methyl)-β-cyclodextrin in OV-1701 (0.07 M), at 110 °C, carrier gas 0.6 bar H_2]. a) Extract from *Otanthus maritimus* [11] containing (−)-silphinene [(−)-**6**], (−)-modhephene [(−)-**5**], (−)-isocomene [(−)-**7**], and (−)-β-isocomene [(−)-**8**]; b) synthetic (±)-**5** [6]; c) naturally occurring (−)-**5**; d) synthetic (−)-**5**; e) synthetic (+)-**5**.

As our studies show, none of the earlier samples of (−)-modhephene was really pure. Although the assignment of the absolute configuration as 1*R*,5*S*,8*R*[4c] was correct, it was by no means definite. Care should also be taken in establishing the hitherto unknown absolute configurations of (−)-silphinene [(−)-**6**, $[\alpha]_D$ − 21.3,[13] − 46.7[5]], (−)-isocomene [(−)-**7**, $[\alpha]_D$ − 67.8,[1b] − 85,[13] − 85.2[5]] and (−)-β-isocomene [(−)-**8**, $[\alpha]_D$ − 63.2[5]]. Here too, contradictory values exist, although besides (−)-modhephene [(−)-**5**] at least (−)-isocomene [(−)-**7**] is produced enantiomerically pure by *Othanthus maritimus* (Fig. 2).[14] Since (±)-modhephene can be rearranged to (±)-isocomene,[6] we can now determine the absolute configuration of (−)-isocomene also, using (+)- and (−)-modhephene.

[14] We have ascertained that the enantiomers of (±)-**7** [6] are separable under the conditions given in Figure 2. This test has not yet been undertaken for (±)-**6** and (±)-**8**.

formed thereby is trapped by addition of triethylamine, yields between 84 and 89% can be achieved.[10]

The corresponding iron(III) complexes **2d–f** (yields: 60–90%) can be obtained analogously from the 1-(1-alkyl/aryl-1*H*-tetrazol-5-yl)-2-alkanones **1d–f**.[12] On the basis of the elemental analyses and mass spectrometric data **2a–f** are mononuclear iron(III) complexes of the general composition FeL_3 (HL = **1a–f**). In the reaction of **1a** with aluminum trichloride, the corresponding aluminum complex **3a** is formed.[10]

Synthetic Siderophores of the Tetrazolylenol Type: Iron(III) Complexes and Three-Dimensional Iron(II) Coordination Polymers**

By *Rolf W. Saalfrank,* Claus-Jürgen Lurz, Klaus Schobert, Oliver Struck, Eckhard Bill,* and *Alfred X. Trautwein**

Dedicated to Professor Hiroshi Taniguchi on the occasion of his 60th birthday

Naturally occurring and synthetically accessible siderophores (iron carriers) contain predominantly bidentate pyrocatechinato- or hydroxamato-ligands and are of special interest because of their high affinity towards trivalent metal ions, especially towards iron(III) ions.[1–8] The methyl (*E*)-2-(1-alkyl/aryl-4,5-dihydro-1*H*-tetrazol-5-ylidene)-2-cyanoacetates **1a–c**, first prepared by us with a completely different intention,[9] appeared to be also suitable as siderophores. Upon reaction of **1a–c** in ether with aqueous iron(III) chloride solutions, a deep blue coloration of the ether phase suddenly occurs, and, after addition of *n*-hexane, **2a–c** separate in the form of deep blue microcrystals. If the hydrochloric acid

The Mössbauer spectra of powdered samples of the complexes **2a,b** at 298 K show relatively poorly resolved quadrupole doublets with quadrupole splittings $\Delta E_Q \approx 0.5$ mms^{-1} and isomeric shifts $\delta \approx 0.45$ mms^{-1} (not shown). The values of the isomeric shifts point to high-spin iron(III) ($S = 5/2$) in a quasi-octahedral environment.[13] The temperature dependence of the Mössbauer spectra is similar to that of the spectra of other siderophore complexes, e.g. ferrichrome A.[14]

X-band-EPR spectra of the complexes **2a,b** confirm the high-spin state ($S = 5/2$) of the iron(III) center. Powdered samples already afford strong resonance signals at lower field, from about $g = 10$, but these were not analyzed further because of their extreme broadening by intermolecular spin-spin interactions. **2a,b** dissolved in dichloromethane, however, show the same spectrum at 10 K with a strong isotropic line at $g = 4.3$ and a weaker anisotropic line at $g = 9.6$ typical for magnetically isolated Fe^{III} centers ($S = 5/2$) with maximum rhombicity, $E/D = 1/3$ (E and D are zero-field interaction parameters in the spin-Hamilton formulation for the description of the electronic fine structure of the iron(III) center).[15] The rhombicity shows that apparently in each case only the statistically most probable (Δ)/(Λ)-*mer*-isomers **2** of the two theoretically possible (Δ)/(Λ)-configurational isomers, FeL_3, are formed. This finding is supported by the ^{13}C-NMR spectrum of the aluminum complex **3a**, which shows the set of signals expected for the three nonequivalent ligands.[10] Whereas **1a–c** function as bidentate ligands towards iron(III) ions and form the *mer*-complexes **2a–c**, the same compounds **1a–c** should function as tridentate ligands towards iron(II) ions and afford, by *spontaneous self-organization*,[16] three-dimensional coordination polymers.[17]

In order to check this assumption we have carried out reactions of **1a–c** in diethyl ether with aqueous iron(II) sulfate solutions. Pale green precipitates are obtained which are almost insoluble in noncoordinating solvents and still show no changes even at 570 K. According to microanalyses, the

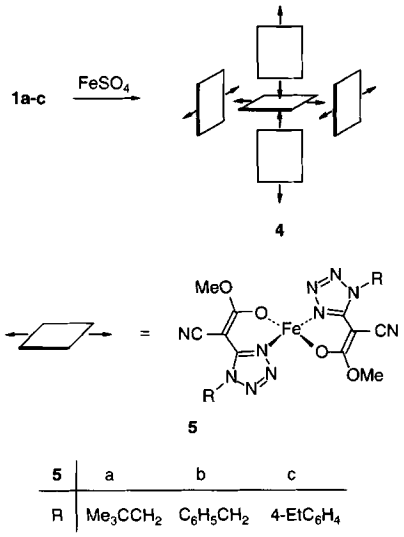
[+] EPR and Mössbauer spectra.

[**] Siderphores, Part 1. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie, and would hardly have materialized without the stimulating discussions with J.-M. Lehn, Strasbourg, during a research visit by *R. W. S.* We thank Dr. *M. Moll*, Institut für Anorganische Chemie der Universität Erlangen-Nürnberg, for recording the NMR spectra, and Dr. *A. van Dorsselaer*, Institut de Chimie de l'Universite Strasbourg, for measuring the FAB-MS spectra.

products obtained are compounds of the general composition $[FeL_2]_n$, the FAB-MS data (FAB = Fast Atom Bombardment) of **4a** indicating the presence of a polymer.[10]

The formation of coordination polymers of type **4** is understandable if **1a–c** or their enolates are considered as tridentate chelate ligands and if one assumes intermediary formation of the coordinatively unsaturated iron(II) building block **5**. The monomers are bidentate coordinating through the two CN groups, which leads to linking of monomers and to coordinative saturation at the iron(II) center of **5** with formation of the corresponding three-dimensional coordination polymers **4**.[18] In agreement with a polymeric structure of **4** is the finding that compounds **4** are readily soluble in coordinating solvents such as pyridine, acetonitrile etc. and are depolymerized.



5	a	b	c
R	Me_3CCH_2	$C_6H_5CH_2$	4-EtC_6H_4

In contrast to **1a–c**, the prerequisites for an "internal" coupling are lacking in **1d–f** because of the absence of additional CN groups, so that in these cases the formation of coordination polymers with iron(II) ions does not occur.[20]

The DMSO solutions of compounds **4a,b** in contrast to their powdered samples, belong to the few systems with integer spin $S = 2$, which give EPR spectra (Fig. 1). The broad

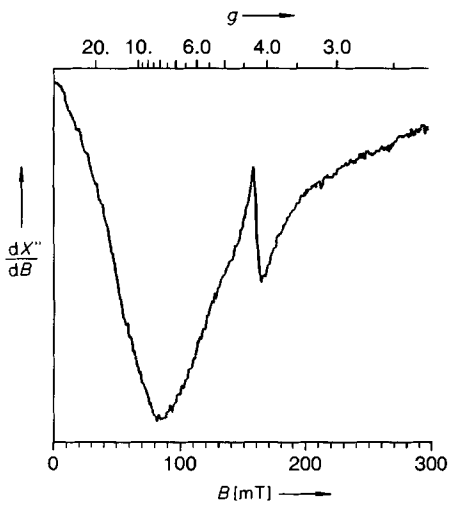


Fig. 1. EPR spectrum of a DMSO solution of compound **4a**. Temperature: 10 K, frequency: 9.434 GHz, power: 20 mW. (The weak resonance signal at $g = 4.3$ arises from slight contamination of the solution with iron(III).)

resonance signals can be explained as quasi "$\Delta m = 4$" transitions between the states "$S_z = +2$" and "$S_z = -2$" of the $S = 2$ quintet.[15] They are only measureable under the condition that the zero-field splitting of the quintet is very small (< 0.3 cm). Possibly the CN bond of the "axial" ligands in the solid, in contrast to the weak coordination in solution, effects too strong a zero-field interaction to allow EPR transitions.

The Mössbauer spectra of powdered samples of the complexes **4a, b** show almost temperature-independent quadrupole doublets with splittings $\Delta E_Q = 3.16\ mms^{-1}$ (**4a**), $3.0\ mms^{-1}$ (**4b**) in the temperature range 4.2 to 300 K and the isomeric shift $\delta = 1.22\ mms^{-1}$ (**4a, b**) typical for high-spin iron(II) at 4.2 K (Fig. 2, left). The high δ value confirms the sixfold coordination of the iron by nitrogen and oxygen ligands in the coordination polymer. A quasi-tetrahedral ligand arrangement would give $\delta < 1\ mms^{-1}$.[13] Below 4.2 K the two complexes **4a** and **4b** behave differently. At 1.6 K without external magnetic field, **4a** shows *spontaneous magnetic ordering*, recognizable by the magnetic hyperfine interaction in the Mössbauer spectrum (Fig. 2, right), which furnishes further proof of the polymeric structure of **4a**. An

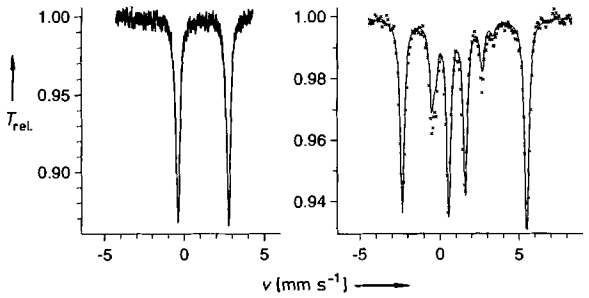

Fig. 2. Left: Mössbauer spectrum of a powdered sample of compound **4a**, recorded at 77 K. The solid line is a best fit with Lorenz lines. Right: Mössbauer spectrum of a powdered sample of compound **4a**, recorded at 1.6 K. The solid line is a simulation with the parameters: $\delta = 1.22\ mms^{-1}$; $\Delta E_Q = 3.10\ mms^{-1}$; $B^{int} = 17.7$ T; $\Gamma = 0.30\ mms^{-1}$; polar angle of B^{int} based on the molecular principal axis system of the electric field gradient: $\theta = 30°$, $\varphi = 90°$ (right). T_{rel} = relative transmission, v = relative velocity.

external field of 0.18 T has no measureable influence on the 1.6 K spectrum of **4a**, thus indicating that the magnetic ordering is of an antiferromagnetic nature. In contrast to the spectrum of **4a**, the spectrum of **4b** at 1.6 K shows no signs of a magnetic hyperfine interaction. The antiferromagnetic interaction in **4b** should thus be weak and only observable below 1.6 K in the Mössbauer spectrum.

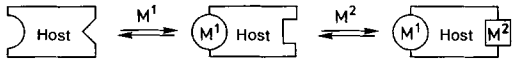
Metal-Assisted Organization rather than Preorganization for the Design of Macrocyclic Hosts

By *Yoshiaki Kobuke,* Yasutaka Sumida, Minoru Hayashi,* and *Hisanobu Ogoshi*

The strategy of preorganization of macrocyclic hosts ensures the efficient as well as selective binding of guest molecules.[1] Here, the unfavorable entropy term for assembling ligands around the guest is already overcome during the chemical synthesis so that large changes in free enthalpy, $-\Delta G^0$, and large differences $-\Delta\Delta G^0$ can occur upon host–guest complexation. This is clearly demonstrated in a vast number of publications, in which it is shown that stability and selectivity generally increase along the series podands, coronands, and cryptands.[2] Nevertheless, there are also arguments against strategies with such nicely arranged hosts: 1) the synthesis of such well-organized hosts may not be easy; 2) once synthesized, the hosts can be modified structurally only with difficulty; 3) a host with strong binding generally decomplexes too slowly, and the efficiency of regeneration is low.

We would like to introduce here a new concept for the design of macrocyclic hosts and cooperative metal binding (Scheme 1). A host with two metal binding sites is synthesized in which the binding of M^1 to the first site influences the second site both electronically and conformationally, converting it from an otherwise weak binding site into a potent site for the cooperative binding of M^2. Since the final structure formation is completed with the aid of M^1, the synthesis of the parent host itself becomes much easier and various structural modifications become possible by appropriate selection of M^1. Moreover, the decomplexation of M^1 destroys the final ligand organization and regenerates the starting host. Therefore, all of the negative aspects cited above can be avoided. In this report, the synthesis of hosts according to the above concept and their preliminary binding characteristics will be demonstrated.[3]



Scheme 1. Cooperative metal binding with influence of the M^2 binding site by binding of M^1.

The catecholate group was chosen as the unit for the M^1 binding site, since it shows the highest degree of chelating ability towards a large variety of metal ions as a result of its *ortho*-dianionic form;[4] a neutral polyether group was used as unit for the coordination of alkali metal ions M^2. Accordingly, both a podand (**1**) and a coronand (**3**) were synthesized as parent hosts (Scheme 2). We employed a benzyl group for protecting the catechol unit.

The precursor molecule for podand **2** was easily obtained by treatment of 2,3-bis(benzyloxy)benzyl bromide with triethylene glycol. In the synthesis of the coronand precursor **4**, 2,3-bis(benzyloxy)-1,4-bis(bromomethyl)benzene (**5**) was first treated with an excess of triethylene glycol and the resulting intermediate was cyclized under high dilution conditions in dioxane with **5** to give **4**. The benzyl–O bonds of the aryl benzyl ether units were cleaved by controlled hydrogenation over palladium/carbon (5%) without attack at the benzyl–O bonds of the alkyl benzyl ether units in the main chain; this led to quantitative formation of **1** and **3**.

A buffer solution (pH 8.0, phosphate) of **1** was titrated with boric acid to give a smooth change in absorption of the catecholate–boron complex at 290 nm. The titration curve was consistent with formation of a 1:1 complex and the equilibrium constant was estimated to be $3700 \pm 90\ M^{-1}$.

An ethanolic solution of **1** was treated with four equivalents of aqueous KOH and then with one equivalent of boric acid. A colorless precipitate was formed, whose FAB mass spectrum gave a peak at *m/z* 440, corresponding to the ternary complex of the tetranion of **1**, boron, and potassium $(\mathbf{1} - 4H)^{4-} \cdot B^{3+} \cdot K^{+}$ (**6**). In the NMR spectrum of **6** in $CDCl_3$ the benzyl protons give rise to an AB quartet at $\delta = 4.03$ and 4.96 ($J = 9.6$ Hz), while those in the parent podand **1** afford a sharp singlet at $\delta = 4.52$. When the complexation was undertaken in the presence of NaOH, the benzyl protons in the resulting complex **7** gave an AB pattern at slightly different δ values (4.10 and 4.97; $J = 10.0$ Hz). The differences in the chemical shifts and in the coupling constants between **6** and **7** suggest that benzyl protons are close enough to the cationic metal center to be influenced by even the subtle change from K^+ to Na^+. Upon treatment of the Na complex **7** with excess KPF_6, **6** was regenerated (NMR spectroscopic detection). These results clearly indicate that boron is complexed with two catecholate ligands in the same molecule leading to formation of a boron-assisted coronand, in which two anionic oxygen atoms from the catecholate units and four neutral oxygen atoms from the polyether chain are nicely arranged to afford an additional metal binding site. K^+ or Na^+ may be entrapped in this monoanionic crown-like cavity to give the respective neutral species $(\mathbf{1} - 4H)^{4-} \cdot B^{3+} \cdot K^{+}$ or $(\mathbf{1} - 4H)^{4-} \cdot B^{3+} \cdot Na^{+}$. It should be noted that the parent podand possesses the basic structural units for alkali-metal binding but it is inert unless the complexation with boron organizes them into a macrocyclic structure which still bears an anionic charge.

It is well established that boron is generally surrounded tetrahedrally by ligands, and that the metal-assisted coronand is presumably a C_2 symmetric and should be a mixture of *A* and *Δ* isomers. When 0.1 molar equivalents of europium (III) tris[3-(hydroxyl)trifluoromethylmethylene)-(+)-camphorate] was added to **6** in $CDCl_3$ the AB quartet was separated into two sets of AB quartets, one at $\delta = 4.04$ and 5.07

Scheme 3. Probable structures of **6** and **7**; right: drawn schematically for one enantiomer.

Table 1. ^1H NMR, mass spectrometric, and elemental analysis data of **1**–**4** and **6**–**8**.

1: ^1H NMR (90 MHz, $CDCl_3$): $\delta = 3.73$ (s, 12H, OCH_2CH_2O), 4.70 (s, 4H, OCH_2Ar), 6.02 (s, 2H, OH), 6.45–6.95 (m, 6H, C_6H_3), 7.81 (s, 2H, OH); MS (FAB): *m/z* 394 (M^+); correct C,H,O analysis.

2: ^1H NMR (90 MHz, $CDCl_3$): $\delta = 3.44$–3.78 (br. s, 12H, OCH_2CH_2O), 4.56 (s, 4H, OCH_2Ar), 5.05 (s, 4H, $PhCH_2OAr$), 5.13 (s, 4H, $PhCH_2OAr$), 7.01 (m, 6H, C_6H_3), 7.26–7.50 (br. s, 20H, C_6H_5); MS (FAB): *m/z* 754 (M^+); correct C,H,O analysis.

3: ^1H NMR (90 MHz, $CDCl_3$): $\delta = 3.72$ (s, 24H, OCH_2CH_2O), 4.61 (s, 8H, OCH_2Ar), 6.64 (s, 4H, C_6H_2), 7.13 (br. s, 4H, OH); MS (FAB): *m/z* 569 ($M^+ + H$), 591 ($M^+ + Na$), 607 ($M^+ + K$).

4: ^1H NMR (90 MHz, $CDCl_3$): $\delta = 3.63$ (s, 24H, OCH_2CH_2O), 4.52 (s, 8H, OCH_2Ar), 5.03 (s, 8H, $PhCH_2OAr$), 7.16 (s, 4H, C_6H_2), 7.34 (s, 20H, C_6H_5); MS (FAB): *m/z* 928 (M^+); correct C,H,O analysis.

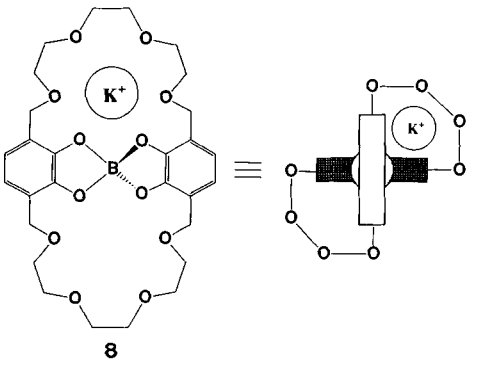
6: ^1H NMR (90 MHz, $CDCl_3$): $\delta = 3.37$–3.77 (m, 12H, OCH_2CH_2O), 4.03 and 4.96 (q, 4H, $J = 9.6$ Hz, OCH_2Ar), 6.47–6.88 (m, 6H, C_6H_3); UV ($CHCl_3$): λ_{max} [nm] = 290, MS (FAB): *m/z* 440 (M^+); correct C,H analysis.

7: ^1H NMR (90 MHz, $CDCl_3$): $\delta = 3.51$–3.78 (m, 12H, OCH_2CH_2O), 4.10 and 4.97 (q, 4H, $J = 10.0$ Hz, OCH_2Ar), 6.44–6.87 (m, 6H, C_6H_3); MS (FAB): *m/z* 424 (M^+)

8: MS (FAB): *m/z* 615 ($M^+ + H$), 637 ($M^+ + Na$), 653 ($M^+ + K$)

with $J = 9.6$ Hz and the other at $\delta = 4.09$ and 5.24 with $J = 10.2$ Hz. Further addition of the shift reagent gave a larger downfield shift and a larger broadening of the latter set of signals selectively at the lower field. This observation is in complete agreement with the expectation. Therefore the structures of the complexes may safely be formulated as shown in Scheme 3.

When **3**, which already has a coronand structure, was treated with boric acid in the presence of KOH, a similar neutral triple complex, $(\mathbf{3} - 4H)^{4-} \cdot B^{3+} \cdot K^{+}$ (**8**) was obtained. The FAB mass spectrum showed a peak corresponding to $(\mathbf{8} + H)^+$ together with peaks for $(\mathbf{8} + Na)^+$ and $(\mathbf{8} + K)^+$. The latter two ions must therefore be formed from a quaternary complex $[(\mathbf{3} - 4H \cdot B \cdot K \cdot M]^+$, with M = Na or K. Presumably an additional monovalent metal cation had been entrapped in the vacant coronand cavity of **8** (Scheme 4).



8

Scheme 4. Probable structure **8**; right: drawn schematically for one enantiomer.

In summary, the achiral parent podand or coronand was converted upon complexation with boron into the respective chiral coronand or a chiral bicyclic coronand with a C_2-symmetry. Alkali-metal ions are bound in this newly organized monoanionic cavity. This is a successful example of positive cooperativity for the binding of different metal ions in a single host. It shows a clear distinction from previous reports in which attempts at metal binding showed no cooperativity or if so, in negative or only marginally positive

terms.[5] The use of anionic ligation seems essential for achieving positive cooperativities so that the occurrence of a positive charge in the structure through the first metal cation is carefully avoided.

Antiperovskite Structure with Ternary Tetrathiafulvalenium Salts: Construction, Distortion, and Antiferromagnetic Ordering**

By *Patrick Batail,* Carine Livage, Stuart S. P. Parkin, Claude Coulon, James D. Martin*, and *Enric Canadell*

Our present ability to rationally design and prepare molecular solids within a predicted structure type is still in its infancy.[1] Here we report that a series of ternary tetrathiafulvalenium salts of large, divalent all-inorganic hexanuclear molybdenum halides, formulated as $(TTF^{\bullet+})_3[(Y^-)(Mo_6X_{14}^{2-})]$ (X = Y = Cl; X = Br, Y = Cl, Br, I), has been electrochemically assembled and shown to actually adopt a perovskite-type[2] structure. The latter features a unique three-dimensional arrangement of tetrathiafulvalene (TTF) cation radicals, located at the oxygen sites of the $BaTiO_3$ prototypical structure. Thus, a rhombohedrally distorted antiperovskite network is identified, in which, in all four compounds, the unpaired π-electron spins ($S = 1/2$) for each of the tetrathiafulvalenium HOMOs, centered at the vertices of vertex-sharing $\{Y^-(TTF^{\bullet+})_6\}$ octahedra, undergo sharp, long-range antiferromagnetic ordering at roughly 6–8 K. In fact, the initial discovery that antiferromagnetic ordering occurs in $(TTF)_3[(Cl)(Mo_6Cl_{14})]$ **1** prompted the preparation of $(TTF)_3[(Y)(Mo_6Br_{14})]$, Y = Cl (**2**), Br (**3**), and I (**4**) with the two-fold anticipation that they would form the same antiperovskite structure and indeed order antiferromagnetically.

These observations suggest that significant molecular information can be expressed and manipulated by substitution into a predicted target structure in order to design highly ordered, specialized three-dimensional molecular solids. These structures act as efficient receptors for halides with unique magnetic properties, very much along the same approach that has proven so successful in solid state inorganic chemistry. In this respect, such a unique family of compounds bridges the gap between organic and inorganic materials: it is indeed a novel simple structure type recognized[3] in complex molecular solids in the CsCl,[4a] NaCl,[4b,c] and $CdCl_2$ structures.[4d] It is also suggested that the three-dimensional nature of the perovskite structure has played a role in preventing the occurrence of the spin-Peierls transition commonly observed[5] in other cation radical salts, albeit of lower dimensionality, thereby providing a particularly simple example of geometric control of the electronic structure in the solid state. An exchange mechanism by direct, through-space coupling of the organic spins inside the octahedron—unprecedented in the molecular solid state—could be revealed by consideration of structural and antiferromagnetic resonance data and MO calculations.

The electrochemical assembling of the units $[Mo_6Cl_{14}]^{2-}$, $TTF^{\bullet+}$, and Cl^- was purposely attempted in order to demonstrate that the formation of the perovskite framework is a consequence of the divalent character of the large cluster anion (site A). This assumption was based on recent evidence that (a) such associations with the monovalent, isoelectronic, and isostructural hexarheniate cluster anions $[Re_6Q_5Cl_9]^-$ (Q = S, Se)[6] result in the formation of 2:1 binary phases with discrete mixed-valence $[(TTF)_2^{+}]$ dimers;[7] and (b) that the monovalent rhenium cluster-based, paramagnetic perovskite previously obtained by serendipity,[6] was actually a disordered material with only a fraction of the monovalent anions on the A site. Indeed, we have shown that in the latter phase, now formulated as $\{(TTF^{\bullet+})_5(TTF)\}\{(Cl^-)_2\}\{(Re_6Se_6Cl_8^{2-})(Re_6Se_5Cl_9^-)\}$ one spin fails per TTF octahedron and no antiferromagnetic ordering occurs.[7]

Black, rhombohedrally-shaped single crystals of **1**–**4** were grown on a platinum wire anode upon constant low current density (1.3 $\mu A\,cm^{-2}$) oxidation of TTF (0.067 mmol) in anhydrous acetonitrile in the presence of equimolecular amounts (0.045 mmol) of the tetrabutylammonium (TBA) salts of the hexanuclear halomolybdate[8] and of the appropriate halide. The proportions and amounts of the two anionic components in the 30 mL electrochemical cells proved to be critical for the formation of the proper 3:1:1 stoichiometry. While

L.*), the Centre National de la Recherche Scientifique (France), and the National Science Foundation Office of International Programs (postdoctoral fellowship for *J.D.M.*). We thank *P. Auban* for her contribution to the ESR experiments.

we have found no evidence so far of other ternary phases with different stoichiometry, single crystals of a binary 11:2 phase (for example, $(TTF)_{5.5}(Mo_6X_{14})$, X = Cl, Br) have been identified, whose formation competes with that of the 3:1:1 antiperovskite; more about this will be described separately. This binary phase was obtained earlier, independently by us and by *Fuchs*,[9] when the electrocrystallization was conducted without TBA^+Y^- in the cells.

The compounds, which crystallize in the space group $R\bar{3}$ (Table 1) are isostructural. Their structure,[10] shown in Figure 1a, emphasizes the analogy with the classical representation of the cubic perovskite-cage (Fig. 1b). Attention is thus drawn to the three-dimensional framework of vertex-sharing $\{(TTF^{\bullet+})_6Y^-\}$ octahedra, with the divalent inorganic cluster anion encapsulated in the organic cage. Both the center of the cage and that of the cluster anion are located at the origin of rhombohedral unit cells (Table 1); the discrete halide ion is found at the center of the unit cell and the $TTF^{\bullet+}$ ions at the middle of the faces.

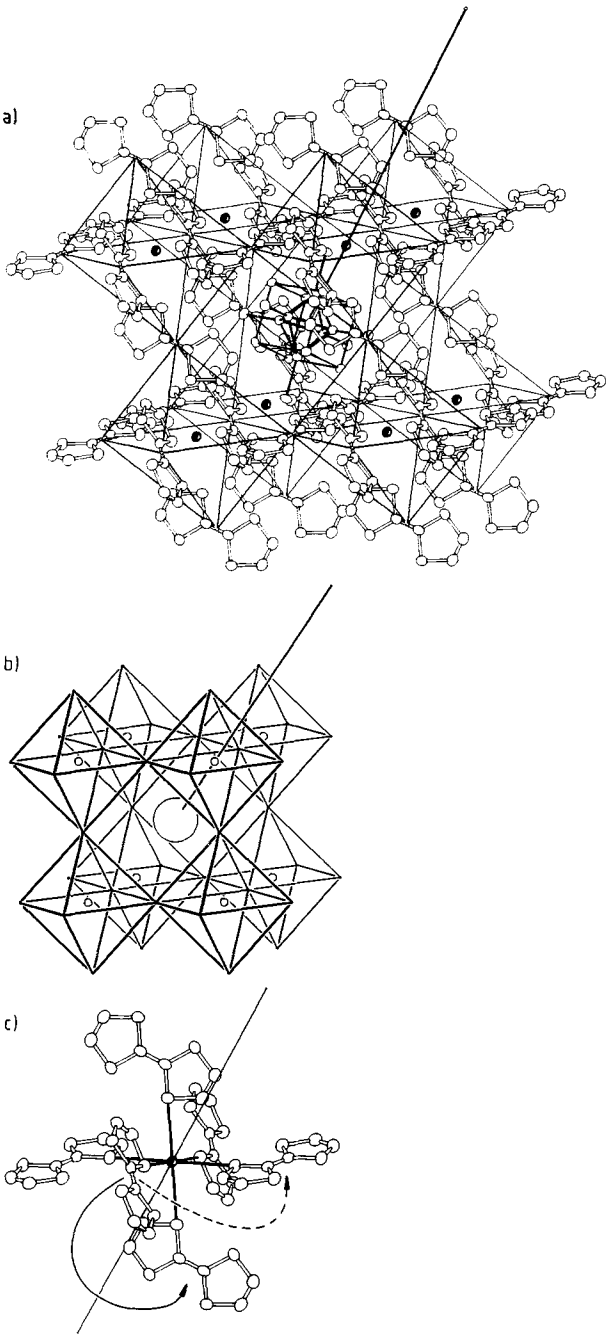

Fig. 1. a) Structural organization of the antiperovskites **1**–**4**. b) The cubic perovskite structure. c) Binding geometry within the $\{(TTF)_6^+Y^-\}$ octahedra (see text). In all figures the unique $\bar{3}$-axis direction of the $R\bar{3}$ unit cell is indicated.

Table 1. Crystallographic and magnetic data for compounds **1**–**4**.

Quantity	Unit	**1** X=Y=Cl	**2** X=Br, Y=Cl	**3** X=Y=Br	**4** X=Br, Y=I

T_{max}	K	11	13	11	8
T_N	K	8.2	8.2	7.5	6.3

[a] N = number of the observed intensities, corrected for absorption such that $I \geq 3\sigma(I)$. [b] R and R_w are the residuals for the structure factors and their weighted sum, respectively. [c] The observed Curie constants C are given in cgs units per mol TTF (in SI units this is 3.75 JT^{-2}K); the calculated value is 0.3723 emu. mol^{-1} for $S = 1/2$ and $g = 2$.

The analysis of the crystal structures reveals a set of six symmetry-equivalent, short S–Y contacts (Table 1). These might be primarily responsible for the binding geometry inside the octahedral motif, since the orientation of the $TTF^{\bullet+}$ ions on their lattice site is such as to satisfy quasilinear C–$S^{\delta+}\cdots Y\cdots{}^{\delta+}$S–C electrostatic interactions across the central halide ion (Fig. 1c). Therefore, the small rhombohedral distortions in the unit cell would specifically reflect the offset between the former direction of optimum, long range Coulomb forces[11] and that of the unit-cell translational symmetry vector linking the centroids of the TTF ions. This is a novel type of geometrical distortion for the perovskite structure, since the quadratic, rhombohedral, and orthorhombic distortions commonly observed in inorganic compounds result rather from the mismatch between the metal–oxygen and the metal–halide bond lengths.[12]

We then observe that this novel distortion of the perovskite structure demonstrated in this series of isostructural salts allows for a striking crystallographic expression of the anisotropic shape and binding capabilities of their common organic component when assembled with essentially spherical inorganic counterparts. A macroscopic manifestation of this molecular shape-selective binding symmetry is to be found in the actual rhombohedral habit of the single crystals.

The $TTF^{\bullet+}$ centers are 6.754 ($\bar{3}$-axis related) and 8.272 Å (for **1**) to 6.984 and 8.521 Å (**4**) apart along the edges of the $\{Y^-(TTF^{\bullet+})_6\}$ octahedra. This is another remarkable feature of this three-dimensional network of organic cation radicals, given the propensity of such planar aromatic cations to overlap and favor electron delocalization along one-dimensional stacks of closely spaced molecules (3.47 Å). As expected then, the compounds **1**–**4** are insulating.

As follows from the temperature dependence of their static magnetic susceptibilities, the compounds are paramagnetic down to low temperatures (as shown for example for **3** in Fig. 2). Above 50 K, the data obey the Curie–Weiss law, and the observed and calculated Curie constants and effective magnetic moments (Table 1) are in excellent agreement with the assumption of one spin per TTF molecule. The data also reveal (Fig. 2) that the susceptibility of each compound goes through a maximum at the temperatures T_{Max} given in Table 1. The magnetic susceptibilities were measured at var-

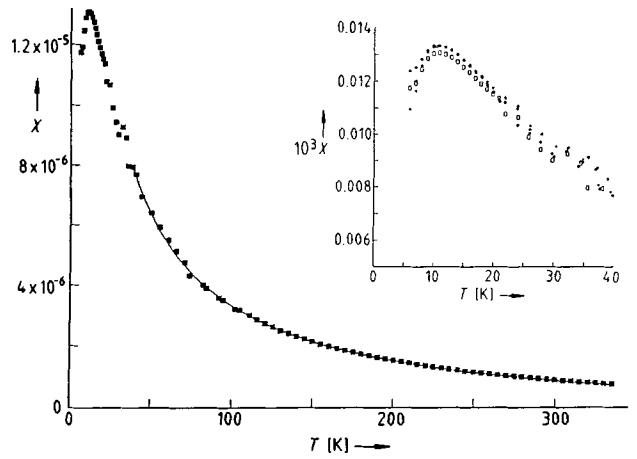

Fig. 2. Temperature dependence of the specific magnetic susceptibilities (in cgs units) measured directly on some single crystals of **3** using a SQUID susceptometer. The solid lines represent the fit of the data to $\chi = \chi_0 + C(T + \theta)^{-1}$. The observed Curie constants and Weiss temperatures for **1**–**4** are given in Table 1. The inset shows that T_{max} is independent of the field strength. o = 1 kOe, ● = 2 kOe, □ = 5 kOe, ■ = 50 kOe. χ in emu g^{-1}.

ious field strengths from 50 kOe (3.98×10^6 A m^{-1}) down to 1 kOe, and T_{Max} values were found to be independant of the field. A typical example is given for **3**, between 5 and 40 K, in the insert of Figure 2. These indications of anisotropic antiferromagnetic (AF) fluctuations suggest the possibility of AF ordering at lower temperature.

This assumption was suppported by single-crystal electron spin resonance (ESR) experiments showing in each case that the narrow single line observed in the paramagnetic regime, with Lorentzian shape and isotropic characteristics typical of $TTF^{\bullet+}$ spins,[13] abruptly vanishes in a few tenths of a degree at Néel temperatures (T_N) lower than T_{max} (Table 1). Finally, the observation of antiferromagnetic resonances (AFMR) below T_N definitely confirms the existence of magnetic ordering.

So far we have only incomplete information on the mechanism of the magnetic interaction. A classical description[14] of the perovskite structure requires, however, that **1**–**4** are built up by the stacking of pseudo-close-packed $(TTF^{\bullet+})_3$-$(Mo_6X_{14}^{2-})$ layers which form octahedral holes occupied by the discrete halide ions Y^-. Owing to the rhombohedral distortion there is only one such stacking direction in the structure, that is the layers of organic spins are stacked along the unique threefold inversion axis. The most likely interactions are either the two through-space interactions symbolized by the arrows in Figure 1c, or the indirect *trans*-coupling across the halide at the center of the octahedron. Extended Hückel-type calculations[15] demonstrate that the latter coupling is extremely weak. Remarkably, the strongest interaction is between the TTF ions related by symmetry by the $\bar{3}$-axis (solid arrow in Fig. 1c). These interactions (5×10^{-2} eV in **2**) are about three times stronger than those between the TTF ions *not* related by symmetry (dashed arrow in Fig. 1c) and indeed thirteen times stronger than the indirect *trans*-coupling. This would suggest that most of the magnetic interaction might occur by direct exchange between spins of successive layers.

The quantitative analysis of the AFMR rotation patterns provides information on the magnetic anisotropy.[16] The AFMR spectrum is complex and composed of several narrow lines, the origin of which will be discussed in a separate paper. However, the evolution of the mean position of the spectrum as a function of the field orientation for **1**–**4** is reminiscent of the room temperature crystal structure symmetry. That is, we find that the single $\bar{3}$-axis, actually the short diagonal of the crystals, is the magnetic hard axis. In addition there exists an easy plane, that is the spin-flop field vanishes ($H_{SF} = 0$). These results agree with the absence of any sizeable field dependence of the magnetic susceptibility below T_N. Thus, with this approximation, we are left with only one adjustable parameter to describe the anisotropy of the system, that is, $H^+ = \hbar\Omega_+/\mu_B$.[16a] Preliminary estimations yield an H^+ field strength on the order of 5 kG, a value similar to those found previously for other TTF-based charge transfer salts.[16b] This convincingly supports the hypothesis that the magnetic anisotropy has the same origin, i.e. is due to magnetic dipolar interactions.[17]

Altogether, the structural analysis and molecular orbital calculations are consistent with the ESR and AFMR experiments and favor a direct exchange mechanism for the antiferromagnetic ordering. Thus, the strength and anisotropy of the magnetic interaction are expected to be very sensitive to even small modifications of the $\{(TTF^{\bullet+})_6Y^-\}$ octahedral geometry. The electrochemical assembling of three components associated with the control of the site location of the molecular ions, allows for many substitutions in these series of compounds. One possible aim is the synthesis of a related molecular equivalent of the K_2NiF_4-type of structure, particularly with the prospect of the occurrence of two-dimensional magnetic ordering reminiscent of the antiferromagnetic phase of La_2CuO_4;[18] this would require the stabilization of single perovskite layers, which might be achieved by decoupling the $(TTF)_6$ octahedra either by alloying with unsymmetrical TTF ions or by using bulkier divalent cluster anions. Such possibilities are being explored.

Solvated Electrons in the Synthesis of Ionic Clusters in Zeolites**

By *Paul A. Anderson,* Donald Barr*, and *Peter P. Edwards**

It has long been known that the interaction of alkali metal vapor with certain zeolites results in the formation of paramagnetic centers such as Na_4^{3+}, Na_6^{5+}, and K_4^{3+} within the pores of the zeolite, whose presence can be detected through electron spin resonance (ESR) spectroscopy.[1, 2, 3] As a result of recent studies the existence of two more such centers, Na_5^{4+} and K_3^{2+}, has come to light,[4, 5] suggesting that a whole series of similar species may exist. These unusual ion clusters are of interest both on account of the comparative rarity of alkali metal clusters[6] and because of their potential as basic catalysts.[7] But a major problem associated with their characterization has been that the direct reaction between zeolites and the various metal vapors tends to provide an excess of metal atoms which results in the formation of aggregates or metal particles.[2, 3] The same problem attends the alternative preparation for sodium-containing zeolites devised by *Martens* et al.,[7, 8] which involves the pyrolysis of sodium azide. Although *Yoon* and *Kochi*[9] demonstrated that a simple reduction of the sodium cations in Na-X and Na-Y zeolites by organolithium reagents resulted in the selective formation of Na_4^{3+}, we have found their method to be ineffective in other cases.

Here we present the novel use of solvated electrons, formed in situ by dissolving lithium metal in primary amines, as a welcome solution to this problem. The solvated electron solutions are powerful enough reagents that they have the potential to reduce the cations of virtually any zeolite. Although the reduction of a substantial proportion of the zeolite cations can be achieved in this manner, the concentration of the solutions is easily controlled to enable the preparation of ionic clusters in the absence of excess metal atoms. In fact, the scope of this new method is much wider than that: the solvated electron solutions also facilitate the reduction of certain zeolites (those containing lithium for instance) that tend to decompose when exposed to alkali metal. This has enabled us to compare the ESR parameters of Na_4^{3+} in a range of zeolites and to report the discovery of another new cluster, Na_3^{2+}.

The reduction of three of the zeolites used in this work resulted in compounds whose ESR spectrum exhibited the hyperfine pattern of thirteen lines characteristic of the Na_4^{3+} cluster.[1, 9] The *g*-values and hyperfine splittings are given in Table 1. The selective reduction of the Na-X zeolite to produce the Na_4^{3+} cluster is of particular interest, since that zeolite plays host to different paramagnetic centers when treated with alkali metal vapor.[4] Similar selectivity was observed by *Yoon* and *Kochi*[9] in their reduction of Na-X with organolithium reagents. The origin of these differences must lie either in the fact that the reaction with metal vapor necessarily takes place at temperatures above ambient, or in the presence of solvent molecules within the zeolite structure. The Na_4^{3+} cluster can also be formed through the exposure of dehydrated Na-Y to γ-rays.[10] Having found that the irradiation of dehydrated Na-X did not produce Na_4^{3+}, we conclude that, under vacuum, the zeolite is not disposed to the creation of that cluster, and that the effect of the solvent is critical. Remarkably, Na_4^{3+} was also the product of the reduction of $Li_{44}Na_{12}$-Y. Evidently in this case the valence electron of the cluster prefers to associate with the sodium ions rather than with those of lithium which heavily outnumber them. Since the residual charge on a lithium ion in dehydrated zeolite Y is calculated to be less than one sixth of that on a sodium ion in a similar site,[11] this is perhaps not surprising.

The apparent inertness of lithium in this respect led us to attempt the preparation of new sodium clusters containing fewer than four cations by restricting the concentration of sodium ions in the zeolite to a minimum. Success was achieved in the reduction of $Li_{50}Na_6$-Y and $Li_{82}Na_5$-X, to give the colored solids whose ESR spectra are reproduced in Figure 1.[12] The reduction of $Li_{50}Na_6$-Y produced a purple-gray solid whose spectrum (Fig. 1 a) consisted of a hyperfine pattern of ten lines with $a = 4.50 \pm 0.10$ mT and $g = 2.002 \pm 0.001$. Ten lines are expected from an electron interacting with three equivalent nuclei with nuclear spin $I = 3/2$, but although both the ^{23}Na nucleus and the more abundant isotope of lithium (^7Li) have spin $I = 3/2$, the unambiguous assignment of the hyperfine pattern of reduced $Li_{44}Na_{12}$-Y

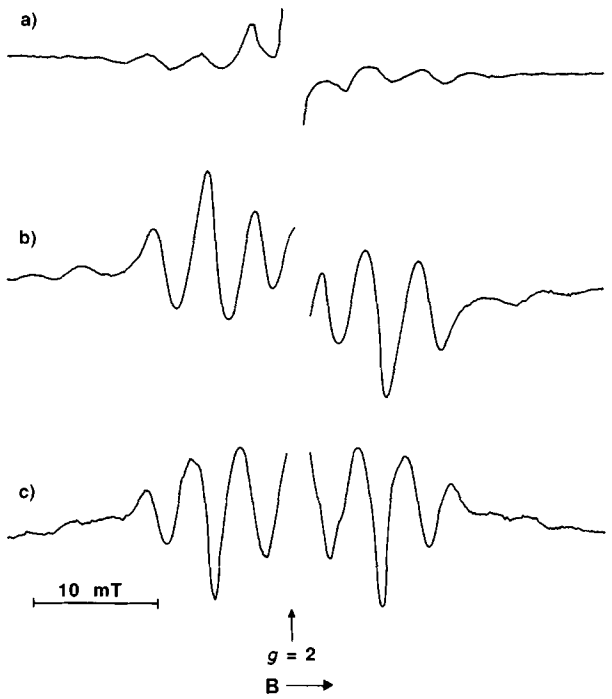

Fig. 1. a) The ESR spectrum of $Li_{50}Na_6$-Y reduced by a solution of lithium metal in propylamine, b) the first derivative, and c) the second derivative spectrum of $Li_{82}Na_5$-X after similar treatment.

Table 1. The *g*-values and hyperfine splittings (*a*) of Na_4^{3+} clusters, prepared by reduction of certain zeolites with solvated electron solutions.

Zeolite[a]	Si/Al	Color	*g*-value	*a* [mT] (298 K)
Na_{56}-Y	2.4	violet-pink	2.003 ± 0.001	3.33 ± 0.10
Na_{87}-X	1.2	purple	2.001 ± 0.001	2.92 ± 0.10
$Li_{44}Na_{12}$-Y	2.4	pinkish gray	2.0025 ± 0.0025	3.75 ± 0.10

to Na_4^{3+}, and the lack of other lines due to ^6Li, means that the pattern of ten lines recorded from $Li_{50}Na_6$-Y may be regarded with confidence as the first observation of an Na_3^{2+} cluster.

The deep pink solid obtained from the reduction of $Li_{82}Na_5$-X exhibited a more complex ESR spectrum (Fig. 1 b and c). Although the pattern was symmetric about its midpoint ($g = 2.0028 \pm 0.0005$), the spacing of the lines was not constant, a clue that more than one component was involved. Figure 2 shows simulations of the first and second derivative spectrum expected from a sample containing an equal number of Na_4^{3+} and Na_3^{2+} centers. The simulations reproduce many features of the experimental spectrum (this is particularly clear in the second derivative), suggesting that the zeolite plays host to two such clusters in roughly equal numbers. A similar situation occurs in zeolite Na-X after reaction with alkali metal vapor, where the ESR spectrum provides proof of the presence of both Na_5^{4+} and Na_6^{5+} clusters.[4]

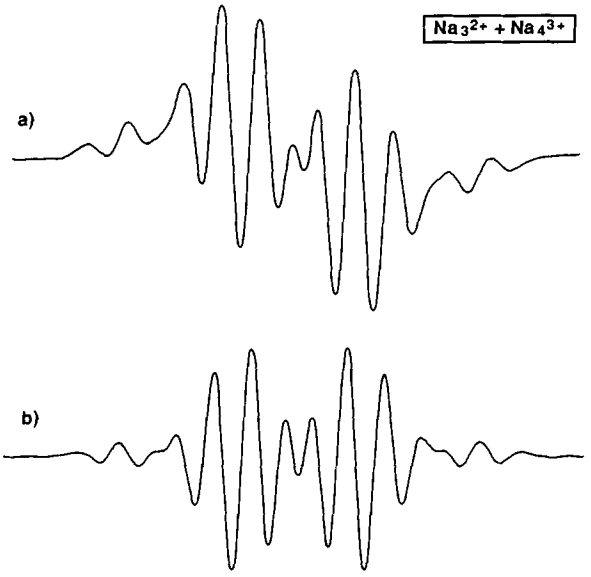

Fig. 2. Simulated ESR spectrum for an equal mixture of Na_3^{2+} and Na_4^{3+} centers: a) first, b) second derivative.

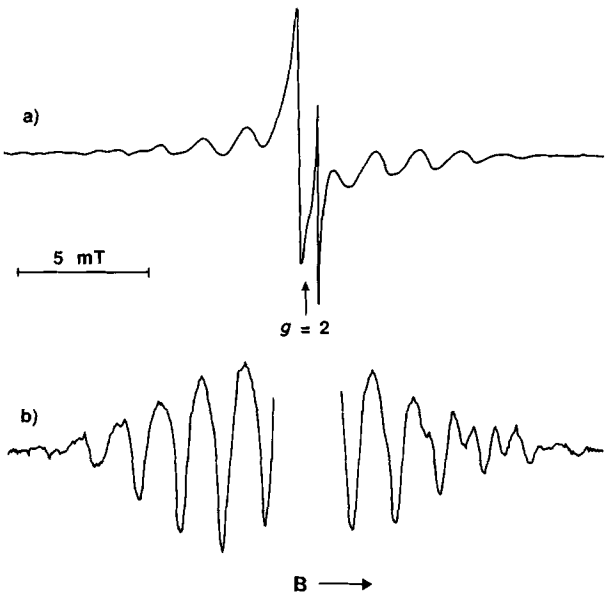

Fig. 3. The ESR spectrum of K_{56}-Y reduced by a solution of lithium metal in butylamine: a) first derivative, b) second derivative.

The reduction of zeolites K_{56}-Y and K_{87}-X produced brilliant blue solids, whose ESR spectra were qualitatively similar to those observed after the reaction of the same zeolites with potassium vapor,[2, 3, 5] and betray the presence of K_4^{3+} and K_3^{2+} respectively. In the absence of excess potassium atoms, the spectrum of K_{56}-Y reduced by the solvated electron solution (Fig. 3) is much better resolved than that obtained after exposure of the same zeolite to potassium vapor. The second derivative in particular clearly shows the secondary lines on the high field side of the spectrum, first noted by *Harrison* et al.[3] These lines may indicate the presence of other paramagnetic centers or may simply result from anisotropy in the spectrum of K_4^{3+} itself. Further studies are in progress to investigate this point.

Experimental Procedure

Zeolites Na_{56}-Y (silicon to aluminum ratio $r = 2.4$) and Na_{87}-X ($r = 1.2$) were supplied by Laporte, from which samples containing potassium and lithium cations were prepared by standard ion exchange.[13] The crystallinity of the resultant solids was checked by powder X-ray diffraction and their composition determined by atomic absorption.

In preparation for reaction, a suitable amount of zeolite (typically ca. 1 g) was placed in a pyrex Schlenk tube, which had been soaked in strong detergent, rinsed thoroughly with tap water and distilled water, and fired overnight at 500 °C. The vessel was then connected to a vacuum line, heated gradually to 450 °C, and evacuated overnight to ca. 10^{-5} mbar. The zeolite was subsequently placed in suspension in propylamine or butylamine, under an argon atmosphere, to await the addition of high-purity lithium shot, which had been cleaned in hexane, toluene, hexane again, and finally by stirring for several hours under argon in the same amine. This cleaning procedure was found to be particularly effective in thoroughly removing the oxide/nitride coating from the surface of the lithium granules. If at any stage the stirrer was switched off, the characteristic blue color of solvated electrons could be seen diffusing from the surface of the lithium into the bulk of the amine. After the suspension was stirred for up to 72 hours, it was filtered to yield a colored solid, which was washed with hexane and taken into an argon glovebox to be loaded into an airtight ESR tube. First and second derivative ESR spectra of the products were recorded at room temperature on a Varian ER-109 spectrometer operating at X-band frequencies (ca. 9.3 GHz).

Chemoenzymatic Syntheses of Sialyloligosaccharides with Immobilized Sialidase**

By *Joachim Thiem** and *Bernd Sauerbrei*

Sialylated oligosaccharides participate in many biological processes as components of glycoproteins and -lipids.[1a, b] They have essential functions as terminal structures in cell receptors[1c, d] for the specific binding of viruses, blood-group- and tumor-recognizing antibodies, bacterial toxins, and a variety of lectins.[1a, e, f] To understand these recognition phenomena on a molecular basis, studies with comparable substances are needed. Although their syntheses by classical chemical routes is possible, the procedures often still involve many steps and are complicated.[2] The promising chemoenzymatic access through the use of sialyltransferases has already become a preparative technique.[3] The isolation of these enzymes is, however, laborious since especially the (2–3)-sialyltransferases occur in animal tissues only in very low concentrations and are extremely unstable. Furthermore, the pronounced acceptor specificity of the transferases limits their synthetic potential.[2d, 3b]

At first our attention focused mainly on the synthesis of partial structures common in nature in which *N*-acetylneuraminic acid (**1**, Neu5Ac) is terminal and α(2–3)- and α(2–6)-glycosidically bonded to β-galactose. Moreover, we were interested in the preparation of unusual and nonphysiological sialyloligosaccharides.

In order to make sialidase (EC 3.2.1.18) useful for the synthesis of sialyloligosaccharides, it was first necessary to investigate whether it showed transferase activity besides its significant physiological hydrolysis activity. Also, in analogy to successful reactions with other glycosidases,[4] experiments with reverse hydrolysis and transglycosylation were performed (Fig. 1).

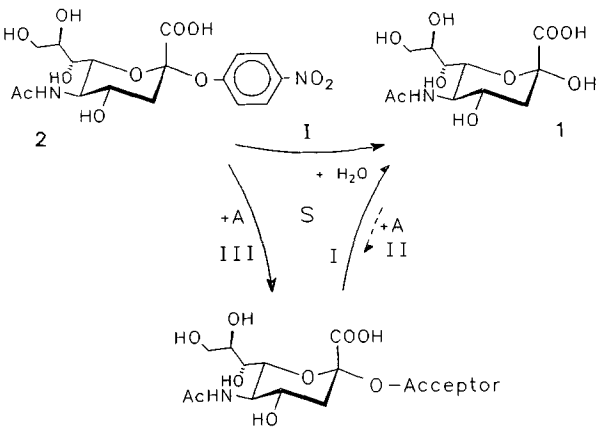

Fig. 1. Sialidase catalysis of transsialylation and potential side reactions. I = hydrolysis, II = reverse hydrolysis, III = transglycosylation; A = acceptor, S = sialidase.

Sialidase from *Vibrio cholerae*[5] (1 U mL^{-1}) was immobilized on a polymeric carrier (VA-epoxy, Riedel-de Haën). In this way the enzyme could be reused several times, and the enzyme incubation could be interrupted at a particular point by separating it completely from the protein. Binding to the carrier was achieved by reaction of the amino functions of the protein with the epoxide groups of the carrier material.[6] After the immobilized enzyme had been freeze-dried, the activity yield was 68% (1.36 U per g carrier). Shaking for six days at 26 °C in the incubation buffer caused an additional activity loss of 24%. The activities of the immobilized enzyme and the free enzyme were determined by hydrolytic cleavage of *p*-nitrophenyl 5-acetamido-3,5-dideoxy-α-D-*glycero*-D-*galacto*-2-nonulopyranosylonic acid (**2**, αNeu5Ac-O(pNPh)). The amount of *p*-nitrophenolate formed was determined photometrically at 400 nm (Fig. 1).[7]

The acceptor molecules for the sialylations are likewise accessible chemoenzymatically. Thus the galactosylation of *N*-acetylglucosamine by galactosyltransferase and UDP-galactose is a proven method for the preparation of *N*-acetyllactosamine (**11**).[8] The donor **2**, on the other hand, can be easily obtained by nonenzymatic techniques from **1** in six steps. In this sequence the transformation of glycosyl chloride by *p*-nitrophenolate is the key reaction.[7]

Transformations according to the principle of reverse hydroloysis are conducted at relatively high temperatures, high acceptor concentrations, and with the free sugar as donor.[4a] This treatment of **1** (lyophilized from aqueous solution after the pH value was adjusted to 6.4 with dilute NaOH) in a 7.8 M solution of methyl β-D-galactopyranoside (**3**, molar ratio 1:13) with sialidase at 44 °C afforded the methyl(5-acetamido-3,5-dideoxy-α-D-*glycero*-D-*galacto*-2-nonulopyranosylonic acid)-β-D-galactopyranoside **4a, b** (αNeu5Ac-βGal-OCH$_3$) in only 1% yield. The ratio of (2–3)- to (2–6)-bonded isomer was 1:10 according to the ^{1}H NMR spectrum.

In contrast to reverse hydrolysis, transglycosylations are usually conducted at low temperatures and in general give higher yields.[4a] However, they require donors in which the sugar to be transferred is in an activated form, for example as glycoside. At first this principle was applied with **2** as donor, **3** as acceptor, and the free enzyme, at 26 °C. The degradation of **2** was followed photometrically at 400 and 303 nm (absorptions of **2**). To minimize the hydrolysis of the products, the incubations were stopped as soon as 65–75% of the starting material had reacted. Variation of the acceptor concentrations had substantial influence on both the yield and the ratio of the isomeric products (Table 1). In all cases, however, the (2–6)-isomer predominated, which probably is attributable to a partial hydrolytic cleavage of the products because sialidase from *Vibrio cholerae* hydrolyses the (2–3)-isomer faster than the (2–6)-isomer.[9] A further increase in yield can be achieved by using immobilized sialidase. The reason for this is not known.

Table 1. Transsialylation with free sialidase. Donor: αNeu5Ac-O(pNPh) **2**; acceptor: βGal-OCH$_3$ **3**.

Molar ratio donor : acceptor	Acceptor concentration [mol L^{-1}]	Total yield [%]	Molar ratio **4a** : **4b**
1 : 4	0.67	1.8	1 : 1.6
1 : 7	2.37	9.5	1 : 5.8
1 : 15	3.37	5.4	1 : 9.0

The incubation conditions and results for the acceptors investigated are listed in Table 2. The coupling pattern of the synthesized di- and trisaccharides have been established by ^{1}H NMR spectroscopy (Table 3). The biologically important (2–3)- and (2–6)-glycosidic bonds of αNeu5Ac to β-galac-

4a: δ = 4.31 (d, 1H, H-1, $J_{1,2}$ = 8.0 Hz), 3.57 (s, 3H, OCH_3), 2.73 (dd, 1H, H-3′ eq., $J_{3'eq,3'ax}$ = 12.2 Hz, $J_{3'eq,4'}$ = 4.7 Hz), 2.04 (s, 3H, NAc), 1.69 (dd, 1H, H-3′ax, $J_{3'ax,4'}$ = 12.2 Hz); **4b**: δ = 4.39 (d, 1H, H-1, $J_{1,2}$ = 8.0 Hz), 4.08 (dd, 1H, H-3, $J_{2,3}$ = 9.7 Hz, $J_{3,4}$ = 3.2 Hz), 3.57 (s, 3H, OCH_3), 2.75 (dd, 1H, H-3′ eq, $J_{3'eq,3'ax}$ = 12.0 Hz, $J_{3'eq,4'}$ = 4.6 Hz), 2.04 (s, 3H, NAc), 1.78 (dd, 1H, H-3′ax, $J_{3'ax,4'}$ = 12.0 Hz); **6a**: δ = 4.81 (d, 1H, H-1, $J_{1,2}$ = 3.3 Hz), 3.41 (s, 3H, OCH_3), 2.73 (dd, 1H, H-3′ eq, $J_{3'eq,3'ax}$ = 12.3 Hz), $J_{3'eq,4'}$ = 4.6 Hz), 2.04 (s, 3H, NAc); 1.68 (dd, 1H, H-3′ax, $J_{3'ax,4'}$ = 12.3 Hz); **6b**: δ = 4.88 (d, 1H, H-1, $J_{1,2}$ = 3.3 Hz), 4.30 (dd, 1H, H-3, $J_{2,3}$ = 10.0 Hz, $J_{3,4}$ = 2.6 Hz), 3.41 (s, 3H, OCH_3), 2.73 (dd, 1H, H-3′eq, $J_{3'eq,3'ax}$ = 12.3 Hz, $J_{3'eq,4'}$ = 4.6 Hz), 2.04 (s, 3H, NAc), 1.81 (dd, 1H, H-3′ax, $J_{3'ax,4'}$ = 12.3 Hz); **8a**: δ = 4.38 (d, 1H, H-1, $J_{1,2}$ = 8.0 Hz), 3.57 (s, 3H, OCH_3), 2.75 (dd, 1H, H-3′eq, $J_{3'eq,3'ax}$ = 12.4 Hz, $J_{3'eq,4'}$ = 4.8 Hz), 2.03 (s, 3H, NAc), 1.72 (dd, 1H, H-3′ax, $J_{3'ax,4'}$ = 12.1 Hz); **8b**: δ = 4.51 (d, 1H, H-1, $J_{1,2}$ = 8.0 Hz), 4.12 (dd, 1H, H-3, $J_{2,3}$ = 10.0 Hz, $J_{3,4}$ = 10.0 Hz), 3.57 (s, 3H, OCH_3), 2.71 (dd, 1H, H-3′eq, $J_{3'eq,3'ax}$ = 12.4 Hz, $J_{3'eq,4'}$ = 4.8 Hz), 2.04 (s, 3H, NAc), 1.77 (dd, 1H, H-3′ax, $J_{3'ax,4'}$ = 12.4 Hz); **10a**: δ = 4.43 (d, 1H, H-1, $J_{1,2}$ = 8.0 Hz), 4.41 (d, 1H, H-1′, $J_{1',2'}$ = 8.0 Hz), 3.58 (s, 3H, OCH_3), 2.71 (dd, 1H, H-3″eq, $J_{3''eq,3''ax}$ = 12.5 Hz, $J_{3''eq,4''}$ = 4.6 Hz), 2.02 (s, 3H, NAc), 1.75 (dd, 1H, H-3″ax, $J_{3''ax,4''}$ = 12.5 Hz); **10b**: δ = 4.52 (d, 1H, H-1′, $J_{1',2'}$ = 7.9 Hz), 4.39 (d, 1H, H-1, $J_{1,2}$ = 8.1 Hz), 4.11 (dd, 1H, H-3′, $J_{2',3'}$ = 10.0 Hz), 3.58 (s, 3H, OCH_3), 2.75 (dd, 1H, H-3″eq, $J_{3''eq,3''ax}$ = 12.5 Hz, $J_{3''eq,4''}$ = 4.9 Hz), 2.02 (s, 3H, NAc), 1.79 (dd, 1H, H-3″ax, $J_{3''ax,4''}$ = 12.5 Hz; **12a**: δ = 5.18 (d, 1H, H-1α, $J_{1,2}$ = 2.2 Hz), 4.44 (d, 1H, H-1′, $J_{1',2'}$ = 8.0 Hz), 2.67 (dd, 1H, H-3″eq, $J_{3''eq,3''ax}$ = 12.4 Hz, $J_{3''eq,4''}$ = 4.5 Hz), 2.07 (s, 3H, NAc (βGlcNAc)), 2.03 (s, 3H, NAc (αNeu5Ac)), 1.71 (dd, 1H, H-3″ax, $J_{3''ax,4''}$ = 12.4 Hz); **12b**: δ = 4.54 (d, 1H, H-1′, $J_{1',2'}$ = 8.0 Hz), 4.11 (dd, 1H, H-3′, $J_{2',3'}$ = 9.1 Hz, $J_{3',4'}$ = 2.8 Hz), 2.77 (dd, 1H, H-3″eq, $J_{3''eq,3''ax}$ = 12.2 Hz, $J_{3''eq,4''}$ = 4.4 Hz), 2.04 (s, 3H, NAc (αNeu5Ac)), 2.05 (s, 3H, NAc (βGlcNAc)), 1.80 (dd, 1H, H-3″ax, $J_{3''ax,4''}$ = 12.2 Hz).

tose are achieved in the products **4a**, **4b**, **10a**, **10b**, **12a**, and **12b** (Table 4). A general rule holds: the larger the acceptor, the smaller the yield.

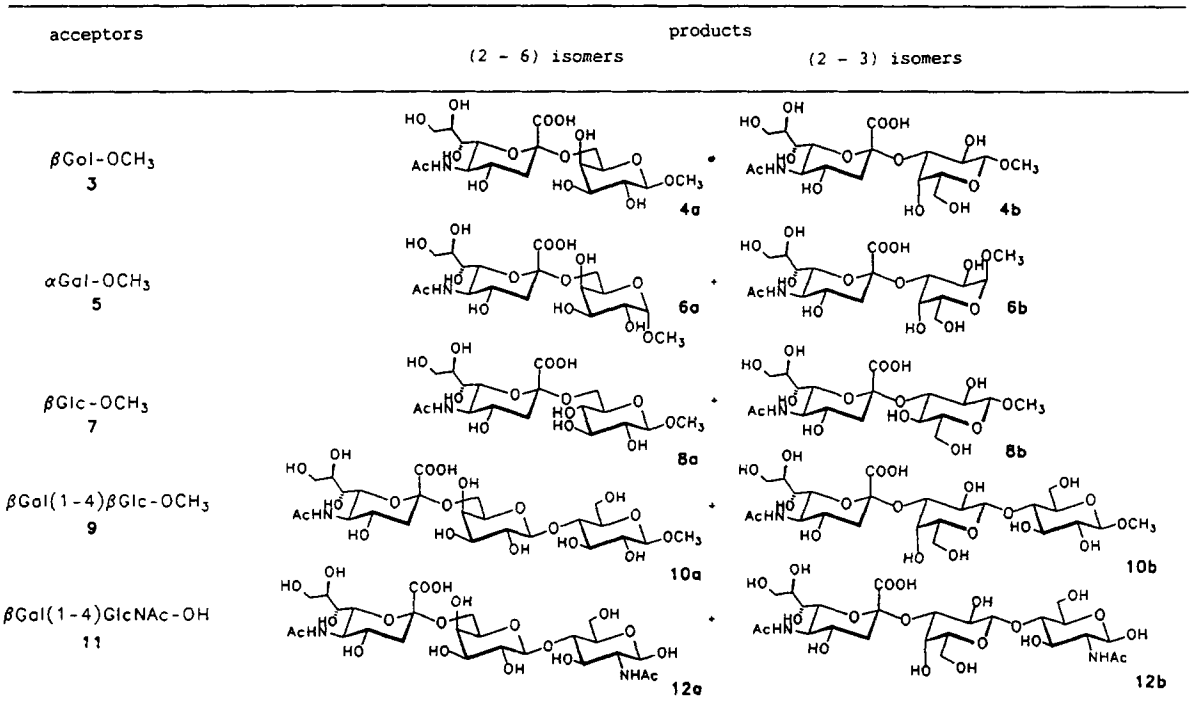
The acceptor **3** was not only treated under the standard conditions, but also in a 30% by volume dimethylsulfoxide (DMSO)/water mixture. To achieve the same yield the length of the incubation period and the enzyme concentration had to be drastically increased. Nevertheless, organic cosolvents could be of interest for effective sialylation of less polar acceptors.

The saccharide structure of **10b** is a frequently occurring fragment in gangliosides,[1b] while no biological relevance has yet been proved for the (2–6)-bonded analogue **10a** and for **6a**, **6b**, and **8b**. Compounds **12a** and **12b** are universal building blocks, mainly for *N*-glycosidic glycoproteins, but also for gangliosides.[11] The sialylation of β-glucose at the 6-position, realized in **8a**, has as yet been found only sporadically in nature in gangliosides[10a] and in glycolipids from sea urchins of the species *Strongylocentrotus intermedius*.[10b]

In comparison with the other acceptors, the transformation with methyl α-D-galactopyranoside **5** gives not only the highest total yield but also an unusual isomer ratio shifted in favor of the (2–6)-bond. This can be interpreted resulting from as a specific interaction with the enzyme that stems from the larger spatial requirements and higher hydrophobicity of the bottom side of the molecule **5**.

The yields of these syntheses of sialyloligosaccharides are smaller than those of the sialyl transferase catalyzed reactions and the regioselectivity is less pronounced. The latter feature, however, enables an uncomplicated access to the (2–3)-coupled sialyloligosaccharides, whose synthesis is un-

Table 4. Transsialylation with immobilized sialidase.



satisfactory not only with classical chemical methods, but also with the (2–3)-sialyl transferase as long as this enzyme cannot be produced in sufficient quantities by genetic engineering techniques. Also the low aglycon specificity of the sialidases proves to be an advantage, because it makes possible the sialylation of nonphysiological acceptors. Moreover, the isolation of sialidases is comparatively trouble-free, they are easy to handle, and require relatively simple substrates.

Experimental Procedure

Immobilization of the sialidases: To 1 mL enzyme solution (1 U^2mL^{-1}) and 4 mL potassium phosphate buffer (1 M, pH 7.5) was added VA-epoxy (500 mg) and the suspension was shaken for 3 d. Thereafter the immobilized enzyme was washed several times with 0.1 M potassium phosphate buffer (pH 7.5) and finally shaken with 2 mL mercaptoethanol solution (5%, pH 8.0) for 3 days at 20 °C. After renewed washing the activity yield of the lyophilized preparation was 68% (1.36 $U g^{-1}$).

Sialylation with immobilized sialidase: a) A paste was made with donor **2** (25 μmol), acceptor (175 μmol), immobilized enzyme (40 mg, 60 mU) and degassed incubation buffer (130 μL, 0.1 M NaOAc, 0.5 mM $CaCl_2$, 0.03% NaN_3, pH 5.5) and incubated at 26 °C (see Table 2). The reaction was interrupted by dilution with doubly distilled water and immediate removal of the immobilized enzyme by centrifugation. Workup by anion exchange chromatography (Dowex 1 × 2, PO_4^{3-} form) [3b] was followed by desalination by gel chromatograpy (Sephadex G15). The product fraction was monitored conductometrically. b) DMSO (30 vol.% in water) was added to the incubation buffer and procedure a) was followed.

Analytical HPLC to determine the relative amounts of the positional isomers [12] (see Table 2): Column Lichrosorb-NH_2 (5 × 240 mm), eluant 15 mM KH_2PO_4/acetonitrile 28:72, flowrate 1.2 mL min^{-1}. Detection at 200 nm.

Synthesis and Characterization of a New Binary Deca-Osmium Carbonyl Cluster Anion—An Intermediate in the Formation of Other High-Nuclearity Osmium Carbonyl Clusters; Crystal and Molecular Structure of $(Ph_4P)_2[Os_{10}(CO)_{26}]$**

By *Angelo J. Amoroso, Brian F. G. Johnson, Jack Lewis,* Paul R. Raithby*, and *Wing-Tak Wong*

We are currently interested in the synthesis of high nuclearity Ru and Os carbonyl clusters and the study of the necessary build-up processes.[1] Early work from this group has shown that the vacuum pyrolysis of Os_3 derivatives[2] (such as $[Os_3(CO)_{11}(py)]$ and $[Os_3(CO)_{10}(NCMe)_2]$) at high temperatures (> 220 °C) gives moderate to good yields of a thermodynamically very stable ion $[Os_{10}C(CO)_{24}]^{2-}$ **1**. The chemistry of this carbido cluster has been extensively studied.[3] However, little is known about the mechanism of its formation or the source of the interstitial carbide. Recently, we reported the isolation and characterization of two large osmium carbonyl clusters, $[Os_{17}(CO)_{36}]^{2-}$ **2**[4] and $[Os_{20}(CO)_{40}]^{2-}$ **3**[5] from the same solid-state pyrolysis reaction of $[Os_3(CO)_{10}(NCMe)_2]$ in vacuo. It was thus interesting for us to isolate and study some of the intermediate species that we believe are involved in cluster build-up processes.

Vacuum pyrolysis of $[Os_3(CO)_{10}(NCMe)_2]$ was investigated in the temperature range of 150–210 °C. A typical product distribution at 190 °C is: 20% $[Os_3(CO)_{12}]$, 5% $[Os_5(CO)_{16}]$, 15% $[Os_6(CO)_{18}]$, 5% $[Os_7(CO)_{21}]$, traces of $[Os_8(CO)_{23}]$, and 16% $[Os_9H(CO)_{24}]^-$ (as $(PPh_3)_2N^+$ salt). A previously unknown brown cluster anion, formulated as $[Os_{10}(CO)_{26}]^{2-}$ **4** on the basis of spectroscopic data,[8] can be isolated, as either the $(PPh_3)_2N^+$ or Ph_4P^+ salt, in reasonable yield (10% at 150 °C, 13% at 170 °C, 18% at 190 °C). Above 190 °C, substantial amounts of **1** are formed which impose problems on the purification of **4** since both have very similar chromatographic properties.

The structure of the new anion **4** has been established by an X-ray analysis of its $[Ph_4P]^+$ salt (Fig. 1).[9] The novel metal framework geometry may be described as a tricapped octahedron with an extra $Os(CO)_3$ unit on one of the caps of the octahedron. Although unusual for third row cluster carbonyls, the structure contains two bridging carbonyl ligands [C(43)–O(43) and C(93)–O(93)]. There are also two incipient bridging carbonyls, C(51)–O(51) and C(71)–O(71) [Os(10)···C(51), 2.76(3) Å, Os(10)···C(71), 2.75(3) Å], which presumably help to reduce the electronic imbalance between the formally electron-rich osmium atoms, Os(5) and Os(7) (19 e^- each) and the electron-poor osmium atom, Os(10) (17 e^-). The individual formal electron counts for the metal atoms reflect the uneven electron distribution within the cluster framework; Os(6), Os(8), and Os(10) are formally electron-poor, each with a count of 17 e^- and with three terminal COs bonded to each metal; Os(1) has a count of 18 e^- with two terminal COs bonded to it; Os(2), Os(4), and Os(9) each have a count of 18 e^- and each metal is associated with two terminal and one bridging CO; Os(7) has a count of 19 e^- and is coordinated to two terminal and one

bridging CO; Os(5) is also electron-rich with a count of 19 e^- and has two coordinated terminal COs; Os(3) has a count of 19 e^- and has three terminal CO ligands. In terms of overall electron counting, the species is a 134 e^- system, which may be rationalized in terms of the Condensed Polyhedral approach,[6] and is isoelectronic with $[Os_{10}C(CO)_{24}]^{2-}$ **1**.

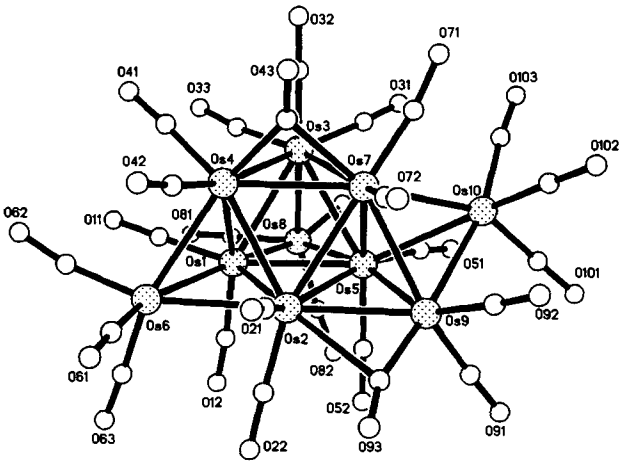

Fig. 1. The molecular structure of **4** in the crystal showing the atom numbering scheme. Selected bond distances [Å] and angles [°]: Os1-Os2, 2.738(2); Os1-Os3, 2.789(2); Os1-Os4, 2.787(2); Os1-Os5, 2.770(2); Os1-Os6, 2.722(2); Os1-Os8, 2.678(2); Os2-Os4, 2.804(2); Os2-Os5, 2.849(2); Os2-Os6, 2.840(2); Os2-Os7, 2.860(2); Os2-Os9, 2.768(2); Os3-Os4, 2.908(2); Os3-Os5, 2.825(2); Os3-Os7, 2.941(2); Os3-Os8, 2.925(2); Os4-Os6, 2.810(2); Os4-Os7, 2.807(2); Os5-Os7, 2.772(2); Os5-Os8, 2.806(2); Os5-Os9, 2.778(2); Os5-Os10, 2.868(2); Os7-Os9, 2.809(2); Os7-Os10, 2.816(2); Os9-Os10, 2.739(2); Os4-C43, 2.04(3); Os7-C43, 2.21(3); Os9-C93, 1.91(3); Os2-C93, 2.55(3); Os4-C43-O43, 143(3); Os7-C43-O43, 134(3); Os4-C43-Os7, 82(1); Os2-C93-O93, 124(2); Os9-C93-O93, 161(3); Os2-C93-Os9, 75(1).

Both the structures for **1** and **4** may be derived from PSEP theory (PSEP = Polyhedral Skeleton Electron Pair) with $S = 7$ and $n = 10$, since the asymmetric structure of **4** is isomeric to the symmetric tetracapped octahedron **1**.[2] However, the more open metal framework of **4** generates additional coordination sites on the periphery of the cluster which can accommodate the two extra carbonyl groups in comparison with **1**. The metal frameworks in both **1** and **4** may be thought of as derived from the tricapped octahedral arrangement recently reported[7] for $[Os_9H(CO)_{24}]^-$ **5** by the addition of the tenth metal atom to a different triangular face.

The subsequent vacuum pyrolysis of **4** as Bu_4P^+ or Ph_4P^+ salts, at 230 °C, leads to **1** (> 85 %), **3** (< 5 %), and other uncharacterized products in trace quantities. The yield of **3** increases as the temperature of the pyrolysis increases. At 300 °C, yields of **1** and **3** are 60 % and 25 % respectively. Both CO and CO_2 evolved in this reaction, have been trapped and identified by their characterized IR absorption spectra (P and R bands centered at 2352 cm^{-1} for CO_2; 2143 cm^{-1} for CO). On the basis of these observations, it is reasonable to believe that **4** is the common precursor for **1** [Eq. (a)] and **3** [Eq. (b)] in the vacuum pyrolysis of $[Os_3(CO)_{10}(NCMe)_2]$ at high temperatures (see Scheme 1).

$[Os_{10}(CO)_{26}]^{2-}$ **4** $[Os_{10}C(CO)_{24}]^{2-}$ **1** $[Os_{20}(CO)_{40}]^{2-}$ **3**

Scheme 1. Conversion of **4** into **1** and **3**.

Experimental Procedure

To a flame-dried Carius tube (180 cm^3), solid $[Os_3(CO)_{10}(NCMe)_2]$[10] (1.0 g) was introduced as a suspension in hexane (5 mL). The solvent was removed under reduced pressure to give a thin layer of the Os_3-compound deposited on the inner wall of the tube. It was evacuated to 10^{-3} torr for 2 hours and sealed at this pressure. This compound was pyrolyzed at the required temperature (150–190 °C) for 12 hours to give a dark brown powder, which was first extracted with CH_2Cl_2 (50 mL) to remove $[Os_5(CO)_{16}]$, $[Os_6(CO)_{18}]$, $[Os_7(CO)_{21}]$, and $[Os_8(CO)_{23}]$. The brown CH_2Cl_2 insoluble residue, mainly consisting of $[Os_3(CO)_{12}]$, $[H_2Os_9(CO)_{24}]$, and $[H_2Os_{10}(CO)_{26}]$, was extracted with acetone (10 mL) to give a dark brown solution and a yellow powder of $[Os_3(CO)_{12}]$. Separation of the acetone extract by thin-layer chromatography (silica gel) using acetone/hexane (1/1) as eluent, gave an orange-brown band of $[Os_9H(CO)_{24}]^-$ **5** ($R_f \sim 0.6$) and a dark brown band of $[Os_{10}(CO)_{26}]^{2-}$ **4** ($R_f \approx 0.2$). The $(PPh_3)_2N^+$ salt of **5** (167 mg, 16 %) and Ph_4P^+ salt of **4** (191 mg, 18 %) were obtained through cation metathesis with $[(PPh_3)_2N]Cl$ and $(Ph_4P)Br$ respectively and crystallized by slow evaporation of a solution of the salt in CH_2Cl_2/ethanol (1/1).

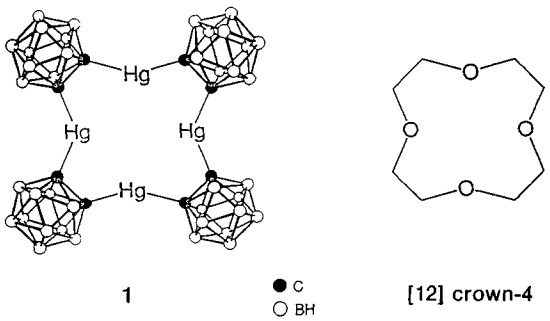
"[12]Mercuracarborand-4", the First Representative of a New Class of Rigid Macrocyclic Electrophiles: The Chloride Ion Complex of a Charge-Reversed Analogue of [12]Crown-4 **

By *Xiaoguang Yang, Carolyn B. Knobler,* and *M. Frederick Hawthorne**

Dedicated to Professor Donald J. Cram

Until very recently the field of molecular recognition has been dominated by studies of electrophilic guests surrounded by preorganized nucleophilic host molecules.[1] Molecular recognition of anionic guests by similarly preorganized Lewis acid hosts has only lately been achieved[2-5] and offers new prospects for selective molecular recognition, anion transport, and the catalytic activation of electron-rich organic and inorganic substrates.[3c, 6] In all known cases, electrophilic hosts that employed tin,[2] mercury,[3] silicon,[4] and boron[5] atoms as binding sites for anion guests function as bidentate or bisbidentate Lewis acids, although a few potential tridentate silicon- and tin-containing hosts have been reported.[2d, 2e, 4]

Wuest and co-workers recently described a series of halide complexes of 1,2-phenylenedimercury dihalides that, unlike simple monodentate organomercuric halides, bind additional halide ions.[3a] They have also reported a macrocyclic mercury-containing Lewis acid which functions as an electrophile[3d, e] and binds nucleophilic organic solvents. We here report the first example (**1**) of a portentous new class of macrocyclic, multidentate, and electrophilic host species as well as the structural characterization of the chloride ion complex **1** · Cl^-. The species **1** is a charge-reversed analogue of the well-known [12]crown-4 macrocycle, which we have therefore named [12]mercuracarborand-4.



The icosahedral carborane 1,2-$C_2B_{10}H_{12}$ (**2**) contains relatively positive C atoms and can be easily lithiated by *n*BuLi at the carbon positions to give **3**.[7] The reaction of mercury(II) chloride with **3** results in the formation of the cyclic tetramer Li[$(HgC_2B_{10}H_{10})_4Cl$](**1** · ClLi) in 75% yield, in accord with Equation (a).

The species **1** · ClLi is quite soluble in most organic solvents except aliphatic hydrocarbons. Like other organomercurials, **1** · ClLi decomposes upon prolonged heating at 300°C or during UV irradiation to form mercury, **2**, and carborane-containing polymers. The ^1H, ^{13}C, ^{11}B, and ^{199}Hg NMR data revealed that **1** · ClLi has a highly symmetrical structure with single types of both carbon and mercury atoms. The negative-ion FAB mass spectrum exhibited an anion with $m/z = 1414$, which corresponds to **1** · Cl^-. The metathesis reaction of **1** · ClLi with $[As(C_6H_5)_4]Cl$ gave **1** · $Cl[As(C_6H_5)_4]$ in ca. 80% yield. The ^1H NMR spectrum of **1** · $Cl[As(C_6H_5)_4]$ displayed resonances due to $[As(C_6H_5)_4]^+$ and B-H in the ratio 1:2, which is consistent with the assigned formulation. The ^{13}C and ^{11}B NMR spectra of **1** · $Cl[As(C_6H_5)_4]$ are identical to those of **1** · ClLi except for the presence of $As(C_6H_5)_4^+$ ^{13}C resonances.

A single crystal of **1** · ClLi grown from *o*-dichlorobenzene/hexane was selected for the X-ray diffraction study.[8] The anion **1** · Cl^- (Fig. 1) consists of four bivalent 1,2-$C_2B_{10}H_{10}$

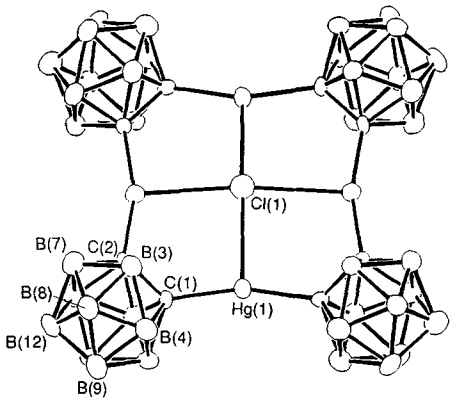

Figure 1. ORTEP representation of **1** · Cl^- with hydrogen atoms removed for clarity. Atoms labeled are in the x, y, z positions, all other atoms are generated by the fourfold and mirror symmetry of the tetramer.

cages linked by four Hg atoms in a cyclic tetramer with a chloride ion located in the center of the array and 2.944(2) Å from each Hg. The anion possesses crystallographically imposed C_{4h} symmetry with the four Hg atoms, the eight cluster carbon atoms, and eight boron atoms in the mirror plane. The chloride ion is displaced 0.383 Å above and below this plane, on the fourfold axis, with half occupancy of each of these two positions. Each Hg atom links carbon atoms of two carborane icosahedra (Hg–C distances: 2.105(13) and 2.080(13) Å). The Hg-C-C angles are 126.0(6) and 125.4(6)°, and the C-Hg-C angle is 162.0(3)°, which is the largest deviation from 180° yet observed in diorganomercurials.[9] The distance between the adjacent mercury atoms is 4.129(1) Å. In comparison, the trimer of *ortho*-phenylenemercury, $(C_6H_4Hg)_3$, has a planar structure with an average C–Hg distance of 2.10 Å, a C-Hg-C angle of 177.7°, and a Hg-C-C angle of 120.5° for the orthorhombic crystal.[10] The deviation from linear coordination of the mercury atoms in **1** · Cl^- is induced by strain in the tetramer ring. The average Hg-C-C angle of 125.7° in **1** is smaller than the 135° required for a strain-free tetramer. Consequently the mercury centers are displaced toward the cavity of the ring, resulting in a conformation of the ring that maximizes the bonding between the chloride ion and the four mercury centers. The deviation from linear mercury coordination requires the mixing of some additional p character into the sp hybrid mercury orbitals involved in bonding to carborane C atoms.

The nearly square planar coordination geometry of the chloride ion in $1 \cdot Cl^-$ is unprecedented. The Hg–Cl distance of 2.944(2) Å is significantly shorter than the van der Waals distance. The structure of the 1:2 adduct of chloride ion with 1,2-diphenylenedimercury dichloride has two short Cl–Hg distances (2.925 Å) and two long Cl–Hg distances (3.167 Å).[3b] In organomercury compounds Hg(II) is normally sp hybridized and forms two linear covalent bonds while retaining two empty and mutually perpendicular p orbitals.[9] The location of Cl^- in the [12]mercuracarborand-4 host maximizes the cooperative interaction of four empty mercury orbitals with two filled p orbitals of the chloride ion, which are essentially within the plane of the macrocycle. The trapped chloride ion is therefore bound to the host by a pair of three-orbital two-electron bonds. Four empty nonparticipating p orbitals perpendicular to the host ring arise from the set of four mercury atoms.

The synthesis of $1 \cdot ClLi$ is significant because it efficiently produces a macrocyclic multidentate Lewis acidic host in a single step. We believe that Cl^- functions as a template which directs the assembly of the host macrocycle, since either a cyclic trimer or a linear polymer is expected to have more favorable geometries for coordination of Hg(II) with the carbon atoms of the carborane cage, as seen in the case of $(C_6H_4Hg)_3$.[10–12] The template effect of metal ions in promoting certain cyclization reactions has been recognized for a very long time.[1c, 13] Two recent examples of the template effect of organic molecules are the syntheses of cyclic porphyrin oligomers[14] and a macrocyclic ligand from a so-called (template)^2 synthesis.[15] As far as we know, the synthesis of $1 \cdot ClLi$ is the first example of a guest anion acting as template for the formation of its organic host structure.[16]

The chloride ion adduct of **1** is the only structurally defined anionic halide complex of a diorganomercury compound.[3b] We suggest that the electron-withdrawing ability of the carborane cages greatly increases the electrophilicity of the four Hg(II) centers and thus enhances the interaction of Cl^- with the four empty in-plane mercury orbitals.[17] The adduct $1 \cdot Cl^-$ is sufficiently stable to be detected in the negative ion FAB mass spectrum with a relative intensity of 100%, and the cation exchange reaction proceeds smoothly without the destruction of the anionic adduct. Unlike crown ethers and cryptands, **1** is a planar preorganized host with a cavity in the uncomplexed state and promises to be an excellent electrophilic host for the complexation of anions or nucleophilic organic substrates. Such a preorganized host should result in higher thermodynamic and kinetic stabilities of its complexes.[18] Moreover, the four mercury binding sites are arranged in such a way that a cooperative interaction with a variety of guests is anticipated. Thus, one of the empty orbitals at each mercury in **1** can be directed into the cavity, as in the case of $1 \cdot Cl^-$, or both empty orbitals can be directed 45° above and below the plane of the host, thus allowing **1** to bind two nucleophiles simultaneously. Preliminary work indicates that chloride ion may be removed from $1 \cdot Cl^-$ by Ag^+ without decomposition of the host, and ^{199}Hg NMR experiments prove that I^- is tightly bound by **1**. We are now studying the ability of **1** and related mercuracarborands to interact with a variety of inorganic anions and organic substrates and are evaluating their capabilities as homogeneous catalysts.

Experimental Procedure

$1 \cdot ClLi$: *n*BuLi (43.7 mmol, 17.5 mL, 2.5 M in hexane) was added to an ethereal solution (50 mL) of *o*-carborane **2** (20.8 mmol, 3.00 g) at 0 °C, and the slurry was stirred at room temperature under argon. After two hours, the mixture was treated with solid $HgCl_2$ (20.8 mmol, 5.65 g) and stirred overnight. The mixture was then treated with 100 mL H_2O, and the organic phase was washed three times with H_2O (100 mL) and dried over $MgSO_4$. The solvent was removed and the residue was recrystallized from ether to give colorless, air-stable crystals of $1 \cdot ClLi$ in 75% yield. M.P. > 300 °C. ^1H NMR (200 MHz, $(CD_3)_2CO$, 25 °C): $\delta = 0.6-3.6$. ^{13}C NMR (50 MHz, $(CD_3)_2CO$, 25 °C, decoupled): $\delta = 94$. ^{11}B NMR (160 MHz, $(CH_3)_2CO$, 25 °C, relative to external $BF_3 \cdot Et_2O$, decoupled): $\delta = 0.3, -6.0, -8.3, -10.2$. ^{199}Hg NMR (89.6 MHz, 0.25 M in $(CD_3)_2CO$, 25 °C; 1.0 M PhHgCl in $[D_6]$DMSO as an external reference at $\delta = -1187$, [19] upfield to neat Me_2Hg, decoupled): $\delta = -1077$; IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 2560 (B-H). Negative ion FAB-MS: *m/z* 1407 ($1 \cdot Cl^-$, 100%), 1204 ($1 \cdot Cl^- - Hg$, 2.5%), 1064 ($1 \cdot Cl^- - HgC_2B_{10}H_{10}$, 18%). A correct elemental analysis was obtained for $1 \cdot ClLi$.

Microporous Silica Films

By *Wilhelm F. Maier,* Michael Wiedorn,* and *Herbert O. Schramm*

Thin ceramic films are useful for optical or protective coatings. Microporous ceramic membranes with pore diameters from 5–10 Å are of interest for separations in the food industry, gas separation, nonlinear optics, and for microelectronic sensors. The present activity in the field of microporous ceramic films focuses on zeolites, due to its well-defined pore structure. However, because of the limited crystallite size of zeolites, the preparation of homogeneous, pinhole-free films is still very difficult. We now report the pore size distribution of new, microporous, homogeneous silica films, which can be prepared in any thickness by electron beam evaporation. Such films may be used for the preparation of microporous ceramic membranes.

Our interest in the study of the microporosity of thin silica films originates in heterogeneous catalysis. In studies on the mechanism of hydrogenation and H/D-exchange reactions on hydrocarbons we have used thin silica films (50–200 nm) that covered the surface of the catalyst[1] to shield the catalytically active metal film (Pt film on a Si wafer) from direct interaction with the organic reagent. The silica layer is impervious to the organic reagent, while hydrogen apparently diffuses through the oxide layer and is activated at the Pt–SiO_2 interface. The activated hydrogen diffuses as spill-over hydrogen back to the surface (a steady-state concentration gradient is set up), where it reacts with the organic reagent. However, the mechanism of diffusion remained unclear, since no cracks or holes in the silica film were evident. Because of the small amounts of film material it was not possible to check for micropores, which remained as a possible explanation for our data. Various published discussions document the broad interest in our results.[2]

We have now determined the pore size distribution of the silica films, prepared by electron-beam evaporation, through nitrogen adsorption. Instead of Pt/Si wafers as basis for the silica coatings, commercial aluminum foil was used as substrate for silica deposition, because the silica film could be separated from the substrate mechanically, by immersion in pure water, or by dissolving the aluminum foil in 2 N HCl. It has been shown that the films are amorphous, and that a silica film on platinum can differ from that on alumina only in the first few atomic layers. Their structure should thus be independent of the substrate, especially at thicknesses larger than 50 nm. From the nitrogen adsorption isotherm the specific surface and pore volume was determined according to BET[3] and to *Dubinin*[4]. The pore radius distribution (3–300 Å) was determined from the adsorption data by applying the Kelvin equation[5] as well as by the micropore method.[6]

The N_2-adsorption isotherm of the silica (Fig. 1) documents the microporosity of the material. Figure 2 shows the associated pore radius distribution determined by the Kelvin equation. Although the equation is not valid for pore radii smaller 15 Å,[7] the analysis reveals a very narrow pore size distribution with a maximum clearly below 15 Å and no pores of larger diameter. To analyze the micropores with radii smaller than 10 Å, we relied on the MP method, using the t-plot method of *de Boer*.[8] As a criterium for the quality

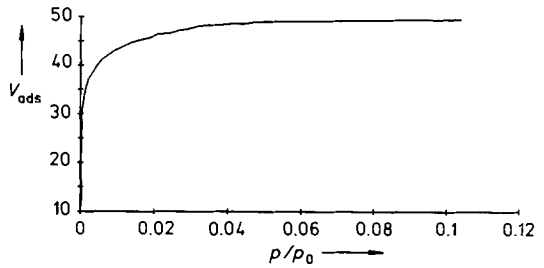

Fig. 1. Section of the nitrogen adsorption isotherm of silica, prepared by electron-beam evaporation. At $p/p_0 > 0.1$ (not shown) there was no further N_2 desorption. Adsorption volume V_{ads} in $cm^2 g^{-1}$

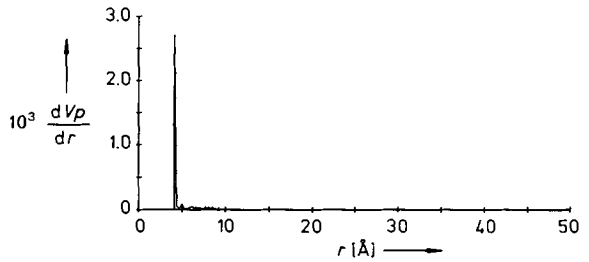

Fig. 2. Pore radii distribution of the silica film from Fig. 1, calculated by applying the Kelvin equation. $d Vp/d r$ in mL Å^{-1}.

of the data produced by the MP method, the surface and pore volume were compared with the data obtained by the BET and Dubinin treatment. Isotherms for the t-plot calculated from the Halsey equation[9] did not result in reasonable surfaces and pore volumes. Good results were obtained by the use of finely ground quartz wool as nonporous reference material. The t-plot[6] shows a decrease in slope at a layer thickness of about 3 Å, which indicates a pore maximum at 3.1 Å (see Fig. 3). This procedure was tested on various molecular sieves. We thus estimate the error of our analysis to better than $\pm$ 1 Å, which points to pore diameters of 6 ± 2 Å[13] for the microporous silica.

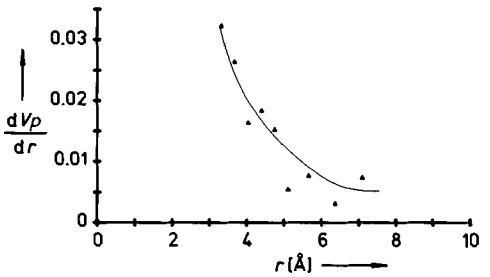

Fig. 3. Pore radius distribution of the silica film of Fig. 1, calculated by applying the MP method.

To test whether the determined pore volume is due to inner pore structure or to surface structure, the adsorption isotherm was obtained from 10 films of different thickness (between 250 and 4000 nm). The total surface of the material varied between 155 and 259 $m^2 g^{-1}$ and the pore volume between 0.055 and 0.09 cm^3/g^{-1}, independent of the film thickness. The maximum of the pore radius distribution was the same in all cases. The measured pore volume is thus not due to surface characteristics of the films, but only to inner pore and channel structures.

Table 1. BET analysis of nitrogen adsorption isotherms.

	SiO_2 film	zeolite 3 Å	4 Å	5 Å	NaY
pore volume [$cm^3 g^{-1}$]	0.07	0.003	0.013	0.23	0.34
surface e [$m^2 g^{-1}$]	192	9.3	37.2	661.7	960

Because the size of the pores of our materials was clearly at the limits of the methods used, we were interested in a seperate method to estimate the actual pore size, in particular for pores too small to be determined by nitrogen adsorption. The adsorption isotherms of three molecular sieves and a NaY zeolite were determined (Table 1). While the NaY-zeolite and the 5 Å molecular sieve adsorbed nitrogen readily, the 4 Å and 3 Å molecular sieve showed little N_2 adsorption, confirming that these pores are to small for nitrogen as adsorbate (rotational diameter 4.3 Å).[11]

To test whether the silica films contain similarly small pores we had to use an adsorbate smaller than nitrogen. One of the few suitable molecules is water (rotational diameter 2.6 Å). Because of technical problems with recording the adsorption isotherm of water on our equipment, we have used thermogravimetry (TGA). Two silica films and three molecular sieves were saturated with water, dried for one hour at 120 °C (for the 4000 nm film, 80 °C), and analyzed in a SETARAM TGA92. The temperature-dependent water loss was registered (Table 2). The temperature of maximal

Table 2. Thermogravimetric study of water adsorption by zeolites and silica films

Mass used [mg]	85.0	86.7	85.6	41.7	54.9
ΔM [mg] [a]	11.7	11.9	11.9	2.0	3.9
ΔM [w%] [a]	13.8	13.7	13.9	4.7 (6.6) [b]	7.1
T_{max} [°C] [c]	211.9	206.0	201.9	118.1	121.2

[a] ΔM = change in mass. [b] The value in parentheses includes the weight loss during the predrying stage (see text). [c] T_{max} = temperature of maximal water loss.

water loss increases with decreasing pore size of the molecular sieves. The relatively low temperatures of maximal water loss for the silica films shows that they adsorb water less strongly. In contrast to the pore volume from nitrogen adsorption, but as expected from the identical porosities of the molecular sieves, the pore volume obtained from water loss for the three molecular sieves is virtually identical. In the case of the 5 Å molecular sieve the pore volume obtained from TGA is about 40% below the BET volume (0.23 mL g^{-1}), which corresponds to the known water adsorption capacity of the molecular sieve. The difference can be traced to the predrying procedure of the molecular sieves, because the volume obtained from TGA for the more mildly predried 4000 nm film was identical with its BET pore volume. Therefore, all micropores in the silica films are larger than the critical diameter of nitrogen.

From these studies we conclude that silica films prepared by electron-beam evaporation have a porosity of 14 %, and a very narrow micropore distribution comparable to that of a 5 Å molecular sieve. Silica films are therefore potential materials for the preparation of microporous membranes and surface coatings. The simple preparation procedure and the homogeneity of the films make these materials very promising alternatives to zeolite films.

The extreme microporosity of the silica films supports the interpretation of our previous catalytic studies on silica coated Pt/Si-catalysts.[1] The narrow pore diameter of about 6 Å is readily penetrable by hydrogen, while diffusion of the organic reactant through the silica layer is highly hindered. Also formation of a concentration gradient of spill-over hydrogen as explanation for the observed catalytic phenomenon[1] seems plausible.

Experimental procedure

The films were prepared in a Balzers (BAE 250) evaporation unit, equipped with a 3 kW electron gun (Edwards, E 036-15). The rate of evaporation was 2–20 nm min^{-1} at a pressure smaller than 10^{-5} torr. The silica film was deposited onto aluminum foil, from which it was subsequently removed. After washing and drying of the film, the nitrogen adsorption isotherm was recorded on a modified Sorptomatic 1900 from Carlo Erba (smaller sample volumes, a dosage unit for smaller dosage pressures (p = 0–100 torr), and a pressure gange for the range 0–100 torr). The modifications allowed a reduction of the sample size needed and the recording of more data in the micropore range. For data treatment[12] a makro, programmed for the spreadsheet Excel®, was developed. Repeated measurements showed only small deviations in surface area and pore volume.

Data treatment by the method of *Horváth* and *Kawazoe* [10] gave a maximum for the pore diameter distribution at 5.5 Å, confirming our data.

Crystal Structure of Chlorine Dioxide **

By *Anette Rehr* and *Martin Jansen**

By virtue of their small number, stable radicals or radical ions play a subordinate role in the chemistry of the nonmetals. In this setting, the characteristically increasing number of examples found in the case of the triatomic 19-electron systems is striking. These can be homoatomic such as S_3^-,[1] O_3^-,[2] or P_3^{4-}[3] or heteroatomic such as ClO_2, NF_2[4] and SO_2^-,[5] with the more electronegative atom in the terminal position. A gradual change in tendency to dimerize is ob-

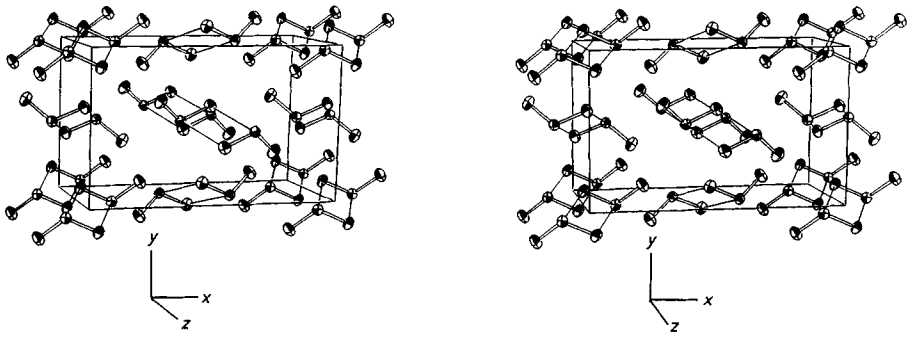

Fig. 1. Stereoview of the crystal structure of ClO_2; intermolecular bond interactions are indicated by lines.

served between the extreme cases: O_3^-, P_3^{4-} are exclusively monomeric, SO_2^- ($S_2O_4^{2-}$) is known only as the dimer, whereas $2\,S_3^- \rightleftarrows S_6^{2-}$ and $2\,NF_2 \rightleftarrows N_2F_4$ are solvent- and temperature-dependent equilibria, respectively. These gradual changes are difficult to interpret. An influential factor is undoubtedly the difference in electronegativity, and thus the site of greatest residence probability for the unpaired electron (antibonding π-orbital $2\,b_1$). Since gas-phase equilibria naturally cannot be investigated in the case of the charged compounds, and electrostatic effects would dominate in the condensed phase, the behavior of NF_2 and ClO_2 is of particular importance. In the case of NF_2 a temperature-dependent equilibrium could be detected, whereas ClO_2 should show no tendency whatsoever to dimerize and should be isotypic with SO_2 in the crystalline state.[6] To check this hypothesis we have determined the crystal structure of ClO_2 and carried out measurements of the magnetic susceptibility of solid ClO_2.

ClO_2, prepared by reaction of sodium chlorite with chlorine, was carefully purified and recondensed into a capillary tube or into the sample tube of the magnetometer. Crystal growth was carried out in situ on a four-circle diffractometer. The X-ray structure analysis[7] confirmed that a molecular crystal was indeed formed, but revealed no signs of isotypy with SO_2. In SO_2, all molecules are oriented equidirectionally with respect to their dipole moments and their relative arrangement can easily be reduced to a cubic face-centered packing. In contrast, the ClO_2 molecules arrange themselves pairwise with oppositely directed dipole moments (cf. Fig. 1). From the spectrum of bond lengths from one ClO_2 molecule to its nearest neighbors there always is a pair of significantly shorter Cl–O bond lengths. The chlorine and one terminal oxygen atom each of the two neighboring molecules approach each other with formation of a head-to-tail dimer. The resulting shortest intermolecular Cl–O bond length (274 pm) is 46 pm shorter than the van der Waals distance; thus, the relative shortening corresponds approximately to that in solid NO (240 compared to 290 pm[8]). The mass centers of the dimers of ClO_2 lie on all corners and face centers of the orthorhombic unit cell and are inversion symmetric, that is the planes through the two molecules are parallel to each other. The bond from chlorine to the "terminal" oxygen atom within the dimer forms an angle of 101.5° with the Cl_2O_2 plane. The structural factors thus clearly indicate an association of two ClO_2 molecules in the crystal; however, a two-electron two-center bond is not formed thereby. Namely, if one bears in mind the S–S bond lengths in $S_2O_4^{2-}$ (239 pm)[9] then a chlorine–chlorine bond length of at most 240 pm would be expected in such a case.

With the aim of independently demonstrating this intermolecular interaction we have carried out magnetic measurements on solid ClO_2.[10] As the plot of χ against T (Fig. 2) shows, ClO_2 is initially paramagnetic below the melting point and becomes diamagnetic below $-108\,°C$. Thus, it is proven beyond doubt that ClO_2 is present in the form of dimers with compensated spin moments at low temperatures. That the observed interaction cannot be of an electrostatic nature (dipole–dipole interactions) follows from the relative arrangement of the molecules with respect to one another. Moreover, SO_2, with the higher dipole moment, would then have to tend to undergo association to a greater extent, which obviously is not the case. Interestingly, two monomers are always so related to each other that the antibonding π-orbitals ($2\,b_1$) can overlap. An intermolecular interaction should increase the electron density in these antibonding orbitals and should thus concomitantly expand the respective Cl–O bond. This is in fact observed: the Cl–O bond, through which the dimerization takes place, is longer (147.5 pm) than the non-bridging bond (146.4 pm). The effect, however, lies almost in the range of experimental error. The bond length determined for gaseous ClO_2 by microwave spectroscopy corresponds exactly to the mean value of the bond lengths found in the crystal; the angle (116.0°) is slightly reduced compared to 117.4° (gaseous).

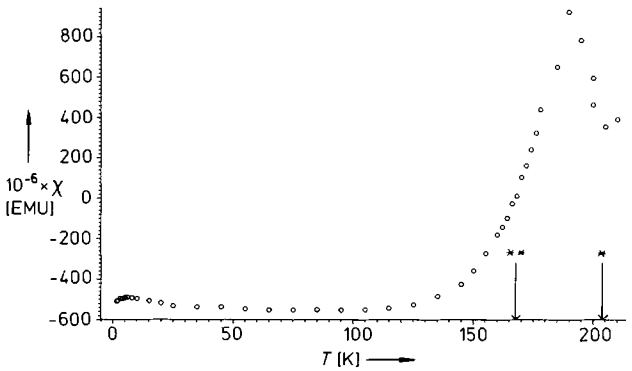

Fig. 2. Relative magnetic susceptibility of ClO_2 in dependence of the temperature (* melting point; ** temperature at which X-ray data was collected.

Experimental

The synthesis was carried out analogously to that described by G. Brauer: *Handbuch der Präparation Anorganischen Chemie*, 3rd ed., Enke, Stuttgart 1974, p. 312.

Warning: Chlorine dioxide is extremely explosive! At temperatures below $-40\,°C$ and pressures below 50 mbar it is relatively safe to handle. When subjected to any source of energy it decomposes explosively; on handling ClO_2, therefore, exposure to light was avoided if possible, otherwise all operations were carried out under a red light. The apparatus was painstakingly cleaned and KEL-F paste was used.

ClO_2 was distilled over ($-50 \rightarrow -120\,^{\circ}C$) from the cooling trap into a capillary tube previously cleaned with aqua regia and sealed onto the trap. The capillary and cooling trap were then cooled to $-196\,^{\circ}C$ and the capillary detached under vacuum (1.3×10^{-3} mbar). Storage and transfer to the diffractometer were carried out under continous cooling to $-196\,^{\circ}C$.

An analogous procedure was used on condensing ClO_2 into the sample tube of the magnetometer except that this was immediately cooled to $-196\,^{\circ}C$ and filled to a height of 3–4 mm. The substance used for crystal growing was purified by zone-refining. At a cooling temperature 0.3 K below the melting point of ClO_2 the intensity of the IR lamp was regulated so that the substance just melted. Several rapid cycles were run through, but always in only one direction. The crystal growth was finally carried out in a zone shortened by about 1/10 mm and the melting zone was moved slowly (1 mm h^{-1}) run. The crystal quality was checked by X-ray diffraction (film methods).

Bond lengths [pm] and selected bond angles [°]: Re-Rea 263.6(1), Re-S1 230.7(2), Re-S2 243.2(2), Re-S5 248.3(2) Re-S8 248.3(2), Re-S1a 230.0(2), Re-S4a 243.7(2), S2-S3 206.6(3), S3-S4 208.3(2), S5-S6 206.7(3), S6-S7 205.2(3), S7-S8 207.0(3); S-Re-S 76.3(1)-110.2(1), 163.9(1)-167.2(1), Re-S1-Re 69.8(1), Re-S-S 106.3(1)-109.3(1), S-S-S 99.8(1)-100.2(1). The bond lengths and angles of **1b** do not differ significantly from those of **1a**.

$(NH_4)_2[Re_2S_{16}]$, a Soluble Metal Sulfide with Interesting Electronic Properties and Unusual Reactivity**

By *Achim Müller,* Erich Krickemeyer, Volker Wittneben, Hartmut Bögge,* and *Michael Lemke*

Dedicated to Professor Hans Georg von Schnering on the occasion of his 60th birthday

"Molecular" metal sufides[1] are topical for many reasons: they are the active centers in a number of, in part, ubiquitous proteins that are of importance in fundamental biological processes,[2] and are also used as starting materials for important catalysts;[3] however, only in the last 20 years have they become preparatively accessible.[4] In this communication an unusual sulfide is presented in which the metal–metal bond has largely double-bond character and whose electronic structure can be correlated with its unusual reaction behavior and that of other metal sulfides. A molecular metal sulfide with a metal–metal double bond has heretofore not been described in the literature.

By reaction of ammonium perrhenate with an aqueous ammonium poly-sulfide solution (with a high proportion of atoms linked via two μ_2-S^{2-}-centers and two S_3^{2-} ligands. Each Re atom bears, in addition, a chelating S_4^{2-} ligand, and thus has a distorted octahedral geometry (the angle S1–Re–S1a (110.2(1)°) deviates the most from 90°); two ReS_6 octahedra are linked via one edge (for structure type see Ref. [6]). The Re_2S_3 rings are present in an "envelope" conformation; the ReS_4 rings form approximate "half-chair" conformations in **1a** and exact "half-chair conformations symmetric about the twofold axis in **1b** (torsion angles 17.9; −49.1, 60.6; −49.1, 17.9°). Especially interesting from the structural point of view is the eight-membered Re_2S_6 ring with a strong transannular Re–Re interaction (cf. below).

In the system $[ReO_4]^-/S_x^{2-}$ the formation of **1** competes with that of $[Re^{VII}S_4]^-$, $[Re^{V}S(S_4)_2]^-$, $[Re_4^{IV}S_4(S_3)_6]^{4-}$, and $[Re_4^{IV}S_4(S_3)_4(S_4)_2]^{4-}$.[7a] When the S_x^{2-} solution contains a high proportion of sulfur, **1** is formed preferentially instead of the Re^{IV} clusters, since further reduction is hindered thereby. Accordingly, it contains the highest S/M proportion (M = V, Mo, W, Re) of all multinuclear sulfides of the early transition metals (except some mononuclear species like $[Re^{V}S(S_4)_2]^-$).

1 is a novel type of molecular sulfide not only with regard to structure, but also with regard to electronic properties.[8] Compared to Mo–S and W–S systems, Re–S systems are characterized by the lower energy of the rhenium 5d function[9a] and the possibility thereby of stronger covalent Re–S interactions. Due to the very similar energies of the

[*] Prof. Dr. A. Müller, E. Krickemeyer, Dipl.-Chem. V. Wittneben, Dr. H. Bögge, Dipl.-Chem. M. Lemke
Fakultät für Chemie der Universität
Postfach 8640, W-4800 Bielefeld 1 (FRG)

[**] We thank Degussa AG for gifts of rhenium compounds.

Re-5d and S-3p functions,[9a] ligand and metal functions mix better in Re–S-compounds than in analogous Mo and W compounds.[10] This contributes for example to the high Re–S bond order in $[ReS_4]^-$.[10,11] All "Re-containing" molecular orbitals in **1** are so strongly stabilized that also orbitals with partial δ, δ^*, and π^* character are populated.[9b] The Re–Re π bond is thereby partially compensated, i.e. the metal–metal bond weakened (cf. values for W–W and Re–Re single bond lengths[6,8]).

The presence of orbitals that have not only Re–Re π-bonding character but also a pronounced delocalization of the electrons (with a high proportion of ligand contributions), also explains the characteristic redox behavior of **1**. In all the solvents investigated, a remarkable electron transfer (with exclusion of O_2 !) takes place spontaneously (e.g., in dimethyl sulfoxide with 75 % yield), which has model character for catalytic processes [Eq. (a)]. The S_x^{2-} ligands probably oxi-

$$[Re^{V}_2S_2(S_3)_2(S_4)_2]^{2-} \xrightarrow{DMSO} [Re^{VII}S_4]^- \qquad (a)$$

dize Re^V to Re^{VII} in a complicated reaction pathway (the prerequisite for electron transfer from Re to S is evident, e.g., by virtue of the fact that, in the case of $[Re^VS(S_4)_2]^-$, a relatively high bonding energy is measured for the Re-4$f_{7/2}$ electrons in the ESCA experiment (*E*lectron *S*pectroscopy for *C*hemical *A*nalysis)[7a].

Similar reactions are *not* observed, e.g., in the clusters $[Re_4S_4(S_3)_6]^{4-}$ and $[Re_4S_4(S_3)_4(S_4)_2]^{4-}$,[7a] since in these cases the valence electrons are located in "stable" metal–metal σ bonds and are not available for intramolecular redox reactions (for intramolecular redox reactions in the case of Mo–S compounds, cf. Ref. [12]). This generally confirms our hypothesis that easily displaced electrons in exchange coupled clusters, and also as here in strongly delocalized MOs (i.e. not fixed in strong metal–metal bonds), are of importance for electron transfer in biology and catalysis.[13] Accordingly, Re sulfides have other, and in part better, catalytic properties in redox reactions than the Mo and W analogues.[14]

A further remarkable reaction in this connection takes place when **1** is treated in the presence of air at 90 °C with an aqueous KCN solution [Eq. (b)]. The formation of the

$$[Re_2S_2(S_3)_2(S_4)_2]^{2-} \xrightarrow{CN^-, O_2} [Re_2(SO_2)_2(CN)_8]^{6-} \qquad (b)$$

$K_6[Re_2(SO_2)_2(CN)_8]\cdot 2H_2O$ **2**

anion of **2** (for structure see Fig. 2) proceeds with ligand exchange and S^0-abstraction (NCS^- formation), whereby Re^V is reduced to Re^{III}; cf. Ref. [15].

The highly negative partial charge at the μ_2-S^{2-} bridges facilitates attack by O_2 and the formation of SO_2^{2-} bridges in this reaction (cf. discussion in Ref. [15]), but also hinders a further nucleophilic attack of CN^- with formation of NCS^-, i.e. cleavage of the Re–S–Re bonds. Cyanolysis of amorphous metal sulfide catalysts also permits differentiation of the various metal-bound S_x^{2-} groups.

These results provide an indication of how one can interpret the different influence of nd-metal centers (n = 4 and 5) regarding the reactivity and catalytic activity of metal-sulfur systems. Both the absolute energy of the d function as well as its relative position to the S-3p level are of importance.

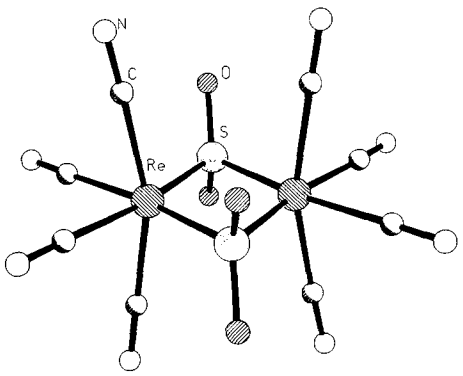

Fig. 2. Structure of the anion of **2** in the crystal. Important bond lengths [pm] and angles [°]: Re-Re 265.3(1), Re-S 232.5(2), 232.6(2), Re-C 209.5(8)-211.8(6), S-O 149.5(6), 149.9(5), S-Re-S, S-Re-C, C-Re-C 78.4(2)-96.2(2), 162.0(2)-171.1(2), Re-S-Re 69.6(1), Re-S-O 118.8(2)-119.3(2), O-S-O 107.5(3), Re-C-N 173.7(6)-179.0(5).

Experimental

1: H_2S gas was passed into a suspension of sulfur powder (150 g) in 500 mL of a 12.5 % aqueous ammonia solution for 4 h (20 $L\,h^{-1}$; the first hour with stirring); the sulfur dissolved almost completely. The polysulfide solution was then treated with a solution of ammonium perrhenate (0.5 g, 1.86 mmol) in H_2O (25 mL) and the mixture kept in a closed 1 L round bottom flask at 20–25 °C. The dark brown precipitate which initially formed after a rapid change in color of the reaction solution from red through dark red to reddish brown went into solution again. The black crystals of **1** which had precipitated after one to one and a half weeks (**1a**: distorted rectangular platelets (ca. 75 %); **1b**: tetragonal bipyramids (ca. 25 %) were filtered off, washed with 2-propanol, carbon disulfide, and 2-propanol, and then dried and stored under argon. Yield: 0.2 g (21.6 % based on $NH_4[ReO_4]$ employed).

Correct elemental analysis. IR (CsI): $\tilde{\nu}[cm^{-1}]$ = ca. 3500(m) ($\nu(H_2O)$); ca. 3130(m) ($\nu_{as}(NH_4^+)$); 1590(m) (br), 1560(m) ($\delta(H_2O)$); 1410(sh)/1390(s) ($\delta_{as}(NH_4^+)$); 455(m), ca. 430(m) (br), 392(s) (ν_{as}(S-S), ν_{as}(Re-S)). UV/VIS/NIR (KBr/transmission): λ[nm] = ca. 1200, 780, 620, 540, 440, and 375 (sh). **1** decomposes according to equation (a) at 30–40 °C in H_2O, dimethyl sulfoxide, *N*,*N*-dimethylformamide, pyridine, and methanol.

2: A solution of potassium cyanide (0.50 g, 7.68 mmol) in H_2O (20 mL) was treated with **1** (0.13 g, 0.13 mmol) in a 100-mL Erlenmeyer flask (wide-necked, covered with a watch glass) and allowed to stand on a hotplate at 90 °C until brown crystals of **2** precipitated from the solution. After filtration of the hot solution, the crystals were washed with aqueous 2-propanol (80 %), then absolute 2-propanol, and dried on filter paper. Yield: 0.10 g (78 % based on initial amount of **1**).

IR (CsI): $\tilde{\nu}[cm^{-1}]$ = 1063(m) (ν_{as}(S-O)); 963(s) (ν_s(S-O)). X-ray structure analysis of **2**: $P\bar{1}$; a = 804.0(2), b = 887.2(3), c = 901.3(3) pm, α = 83.79(2), β = 64.52(2), γ = 81.61(2)°, $V = 573.4 \times 10^6$ pm^3, R = 0.036 (for deposition of structural data see [5]).

Rehder, *Chimia 40* (1986) 50 and unpublished results.

[8] The relatively short distance between the two Re^V centers (electron configuration d^2) (263.6(1) pm in **1a** and 263.2(1) pm in **1b**) points, according to the argument put forward by *Hoffmann* et al. and *Cotton* [6], to the presence of a formal M=M double bond. Example: $[W_2^{IV}S_2(dtc)_4]$ with a W–W distance of 253.0(2) pm; cf. A. Bino, F. A. Cotton, Z. Dori, J. C. Sekutowski, *Inorg. Chem. 17* (1978) 2946; cf. also L. Wei, T. R. Halbert, H. H. Murray III, E. I. Stiefel, *J. Am. Chem. Soc. 112* (1990) 6431 as well as F. A. Cotton, R. A. Wolton: *Multiple Bonds between Metal Atoms*, Wiley, New York 1982, p. 290.

[9] a) Cf., e.g., Hartree-Fock-Slater orbital energies: S–3p: 10.3; Mo–4d: 7.2; W–5d: 9.3; Re–5d: 10.6 eV (J. J. Yeh, I. Lindau, *At. Data Nucl. Data Tables 32* (1985) 1); b) X_α calculations were carried out in spin-unpolarized form using the XASW program by M. Cook and D. A. Case (D. A. Case, *Annu. Rev. Phys. Chem. 33* (1982) 151; *Quantum Chemistry Program Exchange*, Bloomington, IN 47405 (USA), Program 465). In contrast to the markedly localized Re–Re σ-bonding orbital ($E(\sigma) = -7.7$ eV with 61% Re contribution) the expected Re–Re π-bonding orbital splits significantly due to strong Re–S interactions ($E(\pi_1) = -8.1$ eV with 35% Re contribution and $E(\pi_2) = -5.0$ eV with 34% Re contribution, whereby the energetically destabilized orbital (π_2) lies at almost the same energy with the Re–Re δ^* antibonding orbital ($E(\delta^*) = -5.1$ eV with 51% Re contribution) in the region of the frontier orbitals (HOMO-LUMO). This can explain the small μ_{eff} value at room temperature ($\approx 0.4\ \mu_B$) (Further details will be published later).

[10] A. Müller, V. Wittneben, U. Kuetgens, J. Hormes, unpublished.

[11] X_α calculations, XPS data, and energies from XANES spectra in the region of the S–K edge show that, e.g., the HOMO t_1 and the LUMO $2e$ in the simplest system, namely $[ReS_4]^-$ are, e.g., stabilized by about 1 eV compared to $[MoS_4]^{2-}$, whereby the LUMO in the case of $[ReS_4]^-$ contains more S contributions [10] (corresponding to stronger Re–S interaction; cf. also thermodynamic stability corresponding to Equation (a)). This results, e.g., in the Re cluster compounds of the type $[(FeCl_2)_2(MS_4)]^{n-}$ (M = V, Mo, W, Re) taking up one electron "more" under the same conditions [Eq. (c)], and in $[ReS_4]^-$, in contrast to $[MoS_4]^{2-}$ and $[WS_4]^{2-}$, being reduced reversibly [7b]. See also A. Müller, R. Jostes, K. Schmitz, E. Krickemeyer, H. Bögge, E. Bill, A. Trautwein, *Inorg. Chim. Acta 149* (1988) 9.

Switch Peptides: pH-Induced α-Helix to β-Sheet Transitions of Bis-amphiphilic Oligopeptides**

By *Manfred Mutter,* R. Gassmann, U. Buttkus,* and *K.-H. Altmann*

The de novo design of peptides and proteins exhibiting well-defined structural and functional properties has developed into an area of major theoretical as well as practical interest.[1] Of particular importance for the construction of novel proteins is the understanding of the conformational properties of amphiphilic peptides, where secondary structure formation in aqueous solution is usually associated with the formation of multimeric aggregates.[1a–c, 2] Apart from the intrinsic tendency of the constituent amino acid residues to form α-helix or β-sheet structures, ordered conformations of this type of peptides are stabilized by hydrophobic interactions within the intermolecular aggregates; thus, the process of self-association of amphiphilic peptides in aqueous solution may be regarded as a model for the folding of globular proteins that mimics the effect of long-range interactions in protein folding.[3] While the intrinsic propensity of various types of model peptides (including amphiphilic sequences) for α-helix[4] or β-sheet[5] formation has been studied in great detail, very little is known about α-helix to β-sheet transitions in such systems. Although temperature- and solvent-induced $\alpha \rightarrow \beta$ transitions have been previously observed for homo*poly*peptides[6] and solvent-induced (reversible) $\alpha \rightleftharpoons \beta$ transitions have been recently reported for amphiphilic *oligo*peptides,[2d] amphiphilic sequences exhibiting reversible $\alpha \rightleftharpoons \beta$ transitions under purely aqueous conditions have not been described so far.

We now report on the design and conformational properties of *oligo*peptides that are amphiphilic with respect to α-helix and β-sheet formation. Due to the major contribution of intramolecular hydrophobic interactions to the stabilization of amphiphilic α-helices as well as β-structures, these peptides ("switch peptides") should posses the potential for reversible conformational transitions of the type $\alpha \rightleftharpoons \beta$ in aqueous solution; that is they should switch between two different (ordered) conformational states depending on the experimental conditions such as pH, temperature, salt concentration, etc. (Fig. 1).

The general principles for the design of switch are outlined in Figure 2. Starting from the repetitive pattern of an amphiphilic β-sheet (alternating arrangement of hydrophilic and hydrophobic residues as in **I**), hydrophobic (hydrophilic) residues located on what is supposed to become the

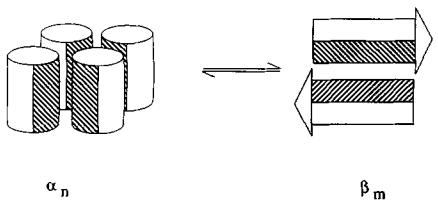

Fig. 1. Schematic representation of the conformational transition between an aggregated α-helical state and a bilayer sheet (β-structure); n, m denote the (unknown) respective degree of aggregation. The conformational transition may be induced by a change in the experimental conditions (concentration, temperature, pH, or solvent).

hydrophilic (hydrophobic) face of the helical cylinder are replaced by indifferent that is, neither polar nor hydrophobic) amino acids (Fig. 2, **II** → **III**). These manipulations result in a primary sequence that is amphiphilic in nature with respect to an α-helical (Fig. 2, **III**) as well as a β-sheet conformation (Fig. 2, **IV**) and the switch peptides obtained in this

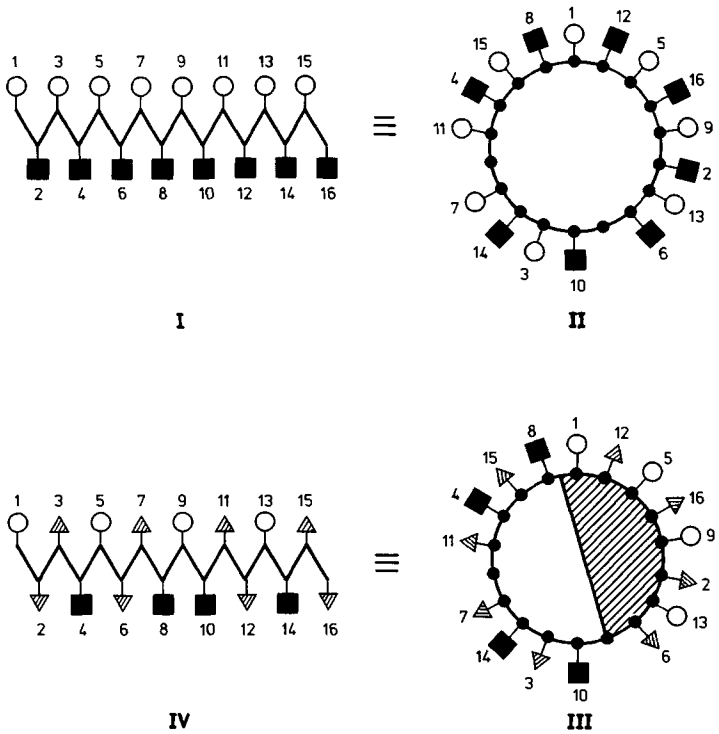

Fig. 2. Design of switch peptides. Left: Schematic representation of a β-sheet conformation for the starting sequence (**I**) and the final switch peptide sequence (**IV**). Right: Helical wheel representation [7] of the starting sequence (**II**) and a final switch peptide sequence (**III**). Note that sequence **II** is still identical with **I** and **IV** with **III**. Cycles, squares, and triangles denote hydrophilic, hydrophobic, and neutral residues, respectively.

way exhibit the following general sequence (shown for a chain length of 16 residues, which is the length of the peptides studied in this paper):

P–N–N–H–P–N–N–H–P–H–N–N–P–H–N–N **A**

P=hydrophilic (polar), H=hydrophobic, N=indifferent (neutral) amino acid residues

As the first representative examples of this new class of peptides, we have designed four sequences comprising 16 amino acid residues each, using Leu, Lys or/and Glu, and Ala as hydrophobic (H), hydrophilic (P), and neutral (N) residues, respectively (Scheme 1). While peptides **1** and **2** contain only one type of ionizable group, **2** and **4** each contain an equal number of Lys and Glu residues in an (i, i+4) sequence relationship.[4b] The chain length of the peptides was chosen to be well above the critical length for α-helix and β-sheet formation[4, 5] in order to ascertain a sufficient general potential for the formation of either secondary structure.

4 Ac-EAALKAALELAAKLAA-NH_2

Scheme 1. Amino acid sequences of switch peptides **1**–**4**. A = alanine, L = leucine, E = glutamic acid, K = lysine, Ac = acetyl.

As a general feature, all peptides investigated undergo pH-induced, reversible conformational transitions from helical to β-sheet conformations and vice versa (Fig. 1). As demonstrated by the CD spectra (Fig. 3, left), peptide **1** clearly exists in a β-structure conformation at pH 4, while it adopts a partially helical conformation at pH ≥ 7. Based on $[\theta]_{222}$ a helix constant of 23% may be calculated at pH 7 and 25 °C by using α-helix poly-L-Lys as a reference.[8] It is interesting that the spectra obtained at pH 5 and pH 6 (transition region) display very unusual curve shapes that are not observed for simple helix-coil or β-structure-coil transitions.[4, 5] For peptide **2** the conformational transition (partial) helix ⇌ β takes place at pH ~ 4.5: peptide **2** exists in a partially helical conformation at pH 2 and pH 3 (helix content at pH 3 ca. 19%), while only β-structure formation is observed for pH ≥ 6. In contrast to peptides **1** and **2**, peptide **3** exhibits *three* pH-induced conformational transitions at pH ≈ 5, pH ≈ 8, and pH ≈ 10. As can be seen in Figure 3, right the CD spectra of peptide **3** at pH 3 and pH 9 are characteristic for peptides in a predominantly α-helical conformation with an estimated helix content of 60% and 53%, respectively. On the other hand, the spectra observed at pH 7 and pH 11 are indicative of predominant and complete β-structure formation, respectively—the assigment of the former spectrum is based on the location of the negative Cotton effect at 218 nm as well as the lack of any pronounced minimum between 200 and 210 nm.[8] Likewise, three conformational transitions are observed for peptide **4**, which, for example, adopts a helical conformation at pH 3 (48% helicity)

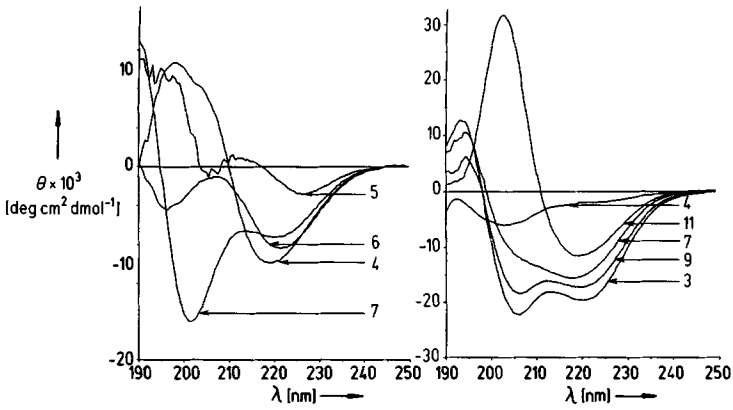

Fig. 3. CD-spectra, left of peptide **1** (c = 0.5 mg mL^{-1}) and right of peptide **3** (c = 0.5 mg mL^{-1}) in aqueous solution at different pH values.

and pH 7 (66 % helicity); β-structure formation occurs at pH 5 and 6 and at pH 10. The high tendency of peptides **1**–**4** to switch between helical and β-sheet conformations is further documented by the sensitivity of the specific conformational features to minor changes in the experimental conditions other than pH. For example, a $\beta \rightarrow \alpha$ transition is observed for peptide **4** at pH 10 upon dilution from 0.5 mg mL^{-1} (Fig. 3, right) to ca. 0.25 mg mL^{-1}. Similarly, addition of increasing amounts of 2,2,2-trifluoroethanol (TFE) to an aqueous solution of peptide **3** at pH 11 results in a $\beta \rightarrow \alpha$ transition between TEF concentrations of 20 and 30 %. In pure TFE only α-helical conformations are observed in all four cases.

In summary, these data demonstrate that peptides displaying sequence regularities that allow for the formation of amphiphilic structures in either a α-helical or a β-sheet conformation do indeed undergo medium-induced conformational transitions of the type $\alpha \rightleftharpoons \beta$ under purely aqueous conditions. What exactly determines the preference for one or the other type of secondary structure under different sets of experimental conditions remains elusive at this stage. However, it is reasonable to conclude that the occurrence of a particular conformation under certain experimental conditions (but not others) is mainly dominated by factors related to the intermolecular association process (i.e. intermolecular hydrophobic interactions) rather than by the intrinsic tendency of the peptides to adopt a specific type of secondary structure (short range interactions). This view is supported by the fact that β-sheet formation is favoured over helix formation under a variety of experimental conditions, despite the much higher probability predicted for a helical conformation ($\langle P_\alpha \rangle = 1.39$, $\langle P_\beta \rangle = 0.92$ for peptides **3** and **4**.[9] Furthermore, a number of recent studies demonstrated that sequential oligopeptides that have similar sequences as peptides **1**–**4** but are nonamphiphilic in nature do not form β-structures in aqueous solution.[4b–d, 4h] In all those cases α-helical structures were observed as the only type of ordered conformation. Conformational transitions of peptides are accompanied by distinct changes in their physicochemical and functional properties like solvation, association state, membrane activity, and catalytic and biological activity.[2, 10] In a very recent report on the CD4-binding properties of 15-residue peptides related to the CD4-binding domain of gp 120 from HIV I it was also suggested that a conformational switch of the type $\beta \rightarrow \alpha$ is essential for binding to the receptor.[11] The detailed elucidation of the structural determinants (e.g., nature of the amino acid residues, chain length) that govern the unique conformational properties of peptides **1**–**4** should make possible the design of peptides exhibiting tailor-made, medium-induced conformational transitions. These switch peptides may then serve as conformational modules (relay systems) in a number of applications. Furthermore, they should be a versatile tool for the investigation of the structural and dynamic factors involved in secondary and tertiary structure formation. Clearly, switch peptides should represent a much more adequate model system than (exclusively) helix-forming nonamphiphilic peptides for promoting a better understanding of the conformational preferences of the different amino acids in proteins. Not only does intermolecular aggregation of switch peptides approximate the occurrence of long-range interactions during protein folding, but in constrast to α-helical model systems[4f–g] they are also unbiased with respect to any particular type of secondary structure. This should, in principle, allow the elucidation of secondary structure potentials not only in relation to a random coil state but also in relation to an alternative type of ordered conformation.

Experimental

Peptide synthesis: All peptides were synthesized by the solid-phase method [12] (Fmoc/*t*Bu strategy [13]) on an Advanced ChemTech ACT II peptide synthesizer (semi-automatic operation) using Rink's amide resin [14]. Double couplings were performed in DMF/CH_2Cl_2 (3:2) for 90 min (first coupling) and in DMF for 60 min (second coupling) by using a 3.5-fold and 2-fold excess, respectively, of the preformed 1-hydroxybenzotriazole (HOBt) ester (preactivation with diisopropylcarbodiimide (DIC)/HOBt in DMF for 15 min). Three equivalents of Hünig's base (DIEA) were added to the reaction mixture directly after active ester addition. The Fmoc group was removed by treatment with 20 % piperidine/DMF for 2 and 15 min. After the last Fmoc removal the *N*-terminus was acetylated and the peptide was cleaved from the resin by treatment with CF_3COOH/CH_2Cl_2/ethanedithiol/thioanisole (75:22:1:2) for 45 min at room temperature. The resin was removed by filtration, washed, and the combined filtrates concentrated in vacuo. The peptides were precipitated with ether and isolated by centrifugation. Crude yields of 230–340 mg were obtained starting from 0.8 g of Fmoc protected resin (0.38 mmol Fmoc g^{-1}). The crude peptides were purified by preparative RP-HPLC (Waters Delta Prep 3000 Preparative Chromatography System) on a Vydac RP C18 column (2.5 × 20 cm). (Gradient elution with 0.05 % CF_3COOH/CH_3CN (B) into 0.05 % CF_3COOH/H_2O (A). **1**: 40 % B to 55 % B in 30 min; **2**: 30 % B to 55 % B in 20 min; **3**: 20 % B to 45 % B in 15 min; **4**: 35 % B to 50 % B in 15 min). According to analytical RP-HPLC the peptides were > 95 % pure and gave correct amino acid analyses.

CD spectroscopy: CD spectra were recorded on a Jobin Yvon Mark VI Dichrograph at 23 °C. Samples were prepared by dilution of stock solutions whose concentrations had been determined by amino acid analysis. Sample concentrations were 0.5 mg mL^{-1}.

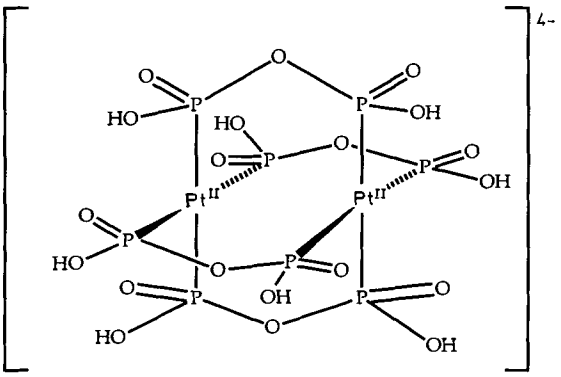
Photolytic Cleavage of DNA by $[Pt_2(P_2O_5H_2)_4]^{4-}$ **

By *William A. Kalsbeck, Neena Grover,* and *H. Holden Thorp**

The oxidative cleavage of DNA by metal complexes has attracted the interest of chemists interested in drug applications and the design of synthetic restriction enzymes.[1] Oxidative DNA cleavage reactions mediated by $[Fe(edta)]^{2-}$ have also been used to image unusual structures, such as helical twists and bent DNA, by high-resolution gel electrophoresis.[2] In the $[Fe(edta)]^{2-}$ system, the anionic metal complex does not bind to the DNA and generates $(OH)^{\bullet}$ in the bulk solution. Cleavage via abstraction of ribose H atoms by $(OH)^{\bullet}$ is therefore more efficient in regions of the DNA that are more exposed to the bulk solvent; quantitation of the cleavage efficiency by electrophoresis therefore allows for structural imaging. We hope to develop a highly discriminating imaging reagent by finding an anionic metal complex that can cleave DNA without binding and without generating a high-energy intermediate, such as $(OH)^{\bullet}$, $(O_2)^{\bullet-}$, or $^1O_2$. The excited state of $[Pt_2(pop)_4]^{4-}$ (**1**, pop = $P_2O_5H_2^{2-}$) fulfills these initial criteria.



1

The d^8-d^8 dimer **1** is an effective photoreagent for H atom abstraction reactions such as the oxidation of alcohols and hydrocarbons (Eq. (a)–(c)).[3, 4] The reactive ($d\sigma^* \rightarrow p\sigma$) excited state is populated by irradiation at 367 nm ($^1A_{1g} \rightarrow {}^1A_{2u}$, $\varepsilon = 35000\ M^{-1}cm^{-1}$) or 435 nm ($^1A_{1g} \rightarrow {}^3A_{2u}$, $\varepsilon = 110\ M^{-1}cm^{-1}$);[5] the long-lived ($\tau = 9.5\ \mu s$) triplet state is responsible for the oxidative activity. The dihydride species retains the Pt–diphosphonate framework, coordinating the two H^- ligands in open axial positions.[4] Irradiation at 458 nm of **1** in the presence of φX174 DNA leads to complete conversion of supercoiled DNA (form I) into nicked DNA (form II) in 20 min (Fig. 1, lane D) under anaerobic conditions at an ionic strength of 50 mM.[6] As seen in the controls, no significant cleavage occurs upon irradiation in the absence of **1** (lane F) or incubation with **1** in the dark (lane G).

$$[Pt_2^{II}(pop)_4]^{4-} \xrightarrow{h\nu} \{[Pt_2^{II}(pop)_4]^{4-}\}^{\bullet} \quad \text{(a)}$$

1 → **1***

$$\mathbf{1}^* + \text{OH} \xrightarrow{\text{H atom transfer}} [Pt^{II}Pt^{III}(pop)_4H]^{4-} + \text{OH}^{\bullet} \quad \text{(b)}$$

$$2\,\mathbf{2} \longrightarrow \mathbf{1} + [Pt_2^{III}(pop)_4H_2]^{4-} \quad \text{(c)}$$

3

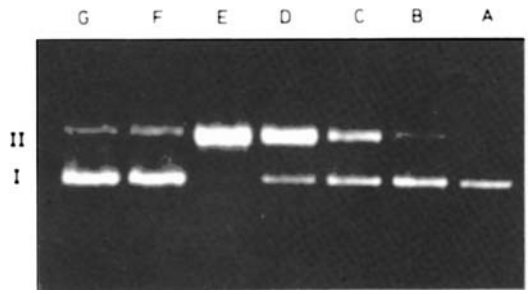

Fig. 1. 1% Agarose gel showing the results of electrophoresis of solutions of 60 μM φX174 DNA (50 mM phosphate, pH 7) containing (A) no platinum and 40 μM $K_4[Pt_2(pop)_4]$ after photolysis at 458 nm for (B) 2 min, (C) 5 min, (D) 10 min, (E) 20 min; (F) 60 μM φX174 DNA that has been photolyzed for 20 min; (G) 60 μM φX174 DNA that has been incubated with 40 μM $K_4[Pt_2(pop)_4]$ for 2 h in the dark. Concentrations of DNA are expressed as nucleotide phosphate.

It is clear that photocleavage is occurring via direct reaction of the excited state of **1** with the DNA. The excited-state, one-electron oxidation potential (ca. 0.7 V vs. saturated calomel electrode) is far too low for generation of $(OH)^{\bullet}$.[3, 7] The reaction is performed in the absence of O_2, so we can rule out the intermediacy of $^1O_2$ and $(O_2)^{\bullet-}$.[8] Furthermore, in the oxidation of organic substrates direct H atom abstraction by the excited state of the complex is the demonstrated reaction pathway [Eq. (b)].[4]

If **1** does not bind to DNA but cleaves by direct collision of the excited state with the double helix, the reaction efficiency should increase with solution ionic strength. At higher ionic strength, electrostatic repulsions between the tetraanionic **1** and the DNA polyanion will be lower,[9] facilitating approach of the excited metal complex to the DNA sugars. Figure 2 shows that increasing the solution ionic strength from 50 mM (lane A) to 150 mM (lane D) significantly in-

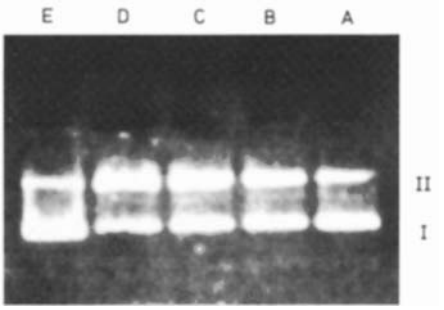

Fig. 2. 1% Agarose gel showing the results of electrophoresis of 60 μM φX174 DNA photolyzed in the presence of 20 μM $K_4[Pt_2(pop)_4]$ for 5 min in pH 7 phosphate buffer at ionic strengths of (A) 50 mM, (B) 75 mM, (C) 100 mM, (D) 150 mM; (E) φX174 DNA control.

creases the cleavage efficiency.[10] If the complex were bound to DNA, we would expect to see the efficiency *decrease*; if $(OH)^{\bullet}$ or $^1O_2$ were generated, we would expect at most a very small effect of ionic strength on the cleavage efficiency.

The final product of the reaction is the d^7-d^7 dimer $[Pt_2(pop)_4(H_2O)_2]^{2-}$ (**4**). We have detected the conversion of **1** into **4** by optical spectroscopy of calf thymus DNA solutions irradiated at 458 nm under N_2. This conversion is characterized by an isosbestic point at 306 nm (λ_{max} (**4**) = 245 nm).[5, 11] The $[Pt_2^{III}H_2]^{4-}$ species is known to eliminate H_2 in aqueous solution,[4] and we therefore propose the mechanism shown in Equations (d)–(f).

$$\mathbf{1}^{*} + \text{DNA (form I)} \xrightarrow{\text{H atom transfer}} \mathbf{2} + \text{DNA (form II)} \quad \text{(d)}$$

$$2\,\mathbf{2} \longrightarrow \mathbf{1} + \mathbf{3} \quad \text{(e)}$$

$$\mathbf{3} + 2H_3O^{+} \longrightarrow \underset{\mathbf{4}}{[Pt_2^{III}(pop)_4(H_2O)_2]^{2-}} + 2H_2 \quad \text{(f)}$$

It is now clear that **1** may be a versatile new imaging reagent; approach of the tetraanion excited state to the double helix is certainly more demanding sterically and electrostatically than approach of $(OH)^{\bullet}$, yet not so demanding as to prevent efficient cleavage. Other characteristics of this reaction are also noteworthy because they fulfil a number of general goals in DNA photocleavage.[12] First, we have succeeded in achieving efficient photocleavage with visible light (458 nm), where no background cleavage of the DNA occurs. Second, **1** photocleaves DNA under conditions where there is unambiguously no intervention of species such as $^1O_2$, $(O_2)^{\bullet -}$, or $(OH)^{\bullet}$. Third, the product of the reaction (**4**) still retains the Pt–diphosphonate framework and can be readily converted into **1** with mild reductants. Thus, we might ultimately observe photocatalytic cleavage in the presence of sacrificial reductants, similar to the thermal catalysis of the $[Fe(edta)]^{2-}$[13] and $[Cu(phen)_2]^{2+}$ (phen = 1,10-phenanthroline)[14] systems.

[6] $K_4[Pt_2(pop)_4]$ was prepared as described in [5]. Solutions were irradiated at 458 nm with an Ar ion laser at an incident power of 250 mW. Solutions were degassed with N_2 prior to photolysis and N_2 bubbling was continued throughout the reaction. φX174 DNA was purchased from Pharmacia and used as received. Solutions were electrophoresed for 1 h at 44 V, and the gels were stained with ethidium bromide and photographed under UV light.
[7] We also observe cleavage in the presence of sodium formate, an efficient scavenger of $(OH)^{\bullet}$: J. D. Rush, Z. Maskos, *Inorg. Chem. 29* (1990) 897.
[8] We have performed the photolysis both with and without degassing the solution and find that degassing has no effect on the cleavage efficiency. Thus, it appears that even in aerated solutions, an O_2-dependent pathway is not involved.

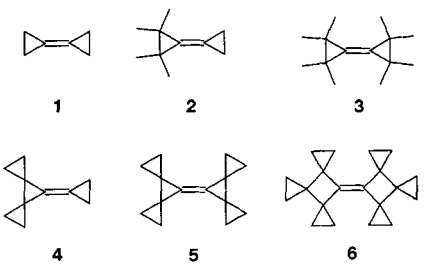
7,7′-Bi(dispiro[2.0.2.1]heptylidene)—the Perspirocyclopropanated Bicyclopropylidene**

By *Stephan Zöllner, Herwig Buchholz, Roland Boese, Rolf Gleiter,* and *Armin de Meijere**

Dedicated to Professor Michael Hanack on the occasion of his 60th birthday

Unsubstituted bicyclopropylidene **1**[1] is in itself already an unusual tetrasubstituted alkene;[2] due to its high-lying HOMO[3] and its strained double bond,[4] it is particularly reactive towards electrophiles.[5] Four or eight methyl substituents, as in **2** and **3**, respectively, lower the π-ionization energy[6] and thus increase the nucleophilicity, though spiroannelated cyclopropane rings are more reactive, as evidenced[8] by the He(I)-photoelectron spectrum of 7-cyclopropylidenedispiro[2.0.2.1]heptane (**4**).[7] The ultimate reactivity in this series may very well be observed in the case of the hitherto unknown perspirocyclopropanated bicyclopropylidene **5**. Even if this should not be reflected in the position of the π-HOMO, the nucleophilicity of **5** could still surpass that of the perspirocyclopropanated bicyclobutylidene **6** described by us in an earlier work.[9]



Of several possible routes to **5** that were tried out, one finally led to the target compound (Scheme 1). The starting material was the readily accessible compound **4**,[7] which smoothly furnished—via the dibromocarbene adduct **7**[10]

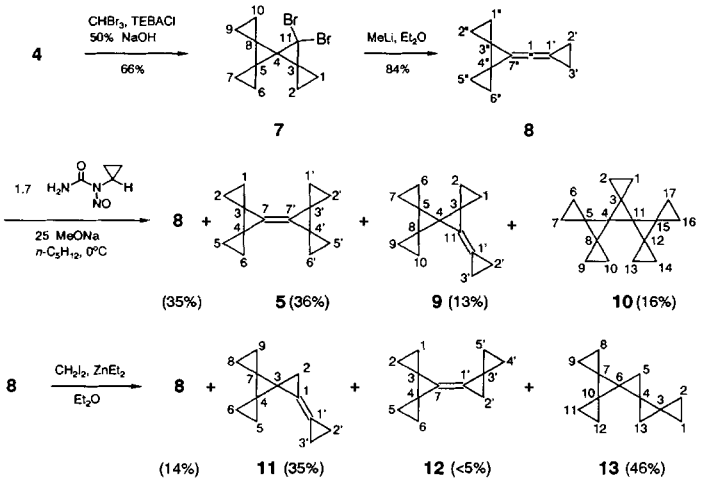
(66% yield after chromatography)—the cyclopropylidene(dispiro[2.0.2.1]heptylidene)methane **8**[10] (84%). Analogous to the first synthesis of [3]rotane[11] from bicyclopropylidene **1** and diazocyclopropane,[12] the treatment of **8** with diazocyclopropane generated in situ furnished, besides the fourfold spirocyclopropanated [3]rotane **10**[10, 13, 14] (8% yield, based on reacted **8**) and 11-cyclopropylidenetetraspiro[2.0.0.2.0.2.0.1]undecane (**9**)[10] (7%), the title compound 7,7'-bi(dispiro[2.0.2.1]heptylidene) (**5**)[10] as the main product (31% yield, based on reacted **8**). Decisive for a satisfactory conversion of the allene **8** (up to 65%) was that a relatively dilute solution of **8** in *n*-pentane was treated at 0°C with 1.7 equiv of *N*-cyclopropyl-*N*-nitrosourea[15] and 25 equiv of solid sodium methoxide.



Scheme 1. TEBACl = benzyltriethylammonium chloride.

The selectivity of the attack of diazocyclopropane at the sterically less shielded double bond of **8**, which is favorable for the formation of **5**, is not observed in the Simmons–Smith cyclopropanation with diiodomethane/diethylzinc[16] (Scheme 1, bottom). The smaller reagent preferentially attacks at the central double bond, which is obviously more reactive due to strain; this affords predominantly **11** (35%) and the product of double cyclopropanation **13**[17] (46%), besides small amounts of **12** (<5%).

The products **5**, **9**, and **10** and the main products **11** and **13** of the carbene additions to **8** could be separated by chromatography on silica gel. Upon recrystallization from methanol, **5** and **10** precipitated as crystals that were suitable for X-ray structure analyses (Fig. 1).[18] The most striking structural features of **5** and **10** are the differences in lengths between the proximal and distal bonds in the external cyclopropane rings, while all CC bonds in the internal cyclopropane rings are shortened.[19] Both of these features are a consequence of the increased strain, along with the accompanying changes in hybridization.[20] The double bond in **5** (130.5(4) pm) is almost the same length as that in bicyclopropylidene **1** (130.4(8) pm[4]). Accordingly, the hybridization of the central C atoms is scarcely altered by the fourfold spiroannelation,[20] and the electronic properties of the double bond are largely determined by the four α-cyclopropane groups. The result is an ionization energy of 8.20 eV, which is significantly lower than that of the octamethyl derivative **3** (IE_{iv} = 8.35 eV).[6]

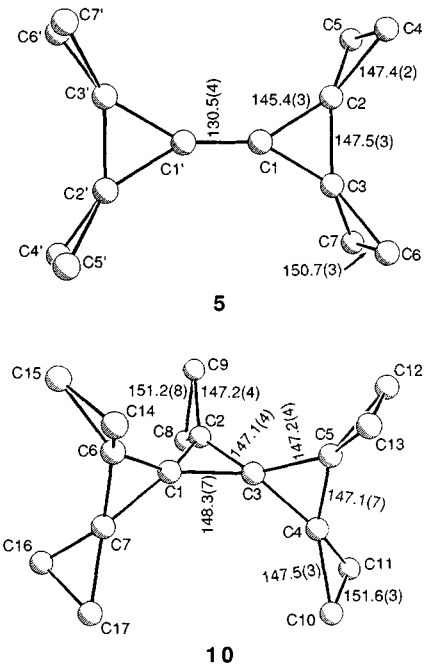


Fig. 1. Structures of **5** and **10** in the crystal. The bond lengths [pm] are determined in each case via the *mmm* symmetry, and in the case of **10** also via two independent molecules in the asymmetric unit. The numbering does not agree with that recommended by IUPAC and used in Table 1.

In contrast to bicyclopropylidene **1**, which reacts with bromine[21] and many other electrophiles[5e] with rearrangement, the perspirocyclopropanated **5** reacts with hydrogen bromide and bromine in *n*-pentane at −15°C to give, without rearrangement, the respective products **15a** (≥95%) and **15b** (≥95%, isolated 71%). This can be taken as an

BOOK REVIEWS

Book Reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the following address: Redaktion Angewandte Chemie, Postfach 101161, D-6940 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

Organic Synthesis via Organometallics. Edited by *K. H. Dötz* and *R. W. Hoffmann*. Vieweg, Braunschweig 1991. viii, 323 pp., hardcover DM 92.00.—ISBN 3-528-08947-4

This volume contains 17 papers presented at the third symposium on research topics sponsored by the Volkswagen-Stiftung, which was held in Marburg in July 1990. It is a wide-ranging and readable survey of recent applications of organometallic reagents and reactions in organic synthesis. The organizers have once again put together an attractive program of lectures, containing a balanced mixture of "classical" topics and new developments in the field of organometallic chemistry.

R. H. Grubbs reports on the use of titanacyclic compounds and alkylidene complexes in "Living Ring-Opening Metathesis Polymerization" (ROMP) and the application of this method to the preparation of block copolymers and highly conjugated polymers, of which the extreme example is polyacetylene. *W. Keim* et al. give a wide-ranging review of the enantioselective telomerization of 1,3-dienes using palladium and nickel catalysts, including discussions of analytical and mechanistic aspects. A short article by *H. H. Brintzinger* on chiral *ansa*-metallocenes, in which the stereoselectivity of α-olefin polymerizations is explained by mechanistic arguments, is then followed by *H. Fischer*'s contribution on benzylidene complexes as C_1 sources, which is a somewhat longer report describing their stereoselective conversion to give cyclopropane derivatives and heterocycles. In a very interesting and highly imaginative article *D. Astruc* summarizes the work of his group on "Organo-Iron Complexes in Aromatic Synthesis". This describes how simple cationic complexes of hexamethylbenzene with iron are used, in a single-pot reaction, to prepare "tentacle" molecules, and how the benzyl sites are then activated by electron transfer reactions to yield a wide variety of new complexes, many of which are multinuclear. Especially worth mentioning here is a compilation of literature references on the activation of arenes by transition metals. The article by *D. Walther* et al. describes the activation of CO_2 using nickel(0) complexes and alkenes or alkynes to give nickela-cyclic carboxylates, which can also be prepared by reacting a bipyridyl-stabilized diethylnickel species with cyclic anhydrides. Especially interesting here are the cyclizations with alkynes leading to the formation of the preparatively very useful 2-pyrones with selectivities of more than 90%; the trimerization reaction of the alkyne is almost completely suppressed. A description of the use of steroid systems in cross-coupling reactions with nickelacarboxylates and a section on the carboxylation of C–H bonds and of imines as "reversible CO_2 carriers" serve to emphasize the close relationship between organometallic and bioorganic CO_2 chemistry. The next article by *J. K. Kochi* on "Charge-Transfer Activation of Organometallic Reactions" is quite long, and is of fundamental importance to an understanding of many of the reactions of organometallic chemistry. However, the relevance to organic synthesis here is rather tenuous.

The review by *H.-J. Knölker* on the use of dienyliron complexes in synthesizing natural products is very well worth reading and full of information. It is pleasing to find that a large number of the author's published papers, which have appeared within a remarkably short period, are here summarized. The emphasis is again on iron in the article by *P. Eilbracht* et al.; these authors have converted cyclohexadiene derivatives, via their complexes with $Fe(CO)_3$ with insertion of CO, into a wide variety of carbocycles, some of which are quite complicated, and have investigated the mechanisms of the reaction steps. *G. R. Stephenson* et al. are concerned with the control of regiospecificity in alkylation reactions using cyclohexadienyliron complexes, and the very careful and thorough study reported here shows that there are close relationships to alkaloid syntheses. *C. P. Casey* et al. summarize their recent investigations on new reactions of organorhenium compounds, which are very interesting from a mechanistic standpoint; they also discuss the importance of heterobimetallic systems. *J. Okuda* et al. describe the ligand (3-butenyl)tetramethylcyclopentadienyl; as a ligand with an olefinic side-chain this is capable of reversibly blocking one of the coordination sites of the metal atom in the corresponding cyclopentadienyl complexes. The chemical behavior with cobalt is particularly interesting here, since the [2 + 2 + 2]-cycloadduct was formed from two alkyne molecules and the double bond of the ligand, which, however, is irreversibly attached to the ligand. The contribution by *C. Bolm* is concerned with the use of optically active bipyridines in enantioselective synthesis; the author has alkylated aldehydes and α,β-unsaturated ketones with varying degrees of enantioselectivity in the presence of these chiral ligands using palladium or nickel catalysts. In the article by *V. Schurig* the main preparative interest is centered on enantioselective methods for preparing simple oxiranes. The author also discusses aspects of prochiral and chiral recognition using complexation gas chromatography. In the article by *D. Hoppe* we are reminded that "organometallics" are not confined to transition metal compounds: *N,N*-dialkylcarbamoyloxy groups not only facilitate lithiation at the adjacent sites but also, as a result of intramolecular complexation, increase the configurational stability of the ion pairs that are formed, which has very important consequences for enantioselective syntheses. An industrial research team led by *A. Hafner* describes a fruitful combination of transition metal chemistry with carbohydrate chemistry: by forming chiral complexes of carbohydrates with titanium, zirconium and hafnium, the authors were able to prepare a number of enantiomerically pure reactive alkylating agents. In a large number of reactions this good idea yielded enantiomeric excesses and diastereoselectivities that were in most cases very high. Last but not least in this collection of articles, *R. Noyori* et al. present a very lucid contribution on "Multiplication and Amplification of Chirality". Catalytic concentrations of enantiomerically pure 3-*exo*-(dimethylamino)isoborneol (DAIB) cause alkylzinc compounds to react with aldehydes giving secondary alcohols with *ee* values up to 99%. Even when the DAIB present in catalytic amounts has an *ee* value of only 14%, a product with an *ee* value of 98% is obtained.

The 17 articles have been reproduced directly, which means that the publishers have had almost no typesetting or correction work to do. The authors too have done their work thoroughly, and there are very few errors; in the case of the German authors one occasionally comes across idioms carried over from the German language. It would have been desirable in the reaction schemes to give details of yields and reaction conditions wherever possible. The book can be recommended to everyone interested in organometallic chemistry and organometallic methods of synthesis; it is suitable, rather in the manner of an advanced seminar, as an introduction to the areas of work described. A cheaper paperback edition would have been desirable.

Materials Science and Technology (A Comprehensive Treatment). Volume 5: Phase Transformations in Materials. Edited by *P. Haasen*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York 1991. xiii, 648 pp., hardcover DM 430.00.—ISBN 3-527-26818-9/0-89573-693-4

This series is planned to consist of 18 volumes altogether; by the end of this year a further six volumes will have been published in addition to Volume 5 which is reviewed here. One can expect this to be an exciting series when complete—and the same also goes for the price. The editors (*R. W. Cahn*, *P. Haasen* and *E. J. Kramer*), on behalf of the authors (of whom there are more than 200), introduce the series as follows: "The new series is intended to mark the coming-of-age

of that new discipline, define its nature and range and provide a comprehensive overview of its principal constituent themes". The series appears at an opportune time and fills a real gap. Can there be anyone who has not already come into contact in some way with the field of "materials science and technology"? This in itself illustrates the interdisciplinary nature of this now virtually "exploding" area of science and technology. In the past we used to refer simply to "materials science", but often the technological and economic implications were underestimated.

It is certainly appropriate here to briefly indicate where Volume 5, which is the first to appear, fits into the overall series. In this way one can explain most clearly the aim of the series and its level (and thus also the position occupied by each individual volume). The topics to be treated in the 18 volumes are as follows: 1. Structure of Solids, 2. Characterization of Materials, 3. Electronic and Magnetic Properties of Metals and Ceramics, 4. Electronic Structure and Properties of Semiconductors, 5. Phase Transformations in Materials, 6. Plastic Deformation and Fracture of Materials, 7. Constitution and Properties of Steels, 8. Structure and Properties of Nonferrous Alloys, 9. Glasses and Amorphous Materials, 10. Nuclear Materials, 11. Structure and Properties of Ceramics, 12. Structure and Properties of Polymers, 13. Structure and Properties of Composites, 14. Medical and Dental Materials, 15. Processing of Metals and Alloys, 16. Processing of Semiconductors, 17. Processing of Ceramics, 18. Processing of Polymers. Thus a picture of materials science embracing both basic research and technology is built up.

Phase equilibria, phase transformations, transport and diffusion processes, reactions at interfaces, decomposition reactions, structure-forming processes, precipitations, superlattices and crystallization processes are, of course, all of fundamental importance to materials science. The volume reviewed here is devoted to this topic area, which is covered in ten chapters of roughly equal length, namely: 1. Thermodynamics and Phase Diagrams of Materials: aspects covered are chemical equilibria and Gibbs free energy, thermodynamics of solutions, binary and ternary phase diagrams (including reciprocal salt pairs), thermodynamics and the analysis of phase diagrams.– 2. Diffusion in Crystalline Solids: this chapter discusses macroscopic and microscopic diffusion, diffusion in solid materials, and experimental methods for determining diffusion coefficients. – 3. Statistical Theories of Phase Diagrams: topics here include phenomenological approaches, computer methods (models) and metastability. – 4. Homogeneous Second Phase Precipitation: this chapter covers experimental methods for studying the kinetics of decomposition reactions, the morphology of precipitates, the kinetics of decomposition reactions, increasing the particle size of primary precipitates, and numerical calculations on nucleation, growth and increasing particle sizes. – 5. Transformations Involving Interfacial Diffusion: the structures of particle and phase boundaries, diffusion (the roles of capillary forces, chemical forces and mechanical forces), chemically induced migration of grain boundaries, and discontinuous precipitations are discussed. – 6. Diffusionless Transformations: here the reader learns about mechanisms, microstructures, morphological changes, dilative and martensitic transformations, shear transformations, techniques of investigation, and finally properties and applications. – 7. Spinodal Decomposition: this chapter discusses separation kinetics, the equation of nonlinear diffusion, spinodal decomposition processes, influence of cooling rates (quenching), systems in the neighborhood of a triple point, spontaneous growth of ordered domains, and some experimental results (selected examples from the fields of metallic alloys, glasses, ceramics, liquid mixtures and polymer mixtures). – 8. High Pressure Phase Transformations: this chapter is concerned with experimental techniques, elements of Group IV, III–V compounds, barium chalcogenides, cesium halides, xenon, semimetal/semiconductor/metal transitions, and molecular solids (iodine, oxygen, hydrogen). – 9. Atomic Ordering: here the topics are atomic configurations, domains and configuration polyhedra, ground states, calculations of phase equilibria (by the cluster variation or Monte-Carlo methods) and applications to real systems. – 10. Solidification: the final chapter discusses first-order phase transformations, experimental methods, dendritic growth, orientated (directional) crystallization, and eutectic growth.

All the chapters, including even the strongly computing-orientated Chapters 3 and 9, are elucidated by describing selected chemical systems as examples wherever possible, thereby ensuring that the discussion is always related to real situations. The topics are dealt with in a rigorous and concise manner throughout; the reader is assumed to already have some basic knowledge of the subject. Adequate and appropriate references to original papers, review articles and books for more advanced or supplementary reading are provided. The choice of topics and their treatment are without doubt appropriate for such an interdisciplinary field of study.

Research groups with interests in materials science will need to have direct access (through their institutes and libraries) not only to Volume 5 but (presumably!) to the entire work. This certainly also applies to groups working in the area of "basic scientific research", whose problems and aims are much closer to materials science than is generally recognized.

This volume can be recommended, and the further volumes in the series that are to follow will be eagerly anticipated!

High Vacuum Techniques for Chemical Synthesis and Measurements. By *P. H. Plesch*. Cambridge University Press, Cambridge 1989. xiii, 167 pp., hardcover £ 35.00.—ISBN 0-521-25756-5

P. H. Plesch discusses the advantages and possible applications of high-vacuum techniques in the research laboratory in a very personal style. "This book may have a slightly old-fashioned look" writes the author in the introduction, and he's not wrong in saying that. Yet the book was written by an experienced practitioner for practical use, and contains countless tips and tricks which are difficult to find elsewhere in comparable literature.

This book is divided into 5 sections, and is very readable throughout. Chapter 1 (Fundamentals) covers first of all the fundamentals of working under an inert gas, as well as the advantages and disadvantages of different working techniques. There then follows a short section on the theoretical principles. Section 1.3 (Essential skills and equipment) introduces the rudiments of glass-blowing, where one is advised not to forget Murphy's Law. In this context I felt the advice on safety in Section 1.4 (General comments on safety) was especially important. Various sources of hazard are mentioned here, which cannot be overemphasized (for example,

the condensation of oxygen in cold traps). I would like to add that substances hazardous to health, such as Na/Pb alloys (p. 8) or chromic acid (p. 75) should no longer be used in a modern research laboratory, and should be replaced by more suitable drying and cleaning agents. Chapter 2 (The main vacuum line) can be considered the heart of the book. It contains detailed descriptions of the building and running of a high-vacuum line. After a short overview, the individual components of this equipment (pumps, cold-traps, taps, valves, manometers) are described and compared. The reader thereby obtains important advice on which device best suits each situation. Here too, *Plesch* succeeds in giving the reader the experience he has gained from many years of working with high-vacuum techniques. Even apparently minor particulars, like the correct greasing of ground glass connections, are not to be underestimated in practice. Practical advice of this kind makes the book useful reading material for every diploma or PhD research student who needs to use some form of vacuum technique. After the construction of the vacuum line the sometimes laborious task of detecting leaks is discussed. In Chapter 3 (Applications and procedure) countless specialized apparatus and additional possible applications for high-vacuum techniques are described. *Plesch* gives particular attention to the filling and melting of glass phials. Much of this equipment (burettes, dilatometers, viscometers, calorimeters, etc.) is useful, but some, in my view, is a little too exotic (e.g., on page 93, the device for simultaneous filling of several dilatometers). On the other hand the section on NMR measurements (p. 96) is a little too short. Sealing NMR tubes under vacuum should be a routine operation for any advanced graduate student. However, I consider the making of NMR tubes (p. 97) a waste of time. Chapter 4 (Purification, including drying) contains countless useful tips for practical work. Every synthetic chemist will daily encounter problems with cleaning and drying reagents and solvents. A book about potential applications of vacuum techniques would therefore be incomplete without advice on drying glass apparatus (p. 119) as well as degassing and drying the solvent to be used. Thus, Section 4.6 (What is so special about drying?) particularly is worth reading attentively. Chapter 5 concludes the book with a few syntheses and measurements, chosen to show the advantages of the high-vacuum technique.

In the introduction *P. H. Plesch* defines the aim of the book: "...to enable a chemist to assess the possible utility of high-vacuum techniques for his purposes, to design and build a high-vacuum system, and to do good chemistry with it". The author has succeeded in doing this.

Frank T. Edelmann [NB 1178 IE]

der Universität Göttingen (FRG)

Basic Principles and Techniques of Molecular Quantum Mechanics. By *R. E. Christoffersen*. Springer, Berlin 1990. xiv, 686 pp., hardcover DM 178.00.—ISBN 3-540-96759-1

This book is a comprehensive student text and work of reference on the theoretical fundamentals of quantum chemistry and their practical applications. It differs from other books on this theme in several respects, including the amount of space devoted to describing the mathematical basis of quantum-mechanical methods.

A brief introductory section reminds the reader of some of the concepts of classical mechanics, and describes the experimental observations that led to the formulation of quantum mechanics. This is followed by 140 pages on vector space and function space, matrix algebra, operator algebra, etc. After this come several chapters in which the postulates of quantum mechanics are introduced and the usual model problems are treated (particle in a box, harmonic oscillator, the hydrogen atom, etc.). The Hamiltonian operator for molecular systems is discussed in considerable detail, including the effects of external magnetic fields as well as relativistic effects. The final chapter of the book contains an equally detailed treatment of the approximate methods that are commonly used in quantum chemistry, such as the closed- and open-shell Hartree-Fock SCF approximations, perturbation theory and configuration interaction.

The overall impression is of a sound and competently written book. Explanations are given of many points that are not often covered in comparable textbooks; for example, there are discussions of the Rayleigh-Schrödinger and Brillouin-Wigner perturbation theories, of methods of calculating lower limits for the energy, and of such details as the origin of the s,p,d... nomenclature for atomic orbitals. Nevertheless, there is some doubt as to whether the book entirely succeeds in the ambitious aim of presenting the complex mathematical background in a form which is both detailed and comprehensible to the student. Too often one finds that proofs and theorems are glossed over, and the reader is referred, in one of the many footnotes, to the original literature. Also the mathematics is presented without directly relating it to applications, and one suspects that many students will consequently feel that this part of the book is an unappealing and barren slog.

It is also regrettable that the discussion of quantum-mechanical computational methods is not always completely up-to-date. New developments such as the use of direct SCF methods for calculations on large molecules or of natural atomic orbital basis sets are not described. In the discussion of the multiconfigurational SCF approach one searches in vain for a mention of the CASSCF method that is now most commonly used; also the direct CI methods that have now become so important are treated rather too briefly. A further example of the sometimes rather outdated treatment is the comment by *Christoffersen* that the diagonalization of a 1000×1000 matrix takes several seconds of computation, whereas fast modern computers can in fact perform such tasks in fractions of a second. This tendency towards outdatedness is also reflected in the choice of literature references, which mostly come from the 1970s and early 1980s.

It is also unfortunate that many printing errors have found their way into the text, including some that are rather confusing. For example, "yield" has become "field", a factor of 1/2 has been omitted from one formula, and one suddenly finds that instead of an external force one is dealing with an "external face". With monotonous regularity a trial wave-function becomes a "trail" wave-function, and even the names of authors in the literature citations do not escape distortion. A particularly annoying error is a reference to a figure at the end of Chapter 7, where one looks in vain for it; it is not until four chapters later that one suddenly comes across an identical paragraph, this time with the figure. Blunders such as these could certainly have been avoided with a little care.

However, if one leaves aside these deficiencies in the preparation, the tendency towards outdatedness in some parts, and the fact that the planning of the mathematical part is perhaps not entirely successful, *Christoffersen*'s book is an interesting addition to the range of textbooks on theoretical

chemistry, and is to be welcomed especially for its many-faceted treatment of the subject.

Houben-Weyl. Methoden der Organischen Chemie. 4th Edition, supplementary volumes. **Volume E 16a, Parts 1 and 2: Nitrogen Compounds I.** Edited by *D. Klamann*. Thieme, Stuttgart 1990. Part 1: xxxvi, pp. 1–855; Part 2: xiv, pp. 856–1516; hardcover DM 2100.00 (subscription price: DM 1890.00).—ISBN 3-13-218-604-X

The publishing house Thieme continues to press on with the work of updating the Houben-Weyl volumes written in the period from the 1950s to the 1980s, by publishing a supplementary work which takes into account the latest state of development on methods and the most recent literature. In these two part volumes on organonitrogen compounds they have again succeeded in an impressive way.

This work again meets the aim (which has never been explicitly stated) of not only giving an appropriate experimental procedure for each special case, but also providing the reader who has not yet become a specialist in a particular field with an introductory, but nevertheless thoroughly sound, overview of the possibilities. The reader may look up a specific method and gain some additional information as a result, or browse around the special problem of interest, or again may read a few dozen pages almost in the manner of a textbook. Each of these types of readers will get good value from the work, helped by the information-packed and mainly well chosen subject matter, although not necessarily by the arrangement of the contents, which follows an ever more rigid pattern. The strict adherence to the ten hierarchical levels of classification sometimes results in an undue emphasis on unimportant features, and often separates closely related topics. For example, the closely similar procedures of the *N*-alkylation of hydroxylamine and that of *N*-alkylhydroxylamines appear in different sections, as also do the entirely analogous methods used to synthesize mono- and dihalogenated amines.

The limitation to work published during the last twenty to thirty years, which is usually applied very consistently, sometimes results in an emphasis on procedures that have been overrated. Without actually copying "Beilstein" it would have been useful to keep in mind the system used there, in which the variety of routes to a class of compounds is shown under the heading "Bildungsweisen", whereas under "Darstellung" the more generally useful and perhaps less elegant method is chosen. The recommended procedures should always be rather more generally applicable than the reactions described in between these. A welcome feature is the caution that has been applied with regard to mechanisms, avoiding unnecessary embellishments on this theme; in view of the need for "Houben-Weyl" to remain up-to-date for decades, speculations of that nature would be likely to become obsolete more rapidly than the established facts.

The first of the two part volumes contains two very long chapters on organic hydroxylamine compounds (395 pp.) and organic hydrazine compounds (435 pp.), together with much shorter chapters on nitroxyl radicals, nitroxides and amino-oxides. The considerable length of the chapter on the hydroxylamines is no doubt due to the many different types of redox reactions of N–O compounds and the biological activity shown by many individual compounds. In the case of the hydrazines the reason for the length is that the alkylhydrazines have made a welcome appearance in the last few decades; previously these could only be prepared with great difficulty by laborious alkylation of hydrazine or by reduction of nitrosamines, whereas they are now accessible by a variety of interesting reactions, mainly by forming N–N bonds. The lengths of these two chapters are therefore justified. However, the lengths of some of the subsections are not commensurate with the importance of the topics. Addition reactions of nitrones and olefins occupy 20 pages with an enormous table, and the (admittedly interesting) criss-cross cycloaddition of alkenes to hexafluoroacetone is given a six-page table. Such comprehensive treatments of examples that are analogous should be left to specialized monographs. The same also applies to the 16 pages with analogous examples of *Meerwein*'s reaction of diazonium salts with alkenes in Part 2 of the work. On the other hand the work does not give an up-to-date procedure for preparing solutions of chloramine; the conventional procedure giving a yield of 30–40% (reproduced here on p. 250) can be improved to give reproducibly more than 90% simply by adding ammonium chloride (*Z. Anorg. Allg. Chem. 396* (1973) 178).

In the chapter on hydrazines it would have been useful in a number of cases to indicate how precursors that are not altogether commonplace can be prepared, for example, when describing the reduction of alkoxy(alkyl)diazene-*N*-oxides (p. 463). The usefulness of the method for preparing 1,2-diethylhydrazine by reduction of the azo compound (p. 523) could be better appreciated if one knew whether it was possible to make the azo compound by some route other than the reverse of the reaction described, i.e. by oxidation of diethylhydrazine. The interesting synthesis of arylhydrazines by acid hydrolysis of arylsydnones cannot give acetic acid as the secondary cleavage product, as is shown in the formula on page 793. Also, the preparation of methylhydrazine from methylamine (p. 426) should not be described as an oxidation.

In Part 2 the long chapter on *N*-halogenated amines possibly puts too much emphasis on the preparation of pure compounds; it is more important to have straightforward methods for preparing well-defined solutions for use in further reactions. This chapter is followed by the subject of *C*-nitroso compounds, which obviously has a great many subdivisions and requires no less than 129 headings in 47 pages of text. In the description of the nitrosation of arenes it would have been desirable to show a clear division between those nitrosation reactions that are useful for synthetic purposes (e.g. those of phenols) and the nitrosations of simple arenes such as benzene that have also been investigated. The chapter by *J. Goerdeler* on ammonium compounds is excellent; this describes the quaternization of amines of increasing inertness on reaction with alkylating agents of increasing reactivity. A separate chapter is devoted to the hydrazinium compounds, which have only attained importance in recent years. This is followed by the classical diazonium compounds; as these have had a career of more than a hundred years their preparation occupies less space (35 pp.) than their reactions (49 pp.). Next come chapters on a few special classes of compounds such as nitrosamines, triazenes and tetrazenes; the work ends with a chapter on azides.

Finally a few errors and incorrect usages need to be mentioned. On page 462 the statement that the pressure falls from 73 694 torr to 60 765 torr is hardly in accord with the precision of typical pressure measurements in the preparative laboratory. Quoted values such as 101.87 kPa (p. 878) probably

arise from giving the results of calculations with too high a precision. One should not refer to "activated alkenes" without indicating whether they are activated in the direction of electron deficiency (unsaturated esters, nitriles or ketones) or electron excess (vinyl ethers, enamines). In this light many reactions are quickly seen to be plausible. Sodium sulfate is a water-binding agent, not a dehydrating agent (p. 876). On page 947 the precursor of quinuclidine has a carbon atom missing. What is meant by the statement on page 879 that sodium chlorite ($NaClO_2$) is oxidized to chlorine? On page 258 the formula of *O*-sulfohydroxylamine is shown without the crucially important oxygen atom between N and S. In two preparative methods on pages 444 and 468 one of the reagents has been omitted in each case.

The fact that in over 1500 pages only about twenty printing errors could be found is an indication of the high quality of the typesetting. However, one of these is an incorrect spelling of the name *Birkofer*; this is again repeatedly shown with an extra "h", despite this error having been pointed out by *Richard Kuhn* in a review[*] of the 4th Edition.

A tribute must be paid to the hard work by the authors. Since a chemist's range of interests is not nowadays defined in terms of compound classes, a specialist dealing with a particular class of compounds is now a rarity. Despite all the aids that are now available, collecting together the required information is still an arduous task; the essential job of evaluating facts costs time and effort.

Crystalline Symmetries. An Informal Mathematical Introduction. By *M. Senechal*. Adam Hilger, Bristol 1990. xi, 137 pp., hardcover £ 79.50.—ISBN 0-7503-0041-8

Chemists are generally comfortable with the geometry of structure, the algebra of stoichiometry, and the calculus of kinetics. Most of them have learned to live with the eigenvalue problems of quantum mechanics. As to the less familiar mathematics of group theory graph theory or topology, many chemists have only a vague concept of the mathematical fundamentals and employ terminology in a manner that is at best intuitive and idiosyncratic. Discussing the application of mathematics to chemistry with a real mathematician can be an uncomfortable, confusing, and humbling experience.

In this small, aptly-titled book Professor *Senechal*, a professional mathematician, provides a friendly introduction to the mathematical fundamentals of crystallography that will entertain and reward casual readers as well as chemists and materials scientists who work with crystallography.

Almost two-thirds of the text involves familiar concepts of symmetry, lattices and space groups, but the treatment is novel: it is written by a mathematician for experimental scientists. Familiar and less familiar concepts, such as orbits, cosets, the Voronoï cell, isometries, and symmorphic space groups, are clearly defined and illustrated. Simple theorems are proven while others are invoked or outlined with reference to an extensive bibliography for more detailed treatment. After reading this book one can feel more comfortable with the assertion that there are 4901 four-dimensional space groups, or with the impossibility of having space groups with fivefold rotation axes. Most of the discussion is clear and satisfying, with only the occasional difficulty, such as on page 56 where an unnatural definition of density in a two-dimensional lattice leads to difficulty in relating the reciprocal lattice to crystal form.

There are appetizing but less complete chapters that introduce the modern topics of color symmetry and *N*-dimensional crystallography, including mention of Penrose tiling and local fivefold symmetry, and a fifteen-page chapter which discusses crystal classification and how to interpret space group information in the *International Tables for X-Ray Crystallography*. The bibliography includes twenty books and journal articles published since 1980.

Throughout the book, particularly in the first chapter, special attention is given to the historical development of crystallography as an experimental, mathematical, and artistic science. This emphasis is effective both for holding the reader's interest and for illuminating the logic of the subject. A four-page appendix provides concise information about the contributions to crystallography by 34 natural philosophers and mathematicians from *Plato* to *Roger Penrose*.

Professor *Senechal* notes that although the French mathematician *Jordan* had combined the proper motions (rotations, translations, and screw rotations) with Bravais' lattices by 1868, it took another 23 years before *Fedorov* and *Schoenflies* completed the 232 space groups by adding the reflections, glides and rotary reflections that interconvert enantiomers. This seems curious because by 1850 *Pasteur* had already demonstrated the need for such improper symmetry elements by revealing the relation between molecular and morphological chirality. *Senechal* wonders, "Was [this delay] due to differences in scientific fields, or differences in language? Are there similar gaps today of which *we* are unaware?". By providing a simple introduction to the mathematics of crystallography this small book should help to bridge one of the gaps between scientific fields that persists today.

J. Michael McBride [NB 1196 IE]

New Haven, CT (USA)

Microbial Polyesters. By *Y. Doi*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York 1990. ix, 156 pp., DM 74.00.—ISBN 3-527-27860-5/0-89573-746-9

In the future biopolymers are likely to play an ever increasing role. Such compounds are interesting for several reasons: for one thing they are biodegradable and therefore do not contribute to environmental problems; for another they are produced from renewable resources. Commercial utilization of such materials has already begun: shampoo containers manufactured from polyesters which have been made by biotechnological methods have appeared on the market. A comprehensive review of polyesters that are produced by microbial synthesis is therefore welcome, even if the present author has chosen to give pride of place to his own contributions.

The monograph, which has a convenient A5 format ($8\frac{3}{4} \times 5\frac{1}{2}$ inches), presents in eight chapters a discussion and comparison of the properties of poly-(*R*)-3-hydroxybutyrate (PHB) and of two copolymers, poly(3-hydroxybutyrate-co-3-hydroxyvalerate) (P(3-HB/3-HV)) and poly(3-hydroxybutyrate-co-4-hydroxybutyrate) (P(3-HB/4-HB)), the latter discovered and investigated by the present author.

[*] *Angew. Chem. 72* (1960) 502.

The early chapters deal mainly with biological aspects, while the later chapters emphasize physical properties and applications. A brief introduction (Chapter 1) is followed by a discussion of the preparation of polyesters by fermentation and of current methods of their analysis (Chapter 2) and of the natural occurrence of a wide range of microbial polyhydroxyalkanoates (Chapter 3). The dependence of yield and composition of the copolymers on carbon source, bacterial strain, and culture conditions, as well as the function of PHB as a storage material are also discussed. Regrettably, the occurrence of PHB in cell membranes is not mentioned. Chapter 4 presents an overview of the routes of biosynthesis and of the enzymology of the polyesters. It is interesting to note that several research groups have located the gene responsible for PHB biosynthesis in *Alcaligenes eutrophus*, and have expressed it in *Escherichia coli*, a bacterium which normally does not produce PHB as a storage material. Chapter 5 is devoted entirely to a discussion of the copolymer, P(3-HB/4-HB), whose promising properties have not yet been fully explored. The next two chapters deal with the structure and properties of PHB and P(HB/HV)-copolymers. Investigations of the solids by X-ray diffraction and NMR are described in detail. Also dealt with are mechanical and thermal properties. These are important from the point of view of industrial applications. The current state of knowledge of the structure of the polymers in solution—the existence of secondary structure is still in dispute—is summarized briefly. Chapter 8 deals with the extracellular depolymerases that catalyze the biodegradation of the polyesters. This is followed by a brief discussion of possible uses of the polymers. Here one looks in vain for any indication that depolymerization of PHB generates chiral molecules which are potentially useful as starting materials in stereospecific syntheses. Nor is there any mention of attempts to generate PHB by polymerization.

Throughout the book, experimental data are presented clearly in tables and graphs, but occasionally one wishes there were a better juxtaposition of text and tables. Each chapter concludes with an extensive and up-to-date bibliography (to 1990).

This monograph is a valuable supplement to the numerous reviews of the topic that have appeared. In particular, the book can be recommended to readers who are interested in biological aspects of the field on the one hand, and in macromolecular aspects on the other. In view of the ecological significance of the new materials, the book can be recommended also to environmental scientists.

Essentials of Molecular Photochemistry. By *A. Gilbert* and *J. Baggott*. Blackwell Scientific Publications, Oxford 1991. xii, 538 pp., paperback £ 17.85.—ISBN 0-632-02429-1

More than 13 years have elapsed since the publication of *Turro*'s "Modern Molecular Photochemistry".[1] Although a significant number of monographs on particular areas of organic photochemistry have appeared during that time, there has been no new attempt at a comprehensive treatment of the fundamentals of molecular photochemistry. For that reason alone it is very pleasing that the authors of this book have now undertaken that risky task, and it can be said at the outset that they have succeeded in fulfilling it.

The risk element lies in the need to bring together such widely different aspects as, on the one hand, the basic principles of quantum mechanics, spectroscopy and kinetic methods and, on the other hand, organic photoreactions, their potential applications in synthesis and the reaction mechanisms involved. In contrast to "ground-state chemistry", a knowledge of the underlying quantum mechanical and photophysical principles is essential in order to plan and carry out experimental work on photoreactions, and it is therefore entirely appropriate that these aspects occupy nearly half the book. It begins with lucidly written chapters on the electronic structures of molecules, radiation and molecular orbital theory, which are then followed by two excellent sections on molecular photophysics and the theory of photochemical reactions. However, it is noticeable that in the series of tables listing photophysical properties, much of the data is quite old: the main sources used are *Birks*' classic work "Photophysics of Aromatic Molecules" (Wiley, 1970) and the book by *Turro* that has already been mentioned (1978). It would have been useful to also provide an index of tables, so that one could quickly find the required data. In many cases one is only referred to more recent collections of tables, such as the "Handbook of Photochemistry",[2] although the latter too suffers from some intrinsic defects.

With regard to those photophysical parameters that have long been familiar, such as triplet and singlet state energies, lifetimes of excited states, and IC and ISC rates, one does not expect to find any very significant changes. However, the ability to determine dynamic quantities, through the recent rapid developments in time-resolved laser spectroscopy, has radically extended our understanding of photochemical reactions. The authors have responded to this situation by including separate sections on laser effects and spectroscopic techniques, and also by covering these aspects in each of the photochemically orientated chapters in the second part of the book. This, of course, carries the risk that some of the statements included there may already have been superseded by the time they are printed; for example, this has occurred in the case of the comments on the "Marcus inverted region" in the (unduly short) chapter on photoinduced electron transfer reactions. In the discussion of pericyclic reactions I would have expected to find a detailed treatment of the Salem correlation diagram; admittedly this is introduced later in connection with the α-scission of carbonyl compounds, but this does not do justice to the importance of the concept.

The theoretically orientated first part is followed by five chapters that are arranged according to the different types of chromophores: alkenes and alkynes, carbonyl groups, arenes, nitrogen compounds and "others" (alkyl halides, peroxides and sulfur compounds).

This concept has already proved useful in the past, and it is here applied to a remarkably large number of recent examples (up to 1989 in some cases). Most of the types of reactions mentioned here have been covered in at least one review article during the last few years, and therefore every aspect has not been discussed in detail here—in fact such a thorough treatment would not have been desirable. Each type of chromophore is introduced by describing its photophysical properties; thus the energies, lifetimes and excitation and deexcitation behavior of the excited states are discussed and correlated with the reactivities or selectivities of these "electronic isomers". These characteristics are then illustrated by numerous examples, including detailed descriptions of the analytical methods used (flash photolysis, laser spectroscopy, measurement of quantum yields, Stern–Volmer kinetics, labeling experiments, scavenging experiments, etc.). In my opinion the enormous growth in the importance of photoin-

duced electron transfer processes during the last few years has not yet been as fully appreciated as it should be. However, this subject is currently in a state of flux, and a detailed discussion of these aspects would have been outside the scope of a textbook such as this.

In the area of "ground-state chemistry" many different approaches to the problem of synthesizing diastereomerically or enantiomerically pure compounds (EPC syntheses) have been developed. Photochemistry too is making considerable contributions in this field. This aspect is not adequately covered in the book; for example, there are no detailed descriptions of the important studies that have been carried out on the synthesis of enantiomerically pure compounds using Paternò–Büchi reactions (e.g. the work of *Schreiber* and of *Scharf*), on oxa-di-π-methane rearrangements (*Schaffner, Demuth*), or on *meta* photocycloadditions (*Wender*). One could argue that these topics belong instead to a textbook on organic synthesis, but I believe that this is where the future of organic photochemistry must lie. This subject area should therefore have been given more space.

The final chapter departs from the system adopted up to this point whereby the subject matter is arranged according to chromophores, as it describes aspects of photochemically induced oxygen transfer. Here PET-induced oxygenation reactions are discussed on an equal footing with "pure" singlet oxygen reactions. Regrettably, however, there is no mention of the very interesting chemoluminescence or CIEEL phenomena observed for 1,2-dioxetanes.

The incidence of errors is gratifyingly low for a first edition (although trivial mistakes have crept into some of the formula diagrams), and both the text and the figures are of excellent quality. The book can be thoroughly recommended as a textbook to accompany a course of lectures on photochemistry, and the remarkably low price should serve as an example to other publishers.

Selective Hydrocarbon Activation. Principles and Progress. Edited by *J. A. Davies, P. L. Watson, J. F. Liebman* and *A. Greenberg*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York 1990. xiv, 568 pp., hardcover DM 275.00.—ISBN 3-527-26959-2

The search for routes whereby hydrocarbons—especially paraffins—can be converted into higher value products by reactions that are as "mild" as possible, stoichiometric, preferably catalytic, and above all selective is, for obvious reasons, one of the most important and ever-present tasks of chemical research. It is only in the last decade that crucial progress has been achieved in the intermolecular activation of C–H bonds in saturated hydrocarbons and related compounds; this has led to an enormous growth in the literature on this topic, especially on homogeneous C–H activation at transition metal centers. Compared with only a few publications per year up to the end of the seventies, there are now well over a thousand papers every year that are concerned with one or other aspect of the subject "C–H activation". Many review articles have appeared in recent years, and the time was undoubtedly ripe for comprehensive treatments in book form.

In the work reviewed here 20 authors have covered, in 15 chapters, every important aspect of the homogeneous activation of hydrocarbons. The form chosen here, that of a multiauthor volume with contributions from relevant specialists, is appropriate to the topicality and interdisciplinary character of this field of research, and offers the most effective way of taking into account to some extent the rapid pace of new developments, without abandoning the claim of providing a sound treatment. The four editors (three of whom are also among the authors) have succeeded in putting together a selection of topics which ensures that this book will be worthwhile reading for everyone who seeks a comprehensive coverage of the subject corresponding (nearly) to the current state of knowledge.

In the first chapter, "The Homogeneous Activation of H–H and X–H Bonds by Metals" (17 pp., 49 references), *R. H. Crabtree* gives a brief summary of the various mechanisms of C–H activation reactions, followed by a more detailed treatment of the related topics of the activation of H_2, silanes and X–H bonds (OH, NH etc.). A section on two-electron/three-center interactions (agostic interactions, H_2 complexes, etc.) and electrophilic X–H activation is followed by a description of the mercury-sensitized photochemistry of C–H and X–H bonds, which the author has himself investigated in detail. *Crabtree*'s contribution is informative and provides a good introduction to the subject, although it is not nearly as good as other reviews on the topic of C–H activation by the same author. In Chapter 2, "Alkane Oxidation: The Oxidation of Alkanes by Group VIII Metal Ions" (21 pp., 66 references), *J. V. Zeile Krevor* is concerned with problems in the partial catalytic oxidation of hydrocarbons and with species bonded to SiO_2 surfaces. The article discusses stoichiometric homogeneous C–H activation reactions using transition metal complexes (the standard examples based on Rh, Ir, Pt and Os), and also briefly touches on the related chemistry of metal ions in the gas phase (see below). The chapter concludes with short digressions into models for biological oxidation systems and the use of inorganic complexes absorbed in zeolites. In *I. P. Rothwell*'s contribution, "The Homogeneous Activation of Carbon-Hydrogen Bonds by Electrophilic Early Transition Metal Systems" (31 pp., 100 references), the main topics are the "early" transition metals in high oxidation states, including intramolecular C–H activations by hydrogen abstraction at the α, β... up to ε positions, and cyclometalations of heteroligands, where the author's own research is concerned especially with aryloxy ligands. Partly anticipating the next contribution, the chapter then deals with C–H activation chemistry based on organometallic compounds of the lanthanoids and actinoids, and concludes with a discussion of mechanistic aspects. Following up the previous topic is *P. L. Watson*'s very interesting review of "C–H Bond Activation with Complexes of Lanthanide Elements" (30 pp., 86 references). The basic principles of electrophilic C–H activation are thoroughly discussed, including thermochemical aspects. This is followed by a detailed treatment of agostic interactions with electron-deficient lanthanoid and actinoid metal centers, and an excellent survey of the relevant activation reactions on C–H bonds of alkanes, alkenes, alkynes, arenes and coordinated ligands, ending with a look at β-elimination processes. In this chapter one clearly recognizes the expertise of this author and coeditor of the book, who has to her credit the discovery of the first well-defined homogeneous reaction of methane with an organometallic compound, and whose experience in basic industrial research has certainly been used to good effect in this review article.

In Chapter 5, "Development of Catalytic Processes for the Synthesis of Organic Compounds that Involve C–H Bond Activation" (32 pp., 75 references), *W. D. Jones* first defines the important (but often overlooked) thermodynamic limitations to the long-term objective described in the title, then addresses the crucial question of the functionalization of C–H bonds in arenes and alkenes, in this case involving mainly the "late" transition metals. After considering the stoichiometric cases, the author goes on to deal with the less common examples of systems having at least short-term catalytic activity, some of which he has investigated himself. A wide variety of complexes and reaction types that have been studied are described in this well-informed review. The next chapter is devoted to thermochemistry, an area already touched on frequently in earlier contributions: *J. F. Liebman* and *C. D. Hoff* deal with "The Thermochemistry of Hydrocarbon Activation Reactions: A View from the Organic and Metal Perspectives" (52 pp., 118 references). This is a detailed and soundly-based, but also very entertainingly written, account of the thermodynamic aspects of insertion reactions in C–H and C–C bonds of hydrocarbons, supported by 15 tables and much additional data. About 20 pages are directly concerned with organometallic thermochemistry, and especially with the role of M–C and M–H bond strengths in complexes of the "late" transition metals in relation to catalysis. This part also includes a critical evaluation of the available data, as well as an up-to-date literature survey and references to relevant results from theoretical chemistry. The sections on ligand effects on L_nM-X bond energies, on the importance of the L_nM-X bond strength in catalytic reactions, and the compilation of important representative data on M–C and M–H bond energies facilitate the important task of estimating thermodynamic relationships in the search for metal-catalyzed reactions of hydrocarbons leading to useful products. The only purely theoretical chapter of the book, "Theoretical Aspects of Alkane C–H Activation by Organometallics" (28 pp., 98 references), has been written by *J.-Y. Saillard*, who puts the main emphasis on the description of qualitative relationships between bonding and reactivity; nearly all of these are based on EH model calculations, interaction and correlation diagrams, fragment MO analyses, frontier orbital considerations and the isolobal concept, and they originate almost exclusively from the published work of *Roald Hoffmann*'s school of theoretical chemistry. However, this section of the book also reviews other, more quantitatively orientated, theoretical work on C–H activation that has appeared up to now; a careful study of this part will also give the reader an appreciation of the limitations of qualitative descriptions and the need for reliable numerical methods for quantum chemical calculations.

L. D. Field's review "Alkane Activation with Superacids" (20 pp., 66 references) then turns to a quite different area of alkane activation, dealing with the chemistry of alkanes exposed to the effects of superacids. This chapter discusses the types of superacid reagents and their strengths, mechanistic aspects of C–H and C–C activation, and especially the conversion of alkanes to higher value products. Naturally the name of *G. Olah* appears prominently in the background of the discussion. The resemblances and differences between these reactions and the alkane activations that occur at metal centers are clearly brought out. The following chapter, "On the Mechanism of Action of Vitamin B_{12}" by *P. Dowd* (35 pp., 62 references), takes us into the area of biological systems, whose ability to activate C–H and C–C bonds first made life possible. The author gives an up-to-date status report and a review of all the important aspects and hypotheses concerning the mechanism of B_{12}-mediated substrate conversions; here C–H abstractions at aliphatic carbon atoms emerge again and again as the most important and least understood of the elementary steps. The variety of biological systems in which processes involving the dissociation of C–H bonds play a crucial role is greatly extended in the following very comprehensive chapter by *S. E. Groh* and *M. J. Nelson* on "Mechanisms of Activation of Carbon-Hydrogen Bonds by Metalloenzymes" (61 pp., 339 references). As well as vitamin B_{12} this covers all the other important enzyme systems that have the ability to catalyze C–H bond activations by means of metal centers. Here the authors not only list such systems according to the types of metal ions involved, but also provide detailed descriptions and critical comments regarding mechanistic experiments, methods of investigation and hypotheses, and point out the differences compared with typical organometallic activation mechanisms. Next the review by *J. A. Davies* and *R. J. Staples* of "Electrochemical Approaches to Transition Metal Mediated C–H Bond Activation" (27 pp., 88 references) returns us to the area of "inorganic or organometallic" C–H activations. These authors describe electrochemically generated low-valency intermediates of the type d^{10}-ML_2 (M=Ni, Pd, Pt), and also the corresponding species for the elements Rh, Ir, Fe and Ru. Although the electrochemical results described here are in themselves very interesting, the number of genuine electrochemically induced intermolecular C–H activation processes is actually very small, and consequently the prospects for electrochemical generation of reactive species, which are also accessible by thermal or photochemical methods, cannot yet be reliably assessed. This chapter ends with a section on the electrochemistry of M–H and M–C bonds.

The next three contributions are concerned with results obtained using specialized physical techniques to study the key elementary processes involved in the activation of C–H and C–C bonds at metal centers. *Z. H. Kafafi* in "Metal Atom/Cluster Reactions via FTIR Matrix Isolation Studies: C–H vs. C–C Bond Activation" (19 pp., 51 references) reports results from studies of the metal atom chemistry of a number of representative hydrocarbons in matrices at 10 K, then compares these with well known organometallic systems and with results from theoretical studies. In Chapter 13, "Ground State Metal Atoms and Clusters in Low-Temperature C–H and C–C Activation: Periodic Trends and Unusual Structural Effects" (30 pp., 85 references), *K. J. Klabunde, G. H. Jeong* and *A. W. Olsen* give a detailed account of the principles involved in studies of low temperature reactions between metal atoms or metal atom clusters (surface models) and alkanes in a matrix. The great value of this article is that it covers all the different transition metal atoms and derives relationships and trends. The importance of the rapidly growing number of studies of C–H and C–C activation in the gas phase using "bare" metal ions is acknowledged by the inclusion of one of the best contributions in the book: Chapter 14, "C–H Bond Activation by Gas Phase Atomic Metal Ions", by *P. B. Armentrout* (62 pp., 119 references). This article is of an exemplary standard with regard to both the breadth and depth of the treatment. The only criticism is that the choice of literature citations seems rather limited; many important publications by other authors, especially in Europe, are not mentioned. The last of these reviews, Chapter 15, "Alkane Acidities and Organosilanes in the Gas Phase: A Silicon Reaction Makes Good", by *R. Damrauer* (20 pp., 30 references), is not directly concerned with metals nor with the activation of hydrocarbons, but the gas phase chemistry of anions and molecules of organosilanes that is described here leads to important new insights

regarding gas phase acidities of alkanes, which are relevant in connection with the scission of their C–H bonds.

A minor weakness of this book is that in many of the chapters there are frequent repeated references to the standard examples of C–H activations that have become well-known. This is, admittedly, almost unavoidable in a collection of individual articles, but it does become a little tedious for the reader. There is a large preponderance of authors from the USA (18 out of 20, although regrettably a few of the greatest names in this field are not included; the remaining two are from Australia and France). This is perhaps not surprising in view of the make-up of the group of editors, but nevertheless it does, unfortunately, reflect to some extent the relative output of contributions from different countries in this area of research. The greatest value of the book lies in the wide and interdisciplinary coverage of the subject, which is what the editors have set out to achieve and have succeeded in producing, without at the same time sacrificing detailed information. The fact that the title of the book describes a hope for future developments rather than the existing situation does not diminish the value of this collection of articles; on the contrary it emphasizes the need for intensive and interdisciplinary research using all the available methods and tools, and provides some pointers in that direction. For a field that is undergoing such rapid developement it is unfortunate that a book of this nature appearing in 1990 cannot include references to the very latest work (i.e. papers published in the latter part of 1989 or in 1990), but one presumably has to accept this as a necessary evil. Obviously in the very near future one could only justify buying the book on the grounds of the "Principles" mentioned in the subtitle rather than "Principles and Progress", but nevertheless one can be confident about the coverage of the former.

This specialized work can definitely be recommended unreservedly for everyone whose work is concerned with the activation and functionalization of hydrocarbons, or who wishes to learn about this field; it is at present the best treatment available on the market. It is certainly essential for appropriate libraries.

Physics and Chemistry of the Upper Atmosphere. By *M. H. Rees*. Cambridge University Press, Cambridge (UK) 1989. ix, 289 pp., paperback £ 15.00.—ISBN 0-521-36848-0

To fully understand the upper atmosphere requires a knowledge of many disciplines: the physics and chemistry of radiation, spectroscopy, fluid dynamics and the chemistry of gases. A typical student of physics or chemistry will have a knowledge of some, but probably not all, of these fields. In the introduction to this book the author sets himself the task of bridging the gap between the material covered in standard physics textbooks and the literature on upper atmosphere research. The resulting book succeeds in this aim. In it the student will find a good survey of the science of the upper atmosphere with useful references to the research literature.

In the introductory chapter *M. H. Rees* defines the upper atmosphere as the zone in which the energy sources consist of solar UV radiation, energetic particles, electric fields and electric currents, where the most important neutral species are O, N_2 and O_2, and the dynamic behavior of the neutral gas atmosphere is largely determined by plasma dynamics. The rest of the chapters consist of explanations and discussions of this theme.

Chapter 2 deals with photochemistry, in particular with the interaction of solar UV photons with N_2 and O_2 molecules, leading to the production of atomic nitrogen and oxygen together with $N_2^{\oplus}$, $O_2^{\oplus}$, $N^{\oplus}$ and $O^{\oplus}$ ions in the upper atmosphere. The basic theory of radiation transfer and photochemistry is described. High-energy electrons that are produced in the upper atmosphere interact strongly with the ions present, and this interaction is the subject of Chapter 3. In Chapter 4 the effects of collisions between particles in the ionosphere are analyzed: the distinction between elastic, inelastic and reactive collisions is explained and the theory of these processes is developed. Chapter 5 describes the composition of the upper atmosphere. The different temperatures of the molecules and ions in the ionosphere are discussed in Chapter 6. Chapter 7 is concerned with the spectroscopy of the emitted radiation, with the night sky light or airglow (which is also important in daytime), and with the polar aurora. Lastly, Chapter 8 describes the dynamics of the thermosphere and ionosphere.

The main emphasis of the book is on interpreting the results of observations on the composition of the upper atmosphere, often also with the help of relatively new data obtained from artificial satellites. Although the theoretical basis is adequately explained, enabling the reader to understand the important processes and to interpret data, some prior knowledge of theoretical physics would also be an advantage. Also it is difficult for a reader with no previous knowledge of the atmosphere to understand some parts of the book: for example, the D and F zones are referred to before they have been defined.

The text contains some inaccuracies. For example, in the treatment of dynamics in Chapter 8 the meaning of the hydrostatic equation is wrongly stated. It is not correct to say that the vertical velocity vanishes in this case; instead one should say that the vertical acceleration is small compared with the vertical gradients of the pressure field and of the gravitational force.

The example problems provided at the end of each chapter are very well chosen, since they are relevant to the main points covered in the chapters. Also at the end of each chapter there are literature references to results of recent research. These are an important help for readers wishing to study the subject at a more advanced level. The book includes a great deal of useful data, e.g. on the structure of the atmosphere and on the effects of solar radiation. To summarize, this is a well written and informative book. It is suitable as a textbook on the complex subject of upper-atmosphere science and can be recommended as such.

Steven Pawson [NB 1111 IE]
Institut für Meteorologie
der Universität Berlin (FRG)

Biocatalysis. (Van Nostrand Reinhold Catalysis Series). Edited by *D. A. Abramovicz*. Van Nostrand Reinhold, New York 1990. xxv, 369 pp., hardcover $ 89.95.—ISBN 0-442-23848-7

This volume, published as part of a series on catalytic methods of synthesis, is based on selected papers presented at an international conference on "Biocatalytic Synthesis of Organic Compounds", held in August 1988 at Saratoga Springs, NY (USA). It contains 17 articles related to different problem areas of biotechnology; without claiming com-

pleteness, the authors discuss some highly topical aspects of biocatalysis, a field that is characterized by very rapid development and increasingly importance. As the articles are written in the form of progress reports the emphasis is, as expected, not so much on completed solutions to general problems as on new lines of research and specific developments.

The range of topics encompasses a wide variety of methods for preparing organic fine chemicals, with a nearly equal balance between processes based on fermentation and those characterized by on applied enzymology. The articles deal with such widely varied problem areas as the application of genetic engineering to the optimization of microbial metabolic systems or the creation of new ones, single-stage and multi-stage enzymic conversions, and the use of free or immobilized enzymes in aqueous or organic media, as well as investigations of a more process-orientated nature on multiphase systems and reactor design, or on the use of thermophilic or other extremophilic organisms. Some examples of the detailed studies described are the use of enzymes in the hydroxylation of arenes, the synthesis of vitamin C, the synthesis of acrylamide by nitrile hydrogenation, the lipase-catalyzed formation of polyesters, the synthesis of amino acids by transamination, enantioselective dehalogenations, and the use of unusual oxidoreductases or of stereoselective aldolases. The main emphasis in most cases is on preparative applications, often supported by relevant enzymological data or by mechanistic evaluations. The first article is a (critical) account of the historical development of enzymology and of the growth in the understanding of biocatalytic processes—a rather unexpected theme in this context, but one that will probably be of particular interest to newcomers to the field.

The articles are, without exception, excellently written, clearly presented and carefully printed; the many tables, schemes, diagrams and even photographic illustrations contribute to the clarity of presentation and to the pleasure of reading the book. Since the topics are mostly very different from each other there is little overlapping, but on the other hand there are few internal cross-references. The bibliographies appended to each article usually list, as well as references to the authors' own research, the most important relevant papers by others, thus directing the reader to suitable background reading on topics that are unfamiliar. A useful feature in this respect, and one that other editors and authors are strongly recommended to copy, is that the citations give the complete title of the original publication in most cases. In contrast to this, however, the subject index is too brief.

Up-to-date information is a perishable commodity, and specialist reviews of rapidly developing subject areas are particularly affected by this problem. Inevitably some of the articles in this volume already no longer represent the latest state of knowledge in every detail, but nevertheless the choice and variety of the topics and the quality of presentation ensure that on average the book will have a "user-friendly expiry date".

To summarize, the book offers the reader, at several different levels, a stimulating cross-section of recent developments in a wide variety of topical areas of biocatalysis research, chosen so as to provide pointers to future trends. It can be recommended (also because of its price) as an addition to existing monographs on related subjects, particularly for libraries and scientists with interests in this area.

New Approaches to the Use of Amino Acids as Chiral Building Blocks in Organic Synthesis

New Synthetic Methods (85)

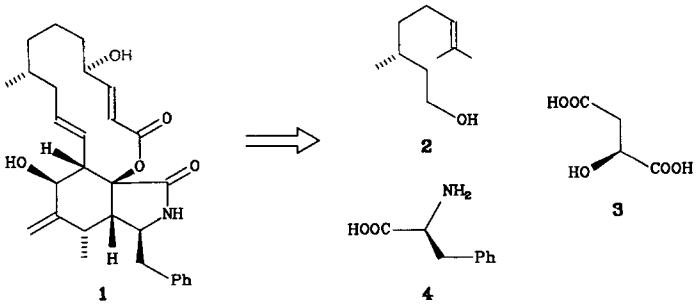
By Manfred T. Reetz*

Dedicated to Professor Karl Heinz Büchel on the occasion of his 60th birthday

α-Amino acids protected at nitrogen in quite different ways can be transformed without racemization into the corresponding α-amino aldehydes. Provided one chooses the right protecting groups (e.g., two benzyl residues on nitrogen) it is possible for the first time to carry out Grignard-like, aldol, and Me_3SiCN additions, and hetero-Diels–Alder reactions with a high degree of nonchelation control. If the reactions of classical carbanions turn out to be nonselective, transmetalation, for example into organotitanium reagents, constitutes an important tool in controlling stereoselectivity. Diastereoselectivity can be reversed by specific variation of the protecting group and reagent. "Protecting-group tuning", "metal tuning", and "ligand tuning" are very useful in reactions of α-amino aldimines as well. The α-amino aldehydes can also be converted by Wittig reactions into electron-poor γ-amino olefins, which in turn undergo stereoselective cuprate, Michael, and cycloadditions.

1. Introduction and Goals

Chiral, nonracemic natural products, including amino acids, have long been utilized as building blocks for organic synthesis.[1] An impressive example is the synthesis of cytochalasine B (**1**) by *Stork* et al.,[2] in which three different natural products are incorporated into the target: L-phenylalanine (**4**), L-malic acid (**3**), and (+)-citronellol (**2**).



Nearly all the common L-amino acids have been employed in synthesis, and in quite diverse ways.[1] Such a strategy has gained in importance because efficient enzymatic processes, asymmetric syntheses, and new separation procedures have significantly expanded the number of available nonracemic amino acids.[3] The synthetic chemist today has available not only the many natural and synthetic L-amino acids, but also their enantiomeric D forms. An example of a particularly efficient enzymatic "separation procedure" involves the hydrolysis of amino acid amides with the aminopeptidase *Pseudomonas putida*.[4] This enzyme is capable of converting a racemic mixture of amino acid amides (**5**) into the corresponding L-amino acids (**6**) and D-amino acid amides (**7**), which are easily separable. The procedure displays nearly 100% stereoselectivity and is applicable to an unusually wide range of substrates.

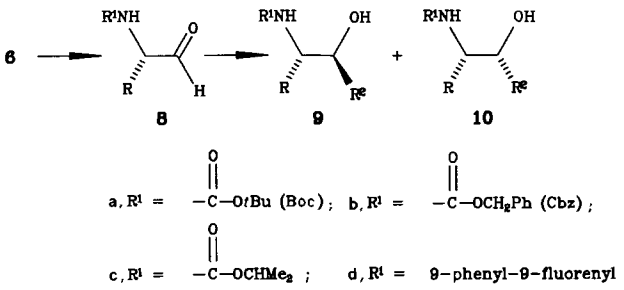
5 (rac.) 6 7

Apart from using amino acids in the synthesis of biologically active compounds and natural products, another goal has also become apparent in recent years: the development of stereoselective synthetic methods for transforming amino acids into other classes of compounds. Efforts to date have been directed particularly toward the preparation of β-amino alcohols **9**/**10** from protected α-amino aldehydes **8**, which in turn are accessible from the corresponding amino acids.[5] A number of highly interesting results have been recorded,[5] but so far no generally applicable method has appeared. For example, Grignard reagents and lithium enolates usually add to α-amino aldehydes **8** bearing *tert*-butoxycarbonyl (Boc) or benzyloxycarbonyl (Cbz) protecting groups with the formation of 1:1 or 2:1 mixtures of the diastereomers **9**/**10**.[5] Notable exceptions include additions

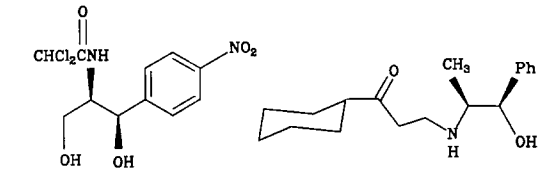


8 9 10

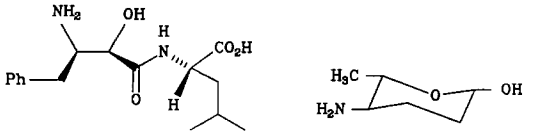
to certain α-amino aldehydes **8**, prepared, for example, from serine (cf. Section 3), as well as reactions of specific α-amino aldehydes with special reagents for the synthesis of particular natural products.[5]

A further complication is the fact that many protected α-amino aldehydes show a tendency to undergo racemization, and need to be handled in cold solvent and subjected to reaction as quickly as possible after their preparation.[5] The very bulky 9-phenyl-9-fluorenyl protecting group confers configurational stability on the aldehydes **8d** at room temperature, but Grignard and aldol additions result in the formation of 2:1 mixtures of diastereomers **9d**/**10d**.[6]

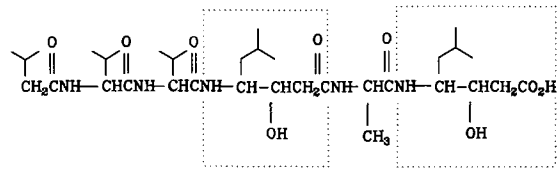
The lack of stereoselective methods is unfortunate, because β-amino alcohols constitute a pharmaceutically and biologically interesting class of substances. The compounds themselves frequently display appreciable biological activity, as in the case of the antibiotic chloramphenicol (**11**);[7] in other cases these structures are found as components of more complex active substances or natural products—for example, in the coronary agent alifedrin (**12**),[8] the aminopeptidase-B inhibitor bestatin (**13**),[9] the blood-pressure-reducing renin inhibitor pepstatin (**14**) and its synthetic analogues,[10] amino sugars [e.g., tolyposamine (**15**)],[11] and sphingolipids[11] and alkaloids.[12]



11 12



13 15



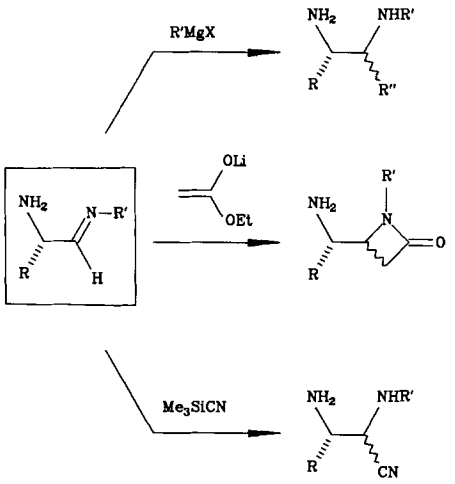
14

The first part of this progress report describes methods by which α-amino aldehydes (and α-amino ketones) can be converted selectively into either of the two diastereomeric forms of β-amino alcohols. Attention will be given not only to Grignard and aldol additions, but also to cyanohydrin- and epoxide-forming reactions of Me_3SiCN and sulfur ylides, respectively, as well as to hetero-Diels–Alder reactions. The emphasis here is on our own recent work; the complete literature on the subject up to 1988 has been summarized elsewhere.[5]

Another class of potentially accessible substances, again starting from α-amino aldehydes or amino acids, includes the

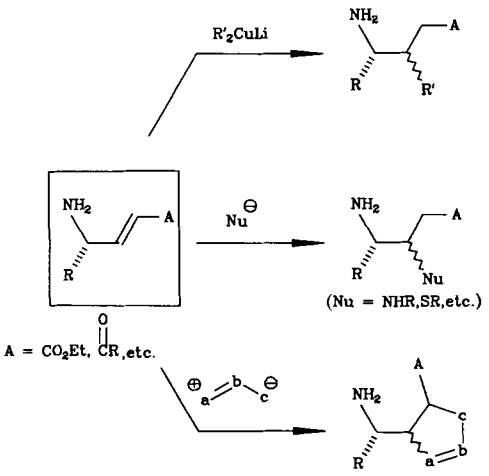
Manfred Reetz was born in Hirschberg, Silesia, studied chemistry at Washington University, St. Louis, and the University of Michigan, and obtained his doctorate under U. Schöllkopf at the Universität Göttingen in 1969. After a post-doctorate in Marburg with R. W. Hoffmann he habilitated there in 1974 in the field of dyotropic rearrangements. From 1978 to 1980 he was professor in Bonn and moved to the Universität Marburg in 1980. Since the summer of 1991 he has been Director at the Max-Planck-Institut für Kohlenforschung in Mülheim an der Ruhr. His research priorities lie in the development of new methods in synthetic organic chemistry, in particular the search for new organometallic reagents for chemo- and stereoselective C–C bond formation. Other fields of interest are peptide chemistry, molecular recognition, and polymer chemistry.

vicinal diamines. In contrast to the many known reactions of α-amino aldehydes, analogous C–C bond-forming reactions of α-amino aldimines as outlined in Scheme 1 have not been attempted until quite recently. Initial results are summarized in Section 5.



Scheme 1. Reactions of α-amino aldimines (protecting groups omitted).

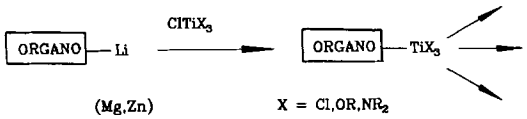
Finally, in Section 6 attention is paid to stereoselective reactions of electron-poor γ-amino olefins, which can be prepared from the corresponding α-amino aldehydes via Wittig reactions (Scheme 2).



Scheme 2. Reactions of electron-poor γ-amino olefins (protecting groups omitted).

2. Methods

What methods are in fact available to the synthetic organic chemist who wishes to carry out the C–C bond formations outlined above stereoselectively and without racemization? Since most of the reactions discussed here involve organometallic agents, the choice of the metal ("metal tuning") and the ligand ("ligand tuning") must be made at the outset. Thus, unselective classical "carbanions" can be subjected to transmetalation—for example with the titanation reagents $ClTiX_3$ (Scheme 3).[13] This generates a new class of organometallic reagents $RTiX_3$ with electronic and steric properties that depend upon the nature of the ligands X at the metal. Thus, the chlorides $RTiCl_3$ are especially Lewis acidic, a characteristic that proves decisive, for example, in chelation-controlled reactions of chiral α- and β-alkoxy aldehydes.[14] Intermediate chelates form during the process, and these are attacked from the sterically less hindered side.[14] On the other hand, alkoxy and amino ligands increase the electron density at the metal as well as the overall size of the reagent, resulting in compounds of the type $RTi(OiPr)_3$ and $RTi(NEt_2)_3$, which are generally incapable of chelation. In some cases the observed stereochemical consequences then represent what has been interpreted within the framework of the Felkin–Anh model[15] as "nonchelation control".[14] This phenomenon is less general than chelation control, however, because the number of degrees of freedom of the free aldehydes is larger than that of the complexed forms.



Scheme 3. Control of carbanion selectivity by titanation.

The extensive work in the area of organotitanium reagents as delineated above has stimulated a number of research groups to test other metals in a similar manner,[16] although systematic studies of ligand effects are still lacking. A particularly valuable metal in this context is cerium. Transmetalation of Grignard and organolithium compounds with $CeCl_3$ leads to reagents of the type $RCeCl_2$, which have proven to be especially useful in chemoselective additions to enolizable ketones.[16]

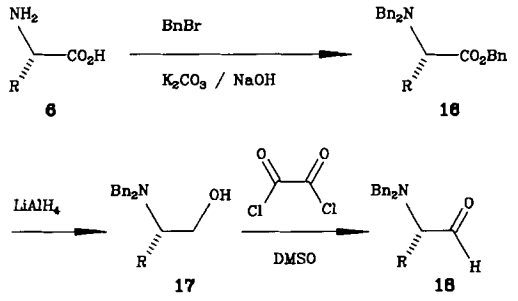
A further possibility for control—one that has generally been neglected—involves careful choice of the protecting groups to be used with polyfunctional molecules that are to be subjected to organometallic reactions.[17] It will be demonstrated below that protecting-group tuning in this sense can become a third and extraordinarily powerful method in the optimization of a stereoselective reaction, often in the proper combination with particular metals and ligands.

3. Preparation and Reactions of α-Amino Aldehydes

3.1. Nonchelation-Controlled Additions

Early attempts to design stereoselective addition reactions like those described above starting with traditionally protected α-amino aldehydes **8** and utilizing organotitanium reagents resulted in only sporadic success.[18] In the hope of evoking a positive protecting-group effect, doubly protected substrates were then synthesized, in particular the *N*,*N*-dibenzylamino aldehydes **18**.[19]

The readily accessible and isolable aldehydes **18** are configuratively stable at room temperature, and thus easy to handle.[19] The surprise actually came in the course of the subsequent reactions with Grignard and organolithium



a, R = CH_3 ; **b**, R = $PhCH_2$; **c**, R = $(CH_3)_2CHCH_2$; **d**, R = $(CH_3)_2CH$; **e**, R = $tBu(CH_3)_2SiOCH_2$; **f**, R = $PhCH_2OCH_2$; **g**, R = $Bn_2N(CH_2)_3$; **h**, R = $Bn_2N(CH_2)_4$

Scheme 4. Bn = benzyl, DMSO = dimethylsulfoxide.

reagents. In nearly every case a diastereoselectivity of > 90% was observed in favor of the nonchelation-controlled adduct **20** (Table 1).[19] This result is rather remarkable, because it *cannot* involve chelation-induced reduction of degrees of freedom. Only in the case of the very reactive allylmagnesium chloride was a 1:3 mixture of diastereomers produced (cf. entry 12, Table 1). This particular problem can be solved by prior titanation of the Grignard reagent with $ClTi(NEt_2)_3$ (entries 13, 16). Nonchelation control is also applicable to reactions of cuprates and organocerium compounds (entries 6, 7), albeit with somewhat lower diastereoselectivity. Cyanohydrin-forming reactions can be effected quite generally with $Me_3SiCN/ZnBr_2$ (cf. entry 8, Table 1).[20] Here again the *N*,*N*-dibenzylamino aldehydes

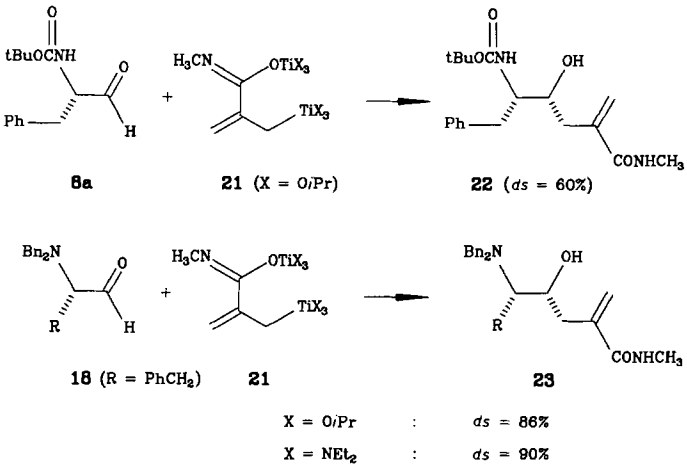
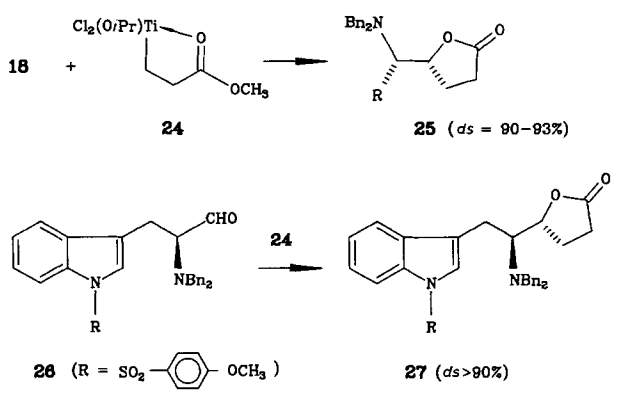
18 prove to be fortuitous representatives, since cyanohydrin-forming reactions with Boc-protected aldehydes **8a** display no selectivity.[9b, 21] The resulting products are key intermediates in the synthesis of such complex molecules as bestatin (**13**), epibestatin, amastatin, and epiamastatin.[9b, 21] Although the reactions proceed under conditions that are either quite basic or Lewis acidic, the C–C bond formations listed in Table 1 occur without any signs of racemization.

Although no organic chemist is likely to replace the inexpensive, naturally occurring norephedrin with a synthetic starting material in the preparation of such compounds as alifedrin (**12**), meaningful synthetic possibilities arise when substituted aryl or heteroaryl analogues are to be prepared (cf. entry 19, Table 1).[22] A further example of an intricate interplay between metal, ligand, and protecting group is illustrated by the synthesis of the amino alcohol **22**, which can be incorporated in modified form into peptide chains as an isosteric component. Whereas the organotitanium reagent **21** (X = O*i*Pr) provides a 60:40 mixture of diastereomers with the Boc-protected aldehyde **8a**,[23] the same reaction with the doubly protected analogue **18** (R = $PhCH_2$) is significantly more stereoselective (86:14 mixture).[24] A further increase in diastereoselectivity to 90% can be effected by the use of amino ligands (X = NEt_2) at titanium.[24]

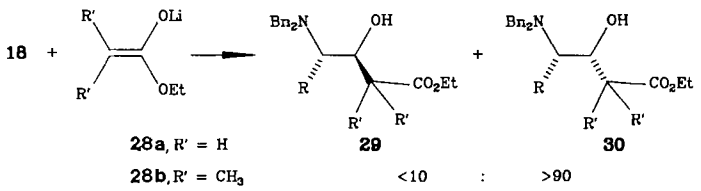


Although many reagents are known for homo-aldol additions,[25] so far only the homoenolate **24** has been subjected to reaction with aldehydes **18**.[26] Nonchelation control of 90–93% (yield 45–65%) has been achieved with several common members of the series (R = CH_3, *i*Bu, $PhCH_2$).

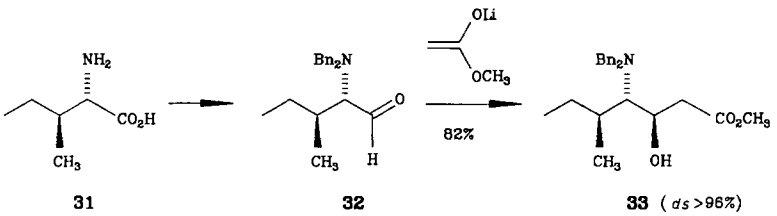


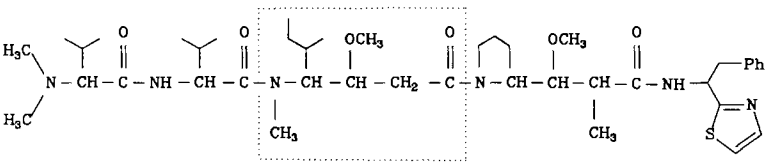
The aldehyde **26** derived from tryptophane reacts similarly.[26]

Ordinary lithium enolates (**28**) add surprisingly stereoselectively to the *N,N*-dibenzyl aminoaldehydes **18** (**29**:**30** = < 10:> 90), again without racemization.[19]



One example of the application of this nonchelation-controlled aldol addition pertains to the synthesis starting from isoleucine (**31**) of the unusual amino acid ester **33** with the (3*R*,4*S*,5*S*) configuration.[27] Compound **33** represents a building block useful in the synthesis of dolastatin 10 (**34**), recently isolated by *Pettit* et al. from the sea hare *Dolabella auricularia*.[28] This peptide is said to have the most powerful antineoplastic activity ever recorded for any natural or synthetic substance, and for this reason effective synthetic approaches to **33** and its analogues are important in cancer research. Aldol addition to aldehyde **32** gives essentially the

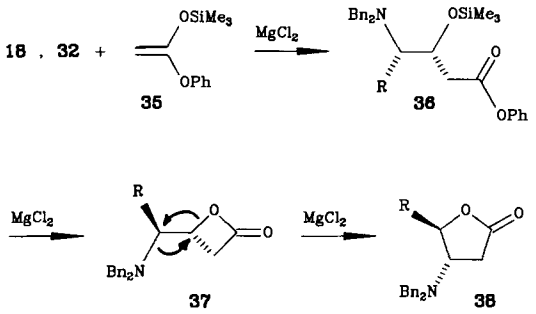




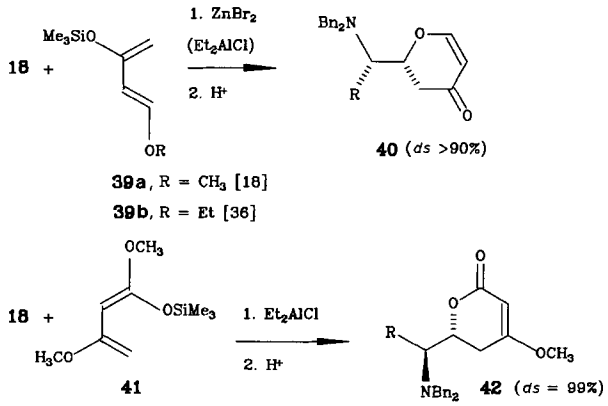
single product **33**, which has the desired absolute and relative configuration.[27] The conventional synthesis starting with Cbz-protected isoleucinal entails unselective lithium enolate addition, with formation of a 3:2 mixture of diastereomers (33% yield).[28] Stereoselective synthesis of similar components found in the peptides didemnin A and B[29] is comparably straightforward.[18]

An attempt was made to add *O*-phenyl-*O*-silylketene ketal (**35**) to the aldehydes **18** and **32**; however, the products isolated were not the aldol adducts **36**, but rather the β-amino γ-lactones **38** in diastereomerically and enantiomerically pure form.[30] This unexpected finding is a consequence of three successive $MgCl_2$-catalyzed reactions: nonchelation-controlled aldol addition to give **36** followed by lactone formation (**37**) and dyotropic rearrangement[31] (→ **38**). β-Amino γ-lactones are of interest in the synthesis of unusual amino acids[32] and amino sugars (cf. ristosamine).[33]

$EtAlCl_2$-induced additions of *O*-alkyl-*O*-silylketene ketals to the aldehydes **18** occur as expected with nonchelation control (94–99%), although under the experimental conditions the aldol adducts **30** undergo no further reactions.[34] Such *O*-silylketene ketals also react with the aldehydes **18** under nonchelation control provided *catalytic* amounts of europium salts like $Eu(fod)_3$ are employed.[18]

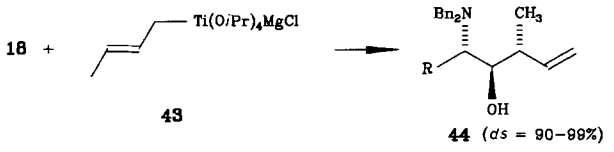


Three different research groups recognized simultaneously the value of *N,N*-dibenzylamino aldehydes **18** in the (formal) hetero-Diels–Alder reactions of electron-rich siloxydienes.[18,35,36] Both the Danishefsky diene **39**[18,36] and the Brassard diene **41**[35] react exclusively under nonchelation control. These reactions may actually involve an aldol addition followed by cyclization to the pyranes **40** and **42**. The



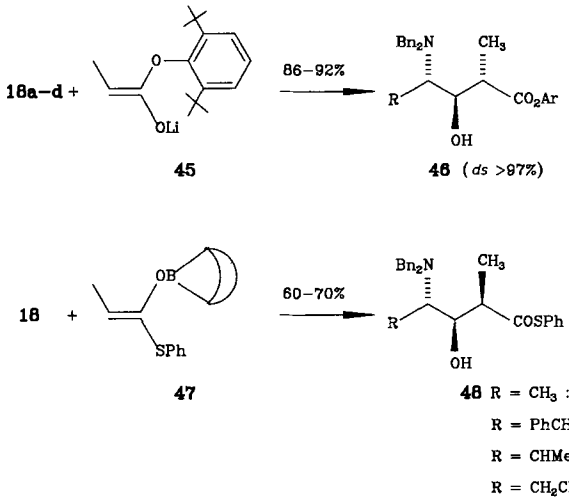
first examples of hetero-Diels–Alder reactions of the aldehydes **18** under high pressure (5 kbar) were recently described.[37]

If the reagents are prochiral, then along with the previously discussed diastereofacial selectivity the so-called simple diastereoselectivity also becomes relevant, and four diastereomeric products are possible. Starting with the titanium reagent **43**, readily accessible from crotylmagnesium chloride and $Ti(OiPr)_4$,[38] diastereomer **44** is essentially the only one formed.[27,39] This implies the usual nonchelation control as well as a predictably high simple diastereoselectivity (*anti*-selectivity). Titanation is absolutely essential, since the Grignard reagent alone reacts in a totally unselective way.



43 **44** (*ds* = 90–99%)

The *anti*-selective Heathcock enolate **45**[18,27] also reacts with complete stereoselectivity. Reversal in simple diastereoselectivity can be achieved with the *syn*-selective Masamune reagent **47**, although a second diastereomer that has not been characterized arises in the case of the bulky aldehydes **18** (R = $CHMe_2$, CH_2CHMe_2).[18]



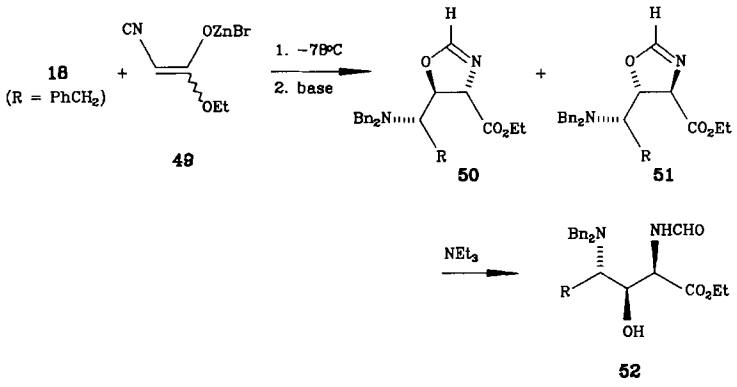
45 **46** (*ds* >97%)

47

48 R = CH_3 : *ds* >97%
R = $PhCH_2$: *ds* >97%
R = $CHMe_2$: *ds* = 76%
R = CH_2CHMe_2 : *ds* = 76%

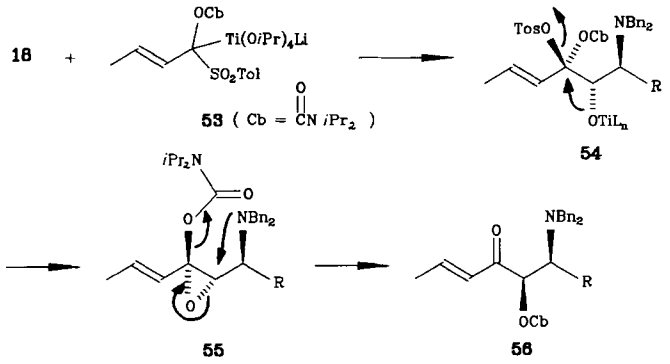
Furthermore, the zinc enolate **49** derived from isocyanoacetic ester adds in a stereoselective way with formation of the adducts **50**/**51**. These lead after ring opening to the unusual class of α,γ-diamino acids **52**.[40] The crude reaction product consists here of a 10:90 mixture of **50** and **51**. A single recrystallization leads to the diastereomerically and enantiomerically pure ester **51** (81% isolated yield), which can be converted quantitatively into the diamino acid ester **52** by the method of *Schöllkopf* and *Hoppe*.[41]

An elegant one-pot procedure for stereoselective nucleophilic acylation of the aldehydes **18** resulting in the enones **56** takes advantage of the titanium reagent **53**.[42] This again involves a nonchelation-controlled nucleophilic addition,

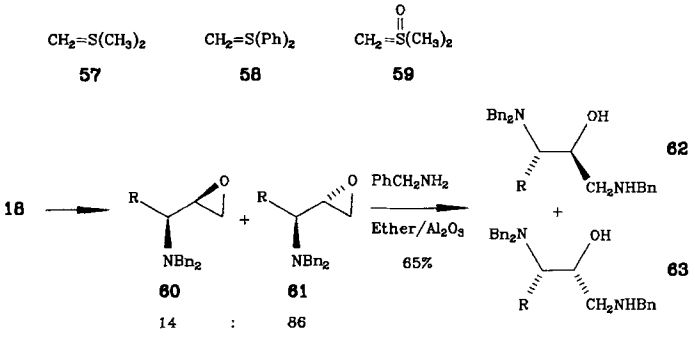


49 **50** **51** **52**

followed in this case by stereospecific elimination and rearrangement **54** → **55** → **56**. The lithium precursor to **53** reacts unselectively.[43]



Since aminoalkyl oxiranes are valuable building blocks in the synthesis of dipeptide isosteres and other pharmacologically important amino alcohols, there have been many attempts to perform stereoselective reactions of protected α-amino aldehydes with sulfur ylides.[44] Nevertheless, every case so far reported has led to a 1:1 mixture of the two possible diastereomers and a maximum total yield of 50%.[44] In the hope of achieving stereochemical results comparable to those of the previously investigated organometallic addition reactions, the *N*,*N*-dibenzylamino aldehydes **18** were allowed to react with the ylides **57**, **58**, and **59**. Indeed, the desired adducts **61** were formed as the predominant diastereomers, although the extent of stereoselectivity turned out to be less than 90%.[45] A possible reason why a sterically less demanding reagent like CH_3MgCl produces significantly *higher* diastereoselectivity than ylides of



57 **58** **59**

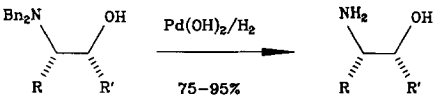
60 : **61**
14 : 86

62

63

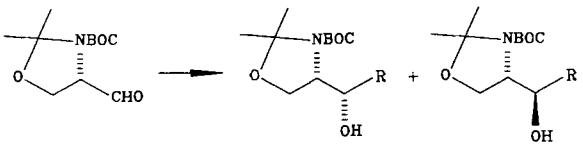
the type $CH_2{=}SR_2$ will be discussed in Section 3.2. Only with the bulky arsenic ylide $CH_2{=}As(Ph)_3$ were "normal" diastereoselectivities again observed (90–99%).[45] Whereas oxiranes **60**/**61** cannot be separated easily, the corresponding open-chain compounds resulting from nucleophilic substitution (e.g. **62**/**63**) are readily separable by chromatography.[45]

With respect to cleavage of the benzyl protecting groups by hydrogenolysis, the catalyst originally selected was Pd black (65–90% yield).[19] Problems were occasionally encountered, however, especially with catalysts that were no longer sufficiently fresh.[18] Generally, deprotection is much more efficient with the Pearlman catalyst [$Pd(OH)_2$] according to the method of *Yoshida*[46] (75–95% yields).[18] Since the products **64** are quite polar, careful extraction is essential.



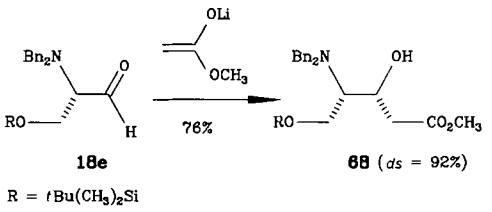
20 **64**

The preceding discussion indicates that the presence of the *N*,*N*-dibenzylamino group is a prerequisite for high diastereoselectivity. There are special situations in which this is not the case, however.[5] For example, serinal has been investigated with quite a wide variety of protecting groups. The Garner aldehyde **65**—accessible in four steps from serine—is of particular preparative significance.[47] A diastereoselectivity of about 88% in favor of the nonchelation-controlled adduct **67** has been achieved with lithium enolates.[48] Diastereoselectivity can be reversed under Lewis acidic conditions (cf. Section 3). Addition of Grignard and alkyllithium reagents occurs under nonchelation control, although there is some scatter in the selectivities (84–95% *ds*).[49] Results achieved in the addition of alkynyllithium compounds are quite acceptable—diastereoselectivities of 95% are the rule. This finding has been exploited in the synthesis of sphingoid bases.[50,51] Since the protecting groups are also easily cleaved, aldehyde **65** can be described as a real winner. It must be noted, however, that the compound cannot be isolated in a state of complete enantiomeric purity (*ee* = 93–95%).[47]



65 **66** **67**

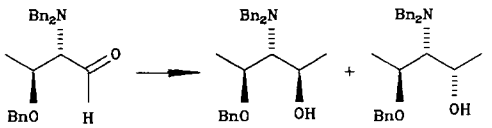
The serinal derivatives **18e** and **18f**[18,52] offer both advantages and disadvantages relative to the Garner aldehyde **65**. On one hand, any olefin residues present in the reaction product are subject to undesirable reduction during cleavage of the protecting groups by hydrogenolysis. On the other, no racemization is observed during either the synthesis or the highly selective reactions of aldehydes **18e**/**18f** (entries 21–23, Table 1).[18,52] Also aldol additions proceed with nonchelation control.[52]



18e **68** (*ds* = 92%)

R = *t*Bu(CH$_3$)$_2$Si

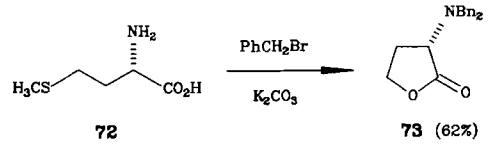
Grignard-type addition to the allothreoninal **69** that has two stereogenic centers proceeds according to the usual pattern, although the observed nonchelation control here is somewhat less pronounced.[52] Apart from studies of the serinal derivatives **18e**/**18f**,[52] allothreoninal (**69**),[52] tryptophanal (**26**),[26] ornithinal (**18g**) (entries 24–25, Table 1),[18] and lysinal (**18h**) (entry 26, Table 1),[18,53] relatively few attempts have been made to transform amino acids containing additional functional groups into the corresponding *N*,*N*-dibenzylamino aldehydes.



69 **70** **71**

CH_3MgI(−78°C/18h)	86	:	14(88%)
$CH_3Ti(O{i}Pr)_3$(22°C/16h)	93	:	7(73%)

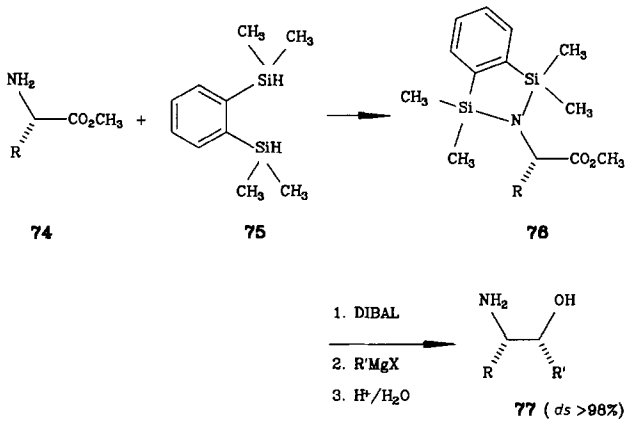
Efforts to synthesize the corresponding aldehyde from methionine (**72**) have proven unsuccessful, since the sulfur function is alkylated under the benzylation conditions. This results in the expected formation of the lactone **73**, an interesting molecule in other contexts.[30]



72 **73** (62%)

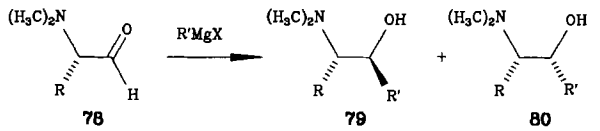
The desire to extend the spectrum of nonchelation-controlled nucleophilic additions to α-amino aldehydes started a quest for other potential protecting groups. In the course of a search for systems in which the protecting group can be cleaved by hydrolysis, the benzostabase protecting group (BSB) was developed. This group can be introduced smoothly into the amino acid esters **74** under Pd catalysis.[54] A one-pot reaction of the ester **76** protected in this way entails reduction followed by a highly nonchelation-controlled reaction of the intermediate aldehyde with Grignard or organolithium reagents, and subsequent deprotection of the product in the course of acidic workup. The analytically pure products **77** can be isolated in 40–60% yield, which is quite respectable given the three steps involved.

Nonetheless, the development of additional protecting groups remains a worthwhile endeavor.[55]



74 75 76

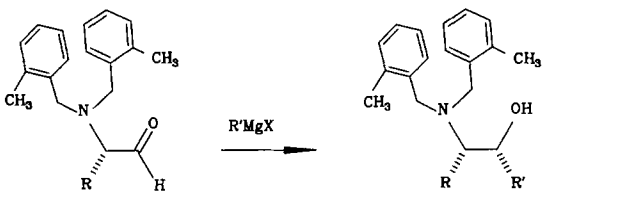
While attempting to uncover the origin of the unanticipated nonchelation control, both smaller and larger protecting groups were investigated. A dramatic influence of steric parameters was especially apparent in the reactions of *N*,*N*-dimethylamino aldehydes **78**:[18] absolutely no useful diastereoselectivity whatsoever was observed!



78 79 80

a) R = CH_3 ; R' = Ph	50	:	50
b) R = $PhCH_2$; R' = CH_3	35	:	65
c) R = $PhCH_2$; R' = Ph	48	:	52

The conclusion that the number and size of the protecting groups is decisive has been substantiated by studying the synthesis and reactions of the *ortho*-methylbenzyl-protected aldehydes **81**. The 99% stereoselectivity achieved for Grignard additions in this case exceeds that of analogous additions to the *N*,*N*-dibenzylamino aldehydes **18**.[18] This selectivity-enhancing effect is also applicable to additions of sulfur ylides, although nonchelation control cannot be driven above 92%.[45]

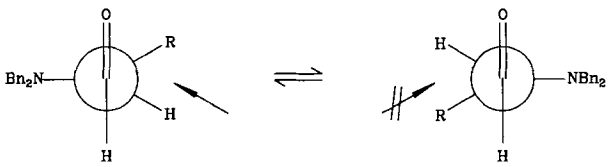


81 82 (ds = 99%)

3.2. Models for Explaining the Observed Nonchelation Control

Theoretical studies concerning the origin of the nonchelation control described in the previous section are not yet complete, but two possible explanations have emerged.[27]

From a formal standpoint the observed stereochemical results are in agreement with the Felkin–Anh model.[15] One particular conformation (in this case **83**) leads to maximum lowering in energy of the LUMO (π^* bond), hence a maximum degree of reactivity.[27] Nevertheless, MO calculations show that the requisite π^*–σ^*_{C-N} conjugation in the parent amino compound **84** (R = NH_2) is nearly insignificant,[56] in contrast to the π^*–σ^*_{C-Cl} conjugation in the chloro compound **84** (R = Cl) (Fig. 1). The σ^*_{C-N} orbital simply lies too



83a 83b

high. However, since metal ions may complex at nitrogen (without necessarily entering into chelation), the possibility of a dramatic change in the electronic nature of the C–N σ bond emerges. Indeed, MO calculations for α-amino aldehydes complexed at nitrogen with BH_3 (where the Lewis acid BH_3 serves as a model for a metal ion) show a drastic lowering in the energy of the π^* orbital (cf. Fig. 1).[56] The Anh model extended in this sense would also explain differences in diastereoselectivity with Grignard and essentially salt-free sulfur ylide reactions. Not so easily interpreted, however, is the enormous protecting-group effect on changing from *N*,*N*-dibenzyl- to *N*,*N*-dimethylamino aldehydes (**18** and **78**, respectively).

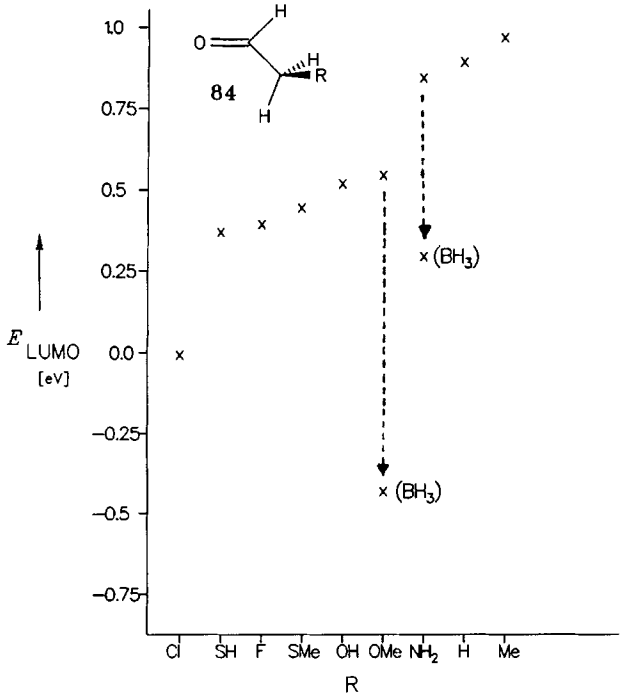


Fig. 1. Location of the LUMOs in aldehyde **84** as a function of substituents R. Dashed arrows indicate lowering of the LUMOs through complexation with BH_3 at the NH_2 or CH_3O groups.

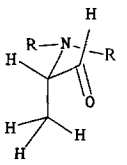
A second model takes into account the ground-state structures of the various α-amino aldehydes.[27,57] Preliminary force-field calculations on the parent structure **18a** show

that conformation **85** represents the most stable form, and that small conformational changes involving the benzyl groups result in certain energy differences. The prediction that the carbonyl function and the α and β C-atoms lie essentially in a single plane is the most significant result. This also



85 R = $PhCH_2$

represents the preferred conformation for propanal and other simple achiral aldehydes, an observation that has been explained by *Wiberg* on the basis of dipole–dipole interactions.[58] A recently completed X-ray structural analysis on the amino aldehyde **18b** confirms the validity of the force-field calculations (Fig. 2).[59] It is apparent that the back side

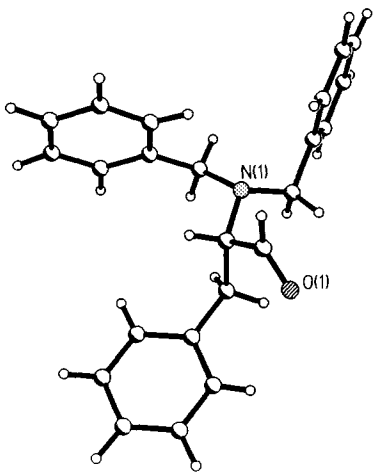


Fig. 2. Crystal structure of the aldehyde **18b**.

of the carbonyl function is sterically shielded. Assuming that the conformation of the ground state corresponds to that of the reacting molecule, front-side attack—and thus nonchelation control—can be rationalized. When the space behind the carbonyl function is less completely occupied, as in the case of the *N,N*-dimethylamino aldehydes **78** or the monoprotected analogues **8**, this model explains the lower diastereoselectivity. Furthermore, larger protecting groups should have the opposite effect, a conclusion consistent with experimental observations (cf. **76** and **81**). The metal complexation at nitrogen considered previously would have the further effect of increasing the passive volumes of the amino groups.[56]

3.3. Chelation-Controlled Additions

Chelation of chiral α- and *β-alkoxy* aldehydes with $TiCl_4$, $SnCl_4$, or $MgBr_2$, followed by diastereoselective addition of appropriate carbon nucleophiles such as R_2Zn, allyl and enol silanes, or Me_3SiCN has become a general principle in stereoselective synthesis.[14] However, attempts to carry out an analogous procedure with the *N,N*-dibenzylamino aldehydes **18** did not always result in diastereoselectivities above 90% (Table 2).[19] In contrast, $TiCl_4$-mediated ene reactions on the same aldehydes lead to high degrees of chelation control.[34] $MgBr_2$-mediated addition of Me_3SiCN to the aldehydes **18** proceeds with modest chelation control (*ds* ≈ 80%).[20]

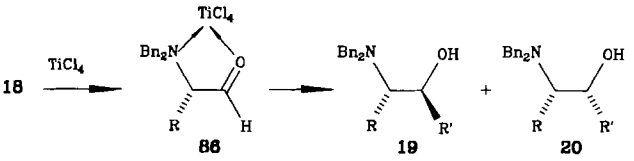

Table 2. Typical examples of chelation-controlled additions to the aldehydes **18** [18–20]. C_3H_5 = allyl

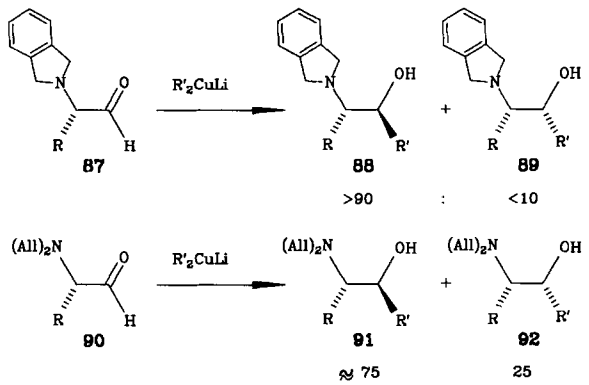
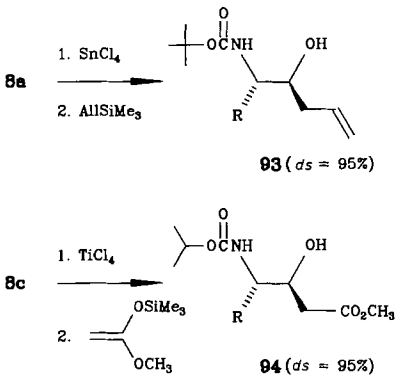
no.	aldehyde	reagent	yield [%]	**19**:**20**
1	**18a**	$TiCl_4/(CH_3)_2Zn$	82	94: 6
2	**18a**	$SnCl_4/C_3H_5SiMe_3$	85	84:16
3	**18b**	$SnCl_4/C_3H_5SiMe_3$	79	87:13
4	**18b**	$TiCl_4/(CH_3)_2Zn$	63	78:22
5	**18b**	$TiCl_4/Me_3SiCN$	58	78:22
6	**18c**	$SnCl_4/C_3H_5SiMe_3$	78	90:10
7	**18c**	$TiCl_4/Me_3SiCN$	63	88:12
8	**18d**	$TiCl_4/(CH_3)_2Zn$	65	65:35
9	**18d**	$SnCl_4/C_3H_5SiMe_3$	79	95:5
10	**18d**	$TiCl_4/Me_3SiCN$	63	84:16

The explanation for these nonuniform findings may be based on steric inhibition of chelation. Whereas chiral α-alkoxy aldehydes form only a single reactive species (chelate) with $TiCl_4$,[14,60] NMR studies reveal that there are actually several species involved with the *N,N*-dibenzylamino aldehyde/$TiCl_4$ complexes **86**.[18] As a result of weaker N–Ti bonding and steric interaction between the chlorine ligands, benzyl groups, and other residues on the five-membered ring, complex **86** opens rather readily. According to the Curtin–Hammett principle, the most reactive species then undergoes reaction, and this need not always lead to the chelation-controlled adduct. Consequently, investigations were undertaken on less sterically demanding protecting groups (cf. **87**[19] and **90**[18]). This approach did in fact result in efficient chelation control in the Grignard-like addition of cuprates. In other words, a change from benzyl protecting groups to the smaller analogues present in **87** and **90** results in complete reversal of diastereoselectivity! This example of



protecting-group tuning is only effective, however, in combination with metal tuning, since alkyllithium reagents react with the aldehydes **87** and **90** (All = allyl) in an unselective way.[18] A relevant observation here is the fact that the *N,N*-dimethyl analogues **78** react with cuprates under 99% chelation control.[18]

In the case of the aldehydes **87** such results are mainly of mechanistic interest, since the protecting groups are not easily cleaved. The situation is different with the monoprotected aldehydes **8a** and **8c**, which after treatment with $SnCl_4$ or $TiCl_4$ undergo particularly facile chelation-controlled allyl[61] and enol silane additions,[62] as well as ene reactions,[34] and the products can be readily deprotected. However, Grignard-like additions with cuprates proceed with nonuniform stereochemical results.[18] Chelation-controlled hetero-Diels–Alder reactions are possible using the Garner aldehyde **65**.[48]

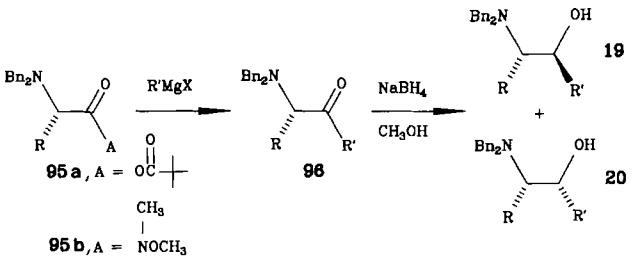


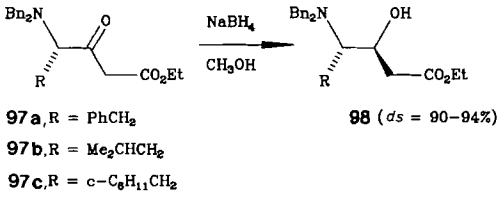
Very effective chirally modified boron enolates add to the aldehydes **18** to give aldol products **29** or **30** depending on the absolute configuration of the reagent.[63] Nevertheless, relying solely on reagent control[64] implies greater effort and cost.

4. Preparation and Reactions of α-Amino Ketones

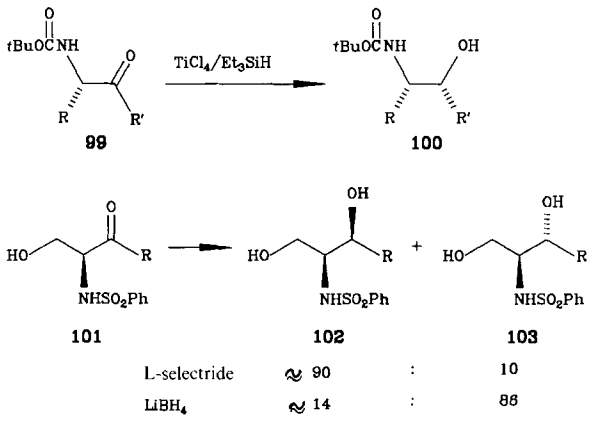
Stereoselective reductions of α-amino ketones have been studied extensively in the earlier literature.[65] However, the reported cases refer almost exclusively to racemic starting materials or to systems bearing residues on nitrogen that are difficult to cleave (alkyl, aryl). A first systematic study has shown that the activated amino acids **95** can be converted without racemization into the ketones **96**.[66] On using $NaBH_4$ in methanol the reduction occurs under nonchelation control (**19**:**20** > 90:10). The products are the same ones that arise in chelation-controlled C–C bond-forming reactions of the aldehydes **18**. Since the latter processes do not always occur stereoselectively, a route via the ketones **96** is an attractive alternative. Compounds prepared in this way include statin (derivative **98b**), which occurs in pepstatin (**14**).[67]

Boc-protected α-amino ketones **99** undergo chelation-controlled reduction with $Et_3SiH/TiCl_4$.[68] Ketones **101** derived from *N*-phenylsulfonylserine can be transformed selectively into the adducts **102** or **103** depending upon the nature of the reducing agent.[69] It remains unclear whether





this method can be generalized to substrates derived from other amino acids.

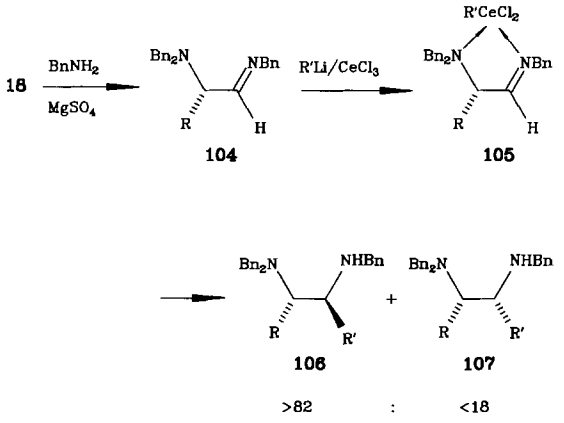


Grignard additions to the *N,N*-dibenzylamino ketones **96** occur with a high degree of nonchelation control (*ds* > 95%).[18]

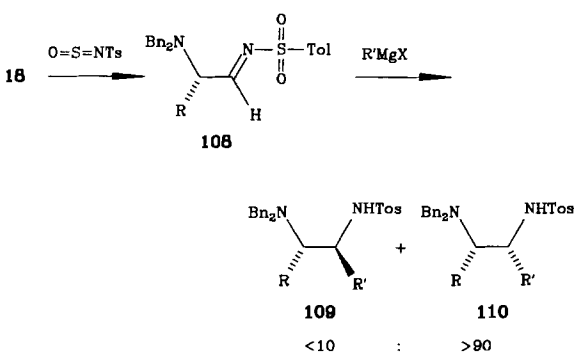
5. Preparation and Reactions of α-Amino Aldimines and α-Amino Ketimines

The first transformation of chiral α-amino aldehydes into the corresponding aldimines has recently been described using the *N,N*-dibenzyl derivatives **18** → **104**.[70] Since Grignard-like additions to simple aliphatic aldimines are notoriously difficult due to competition from α-deprotonation, it was not expected that corresponding C–C bond formation in the case of the aldimines **104** would be easy. Indeed, essentially no conversion was observed using R_2CuLi/BF_3[71] or Grignard and alkyllithium reagents in THF. In contrast, organocerium compounds $RCeCl_2$[16] are capable of adding to **104**, and they do so under chelation control (cf. **106**).[70] In some instances even alkyllithium reagents add, provided *ether* is used as the solvent. In the case of CH_3Li and $CH_3Li/CeCl_3$, diastereoselectivity is >95%, although the yield does not exceed 40%. This shortcoming can be eliminated with the very reactive reagent $3CH_3Li/CeCl_3$ (>75% yield with >95% diastereoselectivity). It has not yet been established

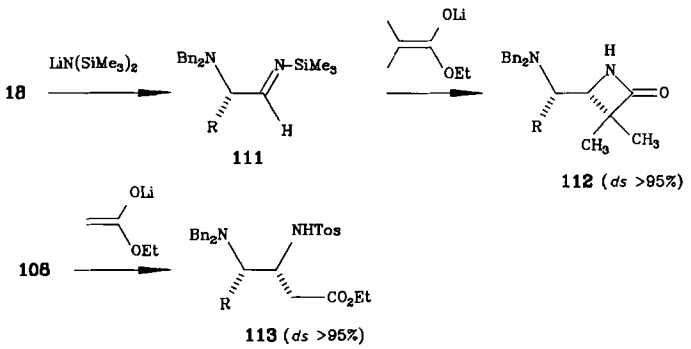
whether $(CH_3)_3Ce$ or ate complexes are involved.[70] In any event, the intermediacy of chelates of the type **105** is probable. Since the reagents RLi and $RLi/CeCl_3$ add to the analogous aldehydes **18** under nonchelation control, aldimines apparently constitute better chelating agents. This is a consequence, among other things, of the (*E*) configuration of the C–N double bond, which permits only *syn* complexation necessary for chelation. Analogous hydrazones derived from *N*,*N*-dimethylhydrazine also react with alkyllithium reagents under chelation control.[18]



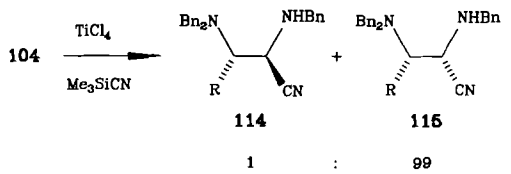
In order to reverse the sense of diastereoselectivity the donor strength of the nitrogen atoms in the α-amino aldimines must be weakened to such an extent that effective chelation is precluded. This can in fact be achieved by replacing the benzyl protecting group on the aldimine nitrogen by the electron-withdrawing tosyl function. Thus, aldimines **108** prepared according to the Weinreb method[72] react with Grignard reagents under nonchelation control to give the adducts **110** (61–95% yield; *ds* = 90–99%).[70] These substrates therefore behave stereochemically like the aldehydes **18**. Adducts **106** and **110** can usually be deprotected without difficulty. In those cases in which difficulties are encountered, other protecting groups must be used. To this end phosphorus-based groups are being developed.[18] It is significant to note that both the preparation and the reactions of the aldimines **104** and **108** occur without racemization.[70] Vicinal diamines are encountered as ligands in metal-induced stereoselective reactions, in various chemotherapeutic contexts (cisplatin analogues and technetium-99 contrasting agents), as well as in a wide variety of natural products.[70]



Other very different types of C–C bond-forming reactions of α-amino aldimines are currently under intensive investigation.[18] Preliminary experiments with the aldimines **111** prepared according to the Cainelli method[73] show that stereoselective aldol additions are possible, resulting in formation of the unusual β-lactams **112**. As proven by an X-ray structural analysis of adduct **112** (R = CH_3), the process involves nonchelation control.[18] Since the bulky aldimines **111** are relatively unreactive (failing, for example, to react with the Li enolate of ethyl acetate at low temperature), the more reactive *N*-tosylaldimines **108** were employed. These do in fact react highly selectively with virtually all Li ester enolates to give the diamines **113**.[18] Nonchelation control is likely, but remains to be proven.



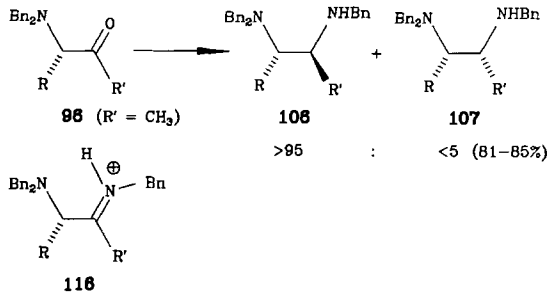
Stereoselective addition of Me_3SiCN to α-amino aldimines (e.g. **104**) would be another important step toward preparative exploitation of this class of compounds. Hydrolysis of the nitrile function, for example, would lead to the biologically important class of α,β-diamino carboxylic acids. As a first example we cite the $TiCl_4$-mediated addition of Me_3SiCN, resulting in formation of the adduct **115**. Definitive proof of the stereochemistry remains to be presented.[18,74] However, since BF_3/OEt_2 also leads to the same product, nonchelation control is likely. This cannot involve a thermodynamically based equilibrium favoring **115**, be



cause higher reaction temperatures result in a 1:1 mixture of **114**/**115**. Whether reversal of diastereoselectivity can be achieved with other protecting groups or alternative reagents remains to be seen. Reaction of the aldimine **108** (R = $PhCH_2$) with $Me_3SiCN/SnCl_4$ leads as expected to the corresponding nonchelation-controlled adduct **115**, the relative configuration of which has been verified by X-ray analysis.[74]

In principle, α-amino ketones **96** should be amenable to reductive amination to give the corresponding vicinal diamines. In practice this actually succeeds only with the methyl ketones **96** (R′ = CH_3); all other substrates are too

bulky or too unreactive.[75] With $NaCN \cdot BH_3$ in the presence of benzylamines, for example, reaction occurs without difficulty, resulting in virtually exclusive formation of the products **106**. It is probable that the process involves reduc-

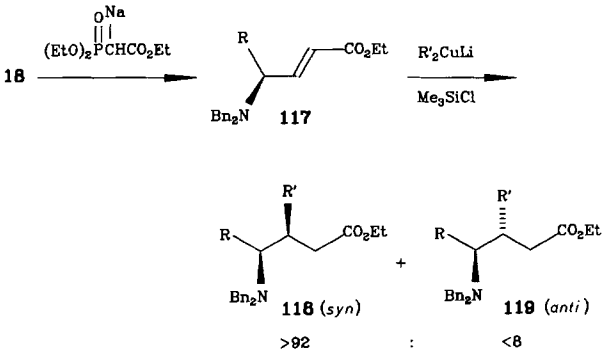


tion of the intermediate ammonium ions **116** under nonchelation control.

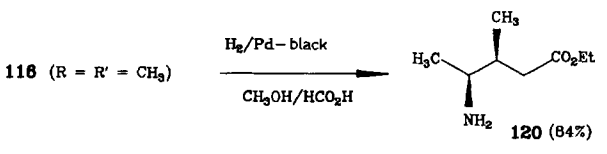
6. Preparation and Reactions of Electron-Poor γ-Amino Olefins

6.1. Cuprate and Other Michael Additions

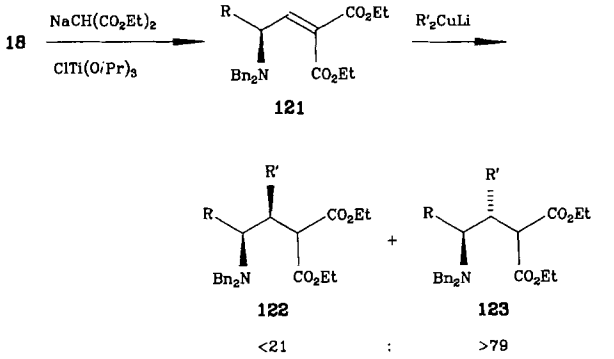
In order to take advantage of the synthetic potential of *N*,*N*-dibenzylamino aldehydes **18** in yet another context, the electron-poor olefins **117** were prepared without racemization by using the Horner–Wittig reaction.[76] This provides an enantiomerically pure class of compounds suitable for cuprate and other 1,4-Michael additions as well as epoxidation and Diels–Alder or 1,3-dipolar cycloadditions. Although not all of our expectations have been fulfilled, results to date are quite promising. For example, cuprates add highly diastereoselectively in the presence of Me_3SiCl to form the enantiomerically pure *syn*-configurated adducts **118**.[76]



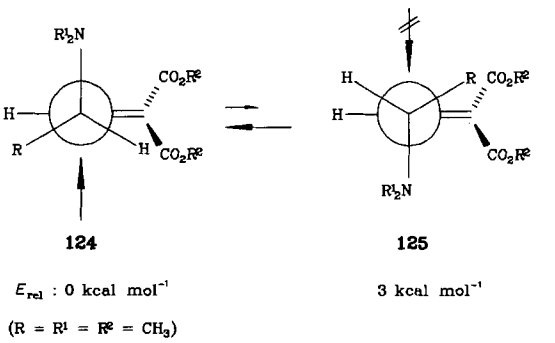
Since γ-aminobutyric acid (GABA) is a compound of considerable biological importance, the products **118** could well be of interest, especially in unprotected form (e.g. **120**).[76]



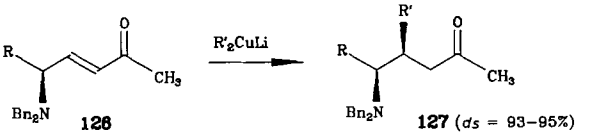
Knoevenagel products **121** were prepared in order to reverse the sense of diastereoselectivity. These proved to be considerably more reactive, with no requirement for Me_3SiCl in cuprate addition, and lead preferentially to the *anti* adducts **123** (*ds* = 79–99%).[76]



What is the origin of the observed diastereoselectivity in the reactions described above? In the case of the diesters **121** 1,3-allylic strain[77] certainly plays the decisive role.[76] This factor causes conformation **124** to be favored relative to **125**; steric interaction between the residue R and the *cis* ester group would otherwise result in an energetically unfavorable situation, a conclusion supported by force-field calculations.[78] NMR studies reveal that the reaction commences with the formation of Cu–olefin π complexes.[78] Mechanistic interpretation of additions to the ester **117** is more difficult, since force-field calculations show that no particular conformation is favored.[78] For this reason only speculation is possible, for example by assuming a Bürgi–Dunitz trajectory.[79]

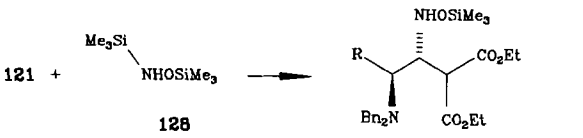


Analogously to the esters **117**, the more reactive ketones **126** also react with cuprates.[78]



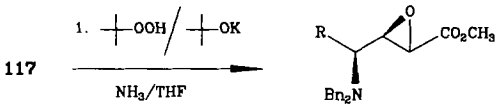
Quite recently the α,β-unsaturated esters have also been subjected to reaction with nitrogen nucleophiles. Whereas amines such as benzylamine react primarily with the ester function to give the undesired amides, the silylated hydroxy-

lamine **128** undergoes smooth and highly stereoselective Michael addition with diesters **121** (though not with **117**).[78] The sense of the diastereoselectivity is the same as in the case of cuprate additions; that is, 1,3-allylic strain is once again the controlling factor (cf. **124**).

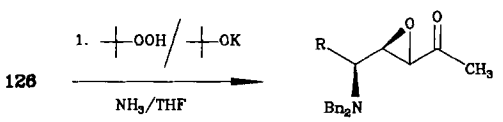


128 **129** (*ds* = 91–95%)

Since epoxides are useful vehicles for subsequent synthetic transformations, special attention has been directed toward epoxidation of the esters **117**.[80] By using special conditions (*tert*-butylhydroperoxide/potassium *tert*-butoxide in ammonia/THF) smooth epoxidation can be effected. From a mechanistic point of view this probably involves 1,4-addition/elimination, in which the same diastereotopic face of the electron-poor π system is attacked as in the case of the cuprates. The conditions employed result in saponification to the corresponding carboxylic acids, which are then esterified to simplify isolation (overall yield of **130** ca. 50%). Epoxidation is also possible with the ketones **126**, providing a significantly higher isolated yield of the epoxides **131** (>80%; *ds* > 95%).[80]

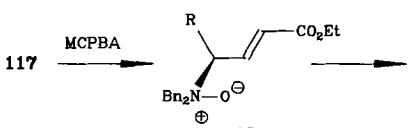


130 (*ds* >95%)

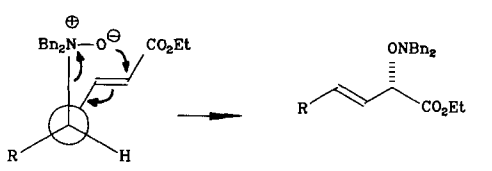


131 (*ds* >95%)

Electrophilic epoxidizing agents such as *m*-chloroperbenzoic acid (MCPBA) oxidize not the double bond, but rather the nucleophilic nitrogen.[81] This entails formation of intermediate amine oxides **132**, which then undergo stereoselective [2,3]sigmatropic rearrangements[82] to the esters **134** with complete 1,3-transfer of chirality.[81] Transition state



132

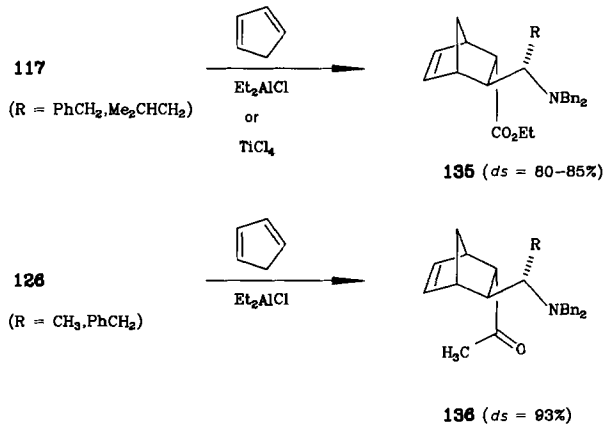


133 **134** (*ee* >95%)

133 is consistent with the stereochemical result[81] and has also been postulated in related cases.[83]

6.2. Cycloadditions

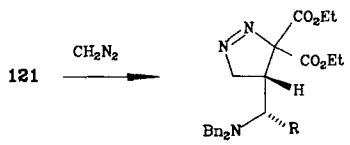
Esters **117** and ketones **126** smoothly undergo $EtAlCl_2$ mediated Diels–Alder reactions with cyclopentadiene (though not with butadiene). Of the four possible diastereomeric products there is a pronounced preference for the adducts **135** and **136**, respectively.[78] In the case of the ketones **126** it was possible to make a definitive assignment of configuration on the basis of X-ray structural analysis. This demonstrates that the Diels–Alder reaction involves attack on the same diastereotopic face of the electron-poor π system as observed during cuprate addition.



135 (*ds* = 80–85%)

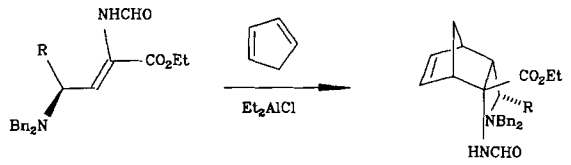
136 (*ds* = 93%)

Nevertheless, it would be premature to conclude that Diels–Alder reactions and Michael additions always follow the same stereoselective course. For example, the diesters **121** react unselectively with cyclopentadiene, providing, in the case of **121** (R = $PhCH_2$), a 58 : 24 : 11 : 7 mixture of four diastereomers. Here both diastereofacial selectivity and *endo* selectivity are relatively low.[78] This is surprising, since 1,3-allylic strain should be an especially important factor as delineated previously in cuprate addition to the diesters **121**. It is not yet clear whether protecting-group tuning might be a last resort in controlling stereoselectivity.[84] The theoretical interpretation is also difficult, because 1,3-dipolar cycloadditions with diazomethane prove to be extraordinarily stereoselective (*ds* = 92–99% in favor of **137**).[78]



137 R = CH_3; *ds* = 92%
R = $PhCH_2$; *ds* = 99%
R = Me_2CHCH_2; *ds* = 99%

Cycloadditions to the "functionalized" esters **138** have also led to interesting results.[85] A Diels–Alder reaction of **138a** with cyclopentadiene gave a single adduct **139a** with an



138 **139**

a, R = CH_3 *ds* > 96%

b, R = $PhCH_2$ *ds* = 82%

c, R = Me_2CHCH_2 –

d, R = $tBu(CH_3)_2SiOCH_2$ *ds* = 78%

initially unknown relative configuration. After X-ray structural analysis of the starting material **138a** suggested that it constituted a classic example of a system subject to 1,3-allylic strain (Fig. 3), preferential attack from the upper, sterically less shielded π-face seemed plausible. However, X-ray structural analysis of the product revealed the configuration to be as shown in structure **139a**. This means that the attack of cyclopentadiene occurs not from above (C3-*Si*, C4-*Re*), but from below (C3-*Re*, C4-*Si*)!

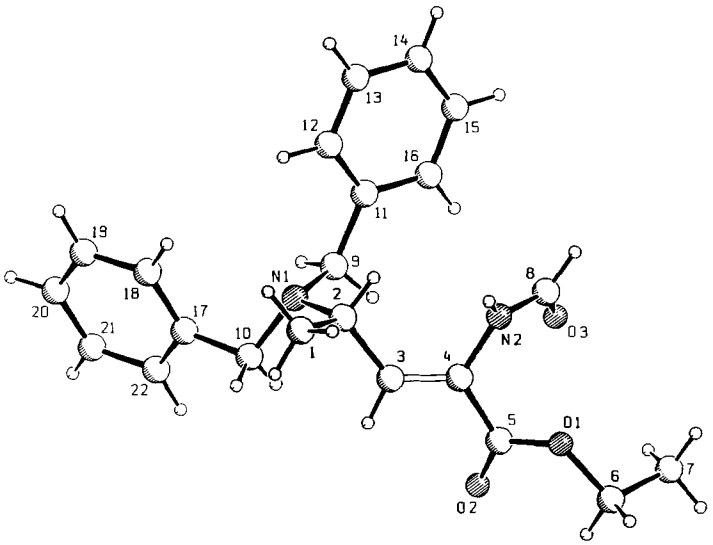


Fig. 3. Crystal structure of the ester **138a**.

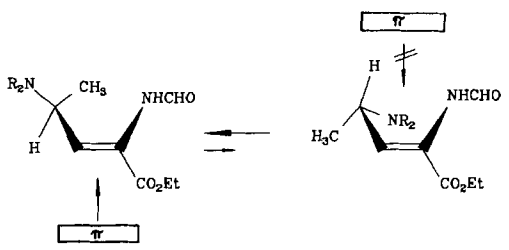
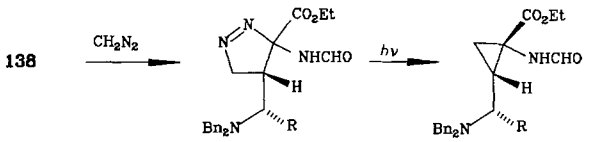
Why does the traditional application of the principle of 1,3-allylic strain[77] lead to the wrong conclusion? Perhaps the steric relationships in the transition states of Diels–Alder reactions are different from those in Michael additions. It may be that in the transition state the π system of the diene approaches the dienophile **138** like a flat "board" in a way



140 (R = $PhCH_2$) **141**

that avoids direct steric interaction with both the amino and benzyl groups. This can be achieved by appropriate rotation of the relevant C–C bond, because then the sterically least demanding H atom would point toward the attacking diene. Of the two possibilities (cf. **140** and **141**), the latter is less energetically favored, since here the larger *N*,*N*-dibenzylamino residue is pressed inward, leading to unfavorable 1,3-allylic strain.

If this analysis is correct,[85,86] then dienophiles **138** with *larger* alkyl residues at the stereogenic center should lead to *lower* diastereoselectivity. This is precisely what is observed (cf. **138b,d**); strict *endo* selectivity of the *N*-formylamino group is maintained. The same trend is apparent in a series of 1,3-dipolar cycloadditions with diazomethane leading to formation of the adducts **142**.[85] Here again the relative



142a, *ds* = 95% **143**

142b, *ds* = 86%

142c, *ds* = 74%

142d, *ds* = 90%

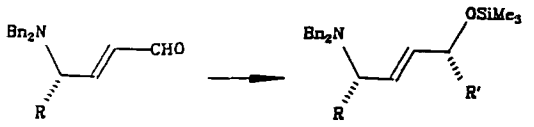
configuration has been verified by X-ray structural analysis. On the synthetic side, compounds **142** can be converted photolytically into cyclopropane derivatives **143** without loss of stereochemical information.[18,85]

7. Conclusions and Prospects

The chemistry described in this progress report constitutes a significant extension of the use of amino acids as chiral, nonracemic building blocks in organic synthesis. The stereochemical results—in some cases unexpected—present a challenge to theoreticians. From a methodological point of view the function of protecting groups is not only to prevent undesirable side reactions; their steric and electronic characteristics can be exploited as important parameters in controlling the stereoselectivity of organometallic and cycloaddition reactions. When protecting groups are called upon to act in this sense they must be carefully tailored to match the nature of particular metals and ligands present. Nevertheless, a number of important problems persist. For example, chelation-controlled additions of Me_3SiCN to α-amino aldimines have yet to be realized. It remains to be seen whether here and in other problematic chemical situations the combination of metal, ligand, and protecting-group tuning will open of new synthetic avenues.

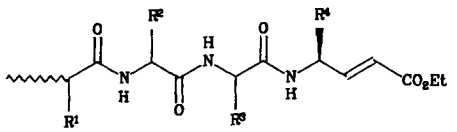
Recently further applications of *N*,*N*-dibenzylamino aldehydes **18** have been described, for example, stereoselective additions of α-phenylselenoalkyllithium reagents,[87] 1-lithiomethoxyallene,[88] and "second generation" Grignard reagents (e.g., RMgOAc).[18,89] Aldol additions to *N*,*N*-dibenzylamino aldehydes that were *not* prepared from amino acids occur diastereoselectively.[90] Finally, α,β-unsaturated esters **117** were converted into the corresponding aldehydes

144; these react with cuprates in the presence of Me_3SiCl/HMPA regioselectively in a 1,2-manner with notable diastereoselectivity in favor of **145** (ds = 79–92%).[91] This surprising result can be explained on the basis of initial diastereoselective π complexation at the C–C double bond followed by a stereoselective "walk" to the π terminus.[91]



144 **145**

As part of a new project, vinylogous amino acids of the type **117** were incorporated in peptides (cf. **146**). Michael additions, for example with R_2CuLi, occur stereoselectively,



146

depending upon the nature of the R group being transferred and on the configuration of the stereogenic centers along the peptide chain.[89, 92]

I am particularly grateful to my committed co-workers, whose names appear in the works cited from our research group. I wish also to thank the Deutsche Forschungsgemeinschaft (SFB 260 and the Gottfried-Wilhelm-Leibniz Program) and the Fonds der Chemischen Industrie for generous financial support.

ANGEWANDTE CHEMIE
A Journal of the Gesellschaft Deutscher Chemiker
International Edition in English

30 Year Index of Reviews
– in print or on diskette –

The reviews in Angewandte Chemie are amongst the most often cited chemical publications of each year. Many have become classics of the chemical literature. For thirty years they have been available in English as well as German. The 30 year review index now celebrates this anniversary by facilitating access to these important documents of the rapid development of our discipline. The index—both a chemical dictionary and a history book—offers you:

1. A list of all authors, indicating the main author and the title of the review.
2. A subject index giving the main author.
3. Both indexes provide complete information on date of issue and first and last page numbers of the German and English editions.

The electronic version of the index is available on 5¼" and 3½" diskettes.

If you order immediately, you save about 30% since the prepublication price is U.S. $44.00/£26.00 (plus postage) only until the end of January. Please order by telephone or in writing to **VCH, Software und Datenbanken, Postfach 10 11 61, D-W-6940 Weinheim, Tel. 0 62 01/6 02-2 71, Telefax 0 62 01/6 02-3 28.**

Volume Effect or Paddle-Wheel Mechanism—Fast Alkali-Metal Ionic Conduction in Solids with Rotationally Disordered Complex Anions

By Martin Jansen*

Dedicated to Professor Karl Heinz Büchel on the occasion of his 60th birthday

Transport phenomena in the solid state are of equal importance in basic research and practice. In the past two decades particular interest has been directed towards so-called "fast" or "super" ionic conductors because of their attractive potential applications. We have synthesized highly conductive alkali-metal ionic conductors based on ionic crystals in which, on the one hand, high concentrations of the charge carriers can be realized by doping (point defects in the cation substructure) and, on the other, the activation energy of the interchange of sites is decreased by translationally fixed but rotationally mobile complex anions. Mixed crystals with Na_3PO_4 or Na_3AlF_6 structures have proven especially suitable in this connection. With the object of establishing a broader experimental foundation for clarifying the controversially discussed question of whether the higher free transport volume or the rotational motion of the anions is responsible for the high cation mobility in these rotary phases we have systematically varied the type of anions and concentration of defects and monitored the resulting changes in conductivity. Although the macroscopical characteristics investigated are not suitable for explaining mechanisms in detail at the atomic level, the results afford clear support for the assumption of a "paddle wheel mechanism"; but also effects of the enlarged transport volume are not to be disputed. Both these effects enhancing the cationic conductivity are concomitantly operative in amounts varying from system to system; they cannot be totally separated from each other. Seen in this light, the alternative, "volume effect" or "paddle wheel mechanism," is not as sharply defined as was previously discussed.

1. Introduction

The solid state is still the least well understood form of aggregation. Both prognoses as well as the later interpretation of experimental findings leave much to be desired, even with regard to the composition of solids, their structures, their bond behavior, and particularly with respect to certain material properties. Tailormade syntheses aimed at elucidating one or more of the aforementioned differentia specifica are only possible—if at all—in exceptional cases; extrapolations from the known to the unknown are risky. Difficulties are met in going from the fictitious ideal crystal—as a rule fundamental to a discussion of structural features and the calculation of, e.g., band structures or phonon spectra—to the real crystal. The microstructure, determined, inter alia, by the type and number of non-equilibrium defects, mosaic structure, morphology of internal boundary surfaces, can vary widely from one individual sample to another. Thus, in solids of the same chemical composition a broad variation is found with regards to their reactivity and most of their physical properties. This affects in particular the transport properties, which are of utmost importance for the formation and decomposition of solids, and thus play a role in all studies, basic as well as application-oriented areas of solid-state research. The present review is concerned with one aspect of the transport properties of solids, namely the fast transport of ions in ionic crystals. Ionic crystals whose ionic conductivities σ lie between ca. 10^{-10} and $10^{-4}\,S\,cm^{-1}$ are usually referred to as solid electrolytes, those with $\sigma = 10^{-4}$ to $10^{0}\,S\,cm^{-1}$ as fast ionic conductors.[1]

Materials whose electric conductivity is due to charge transport by ions (solid electrolytes), have undoubtedly been known since the end of the last century. Systematic research in this area began with such works as those of *Tubandt* and *Lorenz*,[2] who reported the results of the first quantitative investigations on silver iodide and, inter alia, the unusual finding that the conductivity of AgI is higher below the melting point than above. The theoretical models for ion transport via defects in the crystalline solid state, which, in principle, still apply today, were developed by *Frenkel*[3] and by *Schottky* and *Wagner*[4] in the twenties. Since then our understanding of the mechanisms involved in charge transport has developed so far as to include such mechanisms at the atomic level.[5]

There has been a dramatic revitalization of research in the area of solid-state electrolytes through a pioneering work by *Yao* and *Kummer*:[6] β-aluminum oxide, long known in the solid state and initially considered to be a further modification of aluminum oxide but later identified by X-ray structure analysis as sodium oxoaluminate $NaAl_{11}O_{17}$,[7] is an exceptionally good and still unsurpassed sodium ion conductor. The actual stimulating aspect of these author's work was not the new "record" reached for sodium ion conductivity but rather the concepts developed there from for the technological utilization[8] of such materials. The possible use of such electrolytes in galvanic chains for thermodynamic and kinetic studies in solid-state chemistry and as sensors for direct measurement of the partial pressures of different gases, and especially the prospect of developing efficient energy storage and conversion systems (solid-state batteries and fuel

[*] Prof. Dr. M. Jansen
Institut für Anorganische Chemie der Universität
Gerhard-Domagk-Strasse 1, W-5300 Bonn (FRG)

cells) based on solid-state electrolytes, has motivated the interest of numerous groups world-wide in this area of research.

For practical purposes, most important at present are sodium, lithium, oxygen, and hydrogen ion conductors. The temperature dependence of the conductivity of the respective solid electrolytes, with, in each case, the highest conductivities achieved so far, is reproduced in Figure 1 as an Arrhenius plot ($\log \sigma T$ versus $1/T$). the curves for AgI and conc. H_2SO_4 are included for comparison.

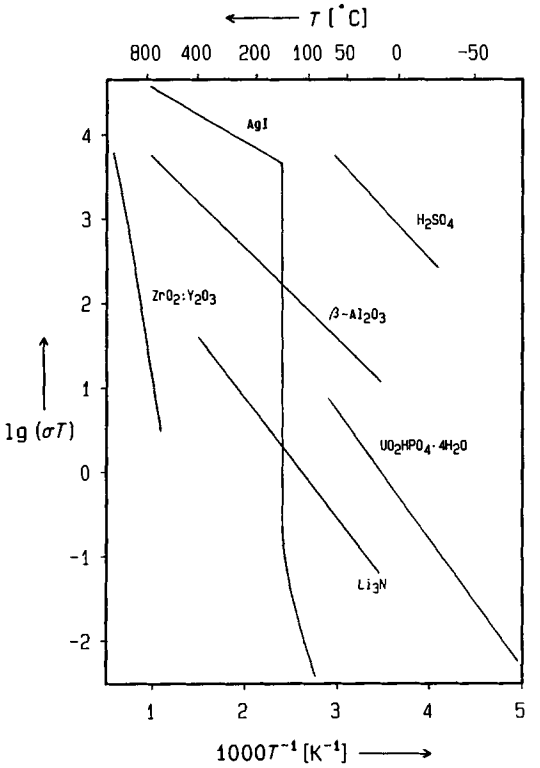

Fig. 1. Temperature dependence of the ionic conductivity in AgI [2,9] conc. H_2SO_4 [10], β-Al_2O_3 [11], ZrO_2: Y_2O_3 [12], Li_3N [13], and $UO_2HPO_4 \cdot 4\,H_2O$ [14]; Arrhenius diagram.

Even though mass-produced devices based on solid-state electrolytes (λ-probes[5] and Na/S batteries[16]) are meanwhile on the market, the ion conductors developed so far do not fulfill all practical requirements, especially with regards to their thermodynamic and mechanical stability and conductivity at low temperatures (300–400 K). Further research into the rudimentary steps of ion transport and the search for new ionic conductors is therefore essential.

2. Concepts in the Search for New Ionic Conductors

The thermodynamic prerequisite for an effective charge transport in solids by ions, namely the presence of a gradient, either in the chemical or electrical potential, is trivial. The kinetic requirement is a high translational mobility of the ions. Three mechanisms[17] of ion migration usually come under discussion:

1. Conventional transport by uncorrelated jump processes of point defect sites. The difference from the diffusive behavior of normal ionic crystals is thereby only of a quantitative nature; the jump rates and defect concentrations are in comparison a few orders of magnitude higher. Examples are β-Al_2O_3 and CeO_2:Y_2O_3.
2. Highly correlated jump processes, in which fast ion transport is brought about by collective movement of several ions. As examples Li_3N and $RbBiF_4$ may be mentioned.
3. A more fluent movement of the cations in a high-grade disordered cation substructure with flat potential surface. This description applies above all in the case of compounds such as silver(I) sulfide.

For by far the greatest number of ionic conductors, the mechanism via uncorrelated, thermally activated jump processes listed under 1 would be the correct mechanism. In this case, the parameters on which the ionic conductivity depends are essentially known.

From the general expression for the conductivity

$$\sigma = nq\mu \tag{a}$$

incorporation of the Nernst–Einstein equation

$$\mu k T = q D \tag{b}$$

and of the expression for the diffusion coefficients

$$D = \gamma(1 - c)\, d^2 \nu_0 \exp(-E_a/kT) \tag{c}$$

gives the relationship

$$\sigma T = N q^2 \gamma c(1 - c)\, d^2 k^{-1} \nu_0 \exp(-E_a/kT) \tag{d}$$

μ = mobility of the charge carrier, N = number of structural sites for the migrating ion, c = degree of occupation of the N positions, $n = Nc$ = charge carrier concentration, q =

Martin Jansen, born on Pellworm in 1944, studied chemistry at the Justus-Liebig-Universität Giessen where he gained his doctorate in 1973 under the supervision of R. Hoppe. After his habilitation in 1978 he was offered and accepted a professorial chair for inorganic chemistry at the Universität Hannover; in 1987 he moved to the Rheinische Friedrich-Wilhelms-Universität in Bonn. His research interests lie in the fields of preparative solid-state chemistry, crystal chemistry, and the structure properties relationships of solid materials.

charge, d = jump distance, ν_0 = characteristic vibration frequency, k = Boltzmann constant, E_a = activation energy, γ = geometry factor (contains activation entropy).

Of the factors included in Equation (d), N, d, q, and ν_0 are the least variable when one attempts to optimize the conductivity, since they are largely fixed, either for the chosen type of structure or for the type of ion. The best possibilities for an optimization are provided by the defect concentration c and activation energy E_a. Table 1 lists a collection of the prerequisites for high ionic mobility in the solid state. If an

Table 1. Prerequisites for high ionic mobility in the solid state.

1) Prerequisites in the structural geometry
   a) vacant sites in the substructure of the migrating particle type and/or corresponding interstitial sites
   b) diffusion paths with flattest possible potential curve
      α) flat potential trough of the regular and/or interstitial site
      β) narrowest site ("bottle neck") in the diffusion path as wide as possible
   c) branched diffusion paths
2) Prerequisites in the chemical nature of the participating species
   a) high polarizability of the migrating ions
   b) high polarizability of the immobile matrix

appropriate number of energetically favorable interstitial sites or defects of the migrating ion type are not available in the pure substance an adequate concentration of defects (50 % of all positions of the migrating ion would be optimal) can generally be realized quite easily by doping. In contrast, the possibilities of decreasing the activation energy for the hopping processes are very limited. A low coordination number for the migrating ions on the regular lattice position has a favorable effect, since in such cases the difference between the space available inside the polyhedron to that on the surface is relatively small. The energy required for elastic deformation of the electron shells upon passage of the cations through one of polyhedra faces ("bottle necks") is then smaller. Of advantage, furthermore, is a high polarizability of the migrating cations and/or of the anionic matrix. These facts explain the generally very high diffusion coefficients of the monovalent coin metals in the solid state[18] and the high lithium conductivity in Li_3N (polarizability of N^{3-}).[13] If alkali-metal ionic conductivity without any electronic contributions is the more important objective regarding the potential application of such electrolytes, there remains only modification of the anionic matrix. However, here also there is little latitude. Only non-metals of the higher periods in lower oxidation states come under consideration as anions with a polarizability greater than N^{3-}; however, their electronic contribution to the total conductivity is frequently undesirable.

Fundamental to our working hypothesis in the search for fast ion conductors is the assumption that in structures with translationally fixed complex anions having increased rotational mobility these facilitate the passage of the alkali metal ions through one of the faces of their coordination polyhedra somewhat in the sense of a "paddle wheel" and thereby drastically decrease the activation energy for ionic conduction. Such a mechanism[19] was first discussed in the case of the high-temperature form of Li_2SO_4,[20] which crystallizes with disordered anions in the cubic anti-fluorite structure. Since rotational diffusion of the sulfate anion with high frequency for this modification and concomitant marked increase of the lithium ion conductivity (by a factor of 10^2) during the phase transformation was established, one assumes a causal relation in the above-mentioned sense, namely a favoring of Li^+ hopping by the quasi freely rotating anions. With the aim of exploiting this effect in the search for new alkali-metal ion conductors, we have chosen ionic crystals of alkali-metal ions and complex oxo or fluoro anions as basic compounds which are susceptible to orientational disorder of the complex anion. In addition, either a sufficient concentration of intrinsic cation defects (not too energy-rich interstitial sites) must be present or corresponding extrinsic defects in the cation substructure must be producible by doping (mixed crystal formation).

The demand for branched, two-dimensionally or better still three-dimensionally cross-linked diffusion routes is generally fulfilled in such materials, since their structural makeup is usually dominated by arrangement of the complex groups in the sense of hexagonal closest, cubic closest, or cubic body-centered packing.

3. Choice of Suitable Basic Structures

The tendency of a complex anion to develop rotational disorder in the crystal is generally deducible from the crystal structure: if the symmetry of the environment is higher than the point symmetry of the (to a first approximation) rigid anion, there are several energetically equivalent orientations for the latter, which, on a time average, are occupied with equal frequency. Transitions between these orientations are brought about by thermally activated rotational jumps (rotational diffusion), which, phenomenologically, are closely related to the elementary steps of translational motion. The jump rates can vary widely, so that all intermediary steps from practically static disorder to quasi free rotation are possible. This spectrum of jump frequencies can also be observed as a function of the temperature on one and the same material, whereby the transition to free rotation is frequently accompanied by a reconstructive phase transformation. Since practically all alkali-metal salts with complex anions convert into such rotary phases at elevated temperature, we have directed special attention in preselection of the salt to a lowest possible transformation temperature and to available or producible concentration of charge carriers (defects). In the systems studied in detail by us, in the case of Na_3PO_4 and Na_3AlF_6 it involved a directed selection[21] on the basis of the above-mentioned criteria; in the case of the antiperovskite-type $(NO_2)ONa_3$, an accidental discovery with regard to high ionic conductivity. At first it was not known in which way the required charge carrier concentration could be achieved in the latter case.

3.1. The Na_3PO_4 Family or the Cryolite Problem

Difficulties in the refinement of the crystal structure[23] of K_3PO_4 as a result of the disorder of the phosphate anion turned our attention to the group of alkali-metal orthophosphates, and with a view to possible practical applications, especially to the air-stable anhydrous Na_3PO_4. To our surprise, on searching through the literature, we established that

in the case of this well-known inorganic salt, the number and stabilities of the polymorphic modifications were highly controversial and, moreover, no structural information was documented.[24] After optimization of the synthesis, which turned out to be unexpectedly lengthy (see below), we have been able to attribute the controversial data for Na_3PO_4 to the different degrees of purity of the samples investigated:[21a] pure Na_3PO_4 exists only in two modifications, a low-temperature and a high-temperature form (L-Na_3PO_4 and H-Na_3PO_4). The phase transformation occurs reversibly at 598 K. Single crystals of H-Na_3PO_4, grown just below the melting point at 1573 K, could be quenched metastably to room temperature and investigated by the usual single-crystal technique. As confirmed by a comparison with the X-ray powder diagram of H-Na_3PO_4 above the transformation temperature, the observed structure (cf. Fig. 2) practically represents the dynamically disordered high-temperature form in the "frozen in" state. If the PO_4^{3-} group is regarded as a pseudoatom, a

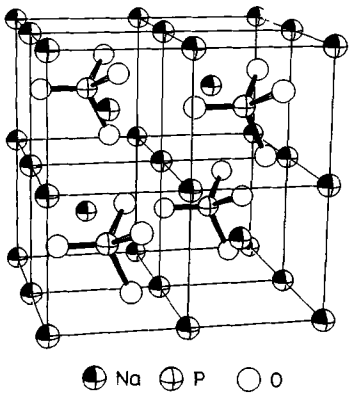

Fig. 2. Perspective plot of the crystal structure of H-Na_3PO_4; phosphate groups in one of the possible orientations.

very simple description of the basic structure is obtained: The particles X^{3-} form a cubic close packed arrangement, whose tetrahedral and octahedral voids are completely occupied by sodium ions. From this structural principle there immediately follow constraints that hinder the formation of an ordered structure and, in retrospect, make the difficulties of synthesizing pure Na_3PO_4 understandable. Easily recognizable in Figure 2 is the incompatibility of the positional symmetry (O_h) and point symmetry (T_d) of the anion, which necessarily leads to disorder. Above the transformation temperature it is dynamic in nature.

The six preferred orientations of the tetrahedron, each with one of its threefold rotational axes parallel to the cubic axes, lead to a displacement of the sodium ions from their ideal positions too; this is so strong that it can no longer be simulated by harmonic temperature parameters.[21a]

The second of the above-mentioned difficulties results from the simultaneous occupation of all tetrahedral and octahedral sites by sodium. Such an arrangement is energetically extremely unfavorable in ionic crystals, because of the short distances between neighboring tetrahedral and octahedral sites. This is recognizable best with sodium ions at the "octahedral sites"; these are first surrounded by eight further sodium ions and only in a secondary coordination sphere by six phosphate groups. Only in the case of less polar compounds, e.g. with predominantly metallic bonding, is this structure realized undistorted and with complete occupation of all positions; the prototype is Li_3Bi.[25] In the case of the ionic crystal Na_3PO_4 this leads to the incorporation of any "impurity" if it is suitable for reducing the number of cations per anion. This holds true for anions with a lower ionic charge than 3− and for cations with a higher charge than 1+. It follows that ionic crystals with this structure are obtainable in pure form only with difficulty if at all. Further examples are Na_3AlF_6[26] ("cryolite problem") and BiF_3,[27] which only occurs in this structure type contaminated with oxygen as $BiF_{3-2x}O_x$; pure BiF_3 has another structure.[28] Na_3PO_4 (and with limitations also Na_3AlF_6) thus fulfills important prerequisites for fast ion conductivity both with respect to its dopability as well as to the potential rotational mobility of the complex anion according to our above-mentioned concept (Section 2).

A further favorable feature is the close relationship of the modification with ordered anions, which is thermodynamically stable at low temperatures (cf. Fig. 3), with the high-

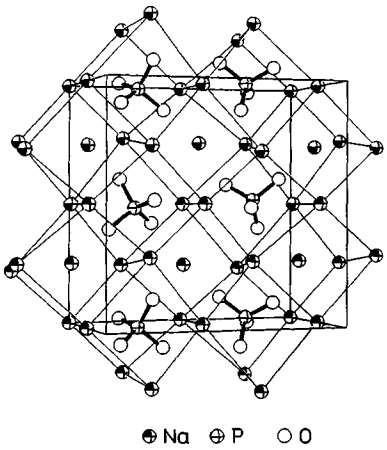

Fig. 3. Section of the crystal structure of L-Na_3PO_4.

temperature form, from which the good dopability also of this modification and a displacive transition in the rotary phase immediately follow.

3.2. The Orthonitrites of the Alkali-Metals and Related Compounds

Na_3NO_3 was originally considered to be the ortho salt of sodium nitrite with NO_3^{3-} ions.[29] In fact these compounds, in contrast to the alkali-metal orthonitrates, are not ortho salts but oxide nitrites[30] with perovskite structure in accordance with the formulation $(NO_2)ONa_3$. Unexpectedly, the crystal structure at room temperature is cubic with one formula unit in the unit cell. This necessarily leads to orientational disorder of the complex NO_2^- anion (point group C_{2v}) located in a cubooctahedron of sodium (positional symmetry O_h). This was confirmed by a single-crystal structure analysis (cf. Fig. 4). The disorder of the anion is apparently of a dynamic nature, confirmed in particular by the behavior upon lowering the temperature.[31, 32] A sequence of phase trans-

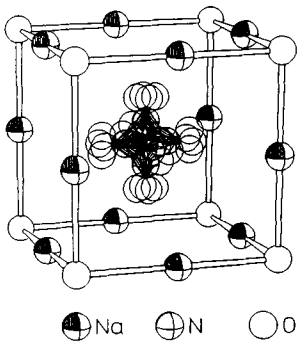

Fig. 4. Crystal structure of H-Na_3NO_3 (≡$(NO_2)ONa_3$); dynamic disorder of the nitrite anion outlined by superposition of 24 orientations.

formations is observed, H-Na_3NO_3 $\xrightarrow{235\,K}$ M-Na_3NO_3 $\xrightarrow{180\,K}$ L-Na_3NO_3 $\xrightarrow{72\,K}$ LL-Na_3NO_3, in the course of which the disorder decreases to complete order in LL-Na_3NO_3 (cf. Fig. 5). In L-Na_3NO_3, still two equivalent

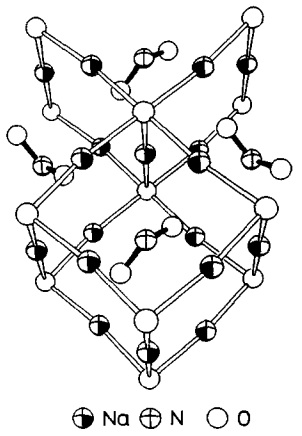

Fig. 5. Crystal structure of LL-Na_3NO_3.

orientations of the nitrite groups occur; the structure can be generated from that of LL-Na_3NO_3 by mirror imaging the latter through an imaginary plane at $z = 1/2$ parallel to (001). Even this disorder is still dynamic in nature: with the help of alternating current techniques, Debye relaxation with jump

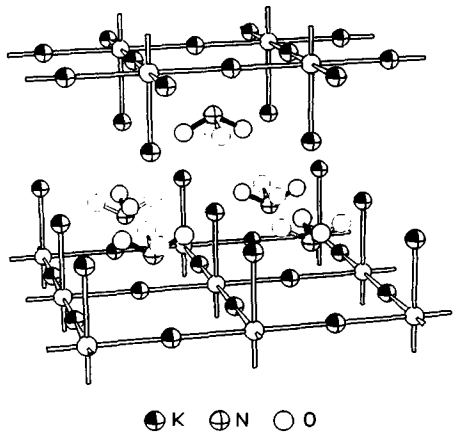

Fig. 6. Crystal structure of $K_4N_2O_5$ ($Na_4N_2O_5$ forms a superstructure of the anti-K_2NiF_4 type), disorder of the nitrite anion illustrated by superposition of the two possible orientations.

rates of $10^{-6}\,s^{-1}$ was established at 100 K.[22] Extrapolation to room temperature, which naturally can afford only a rough approximate value, gives jump rates in the gigahertz range. Since we considered Na_3NO_3 a daltonide compound, the high ionic conductivity established in a routine measurement surprised us (see Section 5).

This discovery incited us to vary $(NO_2)ONa_3$ by changing the individual components and by structural modification—as has been achieved for example in numerous other cases for the perovskite family. The variants obtained, like $(NO_2)_2ONa_4$ (Fig. 6), are to be assigned the anti-K_2NiF_4 structure, or like $(CN)ONa_3$ contain another disordered anion in place of NO_2^-.[32, 33] The close relationship of these compounds is underscored by the mutual solubility[34] of $BrONa_3$[35] and $(NO_2)ONa_3$.

4. Sodium Ionic Conductors with Sodium Orthophosphate or Cryolite Structure

The ionic compounds of the cryolite family, commonly considered to have well-defined formulas (see Section 3.1) already exhibit cation defects to a more or less marked extent, due to the above discussed structural features and the resulting difficulty to realize their ideal composition. In spite of that it appeared meaningful in view of the optimization of the sodium ion conductivity to approximate as close as possible the maximum charge carrier concentration (50 % vacant sites in the cationic substructure) by doping.

Basically, this sodium can be substituted by divalent metal ions[36, 37] such as e.g., Cd^{2+} or Ca^{2+}, or the threefold negatively charged complex anions can be replaced by groups of lower ionic charge. Besides these two possibilities of substitution, there are further possibilities which can generate anionic defects or lead to interstitial cations,[37] which are either undesirable or in view of the nevertheless already overcharged cation substructure in Na_3PO_4, will play no greater role.

Each substituted particle changes the potential on the corresponding lattice site and thus effects, inter alia, a more or less strong deformation of its surroundings and thus lowers the mobility of the charge carrier. Since this effect could be most noticeable in the case of the cation conductivity upon aliovalent exchange in the cation sublattice, we have, in our studies, substituted exclusively the anions. The replacement of a phosphate anion by a sulfate anion with retention of the structure has essentially the following effects with regard to the cation conductivity:

1. Increasing the concentration of defects in the cation substructure.
2. Changing the so-called free transport volume for the cations
3. Increasing the rotational motion of the complex anion ("paddle-wheel effect").

Further, less significant effects, such as the already indicated different trapping of the charge carrier in the proximity of different anions, are not taken into consideration in the following.

The above-mentioned effects are not strictly separable, as would be desirable for their selective exploitation in the opti-

mization of ionic conductors. In order to gain at least some information about how strongly which parameters influence the ionic conduction, we have chosen mixed-crystal systems and compared them with one another, eliminating at most one of the three influential parameters (Table 2).

Table 2. Mixed crystals investigated and effectivity of the factors favoring ionic conduction, minus = no effect, plus = positive effect.

System	Defect site concentration	Transport volume	Paddle-wheel effect
Na_3PO_4/Na_3AlF_6	–	+	+
Na_3PO_4/Na_2SO_4	+	–	+
Na_3PO_4/Na_2CO_3	+	+	+
Na_3AlF_6/Na_2SiF_6	+	–	+
Na_3AlF_6/Na_2SO_4	+	+	+

In connection with our own studies the synthesis of the mixed crystals was in each case accomplished by solid-state reaction of the pseudobinary components. It proved absolutely essential to elucidate the corresponding sections of the phase diagrams. The samples were characterized by X-ray diffraction techniques, and their homogeneity was checked by energy dispersive microanalysis. The characteristic electrical quantities were determined on sintered samples by alternating current techniques, by measurement of the Hebb-Wagner polarization and, on selected samples, by measurement of the sodium ion transference.[38]

The good dopability of both Na_3PO_4 and Na_3AlF_6 predicted on the basis of structural conditions is impressively confirmed by the experimental findings: thus, for example, Na_3AlF_6 dissolves in the cubic high-temperature phase Na_2SO_4 with retention of the structure up to $x_S = 0.8$ (x_S = mole fraction of dissolved component) and at room temperature up to $x_S = 0.125$.

In the case of Na_3PO_4/Na_2SO_4 the formation of mixed crystals extends to $x_S = 0.6$. The range can even be extended to $x_S = 0.75$ by quenching. Figure 7 shows as a typical example the phase diagram of the pseudobinary system Na_3AlF_6/Na_2SO_4.

According to direct current measurements[38] the electronic part of the conductivity always lies about five to six orders of magnitude below the total conductivity. Hereby, and by transference measurements on selected random samples the mixed crystals are characterized as practically pure sodium ion conductors. A confirmation of our working hypothesis is seen in the considerably high values for the conductivities, especially in the case of the mainly cubic high-temperature forms with dynamically disordered anions. In the system Na_3AlF_6/Na_2SO_4 two regions can be differentiated: on the one hand that with miscibility in the low-temperature and high-temperature forms and on the other, that with demixing at low temperatures. In the first case, Arrhenius behavior is observed in the whole temperature range examined with a sudden increase in the conductivity and at the same time decrease in the activation energy at the monoclinic → cubic transformation (cf. Fig. 8).

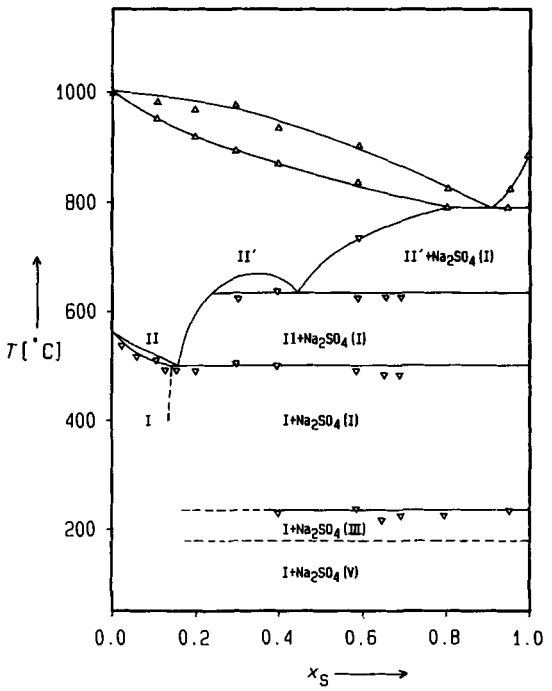

Fig. 7. Phase diagram of the pseudobinary system Na_3AlF_6/Na_2SO_4. x_S = mole fraction of Na_2SO_4, △ = DTA heating mode, ▽ = DTA cooling mode (DTA = differential thermal analysis). I–V represent the different polymorphic modifications of Na_2SO_4.

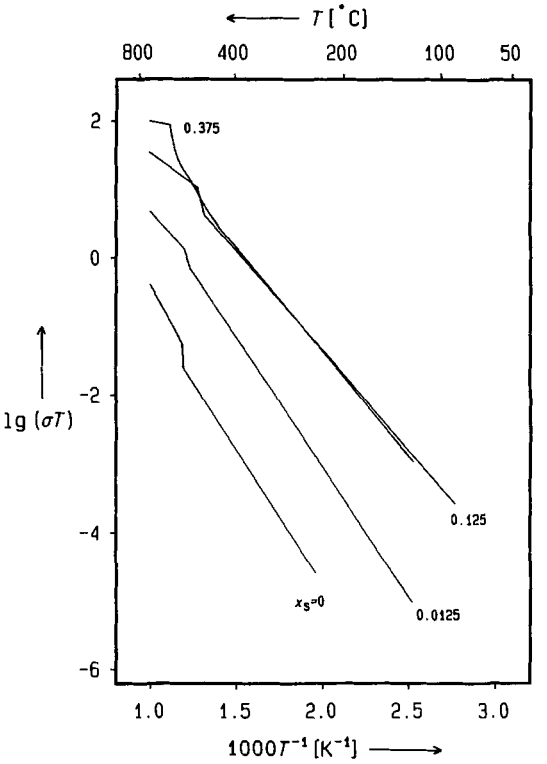

Fig. 8. Temperature dependence of the sodium ion conductivity in the system Na_3PO_4/Na_2SO_4. x_S = mole fraction of Na_2SO_4.

In studies on Na_3PO_4[21a] there were initially discrepancies with respect to the ion conductivity of the mixed crystal systems;[40] in the meantime, however, these have largely been resolved[41, 42] and numerous new systems have been included.[42] In one respect the electrical behavior of the solid solutions based on Na_3PO_4 is fundamentally different from the cryolite solutions. Obviously as a result of the fact

that even very slight doping is enough to stabilize the cubic form at room temperature, the sudden increase in conductivity and the corresponding decrease in the activation energy of the pure Na_3PO_4 during the phase transformation is no longer observed in the mixed crystals.[42] At low temperatures (298 K) the conductivity increases by up to four orders of magnitude with doping. The activation energy corresponds to that of pure Na_3PO_4 at this temperature and decreases constantly on elevating the temperature until the activation energy of pure Na_3PO_4 in the high-temperature form is approximately reached. These facts are illustrated by way of example for the system Na_3PO_4/Na_2SO_4 in Figure 9. Qualitatively, all systems in which Na_3PO_4 participates show an analogous behavior.[43]

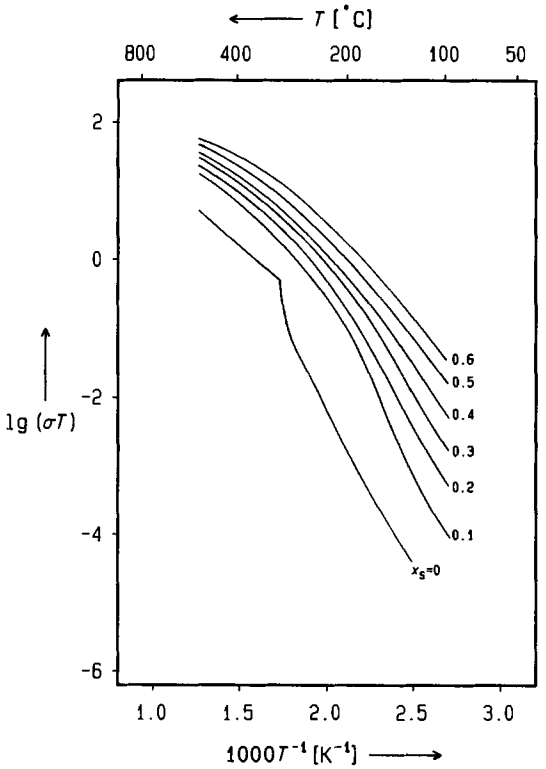

Fig. 9. Temperature dependence of the sodium ion conductivity in the system Na_3PO_4/Na_2SO_4. x_S = mole fraction of Na_2SO_4.

An intermediary position is assumed by Na_3AlF_6/Na_2SiF_6 solid solutions, in which the sudden transition into the cubic modification in the case of pure cryolite smears out more and more and disappears at $x_{Si} = 0.73$ completely[44] (Fig. 10).

The influence of volume and "paddle-wheel effect" without alteration of the charge carrier concentration can be monitored by substitution of the AlF_6^{3-} in Na_3AlF_6 by PO_4^{3-}.[45] As follows from the pseudobinary section (Fig. 11), complete miscibility and cubic structure occurs above ca. 913 K. In the phosphate-rich part, the temperature-dependence of the conductivity shows the nonlinear relationship $\log(\sigma T)$–$1/T$ typical for doped Na_3PO_4, while in the cryolite-rich part, Arrhenius behavior and conductivity jumps are observed in the region of the phase transformations (Fig. 12).

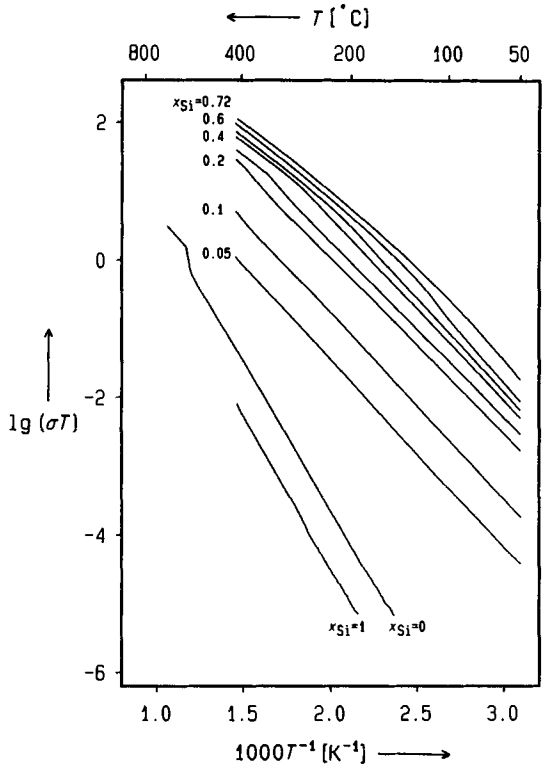

Fig. 10. Temperature dependence of the sodium ion conductivity in the system Na_3AlF_6/Na_2SiF_6. x_{Si} = mole fraction of Na_2SiF_6.

The increase in conductivity by an order of magnitude at unchanged charge carrier concentration, is higher than expected.

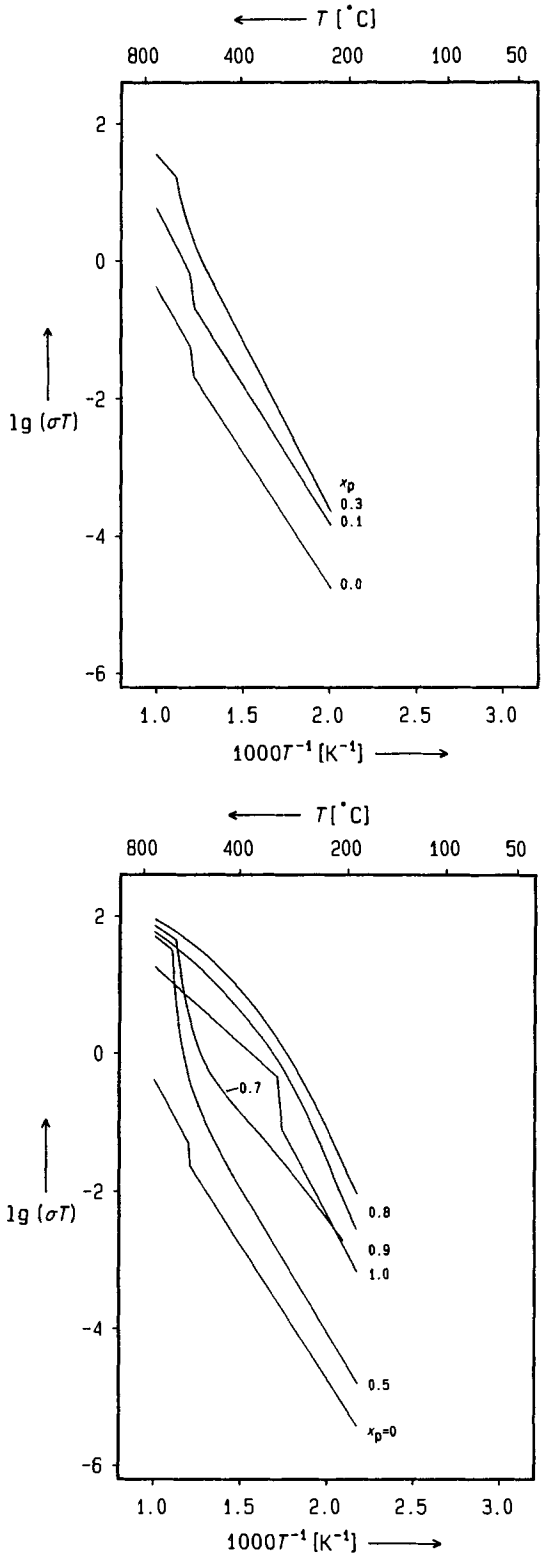

Fig. 12. Temperature dependence of the sodium ion conductivity in the system Na_3AlF_6/Na_3PO_4. Solid solutions of phosphate in cryolite (top) and of cryolite in phosphate (bottom). x_P = mole fraction of Na_3PO_4.

5. Sodium Ion Conduction in anti-Perovskite Variants $XONa_3$ (X = NO_2, Br, CN) and X_2ONa_4 (X = NO_2)

In the above-mentioned attempts to confirm the dynamic nature of the disorder in $(NO_2)ONa_3$ by measurement of the Debye relaxation by alternating current techniques,[22] the temperature range above room temperature to 500 K was also included (at still higher temperatures reactions with all common electrode materials or decomposition are observed). Surprisingly, drastic increases in conductivity by a total of three orders of magnitude occurred in two steps at 500 and 520 K. These at first completely unexplainable observations quite clearly indicate (confirmed by sodium transfer measurements) jumps in the sodium ion conductivity. They are accompanied by strong endothermic effects without mentionable hysteresis and do not coincide with the eutectics of the pseudobinary system $NaNO_2/Na_2O$. Since reconstructive phase transformations (type 1 according to the Ehrenfest classification) are not involved there are only two possible explanations left: Increasing rotational mobility of the NO_2^- anion or melting of the sodium ion substructure. NO_2^- is dynamically disordered with jump rates in the gigahertz range already at room temperature. However, for steric reasons the bent anion can only move around its longitudinal axis. Conceivable now would be that rotations about the other axes are possible at elevated temperatures. This could only happen, however, if the sodium ions leave their regular positions. This would then provide an explanation for their translational mobility and for the high sodium ion conductivity. Independent of the effects of the dynamic behavior of the complex anion, the general structural makeup with a "cubic body-centered" arrangement of the anions, as in α-AgI or Ag_3SBr, which are the best solid-state electrolytes of all, could favor a melting of the cation substructure. Indeed, there are a series of features in common with the behavior of AgI.

An experimental differentiation of the two proposed models can be accomplished by substitution of NO_2^- by anions such as CN^- or Br^- which have fewer degrees of rotational freedom. Indeed the results of the conductivity measurements and of the differential thermal analyses of the two compounds Na_3OCN and Na_3OBr isotypic with Na_3NO_3 (cf. Fig. 13) are very informative:[33] Even without the possibility of rotation diffusion, in the case of Na_3OBr, sudden jumps in conductivity and an endothermic effect are observed, albeit to a lesser extent than in the case of Na_3NO_3 and in one step. Na_3OCN shows qualitatively the same behavior, but with the largest conductivity jump found so far in these systems. These findings can now be explained by assumption of a combination of both effects in Na_3NO_3 and Na_3OCN, in the case of Na_3OBr exclusively as a result of the structurally ("cubic body-centered" arrangement of the anions) promoted premelting of the cation substructure. That Na_3OCN exhibits only one thermal effect is accounted for by the complete activation of the possible rotations of the smaller rod-shaped anions already at room temperature.

A similar argument holds in the case of oxide nitrites of the anti-K_2NiF_4 type[32] (cf. Fig. 6) such as $(NO_2)_2ONa_4$ or $(NO_2)_2OK_4$, in which the ONa_4 structural moieties are topologically related to that of ONa_3 in Na_3NO_3. As follows from Figure 13, the effect here is even more drastic; the activation energy in the high-temperature modification approaches that of liquid electrolytes. This could be connected with the more weakly bound sodium ions at the octahedral apices in the $^2_\infty(ONa_4)$ layers.

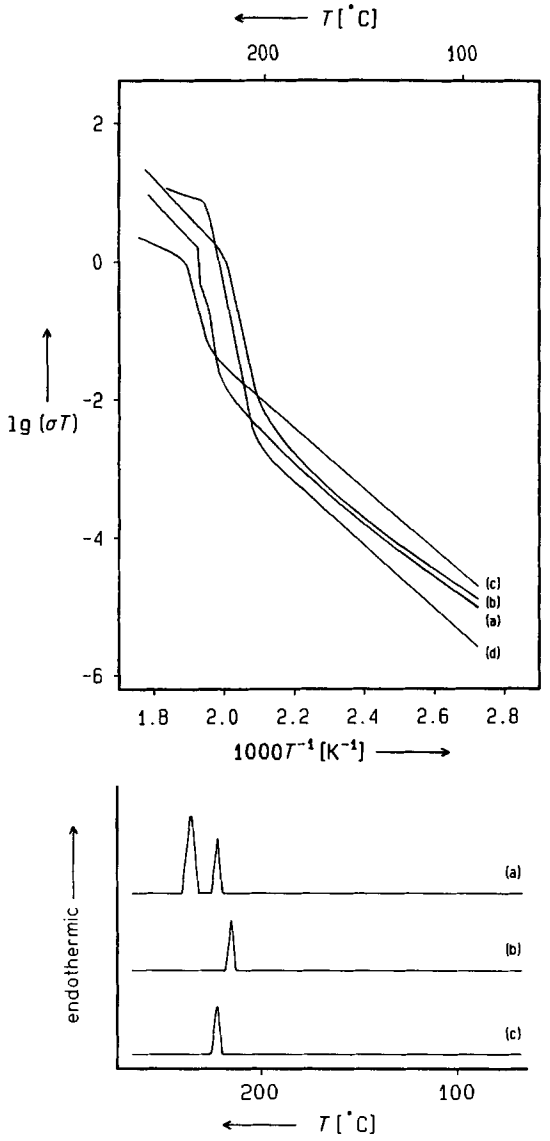

Fig. 13. Sodium ion conductivity in $(NO_2)ON_3$ (a), $(CN)ONa_3$ (b), $BrONa_3$ (c), and $(NO_2)_2ONa_4$ (d) (top) and schematic reproduction of the DTA curves of (a)–(c) (bottom).

6. Trends, Interpretations

The aim of our studies is to collect empirical material through the development of novel alkali-metal ionic conductors by the choice of suitable basic structures and material systems, in order to assess the importance of the parameters influencing ion conduction and their destructive and constructive interplay. The most homogeneous and thus best data for comparison are known for the highly symmetric rotationally dissolved phases of the respective systems. Here, without exception, the maximum achievable defect concentration is highest (in agreement with the findings in the case of Li_2SO_4[46]) and the macroscopic transport behavior can be described in the form of Arrhenius diagrams. In the case of the low-temperature modifications the solubility is lower, and regions of demixing are very soon reached. The conductivities in the two-phase regions are highly dependent on the temperature programs run for the AC measurements. This is accounted for, on the one hand, by the solid-state reactions (demixing) taking place on establishment of equilibrium, and, on the other, by an irregular distribution of the readily and poorly conducting volumes of the electrolyte (percolation phenomena). From the data available, the quantities

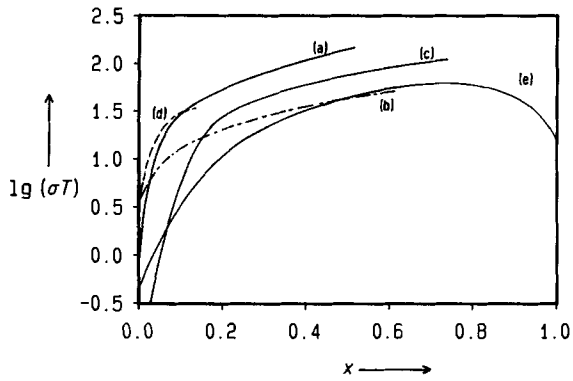

Fig. 14. Sodium ion conductivities in Na_3AlF_6/Na_2SO_4 (a), Na_3PO_4/Na_2SO_4 (b), Na_3AlF_6/Na_2SiF_6 (c), Na_3PO_4/Na_2CO_3 (d) and Na_3AlF_6/Na_3PO_4 (e) as a function of the composition (950 K for cases (a) and (e), 773 K for (b) and (d) 683 K for (c)). x = mole fraction of last named component in each system.

characterizing alkali-metal ionic conductivity, namely the activation energy and the conductivities, for the high-temperature and low-temperature phases have been chosen as the most informative (Fig. 14 and 15). The trends derived from changes in these characteristics with changing composition can be related to the various influencing parameters:

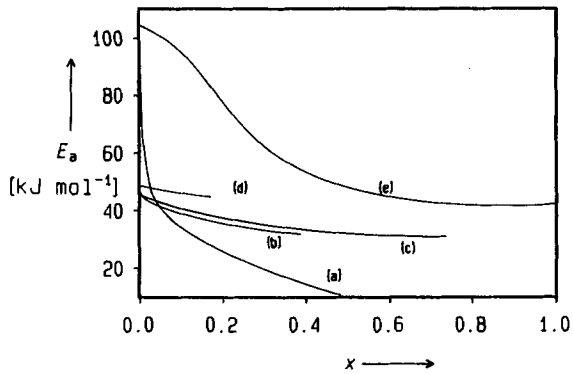

Fig. 15. Activation energies of the sodium conductivity in Na_3AlF_6/Na_2SO_4 (a), Na_3PO_4/Na_2SO_4 (d), Na_3AlF_6/Na_2SiF_6 (c), Na_3PO_4/Na_2CO_3 (d) and Na_3AlF_6/Na_2PO_4 (e) as a function of the composition in the region of the high-temperature modifications. x = mole fraction of last named component in each system.

Extrinsic Disorder in the Cationic Substructure

Increasing the defect concentration in the cationic substructure not unexpectedly (cf. Equation (d)) favors the conductivity quite significantly. As for the aliovalent substitution of cations,[36, 37] this is found also in the previously described (Section 4) solid solutions with anions of different ionic charge. The effect is clearly recognizable in the system Na_3AlF_6/Na_2SiF_6. Here, the volume of the unit cell remains practically constant during the course of doping and at the same time the conductivity at 473 K increases by five orders of magnitude between $x_{Si} = 0$ and $x_{Si} = 0.73$. If all parame-

ters except the term $c(1-c)$ in Equation (d) were fixed, then the maximum conductivity should lie at $c = 0.5$. This is in fact observed (cf. Fig. 14 and 15); however, at small values of doping it increases faster than with the factor $c(1-c)$. Here, it becomes evident that the influenced factors do not act independently of each other.

Volume Effects

The assumption that the increase of lattice constants upon doping leads to an expansion of the "transport volume" for the cations and thus effects a decrease in the activation energy of the ion transport seems plausible. The environment of a vacancy in the cationic lattice experiences a broadening and thus contributes to the expansion of the transport volume. Naturally the volume of the vacancy itself may not be taken into account, since the following consideration concerns primarily the *activation* of the macroscopic ion migration. The former local contributions are hardly measureable exactly. On the other hand, the changes in the lattice constants afford useful information: the increase in volume upon doping could fully augment the transport volume. If, in addition, one takes into account the difference between the volume increment[47] of the regular anion and that of the substituted anion, this could give a quantity which almost correctly measures the change in the free transport volume. In the system Na_3AlF_6/Na_3PO_4 the charge carrier concentration remains constant over the whole range of composition. As a comparison of the trends of σ, E_a, and V (the latter only for the sodium phosphate-rich part) with changing mole fraction x_p shows (cf. Fig. 16), there does in fact seem

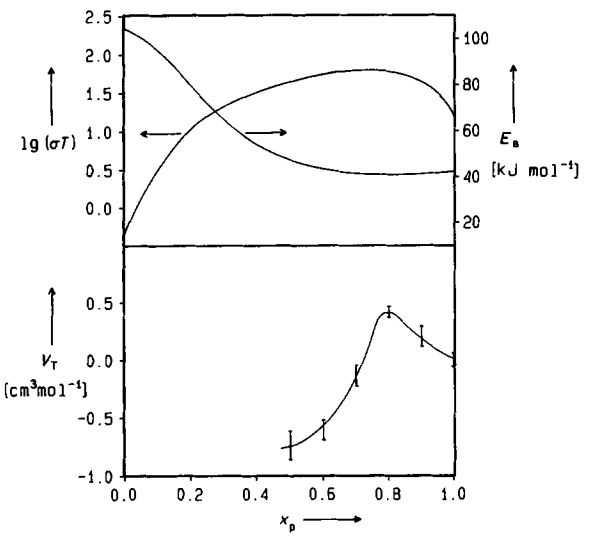

Fig. 16. Course of the sodium ion conductivity, activation energy, and "free transport volume" in a solution of Na_3PO_4 in Na_3AlF_6 and a solution of Na_3AlF_6 in Na_3PO_4. x_P = mole fraction of Na_3PO_4.

to be a connection between ionic conductivity and free transport volume; a volume increment of PO_4^{3-} (39 cm^3 mol^{-1}) is significantly smaller than that of AlF_6^{3-} (46 cm^3 mol^{-1}). On the other hand, it is obvious that the smaller PO_4^{3-} ion at an AlF_6^{3-} lattice site will also exhibit an increased rotational mobility on steric and symmetry grounds.

"Paddle-Wheel Effect"

The effect of the rotational diffusion of complex anions on the activation energy of translational transport is just as difficult to separate from the other influential factors as is the volume effect. Indications of this effect are given by the jumps in conductivity and the generally decreasing activation energies upon transition into the high-temperature phase with dynamically disordered anions. Convincing evidence for the effectiveness of the paddle-wheel effect appears to be derivable from the systems with doped Na_3PO_4 and the NO_2^--containing perovskite variants.

As already mentioned, slight doping of Na_3PO_4 stabilizes the high-temperature form at room temperature. The temperature dependence of the conductivity in the Arrhenius plot is completely different for doped and undoped Na_3PO_4 (cf. Fig. 9). Upon transition into the rotational phase with significant change in structure, pure Na_3PO_4 shows a corresponding increase in conductivity and an activation energy which differs for L- and H-Na_3PO_4 but is constant in their respective regions of existence. In contrast the activation energies in all solid solutions based on Na_3PO_4 change continuously with the temperature. Here, an influence of the volume effect can now be virtually ruled out, since such drastic changes in the activation energy with temperature as a result of the thermal expansion would then have to occur in all ion-conducting materials, and this is not the case.

A logical explanation, on the other hand, is provided by the concept that in H-Na_3PO_4, stabilized at room temperature by doping, the rotation of the anion is "frozen in", and this is gradually excited via thermal activation with increasing temperature up to quasi free rotation. Since, in our opinion, also rotational jumps of complex anions decrease the activation energy of translational cation transport, this model consistently explains the temperature dependence of the activation energy of mixed crystals based on Na_3PO_4.

The influence of the changing distribution of defects with temperature on the octahedral and tetrahedral holes (by means of neutron diffraction a ratio of 75:25 was measured at room temperature, and 100:0 at 673 K),[48] is not forseeable at the present time.

Especially instructive in this connection seems to be the situation in the anti-perovskites of type $XONa_3$ with $X = NO_2^-$, CN^-, Br^-. Due to the packing of the anions (cubic body-centered) we have a structural principle common to all three compounds, which we see as a prerequisite for the surprisingly high ionic conductivity. In addition, a further increase in the conductivity by a few orders of magnitude manifests itself as a result of the rotational degrees of freedom of the anionic groups in $(CN)ONa_3$ and $(NO_2)ONa_3$. We consider the fact that $(NO_2)ONa_3$ shows two jumps (NO_2^- has one more degree of rotational freedom available than CN^-) with endothermic effects as lending support to the opinion that the rotational diffusions of the anions promote the translational mobility of the cations.

Packing of the Anions

The type of packing of the anions to give ideally an immobile matrix has been somewhat neglected in previous work. This aspect has, however, been vividly brought to mind in direct connection with discussions of the electrical behavior

of the anti-perovskites. It is certainly not without good reason that just α-AgI and Ag_3SBr with cubic body-centered arrangement of the anions are the solid-state electrolytes with the highest conductivity found so far. The unforseen high sodium ion conductivity in $BrONa_3$ or $(NO_2)ONa_3$ is certainly accounted for in part in terms of this anionic structure with its characteristically distorted and mutually interpenetrating "tetrahedral" and "octahedral" holes. This can be taken as an indication that also the packing and thus the type and connectivity of the holes for the cations may in no way be ignored when designing fast ion conductors based on large complex anions.

7. Volume Effect or Paddle-Wheel Mechanism?

Parallel to our attempts to develop new solids with high alkali-metal ion conductivity exploiting the rotational mobility of complex anions, a very controversial discussion has developed as to whether the rotational motion of the anions actually and effectively favors the cationic conductivity. *Lunden* et al.[46, 49] are of the opinion that a paddle-wheel mechanism provides the actual explanation for the high conductivity of ionic crystals with dynamically disordered anions, particularly of Li_2SO_4, whereas *Secco* et al.[50] disagree with involvement of such an effect and make the increase in volume during the transition into the rotational phase responsible for the increase in conductivity. The argument in each case is based predominantly on macroscopic material properties. *Lunden* et al. have indeed demonstrated beyond doubt the nature of the high-temperature form of Li_2SO_4 as rotational phase, however direct proof of an immediate interaction between translational mobility of the cations and rotational diffusion of the anions is still lacking. Attempts to come to a decision here were impaired by insufficient employment of local probes responding to the dynamics in solids and by certain limitations coupled with the heterogeneity of the systems investigated. A further deficiency lies in the diffuse definition of the mechanism: Corresponding to the images employed "paddle wheel", "cog wheel", or "revolving door" are different concepts, from the one extreme of an active role of the anions transporting the cations mechanically, to a passive function responding with an evasive motion toward the passage of the cation.

The following classification of the differences would seem meaningful:

1. Cooperative rotational movements of the anions transport the cation actively (paddle-wheel or cog-wheel mechanism).
2. Uncoupled rotational jumps permit passage of the cations according to the random principle and thus lead to a high mobility of the cations.
3. The mobile anions react with an evasive motion towards the passage of the cation (revolving door mechanism).
4. The rotational diffusion generates periodically fluctuating potentials at the cation positions and thus favors cation mobility.

All synchronous mechanisms are less likely. The assumption of coupled motions of neighboring anions ("cog-wheel" mechanism) would signify considerable interaction between these anions, which in turn would not be reconcilable with the suggested quasi free rotation. Comparable jump rates for anions and cations over a greater temperature range are also not conceivable, since this would require matching activation energies.

For differentiation between the remaining models quantitative data for the local dynamics are essential. But already the data available permit a first classification. In agreement with *Lunden* et al. we have, according to our results, no doubt that the rotational diffusion of the anions increases the cationic conductivity and decreases the associated activation energy. In any case the observations on the anti-perovskites $XONa_3$ and the mixed crystals based on Na_3PO_4 are not to be understood otherwise. On the other hand, a favoring of the ion transport by a higher transport volume is equally incontestable. The two effects can not be strictly separated. The phase transformation in a rotational phase is also always accompanied by an increase in volume; conversely an increase in volume at the lattice of the anion promotes its rotational mobility. In this respect the question "volume effect" or "paddle-wheel mechanism" is not so closely defined, as is presently being discussed. Moreover there is no reason to grant Li_2SO_4 a special position. The differences from other ionic crystals with dynamically disordered complex anions such as Na_3PO_4 or Na_2SO_4 are only of a qualitative nature; at correspondingly elevated temperatures PO_4^{3-} in Na_3PO_4 will, e.g., exhibit similarly high jump rates as SO_4^{2-} in Li_2SO_4.

It can be clearly shown that a "paddle-wheel mechanism" is effective during cation transport (albeit to a differing extent from compound to compound); the respective contribution and the mechanism on a microscopic level cannot be determined via the macroscopic properties predominantly determined here.

8. Conclusion

On the basis of the results collected so far we consider our concept to promote the translational motion of cations in ionic crystals by introducing complex anions with rotational mobility as having been validated. Right from the start, material with negligible electronic contributions, showed cation conductivities comparable with those of the so-called "fast-ion conductors". However, the values of the hitherto best sodium ion conductor, β-aluminum oxide, could not be outrun or even reached. The results are concomitantly documentary evidence that the factors influencing ionic conduction appear to be principally understood. Remarkable progress has also been made in our understanding of the microscopic mechanisms and in deducing quantitative relationships.[51] Even if it is difficult to surpass the previous "record marks" through the synthesis of tailormade solids then this in our opinion has nothing to do with the respective optimum compounds being found already, but rather with the difficulties in realizing the required structural and chemical circumstances with the necessary precision. In this context we might only mention the ionic radius of the migrating particle, which must be accurately matched to the free cross

section of the diffusion path; even slight deviations below or above the ideal value lead to drastic breaks in the conductivity.

As shown, for example, by the development of NASICON,[52] our understanding certainly suffices in order to develop suitable material systems with predicted high ionic conductivity in a practically deductive way. On the other hand, the accidental discovery of the high sodium ion conductivity in Na_3NO_3 and in the compounds structurally derived therefrom already in the undoped state demonstrates that a more inductive approach also still has justification.

The systems newly introduced by us broaden the material basis for discussions in connection with the paddle-wheel mechanism. They support the concept according to which the rotational diffusion of the anions favor cation conduction. We expect to acquire further supporting evidence for this interpretation by measuring the local motions in the systems described, e.g. with the help of nuclear magnetic resonance spectroscopy. Although valuable additional atom-specific information might be accessible thereby, the attempt to strictly separate rotational and translational motions from each other or even to establish cause–effect relationships will fail—as much as this would be desirable for an understanding of the processes and their description. It is an essential characteristic of chemical systems and especially of solids that they always respond collectively to external impacts, for example in the course of a physical measurement.

Our own works mentioned in this review were supported by the Fonds der Chemischen Industrie and the Deutsche Forschungsgemeinschaft (SFB 173 and Gottfried Wilhelm Leibniz Program). I wish to thank all co-workers who participated in the individual studies cited in this work. Thanks are also due to Dipl.-Chem. U. Henseler, Dr. R. Hundt, Dipl-Chem. D. Trinschek, and Frau K. Schirop for help in preparing the manuscript.

1,4-Dihydropyridines: Effects of Chirality and Conformation on the Calcium Antagonist and Calcium Agonist Activities

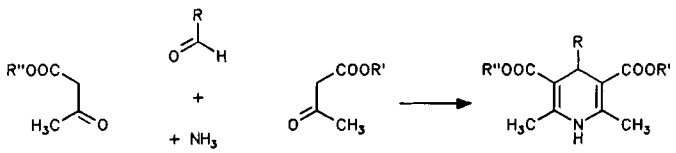
By Siegfried Goldmann* and Jürgen Stoltefuss

Dedicated to Professor Karl Heinz Büchel on the occasion of his 60th birthday

4-Aryl-1,4-dihydropyridine-3,5-dicarboxylic diesters of the nifedipine type have become almost indispensable for the treatment of cardiovascular diseases since they first appeared on the market in 1975. There are some twenty derivatives currently under clinical development worldwide and work in this area is continuing undiminished. The 1,4-dihydropyridines are the most effective of the calcium antagonists or calcium channel blockers. They are valued not only for their pharmacological effect, but also as a tool for the investigation of the calcium channel, particularly since the discovery that this class also includes compounds that have exactly the opposite action profile and are known as calcium agonists. There are even instances in which this reversal of activity is found between enantiomers. In view of the importance of chirality to pharmacological activity, the present article will describe methods for the separation of enantiomers, point out the structural differences between calcium antagonists and calcium agonists, and attempt to explain the difference in their behavior.

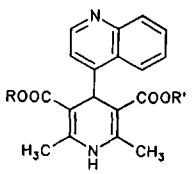
1. Introduction

1,4-Dihydropyridines of type **1** were first synthesized by *A. Hantzsch* in 1882 from acetoacetic esters, an aldehyde, and ammonia.[1] It was not until 60 years later, however,



1

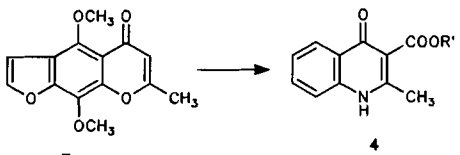
that compounds of this class were shown to exhibit pharmacological activity. The 4-quinoline-substituted 1,4-dihydropyridines **2**, which have analgesic, morphine agonist, and spasmolytic properties, were described in a Wellcome patent in 1943.[2] However, this patent had no influence on the present importance of 1,4-dihydropyridines.



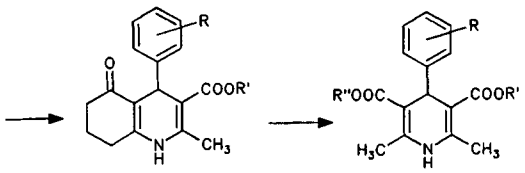
2

Twenty years later, in an investigation on cardioactive compounds of the khellin type, **3**,[3,4] *Bossert* and *Vater* at Bayer AG attempted to produce more effective and more soluble compounds by modification of the basic skeleton.

Starting with **3** and proceeding via the 4-quinolones **4** and the fused dihydropyridine derivatives **5**, they obtained the

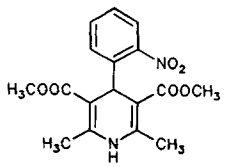


3 **4**



5 **6**

1,4-dihydropyridines **6** of the Hantzsch type,[5] which were characterized by outstanding coronary vasodilator activity.[6] The 2-nitrophenyl derivative **7** was selected as a promising compound for development. As nifedipine (Adalat®), it was successfully introduced in Germany at the beginning of 1975 for the treatment of coronary diseases.[7] *Loev* et al. at Smith, Kline and French independently studied similar derivatives having antihypertensive properties.[8-10]

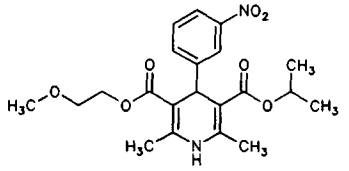


7

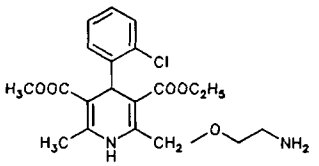
Very soon after the discovery of the cardiovascular properties of 1,4-dihydropyridines, it was found that these substances act by inhibiting the entry of Ca^{2+} into the cells of cardiac and vascular muscle through the voltage-dependent calcium channels.[11,12] To this day, the 1,4-dihydropyridines are still the most potent group of calcium channel blockers or "calcium antagonists".

[*] Dr. S. Goldmann, J. Stoltefuss
Bayer AG, Pharma-Forschungszentrum
W-5600 Wuppertal 1 (FRG)

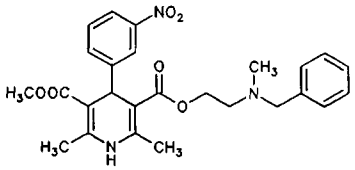
With these early studies as a foundation, many dihydropyridine derivatives have now been synthesized worldwide[5, 13–21] and have led to numerous second-generation commercial products,[16, 22] such as nimodipine (**8**),[23, 24] nisoldipine,[25] nitrendipine,[26] amlodipine (**9**),[27] felodipine,[28] isradipine,[29] manidipine,[30] nicardipine (**10**),[31] and nilvadipine.[32] Some of these compounds are characterized by longer bioavailability or greater tissue selectivity.



8



9



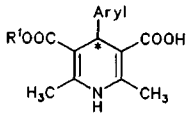
10

Symmetrically substituted dihydropyridines such as nifedipine **7** are achiral compounds. Different substituents in compounds of the second generation lead to chiral derivatives whose enantiomers differ in their pharmacological effects. In the case of the calcium antagonists, the differences are quantitative. However, the introduction of certain substituents in positions 3 or 5 can lead to calcium agonists. The enantiomers exhibit opposite activity, one of them acting as an agonist, the other as an antagonist.[33]

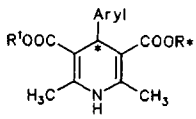
Because of the great importance of chirality in 1,4-dihydropyridines, the present article will be particularly concerned with the synthesis of the enantiomers and the differences in their activities. The question of which of the conformations of 1,4-dihydropyridines could be "pharmacologically active" will also be discussed, and an attempt will be made to explain the differences in pharmacological behavior.

2. Synthesis of Enantiomerically Pure 1,4-Dihydropyridines

The methods used most frequently for the separation of the enantiomers are (1) resolution of the racemic monocarboxylic acids **11** via diastereomeric salts and (2) separation of the diastereomeric esters **12** followed by selective removal

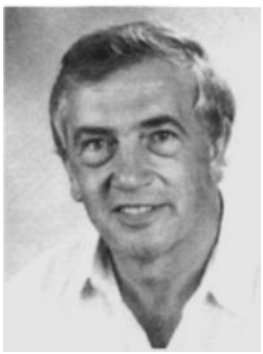


11



12

of the esterifying group to produce the monocarboxylic acid **11** or direct transesterification to form the desired dihydropyridine. Enantioselective synthesis with a chiral auxiliary group on the nitrogen has also proved to be particularly successful.



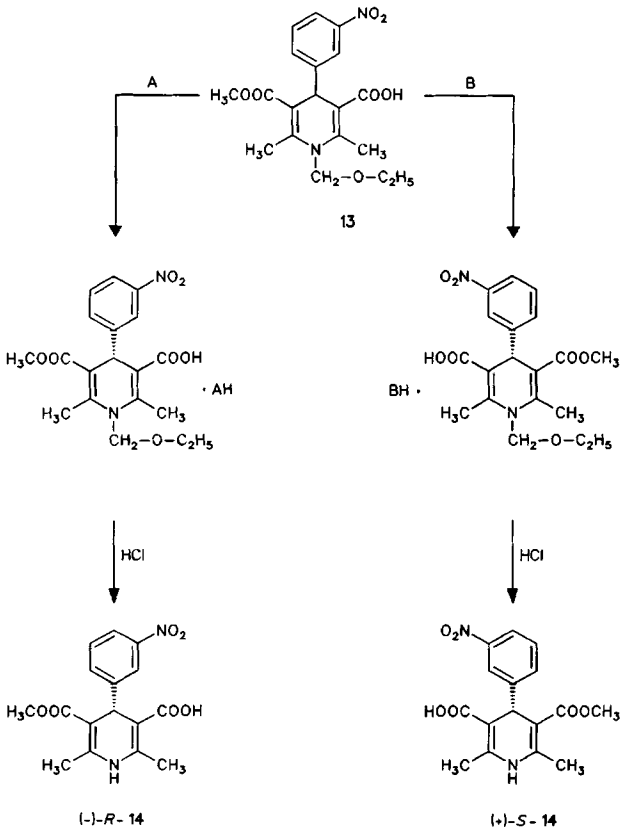
Siegfried Goldmann was born in Mölln in 1947. He studied chemistry at Marburg and was awarded a doctorate with distinction in 1979 for his work on „The stereochemistry of the [2,3]-sigmatropic rearrangement of allyl sulfoxides and the preparation of optically active allyl alcohols" under Prof. R. W. Hoffmann in Marburg. He has been employed in pharmaceutical research for Bayer AG since 1979 and works mainly in the field of 1,4-dihydropyridines for cardiovascular and metabolic indications.

Jürgen Stoltefuss was born in Wuppertal in 1941. After training as a chemical laboratory assistant for Bayer AG, he studied chemistry at Essen Technical College from 1966 until 1969. Since 1969 he has been employed by Bayer AG as a graduate engineer at the Wuppertal Research Center. His work centers mainly on synthetic investigations in the field of deoxynojirimycins and dihydropyridines.

2.1. Resolution of Racemic Dihydropyridinecarboxylic Acids

Most resolutions of racemic dihydropyridines proceed via diastereomeric salts of dihydropyridinecarboxylic acids **11** with chiral bases. A number of special methods have been developed for the preparation of dihydropyridinecarboxylic acids,[34-39] either via readily cleavable esters[35-48] or via *N*-blocked dihydropyridine dialkyl esters.[42,49] The most important of these preparation methods begin with esters of dihydropyridinecarboxylic acids having an electron-attracting group in the β position, so that they readily undergo β eliminations.[35-44] Even sensitive monocarboxylic acids can be obtained in yields of more than 70% by this means.

Cinchonidine, quinidine, cinchonine, and brucine are used as chiral bases, though other enantiomerically pure amines can also be used.[50] The first resolution of racemic dihydropyridinecarboxylic acids was carried out with the *N*-blocked 3-nitrophenyldihydropyridinecarboxylic acid **13** (Scheme 1).[51]



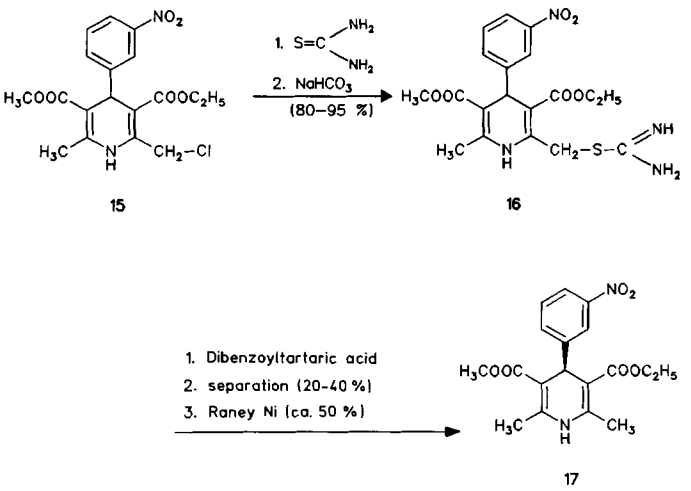
Scheme 1. Path A: Addition of cinchonidine (AH), recrystallization. Path B: Addition of cinchonine (BH), recrystallization.

Compound **13** is allowed to react with cinchonidine to form the diastereomeric salts. The *R* enantiomer **14** is obtained by repeated recrystallization and hydrolysis with hydrochloric acid (path A).[51,52] If cinchonine is used as the chiral base, on the other hand, the (+)-*S* enantiomer forms a sparingly soluble salt (path B).[52] With a suitable choice of the chiral base, therefore, either the *R* or the *S* enantiomer can be obtained by simple purification steps in an overall yield of about 10% and with high enantiomeric purity (*ee* > 99%). In DMF/water mixtures (DMF = *N*,*N*-dimethylformamide), separation of **14** is possible even without prior protection of the NH function.[50]

The resolution of racemates via diastereomeric salts has been successfully used for dihydropyridinecarboxylic acids with various structures, both of the calcium antagonist type[49,53-61] and of the calcium agonist type.[50,62] The enantiomers of the dihydropyridinecarboxylic acids are important starting compounds for the preparation of enantiomerically pure commercial and development products and of other pharmacologically interesting dihydropyridinecarboxylic esters.[49-77]

2.2. Resolution of Racemic Mixtures of Basic Dihydropyridine Derivatives

Chiral acids such as camphorsulphonic acid and substituted tartaric acids have been used to separate the enantiomers of basic dihydropyridine derivatives in yields of up to 30%.[51,55,59,67,68,73,78-79] A resolution by temporary introduction of a basic isothiourea is illustrated in Scheme 2.[45] The enantiomers obtained after separation of **16** with chiral acids may be converted into 2-substituted derivatives or into 2,6-dimethyldihydropyridines. By the use of a suitable ester group (allyl or *tert*-butyl ester), it is possible to obtain *both* enantiomerically pure compounds from *one* diastereomerically pure salt by changing the sequence of the cleavage and esterification steps.[45]



Scheme 2.

This method of enantiomer separation is suitable for many 2-substituted dihydropyridine derivatives (some of them new). However, it offers no advantages over the resolution of racemic dihydropyridinecarboxylic acids for the preparation of the enantiomers of 2,6-dimethyldihydropyridines, simply because of the greater number of steps involved in the synthesis.

In general, the resolution of racemic mixtures of basic dihydropyridines is of minor importance in comparison with that of dihydropyridinecarboxylic acids, mainly because the dihydropyridinecarboxylic acids are easy to prepare and can

be used as starting compounds both for neutral alkyl esters and for acidic and basic esters.

2.3. Separation via Diastereomeric Esters

The separation of enantiomeric dihydropyridines via diastereomeric esters is superior to other separation methods with regard to chemical yield and enantiomeric purity. If diastereomers **12** are produced by esterification with an optically active alcohol R*OH, regioselective removal of the alcohol must be possible after the separation has been performed. Three different variants are known:

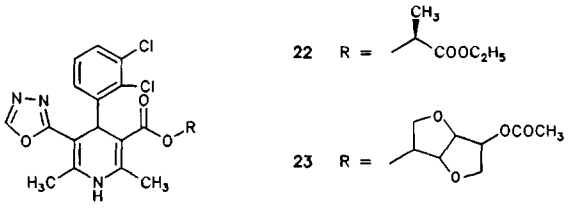
1. The chiral ester group is activated, so that it can react selectively.
2. The structure of the chiral esterifying group is such that it can be removed by β elimination.
3. The chiral esterifying group can be removed by hydrogenolysis.

In certain cases the optically active group remains in the pharmacologically active molecule, so that the diastereomers can be separated without further derivatization.[65, 80–89]

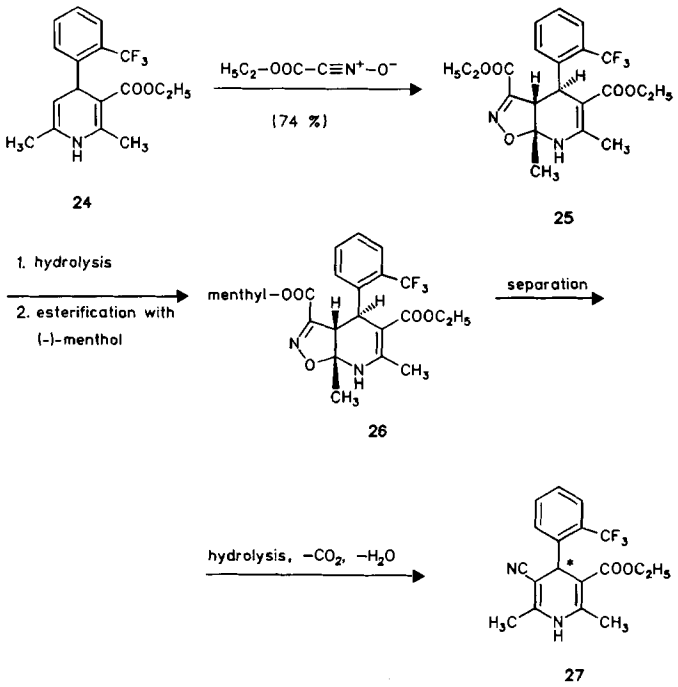
2.3.1. *Activation of the Ester Group*

The first synthesis of enantiomerically pure dihydropyridines with activated chiral ester groups was performed by *E. Wehinger* et al. (Scheme 3).[90] With mandelic acid (**18**) as the starting material, the alcohol **19** is obtained in two steps; this alcohol is then used via the corresponding acetoacetic ester, to prepare the dihydropyridine **20**. Recrystallization yields a diastereomerically pure product. By regioselective transesterification with sodium methoxide, the desired enantiomer **21** can be obtained from the ester **20** in enantiomeric purities of *ee* > 99%. The ester group here is presumably activated by chelation with metal ions, so that the transesterification proceeds regioselectively. This method has been successfully used to prepare the enantiomers both of calcium antagonists[54, 91–95] and of calcium agonists.[96]

The use of lactic acid as the ester component has certain advantages. Lactic acid is considerably cheaper than mandelic acid, and it can also be used without derivatization. Esters of lactic acid were first used for the diastereomer separation of 3-(1,3,4-oxadiazol-2-yl)dihydropyridines such as **22**.[97] The isolated diastereomers were transesterified with sodium alkoxide in yields of about 30%.

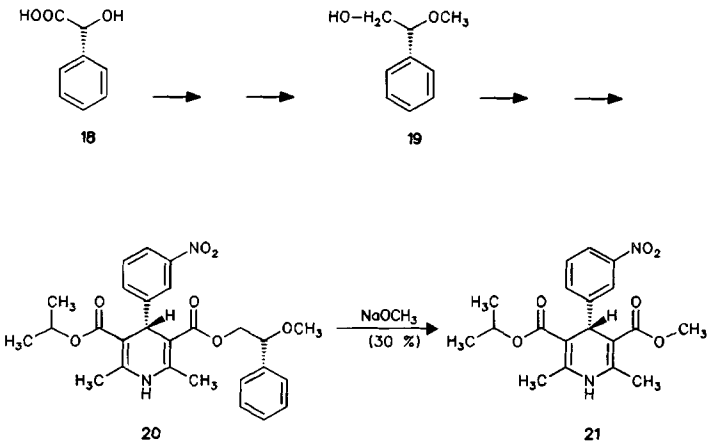


Esters of lactic acid have also been used successfully for the diastereomer separation of dihydropyridine lactones,[98] 3-nitrodihydropyridines,[99–100] and 3-cyanodihydropyridinecarboxylic esters.[101] Here again it is possible that the esters were activated by complex formation with metal ions. The same could be true of the 2-acetate of isosorbide as the alcohol component, as in **23**.[97]



Scheme 4.

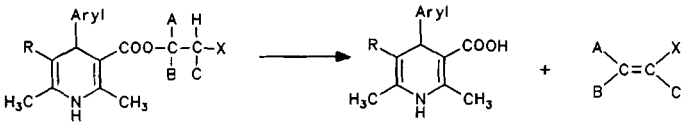
A method for the preparation of optically active 3-cyanodihydropyridines has been described with the compound **27** as an example (Scheme 4).[102] With the monoester **24** as the starting material, the isoxazolo[5.4-*b*]tetrahydropyridine **25** is obtained as the sole product of 1,3-dipolar cycloaddition with a nitrile oxide. Hydrolysis of the ester followed by reesterification with (−)-menthol leads to the formation of diastereomers, which are separated by flash chromatography. The enantiomers of the 3-cyanodihydropyridines are then obtained by hydrolysis of the methyl ester followed by decarboxylation.



Scheme 3.

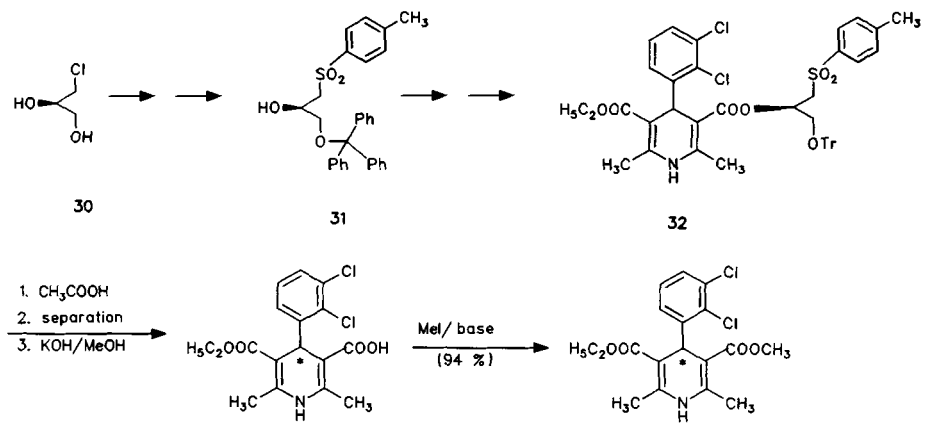
2.3.2. Removal of the Esterifying Group by β Elimination

A fundamentally different method for the selective removal of the chiral auxiliary alcohol is β elimination of a chiral esterifying group with a special structure (e.g., **28** → **29**). X in this formula must be an electron-attracting group or must be capable of being converted into such a group. A disadvantage of this method is the often demanding synthesis of the special alcohols, particularly since the chiral auxiliary alcohol is lost and cannot be recycled.



28 **29**

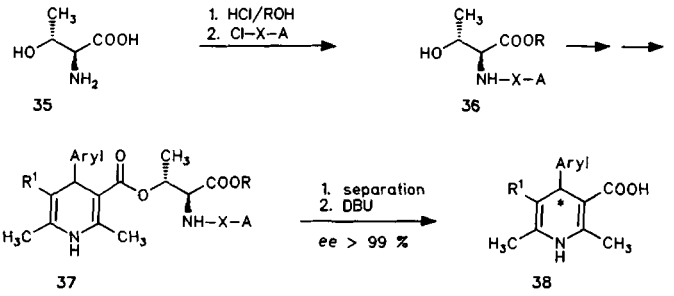
To prepare the enantiomers of felodipine (**34**) (Scheme 5), the dihydropyridine derivative **32** is synthesized from the optically active diol **30** in an overall yield of 50–55%.[103] The chromatographic separation of the diastereomers is advantageously performed after acidic removal of the trityl group. By hydrolysis and esterification, the enantiomers **34** are obtained with an enantiomeric excess of $ee \geq 99\%$.



Scheme 5. Tr = trityl.

30 **31** **32** **33** **34**

Esters have also been successfully used as acidifying groups.[104] After esterification and protection of the amino group, threonine (**35**) is coupled via the corresponding acetoacetic ester to the dihydropyridine moiety of **37**. An advantageous feature of this method is the wide range of variation possible in the chiral threonine structure; thus, the best combination of substituents can be chosen for each separation problem. The diastereomers are separated by crystallization, chromatography, or Craig distribution. Finally, the threonine group is preferably removed with bases such as 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) or 1,5-diazabicyclo[4.3.0]non-5-ene (DBN) to give the dihydropyridinecarboxylic acid **38** in a yield of over 70%. This method was used to synthesize the enantiomers of nimodipine (**8**) in fairly large quantities for the first time.[105] Chiral trichloroethyl esters which can be removed by β elimination have also been used.[106]

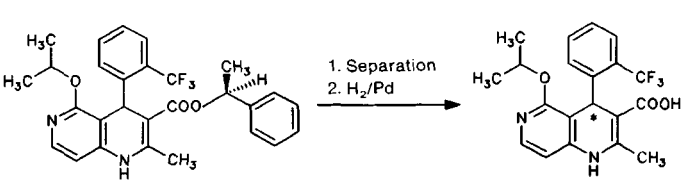


35 **36** **37** **38**

2.3.3. Removal by Hydrogenolysis

Another method for the preparation of enantiomeric dihydropyridines via diastereomeric esters involves the use of chiral benzyl esters, which can be removed regioselectively by hydrogenolysis after the enantiomer separation has been performed.[73, 107] The enantiomers of 1-phenylethyl ester **39** were separated by this method, the chiral carboxylic acid **40** being obtained by hydrogenolysis.

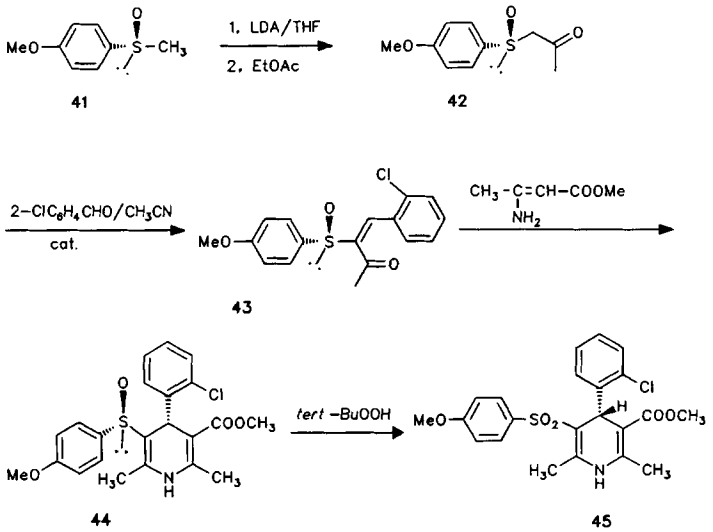
Once again, the chiral alcohol cannot be recycled. Moreover, the use of esterifying groups that can be removed by hydrogenolysis is severely limited by the ready hydrogenolysis of substituents often used in dihydropyridine chemistry. For example, the mandelic acid group cannot be removed from a felodipine precursor by hydrogenation without removal of the chlorine atoms.[103]



39 **40**

2.4. Enantioselective Synthesis of Special Dihydropyridines via Sulfoxides

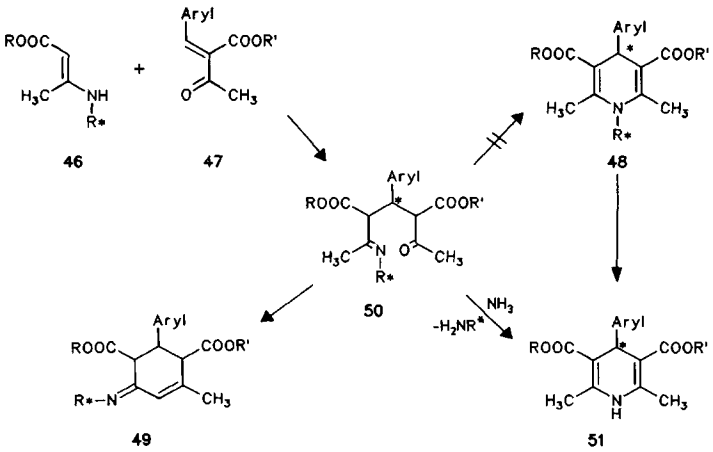
Hantzsch dihydropyridine syntheses with chiral ester groups are only rarely diastereoselective, though one diastereomer is often formed in excess. However, a diastereoselective synthesis of the dihydropyridine sulfone **45** has recently been described.[108]



The Knoevenagel product **43** is obtained from the *R* sulfoxide **41** by *C*-acetylation (LDA = lithium diisopropylamide) followed by condensation with 2-chlorobenzaldehyde. Reaction with methyl 3-aminocrotonate then leads to the *S,S* diastereomer **44** in a yield of 48% (*de* = 94.0%). Oxidation of the sulfoxide yields the desired sulphone **45**.

2.5. Enantioselective Synthesis with Chiral Auxiliary Groups on the Nitrogen

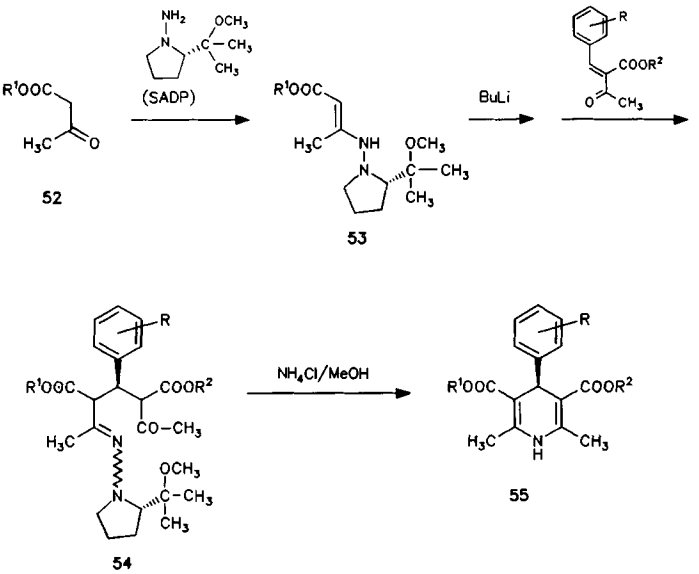
Another possibility for the enantioselective synthesis of dihydropyridines is to attach the chiral auxiliary group (R*) to the nitrogen atom of the dihydropyridine ring (Scheme 6). However, difficulties arise in the preparation of the *N*-alkyldihydropyridines **48**, since reaction of **46** with **47** generally occurs preferentially at the methyl groups of the aminocrotonic esters to form the cyclohexene derivatives **49**. If the desired *N*-alkyldihydropyridines **48** are formed at all, the yields are poor.[5,10] Moreover, the chiral auxiliary group R* must still be removed. Both the need to remove the auxiliary group R* and the preparation of **48** can be avoided if the chiral auxiliary amine H_2NR^* is replaced by ammonia at the stage of the intermediate product **50** after the Michael addition of the enamine **46** to the benzylidene compound. However, this calls for high diastereoselectivity in the Michael addition **46** → **50**, since subsequent purification via diastereomers is not possible.



Scheme 6.

2.5.1. *Use of Chiral Hydrazones*

The reaction of acetoacetic ester **52** with the chiral hydrazine SADP yields the enamine **53**, from which the Michael addition product **54** is obtained after metalation with BuLi in THF at −78 °C and addition to benzylidene compounds having the *Z* configuration. Reaction with ammonium chloride in methanol leads to removal of SADP and formation of the desired dihydropyridine **55** with an enantiomeric excess of up to 90% in some cases.[109,110]

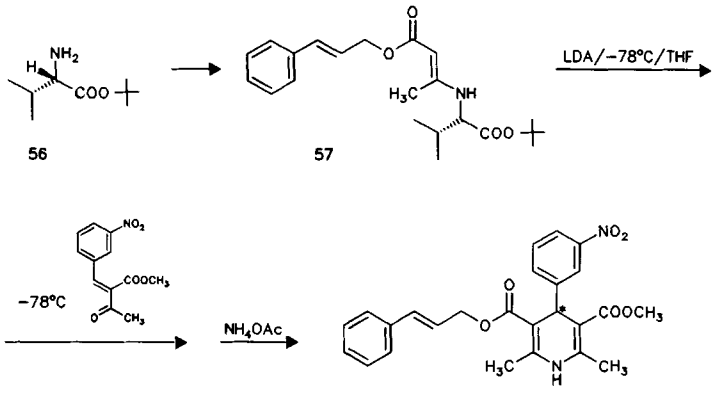


This method appears to produce particularly high enantiomeric excesses in the case of methoxy-substituted aromatic compounds and bulky *tert*-butyl esters.

2.5.2. *Use of Amino Acid Derivatives*

Variants of this method with amino acid derivatives as chiral auxiliary amines (Scheme 7) have been described, for example, for the preparation of the enantiomers of FRC 8411 (**58**) in enantiomerically pure form.[72,111,112] Valine *tert*-butyl ester (**56**) is converted into the chiral 3-aminocrotonic ester **57**. Metalation with LDA in THF under argon at −70 °C and reaction with the Michael acceptor

leads, after replacement of the valine ester with ammonia, to the (−) enantiomer **58** in a yield of almost 80% and with an enantiomeric excess of 94%.[111]



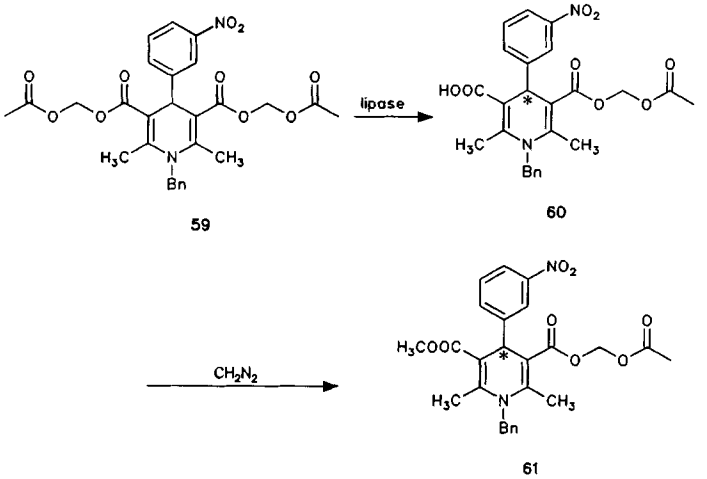
56 57 (−)-FRC 8411 58

Scheme 7.

The enantioselective dihydropyridine syntheses described above involve the use of chiral ligands that also have an additional oxygen ligand to fix the conformation of the anion. This could be a necessary condition for a diastereoselective Michael addition. Further support for this supposition is provided by the fact that for ligands without the additional complexing site (e.g., chiral esters of *N*-(1-phenylethyl)-3-aminocrotonic acid) the maximum optical yields obtainable were only 60%.[111, 113]

2.6. Chemoenzymatic Separation of Dihydropyridines

The stereoselective cleavage of simple prochiral dihydropyridinedicarboxylic diesters should be an effective method for the preparation of enantiomerically pure dihydropyridines. Initial successes have recently been achieved with the readily hydrolyzable *N*-benzyl-protected dihydropyridine derivative **59** (Bn = benzyl).[114]



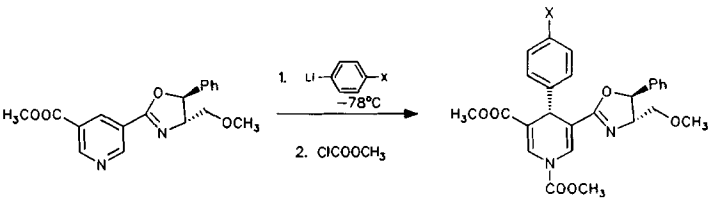
59 60 61

The monocarboxylic acid **60** was obtained by enzymatic hydrolysis of **59** with various lipases in a 10:1 mixture of *n*-butanol and water and was converted with diazomethane into the methyl ester **61**. Yields of up to 34% with an enantiomeric excess of *ee* = 88% were obtained with the lipase Pseudomonas P-30. Longer reaction times lead to higher enantiomeric excesses, but the chemical yields are markedly reduced.

2.7. Selective Reduction of Pyridines

The enantioselective reduction of pyridines would be an elegant route to optically active 1,4-dihydropyridines. Attempts to carry out the electrochemical reduction enantioselectively with ephedrinium bromide as an optically active conducting salt yielded only racemic 1,4-dihydropyridines.[115]

Since attack in position 4 by the bulky complex hydrides is particularly difficult in the case of 4-aryl-substituted pyridines, a fundamental drawback in such reductions is incorrect regioselectivity, leading to the formation of 1,2-dihydropyridines and reduction of the ester to the alcohol as a competing reaction.[116, 117] However, the addition of aryl anions to pyridines with no substituent in position 4, which is a basically similar route, has been successfully used for simple derivatives. Thus, in the case of **62** with chiral modification of the ester group, aryllithium can be added diastereoselectively in position 4 at −78 °C.[118]



62 63

The diastereomeric excess is between 78% (X = H) and 90% (X = OMe). The addition of methyllithium is also highly diastereoselective.[119] It is doubtful whether the synthesis could be used for pharmacologically more important dihydropyridines with methyl substituents in positions 2 and 6, in view of the acidity of the methyl groups. The preparation of the pharmacologically important 4-aryldihydropyridines could also be limited by the difficulty in preparing suitable aryllithium reagents.

2.8. Chromatographic Separation of Enantiomers

The direct chromatographic separation of enantiomeric dihydropyridines on enantioselective chiral stationary phases has developed rapidly in recent years and is now one of the standard methods for the detection of the enantiomers in plasma and in tissue, for the verification of enantiomeric purity, and for the preparation of small quantities of enantiomers for initial pharmacological studies.

Optically active acrylamide polymers were already known in the mid-1980s[120] and were used for the resolution of racemic mandelic acid. Improved (meth)acrylamide poly-

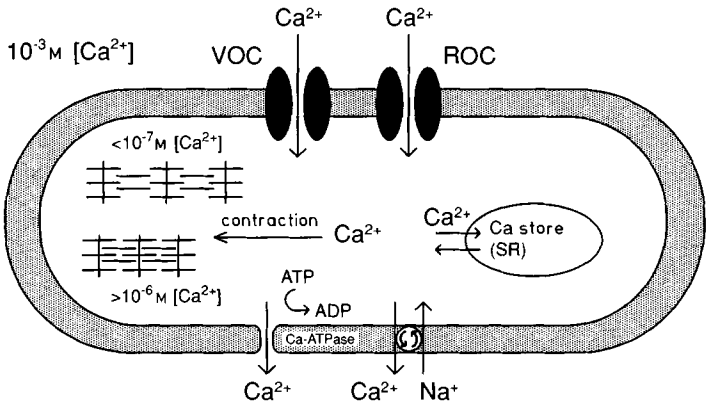
mers were later used by *R. Grosser* et al. for the resolution of racemic dihydropyridines.[121, 122]

A large number of chiral stationary phases based on β-cyclodextrins,[123, 124] methacrylates,[125] glycoproteins,[126] and amylose and cellulose derivatives[127–131] are now available for the separation of enantiomeric dihydropyridines with various structures; these allow the determination of enantiomers in plasma in the nanogram range, as well as the resolution of racemates on the gram scale.

3. Influence of 1,4-Dihydropyridines on the Ca^{2+} Balance of the Cell

3.1. Importance of Ca^{2+} Ions in Contraction

Ca^{2+} ions play a fundamental role in the contraction of heart and smooth muscle cells. This was discovered by *Ringer* more than 100 years ago in experiments on spontaneously beating frog hearts.[132] He was able to show that the contractility of the hearts was greatly reduced in calcium-free solution, but returned to normal on addition of Ca^{2+} ions. The importance of Ca^{2+} ions to the contraction of the cell and the most important regulation mechanisms for the concentration of free Ca^{2+} ions are illustrated in Scheme 8.



Scheme 8. The principal mechanisms for the regulation of the Ca^{2+} concentration in the heart cell. SR = sarcoplasmic reticulum, ROC = receptor-operated channels, VOC = voltage-operated channels.

The intracellular Ca^{2+} concentration is lower than the extracellular concentration by a factor of up to 10000 (10^{-7} to 10^{-6} M compared with about 10^{-3} M). At intracellular Ca^{2+} concentrations of $< 10^{-7}$ M, the filaments are fully dilated. When specific calcium channels in the cell membrane are opened for a short time, the calcium ion concentration in the cell increases. This triggers the release of Ca^{2+} ions from the intracellular calcium stores, mainly the sarcoplasmic reticulum (SR). The intracellular calcium ion concentration increases to $> 10^{-6}$ M and the filaments contract. The calcium ions are returned by transport mechanisms to intracellular storage (SR) or carried into the extracellular space (Ca-ATPase, Na^+/Ca^{2+} exchangers). When the Ca^{2+} concentration falls to less than 10^{-7} M, the filaments fully dilate and the original situation is restored. An increase in the Ca^{2+} concentration leads physiologically to an increase in the contractility of the heart and in the vascular tonus. The regulation of the intracellular Ca^{2+} concentration thus plays an important role in the contractility of the heart and the regulation of blood pressure.

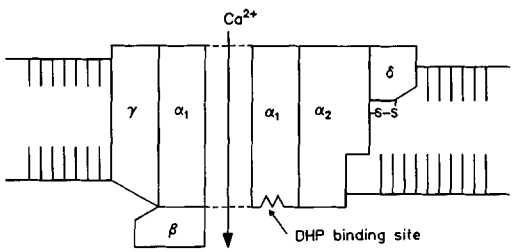
3.2. Calcium Channels

Calcium channels can be classified according to how they are activated (Scheme 8, top):

1. *Receptor-operated channels* (ROC), which can be activated, for example, by catecholamines such as adrenaline or noradrenaline. These channels can be influenced pharmacologically, for example by α-receptor or β-receptor blockers.
2. *Voltage-operated channels* (VOC), which regulate the entry of calcium according to the membrane potential. These channels can be inhibited pharmacologically by so-called calcium antagonists belonging to various classes of compounds. These include the 1,4-dihydropyridines of the nifedipine type, benzylalkylamines of the verapamil type, and benzothiazepines such as diltiazem. The most potent are still the 1,4-dihydropyridines, which include not only derivatives that inhibit the entry of Ca^{2+} into the cell (calcium antagonists), but also others that increase it (calcium agonists). This class of compounds is therefore outstandingly suited for use in the investigation of calcium channels.

3.2.1. Characterization of the Voltage-Operated Calcium Channel (VOC)

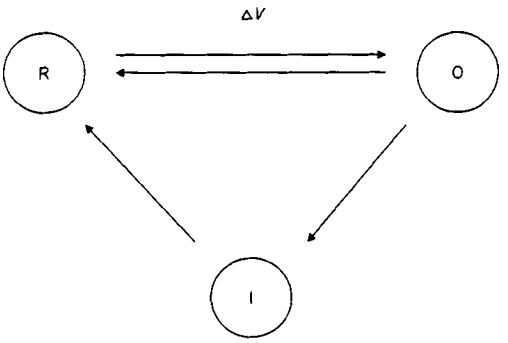
Major advances have been achieved during recent years in the identification and characterization of the calcium channel proteins. Tritiated dihydropyridine ligands have been used to purify and identify the calcium channel proteins and to establish their primary structure.[133] The channel consists of four subunits, the α_1, α_2, β, and γ subunits, with molecular weights of 175, 170, 50, and 33 kD, respectively.[134–138] A 30-kD unit (δ unit) can be removed by reduction from the α_2 subunit, to which it is presumably attached through disulfide bridges. A proposal for the organization of these subunits (after Ref. [138]) is shown in Scheme 9. The α_1 unit contains the binding site for 1,4-dihydropyridines.[136, 138]



Scheme 9. Possible organization of the subunits of the Ca^{2+} channel (after [138]). DHP = 1,4-dihydropyridine.

The amino acid sequence of the α_1 unit exhibits similarities to the sequences of other ion channels, such as the extensively studied Na^+ channel.[133] As in the case of the Na^+ channel, various states are proposed for this channel (Scheme 10).

In the resting state (R) the channel is not conducting, but it can pass into the conducting open state (O) by depolarization. This depolarization can be achieved experimentally in vitro by increasing the extracellular K^+ concentration. From the open state, the channel can revert to the resting state (R) or switch over into the inactive state (I). Biologically, this inactivation is a sensible protection mechanism to safeguard the cell against Ca^{2+} overload. The inactive state has no ionic conductivity and *cannot* be activated by voltage changes. From this state the channel slowly returns to the resting state (R).



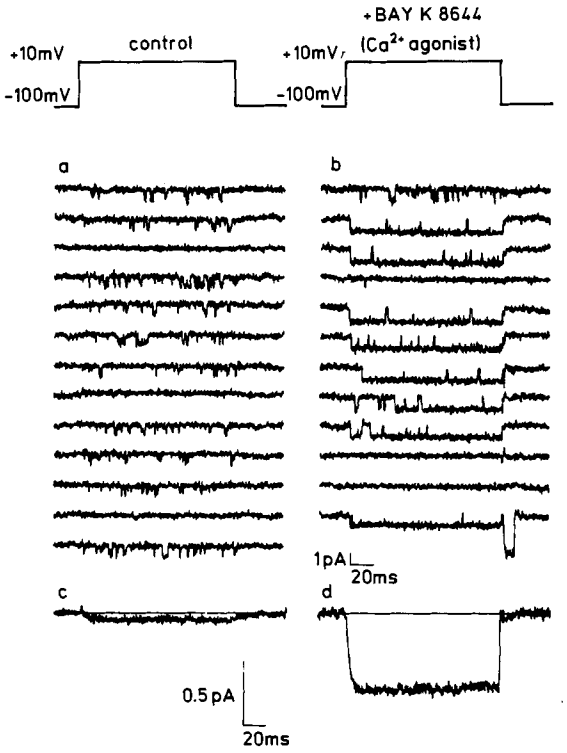
Scheme 10. Potential-dependent states of the Ca^{2+} channel (R = resting state, O = open state, I = inactive state).

Since membrane preparations are in a depolarized condition, the calcium channels are predominantly in the inactive state, so that binding data for 1,4-dihydropyridines refer to the inactive state. This is also shown by binding experiments on intact cells with calcium channels in working condition. These experiments confirm that depolarization of the cells with K^+ ions (concentration of the inactive state I increases) leads to a marked increase in the specific binding of 1,4-dihydropyridine calcium antagonists, with the result that it approaches the values found for membrane preparations.[139]

These investigations reveal that dihydropyridine calcium antagonists bind to and stabilize the inactive state of the calcium channel. Consequently, the number of channels capable of being activated (R) decreases and the entry of Ca^{2+} into the cell is reduced. Physiologically, this leads to a negatively inotropic effect on the heart and a decrease in the vascular tone, and hence in the blood pressure.

Ionic flux measurements on individual calcium channels provide evidence on how dihydropyridine calcium *agonists* act at the molecular level. Scheme 11 shows so-called patch-clamp recordings for groups of 12 individual channels in the absence (left) and in the presence of the calcium agonist BAY K 8644 at 5 μM concentration (right).[140]

It can be seen that the channel is closed at a membrane potential of -100 mV in the control (a). Changing the membrane potential to $+10$ mV occasionally causes the channel to open for a few milliseconds (downward deflections). Summation over many channels results in a calcium flux of the size found for intact cells. In the presence of BAY K 8644, the prototype calcium agonist, the channel is open for considerably longer (b), and this leads to a higher calcium flux on average (d). These results can be explained as arising from stabilization of the open state by calcium agonists.

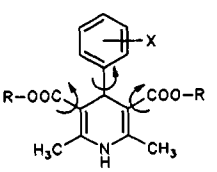


Scheme 11. Patch-clamp recording for individual Ca^{2+} channels in the absence (left) and in the presence (right) of a calcium agonist. Top: Course of the membrane potential with voltage jump from -100 mV to $+10$ mV. a,b: Measured single-channel activities; c,d: Averages of all measured single-channel activities. (After *Hess* et al. [140]).

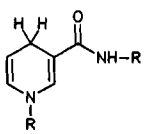
The states R, O, and I describe only the function. The steric structures corresponding to these states can only be surmised, though the recent elucidation of the primary structure of the α_1 unit may lead to further advances in our understanding.[141] On the other hand, a large number of dihydropyridines have been synthesized over the last 20 years, so that inferences regarding the structure of the binding site ("lock") can be drawn from the shape of the "key". These aspects will be examined further in the following sections.

4. Conformational Aspects Relating to 4-Aryl-1,4-dihydropyridine-3,5-dicarboxylates

Dihydropyridines of the nifedipine type, **64**, are flexible molecules, in which the aryl ring and the ester groups can rotate and the conformation of the dihydropyridine ring can change.



64



65

Since the discovery of the pharmacological effects of this class of substances, it has been of interest to know which conformation produces the optimum effect, and whether a

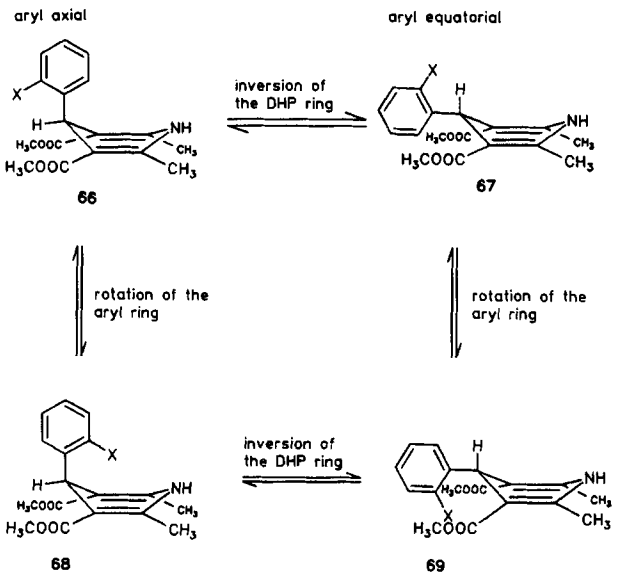
reversal of the pharmacological effect can be traced to changes in conformation.

A series of investigations on rigid dihydropyridines in recent years have yielded information on the "active conformation". This information has also been supported by theoretical calculations and X-ray structural analyses.

4.1. Conformations of the 1,4-Dihydropyridine Ring and Position of the 4-Aryl Substituent

In 1,4-dihydropyridines with no substituent in position 4, such as NADH model compounds of the type **65**, the dihydropyridine ring in the crystal is practically planar.[142-145] Ab initio calculations for the unsubstituted dihydropyridine ring also show only a minimal preference for a very flat boat conformation.[146]

A different picture is found for 4-aryl-substituted 1,4-dihydropyridines of the nifedipine type, **64**. Calculations for these compounds show a preference for the boat form,[147] and this has also been confirmed by numerous X-ray structural investigations. However, a boat conformation for the dihydropyridine ring has considerable consequences with regard to possible conformers. Thus, the 4-aryl substituent may occupy a pseudoaxial position as in **66**, or it may be equatorial as in **67** (Scheme 12). Interconversion between the two forms is possible by inversion of the dihydropyridine ring.

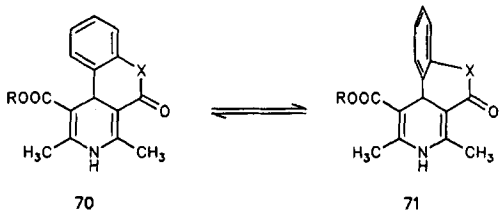


Scheme 12. Boat conformation of the 1,4-dihydropyridine ring and position of the 4-aryl substituent.

Further rotamers can be visualized if the 4-aryl substituent is substituted in the *ortho* or *meta* position (X ≠ H). The group X may then either be on the same side as the hydrogen, as in **66** (synperiplanar, *sp*), or, following rotation of the phenyl ring, it may lie above the dihydropyridine ring as in **68** (antiperiplanar, *ap*). These rotamers are also conceivable if the aryl substituent is in a pseudoequatorial position (**69** ⇄ **67**).

As was mentioned earlier, many X-ray structural analyses of dihydropyridines of the nifedipine type, **64**, show that the dihydropyridine ring is in fact in a flattened boat conformation, with the 4-aryl substituent in the pseudoaxial position and orthogonal to the plane of the dihydropyridine ring;[66,91,108,148-162] that is, the conformation **66** is favored in the crystal. It was postulated even in the early work that this orthogonal arrangement of the 4-phenyl substituent was important to the pharmacological activity,[10] since *ortho* substitution in the 4-phenyl ring gave particularly active derivatives and suggested an enforced orthogonal arrangement as in biphenyls.

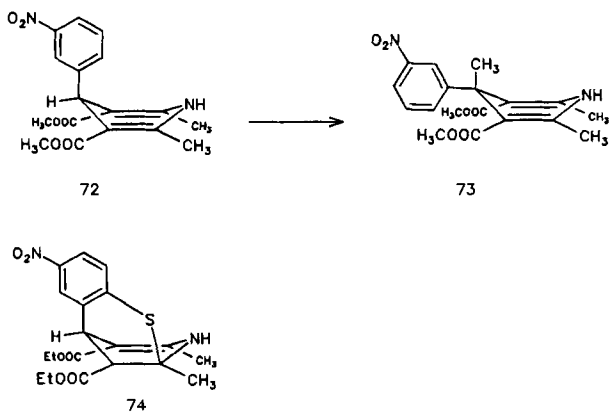
A correlation was also found between the bulk of the *ortho* substituent X and the pharmacological effect.[163] Investigations on rigid dihydropyridines have shown that this orthogonal arrangement of the two rings is essential.[164,165] Compound **70a**, in which the aryl ring has been forced into an unfavorable conformation, is pharmacologically inactive. Only when the size of the lactone ring is increased to 12 members does the favorable orthogonal arrangement of the aryl group, as in **71b**, become possible, leading to active compounds.



a X = -O-

b X = -O-(CH$_2$)$_5$-O-

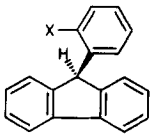
The axial position of the 4-phenyl substituent in **66** also appears to be essential to the pharmacological activity of the compound. Thus, replacement of the C4 hydrogen with a methyl group (**72** → **73**) leads to a dramatic change in the conformation, as has been shown by AM1 calculations and X-ray structural analyses.[166] In the crystal, the phenyl substituent in **73** is no longer axial, but has moved into the equatorial conformation. The antihypertensive activity of **73** is three orders of magnitude weaker than that of **72**. Derivatives in which the axial conformation of **72** is fixed by a sulfur



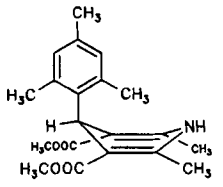
bridge (e.g., **74**) also exhibit excellent binding to dihydropyridine receptors and act as strong calcium antagonists,[167] though the Michael addition product **74** is no longer a dihydropyridine. This example demonstrates very impressively that with the correct steric arrangement of the necessary substituents, the dihydropyridine structure plays only a minor role in the biological activity.

Another aspect that has already been mentioned is the arrangement of the *ortho* or *meta* substituents X in the phenyl ring in relation to the dihydropyridine ring. Two rotamers are possible with orthogonal and axial arrangements of the phenyl ring. In the synperiplanar arrangement, the substituent X lies on the same side as the C4 hydrogen on the dihydropyridine ring (**66**), whereas rotation through 180° brings it above the plane of the dihydropyridine ring, antiperiplanar to the hydrogen (see Scheme 12).

In 9-arylfluorenes, **75**, which have a very similar structure, rotamers of this type are not only detectable by NMR spectroscopy, but can even be isolated in a few cases.[168–170] Isolation of rotamers is not possible for 1,4-dihydropyridines of type **66**. This points to a fast equilibrium, **66** ⇄ **68**, with a lower activation barrier than in the fluorenes **75**.



75

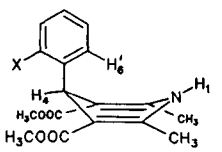


76

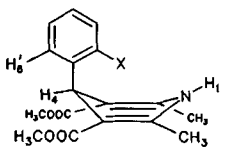
Hindered rotation has been demonstrated in one case for a derivative with extreme steric hindrance, **76**.[171] The NMR spectrum of **76** shows a broad singlet for the two *ortho* methyl groups. On cooling, coalescence occurs at $-18\,^{\circ}C$, and the signal splits into two singlets at $-50\,^{\circ}C$. The calculated activation energy, $\Delta G^{\neq} = 51\ kJ\,mol^{-1}$, correlates well with calculated values for similar compounds ($44\ kJ\,mol^{-1}$[172]).

With a few exceptions,[148, 154] the form **66** is favored in the crystalline state.[66, 91, 108, 149–162] Theoretical calculations[172–174] also indicate a preference for the *sp* conformer rather than the *ap* conformer. The calculated activation energy of $44\ kJ\,mol^{-1}$[172] also indicates that the equilibrium **66** ⇄ **68** is fast.

The thermodynamic preference for the *sp* conformation in solution can also be confirmed by NMR spectroscopy. By measurement of nuclear Overhauser effects of the hydrogen atom H_6 with H_4 in **77**, it can be shown that, for derivatives of the type **66** in comparison with **68**, the *sp* conformation is favored in solution.[171–175] On the other hand, it appears



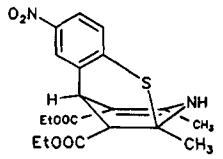
sp-77



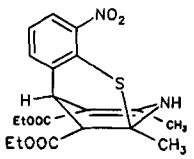
ap-77

from measurements on pharmacologically less active bicyclic dihydropyridines that the *ap* form is favored here.[176] It is also possible, by direct measurement of the two nuclear Overhauser effects, H_6/H_1 and H_6/H_4, to determine the thermodynamic distribution of the two conformers and hence to find the energy difference.[154]

Though the *sp* form is usually favored in the crystal and in solution, the energy differences are too small to rule out the possibility of interactions that favor other conformers at the site of biological action. However, this possibility does not arise in the case of the bridged derivatives **74** and **78**. The



74

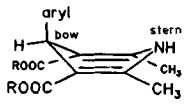


78

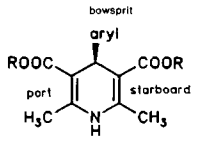
possible conformers *sp* and *ap* are immobilized here by a sulfur bridge. The calcium antagonist activity of **74**, with the forced *sp* arrangement of the nitro group, is two orders of magnitude greater than that of the *ap* form **78**.[167] The *sp* conformation **66** is thus probably essential at the site of action, at least in the case of the 3-nitrophenyl derivatives.

4.2. Influence of the Ester Groups on the Pharmacological Effect

The ester groups are of crucial importance to the pharmacological effect. Not only does variation of the ester groups lead to quantitative changes in the activity, but replacement of an ester group by other groups can also produce dramatic qualitative changes (Section 4.2.3). A method that has been adopted to distinguish clearly between the two sides of dihydropyridines is to regard the preferred conformation of the 1,4-dihydropyridine ring as a flattened boat (**79**) with C4 as the bow, the axial aryl ring as the bowsprit, and the nitrogen as the stern.[14]



79



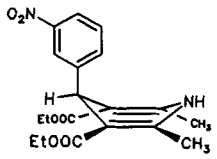
79a

The two sides of the dihydropyridine ring can then be referred to as the port side (left) and the starboard side (right).[177] This designation is more suitable for our discussion and less specialized than the *pro R/S* or the *re/si* nomenclature for enantiotopic sides.[178]

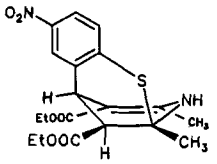
4.2.1. Conformation of the Ester Group

The "equatorial" arrangement of the ester groups, which is forced by sp^2 hybridization in the dihydropyridine **80**, is

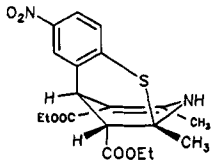
essential to the pharmacological activity of the compounds, as is shown by **74** and **81**. The pharmacological activity of **81**, with the ester group in axial position, is weaker by two orders of magnitude than that of **74** or **80**.[167]



80



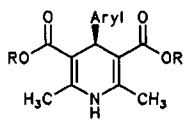
74



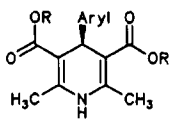
81

Another important aspect is the rotation of the ester group. Assuming a favored coplanar arrangement of the ester carbonyl with the double bond of the dihydropyridine ring, three conformations are possible in principle for the ester groups: *trans/trans*, in which the carbonyl groups of both esters are *trans* to the double bond of the dihydropyridine (**82a**), *cis/cis* with a *cis* arrangement of both carbonyl groups (**82c**), and enantiomeric *cis/trans* and *trans/cis* arrangements (**82b**). An analysis of the results of 26 X-ray structural investigations shows a preference for the *cis/trans* and *cis/cis* arrangements in the crystal (Table 1).[14]

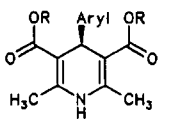
Table 1. Conformations of the ester groups in compounds of type **82a–82c** as determined by X-ray structural analyses.



82a (*trans/trans*)



82b (*cis/trans*)



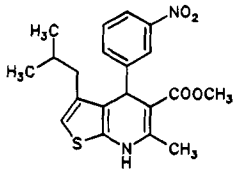
82c (*cis/cis*)

	82a	**82b**	**82c**
with *ortho* aryl substituent	0	3 out of 10	7 out of 10
without *ortho* aryl substituent	0	14 out of 16	2 out of 16

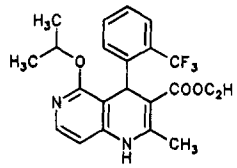
A preference for the *cis/cis* arrangement is found for *ortho*-substituted derivatives (7 out of 10), whereas the asymmetric *trans/cis* conformation is favored for derivatives without *ortho* substitution (14 out of 16). The *trans/trans* arrangement has not been observed and is also energetically unfavorable according to theoretical calculations.[179]

Fused 1,4-dihydropyridines also suggest that for a satisfactory calcium antagonist effect, at least one ester must be in the *cis* arrangement, since the compounds **83**,[61] **84**,[180] and **85**[181] may be regarded as derivatives with an immobilized ester group.[182]

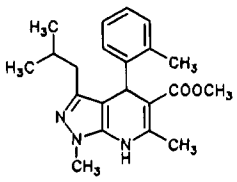
The assumption that a *cis* arrangement of the ester group (see **86**) is necessary for hydrogen bonding to the receptor (Rec)[158, 179, 188] may also be valid for the imido analogues **84** and **85**, but less so for the thiophene derivative **83**. On the contrary, with the *cis* arrangement of the ester group, it appears to be more important that the bulky lipophilic alkyl chain should lie parallel to the aromatic ring. This is supported by the fact that the derivative **87**, in which the lipophilic chain of the ester group corresponds more to the *trans* arrangement of this group, is practically inactive.[61] A similar decrease in activity has also been found for the corresponding *N*-alkyl derivatives **88** of CI-951 (**84**).[189] The example **83** also shows on *which* side the ester group must have the *cis* conformation and can be replaced by the alkylthiophene group, since the absolute configurations of the enantiomers of **83** are known.[61]



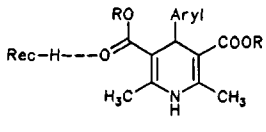
83



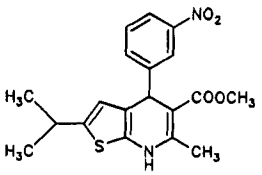
84



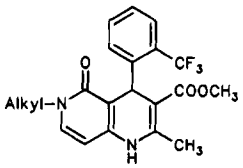
85



86



87



88

(*S*)-**83** is 50 times more active in the receptor binding test than (*R*)-**83**, and its calcium antagonist activity is 20 times stronger (Table 2). This shows, that for a good pharmacological effect, the ester group on the port side of the dihydropyridine ring must have the *cis* conformation, whereas replacement of the ester group on the starboard side with the alkylthiophene group has an adverse effect, as is shown by a comparison with the flexible diester **89**.[190, 191] The weak activity of (*R*)-**83** does not appear to be due to the enforced unfavorable *cis* arrangement of the ester group in (*R*)-**83**, since racemic **87** (and hence also (*R*)-**87** with the enforced

trans arrangement) is inactive, but rather to the impossibility of additional hydrogen bonding on the starboard side.

4.2.2. *Influence of the Size of the Ester Groups*

Once the preparation of enantiomerically pure dihydropyridines had been established, it quickly became apparent that dihydropyridines with unsymmetrical ester substitution are generally more active pharmacologically than those with symmetrical substitution. The increase in activity is mainly associated with an increase in the size of the ester group on the port side, as can be seen from Table 3.

Table 3. Influence of the size of the ester group on the calcium antagonist activity.

Compound	Relative activity
 **89**	1
 (*S*)-**90**	15
 (*R*)-**90**	16

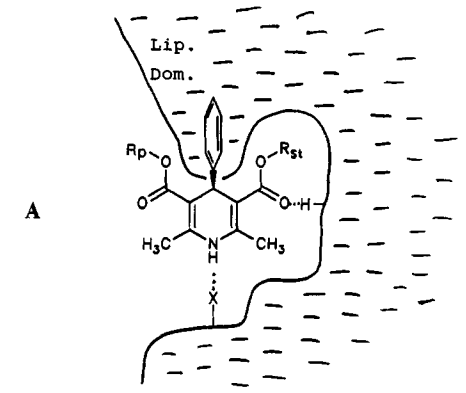
[a] Inhibition of the Ba^{2+}-induced contraction of aorta rings

Thus, in the flexible diester **89**, replacement of the methyl ester group on the left with isopropyl ((*S*)-**90**) increases the activity by a factor of 15, whereas replacement of the ester on the right with isopropyl ((*R*)-**90**) has little effect.[192] Numerous enantiomerically pure dihydropyridines with known absolute configurations[193] subsequently confirmed the discovery that for dihydropyridines with sterically different substituents, the enantiomer with the larger ester group on the port side is the more potent. Thus, for other mixed methyl/isopropyl esters such as **91** and **92** (Table 4), the enantiomers with the larger isopropyl ester group on the port side are the more active, and the same is true of the dihydropyridine analogue **94**. If an ester group is replaced by an oxadiazole group as in **93** or by an amide group as in **95**, the more active enantiomer has the larger substituent again on the port side.

This rule is also valid for nicardipine (**10**) and a series of analogues with a lipophilic ester group containing nitrogen (**96**–**101**). Example **102** appeared to be a puzzling exception, since the *R* enantiomer was described as the more active in this case;[74] however, subsequent checks showed that an error had been made in the assignment.[202]

An important published observation that does not agree with this reasoning is that the active enantiomer of amlodipine (**103**) has the larger group on the starboard side.[91] This could possibly be explained by the essential hydrogen bonding of the starboard ester group, which dominates in the case of amlodipine because of the free amino group and outweighs the influence of the relative sizes of the ester groups. If this is correct, the activity of amlodipine derivatives should be largely independent of the size of the ester groups. A similar explanation could apply to the phenylsulfone **104**.[108]

To summarize, it is possible to say that the two ester groups in calcium antagonists have different functions at the site of action. Whereas the smaller ester group on the starboard side (R_{St}) in **A** is important for the formation of a



hydrogen bond with the binding site, the larger ester group on the port side with its lipophilic group (R_P) may occupy a lipophilic domain (Lip. Dom.) at the binding site. However, this binding cannot be very specific, since very different groups are tolerated.

4.2.3. *Reversal of the Pharmacological Activity by Replacement of the Ester Function*

The effects of the enantiomers of the dihydropyridinecarboxylic esters discussed in Section 4.1.2 differ in their intensity, but are qualitatively similar. However, there is another

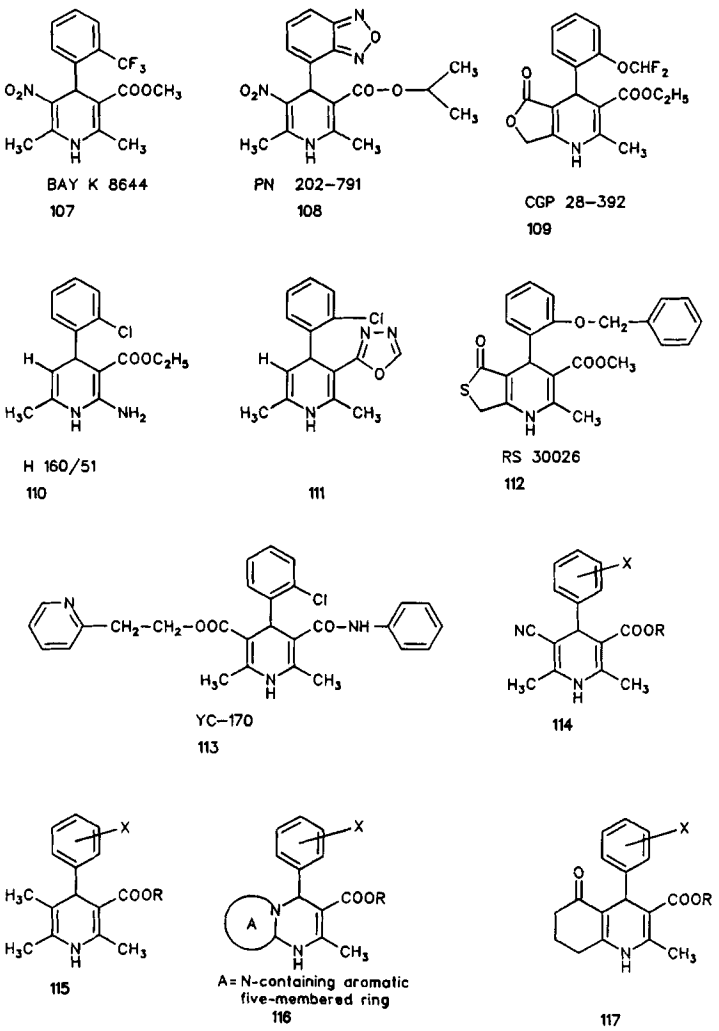
[a] The activity index indicates how many more times potent the active enantiomer is compared to the other enantiomer.

group of derivatives whose enantiomers have dramatically different pharmacological action profiles.[36] If one of the ester groups in 3,5-diesters (**105**) exhibiting calcium antagonist activity is replaced by a nitro group (**106**), the resulting compounds have exactly the opposite pharmacological effect.[204] Instead of blocking the entry of calcium into cardiac and vascular muscle, these derivatives enhance it. They thus increase the blood pressure and have a positively inotropic effect, and are therefore known as calcium agonists or calcium channel activators. In addition to the best-known

prototype BAY K 8644 (**107**), another nitro derivative, PN 202-791 (**108**), has also been reported to produce these effects[39] (Scheme 13).

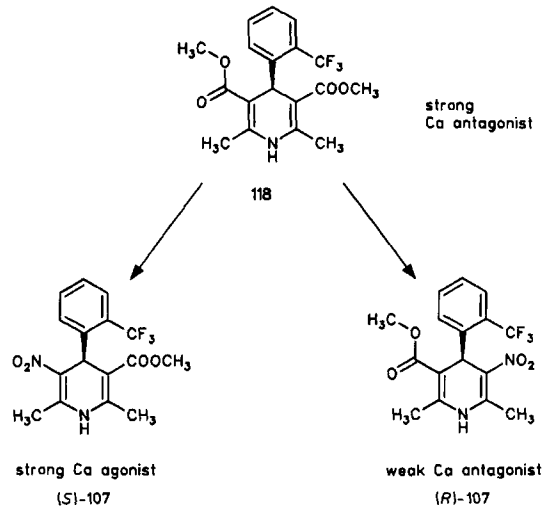
The class of five-membered lactones also includes compounds having a similar effect,[36, 205] the most extensively studied of these being CGP 28-392 (**109**).[206] The same is true of the thiolactone derivative RS 30026 (**112**).[207, 208] Other calcium agonist prototypes are dihydropyridines in which one ester group has been replaced by hydrogen, such as H 160/51 (**110**)[36, 209] and the compound **111**.[210] The mixed ester/amide YC-170 (**113**)[211] has also been reported to exhibit calcium agonist properties, but these are considerably weaker than those of the prototypes mentioned above. Calcium agonist effects have also been reported for derivatives of the classes of compounds **114**,[36, 212] **115**,[36] **116**,[213] and **117**.[214]



Scheme 13. Dihydropyridine calcium agonists.

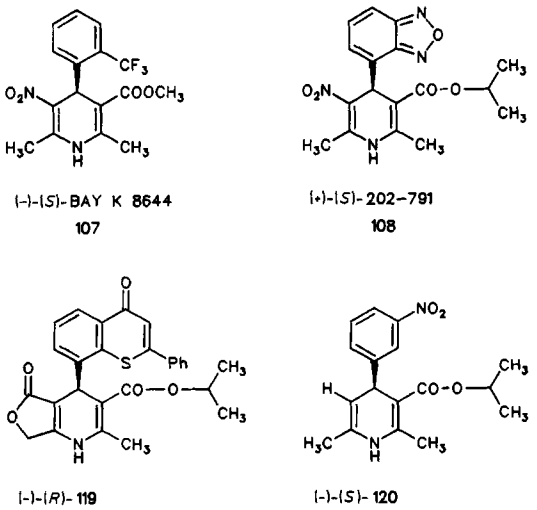
If these structures are compared with those of the typical calcium antagonists, it is noticeable that one ester group has always been replaced by a relatively small group (except in the case of the weak calcium agonist YC-170). Obviously, since the two ester groups of the calcium antagonist diesters must satisfy different requirements in relation to the receptor, it is extremely important to know which of the two ester groups would have to be replaced by a nitro group in order to produce calcium agonist activity.

After separation of the enantiomers of **107**,[33] **108**,[39] and **110**,[215] it was found that only one enantiomer exhibited calcium agonist properties, whereas the other acted as a typical calcium antagonist. By determination of the absolute configurations of **107** and **108**, it was shown that only the replacement of the ester group on the port side by a nitro group leads to reversal of the activity, that is, to calcium agonist activity, whereas replacement of the ester group on the starboard side merely weakens the calcium antagonist activity (Scheme 14).



Scheme 14.

The same is true of the five-membered lactones. (*R*)-**119** (Scheme 15) is the calcium agonist enantiomer, whereas (*S*)-**119**, as expected, is found to be a weak calcium antagonist.[212]



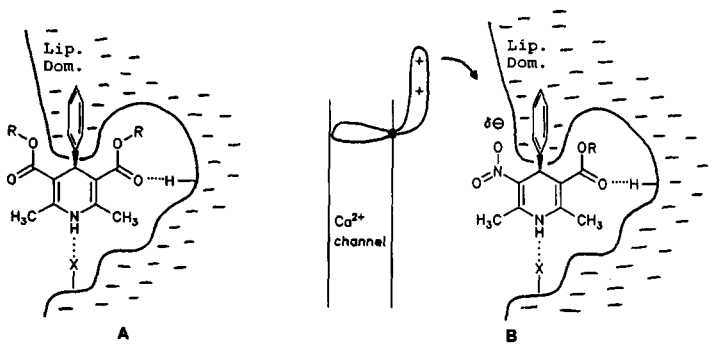
Scheme 15. Dihydropyridine calcium agonists having known absolute configurations (from X-ray structural data).

The smaller group in the calcium agonist enantiomer of **110** should also be on the port side. Though the absolute configurations of the enantiomers are unknown in this case,

they are known for the analogous derivative **120**,[216] whose *S* enantiomer, as expected, acts as an agonist. The same is true of the enantiomers of the nitriles **114**.[217, 218]

4.2.4. *Possible Reasons for the Calcium Agonist Activity*

If the structural requirements for a calcium antagonist (i.e., a larger ester group in the *cis* conformation on the port side; Scheme 16, **A**) are compared with those for a calcium agonist (Scheme 16, **B**), two striking differences are found:



Scheme 16. Possible interactions of a typical calcium antagonist (**A**) and a typical calcium agonist (**B**) with a lipophilic domain and with a positively charged protein domain (case **B**).

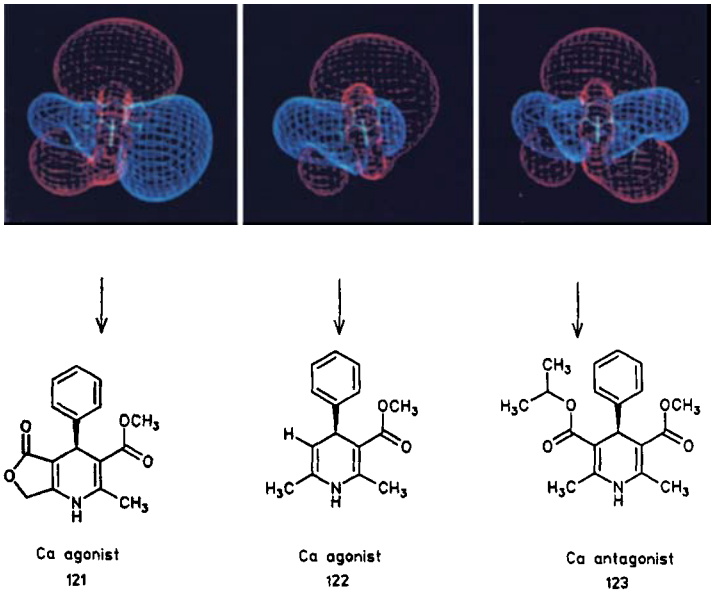
the agonists lack the large lipophilic alkyl group on the port side and in its place they have a partial negative charge on the nitro group. Three possible interactions can therefore be considered:

1. The agonist cannot occupy lipophilic sites.
2. The negative charge on the *trans* oxygen of the nitro group may attract the positive charge of a protein (also through hydrogen bonding).
3. The agonist may repel negative charges in the protein.

It is conceivable, for example, that when the calcium channel is opened, a positively charged section of protein moves into the vicinity of the negative charge (Scheme 16, **B**) with the result that the open state is stabilized and the channel remains open longer. In contrast, the open time should be unchanged or may even be shortened by calcium antagonists. The function of the lipophilic group in the antagonists could be to produce stronger binding with the inactive state and hence to stabilize the latter.

The presence of the negative charge on the port side in the vicinity of the aromatic ring is understandable in nitro derivatives **107**, lactones **109**, and thiolactones **112**, but presents problems at first glance in the unsubstituted derivatives **110**/**111** or the methyl compounds **115**. However, calculations of surface potential show that negative potentials are also present in these molecules.[173] The reason is that the ester group on the starboard side is no longer present to shield the negative potential of the aromatic ring.

Scheme 17 shows the potential surfaces (blue = negative, red = positive) of three dihydropyridines viewed from the direction indicated by the arrows. The lactone **121** has a pronounced negative potential on the right due to the carbonyl group of the lactone; the H compound **122** has a smaller negative potential on the same side. In the calcium antagonist **123**, on the other hand, the positive potential of the isopropyl ester group can be seen on the lower right, shielding the negative potential from below.[219]

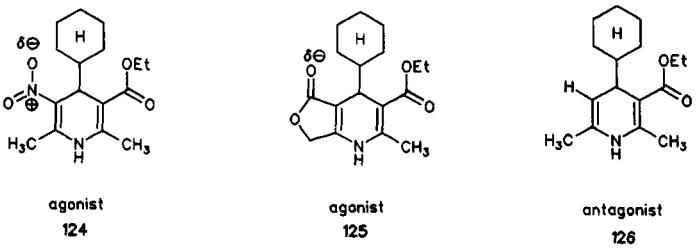


Scheme 17. Potential surfaces of an "active" calcium agonist, a "passive" calcium agonist, and a calcium antagonist. Blue = negative, red = positive.

Dihydropyridine calcium agonists can thus be divided into two classes:

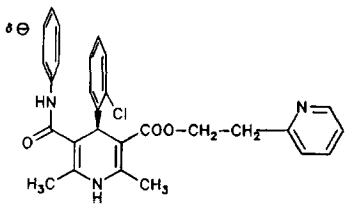
1. *Active* calcium agonists, which bring with them a negative charge on the port-side substituent (nitro, lactone, thiolactone).
2. *Passive* calcium agonists, in which the negative potential of the π electrons of the aromatic ring on C4 is no longer shielded (H, CH_3).

This would mean that without the negative charge of the aromatic ring the *passive* calcium agonists would lose their agonist activity. The cyclohexyl derivatives **124**–**126** were used to test this hypothesis.



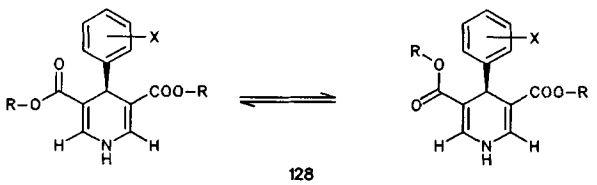
It was indeed found that only **124** and **125** are calcium agonists, whereas **126** exhibits typical calcium antagonist behavior.[216] A satisfactory explanation could even be provided for the very weak calcium agonist activity of YC-170 (**127**).

If the amide group, like the ester group, is in the *cis* conformation, the negative partial charge of the anilide could be responsible for the weak agonist activity. The calcium agonist enantiomer of **127** should thus have the *R* configuration.



127

Calcium agonist activity has recently also been reported for compounds of the class of dihydropyridines in which positions 2 and 6 are unsubstituted (**128**).[208] A possible explanation for this observation is that the energy of the *trans* conformation of the ester group is reduced by the absence of steric interaction with the methyl group. Rotation of the port-side ester group from the possible "agonistic" *trans* conformation into the *cis* conformation, which would be more stable on the receptor, could also explain the observation that some calcium antagonist diesters may exhibit weak calcium agonist activity at lower concentrations.[220]



128

agonist conformation antagonist conformation

If this assumption is correct, this phenomenon should not be found with derivatives having an "immobilized" ester grouping, such as **83**. The calcium agonist effects of the dihydropyridines synthesized so far can be qualitatively explained by this model.

5. Summary and Outlook

4-Aryl-substituted 1,4-dihydropyridine-3,5-dicarboxylic esters of the nifedipine type have had an established place in the treatment of cardiovascular diseases for 15 years. In view of the extreme importance of the enantiomers of the 1,4-dihydropyridines, the existing methods for the preparation of the enantiomers have been discussed. The most important of these methods are the conventional resolution of racemic dihydropyridinemonocarboxylic acids and the cleavage of diastereomeric esters. A number of diastereoselective Michael additions with valine esters as optically active enamines exhibit high diastereoselectivity and appear very promising.

The pairs of enantiomeric 1,4-dihydropyridinedicarboxylic diesters exhibit both quantitative and qualitative differences in activity. Replacement of an ester grouping with a nitro group leads to derivatives with exactly the opposite pharmacological effect. Comparison of the absolute configurations has revealed, that in order to bring about this reversal of activity, it is important to determine which of the two ester groups in the calcium antagonist needs to be replaced by the nitro group. Substituents other than the nitro group are also able to produce this effect in a weaker form.

The switch from antagonism to agonism is produced by replacement of a larger lipophilic ester group with a smaller group having a negative potential (active agonists). Substituents with no negative potential of their own can also give rise to these effects, because they no longer shield the negative potential of the 4-aryl grouping (passive agonists). Many observed calcium agonist effects can be qualitatively explained by this model. It remains to be seen whether effects at the molecular biological level can be explained.

Our thanks are due to all those who have made their mark on dihydropyridine chemistry at Bayer during the last 25 years, particularly H. Meyer, E. Wehinger, and G. Franckowiak, as well as H. Böshagen, E. Schwenner, W. Seidel, and A. Straub. We are grateful to L. Born, R. Grosser, J. Kurz, V. Muschalek, P. Schmitt, and C. Wünsche for their analytical and spectroscopic support, and to M. Bechem, R. Gross, S. Hebisch, J. Hütter, M. Kayser, S. Kazda, A. Knorr, H. P. Rounding, M. Schramm, and G. Thomas for pharmacological tests and advise. We thank C. Lettner and E. Sauer for their patience in the preparation of this manuscript. Special thanks are due to F. Bossert and W. Vater for the discovery of the dihydropyridines as drugs exactly 25 years ago.

ANGEWANDTE CHEMIE
A Journal of the Gesellschaft Deutscher Chemiker
International Edition in English

30 Year Index of Reviews
– in print or on diskette –

The reviews in Angewandte Chemie are amongst the most often cited chemical publications of each year. Many have become classics of the chemical literature. For thirty years they have been available in English as well as German. The 30 year review index now celebrates this anniversary by facilitating access to these important documents of the rapid development of our discipline. The index—both a chemical dictionary and a history book—offers you:

1. A list of all authors, indicating the main author and the title of the review.
2. A subject index giving the main author.
3. Both indexes provide complete information on date of issue and first and last page numbers of the German and English editions.

The electronic version of the index is available on 5¼" and 3½" diskettes.

If you order immediately, you save about 30% since the prepublication price is U.S. $44.00/£26.00 (plus postage) only until the end of January. Please order by telephone or in writing to **VCH, Software und Datenbanken, Postfach 10 11 61, D-W-6940 Weinheim, Tel. 0 62 01/6 02-2 71, Telefax 0 62 01/6 02-3 28.**

Silicon Nitride—From Powder Synthesis to Ceramic Materials

By Horst Lange,* Gerhard Wötting, and Gerhard Winter

Dedicated to Professor Karl Heinz Büchel on the occasion of his 60th birthday

Silicon nitride is a ceramic material of great interest to advanced engine construction and mechanical engineering owing to an outstanding combination of favorable properties like high mechanical strength at high temperatures, corrosion and wear resistance, great hardness, and low density. The material is based on high-quality Si_3N_4 powders, which are shaped and sintered to the ceramic component. This overview outlines the properties required for Si_3N_4 powders suitable for advanced ceramics. Processes in commerical use and those under development for the production of high quality Si_3N_4 powders are discussed as well as material manufacturing processes and material properties. By steadily improving powder quality, material properties, and the economy of powder and component production, chemistry and chemical technology play a major role in recent efforts to create a solid fundament for broad applications of silicon nitride ceramics.

"If one would surrender to geological phantasies, one could imagine that during the formation of our planet, when elements combined to the compounds making up its crust and mountain ranges, silicon reacted with nitrogen, and the still red-hot nitrogen-silicon, on contact with water, may have decomposed to silicic acid and ammonia. Thus, ammonia may have been formed originally and nitrogen thereby introduced into the forming organic compounds when living nature first started to appear."

H. Sainte-Claire Deville and F. Wöhler[**]

1. Introduction

Following speculations by *Deville* and *Wöhler*,[1] silicon nitride attracted attention for the first time as a possible raw material for the technical synthesis of ammonia. A series of patents from the period 1909–1918 describes the synthesis of ammonia by heating Si_3N_4 with solutions or dispersions of basic oxides, hydroxides, or salts, by treatment with hot water vapor, or by heating it in hydrogen atmosphere.[2–11] Because of the concurrent development of the Haber–Bosch process, these methods never gained any importance. It is not surprising, therefore, that this early interest in silicon nitride soon declined.

However, silicon nitride saw a remarkable renaissance after the discovery that it can be converted into a ceramic material. Silicon nitride ceramics significantly extend the limits of metallic materials under combined thermal and mechanical stress in corrosive environments.

2. Silicon Nitride as Ceramic Material

Silicon nitride is of great interest as a heavy-duty material for applications in chemical engineering, wear technology, metal working, energy technology, and especially in engine and turbine construction.[12–24] This broad interest arises from a favorable combination of great hardness, wear resistance, chemical stability, low density, and high mechanical strength at temperatures up to 1300 °C. The application of Si_3N_4 ceramic parts in combustion engines and gas turbines promises advantages like higher efficiency and better fuel use due to higher combustion temperatures, faster response of oscillating or rotating engine components (valves, pistons, turbocharger, and turbine rotors) due to low density, and longer service intervals due to a generally improved wear behavior.

Silicon nitride ceramics are produced either by nitriding silicon powder compacts or by sintering Si_3N_4 powder compacts.[25,26] The first method produces a porous, reaction-bonded material (RBSN, reaction-bonded silicon nitride) with almost negligible shrinkage; this material is used either directly or may be densified by a following sintering step (SRBSN, sintered RBSN).[25–30] The second method, which is covered comprehensively in this article, leads to Si_3N_4 ceramics of superior quality. These are of special interest to

[**] "Ueber die directe Bildung des Stickstoffsiliciums" in: *Ann. Chem. Pharm. 34* (1859) 248: "If one would surrender to geological phantasies, one could imagine that during the formation of our planet, when elements combined to the compounds making up its crust and mountain ranges, silicon reacted with nitrogen, and the still red-hot nitrogen-silicon, on contact with water, may have decomposed to silicic acid and ammonia. Thus, ammonia may have been formed originally and nitrogen thereby introduced into the forming organic compounds when living nature first started to appear.

advanced engine construction and advanced mechanical engineering.

To demonstrate their technological benefits reliably, Si_3N_4 components require a perfect and economical control of the entire manufacturing process, from the synthesis of the Si_3N_4 powder, its processing, forming, sintering to the precise finishing of the structural component (Fig. 1).

Nonuniformity of the starting powder—for example, even just a few extraneous particles, ill-defined particle clusters, or particle morphologies such as a mass of disordered, more or less agglomerated lumps, fibers, or whiskers, as well as extraneous particles or impurities dragged in through powder processing—induce fracture-causing structural defects, which cannot be remedied in the following manufacturing steps. Products of inferior quality and reliability are the result. Since powder-inherent sources of defects can hardly be eliminated by subsequent ceramic processing, the powder producer has a special responsibility to supply extremely well-defined, high-quality powders. To avoid environmental contamination by, say, dust particles, the transfer of powder processing, shaping, and sintering into clean rooms has been discussed.[31, 32] Repeatedly, this measure has been described to improve fracture strength and reliability.[33, 34] Furthermore, defects also arise during shaping, sintering, and finishing. These nowise trivial problems have to be solved convincingly to allow an economical, large-scale production of silicon nitride components. Here, chemistry plays an important role, since powder synthesis and component

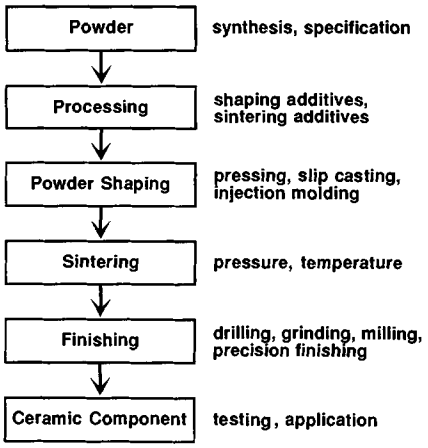

Fig. 1. Manufacturing process from powder to component.

manufacturing touch many problems of solid-state chemistry, surface chemistry, tribochemistry, and chemical engineering,[26, 35] some of which are fundamental.

3. The Structure of Silicon Nitride—Origin of Hardness, Durability, and Strength

Crystalline silicon nitride exists in two hexagonal modifications, α and β, which are built up from a three-dimensional

Horst Lange was born in 1957 in Enkhausen (Sauerland) and studied chemistry from 1975 to 1981 at the Universität Dortmund. In 1983 he received his Ph.D. under Prof. Nauman for work on perfluoroalkylzinc and -cadmium compounds and then worked for one year as a postdoc with Prof. Shreeve at the University of Idaho. Since 1985 he has worked at Bayer AG (Uerdingen) and since 1989 he has been leader of the engineering ceramics group.

Gerhard Wötting was born in 1951 in Markredwitz (Oberfranken) and studied Materials Science from 1969 to 1977 at the Fachhochschule Selb/Regensburg and the Technische Universität Berlin with emphasis on glass and ceramics. In 1982 he received his Ph.D. under Prof. Hausner for work on the sintering behavior of silicon nitride powders. From 1981 to 1987 he worked as a researcher at the Institut für Werkstoff-Forschung der Deutschen Forschungs- und Versuchsanstalt für Luft- und Raumfahrt in Cologne. Since 1987 he has been involved in developmental work in the area of materials technology/high-performance ceramics at the Cremer Forschungsinstitut, Rödental.

Gerhard Winter was born in 1937 in Klein-Mohrau (Sudetenland) and studied chemistry from 1957 to 1963 at the Universität Tübingen. He earned his doctorate in 1966 with a dissertation on graphite inclusion compounds under Prof. Rüdorff. In 1967 he began work at Bayer AG. Since 1986 he has taught at the Universität-Gesamthochschule Siegen. He currently heads research and development at Hermann C. Starck Berlin in Goslar and is the author of the book "Industrielle Anorganische Chemie".

network of SiN_4 tetrahedrons.[36, 37] Rigid structure and strong covalent bonds are the cause of the extraordinary hardness, durability, and mechanical strength of this material.

Figure 2 shows the crystal structure of β-Si_3N_4, which is built from a Si_6N_8 unit cell.[38] Along the crystallographic c axis, channels with a diameter of about 0.15 nm play a certain role in the diffusion of atoms, even large ones. α-Si_3N_4 is built from a $Si_{12}N_{16}$ unit cell;[24] since no channels occur in this structure, diffusion is much more difficult than in β-Si_3N_4 (Fig. 3).

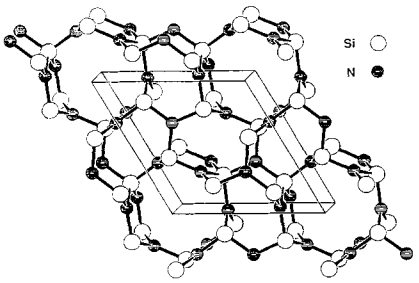

Fig. 2. Section of the crystal structure of β-Si_3N_4; view approximately along c.

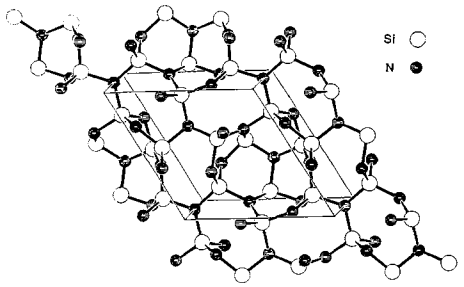

Fig. 3. Section of the crystal structure of α-Si_3N_4; view approximately along c.

Early work on the conditions leading to formation of either the α or β phase indicated that the α phase, assumed to be an oxygen-stabilized low-temperature modification with a narrow range of existence, has the empirical formula $Si_{11.4-11.5}N_{15}O_{0.3-0.5}$ (actually an oxinitride phase).[36, 40-42] However, the formation of the α phase required significantly less oxygen than presumed.[43] By chemical vapor deposition it was possible to produce α-Si_3N_4 single crystals extremely low in oxygen.[39, 44-47] Today α- and β-Si_3N_4 are regarded as polymorphic modifications; α-Si_3N_4 is the stable low-temperature modification, since the α-Si_3N_4 content of a powder increases as the temperature of synthesis decreases and since $\alpha \rightarrow \beta$ transformation occurs only at temperatures exceeding 1650 °C. Probably for kinetic reasons, a $\beta \rightarrow \alpha$ transformation has not yet been observed.

The α/β ratio of commercially available powders is usually determined by X-ray diffraction,[48, 49] but also IR[50-52] and ^{29}Si MAS NMR spectroscopy may be applied.[53-55] ^{29}Si MAS NMR spectroscopy is particularly useful since it can be employed to distinguish and quantify not only the crystalline phases but also amorphous Si_3N_4.[54] This method is also suitable for the study of sintering phenomena.[56, 57]

4. The Synthesis of Si_3N_4 Powders

For the technical synthesis of high-quality Si_3N_4 powders the three following methods are important (see Sections 4.2 to 4.4): nitridation of silicon powder [Eq. (a)],[58-61] carbothermal reduction of SiO_2 in the presence of nitrogen [Eq. (b)] or ammonia,[62-66] and ammonolysis of reactive silicon compounds [Eqs. (c) and (d)].[67-71]

$$3Si + 2N_2 \xrightarrow{1100-1400\,^\circ C} Si_3N_4 \quad (a)$$

$$3SiO_2 + 2N_2 + 6C \xrightarrow{1450-1600\,^\circ C} Si_3N_4 + 6CO \quad (b)$$

$$3SiCl_4 + 4NH_3 \xrightarrow{\text{ca. } 25-1400\,^\circ C} Si_3N_4 + 12HCl \quad (c)$$

$$3SiH_4 + 4NH_3 \xrightarrow{600-1400\,^\circ C} Si_3N_4 + 12H_2 \quad (d)$$

In contrast to direct nitridation or carbothermal reduction, ammonolysis does not yield crystalline Si_3N_4 directly. The reaction leads initially to extremely moisture-sensitive silicon diimide [Eq. (e)], which is then transformed by pyrolysis, via amorphous Si_3N_4, to α-Si_3N_4 [Eqs. (f) and (g)].[67-69, 72]

$$SiCl_4 + 6NH_3 \xrightarrow{\text{ca. } 25\,^\circ C} Si(NH)_2 + 4NH_4Cl \quad (e)$$

$$3Si(NH)_2 \xrightarrow{900-1200\,^\circ C} Si_3N_4 \text{ (amorphous)} + 2NH_3 \quad (f)$$

$$3Si_3N_4 \text{ (amorphous)} \xrightarrow{1300-1500\,^\circ C} \alpha\text{-}Si_3N_4 \quad (g)$$

Several other reactions [Eq. (h),[73-75] (i),[76] (j)[77, 78]] have not gained importance for technological or economical reasons, such as too great expense, too slow reaction kinetics, or the development of undesirable particle morphologies.

$$3SiS_2 + 4NH_3 \longrightarrow Si_3N_4 + 6H_2S \quad (h)$$

$$3SiC + 4NH_3 \longrightarrow Si_3N_4 + 3CH_4 \quad (i)$$

$$3SiO_2 + 4NH_3 \longrightarrow Si_3N_4 + 6H_2O \quad (j)$$

Furthermore, there have been numerous attempts to synthesize Si_3N_4 by pyrolysis or carbothermical reduction from silazanes [Eq. (k)] or siloxanes.[79] Because of the comparatively complicated and costly production and handling of silazanes, this method is less interesting for powder synthesis than for the manufacturing of Si_3N_4 fibers or coatings. Polymeric silazanes of suitable structure may be processed by spinning to produce fibers or by melt or solution coating; subsequent pyrolysis usually gives a 60–80% ceramic yield. There is also some fundamental interest in the use of silazanes as binders or plasticizers for silicon nitride powder molding by dry pressing or injection molding, since pyrolysis leaves nothing but Si_3N_4.

$$\frac{1}{n}[SiR_2 - NR]_n \xrightarrow[-RH,\ -H_2]{800-1400\,^\circ C,\ NH_3} Si_3N_4 \quad (k)$$

4.1. Required Powder Properties

A Si_3N_4 powder qualified for applications in advanced ceramics has to meet numerous demands regarding chemical

and physical properties. Important criteria for powder quality include purity, crystallinity, particle shape, particle size distribution, degree of particle agglomeration, and α/β ratio, as well as technological properties like good processing behavior in different powder shaping techniques and good sintering activity.

To minimize shrinkage and to avoid the development of density gradients during sintering, powder shaping has to aim at particle packing densities as high and as homogeneous as possible. This is achieved by defined particle size distributions, spherical particle shapes, mean particle sizes less than 1 μm, and exclusion of coarse or hard agglomerated particles. These factors, together with defined C and O contents, exclusion of extraneous particles, and a high α/β ratio, are important characteristics of powders with good sintering behavior and favor the development of a homogeneous grain structure during sintering. The spectrum of all these properties influences the general sintering activity of a powder. Roughly, sintering activity increases with decreasing particle size. However, powder processing becomes increasingly difficult (dust generation, bad densification behavior in dry pressing, high sintering shrinkage) as particle sizes decrease. Therefore, the search for universally applicable powders often requires a compromise between opposing demands. These circumstances, in turn, offer possibilities for special "powder designs", that is, tailor-made powders with special advantages in certain manufacturing processes. A free-flowing granulated Si_3N_4 powder, which will not crumble into dust particles but which is easy to densify, is favorable for charging automated dry presses and may illustrate this point.

Some powder properties, like the α/β ratio, have to be adjusted during the Si_3N_4 synthesis; others, like particle size, particle size distribution, or C and O content, may be influenced subsequently by suitable powder processing (e.g., milling, screening, or annealing). In order to minimize the efforts spent on powder processing, it is advantageous to adjust as many of the required properties as possible during the synthesis. To what extent this approach is technologically feasible and economically appropriate depends on the synthetic method chosen.

4.2. Si_3N_4 Synthesis by Direct Nitridation of Elemental Silicon

Direct nitridation of elemental silicon—the process used more than 80 years ago to show the correct stoichiometry of silicon nitride to be Si_3N_4[80]—is still the dominant procedure for the industrial synthesis of silicon nitride powders.[45-46] The main processing steps are nitridation of silicon powder, milling, and finally purification of the crude product (Fig. 4).

The selection of silicon powders of different purities strongly influences the impurity level of Si_3N_4. Besides commercially available, low-cost, metallurgical-grade silicon of different levels of purity, it is possible to use semiconductor-grade silicon as starting material of extremely high purity.[81]

For the actual synthesis, piles of silicon powder are allowed to react with nitrogen either discontinuously in chamber furnaces or continuously in conveyor-type pusher furnaces according to Equation (a) ($\Delta H = -750\ kJ\,mol^{-1}$). The reaction proceeds at a reasonable rate only above 1100 °C. Reaction rates strongly depend on particle size and chemical purity of the silicon powder.[60, 61, 82, 83] Especially traces of Fe catalyze the nitridation.[82, 84] Owing to its strong exothermal character the reaction has to be controlled carefully. Generally, low temperatures and the presence of hydrogen in the nitriding gas favor the formation of α-phase material.[60, 61, 85] Too high temperatures cause not only the formation of undesired β-Si_3N_4 but also strongly sintered agglomerates of Si_3N_4 primary particles, which finally require a more intensive milling process. Careful control of the exothermic reaction is also necessary to avoid an uncontrolled temperature rise exceeding the melting point of silicon in the powder bed.[60, 61, 82] The evolution of heat can be reduced by lowering the concentration of nitrogen in the nitriding atmosphere after onset of the reaction ("exothermal control"[86]). It may also be linited by a suitable, often empirically determined temperature control depending on nitridation kinetics, powder packing density, depth of powder bed, charge size, and type of furnace.[60, 61, 82]

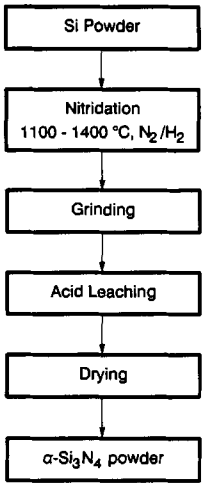

Fig. 4. Process for Si_3N_4 synthesis by direct nitridation.

After synthesis the sintered product is crushed and finally milled to the desired particle size. Depending on the powder processing, possible metallic impurities due to milling wear are removed by subsequent acid leaching.

A variation of the direct nitridation described here is the so-called SHS synthesis (self-propagating high-temperature synthesis[87-90]). Here the reaction proceeds very fast ("thermite-like") after local ignition under increased N_2 pressure.[91-95] Under these conditions the reaction zone moves with a speed of up to 0.1 $m\,sec^{-1}$ through the powder bed with temperatures often exceeding 1700 °C. The product is a high-β-phase material ($\beta > 95\%$), which requires the usual processing by milling and acid leaching.[95] So far the question whether high-β-phase Si_3N_4 powder is suitable for manufacturing advanced silicon nitride ceramics has been answered positively only sporadically;[96, 97] further investigation is required.[95] Other open questions in the further development of SHS synthesis, which may also be used for the production of other refractory compounds,[87-90, 94] concern the control of the α/β ratio and the mastery of cost-efficient, large-scale production. Whether SHS synthesis will

allow direct manufacturing of high-quality sintered components is another interesting issue.

4.3. Si_3N_4 Synthesis by Carbothermal Reduction

This method uses the reaction of SiO_2 powder with carbon at temperatures of about 1500 °C in a N_2 atmosphere, producing Si_3N_4 via a series of reactions [e.g., Eqs. (a), (l), and (m)]. The overall reaction is given by Equation (b).

$$SiO_2 + C \longrightarrow SiO + CO \quad (l)$$

$$SiO + C \longrightarrow Si + CO \quad (m)$$

$$3Si + 2N_2 \longrightarrow Si_3N_4 \quad (a)$$

$$3SiO_2 + 6C + 2N_2 \longrightarrow Si_3N_4 + 6CO \quad (b)$$

Since cheap and readily available silicate raw materials may be used, carbothermal reduction attracted early interest during the first attempts to synthesize Si_3N_4 as starting material for industrial-scale ammonia synthesis.[5-11, 98] There was no concern about chemical purity or particle morphology; reaction mixtures of quartz sand, silicates, carbon, and coke were even compounded with metal oxides to decrease the reaction temperature. Purification of the product from metallic impurities and nonreacted carbon was first achieved by acid leaching and oxidative treatment.[11]

Modern procedures ensure chemical purity by careful control of the purity levels of the starting materials. Besides high-purity, synthetic materials from pyrolysis[62] or sol–gel reactions,[63, 99, 100] natural products like quartz sand[98] and clay[101] may also be used, although at the expense of purity. Though stoichiometry requires a SiO_2/C ratio by weight of just 1:0.4 for a complete reaction, a considerable excess of carbon is required in practice. Usually, SiO_2/C ratios of 1:2 to 1:10 are employed.[62-66, 102, 103] Very good results yield extremely fine SiO_2 and C powders from, for example, gas-phase pyrolysis.[62, 103, 104] An intensive homogenization of the powders is necessary to ensure that the reaction is homogeneous and proceeds to completion. A very good alternative is provided by sol–gel-type methods, in which polycondensation of silicon halides with alcohols prone to polymerization (e.g., furfurol) yield easy-to-handle polymeric granules containing Si, O, and C in ultradisperse distribution. Thermal cracking yields an extremely homogeneous SiO_2/C mixture, which undergoes ready carbothermal reduction.[105]

Because carbothermal reduction may also proceed reversibly, CO formed in the course of the reaction has to be removed. In practice, the reaction is carried out either continuously in conveyor-type pusher furnaces or in chamber kilns, where the CO partial pressure is kept low by flowing N_2. Though Si_3N_4 formation generally increases with increasing temperature, increasing amounts of SiC, depending on CO partial pressure, are formed at temperatures exceeding 1450 °C; the SiC is practically inseparable from the Si_3N_4[65, 99, 106] (Fig. 5).

Particle size and particle morphology may be controlled by adding either crystalline spheroidal Si_3N_4 particles or Si_3N_4 whiskers as nuclei to the reaction mixture.[66] Since carbon acts also as a nucleation center for Si_3N_4 formation, its particle size influences Si_3N_4 powder characteristics as well. Very fine, high-surface carbon powders favor the formation of spheroidal Si_3N_4 particles; coarse, low-surface powders favor whisker formation.[99, 102]

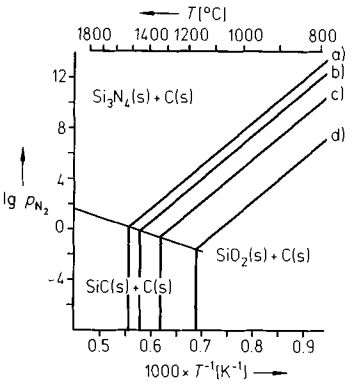

Fig. 5. Stability diagram for the system $SiC/Si_3N_4/SiO_2/C$ under varying CO partial pressures [106]. All compounds are present as solids. p_{CO}: a) 1 atm, b) 0.345 atm, c) 0.1 atm, d) 0.01 atm.

After synthesis the reaction product is milled to adjust the desired particle size and the particle size distribution (Fig. 6).

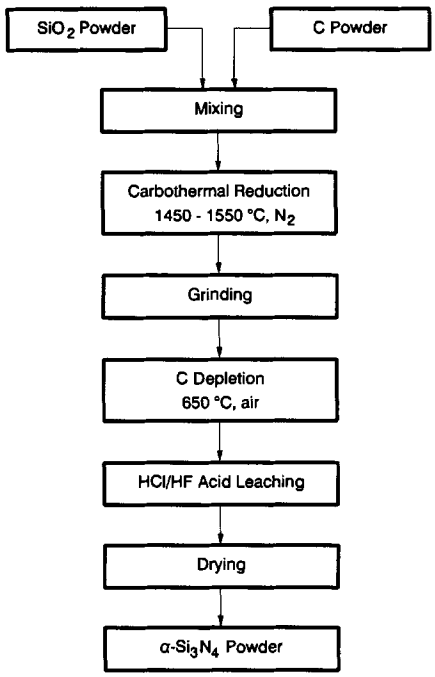

Fig. 6. Process for Si_3N_4 synthesis by carbothermal reduction.

By tempering in air,[66] NH_3, or chlorine-containing atmospheres[107, 108] at temperatures in the range of 600–800 °C excess carbon is removed. If required, incompletely reacted SiO_2 may be removed by HF leaching.

4.4. Ammonolysis of Reactive Silicon Compounds

4.4.1. Si_3N_4 Synthesis by Liquid-Phase Reaction of $SiCl_4$ and NH_3

The work on the liquid-phase reaction of $SiCl_4$ and NH_3 dates back to 1830, when *Persoz*[109] isolated a white precip-

itate, which he considered to be silicon tetraamide, $Si(NH_2)_4$. Subsequently, however, this precipitate was identified as silicon diimide, $Si(NH)_2$.[67-69, 110-114] Though this reaction may be described in its most simple form by Equation (e), further investigation showed a very complex

$$SiCl_4 + 6NH_3 \longrightarrow Si(NH)_2 + 4NH_4Cl \quad (e)$$

process, which led to differently polymerized, extremely moisture-sensitive $[Si(NH)_2]_x$.[112] Subsequent high-temperature pyrolysis leads to stable, processable α-Si_3N_4 via several intermediates and amorphous Si_3N_4 accompanied by NH_3 or N_2/H_2 liberation [Eq. (n)].[67-69, 112-117] The transformation of amorphous silicon nitride to crystalline α-Si_3N_4 proceeds above 1200 °C in a diffusion-controlled manner with an activation energy of 306 kJ mol^{-1}.[118]

$$\frac{3}{x}[Si(NH)_2]_x \xrightarrow{1200-1400\,^\circ C} \alpha\text{-}Si_3N_4 + N_2 + 3H_2 \quad (n)$$

It is remarkable that NH_4Cl still present from the $SiCl_4/NH_3$ reaction [Eq. (e)] influences the $Si(NH)_2$ pyrolysis.[115] In the absence of NH_4Cl, $Si(NH)_2$ is stable to 200 °C; it gradually loses NH_3 with increasing temperature, until finally amorphous Si_3N_4 is formed. However, thermal decomposition in the presence of NH_4Cl results in reaction of $Si(NH)_2$ and HCl to give a compound of the composition $Si_2N_3H_2Cl$, which decomposes to amorphous silicon nitride above 800 °C.

Pyrolysis of $Si(NH)_2$ at temperatures below 1200 K leads to the formation of an extremely fine, moisture-sensitive, amorphous Si_3N_4 powder showing primary particle sizes of about 10–30 nm and BET surfaces greater than 100 m^2 per g. Prolonged heating at temperatures of 1200 to 1400 °C induces crystallization of α-Si_3N_4 accompanied by particle coarsening. At temperatures exceeding 1500 °C mainly β-Si_3N_4 is formed.[69] Particle morphology, particle size, and α/β ratio are influenced by temperature, retention time, and impurities.[119, 120]

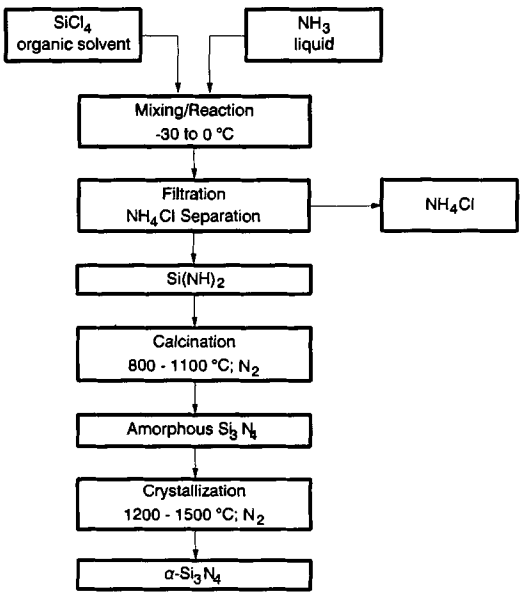

Fig. 7. Process for Si_3N_4 synthesis by $SiCl_4/NH_3$ liquid-phase reaction.

Since $SiCl_4/NH_3$ liquid-phase reaction allows the synthesis of a very pure and fine Si_3N_4 powder from easily purified and readily available starting materials, this method (often referred to as the *diimide process*) has been developed on a pilot scale (Fig. 7). The $SiCl_4/NH_3$ reaction is carried out in a two-phase system consisting of an organic solvent and liquid NH_3[72, 116, 117, 121] or by reacting $SiCl_4$ vapor with excess liquid NH_3,[122] thus dissolving the by-product NH_4Cl. The $Si(NH)_2$ precipitate is filtered and washed with liquid ammonia to remove residual NH_4Cl and finally calcined and crystallized to give α-Si_3N_4. In contrast to thermal NH_4Cl separation by sublimation, this procedure offers the technological advantage that no corrosive NH_3/HCl vapors are generated. However, upscaling has to take into consideration the large amount of NH_4Cl by-product, generated according to Equation (o). An economically favorable and ecologically safe application or disposal has yet to be found for this by-product.

$$3SiCl_4 + 16NH_3 \longrightarrow Si_3N_4 + 12NH_4Cl \quad (o)$$

4.4.2. Si_3N_4 Synthesis by Gas-Phase Reactions of $SiCl_4$ or SiH_4 with NH_3

Owing mainly to homogeneous nuclei formation, gas-phase reactions have a great potential for the production of extremely fine powders.[123] After formation and growth of nuclei in the reaction zone, particles cluster to aggregates and agglomerates, which may be separated as fine dust (Fig. 8).

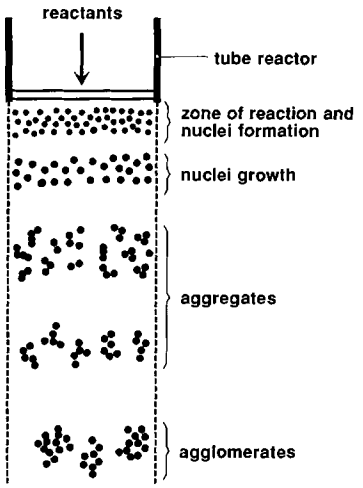

Fig. 8. Particle formation in gas-phase reactions [123].

For economical and technical reasons gas-phase reactions of $SiCl_4$ or SiH_4 with NH_3 are of special interest. From a technological point of view the use of cheap $SiCl_4$ requires the separation of the corrosive NH_4Cl by-product through either hot-gas filtration, extraction, or sublimation. Because of spontaneous ignition of SiH_4 in contact with air, however, the use of expensive SiH_4 requires extensive safety precautions. A technological advantage, though, is the formation

of hydrogen as gaseous by-product, which is easily separated. If $SiCl_4$ is used, reaction parameters may be adjusted to approach the stoichiometry of the reaction [Eq. (p)], thus

$$SiCl_4 + 2NH_3 \longrightarrow Si(NH)_2 + 4HCl \qquad (p)$$

keeping the amount of solid NH_4Cl by-product low compared to the corresponding liquid-phase reaction. Instead of using expensive pressure vessels, gas-phase reactions are run at atmospheric pressure in heated tube reactors (Fig. 9). Similar to industrial-scale synthesis of SiO_2 and TiO_2 powders, these reactions represent a good technological basis for a continuous, large-scale production of fine powders. As liquid-phase reactions, $SiH_4/SiCl_4$-NH_3 gas-phase reactions also yield amorphous Si_3N_4 precursors because of the short retention times of gas and particle streams in the hot reaction zone. These amorphous precursors have to be crystallized separately in a subsequent step.

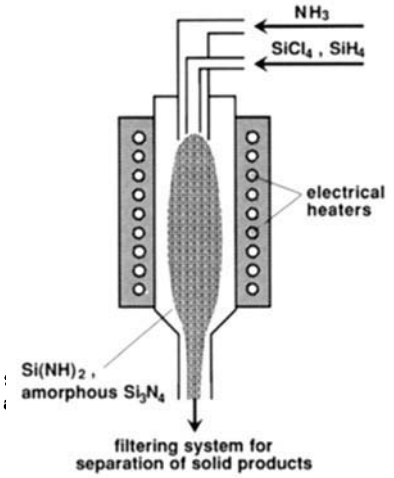

Fig. 9. Setup of a gas-phase reactor for the synthesis of Si_3N_4 from $SiCl_4$ and NH_3.

The reaction of SiH_4 and NH_3 in the temperature range of 500–900 °C yields amorphous powders with particle sizes of 30–200 nm and BET surfaces up to 26 $m^2 g^{-1}$.[70, 71] Our investigations on $SiCl_4/NH_3$ gas-phase reactions at temperatures of 300–1700 °C showed the formation of extremely fine, spheroidal and amorphous particles with BET surfaces up to 300 $m^2 g^{-1}$.[124, 125] Crystallization of these precursors induces particle coarsening; thus, the BET surface may be adjusted in the range of 2–20 $m^2 g^{-1}$.[70, 125]

Strict control of impurities, temperature, and retention time is important for the generation of very fine, uniform, high-α-phase Si_3N_4 particles by crystallization of amorphous Si_3N_4 (Fig. 10). The powders from $SiCl_4/NH_3$ gas-phase reactions require significantly less processing (Fig. 11) than products from direct nitridation or carbothermal reduction because of their inherent fine particle size and weak agglomeration. They are characterized by high chemical purity, good manufacturing properties, and high sintering activity.

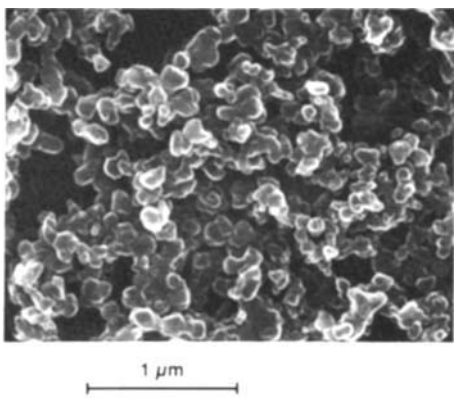

Fig. 10. α-Si_3N_4 powder by crystallization of amorphous Si_3N_4 from $SiCl_4/NH_3$ gas-phase reaction.

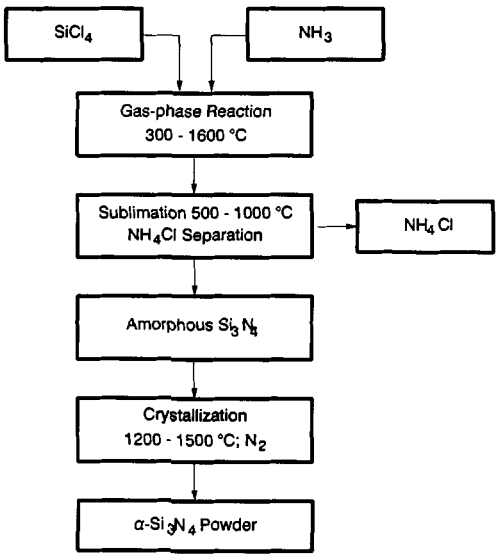

Fig. 11. Process for Si_3N_4 synthesis by $SiCl_4/NH_3$ gas-phase reaction.

4.5. Si_3N_4 Synthesis by Laser-Induced and Plasmachemical Reactions

The work on laser-induced[126–129] and plasmachemical reactions[130–134] as alternatives to "usual" thermal gas-phase reactions tries to avoid any heterogeneous nuclei formation due to contact of the reacting gases with hot reactor walls; thus, an extremely high degree of particle fineness and uniformity is guaranteed. Characteristic properties of both processes, which are based on chemical reactions already described above, are extremely fast heating and cooling rates of about 10^5 to 10^6 $K s^{-1}$ and fast reaction rates on the order of about 10^{-3} s. Figures 12 and 13 show experimental setups for laser-induced and plasmachemical Si_3N_4 synthesis from reactions of SiH_4 or $SiCl_4$ with NH_3. Particle size, crystallinity, α/β ratio, and stoichiometric composition of the reaction product are influenced by mass flow, pressure, stoichiometric ratio of reactants, and laser or plasmagenerator power output. A major problem of laser-induced synthesis is the small reaction diameter of the laser beam, which allows only product formation rates on the order of just a few grams per hour. Because of the extreme temperatures of several

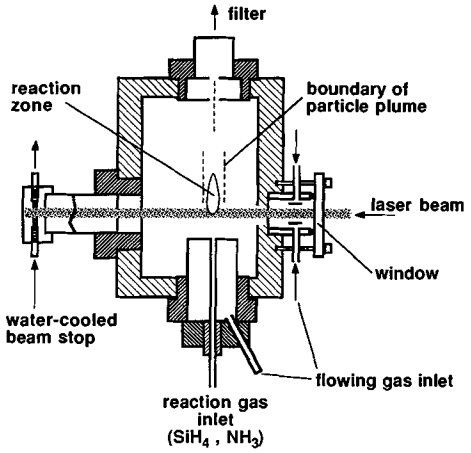

Fig. 12. Reactor for laser-induced Si_3N_4 synthesis from SiH_4 and NH_3 [126].

thousand K in plasmachemical reactions, the reactants are broken apart to different radicals, which may recombine in various ways in the temperature gradients of the reaction zone. Since fluid dynamics is also very important, it is very difficult to control the reaction precisely. Both laser-induced

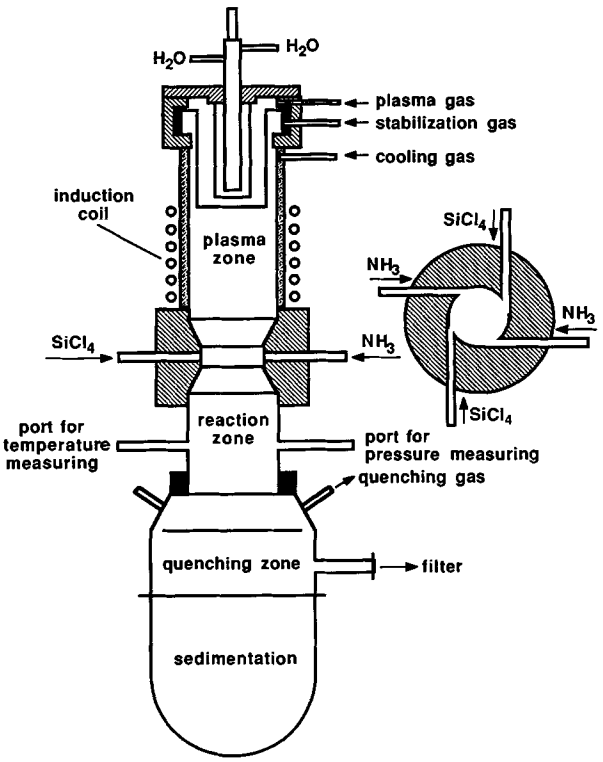

Fig. 13. Reactor for plasmachemical synthesis of Si_3N_4 from $SiCl_4$ and NH_3 [133].

and plasmachemical synthesis allow the generation of extremely fine powders with particle sizes of just 10–30 nm and BET surfaces greater than $100\,m^2g^{-1}$. However, the products often show incorrect stoichiometric composition, are amorphous, or possess changing, not exactly reproducible α/β ratios. Furthermore, they may contain free silicon as an undesired by-product from decomposition reactions. Because of these difficulties, laser-induced and plasmachemical reactions are not yet of importance to large-scale synthesis of Si_3N_4 powders, despite intense research.

5. Silicon Nitride Whiskers

After the discovery that crystal whiskers show unusual mechanical strength,[135] interest in the properties, production, and applications of ceramic whiskers grew.[136, 137] The use of whiskers to reinforce metallic or ceramic materials aims at improving fracture toughness or, more generally, mechanical properties of the matrix material. In spite of the strong general interest in ceramic whiskers, there are still problems in producing pure and uniform whiskers on a large scale in an economical way. The development of whisker production and processing methods especially has to take into account health precautions in order to exclude a potential hazard like that arising from asbestos fibers.[138, 139]

Chemically, the same methods as in the synthesis of spheroidal Si_3N_4 powder particles are used for the production of Si_3N_4 whiskers. However, additional measures are required in order to apply general techniques like vapor-phase transport or crystallization by vapor-liquid-solid (VLS) mechanisms to favor whisker formation.

5.1. Whiskers from the Reaction of Si and N_2

In direct nitridation of elemental silicon, Si_3N_4 whiskers are formed by reaction of silicon vapor and N_2. Figure 14 shows a simple experimental setup for this production method. Silicon is evaporated from a crucible at the bottom;

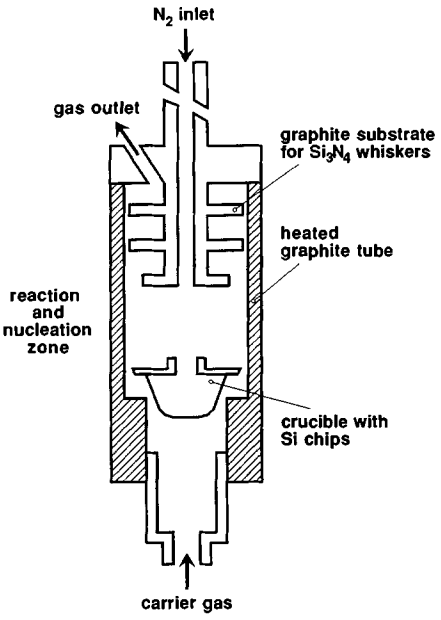

Fig. 14. Reactor for Si_3N_4 whisker synthesis from a Si/N_2 gas-phase reaction [140].

a stream of inert carrier gas is used to guide the Si vapor into a reaction zone in the upper part of the apparatus where it reacts with N_2 or NH_3. The Si_3N_4 whiskers precipitate onto graphite baffles from where they may be collected.

5.2. Whiskers from Carbothermal Reduction of SiO_2

This process, which may be run continuously in conveyor-type pusher furnaces, yields whiskers from the gas-phase reaction of SiO and N_2 or NH_3 in CO-containing atmospheres.[141-143] By adjusting stoichiometry, particle size, homogeneity, and packing density of the reaction mixture of silica and carbon raw materials, addition of silicon or metal oxides, and control of the reaction temperature, the amount of SiO generation and, consequently, Si_3N_4 whisker formation is optimized. Whisker formation is also favored if Si_3N_4 whiskers are added to the reaction mixture as growth nuclei.[143]

5.3. Whiskers from the Reaction of $SiCl_4$ with NH_3

As described above, the reaction of $SiCl_4$ with NH_3 leads to $Si(NH)_2$, which yields amorphous Si_3N_4 on calcination. If small amounts of Fe or SiO_2 are added to this material and the resulting mixture is heated to 1200–1500 °C in the absence of oxygen, Si_3N_4 whiskers are formed by a vapor-liquid-solid mechanism from Fe- or silicate-containing eutectic melt droplets[72, 143] (Fig. 15).

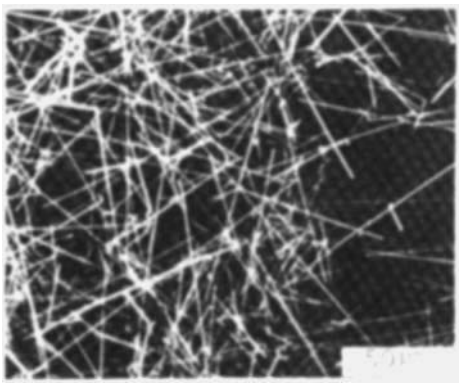

Fig. 15. α-Si_3N_4 whiskers by crystallization of amorphous Si_3N_4 [72].

5.4. Whiskers from the Reaction of SiS_2 with NH_3

Originally intended to produce high-purity Si_3N_4 powder, the reaction of SiS_2 with NH_3 offers a good way to produce Si_3N_4 whiskers.[73-75] In the first step, SiS_2 is synthesized by reaction of Si powder with H_2S at high temperature [Eq. (q)].

$$Si + 2H_2S \xrightarrow{900\,^\circ C} SiS_2 + 2H_2 \qquad (q)$$

The high vapor pressure of SiS, which forms on dissociation of SiS_2, leads to SiS_2 whisker growth by a VLS mechanism from eutectic droplets of SiS and sulfur vapor. Reaction of SiS_2 with NH_3 affords a $(Si\text{-}S\text{-}N\text{-}H)_x$ polymer, which thermally decomposes under NH_3 to amorphous silicon nitride [Eqs. (r) and (s)]. The amorphous silicon nitride is obtained in "spaghetti-like" morphology (Fig. 16) and may be crystallized to α-Si_3N_4 with retention of morphology.

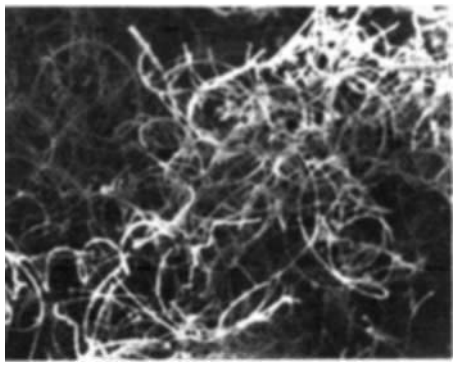

Fig. 16. Amorphous Si_3N_4 "spaghetti" from thermal decomposition of $(Si\text{-}S\text{-}N\text{-}H)_x$ polymers [74].

$$SiS_2 \xrightarrow[\text{ca. } 25-900\,^\circ C]{NH_3} (Si\text{-}S\text{-}N\text{-}H)_{polymer} \qquad (r)$$

$$(Si\text{-}S\text{-}N\text{-}H)_{polymer} \xrightarrow[900-1500\,^\circ C]{NH_3} Si_3N_4 \text{ (amorphous, crystalline)} \qquad (s)$$

5.5. Whiskers from the Reaction of SiC and NH_3

The reaction of SiC with NH_3 is remarkable since it leads to Si_3N_4 particles of unusual morphology. By heating a mixture of SiC and Fe powder in NH_3 to 1440 °C followed by a short-term temperature rise to 1480 °C, *Glemser* und *Horn*[76] obtained spiral-shaped α-Si_3N_4 whiskers (Fig. 17, left). Some of these spirals could be seen with the naked eye.

Recently, similar observations have been made in the investigation of vapor-phase deposition of Si_3N_4 from Si_2Cl_6,

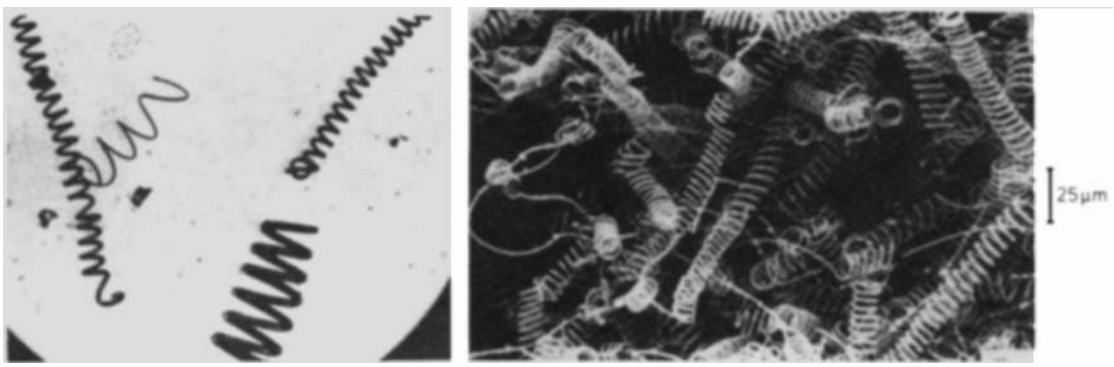

Fig. 17. Left: α-Si_3N_4 spirals from the reaction of SiC and NH_3 in presence of Fe [76]. Right: α-Si_3N_4 spirals by vapor-phase deposition from a mixture of Si_2Cl_6, NH_3, and H_2 onto a Fe-coated graphite substrate [144].

NH_3, and H_2 at 1200 °C onto a graphite substrate coated with Fe-containing compounds.[144, 145] The spiral-shaped whiskers (Fig. 17, right) are about 0.5–1.0 μm thick and consist of α-phase Si_3N_4 slightly contaminated by carbon and oxygen. They show a quite uniform morphology with a regular pitch of 3–5 μm, a spiral diameter of 5–10 μm, and a length of 50–100 μm. Obviously, spirals are formed only in a narrow fiber-diameter range of about 0.1–5 μm.

5.6. Properties of Si_3N_4 Whiskers

Some properties of commercially available Si_3N_4 whiskers are shown in Table 1. The principal problems in whisker production are the requirements of high chemical purity and uniform whisker morphology. Because of technological difficulties in producing a homogeneous distribution of Si_3N_4 whiskers in a matrix material, fracture-causing structural defects are often induced during material processing; in these cases, the originally intended toughening of the matrix actually turns out to be a weakening.[146, 147] Fundamental problems in whisker processing are often connected with shaping and sintering, since heaps of needlelike particles are much more difficult to compact by, say, dry pressing than heaps of spheroidal particles.

Table 1. Properties of commercially available Si_3N_4 whiskers.

Product	Tateho SNW [a]	Ube SN-W [b]
Synthetic method	carbothermal reduction	from amorphous Si_3N_4
Crystal phase	α	α
Diameter *d*	0.1–1.6 μm	0.1–0.4 μm

6. Remarks on the Procedures for Synthesis of Si_3N_4 Powders

A comparison of chemical and physical characteristics of powders from commercially used synthetic methods shows that direct nitridation, carbothermal reduction, and ammonolysis of reactive silicon compounds are principally able to furnish very fine, high-purity Si_3N_4 powders for applications in advanced ceramics (Table 2). Often variations of particle sizes, particle size distribution, and particle surface properties, which are important to ceramic processing, may be carried out after Si_3N_4 synthesis by suitable powder processing. Direct nitridation and carbothermal reduction use cheap raw materials and yield crystalline Si_3N_4 directly. However, the reaction products require extensive subsequent processing. On the other hand, ammonolysis of reactive silicon compounds yields moisture-sensitive products which require further thermal treatment for crystallization to yield α-Si_3N_4. Because of their inherent fine particle size and only weak particle agglomeration, the extent of subsequent powder processing is considerably reduced compared with direct nitridation and carbothermal reduction. Direct nitridation and $SiCl_4/NH_3$ gas-phase reactions seem to offer the best chances to furnish economically high-quality powders for the manufacturing of broadly applicable silicon nitride ceramics.

Table 2. Comparison of high-purity Si_3N_4 powders from different synthetic methods.

Powder type	DN 1 [a]	DN 2 [b]	GP [c]	FP [d]	CT [e]
Elemental analysis [wt %]					
N	38.2	38.2	38.5	>38.0	37.5
O	1.8–2.1	1.7–2.0	1.1–1.6	<2.0	2.0
C	<0.2	<0.2	<0.05	<0.2	0.9
Cl	<0.001	<0.001	<0.1	<0.01	[f]
Fe	<0.008	<0.03	<0.01	<0.01	0.007
Al	<0.005	<0.06	<0.004	<0.005	0.2
Ca	<0.002	<0.01	<0.002	<0.005	0.01
α-Si_3N_4	>92%	>94%	>90%	>95%	98%
Mean particle size d_{50} [μm]	0.6	0.8	0.5	0.5	0.9

[a] DN 1 = direct nitridation (LC 12 – SX, H. C. Starck, Berlin). [b] DN 2 = direct nitridation (LC 10, H. C. Starck, Berlin). [c] GP = $SiCl_4/NH_3$ gas-phase reaction (Grade GP, H. C. Starck, Berlin). [d] FP = $SiCl_4/NH_3$ liquid-phase reaction (SN E 10, Ube Ind., Tokyo). [e] CT = carbothermal nitridation (A 200, Toshiba Ceramics, Tokyo). [f] Not determined.

The production of Si_3N_4 whiskers is not yet commercially important, since Si_3N_4 whisker-reinforced materials have not found broad applications because of high costs and a lack of large-scale production methods for reliable components. For technological and economical reasons, especially carbothermal reduction and whisker growth from amorphous Si_3N_4 should be suited best to meet an eventually increasing demand.

7. The Manufacture of Sintered Si_3N_4 Ceramics

7.1. Fundamentals of Sintering and Structure Development

7.1.1. Physical and Chemical Aspects of Si_3N_4 Sintering

"Dry" sintering techniques used in densification of oxide ceramics cannot be applied to the sintering of Si_3N_4 powder compacts. Strong covalent Si–N bonds hinder useful mass transport through grain-boundary or lattice diffusion. The activation of diffusion by simply raising the sintering temperature is limited by ever-increasing thermal decomposition [Eq. (t)].

$$Si_3N_4\ (solid) \longrightarrow 3Si\ (liquid) + 2N_2\ (gas) \longrightarrow 3Si\ (gas) \qquad (t)$$

Since a N_2 partial pressure of 1 bar is reached at about 1900 °C, several precautions have to be taken in order to prevent excessive decomposition during sintering of Si_3N_4 at high temperatures. Most important is the addition of com-

pounds that form molten silicate phases and allow densification by liquid-phase sintering mechanisms. Well-suited additives include alkaline-earth oxides and rare-earth oxides either alone or in combination with Al_2O_3 or AlN.[148-152]

Above 1300 °C sintering additives react with SiO_2 or Si_2N_2O always present in Si_3N_4 powders to yield molten silicate phases. In the case of sufficient wetting and solubility of Si_3N_4, these silicate melts allow densification by capillary-force-induced particle rearrangements and dissolution/reprecipitation processes.

The efficiency of these mechanisms is illustrated by a model experiment using a presynthesized, nitrogen-saturated Mg-Al silicate glass as sintering additive (Fig. 18). At

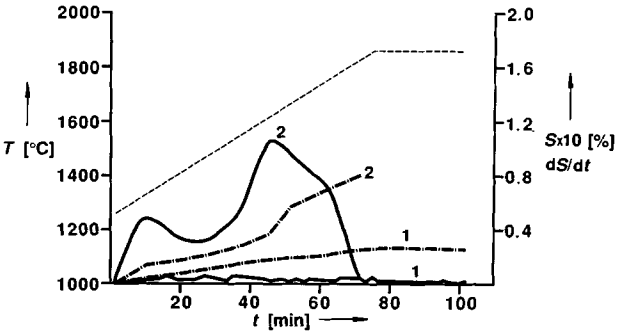

Fig. 18. Dilatometric investigation of Si_3N_4 sintering in the absence (1) and presence (2) of a nitrogen-saturated glass [153]. Temperature ----, dS/dt ——, shrinkage S -·-·-·-·-, dS/dt in [% min^{-1}].

1300 °C dilatometric monitoring of the process shows densification by capillary-force-induced particle rearrangement, since nitrogen saturation of the silicate glass does not allow further dissolution of N_2 or Si_3N_4. With increasing temperature Si_3N_4 solubility increases and densification via dissolution/reprecipitation is observed. A Si_3N_4 sample without sintering additives shows a completely unsatisfactory densification.

Another important precaution is sintering under high N_2 pressure to suppress decomposition according to Equation (t). Figure 19 shows that this technique significantly extends the temperature range of Si_3N_4 sintering.

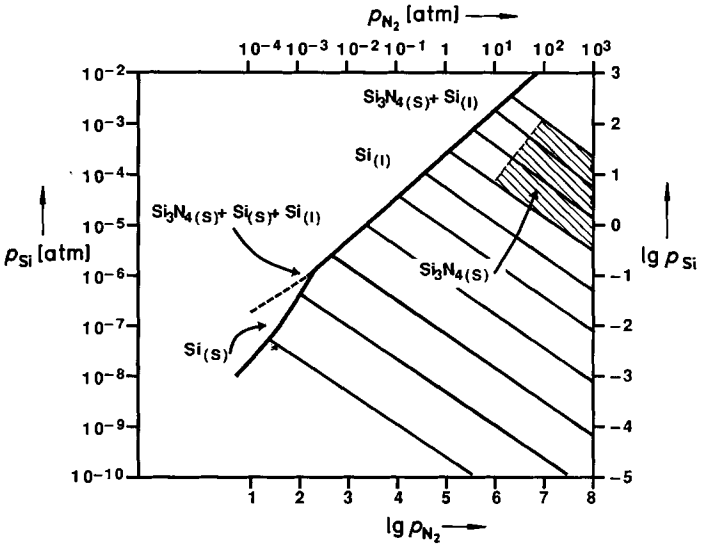

Fig. 19. Silicon vapor pressure in equilibrium with silicon nitride as a function of N_2 pressure and temperature [149]. The bold lines show temperature intervals of 100 K from 1300 °C to 2200 °C. The hatched region represents the range where sintering of Si_3N_4 takes place. The pressures were measured in Pa.

7.1.2. Structure Development

After particle rearrangement at low temperatures, which increases the packing density almost without influencing particle shape and particle size distribution, true sintering by dissolution/reprecipitation occurs at higher temperatures. At present, structure development is thought to depend on the kind of Si_3N_4 starting powder. Starting from α-Si_3N_4, reprecipitation of dissolved α-Si_3N_4 from almost saturated or slightly oversaturated solutions leads to crystallization of needle- or rodlike β-Si_3N_4 grains far from the energetic minimum.[154] Since a fine-grained, needlelike structure has a positive influence on fracture-mechanical properties ("in-situ whisker reinforcement") for numerous applications, this grain morphology is desired.[155, 156]. If β-Si_3N_4 powder is used, dissolution/reprecipitation occurs almost in equilibrium. The surface energy difference between small and large particles causes a continuous dissolution of small particles and their reprecipitation on large grains. This process allows grain growth with minimization of boundary surface energy

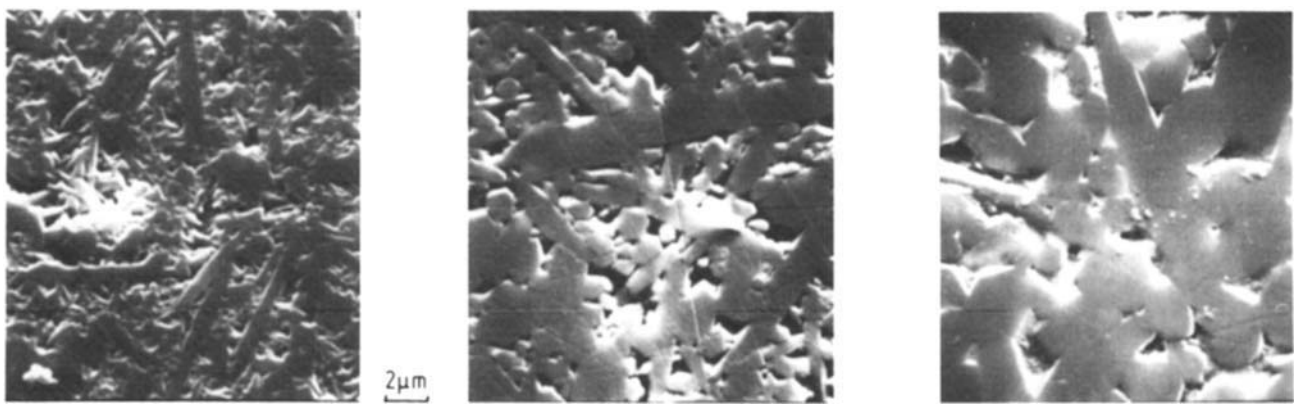

Fig. 20. Structure development in sintering of a Y_2O_3/Al_2O_3-doped Si_3N_4 powder [158]. Left: 1800 °C (10 min). Middle: 1800 °C (2 h), then 1820 °C (2 h). Right: 50 sintering cycles (see middle for conditions). Additives: 15 wt% Y_2O_3 + 3.4 wt% Al_2O_3.

leading to the development of approximately globular grains.[157]

Prolonged thermal treatment, far beyond the moment when densification is complete, favors grain growth by minimization of boundary energy ("Ostwald ripening") also in needle-grained structures and leads to grain coarsening with growth of spheroidal grains. In this case, structural development leads to the formation of globular grains, no matter whether α- or β-Si_3N_4 has been used as starting material. A study on structure development on prolonged heat treatment of α-phase Si_3N_4 is shown in Figure 20.

After sintering, all these materials contain an amorphous or semicrystalline secondary phase in between grain boundaries or in grain triple points (Fig. 21). Since especially

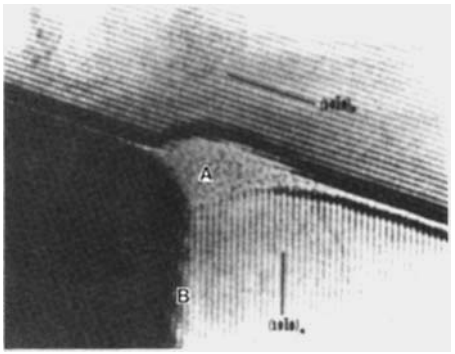

Fig. 21. Transmission electron microscopy (TEM) of amorphous secondary phase along grain boundaries in sintered Si_3N_4 [159]. The black lines show the direction $(10\bar{1}0)_\alpha$, A a grain triple point, B a grain boundary.

material properties at high temperatures are greatly influenced by the secondary phase, the reduction, modification, or complete elimination of this phenomenon is of major importance to the optimization of Si_3N_4 ceramic properties.[160]

7.1.3. Influence of Sintering Additives

The amount and chemistry of the molten silicate phase, which is formed by sintering additives, are of importance to the course of sintering, since they determine sintering kinetics. For example, the kinetics of MgO-doped systems are governed by dissolution, whereas the rate of diffusion is crucial in Y_2O_3-doped materials.[161] The influence of typical additives on sintering behavior is shown in Figure 22. For instance, the densification of Y_2O_3-doped Si_3N_4, which sinters at relatively high temperatures, may proceed at the low temperature level of ($MgO + Al_2O_3$)-doped materials if Al_2O_3 is added.

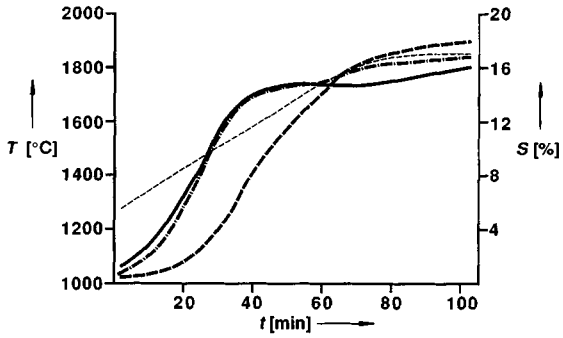

Fig. 22. Influence of type of additives on sintering behavior. ---- temperature, —— $MgO + Al_2O_3$, — • — $Y_2O_3 + Al_2O_3$, — — — Y_2O_3, S = shrinkage.

Different additive systems may form compounds of the type α'-$Me(Si,Al)_3(N,O)_4$ or β'-$Si_{6-x}Al_xO_xN_{8-x}$ with newly precipitated Si_3N_4 grains.[162, 163] The expectation that Si_3N_4 ceramics free of secondary grain-boundary phases can be produced by using this principle has only been fulfilled for Be-doped materials.[149, 160]

The amount and kind of additives also influence structure development and thus material properties. Fine-grained Si_3N_4 structures are favored in systems where the molten silicate phase shows a relatively high viscosity at sintering temperatures (e.g., systems doped with rare-earth oxides). The influence of additives is especially clear in the structure development of β'-SiAlON materials, where globular grains are favored. Figure 23 shows a comparison of these materials with a material sintered with MgO/Al_2O_3, which developed a needlelike structure. The exact reasons for this behavior are not yet completely understood.

7.1.4. Influence of Powder Characteristics

Besides the kind and amount of additives, the sintering behavior, structure development, and, finally, material properties depend strongly on the powder characteristics of the starting Si_3N_4 powder. Of further importance are the powder properties resulting from processing prior to shaping and sintering; in particular, it is necessary to break up particle agglomerates and to produce a homogeneous distribution of sintering additives. Relevant powder properties can be divid-

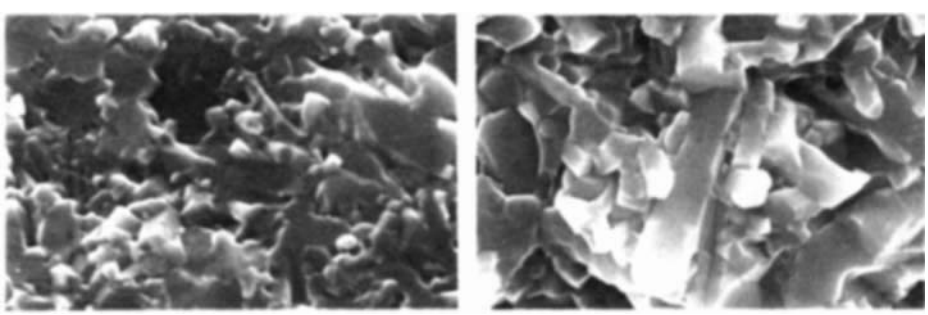

Fig. 23. Left: Globular structure in a β'-Si-Al-O-N material; right: needle-type structure in a MgO/Al_2O_3-doped material.

ed into physical, chemical, and technical characteristics, which together determine processing behavior and sintering activity in a complex way.

The influence of α/β-Si_3N_4 ratio has already been mentioned and is still a subject of intensive discussion.[54, 124, 155, 164, 165] A high α-phase content enhances sintering activity and favors the development of rodlike β-Si_3N_4 grains. With respect to sintering activity, amorphous Si_3N_4 would be of even greater advantage. However, its large-scale use is complicated owing to its sensitivity towards hydrolysis and its low powder-packing density, which results in enormous shrinkage during sintering.

Among chemical powder characteristics, the oxygen content is of special importance, since it influences the softening behavior and the amount and viscosity of the silicate phase formed on reaction with sintering additives. Although a great amount of low-viscosity silicate melt phase enhances sintering, it has a negative effect on the high-temperature properties of the material if the silicate phase remains as an amorphous, glassy grain-boundary phase. Thus, the oxygen content has to be adjusted to the amount of sintering additives required (or vice versa); it is a compromise between beneficial effects on sintering behavior and detrimental effects on high-temperature material properties. Usually, commercially available powders possess an oxygen content in the range of 1–2%.

Also the distribution of oxygen in the particle itself is of importance. If oxygen is concentrated on particle surfaces, it is directly available for silicate phase formation by reaction with sintering additives. In this way, surface oxygen improves sintering activity considerably.[166, 167] Therefore, high-quality Si_3N_4 powders usually possess oxygen-enriched particle surfaces, which allow fine-tuning of the amount of sintering additives required for complete densification and thereby result in improved material properties. The coating of a Si_3N_4 particle with an amorphous layer rich in oxygen is shown in Figure 24.[168]

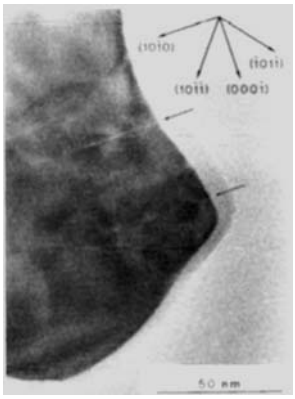

Fig. 24. TEM picture of the coating of a Si_3N_4 particle with an amorphous layer rich in oxygen [168]. Beam direction ($\bar{1}2\bar{1}0$). The arrows indicate Schottky partial dislocations.

Free carbon has a negative influence on sintering behavior, since it reduces the oxygen content of the powder with formation of volatile SiO and CO. The resulting ill-defined variations in silicate phase chemistry may cause incomplete sintering, undesired structure development, and, finally poor material properties.[153, 169] Chemically bonded carbon in the form of SiC is much less critical. Because of its inherent stability, this material may be considered as inert filler.[108, 147] The effects of other impurities have to be judged by their behavior in sintering; they may dissolve in the liquid phase with incorporation in the silicate structure or they may remain as particle inclusions with or without reaction with the Si_3N_4 matrix. Metal oxides and metal halides either evaporate during sintering or dissolve in the liquid phase, lowering its viscosity with the already discussed effects on sintering behavior, structure development, and material properties.

Metal particles like Fe, Mn, and Ti react with the Si_3N_4 matrix to form silicides or nitrides.[170] Compared to original particle sizes, inhomogeneities due to chemical reactions are larger[170] and thus generally detrimental to mechanical properties like fracture strength (Fig. 25).

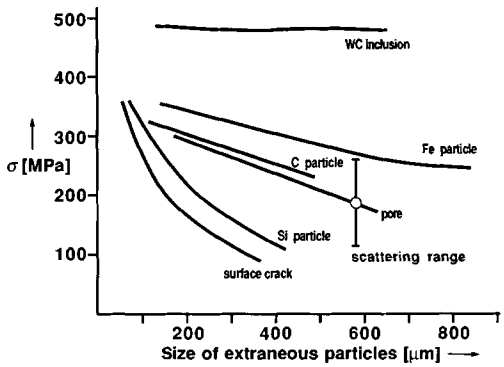

Fig. 25. Dependence of fracture stress σ on size of extraneous particles in Si_3N_4 sintered ceramics [171].

Granulometric powder properties, which involve particle size distribution, particle morphology, and particle agglomeration, influence processing behavior and the extent of powder processing required to produce an admixture of high sintering activity. Since sintering activity increases with increasing surface energy, "sub-μm" powders with a high content of particles less than 1 μm are advantageous. The amount of "coarse grains" attracts special attention, since these particles will dissolve in the silicate phase comparatively slowly. Therefore, sintering is slowed down and some particles may survive more or less unchanged to form structure inhomogeneities.

Whisker- or fiberlike Si_3N_4 particles cause similar effects, additionally making powder shaping more difficult. "Coarse grains" greater than 1 μm, as well as deviant particle morphologies, usually are not destroyed during powder processing to generate the sintering admixture. Powder processing has to guarantee that agglomerates of primary crystallites, which are principally present, are broken apart, since their size and the lack of sintering additives in their cores would induce very large defects and thus limit strength and reliability of the sintered component. Furthermore, the size and hardness of these agglomerates determine dispersibility and homogeneity of the sintering admixture; these properties are very important quality criteria. A qualitative and quantitative description of agglomeration mechanisms and agglom-

erate properties is steadily gaining importance as a goal of research.[172]

The shape—sharp-edged to spheroidal/globular—and the size distribution of primary crystallites determine also the limits of densification and the extent of sintering shrinkage. Green densities (i.e., the densities of the powder-shaped bodies prior to sintering) must be as high as possible to reduce the danger of critical tensions due to high shrinkage; these tensions would otherwise lead to cracks and fissures during temperature treatment.

Physical, chemical, and technological powder properties have a complex influence on sintering behavior, structure development, and final material properties. The relative influence of a single powder property may be estimated by means of statistical calculations.[167, 171]

7.2. Technological Aspects

7.2.1. Powder Processing

The processing of a Si_3N_4 powder to a highly sintering active admixture aims at breaking up particle agglomerates and distributing homogeneously the sintering additives. Wet processing in mills of high-energy density is well-suited for this purpose. However, attention has to be paid to the kind and amount of wear debris from these machines. Oxygen contamination due to partial hydrolysis of Si_3N_4 and carbon contamination are important if processing is done in either water- or organic-solvent-containing media. The extent of processing depends on starting powder quality, the desired powder shaping and sintering techniques, and the material property profile of the component to be manufactured. Since powder characteristics may vary considerably during processing, rigorous controls are necessary to ensure the highest possible uniformity of processing from lot to lot.

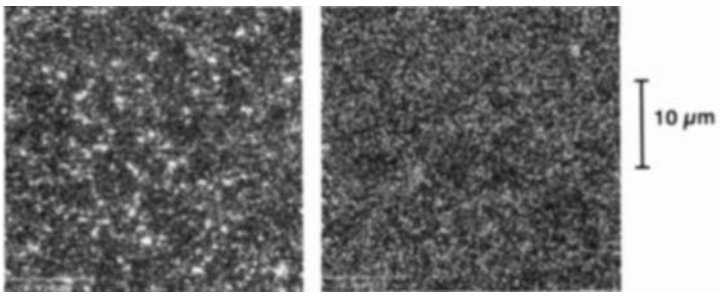

Fig. 26. Y distribution in Y_2O_3-doped Si_3N_4 sintering powder admixture. Left: By mechanical dispersal of Y_2O_3. Right: By precipitation of $Y(OH)_3$.

Extremely homogeneous distribution of sintering additives may be achieved far better by precipitation from solution than by intensive mechanical dispersion. Here, codrying of salt solutions and Si_3N_4 slips[153] has been investigated as well as precipitation of hydroxides from salt solutions[173] and precipitation by hydrolysis of metal alcoholates.[174, 175] Figure 26 shows that this approach leads to extremely homogeneous additive distributions.

7.2.2. Powder Shaping

Axial or isostatic dry pressing, extrusion, slip casting, or injection molding is used for powder shaping (Fig. 27). These procedures are well-known to the ceramic industry. Selection criteria depend on component complexity, on economics and, if required, on the feasibility of large-scale production. Dry pressing is used mainly for the production of

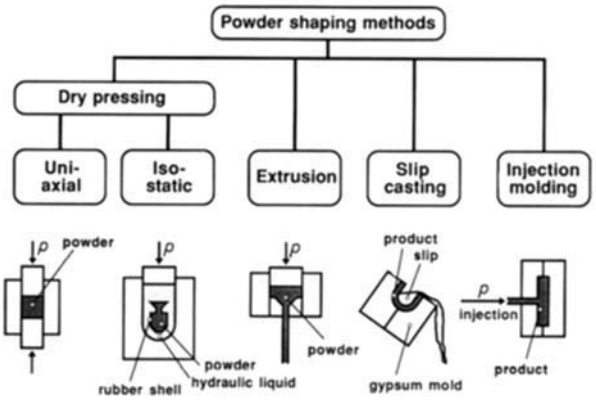

Fig. 27. Ceramic powder shaping methods. p = pressure.

components with simple geometry like plates, tubes, or cylinders. Slip casting and injection molding are favored to produce net-shape components of complex geometry on a large scale. All shaping techniques require certain, usually organic, processing additives. Binders ensure the stability of powder compacts in dry pressing, dispersion agents allow the production of highly particle-loaded, stable slips for slip casting, and plasticizers allow injection molding. Since especially injection molding promises an economical, large-scale production of complex components, its development has attracted worldwide attention.[176–178] All organic additives have to be burned out quickly and quantitatively prior to sintering without inducing defects like pores, cracks, or fissures. Because of the high amount of plasticizers, usually about 10–25 weight percent, this step is especially critical in injection molding. Although shaping is finished in a few seconds, plasticizer burnout requires several hours to several days depending on component thickness and kind of plasticizer. To improve this situation the development of new organic plasticizer systems, which may be decomposed either chemically or thermally after powder shaping, is of fundamental importance.

7.2.3. Sintering

The sintering techniques used for the manufacture of Si_3N_4 ceramics are compiled in Figure 28 together with process characteristics. Axial hot pressing in graphite matrices is used almost only for components of relatively simple geometry like rods, plates, or cylinders. Hot isostatic pressing (HIP), however, allows sintering of complex components.[179] Powder compacts are sealed gas-tight in metals or glasses of high melting point; plastic deformation of the softening material of the capsule results in uniform applica-

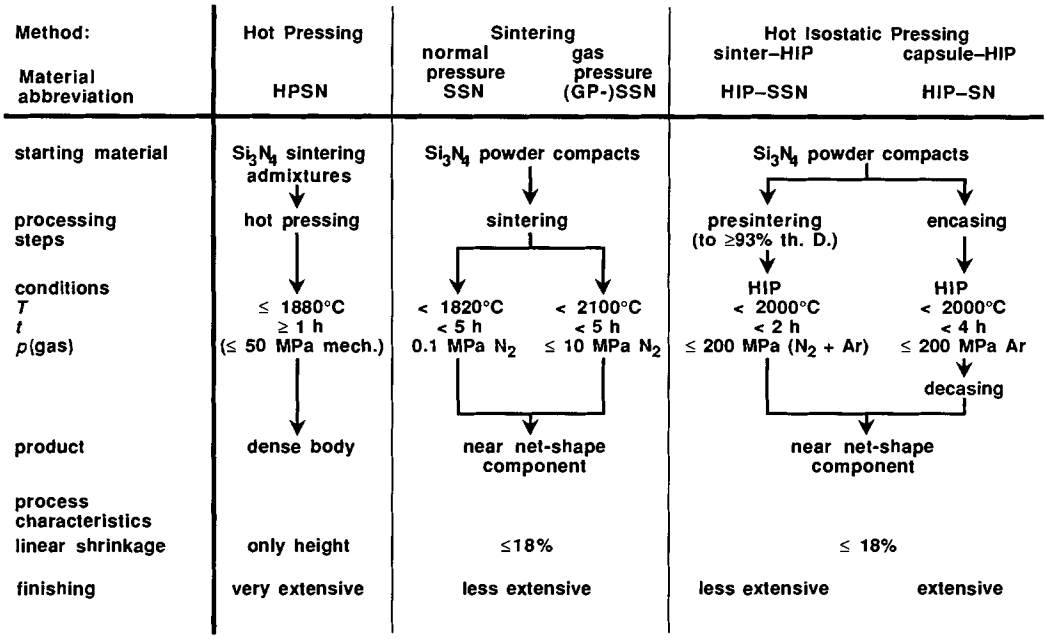

Fig. 28. Sintering processes for the manufacturing of dense Si_3N_4 components. mech. = mechanical, th. D. = theoretical density.

tion of the external gas pressure on the powder compact. Densification occurs with very precise retention of shape. After sintering is complete, the capsule is removed mechanically (sandblasting) or chemically (etching). Thus, this so-called capsule-hipping is an expensive and slow procedure not suited for low-cost mass production of ceramic components. Usually, it is applied for the production of components which are used under extreme conditions and would otherwise require an even greater effort for production.[180] However, "hipping" allows the manufacture of Si_3N_4 sintered materials with very good high-temperature properties due to the only very small amount—or even absence—of an amorphous grain-boundary phase.[181, 182] These developments, to date on laboratory scale, may gain importance for the manufacturing of Si_3N_4 components showing long-term mechanical strength at high temperatures.

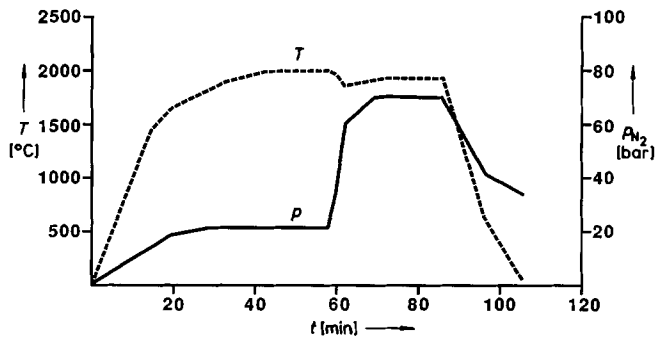

Fig. 29. Temperature–pressure–time profile during gas-pressure sintering of Si_3N_4 [149].

Cost-efficient mass production of near-finished Si_3N_4 components is possible by N_2 gas-pressure sintering, which was developed during the seventies and which is meanwhile industrially employed.[149] In this process a powder compact is heated to sintering temperature in a powder bed consisting of Si_3N_4 and BN. The course of temperature and pressure has to be adjusted to furnace geometry, sintering additives, and powder compact geometry (characteristic data in Fig. 28). Sintering under normal pressure limits the maximum temperature to about 1820 °C owing to the decomposition of Si_3N_4. However, sintering at increased N_2 pressure allows a further temperature increase and results in a pressure-assisted densification, which is effective only if the stage of closed porosity above 93% theoretical density was reached by normal pressure sintering. This method shortens the overall time required for complete densification; it even has a (limited) ability to increase strength and reliability of Si_3N_4 sintered components because of some defect healing. A typical course of temperature/pressure versus time in gas pressure sintering is shown in Figure 29.[149]

7.2.4. Finishing

Since sintered components are rarely used as fired, that is, without precise finishing, corrections of shape with adjustments of tolerances, as well as high-quality surface finishing, are required, especially for applications as engine or turbine components. Because of high hardness and comparatively high toughness of Si_3N_4 materials, these steps are time-consuming and expensive. Mainly cutting, grinding, honing, lapping, and ultrasonic erosion are used for finishing. Laser cutting and spark erosion are under development.[183, 184] Ultrasonic erosion is of special interest, since it allows the production of very complex components (e.g., gas turbine rotors) from simple monolithic shapes (Fig. 30). Generally, finishing has to be done extremely carefully in order to avoid strength and reliability deterioration by fracture-causing surface defects like cracks, fissures, and pits.

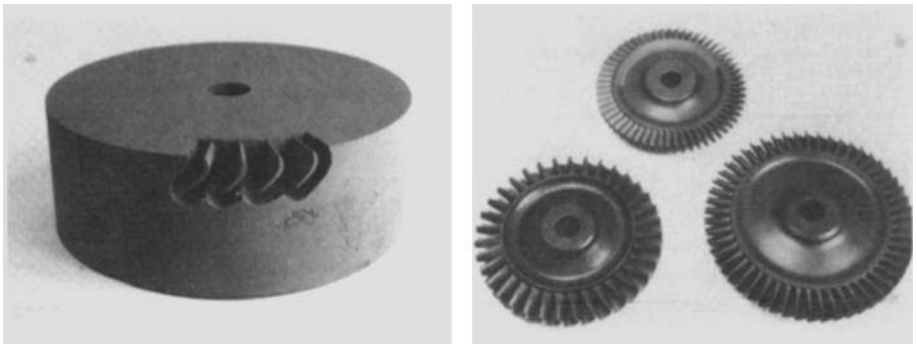

Fig. 30. Left: Manufacturing study for ultrasonic erosion of a turbine wheel from a hot-pressed Si_3N_4 monolith [185]. Right: Turbine wheels made of Si_3N_4 for applications in automotive gas turbines [186].

8. Physical and Chemical Properties

8.1. Physical Properties

Table 3 shows a compilation of important properties of completely densified Si_3N_4 ceramics. The scattering range of the data is mainly due to structural differences, which are influenced by starting powder characteristics, amount and kind of sintering additives, powder shaping, and sintering techniques as well as temperature, pressure, and soaking time during sintering. Fracture strength is surely the characteristic property determined most often; usually it is considered as a key criterion of quality. Some years ago, a significant dependence of material properties on the method of producing the starting powder was observed.[187] However, these differences almost vanished as a result of constant efforts to improve Si_3N_4 powder quality and production methods. The influence of sintering techniques on material properties is reflected in the so-called Weibull modulus (a statistical parameter to characterize a property distribution over a manifold of samples), which is used to characterize the scattering of fracture strength and thus the reliability of the material. The (limited) ability of a particular sintering process to anneal defects like pores, bubbles, internal cracks, and fissures is thereby quantified to a certain extent. The following values are typical for Weibull moduli of commercial materials: pressureless sintered Si_3N_4 >10; gas-pressure-sintered Si_3N_4 (GP-SSN) >15; isostatically hot-pressed Si_3N_4 (HIP-SSN), >20.

Table 3. Physical properties of dense Si_3N_4 material.

Property	Value
Decomposition temperature	2173 K
Theoretical density (th. D.)	α-phase: 3.168–3.118 $g cm^{-3}$ β-phase: 3.19–3.202 $g cm^{-3}$
Material density	95–100% th. D.
Thermal expansion coefficient (293–1473 K)	2.9–3.6 $10^{-6} K^{-1}$
Specific heat	700 $J K g^{-1} K^{-1}$
Electrical resistance [a]	10^{13} Ωcm
Microhardness (Vickers)	1400–1700 $MN m^{-2}$
Bending strength [a] [b]	600–1000 MPa
Fracture toughness [a]	5–8 $MPa m^{1/2}$
Elasticity modulus [a]	280–320 GPa
Thermal conductivity [a]	15–30 $W m^{-1} K^{-1}$
Critical temperature difference in thermal shock	600–800 K

[a] RT = room temperature. [b] Four-point bending

A general comparison of fracture strength is difficult, since materials for specialized applications have been developed. Here, the main criteria of quality include not only fracture strength, but also the strength level at temperatures greater than 1000 °C, fracture toughness, and hardness or wear resistance. Today, the state of the art is a strength level of 800–1000 MPa at room temperature; however, materials with fracture strengths exceeding 1000 MPa have been described.[188, 189]

By controlled structure development (in situ whisker reinforcement) it is possible to increase the fracture toughness of Si_3N_4 materials from a level of about 7 $MPa m^{1/2}$ to almost 10 $MPa m^{1/2}$;[190] a conventional material is compared to an "in situ whisker reinforced" material in Fig. 31.[191] The toughness level attained here could formerly be achieved only by reinforcement with extraneous particles (like whiskers or platelets).[192, 193]

At temperatures exceeding 1000 °C a decrease of strength in many materials is caused by slowly softening amorphous grain-boundary glass phases. The amount and kind of these phases determine creep and long-time fracture strength. All modifications of materials or technological processes to im-

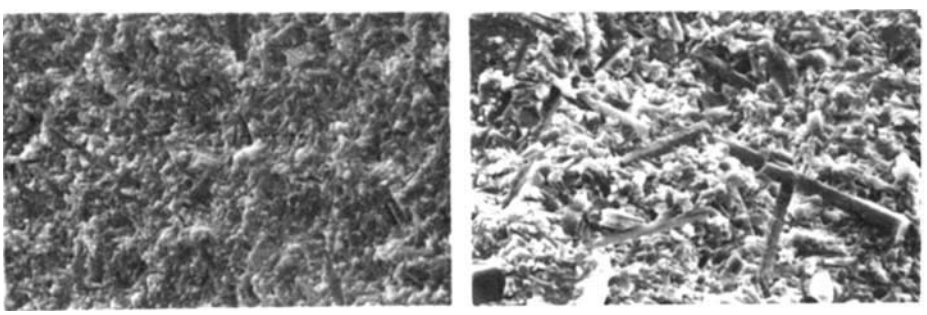

Fig. 31. Improving fracture toughness K_{Ic} by in situ whisker reinforcement [191]. Left: Structure of a conventional Si_3N_4 material ($K_{Ic} = 6.5$ $MPa m^{1/2}$). Right: Structure of an in situ whisker-reinforced material ($K_{Ic} = 9.5$ $MPa m^{1/2}$).

prove the dependence of fracture strength on temperature and to improve the strength level at high temperatures aim at reducing the amounts of amorphous grain-boundary glass phases or at generating higher refractory, crystallized grain-boundary phases together with optimization of structure. Recently, a successful realization of these concepts has been reported.[189]

An evaluation of a commercially available MgO-doped material is given in Figure 32.[194] Here, the failure probability resulting from Weibull analysis in the range of linear elastic stress up to 900 °C and probable reasons for positive or negative deviations caused by defect annealing or defect induction is shown. Figure 32 also shows the life expectancy of the material below short-time fracture load. To avoid

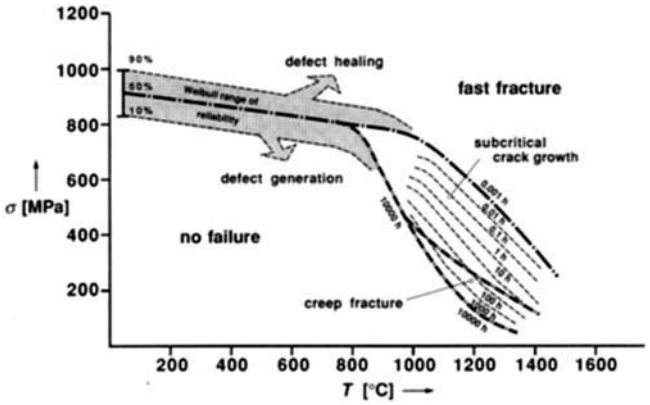

Fig. 32. Fracture strength of hot-pressed, MgO-doped Si_3N_4 as a function of temperature and time [164]. σ = flexural strength.

premature failure at a given temperature, the material should bear only considerably lower mechanical stresses than short-time fracture strengths would indicate.

8.2. Chemical Properties

Owing to the broad possible applications of sintered Si_3N_4, its chemical properties have been investigated with special regard to corrosive behavior.[195–198]

Silicon nitride is inert to numerous molten metals (e.g., Al, Zn, Sn, Pb, Cu, Ag, and Cd); however, in contact with molten transition metals like Fe, Co, Ni, V, and Cr, it reacts readily to form metal silicides and N_2. In contract with molten salts, oxidic slags, and glasses, only slow corrosion occurs. With the exception of hydrofluoric acid, Si_3N_4 ceramics are resistant to mineral acids. Mainly porous Si_3N_4 materials are attacked by hot strong caustic solutions or melts with formation of NH_3.

In the use of engine components made of Si_3N_4 (e.g., valves, turbocharger, gas turbines) the oxidation behavior of sintered Si_3N_4 is especially important. Since Si_3N_4 is coated with a thin protective layer of SiO_2 on heating in air, a good oxidation resistance is shown up to 1400 °C. In high-temperature oxidation two fundamentally different mechanisms of damage are observed.[196]

The first mechanism is based on the diffusion of sintering additives and impurities along grain boundaries owing to the higher oxygen potential at the surface of the material. Reaction with SiO_2 at the surface results in the formation of oxidic glass phases of low viscosity, which induce enhanced corrosion accompanied by N_2 formation. N_2 pores and modification changes of grain-boundary phases leading to different thermal expansion coefficients between glass phase and matrix material induce defects which lower the fracture strength of the material.

A second mechanism will lead to complete destruction if—depending on sintering additives—crystalline phases are formed during sintering, which are readily oxidized with concomitant volume expansion. Internal stress may build up so strongly, that the sintered component is completely destroyed in a short time. This phenomenon has been observed primarily in some ternary Y-Si-O-N and Ce-Si-O-N phases.[199] A suitable selection of sintering additives, the use of high-purity starting powders, and a reduction of additive and oxygen content are important in the development of high-temperature oxidation-resistant sintered Si_3N_4 materials.

9. Summary

Sintered silicon nitride is a promising material for applications in engine construction, mechanical engineering, wear and chemical technology, where high mechanical strength at high temperatures, corrosion and wear resistance, hardness, and low density are desired. Cutting tools, bearings, mill cladding, bearing gaskets, and engine components like valves, valve guides, turbocharger rotors, and gas turbines are prominent examples where this material is already used routinely or where it is being tested as a basic material.

To date, the required high-quality Si_3N_4 powders are commercially produced mainly by direct nitridation, to a lesser extent also by $SiCl_4/NH_3$ liquid-phase reaction (diimide process). Among processes under development, the $SiCl_4/NH_3$ gas-phase reaction seems to offer the best potential to furnish economically high-purity, highly sintering-active Si_3N_4 powders on a large scale.

Chemical and physical characteristics of the starting material, kind and amount of sintering additives, and sintering technique determine material properties. Their interdependence influences structure development as well as the kind and composition of silicate phases formed at grain boundaries.

Crystallization and reduction of the amount of these silicate phases are important to further improve material properties like fracture strength, creep, and corrosion resistance especially at high temperatures.

A flawless manufacturing process from powder synthesis to finished component is required to produce high-quality, reliable ceramic components. Injection molding, as a powder-shaping technology using cheap, high-quality, easily processible Si_3N_4 powders, has a great potential for the large-scale manufacturing of very complex components. Pressureless or low-pressure sintering is of great interest for the low-cost production of near-finished components. The development of economical methods for finishing sintered components of this very hard material is still necessary to decrease the very high finishing costs.

The work on economical methods to produce high-quality Si_3N_4 powders, to improve steadily powder and material

properties, and to manufacture reliably working ceramic components of superior quality should be viewed in its entirety as a necessary requirement for a broad application of silicon nitride advanced ceramics in the future.

Routes to New Aromatic Polycarbonates with Special Material Properties

By Dieter Freitag,* Gerd Fengler, and Leo Morbitzer

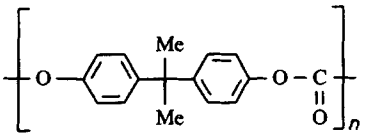
Polycarbonate together with the acrylonitrile/butadiene/styrene copolymers, and the polyamides constitute the leading groups of engineering thermoplastics; for polycarbonate in particular, continued dynamic growth is prophesized.

The underlying reason for this lies not only in its outstanding combination of technical properties and excellent price/performance balance, but also in the chemical and physical potential inherent in the basic structure of polycarbonate. The following review demonstrates with examples how this potential can be used in the development of new polycarbonates through the incorporation of alternative monomers, changes in the linear structure, end group variation, addition of special additives, and blending. The main emphasis of this article lies in the development of polycarbonates resistant to high temperature, with a good balance of technologically valuable properties. For scientific and practical interests a new criterion is offered for polycarbonates having both high-temperatures stability and impact strength.

"One must not only make a discovery, but also realize that a discovery has been made."
Hermann Schnell [1]

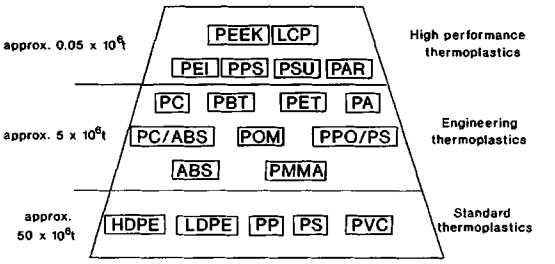
1. Introduction

Polycarbonate **1** from 2,2-bis(4-hydroxyphenyl)propane (Bisphenol A or BPA) has a worldwide consumption of ca. 595000 t (1989), along with the ABS-copolymers (1989 ca. 2000000 t) and polyamides (1989 ca. 800000 t in injection molding and extrusion grades, excluding fibers), forming the leading group of engineering thermoplastics (see Fig. 1). A segmental breakdown of the current polycarbonate market is shown in Table 1.[2] The major production sites are located in the USA, Western Europe, and Japan. The leading producers of polycarbonate are General Electric Corp. and Bayer AG.



1

Due to the inherent chemical and physical potential of the basic structure of polycarbonate, a dynamic growth is still expected (polycarbonate consumption doubled between 1982 and 1988![2]) Polycarbonate has a good chance of surpassing polyamides (injection molding and extrusion grades, excluding fibers). It is predicted that in 1993 the polycarbonate consumption in the USA will be 385000 t, 30000 t higher than polyamide consumption (355000 t).[3] There are primarily three reasons for this outstanding "boost" in polycarbonate consumption (remembering that polycarbonate was first discovered in 1953,[1,4] nearly 20 years after the discovery of polyamides!):



PEEK	Polyetheretherketone	PC/ABS	Polycarbonate/ABS-blend
LCP	Liquid crystalline polyester	POM	Polyoxymethylene
PEI	Polyetherimide	PPO/PS	Polyphenyleneoxide/polystyrene-blend
PPS	Polyphenylensulfide	ABS	Acrylonitrile/butadiene/styrene-copolymers
PSU	Polysulfone	PMMA	Polymethylmethacrylate
PAR	Polyarylate	HDPE	Polyethylene, high density
PC	Polycarbonate	LDPE	Polyethylene, low density
PBT	Polybutylene terephthalate	PP	Polypropylene
PET	Polyethylene terephthalate	PS	Polystyrene
PA	Polyamides	PVC	Polyvinylchloride

a) In comparison to other engineering thermoplastics, polycarbonate possesses an outstanding combination of fundamental properties including transparency (BPA-polycarbonate is normally amorphous, i.e. optically homogeneous to visible light), relatively high temperature resistance (expressed by a glass transition temperature T_g of 150 °C, therefore maintaining its essential properties to near this temperature), outstanding toughness (i.e. high energy absorption capacity during impact), and blending potential (based on miscibility or at least partial miscibility of the polycarbonates with themselves or with various other polymers).
b) Excellent price/performance balance.
c) Technological exploitation of the chemical (structural modification) and physical potential of the polycarbonate structure has been more extensive compared to that of the other engineering thermoplastics, for example through i) incorporation of alternative monomers such as bisphenols (including telechelic phenols), which furnishes homopolycarbonates and both statistical and block copolycarbonates, ii) incorporation of tri- or polyfunctional monomers, which results in branching, iii) incorporation of aromatic dicarboxylic acids or hydroxycarboxylic acids instead of carbonic acid, which affords access to aromatic polyester carbonates, iv) variation of endgroups, v) the addition of special additives, and vi) the preparation of blends.

The following article focuses in particular on topic c), with emphasis on those developments in the polycarbonate field that, besides their scientific and economic importance, can serve as a model for further development of other thermoplastics.

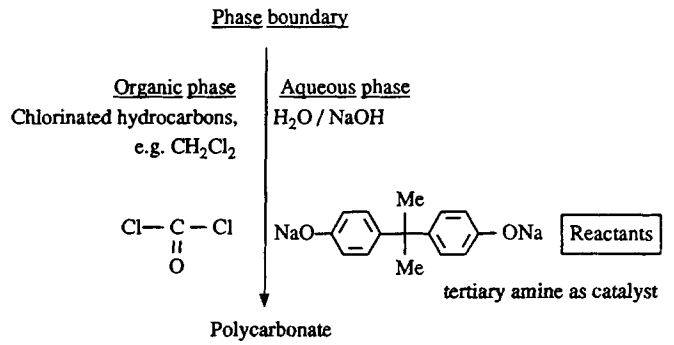
2. New Aspects in the Commercial Production of Aromatic Polycarbonates

Of the various production methods, the interfacial polymerization process is currently employed almost exclusively for the production of polycarbonate (Scheme 1). The catalytic transesterification of diphenyl carbonate with bisphenol A and subsequent removal of phenol in the melt (Scheme 2), as well as the homogeneous polycondensation of bisphenol A with phosgene (pyridine process) have lost their earlier importance (a review of the commercial processes has been published[5]). Recently, the transesterification process in the melt has been given more recognition (laboratory and pilot

Dieter Freitag was born in 1939 in Offenbach, Germany. He studied chemistry at Freiburg and Frankfurt and received his doctoral degree with Professor Ried in Frankfurt. After postdoctoral studies with Professor Ried he joined Bayer AG in 1968 and did basic and polymer research in the Central Research and Development Department. In 1978 he joined the Plastics Business Group with responsibility for research in the field of new Engineering Thermoplastics and was later responsible for the research of all Bayer polycondensates. From 1986 to 1988 he led the development of high-performance engineering thermoplastics, thermosets, films, and additives in the applications department in Leverkusen. Since 1988 he has been director of Plastics Research, and is now head of the Plastics Research and Development Department.

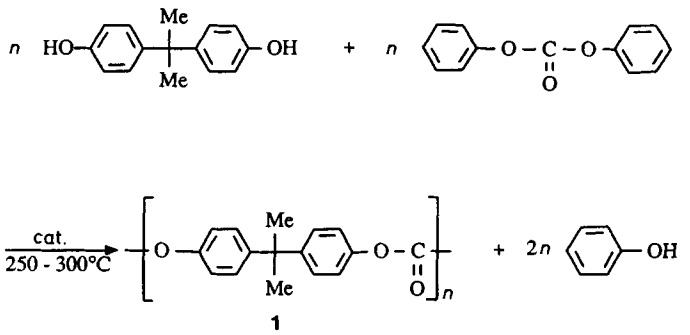
Gerd Fengler, born 1943 in Stapelburg/Harz, studied chemistry in Braunschweig and in Hannover, where he received his doctorate in 1973 under the supervision of Professor E. Winterfeldt (TU Hannover). In 1974 he joined the Central Research Department of Bayer AG in Uerdingen. Since 1987 he has been with the Plastics Business Group, and in 1988 he became a group leader in the Plastics Research Department, which is currently the Plastics Research and Development Department.

Leo Morbitzer, born in 1934, graduated with a doctoral degree in physics at the Justus-Liebig-Universität in Giessen. In 1965 he joined Bayer AG in Leverkusen and was active in different fields of polymer physics. In the Central Research and Development Department he is now leader of a group concerned with the physics of thermoplastic multiphase polymers, theoretical aspects of polymer physics, and computer simulations.



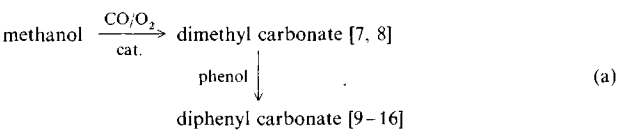
Scheme 1. Industrial manufacture of polycarbonate by interfacial polycondensation (interfacial process).

plant scale). The reason for this concern is on the one hand, the environment: the process requires no solvent such as dichloromethane and involves no waste water; no salt is formed (if the diphenyl carbonate salt-free process[6] is



Scheme 2. Manufacture of polycarbonate by transesterification in the melt. cat. = catalyst.

used); this polycarbonate synthesis is phosgene free (if diphenyl carbonate is prepared phosgene-free e.g. by the reaction sequence (a), which is also salt free).



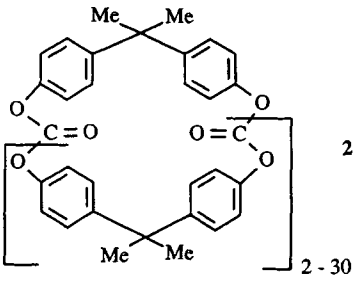
On the other hand not only can the starting materials (diphenyl carbonate, bisphenol A) be prepared in higher purity but also more reactive substituted diphenyl carbonates[17] and new catalyst systems[18-20] have become available; new reactors for high viscosity materials have been described;[21-25] variants of the process (e.g. intermediate isolation of oligocarbonates, crystallization, and subsequent solid-phase polycondensation of the crystallized oligocarbonate[26-28]) have been developed. Due to these innovations, side reactions previously associated with the melt transesterification process (which caused, for example, color problems) can be suppressed.

Variants of the transesterification process have also been described which use dialkyl carbonates (in particular dimethyl or diethyl carbonate)[29-34] instead of diphenyl carbonate. Dimethyl carbonate is currently produced in commercial quantities from CO and methanol using a phosgene-free process.[7, 8] However, the transesterification of dimethyl carbonate with bisphenol A to produce polycarbonate is not as simple as that with phenol to produce diphenyl carbonate, even if the catalysts that are successful in the latter reaction are used.

Semicrystalline polycarbonates, such as those prepared from bis(4-hydroxyphenyl)sulfane and (thermotropic[35-38]) aromatic polyester carbonates (see also Ref.[5]) are normally insoluble in conventional solvents. Therefore the melt transesterification process is the most practical way to produce high molecular weight polymers.

The direct reaction of bisphenols with carbon monoxide by catalysis to produce high molecular weight polycarbonates is still in an experimental stage. The large excess of catalyst (usually Pd compounds) and auxiliary base (sterically hindered tertiary amines) used in this process lead only to relatively low molecular weight polycarbonates ($M_n = 1700$–$11\,000\ g\,mol^{-1}$).[38-41, 43-46] Similar routes as for the coupling of bisphenols with carbon monoxide have also been described for the synthesis of diphenyl carbonate—the starting material in the melt process—from phenol and carbon monoxide.[38-43, 45-52]

An interesting polycarbonate production technique based on earlier studies[53, 54] of the catalyzed ring-opening polymerization of low viscosity cyclic oligocarbonates **2** to high molecular weight polycarbonates ($M_w = 200\,000$–$400\,000\ g \cdot mol^{-1}$) has recently been reported.[55-59] However the synthesis of the oligomers ((pseudo) dilution principle) as well as their processing, which is somewhat similar to reaction injection molding (RIM) is not yet commercially feasible.



The use of this technique has in particular been proposed for the production of composites by polymerization of a mixture of cyclic oligomers and fillers such as glass or carbon fibers (prepregs). It is doubtful, however, whether polycarbonate will be a suitable matrix resin for composites, owing to its limited hydrolytic stability and—for this purpose—relatively low glass transition temperature (see also Refs.[60, 61]).

3. Modification of the Polycarbonate Structure

3.1. Homopolycarbonates and Copolycarbonates from Bisphenol A Derivatives and BPA-Copolycarbonates

In the course of polycarbonate research, numerous examples have been prepared from monomers of the bisphenol type. The driving force of these efforts was, on the one hand,

to overcome some of the inadequacies of BPA-polycarbonate (hydrolytic instability to bases, stress cracking on contact with many organic solvents); on the other hand, many of these efforts were directed at improving the properties of BPA-polycarbonate still further, and have in particular focused on raising its temperature resistance (expressed by T_g). However, temperature resistance can only be improved within certain limits if transparency, impact strength, melt flow, hydrolytic stability, and finally production costs are not to deviate too far from standard polycarbonate.

Of particular interest in this area are polycarbonates based on (substituted) alkylidene- and cycloalkylidene-bisphenols, and bisphenols containing cycloaliphatic ring systems. Tables 2 and 3 show the dependence of the T_g of some polycarbonates on the structure of the corresponding bisphenols (for a more detailed study see Ref.[5]). It is obvious that the main problem is not related to T_g, but in satisfying the other above-mentioned property limitations.

Table 2. Glass transition temperatures of polycarbonates from *o,o',o'',o'''*-tetrasubstituted bisphenols in comparison to polycarbonates from unsubstituted bisphenols.

Polycarbonate from HO–R–OH			Polycarbonate from		
R	T_g [°C]	Ref.	R'	T_g [°C]	Ref.
CH_2	147	[1,62–64]	Me	185	[66–68]
$C'Me_2$	149	[1,62–65]	Me	203	[66]
			Cl	230	[1,62–64,69,70]
			Br	265	[1,62–64,69,70]
Cyclohexylidene	179	[1,62–64]	Me	213	[66]
			Cl	290	[65]

Two especially informative developments (structural variations of BPA-polycarbonate) should help to demonstrate the underlying factors governing T_g and temperature resistance of polymers.

The temperature resistance of semicrystalline polymers is determined by the degree of crystallinity, crystal morphology, and by the magnitude of the melting point. With amorphous polymers such as the polycarbonates described here, the glass-transition temperature plays a decisive role in their temperature resistance. Only in the melt state (T_m) can the thermodynamic relationship described by the Gibbs–Helmholtz equation (b) have any physicochemical meaning. ΔH_m refers to the melt enthalpy and ΔS_m is the melt entropy. The magnitude of ΔS becomes smaller with increasing chain rigidity. Rigid chain polymers generally melt at higher temperatures.

$$T_m = \frac{\Delta H_m}{\Delta S_m} \qquad \text{(b)}$$

Unfortunately there is no thermodynamic equivalent in the sense of relationship (b) for the glass transition temperature, because the glass transition is a dynamic relaxation process. However, for many polymers, including polycarbonates, the empirical relationship $T_g \sim 2/3\ T_m$ holds. Polymers with increased chain rigidity or decreased chain mobility show, in general, a higher T_g than polymers with flexible chains. From earlier as well as on-going research, two developmental routes to polycarbonates with lower chain mobility and consequently higher temperature resistance (expressed as T_g) have been pursued:

- incorporation of 3,3′5,5′-tetramethyl bisphenol A (TMBPA) instead of bisphenol A
- full or partial substitution of BPA by a bisphenol based on hydrogenated isophorone (bisphenol TMC)

The replacement of BPA by TMBPA results in a polycarbonate, **3**, (space-filling model shown in Fig. 2) with a higher T_g (203 °C).[66] The reason for this increase in T_g (+ 53 °C higher than BPA-polycarbonate) is due to the hindered rotation about the phenyl–carbonate bond combined with the increased mass and volume of the monomer unit.

3

This polymer additionally exhibits a low melt viscosity (advantageous for processing!) and better stability towards hydrolysis. A severe disadvantage is, in addition to higher production costs, the loss in impact strength. It shows a brittle break behavior with low energy absorption capacity. These are the aspects that foil any large commercial success of TMBPA-polycarbonate.

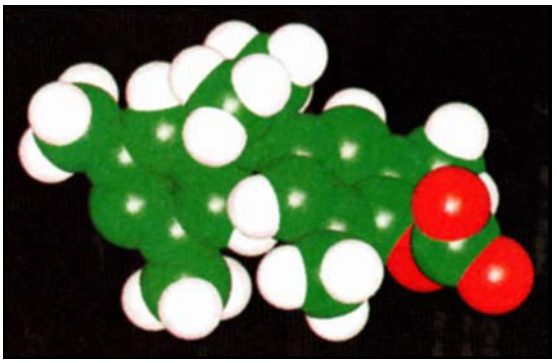

Fig. 2. Space-filling model of a unit of TMBPA-polycarbonate **3**.

How can this dramatic reduction in impact be explained? The modulus/temperature dependance of BPA- and TMBPA-polycarbonate as determined by dynamic mechanical analysis makes it possible to gain insights into the segmental motions of polymer chains. These segmental motions, which exist far below the glass transition, are the essential factors affecting the temperature-dependent polymer-relaxation processes in the solid state and are also responsible for possible macroscopic deformation under stress and consequently for the energy absorption capacity. It emerges (Fig. 3) that the replacement of BPA with TMBPA in polycarbonate not only raises the T_g to 203 °C, but also shifts the γ-relaxation maximum from −105 °C (BPA-polycarbonate) to +45 °C

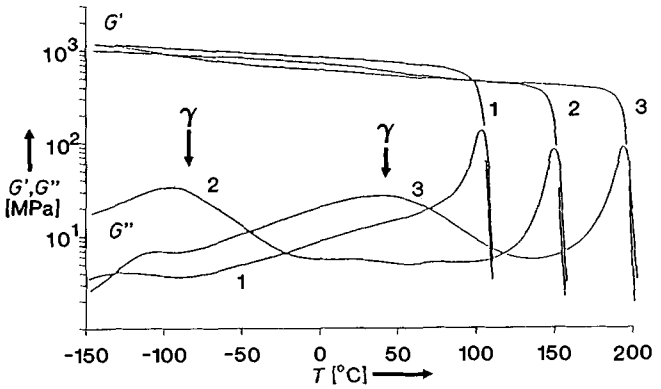

Fig. 3. Comparison of the modulus-temperature relationships of polystyrene (1), BPA-polycarbonate **1** (2), and TMBPA-polycarbonate **3** (3). G' = storage modulus, G'' = loss modulus.

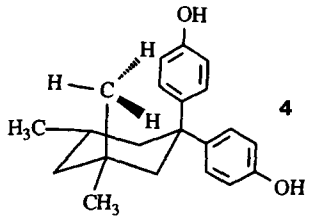
(TMBPA-polycarbonate). Both effects are caused by steric hindrance exerted by the methyl groups which results in reduced rotational freedom of the phenyl–carbonate bond. It should be emphasized that the temperature shift in the γ-relaxation maximum is substantially larger than that for the glass transition. The decreased impact strength of TMBPA-polycarbonate can then be interpreted as a consequence of the shift in the γ-relaxation maximum (for a more detailed discussion see Ref.[81]).

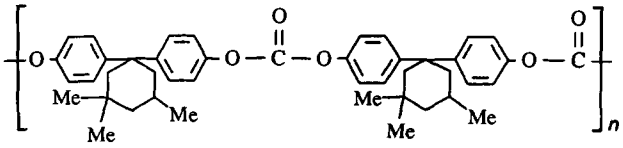
These findings provide an important *new criterion* for the development of high temperature resistance, and at the same time sufficiently impact-resistant polycarbonates. The ratio of the glass transition temperature T_g to the temperature of the maximum of the γ-relaxation T_γ (in Kelvin, determined at 1 Hz) must be equal to or greater than the value of 2.52 determined for BPA-polycarbonate. By comparison T_g/T_γ for TMBPA-polycarbonate is 1.5, significantly lower than that for BPA-polycarbonate, i.e. a technologically valuable polycarbonate with high T_g must have a sufficiently low T_γ.

The comparison of such T_g/T_γ ratios for different polycarbonates assumes that the γ-relaxation intensities are similar. In addition T_g/T_γ is not a direct measure of impact strength because impact behavior is also influenced by other factors and occurs in the nonlinear deformation region.



4

A real breakthrough in the solution to this problem (high T_g *and* good impact) was made in 1989 by the introduction of new (co)polycarbonates based on a bisphenol from hydrogenated isophorone (= bisphenol TMC) **4**.[82] The homopolycarbonate **5** (space-filling model shown in Fig. 4) ob-



5

tained from **4** has a T_g of 239 °C and T_g/T_γ ratio of 3.1! The significance of this extremely high value can be seen in Table 4 when it is compared to other polycarbonates. How can such a high value of T_g/T_γ be explained? It can be assumed that the restriction in molecular mobility is due to the following additive effects (see the three-dimensional formula of **4**): a) restriction in the conformational mobility of the cyclohexane ring, and b) hindered rotational mobility of a phenyl ring through 1,3-diaxial interactions.

Since the mobility of the carbonate group is not affected ($T_\gamma = -108$ °C!), the polymer retains good impact strength. The T_γ of the bisphenol-TMC-polycarbonate is, in compari-

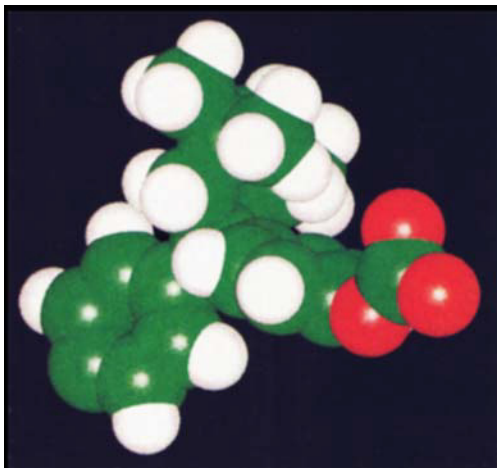


Fig. 4. Space-filling model of a unit of bisphenol-TMC-polycarbonate **5**.

Table 4. Comparison of the glass transition temperature and the temperature of the γ-relaxation maximum of bisphenol-TMC-polycarbonate with those of other polycarbonates and those of an aromatic polyester (based on BPA).

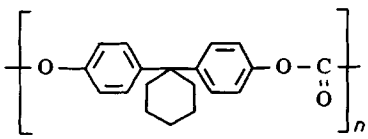
[a] Temperatures in Kelvin.

son to the value of bisphenol-Z-polycarbonate, **6**, surprisingly low. A more detailed study and explanation of this effect will be published later.



6

Bisphenol-TMC-polycarbonate can be produced in the same way as bisphenol-A-polycarbonate by the same interfacial polymerization process (from **4** and phosgene). Because the phenolic hydroxy groups of bisphenol-TMC have comparable reactivity with those of BPA, copolycarbonates in practically every ratio can be produced. In this way it is possible, depending on the comonomer ratio, to obtain copolycarbonates with T_g's between 150 °C and 239 °C.

The dependence of the glass transition temperature on the comonomer ratio is reflected quite well in the empirical Fox relationship $1/T_g = (C_1/T_{g1}) + (C_2/T_{g2})$ where T_{g1} and T_{g2} are the glass transition temperatures of the corresponding homopolymers, and C_1 and C_2 are the weight fractions of the corresponding bisphenols in the copolymer.

These copolycarbonates can be used as important vehicles in the study of molecular dynamics, particularly in studying low-temperature relaxation phenomena. As was previously mentioned, the maxima of the γ-relaxation for BPA- and TMBPA-polycarbonate are −105 °C and 45 °C respectively. To a first approximation, the positions of these maxima remain constant, independent of copolymer composition—only the peak intensities vary. New relaxation peaks of low intensity can be observed between the two γ-relaxation maxima. By systematic variation of the molecular structure of such polycarbonates it is possible to gain an insight into the length of those segments which are responsible for the low-temperature relaxation processes. Unfortunately the literature does not provide a complete picture of this situation.

BPA- and bisphenol-TMC-copolycarbonates show practically no impact problems while BPA/TMBPA copolycarbonates have serious deficiencies in impact strength. The main reason for these differences, as has already been mentioned, is that the γ-relaxation maxima of BPA- and BPTMC-polycarbonates are practically identical, while the γ-relaxation maximum for TMBPA-polycarbonate is shifted to a significantly higher temperature. Tables 5 and 6 show the basic properties of bisphenol-TMC-copolycarbonates in comparison to those of BPA-polycarbonate and other high-temperature-resistant amorphous thermoplastics.

While bisphenol-TMC-copolycarbonates have thermal stabilities comparable to those of aromatic polyester carbonates, their lower melt viscosity allows for better processibility. This processing advantage (due to lower melt viscosity) of bisphenol-TMC homo- and copolycarbonates as compared to other amorphous thermoplastics with similar temperature resistance can also be seen in Tables 5 and 6.

Table 5. Bisphenol-TMC-copolycarbonates in comparison to aromatic polyester carbonates and to bisphenol-A-polycarbonate.

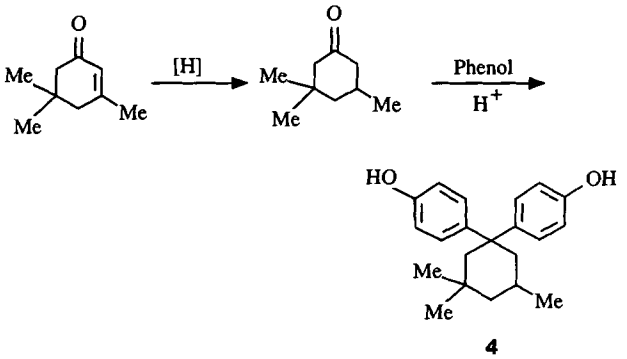
These findings, high T_g and good impact strength combined with good melt flow, has not yet been obtained with any other aromatic polycarbonate. Another advantage of bisphenol-TMC-polycarbonates is their UV-stability, which is close to that of standard polycarbonate. Short term exposure of bisphenol-TMC-homopolycarbonate to temperatures of up to 400 °C (in air) results in only minimal discoloration. There is also a significant drop in the melt viscosity between 360 °C and 395 °C which can be used to increase product output (see Table 7).

Table 7. Melt viscosities [Pa s] at different shearing rates and temperatures.

	360 °C		395 °C	
Shear rate [s^{-1}]	100	1000	100	1000
BPA-polycarbonate **1** (η_{rel} = 1.32) [a]	139	116	91	83
Polyester carbonate from 50 wt % BPA-carbonate and 50 wt % bisphenol A-iso-/terephthalate (1/1), (η_{rel} = 1.30) [a]	256	261	131	111
Polyester carbonate from 20 wt % BPA -carbonate and 80 wt % bisphenol A-iso/terephthalate (1/1) (η_{rel} = 1.30) [a]	831	643	300	267
Bisphenol-TMC-polycarbonate **5** (η_{rel} = 1.296) [a]	1385	921	275	212

[a] η_{rel} = solution viscosity.

The starting materials are available in commercial quantities, and this together with the outstanding basic properties of these polycarbonates helps in commercializing the final products. The polymer precursor, bisphenol-TMC **4**, is produced in yields greater than 80 % by hydrogenation of isophorone and subsequent condensation of the resulting dihydroisophorone with phenol (Scheme 3).



4

Scheme 3. Synthesis of **4** from isophorone.

To conclude this section some homo- or copolycarbonates will be described which can either supplement the inherent weaknesses of BPA-polycarbonate, or exhibit new properties such as liquid crystalline behavior (for a more detailed review see Ref.[5]).

a) Copolycarbonates of bisphenol A and tetrabromobisphenol A are of commercial importance. A small mol % of the comonomer enhances the flame resistance while having little effect on the standard property characteristics of BPA-polycarbonate (V 0/3.2 mm under UL 94 for transparent grades).

b) Polycarbonates with lower or zero birefringence are required for laser-optical data storage systems. One approach is to choose bisphenols which have built-in compensation of their birefringent components. The relatively high birefringence of BPA-polycarbonate can be attributed to the alignement of the phenyl rings "in series". Polycarbonates with low birefringence can be obtained from bisphenols containing bulky, polarizable side groups such as bisphenol AP (from acetophenone and phenol).[83, 83a] (For a review on "Polycarbonate and Light", see Ref.[83a]). An intramolecular compensation of birefringent components is also possible if both phenyl rings of the bisphenol are fixed perpendicular to each other via a spirocenter. An example of this type of structure is found for 6,6′-dihydroxy-3,3,3′,3′-tetramethyl-1,1-spiro(bisindane)polycarbonate.[80] The homopolymer is virtually birefringence-free, while the birefringence of the copolycarbonate with bisphenol A is dependent on the spiro(bisindane) content.

c) Fully aromatic copolycarbonates obtained by incorporation of at least 25 mol % 4,4′-dihydroxydiphenyl (based on the total bisphenol content) in combination with other bisphenols such as 4,4′-dihydroxydiphenyl ether surprisingly show thermotropic behavior.[84]

3.2. Block Copolycarbonates

By incorporating chemically different segments—for example flexible, hydrophilic, or hydrophobic blocks—in the polymer chain, it is possible to modify the property profile of polycarbonates (see also Ref.[5]). These segmented polycarbonates are preferably made as tri-block A–B–A, or multiblock ($(A\text{-}B)_n$) systems.

The synthesis of block copolycarbonates is best carried out in a homogeneous phase using inert solvents, or by interfacial polycondensation through the use of preformed mono- or bifunctional oligomers. By coupling equimolar amounts of bifunctional, reactive prepolymers, e.g. hydroxyl-terminated oligomers, and chloroformate-terminated oligomers, it is possible to obtain block copolycarbonates with an exact alternating sequence. On the other hand, the phosgenation of several hydroxyl-terminated species (bisphenols, oligomers) results in a nonuniform, more or less statistical arrangement. A completely random structure is only obtained when the hydroxyl-terminated components have the same reactivity toward phosgene. When the components differ in reactivity, fairly long sequences of the same structure are formed. The phosgenation of bisphenols of different acidities gives a block structure.[85]

3.2.1. Aromatic Poly(carbonate-cocarbonates)

These block copolymers are prepared by a two-stage interfacial process.[86, 87] Bisphenols used in this manner along with BPA include TMBPA,[88] 3,3′,5,5′-tetrabromobisphenol A, and 3,3′,5,5′-tetrachlorobisphenol A.[89, 90] These block copolymers have higher softening temperatures than the corresponding statistical copolymers.[89]

3.2.2. *Aromatic-Aliphatic Poly(carbonate-cocarbonates)*

For the preparation of mixed aromatic-aliphatic polycarbonates by the interfacial method, aliphatic hydroxyl groups have to be first converted into more reactive terminal groups (see also 3.2.3).

3.2.3. *Poly(ether-cocarbonates)*

The synthesis of poly(ether-cocarbonates) from poly(oxyethylene) glycol or poly(oxytetramethylene) glycol can be achieved using the corresponding bischlorocarbonates.[91] Under special conditions, the poly(ether)diols may also be incorporated directly by the interfacial method.[92] Through the incorporation of 20–30 wt. % of polyether blocks in BPA-polycarbonate as soft segments, a thermoplastic elastomer is obtained which is characterized by a remarkable combination of high strength and elastic recovery.[93, 94]

These block copolymers have been developed for use as oil-resistant elastomers and biocompatible membrane materials. The polar hydrophilic character of the flexible polyether segments is exploited in the separation of polar from nonpolar gases, microfiltration, ultrafiltration, electrophoresis, dialysis (blood purification), and reverse osmosis (desalination of seawater). The permeation properties are better than those of cellulose hydrate membranes.[5]

3.2.4. *Poly(ester-cocarbonates) with Aliphatic Polyester Segments*

These block copolymers, which, for example, contain dimeric acid[*]/hexanediol polyesters as soft segment, can be synthesized by interfacial polycondensation. Polycarbonate elastomers with a high content of dimeric fatty acid ester soft segments are expecially suitable as packaging materials for biological fluids. Block copolycarbonates containing less than 10 wt % dimeric acid, in comparison with the corresponding homopolycarbonate, have better low-temperature impact strength, better mold release properties, and higher stress-crack resistance to organic solvents.[95]

3.2.5. *Poly(siloxane-cocarbonates)*

Polysiloxane cocarbonates, in particular those based on polydimethylsiloxane and bisphenol A, count among the most investigated block copolymers. They are synthesized by cophosgenation of BPA with suitably terminated siloxane oligomers.

Exact alternating poly(siloxane-cocarbonates) of this type can be obtained by reaction of hydroxy-terminated oligocarbonates either with chlorine-terminated polysiloxanes in the presence of tertiary amines, or with dimethylamino-terminated polysiloxanes with elimination of dimethylamine by thermal cleavage.[87, 96–100] By suitable variation of stoichiometry or block lengths, it is possible to produce a wide variety of polymers representing the whole range of hardness and deformation, i.e. from an elastomer-modified thermoplastic to a thermoplastic elastomer. Their mechanical and optical properties are due to their two-phase nature caused by the formation of domains of different size and structure (microphase separation). Block copolymers with low polysiloxane content have outstanding low-temperature impact strength, while block copolycarbonates with a high polysiloxane content act as thermoplastic elastomers. In the latter case the dispersed polycarbonate domains can be thougth of as physical cross-links which allow the polysiloxane matrix to have a high elastic recovery across a broad temperature range.[101–104]

3.3. The Incorporation of Tri- or Higher Functional Monomers

In the melt, linear bisphenol A-polycarbonate exhibits Newtonian flow behavior up to high shear rates, i.e. the viscosity is nearly independent of shear rate. The incorporation of small amounts of tri- or multifunctional monomers gives branched polycarbonates exhibiting structural viscosity, i.e. non-Newtonian flow behavior (Fig. 5).

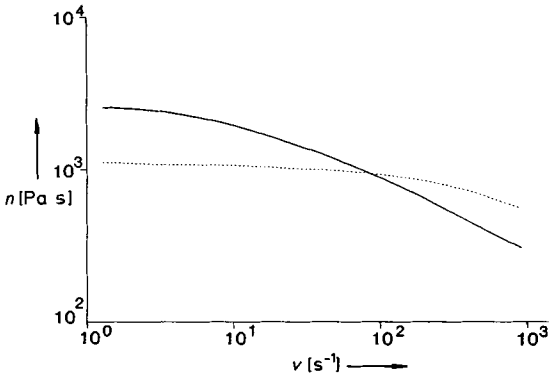


Fig. 5. Dependence of the melt viscosity η of linear (– – –) and branched (——) polycarbonates on shear rate ν at 300 °C.

From a commercial point view this means that branched polycarbonates are well suited for extrusion applications due to their high melt strength. In addition to the thermal stability of the branched junctions, the functional groups of the branching agent should have the same reactivity during the polymerization; 1,4-bis(4,4'-dihydroxytriphenylmethyl)benzene fulfills these conditions.[105] However nitrogen-containing branching agents have been described such as 3,3-bis(4-hydroxyphenol)-2-oxo-2,3-dihydroindole,[106] whose third functional group reacts after the branching agent has been incorporated into the polymer chain (→ long chain branching).

Branched BPA-polycarbonates are used primarily in the production of twin wall sheets, which is one of the largest growth areas for polycarbonate.[2] Twin wall sheets exhibit the following characteristics: excellent insulation, easy handling, high rigidity combined with good impact strength. In addition they are lightweight materials.

[*] Dimeric acids are dicarboxylic acids containing at least two side chains and one double bond which are obtained by dimerization of unsaturated fatty acids.

As a result, twin wall sheets can be used in applications such as glazing greenhouses, industrial windows, and dome construction. This effective control of melt viscosity behavior in BPA-polycarbonates has stimulated further, similar investigations on other industrial thermoplastics such as polyamides.

3.4. Modification of BPA-polycarbonate by Acid Moieties

Another way to improve the temperature resistance of BPA polycarbonate is through the incorporation of rigid aromatic ester units from terephthalic or isophthalic acid and BPA. The higher glass-transition temperatures of these polymers are due to the amount as well as the increased lengths of these rigid molecular units, i.e. the persistence length (Fig. 6). Even so, there is no severe restriction in the

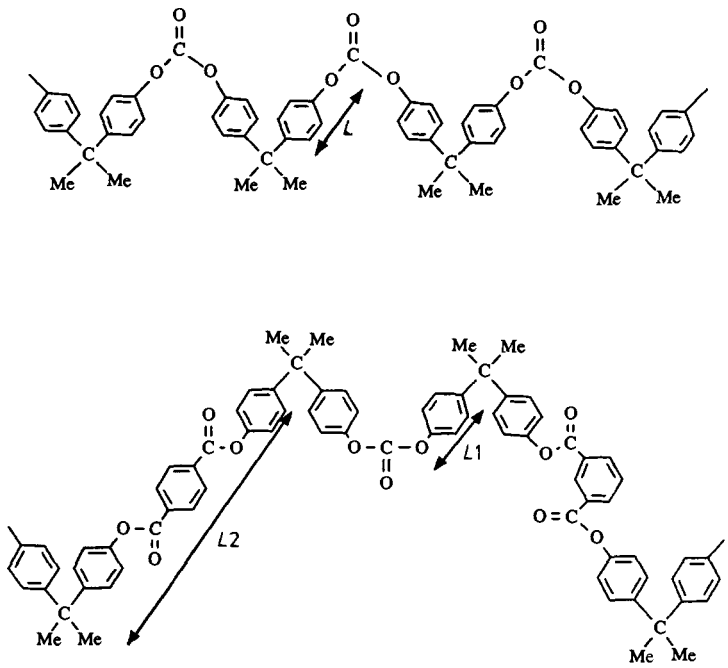

Fig. 6. Differences in the persistence lengths L in polycarbonates and aromatic polyester carbonates.

mobility of the carbonate group in aromatic polyester carbonates, as is observed in TMBPA-polycarbonate. Therefore these copolycarbonates have impact strengths similar to BPA-polycarbonate. Unfortunately, due to a stronger "physical cross-linking" effect (caused by higher entanglement density, see Ref.[81, 107–109]), aromatic polyester carbonates have higher melt viscosities than BPA-polycarbonate, which results in processing difficulties, particularly in molds containing long thin flow paths (see Tables 5–7).

Despite the higher melt viscosity, Bayer, General Electric, and Unitika (Japan) have commercialized aromatic polyester carbonates with glass-transition temperatures, depending on the aromatic ester content, of between 150 °C and approx. 190 °C. These materials have found typical applications in the electrical, electronic, lighting, automobile, and medical sectors, and in household appliances.

In nearly all of these market applications high temperature resistance, transparency, and impact strength are prerequisite.

This general concept of the incorporation of rigid units is currently being used also in the polyamide field (new aromatic-aliphatic polyamides from BASF, Ultramid T®, and Amoco, Amodel®).

Other polycarbonate modifications have been described in the literature such as partial replacement of the carbonate group by phosphonate groups thereby producing aromatic polyphosphonatocarbonates. These thermoplastic materials are inherently flame resistant and halogen-free,[5] however they are not commercially used because more effective alternatives for polycarbonate exist (see Section 5).

4. End-Group Variation

Typically, linear bisphenol A-polycarbonates of commercial significance have a molecular weight of ca. $M_w = 22000$ to $M_w = 35000\ g\,mol^{-1}$. The melt viscosity of these polycarbonates is relatively high, which means that the production of intricate molded parts, such as digital audio compact disks, is difficult.

In order to regulate the molecular weight and control the melt viscosity, phenol or *tert*-butylphenol are used as typical end groups. A reduction of the molecular weight to less than $M_w = 22000\ g\,mol^{-1}$ and a subsequent reduction in the melt viscosity, which is needed for compact disk production, is not possible without a corresponding loss in mechanical properties, particularly impact strength, when using the above-mentioned end groups.

The use of *p*-alkylphenols with branched alkyl groups containing eight or nine carbon atoms results in extremely high melt flow polycarbonates with a molecular weight of approx. $M_w = 18000\ g\,mol^{-1}$, which for all practical purposes have sufficient impact strength.[110] The improvement in toughness can be attributed to an additional relaxation process on the high-temperature shoulder of the γ-relaxation maximum.

These polycarbonates flow easily and uniformly, resulting in minimal entropy-elastic strain frozen into the material, and consequently lower optical birefringence. The relationship between mechanical properties, melt flow index (MFI),

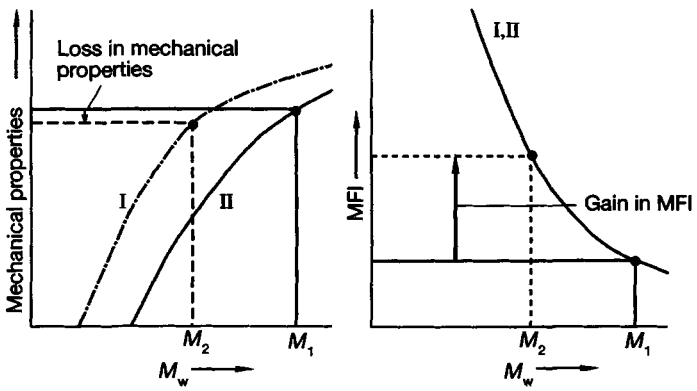

Fig. 7. Relationships between the general mechanical properties, the melt flow index MFI, and the molecular weight M_w for a CD-type (I) and standard polycarbonate (II).

and molecular weight for end-group-modified polycarbonate is shown in Figure 7.

Polycarbonates with branched long-chain *p*-alkylphenyl end groups are advantageous in the production of high-quality compact disks. Due to the lower optical birefringence of these disks the stored digital information can be read accurately by laser-optics. The digital information is precisely stored in cavities, the so-called pits, on the polycarbonate surface, which have a depth of approx. one quarter of the wavelength of the incident laser light (Fig. 8).

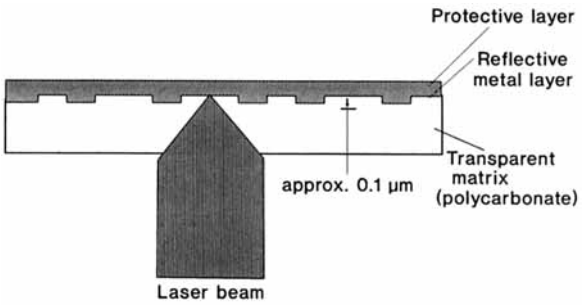

Fig. 8. Schematic model of a music-CD.

The cycle-time for producing a CD, a measure of productivity, which in 1984 was between 15 and 20 seconds, had in 1990 been reduced to approx. seven seconds. Accordingly, the recording industry has been revolutionized, replacing the PVC long-play disks by compact disks. Over 1.15 billion compact disks were produced in 1990 from approx. 23000 t polycarbonate.[2]

5. Property Modifications by Additives

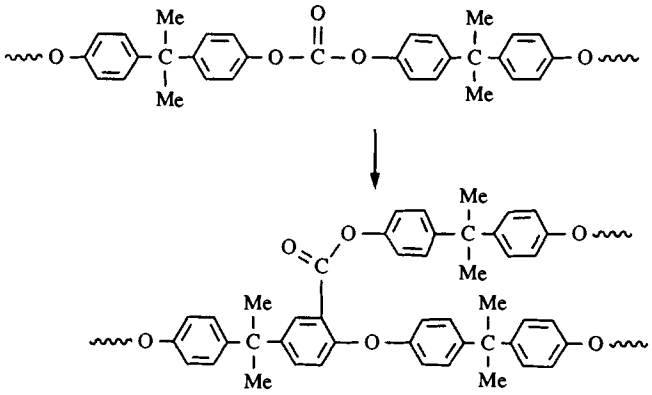
Since the field of additives is so broad (for a comprehensive review see Ref.[5]), only flame retardant additives will be discussed here. The inherent flame resistance of BPA-polycarbonate (oxygen-index 26), as opposed to other engineering thermoplastics, is satisfactory enough for many applications.

The first generation of flame retardant additives for engineering thermoplastics were based on aromatic halogen compounds. For polycarbonate, tetrabromobisphenol-A-oligocarbonate is added either as an additive or directly as a copolycarbonate based on bisphenol A and tetrabromobisphenol A. This type of flame retardant technology has the disadvantage of producing hydrogen bromide (as well as other degradation products), which causes corrosion and introduces toxicity problems.

The second generation of flame retardant additives for polycarbonate employs additives free of chlorine and bromine, and the underlying principle may also be a key in solving the flame retardancy problems in other thermoplastics. In this technique, specific alkali salts of sulfonic acids and in particular the salts of perfluoroalkyl sulfonic acids[111] are used.

As little as 0.1 wt. % of such an additive is required for flame retardancy, which is low enough for the polycarbonate to remain transparent and to retain its mechanical properties.

The mechanism of flame retardancy by these additives is based on a Fries rearrangement of the aryl carbonate group, which results in the branching or cross-linking of the polycarbonate matrix at flame temperatures (see Scheme 4).[112, 113]



Scheme 4. The Fries rearrangement responsible for the flame-retarding action of alkali-metal sulfonates.

By this process, the melt behind the flame front is stabilized against burning drips, and also aids in the formation of a carbon protective layer. This flame retardancy effect can be improved by starting with branched, and therefore structurally viscous, polycarbonate.

6. Polycarbonate blends

Within the family of polycarbonates many interesting miscibility effects can be found (see also Ref.[5]).[114-116]

Miscibility is observed over the entire compositional range for the following binary systems: polycarbonates of TMBPA and BPA, TMBPA and bisphenol Z, TMBPA and bisphenol TMC, and BPA and bisphenol Z.

TMBPA-polycarbonate has in this respect the nature of a quasi-universal blending partner in producing single phase systems. This behavior is probably due to a steric shielding effect of the four methyl groups, which limits the interactions of parts of the TMBPA-polycarbonate molecules. This can be supported by the low cohesive energy-density of TMBPA-polycarbonate as compared to other polycarbonates.

Blends of BPA-polycarbonate and TMBPA-polycarbonates show, across the entire temperature spectrum, a similar relaxation behavior to the corresponding copolycarbonates: For both blend partners the typical γ-relaxation peaks vary in intensity with composition but the position of the γ-relaxation maxima remains constant. This suggests that the local segmental mobilities responsible for the γ-relaxation behavior are mainly of an intramolecular nature.

Two-phase systems with low partial miscibility are found for example, in the case of BPA-PC/BPTMC-PC blends. Blends from BPA- or BPTMC-polycarbonates and BPA/BPTMC-copolycarbonates with appropriate compositions are fully miscible, i.e. single-phase systems. These examples reflect the broad variability in structure/property relationships of blends in the "polycarbonate family."

Blends from polycarbonates and vinyl thermoplastics are also important from both a scientific as well as a commercial point of view. Table 8 shows some selected examples. Of these systems two have acquired special commercial importance: BPA-PC/SAN and BPA-PC/PBT (or BPA-PC/PET).

Table 8. Examples of blends from polycarbonates and vinyl thermoplastics.

Blend [a]	Remarks on miscibility (see also Ref. [115,116]) [b]
BPA-PC/PS	Two phases with marginal miscibility
BPA-PC/SAN 28 [c]	Two phases with increased partial miscibility
BPA-PC/PMMA	Two phases with significant partial miscibility, LCST [d] of approx. 180 °C
TMBPA-PC/PS	Complete miscibility with LCST [d] of approx. 240 °C [117]
TMBPA-PC/SAN	Extent of miscibility is controlled by the acrylonitrile content of the SAN blend partner
TMBPA-PC/SMA	Extent of miscibility is controlled by the maleic anhydride content of the SMA blend partner [e]
BPA-PC/PBT	Complete miscibility possible. The degree of miscibility is extremely dependent on the thermomechanical history of the blend. The degree of phase separation is driven by the ability of the PBT component to crystallize as well as by the degree of transesterification.
BPA-PC/PET	Not completely miscible as for BPA-PC/PBT
BPA-PC/poly-(ε-caprolactone)	Completely miscible as with many other aliphatic polyester

[a] For meaning of abbreviations see Figure 1; SAN = styrene/acrylonitrile copolymer, SMA = styrene/maleic anhydride copolymer. [b] According to typical compounding procedures followed by immediate quenching. [c] SAN with 28 wt% acrylonitrile. [d] LCST = Lower Critical Solution Temperature.

Both systems generally require the addition of an impact modifier, (for example, certain elastomers, from graft copolymers) to guarantee sufficient toughness, particularly in the low-temperature region, thus producing ternary or even quaternary systems of extreme complexity. Besides the partial miscibility of the blend components, which is required for their phase coupling, the deformation modes of the system are also dependent on the deformation mechanisms of the blend partners, (such as PC and SAN), as well as on the morphological architecture of the blend as a whole. In these blends, the polycarbonate component determines the character of the respective multi-phase systems.

6.1. Polycarbonate/ABS blends

Since their introduction in 1967, there has been a dramatic growth in the market volume of PC/ABS blends; in Western Europe, USA, and Japan it reached 29000 t by 1986. In 1996 the consumption of these blends is expected to reach 100000 t with a yearly growth of 12–13%, an overproportionate growth compared to even polycarbonate. The reason for this success is a better cost/performance balance. PC/ABS blends have found application in the automobile industry and in the electrical engineering and electronics sectors.

The outstanding characteristic of PC/ABS blends is their synergistic improvement of the notched impact strength at low temperature (Fig. 9). The aforementioned partial miscibility between BPA-polycarbonate and SAN is the main reason for this effect.[118]

Flame retardant PC/ABS blends are becoming more important (particularly those flame retardant grades which are chlorine- and bromine-free, which set the trend for the future). In these systems, flame retardancy is achieved through the combination of organic phosphates and finely dispersed polytetrafluoroethylene. This technology can serve as a model for the development of other flame retardant technical thermoplastics.

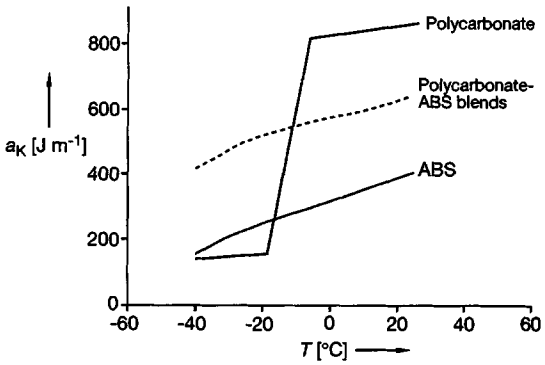


Fig. 9. Ductile–brittle transition of polycarbonate, ABS copolymers and polycarbonate-ABS blends (a_k = notched impact strength).

6.2. Polycarbonate-Polyester blends

The second most important class polycarbonate blends are the elastomer-modified polycarbonate/polyester blends, whose market volume in 1986 had reached 30000 t worldwide only six years after their introduction. In 1991 a market volume of approx. 70000 t is predicted.

This extraordinary growth can mainly be attributed to a combination of good temperature resistance, high toughness, and stress-crack resistance which are prerequisites for exterior applications in the automobile industry. These blends can be tailor-made for specific applications. For example, a blend from polycarbonate, polyethylene terephthalate, and an elastomer modifier has been developed for online paintable bumpers, which are stable towards benzene and can withstand an impact of up to 8 km h^{-1} down to −20 °C without irreversible deformation.

7. Outlook

The chemical and physical potential of the polycarbonate structure has by no means been exhausted, despite extensive application of fundamental polymer principles, as has been described in this article. On the contrary, new theoretical approaches are constantly being developed, such as computer simulation of the solid state (static as well as dynamic), which are more advanced for polycarbonates than for other engineering thermoplastics (see Ref.[120–122]). Through these methods, new insights into the microstructure of polycarbonates will be obtained which will act as guidelines for future chemical and technical developments.

Glycolipids as Immunomodulators: Syntheses and Properties

By Oswald Lockhoff*

Dedicated to Professor Karl Heinz Büchel on the occasion of his 60th birthday

Although the most successful vaccines still consist of attenuated or killed pathogens, it is evident that genetic engineering will eventually provide pure antigens in sufficient quantities. To achieve a protective effect, however, the immune response to these structures, which are only weakly immunogenic, must be activated by adjuvants. The discovery of chemically defined, well-tolerated, synthetic adjuvants is therefore especially important in effective immunoprophylaxis. A very promising class of compounds in this respect are synthetic glycosylamides, with two long alkyl chains consisting of alkylamines and fatty acids. Unlike natural glycolipids, which exert an immunosuppressive effect, the new glycolipid analogues described here show marked immunostimulation. In vaccination experiments with various antigens they provide efficient protection. Their mode of action, which differs from that of known adjuvants, makes glycolipid analogues particularly interesting for immunization of patients with defective T lymphocyte function, for example AIDS patients.

1. Introduction

One of the vital tasks of the mammalian immune system is to provide protection against infectious diseases. This is achieved by a network of interactions of various lymphoid cells (B and T lymphocytes) and phagocytic cells (monocytes, macrophages, granulocytes) through the formation and release of a number of activation, growth, and differentiation factors (interleukin I, interleukin II, tumour necrosis factor). Thus pathogens are selectively neutralized and eliminated, and the body itself remains unharmed.[1] Normally the immune system performs this task extremely well. In some cases, however, it is advisable to modulate the immune system pharmacologically, either by immunostimulation or by immunosuppression. Specific immunostimulation—enhancement of the immune response to specific exogenous structural elements (antigens)—is the aim of vaccination. Besides this there is now increasing interest in nonspecific immunostimulation, which uses a broad, nonantigen-dependent stimulus to elicit a more fundamental defensive response. The vaccination aspects will now be discussed in greater detail.

Most of the vaccines commonly used in human and veterinary medicine still consist of killed or weakened bacteria, viruses, or parasites. Although such vaccines have brought immense achievements to medicine, their potential applications have still not been exhausted. Currently under development are vaccines based on refined surface structures of pathogens (subunit vaccines) or on peptidic immunodominant epitopes hybridized with proteins. This trend has been enhanced by the availability of recombinant DNA technology[2] which makes it possible, for example, to express viral surface proteins in bacteria or cultures of animal cells. One of the great advantages of this approach is that it is much safer because the virulence of the pathogen is absent. However, it also poses the problem that these antigens are much less immunogenic in their pure form. To elicit an adequate protective effect they must be administered together with adjuvants that enhance the specific immune response to the antigens.[3,4]

In adjuvant research the separation of immunostimulation from inflammatory side effects is of central importance. Many adjuvants, such as the classic Freund's Complete Adjuvant (FCA, a water-in-oil emulsion with complete extracts of mycobacteria), are so poorly tolerated that they cannot even be used for veterinary vaccines. The only adjuvants registered for human use are inorganic gels such as aluminum hydroxide, a component of the first peptidic hybrid vaccine, which was tested against malarial diseases in humans.[5-7] In comparison with FCA, however, aluminum hydroxide exerts only weak activity and its use is therefore limited. Accordingly the search for well-tolerated, potent adjuvants has recently intensified enormously.[8]

There are numerous candidates, as described in several review articles:[9-14] metabolites such as interleukins, interferons, or peptide hormones, high molecular weight compounds of microbial origin, or chemically synthesized derivatives of numerous structural classes. Of particular interest are the low molecular weight adjuvants found in bacterial cell walls. These include compounds derived from the active component of mycobacteria (present in FCA), that is, muramyl dipeptide **1** (MDP),[15,16] such as murabutide, muroctasine, and muramyl tripeptide phosphatidylethanolamine (MTP-PE). Other potent adjuvants are compounds from the endotoxin family[17] whose active component is lipid A **2**.[18,19] Derivatives of this basic structure are lipid X or lipid Y, for example. Some of these compounds are undergoing clinical trials as vaccine components.

Modification of the basic structures of active compounds has shown that even tiny variations often lead to complete loss of biological activity. In many cases, however, it was possible to obtain highly active derivatives by covalent conjugation of the active basic structure with lipid residues, as in the examples above.

We have recently discovered a new class of conjugates of carbohydrates and lipids, which have adjuvant properties but are not derivatives of muramyl peptides or endotoxins. They are glycolipid analogues (GLAs), which offers an interesting alternative to existing structures.

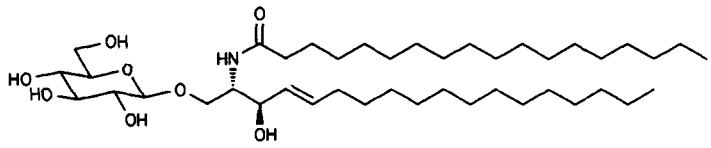
2. Glycosylamides as Glycolipid Analogues

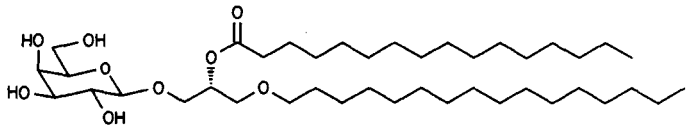
Glycolipids are found at the surface of every cell. By virtue of their exposed position in the cell membrane, they serve as binding sites for lectins, antibodies, toxins, bacteria, or viruses and are therefore important in mediating the cell's communication with its external environment.[20-22]

Several hundred glycolipid structures on the mammalian cell surface are currently known. On the basis of their hydrophobic portion, they are divided into two classes, the glycosphingolipids **3** and the glycoglycerolipids **4**. The building blocks for glycosphingolipids are sphingosine, fatty acids, and carbohydrate residues and for glycoglycerolipids glycerol, fatty acids or fatty ethers, and carbohydrates. The sugar residues are *O*-glycosidically bonded.[23]

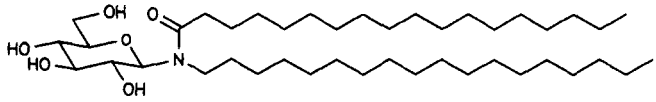
In view of the fundamental properties of this interesting class of cell wall components, their amphiphilic character conferred by the combination of lipophilic chains with hydrophilic carbohydrate head groups, and their immense biological importance, we began in the early 80s to investigate the chemistry of glycolipids and their simpler analogues in greater details. Our original aim was to synthesize simple



3 glycosphingolipids – glycosylceramides
– gangliosides
– sulfatoglycosphingolipids



4 glycoglycerolipids – galactoglycerolipids
– sulfatogalactoglycerolipids



5 glycosylamides (glycolipidanalogues, GLA)

Fig. 2. Prototypes of the naturally occuring glycolipids **3** and **4** and of glycolipid analogues **5**. In **3** and **4** the monosaccharide moieties stand for mono- and oligosaccharides, which can contain *o*-sulfate esters.

glycosylamides such as **5** with long alkyl residues and variations in the polar region and to investigate the response these structures would elicit in biological systems. We expected lipophilic amide residues, formed from long-chain alkylamines and fatty acids and linked directly with the sugars

Oswald Lockhoff was born in 1949 in Cuxhaven, Germany. He studied chemistry at the University of Hamburg and was awarded his Ph.D. in 1980, having worked in the field of oligosaccharide synthesis under the supervision of Hans Paulsen. In the same year he joined Bayer AG as a research chemist in the Central Research Laboratories in Leverkusen and became a group leader in 1986. In 1988 he joined Bayer's Pharmaceutical Research Center in Wuppertal and in 1990 he returned to his position in Leverkusen. His research interests lie in the area of anti-infectives.

through the anomeric carbon atom, to mimic the functions of naturally occurring lipid residues.

2.1. Synthesis of Glycosylamides

Amides are not sufficiently basic to permit direct condensation with free sugars to form glycosylamides.[24] The use of the Hilbert–Johnson reaction[25] with *N*-alkylcarboxylic acid amides is also unsuitable because it produces only *N*-silylated derivatives which prevent *N*-glycoside synthesis.[26] The synthesis of glycosylamides is possible, though, if a two-step process is used.[27] The first step is the reaction of the free hydroxyl group on the anomeric C-atom of a sugar with an amine. This reaction leads to the glucopyranosylamine which, owing to the weak anomeric effect of the nitrogen atom, is obtained with an equatorial configuration.[28] The second step is the selective acylation of the basic nitrogen atom with an activated carboxylic acid derivative to form the glycosylamide.

A glycosylamine can be readily synthesized from a free sugar and ammonia or a short-chain aliphatic amine in a polar solvent at room temperature to give a crystalline product.[24] Owing to the differing solubilities of the free sugar and the fatty amine, however, this variant could not be used in our systems. Only at higher temperatures do the two components react to form glycosylamines. Under these conditions, however, increased quantities of by-products result from the irreversible degradation of the carbohydrates (browning reaction).[24, 29]

The synthesis of long-chain *N*-glycopyranosylamines is most successful if the free sugar such as D-glucose **6a** is warmed to 80 °C for about 15 min with stearylamine **7** (two to three molar excess) in an alcohol–water mixture or dimethylformamide (DMF). The excess of amine suppresses the formation of *N*,*N*-diglycosylamines.[30] Under these conditions the main product of the reaction is the β-glycosylamine **8a**, which precipitates together with the alkylamine **7** when the reaction mixture is cooled. Browning reactions occur to only a modest degree.

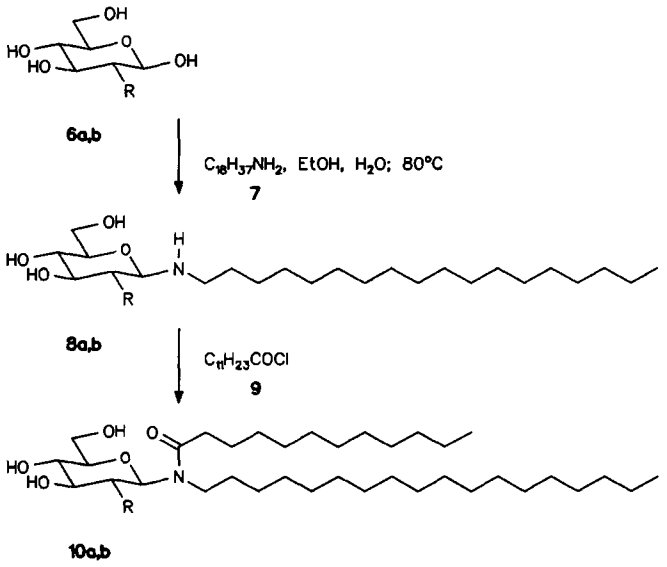


Fig. 3. Synthesis of simple glycosylamides. **a**: R=OH, **b**: R=NHAc.

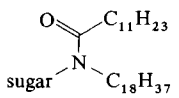
The subsequent *N*-acylation of the amine mixture was possible in alcoholic solvents with an excess of activated fatty acid derivatives such as lauric acid chloride (**9**) or the mixed anhydride of lauric acid and ethyl chloroformate. This reaction gave a mixture of *N*-(β-D-glucopyranosyl)-*N*-stearyllauramide (**10a**) and *N*-stearyllauramide, from which the glycosylamide **10a** could be isolated chromatographically. Amide **10a** crystallizes from methanolic solution.

Other hexoses and pentoses can be converted to the corresponding glycosylamides under similar conditions. 2-Deoxy-D-glucose reacts with stearylamine **7** at 60 °C to give the corresponding glycosylamine within a few minutes, while the analogous reaction of *N*-acetylglucosamine **6b** with stearylamine **7** to give **8b** requires about 3 hours at 80 °C. Here too, higher temperatures lead to more browning products. Subsequent selective *N*-acylation of **8b** gives the *N*-(2-acetamino-2-deoxy-β-D-glucopyranosyl)-*N*-octadecylcarboxamide (**10b**).

Table 1. Comparison of the specific rotations of *N*-glycopyranosyl-*N*-octadecyldodecanoic acid amides **10**–**16**.



Compound	Sugar	$[\alpha]_D$	Solvent
10a	β-D-glucopyranosyl	8.6	CH_2Cl_2
10b	2-acetamino-2-deoxy-β-D-glucopyranosyl	13.9	THF
11	β-D-galactopyranosyl	11.4	CH_2Cl_2
12	β-D-mannopyranosyl	11.3	CH_2Cl_2
13	2-deoxy-β-D-glucopyranosyl	3.8	THF
14	α-D-arabinopyranosyl	−20.1	THF
15	α-L-arabinopyranosyl	20.0	THF
16	β-D-ribopyranosyl	4.2	THF

The analogous reactions of other hexoses and pentoses with stearylamine and lauric acid chloride gave the glycosylamides listed in Table 1, in yields of 50–70 %.[31]

2.2. Physical Properties of Glycosylamides

The synthesized glycosylamides are chromatographically pure and show small positive optical rotations (Table 1) which confirm the β-configuration.[32] For arabinose derivatives the α-configuration with an equatorial amide residue at C1 was the preferred derivative. The FAB mass spectra show distinct molecular peaks.

Both the ^1H and ^{13}C NMR spectra show the doubling of some signals which indicates the presence of two conformational isomers in solution. In the ^1H NMR spectrum the signals of the anomeric protons of **10a** are detectable at $\delta = 5.45$ and 4.84 with coupling constants of more than 8 Hz (solvent CD_3OD). In the ^{13}C NMR spectrum the signals of the anomeric carbon atoms appear at $\delta = 88.17$ and 84.28 in the intensity ratio 2:1 (solvent CD_3OD). ^{13}C NMR spectra of **10a** in [D_6]dimethyl sulphoxide at various temperatures show that the signals of the anomeric C atoms of this compound are well separated at 300 K ($\delta = 86.25$ and 81.90, intensity ratio 2:1), whereas at 353 K they coalesce. Other *N*-alkyl-*N*-glycosyl fatty acid amides of this class show simi-

lar behaviour. The phenomenon of signal doubling in the NMR spectra of glycosylamides is similar to that observed for analogous glycosylamides in the *N*-acetyl-*N*-(β-D-glucopyranosyl)-naphthylethylamine class, in which hindered rotation about the amidic C–N bond was investigated.[33]

A distinctive feature of amphiphilic molecules is the formation of high molecular weight aggregates above the critical concentration in aqueous media. The driving force is provided by the hydrophobic interactions between the alkyl chains, which in this arrangement are protected from interaction with water molecules.[34] The aggregates may form spherical, globular, oblate, or cylindrical micelles, single- or multi-walled vesicles (liposomes), double-layer lamellar phases, or inverted structures, in which the alkyl chains are parallel to each other. This parallel arrangement is also found in cell membranes, where the polar head groups of the phospholipids are at the membrane boundary and the alkyl chains point into the interior of the membrane.[35, 36]

The *N*-alkyl-*N*-glycosyl fatty acid amides also form aggregates in which the alkyl chains orient themselves parallel to each other. Evaluation of shear-area diagrams (Langmuir isotherms) of monomolecular films of these compounds at the water–air interface gave an area requirement of 40 Å^2 per molecule for each of the compounds **10a** and **12**.[37] This is consistent with the assumption of two parallel alkyl chains. By using small-angle X-ray scattering, it was shown that these compounds may form lamellar or hexagonal phases, depending on temperature.[38]

2.3. Adjuvant Effect of Glycosylamides

Investigation of *N*-alkyl-*N*-glycosyl fatty acid amides in immunological test systems surprisingly showed that several of these relatively simple compounds enhance the production of antibodies against various antigens. *N*-(β-D-Glucopyranosyl)-*N*-stearyllauramide (**10a**) was found to produce a dose-dependent increase in the formation of antibodies against sheep erythrocytes in vitro in the concentration range 3–100 μg mL^{-1}. Of particular interest was the finding that **10a** alone caused no mitogenic activity (induction of cell division): the formation of antibodies was detectable only in combination with an antigenic stimulus.[39] Thus **10a** acted like the known immunomodulators in the same dosage range, but evidently through a different, unknown mechanism. The immunological characterization of the glycosylamides is described in greater detail in Section 3. These findings motivated us to study the structure–activity aspects of this class of compounds more closely.

2.4. Chemical Optimization of the Basic Structure

We made modifications in the sugar residue, the lipophilic residues, and the branching region to investigate the influence of each of these substructures. Straight-chain alkylamines and aliphatic fatty acids were combined with hexopyranosyl and pentopyranosyl residues as shown in Figure 3. The effect on antibody synthesis in vitro depends on both the combination of alkyl chains and the nature of the carbohydrate components, the influence of the polar group being stronger. A β-D-glucopyranosyl residue has a strong effect similar to that of the 2-acetylamino-2-deoxy-β-D-glucopyranosyl residue and the β-D-mannopyranosyl residue; weaker activity was found for the β-D-galactopyranosyl residue. Pentopyranosyl and 2-deoxy-β-D-glucopyranosyl residues have little or no effect (Scheme 1).

Glycolipid	**10a**	**10b**	**11**	**12**	**13**	**14**	**15**	**16**
Antibody production	3	3	2	3	0	0	0	1

Scheme 1. Influence of the carbohydrate moiety on the primary immune response in vitro (murine spleen cells, antigen: sheep erythrocytes). The numbers indicate: 3 strong effect, 2 medium effect, 1 weak effect, 0 no effect.

In these in vitro models the biological effects are less dependent on the *n*-alkyl chains. However, each alkyl chain must be at least 12 carbon atoms long, since shorter chains lead to cytotoxic effects. The same has also been found for amphiphilic compounds comprising a pyranose residue and just one alkyl chain.

As a branching region, the amide grouping is also of great biological importance. Investigation of glycolipids with urethane, urea, thiolcarbamate, or allophanate groups **17**–**20**—obtained by reacting *N*-alkyl-*N*-β-D-glucopyranosylamines with alkyl chloroformates, alkyl isocyanates, alkylthiocarbonyl chlorides, or alkoxycarbonyl isocyanates—showed that, unlike glycosylamides, these compounds have only a slight effect on antibody production in vitro.

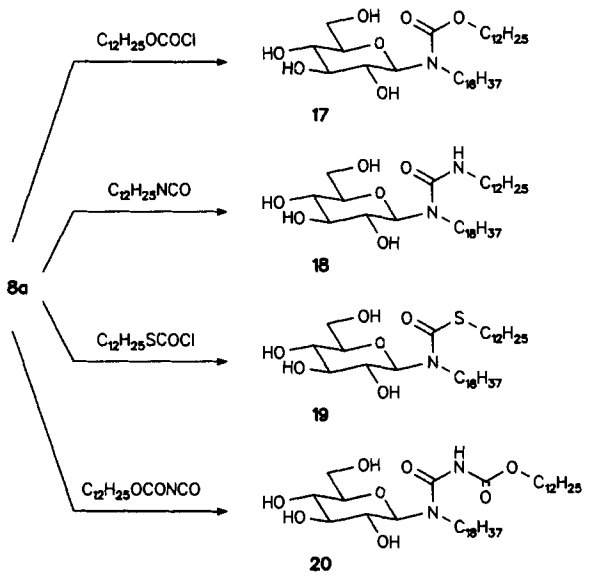


Fig. 4. Syntheses of glycosyl urethane **17**, urea **18**, thiocarbamate **19**, and allophanate **20** from **8a**.

The effect of increasing the lipophilicity of glycolipids was investigated by introducing a third alkyl chain into 2-amino-2-deoxy-D-glucose derivatives. Thus D-glucosamine hydrochloride **21** was reacted with octadecylamine in isopropanol at 65 °C to give *N*-(2-amino-2-deoxy-β-D-glucopyranosyl)-*N*-octadecylamine hydrochloride (**22**). Reaction with two equiv-

alents of stearoyl chloride gave *N*-(2-deoxy-2-octadecanoylamino-β-D-glucopyranosyl)-*N*-octadecyl-octadecanamide (**23**), which has three chains of 18 carbon atoms each. A derivative with three alkyl residues of different lengths on the glucosamine was produced as follows: acylation of the 2-amino group of glucosamine with dodecanoyl chloride gives 2-deoxy-2-dodecanoylamino-D-glucopyranose (**24**), *N*-glycosylation of which with dodecylamine provides *N*-(2-deoxy-2-dodecanoylamino-β-D-glucopyranosyl)-*N*-dodecylamine (**25**). Subsequent *N*-1-acylation of **25** with octadecanoyl chloride leads to *N*-(2-deoxy-2-dodecanoylamino-β-D-glucopyranosyl)-*N*-dodecyloctadecanamide (**26**). By using various alkylamines and acid chlorides a broad range of glucosamine derivatives with lipid residues with different chain lengths can be produced (Fig. 5).

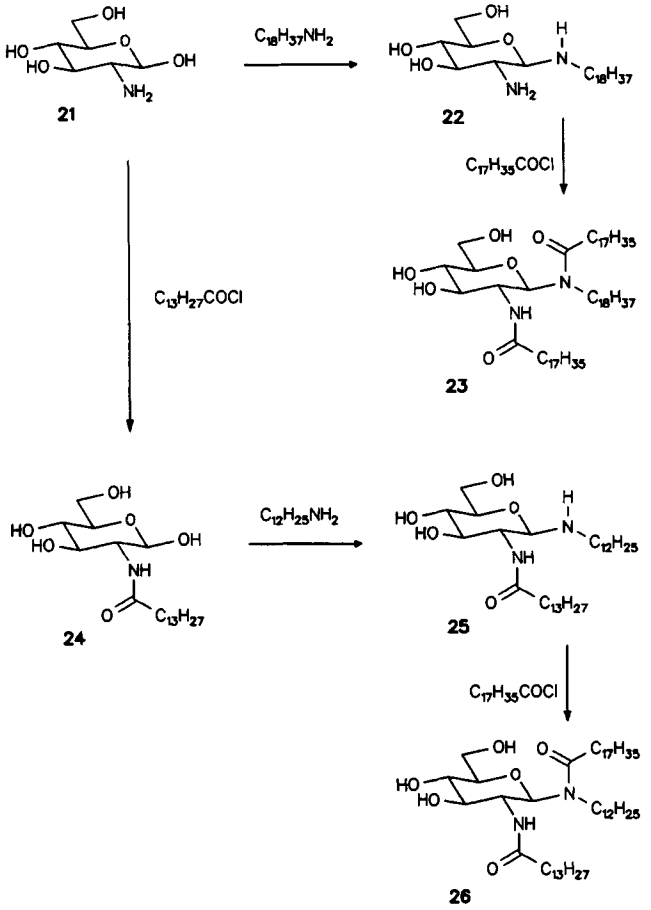

Fig. 5. Syntheses of glycolipids with three alkyl chains.

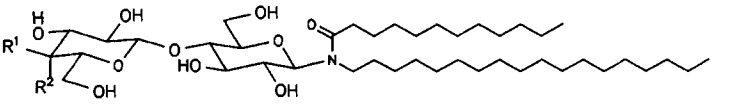
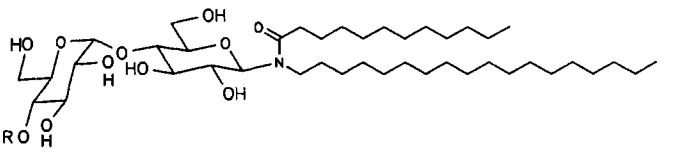
However, the investigations of compounds **23** and **26** and their homologues for biological activity proved very difficult because of their poor solubility in aqueous systems. The structure–activity relationships were not consistent, and so ultimately it was not possible to assess the biological effects of this subclass.

On the other hand, glycolipids with several hydroxyl groups or with charged functional groups should be much more solubile in water. With this aim we treated the disaccharides cellobiose, lactose, and maltose as well as the trisaccharide maltotriose successively with long-chain alkylamines and then fatty acid chlorides to give di- or trisaccharide lipids **27**–**30** (Fig. 6). These glycolipids are much more readily dispersible in water.



27 R^1 = OH, R^2 = H : β-cellobiosylamide
28 R^1 = H, R^2 = OH : β-lactosylamide



29 R = H: β-maltosylamide
30 R = α-D-glucopyranosyl: β-maltotriosylamide

Fig. 6. Glycosylamides of di- and trisaccharides.

Of particular interest were glycosylamides with phosphate ester groups. In immunomodulators derived from lipid A a phosphate ester group on the sugar is essential for biological activity; selective *O*-phosphorylation of lipids of monosaccharide amides was therefore investigated more closely.

We planned to achieve selective phosphorylation by exploiting increased nucleophilicity of the primary hydroxyl group at the C6 position. The reaction of **31** (obtained by a two-step reaction from D-galactose, dodecylamine, and stearoyl chloride) with dibenzylphosphoric acid chloride in the presence of pyridine leads to a phosphoric acid triester which, in the presence of palladium on carbon, can be hydrogenated to the 6-*O*-phosphorylated glycosylamide **32** (Fig. 7). This phosphorylation produced a qualitative change in the biological acitivity. Although **31** strongly stimulates antibody synthesis in vitro, this effect is somewhat less marked with **32**. However, **32** shows a significant antiviral activity against Herpes simplex virus type I (HSV I). This effect relies on the increase in the interferon titer induced by a virus infection.[40]

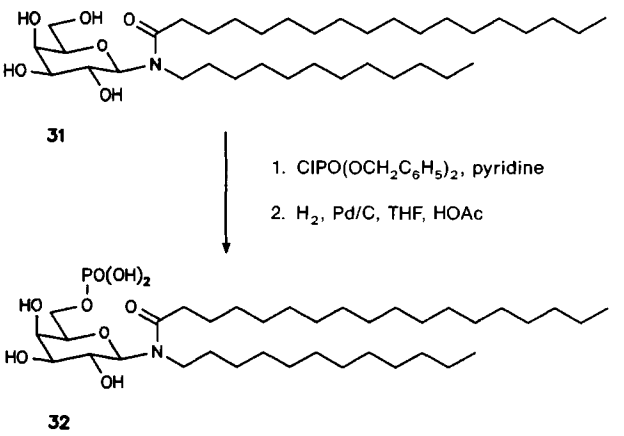


Fig. 7. Synthesis of an *O*-phosphorylated glycosylamide with antiviral activity.

2.5. Glycosylamides of Glucosamine

In order to introduce other charged functional groups in our studies of glycolipid derivatives, 2-amino sugars were investigated. Since glucosamine hydrochloride reacts with alkylamines to give *N*-alkyl-*N*-(2-amino-2-deoxy-β-D-glucopyranosyl)amine, the differentiation of the two amino functions is best achieved by blocking the amino group on the sugar. Since a benzyloxycarbonyl protecting group should offer the possibility of selective cleavage in the presence of a C1 amide function, D-glucosamine was converted to *N*-benzyloxycarbonyl derivative **33**. Compound **33** reacted with alkylamines in analogy to sugars with a 2-hydroxyl group, but much more slowly, to give glycosylamines. In DMF with tetradecylamine as the amine component glycosylamine **34** is obtained with a yield of 50–60 % after 4 h at 80 °C (Fig. 8). Owing to the longer reaction time the temperature- and time-dependent formation of by-products is more evident. The slow and incomplete course of the reaction is apparently due to the deactivating effect of the carbamate on the C2 of the sugar, which also improves the stability of the glycosylamine **34** against hydrolysis.

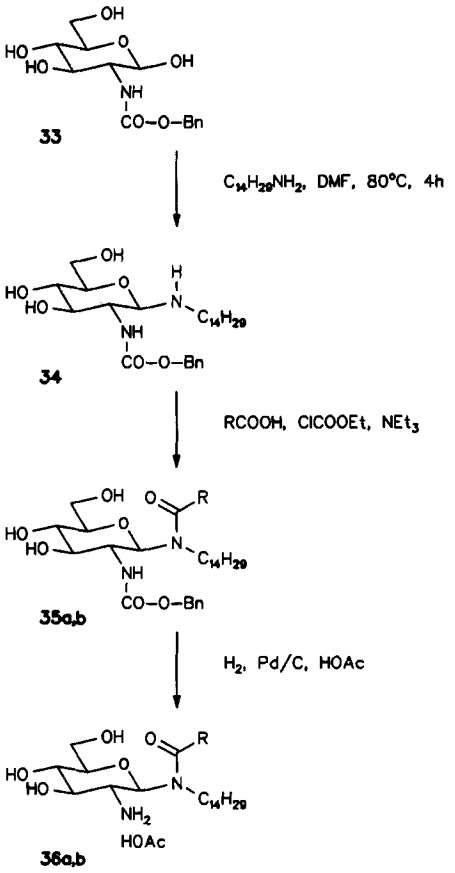

Fig. 8. Synthesis of 2-amino-2-deoxy-glycosylamides. Bn = benzyl, **a**: R = $C_{17}H_{35}$, **b**: R = $C_{11}H_{25}$.

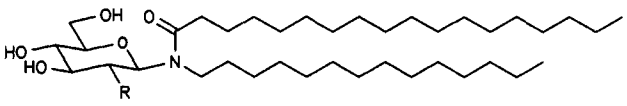
Acylation of the C1 amino group of **34** with the mixed anhydride of stearic acid and ethyl chloroformate gives the glycosylamide **35a**, which after chromatographic purification can be readily hydrogenated to *N*-(2-amino-2-deoxy-β-D-glucopyranosyl)-*N*-tetradecyloctadecanamide (**36a**). Homologous compounds can be synthesized with other aliphatic amines and fatty acids.

As expected, the ammonium group in **36a** and its homologues enhances solubility in water. Solubility in water–ethanol (99:1 v/v) was determined by HPLC (Fig. 9).



R	Solubility in water-ethanol 99:1 (v/v) [mg mL^{-1}]
OH	2.1
NH–Ac	2.0
NH_2 · HOAc	13.2

Fig. 9. Comparison of solubilities of glycosylamides with different C2-substituents on the glucose moiety.

The 2-amino-2-deoxy-glucosylamides have a marked effect on antibody synthesis in vitro and in vivo. The activities of several compounds, particularly **36a** and **36b**, are distinctly superior to that of **10a** and **10b**.

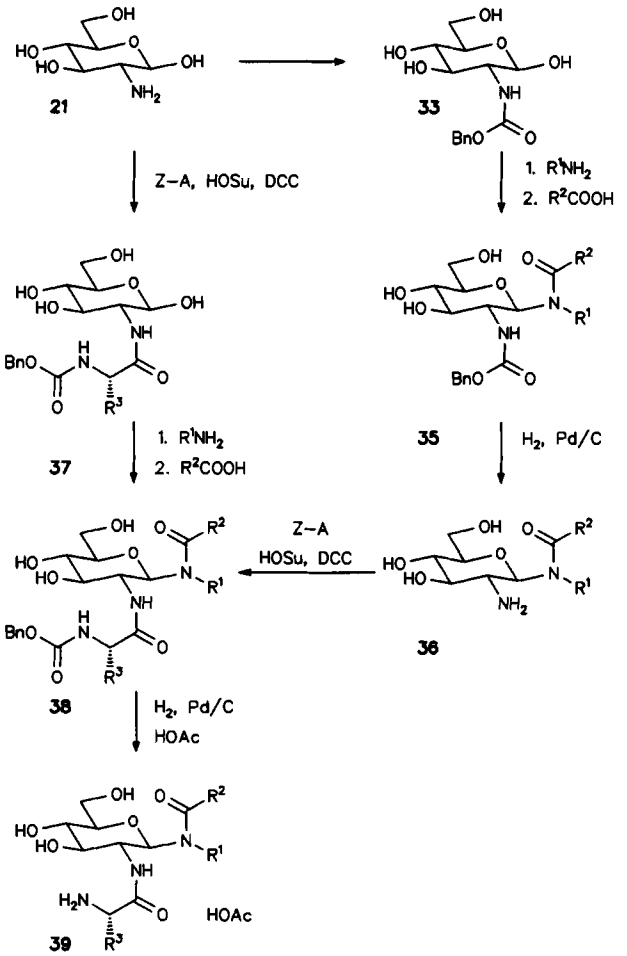


Fig. 10. Two routes to peptidoglycolipids. Z–A = benzyloxycarbonyl-protected amino acid, HOSu = *N*-hydroxysuccinimide, DCC = dicyclohexylcarbodiimide, R^1, R^2 = $C_{11}H_{23}$ to $C_{18}H_{37}$.

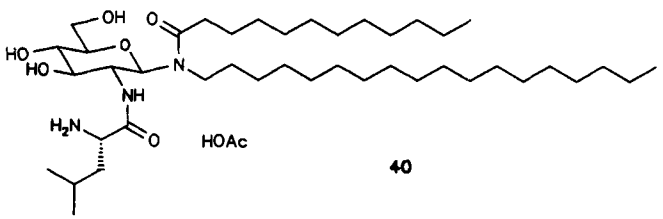
The compounds **36** and other homologues from this class permit further selective derivatization via the free amino function. Since previous findings suggested that glycolipids with ammonium groups in the head region would be of greatest interest, linkages with amino acids were targeted. The classic racemization-free condensation of **36** with protected amino acid *N*-hydroxysuccinimide esters provided *N*-(2-aminoacylamino-2-deoxy-β-D-glucopyranosyl)-*N*-alkyl fatty acid amides **38**, which can be deprotected by hydrogenolysis to the free amines **39** (Fig. 10). Thus, by combining aliphatic amines, fatty acids, and amino acids, a variety of glycolipids **39** with polar character could be produced.[41]

The synthesis of the peptidoglycolipids **39** was also achieved by a shorter route, with equally good results (Fig. 10). The first step was to produce the conjugate **37** from glucosamine and an *N*-benzyloxycarbonyl-protected amino acid. Compound **37** was treated with alkylamines and activated fatty acids in two steps, in the same way as *N*-acetyl-glucosamine, to give the blocked peptidoglycolipids **38**, which were deprotected to give **39**.



40

Fig. 11. Structural formula of BAY R 1005 (**40**).

From a variety of compounds of the type **39**, *N*-(2-deoxy-2-L-leucylamino-β-D-glucopyranosyl)-*N*-octadecyldodecanamide acetate (**40**, BAY R 1005) (Fig. 11) was selected for further biological development (see Section 3).

2.6. Lipophilic Glycosylamides of Muramyl Dipeptides

We were particularly interested in the linkage of the glycosylamide residue (as found in the GLA molecules) to muramyl dipeptide (MDP), **1**) and the effects such a modification would have on biological activity. MDP has already been linked with other lipophilic structures. Thus 6-*O*-mycolyl-MDP, 6-*O*-corynomycolyl-MDP,[42] and 6-*O*-ubiquinyl fatty acid esters of MDP[43] have been synthesized and have antitumour activity. Anti-infective or antitumour activity has also been found in MDP derivatives whose peptide segment is linked to a lipid residue by a covalent bond. Examples of this group are the conjugates of muramyl tripeptide and dipalmitoyl-phosphatidylethanolamine (CGP-19835A, MTP-PE)[44] or muramyl dipeptide and stearoyl-L-lysine (MDP-Lys (L18), muroctasine),[45] both of which are at an advanced stage of clinical development.[13]

The sugar element of MDP (**1**) is D-glucosamine. This structure also occurs in glycolipids of type *N*-(2-acetylamino-2-deoxy-β-D-glucopyranosyl)-*N*-alkylcarbonamide **41**. An attempt was therefore made to combine the two structural units in a single molecule in which the common element would be the amino sugar. In principle it ought to have been possible to synthesize the MDP lipids from muramyl dipeptide in two steps, by *N*-glycosylation followed by *N*-acylation. As expected, however, *N*-glycosidation of a 2-acetamino sugar entailed heavy losses, and it therefore seemed more economical to start from *N*-(2-acetylamino-2-deoxy-β-D-glucopyranosyl)-*N*-alkyl fatty acid amides **41**, introduce the 3-*O*-lactyl ether, and link with a dipeptide element. To introduce the lactyl ether residue at C3 of the sugar element **41**, the C4 and C6 hydroxyl groups were first blocked as benzylidene acetal. The compounds **42** were then isolated by crystallization (Fig. 12).

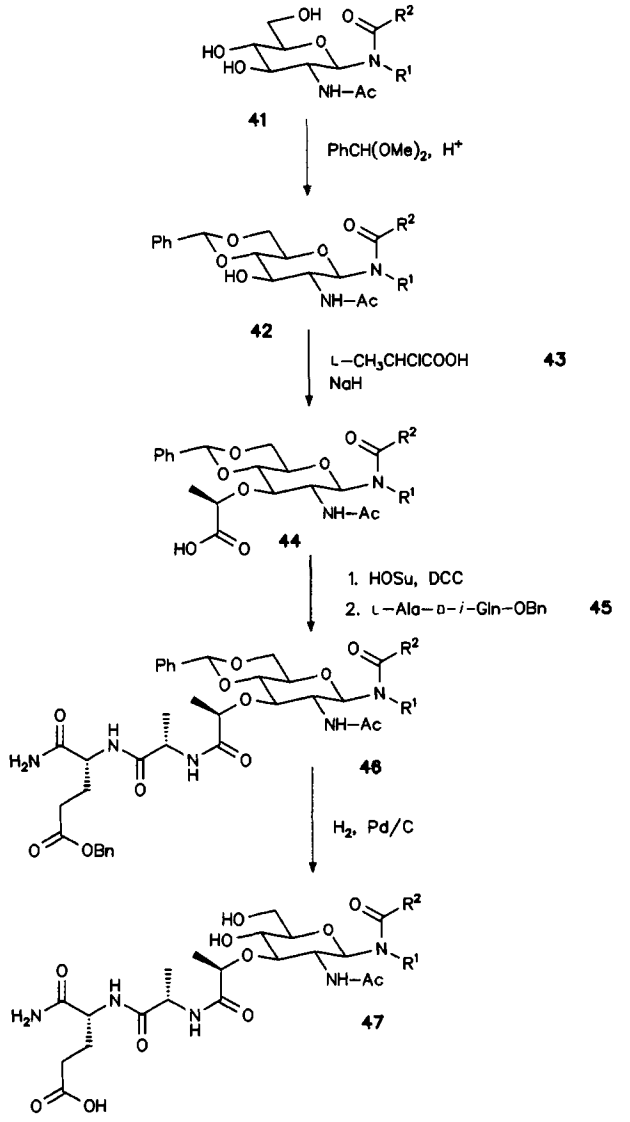


Fig. 12. Synthesis of *N*-glycosides of muramyldipeptide (MDP). R^1, R^2 = $C_{11}H_{23}$ to $C_{18}H_{37}$, *i*-Gln = isoglutamine.

The ^{1}H NMR spectra of the derivatives of **42** could be assigned completely. The amide rotamerism observed in the 4,6-unsubstituted glycolipids **41** is completely absent in **42**. Also in solution the compounds **42** are present in only a single conformation.

The alcohol function in **42** was then converted stereoselectively with L-chloropropionic acid **43** and sodium hydride to the lactyl ether derivative **44**.[46] The ether synthesis proceed-

ed with Walden inversion under conditions comparable to those reported for α-configured *O*-methyl glycosides.[47] No diastereomers were detectable by NMR spectroscopy. After activation of the carboxyl function as a hydroxysuccinimide ester, coupling with the dipeptide element[48] L-alanyl-D-isoglutamine benzyl ester **45** gave the protected MDP lipid derivative **46**, which could be converted into the free peptidoglycolipids **47** by hydrogenolysis.

As is often found in drug research the combination of two active structures into one molecule may result in a loss of activity. This proved also to be the case with the MDP glycolipids **47**, which induced little or no increase in antibody synthesis.

2.7. X-ray Crystallographic Studies

Knowledge of the conformation of lipids is key to understanding their mutual arrangement and their organization in a cell membrane. X-ray crystallographic studies of phospholipids[49–52] revealed that the two alkyl chains are arranged parallel to each other in an all-*trans* conformation with a spacing of 4.8 Å. The dihedral angle between the two planes is only a few degrees. The structure[53] of 1,2-dilauroyl-*sn*-*glycero*-3-phosphocholine **48** is shown in Figure 13.

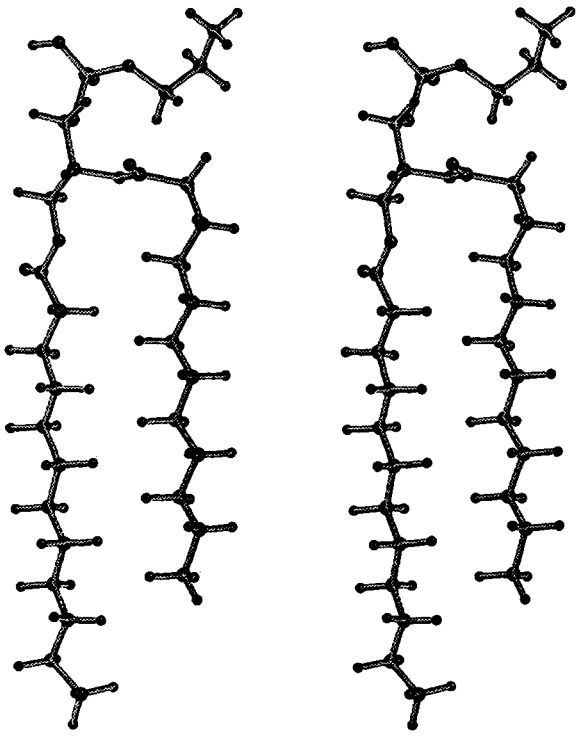

Fig. 13. Stereoplot of the structure of 1,2-dilauroyl-*sn*-*glycero*-3-phosphorylcholine **48** in the crystal [53].

No crystals suitable for X-ray structural analysis could be obtained from BAY R 1005 (**40**) itself, but this proved possible for a blocked precursor, the tri-*O*-acetate **49**, which crystallized in long needles from methanolic solution. Figure 14 shows the result of the X-ray crystallographic investigation.[54]

As expected, the sugar ring in **49** is present in the $^4C_1$-conformation with equatorial arrangement of all substituents. The lauric acid residue extends linearly into the plane of the sugar ring, while the alkyl chain of the alkylamine is situated above the plane of the ring. Also in this lipid derivative the two alkyl chains are parallel to each other with a mean separation of about 5 Å. A striking feature is the dihedral angle (ca. 90°) between the zigzag planes of the two alkyl chains which differs markedly from that of phospholipids. This arrangement is possible owing to two *gauche* conformations between C2–C3 and C3–C4 of the alkylamine fragment. The dihedral angle between C1–H1 in the sugar ring and the carbonyl group in the amide grouping at the anomeric carbon atom of the sugar is almost 0°.

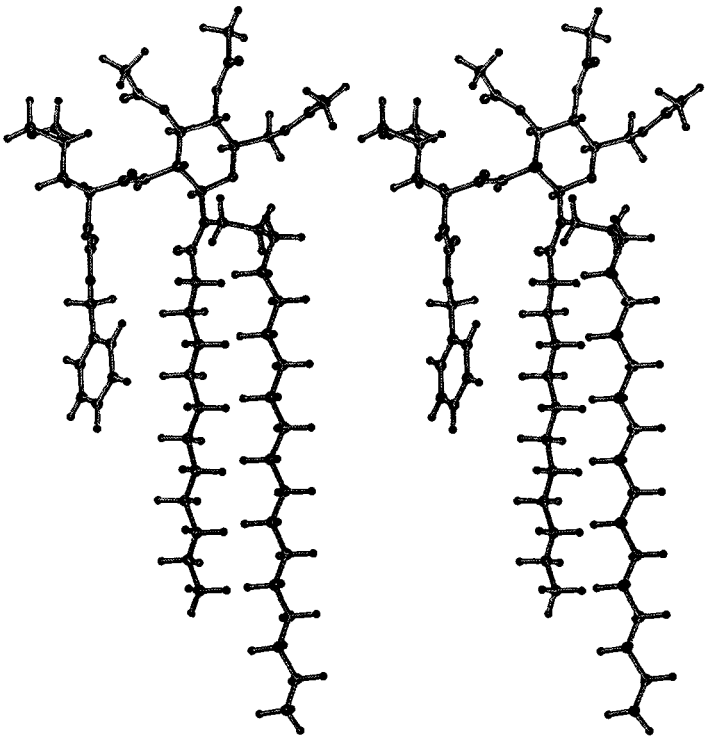

Fig. 14. Stereoplot of the structure of the glycosylamide **49** in the crystal.

Whether this orientation of the lipid residues relative to each other and relative to the sugar ring is also present in solution cannot be stated with certainty because this structure is probably favored by the parallel arrangement of the benzyloxycarbonyl protecting group in the crystal. However, ^{1}H NMR measurements indicate that **49** is present as a single conformer (without amide rotamerism) also in solution. This conformation must therefore be regarded as probable in the solution state as well.

After conversion of **49** to BAY R 1005 (**40**), amide rotamerism is again evident in the ^{1}H and ^{13}C NMR spectra, indicating that two different conformations are present in solution. The conformation found in the X-ray structural analysis may possibly be one of those that are present in BAY R 1005.

3. Adjuvant Activity

The biological activity profile of this new class of glycolipids is of extraordinary interest for vaccination. Both in vitro and in vivo they enhance the specific immune response (adjuvant effect), which we will now describe in more detail using the example of BAY R 1005 (**40**).

In the primary humoral immune response[55] (antibody synthesis of class IgM) of spleen cell cultures (mouse) to sheep erythrocytes as antigens in the presence of BAY R 1005 (**40**), this substance induces a dose-dependent increase in the number of antibody-forming cells in the concentration range 1–100 $\mu g\,mL^{-1}$. It is particularly important that this effect is completely independent of T lymphocytes and that the increase in antibody synthesis is strictly antigen-dependent and not the result of nonspecific polyclonal stimulation. Cultures that have not been stimulated with sheep erythrocytes show only a negligible increase in the number of antibody-forming cells in the presence of BAY R 1005 (**40**).[39, 56] Thus, unlike virtually all other adjuvants,[57, 58] GLAs show no mitogenic effect but act on B lymphocytes only when an antigenic stimulus is present. BAY R 1005 seems to act on populations of B lymphocytes as a second signal which is effective only if the primary signal of the antigen is sent first.

This adjuvant effect can also be reproduced in vivo in the immunization of mice. After the intraperitoneal administration of sheep erythrocytes and simultaneous subcutaneous administration of BAY R 1005 (**40**), a dose-dependent increase in the number of antibody-forming cells was detected (Fig. 15). Comparable increases in antibody titer were also observed after immunization with the soluble antigen ovalbumin.

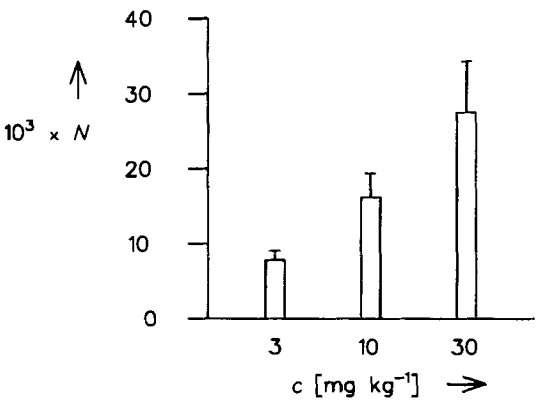

Fig. 15. Adjuvant effect of BAY R 1005 on the primary humoral immune response against sheep erythrocytes. An increasing dose c enhances the number N of antibody forming cells.

In vivo, BAY R 1005 (**40**) also induces an increase of antibody synthesis in response to viral vaccines administered in suboptimal concentrations.[59] By administering BAY R 1005 simultaneously, the protective effect of immunization with an inactivated pseudorabies virus vaccine was enhanced significantly. After the injection of infectious virus the survival rates and mean survival times were distinctly higher in the animals that had been additionally immunized with BAY R 1005 than in the controls (Table 2). Parallel to the protective effect, increased serum antibody titers with neutralizing properties were also detected. Conventional adjuvants led to no improvement in the protection of virus-infected mice.

BAY R 1005 is also effective in animals whose defense has been weakened. Restorative and adjuvant effects were observed in mice whose immune system had been suppressed by bacterial lipopolysaccharides or melanoma B_{16} tumors.

Table 2. Adjuvant effect of BAY R 1005 in CF-1 mice after immunization with pseudorabies virus inactivated with β-propiolactone in comparison to conventional adjuvants.

Treatment	Survival Rate [%] [a]
Control	
formulation (without immunization)	0
vaccine (without adjuvant)	60
Conventional adjuvants	
Freund's complete adjuvant [b]	60
$Al(OH)_3$ – saponin [b]	50
BAY R 1005 **40** [mg kg^{-1}]	
3	90
6	100
12	100

[a] Determined from tests with ten animals. [b] Mixed 1:1 with antigen.

All the data accumulated to date indicate that BAY R 1005, due to its efficacy and its mode of action, is a very interesting compound from a new class of adjuvants and is also very well tolerated both locally and systemically. Its effects on the immune system are very different from those of amphiphilic substances from other structural classes, which show strong immunosuppressive effects even at relatively low concentrations.[60] Its effects also differ significantly from the immunomodulatory properties of natural glycolipids from the glycosphingolipid class, which similarly suppress the response of lymphocytes to antigens in vitro.[61]

4. Summary and Prospects

The molecular mechanisms responsible for the immunological activity of glycolipid analogues are still largely unknown because of their complexity. According to the fluid mosaic model of membranes,[35] lipids play only a passive role in the stabilization of the cell membrane. But this model does not explain why nature synthesizes several hundred different lipids, expending considerable metabolic effort in doing so. Recent studies have shown that the lipid composition of a membrane influences the metabolic activity inside the cell. Even small structural changes in the polar head groups of glycolipids and phospholipids have strong effects on mutual miscibility in solid and liquid crystalline phases,[62] which in turn has an influence on membrane fluidity. Thus the conformation of proteins or receptors in the membrane can be affected.[63] Such a change in fluidity may perhaps be associated with the observed conformational isomer equilibria of glycolipids of the glycosylamide type. Also interesting in this context is the recent finding that cleavage products of sphingolipids, sphingosine, and lysosphingolipids can act as endogenous modulators of cell function by inhibiting protein kinase C.[64] The effect of BAY R 1005 (**40**) or of cleavage products possibly formed by lipases in the membrane on the second messenger systems has not yet been investigated.

In contrast to these speculations, the observed effects exerted by the glycolipids in our vaccination experiments are unequivocal. In combination with purified virus vaccines and subunit vaccines BAY R 1005 (**40**) leads to increased protection of virus-infected mice. Since preclinical trials in vivo in other animal species (pig, sheep, horse) and in vitro in isolated human blood cells[65] gave comparable results, use in veterinary and human medicine should be possible. In addition to the general efficacy of the substance, however, its mode of action deserves particular attention: the increase in antibody synthesis induced by BAY R 1005 (**40**) is specifically dependent on the antigen and is not the result of polyclonal stimulation. GLAs act on the proliferation of B lymphocytes as a second signal which has no effect until the antigen acts as a first signal. Since BAY R 1005 is capable of activating B lymphocytes without the helper function of T lymphocytes, it may prove very helpful as an adjuvant, particularly for the immunization of patients with diseases such as AIDS whose T lymphocytes function is defective.

This review contains results obtained by numerous colleagues who have been studying the chemical, physical, and biological aspects of these glycolipids. I am grateful for their commitment and persistence. The main synthetic work was done by P. Stadler, Y. Hayauchi, B. W. Krüger, and L. Röben. Physical aspects were studied by A. Zembrod and J. Goossens. The biological and mode of action studies and the evaluation of the glycolipids for vaccination were carried out by H. G. Opitz, K. G. Stünkel, G. Streissle, V. Klimetzek, and P. Thein. The spectroscopic structural analyses were performed by P. Schmitt, C. Wünsche, and D. Wendisch. I am grateful to L. Born for the X-ray structural analyses.

Herbicides in Photosynthesis Research

By Wilfried Draber, Klaus Tietjen, Joachim F. Kluth, and Achim Trebst*

Dedicated to Professor Karl Heinz Büchel on the occasion of his 60th birthday

Photosynthesis and herbicide research have a long common history. Soon after the introduction of a new group of highly effective herbicides in 1956, the substituted aryl ureas, their mode of action was recognized to be the inhibition of light-driven electron flow and photosynthetic oxygen evolution. Many subsequent highly successful commercial herbicides, including those from other chemical classes, act by this mechanism. The study of their interaction with the photosynthetic system at the molecular level is a prime example of how rapidly advances in unraveling the mechanism of photosynthesis can be translated into practical uses. At the same time the herbicides continued to be valuable and efficient tools in photosynthesis research. In the past herbicides were instrumental in establishing many principal features of the biochemistry and biophysics of photosynthesis, in particular the role of plastoquinone, which is displaced from its binding pocket in one of the protein subunits of the photosystem II. Their further use in elucidating the molecular biology of photosynthesis is illustrated by the recent importance of herbicide-tolerant mutants for determining structural aspects of photosystem II. We will review the past and present state of the interaction of herbicide and photosynthesis research and will provide a model for the orientation of herbicides within the three-dimensional structure of their target, the D1 protein of photosystem II.

1. Introduction

A large number of commercial herbicides inhibit photosynthesis,[1-4] representing about 30% of the sales market in 1989. This report is concerned with those compounds that interfere with photosynthetic electron flow of photosystem II, which includes the majority of photosynthesis herbicides. The chemical structures of typical examples are shown in Figure 1. Their specific target has been identified as one of the protein subunits of photosystem II. Their mode of inhibition on PS II function is displacement of a plastoquinone (Q_B) from its binding site on that protein.[5] This herbicide-binding protein is now known to be one of the reaction-center polypeptides of PS II, called the D1 polypeptide subunit.

Rather early the correlation of the biochemistry of herbicides and their inhibitory pattern in photosynthesis with physicochemical descriptors of the compounds (QSAR studies, QSAR = Quantitative Structure–Activity Relationship) allowed the definition of basic chemical elements and substructures essential to their potency. This knowledge enabled specific biochemical and biophysical properties of the then hypothetical herbicide-binding protein to be recognized. It even became possible to determine the dimensions of the binding niche in the protein target required for good inhibition by inspecting the mirror image of the dimensions of the herbicide, before the binding protein had been identified in 1981. Thus research on the biochemistry and biophysics of PS II herbicides is at a more advanced stage than for most other types of herbicides.

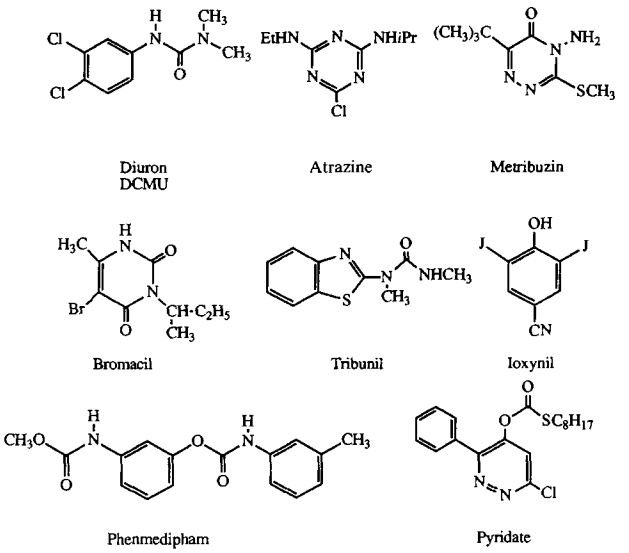

Fig. 1. Herbicides that inhibit photosystem II.

The identification of the herbicide-binding protein provided an important contribution in the biochemical and biophysical characterization of PS II. The decisive step in the elucidation of the structure of PS II was the X-ray structure analysis of the crystallized reaction center of purple bacteria,[6-8] which showed the homology of PS II to the photosystem of purple bacteria not only in function but also in structure and protein folding. However, a detailed understanding of PS II and its homology with the purple bacterial system would not have been possible without the use of inhibitors that are also herbicides.[9] This will be documented in this paper. The herbicide-binding protein was found to be a subunit of PS II as a result of experiments with radioactively labeled herbicides and of the sequencing of the *psb*A gene of herbicide-tolerant mutants. It is possible now to discuss the three-dimensional folding of the herbicide-binding

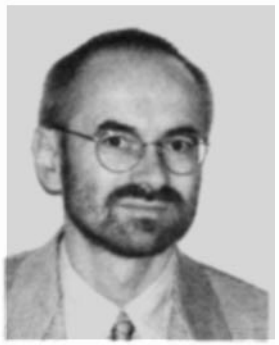
protein and the specific docking of a herbicide into its binding niche. The dimensions deduced from QSAR studies can now be equated with distances to amino acid residues in that niche.

2. The Electron-Flow System in the Photosynthesis Reaction Center

On illumination photosystem II oxidizes water to oxygen and reduces plastoquinone (PQ) to plastohydroquinone (PQH_2).[10, 11] The mechanism of this complex reaction sequence involves several electron carriers. The reaction center of PS II (RC) where the primary light event takes place consists of chlorophyll *a*, probably a dimer (P_{680}), that is bound via two histidines (His 198) to two homologous proteins about 32 kDa in size (the D1 and D2 polypeptides). When the reaction center P_{680} is excited, charge separation occurs, and in 10 psec the electron is passed from the excited primary electron donor P^*_{680} on to a primary electron acceptor, a pheophytin bound to the D1 protein subunit. The pheophytin in turn reduces the first plastoquinone in the electron-flow system (Q_A) in about one nsec. Q_A is reduced only to the semiquinone state, which remains bound tightly to the D2

Achim Trebst (born in Zeitz in 1929) graduated with a doctorate in Chemistry from the University Heidelberg in 1955 under F. Weygand and A. Wacker. After a brief interlude at the Technische Universität Berlin, he spent four years with D. I. Arnon in Berkeley, California, where he was introduced to the biochemistry of photosynthesis and of isolated chloroplasts. On his return he completed his habilitation under F. Weygand at the Technische Universität München. In 1963 he became Professor of the Biochemistry of Plants at the Universität Göttingen, and from 1967 he built up the chair of Biochemistry of Plants at the newly established Universität Bochum. He is member of the Leopoldina and Rheinisch-Westfälische Academy, honorary Doctor of the University of Stockholm and Purdue University, and E. and J. Michael Professor in the Weizmann Institute in Rehovot. His particular interest in the biochemistry of photosynthesis lies in the photosynthetic electron transport system and photophorylation in the thylakoid membrane of the chloroplasts.

Wilfried Draber was born in Schneidemühl in 1929 and studied in Kiel and Freiburg where he completed his doctorate under K. Wallenfels in 1960. He joined the Shell Basic Research in Birlinghoven and was transferred for a long period to the Agricultural Research Centre of Shell in Sittingbourne. From the end of 1966 he has worked in Pflanzenschutz-Forschung in Bayer AG. His particular interests involve the quantitative relationships between chemical structure and biological activity.



Klaus Tietjen was born in Cuxhaven in 1951 and studied chemistry in Freiburg. After obtaining his Diplom (1977) he worked in the Medizinische Universitätsklinik Freiburg on immunoassays for $1\frac{1}{2}$ years. He completed his doctorate at the Biologische Institute der Universität Freiburg under U. Matern in 1982 and pursued these studies in phytopathology as a postdoctoral fellow. In 1984 he became head of a laboratory investigating the biochemistry of herbicides and insecticides in the chemical research department of the Pflanzenschutzzentrum Monheim, Bayer AG.

Joachim Friedrich Kluth, born in Cologne in 1950, completed his Diplom in Chemistry there in 1975 and moved to the Max-Planck-Institute für Kohlenforschung, Mülheim/Ruhr. He obtained his doctorate from the University of Essen under P. Heimbach (1980) in the field of homogeneous transition-metal catalysis where he continued this research as Hochschulassistent. Since 1982 he has been in the chemical research of the Pflanzenschutzzentrum Monheim, Bayer AG.

protein subunit. The semiquinone (the radical anion $Q_A^{\bullet -}$) reduces the second plastoquinone Q_B, which is bound loosely to the D1 protein subunit. It is the Q_B reduction that is inhibited by the herbicides.

After charge separation the oxidized P_{680} is reduced to its initial state by the manganese complex of the oxygen-evolving system. A tyrosin participates in this reaction via a stabilized radical of Tyr 161 in a hydrophobic pocket in the D1 protein.[1,2] After four consecutive oxidation steps the manganese complex produces oxygen from water.

The primary charge separation in PS II occurs across the inner thylakoid membrane of the chloroplast. The reaction center P_{680} is oriented towards the lumen face of the thylakoid membrane. The plastoquinones that are reduced (Q_A and Q_B) are localized in the membrane to face the matrix space of the chloroplast. Therefore the electron released by the oxidation of P_{680} is moved quickly through ca. 30 Å, away from the positive, oxidized P_{680}. This slows down charge recombination in the reaction center and instead the oxidized P_{680} is reduced back to its original state by an electron from the water-splitting reaction. This is depicted in Figure 2. The result of the light-driven charge separation and the redox reaction across the membrane is that a more electronegative reducing equivalent (reduced quinone) has been generated from an electropositive electron donor (water).

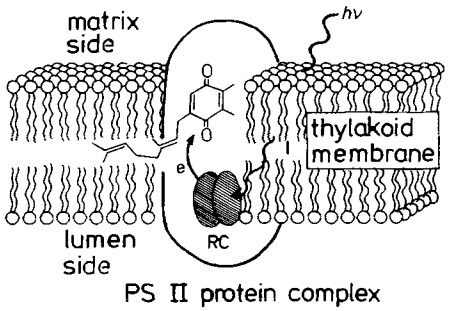


Fig. 2. Light-driven quinone reduction by photosystem II. An integral protein complex is embedded in the thylakoid membrane and orients the reaction center of PS II towards the lumen side of the membrane. On light excitation of the reaction center—depicted as a chlorophyll dimer P680—an ejected electron reduces plastoquinone, which is located on the opposite (matrix) side of the membrane. Herbicides displace this quinone.

After a second similar excitation cycle, Q_B accepts a second electron and becomes reduced to the hydroquinone state; the plastohydroquinone leaves the quinone binding pocket in the protein and equilibrates with a larger free plastoquinone/hydroquinone pool. A new plastoquinone moves into the D1 protein to become a new Q_B and the cycle continues. Two more excitations of P_{680}—i.e., 4 quanta in toto—are needed to oxidize the manganese complex (a cluster of four manganese atoms) to the redox state that produces one O_2 molecule from two water molecules (Fig. 3). The overall reaction of PS II leads to the formation of two stable products: plastohydroquinone and oxygen [Eq. (a)].

$$2H_2O + 4h\nu + 2PQ \longrightarrow 2PQH_2 + O_2 \qquad (a)$$

As Figure 3 also indicates, the protons in the water-splitting reaction are released into the inner lumen space of the thylakoid membrane, whereas the protons needed for hydroquinone formation are taken up from the matrix space. In this way a proton concentration gradient is established between the inner and outer space of the thylakoid, a consequence of vectorial electron flow across the membrane.

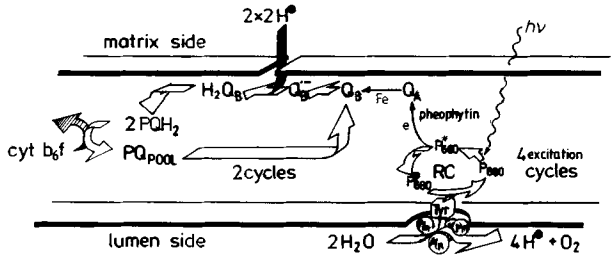

Fig. 3. Photosystem II and oxygen evolution. The reaction center P680 of PS II reduces plastoquinone Q_B via pheophytin and plastoquinone Q_A. Two excitation cycles are needed to reduce Q_B to the hydroquinone. Protons are taken up from the matrix space. The plastohydroquinone leaves the binding site on PS II and equilibrates with a larger plastoquinone/hydroquinone pool. Four excitation cycles through P680 are needed to oxidize the manganese complex via a tyrosine radical. The fully oxidized manganese complex oxidizes 2 molecules of water to evolve one O_2.

The free plastohydroquinones provided by photosystem II can move both laterally in the membrane and across it. They are oxidized by a cytochrome b_6/f complex, which transfers the electrons via plastocyanin (PC) to photosystem I (PS I). The protons liberated in the PQH_2 oxidation are released into the lumen space of the thylakoid, thus doubling the proton potential. Upon illumination photosystem I oxidizes plastocyanin and reduces $NADP^+$.

The photosynthetic electron transport chain causes oxygen evolution and provides the reducing power required for CO_2 assimilation in the form of NADPH (two NADPH are needed per CO_2 reduced or O_2 evolved). As this is an endergonic reaction, absorbed light quanta have to provide the driving force. The whole electron-flow system is depicted in Figure 4, which shows that the redox carriers of the electron-flow system are bound to three integral protein complexes (PS I, PS II, cytochrome b_6/f complex). Each complex spans the membrane and contains several carriers each oriented in or at the membrane by specific binding to the protein subunits of the complexes for optimal rates and directional electron flow. Peripheral proteins are connected to the integral complexes either on the lumen face of the membrane as, for example, the watersplitting system, or on the matrix face as for the $NADP^+$ reducing system via ferredoxin. The large integral complexes each consist of several hydrophobic protein subunits and are interconnected by carriers that can move laterally in or on the membrane: plastoquinone, plastocyanin, and ferredoxin. Figure 4 also indicates the site of inhibition for three types of inhibitors of photosynthetic electron flow: diuron inhibits photosystem II at the Q_B level, and dibromothymoquinone the cytochrome b_6/f complex at the FeS level; paraquat drains electrons from PS I and thus inhibits $NADP^+$ reduction.

In the mechanism of electron flow across the membrane, protons are taken up in certain redox reactions on the matrix side and released by others on the inside of the membrane. Together with the membrane potential of the electrogenic

steps (that is, steps that generate an electric field) of the charge separation in the two photosystems, these reactions result in a proton motive force that drives the proton-dependent adenine triphosphate (ATP) synthesis. ATP synthesis is catalyzed by the ATP synthase, a fourth transmembrane complex (Fig. 4).

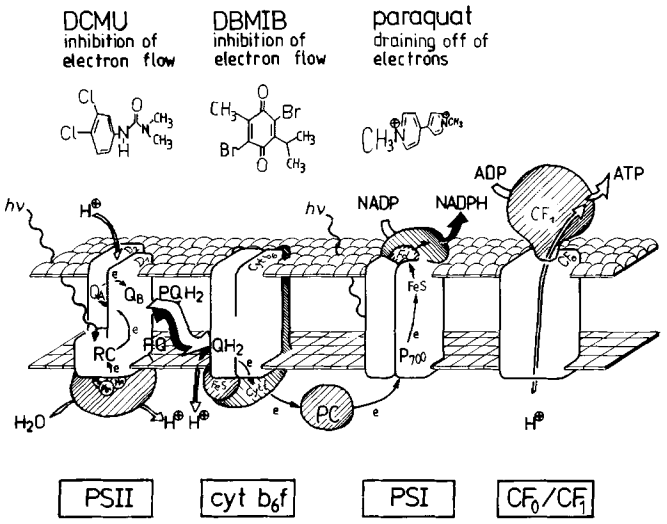

Fig. 4. Integral protein complexes and typcial inhibitors in photosynthetic electron flow and photophosphorylation. Photosystem I, photosystem II, and the cytochrome b_6/f complex contain several electron carriers bound to their polypeptide subunits. Mobile carriers like plastoquinone (PQ) and plastocyanin (PC) form the functional connection between the complexes. Peripheral polypeptides are attached to the integral complexes; for water-splitting on the lumen side of PS II and for $NADP^+$ reduction via ferredoxin (Fd) and bound FeS centers on the matrix side. The ATP synthase consists of a membrane-spanning proton channel (CF_0) and a peripheral CF_1 part. The complex uses the proton gradient, generated by proton liberation by the water-splitting and plastohydroquinone oxidation reaction, for ATP synthesis. Only the D1 and D2 subunits of PS II are indicated; the others (see text) are left out for clarity.

Equation (b) summarizes the generation of reducing power (NADPH) from water oxidation.

$$2H_2O + 2NADP^+ + 8h\nu \longrightarrow O_2 + 2NADPH + 2H^+ \qquad (b)$$

In an abbreviated flow system (Scheme 1) arrows indicate the transport of electrons from the donor to the acceptor electron carrier. Inhibitor sites are indicated.

3. Comparison of the Structure and Function of Photosystem II to the Photosystem of Purple Bacteria

The oxygen-evolving PS II of plant photosynthesis shows homology in structure and function to the photosystem of purple bacteria.[13, 14] The crystallization and X-ray structure analysis of the latter[6-8] was a recent breakthrough in photosynthesis research.

3.1. Photosystem II

The integral membrane complex of photosystem II (Fig. 4) consists of at least ten protein subunits.[15] However all the electron-flow events in PS II take place via prosthetic groups bound to only two polypeptides, called D1 and D2. They form the actual reaction center of PS II. These two protein subunits of PS II are highly hydrophobic integral proteins of about 32 KDa in the thylakoid membrane. They contain the pigments, redox systems, and other components involved in the light-driven redox reaction across the membrane: P_{680}, two monomeric chlorophylls *a*, two pheophytins, two plastoquinones, and an iron ion bound via four histidines. Attached to these two polypeptides are two integral proteins of 47 and 43 kDa which carry about 30 core "antenna chlorophylls" to transfer excitation energy to chlorophyll in the reaction center.

In addition, preparations of a functional PS II contain two cytochrome b_{559} subunits.[16] Their function is still unclear, as is the role of the other smaller protein subunits. One small protein (4.8 kDa) always remains attached to a highly enriched, functional photosystem II, signalling a particular role, perhaps in conferring structural stability.[17] In the in

situ PS II complex, three hydrophilic peripheral polypeptides that stabilize the manganese complex of the water-splitting system are attached to the D1and D2 subunits.[18]

The amino acid sequences of all the protein subunits of PS II are known (Table 1). The major integral proteins are encoded in the chloroplast genome: the two reaction-center polypeptides D1 and D2 by the *psb*A and *psb*D gene and the 47 and 43 kDa polypeptides by the *psb*B and *psb*C, respectively.[19] However, the three peripheral polypeptides are en coded in the genome of the nucleus and are imported into the chloroplast.

The principal properties and mechanisms in electron flow through PS II have been known for a long time.[10, 11] Also long since recognized is the close similarity in the function of PS II with that of the reaction center of the photosynthetic purple bacteria[13] (whereas PS I is similar to the reaction center of some photosynthetic *green* bacteria). This homology of PS II to the photosystem of purple bacteria led to the breakthrough in understanding the structure of PS II.

3.2. The Photosystem of Purple Bacteria

The modern concept of the mechanism of plant photosynthesis as a water-splitting reaction accompanied by formation of a strong reductant was based on theoretical work by *van Niel* as early as 1941[20a] that recognized the similarities (rather than differences like the fact that bacteria cannot evolve oxygen) between plant and bacterial photosynthesis. This hypothesis was in contradiction to *Warburg's* notion of CO_2 splitting to oxygen and a "C" photolyte as the primary reaction.

Just how extensive the homology of photosynthetic electron flow in plants and purple bacteria is, became clear later. The carriers and the mechanisms of the electron flow in purple bacteria are very similar to those of PS II.[12-14, 21] Bacterial reaction centers (from *Rhodobacter sphaeroides*) contain four bacteriochlorophylls, among them a reaction center chlorophyll dimer P 870, two bacteriopheophytins, two bound ubiquinones, and iron ion bound to four histidines.[22] Exactly the same composition is found in PS II (Table 1). It is thus not surprising that a result in one system immediately stimulates research in the other. For example the concept of two bound quinones in the reaction center was established first in the bacterial system.[23] In agreement with this, terbutryn, a potent herbicidal inhibitor of photosystem II, is also an inhibitor of quinone reduction in purple bacteria.[24] The other herbicides, though, have little or no effect on bacterial photosynthesis.[24] The protein composition of the photosystem of purple bacteria is much simpler than that of PS II; it consists of only three protein subunits.[6, 22] The redox carriers of the photosystem are bound to two of them, called L and M. (Note that the reaction center of PS II is also bound to only two protein subunits.) Together with an H subunit they form the integral membrane complex in the bacterial system. The DNA sequences of the genes for the two proteins involved in the reaction center[22, 25] have a certain homology[25] to the amino acid sequences of the D1 and D2 subunits of PS II. After the X-ray structure of the photosystem of *Rhodopseudomonas viridis* became available,[6, 8] it was recognized that the folding of the protein sequences and therefore the structure of the reaction-center subunits of PS II and of the purple bacteria photosystem is also very similar indeed.[7, 26, 27]

The major difference between photosynthesis in bacteria and in plants is that bacteria cannot evolve oxygen. Instead they oxidize other inorganic or organic electron donors to generate the reducing power required for CO_2 assimilation. The electron donor for the bacterial reaction center is not a manganese complex but cytochrome c_2. The composition of plant and bacterial photosystems is summarized in Table 1.

Common to photosynthesis in bacteria and plants is that they can cycle electrons around a photosystem. Light excitation of the photosystem is the driving force for the charge separation across the membrane and vectorial electron flow. The ubiquinone pool reduced by the bacterial reaction center is oxidized back to the initial state by a cytochrome b/c_1 complex. This is analogous to the plastoquinone oxidation by the cytochrome b_6/f complex in the plant. In bacterial photosynthesis the electron is returned to the photosystem via a cytochrome c_2. This cytochrome is functionally homologous to plastocyanin, which is oxidized back by PS I. The vectorial redox reactions in bacterial systems also generate a proton potential that is used for ATP synthesis, as it is in plant photosynthesis. For this cyclic electron flow, bacteria need only one photosystem (Fig. 5). In the plant the generation of the reductant for CO_2 assimilation (NADPH) at the expense of water requires two photosystems.

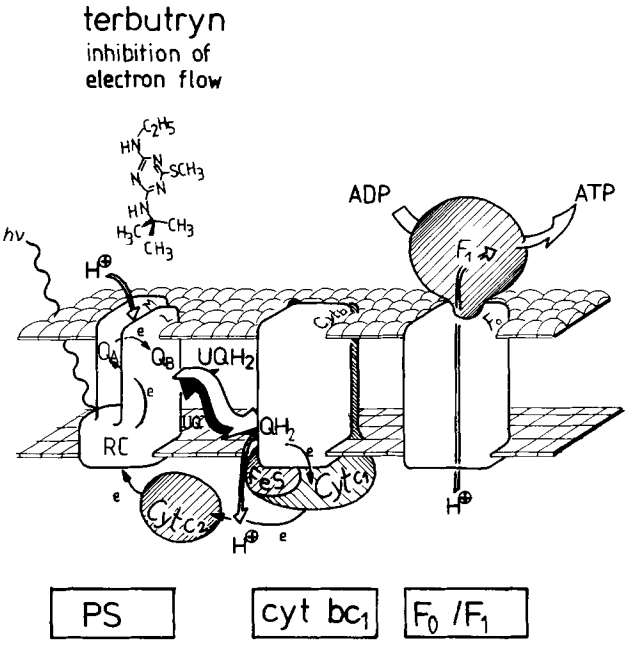

Fig. 5. Integral protein complexes and typical inhibitors in cyclic electron flow in purple bacteria. The integral complex of the photosystem and a cytochrome bc_1 complex participate in a cyclic system, in which ubiquinone mediates between the two complexes and pumps protons across the membrane. The ATP synthase is driven by the proton gradient.

The X-ray structure of the photosystem of purple bacteria of *Rhodopseudomonas viridis*[7, 8] and then of *Rhodobacter sphaeroides*[22] established the existence of five transmembrane helices each for the two reaction-center polypeptides L and M. It clearly indicated the orientation and binding to specific amino acids of the prosthetic groups (the reaction

center bacteriochlorophyll, bacteriopheophytins, Fe, and the two quinones) to these helices. Furthermore, the terbutryn orientation in the Q_B binding site was obtained directly by X-ray analysis after soaking the crystals with the herbicide.[7, 8] Thus the detailed structure of one photosystem was suddenly revealed and extrapolation to PS II could be attempted.

Accordingly it was proposed,[9, 26, 27] and subsequently experimentally verified,[16] that the D1 and D2 polypeptides are the reaction-center protein subunits of PS II. This was based not only on the (relatively low) amino acid sequence homology (about 27%) but more convincingly on their great folding homology to the L and M subunit of the bacteria according to hydropathy profile analysis.[26] Furthermore histidines for the binding of P_{680} and Fe in the D1 and D2 proteins of PS II were conserved at equivalent positions in the amino acid chains L and M[27] (as seen in the X-ray structure[6-8] of *R. viridis*), when the folding of the amino acids of these four polypeptides was aligned.

The key information that led to the proposal of the folding model for the PS II reaction-center polypeptides[26] was the identification of the amino acids in the D1 protein of plants and algae substituted in herbicide-tolerant mutants.[28] Equivalent amino acid substitutions occurred in purple bacteria resistant to the triazine herbicide terbutryn.[29] This surprisingly large homology in general, and even larger in the specific amino acid residues, permitted conclusions on the direct alignment of these amino acids in the vicinity of the Q_B sites. The terbutryn site is depicted in Figure 6 and will be explored in detail in Section 8.

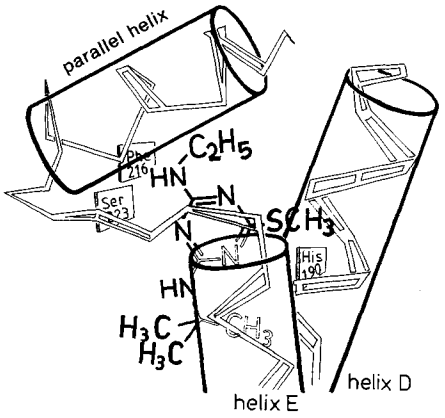

Fig. 6. The herbicide terbutryn in the L polypeptide subunit of the bacterial reaction center. The end of two transmembrane helices and a parallel helix are shown. They contain the Q_B- and herbicide-binding site according to [7]. Compare with Figure 11 for the binding of terbutryn in the equivalent D1 protein of PS II.

4. Photosynthesis and Herbicides

The first photosynthesis-inhibiting herbicides such as aryl urea (e.g. Diuron, DCMU) and triazine derivatives were identified 1956[1] even before the two light reactions and two photosystems were known and before plastoquinone had been discovered. Early on their mode of action was thought to involve the oxygen evolution system, but this could not be specified more closely at that time. When the two photosystems in plant photosynthesis were identified in 1960, the locus of herbicide action was narrowed down to photosystem II, which reduces plastoquinone (discovered in 1959). This progress in photosynthesis research now allowed a more detailed description of the biochemical and biophysical events in a photosystem and increased the usefulness of herbicidal inhibitors.

A prime example of the importance of this specific herbicide inhibition of a photosystem was the identification of quinones as the primary electron acceptor.[23, 30] Herbicides were also essential for the understanding of the features of a photosystem, such as the elucidation of the pathway of light excitation of PS II from varying antenna size and the accompanying fluorescence patterns and kinetics.[31, 32]

The concept of control of a reaction center's function by a hypothetical "state", called Q or A, was proposed by *Duysens*[31] and by *Butler*.[32] If the state Q is already reduced, it cannot accept an electron from the reaction center. As the photosystem is further excited, the excitation energy must be released and is observed as an increase in chlorophyll fluorescence. Herbicides prevent oxidation of the reduced state Q,[31] enhancing fluorescence. In this way the properties of PS II can be easily followed. The property of enhanced fluorescence upon addition of a herbicide is now often used as a convenient way of checking herbicide efficiency under field conditions.

The primary quencher Q of PS II, originally defined as a state rather than a specific compound, was identified ten years later to be a quinone by its absorption at 320 nm[30] and is now known to be the bound plastoquinone Q_A. The existence of two bound sites, Q_A and Q_B, in photosystem II was discovered after two quinones a were found in the bacterial system.[23] It became clear that a second bound quinone is necessary to transfer the electrons from the semiquinone of Q_A to the stable two-electron-accepting form: quinone Q_B (called a two-electron gate).[23]

Diuron and its class of herbicides were important not only for the characterization PS II, but also for identifying PS I reactions. Because the activity of PS I is not affected by these compounds its properties may be studied when PS II activity is inhibited by the presence of a herbicide.[33] Two other inhibitors, dibromothymoquinone (DBMIB)[34] and the dinitrophenyl ether of iodonitrothymol (DNP-INT),[35] were designed as possible PS II herbicides, and indeed turned out to be very potent quinone antagonists. Since they are also very effective in preventing plastohydroquinone oxidation, they became very important inhibitors of the cytochrome b_6/f complex[33] [see Fig. 4 and Equation (a)].

DBMIB was particularly instrumental in establishing the following facts: 1) there are two energy-conserving sites in the electron-flow system, that is, two proton transduction sites through the membrane that couple to ATP synthesis[36, 37] (shown in Figs. 2 and 4). 2) there is artificial proton pumping through the membrane possibly coupled to ATP formation.[38] This proved the existence of vectorial electron flow, which led to the final acceptance of the chemiosmotic theory of *P. Mitchell*, the major interest of photosynthesis research in the seventies.

The use of inhibitors (herbicides) continues unabated; their impact in recent years on the molecular biology of

photosynthesis is taken up again below. The number of papers in the literature on photosynthesis which use herbicides as convenient and powerful tools in photosynthesis research extends into the thousands.

5. The Chemistry and Biochemistry of Herbicides in Photosystem II

Advances in the understanding of photosynthetic mechanisms naturally gave strong impetus to industrial herbicide research as well. Photosynthetic assay systems are now routinely employed in industrial laboratories for a quick assay of the mode of action. The inhibitory potency of a herbicide, expressed by a pI_{50} value (= the negative logarithm of inhibitor concentration at which the photosynthetic activity is reduced by half) obtained in a cell-free system, that is, in isolated thylakoid membranes, is a direct measure of its primary action and is not complicated by secondary effects in the screening with intact plants, such as rate limitation by uptake, translocation, or degradation during transport to the target site. Important is the extrapolation to new chemical classes in the rational design of new compounds.

The correlation of inhibitory potency (as measured in isolated thylakoid membranes) to its descriptors in a group of herbicides (=QSAR), provides information on the possible contribution of electronic, steric, and lipophilicity parameters. These help to describe a mirror image of the binding pocket, from which its properties and dimensions and the interactions between the herbicide and amino acids may be deduced.

In 1961 already *Good*[39] suggested an interaction via hydrogen bonds of the essential element of the herbicide with specific peptide bonds in a hydrophobic pocket of the target protein. This concept turned out to be correct; these hydrogen bonds and the specific amino acids involved have now been identified and will be discussed in Section 8. The essential substructure in the classical type of PS II herbicides is considered to be an X=C−NH− group with an sp^2 hybridized carbon atom. This substructure is found in ureas, triazines, triazinones, carbamates and biscarbamates, pyridazinones, uraciles, anilides, and benzimidazoles. *Büchel* summarized the information in detail in 1972.[40] Classical and recent examples are shown in Figure 1 and Figure 7.

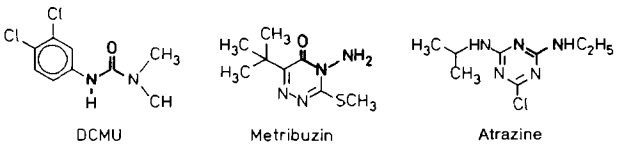

Fig. 7. The basic chemical unit in herbicides of the classical type (in boldface in the formulas). This element is essential for the binding to the protein of PS II.

Hansch and *Fujita*[41] introduced in 1964 a method for studying the correlation of chemical structure and biological activity by quantifying the biological potency with various physical parameters. This linear regression analysis method known as QSAR is applied to many pharmacologically active compounds and potential plant-protection agents. Photosynthesis inhibitors were among the first to be studied.[42, 43] The first QSAR study of arylureas by *Hansch* and *Deutsch*[43] led to Equation (c) in which the pI_{50} value is

$$pI_{50} = 4.183 + 1.290\,\pi + 0.544\,\sigma \qquad (c)$$

the easily determined negative logarithm of the concentration that inhibits 50% of photosynthesis activity in isolated thylakoids. The parameter π is proportional to the logarithm of the partition coefficient in octanol/water and σ is the Hammett constant. Later this QSAR was applied to many more ureas with other structures and to other photosynthesis herbicides.

At the photosynthesis meeting at Freundenstadt (1968) the QSAR of the just discovered 1,2,4-triazinone derivatives was reported.[44] The relatively simple equation has the form (d), where lg P is again the logarithm of the partition

$$pI_{50} = 4.608 + 1.959\,\lg P - 0.486\,(\lg P)^2 \qquad (d)$$

coefficient in octanol/water. The herbicide metamitron was developed as a result of this regression analysis. Other triazinones were analyzed and the QSAR published in 1979[45] even allowed a calculation of the dimensions in the binding niche (Fig. 8). The dimensions are now supported by computer modeling, as discussed below.

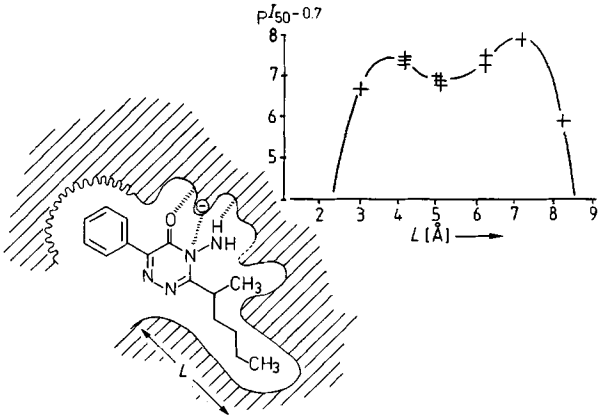

Fig. 8. Dimensions in the protein pocket binding of a triazinone herbicide. The dimensions were obtained in 1979 from QSAR studies on the correlation of the spatial parameters of a series of triazinone herbicides on the inhibitor potency in PS II [45]. These dimensions should be compared with those obtained after computer modeling in Figure 13. The inset shows the dependance of the inhibitory potency as pI_{50} on the chain length L of the 3-alkyl-4-amino-6-phenyl-1,2,4-triazin-5-ones, among them the commercial sugarbeet herbicide Goltix®.

6. Two Classes of Photosystem-II Herbicides in Overlapping Binding Sites

The "classical" herbicides of the urea and triazine type among others (Fig. 1) still dominate the field. But a second class of photosystem-II inhibitors with different chemical properties was recognized in 1979,[46] among them long-

known herbicides like dinoseb and ioxynil.[2, 3] They are, in the broadest sense of the term, phenolic inhibitors, for instance compounds like pyridate (Fig. 1) in which the effective form is the deacyl derivative, that is, a phenol. Nitrophenols, once thought to act by their uncoupling activity on respiratory phosphorylation, were shown to be very potent inhibitors of photosynthetic electron flow, like the cyanophenols (Fig. 9). Although they inhibit the PS II reaction somewhat differently from the classical PS II herbicides, they also interfere with Q_B function.[47]

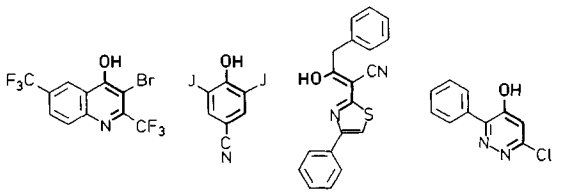

Fig. 9. The basic chemical unit in phenol type herbicides. A substituted quinoline, ioxynil, a ketonitril, and deacylpyridate are illustrated for comparison with the classical type herbicides in Figure 7.

The measurement of binding constants and studies of specific displacement of homologous inhibitors, introduced by *Tischer* und *Strotmann*,[48] indicated that phenol type herbicides also displace classical herbicides, although in a somewhat different way to the competitive displacement within the group of classical compounds.[49] A concept of overlapping binding sites in a common binding domain was developed[33, 46, 50] to accommodate different classes of chemical compounds in the same binding pocket of one protein (Fig. 10). Significantly phenol type compounds do

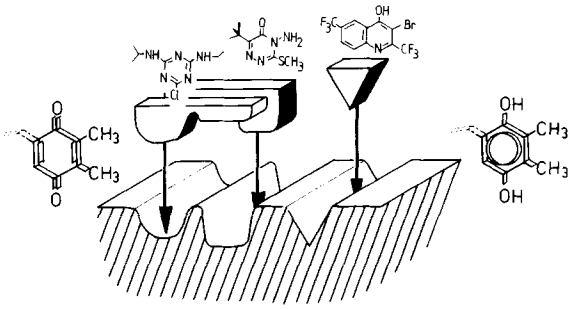

Fig. 10. Overlapping binding sites in the herbicide binding protein. Specific binding pockets were postulated for specific substituents of several herbicides in a common binding domain in order to explain different inhibition patterns of the two herbicide families that displace plastoquinone. Today this model from 1979 has given way to the postulate that different amino acid residues in the binding niche on the D1 protein are responsible for the binding of the herbicides as depicted in Figures 13 and 14.

not contain the essential structural element mentioned for ureas and classical herbicides. Furthermore, QSARs indicate a greater dependence on steric parameters, and those of *Verloop* in particular proved appropriate.[46] Molecular orbital calculations confirmed the very different charge distribution of the two groups,[51, 52] which, however, has not yet been incorporated into QSAR studies. In addition to nitro- and cyanophenols, more groups of compounds are known now to belong to the phenol type: hydroxyquinolines,[52] hydroxypyridines,[53] ketonitriles,[54] and the herbicide pyridate[55] in its deacyl form. Perhaps compounds in this class that are still under development will guide rational design into a new direction, because they show a different effect on regulatory processes in photosynthesis (Section 9).

7. Mutations in the *psb*A Gene in Herbicide-Tolerant Plants

The herbicide-binding protein D1 is encoded by the *psb*A gene in the chloroplast genome, sequenced first in 1982 by *Zurawski* et al.[56] A mutation in the *psb*A gene that led to atrazine tolerance in weeds growing close to maize or wheat fields[57] was shown to be due to an amino acid substitution in the D1 protein (Ser 264 → Gly).[58] This Ser 264 mutation has now been found in quite a number of higher plants that were exposed for longer periods to herbicides.[59] In nature only the Ser 264 to Gly change has been found. In cell cultures of higher plants Ser 264 to Thr[60] and to Asn[61] substitutions were also identified.

In green and blue-green algae (cyanobacteria) many more mutations can be produced, either by site-selected or site-directed mutageneses.[28] These algae have the same mechanism of photosynthesis as higher plants. Since the function and structure of the photosystems are the same, these algae are useful organisms for studying both photosynthesis and herbicides in the laboratory. As both cyanobacteria[62] and green algae[63] can now be transformed by mutagenized DNA, these organisms are very useful for genetic engeneering in herbicide research.

The significance of the mutations in the *psb*A gene and the resulting amino acid substitutions in the D1 protein (the herbicide-binding protein) is the identification of amino acid residues participating in herbicide binding in the protein target. Moreover, this is the basis for the future development and design of manipulated herbicide tolerance in crops. Altogether eight mutations that provide herbicide tolerance have now been identified by site-selected screening of natural mutants or mutants produced by mutagens.[64] They are Phe 211 to Ser, Val 219 to Ile, Ala 251 to Val, Phe 255 to Tyr, or Leu, Gly 256 to Asn or Glu, Ser 264 to Gly, Ala, or Thr, Asn 266 to Thr and Leu 275 to Phe. More recently site-directed mutagenesis (i.e. manipulating the DNA in vitro and then transforming cyanobacteria and green algae) has revealed many more amino acid substitutions in the D1 protein that can be analyzed for herbicide tolerance. The effect that conclusions from mutant studies have on computer modeling of protein folding and herbicide docking are discussed in Section 8.

Most of the mutants of the green algae *Chlamydomonas reinhardtii* tolerant to metribuzin are also resistant (cross resistance) to triazines, ureas, and other herbicides of the classical type (Fig. 1). To phenol type inhibitors (Fig. 9), however, these mutants show little tolerance or even hypersensitivity (or negative cross resistance).[65] These mutant studies show even more clearly that the classical and phenol type herbicides share some but not all of the amino acid binding sites of the Q_B binding pocket. Whereas the classical herbicides are bound to Ser 264 and Ala 251 (and therefore mutants become tolerant when these amino acids are

changed) phenols orient differently and do not change potency with a Ser 264 or Ala 251 mutation. The concept of overlapping binding sites[46, 50] has been replaced by computer models in which the correct orientation of each individual compound towards a particular amino acid residue in the binding domain of the Q_B site can be specified. Hypersensitivity to substituted triazinones was predicted[67] and in fact is found in certain mutants of *Chlamydomonas*.[66-68]

8. Topology of the Herbicide-Binding Niche in D1 Protein

The general topology of the D1 protein and the herbicide-binding site was proposed in 1986[26] after comparing its amino acid sequence and that of the L subunit of the purple bacteria. The first five mutants in herbicide-tolerant plants and algae known at that time agreed with the model because the amino acid substitutions could be well rationalized (see Section 1). For detailed modeling further information was used, such as results on natural or engineered mutants and from the cross resistance patterns.[65, 66, 68] The cross resistance of herbicides of different inhibitor families to different mutants is interpreted as reflecting different binding orientations. The two families of PS II herbicides were grouped as a serine- and a histidine-binding family.[69] Indeed this corresponded to the orientation of two inhibitors in the Q_B binding pocket of the photosystem of *Rps. viridis* observed by X-ray analysis.[7, 8] Recently the orientation of diuron in a diuron-sensitive mutant of *Rps. viridis* was also shown.[70] In this mutant the carbonyl group of diuron points towards a histidine. As diuron is a serine type inhibitor, but can point toward histidine as well, the classification is apparently not sufficient.

Photoaffinity labeling is another valuable technique for identifying amino acids in the herbicide-binding niche. When a radioactive azido derivative of the inhibitor is irradiated in the target pocket, it becomes covalently attached to the protein. In the first application *Pfister* and *Arntzen*[71] identified a 32 kDa protein as the herbicide-binding protein using azidotriazine. Proteolysis of the labeled protein indicated that Met 214 of the D1 protein was the binding site.[72] *Oettmeier* et al. sequenced the D1 protein after labeling it with azidomonuron[73] and azidocyanophenol.[74] They found that Tyr 237 and 254 and Val 246 were further aminoacids of the plant Q_B binding pocket.[73, 74]

With this information a number of herbicides were modeled in the Q_B binding niche of the reaction center polypeptide of PS II.[66, 68] Figure 11 shows schematically the binding of terbutryn in the D1 protein of PS II. In the analogous scheme for bacteria depicted in Fig. 6 terbutryn is bound to the L subunit of the photosystem. Figure 12 shows the part of the amino acid sequence of the L subunit of *Rps. viridis*[6-8] that is relevant for herbicide binding superimposed on the corresponding section of the D1 protein of PS II: the end of two transmembrane helices (IV and V), of a parallel helix and the connecting sequence. There are three additional amino acids in the D1 protein as can be seen in Fig. 12. The sequence from amino acid 222 to 247 in the D1 protein is omitted, as this has no homology to the L subunit of the bacterial system; the corresponding sequence of the L subunit therefore protrudes. The role of this sequence is discussed in Section 9, which deals with regulatory phenomena.

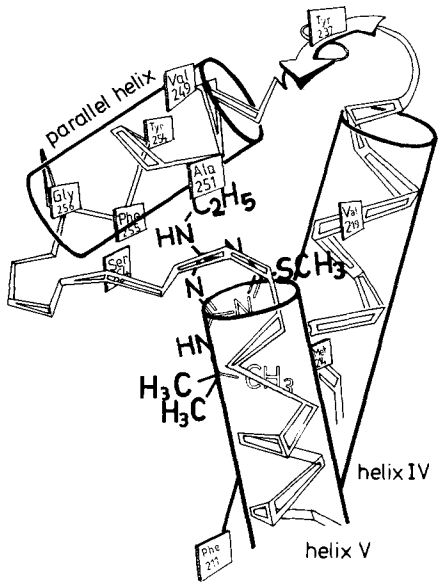

Fig. 11. The herbicide terbutryn in the D1 protein subunit of PS II. This computer model was constructed by using the homology with the folding of the L subunit in purple bacteria in Figure 6. Just the end of two transmembrane helices and the parallel helix participating in Q_B binding were involved. Aminoacids known to be involved in herbicide binding by amino acid substitutions in herbicide-tolerant plants (Phe 211, Val 219, Ala 251, Phe 255, Gly 256, Ser 264 and Leu 275) or tagged by photoaffinity labeling (Met 214, Tyr 237, Val 249, and Tyr 254) are marked.

To dock a herbicide into the Q_B binding pocket in the D1 protein, we used the data of cross resistance for a number of 3-alkyl derivatives of 4-amino-6-phenyl-1,2,4-triazin-5-ones, among them the sugarbeet herbicide metamitron (Goltix®, no. 2 in Table 2). The five mutations in *Chlamydomonas reinhardtii* are Val 219 to Ile, Ala 251 to Val, Phe 255 to Tyr, Ser 264 to Ala, and Leu 275 to Phe. The positions of these mutations in our model of the Q_B binding niche are depicted in Figure 13.

The inhibitor data for metamitron and six other 3-alkyl derivatives is given in Table 2. In the serine mutant the inhibitor potency of all triazinones is greatly reduced. This can be explained by the loss of a hydrogen bond between the hydroxyl group of serine and the triazinones. A detailed consideration of the possible spatial orientation indicates that a hydrogen atom of the free amino group of the inhibitor participates in the hydrogen bond to serine, whereas the carbonyl group of the triazinone participates in a hydrogen bond to the peptide group Phe 265 adjacent to serine. The phenyl ring of the triazinones accordingly points in the same direction as the isoprene side chain of plastoquinone. In this assumed basic orientation of the triazinones, the substituent R that we varied points to the direction of Ala 251, Ser 268 and finally Asn 247 (Fig. 13). The space for the side chain R is very similar to that proposed in 1978[45] from QSAR studies (compare Fig. 8 and Fig. 13).

There is a bottleneck between Ala 251 and Ser 268, which becomes narrower by the mutation of Ala 251 to Val. This

Fig. 12. Stereoplot of the protein folding of the Q_B binding pocket of the D1 protein of PS II (green)[68] superimposed on that of the L subunit of the bacterial photosystem (purple)[75]. The three-dimensional folding of the amino acid backbone is viewed perpendicular to the membrane plane, looking into the Q_B binding niche. To superimpose the D1 protein on the known folding of the L subunit, the four amino acids that have identical functions in both photosystems were brought into optimal correspondence. These are the two iron-binding histidine units 190 and 230 in the bacteria (215 and 272 in PS II) serine 223 (264 in plants) and phenylalanine 216 (255 in PS II), which is oriented behind the quinone ring. The D1 protein has more amino acids than the L subunit in this sequence: one between Ser 264 and transmembrane helix V and two between the parallel helix and the stretched sequence around Ala 263. Fourteen additional amino acids in the D1 protein between the parallel helix and transmembrane helix 4 have been omitted.

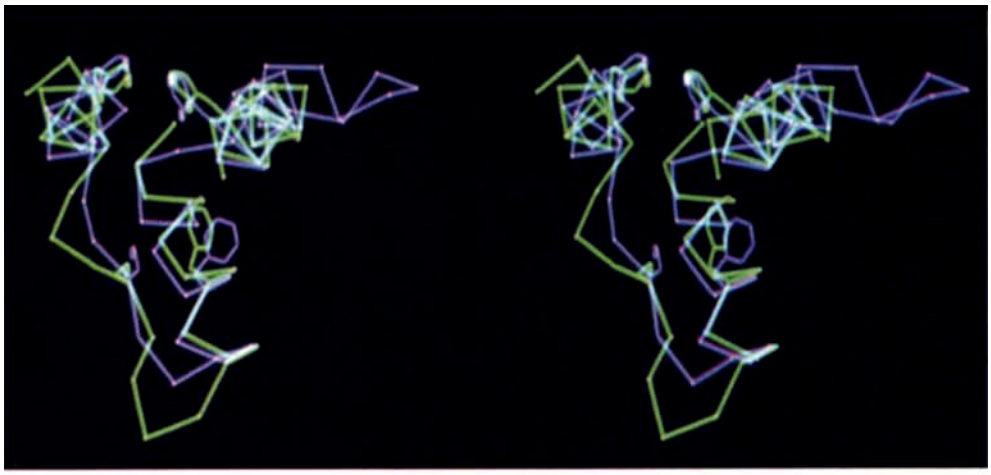

Fig. 12.

Fig. 13. Stereopicture of the orientation of an ethyl derivative of triazinone (compound 3 in Table 2, in red) in the Q_B binding pocket in the D1 protein of PS II (green). The protein folding of the D1 sequence in the Q_B site is viewed parallel to the membrane plane, that is, perpendicular to the view in Figure 12. Amino acid residues are indicated (in the atomic colors): Val 219*, Ala 251*, Phe 255*, Ser 264* and Leu 275*, Asn 247 and Ser 268. An asterisk indicates those that are substituted in herbicide-tolerant plants. A water molecule is postulated between Asn 247 and Ser 268.

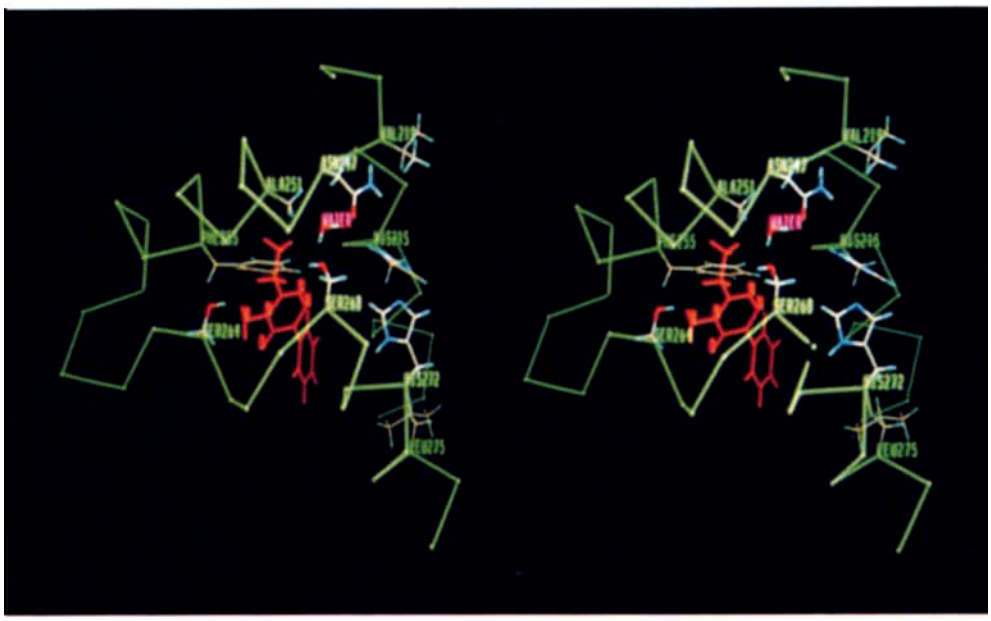

Fig. 13

Fig. 14. Stereopicture of the orientation of a pentyl derivative of triazinone (compound 6 in Table 2, in red) in the Q_B binding pocket in the D1 protein of PS II. The water molecule between Asn 247 and Ser 268 has been replaced by the herbicide and therefore the side chain of Ser 268 is turned sideways if compared with its orientation in Figure 13.

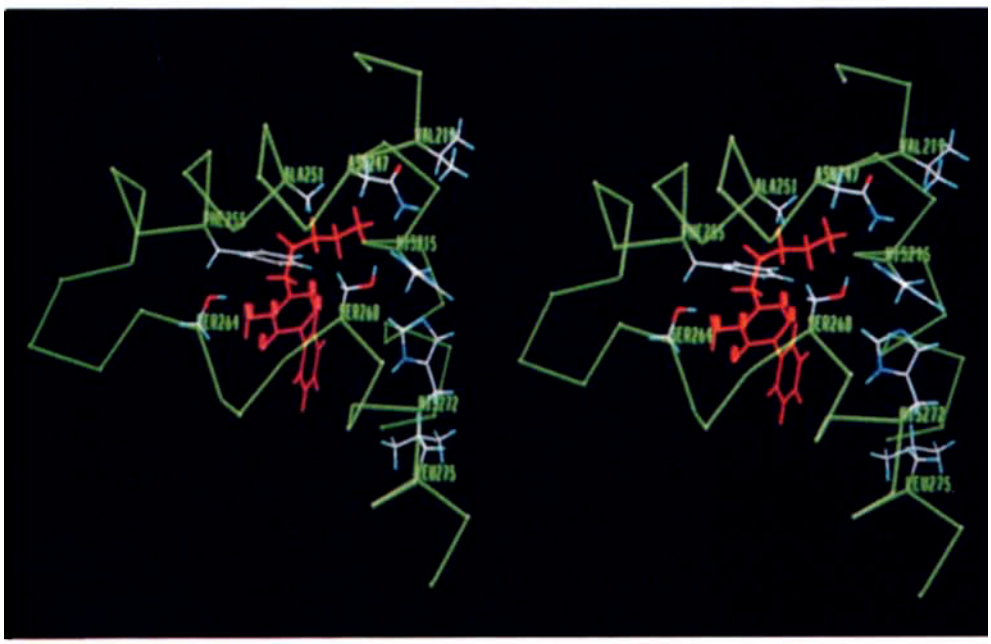

Fig. 14

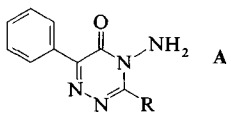
feature which easily explains the strong decrease of the inhibitor values for the triazinones (Table 2). The decrease in inhibitor potency by increasing the chain length R of the triazinones indicates that the hexyl group extends to the end of the binding niche (Fig. 13). However, by compact folding of heptyl and octyl groups, these alkyl chains can also just be accommodated in the wild type (data not shown). Here the side chain of Asn 247 forms the bottom of the binding pocket. Though Val 219 is oriented behind Asn 247 and does not directly extend into the binding pocket, its mutation to the larger isoleucine further diminishes the space available by shifting Asn 247 into the binding area; the potency of the inhibitors falls.

Table 2. Inhibition of photosynthesis in wild type *Chlamydomonas reinhardtii* and five mutants by triazinones of type A.



A

No.	R	pI_{50} wild type[a]	resistance factor for the mutants[b] Ser 264	Ala 251	Leu 275	Phe 255	Val 219
1	H	4.0	>1	>1	>1	0.5	>1
2	methyl	5.5	>30	130	6.3	0.3	1.3
3	ethyl	6.4	>250	100	6.3	0.2	16
4	propyl	5.2	>16	>16	4	0.1	1.6
5	butyl	6.0	>100	>100	10	0.16	2
6	pentyl	6.5	>320	>320	20	0.5	6.3
7	hexyl	4.0	>1	>1	>1	0.4	>1

[a] pI_{50} = negative logarithm of the molar concentration I_{50} of the inhibitor required to reduce the activity to half. [b] Resistance factor = I_{50} (mutant)/I_{50} (wild type).

Triazinones with a short substituent R (H, methyl, ethyl) only just reach Ala 251 (changed to Val in the mutant); surprisingly their potency is also lower. We conclude that in the mutant not only the local space for amino acid 251 is changed, but also the relative position of the parallel helix (position 247 to 258) towards Ser 264. Serine's hydrogen bonds dominate the overall binding affinity to triazinones. The triazinone with R = propyl exactly reaches the bottleneck between Ala 251 and Ser 268. A similar shift as in the Val 219 mutant will thus reduce its potency. The triazinones with larger substituents R like butyl and pentyl bind better to both wildtype and mutants than the propyl derivatives, possibly due to better spacefilling.

We further assume the presence of a water molecule between Ser 268 and Asn 247 in the wildtype (see Fig. 13), because the bacterial system contains a water molecule at an equivalent position.[7, 75-77] The displacement of the water molecule in the D1 protein by the Ala 251 and Val 219 mutations might explain the irregularities in the correlation of inhibitor potency with chain length (Table 2 and Fig. 8). Fig. 14 illustrates the binding of the pentyl derivative after the displacement of the water molecule visible in Figure 13.

All triazinone derivatives of Table 2 show higher inhibitor potency in the mutant Phe 255 to Tyr compared with the wildtype. The phenyl ring of Phe or Tyr 255 and the ring system of the triazinones are probably stacked with parallel ring orientations. The introduction of a hydroxyl group in the mutant should not disturb the stacking. As we see no possibility for an additional hydrogen bond between tyrosine and the triazinones, we cannot yet explain the increase in potency. As Leu 275 is not in direct contact with the triazinones, the inhibitor potency in the Leu 275 mutant is not affected.

9. Regulatory Phenomena Inhibited by PS II Herbicides

The mode of action of PS II herbicides was hitherto described as a competitive inhibition of Q_B function in the electron flow of PS II (i.e., arresting photosynthesis). An additional effect might have even more important consequences. This involves the inhibition of the fast degradation and biosynthesis (the rapid turnover) of the herbicide binding protein in the chloroplasts. Surprisingly, even under normal growth conditions the D1 polypeptide of PS II shows a much higher light-dependent degradation–biosynthesis turnover than all other thylakoid membrane proteins.[78, 79] It is thought that the rapid turnover is part of a repair mechanism.[5, 80] Apparently photosystem II is continuously deactivated by excess light, a process called photoinhibition.[80] The mechanism of deactivation is not yet defined but it appears to be due to damage in the amino acid sequence or a modification of the folding of the D1 protein. The damage to the D1 protein can be repaired only by displacement and complete resynthesis of the polypeptide and reassembly of photosystem II. This turnover and repair mechanism is prevented by most of the inhibitors of the Q_B site, such as diuron or atrazine,[78, 79, 81] but not by certain inhibitors of the phenol type, for example bromonitrothymol and ketonitrile.[82, 84] It might be significant that those inhibitors of PS II that inhibit turnover are also herbicides, whereas the others are not.

Interference of a herbicide with a regulatory process in photosynthesis might have much greater impact on the secondary response of the plant than mere interruption of the photosynthetic electron flow—after all, a plant survives extensive dark periods where no photosynthesis is possible. Interference with a repair process in photoinhibition would sustain and aggravate the inhibition of PS II.[66, 83, 84] Perhaps this provides a hint why the PS II herbicides do not destroy the plant just by starvation, but bleach it as well.[85]

The molecular basis for this interference with the light-dependent degradation of the D1 protein is slowly becoming clear. Apparently certain amino acids forming the Q_B binding pocket not primarily involved in electron flow participate in the photodegradation process. The primary cleavage site is close to Glu 240.[86, 87] A recognition sequence (PEST sequence) that would signal to a protease (Fig. 15) is postulated in a position just in front of Arg 238. As already mentioned, the photoaffinity technique tagged Tyr 237 with azidomonuron.[73] So this amino acid lies close to the cleavage site (Fig. 15). A substituent of a herbicide might extend into the extra loop in the amino acid sequence of the D1 protein that is specifically involved in regulatory processes in photoinhibition. In computer modeling (Figure 11–14) Tyr 237 can be placed close to Asn 247 and Val 219. Mutants have already shown that Val 219 is involved in herbicide binding. Thus it becomes conceivable that photoinhibition

and turnover processes are modulated by the redox and occupancy state of the Q_B site.[80, 84] Herbicides in the extra loop of the Q_B binding pocket interfere with the photodegradation, possibly by preventing necessary conformational changes involved in the cleavage process. In the vicinity of the protein cleavage site of the D1 protein in rapid turnover is Arg 238, a trypsin cleavage point. The behavior of Arg 238 toward trypsination mirrors that of the loop sequence toward photodegradation: the blocking of trypsination at Arg 238 by herbicides like DCMU and atrazine, but not by herbicides of the phenol class[84] is exactly analogous to the behavior of the two types of herbicides in photodegradation. The trypsination of the D1 protein has a long experimental history and actually led to the discovery of the protein site for herbicide binding to PS II.[88]

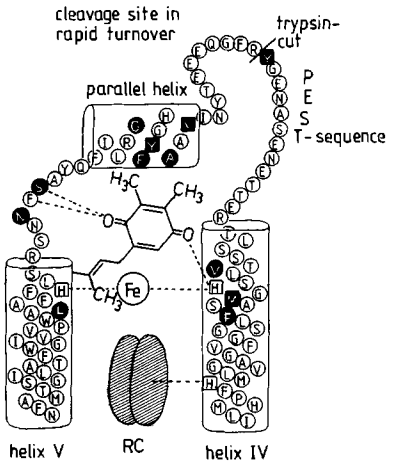


Fig. 15. Scheme of the folding of the amino acid sequence of protein D1 involved in herbicide binding and regulation (photodegradation). Broken lines represent interactions between plastoquinone and amino acid groups in the Q_B binding protein. Solid circles indicate amino acids substituted in mutants and blocks those tagged by photoaffinity labeling. A specific trypsin cut occurs at Arg 238 that is close to Tyr 237, tagged by azidomonuron. Amino acids 228 to 246 are significant for the cleavage of the D1 protein in its rapid turnover and in recognition of hypothetical protease (PEST sequence). This extra loop in the D1 protein of PS II (not present in the L subunit of bacteria) folds back over the Q_B site, probably placing Tyr 237 close to Asn 247 and Val 219. Certain herbicides in the Q_B site influence the rate of cleavage by an endogenous protease in rapid turnover, and by trypsin at Arg 238. (To compare this figure with the stereo plots in 12–14, helix V is drawn to the left of helix IV.) RC = reaction center.

Protein phosphorylation might play a role in control of photodegradation of the herbicide-binding protein, because the redox state of the plastoquinone pool also modulates the phosphorylation of a number of thylakoid proteins, among them the D1 polypeptide. This protein phosphorylation is inhibited by diuron,[89] another manifestation of herbicidal action. This is probably of great significance for understanding both the regulation of PS II and the mode of action of herbicides. The amino acid loop in the D1 protein from Arg 225 to Asn 247 has no equivalent in the otherwise homologous L subunit of the purple bacteria, which shows neither light-dependent protein turnover nor photoinhibition.

The recently recognized additional mode of action of the PS II herbicides will be a new field of mutual interest for photosynthesis and herbicide research. It promises insight into the molecular basis of the response of the photosynthetic electron-flow system to changes in physiological and light conditions as well as in stress situations.

10. Summary and Outlook

The original common goal of photosynthetic and herbicide research, namely the identification and both structural and functional characterization of the herbicide-binding protein, has been achieved. Surprisingly, it is a reaction-center polypeptide of photosystem II. Herbicide-tolerant mutants proved to be extremely useful in the construction of a three-dimensional model of the folding of this protein. Inhibitors can be modeled within the folded protein, and the amino acids involved in the binding (specific for individual herbicides) can be identified. The particular interactions can be approximated by force-field calculations. The rational design of chemically new photosynthesis inhibitors is no longer the limiting step in the development of a herbicide.

Knowledge of the binding of photosynthesis-inhibiting herbicides allows, in principle, the introduction of resistance on the primary function level by mutagenesis. The acceptance and economic viability of such a procedure is another question.

The knowledge of the three-dimensional folding of a membrane protein, first achieved through a crystal structure analysis by *Michel*, *Deisenhofer*, and *Huber*, gave research into photosynthesis an enormous thrust forward. Certain is that the nowhere near exhausted potential of the molecular genetic method will provide many more unsuspected and surprising insights. The elucidation of other, hitherto unknown regulatory phenomena, which probably also affect the herbicide-binding protein, will also give herbicide research new impetus. Even the properties of the D1 protein known at present, such as its turnover and its participation in protein phosphorylations, as well as the complicated control of the expression of its *psb*A gene, will challenge the molecular biologists for a long time. Photosynthesis and herbicide research promises to remain an outstanding example of cooperation between university and industry.

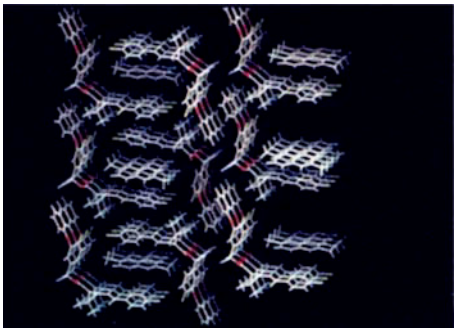

Fig. 1. Structure of the crystal lattice of the flumethrin inclusion compound **3**.

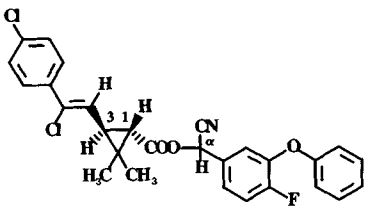
Diastereomer Separation by Formation of Inclusion Compounds: 2,6-Dimethylnaphthalene Complexes of Flumethrin

By *Liborius Born* and *Rainer Fuchs**

Dedicated to Professor Karl Heinz Büchel on the occasion of his 60th birthday

Flumethrin (**1**)[1] is a synthetic pyrethroid used in very small dosages to combat ticks of all types. It consists of 55–60% of the isomeric pair **1a**, (1*R*,3*S*,α*R*/1*S*,3*R*,α*S*), and 40–45% of isomeric pair **1b**, (1*R*,3*S*,α*S*/1*S*,3*R*,α*R*).



Flumethrin **1**

Some time after **1a**/**1b** is dissolved in a technical solvent, usually C_{11}–C_{13} alkyl naphthalenes, to prepare a commercial formulation (emulsion concentrate), the precipitation of crystals whose melting point (100 °C) is distinctly higher than that of **1a** (m. p. = 50 °C) or **1b** (waxy) is observed. Analyses by ^{1}H NMR spectroscopy, GC-MS, and HPLC show that the crystals contain a defined amount of 2,6-dimethylnaphthalene (**2a**), namely, two molecules of flumethrin (**1**) to one of **2a**. The analyses indicate further that the ratio **1a**:**1b** of 55:45 in the emulsion has changed in the crystalline precipitate to 96:4 (after recrystallization); that is, the crystals contain a much higher proportion of **1a**. The hypothesis that the isolated crystals were an inclusion compound of **1a** and **2a** was confirmed on warming 2 mol of **1a** and 1 mol of **2a** in 2-propanol to 50 °C to dissolve them, and cooling the solution to 20 °C. A crystalline inclusion compound (**3**) is obtained (m. p. 108 °C)[2] in 85–90% yield. In **3** the ratio **1a**:**2a** is also 2:1. To obtain more details on the structure of the crystalline inclusion compound **3**, an X-ray crystal analysis was undertaken.[3]

Figures 1 and 2 depict clearly[4] the role that **2a** plays in the lattice of **3**. The two isomers of **1a** form a pseudocycle that corresponds to a 32-membered macrocycle. This macrocycle encloses **2a** as guest[5] in such a way that the methyl groups are positioned in the gaps which remain when the host dimer forms its cavity. Thus **2a** interacts mainly with the chlorophenylvinyl residue of **1a**. This conclusion is supported by an analysis of the shorter heteromolecular distances (≤ 3.60 Å) between **1a** and **2a** which almost without exception involve the H atoms of the chlorophenyl groups. Electron donor/acceptor (EDA) interactions may therefore be the driving force for the formation of **3**.[6] The importance of potential EDA interactions on the formation of **3** is underlined by the fact that crystalline inclusion compounds are also obtained with the acid **4a** (see Table 1).

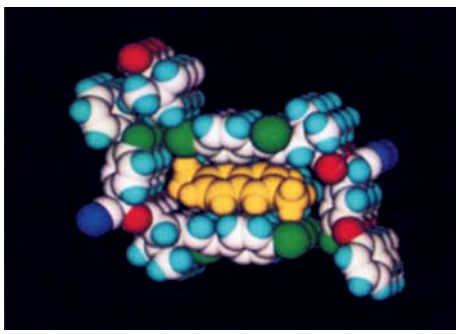


Fig. 2. Space-filling model of the flumethrin inclusion compound **3**.

The formation of flumethrin inclusion compounds is not limited to the guest molecule **2a**. The pseudocycle is large enough to accommodate anthracene (Table 1). The particular selectivity for **2a** is exemplified by the fact that the crystals formed from the technical solvent in which this effect was first noticed included exclusively **2a** as guest, although it represents only 4.8% of this mixture of naphthalene derivatives.[7]

Far more interesting than the separation of specific methylnaphthalenes is the diastereomeric separation on formation of the inclusion compound (Table 2). In contrast to common separations of stereoisomers of guest molecules,[8] the inclusion compounds described here cause the separation of diastereomers of the host molecule.

Table 2. Separation of diastereomers of flumethrin by formation of inclusion compounds.

host		guest	inclusion compounds			
			1st cryst.		after recryst.	
1a	**1b**		**1a**	**1b**	**1a**	**1b**
55	45	**2a**	80	20	96	4
0	100	**2a**		no crystallization		
55	45	**2j**	71	29	92.5	7.5
55	45	**2b**			93	7
55	45	**2k**			92	8

[a] The crystalline inclusion compounds were prepared by mixing 1 mol of the host and 0.5 mol of the guest in 2-propanol. Recrystallization was from 2-propanol or toluene. The diastereomeric composition was determined by HPLC.

As shown in Figure 3, the two enantiomeric isomers of **1a** form a pseudocyclic dimer in which the CN groups are directed outwards. The isomers **1b** that are diastereomeric

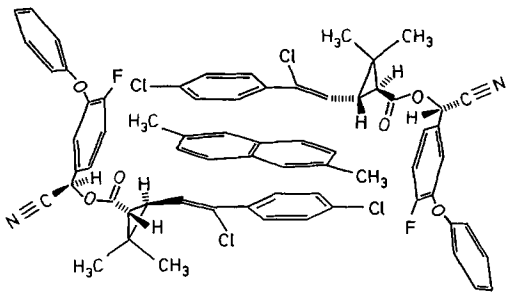

Fig. 3. Inclusion compound **3** with the isomeric pair **1a** (1*S*,3*R*,α*S*/1*R*,3*S*,α*R*). The CN groups point outward.

with **1a** were obtained by changing the configuration at the α-C atom. In this case (Fig. 4) if the rest of the molecular arrangement remained the same, the CN groups would point toward the carbonyl group, yielding a less favorable arrangement. Therefore the separation of the diastereomers may depend on the fact that only **1a** can adopt a configuration favorable for cavity formation and thus for the formation of a stable, well-crystalline inclusion compound. Cavity formation in the case of **1b** is less favorable and the inclusion compound less stable.

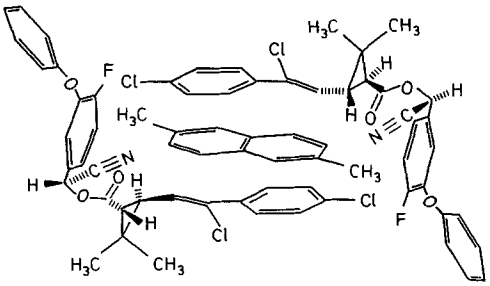

Fig. 4. By changing the configuration at the α-C atom, the inclusion compound with the isomer pair **1b** (1*S*,3*R*,α*R*)/1*R*,3*S*,α*S*) is obtained. The CN groups point inward.

Differentiation of diastereomers on formation of flumethrin–dimethylnaphthalene inclusion compounds has a parallel in the different insecticidal and acaricidal activity of flumethrin diastereomers. Only the isomer with the (1*R*,3*S*,α*S*) configuration is biologically active;[9] that is, it can adopt the correct configuration for its function. The elucidation of the structure of the stable flumethrin inclusion compound **3** might contribute to the understanding of the bonding of pyrethroids to receptor proteins. The observed separation of the flumethrin diastereomers also has a technically interesting aspect. In the technical isomeric mixture **1a**/**1b** the biologically active isomer is present in the pair **1b**. Selective precipitation and removal of the inactive isomeric pair by formation of a crystalline inclusion compound significantly increases the proportion of the active ingredient in the insecticide. This in turn reduces the dosage required for tick control, a desirable economical and ecological factor.

Methyltrioxorhenium as Catalyst for Olefin Metathesis**

By *Wolfgang A. Herrmann,* Werner Wagner, Uwe N. Flessner, Ursula Volkhardt,* and *Hartmut Komber*

Dedicated to Professor Karl Heinz Büchel on the occasion of his 60th birthday

Methyltrioxorhenium (MTO, CH_3ReO_3) is the most easily accessible organometal oxide. It is prepared from dirhenium heptaoxide and tetramethyltin, may be conveniently purified by vacuum sublimation, is stable far above its melting point (m.p. 106 °C), dissolves in all organic solvents *and* water without decomposition, and is stable to air and acid.[1] In addition to these advantageous properties, MTO has exceptional catalyst qualities which we describe in this and the two subsequent communications.

[**] Multiple Bonds between Main-Group Elements and Transition Metals, Part 100, first communication. (The second and third communications follow directly.) This work was supported by the Hoechst AG and the Fonds der Chemischen Industrie. Part 99: W. A. Herrmann, S. J. Eder, P. Kiprof, *J. Organomet. Chem. 412* (1991) 407–414.

The olefin metathesis is a reaction catalyzed by organometallic compounds, and its significance for the synthesis of basic and fine-chemical olefins as well as of polymers (polyalkenamers) is steadily increasing.[2,3] Variants, including both homogeneous and heterogenous catalysis, are presently used in eight technical processes,[2a,3] but the metathesis of *functionalized* olefins still presents problems (e.g., high catalyst concentrations, catalyst poisoning). In these cases cocatalysts (preferably alkyltin compounds) are essential, even for the more active systems (e.g. Re_2O_7/Al_2O_3).[2–4]

We have now discovered that the title compound MTO (**1a**) and higher homologues ($RReO_3$, R = alkyl, aryl) on acidic metal oxide supports form metathesis catalysts that are active without additives even for functionalized olefins.[5] The π complexes **1b, c** and the *N*-complex **1d** are, however, not suitable. The standard system MTO/Al_2O_3–SiO_2 (**I**) is simple to prepare and the most thoroughly studied. It catalyzes in particular the self-metathesis of allyl halides, ethers, silanes, and unsaturated carboxylates and nitriles, but also the ethenolysis of olefins with internal double bonds (Table 1). Catalyst **I** operates at room temperature and is also suitable for the metathesis of simple open-chain and cyclic olefins (Table 1 and 2). Otherwise frequent side reactions such as double-bond isomerization and olefin dimerization[2] are insignificant in the presence of **I**. The equilibrium in the metathesis of 1- and 2-hexene is established within minutes at 25 °C. For use with suspensions, the

[a] Heterogeneous catalyst MTO on Al_2O_3–SiO_2 [5, 6]; room temperature. The equilibrium turnover is (absolute) 50% (= 100% of the theoretical turnover). With the exception of b) and n), closed systems were used. [b] Absolute yields with respect to the starting olefin. [c] Ethylene pressure: 7 bar.

solvents dichloromethane and chlorobenzene proved best. The volume of solvent used seemed not to affect the metathesis equilibrium.

Figures 1 and 2 show that **I** is a more efficient catalyst than Re_2O_7,[7] which for functionalized olefins is active only in the presence of organotin compounds. In the case of methyl

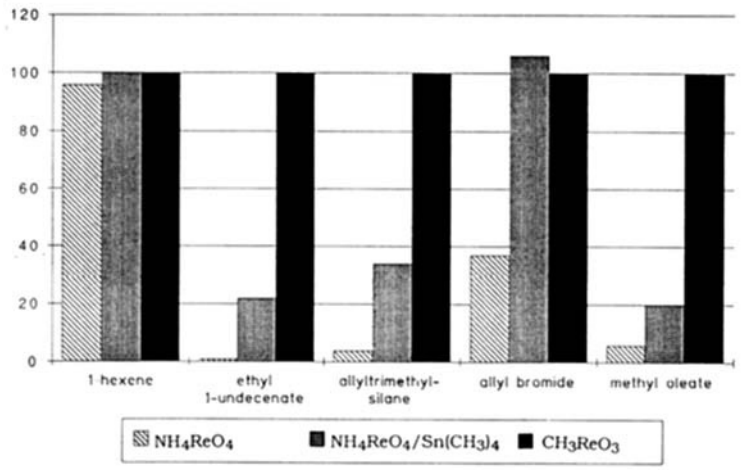

Fig. 1. Relative productivity of rhenium-containing heterogeneous metathesis catalysts, determined under standardized test conditions (25 °C, 60 min, carrier Al_2O_3–SiO_2 13/87, 3 wt% rhenium charge).

oleate, the conventional catalyst system prepared from NH_4ReO_4 approaches the activity of the new catalyst **I** only when the considerably higher maximum rhenium charge of about 10 wt% is employed.

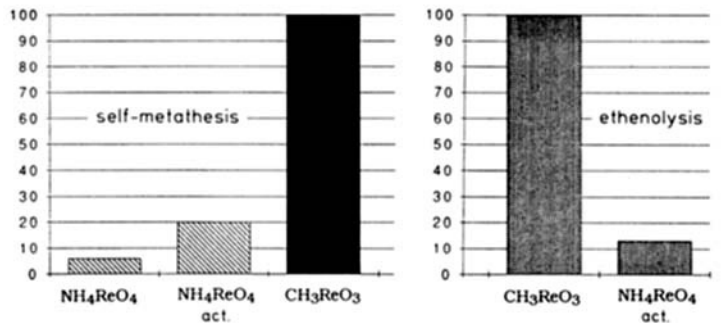

Fig. 2. Relative productivity of heterogeneous catalysts for the metathesis and ethenolysis of methyl oleate under standardized test conditions (25 °C, 60 min, support Al_2O_3–SiO_2 13/87, 3 wt% rhenium charge). Tetramethyltin was used for activation ("act.").

The special catalyst activity of MTO is lost when the methyl groups are cleaved. To avoid this degradation/deactivation reaction (which forms methane!), thermally pretreated carriers are required.[6] Besides Al_2O_3-containing systems, Nb_2O_5 is suitable.[8] Usually the catalyst loading rates are 1–3 wt% (ca. 13 g MTO per kg).

The following picture of the nature and mechanism of the MTO/Al_2O_3-SiO_2 system has been formed from physical studies of 900 metathesis experiments:

1) ESCA studies reveal that the metal oxidation state (Re^{VII}) is largely maintained on impregnation of the oxide support. Nevertheless, a very small proportion (not quantifiable by ESCA) of reduced species (Re^{VI}, Re^{V}) might be catalytically relevant.

2) MTO loses maximally 5% of the organic groups as methane and ethylene on the preparation of catalyst **I**. Use of CD_3ReO_3 (>99% D) confirmed the participation of metal-coordinated CD_3 groups in olefin metathesis (formation of $CD_2{=}CHC_2H_5$ and $CD_2{=}CH_2$ from 1-butene).

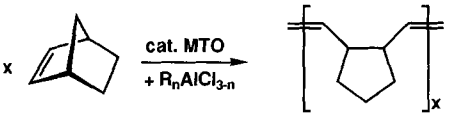
3) Free MTO cannot be separated from the carrier even under high vacuum at temperatures up to 150 °C. At higher temperatures decomposition accompanied by predominantly methane and ethylene evolution is observed. MTO can also not be removed from the carrier by solvents. We assume that MTO is fixed by condensation reactions such as that represented in the model equation (a).[9]

$$CH_3ReO_3 + HOCR_2CR_2OH \longrightarrow [CH_3ReO_2(OCR_2CR_2O)] + H_2O \quad (a)$$
$$R = CH_3$$

The condensation reaction increases the Lewis acidity of the rhenium, as is shown by solid state IR spectroscopy (diffuse reflectance):[10] the asymmetric ReO stretching band of catalyst **I** is shifted by up to 25 cm^{-1} to shorter wavelength relative to that of free MTO. This electronic change at the central atom is also reflected in the increased moisture sensitivity of catalyst **I**. Although free MTO is relatively stable in water and acid, the system MTO/Al_2O_3–SiO_2 is rapidly decomposed on hydrated surfaces to methane, ethylene, and perrhenate (GC, IR). Perrhenate bonded to the surface has been detected for the system Re_2O_7/Al_2O_3.[11]

MTO is also suitable for use in homogeneous catalyst systems for olefins that have no functional groups. Thus, the system MTO/R_nAlCl_{3-n} (**II**, R = CH_3, C_2H_5; n = 1, 2) is very efficient for the metathesis of 2-pentene at room temperature; equilibrium is achieved in less than 5 min (Re: olefin = 1:100).

Furthermore, *ring-opening polymerization* is catalyzed by the homogeneous catalyst **II**, as shown by the example of norbornene and some derivatives. Within minutes at room temperature polynorbornene of high molecular weight and medium polydispersity is formed [Equation (b) and Table 2].



(b)

The products are very soluble and have a high proportion of *cis*-configurated moieties (up to 84%, Table 2). The *cis*-stereoselectivity can be controlled by the rhenium/cocatalyst ratio: an increase in the organoaluminum component yields a polymer with a higher proportion of *trans*-configuration. However, an eightfold excess of the cocatalyst causes low molecular weight products and insoluble polymers to form.[12]

Because practically all metathesis catalysts are based on oxides or halides of molybdenum, tungsten, and rhenium, MTO introduces—after 30 years of research in this field[2]—a new generation of structurally defined catalysts. Even though the mechanism (metal–carbene formation from MTO) has not been finally elucidated, the multifarious applications of the catalyst are already convincing. Still more important is the possibility of a designed catalyst optimization by variation of the alkyl groups on the metal. The activity and stability of the "classical" olefin metathesis catalyst

metals, molybdenum and tungsten, could also be optimized in this way. Moreover, catalytic properties are expected for the organic oxides of the neighboring element, osmium. Simple compounds such as $O{=}Os(CH_3)_4$ are known.[13]

Experimental Procedure

MTO as heterogeneous catalyst: MTO (**1a**, 1.25 g, 5.0 mmol) was dissolved in 50 mL of CH_2Cl_2 and added to a well-stirred suspension of the carrier material ([6], 130 g in 500 mL of CH_2Cl_2).

Metathesis of 1-hexene: CH_2Cl_2 (24.5 mL) was added to 1% of this contact suspension (3 wt% Re) in a 100 mL round-bottomed flask fitted with a nitrogen inlet and a reflux condenser. The mixture was treated with 1-hexene (5 mL, 40 mmol; Re:olefin = 1:800). The system was kept under slight positive pressure of dry nitrogen by means of a mercury check valve. (If the reaction was carried out under reflux to drive off the evolving ethylene, 93% of the initial olefin was converted after 30 min.) After fractional microdistillation of the reaction mixture 5-decene was isolated as *cis/trans* mixture. Yield: 2.0 g (77%).

Cometathesis of methyl oleate and ethylene: CH_2Cl_2 (35 mL) and methyl oleate (1.7 mL, 5 mmol) were added to 1% of the contact suspension (Re: olefin = 1:100) in a 1000 mL laboratory glass autoclave and pressurized with 7 bar ethylene. After 2 h at room temperature 27% of the starting material had reacted (see Table 1).

Norbornene polymerization: To a solution of MTO (6.3 mg, 2.5×10^{-2} mmol), chlorobenzene (3 mL), and CH_3AlCl_2 (100 µL of a 1 M solution in *n*-hexane) was added a solution of norbornene (1.2 g, 12.5 mmol) in 10 mL of chlorobenzene (Re:Al:olefin = 1:4:500). No starting material could be detected after 30 min. The reaction was stopped with 20 mL of methanol. A white polymer precipitated and was purified by dissolution in $CHCl_3$ and reprecipitation with CH_3OH. Yield: 1.1 g, 94%.

Methyltrioxorhenium as Catalyst for Olefin Oxidation**

By *Wolfgang A. Herrmann,* Richard W. Fischer,* and *Dieter W. Marz*

Dedicated to Professor Karl Heinz Büchel on the occasion of his 60th birthday

The oxides of the neighboring elements of rhenium are active catalysts for olefin oxidation.[1] They depend, however, on different mechanisms for their activity: With hydrogen peroxide, molybdenum and tungsten oxides form "inorganic peroxides" of type L_nM–OOH, which have proved to be efficient epoxidation agents. Osmium tetroxide reacts with olefins *cis*-stereoselectively—in stoichiometric and catalytic processes—to yield vicinal diols, which are formed via structurally defined osmate esters.[1,2] However, no

organorhenium oxidation catalyst displays a high enough activity and selectivity under practicable conditions. Even in the current literature, doubts about rhenium and its compounds' potential for catalysis of olefin oxidations are expressed.[1d, 3]

Although the simple rhenium oxides (such as Re_2O_7, ReO_3, and ReO_2), perrhenic acid, its inorganic esters (e.g. $(CH_3)_3SnOReO_3$), and the π complexes $[C_5H_5ReO_3]$ and $[\{C_5(CH_3)_5\}ReO_3]$[4] activate neither oxygen nor peroxides, alkylrhenium oxides $R_aRe_bO_c$ in general,[5] but especially the very stable, easily accessible methyltrioxorhenium (MTO, **1**), are highly active and selective catalysts for the oxidation of CC unsaturated compounds. In particular, **1** catalyzes the epoxidation of olefins with hydrogen peroxide. Both the alkene and the reaction temperature can be varied within a wide range (Table 1). The standard system MTO/H_2O_2/

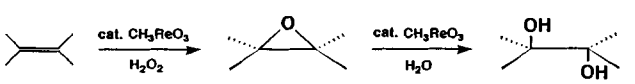
[a] Those yields marked with an asterisk were determined by GC/MS. All others refer to isolated products. [b] Yields relative to reacted olefin (reaction at ambient pressure).

t-C_4H_9OH usually operates at room temperature with 0.1 to 1 mol% MTO with respect to the olefin. The yellow solution is stable for weeks below ca. 0 °C and need thus not be freshly prepared.



(a)

Depending on the constitution of the epoxide, a ring opening that is also catalyzed by MTO can take place to form *trans*-configurated 1,2-diols. In spite of the low pH of the catalyst solutions (pH ≈ 1–2) the activity of MTO can be traced not only to its Brønsted acidity but also to a metal effect.

Addition of an excess of amines such as 4,4'-dimethyl-2,2'-bipyridine, quinine, or cinchonine, suppresses the epoxide

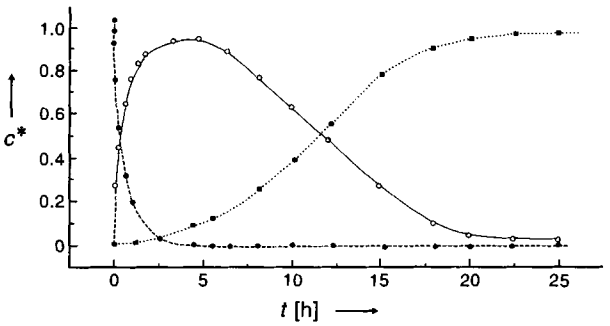


Fig. 1. Kinetics of the MTO-catalyzed cyclohexene oxidation. c^* = normalized concentration = c(starting material or product at $t = 0$)/c(cyclohexene at $t = 0$). ● c^*(cyclohexene); ○ c^*(1,2-epoxycyclohexane; ■ c^*(cyclohexane-1,2-diol)

ring opening even in 1,2-epoxycyclohexane, as a comparison of Figures 1 and 2 shows. Such amines lower the proton activity (pH ≈ 4) and form dissociation equilibria with the catalyst MTO[4,5] [Eq. (b)].

$$CH_3ReO_3 + n\,L \rightleftharpoons CH_3ReO_3(L)_n \qquad (b)$$

Besides *tert*-butyl alcohols, solvents such as tetrahydrofuran, ethyl acetate, toluene, and water may be used. Temperature control is essential for reactive olefins because of the high catalyst activity.

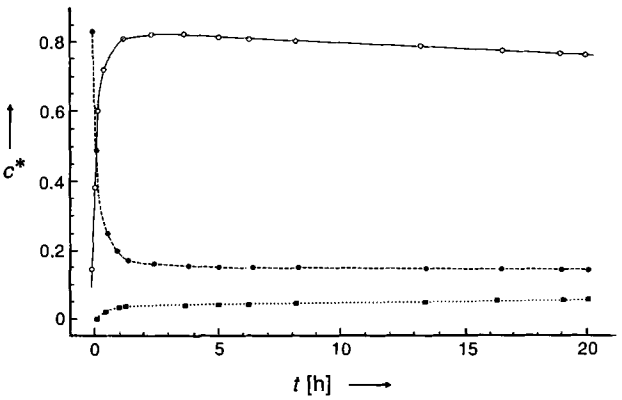

Fig. 2. Kinetics of the cyclohexene epoxidation with the MTO/coligand system. Labeling as in Fig. 1.

For storage a particularly stable form of MTO is easily prepared by warming a solution of MTO in distilled water, filtering the golden precipitate, washing with water, and drying in a vacuum. The solid is then pressed into 30–100 mg tablets. This procedure forms the first polymeric organometallic oxide:[7] it has the approximate empirical formula $\{CH_3ReO_3\}_\infty$, is in contrast to sublimable MTO no longer volatile, is stable to air and moisture, and is insoluble in all noncoordinating solvents but soluble in hydrogen peroxide. Polymer-MTO is very simple to dose in tablet form.

An immobilization of MTO can be achieved by the addition of polymeric materials that contain the required basic center for rhenium attachment, in particular amine- and amide-nitrogen atoms. Typical examples are the commercially available polyvinylpyridines which are charged with 1–10 wt% MTO. This procedure also lowers the volatility substantially: the monomers cannot be removed from the carrier even when heated to 150 °C under high vacuum. The advantage of this form of MTO lies in the easy recovery of the catalyst by filtration from the catalyst solution.

Although CH_3ReO_3 (MTO) and OsO_4 are isovalent molecules with similar structural and coordination chemistry—for instance, both yield stable adducts with amines like quinuclidine—they have different functions in the olefin/hydrogen peroxide system: in the first step OsO_4 forms osmate esters, which then undergo a stereoselective acid cleavage to afford vicinal *cis*-diols, whereas CH_3ReO_3 (unlike CH_3TcO_3[8]) reacts *not* with the olefin, but with H_2O_2 to be transformed in a multistep reaction into a hydroperoxo complex, probably of constitution **C** (Scheme 1), which is an exceptionally selective epoxidizing agent.

CH_3ReO_3 (a 14e compound) has a more pronounced Lewis-acidity than OsO_4 (a 16e compound). One may assume that this is responsible for the different catalytic mechanisms. Although the catalytic species has not yet been fully characterized, the alkyl groups of MTO and its derivatives are clearly indispensible: on one hand, monitoring the olefin oxidation by NMR spectroscopy shows that the methyl group of the catalyst remains coordinated to MTO; on the other hand addition of methyl-cleaving reagents halts the activity immediately. In this way inactive perrhenate is formed on addition of base [Eq. (c)].

$$CH_3ReO_3 + OH^- \longrightarrow CH_4 + [ReO_4]^- \qquad (c)$$

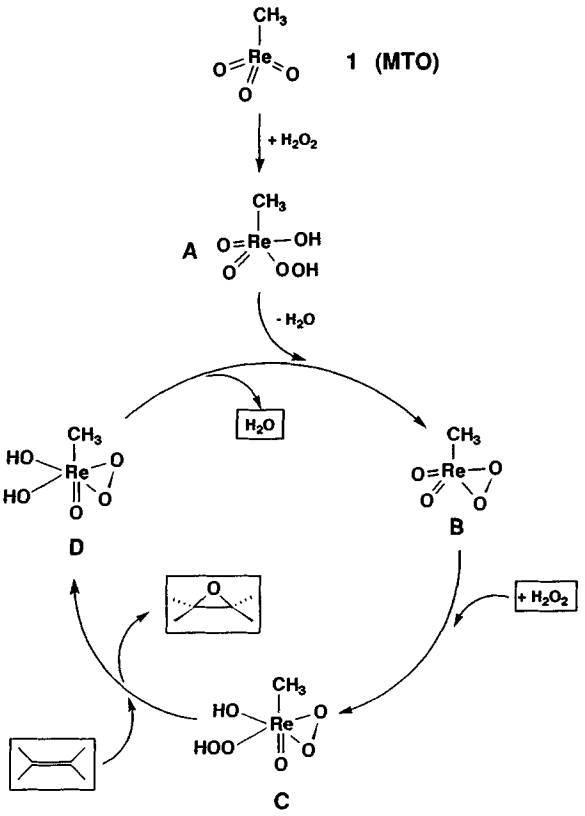
NMR and labeling experiments suggest the sequence of steps formulated in Scheme 1. There are *two* moles of H_2O_2 per mole of MTO required to form the active species **C** (δ_{CH3} = 2.6), which can be cleanly titrated against olefin. **C** can be extracted from MTO/perhydrol (a 30% H_2O_2 solution in water) into diethyl ether as a yellow complex and shows an IR band at 872 cm^{-1} typical for η^2-peroxo complexes, but it has so far eluded isolation. After prolonged reaction times, methanol is formed as a deactivation product of MTO.

tert-Butyl hydroperoxide is neither formed in the oxidation solution described here, nor can it be activated by MTO for olefin oxidations. Even after a pretreatment of MTO with H_2O_2, *t*-C_4H_9OOH does not function as a primary oxidizing agent.

The MTO/H_2O_2/*t*-C_4H_9OH system also oxidizes several alkynes: the major product from 3-hexyne is 4-hexen-3-one (*cis*/*trans*) in 55% yield; tolane yields 71% benzil. A catalytically accelerated Baeyer-Villiger oxidation can be performed with, for example, cyclobutanone.

The new class of oxidation catalysts is distinguished by a series of practical advantages: 1) High epoxide selectivity with the possibility of controlling the epoxide ring-opening kinetics through coligands, pH, and temperature; 2) high activity in a wide temperature range (−10− + 100 °C); 3) good stability of the oxidation-active system MTO/H_2O_2/*t*-C_4H_9OH at low temperatures (storable for months at −30 °C); 4) also active with electron-poor olefins (e.g. 2-bromo-2-butene) and simple gaseous olefins (e.g. propene, 2-butene); 5) use both as a homogeneous and a heterogeneous catalyst.

Furthermore, in no other epoxidation catalyst can the activity and selectivity be controlled as here by replacing the methyl groups with other alkyl groups. Important derivatives of the class of compounds have been described.[10] In particular, electron-withdrawing substituents promise further applications in catalytic oxidation as a result of the enhanced Lewis acidity of their metal center. The derivatization of MTO through the oxo groups is also known.[11] This also sets the new system aside from the "Milas reagents" (consisting of hydrogen peroxide and acidic metal oxides such as MoO_3, V_2O_5, and TiO_2), which have no constitutionally adjustable parameters.[12a]



Scheme 1. Proposed mechanism for MTO-catalyzed epoxidation.

The oxidizing power of MTO/H_2O_2 is normally too weak for olefin cleavage, a reaction typical of ruthenium oxide catalysts;[11b] stilbene and some styrene derivatives alone are cleaved oxidatively. Re_2O_7 is said to catalyze the oxidative cleavage of cycloolefins by H_2O_2 to ω,ω'-dicarboxylic acids, but only in boiling glacial acetic acid.[12b]

Experimental Procedure

Oxidation solution: *tert*-Butyl alcohol (1 L) was kept at 30 °C and mixed with 0.3 L of perhydrol. The solution was stirred with anhydrous $MgSO_4$ (200 g) for 3 h and then filtered.

Catalytic olefin oxidation: Catalyst **1** (10–50 mg, 0.04–0.2 mmol) was dissolved in oxidation solution (3–30 mL, 6–60 mmol of H_2O_2). The olefin to be oxidized (5–25 mmol) was added to this yellow catalyst solution, which was either cooled by ice, held at a constant temperature of 10–20 °C, or allowed to react at ambient temperature. In the latter case the reaction mixture often reached boiling point (ca. 80 °C). At the end of the reaction, which was indicated by a decolorization of the solution, any remaining H_2O_2 was decomposed with a catalytic amount of MnO_2. The suspension was then filtered through a glass frit coated with celite, and the solvent removed under vacuum. The residue, a solid or a viscous mass, was either washed with or recrystallized from, common solvents (e.g. acetone, ethanol). Liquid products were distilled.

Oxidation of *cis*-1,4-dichloro-2-butene: MTO (0.3 g, 1.2 mmol) was dissolved in 100 mL oxidation solution (ca. 1.8 M in H_2O_2). *cis*-1,4-Dichloro-2-butene (15 mL, 0.14 mmol) was added dropwise to this yellow catalyst solution (molar ratio H_2O_2 : olefin : MTO = 150:120:1). The mixture was then stirred for 48 h at 25 °C. After the addition of manganese dioxide (0.5 g) the gray suspension was filtered over a glass frit coated with celite. The solvent was removed from the colorless filtrate under vacuum (oil pump). The crude product (ca. 80% 1,4-dichloro-2,3-epoxybutane and starting material) was purified by Vigreux distillation. Yield 14.52 g (74%).

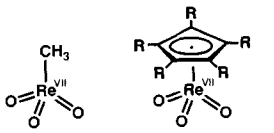
Methyltrioxorhenium as Catalyst of a Novel Aldehyde Olefination**

By *Wolfgang A. Herrmann** and *Mei Wang*

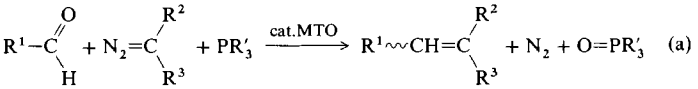
Dedicated to Professor Karl Heinz Büchel on the occasion of his 60th birthday

One of the most important syntheses for olefins is the Wittig reaction.[1] Although restricted to the preparation of terminal double bonds, an organometallic variation that uses the organotitanium Tebbe–Grubbs reagent is a particularly efficient process for open-chain and cyclic enol ethers.[2] The driving force for this reaction is the high stability of the resulting TiO bond, which leads to drawbacks such as the necessity of stoichiometric quantities of the reagent. Here we describe the first aldehyde olefination catalyzed by a structurally defined organometallic compound.

Aldehyde **2** treated with diazoalkane **3** in the presence of an equimolar amount of a tertiary phosphane, preferably triphenyl- or tri-*n*-butylphosphane (**4a** or **4c**), affords the olefinic coupling product **5** according to Equation (a) if methyltrioxorhenium (MTO, **1a**)[3a] is used as catalyst. Although the scope of the applications of this olefin synthesis has not been exhaustively studied, the advantages of easily accessible reagents, simple procedures, mild reaction conditions (room temperature), and good yields are apparent. In particular, diazoacetates and -malonates may be transformed with saturated and unsaturated aliphatic and aromatic aldehydes into the olefins **5** containing terminal carboxyl groups. Neither by a Wittig reaction nor with Tebbe–Grubbs reagents can this class of compound be synthesized. In contrast to MTO (**1a**), the π complexes **1b,c**[3b] are not catalytically active.



1a **1b**, R = H; **1c**, R = CH_3



2 **3** **4** **5** (a)

2a, $R^1 = (CH_3)_2CH$
2b, $R^1 = C_6H_5CH{=}CH$ (*trans*)
2c, $R^1 = (CH_3)_2C{=}CH(CH_2)_2CH(CH_3)CH_2$
2d, $R^1 = (CH_3)_2C{=}CH(CH_2)_2C(CH_3){=}CH$
2e, $R^1 = C_6H_5$
2f, $R^1 = 4\text{-}BrC_6H_4$
2g, $R^1 = 4\text{-}NO_2C_6H_4$
3a, $R^2 = H$, $R^3 = CO_2C_2H_5$
3b, $R^2 = CO_2CH_3$, $R^3 = CO_2CH_3$
4a, $R' = (C_6H_5)$
4b, $R' = (m\text{-}C_6H_4SO_3^-Na^+)_3$
4c, $R' = (n\text{-}C_4H_9)$

The reaction is generally carried out at room temperature by adding the diazoalkane dissolved in benzene or tetrahydrofuran dropwise to a solution of stoichiometric amounts of aldehyde and triphenylphosphane and a catalytic amount of MTO (1–10 mol%) in the same solvent.[4] The reaction temperature (−20–+80 °C) has little effect on the product distribution. Minor products are formed in metal-catalyzed side reactions of the diazoalkane (formation of ketazines and olefins). Table 1 provides a preliminary summary of the scope of the new reaction. Existing double bonds or those being formed remain intact, because MTO does *not* catalyze cyclopropanation.[5]

If the molybdenum complex $[MoO_2\{S_2CN(C_2H_5)_2\}_2]$ is used in place of MTO, the olefins derived from diazomalonate according to Equation (a) are not obtained; instead stable phosphorus ylides are formed, which do not react with the aldehyde.[6]

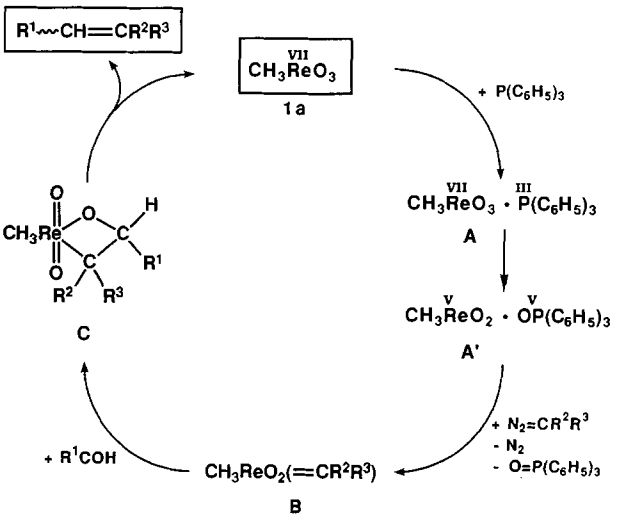
Both saturated and α,β-unsaturated aldehydes react, as well as benzaldehyde and its derivatives. Electron-withdrawing substituents on the aldehyde favor the olefination (Table 1). Some cycloketones undergo the reaction as well, although the yields and catalyst activities still need improvement: the olefin $(CH_2)_3C=CHCO_2C_2H_5$ is formed in ca. 45% yield from cyclobutanone and MTO/$P(C_6H_5)_3$ (20 °C, 2 h, 8 mol% MTO). The predominant side reaction here is a metal-catalyzed olefin formation from diazoalkane. An interesting variation with a two-phase water/benzene solvent system is possible for applications with the water-soluble phosphane **4b**; the workup then is limited to a simple phase separation, and phosphane and the rhenium catalyst remain in the aqueous phase. Tri(*n*-butyl)phosphine (**4**) is also suitable as cocatalyst.

The following has been established about the reaction mechanism of the new olefin synthesis:

1) MTO first forms the adduct $CH_3ReO_2 \cdot OP(C_6H_5)_3$ (**A'**) with the phosphane as formulated in Scheme 1. The adduct is known to afford complexes of the type CH_3ReO_2L (L = alkyne, for instance) under mild conditions.[7]
2) The isolated phosphane oxide adduct **A'** reacts with diazoalkanes to yield olefins. In the presence of aldehydes the formation of the symmetrical olefins (from diazoalkane) is suppressed in favor of the desired unsymmetrical olefins. Thus intermediate **A'** functions as a C–C coupling catalyst; in other words, the phosphane is necessary chiefly for aldehyde deoxygenation.
3) The stable phosphorus ylide $(C_6H_5)_3P=C(CO_2CH_3)_2$ does not even react with aldehydes in boiling benzene. At room temperature, but only in the presence of stoichiometric amounts of MTO, the olefins $R^1CH=C(CO_2CH_3)_2$ are formed (e.g., R^1 = 4-$NO_2C_6H_4$; ca. 80%). MTO (in benzene at 20 °C) does not catalyze olefin formation from ylides and phosphazines [Eq. (b) or (c)].
4) In the absence of phosphanes MTO acts as catalyst for diazoalkane decomposition: diazoacetate is transformed into fumarate and maleate at 20 °C *without formation of any side products* [Eq. (d)]. If aldehydes are added to such reactions, the product spectrum remains unchanged.
5) Stable five- and six-coordinate amine adducts of the type CH_3ReO_3L' (L' = quinuclidine; 2,2'-bipyridine)[8] react neither with aldehydes nor diazoalkanes. This shows that other complexes cannot be used instead of MTO.

Apparently the Lewis acidity of MTO and its reactivity with phosphanes is the determining factor for the olefin synthesis described here [Eq. (a)]. The phosphane-induced deoxygenation of MTO possibly enables a C–C bond to be formed between a metal-stabilized carbene species and the aldehyde, while the metal is oxidized back from Re^V to Re^{VII}. Although we have not yet isolated carbene complexes of type **B**, the nucleophilicity of the carbene ligands attached to metals in high oxidation states has been documented.[9,10] The C–C coupling step via metallaoxetane **C** formulated in Scheme 1 is not only plausible, but is also in accord with the observation that increasing the *C*-electrophilicity of the aldehyde employed increases the reaction rate and the yield. The



Scheme 1. Proposed mechanism of the olefination reaction according to Equation (a).

metal–carbene species **B** results from the displacement of the phosphane oxide by the diazoalkane, which thereby loses nitrogen (Scheme 1). Phosphorus ylides can be disregarded as carbene precursors, because carbenes do not even form from **3a** and **3b** under the reaction conditions. The reaction mechanism in Scheme 1 could be extended, however, if phosphazines are rapidly formed according to Equation (e); they also afford olefins **5** under the reaction conditions of Equation (a).

Thus rhenium-containing species are involved in every step of the catalytic cycle. Moreover, MTO implements the

$$2(C_6H_5)_3P=C(CO_2CH_3)_2 \xrightarrow{\text{cat. } CH_3ReO_3} \{CH(CO_2C_2H_5)\}_2 + 2P(C_6H_5)_3 \quad \text{(b)}$$

$$2(C_6H_5)_3P=N-N=C(CO_2CH_3)_2 \xrightarrow{\text{cat. } CH_3ReO_3} \{C(CO_2CH_3)_2\}_2 + 2P(C_6H_5)_3 + 2N_2 \quad \text{(c)}$$

$$2N_2=CH(CO_2C_2H_5) \xrightarrow{\text{cat. } CH_3ReO_3} \{CH(CO_2C_2H_5)\}_2 + 2N_2 \quad \text{(d)}$$

$$P(C_6H_5)_3 + N_2=C(C_6H_5)_2 \longrightarrow (C_6H_5)_3P=N-N=C(C_6H_5)_2 \quad \text{(e)}$$

$$(C_6H_5)_3P=C(CO_2CH_3)_2 + C_6H_5CHO + CH_3ReO_3 \longrightarrow C_6H_5CH=C(CO_2CH_3)_2 + O=P(C_6H_5)_3 \quad \text{(f)}$$

Wittig olefination of aldehydes with otherwise unreactive phosphorus ylides. Herein lies a potential extension of this important reaction [Eq. (f)]. Furthermore, a generalization of the catalytic diazoalkane decomposition according to Equation (d) is conceivable. Only the ketazine formation from aldehydes and diazoalkane, which can play a role with components other than **3a**, **b**, restricts the scope of the conversion formulated in Equation (a); ketazines are inert to MTO.

MTO is the first organometallic compound that enables catalytic olefin synthesis from easily accessible precursors. This property does not necessarily apply to other metal oxides: with the Mo^{VI} complex, $[MoO_2\{S_2CN(C_2H_5)_2\}_2]$, as catalyst the benzaldehyde/diazomalonate/triphenylphosphane system[6] affords predominantly the phosphorus ylide $(C_6H_5)_3P{=}C(CO_2R)_2$ ($R = C_2H_5$, 67%) even in boiling benzene, whereas MTO yields 90% of the desired olefin already at room temperature. The scope of the olefin synthesis described here should be able to be extended through designed exchange of the methyl groups of MTO for functionalized residues.[3c] In addition the search for analogous complexes of other cheaper metals with low coordination numbers and in high oxidation states will be worthwhile.

Salt-free Synthesis of Azo and Hydrazone Dyes Under CO_2 Pressure

By *Roderich Raue*,* *Alfred Brack*, and *Karl H. Lange*

Dedicated to Professor Karl Heinz Büchel on the occasion of his 60th birthday

We present here a new method for the preparation of azo dyes in which the nitrous acid essential for the diazotization is liberated from its salts or esters by carbon dioxide at a pressure of 5 to 65 bar. Consequently, the amount of inorganic and organic salts produced as by-products is reduced considerably compared to the conventional procedure. This is of great ecological importance.

Azo dyes can be prepared in a two-step or single-step procedure. In the two-step process treatment of an amine with sodium nitrite in aqueous acidic solution leads to formation of a diazonium salt, which is subsequently treated with the coupling component.[1] In the one-step process diazotization in the presence of the coupling component provides the desired product.[2] Active methylene compounds as well as aromatics can be used as the nucleophilic coupling component.[3,4]

A disadvantage of both methods is the large amount of salts produced in the neutralization of the acid. Thus we sought to improve the procedure, by avoiding the formation of these by-products.

CO_2 is an inert, gaseous acid anhydride which can be easily removed from the hydration equilibrium by change of pressure or temperature. At atmospheric pressure an aqueous solution of carbon dioxide is only weakly acidic. Not unexpectedly, the passage of a vigorous CO_2 stream through a mixture of the aromatic amine, the coupling component, and an aqueous solution of sodium nitrite did not give even traces of an azo compound.

The apparent first dissociation equilibrium constant of carbonic acid has a pK of 6.46. This value is composed of the sum of the preceding hydration equilibrium constant of CO_2 ($pK = 3.16$) and the equilibrium constant of the true first dissociation step of carbonic acid ($pK_a = 3.3$).[5] It should be possible to shift the preceding hydration equilibrium of carbon dioxide by application of pressure such that the true first dissociation step of carbonic acid can be used for diazotization.

First we investigated the one-step synthesis of a precursor of hydrazone dyes [Eq. (a)].

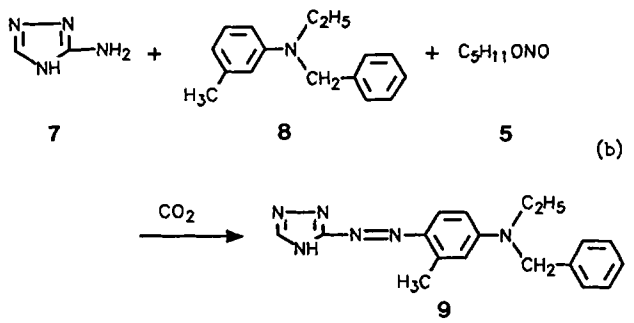
At a pressure of 5 bar a noticeable reaction took place, at 30 bar **4** was produced in >80% yield, and at 50 bar a complete conversion was achieved. Product yield and purity can be improved by employing mixtures of water and methanol as solvents. Not only the amines and coupling components, but also CO_2 is more soluble in methanol.[6] Because the dye **4** is obtained almost free of salt, the methylation to the *N*-alkyl-*N*-arylhydrazone dye could follow immediately. Instead of sodium nitrite esters of nitrous acid, for example, isoamyl nitrite (**5**) or methyl nitrite (**6**), can be used to avoid the formation of salt.[7]

This method has been used to prepare a large number of azo dyes. It is of particular interest that the one-step diazotization and coupling of heterocyclic amines with tertiary aromatic amines proceeded in quantitative yield. Usually heterocyclic amines can only be diazotized in concentrated acids by nitrosyl sulphuric acid. However, application of our procedure to the reaction of 3-amino-1,2,4-triazole (**7**), *N*-benzyl-*N*-ethyl-3-methylaniline (**8**), and isoamyl nitrite (**5**) in a mixture of methanol and water at a CO_2 pressure of 53.5 bar provided azo dye **9** in quantitative yield[7] [Eq. (b)].



Experimental Procedure

2,3-Dihydro-1,3,3-trimethyl-indole-2-ylidenmethaneazo(4'-methoxybenzene) (**4**): 2,3-Dihydro-1,3,3-trimethyl-2-methyleneindole (**2**) (173 g, 1 mol), 4-methoxyaniline (**3**) (123 g, 1 mol), and a solution of sodium nitrite **1** (73 g, 1.06 mol) in 300 mL water were placed in an autoclave and CO_2 was introduced until a pressure of 50 bar was reached. The temperature then rose to 35 °C, and the pressure dropped. A pressure of 50 bar was maintained by further passage of CO_2 into the reaction vessel. After the reaction mixture was stirred at 35–40 °C for 3 h the autoclave was depressurized. The vented CO_2 can be recycled. The weakly alkaline suspension of the dye base was vacuum-filtered, washed to neutral pH, and dried. Yield: 301.2 g (98%) **4**; m.p.: 147–150 °C; correct C,H,N analyses; MS (EI, 70 eV): *m/z* 307 (M^+, 100%), 185 (39), 159 (92); IR (KBr) $\tilde{\nu}$[cm^{-1}] = 1585 (s), 1245 (s).

1,2,4-Triazolyl-3-azo-4'-*N*-ethyl-*N'*-benzyl-3'-methylaniline (**9**): In an autoclave were mixed **7** (16.8 g, 0.2 mol), **8** (45 g, 0.2 mol), **5** (30.4 g, 0.26 mol), 80 mL of methanol and 40 mL of water. CO_2 was introduced until a pressure of 53.5 bar was reached. The vessel was heated to 40 °C and for 3 hours the pressure was maintained by further passage CO_2 into the autoclave. After the reaction mixture was cooled to room temperature, the pressure was released. The vented carbon dioxide can be reused. The methanol was distilled off and the residue crystallized by treatment with saturated NaCl solution and some HCl. The dye was purified further by stirring with methylene chloride and was then dried. Yield: 61.4 g (100%) **9**; m.p.: 80–94 °C; correct C,H,N analyses; ^{1}H NMR ($CDCl_3$, 270 MHz): δ = 1.25 (t, 3H), 2.53 (s, 3H), 3.53 (q, 2H), 4.61 (s, 2H), 6.52 (s, 1H), 7.05–7.40 (several m, 7H), 7.78 (d, 1H), 8.26 (s, 1H); MS (EI, 70 eV): *m/z* 320 (M^+, 55%), 265 (8), 250 (9), 229 (M^+-C_7H_7, 26), 91 (100); IR (KBr): $\tilde{\nu}$[cm^{-1}] = 3430 (s), 1595 (s), 1230 (s).

Synthesis and Structure of Ethynyl Isocyanide**

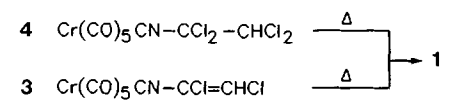
By *Michael Krüger, Helmut Dreizler,* Dagmar Preugschat,* and *Dieter Lentz**

Alkynyl isocyanides are a class of substances not previously accessible to experimental investigation. Here we report on the synthesis and gas-phase structure of the parent compound, ethynyl isocyanide (**1**),[1] which exhibits an unexpectedly high stability toward polymerization and isomerization. Whereas ethynyl cyanide (**2**), a constitutional isomer of **1**, was first described over 70 years ago[2] and, since its radioastronomic detection in interstellar space by *Turner*,[3] has been regarded as a "classical" interstellar molecule, all attempts so far to generate **1** have failed.[4] The synthesis of

HC≡C–N≡C **1** HC≡C–CN **2**

an ethynyl isocyanide ligand on a pentacarbonylchromium fragment by dehalogenation of pentacarbonyl(1,2-dichlorovinyl isocyanide)chromium (**3**) or by dehydrohalogenation of [Cr(CO)$_5$(CN–CCl=CH$_2$)] was also unsuccessful.[5]

In an investigation of the pyrolysis of partially halogenated (alkyl isocyanide)pentacarbonylchromium complexes by microwave spectroscopy, we were able to detect **2**. We suspected that it had arisen by isomerization[6] of **1**, and we therefore synthesized **3**[5a] as well as pentacarbonyl(1,1,2,2-tetrachloroethyl isocyanide)chromium (**4**).[7] Flash vacuum pyrolysis of **3** or **4** at 240 °C affords ethynyl isocyanide (**1**) (Scheme 1), which was characterized on the basis of its microwave spectrum and its gas-phase FT IR spectrum.



Scheme 1. Synthesis of **1**. Δ: temperature 240 °C, pressure 1–10 Pa.

Ethynyl isocyanide (**1**) can be prepared from **3** on a 10-mg scale. The synthesis from **4**, however, is accompanied by unavoidable partial isomerization of **1** to **2**. Compound **1** is

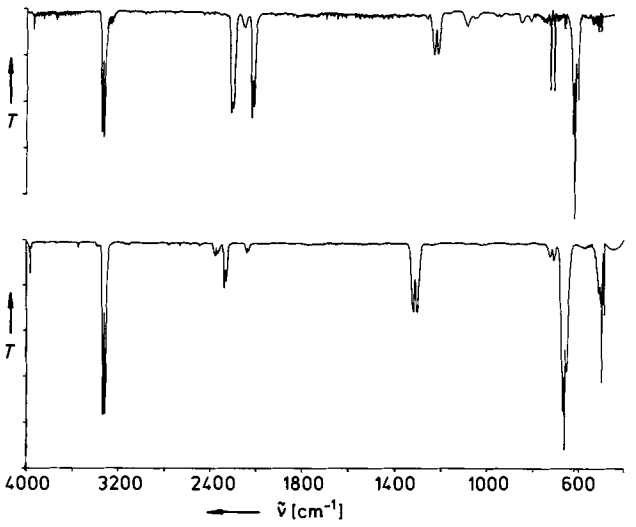

Fig. 1. Gas-phase FT IR spectra of H–C≡C–N≡C (**1**), top, and H–C≡C–C≡N, bottom. T = transmission.

stable for several weeks at −196 °C and for several days at room temperature in the gas phase at a partial pressure of a few torr. On slow thawing of the condensed phase, colorless **1** starts to turn brown above about −80 °C. The isocyanide is very volatile; thus, on fractional condensation in vacuum (1 Pa), it does not condense into a trap cooled to −120 °C. Compound **1** has the strong smell typical of isocyanides.

Figure 1 shows the gas-phase FT IR spectra of **1** and **2**. The spectra clearly differ with respect to the positions and intensities of the bands. The vibrational frequencies of **1** are in good agreement with the calculated data.[1a]

The Stark effect could be observed for the absorption lines corresponding to the rotational transitions $J' \leftarrow J = 3 \leftarrow 2$ and $4 \leftarrow 3$ in the continuous wave (CW) microwave spectrum[8] of **1**; the dipole moment of **1** was thus calculated to be $\mu = 2.93(4)$ D (Fig. 2)—in very good agreement with the

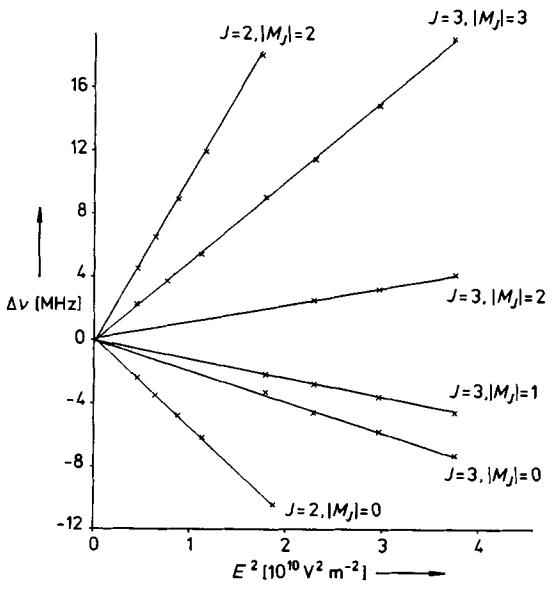

Fig. 2. Second-order Stark effect of **1**: frequency difference $\Delta\nu$ of the Stark components of the zero-field frequency as a function of the square of the electric field (E^2) for the rotational transitions $J+1 \leftarrow J$, $M_J \leftarrow M_J$ (J, rotational quantum number; M_J, projection quantum number). The dipole moment of **1** was calculated to be $\mu = 2.93(4)$ D. Calibration was carried out with carbonyl sulfide (OCS, $J' \leftarrow J = 3 \leftarrow 2$), $\mu = 0.715196(10)$ D [38].

results of ab initio calculations[9] ($\mu_e = 2.96$ D). The dipole moments of the isomer pair CH_3CN/CH_3NC are 3.925 D[10] and 3.83 D,[11] respectively; the perfluorinated derivatives have dipole moments of 1.262 D (CF_3CN)[12] and 1.153 D (CF_3NC).[13] The dipole moment of hydrogen cyanide is 2.985 D,[14] whereas isocyanic acid, HNC, exhibits a dipole moment of 3.05(10).[15] It is noteworthy that the dipole moments of the pairs of isomers discussed here are very similar, whereas the dipole moments of **1** and **2** (μ = 3.73171(1) D)[16] differ by 0.8 D.

To characterize **1** in greater detail by microwave spectroscopy, we measured the rotational transitions $J' \leftarrow J = 1 \leftarrow 0$ with a high-resolution[17] molecular-beam microwave FT spectrometer.[18] It was possible to observe, besides the main isotopomer, the species **1a–d** in natural abundance; these are the four conceivable isomers with a single isotopic heavy atom. Deuterated **3**[19] gave deuterated ethynyl isocyanide (**1e**), which was also characterized on the basis of its microwave spectrum. The rotational constants of **1–1e** are summarized in Table 1.

Table 1. Rotational constants of **1–1e** from the rotational transition $J' \leftarrow J = 1 \leftarrow 0$. Molecular beam measurement; errors in parentheses refer to the last digit.

Isotopomer		Rotational constant B_0 [MHz]
H–C≡C–N≡C:	**1**	4967.8370(3)
H–^{13}C≡C–N≡C:	**1a**	4813.1175(10)
H–C≡^{13}C–N≡C:	**1b**	4949.4452(7)
H–C≡C–^{15}N≡C:	**1c**	4944.7390(1)
H–C≡C–N≡^{13}C:	**1d**	4804.8725(3)
D–C≡C–N≡C:	**1e**	4598.2881(2)

The set of six rotational constants allows calculation of both an effective structure (r_0)[20, 21] and a complete substitution structure (r_s).[21, 22] In Table 2, the experimental r_s and r_0 values of **1** and **2** are compared with the ab initio equilibrium values (r_e).[1b] The C–C triple bond and the C–H bond

Table 2. Comparison of experimental and calculated bond lengths r [pm] of ethynyl isocyanide (**1**) [a] and ethynyl cyanide (**2**) [b]. Errors in parentheses refer to the last digit.

Compound	Bond	r_s	r_0	r_e [c]
1	C–H	105.5(1)	105.5(1)	106.5
1	C≡C	120.3(1)	120.2(1)	119.3
1	C–N	131.7(1)	131.8(1)	131.8
1	N≡C	117.5(1)	117.6(1)	117.3
2	C–H	105.8(2)	105.7(2)	106.6
2	C≡C	120.5(2)	120.3(2)	119.7
2	C–C	137.8(2)	138.2(2)	138.6
2	C≡N	115.9(2)	115.7(2)	115.3

[a] The uncertainties in the experimental bond lengths due to the errors in the rotational constants are far less than the errors given here. Methodical errors dominate [21]. [b] r_s and r_0 values of **2** from [32]. [c] SCF ab initio calculation with double zeta basis [1b].

are equally long in **1** and **2** within the limits of error; the bond lengths in acetylene[23] (120.3 and 106.1 pm) are also of nearly equal length. The length of the N–C triple bond of **1** is similar to the corresponding bond lengths in HNC (117.3 pm),[24] CH_3NC (116.6 pm),[25] CF_3NC (117.1 pm),[13] and the isocyanide triple-bond length in the recently prepared[26] and unequivocally identified[27] cyanoisocyanide (NC-CN,

Table 3. C–NC and C–CN single bond lengths in isocyanides and cyanides, respectively [pm].

Isocyanide	r (C–NC)	Ref.	Cyanide	r (C–CN)	Ref.
H_3C–NC	142.8(2)	[25]	H_3C–CN	145.8(3)	[33]
Ph–NC	141.0	[34]	Ph–CN	145.5(7)	[35]
H_2C=CH–NC	137.9(6)	[36]	H_2C=CH–CN	142.6(3)	[37]
NC–NC	131.60(26)	[28]	-		
HCC–NC	131.7(1)	This work	HCC–CN	137.8(2)	[32]

117.49(18) pm).[28] C–NC and C–CN single-bond lengths in isocyanides and cyanides, respectively, are compared in Table 3. The bond lengths strongly decrease in both classes of substance on going from the alkyl and aryl derivatives to the vinyl and, finally, the ethynyl compounds. The C–N single bonds in **1** and NC-NC[28] are the shortest bonds of this type so far found in isocyanides.

Since the microwave data of ethynyl isocyanide (**1**) are now known, it is possible to use radioastronomy to detect it in interstellar space, where its constitutional isomer **2** and its homologues $H-C\equiv C\!\left(-C\equiv C\right)_n CN$ (n = 1–4) are widely distributed.[29] In addition to HCN/HNC[30] and CH_3CN/CH_3NC,[31] this third nitrogen-containing isomer pair consisting of uncharged closed-shell molecules could further extend the radioastronomy studies on isomer relationships and contribute to the elucidation of interstellar chemistry.[39]

Experimental Procedure

1: **3** (440 mg, 1.7 mmol) was sublimed at ca. 1–10 Pa over 12 h through a Duran glass tube (30 × 2.5 cm) heated to 240 °C. Poorly volatile products were condensed in a trap cooled with dry ice/acetone. H–C≡C–N≡C (**1**) condensed in a trap cooled with liquid nitrogen and was pure according to the gas-phase IR spectrum. MS (80 eV): *m/z* 51 (M^+, 100%), 50 (M^+ – H, 17), 26 (M^+ – C_2H, 15); FT-IR (< 100 Pa): $\tilde{\nu}$[cm^{-1}] = 3345/3329 (C–H), 2223/2203 (C≡N), 2041/2024 (C≡C), 1237/1220, 730/713, 628/621/614/608; Molecular beam FT microwave spectrum (central frequencies $J' \leftarrow J = 1 \leftarrow 0$): ν[MHz] = 9935.6740(6), (**1**), 9626.2350(20) (**1a**), 9898.8904(15) (**1b**), 9889.4780(2) (**1c**), 9609.7450(6) (**1d**), 9196.5762(4) (**1e**).

A New Chromogenic β-Galactosidase Substrate: 7-β-D-Galactopyranosyloxy-9,9-dimethyl-9*H*-acridin-2-one **

By *Paul F. Corey**, *Robert W. Trimmer*, and *William G. Biddlecom*

Dedicated to Professor Karl Heinz Büchel on the occasion of his 60th birthday

The enzyme β-galactosidase (E.C. 3.2.1.23) has found wide use as an indicator enzyme for immunoassays[1] because of its relative stability and tolerance of conjugation to antibodies, other proteins, and solid supports, while retaining substantial activity. Derivatization of a phenolic chromogen or fluorogen with sugars such as β-galactose has been the basis for preparing indicating glycosidase substrates since *Aizawa*[2] introduced *p*-nitrophenyl β-D-galactopyranoside

[**] We thank Dr. *H. Arndt* for assistance in assigning the NMR spectra and Dr. *R. Carrico* for determining the enzyme kinetics of **10**.

in 1939. Over the years substrate derivatives of fluorescein, indoxyl, and methylumbelliferone have been synthesized, but their use has required coping with complex kinetics, poor solubility, and the need for expensive instrumentation.

The development of highly sensitive enzyme immunoassays that can be evaluated either visually or with simple instruments requires a chromogenic substrate that exhibits good aqueous solubility, a fast rate of enzymatic hydrolysis, a low Michaelis constant, and a large difference between the absorption maxima of the substrate and its hydrolysis product. Additionally, the hydrolysis product (chromogen) must have a pK_a below the pH optimum of the enzyme, an absorption maximum at long wavelength to assure minimal interference from colored constituents of the sample being evaluated (usually blood serum or urine), and a large extinction coefficient.

Only recently have long-wavelength β-galactosidase substrates been described that begin to satisfy these criteria. Resorufin β-galactoside[3] exhibits a 102 nm color shift (470 → 572 nm) upon hydrolysis, a Michaelis constant (K_m) of 0.38 mM, and fast turnover. But in our hands its solubility in 50 mM phosphate buffer (pH 8.0) is only 0.25–0.50 mM. Chlorophenol red β-galactoside[4] has a 160 nm color shift (414 → 574 nm) and excellent aqueous solubility, but we found its K_m to be more than twice as high as that reported for the resorufin substrate.

Our search for an improved long-wavelength β-galactosidase substrate led to the synthesis of the title compound **10**, a substrate with 20–25 mM solubility in 50 mM phosphate buffer (pH 8.0) and a 196 nm color shift (438 → 634 nm) as shown in Figure 1. β-Galactosidase cleaves the substrate

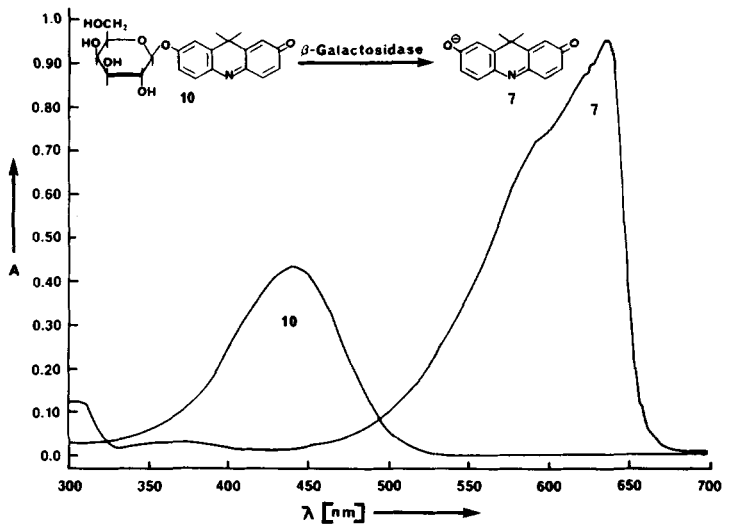

Fig. 1. The absorption spectra of solutions of **10** and **7** in sodium borate buffer (0.1 M, pH 10). A = Absorption in arbitrary units.

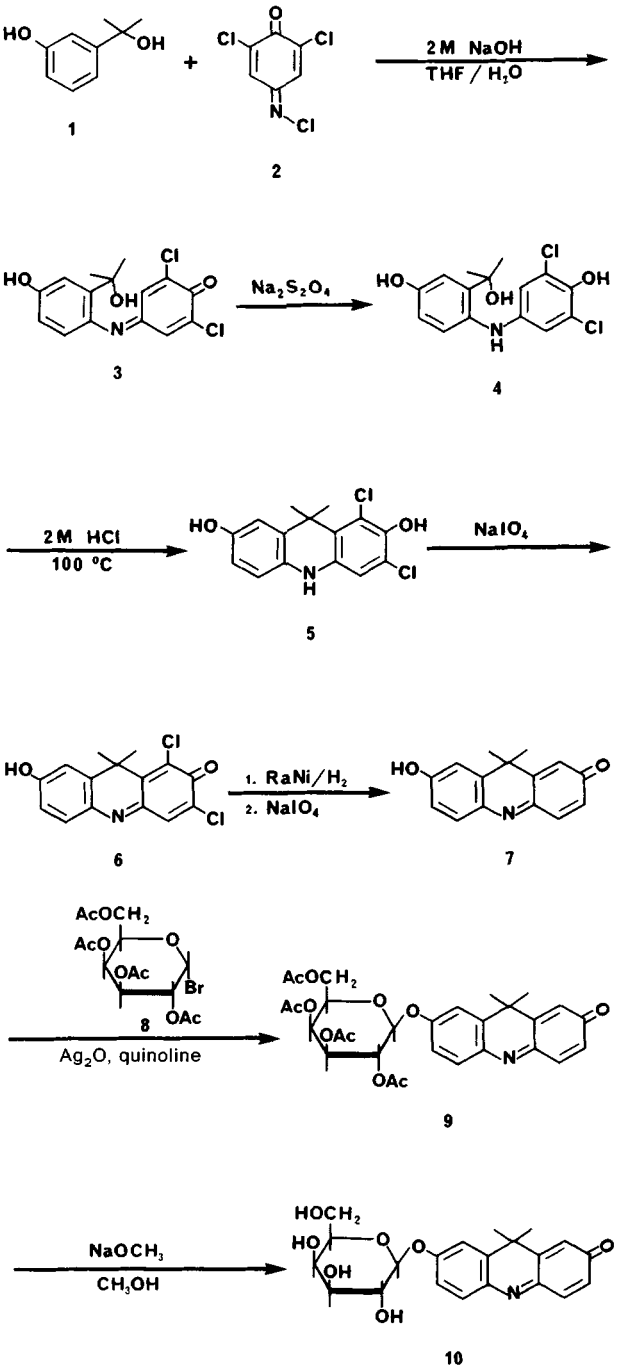
(k_{cat}) at the rate of 1.32×10^4 mol min^{-1} per mole of enzyme active site in a 50 mM phosphate buffer (pH 7.4) containing 5 mM $MgCl_2$, and exhibits a K_m of 0.17 mM. The absorbance of the deprotonated hydrolysis product at 634 nm (ε = 56000) is spectrally well removed from those of interfering colored sample constituents. Combined with good solubility, low K_m, fast turnover, and a large color shift, this makes **10** particularly well suited to immunoassays involving biological fluids. This substrate is presently used as the readout in an enzyme-labeled immunometric assay for measuring serum or plasma concentrations of the cardiac glycoside digoxin. In this assay[5] an excess of a monoconjugate of β-galactosidase with a Fab' fragment of an anti-digoxin mouse monoclonal antibody binds digoxin in the sample. The conjugate not bound to digoxin is then removed and the β-galactosidase activity of the assay solution is determined by using a dry reagent strip containing **10**. The test takes less than 15 min and can measure digoxin concentrations as low as 0.20 μg L^{-1}.

7-Hydroxy-9*H*-acridin-2-one (**7**) was first synthesized in 1928 by *Goldstein* and *Kopp*[6] and in 1970 by *Hill*, et al.[7] Poor yields from these procedures obligated us to work out the improved synthesis outlined in Scheme 1. Because commercially available 2,6-dichloroquinone-4-chloroimide (**2**) was used instead of the *p*-benzoquinone chloroimine employed in



Scheme 1. Synthesis of 7-β-D-Galactopyranosylyloxy-9,9-dimethyl-9*H*-acridin-2-one (**10**).

Hill's procedure, it was possible to obtain the highly crystalline **6** in 82 % overall yield without isolation of every intermediate. The cyclization of dichloro compound **4** is more facile than that of the corresponding unchlorinated analogue and largely accounts for the improved yield of **6** with this process. Raney nickel dehalogenation of **6** followed by in situ oxidation gives **7** in 89 % yield.

Silver-promoted coupling of **7** with acetobromo-α-D-galactose (**8**) affords the bright yellow tetraacetate **9** in 80 % yield and deprotection of **9** gives the orange title compound **10** in 88 % yield.

Experimental Procedure

The ^1H and ^{13}C NMR spectra were recorded in $(CD_3)_2SO$ at 25 °C at 300.12 and 75.47 MHz, respectively.

6: A mixture of **1** [8] (1.52 g, 10.0 mmol) and **2** (2.10 g, 10.0 mmol) in THF (5 mL) was diluted with H_2O (5 mL) and cooled in ice. Aqueous 2 M NaOH (10.5 mL, 21 mmol) was added over 10 min. The deep blue reaction mixture was cooled at 0 °C for 1.5 h then blended into EtOAc (300 mL) and extracted twice with saturated aqueous NH_4Cl (350 mL). The resulting EtOAc solution of **3** was washed twice with a solution of $Na_2S_2O_4$ (25 g) in H_2O (250 mL) and once with saturated NaCl solution (brine), dried over Na_2SO_4, and concentrated to dryness to obtain crude **4**. A solution of **4** in MeOH (10 mL) was slowly blended into rapidly stirring, deoxygenated aqueous 2 M HCL (250 mL) at ambient temperature. The resulting suspension was heated in a 100 °C bath under Ar atmosphere for 1.25 h, during which time a gummy solid separated. The mixture was cooled, extracted twice with EtOAc (200 mL), and the combined extracts washed with brine (50 mL). The resulting solution was stirred vigorously for 15 min with a solution of $NaIO_4$ (3 g) in H_2O (100 mL) to oxidize **5**. The phases were then separated and the organic layer was washed with brine (100 mL), dried over Na_2SO_4, and concentrated to dryness. The residue was taken up in hot EtOH (500 mL) and concentrated to ca. 150 mL by boiling. Upon cooling **6** separated as black needles to afford, in 2 crops, 2.5 g (82 %). Recrystallization from EtOH gave the analytical sample (m.p. > 250 °C). ^1H NMR: $\delta = 7.76$ (s, 1H; C4-H), 7.50 (d, $J = 8.5$ Hz, 1H; C5-H), 7.06 (d, $J = 2.4$ Hz, 1H; C8-H), 6.84 (dd, $J = 8.5$, 2.4 Hz, 1H; C6-H), 3.32 (s, 1H; OH), 1.74 (s, 6H; 2 CH_3); ^{13}C NMR (assignment by ^1H-^{13}C correlation): $\delta = 172.1$ (C2), 162.7 (C7), 145.8 (C4a), 141.2 (C8a), 140.9 (C9a), 139.3 (C4), 134.9 (C1), 134.7 (C10a), 134.7 (C10a), 134.3 (C5), 132.6 (C3), 116.0 (C6), 114.2 (C8), 38.8 (C9), 26.3 (CH_3); UV/VIS (0.01 M NaOH) λ_{max} [nm] (ε) = 646 (42000). Correct C, H, N analyses.

7: A solution of **6** (2.0 g, 6.49 mmol) in 1 M NaOH (60 mL) and EtOH (40 mL) was treated with Raney Nickel 2800 (ca. 6 mL) and hydrogenated at 2.72 atm H_2 at ca. 70 °C for 5 h. After cooling to ambient temperature the reaction mixture was filtered through Celite, diluted with H_2O (500 mL), and exhaustively extracted with EtOAc. The combined EtOAc layers were vigorously stirred with a solution of $NaIO_4$ (4 g) in H_2O (300 mL) for 10 min at ambient temperature and then treated with 1 M HCl (100 mL). The phases were separated and the organic layer was washed with brine (50 mL), dried over $MgSO_4$, and concentrated to dryness to give **7** (1.38 g, 89 %). Crystallization from EtOAc/hexane (1:1), v/v) afforded **7** as ruby red needles identical to that prepared by the method of *Hill*, et al.[7] UV/VIS (0.01 M NaOH) λ_{max} [nm] (ε) = 634 (56000).

9: A mixture of **7** (1.57 g, 6.56 mmol), **8** (3.24 g, 7.87 mmol), Ag_2O (1.83 g, 7.87 mmol), and $CaSO_4$ (2.63 g) in EtOAc (31.65 mL) containing anhydrous quinoline (15.8 mL) was stirred for 19 h at ambient temperature in a closed flask protected from light. The reaction mixture was diluted with EtOAc (75 mL), filtered through Celite, extracted twice with aqueous 1.25 M HCl (75 mL), washed twice with brine (35 mL), extracted three times with 5 % aqueous $NaHCO_3$, washed again with brine (75 mL), dried over Na_2SO_4, and concentrated to dryness. The residue was taken up in EtOAc/hexane (3:2 v/v; 55 mL), stirred with Darco G-60 (4.78 g) at ambient temperature for 1 h, filtered through Celite, and concentrated to dryness. The residue was taken up in boiling EtOAc (5.5 mL), diluted with hexane (9 mL), and vigorously scratched; **9** separated upon cooling to yield 3.0 g (80 %) in two crops. Recrystallization from EtOAc/hexane (2:1 v/v) provided rosettes of fine yellow needles (m.p. = 156.5–158.0 °C). ^1H NMR: $\delta = 7.65$ (d, $J = 8.7$ Hz, 1H; C5-H), 7.44 (d, $J = 9.8$ Hz, 1H; C4-H), 7.29 (d, $J = 2.6$ Hz, 1H; C8-H), 7.04 (dd, $J = 8.7$, 2.6 Hz, 1H; C6-H), 6.82 (d, $J = 2.0$ Hz, 1H; C1-H), 6.63 (dd, $J = 9.8$, 2.0 Hz, 1H; C3-H), 5.75 (d, $J = 7.3$ Hz, 1H; C1′-H), 5.39 (d, $J = 2.1$ Hz, 1H; C4′-H), 5.32 (m, 1H; C3′-H), 5.29 (m, 1H; C2′-H), 4.54 (dd, $J = 7.0$, 5.2 Hz, 1H; C5′-H), 4.09 (m, 2H; C6′-H), 2.15 (s, 3H; $COCH_3$), 2.00 (s, 3H; $COCH_3$), 1.96 (s, 3H; $COCH_3$), 1.53 (s, 6H; CH_3); ^{13}C NMR (assignment by ^1H-^{13}C correlation): $\delta = 186.4$ (C2, C=O), 169.9 (OC=O), 169.5 (OC=O), 169.2 (OC=O), 158.1 (C7), 151.0 (C4a), 147.3 (C9a), 141.5 (C4), 139.6 (C8a), 137.3 (C10a), 133.1 (C5), 131.3 (C3), 127.5 (C1), 115.5 (C6), 113.8 (C8), 96.7 (C1′), 70.7 (C5′), 70.2 (C3′), 68.2 (C2′), 67.5 (C4′), 61.8 (C6′), 36.9 (C9), 32.3 (CH_3), 31.8 (CH_3), 20.6 ($COCH_3$), 20.5 ($COCH_3$), 20.4 ($COCH_3$); $[\alpha]_D$ + 37.3 ($c = 0.5$, $CHCl_3$). Correct C, H, N analyses.

10: A solution of **9** (5.3 g, 9.3 mmol) in warm MeOH (HPLC-grade, 250 mL) was cooled to ambient temperature and treated with NaOMe (0.106 g, 1.96 mmol). The hydrolysis reaction was monitored by TLC (silica gel; MeOH/$CHCl_3$ (15:85 v/v)) and was complete after 1.33 h, whereupon the reaction was quenched with HOAc (0.112 mL) and concentrated to dryness. The residue was dissolved in hot EtOH (75 mL), stirred for 10 min with Darco G-60, filtered through Celite, and concentrated in vacuo until the product began to separate. The solution was then further concentrated to a volume of 50 mL by boiling from which **10** separated upon cooling to yield 3.3 g (88 %) **10** in two crops. Recrystallization from EtOH followed by vacuum drying (1 h, 0.1 torr) at 132 °C gave the analytical sample which sinters at ca. 140 °C and melts with decomposition at 184–186 °C. ^1H NMR: $\delta = 7.59$ (d, $J = 8.7$ Hz, 1H; C5-H), 7.43 (d, $J = 9.8$ Hz, 1H; C4-H), 7.31 (d, $J = 2.6$ Hz, 1H; C8-H), 7.06 (dd, $J = 8.7$, 2.6 Hz, 1H; C6-H), 6.80 (d, $J = 2.1$ Hz, 1H; C1-H), 6.60 (dd, $J = 9.8$, 2.1 Hz, 1H; C3-H), 5.21 (d, $J = 5.1$ Hz, 1H; C2′-OH), 5.00 (d, $J = 7.7$ Hz, 1H; C1′-H), 4.91 (d, $J = 5.7$ Hz, 1H; C3′-OH), 4.68 (t, $J = 5.4$ Hz, 1H; C6′-OH), 4.54 (d, $J = 4.5$ Hz, 1H; C4′-OH), 3.38–3.73 (m, 6H; C2′–6′-H), 1.50 (s, 6H; CH_3); ^{13}C NMR (assignment by ^1H-^{13}C correlation): $\delta = 186.4$ (C2, C=O), 159.6 (C7), 150.3 (C4a), 147.5 (C9a), 141.5 (C4), 139.5 (C8a), 136.7 (C10a), 133.0 (C5), 131.0 (C3), 127.3 (C1), 115.4 (C6), 114.1 (C8), 100.4 (C1′), 75.8 (C5′), 73.4 (C3′), 70.2 (C2′), 68.2 (C4′), 60.5 (C6′), 37.1 (C9), 32.3 (CH_3), 31.9 (CH_3); UV/VIS (0.05 M phosphate pH 7.4) λ_{max} [nm] (ε) 438 (24700); $[\alpha]_D$ − 68.8° ($c = 1.3$, EtOH). Correct C, H, N analyses.

The Reaction of $PtCl_2$ with an *N,S,O*-Coordinated Calcium Complex: Synthesis and Structure of a Complexed CaPt Anion**

By *Matthew G. Davidson, Paul R. Raithby, Ronald Snaith, Dietmar Stalke,* and *Dominic S. Wright**

Recently we have described several aqua complexes of metalated organic molecules.[1] Most relevant here is $[Ox_2Ca(HMPA)_2(H_2O)_2]$ (**1**, Ox = 2-mercaptobenzoxazoyl), obtained from the reaction of 2-benzoxazolthione (OxH, 2 equiv), $Ca(OH)_2$ (1 equiv), and hexamethylphosphoric triamide (HMPA) (2 equiv). Complex **1** is easily dehydrated, giving $Ox_2Ca(HMPA)_2$ **2**.[1a] The key features of **1**

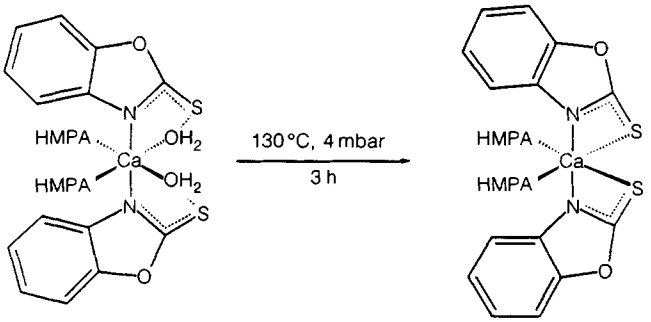
(CASE Studentship for *M. G. D.*). We thank also Professor G. M. Sheldrick, University of Göttingen for financial support for *D. S.* (DAAD, NATO scholarship). All of the new work described is being patented by the Associated Octel Co., Ltd.

and **2** deserve note: In the anhydrous complex **2** the thioxo sidearms are coordinated to $Ca^{2\oplus}$; in complex **1**, however, the thioxo sidearms are displaced from the coordination sphere of the metal by the insertion of H_2O and participate in stabilizing the resulting H_2O complex by $S^{\delta\ominus} \cdots H_2O$ hydrogen bonds.



1 **2**

Encouraged by these results we postulated that chelate complexes like **2** might function as novel donor ligands to metal salts, MZ_n. The evidently weak Ca–S contacts in **2** could be disrupted and replaced by stronger M–S bonds (though maintaining the Ca–N coordinations) whilst the $Ca^{2\oplus}$ center of **2** could capture the salt anions, $Z^{\ominus}$. In hard/soft terms, $PtCl_2$ was an obvious choice for MZ_n since $Pt^{2\oplus}$ is compatible with $S^{\delta\ominus}$ and $Ca^{2\oplus}$ with $Cl^{\ominus}$. The idea works. Heating a mixture of complex **2** (3 equiv) with $PtCl_2$ (2 equiv) in toluene gives a bright yellow solution and a yellow powder, Ox_2Pt [Equation (a)]. After filtration, cooling of the solution gave golden yellow crystals of **3** in good yield.

$$\underset{\mathbf{2}}{3[Ox_2Ca(HMPA)_2]} + 2PtCl_2 \xrightarrow{C_6H_5CH_3} \underset{\mathbf{3}}{[(HMPA)_3Ca(\mu_2\text{-}Cl)_3Ca(HMPA)]^{\oplus}[Pt(Ox)_4CaCl]^{\ominus}} + Ox_2Pt \quad \text{(a)}$$

The solid-state structure of **3**, determined by X-ray crystallography,[2] consists of two Ca cations complexed by $Cl^{\ominus}$ and HMPA and a heteronuclear anionic complex. In addition, two toluene solvate molecules occupy general positions in the lattice, not interacting strongly with either the cation or the anion. The cation (Fig. 1, above) consists of two $Ca^{2\oplus}$ ions with pseudo-octahedral coordination geometries linked by three μ_2-$Cl^{\ominus}$ ions (mean Ca–Cl distance, 2.80(1) Å). Each Ca^{2+} ion is also complexed by three HMPA ligands [mean Ca–O distance, 2.27(2) Å]. This cation is apparently quite stable since it has been found in $CaCl_2(HMPA)_3$ which exists as $[(HMPA)_3Ca(\mu_2\text{-}Cl)_3Ca(HMPA)_3]^{\oplus}Cl^{\ominus}$.[3] Other cationic Ca_2-complexes are not known, although a magnesium analogue, $[Mg_2Cl_3(THF)_6]^{\oplus}[MoOCl_4(THF)]^{\ominus}$, has been reported.[4]

The structure of the anion of **3** (Fig. 1, below) lends credence to our initial musings. The $Pt^{2\oplus}$ center is coordinated by the four thioxo sidearms of four $Ox^{\ominus}$ ions (mean Pt–S distance, 2.32(2) Å) in the square-planar coordination geometry typical for Pt^{II} complexes[5a] (Pt deviates by 0.1 Å from the S_4 plane). The N centers of these $Ox^{\ominus}$ ions in turn bind to a $Ca^{2\oplus}$ center (mean Ca–N distance, 2.46(2) Å; cf 2.545(6) Å in **1**) which lies directly above Pt. The distance between Ca and Pt, 2.960(5) Å, precludes any interaction between the two atoms, because the sum of the radii of $Ca^{2\oplus}$ and $Pt^{2\oplus}$ is only ca. 1.8 Å.[5b]

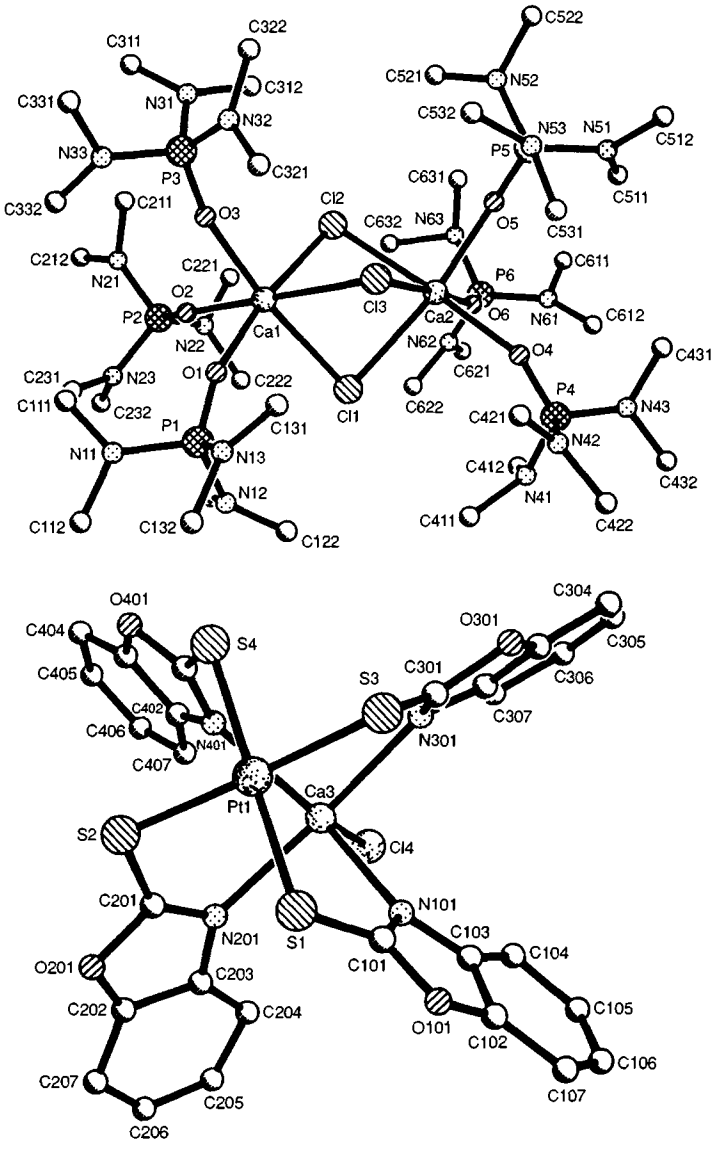


Fig. 1. Above: The structure of the cation of **3**. Below: The structure of the anion of **3**. The toluene molecules in the crystal have not been included.

A $Cl^{\ominus}$ ion completes the coordination of the $Ca^{2\oplus}$ ion as square-based pyramidal, to our knowledge a new geometry for this metal.[6] The anion of **3** can be viewed as a tetradentate $[Ox_4CaCl]^{3\ominus}$ ligand coordinated to a $Pt^{2\oplus}$ cation. In this way the $Pt^{2\oplus}$ and one $Cl^{\ominus}$ ion are built into the anion complex, while the second $Cl^{\ominus}$ from $PtCl_2$ is incorporated into the cation complex.

The results show that sidearm-donating complexes such as **2** can act as ligands to other metals. Indeed, a solution of **2** (or of the barium analogue $[Ox_2Ba(HMPA)_3]$ will react with other soft metal species, for example, $PdCl_2$, $CoCl_2$, $NiCl_2$, $SnCl_2$, resulting in crystalline products. The ligand precursor OxH can be described as Y–R–XH (Y = S, X = N). Since countless organic acids belong to this category, one might tailor Y–R–XH ligands (X, Y = O, S, N) using hard/soft concepts to give complexes with the general formula Y-R-XM′ which will react with MZ_n salts. For example, $[(C_6H_4OC(\cdots O)\cdots N)_2Ca(HMPA)_2]$, an analogue of **2** but with X,Y = N,O rather than N,S, reacts with $TiCl_3$ (containing the harder $Ti^{3\oplus}$ metal ion) to give a crystalline product containing both Ca and Ti whose structure is as yet unknown. Such ideas are relevant to metal–ion separation and

extraction, and to the development of heteronuclear catalysts. In addition, Pt–Ca co-complexes such as **3** could serve as models for complexes with deprotonated DNA bases as ligands since such bases also fit the Y–R–XH formula. (For C, G, and T, X = N and Y–R = C=O; for A, X = NH and Y–R = C=N.

Experimental Procedure

3: Platinum(II) chloride (0.266 g, 1 mmol) was added to a solution of $[Ox_2Ca(HMPA)_2]$ **2** (1.050 g, 1.5 mmol) in toluene (10 mL). The mixture was heated to 100 °C for 15 min whereupon all the $PtCl_2$ had reacted to give a yellow solution and a small quantity of yellow powder (Ox_2Pt). Filtration and cooling of the reaction mixture to 20 °C produced yellow cubic crystals of **3**. (Yield 0.660 g, 56%); m.p. 210–213 °C; correct C, H, N, Cl, P analyses; ^{1}H NMR [$(CD_3)_2SO$, 250 MHz, 20 °C] $\delta \approx 7.1$ (m, 26H, $Ox^{\ominus}$-*H*, $C_6H_5CH_3$), 2.53 (d, 108H, HMPA, $J = 9.5$ Hz), 2.30 (s, 6H, $C_6H_5CH_3$). Suitable crystals of **3** for X-ray diffraction were mounted under argon in a polyfluorinated hydrocarbon oil into Lindemann tubes.

Dedicated to Professor Karl Heinz Büchel on the occasion of his 60th birthday

Polymer latices have found widespread use for a multitude of applications such as carpet backing, paper coating, protective or decorative coatings, dipped goods, textile pigment printing, leather finishing, nonwoven fabrics, and molded foam products. The structure of the latex particle determines the properties necessary for a given application. An important example of a heterogeneous structure of a latex particle is given by the core-shell morphology in which a spherical core of polymer A is enclosed by a shell of polymer B.[1] The analysis of such particles presents a difficult problem. Investigation by electron microscopy requires thin cuts and subsequent chemical staining of the polymeric phase by, for example, OsO_4.[2] It is obvious that this method only works for systems in which a contrast between the different phases can be effected. Small-angle neutron and small-angle X-ray scattering techniques,[3–5] however, give information on the morphology of latex particles without prior treatment. A necessary prerequisite is a sufficient contrast with regard to the scattering length density or the electron density between the different polymers and the dispersing medium. Here we present a small-angle X-ray (SAXS) analysis of core-shell particles composed of polystyrene (PS) and polymethylmethacrylate (PMMA). The particle size distribution of the latex necessary for the interpretation of the SAXS data has been determined by ultracentrifuge sedimention.[6, 7]

The intensity $I(q)$ of the scattered X-rays of spherical particles with equal diameter (normalized to the scattering intensity of a single electron) is given by Equation (a),[8] where $q(= 4\pi \sin(\theta/2)/\lambda; \theta =$ scattering angle) is the magnitude of the scattering vector and N the number of scattering particles per volume V. The scattering amplitude f is defined by Equation (b),[8] where $\rho_P(r)$ denotes the electron density of the particle as a function of the distance to the midpoint and ρ_S is the electron density of the dispersing agent. The form factor $P(q)$, which describes the intraparticle interferences, is characteristic of the internal structure of the particle. It is given by Equation (c).[8]

$$I(q) = (N/V) f^2 P(q) S(q) \quad \text{(a)}$$

$$f = 4\pi \int_0^\infty [\rho_P(r) - \rho_s] r^2 dr \quad \text{(b)}$$

$$P(q) = \{f^{-1} 4\pi \int_0^\infty [\rho_P(r) - \rho_S][\sin(q \cdot r)/q \cdot r] r^2 dr\}^2 \quad \text{(c)}$$

The structure factor $S(q)$ is related to the interparticle interferences at finite particle concentration.[8] $S(q)$ can be derived by Fourier transformation of the pair correlation function.[8]

Equation (a) holds true for a system of spheres uniform in diameter. For the interpretation of measurements on colloidal systems the size distribution of the particles must be taken into account explicitly. *Vrij* and co-workers[9, 10] were able to generalize Equation (a) to polydisperse systems. In particular, they were able to show that $S(q)$ can be calculated exactly for a system of hard spheres differing in size.

Figure 1 demonstrates the influence of the size distribution on the scattering intensities by displaying the form factor of homogeneous spheres under the assumption of a Gaussian size distribution (number average diameter 80 nm). The pronounced minima of the form factor of monodisperse spheres vanish with increasing nonuniformity (Fig. 1a). The marked influence of polydispersity must be taken into account for a quantitative evaluation of the SAXS experiment.

Since the SAXS experiment is done at finite concentrations, the structure factor $S(q)$ must not be disregarded.[11] Figure 1b shows $S(q)$ for a system of hard spheres at a volume fraction of the spheres of 0.2.[10] For monodisperse

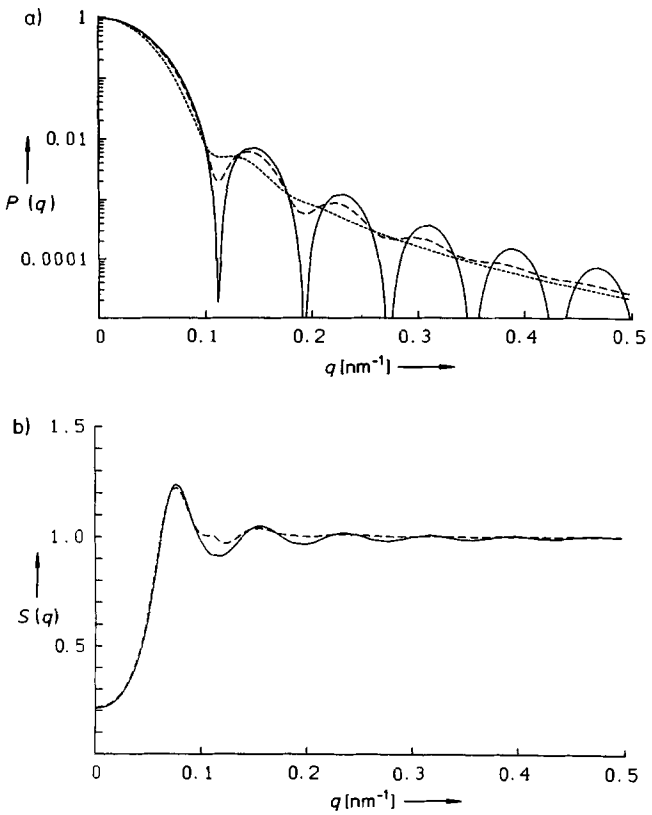

Fig. 1. a) Calculated form factor $P(q)$ [Eq. (c) and ref. [9]] for homogeneous spheres with a number average diameter of 80 nm and a Gaussian distribution of the diameters. ——, standard deviation $\sigma = 0$ nm (uniform size); — —, $\sigma = 6$ nm; - - - -, $\sigma = 12$ nm. b) Structure factor calculated according to [10]) for a system of hard spheres with a number average diameter of 80 nm and a Gaussian distribution of diameters. The volume fraction of the particles is 0.2. ——, standard deviation $\sigma = 0$ nm; — —, $\sigma = 6$ nm.

systems the structure factor differs from unity only below $q = 0.15$ nm^{-1}. Hence the scattering intensity in the region of higher q values is solely governed by the form factor $P(q)$. For polydisperse systems the oscillations of $S(q)$ are less pronounced. Here the influence of interparticle interferences is restricted to the region $q < 0.1$ nm^{-1}.

Figure 2 shows the experimental ("smeared") scattering intensities of the PS-latex forming the core and of the shell-core latex after adding the shell through subsequent polymerization of PMMA. The respective corrected ("desmeared") intensities are displayed in Figure 3.

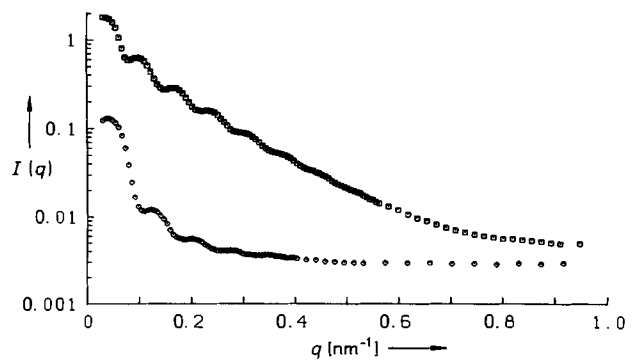

Fig. 2. Experimental (smeared) scattering intensities $I(q)$ of the shell-core latex (upper curve) and the polystyrene seed latex (lower curve). $I(q)$ in units of 10^5 impulses per 600 s.

An additional investigation of the region of smallest angles as a function of concentration showed that the scattering intensities above 0.1 nm^{-1} are solely determined by $P(q)$; that is, these data only refer to the internal structure of the particle. This finding is in accordance with the general discussion in Figure 1. Electron microscopy furthermore demonstrated that the PS seed latex, as well as the PS/PMMA shell-core latex, exhibits a spherical shape.

For a quantitative interpretation of the scattering intensities (Fig. 3) the size distribution was determined by ultracentrifuge sedimentation. The number distribution of the diameter d used for the SAXS analysis of the PS seed latex is shown in Figure 4. The theoretical form factor calculated for such a distribution is shown in Figure 3 as a solid line. The number average diameter of the particles resulting from this analysis is 80.2 nm. This value is higher than the diameter (71.5 nm) determined by sedimentation and electron microscopy. The reason for this discrepancy may be certainly traced back to the fact that the present fit does not take into account the soap molecules adsorbed on the surface of the PS particles. The emulgator used herein exhibits a pronounced electron density difference with regard to water as well as to the polymer. Its maximum length is 2.5 nm.[12, 13] Moreover, the surface of the

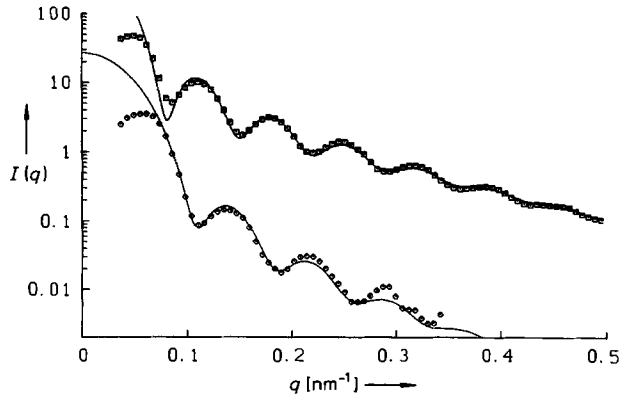

Fig. 3. Corrected (desmeared) intensities of the shell-core latex (upper curve) and of the polystyrene seed latex (lower curve). The solid lines represent the calculated form factors (see text for explanation). $I(q)$ in units of 10^5 e.u. per nm^3.

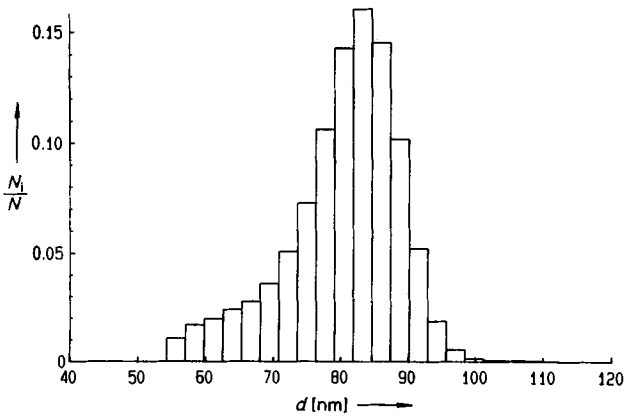

Fig. 4. Number distribution N_i/N of the diameters of the polystyrene seed latex used in the SAXS analysis (shape determined by ultracentrifuge sedimentation according to [6]).

particles contains sulfate end groups from the polymerization, which can also modify the interface between polymer and water.[14]

The experimental scattering intensities of the PS/PMMA latex were fitted by a shell-core model[15] consisting of a PS core (electron density difference to water: $\Delta\rho_e = 8\ e^-\ nm^{-3}$) with the shape of the size distribution identical to that in Figure 4. The PMMA shell ($\Delta\rho_e = 46.73\ e^-\ nm^{-3}$) was assumed to be of constant thickness (cf. also Ref. [5]). A fit of the experimental result based on the assumption of homogeneous spheres could not be achieved. The shell-core model yields 76.2 nm for the number average of the core diameter and 6.9 nm for the thickness of the shell. The resulting overall diameter is therefore 90 nm. The dimension of the shell compared favorably with the value of 6.25 nm deduced from mass balance. An investigation of the latex by rapid density gradient centrifugation showed that all particles have the same density. Thus, the size distribution could be determined by ultracentrifuge sedimentation and the number average diameter obtained is 90.2 nm.

The agreement between the different methods is excellent in the case of the PS/PMMA latex. It has to be noted, however, that the applied shell-core model leads to a slightly varying density of the particles. The effects of the sulfate end groups and of soap molecules adsorbed on the surface of the particles are less important in the case of the shell-core latex because of the much larger electron density difference between PMMA and water. All results clearly demonstrate that quantitative agreement between measured and calculated scattering intensities can be achieved if the size distribution of the latex particles is known accurately. Small-angle X-ray analysis therefore is a reliable method for the study of the morphology of polymer latices.

Experimental Procedure

Synthesis: The monomers styrene (Fluka, purum) and methyl methacrylate (Fluka, purum) were destabilized and distilled prior to use; the initiator potassium peroxodisulfate (Fluka, p.a.), the emulsifier (sodium *p*-dodecylbenzenesulfonate, Fluka, technical) and the inhibitor (*N,N*-diethylhydroxylamine (DEHA), Aldrich) were used without further purification; water used for polymerization was deionized and distilled in an apparatus made from quartz.

PS latex: Batch polymerization; heating of the mixture to 80 °C under nitrogen; start of the reaction by addition of initiator; reaction time 6 h with continuous stirring (300 rpm); termination of the reaction by addition of inhibitor; 525 g H_2O, 15 g 10 wt % emulsifier solution, 150 g styrene, 0.3 g $K_2S_2O_8$ in 6.0 g H_2O, addition of 15 g 10% emulsifier solution after 0.5 h, addition of 0.61 g 25 wt % DEHA solution after 6 h; conversion (of styrene) 93%.

PS/PMMA latex: Polymerization under starved conditions [16]; heating of the mixture to 80 °C under nitrogen, addition of initiator, addition of MMA (25 μL min^{-1}) over 7 h with continuous stirring at 300 rpm; termination of the reaction by addition of inhibitor; 79.36 g PS latex, 0.144 g $K_2S_2O_8$ in 9.92 g H_2O, 9.868 g MMA, addition of approximately 0.07 g 25 wt % DEHA solution after 7 h; conversion of MMA 100%.

Characterization: (1) Electron microscopy: transmission electron microscope Hitachi H700H; particle counter Zeiss TGZ-3; calibration of the magnification factor by internal standard PS latex (Balzers, $d = 313 \pm 2$ nm) and a grating replica (Balzers, 2160 lines mm^{-1}). (2) Ultracentrifuge: see [6]. (3) SAXS: Kratky-Kompakt-Kamera (A. Paar, Graz, Austria) with step scan device, recording of the intensity by a scintillation counter with pulse height discrimination, Nickel-filtered $Cu_{K\alpha}$ radiation ($\lambda = 0.154$ nm); determination of the primary intensity by the "moving slit" method [17]; width of the entrance slit; 20 μm; width of the detector slit, 50 μm; subtraction of the scattering intensities due to the empty capillary and to the electron density fluctuation of the samples (the latter correction according to [18] by determination of the background in the region of high angles); the correction of smeared intensity was done using the procedure of *Strobl* [19].

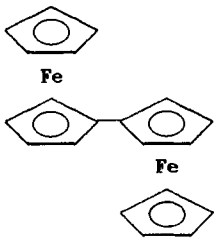
Derivatives of 1,1″-Biferrocene with Sulfur and Selenium Bridges**

By *Max Herberhold,** *Hans-Dieter Brendel*, and *Ulf Thewalt*

Dedicated to Professor Erwin Weiss on the occasion of his 65th birthday

In view of the great amount of work on the lithiation of ferrocene,[1-5] it is surprising that nothing has been reported on the lithiation of 1,1″-biferrocene, $[Fe_2C_{20}H_{18}]$ (Fc-Fc) (**1**). Here we describe the preparation of a tetralithiated intermediate, **2**, and its reaction with sulfur and selenium.



1

1: $[Fe_2C_{20}H_{18}]$ (Fc-Fc)
2: $[Fe_2C_{20}H_{14}Li_4 \cdot (tmeda)_n]$

tmeda = Me_2N–CH_2CH_2–NMe_2

In the presence of tetramethylethylenediamine (tmeda), ferrocene reacts with *n*-butyllithium to give the tmeda-stabilized 1,1′-dilithioferrocene **3**,[2,3] which reacts with sulfur in excess to give 1,2,3-trithia[3]ferrocenophane, $[FeC_{10}H_8S_3]$ (**4a**).[3,6]

The analogous lithiation of **1** with an excess of *n*-butyllithium in the presence of tmeda leads preferentially to the

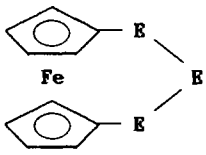
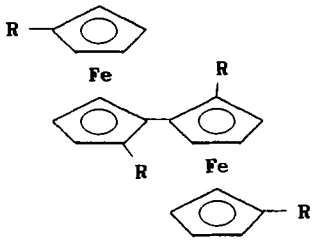
3



4a: E = S
4b: E = Se

tetralithiated product **2**, in which each of the four cyclopentadienyl rings is monolithiated and the fulvalene system contains the lithium substituents at positions 2 and 2″ (for numbering see Fig. 1). This was established by ^{1}H and ^{13}C NMR spectroscopy of the tetrasubstituted 1,1″-biferrocene derivatives **5** and **6**, obtained by reaction of **2** with excess Me_3SiCl and MeSSMe, respectively. Tetrasubstituted 1,1″-biferrocenes were previously unknown.



5: R = $SiMe_3$
6: R = SMe

Sulfurization of **2** with *cyclo*-octasulfur allows either two S_3 or two S_2 bridges to be introduced into **1**. A mixture of $[Fe_2C_{20}H_{14}(S_3)_2]$ (**7a**, side product) and $[Fe_2C_{20}H_{14}(S_2)_2]$ (**8a**, main product) is thereby formed. The selenium compounds $[FeC_{10}H_8(Se_3)]$ (**4b**)[6, 7] and $[Fe_2C_{20}H_{14}(Se_2)_2]$ (**8b**) are accessible in a corresponding way by reaction of **3** and **2**, respectively, with an excess of selenium; a selenium derivative analogous to **7a** was not obtained.

The NMR spectra of complexes **5**, **6**, **7a**, and **8a**,**b** confirm the presence of a tetrasubstituted 1,1″-biferrocene. In the ^{1}H NMR spectrum, two doublets of doublets and a triplet are observed for the fulvalene protons and four multiplets are found for the protons of the monosubstituted cyclopentadienyl rings. In the ^{13}C NMR spectrum, seven signals are observed for the carbon atoms bearing hydrogen atoms and three weaker-intensity signals for the C atoms at the substituted positions of the cyclopentadienyl rings. In the EI mass spectra, the molecular ion appears with high intensity, usually (except for **8b**) as the base peak.

According to the X-ray structure analysis,[8] the molecules of **7a** (Fig. 1, left) consist of two 1,2,3-trithia[3]ferrocenophane units; thus, the distances and angles in the S_3 chains correspond to those in **4a**.[9] In **8a**, the S_2 units bridge the two ferrocene moieties (Fig. 1, right). The molecules **7a** and **8a** are chiral; both compounds crystallize as racemates. Compound **7a** has no crystallographic symmetry, whereas **8a** displays crystallographic C_2 symmetry.

The molecular structures of **7a** and **8a** are shown in Figure 1 in such a way that the right (lower) ferrocene units of the 1,1″-biferrocene framework[10] have the same orientation; the central C1–C1″ bond of the fulvalene lies in the plane of the paper. The C1–C1″ distance in bridged $[Fe_2C_{20}H_{14}(S_2)_2]$ (**8a**) (1.459(4) Å) is hardly shorter than in $[Fe_2C_{20}H_{14}(S_3)_2]$ (**7a**) (1.479(7) Å); a value of 1.48(4) Å was given for 1,1″-biferrocene.[10c] The two five-membered ring planes of the fulvalene ligand are tilted toward each other by 23.3° in **7a** and 46.3° in **8a**. As in **4a**, the two five-membered

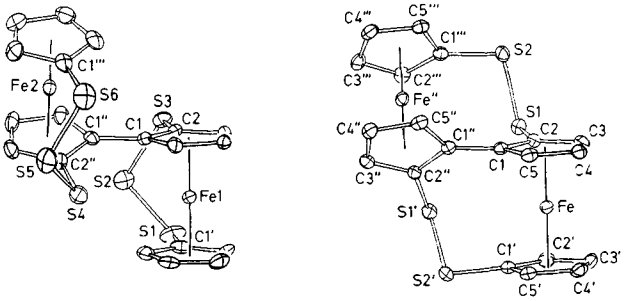


Fig. 1. Left: Molecular structure of $[Fe_2C_{20}H_{14}(S_3)_2]$ (**7a**) in the crystal. Selected bond lengths [Å] and angles [°]: S3-C2 1.755(5), S3-S2 2.052(2), S2-S1 2.045(2), S1-C1′ 1.754(6), C1-C1″ 1.479(7); C2-S3-S2 103.3(2), S1-S2-S3 105.1(1), C2″-C1″-C1-C2 23.2. Right: Molecular structure of $[Fe_2C_{20}H_{14}(S_2)_2]$ (**8a**) in the crystal. Selected bond lengths [Å] and angles [°]: S1-C2 1.751(3), S1-S2 2.066(1), S2-C1‴ 1.765(3), C1-C1″ 1.459(4); S2-S1-C2 100.3(1), S1-S2-C1‴ 103.8(1), C2″-C1″-C1-C2 46.3.

rings of the ferrocene units nearly eclipse each other; the deviations from the ideal eclipsed conformation (cf. Ref. [11]) are 0.08° in **4a**,[9] 0.4° and 1.7° in the Fe1 and Fe2 halves, respectively, of **7a**, and 9.5° in **8a**. For **1**, on the other hand, a twisting of 16–17°—between an eclipsed (0°) and a staggered (36°) conformation—has been reported.[10b, c] The rings of the ferrocene units lie practically parallel to each other; the tilting (i.e., the angle between the normals of the five-membered ring planes) is 2.85° in **4a**,[9] 1.5 and 1.9° in **7a**, and 2.0° in **8a**. The sulfur atoms are coplanar with the five-membered ring to which they are attached; the deviation of the sulfur atom from the ring plane is 0 Å in **4a**, <0.03 Å for all four relevant S atoms in **7a**, and 0.10 Å (away from Fe) in **8a**.

Experimental Procedure

2: *n*-Butyllithium (4.22 mL, 6.75 mmol) as a 1.6 M solution in hexane (Merck) was added to a solution of **1** (500 mg, 1.35 mmol) in 100 mL of hexane followed by addition of tmeda (1.01 mL, 6.75 mmol). The reaction mixture was heated at reflux for two days. The orange precipitate thereby formed contained **2**, which, after drying in a high vacuum, was dissolved in ether, THF, or toluene/THF and allowed to react directly with Me_3SiCl (at −78 °C), MeSSMe (at 0 °C), sulfur, or selenium (at 25 °C), each in excess.

5 and **6**: The reaction solution (50 mL of THF or diethyl ether) was stirred overnight, during which time it warmed to room temperature. It was then evaporated to dryness. Purification by chromatography on silica gel.

5: Elution with pentane; red-brown oil, which slowly crystallized on standing; yield 12%. ^{1}H NMR (C_6D_6, 25 °C): δ = 4.76 (dd, 2H), 4.12 (dd, 2H), and 4.31 (t, 2H) (fulvalene); 4.25, 4.14, 4.08 and 3.94 (each m, 2H) (cyclopentadienyl); 0.51 and 0.23 (each s, 18H) ($SiMe_3$ groups).

6: Elution with dichloromethane/pentane (1:4); light yellow powder; yield 16%. ^{1}H NMR (C_6D_6, 25 °C): δ = 4.79 (dd, 2H), 4.27 (dd, 2H), and 4.19 (t, 2H) (fulvalene); 4.43, 4.40, 4.30, and 4.22 (each m, 2H) (cyclopentadienyl); 2.15 and 1.72 (each s, 6H) (SMe-groups).

7a, **8a**: The reaction solution (50 mL of toluene/THF (1:1)) obtained from the reaction of **2** with sulfur (in five- to tenfold molar excess) was stirred at 25 °C for 48 h. After addition of 20 mL of water, the organic phase was separated and dried with Na_2SO_4 and the solvents were removed under vacuum. The residue was chromatographed on TLC plates (SiO_2). Development of the plates with pentane/dichloromethane (3:1) resulted in four orange zones, which contained **1** (small amount), $[Fe_2C_{20}H_{16}(S_3)]$ (small amount), $[Fe_2C_{20}H_{14}(S_3)_2]$ (**7a**), and $[Fe_2C_{20}H_{14}(S_2)_2]$ (**8a**). The zones were removed and the products, **7a** and **8a**, respectively, were purified again by TLC.

7a: Orange crystals, m.p. 194–197 °C; yield 8%. ^{1}H NMR (C_6D_6, 25 °C): δ = 4.30 (dd, 2H), 3.84 (dd, 2H), and 3.90 (t, 2H) (fulvalene); 4.26, 3.86, 3.79, and 3.46 (each m, 2H) (cyclopentadienyl).

8a: Orange crystals, darkening and decomposition above 180 °C; yield 23% based on **1**. ^{1}H NMR (C_6D_6, 25 °C): δ = 4.33 (dd, 2H), 4.24 (dd, 2H), and 3.84 (t, 2H) (fulvalene); 4.31, 4.08, 3.99, and 3.77 (each m, 2H) (cyclopentadienyl).

8b: TLC workup of the orange products obtained from the reaction of **2** with selenium (1:10) gave, besides $[Fe_2C_{20}H_{16}(Se_3)]$ (dec. 229 °C, yield 8%), $[Fe_2C_{20}H_{14}(Se_2)_2]$ (**8b**) as the main product: orange crystals, dec. 238 °C; yield

27%. ^{1}H NMR (C_6D_6, 25 °C): δ = 4.40 (dd, 2H), 4.20 (dd, 2H), and 3.84 (t, 2H) (fulvalene); 4.24, 4.10, 3.99, and 3.77 (each m, 2H) (cyclopentadienyl).

New Routes to the Synthesis of Polymers Containing Nitrile Groups**

By *Holger Brackemann, Michael Buback,* Frank Rindfleisch,* and *Stefan Rohde*

Dedicated to Professor Karl Heinz Büchel on the occassion of his 60th birthday

Demands for specialty elastomers are constantly increasing. In particular, low temperature flexibility and heat resistance are expected and considerable emphasis is placed on improving oil and aging resistance. A high-performance elastomer[1] was obtained by selective hydrogenation of nitrile rubber (butadiene/acrylonitrile copolymer). But this type of polymer modification is costly and alternative ways of producing polymers containing only C–C single bonds in the chain with nitrile substituents should therefore be investigated.

Hydrogenated nitrile rubber is formally a terpolymer consisting of units derived from ethene, acrylonitrile, and to a small extent 1-butene.[1] A corresponding material should thus be accessible by free-radical copolymerization of ethene (E) and acrylonitrile (AN) with small amounts of 1-butene.[2] The study of E/AN copolymerization, however, showed that the initiator consumption in this reaction is unexpectedly high and that adhesive products are formed. It is presumably on these grounds that direct chemically initiated copolymerization has not yet become a technical process.

During recent years considerable progress has been achieved in the field of free-radical polymerizations induced by excimer laser light.[3] A substantial advantage in these reactions relates to initiation being "nonmaterial" which allows the production of polymer free from initiator fragments. This aspect is especially important for reactions such as the E/AN copolymerization where initiator consumption is very high. Moreover, by variation of laser pulse energy and pulse repetition frequency, excimer laser-induced polymerizations may be easily and effectively controlled.

An alternative route to products similar to fully hydrogenated nitrile rubber might proceed from macromolecules with a polymer chain exclusively consisting of C–C single bonds. Appropriate substituents on the chain may be converted to nitrile groups. Both routes are outlined in the subsequent text.

The free-radical copolymerization of ethene and acrylonitrile induced by excimer laser light (KrF-line at 248 nm) has been studied in the temperature range of 423 to 523 K at pressures up to 2900 bar.[4, 5] Apart from the suggested prospects for polymer synthesis, the excimer laser offers unique possibilities for a detailed study of free-radical polymerization kinetics.[6] The reactivity ratio for ethene, r_E, was determined to be $r_E = 3.50 \exp[-2273\ (T/K)^{-1}]$ (at a constant pressure of p = 2450 bar). Taking the experimental uncertainty into account, r_E changes from 0.016 ± 0.003 at 423 K to 0.045 ± 0.008 at 523 K. While r_E is well below unity, the corresponding value for the reactivity ratio of acrylonitrile, r_{AN}, is close to 7.5. It follows from these r_E and r_{AN} values that at about 473 K and 2450 bar a monomer mixture containing 0.5 mol % AN produces (at differential conversion) a polymer containing approximately 15 mol % acrylonitrile units which is equivalent to 25 weight %. By applying the equations for ideal copolymerization kinetics to a copolymer system such as E/AN with this appreciable difference in the reactivity ratios, one can see that the polymerization rate is considerably slowed by low acrylonitrile monomer concentrations, for example of 0.5 mol %. This is simply because a free-radical chain end to which ethene has been added in the preceding step undergoes cross-propagation preferentially since $r_E \ll 1$. The subsequent addition of another acrylonitrile molecule, which is favorable because of $r_{AN} \gg 1$, is slow because the concentration of AN is very small. In addition, the rate coefficient for homopolymerization of AN is lower than for E. In contrast to chemically initiated polymerizations, the rate of laser-induced reaction can be accelerated by enhancing initiation without introducing considerable quantities of initiator fragments into the polymer. Along these lines, laser-induced high-pressure polymerization at 523 K has produced colorless, nonadhe-

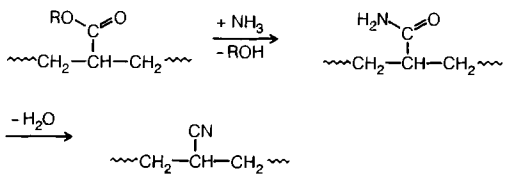
sive E/AN copolymers with technically relevant AN contents up to 25 weight %.[5] It is difficult to increase the AN content further in experiments with excimer lasers, because the reacting system becomes inhomogeneous. Increasing the polymerization temperature or adding a solvent may extend the homogeneous region which offers the possibility of producing copolymers with even higher acrylonitrile content. The glass transition temperature of E/AN copolymers from laser-induced experiments is about 10 °C above T_g of corresponding material from the complete hydrogenation of butadiene–acrylonitrile rubber. By performing laser-induced E/AN polymerization in the presence of small amounts of 1-butene monomer, T_g should be lowered since the crystallinity due to ethylene sequences will be further reduced.

The difference in reactivity ratios for ethene/acrylic ester (AE) systems is less than that for E/AN. Starting from ethene/acrylic ester copolymers, which are more easily accessible, it seemed rewarding to study whether the ester group in a polymer modification reaction could be transformed into a nitrile group. The number of additional components required for this process should be as small as possible. Moreover, these components should be simple and easy to remove. In line with these prerequisites, the reaction of E/AE ester copolymer in dense fluid ammonia was investigated, in which NH_3 acts as reactant, dehydration agent, and solvent. The conversion to a copolymer of E/AN type proceeds via an intermediate copolymer of ethene/acrylamide (AA) type (Scheme 1). The first step in the reaction sequence with NH_3 dissolved in xylene and also with further auxiliary agents has already been investigated.[7, 8]



Scheme 1. Transformation of ester groups to nitrile functions in a polymer.

Polymer modification was studied at 1500 bar at temperatures between 448 and 523 K on ethene/butyl acrylate (BA) copolymer containing 7.8 mol % BA. At 523 K additional experiments were performed at 200 and 700 bar. Ammonia was employed in large excess. The ratio of NH_3 to BA groups at the beginning of the reaction was approximately 200 : 1. At specific reaction times the polymeric product was collected and the concentration of amide and nitrile functional groups was determined by IR analysis on polymer films. The concentration of ester groups in the polymeric material was obtained from the difference between the spectroscopically determined AA and AN concentrations and the known total concentration of functional groups. The spectroscopic determination was verified by elemental analysis. The IR analysis provides no indication of intra- or intermolecular reactions between polymeric functional groups. In preliminary tests, fully hydrogenated butadiene/acrylonitrile rubber with 34.9 mol % AN was kept in fluid ammonia at 523 K and 1500 bar for 24 hours. The IR spectra of polymer before and after this experiment did not indicate any reaction between nitrile groups.

In Figure 1 the fraction X of functional groups within the polymer (with $X = 100$ % referring to the absolute concentration of 7.8 mol % BA in the initial E/BA copolymer) is plotted versus reaction time for several reactions at 523 K and 1500 bar. The ester group (BA) reacts relatively rapidly.

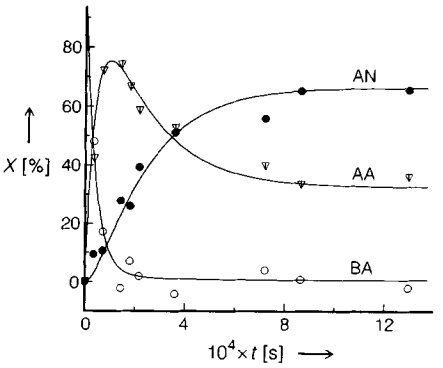


Fig. 1. Dependence of the fraction X of ester (BA), amide (AA), and nitrile (AN) functional groups in ethene/butyl acrylate copolymer (7.8 mol % BA) on reaction time t for polymer modification reactions with pure fluid ammonia at 523 K and 1500 bar. ($X = 100$ % refers to the total content of 7.8 mol % of functional groups.)

The amide group (AA) concentration passes through a pronounced maximum after a reaction time of about 3 hours and reaches a constant value at longer reaction times, as does the concentration of nitrile groups (AN). In the experiments at 523 K and 1500 bar the fraction of AN groups reaches a maximum value of about 70 %. Figure 2 shows corresponding data for 523 K and 200 bar. The intermediate maximum in AA concentration is less pronounced. In marked contrast to the reaction at 1500 bar (Fig. 1), the polymeric material contains ester groups in addition to nitrile and amide functional groups, even after long reaction times. The data in Figures 1 and 2 suggest that the polymer modification reaction should be treated as a consecutive-type reaction in which both steps are reversible.

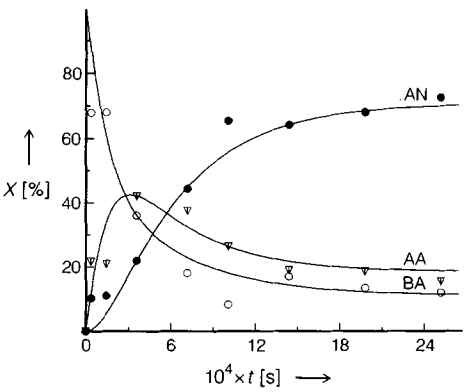

Fig. 2. Dependence of the fraction X of ester (BA), amide (AA), and nitrile (AN) functional groups in ethene/butyl acrylate copolymer (7.8 mol % BA) on reaction time t for polymer modification reactions with pure fluid ammonia at 523 K and 200 bar. ($X = 100$ % refers to the total content of 7.8 mol % of functional groups.)

The notations "ester (BA)", "amide", and "nitrile" in Scheme 2 denote the functional groups of the polymer. An analytical solution for this kinetic scheme is not available. Thus rate coefficients k_1 to k_4 are determined with an iterative computer program. The results are presented in Table 1. The forward reaction from ester to amide groups is treated

$$\text{ester (BA)} + NH_3 \underset{k_2}{\overset{k_1}{\rightleftharpoons}} \text{amide} + \text{butanol} \underset{k_3}{\overset{k_3}{\rightleftharpoons}} \text{nitrile} + H_2O$$

Scheme 2.

Table 1. Rate coefficients k of the polymer modification reaction of ethene/butyl acrylate copolymer (7.8 mol % BA) in dense fluid ammonia. The rate coefficients are assigned according to Scheme 2. (Mol % in k_2 and in k_4 refers to the concentration of amide and of nitrile functional groups in the polymer, respectively. The concentrations of the low molecular weight reactants, butanol and water, are determined, since only E/BA copolymer and pure NH_3 are employed in the experiments).

T [K]	p [bar]	$10^{-5} \times k_1$ [s^{-1}]	$10^{-5} \times k_2$ [s^{-1}(mol %)$^{-1}$]	$10^{-5} \times k_3$ [s^{-1}]	$10^{-5} \times k_4$ [s^{-1}(mol %)$^{-1}$]
448	1500	0.56	–	0.08	0.06
473	1500	2.87	–	0.30	0.18
498	1500	9.11	–	0.76	0.19
523	1500	24.30	–	2.66	0.25
523	700	6.48	0.65	3.70	0.21
523	200	3.66	0.32	1.92	0.09

as a pseudo-first-order reaction, as NH_3 is present in a large excess.

In the experiments up to 1500 bar, k_2 is too small to be reliably determined. The accuracy is assumed to be ± 10 % for k_1 and k_3 and ± 15 % for k_2 and k_4. Arrhenius plots for k_1 and k_3 are given in Figure 3. The data are well represented by a straight line. The activation energies (1500 bar) are 98 ± 9 kJ mol^{-1} for the ester to amide reaction (k_1), and 87 ± 8 kJ mol^{-1} for the amide to nitrile reaction (k_3). These values suggest that the reaction takes place in a homogeneous fluid phase. From the pressure dependence of k_1 an activation volume of $\Delta V^{\neq}(k_1) = -63 \pm 12$ cm^3 mol^{-1} is obtained. From the presently available experimental data activation energies for k_2 and k_4 and activation volumes for k_2, k_3, and k_4 cannot be determined to an accuracy of better than ± 40 %.

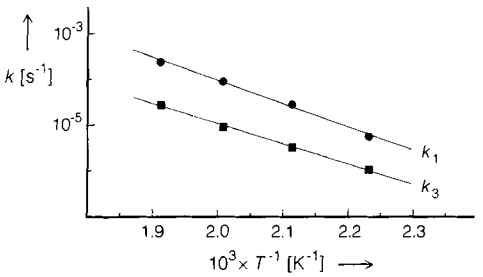

Fig. 3. Temperature dependence of the rate coefficients k_1 and k_3 (see Scheme 2).

The curves in Figures 1 and 2 have been calculated using the rate coefficients in Table 1. Based on the activation parameters, X–t diagrams may also be estimated for other temperatures and pressures. These data reveal the reaction time t after which the modification reaction has to be stopped in order to achieve a certain fraction of ester, amide, and nitrile groups (at fixed ethylene content). Moreover, the kinetic scheme allows an estimation of the reaction temperatures and pressure which are required to achieve a desired composition of functional groups (for high values of reaction time t). Because of the reversibility of all reaction steps (Scheme 2) polymers which have a broad distribution in the concentration of ester, amide, and nitrile groups can be converted into a chemically more uniform material.

With respect to the synthesis of polymers containing only nitrile functional groups, the results suggest that reaction be conducted in a countercurrent of pure fluid NH_3 or with the continuous removal of water from the system. As is to be expected, treating the product of a polymer modification reaction a second time with fluid ammonia increases the content of nitrile groups. But for technical purposes, the reaction times are too long (Figure 1 and 2). The modification reaction should thus be accelerated by applying still higher temperature or by using catalysts. The reaction rate should also increase when ethene/acrylic ester copolymers with an ester group smaller than in BA are employed.

In further experiments the modification reaction with fluid ammonia will be studied for ethene/acrylic ester compounds with higher ester content. In addition, larger quantities of polymeric material should be produced to enable a comprehensive characterization of product properties.

The X-ray Crystal Structure Analysis of a Fragmentable *N*-Acylpyridinium Ion**

By *Christian Lohse, Sandro Hollenstein,* and *Thomas Laube**

The catalytic effect of pyridines in acylation reactions is explained by the formation of an intermediate *N*-acylpyridinium ion **1**, which then undergoes nucleophilic attack by an alcohol or amine (Einhorn method, a variant of the Schotten–Baumann reaction).[1] The existence of this type of ion has been proven by NMR spectroscopy by *Olah* et al.[2] and by crystal structure analysis by *Jones* et al.[3] The molecular structure and crystal packing of **2**-BF_4 reported here allow conclusions regarding charge delocalization and the

two main reactions of **2**, namely, nucleophilic attack on the carbonyl C atom and fragmentation.

We attempted to obtain suitable crystals of several salts with cation **1** for X-ray structural analysis. *N*-Boc-4-dimethylaminopyridinium-tetrafluoroborate (**2**-BF_4), a reagent used for the transfer of Boc groups (Boc = *tert*-butoxycarbonyl), was prepared by the method of *Guibé-Jampel* and *Wakselman*.[4] Crystallization of **2**-BF_4 by isothermal distillation with acetonitrile/ether at room temperature led to partial decomposition, presumably to 4-dimethylaminopyridinium-tetrafluoroborate, producing crystals of **2**-BF_4 and the decomposition product.

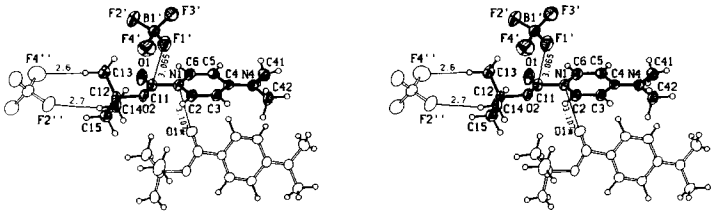

Fig. 1. ORTEP stereoview of the structure of **2**-BF_4 in the crystal. The ellipsoids are drawn at 50% probability; the H atoms are represented by spheres with a radius of 0.1 Å. One ion pair forms the asymmetric unit. Symmetry operations: ′ = $1-x, 2-y, -z$; ″ = $x-1, y, z-1$, * = $x, 1.5-y, z+0.5$.

Figure 1 shows the crystal structure of **2**-BF_4.[5] In cation **2**, which formally contains a urethane fragment, the carbonyl group, pyridine ring, and dimethylamino group are almost coplanar, making π interactions possible (see Table 1). The *tert*-butyl ester fragment, O1=C11−O2−*t*Bu,

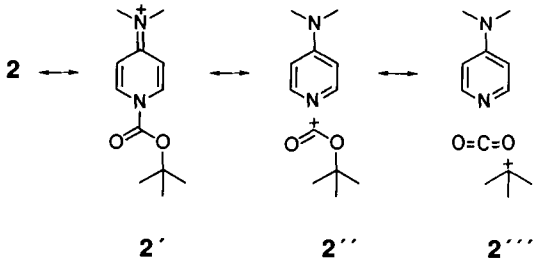
C11-O2-C12-C15 + 73.0(5)	O2-C11-N1-C6 − 177.0(4)	C5-C4-N4-C42 − 176.7(4)

displays the conformation typical for such esters.[6] The bond lengths in the pyridine ring of **2** systematically deviate from those of 4-dimethylaminopyridine.[7] In **2** the bonds N1−C2, N1−C6, C3−C4, and C2−C5 are 0.031(5), 0.015(5), 0.009(5), and 0.017(5) Å longer, while the bonds C2−C3, C5−C6, and C4−N4 are shorter by 0.031(5), 0.032(6), and 0.021(5) Å. These differences suggest a charge delocalization in the π system in accordance with the resonance structure **2′**.[8]

The deviations in the urethane-like part of **2** are more evident if one refers to the mean bond lengths of four *O-tert*-butylurethanes substituted on nitrogen with two sp^2 C atoms.[9] The N1−C11 and O2−C12 distances are 0.055(8) and 0.035(9) Å longer; the C11−O2 distance, 0.025(6) Å shorter; and the O1−C11−O2 angle, 4.3(6)° larger than expected. These deviations could be interpreted as proof of the contribution of resonance structures **2″** and **2′** to the overall description of **2**. This corresponds to a conjugation in the σ system (second-order hyperconjugation). These deviations are also in keeping with the reactions of **2**: the Boc group is easily transferred and under suitable conditions fragments to CO_2 and isobutylene.[10]



The counterion drawn with primed atom labels (Fig. 1) is in a favorable position for nucleophilic attack on C11 in the course of an acylation reaction.[11–13] The distance between C11 and F1′ is 3.065(5) Å (i.e. 0.085 Å less than the sum of the van der Waals radii); the O1=C11···F1′ angle is 109.1(3)°. The other face of the carbonyl C atom does not interact with a potential nucleophile. However, a carbonyl O atom, O1*, from another cation appears to have a purely electrostatic interaction with N1 (N1···O1* = 3.107(5) Å). In the crystal the *tert*-butyl group is surrounded by four BF_4 ions (shortest H···F distance, H132···F2′ = 2.5 Å). One of these anions is in a position favorable for the deprotonation of the *tert*-butyl group (antiperiplanar arrangement of N1−C11, O2−C12, and C−H; H143···F2″ = 2.7 Å; H133···F4″ = 2.6 Å). Thus **2** can be viewed as a model for **1**, and as a further example of hyperconjugation[14,15] and the correlation between chemical reactivity and crystal packing.[13]

Double Insertion of Alkynes into Chromium–Carbon Bonds of β-Donor-Substituted Vinylcarbene Complexes of Chromium—A Simple Route to Cyclopenta[*b*]pyrans*

By *Frank Stein, Michael Duetsch, Rolf Lackmann, Mathias Noltemeyer,* and *Armin de Meijere**

Dedicated to Professor Karl Heinz Büchel on the occasion of his 60th birthday

Fischer carbene complexes have now found application in preparative organic chemistry.[1] Of particular interest is the cycloaddition of α,β-unsaturated Fischer carbene complexes to alkynes, the so-called Dötz reaction, which, in the case of 1-alkoxycarbene complexes, leads to phenol or cyclohexadienone derivatives.[2] There have been numerous reports on the synthesis and chemical behavior of β-donor-substituted Fischer carbene complexes,[3] but not on their reactions with alkynes. We recently described the unusual behavior of β-(dimethylamino)vinylcarbene complexes of chromium on treatment with alkynes;[4] these complexes were easily obtained in excellent yields by Michael addition of dimethylamine to alkylvinylcarbene complexes. The cyclopentadiene products were obtained in good yields, however, only if a cyclopropyl substituent was also present at the β position. To determine whether the donor character of the cyclopropyl group exerts a significant effect in these reactions, we have now prepared the corresponding complex **3a** with a 1′-ethoxycyclopropyl group.

Compound **2a** was obtained in the usual way[3a, 5] from an alkyne[6] and hexacarbonylchromium followed by alkylation. Complex **3a** was then prepared in good yield by addition of dimethylamine to **2a** (Scheme 1). Surprisingly, reaction of **3a** with phenylacetylene (**5**) gave neither the corresponding cyclopentadiene[4] nor the expected cyclohexadienone product of the Dötz reaction.[2] Instead, a dark red solid was isolated in 17% yield. ^1H, ^{13}C NMR, and IR spectroscopy, as well as mass spectrometry, revealed that the product could only have arisen by incorporation of two alkyne molecules and a carbonyl ligand, and elimination of dimethylamine. An X-ray structure analysis established the identity of the product as the cyclopenta[*b*]pyran **7a** (Fig. 1).[7] Compound **7a** is a so-called pseudoazulene, a heterobicycle isoelectronic to azulene.[7, 8] Its skeleton deviates only slightly from planarity, the two rings forming an angle of 3.7°.

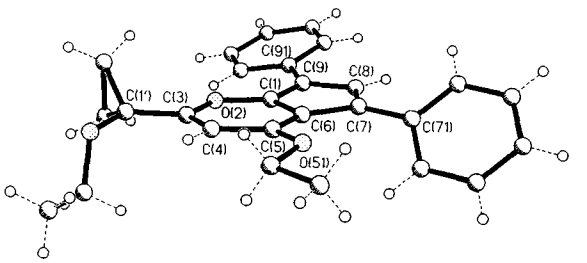

Fig. 1. Molecular structure of **7a** (SCHAKAL drawing)[9]. Important bond lengths [pm]: C(1)-O(2) 137.4(2), C(1)-C(6) 143.7(2), C(1)-C(9) 137.6(2), O(2)-C(3) 134.8(2), C(3)-C(4) 135.1(2), C(3)-C(1′) 148.3(2), C(4)-C(5) 142.0(2), C(5)-C(6) 138.0(2), C(5)-O(51) 133.7(2), C(6)-C(7) 144.7(2), C(7)-C(8) 138.0(3), C(7)-C(71) 147.5(2), C(8)-C(9) 143.7(2), C(9)-C(91) 146.5(3); angle between the planes C(1)-O(2)-C(3)-C(4)-C(5)-C(6) and C(1)-C(6)-C(7)-C(8)-C(9) 3.7°. The dotted atoms are oxygen atoms.

When an eightfold excess of alkyne **5** was used, **7a** could be obtained from **3a** in a yield of 41%. Since such pseudoazulenes, despite intensive research, were previously only accessible by multistep syntheses with in part strongly limited substitution patterns and/or in low yields,[7, 8] we examined whether this synthetic route could be generalized with respect to the alkynes employed, **1a–d**, as well as **5** and **6** (Scheme 1).

Indeed, the cyclopenta[*b*]pyrans **7b–d** and **8a–d** are also formed in the reaction of (β-dimethylaminovinyl)carbenechromium complexes **3a–d** with phenylacetylene (**5**) and with 1-pentyne (**6**). The best yields are obtained with complex **3b**, which contains a (2′-ethoxyprop-2′-yl) group and is particularly easy to prepare (see Table 1). In contrast to 2-cyclopropyl-substituted (2-ethoxyvinylcarbene) chromium complexes,[10] the ethanol adduct obtained from **2b** and **5** also reacts to give **7b**, albeit in lower yield. Accord-

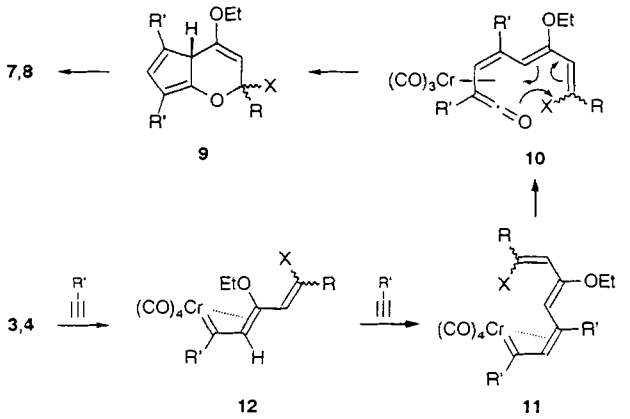
[a] Yield after isolation: 66 %.

The mechanism of formation of **7** and **8** undoubtedly involves as the last step a 1,4 elimination of dimethylamine and ethanol, respectively, from the dihydro derivative **9**, which is presumably formed from a (trienylketene)tricarbonylchromium complex, **10**, by intramolecular [4 + 2] cycloaddition. Complex **10** results from CO insertion into a 1-chroma-(2 *Z*,4 *Z*)-octatetraene, **11**, which is formed, in turn, by double insertion of alkyne **5** or **6** into the chromium–carbon bond of **3** or **4**, respectively. The first insertion presumably leads primarily to (*Z*)-**12**, since otherwise, CO insertion and subsequent cyclization to the cyclohexadienone[12] could occur at this stage. The *Z* configuration of the newly formed



Scheme 2. Proposed mechanism for the formation of cyclopenta[b]pyrans **7** and **8** from **3** and **4**, respectively.

double bond in (*Z*)-**12** is probably due to the steric demand of the R group in 1-chroma-1,3-diene **3** or **4**, which, for *Z* configuration of the 3,4 double bond and assumed coplanarity, strives to attain the greatest possible separation from the 4-ethoxy group or the 3-H, respectively. NOE measurements[12] on **3b** established a *Z* configuration for the 3,4 double bond, whereas the dimethylamine and the ethanol adducts with (cyclopropylethynyl)pentacarbonylchromium complexes[4] exhibit *E* configurations. On the other hand, the ethanol adduct **4b**, prepared from **2b**, was obtained as an *E*/*Z* mixture (*E*/*Z* = 1.5:1).

Comparison of the absorption bands in the UV spectra of **7a** and **8a** with those of carbocyclic analogues is possible only qualitatively, since the correspondingly substituted azulenes are unknown. The spectra of **7a** and **8a**, however, are very similar to those of known pseudoazulenes:[8d-f] strong absorptions are observed at λ_{max} (log ε) = 204 (4.55), 233 (4.50), and 308 (4.53) for **7a** and 220 (4.22), 262 (3.98), and 3.41 (3.80) for **8a** and a very broad band is found in the visible region with a maximum at 484 (3.02) and 455 (2.52), respectively.

Calculated for *m*/*z* ($M^{\oplus}$) 400.2038, found 400.2038.

Experimental Procedure

4-Ethoxy-2-(2′-ethoxyprop-2′-yl)-5,7-di-*n*-propylcyclopenta[*b*]pyran (**8b**): A solution of **3b** (304 mg, 0.75 mmol) and 1-pentyne (**6**; 410 mg, 6 mmol) in 15 mL of tetrahydrofuran was heated in a sealed Pyrex flask for 7 d at 52 °C. The reaction mixture was then filtered, the filtrate was concentrated to dryness, and the residue was chromatographed on 50 g of silica gel (pentane/diethyl ether 1:1, R_F = 0.66); 148 mg (59 %) of **8b** was obtained as red crystals, m.p. 132 °C; 28 mg (9 %) of the starting compound was recovered. The spectroscopic data for **3b** and **7b** are summarized in Table 2.

Surface Organometallic Chemistry on Oxides: Selective Catalytic Low-Temperature Hydrogenolysis of Alkanes by a Highly Electrophilic Zirconium Hydride Complex Supported on Silica

By *Christine Lecuyer, Francoise Quignard, Agnès Choplin, Danielle Olivier,* and *Jean-Marie Basset**

The electrophilic activation of the C–H bond of alkanes on d^0 complexes of early transition metals (groups III–VI), lanthanides, and actinides is now well documented.[1] However, if one excludes H/D exchange between methane and deuterium,[2] no catalytic reaction involving a C–H activation step has been reported so far with d^0 metals. We report here the catalytic properties of a zirconium hydride supported on silica for the hydrogenolysis of neopentane, isobutane, and propane; the reaction forms isobutane, propane, and ethane respectively, together with methane.

Reaction of tetraneopentylzirconium ([$ZrNp_4$]) with the surface of silica previously dehydroxylated at 500 °C leads to the surface complex [($\equiv$SiO)$ZrNp_3$] (**1**), which has been characterized by elemental analysis, ^{13}C MAS NMR (MAS = magic angle spinning), in situ IR spectroscopy, and by its chemical reactivity with water.[3] A supported zirconium hydride **2** is obtained when **1** is reacted with molecular hydrogen (450 torr) at 150 °C.[4]

Hydride **2** has been qualitatively identified by in situ IR spectroscopy, and by its chemical reactivity with CH_3I and aqueous KOH.[5] Although this surface species is not yet fully characterized, the structure [($\equiv$SiO)$_3$ZrH] can be tentatively assigned to **2**. The only gaseous products detected on formation of **2** are methane and ethane. Therefore under these conditions, the neopentyl ligand, or the neopentane initially produced by cleavage of the neopentyl–zirconium bond, has undergone hydrogenolysis to yield as final products methane and ethane.

In effect, above 50 °C **2** catalyzes the hydrogenolysis of alkanes such as neopentane, isobutane, and propane. At 50 °C, neopentane ($p_{NpH} = 40$ torr, $p_{H_2} = 230$ torr) is totally converted in 100 hours. Up to a level of 50 % conversion, 85 % of the products are isobutane and methane (Fig. 1). At

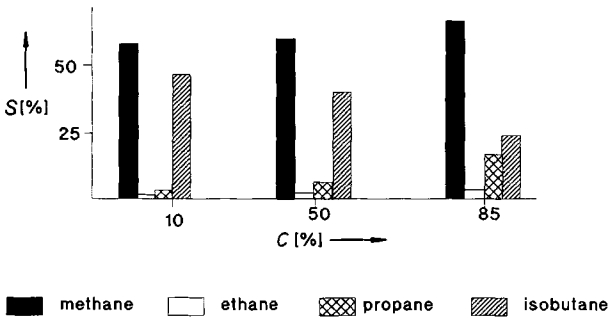

Fig. 1. Hydrogenolysis of neopentane: product distribution (S)/conversion (C) histograms ($T = 50$ °C, $p_{NpH} = 40$ torr, $p_{H_2} = 230$ torr, %Zr: 1.5 wt.%.)

higher conversion, isobutane is transformed into methane and propane, and the propane is subsequently transformed into methane and ethane. Interestingly, ethane does not undergo any significant further hydrogenolysis: this must have a mechanistic implication. Traces of 2-methylbutane are observed during the hydrogenolysis of neopentane.

When the reaction is performed at higher temperatures (e.g. 100 °C), the rate of hydrogenolysis is higher, but an increase in secondary reactions of the first-formed alkanes is observed: isobutane gives propane and methane and subsequently ethane and methane (Fig. 2). Hydrogenolysis of isobutane and propane has been carried out independently at 150 °C. The results confirm the relative simplicity of the reaction path observed with neopentane. In particular, hydrogenolysis of propane yields only methane and ethane at any conversion.

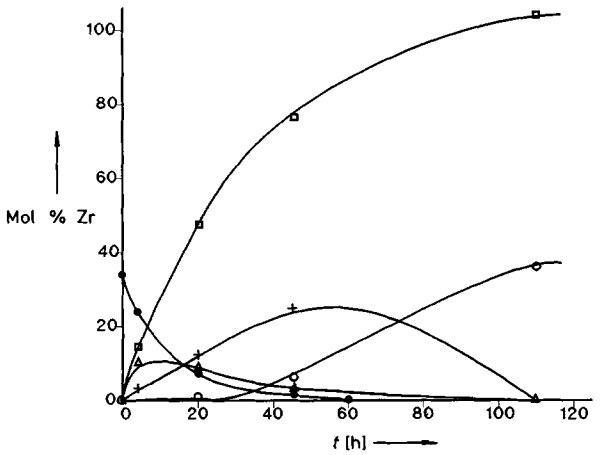

Fig. 2. Hydrogenolysis of neopentane at 100 °C. Concentration of the alkanes as a function of time ($p_{NpH} = 40$ torr; $p_{H_2} = 200$ torr). □ = methane, ○ = ethane, + = propane, △ = isobutane, ● = neopentane.

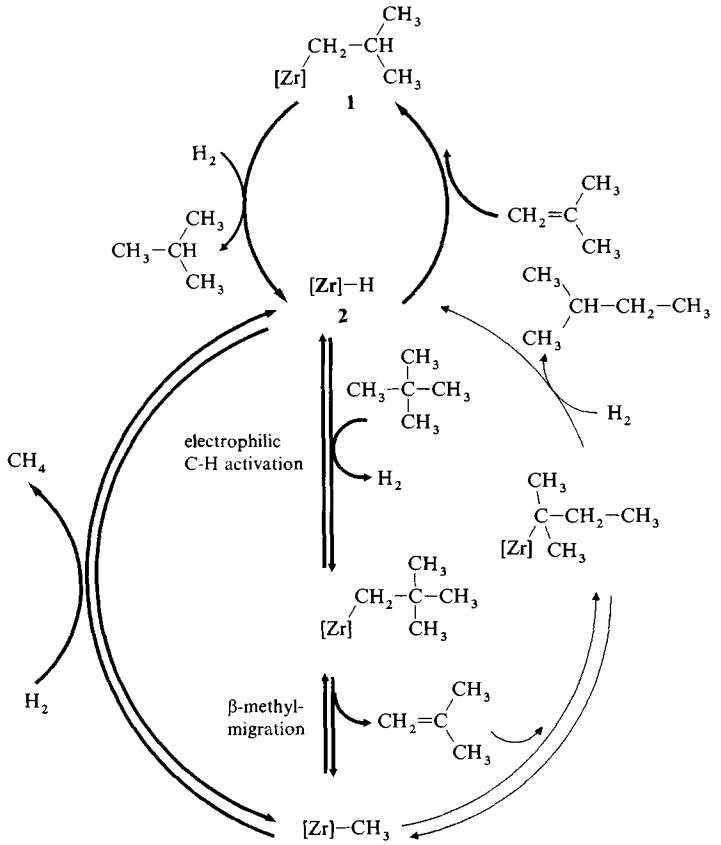
[**] The financial support of the consortium ACTANE (Centre National de la Recherche Scientifique/French Industries) is gratefully acknowledged.

The mechanism proposed in Scheme 1 accounts for the products obtained from the hydrogenolysis of neopentane and lower alkanes. The first step is a C–H bond activation through σ bond metathesis[1e, 6, 7] on the surface zirconium hydride. It is deduced from a detailed investigation of the



Scheme 1. **1**: [Zr] = (≡SiO)ZrNp$_2$, Np = neopentyl; **2** and following products: [Zr] = (≡SiO)$_3$Zr.

reactivity of **2** with cyclooctane and methane:[8] **2** reacts stoichiometrically to give the corresponding alkylzirconium complex and molecular hydrogen [Equation (a)]. This exchange reaction, which is believed to involve a four-center transition state with d^0 metals,[6, 7] occurs at 25 °C for cyclooctane and 150 °C for methane.[8]

$$[(\equiv SiO)_3ZrH] + RH \longrightarrow [(\equiv SiO)_3ZrR] + H_2 \qquad (a)$$
2

The surface hydride **2** is highly electrophilic: if one applies the Green formalism to oxide surfaces,[9] [(≡SiO)$_3$ZrH] can be considered an 8-electron d^0 species. Formation of molecular hydrogen and of a surface zirconium–neopentyl complex results from this first step.[8]

The next step is probably a β-methyl transfer leading to isobutene and a surface zirconium–methyl moiety.[10, 11] Hydrogenolysis of this latter fragment would then lead to methane. Isobutane would result from the hydrogenation of isobutene on a surface zirconium hydride.[4c] Formation of 2-methylbutane is easily explained by an anti-Markovnikov type addition of isobutene into the Zr–Me moiety followed by the hydrogenolysis of the Zr–alkyl bond. The reason why hydrogenolysis of ethane does not occur may be related to either the absence of a β-methyl group or the possible existence of an agostic interaction with the β-hydrogen as already observed on a scandium–ethyl fragment,[12] or both.

The results indicate clearly that an *immobilized* zirconium hydride is able to activate catalytically the C–H bonds of alkanes at low temperature, which has never been reported for any molecular analogue. Various reasons may be invoked for such a behavior:

- the zirconium hydride is very likely an 8-electron species which has, to our knowledge, no equivalent in molecular chemistry. Molecular zirconium(IV) hydrides are generally stabilized by two cyclopentadienyl ligands; they are thus 16-electron species and therefore less electrophilic than **2**.
- the extremely strong zirconium–oxygen bond which is responsible for the strong grafting of the transition metal to the support, does not allow any bimolecular deactivation as would certainly occur with a true molecular species.

Experimental procedure

Silica (Aerosil Degussa, 200 m^2 g^{-1}) was dehydroxylated under vacuum (500 °C, 16 h, 10^{-4} torr) and used in situ. [ZrNp$_4$] was synthesized following published procedures [13]. [ZrNp$_4$] was sublimed under vacuum (60 °C, 10^{-4} torr) on the freshly dehydroxylated silica; unreacted complex was removed by evacuation at the same temperature. The solid samples thus obtained were 1.5 wt% Zr. All gaseous reactants were carefully dried and deoxygenated over freshly regenerated molecular sieves (4 Å) and deoxo traps. All the catalytic tests were carried out in a pyrex batch reactor. The composition of the gas phase was followed by chromatography.

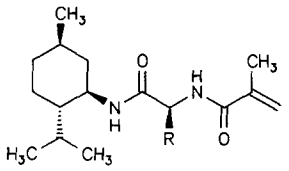
New Chiral Polyamide Stationary Phases for Chromatographic Enantiomer Separation

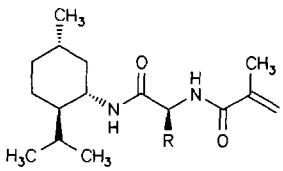
By *Dieter Arlt, Bruno Bömer, Rolf Grosser,* and *Walter Lange**

Dedicated to Professor Karl Heinz Büchel on the occasion of his 60th birthday

Many biologically active substances are now tested in their enantiomerically pure form. Chiral stationary phases (CSPs) can ensure not only reliable enantiomer analysis but also ready availability of the two enantiomers of a racemic active substance at a very early point in biological screening. Extensive use requires a range of CSPs which permit preparative separation at reasonable cost. Until now only a few types of CSPs could be considered: cellulose triacetate, cellulose tribenzoate,[1-3] and more recently cellulose urethanes,[4] *N*-(3,5-dinitrobenzoyl)amino acid phases,[5] and polyamide phases from optically active *N*-(meth)acryloyl monomers.[6-8] The present report concerns new, highly selective polyamide phases prepared from the optically active amino acid amides **1a–c** and **2a–c** for chromatographic separation of enantiomers.



1a–c



2a–c

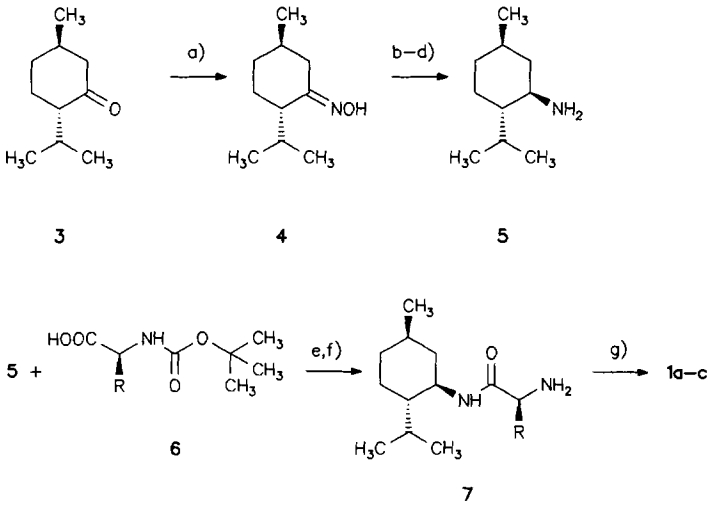
a, R=CH_3; **b**, R=$CH_2CH(CH_3)_2$; **c**, R=(*S*)-$CH(CH_3)C_2H_5$

Since good separation results had been obtained with poly(meth)acrylamides, it was expected that new adsorbents of this type would extend the possibilities of direct enantiomer separation without prior derivatization. Besides the development of analytically useful HPLC phases,[9,10] these monomers should also make the synthesis of cross-linked bead polymers for preparative separations possible.[6-8] Poly(*N*-acryloyl-(*S*)-phenylalanine ethyl ester)[7] shows a good enantioselective separation of some racemates.[6,11] But more broadly applicable CSPs, distinguished by higher enantioselectivities particularly for the more polar, biologically active racemates, are also desirable.

It seemed necessary to us first of all to strongly restrict the conformative mobility of the monomer molecule by the incorporation of an additional amide group and a bulky residue. This reduces the number of energetically equivalent conformers which possibly have opposite effects on enantioselectivity. Secondly, the use of a rigid, bulky, and also chiral residue should enable a further increase in enantioselectivity through double stereodifferentiation.

Our new CSPs contain an amino acid structural unit which permits rational synthesis and fulfills the requirements mentioned. The increased rigidity in the immediate surroundings of the stereogenic center of the amino acid is ensured by a peptide bond. As the rigid bulky and additionally chiral group we chose optically active menthylamine, used in our earlier studies and available in both enantiomeric forms starting from (−)-menthone (**3**) or (+)-menthol.

(−)-Menthone (**3**) was converted into (−)-menthonoxime (**4**) with aqueous hydroxylamine solution in the presence of small quantities of an emulsifier at room temperature (Scheme 1). The highly diastereoselective reduction of the



Scheme 1. Synthesis of optically active monomers. a) $NH_2OH \cdot HCl$, Na_2CO_3, sodium lauryl sulphate (15% in H_2O, catalytic amount), RT, 48 h, 95%; b) Na, EtOH, reflux; c) steam distillation, conc. HCl; d) NaOH, H_2O, 0 °C, 1 h, 75% for b–d; e) NEt_3, ClCOOEt, THF, −15 °C to RT, 30 min; 85–95%; f) CF_3COOH, CH_2Cl_2, 0 °C to RT, 2 h, NaOH, 90–95%; g) methacryloyl chloride, NEt_3, CH_2Cl_2, 0 °C to RT, 1 h, 75–85%).

oxime was possible even on a kg scale with sodium and ethanol under Wallach's conditions.[12] By recrystallization of the hydrochloride >98% epimerically pure (−)-menthylamine **5** was obtained. Linkage with an optically active amino acid, for example **6**, protected by a *N*-*tert*-butoxycarbonyl residue, was possible by activation of the carboxyl function as usual in peptide chemistry. The final products **1** were formed after removal of the protecting group with trifluoroacetic acid in dichloromethane, and subsequent treatment with methacryloyl chloride in the presence of triethylamine. Monomers **2** were prepared using an analogous reaction sequence starting from (+)-menthol. The diamides **1a–c** and **2a–c** were isolated by recrystallization with diastereomeric purity of >99:1.[13]

Analytical HPLC phases can be prepared from the optically active *N*-methacryloyl compounds by covalent bonding to modified silica gel under the conditions of radical polymerization (Scheme 2).

The base can be a methacrylate-modified diol silica gel[9, 10, 14] or preferably vinylsilica.[15, 16] CSPs prepared in this way are not sensitive to pressure, extremely stable chemically, and can be used under any elution conditions without restriction. Bead polymerization in the presence of a crosslinking agent such as ethylene glycol dimethacrylate can be used to obtain CSPs for preparative purposes from methacrylamides.[7, 8, 13] The bead polymers are gels which work only under low-pressure conditions and are clearly superior to the HPLC phases in preparative separations because of their higher loadability and lower solvent requirements. For example, 0.4 g of **9** was separated completely into its enantiomers on 32 g of bead polymerizate derived from **2b** in one run.

Table 1. Enantioselectivity values α [a] for racemates **8**–**13** [b] on CSPs [c] from monomers **1a**–**c**, **2a**–**c**, and (−)-menthylacrylamide. [17]

CSP from monomer	Amino acid	Menthyl group	**8**	**9**	**10**	**11**	**12**	**13**
1a	(*S*)-Ala	(−)	2.62	2.05	–	3.13	–	1.98
2a	(*S*)-Ala	(+)	1.34	1.56	1.29	–	–	–
1b	(*S*)-Leu	(−)	4.05	2.27	–	11.40	–	2.91
2b	(*S*)-Leu	(+)	1.68	2.34	1.14	6.12 [d]	1.11	2.60
1c	(*S*)-Ile	(−)	1.37	4.00	–	5.77	–	2.28
2c	(*S*)-Ile	(+)	2.60	3.31	1.18	3.56	1.26	1.89
(−)-menthylacrylamide	–	(−)	1.43	–	–	–	–	1.83

[a] $\alpha = (k'_2)(k'_1)^{-1}$, $k'_{1(2)} = (t_{1(2)} - t_0)(t_0)^{-1}$, t_0 = dead time. [b] The eluents were *n*-heptane/THF mixtures, in ratios of 1:2 for **8** und **9**, 3:2 for **10**–**12**, and 1:1 for **13**, to give a k'_1 value between 0.5 and 4. [c] 10–15% of optically active polymer on vinylsilica (5 μm) [16]. Columns: 25 × 0.46 cm; flow rate: 1 mL min^{-1}; T = 20 °C. [d] Flow rate: 2 mL min^{-1}.

Table 1 provides a review of the separation of various racemates on the new CSPs. It should be noted that these high enantioselectivities were obtained without arene interaction. This is an indication that the criteria outlined previously are valid for enantiomer discrimination.

The combined influence of the optically active menthyl residue and the stereogenic center of the amino acid led to substantially better separations in many cases. Thus, all the above-mentioned CSPs prepared from the (*S*)-(+) diastereomers **2a**–**c** separated ketoprofen **10** into its enantiomers, whilst this is not achieved on either the *S*-(−) CSPs derived from **1a**–**c** investigated previously or on the CSP from (−)-menthylacrylamide. For the biphenyl derivative **11** (Fig. 1) we have the opposite situation, namely that the

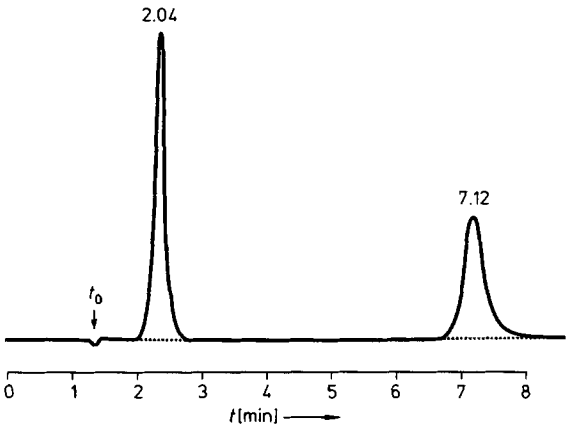

Fig. 1. Chromatographic enantiomer separation of **11** on the CSP prepared from **2b** (see Table 1).

enantioselective separations on the *S*-(−) CSPs were fundamentally superior to those on the *S*-(+) CSPs, although some of the latter also showed an outstanding selectivity for **11**. Such regularities were not observed in separations of racemic oxazepam **8** and chlorthalidone **9**, but at least one of the diastereomeric phases showed a clearly higher selectivity for these racemates than the simple polymer from (−)-

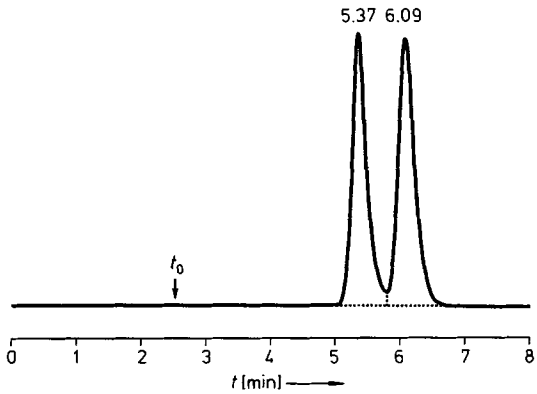

Fig. 2. Chromatographic enantiomer separation of **12** on the CSP prepared from **2c** (see Table 1).

menthylacrylamide. The separation of the nimodipine enantiomers **12** (Fig. 2) on the CSPs from the *S*-(+) diastereomers **2b** and **2c** with a larger amino acid alkyl residue was surprising, since the racemate **12** does not have

a good hydrogen bonding function in the vicinity of the stereogenic center.

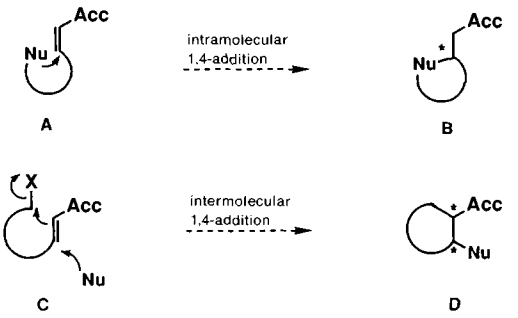
[17] Preparation of vinylsilica: 10 g silica gel (Si 100, 5 μm) dried at 120 °C under high vacuum was suspended in 100 mL toluene, treated with 7 g trichlorovinylsilane, and heated at reflux. After the addition of 12.4 g triethylamine in 30 mL toluene the mixture was stirred for 16 h at 110 °C. The vinylsilica was washed with toluene, methanol, and dichloromethane and dried under high vacuum at 70 °C. Yield: 10.6 g; C,H analysis: 3% C, 0.8% H. Preparation of CSPs: 3 g monomer, 3 g vinylsilica, and 60 mg AIBN were stirred with 15 mL chloroform under nitrogen for 2 h at 65 °C. The product was filtered off under suction, washed with chloroform, dimethylformamide, and 2-propanol, and dried under high vacuum at 25 °C. Yield: 3.1–3.2 g; polymer coating 10–15%.

Diastereo- and Enantioselective Michael Addition Initiated Cyclizations to *trans*-Substituted Cyclopentanecarboxylates **

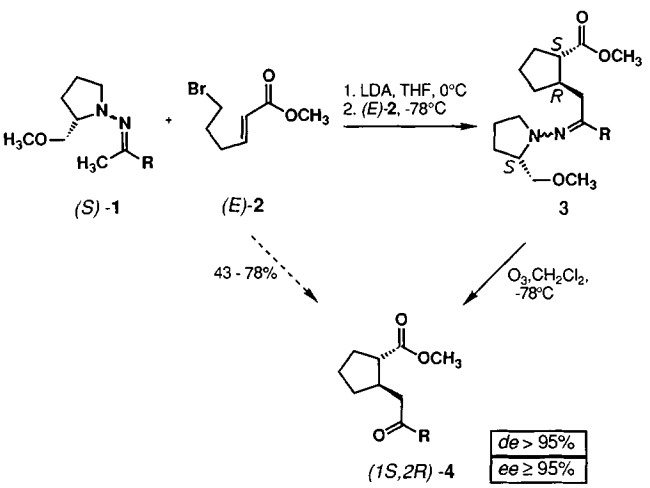
By *Dieter Enders,* Hermann J. Scherer,* and *Gerhard Raabe*

Dedicated to Professor Kurt Schaffner on the occasion of his 60th birthday

Intramolecular Michael additions are frequently used in the construction of cyclic systems (**A** → **B**).[1] If the primary addition product of an intermolecular Michael addition is intercepted with a tandem intramolecular reaction, cyclic products may be obtained too (**C** → **D**).[2,3] Because metalated SAMP/RAMP hydrazones (SAMP = (*S*)-1-amino-2-methoxymethylpyrrolidine, RAMP = (*R*)-1-amino-2-methoxymethylpyrrolidine) are proven chiral Michael donors,[4] asymmetric MIRC reactions (*M*ichael-*I*nitiated *R*ing *C*losure)[5] of the type **C** → **D** should be possible with high stereoselectivity. The 1,2-disubstituted cycloalkanes **D** with various nucleophile (Nu) and acceptor (Acc) functional groups in both side chains are important building blocks in the syntheses of bioactive compounds and natural products containing five-membered rings.[6]



We report here the synthesis of highly diastereo- and enantiopure *trans*-disubstituted cyclopentanecarboxylates **4** by the MIRC reaction of SAMP/RAMP hydrazones **1** with methyl (*E*)-6-bromo-hex-2-enoate (**2**). SAMP hydrazones (*S*)-**1**, available from the corresponding methyl ketones, are metalated with lithium diisopropylamide at 0 °C and then treated with the ω-functionalized Michael acceptor at −78 °C. After workup the cyclized (*E*/*Z*)-hydrazones are



Scheme 1. LDA = lithium diisopropylamide. **a**, R = Me; **b**, R = *n*Bu; **c**, R = *i*Bu; **d**, R = Ph; **e**, R = *p*-BrC_6H_4.

obtained, which may be purified by chromatography and characterized. Usually the crude products **3** are converted directly to the final products (1*S*,2*R*)-**4** by oxidative cleavage with ozone. After chromatographic purification the *trans*-disubstituted cyclopentanecarboxylates **4** are obtained in 43–78% total yield and with high diastereomeric (*de* ≥ 95–99%) and enantiomeric excesses (*ee* ≥ 95–97%) (Table 1).

The *de* values for the cyclization products **3** and **4** were determined by ^{13}C NMR spectroscopy; the *ee* values for compounds **4a–c**, by gas chromatography with a chiral permethylated β-cyclodextrin stationary phase. The determination of the enantiomeric excesses of **4d, e** was possible by means of ^{1}H NMR experiments using the shift reagent

[a] The yields are for the MIRC reaction and subsequent ozonolysis without isolation of the hydrazone intermediates **3**. [b] Determined by gas chromatography on a chiral stationary phase (permethyl-β-cyclodextrin, 115 °C, 1 bar H_2, see Fig. 1). [c] Determined by ^{13}C NMR spectroscopy. [d] RAMP was used as chiral auxiliary. [e] Determined by ^1H NMR Lanthanide Induced Shift (LIS) with $[Eu(hfc)_3]$. [f] M.p. = 46–47 °C.

$[Eu(hfc)_3]_3$. The racemic *trans*-cyclopentanecarboxylates, *rac*-**4a–e**, required for comparison were prepared in high diastereomeric purity from the corresponding dimethylhydrazone homocuprates according to the method previously described.[8]

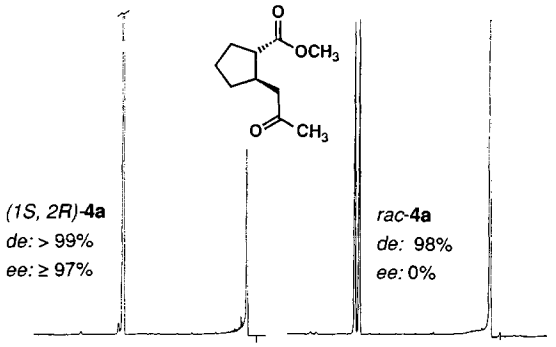

Fig. 1. Determination of diastereomeric and enantiomeric excesses by gas chromatography (fused silica capillary, heptakis(2,3,6-tri-*O*-methyl)-β-cyclodextrin in OV 1701, 115 °C, 1.0 bar H_2) [7].

The relative and absolute configurations of the cyclopentanecarboxylates were unambiguously assigned by X-ray structural analysis of compound **4e**.[9–12] This product obtained from the SAMP auxiliary was determined to have an (1*S*,2*R*) configuration. The simple change in auxiliaries from SAMP to RAMP affords access to the other enantiomer (Table 1). The absolute configuration (2*R*) of the stereogenic center generated in the first step of the 1,4-addition is in agreement with previous results of Michael additions with SAMP hydrazones [4] and the postulated mechanism of electrophilic substitutions with SAMP/RAMP hydrazones.[13]

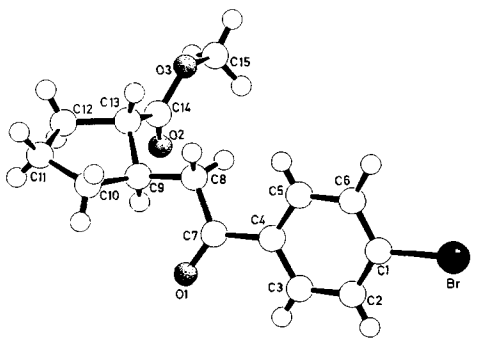

Fig. 2. X-ray crystal structure of (1*S*,2*R*)-**4e** [9].

The MIRC variation described here offers a direct and highly stereoselective approach to important synthetic building blocks.[14] Initial results show that this method can be applied in the syntheses of rings of other sizes (three-, six-, and seven-membered rings) as well as with other acceptors, for example sulfones.[15]

Experimental Procedure

To a stirred solution of 5.5 mmol lithium diisopropylamide [prepared from 0.78 mL diisopropylamine and 3.67 mL *n*-butyllithium solution (1.5 N in *n*-hexane)] at 0 °C under argon was added dropwise 5 mmol hydrazone **1**. The mixture was stirred 2 h at 0 °C and then cooled to −78 °C before a solution of 5 mmol (*E*)-**2** in 5 mL THF was added dropwise. The reaction mixture was stirred about 12 h during which time the temperature rose from −78 °C to 0–10 °C. After addition of 30 mL NH_4Cl solution and 50 mL ether, the phases were separated. The aqueous phase was extracted with ether (2 × 50 mL). The collected organic phases were washed with 10 mL saturated NaCl solution and dried over $Na_2SO_4/MgSO_4$. The solvent was removed under reduced pressure and the crude hydrazone was dissolved in 30 mL CH_2Cl_2 and cooled to −78 °C under argon. Ozone was then passed through the solution at this temperature until a blue-green color was observed. The excess ozone was dispelled by purging with an argon stream. Then the solvent was removed and the products were purified by column chromatography (ether/petroleum ether 1:3).

[9] Suitable crystals were obtained at −20 °C from petroleum ether. Orthorhombic, space group $P2_12_12_1$ (19) $a = 6.005(2)$, $b = 13.958(2)$, $c = 17.282(1)$ Å, $V = 1448.5$ Å^3, $M_{calc} = 325.2$, $Z = 4$, $F(000) = 664$, $\rho_{calc} = 1.491$ g cm^{-3}, $\mu = 30.11$ cm^{-1} (correction for spherical absorp-

tion), Enraf-Nonius four-circle diffractometer, $\omega/2\beta$ scans, 20 °C, $Mo_{K\alpha}$ radiation ($\lambda = 0.7169$ Å, graphite monochromator). 3336 independent reflections ($\pm h + k + l$), of which 2082 were observed [$I > 2\sigma(I)$, $R_m = 0.030$], $\sin\theta/\lambda_{max} = 0.6$ for solution and refinement. The structure was determined by the heavy atom method using the XTAL2.6 program package. Positions of hydrogen atoms calculated, 173 parameters refined, $R = 0.053$ ($R_w = 0.048$), residual electron density 0.7 e Å^{-3}. An enantiopole parameter[11,12] refined to 0.004 confirms the absolute configuration shown in Figure 2. Further details of the crystal structure may be obtained from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, W-7514 Eggenstein-Leopoldshafen 2, on quoting the depository number CSD-55614, the names of the authors, and the journal citation.

Nickel(0)-Carbene Complexes

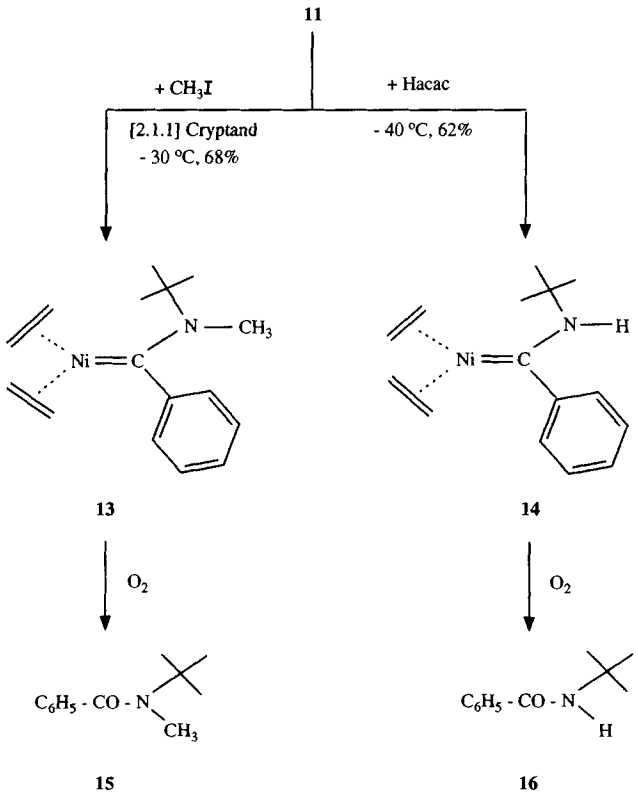
By *Barbara Gabor, Carl Krüger, Bernd Marczinke, Richard Mynott*, and *Günther Wilke**

Dedicated to Professor Horst Prinzbach on the occasion of his 60th birthday

Isocyanides can be metalated, e.g. with *n*-butyllithium, in the α-position.[1] We were interested whether $[Ni(CNCH_3)_4]$ **1** reacts with *n*BuLi in the same way to give $[Ni(CNCH_2Li)_4]$ **2**. Compound **1**, which is insoluble in pentane, dissolves when treated in this solvent at −20 °C with four equivalents of *n*BuLi. No liberation of *n*-butane is observed, either immediately or upon subsequent hydrolysis. Apparently, *n*BuLi adds to the C=N bond, possibly with formation of $[Ni\{=C(C_4H_9)NLi(CH_3)\}_4]$ **3**, which, however, could hitherto not be isolated, since it undergoes secondary reactions.

Attempts to obtain **2** from $LiCH_2NC$ and $[Ni(cod)_2]$ led to displacement of 1,5-cyclooctadiene (cod) and loss of methylene to give $Li_4[Ni(CN)_4]$ **4**,[2] which reacts with $(CH_3)_3SiCl$ to the homoleptic complex of trimethylsilyl isocyanide $[Ni\{CNSi(CH_3)_3\}_4]$ **5**.[3] In a completely analogous way $[(tpp)_3NiCN][Li(thf)_2]$ **6** (tpp = triphenylphosphane) reacts with $(CH_3)_3SiCl$ to give $[(tpp)_3Ni\{CNSi(CH_3)_3\}]$ **7**. A compound analogous to **6** is formed from [Ni(cdt)] (cdt = all-*trans*-1,5,9-cyclododecatriene) and the addition products **8** of phenyllithium and *tert*-butyl isocyanide. Aside from benzene and isobutene, formation of an adduct of LiCN and [Ni(cdt)] is observed, in the presence of *N,N,N'N'*-tetramethylethylenediamine (TMEDA) $[(cdt)NiCN][Li(tmeda)_2]$ **9** and of pentamethyldiethylenetriamine (PMDTA) [(cdt)-NiCN][Li(pmdta)] **10**. According to the NMR spectra all three C=C bonds of cdt are coordinated to the Ni atom. **9** and **10** can also be prepared directly from [Ni(cdt)] and LiCN.[4]

$[Ni(C_2H_4)_3]$ forms well-defined complexes with organolithium[5] and organomagnesium compounds.[6] Metalated aldimines, such as the adduct **8** of phenyllithium and *tert*-butyl isocyanide, should likewise coordinate as masked acyl carbanions to nickel(0) complexes.[7] **8** reacts with $[Ni(C_2H_4)_3]$ in this sense in the presence of one equivalent of PMDTA with formation of **11** (yellow crystals).[8] With TMEDA, **12** is obtained.



Whereas lithiumacetyl- and lithiumcarbamoylnickel(0) complexes cannot be converted into neutral nickel(0)-carbene complexes,[9] the alkylation of **11** with CH_3I in the presence of [2.1.1]cryptand successfully leads to formation of the neutral 16e nickel(0)-carbene complex **13**.[10] Without cryptand, only amorphous products are obtained. The protonation of **11** with acetylacetone (Hacac) in ether leads in a comparable way to **14**.[11] **13** and **14** precipitate in the form of orange-

[*] Prof. Dr. G. Wilke, B. Gabor, Prof. Dr. C. Krüger, Dr. B. Marczinke, Dr. R. Mynott

Kaiser-Wilhelm-Platz 1, W-4330 Mülheim a. d. Ruhr (FRG)

yellow crystals, which are readily soluble in ether and THF, but only sparingly soluble in pentane. **13** and **14** are the first 16e nickel(0)-carbene complexes; moreover, they contain only olefins as further ligands.

For chemical characterization, **13** and **14** were converted with oxygen into the acid amides **15** and **16**, respectively. **13** and **14** are stable up to about room temperature and could be characterized on the basis of NMR spectra. The 400-MHz ^{1}H NMR and 75.5-MHz ^{13}C NMR spectra of solutions of **13**[10] in [D$_8$]THF are temperature dependent. At -30 °C a sharp signal is observed at $\delta = 48.6$ for the ethene C atoms and an AA'BB' multiplet ($\delta_A = 2.38$, $\delta_B = 2.18$) for the diasterotopic geminal ethene protons. The signal for the carbene-C atom, with $\delta = 280.4$, lies in the range characteristic for aminocarbene complexes.[12] At -110 °C the rotation of the ethene ligand about the bond axis to the Ni atom is frozen, i.e. the ethene-C atom now affords two sharp signals at $\delta =$ 50.4 and 46.0.

An unequivocal proof of the structure was provided by a crystal structure analysis of **13** at -173 °C.[13]

It can be seen from Figure 1 that the ligands are arranged around the nickel atom in a trigonal planar fashion. Two

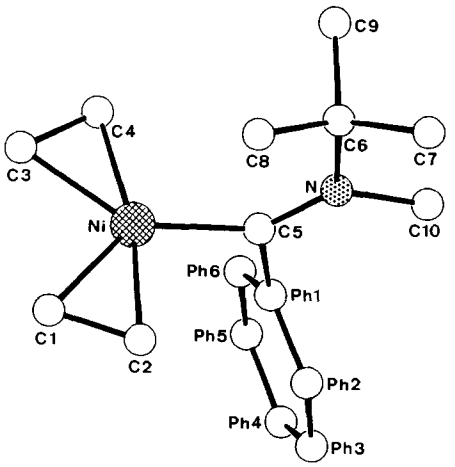

Fig. 1. Structure of **13** in the crystal. Selected bond lengths [Å] and angles [°]: Ni-C1 2.008(1), Ni-C2 2.008(1), Ni-C3 2.000(1), Ni-C4 1.999(1), Ni-C5 1.889(1), C5-N 1.320(1), C5-Ph1 1.503(1), C1-C2 1.392(2), C3-C4 1.398(2); Ph1-C5-N 115.3(1), Ph1-C5-Ni 108.7(1), N-C5-Ni 136.1(1) [13, 16].

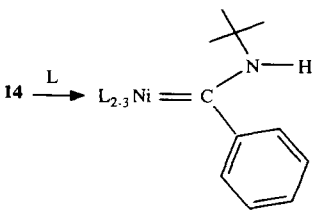
coordination sites are occupied by the ethene units, the third by the planar aminocarbene ligand. The coordination plane of the metal (Ni, midpoint of C1–C2, midpoint of C3–C4) forms a dihedral angle of 81.3° with the plane of the carbene (N,C5,Ph1), the phenyl ring an interplanar angle of 74.3° with the latter plane. From the torsion angles (Ph1,C5,N,C6 $=180°$ and Ph1,C5,N,C10 $= 4.9°$) it follows that there is a flattening of the coordination geometry of the nitrogen atom and thus a demonstrated double bond character for C5–N (1.320(1) Å) that is typical of aminocarbene complexes.

By reaction of **14** with phosphanes PR_3 (R = Et, cyclohexyl (cHex), Ph) one or two ethene ligands can be displaced,



17, L = C_2H_4 + PEt_3
18, L = C_2H_4 + $PcHex_3$
19, L = C_2H_4 + PPh_3
20, L = 2 PPh_3
21, L = 3 CO

with formation of the monophosphane complexes **17**–**19** in good yields in the form of red crystals as well as of the bisphosphane complex **20**. Both in the case of **14** and **13**, reaction with CO leads to the tricarbonylnickel carbene complexes **21** and **22**, respectively, which are not accessible from [Ni(CO)$_4$] and organolithium compounds.

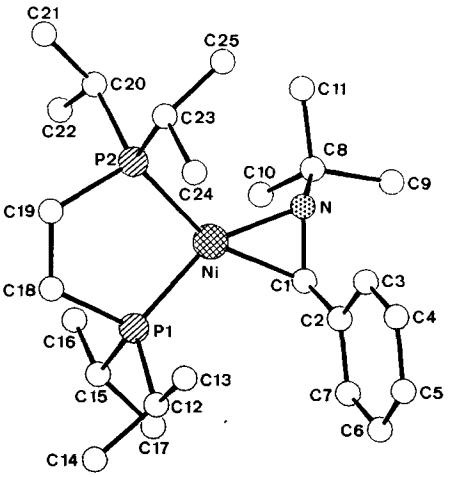


Fig. 2. Crystal structure of **23**. Selected bond lengths [Å] and angles [°]: Ni-P1 2.165(1), Ni-P2 2.188(1), Ni-N 1.915(3), Ni-C1 1.959(4), N-C1 1.375(5), C1-Ni-N 41.6(2), C1-Ni-P2 157.3(1), C1-Ni-P1 110.8(1), N-Ni-P2 116.7(1), N-Ni-P1 152.3(1), P2-Ni-P1 91.0(1) [15, 16].

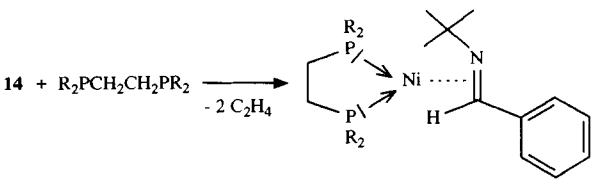
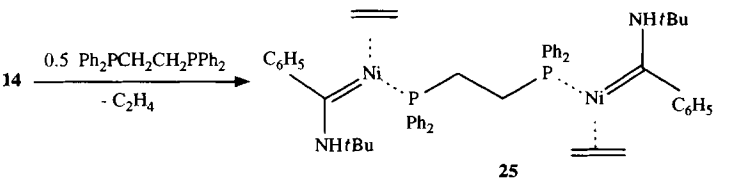
Surprisingly, displacement of the ethene ligands from **14** takes a completely different course when chelate phosphanes $R_2PCH_2CH_2PR_2$ are employed. Between -20 °C and room temperature the complexes **23** and **24** are obtained in which imines are coordinated to nickel(0), i.e. a rearrangement takes place en route from **14** to **23** and **24**.[14] The structures follow unequivocally from the NMR spectra and a crystal structure analysis of **23** (Fig. 2).[15] Reaction of **14** with half an equivalent of $Ph_2PCH_2CH_2PPh_2$ affords a red, finely crystalline precipitate, whose composition and spectroscopic data are consistent with the presence of **25**.



23, R = *i*Pr
24, R = cyclohexyl



25

The results suggest a path by which the tetracarbenenickel(0) complex **3** might be formed.

[8] All the new compounds gave correct elemental analyses. Procedure for **11**: A solution of LiC_6H_5 (2.75 g, 30.6 mmol) in ether (100 mL) was treated with *t*BuNC (3.3 mL, 29.2 mmol) and PMDTA (9.0 mL) at −25 °C. After 20 min, an orange precipitate separated out from the deep-red solution which dissolved upon addition of a solution of $[Ni(C_2H_4)_3]$ prepared from [Ni(cdt)] (6.43 g, 29.1 mmol) in 50 mL of ether. After 12 h at −78 °C a yellow crystallizate was obtained which was isolated cold by suction, washed with cold ether, and dried at −30 °C in a high vacuum. Yield: 8.2 g (62%). ^{1}H NMR (200 MHz, [D$_8$]THF, −30 °C): δ = 1.27 (s, 9H; $C(CH_3)_3$), 1.93–2.09 (m, 8H; C_2H_4), 2.12 (s, 12H; $N(CH_3)_2$), 2.20 (s, 3H; NCH_3), 2.30–2.40 (m, 8H; NCH_2CH_2N), 6.96–7.13, 5H; C_6H_5). ^{13}C NMR (75.5 MHz, [D$_8$]THF, −30 °C): δ = 260.0 (Ni=C), 155.3, 123.8, 128.1, 124.3 (C_6H_5), 58.5, 56.3 (NCH_2CH_2N), 57.8 ($C(CH_3)_3$), 46.2 ($N(CH_3)_2$), 43.4 (C_2H_4), 32.1 ($C(CH_3)_3$), 44.2 (NCH_3).
[9] E. O. Fischer, F.R. Kreissl, E. Winkler, C. G. Kreiter, *Chem. Ber. 105* (1972) 588.
[10] Procedure for **13**: A solution of **11** (1.29 g, 2.82 mmol) in THF (20 mL) was treated at −30 °C with 0.75 mL (2.86 mmol) of 4,7,13,18-tetraoxa-1,10-diazabicyclo[8.5.5]eicosane (Kryptofix 211) and 395 mg (2.8 mmol) of CH_3I in 10 mL of ether. A yellow precipitate was formed. The mixture was warmed within 1 h to 0 °C and the ether removed in a high vacuum. The residue was taken up in pentane and filtered. On cooling the red filtrate to −78 °C orange-red prismatic crystals separated out; these were filtered off, washed with pentane, and dried in a high vacuum at 0 °C. 558 mg (68%). ^{1}H NMR (400 MHz), [D$_8$]THF, −30 °C): δ = 1.52 (s, 9H; $C(CH_3)_3$), 2.18, 2.39 (m, 8H; C_2H_4), 2.99 (s, 3H; NCH_3), 6.67–7.16 (m, 5H; C_6H_5). ^{13}C NMR (75.5 MHz, [D$_8$]THF, −30 °C): δ = 280.4 (Ni=C), 148.1, 120.5, 128.7, 124.6 (C_6H_5), 63.9 ($C(CH_3)_3$), 48.6 (C_2H_4), 38.4 (NCH_3), 29.4 ($C(CH_3)_3$). Mass spectrum (70 eV/50 °C): *m/z* 289 ($M^{\oplus}$) (calcd. 289 for ^{58}Ni).
[11] Procedure for **14**: A suspension of **11** (9.13 g, 20.1 mmol) in 80 mL of ether was treated at −40 °C with a solution of acetylacetone (2.1 mL, 20.4 mmol) in ether (20 mL) and warmed to 0 °C. After 30 minutes the precipitated lithium acetylacetonate was removed by filtration and the red solution cooled to −78 °C. The orange crystals that separated from the filtrate were recovered by filtration, washed with pentane, and dried at −20 °C in a high vacuum. **14** initially crystallized together with a half equivalent of PMDTA, which was removed by recrystallization from pentane. 3.44 g (62%). ^{1}H NMR (400 MHz, [D$_8$]THF, −30 °C): δ = 1.40 (s, 9H; $C(CH_3)_3$), 2.21–2.35 (m, 8H; C_2H_4), 7.0–7.18 (m, 5H; C_6H_5), 9.27 (s, 1H; NH). ^{13}C NMR (75.5 MHz, [D$_8$]THF, 40 °C): δ = 277.3 (Ni=C), 150.4, 123.4, 128.5, 127.4 (C_6H_5), 57.4 ($C(CH_3)_3$), 48.3 (C_2H_4), 30.1 ($C(CH_3)_3$). Mass spectrum (70 eV/40 °C): *m/z* 275 ($M^{\oplus}$) (calcd. 275 for ^{58}Ni).

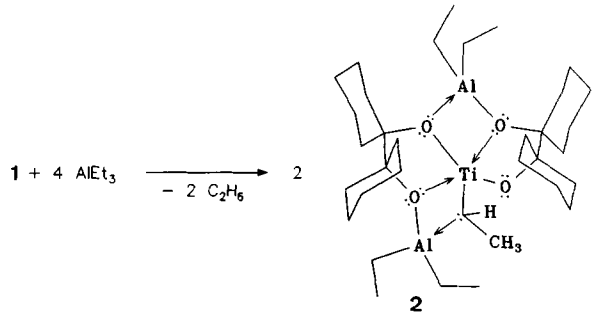
Tetraalkoxytitanium-Carbene Complexes with Double Intramolecular Et_2Al Bridging

By *Carl Krüger, Richard Mynott, Carsten Siedenbiedel, Ludwig Stehling*, and *Günther Wilke**

Dedicated to Professor Kurt Schaffner on the occasion of his 60th birthday

During investigations of the vaporization of elemental titanium in ketone and aldehyde matrices we have observed C–C coupling with formation of titanium(II) diolates. They contain, in addition, end-on coordinated ketones or aldehydes. In the case of the di-*tert*-butyl ketone no coupling takes place, and only two ketone molecules are bound side-on per Ti atom.[1] The product of a vaporization of titanium in ketone surprisingly forms a catalyst with $AlEt_3$, with which high molecular weight polyethylene can be prepared. In this connection we have investigated the synthesis and the behavior of titanium(IV) bisdiolates as components of Ziegler catalysts. Already in 1956 *H. Martin*[2] was able to show that a catalyst is formed from $Ti(OnBu)_4$ and $AlEt_3$ which preferentially dimerizes ethene to butene at normal pressure, without significant amounts of polyethylene being formed. At the same time *Wilke* found[3] that butadiene affords high molecular weight 1,2-polybutadiene with this catalyst system.



Scheme 1. **1** is a titanium bisdiolate (see Text).

When $Ti(OEt)_4$ is allowed to react with bicyclohexyl-1,1'-diol, ethanol can be removed, and a very sparingly soluble titanium bisdiolate **1** is obtained, which according to its mass spectrum is dimeric (*m/z* 880 ($M^{\oplus}$)). The product of the same

[+] Deceased.

composition obtained from cyclohexanone and Ti atoms is extremely soluble even in pentane. Colorless **1** reacts with two equivalents of $AlEt_3$ per Ti atom in toluene at $-78\,^{\circ}C$ to $-30\,^{\circ}C$ with evolution of two equivalents of ethane to give a red solution. After removal of the toluene a red oil remains, which can be crystallized in pentane at $-78\,^{\circ}C$ (Scheme 1). The red crystals of **2** (40–50% yield) are stable at room temperature. According to elemental analysis **2** has the composition $C_{34}H_{64}O_4Al_2Ti$ (mass spectrum (70 eV/140 °C): m/z 638 ($M^{\oplus}$)). The structure of **2** could be elucidated on the basis of the NMR spectra[4] and a crystal structure analysis[5] (Fig. 1).

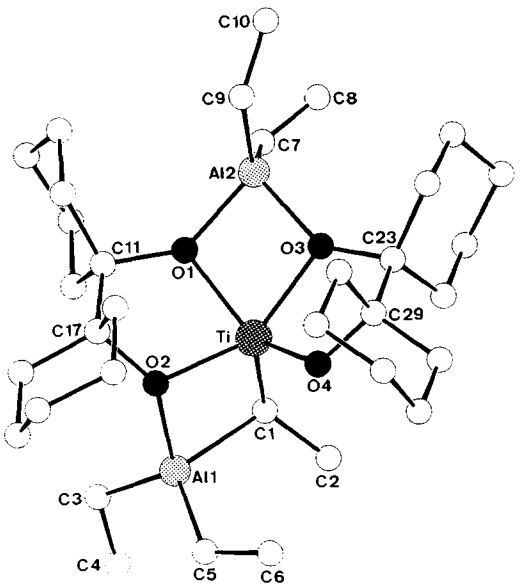

Fig. 1. Crystal structure of **2**. Selected bond lengths [Å] and angles [°]: Ti-O1 2.022(3), Ti-O2 1.960(3), Ti-O3 2.026(3), Ti-O4 1.801(3), Ti-C1 1.933(6), Al1-O2 1.872(3), Al1-C1 2.108(6), Al2-O1 1.853(3), Al2-O3 1.833(3), C1-C2 1.49(1); O2-Ti-C1 88.6(2), Ti-O2-Al1 93.9(1), O2-Al1-C1 86.0(2), Al1-C1-Ti 87.7(2), Al1-C1-C2 114.8(4), C2-C1-Ti 134.3(5).

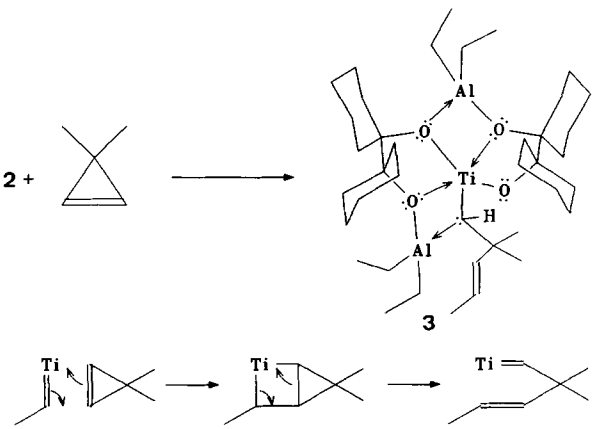
The ^1H and ^{13}C NMR spectra show that **2** is present in solution in the form of two isomers in the ratio 3.3:1. The positions of the carbene C signals at $\delta = 202.1$ (major component) and 192.2 (minor component) are consistent with those of alkylidene-bridged heterobimetallic carbene complexes such as the structurally analogous Tebbe compounds.[6] Both compounds lack symmetry elements: All 34 C signals of the major component are observed. The occurrence of the two diastereomers can be formally explained in terms of an (*R**)- and an (*S**)-configurated carbene C atom.

The formation of the carbene ligand rests on the fact that two ethyl groups are transferred from the same side to the Ti atoms of **1** so that subsequently an α-H-elimination with cleavage of ethane can take place. As expected, the protolysis of **2** with 2-ethylhexanol affords five equivalents of ethane. With oxygen a product of the composition $C_{32}H_{60}O_9Al_2Ti$ is formed following reaction of all Al–C bonds and replacement of the carbene group by an O atom. The expected acetaldehyde could be detected only in traces under these conditions; in the oxidation with ozone, however we found 97% aldehyde.

Ethene cannot be polymerized with **2** alone; the polymerization takes place only upon addition of excess $AlEt_3$. With the strongly ring-strained 3,3-dimethylcyclopropene, however, **2** reacts in toluene already at room temperature. Addition takes place with ring-opening and formation of the carbene complex **3**. So far, it has not been possible to crystallize the red-brown product. The elemental composition corresponds to $C_{39}H_{72}O_4Al_2Ti$, and in the mass spectrum a peak was observed at m/z 706 ($M^{\oplus}$). The constitution could be ascertained on the basis of the NMR spectra.[7] As in the case of **2**, two isomers are observed which differ in the relative configuration of the carbene C atom. In the ^{13}C NMR spectrum the carbene C signal of the main component (87%) lies at $\delta = 214.9$ ($^1J_{C,H} = 102$ Hz). The double bond in the side chain is *trans*-configurated in both isomers. Remarkably, **3** reacts no further with excess dimethylcyclopropene, possibly on steric grounds.



Scheme 2. Reaction of 3,3-dimethylcyclopropene with **2** to give **3**, including proposed mechanism.

To our knowledge **2** is the first example of a titanium-carbene complex, which is not derived from "titanocene" but from a titanium alkoxide, even though the analogy to a "Tebbe reagent"[6] is unmistakable. Also consistent with this is the reaction with 3,3-dimethylcyclopropene to give **3**, which may proceed according to the mechanism formulated in Scheme 2. So far, the titanium bicyclo[2.1.0]pentane intermediate could not be isolated, presumably since it immediately rearranges under the influence of the Et_2Al group; this would be consistent with observations made with corresponding titanocene derivatives.[8, 11]

Novel Tetranuclear Iron–Hexapentaene Complexes: The First Examples of Poly-π-Allyl Complexes

By *Masahiko Iyoda,* Yoshiyuki Kuwatani, Masaji Oda, Kazuyuki Tatsumi,* and *Akira Nakamura*

Dinuclear iron complexes of [3]cumulenes (butatrienes) have received considerable attention because of their high stability and their unique twofold π-allyl structure **1** with an iron–iron bond.[1] Although tetranuclear π-allyl complexes of [5]cumulenes (hexapentaenes) with transition metals might have an interesting π-allyl complex chain structure **2**, transition metal complexes of [5]cumulenes have not yet been extensively studied.[2] Previously, the reaction of hexapentaene with [$Fe_3(CO)_{12}$] was reported to produce only deep purple-red crystals.[3] We reinvestigated the reactions of [5]cumulenes with [$Fe_3(CO)_{12}$] and found the formation of novel tetranuclear iron complexes **2** with iron–iron bonds.

1 **2**

Because of its instability, hexapentaene (C_6H_4) was generated in situ by the reduction of 1,6-dichloro-2,4-hexadiyne (**3**) with zinc.[4] Thus, **3** was treated with zinc in benzene–isooctane at 90–100 °C in the presence of [$Fe_3(CO)_{12}$] to give two isomeric iron–hexapentaene carbonyl complexes **4** (1.6%) and **5** (2%). These complexes are stable both in solid state and in solution. Interestingly, **4** isomerizes to **5** on either heating at 110 °C or irradiation (> 300 nm). In a similar manner treatment of **6** with zinc at 90–100 °C in the presence of [$Fe_3(CO)_{12}$] yielded complexes **7** (2%) and **8** (0.5%), together with the known **9**[2] (2%). The tetranuclear complexes **7** and **8** are less soluble than the dinuclear complex **9**. In particular, **8** is only slightly soluble in organic solvents, presumably due to its rigid molecular structure. Since **9** produces **7** (19%) and **8** (2%) in its reaction with [$Fe_3(CO)_{12}$] in refluxing isooctane, dinuclear complexes such as **9** can be regarded as precursors to the tetranuclear complexes **4** and **5** as well as **7** and **8**. Although isomer **7** was usually the major product, ultraviolet irradiation (> 300 nm) causes its isomerization to **8**.

The tetranuclear complexes exhibit characteristic electronic and NMR spectra (Table 1), the latter reflecting the highly symmetrical structures. The ^{1}H NMR spectra of **4** and **5** show two doublets at $\delta = 4.82$ and 4.31, and 4.97 and 4.50, respectively. The ^{1}H NMR spectra of **7** and **8** contain only two singlets of methyl groups at $\delta = 2.57$ and 2.13, and 2.56 and 2.19, respectively. The ^{13}C NMR spectra of **4** and **5** show three signals of carbon skeleton (**4**: $\delta = 143.2$, 84.9, 68.5; **5**: $\delta = 131.7$, 79.2, 70.4) besides carbonyl signals. The strong IR bands at 1970–2085 cm^{-1} arise from the stretching of the terminal carbonyl groups. None of the spectra show absorptions in the bridging carbonyl region. Interestingly, the mass spectra of these complexes reveal the stepwise elimination of twelve CO groups to $[R_4C_6Fe_4]^{\oplus}$ (R = H, CH_3). Similar fragmentation processes were reported in the mass spectra of the butatriene–iron carbonyl complexes $[(R_4C_4)Fe_2(CO)_6]$.[5, 6]

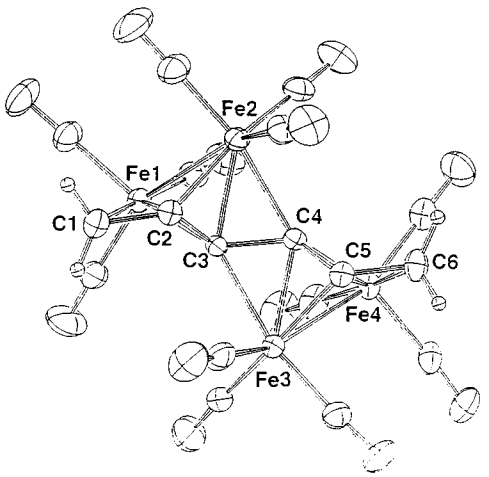

Fig. 1. X-ray crystal structure of **4**. Selected bond distances [Å] and angles [°]: Fe1-Fe2 2.5991(8), Fe3-Fe4 2.589(1), Fe1-C1 2.216(5), Fe1-C2 2.018(4), Fe1-C3 1.965(3), Fe2-C2 1.903(4), Fe2-C3 2.096(4), Fe2-C4 2.222(4), F3-C3 2.208(4), Fe3-C4 2.104(4), Fe3-C5 1.897(4), Fe4-C4 1.955(4), Fe4-C5 2.013(4), Fe4-C6 2.195(4), C1-C2 1.378(5), C2-C3 1.386(5), C3-C4 1.461(5), C4-C5 1.382(5), C5-C6 1.377(5); C1-C2-C3 126.1(4), C2-C3-C4 125.8(3), C3-C4-C5 124.9(3), C4-C5-C6 125.6(4).

The structures of **4** and **5** were determined by X-ray diffraction (Fig. 1 and 2).[7] As shown in Figure 1, **4** has an approximate C_2 symmetry with a twofold axis passing through the midpoint of the C3–C4 bond. The Fe–Fe and Fe–CO bond lengths are normal. The hexapentaene skeleton has a zig-zag configuration in which the average bond angle between each set of three carbon atoms is 125.6°. The atoms C1–C4 and C3–C6 lie in two planes which are twisted 79.6(5)° respective to each other. The dihedral angle between Fe2–C3–C4 and Fe3–C3–C4 is 155.0(1)°. Complex **5** has a crystallographic center of symmetry (Fig. 2) and the central four-membered ring consisting of Fe1–C1–Fe1*–C1* is exactly planar. The hexapentaene skeleton has a zig-zag configuration with bond angles of 124.1° and 127.9°. Of special note is the coplanarity of the six carbon atoms of the hexapentaene ligand (maximum deviation 0.02 Å).

The coordination geometry of each iron atom of **4** and **5** is best described as distorted octahedral. Each complex has two short (1.897–1.984 Å) and four long bonds (2.018–2.222 Å) between the iron atoms and the carbon atoms in the cumulene ligand. This bonding mode is analogous to that of butatriene[bis(tricarbonyliron)] complexes.[8]. It is noteworthy that the cumulenic carbons (C3 and C4 in **4** and C1 and

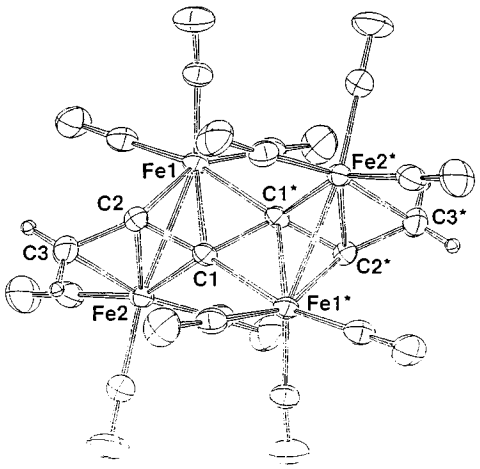

Fig. 2. X-ray crystal structure of **5**. Selected bond distances [Å] and angles [°]: Fe1-Fe2 2.577(1), Fe1-C1 2.096(5), Fe1-C2 1.927(5), Fe1-C1* 2.183(5), Fe2-C1 1.984(5), F2-C2 2.024(5), Fe2-C3 2.198(6), C1-C2 1.386(7), C2-C3 1.370(8), C1-C1* 1.454(9); C1*-C1-C2 124.1(6), C1-C2-C3 127.9(5).

C1* in **5**) form bonds to five other atoms. Thus, two π orbitals of these central carbon atoms are equally shared with two iron atoms (Fe2 and Fe3 in **4** and Fe1 and Fe1* in **5**). The double coordination on both sides of π bond causes the lengthening of the central bonds to 1.461(5) Å in **4** and 1.454(9) Å in **5**. Although similar coordination has been previously described in transition metal complexes of acetylenes,[9] this is new in the complexes of cumulenes. The four $Fe(CO)_3$ groups in each complex are aligned along the hexapentaene linkage with η^3-allyl-like coordination,[10] and make a π-allyl chain complex.

Extended Hückel calculations were performed on **4** and **5**.[11] Despite the substantial differences in their geometries, the two isomers were found to be comparable energetically; isomer **4** is calculated to be only 0.31 eV lower in energy. Also the calculated charge distribution (Q) as well as the Fe–C and C–C overlap populations (P) are remarkably similar, indicating that the nature of the Fe–hexapentaene bonds in **4** and **5** is essentially the same. The salient results of the population analyses are: 1) P(Fe1–C3) of 0.347 (**4**) and 0.340 (**5**) and P(Fe2–C2) of 0.369 (**4**) and 0.370 (**5**) are notably larger than the other Fe1(Fe2)–C overlap populations (0.058–0.168), because these bonds contain contributions from Fe–C σ-bonding in addition to the Fe–π-allyl type interactions. 2) The inner C3–C4 bond is evidently weaker than the outer C–C bonds; P(C3–C4) = 0.903 (**4**) and 0.915 (**5**) versus P(C1–C2), P(C2–C3) = 1.036–1.080. 3) The innermost carbons (C3 and C4) are highly positively charged; Q = +0.201e (**4**) and +0.187e (**5**). 4) The Fe–Fe bonding interaction is retained upon coordination to hexapentaene; P(Fe–Fe) = 0.187 (**4**) and 0.184 (**5**) versus 0.200 for $[Fe_2(CO)_6]^{2+}$. These theoretical results are consistent with our experimental findings.

[10] A similar bond between butatriene and iron atoms has been suggested to be an η^3-allyl bond. [8a]
[11] Our calculations reasonably reproduced the main features of the X-ray derived structure of **4** and **5**. The extended Hückel parameters for Fe are the following: orbital exponents: 4s and 4p, 1.9; 3d, 5.35(0.5366) + 1.8(0.6678). H_{ii}: 4s, −9.17 eV; 4p, −5.37 eV; 3d, −12.7 eV. The parameters for C and H are the standard ones. Geometrical assumptions include the followings: C–C, 1.4 Å; C–H, 1.09 Å; Fe–Fe, 2.6 Å; Fe–C(carbonyl), 1.8 Å; C–O 1.13 Å; the center of Fe–Fe bond is situated 1.45 Å above the center of C2–C3 or C4–C5 bond.

$(NBu_4)[Mn_4O_2(H_2O)(O_2CPh)_9]$, a Butterfly Complex with Bound H_2O, and Its Use to Prepare Octanuclear and Undecanuclear Metal Complexes**

By *Sheyi Wang, John C. Huffman, Kirsten Folting, William E. Streib, Emil B. Lobkovsky,* and *George Christou**

Manganese chemistry at the higher metal oxidation states ($\geq$ II) is currently an area of great activity. One reason for this is the occurrence of Mn in biological systems,[1] particularly the Mn_4 aggregate in the photosynthetic water oxidation center (WOC).[2] To model the WOC, we have prepared complexes of formulation $[Mn^{III}_4O_2(O_2CR)_x(L\text{–}L)_2]^z$ ($x = 6$ or 7; L–L = a chelate ligand; $z = -1, 0, +1$) possessing the $[Mn_4(\mu_3\text{-}O)_2]^{8+}$ core with a butterfly disposition of Mn atoms.[3] Higher nuclearity Mn_y aggregates ($y \geq 6$) have also been attracting increasing interest, not least for their aesthetic qualities.[4–8] More importantly, however, these aggregates have displayed a propensity for large spin ground states.[4c, 8b, d] Only a limited number of higher nuclearity Mn aggregates are currently known, including various structural types and oxidation levels;[4–8] we have pointed out elsewhere the potential utility of discrete Mn aggregates with large spin ground states as precursors to molecular ferromagnets.[8b] We herein describe results of relevance to both the above areas: namely, the preparation of an Mn_4O_2 complex with a bound H_2O ligand, and its employment as a stepping-stone to new Mn_8 and Na_2Mn_9 aggregates.

The comproportionation between $[Mn(O_2CPh)_2] \cdot 2\,H_2O$ and NBu_4MnO_4 (Bu = *n*Bu) in an approximate 2.5:1 ratio in EtOH/MeCN yields dark red crystals of $(NBu_4)[Mn_4O_2(H_2O)(O_2CPh)_9]$ (**1**) in 90–95 % yield after recrystallization.[9] The structure[10] of the anion of **1** (Fig. 1) shows a butterfly $[Mn^{III}_4O_2]^{8+}$ core similar to that in, for example, $[Mn_4O_2(O_2CMe)_7(bpy)_2]^+$ and $[Mn_4O_2(O_2CMe)_7(pic)_2]^-$ (bpy = 2,2′-bipyridine; pic^- = 2-picolinate).[3] However, the absence of chelating bpy or pic has interesting consequences; Mn4 possesses instead an additional benzoate group in a rare asymmetrical chelating mode, where Mn4–O24 (2.373(11) Å) is much longer than Mn4–O22 (1.947(11) Å). There is also an additional benzoate group at Mn3 but this is ligated in a monodentate fashion; the remaining site is occupied by a terminal aqua ligand (O18), which is hydrogen-bonded to the unligated benzoate atom O25 (O18 ··· O25, 2.634(24) Å).

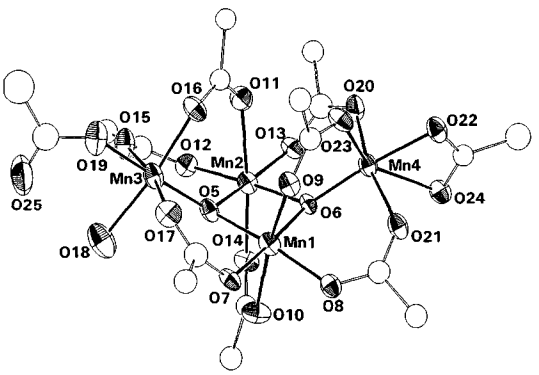

Fig. 1. ORTEP representation of the anion of complex **2**. For clarity, only one benzoate phenyl carbon atom is shown. Selected bond distances [Å]: Mn1 ··· Mn2, 2.816(4), Mn1 ··· Mn3, 3.367(4), Mn1 ··· Mn4, 3.296(4), Mn2 ··· Mn3, 3.302(4), Mn2 ··· Mn4, 3.365(4), O5-Mn1, 1.900(11), O5-Mn2 1.913(10), O5-Mn3 1.823(11), O6-Mn1 1.909(10), O6-Mn2 1.905(11), O6-Mn4 1.825(10), Mn1-O7, 1.946(11), Mn1-O8, 1.940(12), Mn1-O9, 2.206(11), Mn1-O10, 2.206(12), Mn2-O11, 2.202(12), Mn2-O12, 1.923(11), Mn2-O13, 1.973(11), Mn2-O14, 2.136(11), Mn3-O15, 2.136(12), Mn3-O16, 1.982(11), Mn3-O17, 2.111(12), Mn3-O18, 2.102(13), Mn3-O19, 1.903(13), Mn4-O20, 2.038(12), Mn4-O21, 2.037(12), Mn4-O22, 1.974(11), Mn4-O23, 2.016(12), Mn4-O24, 2.373(11), O18 ··· O25, 2.634(24).

Complex **1** represents important progress for our WOC modeling work since it possesses a water-binding site. The ligation of H_2O and its hydrogen bonding to a carboxylate group may be providing a glimpse into how the WOC binds its substrate H_2O and activates it to deprotonation, a necessary step in water oxidation. We are, therefore, studying the reactivity of **1**. Initial efforts have unearthed unusual products from the reactions with benzoyl peroxide and Me_3SiCl.

Attempted oxidation of **1** with equimolar amounts of $(PhCO)_2O_2$ in MeCN causes a darkening of color and crystallization of $[Na_2Mn_9O_7(O_2CPh)_{15}(MeCN)_2] \cdot 3$ MeCN (**2** · 3 MeCN) in 31 % yield after addition of $NaClO_4$.[11] The structure[12] of **2** (Fig. 2) comprises a mixed-metal undecanuclear $[Na_2Mn_9O_7]^{15+}$ core peripherally ligated by benzoate and MeCN groups; the two Na^+ ions are linked to the Mn atoms by both core oxide and benzoate bridges. Thus we

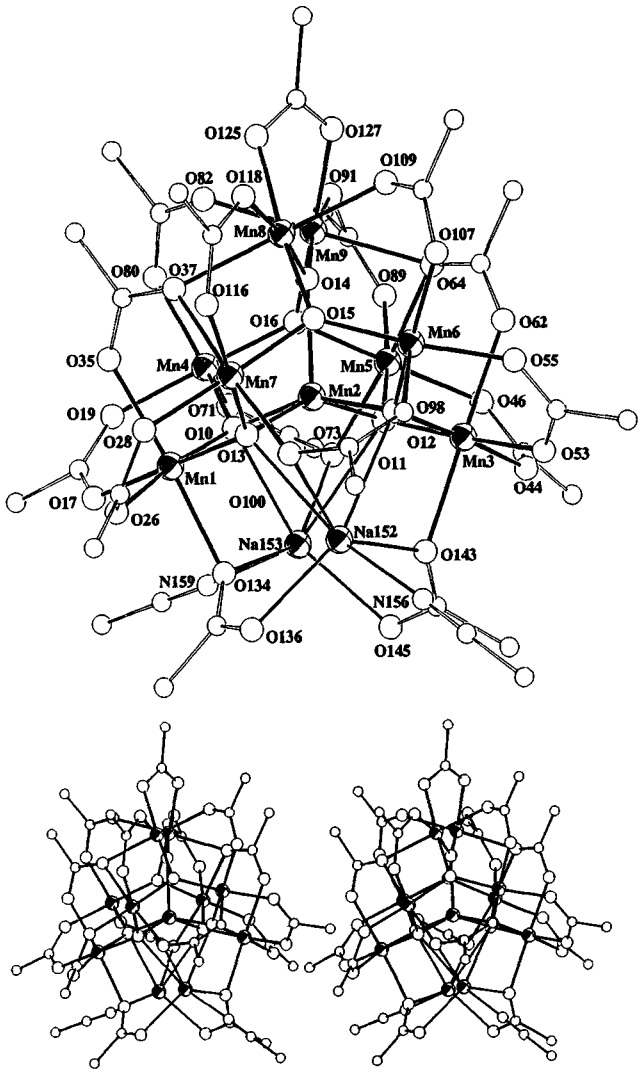

Fig. 2. ORTEP representation and stereoview of complex **2**. Only one phenyl carbon of the benzoate ligand is shown. Selected bond distances [Å]: Mn1···Mn2, 2.886(3), Mn2···Mn3, 2.871(3), Mn1···Mn4, 3.359(3), Mn1···Mn7, 3.318(3), Mn2···Mn4, 3.311(3), Mn2···Mn5, 3.241(3), Mn2···Mn6, 3.318(3), Mn2···Mn7, 3.261(3), Mn3···Mn5, 3.315(3), Mn3···Mn6, 3.358(3), Mn2···Mn8, 3.388(3), Mn2···Mn9, 3.393(3), Mn8···Mn9, 3.281(3), O10-Mn1, 1.893(4), O10-Mn2 1.934(4), O10-Mn4 1.888(4), O10-Na153, 2.537(5), O11-Mn2 1.906(4), O11-Mn3 1.884(4), O11-Mn5 1.858(4), O11-Na153, 2.824(5), O12-Mn2 1.927(4), O12-Mn3 1.895(4), O12-Mn6 1.891(4), O12-Na152, 2.610(5), O13-Mn1 1.892(4), O13-Mn2 1.911(4), O13-Mn7 1.890(4), O13-Na152, 2.596(5), O14-Mn2 2.111(4), O14-Mn8 1.851(4), O14-Mn9 1.859(4), O15-Mn6 1.845(4), O15-Mn7 1.872(4), O15-Mn8 1.884(4), O16-Mn4 1.849(4), O16-Mn5 1.886(4), O16-Mn9 1.889(4).

prefer a mixed-metal aggregate description to an ion-pairing description. The Mn atoms are all in the +III oxidation state as evidenced by interatomic distances and Jahn–Teller elongations; the Mn_9 portion of **2** is similar to that observed in $[Mn_9O_7(O_2CPh)_{13}(py)_2]$.[6b] It consists of two $[Mn_4O_2]^{8+}$ units (Mn(1,2,4,7) and Mn(2,3,5,6)) which share the square-pyramidal Mn2 atom and are capped by Mn8 and Mn9 through μ_3-oxides O14, O15, and O16. The complex has idealized C_2 symmetry. There were no changes in the metal's oxidation state in the conversion of **1** into **2**, so the precise function of the $(PhCO)_2O_2$ is unclear; however, the yield of **2** is only 31% and the presence of other products in the reaction filtrate is under investigation. The influence of experimental conditions on the reaction of **1** with $(PhCO)_2O_2$ is also being studied.

Carboxylate abstraction from complex **1** with 4 equiv of Me_3SiCl in CH_2Cl_2, followed by addition of Et_2O to the red-brown solution, produces a dark red precipitate. Recrystallization from CH_2Cl_2/Et_2O yields dark red crystals of the octanuclear Mn^{III} complex $(NBu_4)[Mn_8O_6Cl_6(O_2CPh)_7(H_2O)_2]\cdot x CH_2Cl_2$ (**3**, Bu = *n*Bu, 45–60% yield).[13] The structure[14] of the anion of **3** (Fig. 3) consists of an $[Mn_8O_6Cl_4]^{8+}$ core coordinated on its periphery to bridging $PhCO_2^-$, terminal Cl^-, and terminal H_2O ligands. As in **2**, the $[Mn_8O_6Cl_4]^{8+}$ core may again be conveniently considered to be constructed from the fusion of two $[Mn_4O_2]^{8+}$ butterfly units (Mn(1,2,4,7) and Mn(2,3,5,6)) sharing Mn2; this time there is only one capping Mn atom (Mn8) connected through O13 and O14. Moreover, the core now contains bridging Cl^- atoms. The core would possess C_{2v} symmetry and a C_2 axis passing through Mn2, the midpoint of the O13···O14 vector, and Mn8, except that the Mn8 lies off the C_2 axis to form a bond to Cl15. This converts Cl15 into an unusual example of a μ_4-Cl atom, bridging a nearly planar

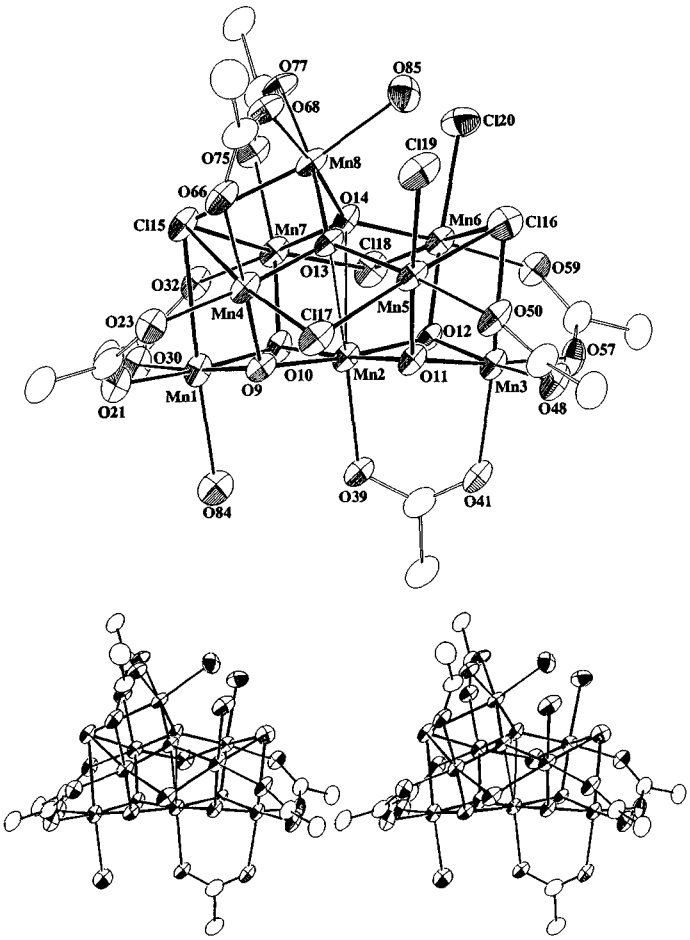

Fig. 3. Labeled ORTEP representation and stereoview of the anion of complex **3**. For clarity, only one phenyl carbon of each benzoate group is shown. Selected bond distances [Å]: Mn1···Mn2, 2.828(3), Mn1···Mn4, 3.145(2), Mn1···Mn7, 3.137(3), Mn2···Mn3, 2.791(3), Mn2···Mn4, 3.191(2), Mn2···Mn5, 3.218(2), Mn2···Mn6, 3.197(3), Mn2···Mn7, 3.180(3), Mn2···Mn8, 3.625(2), Mn3···Mn5, 3.141(2), Mn3···Mn6, 3.131(3), Mn4···Mn5, 3.171(3), Mn4···Mn8, 3.150(3), Mn5···Mn8, 3.493(3), Mn6···Mn7, 3.176(3), Mn6···Mn8, 3.508(3), Mn7···Mn8, 3.158(2), O9-Mn1 1.887(8), O9-Mn2 1.900(7), O9-Mn4 1.881(8), O10-Mn1 1.872(7), O10-Mn2 1.928(8), O10-Mn7 1.878(7), O11-Mn2 1.912(8), O11-Mn3 1.881(7), O11-Mn5 1.867(8), O12-Mn2 1.901(7), O12-Mn3 1.888(8), O12-Mn6 1.883(7), O13-Mn2 2.676(7), O13-Mn4 1.878(7), O13-Mn5 1.929(8), O13-Mn8 1.885(7), O14-Mn2 2.636(7), O14-Mn6 1.932(7), O14-Mn7 1.892(8), O14-Mn8 1.891(7), Cl15-Mn1 2.692(4), Cl15-Mn4 2.787(3), Cl15-Mn7 2.776(3), Cl15-Mn8 2.709(4), Cl16-Mn3 2.602(4), Cl16-Mn5 2.703(4), Cl16-Mn6 2.685(4), Cl17-Mn4 2.461(4), Cl17-Mn5 2.571(3), Cl18-Mn6 2.616(4), Cl18-Mn7 2.466(3), Mn5-Cl19, 2.263(4), Mn6-Cl20, 2.246(4), Mn1-O84, 2.191(9), Mn8-O85, 2.184(9).

Mn_4 unit. Another unusual structural feature is to be found at Mn2. The core structure as described above designates Mn2 as five-coordinate with square-pyramidal geometry as seen for Mn2 in complex **2**. It is clear, however, that Mn2 has two additional bonds to O13 and O14; these are long (average 2.656 Å) but they are real because Mn2 lies approximately in the plane containing O9–O12[15a] and not below it, as expected for sp geometry and seen in **2**, and because O13 and O14 are approximately trigonal planar, whereas the other bridging oxides are pyramidal. Indeed, O13 and O14 lie slightly out of their Mn_3 planes towards Mn2.[15b] Thus, Mn2 is best described as seven-coordinate, and O13 and O14 as four-coordinate trigonal pyramidal.

Very unusually for higher nuclearity Mn aggregates, complex **3** supports reversible redox processes. Shown in Figure 4 is the cyclic voltammogram in CH_2Cl_2. Both a reduction

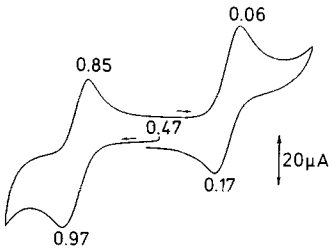

Fig. 4. Cyclic voltammogram at $50\,mVs^{-1}$ for complex **3** in CH_2Cl_2. The quoted potentials are referred to the ferrocene/ferricinium couple under the same conditions.

and an oxidation process are observed at potentials of 0.12 and 0.91 V vs. ferrocene, respectively. Complex **3** is thus the central member of the electron transfer series shown in Equation (a). While the oxidation is at a quite high potential,

$$\underset{7\,Mn^{III},Mn^{IV}}{[\,]} \overset{0.91\,V}{\rightleftharpoons} \underset{8\,Mn^{III}}{[Mn_8O_6Cl_6(O_2CPh)_7(H_2O)_2]^-} \overset{0.12\,V}{\rightleftharpoons} \underset{Mn^{II},7\,Mn^{III}}{[\,]^{2-}} \quad (a)$$

the reduction is much more facile. Attempts to generate and isolate both the neutral and dianionic forms are currently in progress; it will be interesting to determine the site of oxidation/reduction and any resulting structural perturbations.

In summary, the preparation of complex **1** is both important for continuing WOC modeling efforts and provides a new, easily prepared, and convenient starting point for the preparation of the new higher nuclearity Mn aggregates **2** and **3**.

[9] Correct elemental analysis for $C_{79}H_{83}NO_{21}Mn_4$; electronic spectrum in CH_2Cl_2: λ_{max} [nm] (ε_M [$L\,mol^{-1}\,cm^{-1}$]), 476 (11,560).

[10] Crystal data: $C_{79}H_{83}NO_{21}Mn_4$, monoclinic, $P2_1/c$, $T = -129\,°C$, $a = 17.394(3)$, $b = 19.040(3)$, $c = 25.660(5)$ Å, $\beta = 103.51(1)°$, $V = 8262.73$ Å^3, $Z = 4.6° \le 2\theta \le 45°$, 10788 unique, 4590 observed reflections, $F > 2.33\sigma(F)$. All non-hydrogen atoms were readily located. Due to the large number of independent atoms, only the Mn and O atoms were refined anisotropically. Hydrogen atoms, except those of the water molecule, were included in calculated positions as fixed contributors. Final $R = 0.0911$, $R_w = 0.0926$.

[11] The crystals lose MeCN on drying and appear to be hygroscopic. Correct elemental analysis for $C_{109}H_{84}N_2O_{38.5}Na_2Mn_9$ ($2 \cdot 1.5\,H_2O$).

[12] Crystal data: $C_{109}H_{84}N_2O_{38.5}Na_2Mn_9$, triclinic, $P\bar{1}$, $T = -170\,°C$, $a = 15.116(2)$, $b = 27.903(4)$, $c = 15.007(2)$ Å, $\alpha = 102.40(1)$, $\beta = 112.36(1)$, $\gamma = 84.17(1)°$, $V = 5715.26$ Å^3, $Z = 2.6° \le 2\theta \le 45°$. All non-hydrogen atoms were refined with anisotropic thermal parameters except those of the lattice solvent molecules; the latter were refined isotropically, as were the hydrogen atoms, which were included in calculated positions. $R = 0.0514$, $R_w = 0.0525$.

[13] The crystals lose CH_2Cl_2 on drying and the analysis shows no solvent of crystallization. Correct elemental analysis for $C_{65}N_{75}NO_{22}Cl_6Mn_8$; electronic spectrum in CH_2Cl_2: λ_{max} [nm] (ε_M [$L\,mol^{-1}\,cm^{-1}$]), 442 (4200), 488 (3510).

[14] Crystal data: $C_{65}H_{75}NO_{22}Cl_6Mn_8 \cdot x CH_2Cl_2$, triclinic, $P\bar{1}$, $T = -169\,°C$, $a = 16.104(4)$, $b = 21.501(6)$, $c = 14.843(4)$ Å, $\alpha = 94.24(1)$, $\beta = 105.96(1)$, $\gamma = 89.07(1)°$, $V = 4927.79$ Å^3, $Z = 2$, $6° \le 2\theta \le 45°$, 11794 unique, 10108 observed reflections, $F > 3\sigma(F)$; one butyl group and one phenyl group showed disordered C atoms; H atoms were included as fixed contributors, three CH_2Cl_2 groups were clearly observed but with approximately half occupancy; two additional peaks with low occupancy were also found that were lower occupancy CH_2Cl_2 groups or possibly H_2O groups. Final $R = 0.0912$, $R_w = 0.0944$. Further details of the crystal structure investigations are available on request from the Director of the Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, GB-Cambridge, CB2 1EW (UK), on quoting the complete journal citation.

[15] a) Mn2 lies only 0.084 Å below the least-squares plane containing atoms O9–O12. b) O13 and O14 lie 0.104 and 0.129 Å, respectively, out of their Mn_3 planes towards Mn2.

Template-Controlled Formation of Cluster Shells or a Type of Molecular Recognition: Synthesis of $[HV_{22}O_{54}(ClO_4)]^{6-}$ and $[H_2V_{18}O_{44}(N_3)]^{5-}$

By *Achim Müller,* Erich Krickemeyer, Michael Penk, Ralf Rohlfing, Anja Armatage,* and *Hartmut Bögge*

Dedicated to Professor Karl Heinz Büchel on the occasion of his 60th birthday

In a recently published article[1] on the metal-chalcogenide clusters, the old problem was addressed that the possibilities of designing a directed synthesis for the sponta-

[*] Prof. Dr. A. Müller, E. Krickemeyer, Dipl.-Chem. M. Penk, Dipl.-Chem. R. Rohlfing, A. Armatage, Dr. H. Bögge

neous formation of a cluster in solution are limited. Here it will be shown that by different types of linking of an inorganic basic unit—controlled by a central anionic template—one can influence the shape and size of cluster shells.[2] It is even possible to reach the region of "nanostructures",[3, 4a] bordering the domain of molecular and supramolecular designs.[4b] Herein, we report on the title compounds **1** and **2**, which contain a cluster shell structurally complementary to "guest" ions ClO_4^- and N_3^-, respectively. They were prepared as NEt_4^+ salts by oxidation of $[H_9V_{19}O_{50}]^{8-}$[5] in aqueous solution and characterized by elemental analysis (including manganometric V^{IV} determination), IR spectroscopy, and single-crystal X-ray structure analysis.[6]

$(NEt_4)_6[HV_{22}O_{54}(ClO_4)]$ **1** $(NEt_4)_5[H_2V_{18}O_{44}(N_3)]$ **2**

$[V_{34}O_{82}]^{10-}$ **3** $[HV_{18}O_{44}(NO_3)]^{10-}$ **4** $[H_9V_{19}O_{50}]^{8-}$ **5**

The anions of **1** and **2** (Fig. 1), which can be formally written as $[HV_8^{IV}V_{14}^{V}O_{54}(ClO_4)]^{6-}$ and $[H_2V_8^{IV}V_{10}^{V}O_{44}(N_3)]^{5-}$, form cluster shells with approximate D_{2d} and D_{2h} symmetry, respectively (without taking the H atoms in account). Compounds **1** and **2** are built up of edge- and corner-sharing tetragonal OVO_4 pyramids and encapsulate ClO_4^- and N_3^- ions, respectively.

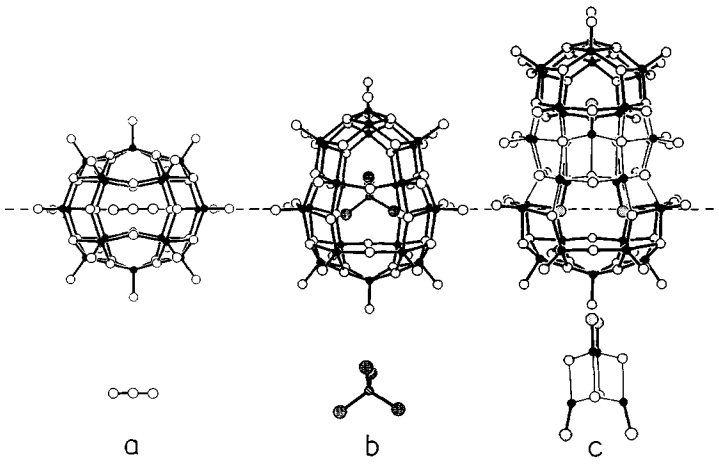

Fig. 1. Comparison of the structures of the ions a) $[H_2V_{18}O_{44}(N_3)]^{5-}$, b) $[HV_{22}O_{54}(ClO_4)]^{6-}$ and c) $[V_{34}O_{82}]^{10-}$ with their central units. The cluster shell of $[HV_{22}O_{54}(ClO_4)]^{6-}$ is formally formed from $[V_{34}O_{82}]^{10-}$ by removal of the two middle layers (thinly drawn bonds) and linking of the half-shells thus formed; $[H_2V_{18}O_{44}(N_3)]^{5-}$ is formed by penetration (condensation) of these half shells. The shape-determining templates are shown slightly enlarged and dotted. View perpendicular to the approximate S_4 axes in $[HV_{22}O_{54}(ClO_4)]^{6-}$ and $[V_{34}O_{82}]^{10-}$ and along a C_2-axis of $[H_2V_{18}O_{44}(N_3)]^{5-}$ (V = black, O = white, Cl = hatched; without protons).

The type of synthesis and structure of the novel cluster anions of **1** and **2** compared to some others such as those of **3** (with a central $\{V_4O_4\}O_4$ cluster with four terminal short V=O bonds and corresponding tetragonal $(O_t)_4$ disphenoid with D_{2d} symmetry;[3] Fig. 1), **4** (with an encapsulated NO_3^- ion[2]), and **5**[5] (with six very strong exchange-coupled V^{IV}–V^{IV} pairs that are structure-determining[3]), prove that the cluster shell formation is controlled via the molecular recognition of a template.

This can be substantiated in more detail as follows: There is a structural correlation between the shells of **1**, **2**, and **3** (Fig. 1); **3** consists of six almost planar V–O layers (with exception of the $\{V_3O_7\}$ units at the poles), which are oriented perpendicular to the S_4 axis. The layers correspond to a distorted section from an NaCl lattice, whereby some central positions in the layers neighboring the poles are not occupied. By formal removal of the two middle layers of **3** (a $\{V_{12}O_{28}\}$ fragment which contains the central $\{V_4O_4\}O_4$ cube) with subsequent linking of the remaining $\{V_{11}O_{27}\}$ half shells, the shell of **1** is formed, and the original (approximate) D_{2d} symmetry ($\bar{4}2m$) is retained (D_{2d} is a subgroup of T_d; cf. below). Hereby, a relatively close packing of O-atoms[7] seems to be decisive for the stability of **1** and **3**. Although the $O\cdots O$ distances in the central ClO_4^- ion in **1** (229–237 pm) are considerably shorter than the corresponding two $O_t\cdots O_t$ distances in the $\{V_4O_4\}(O_t)_4$ unit of **3** (332–336 pm), in both cases topologically equivalent half-shells are formed.

The formation of half-shells of **1** and **3** (and their contrarotation by 90°, whereby an S_4 axis results) distinctly follows after the recognition of the "$(O\cdots O)_2$-unit" (Fig. 2). The arrangement of the four shape-determining terminal O_t-atoms of the cube (tetragonal disphenoid) of **3** corresponds to that of the four O atoms of the ClO_4^- unit of **1**. The cluster shell of **2** (approximate symmetry D_{2h}) can formally be generated in a similar way by "condensation" of two $\{V_{11}O_{27}\}$ half-shells, the tendency of formation of which is obviously high (Fig. 1). The linear azide ion ($D_{\infty h}$) now acts as template (N(N)N instead of $(O\cdots O)_2$), such that the two shells are mirror images, i.e. are arranged without mutual rotation (as in **1** and **3**) and that the cluster shell thus has a more oblong shape, complementary to the azide ion. In **2**, the shortest $N\cdots O$ distances (305 pm!) are still significantly longer than the comparable distances between the cluster shell and the central unit in **1** and **4**.

That is, cluster shells can be generated by various types of linking of OVO_4 square-pyramids[8] (where however, weak metal-metal interactions can also play a role in the structure formation[9]). It is noteworthy here that the template ↔shell interaction can be extremely weak and so far is unique for molecular systems (anion in an anion!). The ions ClO_4^-, N_3^-, and NO_3^- (in **1** and **2** and **4**, respectively) formally appear to "hover", despite fixation (i.e. without disorder) in the cavity (Figs. 1 and 3), and are not an integral component of the cluster shell, e.g. by formation of (strong) covalent V–O (center) bonds,[10] as in classical hetero/isopolyanions[11] (proof: bond length data e.g. in Fig. 2, but also the small halfwidth of the $\nu_3(F_2) = \nu_{as}$(Cl–O) band and the extremely

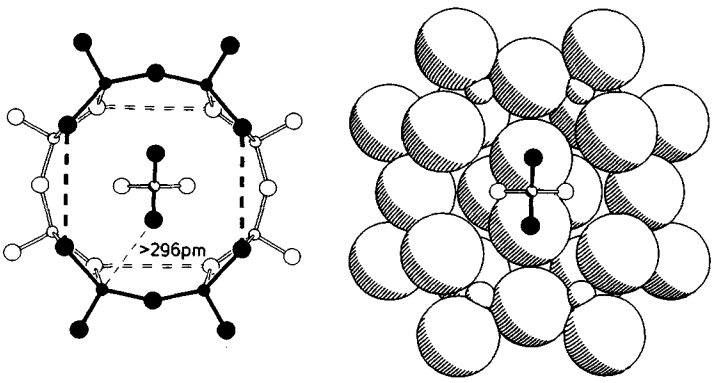

Fig. 2. The two middle layers perpendicular to the approximate S_4 axis with central ClO_4^- in the anion of **1**. Left: the atoms and bonds of the upper layer are shown in black, those of the lower layer, rotated by 90°, in white, and the central Cl shaded. Right: Space-filling model of the same atoms (Cl–O vectors of the central ClO_4^- ion marked as on the left).

small halfwidth of the $\nu_3(E'') = \nu_{as}(N-O)$ band in comparison to known data[12]). Also important in this connection is that the four terminal O_t atoms bound to the $\{V_4O_4\}$ cube ($V-O_t$: 161–166 pm) within the cluster shell or the $\{V_{11}O_{27}\}$-fragment cluster shells of **3** do not show any significant bonding to the V atoms of the shells ($V \cdots O > 254$ pm), since the $V-O_t$ bonds would otherwise be longer.

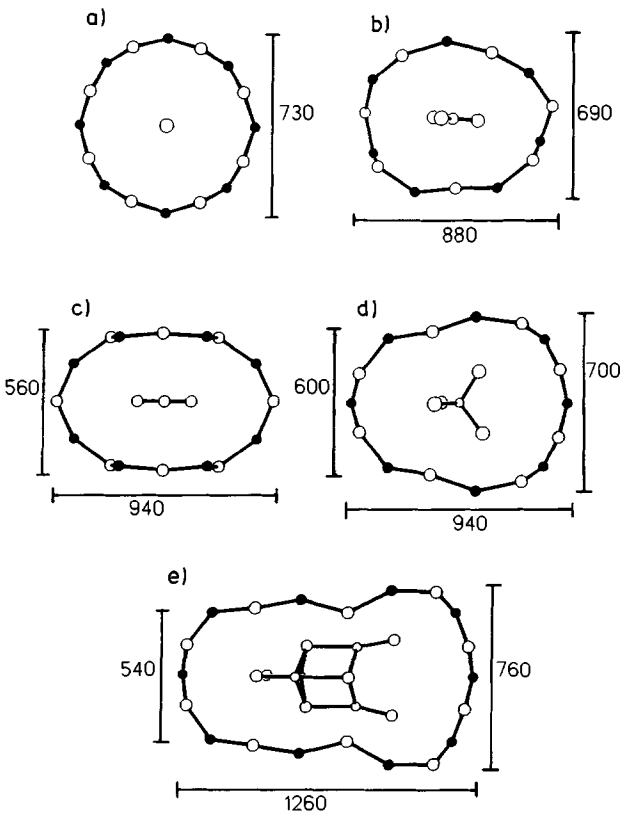

Fig. 3. Illustration of the template effect by simplified representation of the shape and size of some V–O cluster shells (with dimensions in pm). In these "cross-sections" the atoms in the chosen projection have the greatest distance from the "center". a) $[H_4V_{18}O_{42}(X)]^{9-}$, X = Cl, Br, I (A. Müller, M. Penk, R. Rohlfing, E. Krickemeyer, J. Döring, *Angew. Chem. 102* (1990) 927; *Angew. Chem. Int. Ed. Engl. 29* (1990) 926); b) $[HV_{18}O_{44}(NO_3)]^{10-}$ [2]; c) $[H_2V_{18}O_{44}(N_3)]^{5-}$ with view perpendicular to the "mirror plane of the half-shells"; d) $[HV_{22}O_{54}(ClO_4)]^{6-}$; e) $[V_{34}O_{82}]^{10-}$ (the covalent V–O bonds between the $\{V_4O_4\}O_4$ cube and the cluster shell have been omitted here).

Finally, it should be mentioned that the point group of the cluster shell of **1** and **2**, i.e. with highly symmetric template (e.g. with T_d and $D_{\infty h}$ symmetry, respectively) corresponds to a subgroup of the point group of the latter. The phenomenon discussed here has prompted us to speak cautiously of an "induced self-organization".[2, 13, 14] (See also [4b].)

Experimental

1: A solution of NEt_4ClO_4 (16.0 g, 69.65 mmol) in 250 mL of H_2O was treated with 6.6 g (3.11 mmol) of freshly prepared $(NH_4)_8[H_9V_{19}O_{50}] \cdot 11H_2O$ [5] and transferred to a 500 mL Erlenmeyer flask (wide-necked; covered with watch glass). The mixture was heated to 75 °C for 60 h without stirring on a hot plate. The precipitated black crystals of **1** were filtered off from the hot solution, washed with a little cold H_2O, air-dried on the filter paper, and stored under inert gas. Yield: 2.5 g (32.4% based on $(NH_4)_8[H_9V_{19}O_{50}] \cdot 11H_2O$). IR main absorption bands (solid/KBr pellet/[cm^{-1}]): $\tilde{\nu} = 1090$(m). (ν_{as}(ClO)), 992(vs) (ν(V=O_{term})), 825(m), 783(m), 720(s), 625(s)/614(sh) (ν_{as}(VOV)).

2: A solution of 4.0 g (18.43 mmol) of NEt_4BF_4 in 200 mL of H_2O was treated with 1.65 g (0.78 mmol) of freshly prepared $(NH_4)_8[H_9V_{19}O_{50}] \cdot 11H_2O$ [5] and 1.0 g (15.38 mmol) of NaN_3 and transferred to a 300 mL Erlenmeyer flask (wide-necked; covered with a watch glass). The mixture was kept at 75 °C without stirring for 16 h (in a fume cupboard, formation of HN_3!). The precipitated black crystals of **2** were filtered off and stored as described for **1**. Yield: 1.0 g (52.5% based on $(NH_4)_8[H_9V_{19}O_{50}] \cdot 11H_2O$). IR main absorption bands (solid/KBr/pellet/[cm^{-1}]): $\tilde{\nu} = 2019$(s). 2006(w) (ν_{as}(NNN)), 995(vs) (ν(V=O_{term})), 809(sh)/785(m), 698(s), 618(m) (ν_{as}(VOV)).

Further details of the crystal structure investigations are available on request from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, W-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-55644, the names of the authors, and the journal citation.
[7] A. Müller, M. Penk, J. Döring, *Inorg. Chem.*, in press.
[8] Completely different to the situation in the case of polyanions of molybdenum or tungsten, in which an octahedral coordination is preferred: M. T. Pope, A. Müller, *Angew. Chem. 103* (1991) 56; *Angew. Chem. Int. Ed. Engl. 30* (1991) 34.
[9] In the starting material **5**, twelve localized V^{IV} centers which are arranged to give six "very" strongly exchange-coupled pairs are structure determining[3,7]; in comparison, in the case of reduced clusters of 4d- and, above all, 5d-elements the electronic influence is always crucial; cf. A. Müller, E. Krickemeyer, M. Penk, V. Wittneben, J. Döring, *Angew. Chem. 102* (1990) 85; *Angew. Chem. Int. Ed. Engl. 29* (1990) 88. However as a result of the partial oxidation of **5**, this influence is limited. In **1** and **2** the antiferromagnetically coupled V^{IV} centers ($\mu_{eff}[\mu_B] = 4.5$ (**1**), 3.7 (**2**) at 25 °C), are no longer all localized (again unlike 5), as has been shown by calculations of the bond valence sums; cf. also A. Müller, J. Döring, H. Bögge, *J. Chem. Soc. Chem. Commun. 1991*, 273.
[10] In **1**, **2** and **4**, however, the central "anionic group" is remarkably *not* disordered; very weak interactions of the O and N atoms of the central unit with the V and O atoms of the shell "fix" the "guest" ion. The shortest $O \cdots O$ distances are longer than in a "Keggin-like" structure[11] and correspond, e.g., with 289.0(1) and 274.5(4) pm, to about the sum of the effective ionic radii of O^{2-} (140 pm, identical with the van-der-Waals radius of oxygen). A "rotation" of the central unit in **1** and **4** is not possible because the O–O contacts would become too short (cf. Fig. 2). Different attractive $V \cdots O$ (center) interactions are recognizable from the distances (> 296.0 pm in **1** and > 278.5 pm in **4**, but 218–246 pm in **5**), where stronger interactions are found with higher (more negative) charge on the central units. (On weak repulsive interactions between the negative shell and the negative template, see [2].)
[11] M. T. Pope: *Heteropoly and Isopoly Oxometalates*, Springer, Berlin 1983.
[12] The ν_3 band is, e.g., always split owing to the formation of ion pairs in aqueous solutions of nitrates (cf., e.g., Raman spectra in R. E. Hester, R. A. Plane, *Inorg. Chem. 3* (1964) 769). The results of the investigation of weak interactions between anions and cluster shells by Raman and IR measurements will be reported on elsewhere.
[13] The term (dissipative) self-organization usually refers to the formation of macroscopic structures—far apart from equilibrium—and also applies beyond the range of the sciences; see I. Prigogine: *From Being to Becoming—Time and Complexity in the Physical Sciences*, W. H. Freeman, New York 1980; A. Dress, H. Hendrichs, G. Küppers (Eds.): *Selbstorganisation*, Piper, München 1986. Various structure forming processes in the neigh-

borhood of equilibrium, e.g. phase transitions, can however be formally described in a similar way mathematically; see H. Haken, A. Wunderlin: *Die Selbststrukturierung der Materie*, Vieweg, Braunschweig 1991. In our view microscopic structure formation (self-organization) under the influence of a primarily formed matrix (as in the case of **3**[3]) and such that proceed via weak interactions with an external matrix have probably had importance in prebiotic elementary processes (formation of biopolymers) (cf. also the definitions "matrix" and "template" in O.-A. Neumüller: *Römpps Chemie-Lexikon*, Franckh'sche Verlagshandlung, Stuttgart 1985 and 1988, p. 2510 and 4152, respectively).

[14] A further future aspect emerges from the fact that in **1** and **2** not all positions in the two equivalent layers neighboring the polar $\{V_3O_7\}$ units are occupied, so that other units can also be encapsulated in the cluster shells. For example, in the cluster shell of **2** also a disordered NO_3^- ion can occur with one NO moiety replacing the N(N)N one: A. Müller, R. Rohlfing, unpublished results.

Synthesis and Structure of the First Tellurium(III) Radical Cation**

By *Már Björgvinsson, Thorsten Heinze, Herbert W. Roesky,* Frank Pauer, Dietmar Stalke,* and *George M. Sheldrick**

Dedicated to Professor Karl Heinz Büchel on the occasion of his 60th birthday

Although compounds with tellurium–nitrogen bonds have been used for some time in organic synthesis,[1] it is only in the last few years that they have been unambiguously structurally characterized.[2–12] Our interest in Te–N compounds was particularly stimulated by the isolation of the novel tricyclic tellurium nitride $(ClTeNSN)_3N \cdot 3\,DMF$.[10] In general, however, suitable stable precursors for the preparation of new Te–N compounds have been lacking. Recently, we prepared $Te(N(SiMe_3)_2)_2$ (**1**) in relatively good yields.[12] In our study of the coordination properties of **1** toward silver cations, we have isolated and structurally characterized the AsF_6^- salt of the first Te^{III} radical cation, $[Te(N(SiMe_3)_2)_2]^{\bullet+}$ ($\mathbf{2}^{\bullet+}$).

A dark blue solution of **3** was formed when a cold mixture (−78 °C) of **1** and $Ag^+AsF_6^-$ in CH_2Cl_2 was allowed to

$$\underset{\mathbf{1}}{Te(N(SiMe_3)_2)_2} + Ag^+AsF_6^- \xrightarrow[-Ag^0]{CH_2Cl_2} \underset{\mathbf{3}}{[Te(N(SiMe_3)_2)_2]^{\bullet+}[AsF_6]^-} \quad (a)$$

warm to room temperature [Eq. (a)]. Large crystalline blocks of **3** were isolated and its crystal structure was determined by low-temperature X-ray crystallography.[13] The crystals of **3** consist of monomer $\mathbf{2}^{\bullet+}$ coordinated by two AsF_6^- anions; thus, chains of alternating cations and anions are formed (Fig. 1).

The average Te–N distance of $\mathbf{2}^{\bullet+}$ (196.6(4) pm) is 8 pm shorter than that of its neutral analogue **1**,[12] indicating some multiple-bond character. Furthermore, the Si–N distances are longer, the average Si–N–Te bond angle is larger, the average Si–N–Si bond angle is smaller, and the pyramid formed from the N, Si, Si, and Te atoms is flatter than in **1**. These findings correlate well with the model of enhanced back-bonding of nitrogen-atom lone pairs to the positively charged tellurium atom of $\mathbf{2}^{\bullet+}$. Two long interionic Te···F contacts (318.6(1) (F2) and 317.9(1) (F6) pm), shorter than the van der Waals distance (355 pm[14] and 353 pm[15]) are present in **3** (Fig. 1).

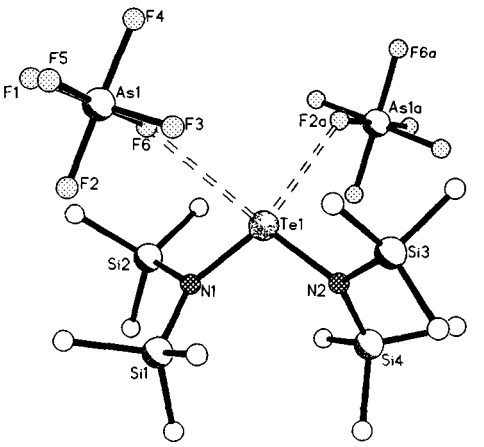

Fig. 1. Molecular structure of $\mathbf{2}^{\bullet+}$ and its nearest AsF_6^- neighbors (hydrogen atoms have been omitted). Broken lines show relatively short interionic contacts. Important distances [pm], bond angles [°], and torsional angles [°] for $\mathbf{2}^{\bullet+}$: Te1-N1 196.4(4), Te1-N2 196.8(4), N1-Si1 179.5(4), N1-Si2 180.0(4), N2-Si3 179.4(4), N2-Si4 179.2(4); N1-Te1-N2 106.8(1), Te1-N1-Si1 123.4(2), Te1-N1-Si2 114.6(2), Te1-N2-Si3 114.2(2), Te1-N2-Si4 122.5(2), Si1-N1-Si2 120.7(2), Si3-N2-Si4 121.3(2); N2-Te1-N1-Si1 51.7, N2-Te1-N1-Si2 −141.0, N1-Te1-N2-Si3 −139.3, N1-Te1-N2-Si4 56.3. For the AsF_6^- ion the bond distances and bond angles lie in the following ranges: As-F 165.9(5) −169.8(4) pm, F-As-F 87.2(4) −91.5(5)°, respectively. The fluorine atoms are disordered in the As–F1–F2–F3–F4 plane [13].

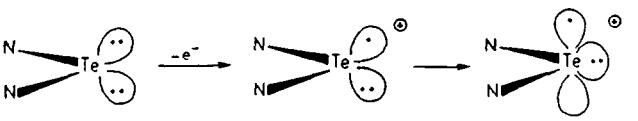
The solution ^1H NMR spectrum of **3** gave a relatively broad signal ($\Delta\nu_{1/2} = 18$ Hz), as expected for a radical. Only a single broad peak ($\Delta\omega_{1/2} \approx 15$ G) was observed in the ESR spectrum of **3** in $CDCl_3$, indicating a small spin density on the nitrogen atoms. Similar behavior has been observed for the isovalent pnictogen analogues of $\mathbf{2}^{\bullet+}$, $[P(N(SiMe_3)_2)_2]^{\bullet}$ ($\mathbf{4}^{\bullet}$) and $[As(N(SiMe_3)_2)_2]^{\bullet}$ ($\mathbf{5}^{\bullet}$).[16] It was further evident from the hyperfine coupling constants of $\mathbf{4}^{\bullet}$ and $\mathbf{5}^{\bullet}$ that the single electron was localized in a p orbital on the pnictogen atoms. Similar behavior is expected for $\mathbf{2}^{\bullet+}$. Thus, assuming an AX_2E_2 electron-pair arrangement around tellurium in **1**,[17] removal of an electron from **1** would result in a rehybridization of the tellurium atom such that a pair of electrons are in a sp^2 orbital and the single electron is in a p orbital.[18]



Scheme 1. Rehybridization of the tellurium orbitals on conversion of **1** to $\mathbf{2}^{\bullet+}$.

The bulky $N(SiMe_3)_2$ groups are expected to hinder the dimerization of $\mathbf{2}^{\bullet+}$. Furthermore, $\mathbf{2}^{\bullet+}$ is stabilized by the interionic $\mathbf{2}^{\bullet+} \cdots AsF_6^-$ contacts. By contrast, dimers with relatively short Te···Te contact distances are present in the crystals of the neutral compound **1**.[12] Dimerization of $\mathbf{2}^{\bullet+}$ is probably hindered owing to steric factors, which would reduce the energetically favorable ion-pair contacts, and electrostatic repulsion between the positively charged telluri-

[**] This work was supported by the Deutsche Forschungsgemeinschaft (Leibniz-Programm), the Fonds der Chemischen Industrie, and the Alexander von Humboldt Foundation (award of a fellowship to *M.B.*). We wish to thank Dr. *D. Marsh* and *B. Angerstein* at the Max-Planck-Institut für Biophysikalische Chemie, Göttingen, for measuring the ESR spectra.

um atoms. Contact ion pairs are presumably also present in CH_2Cl_2 and $CHCl_3$ solvents since no sharp ^{19}F NMR resonances were observed in freshly prepared solutions of **3**. Concentrated solutions of **3** are only metastable at room temperature, however, their blue color disappearing after approximately one week.

The isolation of a Te^{III} radical cation and the determination of its detailed geometry affords a unique opportunity for a general study of the nature of related species. Furthermore, the unexpected oxidation of **1** by $Ag^+AsF_6^-$ strongly suggests that this synthetic method could be generalized to other tellurium compounds.

Experimental Procedure

All manipulations were performed under an inert atmosphere of dry nitrogen gas inside a drybox or on a glass vacuum line. The CH_2Cl_2 and $CHCl_3$ solvents were dried over P_4O_{10} and distilled and stored over molecular sieves (4 Å) prior to use. In a typical preparation, **1** (1.13 g, 2.51 mmol) and $Ag^+AsF_6^-$ (0.74 g, 2.50 mmol) were loaded into separate arms of an H-shaped glass reaction vessel (equipped with teflon valves and a glass frit). After dissolving the compounds in CH_2Cl_2 (30 ml) the solutions were thoroughly mixed at −78 °C and the yellow solution allowed to warm to room temperature. The resulting dark blue solution was then filtered from the white-grey silver metal powder and the solvent slowly condensed off to give large black crystalline blocks of **3**. ^1H NMR (80 MHz, $CDCl_3$, −50 °C, ext. TMS): $\delta = 0.45$ ($\Delta\nu_{1/2} = 18$ Hz). ESR ($CDCl_3$, 10 °C): $g = 2.0$ ($\Delta\omega_{1/2} = 15$ G). UV/VIS (CH_2Cl_2): λ_{max} [nm] = 615.

[13] Crystallographic data for **3** (−120 °C): orthorhombic, $a = 1137.6(2)$, $b = 1253.3(2)$, $c = 1844.1(3)$ pm, $V = 2.6292$ nm^3, space group $P2_12_12_1$, $Z = 4$, $\varrho_{calcd} = 1.61$ g cm^{-3}, 3365 unique reflections [$|F_0| > 3\sigma(|F_0|)$], $2\theta = 8$–$45°$ refined to $R = 0.0261$, $R_w = 0.0279$. The disordered fluorine atoms F 1–F 4 and F 1′–F 4′, with 63 % and 67 % occupancy, respectively, were refined with identical anisotropic displacement parameters for opposite fluorine atoms. All As–F distances in the disordered plane were restrained to the same value, and a separate restraint was applied to make As–F distances perpendicular to the plane equal to one another. In addition, all F ··· F distances involving one disordered fluorine and one nondisordered fluorine were restrained to be equal. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, W-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the deposit number CSD-55340, the name of the authors, and the journal citation.

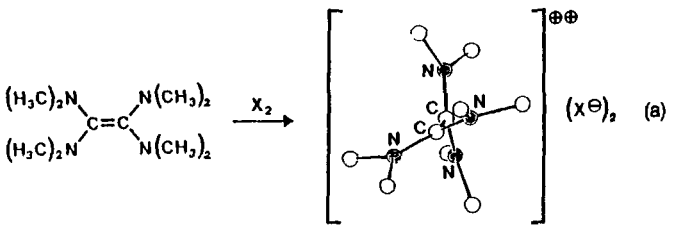
McDougall in J. F. Liebmann, A. Greenberg (Eds.): *From Atoms to Polymers: Isoelectronic Analogies, Ser. 11*: VCH Publishers, New York 1989, pp. 1–51.
[18] As pointed out by one of the reviewers, an alternative rationalization would be that an electron is removed from a doubly occupied tellurium nonbonding p orbital (b_2), perpendicular to the TeN_2 plane. This model is analogous to the MO description of the oxygen-atom lone pair in H_2O. However, for a criticism of this description see [17b], p 32.

Tetrakis(dimethylamino)ethene: An Extremely Electron-Rich Molecule with Unusual Structure both in the Crystal and in the Gas Phase**

By *Hans Bock,* Horst Borrmann, Zdenek Havlas, Heinz Oberhammer,* Klaus Ruppert*, and *Arndt Simon**

Dedicated to Hans Georg von Schnering on the occasion of his 60th birthday

Which organic molecules possess such low first ionization energies that they approach those of the alkaline-metal atoms Li (5.40 eV) and Na (5.14 eV)? Only a few answers can be given to this question and one of them is tetrakis(dimethylamino)ethene ($IE_1^V = 6.13$ eV[1,a,b]). On dissolving in oxygen-free water, therefore, it forms a radical cation, presumably according to $M_{solv.} + H^{\oplus}_{solv.} \rightarrow 1/2\,H_2 + M^{\bullet\oplus}_{solv.}$ with H_2 evolution.[1c] Two-electron oxidation[1d] by halogens (X_2) yields the dication salt, the structure of which is characterized by a central CC single bond of 150 pm length and two cyanine-like molecular halves twisted relative to each other by up to 76°[1e] [Eq. (a)].



(a)

The electron richness of the readily oxidizable title compound[1f] is further illustrated by a comparison with the valence-isoelectronic hydrocarbon derivative, the tetraanion of tetraisopropylethene, $((H_3C)_2C^{\ominus})_2C{=}C(C^{\ominus}(CH_3)_2)_2$, taking into consideration the different effective nuclear charges

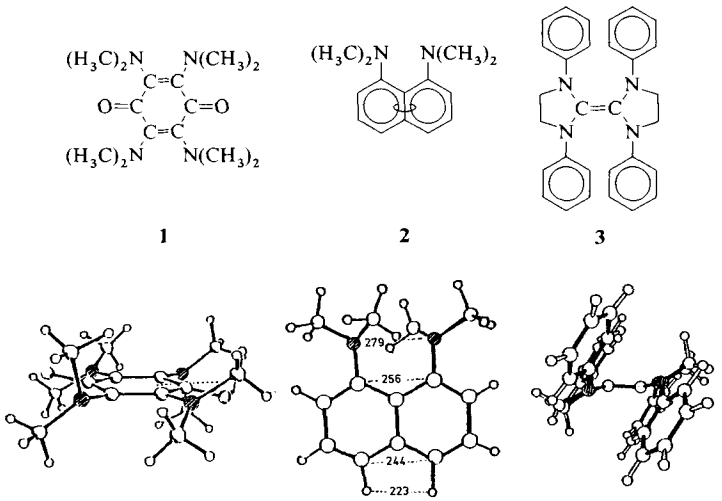
[**] Structures of Sterically Overcrowded and Charge-Perturbed Molecules, Part 12. This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and the State of Hesse. Part 11: H. Bock, *GIT Fachz. Lab. 35* (1991) 557.

($Z_{eff}(N) > Z_{eff}(C)$. In addition, this comparison accentuates the envelope of space-filling substituents, which can both stabilize charges in molecular ions by delocalization and distort considerably the bond skeletons in the neutral molecules,[2] as is observed especially for compounds with vicinal dialkyl or alkylaryl amino groups attached to CC multiple bonds[3] (Scheme 1). Thus, in tetrakis(dimethylamino)-*p*-



Scheme 1. Selected structures of sterically overcrowded, unsaturated nitrogen compounds (N centers hatched; distances in pm; cf. text).

benzoquinone (**1**) a chair conformation is enforced,[3a] in the proton sponge 1,8-bis(dimethylamino)naphthalene (**2**) the N···N distance is stretched by some 35 pm to 279 pm,[3b] and in the tetraphenylaminoethene derivative **3** the rings are arranged in two layers.[3c]

Which structure will the title compound with its extreme redox properties show? A totally geometry-optimized calculation for the 38-atom molecule using the well-tested semiempirical AM1 procedure,[4a] which was performed despite some objections concerning both the presumed violation of the parameter boundaries[4b] and the considerable number of degrees of freedom (108),[4c] predicts a planar $N_2C{=}CN_2$ skeleton with a C=C bond of 138 pm length and with all N lone pairs of the flattened $(H_3C)_2N$ groups in the central molecular plane. However, the calculated first ionization energy deviates by +2.7 eV,[3c] suggesting that only one of the numerous local total energy minima has been found.

The structure of air-sensitive tetrakis(dimethylamino)-ethene,[1f] which solidifies only at 273 K and decomposes above 373 K by loss of $(H_3C)_2NH$, was determined by single-crystal X-ray analysis[5] and, to avoid artifacts due to packing effects,[5] by electron diffraction in the gas phase[6] (Fig. 1). Indeed, the latter proved to be essential for the understanding of a structurally inconspicuous, but chemically significant disorder in the crystal.[7]

The solid-state structure of tetrakis(dimethylamino)-ethene[5] (Fig. 1a) reveals an unusual and chiral bond skeleton. The molecular halves on both sides of the C=C axis (stretched to 135 pm) are twisted relative to each other by 28° and each two opposite $(H_3C)_2N$ groups are either nearly planarized or seemingly fully planar ($\sum \sphericalangle$ CNC = 354° und 360°). Analysis of the radial distribution function, calculated by Fourier transformation from the scattering intensities,[6b] yields a gas-phase electron diffraction structure (Fig. 1b) with a twofold axis through the central C=C bond and confirms the basic X-ray structure data. For instance, the two $(R_2N)_2C$ molecular halves are also twisted by 28° in the gas phase and the R_2N groups are rotated relative to the CN_2 planes by 55°. In contrast to the structure in the crystal, however, all dimethylamino groups are pyramidal ($\sum \sphericalangle$ CNC = 351°) in the gas phase. A subsequently calculated disorder model for the crystal, on the other hand, also yields pyramidal R_2N substituents with angle sums of 351° and 353°. Both in the solid[5] and in the gas phase,[6] therefore, tetrakis(dimethylamino)ethene shows a surprising molecular structure, in which owing to steric overcrowding all four N lone pairs of the largely flattened dimethylamino substituents are twisted by torsion angles ω(CC-NC_2) of 55° out of their optimum π-interaction positions.

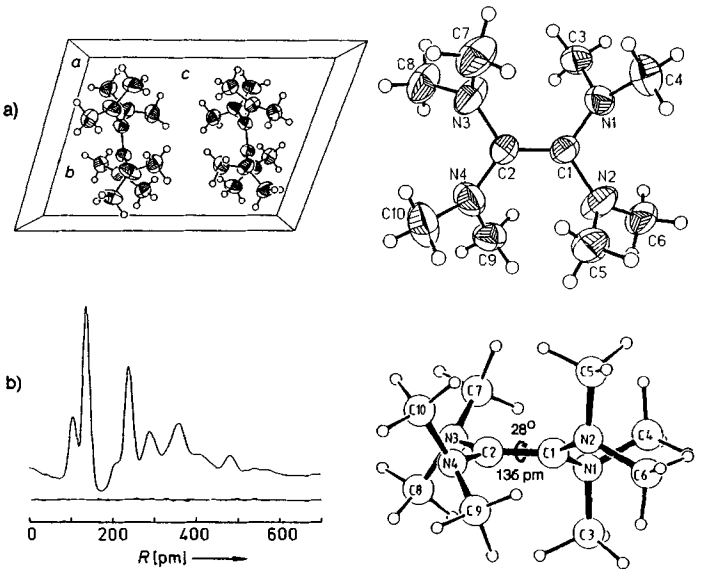


Fig. 1. Structure of $((H_3C)_2N)_2C{=}C(N(CH_3)_2)_2$. a) Results of the single-crystal structure analysis [5]. Left: Unit cell containing two molecules (intermolecular distances H···H > 243 pm); Right: Averaged molecular structure. Important distances [pm] for the averaged structure and, in curly brackets, for the one resolved using a disorder model [7]: C1-C2 135.1(2) {135.0(2)}, C1/C2-N 139.9(2) to 140.8(3) {141.7(3)}, N-C(H) 141.1(4) to 145.1(4) {144.0(3)}. Angle N_2C-CN_2 28.3° (ω = 0° would indicate a twisting of the dimethylamino groups to a position with the N lone pairs perpendicular to the CN_2 plane). For further details see [5, 7]. b) Structure analysis by electron diffraction in the gas phase [6]. Left: Radial distribution function: Right: Molecular structure; important distances [pm] and angles [°]: C1-C2 136, C1/C2-N 140, N-C 145, C-H 111, C2-C1-N 121, N-C1/C2-N 118, (H)C-N-C(H) 113, $\sum \sphericalangle$ CNC 351, N_2C-CN_2 28, C2C1-NC 55. For further details see [6b].

Comparison of these results with literature data confirms that the title compound is one of the most distorted simple ethylenes, $(R_nE)_2C{=}C(ER_n)_2$, even with respect to the record values[8] so far reported for sterically overcrowded fulvene and bis(fluorenylidene) derivatives, which exhibit C=C distances up to 141 pm and twist angles up to 40°. For instance, even the closest approaches to the still unknown tetrakis(*tert*-butyl)ethene, the fourfold 1-methylcyclopropyl- and trimethylsilyl-substituted hydrocarbons show a C=C bond of only 135 pm length and twist angles of only 20° and 29.5°, respectively. In contrast, the tetraisopropyl derivative, $((H_3C)_2HC)_2C{=}C(CH(CH_3)_2)_2$, which is valence-isoelectronic to $((H_3C)_2N)_2C{=}C(N(CH_3)_2)_2$, behaves rather normally ($d_{C=C}$ = 135 pm, ω = 0°).[8] This comparison, therefore, illustrates the spatial requirement of the N lone pairs (Scheme 1), which is evaded in tetrakis(dimethylamino)-ethene by the twisting of the N_2C-CN_2 skeleton and the flattening of the $(H_3C)_2N$ substituents as well as by their torsions around the C–N bonds.[3a, 9]

In conjunction with quantum-chemical calculations,[9] the unexpected structural data allow a plausible rationalization of the basic properties of the extremely electron-rich molecule tetrakis(dimethylamino)ethylene. Thus, its rather low first vertical ionization energy is readily explained by the considerably flattened dimethylamino pyramids – without any contradiction to the considerably reduced π interaction[1b] ($\cos^2 55° = 0.33$) caused by the ω(CC-NR_2) twisting. This interpretation is supported, for example, by the extremely low first vertical ionization energy of triisopropylamine (only 7.18 eV[2]), which is due to its almost planar NC_3 skeleton and is 1.26 eV below that of pyramidal $N(CH_3)_3$ with a CNC angle sum of 333°.[2] Additional AM1 calculations for tetrakis(dimethylamino)ethene starting from the solid-state and gas-phase structural data[9] result, as expected, in different local total energy minima and approximate its first ionization energy via Koopmans' correlation, $IE_n^V = -\varepsilon_j^{SCF}$, satisfactorily down to 7.2 eV. The observation[1f] that $((H_3C)_2N)_2C{=}C(N(CH_3)_2)_2$ exhibits a single ^{1}H NMR signal down to 220 K can be rationalized in terms of the low inversion barrier[10] of largely flattened dimethylamino groups, which together with the CN_2 librations (Fig. 1a) allows time-averaged equivalent positions of the methyl C centers. The tremendous structural change on oxidation to the dication [Eq. (a)] also seems to be "preprogrammed" by the molecular dynamics.

Despite its now-known ground-state structure, the extremely electron-rich title molecule still poses numerous problems. For instance, calculations for its radical cation[10] suggest that the positive charge might be lopsidedly distributed over the two molecular halves – in full agreement with the different ^{1}H coupling constants of 0.28 mT and 0.328 mT obtained by ESR and especially ENDOR spectroscopy, respectively.[1c, f]

Clark*, Universität Erlangen) on an IBM RISC 6000/320 work station with 32-Mb CPU and needed about 8 h of computation time. Selected calculated structure parameters ([pm] or [°]): C=C 138, CN 144, CH 112, CCN 119 and 125, $\sum \sphericalangle$ CNC 338 and 344. Additional results: $\Delta H_f = 225$ kJ mol^{-1}; $\varepsilon_{42} = -8.7$ eV; $q_C = 0.04$; $q_N = -0.26$. Cf. also the MNDO results based on the assumption of pyramidal $(H_3C)_2N$ substituents [1e] as well as from calculations based on the structures determined [10].

[5] Crystal structure: $C_{10}H_{24}N_4$. The air-sensitive compound, which was purified by repeated fractional condensation at 10^{-5} mbar pressure, was placed in a Mark tube (about 2 cm full) and slowly cooled below its melting point of 0 °C. Cautious warming followed again by slow cooling afforded a single crystal (cf. A. Simon, H. Borrmann, *Angew. Chem. 100* (1988) 1386; *Angew. Chem. Int. Ed. Engl. 27* (1988) 1339). On further cooling of the crystal, several phase transformations were observed in Guinier investigations. Reflection data of the high-temperature phase were recorded both at 218 K and 243 K, but did not show any significant deviations on structure refinement. Data: $a = 771.4(2)$, $b = 826.8(2)$, $c = 1138.3(3)$ pm, $\alpha = 106.73(2)$, $\beta = 92.11(2)$, $\gamma = 108.44(2)°$, $V = 653.02 \times 10^6$ pm^3; measurement temperature 218 K, $M = 200.33$, $\rho_{calcd} = 1.02$ g cm^{-3}, $\mu(Mo_{K\alpha}) = 0.06$ mm^{-1}, triclinic $P\bar{1}$ (No. 2 Int. Tab.), $Z = 2$, Syntex $P2_1$ four-circle diffractometer, 3018 measured reflections within $4° < 2\theta < 55°$ ($\omega/2\theta$ scan), of which 2263 are independent with $F > 2\sigma(F)$; structure solved by direct methods (SHELXTL-Plus), 239 parameters, $R = 0.061$, $R_w = 0.063$ ($w = 1/\sigma^2(F) + 0.0001\,F^2$), Goof = 1.311, residual electron density +0.19/−0.15 e/Å^3, C and N atoms, including split positions [7], anisotropically refined, H positions found and refined isotropically applying a common C–H distance and the same temperature factor for each methyl group. Further details are available on request from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, W-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-55907, the names of the authors, and the journal citation.

[6] Electron diffraction in the gas phase. a) The air-sensitive $C_{10}H_{24}N_4$ was purified by distillation at 10^{-4} mbar and kept under Ar in the dark. The scattering intensities were recorded at two camera distances (25 and 50 cm) with a G2 gas diffractograph using an acceleration voltage of about 60 kV. The temperature of the sample was 345 K (vapor pressure between 2 and 3 mbar) and that of the inlet nozzle 350 K; no decomposition was observed. b) For the structure determination, several models with different orientation of the four dimethylamino groups, as well as planar or twisted C_2N_4 skeleton, were tested. Satisfactory agreement between calculated and experimental radial distribution functions (Fig. 1b) was only achieved using a model similar to the solid-state structure of C_2 symmetry with the axis along the C=C bond. The least-squares fit is based on the following assumptions: local C_{3v} symmetry for the CH_3 and C_s symmetry for the $N(CH_3)_2$ groups, each with the same geometric parameters. In the electron diffraction experiment, the C–C distance was insufficiently determined and was therefore set equal to the value from the crystal analysis. The following distances [pm] and angles [°] result (error limits are 3σ values and refer to the last digit): C-H 111.0(4), C=C 136 (assumed), C-N 140.3(4), N-C 145.2(3), N-C-N 118.4(8), C-N-C(H) 119.2, (H)C-N-C(H) 112.8(15), H-C-H 108.3(8), ω(C=C) 28(2), ω(C-N) 55(2) (twisting of the dimethylamino groups around the C–N bond: for $\omega = 0$, the N lone pairs are perpendicular to the CN_2 plane). The methyl groups are staggered with respect to the opposite N–C bond.

[7] Residual electron density within about 50 pm distance from N4 (Fig. 1a) indicates a partial inversion of the pyramids. The elongation of the thermal ellipsoids for N2 and N3 perpendicular to the NC_3 plane also points to a positional disordering, which could be due to the presence of some molecules in inverted orientation. Contrary to this assumption, however, N1 does not show disordering. For an individual disorder of the R_2N groups, a calculation with split positions for N2 (0.5:0.5), N3 (0.65:0.35), and N4 (0.85:0.15) improves the R value slightly from 0.064 to 0.061 and yields a pyramidal structure of all N centers with angle sums of 353° (N1), 352° (N2), 351° (N3), and 352° (N4). At this point we also want to express our gratitude to the "structure-competent" referee for his helpful critical comments.

[8] Review: W. Luef, R. Keese (Nonplanar Carbon-Carbon Double Bonds), *Top. Stereochem. 20* (1991) 231–318: Accordingly, the longest C=C bonds of 141 pm length are found in 1-(*N*-benzyl-1,2-dihydropyridinylidene)fulvenes, followed by the 139-pm-long ones in bis(1-isopropoxycarbonylfluorenylidene), which with a dihedral angle of 40° also exhibits the strongest twisting observed so far. Of the numerous reported ethylene derivatives (cf. e.g., J. Deuter, H. Rodewald, H. Irngartinger, T. Loerzer, W. Lüttke, *Tetrahedron Lett. 26* (1985) 1031), noteworthy are 1,1-di-*tert*-butyl-2,2-diphenylethene ($d_{C=C} = 136$ pm; $\omega = 24°$) and, as an example with an additional bending angle φ, octabromopentalene ($d_{C=C} = 139$ pm, $\omega = 37°$, $\varphi = 3°$). In tetrakis(trimethylsilyl)ethene (A. Sekiguchi, T. Nakanishi, C. Kabuto, H. Sakurai, *J. Am. Chem. Soc. 111* (1989) 3748), the molecular halves are twisted relative to each other by 29.5°.

[9] Additional AM1 calculations based on the crystal and gas-phase structural data, prove that, depending on the starting geometry, different local minima are approached. Thus, AM1 calculations proceeding from the crystal structure (Fig. 1a and [5]) yield $\varepsilon_{42} = -7.19$ eV, $q_C = +0.07$, $q_N = -0.25$, and an enthalpy of formation $\Delta H_f = 303$ kJ mol^{-1}, which is about 80 kJ mol^{-1} above that resulting from a complete geometry optimization

based on standard structure data [4]. In contrast, the C_2 gas-phase structure as an starting point leads to a geometry-optimized structure with $\omega(N_2C=CN_2) = 13°$ and $\varepsilon_{a2}^{AM1} = -8.2$ eV as well as $q_{C1} = 0.12$, $q_{C2} = 0.03$, $q_{N1/2} = -0.28$, and $q_{N3/4} = -0.31$, which add up to a dipole moment of 1.9 D. The calculated enthalpy deviates by only $+20$ kJ mol^{-1}. The enthalpy differences are due to numerous changes within the molecular skeleton, which can be analyzed based on additionally calculated force constants (kJ mol^{-1} pm^{-2} or kJ mol^{-1} degree^{-2}) and be classified according to C=C stretch (0.7) and angle changes, decreasing in the sequence CNC-angle widening (5.0) > N pyramidalization (1.0) > C=C rotation ≈ C-NC$_2$ rotation (0.1). All force constants are positive and therefore prove that the movements covered by them originate from a (local) minimum of the total energy. An additional ab initio SCF calculation employing a 4-31 G basis set predicts for a 28° twisting of ethylene an energy difference of $+48$ kJ mol^{-1}, which further illustrates the steric overcrowding in tetrakis(dimethylamino)ethene.

[10] A totally geometry-optimized AM1 calculation for the radical cation (H. Bock, Z. Havlas, unpublished) predicts $d_{C-C} = 151$ pm, $\omega(N_2C-CN_2) = 61°$, and $\sum \sphericalangle CNC = 360°$ and 349°. For the molecular half containing the cyanine-like flattened $(H_3C)_2N$ groups [cf. Eq. (a)] a total charge of $+0.85$ is calculated. Experiments to isolate a salt of the tetrakis(dimethylamino)ethene radical cation, $[(R_2N)_2^{\oplus}C\text{-}^{\bullet}C(NR_2)_2]X^{\ominus}$, are under way (H. Bock, I. Göbel, unpublished).

Synthesis of an Elicitor-Active Heptaglucan Saccharide for Investigation of Defense Mechanisms of Plants

By *Jens Peter Lorentzen,* Barbara Helpap,* and *Oswald Lockhoff*

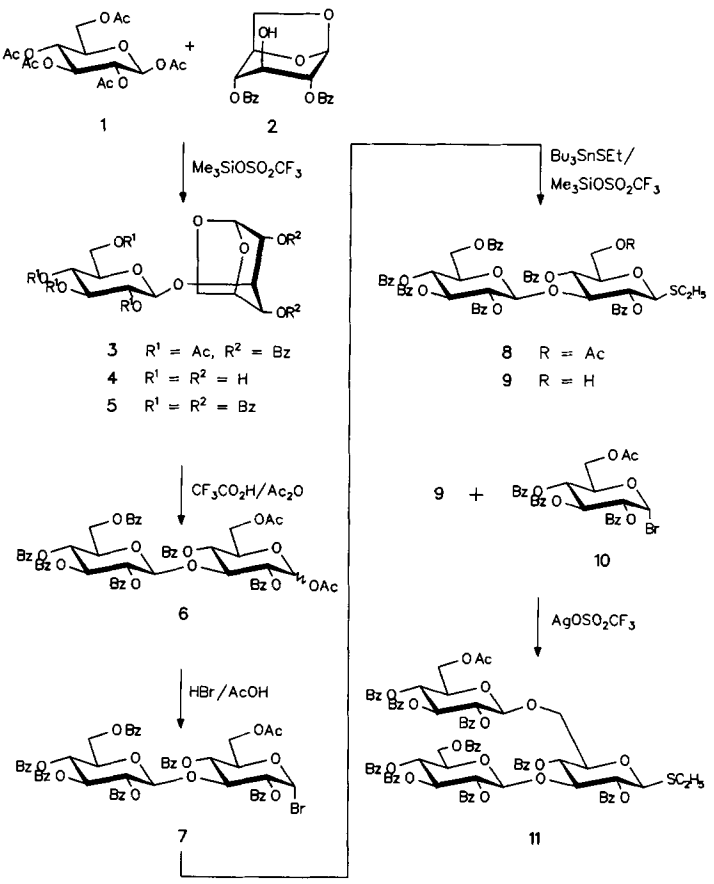
Dedicated to Professor Karl Heinz Büchel on the occasion of his 60th birhday

Elicitors are substances that induce the defense reactions of plants by activating the biosynthesis of phytoalexins. In the soybean/*Phytophthora megasperma* host–parasite system the heptasaccharide **19** is the smallest strong elicitor-active unit[1] that binds to a receptor. This β-glucan structure is formed hydrolytically from the cell wall of the pathogen. The binding of the glucan fragment to a membrane protein of the host organism presumably induces the formation of a second messenger system. The signal chain ends with the biosynthesis of the phytoalexin glyceolin.[2]

The chemical synthesis of defined oligoglucan fragments should make the study of plant defense mechanisms possible starting, for example, from the mechanism of the photoelicitor–binding protein interaction and the resulting signal transmission to the biosynthesis of phytoalexin.

We report here a new and more efficient synthesis of heptasaccharide **19**. Our synthesis distinguishes itself from earlier preparations[3] by its small number of very efficient reaction steps. Outstandingly high yields (16% in 5 steps from **11** and **14**) of the carbohydrate sequence **19** have been obtained by a block synthesis using the thiotrisaccharide donor **11** and the glycosyl acceptor **14**.

The synthesis of thioglycoside **11** began with the preparation of disaccharide **3** (yield 35%, $[\alpha]_D^{20}$ $-28°$ ($c = 1.04$, CH_2Cl_2)). The reaction of penta-*O*-acetyl-β-D-glucopyranose **1** with the only somewhat reactive hydroxyl function of the 1,6-anhydro derivative **2**[4] to give coupling product **3** was possible with Lewis acid catalysis using trimethylsilyl trifluoromethanesulfonate.[5] In one reaction sequence **3** was hydrolyzed to **4**, which was then perbenzoylated to **5** and



Scheme 1. Synthesis of trisaccharide–thioglycoside donor **11**. Ac = CH_3CO, Bz = C_6H_5CO.

cleaved to the diacetate **6** by acetolysis of the 1,6-anhydro ring. Bromide **7** was obtained from **6** under standard conditions and then converted to the thioethyl glycoside **8** in a reaction with ethyl tributylstannyl sulfide,[6] catalyzed by trimethylsilyl trifluoromethanesulfonate. The acetyl function of **8** was cleaved in very high yield with hydrogen chloride in methanol[7] in the presence of the benzoate protecting groups. The glycosyl bromide **10**[8] was a suitable building block for preparation of the trisaccharide–thioglycoside donor **11** (yield 50.5%, $[\alpha]_D^{20}$ $-25°$ ($c = 1.06$, CH_2Cl_2)), which can be obtained under modified Koenigs–Knorr conditions[9] with the aid of silver trifluoromethanesulfonate.

The ethylthio function of the anomeric center functions as a stable protecting group, but can also be activated selectively for further glycoside syntheses.[10] Accordingly, the trisaccharide donor **11** is a good starting material for oligosaccharide syntheses; after the acetyl function has been cleaved, chain lengthening is also possible.

Coupling to the tetrasaccharide **15** (yield 65%, $[\alpha]_D^{20}$ $-48°$ ($c = 0.98$, CH_2Cl_2)) was achieved without difficulty under alkylating conditions[10] with acceptor **14** (Scheme 2). Compound **14** was accessible from perbenzylated glucose **12** by selective acetolysis of the 6-*O*-benzylether followed by hydrolysis of the 6-*O*-acetate **13**. The deacetylation[7] of the primary hydroxyl function on **15** to **16** permitted a further chain extension with the trisaccharide donor **11**. The glycoside synthesis was carried out with methyl trifluoromethanesulfonate catalysis and led to the heptasaccharide **17** (yield 36%, $[\alpha]_D^{20}$ $-36°$ ($c = 0.99$, CH_2Cl_2)). The molecule was deprotected in two steps. Basic hydrolysis of the ester functions was followed under standard conditions by hydrogenation of the

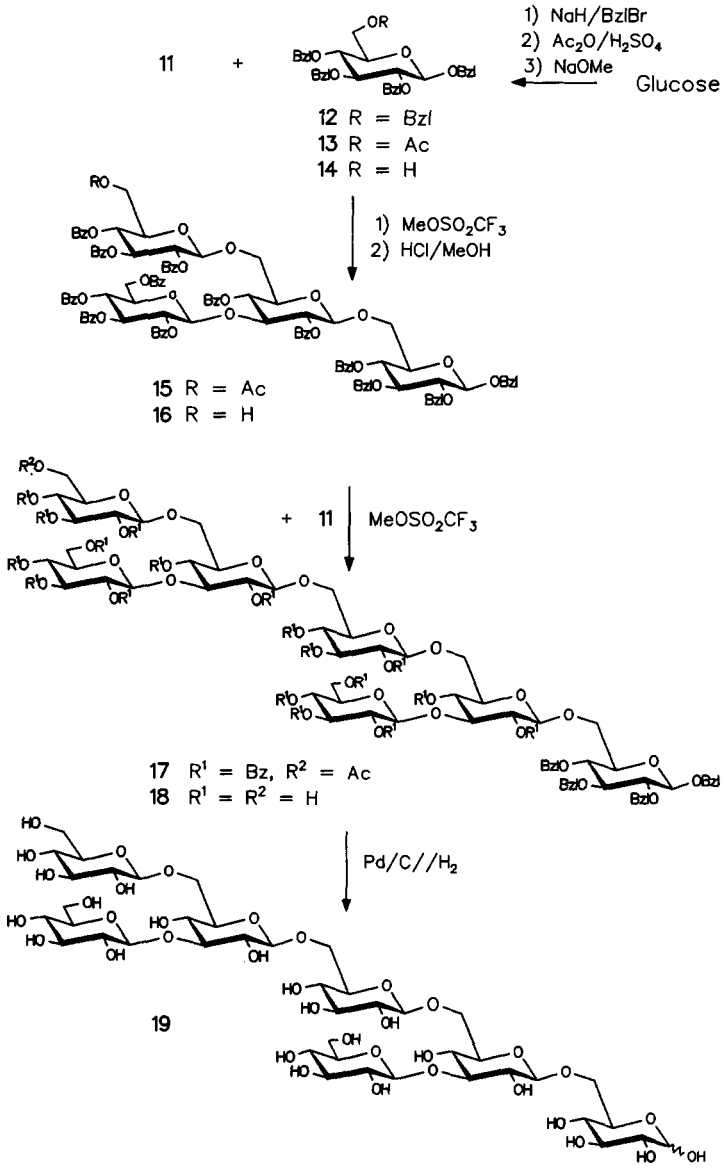
benzyl ether function to give the deprotected heptasaccharide **19** [yield 93.5%, $[\alpha]_D^{20}$ −19° (c = 0.69, H_2O); Lit. [3b]: $[\alpha]_D^{20}$ −12° (c = 0.5, H_2O)].



Scheme 2. Synthesis of heptasaccharide **19**. Bzl = $C_6H_5CH_2$.

Besides the desired heptasaccharide, homologous β-glucan fragments of variable chain length and branching points are obtainable by the efficient synthesis described here. These derivatives should make it possible to study structure–effect relationships.

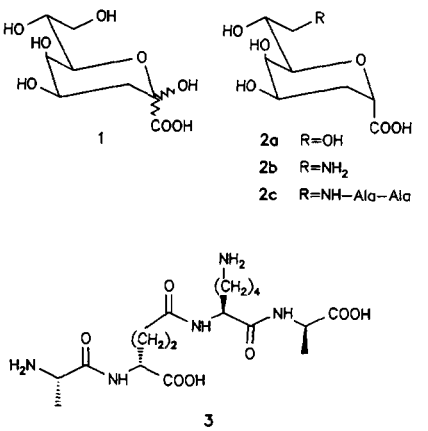
Synthesis of Muropeptide Conjugates of 2,3-Dideoxy-β-D-*manno*-2-octulosonic Acid

By *Hans-Georg Lerchen** and *Hein-Peter Kroll*

Dedicated to Professor Karl Heinz Büchel on the occasion of his 60th birthday

Lipopolysaccharides (LPS) in the outer membrane of gram-negative bacteria play an important role in the growth and virulence of these cells.[1] One structural element in the inner core region specific to bacteria, yet found universally, is 3-deoxy-β-D-*manno*-2-octulosonic acid (KDO) (**1**). The inhibition of its biosynthesis is thus an attractive goal in drug research.[2] The key enzyme in the biosynthesis is cytidinemonophosphate-(CMP)-KDO-synthetase.[3] 2-Deoxy-β-KDO-derivatives like **2a** and **2b** have been described as potent enzyme inhibitors, but are not able to penetrate the bacterial membrane due to structural parameters.[4a] To solve this



problem *Lartey* et al. as well as *Claesson* et al. synthesized the 8-amino-linked dipeptide conjugate **2c**,[4b,c] which is actively transported by peptide permeases into the bacterial cell.

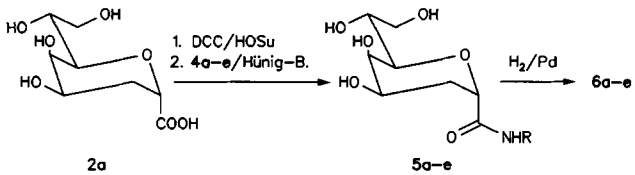
[a] *i*Gln = isoglutamine, 2d-β-KDO = 2,3-dideoxy-β-D-*manno*-2-octulosonoyl, TFA = trifluoroacetic acid, Z = *N*-benzyloxycarbonyl. [b] Purity of the new compounds was assessed by ^1H and ^{13}C NMR spectroscopy.

There, **2c** is cleaved by peptidases with release of the enzyme inhibitor **2b**. However, in vivo this dipeptide cleavage may also be carried out by eukaryotic peptidases outside the bacterial cell.[5] To prove the therapeutic value of 2-deoxy-β-KDO derivatives, prodrugs of **2a** must be synthesized, which should be quite stable in vivo, releasing inhibitor **2a** only inside the bacterial cell.

We herein describe the synthesis of 1-carboxyl-linked peptide conjugates of 2-deoxy-β-KDO **2a**. Their stability can be varied by the introduction of different anchor groups at which cleavage could occur. We chose peptidic carriers derived from bacterial muropeptides, sequences which are taken up preferentially by bacteria during the course of peptidoglycan metabolism.[6] 2-Deoxy-β-KDO **2a** was linked to the terminal amino group of **3** or appropriate partial sequences. The suitably protected peptide derivatives **4** were prepared by known methods[7] (Table 1). The ammonium salts of the oligopeptide fragments **4** were attached efficiently to the carboxyl group of unprotected **2a** by the Wünsch–Weygand method[8] with dicyclohexylcarbodiimide (DCC)/*N*-hydroxysuccinimide (HOSu) in the presence of Hünig base. Hydrogenolysis of **5** provided the deprotected conjugates **6**.

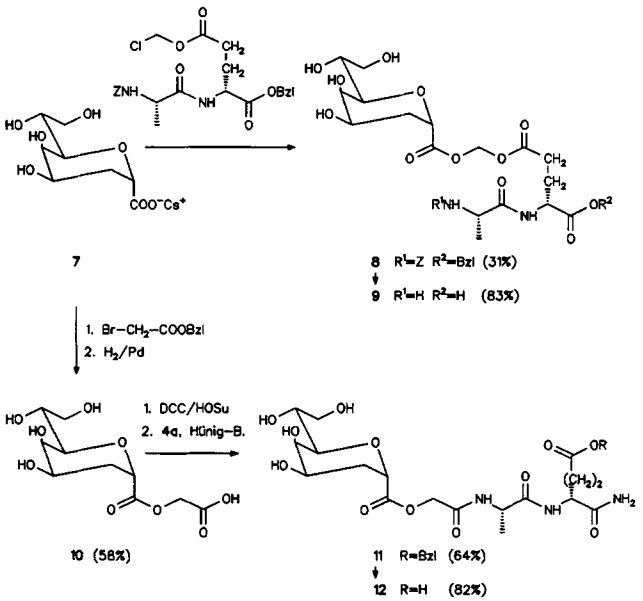


Scheme 1. Linkage of 2-deoxy-β-KDO **2a** with suitably protected peptide derivatives **4a–e** to the conjugates **5a–e** and complete deprotection to **6a–e** (Table 1).

All deprotected glycoconjugates **6** proved to be stable to peptidases. However, the release of the enzyme inhibitor inside the bacterial cell is an additional requirement for antibacterial activity of conjugates such as **6**, after their uptake through the membrane. To check the carrier potential of muropeptide fragments, cleavable anchor groups, for example, active esters[9] had to be introduced between carrier and drug.

The cesium salt method[10] effected the elegant transformation of the carboxyl function of **2a** into labile ester derivatives without the protection of the hydroxyl functions. The selective removal of protecting groups in the presence of activated ester bonds was thus avoided (Scheme 2).

The starting material cesium 2,3-dideoxy-β-D-*manno*-2-octulosonate **7** was obtained from the reaction of **2a** with Cs_2CO_3. Alkylation of **7** with α-benzyl-γ-chloromethyl Z-L-alanyl-D-glutamate[11] yielded the geminal diol ester derivative **8**, which was deprotected by hydrogenolysis providing **9**. The glycolic ester **10** was obtained by alkylation and hydrogenolysis in the same manner and can be modified broadly. Subsequent reactions with muropeptide fragments yielded 2-deoxy-β-KDO conjugates such as **11**, which was deprotected by hydrogenolysis to **12**.



Scheme 2. Attachment of muropeptide derived fragments to **2a** by alkylation of cesium 2,3-dideoxy-β-D-*manno*-2-octulosonate.

Bacterial enzymatic cleavage was shown for the derivatives **9** and **12**.[13] The in vitro antibacterial activity measured for **9** verifies its uptake into the bacterial cell as well as the release of the enzyme inhibitor in the cytoplasm. Thus by different modifications of the 1-carboxyl-function of the 2-deoxy-β-KDO unit in **6**, **9**, and **12** a graduation in in vivo stability is realized with respect to a selective cleavage inside the bacterial cell.

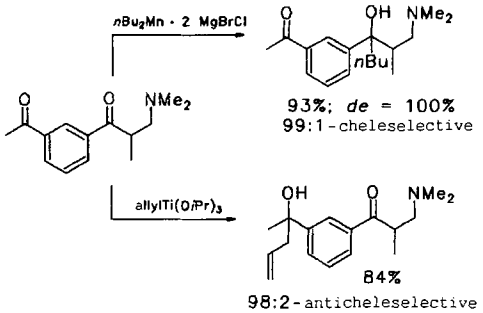
The Reaction-Accelerating Neighboring-Group Effects in the Reaction of Vinyl Bromides with Alkyl-Transition Metal Reagents**

By *Thomas Kauffmann** and *Dirk Stach*

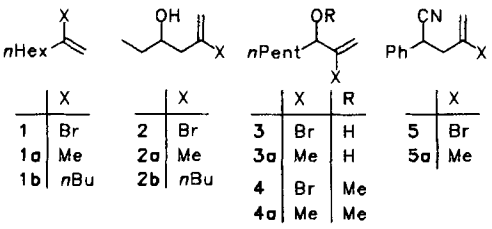
Dedicated to Professor Karl Heinz Büchel on the occasion of his 60th birthday

In the alkylation and carbonyl-olefination of ketones with transition metal reagents, basic groups located in the α- or β-position to the keto group exercise a reaction-promoting[1–4] or reaction-inhibiting influence,[3, 4] which enables very selective ("chele-" and "anticheleselective"[3, 4]) alkylations (for example see Scheme 1) and carbonyl-olefinations.

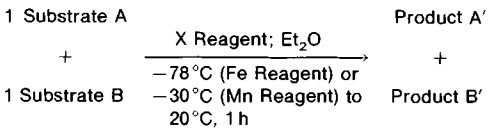


Scheme 1. Example of neighboring group effects in the alkylation and allylation of a diketone [5].

Such neighboring group effects are most probable in reactions, which already proceed rapidly at low temperature.[5] Following the finding that alkyliron and alkylcobalt reagents react rapidly at −78 °C with vinyl bromides with cross-coupling,[6, 7] we have checked by competition experiments with the substrates **1**–**5** (Scheme 2) according to Scheme 3 whether basic groups (OH, OMe, CN) in the α- or β-position to the Br atom of vinyl bromides influence the rate of cross-coupling.[8] We found this to be true on using Me_4FeLi_2, Me_4MnLi_2 and nBu_4MnLi_2 (Table 1), but not on using Me_4CoLi_2 and Me_2CuLi. The cobalt reagent is too reactive to be able to react selectively, while the copper reagent is almost completely deactivated by the functionalized vinyl bromides **2**–**5**. Diethyl ether was substantially more suitable as solvent than the strongly complexing tetrahydrofuran.



Scheme 2. Starting compounds **1**–**5** and products **a**, **b** of the competition experiments (*n*Hex = *n*-hexyl; *n*Pent = *n*-pentyl).



Scheme 3. Conditions in the competition experiments. The molar ratio is evidenced by the factors before the reagents.

Table 1. Competition reactions carried out according to Scheme 3.

Substrates		Mol. equiv. Reagent	Products and yields [%]				Product ratio	Recovery of substrates [a]	
1	**2**	0.66 Me_4FeLi_2	**1a**	6	**2a**	48	11:89	90	25
1	**2**	0.66 Me_4MnLi_2	**1a**	14	**2a**	78	15:85	73	15
1	**2**	1 nBu_4MnLi_2	**1b**	10	**2b**	74	12:88	66	17
1	**3**	1 Me_4MnLi_2	**1a**	<1	**3a**	67	1:99	71	13
1	**3**	0.5 Me_4FeLi_2	**1a**	5	**3a**	79	6:94	66	8
1	**4**	1 Me_4MnLi_2	**1a**	<1	**4a**	72	1:99	55	5
1	**5**	0.5 Me_4FeLi_2	**1a**	4	**5a**	76	5:95	81	0
1	**5**	1 Me_4MnLi_2	**1a**	0	**5a**	0	–	76	73
2	**3**	0.5 Me_4FeLi_2	**2a**	17	**3a**	73	10:90	64	7
2	**3**	0.5 Me_4MnLi_2	**2a**	32	**3a**	82	28:72	41	<1

[a] As percentage of material employed.

The reactions of the hydroxyvinyl bromides **2** and **3** with Me_4FeLi_2 (at −78 °C) and Me_4MnLi_2 (at −30 °C) were examined more closely. In 1 : 1 reactions one mole equivalent of CH_4 was formed in each case, and in the IR spectrum (at −20 °C) the OH-stretching vibration bands of **2** and **3** at 3473 and 3439 cm^{-1}, respectively, disappeared. It follows, therefore, that an Fe- or Mn-alkoxide, respectively, is most likely formed in the course of the reaction. The alkoxide is presumably formed before the cross-coupling, for which we consider, as far as educts **2** and **3** are concerned, the "insertion-deinsertion" mechanism formulated in Scheme 4A more likely than the mechanism formulated in Scheme 4B. Since, to our knowledge, only transition-metal reagents for the cross-coupling with vinyl bromides are suitable whose metal atom can assume a higher oxidation state (Ti^{IV} reagents are e.g. unsuitable), we assume a compound of the type **9** as intermediate of the insertion step **6** → **7**.

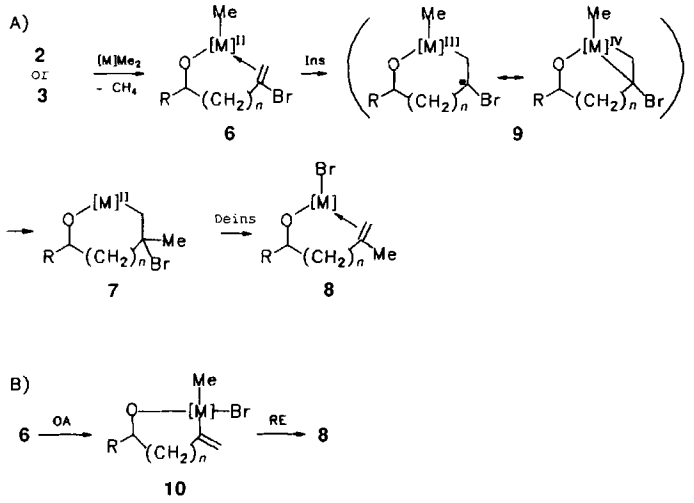
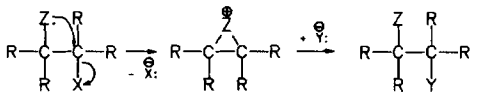
[**] Transition-Metal-Activated Organic Compounds, Part 36. This work was supported by the Volkswagenstiftung, the Deutsche Forschungsgemeinschaft, and the Fonds der Chemischen Industrie.—Part 35: T. Kauffmann, J. Jordan, J. Sander, *Chem. Ber.*, in press.

Due to opposing effects of ring strain and entropy, the series four-membered ring ≪ five-membered ring > six-membered ring generally holds true for the rate of ring formation. In the case of the mechanism of Scheme 4A it is therefore fully understandable that in competition reactions with the substrate pair **2**/**3** (Table 1) α-hydroxyvinyl bromide **3** reacts more rapidly in each case. In the mechanism of Scheme 4B rather the opposite would be expected, since **3** would react via a four-membered ring intermediate. The mechanism of Scheme 4A reveals, moreover, a clear parallel to the confirmed chelate mechanism of the methylation of the α-hydroxyketone benzoin with methyl-transition-metal reagents,[3, 9] in which the hydroxy group likewise exercises an accelerating neighboring effect.[1-3]



Scheme 4. Possible mechanism of the cross-coupling of the hydroxyvinyl bromides **2** and **3** (n = 0, 1; M = Fe, Mn, with additional ligands, which are omitted for simplification). A) Ins and Deins = insertion and deinsertion, respectively. b) OA and RE = oxidative addition and reductive elimination, respectively.

The acceleration of nucleophilic substitutions of sp^3-C-bound halogen atoms by neighboring groups[10] ("anchimeric" assistance[11]) is based on the fact that the neighboring groups assume a direct bond relationship to the reaction center and in this way stabilize transition states or intermediates (for example see Scheme 5). Another principle



Scheme 5. Substitution of an sp^3-C-bound halogen atom with anchimeric assistance.

underlies the substitution of sp^2-C-bound halogen atoms accelerated by neighboring groups described here; it includes involvement of the neighboring group in a bonding relationship to the reaction center of the substitution and also of (in the case of **9** or **10**) the metal atom coordinated to the neighboring group.

Experimental

The methyl reagents, all of which are described in the literature as isolated complexes, were prepared in situ by reaction of four or two mole equivalents, respectively, of MeLi with $FeCl_2$ (conveniently obtainable by 1:1 reaction of $FeCl_3$ and MeLi), $MnBr_2$, $CoCl_2$ and CuI, respectively. nBu_4MnLi_2 was prepared analogously with *n*BuLi. The vinyl bromides used as starting compounds and their alkylation products required as reference substances, of which **3**, **4**, **5**, **2b**, and **4a** have still not been described, were synthesized on a preparative scale[12] (the methylation products by reaction of the vinyl bromides with Me_4CoLi_2). The evaluation of the competition experiments (identification and quantification of the products) was accomplished gas-chromatographically with the aid of authentic reference substances.

Enantioselective and Diastereoselective Total Synthesis of the Antimycotically Active Natural Product Chlorotetaine: Revision of the Relative Configuration**

By *Hanno Wild** and *Liborius Born*

Dedicated to Professor Karl Heinz Büchel on the occasion of his 60th birthday

In common with the longer known and related substance bacilysin,[1] the dipeptide chlorotetaine (recently isolated from the *Bacillus subtilis* strain BGSC 1E2), whose structure has been identified as **1**,[2] possesses interesting antimycotic properties.

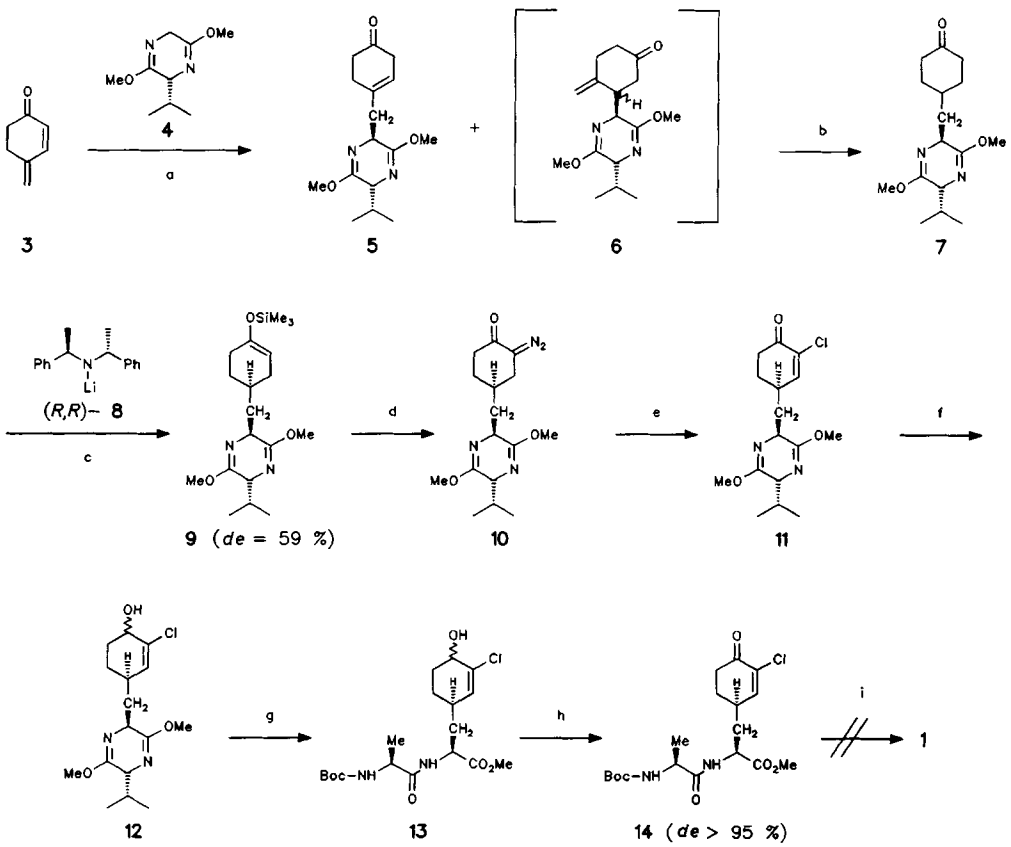
[**] We wish to thank Prof. *Jung*, Tübingen, FRG for supplying a sample of natural chlorotetaine **1**.

Though three syntheses have been published for anticapsin,[3] the *C*-terminal amino acid of bacilysin, no stereoselective general approach to amino acids of this unusual type has been published so far. We report here the first total synthesis of chlorotetaine. Based on this work the natural compound was assigned structure **2** above, which is epimeric to structure **1** with an (*S*)-configurated C-atom in the cyclohexenyl residue. In planning the synthesis it had to be borne in mind that chlorotetaine is only stable in solution at a pH of about 5. Above pH 7 as well as below pH 5 the biological activity decreases rapidly, especially on heating.[2] The main reaction in alkaline media is the intramolecular 1,4-addition of the amide to the enone system, with formation of a 6-oxo-octahydroindole.[3b, c] Since the risk of this side reaction is present during all the intermediate steps of the synthesis as well, the enone should not be liberated until the latest possible moment. Scheme 1 shows the reaction sequence that should lead to the dipeptide **1**, the presumed chlorotetaine.

The cuprate of the bislactim ether **4**[4] reacted with dienone **3**[5] giving the desired diastereomerically pure 3-cyclohexenone derivative **5** from 1,6-addition in a 40% yield, in addition to 24% of the 1,4-adduct **6**. Compound **5** was then hydrogenated to cyclohexanone **7**. In the next step the desired configuration at C1′ was produced as described by *Koga* et al.[6] and *Simpkins* et al.[7] by diastereoselective deprotonation with lithium (*R,R*)-bis(phenylethyl)amide (**8**). By analogy with the reactions of simple 4-alkylcyclohexanones the principal diastereomer should possess the configuration indicated for **9**. To generate the necessary 2-chloroenone system, silyl enol ether **9** was first converted into diazo compound **10** via a *C*-trifluoroacetyl intermediate.[8] The reaction of **10** with phenylselenyl chloride at −5 °C was spontaneous, and subsequent oxidative elimination gave chloroenone **11**.[9] Before the hydrolysis of the bislactim ether, the ketone had to be reduced,[10] since acidic cleavage of **11** with subsequent liberation of the amine led to the already mentioned intramolecular 1,4-addition. Alcohol **12** yielded the dipeptide **13** without problems after hydrolysis and linkage with (*S*)-Boc-alanine. The product could be reoxidized to the cyclohexenone in a good yield by manganese dioxide. At this stage small quantities of the undesired diastereomer could easily be removed by chromatography.[11]

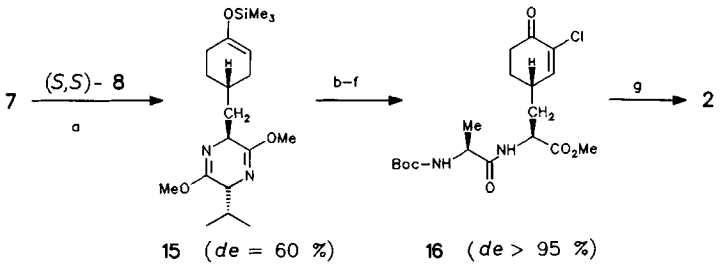
After cleavage of the Boc protecting group, the methyl ester was saponified with porcine pancreas lipase. Despite these mild conditions free dipeptide **1** was not obtained, but rather, a diastereomeric mixture of the octahydroindole arising from intramolecular 1,4-addition.

Scheme 2 shows the synthesis of dipeptide **2**, which is epimeric to **1**. Starting from cyclohexanone **7**, the protected dipeptide **16** was prepared in a reaction sequence completely analogous to that indicated in Scheme 1 and in a comparable yield.[11] The deprotonation of **7** in the presence of trimethylsilyl chloride by (*S,S*)-**8** yielded silyl enol ether **15**, epimeric to **9**, with the same selectivity. Cleavage of the Boc protecting group from **16**, followed by lipase-catalyzed saponification and reverse-phase chromatography to separate off decomposition products, yielded the dipeptide **2**, which



Scheme 1. a) **4**, *n*BuLi, THF, Me_2S, −78 °C; 0.5 equiv CuBr·Me_2S, 30 min, −40 °C; **3**, −78 °C; AcOH (**5**: 40 %, *de* > 95 %; **6**: 24 %, *de* (1,4) > 95 %, *de* (1,5) = 81 %; b) 3 atm H_2, Pd/C, ethyl acetate, 2 h (97 %); c) (*R,R*)-**8**, Me_3SiCl, THF, −78 °C, +7 (76 %); d) MeLi, THF, 0 °C; $CF_3CO_2CH_2CF_3$, −78 °C; TsN_3, NEt_3, CH_3CN, 2 h (66 %); e) PhSeCl, CH_2Cl_2, −5 °C; 3 equiv H_2O_2, pyridine, CH_2Cl_2, 1 h, 0 °C (67 %); f) $NaBH_4$, $CeCl_3$, MeOH (89 %); g) 2 equiv HCl, CH_3CN, H_2O, 2 h; saturated Na_2CO_3 solution; (*S*)-Boc-alanine, dicyclohexylcarbodiimide (DCC), hydroxybenzotriazole (HOBT), THF, 1 h (87 %); h) MnO_2, CH_2Cl_2, 6 h; chromatography on silica gel (59 %); i) CF_3CO_2H, anisole, 1 h, 0 °C; porcine pancreas lipase (Sigma: L 3126), buffer pH 7.5, 4 h.

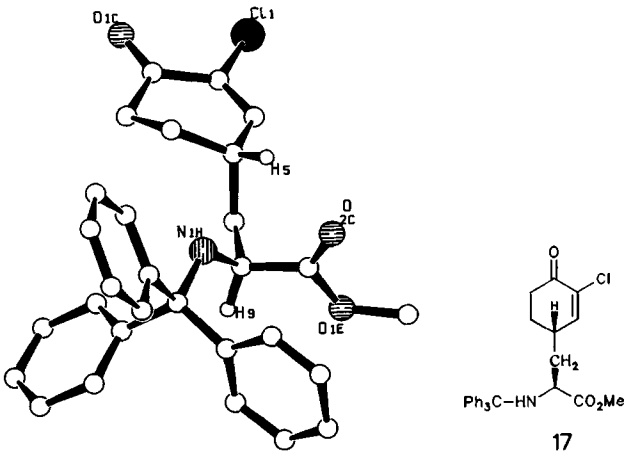
 © VCH Verlagsgesellschaft mbH, W-6940 Weinheim, 1991 0570-0833/91/1212-1686 $ 3.50+.25/0 Angew. Chem. Int. Ed. Engl. 30 (1991) No. 12



Scheme 2. a) (*S,S*)-**8**, Me_3SiCl, THF, $-78\,^{\circ}C$, $+7$ (71 %); b–f) see Scheme 1, **9** → **14**; g) CF_3CO_2H, anisole, 1 h, 0 °C; porcine pancreas lipase (Sigma: L 3126), buffer pH 7.5; purification on RP-8, Lobar with H_2O (52 %).

was in every respect (NMR, UV, DC, HPLC) identical to naturally occurring chlorotetaine.[12]

That the selective deprotonation of the cyclohexanone **7** had actually followed the expected course was demonstrated beyond question by a X-ray structure analysis of the *N*-trityl derivative **17** prepared analogously to **16** from silyl enol ether **15**. The asymmetric C atom in the cyclohexene ring of **17**, thus also in chlorotetaine **2**, was shown by this analysis to possess an (*S*)-configuration. The amino acid residue, at least in the crystal, is in the *axial* position (allylic 1,2-strain[14]). In the original determination of the configuration of chlorotetaine based on its circular dichroism (CD) spectrum, this group was presumed to be equatorial.



17

Fig. 1. Structure of **17** in the crystal (SCHAKAL representation) [13].

The higher stability of chlorotetaine **2** compared with that of epimer **1** is easy to explain: Whereas the cyclization of **1** leads to an octahydroindole with an *exo*-carboxyl substituent, the same reaction starting from **2** is made more difficult by the formation of a product with an *endo*-carboxyl residue.

Tandem Silyl Migrations Leading to α,β-Bis-silylated Enals and Enones**

By *Bernd Mergardt, Klaus Weber, Gunadi Adiwidjaja,* and *Ernst Schaumann**

Dedicated to Professor Michael Hanack on the occasion of his 60th birthday

An α-silyl residue makes α,β-unsaturated carbonyl compounds universally modifiable Michael acceptors and, at the same time, prevents any otherwise ready polymerization.[1] We report here on the productive synthesis of α,β-bis-silylated compounds by two successive mechanistically remarkable silyl migrations.

Deprotonation of the readily accessible[2] 2-alkynyl silyl ether **1** with *n*BuLi affords carbanions, which lead by 1,2-O-C-silyl migration (silyl-Wittig or retro-Brook rearrange-

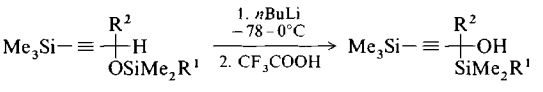
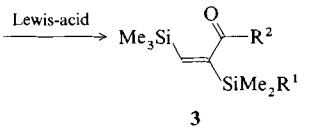
[**] This work was supported by the Fonds der Chemischen Industrie.

ment[3j]) and, when $R^2 = H$, also by 1,3-hydrogen shift to a complex equilibrium system.[4] We have now found that specific protonation to give the β-alkynols **2** silylated in the 1-position can be achieved by addition of trifluoroacetic acid at −78 °C (Table 1). This β-alkynol synthesis is comparable with the corresponding rearrangements of aryl silyl[3b] and allyl silyl ethers,[5] and in the present case leads to silyl-containing synthetic building blocks which are otherwise only accessible indirectly.[6]



1 **2**



3

a: R^1 = Me, R^2 = H; **b**: R^1 = *t*Bu, R^2 = H; **c**: R^1 = CMe_2iPr, R^2 = H; **d**: $R^1 = R^2$ = Me.

Despite their number of functional groups the bis-*C*-silylated β-alkynols **2** are storable at 0 °C, and are also stable in benzene solution. In CH_2Cl_2 as solvent, on the other hand, an internal redox reaction to the α,β-unsaturated carbonyl derivatives **3** is observed,[7] which in the case of the silyl-free parent compounds must, as a rule, be catalyzed by metal complexes.[8] In the case of **2** the reaction is accelerated by Lewis acids (about 10 mol%) and is thus of preparative interest. The conversion of **2a**–**c** into **3a**–**c** with $TiCl_4$ or $FeCl_3$ as catalyst is complete within minutes, whereas with $ZnCl_2$ as catalyst the best yields are obtained after a much longer time (≈10 h). $MgCl_2$, on the other hand, is less effective; $CeCl_3$ and also *p*-toluenesulfonic acid lead to desilylation products. **2d** is converted into **3d** upon catalysis with $TiCl_4$ or BF_3 etherate.

In all cases only one diastereomer of **3** is formed, and according to the results of an X-ray structure analysis of the derivative **5**, the C=C-moiety is (*E*)-configurated.[9]

Table 1. Yields, physical data, and selected spectroscopic data of the products obtained.

Product	Yield [a]	B.p./*p* (m.p.) [b]	IR $\tilde{\nu}$ [c]	^{1}H NMR δ(CH≡C–CH) [d]	^{13}C NMR δ(C≡C–C) [e]

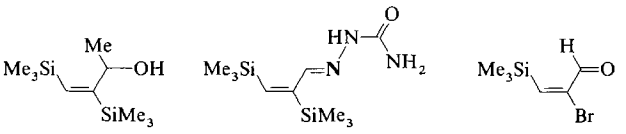
[a] Yield in [%]. [b] B.p./*p* [°C/torr]; m.p. [°C]. [c] IR spectrum recorded as film or in KBr, $\tilde{\nu}$ [cm^{-1}]. [d] ^{1}H NMR (250 MHz, C_6D_6 ≙ δ = 7.16), J [Hz]. [e] ^{13}C NMR (100 MHz, C_6D_6 ≙ δ = 128.0).

Investigations on the reaction behavior of **3** show that the carbonyl group is attacked upon reaction with methylmagnesium iodide or semicarbazide, leading to formation of **4** and **5**, respectively, whereas the α-silyl group is substituted by bromine, leading to formation of **6** (Table 1).



4 **5** **6**

Experimental

Silyl-Wittig rearrangement to **2a**–**c**: An *n*BuLi solution (2.3 M in hexane, 87 mL, 200 mmol) in tetrahydrofuran (200 mL) cooled to −78 °C was treated dropwise with **1** (200 mmol; cooled to temperatures below −50 °C). The mixture was stirred at −78 °C for 30 min and carefully neutralized with trifluoroacetic acid (15.3 mL, 200 mmol). After dilution with diethyl ether (200 mL), rapid washing with saturated NH_4Cl solution (1 ×), and with water (5 ×) for complete removal of THF, the solution was dried over $MgSO_4$ and then evaporated down in a water-jet vacuum and purified by Kugelrohr distillation, preferably in the presence of hydroquinone. The compounds **2a**–**c** are obtained as slightly yellow colored liquids (Table 1). For the preparation of **2d**, THF must be replaced by ether, and, before addition of the acid (at −78 °C), the solution must be stirred for ca. 15 h at room temperature.

Redox reaction to give **3**: A mixture of **2** (120 mmol) and $ZnCl_2$ (1.36 g, 10 mmol; for **3a**–**c**) or $TiCl_4$ (1.90 g, 10 mmol; for **3d**) in dichloromethane (120 mL) was stirred at room temperature; with **2a**–**c** as starting material, a color change from yellow to deep-brown was observed. After completion of the reaction (IR monitoring, about 10 h, see Table 1) the reaction solution was worked up and distilled as described above. Yellow colored liquids were obtained, which, after spinning band column distillation, were analytically pure.

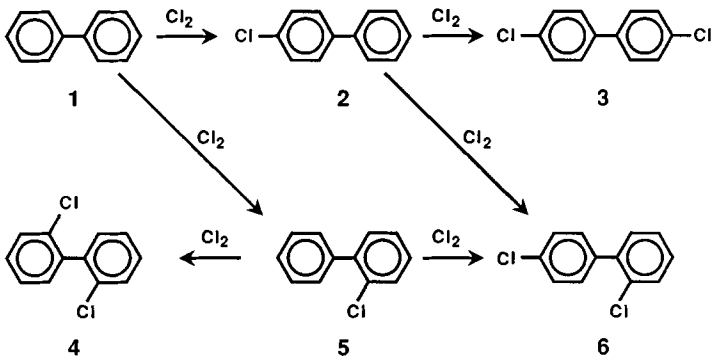
Selective *p*-Chlorination of Biphenyl in L Zeolites**

By *Artur Botta,* Hans-Josef Buysch,* and *Lothar Puppe*

Dedicated to Professor Karl Heinz Büchel on the occasion of his 60th birthday

4,4'-Dichlorobiphenyl (**3**) is regarded as an interesting precursor for high performance polymers,[1, 2] but until now a simple process by which this compound could be synthesized directly on an industrial scale was not available.[3, 4] Conventional chlorination of biphenyl (**1**) with Lewis acid catalysis (Scheme 1) gives mixtures consisting mainly of *o*- and *p*-chloro isomers **2**, **4**–**6**, from which only small amounts of the desired product **3** can be isolated, and then only by laborious procedures. For this reason only polychlorinated biphenyls (PCBs) were used industrially as insulating and hydraulic fluids until their use was recently prohibited.



Scheme 1. Products of the chlorination of biphenyl (**1**).

It was thought that certain zeolites ought to be particularly suitable as catalysts for the desired dichlorination of biphenyl in view of their shape selectivity.[5] As compared with Fe catalysis, catalysis with several types of zeolites in the chlorination of substituted benzenes such as toluene and chlorobenzene with a variety of chlorinating agents shifts the isomer ratio more[6] or less[7] markedly towards *p*-substitution. This applies particularly to zeolite L (structure type LTL).[8] Zeolite-catalyzed chlorinations of **1** have not previously been described.

Chlorinations performed initially in molten **1** with acidic and metal-exchanged zeolites of various structure and pore diameters (see the selected list in Table 1) gave higher *p*-selectivity with respect to **1** than $FeCl_3$ or acidic phyllosilicates (e.g. Tonsil K 10®) and conversions of around 100%. We achieved product selectivities initially exceeding 60% for **3** with zeolite L. As the comparison of K-zeolite L with H-zeolite L shows (Table 1), the nature of the cation plays a crucial role.[9]

The results of the chlorine substitution of **1** in the presence of variously structured zeolites, especially zeolite L, with a variety of cations suggest that a new type of selectivity occurs in the zeolite-catalyzed chlorination of aromatic hydrocarbons. The concept of geometry-related "shape selectivity"[5] cannot be applied here (zeolites of similar pore diameter but of different types behave in different ways). Rather it would appear that the ionic radius, charge, and spatial arrangement of the cations and their force fields are responsible for the activation of the Cl_2 molecule. They are the factors that actually direct the substitution.

Table 1. Product distribution [wt%] for the chlorination of **1**, neat, 100% Cl_2.

[a] Catalyst from Südchemie AG, Munich (FRG). [b] Mixed lattice. [c] 13% based on K-zeolite L.

Despite many attempts at improving the 4,4'-selectivity in the chlorination of neat **1** with K-zeolite L through the use of cocatalysts, reproducible results were achieved only with carboxylic acid derivatives.[6b, 9]. Chlorination with selectivity exceeding 80% was obtained in the particular case of chloroacetic acid (Table 1).

To investigate chlorination of **1** at lower temperatures it was necessary to use solvents. In dichloromethane (20–40 °C) with K-zeolite L as catalyst, product selectivities for **3** exceeding 90% were obtained for the first time.[10, 11, 12] Reactions in other inert solvents were not as selective. Even the use of solvents closely related to dichloromethane, for example tri- and tetrachloromethane or -ethane, reduced the conversion and also the 4,4'-selectivity below the values obtained in the neat chlorination (Table 2).

[a] 40 °C.

Dichloromethane evidently does not act simply as a diluent in the chlorination of **1**. Investigations still in progress suggest that the activation of the reactants and diffusion and transport processes in the zeolite channels[13]—the desired product **3** has poor solubility in dichloromethane—are influenced in a favorable manner. The activity- and selectivity-promoting influence of dichloromethane was found only in L zeolites. Further evidence of the favorable effect of dichloromethane, especially in chlorinations catalyzed by zeolite L are shown in Table 3.

Although H-zeolite L was unselective here, just as in neat chlorinations,[14] the alkaline and alkaline-earth metal-ex-

changed L types showed outstanding *p*-selectivity, which is demonstrated most clearly in the sum of the 4-mono and 4,4'-dichloro selectivities (see the final columns in Tables 1–3). Differences of activity (incomplete Cl_2-conversion) could be equalized by the use of approximately 10% excess chlorine. The yields of **2** and **3** were thus increased for catalysis with L zeolites with Li, Na, K, and Ag ions; however, excess chlorine had no positive effect on reactions with the H, Ca, and Zn type catalysts (Table 3). Thus optimal *p*-selectivities were obtained with L zeolites containing cations with an ionic radius of about 0.13 nm.[15] This applies not only to K, Rb, Sr, Ba, and La but also to Ag and Pb ions. The high degree of *p*-substitution in the chlorination of **1** in the presence of either Li- or Na-zeolite L (ionic radii 0.068 and 0.097 nm!)[15] does not conform to this rule, however.

Experimental Procedure

Neat process: Biphenyl (**1**) (77.1 g, 0.5 mol) was melted under N_2 in a stirring apparatus and catalyst in powder form (15 g) [16] and cocatalyst (if necessary) were added. Then, for 6 h, during which time the temperature was raised from 80 °C to 140 °C, Cl_2 (70.9 g, 1 mol) was introduced. N_2 was then passed through while stirring was continued for 30 min [17].

Solution process: Powdered catalyst [16] (15 g) was suspended in a solution of **1** (77.1 g, 0.5 mol) in dichloromethane (160 mL). Cl_2 (70.9 g, 1 mol or 78.0 g, 1.1 mol) was introduced for 6 h at 20 °C or 40 °C. Product **3** fell out of solution. Stirring was continued for 15 min, during which time N_2 was passed through [17].

[11] In analogy, *p*-terphenyl could be chlorinated with 97% selectivity to 4,4''-dichloro-*p*-terphenyl, in contrast to its *o*- and *m*-isomers.
[12] X-ray analysis of the catalyst after it had been used several times with undiminished activity showed no change.
[13] The assumption that the catalysis actually takes place inside the zeolite is supported by the fact that a sample of K-zeolite L whose external surface was sealed by trimethylsilyation also showed undiminished activity and selectivity (96%).
[14] This agrees with findings obtained for chlorination in the presence of zeolites of the Y series. The zeolites with high acidity lack *p*-selectivity [6d–e, 7].

[16] Before use all the zeolites were calcined at 400 °C for three hours (muffle furnace).
[17] The composition of the reaction mixture was determined by comparing their gas chromatograms with those of authentic samples.

Stereoselective Synthesis of Cyclic Dipeptide Hydroxyalkyl Isosteres via Metalated *N,N*-Dialkylcarbamate 2-Alkenyl Esters**

By *Rudolf Hanko*,* *Klaus Rabe*, *Robert Dally*, and *Dieter Hoppe**

Dedicated to Professor Karl Heinz Büchel on the occasion of his 60th birthday

Peptide isosteres,[1] generated by replacing an amide bond with a hydrolytically stable unit, are of increasing importance in medicinal chemistry for the development of protease inhibitors.[2] Hydroxyalkyl isosteres[3] have attracted our particular interest, because members of this group of peptide isosteres are known to be very potent inhibitors of aspartic proteases like renin[4] and HIV protease.[5] Whereas many strategies have been developed to synthesize noncyclic isosteres,[3, 6] the cyclic derivatives **1a** and **1b** (Scheme 1) have so far eluded every attempt at their stereoselective synthesis.[5, 7, 27] Here we describe the first stereoselective route to **1** via a highly diastereoselective synthesis of the key intermediates **2** and **3** and their transformation into **1a** and **1b**.

We reasoned that a retrosynthetic disconnection of **2** and **3** into amino aldehyde **A** and a homoenolate **B** should allow a highly convergent synthetic approach. Since metalated 2-alkenyl *N,N*-dialkylcarbamates are easily accessible and highly *anti*-diastereoselective synthetic equivalents[8] for homoenolates of type **B**, we examined the reaction of (1-cyclopentenyl)methyl carbamate **4** with protected amino alde-

hydes **6** (Scheme 2). The carbamate **5** (2.0 equiv.) was lithiated in ether, subjected to a metal exchange with titanium tetraisopropoxide, and then added to Cbz- or Boc-(*S*)-phenylalaninal, **6a** and **6b**,[9] respectively (Cbz = benzyloxycarbonyl, Boc = *tert*-butoxycarbonyl). In both cases, only the two expected,[10] easily separable (1 *Z*)-3,4-*anti* diastereomers[11-13] **7a** and **8a** (23 % + 50 %) or **7b** and **8b** (42 % + 50 %) were formed by stereospecific reagent-controlled addition of both enantiomers of the racemic allyl titanate.[8c].

Generation of the "Ψ-(*S*)" configuration at C-2 in dipeptide isosteres derived from precursors **7** requires a *cis* relationship of the substituents on the cyclopentane ring, which

NaOMe, MeOH 15 h at 20 °C; 4 equiv. Br_2, 20 equiv. $NaHCO_3$, MeOH/H_2O, 5 h at 0 °C → 20 °C [16]. e) LiOH, THF/MeOH. f) DMF, PPA, Et_3N [17].

is ensured by lactone formation. Mercury(II) acetate-promoted methanolysis[15] of **7a**, followed by Grieco oxidation,[15b] afforded the Cbz-protected γ-lactone **9a**[11,12] (53 %) via the corresponding lactol ethers. The sequence failed with the acid-labile Boc derivative **7b**, which was therefore subjected to a hydroboration–oxidation sequence to yield the lactone **9b**[11,12] (48 %) via the lactol. For elaboration of the (2*R*) configuration in the (3*R*, 4*R*, 5*S*) diastereomer of **8a**, a thermodynamically driven epimerization to give an appropriate *trans*-disubstituted cyclopentane was envisaged. The hydroboration of the *N*,*O*-acetonides **11a**, **b**[11,12] proceeded via reductive elimination of the carbamoyloxy group and afforded in each case an epimeric mixture of the alcohols **12a**, **b**[11,12] (Scheme 3). The epimeric aldehydes **13a**, **b** obtained by PDC oxidation each formed a single diastereomer on treatment with methanolic sodium methoxide. Aldehydes **13a** and **13b** were subjected to an oxidative esterification under the conditions worked out by *Lichtenthaler*[16] and yielded the methyl esters[11,12] **10a** and **10b** in 39 % and 50 % yield, respectively (based on **11**). Thus, the suitably protected (2*R*, 3*S*, 4*S*, 5*S*) and (2*R*, 3*R*, 4*R*, 5*S*) diastereomers **9a**, **b** and **10a**, **b** of the dipeptide

isosteres Phe-Ψ [CHOHCH]Pro are accessible from amino aldehydes **6a, b** in 12/20 % and 16/23 % overall yield; only one facile diastereomer separation is required.

The *trans* diastereomer **10a**, after transformation into the acid **14a**, was coupled with (*S*)-isoleucine benzylamide **15**[17] by PPA-coupling (PPA = propanephosphonic acid anhydride) to afford the tripeptide isostere **16** (59 %).[12]

The incorporation of the lactones **9** into peptide sequences is hampered by the pronounced tendency of bicyclic hydroxy acids like **17** to relactonize,[18] even if the hydroxyl group is silyl-protected (Scheme 4). A possible way to overcome this problem would be the Weinreb method[19] using dialkylaluminum amides as ring-opening reagents. To our knowledge, this procedure has not yet been used with amino acid derivatives **15** as amine components. Our initial attempts using lactone **9b**[20] together with (*S*)-isoleucine benzylamide (**15a**) in the presence of one equivalent of trimethylaluminum in 1,1,1-trichloroethane at 40 °C for 24 h did not lead to the desired product **18**. The unreacted starting materials were recovered in greater than 90 % yield. However, the desired product **18c**[12] is obtained in 72 % yield if excess trimethylaluminum is used (one equivalent for each acidic NH amide proton in the amino acid or the lactone moiety).

This method provides the first approach to *cis*-substituted cyclic hydroxyalkyl isosteres[7] of type **18** by ring opening of lactones **9**. Taken together with the homoaldol methodology, this approach easily affords *anti*-configurated spacers **16** and **18**. To obtain the corresponding *syn* adducts **21** and **22** as well, we developed the following efficient and stereoselective oxidation/reduction procedure (Scheme 5): Compound **18c** was readily oxidized under phase-transfer conditions[25] to yield 71 % of ketone **19**, which was reduced to the inverted isomer **21**[12] in 69 % yield by treatment with $LiBH_4$ in THF. There was no trace of **18** detectable by 300 MHz ^{1}H NMR spectroscopy or TLC. Similarly, **16** was oxidized to ketone **20** in 95 % yield. Stereoselective reduction of **20** to the epimer **22**[12] was accomplished by treatment with 3.0 equivalents of N-Selectride in THF at −40 °C for 3 h (81 % yield, no detectable trace of **16**).

This methodology thus allows the stereoselective synthesis of the four stereoisomeres **16**, **18c**, **21**, and **22** of the Phe-[CHOHCH]Pro spacer series.[12, 26] We are currently exploring the applicability of this synthetic sequence to spacers of different ring sizes and substitution patterns.

Experimental Procedure

18c: To a suspension of **9c** (102 mg, 300 μmol) in 200 μL of 1,1,1-trichloroethane (TCE) was added 150 μL of a 2 M solution of $AlMe_3$ in TCE at 20 °C. A suspension of **15** (132 mg, 600 μmol) in 150 μL of TCE in a dry reaction vessel under an atmosphere of argon was treated with 600 μL of 2 M $AlMe_3$ in TCE. The vessel was warmed to 60 °C for 1 h, then cooled to 20 °C. The lactone/$AlMe_3$ complex was added to the reaction vessel via syringe with stirring and the reaction solution was warmed to 60 °C until the lactone complex was consumed (about 4 h), The reaction was cooled to 0 °C and quenched by careful addition of AcOH (235 mg, 3.9 mmol). The resulting gel was dissolved in 20 mL of CH_2Cl_2 and washed with 10 mL of HCl solution (pH 4). The aqueous phase was extracted with 2 × 5 mL of CH_2Cl_2. The organic layers were combined and washed with 10 mL of saturated $NaHCO_3$. After evaporation of the solvent, the crude product was chromatographed on 20 cm^3 of silica gel (20 μm) with CH_2Cl_2/MeOH to yield 121 mg (72 %) of **18c**.

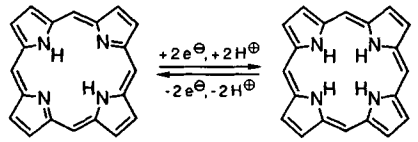
[26] The trifluoroacetyl group can be removed under the conditions described by F. Weygand, E. Frauendorfer, *Chem. Ber. 103* (1970) 2437.
[27] Note added in proof (November 9, 1991): another method based on allylsilanes was published after our manuscript had been submitted: J. V. N. V. Prasad, D. H. Rich, *Tetrahedron Lett. 32* (1991) 5857.

Isophlorins: Molecules at the Crossroads of Porphyrin and Annulene Chemistry **

By *Michael Pohl, Hans Schmickler, Johann Lex,* and *Emanuel Vogel* *

Dedicated to Professor Karl Heinz Büchel on the occasion of his 60th birthday

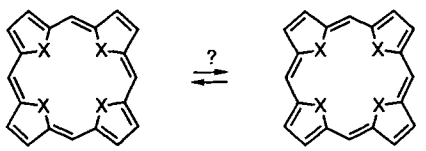
The porphyrin–isophlorin redox system, **1** ⇄ **2**, represents a challenge for porphyrin chemistry and is a prime example of the intertwined structural and chemical relationships between porphyrins and annulenes. Isophlorin (*N,N'*-dihydroporphyrin, **2**), which was discussed for the first time by *Woodward* in connection with the synthesis of chlorophyll[1] but has remained hypothetical up to now, constitutes a bridged [20]annulene with quinodimethane-like partial structures. In contrast to **1**, compound **2** very likely exhibits some deviation from planarity, since, on the basis of structural findings about protonated porphyrins,[2] the presence of four imino hydrogens should cause nonbonding H ··· H interactions in the center of the molecule.



1 *hypothetical* **2**

Recent observations on the porphycene–*N,N'*-dihydroporphycene redox system,[3] which drew our attention to **1** ⇄ **2**, support the conjecture that **2** should readily undergo aromatization to give porphyrin (**1**), either by a sequence of two-electron oxidation and deprotonation or by another pathway.[1] This may explain why isophlorins have managed to defy not only synthesis but also the elucidation of their possible biological relevance. On the other hand, dianionic metal complexes derived from isophlorins are available from the corresponding metalloporphyrins by reduction with alkali metals and have been known for some time.[4]

It occurred to us that the search for **2**, currently pursued in this laboratory, should be paralleled by efforts to obtain tetraoxa-, tetrathia-, and *N,N',N'',N'''*-tetramethylisophlorin (**3**, **4**, and **5**, respectively), taking into account the multifaceted interest [20]annulenes of the isophlorin-type command (π-bonding relationships, dependence of paratropism on geometry, components of supramolecular structures, etc.). Having recently synthesized tetraoxaisophlorin (**3**), a model for a planar [4n]annulene of high symmetry, starting from the tetraoxaporphyrin dication,[5, 6] we have now succeeded in preparing the octaethyl derivative **7** of *N,N',N'',N'''*-tetramethylisophlorin.



3: X = O
4: X = S
5: X = NCH$_3$

A promising synthetic pathway to **7**, analogous to the route to tetraoxaisophlorin (**3**), is offered by two-electron reduction—or four-electron reduction and subsequent partial reoxidation—of *Franck*'s *N,N',N'',N'''*-tetramethyloctaethylporphyrin dication[7] as its diperchlorate **6**.[8] The desired [20]annulene **7** was obtained by treatment of **6**, suspended in THF, for 30 min at −78 °C with a 0.15 molar solution of anthracene-sodium in THF (1.2-fold excess based on two-electron reduction). There was no evidence of overreduction to the potentially aromatic [20]annulene dianion. After excess reducing agent had been destroyed by oxygen, the reaction was worked up conventionally (addition of hydroquinone). Crystallization from ethanol/hexane (4:1) gave **7** as lustrous brown needles, which above 190 °C turned yellow and decomposed (yield 75 %). In contrast to the highly reactive tetraoxaisophlorin (**3**), **7** is moderately stable on exposure to air.

6 7 8

The structural assignment of **7** is based on the temperature-dependent ^{1}H NMR spectrum (Fig. 1). As indicated by the characteristic changes in line shape of the spectrum in the range from -72 °C to 104 °C, the molecule undergoes a rapid degenerate π-bond shift at room temperature in analogy to the behavior of other [4n]annulenes.[9] This dynamic process is sufficiently slow at -72 °C, so that the spectrum recorded corresponds to compound **7** with localized π bonds: a singlet at $\delta = 5.12$ (4H, *meso* H), two singlets at $\delta = 4.51$ and 3.74 (2×6H, *N*-CH_3^a and *N*-CH_3^b, respectively),[10] two quartets at $\delta = 2.63$ and 1.98 (2×8H, CH_2),[11] and two triplets at $\delta = 1.37$ and 1.00 (2×12H, CH_3). When the temperature is raised, the signal of the *meso* protons remains unchanged as expected, whereas the three pairs of signals for the protons involved in the exchange process each coalesce after initial line broadening (16 °C for *N*-CH_3). Raising the temperature still further (to 104 °C) results in the simple spectrum predicted for **7** when it undergoes rapid exchange; this consists of two singlets, one quartet, and a triplet (effective D_{2d} molecular symmetry).

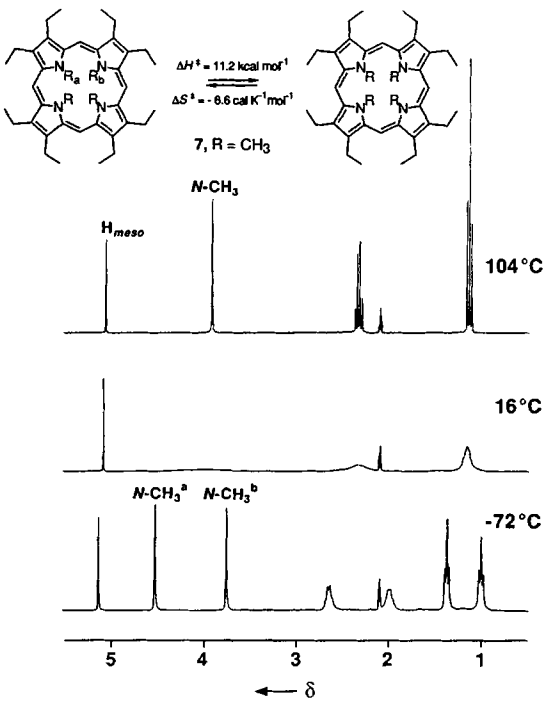

Fig. 1. Temperature dependence of the ^{1}H NMR spectrum (300 MHz, [D_8]-toluene) of **7**: -72 °C (region of slow exchange), 16 °C (coalescence range), and 104 °C (region of fast exchange).

Any discussion of the ^{1}H NMR spectrum must take into account the possible existence of stable conformers of **7** due to the spatial demands of the *N*-methyl groups. The number and kind of proton resonances reveal that **7** is present exclusively as one conformer, which must be either the all-*syn* or the *syn,anti,syn,anti* form (arrangement of the *N*-methyl groups with respect to the mean plane of the ring framework). Since **7** was obtained from **6**, which exists as the *syn,anti,syn,anti* conformer, and since conformational stability is very likely maintained in *N,N',N'',N'''*-tetramethylporphyrins even at higher temperature, **7** may also be assumed to exist as the *syn,anti,syn,anti* conformer. The notion that the π-bond shift in **7** is accompanied by a degenerate conformational change of the *N*-methyl groups that escapes detection by NMR spectroscopy is therefore unrealistic.

An X-ray structure analysis of **7**[12] established that, in the crystal, the compound is saddle-shaped with *syn, anti,syn,anti* conformation of the *N*-methyl groups (Fig. 2), as observed for its dicationic precursor **6**. However, whereas the heterocyclic five-membered rings in the aromatic **6** are equivalent, those in **7** are alternately pyrrole and pyrroline rings, as portrayed in the conventional structural formula (reduction of molecular symmetry from D_{2d} to C_{2v}). Because of the steric hindrance of the *N*-methyl groups, the pyrrole and pyrroline rings are tilted by 49° and 26°, respectively, out of the plane defined by the four *meso*-methine carbon atoms (the corresponding torsion angles C_β-C_α-C_m-C_α are 52° and 11°, respectively). The remarkably strong twisting of the pyrrole rings becomes understandable if one bears in mind that the interaction between the respective methyl groups is especially pronounced owing to the sp^2 hybridization of ni-

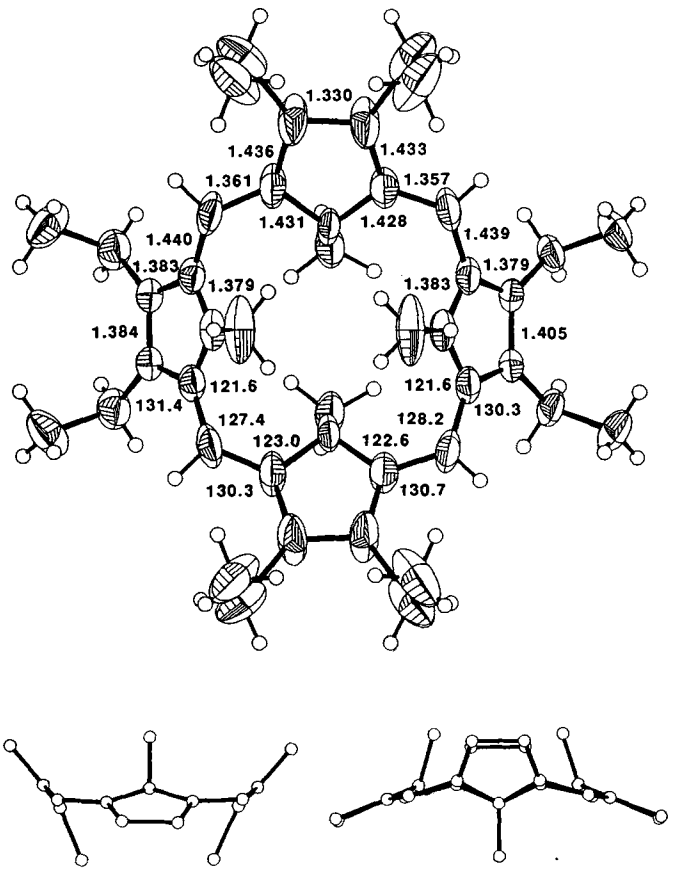

Fig. 2. Molecular structure of **7**. The molecule has approximate C_{2v} symmetry (exact C_s), as the three projections show. Above: Top view with bond lengths [Å] and angles [°]; standard deviations 0.009 Å and 0.5°. The thermal ellipsoids are drawn at 40% probability. Below: Side view (without substituents and H atoms): left, parallel to the crystallographic mirror plane; right, perpendicular to it.

trogen (the N-CH_3 bond forms an angle of only 20° with the pyrrole ring plane; sum of bond angles 356°) and the torsions only affect single bonds. In the case of the pyrroline rings, the nitrogen is sp^3-hybridized as expected (sum of bond angles 340°), since the *N*-methyl groups project by no less than 46° from the ring plane. With regard to the structural parameters of the five-membered rings, it is noteworthy that the pattern of bond lengths in the pyrrole rings does not correspond to that in porphyrins, but is comparable to that of the isolated pyrrole rings in *Franck's* *N,N',N'',N'''*-tetramethyloctakis-(carboxymethyl)porphyrinogen (N-C_α = 1.355 Å, C_α-C_β = 1.373 Å, C_β-C_β = 1.416 Å).[8]

Table 1. Dependence of the paratropism of isophlorins on geometry. ^{1}H NMR chemical shifts (δ values) of the *meso* protons in **3**, **7**, and **9** (vinylic hydrogen atoms), as well as of the *N*-CH_3 protons in **7** and **9** (each 300 MHz, [D_8]THF, −50 °C).

	3	**7**	**9**
H_{meso}	−0.30	4.95	5.32
N-CH_3^a	-	4.38	2.75
N-CH_3^b	-	3.48	1.41

The ^{1}H NMR spectrum of saddle-shaped **7**, when compared with the spectra of nearly planar tetraoxaisophlorin **3** and *N,N',N'',N'''*-tetramethyl-5,10-dihydroisophlorin (as octaethyl derivative **9**)[13] in which the cyclic conjugation is interrupted, is very informative since it reveals in a particularly striking way the dependence of paratropism of [4n]annulenes[14] on molecular geometry (Tables 1 and 2). On going from tetraoxaisophlorin (**3**) to the nitrogen compound **7**, the resonance of the *meso* protons is shifted by no less than $\Delta\delta$ = 5.3 to lower field, and thus comes close to the location of the resonances of the vinylic protons of **9**. Clearly, this shift difference indicates an almost complete geometry-induced loss of paratropism in **7**.[14, 15]

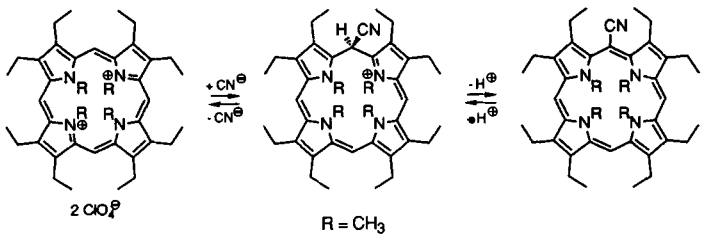
The other spectra of **7** are consistent with the properties of the compound so far determined. The ^{13}C NMR spectrum (at −60 °C) shows, complementarily to the low-temperature ^{1}H NMR spectrum, eleven signals, four of which correspond to quaternary carbon atoms. In the UV/VIS spectrum, a broad band is found at 356 nm (ε = 35000) with a shoulder at 516 nm (ε = 1440) extending beyond 700 nm. An IR band at 1601 cm^{-1} (no equivalent band in porphyrins) can, on the basis of comparisons,[4b, c, 16] be assigned with some certainty to the stretching vibration of the exocyclic C=C bonds at the α-pyrroline positions. In the mass spectrum, the molecular ion (100%) is accompanied by the doubly charged aromatic ion as a prominent peak (25%), a fact that underlines the [4n]annulene character of **7**.

Chemically, the [4n]annulene nature of **7** is reflected above all in its ready oxidizability. Even mild oxidizing agents like iodine, silver(I), and iron(III) ions transform **7** into the dication **6**, whereas bromine is necessary to convert *N,N',N'',N'''*-tetramethyloctaethylporphyrinogen into **6**.[7] On the other hand, reduction of **7** with alkali metals to give the 22 π dianion has not yet met with success,[17] even though there are precedents for the formation of nonplanar, aromatic [4n]-annulene dianions.[18] Reaction of **7** with trifluoroacetic acid in THF affords the protonation product, *N,N',N'',N'''*-tetramethyloctaethylphlorin cation **8** (Table 2), which is stable in solution and was identified by NMR spectroscopy; treatment of **8** with bases regenerates **7**.

The current discussion on the mechanism—particularly the geometry of the transition state—of the π-bond shift in cyclooctatetraenes[9b, 19] and other nonplanar 4n π-electron systems[9c, 20] prompted us to derive the activation parameters of the degenerate π-bond shift in **7** from the ^{1}H NMR spectrum (Fig. 1). To accomplish this, we recorded the spectrum at 17 temperatures from −72 °C to 104 °C[21] and calculated the rate constants by line-shape analysis of the *N*-CH_3 signals (DNMR5).[22] Evaluation of the kinetic data on the basis of the Eyring equation afforded the following parameters for the dynamic process in **7**: $\Delta H^{\neq}$ = 11.2 ± 0.2 kcal mol^{-1}, $\Delta S^{\neq}$ = − 6.6 ± 0.6 cal K^{-1} mol^{-1}, and thus $\Delta G^{\neq}_{298}$ = 13.2 kcal mol^{-1} (the error range results from the statistical standard deviation of the Eyring equation).

The saddle-shaped ring framework of the *N,N',N'',N'''*-tetramethylisophlorin **7** can accommodate a certain flattening, though not a complete planarization, if the pyrrole ring nitrogens also become pyramidalized. Accordingly, the activation energy of the π-bond shift in **7** is on the order of magnitude of that for other nonplanar [4n]annulenes, particularly that of cyclooctatetraene,[9b] whereas, in the case of the essentially planar **3**, it is so strongly lowered (< 3 kcal mol^{-1}) that its measurement verges on the limits of ^{1}H and ^{13}C NMR spectroscopy (the signal of the furanoid hydrogens in **3** remains sharp at −135 °C). A relationship to the dynamics of cyclooctatetraene appears to exist here insofar as *Ermer, Klärner*, et al. have suggested that the transition state of the π-bond shift in this annulene is not necessarily planar, but rather adopts the shape of a flattened saddle.[23] As *Paquette* et al. have convincingly demonstrated in recent investigations, it is justified for at least a number of bridged cyclooctatetraenes to assume such a nonplanar geometry in the transition state of the π-bond shift.[19] The appreciably negative activation entropy found for the double-bond shift in **7** indicates that, in the transition state of this degenerate process, degrees of freedom of internal motion are frozen by strong steric compression of the *N*-methyl groups.

Due to their chirality, singly *meso*-substituted *N,N',N'',N'''*- tetramethylisophlorins should permit the presumed conformational stability of the *N,N',N'',N'''*-tetramethylisophlorin macrocycle **7**—after separation into the enantiomers—to be reexamined. Whereas electrophilic substitutions at **7** have been unsuccessful so far, *N,N',N'',N'''*-tetramethyl-5-cyanooctaethylisophlorin (**11**) could easily be obtained starting from **6**. Reaction of **6** with sodium cyanide (excess) in ethanol (30 min) surprisingly leads not to the expected bisadducts (stereoisomeric *N,N',N'',N'''*-tetramethyl-5,10-dicyano-5,10-dihydroisophlorins), but instead to the air-stable nitrile **11** as the sole isolable product. Compound **11** was obtained, after conventional workup and crystallization from methanol, as green-black needles (m.p. 203 °C, yield 70%). Despite its lower symmetry compared with **7** (C_2 vs. C_{2v}), **11** is still able to undergo a degenerate π-bond shift, which is revealed in the corresponding temperature dependence of the NMR spectra (Table 2). It seems compelling to postulate the *N,N',N'',N'''*-tetramethylphlorin cation **10** as intermediate in the reaction of the dication **6** with cyanide ion to form **11**. That **10** would be deprotonated to **11** by cyanide ion was as unexpected as the transformation of **11** back to **6** by mineral acids.



6 **10** **11**

The resolution of **11** did not prove necessary, since in this case, in contrast to that of **7**,[11] the diastereotopic methylene protons of the ethyl groups allowed the conformational stability of the *N*,*N*′,*N*″,*N*‴-tetramethylisophlorin macrocycle to be established unequivocally by NMR spectroscopy. Apparently, the local anisotropy of the nitrile group causes the diastereotopic methylene protons of the ethyl groups in neighboring position to the *meso* substituent to appear as a well-resolved multiplet, which forms the AB part of an ABX_3 system. When the sample is heated, this group of signals shows no tendency to collapse to a simple quartet, but rather remains sharp to 175 °C (the instrumental limit of measurement). Double resonance experiments,[24] moreover, gave no evidence of energy transfer between the methylene protons. The NMR spectroscopic results indicate that the energy barrier for the conformational change of the *N*-methyl groups in the *N*,*N*′,*N*″,*N*‴-tetramethylisophlorin macrocycle is at least 25 kcal mol^{-1}. The possibility that the π-bond shift in **7** and **11** is accompanied by such a conformational process can therefore be ruled out.

Table 2. Selected physical data for **7**–**9** and **11**.

7: ^{1}H NMR (300 MHz, $C_6D_5CD_3$, −72 °C): δ = 5.12 (s, 4H, H-*meso*), 4.51 (s, 6H, *N*-CH_3^a), 3.74 (s, 6H, *N*-CH_3^b), 2.63, 1.98 (2q, 16H, CH_2), 1.37, 1.00 (2t, 24H, CH_3). ^{1}H NMR (300 MHz, $C_6D_5CD_3$, 104 °C): δ = 5.05 (s, 4H, H-*meso*), 3.91 (s, 12H, *N*-CH_3), 2.32 (q, 16H, CH_2), 1.14 (t, 24H, CH_3). ^{13}C NMR (75.5 MHz, [D$_8$]THF, −60 °C): δ = 156.04, 138.60, 128.72, 128.03, 92.72, 40.79, 36.25, 19.01, 17.89, 16.53, 15.38. MS (EI, 70 eV): *m*/*z* 592 (M^+, 100%), 296 (M^{2+}, 25%). IR (CsI): $\tilde{\nu}$ [cm^{-1}] = 3100, 2964, 2930, 2870, 1601, 1459, 1395, 1357, 1316, 1261, 1191, 1054, 980, 961, 804, 745, 698, 667, 602. UV/VIS (THF): λ_{max} [nm] (ε) = 286 (22000), 356 (35000), 387 (25000) sh, 416 (1450).

8: ^{1}H NMR (300 MHz, [D$_8$]THF, CF_3CO_2H): δ = 6.68 (s, 2H, H-10,20), 5.42 (s, 1H, H-15), 3.84 (s, 2H, H-5), 3.61, 3.26 (2s, 12H, H-21,22,23,24), 2.65 (m, 4H, H-3a,7a), 2.62 (m, 4H, H-2a,8a), 2.50 (m, 4H, H-13a,17a), 2.44 (m, 4H, H-12a, 18a), 1.22 (t, 6H, H-2b,8b), 1.18 (t, 6H, H-3b, 7b), 1.17 (t, 6H, H-12b,18b), 1.13 (t, 6H, H-13b,17b). ^{13}C NMR (75.5 MHz, [D$_8$]THF, CF_3CO_2H): δ = 166.22, 154.79, 150.14, 146.56, 140.12, 128.19, 126.83, 126.28, 114.41, 86.21, 38.96, 35.43, 22.47, 19.09, 18.59, 18.04, 17.81, 16.57, 16.17, 15.63, 14.74. UV/VIS (THF/CF_3CO_2H): λ_{max} [nm] (ε) = 276 (17000), 341 (14000), 434 (20000), 771 (830).

9: ^{1}H NMR (300 MHz, [D$_8$]THF, 20 °C): δ = 5.33 (s, 2H, H-15,20), 3.90 (br. s, 4H, H-5,10), 2.88 (s, 3H, H-22), 2.79 (s, 6H, H-21,23), 2.50 (m, 4H, H-7a,8a), 2.45 (m, 4H, H-3a,12a), 2.40 (m, 4H, H-17a,18a), 2.35 (m, 4H, H-2a,13a), 1.51 (s, 3H, H-24), 1.15 (t, 6H, H-7b,8b), 1.13 (t, 6H, H-17b,18b), 1.10 (t, 6H, H-3b,12b), 1.05 (t, 6H, H-2b,13b). ^{13}C NMR (75.5 MHz, [D$_8$]THF): δ = 151.99, 137.89, 126.95, 126.48, 125.96, 122.71, 122.11, 121.35, 87.29, 32.97, 31.73, 31.56, 22.19, 19.22, 18.80, 18.60, 18.28, 17.47, 17.27, 16.10, 15.43. MS (EI, 70 eV): *m*/*z* = 594 (M^+, 100%). IR (CsI): $\tilde{\nu}$ [cm^{-1}] = 2962, 2929, 2870, 2612, 1453, 1371, 1314, 1263, 1054, 963, 745. UV/VIS ($CHCl_3$): λ_{max} [nm] (ε) = 250 (26000), 362 (14000), 401 (14000).

11: ^{1}H NMR (300 MHz, $CDCl_3$, −59 °C): δ = 5.30, 4.92 (2s, 2H, H-10,20), 4.96 (s, 1H, H-15), 4.25, 4.08, 3.51, 3.12 (4s, 12H, H-21,22,23,24), 2.4–2.7 (m, 4H, H-3a,7a), 2.1–2.4 (m, 12H, H-2a,8a,12a, 13a,17a,18a), 1.14–1.24 (m, 6H, H-3b,7b), 1.00–1.14 (m, 18H, H-2b,8b,12b,13b,17b,18b). ^{1}H NMR (300 MHz, $CDCl_3$, 59 °C): δ = 5.15 (s, 2H, H-10,20), 4.94 (s, 1H, H-15), 3.83, 3.74 (2br.s, 12H, H-21,22,23,24), 2.5–2.8 (m, 4H, H-3a,7a), 2.2–2.4 (m, 12H, H-2a,8a,12a,13a,17a,18a), 1.25 (t, 6H, H-3b,7b), 1.14, 1.12, 1.10 (3t, 18H, H-2b,8b,12b,13b,17b,18b). ^{13}C NMR (75.5 MHz, $CDCl_3$, −59 °C): δ = 163.79, 157.13, 155.77, 148.59, 142.84, 138.56, 137.97, 135.39, 130.09, 130.02, 128.37, 128.31, 127.42, 126.88, 126.56, 123.93, 121.24, 97.44, 94.00, 92.67, 70.74, 40.75, 37.47, 35.75, 34.82, 17.2–17.9 (br.), 16.30, 15.97, 15.68, 15.50, 15.32, 15.16, 14.73. MS (EI, 70 eV): *m*/*z* = 617 (M^+, 100%), 309 (M^{2+}, 50%). IR (CsI): $\tilde{\nu}$ [cm^{-1}] = 3019, 2966, 2933, 2184, 1605, 1560, 1528, 1458, 1056, 959, 798, 685. UV/VIS (hexane): λ_{max} [nm] (ε) = 313 (21000), 376 (36000), 404 (2500).

Thomas, *Angew. Chem. 103* (1991) 1048; *Angew. Chem. Int. Ed. Engl. 30* (1991) 1024; b) cyclooctatetraene: F. A. L. Anet, *J. Am. Chem. Soc. 84* (1962) 671; J. F. M. Oth, *Pure Appl. Chem. 25* (1971) 573; c) bridged [12]annulenes: E. Vogel, H. Königshofen, K. Müllen, J. F. M. Oth, *Angew. Chem. 86* (1974) 229; *Angew. Chem. Int. Ed. Engl. 13* (1974) 281; H. Kohnz, B. Düll, K. Müllen, *ibid. 101* (1989) 1375 and *28* (1989) 1343.

[10] The assignment of *N*-CH_3^a and *N*-CH_3^b (in the region of slow exchange) was based on the fact that, in the case of **9**, the protons of the *N*-methyl group on the pyrrole nitrogen show resonance at lower field than those of the *N*-methyl group on the pyrroline nitrogen (Table 1).

[11] In **7**, the methylene protons of the ethyl groups are diastereotopic owing to the nonplanar conformation of the ring framework and thus form the AB part of an ABX_3 system; however, in toluene at lower temperature, the anticipated multiplet of the methylene protons has degenerated to a poorly resolved quartet. For the exploitation of diastereotopic methylene protons for the detection of dynamic processes by NMR spectroscopy, see K. M. Barkigia, M. D. Berber, J. Fajer, C. J. Medforth, M. W. Renner, K. M. Smith, *J. Am. Chem. Soc. 112* (1990) 8851; C. J. Medforth, M. D. Berber, K. M. Smith, J. A. Shelnutt, *Tetrahedron Lett. 31* (1990) 3719.

[12] $C_{40}H_{56}N_4$, dec. above 190 °C, crystals from acetonitrile; monoclinic space group $C2/m$, $Z = 4$; $a = 14.847(4)$, $b = 22.068(7)$, $c = 11.687(3)$ Å, $\beta = 110.10(2)°$; $\rho_{calcd} = 1.095$ g cm^{-3}; intensity measurements on a four-circle diffractometer (0 °C, $\lambda_{Mo} = 0.71069$ Å, $\theta_{Mo}(max) = 25°$); refinement (C,N anisotropic, H isotropic) taking into consideration 1397 reflections with $F_0 > 4\sigma(F_0)$, $R = 0.082$, $R_w = 0.089$ (under the conditions of measurement, the crystal slowly decomposed; further lowering of the temperature led to a phase change). Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, W-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-55802, the names of the authors, and the journal citation.

[13] The dihydro compound **9** is formed from the *N,N',N'',N'''*-tetramethyloctaethylporphyrin dication **6** by reduction with $NaBH_4$ in methanol (10 min, room temperature). Conventional workup and crystallization from hexane/ethanol affords the dihydro compound **9** as yellow rods, which decompose above 250 °C; yield 80% (see Table 2 for spectral data).

[14] A pronounced geometry dependence of the paratropism in twisted phenanthrene dianions has been demonstrated recently: R. Frim, A. Mannschreck, M. Rabinovitz, *Angew. Chem. 102* (1990) 919; *Angew. Chem. Int. Ed. Engl. 29* (1990) 919.

[15] For a discussion of ring-current effects in [4n]annulenes, see: J. A. Pople, K. G. Untch, *J. Am. Chem. Soc. 88* (1966) 4811; R. B. Mallion, *Pure Appl. Chem. 52* (1980) 1541; A. Minsky, A. Y. Meyer, M. Rabinovitz, *Tetrahedron 41* (1985) 785.

[16] A comparable band is found for *N,N',N'',N'''*-tetramethyl-5,10-dihydrooctaethylisophlorin (**9**) (Table 2).

[17] The difficulty in reducing **7** to the dianion is also borne out by cyclic voltammetry. Two irreversible reduction waves are observed at very negative potentials (−2.42 and −2.69 V vs. the saturated calomel electrode, THF, nBu$_4$NPF$_6$, 100 mVs^{-1}).

[18] [12]Annulene dianion: J. F. M. Oth, G. Schröder, *J. Chem. Soc. B 1971* 904; 1,6-methano[12]annulene dianion: J. F. M. Oth, K. Müllen, H. Königshofen, M. Mann, Y. Sakata, E. Vogel, *Angew. Chem. 86* (1974) 232; *Angew. Chem. Int. Ed. Engl. 13* (1974) 284.

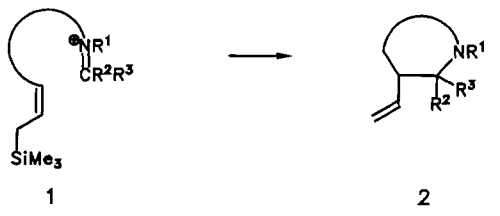
Stereoselective Synthesis of Annelated Piperidines by Photochemical Cycloaddition and Iminium Ion–Allylsilane Cyclization**

By *Lutz F. Tietze** and *Josef R. Wünsch*

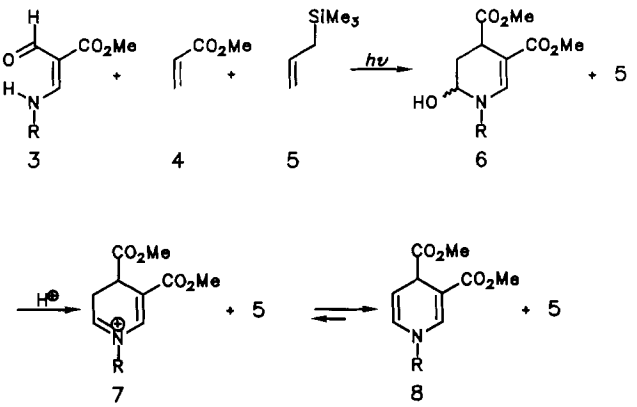
Dedicated to Professor Karl Heinz Büchel on the occasion of his 60th birthday

A general method for the synthesis of *N*-heterocycles **2** is the intramolecular cyclization of iminium ions **1**, which contain a vinyl or allylsilane group. The formation of the iminium ions **1** is usually carried out by condensation of an amine with an aldehyde or ketone, reduction of an imide, decarboxylation of α-amino acids, or cleavage of cyanide from α-amino nitriles or of amines from aminals.[1].



1 2

We have shown that iminium ions can also be formed from photochemically generated intermediates. For example, the photochemical cycloaddition of enamine carbaldehydes[2] such as **3** with alkenes such as **4** leads to 1,4-dihydropyridines **8**[3] (Scheme 1); the initially formed 2-hydroxytetrahydropyridine **6** undergoes acid-catalyzed dehydration, presumably via iminium ion **7**, to give the 1,4-dihydropyridine[4] **8**. In this communication we describe a consecutive sequence of reactions in which an iminium ion formed in this way is trapped by an allylsilane. This photochemical cycloaddition requires reactive alkenes containing an allylsilane moiety, which remains intact during the chemoselective reaction.

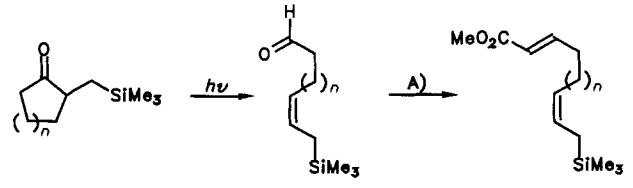


3 4 5 6 7 8

Scheme 1. **3**, **6**–**8**: R = *t*Bu (**a**), H (**b**), CH_3 (**c**), *p*-$MeOC_6H_4CH_2$ (**d**).

The investigations revealed that alkenes with electron-acceptor groups, such as **4**, undergo photochemical cycloaddition much faster than allylsilanes. Thus, irradiation of the enamine carbaldehydes **3** in the presence of a 50-fold excess of methyl acrylate (**4**) and the allylsilane **5** resulted exclusively in chemo- and regioselective formation of the 2-hydroxytetrahydropyridine **6**, which was not isolated but instead treated directly with trifluoroacetic acid to give, via **7**, the 1,4-dihydropyridine **8** in 81% yield (CH_2Cl_2, high-pressure Hg lamp, 500 W, $\lambda > 280$ nm, −40 °C, 18 h). Presumably, **3** and **4** react to form a cyclobutane system,[5] which then gives **6** via several still unknown intermediates.

For the consecutive reactions we used the configurationally uniform alkenes (2 *E*, 6 *Z*)-**13** and (2 *E*, 7 *Z*)-**14**, which are



9: $n=1$ **11**: $n=1$ **13**: $n=1$
10: $n=2$ **12**: $n=2$ **14**: $n=2$

Scheme 2. A) = Horner–Wadsworth–Emmons modification of the Wittig reaction.

[**] This work was supported by the Deutsche Forschungsgemeinschaft (SFB 93) and the Fonds der Chemischen Industrie.
J. R. Wünsch thanks the Fonds for a doctoral fellowship.

easily prepared in 63 and 88 % overall yield, respectively, by photochemical cleavage[6] of **9** and **10** to give **11** and **12**, respectively, followed by the Horner–Wadsworth–Emmons modification of the Wittig reaction[7] (Scheme 2). The configuration of the alkene involved in the photochemical cycloaddition has no influence on the stereoselectivity, because the reaction proceeds via a triplet state.[8].

The photochemical reaction of **3a–d** with a 40- to 50-fold excess of alkene **13** or **14** gives the 2-hydroxytetrahydropyridines **15b–d** or **16b–d**, respectively, which, after chromatographic separation of the excess alkene (column filtration), are transformed into the desired azabicycles **17b–d** or **18b–d**, respectively, by treatment with Brønsted or Lewis acids at −78 °C to −20 °C. The photochemical cycloaddition can also be carried out with a tenfold excess of **13** or **14** if **3a–d** is added in portions during the reaction (no product could be isolated with **3a**). The best yields (44–48 %) in the reaction of **15** were obtained when trifluoroacetic acid in CH_2Cl_2 was used; this also holds for the reaction of **16**, although, in this case, trifluoroacetic acid must be used as the solvent. However, since the esters are thereby partially solvolyzed, reesterification is necessary. This is accomplished, after removal of the trifluoroacetic acid, by refluxing the product in methanol/6 N HCl (5 mol %) for 4 h. The highest yields are obtained in the reaction of **16** (R ≠ H) with tin tetrachloride[8] as promoter in dichloromethane (Table 1).

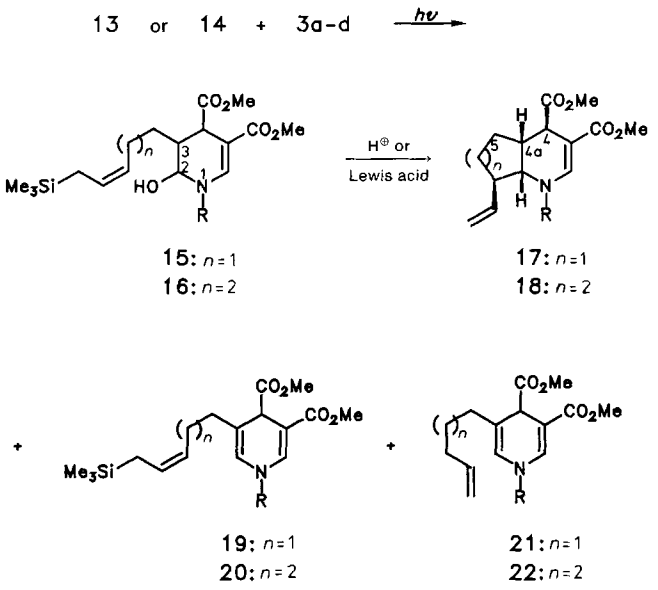

Table 1. Consecutive photochemical cycloaddition and iminium ion–allylsilane cyclization of the enamine carbaldehydes **3a–d** with the alkenes **13** and **14** to give **17** and **18**, respectively.

Enamine carbaldehyde	Alkene	Product	Promoter	Solvent	Overall yield [a]

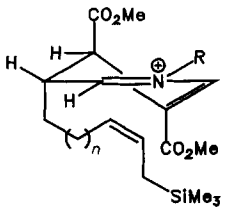
[a] Total yield **3** → **17**/**18** [%].

The 1,4-dihydropyridines **19** and **20** and their protodesilylated derivatives **21** and **22** are formed as side products (10–19 %) in all the reactions. In the presence of trifluoroacetic acid it was also possible to cyclize the 1,4-dihydropyridines **19** and **20** to **17** and **18**, respectively. As expected, the reaction of **15** and **19**, as well as of **16** and **20**, with fluoride ions did not lead to the cyclized products **17** and **18**, respectively.

The photocycloaddition–iminium ion–allylsilane sequence proceeds with high diastereoselectivity. Thus, of the eight possible diastereomers, only the configurational isomers **17** or **18** were found in each case. We presume that intramolecular attack of the allylsilane group on C-2 in the iminium ion **23** occurs *anti* to the hydrogen on C-3. This is in accord with stereoelectronic control[10] of the addition. The *trans* arrangement of the substituents in **23** arises either directly in the photochemical cycloaddition and/or via an iminium–enamine isomerization.



23

The *cis* linkage of the rings in **17** and **18** is revealed by the relatively small coupling constants of $J = 4.0–7.0$ Hz for the 4 a-H and 7 a-H signals and the 4 a-H and 8 a-H signals. The coupling of 7-H and 7 a-H, as well as of 8-H and 8 a-H, has a value of $J = 6.0–9.0$ Hz, that of 4-H and 4 a-H a value of $J = 5.5–9.0$ Hz. These values are only consistent with configurations such as those in **17** and **18**.

Experimental Procedure

A solution of enamine carbaldehyde **3** (1 mmol) and diene **13** or **14** (40–60 mmol) in 150 mL of CH_2Cl_2 was irradiated in a ring photoreactor at −40 °C with a high-pressure Hg lamp (500 W, Hanau) while a stream of argon was bubbled through the reaction solution. After complete conversion, the volatiles were removed under vacuum and the residue was separated from excess diene by flash chromatography on 50 g of basic Al_2O_3 with petroleum ether as eluent. The column was eluted with MeOH, the MeOH was completely removed under vacuum, and the residue was dissolved in 25 mL of CH_2Cl_2. The Brønsted or Lewis acid was then added to this solution at −78 °C, the solution was allowed to warm to 20 °C, the reaction was quenched with a saturated $NaHCO_3$ solution, and the product was purified on silica gel.

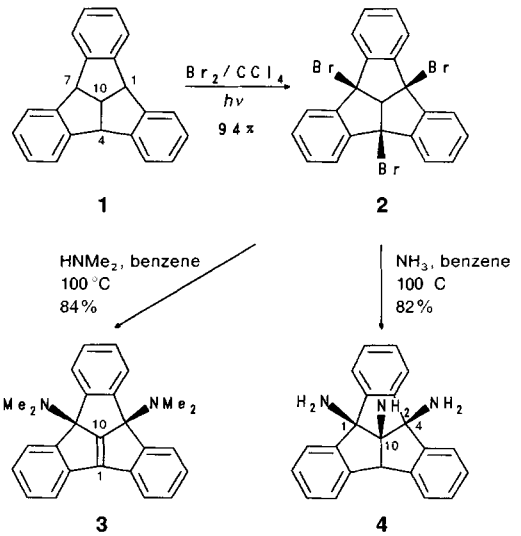
Three- and Fourfold Bridgehead-Substituted Tribenzotriquinacenes**

By *Andreas Schuster* and *Dietmar Kuck**

Dedicated to Professor Michael Hanack on the occasion of his 60th birthday

The threefold benzo-stabilized triquinacene **1**, one of the three prototypic centrotriindanes, provides, in contrast to the parent compound, an opportunity to study reactions at the four bridgehead positions through the formation of stable, well-crystallizing compounds. As we were recently able to show in collaboration with *de Meijere* et al.,[2] the threefold benzoannelation in the case of **1** also contributes considerably to the stabilization of anionic and olefinic derivatives of this system. We now present the particularly stable olefin **3**, which is readily accessible from **1** and which affords a variety of novel bridgehead-substituted tribenzotriquinacenes in some, in part, unusual reactions.

The tribenzoquinacene **1** is accessible via two routes[2, 3] and, despite its extremely poor solubility, can be converted almost quantitatively into the C_{3v} symmetrically substituted tribromo derivative **2** (Scheme 1). Aminolysis of **2** with dimethylamine affords the tribenzodihydroacepentalene **3**, also in high yields. In contrast to the analogously prepared dihydroacepentalenes,[6] crystalline **3** is absolutely air-stable—a remarkable property in view of the two strongly pyramidalized olefinic atoms C1 and C10.[7, 8] The analogous bis(trimethylsilyl) compound is likewise accessible from **1**, but is far less stable than **3**.[2, 9]



Scheme 1. Syntheses starting from tribenzotriquinacene **1**

Surprisingly, *ammonolysis* of **2** leads to the triamino compound **4** with C_s symmetric substitution. The constitution of this compound, which is also obtainable in good yields, is unequivocally confirmed by its NMR spectrum (Table 1). The 1,4,10-triamine is thus the first triquinacene with heterosubstitution at the central bridgehead to be obtained in a direct synthesis.[10, 11] Attempts to explain the unexpected reaction of **2** with ammonia by further experiments were hitherto not very successful.[12] The intermediary analogue of **3** (H instead of Me, **3'**) is, in contrast to **3**, apparently not sufficiently kinetically stabilized.[13]

Two of the reactions of **3** carried out with 1,3-dipolar agents deserve special mention, namely those with azides (Scheme 2). **3** reacts smoothly with phenyl azide to give the regioisomer **9**, a triquinacene substituted by nitrogen at all four bridgehead atoms. Presumably, steric factors are mainly responsible here for the high regioselectivity. On the other hand, with trimethylsilyl azide we could not isolate the expected cycloaddition products, despite all measures to exclude moisture. Instead the 1-azido-4,7-bis(dimethylamino) derivative **6** was obtained in good yields, once again as a well-crystallizing compound. The NMR data and thermolysis results indicate that the three outer bridgehead atoms carry substituents (Table 1);[14] conclusive chemical proof (Scheme 2) was provided by the reduction of **6** with $LiAlH_4$ to give **7**, and the subsequent methylation according to *Eschweiler* and *Clarke* to give 1,4,7-tris(dimethylamino)tribenzotriquinacene **8**, whose C_{3v} symmetric constitution unambiguously followed from the ^{1}H and ^{13}C NMR spectra (Table 1).

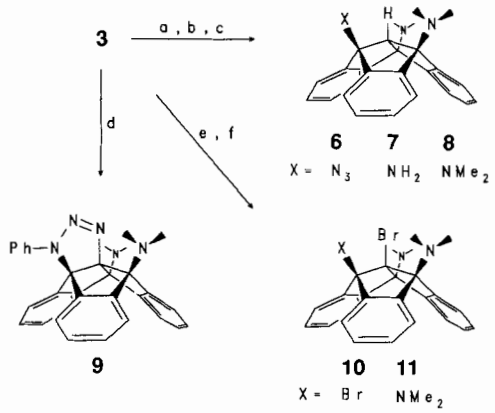
[**] Benzoannelated Centropolyquinanes, Part 10. This work was supported by the Deutsche Forschungsgemeinschaft.—Part 9: D. Kuck, A. Schuster, R. A. Krause, *J. Org. Chem. 56* (1991) 3472–3495.

A number of fourfold heterosubstituted tribenzotriquinacenes can be prepared from the olefin **3**. Thus **3** reacts at low temperatures with bromine to give the dibromide **10** (Scheme 2), which can be converted as expected with dimethylamine into the, once again, C_{3v} symmetric 10-bromo-1,4,7-tris(dimethylamino)tribenzotriquinacene **11**. All attempts at the solvolysis of the C10–Br bond have so far failed.[15]

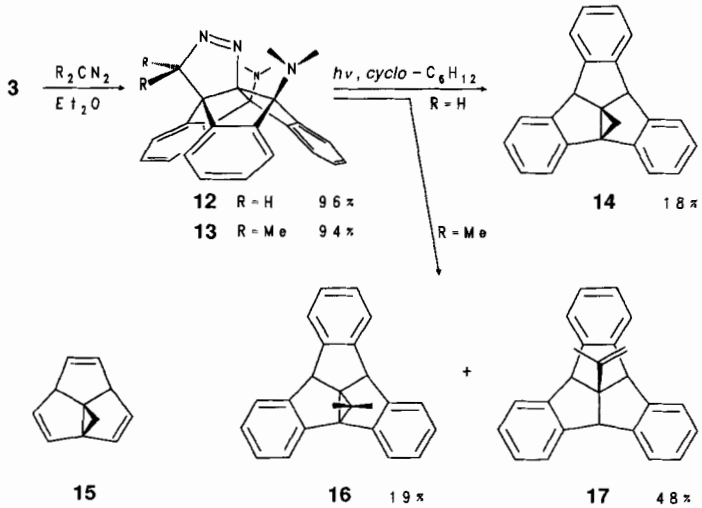


Schema 2. a) Me_3SiN_3/CH_2Cl_2, room temperature, 1 d (76 % **6**); b) $LiAlH_4$/THF, RT, 6 h (96 % **7**); c) $HCO_2H/CH_2O/H_2O$, 130 °C, 2 h (80 % **8**); d) PhN_3/CH_2Cl_2, RT, 1 d (94 % **9**); e) Br_2/CH_2Cl_2, −60 °C, addition over 6 h (85 % **10**); f) $HNMe_2/C_6H_6$, 100 °C, 1 d (54 % **11**).

Furthermore, we found an unexpected direct entry to 1,10-cyclopropa-annelated tribenzoquinacenes starting from **3**. Cyclopropatriquinacenes of type **15** are to our knowledge unknown so far; but several saturated derivatives have, however, been synthesized very recently from the dodecahedrane series.[16, 17] It therefore seemed interesting to check whether *tribenzo*triquinacene analogues are stable compounds despite the conjugation of the central cyclopropane ring with two π systems.[18]

The olefin **3** adds diazomethane and 2-diazopropane quantitatively with formation of the tetracyclic dihydropyrazoles **12** and **13**, respectively (Scheme 3). The similarly high yields and the almost identical NMR chemical shifts of the three *N*-substituted bridgehead atoms point to the same constitution of the two tetracyclic frameworks. Since considerable steric hindrance is assumed for the diazopropane adduct with a $C(CH_3)_2$ substituent on C10, **12** and **13** are assigned the structures shown, with a centro-N=N group.

Irradiation of a suspension of **12** in cyclohexane at room temperature (quartz filter) leads with complete deamination to the tetracycle **14**. Actually the product is formed in only 18 % yield, together with large amounts of polymeric material, but it can be isolated in pure form by medium pressure chromatography (MPLC) and slow crystallization. Surprisingly, it is very soluble compared to many other triben-



Scheme 3. Synthesis of cyclopropatriquinacenes.

Table 1. Physical data of selected compounds [IR(KBr), ^1H NMR ($CDCl_3$, 300 MHz), ^{13}C NMR ($CDCl_3$, 75 MHz), MS (EI, 70 eV)].

zotriquinacenes.[2-5] The ^{1}H NMR, ^{13}C NMR, and mass spectra unequivocally confirm the structure of **14** (Table 1).

Under the same conditions the diazopropane adduct **13** furnishes the tetracycle **16** in 19% yield; the main product, however, is the ring-opened 10-(propen-2-yl)tribenzotriquinacene **17**. Also these two compounds are spectroscopically unambiguously identifiable (Table 1) and like **14** are very stable in crystalline form. **17** is the first triquinacene with an unsaturated substituent on the central C atom and ought to be convertible into further, interesting C10-substituted tribenzotriquinacenes.[4, 5, 19]

The photolytic deamination of the cycloadducts **12** and **13** is surprising.[20] In the tribenzotriquinacenes this process is possibly facilitated by radicals generated in the course of the deazotization and is additionally favored by the formation of highly conjugated isoindene intermediates. Also consistent with this hypothesis is the ring-opening of **13** to give **17**.

The diaminoolefin **3** and the bridgehead-substituted tribenzotriquinacenes presented here for the first time prompt further investigations. Thus, the strictly ecliptic orientation of up to four vicinal substituents on the convex side of the molecule with the rigid triquinacene framework could lead to concerted dipolar interactions. The consequences of the particular stereochemistry of such highly functionalized spherical molecules for structure and reactivity should be studied in more detail.

Experimental Procedure for Selected Compounds

2: A suspension of tribenzotriquinacene **1** (560 mg, 2.00 mmol) in tetrachloromethane (100 mL) was treated dropwise at 50 °C with 6.00 mL of a 1.0 M solution of bromine in tetrachloromethane (6.00 mmol). The suspension was additionally irradiated with a photolamp (500 W). After very rapid uptake of the bromine (effervescence!), the solvent was removed and the yellow-brown residue recrystallized from toluene. **2** (970 mg; 94%) was obtained in the form of brownish platelets; m.p. 320–325 °C (decomp.).

3: **2** (517 mg, 1.00 mmol) was frozen in anhydrous benzene (10 mL) in a test tube (180 mm × 22 mm) containing a small stirring rod. Dimethylamine (20 mL) was condensed into the tube which was then placed in a steel autoclave (190 mm × 26 mm, Roth); the autoclave was sealed tight and the reaction mixture stirred magnetically in an oil bath at 100 °C for 20 h. After the reaction mixture cooled, the excess amine was removed and the contents of the test tube were diluted with 20 mL of dichloromethane and 20 mL of water. After extractive workup with CH_2Cl_2, drying with Na_2SO_4, and removal of the solvent, a light-brown crystalline residue was obtained, which upon recrystallization from CH_2Cl_2/MeOH afforded 305 mg (84%) of **3** in the form of colorless needles; m.p. 231 °C.

4: As described for **3**, **2** (517 mg, 1.00 mmol) was allowed to react in benzene (precooled to −40 °C) with liquid ammonia (10 mL) in a sealed tube. After workup and recrystallization from CH_2Cl_2/*n*-heptane **4** (266 mg, 82%) was obtained in the form of very fine, colorless needles; m.p. 248 °C (decomp.).

9: A solution of **3** (364 mg, 1.00 mmol) in dichloromethane (10 mL) was treated with phenyl azide (300 mg, 2.50 mmol) and the mixture stirred for 24 h at room temperature. Methanol was then added and the solution slowly evaporated down in a rotary evaporator until crystallization started. **5** (514 mg, 94%) was obtained in the form of colorless crystals; m.p. 251 °C.

10: To a solution of **3** (364 mg, 1.00 mmol) in anhydrous dichloromethane precooled to −60 °C was added dropwise a 50.0 mM solution of bromine (1.00 mmol) in dichloromethane (20 mL) over 6 h using a fine-bore dropping funnel. After warming to room temperature, the suspension was evaporated down in vacuo to a volume of 10 mL and treated with an equal amount of anhydrous ethyl acetate. The precipitated crystals were recovered by suction and recrystallized from CH_2Cl_2/EtOAc. **10** (445 mg; 85%) was obtained in the form of yellow crystals; m.p. 216 °C (decomp.).

11: Aminolysis of **10** (131 mg, 250 mmol), analogously to the reaction of **2** with dimethylamine, afforded a crude product, which, after recrystallization from CH_2Cl_2/MeOH, furnished **11** (65 mg; 54%) in the form of colorless crystals; m.p. 278 °C (decomp.).

14, **16**, and **17**: The cycloadducts **12** (m.p. 272 °C) and **13** (m.p. 330 °C) were obtained from **3** by standard methods.—Photolysis: In a falling film photoreactor (Normag, 400 mL volume, quartz glass cooling and immersion tubes, Hanau T 718Z1, 500 W mercury vapor lamp) a suspension of 500 μmol of **12** (204 mg) or **13** (217 mg) in 350 mL of cyclohexane (Uvasol, Merck) was purged of dissolved oxygen by passage of nitrogen for 10 min. After tempering to 20 °C, the photoreaction was started; after about 10 min the reaction mixture clarified, and after a further 40 min a renewed yellowish clouding was observed. Optimal yields were achieved after radiation for 90 min. The reaction mixture was evaporated to dryness in a rotary evaporator.—Isolation of **14**: The yellow residue was taken up in a little dichloromethane and filtered through silical gel. Finally, the nonpolar components (hydrocarbons) were isolated by MPLC (LiChroprep Si60, 40–60 μm, Merck, *n*-hexane/dichloromethane 4/1) as a yellow oil. Subsequent vapor-diffusion crystallization furnished up to 26 mg of **14** (18%) in the form of very fine needles; m.p. 272 °C.—Isolation of **16** and **17**: The yellow residue was taken up in a little dichloromethane and filtered with dichloromethane/*n*-hexane (1/1) through silica gel. The mixture of isomers (MS; 120 mg, 75%) was separated by MPLC with *n*-hexane/dichloromethane (5/1): 30 mg (19%) of **16** was obtained in the form of colorless crystals (m.p. 242 °C) and 76 mg (48%) of **17** as colorless needles (m.p. 161 °C).—All the new compounds gave satisfactory elemental analyses.

1,3-Dipolar Cycloaddition as the Key Reaction in the Synthesis of Potent Renin Inhibitors

By *Günter Benz,* Rolf Henning,* and *Johannes-Peter Stasch*

Dedicated to Professor Karl Heinz Büchel on the occasion of his 60th birthday

The renin–angiotensin system plays a central role in the pathogenesis of hypertension, mostly via the circulating vasoconstrictor angiotensin II. Although Angiotensin-Converting Enzyme Inhibitors (ACE Inhibitors) like captopril and enalapril[1] have already been introduced to therapy, emphasis has been directed toward renin inhibitors in recent years because of their supposedly better selectivity.[2] This increased interest has spurred synthetic work.

The most important reaction of renin is the proteolysis of the *N*-terminus of the globular protein angiotensinogen to the decapeptide angiotensin I. If the Leu-Val peptide bond in **1** cleaved in this reaction is replaced by an (*S*)-hydroxyethylene amide bond surrogate, renin inhibitors of the type **2** are obtained.[3] Because these molecules resemble the transition state for cleavage by aspartyl proteases they possess a high affinity for renin[4] but are not cleavable by the enzyme. Many renin inhibitors are rapidly degradated in vivo. This proteolysis should be hampered when the *C*-terminal amide bond is inverted. For this reason we propose renin inhibitors of the type **3** which has both modifications—the inverted peptide bond and the hydroxyethylene unit. To maintain the topology of the peptide chain the adjacent amino acid must have the D-configuration.

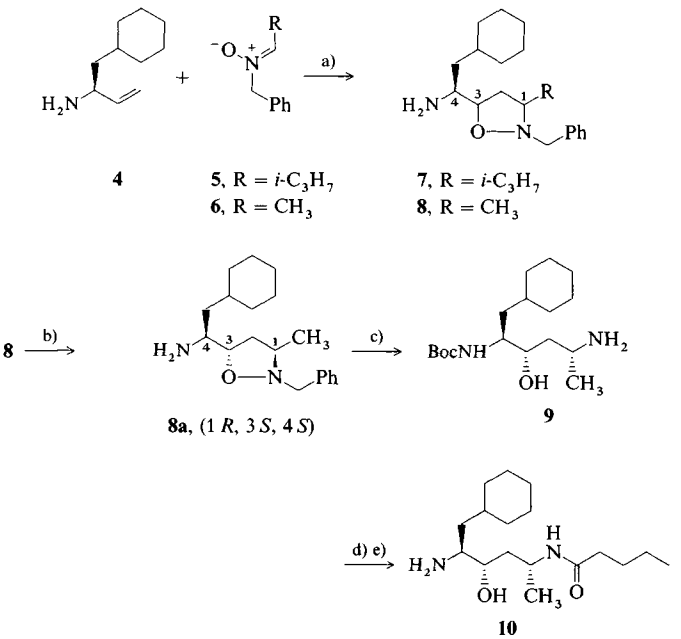
The 1,3-dipolar cycloaddition of allylamines with *N*-benzylnitrones[5] provides an easy access to this type of structure in which two stereocenters are generated early in the reaction sequence. The stereochemical course of the reaction can be influenced either by chiral nitrones[6] or by chiral allylamines.[7] The synthesis of the isoxazolidines and a potent renin inhibitor **14** is shown in Scheme 1.[8].

N-Boc-allylamine **4**[9] was prepared in four steps from *N*-Boc-phenylalanine. The subsequent reaction with benzylnitrone **5** at 140 °C in mesitylene led after 8 h to a mixture of four diastereomeric isoxazolidines **7**, in the ratio **7a** (1*R*, 3*S*, 4*S*) 0.75, **7b** (1*S*, 3*S*, 4*S*) 1.00, **7c** (1*S*, 3*R*, 4*S*) 0.60, **7d** (1*R*,



4 **5**, R = *i*-C_3H_7; **6**, R = CH_3 **7**, R = *i*-C_3H_7; **8**, R = CH_3

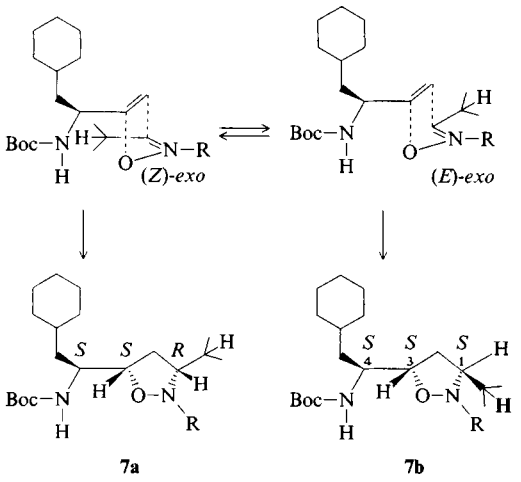
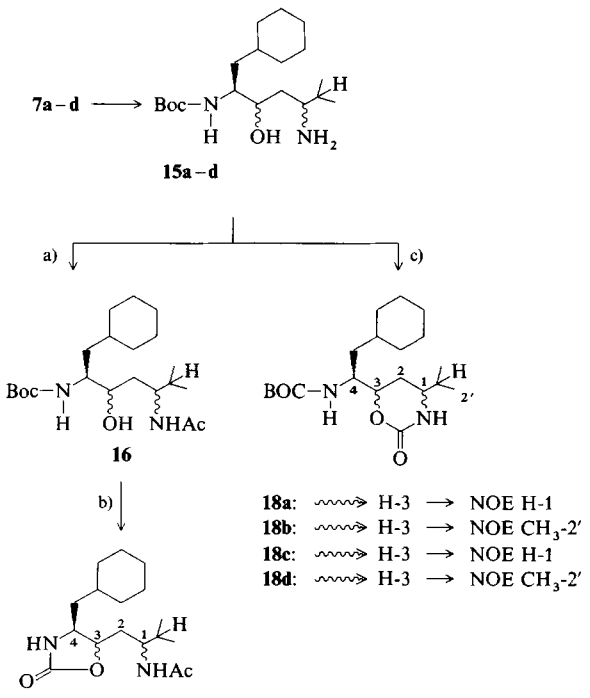


Scheme 2.

3*R*, 4*S*) 0.64 (HPLC analysis). Because of the allylic stereocenter, the attachment of the nitrone should be directed from the less hindered *Si* side. The variation of solvent (toluene, dimethoxyethane, dimethyl sulfoxide, dimethylformamide), temperature (40 °C–140 °C), and reaction time (30 min to 48 h) did not improve the stereoselectivity.

The generation of the preferred diastereomer **7b** is explained by an (*E*)-*exo* transition state (Scheme 2). The ground state *Z*-configured nitrones equilibrate to *E*-nitrones at higher temperatures[10] depending on substituents and solvent and react under kinetic control from the *exo* side. The configurations of the four diastereomers **7a–d** could be determined easily from the cyclic derivatives **17**[11] and **18** by NMR experiments (Scheme 3).



17a: $J_{3,4}$ = 5.2 Hz
17b: $J_{3,4}$ = 5.9 Hz
17c: $J_{3,4}$ = 7.2 Hz
17d: $J_{3,4}$ = 7.9 Hz

Scheme 3. a) AcOAc, CH_3OH, 20 min, room temperature; b) NaH, DMF, 60 min, room temperature; c) *N,N'*-carbonyldiimidazole, CH_2Cl_2, 60 min, *N*,*N*-dimethylaminopyridine, room temperature.

Vicinal coupling constants in **17** with values between 5 and 6 Hz suggest a 3,4-*threo* configuration (**17a,b**), between 7 and 8 Hz suggest a 3,4-*erythro* configuration (**17c,d**).[12] Based on the results of NOE NMR experiments a *trans* orientation of the substituents at C1 and C3 is proposed in oxazolones **18b,d** and a *cis* configuration in **18a,c**. From consideration of the absolute configuration at C4 (obtained from L-amino acid), the configuration of all centers C1, C3, C4 can be assigned with certainty.

With **7b** and the stereochemically identical (Cahn–Ingold–Prelog-sequence rule!) **8a** as a central intermediate, potent renin inhibitors as exemplified by **14** can be synthesized. Catalytic transfer hydrogenation on Pd/C led to the acyclic 1,3-aminoalcohol **9**, which after acylation was deprotected on the nitrogen terminus to **10**. Cyclopentylglycine **11**[13] and *N*-morpholinocarbonylphenylalanine **13**[14] were coupled under standard peptide coupling conditions. The resulting inhibitors were purified by silica gel chromatography. The renin inhibitors **19–21** were prepared by analogous routes. Their enzyme inhibitory activity against endogenous renin from human plasma[15] is shown in Table 1.

Table 1. Human plasma renin inhibition of selected renin inhibitors. For IC_{50} value see [15].

Structure	IC_{50} [nmol L^{-1}]

 **14**	1.3

Experimental Procedure

7: In a three-necked 3 L flask equipped with a mechanical stirrer and a water separator *N*-Boc-allylamine **4** (202.4 g, 0.8 mol) was dissolved in mesitylene (1 L) and heated to 140 °C. At this temperature a mixture of *N*-benzylhydroxylamine (197 g, 1.6 mol) and 2-methylpropanal (115.2 g, 1.6 mol) in mesitylene (800 mL) was slowly added over 2 h. After 4 h the same amounts of *N*-benzylhydroxylamine, 2-methylpropanal, and mesitylene were added. After 4 h the solvent was evaporated. The residue was dissolved in diethyl ether and washed with 1 M $KHSO_4$ solution. The mixture of the diastereomers was purified on silica gel [eluent: *n*-hexane/diethyl ether (7:3)]. A second chromatographic separation provided the pure diastereomers: **7a** (34 g), **7b** (69 g), **7c** (10 g), **7d** (11 g), and 44 g mixed fractions. Total yield: 168 g (52.2%).

[15] Human plasma renin inhibition assay: Human plasma was stored at −20 °C after the addition of ethylenediaminetetraacetic acid (EDTA) as anticoagulant. The plasma renin activity (PRA) was determined as the rate of formation of angiotensin I from endogenous angiotensinogen and renin after incubation at 37 °C. The reaction solution contained 150 μL of plasma, 3 μL of 6.6% 8-hydroxyquinoline sulfate solution, 3 μL of 10% dimercaprol (2,3-dimercapto-1-propanol) solution, and 144 μL of sodium phosphate buffer (0.2 M; 0.1% EDTA; pH 5.6) with or without the test substances in various concentrations. The angiotensin I formed per time unit was determined with a radioimmunoassay (Sorin Biomedica, Italy). The percentage inhibition of plasma renin activity was calculated by comparison of the amount of angiotensin I with and without inhibitor.

A New Approach to 2-Equivalent Couplers for Color Photography

By *Peter Bergthaller*

Dedicated to Professor Karl Heinz Büchel on the occasion of his 60th birthday

Materials for today's color photography, which function almost exclusively according to the Fischer principle of chromogenic coupling (Scheme 1),[1] are increasingly produced using 2-equivalent couplers **1**. In contrast to 4-equivalent couplers **2**, 2-equivalent couplers consume two rather than four equivalents of silver halide[2] per dye molecule formed, which explains our economic motivation in this research.

[*] Dr. P. Bergthaller

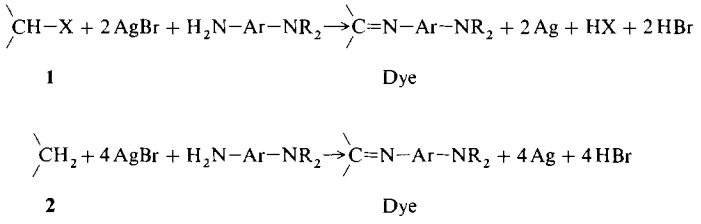
The anions of diazoles and triazoles, cyclic dicarboximides, hydantoins, and phenols are classic nucleophilic leaving groups $X^{\ominus}$. They raise the acidity of the couplers and affect the kinetics of the coupling process. The leaving groups HX which have been split off can behave in two ways, being either photographically inert or intervening in the photographic process. They can, for example, deactivate existing development nuclei or produce new development nuclei, as a result of their redox or ligand properties. These photographic effects[3, 4] as well as their greater color yield make 2-equivalent couplers indispensable for modern color film.



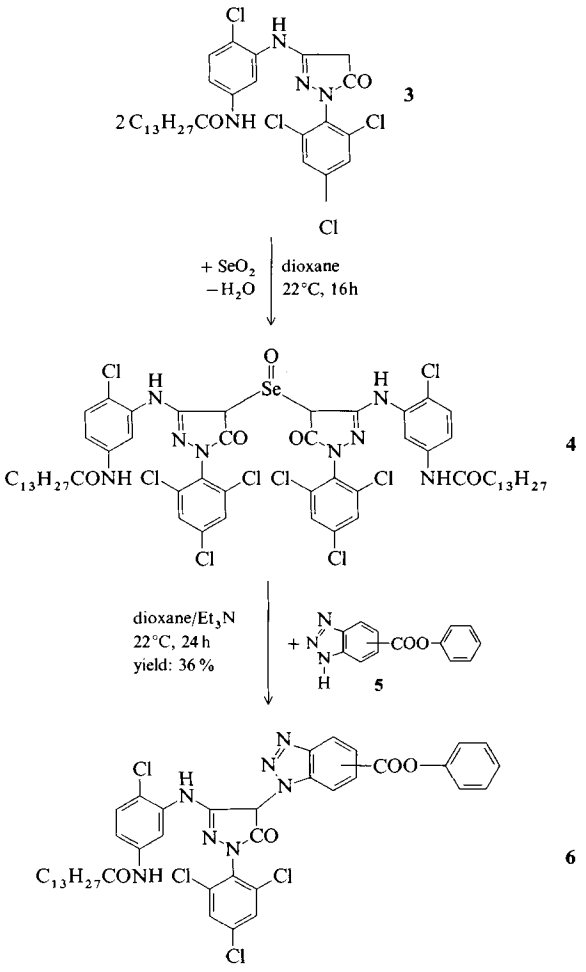
Scheme 1. Chromogenic coupling (Ar = aryl).

Both photographic and synthetic factors must be taken into account when choosing the optimum leaving group. The prerequisite for the linking of the 4-equivalent coupler and leaving group—both are nucleophiles—is that one of them can be converted into an electrophile. The introduction of the leaving group as an electrophile is only possible in thiol leaving groups by way of sulfenylation. N and O leaving groups cannot be introduced into the synthesis as electrophiles. For the acylacetanilides used as yellow couplers, this linkage problem can be solved by introducing a halogen atom into the coupling position. α-Chloro- and α-bromoacylacetanilides easily exchange the halogen atom for O or N nucleophiles under suitable reaction conditions.

This *umpolung* is no longer possible for the industrially used magenta couplers of the pyrazolone and pyrazoloazole classes. After introduction of a halogen atom the coupling position remains strongly nucleophilic. Thus, bromination continues in the case of the anilinopyrazolone **3** to the 4,4′-dibromo compound. Dihalogen-substituted pyrazolones are base-sensitive, however, and disintegrate with ring fission on contact with strong bases.[5] When attacked by basic nucleophiles, monohalogen pyrazolones easily disproportionate. Only with *N*-acyl protecting groups may they be converted to weak C-electrophiles.[6] In the cyan couplers from the phenol and naphthol classes, nucleophilic substitution of the chemically inert, aromatically bonded halogen at the coupling position by an imidazole or triazole residue is not at all possible.

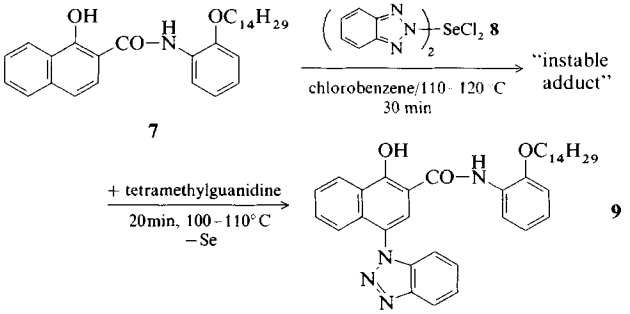
In our attempts to find a preparative method for the direct bonding of 4-equivalent couplers with leaving groups from the classes of 1,2,3-triazoles, 1,2,4-triazoles, or benzotriazoles, we chose leaving groups which could be introduced as electrophiles. In the chemistry of the yellow couplers, this function is optimally fulfilled by Cl and Br. Lead(IV) acetate is a classic reagent for the *umpolung* of a C-nucleophile,[7] but its use in the introduction of leaving groups is greatly restricted due to its strong oxidizing effect. With suitable phenols, for example, it forms quinol acetates which trap nucleophiles, mainly by Michael addition, thus not directing them to the coupling position.[8] Iodophenyl chloride and 2-iodosobenzoic acid[9, 10] are unsuitable *umpolung* reagents for reasons of stability.

We found a preparatively useful system of reagents in the selenium(IV) compounds.[11] A predecessor to our reaction possibly operating on a principle of its own, is the reaction of acetophenones with seleninyl chloride,[12] in which isolable diphenacylselenium dichlorides are formed, which thermally dissociate to phenacyl chlorides[13] with selenium extrusion. This reaction cannot generally be applied to color couplers because seleninyl chloride is also a chlorinating agent. The selenium bromides, for example aryl selenyl bromides, aryl selenium tribromides, and diaryl selenium bromides, are also primarily brominating agents.



In contrast, the Lewis acids selenium dioxide and ditosylselenium diimine,[14] both difunctional electrophiles, attack highly reactive couplers, such as 3-anilinopyrazolone **3**. The hardly soluble and surprisingly stable primary product **4** (a bispyrazolyl selenium oxide according to elementary analysis) can itself be attacked by bases and adds the anions of benzotriazoles **5** in aprotic media. The dark red solution of the anions of **4** and **5** precipitates selenium while forming the 2-equivalent coupler **6** and yet unidentified by-products. Of two coupler molecules used, only one is converted to the desired 2-equivalent coupler. We have not yet established whether the fission of the adduct occurs as nucleophilic substitution with emission of a selenenate ion, which can itself disproportionate to elemental selenium, or as genuine extrusion. Direct substitution of the selenium oxide group by the triazolide ion can also not be ruled out.

Related experiments with the cyan coupler **7** from the class of 1-naphthol-2-carboxylic acid anilides were successful only with more active selenylation reagents. The course of the reaction could not be explained due to the instability of the intermediate stages. For example, when $SeCl_4$ is heated in chlorobenzene with *N*-trimethylsilyl-benzotriazoles at a molar ratio of 1:2, a nonuniform Se^{IV}-benzotriazolide **8** forms, which still demonstrates Lewis acid characteristics and forms a number of products with the cyan coupler, including an adduct of unknown structure. This adduct disintegrates



when attacked by the strong base tetramethylguanidine, releasing the 2-equivalent coupler **9**.

Experimental Procedure

6: To 6.14 g (10 mmol) commercial magenta coupler **3** in 100 mL dioxane was added 0.6 g (5.5 mmol) SeO_2 with stirring. The flask was sealed and agitated 6 h at 22 °C. The resultant dark green suspension of **4** was treated with 2.71 g (10 mmol) **5** and 5 mL triethylamine, and agitated further in a sealed flask. Within 3 h **4** had dissolved and the reaction mixture turned red. After 24 h the selenium was removed by filtration. The filtrate was concentrated under reduced pressure and then stirred with 25 mL acetic acid. Unreacted **5** was thus converted into the poorly soluble acetate and removed by filtration. The filtrate was concentrated under reduced pressure, recrystallized from 15 mL acetonitrile, and purified by column chromatography on 300 g silica gel (eluent: toluene/acetone gradient with increasing polarity). The polar fractions were stirred with acetonitrile, yielding 3.15 g **6** as gray crystals (m.p. = 145–150 °C). The thin-layer chromatogram shows **6** to be a mixture of two clearly separated isomers (eluent: toluene/ethylacetate/propanol/methanol 10:6:3:1; R_f values: 0.30 and 0.37). IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 2920, 2850 (C–H), 1745 (C=O) ^{1}H NMR (200 MHz, [D_6] dimethyl sulfoxide, TMS): δ = 9.73 (2s), 8.87 (s), 8.08–8.4 (m, 2 H), 7.69–7.82 (m), 7.1–7.53 (m), 3.85 (s), 2.1–2.3 (2t, CH_2), 1.5–1.6 (2t, CH_2), 1.15–1.33 (m, CH_2), 0.82–0.9 (t, CH_3).

9: 1.92 g *N*-trimethylsilylbenzotriazole (10 mmol) and 1.1 g selenium tetrachloride (5 mmol) were heated at reflux in 20 mL dry chlorobenzene until the selenium tetrachloride dissolved. Then 4.71 g (10 mmol) **7** prepared by melting phenyl 1-naphthol-2-carboxylate with 2-aminophenyltetradecylether at 140 °C was added to the brown solution while stirring. The initially purple suspension turned brown and was heated at 115–120 °C for a further 30 min. After the addition of 1.6 mL 1,1,3,3-tetramethylguanidine, the reaction mixture was cooled and taken up in 200 mL ethyl acetate. 0.25 g Gray selenium was removed by filtration. The filtrate was washed with 100 mL water and 2 mL 35 % HCl, dried, and concentrated with a rotary evaporator. The residue was purified by column chromatography (70 g silica gel; eluent: cyclohexane with increasing toluene component). The polar fractions were concentrated and stirred with cyclohexane, providing 0.2 g **9** (m.p. = 110–112 °C from cyclohexane). IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 3440 (N–H) 2920, 2850 (C–H), 1645 (C=O), 1550, 760, 742 (C=C). ^{1}H NMR (200 MHz, $CDCl_3$, TMS): δ = 14.06 (s, OH), 8.79 (s, NH), 8.6–8.66 (d, CH), 8.38–8.45 (d, CH), 8.2–8.26 (d, CH), 6.86–7.71 (m, CH), 4.0 (t, CH_2), 1.84 (m, CH_2), 1.0–1.24 (m, CH_2) 0.9 (t, CH_3).

The Synthesis of the First Decametal Nitrido Cluster; X-Ray Structure Analysis and ^{14}N NMR Studies of $[(Ph_3P)_2N][Ru_{10}N(CO)_{24}]$**

By *Philip J. Bailey, Gráinne C. Conole, Brain F. G. Johnson, Jack Lewis,* Mary McPartlin,* Adrian Moule,* and *Della A. Wilkinson*

The chemistry of nitrido-metal clusters is of widespread interest because it provides model systems for study of the species formed during chemisorption of nitrogen and nitrogen compounds on bulk metal surfaces during heterogeneous catalysis.[1] Although several large nitrido clusters of cobalt and rhodium have been reported,[2] the synthesis of high-nuclearity nitrido-metal carbonyls of the iron triad has proved difficult because of the ease with which the CO ligands undergo scission to generate contaminating carbido analogues from which separation of the nitride is very difficult. We now report that the first decametal nitrido species, the monoanion $[Ru_{10}N(CO)_{24}]^-$ (**1**), has been isolated cleanly from redox condensation of the hexanuclear nitrido cluster $[Ru_6N(CO)_{16}]^-$ (**2**) with $[Ru_3(CO)_{12}]$ **3**. X-ray studies confirm that the $[Ru_6N]$ unit has remained intact, giving a nitrido cluster with the tetracapped octahedral metal framework previously only known for carbido or hydrido species.[3-5]

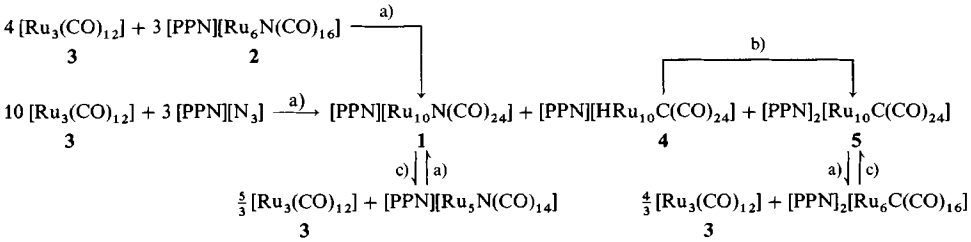
Our first synthesis of the the decanuclear nitrido monoanion **1** involved direct reaction of stoichiometric amounts of the azide salt $[(Ph_3P)_2N][N_3]$ with the triruthenium cluster **3** in diglyme under reflux at 162 °C (Scheme 1). This route gave moderate yields of **1** but proved unsatisfactory because it also gave significant quantities of the carbido monoanion $[HRu_{10}C(CO)_{24}]^-$ (**4**), from which the nitride could not readily be separated by chromatography, together with the carbido dianion $[Ru_{10}C(CO)_{24}]^{2-}$ (**5**). Deprotonation of the hydride **4** to to the dianion **5** followed by TLC enabled separation of the nitride **1**, but there always remained a weak hydride signal in the ^1H NMR spectrum, indicating residual traces of contamination by **4**.

The recent[4] report of the synthesis of the decaruthenium carbido dianion **5** by redox condensation of the interstitial carbido dianion $[Ru_6C(CO)_{16}]^{2-}$ with $[Ru_3(CO)_{12}]$ (**3**) prompted a new approach to the synthesis of the nitride $[Ru_{10}N(CO)_{24}]^-$ (**1**). The direct buildup of the decanuclear species from the known[6] preformed nitrogen-centered octahedral cluster $[Ru_6N(CO)_{16}]^-$ (**2**) on reaction with **3**, as shown in the Scheme 1, has now given **1** in good yield free from carbide contamination.

Single-crystal X-ray structure analysis of the $[(Ph_3P)_2N]^+$ salt of the nitride **1**[7] established its tetracapped octahedral framework (Fig. 1). The overall structure is almost indistinguishable from that observed in X-ray studies of the formally isoelectronic carbido monohydride $[HRu_{10}C(CO)_{24}]^-$ (**4**),[2] and there are no significant differences in lengths between equivalent bonds in the two isomorphous compounds. Initial evidence that the monoanion **1** was the nitride was based mainly on the nature of the synthetic route, and evidence from the X-ray study was consistent with this because refinement of the central atom as carbon, instead of nitrogen, led to an improbably low value for its thermal parameter.

Unequivocal confirmation of the presence of an interstitial nitride was obtained from the ^{14}N NMR spectrum[8] of $[(Ph_3P)_2N][Ru_{10}N(CO)_{24}]$, which consits of a singlet at $\delta = 410$, assigned to the nitride, and a second singlet at $\delta = 310$ due to the nitrogen atom of the counterion. The low-frequency shift of the interstitial nitride resonance, relative to that $[Ru_6N(CO)_{16}]^-$ (**2**) ($\delta = 538$),[6] follows a similar trend to that observed in the ^{13}C NMR spectra of the analogous carbido species $[Ru_{10}C(CO)_{24}]^{2-}$ ($\delta = 362$)[5] and $[Ru_6C(CO)_{16}]^{2-}$ ($\delta = 461.2$).[9]

Reaction of **1** with carbon monoxide (1 atm, 20 °C in CH_2Cl_2) results in quantitative conversion to $[Ru_5N(CO)_{14}]^-$ and $[Ru_3(CO)_{12}]$ (**3**) within five minutes (Scheme 1). It has previously been established that the precursor hexaruthenium nitride decomposes to these species in the presence of excess CO,[6] so it seems probable that $[Ru_6N(CO)_{16}]^-$ (**2**) is an intermediate in the decomposition to the pentanuclear species and that the synthesis of **1** is therefore reversible. Prompted by this, we subjected the decaruthenium analogue $[Ru_{10}C(CO)_{24}]^{2-}$ (**5**) to carbon monoxide under the same mild conditions and found that it also is completely degraded, giving $[Ru_6C(CO)_{16}]^{2-}$ and **3**; thus, the synthesis of **5** is also reversible. That the degradation of the decaruthenium



Scheme 1. a) Diglyme, 162 °C, 3 h. The decaruthenium clusters were obtained in variable proportions from this reaction. The origin of the hydrido ligand is unknown, but is assumed to be due to traces of water in the solvent. b) Diazobicyclo[5.4.0]undec-7-ene (DBU), CH_2Cl_2, 5 min. c) CO, 1 atm, 5 min, CH_2Cl_2. PPN = $[(Ph_3P)_2N]^+$.

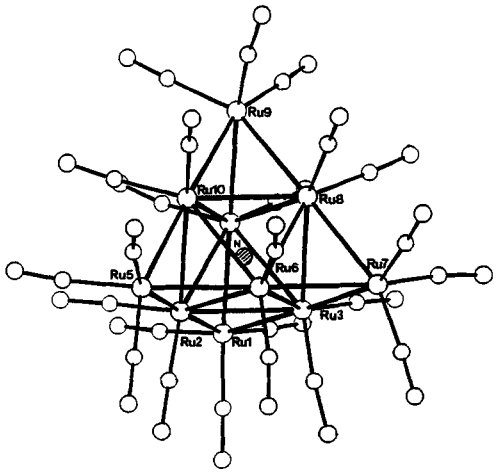

Fig. 1 Structure of the nitrido monoanion $[Ru_{10}N(CO)_{24}]^-$ (**1**). Principal Ru–Ru distances [Å] (maximum standard deviation 0.005 Å): Ru2-Ru3 2.884, Ru2-Ru4 2.854, Ru2-Ru6 2.849, Ru2-Ru10 2.845, Ru3-Ru4 2.846, Ru3-Ru6 2.855, Ru3-Ru8 2.862, Ru4-Ru8 2.864, Ru4-Ru10 2.861, Ru6-Ru8 2.855, Ru6-Ru10 2.856, Ru8-Ru10 2.842, Ru1-Ru2 2.761, Ru1-Ru3 2.790, Ru1-Ru4 2.767, Ru5-Ru2 2.789, Ru5-Ru6 2.774, Ru5-Ru10 2.791, Ru7-Ru3 2.773, Ru7-Ru6 2.778, Ru7-Ru8 2.781, Ru9-Ru4 2.780, Ru9-Ru8 2.787, Ru9-Ru10 2.783. Selected bond ranges Ru–C (carbonyl): 1.70–1.90(5), C-O 1.12–1.28(5), Ru-N (nitrido) 1.97(3)–2.08(2) Å.

carbide **5** does not continue to the pentanuclear stage is evidence of the superior ability of carbido ligands, compared to nitride, to maintain the integrity of a cluster, and it is relevant that severe conditions (90 atm, 100 °C) are required for the conversion of $[Ru_6C(CO)_{17}]$ to $[Ru_5C(CO)_{15}]$.[10] The behavior of these decaruthenium species is in marked contrast to that of the decaosmium cluster $[Os_{10}C(CO)_{24}]^{2-}$, with resists degradation by CO even under extreme conditions.[11]

The reaction of an interstitial hexaruthenium species with **3** has not proved to be generally applicable as a route to tetracapped octahedral clusters, as we have shown that reaction of the octahedral cluster hydride $[Ru_6H(CO)_{18}]^-$ with **3** gives $[H_2Ru_{10}(CO)_{25}]^{2-}$, which has a unique structure based on the capping of a polyhedron by fusion of an octahedron with a square pyramid, a structure which probably reflects the necessity of accommodating a further carbonyl ligand on the cluster surface, both this structure and the tetracapped octahedron having the same polyhedral electron count of 134.[12]

Dilithiation of a Primary Amine: Synthesis and Structure of $[(\alpha\text{-Naphthyl-NLi}_2)_{10}(Et_2O)_6] \cdot Et_2O$, a Paramagnetic Li_{20} Aggregate**

By *David R. Armstrong, Donald Barr, William Clegg, Simon R. Drake, Richard J. Singer, Ronald Snaith,* Dietmar Stalke,* and *Dominic S. Wright*

Lithium amides $(RR'NLi)_n$ and their complexes $(RR'NLi \cdot xL)_n$ (L = Lewis base) are valuable deprotonating reagents in organic synthesis.[1] Many such reagents have been structurally characterized not only in the solid state[2] but also in solution (where they operate) chiefly by ^{6}Li, ^{7}Li, and ^{15}N NMR spectroscopy.[2b, 3] However, all this effort has centered on *N*-monolithiated species usually derived from secondary amines RR'NH with R, R' ≠ H (exceptions are $[2,4,6\text{-}tBu_3C_6H_2N(H)Li(OEt_2)]_2$[4a] and $[mesityl_2BN(H)Li(OEt_2)]_2$[4b]). Here we describe the first full investigation of the dilithiation of a primary amine, 1-aminonaphthalene, by *n*-butyllithium in diethyl ether. The high-yielding, crystalline product **1** of this reaction is paramagnetic. Its main structural element is an $N_{10}Li_{14}$ central cluster, to which six $[Li(Et_2O)]^+$ units are attached by coordination to the N atoms.

$[(1\text{-}C_{10}H_7NLi_2)_{10}(Et_2O)_6] \cdot Et_2O$ **1**

Ab initio MO calculations (3-21G basis set) were conducted to probe the possibilities in the dilithiation of naphthylamine. Three types of products were examined

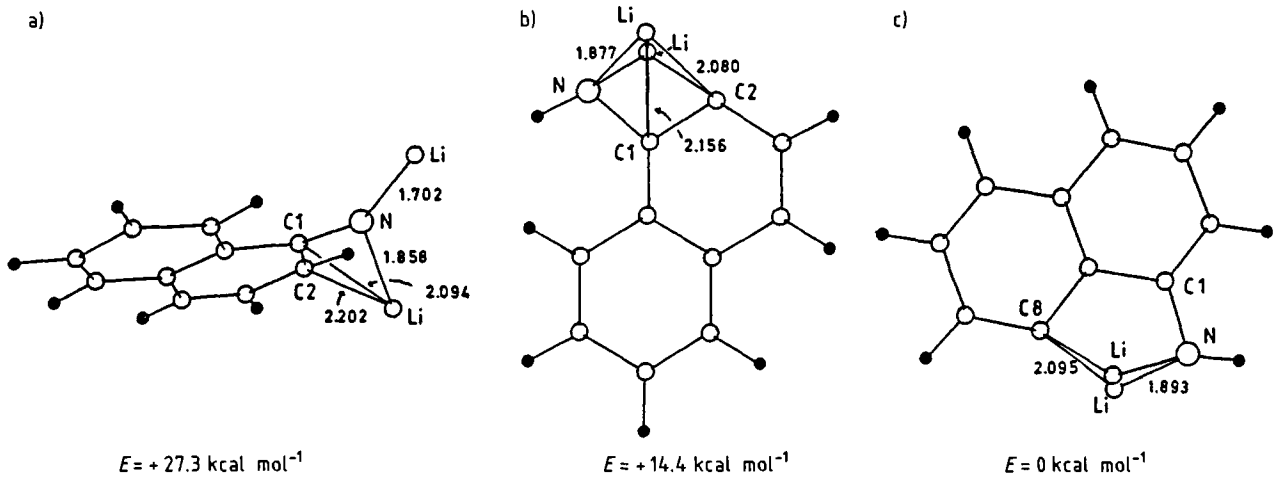

Fig. 1. Ab initio optimized geometries of the isomers of dilithiated α-naphthylamine. The most stable structures for the a) *N,N*-, b) *N,C*2-, and c) *N, C*8-dilithiated species (distances in Å). The ab initio optimized geometries described were obtained from the computer program GAMESS[8] using the 3-21 G basis set [9]. The absolute energies calculated for the optimized structures of dilithiated naphthylamine are −449.593006, −449.613554, −449.636457 Hartree.

resulting from *N,N*-dilithiation, *N*- and *C*2-dilithiation (*ortho*), and *N*- and *C*8-dilithiation (*peri*). For each of these Li_2 products several starting geometries were optimized without symmetry restrictions. Figure 1 illustrates the most stable optimized structure found for each type and notes their relative energies. The least stable structure (Figure 1a) displays *N,N*-dilithiation; here one Li atom also interacts with C1 and C2 while the other Li atom is bonded only to N. The product of *N*-, *C*2-dilithiation is more stable; in it, each Li atom is coordinated to N, C1, and C2 on opposite faces of the naphthyl ring (Figure 1b). The most stable structure found has *N*-, *C*8-dilithiation (Figure 1c), in which two Li atoms bridge N and C8. These initial calculations imply that dilithiation of a primary amine RNH_2 could well afford an N–Li/C–Li rather than an N–Li_2 species. This conclusion is not restricted to aromatic amines. Calculations for the products of the dilithiation of vinylamine $H_2C{=}CH{-}NH_2$ (at the higher 6-31G level, again without symmetry constraints) conclude that the most stable structure is CHLi=CH–NLi, in which both Li atoms bridge N and C2 above and below the nearly planar C=C–N moiety. The lowest energy structure of $CH_2{=}CH{-}NLi_2$, in which one Li atom bridges the CC double bond and the other is bound terminally on N, is 6.8 kcal mol^{-1} less stable. However, it must be stressed that all such calculations relate to isolated, monomeric molecules free of donating solvent interactions.

The dilithiated compound **1** was isolated as yellow cubic crystals. Its IR spectrum (Nujol mull) fails to reveal ν(N–H) stretches. These bands, which are strong in the spectrum of 1-$C_{10}H_7NH_2$ (at 3340, 3220 cm^{-1}), reappear on the slightest exposure of **1** to air (along with a ν(O–H) stretch at 3680 cm^{-1} for LiOH); **1** also turns black on contact with air. The ^{1}H NMR spectrum (in [D_8]dimethyl sulfoxide) shows the characteristic patterns for the naphthyl unit (7H) and for Et_2O ($\approx$5 H $\hat{=}$ $\frac{1}{2}$ Et_2O; the crystals lose ether rapidly). But there is no signal for the NH_2 groups (1-$C_{10}H_7NH_2$: δ = 5.77). ^{1}H NMR spectra measured in CD_3OD (which could react with **1** to give $LiOCD_3$ and 1-$C_{10}H_7ND_2$, 1-$C_{10}H_7NDH$, or 1-$C_{10}H_7NH_2$, depending on the identity of **1**) fail to reveal any NH protons.

The crystal structure of **1** ratifies these spectroscopic results.[5] Despite considerable disorder, which can be only partially resolved, the molecular structure is quite clear (Figure 2). Each naphthyl N^{2-} group interacts with four or six Li atoms in a central $N_{10}Li_{14}$ cluster, to which are attached six $(Et_2OLi)^+$ groups. Four of these are terminally bonded to one N each at the ends of the cluster; the other two are more centrally positioned and bridge two N atoms each. Thus every N atom is surrounded by either five or six closest Li neighbors, resulting in an overall neutral molecule. The

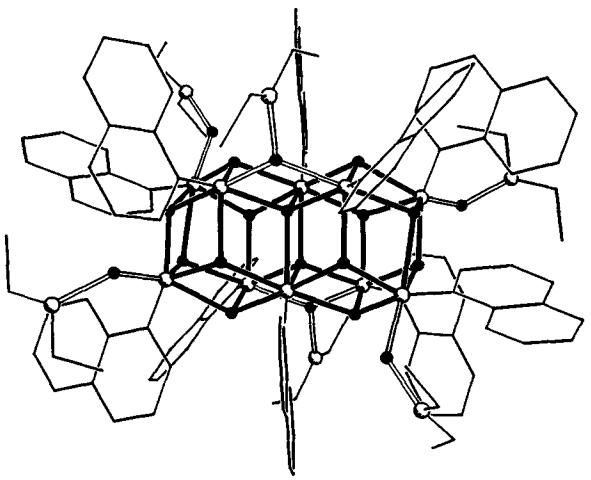

Fig. 2. Structure of **1** in the crystal (without H atoms and without the uncoordinated Et_2O molecule). Only one component of disordered groups is shown. Li atoms are shown as filled circles; O and N atoms, as open circles. Li-N bonds of the $N_{10}Li_{14}$ core are depicted as filled lines, bonds to the six surrounding $LiOEt_2$ groups (both terminal and bridging), as outlines. Key distances [Å]: N-Li 1.91(2)–2.25(2), O-Li 1.89(4)–2.00(3), Li···Li close contacts within the $N_{10}Li_{14}$ core 2.30(3)–2.56(4), Li···C (naphthyl) contacts 2.20(3)–2.49(3).

remaining ether isnot coordinated to Li but occupies a vacant lattice site. The coordination numbers of the Li centers range from 2 (for four Li atoms), to 3 (for fourteen), to 4 (for two). The central $N_{10}Li_{14}$ core consists of two rhombic dodecahedra sharing a common face which contains an inversion center. Li and N atoms occupy alternate vertices. Besides participating in Li–N and Li–O interactions, the Li centers are necessarily brought into close contact with the carbon and hydrogen atoms of the naphthyl groups. Other

highly-aggregated dilithiated organics akin to **1** include the nitrile dodecamer **2**[6a] and the sulfone hexamer **3**.[6b] It is also noteworthy that the core of **1** can be considered as belonging to the fluorite (CaF_2) structural type (N corresponding to Ca, Li to F) and that even the "external" Et_2O-complexed Li atoms fit this quasi-isomorphicity. Many AB_2 species, including alkali metal oxides and sulfides[7a] (and, indeed, Li_2NH[7b]), crystallize in this fluorite arrangement.

$[\{(Me_3SiCCN)Li_2\}_{12}(Et_2O)_6]$ **2**

$[\{(Me_3SiCSO_2Ph)Li_2\}_6Li_2O(THF)_{10}]$ **3**

An unexpected feature of **1** is that it is paramagnetic. The ^1H NMR signals found for **1** in benzene solutions are broad. The ^7Li NMR spectrum (139.97 MHz) of **1** in the same solvent at 25 °C shows (most unusually) three distinct resonances, centered at $\delta = 3.34$, 0.69, and -1.35 (the reference is PhLi in benzene); however, these signals are too broad to allow meaningful integration. The repeated ESR spectra of solid **1** (in a sealed tube under an inert atmosphere) measured between 4.5 K and room temperature consist of a single, slightly asymmetric signal, which can not be attributed to common impurities such as iron or oxygen. No hyperfine interaction could be resolved, though broadening in the shoulders of the signal may be associated with a nitrogen hyperfine interaction (if so, the nitrogen coupling constant would be ca. 15 G). The resonance has a g value of 2.0047 ± 0.0005 and a line width $\Delta H_{pp} = 17\ G \pm 0.5\ G$ and remains essentially unchanged at all temperatures. The g value is consistent with that of a low symmetry nitrogen radical with a p^5 configuration, though a neutral $(1\text{-}C_{10}H_7NLi_2)_{10}$ cluster requires all ten nitrogens to have p^6 configuration. Since we observed no signal attributable to a naphthyl radical anion, charge transfer from N to the naphthyl unit seems unlikely. At this stage we cannot deduce the number of unpaired electrons in the cluster.

The structure of **1** can be understood in terms of electrostatic bonding between Li^+ cations and organic anions. A RN^{2-} dianion will interact with as many Li^+ ions as is sterically possible. This leads to the formation of an aggregate or cluster, especially when R is a flat group such as naphthyl.

Experimental Procedure

1: *n*-Butyllithium (6.2 mL of a 1.6 M solution in hexane, 10 mmol) was added to a chilled (−40 °C) solution of 1-aminonaphthalene (0.715 g, 5 mmol) in diethyl ether (7.5 mL) under nitrogen. The reaction mixture displayed an initial green fluorescence and then turned red and finally orange. At ca. −20 °C a yellow powder precipitated which dissolved at ca. 0 °C. Refrigeration of this yellow solution afforded pale yellow cubic crystals of **1** (first batch yield, 68%); m.p. = 230 °C (decomp. to a red solid); correct C,H,N,Li-analysis; ^1H NMR (250 MHz, 25 °C, $(CD_3)_2SO$): $\delta = 8.03$ (s, 1H), 7.24 (d, 1H), 7.03 (t, 1H), 6.84 (t, 1H), 6.70 (t, 1H), 5.94 (d, 2H), 3.39 (q, ca. 2H), 1.11 (t, ca. 3H); ^1H NMR (250 MHz, 25 °C, CD_3OD) $\delta = 7.94$ (m, 1H), 7.68 (m, 1H), 7.37 (m, 2H), 7.20 (m, 2H), 6.78 (m, 1H), 3.36 (q, ca. 2H), 1.12 (t, ca. 3H)}.

4-Acyl-2,3,4,5-tetrahydro-2-methyl-2,5-methanobenz-1,4-oxazepine, Derivatives of a New Heterocycle

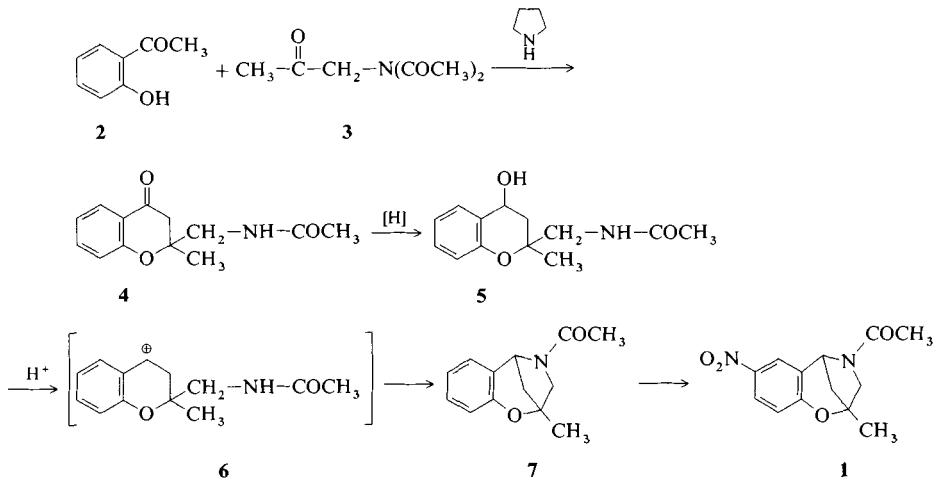
By *Hans-Joachim Kabbe,* Helmut Heitzer,* and *Liborius Born*

Dedicated to Professor Karl Heinz Büchel on the occasion of his 60th birthday

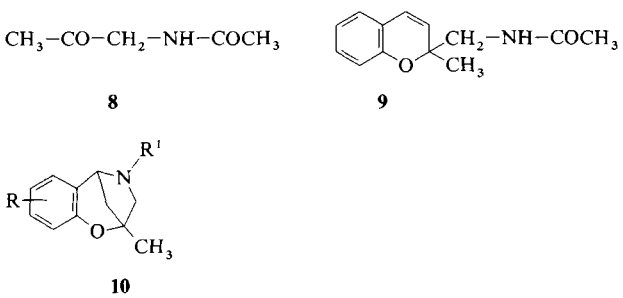
In the context of an investigation into ion channel modulators[1, 2] the previously unknown heterocycle **1** was required. We planned a synthesis following the sequence **2** → **7** → **1**. Prerequisites for its successful implementation were: a) the availability of the chromanones **4**, which we hoped to obtain through the pyrrolidine-catalyzed reaction[3, 4] of the ketones **2** and **3**; b) the intramolecular addition of the amide group to the carbenium ion **6** to give **7**; and c) the selective nitration of **7** to give the target molecule **1**.

The reaction of aminoacetic acid with acetic anhydride under the standard conditions of the Dakin–West reaction gave the diacyl compound **3**,[5] which was converted to **4** via pyrrolidine-mediated cleavage of one of its acyl groups. Reduction

[*] Dr. H.-J. Kabbe, Dr. H. Heitzer, Dr. L. Born
Bayer AG, Zentrale Forschung
W-5090 Leverkusen 1 (FRG)



of **4** (excess sodium borohydride in methanol, 2 days, 25 °C) delivered **5** as a mixture of diastereomers. In the presence of anhydrous acid both isomers gave rise to the carbenium ion **6**, which underwent intramolecular reaction providing tricycle **7** (75% yield). Chromene **9** was produced as a side-product (ca. 10%). Nitration of **7** ($[Cu(NO_3)_2] \cdot 3H_2O$, acetic anhydride, 2 h, 55 °C) afforded the target molecule **1**.



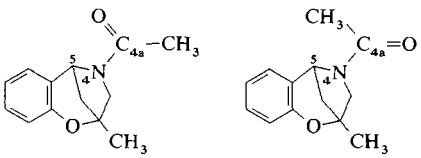
Variation of the starting materials allowed the preparation of other benzoxazepines **10**. Other new derivatives were simply obtained by hydrolysis of the *N*-acetyl compounds available from **8** followed by reacylation (e.g. to **10h**, Table 1). Isocyanates and sulfonyl chlorides gave ureas (**10g**) and sulfonamides (**10f**).

Table 1. Selected examples of **10**.

X	R	R¹	yield [a] [%]	m.p.
10a	H	CHO	41 [b]	103–105 °C
10b	H	C_6H_5CO	68 [b], 58 [c]	104–106 °C
10c	H	$C_6H_5CH_2CO$	73 [b]	86– 88 °C
10d	7-NO_2	C_2H_5CO	80 [b]	106–108 °C
10e	8-CH_3O	CH_3CO	83 [c]	132–134 °C
10f	H	$C_6H_5SO_2$	86 [b]	108–110 °C
10g	7-NO_2	CH_3NHCO	92 [b]	189–191 °C
10h	H	H	89 [d]	87– 89 °C

[a] Refers to the last step. [b] From reacylation of the corresponding amine. [c] Cyclization of analogues of **5**. [d] 10 h at reflux in dimethoxyethane/4 N NaOH.

The ^1H NMR spectra of compounds of type **7** show doubling of all the expected signals. At higher temperatures (DMF, DMSO, 120 °C) these signals did not coalesce. These observations suggest a strongly hindered amide bond rotation. Two methods of recrystallization allowed the isolation of two distinct crystal forms: a coarse modification from the melt (rotamer **1**) and a fine modification from solution (rotamer **2**). Subsequent X-ray crystallographic examination



7, modification 1 **7**, modification 2

showed the carbonyl group in **7** to be pointing either towards or away from the aromatic ring. This is the first case known to us of two crystalline amide rotamers isolable at room temperature. This high stability is restricted to the solid state in which the two rotamers are ordered in different crystal lattices; the carbonyl group and the N4–C5 bond lie virtually in the same plane.[6] In solution (chloroform, DMSO, DMF)

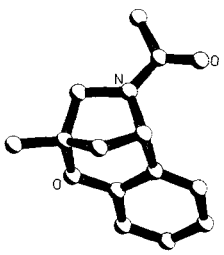


Fig. 1. X-ray crystal structure of compound **7**, modification 1.

the two crystal forms equilibrate within the time required for preparation of an NMR sample to the originally noted 1:1 mixture of rotamers. Consequently, separation by HPLC is not possible. As expected these isomeric mixtures are not present in the ureas (e.g. **10g**) or the sulfonamides (e.g. **10f**), and thus no doubling of their ^1H NMR signals is observed.

Experimental Procedure

4: To a solution of **3** (142 g, 0.88 mol) and **2** (120 g, 0.88 mol) in toluene (400 mL) was added pyrrolidine (185 mL). The mixture was stirred for 4 days at 25 °C. After successive washes with 2 N HCl, 2 N NaOH, and water the organic phase was evaporated in vacuo. Ether was added and 67.8 g of **4** precipitated (m.p. = 98–100 °C). The aqueous solutions were extracted with *n*-butanol. This organic phase was evaporated and the residue purified by

chromatography to give a further 69 g of the same chromanone. Yield: 136.8 g **4** (68%).

7: To a solution of **5** (50 g) in chlorobenzene (600 mL) heated to 90 °C was added cyclohexane (400 mL) and *p*-toluenesulfonic acid (3 g). The mixture was stirred at reflux for 25 minutes with continuous removal of water (Dean-Stark trap). The mixture was then poured into a sodium bicarbonate solution. The organic phase was washed with water, dried over Na_2SO_4, and evaporated under reduced pressure to give **7** (34.5 g, 75%), m.p. = 110–112 °C (The dehydration sometimes occurrs spontaneously and should be performed in a flask not more than half full). ^{1}H NMR (Varian XL-200, 200 MHz, $CDCl_3$, 25 °C, TMS): δ = 1.65 and 1.66 (2 singlets, CH_3, C2); 1.90 and 2.15 (2 singlets, acetyl CH_3); 2.1–2.3 (2 ABX systems, 2H, methano bridge); 3.5–3.8 (2 AB systems, 2H, C3); 4.81 and 5.37 (dd, 1H, C5); 6.8–7.3 (multiplet, 4H, aromatic H). IR (KBr): $\tilde{\nu}_{CO}$ = 1650 cm^{-1}.

10g: ^{1}H NMR ($CDCl_3$): δ = 1.70 (s, CH_3, C2); 2.2 (ABX multiplet, methano CH_2); 2.73 (d, NH-CH_3); 3.6 (AB quartet, 2H, C3); 4.63 (broad q, NH); 5.10 (H, C5); 6.8–8.2 (3 aromatic H: 6.81 (d), 8.02 (dd), 8.15 (d)).

Antibody Catalysis of Glycosidic Bond Hydrolysis**

By *Jean-Louis Reymond, Kim D. Janda,** and *Richard A. Lerner**

Monoclonal antibodies raised against transition state mimics have been shown to catalyze a number of chemical reactions[1] and for this reason have been called abzymes (*antibody enzymes*). Existing examples have focused on base-catalyzed transformations involving negatively charged transition states and to a lesser extent on electrocyclic and redox reactions. We report here the first antibody which catalyzes the acid-promoted hydrolysis of an activated glycosidic bond.[2]

The reaction which we chose to investigate was the hydrolysis of aryloxytetrahydropyran **1**. This type of acetal, although much more labile than a real glycoside, is a prototypical model for a glycosidic bond.[3a, b] Both the spontaneous and the acid-catalyzed cleavage involve rate determining heterolytic dissociation of the exocyclic carbon-oxygen bond.[3c] Due to stereoelectronic effects the reaction rate is conformation dependent; the axial chair conformer is the more labile form (Fig. 1).[3d] A detailed semi-empirical calculation of the transition state geometry suggests that the exocyclic C–O bond is approximately 1.8 to 2.2 Å in length.[4] We reasoned that piperidinium ions like **2** or **3**, with a carbon–nitrogen bond of approximately 1.5 Å, might be acceptable mimics for the proposed cationic transition state involved in the acid-catalyzed cleavage of **1**, provided that the benzylic nitrogen substituent could be constrained to the axial position. This was achieved by substituting the 3-position of **2** and **3** to form our antigens **4**, **5**, and **6**. In addition, a convenient handle was created for hapten–carrier protein immobilization (Fig. 1).

5	CH_3	CH_2Ar	$CH_2NH_3^+$
6	CH_2Ar	CH_3	$CH_2NH_3^+$

Fig. 1. Above: Mechanism of the hydrolytic cleavage of 2-aryloxytetrahydropyrans. Below: Transition state models.

Hapten **4** was synthesized in 8 steps starting from 3-hydroxymethylpiperidine and 4-(chloromethyl)-*N*-(2′-hydroxyethyl)benzamide.[5] In a similar fashion, a 1:1 mixture of diastereoisomeric haptens **5** and **6** was obtained starting with *N*-methyl-3-hydroxymethylpiperidine. Both **5** and **6** were separated by reverse phase high performance liquid chromatography (RP-HPLC)[6a] and their relative configuration was assigned on the basis of the ^{1}H NMR spectrum of **5**.[6b] A linker was attached to **4**, **5**, and **6** to insure immunogenicity (5-[(2,5-dioxo-1-pyrrolidinyl)oxy]-5-oxopentanoyl chloride, Et(*i*Pr)$_2$N, dimethylformamide (DMF), –30 °C) and these activated haptens were coupled to the carrier proteins bovine serum albumine (BSA) and keyhole limpet hemocyanin (KLH). Balb/c mice were immunized with the KLH conjugates and antibodies were generated by standard protocols.[7] Monoclonal antibodies were purified from ascites fluid by anion exchange chromatography (16 antibodies were obtained from immunization with **4**, 26 from **5**, and 3 from **6**) and assayed against substrate **1** for production of 4-hydroxy-*N*-(2′-hydroxyethyl)benzamide.[8] Two monoclonal antibodies, both derived from immunization with hapten **5**, were found to be catalytic. After affinity chromatography

(protein G), antibody 14D9 was chosen for further characterization due to its rate of reaction and stereoselectivity.

The hydrolysis of **1** catalyzed by 14D9 initially followed Michaelis–Menten kinetics ($K_m = 100\ \mu M$, $k_{cat} = 7.8 \times 10^{-5}\ s^{-1}$).[9] Potent inhibition by hapten **3** was observed and this allowed quantitative titration of the catalytic activity.[10] At pH = 5.7, the abzyme reaction is approximately 70 times faster than the "background reaction". A pH–rate profile study (Fig. 2) indicated the rate of the background hydrolysis of **1** to be the sum of a pH-independent reaction ($k_0 = 4.8 \times 10^{-7}\ s^{-1}$) and a H^+-catalyzed reaction ($k_{H^+} = 0.33\ M^{-1} s^{-1}$). In contrast, the antibody-catalyzed reaction seems to be completely pH-dependent, and thus would appear to be an acid-catalyzed process. However, this must be viewed with caution because the pH range investigated was limited (Fig. 2).[11]

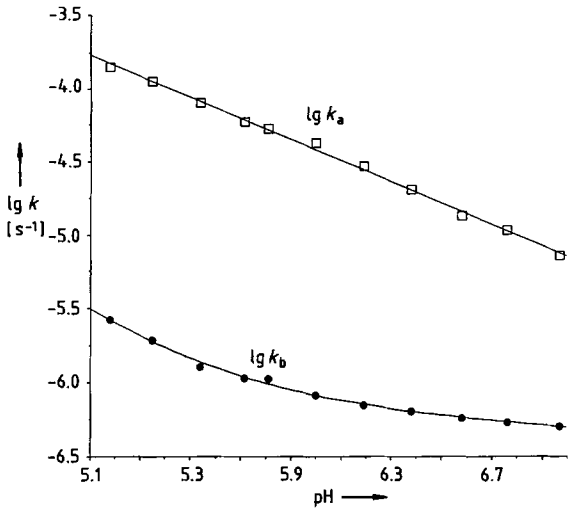

Fig. 2. Plot of $\lg k_a$ and $\lg k_b$ vs. pH. (□ antibody 14D9-catalyzed hydrolysis, • background hydrolysis of **1**). The assays were performed at 20 °C in solutions which were 50 mM in MES and 100 mM in NaCl. The upper trace is the result of the best linear fit of all the points. The lower line was calculated from the equation $k_{obsd} = k_0 + k_{H^+} \cdot [H^+]$.

To examine the hypothesis that the abzyme reacts with conformational selectivity, we synthesized diastereoisomers **7**–**10** (Fig. 3).[12] ^1H NMR spectra of these compounds in D_2O show them to have a chair conformation in solution. The phenolic leaving group is fixed either in the axial (**7** and **9**) or the equatorial (**8** and **10**) position. None of these compounds was accepted as a substrate,[13] but all competitively inhibited the reaction of **1** and 14D9 (Fig. 3). A clear selectivity was observed for the (2*S*,6*R*)-(−)-isomer **7**. This strongly

		K_i
7	(2*S*,6*R*) (−)	35 μM
8	(2*R*,6*R*) (+)	500 μM
9	(2*R*,6*S*) (+)	600 μM
10	(2*S*,6*S*) (−)	250 μM

Fig. 3. Stereoselective competitive inhibition of the antibody 14D9-catalyzed cleavage of **1**.

suggests that the immune response was directed to the corresponding enantiomer of our racemic hapten **5**, and that the stereochemical information concerning the axial placement of the phenolic leaving group was effectively transferred to the antibody binding pocket. This stereochemical selectivity probably allows the antibody to bind substrate **1** in the reactive axial chair conformation, and to achieve catalysis by a reaction pathway very similar to the well-characterized process in solution. However, we could not determine whether *both* enantiomers of the racemic substrate **1** actually reacted within the antibody binding pocket (Fig. 3). Interestingly, if only one enantiomer were a substrate, then the other would probably be quite a good inhibitor, which means that the observed catalytic rate with racemic **1** would not reflect the true catalytic rate for the reactive enantiomer.

To further characterize the specific interactions within our abzyme's binding pocket, we employed compounds **11**–**14**. These compounds, truncated versions of the tightly binding inhibitor **3**, competitively inhibited the hydrolysis of **1** by 14D9 (Fig. 4). From the weak inhibition observed with ben-

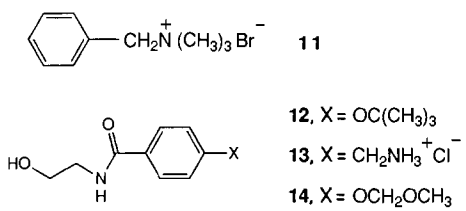

Fig. 4. Competitive inhibitors of antibody 14D9 (see text).

zyltrimethylammonium bromide (**11**, $K_i = 400\ \mu M$), it is apparent that the recognition of the aromatic side chain is an important factor in abzyme–antigen binding. Furthermore, the bulky, hydrophobic, *tert*-butyl ether **12** ($K_i = 5 \mu M$) is a much better inhibitor than either the charged primary benzylammonium salt **13** ($K_i = 90\ \mu M$) or the hydrophilic methoxymethyl ether **14** ($K_i = 600\ \mu M$). Abzyme–antigen binding thus appears to be mediated more efficiently by hydrophobic interactions between the abzyme binding pocket and the hydrocarbon envelope of the quaternary ammonium center than by coulombic interactions between the haptenic positive charge and the antibody.[14] Significant hydrophobic interactions are not surprising in an aqueous system and probably partly account for the low catalytic efficiency of 14D9 since the hydrolytic rate of **1**, as in many reactions involving charged transition states, strongly depends on solvent polarity.[15]

In summary, acid-mediated antibody-catalyzed cleavage of a prototypical activated glycosidic bond was achieved, and a first step toward the development of an antibody capable of glycosidic bond cleavage has been made. The results of this preliminary study point to the importance of stereochemical control in the haptenic design. The need to secure chemical catalysis within an antibody binding pocket is also evident. Future research will address this point.

[5] All new compounds were characterized by ^{1}H NMR and MS. Crystalline products gave satisfactory elemental analyses (±0.3%).

[6] a) Semi-preparative RP-HPLC (C-18 column, 0.1% HCl/H_2O, 1 mL min^{-1}): **5**: retention time, t_R = 15.0 min, **6**: t_R = 15.7 min; b) Nuclear Overhauser effects (NOE) (D_2O, 500 MHz): **5**: Irradiation of the CH_3-N$^+$ signal affected the piperidine ring protons $H_{eq}C(2) + H_{eq}C(6)$ (2.6%), $H_{ax}C(6)$ (4.5%) and $H_{ax}C(2)$ (4.5%); Irradiation of the signal at δ = 4.6 (Ar-CH-N$^+$) affected $H_{eq}C(2) + H_{eq}C(6)$ (2.1%), $H_{ax}C(3)$ (2.8%) and $H_{ax}C(5)$ (2.1%).

[7] a) G. Köhler, C. Milstein, *Nature (London) 256* (1975) 495; b) E. Enguall, *Methods Enzymol. 70* (1980) 419.

[8] 20 μM Antibody, 500 μM substrate **1**, 100 mM bis-tris pH 6.0, 100 mM NaCl. 20 °C. Formation of the phenol product was followed by RP-HPLC (C-18, CH_3CN/H_2O 20:80, 0.8 mL min^{-1}, t_R = 4.20 min) against an internal standard (2-acetamidophenyl-2′-hydroxyethylether, t_R = 7.41 min).

[9] Assay conditions: 2 to 15 μM antibody, 25 to 300 μM substrate **1**, 100 mM morpholinoethanesulfonic acid (MES), pH 5.7, 100 mM NaCl, 20 °C (see also ref. [8]). There was no difference in the observed rates with antibody 14D9 when tested at pH 6.0 in either bis-tris or MES (100 mM and 50 mM buffers).

[10] Potent inhibition by our hapten **3** was demonstrated by the following experiment: a 4 μM solution of 14D9 was completely inhibited by 10 μM of **3**. After 5 days of extensive dialysis at 37 °C, the inhibited antibody recovered only 40% of the activity of the noninhibited control sample.

[11] Antibody 14D9 was unstable below pH = 5.2.

[12] a) The key intermediate was 2-aminomethyl-3,4-dihydro-2*H*-pyran, which was resolved with mandelic acid. Absolute configuration was tentatively assigned by comparison of the optical rotation of its chloroacetamide derivatives with known γ-substituted valerolactone derivatives: W. H. Pirkle, P. E. Adams, *J. Org. Chem. 44* (1979) 2169.

[13] The lack of antibody catalysis on compounds **7** to **10** could result from nonproductive binding of the propanamidomethyl side chain, leading to an unreactive abzyme–substrate complex.

[14] a) Recent mutagenesis studies on the anti-phosphocholine antibody McPC603 suggested that binding of the alkyltrimethyl ammonium moiety is mediated by electrostatic interactions with two carboxylates on the protein. Van der Waals contacts to the alkyl groups were judged less important: R. Glockshuber, J. Stadlmüller, A. Plückthun, *Biochemistry 30* (1991) 3049.

[15] a) The rate for the H$^+$-catalyzed hydrolysis of **1** in 100% H_2O is 30 times the rate reported for the hydrolysis of *p*-(2-tetrahydropyranyloxy)benzoic acid in 50% aqueous dioxane ($k_2 = 9.2\ 10^{-3}$ M^{-1} s^{-1}): T. H. Fife, E. Anderson, *J. Am. Chem. Soc. 93* (1971) 6610.

Corrigendum

In the communication "Enzymatic Two-Step Synthesis of *N*-Acetylneuraminic Acid in the Enzyme Membrane Reactor" by U. Kragl, D. Gygax, O. Ghisalka, and C. Wandrey (*Angew. Chem. Int. Ed. Engl. 30* (1991) 827, the units of the time *t* on the abscissa of Figure 2 should be hours and not minutes.

INDEX OF AUTHORS AND REVIEWERS OF BOOKS

This index lists separately the names of Authors/Editors and Reviewers, respectively, of books reviewed in *Angew. Chem. Int. Ed. Engl. 30* (1991).

Bookauthors

Abramovicz, D. A. 1529
Adams, R. D. 337
Almond, M. J. 610
Anpo, M. 111
Atkins, P. W. 609
Baggott, J. 1526
Baranowski, B. 110
Bencini, A. 340
Bernstein, E. R. 1382
Betina, V. 214
Bleha, T. 341
Block, E. 1190
Boyd, D. B. 452
Casey, M. 213
Christoffersen, R. E. 1523
Constable, E. C. 1384
Conway, W. D. 892
Davies, J. A. 1527
Doi, Y. 1525
Dötz, K. H. 1520
Downs, A. J. 610
Drayton, C. J. 890
Emmett, J. C. 888
Ermolenko, I. N. 213
Field, L. D. 721
Friebolin, H. 1383
Gatteschi, D. 340
Giese, B. 611
Gilbert, A. 1526
Göpel, W. 110
Greenberg, A. 1527
Gulko, N. V. 213
Haasen, P. 1521
Hargittai, I. 1382
Hart, J. P. 1049
Hartley, F. R. 1046
Hattori, H. 720
Haufe, G. 1191
Hesse, J. 110
Hoffmann, R. W. 1520
Janson, J.-C. 212
Jurczac, J. 110
Kaesz, H. D. 337
Karlson, P. 891
Kaye, B. H. 339
Kennewell, P. D. 886
Klamann, D. 1524
Krätz, O. 1046
Lazár, M. 341
Lee, S. M. 609
Leigh, G. J. 721
Leonard, J. 213
Ley, S. V. 1386
Liebman, J. F. 1527
Lipkowitz, K. B. 452
Lis, H. 338
Low, C. M. 1386
Lygo, B. 213
Lyubliner, I. P. 213
Mann, G. 1191
Mann, S. 214
Mason, T. J. 1385
Matsuura, T. 111
Misono, M. 720
Mukaiyama, T. 1381
Naumann, K. 453
Ono, Y. 720
Ozawa, L. 1048
Patai, S. 718, 719
Pileni, M. P. 339
Plesch, P. H. 1522
Procter, G. 213
Ramsden, C. A. 889
Rees, M. H. 1529
Regitz, M. 611, 1047
Rogers, D. W. 1384
Rychlý, J. 341
Rydén, L. 212
Sammes, P. G. 887
Scherer, O. J. 1047
Schomburg, G. 1050
Seeman, J. I. 1190
Senechal, M. 1525
Serratosa, F. 340
Sharon, N. 338
Shriver, D. F. 337
Sternhell, S. 721
Tanabe, K. 720
Taylor, J. B. 889
Taylor, R. 337
Vögtle, F. 215
Watson, P. L. 1527
Webb, J. 214
Wendisch, D. A. W. 1381
Williams, R. J. P. 214
Williams, T. I. 1049
Zemel, J. N. 110

SUBJECT INDEX

(A second page number to an entry indicates an erratum to the corresponding article.)

(R) = Review Article (H) = Highlights (C) = Short Communication (B) = Book Review (L) = Correspondence

Ab initio calculations
- Ab initio Calculations on the $(ClAuPH_3)_2$ Dimer with Relativistic Pseudopotential: Is the "Aurophilic Attraction" a Correlation Effect? (C) 604
- Basic Principles and Techniques of Molecular Quantum Mechanics (B) 1523
- $[Cu(\eta^2\text{-}H_2)Cl]$, a Model Compound for H_2 Complexes. Ab Initio Calculations and Identification by IR Spectroscopy (C) 832
- Dilithiation of a Primary Amine: Synthesis and Structure of $[(\alpha\text{-Naphthyl-}NLi_2)_{10}(Et_2O)_6] \cdot ET_2O$, a Paramagnetic Li_{20} Aggregate (C) 1707
- On the Origin of π-Facial Diastereoselectivity in Addition Reactions of Cyclohexane-Based Systems (C) 1146
- Solvation Effects on Geometry and Chemical Shifts. An Ab Initio/IGLO Reconciliation of Apparent Experimental Inconsistencies on $H_3B \cdot NH_3$ (C) 1160
- The Radical Cations of Silaketene and Several Isomers of $[C,H_2,Si,O]^{\bullet\oplus}$: An Ab Initio MO Investigation (C) 1323
- The Structure of the Trimethylenemethane Dianion and the Question of Y-Aromaticity (C) 1001

Abzyms
- Antibody Catalysis of Glycosidic Bond Hydrolysis (C) 1711

Acenaphthylenes
- σ-Homoacenaphthylene and π-Homoacenaphthene (C) 683

Acetals
- Stereoselective Synthesis of Acetal-β,β-diglucosides, a Novel Class of Glycosides and Chiral Acetals (C) 868

Acetoxyalkynes
- Palladium(II)-Induced Conversion of α-Acetoxyalkynes into α,β-Unsaturated α-Acetoxyketones; a Novel Access to α-Diketones (C) 593

ACRL Toxin I
- ACRL Toxin I: Convergent Total Synthesis of Its 3-Methyl Enol Ether from D-Glucose (C) 1339

Actinide compounds
- Cyclopentadienyl-Actinide Complexes: Bonding and Electronic Structure (R) 1069

Adamantanes
- $Li_{10}P_4N_{10}$—A Lithium Phosphorus(v) Nitride Containing the New Complex Anion $P_4N_{10}^{10\ominus}$ (C) 830

1,4 Additions
- β-Alkyl and β-Alkyl-α-Hydroxy Carboxylic Acid Derivatives from Radical or Ionic 1,4 Addition of Dialkylaluminum Chlorides to α,β-Unsaturated *N*-Acyl Urethanes (C) 694

Aerosols
- Chemical Characterization of Aerosols: On-Line and In Situ (R) 466

Aldol reactions
- Diastereoselective Enzymatic Aldol Additions: L-Rhamnulose and L-Fuculose 1-Phosphate Aldolases from *E. coli* (C) 555
- *Anti*-Selective and Diastereofacially Selective Aldol Reactions with (*R*)-2-Siloxy-1,2,2-triphenylethyl propionate (C) 1318

Alicyclic compounds
- Chemistry of Alicyclic Compounds. Structure and Chemical Transformations (B) 1191

Alkali metal compounds
- η^1-(1*S*,2*E*)-1-(*N*,*N*-diisopropylcarbamoyloxy)-3-trimethylsilylallyllithium · (−)-Sparteine: Structure of a Chiral, Carbamoyloxy-substituted Allyllithium Compound (C) 321
- Dilithiation of a Primary Amine: Synthesis and Structure of $[(\alpha\text{-Naphthyl-}NLi_2)_{10}(Et_2O)_6] \cdot ET_2O$, a Paramagnetic Li_{20} Aggregate (C) 1707
- $LiClO_4$ in Ether—an Unusual Solvent (H) 1306
- (2-Lithio-3-bromobenzofuran · Diisopropyl Ether)$_2$ and 1-Phenylsulfonyl-2-lithio-3-fluorobenzene Pentamethyldiethylenetriamine: Crystal Structures of Compounds with Lithium and Halogen on Neighboring Carbon Atoms (C) 1455
- 5-Lithio-2*H*-tetrazolium Carbenoids: NMR Spectroscopic Detection and Reactions with Nitrogen Electrophiles (C) 1162
- Mixed-Anion Aggregates of Metalated Organics: Preparation and Structure of the Mixed-Anion Tetramer $(PhO^{\ominus}Li^{\oplus} \cdot HMPA)_3(\mu_3\text{-}HMPA \cdot Li^{\oplus})NCS^{\ominus}$ (C) 1011
- Observation of a Direct Sn–Li Bond; The Crystal and Molecular Structure of Monomeric $[Ph_3SnLi \cdot PMDETA]$ and the Detection of $^{119,117}Sn\text{–}^7Li$ NMR Coupling in Solution (C) 1459
- On the Electrochemical Oxidation of $Cs^{\oplus}$ and Other Alkali-Metal Ions in Liquid Sulfur Dioxide and Acetonitrile (C) 836
- Phenylsodium Compounds with η^3-Allyl or η^6-Phenyl Coordination (C) 825
- Solvated Electron in the Synthesis of Ionic Clusters in Zeolites (C) 1501
- Solvent-free Tris(trimethylsilyl)methyllithium (C) 324
- Synthesis and Structure of the Potassium Salts of 1,3,2-Diazaboroles (C) 1015
- The Two-Electron Reduction of 1,1′-Diphenylethene by Lithium or Sodium to Different 1,1,4,4-Tetraphenylbutane-1,4-diide Salts via C—C Bond Formation—A Monomeric Dilithium Contact Ion Triple and a Polymer String of "Hydrocarbon Oysters Containing Solvated Sodium Pearls" (C) 1183
- Volume Effect or Paddle-Wheel Mechanism—Fast Alkali-Metal Ionic Conduction in Solids with Rotationally Disordered Complex Anions (R) 1547

Alkaline earth metal compounds
- Alkaline Earth Metal Complexes Containing Deprotonated Organic Acids and Water: Preparation, Structures and a New Synthetic Strategy (C) 428
- The Synthesis and Structure of Some New Sodalites: The Lithium Haloberyllophosphates and -arsenates (C) 1169

Alkanes
- Surface Organometallic Chemistry on Oxides: Selective Catalytic Low-Temperature Hydrogenolysis of Alkanes by a Highly Electrophilic Zirconium Hydride Complex Supported on Silica (C) 1660

Alkene complexes
- *mer*-$[Cr(CO)_3(\eta^4\text{-norbornadiene})(\eta^2\text{-ethene})]$: A Key Compound in Understanding the Mechanism of the Photocatalytic Diene Hydrogenation with Chromium Carbonyl Complexes (C) 1343
- Nickel(0)-Carbene Complexes (C) 1666

Alkenes
- Methyltrioxorhenium as Catalyst for Olefin Oxidation (C) 1638
- Methyltrioxorhenium as Catalyst of a Novel Aldehyde Olefination (C) 1641
- Tetraethynylethene (C) 698
- The Reaction-Accelerating Neighboring-Group Effects in the Reaction of Vinyl Bromides with Alkyl-Transition Metal Reagents (C) 1684

Alkyne complexes
- Unique Reactivity of Heterodinuclear Pentacarbonyl(Fulvalene)Molybdenumruthenium with Alkynes: Fluxionality, Rearrangements, Structures, and First Reversible Conversion of a "Side-on"- to a Semi-Bridging Alkenylidene Ligand (C) 1463

Alkynes
- Flash Photolytic Generation and Study of Ynamines. First Observation of Primary and Secondary Ynamines in Solution (C) 1356
- Synthesis and Characterization of Radical-Substituted Diacetylene Derivatives (C) 450
- Tetraethynylethene (C) 698

Allyl sulfides
- 1,2-Asymmetric Induction in the Ketene Claisen Rearrangement of Allyl Sulfides (C) 1465

Aluminum compounds
- $[InAs_3]^{6\ominus}$ and $[AlSb_3]^{6\ominus}$, Trigonal Planar Anions in Cs_6InAs_3 and Cs_6AlSb_3 (C) 326
- $K_2[Al_{12}iBu_{12}]$, a Compound with Al_{12} Icosahedra (C) 179
- Monovalency of the Third Main-Group Elements: News from EX-Type Compounds (H) 544
- Tetraalkoxytitanium-Carbene Complexes with Double Intramolecular Et_2Al Bridging (C) 1668
- Tetrameric Gallium and Aluminum Chalcogenides, $[t\text{BuME}]_4$ (M = Al,Ga; E = S,Se,Te). A New Class of Heterocubanes (C) 1143
- The Tetrameric Aluminum(I) Compound $[\{Al(\eta^5\text{-}C_5Me_5)\}_4]$ (C) 564

Amines
- Dilithiation of a Primary Amine: Synthesis and Structure of $[(\alpha\text{-Naphthyl-}NLi_2)_{10}(Et_2O)_6] \cdot ET_2O$, a Paramagnetic Li_{20} Aggregate (C) 1707
- Stereoselective Synthesis of Vicinal Diamines (C) 103
- Synthesis of a Novel Macrobicyclic Cavity Possessing Six Convergent Hydroxyl Groups and Acting as a Siderophore (C) 85

Amino acids
- 3-Amino-2*H*-Azirines. Synthons for α,α-Disubstituted α-Amino Acids in Heterocycle and Peptide Synthesis [New Synthetic Methods (84)] (R) 238

- Chemoenzymatic Syntheses of ω-Ureido D-Amino Acids (C) 712
- 6-Deoxy-6-*N*-histamino-β-cyclodextrin Copper(II) Complex, a New Enantioselective Receptor for Aromatic Amino Acids (C) 1348
- New Approaches to the Use of Amino Acids as Chiral Building Blocks in Organic Synthesis [New Synthetic Methods (85)] (R) 1531
- Synthesis of β,γ-Unsaturated D-α-Amino Acids from L-Cysteine (C) 705

Amino sugars
- Amino-substituted β-Benzyl-*C*-glycosides; Novel β-Glycosidase Inhibitors (C) 1328
- Enzymatic Two-Step Synthesis on *N*-Acetylneuraminic Acid in the Enzyme Membrane Reactor (C) 827 (1713)

Ammonia
- Facile N–H Cleavage of Ammonia (C) 707

Analytical methods
- Chemical Characterization of Aerosols: On-Line and In Situ (R) 466
- Electroanalysis of Biologically Important Compounds (B) 1049
- Pulsed Electron Spin Resonance Spectroscopy: Basic Principles, Techniques, and Examples of Applications [New Analytic Methods (43)] (R) 265
- Ultramicroelectrodes—a New Dimension in Electrochemistry? (H) 170

Annulenes
- [14]Annulenequinones with Anthraquinone Periphery: "Isopyrenequinone" (C) 681
- Conversion of a Diatropic Bridged Annulene into a Paratropic Species on Metal Complexation (C) 1013
- Isophlorins: Molecules at the Crossroads of Porphyrin and Annulene Chemistry (C) 1693

Anomeric effect
- Conformational Preference of 2-Triphenylphosphonio-1,3-dithianes: Competition between Steric and Anomeric Effects (C) 578

Anthocyanins
- Structure and Molecular Stacking of Anthocyanins—Flower Color Variation (R) 17

Antibiotics
- Chemistry and Biology of the Enediyne Anticancer Antibiotics (R) 1387
- Lantibiotics—Ribosomally Synthesized Biologically Active Polypeptides containing Sulfide Bridges and α,β-Didehydroamino Acids (R) 1051
- Synthetic Strategy for the Coupling of the Calicheamicin Oligosaccharide with Aglycons: Synthesis of Dynemicin A-Calicheamicin Hybrid Structures (C) 585

Antibodies
- Antibody Catalysis of Glycosidic Bond Hydrolysis (C) 1711

Antimony compounds
- Synthesis and Structure of an N_2Sb_2 Ring with Different Types of Coordination for Antimony Atoms (C) 860

Antitumor agents
- Chemoenzymatic Syntheses of ω-Ureido D-Amino Acids (C) 712
- Enediyne Compounds Equipped with Acid-, Base- and Photo-Sensitive Triggering Devices. Chemical Simulation of the Dynemicin A Reaction Cascade (C) 1032

Arene complexes
- Ring Opening of a Cyclobutabenzene Complex under Very Mild Conditions (C) 880
- The Reduction of the NbX_5/AlX_3 System with Aluminum in the Presence of Aromatic Hydrocarbons: An Approach to Niobium(II), Niobium(I), and Niobium(0) Organometallics (C) 102

Arenes
- A General Entry to Rigid Systems with Alternatingly Orthogonal Arene Units via Diels–Alder Reactions (C) 1361
- A Homogeneous Platinum Catalyst in the Stationary $BF_3 \cdot H_2O$ Phase for the Hydrogenation of Arenes (C) 1009
- Aromatic Systems with Polymethine-like Structures: A Structural Comparison of Bis- and Tris(dimethylamino)-phenalenium Ions (C) 1030
- Bryophytes, a Source of Biologically Active, Naturally Occurring Material? (R) 130
- Ring Inversion in Sterically Hindered Arenes (C) 1484
- Stereoselective Synthesis of Annelated Piperidines by Photochemical Cycloaddition and Iminium Ion–Allylsilane Cyclization (C) 1697
- 1,4,5,8-Tetrakis(dimethylamino)naphthalene: Synthesis, Structure, "Proton Sponge" and Electron Donor Properties (C) 1028

Aromatic substitution
- Electrophilic Aromatic Substitution (B) 337

Aromaticity
- 2,3a,5,6a-Tetraazapentalene Dications and Tetraamino-1,3,5,7-tetrazocine (C) 334
- [14]Annulenequinones with Anthraquinone Periphery: "Isopyrenequinone" (C) 681
- Conversion of a Diatropic Bridged Annulene into a Paratropic Species on Metal Complexation (C) 1013
- σ-Homoacenaphthylene and π-Homoacenaphthene (C) 683
- Synthesis of a Highly Amphoteric *s*-Indaceno[1,2,3-*cd*:5,6,7-*c'd'*]diphenalene: Switching between Diatropism and Paratropism Due to Changes in Oxidation Level (C) 172
- Tercalicene and Quatercalicene (C) 446
- 1,3,5,7-Tetrakis(diethylamino)-*s*-indacenediylium bis(tetrafluoroborate)—a Stable *s*-Indacene Dication (C) 332
- 2,3,6,7-Tetramethoxythianthrene Dication: An "Aromatic" π System "Gives Up the Ghost" (C) 714
- The Structure of the Trimethylenemethane Dianion and the Question of Y-Aromaticity (C) 1001

Arsenic compounds
- Arsenic Compounds in Organic Synthesis: Pentamethinium Salts from Aminoarsanes and Pyrylium Salts (C) 994
- Do Partial Charges Alone Govern the Relative Stability of the Isomeric Heptaheteronortricyclane Anions $[P_{7-x}As_x]^{3\ominus}$? (C) 828

Arynes
- (2-Lithio-3-bromobenzofuran · Diisopropyl Ether)$_2$ and 1-Phenylsulfonyl-2-lithio-3-fluorobenzene Pentamethyldiethylenetriamine: Crystal Structures of Compounds with Lithium and Halogen on Neighboring Carbon Atoms (C) 1455

Asymmetric protonations
- Enantioselective Protonation of a Simple Enol: Aminoalcohol-Catalyzed Ketonization of a Photochemically Produced 2-Methylinden-3-ol (C) 416

Asymmetric syntheses
- η^1-(1*S*, 2*E*)-1-(*N*,*N*-diisopropylcarbamoyloxy)-3-trimethylsilylallyllithium · (−)-Sparteine: Structure of a Chiral, Carbamoyloxy-substituted Allyllithium Compound (C) 321
- Addition of Chiral Nucleophiles to Pyridine Compounds: Total Synthesis of (−)-Isovallesiachotamine and (+)-Vallesiachotamine (C) 1320
- 1,2-Asymmetric Induction in the Ketene Claisen Rearrangement of Allyl Sulfides (C) 1465
- Bis(4,5-dihydrooxazolyl) Derivatives in Asymmetric Catalysis (H) 542
- Catalytic and Stoichiometric Enantioselective Addition of Diethylzinc to Aldehydes Using a Novel Chiral Spirotitanate (C) 99
- Catalytic Enantioselective Epoxidations of Simple Olefins (H) 403
- Chirality and Crop Protection (R) 1193
- Diastereo- and Enantioselective Michael Addition Initiated Cyclizations to *trans*-Substituted Cyclopentanecarboxylates (C) 1664
- 2,2-Dimethyl-α,α,α',α'-tetrakis(β-naphthyl)-1,3-dioxolan-4,5-dimethanol (DINOL) for the Titanate-Mediated Enantioselective Addition of Diethylzinc to Aldehydes (C) 1321
- Double Stereodifferentiation in Carbohydrate Coupling Reactions: The Mismatched Interaction of Donor and Acceptor as an Unprecedented Factor Governing the α/β Ratio of Glycoside Formation (C) 180
- Efficient Stereoselective Total Synthesis of Denticulatins A and B (C) 97
- Enantioselective Addition of Organometallic Reagents to Carbonyl Compounds: Chirality Transfer, Multiplication, and Amplification [New Synthetic Methods (83)] (R) 49
- Importance of Oxyanion Orientation to the Stereochemical Control of Anionic Oxy-Cope Rearrangements (C) 1368
- Intramolecular Diels–Alder Reactions: Diastereofacial Selectivity and Coupling with an Aliphatic Claisen Rearrangement (C) 414
- New Approaches to the Use of Amino Acids as Chiral Building Blocks in Organic Synthesis [New Synthetic Methods (85)] (R) 1531
- *Anti*-Selective and Diastereofacially Selective Aldol Reactions with (*R*)-2-Siloxy-1,2,2-triphenylethyl propionate (C) 1318
- Stereoselective Synthesis of Cyclic Dipeptide Hydroxyalkyl Isosteres via Metalated *N*,*N*-Dialkylcarbamate 2-Alkenyl Esters (C) 1690
- Stereoselective Synthesis of Vicinal Diamines (C) 103
- The Isoinversion Principle—a General Model of Chemical Selectivity (R) 477
- Titanate-Catalyzed Enantioselective Addition of Dialkylzinc Compounds—Generated in situ from Grignard Reagents in Ether—to Aldehydes (C) 1008

Aurophilicity
- Ab initio Calculations on the $(ClAuPH_3)_2$ Dimer with Relativistic Pseudopotential: Is the "Aurophilic Attraction" a Correlation Effect? (C) 604
- Direct Observation of the Central Atom in $[C(Au\{P(C_6H_5)_2(p\text{-}C_6H_4NMe_2)\})_6](BF_4)_2$ by ^{13}C NMR Spectroscopy (C) 1488
- Triaurated Phosphonium Cations $[RP(AuPPh_3)_3]^{\oplus}$ and the Electron-deficient, Hypercoordinated Phosphonium Dication $[P(AuPPh_3)_5]^{2\oplus}$ (C) 433

Autobiographies
- Profiles, Pathways and Dreams. Autobiographies of Eminent Chemists (B) 1190
Azadodecaborane
- *closo*-Azadodecaborane, $NB_{11}H_{12}$ (C) 175
Azarhoda-*closo*-dodecaborane (C) 1377
Azirines
- [3 + 2] Cycloadditions with Azirine Radical Cations: A New Synthesis of *N*-Substituted Imidazoles (C) 1336
- 3-Amino-2*H*-Azirines. Synthons for α,α-Disubstituted α-Amino Acids in Heterocycle and Peptide Synthesis [New Synthetic Methods (84)] (R) 238
Azo dyes
- A New Approach to 2-Equivalent Couplers for Color Photography (C) 1704
- Salt-free Synthesis of Azo and Hydrazone Dyes Under CO_2 Pressure (C) 1643
Azobenzene
- Reduction of Azobenzene by Naphthaleneytterbium: A Tetranuclear Ytterbium(III) Complex Combining 1,2-Diphenylhydrazido(2−) and Phenylimido Ligands (C) 1149
Azomethines
- Effects of Perturbed Symmetry: Low-Melting Stable Mesogens Based on *ortho*-Palladated Imines (C) 711

Beckmann rearrangements
- Synthesis of Heterocycles by Tandem Reactions: Beckmann Rearrangements/Allylsilane Cyclizations (C) 687
Benzene isomers
- Tricarbonyl-η^6-(3,4-dimethylenecyclobutene)chromium(0), a Second Isomer of [(Benzene)Cr(CO)$_3$] (C) 870
Benzilic acid
- The Structure of "Organic Permanganate" (C) 704 (1192)
Benzobicyclooctenes
- *syn*-Sesqui- and -Sesterbenzobicyclo[2.2.2]octene, Molecules with Stacked Benzene Rings (C) 205
Benzonitriles
- Extension of Free Energy Correlations to Gas-Phase Ionic Reactions. Competitive Alkylation of Substituted Benzonitriles by $(CH_3)_2Cl^+$ Ions (C) 1457
Benzoxazepines
- 4-Acyl-2,3,4,5-tetrahydro-2-methyl-2,5-methanobenz-1,4-oxazepine, Derivatives of a New Heterocycle (C) 1709
Benzyl cation
- Laser Flash Photolysis Generation, Spectra, and Lifetimes of Phenylcarbenium Ions in Trifluoroethanol and Hexafluoroisopropyl Alcohol. On the UV Spectrum of the Benzyl Cation (C) 1337
Betaine dyes
- Chromoionophoric Pyridinium-*N*-phenolate Betaine Dyes (C) 558
Biocatalysis (B) 1529
Biochemistry
- Chemistry and Biology of the Enediyne Anticancer Antibiotics (R) 1387

- Heterotopic Host Molecules for Binding Two Different Guests (C) 1474
- "[12]Mercuracarborand-4", the First Representative of a New Class of Rigid Macrocyclic Electrophiles: The Chloride Ion Complex of a Charge-Reversed Analogue of [12]Crown-4 (C) 1507
- Metal-assisted Organization rather than Preorganization for the Design of Macrocyclic Hosts (C) 1496
- Monovalency of the Third Main-Group Elements: News from EX-Type Compounds (H) 544
- Solvation Effects on Geometry and Chemical Shifts. An Ab Initio/IGLO Reconciliation of Apparent Experimental Inconsistencies on $H_3B \cdot NH_3$ (C) 1160
- Synthesis and Structure of the Potassium Salts of 1,3,2-Diazaboroles (C) 1015
- Synthesis, Structure, and Rearrangement of 1,3-Dibora[5]radialenes (C) 84
- Tetra-*tert*-butyltetraboratetrahedrane (C) 173
Bredt rule
- An Exception to the Bredt Rule in the Photoenolization of 4-Benzoyl[2.2]paracyclophane (C) 432
Brevetoxin A
- Novel Strategies for the Construction of Complex Polycyclic Ether Frameworks. Stereocontrolled Synthesis of the FGHIJ Ring System of Brevetoxin A (C) 299
Bridging ligands
- A Cluster with the Triply Facially Bridging Trimethylenemethane Ligand: Structure and Bonding of $[\{Rh(cod)\}_3(\mu_3\text{-}H)\{\mu_3\text{-}C(CH_2)_3\}]$ (C) 313
- $[Cp_2Fe_2(CO)_3(\mu\text{-}SitBu \cdot NMI)]I$: The First Silanetriyldiiron Complex (C) 843
- Derivatives of 1,1''-Biferrocene with Sulfur and Selenium Bridges (C) 1652
- Dinuclear Cyanoalkylidene Complexes of Iron (C) 847
- Formation of Doubly Vinyl-Bridged Binuclear Iridium Complexes by C-H Activation (C) 1006
Butenandt
- Adolf Butenandt. Biochemiker, Hormonforscher, Wissenschaftspolitiker (B) 891
Butenolides
- A Simple Way to Predict the Products of Topochemical Photoreactions on the Basis of Force Field Calculations (C) 1354

C_1 building blocks
- Designed Coupling of C_1 Ligands: Organometallic Model Reactions (H) 1119
C_4 building blocks
- Enzymatic Synthesis of Chiral C_4 Building Blocks from *meso*-Tartaric Acid (C) 86
Cadmium compounds
- Synthesis of Sterically Hindered Tellurophenols and the Structure of $[Cd(\mu\text{-}TeC_6H_2Me_3)_2]_\infty$ (C) 973
Cage compounds
- Inclusion of Metal Ions within a Tin–Oxygen Cage Stabilized by Organic Residues: Crystal Structure of $[(i\text{PrSn})_{12}O_4(OH)_{24}][Ag_7I_{11}] \cdot NaCl \cdot H_2O \cdot 10\,DMSO$ (C) 1482
Calcium antagonists
- 1,4-Dihydropyridines: Effects of Chirality and Conformation on the Calcium Antagonist and Calcium Agonist Activities (R) 1559
Calcium compounds
- The Reaction of $PtCl_2$ with an *N,S,O*-Coordinated Calcium Complex: Synthesis and Structure of a Complexed CaPt Anion (C) 1648
Calicenes
- Tercalicene and Quatercalicene (C) 446

Calicheamicins
- Chemistry and Biology of the Enediyne Anticancer Antibiotics (R) 1387
- Synthetic Strategy for the Coupling of the Calicheamicin Oligosaccharide with Aglycons: Synthesis of Dynemicin A-Calicheamicin Hybrid Structures (C) 585
Calixarenes
- Triple Inclusion by a Calixarene: the Crystal Structure of the Europium(III) Complex of Bis(homooxa)-*p*-*tert*-butylcalix[4]arene (C) 854
Carbamic acids

- Photocatalysis of the Homogeneous Water-Gas Shift Reaction under Ambient Conditions by Cationic Iridium(III) Complexes (C) 844
- Surface Organometallic Chemistry on Oxides: Selective Catalytic Low-Temperature Hydrogenolysis of Alkanes by a Highly Electrophilic Zirconium Hydride Complex Supported on Silica (C) 1660
- Syndiotactic Poly(1-oxo-2-phenyltrimethylene): On the Mode of the Chain Growth under Palladium Catalysis (C) 989
- Synthesis and Characterization of P-containing ZSM-5 Zeolites (C) 686
- Tetraalkoxytitanium-Carbene Complexes with Double Intramolecular Et_2Al Bridging (C) 1668
- Titanate-Catalyzed Enantioselective Addition of Dialkylzinc Compounds—Generated in situ from Grignard Reagents in Ether—to Aldehydes (C) 1008

Catenanes
- Molecular Trains: The Self-Assembly and Dynamic Properties of Two New Catenanes (C) 1042
- Self-Assembling [3]Catenanes (C) 1039

Ceramics
- Silicon Nitride—From Powder Synthesis to Ceramic Materials (R) 1579

C-H activation
- Activation of Methane (H) 820
- Formation of Doubly Vinyl-Bridged Binuclear Iridium Complexes by C-H Activation (C) 1006
- Oxidation of Alkanes by $[Fe(O)OH]^{\oplus}$ in the Gas Phase—the Role of Iron Oxidation State in C–H Activations (C) 991
- Selective Hydrocarbon Activation. Principles and Progress (B) 1527
- Surface Organometallic Chemistry on Oxides: Selective Catalytic Low Temperature Hydrogenolysis of Alkanes by a Highly Electrophilic Zirconium Hydride Complex Supported on Silica (C) 1660

Chalcogen compounds
- Tetrameric Gallium and Aluminum Chalcogenides, $[t\mathrm{BuME}]_4$ (M = Al,Ga; E = S,Se,Te). A New Class of Heterocubanes (C) 1143

Charge separation
- Solvent Dependence of Photoinduced Intramolecular Electron Transfer: Criteria for the Design of Systems with Rapid, Solvent-Independent Charge Separation (C) 1358

Charge transfer complexes
- A Distorted *anti*-Perovskite Structure in Ternary Tetrathiafulvalenium Salts: Construction, Distortion, and Antiferromagnetic Ordering (C) 1498
- Benzene Bis(diazocyanides)—the First Acceptors of the Inverse Wurster Type for Conductive Organic Materials (C) 561
- Novel Building Blocks for the Synthesis of Organic Metals (H) 1121
- $[\{Re_2Cl_4(dppm)_2\}_2(\mu\text{-TCNQ})]$, a Novel Charge Transfer Complex Derived from a Donor with a Metal-Metal Multiple Bond (C) 448

Chelate ligands
- Chelate Complexes with Triisocyanide Ligands (C) 203
- Cp'_2TiS_5O and Cp'_2TiOS_5—Isomeric Titanocene Complexes with Two Novel S-O Chelate Ligands ($Cp' = \eta^5\text{-}CH_3C_5H_4$) (C) 550
- Hexanuclear Ferric Complex with a Novel $S = 5$ Ground State (C) 598

Chemical bonding
- Bonding Patterns in Intermetallic Compounds (R) 789

Chemical structures
- Representation in Chemistry (R) 1

Chemical systems
- Groups of Organic Molecules That Operate Collectively (R) 1086

Chiral auxiliaries
- β-Alkyl and β-Alkyl-α-Hydroxy Carboxylic Acid Derivatives from Radical or Ionic 1,4 Addition of Dialkylaluminum Chlorides to α,β-Unsaturated *N*-Acyl Urethanes (C) 694
- Catalytic and Stoichiometric Enantioselective Addition of Diethylzinc to Aldehydes Using a Novel Chiral Spirotitanate (C) 99
- 2,2-Dimethyl-α,α,α′,α′-tetrakis(β-naphthyl)-1,3-dioxolan-4,5-dimethanol (DINOL) for the Titanate-Mediated Enantioselective Addition of Diethylzinc to Aldehydes (C) 1321
- Enantioselective Addition of Organometallic Reagents to Carbonyl Compounds: Chirality Transfer, Multiplication, and Amplification [New Synthetic Methods (83)] (R) 49
- *Anti*-Selective and Diastereofacially Selective Aldol Reactions with (*R*)-2-Siloxy-1,2,2-triphenylethyl propionate (C) 1318

Chirality
- Chirality and Crop Protection (R) 1193
- Dyes for Visual Distinction between Enantiomers: Crown Ethers as Optical Sensors for Chiral Compounds (H) 958
- Helical Semiquinones: Proof of Chirality by ENDOR Spectroscopy (C) 602
- Optically Active "Stereocomplexes" of Isotactic Poly(methyl methacrylates) with Main-Chain Chirality (C) 849
- Recombination of Carbocation-Sulfinate Ion Pairs (C) 1018
- Spontaneous Resolution by Stirred Crystallization (H) 293

Chlorinated hydrocarbons
- Enantioselective Metabolism of (±)-α-1,2,3,4,5,6-Hexachlorocyclohexane in Organs of the Eider Duck (C) 320

Chlorinations
- Selective *p*-Chlorination of Biphenyl in L Zeolites (C) 1689

Chlorine dioxide
- Crystal Structure of Chlorine Dioxide (C) 1510

Chlorophyll
- On the Enigma of Chlorophyll Degradation: The Constitution of a Secoporphinoid Catabolite (C) 1315

Chlorotetaine
- Enantioselective and Diastereoselective Total Synthesis of the Antimycotically Active Natural Product Chlorotetaine: Revision of the Relative Configuration (C) 1685

Chromatography
- Countercurrent Chromatography (B) 892
- 6-Deoxy-6-*N*-histamino-β-cyclodextrin Copper(II) Complex, a New Enantioselective Receptor for Aromatic Amino Acids (C) 1348
- Dynamic HPLC: A Method for Determining Rate Constants, Energy Barriers, and Equilibrium Constants of Molecular Dynamic Processes (C) 74 (216)
- Enantiomer Separation on Immobilized Chirasil-Metal and Chirasil-Dex by Gas Chromatography and Supercritical Fluid Chromatography (C) 987
- Gas Chromatography—A Practical Course (B) 1050
- New Chiral Polyamide Stationary Phases for Chromatographic Enantiomer Separation (C) 1662

Chromium compounds
- *mer*-$[Cr(CO)_3(\eta^4\text{-norbornadiene})(\eta^2\text{-ethene})]$: A Key Compound in Understanding the Mechanism of the Photocatalytic Diene Hydrogenation with Chromium Carbonyl Complexes (C) 1343
- Double Insertion of Alkynes into Chromium–Carbon Bonds of β-Donor-Substituted Vinylcarbene Complexes of Chromium—A Simple Route to Cyclopenta[*b*]pyrans (C) 1658
- Reversible Intramolecular Base Stabilization of a Low-Coordinate Silicon Atom in the Silanediyl Complex $[(o\text{-}Me_2NCH_2C_6H_4)_2Si = Cr(CO)_5]$ (C) 1132
- Ring Opening of a Cyclobutabenzene Complex under Very Mild Conditions (C) 880
- Tricarbonyl-η^6-(3,4-dimethylenecyclobutene)chromium(0), a Second Isomer of [(Benzene)$Cr(CO)_3$] (C) 870

Chromoionophores
- Chromoionophoric Pyridinium-*N*-phenolate Betaine Dyes (C) 558
- Dyes for Visual Distinction between Enantiomers: Crown Ethers as Optical Sensors for Chiral Compounds (H) 958

Circular dichroism
- Circular Dichroism of a Chiral Cyanine Dye Dimer Trapped in γ-Cyclodextrin (C) 869

Circulenes
- [7.7]Circulene, a Molecule Shaped Like a Figure of Eight (C) 1173

Claisen rearrangements
- 1,2-Asymmetric Induction in the Ketene Claisen Rearrangement of Allyl Sulfides (C) 1465
- Intramolecular Diels–Alder Reactions: Diastereofacial Selectivity and Coupling with an Aliphatic Claisen Rearrangement (C) 414

Clusters
- A Novel Oligomer of Condensed Metal Atom Clusters in $[Y_{16}Ru_4I_{20}]$ (C) 856
- An Unusual Polyoxovanadium Organophosphonate Anion, $[H_6(VO_2)_{16}(CH_3PO_3)_8]^{8\ominus}$ (C) 422
- $[As^{V}V^{V}_{12}V^{IV}_{2}O_{40}]^{7\ominus}$, a Topologically Interesting, Mixed Valence Cluster as Model for Vanadium Minerals Formed by Weathering (C) 210
- Atomic and Molecular Clusters (B) 1382
- *closo*-Azadodecaborane, $NB_{11}H_{12}$ (C) 175
- $(n\mathrm{Bu}_4\mathrm{P})_2[Os_{20}(CO)_{40}]$, a Thermolytically Generated High-Nuclearity Cluster with a Tetrahedral Cubic-Close-Packed Metal Core (C) 107
- Direct Location of the Hydrido Ligands in the Dianion $[H_4Os_{10}(CO)_{24}]^{2-}$ by a Neutron Diffraction Study of Its $[(Ph_3P)_2N]^+$ Salt at 20 K (C) 1164

- Formation of a Cluster Sheath around a Central Cluster by a "Self-Organization Process": the Mixed Valence Polyoxovanadate $[V_{34}O_{82}]^{10\ominus}$ (C) 588
- Isolated and Condensed Ta_2Ni_2 Clusters in the Layered Tellurides $Ta_2Ni_2Te_4$ and $Ta_2Ni_3Te_5$ (C) 840
- $K_2[Al_{12}iBu_{12}]$, a Compound with Al_{12} Icosahedra (C) 179
- Molecular Systems with Perfect Metal Structure (H) 72
- $(NBu_4)[Mn_4O_2(H_2O)(O_2CPh)_9]$, a Butterfly Complex with Bound H_2O, and Its Use to Prepare Octanuclear and Undecanuclear Metal Complexes (C) 1672
- Polyoxometalate Chemistry: An Old Field with New Dimensions in Several Disciplines (R) 34
- Spontaneous Self Assembly of an Octanuclear Iron-Nickel Cluster by Reaction of $[Fe_6S_6I_6]^{2\ominus}$ with $[NiI_4]^{2\ominus}$ (C) 881
- Synthesis and Characterization of a New Binary Deca-osmium Carbonyl Cluster Anion—An Intermediate in the Formation of Other High-nuclearity Osmium Carbonyl Clusters; Crystal and Molecular Structure of $[Ph_4P]_2[Os_{10}(CO)_{26}]$ (C) 1505
- Template-Controlled Formation of Cluster Shells or a Type of Molecular Recognition: Synthesis of $[HV_{22}O_{54}(ClO_4)]^{6-}$ and $[H_2V_{18}O_{44}(N_3)]^{5-}$ (C) 1674
- $Th_6Br_{15}H_7$—Stabilization of a Th_6Br_{12} Cluster by Seven Hydrogen Atoms (C) 101
- The Chemistry of Metal Cluster Complexes (B) 337
- The Cluster Anion $[Ru_6H(CO)_{15}S_3]^-$: A Planar Hexanuclear Metal Framework with Almost Perfect C_{3v} Symmetry (C) 1126
- The Synthesis of the First Decametal Nitrido Cluster; X-Ray Structure Analysis and ^{14}N NMR Studies of $[(Ph_3P)_2N][Ru_{10}N(CO)_{24}]$ (C) 1706

Cobalt compounds
- Intermediates in Nitrogenase Models: N_2H_3 and N_2H_4 as η^2-Coordinated Ligands (C) 303
- New Discoveries in the Realm of Metal-Metal Multiple Bonds: $[\eta^5$-$C_5Me_5)_2Co_2]$, the First Organometallic Multiple-Bond Complex without Bridging Ligands (H) 1120
- Pressure-Assisted Formation of a Cobalt–Carbon σ Bond: A High-Pressure Pulse Radiolysis Study (C) 1158
- Reactions of Substituted Alkynes at a Conformationally Rigid (Olefin)cobalt Fragment (C) 430
- Reactivity of Cobalt Atoms towards 1,2,3,4,5-Pentamethylcyclopentadienyl: Synthesis and Structure of Bis(η^5-pentamethylcyclopentadienyl)-(μ_2-η^5:η^5-pentamethylcyclopentadienyl)dicobalt and Bis(η^5-pentamethylcyclopentadienyl)dicobalt (C) 1124
- Structure of a Self-assembling Triple-helical Complex containing two Cobalt^{II} Ions (C) 1490

Colloids
- Formation of Colloidal Transition Metals in Organic Phases and Their Application in Catalysis (C) 1312
- Ligand-Stabilized Bimetallic Colloids Identified by HRTEM and EDX (C) 874

Complexes with arsenic ligands
- *cyclo*-As_8 as Complex Ligand (C) 850

Complexes with carbon ligands
- Mononuclear Silylvinylidene Rhodium Complexes from Silylalkynes: The $SiMe_3$ Migration as an Alternative to the [1,2]-H Shift (C) 700
- Novel Tetranuclear Iron–Hexapentaene Complexes: The First Examples of Poly-π-Allyl Complexes (C) 1670
- Reactions of Substituted Alkynes at a Conformationally Rigid (Olefin)cobalt Fragment (C) 430

Complexes with chalcogen ligands
- The Synthesis and Structure of the Yellow and Green Forms of $[Nb(O)Cl_3(PMe_3)_3]$ and the Orange and Green Forms of $[Nb(S)Cl_3(PMe_3)_3]$; Examples of Perfectly Matched Bond-Stretch Isomers? (C) 980

Complexes with diene ligands
- $[Cp_2^*La(thf)(\mu$-η^1,η^3-$C_4H_6)LaCp_2^*]$: Synthesis and Structure of a Butadiene-Lanthanoid Complex (C) 435

Complexes with hydrido ligands
- Direct Location of the Hydrido Ligands in the Dianion $[H_4Os_{10}(CO)_{24}]^{2-}$ by a Neutron Diffraction Study of Its $[(Ph_3P)_2N]^+$ Salt at 20 K (C) 1164
- $Th_6Br_{15}H_7$—Stabilization of a Th_6Br_{12} Cluster by Seven Hydrogen Atoms (C) 101
- The Cluster Anion $[Ru_6H(CO)_{15}S_3]^-$: A Planar Hexanuclear Metal Framework with Almost Perfect C_{3v} Symmetry (C) 1126

Complexes with hydrogen ligands
- $[Cu(\eta^2$-$H_2)Cl]$, a Model Compound for H_2 Complexes. Ab Initio Calculations and Identification by IR Spectroscopy (C) 832

Complexes with nitrogen ligands
- Alkaline Earth Metal Complexes Containing Deprotonated Organic Acids and Water: Preparation, Structures and a New Synthetic Strategy (C) 428
- Bis(4,5-dihydrooxazolyl) Derivatives in Asymmetric Catalysis (H) 542
- Effect of Intramolecular Coordination on Tantalum-Alkylidene-Centered Reactions: Synthesis and Structure of a Tantalum-Olefin Adduct and a Tantalum-Zinc-Alkylidene Complex (C) 996
- Intermediates in Nitrogenase Models: N_2H_3 and N_2H_4 as η^2-Coordinated Ligands (C) 303
- Metal-Ion Dependent Regioselectivity in Cyclometalation Reactions (C) 1363
- Nickel-catalyzed Cyclotrimerization of Malononitrile: The Dicyanomethanide-bridged, Anionic Ni^{II} Complex $[\{Ni(C_5F_5)_2(\mu$-$NCCHCN)\}_2]^{2\ominus}$ (C) 716
- Oxidative Cleavage of Triethylenetetramine (trien) to Yield Diethylenetriamine (dien): Structure of the Mn^{II}/Mn^{III} Heptanuclear Complex $[Mn_7(trien)_2(dien)_2O_4(OAc)_8](PF_6)_4 \cdot 2H_2O$ (C) 688
- Reduction of Azobenzene by Naphthaleneytterbium: A Tetranuclear Ytterbium(III) Complex Combining 1,2-Diphenylhydrazido(2−) and Phenylimido Ligands (C) 1149
- The High-Yield Synthesis and Characterization of the First Porphyrin-Cyclam Dinucleating Ligand and Its Iron(III)/Copper(II) Complex (C) 572
- The Synthesis of the First Decametal Nitrido Cluster; X-Ray Structure Analysis and ^{14}N NMR Studies of $[(Ph_3P)_2N][Ru_{10}N(CO)_{24}]$ (C) 1706

Complexes with oxygen ligands
- Alkaline Earth Metal Complexes Containing Deprotonated Organic Acids and Water: Preparation, Structures and a New Synthetic Strategy (C) 428
- Chloride-Induced Conversion of $[Mn_4O_2(OAc)_6(py)_2(dbm)_2]$ to $[Mn_4O_3Cl(OAc)_3(dbm)_3]$: Potential Relevance to Photosynthetic Water Oxidation (C) 305
- Oxidative Cleavage of Triethylenetetramine (trien) to Yield Diethylenetriamine (dien): Structure of the Mn^{II}/Mn^{III} Heptanuclear Complex $[Mn_7(trien)_2(dien)_2O_4(OAc)_8](PF_6)_4 \cdot 2H_2O$ (C) 688

Complexes with phosphorus ligands
- A Cp_2Zr Complex of a Phosphaalkyne Dimer as Educt in the Synthesis of Cyclic Phosphorus Compounds (C) 207
- Bicyclic P_6 as Complex Ligand (C) 553
- Carbonyl(pentaphosphacyclopentadienyl)-Transition Metal Complexes (M = Cr, Mo, W, Mn) through Directed Syntheses with *cyclo*-$P_5^{\ominus}$ (C) 580
- Direct Observation of the Central Atom in $[C(Au\{P(C_6H_5)_2(p$-$C_6H_4NMe_2)\})_6](BF_4)_2$ by ^{13}C NMR Spectroscopy (C) 1488
- Phosphorus Monoxide (PO) as Complex Ligand (C) 852
- The First Metallobis(methylene)phosphoranes—Unexpected Isomerization to a Phosphaferrocene (C) 312
- The *cyclo*-P_4 Ligand as 12-Electron Donor (C) 969

Complexes with silicon ligands
- $[Cp_2Fe_2(CO)_3(\mu$-Si*t*Bu · NMI)]I: The First Silanetriyldiiron Complex (C) 843
- Intramolecular Base Stabilization of Si = N and Si = P Compounds and Related Transition-Metal Silanediyl Complexes (C) 1130
- Reversible Intramolecular Base Stabilization of a Low-Coordinate Silicon Atom in the Silanediyl Complex $[(o$-$Me_2NCH_2C_6H_4)_2Si = Cr(CO)_5]$ (C) 1132

Complexes with sulfur ligands
- Cp'_2TiS_5O and Cp'_2TiOS_5—Isomeric Titanocene Complexes with Two Novel S-O Chelate Ligands ($Cp' = \eta^5$-$CH_3C_5H_4$) (C) 550
- $[\{Fe(\mu$-$'S_4')\}_2(\mu$-$S_2)\}$: A Model Complex for [Fe–S] Enzymes with a New Type of [2Fe–2S] Center (C) 1477
- $[Mo(CO)_2(^{t}buS'_2)_2]$ and $[MoCO(PPh_3)(^{t}buS'_2)_2]$: CO Coordination at [Mo—S] Centers Where Mo Is in a High Oxidation State (C) 1311
- Proof of Strong S−H···S Bridges in $[Ru(SH_2)(PPh_3)('S_4')] \cdot THF$, the First H_2S Complex Characterized by X-Ray Crystallography (C) 552
- $[Re_2S_{16}]^{2-}$, a Soluble Metal Sulfide with Interesting Electronic Properties and Unusual Reactivity (C) 1512
- Spontaneous Self Assembly of an Octanuclear Iron-Nickel Cluster by Reaction of $[Fe_6S_6I_6]^{2\ominus}$ with $[NiI_4]^{2\ominus}$ (C) 881
- The Neutral Transition Metal Thiolates $[M(SAr)_2]_2$ (M = Mn, Fe or Co, Ar = 2,4,6-*t*-$Bu_3C_6H_2$) (C) 330
- The Reaction of $PtCl_2$ with an *N,S,O*-Coordinated Calcium Complex: Synthesis and Structure of a Complexed CaPt Anion (C) 1648
- Transition-Metal Thiolates: From Molecular Fragments of Sulfidic Solids to Models for Active Centers in Biomolecules (R) 769

Complexes with tin ligands
- Eight-Coordinate Metal Carbonyls Containing Only Monodentate Ligands. Syntheses and Structural Characterization of $[nPr_4N]_2[(Ph_3Sn)_4M(CO)_4]$, M = Zr, Hf (C) 194

- Enantioselective Metabolism of (±)-α-1,2,3,4,5,6-Hexachlorocyclohexane in Organs of the Eider Duck (C) 320
Metalates
- Eight-Coordinate Metal Carbonyls Containing Only Monodentate Ligands. Syntheses and Structural Characterization of $[nPr_4N]_2[(Ph_3Sn)_4M(CO)_4]$, M = Zr, Hf (C) 194
- Highly Reduced Metal Carbonyls (H) 168
Metallacycles
- Competing Occurrence of Isomeric (Dialkyltartrato)zirconocene Dimers with Dimetallatricyclic and Ten-Membered Dimetallamonocyclic Frameworks (C) 1349
- Metal-Ion Dependent Regioselectivity in Cyclometalation Reactions (C) 1363
Metalla-enes
- Metalla-enes and Metalla-ynes—from Small Molecules to Infinite Polymers (H) 673
Metallomesogens
- Metallomesogens: Metal Complexes in Organized Fluid Phases (R) 375
Metathesis
- Methyltrioxorhenium as Catalyst for Olefin Metathesis (C) 1636
- On a Metathesis Reaction of Tetrathiafulvalene (TTF) (C) 1127 (1386)
Methane
- Activation of Methane (H) 820
Methionine
- A Metal-Ion- and Cofactor-independent Enzymatic Redox Reaction: Halogenation by Bacterial Nonheme Haloperoxidases (C) 1487
Methylation
- Methylating Reductive Dimerization of Aromatic Carbonyl Compounds, a Novel Organometallic Reaction (C) 1138
Methylene phosphonium ions
- Methylene Phosphonium Ions (C) 709
Methyleneboranes
- A Cyclic Methyleneborane with Trapezoidal Geometry (C) 594
Methylindenol
- Enantioselective Protonation of a Simple Enol: Aminoalcohol-Catalyzed Ketonization of a Photochemically Produced 2-Methylinden-3-ol (C) 416
Methyltrioxorhenium
- Methyltrioxorhenium as Catalyst for Olefin Metathesis (C) 1636
- Methyltrioxorhenium as Catalyst for Olefin Oxidation (C) 1638
- Methyltrioxorhenium as Catalyst of a Novel Aldehyde Olefination (C) 1641
Micelles
- Alkane Cascade Polymers Possessing Micellar Topology: Micellanoic Acid Derivatives (C) 1176
- Groups of Organic Molecules That Operate Collectively (R) 1086
- Structure and Reactivity in Reverse Micelles (B) 339
- Unimolecular Micelles (C) 1178
Michael additions
- Diastereo- and Enantioselective Michael Addition Initiated Cyclizations to *trans*-Substituted Cyclopentanecarboxylates (C) 1664
- Tandem Silyl Migrations Leading to α,β-Bis-silylated Enals and Enones (C) 1687
Mixed-valent compounds
- A Mixed-Valent Pentanuclear Gold Complex Containing a Linear $Au_5^{9\oplus}$ Chain (C) 198
- $Ag_{25}Bi_3O_{18}$, a Potentially Valence-Unstable Bi^{III}/Bi^{V} Compound (C) 883
- $[As^{V}V^{V}_{12}V^{IV}_{2}O_{40}]^{7\ominus}$, a Topologically Interesting, Mixed Valence Cluster as Model for Vanadium Minerals Formed by Weathering (C) 210
- Formation of a Cluster Sheath around a Central Cluster by a "Self-Organization Process": the Mixed Valence Polyoxovanadate $[V_{34}O_{82}]^{10\ominus}$ (C) 588
- $K_2Cu_5Te_5$, a Novel Mixed-Valence Layered Compound with Metallic Properties (C) 1325
- Reduction of the Small Subunit of Ribonucleotide Reductase by Diimide: Evidence for the Formation of the Mixed-Valence Fe^{II}–Fe^{III} Center (C) 1135
Modhephene
- Synthesis, Absolute Configuration and Specific Rotation of (+)- and (−)-Modhephene (C) 1492
Molecular dynamics
- Molecular Structures from Density Functional Calculations with Simulated Annealing (R) 630
Molecular recognition
- Complexation of Transition Metal Ions with Substituted Aza Macrocycles: Induction of Columnar Mesophases by Molecular Recognition (C) 1375
- Direct Observation of Streptavidin Specifically Adsorbed on Biotin-Functionalized Self-Assembled Monolayers with the Scanning Tunneling Microscope (C) 569
- Enantioselective Complexation of Flexible and Rigid Substrates through Molecular Recognition (C) 858
- Molecular Recognition and Transport of Nucleobases—Superiority of Macrobicyclic Host Molecules (C) 442
- Sandwiches Bring a New Element to Molecular Recognition (H) 407
Molecular sieves
- The Synthesis and Structure of Some New Sodalites: The Lithium Haloberyllophosphates and -arsenates (C) 1169
Molybdenum compounds
- A Distorted *anti*-Perovskite Structure in Ternary Tetrathiafulvalenium Salts: Construction, Distortion, and Antiferromagnetic Ordering (C) 1498
- $[Mo(CO)_2(^{tbu}S'_2)_2]$ and $[MoCO(PPh_3)(^{tbu}S'_2)_2]$: CO Coordination at [Mo–S] Centers Where Mo Is in a High Oxidation State (C) 1311
- Mo–Mo Quadruple Bonds Bridged by 1,8-Naphthyridinyl-2,7-Dioxide: an Insight into the Nature of a Parallel-Linked Stiff-Chain Polymer: $+M^nM\sim M^nM+_x$ (C) 862
- *trans*-[Mo(η^2-*O,C*-PhNCO)(η^2-*C,N*-PhNCO)(*syn*-Me_8[16]aneS$_4$)]; Novel Discrimination of the C=O and C=N Bonds of PhNCO at Stereochemically Different Axial Sites (C) 982
- Synthesis, Structure, and Rearrangement of 1,3-Dibora[5]radialenes (C) 84
- Unique Reactivity of Heterodinuclear Pentacarbonyl(Fulvalene)Molybdenum-ruthenium with Alkynes: Fluxionality, Rearrangements, Structures, and First Reversible Conversion of a "Side-on" to a Semi-Bridging Alkenylidene Ligand (C) 1463

Mosses
- Bryophytes, a Source of Biologically Active, Naturally Occurring Material? (R) 130
Multiple bonds
- Fluorine-Stabilized Sulfur–Carbon Multiple Bonds (R) 361
