12, R = CH_3

The analogies to the benzene-like oligo(phenylene vinylenes) (**1**) are useful in the description of the chemical and physical properties of the compounds **10a**, **11**, and **12** (type **3**) and **13a**, **14**, and **15** (type **4**). As in the oligo(phenylene vinylenes),[14] (*E*/*Z*)-**13a** is slowly transformed into the (*E*/*E*) isomer (36 days, 32%) on irradiation with a mercury high pressure lamp (180 W, Q-600, Pyrex filter). Neither (*E*/*E*)-**13a** nor (*E*/*E*)-**14** are changed by irradiation at $\lambda \geq 300$ nm over the same period. The question whether photochemically initiated *Z*/*E* isomerizations of stilbene and **1a**[14] are diabatic or adiabatic makes a comparison of these compounds with the COT system **13a** desirable.

[a] All NMR spectra, unless stated otherwise, are recorded in [D_8]THF, the neutral compounds at 25°C and ions at −30°C. [b] Assignment of the signals by H, C COSY NMR spectra (^{1}H: 300 Hz, ^{13}C: 75 MHz). [c] Assignment of the signals by correlation with chemical shifts with Hückel charge densities. [d] Assignment of the signals by selective ^{1}H decoupling. [e] Eight ring protons. [f] Assignment not possible. [g] Arene protons.

The electrochemical reduction of the title compounds by cyclic voltammetry convincingly documents their unusual redox systems (Table 2).

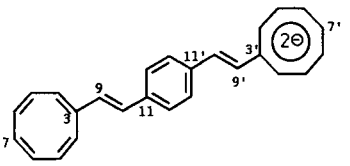
– In the homologous series of **1**, completely reversible one-electron transfers are observed. Increasing the chain length increases the number of redox steps, shifts the reduction potential to more negative values, and causes the potential difference between the first and second reduction, $\Delta E = E_1 - E_2$ to approach a minimum as a result of the decreasing Coulomb repulsions.[1]

– For the reduction of cyclooctatetraenylene vinylenes, the first wave corresponds to an electrochemically irreversible, but chemically reversible, two-electron transfer (see Table 2). This situation is similar to that of COT itself;[15–17] there the reason for the small potential difference ΔE is the electronic stabilization of the dianion, and the lack of electrochemical reversibility is due to the planarization of the ring at the radical anion stage. Thus as a first approximation, the first two-electron transfer in **10a**, **11**, **12**, **13a**, **14**, and **15** may be understood as a charging of the COT unit.

– The dominance of COT units as electrophores—in spite of potentially extended π conjugation—is also shown by the successive reductions. Finally each COT ring has taken up two electrons, and the "tetra-COT" system **12** is transformed into an octaanion!

– The difference in behavior between the "bis-COT" compounds **10a** and **14**, which are distinguished from one another by the length of the bridging group between two COT units, is characteristic. Compound **14** is reduced in two separate, irreversible, two-electron transfers, whereas in **10a** a reversible one-electron transfer follows an irreversible two-electron transfer. Evidently the addition of electrons to one of the COT units in **10a** leads at least to a partial planarization of the second ring. *Staley* et al. [18, 19] reached a similar conclusion for the dianion formation in a series of "bis COT" compounds.

The reduction with alkali metals allows a characterization of the resulting diamagnetic ions by spectroscopy.[20] A correlation of the ^{13}C NMR chemical shifts of (*E,E*)-**13a**$^{2\ominus}$/2K$^{\oplus}$ with the local π charge density (Table 1) suggests that the excess charge is localized mainly on the eight-membered ring and the olefinic centers C10(10′). No significant charging of the phenyl units is suggested by the ^{1}H NMR signals of the tetraanion salt (*E,E*)-**14**$^{4\ominus}$/4K$^{\oplus}$ (Table 1). Complete alkali-metal reduction of **10a** yields a tetraanion. The ^{1}H NMR signals of the olefinic protons occur at low field due to the diatropism (δ = 6.95, (s)) of the two eight-membered rings.



14$^{2\ominus}$

The occurrence of *two* AB systems for the olefinic protons in the ^{1}H NMR spectrum of the dianion salt (*E,E*)-**14**$^{2\ominus}$/2K$^{\oplus}$ (200 MHz, −30°C) suggests an "unsymmetric" charge distribution. The charge is localized on one COT ring. The spectra show no change at different temperatures, even up to 50°C (90 MHz), which excludes a thermally induced charge fluctuation below this temperature, although delocalization of charge should be the preferred electrostatic configuration. Such a charge redistribution in the anion implies that the second COT ring becomes coplanar in the intermediate stage, which results in an activation energy caused by geometric factors.[18, 19, 21]

That at low temperatures (−80°C) the charge in dianion **10a** is mainly localized on one ring may be deduced from the ^{1}H NMR spectrum ([D_8]THF, 200 MHz). Only one AB spin

Table 2. Cathodic peak potentials (E_{pc}) of cyclooctatetraenylene vinylenes as determined by cyclic voltammetry [a].

system is observed for the olefinic protons (H9 and H10), $\delta = 6.78$ and 6.57, $^3J = 14.8$ Hz). Due to an increase in temperature the shape of the lines changes. Coalescence occurs at $-15\,^{\circ}C$, and at temperatures $> 25\,^{\circ}C$ a sharp singlet is observed ($\delta = 6.67$). The Gibbs activation energy of this process that can be understood as an intramolecular charge redistribution, is estimated at $\Delta G^{\ddagger}_{(-15\,^{\circ}C)} = 12.8 \pm 0.3$ kcal mol^{-1}. In agreement with the cyclic voltammetry findings, the charge redistribution apparently occurs more easily in **10a**$^{2\ominus}$/2K$^{\oplus}$ than in **14**$^{2\ominus}$/2K$^{\oplus}$.

Whereas (*Z*)-stilbene is rapidly transformed into the *E* isomer on reduction with alkali metals,[22] at $-80\,^{\circ}C$ (*E,Z*)-**13a** can be converted into a dianion with its configuration intact, which isomerizes only very slowly into the *E,E* isomer (20% after 13 weeks at $-80\,^{\circ}C$).

[11] All new compounds were characterized by elemental analysis and spectroscopic data. For typical examples see Table 1.
[12] The dianion of **10a** is already known [19], but the neutral compound and its electron transfer reactions have not been described.
[13] The electron absorption spectra of the compound types **3** and **4** are distinctly different. Compounds **10a**, **11**, and **12** have a broad poorly structured band at large wavelengths, which broadens further and undergoes a bathochromic shift on lengthening the chain (**10a**: $\lambda_{max} = 328$ nm ($\varepsilon = 3135$); **11**: 332 (5487); **12**: 431 (4298)), whereas **13**, **14**, and **15** are characterized by a narrow band at short wavelenths as well as an intensive, broad band at longer wavelengths (**13**: $\lambda_{max} = 293$ nm ($\varepsilon = 30799$); **14**: 365 (26483); **15**: 354 (91678)). On going from **14** to **15** the longer wavelength band increases in intensity, but, in complete contrast to the compound of the homologous series **1**, undergoes a slight hypsochromic shift.

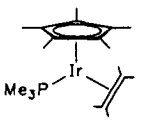
Formation of Doubly Vinyl-Bridged Binuclear Iridium Complexes by C-H Activation**

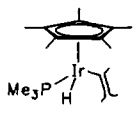
By *Angelika Nessel, Oliver Nürnberg, Justin Wolf,* and *Helmut Werner**

Dedicated to Professor Kurt Dehnicke on the occasion of his 60th birthday

Vinyl transition-metal complexes can be formed from nonactivated olefins in general only under drastic reaction conditions. *Bergman* and *Stoutland*[1] reported in 1985 that photolysis of [Cp*IrH$_2$(PMe$_3$)] (Cp* = C$_5$Me$_5$) in presence of ethene leads not only to the formation of the expected olefin compound [Cp*Ir(C$_2$H$_4$)(PMe$_3$)] (**1**), but also to the hydrido(vinyl) complex [Cp*IrH(HC=CH$_2$)(PMe$_3$)] (**2**), which on heating to ca. 180 °C isomerizes to give **1**. We now describe binuclear doubly vinyl-bridged iridium complexes that are obtained from well-known, easily accessible precursors and H$_2$C=CH*t*Bu in presence of base without photochemical activation.

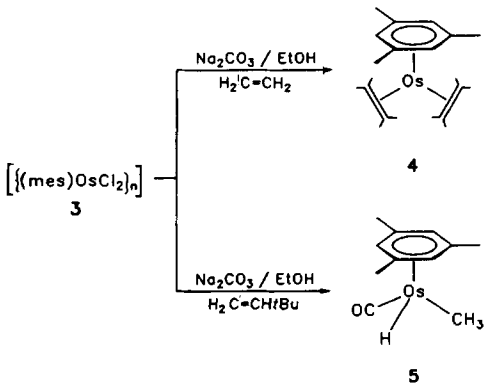


1



2

Previously, *Maitlis* et al. have shown[2] that [Cp*IrCl$_2$]$_2$ reacts with ethene and Na$_2$CO$_3$/EtOH to give [Cp*Ir(C$_2$H$_4$)$_2$]. The mesitylene osmium complex **3** behaves analogously and on treatment with C$_2$H$_4$ and Na$_2$CO$_3$/EtOH affords compound **4**.[3] If, however, ethene is replaced by 3,3-dimethyl-1-butene the carbonyl(hydrido)methyl complex **5** is formed.[4] Labeling experiments confirm that the ligands CO, CH$_3$, and H are really generated by stepwise fragmentation of ethanol in the coordination sphere of the metal.



In contrast to our expectation, the reaction of [CpIrBr$_2$]$_2$ (**6**, Cp = C$_5$H$_5$) with H$_2$C=CH*t*Bu and Na$_2$CO$_3$/EtOH does not give [CpIrH(CH$_3$)(CO)],[5] but leads to a mixture of

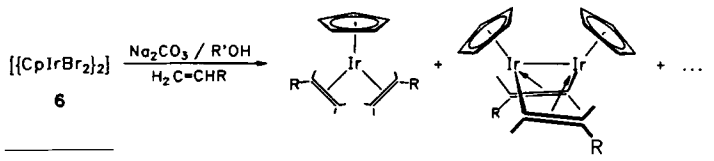
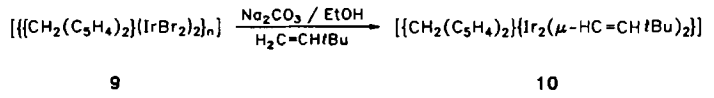
products in which, besides $[CpIr(H_2C{=}CHtBu)_2]$ (**7**),[6] also a small amount of the binuclear complex **8** is present. By using *i*PrOH instead of EtOH, compound **8** is isolated in 30% yield. The supposed structure of **8** is supported by the ^1H as well as the ^{13}C NMR data,[7] which unequivocally show the presence of a β-C-substituted vinylic ligand.





A clean reaction occurs between the polymeric dibromoiridium complex **9**,[8] prepared from $[\{CH_2(C_5H_4)_2\}\{Ir(C_2H_4)_2\}_2]$, and Na_2CO_3/EtOH in the presence of $H_2C{=}CHtBu$. The reaction mixture is warmed to 75–80 °C for 3 h, after which a red, moderately air-stable solid **10** is isolated. The NMR data of **10** are similar to those of **8**.[7] The structure of **10** is shown in Figure 1.[9] Each vinylic

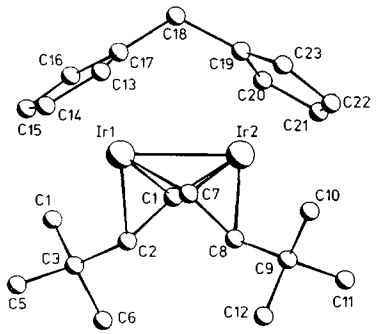


Fig. 1. Structure of **10** in the crystal. Selected bond distances [Å] and bond angles [°]: Ir1–Ir2 2.5495(5), Ir1–C1 2.098(9), Ir1–C2 2.212(9), Ir1–C7 2.037(9), Ir2–C1 2.010(9), Ir2–C7 2.137(9), Ir2–C8 2.204(9), C1–C2 1.40(1), C7–C8 1.42(1); Ir1-C1-Ir2 76.7(3), Ir1-C7-Ir2 75.2(3), Ir1-Ir2-C1 52.2(3), Ir2-Ir1-C7 54.2(3), Ir1-Ir2-C7 50.6(3), Ir2-Ir1-C1 50.1(3), C1-C2-C3 124(1), C7-C8-C9 123.1(8), C17-C18-C19 119.1(9).

group is coordinated to one metal atom via a σ and to the other metal atom via a π bond and thus behaves as a bridging unit. The Ir–Ir distance of 2.5495(5) Å is noteworthy because it is significantly shorter than a Ir–Ir single bond [2.70–2.75 Å][10] (which for electronic reasons would be expected for **10**) and comparable to that of a Ir–Ir double bond [2.554 Å].[11] We assume that the short metal–metal bond length is caused by the strain which is exerted by the bis(cyclopentadienyl)methane ligand on the rest of the molecule. An indication of this strain can be seen in the size of the C17-C18-C19 angle [119.1(9)°] which is ca. 10° wider than the tetrahedral angle.[12] The M–C and C–C distances in the $Ir_2(\mu\text{-}HC{=}CHtBu)_2$ unit correlate quite well with those of the binuclear rhodium complex $[(C_9H_6Me)_2Rh_2(\mu\text{-}HC{=}CH_2)(\mu\text{-}MeC{=}CHMe)]$ which has been prepared from $[(C_9H_6Me)Rh(C_2H_4)_2]$ and but-2-yne.[13]

To the best of our knowledge, compound **10** is the first example of a binuclear iridium complex in which two iridium atoms in the oxidation state +II are bridged by three organo groups and in which no terminal ligands such as CO, PR_3, or Cl are present. Particularly noteworthy in the synthesis of **10** are the mild conditions for the activation of a C–H bond in $H_2C{=}CHtBu$ with Na_2CO_3/EtOH which leads to the formation of a vinylic group. A similar conversion of an olefin $H_2C{=}CHR$ (R = *i*Pr, Ph) into a vinylic ligand HC=CHR in a mononuclear rhenium complex with *t*BuOK as base has recently been described by *Gladysz* et al.;[14] in that case the positive charge at the metal center is presumably crucial for the cleavage of the C–H bond.

Experimental Procedure

8: A suspension of **6** (121 mg, 0.15 mmol) in *i*PrOH (10 mL) was treated with Na_2CO_3 (500 mg, 4.72 mmol) and $H_2C{=}CHtBu$ (0.4 mL, 3.17 mmol) and warmed to 75 °C for 3 h. After cooling to room temperature, the solvent was removed, the residue was extracted with pentane (25 mL), and the extract was evaporated to dryness in vacuo. The red-brown oily residue was dissolved in hexane (4 mL), and the solution was chromatographed on Al_2O_3 (neutral, activity grade V, column length 20 cm). With hexane, first an orange and then a yellow fraction was eluted. The yellow fraction was evaporated to dryness in vacuo, and the residue was recrystallized from pentane (2 mL) at −78 °C. Yellow, moderately air-stable crystals were obtained: yield 30 mg (30%); m.p. 154 °C (dec.); correct elemental analysis. **10**: Prepared as described for **8**, using **9** [8] as starting material and ethanol as solvent; red crystals: yield 59%; m.p. 159 °C (dec.); correct elemental analysis.

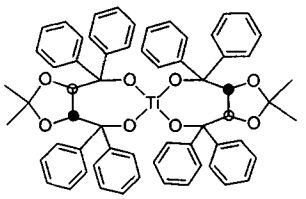
Titanate-Catalyzed Enantioselective Addition of Dialkylzinc Compounds—Generated in situ from Grignard Reagents in Ether—to Aldehydes**

By *Dieter Seebach,* Linda Behrendt,* and *Dorothee Felix*

Dedicated to Prof. Dr. Vlado Prelog on the occasion of his 85th birthday

Although zinc compounds are much older than Grignard reagents,[1] they play only a minor role in modern organic synthesis. Thus, the catalytic enantioselective addition of R_2Zn compounds[2] to aldehydes has been performed almost exclusively with commercially available solutions of diethylzinc in hexane or toluene.[3] Recently we discovered[4] that the reaction of diethylzinc with benzaldehyde, catalyzed by the spirotitanate **1**, gives enantioselectivities of 99:1 both



1

Scheme 1. Spirotitanate **1** synthesized from (*R,R*)-tartaric acid.

in ether and in toluene. This lead us to wonder if it would be possible to prepare MgX_2-free solutions of other dialkylzinc compounds[5a] directly from Grignard reagents,[5b] generated under the usual conditions according to Equation (a).

We took advantage of the well-known Schlenk equilibrium [Eq. (b)], which enables dialkylmagnesium compounds to be obtained pure after precipitation of MgX_2 with dioxane,[6] and treated Grignard solutions first with anhydrous $ZnCl_2$ [Eq. (c)], and then with dioxane. Separation of the precipitated $MgX_2 \cdot C_4H_8O_2$ complex, Equation (d),[2] gave clear solutions[7] which were used directly in the tetraisopropyltitanate-mediated addition to aldehydes, enantioselectively catalyzed by **1**. The whole one-pot procedure is shown in Equation (e); details about the conversions leading to alcohols **2**–**14** in > 90% *ee* are given in Table 1. Our initial concern that the longer chain alkylzinc and/or -titanium derivatives formed in solution would decompose by β-hydride abstraction[12] proved to be needless. Only primary alkylzinc reagents reacted with high enantioselectivities;[13] the conversion seems sensitive to steric congestion.[14]

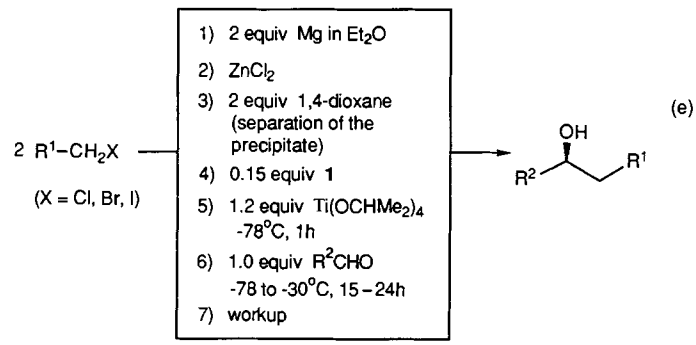
In the course of determining the enantiomeric excess of the *sec*-alcohols produced—some of which have not yet been described in optically active form—we reached the limits of routine NMR methodology.[15] We therefore switched to GC analysis on chiral phases; details are given in Table 1.[16]

$$RCH_2X + Mg \xrightarrow{Et_2O} RCH_2MgX \quad (a)$$

$$2\,RCH_2MgX \rightleftharpoons (RCH_2)_2Mg + MgX_2 \quad (b)$$

$$2\,RCH_2MgX + ZnCl_2 \rightleftharpoons (RCH_2)_2Zn + MgX_2 + MgCl_2 \quad (c)$$

$$MgX_2 + \text{dioxane} \longrightarrow X_2Mg \cdot \text{dioxane} \downarrow \quad (d)$$



(e)

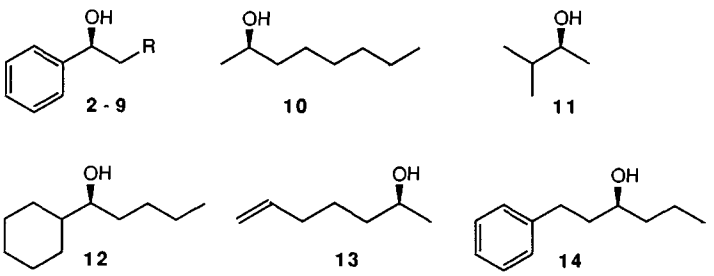


Table 1. Reaction of several primary Grignard reagents with aldehydes under the conditions given in Eq. (e) and in the experimental procedure [8a]. *R/S* ratios determined by gas chromatography [8–11].

Grignard reagent	aldehyde	product	yield [%]	*S/R*
CH_3MgI	C_6H_5CHO	**2**	55	97:3
C_2H_5MgBr	C_6H_5CHO	**3**	40	99:1
C_3H_7MgBr	C_6H_5CHO	**4**	52	99:1
C_4H_9MgBr	C_6H_5CHO	**5**	82	98:2
C_4H_9MgCl	C_6H_5CHO	**5**	70	99:1
$C_8H_{17}MgBr$	C_6H_5CHO	**6**	31[a]	98:2
$(CH_3)_2CHCH_2MgBr$	C_6H_5CHO	**7**	30[b]	97.5:2.5
$(CH_3)_2CH(CH_2)_2MgBr$	C_6H_5CHO	**8**	82	98.5:1.5[e]
$CH_2{=}CH(CH_2)_2MgBr$	C_6H_5CHO	**9**	83	95:5[e]

CH_3MgBr	$(CH_3)_2CHCHO$	**11**	40[c]	> 95:5
C_4H_9MgBr	*cyclo*-$C_6H_{11}CHO$	**12**	35[d]	95:5
CH_3MgI	$CH_2{=}CH(CH_2)_3CHO$	**13**	69	97.5:2.5
C_3H_7MgBr	$C_6H_5(CH_2)_2CHO$	**14**	60	> 95:5[e, f]

[a] The zinc reagent was used in insufficient amounts. [b] Conversion occurred very slowly; reaction time 60 h. [c] Isolation made difficult by low b.p. of **11**. [d] Reaction was quenched too early. [e] Determination of the absolute configuration of the main enantiomer is based on the assumption that the alkyl group is transferred to the *Si* face of the aldehyde. [f] GC separation was not successful; *S/R* ratio determined by $[\alpha]_D$.

[**] The results described herein are part of the proposed dissertation of *L. Behrendt*. This research was generously supported by Firmenich SA (Geneva) and Sandoz AG (Basel).

The results in this communication are progress toward development of enantioselective and catalytic variants of classical reactions in organic synthesis.[3, 17]

Typical procedure

8: A 1.0 M zinc chloride solution in Et_2O (Aldrich) [20 mL, 0.02 mol] was diluted with 10 mL Et_2O and isopentyl magnesium bromide (0.04 mol in ether, ca. 2.2 M) was added. The resulting suspension was stirred at room temperature for 2 h, then treated with 12 mL 1,4-dioxane, and stirred for an additional 45 min. Subsequent filtration under an inert atmosphere yielded a clear solution of zinc reagent. This was added at −78 °C to a previously prepared solution of spiro compound **1** (1.38 g, 1.4 mmol) and $Ti(OCHMe_2)_4$ (3.57 mL, 12 mmol) in 20 mL of Et_2O. The mixture was stirred at −78 °C for 1 h, PhCHO (1.0 mL, 10 mmol) was added, and the reaction temperature was raised to − 30 °C. After complete conversion (TLC assay) the reaction was quenched at − 30 °C with saturated NH_4Cl solution (20 mL), ether added (50 mL), and the mixture filtered through Celite. The organic layer was washed with water and brine, dried over Na_2SO_4, filtered, and evaporated in vacuo. Pentane was added to the resulting oil, which initiated the crystallization of the diol ligand originating from spiro compound **1**. The supernatant was again concentrated in vacuo and compound **8** isolated by bulb-to-bulb distillation. (For other conversions the product was additionally purified by flash chromatography through a short silica gel column.)

[3] Of nearly 100 cited examples in the newest review article, about 85 are performed with diethylzinc and nearly all of them in toluene or hexane: R. Noyori, M. Kitamura, *Angew. Chem. 103* (1991) 34–55; *Angew. Chem. Int. Ed. Engl. 30* (1991) 49–69.

[4] B. Schmidt, D. Seebach, *Angew. Chem. 103* (1991) 100; *Angew. Chem. Int. Ed. Engl. 30* (1991) 99.

[5] a) By this procedure the handling of hazardous dialkyl zinc compounds is avoided. The principle of transmetalation from Mg to Zn derivatives has been known for quite a long time; see [1, 2]. b) The example of $Bu_2Mg + C_6H_5CHO$ showed that magnesium alkyl compounds do not themselves add enantioselectively to aldehydes with **1**/$Ti(OCHMe_2)_4$ (solvent: Et_2O/dioxan 10/1; − 100 to −78 °C, 53% **5**, 5% *ee*).

[6] W. Schlenk, W. Schlenk, *Ber. Dtsch. Chem. Ges. 62* (1929) 920; see also [2] p. 197.

[7] The transmetalation of Li compounds is also possible; a Bu_2Zn solution generated from BuLi and $ZnCl_2$ (2/1 in toluene) afforded, after steps 4–7 in Equation (e), **5** in a *S*/*R*-ratio of 99.5:0.5.

[8] a) All experiments have been carried out only once and are therefore not optimized. In contrast to most other catalysts used for enantioselective additions to carbonyl compounds to date, *both* enantiomeric forms of the one used in this case are easily accessible! The given configuration (*R*,*S*) of the enantiomer formed in excess was deduced by comparison of the measured $[\alpha]_D$ rotations with the literature values (*S* in the cases of **2**–**9** and **11**–**14**, *R* in the case of **10**) [8 b]. Unless otherwise noted, the enantiomeric excesses have been determined by gas chromatography: Alcohols **2**, **3**, **5**–**8**, **11**–**13** on heptakis(2,3,6-tri-*O*-methyl)-β-cyclodextrin in OV 1701 Vi [9, 11], 52 m × 0.27 mm (I.D.); **4**, **9** (TFA derivative) on octakis(3-*O*-butanoyl-2,6-di-*O*-*n*-pentyl)-γ-cyclodextrin in OV 1701 Vi (1:2) [10, 11], 50 m × 0.27 mm (I.D.). b) J. J. C. Gros, S. Bourcier in H. B. Kagan (Ed.): *Stereochemistry—Fundamentals and Methods, Vol. 4*, ("Absolute Configurations of 6000 Selected Compounds with One Asymmetric Carbon Atom") Thieme, Stuttgart 1977; S. H. Wilen in E. L. [12] D. Seebach, B. Weidmann, L. Widler in R. Scheffold (Ed.): *Modern Synthetic Methods, Vol. 3*, Salle & Sauerländer, (Aarau, Schweiz) and J. Wiley & Sons (New York, USA) 1983, pp. 217–353; H. G. Raubenheimer, D. Seebach, *Chimia 40* (1986) 12. The ate-complexes of **1** mentioned in [4] have only been stable with methyl or allyl; with butyl a green colour appeared [indicates Ti(III)derivatives].

[13] $(Me_2CH)_2Zn$ generated from $Me_2CHMgBr$ yielded after 55 h 88% of the adduct with PhCHO, *S*/*R* = 71/29. With $PhCH_2Cl$ and PhCHO 27% *rac*-$PhCH(OH)CH_2C_6H_5$ was obtained according to Equation (e).

[14] Cf. the slow formation of **7** (Table 1). With Me_3CCH_2Br and PhCHO, according to Equation (e) except at room temperature and for 72 h, we did not obtain any product. Me_3CCHO and Bu_2Zn gave 10% yield of $Me_3CCH(OH)Bu$ in 65% *ee* after 4 d.

[15] NMR shift reagents often cause a signal broadening unfavorable for determining extreme enantiomeric ratios. Derivatization, e.g. according to Mosher, may lead to changed isomeric ratios (kinetic resolution) and depends on the enantiomeric purity of the reagent, cf. W. A. König, K.-S. Nippe, P. Mischnick, *Tetrahedron Lett. 31* (1990) 6867.

[16] The diol used to prepare **1** has a great tendency to form inclusion compounds [K. Mori, F. Toda, *Tetrahedron: Asym. 1* (1990) 281; F. Toda, R. Toyotaka, H. Fukuda, *ibid. 1* (1990) 303]; we ensured in every case that the diol which separated during workup had no alcohol included—in which case the enantiomeric ratio could have been altered.

A Homogeneous Platinum Catalyst in the Stationary $BF_3 \cdot H_2O$ Phase for the Hydrogenation of Arenes**

By *István T. Horváth**

Although liquid-phase homogeneous catalysts generally have higher catalytic activity and selectivity than heterogeneous systems, product separation could be a major obstacle for industrial application.[1] An attractive solution to the separation problem is the immobilization of the liquid phase on solid carriers (Fig. 1).[2] The liquid phase can be the catalyst itself, or it may contain a dissolved catalyst. In order to maintain the catalytic performance of a supported liquid-phase (SLP) catalyst, the liquid phase must remain on the support throughout the reaction. An ideal SLP catalyst does not lose its liquid phase, which is therefore stationary, and the catalyst may be called a *stationary liquid-phase catalyst*.[3] Most of the SLP catalysts are used to catalyze reactions between gaseous reactants leading to gaseous products.[2g] SLP catalysts can also use a supported liquid phase with limited solubility in the reactants, products, and/or solvents. Water or aqueous acids are excellent choices for organic reactions performed in apolar media, and several such aqueous systems have been developed.[4]

Reduction of aromatic hydrocarbons has recently received much attention as a result of increased environmental

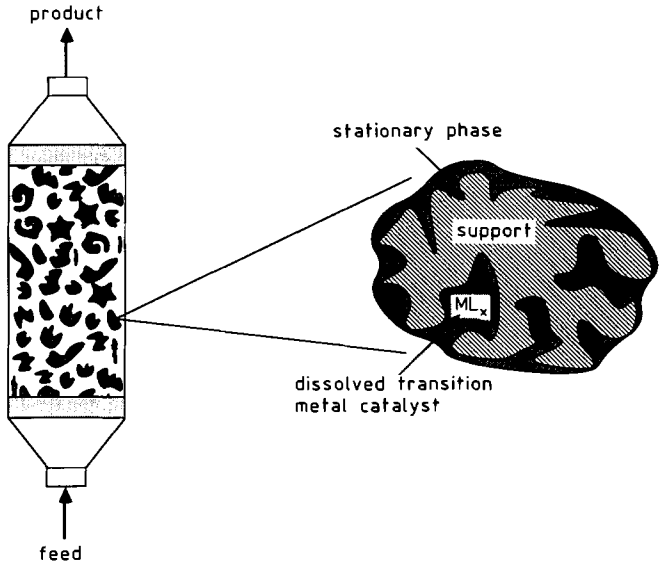

Fig. 1. Catalytic liquid phase immobilized on a solid support.

concern. Although heterogeneous transition-metal catalysts could be used for the hydrogenation of arenes, they generally require severe reaction conditions under which cracking and other undesirable side reactions could occur. In contrast, several homogeneous transition-metal catalysts are capable of selectively hydrogenating arenes at mild conditions.[5] Their application however, is limited by the difficult separation of the products from the catalysts. We wish to report the development of a stationary $BF_3 \cdot H_2O$ phase platinum catalyst for the hydrogenation of aromatic hydrocarbons at mild conditions.

A typical catalyst is prepared by impregnating 2 g of support[6] with a yellow solution of 0.2 mmol $PtCl_2(CH_3CN)_2$ in 1.4 g $BF_3 \cdot H_2O$ (an ionic platinum hydrogenation catalyst system developed by *Larsen* et al.[5i]) by the incipient wetness technique under N_2. The system is used without further treatment. The fresh catalyst is light yellow, and ^{195}Pt NMR spectroscopy of the liquid phase indicates the presence of two Pt^{II} species.[7] Hydrogenation of arenes occurs rapidly even at 25 °C under 2.76 MPa (400 psi) H_2 (Table 1), and the colorless products can be separated from the catalyst by filtration.[8] The hydrogenation of benzene leads to the quantitative formation of cyclohexane: no GC or NMR evidence was found for the presence of hydrogenolyzed, cracked, or partially reduced products. The benzene hydrogenation rate increases proportionally with increasing concentration of $[PtCl_2(CH_3CN)_2]$. Reduction of naphthalene results in the transient formation of tetralin, as expected, which is then hydrogenated to *cis*- and *trans*-decalin

Table 1. Hydrogenation of aromatic hydrocarbons with a homogeneous SLP $BF_3 \cdot H_2O$–platinum catalyst.

Arene	[C] [mmol]	[Pt] [mmol]	$BF_3 \cdot H_2O$ [g]	Support[a]	M[b] [g]	T [°C]	p[c] [MPa]	k[d] [mmol h^{-1}]

in a ratio of 9:1. During the course of the reactions the catalyst turns black, indicating slow reduction of some Pt^{II} species to metallic platinum. Treatment of the catalyst with H_2 prior to the addition of benzene also results in metallic platinum formation and catalyst deactivation.[9] In order to monitor the possible role of the chemical composition of the support, the hydrogenation of the 1:1:1:1 mixture of benzene, toluene, *o*-xylene, and 1,2,4-trimethylbenzene was investigated using different supports. The same catalytic system supported on CPG-240[6a] or on clay[6b] shows almost identical hydrogenation activities (Table 2). These data suggest that the support does not participate chemically in the hydrogenation, and the catalyst is operating in the aqueous acid phase.

Since SLP catalysts could lose catalytically active species into the organic phase, a leaching test was performed by using two autoclaves connected through a 7 μm filter. In the first autoclave toluene was hydrogenated at 2.76 MPa (400 psi) H_2 partial pressure and 25 °C to methylcyclohexane up to 68% conversion.[8] The solution was then pumped through the filter at 2.76 MPa and 25 °C into the second autoclave, leaving the SLP $BF_3 \cdot H_2O$–platinum catalyst in the former. The second autoclave also contained benzene. No further reaction was found for toluene and no reaction at all for benzene in the next 24 hours. These results unambiguously show that no catalytically active platinum species is leached from the stationary $BF_3 \cdot H_2O$ phase under hydrogenation conditions.

The continuous performance of the $BF_3 \cdot H_2O$–platinum catalyst was investigated in a tubular trickle-bed reactor (∅ 12.5 mm).[10] Benzene and solvents were neither dried nor saturated with $BF_3 \cdot H_2O$. The hydrogenation of benzene was performed at 25 °C and 2.76 MPa H_2 using 0.1 g $[PtCl_2(CH_3CN)_2]$ in 1.4 g $BF_3 \cdot H_2O$ on 2.0 g SiO_2[6c] as catalyst. During the first four hours the catalyst reached its steady-state (10% conversion of benzene to cyclohexane)

Table 2. Selectivities for the reduction of a 1:1:1:1 mixture of benzene, toluene, *o*-xylene, and 1,2,4-trimethylbenzene with a homogeneous SLP $BF_3 \cdot H_2O$–platinum catalyst at 22 °C under 2.76 MPa H_2.

and retained this activity over the next 48 hours. After this period the conversion gradually decreased indicating slow catalyst deactivation. The reaction was stopped after 75 hours, while the catalyst was still active, for catalyst characterization. The used catalyst again contained some metallic platinum. Elemental and water analyses revealed that the amount of water on the catalyst had increased slightly and that some BF_3 had leached from the $BF_3 \cdot H_2O$ phase.[11] These results implied that the BF_3/H_2O ratio decreased during the reaction, leading to a weaker and less active acid system. Indeed, when $BF_3 \cdot 1.3\,H_2O$ was used as a liquid phase for the hydrogenation of benzene, the catalytic activity dropped by 30%.

The effect of the lower acidity suggests that the reaction is initiated by the protonation of the arene ring either by $H[BF_3OH]$ or by a cationic platinum species formed by the reaction of $[PtCl_2(MeCN)_2]$ and $BF_3 \cdot H_2O$ under hydrogen. In the first case the formed arenium ion is then hydrogenated by a platinum species able to activate and transfer three moles of molecular hydrogen. In contrast, in the second mechanism the initially formed platinum complex activates and transfers the H_2 to the already coordinated arene ring. To gain further insight into how the catalytic system operates, we are currently investigating the hydrogenation of $[D_6]$benzene at 25 °C and a H_2 pressure of 2.76 MPa.[5b,h] Preliminary GC–MS and NMR analysis of samples taken periodically showed less than 0.5% D/H exchange for $[D_6]$benzene and the formation of 99.5% pure $[D_6]$cyclohexane.[12] While the formation of platinum colloids cannot be ruled out at present, the results are consistent with a homogeneous platinum complex system operating in the liquid phase.

[7] The ^{195}Pt NMR spectrum of 0.28 g $[PtCl_2(MeCN)_2]$ in 5.6 g D_2O shows two signals at $\delta = -2048$ and -2070, both in the typcial chemical shift region for Pt^{II} metal complexes. The identification of this species is in progress.

[8] The hydrogenation reactions were performed at constant pressures in a 300 mL-Hastelloy (H) autoclave equipped with a 7 μm filter attached to the dip-leg for sample removal. In a typcial procedure the reactor was charged with the catalyst and 70 g *n*-heptane as solvent under N_2 at 25 °C. The arenes were added at reaction pressure, and the progress of the reactions were followed by GC analysis of samples taken periodically.

[9] Pretreatment of the catalyst with 2.76 MPa (400 psi) H_2 for 18 and 89 hours decreases the rate of the hydrogenation of benzene by a factor 0.75 and 0.4 respectively.

[10] A solution of 30% benzene in *n*-heptane was used at 0.25 mL min^{-1} feed rate and 75 mL min^{-1} H_2 flow rate.

[11] Addition of 0.5% $BF_3 \cdot OEt_2$ to the feed did not stabilize the catalyst, suggesting a complicated deactivation mechanism.

[12] ^{13}C NMR spectroscopy of the CS_2 solution of $[D_6]$cyclohexane revealed the presence of two species in a ratio of 92 to 8. The elucidation of the stereochemistry of $C_6H_6D_6$ is in progress.

Mixed-Anion Aggregates of Metalated Organics: Preparation and Structure of the Mixed-Anion Tetramer $(PhO^{\ominus}Li^{\oplus} \cdot HMPA)_3(\mu_3\text{-}HMPA \cdot Li^{\oplus})NCS^{\ominus}$ **

By *Paul R. Raithby, David Reed, Ronald Snaith,** and *Dominic S. Wright*

We report the planned syntheses and structures of two unusual lithium compounds. The lithium phenoxide complex **1** [HMPA = $OP(NMe_2)_3$] is *moisture-stable*, and molecular mass measurements and ^{7}Li, ^{31}P NMR spectroscopy show it to be a tetramer ($n = 4$) in arene solutions. Complex **1** has been used as a template in the course of developing a route to *mixed-anion* metalated species. Thus, reaction of phenol *and* an inorganic-anion source, ammonium thiocyanate (NH_4NCS), with butyllithium (3:1:4 molar ratios) in toluene containing HMPA affords **2**. The crystal structure of **2** shows that it also is a cubane-like tetramer; however, the $NCS^{\ominus}$ anion does not bridge $Li^{\oplus}$ cations in a μ_3 manner (as the $PhO^{\ominus}$ anions do), but rather one HMPA so bridges and $NCS^{\ominus}$ is terminal on one $Li^{\oplus}$.

$(PhO^{\ominus}Li^{\oplus} \cdot HMPA)_n$ **1** $(PhO^{\ominus}Li^{\oplus} \cdot HMPA)_3(\mu_3\text{-}HMPA \cdot Li^{\oplus})NCS^{\ominus}$ **2**

Complex **1** aroused our interest in view of our recent findings that water can be a ligand within lithiated organics $R^{\ominus}Li^{\oplus}$ ($R^{\ominus}$ = alkyl, aryl, alkynyl, amido, enolato, alkoxy etc.). Such species are notoriously moisture-sensitive, i.e., equilibrium (a) lies to the right, yet in complexes such as $OxLi \cdot TMEDA \cdot H_2O$ ($Ox^{\ominus}$ = 2-mercaptobenzoxazoyl, $C_6H_4O(C{=}S)N^{\ominus}$, TMEDA = $Me_2N(CH_2)_2NMe_2$),[1a]

[**] This work was supported by Gonville and Caius College, Cambridge (Research Fellowship for *D. S. W.*) and by the Associated Octel Co. Ltd. (*R. S.*). We thank also the Science and Engineering Research Council (S.E.R.C.) for the provision of high-field NMR facilities.

$(OxLi \cdot HMPA \cdot H_2O)_2$, and $(OxLi \cdot HMPA)_2 \cdot H_2O$,[1b] equation (b) is valid.

$$R^{\ominus}Li^{\oplus} + H_2O \rightleftharpoons RH + Li^{\oplus}OH^{\ominus} \quad (a)$$

$$R^{\ominus}Li^{\oplus} + H_2O \longrightarrow R^{\ominus}Li^{\oplus} \cdot OH_2 \quad (b)$$

These aqua complexes are stable because the pK_a of OxH is slightly less than that of H_2O, and H_2O insertion displaces the $S^{\delta-}$ centers of the (NCS)Li chelate ring found in the anhydrous complexes, resulting in stabilizing $S^{\delta-} \cdots H_2O$ hydrogen bonding. We reasoned, therefore, that an $R^{\ominus}Li^{\oplus}$ whose precursor RH is substantially more acidic than H_2O, and which has no displaceable functionality to engage in hydrogen bonding with inserted H_2O, should be moisture-stable, i.e., the left-hand side of equilibrium (a) should dominate. Phenol is one obvious candidate. We found that reaction of PhOH with *n*BuLi (1:1) in toluene yielded an amorphous white solid, $(PhO^{\ominus}Li^{\oplus})_n$. However, a similar reaction in the presence of HMPA (1 equiv) afforded a solution, which gave crystals of **1** on refrigeration. As anticipated, these crystals were indefinitely air-stable: the IR and ^1H NMR spectra of samples exposed to air are identical to those of mulls and solutions made up under dry nitrogen. Indeed, **1** was recrystallized, unchanged, from aqueous toluene.

The crystal structure of **1** has not been resolved due to disorder among HMPA ligands, but it is probably a cubane-like tetramer (see Fig. 1). Such tetramers are the norm for 1:1

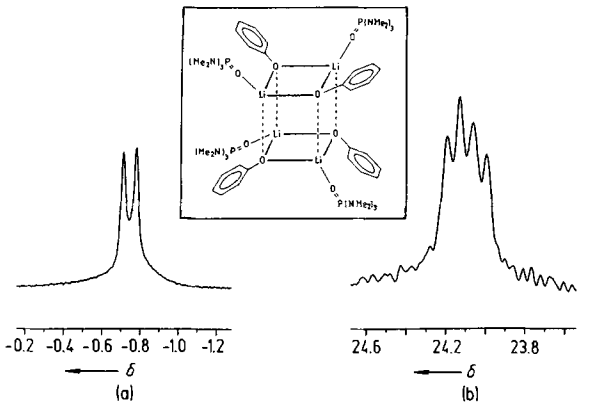

Fig. 1. NMR spectra of **1** in $C_6D_5CD_3$ at $-90\,^{\circ}C$. a) ^7Li b) ^{31}P. Inset: proposed tetrameric structure of **1**.

complexes of lithiated organics containing monodentate Lewis bases (L), such as lithium alkyls R_3CLi, aryls ArylLi, alkynyls $RC{\equiv}CLi$, imides $R_2C{=}NLi$, and enolates $R(=CH_2)COLi$.[2] This widespread occurrence has been rationalized using ring-stacking ideas.[2d, 3] A tetrameric structure is certainly evident from studies on **1** in solution. Cryoscopic relative molecular mass measurements give association state (n) values of 3.7 ± 0.2 (0.05 M benzene solution, relative to $n = 1$) to 4.0 ± 0.1 (0.20 M). The ^7Li NMR (139.96 MHz) spectrum of **1** in $C_6D_5CD_3$ (0.40 M) at $-90\,^{\circ}C$ consists of a doublet [Fig. 1(a)] corresponding to the coupling of each ^7Li nucleus to the ^{31}P atom of just one (i.e., a terminal) HMPA ligand [$^2J_{^7Li^{31}P} = 9.5$ Hz]. Such coupling through (O=P) bonds has been seen before, in the ^7Li NMR solution spectrum of $(LiBr)_2 \cdot 3\,HMPA$;[4] three μ_2-HMPA ligands link the LiBr units, giving a 1:3:3:1 quartet ($^2J = 3.8$ Hz; note the stronger coupling for terminal HMPA ligation in **1**). However, for the first time, such coupling is also observable in the ^{31}P NMR (145.79 MHz) spectrum [Fig. 1(b)]: recorded on the same solution of **1** at $-90\,^{\circ}C$, this consists of the expected 1:1:1:1 quartet (I of $^7Li = 3/2$), $^2J = 9.5$ Hz.

The stability and structure of **1** made it an ideal template for testing a synthetic strategy towards mixed-anion metalated species. Specifically, the recently described "ammonium salt route", which involves reacting solid NH_4X salts with a metal source (metal, hydride, or organometallic) and a Lewis base (L), has afforded many complexes of type $(M_aX_b \cdot xL)_n$, e.g., with M = Li, Na, K,[5a-f] Sr, Ba,[5g] La, Eu, Mn;[5h] X = an inorganic anion like Hal, NCS, BF_4; and L = HMPA, TMEDA etc.

Integration of this route with a usual metalation procedure (RH + metal source) should assemble *mixed-anion* complexes ($X^{\ominus}$ from NH_4X, $R^{\ominus}$ from RH), e.g., equation (c).

$$NH_4X_{(s)} + RH + 2n\text{BuLi} \xrightarrow[\text{toluene}]{x\,L} (Li^{\oplus}X^{\ominus}) \cdot (R^{\ominus}Li^{\oplus}) \cdot xL + NH_3 + 2n\text{BuH} \quad (c)$$

This idea works. It is easy to substitute just one $PhO^{\ominus}Li^{\oplus}$ unit by $Li^{\oplus}NCS^{\ominus}$ in **1**, $n = 4$. Thus, addition of *n*BuLi solution (4 equiv) to NH_4NCS (1 equiv) suspended in a toluene solution of PhOH and HMPA (3 and 4 equiv, respectively) caused a vigorous reaction accompanied by gas evolution. Chilling of the resulting solution afforded crystals of **2** in good yield. In contrast to **1**, **2** is air-sensitive. The solid-state structure of **2**[6] (Fig. 2) is a tetrameric array with four $Li^{\oplus}$

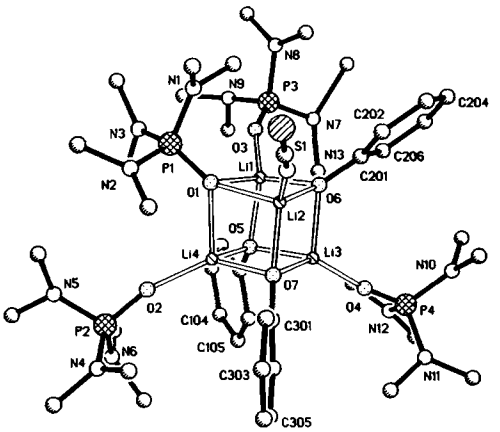

Fig. 2. Molecular structure of **2** in the crystal.

ions, three of which bear terminal HMPA ligands (mean Li–O distance, 1.88(2) Å). The three $PhO^{\ominus}$ anions form μ_3 bridges across the metal cations (mean Li–O distance, 1.98(2) Å). However, the fourth bridging position is taken up not by $NCS^{\ominus}$, which is terminal (Li–N distance, 2.04(2) Å), but by the fourth HMPA molecule (mean Li–O distance, 2.11(2) Å). Such a μ_3 mode for HMPA has been observed once before, in the structure of $(KNCS)_3 \cdot 5\,HMPA$ where two of the HMPA ligands cap a triangle of $K^{\oplus}$ ions.[5e]

Two sets of earlier results are pertinent to our studies on **2**. Firstly, IR spectroscopic investigations into the state of aggregation of LiNCS in ether solvents have shown that the CN stretching frequency is sensitive to structural changes: the monomeric ion pair $Li^{\oplus}NCS^{\ominus}$ (so with a terminal anion) has this band at ca. 2060–2070 cm^{-1},[7a] the $(Li^{\oplus}NCS^{\ominus})_2$ dimer (a μ_2-$NCS^{\ominus}$) at ca. 2030–2040 cm^{-1},[7b] and the

$(Li^{\oplus}NCS^{\ominus})_4$ cubane tetramer (a μ_3-$NCS^{\ominus}$) at ca. 1990–2000 cm^{-1}.[7c] Mixed halide–thiocyanate cubanes, e.g., $(LiBr)_3 \cdot LiNCS$ in Et_2O [$\tilde{\nu}$(CN), 2003 cm^{-1}] have also been detected.[7d] In the Nujol mull IR spectrum of **2** the major band occurs at 2072 cm^{-1}, in accord with the presence of terminal (rather than μ_3-) $NCS^{\ominus}$ ligands. Secondly, two mixed organolithium–lithium bromide tetramers have been isolated: $(PhLi \cdot OEt_2)_3 \cdot LiBr$[8a] and $[(cyclo\text{-}C_3H_5Li)_2 \cdot (LiBr)_2] \cdot 4Et_2O$.[8b] In both, the anions occupy corners of the cube, and all the Et_2O ligands are terminal (cf, the behavior of HMPA in **2**). These complexes were isolated from reactions of excess Li metal with PhBr and with *cyclo*-C_3H_5Br, respectively (yields: unspecified and ca. 30%). Presumably in each case the major product is the complexed "pure" organolithium, $(PhLi \cdot OEt_2)_4$[8a] and (*cyclo*-$C_3H_5Li \cdot OEt_2)_4$. Indeed, the major impetus of such work was the fact that commercially supplied organolithium solutions (e.g., MeLi, PhLi), synthesized from Li + RHal (2:1), are often catalogued as containing lithium halide. The results imply that specific mixed-anion aggregates are present in such solutions, which possess different (often enhanced) reactivity from that of the "pure" reagent. However, the isolation of these RLi–LiBr species can be contrasted with the currently described planned assembly of mixed-anion aggregates as the only product, as exemplified in the synthesis of **2**.

We are exploring the implications of the syntheses and properties of **1** and **2**. Complex **1** establishes likely thermodynamic ground rules for preparing moisture-stable metalated organics. The synthetic strategy leading to **2** promises particularly wide scope. R in RH, X in NH_4X, the metal M, and the donor L of equation (c) could all be varied, as could the $R^{\ominus}$:$X^{\ominus}$ stoichiometry (3:1 $PhO^{\ominus}$:$NCS^{\ominus}$ in **2**). Most importantly, the metal aggregate need not be a tetramer: even restricting M to Li, $(RLi)_n$ aggregates are known[2] with n = 2 and 3 (rings), 4 (rings and cubanes), 5 (trigonal bipyramid), 6 (pseudooctahedron), 8 (stacked dimeric rings), and higher.

Experimental Procedure

1: *n*-Butyllithium (6.3 mL, 1.60 M solution in hexane, 10 mmol) was added at 20 °C to a solution of phenol (0.94 g, 10 mmol) and HMPA (1.79 g, 10 mmol) in toluene (10 mL). A vigorous exothermic reaction ensued, producing a colorless solution. Refrigeration at 0 °C for two days gave an initial crop of colorless cubic crystals of **1**. First batch yield 0.91 g, 33%; further cooling afforded more of **1**; no other product was isolated. M.p. > 260 °C (decomp.); correct C, H, Li, N, P analyses; ^1H NMR (C_6D_6, 250 MHz, 25 °C) δ = 7.33 (m, 4H, *o*- and *m*-H of $PhO^{\ominus}$), 6.79 (t of t, 1H, *p*-H of $PhO^{\ominus}$), 2.35 (d, 18H of HMPA, J = 9.3 Hz). Cryoscopic relative molecular mass measurements on **1** were carried out using previously described procedures [9].

2: *n*-Butyllithium (6.3 mL, 1.60 M solution in hexane, 10 mmol) was added at 20 °C to a stirred suspension of NH_4NCS (0.19 g, 2.5 mmol) in toluene (10 mL) containing dissolved PhOH (0.71 g, 7.5 mmol) and HMPA (1.79 g, 10 mmol). A vigorous exothermic reaction and gas evolution ensued, during which all of the solid NH_4NCS reacted. The resulting solution was cooled to room temperature, giving colorless cubic crystals of **2**. First batch yield 1.51 g, 60%; further cooling afforded more of **2**; no other product was isolated. M.p. 240 °C (decomp.); correct C, H, N, P analyses; IR: (Nujol mull) $\tilde{\nu}$(CN) of $NCS^{\ominus}$ at 2072 cm^{-1} (vs), 2031 cm^{-1} (m); ^1H NMR (C_6D_6, 250 MHz, 20 °C) δ centered at 7.29 (m, 15H of 3 $PhO^{\ominus}$), 2.38 (d, 72H of 4 HMPA, J = 9.1 Hz).

[6] Crystal data for **2**: $C_{43}H_{87}N_{13}O_7P_4SLi_4$, monoclinic, $P2_1/a$ (alternative setting $P2_1/c$, No. 14), a = 15.165(2), b = 18.189(2), c = 23.314(4) Å, β = 108.27(1)°, M = 1322.16, V = 6106(2) Å^3, Z = 4, ϱ_{calcd} = 1.438 g cm^{-3}, $F(000)$ = 2320, $Mo_{K\alpha}$-radiation, λ = 0.71069 Å, $\mu(Mo_{K\alpha})$ = 1.71 cm^{-1}. The structure was solved by a combination of direct methods and Fourier difference techniques and refined by blocked-matrix least-squares. Some of the HMPA ligands show considerable disorder. P, O, Li, the NCS ligand, and the ordered N atoms from the HMPA ligands refined anisotropically. Phenyl and methyl-H atoms on ordered HMPA ligands placed in idealized positions, allowed to ride on the relevant carbon atoms, and refined with a common isotropic thermal parameter. One HMPA ligand severely disordered; two sites of disordered N and C atoms refined with partial occupancies. 8663 reflections measured ($5 < 2\theta < 45°$), corrected for absorption and decay. 4453 unique observed with $F > 5\sigma(F)$. R = 0.100, R_w = 0.109. Further details of the crystal structure investigation may be obtained from the Director of the Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW (U.K.). Conversion of a Diatropic Bridged Annulene into a Paratropic Species on Metal Complexation**

By *Reginald H. Mitchell** and *Pengzu Zhou*

Very little is known about metal-complexed large ring annulenes. A recently prepared[1] tris-(μ-acetylene)dicobalt complex containing the *cyclo*-C_{18} ligand grossly distorts the acetylenic bond so that comparison with the as yet unknown ligand will be difficult. Tricarbonylchromium complexes of two bridged [10]annulenes, 1,6-methano[10]annulene, and 2,7-methanoaza[10]annulene, have been described by *Günther* et al.[2] and *Vogel* et al.[3] respectively, as having delocalized 10π-electron systems. The complexation of a [14]annulene such as **1** interested us since it does not have a conveniently arranged set of six p orbitals to complex to chromium in contrast to the [10]annulenes above. Moreover, the chemical shift of the internal methyl protons in **1** and its derivatives is an excellent probe for the delocalization pres-

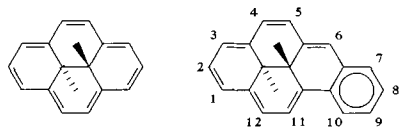
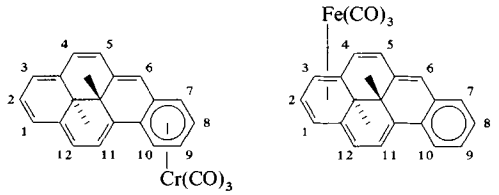
[**] We thank the Natural Sciences and Engineering Research Council of Canada and the University of Victoria for the support of this work.

ent in the periphery.[4–6] We therefore thought that preparation of metal complexes of **1** would bring further insight into annulene complexation.

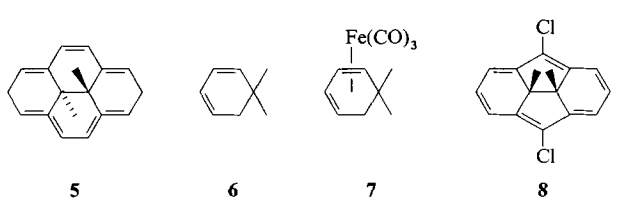


1 **2**



3 **4**

Thus far however, we have not been able to prepare any metal complex of **1**. The attempted reactions of **1** with $[Cr(CO)_6]$, $[Cr(CO)_3(CH_3CN)_3]$, $[Cr(CO)_3(naphthalene)]$, and $[Fe_2(CO)_9]$ failed. Treatment of **1** with $Cp_2Fe/Al/AlCl_3$, or of the dianion of **1** with $FeCl_2$, or irradiation of **1** in the presence of $[CpFe(p\text{-xylene})]PF_6$ all failed to give isolable products. To test whether the strong delocalization present in **1** was in part inhibiting complex formation, we investigated the benzannulene **2**, in which alternation of π and σ bonds in both the benzene and annulene rings is strong (bond fixation). Not surprisingly, the commonly η^6-bonded tricarbonylchromium moiety coordinated only to the benzene ring to give **3**.[3] The commonly η^4-bonded tricarbonyliron moiety, however, formally has a choice and could coordinate either to the partially bond-fixed benzene ring or to the annulene ring of **2**. Complexation of the annulene ring should be preferred, since the resulting bond fixation then permits the formation of a fully delocalized benzene ring, and as a consequence minimal ring current is anticipated in the macro-ring of such a complex. In fact, reaction of **2** with $[Fe_2(CO)_9]$ in refluxing benzene did give a single product (**4**) in 40% yield. The chemical shifts of the internal methyl protons appeared at $\delta = 2.00$ and 1.71, immediately ruling out complexation of the benzenoid ring, since a value close to that of **1** ($\delta = -4.2$) would have been expected. The position of complexation shown for **4** is evident from the shielded chemical shift ($\delta = 3.78$) of proton H1 (at the end of the complexed diene), which together with the small coupling constant between H2 and H3, suggests that **4** is a nonfluxional molecule. The fact that the internal methyl protons of **4** are more deshielded than those of the nonaromatic model **5** ($\delta = 0.97$) is exceptionally interesting. An anisotropic effect of the $Fe(CO)_3$ moiety cannot be the cause, since the chemical shift of both methyl groups in *both* **6** and **7** (which can be considered good model compounds for **2** and **4**) is $\delta = 1.0$. Similarly any deshielding effect from the now full benzene ring in **4**, is easily calculated using *Memory*'s equation[7] to be about $\Delta\delta = 0.05$ ppm, which is again negligible. We therefore propose that a paratropic ring current is present in **4**. This would rationalize the $\Delta\delta = 1$ downfield shifts of the internal methyl protons of **4** relative to **5**, since the chemical shifts of the known,[8] geometrically very similar, paratropic [12]annulene **8** are at $\delta = 2.58$. Moreover *Günther*'s Q value[9] can be calculated for the benzene unit of **2** as 0.99 and 1.02. These are less than the limiting value of 1.04 and thus clearly suggest that the large ring of **4** is paratropic (a delocalized 4n π-electron system). This can be accounted for by assuming a contribution of a resonance structure in which back-donation of two electrons by iron into the π system occurs. The resulting 16π-electron system would be expected to be paratropic. Indeed, the chemical shifts of the benzene-ring protons in **4** (H7–10) are all shielded with respect to those in benzene itself, which would not be expected if the macrocyclic ring were atropic (bond-fixed). Furthermore, the coupling constants of this benzene-like ring are almost equal and not strongly alternating as they would be if **4** were a 20π system, rather than the proposed benzo-fused 16π system. The downfield shifts of the internal methyl groups of **4**, however, are small relative to those observed when two real charges are added to such systems,[10] suggesting only a small degree of charge transfer between metal and the ligand.



5 **6** **7** **8**

Whilst the stability of tricarbonylcyclobutadiene iron is well known,[11] and is consistent with the idea of metalloaromaticity proposed by Fenske,[12] donation to a $(4n + 2)\pi$ system to give what is formally an antiaromatic product, is very remarkable.

Experimental

A mixture of $[Fe_2(CO)_9]$ (262 mg, 0.72 mmol)[13] and benzodihydropyrene **2** (50 mg, 0.18 mmol)[14] in benzene (1 mL) was refluxed with stirring under N_2 for 1 h. After cooling, the residue was chromatographed over silica gel (eluant: petroleum ether). The third fraction contained the complex **4**, (30 mg, 40%), which was recrystallized from chloroform and heptane. Deep red crystals, m.p. 156°C (decomp.); ^1H NMR (360 MHz, $CDCl_3$, 25°C, standard $CHCl_3$ at $\delta = 7.240$); $\delta = 7.24$ (m, $J(7,8) = 7.5$ Hz, $J(7,9) = 1.5$ Hz, $J(7,10) = 0.3$ Hz, 1H; H7), 6.92 and 6.93 (m, $J(8,9) = 7.4$ Hz, $J(8,10) = 1.2$ Hz, 2H; H8,9), 6.77 (m, $J(9,10) = 7.6$ Hz, 1H; H10), 5.96 (d, $J(11,12) = 5.8$ Hz, 1H; H11), 5.90 (d, $J(5,4) = 9.4$ Hz, 1H; H5), 5.85 (s, 1H; H6), 5.43 (dd, $J(1,2) = 6.2(5)$ Hz, $J(2,3) = 4.4$ Hz, 1H; H2), 5.38 (d, 1H; H4), 5.30 (dd, $J(1,3) = 1.3$ Hz, 1H; H), 5.29 (d, 1H; H12), 3.78 (dd, 1H; H1), 2.00, 1.71 (s, 3H; each CH_3); ^{13}C NMR (62.9 MHz, $CDCl_3$): δ = 211.30 (carbonyl C), 143.67, 140.96, 138.37, 134.26, 131.79 (quaternary aryl C), 130.84, 128.52, 127.97, 127.76, 127.40, 123.94, 122.52, 117.26, 112.23 (aryl CH), 81.17 (quarternary aryl C, coordinated to Fe), 79.61, 77.49, 67.25 (aryl CH, coordinated to Fe), 43.04, 42.80 (bridged quaternary C), 25.89, 25.16 (internal $-CH_3$); IR (KBr) $\tilde{\nu}$ [cm^{-1}] = 2040, 1960, 1345, 880, 820, 740, 600, 550; UV/VIS (cyclohexane): λ_{max} [nm](ε) = 348(8750); MS (70 eV): m/z 422 ($M^{\oplus}$, 20%), 394(35), 366(25), 323(100). Correct elemental analysis (C, H).

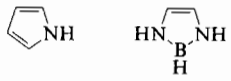
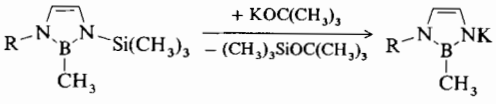
Synthesis and Structure of the Potassium Salts of 1,3,2-Diazaboroles**

By *Günter Schmid,* Jürgen Lehr, Michael Polk,* and *Roland Boese*

Recently we reported the synthesis and properties of a series of 2,3-dihydro-1*H*-1,3,2-diazaboroles **1**.[1] They are formally derived from pyrrole by substitution of C=C– by an isoelectronic BN group.



Diazaboroles have already been used in complexes as 6π electron systems.[1] Like pyrrole, dihydro-1,3,2-diazaboroles can also be converted into their anions, which offer interesting possibilities for preparative chemistry. Thus, in a reaction with potassium *tert*-butyl alcoholate, *N*-trimethylsilyl-substituted diazaboroles **1a–d** can be transformed into the potassium salts **2a–d** in good yields (60–70%) [Eq.(a)] and isolated as colorless to beige pyrophoric powders which are very soluble in THF.



(a)

1 **2**

a, R = CH_3; **b**, R = C_2H_5; **c**, R = $CH(CH_3)_2$; **d**, R = $C(CH_3)_3$

The ^{1}H NMR signals of these anions are hardly shifted with respect to those of the neutral dihydro-1,3,2-diazaboroles, which means that the negative charge is localized mainly on the metalized nitrogen atom. The ^{13}C NMR spectra show that, with the exception of the adjacent carbon atom (for which $\Delta\delta = 10$ to lower field), the transformation from neutral ring into anion leaves the electronic environment of the carbon atoms virtually unchanged. A slight shift of $\Delta\delta \approx 2$ to higher field for the ^{11}B NMR signal on transformation of **1a–d** into the anions **2a–d** is caused by the loss of the trimethylsilyl group, which markedly withdraws the electron density from the nitrogen atom in **1a–d**. In the anion the electron density is distributed across the acidic boron atom to a greater extent (Table 1).

Only in the case of the anion **2d** could crystals suitable for X-ray crystallography be obtained. However, these crystals also contain potassium *tert*-butyl alcoholate and, surprisingly, dipotassium dimethylsilanediolate, $(CH_3)_2SiO_2K_2$, an as yet unknown compound, which we shall discuss later. Anion **2d** is arranged in the crystal in a characteristic way around a threefold rotatory inversion axis (Fig. 1): Twelve diazaborolyl anions (green) are so arranged that six "parallel" rings form an inner circle and a further six an outer circle. The 18 *tert*-butyl alcoholate anions (red) occupy positions on the outer periphery of the circle, with the oxygen atoms directed inwards and the $C(CH_3)_3$ groups outwards. Six

Table 1. NMR data for the compounds **1a–d** and **2a–d** [a].

1a: ^{1}H NMR: $\delta = 0.20$ (s, 9H, $Si(CH_3)_3$), 0.54 (s, 3H, BCH_3), 2.87 (s, 3H, NCH_3), 6.10 (d, 1H, H4, $J = 1.7$ Hz), 6.15 (d, 1H, H5, $J = 1.7$ Hz); $^{13}C\{^1H\}$ NMR: $\delta = -4.7$ (BCH_3, $J(^{11}B, ^{13}C) = 90$ Hz); 0.7 ($Si(CH_3)_3$), 32.2 (NCH_3), 115.2 (C4), 121.1 (C5); ^{11}B NMR: $\delta = 29.4$

1b: ^{1}H NMR: $\delta = 0.20$ (s, 9H, $Si(CH_3)_3$), 0.59 (s, 3H, BCH_3), 1.0 (t, 3H, CH_2-CH_3, $J = 7.3$ Hz), 3.23 (q, 2H, CH_2-CH_3, $J = 7.3$ Hz), 6.19 (br. s, 2H, H4, H5); $^{13}C\{^1H\}$ NMR: $\delta = -4.7$ (BCH_3, $J(^{11}B, ^{13}C) = 80$ Hz), 0.7 ($Si(CH_3)_3$), 18.0 (CH_2-CH_3), 40.2 (CH_2-CH_3), 115.4 (C4), 119.1 (C5); ^{11}B NMR: $\delta = 29.1$

1c: ^{1}H NMR: $\delta = 0.21$ (s, 9H, $Si(CH_3)_3$), 0.65 (s, 3H, BCH_3), 1.10 (d, 6H, $CH(CH_3)_2$, $J = 6.7$ Hz), 6.23 (d, 1H, H4, $J = 2.2$ Hz), 6.34 (sept, 1H, $CH(CH_3)_2$, $J = 6.7$ Hz), 6.77 (d, 1H, H5, $J = 2.2$ Hz); $^{13}C\{^1H\}$ NMR: $\delta = -4.7$ (BCH_3, $J(B^{11}, ^{13}C) = 88$ Hz), 0.8 ($Si(CH_3)_3$), 24.5 ($CH(CH_3)_2$), 45.6 ($CH(CH_3)_2$), 115.2 (C4), 115.6 (C5); ^{11}B NMR: $\delta = 28.9$

1d: ^{1}H NMR: $\delta = 0.22$ (s, 9H, $Si(CH_3)_3$), 0.81 (s, 3H, BCH_3), 1.33 (s, 9H, $C(CH_3)_3$), 6.19 (d, 1H, H4, $J = 2.2$ Hz), 6.43 (d, 1H, H5, $J = 2.2$ Hz)

2a: ^{1}H NMR: $\delta = 0.39$ (s, 3H, BCH_3), 3.14 (s, 3H, NCH_3), 6.09 (d, 1H, H4, $J = 1.8$ Hz), 6.16 (d, 1H, H5, $J = 1.8$ Hz); $^{13}C\{^1H\}$ NMR: $\delta = -4.4$ (BCH_3), 32.6 (NCH_3), 117.9 (C5), 124.1 (C4); ^{11}B NMR: $\delta = 26.8$

2b: ^{1}H NMR: $\delta = 0.38$ (s, 3H, BCH_3), 1.15 (t, 3H, CH_2-CH_3, $J = 7.2$ Hz), 3.45 (q, 2H, CH_2-CH_3, $J = 7.2$ Hz), 6.10 (d, 1H, H4, $J = 1.7$ Hz), 6.17 (d, 1H, H5, $J = 1.7$); $^{13}C\{^1H\}$ NMR: $\delta = -4.1$ (BCH_3), 19.1 (CH_2-CH_3), 40.7 (CH_2-CH_3), 115.5 (C5), 124.4 (C4); ^{11}B NMR: $\delta = 27.5$

2c: ^{1}H NMR: $\delta = 0.44$ (s, 3H, BCH_3), 1.22 (d, 6H, $CH(CH_3)_2$, $J = 6.7$ Hz), 3.89 (sept, 1H, $CH(CH_3)_2$, $J = 6.7$ Hz), 6.26 (br.s, 2H, H4, H5); $^{13}C\{^1H\}$ NMR: $\delta = -4.8$ (BCH_3), 23.2 ($CH(CH_3)_2$), 46.3 ($CH(CH_3)_2$), 112.0 (C5), 120.1 (C4); ^{11}B NMR: $\delta = 28.9$

2d: ^{1}H NMR: $\delta = 0.54$ (s, 3H, BCH_3), 1.37 (s, 9H, $C(CH_3)_3$), 6.11 (d, 1H, H4, $J = 2.0$), 6.26 (d, 1H, H5, $J = 2.0$ Hz); $^{13}C\{^1H\}$ NMR: $\delta = 1.2$ (BCH_3), 32.7 ($C(CH_3)_3$), 52.2 ($C(CH_3)_3$), 114.0 (C5), 121.5 (C4); ^{11}B NMR: $\delta = 29.8$

[**] This work was supported by the Fonds der Chemischen Industrie.

$(CH_3)_2SiO_2^{2-}$ dianions (orange) occupy the innermost sites of the tirelike construction, which together with the methyl groups define the point group $\bar{3}$. Thus, a highly symmetrical ring arises, which has 42 K^+ ions (blue) corresponding to the 12 diazaborolyl, 18 *tert*-butyl alcoholate and 6 silanediolate anions.

The residual electron density above the center of the tire indicates that a disordered THF molecule, which cannot be located precisely, is situated there. The similarly disordered *tert*-butyl groups of the diazaborolyl ring and the *tert*-butanolate anions had to be calculated as rigid groups with fixed bond lengths and bond angles. With the exception of potassium, all atoms were refined isotropically.

Figure 2 shows the asymetric unit in which the environment of the diazaborolyl anions is best recognized. All five atoms of the ring N1′B2′N3′C4′C5′ have contacts to both potassium ions, K2 and K7, and the corresponding bond lengths [pm] are in good agreement: K2–N1′ 329/K7–N1′ 346, K2–B2′ 322/K7–B2′ 343, K2–N3′ 300/K7–N3′ 304, K2–C4′ 315/K7–C4′ 323, and K2–C5′ 294/K7–C5′ 290. K1 has bonding contacts with this ring through N3′ (K1–N3′ 284 pm) and C4′ (K1–C4′ 297 pm), and with the other ring within this asymmetric unit through N3 and C5. The function of K4 corresponds to that of K7. If K4 and K7 are arbitrarily defined as those belonging to the diazaborolyl anions, the cations K1, K2, K3, and K5 compensate for the negative charge of the two *tert*-butyl alcoholate ions and the silanediolate ion.

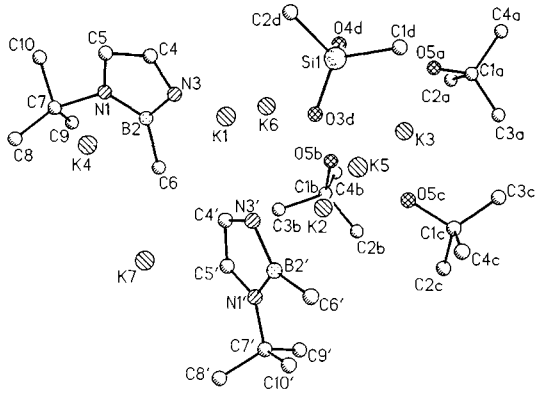

Fig. 2. Environment about the diazaborolyl rings in the asymmetric unit (contacts of potassium ions not shown; atoms have arbitrary radii).

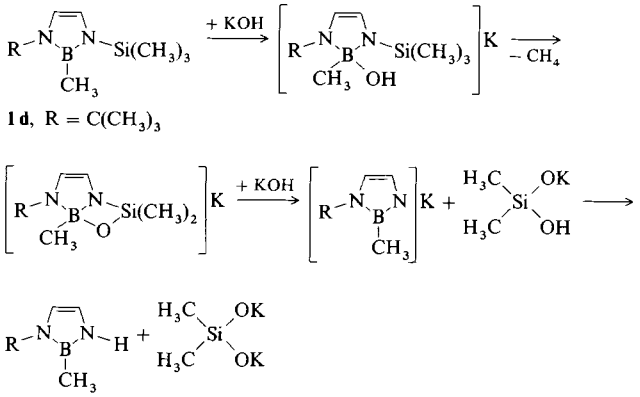
The bond lengths and angles within the two *tert*-butyl-2-methyl-1*H*-1,3,2-diazaborolyl anions in this asymmetric unit agree to a large extent within experimental error. Only the bond between N1′ and B2′ (150 pm) appears significantly longer than the B2′–N2′ bond (143 pm); nevertheless, the corresponding distances in the other ring (146 and 141 pm) suggest that the longer N1′–B2′ distance is due to the inaccuracy of the structure determination resulting from crystal quality. The other B–N bond lengths of between 141 and 146 pm lie within the expected range. A significant difference in distance between the boron atom and the substituted and unsubstituted nitrogen atom is not observed.

The formation of the dimethylsilanediolate, initially detected by X-ray crystallography, is interesting. Till now only the unstable free dimethylsilanediol has been described. The possible utilization of the dipotassium salt formed here in exceptionally small concentrations could be of interest in preparative silicon chemistry. We attribute the formation of $(CH_3)_2SiO_2K_2$ to traces of KOH in the K-*tert*-butyl alcoholate. *R. Köster* et al.[3] showed that $(CH_3)_3Si$ groups in the vicinity of boryl substituents react with KOH by loss of methane. Such a reaction sequence applied twice to **1d** is a plausible explanation for the formation of $(CH_3)_2SiO_2K_2$. Indeed, mass spectrometry shows that more methane is released on increasing the KOH concentration. The formation of 1-*tert*-butyl-2,3-dihydro-2-methyl-1*H*-1,3,2-diazaborole is detected by ^{11}B NMR spectroscopy ($\delta = 26.5$). $(CH_3)_2SiO_2K_2$ has not as yet been isolated.



Experimental Procedure

1d: A solution of *n*BuLi in hexane (580 mmol, 365 mL, 1.6 M) was added dropwise to a solution of *N*-*tert*-butyl-N′-trimethylsilylethylenediamine in pentane (54.6 g, 290 mmol, 500 mL) at −78 °C over 2 h. The mixture was then heated under reflux for 1 h, again cooled to −78 °, and a solution of dibromomethylboron in pentane (53.8 g, 290 mmol, 100 mL) is added dropwise within 2 h. The solution was stirred for 10 h at room temperature, whereupon the solvent was removed under vacuum. **1d** was removed from the nonvolatile components by condensation. Fractional distillation at 107 °C/30 Torr yields pure **1d** (42.4 g, 69 %).

2d: A freshly prepared and titrated solution of K-*tert*-butanolate (6.5 mmol) in THF was added to a THF solution of **1d** (1.8 g, 8.6 mmol, 50 mL). The solution was heated for 1 h under reflux and then evaporated to dryness. The residue was suspended in pentane (50 mL) and the white, pyrophoric **2d** was filtered off (0.68 g, 68 %).

A New Economical Process for the Preparation of Silver(I,III) Oxide, AgO

By *Sabine Kielhorn, Dieter H. Buß, Oskar Glemser,* Roland Gerner,* and *Gerald Jeske*

Silver(I,III) oxide (AgO), a strong oxidizing agent, is used in chemical technology and has become increasingly important in batteries.[1] It is prepared from weakly acidic solutions of silver salts through oxidation by ozone and more often from alkaline silver nitrate solutions at temperatures between 80 and 90 °C through oxidation with peroxodisulfate.[2] Both these preparations are uneconomical.[3, 4]

We now report that AgO can be prepared through oxidation of an aqueous, alkaline silver nitrate solution with mixtures of sulfur dioxide and oxygen or air, or with mixtures of sulfite solutions and oxygen or air in up to 98% yield. Both the pH of the solution (10.5–10.6) and the redox potential (480–600 mV, referred to an Ag/AgCl electrode) are kept constant at temperatures between 70 and 90 °C.

The reaction suspension always requires a small sulfite concentration, but an excess of sulfite or SO_2 must be avoided. Under these conditions the sulfurous acid is formed by a chain reaction of peroxo compounds, as one suspected from reports by *Taube* et al.[5] These intermediates have a higher oxidation potential than oxygen in alkaline solution. The net reaction is formulated in Equation (a).

$$[O_2SOO]^{2\ominus} + 2Ag^{\oplus} + 2OH^{\ominus} \longrightarrow 2AgO + SO_3^{2\ominus} + H_2O \qquad (a)$$

The silver(I,III) oxides prepared by the new process have high charging capacities of between 408 and 426 $mAh\,g^{-1}$; the theoretical value is 497 $mAh\,g^{-1}$.[9]

Experimental Procedure[6]

Two examples are given: 1. The pH of distilled water (1.5 L in a 4-L round-bottomed flask, 70 °C) was adjusted to 10.55 by addition of CO_2-free sodium hydroxide solution (4 mL) and was kept constant within ± 0.05 during the precipitation. A redox potential of 545–555 mV was attained by passing a stream of SO_2 (1 $L\,h^{-1}$) and O_2 (500 $L\,h^{-1}$) through the solution. A solution of silver nitrate (2M) was added dropwise and care was taken that the reduction potential did not change. Yield: 93.3% black powder [7], which showed only those lines of AgO in the X-ray diffraction pattern. [8].

2. To an aqueous alkaline solution prepared as in 1 (pH 10.53 ± 0.03) is added a sodium sulfite solution (0.1 M, 1800 $mL\,h^{-1}$) to attain a redox potential of 600 mV. A solution of $AgNO_3$ is then added dropwise without changing the redox potential. Yield: 97% AgO; the X-ray diffraction pattern is identical to that obtained in method 1 [9].

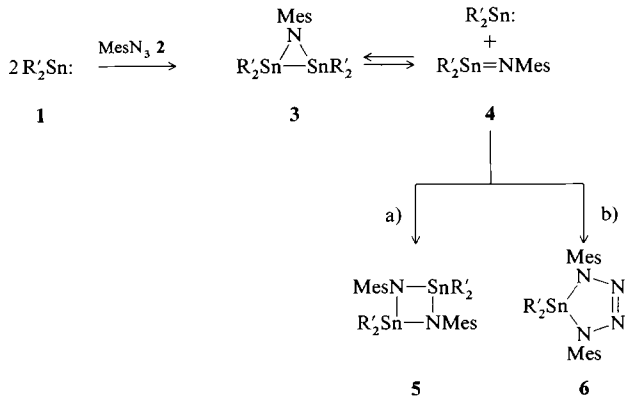
Synthesis and Structure of an Azadistanniridine**

By *Hansjörg Grützmacher** and *Hans Pritzkow*

Three-membered rings containing two silicon or germanium atoms and a heteroatom Y in the ring are known and have remarkable structures.[1] We report now the synthesis and structure of the first azadistanniridine.

The reaction of bis[2,4,6-tris(trifluoromethyl)phenyl]stannylene (**1**), which is also monomeric in the solid state,[2] with mesityl azide (**2**)[3] in the molar ratio 2.5:1 leads to spontaneous nitrogen evolution and the formation of azadistanniridine (**3**) in good yield.[4] This compound crystallizes from the reaction solution in the form of large, red crystals which cannot be dissolved in organic solvents without decomposition (Scheme 1).



Scheme 1. R' = 2,4,6-$(CF_3)_3C_6H_2$, Mes = mesityl; a) Reaction of **1** with **2** in a molar ratio of 2.5:1 or of warmed toluene with **3**; b) reaction of **1** with **2** in a molar ratio of 1:3.5.

If the reaction of **1** with **2** in C_6D_6 is monitored by ^{119}Sn NMR spectroscopy, initially only one signal (**3**, $\delta = -194$) can be detected besides that of **1** ($\delta = 682$). After several hours at room temperature the intensity of the signal of **1**

again increases relative to **3** and as second product of the cycloreversion, the diazadistannetidine **5** begins to crystallize.

On treatment of crystals of **3** with warmed toluene (ca. 60 °C) a color change from red to yellow takes place and again a [2 + 1] cycloreversion[5] yields stannylene **1** and stannanimine **4**, which in agreement with the results of *Wiberg* and *Vasisht*[6] dimerizes to **5**. On reaction of **1** with **2** in the ratio 1:3.5 the stannanimine is trapped almost quantitatively by **2** in a [2 + 3] cycloaddition to form **6**.[6]

The result of the X-ray structure analysis[7] of **3** is shown in Figure 1. Although the tin–nitrogen bond lengths lie within the typical range for sterically hindered cyclic tin–nitrogen compounds,[8] the tin–tin bond in **3** (2.709 Å) is very short:[9] the difference between this distance and that in distannene **7**[10] (2.768 Å, formal Sn–Sn double bond) is significant; in comparison with tetrahedrally surrounded elemental tin (2.81 Å) this bond is 0.1 Å shorter. The sum of the basal exocyclic bonding angles about the tin atoms is 356°, corresponding with that found in three-membered rings containing two Si or Ge atoms and one heteroatom.[1] The trigonal-planar configuration of the nitrogen atom N1 is remarkable. This is not typical for stannaazanes [R_2SnNR'][8] and cannot be attributed to steric influences. The nitrogen atom in **5** is clearly pyramidal (sum of the bond angles 353° and the carbon–nitrogen bond is twisted 21.5° out of the ring plane), although in the four-membered ring the geometry causes crowding of the substituents not present in the three-membered ring.[11] These structural characteristics can be explained if the three-membered rings are understood in terms of π-donor complexes of the Dewar–Chatt–Duncanson model,[12] or if a bent-bond molecular description is used.[13]

Recombination of Carbocation–Sulfinate Ion Pairs**

By *Wolfgang Kirmse** and *Ekkehard Herpers*

Dedicated to Professor Horst Prinzbach on the occasion of his 60th birthday

The study of ion pairs gives an insight into the short-range orientation of charged molecules.[1] Since the pioneering work of *Winstein*[2] on the heterolysis of C–X bonds, the behavior of carbocations in ion pairs has been thoroughly investigated. Most often the counterions chosen were carboxylates[3] and sulfonates.[4] Sulfinates aroused little interest, although the chirality of the sulfur atom in alkyl sulfi-

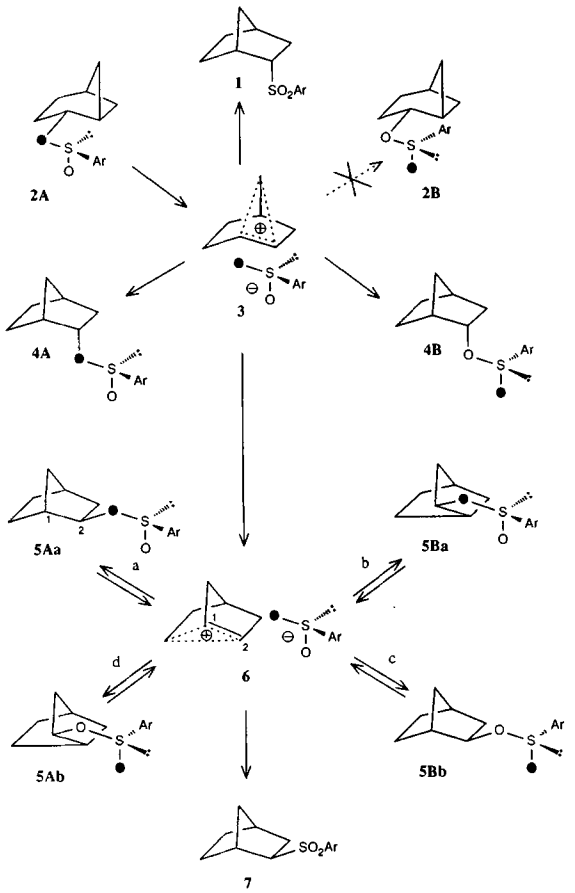
[*] Prof. Dr. W. Kirmse, Dipl.-Chem. E. Herpers
Fakultät für Chemie der Ruhr-Universität
Universitätsstrasse 150, W-4630 Bochum 1 (FRG)

nates and the ambident character of the sulfinate ion promises additional information. The rearrangement of alkyl sulfinates to alkyl sulfones is known,[5, 6] but we are aware of only one report on the recombination of a carbocation with the oxygen atom of a sulfinate ion: *Fava* et al. observed that the racemization of optically active benzhydryl-*p*-toluenesulfinate competes with the rearrangement to sulfone.[7] We have utilized the chirality of the ^{18}O-labeled *p*-toluenesulfinate ion to analyze such reactions in more detail.

First we considered a system in which the dissociation and recombination are practically irreversible. The reaction of 2-norpinanol (bicyclo[3.1.1]heptan-2-ol) with *p*-toluenesulfinyl chloride afforded a mixture (1:1) of the diastereomeric norpinyl-*p*-toluenesulfinates (**2A, B**, 95%). Only one of these could be obtained in pure form, through chromatography.[8] Heating of **2A**[9] in formamide (130°C, 2 h) caused a rearrangement to *endo*-2-norbornyl *p*-tolyl sulfone (**1**)[10] (10%), *endo*-2-norbornyl-*p*-toluenesulfinate (**4**) [12] (two diastereoisomers, 66.7 and 11.4%), *exo*-2-norbornyl-*p*-toluenesulfinate (**5**)[13] (two diastereomers, 5.1 and 5.0%), and *exo*-norbornyl *p*-tolyl sulfone (**7**)[14] (1.2%). In the analogous rearrangement of 2-norpinyl sulfonates and carboxylates to 2-norbornyl derivatives,[15] the norbornyl cation **3** was formed initially and reacted further with nucleophiles at C2 to afford less strained *endo*-2-norbornyl products (**4**). The rearrangement of **3** to the 2-norbornyl cation **6**, from which the *exo*-norbornyl products **5** are formed, competed with nucleophilic capture (Scheme 1).

Besides the product distribution, the following findings are important: 1) Compound **2B** did not form during the rearrangement of **2A**. The isomerizations of **4A** into **4B**, and vice versa, did not occur at 130°C, and those of **5A** and **5B** only very slowly. 2) Labeling of the ester oxygen atom of **2A** with ^{18}O[16] afforded the following distribution of ^{18}O in the products:[17] In the more abundant diastereomer (66.7%) of **4** only the ester oxygen atom was labeled. The less abundant diastereomer (11.4%) bore the label only at the doubly bonded oxygen atom (**4B**). In the diastereomers of **5** the ^{18}O was equally distributed over both oxygen functionalities.[17]

The following conclusions may be drawn from these findings: 1) Under these reaction conditions, thermally induced inversion of the sulfur occurs neither in the *p*-toluenesulfinic acid esters nor in the *p*-toluenesulfinate ion. 2) On recombination of the ion pairs **3** and **6**, the oxygen atom of the sulfinate ion is favored over the sulfur atom as binding partner (**4**:**1** = 7.4; **5**:**7** = 8.4). On **2** → **4** rearrangement (the anion remains on the *endo* side), the carbocation returns preferentially to the oxygen atom of the *p*-toluenesulfinate ion from which it dissociated (**4A**:**4B** = 5.9). 3) The **2** → **5** rearrangement (the anion migrates to the *exo* side) takes place with recombination at both O atoms of the *p*-toluenesulfinate ion, as well as at C1 and C2 of the 2-norbornyl cation;



Scheme 1. • = ^{18}O, Ar = *p*-$CH_3C_6H_4$, a = $^{18}O \rightarrow C2$, b = $^{18}O \rightarrow C1$, c = $^{16}O \rightarrow C2$, d = $^{16}O \rightarrow C1$.

we find equal amounts of **5Aa**, **5Ab**, **5Ba**, and **5Bb** (the upper case letters represent diastereomers and lower case letters isotopomers; see Scheme 1).

Bearing these principles in mind, we turned our attention to the reversible dissociation–recombination of *exo*-2-norbornyl-*p*-toluenesulfinate (**5**). The reaction proceeded at a convenient rate in formamide at 150°C and in trifluoroacetic acid at room temperature. The results of the labeling experiments in these solvents hardly differed (Table 1).[18] The ion pair **6** may recombine in four ways: a) $^{18}O \rightarrow C2$, b) $^{18}O \rightarrow C1$, c) $^{16}O \rightarrow C2$, d) $^{16}O \rightarrow C1$. With **5Aa** as starting material,[19] path a) was not measurable (regeneration of **5Aa**) and b) was favored by a factor 3–4 over c). This preference was confirmed by labeling the norbornyl residue: deuterium from the 2-position of **5A** appeared predominantly in the 1-position of **5B**.[20] The distributions of ^{18}O and D agreed well (nos. 1 and 3, and 4 and 6 of Table 1). As in the

2 → **4** rearrangement, the 2-norbornyl cation returned mainly to the oxygen atom of the *p*-toluenesulfinate ion from which it dissociated. Furthermore, the results in Table 1 show that C1 and C2 of the 2-norbornyl cation are not equivalent in ion pair recombination. For **5Aa** the recombination path c) was favored by a factor 2–3 over d). This finding was supported by experiments with **5Ba** (no. 7 and 8 in Table 1): recombination b) was not measurable; the ratio of paths a), d), and c) was about 8:2:1. The complementary results for **5Aa** and **5Ba** preclude the predominant formation of one diastereomer on recombination of **6**.[21] Instead the *p*-toluenesulfinate ion returned, *after* the exchange of the oxygen atom, preferentially to the carbon atom of the 2-norbornyl cation from which it dissociated (C2). A corresponding preference must also be valid *before* oxygen exchange.

The symmetric, bridged structure of the 2-norbornyl cation has been established by several spectroscopic and theoretical studies.[22] As a rule, nucleophiles do not discriminate between C1 and C2. Exceptions are known, however: for example, the addition of HX to norbornene[23a] or the decomposition of 2-norbornanediazonium ions,[23b] where the norbornyl cation is trapped in unsymmetric form. The dependence of such processes on the solvent[24] suggests the intervention of ion pairs in which the counterion is found closer to C2 than to C1 depending on the history of its formation. In contrast to this interpretation, no regioselective recombination has been observed on heterolysis of 2-norbornyl derivatives.[25] Our results close this gap: they confirm that the close-range order in ion pairs can lead to discrimination between C1 and C2 of the 2-norbornyl cation.

[15] Review: W. Kirmse, *Acc. Chem. Res. 19* (1986) 36.

[16] The incorporation of ^{18}O was achieved by exchange between 2-norpinanone and $H_2{}^{18}O$, followed by reduction ($NaBH_4$), esterification, and separation by HPLC [8]. The sample of **4A** used contained 32% ^{18}O.

[17] The ester ^{18}O atom caused a shift of $\Delta\delta$=0.04 to higher field for the ^{13}C NMR signal of C2. The quantitative analysis was performed by integration of the ^{16}O-^{13}C and ^{18}O-^{13}C signals (**4**: ± 2%; **5**: ± 10% because of the small quantities). For the method, see [4i].

[18] With increasing reaction times, the ratio of the diastereomers and the ^{18}O label approached an equal distribution (cf. no. 1 and 2, 4 and 5 in Table 1); moreover the concentration of **5** decreased as a result of rearrangement to sulfone 7 and solvolysis (formation of 2-norbornyl formate or trifluoroacetate. Theoretically the preferences of the ion-pair recombination are clearest at small turnovers. In practice the experimental error is then large. We chose a compromise between these divergent requirements in our 15–30% turnovers.

[19] ^{18}O-*exo*-2-norbornanol was prepared by hydroxymercuration of norbornene in $H_2{}^{18}O$/THF and treated further to give **5Aa** and **5Ba** [13](53.6% ^{18}O).

[20] Preparation of [2-^{2}H]-*exo*-2-norbornanol: N. H. Werstiuk, D. Dhanoa, G. Timmins, *Can. J. Chem. 61* (1983) 2403. ^{2}H NMR ($CHCl_3$, 61.4 MHz): [^{2}H]-**5A**: δ = 4.28, 2.26; [^{2}H]-**5B**: δ = 4.28, 2.48.

[21] The solvolysis of a 1:1 mixture of **5A** and **5B** also gave no indication of diastereoselective recombination. No significant change in the **5A**:**5B** ratio was observed during the decrease in concentration of **5**.

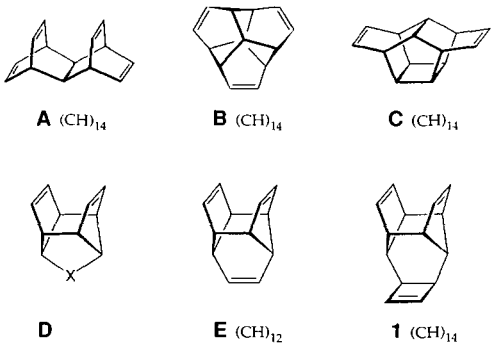
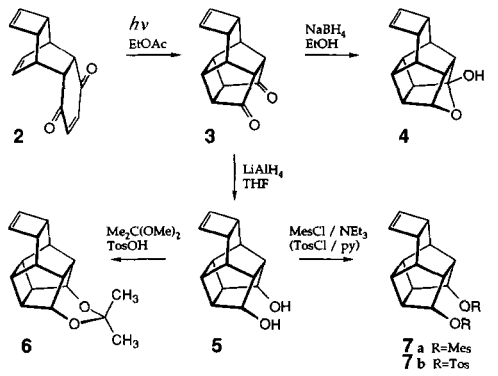
most varied studies because of their theoretical importance and their unusual propensity towards photochemical, thermal, and catalytic conversions. In connection with studies to differentiate between through-space (e.g. in isodrines **A**[1] or homohypostrophenes **D**[2]) and through-bond electronic interactions (e.g. in triblattenes **B**[3] or *hemi*-pagodanes **C**[4]),

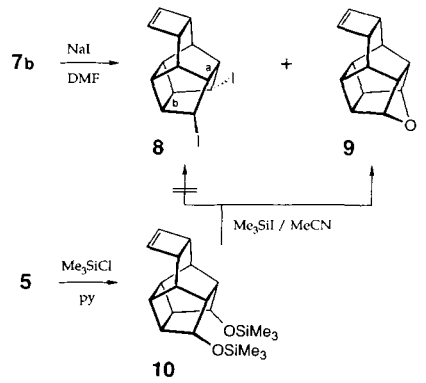


we were interested in the properties of the polycycle **1**, a new unsaturated member of the $(CH)_{14}$ family, and in its potential as precursor for the C_{2v}-symmetric $(CH)_{12}$ triene **E**. Here we report on two high-yield routes to **1**, starting from the known COT–*p*-benzoquinone cycloadduct **2**, and on first results for its thermal and photochemical transformations into further $(CH)_{14}$ isomers.



We chose the structurally related diketone **3** as starting material for the cyclobutene-bridged diene **1**, based on the analogous syntheses of hypostrophene and C_{2v}-symmetric homologues **D**.[2, 5, 6] Compound **3** is obtained efficiently by intramolecular [2+2] photocycloaddition from the tetracycle **2**, which is in turn accessible through the Diels–Alder reaction of COT and *p*-benzoquinone (literature yield[7]: 25%); by improving the [4+2] cycloaddition to a 65–70% yield (sealed tube, THF, 24h at 125°C; or diglyme, 24h at 140°C), the valuable diene component could be used effectively. In contrast to the known synthesis routes for dienes of type **D**—obtained mainly through an acid catalyzed skeletal isomerization with participation by the photochemically formed four-membered ring[2, 6]—the reactivity of the cyclobutene unit required a modified strategy. Therefore, we selected as primary target the *exo,exo*-diiodide **8**, which appeared accessible through nucleophilic substitution from suitable precursors and able to undergo a subsequent 1,4 elimination to **1**.

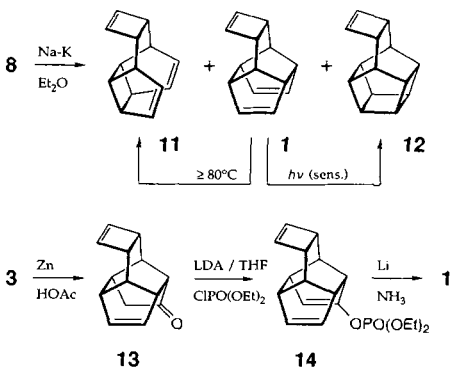
Whereas the reduction of diketone **3** with $NaBH_4$ stops at the hemiacetal (**4**) stage, with $LiAlH_4$ it proceeds smoothly



to form a sparingly soluble diol (70%, m.p. 202°C). The simplicity of the NMR spectra and the coupling pattern suggested high molecular symmetry and an *endo,endo* configuration for the alcohol functions in **5**, which was confirmed by transformation into the acetonide **6** (76%, m.p. 108°C). As the bis(mesyl) ester **7a** (91%, m.p. 102°C) proved to be unstable on storage, we used the bis(tosylate) **7b** (86%, m.p. 134°C) for reaction with NaI. Although the workup yielded the desired inversely configurated compound **8**, the amounts were not satisfactory (18%, m.p. 156°C), and the ether **9** was the major component (36%, m.p. 92°C). The latter is probably formed by a competitive attack of the nucleophile at the sulfonate and subsequent intramolecular substitution. In an attempt to prepare the diiodide **8** from the bis(silyl) ether **10** by treatment with iodotrimethylsilane, only **9** was isolated instead (65%), which must be attributed on one hand to steric hindrance and on the other to anchimeric stabilization of electrophilic intermediates.

After the treatment of **8** with Na/K alloy in ether, the ^1H NMR spectrum of the crude product showed signals due to olefinic compounds. Separation of the components into the heptacycle **12** (9%) and the trienes **11** (5%) and **1** (74%, m.p. 88°C) was achieved by chromatography on $AgNO_3$-impregnated aluminum oxide with pentane/ether mixtures.[8] The ratio of the trienes, which can be attributed to competing 1,4 cleavage of the comparably oriented relay bonds **a** and **b**, may be interpreted as a reflection of the relative bond strain. The formation of a pentaprismane homologue (**12**), however, is without precedent;[5] one can only speculate on the character of the homo- or heterolytic impulse which triggers the transannular bond formation.

The unsatisfactory total yield of **1** and the effort required for its chromatographic separation made us look for an alternative synthesis. And indeed, on treatment with Zn/HOAc[2, 9] the diketone **3** forms the enone **13** surprisingly



smoothly (59%, m.p. 87 °C[8] ; in addition 27% of **4**) without attack on the cyclobutene unit. Esterification of the corresponding enolate to afford the phosphate **14** (91%, oil) and its subsequent reduction with lithium in ammonia yields exclusively the triene **1** (75%) in economical total yield.

The reactions of **1** are noteworthy. Moreover, they serve to confirm its structure: Triplet-sensitized photolysis (acetone, Hg medium pressure lamp, Duran filter) initiates [2+2] cycloaddition to **12** typical for dienes **D**, while heating in solution to ≥ 80 °C induces a quantitative, regiospecific [3,3] shift to **11**. No indication is found in the ^{1}H NMR spectrum for the participation of isomer **15** (≤ 1%, Fig. 1) in

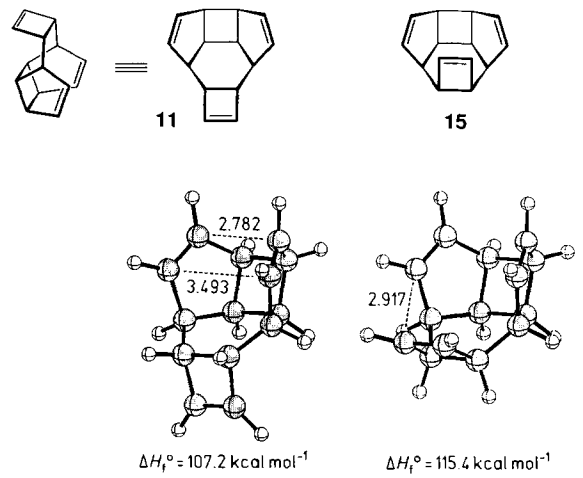


Fig. 1. Comparison of the calculated minimum geometries of the potential Cope isomers of **1**; heat of formation and intramolecular distances from MM2 calculations [11].

an equilibrium. In contrast, attempts to induce the thermal isomerization of the enolate of **13** or of the enol ester **14** were dominated by unspecific decomposition.

The exclusive formation of the *anti* isomer **11** is in agreement with force-field calculations, which estimate an energy higher by ca. 8 kcal mol^{-1} for the *syn* isomer **15** (both higher homologous unsaturated *tris*-[3.2.2]-σ-homobenzenes[10]) as a result of steric compression and unfavorable torsional interactions (Fig. 1). However, the heat of formation of the experimentally less stable structural isomer **1** ($d_{\pi-\pi} = 2.651$ Å) is strongly underestimated (ca. 0.8 kcal mol^{-1} *lower* than **11**),[11] which has to be ascribed in part to destabilizing π–π interactions neglected by the computational method (MM2).

[11] As this trend persists for diverse structural variants of type **D**, the order of magnitude of the error (≥ 5 kcal mol^{-1}) also implies an unsatisfactorily balanced parameterization of the MM2 force field (N. L. Allinger, *J. Am. Chem. Soc. 99* (1977) 8127–8134) for cyclopentene compounds. W.-D. Fessner, W. R. Roth, unpublished results.

1,2,3-Triphospha-4-silabicyclo[1.1.0]butanes from Activated, Stable Phosphasilenes and White Phosphorus**

By *Matthias Drieß**

Bicyclo[1.1.0]butanes in which the ring-C atoms are completely replaced by silicon and/or elements of Group 15 are interesting because of their unusual bonding.[1] Comparative experimental and theoretical studies of bicyclo[1.1.0]butane derivatives with P_4 (**A**) and Si_4 (**B**) frameworks[2] indicate that the bonds between the bridgehead atoms are substantially weakened in the silicon skeleton, but both systems possess remarkable ring dynamics.

Recently the first bicyclo[1.1.0]butane with a Si_2P_2 framework, a 1,3-diphospha-2,4-disilabicyclo[1.1.0]butane derivative (**C**) was reported.[3] The P–P bond in **C** has a diradical nature; this system therefore resembles compounds of type **A** more than type **B**.[4] Type **C** compounds were prepared by treatment of tetraorganodisilenes ($R_2Si{=}SiR_2$) with white phosphorus[3] and lately also by dehydrogenation of 2,2,4,4-tetraorgano-1,3-diphospha-2,4-disiletanes.[5] The smooth access to **C** from disilenes and P_4 raised the question whether this synthesis principle would not also be effective for the as yet unknown SiP_3 systems, **D**. Kinetically stable phosphasilenes ($R_2Si{=}PR$) which must be thermally stable yet reactive enough to react with P_4 are required as starting compounds. The only phosphasilene stable at 60 °C which could be obtained pure (spectroscopic criteria), Is(*t*Bu)Si=PMes*[6] (Is = 2,4,6-triisopropylphenyl (isityl), Mes* = 2,4,6-tri-*tert*-

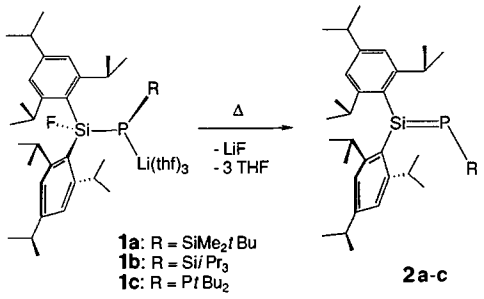
butylphenyl), seemed unsuitable as it reacts only slowly with relatively strong oxidizing agents like sulfur and selenium. Appropriate precursors appeared to be the phosphasilenes **2a** and **b**, which have a triorganylsilyl group attached to the $\lambda^3\sigma^2$-coordinated P atom. Compounds **2a** and **b** were obtained by elimination of LiF from the corresponding lithiophosphanes **1a** and **b**.[7]



Furthermore, **2c**, a phosphasilene with a phosphanyl substitutent at P is accessible by this route. The derivatives **2** are stable under the conditions of the synthesis, in contrast to other analogously prepared compounds such as $t\mathrm{Bu_2Si{=}P{-}Si}t\mathrm{Bu_3}$ and $t\mathrm{Bu_2Si{=}P}t\mathrm{Bu}$.[8] The thermal stability of **2** (**a**, **b** 2 h in toluene at 90 °C and **c** 12h in toluene at 110 °C without change) is attributed in the first instance to the bulky aryl groups on silicon. Compounds **2** were obtained as orange oils and shown by NMR spectroscopy to be pure when the precursors were the analytically pure **1**,[9] but crystals of **2** have not yet been obtained.

The data from ^{31}P and ^{29}Si NMR spectroscopy (Table 1) reflects the unusual bonding mode in the strongly polarized

Table 1. ^{31}P and ^{29}Si NMR data of compounds **2a–c**. Coupling constants J in Hz.

	$\delta(^{31}P)$	$^1J(PP)$	$\delta(^{29}Si)$	$^1J(P{=}Si)$	$^1J(P{-}Si)$
2a	17.7	–	178.4 (d, Si=P)	149	–

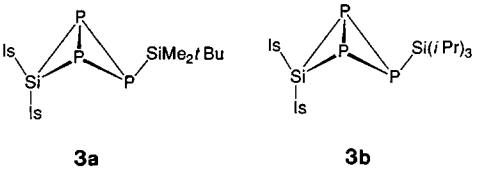
[a] ^2J(Si, P) = 43.

P–Si (p–p)π systems **2**, which are activated by the σ-donor groups on phosphorus. In comparison with the known phosphasilenes of *Bickelhaupt* et al.,[6] which have only aryl substituents on the phosphorus and silicon atoms ($\delta(^{31}P)$ = 136–93.5),[6] the resonance signals of the $\lambda^3\sigma^2$ P atoms in **2** are shifted to higher field by up to $\Delta\delta$ = 124.9 (!). The position of the ^{29}Si signals at extremely low field and the characteristically large $^1J_{P-Si}$ coupling constants leave no doubt that the Si atoms have threefold coordination and Si–P π bonds.[6] The unusual position of the ^{31}P and ^{29}Si NMR signals is attributed to the strong σ-donor influence of the triorganosilyl- and di-*tert*-butylphosphanyl groups on phosphorus. This influence decreases, as anticipated, along the series $\mathrm{SiiPr_3} > \mathrm{SiMe_2}t\mathrm{Bu} > \mathrm{P}t\mathrm{Bu_2}$.

The treatment of **2a, b** with white phosphorus in the molar ratio 2:1 at 60–70 °C does yield the 1,2,3-triphospha-4-silabicyclo[1.1.0]butanes (**3a, b**),[10] whose composition has been



3a **3b**

established by EI mass spectra and correct elemental analysis.[10] Their structure can be unambiguously deduced from NMR data: in the ^{31}P NMR spectrum a doublet is observed for the bridgehead phosphorus atoms at very high field as expected (**3a**: δ = – 331.5, $^1J_{PP}$ = 163 Hz; **3b**: δ = – 328.3, $^1J_{PP}$ = 173 Hz) and a triplet for the peripheral P atom (**3a**: δ = – 257.5; **3b**: δ = – 247.2). The ^{29}Si skeletal atoms in **3a, b** give a doublet of triplets in the ^{29}Si NMR spectrum (INEPT pulse sequence; X part of an A_2MX spin system where A, M = ^{31}P, X = ^{29}Si; **3a**: δ = – 34.4, $^1J_{SiP}$ = 74 Hz, $^2J_{SiP}$ = 27 Hz; **3b**: δ = – 37.1, $^1J_{SiP}$ = 72 Hz, $^2J_{SiP}$ = 23 Hz). The $^1J_{SiP}$ coupling constants are in the same region as those of 1,3-diphospha-2,4-disilabicyclo[1.1.0]butanes (76–78 Hz) and thus typical for silicon atoms in three-membered rings.[11]

Since the isityl groups on silicon are bulky and since in each case only one configuration of **3a, b** is formed, it appears that the triorganosilyl substituent favors the *exo* position.

Besides the disilenes, these phosphasilenes are the only known compounds with (p–p)π bonds between main-group elements which degrade P_4 under relatively mild conditions. This route leads formally to the breaking of the π and the σ bonds of the heteroalkene group.

Experimental Procedure

2a: A solution of analytically pure **1a**[7] (1.25 g, 1.52 mmol) in toluene (20 mL) was heated for 6 h at 60–70 °C, during which the initially colorless solution becomes deep orange. The clear solution was cooled and after the ^{31}P NMR spectrum confirmed that the reaction was complete, an excess of Me_3SiCl (0.82 g, 7.6 mmol) was added and the mixture stirred for a further 12 h at room temperature. The resulting orange suspension was evaporated to dryness at 10^{-2} Torr, and the residue was taken up in pentane (10 mL) and filtered over a G-IV frit. Removal of the pentane yielded **2a** (pure according to the NMR spectrum). Yield: 802 mg (91 %), deep orange oil. **2b, c** were prepared similarly: **2b** (yield 796 mg, 1.28 mmol, 94 %) from **1b** (1.18 g, 1.36 mmol); **2c** (yield 638 mg, 0.84 mmol, 91 %) from **1c** (810 mg, 0.92 mmol).

3a: Freshly sublimed white phosphorus (46.5 mg, 0.37 mmol) was added to a solution of **2a** (400 mg, 0.75 mmol) in toluene (20mL) and heated for 12 h at 70 °C. The initially deep orange solution paled to light yellow. The solvent was removed at 25 °C and 10^{-2} Torr, and the residue taken up in pentane, the volume reduced to ca. 5 mL, and the resulting solution left to stand at – 30 °C to crystallize. Yield: 142.9 mg (0.24 mmol, 32 %); pale yellow, microcrystalline powder. M.p. 214–216 °C. **3b**: Analogous to **3a** from **2b** (492 g, 0.86 mmol). Yield: 223 mg (0.35 mmol, 41 %) of a light yellow solid. M.p. 231–232 °C.

[4] This finding is new. Ab initio MO calculations were done on the parent system $(H_2Si)_2P_2$, which confirm the singlet–diradical character of the P–P bond: R. Janoschek, unpublished results. This explains the relatively large P–P bond length of 2.38 Å in **C** (ca. 0.15 Å longer than a P–P single bond). See also refs. [3], [5].

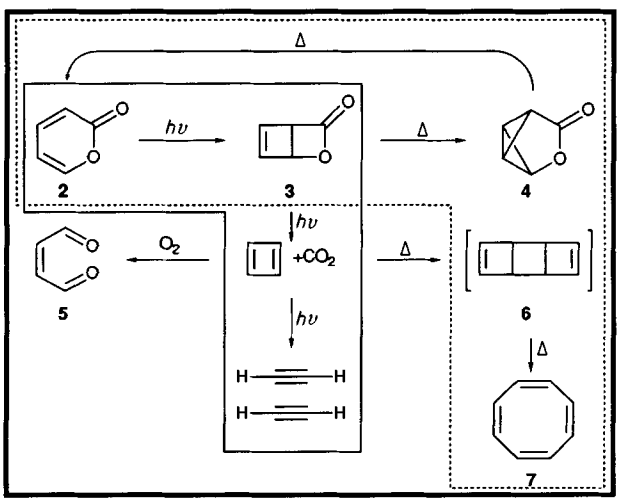
The Taming of Cyclobutadiene**

By *Donald J. Cram,* Martin E. Tanner,* and *Robert Thomas*

Cyclobutadiene, $(CH)_4$, is the Mona Lisa of organic chemistry in its ability to elicit wonder, stimulate the imagination, and challenge interpretive instincts. No other organic compound combines such a fleeting existence and so many different syntheses, with such a propensity for different chemical reactions, and with the variety of calculations of its structure.[1–3]

We report here the synthesis and reactions of cyclobutadiene lodged in the cavity (inner phase) of the hemicarceplex **1** · $(CH)_4$. Hemicarcerand **1** combines an enforced inner phase large enough to accommodate small guest molecules such as dimethylacetamide, benzene, or tetrahydrofuran (THF) with a portal which allows guest entry and exit at temperatures above 100 °C. The eight $C_6H_5CH_2CH_2$ appendages of **1** · G serve as solubilizing groups.[4, 5] In **1** · $(CH)_4$, the shell of the host protects the guest $(CH)_4$ from dimerization[2, 3] and from reactants too large to pass through the portal of **1**, rendering **1** · $(CH)_4$ stable at ordinary temperatures. The synthesis and reactions of $(CH)_4$ are the first that have been carried out in the confined *inner phase* of a hemicarcerand.[4] Scheme 1 formulates these reactions, and identifies them by their enclosure in the rectangular box outlined by the heavy lines. Reactions previously run by *Corey* et al.[6, 7] in ordinary solutions (**2** → **3** → **4**) and by *Maier* et al. and *Schweig* et al.[8] (**4** → **2**, flash pyrolysis) are enclosed by dashed lines. Prior reactions carried out by



Scheme 1. Thermal and photochemical transformations of α-pyrone. The three frames contain reactions carried out: ---- historically in solution and gas phase; —— historically in an argon matrix at 8 K; —— in the inner phase of the hemicarcerand **1**, and reported here (except cyclooctatetraene formation, which occurs outside).

9

in which $(CH_3)_3C$ groups sterically stabilize the cyclobutadiene system.

Hemicarceplex **1** · α-pyrone (**1** · **2**) was prepared by refluxing empty **1**[4, 5] in 3:1 C_6H_5Cl/α-pyrone, then precipitating the cooled complex with hexanes. The host-to-guest ratio of **1** · α-pyrone was established by elemental analysis[13] and its ^{1}H NMR spectrum (Fig. 1). Solutions of **1** · α-pyrone in degassed $CDCl_3$ (ca. 3 mM) or [D_8]THF (ca. 1 mM) were sealed in standard borosilicate-glass NMR tubes, which were irradiated at 25°C with a 75 W xenon arc lamp for 30 min. The 500 MHz ^{1}H NMR spectra of the resulting $CDCl_3$ and [D_8]THF solutions (Fig. 2) each gave a sharp singlet for incarcerated $(CH)_4$ at $\delta = 2.27$ and 2.35 respectively. The latter signal is $\Delta\delta = 3.03$ upfield from that of the ring proton of **9** in [D_8]THF at $\delta = 5.38$[2] due to the shielding effects of the host in **1** · $(CH)_4$. Similarly the proton singlet of **1** · C_6H_6 is $\Delta\delta = 3.49$ upfield of free C_6H_6 dissolved in $CDCl_3$ at 22°C.[5] The host's inward-pointing H_a and H_b protons (see **1** · G) gave sharp doublets in the ^{1}H NMR spectrum of **1** · $(CH)_4$ at $\delta = 4.27$ and 4.36, providing direct evidence that cyclobutadiene possesses a singlet ground state (Fig. 2). Triplet $(CH)_4$ would dramatically broaden and shift the host signals, as did triplet O_2 in the spectrum of **1** · O_2.[4]

The sharpness of these H_a and H_b signals shows that in **1** · $(CH)_4$ the guest is rotating rapidly on the ^{1}H NMR time scale about all its axes with respect to the host. This fact strongly suggests that the CO_2 molecule generated as a companion reaction product was expelled through the portal during the photolysis. Other studies demonstrated that CO_2 rapidly enters and leaves the interior of free **1** dissolved in $CDCl_3$ at 25°C.[5] Examination of Corey–Pauling–Koltun (CPK) molecular models of **1** · $(CH)_4$ · CO_2 suggests that shuffling of the two guests in the cavity should be too slow to randomize their positions rapidly enough on the ^{1}H NMR time scale to provide sharp doublets for the host's H_a and H_b signals. Analogy for the CO_2 ejection is found in the loss by heating, of *only one* of two CH_3CN guests from a termolecular complex similar to **1** · $(CH)_4$ · CO_2.[14]

Changes in the irradiation times pointed to both precursers for, and products of **1** · $(CH)_4$. Shorter times provided up to 60% conversion of **1** · **2** into bound photopyrone (**1** · **3**, ^{1}H NMR), which on further irradiation gave **1** · $(CH)_4$. Longer times enhanced the ^{1}H NMR signal at $\delta = 1.91$, barely visible in Figure 2, which is due to free acetylene. This peak was absent in the starting solution of **1** · α-pyrone. Authentic acetylene dissolved in $CDCl_3$ also gave a signal at $\delta = 1.91$ in its ^{1}H NMR spectrum. When the **1** · $(CH)_4$ solution produced by irradiation was purged with xenon gas, the 1.91 peak disappeared from its ^{1}H NMR spectrum, as did the peak for authentic acetylene on similar treatment. Addition of aqueous ammoniacal cuprous chloride to a post-irradiation solution which contains **1** · $(CH)_4$ and C_2H_2 produced the deep red color of cuprous acetylide.[15] Solutions of **1** · α-pyrone before irradiation or of free **1** in $CDCl_3$ before or after irradiation did not test positively for acetylene. Thus incarcerated cyclobutadiene upon photolysis gave acetylene, just as did cyclobutadiene in an argon matrix at 8 K.

An FTIR spectrum of **1** · α-pyrone in $CDCl_3$ exhibits bands at 1733, 1719, 1539, and 1246 cm^{-1} due to the incarcerated **2**, which compare with bands at 1737, 1719, 1546, and 1247 cm^{-1} for free **2** in $CDCl_3$. These bands disappeared in the spectrum of **1** · $(CH)_4$, which gave no carbonyl

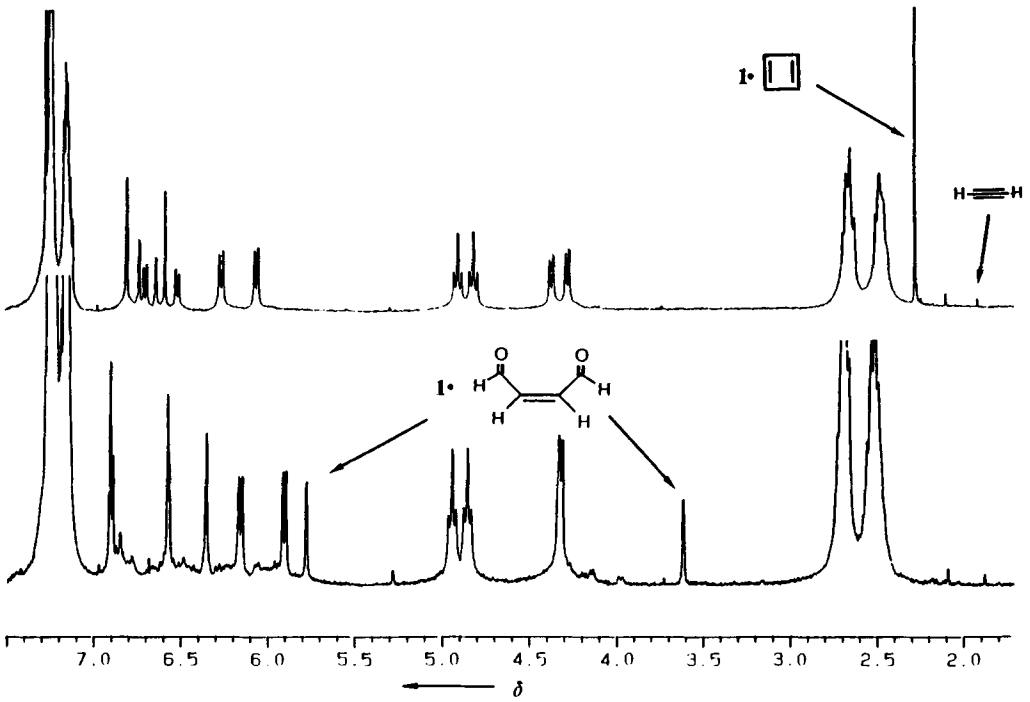

Fig. 2. ^{1}H NMR spectra (500 MHz, $CDCl_3$, 60°C) of hemicarceplexes **1** · $(CH)_4$ and **1** · (*Z*)-OHCCH=CHCHO.

signals in the 1650–1850 cm^{-1} region. The appearance of a signal at 1233 cm^{-1} provides additional evidence for the formation of cyclobutadiene. This band is assigned to the carbon–carbon stretching frequency which appeared at 1240 cm^{-1} in the argon-matrix experiment.[9] Host bands obscured the other signals of $(CH)_4$.

When heated at 220°C for 5 min in an NMR tube sealed under vacuum, **1** · $(CH)_4$ dissolved in [D_8]THF underwent complete guest exchange to give **1** · $(CD_2)_4O$, whose ^{1}H NMR *host* signals corresponded to **1** · THF prepared previously.[5] A new singlet appeared in the spectrum at $\delta = 5.71$, which is due to free cyclooctatetra-1,3,5,7-ene (**7**). The contents of the tube when opened exuded the pungent and characteristic odor of **7**. Addition of authentic **7** to the solution intensified the 5.71 peak. Thus the freed cyclobutadiene must have dimerized to give **6**, which thermally rearranged to give **7**. The intermediacy of cyclobutadiene dimers, though not demonstrated, is hardly in question. They rearrange to give **7**, a reaction whose half-life is ca. 20 min at 140°C.[16]

The cyclobutadiene guest of a **1** · $(CH)_4$ solution in $CDCl_3$ reacts readily with O_2 to give what is probably **1** · (*Z*)-OHCCH=CHCHO. When a stream of O_2 was bubbled vigorously through a solution of **1** · $(CH)_4$ in $CDCl_3$ at 25°C for 10 min, a 50% conversion to a new complex was observed (change in ^{1}H NMR spectrum). The conversion was complete after the resulting solution had stood 30 min under an atmosphere of O_2. The 500 MHz ^{1}H NMR spectrum taken at 60°C of the malealdehyde[17] complex (Fig. 2) provided guest signals as broad singlets at $\delta = 5.77$ and 3.61. These were shown by selective irradiation to be coupled. The signal at $\delta = 5.77$ is good evidence for the aldehydic protons being shifted upfield by $\Delta\delta \approx 4$ from their usual positions. An examination of CPK models of **1** · (*Z*)-OHCCH=CHCHO indicates that these protons are located in the high-shielding polar regions of the host. The position of the signal at $\delta = 3.61$ is typical for a bound alkene proton.[5] Like the guest's signals, several of the host's signals are broad at 25°C (no loss of symmetry), but unlike the former, these sharpened when the spectral solution was warmed. The increased size and somewhat restricted motion of the malealdehyde over cyclobutadiene in the complex accounts for this broadening in the spectrum of **1** · (malealdehyde).

The FTIR spectrum of this new complex exhibited a broad band at 1696 cm^{-1}, indicative of the presence of an unsaturated aldehyde. The formation of **1** · (*E*)-OHCCH=CHCHO instead of the *Z* complex cannot be ruled out based on the spectral data. Precedence for the reaction, **1** · $(CH)_4 + O_2 \rightarrow$ **1** · (*Z*)-OHCCH=CHCHO, is found in the reaction of tetra-*tert*-butylcyclobutadiene (**8**) with O_2 to give (*Z*)-*t*BuCOC(*t*Bu)=C(*t*Bu)CO*t*Bu.[18] The formation of malealdehyde (**5**) from the reaction of gaseous $(CH)_4$ with O_2 has been suggested by *Hedaya* et al., who detected an adduct of $m/z = 84$ by mass spectrometry.[19]

A comparison of the UV spectra of **1** and **1** · α-pyrone (**1** · **2**) in $CDCl_3$ shows no electronic interaction between host and guest. The strong absorbance due to the aromatic rings of the host ends abruptly at 300 nm, leaving a small UV window for the selective photolysis of α-pyrone in **1** · **2**. Irradiation of 2–4 mM solutions of **1** · **2** in $CDCl_3$ at 25°C with a 75 W xenon arc lamp fitted with a filter for $\lambda < 300$ nm ($SnCl_2$/HCl aqueous solution) caused the gradual, quantitative conversion of **1** · **2** to **1** · photopyrone (**1** · **3**, see Scheme 1). The reaction was followed by changes in the 500 MHz ^{1}H NMR spectrum. It required 1 h for completion. Figure 1 shows the spectra of **1** · **2** and **1** · **3** at 60°C. Several of the host signals are broad in **1** · **2** at 25°C due to restricted motion of the guest (relative to host) on the ^{1}H NMR time scale. In the spectrum of **1** · **3**, the host's global signals are fairly sharp at 25°C, but are doubled, indicating that the long axes of **3** and **1** are roughly coincident in **1** · **3**, and that **3** is not rapidly rotating about its short axis on the ^{1}H NMR time scale. These signals are still sharp at 60°C, and three of the signals of bound **3** appeared at $\delta = 3.84$, 2.98, and 2.10 (one proton each). The fourth was located

using ^{1}H-^{1}H COSY spectroscopy ($CDCl_3$, 22 °C). It appeared at $\delta = 2.46$, coupled to the guest signals at $\delta = 2.98$ and 2.10. The δ values for **3** of **1** · **3** are consonant with those of free **3** in CCl_4[6] ($\delta = 6.73$, 6.59, 5.30, and 4.40) after allowing for the shielding effects of the host.

Further evidence for the existence of **1** · **3** was obtained by FTIR spectroscopy ($CDCl_3$). The lactone carbonyl stretch of free **2** appears as a doublet at 1719 and 1737 cm^{-1}. Incarcerated **2** also gives a doublet at 1719 and 1733 cm^{-1}, indicating that residence within the host does not dramatically change the absorption frequency from that in a $CHCl_3$ solution. After irradiation these signals were replaced by a strong absorption at 1847 cm^{-1}, and a weak one at 1823 cm^{-1}. This is consistent with the reported carbonyl absorption of free **3** as a double peak at 1848 and 1818 cm^{-1} (CCl_4).[6] Thin-layer chromatography (silica, 3:7 hexanes/$CHCl_3$) shows that the photoproduct has a higher R_f value than **1** · **2**. The most likely reason for this difference is that the carbonyl group of **1** · **2** can interact with the exterior (through the shell opening), whereas that of the bicyclic lactone cannot. Complex **1** · **3** remained unchanged when stored in the solid state for 2 weeks, and no signs of decomplexation or rearrangement were observed in a $CDCl_3$ solution at 25 °C over a 24 h period.

After **1** · **3** was heated as a solid for 17 h at 90 °C, 80% of the complex existed as **1** · **4**, 13% remained as **1** · **3**, and 7% had reverted to **1** · **2**. The 500 MHz ^{1}H NMR spectrum ($CDCl_3$, 60 °C) of **1** · **4** (Fig. 1) gave guest signals at $\delta = 0.84$ (1H), 0.31 (1H), and 0.03 (2H), and their relationships were positively identified by decoupling experiments. These signals were somewhat broadened at 25 °C. The upfield position of these signals indicates that none are due to C=CH protons. Their chemical shifts are consistent with signals reported for free **4** in $CDCl_3$ of $\delta = 4.72$ (1H), 3.50 (2H), and 2.45 (1H),[7] if allowances are made for the shielding effects of the host in the spectrum of **1** · **4**. The coupling constants for **4** in **1** · **4** were also in agreement with those reported for **4** in $CDCl_3$. Notably, the long range coupling between the protons on either side of the carboxy bridge in **4** of **1** · **4** was 5.0 Hz, compared to 5.2 Hz for **4** in $CDCl_3$ at room temperature.[7] Even though the H_a signals of **1** · **4** were broadened at 25 °C, the north–south hemispheric symmetry of the host is evident. The FTIR spectrum of **1** · **4** in $CDCl_3$ gave a strong peak at 1821 cm^{-1}, not far from the absorptions at 1818 and 1795 cm^{-1} for **4** in $CDCl_3$.[7] The thin-layer chromatographic behavior of **1** · **4** was identical to that of **1** · **2**.

Strong evidence for proposed structures, **1** · **2**, **1** · **3**, and **1** · **4**, was provided by the conversion of **1** · **4** into **1** · **2** by heating solid **1** · **4** at 140 °C for 20 h. Thus the elemental composition of all three complexes was maintained throughout the interconversions of the three complexes. The conversion, **4** → **2**, has been reported to occur during flash vacuum pyrolysis of **4** at 600 °C.[8]

We have illustrated here the following new phenomena: 1) A starting material (e.g. α-pyrone) can be introduced (mass law and heat) into the inner phase of an empty hemicarcerand of complementary dimensions (**1**) to form a hemicarceplex (**1** · **2**) in which constrictive binding[5] contributes substantially to its stability as a complex. 2) Three photochemical reactions have been run in the inner phase, **2** → **3** → $(CH)_4$, $(CH)_4 \rightarrow 2(CH)_2$, and **2** → **3**. Interesting questions arise as to how the lower wavelength light (200–250 nm) required for the formation of cyclobutadiene (and its reaction to give acetylene) is transmitted through the aryl shell of the host (a photosensitization process?). 3) The cyclobutadiene is thermally stable in the inner phase at ordinary temperatures, and exists as a singlet. 4) When heated to 220 °C in [D_8]THF, the following thermal transformations occur: **1** · $(CH)_4 \rightarrow$ **1** + $(CH)_4$, $2(CH)_4 \rightarrow$ [dimer] → $(CH)_8$ (cyclooctatetraene) and **1** + $(CD_2)_4O \rightarrow$ **1** · $(CD_2)_4O$. 5) When oxygen and **1** · $(CH)_4$ are both dissolved in the same $CDCl_3$ solution the oxygen enters the inner phase to produce the bimolecular reaction, O_2 + **1** · $(CH)_4 \rightarrow$ **1** · (*Z*)-OHCCH=CHCHO. 6) Two thermal reactions have been run in the inner phase with the hemicarceplexes themselves being in the solid state: **1** · **3** → **1** · **4** (at 90 °C) and **1** · **4** → **1** · **2** (at 120 °C). Within the limits of ^{1}H NMR spectral criteria, these transformations that occur in the inner phase are quantitative. We anticipate that many highly reactive species containing bent acetylene, allenic, or aromatic rings, radicals, carbenes, etc. can be prepared and examined in the inner phases of appropriate hemicarcerands.

We believe it to be both realistic and useful to regard the "inner phase" of carcerands and hemicarcerands to be a *new phase of matter*.[20] It differs in principle from the inside phases of clathrates and zeolites in its unique molecular composition: *one host molecule provides one discrete molecular inner phase*. Experimentally, hemicarcerands and hemicarceplexes can exist in the solid, solution, or even gaseous phases (inside a mass spectrometer)[5] and therefore their inner phases are not dependent on the bulk phase. Inner-phase reactions have been reported here which occur when the complex is in the solid or bulk-liquid phases. Clathrate inner phases disappear on dissolution of the solvates, and zeolites are insoluble, polymeric solids.

1,4,5,8-Tetrakis(dimethylamino)naphthalene: Synthesis, Structure, "Proton Sponge" and Electron Donor Properties**

By *Thomas Barth, Claus Krieger, Franz A. Neugebauer,* and *Heinz A. Staab**

In the context of our studies on relatives of 1,8-bis(dimethylamino)naphthalene **1** ("proton sponge"),[1,2] the comparison with 1,4,5,8-tetrakis(dimethylamino)naphthalene **2** was of interest, which contains twice the pairwise *peri*-arrangement of dimethylamino groups associated with "proton sponge" properties. This posed the question of the mutual influence of these two structural units, which should be evident from the pK_a values for the first and second protonation steps of **2**. Moreover, being a structural isomer of the recently prepared 2,3,6,7-tetrakis(dimethylamino)naphthalene **3**,[3] **2** was of interest as an electron donor in which formally two structural units corresponding to the 1,4-bis(dimethylamino)benzene ("tetramethyl-*para*-phenylenediamine," TMPD) are coupled together.

3

For the synthesis of **2**, 1,3-dimethyl-1*H*-perimidin-2(3*H*)-one **4**[4] was nitrated in glacial acetic acid to give the 6,7-dinitro compound **5**[5] (m.p. ≈ 310 °C, decomp.; 33% yield), which upon ring-opening (potassium hydroxide, methanol) yielded 1,8-bis(methylamino)-4,5-dinitronaphthalene **6** (m.p. ≈ 235 °C (decomp.); 66%).[5] Subsequent *N*-methylation (methyliodide, potassium carbonate, dimethylformamide) afforded the bis(dimethylamino) compound **7** (dark red crystals, m.p. 280 °C (decomp.); 32%).[5] Catalytic hydrogenation (Pd/C, ethyl acetate) of **7** gave the rather unstable compound **8**, which was converted according to the procedure described by *Quast* et al.[6] (sodium hydride, dimethyl sulfate, tetrahydrofuran) into **2** (yellow crystals, m.p. 193.5 °C; 31% referred to **7**).[5] The ^{1}H-NMR spectrum of **2**, consisting of only two singlets [δ = 2.65 (s, 24H), 6.75 (s, 4H); 500 MHz, [D_6] dimethyl sulfoxide], reflects the high molecular symmetry of **2**.

[**] Novel "Proton Sponge" Compounds, Part 10.—Part 9: H. A. Staab, M. A. Zirnstein, C. Krieger, *Angew. Chem. 101* (1989) 73; *Angew. Chem. Int. Ed. Engl. 28* (1989) 86.

The steric interaction within the two pairs of *peri* dimethylamino groups is a major factor determining the structure of **2**. Figure 1 shows a top view of the naphthalene skeleton of this structure[7] (above) as well as a side view along the central C(4a)–C(8a) bond (middle) and a view perpendicular to the C_2-axis (below). Compared to the situation in **1**[8] the stronger steric strain by the four *peri* substituents leads to a particularly marked twisting of the naphthalene system about the central C(4a)–C(8a) bond (torsion angle C(1)–C(8a)–C(4a)–C(4): 18.8°); as a consequence the N ··· N distances are expanded to 274.5(1) pm.[9] The neighboring dimethylamino groups in the *peri* positions evade steric contacts by rotation about the C(1)–N(1') and

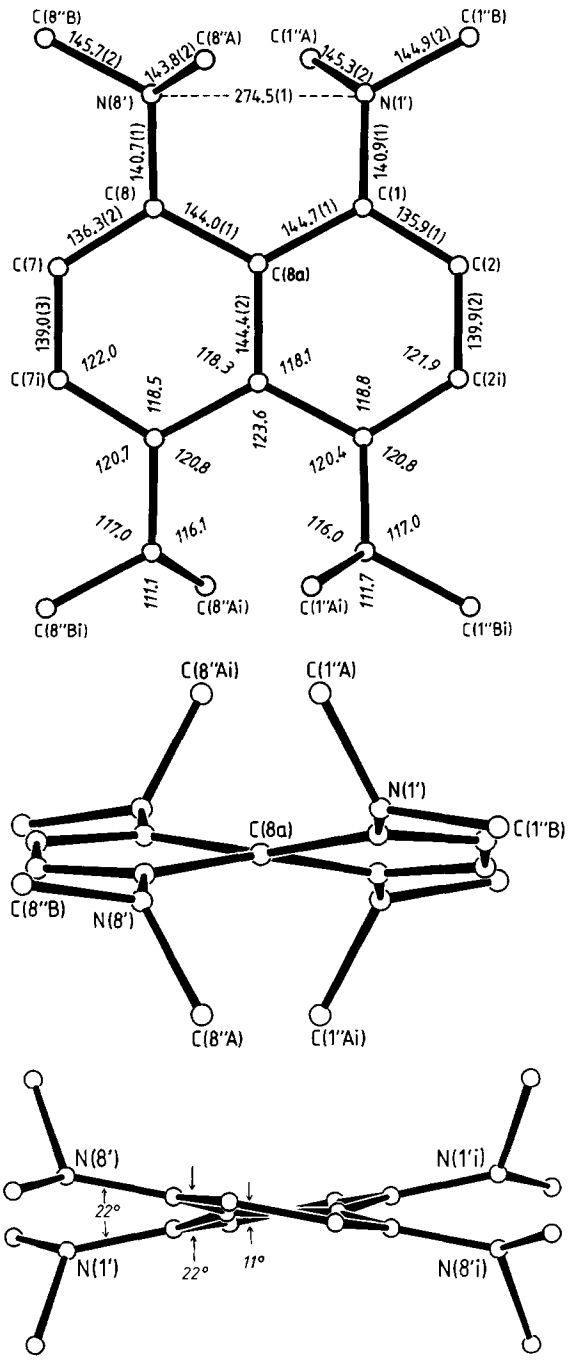

Fig. 1. Structure of **2** in the crystal. Above: Top view of the naphthalene skeleton with bond lengths [pm] and angles [°] (standard deviations for the last place in brackets); middle: side view along the C(4a)–C(8a) bond; below: side view a long the twofold axis perpendicular to the other views with interplanar angles: 11° [angle between C(2)–C(2i)–C(8ai)-C(8a) and C(7)–C(7i)–C((8ai)–C(8a)]; 22° [C(1)–C(2)–C(8a) and C(7)–C(8)–C(8a)] [7].

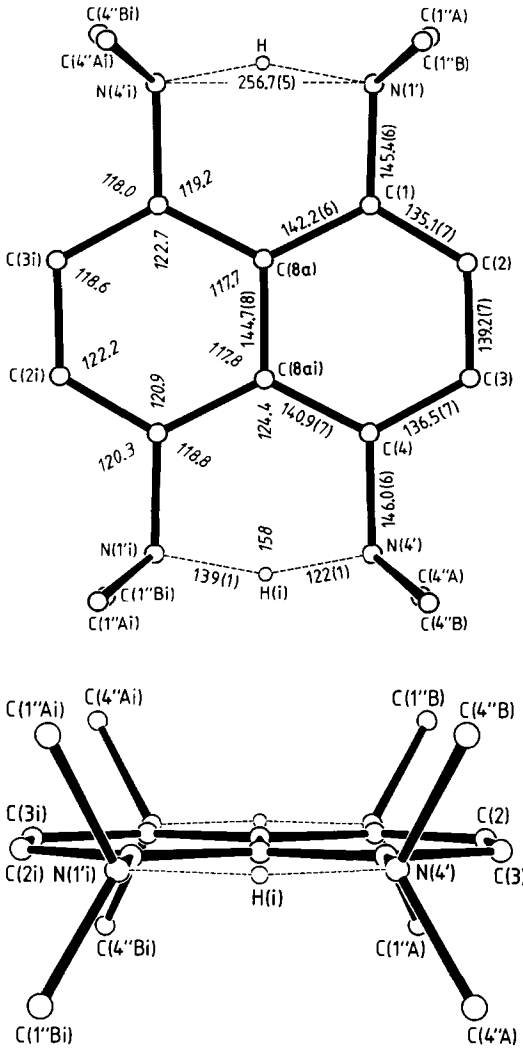

Fig. 2. Structure of the dication of $2 \cdot (HBr)_2$ in the crystal. Above: Top view of the naphthalene plane with bond lengths [pm] and angles [°] (standard deviations in units for the last given place); below: side view along the C(4a)–C(8a) bond [14].

C(8)–N(8') bonds (Fig. 1, middle). This conformation, as also peculiarities in bond lengths and angles, display similar trends as those in **1** and other naphthalene "proton sponges".[10]

The "double proton sponge" **2** is diprotonated by excess strong acid; reaction with tetrafluoroboric acid-etherate in diethyl ether leads to the formation of $2 \cdot (HBF_4)_2$.[5] By deprotonation with an equivalent amount of **2**, also the monoprotonated $2 \cdot HBF_4$ can be detected ^{1}H-NMR spectroscopically in [D$_6$]dimethyl sulfoxide.[11] The ^{1}H-NMR spectra of both salts show the expected downfield shift [$2 \cdot H^{\oplus}$: $\delta = 18.75$; $2 \cdot (2H)^{2\oplus}$: $\delta = 18.80$] for the signals of the protons in the N···H···N bridge. By NMR spectroscopic determination of the protonation-deprotonation equilibria in [D$_6$]dimethyl sulfoxide[12] a first protonation

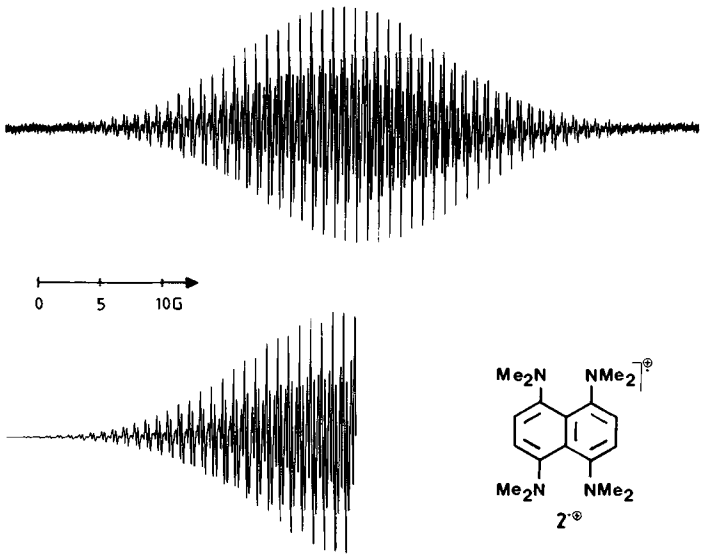

Fig. 3. ESR spectrum of $2^{\cdot\oplus}$ in dichloromethane at 220 K (above) and spectra simulation (below) with the data given in text (line width 0.11 G).

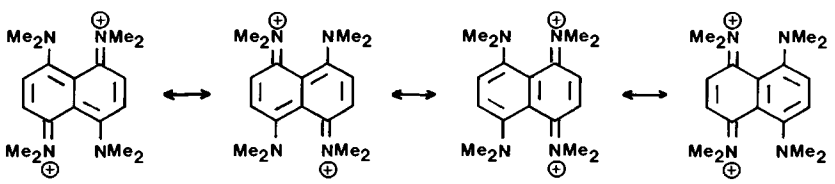
step with $pK_{a(1)} = 9.8 \pm 0.5$ and a second with $pK_{a(2)} = 4.9 \pm 0.2$ (referred to **1** with $pK_a = 7.5$[13]) are obtained for **2** on the dimethyl sulfoxide pK_a scale.[13] **2** is thus a significantly stronger base than **1** in the first protonation step. We attribute this not only to the + M effect of each of the *para* dimethylamino groups but also to an indirect steric ("buttressing") effect, which has also been observed in other 1,8-bis(dimethylamino)naphthalenes with substituents in the two other *peri* positions C(4) and C(5).[10]

A salt of diprotonated **2** suitable for the X-ray structure analysis, namely **2**-dihydrobromide-pentahydrate (m.p. 247 °C (decomp.), from water),[5] was obtained by reaction of **2** with hydrogen bromide. Figure 2 shows the structure of the $2 \cdot (2H)^{2\oplus}$ moiety viewed perpendicularly onto the naphthalene system (top) and from the side along the central C(4a)–C(8a) bond (bottom).[14] Particularly striking is that **2** is almost completely planarized by the diprotonation and the accompanying formation of two strong N···H···H hydrogen bridges. Accordingly, the N···N distances are shortened to 256.7(5) pm. The N···H···N hydrogen bridge forms an angle of about 158° and is unsymmetrical with regard to the N···H bond lengths.

1,4,5,8-Tetrakis(dimethylamino)naphthalene **2** is a much stronger electron-donor than the 2,3,6,7-substituted isomer **3**. Whereas two oxidation steps, each corresponding to a one-electron transition were determined cyclovoltammetrically at $E_{ox} = -0.01$ V and $+0.07$ V (Fc/Fc$^{\oplus}$ = 0.0 V, Fc = ferrocene) for **3**,[3] in the case of **2** under the same conditions[15] the cyclovoltammogram shows a reversible two-electron transition at $E_{ox} = -0.50(1)$ V, which consists of two superposed one-electron steps and leads to the formation of the dication $2^{2\oplus}$. The stability of this dication could be associated with a favorable charge and bond delocalization in which all four dimethylamino groups participate (Scheme 1).



Scheme 1.

By electron transfer to tris(4-bromophenyl)amminium hexachloroantimonate or by oxidation with iodine also the radical cation $2^{\bullet\oplus}$ can be generated, whose ESR spectrum in dichloromethane at 220 K is shown in Figure 3. The analysis was achieved with the aid of the ^{1}H-hyperfine structure coupling constants determined by ENDOR and general triple resonance spectroscopy:[16] a(H) = + 3.55, a(H) = + 1.78, and a(H) = − 1.51 G. Simulation of the ESR spectrum (Fig. 3, bottom) gave a(N) = 2.65 (4 N), a(H) = 3.54 (12 H), a(H) = 1.77 (12 H) and a(H) = 1.53 (4 H) G. The g factor (2.0029) lies in the expected range.[17] The appearance of different N-methyl proton signals in the ESR spectrum of $2^{\bullet\oplus}$ at 220 K indicates a restricted rotation about the C_{aryl}–N bond with two different arrangements of the methyl groups. This effect was also observed in the case of the radical cation of 1,2,4,5-tetrakis(dimethylamino)benzene but not in the case of the radical cation $3^{\bullet\oplus}$ isomeric with $2^{\bullet\oplus}$.[17]

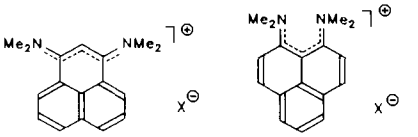
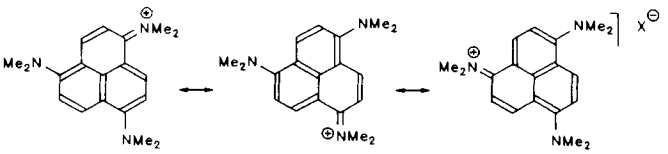
Aromatic Systems with Polymethine-like Structures: A Structural Comparison of Bis- and Tris(dimethylamino)phenalenium Ions**

By *Heinz A. Staab,* Jörg Hofmeister*, and *Claus Krieger*

The structure analysis of the dication of 1,2,4,5-tetrakis-(dimethylamino)benzene[1] showed quite clearly that the cyclic delocalization of aromatic π-systems can be largely removed as a result of the formation of only weakly coupled polymethine-like partial structures. From absorption spectroscopic studies *Dähne* et al.[2] have been able to classify conjugated π-electron systems into aromatic, olefinic, and polymethine-like partial structures; *Fabian*[3] has supported such a "building-block model" by quantum chemical calculations. However, the validity and limits of this heuristic concept require further experimental verification.



1 2



3

In this connection our interest focussed on a comparison of the structures of the 1,3- and 1,9-bis(dimethylamino)phenalenium salts **1** and **2**. In both cases trimethinecyanine partial substructures can be formulated, of which that in the case of **1** has the all-*trans* arrangement, whereas in the case of **2** the *peri* position of the dimethylamino substituents enforce an all-*cis* arrangement. More important in connection with the problem outlined above is, however, that **1** and **2** differ with respect to the part of the π-electron system *not* incorporated in the polymethine moiety: in **1** this would be a naphthalene system, in **2** a benzene system; the benzene system would be bound to the polymethine fragment via double bonds and the central single bond.

In contrast to **1** and **2**, in the case of the 1,4,7-tris(dimethylamino)phenalenium ion **3** polymethine substructures with only weak coupling to the remaining π-electron system were not to be expected since, here, three equivalent mesomeric structures should prevail.

The syntheses of **1**–**3** are based on previous work of other authors,[5, 6] especially of *Hünig* and *Wolff*.[4] **1** (X = BF_4) (red needles, m.p. 201 °C; 91% yield) was formed upon reaction of 1,3-dimethoxyphenalenium tetrafluoroborate[4] with dimethylamine in dichloromethane.[7] For X-ray structure analysis the tetrafluoroborate was converted by bromide ion-exchange (QAE-Sephadex A-25, water) into **1** (X = Br), which crystallized from dichloromethane/ethyl acetate as the

hemihydrate (red prisms, m.p. 230–231 °C (decomp.); 82% yield).[7]

For the synthesis of **2**, 9-dimethylaminophenalenone was allowed to react with trimethyloxonium tetrafluoroborate (dichloromethane, 20 °C) to give 1-dimethylamino-9-methoxyphenalenium tetrafluoroborate (m.p. 192–194 °C (decomp.); 79% yield),[7] from which **2** (X = BF_4) was obtained (m.p. 172 °C; 63% yield) by reaction with dimethylamine.[7] The halogenides **2** (X = Cl, Br, I) can be obtained by ion-exchange; in contrast to the chloride and bromide, which are very hygroscopic, **2** (X = I) can be obtained pure (m.p. 214 °C, from dichloromethane/ethyl acetate).[7] 1,4,7-Tris(dimethylamino)phenalenium salts **3** were synthesized from 4,7-dihydroxyphenalenone,[6] which was methylated with diazomethane (ether/dichloromethane, − 10 °C; 46% yield) to give 4,7-dimethoxyphenalenone (m.p. 180 °C).[7] Upon treatment with trimethyloxonium tetrafluoroborate (dichloromethane, 20 °C) 1,4,7-trimethoxyphenalenium tetrafluoroborate was formed (m.p. 300–310 °C (decomp.); 83%),[7] whose reaction with dimethylamine in acetonitrile gave **3** (X = BF_4) (m.p. 300–303 °C (decomp.); 93% yield).[7] Subsequent anion-exchange reactions furnished **3** (X = I), which crystallized from dichloromethane/diethyl ether with dichloromethane in the ratio 1:1 (dark red crystals, m.p. 289 °C (decomp.)), and **3** (X = Br) (dark red prisms, m.p. 272 °C, from dichloromethane/ethyl acetate).[7]

According to the structure analysis of **1** (X = Br),[8] the bond lengths (Fig. 1 A) for the N(1′)-C(1)–C(3)–N(3′) region are consistent with a symmetrical polymethine structure: the C(1)–C(2) and C(2)–C(3) bonds show the characteristic bond equalization of such a mesomeric system; the C(1)–N(1′) and C(3)–N(3′) distances are consistent with a partial double bond character of these bonds. This polymethine structural unit is coupled via two single bonds with the second substructure of the π-electron system, whose bond lengths correspond to a naphthalene unit. Figure 1 B shows that this naphthalene subunit is almost planar, whereas the polymethine moiety is twisted from this plane so that it can assume an essentially planar arrangement with inclusion of the dimethylamino groups.

In the case of **2** (X = I), an X-ray structure analysis revealed a polymethine substructure, two nearly isolated double bonds and a benzenoid six-membered ring.[9] Due to high vibration amplitudes in the region C(3a)–C(4)–C(5)–C(6)–C(6a) the exact determination of bond lengths and angles was limited. The structure analysis of a mixed crystal of **2** (X = Cl, Br)[10] (measured in a sealed capillary because of the hygroscopicity) led, however, to a confirmation of these results. Characteristic features of this structure are the polymethine moiety with mesomeric bond equalization in the region N(1′)–C(1)–C(9a)–C(9)–N(9′), the high double bond character with bond lengths of 133.9(4) and 134.3(4) pm for C(2)–C(3) and C(7)–C(8), respectively, and the benzenoid character of the remaining six-membered ring (Fig. 2 A). The side view (viewed along the central C(9a) ··· C(5) axis) shows that the polymethine system of **2**, in contrast to that of **1**, is not completely planar due to the *peri*-arrangement, but that the steric interaction between the dimethylamino groups leads to a stronger torsion about the C–N bonds (torsion angle C(9a)–C(1)–N(1′)–C(1″B) 19.5° and C(9a)–C(9)–N(9′)–C(9″B) 25° (Fig. 2 B).

Whereas X-ray structure analyses confirmed the "building block model" of polymethine-like, olefinic and aromatic structural units in the case of **1** and **2**, the results of the structure analyses of the salts of **3** are consistent with expectation that no such substructures are definable in these cases. In the case of **3** (X = I) an approximate C_3 symmetry of the

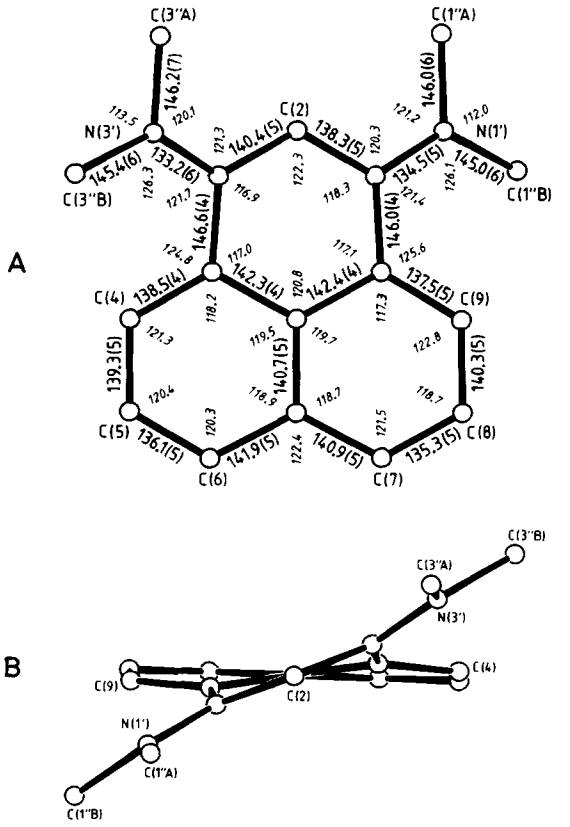

Fig. 1. Structure of the phenalenium ion of **1** (X = Br) viewed perpendicular to the "naphthalene" plane (A) with bond lengths [pm] and angles [°] (in brackets standard deviations in units of the last decimal place) and side view along the C(2) ··· C(6A) axis (B) [8].

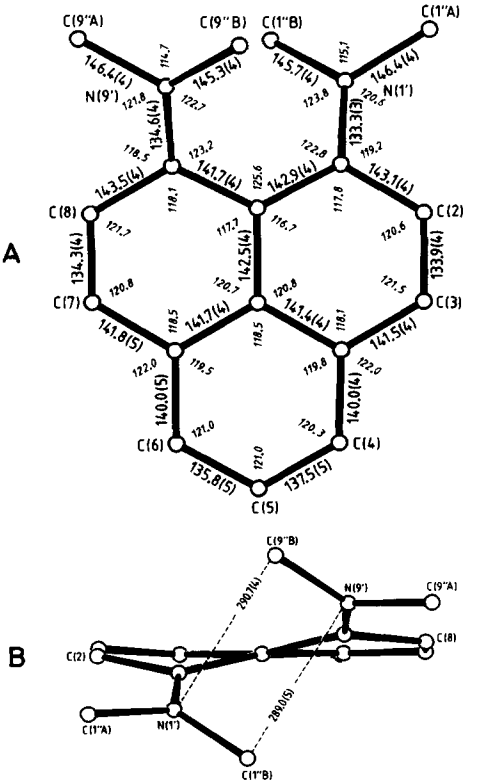

Fig. 2. Structure of the phenalenium ion of **2** (X = Cl, Br) viewed perpendicular to the phenalenium plane (A) with bond lengths [pm] and angles [°] (in brackets standard deviations in units of the last decimal given) and side view along the C(9a) ··· C(5) axis (B) [10].

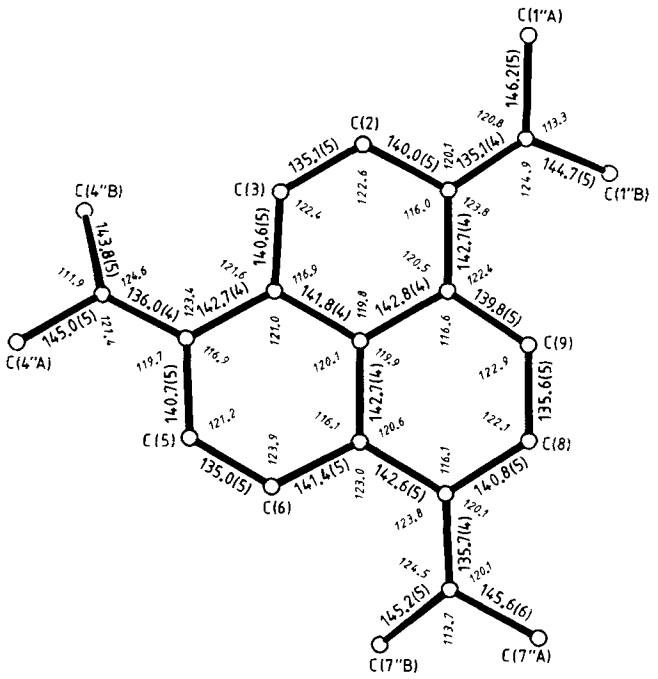

Fig. 3. Structure of the phenalenium ion of $3 \cdot CH_2Cl_2$ (X = I) viewed perpendicular to the phenalenium plane with bond lengths [pm] and angles [°] (in brackets, standard deviations in units of the last decimal given) [11].

cation was found for the phenalenium moiety, and individual polymethine units could not be identified. Remarkable, however, is the high bond order, which can be deduced from the short C(2)–C(3), C(5)–C(6), and C(8)–C(9) distances (Fig. 3).[11]

3 (X = Br), which has the same structure as the iodide with respect to the phenalenium ion, exhibits a particularly interesting lattice packing: the cations of **3** are stacked with an ecliptical arrangement of the phenalene skeletal frameworks along the *c*-axis, whereby the dimethylamino groups of neighboring cations are in exactly staggered positions. The interplanar distances alternate between 376 and 396 pm; the shorter distance is apparently linked to the hexagonal network of bromide ions, which surround the pair of phenalenium ions with the shorter interplanar distance (Fig. 4).[12]

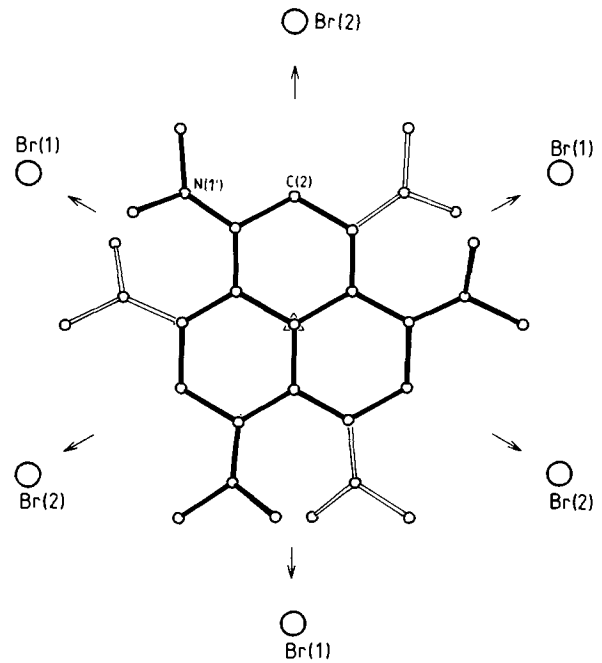

Fig. 4. Structure of **3** (X = Br): view of a pair of phenalenium ions along the stacking axis (*c*-axis) [12].

Enediyne Compounds Equipped with Acid-, Base- and Photo-Sensitive Triggering Devices. Chemical Simulation of the Dynemicin A Reaction Cascade**

By *K. C. Nicolaou,* W.-M. Dai, S. V. Wendeborn, A. L. Smith, Y. Torisawa, P. Maligres,* and *C.-K. Hwang*

The recent isolation of the novel anticancer agent dynemicin A (**1**)[1] and the proposed cascade of reactions

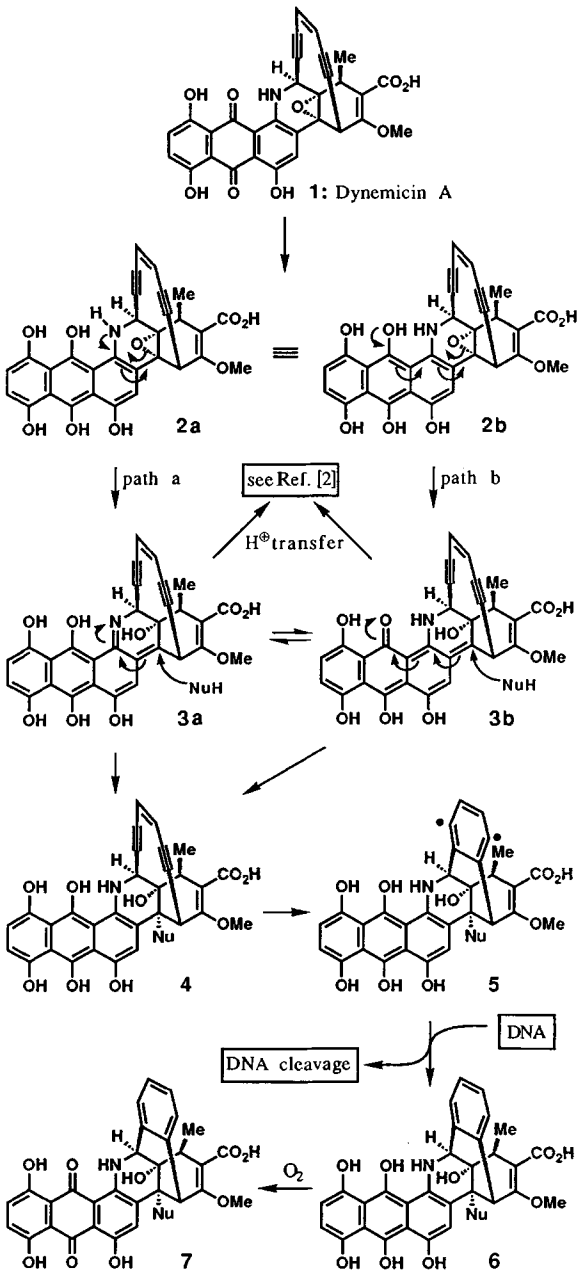
(Scheme 1)[2] for its mode of action generated considerable excitement in the chemical and biological communities.[3] In this communication we report (a) the design, synthesis and chemistry of a number of model systems equipped with acid-, base-, and photo-sensitive triggering devices; (b) the simulation of the dynemicin A cascade; and (c) the observation of a number of labile intermediates along this reaction cascade.

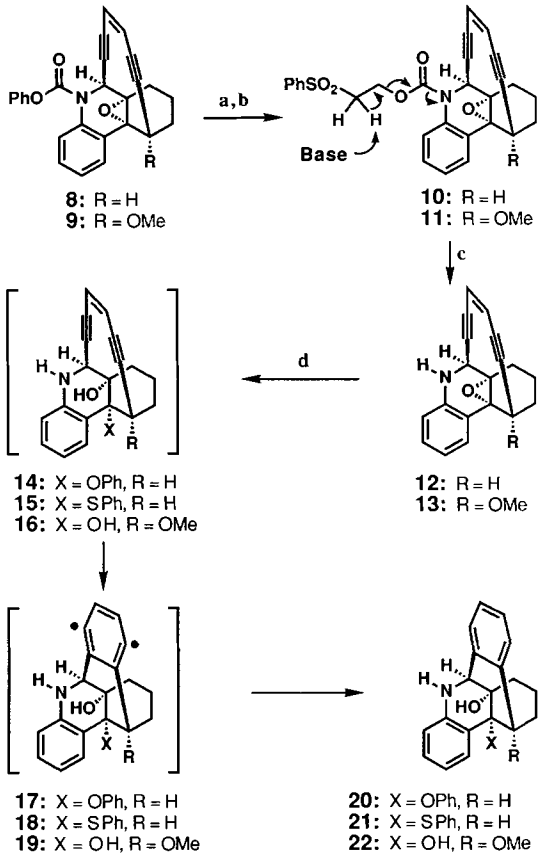
The hypothesized mechanism of action of dynemicin A (**1**) postulates intercalation, bioreduction, epoxide opening, trapping of the generated intermediates with nucleophiles, and electroaromatization to form benzenoid diradicals[4] which damage DNA. Scheme 1 outlines these reactions and



Scheme 1. Proposed mechanism of action of dynemicin A (**1**).

shows the postulated intermediates.[1, 2] Questions, however, remain as to the relevance of the two scenarios, originating from **2a** or **2b** (tautomeric structures), the existence and lifetime of the various intermediates, the timing of bioreduction in relation to intercalation, and the nature of the nucleophiles involved. Of particular interest was the generation of compounds with free amino or hydroxy groups on the aromatic moiety capable of donating their electrons into the epoxide side forming quinone or iminoquinone methide species corresponding to structures **3b** or **3a**, respectively (Scheme 1).

In order to allow for the generation of the parent enediyne system **12**, compound **10** was designed and synthesized from the previously reported **8**[3a, b] as shown in Scheme 2. Thus,



Scheme 2. a) 3.0 equiv. of $CsCO_3$, 0.5 equiv. of [18]crown-6, 10 equiv. of $PhS(CH_2)_2OH$, CH_3CN, 25°C, 12 h; b) 2.5 equiv. of MCPBA, CH_2Cl_2, 0–25°C, 85% overall (**10**), 82% overall (**11**); c) [for **10** → **12**] $CsCO_3$ (excess), 0.5 equiv. of [18]crown-6, dioxane, 25°C, 1 h, high yield based on TLC; [for **11** → **13**] 1.2 equiv. of diazabicycloundecene (DBU), C_6H_6, 5°C, 0.5 h, 97%; d) [for **12** → **20**] 2.0 equiv. of PhOH, 1,4-cyclohexadiene, 25°C, 2 h, 25%; [for **12** → **21**] 2.0 equiv. of PhSH, 1,4-cyclohexadiene, 25°C, 2 h, 33%; [for **13** → **22**] 0.5 equiv. of TsOH · H_2O, dioxane/H_2O/1,4-cyclohexadiene (4:1:1), 60°C, 2 h, 20%.

reaction of **8** with $PhSCH_2CH_2OH$ followed by oxidation with *meta*-chlorobenzoic acid (MCPBA) led to the formation of **10**[5] in 85% overall yield. Indeed, compound **10** served as an excellent precursor to **12**, although the latter proved to be too labile for isolation. The reactivity of **12** and its ability to cleave DNA (*vide infra* and Ref. [3a]) add credibility to the notion of the involvement of pathway **2a** → **3a** → **4** → **5** (Scheme 1) and the intermediacy of an iminoquinone methide as a significantly contributing species in the mode of action of dynemicin A **1**—at least as a partial scenario. Freshly generated **12** was successfully trapped in dioxane/1,4-cyclohexadiene solutions with phenol and thiophenol leading to compounds **20** (25%) and **21**[5] (33%) respectively. Interestingly, the methoxy compound **13**, pre-

pared from **9**[3, a, b] via a similar sequence (**9** → **11** → **13**, Scheme 2) in 97% yield, proved to be quite stable under basic or neutral conditions.[6] Treatment of **13**, however, with $TsOH \cdot H_2O$ in the presence of 1,4-cyclohexadiene resulted in triggering of the cycloaromatization furnishing compound **22** (20% yield). These transformations are assumed to proceed via intermediates **14**–**19**. An X-ray crystallographic analysis of **13**[7] confirmed its molecular structure (Fig. 1) and revealed a number of interesting parameters, e.g. a *cd* distance of 3.63 Å (calcd. 3.61 Å, MMX) and the nonlinearity of the acetylenic groupings.

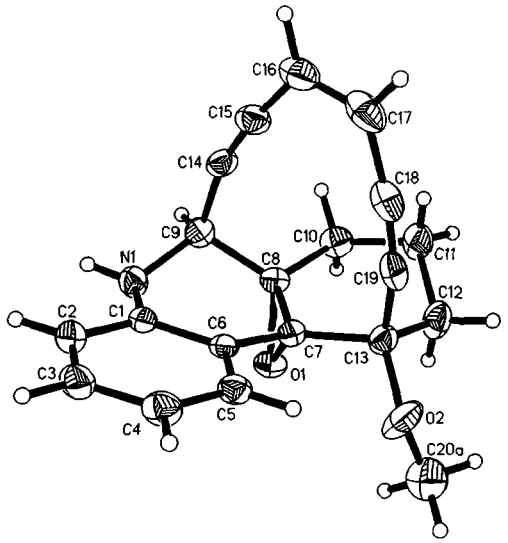


Fig. 1. ORTEP drawing of dynemicin A model compound **13**. *cd* distance [*r*(C14–C19)]: 3.63 Å. Angles at acetylenic carbons: C14, 163.2°; C15, 173.0°; C18, 169.3°; C19, 160.5°.

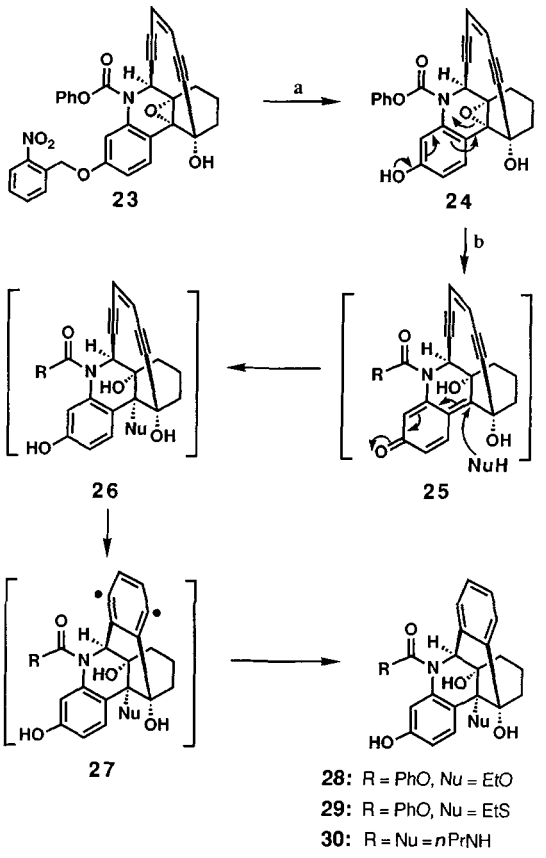
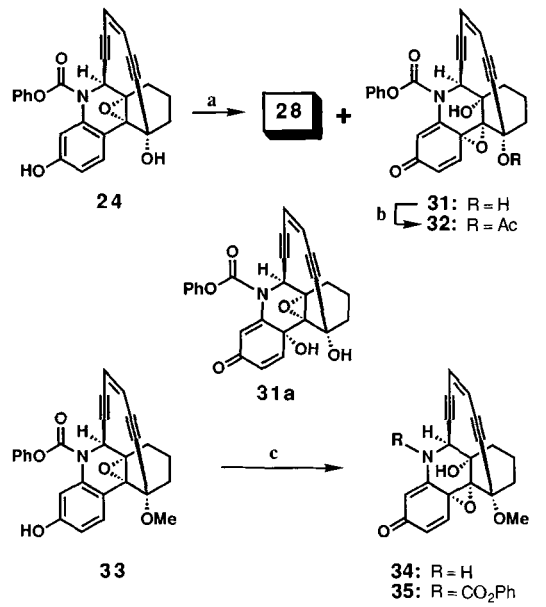


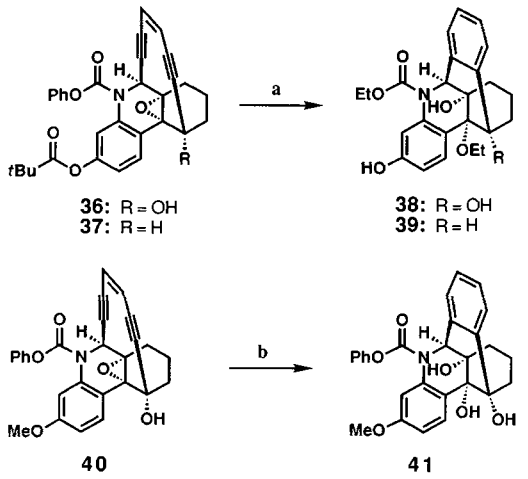
Scheme 3. a) *hv*, THF-H_2O (10:1), argon, 0°C, 40 min; b) EtOH-THF-phosphate buffer (pH 8.0) (1:1:1), argon, 25°C, 1.5 h, **28**, 31% from **23**; or EtSH-THF-phosphate buffer (pH 8.0) (1:1:1), argon, 25°C, 1.5 h, **29**, 34% from **23**; or $nPrNH_2$-THF-phosphate buffer (pH 8.0) (1:1:1), argon, 25°C, 1.5 h, **30**, 46% from **23**.

Enediyne model system **23** (Scheme 3) was designed for its potential to generate species **24** under photolytic, neutral conditions.[8] Following the strategy developed earlier for the synthesis of **8**,[3 a, b] compound **23**[5] was constructed in good overall yield. Irradiation of **23** in aqueous THF (Hanover mercury lamp, pyrex filter) at ice-cooling temperature resulted in clean conversion to **24**[5] as observed by TLC and ^{1}H-NMR spectroscopy ([D_8]THF: D_2O = 10:1, 300 MHz).[5] Attempted isolation of **24** led to decomposition, whereas treatment of crude **24** in a pH 8.0 buffer/THF solution containing the nucleophiles EtOH, EtSH, or $nPrNH_2$ under argon furnished aromatized products **28** (31%), **29** (34%), or **30** (46%) respectively, presumably via intermediates **25**–**27** (Scheme 3). These observations implicate quinone methide intermediate **25**[9] in this cascade formed from **24** under the basic conditions as shown in Scheme 3. Quinone methide intermediates have been implicated in the mode of action of anthracycline antibiotics[10] and dynemicin A **1** (Scheme 1).[2] Noteworthy was the isolation of the novel enediyne compound **31**[11] (Scheme 4) in ~ 10% yield from the reaction of **24** with EtOH (along with **28**) in air as a sensitive but stable molecule under neutral conditions. Remarkably, treatment of the isolable phenol **33**[5] (Scheme 4) under similar conditions (THF/pH 9.0 buffer, air) resulted in the isolation of **34** (35%) and **35** (25%) as stable molecules. Compound **31** represents a novel molecular architecture with DNA cleaving properties (*vide infra*).

The pivaloate esters **36** and **37** (Scheme 5) were also synthesized according to the previously discussed general strate-



Scheme 4. a) EtOH-THF-phosphate buffer (pH 8.0) (1:1:1), air, 25°C, 1.5 h, **28**, 33% plus **31**, 9%; b) Ac_2O-pyridine, dimethylaminopyridine (DMAP) (cat.), 25°C, 1 h, 84%; c) THF-pH 9.0 buffer [boric acid/potassium chloride/sodium hydroxide] (1:1), air, 25°C, 48 h, **34**, 35% plus **35**, 25%.



Scheme 5. a) 4 equiv. of LiOH, EtOH-H_2O (3:1), 25 °C, 4–6 h, **38**, 56% from **36**, or **39**, 42% form **37**; b) 1 equiv. of TsOH · H_2O, C_6H_6-1,4-cyclohexadiene (1:1), 25 °C, 1.5 h, 32%.

gy[3a,b] for their potential to liberate phenolic species of type **24** (Scheme 3), thus presenting yet another triggering mechanism to initiate the dynemicin A cascade. Indeed, upon exposure to LiOH in aqueous EtOH at ambient temperatures, compounds **36** and **37** were smoothly converted into products **38** (56%) and **39** (42%) respectively, presumably via a sequence involving intermediates similar to **24**–**27** and with concomitant carbamate exchange (EtO for PhO). The methoxy compound **40** was also synthesized and exhibited reasonable stability under neutral and basic conditions. As expected, however, this compound cyclized rapidly under acidic conditions. For example, upon treatment with TsOH · H_2O in the presence of 1,4-cyclohexadiene, **40** afforded the aromatized product **41** (32%). Presumably, these reactions proceed via intermediates similar to those shown in Scheme 2.

Compounds **12**, **24**, and **31** were found to cause significant DNA cleavage when incubated with supercoiled ΦX174 DNA (Fig. 2, lanes 2, 4 and 5). Noteworthy in these experiments is the observation of double strand cuts as well as single strand cuts, as is the case with dynemicin A (**1**).[2] As expected from their chemical profiles, the methoxy derivatives **13**, **33**, **34** and **35** exhibited diminished activity against DNA. The potency of these compounds is expected to increase by tethering them to suitable DNA-binding molecules.

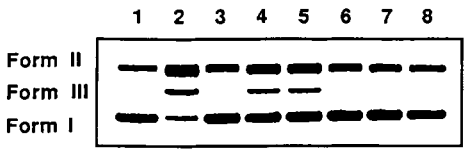


Fig. 2. Supercoiled DNA interaction with selected model compounds. ΦX174 DNA was incubated for 24 h at 37 °C with compounds **12**, **13**, **24**, **31**, **33**, **34** and **35** in buffer (50 mM Tris-HCl, pH 8.0) and analyzed by electrophoresis (1% agarose gel, ethidium bromide stain). Lane 1: DNA control; Lane 2: **12** (5 mM); Lane 3: **13** (5 mM); Lane 4: **24** (5 mM); Lane 5: **31** (5 mM); Lane 6: **33** (5 mM); Lane 7: **34** (5 mM); Lane 8: **35** (5 mM).

The chemistry described here supports the viability of both paths a and b of Scheme 1 as triggering mechanisms for the dynemicin A cascade by showing that a lone pair of electrons on a heteroatom (N or O) strategically positioned on the aromatic ring in relation to the epoxide moiety serves to initiate the cycloaromatization reaction. Such reactive species may be generated within the cell by enzymatic reactions or, as shown above, be released from suitable precursors under mild conditions in the laboratory. In addition, the described observations are interesting in that they allow for the scenario of bioreduction prior to intercalation as well as for the possibility of DNA interacting nucleophilically against quinone methide species such as **3a** or **3b** (Scheme 1).[2b] Thus the proposition that dynemicin A (**1**) may be interacting with DNA by a dual mechanism (nucleophilic and radical) appears attractive, not only because of the observed preference for cleavage at adenine and guanine,[2a] but also in view of the chemistry of **24**.

The foundation is now in place for the development of potent and sequence-specific DNA cleaving molecules by attaching enediyne systems such as the ones described herein to DNA binding moieties, allowing them to bind to their target regions, and then triggering them to initiate cleavage. Analogous applications in the area of drug design, particularly in cancer chemotherapy, may be envisioned.

[6] The striking stability of compound **13** as compared to that of **12** may be attributed to the destabilization of the incipient benzylic carbenium ion by the methoxy group (electron withdrawal).

[7] We thank Dr. *Raj Chadha*, University of California, San Diego, for the X-ray crystallographic analysis. Further details of the crystal structure investigation are available on request from the Director of the Cambridge Crystallographic Data Centre, University Chemical Laboratory. Lensfield Road, GB-Cambridge CB21EW, on quoting the full journal citation.

[8] A hydroxy group at the the other *meta* position from the nitrogen atom on the aromatic ring is expected to show similar triggering capability.

[11] Structure **31** was favored over **31a** (Scheme 4) on the basis of ^1H and ^{13}C NMR data of its monoacetate **32**[5]. Particularly revealing were chemical shift changes and NOE data which are in accord with structures **31** and **32**. Attempts to confirm this structure by X-ray crystallographic analysis are in progess.

Self-Assembling [2]Pseudorotaxanes**

By *Pier Lucio Anelli, Peter R. Ashton, Neil Spencer, Alexandra M. Z. Slawin, J. Fraser Stoddart,** and *David J. Williams*

The ability of the tetracationic cyclophane **1**[1] to form inclusion complexes[2] with π-donor aromatic substrates, e.g. 1,2- and 1,4-dimethoxybenzene, as a result of stabilizing dispersive forces that include (i) π/π-stacking and charge transfer interactions between the π-electron-rich hydroquinone rings and the π-electron-deficient bipyridinium units and (ii) electrostatic "T-type" edge-to-face interactions involving the hydroquinone rings and the *para*-phenylene units in the cyclophane has led us to examine the complexing behavior (Scheme 1) of some polytopic substrates such as **2**–**5** with **1**·4PF$_6$ (Fig. 1). Here, with reference to some fascinating X-ray crystallographic data, we describe the remarkable mutual ordering that occurs between the component molecular species in **1**·**2**·4PF$_6$ and **1**·**3**·4PF$_6$, compare their solid-state structures with that of the [2]catenane **1**·**6**·4PF$_6$ (Fig. 2) formed[3] between **1** and bisparaphenylene-34-crown-10 **6**,[4] and anticipate how the thermodynamically-driven ordered threading of substrates such as **2**–**5** through the centers of tetracations like **1** could be exploited in the construction of quite intricate molecular assemblies.

[**] This work was supported by the Agricultural and Food, and Science and Engineering Research Councils in the United Kingdom and by Consiglio Nazionale delle Ricerche in Italy.

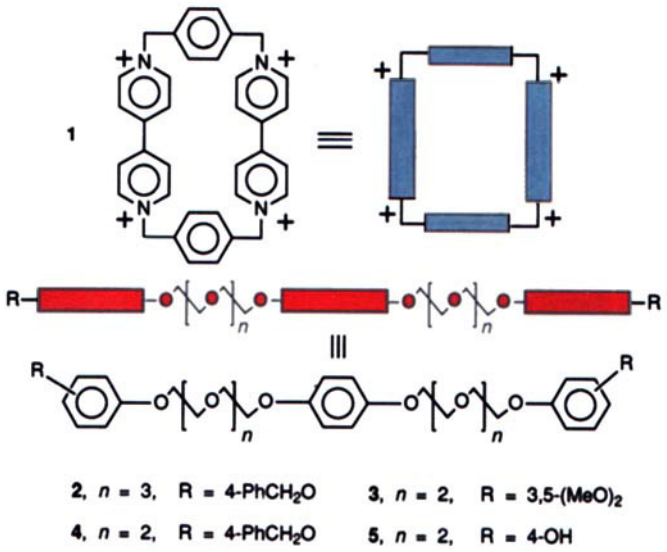

Fig. 1. The molecular components. The 'bead' is blue and the 'threads' are red.

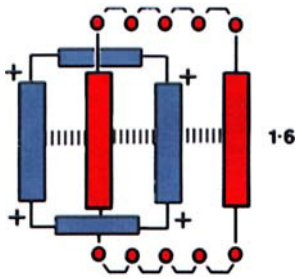

Fig. 2. The [2]catenane. The tetracationic cyclophane subunit **1** is blue and the bisparaphenylene-34-crown-10 **6** subunit is red.

When equimolar amounts of $\mathbf{1}\cdot 4PF_6$ were added, in turn (Scheme 1), to colorless solutions of **2**–**5** in MeCN, the latter immediately assumed a pronounced red color characteristic[2] of inclusion complex formation. In the cases of **2**, **3**, and **5**, vapor diffusion of $i Pr_2O$ into those solutions yielded gem quality crystals suitable for X-ray crystallography. Although the complex $\mathbf{1}\cdot\mathbf{4}\cdot 4PF_6$ did not afford single crystals that were good enough for X-ray crystal structure analysis, crystals of $\mathbf{1}\cdot\mathbf{5}\cdot 4PF_6\cdot 4MeCN$ were obtained of sufficient quality for X-ray crystallography.[5]

The X-ray structural analyses[5, 6] of $\mathbf{1}\cdot\mathbf{2}\cdot 4PF_6\cdot 2MeCN$ (Fig. 3) and $\mathbf{1}\cdot\mathbf{3}\cdot 4PF_6\cdot 2MeCN$ (Fig. 4) show that, in both cases, the polyether 'thread' is not only inserted through the center of the tetracationic 'bead' such that the middle hydroquinone ring is encircled, but its polyether

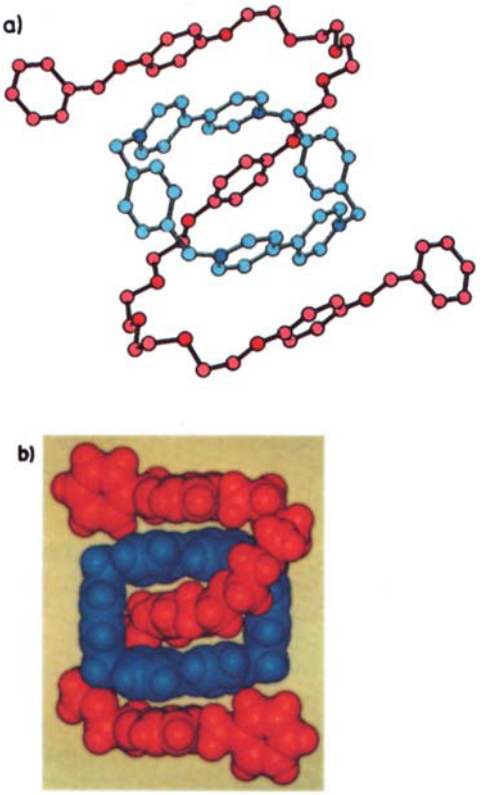

Fig. 3. a) Structure of $\mathbf{1}\cdot\mathbf{2}$ in the crystal. Crystal data for $C_{84}H_{90}N_4O_{12}\cdot P_4F_{24}\cdot 2MeCN$: triclinic, $a = 13.257(2)$, $b = 14.388(2)$, $c = 14.450(3)$ Å, $\alpha = 62.99(1)$, $\beta = 79.12(1)$, $\gamma = 69.03(1)°$, $V = 2292$ Å^3, space group $P\bar{1}$, $Z = 1$ (the molecule is disposed about a center of symmetry), $\rho = 1.46$ g cm^{-3}, $\mu(Cu_{K\alpha}) = 17$ cm^{-1}, 5005 independent observed reflections with $[|F_o| > 3\sigma(|F_o|), 2\theta \leq 116°]$, $R = 0.091$, $R_w = 0.110$. b) Space-filling representation. (The 'bead' is blue and the 'thread' is red.)

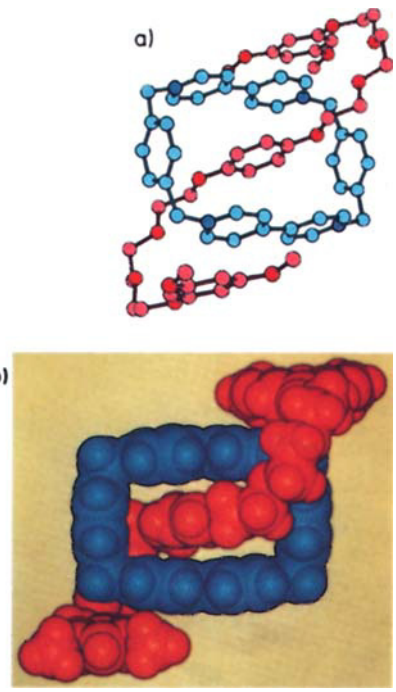

Fig. 4. a) Structure of $\mathbf{1}\cdot\mathbf{3}$ in the crystal. Crystal data for $C_{70}H_{78}N_4O_{12}\cdot P_4F_{24}\cdot 2MeCN\cdot X$ where X corresponds to unidentified solvent fragments of scattering approximately equal to C atoms: triclinic: $a = 11.863(3)$, $b = 13.834(2)$, $c = 13.857(3)$ Å, $\alpha = 77.79(1)$, $\beta = 79.75(2)$, $\gamma = 76.85(2)°$, $V = 2144$ Å^3, space group $P\bar{1}$, $Z = 1$ (the molecule is disposed about a center of symmetry), $\rho = 1.43$ g cm^{-3}, $\mu(Cu_{K\alpha}) = 18$ cm^{-1}, 3352 independent observed reflections with $[|F_o| > 3\sigma(|F_o|), 2\theta \leq 110°]$, $R = 0.113$, $R_w = 0.109$. b) Space-filling representation. (The 'bead' is blue and the 'thread' is red.)

chains also curl back on themselves around the 'bead' enabling the next aromatic donors in both directions to stack against the sides of the π-accepting bipyridinium units of **1**. The gross structure of the 'bead' **1** in both complexes resembles that of **1**[1] and its 1:1 complexes with 1,2- and 1,4-dimethoxybenzene.[2] The degrees of bowing of the sides of the 'beads' in **1·2** and **1·3** differ slightly: a) the $C-CH_2$ bonds, emanating from the *para*-phenylene units, subtend angles of 9° and 14°, respectively, and b) the $N^{\oplus}-CH_2$ bonds, associated with the bipyridinium moieties subtend angles of 28° and 21° respectively. Although there are marked differences in the twist angles between the pyridinium rings (19° for **1·2** and 4° for **1·3**), the separations between the bipyridinium units and the entrapped hydroquinone rings are ca. 3.5 Å in both cases. The angles of tilt[7] of the hydroquinone units within the 'beads' are 48° and 45° in **1·2** and **1·3**, respectively. The geometries adopted, which emphasize the symbiotic relationships between 'beads' and 'threads' capitalize upon stabilizing dispersive forces and associated charge transfer interactions that are enhanced further by electrostatic 'T-type' edge-to-face interactions.[8]

A striking feature of both polyether 'threads' in **1·2** and **1·3** is the presence of a common conformation for the first ten atoms emanating from the central hydroquinone rings. The sequence ($ag^-aag^+aag^-$) of the torsional angles is also present in one of the two polyether chains in the [2]catenane **1·6**. It is noteworthy that the inner surfaces of the polyether loops that pass over the junctions between the bipyridinium units and the *para*-phenylene rings of the 'beads' are lined with oxygen atoms in both cases. Such an arrangement satisfies the mutual electrostatic requirements of these portions of the 'beads' and 'threads'. The polyether chains in **1·2** linking the hydroquinone rings within the 'thread' are of an optimum length and geometry[9] enabling a π/π stacking interaction between these rings and their sandwiched bipyridinium units (interplanar separations, ca. 3.5 Å). This supramolecular arrangement is virtually identical with the molecular geometry present[3] within the [2]catenane **1·6**.

Whereas in **1·2** there is no formation of continuous stacks[10] within the crystals, in **1·3**, however, an interesting stacking arrangement (Fig. 5) is produced. The reduced length of the polyether chain in **1·3** compared to **1·2**, coupled with the retention of the chain conformation, does not permit the terminal 3,5-dimethoxyphenyl groups to approach (closest centroid-centroid distance, 4.4 Å) the center of the outer face of the bipyridinium units such that an optimum stacking interaction may occur. However, this requirement is satisfied by the approach of a lattice-translated and laterally-displaced complex. The resulting centroid-centroid separations between one of the translated bipyridinium rings and the virtually parallel (4° interplanar angle) 3,5-dimethoxyphenyl group is 3.6 Å.

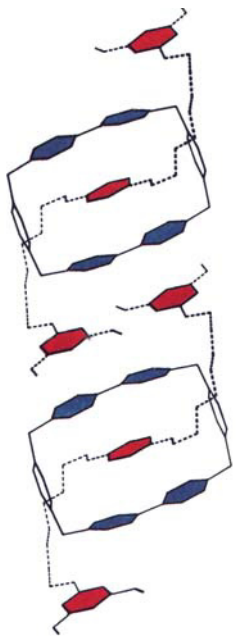

Fig. 5. Part of the continuous sequence of **1·3** in the crystal. The 'threads' are red and the 'beads' are blue.

In CD_3CN solutions, the ^{1}H-NMR spectra of **1·2**·4 PF_6 and **1·3**·4 PF_6 reveal considerable line broadening as well as chemical shift changes of up to 0.5 ppm commensurate with the formation of strong complexes in which slow intra-complex—and possibly also inter-complex—equilibria are clearly operative. Positive-ion FABMS[11] of these two 1:1 complexes afforded[12] peaks corresponding to the loss of *one* and *two* $PF_6^{\ominus}$ counterions respectively at $m/z = 1781$ and 1636 for **1·2**·4PF_6, and $m/z = 1601$ and 1456 for **1·3**·4PF_6.

The self-assembly[13] that functions between the tetracationic 'bead' **1** and the polyether 'threads' can now be exploited to template the synthesis of highly ordered rotaxanes and other prototypes of molecular devices.[14]

Experimental

2: Dialkylation (*t*BuOK/*t*BuOH/THF/reflux/65 h) of 1,4-dihydroxybenzene with 2-[2-[2-(benzyloxy)ethoxy]ethoxy]ethoxy]ethyl-4-methylbenzene sulfonate [15] gave (SiO_2:Et_2O) the dibenzyl ether (73%, oil). Hydrogenolysis (H_2/Pd on C/MeOH/CH_2Cl_2) afforded the diol (94%, oil) which was converted (TsCl/Et_3N/CH_2Cl_2/RT/15 h) into (SiO_2:$CHCl_3$/EtOAc) the ditosylate (78%, oil). Reaction (*t*BuOK/THF/reflux/15 h) with 4-(benzyloxy)phenol (2 mol. equiv.) gave **2** [52%, m.p. 91–93°C (Me_2CO); EI-MS: $m/z = 826$ ($M^{\oplus}$); ^{1}H NMR (CD_3CN): $\delta = 3.54-3.60$ (m, 16H), 3.69–3.72 (m, 8H), 3.97–4.01 (m, 8H), 5.00 (s, 4H), 6.80 (s, 4H), 6.80–6.90 (m, 8H), 7.28–7.43 (m, 10H)].

3 and **4**: Dialkylation (*t*BuOK/*t*BuOH/reflux/65 h) of 1,4-dihydroxybenzene with 2-[2-(2-chloroethoxy)ethoxy]ethanol afforded (SiO_2:EtOAc/MeOH) a diol (78%, m.p. 48–51°C) which was converted (TsCl/Et_3N/CH_2Cl_2/RT/15 h) into (SiO_2:$CHCl_3$/EtOAc) the corresponding ditosylate (94%, oil). Reaction (*t*BuOK/THF/reflux/20 h) with: (a) 3,5-dimethoxyphenol (2 mol. equiv.) yielded (SiO_2:light petroleum/EtoAc) **3** [74%, m.p. 64–66°C (MeOH/Et_2O); EI-MS: $m/z = 646$ ($M^{\oplus}$); ^{1}H NMR (CD_3CN): $\delta = 3.62$ (s, 8H), 3.72 (s, 12H), 3.72–3.75 (m, 8H), 3.99–4.05 (m, 8H), 6.06–6.09 (m, 6H), 6.81 (s, 4H)], (b) 4-benzyloxyphenol (2 mol. equiv.) yielded **4** [61%, m.p. 104–107°C (Me_2CO); EI-MS: m/z 738 ($M^{\oplus}$); ^{1}H NMR ($CDCl_3$): $\delta = 3.65-3.90$ (m, 16H), 3.96–4.15 (m, 8H), 5.00 (s, 4H), 6.80 (s, 4H), 6.78–6.87 (m, 8H), 7.28–7.44 (m, 10H)].

5: Hydrogenolysis (H_2/Pd on C/MeOH/CH_2Cl_2) of **4** afforded **5** [97%, m.p. 102–104°C (EtOH); EI-MS: m/z 558 ($M^{\oplus}$); ^{1}H NMR (CD_3CN): $\delta = 3.62$ (s, 8H), 3.70–3.74 (m, 8H), 3.97–4.02 (m, 8H), 6.52 (brs, 2H), 6.68–6.76 (m, 8H), 6.82 (s, 4H)].

[5] Crystals of **1·5**·4PF_6·4MeCN had $C_{82}H_{52}F_{24}N_{12}O_{10}P_4$: triclinic, $a = 13.648(4)$, $b = 13.881(4)$, $c = 14.670(3)$ Å, $\alpha = 117.86(2)$, $\beta = 92.89(2)$, $\gamma = 103.11(2)°$, $V = 2353$ Å^3, space group $P\bar{1}$, $Z = 1$ (the molecule is disposed about a center of symmetry), $\rho = 1.40$ g cm^{-3}, $\mu(Cu_{K\alpha}) =$

17 cm^{-1}, 4161 independent observed reflections with [$|F_o| > 3\sigma(|F_o|)$, $2\theta \leq 110°$], $R = 0.078$, $R_w = 0.085$. The 'thread' in **1·5** is centrosymmetrically positioned within the 'bead' with the *para*-hydroxyphenyl groups layered between adjacent lattice-translated complexes producing a stacking mode analogous to that observed in **1·3**.

[6] Nicolet R3m diffractometer, ω-scans, $Cu_{K\alpha}$ radiation (graphite monochromator). The structures were solved by direct methods and refined anisotropically. Further details of the crystal structure investigations can be obtained from the Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW (England). Any request should be accompanied by the full literature citation for this communication.

[7] The tilt angle is defined as the angle between the O···O vector within the hydroquinone rings and the N···N axis of the bipyridinium units.

[8] These edge-to-face interactions between the *para*-phenylene units in **1** and the hydroquinone rings in **2** and **3** have centroid-centroid separations of 5.1 and 5.2 Å, respectively, with corresponding interacting H···centroid distances of 2.9 and 2.8 Å. The C–H···centroid angles are 157 and 163°, respectively. For general discussions of these 'T-type' interactions, see R. O. Gould, A. M. Gray, P. Taylor, M. D. Walkinshaw, *J. Am. Chem. Soc. 107* (1985) 5921; S. K. Burley, G. A. Petsko, *Science (Washington, DC) 229* (1985) 23; *J. Am. Chem. Soc. 108* (1986) 7995; *Adv. Protein Chem. 39* (1988) 125; W. L. Jorgensen, D. L. Severance, *J. Am. Chem. Soc. 112* (1990) 4768; C. A. Hunter, J. K. M. Sanders, *ibid. 112* (1990) 5225.

[9] Within the hydroquinone units, there is present both *trans* geometries and coplanar dispositions for the associated oxymethylene functions. In common with the [2]catenane **1·6**, this coplanarity also extends to incorporate the next carbon atom in both directions. Similarly, the methoxy functions on the 3,5-dimethoxyphenyl group adopt characteristic coplanar conformations. See J. D. Mersh, J. K. M. Sanders, S. A. Matlin, *J. Chem. Soc. Chem. Commun. 1983*, 306 and references cited therein.

[10] There are, however, intermolecular 'T-type' edge-to-face interactions between adjacent benzyloxyphenoxy units in **1·2**, the terminal phenyl ring of one thread interacting in the crystallographic *b* direction with the hydroquinone ring of another and vice versa (centroid-centroid separation of 5.1 Å).

[11] FABMS were obtained using a Kratos MS80RF mass spectrometer and DS90 data system. Xenon was used to provide the primary beam of atoms and samples were mixed with a small amount of 3-nitrobenzyl alcohol matrix on a stainless steel probe. Spectra were recorded in the positive-ion mode at a scan speed of 30 s per decade.

[12] Similar fragmentation patterns were observed for **1·4·4PF$_6$** with m/z = 1693 [$(M - PF_6)^{\oplus}$] and 1548 [$(M - 2PF_6)^{\oplus}$] and **1·5·4PF$_6$** with m/z = 1513 [$(M - PF_6)^{\oplus}$] and 1368 [$(M - 2PF_6)^{\oplus}$]. However, with the exception of **1·3·4PF$_6$**, higher mass peaks were observed consistently for these 1:1 complexes at m/z = 2055 and 1910, which correspond to the loss of one and two $PF_6^{\ominus}$ counterions respectively from the dimeric species, $(\mathbf{1}\cdot 4PF_6)_2$. While the reason for this observation, when **2**, **4**, or **5** are initially threaded through **1**, is a subject for much speculation, the detection of cluster ions by FABMS is a well-established phenomenon. For a discussion of the behavior of cesium iodide cluster ions, see M. A. Baldwin, C. J. Proctor, I. J. Amster, F. W. McLafferty, *Int. J. Mass Spectrom. Ion Processes 54* (1983) 97.

[13] The strategy of self-assembly is not a new one. Some recent examples in chemical systems include the following: Catenanes and rotaxanes: C. O. Dietrich-Buchecker, J.-P. Sauvage, *Chem. Self-Assembling [3]Catenanes**

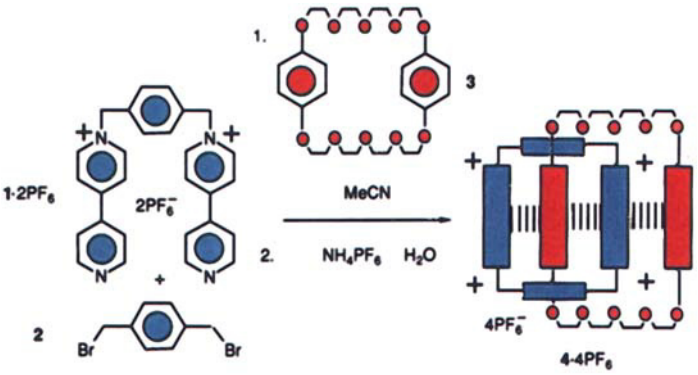
By *Peter R. Ashton, Christopher L. Brown, Ewan J. T. Chrystal, Timothy T. Goodnow, Angel E. Kaifer, Keith P. Parry, Alexandra M. Z. Slawin, Neil Spencer, J. Fraser Stoddart,** and *David J. Williams*

Recently, we reported the template-directed synthesis of the [2]catenane **4·4PF$_6$** in 70% yield as a result of reacting **1·2PF$_6$** with **2** in the presence of three molar equivalents of bisparaphenylene-34-crown-10 **3** (Scheme 1).[1, 2] The non-



Scheme 1. The template-directed synthesis of the [2]catenane **4** [1, 2]. The chemical cartoons are defined in this scheme: *para*-phenylene rings ≡ small blue rectangles, bipyridinium units ≡ large blue rectangles, hydroquinone rings ≡ red rectangles.

covalent bonding interactions, which facilitate the highly efficient ring closure of the tetracationic cyclophane around the neutral macrocyclic polyether ring, 'live on' in both the solid- and solution-state structures of **4**. Molecular modeling indicates that, simply by replacing the phenylene rings in the tetracationic cyclophane by biphenylene units, it might be possible to thread two crown ether rings simultaneously through the interior portion of this 'expanded' tetracationic cyclophane.[3] Furthermore, and rather surprisingly, despite the requirement for the close approach of like entities, this objective has been achieved.

Here, we present results describing: (i) how the [3]catenanes[4] **8·4PF$_6$** and **9·4PF$_6$** can be prepared and isolated (Scheme 2) from MeCN solutions containing **3** and 1,5-dinaphtho-38-crown-10 **7** respectively in several-fold molar excesses whilst reacting **5·2PF$_6$** with almost equimolar amounts of **6** at room temperature; (ii) the FABMS of **8·4PF$_6$** and **9·4PF$_6$**; (iii) the X-ray crystal structure of **8·4PF$_6$**; (iv) the

dynamic ^{1}H-NMR spectroscopic behavior of both **8**·4PF$_6$ and **9**·4PF$_6$; and (v) the electrochemical properties of **8**·4PF$_6$.

The [3]catenanes **8**·4PF$_6$ and **9**·4PF$_6$ were prepared[5] according to Scheme 2 in 20 and 31% yields, respectively. Positive-ion FABMS of **8**·4PF$_6$ and **9**·4PF$_6$ revealed[6] peaks respectively at m/z = 2183, 2038, and 1893, and m/z = 2381, 2236, and 2091 for loss, in each case, of one, two, and three $PF_6^{\ominus}$ counterions. Fragmentation peaks were also observed with the analogous counterion losses at m/z = 1647, 1502, and 1357, and m/z = 1745, 1600, and 1455 for the corresponding [2]catenanes, resulting from loss of a molecule of **3** and **7**, respectively from **8**·4PF$_6$ and **9**·4PF$_6$, respectively. In the former instance, the formation of a [3]catenane was confirmed by obtaining good quality single crystals which were subjected to X-ray crystallographic analysis.[7, 8] The solid-state structure (Fig. 1) of **8**·4PF$_6$ shows that the increase in the lengths of the neutral aromatic spacer groups (phenylene in the case of **1**, biphenylene in the case of **5**) between the two bipyridinium rings in the tetracationic cyclophane did not result in self-filling of the macrocycle. In accordance with the design strategy, the dimensions[9] of the macrocycle permit the simultaneous threading through its center of two molecules of **3** centrosymmetrically disposed with respect to each other. In addition to the sandwiching[10] of a bipyridinium group between approximately parallelly-aligned hydroquinone residues within each molecule of **3**, the inner pair of

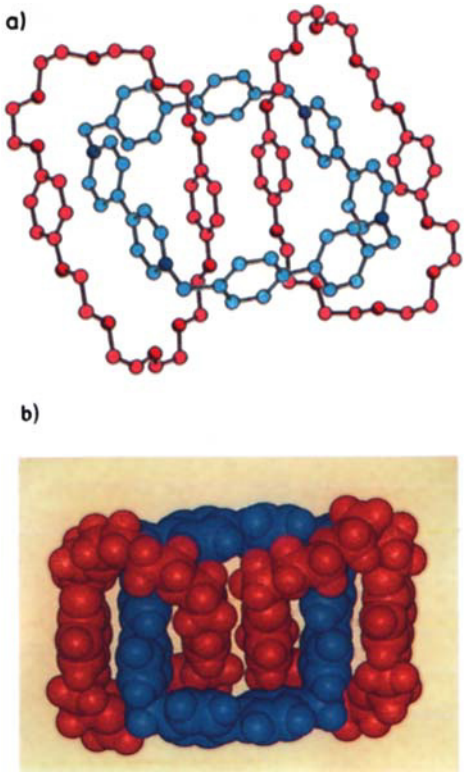

Fig. 1. a) Structure of **8** in the crystal with the donor and acceptor macrocycles shaded red and blue, respectively. O atoms are dark red and N atoms are dark blue. b) A computer-generated space-filling representation of the [3]catenane **8** based on the X-ray crystal structure data. The two polyether molecules are red and the tetracationic cyclophane unit is blue.

hydroquinone residues are positioned in a stacking arrangement (Fig. 2) with their mean planes only 3.63 Å apart. Each of these central hydroquinone units is displaced towards and inclined normal to one of the two phenylene rings within each biphenylene unit providing additional electrostatic edge-to-face stabilization.[10] An interesting feature of this ordering within the molecule is a loss of the alternating pattern

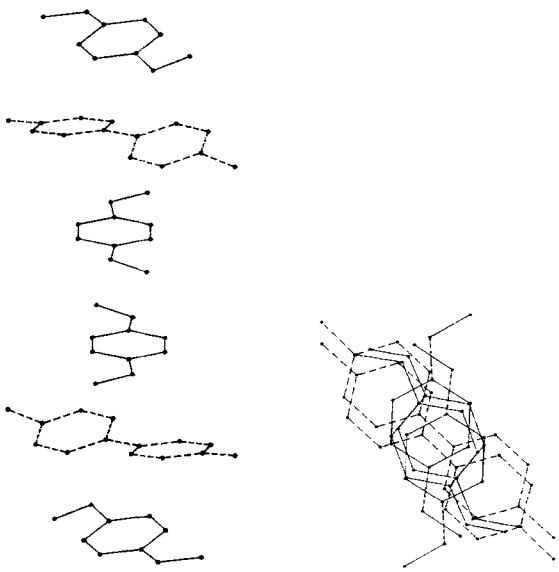

Fig. 2. The stacking arrangement of the 'inside' (green) and 'alongside' (red) donor hydroquinone rings in the solid-state structure of **8** with respect to the acceptor bipyridinium units (blue).

of π-donors (D) and π-acceptors (A) that was observed[1, 2] in the case of the [2]catenane **4**·4PF$_6$. More suprisingly, however, this DADDAD sequence extends (Fig. 3) beyond the molecule throughout the crystal producing a continuously stacked array.[11]

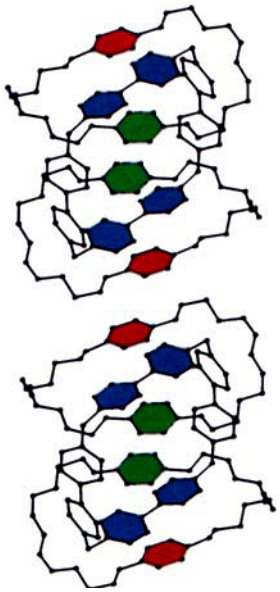

Fig. 3. Part of the continuous sequence of [3]catenanes **8** in the crystal. Donors are red or green and acceptors are blue.

As in the case of the [2]catenane **4**·4PF$_6$[1], both [3]catenanes **8**·4PF$_6$ and **9**·4PF$_6$ exhibit temperature dependencies in their ^{1}H-NMR spectra[12] recorded in CD_3COCD_3:CD_3CN (70:30) solutions. The averaged processes associated with the exchanges of the π-electron-rich *para*-phenylene and 1,5-naphtho units in **8** and **9** respectively, between 'inside' and 'alongside' environments with respect to the tetracationic cyclophane, have been probed by dynamic ^{1}H-NMR spectroscopy (Table 1). The $\Delta\Delta G_c^{\neq}$ of 2.6 kcal mol^{-1} between

Table 1. The parameters obtained from temperature dependent ^{1}H-NMR spectra recorded at 400 MHz in CD_3COCD_3:CD_3CN (70:30) for the [3]catenanes **8**·4PF$_6$ and **9**·4PF$_6$

[3]-Catenane	$\Delta\nu$ [Hz]	T_c [°C]	k_c [a] [s^{-1}]	$\Delta G_c^{\neq}$ [kcal mol^{-1}]
8·4PF$_6$	748 [b]	−25	1660	10.7
9·4PF$_6$	320 [c]	+20	710	13.3

[a] Values for k_c were obtained (I. O. Sutherland, *Annu. Rep. NMR Spectrosc. 4* (1971) 81) using the approximate expression $k_c = \pi(\Delta\nu)/(2)^{1/2}$, and the Eyring equation was then used to calculate $\Delta G_c^{\neq}$ at the coalescence temperature T_c. [b] $\Delta\nu$ value obtained from the limiting chemical shifts of $\delta = 4.32$ and $\delta = 6.19$ recorded at −70 °C, for the 'inside' and 'alongside' *para*-phenylene units, respectively, in **8**·4PF$_6$. [c] $\Delta\nu$ value obtained from the limiting chemical shifts of $\delta = 5.50$ and $\delta = 6.30$ recorded at −60 °C for the H2,H6 protons on the naphthalene units 'inside' and 'alongside', respectively, in **9**·4PF$_6$.

the $\Delta G_c^{\neq}$ values of 10.7 kcal mol^{-1} [13] for **8**·4PF$_6$ and 13.3 kcal mol^{-1} for **9**·4 PF$_6$[13] is a measure of just how much more demanding sterically and electronically it is for a pair of molecules of **7** than it is for a pair of molecules of **3** to revolve simultaneously around the tetracationic cyclophane. The observation of this process, irrespective of its precise mechanism, is a clear demonstration of the order which characterizes both **8**·4PF$_6$ and **9**·4PF$_6$ in the solution states.

Cyclic voltammetry[14] reveals the presence of only two redox couples at −455 and −879 mV vs SSCE for **8**·4PF$_6$, and at −559 and −898 mV vs SSCE for **9**·4PF$_6$. All of these redox couples correspond to reversible two-electron reduction processes, confirming the expected topological equivalence of the two bipyridinium units in both [3]catenanes. The aromatic π-electron donor moieties in **8** and **9** insulate and stabilize substantially the bipyridinium units, making their reduction more difficult. The values for the first reduction step are not dissimilar from those previously assigned[1, 15] to the 'inside' bipyridinium units of the [2]catenane **4**·4PF$_6$ and its analogue incorporating **7**.

The fact that **8**·4PF$_6$ and **9**·4PF$_6$ can be prepared (Scheme 2) with such relative ease is all the more remarkable when it is recognized that all attempts to obtain the tetracationic cyclophane, present in both **8** and **9**, as its tetrakis(hexafluorophosphate), have so far[16] been unsuccessful. *It is easier to construct the molecular assemblies than it is to create one of their components by itself. The message is a simple but exciting one—the prospects for self-assembly, as a synthetic paradigm, are extremely encouraging.*[17]

Experimental

8·4PF$_6$: **6** (208 mg, 0.6 mmol) was added as a solid during ca. 15 min to **5**·2PF$_6$ (400 mg, 0.5 mmol) and **3** (800 mg, 1.5 mmol) dissolved in dry MeCN (30 mL). The reaction mixture, which was stirred under nitrogen, turned deep red within 2 h and a red precipitate formed within 12 h. After continued stirring at room temperature for a further 9 days, the solvent was removed in vacuo to leave a bright red solid, which was extracted into $MeNO_2$. After filtration, an aqueous solution of NH_4PF_6 was added to the red solution until no further precipitation occurred. The precipitate was filtered off and extracted with $CHCl_3/MeNO_2$. Polymeric impurities were removed by filtration and the solvent was evaporated off to give a residue which crystallized from $MeNO_2$/EtOAc. The red product was collected by filtration, washed with H_2O, MeOH, and Et_2O, and then dried to give **8**·4PF$_6$ (240 mg, 20%) as a bright red solid, m.p. > 280 °C. Single crystals, suitable for X-ray crystallography, were grown by vapor diffusion of iPr_2O into a solution of **8**·4PF$_6$ in MeCN.

9·4PF$_6$: **4** (60 mg, 0.17 mmol), **5**·2PF$_6$ (122 mg, 0.15 mmol), and **7** (200 mg, 0.3 mmol) were dissolved in dry MeCN (5 mL)/$CHCl_3$ (1 mL) and the solution was stirred at room temperature for 60 h. The solvents were removed in vacuo to afford a bright purple solid, which was subjected to chromatography [SiO_2:MeOH/2 M $NH_4Cl/MeNO_2$ (7:2:1)]. A saturated aqueous NH_4PF_6 solution was added to the fraction of the eluant containing the crude product and the solvents were evaporated off. The solid residue was dissolved in $MeNO_2$ which was washed with H_2O to remove residual inorganic materials. Evaporation of the solvent gave a purple solid which was filtered as a slurry in H_2O, washed with MeOH and Et_2O, and then dried to give **9**·4PF$_6$ (100 mg, 31%), m.p. > 280 °C.

[3] By employing a similar method to that described in the literature for the preparation of **1**·2PF$_6$ (W. Geuder, S. Hünig, A. Suchy, *Angew. Chem. 95* (1983) 501; *Angew. Chem. Int. Ed. Engl. 22* (1983) 489; *Tetrahedron 42* (1986) 1665), the dication **5**·2PF$_6$, m.p. 151–154 °C, was prepared in 37% yield by reaction of 4,4'-dibromomethylbiphenyl with an 8-fold molar excess of bipyridine in MeCN under reflux.

[4] [3]Catenanes have been obtained previously by multistep directed syntheses (G. Schill, C. Zürcher, *Angew. Chem. 81* (1969) 996; *Angew. Chem. Int. Ed. Engl. 8* (1969) 988; G. Schill, K. Murjahn, W. Vetter, *Justus Liebigs Ann. Chem. 740* (1970) 18; G. Schill, K. Rissler, H. Fritz, W. Vetter, *Angew. Chem. 93* (1981) 197; *Angew. Chem. Int. Ed. Eng. 20* (1981) 187; K. Rissler, G. Schill, H. Fritz, W. Vetter, *Chem. Ber. 119* (1986) 1374) and also, following demetalation, from Cu^{I}-templated syntheses of [3]catenates (J.-P. Sauvage, J. Weiss, *J. Am. Chem. Soc. 107* (1985) 6108; C. O. Dietrich-Buchecker, A. Khemiss, J.-P. Sauvage, *J. Chem. Soc. Chem. Commun. 1986*, 1376; C. O. Dietrich-Buchecker, J. Guilheim, A. K. Khemiss, J.-P. Kintzinger, C. Pascard, J.-P. Sauvage, *Angew. Chem. 99* (1987) 711; *Angew. Chem. Int. Ed. Engl. 26* (1987) 661; J. Guilheim, C. Pascard, J.-P. Sauvage, J. Weiss, *J. Am. Chem. Soc. 110* (1988) 8711); C. O. Dietrich-Buchecker, C. Hemmert, A. Khemiss, J.-P. Sauvage, *ibid. 112* (1990) 8002.

[5] The formation of **8**·4PF_6 and **9**·4PF_6 is quite remarkable given the fact that there is no evidence for complexation in MeCN between **5**·2PF_6 and either **3** or **7**. The mechanism of the reaction shown in Scheme 2—and indeed for the reaction shown in Scheme 1—is open to speculation at this stage. is conceivable that the dication **5**·2PF_6 reacts initially with two molar equivalents of 4,4′-dibromomethylbiphenyl to give an acyclic tetracation which then complexes with two molar equivalents of **3** or **7** before undergoing disproportionation with more of the dication **5**·2PF_6 rapidly and without the competitive unthreading of the macrocyclic polyether rings.

[6] FABMS was carried out on a Kratos MS80RF mass spectrometer (accelerating voltage, 3 kV; resolution, 1500) coupled to a DS 90 data system. The atom gun was an adapted saddle field source (Ion Tech Ltd) operated at ca. 7 keV and a tube current of ca. 2 mA. Xenon was used to provide a primary beam of atoms and the samples of **8**·4PF_6 and **9**·4PF_6 were dissolved in a small volume of 3-nitrobenzyl alcohol which had previously been coated onto a stainless steel probe tip. Spectra were recorded in the positive-ion mode at a scan speed of 30 s per decade.

[7] Crystal data for **8**·4PF_6:X (X represents unidentified partial occupancy solvent fragments): triclinic, $a = 13.462(3)$, $b = 15.002(4)$, $c = 16.180(4)$ Å, $\alpha = 72.40(2)$, $\beta = 83.46(2)$, $\gamma = 73.67(2)°$, $V = 2988$ Å^3, space group $P\bar{1}$, $Z = 1$ (the molecule is disposed about a center of symmetry) $\rho = 1.36$ g cm^{-3}, 3126 independent observed reflections with $[|F_o| > 3\sigma(|F_o|)$, $2\theta \leq 100°]$ refined to a current $R = 0.130$, $R_w = 0.143$.

[8] Nicolet R3m diffractometer, ω-scans, $Cu_{K\alpha}$ radiation (graphite monochromator). The structure was solved by direct methods and refined anisotropically. Further details of the crystal structure investigation can be obtained from the Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW (England). Any request should be accompanied by the full literature citation of this communication.

[9] The tetracationic macrocycle adopts a rigid square box-like conformation with (i) an 18° twist angle between the two pyridinium rings of each bipyridinium unit and (ii) a 29° twist angle between the two phenylene rings of each biphenylene unit. The strain in the molecule is relieved by out-of-plane bending of the eight aromatic rings. Although the strain is distributed throughout the macrocycle, the maximum deviations are associated with the exocyclic N–CH_2 and C–CH_2 bonds emanating from the bipyridinium and biphenylene units respectively. In turn, these bonds subtend angles of 17° and 25° with respect to each other in the two different units. Distortions of this magnitude and more have been observed in the smaller tetracationic macrocycle (B. Odell, M. V. Reddington, A. M. Z. Slawin, N. Spencer, J. F. Stoddart, D. J. Williams, *Angew. Chem. 100* (1988) 1605; *Angew. Chem. Int. Ed. Engl. 27* (1988) 1547; P. R. Ashton, B. Odell, M. V. Reddington, A. M. Z. Slawin, J. F. Stoddart, D. J. Williams, *ibid. 100* (1988) 1608 and *27* (1988) 1550) present in the [2]catenane **4**·4PF_6 as well as in extremely strained macrocyclic biaryls (H. M. Colquhoun, C. C. Dudman, M. Thomas, C. A. O'Mahoney, D. J. Williams, *J. Chem. Soc. Chem. Commun. 1990*, 336) wherein the normally colinear C–CH_2 bonds emanating from the *para* positions subtend an angle of 65°!

[10] The mean planes (Fig. 2) of the inside (green) and alongside (red) hydroquinone rings are stacked 3.56 and 3.32 Å, respectively, from the mean plane of the bipyridinium ring system. There are also edge-to-face interactions (S. K. Burley, G. A. Petsko, *Science (Washington DC) 229* (1985) 23; *J. Am. Chem. Soc. 108* (1986) 7995; *FEBS Lett. 203* (1986) 139; *Adv. Protein Chem. 39* (1988) 125) between the inside (green) hydroquinone rings and the phenylene rings on the biphenylene units. The centroid-centroid distances for these T-type interactions are 5.03 and 5.93 Å, respectively, with the hydroquinone ring orthogonal to the nearer phenylene ring. For recent discussions on the nature of π-π interactions between aromatic molecules, see W. L. Jorgensen, D. L. Severance, *J. Am. Chem. Soc. 112* (1990) 4768 and C. A. Hunter, J. K. M. Sanders, *ibid. 112* (1990) 5525.

[11] The mean plane distance between 'alongside' (red) hydroquinone rings in neighboring [3]catenane molecules is 3.66 Å. It should be noted that all the O–CH_2 bonds are approximately planar (A. Makriyannis, S. Fesik, *J. Am. Chem. Soc. 104* (1982) 6462; L. I. Kruse, J. K. Cha, *J. Chem. Soc. Chem. Commun. 1982*, 1329; J. D. Mersh, J. K. M. Sanders, S. A. Matlin, *ibid. 1983*, 306) with respect to their hydroquinone rings, adopting, in relation to each other, *anti* geometries in the 'alongside' (red) hydroquinone rings and *syn* geometries in the 'inside' (green) hydroquinone rings.

[12] ^{1}H NMR for **8**·4PF_6 (400 MHz in CD_3COCD_3:CD_3CN, 70:30): at −70 °C, $\delta = 2.56$ (brs, 8H, CH_2O α to 'inside' OC_6H_4O), 3.41 (bs, 16H, β CH_2O), 3.61 (s, 8H, CH_2O α to 'alongside' OC_6H_4O), 3.77 (brs, 32H, γ and δ CH_2O), 4.32 (brs, 8H, 'inside' OC_6H_4O), 5.86 (s, 8H, $CH_2N^{\oplus}$), 6.19 (brs, 8H, 'alongside' OC_6H_4O), 7.79 (s, 16H, biphenylene-H), 7.84 (d, 8H, *m*-bpy-H), 9.09 (d, 8H, *o*-bpy-H) and at ambient temperature, $\delta = 3.13$ (brs, 16H, α-CH_2O), 3.60 (m, 16H, β-CH_2O), 3.81 (m, 16H, γ-CH_2O), 3.85 (m, 16H, δ-CH_2O), 5.25 (brs, 16H, OC_6H_4O), 5.88 (s, 8H, $CH_2N^{\oplus}$), 7.70–7.80 (m, 16H, biphenylene-H), 7.85 (d, 8H, *m*-bpy-H), 9.12 (d, 8H, *o*-bpy-H). ^{1}H NMR for **9**·4PF_6 (400 MHz in CD_3COCD_3:CD_3CN, 70:30) at −60 °C, $\delta = 3.49$–4.15 (m, 64H, α-CH_2O, β-CH_2O, γ-CH_2O, and δ-CH_2O), 3.72 (d, 4H, 'inside' H4,H8), 5.24 (t, 4H, 'inside' H3,H7), 5.50 (d, 'inside' H2,H6), 5.74 (d, 4H, $CH_2N^{\oplus}$), 6.02 (d, 4H, $CH_2N^{\oplus}$), 6.30 (d, 4H, 'alongside' H2,H6), 6.69 (d, 4H, *m*-bpy-H), 6.91 (d, 4H, *m*-bpy-H), 6.93 (t, 4H, 'alongside' H3,H7), 7.02 (d, 4H, 'alongside' H4,H8), 7.89 (d, 8H, α-biphenylene-H), 7.92–8.21 (m, 8H, β-biphenylene-H), 8.54 (d, 4H, *o*-bpy-H), 8.88 (d, 4H, *o*-bpy-H), and (400 MHz in CD_3CN) at + 60 °C, $\delta = 3.60$–3.95 (m, 64H, α-CH_2O, β-CH_2O, γ-CH_2O, and δ-CH_2O), 5.84 (brs, 8H, $CH_2N^{\oplus}$), 5.84 (brs, 8H, H2,H6), 6.12 (brm, 8H, H3,H7), 6.37 (d, 8H, *m*-bpy-H), 7.83 (d, 8H, α-biphenylene-H), 7.96 (d, 8H, β-biphenylene-H), 8.48 (brs, 8H, *o*-bpy-H). The signal for H4,H8 (8H) is too broad to be visible and merges into the baseline, presumably in the range $\delta = 5.50$–7.02.

[13] These $\Delta G_c^{\neq}$ values can be compared with those of 15.6 and 17.2 kcal mol^{-1}, both in CD_3CN, for the free energies of activation for the passage of **3** and **7**, respectively, through the smaller tetractionic macrocycle present in **4**·4PF_6 and in the analogous [2]catenane where naphtho units replace *para*-phenylene units. Clearly, it is easier for the two polyether rings to revolve simultaneously through the larger tetracationic macrocycle than it is for them to pass singly through the smaller one.

[14] Electrochemical experiments were performed with a Princeton Applied Research Model 175 universal programmer, a Model 173 potentiostat, and a Model 179 digital coulometer equipped with positive feedback circuitry for IR compensation. Voltammograms were recorded on a Soltec VP-6423S X-Y recorder. A glassy carbon disk electrode (0.080 cm^2), Pt flag, and sodium chloride saturated calomel (SSCE) were used as the working, auxiliary, and reference electrodes, respectively. All solutions for the voltammetric experiments were deoxygenated by sparging with nitrogen gas; a nitrogen atmosphere was maintained above the solution during the experiments.

[15] The *second* redox potential, measured for **4**·4PF_6 and its dinaphtho analogue, are − 438 and − 572 mV, respectively.

[16] So far, all attempts to prepare the large tetracationic macrocycle by template-directed methods, using, for example, bisparaphenylene-22-crown-6 as the template, have been unsuccessful.

[17] For examples of self-assembly in operation in chemical systems, see P. L. Anelli, P. R. Ashton, N. Spencer, A. M. Z. Slawin, J. F. Stoddart, D. J. Williams, *Angew. Chem. 103* (1991) 1052; *Angew. Chem. Int. Ed. Engl. 30* (1991) 1036, and references cited therein.

Molecular Trains: The Self-Assembly and Dynamic Properties of Two New Catenanes**

Peter R. Ashton, Christopher L. Brown, Ewan J. T. Chrystal, Keith P. Parry, Marek Pietraszkiewicz, Neil Spencer, and *J. Fraser Stoddart**

When the cyclobis(paraquat-*p*-phenylene) and cyclobis(paraquat-4,4′-biphenylene) tetracationic macrocycles were formed in the presence of an excess of bisparaphenylene-34-crown-10, a [2]catenane[1] and a [3]catenane[2] re-

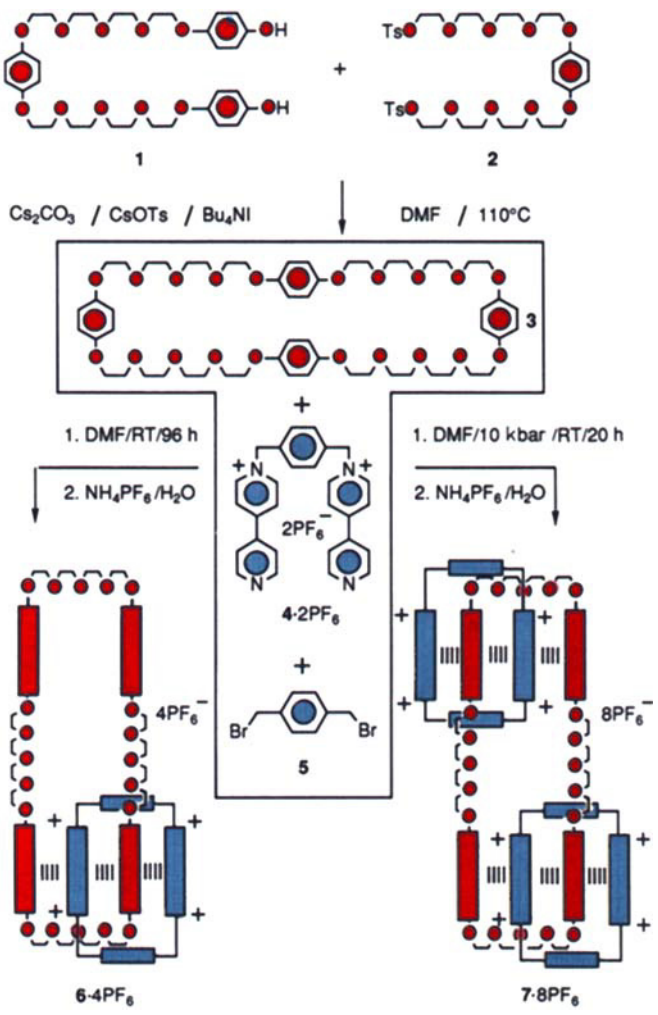
[**] This work was supported by the University of Sheffield, ICI Agrochemicals, and the Agricultural and Food, and Science and Engineering Research Councils in the United Kingdom, and the National Economic Development Organization in Japan.

spectively were obtained in good yields, i.e. increasing the size of the tetracationic macrocycle allowed[2] a [3]catenane to be made to order. With a view to extending the self-assembly protocol to the synthesis of [n]catenanes, we now decided to explore the consequences of increasing the size of the polyether macrocycle by a factor of two.

Here, we report: (i) the high-dilution, cesium-ion promoted,[3] phase transfer catalyzed[4] synthesis of tetrakisparaphenylene-68-crown-20 **3** in excellent yield[5] from its immediate precursors, the diphenol **1** and the ditosylate **2**; (ii) the preparation and isolation of the [2]catenane **6**·4PF_6 from a DMF solution containing **3**, whilst reacting **4**·2PF_6[6] with almost equimolar amounts of **5** at room temperature; (iii) the characterization of this new [2]catenane by FABMS,[7]; (iv) how, according to the temperature dependence of the ^{1}H-NMR spectra,[8] the cyclophane molecules appear to be behaving like a 'molecular train'.[9] We then demonstrate that a [3]catenane **7**·8PF_6 can be obtained when **3**, **4**·2PF_6 and **5** are allowed to react at 10 kbar. Finally, dynamic ^{1}H-NMR spectroscopy[10] shows how two 'molecular trains' in **7**·8PF_6 manage to travel together round the "circle line" formed by **3**.

We decided that the key to further progress in self-assembling catenanes was identifying an efficient synthesis[5] of **3** from readily-available starting materials, e.g. **1** and **2**. This objective was achieved by employing a unique combination of (i) a high-dilution reaction in DMF at high temperature (110 °C) using (ii) the "cesium effect"[3] (Cs_2CO_3/CsOTs) and (iii) phase-transfer catalysis[4] (Bu_4NI) in order to synthesize **3** in 62% yield[5] from **1** and **2** (Scheme 1). Although all our attempts to prepare catenanes incorporating **3** and the cyclobis(paraquat-4,4′-biphenylene) tetracation have been unsuccessful so far, reaction of **4**·2PF_6 in DMF at room temperature for 96 h with 1.1 molar equivalents of **5** in the presence of 0.7 molar equivalents of **3** led to a product (Scheme 1), which, after chromatographic purification and conversion to the tetrakis(hexafluorophosphate), was identified as the [2]catenane **6**·4PF_6. Positive-ion FABMS reveals peaks at m/z = 2028, 1884, and 1739 corresponding to the loss of one, two, and three $PF_6^{\ominus}$ counterions, respectively, from **6**·4PF_6.



Scheme 1. The cesium template-directed synthesis of **3** from diphenol **1** and ditosylate **2** and the subsequent template-directed syntheses of the [2]catenane **6**·4PF_6 and the [3]catenane **7**·8PF_6 from **3**, **4**·2PF_6, and **5**. In the catenanes, **3** and the tetracationic cyclophane formed from **3** and **4** are represented by chemical cartoons: Hydroquinone rings ≡ red rectangles, *p*-phenylene rings ≡ small blue rectangles, bipyridinium units ≡ large blue rectangles, RT = room temperature.

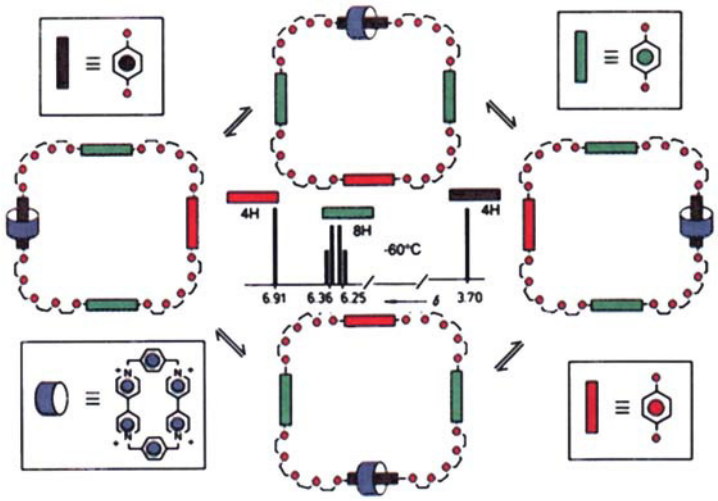
The temperature dependence of the ^{1}H-NMR spectrum of the [2]catenane **6**·4PF_6, recorded in CD_3COCD_3,[8] reveals the presence of two different processes occurring simultaneously within the molecule (Table 1): (i) the macrocycle **3** (red) pirouettes about the OC_6H_4O axis of the "occupied" hydroquinone ring in the [2]catenane exchanging the 'inside' and 'alongside' bipyridinium rings of the tetracationic cyclophane (blue) while (ii) the tetracationic cyclophane moves along the polyether chains from one hydroquinone ring to the other around **3**. The first process, which is associated with a free energy barrier of 9.5 kcal mol^{-1}, is evident at −72 °C from the line broadening (60 Hz) experienced by the signal for the protons α to the nitrogen atoms on the bipyridinium rings in the tetracationic cyclophane (Table 1). Even-

Table 1. Kinetic and thermodynamic parameters [a] obtained from the temperature dependent ^{1}H-NMR spectra recorded at 400 MHz on the [2] catenane **6**·4PF_6 and on the [3]catenane **7**·8PF_6

Probe protons undergoing site exchange	$\Delta\nu$ [Hz]	k [s^{-1}]	T [°C]	ΔG^* [kcal mol^{-1}]
OC_6H_4O in **6**·4PF_6 [b]	32 [d]	101	13.5	14.1
o-bpy in **6**·4PF_6	60 [d]	189	−72	9.5
OC_6H_4O in **7**·8PF_6 [b] [c]	20 [e]	63	0	13.6

[a] Values of k were obtained by the exchange method (J. Sandström: *Dynamic NMR Spectroscopy*, Academic Press, London, 1982, Chapter 6) using the approximate expression $k = \pi(\delta\nu)$. The Eyring equation was used to calculate ΔG^* values at the coalescence temperature T. [b] The probe protons referred to are in the 'occupied' hydroquinone rings (black in Schemes 2 and 3–5). [c] The low-temperature behavior of **7**·8PF_6 is under investigation. However, we anticipate that it will be associated with a ΔG^* value of < 10 kcal mol^{-1}. [d] Recorded in a CD_3COCD_3 solution. [e] Recorded in a CD_3CN solution.

tually, below −80 °C, this signal separates into two signals arising from the 'inside' and 'alongside' bipyridinium units. Long before these low temperatures are reached (e.g. at −60 °C), the second process (Scheme 2) is 'frozen out' on the ^{1}H-NMR time scale in the form of (i) a high field singlet (4H) at ca. δ = 3.70, identified by a saturation transfer experiment, for the black hydroquinone ring 'station' at which the blue 'train' has 'stopped', (ii) an A_2B_2 system (8H) with δ = 6.25 and 6.36 for the hydroquinone rings (green) of the 'adjacent stations', and (iii) a low field singlet (4H) at δ = 6.91 for the hydroquinone ring (red) at the 'opposite station' across the **3** 'track' from the blue 'train'. By +13.5 °C, the signal for this red hydroquinone ring has broadened to 32 Hz, reflecting (Table 1) a free energy barrier of 14.1 kcal mol^{-1} resisting the 'running' of the blue 'train'

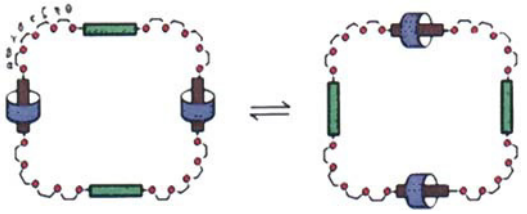


Scheme 2. The degenerate process, which involves movement of the blue tetracationic cyclophane from hydroquinone ring to hydroquinone ring around the red macrocycle **3** in the [2]catenane **6**·4PF$_6$. Bound hydroquinone rings are black. Unbound hydroquinone rings are green or red depending on whether they are, respectively, adjacent to or opposite the bound hydroquinone unit. The ^{1}H-NMR spectrum of the hydroquinone rings **6**·4PF$_6$ at $-60\,^\circ$C is represented by a stick diagram in the middle of the array of the scheme.

between stations. When the solvent is changed to CD_3CN and the temperature is raised to $+80\,^\circ$C, the hydroquinone rings at the black, green, and red 'stations' are averaged out on the ^{1}H-NMR time scale such that their protons resonate as a broad multiplet between $\delta = 5.76$ and 6.30. The blue 'molecular train' is now travelling round the red 'circle line' 14 thousand times a second while it rolls over on itself 9 million times a second!

During the preparation and isolation of the [2]catenane **6**·4PF$_6$, it was suspected that another product—namely the related [3]catenane in which **3** is encircled by two macrocyclic cyclobis(paraquat-*p*-phenylene) tetracations—might be a very minor product of the reaction. Recalling that the Menshutkin reaction[10] is promoted by ultra-high pressures,[11] we conducted the reaction of **4**·2PF$_6$ in DMF with **5** in the presence of approximately a sixth of a molar equivalent of **3** at room temperature under a pressure of 10 kbar for 20 h (Scheme 1). After treatment of the crude product with a saturated aqueous solution of NH_4PF_6 and fractional crystallization of the crude product from $MeNO_2/CHCl_3$ at $-18\,^\circ$C, the [3]catenane **7**·8PF$_6$ was identified by positive-ion FABMS, which revealed peaks at m/z = 3129, 2984, 2839, 2694, and 2549 corresponding to the loss of one, two, three, four, and five $PF_6^\ominus$ counterions, respectively, from **7**·8PF$_6$. Additional peaks at m/z = 2028 and 1884 which correspond (see above) to the loss of one and two $PF_6^\ominus$ counterions, respectively, from **6**·4PF$_6$, indicate that the [3]catenane fragments in the mass spectrometer to give the [2]catenane.

The temperature dependence of the ^{1}H-NMR spectrum[12] of the [3]catenane **7**·8PF$_6$, recorded in CD_3CN, reveals the presence of exchange processes analogous to those observed for the [2]catenane **6**·4PF$_6$. Although the low-temperature process, which occurs below $-40\,^\circ$C, is still under active investigation, a higher temperature one, which is associated with a free energy barrier of 13.6 kcal mol^{-1} (Table 1), relates to a site exchange process between diametrically opposite 'occupied stations', indicated by black hydroquinone rings (ca. $\delta = 3.39$, identified by a saturation transfer experiment at $-40\,^\circ$C), encircled by the blue tetracationic cyclophane and the diametrically opposite 'unoccupied stations', indicated by green hydroquinone rings ($\delta = 6.10$ at



Scheme 3. The degenerate process that involves the simultaneous movement of the blue tetracationic cyclophane from one pair of diametrically opposed hydroquinone rings to the other pair of diametrically opposed hydroquinone rings. Bound hydroquinone rings are black, free hydroquinone rings are green.

$-40\,^\circ$C) (Scheme 3). Only one translational[13] isomer—the one shown in Scheme 3—is evident from an inspection of the ^{1}H-NMR spectrum at $-40\,^\circ$C, i.e. the two 'molecular trains' prefer to keep a free station between them in both directions as they do 'the loop'. Crashes do not happen!

It is really remarkable that such a highly positively-charged [3]catenane as **7**$^{8\oplus}$ can be self-assembled in a controlled, and stepwise manner starting from the 'red' macrocyclic polyether **3** and the components necessary to make the 'blue' tetracationic cyclophane via the intermediacy of the [2]catenane **6**$^{4\oplus}$. Encouragingly, dynamic ^{1}H-NMR spectroscopy reveals how, in both **6**$^{4\oplus}$ and **7**$^{8\oplus}$, the order that is associated with their template-directed syntheses 'lives on' in the highly ordered structural behavior they exhibit in solution.

Both the [2]catenane **6**$^{4\oplus}$ and the [3]catenane **7**$^{8\oplus}$ are reminiscent of 'trains' doing 'the loop' on a 'circle line'. One of the many challenges which remain is to show how a 'molecular train' can be driven in a highly controlled manner employing the appropriate signalling devices!

In particular, template-directed syntheses relying on (i) the "cesium effect" for the efficient production of a large neutral macrocycle and subsequently (ii) part, and then all, of this macrocycle acting as a template for the formation of one, and then two, linked tetracationic cyclophanes is a demonstration[14] of *how molecular recognition begets molecular recognition*. In practical terms, *this progressively cumulative aspect of self-assembly in synthesis is an appealing one.*

Experimental

1: Diphenol **1** was obtained in four steps starting from the commercially-available compounds, 4-benzyloxyphenol and 1,4-bis-(2-hydroxyethoxy)benzene. Alkylation (Bu_4NI, KOH, EtOH, 60°C, 15 h) of the former with 2-[2-(2-chloroethoxy)ethoxy]ethanol, followed by tosylation (TsCl, C_5H_5N) afforded the monotosylate, 1-benzyloxy-4-[2-[2-(2-hydroxyethoxy)ethoxy]ethoxy]benzene-4′-methylbenzene sulfonate, which was used to dialkylate (NaH, DMF) the latter. Catalytic hydrogenolysis (H_2, Pd/C, EtOH) of the dibenzyl ether, obtained from the dialkylation, gave **1** in 31% yield; m.p. 60–62°C; m/z (positive-ion FABMS) = 646 and 669 for $M^\oplus$ and $[M + Na]^\oplus$, respectively; δ_H (CD_3COCD_3) = 3.58–3.65 (m, 16H), 3.73–3.78 (m, 8H), 3.98–4.05 (m, 8H), 6.71–6.79 (m, 8H), 6.84 (s, 4H), 7.88 (s, 2H).

2: Hydroquinone was dialkylated (Bu_4NI, KOH, EtOH, 80°C, 20 h) with 2-[2-[2-(2-(chloroethoxy)ethoxy]ethoxy]ethanol to give a diol (73%), which on tosylation (TsCl, C_5H_5N) afforded the ditosylate **2** in 93% yield; oil; m/z (positive-ion FABMS) = 770 and 793 for $M^\oplus$ and $[M + Na]^\oplus$, respectively; δ_H (CD_3COCD_3) = 2.43 (s, 6H), 3.47–3.52 (m, 8H), 3.52–3.58 (m, 4H), 3.58–3.68 (m, 8H), 3.74–3.78 (m, 4H), 4.01–4.05 (m, 4H), 4.12–4.16 (m, 4H), 6.85 (s, 4H), 7.44–7.49 (m, 4H), 7.78–7.81 (m, 4H).

3: The diphenol **1** (323 mg, 0.5 mmol) and the ditosylate (385 mg, 0.5 mmol) were dissolved in DMF (20 mL) and the solution of these reactants in equimolar proportions was added dropwise during 3 h to a mixture of Cs_2CO_3 (1.63 g, 5 mmol), CsOTs (304 mg, 1 mmol), Bu_4NI (10 mg) in DMF (50 mL) which was heated to 110°C and stirred vigorously. Heating and stirring of the reaction mixture was continued for ca. 12 h. On cooling, the solution was filtered off, the residue was washed with $CHCl_3$, and the organic solvents were evaporated off under vacuum to give a residue which was partitioned between $CHCl_3$ (70 mL) and H_2O (5 mL). The $CHCl_3$ solution was concentrated to afford a crude

product which was subjected to chromatography [SiO_2: 3% MeOH in $CHCl_3$] to affort **3** (333 mg, 62%); m.p. 96–98 °C; *m/z* (positive-ion FABMS) = 1072 and 1095 for $M^{\oplus}$ and $[M + Na]^{\oplus}$ respectively; δ_H ($CDCl_3$) = 3.66–3.69 (m, 16H), 3.69–3.73 (m, 16H), 3.80–3.83 (m, 16H), 4.03–4.06 (m, 16H), 6.81 (s, 16H).

6·4PF_6: **5** (290 mg, 1.1 mmol), **4**·2PF_6 (772 mg, 1.0 mmol), and **3** (750 mg, 0.7 mmol) were dissolved in anhydrous DMF (40 mL) and the solution was stirred at room temperature for 96 h. The reaction mixture was added to a saturated aqueous solution of NH_4PF_6 and the temperature was raised to 90 °C, whereupon a highly colored precipitate formed. It was filtered off and washed successively with H_2O, MeOH, $CHCl_3$, and Et_2O. This solid residue was dissolved in $MeNO_2$ and polymeric material was removed by careful precipitation with $CHCl_3$. After further filtration, removal of the solvent from the filtrate by evaporation under reduced pressure furnished a red solid which was subjected to chromatography [SiO_2:MeOH/2M NH_4Cl/$MeNO_2$ (7:2:1)]. When the fractions containing the red product were mixed with a saturated aqueous solution of NH_4PF_6, the product precipitated out as an amorphous solid which was filtered, washed successively with H_2O, MeOH, and Et_2O, and then dried under vacuum to afford the pure [2]catenane **6**·4PF_6 (200 mg, 12%), as a red compound, m.p. > 280 °C. So far, all attempts to obtain single crystals suitable for X-ray crystallography have been unsuccessful.

7·8PF_6: **5** (180 mg, 0.68 mmol), **4**·2PF_6 (390 mg, 0.55 mmol) and **3** (100 mg, 0.09 mmol) were dissolved in dry DMF (10 mL) and the solution was subjected to ultra-high pressure (10 kbar) for 20 h at room temperature. The reaction was worked up as described above for **6**·4PF_6 prior to the point of chromatography to produce a mixture of this [2]catenane, along with the [3]catenane **7**·8PF_6 (34 mg, 11%), which was obtained by fractional crystallization following addition of $CHCl_3$ to a $MeNO_2$ solution and cooling it down to −18 °C before filtering off the dark red crystals, m.p. > 280 °C. Single crystals were obtained from vapor diffusion of BME (butyl methyl ether) into a MeCN solution (1 ml) of **7**·8PF_6 (5 mg). However, they suffer from severe crazing and rapid decomposition on removal from solution. Repeated attempts [15] with encapsulated small crystals have produced only barely discernible diffraction patterns in very long exposure photographs. These results indicate that the structure is either disordered or suffers from very high thermal vibrations. The photographic data obtained to date have not even been of adequate quality to discern either the unit cell or the space group. Further studies with better quality crystals, which are proving difficult to grow, are needed in order to solve this structural problem.

[3] It is well known that cesium salts (e.g. Cs_2CO_3 and CsOTs) of weak acids—particularly when they are dissolved in a dipolar aprotic solvent like DMF—exhibit some quite remarkable reactivity characteristics that render them extremely useful for synthetic purposes. Besides relating to the enhanced alkylation of nucleophiles, the "cesium effect", as it has been dubbed, refers to the rather spectacular observation that intermolecular substitutions are generally suppressed relative to intramolecular ones. For an assessment of the causes of the "cesium effect", see G. Dijkstra, W. H. Kruizinga, R. M. Kellogg, *J. Org. Chem. 52* (1987) 4230. For a recent critique on the 'cesium effect' see C. Galli, L. Mandolini, *J. Org. Chem. 56* (1991) 3045.

[4] It has been found (M. Pietraszkiewicz, unpublished results) that the alkylations of phenols with halogeno compounds, including chlorohydrins are accelerated significantly by the addition of phase-transfer catalysts, such as Bu_4NI, in basic media. The base-promoted dialkylation of diphenol **1** with ditosylate **2** is probably also subject to the same kind of phase-transfer catalysis.

[5] In the absence of the added cesium salts, the yield of **3** upon reaction of diphenol **1** with ditosylate **3** was very low indeed (< 5%). Other synthetic strategies were no more practical when they were put to the test. For example, after 1,11-bis[4-[2-(2-hydroxyethoxy)ethoxy]phenoxy]-3,6,9-trioxaundecane (3.1 g, 5.6 mmol) had been heated in THF (290 mL) under reflux in the presence of NaH (0.45 g, 18.7 mmol) for 7 days (N_2 atmosphere) with its derived ditosylate (5.0 g, 5.8 mmol) and the crude product was subjected to chromatography (SiO_2:MeOH/$CHCl_3$/Et_2O, 2/28/70), only 150 mg (2.5%) of **3** was isolated as a crystalline product, m.p. 96–98 °C.

[7] FABMS was carried out on a Kratos MS80RF mass spectrometer (accelerating voltage, 3 kV; resolution, 1500) coupled to a DS90 data system. The atom gun was an adapted saddle field source (Ion Tech Ltd) operated at ca. 7 keV and a tube current of ca. 2 mA. Xenon was used to provide a primary beam of atoms and the samples of **6**·4PF_6 were dissolved in a small volume of 3-nitrobenzyl alcohol which had previously been coated on to a stainless steel probe tip. Spectra were recorded in the positive ion mode at a scan speed of 30 s per decade.

[8] ^{1}H NMR for **6**·4PF_6 (400 MHz): at −60 °C in CD_3COCD_3, δ = 3.29–4.15 (64H, m, OCH_2), 3.70 (4H, br s, 'occupied' OC_6H_4O), 5.97 (8H, br s, $CH_2N^{\oplus}$), 6.25 and 6.36 (2 × 4H, 2 × d, 'adjacent unoccupied' OC_6H_4O), 6.91 (4H, s, 'opposite unoccupied' OC_6H_4O), 8.00 (8H, bs, C_6H_4), 8.13 (8H, bd, *m*-bpy-H), 9.27 (8H, br d *o*-bpy-H), 9.27 (8H, br d *o*-bpy-H) and at +80 °C in CD_3CN, δ = 3.70–3.87 (64H, m, OCH_2), 5.72 (8H, s, $CH_2N^{\oplus}$), 5.76–6.30 (16H, br m, 'occupied' and 'unoccupied' OC_6H_4O), 7.74 (8H, d, *m*-bpy-H), 7.78 (8H, s, C_6H_4), 8.89 (8H, d, *o*-bpy-H).

[9] A [2]rotaxane composed of (i) a polyether chain intercepted by two hydroquinone rings and terminated by large triisopropylsilyl end groups and (ii) an encircling cyclobis(paraquat-*p*-phenylene) tetracationic macrocycle has been shown recently to behave like a molecular shuttle (P. L. Anelli, N. Spencer, J. F. Stoddart, *J. Am. Chem. Soc.*, in press).

[11] For a review of the use of ultra-high pressures in chemical synthesis, see N. S. Isaacs, A. V. George, *Chem. Brit. 23* (1987), 47.

[12] ^{1}H NMR for **7**·8PF_6 (400 MHz in CD_3CN): at −40 °C, δ = 3.30–3.35 (8H, m, α-OCH_2), 3.39 (8H, br s, 'occupied' OC_6H_4O), 3.46–3.52 (8H, m, θ-OCH_2), 3.54–3.60 (8H, m, β-OCH_2), 3.65–3.72 (8H, m, γ-OCH_2), 3.75–3.80 (8H, m, η-OCH_2), 3.80–3.83 (8H, m, δ-OCH_2), 3.83–3.90 (16H, br s, ε- and ζ-OCH_2), 5.61 (16H, br s, $CH_2N^{\oplus}$), 6.10 (8H, s, 'unoccupied' OC_6H_4O), 7.59 (16H, d, *m*-bpy-H), 7.70 (16H, s, C_6H_4), 8.80 (16H, d, *o*-bpy-H) and at +80 °C, δ = 3.66–3.70, 3.73–3.77, 3.80–3.84, 3.84–3.88 (4 × 16H, m, OCH_2), 5.05 (16H, br s, 'occupied' and 'unoccupied' OC_6H_4O), 5.71 (16H, s, $CH_2N^{\oplus}$), 7.78 (16H, d, *m*-bpy-H), 7.79 (16H, s, C_6H_4), 8.89 (16H, d, *o*-bpy-H).

[13] For a definition of translational isomerism, see G. Schill, K. Rissler, H. Fritz, W. Vetter, *Angew. Chem. 93* (1981) 197; *Angew. Chem. Int. Ed. Engl. 20* (1981) 187; G. Schill, N. Schweickert, H. Fritz, W. Vetter, *ibid. 95* (1983) 909 and *22* (1983) 889. We thank a referee for drawing our attention to the existence of this term. It is probable that the inversion process between the two degenerate species shown in Scheme 3 involves the intermediacy of the translational isomer where the blue tetracationic cyclophane occupies adjacent 'stations'. However, its concentration is clearly insufficient for it to be detected by ^{1}H-NMR spectroscopy.

[14] For a brief discussion of this concept, see J. F. Stoddart in C. Brown (Ed): *Chirality in Drug Design and Synthesis*, Academic Press, London, 1990, pp. 53–81.

Book Reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the following address: Redaktion Angewandte Chemie, Postfach 101161, D-6940 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

Faszination Chemie. 7000 Jahre Kulturgeschichte der Stoffe und Prozesse. By *O. Krätz*. Callwey, Munich 1990. 331 pp., hardcover DM 148.00.—ISBN 3-7667-0984-4

When a book begins with a dedication "to the memory of Don Domenico Emanuele Cajetano, Count Ruggiero, Prince of Salerno... whose association with the mighty of this world, was to me, despite his sad end, a shining, though unfortunately never attainable, example. And remains such. Wherever the hangman at Küstrin in 1709 may have thrown his poor raven-gnawed remains, may God make the earth light for him!" you know that you are going to face neither a boring chemical text nor a pretentious art critical analysis.

Indeed, this dedication is an indicator of the wonderful style of the author of this book, *Otto Krätz*. In full command of the history of our science, he brings chemistry to life because it is a living enterprise to him. So within the book you will not only read *Cajetano Ruggiero*'s story, but also be faced with the wall paintings, on religious and alchemical themes, with which this alchemist, master of deceit and the politics of his time, decorated a cell in which he was once imprisoned. And you will see reproduced a broadside announcing *Ruggiero*'s demise.

To *Krätz* the history of chemistry is one with its present. He tells the story of the transformers of matter with style and wit—with an understated humor I will dare call British. And with a fantastic hoard of illustrations, drawn often from artifacts or books at the Deutsches Museum, where he has long worked (and obviously had fun...).

Espęcially strong is the extended discussion of alchemy, long a problem for chemists who would like to take the protochemistry, smile at the deceit, and forget the philosophy that powered this world view. *Krätz* does alchemy justice. He also has a wonderful, informed discussion of early synthetic materials. Here and nowhere else, you can learn about "Walosin", a synthetic fishbone for corsets, and the remarkably beautiful plastics from milk products. Hundreds of illustrations, some in the text, but most gathered in a section occupying over half the volume, grace this book.

My only disappointment is that Dr. *Krätz*'s story of our science by and large ignores the spiritual essence of the past century of chemistry. This is the molecule. It is true the external world still sees substances, too many of them, and their transformations. But in the mind of the chemist, even the most applied one, today roams freely the image, replete with distances, angles, bonds and functional groups, of the molecule. He or she, that imagined chemist, knows and thinks of matter transforming molecularly on the microscopic scale. The author of this book shows us *van't Hoff*'s models and a perfunctory α-helix. But nothing more of the way a chemist views the world today. It's a missed opportunity.

But this is a minor complaint about a truly beautiful book. It should be read by all, given as a prize to outstanding high school students the world over. It would make a lovely present by a chemist to her husband's non-chemist parents. "Faszination Chemie" makes wonderful episodic reading. With *Otto Krätz* as a witty, informed guide we see chemistry as an integral part of world culture, created by real people changing the stuff of this beautiful world.

The Chemistry of Organophosphorus Compounds. Vol. 1: Primary, Secondary, and Tertiary Phosphines, Polyphosphines, and Heterocyclic Organophosphorus(III) Compounds. Edited by *F. R. Hartley* (Series: The Chemistry of Functional Groups, Series Editor: *S. Patai*). Wiley, Chichester 1990. XIV, 739 pp., hardcover £ 185.00.–ISBN 0-471-92607-8.

This first volume of a four-volume series on "The Chemistry of Organophosphorus Compounds" was published in 1990 as part of the renowned series "The Chemistry of Functional Groups", edited by *S. Patai*. Many years have passed since the last major handbooks on the organic chemistry of phosphorus were published and, therefore, a new comprehensive work in the area of organophosphorus chemistry is certainly welcome. The seven-volume handbook "Organic Phosphorus Compounds", edited by *G. M. Kosolapoff* and *L. Maier*, appeared in the 1970s, and even the phosphorus supplements of the Houben-Weyl series are almost ten years old.

Primary, secondary, and tertiary phosphanes, as well as heterocyclic phosphorus(III) compounds, are treated in this first volume. The second volume, planned for 1992, will cover phosphane oxides, sulfides, and selenides. Phosphonium salts, ylides, and phosphoranes are the subject of the third volume, and phosphonous, phosphinous, phosphinic, and phosphonic acids, as well as their halogen derivatives, will be dealt with in the fourth and last volume.

It is difficult to judge the overall handbook just on the basis of the first volume, although certain tendencies are apparent and are bound to characterize the entire handbook. The first volume begins with an introductory chapter written by the editor, *F. R. Hartley*. The following chapters cover organophosphorus(III) compounds in terms of such general topics as structure and bonding, electrochemistry, free radical reactions, and thermochemistry (including here not only organophosphorus compounds). Phosphane complexes of transition metals and the biochemistry of phosphanes are also considered. These chapters, as well as those treating particular classes of compounds, are written by experts in the field.

The chapters are, in part, very detailed, clearly written, and well organized. Coverage of the literature is extensive but not exhaustive; even the recent literature is taken into account. Several chapters are almost monographs and are well suited to give an overview of a particular area.

 © VCH Verlagsgesellschaft mbH, W-6940 Weinheim, 1991 0570-0833/91/0808-1046 $ 3.50+.25/0

Noticeable in the first volume is the absence of several classes of compounds containing by phosphorus–carbon bonds: for example, P(III)–halogen compounds such as halophosphanes, R_nPX_{3-n} (R = alkyl, aryl, etc.; X = halogen; n = 1,2). These and related classes of compounds will presumably be covered in the last volume of the series. Whereas phosphaalkynes are discussed in detail in the first volume, no mention is made of phosphaalkenes or systems with P=P bonds. Furthermore, the subjects covered in Volume 1 and, eventually, in Volume 4 are closely related, although this is not stated explicitly. Perhaps Volume 4 should have been planned to directly follow the first volume.

This volume lacks a chapter on the NMR investigations of organophosphorus compounds, especially by ^{31}P NMR spectroscopy. However, several books that treat this subject have been published recently. On the other hand, the ESR spectra of free radicals derived from phosphanes are covered.

The author index is comprehensive, but the subject index leaves much to be desired. To locate specific information, therefore, a certain level of expertise is required. There are no serious typographical errors, apart from the apparently unavoidable misspellings of names.

The first volume of this series appears to have achieved its purpose, even though it is impossible to pass judgment on the entire series. Rapid publication of Volumes 2–4 is highly desirable, since the complete handbook promises to be very useful to phosphorus chemists. Although the very high price will limit wide availability of this first organophosphorus volume of the Patai series, no large chemistry library should be without it.

Multiple Bonds and Low Coordination in Phosphorus Chemistry. Edited by *M. Regitz* and *O. J. Scherer*. Thieme, Stuttgart 1990. xviii, 478 pp., hardcover DM 468.00.—ISBN 3-13-752201-3

This volume entitled "Multiple Bonds and Low Coordination in Phosphorus Chemistry", edited by *M. Regitz* and *O. Scherer*, features numerous articles on a variety of topics which are comprehended by the title. The vast scope and interest of this fascinating field is emphasized by the large number of chapters (25) and the list of distinguished contributors. This research area, which originated in a number of laboratories in the 1960s, is a relatively young one. As the editors point out in their introduction, "hardly any other field of phosphorus chemistry has undergone such a brisk development in such a short time".

The opening chapter by the editors provides a brief overview of most, if not all, of the significant developments in the field. This is followed by an excellent chapter on "Bonding Properties of Low-Coordinated Phosphorus Compounds" by *W. Schoeller*. It begins by highlighting the reasons for the differences between the lighter main group elements and their heavier congeners. Many of the concepts discussed here should eventually be included in undergraduate inorganic textbooks. They will, one hopes, replace the often unsatisfactory "explanations" of such differences that are in current use. The emphasis is, of course, on phosphorus but the chapter should be of general interest to many chemists from a wide variety of areas. There is also much useful factual information on structures, bond strengths, molecular energy levels and computational work concerning phosphorus compounds.

The bulk of the remaining chapters are classified (not always accurately) according to whether the phosphorus coordination number is 1, 2 or 3.

Three chapters concern phosphorus coordination number 1. The first, dealing with phosphinidenes, is further divided into two parts which cover in situ generated phosphinidenes (by *F. Mathey*) and binuclear or bridging phosphinidenes (by *G. Huttner* and *H. Lang*). Owing to the extreme reactivity of the R-$\ddot{P}$: fragment, none of the stable compounds in this chapter involve singly coordinated phosphorus. The phosphinidenes are detected either spectroscopically or by trapping with transition metal–ligand fragments or organic and related substrates.

The second in the series of chapters on one-coordinate phosphorus (by *M. Regitz* and *P. Binger*) deals with the phosphaalkynes (P≡C-R). These are the phosphorus analogues of nitriles, and the existence of such species has been recognized for over 40 years. It was, however, the seminal discovery (by *Becker* in 1981) of a facile route to kinetically stabilized examples that has virtually created this field of investigation. The explosive growth in this area may be gauged from the fact that within 8 years (up to mid-1989) of the initial report about 200 papers have appeared on this subject. This chapter gives a comprehensive and well organized account of these developments.

The final chapter on one-coordinate phosphorus compounds (by *O. Scherer*) is concerned primarily with bonding and ligand properties of phosphorus units such as P≡N, P≡P and P_x. The two former units have no existence as stable separate entities under ambient conditions, although a related ionic species $[P{\equiv}N\text{-}R]^{\oplus}[AlCl_4]^{\ominus}$ has been structurally characterized recently. The vast majority of the work in this area has concerned P_x species as ligands in transition metal complexes. In almost all of these complexes the phosphorus is at least two- or even three-coordinate, so that the inclusion of these compounds in this particular section is somewhat surprising.

The second major part of this volume concerns phosphorus with coordination number 2. This section is the largest part of the book and comprises eleven chapters. Even so, not all types of two-coordinate phosphorus compounds are dealt with here, and there is virtually no coverage of two-coordinate phosphorus anions such as $[PR_2]^{\ominus}$ or of two-coordinate radical species such as $[:\dot{P}R_2]$, some of which are stable at room temperature. The largest chapters in this section are those by *R. Appel* dealing with the phosphaalkenes, phosphacarbaoligoenes and phosphaallenes, and by *G. Märkl* dealing with compounds that have phosphorus as part of an aromatic six-membered ring. There is also a chapter (by *A. Schmidpeter*) that deals with the delocalized five-membered rings involving phosphorus and a variety of heteroatoms. Acyclic delocalized two-coordinate phosphorus systems are covered by chapters on phosphenium cations (by *M. Sanchez, M. R. Mazieres, L. Lamandé, R. Wolf*) and on 2-phosphaallylic cations (by *A. Schmidpeter*). The remaining chapters in this section are concerned with various classes of two-coordinate phosphorus compounds. Included here are the landmark diphosphenes (*M. Yoshifuji*), the iminophosphenes (*E. Niecke*) and phosphorus compounds with multiple bonds to boron, silicon, germanium and tin (*F. Bickelhaupt*). Included also is a treatment of multiple bonds between two phosphorus atoms with different oxidation states and the closely related phosphinylidenesulfuranes (by *A. Schmidpeter*). The section is concluded by a chapter by *L. D. Quin* and *J. Szewczyk* on the oxophosphanes and their sulfur and selenium analogues.

The third major section of the book deals with phosphorus compounds with coordination number 3. While this is not normally regarded as a low coordination number for phosphorus, the compounds covered by this section certainly are unusual. There are eight chapters here, all of which concern pentavalent phosphorus involved in multiple bonding to either C, N, P, O, S or Se. The first three (by *R. Appel, H. Heydt, E. Niecke* and *D. Gudat*) deal with phosphoranes which have at least two multiple bonds to carbon, nitrogen, or a combination of these with bonds to O, S or Se. A chapter (by *M. Yoshifuji*) is devoted to phosphoranes involving double bonds to phosphorus in combination with double bonds to carbon, nitrogen, oxygen, sulfur or selenium. In addition, an article by *M. Meisel* deals with dioxo- and dithioxophosphoranes and the elusive metaphosphate anion. The two remaining chapters in this section by *G. Bertrand* and by *J.-P. Majoral* are concerned with pentavalent phosphorus compounds with triple bonds to carbon or nitrogen. The final chapter in the book (by *K. Karaghiosoff*) is an extremely useful summary of ^{31}P NMR data for low-coordinate and multiply bonded phosphorus compounds.

In summary, this volume covers most of the exciting developments in this field over the last 25 years or so. The list of contributors includes many of the leading figures who made much of this chemistry possible. The literature is scanned up to mid-1989 which, of necessity, means that many of the chapters are already out of date owing to the extremely rapid pace of development in these areas. Many readers will probably be aware that much, if not quite all, of the material within its covers has been previously reviewed in the literature—in some cases more than once. The main advantage with the present volume is that it saves you the trouble of searching for these reviews in the literature. Some of the chapters also serve to update the small number of areas that have not been reviewed within the last five years or so. The book is beautifully produced and is amply illustrated throughout. The standard of writing is, on the whole, excellent and there are only a few obvious typographical errors. Unfortunately, this attention to detail and presentation also exacts a price which, at around $ 300, few individuals can afford. In these days of budget restrictions, even many libraries will be forced to look askance at such an expenditure for a single volume. Having said that, I can think of few books that more effectively summarize so many of the most exciting developments in phosphorus chemistry over the last 25 years.

Cathodoluminescence. Theory and Applications. By *L. Ozawa*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York/Kodansha, Tokyo 1990. x, 308 pp., hardcover DM 196.00.—ISBN 3-527-27982-2/0-89573-936-4/4-06-204033-6

Cathodoluminescence is the physical process which is used in TV screens and Braun tubes of scientific instruments such as oscilloscopes to generate pictures by means of an electron beam. The electrons are accelerated in vacuum by a voltage of several kV and directed onto a screen containing small crystals of a material which emits visible luminescence when it is hit by the electron beam. *Lyuji Ozawa*'s book gives an introduction to the physics of cathodoluminescence, and contains detailed information on a large number of important luminescent crystals and their fields of application. It consists of three main parts.

The first part, which consists of Chapters 1 to 5, describes the fundamental principles of the generation of light by irradiating energetic particles into suitable luminescent materials. These materials, which are called "phosphors", are usually insulating or semiconducting inorganic crystals doped with a small amount of ions of a transition element. The latter emit the luminescence and are therefore called "activators". After a short introduction in Chapter 1, the author describes in Chapters 2 and 3 the basic effects of the irradiating electrons on crystals and activator ions. The important process which distributes the energy in the surface layer of the crystal is the excitation of secondary electrons by inelastic scattering of an incoming high-energy primary electron. The majority of the secondary electrons have rather low energies of only a few electron volts, and they give rise to the luminescence of the dopant ions, mainly via electron–hole recombination. Several possible mechanisms of the excitation of the ions are discussed. Since the energy is transferred from a primary electron to the luminescent centers via secondary electrons or electron–hole pairs, the motion and energy conversion of charge carriers play an important role in phosphor crystals. These topics are addressed in Chapters 4 and 5. It is shown how the motion can be investigated by varying the concentration of the activator ions, and by irradiating pulsed electron beams of different pulse durations into the samples. As a result of such measurements, an explicit model of the cathodoluminescence is proposed for the system Y_2O_2S:Eu.

After these general considerations, the second part of the book (Chapters 6 and 7) provides more detailed information on the optimization of cathodoluminescence phosphors for applications in picture tubes. Chapter 6 addresses some basic physical variables which should or should not be optimized in phosphor materials. It is shown, for instance, that the presence of a charge transfer band between activator ions and host crystal is not important for obtaining an efficient cathodoluminescence phosphor. On the other hand, the choice of the optimum activator concentration plays a much larger role. On the one hand, it is desirable to achieve an efficient radiative recombination of electron–hole pairs, but on the other hand, self-concentration quenching effects should be avoided as far as possible. The optimum concentrations are usually below one mole per cent. Other variables that can be adjusted are the crystal size and crystal structure of the phosphor. In Chapter 7 the author discusses some methods and engineering tricks to obtain bright cathodoluminescence picture tubes. He shows, for instance, how microcrystals of appropriate shape and uniform size can be grown. He also describes the best methods of measuring cathodoluminescence intensities on phosphor screens.

In the third part, which comprises Chapters 8 to 10 and occupies almost half the book, the author lists special properties of a large number of phosphorescent materials. Since it contains many luminescence spectra and other technical details, it will be useful for engineers working in this field. Chapter 8 describes the properties of rare-earth-activated phosphors. Because the visible part of their luminescence spectra consists mainly of relatively few sharp lines, they can be used in color TV screens. A different class of phosphor materials are semiconductor crystals of compounds of elements of Groups II and VI, which are the subject of Chapter 9. Their most important representatives are ZnSe and ZnS. They are characterized by broader luminescence bands, so that they can be used in monochrome screens. By adding

small amounts of metallic activators such as copper or silver, it is possible to change their color. In Chapter 10 characteristic properties of ZnO are described. Here the author does not limit the discussion to cathodoluminescence properties, but also comments on applications of this material in other fields including electrophotography, varistors, piezoelectricity and gas sensors.

In summary, the book is very useful both for the scientist who wants to understand the physical principles of cathodoluminescence and for the engineer who has to select or manufacture the right material for specific applications. The book collects together the research results of several decades, and for further information a number of references are given at the end of each chapter. Its only minor shortcoming is the relatively large number of typographic errors.

Electroanalysis of Biologically Important Compounds. (Series: Analytical Chemistry). By *J. P. Hart*. Ellis Horwood, Chichester 1990. 213 pp., hardcover $ 72.50.—ISBN 0-13-252107-5

Electroanalysis has been found to be widely applicable to many problems of clinical and biological significance. The subject presented by *J. Hart* is thus certainly timely. The objective of this book is to demonstrate the suitability of modern electroanalytical techniques for measuring biologically important compounds. The focus is on controlled-potential techniques, primarily classical voltammetry and liquid chromatography with electrochemical detection (LCEC). New trends such as biosensors, micro and modified electrodes, are also covered but in a limited depth. Detailed theory is not given and the approach is primarily experimental. In particular, the (clearly written) text offers various strategies for the determination of certain groups of biological compounds. The book is full of practical examples, including numerous (very recent) references. The material is divided into five chapters. The first is devoted to the basic principles and instrumentation of finite-current controlled-potential techniques. Chapters 2 and 3 deal with the electroanalysis of purine and pyrimidine derivatives, amino acids and proteins. Electrochemical methods for the determination of vitamins and coenzymes are discussed in Chapters 4 and 5. Overall, this book will be a very useful reference source for those involved in bioelectroanalysis and LCEC. The practical approach makes the book particularly appealing to industrial users.

Robert Robinson—Chemist Extraordinary. By *T. I. Williams*. Clarendon Press, Oxford 1990, viii, 201 pp., hardcover £ 25.00.—ISBN 0-19-858180-7

Some sixteen years have passed since the death of *Robert Robinson* and this book is the first and, as yet, the only biography of one of the greatest figures in the history of organic chemistry. A master of natural product chemistry and an outstanding contributor to our understanding of organic chemical reactions, he dominated chemistry in Britain for half a century and at the same time played a vital part in the development of its chemical industry. That the appearance of a biography should have been so long delayed may seem extraordinary and yet it is understandable. *Robinson* never kept any records, apart from reprints of his published work and, although he repeatedly said that he would record everything in a detailed "scientific autobiography", he did not in fact make any serious attempt to do so until about 1970, by which time he was almost completely blind and unable to properly undertake such a demanding task. He did, nevertheless, set about it with astonishing vigor and, with the help of a few devoted young assistants, collected a vast amount of material so that, by the time of his death in 1975, he had put together a draft manuscript recording his work and career up to 1930, when he went to Oxford as Waynflete Professor. This manuscript was published posthumously by Elsevier in 1976 as Volume I of the planned autobiography *Memoirs of a Minor Prophet*. This volume showed all too clearly the effects of *Robinson*'s age and disabilities: liberally sprinkled with typographical errors which should have been eliminated at the proof stage, it contains recollections of individuals cheek by jowl with large and highly technical discussions of chemical problems, the whole book giving the clear impression of an ill-constructed draft which, had he been alive, would have been completely rewritten by its author before publication. In addition to the material which was published, he left a mass of manuscripts designed to be incorporated in a second volume but these were so incomplete and so preliminary in character that they could not be published and so no Volume 2 ever appeared.

As a result, apart from obituary notices and the long tribute by *Lord Todd* and *J. W. Cornforth* in *Biographical Memoirs of Fellows of the Royal Society* (1976, pp. 415–527), the entry in the *Dictionary of National Biography 1971–80*, and the *Proceedings of a special meeting of the Historical Group of the Royal Society of Chemistry* (1987), there has been no overall portrayal of *Robinson*'s genius and personality until the publication in 1990 of *Robert Robinson—Chemist Extraordinary* by *Trevor I. Williams*.

Overall, the volume gives a valuable and very fair account of *Robert Robinson*—a complex character if ever there was one! Dr. *Williams* has clearly put a great deal of work into collecting and sifting material from both professional and family sources and has produced an informative and well-balanced account of the life and work of an extraordinarily complex yet extremely human scientist. This he has done without getting lost in technicalities in those sections dealing with scientific work; in particular, he has included a chapter on the famous *Robinson–Ingold* quarrel which, I feel, will give the nonspecialist reader a clearer picture of that affair than he is likely to find elsewhere.

It is perhaps only natural that, as one who was closely associated with *Robert Robinson* from the autumn of 1931, when I joined his research group in Oxford, until his death in 1975, I should feel that, admirably comprehensive though it is, this book does not convey fully the warmth of *Robinson* the man, and his great love of children with whom he was always immensely popular. I shall always remember one occasion when, in the Swiss Alps, he and my younger daughter (she aged about 10 and he about 70) scrambled joyfully together on a rocky mountain top in such a way that one might have wondered whether they were not both about the same age.

Robert was completely shattered by the sudden death of his wife *Gertrude* in 1954 after 42 years of happy married life. His loneliness was, however, relieved by his second marriage

(in 1957) to *Stearn Hillstrom*, an American lady whom he first met during a visit to America on behalf of Shell. In his book Dr. *Williams* gives a very good account of *Robinson*'s first meeting with *Stearn* and of the, sometimes stormy, course of the marriage—indeed, as far as I know, it is the only account of that final phase of *Robinson*'s life in existence; *Stearn* had no scientific knowledge or interest but she cared deeply for *Robert* and greatly eased his latter days. Dr. *Williams* records also *Robinson*'s contacts with *Robert Maxwell* but, perhaps unavoidably, he does not seem to me to put quite enough weight on the connection and the friendship between them which had a great influence on *Robinson* in the post-war period.

To summarize: this is a comprehensive, well-written biography of a great scientist, and it will be a standard work of reference for any student of the rise of organic chemistry in the twentieth century and the imprint of *Robert Robinson* upon it.

Lord Todd [NB 1156IE]
Christ's College
Cambridge (United Kingdom)

Gas Chromatography—A Practical Course. By *G. Schomburg*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York 1990. xiv, 320 pp., paperback DM 76.00.—ISBN 3-527-27879-6/0-89573-889-9

Despite the spectacular advances in liquid chromatography during the last two decades, gas chromatography has retained its place as an important analytical technique for relatively volatile organic compounds. The modern gas chromatograph is often microprocessor-controlled and presents an impressive exterior festooned with dials, buttons and input keys, suggesting that the foremost requirement for operation is a high degree of virtuosity on the computer keyboard. It nevertheless remains true that successful gas chromatography depends on an appreciation of the theoretical factors controlling resolution, detection and quantitation, and the practical skill to translate these factors into optimum performance.

Designed as a practical guide, this book gives a detailed overview of the equipment, terminology and mathematical parameters in current use in GC, whilst avoiding unnecessarily elaborate theoretical treatments of the derivation of equations and terms. After presenting the conceptual framework, the author provides a series of chapters covering the techniques of packed and capillary column GC with flame ionization, thermal conductivity and electron capture detection, and the interfacing of GC to mass spectrometry, FT-IR and HPLC. There is a strong emphasis on practical aspects such as column evaluation, use of reference samples and standards for quantitation and for establishing retention parameters such as Kovats indices, and the selection and optimization of conditions for isothermal and temperature programmed separations of complex mixtures. The design and construction of key components of the equipment, such as split and splitless injectors for capillary columns, is examined at some length so that the influence of these factors on performance can be fully appreciated and practical errors resulting from their misuse avoided. Many of the recent developments and special methods in GC are covered, providing practical guidance on dealing with samples of low volatility and high polarity, trace analysis, coupling of capillary columns to one another and to chemical reactors for on-line reduction, pyrolysis and post-column reaction. There is an extensive series of examples of GC separations, demonstrating each of the major themes discussed in the text. The many examples of applications to real problems cover a wide range of compound classes, isothermal and temperature programmed separations of complex mixtures using different phases and detectors, multidimensional techniques and enantiomeric resolutions on chiral columns.

It is surprising that, in a book intended as a guide for the laboratory worker, there is an absence of some useful practical information, such as tables giving recommendations for the selection of appropriate stationary phases for different classes of compounds, and experimental details of standard derivatization procedures such as methylation, silylation and perfluoroacylation. In spite of this deficiency and some weaknesses in the English, punctuation and indexing, this text is highly recommended as a useful guide for those about to embark on the practice of gas chromatography.

Lantibiotics—Ribosomally Synthesized Biologically Active Polypeptides containing Sulfide Bridges and α,β-Didehydroamino Acids**

By Günther Jung*

Lantibiotics are polycyclic peptide antibiotics containing intrachain sulfide bridges, formed from the thioether groups of the amino acids lanthionine and β-methyllanthionine. They also contain α,β-unsaturated amino acids such as didehydroalanine and didehydroaminobutyric acid. A knowledge of the lantibiotic biosynthetic steps and the enzymes involved makes possible a gene technological construction of analogous highly modified polypeptides. To the family of lantibiotics belong nisin, an important food preservative, epidermin, a highly specific therapeutic agent against acne, a series of enzyme inhibitors, as well as immunologically interesting active peptides. Lantibiotics are produced by ribosomal synthesis, starting from inactive precursor proteins (prelantibiotics). The latter are post-translationally converted into the active peptide antibiotics through enzymic modifications. The modifying enzymes effect dehydrations at the serine and threonine residues and stereospecific additions of the cysteine thiol groups to the resulting α,β-unsaturated double bonds, which lead to the formation of several sulfide bridges. Upon subsequent proteolytic cleavage of the leader peptide, the biologically active lantibiotic is formed. Conformational analyses of the lantibiotics, as well as of their prepeptides, enables one to obtain information about the mechanism and steps of the biosynthesis. Antibodies against synthetic prepeptide sequences, and modern instrumental methods for the analysis of peptides, allow structural elucidation of the biosynthetic intermediates.

1. Introduction

Heterodet polycyclic *antibiotics* which contain thioether amino acids such as *lan*thionine as well as α,β-unsaturated amino acids are called *lantibiotics*.[1] To this class of natural products belong nisin, used as a preservative in the food industry,[2, 3] epidermin, a therapeutic agent against acne,[4] many enzyme inhibitors and immunologically active peptides such as ancovenin,[5] Ro 09–0198,[6] duramycin,[7] and the antibiotics mersacidin[8a] and actagardine.[8b] Some lantibiotics such as Pep5[9, 10] induce a voltage-dependent ion current in the lipid bilayer membranes.[10c]

The results of the structural elucidation of several new lantibiotics indicate that the biosynthesis of lantibiotics, with different sequence and secondary structure, proceeds according to a common principle. This differs fundamentally from the usual synthetic mechanism of most other peptide antibiotics. In contrast to the peptide antibiotics, which are synthesized via the multienzyme complexes (thiol esters) and enzyme systems, the biologically active, lanthionine-containing, secondary metabolites evolve from the ribosomally synthesized precursor proteins. These prelantibiotics consist of a leader sequence and a prolantibiotic, which post-translationally is enzymatically modified.[1] The serine and threonine residues are dehydrated to α,β-didehydroamino acids,

Auf der Morgenstelle 18, W-7400 Tübingen (FRG)

[**] Based on a lecture delivered on the occasion of the Max Bergmann Medallion Award 1989, Wangen (Switzerland), October 15–18, 1989.

 © VCH Verlagsgesellschaft mbH, W-6940 Weinheim, 1991 0570-0833/91/0909-1051 $ 3.50+.25/0

and the thiol groups of the cysteine residues add to the resulting double bonds with formation of sulfide rings.

Depending on the variability and specificity of the modifying enzyme systems, one could incorporate analogous protein or peptide substrates into the lantibiotic biosynthesis systems, and thereby produce novel proteins, agonists, antagonists, inhibitors and enzymes which contain dehydroamino acids, sulfide bridges—instead of disulfide bridges—or lysinoalanine bridges. Therefore, lantibiotic biosynthesis is not only of interest in basic microbiological research, but also assumes a special role in the development of new methods in protein engineering.

The interdisciplinary microbiological and chemical research on lantibiotics began already in 1983 in Tübingen, starting with the fermentation, isolation and structural elucidation of the anti-acne therapeutic agent, epidermin. The structure of the tetracyclic, 21-peptide amide antibiotic epidermin was published in 1985.[4] The unusually intensive and well-coordinated collaboration between various research teams in microbiology and peptide chemistry led to the elucidation of additional new lantibiotics and substantial information was collected in a short time about their structural genes. Meanwhile, DNA sequences of several of the enzymes responsible for the biosynthesis have been determined. Therefore, complete elucidation of the biosynthetic steps, and the selective gene technological preparation of modified polypeptides and proteins with unusual building blocks is getting closer to a reality. Recent results of lantibiotic research are presented here for the first time in the form of a review.

2. Lantibiotics, Their Biological Activities and Possible Applications

Lantibiotics are produced by microorganisms of various genera, e.g. *Staphylococcus, Lactococcus, Bacillus*, and *Streptomyces*. It is specially useful to classify the lantibiotics on the basis of their different ring structure, into two sub-

Table 1. Composition of the lantibiotics and the strains producing them.

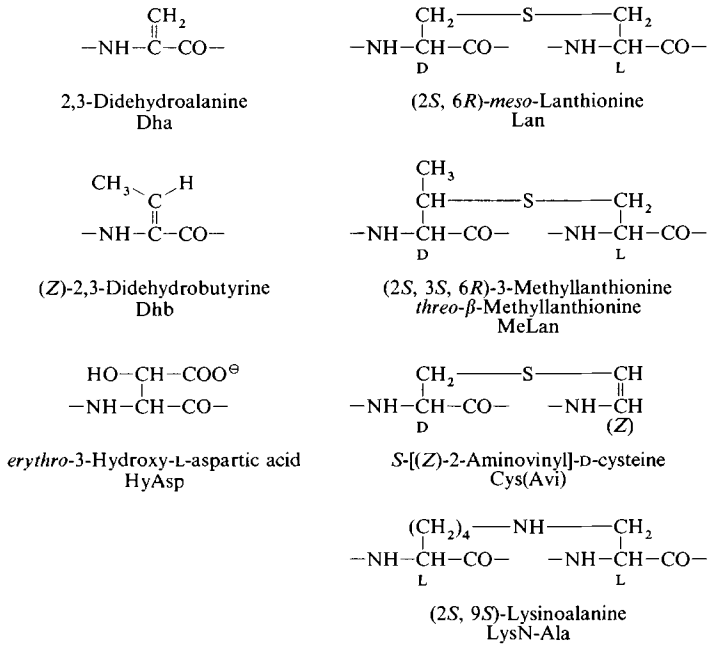
Günther Jung, who was born in Tübingen in 1937, studied chemistry at the Universität Tübingen, where he grained his doctorate in 1967 under the supervision of E. Bayer. After his habilitation 1971 in the natural products area he became professor of organic chemistry and biochemistry at the Universität Tübingen, after turning down numerous calls from other universities. He spent 1967/68 in the USA as an assistant professor at the University of Houston, Texas. In 1989 he was awarded the Max Bergmann Medal for his work on lantibiotics. His areas of research include the structural elucidation, mode of action and biosynthesis of larger polypeptide antibiotics and siderophores, structure-activity relationships of the neuropeptide Y, models for transmembrane channels, multiple peptide synthetic methods, B-, T-helper and T-killer cell epitope mapping and the development of synthetic peptide vaccines.

groups: Type A, lantibiotics of the nisin type, and type B, lantibiotics of the duramycin type (Table 1).

The actual composition of the structurally known lantibiotics is conceived through two recently elucidated representatives. These are the larger polypeptide Pep5[9] with a molecular mass of 3488 Da, and mersacidin[8a] with a molecular mass of 1825 (Table 1). These molecular masses correspond to peptides with 34 and 19 amino acids, respectively, in which the unusual building blocks that originate from the proteinogenic amino acids are also taken into account. Lantibiotics can contain between three and five sulfide rings made from *meso*-lanthionine (Lan) and (2*S*, 3*S*, 2*R*,)-3-methyllanthionine (MeLan). Moreover, they contain α,β-unsaturated amino acids such as α,β-didehydroalanine (Dha), α,β-didehydroaminobutyric acid (Dhb), *S*-aminovinyl-cysteine (Cys(Avi)), as well as *erythro*-3-hydroxyaspartic acid (HyAsp) and amine bridges from lysinoalanine (LysN–Ala) (Scheme 1). The antimicrobial effects of the lantibiotics



Scheme 1. Unusual amino acids in lantibiotics.

nisin,[2, 3] epidermin[4] and gallidermin[11] are predominantly directed against gram-positive bacteria (Table 2). There are a number of reasons why lantibiotics are classified more reasonably as *bacteriocins* and not as common antibiotics.

Nisin, a compound produced by *Streptococcus lactis* plays a very important role in food technology; since 1951 it has been produced by the tons as a natural preservative for vegetables, cheese, meat and cocoa.[3] Nisin has been known since 1928, and it poses no health hazards to humans, for it has presumably been consumed in dairy products for centuries. The proteases of the human stomach and intestinal tract hydrolyze it completely and it does not damage the gram-negative bacteria of intestinal flora. Thus, as a preservative in the cheese and meat industries, nisin has decisive advantages over the still used nitrates and nitrites, which produce carcinogenic nitrosamines.

Table 2. Effects and potential applications of lantibiotics.

Lantibiotic	Effect	Application
Type A		
Nisin [2, 3]	Batericide against gram-positive bacteria (*Clostridium botulinum, Streptococci, staphylococci*), cationic, lytic agent, inhibitor of peptidoglycan biosynthesis	Food preservative, antimalaria
Subtilin	similar to nisin	
Epidermin [4], Galli dermin [11]	against *Propionibacterium acne* (MIC < 0.125 mcg ml^{-1}) and staphylococci	Acne, eczema, folliculitis, impetigo
Pep5 [9, 10]	Autolysis of the gram-positive bacteria	Bacteriocin
Mersacidin [8a]	Bactericide against staphylococci	Antibiotic, Immune suppressor
Actagardine [8b]	Bactericide against streptococci, inhibitor of the peptidoglycan biosynthesis	Infections, septa
Type B		
Ancovenin [5]	Inhibitor of the angiotensin converting enzyme (ACE)	Blood pressure regulation
Cinnamycin [7] (= Ro 09-0198 [6], Lanthiopeptin [12])	Inhibitor of phospholipase A_2, ACE und HSV-1	Inflammations, blood pressure regulation, immune adjuvant, *Herpes simplex* virus
Duramycin [7] (= leucopeptin)	Inhibitor of phospholipase A_2	Antibiotic
Duramycin B, C [7d]	Inhibitor of phospholipase A_2	Inflammations

Interestingly, the strains producing the lantibiotics epidermin[4] and gallidermin,[11] which are biologically active against pathogenic skin germs such as *Propionibacterium acne*, staphylococci and streptococci, derive from human skin or chicken combs. Their effectiveness against acne is comparable to that of the macrolide antibiotic erythromycin. Upon therapeutic treatment with the macrolide antibiotics a resistance rapidly develops. However, no side effects have so far been observed when using epidermin and gallidermin. The highly effective epidermin and its structural analog gallidermin therefore constitute interesting alternatives to the vitamin A derivatives and erythromycin, specially for the therapeutic treatment of juvenile acne. Since Pep5 and epidermin producers are often found on the human skin,[10a] it is assumed that these belong to the healthy skin flora which function as natural protection against pathogenic microorganisms that could cause inflammation of the follicle ducts of the sebaceous glands.

Little is known about the location and mode of action of most of the lantibiotics on the molecular level. However, insights into the principle ("mechanism") of the antibacterial effect of Pep5,[10] nisin, subtilin, epidermin and gallidermin can be gained by biophysical experiments on lipid bilayer membranes, and by conformational analysis using 2D ^{1}H NMR and MDS (molecular dynamics simulations) and circular dichroism (CD). The high bactericidal activity of Pep5 could be attributed to a depolarization of the energized bacterial cytoplasm membrane[13] and induction of autolysis.[13g–j] In intact cells and artificial membranes, beginning with a trans-negative membrane potential of about 100 mV, voltage-dependent and short-lived pores with variable diameters up to 1 nm were induced.[13c] A similar effect could be demonstrated for nisin[13e] and subtilin,[13i] as well as for epidermin and gallidermin. Owing to the high

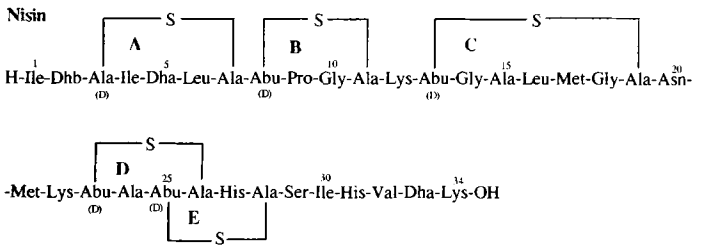
specificity of lantibiotics against certain bacteria, one may assume that besides the formation of the pores, still other mechanisms are involved in the biological activity. In particular, a distinct correlation could exist between the lipid composition of the membranes and the biological activity of the lantibiotics, as was demonstrated[7e-m] for duramycins,[7] which inhibit phospholipase A_2.[7d] Duramycins also increase membrane permeability.[7f] Resistance against duramycin can originate from a change of the lipid composition, e.g. by reduction of the content of diacylphosphatidylethanolamine (PE).[7e]

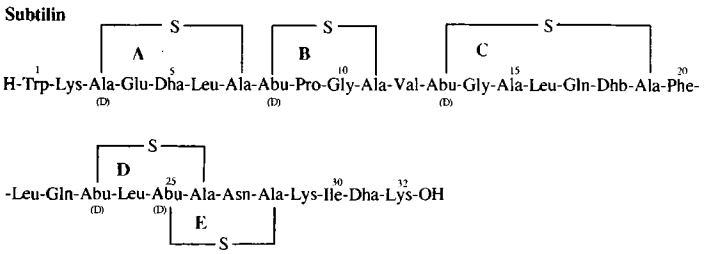
The gram-positive producing strains are sensitive towards the lantibiotics which they themselves produce. Hence, they develop a self-protecting principle which is secerned into the culture medium, and makes the bacteria immune (resistant) against their own products.[14]

3. Structural Elucidation of Lantibiotics

3.1. Nisin and Subtilin

The stereochemistry of lanthionine and related thioether amino acids was investigated by our group using chromatography and circular dichroism.[15] The unusual amino acid lanthionine, as well as lysinoalanine (Table 2) can cause cross-linking of the peptide chains with one another. These compounds are found in wool and food products if they are subjected to heat or alkali. The natural occurrence of lanthionine was demonstrated for the first time when it was found in the polypeptide antibiotic nisin discovered in 1928 (cf. Ref. [3]). The complicated structure of the polycyclic 34-peptide was elucidated by the pioneering work of *Erhard Gross* in 1971.[2] Shortly afterwards the structure of the related compound subtilin was published.[16] These two heterodet pentacyclic polypeptides possess five sulfide bridges at identical positions—formed by a lanthionine and four 3-methyllanthionine residues—as well as two dehydroalanines and one dehydrobutyrine (Fig. 1).





(2S, 6S)-Lanthionine (2S, 3S, 6R)-3-Methyllanthionine

Fig. 1. Structures of the heterodet pentacyclic lantibiotics nisin [2] and subtilin [17].

For the structural elucidation, *Gross* and collaborators employed two different methods to split off the sulfide bridges, before and after the enzymatic cleavage of nisin,[16] and subtilin.[17] One method was a special oxidative cleavage of the sulfide bridges, and the other, reductive ring cleavage by desulfurization with Raney nickel. The latter method led to the formation of one D- and one L-alanine residue from *meso*-Lan, whereas MeLan was converted into L-alanine and D-α-aminobutyric acid. The detection of α,β-didehydroamino acids is neither possible by amino acid analysis of the total hydrolyzate, nor by peptide sequencing using Edman degradation. This problem is due to the fact that Dha and Dhb are thereby decomposed and form a peptide acid amide and a ketoacyl residue. Figure 2 depicts the acid-catalyzed cleavage of nisin at Dha^{33}, which leads to the likewise active nisin (1–32) amide; an analogous cleavage also occurs at Dha^{5}, but not at Dha^{2}. *Gross* utilized this labile peptide bond in order to carry out an interesting solid phase synthesis of a peptide amide, whereby a resin bound dehydroalanine anchor functioned as an acid-labile intermediate and also furnished the nitrogen of the amide functional group.[16c,d] This reaction is reversible and the reactivity of the didehydroamino acids is responsible for the formation of nisin oligomers with molecular masses of up to 12000 Da.[16c] In the case of Pep5, dimers with molecular masses of up to 7000 Da have also been detected.

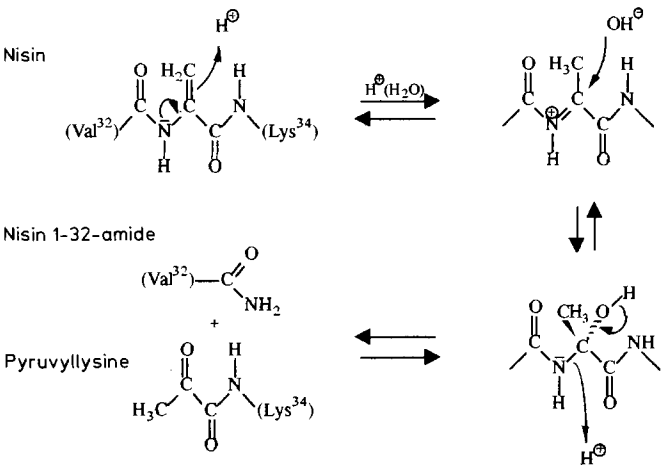


Fig. 2. Acidic cleavage of nisin at didehydroalanine (Dha) in position 33 [16c] leads to a peptide amide and pyruvyllysine [16d].

Besides the catalytic hydrogenation of the α,β-didehydroamino acids, *Gross* also carried out a further key reaction, namely the addition of benzylthiol and mercaptoethylamine to the double bonds of Dha and Dhb.[16,17]

According to our experience, neither desulfurization nor hydrogenation and addition of α-toluenethiol to lantibiotics

proceed quantitatively. Therefore, the accomplishment of the *Gross* team is to be respected all the more highly, for the structures of nisin and subtilin were correctly eludicated, without using HPLC, high-field NMR and FAB-MS. The correctness of these structures has now been proven by the sequencing of the structural genes.[18, 19]

After about 10 years of work, the total synthesis of nisin was achieved by the research group of *Shiba* in 1987.[20] The basic features of the method used are the dehydroalanine synthesis from 2,3-diaminopropionic acid by Hofmann degradation[20c] (Fig. 3), and the dehydrobutyrine synthesis by dehydration of threonine using soluble 1-ethyl-3(3-dimethylaminopropyl)carbodiimide and $Cu^{I}Cl$ catalysis.[20a] The sulfide bridges were prepared by partial desulfurization of the disulfide bridges of the sequence analogous cystine-containing peptides, using tris(diethylamino)phosphane[20d] (Fig. 3). Interestingly, this reaction can also be performed by employing polymer-bound peptides containing disulfide bridges.[20e]

was identical with the naturally occurring compound as regards antibacterial activity, HPLC chromatogram, FAB-mass spectrum and ^{1}H-NMR spectrum. On the basis of the enzymatic and synthetic fragments, it was established that the rings A and B are responsible for the antibiotic activity.

3.2. Epidermin and Gallidermin

One of the central problems in the structural elucidation of the lantibiotics is the sequence specific configurational assignment of the two C_α-atoms all *meso*-lanthionine and (2*S*, 3*S*, 6*R*)-3-methyllanthionine residues. This was resolved by us during investigation of the structure of epidermin, where we used comparative gas chromatographic studies on chiral glass capillaries with Chirasil-Val.[15a] Starting point for the structural elucidation was the preparation of many fragments by combination of enzymatic and chemical degradation steps. A crucial step involved the tryptic fragmenta-

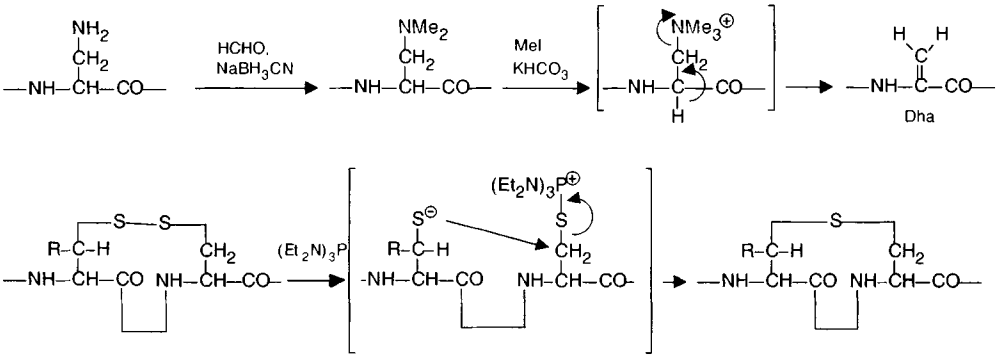

Fig. 3. Preparation of the didehydroalanine (Dha) from 2,3-diaminobutyric acid, and of the sulfide rings from disulfide bridges in the synthesis of nisin [20]; R = H (lanthionine); R = CH_3 (β-methyllanthionine).

The total synthesis of nisin was achieved by the condensation of five fragments (Fig. 4). The synthetic fragments 1–12 and 22–34 correspond to a tryptic and a BrCN cleavage fragment, respectively; therefore, their identification was possible by comparison with natural nisin. Synthetic nisin

tion of epidermin, by which a water soluble N-terminal fragment P1 and an insoluble C-terminal fragment P2 were produced. By using NMR, FAB-MS, and chemical derivatization, we found that as a result of the enzymatic cleavage of the Lys-Dhb peptide bond at the N-terminus of of the pre-

cursor of the fragment P2, a 2-oxobutyryl blocking group is produced (Fig. 5). N-Terminally bound α,β-didehydroamino acids Dha and Dhb are unstable, they add water and are deaminated to the α-ketoacyl residues. In contrast to the acid-catalyzed cleavage at Dha[5] and Dha[33] of nisin (Fig. 2), tryptic digestion produces no peptide amides, but peptides containing a carboxy C-terminus (Fig. 5).

The structural elucidation of the N-terminal fragment P1 (Fig. 6) could be carried out by FD-MS and FAB-MS—before and after desulfurization—as well as by automated Edman degradation of the desulfurized dodecapeptide 1–12. The sulfide bridges of the rings A and B of fragment P1 were assigned on the basis of FAB-MS spectrometry and by a Lys-C-endopeptidase cleavage of the ring 3–7.[4] For the structural elucidation of the N-acylated and C-terminally amidated fragment P2, NMR furnished useful information. Information was also gained by the desulfurization reaction using Raneynickel by which inhomogeneous products were obtained. This reaction afforded the important fragment with the C-terminal L-alanine-*N*-ethylamide (Fig. 6). The compound *S*-(2-aminoethyl)-D-cysteine (4-thialysine), which was identified in the above experiment, was also gas chromatographically detected in the hydrolyzate after hydrogenation of epidermin with Pd/C. Further information was obtained from the fragments of a wild partial hydrolysis using 0.1 N HCl at 93 °C. The structural investigation of

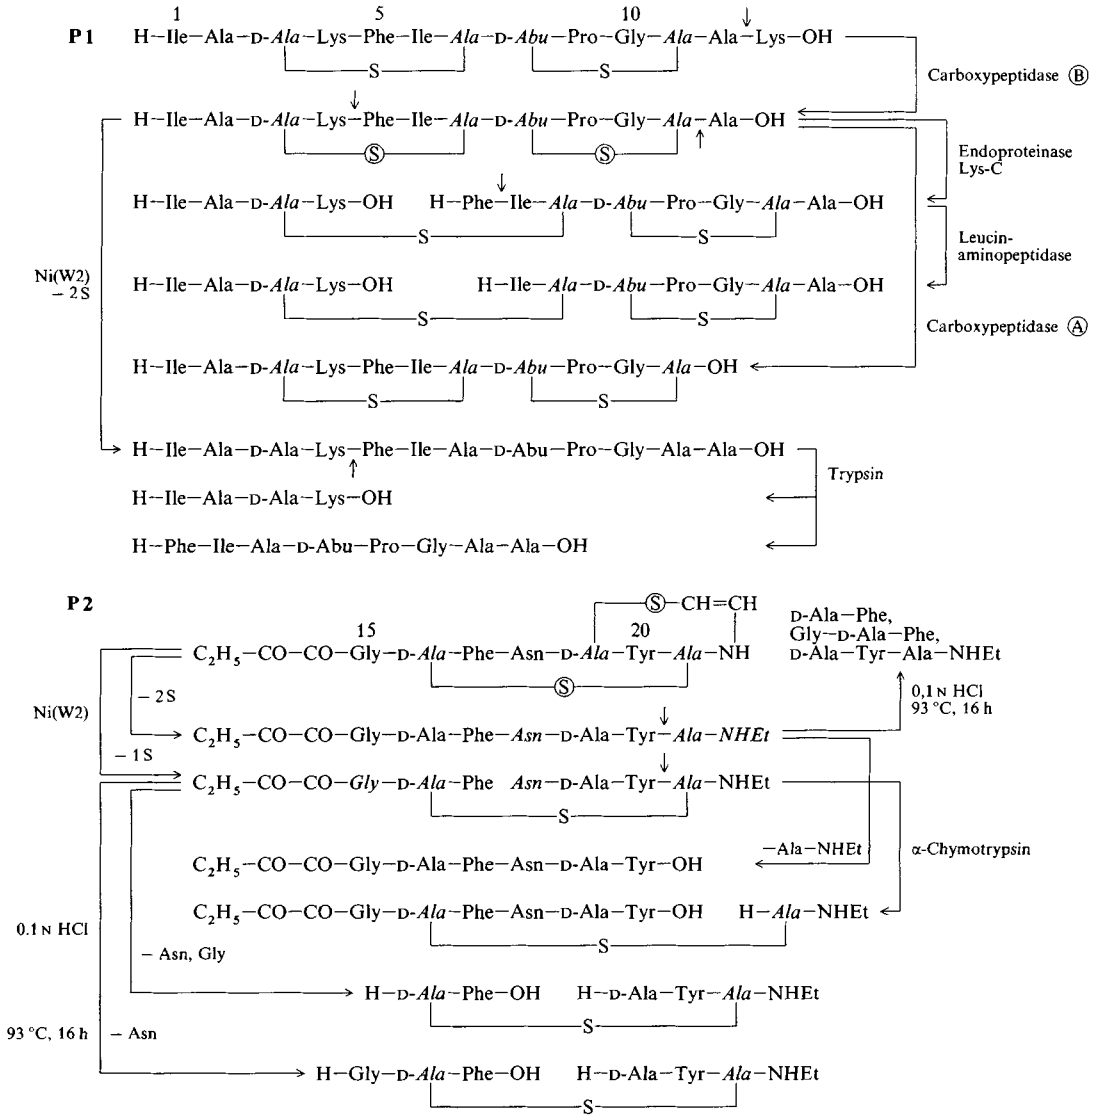

Fig. 6. Structural elucidation of epidermin by the preparative isolation of fragments **P1** and **P2** of the tetracyclic 21-peptide amide [4].

these fragments was achieved by means of mass spectrometry, end-group analysis and gas chromatography (GC) on chiral phases. Thus, for the first time in the case of epidermin, *S*-aminovinyl-D-cysteine could be determined as a building block in the C-terminal cycle of a peptide.[4]

The unequivocal elucidation of the structure of epidermin thus involved the use of many chemical, enzymatic and instrumental methods. For the structural elucidation of gallidermin, which is produced by *Staphylococcus gallinarum F16*,[111] we benefited from our experience with epidermin, but we used predominantly newer methods. The molecular mass of gallidermin was determined by FAB-MS. The sequence of the N-terminal segment up to Dhb^{14}, with the exception of the lanthionine bridge, could be determined by means of a gas-phase sequencer. The C-terminal fragment, obtained by tryptic digestion, could by characterized unambigously by the fragmentation pattern using thermospray LC-MS.[111] The complicated structure of the rings C and D could also be resolved on the basis of the thermospray mass spectrum. Finally, the connection of Lys^{13}-Dhb^{14} to the tryptic cleavage site could be deduced from the daughter ions of the FAB-MS.[111] Gallidermin was thus found to be [Leu^6]-epidermin (Fig. 7); it showed, despite this slight difference, a measurably increased antibiotic activity towards acne-producing germs.[11a]

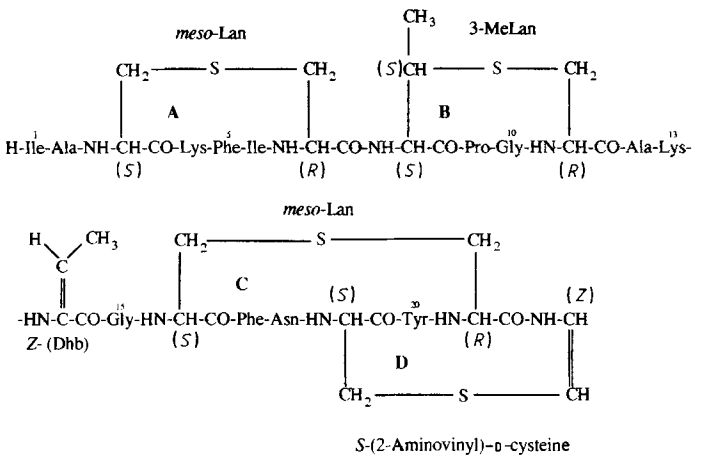

Fig. 7. Structures of the lantibiotics epidermin and gallidermin. The tryptic cleavage products **P1** and **P2** arise from proteolysis of the peptide bonds between residues 13 and 14 (cf. Fig. 5). Epidermin has Ile in position 6, gallidermin is [Leu^6]-epidermin.

The lantibiotics epidermin, gallidermin (Fig. 7) and Pep5 (Fig. 8) can be bound directly to the absorbing resin XAD-1180 from the culture medium.[21a-c] Pure epidermin and gallidermin are obtained by desorption and desalting on the ion exchanger IRC-50, and a final purification on RP-HPLC. Gallidermin can thus be prepared in an analyticaly pure enough form for clinical investigations.[21d]

3.3. The Lantibiotic Pep5

The lantibiotic Pep5 was isolated by *Sahl*,[10a] and, with a molecular mass of 3488 Da (FAB-MS), it is the largest representative of the lantibiotics known so far.[9] Owing to the presence of six Lys and two Arg residues, the tricyclic 34-peptide is extremely basic. Moreover, since it has a strong tendency to form dimers (cf. Section 3.1.), its structural elucidation was especially difficult. Pep5 contains three Dhb, two *meso*-Lan, and a (2*S*, 3*S*, 6*R*)-3-MeLan. In addition, the N-terminal residue is blocked by a 2-oxybutyryl group, which is derived from a Dhb residue, originating from a Thr in the prepeptide.

The key reactions in the structural elucidation of the strongly basic lantibiotic were enzymatic cleavage with chymotrypsin and endopeptidase Arg-C (Fig. 8).[9] Four pure

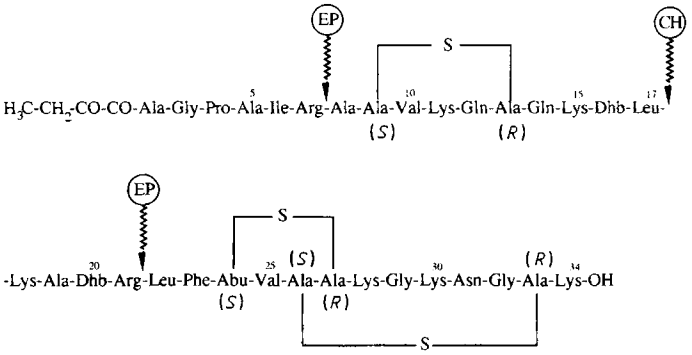

Fig. 8. Structure and main enzymic cleavage sites of the tricyclic, N-terminally blocked, 34-peptide antibiotic Pep5 [11]. Chymotrypsin (CH) cleaves the lantibiotic Pep5 into CH1 (1–17) and CH2 (18–34); endopeptidase Arg C (EP) cleaves CH1 into CA1 (1–7) and CA2 (8–17), CH2 is cleaved by EP to CA3 (18–21) and CA4 (22–34); besides one 2-methyllanthionine and two lanthionine bridges, there exist in position 1 one oxobutyryl (Oxb) and in positions 16 and 20 two dehydrobutyryl (Dhb) residues. Positions 1, 16, 20 and 24 in the precursor protein of Pep5 are occupied by four threonine residues (cf. Fig. 20).

fragments were obtained, which allowed the location of the sulfide bridges and the unsaturated amino acids. Mild acid hydrolysis effected preferentially peptide bond cleavage of Gly^3-Pro-Ala^5 from the N-terminal fragment CA1, which was also chemically synthesized for the comparative analysis. By means of the Edman degradation of enzymatic fragments, and above all, of the chemically derivatized fragments, a 34-peptide backbone could be deduced (Fig. 8). In this investigation, conversion of both Dhb residues into *S*-benzyl-3-methylcysteine by the addition of α-toluenethiol was useful. Interestingly, after this treatment with thiol, the blocked N-terminus becomes also accessible to the sequence determination. Therefore, using this addition product, the sequence 1–22 could be determined using a gas-phase sequencer. During this sequencing, no phenylthiohydantoin(Pth)-amino acids were detected at the sulfide bridges and the original Dhb residues.

3.4. Duramycins

In 1977 *Gross* published[7a], with reservation, the preliminary structures of cinnamycin[7b] and duramycin,[7c] which differed from each another by the Arg/Lys substitution at position 2. The structures published in the Refs. [2b, 7b, c] contain wrong amino acids and partly wrong rings. According to the newer investigations, these two lantibiotics fit into the general structural pattern of duramycins B and C,[7d] to

Table 3. Classification of the lantibiotics according to the charges, conformation and activity.

Lantibiotic	Charges positive	negative	net	Properties
Type A				
Pep5	8	1	7+	Long stretched, helical, cationic, amphiphilic polypeptide antibiotics; voltage dependent membrane channel formers
Nisin	4	1	3+	
Subtilin	4	2	2+	
Epidermin	3	0	3+	
Gallidermin	3	0	3+	
Mersacidin	3	1	0	
Actagardine	1	2	1−	hydrophobic
Type B				
Cinnamycin	3	2	1+	Compact, almost neutral amphiphilic polypeptides; enzyme inhibitors, immunologically active
Duramycin A	3	2	1+	
B	3	2	1+	
C	2	2	0	
Ancovenin	2	2	0	

which also belong the lantibiotics Ro 09-0189[6] (= cinnamycin[7], = lanthiopeptin[12], as well as leucopeptin[22] (= duramycin[7]) and ancovenin[5] (Table 3).

Reductive desulfurization (H_2/Pd, 10 Kp/cm^2, 50 °C) was employed for the structural elucidation of ancovenin[5] and lanthiopeptin.[12] By this ring opening and by using a proline specific endopeptidase, sequenceable fragments can be obtained. These fragments also enable establishment of the lysinoalanine ring position (Fig. 9). *Shiba*'s research group

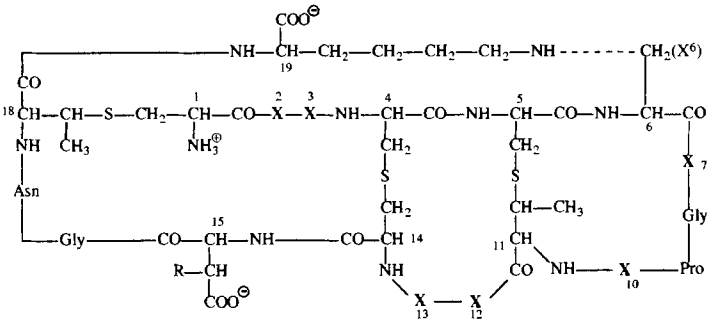

Fig. 9. General structure of the lantibiotics of subtype B (duramycins) according to *A. Fredenhagen* et al. [7d]. Amino acids X and residues R, see Table 4.

[a] Ala bridged with Lys^{19} as lysinoalanine; [b] α,β-didehydroalanine, not bridged with Lys^{19}; [c] L-Phe in cinnamycin; [d] proposed structures [7d].

ascertained the identity of the revised structure of Ro 09-0198[6] with lanthiopeptin.[12a] They pointed out[12c] its further possible identity with the known cinnamycin, and postulated that the lysine-containing duramycin is supposed to have the same ring system as Ro 09-1098 (= lanthiopeptin) (Ref. [10] in [12a]). The authors[12b] classified their lanthiopeptin producer L337-2 as *Streptoverticillium cinnamoneum*, whereas cinnamycin is produced by *Streptomyces cinnamoneus*.[7a] Therefore, cinnamycin has been twice more, duramycin one more rediscovered (cf. Tables 1 and 4).

3.5. Classification of the Lantibiotics according to Their Structural Features

The lantibiotics discussed so far, nisin, subtilin (Fig. 1), epidermin, gallidermin (Fig. 7) and Pep5 (Fig. 8), possess a series of common features which justify their classification in a subtype A, with nisin as a typical representative (Table 1). Lantibiotics of subtype A are strongly cationic peptides with two to seven positive charges and, with the exception of mersacidin and actagardine (Fig. 10), molecular masses of over 2100 Da, (Table 3). In spite of the different chain length, they show a clear structural relationship through sequence homology and similarity of the ring structure. In particular, the thioether amino acids are always N-terminal D- and C-terminal L-configurated, again with the exception of mersacidin and actagardine. Besides the unusual amino acids Lan and MeLan, only Dha and Dhb are to be found. Epidermin and gallidermin, whose C-terminal amino acids are altered through further modification to give Cys(Avi), are the exceptions here.[4, 11] The strains which produce the lantibiotics of subtype A are three *staphylococci*, one *streptococcus* and two *bacilli* (Table 1). Lantibiotics of the duramycin type (subtype B) are predominantly produced by *streptomyces* (Table 1). They have molecular masses of less than 2100 Da, and show markedly high ring homology (Fig. 9). In contrast to the lantibiotics of subtype A related to nisin, they contain at most one positive charge (Table 3).

Aside from the two sulfide bridges belonging to MeLan, and one belonging to Lan, which are always located at the same positions, another special feature of duramycins is the presence of a lysinoalanine bridge which binds the C-terminal Lys^{19} to position 6 (Fig. 9). In the case of ancovenin, this bridge is still not formed, therefore, ancovenin has another dehydroalanine residue at position 6. Not only the ring closure between positions 19 and 6, but also the sulfide bridges between positions 1 and 18 endow the lantibiotics of type B (duramycin) a more compact globular structure. This is in contrast with the more slender and screw-shaped lantibiotics of type A (nisin) (cf. Section 4.). All the duramycins show an *erythro*-3-hydroxyaspartic acid at position 15, with the exception of ancovenin in which this amino acid is not hydroxylated. Further common features within the subtypes A and B will be discussed in connection with the conformation, and above all, with the biosynthesis of lantibiotics.

3.6. Mersacidin and Actagardine

Nothing is known about the conformation or the biosynthesis of mersacidin,[8a] which was recently elucidated by means of 2D-^{1}H-NMR spectroscopy.[8a] It is difficult to classify this neutral lantibiotic (Fig. 10) to one of the sub-

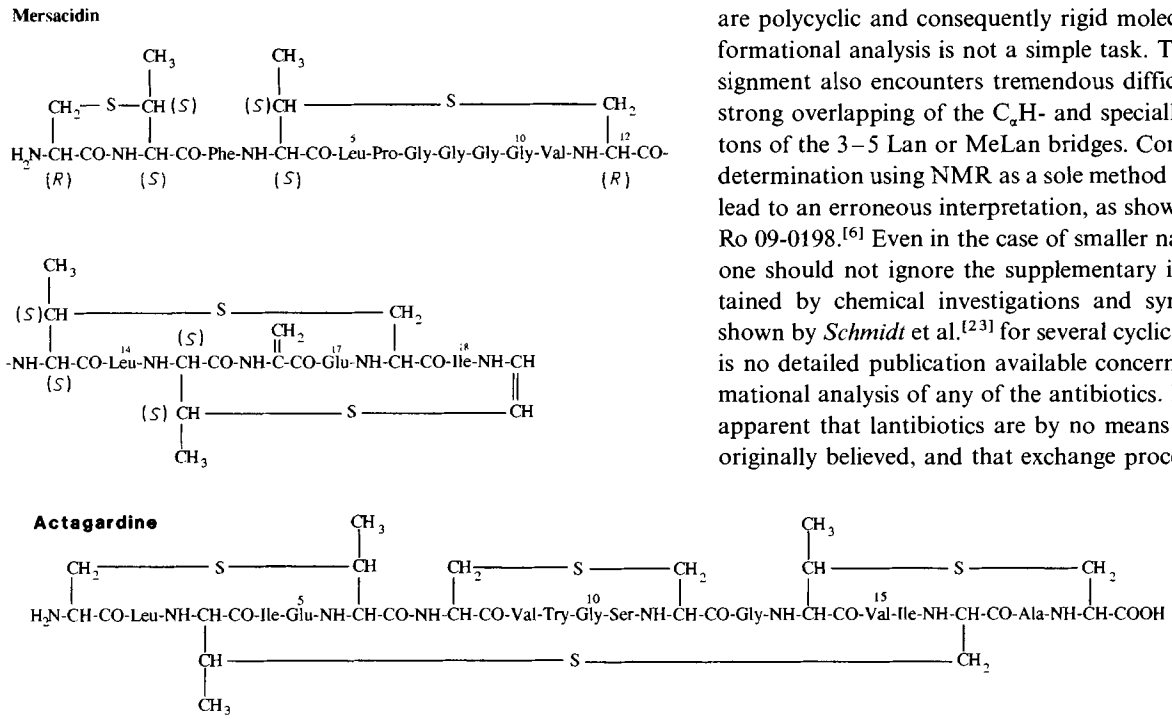

Fig. 10. Proposed structural formulas of the tetracyclic lantibiotics mersacidin [8a] and actagardine [8b] according to NMR studies.

types listed in Tables 1 and 3. On the one hand, like the duramycin type B it has a molecular mass of less than 2100 Da and no cationic properties, and on the other, it lacks the head-to-tail linking by sulfide and amine bridges, typical for duramycins. Since the C-terminus is amidated by a ring closure with the amino group of *S*-aminovinyl-L-cysteine with the *Z* configuration, it could more properly be compared with epidermin/gallidermin. To group A fits also the mersacidin producing bacillus, as well as the ring formation pattern with exception of the unusual MeLan bridge between positions 1 and 2.

The structural classification of actagardine is even more difficult; the proposed structure of this lantibiotic, which is effective against streptococci, was determined mainly by 2D ^{1}H NMR and was shown to be a heterodet tetracyclic 19-peptide.[8b] Actagardine is now the recommended name for an antibiotic family formerly called gardimycin.[8c-e] The published ring structure consists of one Lan and three MeLan bridges. In contrast to the type A lantibiotics, actagardine is an acidic and strongly hydrophilic molecule. Using actagardine as an example, it could be shown that chemical derivatization could convert a lantibiotic into an antibiotic with higher in vivo and in vitro activities.[8c]

4. Conformational Studies

Different research groups are currently investigating the conformation of the lantibiotics, mainly nisin, gallidermin/epidermin, Ro 09-0198, ancovenin and Pep5 by NMR spectroscopy. In this process, the structurally relevant parameters such as coupling constants, NOE-effects and temperature dependency are obtained from 1D and 2D experiments. These studies provide an experimental basis for the molecular geometry calculations. In spite of the fact that lantibiotics are polycyclic and consequently rigid molecules, their conformational analysis is not a simple task. The sequence assignment also encounters tremendous difficulty due to the strong overlapping of the $C_\alpha H$- and specially the $C_\beta H$-protons of the 3–5 Lan or MeLan bridges. Complete sequence determination using NMR as a sole method could especially lead to an erroneous interpretation, as shown in the case of Ro 09-0198.[6] Even in the case of smaller natural products, one should not ignore the supplementary information obtained by chemical investigations and syntheses, as was shown by *Schmidt* et al.[23] for several cyclic peptides. There is no detailed publication available concerning the conformational analysis of any of the antibiotics. It now becomes apparent that lantibiotics are by no means as rigid as was originally believed, and that exchange processes render determination of the solution conformation difficult. Nonetheless, the existing information makes it possible to draw several fundamental conclusions regarding the crude structure of the different lantibiotic types.

4.1. Conformation of Nisin

Several research groups are studying the conformation of nisin. Of these, three groups in the Netherlands, in the U.S.A., and in the UK have made similarly great progress. So far, the sequence specific assignments of the ^{1}H-NMR signals, deduced from the 400/600 MHz 2D experiments in H_2O/D_2O (DQF-COSY, TOCSY, NOESY), have been published.[24] An analysis of the NOE data showed a definite orientation of the rings A and B of the nisin N-terminal segment. Thus, proline 9 of ring B points towards ring A, and the side chains of methionine residues 17 and 21 are turned towards each other. Presumably the N-terminus of nisin forms an amphiphilic screw, similarly as in the case of epidermin and gallidermin (cf. Section 4.2.). A helix-like structure can also be expected on the basis of biophysical measurements on the ion channels[10c] which are induced by nisin, as will be shown in the following section.

Chan et al.[25] carried out further NMR experiments and was able to elucidate the structures of two acidic cleavage products of nisin, as well as a complete sequential signal assignment. Nisin 1–32 amide, which has lost two amino acids at the C-terminus, shows antibacterial activity similar to that of the native molecule (compare Fig. 2), whereas additional removal of Dha^5 or the ring A leads to a loss of activity.[25] *Palmer* et al.[26] report a comparative NMR and MDS conformational study of the separate rings A–E, as well as of the whole nisin molecule. The conformations of the separate rings are said to be very similar to the native nisin.

4.2. Conformation of Epidermins

Investigations on the conformation of the two lantibiotic analogues with Leu/Ile exchange in position 6 have been carried out by 2D ^{1}H NMR in water, dimethyl sulfoxide, and particularly in trifluoroethanol/water (9:1) at 500 MHz.[27] Preliminary results have briefly been described.[28]

Interproton distances from 190 NOEs (NOESY with different mixing times; cf. Fig. 11 and 12), dihedral angles from coupling constants (*J*-resolved 1D DQF COSY), and potential hydrogen bond donors from the temperature dependancy of the amide protons served as a basis for the MDS investigations to deduce the dominant conformation in a lipophilic medium (Fig. 13). For comparison, the conformations of the N-terminal fragment (1–13) and the whole molecule in DMSO and water were investigated. The C-terminus in particular shows a strong signal broadening in DMSO, which can be attributed to exchange processes with the traces of water present in DMSO. The screw-shape conformation is present in all the solvents (no regular helices). In the MDS study, based on the experimental data of the 2D-NMR measurements, the screw-like overall conformation remains surprisingly stable (Fig. 13). Solvent dependent NMR measurements, however, show local conformational changes corresponding to the behavior during the molecular dynamics simulation.

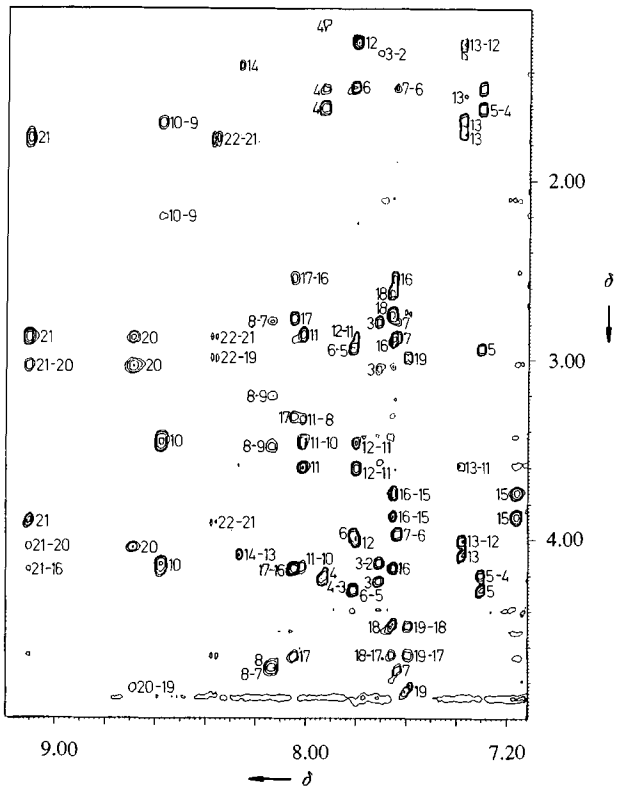

Fig. 12. ^{1}H-NMR NOESY (500 MHz) spectrum of gallidermin (T_M = 200 ms, TFE/H_2O (9:1)): The section shows conformational NOE-effects between the amide protons and CH_α, as well as the side chain protons.

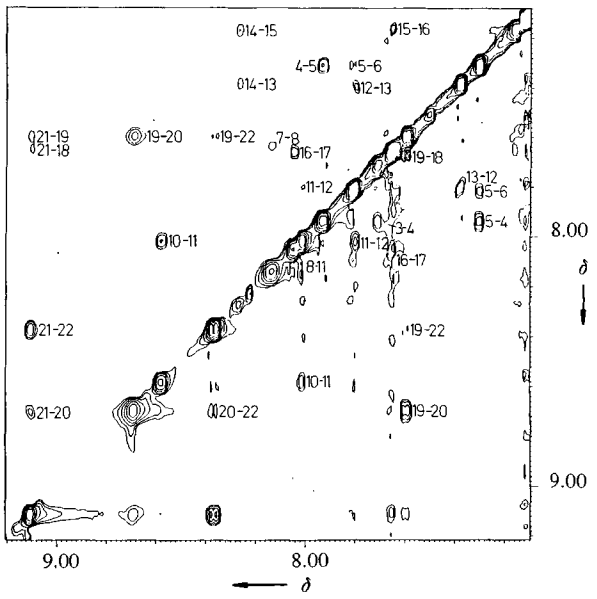

The results of the measurements in trifluoroethanol (Fig. 13) could serve as a clue to the behavior of the epidermins in lipid membranes. The stretching of the molecule to a total length of 30 Å, renders the bridging of the lipid bilayer membrane possible. Moreover, the helical arrangement causes the molecule to become amphiphilic with a lipophilic C-terminal segment, and a threefold positively charged hydrophilic side which is located at the N-terminal half of the helix (Fig. 13). Previous CD measurements on epidermin in different solvents also indicate the existence of a uniform conformation. On the basis of our conformational investigations, the epidermins exhibit a dipole moment of about 54 Debye in DMSO, which increases to 75 Debye through transition to a long stretched helix in the more lipophilic solvent trifluoroethanol. The structure of gallidermin in water is used by us in MDS studies as a guide for developing trypsin stable analogs (Fig. 14).

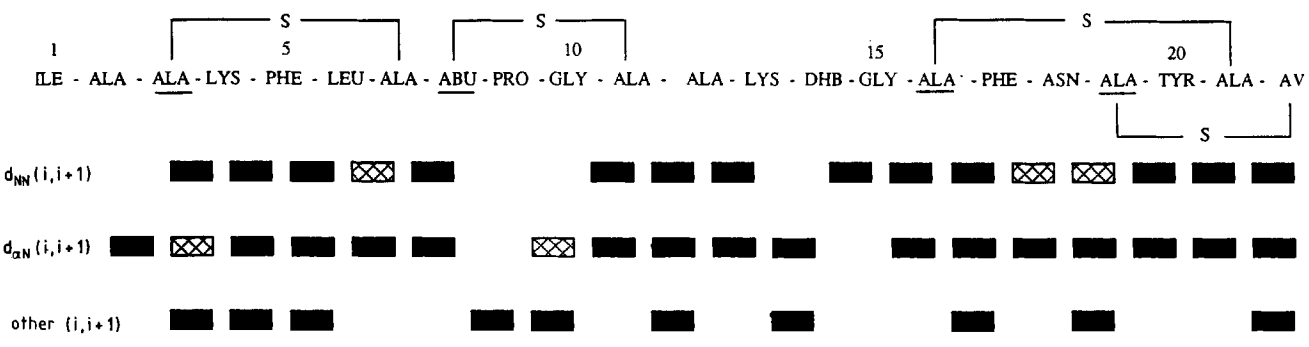

Fig. 11. Top: ^{1}H-NMR NOESY (500 MHz) spectrum of gallidermin (= [Leu^6]-epidermin) in trifluoroethanol/water; mixing time t_M = 200 ms. The segment shows NH_i-NH_{i+1} contacts, which occur typically in the helical parts. Bottom: Summary of all the sequential contacts.

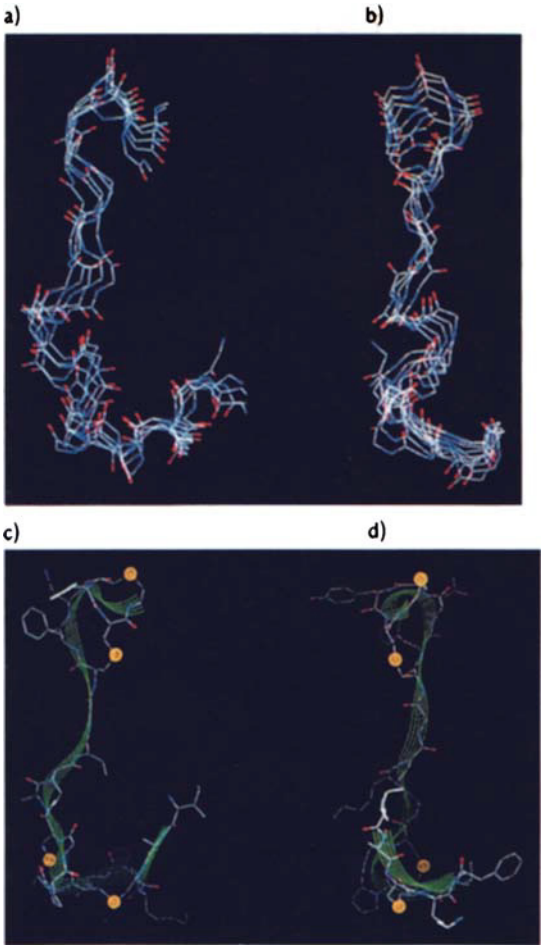

Fig. 13. Representation of the conformation of gallidermin as deduced from an MDS investigation on the basis of the conformational parameters derived from 2D-NMR measurements. a) and b) orthogonal depiction of five convergent structures (only backbone atoms: red = O, blue = N, white = C, light blue = H); c) and d) backbone as ribbon (green) with sulfide rings (yellow = S) and side chains.

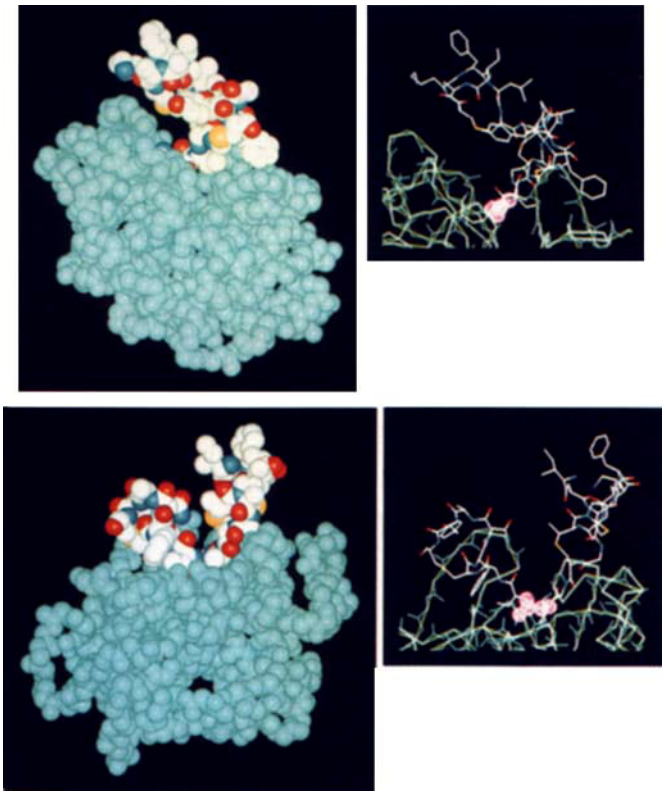

Fig. 14. Model of the gallidermin-trypsin interaction. Trypsin cleaves gallidermin at Lys^{13}-Dhb^{14} (purple atoms; cf. Figs. 5, 6). The model was calculated using distance geometry molecular dynamics simulations (DGEOM, Amber). Gallidermin assumes a bent conformation upon fitting to the enzyme cleft, thus it shows similarity to the trypsin inhibitor BPTI (bovine pancreatic trypsin inhibitor). On the basis of this structural model, it is possible to construct stable analogs against trypsin.

4.3. Conformation of Pep5

For the tricyclic lantibiotic Pep5 with two α,β-didehydroamino acids, we could prove the existence of a helical structure in a lipophilic surrounding by CD measurements. This is formed, e.g., in trifluoroethanol or other alcohols and in water after the addition of sodium dodecylsulfate. According to our preliminary NMR investigations in trifluoroethanol and water, the linear region 14–22 in particular (Fig. 8) is helical ($\alpha/3_{10}$) in the former solvent, as shown by the strong NH–NH-contacts in this segment. We are currently investigating the conformation of Pep5 in trifluoroethanol and water using NMR and MDS methods.

4.4. Conformation of the Duramycin Type B

The conformation of the tetracyclic 19-peptide antibiotic Ro 09-0198 (= cinnamycin = lanthiopeptin) in solution[6] can serve as a model structure for MDS investigations of all the lantibiotics of the duramycin type B (Tables 1 and 3). The cinnamycin molecule has a compact, almost globular structure in DMSO.[6] In this molecule, the hydrophilic amino acids are located on one side, the lipophilic ones, including the three phenylalanines, on the other half of the molecule. The natural exchanges within the lantibiotic series of type B (Fig. 9) such as, e.g., Lys^3/Arg, Gln^3/Asn, Phe^7/Tyr, Phe^{10}/Leu, Phe^{12}/Trp could hardly change the overall conformation; however, they cause pronounced differences in the biological properties.[7] The jump from duramycin C[7d] to ancovenin[5] is considerably larger, which is due to the fact that the lysinoalanine bridge is missing and the position 6 is occupied by dehydroalanine with its conformationally restricting properties.

Interestingly, cinnamycin shows analogous inhibitory properties on the angiotensin converting enzyme (ACE),[6b] as has been reported for ancovenin.[5] Apparently, the fourth ring of cinnamycin does not destroy the binding to the enzyme; but unfortunately no data are available for comparison. Therefore, it is not clear which structural elements are responsible for the ACE inhibitory action. Only a short note has appeared about the ancovenin conformation in DMSO.[5b] Accordingly, ancovenin in DMSO shows, similarly to cinnamycin, a compact conformation with the amphiphilic character.

The antibiotic activity of the duramycins could be due to interactions with the membrane components, as has been shown by studies on duramycin resistant bacilli.[7e–m] Duramycins and cinnamycin are potent inhibitors of human phospholipase A_2 which show activity in the micromolar region.[7d] Also in the enzyme/inhibitor interaction, the am-

phiphilicity and presumably the membrane accessibility of duramycins certainly play a decisive role.

5. Biosynthesis of Lantibiotics

5.1. Lantibiotics Evolve from Precursor Proteins

The most exciting aspect of lantibiotic research is undoubtedly the biosynthesis of these molecules. *Hurst*[3] and *Ingram*[30] found that inhibitors of protein synthesis hinder nisin production in the *Streptococcus lactis* suspension. *Hurst* could demonstrate the plausibility that when basic peptide extracts from a nonproducing strain are added to a cell extract of the wild type, nisin will be produced. These were the first experimental hints that nisin, unlike other peptide antibiotics, is not biosynthesized by a multienzyme thiotemplate mechanism,[31] but by ribosomally synthesized precursor proteins.[3, 31] By employing radioactively labeled cysteine, threonine and serine, *Ingram* showed that these amino acids are precursors of lanthionine and 3-methyllanthionine. By using [^{35}S]-labeled cysteine, it could be shown that the inactive precursor proteins of subtilin could be converted into subtilin.[32] A subtilin precursor was immune-precipitated with the antisubtilin antiserum,[32, 33] however, it was not characterized in detail. Hints about a plasmid controlled biosynthesis of nisin were first reported by *Kazak* et al.[33]

Apart from the structural elucidation of epidermin,[4] we were interested in its biosynthesis. In the case of epidermin, it was likewise possible to prove its ribosomal biosynthesis and to block production of the antibody by addition of inhibitors of the protein and RNA synthesis.[34] At that time, it was not clear whether lantibiotics are built by the cleavage of larger proteins, or whether they are produced by a very special biosynthetic system via independent structural genes, e.g., in the same way as hormones from prepeptides. As long ago as 1985 we first explicitly postulated the amino acid sequence of the precursor peptides of the lantibiotics nisin, subtilin, and epidermin, and we attempted to isolate a precursor peptide of epidermin.[4, 29]

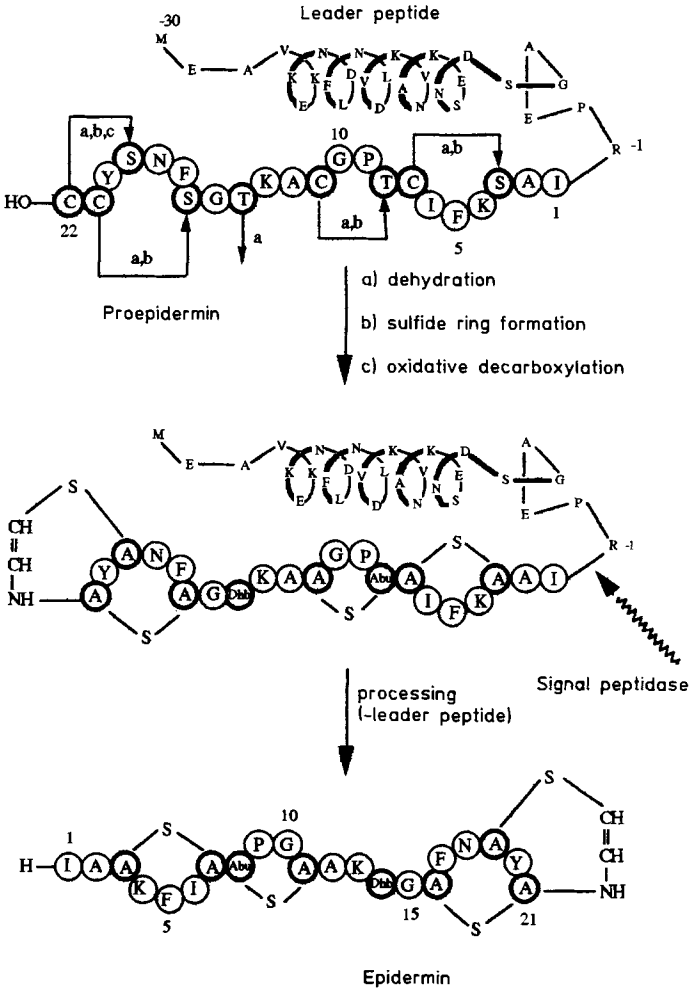

Fig. 15. Postulated [4, 29] and proven [1] events of the epidermin biosynthesis by modification of the precursor protein, preepidermin (amino acids in the single letter codes).

5.2. Prelantibiotics and Their Structural Genes

We assumed a ribosomal synthesis of a proepidermin which is enzymatically dehydrated at the serine and threonine residues in the modification steps (Fig. 15).[4] Subsequently, four cysteine thiol groups are supposed to add stereospecifically to the four α,β-didehydroamino acids to build the sulfide rings.

Assuming this order of events and the sequence-specific proof of the C_α-configurations of the Lan and MeLan residues, we postulated a proepidermin which carries at the resulting lanthionine half with D configuration (= *S*) the precursor amino acid—L-serine for *meso*-lanthionine, and L-threonine for (2*S*, 3*S*, 6*R*)-3-methyllanthionine. The C-terminal half of the sulfide bridges with the L-configuration (= *R*) must then originate from L-cysteine. Consequently, the configuration of the C_α-atoms of the L-Ser and L-Thr residues in the prolantibiotics are inverted during conversion into lantibiotics. In the case of epidermin in particular, an α,β-(*Z*)-didehydrobutyrine residue (from threonine) remains in the middle of the molecule which does not encounter a further cysteine residue for the addition. Furthermore, we postulated an additional enzymatic modification during epidermin synthesis in which the unusual cyclic vinylamide develops at the C-terminus (Figs. 6 and 7). The appearance of the Nδ-amide linked building block *S*-(2-aminovinyl)-D-cysteine in the position 19 can be explained by assuming that a further C-terminal Cys^{22} exists whose thiol group adds to Dha^{16} and is subsequently decarboxylated[4, 29] (cf. Fig. 17).

It was completely unclear in which form such a prelantibiotic could be found: bound to a signal sequence, as a segment of a protein, as a free or membrane bound peptide, unmodified or partially modified. Therefore, several strategies have been used for studying lantibiotic biosynthesis. In the case of epidermin—two experimental attempts—the direct isolation of the basic precursor protein, as well as proof of the prelantibiotic by means of the antipeptide antibodies have long been unsuccessful. In the case of Pep5, however, both methods recently led to success in collaboratory studies with *Sahl*.[38]

In cooperation with the microbiologists *Entian* and *Götz*, gene technological methods have been employed as a third and rapidly successful method.[1] Using a mixed DNA probe derived from the pentapeptide sequence Lys-Phe-Ile-Cys-Thr of proepidermin,[4, 29] the structural gene of epidermin was searched for. This synthetic oligonucleotide 5'-GTG(A)-CAT(G,A)ATG(A)AAT(C)TT-3' gave a hybridization signal with the 54 kilobase (Kb) plasmid *pEpi 32* of *Staphylococcus epidermis Tü 3298*. With restriction analyses, subcloning and rehybridization, the structural gene of epidermin *epi* A could be localized on a 2.2 Kb *Eco* IR/*Bg* III fragment.[1]

The sequencing of *epi* A according to the dideoxy method of *Sanger* yielded an open reading for the epidermin with 52 amino acids (Fig. 16).[1] The beginning of the reading frame

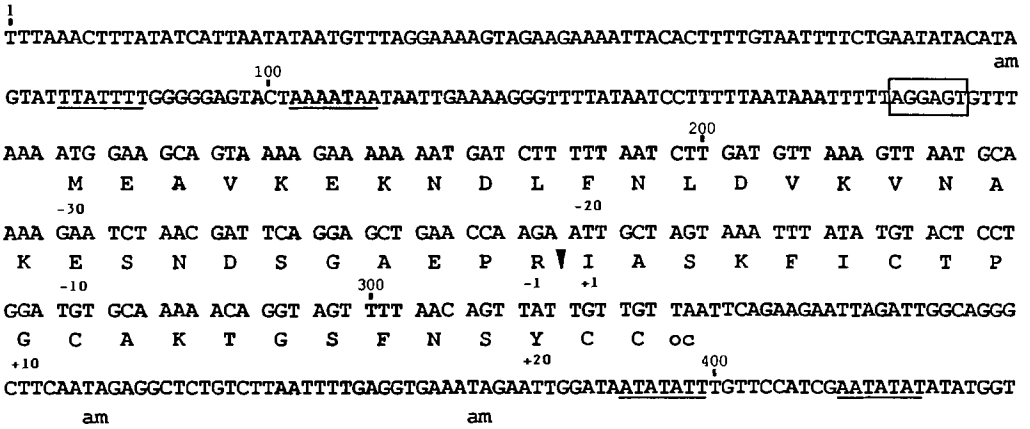

Fig. 16. Preepidermin structural gene: Open reading frame of 237 base pairs is defined by the codons TAG (amber) and TAA (ocher); Shine-Dalgarno sequence is framed; inverted repeats (underlined); proteolytic cleavage point of the signal peptidase (arrow) between leader peptide and proepidermin segment [1]. Amino acids in one letter codes: Leader peptide − 30 to − 1, proepidermin + 1 to + 22.

is marked by a single methionine codon ATG, which localized seven base pairs after a Shine-Dalgarno sequence AGGAGT; a TAA stop codon terminates the structural gene, directly after the two base triplets TGT which code two consecutive cysteine residues. In front of the structural gene of the prolantibiotic there is a leader sequence of 30 amino acids in length. The processing site for epidermin lies between Arg^{-1} and Ile^{+1}. The sequencing of the epidermin structural gene[1] demonstrated for the first time that lantibiotics evolve from ribosomally synthesized precursor proteins (Fig. 16).

Following this breakthrough, further research activities progressed rapidly. After epidermin, the structures of the complex antibiotics gallidermin,[11] Pep5[9] and, in collaboration with *Kessler*, cinnamycin[6] could be elucidated. The research team of *Entian* determined—on the DNA level—the sequences of the structural genes of the prelantibiotics pregallidermin[35] and pre-Pep5,[36] whose structures have been postulated by us, and finally, precinnamycin as a representative of lantibiotics of the type B.[37] The research team of *Götz* succeeded in characterizing the gallidermin-producing gene completely. The sequences of many of the participating enzymes in the biosynthesis of epidermin could be determined—on the DNA level—by *Entian* and his co-workers. At the same time *Hansen* and associates,[18b] and simultaneously *Entian* et al.[18a] determined the sequence of the structural gene of nisin. *Banerjee* and *Hansen* determined the precursor gene of subtilin.[19] In conclusion, it must be emphasized that the chemical structure of the lantibiotics which have been elucidated by us, could also be confirmed in detail by the sequencing of the structural genes. Finally, we could determine the sequences of the precursor proteins of the Pep5 biosynthesis which recently have been isolated by *Sahl*.[38] Some of these results will be discussed in the following section.

5.3. Comparison of the Lantibiotics

A comparison of the prediction profiles of the secondary structure, flexibility, hydropathy and hydrophilicity, which have been plotted with the help of our program EPICON 89,[39] as well as the helix-wheel plots of the six prelantibiotics known so far (Table 5) show surprisingly great similarities (Fig. 17).

Table 5. Lantibiotic precursors: Sequence length and localization of the structural gene (cf. Table 1).

	Leader peptide	Prolantibiotic	Prelantibiotic	Structural gene
Type A				
Epidermin [1]	− 30 → − 1	+ 1 → 22	52	Plasmid
Gallidermin [35]	− 30 → − 1	+ 1 → 22	52	Chrom. DNA
Pep5 [36]	− 26 → − 1	+ 1 → 34	60	Plasmid
Nisin [18]	− 23 → − 1	+ 1 → 34	57	Plasmid/DNA
Subtilin	− 24 → − 1	+ 1 → 32	56	Chrom. DNA
Type B				
Cinnamycin [37]	− 58 → − 1	+ 1 → 19	77	Chrom. DNA

Particularly striking is that all the leader sequences are very hydrophilic and strongly charged, do not contain cysteine, and most probably are folded to an amphiphilic α-helix in a lipophilic environment. In contrast, the prolantibiotic sequence is more lipophilic and its secondary structure is characterized by the preferential β-turn and lack of α-helices. It contains Ser, Thr and Cys, which become mod-

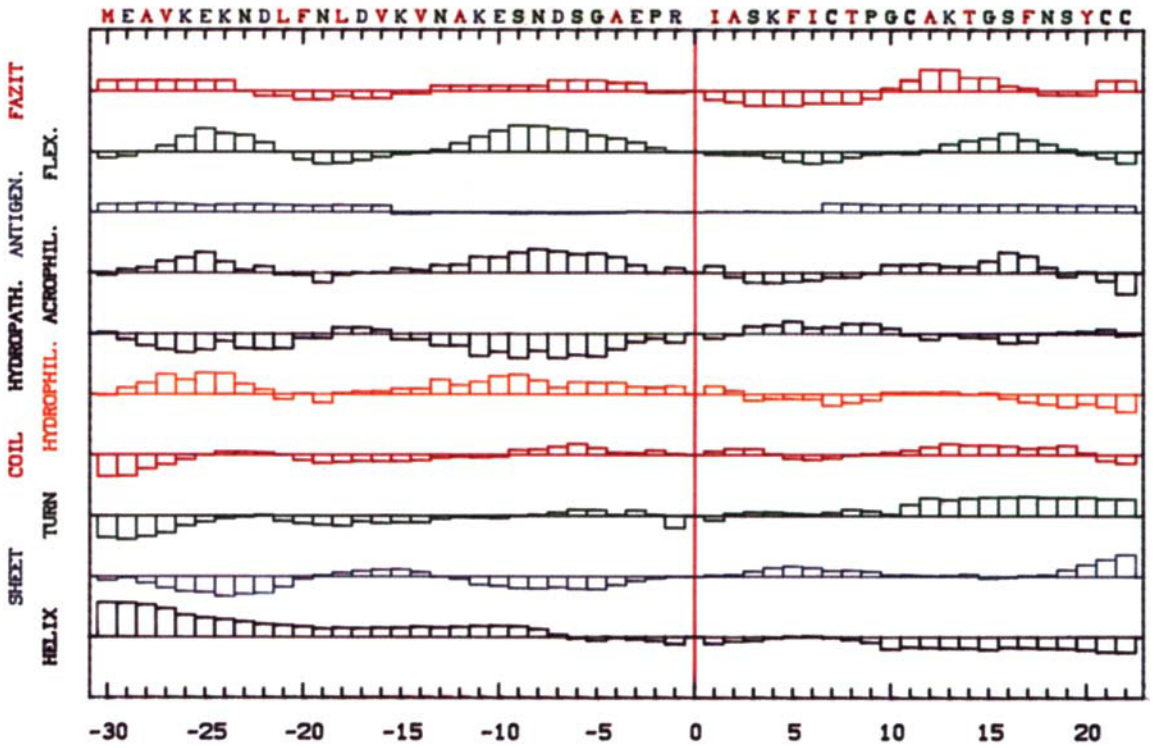

Fig. 17. Prediction profile of the epidermin precursor with the leader sequence − 30 to − 1, and prolantibiotic segment 1–22 [1], as determined by the program EPICON 89 [39]. "Fazit" is the sum of the following differently weighted predictions, and indicates the positions of the possible continuous B-cell epitopes. Flexibility (Flex.) shows flexible surface areas; antigenicity (antigen.) is calculated from the parameters derived from a comparison of the known sequential epitopes for different protein types; acrophilicity (acrophil.) shows the surface probability; hydropathy (hydropath.) predicts hydrophobicity, and hydrophilicity (hydrophil.) hydrophilic region. The prediction of the secondary structure is illustrated by the coil, turn, β-sheet and α-helix probabilities.

Type B Prolantibiotics*:

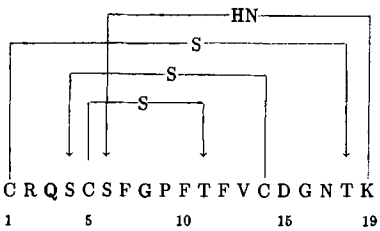

Fig. 18. Formation of the sulfide rings and α,β-didehydroamino acids in the prolantibiotic segment of prelantibiotics of type A (a–e) with the known structural genes (upper half). The prolantibiotic sequences of (f) and (g) are still not confirmed on the basis of their DNA; in the case of (g), configurational assignments of the C_α-carbon atoms are lacking. The sulfide ring formation in prelantibiotics of type B is shown in the lower half of the Figure. From the type B prolantibiotics, so far only the sequence of the structural gene of precinnamycin has been determined. * The arrows indicate direction of the sulfide bridge formation, starting from L-cysteine. Half of the *meso*-Lan and (2*S*, *S*, 6*R*)-3-MeLan molecules with the D-configuration are formed by the addition of L-cysteine thiol groups to Dha (from L-Ser) and Dhb (from L-Thr) residues, respectively. Underlined Ser and Thr residues remain Dha and Dhb in the processed lantibiotic (valid only for the type A). ** No lysinoalanine bridge 19 → 6 in ancovenin; however, with the exception of ancovenin, all the type B lantibiotics possess HyAsp in the position 15.

ified to α,β-didehydroamino acids and build sulfide bridges (Fig. 18).

The atypical leader sequences possess no lipophilic segment containing more than four amino acids; moreover, they contain many bonds accessible to endopeptidase cleavage. In contrast, the prolantibiotic part seems to be more resistant towards proteases. In the mature lantibiotics, such as, e.g., the epidermins and duramycins, there exist mostly only a few typical cleavage sites.

It is interesting to compare the processing site of the prelantibiotics (Table 6). Evidently the signal peptidases, which cleave the mature lantibiotic from the leader sequence, can attack a well-accessible and hydrophilic turn. Table 6 underscores the strong conservation of this site in the prelantibiotics of subtype A: The residues (+ 2) and (+ 1) are mainly hydrophobic, (− 1) is positively charged or polar, (− 2) always Pro, (− 3) negatively charged or polar, (− 4) always hydrophobic. With the help of fluorophor-labeled substrates of the signal peptidase, we are currently searching for the processing enzymes in the cell extracts.

Table 6. Signal peptidase cleavage sites (−) of prelantibiotics and prehormones (for comparison).

Prelantibiotics (cf. Table 5) [a]	− 5	− 1 +1
Nisin	Gly-Ala-Ser-	Pro -Arg—Ile-Thr-Ser-Ile
Subtilin	Lys-Ile-Thr-	Pro -Gln—Trp-Lys-Ser-Glu
Epidermin	Gly-Ala-Glu-	Pro -Arg—Ile-Ala-Ser-Lys
Gallidermin	Gly-Ala-Glu-	Pro -Arg—Ile-Ala-Ser-Lys
Pep5	Glu-Leu-Glu-	Pro -Gln—Thr-Ala-Gly-Pro
Cinnamycin	Thr-Glu-Ala-Phe-Ala—	Cys-Arg-Gln-Ser
Prehormones (for comparison)		
ANP	Ala-Gly-	Pro -Arg—Ser-Leu-Arg
Substance P	Ile-Ala-Arg—Arg-	Pro -Lys-Pro

[a] Modified amino acid residues in the lantibiotic are marked

In comparison to the precursor proteins of the lantibiotic type A (e.g. nisin), the only known prelantibiotic of type B differs considerably. This is precinnamycin (= pre-Ro 09-0198, prelanthiopeptin), whose structural gene sequence was recently determined by *Kaletta* and *Entian*.[37] Remarkably, the leader sequence of this prelantibiotic of subtype B is about twice as long, i.e., it consists of 58 amino acids (Table 5). It is predicted that the part which immediately follows N-terminally to the processing site, has a high α-helix probability. Similarly as in the other lantibiotics, one finds here high lipophilicity and β-turn probability in the 19 amino acid segment which C-terminally follows the leader peptide, and in which the ring formation takes place. The completely different processing site of procinnamycin (Table 6), which by no means shows homology to the prelantibiotics of subtype A, likewise points to different signal peptidases for these two subtypes.

5.4. Synthesis and Conformation of Leader Peptides

In order to obtain experimental data about the α-helix in the leader region of the prelantibiotics, as shown by the prediction plot, we synthesized all the leader peptides by the Merrifield method, using the Fmoc/*t*Bu strategy and maximum side-chain protection.[40] The amino acids were activated by the new coupling reagent TBTU (2-(1*H*-benzotriazol-1-yl)-1,1,3,3-tetramethyluronium tetrafluoroborate). After purification on Sephadex G25 and RP18-HPLC, very pure products were obtained whose identification was achieved by amino acid analysis, racemization test, Edman degradation, and ion-spray mass spectrometry.

Circular dichroism spectra were recorded in trifluoroethanol/water mixtures. Two negative Cotton effects at 207 and 220 nm as well as a positive ellipticity at 194 nm indicated an α-helical conformation in all the leader peptides (Fig. 19). The α-helical content increased as expected with increasing lipophilicity of the solvents. By comparing these peptides with peptides of similar size and known α-helix content, an α-helix content of 70 ± 15% in trifluoroethanol/water (9:1) could be estimated. Therefore, the extremely hydrophilic prelantibiotic leader peptides possess a very high α-helix content in a lipophilic medium. Before discussing the results of these studies concerning the biosynthesis, I would like to outline the exciting results obtained on isolation and characterization of the intermediates in the biosynthesis of the lantibiotic Pep5.

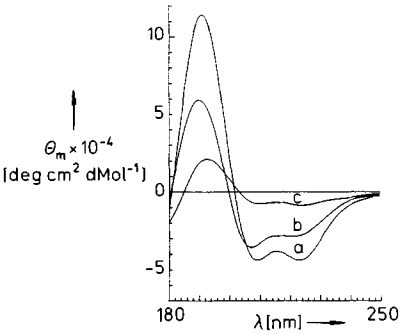

Fig. 19. CD-Spectra of the isolated natural precursor protein pre-Pep5 (sequence −26 to +34) of lantibiotic Pep5 (a), synthetic α-helical leader peptide −26 to −21 of Pep5 (b), and isolated naturally occurring lantibiotic Pep5 (c) in trifluoroethanol/water (9:1).

5.5. Isolation and Structural Elucidation of Modified and Unmodified Prelantibiotics

In collaboration with *Sahl*, we attempted to characterize the precursor protein of pre-Pep5, as a primary translational product in the biosynthesis of the tricyclic lantibiotic Pep5.[9, 10] A 60 amino acids long pre-Pep5 could be deduced from the sequencing of the structural gene.[36] The synthetic helical leader peptide with 26 amino acids was used as an immunogen to produce polyclonal antibodies. In the crude extracts of the Pep5-producing strain *Staphylococcus epidermidis 5*, several similar proteins with molecular masses of 6000 to 7000 Da have been identified. These proteins were subjected to RP-HPLC for a rapid isolation and characterization.[38] For the isolation, a high concentration of the serine protease inhibitor, phenylmethylsulfonyl fluoride (PMSF), had to be added.

One of the two isolated proteins reacted likewise with the polyclonal serum, which was obtained after immunization with a C-terminal Pep5 fragment containing two sulfide bridges. Neither lanthionine nor 3-methyllanthionine have been detected by amino acid analysis of this isolate. We were able to carry out an automated Edman degradation using a gas-phase sequencer and on line PTH detection with about 800 pmol material. The amino acid sequence obtained was comparable to the Edman degradation of 400 pmol of the synthetic leader peptide[40] (Fig. 20). Edman degradation, however, stopped at the first threonine residue of the prolantibiotic region. We considered this an indication of the post-translational modification that had already occurred at this position.[38]

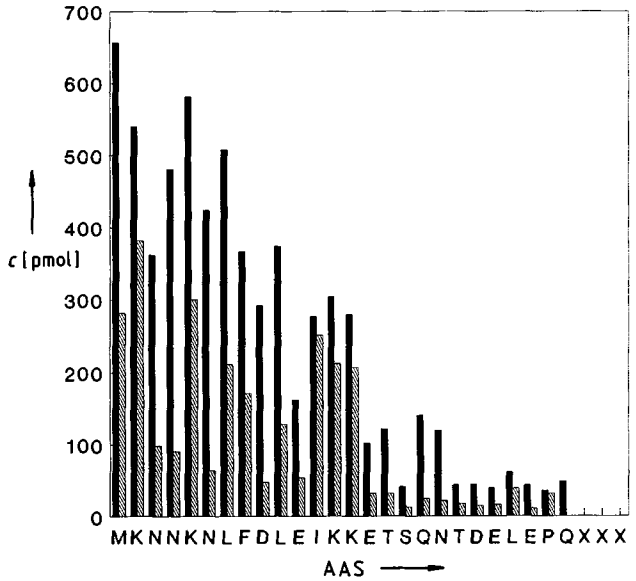

Fig. 20. Yields of the Edman degradation steps of the isolated pre-Pep5 (black columns) compared with the degradation of the synthetic leader peptide −26 to −1 (shaded columns). c = concentration of PTH-amino acid in pmol per degradation step, AAS = amino acid sequence.

With the modest amount of peptide solution which remained available after the Edman degradation, we could carry out a mass spectrometric investigation using the new method of ion-spray mass spectrometry with the API-III spectrometer. The solution was fed to the spectrometer via a glass capillary at the rate of 5 μL/min for 10 min. From the resulting mass spectra of the multiply charged prelantibiotic ions, a molecular mass of 6575 ± 1.7 Da was determined (Fig. 21). This agreed with a pre-Pep5 molecule which is dehydrated at the four threonine and two serine residues of the prelantibiotic region. This sixfold dehydrated protein has a calculated molecular mass of 6576.7 Da.

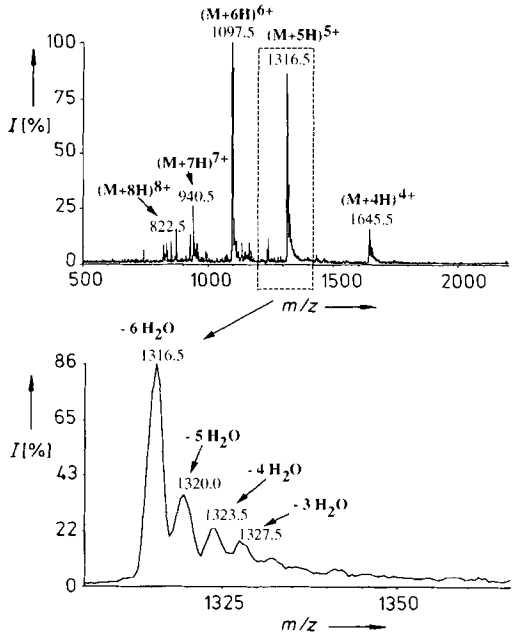

Fig. 21. Ionspray API-III mass spectrum of the isolated and 6-fold dehydrated pre-Pep5. The peaks correspond to each molecular ion with the same molecular mass of 6575 ± 1.7 Da, but with different charges (4+ to 8+). The extra peaks which are visible on the background are due to the masses of the partially dehydrated precursor proteins.

The sixfold dehydrated pre-Pep5 (Fig. 22) is so far the first isolated and characterized precursor protein of a ribosomally synthesized and post-translationally modified peptide antibiotic. Our results show that lantibiotic biosynthesis is initiated by a selective dehydration of the hydroxyamino acids at the prolantibiotic part of the primary translational product. The sulfide ring formation is, therefore, not directly

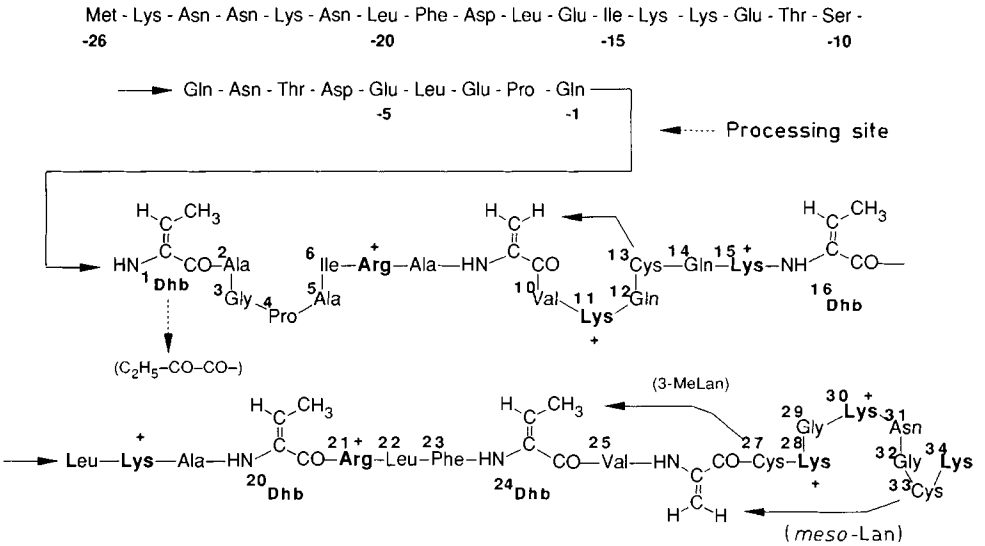

Fig. 22. Structure of the isolated precursor protein of Pep5 (pre-Pep5) with the sixfold dehydrated prolantibiotic region (1 to 34). − 26 to − 1 is the α-helical leader region.

connected with the dehydration step. Consequently, in the biosynthetic scheme of a lantibiotic (Fig. 15), the dehydrated prelantibiotic must be classified as an isolable intermediate. Shortly afterwards, the completely unmodified pre-Pep5 and a pre-Pep5 with sulfide rings and dehydroamino acids could similarly be isolated and characterized by sequencing and mass spectrometry. Thus, all of the intermediates of the modified precursor protein of a lantibiotic postulated so far have been experimentally determined for the first time.

6. Outlook

With the isolation of unmodified, up to sixfold dehydrated and also sulfide ring-containing pre-Pep5 biosynthetic intermediates, it has been possible to make a decisive step towards an unambiguous elucidation of the lantibiotic biosynthesis. The enzymes required for the post-translational modification and processing could so far be localized on the DNA level, but could not be isolated. At the moment, the following areas are being investigated by the research groups of *Entian*, *Götz*, *Sahl* and by us. The mechanism of the enzymatic dehydration is being studied to find out, e.g., whether the hydroxy group is converted into a better leaving group through phosphorylation by cyclic AMP dependent kinases, as happens in the dehydration of free serine and threonine, or whether another activation takes place.

We still do not know how the stereospecific addition of the cysteinyl SH-groups to the double bonds of the α,β-didehydroamino acids is catalyzed. An originally discussed, spontaneous ring formation can be ruled out, although in experimental chemistry these thiol additions are possible. However, for the occurrence of this reaction at room temperature, a thousandfold excess of thiol and many days of reaction time are required. The order of the ring formation, from C-terminal to N-terminal, or vice versa, is also not known. The discovery of the natural intermediates,[38] and the chemical synthesis of unmodified prelantibiotics[40] demonstrate, however, the experimental possibilities of studying the mechanism of the ring formation.

The enzyme which takes part in the modification of the preepidermins and premersacidin, and catalyzes the oxidative decarboxylation to the aminovinyl group, could gain special interest in connection with the findings concerning the biosynthesis of scents from flowers and insects which also contain vinylic structures derived from carboxylic acid precursors.[41]

Finally, we do not know how the signal peptidase functions, and whether at the same time it is a protein involved in an export function. Does this reaction partly occur on a multifunctional enzyme complex, or successively on the isolated localized enzymes?

Especially interesting is also the question of how the producing cells protect themselves against toxic lantibiotics. To clarify the principle of this self-protection,[14] different investigations are presently being carried out in the fields of protein analysis and genetics. In principle, a protecting effect of the leader peptide would be conceivable. As long as the hydrophilic leader peptide is covalently bound to the modified lantibiotic, or when it is bound—by intermolecular interaction—to the already cleaved lantibiotic, the latter cannot exert its toxic effect on the cell wall.

An active participation of the leader region during the modification steps is very probable, this is based on the high content of charged amino acids, the negative net charge, a very similar processing site and the α-helical content. On the basis of the conservation of these properties by all the known prelantibiotics, the leader peptide is at least supposed to have the functional role of stabilizing a definite conformation of the prolantibiotic segment. The leader peptide could also actively participate in the enzymatic modification steps. Finally, the leader peptide could carry the recognition region for the attachment to the modifying enzymes, signal peptidase or exporting protein.

Interestingly, the half-life of the primary translational product is very short, as it is evidently dehydrated immediately in the native producing cells.[38] We use, therefore, totally synthesized pre- and prolantibiotics as substrates for the dehydrating enzymes. The total synthesis of preepidermin with 52 residues has already been carried out successfully by segment condensation of protected purified fragments.[40] Provided that the formation of the double bond does not proceed immediately after the protein synthesis, one could quickly determine the specificity and possible application of these enzymes with the help of a large number of synthetic substrates.

In microbial genetics, sequence modified lantibiotics are already produced by the use of synthetic structural genes. For this purpose, plasmids with mutated structural genes are employed for the transformation of the producing strains. Thus, the resulting altered lantibiotics are investigated for their antimicrobial activity, sequence, and conformation. The first analogue prepared by this procedure through base exchange ("site directed mutagenesis") could already be isolated and tested by *Götz* and his group in Tübingen.[42]

The author is grateful for the intensive and exciting cooperation of the microbiological and gene technological research teams of K.-D. Entian, P. Fiedler, F. Götz, H.-G. Sahl, R. G. Werner, and especially H. Zähner, the coordinator of the Sonderforschungsbereich 323. The structural elucidations, conformational analyses, and peptide syntheses were carried out by my highly motivated co-workers H. Allgaier, R. Kellner, S. Freund, S. Stevanovic and A. Beck-Sickinger. I thank A. Bayer for critically reviewing the manuscript. The molecular dynamics simulation was performed in cooperation with O. Gutbrod and G. Folkers. Thanks are also due to W. A. Gibbons for the work which was carried out by S. Freund in his research laboratory in London and for the unproblematical access to his 500 MHz NMR spectrometer. I also thank the Deutsche Forschungsgemeinschaft for financially supporting the groups of SFB 323.

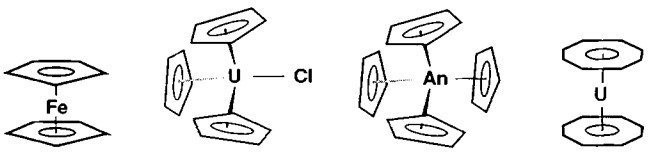
Cyclopentadienyl–Actinide Complexes: Bonding and Electronic Structure

By Bruce E. Bursten* and Richard J. Strittmatter

Shortly after the discovery of ferrocene, *Reynolds* and *Wilkinson* demonstrated that actinide elements are capable of forming organometallic compounds containing the cyclopentadienyl (Cp) ligand. The compound they reported, $[Cp_3UCl]$, was the first of a host of organoactinide complexes that contain Cp and substituted Cp ligands. In 1968, *Streitwieser* and *Müller-Westerhoff* synthesized uranocene, $[(C_8H_8)_2U]$, a molecule whose existence had been predicted five years earlier by *R. D. Fischer*. Because uranocene has no analogue in transition-metal chemistry, its synthesis stimulated new interest in organoactinide chemistry and in comparisons with organotransition-metal chemistry. Since that time, Cp and substituted Cp ligands, such as pentamethylcyclopentadienyl (Cp*), have become the most important and flexible ligands in actinide organometallic chemistry. In the past 15 years especially, the bonding of Cp ligands to actinide elements has been extensively probed by both experiment and theory. There are both significant similarities and equally significant differences in the bonding of the Cp ligand to the f-element metals compared to the d-element metals.

1. Introduction

Since the discovery of the remarkable structure of ferrocene, $[(\eta^5\text{-}C_5H_5)_2Fe]$ (**1**), in 1952,[1] the cyclopentadienyl (Cp) ligand has played a central role in organometallic chemistry. In the flurry of activity that followed the synthesis of **1**, alkali cyclopentadienides were allowed to react with a wide variety of metal halides in an effort to synthesize new organometallics with π-bonded Cp ligands. The birth of the organometallic chemistry of the actinide elements came in 1956, with the report by *Reynolds* and *Wilkinson* of $[Cp_3UCl]$ (**2**), which contains three Cp ligands π-bonded to uranium.[2] In the early 1960s, *E. O. Fischer* and co-workers reported the preparation of $[Cp_4An]$ complexes (**3**; An = Th, U);[3] the presence of four π-bonded Cp ligands is without precedent among the transition elements.



1 **2** **3** **4**

The distinct nature of organoactinide chemistry compared to organotransition-metal chemistry was boldly underscored in 1968 with the synthesis of uranocene $[(\eta^8\text{-}C_8H_8)_2U]$ (**4**) by *Streitwieser* and *Müller-Westerhoff*.[4] This beautiful molecule, whose existence had been considered theoretically five years earlier by *R. D. Fischer*,[5] consists of two planar C_8 rings sandwiching a uranium atom[6] and has no analogue among the transition elements. Actinocenes of many of the other actinide elements were subsequently synthesized[7] and studied both spectroscopically[8] and theoretically.[9] The electronic structure of uranocene is still a matter of intense experimental and theoretical interest; in 1989, for example, state-of-the-art photoelectron spectroscopic[10] and ab initio theoretical[11] studies of the molecule were reported. The synthesis of uranocene is often considered the beginning of modern organoactinide chemistry, and many excellent review articles and monographs on this field have appeared in recent years.[12]

In the past two decades organoactinide chemistry has fluorished with the synthesis of the first isolable compounds containing uranium–carbon σ bonds in 1973,[13] the discovery of facile activation of CO by thorium and uranium alkyls in 1978,[14] the synthesis of the first uranium–carbon multiple bond in 1981,[15] the synthesis of the first compounds containing supported[16] and unsupported[17] metal–metal bonds involving an actinide element in 1985, the synthesis of the first molecular actinide carbonyl complex that is stable at room temperature in 1986,[18] and the synthesis of both the first mixed C_8H_8-Cp complex of an actinide metal[19] and the first neutral homoleptic uranium alkyl complex in 1989.[20] All but the last of these significant developments have involved organoactinide complexes with Cp or substituted Cp ligands.

In this review, we will present the development of bonding models for Cp–actinide complexes, a topic that has been studied in detail only in the last decade. We will focus particularly on the use of molecular orbital (MO) theory as an electronic structural probe of these systems. When possible, we will discuss the relationship of the MO results to experimental studies, particularly those involving photoelectron spectroscopy (PES), which has been the most widely used experimental probe of bonding in organoactinide chemistry.[21] We begin with a brief historical discussion of the challenges posed by the presence of valence f orbitals. The remainder of the discussion is separated, somewhat arbitrarily, into a focus on Cp-to-actinide bonding and the bonding of Cp–actinide complexes to other ligands.

2. The Electronic Structural Challenge of the 5f Elements

Although the development of organoactinide chemistry came shortly after the birth of modern organotransition-

metal chemistry, the level of understanding of the former has lagged well behind that of the latter. For example, in transition-metal organometallics, the effective-atomic-number (or eighteen-electron) rule allows one to predict, a priori, the existence and inherent stability of many compounds. No such rule exists in organoactinide chemistry: compounds have been reported with formal electron counts as low as nine, $[U\{CH(SiMe_3)_2\}_3]$,[20] and as high as twenty-eight, $[Cp_3Np \cdot 3thf]$.[22] The reasons for the comparatively low level of understanding of the bonding in organoactinide complexes are manifold: (1) There is a paucity of experimental results in organoactinide chemistry relative to organotransition-metal chemistry. The high radioactivity and transient existence of most actinide elements preclude systematic studies of organoactinide complexes in which the metal atom is varied. Thorium and uranium are the only actinide elements that are relatively easy to study in the laboratory. (2) The large sizes of actinide atoms lead to highly variable and unpredictable coordination numbers. (3) The number of electrons in organoactinide complexes is large enough to make rigorous quantum-chemical calculations exceptionally demanding computationally. (4) Relativistic effects are profound for the actinide elements. Although there have been numerous studies demonstrating the importance of relativistic effects in the heavy elements,[23] these phenomena remain poorly understood by many chemists, hindering the understanding of electronic-structure results on the actinide elements. (5) Actinide metals contain valence f orbitals, with which many chemists are uneasy.[24] Furthermore, the computer codes for many quantum-chemical methods are not able to accommodate valence f orbitals.

Even before the emergence of organoactinide chemistry, the relative importance of the valence 5f orbitals in describing the bonding and electronic structure in actinide compounds had been, and continues to be, a question of considerable debate among theoretical and experimental chemists. In one of the earliest references to f orbitals, *Van Vleck* pointed out that they are essential for describing the bonding in complexes with high coordination numbers (as are commonly found in organoactinide complexes).[25] *Eisenstein* used a group-theoretical approach to argue for the involvement of 5f orbitals in covalent bonding in $[UO_2]^{2+}$, $[UCl_6]$, and $[UCl_4]$.[26] *Kettle* and co-workers presented stereochemical arguments for f-orbital involvement in bonding,[27] but later concluded that f-orbital bonding is usually weak because of the small size and energetic inaccessibility of the f orbitals.[28]

The first chemical evidence that 5f orbitals are involved in bonding was presented by *Glueckauf* and *McKay* in 1950 in connection with their work on uranyl nitrate.[29] These conclusions were challenged less than five months later by *Katzin*,[30] starting the persistent controversy over the bonding in the uranyl ion.[31] Further work in the 1950s on uranyl and uranyl-like ions also focused on the question of f-orbital participation in bonding.[32] *Coulson* and *Lester* surveyed this early work and concluded that f-orbital covalency is significant, although they suggested that the important orbitals are the 6f rather than the 5f orbitals.[33] Differences in the complexing behaviors of the lanthanide and actinide halides led *Seaborg* and co-workers to invoke hybridization of the 5f, 6d, and 7s orbitals in order to account for the greater tendency of the actinides to form covalent complex ions.[34]

The question of f-orbital participation has also been at the fore of organoactinide chemistry. *Moffitt* reported a qualitative discussion of the orbital interactions in $[Cp_3U]^+$ in the report of the synthesis of **2**.[35] An early review on bonding in f-element organometallics concluded that the properties of these materials, both chemical and physical, are intermediate between the covalent organotransition-metal complexes and the ionic carbocyclic salts of the alkali metals.[36] It further noted that evidence exists for some appreciable f-orbital contribution to the bonding in the early An^{IV} complexes. Later empirical studies of the bonding have concentrated on trends in molecular geometry and steric factors. One such

Bruce E. Bursten was born in Chicago, Illinois, in 1954. He received his S. B. degree with honors in chemistry from the University of Chicago (1974) and his Ph.D. degree (with R. F. Fenske) form the University of Wisconsin (1978). Following two years as an NSF Postdoctoral Fellow at Texas A & M University (with F. A. Cotton), he joined the faculty of The Ohio State University, where he is currently Professor of Chemistry. He has been a Fellow of the Alfred P. Sloan Foundation and a Camille and Henry Dreyfus Foundation Teacher-Scholar and he has received both the Distinguished Teaching Award and the Distinguished Scholar Award at his university. His research interests include the electronic structure of transition-metal and actinide complexes, organometallic photochemistry, metal–metal bonding, and applied quantum chemistry.

Richard J. Strittmatter was born in Washington, DC, in 1963. He received his B. S. degree in chemistry from Wake Forest University (1985) and his Ph.D. degree in inorganic chemistry (with B. E. Bursten) from The Ohio State University (1990). He spent six months of his graduate studies at Los Alamos National Laboratory under the supervision of Dr. A. P. Sattelberger. His dissertation research involved computational and experimental investigations of the bonding and electronic structure of organoactinide and related transition-metal compounds. He is currently a Senior Chemist at Nalco Chemical Company in Naperville, Illinois, where he is a member of the Advanced Recycling Technologies Department in the Water and Waste Treatment Division.

study, based on the limited number of structures available at the time, concluded that the bonding in organoactinides is predominantly ionic.[37] A cone-packing model based on steric effects has been developed and used to explain molecular geometry, reaction pathways, ligand rearrangement, and disproportionation.[38] One very recent study defines a "steric coordination number" that can be used for molecular structure comparison and bond-length prediction,[39] while another uses statistical analysis of structural data to seek evidence for covalency in Cp complexes of the alkaline earths and f elements.[40] The debate over metal–ligand covalency in organoactinide complexes is clearly an unresolved issue.[41]

3. Cyclopentadienyl–Actinide Bonding

Because the Cp ligand has such a dominant role in organotransition-metal chemistry, actinide cyclopentadienyls lend themselves more readily to comparison with transition-metal systems than do the actinocenes. A major theme of this section will be the similarities and differences in the bonding of Cp ligands to actinides and transition metals. In one of the first direct theoretical comparisons of the bonding of a Cp ligand to an actinide and a transition metal, *Tatsumi* and *Hoffmann* used quasi-relativistic extended Hückel (EH) molecular orbital theory[42] to compare the interaction of a Cp^- ligand with a U^{6+} ($5f^0$) and an Fe^{2+} ($3d^6$) ion.[43] They found a vanishingly small U–Cp overlap population for $[CpU]^{5+}$ in contrast to a sizable one for $[CpFe]^+$. This report suggests that the interaction between Cp and U^{VI} is largely ionic, consistent with the fact that only a very small number of organoactinide complexes contain neutral π-donor ligands. It is apparent, however, that covalency could become more important for lower oxidation states of uranium; most known actinide cyclopentadienyls involve metals in a formal +3 or +4 oxidation state, and we will focus on these systems in the ensuing discussion.

3.1. Tetrakis(cyclopentadienyl) Complexes

$[Cp_4An]$ compounds (**3**) have been synthesized for An = Th,[3b] Pa,[44] U,[3a] and Np.[45] The crystal structure of $[Cp_4U]$ shows that it is pseudotetrahedral with all four Cp ligands bound in an η^5 fashion.[46] From the isotropic ^1H NMR shift in $[Cp_4U]$, a total spin delocalization of 24% was estimated over the four Cp ligands,[47] a result that seemed incompatible with the rather long U–C distance and the generally contracted radial distribution of 5f orbitals. Although aspects of this work were questioned,[48] the temperature dependence of the paramagnetic shift between 165 and 428 K confirms the original indication of a remarkably large indirect electron-spin transfer.[49]

The ^{237}Np Mössbauer spectrum of $[Cp_4Np]$ shows an isomer shift of $+0.72\ cm\ s^{-1}$,[22] appreciably different from those of ionic Np^{IV} compounds. This observation suggests a significant electron contribution from the Cp ligands to the metal orbitals in $[Cp_4Np]$, although not as great as that found for $[(\eta^8\text{-}C_8H_8)_2Np]$. This spectroscopic evidence for covalent contributions to the bonding in $[Cp_4Np]$ agrees with chemical evidence for covalent contributions to the bonding in $[Cp_3UCl]$, which does not react with $FeCl_2$ to form ferrocene.[2]

Many theoretical studies of the electronic structure of $[Cp_4An]$ systems have been undertaken. In an effort to interpret the temperature dependence of the magnetic susceptibility of $[Cp_4U]$, calculations were performed on the model tetrahedral system $[(\eta^6\text{-}C_6H_6)_4An]$.[50] Three different semiempirical approaches were used, all of which led to essentially the same results and successfully simulate the temperature dependence of the magnetic susceptibility. In a related study, the bands of the room-temperature absorption spectrum of $[Cp_4U]$ have been identified, with good agreement between observed and calculated values.[51]

Quasi-relativistic EH and Xα-SW molecular orbital calculations on $[Cp_4Th]$ and $[Cp_4U]$ have been reported.[52] In both the EH and Xα-SW results, the calculated molecular orbitals are energetically grouped in a fashion well described by tetrahedral symmetry (Fig. 1). Apart from a small An 7s

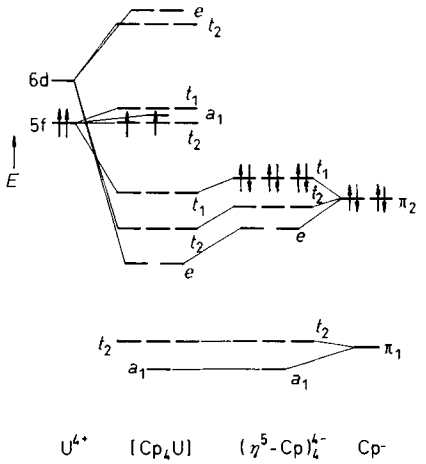

Fig. 1. Qualitative MO diagram of $[Cp_4U]$ under pseudotetrahedral symmetry.

contribution, the Xα-SW results show no important metal contributions to the Cp π_1 orbitals. The Cp π_2 orbitals donate significantly into both the An 5f and 6d orbitals; the ligand donation into the metal 6d orbitals is comparable to or even greater than the donation into the metal 5f orbitals. It was shown further that donation into the 6d orbitals is a more stabilizing interaction than donation into the 5f orbitals.[53] Under tetrahedral symmetry, the energetic ordering of these Cp π_2-based orbitals was calculated to be $t_1 > t_2 > e$. The HOMO of the uranium complex is essentially a pure 5f atomic orbital, in which the two unpaired metal-based electrons reside. In general, the EH calculations show much less metal 5f and 6d involvement in the metal–ligand bonding orbitals than do the Xα-SW calculations.

Prior to these calculations, the valence PE spectra of $[Cp_4Th]$ and $[Cp_4U]$ were reported.[54] Four ionization bands are evident in the 6–10-eV ionization energy (IE) region of $[Cp_4U]$ (Fig. 2). As is the case for uranocene,[10] the first ionization band is readily assigned to ionization of the U-based 5f electrons. The other three bands are due to the ligand-based π_2 MOs. On the basis of relative band intensities under both He(I) and He(II) ionization sources, the authors assigned the Cp π_2 ionization energies in the order

$t_1 < e < t_2$. In conjunction with the above EH and Xα-SW calculations, the He(I) and He(II) PE spectra of the methyl-substituted cyclopentadienyl complexes, [Cp′$_4$Th] and [Cp′$_4$U] (Cp′ = η^5-$C_5H_4CH_3$), were also reported.[52] A satisfactory agreement was found between the calculated Xα-SW transition-state IEs and the experimental ones, although the calculated values are uniformly too low by about 0.3 eV. The calculations support an assignment for the Cp π_2 ionizations of $t_1 < t_2 < e$, in disagreement with the earlier assignment made by *Green* et al.[54] The authors therefore questioned the assumption that the increase in the He(II) PE cross section is greater for the 5f orbitals than for the 6d orbitals.[52]

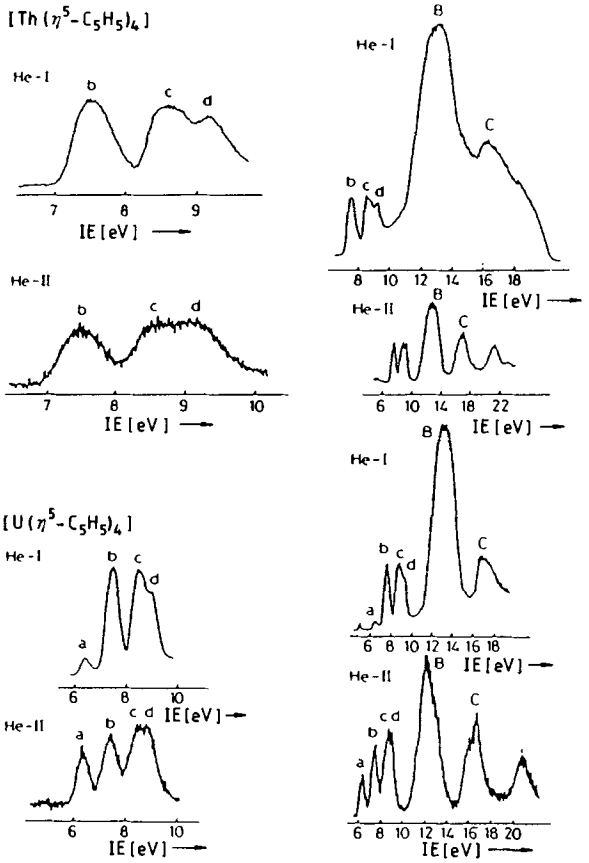

Fig. 2. He(I) and He(II) photoelectron spectra of [Cp$_4$Th] and [Cp$_4$U] [54].

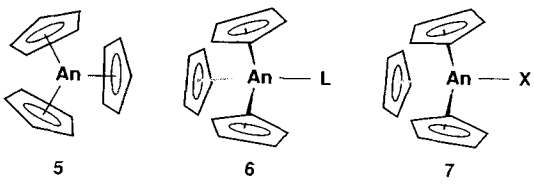
Because the coordination of four η^5-Cp ligands is unique to the 5f elements, the preference of actinides for η^5- over η^1-Cp bonding has been studied. *Tatsumi* and *Nakamura* have used EH calculations to compare [(η^5-Cp)$_4$U] and [(η^5-Cp)$_3$(η^1-Cp)U], the latter being similar to the well-known [Cp$_3$UR] (R = alkyl) complexes. They find [(η^5-Cp)$_4$U] to be more stable than [(η^5-Cp)$_3$(η^1-Cp)U], in agreement with experiment.[55] Similar calculations on the allyl derivatives [Cp$_3$U(η^3-allyl)] and [Cp$_3$U(η^1-allyl)] predict the latter to be more stable than the former, again in agreement with experiment. The authors propose that the preference for monohapto over polyhapto coordination is a consequence of several delicately balanced factors, including the fact that η^1-allyl is a stronger σ donor than η^1-Cp.

3.2. Tris(cyclopentadienyl) Complexes

The binding of three η^5-Cp ligands is arguably the most common coordination sphere found in organoactinide complexes. For actinides in the +3 oxidation state, both the "base-free" [Cp$_3$An] complexes (**5**) and those with an additional bound Lewis base, [Cp$_3$AnL] (**6**), are commonly known. The tetravalent actinides often form neutral complexes of the type [Cp$_3$AnX] (**7**), where X is a formally anionic ligand such as halide or alkyl. In this section we will focus on the bonding of the three Cp ligands to the actinide center; the discussion of the An–L and An–X σ bonds is deferred to Section 4.

Compounds **5** are known for the actinide elements from Th to Cf, and the Cm and Cf adducts represent the only well-characterized organometallic compounds of those elements. Two such compounds have been structurally characterized: both [Cp″$_3$Th][56] (Cp″ = η^5-1,3-(Me$_3$Si)$_2$C$_5$H$_3$) and [Cp‴$_3$U][57] (Cp‴ = η^5-Me$_3$SiC$_5$H$_4$) exhibit planar, pseudo-D_{3h} structures with respect to the metal–Cp(centroid) vectors. Compounds of type **6** or **7** are pseudotetrahedral molecules in which the centroids of the Cp rings occupy three vertices.[58–60] These molecules have actual or near C_{3v} point symmetry.



Placing Cp ligands in threefold symmetry about a metal center imposes interesting symmetry restrictions on the metal–ligand interactions. This fact was first recognized by *Moffitt*, who presented a qualitative treatment of the orbital interactions in [Cp$_3$U]$^+$ as part of the paper on the synthesis of [Cp$_3$UCl].[35] Under C_{3v} symmetry, the π_2 orbitals of the Cp ligands are bases for the $a_1 + a_2 + 2e$ representations. The symmetry-allowed metal–ligand orbital interactions are given in Table 1. It is particularly notable that the ligand-based a_2 orbital cannot interact with s, p, or d orbitals on the central metal, but is allowed to interact with one of the f orbitals. This observation has been used to explain how the seemingly 20-electron transition-metal complex [(η^5-

Table 1. Metal orbital interactions with Cp_3^{3-} under C_{3v} symmetry.

Cp_3^{3-} orbital	Metal	
	s, p, d orbitals	f orbitals
	s	f_{z^3} (fσ)
a_1	p_z (pσ) d_{z^2} (dσ)	$f_{x(x^2-3y^2)}$ (fφ)
	p_x, p_y (pπ)	f_{xz^2}, f_{yz^2} (fπ)
e	d_{xz}, d_{yz} (dπ) $d_{x^2-y^2}$, d_{xy} (dδ)	f_{xyz}, $f_{z(x^2-y^2)}$ (fδ)
a_2	-	$f_{y(3x^2-y^2)}$ (fφ)

$Cp)_3(\eta^1$-Cp)Zr] is, in actuality, an 18-electron complex that satisfies the effective-atomic-number rule.[61] The allowed interaction of the a_2 ligand-based orbital with an f orbital has been proposed as a reason for the abundance of $[Cp_3An]$ complexes vis-à-vis the scarcity of $[Cp_3M]$ complexes among the transition metals.[62]

Quantitative MO calculations on $[Cp_3An]$ systems corroborate *Moffitt*'s symmetry analysis. EH calculations on $[Cp_3U]^+$ indicate 8% U 5f contribution to the ligand-based a_2 orbital.[55] Quasi-relativistic Xα-SW calculations on $[Cp_3U]$ put the U 5f contribution at 29%.[62] These latter calculations were also used to analyze the other donations from the π_2 orbitals of the Cp_3^{3-} ligand fragment to the U^{3+} center. The ligand *e* orbitals, which can donate to the U 5f, 6d, or 7p orbitals, preferentially interact with the 6d orbitals, as was found for the $[Cp_4An]$ complexes. Thus, only the 5f orbital of a_2 symmetry is significantly affected by the ligand field. The ligand a_1 orbital, which is spatially less favorable for interaction with the $6d_{z^2}$ orbital, interacts more weakly with the U atom than the other ligand orbitals. The overall result of these interactions is depicted in Figure 3.

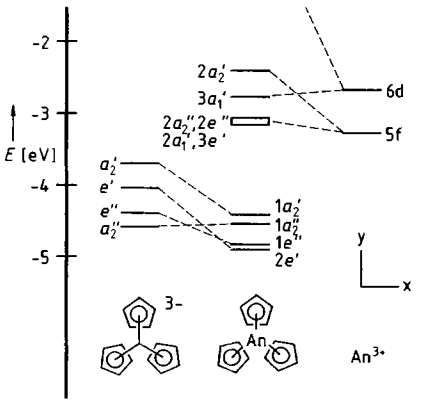


Fig. 3. MO diagram showing the interaction of Cp_3^{3-} with U^{3+} to form $[Cp_3U]$ [69].

A molecular orbital comparison of the bonding in $[Cp_3U]$ and $[UCl_3]$ indicates significantly greater ligand-to-metal donation in the former than in the latter.[62] Similar conclusions were drawn in a comparison of $[Cp_4U]$ and $[UCl_4]$.[53] The greater donation by Cp was taken as evidence of greater covalency in U–Cp bonding than in U–Cl bonding.

EPR spectra of powdered samples and solutions of $[Cp''_3Th]$ were obtained in the temperature range 10–300 K.[63] Using a simplified crystal field model, the authors found that the data are only consistent with a $5f^0 6d^1$ ground electron configuration for the Th^{III} compound. This conclusion was corroborated by quasi-relativistic Xα-SW calculations on $[Cp_3Th]$,[64] which showed a single 6d orbital lower in energy than the Th 5f block of orbitals. These authors also investigated $[Cp_3An]$ compounds where An = Pa to Pu, and found that the 5f block of orbitals was lowered in energy across the series, while the energy of the 6d-based a_1 orbital increased slightly. These results led to the predictions that $[Cp_3Pa]$ should have a $5f^1 6d^1$ ground electron configuration and that the transuranium compounds should have a $5f^n 6d^0$ ground electron configuration. The Xα-SW calculations showed an exceedingly small energy difference between the $5f^2 6d^1$ and the $5f^3 6d^0$ ground electron configurations for $[Cp_3U]$, although more rigorous calculations that include spin–orbit coupling favor the $5f^3 6d^0$ configuration.[65]

The nature of the An^{III}–Cp bonding has been investigated spectroscopically and chemically. An early study involved estimation of the nephelauxetic parameters of $[Cp_3Am]$ and $[Cp_3Cm]$ by a comparison of their visible absorption and emission spectra with those of the aqueous ions.[66] Although the parameters are greater than those of $[Cp_3M]$ compounds of the lanthanide series, the covalency relative to the aqueous +3 ions of 2.8% and 2.5% for $[Cp_3Am]$ and $[Cp_3Cm]$, respectively, is indicative of highly ionic organometallic bonding. The Mössbauer isomer shift of $[Cp_3Np \cdot thf]$ ($+3.64\ cm\ s^{-1}$) is very close to that of $[NpCl_3]$ ($+3.54\ cm\ s^{-1}$), suggesting very little difference in the bonding of the Cp and Cl ligands.[22] Protolysis of the metal–Cp bonds in $[Cp_3U]$ [Eq. (a)] has been taken as chemical evidence for significant ionic character in the metal–ligand bonding.[67]

$$[Cp_3U] + HCN \rightarrow [Cp_2(CN)U] + C_5H_6 \qquad (a)$$

A preliminary account of the bonding in the transuranium $[Cp_3An]$ compounds compares the $[Cp_3An]$ series to the corresponding $[AnCl_3]$ compounds.[68] Proceeding from Th to Cf, the 5f orbitals drop dramatically in energy for $[AnCl_3]$ compounds. Although the same qualitative trends are followed in the $[Cp_3An]$ series, the Cp ligand is a much better donor to the actinide metal than the Cl ligand and consequently buffers the charge on the metal, resulting in a much less dramatic 5f orbital energy drop.[69]

$[Cp_3ThX]$ and $[Cp_3UX]$ compounds (**7**), including Th^{IV} and U^{IV} compounds with the modified Cp ligands Cp′ and indenyl, have been extensively investigated by PES.[54, 70–72] The lowest ionization band in the U^{IV} complexes, at 6.5 to 7.0 eV, is not present in the Th^{IV} compounds and is therefore assigned to the $5f^2$ electrons of U^{IV}. This assignment has been corroborated by He(II) spectroscopic studies. As expected with a change in oxidation state of the metal, the first ionization band in the U^{III} complex $[Cp_3U \cdot thf]$ occurs at lower IE than in the U^{IV} complexes.[54]

The ionizations due to the Cp π_2 orbitals in both $[Cp_3ThX]$ and $[Cp_3UX]$ complexes appear as three bands in their PE spectra. The ionization energies vary with the nature of the Cp ligand in the order indenyl < Cp′ < Cp. Comparison of the He(I) spectra with the He(II) spectra indicates much greater 5f-orbital participation in the metal–ring bonding in the uranium compounds than in the thorium compounds (Fig. 4). Moreover, the spectra indicate that the 5f covalency in the indenyl compounds is much greater than in the unsubstituted Cp compounds.[70]

All $[Cp_3AnX]$ compounds with X = Cl exhibit one ionization band slightly above the Cp π_2 bands, which is assigned to ionization from a lone pair of the chloride ligand (band d, Fig. 4).[71] This assignment is supported by a shift of this band to lower energy when X = Br or OCH_3, and by its complete absence when X = BH_4 or CH_3.

Nonrelativistic DV-Xα calculations on $[Cp_3UX]$ (X = F, Cl, Br) have been performed in conjunction with a PES in-

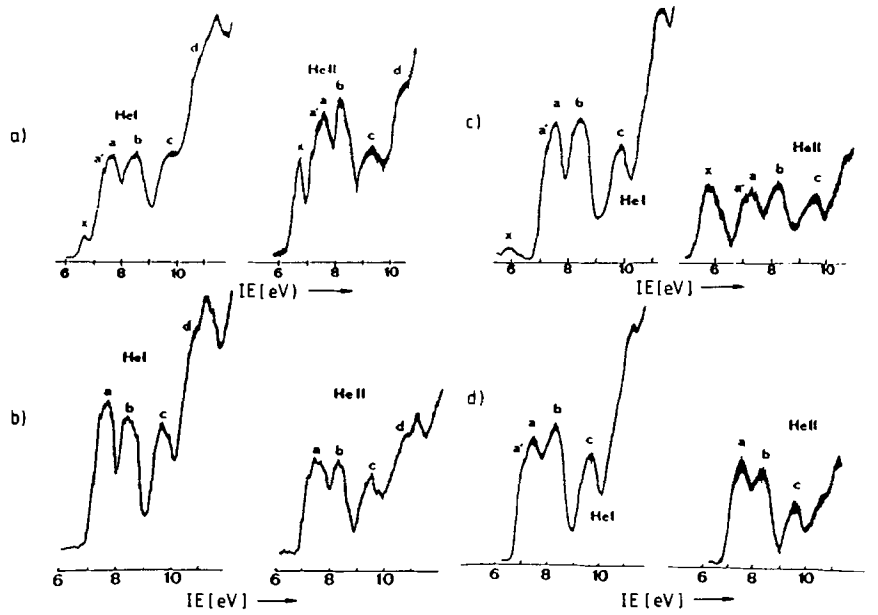

Fig. 4. Low-energy region of He(I) and He(II) spectra of a) [U(indenyl)$_3$Cl], b) [Th(indenyl)$_3$Cl], c) [U(indenyl)$_3$CH$_3$], and d) [Th(indenyl)$_3$CH$_3$] [70].

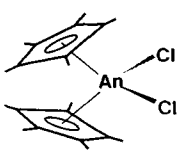
vestigation.[72] The above general assignments agree quite well with the calculations. Transition-state ionization energies were calculated for [Cp_3UCl] and are in good agreement with experiment, including the correlation between the relative intensities of the He(I) spectra and orbital population analysis. The uranium 6d contribution to the metal–ligand bonding orbitals appears to be underestimated in the calculations owing to the nonrelativistic approach.

3.3. Bis(cylcopentadienyl)actinide Complexes

A multitude of early-transition-metal [Cp_2MX_2] compounds are known, and their chemistry has been studied extensively. The corresponding An^{IV} complexes with unsubstituted cyclopentadienyl ligands, [Cp_2AnX_2], are a relatively uncommon class of compounds, largely because of the high affinity of the actinide centers for Cp ligands. Thus, the reactions of [$AnCl_4$] with cyclopentadienide salts generally yield either [Cp_3AnCl] or [Cp_4An];[2, 3] it is not possible to "stop" the reaction at [Cp_2AnCl_2].[73] Some [Cp_2AnX_2] complexes have been isolated when X is a strong π-donor or chelating bidentate ligand.[74]

Sterically hindered cyclopentadienyl ligands, especially pentamethylcyclopentadienyl (Cp*), have been used to generate bis(cyclopentadienyl)actinide complexes. For example, the reaction between [$AnCl_4$] and [Cp*MgCl] leads to the replacement of two Cl ligands by Cp* ligands, yielding [$Cp^*_2AnCl_2$] (**8**; An = Th, U).[75] Complexes **8** are structurally analogous to transition-metal [Cp_2MX_2] and [$Cp^*_2MX_2$] systems, with a pseudotetrahedral geometry about the actinide center.[76, 77] Because the ligand array in **8** is identical to that of well-characterized transition-metal systems, the direct comparison of homologous actinide and transition-metal complexes is facilitated.



8

The valence PE spectra of [$Cp^*_2ThCl_2$] and [$Cp^*_2UCl_2$] are quite similar to those of analogous Zr and Hf compounds.[54, 78] The first ionization band of the uranium complex is due to the 5f electrons of this f^2 complex. The ionization bands due to the Cp π_2 orbitals are lower in energy than the bands due to the chloride lone pairs in [$Cp^*_2MCl_2$] (M = Zr, Th, U); this ordering is reversed in [Cp_2WCl_2]. Furthermore, the bands assigned to the Cp π_2 orbitals are essentially isoenergetic for the [$Cp^*_2MCl_2$] complexes, suggesting that either the metal–ring bonding is similar for the three compounds or that metal–ring interactions are of little importance in determining the relative energies of these ring molecular orbitals. Comparison of these compounds with several Cp-containing organometallic compounds indicates that the metal–ring bonding in these organoactinides tends to be much more ionic than the bonding in [$Cp^*_2MoCl_2$] and [Cp_2VCl], although it is less ionic than in lanthanide compounds such as [(Cp_2GdCl)$_2$] and [(Cp_2YCl)$_2$].[54]

Comparison of the PE spectra of [$Cp^*_2AnMe_2$] compounds with those of the dichlorides reveals the greater electron-releasing ability of the two methyl ligands.[78] The 5f ionization in [$Cp^*_2UMe_2$] is at lower IE than that in [$Cp^*_2UCl_2$] although the energy difference is much smaller than would have been expected in a similar d^2 system. The Cp π_2 bands, which are also at lower IE than in the chloride complexes, show greater energetic dispersion in the actinide spectra than in the spectrum of [$Cp^*_2ZrMe_2$], probably due to enhanced metal–ring interaction involving the 5f orbitals.

PES investigations of [Cp_2UX_2] compounds with unsubstituted Cp ligands and chelating or π-donating X ligands have been reported.[79] The lowest-energy ionization band in each of these compounds is due to the $5f^2$ electrons of the U^{IV} metal center, with the energetic ordering inversely related to the electron-donating ability of the ligand X: S_2CNEt_2 (6.19 eV) < NEt_2 (6.24 eV) < $O_2CC(CH_3)_3$ (6.73 eV) <

BH_4 (7.97 eV). For $[Cp_2U(BH_4)_2]$, which has no low-energy bands due to ionization from the BH_4 ligands, the next three lowest bands have a 1:2:1 ratio and are due to ionizations from the Cp π_2 orbitals. The splitting between the extremes of these bands is comparable to that of other $[Cp_2^*UX_2]$ complexes; as expected, the splitting is smaller than that of the Cp π_2 bands in $[Cp_3UX]$ compounds or Cp_4U. The large energy dispersion of the π_2 ionization bands and their variable He(I)/He(II) intensity ratios indicate that the splitting is not solely due to interligand repulsion, and it was concluded that there is a sizable interaction between Cp π_2 molecular orbitals and uranium 5f and 6d orbitals. The pivalate complex $[Cp_2U\{O_2CC(CH_3)_3\}_2]$, which is dimeric in solution,[74c] possesses a pseudooctahedral geometry and is more sterically crowded than other $[Cp_2UX_2]$ systems. The greater repulsion within the Cp_2 framework results in a broad featureless band for the Cp π_2 ionizations of this complex. The spectra of the NEt_2 and S_2CNEt_2 complexes are complicated by the overlap of bands due to ionizations from nitrogen 2p lone pairs and from sulfur 3p lone pairs, respectively, with the Cp π_2 bands. Nevertheless, in the case of the amido complex, the authors assigned the lowest of these bands to be nitrogen lone-pair orbitals, whereas for the dithiocarbamate complex the lowest-energy band is assigned to the Cp π_2 orbitals.

The PES results have been used to rationalize the reactivity of these complexes.[79] The IEs of the Cp π_2 orbitals in $[Cp_2U(BH_4)_2]$ are the highest yet observed for $[Cp_2UX_2]$ and $[Cp_2^*UX_2]$ complexes, consistent with the high stability and, hence, the low reactivity of the complex. With the exception of the $5f^2$ electrons, the highest occupied orbital of $[Cp_2U(NEt_2)_2]$ is an almost pure nitrogen 2p lone pair, consistent with the higher reactivity of the complex toward molecules containing dipolar double bonds and acidic hydrogens. In $[Cp_2U(O_2CCMe_3)_2]$ and $[Cp_2U(S_2CNEt_2)_2]$, the orbital immediately below the $5f^2$ electrons is localized on the Cp ligands, but is energetically close to molecular orbitals centered on the X ligands. These relative orbital energetics could be responsible for the greater lability of the U–Cp bonds in these complexes relative to $[Cp_2U(NEt_2)_2]$, in which the U–N bond is more labile.

The bonding in $[Cp_2^*UX_2]$ (X = Cl, Me) has been studied via quasi-relativistic Xα-SW calculations on the corresponding Cp complexes.[80] Although the calculated IEs are uniformly too low, the calculated band splittings are in excellent accord with the experimental PES data, indicating that the extent of the uranium–ligand interaction is properly estimated by the quasi-relativistic calculations. The bonding of the Cp rings is similar in the two compounds, with sizable contributions from the metal 6d and 5f orbitals. The CH_3^- ligand is a stronger σ donor than the Cl^- ligand, as evidenced by the higher energy of the 5f orbitals in $[Cp_2UMe_2]$ than in $[Cp_2UCl_2]$. The calculations show no evidence that Cl^- acts as a π donor to uranium. Support for this conclusion comes from a comparison of $[Cp_2UCl_2]$ with $[Cp_4U]$ and $[UCl_4]$.[53] The 5f block of orbitals in $[Cp_2UCl_2]$ is much closer in energy to the corresponding block in $[Cp_4U]$ than in $[UCl_4]$; the energy of the 5f orbitals is principally governed by interaction with the Cp ligands. The remaining two U^{IV} electrons are in essentially pure uranium 5f atomic orbitals that are clustered in a narrow band, consistent with the paramagnetism of the molecules. By contrast, analogous calculations on $[Cp_2MoCl_2]$ predict it to be diamagnetic, again consistent with experiment.

4. Cyclopentadienyl–Actinide Complexes with σ-Bonded Ligands

In addition to An–Cp bonds, the $[Cp_3AnL]$, $[Cp_3AnX]$, and $[Cp_2AnX_2]$ complexes discussed in the preceding section also contain σ bonds between one or more ligands and the actinide atom. The nature of these actinide–ligand σ bonds and their similarities to and differences from actinide–ligand π bonds are the focus of this section.

The differences between σ and π bonds involving the actinide atoms was first addressed theoretically by *Tatsumi* and *Hoffmann*.[43] Using extended Hückel theory, they found a far more substantial interaction between a CH_3^- ligand and a U^{6+} ion than between a Cp^- ligand and the same ion. The U–C overlap population in U–CH_3^{5+} is large and comparable to that found for Fe-CH_3^-. The U $5f_{z^3}$, $6d_{z^2}$, 7s, and $7p_z$ orbitals all contribute to the U–C σ bond.

4.1. Tris(cyclopentadienyl)actinide Complexes

4.1.1. The Nature of An–X σ Bonding

As mentioned in Section 3.2, when a fourth ligand binds to a $[Cp_3An]$ fragment, the Cp ligands pyramidalize to open a coordination site for the ligand to approach. Quasi-relativistic EH calculations on $[Cp_3U]^+$ show that, upon pyramidalization, orbitals possessing primarily uranium 6d character are stabilized owing to increased 6d–7p mixing.[55] This effect is most pronounced for the $6d_{z^2}$ orbital and the $7p_z$ orbital, resulting in an energetically low-lying, hybridized σ-bonding orbital situated to accept electron charge from an incoming fourth ligand. This orbital, which is primarily uranium $6d_{z^2}$, is approximately 4 eV above the 5f block of orbitals in the EH calculations.

Xα-SW results also indicate a low-energy σ-bonding orbital;[64] however, this orbital is approximately isoenergetic with the 5f block of orbitals in $[Cp_3U]$ and is actually lower in energy than the 5f block of orbitals in $[Cp_3Th]$ (cf. Section 3.2). The different oxidation states of uranium in $[Cp_3U]^+$ and $[Cp_3U]$ could account for some of the energetic discrepancy between the EH and Xα-SW results, and the two methods differ in the energetic placement of the 5f orbitals relative to the 6d orbitals. As was the case in the EH calculations, the Xα-SW results also show hybridization of this orbital upon pyramidalization of the Cp ligands.

Ziegler et al. have used local density functional (LDF) theory to study the An–R σ-bond energies in $[Cl_3AnR]$ (An = Th, U; R = H, CH_3) complexes.[81] Their methodology employed *Becke*'s density functional[82] and the Hartree–Fock–Slater LCAO program of *Baerends* et al.[83] In addition to nonrelativistic calculations on the molecules, two levels of relativistic correction were studied: a first-order relativistic method based on perturbation theory, and a quasi-relativistic method based on optimization of the valence density with respect to the first-order relativistic

Hamiltonian. The authors found that the bond energies calculated by the latter method were in excellent accord with the experimental An–R bond energies for $[Cp^*_2An(R)(Cl)]$ complexes.[84] Interestingly, the nonrelativistic calculations, which give very poor calculated bond energies, indicate that the An $5f_{z^3}$ orbital is the most important one in the formation of the An–R bond. When the quasi-relativistic method is used, the energy of the 5f orbitals increases; as a result, the $6d_{z^2}$ orbital becomes the dominant An orbital in the bond.

It is clear from all of the above studies that a hybridized σ-bonding orbital possessing primarily $6d_{z^2}$ character is responsible for the high Lewis acidity of $[Cp_3U]$. An Xα-SW investigation of the interaction of $[Cp_3U]$ with a hydride ligand, to form the hypothetical "σ-only" compound $[Cp_3UH]$, indicates that the metal participation in the U–H bond is indeed dominated by the $6d_{z^2}$ orbital with minor contributions from the $5f_{z^3}$, $7p_z$, and 7s orbitals.[62] Also, the 5f block of orbitals in $[Cp_3U]$ shows no increased splitting upon interaction with the hydrogen atom, further supporting the minor role of the 5f orbitals in σ bonding. The authors note that this σ-bonding interaction is typical for all Cp_3U–X or Cp_3U–L σ bonds. It is interesting to note here a suggestion, based on thermochemical data, as to why $[Cp_3UH]$ has never been isolated despite numerous synthetic attempts.[85] If the bond disruption energy D(U-H) is assumed to be 10 kcal mol^{-1} greater than D(U-CH_3), then bimolecular H_2 elimination from $[Cp_3UH]$ may be sufficiently close to thermoneutrality to be entropically driven. Support for this notion comes from the results of LDF calculations on $[Cl_3AnR]$ systems,[81] which indicate that actinides, like the early transition metals,[86] form bonds of nearly equal strength to hydrogen and alkyls.

4.1.2. An–X Bond Energies

Marks and co-workers have reported extensive thermochemical studies of the nature of actinide–ligand σ bonding. A thermochemical study of alkyl adducts of $[Cp_3U]$ reveals that the U–R bond energies, $D(Cp_3U\text{–}R)$, span a wide range of about 58 kcal mol^{-1}.[85] These values are roughly 20 kcal mol^{-1} lower than the analogous $D(Cp_2UR\text{-}R)$ values; this difference is attributed to the greater steric congestion in the $[Cp_3UR]$ systems. The experimental bond energies indicate that severe nonbonded interligand repulsions destabilize the U–R bond in $[Cp_3UR]$. The bond enthalpies for $[Cp_2UR_2]$ and $[Cp_3UR]$ follow qualitatively similar trends with U-Me ≥ U-$CH_2CH_2CH_2$Me > U-CH_2Ph. Consistent with the calculations of *Ziegler* et al.,[81] the actinide–alkyl bond enthalpies parallel those of the group 4 transition-metal complexes. A plot of $D(Cp_3U\text{-}R)$ versus D(R-H) shows a roughly linear correlation (Fig. 5). The greatest deviations are observed for R = *n*Bu and R = CH_2Ph, for which the D(U-R) values are lower and higher than anticipated, respectively. The deviation in the former may reflect the steric demands of the *n*Bu ligand, while the deviation in the benzyl complex may be indicative of inductive effects in the benzyl ligand. Both R = vinyl and R = C≡CPh fall on the linear plot, evidence that U–R π bonding is not a major effect.

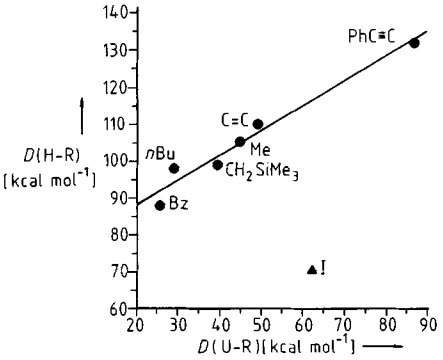


Fig. 5. A plot of U–R bond energies in $[Cp^*_3UR]$ versus R–H bond energies [85].

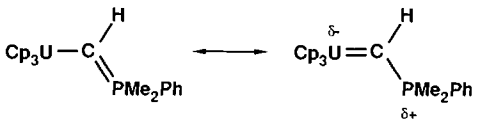
Among the alkyl groups studied thermochemically, the U–C≡CPh bond is the strongest, consistent with the relative shortness of the U–C bond in $[Cp_3UC{\equiv}CPh]$.[87] EH studies of $[Cp_3UR]$ complexes indicate a significant increase in the U–C overlap population of the model complex $[Cp_3UC{\equiv}CH]$ relative to $[Cp_3UCH_3]$.[55] Interestingly, σ interactions in $[Cp_3UC{\equiv}CH]$ account for half of the increase in the overlap population, indicating that π interactions are less important than might be inferred from the short U–C bond. Thus, the calculated results are in good accord with the conclusions of the thermochemical studies.

4.1.3. An–X Multiple Bonds and π Bonding

Cramer, Gilje et al. have explored multiple U–C bonding in $[Cp_3UR]$ systems where R is a phosphoylide.[15] The U–C bond in $[Cp_3UCH\{P(CH_3)_2(C_6H_5)\}]$ (**9**) is the shortest yet

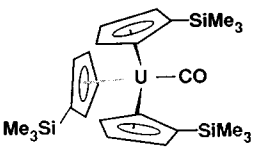


9

observed (2.29 Å); even after correcting for the difference in hybridization of the carbon atom, the U–CH(PR_3) bond is still 0.11 Å shorter than the uranium–carbon bond in $[Cp_3U(n\text{Bu})]$.[88] As was the case for $[Cp_3UC{\equiv}CH]$, EH calculations on the model complex $[Cp_3UCHPH_3]$ show a significant increase in the U–C overlap populations relative to $[Cp_3UCH_3]$.[55] In contrast to the acetylide complex, however, this increase is almost entirely due to a π interaction between the C pπ orbital of $CHPH_3$ and the uranium $5f_{yz^2}$ (7%), $6d_{yz}$ (2%), and $7p_y$ (1%) orbitals.

The π-bonding effects have been found to be important in $[Cp_3UL]$ compounds where the fourth ligand is not an alkyl. For example, phosphite ($P(OR)_3$) and isocyanide (CNR) ligands, which are generally classified as π-acceptor ligands, bind more strongly to $[Cp_3U]$ than do pyridine, THF, or nitriles, which are σ-only ligands.[89] *Andersen* and *Brennan* demonstrated that exposure of carbon monoxide to a hydrocarbon solution of $[Cp^*_3U]$ leads to quantitative evidence for

U–L π bonding.[18] The carbonyl adduct, [Cp‴UCO] (**10**), exhibits a carbonyl stretch in the IR spectrum at ν_{CO} = 1976 cm^{-1}, about 170 cm^{-1} lower than ν_{CO} for free carbon monoxide. This lowering of the C–O stretching frequency is indicative of metal-to-carbonyl π back-bonding.



10

The electronic structure of **10** has been investigated via quasi-relativistic Xα-SW calculations on the model complex [Cp_3UCO].[90] The U–CO σ bond is similar to the U–H σ bond discussed above, with the CO carbon "lone-pair" orbital donating into the predominantly U $6d_{z^2}$ σ-acceptor orbital. A significant π interaction occurs between the CO π* orbitals and the U 5fπ orbitals. The resultant doubly-degenerate U–CO π-bonding molecular orbital is stabilized below the remaining 5f block of orbitals. As such, it is the HOMO of the complex, and, consistent with the experimental findings, it represents significant metal-to-carbonyl π back-bonding (Fig. 6). The interaction of [Cp_3U] with the even stronger π acid NO to give the hypothetical [Cp_3UNO] complex results in greater π back-bonding, which would stabilize the HOMO more than in [Cp_3UCO].[62] Because NO has one more electron than CO, it is predicted that this still unknown molecule could be the first diamagnetic U^{IV} compound.

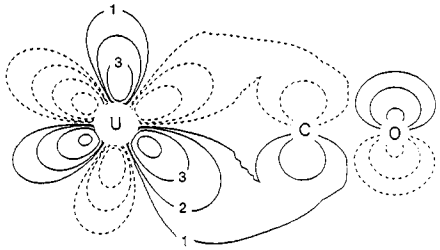


Fig. 6. Contour plot of the HOMO of [Cp_3UCO] in a plane containing the U, C, and O atoms [90].

The U–CO bond disruption enthalpy for **10** is about 10 kcal mol^{-1}.[85] Compared to the typical disruption enthalpies of about 40 kcal mol^{-1} for early transition-metal carbonyls, the U–CO value is quite low, comparable to $D(Cp_3U\text{-thf})$. Because the C–O stretching frequency of **10** suggests bonding similar to that in typical transition-metal complexes, the low bond enthalpy is attributed to severe interligand nonbonded repulsions.

Because the molecular structure of **10** has not been determined conclusively and uranium is known to be highly oxophilic, the possibility of an oxygen-bound isocarbonyl adduct, [Cp_3UOC], was considered.[90] The π* orbitals of CO are localized on the carbon atom, which is not adjacent to the uranium atom in the isocarbonyl complex, precluding any significant π back-bonding. The probable reason that the isocarbonyl complex is unstable relative to the carbonyl complex is that the U–OC σ bond involves the oxygen "lone-pair" orbital of carbon monoxide, which is at too low an energy to interact with the empty σ-acceptor orbital of uranium. Instead, the isocarbonyl interacts with the filled "semi-core" 6p orbitals of uranium, resulting in a "filled–filled" interaction and no net bonding.

Crystallographic studies also provide support for uranium-to-fourth-ligand π back-bonding.[91] A comparison of isostructural uranium and cerium compounds reveals that the M–N distances are comparable in [Cp'_3U(quin)] (quin = [$N(CH_2CH_2)_3CH$]) and [Cp'_3Ce(quin)], whereas the M–P distances in [Cp'_3UPMe_3] and [$Cp'_3U\{P(OCH_2)_3CEt\}$] are significantly shorter than those in the corresponding cerium complexes. The authors conclude that there is π back-bonding from [Cp'_3U] to the phosphine and phosphite ligands, whereas the lanthanide compound, [Cp'_3Ce], can only interact with the Lewis bases in a σ-only or purely electrostatic manner. Similarly, the M–O distances in [Cp_3Pr(thf)] and [Cp_3U(thf)] are comparable, while the M–C distance in [Cp‴UCNEt] is considerably shorter than that in [$Cp_3PrCNEt$], giving evidence for uranium-to-isocyanide π back-bonding.

Further evidence for the different bonding interactions of lanthanides and early actinides with isocyanide ligands comes from an IR spectroscopic investigation of [Cp_3MCNEt] compounds.[92] The C–N stretching frequencies for the lanthanide compounds are all at about 2200 cm^{-1}, approximately 50 cm^{-1} higher than ν_{CN} in free CNEt. The increase in ν_{CN} is common for CNR ligands bound to higher-valent transition-metal atoms and is indicative of little or no π back-bonding.[93] By contrast, the C–N stretching frequencies of the early actinide (Th to Am) compounds span a range of 60 cm^{-1}, with [$Cp_3ThCNEt$] exhibiting the lowest ν_{CN} (2140 cm^{-1}) and [$Cp_3AmCNEt$] the highest (2202 cm^{-1}). The greater sensitivity of ν_{CN} to the metal atom in the actinide series relative to the lanthanide series, while not conclusive evidence of significant π back-bonding, does portend different bonding in the organoactinide complexes from that in the organolanthanide complexes.

Multiple bonding between the [Cp_3U] fragment and nitrogen- and oxygen-containing donor ligands has been extensively investigated both experimentally[94, 95] and theoretically.[96] A variety of different N-donor complexes, spanning a broad range of U–N bond lengths, have been made and structurally characterized: [Cp_3UNPh_2], 2.29 Å; [Cp_3UNPPh_3], 2.07 Å; [$Cp_3UNC(Me)CHPMePh_2$], 2.06 Å; [Cp_3UNPh], 2.02 Å. All of these U–N bonds are significantly shorter than those generally observed in complexes that contain neutral N-donor ligands bound to uranium, which are typically 2.4–2.8 Å.[91, 95]

The great variations observed in U–N bond length and the difficulties in describing the above structures with single resonance forms have prompted EH calculations on the model complexes $[Cp_3UNH_3]^+$ and [Cp_3UL] (L = NH_2, NPH_3, NHCHCHPH, NPh).[96] The calculations indicate significant N 2pπ-to-U π donation, primarily into the 6dπ orbitals, for the latter three complexes. The authors propose that the strongest U–N π bonding should be observed in a uranium nitride complex such as $[Cp_3UN]^{q-}$. No such organoactinide

nitride complexes are yet known. The σ donation from nitrogen to uranium is much greater for the formally anionic nitrogen ligands than for the neutral NH_3 ligand. The authors demonstrate an excellent correlation between the total U–N overlap population (calculated at a constant U–N bond length of 2.06 Å for all compounds) and the crystallographically observed U–N bond length for this series of five compounds (Fig. 7). The positive charge on U is largest for $[Cp_3UNPh]$, consistent with its formulation as a $5f^1$ U^V complex.

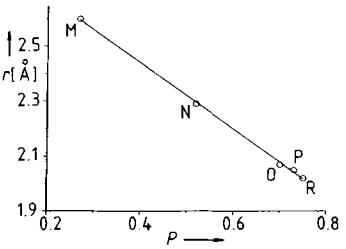

Fig. 7. Plot of observed U–N distances r, versus, U–N overlap populations P calculated at U-N = 2.06 Å for a series of $[Cp_3UX]$ systems: M = $[Cp_3UNH_3]$; N = $[Cp_3UNH_2]$; O = $[Cp_3UNPH_3]$; P = $[Cp_3UNCHCHPH_3]$; R = $[Cp_3UNPh]$ [96].

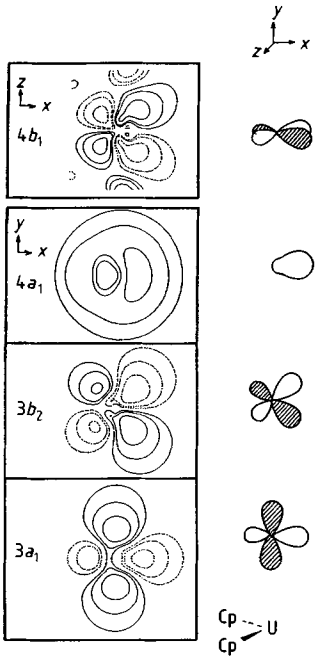

Fig. 8. Contour plots of the important valence orbitals in a $[Cp_2U]^{2+}$ fragment [99].

The same authors also performed calculations on the series of model complexes $[Cp_3UOH_2]$, $[Cp_3UOPH_3]$, $[Cp_3UOCHCHPH_3]^+$, and $[Cp_3UOCH_3]$ in order to investigate variations in U–O bonding.[96] Again, an excellent correlation between calculated U–O overlap population and observed U–O bond length (over a range of > 0.4 Å) was obtained. On comparing homologous compounds containing U–N and U–O bonds, the authors conclude that the nitrogen donors are better able to form multiple bonds to uranium.

Xα-SW calculations on $[Cp_3UOH]$ corroborate the conclusions of the EH studies.[62] Significant donation from the O 2pπ orbitals into the U 6d and, to a lesser extent, the 5f orbitals was observed. The π donation from alkoxide ligands to actinide atoms has been used to rationalize the unusually large U–O–R bond angles observed in actinide alkoxide complexes.[97, 98]

4.2. Bis(cyclopentadienyl)actinide Complexes

4.2.1. The An–X σ Bond

Among the most extensively studied actinide–ligand σ bonds are those in the host of $[Cp_2^*AnX_2]$ (An = Th, U] systems. The An–X bonds in these complexes exhibit a remarkably diverse chemistry, which often parallels that observed in $[Cp_2MX_2]$ complexes of the transition metals. The unoccupied frontier orbitals of a $[Cp_2U]^{2+}$ fragment as obtained from EH calculations are shown in Figure 8.[99] These orbitals, which are primarily 6d in character, closely resemble those of $[Cp_2Ti]^{2+}$,[61] although the $[Cp_2U]^{2+}$ orbitals are somewhat higher in energy and more diffuse. In both the actinide and transition-metal systems, the frontier orbitals are able to accept charge from formally anionic σ-donor ligands, leading to metal–ligand bonds of a_1, b_2, and, for the actinide systems only, b_1 symmetry.

The donor ability of the X ligands in $[Cp_2^*AnX_2]$ systems directly affects the valence orbital energies of the complexes. A comparison of the PE spectra of $[Cp_2^*AnMe_2]$ and $[Cp_2^*AnCl_2]$ reveals that the Cp π_2 ionization bands are at lower IE in the former than in the latter.[78] Similarly, the $5f^2$ ionization in $[Cp_2^*UMe_2]$ occurs at lower IE than that in $[Cp_2^*UCl_2]$, although the difference between the two (0.21 eV) is significantly less than that observed in d^2 transition-metal systems (e.g., a difference of 0.7 eV between the first IEs of $[Cp_2'MoCl_2]$[100] and $[Cp_2MoMe_2]$[101]). It seems surprising that, in spite of strong An–Me σ-bond formation, the decrease in $5f^2$ IE for $[Cp_2^*UMe_2]$ relative to $[Cp_2^*UCl_2]$ is so much less than that for $[Cp_2^*UCl_2]$ relative to $[UCl_4]$. Xα-SW calculations on $[Cp_2AnX_2]$ (X = Cl, Me) also indicate that CH_3^- is a stronger σ donor than Cl^-, and that Cl^- is not a significant π donor to uranium.[80]

Marks et al. have done detailed studies on the structures, reactivities, and bond energies of $[Cp_2^*AnR_2]$ (R = hydride or alkyl) systems.[102] The bis(neopentyl) complex $[Cp_2^*Th(CH_2CMe_3)_2]$ (**11**) exhibits an unusual geometry in which the two neopentyl groups are significantly inequivalent: one has a much shorter Th–C bond and shows a very obtuse Th–C–C angle[103] (Fig. 9). This behavior is attributed to an agostic interaction[104] between the α C–H bonds and the Th center. An EH analysis of the model complex $[Cp_2Th(C_2H_5)_2]$ indeed indicates a significant agostic interaction at large Th–C–C angles.[99, 105] The calculated potential energy curve as a function of one Th–C–C angle is at a minimum near the experimentally observed angle of 158°. The potential curve is quite shallow, consistent with the observed stereochemical nonrigidity of the alkyl groups in **11**.

The apparent affinity of Th^{IV} for additional electron density, as evidenced in the agostic behavior described above,

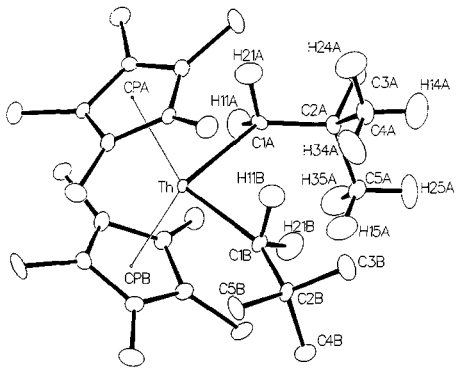

Fig. 9. The 50 K neutron diffraction structure of **11**. Significant bond angles and distances: Th-C1A-C2A = 132.1°; Th-C1A = 2.543 Å, Th-C1B-C2B = 158.2°; Th-C1B = 2.456 Å [103].

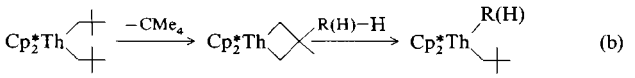
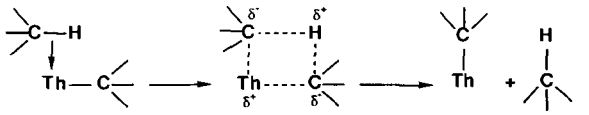
has been used to explain the remarkable ability of such compounds to activate C–H and H–H bonds.[106] For example, **11** can be entropically driven to strained thoracyclobutane **12**, which undergoes facile ring-opening C–H activation reactions [Eq. (b)].[107, 108] Oxidative addition of R–H to **12**



(b)

11 **12** **13**

can be ruled out as a possible step in the transformation of **12** to **13**; such a step would require the formal oxidation of d^0f^0 Th^{IV}. The kinetic data on reactions such as **12** → **13** are consistent with a concerned, four-center heterolytic C(H)–H activation pathway, involving precoordinaton of the activated bond (Scheme 1).[108] This mechanism parallels those that



Scheme 1. Four-center C(H)–H activation mechanism.

have been proposed[109, 110] and studied theoretically[111] for C–H bond activation by d^0 transition-metal and lanthanide organometallics. In both of these latter types of systems, the metal d orbitals are the most important ones with respect to precoordination, suggesting a similar role of the 6d orbitals in the actinide systems.

4.2.2. An–X Bond Energies

Thermochemical studies of $[Cp_2^*AnR_2]$ and $[Cp_2MR_2]$ have yielded experimental values for the An–R and M–R bond disruption enthalpies.[112–114] Representative values of the bond disruption enthalpies for Equations (c) and (d)

$$Cp_2^*AnR_2(g) \longrightarrow Cp_2^*AnR(g) + R^{\cdot}(g) \quad (c)$$

$$Cp_2MR_2(g) \longrightarrow Cp_2MR(g) + R^{\cdot}(g) \quad (d)$$

are listed in Table 2. The Th–R bonds are generally about 5–10 kcal mol^{-1} stronger than the analogous U–R bonds. The An–R bonds are generally stronger than the corresponding M–R bonds, where M is a middle or late transition metal,[113] and slightly stronger than, or comparable to, M–R bonds of the early transition metals.[114] As mentioned earlier, the trends in bond disruption enthalpies have been successfully modeled theoretically, and the greater strength of the M–R bonds of the early transition metals is attributed to the repulsive interactions between the filled d orbitals of the late transition metals and the occupied ligand orbitals.[115]

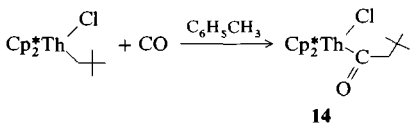
Table 2. Bond disruption enthalpies D(M-R) [kcal mol^{-1}] for selected M–R bonds.

Compound	D(M-R)	Ref.
$[Cp_2^*ThMe_2]$	77.2	[111]
$[Cp_2^*Th(C_6H_5)Cl]$	90.5	[112]
$[Cp_2^*UMe_2]$	67.8	[112]
$[Cp_2^*U(C_6H_5)Cl]$	86.7	[112]
$[Cp_2^*ZrMe_2]$	67.0	[113]
$[Cp_2ZrMe_2]$	67.2	[113]
$[Cp_2^*HfMe_2]$	72.0	[113]

Interestingly, the Th–R bond disruption enthalpies in $[Cp_3ThR]$ complexes are significantly larger (by about 5 kcal mol^{-1}) than those in the corresponding $[Cp_2^*ThR_2]$ complexes.[116] These results were somewhat surprising in that the presence of three Cp ligands should increase the steric congestion about the Th center. The authors propose that the bond-strength difference in the two systems might be due to differences in the Th–R orbital overlap, although significant differences in the bonding are not evident in the PE spectra.[78]

4.2.3. CO Insertion Products and Other Adducts

Marks et al. have demonstrated that, like the early transition-metal metallocene alkyls, $[Cp_2^*An(R)(X)]$ and $[Cp_2^*AnR_2]$ systems readily insert CO and other small molecules into their An–R bonds [Eq. (e)].[117]



(e)

14

The crystal structure of **14** (Fig. 10) reveals an unusually short Th–O distance, 0.07 Å shorter than the Th–C(acyl) bond. In contrast, the M–O distances observed in most transition-metal acyls are invariably longer than the M–C distances. These observations led the authors to favor formulation of the actinide-acyl moiety as a carbene-like dihapto acyl (**15**) rather than as a "normal" metal acyl group (**16**). Similar observations have been made for the insertion of CO into An–NR_2 bonds, yielding η^2-carbamoyl complexes[118] and for the insertion of isocyanides into An–R bonds.[119] The carbene-like description (**15**) of the bonding in actinide-

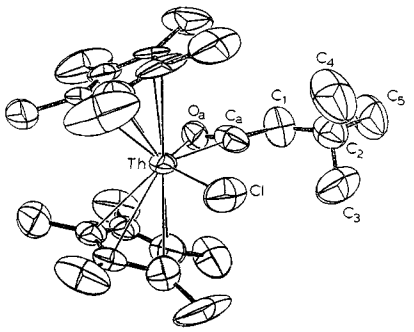


Fig. 10. ORTEP drawing of the nonhydrogen atoms for the $[Th\{(CH_3)_5C_5\}_2\{\eta^2\text{-}COCH_2C(CH_3)_3\}]Cl$ molecule [117].

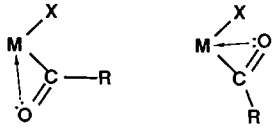
acyl and related complexes is in accord with the remarkable C–C coupling reactions that they exhibit.[14a, 117]

15 16

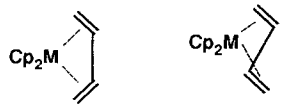
A notable difference in the structures of actinide acyls and those of transition metals is the orientation of the η^2-acyl C–O bond relative to the other σ-bonded ligand. Actinide acyls exhibit both the "O-outside" (**17**) and "O-inside" (**18**) structures; in the carbamoyl complexes $[Cp^*_2An(CONMe_2)Cl]$, for example, both isomers exist in equilibrium in solution.[120] By contrast, all structurally characterized acyl complexes of the group 4 metals show only the O-inside structure **18**.[121, 122] *Tatsumi, Hofmann,*



17 18

Hoffmann et al. have used EH calculations to investigate the preference for η^1- versus η^2-acyls and, for the latter, the preference for O-outside versus O-inside coordination.[123] The question of η^1 versus η^2 coordination was addressed by comparison of the interactions of a $COCH_3^-$ ligand with the $[Mn(CO)_5]^+$, $[Cp_2ZrMe]^+$, and $[Cp_2UCl]^{3+}$ metal fragments. Each fragment has a frontier orbital appropriate for the formation of a M–C σ bond with the acyl ligand. The latter two fragments also contain an unoccupied orbital that is capable of accepting density from the acyl oxygen lone pair, thus favoring the η^2-acyl geometry. In the more electron-rich $[Mn(CO)_5]^+$ fragment, the 3d orbital that would be appropriate to accept charge from the acyl oxygen is occupied, precluding a Mn–O(acyl) interaction and leading to an η^1-acyl structure. The shape of the U-based hybrid orbital in $[Cp_2UCl]^{3+}$ that fosters the η^2-acyl bonding stabilizes the O-outside structure **17** in the actinide-acyl relative to that in the transition-metal complex: for $[Cp_2Zr(COMe)Me]$, structure **17** is calculated to be about 5 kcal mol^{-1} less stable than structure **18**; for $[Cp_2U(COMe)Cl]^{2+}$, the two structures are essentially isoenergetic, in accord with the experimental observations.

The electronic structure of the 1,3-diene compounds of $[Cp^*_2Th]$ and $[Cp^*_2U]$ has also been investigated. The 1,3-diene complexes of zirconium, $[Cp_2Zr(1,3\text{-diene})]$, can exhibit either s-*cis* (**19**) or s-*trans* (**20**) structures.[124] On the other



19 20

hand, $[Cp^*_2Th(C_4H_6)]$ shows only the s-*cis* structure.[125] EH calculations show a sizable energy gap between the minima of the s-*cis* and the s-*trans* isomers for both $[Cp_2Th(C_4H_6)]$ (0.74 eV) and $[Cp_2U(C_4H_6)]$ (0.42 eV), favoring the s-*cis* geometry in each case.[99] Similar calculations on $[Cp_2Zr(C_4H_6)]$ show that the s-*cis* and the s-*trans* geometries are well balanced (0.07 eV in favor of s-*cis*). The difference between the actinide and the zirconium results stems from the $3a_1$ frontier orbital of the $[Cp_2M]$ fragment (Fig. 8). For zirconium this a_1 orbital interacts with the π_3^* orbital of butadiene equally well in either the s-*cis* or the s-*trans* geometry, but for the actinide compounds the $3a_1$–π_3^* interaction is much greater in the s-*cis* geometry. The butadiene terminal carbon atoms in the actinide compounds have a large negative charge. The high polarity in the Th–C(terminal) bonds is consistent with the violent reactivity of the complex with organic carbonyls and with the facile insertion of pyridine into the Th–C bond.

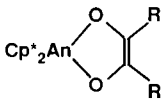
Tatsumi and *Nakamura* have also compared two isomers of $[Cp_2U(C_4H_4)]$, namely, the actinacyclopentadiene complex, $[Cp_2UCH{=}CHCH{=}CH]$, and the cyclobutadiene complex, $[Cp_2U(\eta^4\text{-}C_4H_4)]$.[99] While no examples of actinide cyclobutadiene compounds exist, there is a known actinacyclopentadiene complex, $[Cp^*_2U(C_4Ph_4)]$.[126] The metallacyclopentadiene complex is calculated to be 2.5 eV more stable than the hypothetical cyclobutadiene complex. However, the authors note that $[Cp_2U(\eta^4\text{-}C_4H_4)]$ would be kinetically stable because (1) the U-to-η^4-C_4H_4 bonding is reasonably strong (actually stronger than U-to-Cp bonding) and (2) a C–C bond cleavage of $[Cp_2U(\eta^4\text{-}C_4H_4)]$ with simultaneous formation of two U–C σ bonds is symmetry forbidden.

The bonding in the bis-pyrazolate complexes $[Cp_2Mo(pz)_2]$, $[Cp_2Mo(pz)_2]^{2+}$, and $[Cp_2U(pz)_2]$ (pz = $C_3H_3N_2^-$) has been investigated via EH calculations.[127] The pz ligand can adopt either an η^1 (two-electron donor) or an η^2 (four-electron donor) coordination geometry, as it does in the case of $[Cp_3U(pz)]$.[128] The electronically favored structures for the molybdenum complexes are those predicted by the effective-atomic-number rule, that is η^1,η^1 for the neutral complex and η^2,η^2 for the dicationic complex. In contrast, $[Cp_2U(pz)_2]$ exhibits an η^2,η^2 minimum with the calculated U–N–N angles in close agreement with the crystal structure of $[Cp^*_2U(pz)_2]$.[129] The choice of η^1 versus η^2 coordination is similar to that of the acyl complexes and can be explained in terms of the same frontier orbitals.

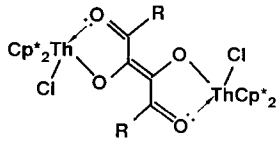
There have been several studies of the mechanism of CO insertion into the actinide–alkyl bonds of $[Cp^*_2AnR_2]$ sys-

tems. EH calculations have been used to investigate the pathway by which a CO molecule approaches $[Cp_2U(CH_3)_2]^{2+}$ prior to insertion into the M–R bond.[123] Approach of the CO ligand along a path perpendicular to the plane containing the two Cp centroids and the metal atom is found to have no appreciable barrier, consistent with the experimental result that CO insertion is extremely facile.

$[Cp^*_2AnR_2]$ and $[Cp^*_2AnRX]$ have been shown to undergo facile carbonylation with subsequent C=C bond formation to yield monomeric or dimeric products such as **21** and **22**.[130] A possible mechanism for the formation of **21** via



21



22

stepwise CO insertion to yield the bis(η^2-acyl) complex, with subsequent coupling of the two acyl ligands, has been considered.[131] The bis-acyl complex $[Cp_2U(COR)_2]^{2+}$ is predicted to have a bis-η^2 structure, in contrast to early-transition-metal complexes in which the η^1,η^2 structure is found to be the most stable. The HOMO of $[Cp_2Ti(COR)_2]$ is destabilized on proceeding from the η^1,η^2 structure to the η^2,η^2 structure by an unfavorable out-of-phase interaction of the acyl lone pairs. For $[Cp_2U(COR)_2]$, the HOMO also has out-of-phase acyl lone-pair orbitals in the η^2,η^2 structure; now, however, these can interact favorably with a U 5f orbital. The HOMO is therefore stabilized on going from η^1,η^2 to η^2,η^2. These results are consistent with the observed η^2,η^2 structure of $[Cp^*_2U(CONMe_2)_2]$.[132]

The least-motion pathway for acyl coupling (C=C bond formation) in $[Cp_2U(COR)_2]^{2+}$ is a symmetry-forbidden process with a calculated barrier as high as 1.6 eV. The optimum reaction path is one in which the two acyl groups rotate up to 30° out of planarity on the approach to the transition state, which then collapses to the planar enediolate product **21**. The barrier for this pathway is 0.7 eV. The resulting enediolate compound is 2.9 eV more stable than the $(\eta^2\text{-COR})_2$ structure, indicating that the coupling is highly exothermic. The twisting of the η^2-COR groups out of the equatorial plane costs surprisingly little energy (0.1 eV), and support for this motion comes from the structure of the complex $[Cp^*_2U(CONMe_2)_2]$, which has twisted cabamoyl groups.[132] The absence of carbamoyl coupling is due to the electronic influence of the NR_2 groups, which results in a "more-forbidden" least-motion pathway with a barrier of 2.9 eV and a non-least-motion pathway having a barrier of 1.1 eV. A completely different pathway has been proposed for acyl coupling to enediolates at a $[Cp_2Zr]$ center.[133]

Polysulfide ligands such as S_5^{2-} form metallacycles with both actinide and transition-metal atoms. In contrast to transition-metal MS_5-containing complexes, which all exhibit chair conformations of the MS_5 ring, $[Cp^*_2ThS_5]$ shows an unprecedented twist-boat conformation (Fig. 11).[134] This compound has unusually short Th–β-S distances, indicative of some interaction between the metal and the terminal S–S bonds (S_1-S_2 and S_4-S_5) of the S_5^{2-} ligand. EH calcu-

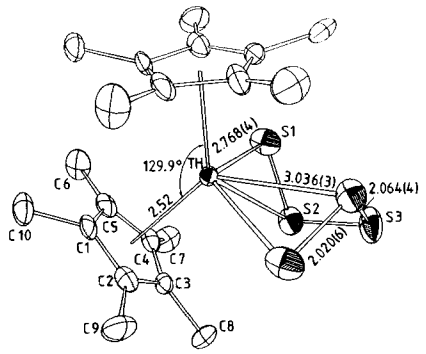


Fig. 11. Crystal structure of $[Cp^*_2ThS_5]$ [134].

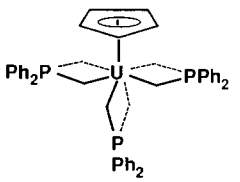
lations on $[Cp_2ThS_5]$ indicate donation from the two highest occupied MOs of S_5^{2-} into empty orbitals (predominantly 6d) on the $[Cp_2Th]^{2+}$ fragment. While the Th–α-S bonding dominates, significant Th–β-S bonding is also indicated.

4.3. Mono(cyclopentadienyl)actinide Complexes

$[CpU\{(CH_2)(CH_2)P(C_6H_5)_2\}_3]$ (**23**) has the longest U–C σ bonds yet reported (2.66 Å). EH calculations on this compound give an average U–C σ-bond overlap population of 0.26 compared with an overlap population of −0.03 for U–C(Cp), indicating covalency in the U–C σ bonds.[135] However, the overlap populations for the U–C σ bonds in this compound are much smaller than that found for the U–C σ bond in $[Cp_3UCH_3]$. That the difference is not a result of the long U–C bonds in **23** was supported by calcu-



23

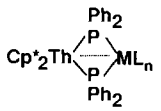
lations on the compound with U–C distances of 2.4 Å (the same as in $[Cp_3UCH_3]$. At this distance the overlap population increases only slightly to 0.27. The small overlap populations (and, hence, the long U–C distance) are due to the outward deformation of the ylide-carbon lone pairs along a direct line to the uranium atom. In addition, the coplanarity of the five carbon atoms and slight repulsive interactions between the lone pairs on adjacent ylides will further reduce the size of the inward-pointing orbital lobes.

5. Actinide–Cyclopentadienyl Complexes Containing Metal–Metal Bonds

To date, no bonds between two actinide centers have been observed in organoactinide chemistry. The possibility of 5f-based metal–metal bonds in the naked uranium and neptunium dimers have been investigated via nonrelativistic Xα-SW molecular orbital calculations.[136] These results suggest a

$\sigma^2\pi^4\delta^4\phi^2$ configuration for U_2, leading to a sextuple bond, and a $\sigma^2\pi^4\delta^4\phi^4$ configuration for Np_2, yielding a septuple bond. The separation between the ϕ_u and the ϕ_g orbitals is only 0.3 eV in Np_2, which might lead to a high-spin configuration and a pentuple bond. A recent ab initio calculation of the electronic structure of U_2, including relativistic effective core potentials and electron correlation, casts doubt on the simple f-orbital overlap model for U–U bonding.[137]

Two systems that contain phosphido-bridged bonds between Th and a transition metal have recently been reported. Reaction of $[Cp^*_2Th(PPh_2)_2]$ with $[Pt(cod)_2]$ in the presence of PMe_3 yields complex **24a**, which has a Th–Pt distance of 2.98 Å, 0.2 Å shorter than the sum of the covalent radii of the metal atoms.[138] On the basis of this structural information, along with ^{31}P NMR data and comparisons with other heterobimetallics, the authors conclude that **24a** contains a direct Th–Pt bond. Their Hartree–Fock and generalized valence bond (GVB) ab initio calculations on the model compound $[Cl_2Th(\mu\text{-}PH_2)_2Pt(PH_3)]$ lead to qualitatively similar descriptions of the metal–metal bonding. The bond is formed between the $5d_{x^2-y^2}$ orbital on Pt and the $6d_{x^2-y^2}$ orbital on Th, with a larger fraction of electron density on the Pt center. A Mulliken population analysis reveals a charge of + 1.48 on the Th atom and a charge of 0.00 on the Pt atom. The authors conclude that the Th–Pt bond can be regarded as a formal donor–acceptor, or dative, bond from the "filled" $5d^{10}$ shell of Pt into the "empty" 6d shell of Th.

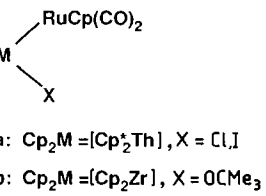


24 a: $ML_n = [PtPMe_3]$

b: $ML_n = [Ni(CO)_2]$

Complex **24b** has a Th–Ni distance of 3.206 Å, shorter than that expected from ionic model assumptions. EH calculations indicate that the Th–Ni overlap population, although negative at all distances investigated, is most favorable at the experimental distance of 3.2 Å and becomes increasingly more negative as the Th–Ni distance is lengthened to 3.7 Å.[139] Furthermore, of the major interactions among the metals and the bridging phosphido ligands, the Th–Ni interaction is the most sensitive to this geometrical change, indicating that the M–P bonds have some geometrical flexibility. When the molecule is divided into two fragments, two principal sources of Th–Ni interaction are discernible. The first is the filled–filled repulsion between the d levels of the Ni atom and the Th–PH_2 bonding orbitals resulting in a net antibonding interaction between Th and Ni. The second is the interaction between the filled d levels of $[Ni(CO)_2]$ and the frontier orbitals of $[Cp_2Th(PH_2)_2]$. The largest of these is a π interaction between the HOMO of $[Ni(CO)_2]$, which is a hybrid of d_{xz} and p_x that points toward the Th atom, and the $3b_2$ frontier orbital of Th. A σ interaction takes place between the SHOMO of $[Ni(CO)_2]$, a mixture of Ni $d_{x^2-y^2}$, d_{z^2}, p_z, and s orbitals, and the $3a_1$ frontier orbital of Th, a mixture of d_{z^2}, p_z, and s orbitals. Owing to the superior radial extension of the Th 6d orbitals, both the σ and the π interactions are dominated by the Th 6d orbitals rather than the Th 5f orbitals. Similar conclusions were reached on the basis of an Xα-SW calculation on compound **24b**.[140]

Marks et al. have prepared the first two complexes that contain a direct, unsupported bond between an actinide atom and a transition metal. The reaction of $[Cp^*_2ThX_2]$ with $[CpRu(CO)_2Na]$ yields compounds **25a** (X = Cl, I).[117] The iodo derivative has a Th–Ru bond length of 3.028 Å, comparable to the Zr–Ru bond length of 2.910 Å in compound **25b** ($X = OCMe_3$).[141] The nature of the metal–metal bonding in compounds **25** has been investigated using quasi-relativistic Xα–SW calculations on the model systems $[Cp_2(I)M\text{-}RuCp(CO)_2]$ (M = Zr, Th).[142] The M–Ru bonding is virtually the same in these two systems and consists of donation from the filled $4d_{z^2}$ orbital of Ru into the empty d_{z^2} orbital of Th or Zr. The result is a slightly "bent" M–Ru σ bond (Fig. 12) that is highly polarized (ca. 70%) toward the Ru atom. Thus, the bond is best described as a dative donor–acceptor bond formed by donation from $[CpRu(CO)_2]^-$ to a d^0 or d^0f^0 M^{IV} center. The authors note that $[CpRu(CO)_2]^-$ can be regarded as an "organometallic pseudohalide". This notion has been extended in the synthesis of several $[Cp_3AnMCp(CO)_2]$ (An = Th, U; M = Fe, Ru) derivatives.[143]



25 a: $Cp_2M = [Cp^*_2Th]$, X = Cl, I

b: $Cp_2M = [Cp_2Zr]$, $X = OCMe_3$

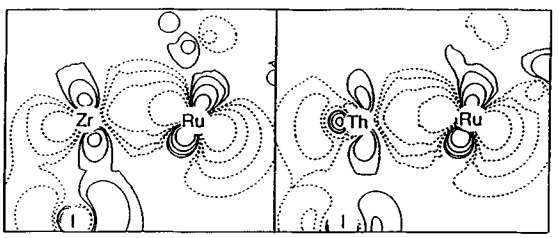


Fig. 12. Contour diagrams of the metal–metal bonding orbitals in the heterobimetallic complexes $[Cp_2(I)M\text{–}RuCp(CO)_2]$ (M = Zr, Th) [142].

6. Conclusion and Outlook

In this review, we have tried to emphasize the interplay between experimental and theoretical electronic structure investigations in the comparatively new and very exciting field of organoactinide chemistry. As is evident from the compounds discussed in this review, the lion's share of electronic structural study of organoactinide chemistry has involved complexes of the two most experimentally accessible actinide elements, namely, thorium and uranium. These studies point to some general conclusions concerning the qualitative description of the bonding in these systems:

1. The strong donor ability of formally anionic ligands leads to a generally high degree of covalency in organoactinide complexes, particularly compared to the actinide halides.

2. The actinide 6d orbitals are generally greater participants in the metal–ligand bonding than are the 5f orbitals, a notion first proposed by *Clark* and *Green* in their interpretation of the PE spectrum of uranocene.[144] As a result, the 6d orbitals are more affected by the organic "ligand field" than are the 5f orbitals.
3. The actinide 5f orbitals participate in metal–ligand bonding when symmetry dictates that no other actinide orbitals are available.
4. The metal-localized electrons in "non-f^0" complexes (such as those of U^{IV}) reside in nearly pure actinide 5f orbitals. Exceptions to this generalization can occur in coordinatively unsaturated early actinide complexes, such as $[Cp_3Th]$.

The picture that emerges is one in which there is a dichotomy in the roles of the actinide 5f and 6d orbitals, wherein the latter are used to bind the ligands and the former are used to house metal-based electrons. By contrast, in organotransition-metal complexes the valence nd orbitals serve as both the principal source of metal–ligand bonding and as the repository of metal-based electrons. This situation is shown schematically in Figure 13, wherein it can be seen how this simple description accounts for the paramagnetism of U^{IV} complexes vis-à-vis the diamagnetism usually observed in d^2 transition-metal organometallics, such as $[Cp_2MoCl_2]$.[80]

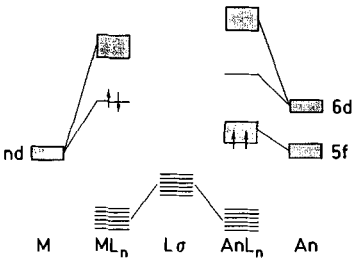

Fig. 13. Qualitative MO diagram comparing the roles of the metal-based orbitals in transition-metal complexes (left) and actinide complexes (right).

What is the future of organoactinide electronic structure investigations? The studies to date have focused primarily on the relative roles of the actinide orbitals in bonding and on the relationship of this bonding to that in transition-metal systems. From a quantum-chemical point of view, the electronic structure calculations on organoactinides have been comparatively crude; very little has been done with respect to electron correlation in these systems, and, although quasi-relativistic corrections have been employed, there has been scant consideration of the effects of spin–orbit coupling. This situation is changing rapidly as the speed and accessibility of supercomputers increases. The recent spin–orbit configuration interaction calculation on uranocene by *Chang* and *Pitzer*[111] is a portent of what may be expected in this field in the future.

Glossary: A Brief Outline of Electronic Structure Methods for Actinide Systems

As is apparent from the preceding discussion, a wide variety of electronic structure methods have been applied to large actinide-containing molecules. Each method employs certain approximations in the construction or solution of the electronic-structure problem, and each has inherent advantages and disadvantages. The following is a very brief summary (without references) of the methods cited in this review; for an in-depth discussion of the electronic structure methodologies, we refer the reader to our recent detailed review of these methods as well as their applications in organometallic and nonorganometallic actinide chemistry [145].

Nonrelativistic versus Quasi-relativistic versus Relativistic Methods: "Conventional" molecular electronic structure calculations, based on the Schrödinger wave equation, include no consequences of subjecting the system to the tenets of special relativity. These *nonrelativistic methods* assume that the mass of every electron in the system is equal to the rest mass of the electron and that the electron-spin coordinate can be treated completely independently of the spatial coordinates. For the heavier elements, such as the third-row transition metals and the actinide elements, these assumptions are invalid. The classical angular speeds of the core electrons in these elements are nonnegligible fractions of the speed of light and thus a relativistic mass correction is necessary. *Quasi-relativistic methods* are those that include such mass corrections (as well as more arcane effects, such as the Darwin correction) but still maintain separate spin and spatial coordinates. The results of quasi-relativistic molecular orbital methods resemble those of nonrelativistic methods in that spatial molecular orbitals, to which spin functions can be attached, are derived. The *quasi-relativistic extended Hückel* and *quasi-relativistic Xα-SW* methods are examples of quasi-relativistic molecular orbital methods.

In addition to the effects noted above, *relativistic methods* include the interaction of the spatial and spin properties of the electrons, that is, spin–orbit coupling. The Dirac equation, which merges quantum mechanics and special relativity, is the usual starting point for relativistic electronic structure methods. The application of the Dirac equation to molecules is far more complex than that of the nonrelativistic Schrödinger equation, and several calculational approaches to solving the equation have been used. The *relativistically parametrized extended Hückel (REX)* method of *Lohr* and *Pyykkö* is probably the simplest approach to a fully relativistic calculation. Because relativistic approaches explicitly include spin–orbit coupling, the states and orbitals that result are bases for the double group of the molecule rather than the more familiar single group. Owing to the computational complexity of fully relativistic methods, relatively few such calculations have been performed to date on organoactinide systems.

Molecular Orbital Methods: Most of the electronic structure calculations reported here employ the molecular orbital approximation, in which it is assumed that each electron experiences the average field of all the other electrons in the molecule. The molecular orbitals are usually expanded as a linear combination of atomic orbitals (LCAO), which can be either analytical or numerical functions. In the *Hartree–Fock* method, which has been used sparingly for heavy element systems, all of the relevant integrals are solved exactly. In order to make such calculations computationally feasible, *relativistic effective core potentials* (ECPs or RCPs) are generally used. ECPs, which are based on relativistic atomic calculations, replace the core atomic orbitals and thus greatly reduce the number of molecular integrals while preserving the relativistic effects on the core electrons. Approximate LCAO-MO methods, such as the *extended Hückel method*, use either empirical or semiempirical approximations to some of the molecular integrals.

A family of molecular orbital methods that has moved to the fore in recent years is that based on *local density functional (LDF)* methods. These methods replace the nonclassical, nonlocal exchange interaction inherent to the Hartree–Fock method with a local exchange operator, which is dependent on the electron density raised to a fractional power. Because the equations involving the local exchange operator cannot be solved readily using analytical methods, the application of LDF methods depends on several numerical methodologies. The earliest LDF method, the *Xα scattered-wave (Xα-SW)* or *multiple-scattering Xα (MS-Xα)* method, uses a model Hamiltonian based on surrounding each atom of the molecule with a sphere. Scattering theory techniques are used to satisfy the boundary equations at the sphere surfaces. The orbitals ob-

tained are hybrid numerical/analytical functions that are based in part on a multicenter scattering wave function. Quasi-relativistic corrections can be easily added to Xα-SW calculations, and a fully relativistic version of the method has also been implemented.

The newer LDF methods use an atomic orbital basis in which to expand the molecular orbitals. The necessary molecular integrals are calculated by using numerical integration techniques. The *discrete-variational Xα (DV-Xα)* method uses numerical atomic orbitals that are obtained from atomic calculations. A fully relativistic implementation of this method, called the *Dirac–Slater discrete variational (DS-DV)* method, provides a relatively inexpensive means of performing relativistic calculations on large molecules. The *Hartree–Fock–Slater (HFS)* method is very similar to the DV-Xα method, except that analytical functions are used to represent the atomic orbitals. Quasi-relativistic and relativistic effects have also been incorporated into the HFS method.

Electron Correlation Methods: The importance of including electron correlation in electronic structure calculations has been well established for light-atom systems. Using a molecular orbital solution as a starting point, correlation is generally included via additional *configuration interaction (CI)* or *multiconfiguration self-consistent-field (MCSCF)* calculations. Because these techniques are extremely computationally demanding, only recently have they seen application to organoactinide complexes. ECPs are used to replace core electrons in such calculations, and spin–orbit effects can be included explicitly. The *generalized valence bond (GVB)* method, which includes electron correlation relative to a molecular orbital description, has also seen limited application to organoactinide systems. The GVB method uses a different form of the wave function than do molecular-orbital-based methods.

It is a great pleasure to acknowledge our co-workers at The Ohio State University, especially Anne Fang, Kevin Novo-Gradac, Melanie Pepper, Larry Rhodes, and Bill Schneider, who have made significant contributions to our understanding of organoactinide chemistry. We are also grateful to many colleagues elsewhere for stimulating discussions and to the Isotope and Nuclear Chemistry Division of Los Alamos National Laboratory for generously hosting both of us. We wish to thank the U.S. Department of Energy, the Petroleum Research Fund (administered by the American Chemical Society), the Ohio Supercomputer Center, the Associated Western Universities, and the Ohio State University Graduate School for their generous support of our research in actinide chemistry.

Groups of Organic Molecules That Operate Collectively

By Fredric M. Menger*

A "chemical system" is defined as an assemblage of molecules that collectively does something interesting or useful. The key word here is "collectively", a word that implies an interdependency and a group behavior that can be quite different from that of individual molecules. Batteries, computer chips, concrete, mayonnaise, shampoo, paint, liquid crystal displays, composites, and viruses are all examples of commonly encountered systems. A host–guest or "supramolecular" complex, on the other hand, would not be considered a system (as defined here), because only two species are involved. A chemical system is multimolecular, a collection of molecules interlocked in a tangle of dependencies. The review delves into a variety of chemical systems investigated by the author, including micelles, water pools, films, vesicles, and polymers. All of them can be categorized as "self-assembling" or "self-organizing" in the sense that defined structures arise spontaneously owing to noncovalent forces among the component molecules. Such chemical systems are useful for many purposes, including decontamination of environmentally dangerous substances, drug delivery, and separation of organic compounds.

1. Introduction

This review deals with "chemical collectivism": the chemistry of molecules that operate within organized assemblies called "systems". A living cell is the most remarkable example of a chemical system. Through a poorly understood cooperation and interdependence among the cellular components, an entity is created that exceeds the sum of the parts. Groups of molecules, properly assembled, can obviously accomplish much more than an equal number of molecules functioning separately. In this article, I will describe organic systems that play on that principle.

H. Ringsdorf et al.[1] wrote recently, "macromolecular chemistry... has become a classical discipline... with all the advantages and handicaps of maturity. Harvest is plentiful, the results are abundant—but one has to ask: where is the future, where are the adventures?" It seems likely that a major path for future organic research will course its way through communities of molecules. As with human communities, the individual molecular species dictates the behavior of the group, while, concurrently, the group imposes constraints upon the individuals. One would wish to understand this interrelationship in greater detail.

Tens of thousands of organic reactions, generally carried out one at a time in a nonaggregated mode, are now in hand. Although no one can deny the value of adding further to this wealth, one can likewise not ignore the need to incorporate into organic chemical thought many relatively unfamiliar forms of matter such as the coacervate, microemulsion, polyaphron,[39] vesicle, and film. These aggregated systems are, after all, composed of simple organic molecules, and they provide unique capabilities (to be described) for performing tasks such as running reactions, delivering drugs, and separating compounds. It is the goal of this article to promote research into organic molecules that self-assemble and do interesting things as a consequence.

In the biological world, self-assembly is a built-in tendency. Amino acid chains, for example, fold spontaneously into enzymes of precise shape. Raw flagellin from bacteria will, when placed in a petri dish, rapidly transform itself into isolated flagella. Ribosomes, membranes, and (at the highest level) developing embryos exemplify the wondrous ability to self-organize into complex structures. It is this capacity to create "form" that prompted *E. Schrödinger* to call living material "aperiodic crystals". Chemists will no doubt contribute substantially to future research into biological "form" just as they have to our current understanding of biological "substance". Progress in the subject is already evident from the growing number of publications on organic "forms" such as micelles, vesicles, films, and emulsions. Although these self-assembling systems are pitifully simple compared to biological structures, they represent a necessary first step in the evolving field.

Our past research has focused heavily on self-assembling systems, a wide variety of which are covered in this article. Since each topic is discussed herein via experiments carried out at Emory, the article is more a personalized "lecture in print" than a review. By including an assortment of self-assembling systems, I illustrate the richness of "chemical collectivism", but, unfortunately, I also make a thorough literature coverage impractical. To counter this problem, general references, containing comprehensive lists of relevant citations, are given at the beginning of each section. Thus, the reader can quickly locate work from a worldwide body of scientists who are also involved in chemical systems and who have provided key insights and inspirations in the area.

It will be noted that this article contains few tables, equations, and graphs. Perhaps, I have been unduly influenced by a quote from *R. J. Waller*:[2] "Excessive focus on detail and procedure at the expense of vision, of dreams, of reflection, is a good way to get rid of romance. We in the academic world have mastered this approach." Missing details (including all the synthetic sequences) can be obtained from the original literature.

2. Acidity at a Micelle Surface[3]

A "surfactant" is a compound possessing an ionic or polar head group attached to a long hydrocarbon tail (Scheme 1).

[*] Prof. F. M. Menger
Department of Chemistry, Emory University
Atlanta, GA 30322 (USA)

Upon exposure to water, 20–150 surfactant molecules assemble into a roughly spherical aggregate called a "micelle".

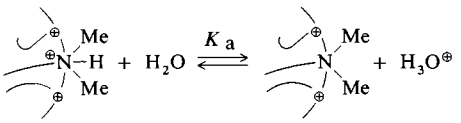
$CH_3(CH_2)_{11}OSO_3^{\ominus}Na^{\oplus}$ $\quad$ $CH_3(CH_2)_{15}\overset{\oplus}{N}(CH_3)_3Br^{\ominus}$

Scheme 1. Two examples of surfactants with ionic head groups.

The chains point inward, while the ionic head groups reside at the micelle surface near the bulk water. Surfactants, and their micellar systems, have found their way into almost every major commercial industry (food, cosmetic, pharmaceutical, petroleum, metal, and paper, to name a few). Being so useful and relatively simple, micelles seemed ideally suited for our initial entry into the chemical systems field. Since surfactants assemble only above a critical micelle concentration (cmc), we could compare directly monomer and aggregate properties by operating both below and above the cmc.

One of the first questions we asked was, "What is the pK_a of an ionizable head group at the micelle surface?"[4] This question brings up two notable points: (1) Even the most basic information on molecular aggregates was unavailable just a few years ago. (2) Securing such information (which would require only an afternoon with single-molecule chemistry) can extend to many months when an aggregate is involved. Chemical systems do not confess their secrets without arduous prodding.

Micellar dodecyldimethylammonium ion (Scheme 2) was selected for the pK_a studies. Now determining the pK_a of a monomeric amine, such as $C_6H_{13}NH_3^{\oplus}$, is trivial—one



Scheme 2. Acid-base reaction of a micellar ammonium surfactant, n-$C_{12}H_{25}NMe_2$.

merely titrates. Unfortunately, this is not possible with an aggregated amine salt, because titration with base generates free amine and destroys the micelle. There appeared only one way to obtain the pK_a: determine the forward and reverse rate constants and calculate K_a from the quotient of the two values. Dynamic NMR (a technique that provides rate data on species at equilibrium) was called upon for the purpose. Thus, if the proton remains on the nitrogen for a long time relative to the NMR time scale, one observes a methyl signal that is split into a doublet. If, on the other hand, the proton departs and returns rapidly, the splitting is washed out, and one sees only a singlet. Intermediate cases give line shapes that, with the aid of a computer, allow calculation of proton-transfer rates. The main experimental requirement is that the pH be adjusted to low values where the proton exit/entry process is neither too fast nor too slow for the NMR measurement.

It was found that the pK_a of the micellized amine is 1.4 units more acidic than the equivalent monomeric form. Positive charge accumulated on the micelle surface drives proton loss to the right relative to that of monomeric amine. A pK_a differential of 1.4 between aggregate and monomer was, historically, an important number because it constituted our first evidence that the micelle periphery is "rough". If the cationic head groups had been confined to a smooth spherical surface, then electrostatic effects among the proximate head groups would have produced discrepancies even greater than 1.4 pK_a units.

Acid-base properties at the interface of a molecular assembly can, in principle, be determined by adsorbing a pH-sensitive dye onto the aggregate. (Cationic dyes, for example, bind strongly to anionic micelles and vice versa.) Two problems plague this widely employed "probe" approach:[5] (1) Since dyes are often large, multifunctional molecules, they easily modify the fragile environment on which they are asked to report. (2) Since the location(s) of the dye in or on the aggregate is (are) difficult to establish, uncertainty exists over exactly what portion of the micelle is represented by the observed pK_a values. These problems, common to most probe studies, are avoided in our kinetically determined pK_a method because no potentially damaging probe is involved and the "site of action" necessarily corresponds to the head-group region.

Defining the structure and behavior of "single" organic compounds can often be a simple task owing to the power of modern instrumentation. Such is not the case, as we have just seen, for molecular aggregates where a higher dimension of complexity pervades the experiments. Thus, a chemical system requires an in-depth evaluation of numerous attributes that are irrelevant to single-molecule chemistry: aggregation number, shape, exit/entry rates of components, internal viscosity, water content, chain conformation, heats of aggregation, ion binding, solubilizing power, interfacial acidity, etc.

Fredric M. Menger's biographical data are omitted because, he claims, "they are of doubtful general interest". Suffice it to say that the unusual collage of ideas assembled in the accompanying article reflects his philosophy that "life, though short, is wide enough for a multitude of adventures if only the love of comfort and habit do not entomb the soul."

Characterization is burdened further by the fact that many properties (e.g., water content) are almost certainly not uniform throughout the assembly. Yet technical difficulties should not discourage research into chemical systems; their inherent interest, their prevalence in nature, and their considerable commercial potential more than compensate for the problems.

3. Chain Conformation within Assemblages[6]

Chemical systems in water are frequently stabilized by hydrophobic interactions among hydrocarbon chains of the component molecules. Chain conformation becomes a central issue in such cases. Are the chains linear or bent? If bends are present, where along the chains do they predominate? Are the kinks transient or permanent? How does chain-bending affect behavior (such as ion permeability through a membrane assembly)? The following sections describe three entirely different approaches (spectrometric, kinetic, and double ^{13}C-labeling) which our laboratory has used to deduce conformational properties within molecular assemblies. Although the examples are taken from the micelle area, the methodologies can be applied to additional chemical systems such as membranes and microemulsions.

3.1. Spectrometric Approach[7]

The acetylenic proton of RC≡CH has a solvent-dependent chemical shift. For example, the δ value for 1-hexyne increases from 1.66 in cyclohexane to 2.04 in acetone to 2.19 in 2:1 methanol/water. An acetylenic unit buried within an aggregate can, therefore, be used to sense and monitor micropolarity. If the terminal acetylenic unit in surfactants **1** and **2** encounters only an "oil droplet" within the micelle

$HC{\equiv}CCD_2(CH_2)_{10}OSO_3^{\ominus}$ **1** $HC{\equiv}CCD_2(CH_2)_{10}\overset{\oplus}{N}(CH_3)_3$ **2**

interior, then the chemical shift should be similar to that in cyclohexane. To the extent that the acetylenic proton "sees" water, the chemical shift will increase. Since motion within a micelle is rapid relative to the NMR time scale, the observed shift will simply be a weighted average from the nonpolar and aqueous environments. We found that micellar **1** and **2** possess δ values of 2.10 and 2.16, respectively, proving that the chain termini come into contact with water a surprisingly high percentage of the time. Note that monomeric molecules, in equilibrium with aggregated material, cannot be affecting the results; under our conditions (i.e., concentrations 25 times above the cmc) the monomer levels were far too low to contribute significantly to the weighted average. The conclusion is inescapable: chain termini are definitely not buried in a dry "oil droplet".

In order to grasp the import of the results with **1** and **2**, it is necessary to understand how micellar structure was perceived prior to the time that our experiments were carried out. For decades, both journal articles and texts discussed micellar organization in terms of the so-called Hartley model (Fig. 1 A).[8] Two features in particular were widely accepted, namely, linear chains and a dry interior. In fact, a micelle was often referred to as "an oil droplet with an ionic coat" and analyzed in terms of a "two-state" Hartley model. Our experiments with **1** and **2** (buttressed by theoretical work of others[9]) forces one to abandon the classical picture. Either water penetrates into the aggregate, wherein lie the acetylenic reporter groups, or else the chains loop around so as to expose the chain termini to the aqueous surface. In actual fact, we now believe that both phenomena occur,[10] and that micelles are far more disorganized than was believed in the past (Fig. 1 B). At first, chemists clung tenaciously to the Hartley model despite accumulating evidence, such as given above, that would seem to demand a revision. Only slowly did the idea of "wet" chain termini and other manifestations of micellar disorder diffuse into colloid literature. One sees here how difficult it is to define indisputably the structure of even a "simple" chemical system such as a micelle.

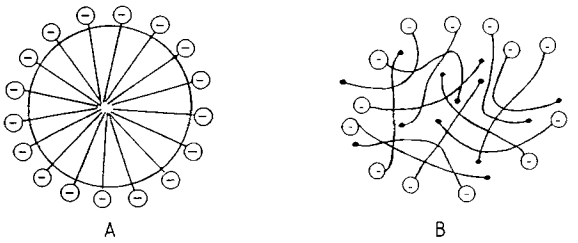


Fig. 1. A) The Hartley "two-state" model showing a dry oil droplet surrounded by an ionic coat. Terminal methyl groups are buried in the center of the system. B) Schematic of a revised micelle model [10] embodying many features absent in the Hartley model: rough surface, water-filled pockets, chain looping, nonradial distribution of chains, and contact of terminal methyls (indicated by heavy dots) with water.

Could it be that acetylenic surfactants **1** and **2** behave differently from their totally saturated counterparts? Or, rephrased, could the acetylene moieties of **1** and **2** be perturbing the "normal" micelle structure? We had, of course, specifically selected the acetylenic probe because of its relatively innocuous properties. Thus, the acetylene group has spatial requirements similar to the ethyl group (19.6 and 23.9 $cm^3 mol^{-1}$, respectively) and a positive Hansch hydrophobicity of + 0.40 (compared to −0.67 for OH and +0.56 for CH_3).[11] Relative to conventional fluorescent, ESR, and NMR probes, the acetylenic unit seemed to us fairly harmless. Perhaps the best evidence that the acetylenic probe was nonperturbing came from an observed similarity between cmc values for **1** and **2** and their saturated counterparts. Since looping halves the chain length, one would have expected unusually large cmc values had the triple bond actually induced looping in **1** and **2** over and above what occurs "normally".

3.2. Kinetic Approach[12]

The basic plan was to incorporate double bonds into the surfactant chains and then measure their rates of oxidation

by $KMnO_4$ present in the water external to the micelles.[13] Rates of $KMnO_4$ consumption were easily monitored via its intense absorption at 545 nm. If the olefinic units were confined to a close-packed hydrocarbon core, such as portrayed in classical micelle models,[8] then the permanganate (being ionic) would be unable to reach the double bonds and convert them into diols.

Two olefinic surfactants, **3** and **4**, suffice to illustrate the main conclusions from a more extensive kinetic study. Micellar **3** oxidized at a rate similar to simple monomeric olefins (both terminal and internal). But it reacted 156 times faster than micellar **4**. The fast oxidation of micellar **3**, and the

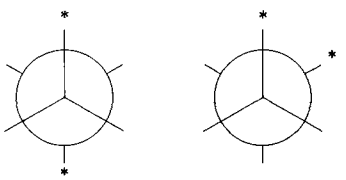
$H_2C{=}CH(CH_2)_8CO_2^{\ominus}$ **3** $CH_3(CH_2)_7CH{=}CH(CH_2)_7CO_2^{\ominus}$ **4**

unexpected difference between terminal and internal olefins within the aggregates, can be explained only in terms of looping and molecular disorder that place chain termini of **3** at the water-rich micellar periphery. Double bonds in the middle of **4** remain effectively buried despite nonlinear conformations imposed on the surfactant molecules. These simple but revealing experiments once again point to a nonradial organization within micelles. Chain termini, once thought to congregate permanently near the center of the system,[8] must "sample" the micelle surface frequently.

The double bond is a small, apolar functionality prevalent in naturally occurring lipids. Consequently, we felt it unlikely that surfactant **3** loops abnormally (owing, perhaps, to a "hydrophilicity" of the double bond relative to fully saturated chains). But the possibility cannot definitely be ruled out. In the next section, I discuss another method for investigating chain conformation where uncertainty is totally eliminated.

3.3. Double ^{13}C-Labeling[14]

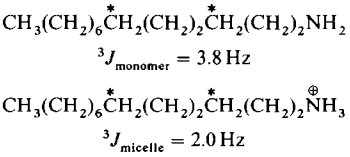
Long-range coupling (^3J) between two ^{13}C atoms through three bonds obeys a typical Karplus-type function. Thus, $^3J_{anti} = 3.5-4.0$ Hz, whereas $^3J_{gauche} = 1.5$ Hz. By synthesizing chains bearing two ^{13}C atoms at known locations, we can deduce the time-averaged conformation at a particular linkage. The method is nondisruptive and works equally well for single compounds or multimolecular systems.



$^3J_a = 3.5-4.0$ Hz $^3J_g = 1.5$ Hz

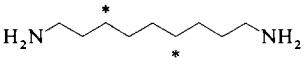
Scheme 3. ^3J coupling between ^{13}C atoms.

Monomeric [3,6-$^{13}C_2$]tridecylamine (Scheme 4) in chloroform has $^3J = 3.8$ Hz. However, in acidic water (pH = 2) at concentrations manyfold higher than the cmc, the corresponding amine salt has $^3J = 2.0$ Hz. As seen from the limiting values of $^3J_{anti}$ and $^3J_{gauche}$ (Scheme 3), the monomeric state is essentially linear, whereas the majority of the C4–C5 linkages in the micelle are *gauche*. Aggregation clearly imposes severe bending at the C4–C5 site. Information of this type is almost impossible to achieve by any other current method.

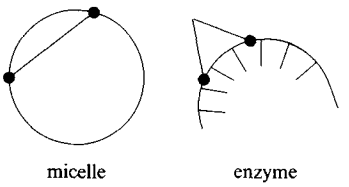


Scheme 4. Effect of the degree of aggregation on the J value. Top: In chloroform. Bottom: In aqueous acid.

The nonaggregating diamine in Scheme 5 has $^3J = 3.8$ Hz in ethanol and in acidic water, once again demonstrating a preferred linearity in the monomeric state. When the diamine was adsorbed into or onto a sodium dodecyl sulfate micelle, the coupling constant changed only slightly to 3.5 Hz. Adsorbed diamine clearly maintains its transoid character within the aggregate owing, very likely, to a tangential orientation (Scheme 6). Such an orientation allows both ammonium groups to reside near the bulk water. In contrast to the micelle behavior, diamine bound to an enzyme, trypsin, gives a ^3J value characteristic of 100% *gauche* (Scheme 6). Double ^{13}C-labeling requires a tedious synthetic effort, and at present we appear to be the only ones using it (not only with micelles but with DNA complexes, single-molecule chemistry, etc.). But the method would seem to have a promising future, particularly in characterizing fragile chemical and biological systems that are easily perturbed by conventional probes. In fact, double ^{13}C-labeling would be an excellent way of determining exactly how probes or additives modify chain conformation when they enter molecular aggregates. Data are currently unavailable on the subject. Systems research is a field in its infancy!



Scheme 5. A nonaggregating diamine.

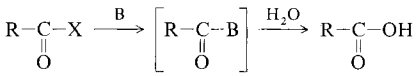


Scheme 6. Conformation of a diamine bound to a micelle or to an enzyme.

4. Self-Assembling Systems as Catalysts[12]

We have for many years been interested in developing catalysts based on molecular assemblages. But before providing specifics, it is worthwhile to define the word "catalyst". First and foremost, a catalyst must significantly accelerate a reaction. The question then arises, "What constitutes a significant acceleration?" Ten percent increase? One-hundred-fold? A million? As discused in a publication entitled "An Essay on Significance", a newly encountered effect should, if possible, be related to a carefully defined "expectation".[15] In some cases, even a ten percent increase might be considered significant (e.g., a 10% pay raise relative to a 3% inflation). In our work with catalytic systems, it was easy to "frame" the data: we desired accelerations of $\geq 10^5$, similar to those found with enzymes. Such large accelerations were necessary because (1) we wanted (as a challenge) to imitate enzymes as closely as possible and (2) we wanted to destroy certain chemical warfare agents at a rate that would be useful from a practical standpoint. According to this definition of significance, a 10- to 100-fold catalysis would be considered a failure for us.

Catalysis also incorporates the concept of "turnover". A single catalyst molecule must operate on a substrate molecule, finish the job, and then go on to operate on additional substrate molecules. This somewhat obvious point is mentioned here because stoichiometric reactions have at times been incorrectly termed "catalytic". The most common example involves a nucleophilic attack on a carboxylic acid derivative (Scheme 7). Only if the intermediate, RCOB, is

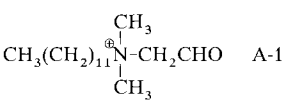


Scheme 7. An example of a stoichiometric reaction when RCOB is stable.

hydrolytically reactive can one accurately claim that B is a catalyst; otherwise, the reaction is stoichiometric in B. Stoichiometric reactivity in our work on chemical systems was unacceptable because we were interested in destroying environmentally dangerous compounds at reasonable cost. This required devising true catalysts that are not irreversibly consumed during the reactions. The use of three quite different molecular assemblies in catalytic processes is summarized in the next section.

4.1. Atlanta-1 ("A-1")[16]

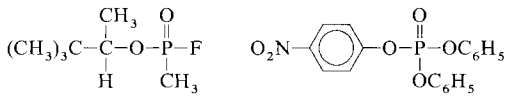
In 1985, we synthesized and examined a micellar catalyst, dubbed A-1, that hydrolyzed phosphate esters. As will be shown, the aggregated catalyst functions by (1) noncovalently binding the phosphate ester, (2) splitting the ester while



A-1

covalently retaining the phosphoryl portion, and (3) dephosphorylating to regenerate the original catalytic entity. Thus, true catalysis was achieved.

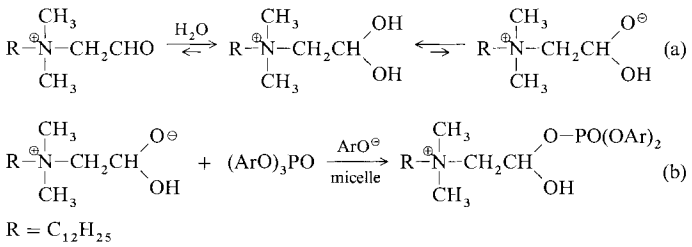
Our interest in phosphate esters was related to the goal of destroying nerve agents, such as GD, which are among the most moathsome compounds known to man. We used the less toxic *p*-nitrophenyl diphenyl phosphate (PNPDPP) for



GD PNPDPP

our experiments because PNPDPP is not as reactive as GD; therefore, any catalyst that manages to hydrolyze PNPDPP is likely to be effective with the actual nerve agents.

A-1 forms micelles abruptly at its cmc of 8×10^{-4} M. Spectroscopic data proved that the catalyst exists as the aldehyde hydrate, which, under the reaction conditions (25°, pH = 9.0), forms a kinetically significant level of oxyanion [Eq. (a)]. The water-insoluble phosphate ester partitions to-

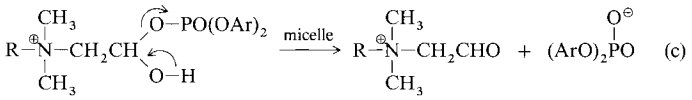


(a)

(b)

$R = C_{12}H_{25}$

tally from the buffer to the micelle where the phosphoryl group is transferred to an oxyanion [Eq. (b)]. Finally, and this is crucial for turnover, the presence of a second hydroxyl allows for a rapid dephosphorylation and, consequently, a regeneration of the original aldehyde catalyst [Eq. (c)].



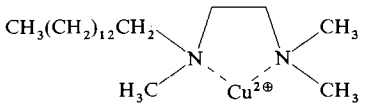
(c)

Proof that substrate preassociation to A-1 micelles is important consisted of showing that catalysis was lost with short-chain (nonmicellar) analogues of A-1. Proof that turnover is indeed taking place consisted of observing a 100% product yield even when the phosphate ester was in great excess over A-1. Preassociation and turnover are, of course, both reminiscent of enzymatic behavior.

Phosphate hydrolysis is 1800 times faster with 8 mM A-1 than in pure buffer without catalyst. Although reasonably fast by many standards, the rate is several orders of magnitude less than the $\geq 10^5$ we were seeking. Therefore, a second micellar catalyst, A-2, described in the next section, was developed to improve on this shortcoming.

4.2. Atlanta-2 ("A-2")[17]

A-2 is a copper-containing surfactant that forms "metallomicelles" above a cmc of 1.8×10^{-4} M. The copper-coated micelles bind PNPDPP with an enzymatic efficiency ($K_{assoc} = 2.6 \times 10^5$ M). Moreover, the micelles induce a 10^5 rate enhancement in the hydrolysis of PNPDPP (1 mM catalyst, 25 °C, pH = 8.0). Accelerations are even larger (10^6)



A-2

with a phosphodiester, bis(p-nitrophenyl) phosphate. There is no doubt that the aggregation process contributes substantially to the catalysis, because nearly 10^3 of the overall enhancement disappeared when A-2 was replaced by simple, nonmicellar copper complexes. Single-molecule chemistry is no match for systems chemistry!

The above results show that cupric ion is catalytically far more effective when confined to the micelle surface than when floating free in solution. High concentrations of cupric ion at the micelle surface create a large positive charge that enhances the electrophilicity of the metal. This was substantiated by polarographic studies in which we detected an unusual propensity of micellar cupric ion to accept electrons. The surface-activated copper is thought to polarize the P=O bond of the substrate and thus catalyze nucleophilic attack on the phosphorus (Fig. 2).

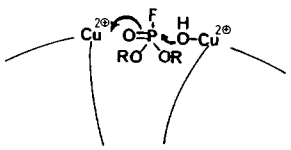


Fig. 2. Proposed mechanism for the 10^5–10^6-fold rate enhancement of nerve-agent hydrolysis by metallomicelles. $Cu^{2\oplus}$ ion confined to the cationic surface of the micellar system manifests an anhanced electrophilicity.

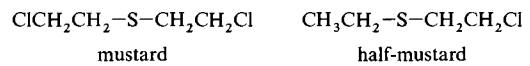
The half-life at 25 °C and pH = 7.0 of the nerve agent GD with 5.3 mM A-2 is only 50 s as opposed to 60 h at pH = 10.0 in the absence of A-2. Recall that this article began by defining a chemical system as "an assemblage of molecules that collectively do something interesting or useful". Self-assembling A-2 certainly complies with the definition.

4.3. Destruction of Mustards in Microemulsions[18]

No endeavor, however lofty, escapes exploitation, and chemistry is not an exception. The discipline that has given us antibiotics, nylon, and gasoline has also produced loathsome compounds such as chemical warfare agents. A solution to the problem, in the absence of restraint, is to develop chemical means to deactivate the compounds, that is, to combat chemistry with chemistry. Notable progress along these lines with regard to nerve agents was discussed in Section 4.2. Recently, our attention has turned toward mustard and related sulfides (Scheme 8). Mustards are environmentally persistent cytotoxic alkylating agents that can be manufactured with low technology and used in chemical weaponry. Their detoxification is hampered by an extreme insolubility in the solvent where they are potentially most reactive, water. We have oxidized mustard simulants (e.g., half-mustards) to nontoxic sulfoxides on a reasonable scale with a method that is simple, cheap, mild, and rapid.[19] The strategy (which could have general utility in organic chemistry) is based on an interesting type of multicomponent system, the microemulsion.



Scheme 8. Structure of mustard and half-mustard.

A microemulsion is an isotropic and optically transparent dispersion of oil in water (O/W) or water in oil (W/O) where "oil" is a hydrocarbon (Fig. 3). Such chemical systems form spontaneously when water, a hydrocarbon, a surfactant, and a "cosurfactant" (generally a low-molecular-weight alcohol) are mixed in specific proportions. Microemulsions, with dispersed droplets averaging 50–500 Å in diameter, remain clear indefinitely.

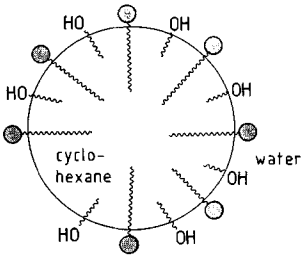


Fig. 3. Schematic representation of an O/W microemulsion stabilized by a long-chain surfactant and an alcoholic cosurfactant.

A favorite recipe of ours for an O/W microemulsion consists of (by weight) 3% cyclohexane in 82% water stabilized by 5% sodium dodecyl sulfate and 10% *n*-butanol. Although we have examined over two dozen additional microemulsions (both O/W and W/O of widely varying compositions), I will, for brevity, confine the discussion to this single preparation.

Half-mustard (Scheme 8, 0.18 mL) was dissolved in 15 mL of microemulsion. When 5% hypochlorite was then added to the system in a twofold excess over half-mustard, the half-mustard was, according to NMR spectroscopy, converted into sulfoxide extremely rapidly (i.e., in less than 15 s). Mustard present in the environment can, in contrast, persist for months.

Microemulsions formulated with nonalcoholic cosurfactants were not very active. We believe, therefore, that reactivity depends on an alkyl hypochlorite forming at the oil/water

interface where the alcohol is known to reside (Fig. 4). Subsequent oxidation of the half-mustard then proceeds either in or on the oil droplets.

Reaction capacity is excellent, 15 mL of microemulsion being capable of oxidizing as much as 1 mL of sulfide. Oil droplets in an O/W microemulsion can, obviously, solubilize large amounts of water-insoluble organic reactants. Since the reaction mixtures are homogeneous, no continuous stirring is necessary (a distinct advantage for applications in the real world).

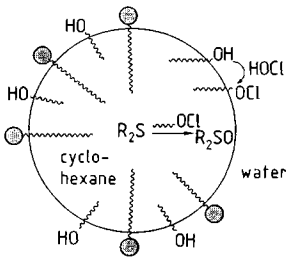

Fig. 4. Proposed mechanism for oxidation of mustard by hypochlorite in an O/W microemulsion. The speed of the reaction (see text) can be attributed to a large hydrocarbon/water contact area that permits "communication" between the water-soluble HOCl and the oil-soluble mustard with interfacial cosurfactant serving as an intermediary.

The speed and capacity of the oxidation are predicated on five components (water, cyclohexane, sodium dodecyl sulfate, *n*-butanol, and hypochlorite) all working in concert. Absence of any one of these components would impede or prevent reaction. Self-assembly converts what might have been a useless and intractable mixture into a system that can undo what mankind should not have wrought in the first place.

5. Monolayer Film Systems[20]

There ist a growing need for chemists, particularly those with biological leanings, to understand the principles governing noncovalent interactions. Host and guest, sensor and activator, channel and permeant, reactor and drug, enzyme and substrate, antibody and antigen, DNA and carcinogen: all partners recognize each other by noncovalent forces. Since noncovalent forces are involved in so many vital processes, and since (more to the point with regard to this article) intermolecular association holds together many chemical systems, we initiated a study of "molecular packing". A unique type of aggregate, the monolayer film, provided the experimental backdrop.[21, 22]

It should be stated forthwith that monolayer films have been an active branch of physical chemistry ever since the days of *Irving Langmuir*. No possibility exists of covering even a small portion of the vast literature on the subject in this article. Yet a sample of our recent experiments might be useful, particularly to illustrate the type of information made available by monolayer systems.

A monolayer film is a two-dimensional network one molecule thick. Most commonly, the film rests on a water "subphase". Monolayer films are often examined by means of a

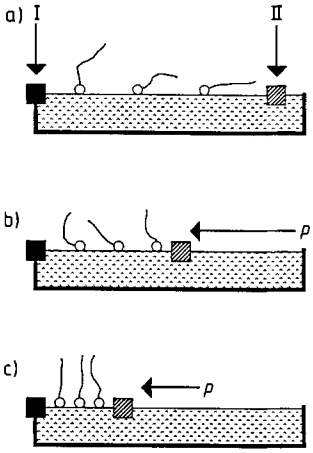

Fig. 5. Operation of a film balance with which, by means of a mobile barrier, it is possible to mechanically reorient molecules in the monolayer system. I = fixed barrier; p = pressure on the mobile barrier II. a) "Gaseous" phase; b) "liquid-expanded" phase; c) "condensed" phase.

simple and ingenious device: the film balance. Film balances measure the pressure exerted by a film while the area available to the component molecules is continuously reduced with a movable barrier (Fig. 5). As the film is compressed, molecules lying flat on the subphase are thereby forced into more vertical positions where they require less space. The ease of compressing the film, and the area per molecule at a given pressure, reveal how readily a film molecule tolerates the presence of its neighbors. Such information is, of course, crucial to the understanding of chemical systems.

Films were prepared from synthetic fatty acids and phospholipids composed of 18-carbon chains substituted at one of the four loci with groups of various sizes and polarities (methyl, *n*-butyl, phenyl, hydroxyl, and keto) (Scheme 9).

$$\underset{\substack{\uparrow\\16}}{CH_3CH_2CH_2}CH_2CH_2CH_2\underset{\substack{\uparrow\\12}}{CH_2}CH_2CH_2CH_2\underset{\substack{\uparrow\\8}}{CH_2}CH_2CH_2CH_2\underset{\substack{\uparrow\\4}}{CH_2}CH_2CH_2CO_2R$$

Scheme 9. C_{18} chains used to prepare films for film-balance studies. The positions substituted with Me, *n*Bu, Ph, OH, or O substituents are shown.

We were then able to pose, for example, the following questions: (1) How does film packing (i.e., the molecular area at a given pressure) vary with substituent size at a fixed location? (2) How does packing depend on where a particular substitutent is situated along the chain? (3) How does a mixed-film, composed of 50% 4-methyl and 50% 16-methyl fatty acid, differ in behavior from a film made from isomerically pure material? In effect, the film balance allowed us to ask questions about steric effects (*intermolecular* steric effects, not the more usual ones within a single molecule).

Having five substituents, four different locations, and the possibility of all sorts of mixture, we could obviously gather more data than can be described here. Brief examples suffice, however, to illustrate the utility of the method.

5.1. Butyl Substituents[21]

Figure 6 shows pressure–area isotherms (23.0 °C) for mixtures of unsubstituted stearic acid (SA) and 8-butylstearic

acid (8-BSA). As would be expected, the area per molecule decreases as the pressure on the film increases. The plots terminate when the film collapses (i.e., molecules in the monolayer pile up on one another). Two observations are of particular note: (1) An 8-butyl substituent caused a massive film expansion. At 5 dyn cm^{-1} pressure, the area occupied

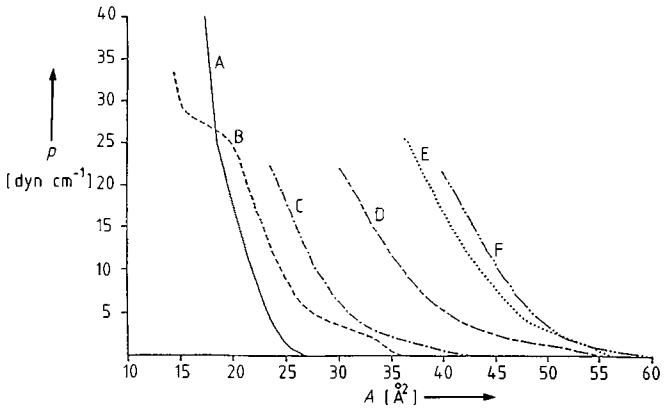

Fig. 6. Pressure–area isotherms (23.0 °C): A) stearic acid (SA); B) 10% 8-butylstearic acid (8-BSA) + SA; C) 25% 8-BSA + SA; D) 50% 8-BSA + SA; E) 75% 8-BSA + SA; F) 8-BSA. A = area per molecule.

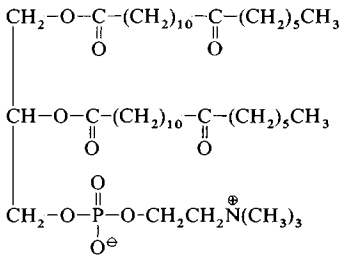
per molecule increased from 23 Å^2 for 100% SA (plot A) to 48 Å^2 for 100% 8-BSA (plot F). It could be shown that alkyl substitution at position 8 has a far greater expansive effect than substitution at positions 4 or 16. (2) A mixture of 10% 8-BSA and 90% SA exhibited an anomalous pressure–area isotherm (plot B). Formation of "bulk" 8-BSA was observed at 25 dyn cm^{-1} where plot B forms a kink. Above 30 dyn cm^{-1} pressure, the SA film, separated from its 8-BSA, continued to compress more or less normally. Thus, the film balance can detect an extrusion of one phase from another within the two-dimensional array of mixed lipids.

5.2. Keto Substituents[22]

Film studies were performed on the keto-substituted phospholipid shown in Scheme 10. At 35 dyn cm^{-1} pressure, the lipid occupied 22 Å^2 per molecule. This is a surprisingly low value (similar to that of a single-chained surfactant and al-



Scheme 10. Keto-substituted phospholipid used in film-balance studies.

most one-half that of the corresponding lipid without keto groups).

Apparently, at low pressures the keto lipid lies horizontally on the water surface (Fig. 7). High pressures force the reorientation of the molecules within the film such that one chain extends vertically into the air and the other vertically into the water. With the unsubstituted lipid, both chains point upward side-by-side and, consequently, require double the area. For reasons that are not understood, abnormally low packing areas were found for the 12-keto lipid but not for positional isomers having 6- or 8-keto substitution. These latter two lipids assume the usual side-by-side conformation.

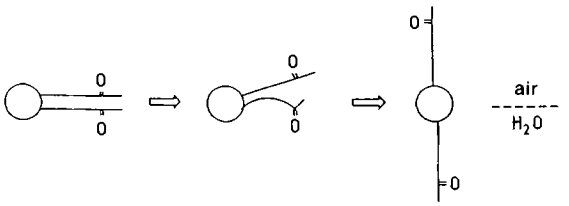


Fig. 7. Reorientation of a diketo lipid in a monolyer film system as pressure is exerted on the film. In the absence of keto groups, the lipid will reorient such that *both* chains extend upward into the air, and the area per molecule will be twice as great.

The point of citing these examples from more extensive studies is simply to draw attention to the power of the film balance in studying molecular packing. No other method allows such a controlled manipulation of molecular orientation. Information about molecular assemblages is obtained that cannot be secured by any other means.

6. Vesicles[23]

In Section 3.1, I mentioned how a surfactant with an ionic head group and a long hydrocarbon tail forms micelles. If, instead, the head group is attached to *two* tails, then the compound spontaneously aggregates into bilayers rather than micelles. This bilayer assumes the form of a closed sphere, called a vesicle, when the system is sonicated in water (Fig. 8).

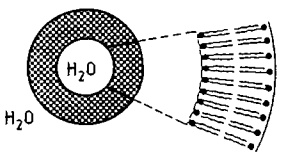

Fig. 8. Schematic of a vesicle composed of a bilayer of lipid molecules.

Vesicles represent an important and widely investigated type of chemical system. They give the investigator a feature unavailable in single-molecule chemistry: an inside and an outside separated by a physical barrier. It is a relatively simple matter to place compounds, such as dyes or drugs, within the vesicles, a capability that leads to a host of interesting experiments and potentially useful chemical devices.

6.1. Ion Channels[24]

The story begins with a remarkable biological compound called gramicidin. Gramicidin is a pentadecapeptide antibi-

otic which, in a dimeric form, enters membranes and creates a channel through which ions can flow (Fig. 9). So potent is gramicidin that a single channel carries a greater ion current than can an entire 1.0 × 1.0 mm gramicidin-free membrane. Our goal was to synthesize simple organic compounds that emulate the ion-channeling ability of gramicidin. As will be related, we succeeded in making a flux-promoting compound which is active in nanomole quantities and which actually surpasses gramicidin as a promoter of ion flux.

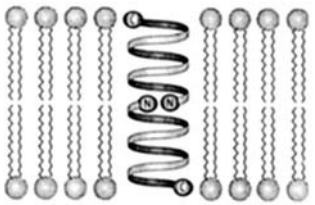

Fig. 9. Schematic of a gramicidin dimer embedded in a bilayer membrane. The interior of the coil provides a channel for ion flux across the membrane.

Before describing the channel compound, it is useful to describe the basic experiment (Fig. 10). Vesicles were prepared by sonicating a phospholipid mixed with an acid-responsive dye in a weak pH = 7.7 buffer. The vesicles enclosed a portion of the dye, the remainder residing outside. The latter was removed by gel permeation chromatography.

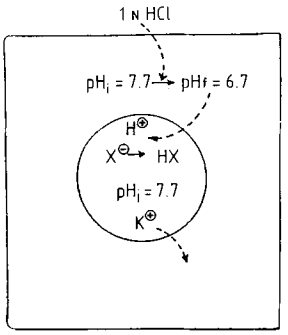

Fig. 10. Experimental scheme for detecting proton transport across a vesicle wall. Anionic dye (X^-) loses its fluorescence when protonated. Therefore, when the external pH is made more acidic than the internal pH with an aliquot of 1 N HCl, the fluorescence of internal dye will diminish according to how fast protons move through the membrane barrier.

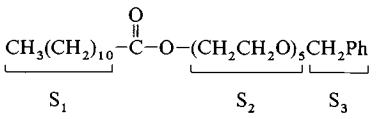
When an aliquot of HCl was added, the external pH dropped immediately by a full pH unit. This created a "proton potential" with the proton concentration being greater on the outside than internally. Consequently, protons migrated inside in an attempt to equalize the pH. In so doing, encapsulated dye became protonated, thereby losing its fluorescence. The setup allowed us to follow the decrease of fluorescence as a function of time with and without the presence of a proton-conducting channel in the vesicle membrane.

It is interesting, but only from a historical point of view, that a certain compound we designed and synthesized to serve as a channel turned out to be inactive. As fortune would have it, however, intermediates in the preparation of the target molecule (and much simpler in structure than the target!) manifested an amazing ability to conduct ions at extremely low concentrations. The best of these is compound **5**. At nanomole levels, corresponding to only 45 molecules of



5

5 per 5000-lipid vesicle, the rates were measurably faster than with an equivalent amount of gramicidin.

Flux enhancement is structurally specific. Thus, all three sections of **5** (S_1, S_2, and S_3) are necessary. Activity is lost if both S_1 and S_3 are long chains, or if both S_1 and S_3 are benzyl groups. Activity also disappears when the S_1 tail or S_2 polyether is too short, or when the S_3 terminus is a hydroxyl. An investigation of over 25 analogues (both more and less hydrophobic than **5**) suggests strongly that precise alignment, rather than gross disruption, is required for ion conduction.

We surmise that a transport capability requires the benzyl group to anchor to the membrane surface (via an ion–dipole attraction known to occur between aromatic rings and the quaternary nitrogen of the lipid head group),[25] while the tail embeds itself in the membrane interior (Fig. 11). The

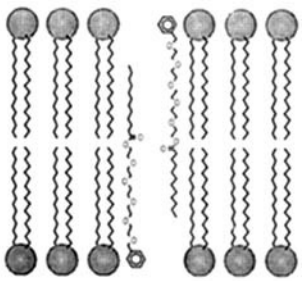


Fig. 11. Proposed orientation of **5** within a vesicle bilayer. A minimum of two molecules is required to span the entire membrane.

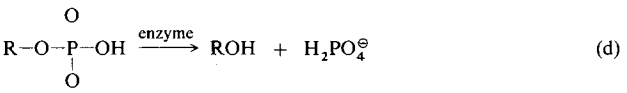
polyether moiety is thereby forced to span the leaflet where it, or its hydration shell, can conduct ions. A minimum of two molecules of **5** must become aligned to permit passage across the entire membrane.

There is no possibility that **5** acts merely as a "carrier" (i.e., a molecule that complexes with an ion and shuttles it dynamically through the membrane). Thus, **5** is useless in transmitting ions through a "liquid membrane" consisting of bulk chloroform. If **5** were a carrier, it would function well even in organic solvents.

We have just seen how a low ion flux can be converted into a high ion flux by trace quantities of a promoter. If a mechanism were available to rid the system of the promoter once the high ion flux has performed a particular function, then the components of a chemical switch would be at hand. Nature has already made wide use of such a process, and systems research will ultimately enable chemists to do likewise.

6.2. An Enzyme-Labile Vesicle[26]

Bone cancer cells produce and exude an inordinate amount of an enzyme, alkaline phosphatase, which catalyzes the hydrolysis of monophosphate esters [Eq. (d)]. Now consider the following scenario: (1) Vesicles loaded with an anti-



$$R{-}O{-}\overset{\overset{O}{|}}{\underset{\underset{O}{|}}{P}}{-}OH \xrightarrow{\text{enzyme}} ROH + H_2PO_4^{\ominus} \qquad \text{(d)}$$

tumor drug are prepared from a double-tailed surfactant having a phosphate head group. (2) When a vesicle comes into proximity of a bone cancer cell, the high local concentration of alkaline phosphatase removes the vesicular head groups (Fig. 12). (3) The destabilized vesicle "bursts" and

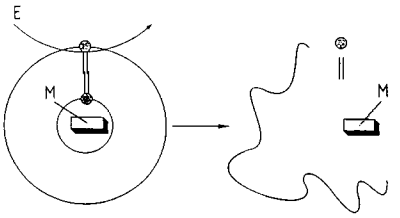


Fig. 12. Schematic of an enzyme-labile vesicle for use in drug release. M = drug, E = enzyme exuded by pathological cell.

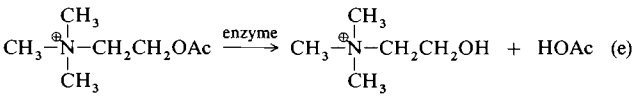
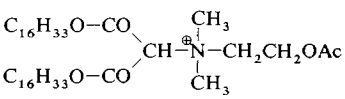
releases its contents (the drug) thereby killing the cancer cell. Note that the scheme imparts specificity to the cancer therapy. Since the specificity derives not from the drug but from the shell around it, any cytotoxic drug may be used.

Although we have not yet developed a working system with alkaline phosphatase, we have made vesicles that are labile to another enzyme, acetylcholine esterase, which is produced in abnormal amounts by certain neuroblastoma cells. Acetylcholine esterase hydrolyzes acetylcholine as shown in Equation (e). Thus, it was expected that the double-tailed surfactant **6** could, by virtue of the acetylcholine-



$$CH_3{-}\overset{\overset{CH_3}{|}}{\underset{\underset{CH_3}{|}}{\overset{\oplus}{N}}}{-}CH_2CH_2OAc \xrightarrow{\text{enzyme}} CH_3{-}\overset{\overset{CH_3}{|}}{\underset{\underset{CH_3}{|}}{\overset{\oplus}{N}}}{-}CH_2CH_2OH + HOAc \qquad \text{(e)}$$

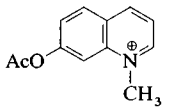
like unit incorporated within it, act as a substrate for the enzyme. This in fact turned out to be the case.



$$C_{16}H_{33}O{-}CO \quad \overset{\overset{CH_3}{|}}{CH{-}\overset{\oplus}{N}{-}CH_2CH_2OAc} \quad Br^{\ominus} \qquad \mathbf{6}$$
$$C_{16}H_{33}O{-}CO \quad \underset{\underset{CH_3}{|}}{}$$

Acetylcholine esterase removed the acetyl group of **6**, whereupon the resulting alcohol spontaneously cyclized to form a six-membered lactone plus hexadecanol. In other words, the vesicular surfactant loses one of its hydrocarbon tails subsequent to the enzyme action. Since surfactants with only one tail form micelles (not vesicles), the vesicles disintegrate in the presence of the enzyme.

Enzyme-induced vesicle destruction causes the release of guest molecules encapsulated within the vesicles. This was proven in the following manner. A water-soluble substrate of acetylcholine esterase, **7**, was placed inside vesicles composed of **6**. Hydrolysis of **7** was known to produce a highly



7

fluorescent product. Thus, when vesicles of **6**, loaded with **7**, were mixed with the enzyme, a burst of fluorescence appeared as the enzyme first chewed up the vesicles and then hydrolyzed **7** upon its escape from captivity. Heat-denatured acetylcholine esterase gave no such instantaneous emission of light, as would be expected with an enzyme-specific destructability.

6.3. Branched Lipids and Bilayer Membranes[27]

In Section 5, it was mentioned that we have synthesized a library of alkyl-substituted phospholipids. These materials were found to be potent inhibitors in multicomponent systems containing the enzyme phospholipase A_2[28] or protein kinase C.[29] Since it is preferable to confine the discussion here to chemical issues, I will relate only how branching affects the properties of bilayer membranes. Once again, extensive compilations of data, graphs, and details[27] are omitted for the sake of brevity and charm.

In 1884, it was written that phospholipids are the "centre, life, and chemical soul of all bioplasm. Amongst their properties, none are more deserving of further inquiry than those which may be described as their power of colloidation."[30] In modern terms, "colloidation" refers to the molecular bilayers that phospholipids spontaneously form when mixed with water. As already pointed out in Section 6, bilayers assume the shape of vesicles when the phospholipids are sonicated in water.

Bilayers undergo thermal transitions owing to changes in molecular packing within the hydrocarbon and head-group regions. These transitions are best detected by differential scanning calorimetry (DSC) in which excess heat capacity (corresponding to absorption of energy) is plotted versus temperature. DSC monitors the thermally induced transition of phospholipid bilayers from a relatively ordered state (below the transition temperature, T_c) to a more random state (above T_c). This process, not unlike that of melting, causes a sharp spike at T_c in the DSC graph.

Figure 13 shows a plot of T_c versus the methyl substitution site for six loci along the 18-carbon lipid chain. A striking "V-shaped" curve is observed. Methyls at position 10 clearly have a much greater effect on lowering T_c than do methyls at either end of the chain (i.e., at positions 4 or 16). We believe that this effect is due to a central kink in the lipids within the bilayers (as in a chevron on military uniforms). Arguments

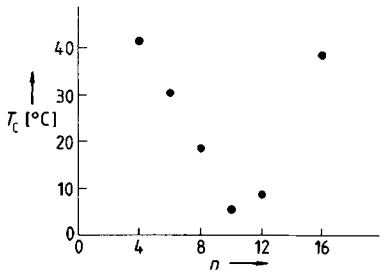


Fig. 13. Distearoyl phosphatidylcholines with methyl groups on both chains at position $n = 4, 6, 8, 10, 12$, or 16 show how the transition temperature of the lipid, T_c, varies with the methyl substitution site. Methyls in the center of the chain clearly perturb lipid packing more than methyls at either end. The same was shown to be true for ion transport through vesicle membranes prepared from the synthetic lipids.

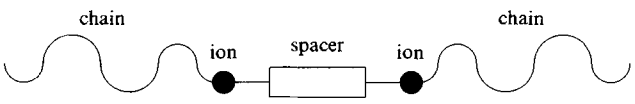
in favor of such a packing mode are given elsewhere.[27] The main point worth making here is that we were able to exploit the observed disruptions to control membrane permeability, as described below.

We measured (by methods outlined in Section 6.1) ion permeability through vesicle walls made from our various chain-substituted phospholipids.[31] In essence, we carried out a "structure–activity" study where the focus of attention was the structure of a system rather than that of a single molecule. The fundamental discovery was that centrally located methyls promote transport of ions through the bilayer membranes more efficiently than do methyls at either end of the chains (similar to their effect on T_c). At a given location, an *n*-butyl group disrupts the membrane more than a methyl as measured by the efficiency of ion flux. Controlling membrane permeability via rational design of the component species would seem to be a highly promising and useful topic for future systems research.

6.4. Gemini Surfactants[32]

The final section on vesicles deals with a new type of double-chained compounds that we call "gemini surfactants". Although work is only partially completed, I mention it to drive home a point. Synthetic organic chemistry allows chemists access to a seemingly endless variety of new self-assembling molecules. These molecules are a scientific bonanza, allowing entry into a huge unfenced area where few people have staked claims and where the imagination can roam free. Take gemini surfactants for example. The molecules possess, in sequence, a long hydrocarbon chain, an ionic group, a rigid spacer, a second ionic group, and another hydrocarbon tail (Scheme 11). Geminis were synthesized as



Scheme 11. Structure of a gemini surfactant.

the result of our asking a simple question that, to our surprise, had never before been addressed in the literature: How does a double-chained surfactant behave when the two chains within a molecule are prevented, by means of a large spacer such as stilbene, from lying side by side? We also wondered whether aggregation of geminis in water would superficially resemble polymer growth. In polymerizations, reactive end groups are always being generated, permitting continual elongation. The same is true for gemini aggregation except that the end groups are hydrophobically active rather than susceptible to covalent bonding.

According to surface tension measurements, geminis with 20 carbons per chain have a much *higher* cmc than geminis with 12 carbons per chain! This runs counter to all previously reported trends in surfactant chemistry. Normally, long-chained surfactants, with their greater propensity to aggregate in water, possess low cmc's. Dye-binding studies have shown that geminis with two 20-carbon chains form small clusters at extremely low concentrations ($<1 \times 10^{-5}$ M). Only at concentrations near 10 mM will these clusters cooperatively assemble into larger aggregates and, thereby, manifest a cmc. Geminis with 12 carbons, on the other hand, behave normally in that their cmc represents facile conversion into micelles from the *monomeric* state. Although geminis have just been synthesized, and we do not fully understand the structure of their aggregates, they exemplify how readily one can design and construct new self-assembling compounds that display unusual and potentially useful properties.

7. Of Pools and Polymers[33]

An entirely different type of chemical system will now be discussed: the water pool and porous polymers derived therefrom. Years ago, the term "water pool" was coined to depict aqueous microdroplets that can form in apolar solvents containing a surfactant, AOT.[34] So effective is AOT that one can readily dissolve 10–20% water in heptane to give optically clear solutions. The pools, on the order of 50 Å in diameter, are stable owing to the "molecular coating" of AOT at the water–heptane interface (see Fig. 14).

The central idea in our work was to use styrene/divinylbenzene instead of heptane for the apolar continuous phase.[35] This enabled us to photopolymerize the water-pool systems. The resulting solid was ground to a powder, leached with methanol to remove AOT, and dried (see Fig. 14) to produce porous polystyrene.

So-called BET measurements (based on N_2 adsorption data) proved that the polymers can achieve surface areas as high as 30 $m^2 g^{-1}$. Scanning electron micrographs confirmed the porous nature of the polymers. Preliminary results showed that the new materials have potential applications in controlled-release systems and in chromatographic separations.

7.1. Controlled Release[35]

As depicted in Figure 14, cupric ion can be dissolved in the water pools prior to photolysis. In this manner, it was possible to prepare copper-containing solid polymers that only slowly released the metal when stirred in water. Industrial testing of the materials for use as antifouling agents in marine paints is now in progress. A variety of water-soluble compounds should be amenable to controlled release by the same methodology.

Outwardly, the above chemical system appears complex: a mixture of styrene, divinylbenzene, water, AOT, and cupric ion. Molecular organization and compartmentalization, however, "derandomize" the system and convert it into something interesting and, perhaps, into something useful.

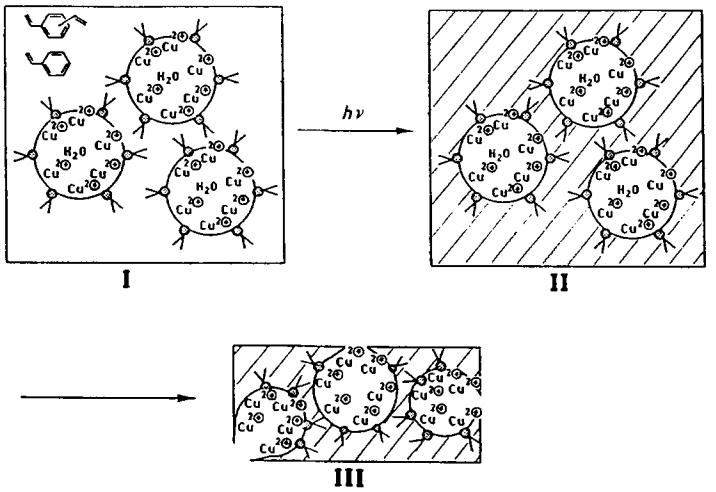


Fig. 14. Scheme for synthesizing porous polystyrene containing occluded copper ion. The darkened circle with two tails represent AOT surfactant. **I**: AOT-stabilized water pool in styrene/divinylbenzene. **II**: Pool in cross-linked polystyrene. **III**: Porous polystyrene obtained by grinding and drying.

7.2. Chromatography[35]

TLC plates were prepared from powdered porous polymer mixed with calcium sulfate as a binder. Using methanol as the developing solvent, we separated nitrobenzene, aniline, and phenol much more effectively on the polymer plates (R_f = 0.45, 0.65, and 0.92, respectively) than on silica plates (R_f = 0.94, 0.88, and 0.80, respectively). This was also true for the separation of the three nitrophenol isomers.

7.3. Porous Polystyrene with Chemically Active Surfaces[36]

Figure 15 presents a scheme, based on our water-pool method, for synthesizing porous polymers with high surface functionality. A monomer with the structure $XArCH{=}CH_2$, where X is a polar and chemically interesting moiety, orients at the water–hydrocarbon interface with X immersed in or near the pools. Since, as shown, the pool interface transforms into irregularities on the polymer surface, the X group becomes fixed to the polymer exterior rather than getting buried. The concept was tested with the diamine monomer **8**. It was demonstrated (by titration with $Cu^{2\oplus}$) that up to 89% of the diamine groups were fully exposed and available at the surface of the solid polymer. This compares with only 0.6% in copolymers formed without the surfactant-stabilized water pools.

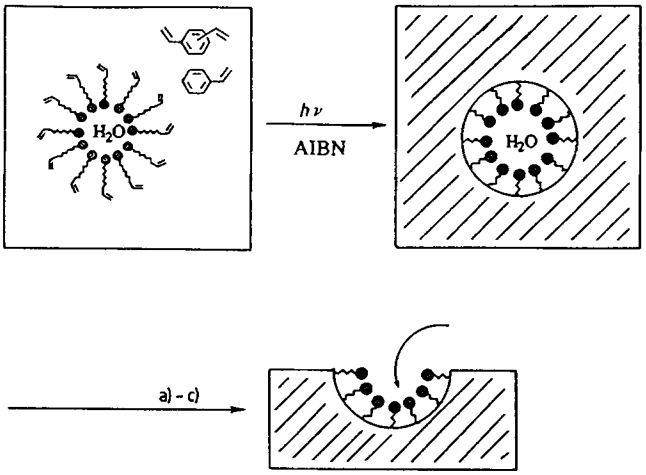

Fig. 15. Scheme for making polymers with high surface area plus high surface functionality. The heavy circles represent a functional group that is useful for catalytic, chromatographic, or other purpose where its existence on the polymer surface is required. The functional groups are polar and tend to assemble at the interface of the AOT-stabilized water pools. This is a multicomponent system containing initially styrene, divinylbenzene, water, AOT, functionalized monomer, and azodiisobutyronitrile (AIBN; a radical initiator). Organization and compartmentalization convert the complex mixture into a useful entity. a) Grind and sieve. b) Wash with MeOH and 20% aqueous NaOH. c) Dry. The arrow indicates the active surface.

8

As a result of systems research, the potential now exists of creating new polymers that have (1) a high surface area and (2) a high surface functionalization. Applications of such materials in the field of catalysis and chiral separations are now being investigated.

8. Molecular Laminates[37]

Periodicity in crystalline solids leads to cooperative electronic effects and thus to useful properties of organic metals, semiconductors, ferromagnets, and optical devices. Yet the rational design of periodicity ("crystal engineering") remains a primitive art and an attractive subject for further pursuit. With this in mind, and with our ongoing affection for diverse organized assemblies (of which crystals are the most perfect), we set out to prepare crystals with alternating layers of metal and hydrocarbon.[38] Such "molecular laminates" were ultimately achieved via three new long-chain copper complexes (Fig. 16). The compounds assemble into layered arrays, each with its own peculiar packing mode.

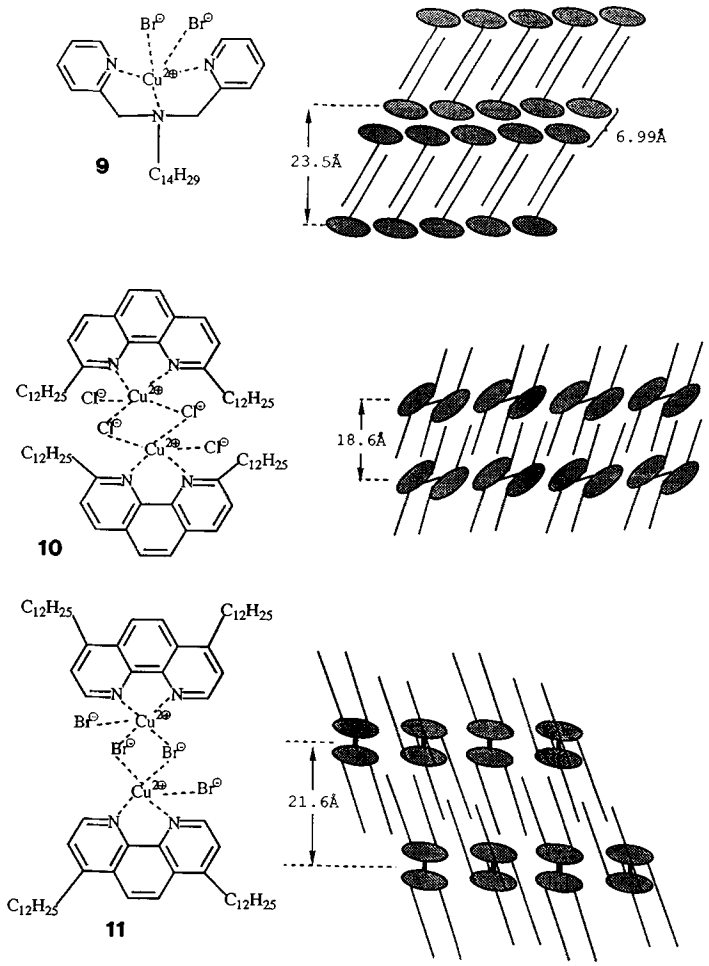

Fig. 16. Crystal packing differences among three long-chain copper complexes.

All three molecules crystallize with copper "sheets" separated by hydrocarbon. Compound **9** packs with heavily interdigitated chains that are fully extended except for one *gauche* linkage per chain. As indicated, the lattice is characterized by Cu–Cu distances of 6.99 Å and 23.5 Å. Compound **10** exists as a dimeric complex. Each aromatic ligand extends one of its chains upward and the other downward (again with a single *gauche* linkage per chain). The copper layers are only 18.6 Å apart. Compound **11** also exists as a dimeric complex, but (in contrast to **10**) chains from a given aromatic ring project in the same direction. Only one of the two side-by-side chains possess a *gauche* linkage. Copper layers are separated by 21.6 Å.

Layer-to-layer distances between sheets of heavy metals can obviously be affected by the number of chains, the length of the chains, and the location of the chains on the supporting scaffold. Information relating such parameters to crystal packing will ultimately allow a priori control of periodicity in solid systems.

9. Final Remark

Thus ends this personalized tour of "systems research". If the account is regarded as an interesting scientific tale, albeit a somewhat egocentric one, then I have fulfilled my objective. And if, perchance, somewhere a student happens to read this account, and is moved to pursue the field of chemistry, then this would be success in its purest, simplest, and most lasting form.

Three agencies (the Army Research Office, the National Institutes of Health, and the National Science Foundation) generously supported our research over the years. The Arakawa Chemical Co. and the Orient Chemical Co., both in Osaka, funded two fellowships. Dow Chemical Co. and LASPAU (Latin American Scholarship Program of American Universities) also provided fellowship support for our systems research. I am, of course, grateful to all the fine young chemists who did the actual experimentation; their names appear in the references. Professor Roald Hoffmann provided valuable comments about the original manuscript. I have also benefited considerably from regular visits with chemists at 3M Corp. (a company doing very well in the "systems research" business). Finally, I must mention my admiration of, and debt to, the diverse body of scientists from both hemispheres who have inspired my research group and who have given the field of self-assembling systems its key insights. There is something particularly egalitarian about systems research.

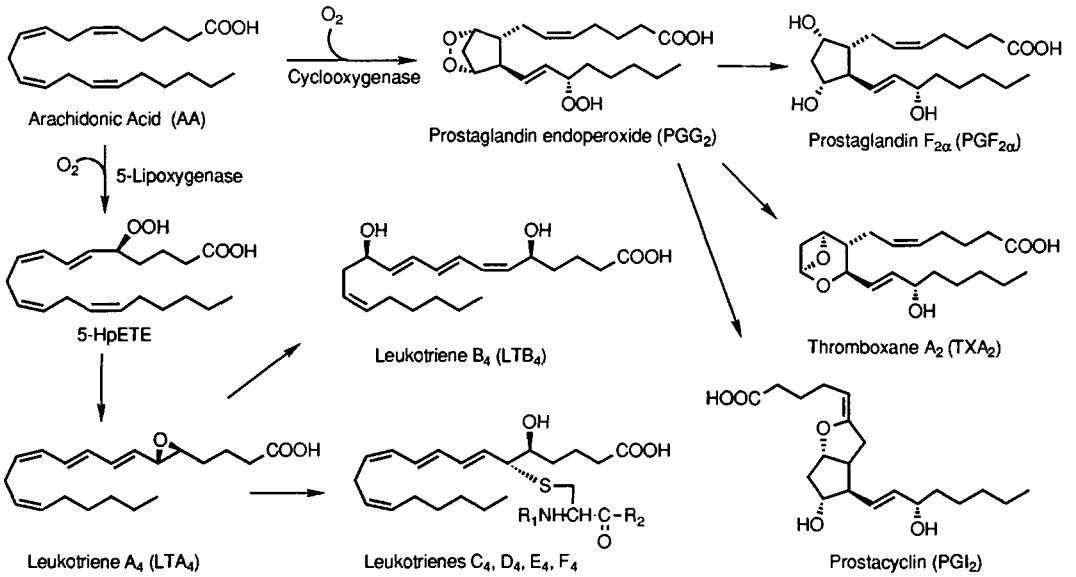
Lipoxins and Related Eicosanoids: Biosynthesis, Biological Properties, and Chemical Synthesis

By K. C. Nicolaou,* John Y. Ramphal, Nicos A. Petasis, and Charles N. Serhan**

Among the various enzymes found in human tissues that act on arachidonic acid, there are three major types of lipoxygenases (LO), operating at the 5-, 12-, and 15-positions. The 5-LO is a key enzyme and plays a central role in the biosynthesis of leukotrienes, which are potent arachidonate-derived mediators of allergy and inflammation. Because of the importance of the 5-LO-derived products in human pathophysiology, studies were initiated to examine the consequences of initial lipoxygenation at C15 of arachidonic acid as well as to probe interactions between the major LO pathways. These studies led to the identification of a new series of biologically active tetraene-containing eicosanoids termed lipoxins. This article summarizes the isolation, biosynthesis, and chemical synthesis of lipoxins and related systems, and reviews recent results concerning their formation and biological activities. The total synthesis of these molecules based on a new and general synthetic strategy involving palladium catalysis is reviewed. This synthetic approach has allowed the preparation of several types of acyclic eicosanoids in their naturally occurring forms which, in turn, allowed comparisons with naturally derived materials and enabled detailed studies of the biological actions of these biomolecules. Structure–activity relationships were also derived by combining chemical synthesis and biological investigations.

1. Introduction

The oxygenation of arachidonic acid (AA) by a wide range of human cell types results in the formation of several classes of biologically active products, termed eicosanoids because they contain twenty C atoms (Scheme 1). These metabolites have long been a focus of biomedical research due to their involvement in the regulation of inflammatory reactions,



Scheme 1. Conversion of arachidonic acid (AA) to various eicosanoids.

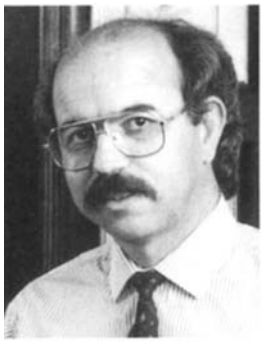
smooth muscle tone, and hemodynamic events, allergy and asthma, as well as many other important physiological and pathophysiological phenomena.

The discoveries in the 60's and 70's by *S. Bergström*[1] and *B. Samuelsson*[2] on the structure and function of the prostaglandins (PG), the thromboxanes (TX), and the prostaglandin endoperoxides (PGH_2, PGG_2) have sparked extensive investigations in the eicosanoid field. Among the major findings that emanated from these efforts was the discovery of prostacyclin (PGI_2) by *J. Vane*,[3] who also

found that cyclooxygenase (PG endoperoxide synthetase), the central enzyme in the biosynthesis of both PG's and TX's, is inhibited by aspirin and other anti-inflammatory drugs, suggesting a mechanism of action for these molecules. Further studies by the *Samuelsson* group[4] on the metabolism of AA in leukocytes led to two other major pathways which are insensitive to treatment with aspirin. These involve the action of lipoxygenase enzymes (LO), one of which initiates oxygenation at C5 of AA (5-LO) and the other acting at C15 (15-LO). Additional work revealed that the 5-LO is a key enzyme in the biosynthesis of another major group of eicosanoids, the leukotrienes (LT), which were identified with the slow reacting substances of anaphylaxis. The LT's have generated considerable excitement because these compounds have proven to be important mediators of the cardinal signs of inflammation-eliciting vascular



K. C. Nicolaou was born in Cyprus and received his Ph. D. degree from the University of London under Professors F. Sondheimer and P. Garratt. After postdoctoral work at Columbia University with Professor T. Katz and at Harvard University with Professor E. J. Corey, in 1976 he joined the faculty at the University of Pennsylvania, where he was promoted to Rhodes-Thompson Professor of Chemistry. He moved to La Jolla in 1989 to fill an unprecedented joint appointment as a Professor of Chemistry at the University of California San Diego and as the Darlene Shiley Professor of Chemistry and Chairman of the Department of Chemistry at the Research Institute of the Scripps Clinic. The recipient of numerous awards including the Alfred P. Sloan Award, a Guggenheim Fellowship, and a Humboldt Senior American Scientist Award, Nicolaou has been involved with the development of new ways of synthesizing complex organic molecules of natural or nonnatural origin. His research interests currently include the synthesis of molecules from the eicosanoid, macrolide, marine ionophore, and oligosaccharide areas, and the design, synthesis and study of biologically active molecules with DNA-cleaving and molecular-recognition properties.

John Y. Ramphal was born in 1963 in Georgetown, British Guiana. He studied at St. John Fisher University and Bucknell University where he completed his M. Sc. degree under Professor H. W. Heine, before joining Professor Nicolaou's group at the University of Pennsylvania. In 1989 he followed Professor Nicolaou to California, where he is currently in his final year of graduate studies. His research involves the synthesis of molecules from the eicosanoid and carbohydrate areas.

Nicos A. Petasis was born in Cyprus and received his undergraduate education at the Aristotelian University of Thessaloniki in Greece. In 1979 he joined the research group of Professor K. C. Nicolaou at the University of Pennsylvania and worked on the synthesis of endiandric acids and eicosanoids. After completing his Ph. D. in 1983, he stayed on as a postdoctoral fellow until 1987, when he joined the University of Southern California as an Assistant Professor of Chemistry. His current research interests include the development of new synthetic methods involving pericyclic reactions and organotitanium compounds, the development of bio-inspired strategies for the synthesis of natural products, and the design and synthesis of biomimetic systems.

Charles N. Serhan was born in New York and studied biochemistry at the State University of New York at Stony Brook. He received his Ph. D. degree in 1982 from New York University, where in the laboratory of G. Weissmann he first became interested in the biochemistry and cell biology of inflammatory responses. He spent the following years (1982–1986) as a visiting scientist at the Karolinska Institute in Stockholm, with Bengt Samuelsson. In 1987 he joined the faculty at Brigham and Women's Hospital and Harvard Medical School as Assistant Professor of Medicine (Biochemistry). Serhan has received several awards including the J. V. Satterfield Arthritis Investigator Award from the Arthritis Foundation, a Medical Foundation Research Fellowship from the Medical Foundation Inc., and an Established Investigatorship Award from the American Heart Association National Center. He was also named a Pew Scholar in the biomedical sciences. His current research interests include lipid and membrane biochemistry, signal transduction in human leukocytes and platelets, the biosynthesis and structural elucidation of biologically active lipids, and the role of lipid mediators in transcellular communication.

permeability, leukocyte influx, and contraction of smooth muscle. For their contributions, *Bergström*, *Samuelsson*, and *Vane* shared the 1982 Nobel Prize in Medicine.

Following the discovery of each of the major families of eicosanoids, there has been extensive work by synthetic chemists in academic and industrial laboratories aimed at the synthesis of the naturally occurring molecules as well as their structural analogues. This has led to the complete stereochemical assignment of these compounds and has prompted further studies on their biological actions. The chemistry and biology of eicosanoids, including the prostaglandins,[1, 5] the thromboxanes,[2, 5, 6] the prostacyclins,[3, 5, 6] and the leukotrienes,[4, 5] have been thoroughly reviewed.

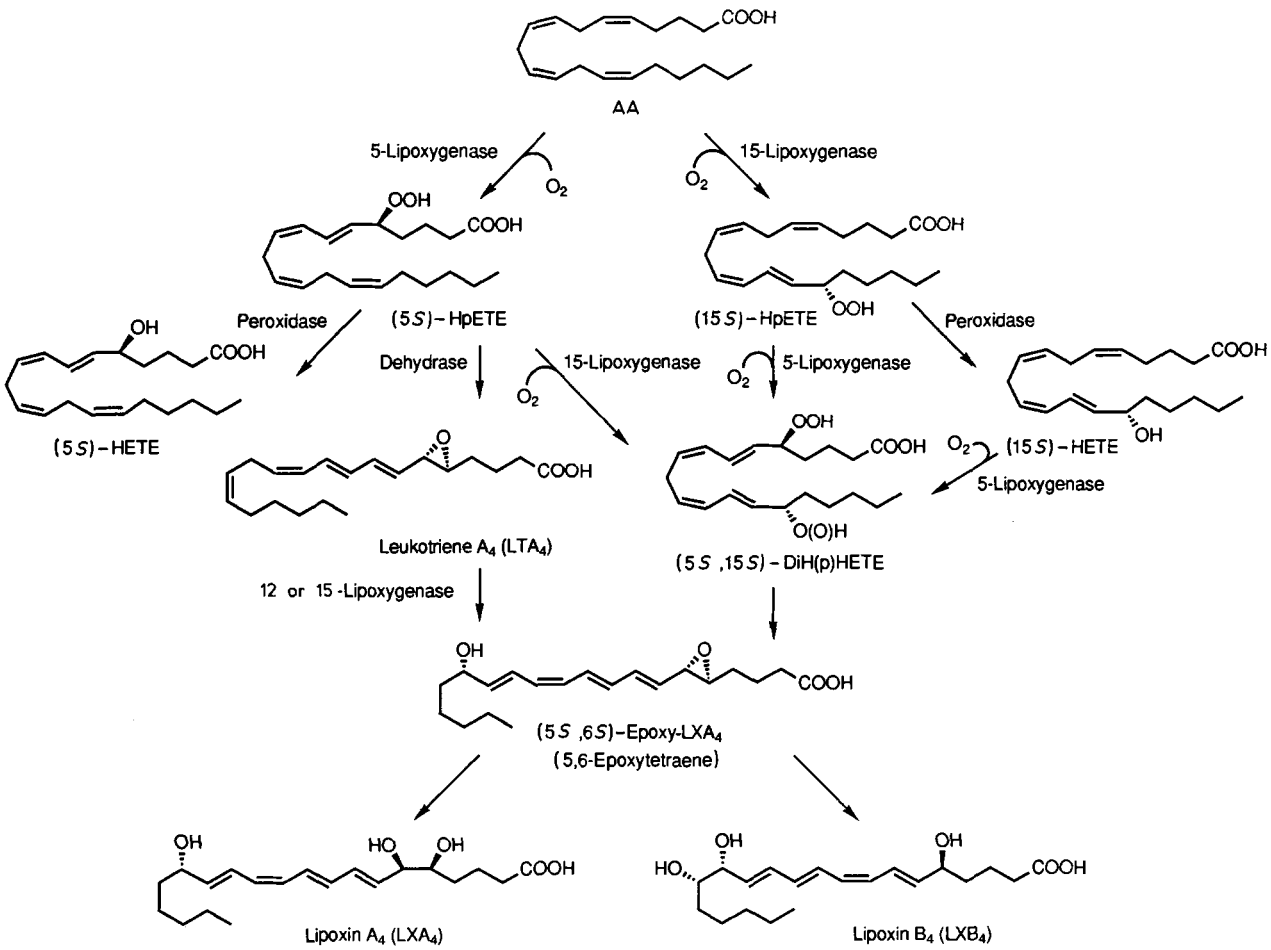
A new class of LO-derived eicosanoids was recently discovered. The realization that the lipoxygenase enzymes (5-LO, 12-LO, 15-LO), previously found in plants, are also widely distributed in human tissues, has prompted investigations aimed at the interactions between these LO pathways. These studies led to the isolation of several new biologically active molecules, termed lipoxins (LX),[7–9] which can be generated by interactions between the human 5/15-LO's and 5/12-LO's (Scheme 2).

leukotrienes.[10–13] Also, recent results indicate that the LX's are formed in vivo and that they are associated with human disease.[14–16] Specifically, LXA_4 has been identified in bronchoalveolar lavage fluids[14] and LXA_4/LXB_4 in nasal polyps,[15] while a defect in LX production is observed with cells from patients with chronic myeloid leukemia.[16] Taken together, these findings suggest that the LX's are generated in vivo and may exhibit counterregulatory roles.

Below we review the isolation, biosynthesis, and biological actions of the lipoxins, and the total synthesis of these and related acyclic eicosanoids.

2. Isolation and Structural Elucidation of Lipoxins

While studying the transformation of [1-^{14}C]arachidonate (AA) in suspensions of mixed human leukocytes (e.g., neutrophils, eosinophils, basophils, etc.) with *Samuelsson* and *Hamberg* at the Karolinska Institute, *Serhan* observed that labeled AA was transformed into polar compounds that had not been previously described. Human leukocytes (e.g. A23187), without addition of other stimuli, rapidly oxygenate exogenous AA at the C15 position.[17, 18] Therefore,



Scheme 2. Biosynthesis of the lipoxins in various systems.

The lipoxins display a unique spectrum of biological properties. For example, it was recently reported that LXA_4 can inhibit some of the "proinflammatory" actions of the

we investigated the products associated with 15-lipoxygenation of arachidonate. Results from several laboratories suggested that initial lipoxygenation at C15 could lead to the

formation of eicosanoids of biological interest.[17, 18] For example, (15*S*)-hydroxy-(5*Z*,8*Z*,11*Z*,13*E*)-icosatetraenoic acid, (15*S*)-HETE, had been identified as a major product of AA in both normal and asthmatic human lung tissue[19] and is found in microgram quantities in bronchoalveolar lavage fluids obtained from patients with chronic stable asthma after challenge.[20] Although 15-lipoxygenation of AA is a major route of its oxidation in a wide range of mammalian tissues and cell types,[21] receptor-mediated activation of 15-LO and the general physiological role of its products has remained an area of interest.

In order to mimic the cellular events that could have given rise to these novel polar compounds, as well as to prepare large amounts of the materials for both structural and biological studies, (15*S*)-HETE and the corresponding hydroperoxy derivative, (15*S*)-HpETE, were prepared, and the products formed upon their exposure to human leukocytes were monitored.[7, 8, 22–25] This approach facilitated the isolation and characterization of a new series of oxygenated products derived from AA that contain an unusual conjugated tetraene system (Scheme 2). These compounds arose through interactions between LO pathways and possess unique structures and novel biological properties. Therefore the trivial name lipoxin (*lipox*ygenase *in*teraction product) was proposed.[7, 8, 23]

Human leukocytes with an ionophore of divalent cations (A23187) gave an increased formation of these tetraene-containing eicosanoids, which facilitated their isolation in larger amounts.[7, 8, 22] The basic structures of the first two members of this series were determined by physical methods that included high-pressure liquid chromatography (HPLC), UV spectroscopy, gas chromatography–mass spectrometry (GC-MS), and oxidative ozonolysis. One compound was identified as 5,6,15-trihydroxy-7,9,11,13-icosatetraenoic acid,[7] and the other proved to be a positional isomer, 5,14,15-trihydroxy-6,8,10,12-icosatetraenoic acid.[8] When these biologically derived products were isolated following HPLC procedures and added to either human neutrophils, natural killer (NK) cells, or lung strips from guinea pigs, they elicited biological actions different from those previously observed with other eicosanoids. Therefore these new biologically active compounds were termed lipoxin A_4 (LXA_4) and lipoxin B_4 (LXB_4).[8, 24]

3. Biosynthesis and Stereochemistry of LXA_4 and LXB_4

It was important to determine next the complete stereochemistry of the biologically active LXA_4 and LXB_4, as well as identify the structures and actions of their naturally occurring isomers. Results obtained from isotopic oxygen investigations guided these studies: each of the tetraene-containing compounds generated by intact leukocytes carried an ^{18}O atom at C5 and the oxygen atoms of C6 of LXA_4 and C14 of LXB_4 and their isomers were not exclusively derived from molecular oxygen.[24] These findings and results of trapping studies with alcohol suggested that the formation of lipoxins in human leukocytes proceeds via an epoxide-containing intermediate.[22–26]

A synthetic approach was undertaken at this point to establish the stereochemistry of LXA_4 and LXB_4 (i.e., the geometry of the double bonds and the chirality of the C6 and C14 hydroxy groups). Both synthetic and biologically derived materials and several of their derivatives were subjected to analysis by UV spectroscopy, HPLC (cochromatography in several systems), and GC-MS, and, most importantly, they were assessed and compared for biological activities. LXA_4 proved to be (5*S*,6*R*,15*S*)-trihydroxy-(7*E*,9*E*,11*Z*,13*E*)-icosatetraenoic acid,[22] and LXB_4 (5*S*,14*R*,15*S*)-trihydroxy-(6*E*,8*Z*,10*E*,12*E*)-icosatetraenoic acid[25] (Scheme 2). A (6*S*) isomer of LXA_4, 6-epi-LXA_4, and two all-*trans* diastereomers, 11-*trans*-LXA_4 and 6-epi-11-*trans*-LXA_4, were also identified.[22, 24] These compounds are much less active than native LXA_4 in several bioassay systems.[22, 27]

Since multiple biosynthetic routes as well as cell–cell interaction can lead to formation of tetraene-containing eicosanoids, the finding that (15*S*)-HETE was rapidly transformed by activated leukocytes provided an important model for investigating one pathway in their formation.[22, 25] This route, the first to be documented, is outlined in Scheme 2.

(15*S*)-HETE is converted into (5*S*)-hydroperoxy-(15*S*)-hydroxy-(6*E*,8*Z*,11*Z*,13*E*)-icosatetraenoic acid ((5*S*,15*S*)-DiHpETE) by activated human leukocytes and further transformed into a 5,6-epoxytetraene, (5*S*,6*S*)-epoxy-LXA_4. This epoxide, or its equivalent, could be enzymatically transformed either into LXA_4 by the action of an epoxide hydrolase to yield the (5*S*,6*R*) diol moiety or into LXB_4 by attack at the C14 position with the generation of an 8*Z* double bond. Additional evidence for a 5,6-epoxytetraene intermediate in the biosynthesis was obtained with (15*S*)-hydroxy-(5*S*,6*S*)-epoxy-(7*E*,9*E*,11*Z*,13*E*)-icosatetraenoic acid prepared by chemical synthesis. This epoxide was quantitatively converted into LXA_4 (in vitro) by a purified cytosolic epoxide hydrolase.[26]

Other investigators have also postulated the role of epoxytetraenes in the formation of LXA_4, LXB_4, and their isomers[28–31] in model systems. *Kühn* et al.,[31] *Fitzsimmons* et al.,[28] and *Adams* et al.[29] have considered several hypothetical schemes to generate lipoxins. One involved an epoxide intermediate and another three consecutive oxygenations catalyzed by LO's which were not expected to involve oxygen not derived from molecular oxygen. It is clear from these results as well as results obtained from our biosynthetic studies with human leukocytes that the generation of 5,6-epoxytetraene from (15*S*)-HETE is an enzymatic event.[22, 24, 25]

Fitzsimmons et al.[28] suggested that, once formed, the 5,6-epoxytetraene could undergo nonenzymatic hydrolysis to yield a mixture of products including 14-epi-8-*trans*-LXB_4, 8-*trans*-LXB_4, and a racemic mixture of both LXA_4 and its (6*S*) isomer (6-epi-LXA_4), but not LXB_4. This notion was based upon the findings from experiments in which synthetic 5,6-epoxytetraene was added to leukocytes in suspension. However, those results did not clearly show whether the 5,6-epoxytetraene entered the cells when added exogenously, or whether it underwent hydrolysis in the extracellular medium before gaining access to cellular compartments. Moreover, the results of our time-course studies were not consis-

tent with this proposal. In particular, quantitatively higher amounts of LXA_4 were observed with cells that have not undergone lysis.[22, 32]

4. Enzymes Capable of Generating Lipoxins and Related Compounds

The initial proposal[7, 8] that tetraene-containing eicosanoids such as LXA_4 and LXB_4 are formed by several distinct biosynthetic routes has now been explored in several model systems using both purified and partially purified enzymes (Table 1). *Kühn* et al.[31] showed that a purified LO obtained from reticulocytes could convert the dihydroxy derivative, (5*S*,15*S*)-DiHETE, into trihydroxytetraenes. These transformations were blocked by inhibitors, heat denaturation, and anaerobic conditions. Thus, it was suggested that the products were enzymatically generated by LO reactions and two independent mechanisms were proposed.[31] One involves a 5,6-epoxide intermediate (vide supra), while the other implicates an intermediate generated by the action of LO on either the dihydroperoxy derivative, (5*S*,15*S*)-DiHpETE, or (5*S*,15*S*)-DiHETE. This second route can be considered a sequential triple lipoxygenation where a product of dioxygenation becomes a substrate for the third attack by an LO. Recently, these investigators[33, 34] have also demonstrated that the reticulocyte enzyme can convert 5,15-DiHETE into LXB_4, illustrating this triple lipoxygenation route. Along these lines, *Ueda* et al.[35] have shown that a 5-LO purified from porcine leukocytes can enzymatically generate a 5,6-epoxytetraene with either (15*S*)-HpETE or (15*S*)-HETE as substrate. Studies by this group, using a purified 12-LO from porcine leukocytes, indicate that LXB_4 can be generated by both the (14*R*)-oxygenase activity and the LXB_4 synthase activity of this enzyme with (5*S*,15*S*)-DiHETE.[36] Thus, the porcine enzyme can generate LXB_4 by both triple oxygenation and the formation of a putative 14(15)-epoxytetraene. However, unlike the porcine leukocyte, human neutrophils do not possess a 12-LO, and when 5,15-DiHpETE was added to intact human platelets, which contain 12-LO, LXB_4 was not generated.[25] Nevertheless, the results obtained with purified 12-LO from porcine leukocytes have suggested a potential enzymatic route to LXB_4 biosynthesis with intriguing mechanistic implications which may be of importance during cell–cell interactions.

In addition to utilizing hydroxy- and hydroperoxy-containing compounds as substrates, LO's can also utilize epoxide-containing compounds as substrates for the generation of lipoxin precursors. The soybean 15-LO, for example, rapidly transforms LTA_4 into a 5,6-epoxytetraene,[39] suggesting that 15-lipoxygenation of LTA_4 could give rise to lipoxins in various cells.

The role of initial oxygenation of AA by 5-LO, followed by interactions with either 12-LO or 15-LO, has been explored in studies with intact human platelets,[39, 41] rat mesangial cells,[42] and neutrophils.[40] Studies with human platelet-derived 100 000g supernatants, which display 12-LO activity, indicate that this 12-LO can react with LTA_4. These results exemplified the 12-LO's ($\omega - 6$) oxygenase activity and provide a role for this enzyme in lipoxin formation[40] (Scheme 2). Together, the results obtained with isolated enzymes have illustrated potential mechanisms for lipoxin production, some of which may be utilized by specific cell types. Whether two or more of these routes can operate simultaneously in a given cell system remains of interest.

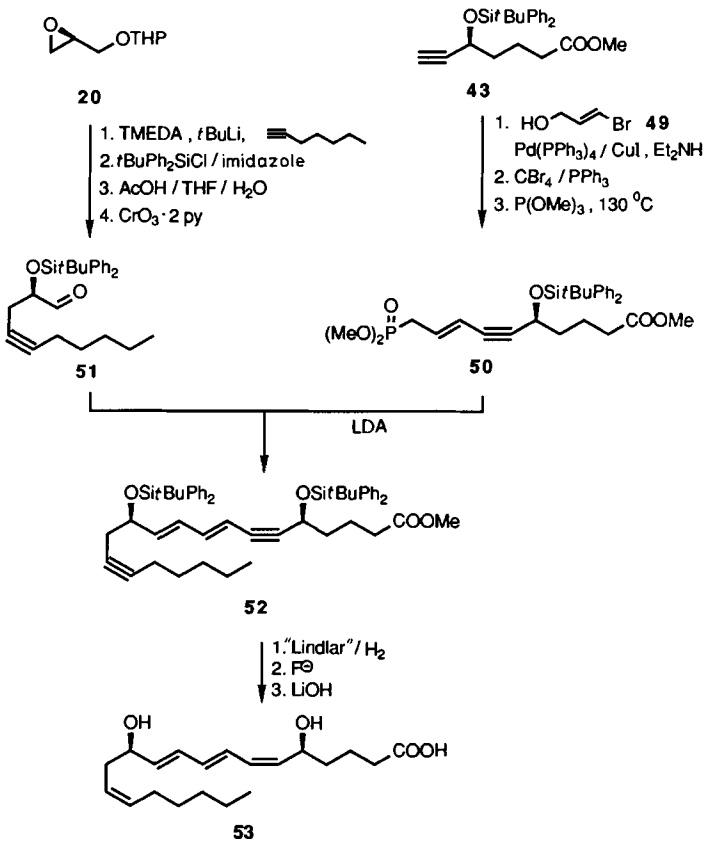
Table 1. Generation of lipoxins and related compounds by cell-free and isolated enzyme systems.

Enzyme	Source	Substrates	Products	Ref.
15-/12-Lipoxygenase	Rabbit reticulocytes/Soybean	(5*S*,15*S*)-DiHETE	Trihydroxytetraenes	[31]
15-/12-Lipoxygenase	Reticulocyte	(15*S*)-HETE, AA	Lipoxin B_4	[33] [34]
5-Lipoxygenase	Porcine leukocytes	(15*S*)-HpETE, (5*S*,15*S*)-DiHETE	5,6-Epoxytetraene	[35]
12-Lipoxygenase	Porcine leukocytes	(15*S*)-HpETE, (5*S*,15*S*)-DiHpETE	Lipoxin B_4	[36]
5-Lipoxygenase	Potato tubers	(15*S*)-HpETE/AA	Lipoxin A_4/ Lipoxin B_4	[37] [38]
15-Lipoxygenase	Soybean	Leukotriene A_4	5,6-Epoxytetraene	[39]
12-Lipoxygenase	Human platelets (100 000g supernates)	Leukotriene A_4	Lipoxin A_4	[40]
Epoxide hydrolase (cytosolic)	Human liver	5,6-Epoxytetraene	Lipoxin A_4	[26]

5. Cell Types Which Generate Lipoxins

Several species have now been shown to generate lipoxins from endogenous and/or exogenous sources of substrates (Table 2). The first published reports of lipoxin formation from endogenous sources of either C20:4 (AA) or C20:5 were introduced by *Wong* et al.[44] and *Lam* et al.,[45] who demonstrate that addition of an isolated PLA_2 isoenzyme to porcine leukocytes generates LXB_4 and its isomers. Furthermore, eosinophil-rich granulocyte suspensions from humans form LXA_4, which correlates with the number of eosinophils in the incubation.[46] Eosinophils also generate peptidolipoxins via the 5,6-epoxytetraene intermediate.[47] The biological significance and role of these new products is under investigation.

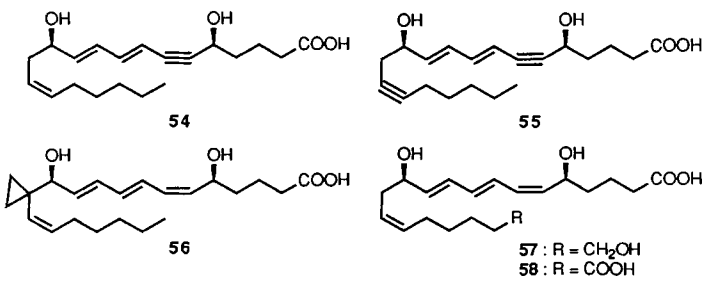
Lipoxins were also recently found to be the major lipoxygenase products of macrophages isolated from Rainbow trout exposed to A23187.[48] This finding represents the first



Scheme 11. Pd^0/Cu^I-catalyzed total synthesis of leukotriene B_4 (**53**). TMEDA = tetramethylethylendiamine, LDA = lithium diisopropylamide.

cidol THP ether **20** by epoxide opening with the lithio derivative of 1-heptyne, followed by silylation, removal of the THP group, and oxidation. Coupling of **50** and **51** under basic conditions furnished skeleton **52**, which was subjected to hydrogenation under Lindlar conditions to afford, after deprotection, leukotriene B_4 (**53**).

The acetylenic LTB_4 analogues **54** and **55** (Scheme 12) were also prepared from intermediate **52**. Similar chemistry

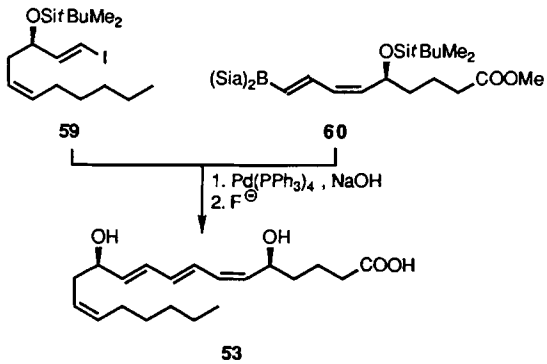


Scheme 12. Structures of synthesized leukotriene B_4 derivatives (**54–58**).

led to the ethano-substituted compound **56** and its dehydro analogues. These derivatives were targeted because replacing an allylic methylene group with a cyclopropyl moiety is a means of modulating the normal metabolism of arachidonic acid.[122]

The ω-oxidation products of LTB_4, 20-hydroxy- (**57**) and 20-carboxy- (**58**) leukotrienes B_4, are produced during the metabolism of LTB_4 (**53**) by human neutrophils. These molecules were also synthesized in enantiomerically pure forms following similar chemistry as described for LTB_4.[88]

A recent report from *Kobayashi*'s laboratories reported a highly practical route to LTB_4 by palladium-catalyzed coupling of vinyl iodide **59** with vinyl borane **60** (Scheme 13).[123]



Scheme 13. Synthesis of LTB_4 (**53**) by *Kobayashi* et al. [123]. Sia = 1,2-dimethylpropyl (siamyl).

7.5. Synthesis of Lipoxins

As described in Sections 2 and 3, the basic structures assigned for the lipoxins were derived from biosynthetic considerations and degradation studies on isolated biological materials. These assignments were incomplete: configurations at C6 for lipoxin A_4 and C14 for lipoxin B_4 were not initially defined due to limited amounts of biologically derived materials. Moreover, the geometry of the double bonds at C11 of LXA_4 and C8 of LXB_4 needed to be confirmed.[7, 8] These stereochemical uncertainties, giving rise to several possible stereoisomers, dictated the design of a general and flexible strategy that would deliver each of these isomers stereoselectively and unambiguously for comparison and matching studies with natural samples and for biological evaluation. The Pd^0/Cu^I-based strategy that we had developed proved ideal for these targets. Indeed, we were able to synthesize a large number of isomeric lipoxin A[89–93] and lipoxin B[92–95] derivatives. With the availability of these compounds, and by the series of comparative studies with the natural materials discussed in Sections 2 and 3, we were able to assign the complete structures of both LXA_4 and LXB_4, as well as identify some additional naturally occurring isomers of this series.

Our syntheses of these compounds are outlined below. Other laboratories have also reported approaches to a number of these molecules.[28, 29, 78b, 124–127]

7.5.1. Synthesis of Lipoxin A_4 and Stereoisomers

Scheme 14 shows the retrosynthetic analysis of lipoxin A_4 (**61**) which led to intermediates **62**, **63**, and **64** as potential starting materials.[89] We anticipated that this strategy would generate sequentially a *cis* and a *trans* double bond

Lipoxins also exert unique actions on specific cell types (Table 5). LXA_4 elicits selective actions on human neutrophils,[8, 65–70] and recent results indicate that, in addition to inducing chemotaxis,[65] LXA_4 can also block both LTB_4- and FMLP-induced responses (i.e., LXA_4 blocks IP_3 generation and $Ca^{2\oplus}$ mobilization).[66, 67] Both LXA_4 and LXB_4 selectively stimulate lipid remodeling with neutrophils and release AA without stimulating LO activity.[68] LXA_4 and LXB_4 also display selective actions with natural killer cells blocking cytotoxicity,[71] while LXB_4 stimulates colony formation with human mononuclear cells.[61] In addition to its potential extracellular roles, LXA_4 may also have an intracellular role within its cell type of origin before its release to the extracellular environment. Thus, LXA_4 activates isolated protein kinase C (PKC) and is more potent than either diacylglyceride or native arachidonate.[73] The actions of LXA_4 appear to be more specific for the γ-subspecies of PKC, which is found in brain and spinal cord.[74] These events are of interest since PKC and its subspecies may play important roles in regulating cellular responses in a wide range of cell types including differentiation, cell proliferation, and hormone actions.

Table 5. Biological activities of lipoxins on individual cell types.

Bioassay	Compound	Response	Ref.
Human neutrophils	$LXA_4 > LXB_4$	Chemotaxis without aggregation	[65]
Human neutrophils	LXA_4	Inhibition of leukotriene and FMLP-induced chemotactic responses; i.e. blocks $Ca^{2\oplus}$ mobilization and IP_3 generation	[66, 67]
Human neutrophils	LXA_4 and LXB_4	Stimulation of lipid remodeling and release of AA without LO activation, $Ca^{2\oplus}$ mobilization or blocking of LTB_4 binding	[68]
Human neutrophils	5,6-epoxy-tetraene	Stimulation of mobilization of intracellular $Ca^{2\oplus}$	[70]
Human endothelial cells	LXA_4 and LXB_4	Stimulation of prostacyclin generation and release	[77]
Kidney mesangial cells	LXA_4	Inhibition of LTD_4-induced IP_3 generation and LTD_4 binding	[57]
Human mononuclear cells	LXB_4	Stimulation of colony formation in diffusion chambers	[72]
Human natural killer cells	LXA_4 and LXB_4	Blocking of cytotoxicity without altering target-cell binding	[71]
Protein kinase C (PKC) from human placenta	LXA_4	Activation of phosphorylation in the presence of $Ca^{2\oplus}$ and selection of substrate specificity	[73]
PKC-γ-subspecies bovine cerebellum	LXA_4	Selective activation	[74]

Results to date indicate that lipoxins can be generated by several biosynthetic routes, which can include lipoxygenase as well as cell–cell interactions. Both LXA_4 and LXB_4 carry selective biological activities in both in vivo and vitro systems, which suggests that they may be involved in regulating cellular responses of interest in inflammation and host defense. Future studies will clarify whether the lipoxins can inhibit or regulate the signs of inflammation in specific disease models.

7. Chemical Synthesis

Since the lipoxins, like other eicosanoids, were isolated from natural sources only in small quantities, the chemical synthesis of these molecules played a key role in the determination of their stereochemistry and allowed a systematic investigation of their biological properties and function. Because of the need to identify the naturally occurring stereoisomers and the desire to compare the biological activities of the various isomers, a flexible synthetic plan that would deliver a maximum number of isomers was sought.

The synthetic challenges posed by the lipoxins and other acyclic eicosanoids, such as the various mono- and dihydroxyeicosatetraenoic acids (HETE's, LTB_4, other DiHETE's) are twofold. Firstly, the eicosanoid skeleton with the correct double-bond geometries must be constructed, and secondly the proper stereochemistry of the hydroxyl-bearing stereocenters must be secured. The carbon skeleton of these polyunsaturated systems has often been assembled by Wittig-type C=C bond-forming reactions. We have designed an alternative general strategy based on a C–C bond-forming process involving palladium-catalyzed coupling of vinyl precursors. The stereochemical control at the various hydroxylated positions of these target molecules can be accomplished by using starting materials from the chiral pool, such as 2-deoxyribose or lactic acid. Our approach, however, relied heavily on the Sharpless asymmetric epoxidation reaction, which provides a highly flexible method for the preparation of a number of stereoisomers with high and predictable enantioselectivity. In this manner, we were able to synthesize a large number of frameworks with varying chirality.

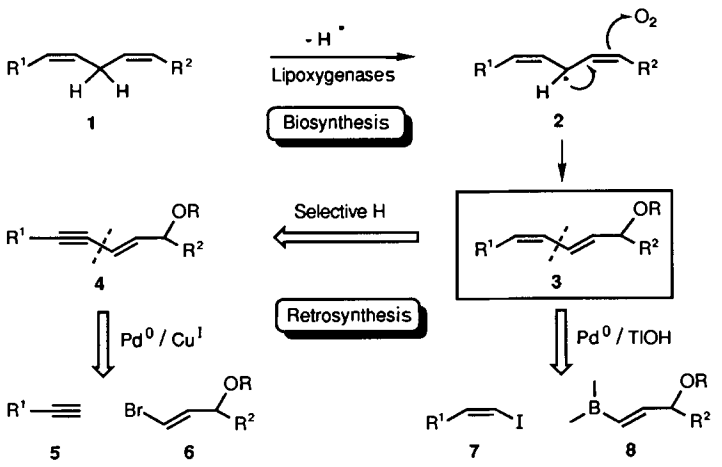
In this section we review aspects of the inception, evolution, and application of our strategy to the total synthesis of a variety of natural and designed eicosanoids. Other approaches to these molecules developed elsewhere,[78] mainly by the groups of *E. J. Corey* and a group at Merck-Frosst, are not discussed.

7.1. The Palladium Catalysis Strategy

The evolution of our general strategy towards acyclic eicosanoids had its origin in the proposed biosynthetic mechanism involved in the formation of these naturally occurring molecules. According to this mechanism, an ($\alpha Z,\delta Z$)-pentadiene system (**1**) of arachidonic or related skeleton is converted by lipoxygenases and molecular oxygen via **2** into a conjugated (*Z,E*)-diene system (**3**) as shown in Scheme 3. It occurred to us, therefore, that focusing on a stereocontrolled and efficient construction of the framework of **3** may provide a general entry into this class of compounds.

The key retrosynthetic disconnection of our approach to **3** involved the formation of the middle C–C bond by Pd catalysis. Formation of **3** through selective hydrogenation of **4** allows the synthesis of this system by Pd^0/Cu^I coupling[79] of a terminal alkyne (**5**) and a vinyl bromide (**6**). Alternatively, direct construction of **3** is possible by using the Suzuki coupling reaction[80] of a vinyl iodide (**7**) and a vinyl boron derivative (**8**). For this purpose we utilized *Kishi*'s modification[81] of this process, involving Pd^0/TlOH catalysis. The central functionality in our construction of the polyunsaturated carbon frameworks was the alkyne moiety, which could be used as a precursor to a *Z*-olefin by serving as a coupling partner, or it could be converted stereoselectively

into the required vinyl derivatives **6**, **7**, or **8**. This feature of our strategy allowed the economical and expeditious preparation of a variety of desired intermediates. This synthetic planning had the flexibility to deliver a variety of skeletons by using a library of common intermediates and reactions. We have synthesized several types of acyclic eico-



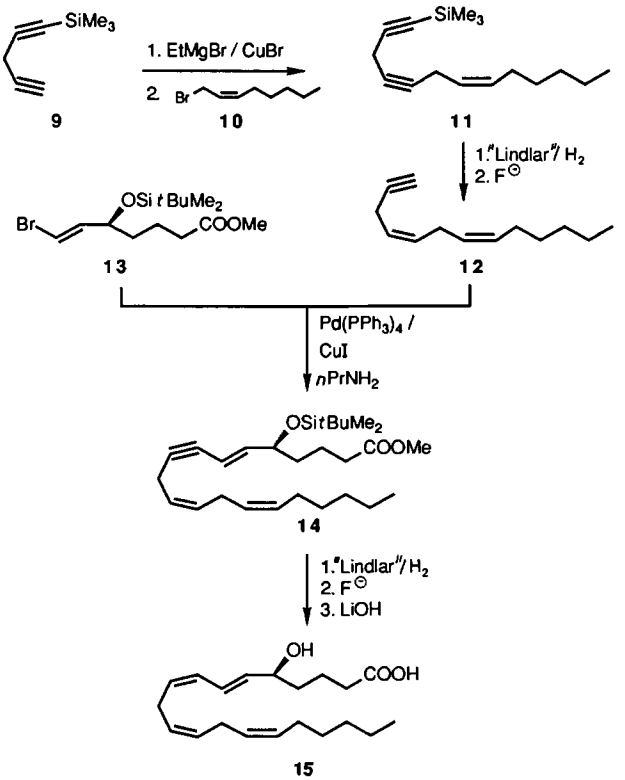
Scheme 3. Biosynthesis and retrosynthesis of acyclic eicosanoids. Here and in the following schemes, the R–C≡C–R′ units are often bent in order that the alkyne intermediates pictorially resemble the desired alkenes.

sanoids with this method, including monohydroxyicosatetraenoic acids (HETE's),[82–84] dihydroxy compounds (DiHETE's),[85, 86] leukotrienes B,[87, 88] lipoxins A,[89–93] and lipoxins B.[92–95]

7.2. Synthesis of Monohydroxyicosatetraenoic Acids (HETE's)

Several HETE's derived from the action of lipoxygenases on arachidonic acid have been identified. The main isomers are the 5-, 12- and 15-HETE's, while other isomers that have been isolated include the 8-, 9-, 11-, 19- and 20-HETE's. While a number of biological activities have been associated with these compounds, they also serve as precursors to a large number of other metabolites, such as several isomeric dihydroxy derivatives (DiHETE's), and some more highly oxygenated products. The isolation, structure elucidation, and biological properties of HETE's have recently been reviewed.[96] As outlined below, we have targeted a number of these acyclic eicosanoids.

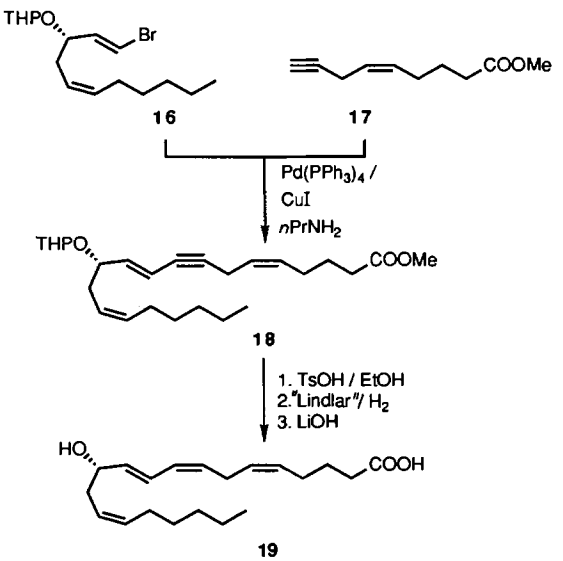
(5*S*)-HETE: Several syntheses of 5-HETE (**15**) have been reported.[97–102] Our total synthesis of the (5*S*) enantiomer (Scheme 4)[82] involved the Pd^0/Cu^I strategy. The synthesis began with the diacetylene **9** which was coupled with allylic bromide **10**, and the resulting derivative **11** was selectively hydrogenated at the internal triple bond without interference from the silicon-bearing triple bond. After desilylation, the resulting alkyne with a terminal triple bond (**12**) was coupled with vinyl bromide (**13**, the synthesis analogous to that for the Ph_2tBuSi derivative is described in Scheme 9) under standard Pd^0/Cu^I conditions to afford skeleton **14**, which was again selectively reduced under Lindlar conditions leading,



Scheme 4. Pd^0/Cu^I-catalyzed total synthesis of (5*S*)-HETE (**15**). "Lindlar" represents a palladium catalyst poisoned with lead as described by *Lindlar*.

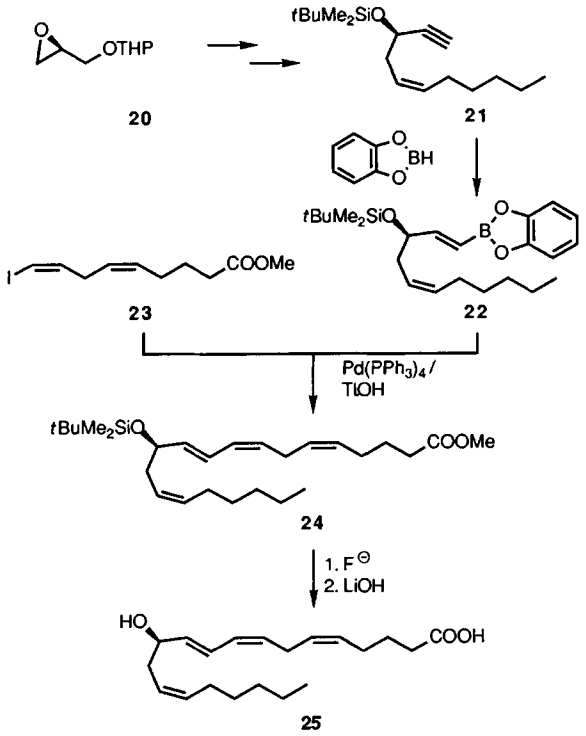
after deprotection, to (5*S*)-HETE (**15**) in excellent overall yield (18%).

(12*S*)-HETE: A number of synthetic routes to both racemic and enantiomerically pure (12*S*)-HETE (**19**), the major product of 12-LO, have been accomplished.[103–109] We have devised stereocontrolled sequences to both enantiomers of this molecule. For the synthesis of (12*S*)-HETE (**19**) we utilized the standard strategy based on Pd^0/Cu^I coupling of vinyl bromide **16** and alkyne **17**, followed by mild hydrogenation of **18** and deprotection (Scheme 5).[82]



Scheme 5. Pd^0/Cu^I-catalyzed total synthesis of (12*S*)-HETE (**19**). THP = tetrahydropyranyl.

(12*R*)-HETE: This enantiomer (**25**), which can be generated by the action of the cytochrome P450 system on arachidonic acid, was also synthesized in these laboratories recently.[83] This synthesis was based on the Pd^0/TlOH-catalyzed coupling of vinyl boranes and vinyl halides. The strategy (Scheme 6) eliminates the need for selective reduction of C≡C bonds after the coupling step, and was also employed by us in the synthesis of (12*S*)-hydroxy-(5*Z*,8*E*,10*E*)-heptadecatrienoic acid (HHT),[110] a major metabolite of arachidonate. Thus, the enantiomerically pure epoxide **20**



Scheme 6. Pd^0/Cu^I-catalyzed total synthesis of (12*R*)-HETE (**25**).

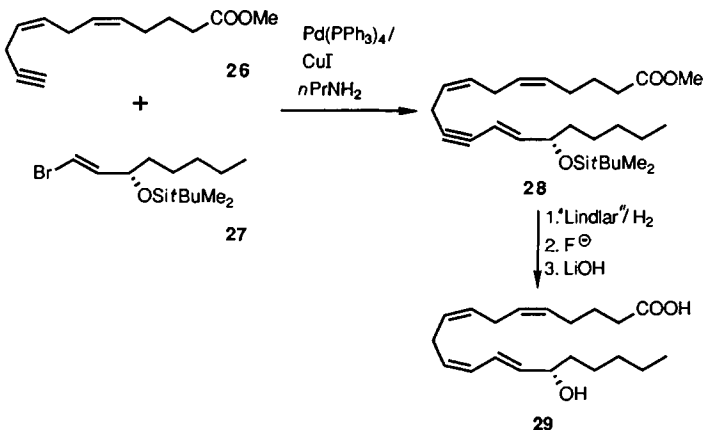
was converted into acetylenic derivative **21**, which was reacted with catechol borane to give the vinyl borane **22**. Coupling of **22** with vinyl iodide **23** using *Kishi*'s palladium(0)/thallium hydroxide method[81] directly afforded **24**. Finally, deprotection of **24** led to the targeted (12*R*)-HETE (**25**).

(15*S*)-HETE: The key step in our synthesis[84] of (15*S*)-HETE (**29**) (Scheme 7) was the coupling of acetylenic ester **26** with vinyl bromide **27** (for the synthesis see Scheme 9) under the Pd^0/Cu^I conditions to afford the desired skeleton **28**. Lindlar hydrogenation of **28** followed by deprotection led to (15*S*)-HETE (**29**) in high overall yield (63%). Other syntheses of this molecule have also been reported.[111, 112]

7.3. Synthesis of Dihydroxyicosatetraenoic Acids (DiHETE's)

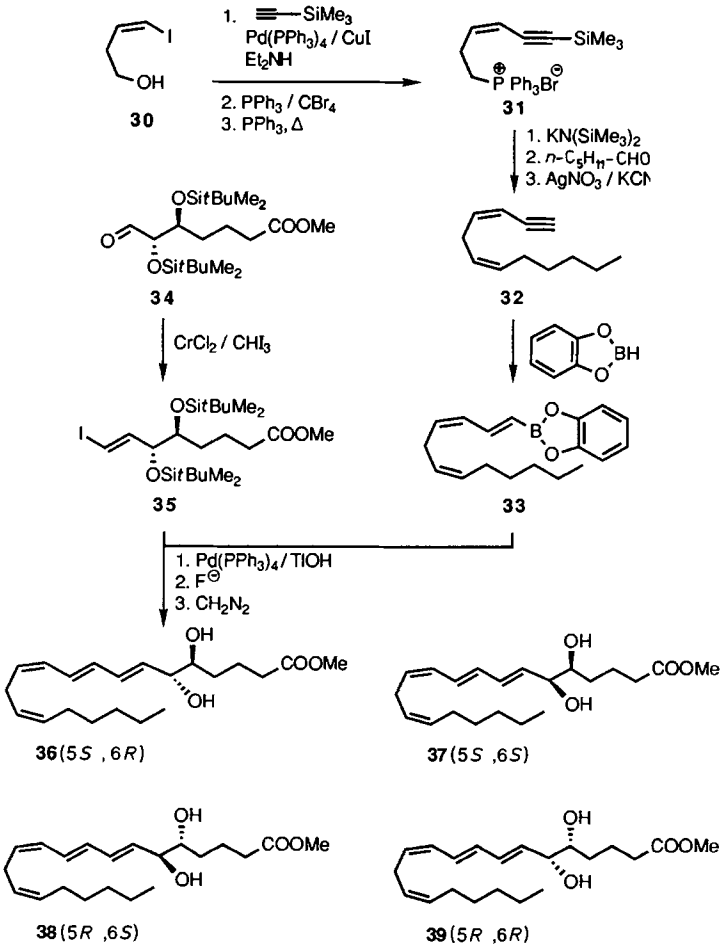
Several naturally occurring DiHETE's have been identified which are formed either by the action of two lipoxygenases or by the hydrolysis of epoxide intermediates.

(5*S*,6*R*)-DiHETE: This is a biologically active metabolite of arachidonic acid derived from leukotriene A_4 (LTA_4,



Scheme 7. Pd^0/Cu^I-catalyzed total synthesis of (15*S*)-HETE (**29**).

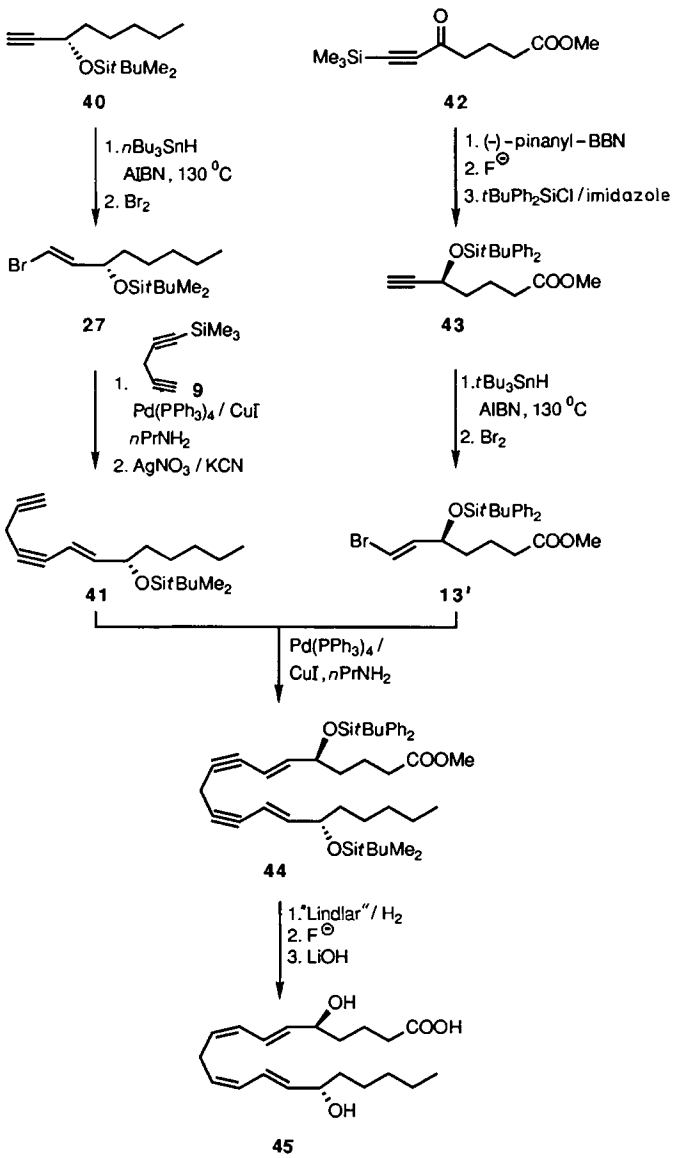
Scheme 1) by regio- and stereoselective enzymatic hydrolysis. Nonenzymatic hydrolysis of LTA_4 leads to a mixture of (5*S*,6*R*) and (5*S*,6*S*) isomers. In order to render these and other isomers readily available for biological studies and to compare their actions with those of lipoxin A_4, we synthesized all four 5,6-isomeric DiHETE methyl esters.[86] The synthesis of (5*S*,6*R*)-DiHETE methyl ester (**36**) is shown in Scheme 8.[86] Coupling of vinyl iodide **30** with (trimethylsilyl)acetylene assisted by $Pd(PPh_3)_4$/CuI catalysis, followed



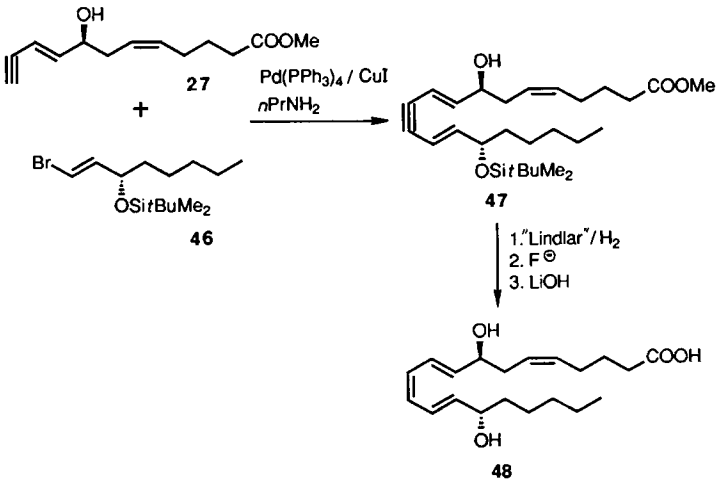
Scheme 8. Pd^0/Tl^IOH-catalyzed total synthesis of the (5*S*,6*R*)-diHETE methyl ester (**36**) and related compounds **37**–**39**.

by conversion of the alcohol into a bromide, and phosphonium salt formation, furnished compound **31** which was extended to acetylene **32** through a Wittig reaction. The vinyl borane **33** was then formed regioselectively and was coupled to vinyl iodide **35** under the usual conditions to afford, after functional group manipulation, the requisite (5*S*,6*R*)-DiHETE (**36**). The coupling partner **35** was prepared from aldehyde **34** (for synthesis see Scheme 14) by the action of $CrCl_2$ and CHI_3, according to the method of *Takai* et al.[113] Starting with the appropriate isomeric vinyl iodides and following similar chemistry as for **36**, (5*S*,6*S*)-**37**, (5*R*,6*S*)-**38**, and (5*R*,6*R*)-**39** DiHETE methyl esters were also prepared. A conceptually different synthesis of 5,6-DiHETE was reported by *Adams* et al.[29]

(5*S*,15*S*)-DiHETE: The interesting dihydroxylated arachidonic acid metabolite (5*S*,15*S*)-dihydroxy-(6*E*,8*Z*,11*Z*,13*E*)-icosatetraenoic acid (**45**) was the first linear eicosanoid to be synthesized by the Pd^0/Cu^I technology in these laboratories.[84] Its two *Z*,*E* diene systems provided two strategic disconnections that allowed its facile construction as summarized in Scheme 9. Thus, the key vinyl bromides **27** and **13′**, the Ph_2-substituted analogue of **13**, were synthesized from the protected acetylenic alcohols **40** and **43** (derived by enantioselective reduction of **42**) by tri-*n*-butyltin hydride addition and brominolysis. Coupling of **27** with the monoprotected α,ω-diyne **9** under the influence of Pd^0/Cu^I catalysis, followed by desilylation and a second coupling with vinyl bromide **13′** under the same conditions, led quickly to the desired skeleton **44** in high yield (62%). Lindlar hydrogenation of **44** followed by desilylation and ester hydrolysis afforded **45**, whereas deprotection of **44** allowed the formation of the novel 8,9,11,12-tetradehydro analogue of **45**.[84] *Fitzsimmons* and *Rokach*[114] have also reported the synthesis of **45**.



Scheme 9. Pd^0/Cu^I-catalyzed total synthesis of (5*S*,15*S*)-DiHETE (**45**). AIBN = azodiisobutyronitrile; BBN = 9-borabicyclononane.

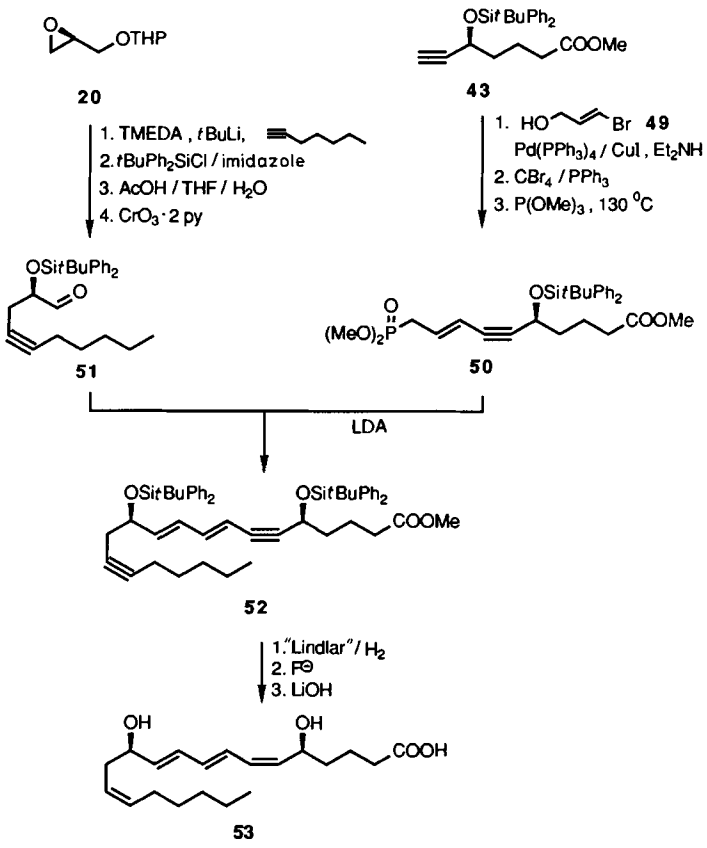


Scheme 10. Pd^0/Cu^I-catalyzed total synthesis of (8*S*,15*S*)-DiHETE (**48**).

(8*S*,15*S*)-DiHETE: The naturally occurring (8*S*,15*S*)-DiHETE (**48**) was synthesized in a stereocontrolled manner through the standard Pd^0/Cu^I coupling step between alkyne derivative **46** and vinyl bromide **27** as shown in Scheme 10.[85] Lindlar hydrogenation of the resulting **47** followed by desilylation and saponification gave **48** in high overall yield (66%). The 11,12-didehydro analogue of **48** was also generated from **47** by standard deprotection techniques.[85]

7.4. Synthesis of Leukotriene B_4 and Derivatives

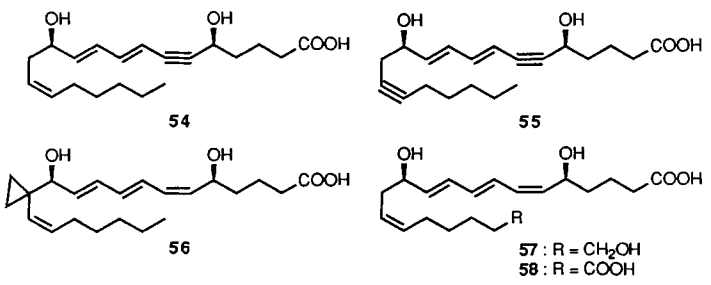
One DiHETE of particular interest that has been studied extensively is leukotriene B_4 (LTB_4, **53**), derived from the enzymatic hydrolysis of the epoxide-bearing leukotriene A_4 (see Scheme 1). A number of synthetic approaches to this compound, an important chemotactic agent, have been developed at various laboratories.[78,115-121] Our synthesis of this molecule is indicated in Scheme 11.[87] Thus, Pd^0/Cu^I-catalyzed coupling of **43** (see Scheme 9) with vinyl bromide **49** followed by allylic bromide formation and Arbuzov reaction with trimethyl phosphite gave the key phosphonate **50**. This intermediate served as the C_1–C_{10} fragment for the synthesis of LTB_4 and several structural analogues. The other requisite key intermediate **51** was prepared from (*R*)-gly-



Scheme 11. Pd^0/Cu^I-catalyzed total synthesis of leukotriene B_4 (**53**). TMEDA = tetramethylethylendiamine, LDA = lithium diisopropylamide.

cidol THP ether **20** by epoxide opening with the lithio derivative of 1-heptyne, followed by silylation, removal of the THP group, and oxidation. Coupling of **50** and **51** under basic conditions furnished skeleton **52**, which was subjected to hydrogenation under Lindlar conditions to afford, after deprotection, leukotriene B_4 (**53**).

The acetylenic LTB_4 analogues **54** and **55** (Scheme 12) were also prepared from intermediate **52**. Similar chemistry

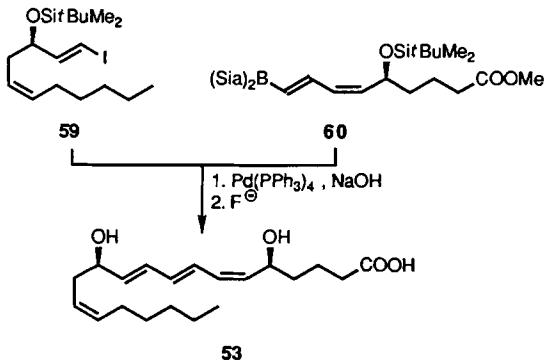


Scheme 12. Structures of synthesized leukotriene B_4 derivatives (**54–58**).

led to the ethano-substituted compound **56** and its dehydro analogues. These derivatives were targeted because replacing an allylic methylene group with a cyclopropyl moiety is a means of modulating the normal metabolism of arachidonic acid.[122]

The ω-oxidation products of LTB_4, 20-hydroxy- (**57**) and 20-carboxy- (**58**) leukotrienes B_4, are produced during the metabolism of LTB_4 (**53**) by human neutrophils. These molecules were also synthesized in enantiomerically pure forms following similar chemistry as described for LTB_4.[88]

A recent report from *Kobayashi*'s laboratories reported a highly practical route to LTB_4 by palladium-catalyzed coupling of vinyl iodide **59** with vinyl borane **60** (Scheme 13).[123]



Scheme 13. Synthesis of LTB_4 (**53**) by *Kobayashi* et al. [123]. Sia = 1,2-dimethylpropyl (siamyl).

7.5. Synthesis of Lipoxins

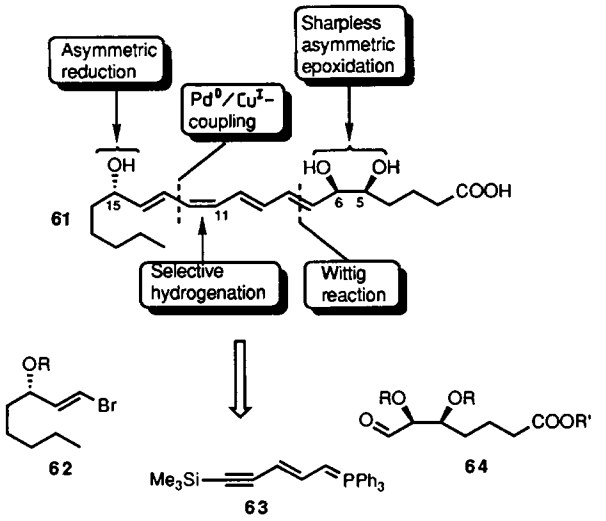
As described in Sections 2 and 3, the basic structures assigned for the lipoxins were derived from biosynthetic considerations and degradation studies on isolated biological materials. These assignments were incomplete: configurations at C6 for lipoxin A_4 and C14 for lipoxin B_4 were not initially defined due to limited amounts of biologically derived materials. Moreover, the geometry of the double bonds at C11 of LXA_4 and C8 of LXB_4 needed to be confirmed.[7, 8] These stereochemical uncertainties, giving rise to several possible stereoisomers, dictated the design of a general and flexible strategy that would deliver each of these isomers stereoselectively and unambiguously for comparison and matching studies with natural samples and for biological evaluation. The Pd^0/Cu^I-based strategy that we had developed proved ideal for these targets. Indeed, we were able to synthesize a large number of isomeric lipoxin A[89–93] and lipoxin B[92–95] derivatives. With the availability of these compounds, and by the series of comparative studies with the natural materials discussed in Sections 2 and 3, we were able to assign the complete structures of both LXA_4 and LXB_4, as well as identify some additional naturally occurring isomers of this series.

Our syntheses of these compounds are outlined below. Other laboratories have also reported approaches to a number of these molecules.[28, 29, 78b, 124–127]

7.5.1. Synthesis of Lipoxin A_4 and Stereoisomers

Scheme 14 shows the retrosynthetic analysis of lipoxin A_4 (**61**) which led to intermediates **62**, **63**, and **64** as potential starting materials.[89] We anticipated that this strategy would generate sequentially a *cis* and a *trans* double bond

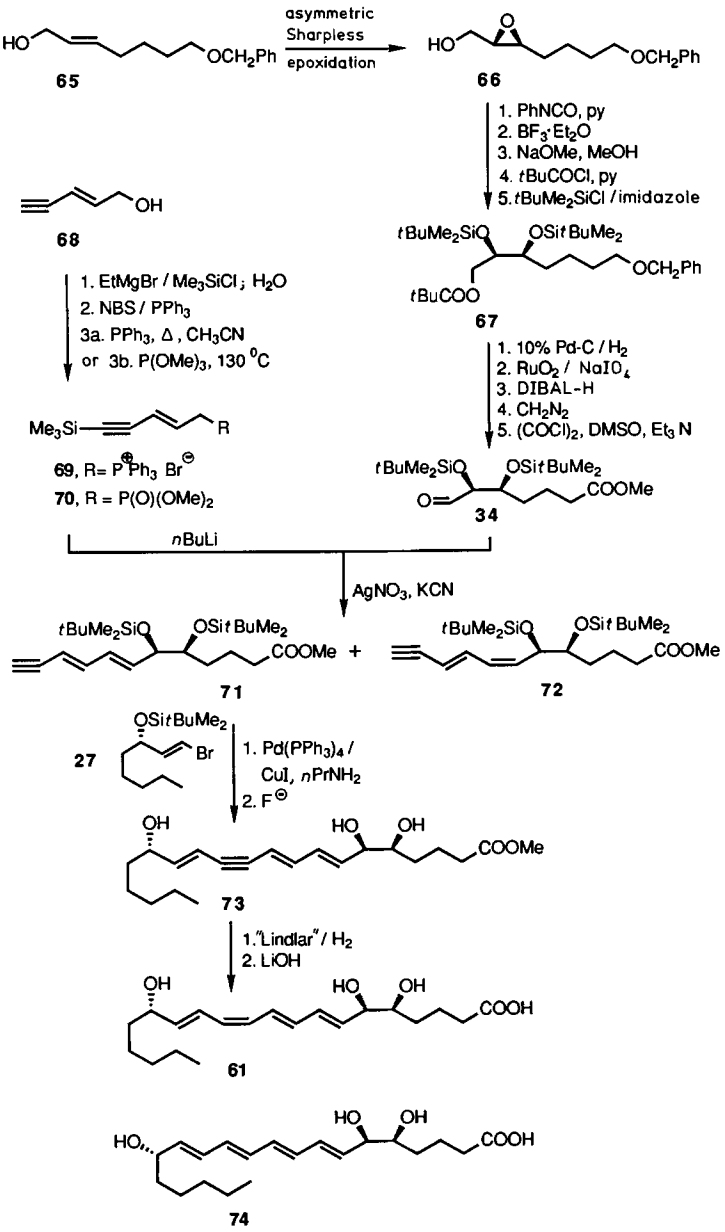
between C11 and C12 in the final structure. Furthermore the Sharpless asymmetric epoxidation procedure could be applied to obtain all four possible stereoisomers of fragment **64** by varying the double-bond geometry of the allylic alcohol precursor and the absolute configuration of the chiral auxiliary.



Scheme 14. Retrosynthetic analysis of lipoxin A_4 (**61**).

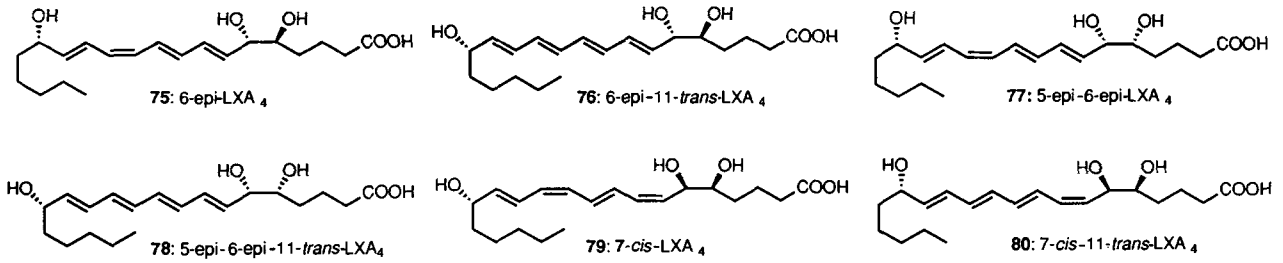
The total synthesis of (5*S*,6*R*,15*S*) lipoxin A_4 (**61**) and its all-*trans* isomer (**74**) summarized in Scheme 15 exemplifies the strategy for the synthesis of the lipoxin A_4 series.[89] Scheme 15 shows the construction of the requisite fragments **34** and **69** or **70** in pure forms by well-known methodology and depicts the key coupling reactions and final elaborations leading to the target molecules. Thus, coupling of the phosphorane derived from phosphonium salt **69** with aldehyde **34** led, in excellent yield (98%), to a mixture of *E* and *Z* products **71** and **72** (ca. 1:1 ratio), whereas coupling with the anion of the phosphonate **70** led to a lower *E*:*Z* ratio (ca. 1:3). The *Z* isomer **72** was, however, easily isomerized to the *E* compound (ca. 11:1 equilibrium mixture) with catalytic amounts of iodine. Pure **71** was then coupled with vinyl bromide **27** (see Scheme 9) under the standard Pd^0/Cu^I conditions to afford in excellent overall yield (80%) after desilylation, the basic lipoxin skeleton **73**. Although this compound was obtained as a 1:1 mixture with the δ-lactone formed by intramolecular transesterification, the latter could be converted into **73** upon hydrolysis and diazomethane treatment. Compound **73** was easily converted into lipoxin A_4 (**61**) by Lindlar hydrogenation and hydrolysis. The isomeric all-*trans* LXA_4 (**74**) was synthesized by hydrogenation of **73** followed by olefin isomerization with iodine and ester hydrolysis. In a similar manner we have also synthesized 19,19,20,20,20-pentadeuterio-LXA_4,[91] in an effort to aid the quantitative detection of eicosanoid **61** by GC-MS.

Biosynthetic studies using synthetic lipoxin epoxide (vide infra) and (15*S*)-HETE revealed the generation of additional compounds that contained the basic lipoxin structure (e.g. trihydroxytetraenes). In order to aid in the complete stereochemical assignment of these structures, as well as to make



Scheme 15. Pd^0/Cu^I-catalyzed total synthesis of lipoxin A_4 (**61**) and 11-*trans*-LXA_4 (**74**). DIBAL-H = diisobutylaluminium hydride, DMSO = dimethyl sulfoxide.

them available for further biological studies, we targeted a number of stereoisomers of lipoxin A_4[92] which retain the (15*S*) stereochemistry of LXA_4 but differ from the original lipoxins in the geometry of the tetraene system and the stereochemistry at C5 or C6 or both. The construction of these new lipoxins was based on our general strategy towards linear eicosanoids described above, in which both the absolute stereochemistry of the stereogenic centers and the geometry of the double bonds is controlled. The powerful Pd^0/Cu^I-catalyzed coupling reaction between compounds with terminal triple bonds and vinyl halides features heavily in these syntheses. The Sharpless asymmetric epoxidation was also used to prepare, in optically active form, the diol moieties in these systems. The isomers synthesized (**75**–**80**) are shown in Scheme 16. Comparison of these synthetic compounds with biologically derived materials established[50] the complete

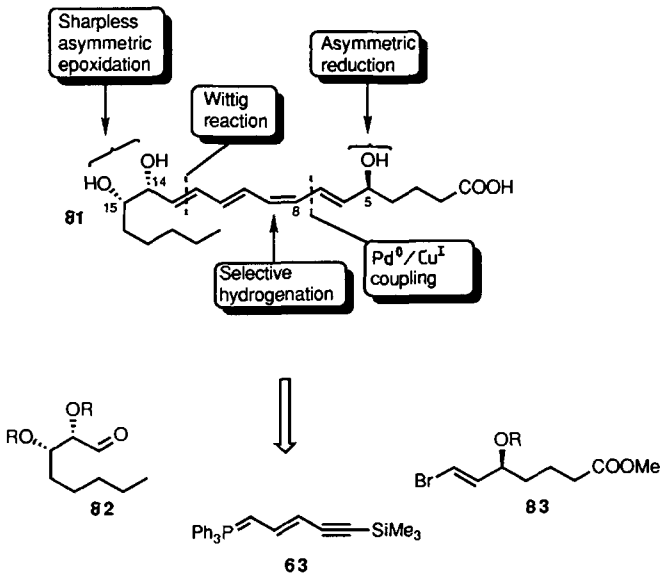


Scheme 16. Structures of synthesized lipoxin A_4 stereoisomers.

molecular structure of a new, naturally occurring lipoxin A_4, namely 7-*cis*-11-*trans*-lipoxin A_4, (**80**). Furthermore, the availability of these stereoisomers has already provided additional evidence for the high degree of stereospecificity involved in evoking biological responses by lipoxins.

7.5.2. *Total Synthesis of Lipoxin B_4 and Stereoisomers*

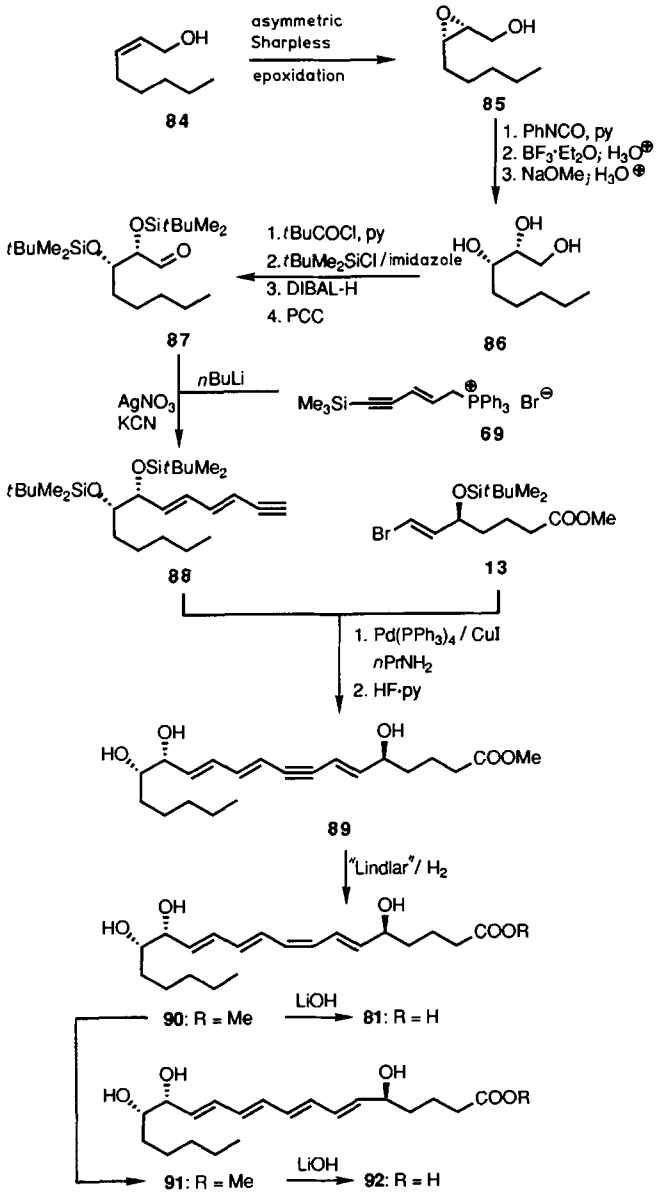
Biogenetic considerations and structural studies left the issues of geometry at C8 and of configuration at C14 of lipoxin B_4 (**81**) as the main stereochemical questions to be resolved. We therefore designed our strategy for the total synthesis of this molecule with the flexibility to vary these parameters.[94, 95] Scheme 17 presents the overall retrosynthetic analysis for this target and its isomers. The expectation



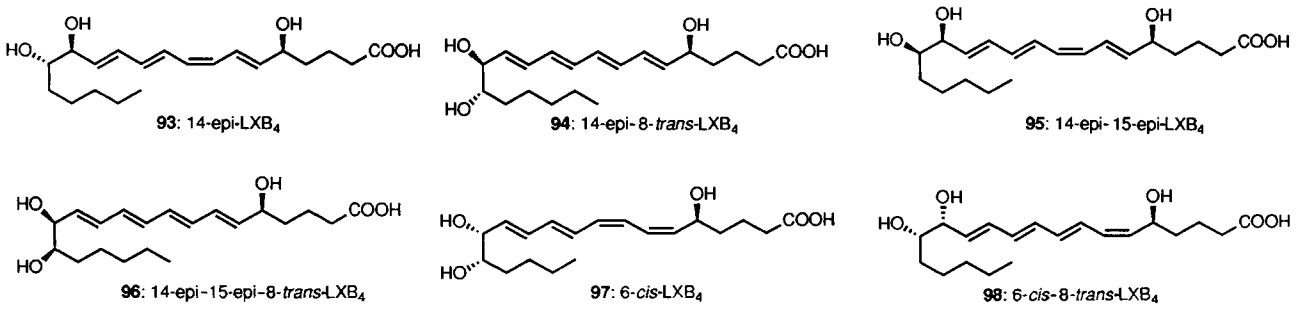
Scheme 17. Retrosynthetic analysis of lipoxin B_4 (**81**).

of a facile isomerization of an 8*Z* to an 8*E* double bond led us to target the 8*Z* isomers as the initial goals. Furthermore, the Sharpless asymmetric epoxidation reaction was expected to provide the necessary flexibility for preparing the requisite hydroxy compounds as well as other isomers for biological evaluation. The desired stereochemistry at C5 was to be secured by asymmetric reduction of a carbonyl function, whereas the 8*Z* geometry was expected from a selective Lindlar-type reduction. Finally, the key coupling reactions chosen to construct the lipoxin B skeleton were based on Wittig and Pd^0/Cu^I technologies as previously demonstrated in these laboratories.

The synthesis of the lipoxin B_4 and other members of this series[94, 95] (Scheme 18) began with the allylic alcohol **84** which, upon Sharpless asymmetric epoxidation, gave **85** which was in turn converted into triol **86** via urethane forma-



Scheme 18. Pd^0/Cu^I-catalyzed total synthesis of lipoxin B_4 (**81**) and 8-*trans*-LXB_4 (**92**). PCC = pyridinium chlorochromate.



Scheme 19. Structures of the synthesized lipoxin B_4 stereoisomers.

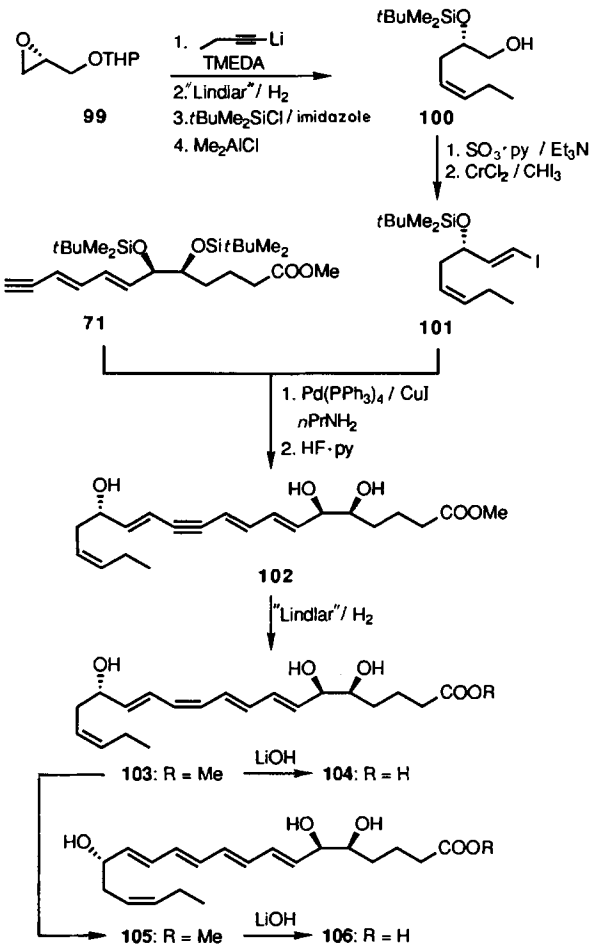
tion and rearrangement. Standard chemical manipulations converted **86** into aldehyde **87**, which was condensed with the phosphorane derived from **69** to afford alkyne **88** together with its *cis* isomer (ca. 1:1 ratio). The *cis* isomer was isomerized by catalytic amounts of iodine to the *trans* compound (*trans*:*cis* ≈ 11:1 at equilibrium), and **88** coupled to the vinyl bromide **13** under the standard Pd^0/Cu^I conditions. Treatment of the resulting compound with HF · py gave a mixture of the LXB skeleton **89** and the corresponding δ-lactone (ca. 2:1 ratio), which was easily converted into **89** by saponification and methylation with diazomethane. Finally, Lindlar hydrogenation of **89** afforded lipoxin B_4 methyl ester (**90**) from which lipoxin B_4 itself (**81**) was generated in high yield (90%). In addition, **90** was isomerized to the all-*trans* lipoxin B_4 methyl ester **91**, which was hydrolyzed to the carboxylic acid **92**.

As discussed in Section 7.5.1 for LXA_4, it was desirable to obtain isomers of LXB_4 which retained the (5*S*) stereochemistry but varied the geometry of the olefinic bonds and the stereochemistry at the other hydroxyl-bearing stereocenters. Therefore, starting with the *E* isomer of alcohol **84** and utilizing (+)- or (−)-diethyl tartrate, we synthesized the LXB_4 isomers **93**–**98**, shown in Scheme 19, by modifications of the general strategy.[95]

7.5.3. *Total Synthesis of Lipoxins A_5 and B_5*

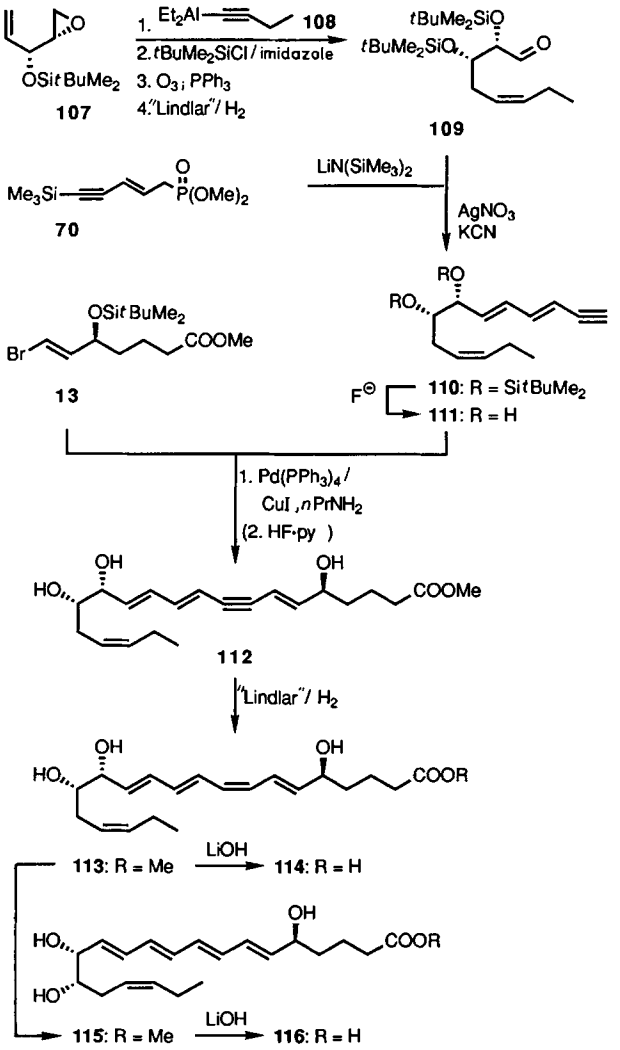
The isolation of lipoxins A_5 (LXA_5, 5,6,15-trihydroxy-7,9,11,13,17-icosapentaenoic acid) and B_5 (LXB_5, 5,14,15-trihydroxy-6,8,10,12,17-icosapentaenoic acid) by *Wong* et al.[128] prompted us to design and execute a stereocontrolled total synthesis of the suspected isomers (by analogy to LXA_4 and LXB_4). The targeted isomers were (5*S*,6*R*,15*S*)-trihydroxy-(7*E*,9*E*,11*Z*,13*E*,17*Z*)-icosapentaenoic acid and (5*S*,14*R*,15*S*)-trihydroxy-(6*E*,8*Z*,10*E*,12*E*,17*Z*)-icosapentaenoic acid.

The synthetic sequences were based upon the Pd^0/Cu^I-catalyzed strategy.[93] Scheme 20 summarizes the synthesis of LXA_5 starting with the readily available (*R*)-epoxyalcohol derivative **99**. Thus, 1-lithiobutyne reacted with **99** in the presence of TMEDA to afford, after Lindlar hydrogenation, silylation, and depyranylation, the *cis* olefin **100** in high overall yield (65%). Oxidation of **100**, followed by reaction with $CrCl_2/CHI_3$,[113] led to the vinyl iodide **101**. Coupling of **101** with the alkyne **71** (see Scheme 15) under the standard Pd^0/Cu^I conditions gave, after exposure to HF · py, a mixture of 11,12-didehydro lipoxin A_5 methyl ester **102**, and the corresponding δ-lactone. The latter compound was converted into **102** by treatment with methanol and triethylamine. Selective hydrogenation of **102** using Lindlar catalyst gave lipoxin A_5 methyl ester (**103**), together with small amounts of its 11-*trans* isomer (**105**). Compound **103** isomerized slowly at ambient temperatures to its *trans* isomer **105**, a process that was accelerated by catalytic amounts of iodine. Alkaline hydrolysis of **103** and **105** generated lipoxin A_5 (**104**) and its 11-*trans* isomer (**106**) respectively.



Scheme 20. Pd^0/Cu^I-catalyzed total synthesis of lipoxin A_5 (**104**) and 11-*trans*-LXA_5 (**106**).

The synthesis of lipoxin B_5 (**114**)[93] (Scheme 21) utilized the readily available epoxide **107**, phosphonate **70**, and vinyl bromide **13** as starting materials. The chemistry proceeded for the most part along similar lines as described for LXA_5 and LXB_4 with the three key coupling reactions: epoxide

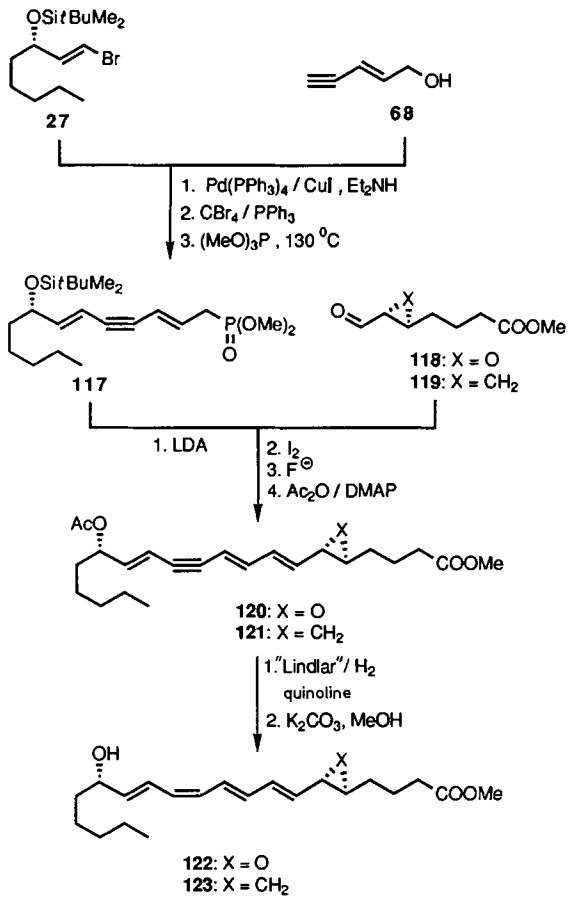


Scheme 21. Pd^0/Cu^I-catalyzed total synthesis of lipoxin (**114**) and 8-*trans*-LXB_5 (**116**).

opening of **107** with **108**, condensation of phosphonate **70** with **109**, and Pd^0/Cu^I-catalyzed coupling of **110** (or **111**) with **13** to give compound **112**. Ester **113** and then LXB_5 (**114**) were then formed as usual. The corresponding 8-*trans*-LXB_5 **116** was also generated from **113** through isomerization and alkaline hydrolysis of **115**.

7.5.4. Total Synthesis of the 5,6-Epoxytetraene, the Biosynthetic Precursor to Lipoxins A_4 and B_4, and Its 5,6-Methano Analogue

The early proposition of (15*S*)-hydroxy-(5*S*,6*S*)-epoxy-(7*E*,9*E*,11*Z*,13*E*)-icosatetraenoic acid as precursor to lipoxins A_4 and B_4 suggested this compound (see Scheme 2) as a synthetic target. Scheme 22 outlines the synthesis of the methyl ester of this epoxide (**122**) in enantiomerically pure form.[90] Thus, Pd^0/Cu^I-catalyzed coupling of the vinyl bromide **27** (see Scheme 9) with the alkynyl alcohol **68** proceeded smoothly to afford, after bromination and phosphonate formation, the key phosphonate intermediate **117**. Condensation of the lithio derivative of **117** with aldehyde **118** gave a 3:1 mixture of 7*E* and 7*Z* isomers of coupling product, which was converted into a 9:1 mixture by treatment with catalytic amounts of iodine. Difficulties with the reduction of the triple bond of this product necessitated the exchange of the silyl protecting group for an acetate to afford compound **120**. Purified **120** was successfully converted into the targeted compound **122** by Lindlar hydrogenation in the presence of quinoline, followed by deacetylation. Other groups have also reported syntheses of **122**.[30, 43] This labile epoxide could be stored with traces of triethylamine in benzene at $-40\,^{\circ}C$ for several days and used directly for biogenetic studies. It was indeed shown[26] that this compound could serve as a precursor to enzymatically generated LXA_4 and LXB_4.



Scheme 22. Total synthesis of lipoxin epoxide methyl ester (**122**) and its 5,6-methano analogue (**123**). DMAP = 4-dimethylaminopyridine.

In order to selectively inhibit the enzymatic transformation of **122**, as we had earlier shown for leukotriene A_4,[129] we also targeted the methano analogue **123** (Scheme 22), which has a stable cyclopropyl group in the place of the labile epoxide moiety. This compound was prepared by similar chemistry from enantiomerically pure aldehyde **118** via intermediate **121** (Scheme 22).[90]

8. Summary and Future Outlook

The investigations on the combined effects of the major lipoxygenase pathways on arachidonic acid have resulted in the discovery of the lipoxins, a new class of biologically active eicosanoids. These trihydroxytetraene derivatives are

formed by initial lipoxygenation at either C15 or C5 and occur in two different substitution patterns termed lipoxins A_4 and lipoxins B_4, respectively. Many types of cells and enzyme systems were shown to produce these novel biomolecules. The stereochemical integrity (olefin geometry, chirality of hydroxy substituents) of the naturally derived lipoxins has been determined by comparisons with synthetically prepared materials.

To obtain all of the required compounds in isomerically pure form, a general synthetic strategy involving a key Pd^0/Cu^I-catalyzed coupling reaction between vinyl halides and terminal acetylenes was devised. Subsequent Lindlar hydrogenation affords the unique *E,Z*-diene system, common in a variety of acyclic eicosanoids. Since the labile conjugated *Z*-olefin moiety is generated during the final stages of the synthesis under neutral conditions, it becomes possible to form and maintain the desired conjugated olefin system in these acid- and base-sensitive molecules. An alternative strategy involving the Pd^0/Tl^I-catalyzed coupling of vinyl boronates with vinyl halides affords the conjugated systems directly.

We have demonstrated the powerful nature of this strategy by synthesizing not only the lipoxins and a large number of their isomers, but also several natural and nonnatural hydroxy (HETE) and dihydroxy (DiHETE) derivatives, including leukotriene B_4. Further applications of this synthetic approach to other acyclic eicosanoid systems, including a large number of structural analogues for biological evaluation, can be envisioned.

The discovery of the lipoxins and the availability of a variety of synthetic materials has prompted extensive studies on the biosynthesis and biological activities of these compounds. The lack of all the required enzymes in some cell types indicates the involvement of cell–cell interactions. Continuing work in this area has uncovered some distinct biological activities of the lipoxins, which suggest a regulatory role in the biosynthesis and action of other eicosanoids, including the leukotrienes and cyclooxygenase products. As such, the lipoxins may be involved in the cellular responses taking place during inflammation and other immunologically related conditions. These novel arachidonate-derived metabolites, therefore, constitute yet another self-regulating element of the remarkable eicosanoid cascade.

We are grateful to Professor B. Samuelsson and our many collaborators on this project, whose names appear in the references, for their valuable contributions. Financial support for this work by NIH, Merck Sharp & Dohme, Smith Kline & French and the Camille & Henry Dreyfus Foundation (K. C. N.), the PEW Scholar Program in the Biomedical Sciences, and American Heart Association (C. N. S.) is deeply appreciated.

Incarcerated Atoms and Reactive Molecules

*By Henning Hopf**

The desire to "incarcerate" electrons, atoms, ions, and eventually complete molecules in compounds that are hollow in some way has been not only renewed again and again by the exceptionally rapid development of supramolecular chemistry, but also fulfilled in increasing measure. The attempts at encapsulation are older than host–guest chemistry itself, as such experiments with adamantane (which is, after all, also hollow) and related bi- and polycycles show. The source of this strong tendency to "conceal" species can possibly be explained only by psychology, but probably has something to do with the fact that compartmentalization is a characteristic of life itself: when the distinction between "inside" and "outside" disappears, life is snuffed out.

Whatever the underlying cause of this desire to hide things (which is also manifest in Art and Folklore as the innumerable examples from the artist *Christo* to the Russian Matrioschka doll-in-the-doll show), two papers will be discussed here in which spectacular incarcerations (Latin carcer = enclosure, prison, dungeon) are reported. In the first case a reactive molecule is stabilized by locking it into a molecular high security prison; in the second a (this time completely inert) atom is captured within a molecule never before proven to be a molecular trap.

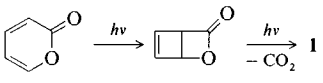
To enable the direct or indirect observation of highly reactive compounds that have, under normal conditions, not the slightest chance of survival is a stimulating and important assignment, since such molecules are not only suitable for testing theoretical models, but always also challenge and incite the development of preparative and instrumental methodology.

Over the years several high-performance chemical procedures have been developed to tame "nonexistent" molecules; among them the protection of reactive species from external attack by bulky substituents, the decrease in reactivity by complexation with metal atoms or metal-containing fragments, and the freezing and isolation in low-temperature matrices are most prominent. The observation of exceptionally reactive compounds by ultrafast spectroscopic methods or in a mass spectrometer (lately also in the perfectly isolating conditions of interstellar space) has the disadvantage for the preparative chemist that no directly (that is, with the naked eye) visible quantities of the substance are produced. But the "chemical" techniques also have disadvantages: they can alter the properties of the object of observation drastically. Furthermore, the most powerful spectroscopic method of chemistry, NMR spectroscopy, is of limited value only, and sometimes not even applicable under the stabilizing conditions mentioned above.

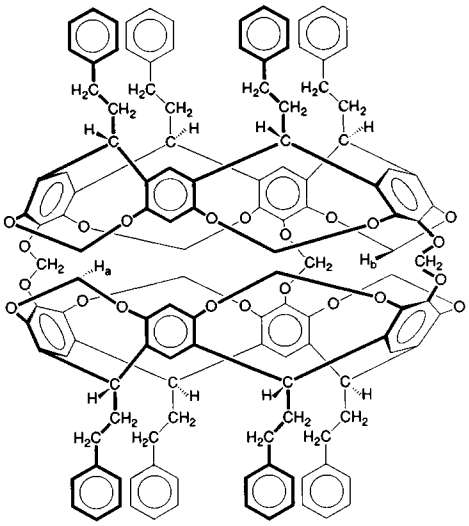
There is probably no other molecule in organic chemistry that has been so thoroughly and successfully studied by the described stabilization methods than cyclobutadiene (**1**), a key compound besides benzene for testing all criteria and theories of aromaticity. A few years ago this led to the opinion of a leading researcher in this field that this chapter in organic chemistry could be closed, as "it is now secured textbook material".[1]

1

D. J. Cram, M. E. Tanner, and *R. Thomas* of the University of California in Los Angeles did not follow this advice and turned their attention to a long-known cyclobutadiene-forming process. They studied, *within* a cage molecule, the hemicarcerand **4**,[2] the photoisomerization/fragmentation of α-pyrone (**2**), originally proposed by *Corey* and studied by several research groups, which affords cyclobutadiene via the bicycle **3**.



2 **3**



4

On irradiation of the **2** · **4** complex (formed from its components on boiling at reflux in chlorobenzene) in $CDCl_3$ or $(CD_2)_4O$ with light from a xenon lamp at room temperature in an NMR tube, a sharp new singlet is immediately observed in the 500 MHz ^1H NMR spectrum. This signal must be assigned to the complex between **1** and the host molecule **4**. The protons of the ligand which point inwards, H_a and H_b, also give rise to a sharp signal (doublet) in the ^1H NMR spectrum, which is interpreted as a clear indication of the singlet state of the **1** · **4** complex. A triplet state for **1** would cause drastically broadened and also shifted host signals, as for instance, a comparison with the (triplet) oxygen complex of **4** shows. Furthermore, the sharpness of these carcerand

[*] Prof. Dr. H. Hopf
Institut für Organische Chemie der Technischen Universität
Hagenring 30, W-3300 Braunschweig (FRG)

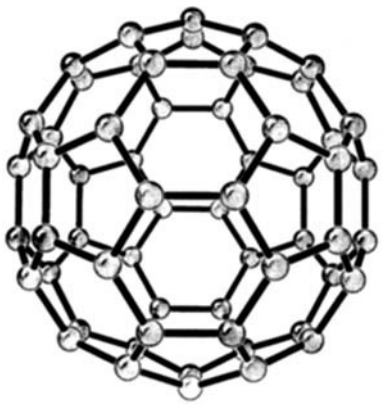
signals suggests that the cyclobutadiene guest is rapidly rotating in its cage and that the carbon dioxide that is also formed must have escaped its jail, which is too small for two inmates.

The mechanism of the formation of cyclobutadiene under these conditions of "complexation" and the subsequent chemistry of **1** was also studied. Among the interesting results is the observation that encapsulated **1** breaks down to acetylene on further irradiation, as does **1** prepared in an argon matrix at 8 K. Besides the ^{1}H NMR spectrum—unfortunately the authors have not yet reported further NMR studies such as the ^{13}C NMR spectrum and coupling constants—the FTIR spectra of the guest–host precursors **2** · **4** and **3** · **4** and finally the **1** · **2** complex were recorded.

Cram's paper is refreshingly "chemical": **1** reacts further by cyclobutadiene dimerization/valence tautomerization to afford cyclooctatetrene, which is (also) identified by its typical smell, and the scission product, acetylene, precipitates as copper salt. The question still remains unanswered how the exciting light penetrates the prison and reaches α-pyrone (**2**). The aryl substituents perhaps serve as photosensitizers.

At the end of this elegant paper, *Cram* presents a thought that will surely provoke exciting and possibly even controversial discussion. In his opinion the "inner phase" of carcerands and hemicarcerands form a new form of material or state of aggregation ("a new phase of matter"). In contrast to the hollow space inside clathrates and zeolites, for instance, the cages of these molecules are independent of the form and physical state: Hemicarcerands and related supramolecular systems and their complexes ("hemicarceplexes") exist in the solid, liquid, or gas phase. The characteristic peculiar to them—the hollow space, the inside surface—is maintained across all phase transitions. In other words, the inner surfaces and spaces of these systems are not bulk properties.

A second molecular container which was discussed from the beginning as a potential trap for a molecule, or at least an atom, is C_{60} fullerene (**5**). Already in their pioneer experiments (the simultaneous laser evaporation of salt/graphite mixtures), *Smalley* et al. maintained that they had obtained $C_x \cdot M$ clusters ($x \geq 60$, M = La, Cu, Ba, Sr) where the metal atoms were bound to the inside of the molecule. This interpretation was criticized by *Kaldor* et al. in whose opinion the metal ion of $C_{60} \cdot La$ is coordinated to the outer surface. As metal complexes of C_{60} fullerene (**5**) with externally bound metal atoms have since been found (structural evidence from X-ray crystallography!), *Kaldor*'s proposal has indeed some substance.



5

After the Krätschmer–Huffman method provided a convenient method of preparing macroscopic quantities of C_{60} (**5**) and C_{70}, the search for an "endohedral" chemistry of the fullerenes could be resumed. Now, the inclusion of helium atoms in $C_{60}^{\bullet\oplus}$ and $C_{70}^{\bullet\oplus}$ fullerene within a mass spectrometer, on collision of the preselected fullerene ions with a "stationary" noble gas, has been reported by four research groups in a common paper [*H. Schwarz* and *T. Weiske* (Technische Universität, Berlin), *K. Böhme* (York University, Ontario), *J. Hrušák* (Czechoslovakian Academy of Science, Prague) and *W. Krätschmer* (Max-Planck-Institut für Kernphysik, Heidelberg)].[3]

In a specialized tandem mass spectrometer accerelerated $C_x^{\bullet\oplus}$ ions were "stopped" by the collision gases H_2, D_2, Ar, and SF_6. In all cases the pattern obtained corresponded to the fragmentation of the $C_{60}^{\bullet\oplus}$ ion by expulsion of C_2, C_4, C_6, and C_8 units. A completely different pattern was recorded when helium was the collision partner. Under these conditions C_n fragments were also split off, but all signals showed an additional neighboring peak at higher mass (+ 4 for ^{4}He and + 3 for ^{3}He). This surprising observation at first said nothing about the site of coordination of the noble gas atom. Complexes with an exohedrally coordinated helium atom would probably give a similar fragmentation pattern.

Why then did the authors favor the inclusion structure? First, the $C_{70}^{\bullet\oplus}$ ion (which otherwise behaves similarly to **5** with the other collision gases) contains the fragment $C_{60}^{\bullet\oplus}$/He among others in the collision experiment with helium. That an externally bound helium atom can remain "glued" to the surface during this extreme fragmentation/cage repair process stretches the imagination—especially since ab initio MO calculations on model compounds without inside/outside discrimination (e.g. benzene) predict He bonding energies of ca. 0.2 eV, while for the process $C_{60}^{\bullet\oplus} \rightarrow C_{58}^{\bullet\oplus} + C_2$, for instance, at least 4–5 eV is required. The exohedral helium atom must therefore have long since disappeared before the C_n fragmentation begins—a direct contradiction of the experiment.

In the meantime collision experiments show that neon can also be captured by $C_{60}^{\bullet\oplus}$, but with a much reduced yield than in the case of the smaller helium.

The development of fullerene chemistry began on a "nonmeasurable" scale in outer space or within the mass spectrometer: only when visible quantities were obtained could one speak of a preparative breakthrough. Perhaps such a development will be repeated for endohedrally coordinated fullerene derivatives, now that the first atoms have been successfully enclosed within this molecular container.

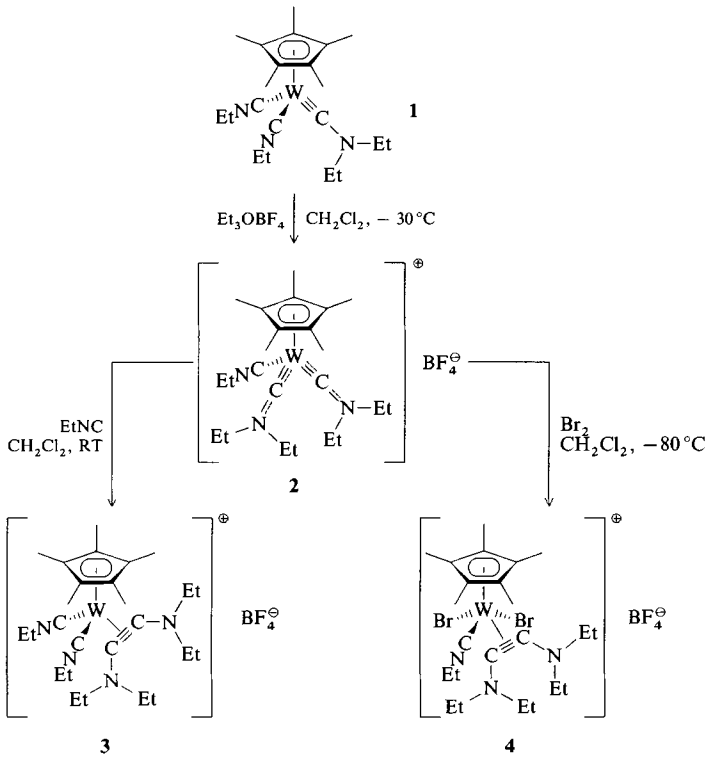
Designed Coupling of C_1 Ligands: Organometallic Model Reactions

By *Helmut G. Alt**

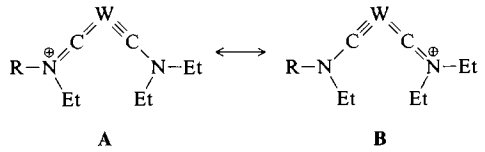
Carbon to carbon coupling is the most important step for the manufacture of organic fine and industrial chemicals. Metallic compounds, mostly catalysts, play an indispensible role in this process. Yet there is still a long way to go to understand the mechanism of metal-centered coupling of C_1 units such as in the Fischer–Tropsch synthesis. Now in this issue *Filippou* et al.[1] of the Technische Universität München reports astounding progress in this fundamentally important field. He not only achieved the planned synthesis of mononuclear bis(carbyne) metal complexes (**2**), but also the $C_1 + C_1$ coupling of the carbyne ligands to form an alkyne ligand (**2** → **3**/**4**, see Scheme 1).



Scheme 1. Synthesis of the bis(carbyne) complex **2** by alkylation of **1** with Meerwein's reagent and $C_1 + C_1$ coupling in the ligand sphere of **2** to afford **3** and **4**.

How can two metal–carbon multiple bonds be opened simultaneously under mild conditions when thereby an electron deficiency arises at the metal center? *Filippou*'s concept is based on extended Hückel calculations, which predict that the coupling of two carbyne ligands is symmetry-allowed at a d^4 metal center and should proceed spontaneously, whereas a stabilization of the bis(carbyne) complexes is attained when the carbyne carbon atom is attached to π-donor substituents.[1–3] Exactly this is the case in *Filippou*'s complex: the limiting resonance formulas **A** and **B**, for which spectroscopic evidence exists,[1,4–6] show that in such bis(carbyne) complexes a "partially reduced" metal–carbon multiple bond is present.

The alkyne that results from the coupling reaction functions as a four-electron ligand, and the metal center thus must accommodate a deficit of only two electrons, which can be compensated by the entering isonitrile ligand or by the two bromine ligands.



This classic coupling reaction was not coincidental, but the result of a well-planned strategy: previously *Filippou* et al. had assigned a key role to the ynamines in the acid-induced C–C coupling of carbyne and isocyanide ligands and to bis(carbyne) complexes in the reductive C–C coupling of two isocyanide ligands to yield ynediamines.[7]

In the light of *Filippou*'s findings,[1] it is logical to postulate the existence of bis(carbyne) intermediates for other metal-centered coupling reactions of C_1 units[8,9] as well, such as in the coupling of two carbonyl ligands to form bis(siloxy)acetylenes.[10] The exemplary results described here suggest a series of prospects: The designed construction of unsaturated C_2 ligands not capable of existence in unbound form opens new possibilities for the metal-centered synthesis of heterocycles. Furthermore, the transfer of this concept to transition-metal centers with other electron configurations gives a positive outlook for the directed cleavage of alkynes into unsaturated, metal-fixed C_1 fragments. The first successes have already been recorded.[7d]

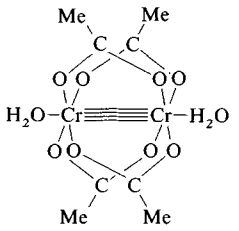
New Discoveries in the Realm of Metal–Metal Multiple Bonds: $[\eta^5\text{-}C_5Me_5)_2Co_2]$, the First Organometallic Multiple-Bond Complex without Bridging Ligands

By *Joachim Wachter**

Every advanced chemistry student should be clearly aware of the significance of the following experiment, which is relatively easy to perform, provided that it is carried out under inert gas atmosphere: If a light blue aqueous Cr^{II} solution is allowed to react with sodium acetate, red crystals of Cr^{II} acetate precipitate out. However, the path leading from the first synthesis of this compound in 1844 by *E. Peligot*[1] to the correct interpretation of its structure[2] (dimeric, extremely short Cr–Cr bonds) has been long. Only X-ray structure analysis was capable of revealing that the M–M distances in such compounds are much shorter than those in the corresponding metals. Hence, defined multiple-bond orders (2 for $[Re_3Cl_{12}]^{3\ominus}$[3] and 4 for $[Re_2Cl_8]^{2\ominus}$[4]) were first formulated in 1964.

Further examples were reported soon thereafter and led, in turn, to theoretical investigations and interpretations (for example, the involvement of d orbitals in the bonding system). An almost immediate consequence was the distinction between bridged and nonbridged systems, as exemplified by the two historical protagonists **1** and **2**, respectively.

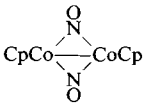


1

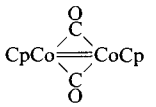
2

The significance of this classification only becomes clear when the chemistry of transition-metal carbonyl complexes and their derivatives is examined. It is immediately apparent that "... even today no unequivocal case of multiple M–M bonding (i.e., a bond without bridges) has ever been found in a metal carbonyl type system..."[5] This statement, made in 1982 by the grand master of the M–M bond, *F. A. Cotton*, is still valid today.

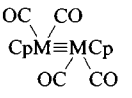
Numerous examples of double- and triple-bond systems involving π-acceptor ligands are known for elements of groups 3–8 of the periodic table. Although the diverse reactivity of these complexes has attracted much interest, the determination of defined bond orders has proven to be very problematic. For example, the distances in complexes **3** and **4** are equal despite differing bond orders.[6] Thus, bridging ligands complicate the matter. Similar relationships are found in the important class of compounds $[Cp_2M_2(CO)_4]$ (**5**; M = Cr, Mo, W).[7] On the basis of the 18-electron rule and the experimentally found M–M distances, an M–M triple bond has been postulated for these d^5–d^5 systems. In order to understand the overall system, however, it is necessary to consider the electronic situation of the CO bridges (σ + π bond, referred to as semi-bridging) and even that of the Cp ligands.



3



4

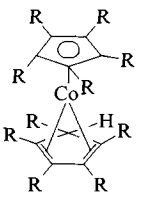


5

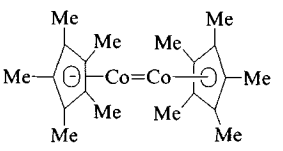
But how does one synthesize organometallic multiple-bond systems without bridging ligands? The answer, recently found by *J. J. Schneider* et al.,[9] is to cocondense a potential π ligand with cobalt atoms in a metal vaporization reactor. *G. A. Ozin* et al. have already had a similar idea, namely, the addition of naked metal atoms to benzene-derived ligands with the formation of bis(arene)metal complexes, but they were unable to isolate weighable amounts of a corresponding substance.[10]

Since the synthesis of dibenzenechromium from chromium vapor and benzene by *P. L. Timms* in 1969,[11] the cocondensation method has been continually developed in order to obtain organotransition-metal complexes.[12] For instance, the cocondensation of metal vapors with a wide range of substituted cyclopentadienes has usually afforded metallocene hydrides of the type $[Cp_2MoH_2]$ or $[Cp_2ReH]$.[13] Cobalt atoms, on the other hand, react with unsubstituted cyclopentadiene to give the mononuclear compound $[(\eta^5\text{-}C_5H_5)(\eta^4\text{-}C_5H_6)Co]$ (**6a**) as the sole isolable product.[14]

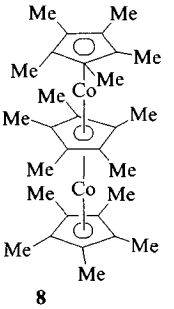
The decisive turn of events leading to a binuclear cobalt complex, as reported by *Schneider* et al., was brought about by increasing the proportion of metal to about 33% and using pentamethylcyclopentadiene (Cp*H). In this way, complex **7**, the first nonbridged organometallic multiple-bond complex, was obtained in 5–15% yield. At the same time, the permethylated sandwich complex **6b**, analogous to **6a**, and the complex **8** were formed; **8** is only the fifth structurally characterized homoleptic triple-decker complex and is thus a noteworthy rarity.



R = H: **6a**
R = Me: **6b**



7

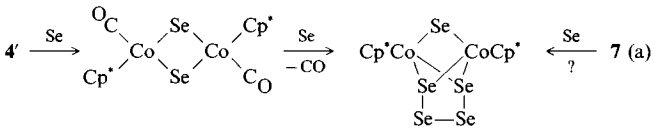


8

[*] Dr. J. Wachter
Institut für Anorganische Chemie der Universität
W-8400 Regensburg (FRG)

The structure of **7** is characterized by two parallel Cp* rings; the distance between the two Co atoms (2.253(1) Å) is 0.08 Å shorter than in $[Cp^*_2Co_2(\mu\text{-}CO)_2]$.[15] This finding and the effective atomic number (EAN) rule indicate the presence of a nonbridged M–M double bond, for which, on the whole, only one example has been established.[16] The relationship to **4** merely involves the addition of two CO bridges. These conclusions are contradicted, however, by the ^1H NMR spectrum of **7** ($\delta = 61.3$), which supports a marked paramagnetic component. Clearly, theoretical chemists have much to look into here! Similarly, a certain resistance of **7** toward C_2H_4 and Co (at least under the normal conditions used so far) seems not to support the presence of a Co–Co double bond.

The question now is whether relationships to the reactivity of **4'**, the pentamethylated derivative of **4**, can be established. A salient feature of ligand-bridged multiple-bond complexes



is that, usually, they readily undergo addition reactions involving opening of the bridge and only afterwards do they undergo substitution reactions [Eq. (a)]; the analogous transformation could occur directly from **7**, starting with addition.[17]

The prospect of being able to investigate the bonding and reactivity of nonbridged organometallic multiple-bond systems is why the successful synthesis of **7** is so significant. A sure goal will be to extend the preparation to other transition metals.

Novel Building Blocks for the Synthesis of Organic Metals

By *Volker Enkelmann**

Organic crystals with special electrical, optical or magnetic properties are attracting increasing interest as "unconventional materials".[1] The special properties alluded to are not determined alone by the electronic structure of the individual molecule, but are only manifested upon interaction of many molecules in the solid state. It therefore does not suffice just to master the synthesis of suitable building blocks, an important step is obtaining the desired interactions in certain crystal structures. This has led to interest being always concentrated on a few model systems in which all steps, from the synthesis of the starting components up to and including reproducible crystallization, have been perfected.

High electrical conductivities in organic metals are, independently of the nature of the building blocks, always associated with certain structural principles. The crystal structure of the long known charge transfer (CT)-salt TTF/TCNQ (TTF = tetrathiafulvalene, TCNQ = tetracyanoquinodimethane, Fig. 1)[2] exhibits the most important features:[3] 1) crystallization of donor and acceptor molecules in segregated stacks with 2) uniform interstack distances; 3) formation of mixed valence states, i.e. only partial charge transfer between the stacks of the redox partners. The charge transport takes place along the stacks, whereby in TFF/TCNQ the two stacks contribute to the total conductivity independently of each other.

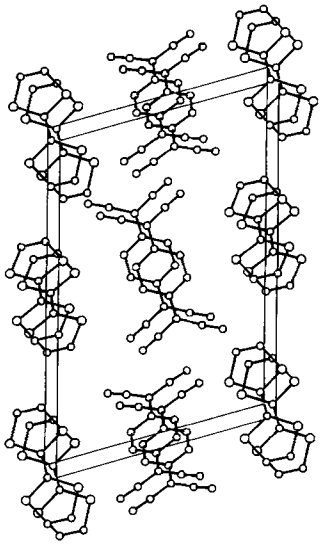

Fig. 1. Section of the crystal structure of TTF/TCNQ along the stack direction.

One could imagine that, by simple combination of many different electron donors and acceptors, a sort of building-block kit would be available with which one could construct almost any desired organic metal having tailor-made properties. Unfortunately this expectation is deceptive. In CT complexes of the type TTF/TCNQ, the redox potentials of the two partners must be carefully harmonized so as to guarantee the required partial charge exchange. In addition, there is the problem that the desired structures are not obtained during the crystallization step following the redox reaction. In many cases mixed stacks are formed in which donor and acceptor molecules interchange. These difficulties can be partly overcome if one of the two redox partners is replaced by stable counterions with formation of radical ion salts. However, crystal engineering, i.e. the selective growth of crystals with predetermined structure, is still an unachieved ideal.

A further reason for the number of building blocks being limited lies in the interdisciplinary nature of the work, which is necessary in this field. An overview of the organic metals so far investigated in detail—TTF/TCNQ, radical cation salts of TTF and analogously built fulvalenes such as, for example, tetramethyltetraselenafulvalene (TMTSF) or bis-(ethylenedithio)tetrathiafulvalene (BEDT-TTF), radical anion salts of TCNQ, aromatic radical cation salts[1]—shows that these systems have all been investigated and optimized over a long period of time by several working groups who have contributed their expertise and knowledge from the most diverse areas of organic synthesis, crystal growth through to special methods of solid-state spectroscopy and theory.

Whereas TTF has often been modified chemically (substitution, expansion of the π system, replacement of S by Se or Te), modification of the acceptor has so far been neglected, so that TCNQ is still used almost exclusively. *Hünig* and co-workers, however, have developed some valuable new acceptors, which can give new impetus in the field of organic metals.[4, 5]

For some time now, *N,N'*-dicyanoquinodiimine (DCNQI) and its derivatives have been readily accessible by a facile, one-step synthesis.[4] Like TCNQ they are two-step, reversible redox systems of the Wurster type which form stable radical anions. On the basis of the known analogy between the $=C(CN)_2$ and $=NCN$ groups it was expected that DCNQI would behave analogously to TCNQ. This has indeed been confirmed, since CT complexes such as, e.g., TTF/DCNQI can be obtained which behave similarly to the corresponding TCNQ salts. The special significance of DCNQI compounds lies in their ability to form metal salts having unusual properties.[6–9] Whereas the TCNQ salts are semiconductors, some DCNQI salts, e.g. [(2,5-dimethyl-DCNQI)$_2$Cu], exhibit typical metallic behavior. Figure 2 shows the temperature dependence of the specific conductivity and the crystal structure of this salt. The specific conductivity, which increases steadily to values of 500000 S cm^{-1} with decreasing temperature, underscores the metallic character of this salt, which counts among the most conductive organic metals (for comparison, the specific conductivity of copper at room temperature is 650000 S cm^{-1}).

Remarkable, and apparently essential for the resulting extraordinary properties, is the tight tetrahedral coordination of the copper ions by the C≡N groups of four neighboring

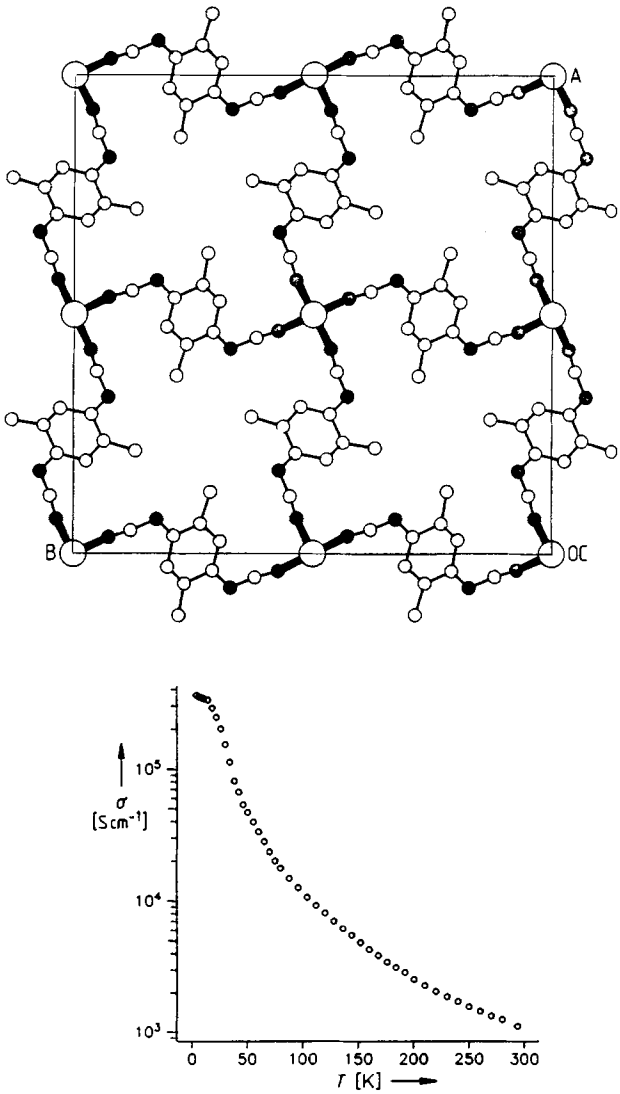

Fig. 2. Section of the crystal structure (top) and temperature dependence of the specific conductivity σ of [(2,5-DM-DCNQI)$_2$Cu] (bottom)[6].

stacks. This coupling of the DCNQI stacks increases the dimensionality and impairs Peierls transitions, which usually lead to semiconducting low-temperature phases in one-dimensional systems. Similar couplings by sulfur–sulfur interactions between one-dimensional molecular stacks are observed in many salts of TTF derivatives which form superconducting low-temperature phases. The particular importance of the DCNQI salts lies in the fact that the strength of the coupling can be varied by suitable choice of the counterion. When Cu is replaced by other metals isomorphic structures are obtained in which the C≡N···M distance increases in the sequence $Ag^{\oplus}$, $Tl^{\oplus}$, $Li^{\oplus}$. The conductivity decreases with decreasing coupling strength, and the transition temperature to superconducting low-temperature phases increases in the same sequence. The metal salts of DCNQI thus constitute ideal building blocks with which one can, within certain limits, selectively change macroscopic properties such as the conductivity, by suitable choice of molecular parameters (counterion, substitution).

Recently *Hünig* and co-workers have even gone one step further. TCNQ and DCNQI are acceptors of the Wurster type, whereas by means of a simple method for the synthesis of dicyanoazobenzenes (DCNABs) we now have access to acceptors of the inverse Wurster type (aromatic ground state and quinonoid oxidized form). Preliminary results obtained with CT complexes and salts of this new class of acceptors have shown that they have redox potentials similar to TCNQ and DCNQI and thus form radical anions of comparable stability. Moreover, they do not differ substantially from the well-known acceptors in their ability to form metal salts and conductive CT complexes.[10, 11] As an example, the crystal structure of 2,5-dimethyl-DCNAB/TFF is shown in Figure 3.

How are we to assess this new development? Since the concepts underlying the makeup of an organic metal have long been known, one cannot foresee any fundamentally new insights being gained in this area. It must be remembered, however, that the structural principles outlined here have been derived empirically from the common characteristics of many organic metals and are therefore of rather a qualitative nature. The new acceptors now readily accessible through the works of *Hünig* et al. improve the available set of building blocks considerably, and, within certain limits, make possible the fine tuning of molecular interactions by suitable choice of components. So there is hope that in the near future one will be able to make virtually quantitative predictions. The problems which could be solved with the help of new model structures include, in particular, the quantitative description of such macroscopic properties as the temperature dependence of specific conductivity and phase behavior (transition to semiconducting or superconducting low-temperature phases) on the basis of molecular interactions along the stack and between neighboring stacks of molecules.

One of the fundamental problems, however, remains unsolvable: the prediction of the crystal structure of organic molecules and the planned assembly of structures with predetermined properties is possible only within modest limits. Even with a much greater number of possible building blocks and a greater number of empirical structural rules it will depend upon the luck and skill of the experimenter as to whether a structure with the desired properties will be obtained.

In comparison to other properties which are only realized by the interaction of many molecules in larger units, the electrical conductivity in organic crystals is relatively well understood. Investigations on these systems therefore constitute ideal excercises for ambitious aims which are summarized under the concept molecular electronics. Here, one hopes that molecules which act as switches, energy transport media (molecular wires), logic units or storage systems can be used to construct larger functional units and actively participate in the processing, transmitting, and storage of information. The developments outlined here hint at the course that will have to be taken in the case of more complicated systems: 1) developing an improved building-block kit of suitable molecules; 2) synthesis of the simplest possible, well characterized models, e.g. single crystals; 3) empirical determination of structure-property relationships; 4) extension of these model concepts to the construction of more complicated structures.

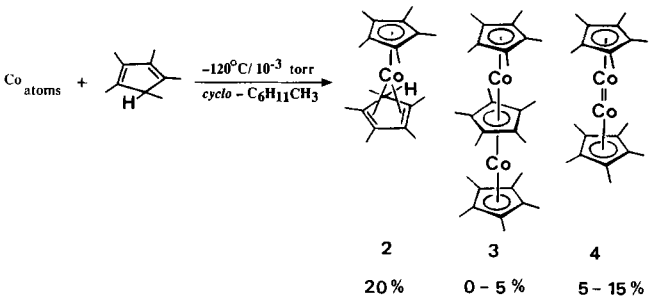
Reactivity of Cobalt Atoms towards 1,2,3,4,5-Pentamethylcyclopentadienyl: Synthesis and Structure of Bis(η^5-pentamethylcyclopentadienyl)-(μ_2-η^5:η^5-pentamethylcyclopentadienyl)dicobalt and Bis(η^5-pentamethylcyclopentadienyl)dicobalt **

By *Jörg J. Schneider,* Richard Goddard, Stefan Werner,* and *Carl Krüger*

Dedicated to Professor Kurt Schaffner

A directed synthesis of clusters with the help of "naked" metal atoms has so far only succeeded in a limited number of cases;[1] as a rule, clusters are formed only as by-products in metal atom reactions.[2] If cluster formation does not take place at all, this can be due to an unfavorable choice of stoichiometric ratios, temperature, or other more difficultly controllable reaction conditions (e.g. metal evaporation rate) during the metal atom reaction. We have now investigated the reaction of cobalt atoms with 1,2,3,4,5-pentamethylcyclopentadiene (Cp*H). Cp*H appeared to us to be especially suitable as ligand because of its unusual electronic properties and of the frequently excellent crystallization behavior of the resulting complexes.[3] Thereby we obtained, inter alia, a triple-decker complex and a novel Cp*Co dimer with an unusually short Co–Co bond. In the reaction of cobalt atoms with the unsubstituted ligand cyclopentadiene (CpH) only the sandwich complex (η^5-cyclopentadienyl)-(η^4-cyclopentadiene)cobalt **1** was formed.[4] As we have already been able to show in the case of reactions of nickel atoms with mono- and disubstituted cyclopentadienes, by skillful choice of the reaction conditions, not only the formation of mononuclear metal complexes but also the synthesis of clusters can be achieved.[5] We have now found that if cobalt atoms are allowed to react with Cp*H under comparable conditions, i.e. in a ligand/metal ratio of ca. 2:1 to 4:1, then, after column chromatographic work-up and subsequent crystallization of the crude product, the three cobalt complexes **2**, **3** and **4** can be isolated (Scheme 1). **2** is the permethylated 18-VE Co^I-sandwich complex analogous to **1**, and under the chosen conditions (ratio Cp^*H/Co_{atoms} ca. 3:1, $T = -120\,^\circ C$) is the main product (20%) of the reaction. **2** is characterized unequivocally by the spectroscopic data and the elemental analysis; the complexes **3** and **4** co-crystallize in varying yields (**3**: 0–5%, **4**: 5–15%) (see *Experimental*). So far, it has only been possible to isolate analytically pure **4** by repeated recrystallization. Despite careful crystallization from saturated hexane solutions we have always obtained single crystals of **3** grown in admixture with **4** which could only be separated by hand. Both compounds are deep black and are readily soluble in all the common solvents. **3** and **4** are more air-sensitive in solution than in the solid state. Crystals of **3** and **4** are stable for more than three months.



Scheme 1. Synthesis of **2**, **3** and **4** by metal atom reaction.

The molecular structure of **3** was elucidated by a crystal structure analysis[6] (Fig. 1). The disorder in the crystal structure of **3**, however, allows no detailed discussion of the individual bond lengths and angles. The Co atoms and the centroids of the Cp* rings are linear. The distance from the

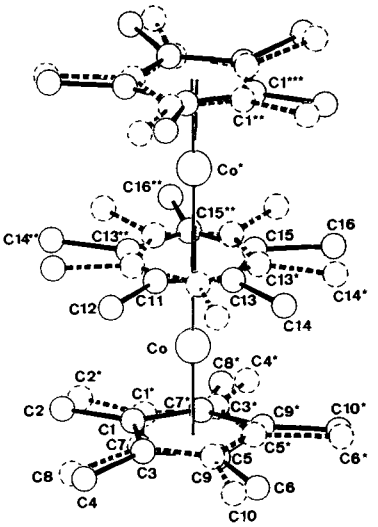


Fig. 1. Structure of **3** in the crystal. Important bond lengths, see text. The disorder is generated by the space group symmetry (2/*m*).

Co atom to the central Cp* ring is 1.770(2) Å, to the outer 1.724(1) Å. The Co–Co* distance is 3.539(1) Å, a direct metal–metal interaction can thus be ruled out. The compound is a further example of the previous group of structurally characterized homoleptic triple-decker complexes comprising only four complexes: the triple-decker cation $Cp_3Ni_2^{\oplus}$ **5** synthesized by *Werner* and *Salzer*,[7] the vanadium complex bis(η^5-cyclopentadienyl)(μ_2-η^6:η^6-benzene)divanadium **6** re-

[**] Metal Atoms in the Synthesis of Metal Clusters, Part 4. *J. J. S.* thanks Prof. *Dr. G. Wilke* for supporting this work.—Part 3: J. J. Schneider, M. Nolte, C. Krüger, *J. Organomet. Chem. 403* (1991) C4.

ported by *Jonas* et al.,[8] the complex bis(η^6-mesitylene)-(μ_2-η^6:η^6-mesitylene)dichromium **7** recently prepared by *Lamanna* et al., likewise by a metal atom reaction,[9] and the triple-decker cation $Cp^*_3Ru_2^{\oplus}$ **8** synthesized by *Rybinskaya* et al.[10] In contrast to **5**, **7** and **8**, each of which fulfill the 30/34 valence electron (VE) rule of *Lauher* and *Hoffmann* for triple-decker complexes[11] (**5**: 34 VE; **7**, **8**: 30 VE), complex **3** with formally 33 VE—like **6** (26 VE)—is an exception to this rule. Accordingly, different paramagnetically induced shifts δ_{para} are observed in the ^{1}H-NMR spectrum for **3**. Thus, the signals for the two terminal Cp* rings are shifted downfield, whereas that for the bridging Cp* ring is shifted upfield relative to the solvent signal. This can be attributed to different spin transfer mechanisms. Surprisingly, **4** also exhibits paramagnetism in the ^{1}H-NMR spectrum. The presence of a triplet state is possibly an explanation for this observation. EPR investigations and calculations should prove informative here.[12] As expected a singlet ($\delta_{para} = 61$) is found for both Cp* rings. Preliminary investigations of the behavior of **4** on varying the temperature reveal a linear dependence between δ_{para} and the reciprocal temperature $1/T$.

Compound **4** is without precedence, as confirmed by a crystal structure analysis (Fig. 2).[6] A striking feature is the

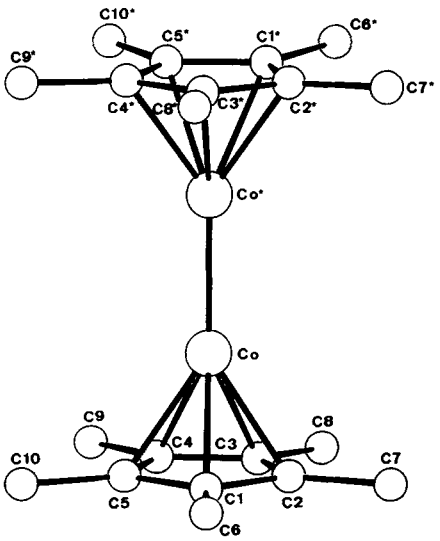

Fig. 2. Structure of **4** in the crystal. Important bond lengths, see text.

dumbbell-like, exactly linear arrangement of the two Cp*Co units. The Co—Co bond vector is perpendicular to a crystallographic twofold axis of rotation. The centroids of the Cp* rings are 1.689(1) Å distant from the Co atoms, while the corresponding distance in the triple-decker complex **3** is 1.724(1) Å. A possibly stronger interaction between the Cp* ligand and the Co atom in **4**, however, does not influence the arrangement of the methyl groups on the five-membered ring; the C atoms of the methyl groups lie approximately in the plane of the five-membered ring. The Co—Co bond length (2.253(1) Å) corresponds formally to a double bond, resulting in a 16 VE shell for each metal center in **4**. Other known compounds of similar structure contain either additional bridging ligands, in some cases resulting in a bending of the terminal rings,[13] or they exhibit far greater metal–metal distances, which then, despite additional bridging, still enable a linear arrangement of the metal-ligand units.[14]

According to preliminary investigations, **4** does not react with ethylene or even CO (1 bar, room temperature); it is recovered unchanged from the reaction mixture. We attribute the formation of the triple-decker complex **3** and the dimer **4** to the comparatively high metal atom concentrations in comparison to those usually used in metal atom reactions.[15] As the reaction progresses the reaction solution becomes largely depleted of the free ligand Cp*H, since this is consumed for the formation of **2** and Cp*Co units.[16] These Cp*Co units can then dimerize to **4** when present in sufficient concentration in the reaction solution. On the basis of matrix isolation experiments *Ozin* and *Andrews* already postulated a type of complex analogous to **4**[17] which should be formed upon addition of naked metal atoms to bis(arene)metal complexes.

The reaction of highly reactive Cp*Co units with the **2** already formed leads via cleavage of hydrogen to formation of **3**. Also conceivable, however, would be a reaction of Cp*Co units with previously formed decamethylcobaltocene leading to formation of **3**, similarly to the formation of **7** from mesitylene and chromium atoms.[18] By optimization of the reaction conditions (temperature, metal atom/ligand ratio, metal vaporization rate, etc) we hope to increase the yields of **3** and **4** in order to make these complexes accessible in larger amounts and with a view to possibly interesting secondary reactions.

Experimental

Cobalt metal (3 g, 50.9 mmol) was evaporated into 150 mL of a 5% solution of Cp*H in methylcyclohexane cooled to -120 °C by using a rotating metal vaporization reactor[19] (80 rpm). On completion of reaction a brownish-black solution had formed. This was siphoned out of the reactor, filtered, and the brownish-black filtrate evaporated down in a high vacuum. The oily residue was taken up in a little THF, treated with 20 g of Al_2O_3 (5% H_2O) and dried until flowable.

Chromatography on Al_2O_3 (5% H_2O) with pentane furnished, after subsequent crystallization, 3.3 g (10 mmol) of **2** (red crystals, -30 °C, ethanol/pentane); further elution with pentane/ether (1 : 1) afforded **3** and **4** as black zone (yield 2.5 g, black crystals, -20 °C, hexane).

2: ^{1}H NMR ([D$_8$]toluene, 200 MHz): $\delta = 1.62$ (s, 15H; CH_3), 0.38 (d, ^3J(H,H) = 6.1 Hz, 3H; CH_3), 0.92 (s, 6H; CH_3), 1.81 (s, 6H; CH_3), 2.15 (q, ^4J(H,H) = 0.3 Hz; 1H); ^{13}C NMR [D$_6$]benzene, 75.5 MHz): $\delta = 9.3$ (q, ^1J(C,H) = 125 Hz; CH_3(Cp*)), 10.6 (q, ^1J(C,H) = 124 Hz; CH_3), 11.8 (q, ^1J(C,H) = 124 Hz; CH_3), 19.3 (q, ^1J(C,H) = 125 Hz; CH), 54.4 (s, C_{diene}), 55.7 (d, ^1J(C,H) = 135 Hz; C_{sp^3}), 85.1 (s, C_{diene}), 87.6 (s, Cp* (C_{sp^2}), MS (70 eV): *m/z* 330 ($M^{\oplus}$, 10%), 315 ($M^{\oplus}$-CH_3, 100). Correct C, H, Co-analysis.

3: ^{1}H NMR ([D$_8$]) toluene, 200 MHz, 30 °C): $\delta = 38.8$ (s, 30H; CH_3), -41.0 (s, 15H; CH_3(μ-Cp*)), MS (70 eV): *m/z* 523 ($M^{\oplus}$, 21%), 329 ($M^{\oplus}$-Cp*-Co, 100).

4: ^{1}H NMR ([D$_8$])toluene, 200 MHz, 30 °C): $\delta = 61.3$ (s, br; CH_3), MS: decomposition. Correct C, H, Coanalysis.

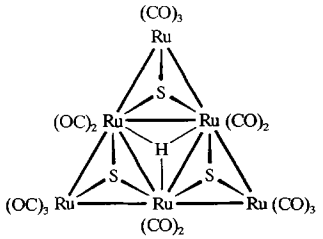
The Cluster Anion $[Ru_6H(CO)_{15}S_3]^-$: A Planar Hexanuclear Metal Framework with Almost Perfect C_{3v} Symmetry

By *Ulf Bodensieck, Helen Stoeckli-Evans,* and *Georg Süss-Fink**

The structure analysis of the osmium complex $[Os_6(CO)_{17}\{P(OMe)_3\}_4]$ by *Lewis* et al.[1] showed that a hexanuclear cluster framework can be planar. Although several such "raft" clusters have been synthesized since then, the planar arrangement of the metal atoms in a hexanuclear cluster is more the exception than the rule.[2]

In an attempt to extend the activation of C_{sp^3}–H bonds observed in the rutheniumcarbonyl–alkylthiourea system[3] to methane, we were surprised to obtain the new cluster anion $[Ru_6H(CO)_{15}S_3]^-$ (**1**), which contains an approximately planar hexanuclear ruthenium skeleton with C_{3v} symmetry. Anion **1**, which has three outer Ru_3S tetrahedrons enclosing an inner Ru_3H tetrahedron, captures the imagination by the aesthetics of its molecular architecture.



1

It is unclear how the cluster anion **1** arises on treatment of $[Ru_3(CO)_{12}]$ with tetramethylthiourea in an inert atmosphere (60 bar methane or nitrogen) in THF solution at 150 °C; during workup of the reaction mixture it precipitates as the tetramethylformamidinium salt from dichloromethane. It does not form under ambient pressure.

The single-crystal X-ray structure analysis of **1**[4] (Fig. 1) shows the almost planar metal framework in the form of a large triangle comprising four small triangles. The outer three small triangles are each capped by a μ_3-sulfido ligand, while the inner Ru_3 triangle is capped on the opposite side of the plane to the sulfido ligands by a μ_3-hydrido ligand. The ruthenium atoms Ru1, Ru3, and Ru5, situated at the corners of the large triangle, lie on average 0.55 Å out of the plane defined by Ru2, Ru4, and Ru6, on the side of the sulfido ligands.

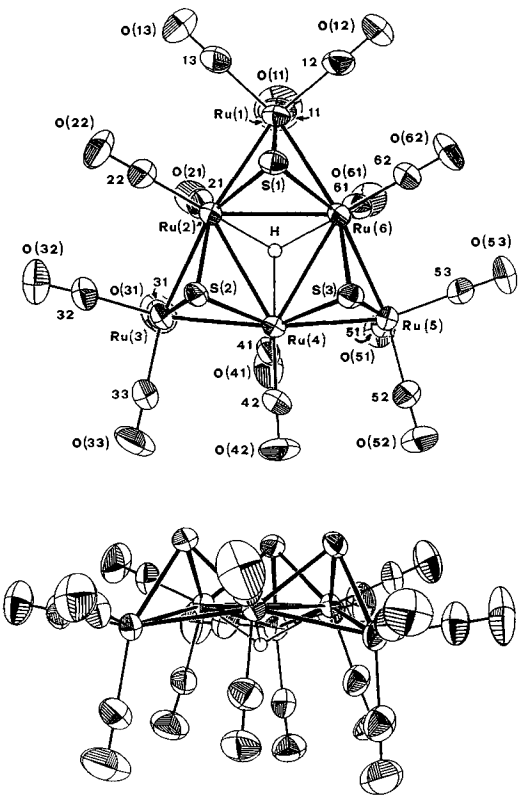


Fig. 1. View from above (top) and from the side (bottom) of the cluster anion $[Ru_6H(CO)_{15}S_3]^-$ (**1**) (ORTEP, 50% probability ellipsoids, C atoms of CO ligands are indicated by numbers only). Important atomic distances [Å] and angles [°]: Ru(1)-Ru(2) 2.779(1), Ru(1)-Ru(6) 2.767(1), Ru(2)-Ru(3) 2.776(1), Ru(2)-Ru(4) 3.027(1), Ru(2)-Ru(6) 3.003(1), Ru(3)-Ru(4) 2.790(1), Ru(4)-Ru(5) 2.763(1), Ru(4)-Ru(6) 3.034(1), Ru(5)-Ru(6) 2.772(1), Ru(1)-S(1) 2.302(1), Ru(2)-S(1) 2.384(1), Ru(2)-S(2) 2.370(1), Ru(3)-S(2) 2.303(1), Ru(4)-S(2) 2.375(1), Ru(4)-S(3) 2.372(1), Ru(5)-S(3) 2.308(1), Ru(6)-S(1) 2.379(1), Ru(6)-S(3) 2.371(1); Ru(2)-Ru(1)-Ru(6) 65.58(1), Ru(1)-Ru(2)-Ru(3) 157.92(2), Ru(1)-Ru(2)-Ru(6) 57.01(1), Ru(3)-Ru(2)-Ru(4) 57.27(1), Ru(4)-Ru(2)-Ru(6) 60.41(1), Ru(2)-Ru(3)-Ru(4) 65.89(1), Ru(2)-Ru(4)-Ru(3) 56.84(2), Ru(2)-Ru(4)-Ru(6) 59.40(1), Ru(3)-Ru(4)-Ru(5) 153.32(2), Ru(5)-Ru(4)-Ru(6) 56.92(1) Ru(4)-Ru(5)-Ru(6) 66.48(2), Ru(1)-Ru(6)-Ru(2) 57.40(2), Ru(1)-Ru(6)-Ru(5) 156.63(2), Ru(2)-Ru(6)-Ru(4) 60.19(1), Ru(4)-Ru(6)-Ru(5) 56.60(1).

The unusually high-field NMR signal ($\delta = -33.36$) for the hydrido ligand indicates that it is μ_3-bridging. In contrast, the anion $[Ru_6H(CO)_{18}(OCNMe_2)_2]^-$ (**2**) synthesized by *Kaesz* et al. contains a μ_2-hydrido ligand ($\delta = -17.08$), and the hexanuclear metal framework is folded.[5] In anion

1 the distances between the ruthenium atoms which define the outer triangle are on average shorter (2.77 Å) than those of the inner triangle (3.02 Å). In the six-membered metal ring described for anion **2**, however, the Ru–Ru distances of the inner triangles (3.22 Å) are clearly longer. This is explained by only a partial transannular interaction in **2**.[5]

The hexanuclear ruthenium skeleton in **1** is stabilized by 15 CO ligands. Every Ru atom bears an axial CO ligand, while Ru2, Ru4, and Ru6 are each bonded to one and Ru1, Ru3, and Ru5 to two additional equatorial CO ligands. The three μ_3-sulfido ligands are situated on the same side of the plane of metal atoms. The μ_3-hydrido ligand must therefore lie on the other side for steric reasons, as the space-filling model shows (Fig. 2).

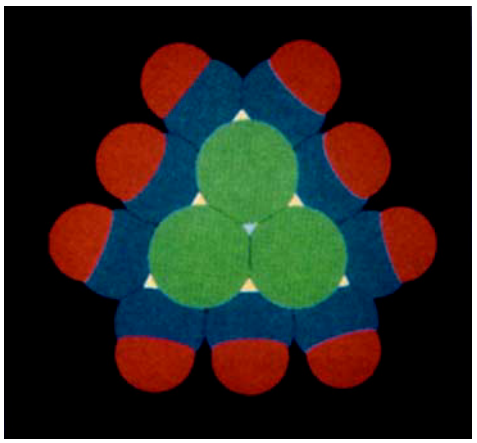

Fig. 2 SCHAKAL representation [6] of the cluster anion $[Ru_6H(CO)_{15}S_3]^-$ (**1**) (Ru yellow, S green, H gray, C blue, O red).

Experimental Procedure

All steps were performed under a N_2 atmosphere in dried, N_2-saturated solvents. $[Ru_3(CO)_{12}]$ (320 mg, 0.5 mmol) and $(Me_2N)_2CS$ (86 mg, 0.65 mmol) were dissolved in THF (20 mL) in a stainless steel autoclave (working volume 100 mL); the mixture was pressurized with methane (65 bar) and heated to 150 °C under constant stirring. After 2 h the reactor was cooled, the pressure released, and the red-brown solution evaporated to dryness. The residue was taken up in dichloromethane and anion **1** precipitated as the $[(Me_2N)_2CH]^+$ salt in the form of red-brown crystals. Yield: 38 mg (14%). IR(THF): $\tilde{\nu}$[cm^{-1}] = 2079w, 2051vs, 2001vs, 1987(sh)m, 1933vw (ν(CO)). ^{1}H NMR ($CDCl_3$, 200 MHz): δ = 8.04 (s, 1H; CH), 3.53 (s, br, 6H; Me), 3.38 (s, br, 6H; Me), − 33.36 (s, 1H; Ru_3H). Satisfactory C, H, N analyses.

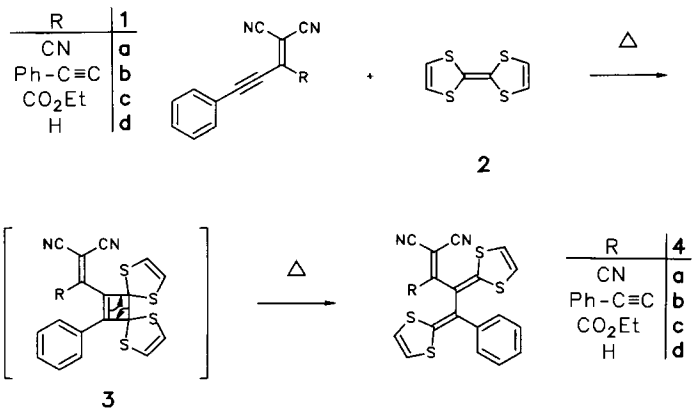
On a Metathesis Reaction of Tetrathiafulvalene (TTF)**

By *Henning Hopf*,* *Martin Kreutzer*, and *Peter George Jones**

Dedicated to Professor Horst Prinzbach on the occasion of his 60th birthday

We recently reported[1] an efficient method for the preparation of cyano(ethynyl)ethenes of type **1** and described their behavior as dienophiles in [2 + 4] cycloadditions. Because of the electron-withdrawing effect of the cyano substituents on the π-electron system, these compounds are potential acceptors for charge-transfer (CT) complexes, those with tetrathiafulvalene (**2**) and related compounds being of particular interest. Compound **2** is known to form electrically conducting "organic metals" with a large number of acceptor systems.[2, 3] We therefore allowed the enyne **1a** to react with **2**



for two days in refluxing toluene and thereby obtained highly lustrous, black-violet crystals (77%). An X-ray structure analysis showed, however, that the product was not the expected CT complex but, surprisingly, the covalent compound **4a** (Fig. 1).[4] Its structure in the crystal is character-

[**] New Planar π Systems, Part 3. This work was supported by the Fonds der Chemischen Industrie and by BASF. Part 2: H. Hopf, M. Kreutzer, P. G. Jones, *Chem. Ber. 124* (1991) 1471.

ized by an almost orthogonal arrangement of the two nearly planar halves of the molecule (mean deviation 3 pm); the dihedral angle around the central C9–C10 bond is 96.79°. The spectroscopic and analytical data are also consistent with the proposed structure.[4] This reaction, in which tetrathiafulvalene is virtually cut in two, is not an isolated case. This was shown by further experiments with the acceptors **1b–d**, which afforded the cross-conjugated compounds **4b–d** (**4b**, 77; **4c**, 47; **4d**, 33% yield;[5] not optimized).

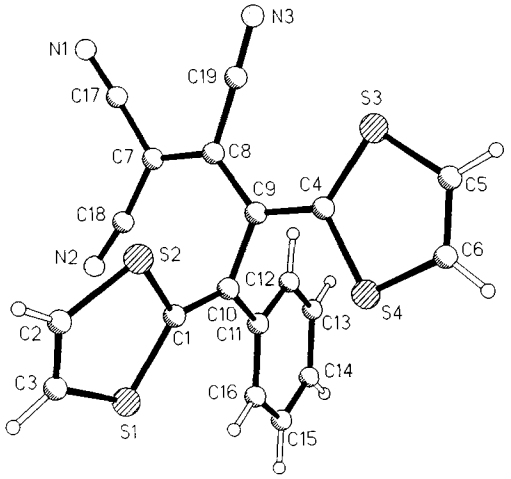

Fig. 1. Molecular structure of **4a**[9].

We assume that this reaction involves a metathesis process, which begins with the [2 + 2] cycloaddition of the triple bond of **1** to the central double bond of **2** to form the cyclobutene derivative **3**, which, in turn, is stabilized by electrocyclic ring opening to give **4**. Compounds of type **4** are not new. As early as 1970, *Hartzler* obtained adducts of type **4**, in addition to derivatives of tetrathiafulvalene, on reaction of electron-poor triple-bond dienophiles with carbon disulfide.[6] Control experiments showed, however, that the former reaction products are not transformed into the latter under the reaction conditions and that the formation of all reaction products can best be explained by the intermediacy of 1,3-dithiolium carbenes.[7] The above, simple route to **4** thus offers a new and variable approach to this class of substances. The success of the reaction is largely dependent on the structure of **1**, as is shown by addition experiments in which attempts were made in vain to add triple-bond dienophiles, such as diethyl acetylenedicarboxylate and ethyl phenylacetylenecarboxylate to **2**.

Compounds **4** are not only possible reaction partners for the preparation of novel donor/acceptor systems. The dicyanomethylene group also offers a broadly modifiable functionality.[8]

A Polymeric Tellurium Cation by Oxidation of Tellurium with Tungsten Bromides

By *Johannes Beck**

Transition-metal halides in which the metal is in a high oxidation state can oxidize tellurium to tellurium polycations. WCl_6 was used as oxidizing agent to synthesize $Te_8[WCl_6]_2$ (**1**), which contains the previously unknown $Te_8^{2\oplus}$ cation.[1] In the structure of **1**, an association of chalcogen cations was observed for the first time and the compound was formulated as the polymeric cation $[Te_n]^{n/4\oplus}$. The shortest interionic Te–Te distances in **1** (342.4 pm), however, are considerably longer than the intraionic distances of 270.4 to 299.3 pm.

A polymeric tellurium cation with largely equal Te–Te distances is present in Te_7WOBr_5 (**2**), which has now been prepared, likewise by oxidation of tellurium with tungsten halides. Reaction of seven equivalents of tellurium with one equivalent of a $WBr_5/WOBr_4$ mixture in an evacuated glass ampoule with a temperature gradient of 230 → 210 °C results in the formation of **2** as black, lustrous crystals, which are transported to the cooler end of the ampoule. This transport is made possible by the use of excess halide. Mixtures corresponding exactly to the composition Te_7WOBr_5, for example, $WOBr_4 + 5\,Te + Te_2Br$ or $WOBr_3 + 3\,Te + 2\,Te_2Br$ lead to the formation of **2** at 250 °C, though only as fine crystals; no transport is observed under these conditions. Above 300 °C, **2** decomposes to tellurium and volatile tungsten halides such as $WOBr_4$ and WO_2Br_2. When the temperature is decreased to 230 °C, **2** is formed once again. This thermal reversibility of formation and decomposition has already been observed for **1** and $Te_4[WCl_6]_2$[2] and is thus characteristic of polytellurium halotungstates.

The crystal structure analysis[3] shows that **2** is composed of one-dimensional polymeric tellurium cations, one-dimensional $[WOBr_4]_n$ chains, and free bromide ions. The poly-

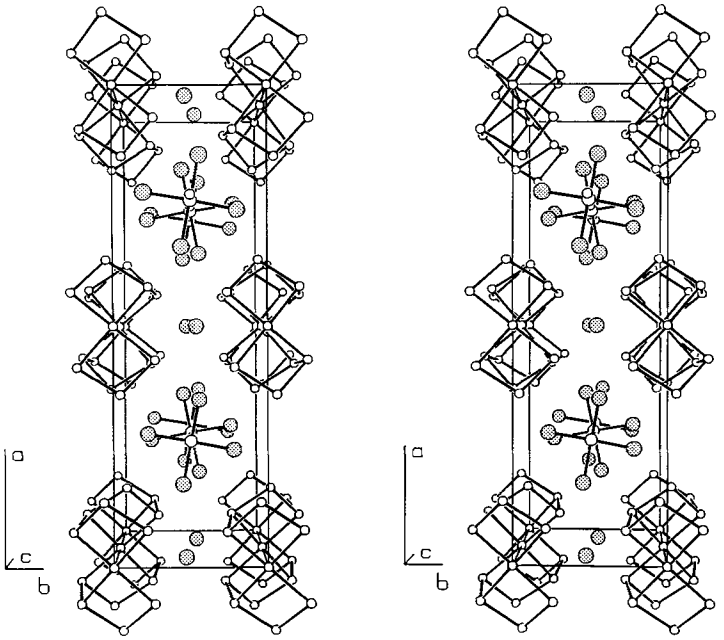

Fig. 1. Stereoscopic representation of the unit cell of **2**. Large dotted circles, Br atoms; small empty circles, Te atoms.

meric substructures extend along the crystallographic *c* axis (Fig. 1). In the $[WOBr_4]_n$ chains, square-pyramidal $WOBr_4$ monomers are present and are associated through asymmetric, linear $\cdots W{=}O \cdots W{=}O$ bridges (Fig. 2). This part of the structure is thus closely related to the structure of pure $WOBr_4$,[4] though the $WOBr_4$ groups in **2** are not arranged in an eclipsing fashion, but rather alternately twisted by 22° with respect to one another. The $[WOBr_4]_n$ substructure may be regarded either as a polymeric anion $[WOBr_4^{\ominus}]_n$ with W^V or as an uncharged chain with W^{VI}. There are thus two possi-

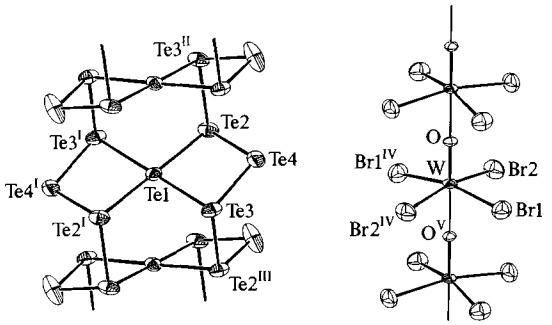

Fig. 2. Section of the polymeric chains composed of the ions $[Te_7^{2\oplus}]_n$ and $[WOBr_4^{\ominus}]_n$ in the structure of **2**. The ellipsoids of thermal vibration correspond to 70% probability. The superscripts refer to the symmetry operations that generate the symmetry-equivalent atoms. Selected bond lengths [pm] and angles [°]: Te1-Te2 297.6(1), Te1-Te3 293.9(1), Te2-Te4 274.7(1), Te3-Te4 277.4(1), Te2-Te3II 288.1(1), Te2-Te1-Te3 91.5(1), Te2-Te1-Te3I 88.5(1), Te1-Te2-Te4 83.4(1), Te1-Te3-Te4 83.6(1), Te2-Te4-Te3 100.2(1), W-O 172.8(7), W-OV 216.8(7), W-Br1 249.5(1), W-Br2 250.4(1), O-W-Br1 97.6(1), O-W-Br2 96.8(1).

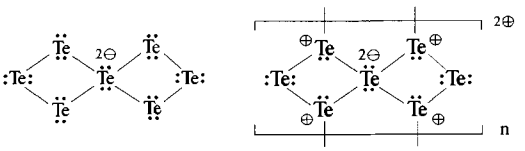
bilities for an ionic formulation of **2**: $[Te_7^{\oplus}]_nBr^{\ominus} \cdot WOBr_4$ or $[Te_7^{2\oplus}]_n\,[WOBr_4^{\ominus}]_n\,Br^{\ominus}$. Both formulations include a paramagnetic center, $Te_7^{\oplus}$ in the former and W^V in $WOBr_4^{\ominus}$. The magnetic measurement on **2** shows the expected paramagnetism of one unpaired electron per formula unit. The reciprocal susceptibility is linear from 20 K to 320 K, the Curie–Weiss constant being −37 K and the magnetic moment 1.45 B.M. A decision on the oxidation state of the W atom can be made on the basis of the W–Br distances, which are 245 pm for W^V-Br[5] and between 250 and 260 pm for W^{VI}-Br.[6] The W–Br distances in **2** are 250.0 pm on average, favoring a formulation as the polymeric anion $[WOBr_4^{\ominus}]_n$. Analogous columnar arrangements of anions are known for $MoOCl_4^{\ominus}$[7] and $MoNCl_4^{\ominus}$.[8]

The polymeric tellurium cation in **2** consists of nearly planar centrosymmetric Te_7 units linked together to form a folded band (Fig. 2). The Te atoms show three different bonding capacities. Te1 is surrounded by four other Te atoms at a mean distance of 295.7 pm in a planar and nearly square fashion; Te2 and Te3 form three bonds and are joined to the neighboring Te_7 groups through bonds 288.1 pm long. Te4 forms two relatively short bonds to Te2 and Te3 (average 276.0 pm). In compounds with tellurium polyanions, structural motifs of the polymeric tellurium cation of **2** are realized in various ways.[9] The square-planar $Te_5^{6\ominus}$ anion in Ga_2Te_5 has 36 valence electrons.[10] A polymeric 32-electron anion, $[Te_5^{2\ominus}]_n$, is present in Rb_2Te_5[11] and Cs_2Te_5.[12] Because they have four valence electrons too few, the square Te_5 groups in these compounds are linked together through four Te–Te bonds to form polymeric bands. Re_2Te_5[13] contains discrete 44-electron anions, $Te_7^{2\ominus}$, which are isostructural to the central Te_7 unit of the polymeric cation in **2**. Assuming an ionic charge of +2 ($Te_7^{2\oplus}$) and 40 valence electrons and therefore four additional Te–Te bonds, the polymeric tellurium cation fits into this series. This is illustrated by the valence dash formulas in Scheme 1. Compound



Scheme 1. Valence dash formulas for the ions $Te_7^{2\ominus}$ [13] und $[Te_7^{2\oplus}]_n$.

2 is thus best characterized by an ionic formula, $[Te_7^{2\oplus}]_n[WOBr_4^{\ominus}]_nBr^{\ominus}$. Extended Hückel band-structure calculations on the polymeric anions $[Te_5^{2\ominus}]_n$[14] show that the lengthening of the central four Te–Te bonds in the Te_5 unit is due to the additional occupation of antibonding states. The structural similarity to the $[Te_7^{2\oplus}]_n$ cation indicates that the bonding model for $[Te_5^{2\ominus}]_n$ may be extended to $[Te_7^{2\oplus}]_n$.

As in all compounds with chalcogen cations and halometalate anions, the structure of **2** reveals tellurium–bromine contacts that are considerably shorter than the sum of the van der Waals radii of 415 pm.[15] Figure 1 shows that the polymeric Te cations are completely surrounded by Br atoms. The shortest Te···Br distances of 333.7 and 343.7 pm occur between Te3 and the free $Br^{\ominus}$ ions.

Experimental Procedure

2: Te (2 g), WBr_5 (0.6 g), and $WOBr_4$ (0.6 g) were placed in a glass ampoule of 15-cm length and 1.5-cm diameter. The ampoule was evacuated and sealed and then put into a tube oven with a temperature gradient of 230 → 210 °C. Compound **2** separated out over several weeks at the cooler end of the tube as black, lustrous, needle- and plate-shaped crystals. The yield was about 80%. Small amounts of red WO_2Br_2 were always formed and precipitated along with the crystals of **2**, but they could be separated mechanically. The crystals of **2** hydrolyze slowly in moist air.

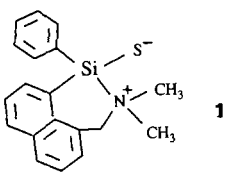
Intramolecular Base Stabilization of Si=N and Si=P Compounds and Related Transition-Metal Silanediyl Complexes

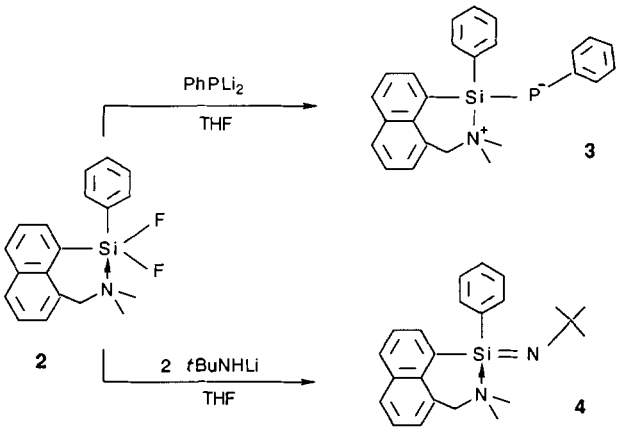
By *Robert Corriu,* Gérard Lanneau*, and *Christian Priou*

The efficiency of Lewis base coordination in stabilizing unsaturated species of silicon or germanium has been demonstrated.[1] For example, compound **1**, stabilized by intramolecular coordination of an amino naphthyl substituent, is a zwitterionic species.[2] Here we describe the analogous silicon derivatives **3** and **4**, which are stabilized by intramolecular coordination of the same amino aryl group and in which the silicon atom is directly bonded to nitrogen or phosphorus, as well as two transition-metal silanediyl complexes, **6** and **7**.



1

The silaphosphene **3** is obtained through the coupling reaction of aminonaphthyl(difluoro)phenylsilane, **2**, with $PhPLi_2$. In solution, the silaphosphene exists as an equilibrium mixture of two diastereomers, **3a** and **3b**, differing in the relative orientation of the *P* phenyl group, in the ratio 2/1 (observed by both ^{31}P and ^{29}Si NMR spectroscopy). Crystallization of the crude mixture from acetone affords isomer **3a**. In chloroform, equilibrium between the two isomers is reached in about one hour.



The NMR data of **3** reveal some interesting structural features (Table 1). For comparison, the values obtained by *Bickelhaupt* et al. for two sterically hindered base-free silaphosphenes have been also noted.[3] The ^{31}P and ^{29}Si NMR values reported by *Bickelhaupt* et al.[4] for base-free silaphosphenes correspond to strong deshielding: $\delta = +70$ to $+136$ (^{31}P NMR) and $+150$ to $+200$ (^{29}Si NMR) with high coupling constants ($^1J_{PSi} = 130-150$ Hz). The ^{29}Si NMR values for **3a**, **b** are $\delta = -2.7$ and -6.4, respectively, corresponding to an expected upfield shift due to the coordi-

Table 1. Selected NMR data for **1**–**7** [a] and related compounds.

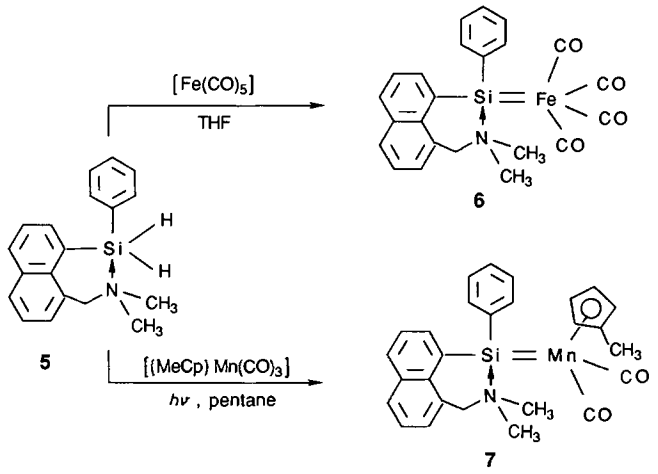
nation of nitrogen to silicon. The zwitterionic character of the diasteromeric silaphosphenes **3a** and **3b** is typified by two very high ^{31}P NMR chemical shifts ($\delta = -97.2$ and -116.5, $^1J_{PSi} = 9.2$ and 24.1 Hz, respectively), which are in accord with a "phosphoranide" structure. Also consistent with a partial Si–N bond are the observed $^3J_{PC}$ coupling constants (5–15 Hz) of the C-methyl atoms directly attached to nitrogen.

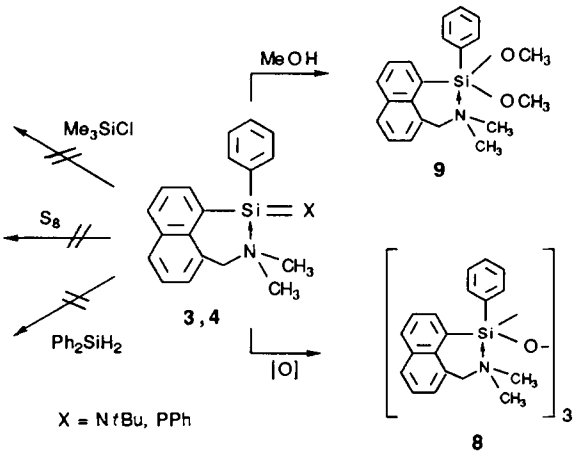
The silaimine **4** is similarly obtained in high yield upon reaction of **2** with two equivalents of *t*BuNHLi (Scheme 1 b). The second equivalent of *t*BuNHLi metalates the aminofluoro silyl intermediate, which cannot be detected by NMR spectroscopy. The by-product, *tert*-butylamine, is removed in vacuo, and the silaimine **4** (amine-free) is distilled off (b.p. 175 °C/0.05 Torr) without dimerization. Only one signal is detected at all temperatures by ^{29}Si NMR spectroscopy ($\delta = -9.6$). A priori, a plausible explanation would be that one diastereomer is favored.[3] Another possibility is that inversion of the imino N atom is too fast for NMR observation of both diastereomers, which is not true in the case of the Si–P derivatives **3a** and **3b**.

The silanediyl transition-metal complexes **6** and **7** are easily obtained by dehydrogenative coupling reaction of pentacoordinated silane **5**. With $[Fe(CO)_5]$, the reaction is performed by simply mixing the reactants in THF at room temperature for one hour, giving **6** in almost quantitative yield. With "methyl cymanthrene", $[(MeCp)Mn(CO)_3]$ (MeCp = η^5-C_5H_4Me), irradiation in THF or pentane is necessary to initiate the reaction; **7** is recrystallized from acetone.

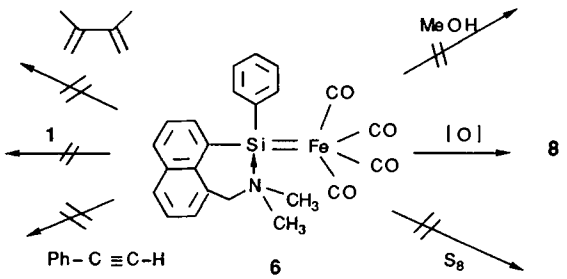


^1H NMR spectra of compounds **6** and **7** exhibit broad signals at all temperatures. As observed for the silanethione **1** ($\delta(^{13}C_{NMe_2}) = 46.0, 44.3$), ^{13}C NMR spectra of **6** and **7** show the presence of two diastereotopic methyl signals for the coordinatively bonded NMe_2 group. These signals ($\delta = 51.4$, 50.3 and 48.0, 45.0) are deshielded relative to the signals of the parent silane **5** ($\delta = 43.4$). Only one signal ($\delta = +217$) is observed for the fluxional CO ligands in the unhindered compound **6**. The more bulky MeCp ligand in **7** allows the two CO groups ($\delta = +234.1$, $+237.0$) to be differentiated. ^{29}Si NMR spectroscopy is a more appropriate analytical method to characterize these low-coordinated silicon species. The ^{29}Si NMR signals of the silanediyl complexes ($\delta = +101.1$ for **6**, 124.0 for **7**) are comparable with the values reported for similar base-stabilized dialkyl (aryl) silanediyl transition-metal complexes.[8] The absence of Si–H bonds in the complexes was demonstrated by using polarization transfer techniques (DEPT, INEPT).[9] A silanediyl complex with reversible intramolecular base stabilization is reported by *Zybill* et al. in the following communication.[10]

Like the silicon–sulfur double-bonded system **1**, stabilized by intramolecular coordination, compounds **3** and **4** are inert towards nucleophiles and electrophiles, Me_3SiCl, Ph_2SiH_2, S_8 and acetone. On the other hand, they are highly sensitive to oxygen or moisture, giving trimeric siloxane **8**.[2] Methanol in excess gives dimethoxysilane **9**.[2]



Preliminary studies have shown terminal silanediyl complex **6** to be unreactive towards alcohols and unsaturated hydrocarbons. A similar behavior has been observed with other transition-metal silanediyl species.[8] In the presence of air or moisture, **6** is immediately and quantitatively transformed into siloxane **8**. An attempt to obtain a disilene



through exchange reaction with silanethione **1** was unsuccessful, despite the great affinity of iron for sulfur. We are currently investigating the use of these compounds as precursors of silanediyls for other reactions.

Experimental Procedure

Preparation of **2**: A solution of *n*-butyllithium (40 mL, 0.1 mol) in hexane (2.5 M) was added to 1-dimethylaminomethylnaphthalene (18.3 g, 0.098 mol) in Et_2O (100 mL). After stirring at room temperature for 24 h, the burgundy solution was added dropwise to phenyltrifluorosilane (16.4 g, 0.1 mol) over 1 h, giving a white precipitate. Compound **2** was isolated by filtration and recrystallization from $CHCl_3$. M.p. 108 °C; yield 16.3 g (50%).^1H NMR (60 MHz, $CDCl_3$, TMS int.): $\delta = 1.95$ (s, 6H, $N(CH_3)_2$), 4.10 (s, 2H; CH_2), 7–8.6 (m, 11H; Ar-H). ^{13}C NMR (62.9 MHz, $CDCl_3$, TMS int.): $\delta = 39.3$ ($N(CH_3)_2$), 57.6 (CH_2), 117–133 (Ar-C). ^{29}Si NMR (49.69 MHz, $CDCl_3$, TMS int.): $\delta = -78.6$ (t, J(Si, F) 253 Hz). ^{19}F NMR (60 MHz, $CDCl_3$, C_6F_6 int.): $\delta = +9.7$. MS (EI, 70 eV): m/z 326 ($M^+ - 1$, 7%). Correct elemental analysis for C, H, N, Si.

3: A yellow solution of dilithiophenylphosphide, prepared just prior to use from phenylphosphane (2.05 g, 18.6 mmol) and *n*-buthyllithium/hexane (2.0 M,

39 mmol) in THF (50 mL) was added dropwise to a solution of the difluorosilane **2** (6.99 g, 18.6 mmol) in THF (50 mL) at −18 °C with stirring. After 12 h at 25 °C, the filtrate was separated and the solvents removed in vacuo. Compound **3** was purified by sublimation at 220 °C/10^{-2} Torr. Yield 5.9 g (80%). Crystallization from acetone afforded 4.8 g (12 mmol) of isomer **3a**, m.p. 164 °C. Correct elemental analysis for C, H, N.

4: To an ice-cooled solution of *tert*-butylamine (0.582 g, 8 mmol) in THF (20 mL) was added dropwise a solution of *n*BuLi (10 mmol, 2.5 M in hexane). After 12 h at room temperature, the yellow solution was added dropwise with a canula to a stirred solution of **2** (1,5 g, 4 mmol) in THF (20 mL) at −18 °C. The dark red solution changed in 6 h to brown-yellow. The reaction mixture was stirred for a further 2 h, then filtered. The solvent was removed in vacuo and the waxy residue extracted with pentane/chloroform (60/40). The yellow oil was purified by kugelrohr distillation (b.p. 175 °C/0.02 Torr), giving **4**, yield 45%. NMR ($CDCl_3$): δ = 1.11 (s, 9H; *t*Bu), 2.10 (s, 6H; $N(CH_3)_2$), 4.10 (s, 2H; NCH_2), 6.9–8.1 (m, 11H; Ar-H). ^{13}C NMR ($CDCl_3$): δ = 34.3 ($C(CH_3)_3$, 44.3 ($N(CH_3)_2$, 50.7 (N-C), 62.5 (NCH_2), 125–145 (Ar-C). MS (EI, 70 eV): *m/z* 360 (M^+, 1%), 345 (60), 289 (15), 215 (10), 184 (18), 141 (40), 58 (100). Correct elemental analysis for C, H, N, Si.

6: **5** (0.52 g, 1.8 mmol) was added to a solution of $[Fe(CO)_5]$ (0.35 g, 1.8 mmol) in THF at 25 °C. The reaction mixture was stirred at that temperature for 1 h. Then, the brown-red solution was concentrated in vacuo, leaving **6** as a red solid (0.67 g, 82%). Recrystallization from acetone gave the analytically pure complex; m.p. 140 °C. ^{13}C NMR ($CDCl_3$): δ = 50.3, 51.4 (2s, N (CH_3)$_2$), 68.3 (s, CH_2), 125.1–139.6 (Ar-C), 217.0 (s, CO). IR (CCl_4): ν (CO) = 1977, 1956, 1916, 1898 cm^{-1}. MS (EI, 70 eV): *m/z* 457 (M^+, 5%) 429 (M^+ − CO, 9), 373 (M^+ − 3 CO, 20), 345 (M^+ − 4 CO, 30). Correct elemental analysis for C, H, N, Si.

7: **5** (2.21 g, 7.6 mmol), diluted in pentane (150 mL), was mixed with methylcymanthrene (1.6 g, 7.6 mmol) in a quartz reactor and irradiated at 20 °C for 5 h with a high-pressure Hg lamp. Removal of the solvent in vacuo left a brown solid, which was recrystallized from acetone. Yield: 1.6 g (44%); m.p. 230–231 °C. ^{13}C NMR ($CDCl_3$): δ = 14.6 (CH_3Cp), 82.8, 82.5 (2s, Cp), 103.1 (C-Me), 45.0, 48.0 (2s, $N(CH_3)_2$), 65.9 (s, CH_2), 121.6–136.2 (Ar-C), 234.1, 237.0 (2s, CO). IR ($CDCl_3$): ν (CO) = 1897, 1822 cm^{-1}. MS (EI, 70 eV): *m/z* 479 (M^+, 18%), 423 (M^+ − 2 CO, 81). Correct elemental analysis for C, H, N, Si.

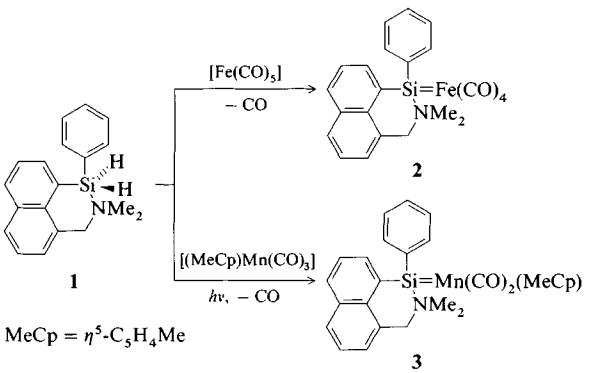
Reversible Intramolecular Base Stabilization of a Low-Coordinate Silicon Atom in the Silanediyl Complex $[(o\text{-}Me_2NCH_2C_6H_4)_2Si{=}Cr(CO)_5]$ **

By *Reiner Probst, Christian Leis, Siegfried Gamper, Eberhardt Herdtweck, Christian Zybill,** and *Norbert Auner**

Since the identification of base-stabilized silanediyl (silylene) complexes,[1, 2] the coordination chemistry of low-valent silicon ligands[3] has been developed rapidly. In addition to donor adducts of silanediyl complexes, also base adducts of cationic complex compounds,[4] metallasilaallenes,[5] and cyclic disilanediyl complexes[6] have become known. In many cases, these donor-stabilized complexes may be regarded as model compounds for reactive, base-free intermediates which play an important role in silanediyl-transfer reactions.[7]

Starting from the pentacoordinated silane **1**, *Corriu* et al. recently prepared the intramolecularly base-stabilized silanediyl complexes **2** and **3**, which are described in the preceding communication.[8] We have pursued this strategy



to obtain the title compound **7** by reaction of the dichlorosilane **6a** with $Na_2[Cr(CO)_5]$ and to prepare **8** from **6b**. Spectroscopic and structural investigations surprisingly indicated a reversible coordination of the "internal" base for both the pentacoordinated silane **6a** and the silanediyl complex **7**.

In solution the dichlorosilane **6a** contains a pentacoordinated silicon atom,[9] which is indicated by the ^{29}Si NMR

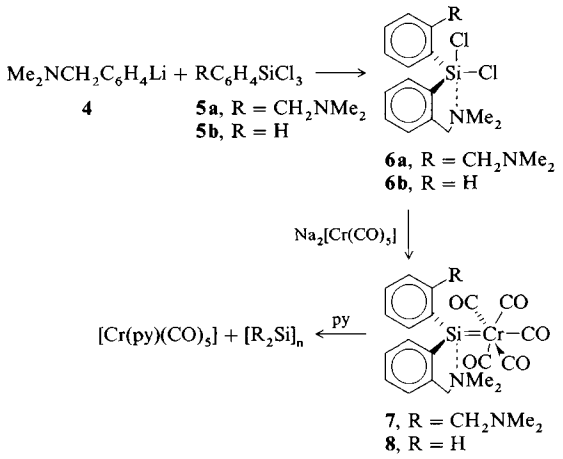
chemical shift ($\delta = -30.1$). The ^{1}H NMR spectra show that the two dimethylaminomethylphenyl substituents are equivalent at room temperature with the two phenyl rings rotating freely. This rotation can be frozen below $-13\,^\circ$C (coalescence temperature);[10] the estimated activation barrier for the process is $\Delta G^{\neq} = 56.3\ (\pm 5)\ \mathrm{kJ\,mol^{-1}}$.



The spectroscopic results are confirmed by a single-crystal X-ray structure determination (Fig. 1).[11] The equatorial Si–Cl and Si–C distances (208.1(1), 186.9(1), and 187.0(1) pm) are similar to those in known pentacoordinated silanes. In accordance with the relatively weak Si–N2 bond (229.1(2) pm), the central silicon atom is slightly pyramidalized (sum of equatorial angles 356.9°).

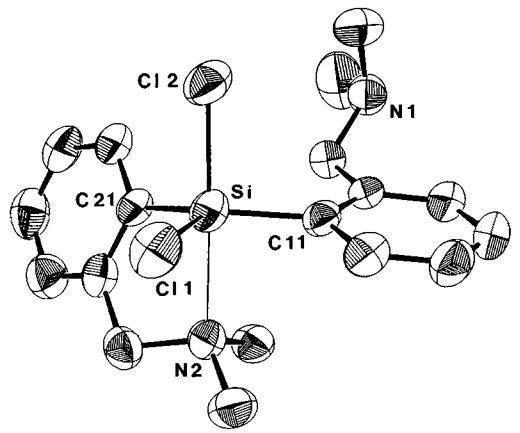


Fig. 1. Molecular structure of the dichlorosilane **6** (ORTEP, hydrogen atoms omitted). Selected distances [pm] and angles [°]: Si-Cl1 208.1(1), Si-Cl2 218.1(1), Si-N2 229.1(2), Si-C11 186.9(1), Si-C21 187.0(1), Si-N1 449.3(2); C11-Si-C21 132.16(6), Cl1-Si-C11 113.22(5), Cl1-Si-C21 111.53(4), Cl1-Si-Cl2 94.46(3), Cl1-Si-N2 86.72(3), Cl2-Si-N2 86.72(3).

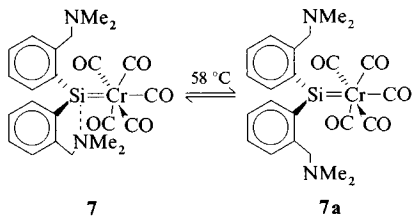
Coupling of **6a** or **6b** with $Na_2[Cr(CO)_5]$ exclusively results in the formation of the complex compounds **7** and **8**. On the basis of the spectroscopic data, **7** and **8** are unequivocally silanediyl complexes; the extreme low-field shift of the ^{29}Si NMR signals (e.g., $\delta = 124.9$ for **7** at 22 °C), in particular, points to a relatively small donor → silicon interaction. The ^{29}Si NMR shifts are strongly temperature-dependent (e.g., $\delta = 138.8$ for **7** at 58.0 °C and 120.9 at $-40.0\,^\circ$C). This situation is reflected in the temperature dependence of the ^{1}H NMR spectra of **7**. At room temperature, the two dimethylamino groups are chemically equivalent; however, in contrast to **6a**, the signals of the methylene protons form an AB pattern ($\delta = 3.80$, 4.09, $^2J_{HH} = 12.2$ Hz). This is the result of hindered rotation of the phenyl substituents with simultaneous fixation of the two dimethylamino groups in the sense of an alternating, dynamical coordination of the nitrogen donor at a time to the silicon center (pentacoordination in the transition state).[12] Below $-21\,^\circ$C (coalescence, $\Delta G^{\neq} = 54.2\ (\pm 5)\ \mathrm{kJ\,mol^{-1}}$) this dynamical coordination does not occur and only one nitrogen donor is coordinated to silicon; the two dimethylaminomethylphenyl substituents are magnetically inequivalent. Above 58 °C, the two substituents on silicon show magnetic equivalence with coalescence of the AB system of the methylene protons to a singlet ($\delta = 3.90$). At temperatures above 58 °C, the "dynamical N–Si coordination" is lifted; the rotation of the phenyl substituents is now rapid on the ^{1}H NMR time scale and the nitrogen donors are no longer fixed to the silicon atom (structure **7a**). For **8**, a coalescence temperature of 95 °C ($\Delta G^{\neq} = 80.2\ (\pm 5)\ \mathrm{kJ\,mol^{-1}}$) was found; below this temperature, the dimethylamino substituent in **8** is rigidly coordinated to the silicon atom.[13]



These findings were confirmed and supplemented by single-crystal X-ray structure analysis of **7** (Fig. 2). The silanediyl ligand in complex **7** is coordinated to the octahedral metal fragment. The Cr–Si bond length (240.8(1) pm) is noticeably short.[14] An ab initio calculation has predicted a Cr–Si distance of 240 pm in $[(OH)HSi{=}Cr(CO)_5]$;[15] a crude estimate based on covalent radii gives a value of 228 pm for a donor-free Cr–Si double bond and about 270 pm

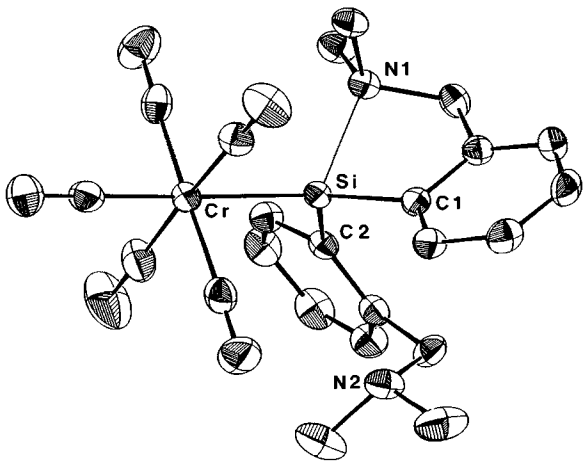


Fig. 2. Molecular structure of the silanediyl complex **7** (ORTEP, hydrogen atoms omitted). Selected distances [pm] and angles [°]: Cr-Si 240.8(1), Si-N1 204.6(2), Si-C1 189.8(2), Si-C2 190.8(2), Si-N2 330.9(2); Cr-Si-C1 120.3(1), Cr-Si-C2 116.9(1), C1-Si-C2 114.1(1), Cr-Si-N1 118.2(1), N1-Si-C1 83.6(1), N1-Si-C2 96.6(1).

for a Cr–Si single bond.[2b] The interaction of the two dimethylamino substituents with the silicon atom leads to a characteristic coordination geometry. The N1–Si distance (204.6(2) pm) is shorter than the N2–Si distance in the pentacoordinated compound **6a**; this underlines the high electrophilicity of the coordinated silanediyl ligand in **7**. On the other hand, this distance is considerably longer than those found in all structurally characterized compounds of this type[16] and is clearly outside the covalent range.[17] The only partially covalent character of the Si–N bond is confirmed by the activation barrier determined by NMR spectroscopy for exchange of the two dimethylamino units ($\Delta G^{\neq} = 67.1\ (\pm 5)$ kJ mol^{-1}). Furthermore, the extremely weak donor interactions (donor $\rightarrow \pi^*$ orbital) leads to $\lambda_{max} = 274$ nm (π–π^* transition of the Cr–Si double bond) in the UV spectrum; such a bathochromic shift has not been previously observed for similar compounds. The second dimethylamino group of **7** in the crystal is, in contrast to **6a**, also directed toward the silicon atom of the same molecule; the Si–N2 distance (330.9 pm) may be regarded as a van der Waals contact. Especially the increased Cr–Si–S1 and Cr–Si–C2 angles (116.9(1) and 120.3(1)°), which are characteristic of a donor adduct, as well as the C1–Si–C2 angle (114.1(1)° (sum of angles 351.3°) show a significant planarization of the coordination polyhedron at silicon formed by the three covalently bonded substituents.

The relatively loose donor bond implies a high reactivity of the complex. Base-induced silanediyl cleavage occurs in pyridine, trimethylphosphane, CO, or 2,3-dimethylbutadiene both thermally and photochemically. The resulting reaction mixtures are complex and contain mostly polymeric silanes.

Experimental Procedure

6: *o*-(*N*,*N*-dimethylaminomethyl)phenyllithium [19] (0.4 mol) was added in portions to a solution of $SiCl_4$ (22.9 mL, 0.2 mol) (distilled from K_2CO_3) and 50 mL of triethylamine in about 700 mL of diethyl ether. The reaction mixture turned pale yellow and began to reflux. After addition was completed, the reaction solution was refluxed for a further 2 h, followed by filtration and removal of all volatiles under vacuum. The crude product was recrystallized from diethyl ether. Yield: 50.5 g (68%). Compound **6b** was obtained analogously.

6a: ^{1}H NMR (270 MHz, $CDCl_3$, 22 °C, TMS): $\delta = 1.94$ (s, 6H; CH_3), 3.56 (s, 2H; CH_2), 7.32–7.36, 8.19 (m, 4H; C_6H_4). ^{1}H NMR (−28 °C, [D$_8$]toluene): $\delta = 3.46$, 3.66 (AB system, $^2J(^1H,^1H) = 12.0$ Hz, 2H; CH_2). ^{13}C NMR (67.8 MHz, $CDCl_3$, 22 °C): $\delta = 45.0$ (CH_3), 63.12 (CH_2), 126.60, 127.19, 130.11, 134.72, 134.85, 142.79 (C_6H_4). ^{29}Si NMR (53.5 MHz, $CDCl_3$): $\delta = -30.1$. CI-MS (70 eV): m/z 367 ($M^+ + 1$ for $C_{18}H_{24}Cl_2N_2Si$, 5%). M.p. 104 °C. Correct elemental analysis (C, H, N).

7: [$Na_2Cr(CO)_5$] (2.31 g, 9.71 mmol) was dissolved in 100 mL of THF with ultrasonication. The brown-yellow solution was cooled to about −40 °C and then dichlorosilane (3.55 g, 9.71 mmol), dissolved in 100 mL of THF, was slowly added dropwise to the stirred solution. After warming to room temperature, the reaction solution was stirred for a further 3 h. It was then decanted from precipitated NaCl by using a steel cannula and concentrated to about 10 mL under vacuum (5×10^{-2} Torr). At −20 °C, **7** crystallized as beige-yellow crystals. Yield: 1.5 g (32%). M.p. 170 °C. The compound is thermochromic (yellow → red). ^{1}H NMR (270 MHz, [D$_8$]toluene, 22 °C): $\delta = 2.57$ (s, 6H; CH_3), 3.80, 4.09 (dd, AB system, $^2J(^1H,^1H) = 12.2$ Hz, 2H; CH_2), 7.18–7.27, 7.61–7.71 (m, 4H; C_6H_4); (58 °C): 3.90 (s, 2H; CH_2). ^{13}C NMR (67.8 MHz, [D$_6$]acetone, 22 °C): $\delta = 43.44$ (CH_3), 64.68 (CH_2), 128.39, 128.69, 132.86, 137.06, 150.13 (C_6H_4), 212.82, 227.25 (CO). ^{29}Si NMR ([D$_8$]THF, 53.5 MHz, 22 °C): $\delta = 124.9$; (58 °C): 138.8; (−40.0 °C): 120.9. EI-MS (70 eV): m/z 488 (M^+ for $C_{23}H_{24}CrN_2O_5Si$ with correct isotopic pattern, 10%). IR (Nujol): ν(CO) = 2036 (m), 1916 (ss), 1884 (ss) cm^{-1}. UV/VIS (cyclohexane) $\lambda_{max} = 274$ nm, $\varepsilon_0 = 27000$. Correct elemental analysis (C, H, N).

8: The synthesis was carried out as described for **7**, 63% yield. M.p. 165–170 °C. ^{1}H NMR (270 MHz, [D$_8$]toluene, 22 °C): $\delta = 1.83$, 2.08 (s, 6H; NCH_3); 2.62, 3.04 (AB system, $^2J(^1H,^1H) = 14.0$ Hz, 2H; CH_2); 6.04 (d, $^3J(^1H,^1H) = 10.1$ Hz, 1H) 7.02 (t, $^3J(^1H,^1H) = 10.0$ Hz, 1H) 7.04 (d, $^3J(^1H^1H) = 10.1$ Hz, 1H) 8.08 (d, $^3J(^1H^1H) = 10.1$ Hz, 1H; $C_6H_4NMe_2$); 6.97 (s, 2H) 7.04 (d, $^3J(^1H,^1H) = 8.9$ Hz, 3H; C_6H_5). ^{29}Si NMR (53.5 MHz, [D$_8$]toluene, 22 °C) $\delta = 121.2$. EI-MS (70 ev): m/z 431 (M^+ for $C_{20}H_{17}CrO_5NSi$ with correct isotopic pattern, 100%). M.p. 165 °C. Correct elemental analysis (C, H, N).

Reduction of the Small Subunit of Ribonucleotide Reductase by Diimide: Evidence for the Formation of the Mixed-Valence Fe^{II}–Fe^{III} center**

By *Catherine Gerez, Jacques Gaillard, Jean-Marc Latour,* and *Marc Fontecave**

Binuclear non-heme iron centers are utilized in living organisms for reversible oxygen binding (hemerythrin, Hr), for oxygen activation (methane monoxygenase, MMO, and ribonucleotide reductase, RR), and for hydrolysis of organophosphate esters (purple acid phosphatase, PAP).[1]

Ribonucleotide reductase from *E. coli* consists of two nonidentical subunits, proteins R1 and R2.[2] Protein R2 is a homodimer, each polypeptide chain sequestering a binuclear ferric center, as recently confirmed by a three-dimensional X-ray analysis.[3] The function of the di-iron(III) center of R2 is to promote the specific one-electron oxidation of tyrosine 122 by dioxygen.[4] The generation of the tyrosyl radical is a prerequisite for an active enzyme.[2]

The presence of an oxo group bridging the two iron atoms is suggested from characteristic resonance Raman vibrations.[1] Moreover, the UV/VIS spectrum of R2 contains two bands at 370 and 325 nm, originating from a charge transfer from O^{2-} to Fe^{3+} and a sharp peak at 410 nm, contributed by the tyrosyl radical.[1] The metal cluster also exhibits a strong antiferromagnetic coupling of the two iron ions ($J = -110\ cm^{-1}$ for $\boldsymbol{H} = -2JS_1S_2$).[5] As a consequence, the di-iron(III) center is EPR-silent and the EPR spectrum of protein R2 only displays the characteristic signal of the tyrosyl radical at $g = 2.0047$.[6]

In general, binuclear iron clusters can also exist in two other redox states, the fully reduced $Fe^{II}Fe^{II}$ state and the EPR-active mixed-valence $Fe^{II}Fe^{III}$ state. However, only the first one has been observed and characterized in the case of protein R2.[4a, 7–9] In particular, its UV/VIS spectrum does not contain the bands at 325, 370, and 410 nm. Therefore, UV/VIS spectroscopy is a convenient method for monitoring the anaerobic reduction of protein R2 to the radical-free Fe^{II}–Fe^{II} state of the protein, called reduced R2.[4a, 7, 8]

In this paper, we report that 1) diimide is a very efficient reducing agent of the redox centers of protein R2, 2) the mixed-valence state of the binuclear center was detected by EPR spectroscopy during this reduction.

When protein R2 ($1\ mg\,mL^{-1}$)[10] was incubated in a spectrophotometric cuvette with diimide formed by in situ hydrolysis of 4 mM potassium azodicarboxylate[11] at pH 8.5 under anaerobic conditions, the spectrum of the solution slowly changed from that of the radical-containing Fe^{III}–Fe^{III} state to that of reduced R2,[4a, 5, 6] in approximately 2 h (data not shown). This clearly indicated that diimide was able to transfer electrons to the redox centers of protein R2, namely the di-iron(III) center and the tyrosyl radical. Probably, the low redox potential, the electric neutrality, and the small size of diimide molecules are responsible for the efficiency of the reaction. Actually, the active site is buried within the protein[3] and protected from negatively charged reducing agents.[7]

The reaction of 0.25 mM protein R2 with 6 mM potassium azodicarboxylate in 0.1 M deaerated Tris buffer, pH 8.5, was performed inside an argon-flushed EPR tube in a glove box to ensure anaerobic conditions. At intervals the tube was frozen in liquid nitrogen and the EPR spectrum was recorded at low temperatures (4–10 K). While the intensity of the characteristic EPR signal of the tyrosyl radical at $g = 2.00$ slowly decreased, a new weak signal appeared with all resonances below $g = 2$. On the other hand, no signal could be detected at $g \approx 16$ during the reaction. Such an EPR feature was recently observed during reduction of protein R2 by dithionite and assigned to reduced R2.[9]

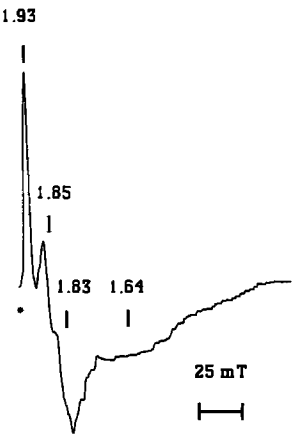

Fig. 1. EPR-spectrum of the R2 mixed-valence state. Experimental conditions: temperature, 5 K; power, 20 mW; amplitude modulation, 1.25 mT; frequency modulation, 100 kHz; resonance frequency, 9223 MHZ. The low field feature (marked with *) is partly caused by the saturated signal of the remaining tyrosyl radical.

Figure 1 shows the new EPR signal. This signal reached maximum intensity after approximately 1 h, when the reduction of the iron center and the tyrosyl radical was near completion, as indicated from the amplitude of the signal of the organic radical. It comprises a sharp resonance at $g_1 = 1.93$, two very close lines at $g_2 = 1.85$ and $g_{2'} = 1.83$, and a broad component at $g_3 \approx 1.64$, and probably originates from the superimposition of two rhombic signals with slightly different g values which causes the doubling of the central line and the broadening of the high-field component. As a consequence of this broadening and of the presence of a residual amount of unreduced tyrosyl radical, the intensity of the relevant $g < 2$ signal cannot be quantified accurately. However, from double integration of this signal, we estimated that the corresponding EPR-active species accounted for 2–

5% of the total protein concentration. It is worth noting that no similar $g < 2$ signal could be detected when protein R2 was reduced by 1,4-dithio-L-threitol (DTT) at alkaline pH.[12] Dithionite in the presence of methyl viologen also failed to generate this signal.[7] This indicates that the corresponding species is extremely unstable.

Introduction of air resulted in the instantaneous increase of the $g = 2.00$ signal and disappearance of the $g < 2$ signal. The regeneration of the tyrosyl radical confirmed that reduced R2 was formed during the anaerobic step.[4a, b, 7-9] However, radical formation was not total (60% yield), probably because the diimide partly mobilized endogenous iron as suggested by the significant increase of the $g \approx 4.3$ signal. Instability of Fe^{II} in R2 is well-documented.[8] We checked that protein R2 was not irreversibly denatured by prolonged incubation with diimide. Actually, diimide-treated R2 could be fully reactivated through one cycle of iron chelation by 8-hydroxyqauinoline 5-sulfonate and reconstitution in the presence of Fe^{II} and ascorbate,[7] as monitoring by EPR spectroscopy shows.

The new signal resembles those previously reported for the two mixed-valence $Fe^{II}-Fe^{III}$ states of hemerythrin (g values of 1.95, 1.72, 1.57 and 1.96, 1.88, 1.66), methane monoxygenase ($g = 1.95$, 1.88, 1.78), and purple acid phosphatase ($g = 1.93$, 1.72, 1.56).[1, 13, 14] Also, a synthetic binuclear iron complex containing an $Fe^{II}-Fe^{III}$ cluster has similar $S = 1/2$ EPR characteristics arising from the antiferromagnetic interaction of a pair of high spin Fe^{II} and Fe^{III} ions.[15] Thus the $S = 1/2$ EPR spectrum of Figure 1 strongly suggests that a mixed-valence $Fe^{II}-Fe^{III}$ state was formed during reduction of R2 to reduced R2 by diimide.

Although the g values of the mixed-valance states of binuclear iron proteins fall in the same range, confirming that the clusters have a similar core structure, the observed differences are nevertheless significant. They reflect distortions at the Fe^{II} site as well as minor changes of the relative magnitudes of the exchange and zero-field splitting parameters.[16] It is therefore remarkable that the mixed-valence state of R2 gives an EPR spectrum which closely resembles that of $(\text{semi-metHr})_R$, the mixed-valence state produced by a one-electron reduction of methemerythrin.[1, 17] This suggests that the two iron atoms are only weakly antiferromagnetically coupled, which in turn suggests that the oxo bridge has been converted into a hydroxo bridge during reduction of R2.[16-19] Moreover, since Fe^{2+} in $(\text{semi-metHr})_R$ is six-coordinate, a similar geometry is likely to occur in the R2 mixed-valence state.

The doubling of the signal could originate from a dipolar interaction between the paramagnetic $Fe^{II}-Fe^{III}$ center and the residual tyrosyl radical, if present in the same polypeptide chain. However, this would also result in the splitting of the $g = 2.00$ signal. Since no change in the position or the width of this signal could be observed, this hypothesis must be excluded. Therefore, the doubling of the signal is probably related to the dissymmetry of the binuclear iron cluster. The presence of two structurally nonidentical iron ions[3] may explain the formation of two slightly different mixed-valent di-iron clusters, as found for the semimethemerythrins.[17, 18]

As mentioned above, reduced R2 obtained from reduction of R2 by dithionite exhibits an EPR signal at $g \sim 16$.[9] On the contrary, the $Fe^{II}-Fe^{II}$ center produced during reduction of R2 by diimide is EPR-silent. This situation is reminiscent of the one in deoxyhemerythrin, for which the generation of an analogous low field ($g \sim 13$) signal depends on the ligand bound at the free coordination site.[20] We therefore tentatively suggest that binding of diimide to the $Fe^{II}-Fe^{II}$ center of reduced R2 makes it EPR-silent. Such a binding would also explain the stabilization of the mixed-valence state. We are currently investigating the possibility for such coordination chemistry in ribonucleotide reductase.

Synthesis, Structure, and Isomerization of the (*E*)- and (*Z*)-Isomers of a Diphosphene**

By *Edgar Niecke,** *Oliver Altmeyer*, and *Martin Nieger*

Dedicated to Professor Leopold Horner on the occasion of his 80th brithday

Aryl-substituted (*E*)-diazenes (E = N) **I** can be photochemically converted into the (*Z*)-form **II**, which, in turn, can be reconverted thermally into the (*E*)-form.[1] Since the isomerization **II** → **I** generally proceeds with release of energy, aryl-substituted diazenes have found lasting interest as storage systems for solar energy.[2]

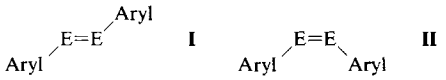
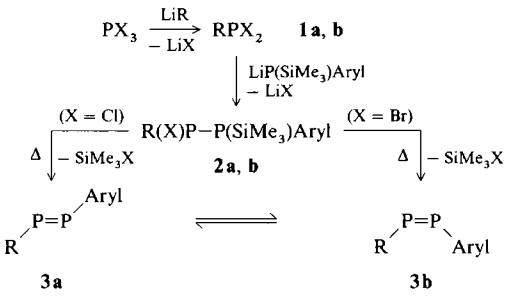
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Partly based on a lecture delivered at the International Conference on Phosphorus Chemistry, Tallinn, USSR, September, 1989: E. Niecke, O. Altmeyer, D. Barion, R. Detsch, C. Gärtner, J. Hein, M. Nieger, F. Reichert, *Phosphorus Sulfur Silicon Relat. Elem.* 49/50 (1990) 321.

In contrast, very little has been reported about (*E*/*Z*)-isomerizations of the homologous diphosphenes (E = P);[3] an isomeric pair, from which the two forms could be isolated is thus far unknown.[4] We report here the synthesis and structure of such an isomeric pair, the isomeric interconversion, and a secondary reaction of the (*Z*)-isomer.



The hydrazinodihalogenophosphanes, **1a** and **1b**, which are accessible from phosphorus(III) chloride or bromide respectively and lithium tris(trimethylsilyl)hydrazide, react with 2,4,6-tri-*tert*-butylphenyl(trimethylsilyl)phosphide to give the thermostable diphosphanes **2a** and **2b**, respectively. Above −10 °C, these eliminate halosilane and form the P=P double-bond systems **3a** and **3b**, respectively (Scheme 1). Remarkable about this reaction is that, in the case of the chloro derivative **2a**, the (*E*)-isomer **3a** is formed selectively from the educts precipitating only in one diasteromeric form, whereas in the case of the bromo derivative **2b**, the *Z*-isomer **3b** is formed selectively.



Scheme 1. **1a**, **2a**: X = Cl; **1b**, **2b**: X = Br; R = $(Me_3Si)_2NMe_3SiN$; aryl = 2,4,6-$tBu_3C_6H_2$.

If it is assumed that the thermally-induced cleavage of halosilane from the diphosphanes **2a**, **b** takes place via a *syn*-elimination and the rotameric equilibrium is controlled by steric effects, then the elimination must proceed from different diasteromeric pairs of enantiomers. On the basis of the very similar ^{31}P-NMR data of the educts (δ = 181, − 41, $J_{P,P}$ = 293 Hz (**2a**); 182, − 42, $J_{P,P}$ = 275 Hz (**2b**)) the (*E*)-isomer **3a** must be formed from the *S,R*-(*R,S*)-form with *trans* arrangement of the aryl and hydrazino substituents (g^1-rotamer), whereas the (*Z*)-isomer **3b** must be formed from the *S,S*-(*R,R*)-form with *trans* arrangement of the aryl and bromine substituents (g^2-rotamer).

In both isomers **3a**, **b** the phosphorus atom in the β-position to the hydrazino substituents is strongly shielded: ($\delta(^{31}P)$ = 311(PC) vs 481(PN) (**3a**); 190(PC) vs 358(PN) (**3b**)), which is consistent with the structure in the crystal (see below), and which can be interpreted in terms of the formation of a 4e-3c-NPP π-system. The relative shift differences between the (*E*)- and (*Z*)-form, $\Delta\delta(^{31}P)$, are of comparable magnitude for correspondingly substituted phosphorus atoms ($\Delta\delta$ = 123(PN), 121(PC)) and compare with those of the (*E*/*Z*) isomeric pair aryl–P=P–aryl ($\Delta\delta$ = 124, Aryl = 2,4,6-$tBu_3C_6H_2$[3]). The UV-VIS spectrum shows two absorption maxima above 300 nm, outside of the range of the π-π* transitions of the aryl substituent, which on the basis of their intensities should belong to the symmetry-forbidden n_+-π*-transition (λ_{max}[nm] = 318 (**3a**), 319 (**3b**)) and π_2-π*-transition of the NPP bond system (λ_{max}[nm] = 355 (**3a**), 365 (**3b**)), respectively.

The diphosphenes, which are storable almost indefinitely in the solid state, equilibrate in solution with formation of the isomeric form, whereby the establishment of equilibrium, with **3a**:**3b** = 11:6 (293 K), indicates a similar thermodynamic stability for both isomers ($\Delta\Delta G < 1$ kcal mol^{-1}). Spectroscopic analysis of the reversible transformation **3a** ⇌ **3b** ($k_{(293)Z/E} = 5.5(5) \times 10^{-7}$ s^{-1}; $k_{(293)E/Z} = 6.7(5) \times 10^{-7}$ s^{-1}) affords the free activation enthalpies $\Delta G^{\ddagger}_{(293)E/Z} = 25.5(5)$ and $\Delta G^{\ddagger}_{(293)E/Z} = 25.4(5)$ kcal mol^{-1}. These are significantly lower than the calculated rotational barrier for the parent compound HP=PH (34.0 kcal mol^{-1}[5]), which possibly can be attributed to the stabilization of the radical transition state.[6] The free activation enthalpy for the (*Z*/*E*)-isomerization, however, is markedly higher than that for the diphosphene aryl–P=P–aryl ($\Delta G^{\ddagger}_{(273)Z/E} = 20.3$ kcal mol^{-1}, aryl = 2,4,6-$tBu_3C_6H_2$[3]), whose (*Z*)-form could therefore not be isolated.

Figure 1 shows the structure of the diphosphenes **3a**, **b** in the crystal.[7] As in the already previously characterized aryl-

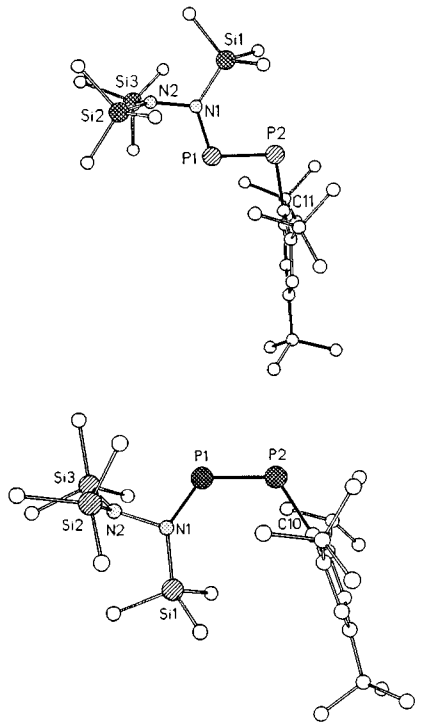


Fig. 1. Structure of the (*E*)-diphosphene **3a** in the crystal (top) and structure of the (*Z*)-diphosphene **3b** in the crystal (bottom). Important bond lengths [pm] and angles [°] of **3a** and **3b** (in square brackets): P-P 203.7(2) [202.7(3)], P-N 170.0(3) [168.6(7)], P-C 186.4(4) [187.8(9)], N-N 147.4(4) [150.6(8)]; P-P-N 106.1(1) [126.3(3)], P-P-C 97.6(1) [121.4(3)], P-N-N 112.5(2) [107.5(5)], P-N-Si 129.3(2) [136.4(4)], N-N-Si 118.1(2) [114.4(5)]; N-P-P-C 179.4(2) [1.5(6)].

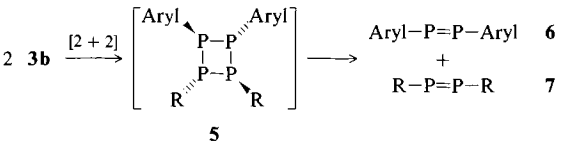
substituted diphosphenes,[9] the aryl substituent is almost orthogonal to the central π-bond system (**3a**: 79; **3b**: 89°). The planar coordinated N atoms of the hydrazino substituents and the P atoms of the double bond system, on the other hand, lie in a plane, which enables formation of a 4e, 3c π-system. This is accompanied by a larger valence angle at P1 compared to P2, both in the (*E*)-form (106 vs 98°) as well as in the (*Z*)-form (126 vs 121°). In the latter, the P–P distance is also shorter (202.7(2) vs 203.7(3) pm in the (*E*)-form),

which can be explained in terms of the considerably greater angle at the phosphorus atoms and the associated greater s-part in the phosphorus bonds. This interpretation would also be consistent with the larger P–P coupling constants for the (*Z*)-isomer (554 compared to 516 Hz for the (*E*)-form). A comparison of the structural data of **3a** with those of the correspondingly substituted iminophosphane **4**[10] ((*E*/*Z*)-

(E)-$(Me_3Si)_2N(Me_3Si)N-P=N-2,4,6\text{-}tBu_3C_6H_2$ **4**

isomers in the iminophosphane system have thus far not been observed because of the energetically favored nitrogen inversion[11]) shows that the stereoelectronic influence of the silylated hydrazino substituents is comparable in both bond systems.

Similarly to the well-known isolable *E*-diphosphenes,[12] **3b** also slowly transforms in solution at room temperature[13] into the two symmetrically substituted diphosphenes **6** and **7**, which can be detected in the reaction solution after a few days.[14] It is assumed that their formation proceeds via the kinetically highly labile cyclotetraphosphane **5**, a head/head dimer of **3b** as intermediate.[12]



Experimental

1a [1b]: A solution of PCl_3 [PBr_3] (22 mmol) in ether (50 mL) was treated at -40 °C with an equimolar amount of $Li[N_2(SiMe_3)_3]$ dissolved in 100 mL of ether. The reaction mixture was warmed to room temperature, stirred for 12 h, and then the solvent was removed by evaporation. The residue was taken up in *n*-pentane, LiCl[LiBr] removed by filtration, and the crude product obtained on evaporation of the filtrate to dryness was recrystallized from a little *n*-pentane. Yield 94%, m.p. 115–116 °C [90%, 85–88 °C]. ^{31}P NMR (C_6D_6): $\delta = 165$ [168]; ^1H NMR (C_6D_6): $\delta = 0.23$ [0.30] (s, $NSiMe_3$) 0.40 [0.37] (s, $N(SiMe_3)_2$). **3a [3b]**: A solution of **1a [1b]** (5.0 mmol) in ether (20 mL) was cooled to -78 °C and treated dropwise with an equimolar amount of LiP($SiMe_3$)Mes* (Mes* = 2,4,6-$tBu_3C_6H_2$). The mixture, containing the NMR spectroscopically characterized phosphane **2a [2b]** was warmed to room temperature and stirred for 2 h. Halosilane cleavage and a deepening in color accompanied formation of the diphosphene **3a [3b]**. After removal of the volatile components, the residue was taken up in *n*-pentane and filtered to remove LiCl[LiBr]. The crude product obtained on evaporation was recrystallized from a little *n*-pentane. Yield: 2.1 g (79%), m.p. 158–160 °C [1.00 g (40%), 110–112 °C]. $^{31}P\{^1H\}$NMR (C_6D_6): $\delta = 481$, 311 (J(P,P) = 554 Hz) [358, 190 (J(P,P) = 516 Hz)]; ^1H NMR (C_6D_6): $\delta = 7.43$ [7.4] (t, J(H,P) = 1.24 Hz, [< 0.2 Hz], 2H (aryl), 1.55 [1.74] (d, J < 0.2 Hz [1.4 Hz], 18H, *o*-*t*Bu), 1.36 [1.30] (s, 9H, *p*-*t*Bu), 0.37 [0.25] (t, 9H, J(H,P) = 0.55 Hz [0.4 Hz], $PNSiMe_3$), 0.29 [0.06] (d, 18H, J(H,P) = 0.2 Hz [< 0.2 Hz], $NN(SiMe_3)_2$).—MS (70 eV): **3a**: *m*/*z* 554 ($M^{\oplus}$, 13%), 497 ($M^{\oplus}$ – *t*Bu, 2), 309 ($M^{\oplus}$ – Mes*, 14), 278 ($(SiMe_3)_3N_2P^{\oplus}$, 48), 276 (Mes*$P^{\oplus}$, 5), 73 ($SiMe_3^{\oplus}$, 100); **3b**: *m*/*z*: 554 ($M^{\oplus}$, 15%), 497 ($M^{\oplus}$ – *t*Bu, 4), 309 ($M^{\oplus}$ – Mes,* 25), 276 (Mes* $P^{\oplus}$, 3), 263 ($(SiMe_3)_3N_2P^{\oplus}$ – Me, 51), 245 (Mes,* 2.5), 205 ($(SiMe_3)_2NNP^{\oplus}$, 41), 160 ($(SiMe_3)_2N^{\oplus}$, 1), 73 ($SiMe_3^{\oplus}$, 100), 57 ($tBu^{\oplus}$, 81).

Methylating Reductive Dimerization of Aromatic Carbonyl Compounds, a Novel Organometallic Reaction**

By *Thomas Kauffmann,** *Jan Jordan*, and *Karl-Uwe Voss*

The reductive dimerization of carbonyl compounds with titanium[1] or tungsten reagents[2, 3] according to Equation (a) is already a well-established reaction in organic synthesis. We have now found a related reaction, according to

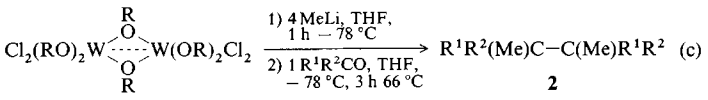
[**] Transition Metal Activated Organic Compounds, Part 35. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. – Part 34. T. Kauffmann, A. Hülsdünker, D. Menges, H. Nienaber, L. Reithmeier, S. Robbe, D. Scherler, J. Schrickel, D. Wingbermühle, *Tetrahedron Lett. 31* (1990) 1553.

Equation (b), for which to our knowledge there is no known analogy.

$$R^1R^2C{=}O \longrightarrow R^1R^2C{=}CR^1R^2 \quad (a)$$

$$R^1R^2C{=}O \longrightarrow R^1R^2(Me)C{-}C(Me)R^1R^2 \quad (b)$$

Reaction of $[WOCl_3(thf)_2]$[4] as well as of the W^{VI} complexes $[WOCl_4]$,[4] $[(MeO)WOCl_3]$,[5] and $[(MeO)_4WCl_2]$[5] with, in each case, two molar equivalents of methyllithium in THF leads to μ-methylene complexes[6] which react as carbonyl olefinating reagents with aldehydes and ketones. In contrast, in the case of the W^V-complexes $[\{(nPrO)_3WCl_2\}_2]$ and $[\{(EtO)_3WCl_2\}_2]$, which were synthesized according to the method described in Refs. [7, 8] and which according to Refs. [8, 9] and some ^{1}H-NMR investigations[5] have the dimeric structures **1a** and **1b**, respectively, the corresponding reaction, with in each case 4 molar equivalents of MeLi and subsequently with *aromatic* aldehydes and ketones [Eq. (c)] led to methylating coupling (Table 1).[5, 10] The two



$$Cl_2(RO)_2W(\mu\text{-}O)_2W(OR)_2Cl_2 \longrightarrow R^1R^2(Me)C{-}C(Me)R^1R^2 \quad (c)$$

2

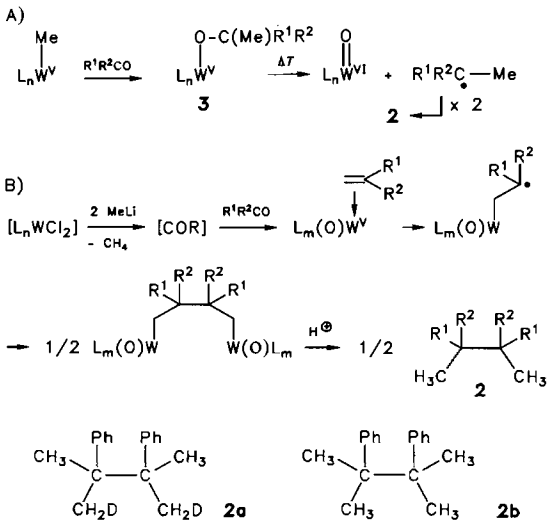
1a, R = *n*Pr; **1b**, R = Et

Table 1. Reactions according to Equation (c).

Reagent	Carbonyl compound	Product **2** Yield [%]	Isomeric ratio	Recovery Carbonyl cpd. [%]
1a	benzaldehyde	77	ca. 1:1	–
1a	4-methoxybenzaldehyde	76	ca. 1:1	–
1b	4-methoxybenzaldehyde	76	ca. 1:1	–
1a	heptanal	–	–	–
1a	acetophenone	83	–	–
1a	benzophenone	90 [a]	–	–
1a	cyclohexanone	–	–	ca. 100

[a] The disproportionation products 1,1-diphenylethane and 1,1-diphenylethene (each ca. 90% of theoretical) were isolated.

aliphatic carbonyl compounds listed in Table 1 did not undergo this reaction. The 2,2,3,3-tetraphenylbutane formed from benzophenone disproportionates to 1,1-diphenylethane and 1,1-diphenylethene;[11] accordingly only these disproportionation products could be isolated. All the products of the reactions listed in Table 1 are known.[12]



Scheme 1. A) Probable reaction mechanism. B) Rejected reaction mechanism. COR = carbonyl olefinating reagent.

For the reactions according to Equation (c) we postulated the mechanism formulated in Scheme 1 A, which probably takes place at the dimeric reagent. The homolysis of the O–C bond of **3** could be favored by the fact that the electron attracting oxo ligand formed enables an energy-decreasing mesomeric interaction with the electron repelling alkoxy ligands. The following observations in the reaction of **1a** with acetophenone rule out the alternative mechanism (Scheme 1 B):[5] a) no methane was liberated; b) on using D_2O instead of H_2O in the reaction the bisdeuterated product **2a** was not formed; c) **2a** was also not formed when $[D_8]$THF was used as solvent instead of THF; d) according to NMR investigations **2b** was already present before the hydrolysis.

Experimental

A solution of complex **1a** (4.32 g, 10 mmol) in tetrahydrofuran (25 mL) was treated under argon at −78 °C with a solution of four molar equivalents of methyllithium in ether (1.6 M). After stirring for 1 h at −78 °C (the negative Gilmann test with Michlers ketone [13] showed complete consumption of the methyllithium) one mol equivalent of the carbonyl compound was added to the mixture. The mixture was then warmed to room temperature within 1 h and heated under reflux for a further 3 hours. After cooling to room temperature the mixture was hydrolyzed with 25 mL of 2 N NaOH and worked up in the usual way.

[**] This work was supported by the Science and Engineering Research Council.

thanoids) perovskites, there have been surprisingly few model compounds reported which would enable magnetic interactions between copper and lanthanoids to be investigated within discrete molecules. The two exceptions to this are the Schiff base complexes of *Gatteschi* and co-workers,[5] and two Ln_2Cu_4 complexes synthesized by *Goodgame* et al.[6][*] Here we report the synthesis, characterization and preliminary magnetometry of two such compounds: an octanuclear La_4Cu_4 complex which contains unprecedented structural features, and a hexanuclear Gd_2Cu_4 complex in which the Gd and Cu atoms are ferromagnetically coupled.

Reaction of the anion of 2-hydroxypyridine (L) with copper nitrate and lanthanum perchlorate in methanol gives blue crystals. The structural analysis[7] reveals a salt (**1**) of ex-

$$[Cu_4La_4(L)_8(LH)_8(ClO_4)_2(NO_3)_2(OH)_4(CH_3O)_2](ClO_4)_2 \cdot 2H_2O \quad \mathbf{1}$$

tremely complicated stoichiometry. The octanuclear centrosymmetric dication is shown in Figure 1. The central region of the dication is dominated by a plane of four La atoms, with each La–La vector bridged by at least two oxygen atoms. The two pairs of Cu atoms are separated by this plane, and overall the eight metal atoms form a distorted hexagonal bipyramid.

La1 and its symmetry equivalent La1′ lie at the apices of the polyhedron (Fig. 1b), bridged by two μ_3-hydroxide ions (O9 and O9′) forming a centric La_2O_2 ring. O9 also bonds to La2, and La1 and La2 are further bridged by an oxygen (O4) from a deprotonated 2-hydroxypyridine. La1 and La2′ share three oxygen donors, O9′ and two oxygens (O2′ and O3) from deprotonated ligands. The La–La distances within these La_2O_2 rings vary from 3.8822(7) Å to 4.1416(7) Å, similar to those found in other Ln_2O_2 rings[8, 9] (allowing for the differing ionic radii of various lanthanoids).

La1 also shares a μ_3-hydroxide ion (O10) with both Cu1 and Cu2, and in addition the two copper atoms are bridged by O40 (an oxygen from a deprotonated methanol molecule) to form a Cu_2O_2 ring with a Cu–Cu distance of 3.0172(16) Å, again similar to those in related compounds.[10, 11] The La and Cu atoms are also linked by L units, which are in the main trinucleating: each oxygen atom bridges two La atoms and the nitrogen binds to Cu.

Each of the four crystallographically independent metal atoms has a different coordination geometry (Fig. 1b). La1 is nine-coordinate, bound to six shared oxygens as itemized above, a bidentate nitrate (O31 and O33) and an oxygen (O8) from a protonated ligand. The geometry is distorted monocapped square-antiprismatic. La2 is eight-coordinate, bound to four aforementioned bridging oxygens, an oxygen (O1) from a binucleating L unit, and three oxygens (O5, O6 and O7) from protonated ligands. The geometry corresponds to a square antiprism. Cu2 is square-pyramidal: the apical oxygen comes from a loosely associated ClO_4^- anion (Cu1–O11 2.508(8) Å); the basal donor atoms are two *cis* nitrogen atoms from L units (N1 and N3) and the two bridging oxygen atoms (O10 and O40) mentioned above. Cu2 has distorted square-planar geometry, again with two *cis* nitrogen atoms (N2 and N4) supplementing the shared oxygens. The bond lengths between metals and donor atoms are unexceptional; La–O varies from 2.37 to 2.69 Å, and Cu–O and Cu–N bonds between 1.93 and 2.00 Å (excepting the long bond to the apical perchlorate).

Several of these features are highly unusual. The plane of four La atoms, each vector bridged by oxygen atoms, is reminiscent of several multinuclear manganese complex-

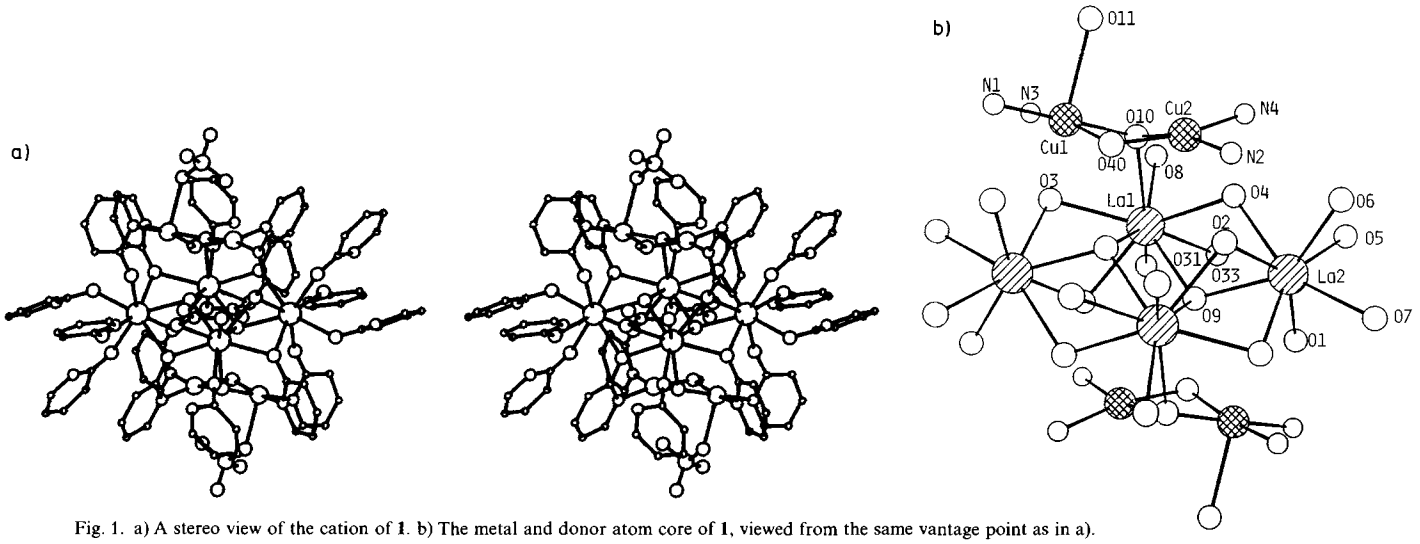

Fig. 1. a) A stereo view of the cation of **1**. b) The metal and donor atom core of **1**, viewed from the same vantage point as in a).

es[12] which have displayed interesting magnetic properties. Only once previously, in an octanuclear erbium complex,[13] has such a feature been observed for an f-block element. The interposing of such a plane between hetero metal atoms is unprecedented. The mean plane of the two Cu atoms and their six basal donor atoms is canted at 24.3° to the plane of four La atoms.

Attempts to make an analogous Gd_4Cu_4 complex have thus far failed. Instead a purple precipitate forms, which on treatment with HCl gives a green solution and, after one day, green crystals. The structure of the resulting compound (**2**) has been determined[7] (Fig. 2). The cation contains an octa-

$$[Cu_4Gd_2Cl_4L_8(LH)_4(H_2O)_4] \cdot 2Cl \cdot H_2O \quad \mathbf{2}$$

hedral metal core of four Cu and two Gd atoms. The arrangement of bridging atoms is similar to that found for other Ln_2Cu_4 complexes.[6] The 2-hydroxypyridine ligands

[*] Note added in proof (July 31, 1991): After this manuscript had been accepted, a paper appeared on the structure of a Y_2Cu_8–2-hydroxypyridine complex (S. Wang, *Inorg. Chem. 30* (1991) 2252). This complex was synthesized in virtually the same way as the Gd_2Cu_4– and Dy_2Cu_4–2-hydroxypyridine complexes described in [6].

act as trinucleating bridges, binding via the O atom to Gd and Cu atoms, and via the N to a second Cu atom. The Gd atoms are eight-coordinate with square antiprismatic geometry; the Cu atoms are five-coordinate with square-pyramidal geometry—two N and two O atoms in the basal plane (arranged *cis*), and a Cl atom in the axial position.

Magnetic measurements on both complexes[14] over the temperature range 310 K to 70 K show interesting behavior. In **1** there is strong antiferromagnetic coupling between pairs of Cu ions, presumably mediated by the μ_2-OMe and μ_3-OH ligands. This leads to a magnetic moment below the spin-only value at room temperature, and diamagnetic behavior below 100 K. In **2** the magnetic moment rises from 8.36 μ_B at 310 K to 8.78 μ_B at 170 K. Below this temperature the moment falls, reaching 8.16 μ_B at 70 K.

An explanation of this behavior in **2** is that there is ferromagnetic coupling between each Gd^{III} and the two Cu atoms with which it shares μ_2-carbonyl bridging oxygens (i.e., the labeled metals in Fig. 2). This accounts for the increase in magnetic moment between 310 K and 170 K. That the moment falls again below this temperature is probably due to anti-ferromagnetic coupling between the two Cu_2Gd "triangles" within each complete molecule of **2**. Thus, as observed previously,[5] copper and gadolinium ions appear to couple ferromagnetically.

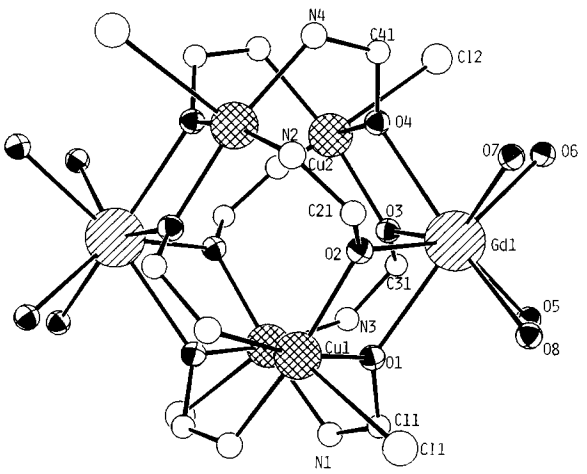

Fig. 2. The cation of **2**, with atoms not involved in metal-atom bridging omitted for clarity. Bond length ranges: Gd-O 2.283–2.507, Cu-O 1.965–2.008, Cu-N 1.969–1.997, Cu-Cl 2.640, 2.644 Å. Standard deviation 0.012 Å.

The straightforward synthetic procedures for **1** and **2** and the dependence of the resulting structure changes on reaction conditions suggest that a rich chemistry of mixed d-block and f-block complexes remains to be explored, and the observation of ferromagnetic coupling between d- and f-block elements confirms that this is a promising approach to new molecular magnets.[15]

Experimental procedure

1: deprotonated 2-hydroxypyridine (1 mmol, prepared from LH and KOH in water) was dissolved in methanol (5 ml) and copper nitrate (0.33 mmol) in methanol (2 ml) was added dropwise. The resulting green solution was filtered and lanthanum perchlorate (0.17 mmol) in methanol (1 ml) was added dropwise giving a purple solution, from which blue crystals grew after standing for 16 hours. IR: $\tilde{\nu}$(OH) = 3595 and 3510 cm^{-1}; $\tilde{\nu}$(CO) 1662, 1645, and 1605 cm^{-1}. No molecular ion observed by FABMS. Magnetic moment, solid state [(*T*/K) μ_{eff}/μ_B per Cu atom]: (309.8) 0.96, (288.6) 0.91, (268.5) 0.85, (247.6) 0.78, (227.7) 0.77, (207.2) 0.71, (187.2) 0.67, (165.5) 0.44, (145.8) 0.39, (125.9) 0.35, (106.0) 0.30. Diamagnetic within error below this temperature.

2: An analogous procedure using gadolinium perchlorate gave a purple precipitate. This was collected by centrifugation and suspended in fresh methanol (7 ml). Concentrated HCl (4 drops) was added, giving a green solution from which crystals formed after one day. IR: $\tilde{\nu}$(CO) 1652 and 1610 cm^{-1}. No molecular ion by FABMS. Magnetic moment, solid state [(*T*/K) μ_{eff}/μ_B per Cu_2Gd unit] (309.6) 8.36, (289.3) 8.49, (267.3) 8.43, (246.0) 8.45, (225.7) 8.68, (206.0) 8.68, (185.9) 8.75, (165.6) 8.78, (145.0) 8.66, (125.4) 8.43, (105.2) 8.13 (84.8) 8.34, (69.6) 8.16. Errors of ca. 1% in each measurement of μ_{eff}/μ_B.

[15] Note added in proof: Since acceptance of this manuscript the crystal structure of a Y_2Cu_8 complex of 2-hydoxypyridine has appeared [S. Wang, *Inorg. Chem. 30*, (1991), 2252]. This complex was prepared by an essentially identical route to that used to synthesize Gd_2Cu_4 and Dy_2Cu_4 complexes of 2-hydroxypyridine, as reported in [6].

A Novel Gallium–Phosphorus Cage Compound**

By *Alan H. Cowley,* Richard A. Jones,* Miguel A. Mardones, Jerry L. Atwood,** and *Simon G. Bott*

The revival of interest in "13–15" compounds of the heavier main-group elements is attributable in part to the potential utility of such species as semiconductor precursors. Thus far, much of the synthetic effort has focused on how the biligated R_2M (M = Al, Ga, In) and R'_2E (E = P, As, Sb)

moieties are bonded together.[1] Significantly less emphasis has been placed on compounds that involve monoligated RM and R'E fragments.[*] In an effort to develop this area further, we treated $K_2[t\text{BuPP}t\text{Bu}]$[2] with $t\text{BuGaCl}_2$[3] in the expectation that a three-membered GaP_2 or six-membered Ga_2P_4 ring would be produced.[4] However, the reaction product is a novel Ga_3P_4 cage compound in which a $t\text{BuGaCl}_2$ unit behaves simultaneously as a Lewis acid and a Lewis base.

Addition of three equivalents of $t\text{BuGaCl}_2$ to two equivalents of $K_2[t\text{BuPP}t\text{Bu}]$ at $-78\,^\circ\text{C}$ in THF, followed by removal of the solvent and recrystallization of the residue from toluene, resulted in light yellow, crystalline **1**. The CI mass spectrum of **1** revealed a parent peak at m/z 804 (1.4%), followed by fragment ions at m/z 607 (59%) and 549 (100%), which correspond to $[M - t\text{BuGaCl}_2]^+$ and $[M - t\text{BuGaCl}_2 - t\text{Bu}]^+$, respectively. The loss of a $t\text{BuGaCl}_2$ fragment suggests a structure in which this molecule is attached to a $(t\text{Bu})_6Ga_2P_4$ ring system. Such a view is consistent with NMR spectroscopic data.[5] Thus, four tBuP groups and two different tBuGa units in 2:1 abundance are evident in the ^{1}H NMR spectrum. The $^{31}P\{^1H\}$ spectrum comprises two broad doublets of equal intensity with a coupling constant (284 Hz) that is indicative of a one-bond interaction. These data suggest that two of the phosphorus atoms are involved in coordination to the $t\text{BuGaCl}_2$ molecule. Further elucidation of the structure of **1** required an X-ray analysis (Fig. 1).[6] The solid state of **1** consists of

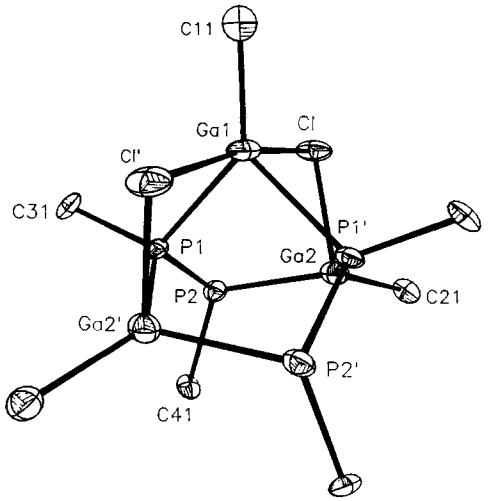

Fig. 1. View (ORTEP) of **1** showing the atom numbering scheme. The tBu methyl groups are omitted for clarity. Important bond distances [Å] and bond angles [°]: Ga1-P1 2.436(3), Ga1-C11 2.04(2), Ga1-Cl 2.681(3), Ga2-P2 2.363(3), Ga2-C21 2.01(1), Ga2-Cl 2.344(3), Ga2-P1' 2.416(3), P1-C31 1.895(9), P1-P2 2.182(3), P2-C41 1.91(1); P1'-Ga1-P1 90.55(8), P1'-Ga1-Cl 81.21(8), P1-Ga1-C11 134.66(6), P1-Ga1-Cl 92.14(8), Cl'-Ga1-Cl 170.47(8), Cl-Ga1-C11 94.78(6), P2-Ga2-Cl 89.8(1), P1'-Ga2-P2 107.8(1), P2-Ga2-C21 120.6(3), P1'-Ga2-Cl 88.7(1), P1'-Ga2-C21 129.6(3), Cl-Ga2-C21 103.4(2), Ga1-P1-Ga2' 87.56(7), Ga2'-P1-P2 122.0(1), Ga2'-P1-C31 117.5(3), Ga1-P1-P2 106.8(1), Ga1-P1-C31 113.6(3), P2-P1-C31 107.5(3), Ga2-P2-P1 97.3(1), P1-P2-C41 110.1(3), Ga2-P2-C41 116.3(3).

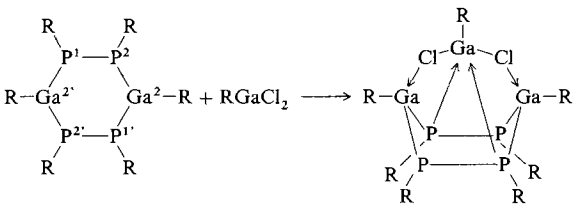
individual molecules and no short intermolecular contacts. Each molecule resides on a twofold axis that passes through Ga1 and C11. A convenient way to visualize the structure of **1** is to regard it as a complex of $t\text{BuGaCl}_2$ and ring system **2**.



2 R = tBu **1**

Two of the phosphorus atoms of ring **2**, P1 and P1', are involved in electron-pair donation to the $t\text{BuGaCl}_2$ molecule and the bonding in the cluster is completed by the formation of Cl bridges between $t\text{BuGaCl}_2$ and the ring gallium atoms. In a formal sense, the $t\text{BuGaCl}_2$ molecule plays the role of both Lewis acid and Lewis base.[7] In this context, the geometry around Ga1 is best described as trigonal bipyramidal. Note, however, that the axial (Cl-Ga1-Cl' = 170.47(8)°) and equatorial (P1-Ga-P1' = 90.55(8)°) angles depart considerably from the ideal values as a consequence of the donor and acceptor interactions with the Ga_2P_4 ring. Note also that the Ga–Cl–Ga bridges are very unsymmetrical and that the Ga1–Cl distances (2.681(2) Å) are unusually long (cf. $[t\text{BuGa(Cl)P(H)Ar}']_2$, Ar' = 2,4,6-$t\text{Bu}_3C_6H_2$, Ga-Cl = 2.397(2) Å).[3] The Ga_2P_4 ring of **2** adopts a boat conformation, doubtless in large measure a response to maximizing the dative interactions between P1 and P1' and the $t\text{BuGaCl}_2$ molecule. Within the Ga_2P_4 ring, the bond lengths between Ga and the three-coordinate P atoms, P2 and P2', are somewhat shorter (2.363(3) Å) than those involving the four-coordinate P atoms, P1 and P1' (2.416(3) Å). Note, however, that the geometry at P2 and P2' is pyramidal (sum of angles = 323.7°); hence there is no evidence for dative P → Ga π bonding.

Attempts to isolate or detect ring system **2** by treatment of $K_2[t\text{BuPP}t\text{Bu}]$ with an equimolar quantity of $t\text{BuGaCl}_2$ were not successful. We therefore conclude that either compound **2** is unstable or the mechanism of formation of **1** does not involve **2**.

Experimental Procedure

A cold (−78 °C) solution of $t\text{BuGaCl}_2$ [3] (0.71 g, 3.61 mmol) in 20 mL of THF was added to a stirred suspension of $K_2[t\text{BuPP}t\text{Bu}] \cdot 0.5$ THF [2] (0.70 g, 2.40 mmol) in 20 mL of THF at −78 °C. The reaction mixture was allowed to attain ambient temperature over a 12 h period. Following this, the solvent and volatiles were removed under vacuum and the residue was extracted with toluene. After filtration and concentration of the filtrate, light yellow crystals of **1** were obtained in 44% yield (0.43 g) by cooling the solution to −20 °C. Compound **1** melts at 190–193 °C (dec.).

Tetrameric Gallium and Aluminum Chalcogenides, [*t*BuME]$_4$ (M = Al, Ga; E = S, Se, Te). A New Class of Heterocubanes**

By *Alan H. Cowley,* Richard A. Jones,* Paul R. Harris, David A. Atwood, Leopoldo Contreras*, and *Christof J. Burek*

Cubic chalcogenide clusters featuring transition-metal fragments, $[L_nM(\mu_3\text{-}E)]_4$ (E = S, Se, Te), constitute a well-known class of compounds.[1] However, the corresponding cubanes in which the organometallic moiety L_nM is replaced by a main-group fragment are nonexistent. The closest examples of main-group species with an M_4E_4 core possess the general formula $[RM(\mu_3\text{-}ER')]_4$ in which M = Mg[2] or Be,[3] E = O or S, and R and R′ are alkyl groups.[4] We were prompted to attempt the synthesis of group 13/16 cubanes of the type $[RM(\mu_3\text{-}E)]_4$ (M = Al, Ga; E = S, Se, Te) for two reasons. First, our recent synthesis of $[t\text{BuAl}(\mu_3\text{-}PSiPh_3)]_4$, the first aluminum–phosphorus cubane,[5] suggested the existence of isoelectronic group 13/16 analogues. Secondly, interest in group 13/16 cubanes stems both from their structures and bonding and also from their potential to function as precursors to layer compounds such as GaS, GaSe, and GaTe.[6]

The reaction of *t*Bu$_3$Ga with elemental sulfur, selenium, or tellurium in toluene at 25 °C affords cubanes $[t\text{BuGa}(\mu_3\text{-}E)]_4$ (**1**, E = S; **2**, E = Se; **3**, E = Te) in yields of 55 to 70%. In the cases of **1** and **2** the reaction mixtures also contain appreciable amounts of *t*Bu$_2$S and *t*Bu$_2$Se as well as other alkylated sulfur and selenium species (e.g., *t*Bu$_2$S$_2$ and *t*Bu$_2$Se$_2$) [Eq. (a)]. The reaction of *t*Bu$_3$Ga with H_2S represents an alternative high-yield route to **1** [Eq. (b)].

$$4\,t\text{Bu}_3\text{Ga} + 4\text{S} \longrightarrow \underset{\mathbf{1}}{[t\text{BuGa}(\mu_3\text{-S})]_4} + t\text{Bu}_2\text{S} + \text{other products} \quad \text{(a)}$$

$$4\,t\text{Bu}_3\text{Ga} + 4\,\text{H}_2\text{S} \longrightarrow \underset{\mathbf{1}}{[t\text{BuGa}(\mu_3\text{-S})]_4} + 4\,t\text{BuH} \quad \text{(b)}$$

After recrystallization or sublimation, compounds **1**–**3** were obtained as clear, colorless crystals. An X-ray diffraction study has been carried out on **1** (Fig. 1).[7] The molecule

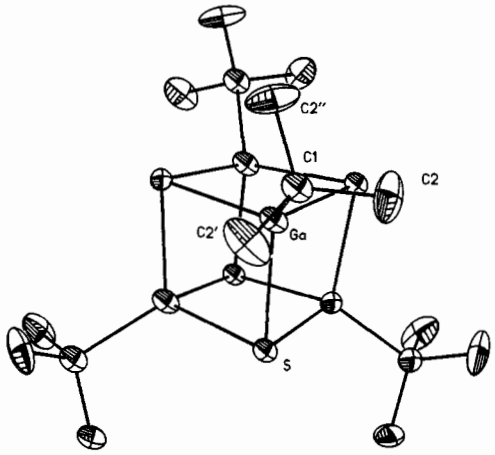

Fig. 1. View (ORTEP) of **1** showing the atom numbering scheme. Important bond distances [Å] and bond angles [°]: Ga-S 2.365(5), Ga-C1 2.00(4), C1-C2 1.48(3); S-Ga-S′ 87.0(3), Ga-S-Ga′ 92.3(3), S-Ga-C1 119.7(2). The atoms labeled with a prime are generated by reflection through a crystallographic center of symmetry.

contains only four unique atoms (Ga, S, C1, and C2) with each gallium atom lying on a fourfold symmetry site. The methyl groups of the *t*Bu units are perfectly disordered over six sites each with 50% occupancy. The angles of the cube

[**] This work was supported by the National Science Foundation, The Robert A. Welch Foundation, the Eastman Kodak Company, and the U.S. Army Research Office (DAAL 03-89-K-0164). Dr. *Contreras* is the recipient of a Fulbright Fellowship (1990/91). We thank Dr. *H. Gysling*, Eastman Kodak Company, for helpful discussions.

are close to the idealized values (Ga-S-Ga′ = 92.3(3) Å and S-Ga-S′ = 87.0(3) Å). The Ga–Ga distance (3.099(6) Å) indicates little or no metal–metal bonding within the cluster. The Ga–S distance of 2.365(5) Å is similar to the Ga–S single-bond distances found in $[Ph_2Ga(\mu\text{-}SEt)]_2$ (2.373(1) Å) and $[I_2Ga(\mu\text{-}SMe)]_2$ (2.398(5) Å).[8] Cubane structures for **1–3** are also consistent with analytical and spectroscopic data (Table 1). Thus, each compound exhibits a parent peak in the EI mass spectrum and the ^1H and $^{13}C\{^1H\}$ NMR spectra reveal that all four *t*Bu groups are equivalent. No ν_{E-H} peaks were detected in the IR spectra.

The corresponding reactions of tBu_3Al with sulfur, selenium, and tellurium also afford cubanes, $[t\text{BuAl}(\mu_3\text{-E})]_4$ (**4**, E = S; **5**, E = Se; **6**, E = Te). However, in these cases it is possible to isolate intermediate dimeric compounds of the type $[tBu_2Al(\mu_2\text{-E}t\text{Bu})]_2$ (**7**, E = S; **8**, E = Se; **9**, E = Te) as summarized in Equation (c). In these reactions no tBu_2E or other alkylated chalcogenide species have been detected.

$$2\,tBu_3Al + 2\,E \longrightarrow \underset{\mathbf{7-9}}{[tBu_2Al(\mu_2\text{-E}t\text{Bu})]_2} \qquad (c)$$

There is precedent[9] for the insertion of sulfur or selenium into aluminum–carbon bonds; however, this appears to be the first such insertion of tellurium. Compounds **4–9** were characterized spectroscopically (Table 1) and structural information for **9** was provided by an X-ray analysis.[7] The solid state of **9** consists of individual dimeric molecules with no short intermolecular contacts (Fig. 2). A twofold axis

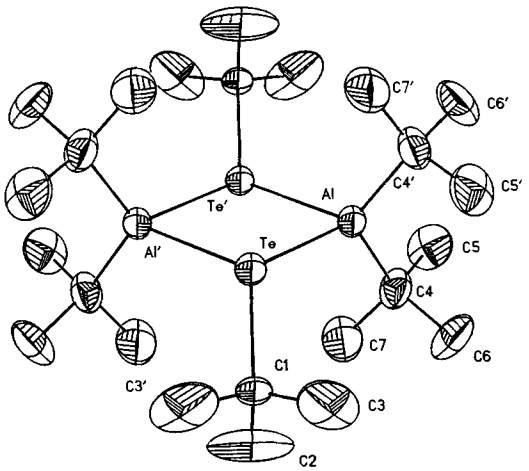

Fig. 2. View (ORTEP) of **9** showing the atom numbering scheme. Important bond distances [Å] and bond angles [°]: Te-Al 2.732(3), Te-C1 2.21(1), Al-C4 2.00(1); Te-Al-Te′ 86.1(4), Al-Te-Al′ 93.9(4), C1-Te-Al 107.1(5), C1-Te-Al′ 121.6(3), Te-Al-C4 121.1(3), Te-Al-C4′ 101.9(2), C4-Al-C4′ 120.8(2).

passes through the Al atoms and the Te, C1, and C2 atoms lie on a mirror plane; hence the Al_2Te_2 core is planar. The gallium–sulfur dimers $[Ph_2Ga(\mu_2\text{-SMe})]_2$ and $[I_2Ga(\mu_2\text{-SMe})]_2$ also have planar rings.[10] Interestingly, however, $[R_2Ga(\mu_2\text{-TePh})]_2$ ($R = Me_3CCH_2$)[11] and $[I_2Ga(\mu_2\text{-}Si\text{Pr})]_2$[12] adopt butterfly structures. The Al–Te bond distance of 2.732(3) Å in **9**, apparently the first such distance of a molecular compound, is 0.15 Å larger than the sum of tetrahedral covalent radii.[13]

Interestingly, the EI mass spectra for **7–9** exhibit molecular ions corresponding to the cubanes **4–6**. These implied dimer → cubane conversions also occur on the attempted sublimation of **7–9** [Eq. (d)]. The production of isobutene and

$$2[tBu_2Al(\mu_2\text{-E}t\text{Bu})]_2 \longrightarrow [t\text{BuAlE}]_4 + 2\,Me_2C{=}CH_2 + 2\,Me_3CH \qquad (d)$$

isobutane was detected by ^1H NMR spectroscopy. Heating toluene solutions of **7–9** at 100 °C for 48 h also results in quantitative conversion to the corresponding cubanes. The isolation of the intermediate dimeric compounds **7–9** and the absence of species such as tBu_2E and tBu_2E_2 in the tBu_3Al + E reaction mixtures suggest that the mechanistic pathway for the formation of the aluminum cubanes is different from those leading to gallium cubanes. Further studies which address this are in progress.

Experimental Procedure

1–3: Neat tBu_3Ga (0.6 mL, 2.5 mmol) was added dropwise to a stirred suspension of 5.0 mmol of elemental sulfur, selenium, or tellurium in toluene (25–30 mL) at room temperature. The suspensions were stirred (**1**, 1 h; **2**, 4 h) at room temperature; in the case of **3** it was necessary to heat the suspension to 60–70 °C for several hours. Toluene and other volatiles were then removed under reduced pressure. Waxy solid **1** was washed with 10 mL of cold (−78 °C) pentane. Mixtures of tBu_2E, tBu_2E_2, and other organochalcogenides were identified by ^1H NMR and mass spectroscopy in the washings. After one sublimation (150 °C, 10^{-2} Torr), the yield of colorless, microcrystalline **1** was 70%. Following filtration of the reaction solution from unreacted elemental Se or Te, pure **2** and **3** were obtained as colorless, crystalline solids in yields of 60 and 55%, respectively, by recrystallization from pentane solutions (−20 °C). Compound **1** can also be prepared by condensing an excess of H_2S (0.5 mL, 1.25 mmol) onto frozen, neat tBu_3Ga (0.3 mL, 1.25 mmol) at −78 °C. The mixture was allowed to warm until the H_2S exerted about 0.5 atm of pressure, as measured by a mercury manometer, before being cooled to −196 °C. This cycle was repeated two to three times to ensure completion of the reaction. Excess H_2S was allowed to boil off under a vigorous stream of nitrogen into a sodium hypochlorite bubbler solution (1%w/w) as the mixture was warmed to room temperature (15 min). The resulting white powder was extracted with warm (40 °C) toluene (15 mL). After filtration and concentration of the filtrate, colorless crystals of **1** formed in virtually quantitative yield (based on the tBu_3Ga consumed).

7–9: Neat tBu_3Al (0.5 mL, 2.5 mmol) was treated with 5.0 mmol of elemental sulfur, selenium, or tellurium as described above for **1–3**. The reaction times at 25 °C for **7** and **8** were 1 and 6 h, respectively; for **9**, the reaction mixture was heated for several hours at 60–70 °C. Following filtration from excess elemental S, Se, or Te and removal of the toluene and other volatiles, the resulting residues were recrystallized from pentane solution at −40 °C. Colorless **7** and **8** and yellow **9** were isolated as crystalline solids in yields of around 60%.

4–6: These cubanes can be produced quantitatively by heating toluene solutions of **7**, **8** and **9** to 100 °C for 48 h. Alternatively, these dimer → cubane conversions can be effected quantitatively by controlled pyrolysis of **7**, **8**, and **9** at 300 °C and 1 atm pressure. Partial conversion was also achieved under sublimation conditions (150 °C, 10^{-2} Torr). The gases evolved during the sublimation of **9** were shown to be an equimolar mixture of isobutene and isobutane by ^1H NMR spectroscopy.

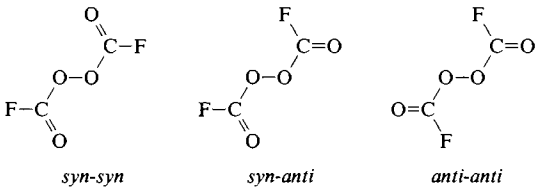
Bis(fluorocarbonyl) Peroxide; an Unusual Molecular Structure **

By *Hans-Georg Mack, Carlos O. Della Védova,* and *Heinz Oberhammer**

Dedicated to Professor Joseph Grobe

The most interesting feature in the structure of peroxides (X_2O_2) is the dihedral angle δ(XOOX). In the gas phase, this angle for the parent compound H_2O_2 is 120(5)°,[1a] but in most other peroxides it is larger: 123(4)° in $(CF_3)_2O_2$,[1b] 129(2)° in $(SF_5)_2O_2$,[1c] 135(5)° in $(CH_3)_2O_2$,[1d] 144(6)° in $(SiMe_3)_2O_2$,[1e] and 166(3)° in tBu_2O_2.[1e, 2] Two trends are evident from this rather limited number of experimental results: the dihedral angle increases with increasing steric requirements of the substituents and decreases with their increasing electron-withdrawing properties (cf. $(CF_3)_2O_2$ and $(CH_3)_2O_2$). Unusual structures that do not conform to these trends are found in difluoro- and dichloroperoxide.[3, 4] The dihedral angles for these compounds are smaller than 90° (88.1(4)° in F_2O_2 and 81.03(1)° in Cl_2O_2. Furthermore, the O–O bond in F_2O_2 is extremely short (121.9(2) pm) and the O–F bonds are very long (158.2(2) pm). Usually the qualitative explanation for the *gauche* orientation of substituents in peroxides is the interaction between the lone pairs on oxygen and the anomeric effect.[5] The latter describes a stabilizing overlap between the lone pairs of oxygen and the σ^* orbitals of the opposite O–X bond. The optimal dihedral angle thus depends on the form of the lone pairs, the size of the anomeric effect, and the steric demands of the substituents: according to this model the angle must be $\geq 90°$. From this point of view the structure of $(C(O)F)_2O_2$ promised to be interesting, since in this molecule a possible conjugation between the C=O π bonds might lead to a planar COOC framework, or at least to a pronounced opening of the dihedral angle.

In oxygen-rich $(C(O)F)_2O_2$ three conformers are possible, depending on the orientation of the two carbonyl groups, regardless of the dihedral angle δ(COOC): *syn-syn*, *syn-anti*, and *anti-anti*. Structures in which the carbonyl groups are



rotated around the O–C bond have not been considered. The C=O vibrational bands in the gas-phase and matrix IR spectra ($\nu_{as} = 1929$ and $\nu_s = 1902$ cm^{-1}) show that at room temperature only one conformer is present, and the shape of the symmetric band suggests a *syn-syn* structure.[6] This interpretation of the spectra is supported by ab initio calculations (HF/6-31G*). These calculations predict that the *syn-anti* conformer is 13.5 and the *anti-anti* conformer 26.9 kJ mol^{-1} higher in energy. The dihedral angle δ(COOC) and the other geometric parameters were determined by electron diffraction in the gas phase.

The analysis of the experimental radial distribution function calculated by Fourier transformation of the molecular scattering intensities (Fig. 1) confirmed the *syn-syn* configuration suggested by IR spectra and MO calculations. The

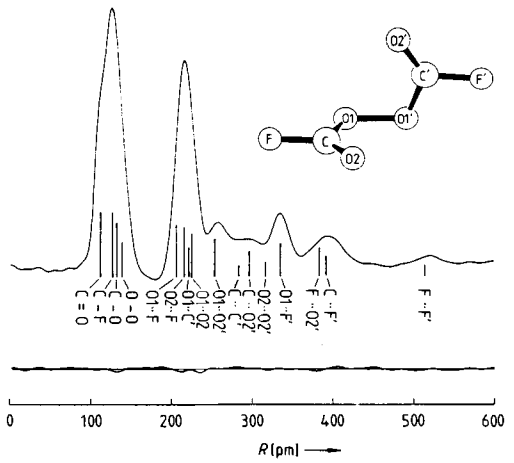


Fig. 1. Experimental radial distribution function for $(C(O)F)_2O_2$ and the difference curve. The positions of interatomic distances are indicated by vertical bars.

length of the interatomic distances between the two carbonyl groups corresponds to a dihedral angle δ(COOC) of ca. 85°. In the subsequent least-squares analysis of the scattering intensities, C_2 symmetry and nonrotated fluorocarbonyl groups (i.e., δ(O-O-C=O) = 0°) were assumed for this molecule. Optimization of the structure allowing for rotated carbonyl groups led to a value of $5 \pm 5°$ for this angle. The C–F

[a] r_a distances [pm] and $\angle_a$ angles [°] from electron diffraction studies. Errors refer to the last digit and are 3σ values. [b] Not refined. [c] Dependent parameter.

Some of the calculated values, in particular the O–O distance, depend strongly on the basis set (3-21G or 6-31G*). In general, experimental bond lengths are better reproduced with the smaller basis set. The agreement in bond angles is excellent, and the small experimental dihedral angle is confirmed by these ab initio calculations. In other peroxides[8] the experimental dihedral angle is correctly predicted by calculations only when electron correlation is taken into account. The dihedral angle in bis(fluorocarbonyl) peroxide is extremely small (83.5(14)°), in contrast with the opening of the angle anticipated for conjugation between C=O π bonds. It is comparable with the corresponding angles in F_2O_2 and Cl_2O_2. These peroxides have strongly electron-withdrawing substituents and the dihedral angle of less than 90° can only be described by the above-mentioned model when an attractive interaction between the substituents is postulated. The overlap populations between the atoms of the fluorocarbonyl groups calculated by *Mulliken*'s method (HF/6-31G*) are indeed slightly *positive* in some cases (+ 0.002 a.u. for C···C', 0.007 a.u. for C···O2'), and the sum of all interactions (0.014 a.u.) corresponds to *attraction* between the substituents. This attraction between the C atom of each carbonyl group and the O atom of the other is responsible for the theoretically predicted twisting of the carbonyl groups about the O–C bond by 4–6°, which leads to a shortening of the C···O2' distances. This slight twisting was not observed in the electron diffraction study.

Experimental Procedure

$(C(O)F)_2O_2$ has been known for more than 20 years and was prepared here by the same method [9]. The scattering intensities were recorded with a Balzers Gas Diffractograph KD-G2 [10] using two camara distances (25 and 50 cm) and an accelerating voltage of ca. 60 kV. The electron wavelength was calibrated with ZnO powder. The temperature of the sample was − 45°C, of the inlet nozzle 10°C. Two photographic plates for each camera distance were evaluated by standard methods [11] and the scattering intensities in the s ranges of 20–180 nm^{-1} and 80–350 nm^{-1} were used for the structure analysis. Molecular scattering intensities were modified by a diagonal weighting matrix and known values [12] were used for the scattering amplitudes and phases. The ab initio calculations were performed using the GAUSSIAN 86 program [13] and 3-21G and 6-31G* basis sets on a Convex-C220 computer (ZDVAM, University of Tübingen).

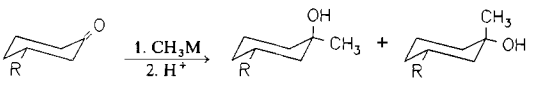
On the Origin of π-Facial Diastereoselectivity in Addition Reactions of Cyclohexane-Based Systems**

By *Gernot Frenking,* Klaus F. Köhler*, and *Manfred T. Reetz*

The failure of the Felkin-Anh[1] model to explain the observed diastereoselectivity in nucleophilic additions to substituted cyclohexanones and related systems and the alternative rationale based on the "Cieplak model"[2] are currently topics of lively discussion in stereochemistry.[2, 3] The most detailed experimental study pertinent to the subject has been carried out by *Cieplak*, who could show that in 3-substituted cyclohexanones the relative proportion of axial attack of the nucleophile *increases* when the substituent becomes more electronegative.[2b] The same trend was also found for the addition of electrophiles to 3-substituted methylenecyclohexanes (Scheme 1).[2b]



Scheme 1. Attack of a nucleophile CH_3M, for example CH_3Li, on a cyclohexanone.

The explanation given by *Cieplak* for the observed trend is based on a rather paradoxical assumption: Stereoelectronic control in cyclohexane-based systems is attributed to electron donation from the occupied orbitals of the cyclohexane

[*] Prof. Dr. G. Frenking, Dipl.-Chem. K. F. Köhler, Prof. Dr. M. T. Reetz

ring into the vacent *antibonding* σ* orbital associated with the incipient bond (Fig. 1).

In our opinion the Cieplak model is dubious for several reasons. First, it is difficult to understand why such orbital interactions are operative only in cyclohexane-based systems, while in other molecules the Cieplak model fails.[4] Second, a model which favors one reaction course relative to others because of better electron donation into the *antibonding* orbital of the incipient bond is not consistent with the concept of "allowed" and "forbidden" reactions in terms of orbital interactions. It is a clear contradiction to the frontier orbital model (FMO).[5] Since the FMO model is one of the most successful qualitative models for organic reactions,[5] it is difficult to believe that in cyclohexane-based systems an "anti-FMO" mechanism such as the Cieplak model is operative.

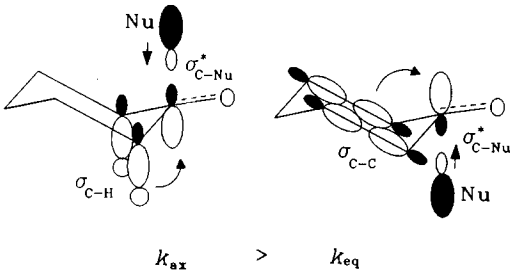

Fig. 1. Cieplak model [2] for the different interactions in the axial and equatorial attack of nucleophiles at cyclohexanones.

In this paper we show that the diastereoselectivity of nucleophilic additions to 3-substituted cyclohexanones observed by *Cieplak*[2b] can be explained without difficulties by the frontier-orbital model. To this end we calculated the transition state structures for the axial (a) and equatorial (e) addition of LiH to cylohexanone (1*(a), 1*(e)) and 3(e)-fluorocyclohexanone (2*(a), 2*(e)) using *ab initio* quantum chemical methods.[6] The optimized structures and relative energies are shown in Figure 2.

The rather long interatomic distances between the carbonyl C and the attacking hydride calculated for 1*(a), 1*(e), 2*(a), and 2*(e) indicate early transition states. Similar results have been found in earlier theoretical studies on the addition of LiH to carbonyl compounds.[4, 7] The axial attack of LiH at cyclohexanone is theoretically predicted to be favored by 1.4 kcal mol^{-1} relative to the equatorial attack (MP2/6-31G(d)//HF/3-21G). This is in agreement with experiments which show that in the reduction of 4-*tert*-butylcyclohexanone with $LiAlH_4$ a 92:8 ratio of equatorial:axial alcohol is obtained.[8] Substitution by fluorine in the (equatorial) 3(e)-position of cyclohexanone increases the calculated energy difference in favor of the axial attack, i.e. 2*(a) is 2.7 kcal mol^{-1} lower in energy than 2*(e) (Fig. 2). Thus, our calculated results for 1*(a), 1*(e), 2*(a), and 2*(e) agree with the observation[2b] that an electronegative substituent in the 3(e)-position of cyclohexanone favors axial attack.

Why are the transition states for axial attack 1*(a) and 2*(a) lower in energy than 1*(e) and 2*(e), respectively? *Houk* et al.[4a] suggested that the transition state for axial attack of a nucleophilic agent at cyclohexanone can be achieved without introducing significant ring strain, while the equatorial attack introduces torsional strain into the ring structure. We have recently shown[4c] that upon addition of LiH to 2-chloropropionaldehyde, the energy difference between the "Cram" and "anti-Cram" transition states is solely caused by the different energies of the substrate fragments in the transition state structures, and not by the interaction energies between the substrate and LiH. Figure 2 shows the relative energies of 1*(a), 1*(e), 2*(a), and 2*(e) calculated without LiH but with a frozen geometry of the substrate.

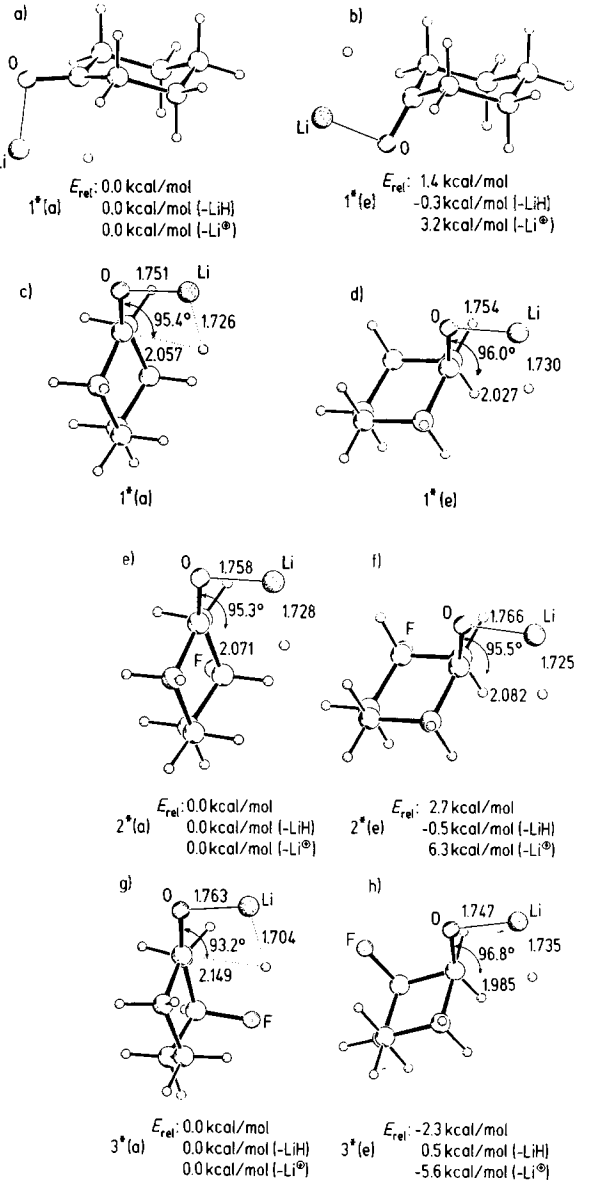

Fig. 2. Optimized transition state structures (HF/3-21G) for LiH attack at cyclohexanone systems. (a) Axial attack at cyclohexanone 1*(a); (b) equatorial attack at cyclohexanone 1*(e); (c) same as (a) but with different perspective which shows that the attacking nucleophile is *trans* to a C–H bond; (d) same as (b) but with a different perspective which shows that the attacking nucleophile is *trans* to a C–C bond; (e) axial attack to 3(e)-fluorocyclohexanone 2*(a); (f) equatorial attack to 3(e)-fluorocyclohexanone 2*(e); (g) axial attack at 3(a)-fluorocyclohexanone 3*(a); (h) equatorial attack at 3(a)-fluorocyclohexanone 3*(e). Interatomic distances are given in Å, relative energies in kcal mol^{-1} at MP2/6-31G(d)//HF/3-21G

The energy differences between the cyclohexanone fragments of the axial and equatorial transition states are very small, even favoring slightly the equatorial attack. This provides clear evidence against the hypothesis that the transition state for axial attack is favored because it needs less ring strain than the equatorial transition state.[4a] It follows that

the stability differences must be due to interactions between the substrate and LiH. Figure 2 also shows the energy differences of the transition states calculated without $Li^{\oplus}$, but with a frozen geometry of the anionic fragment. The data predict that 1*(a) is favored over 1*(e) because of the better interaction of the ketone with $H^{\ominus}$ (3.2 kcal mol^{-1}). The corresponding energy difference between 2*(a) and 2*(e) is 6.3 kcal mol^{-1}. The conclusion is that the higher rate of axial attack of LiH on 3(e)-fluorocyclohexanone is caused by the better electronic interactions of the ketone with the attacking nucleophilic agent, and not by the different deformations of the substrate in the transition states, as suggested for cyclohexanones[4a] and calculated for acyclic compounds.[4c]

What type of orbital interactions are responsible for the differences between axial and equatorial attack? Using FMO theory,[5] the reaction course for the addition of a nucleophile to a carbonyl group should be controlled by the orbital interactions between the HOMO of the nucleophile and the ($\pi^*_{C=O}$) LUMO of cyclohexanone. Then, the axial and equatorial attacks are different due to the nonequivalent distribution of the LUMO on the two faces of the carbonyl π bond. Figure 3 shows that the size of the LUMO of cyclohexanone is clearly larger on the axial side than on the equatorial side. The nonequivalence of the π^* LUMO is determined by the contribution of the 2s orbitals of the C and O atoms of the carbonyl group. Table 1 shows the coefficients of the 2s and 2p AOs[9] of the carbonyl C atom. The contribution of the 2s AO (0.26) is significant and indicates a clear preference for axial attack.[10]

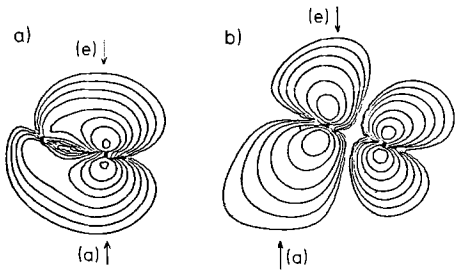

Fig. 3. Plot of the C=O π orbitals of cyclohexanone. The atoms are shown as dots, carbon at the left, oxygen at the right (6-31G(d)//3-21G). (a) $\pi_{C=O}$; b) $\pi^*_{C=O}$. The contour lines correspond to electron densities of 0.001, 0.002, 0.004, 0.008, 0.02, 0.04, 0.08, 0.2 atomic units.

The nonequivalence of the LUMO as the reason for preferential axial attack was originally suggested by *Klein*[11] who proposed that hyperconjugation of the ring C–C bonds with the carbonyl π bond causes unequal distribution of the LUMO, a greater extension being on the axial side (Fig. 4). However, *Klein*[11] also suggested that the occupied π orbital of exocyclic double bonds should be more extended on the equatorial side of the trigonal center, thus favoring equatorial attack for electrophilic addition, e.g. to methylenecyclohexane. This prediction, however, contradicts many experimental data.[2b, 8] Table 1 shows the AO coefficients of the occupied CO π orbital. The sign of the coefficients for the HOMO are the same for the LUMO! This means that both the CO π and π^* orbital are more extended to the axial side of the carbonyl bond. The same result is found for the π and π^* orbitals of the exocyclic double bond in methylenecyclohexane (Table 1). Thus, FMO theory predicts that orbital interactions during nucleophilic addition of small nucleophiles to cyclohexanone and electrophilic addition to methylenecyclohexane should for electronic reasons be preferred from the axial side, which is in agreement with experimental evidence.[2b, 8]

Table 1. Orbital coefficients [9] of the π and π^* orbitals of the exocyclic double bonds at the C_α atom for cyclohexanone and methylenecyclohexanone (Cy), 3(e)-fluorocyclohexanone and 3(e)-fluoromethylenecyclohexane (3F-Cy, e), and 3(a)-fluoromethylenecyclohexane (3F-Cy, a) at HF/6-31G(d)//HF/3-21G.

		Cyclohexanone		Methylenecyclohexane

	$2p_z$(o)	0.10	0.41		

Klein[11] rationalized the axial preference for nucleophilic attack and the equatorial preference for electrophilic attack at the exocyclic double bond with hyperconjugation of the (C_α)p orbital with the (β)C–C σ orbital as shown in Figure 4. He assumed that hyperconjugation of the (C_α)p orbital with the (β)C–H σ orbital, which is also shown in Figure 4, is of secondary importance. However, the natural-bond-orbital (NBO) analysis[12] of cyclohexanone shows that the $\pi^*_{C=O}$ orbital interacts more *strongly* with the (β)C–H σ orbital than with the (β)C–C σ orbital. Since interactions between the $\pi_{C=O}$ and $\pi^*_{C=O}$ orbitals and the bonding and antibonding (β)C–H and (β)C–C orbitals are all symmetry allowed, it is difficult to predict a priori which interactions are dominant without carrying out quantum mechanical calculations.

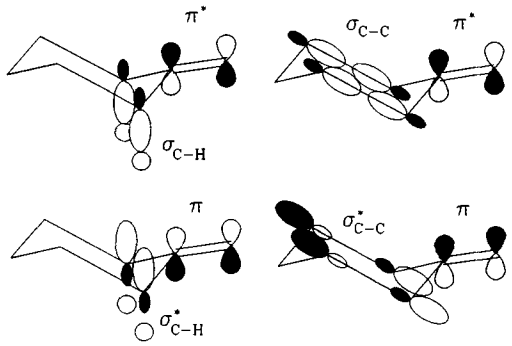

Fig. 4. Schematic representation of the hyperconjugation between the exocyclic π orbital and the (β)C–C and (β)C–H orbitals of cyclohexane systems.

What is the effect of the fluorine atom at the 3(e)-position of cyclohexanone on the relative size of the π orbitals on the axial and equatorial sides of the C–O bond? Table 1 shows the AO coefficients at the carbonyl C atom of the relevant orbitals. The contribution of the 2s(C) AO in the π orbitals is larger in the case of 3(e)-fluorocyclohexanone than in the case of cyclohexanone! Thus, FMO theory correctly predicts

that substitution at the equatorial 3-position of cyclohexanone by an electronegative substituent increases the preference for axial attack. Table 1 also shows that the contribution of the 2s(C) AO in the π orbitals in 3(a)-fluorocyclohexanone is smaller than in cyclohexanone. Indeed, our calculations predict a clear reversal towards equatorial attack for LiH addition to 3(a)-fluorocyclohexanone. This is in agreement with the calculated energies for the transition states 3*(a) and 3*(e) (Fig. 2). Equatorial attack is favored over axial attack by 2.3 kcal mol^{-1}, caused mainly by the better interactions between $H^{\ominus}$ and 3(a)-fluorocyclohexanone (5.6 kcal mol^{-1}). This is a further argument against the Cieplak model,[2] which predicts axial attack whether the electronegative substitutent is in the axial or in the equatorial position. The transition state for axial attack 3*(a) may additionally be disfavored by steric interactions between fluorine and the nucleophilic hydride ion. Our prediction that an electronegative substituent in the 3(a)-position of cyclohexanone enhances equatorial attack of a nucleophilic agent still has to be verified experimentally.

In conclusion, we have shown that symmetry-allowed frontier orbital interactions between the HOMO of the nucleophile and the LUMO of cyclohexanone favor axial over equatorial attack because the LUMO is more extended on the axial side of the carbonyl bond, and that the preference for axial attack is enhanced in 3(e)-fluorocyclohexanone. This inherent electronic preference can be overrided, however, by other factors such as steric interactions in the case of bulky nucleophiles.[13]

Reduction of Azobenzene by Naphthalene-ytterbium: A Tetranuclear Ytterbium(III) Complex Combining 1,2-Diphenylhydrazido(2−) and Phenylimido Ligands**

By *Alexander A. Trifonov, Mikhail N. Bochkarev,* Herbert Schumann,** and *Jörg Loebel*

Ytterbium halides are able to reduce N_2 in the presence of alkali-metal naphthalides under mild conditions to the −3 oxidation level (N^{3-}).[1-3] Attempts to separate a nitrogen-containing intermediate have been unsuccessful so far. The first N_2 complex of a lanthanide element, $[\{Sm(\eta^5\text{-}C_5Me_5)_2\}_2N_2]$, was formed during the recrystallization of $[Sm(\eta^5\text{-}C_5Me_5)_2]$ in a N_2 atmosphere.[4] Decamethylsamarocene also reacted with azobenzene to give three different samarium(III) complexes, which contain reduced azobenzene moieties as bridging ligands.[5, 6] Dicyclopentadienylytterbium(II) also reduces azobenzene to give $[\{Yb(\eta^5\text{-}C_5H_5)(thf)\}_2](N_2Ph_2)_2$.[6] We have investigated the reduction of azobenzene by mixtures of ytterbium(II) iodide and lithium naphthalide as a possible model of N_2 fixation and reduction. Here we report on the isolation of a stable intermediate and the X-ray crystallographic determination of this tetranuclear ytterbium(III) complex.

Ytterbium(II) iodide reacts with lithium naphthalide in THF to give a black pyrophoric powder, which contains $[Yb(C_{10}H_8)(thf)_3]$ (**1**).[7] Addition of **1** to a THF solution of azobenzene at room temperature results in the formation of a red-brown solution from which, after one week, deep red crystals of **2** separate.[8] These crystals are no longer soluble in organic solvents.

$$4[\underset{\mathbf{1}}{Yb(C_{10}H_8)(thf)_3}] + 5\,PhN{=}NPh \xrightarrow{THF} \underset{\mathbf{2}}{[Yb_4(\mu\text{-}\eta^2{:}\eta^2\text{-}Ph_2N_2)_4(\mu_3\text{-}PhN)_2(thf)_4]} + 4\,C_{10}H_8$$

At room temperature **2** shows a magnetic moment of $\mu_{eff} = 4.3$ BM, characteristic of Yb(III) compounds. It is extremely sensitive towards moisture and air. Hydrolysis results in the evolution of some hydrogen and the formation of $Yb(OH)_3$ and THF as well as $PhNH_2$, PhN=NPh, and PhNHNHPh (ratio around 1:2:2). When heated above 76 °C, **2** looses THF; it decomposes above 154 °C with darkening.

Crystallization from THF yielded single crystals of **2** containing two molecules of THF per formula unit. An X-ray crystal structure determination[8, 9] shows four ytterbium atoms forming a planar rhombus with a center of inversion. The Yb atoms are connected by four $\eta^2{:}\eta^2$-bridging azobenzene units and two μ^3-bridging NPh groups, the latter resulting from the reduction of one azobenzene by four electrons (Figs. 1, 2). One N atom of each bridging $[PhNNPh]^{-2}$ lig-

[**] Organometallic Compounds of the Lanthanides. Part 65. This work was supported by the Fonds der Chemischen Industrie and the Deutsche Forschungsgemeinschaft. Part 64: L. Esser, J. Loebel, A. Dietrich, D. van der Helm, Xinhua Ji *Organometallics*, in press.

and lies in the plane of the four Yb atoms (maximum deviation 3 pm); the other is below or above this plane. The N–N bond distance (147 pm) corresponds to a N–N single bond as in hydrazine[10] and is considerably longer than the N=N bond in azobenzene (124.7 pm[10]). Each nitrogen coordinates two ytterbium atoms, one by a short N–Yb single bond (221–229 pm) and the second by a longer coordinative bond (254–259 pm).[11, 12] This bonding situation corresponds very well with that of the PhNNPh ligand in the dinuclear complex $[\{Yb(\eta^5\text{-}C_5H_5)(thf)\}_2(N_2Ph_2)_2]$.[6] The phenyl rings of the PhNNPh units have a *cis* orientation with dihedral angles of 72(2) and 81(2)°. The average N–C(Ph) distance is in the same range as in *trans*-azobenzene.[13]

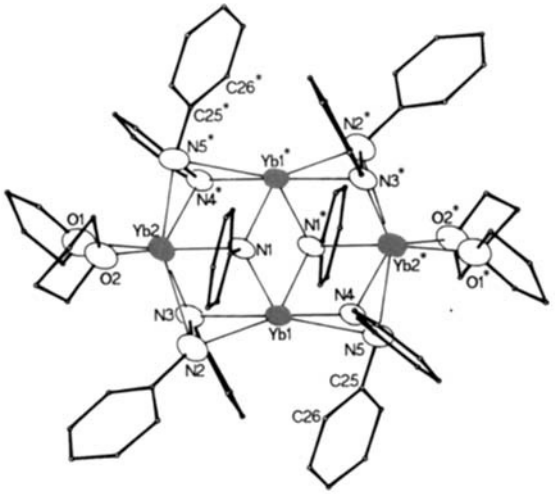

Fig. 1. Molecular structure of **2**. The Yb, N, and O atoms, as well as the important C atoms, are numbered. For clarity, the C atoms are drawn in a simplified way (H atoms omitted). Selected distances [pm] and angles [°]: Yb1···Yb2 336.5(2), Yb1···Yb2* 336.9(2), Yb1-N1* 223(1), Yb1-N3 254(1), Yb1-N5 259(1), Yb1···C26 286(2), Yb2-N2 257(1), Yb2-N4* 235(1), Yb2-O1 236(1), N2-N3 147(2), N2-C7 143(2), N3-C13 143(2), N1-C1 144(2), Yb1···Yb1* 344.1(2), Yb1-N1 221(2), Yb1-N2 227(1), Yb1-N4 229(1), Yb1···C25 280(2), Yb2-N1 229(1), Yb2-N3 220(2), Yb2-N5* 229(1), Yb2-O2 235(1), N4-N5 147(2), N4-C19 146(2), N5-C25 141(2), N1···N1* 280(2); Yb1-Yb2-Yb1* 61.46(3), Yb2-Yb1-Yb2* 118.54(3), Yb1-N1-Yb1* 101.7(6), N1-Yb1-N1* 86.8(4), N2-Yb1-N3 34.9(5), O1-Yb2-O2 78.3(5), C1-N1-Yb2 107(1), C7-N2-N3 118(1), C13-N3-N2 115(1).

Each of the nitrogen atoms N1 and N1*, originating from the reductive cleavage of a fifth azobenzene molecule (N1-N1* = 280 pm), occupies the apex of a trigonal pyramid, the base of which is formed by Yb1, Yb1*, and Yb2 or by Yb1, Yb1*, and Yb2*, respectively. N1 lies above and N1* below the Yb_4 plane. The bonds to the central Yb1 and Yb1* are shorter (221 pm) than to the peripheral Yb2 or Yb2* (229 pm), which are further coordinated by the oxygens of two THF molecules. In addition, there are two Yb_3N_3 rings of approximate chair conformation formed by Yb2, N3, Yb1, N1*, Yb1*, N4* and Yb2*, N3*, Yb1*, N1, Yb1, N4 and connected via Yb1 and Yb1*.

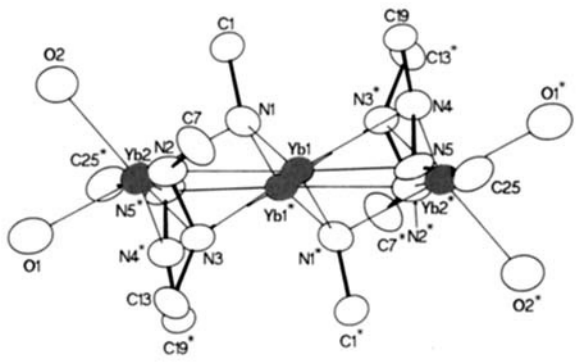

Fig. 2. View of the $Yb_4N_{10}O_4$ skeleton and the tertiary C atoms of **2**.

The coordination number 7 for Yb2 and Yb2* cannot be attained by Yb1 and Yb1* because the bulky arrangement of the phenyl groups does not allow any further coordination by THF molecules. To close this gap, the Yb–C contacts between Yb(1) and C25 (280 pm) or Yb1 and C26 (286 pm) are very short and are in the range of the η^2 interactions between Yb and the phenyl groups in $[Yb_2(\eta^2\text{-}C_6H_5)_5(thf)_4]$[14] or between Sm and the arene ligands in, for example, $[Sm(\eta^6\text{-}C_6H_6)](AlCl_4)_3$ (290 pm),[15] $[Sm(\eta^6\text{-}C_6H_4Me_2)](AlCl_4)_3$ (279 pm),[16] or $[Sm(\eta^6\text{-}C_6Me_6)](AlCl_4)_3$ (283 pm).[17] This interaction explains the unexpectedly short Yb2*–N4 bond (235 pm) and the larger C19–N4–N5–C25 dihedral angle (81°) in comparison to C7–N2–N3–C13 (72°), because there is no short contact between Yb1 and the carbon atoms C7 and C13 of the phenyl ring bonded to N3.

Experimental Procedure

All operations were performed under an argon atmosphere using carefully degassed solutions: **1** (1.23 g, 2.4 mmol) was added to a solution of azobenzene (0.43 g, 2.4 mmol) in 60 mL of THF at room temperature. The reaction mixture was stirred for 45 min, filtered, and stored at room temperature for one week. Deep red crystals of **2** (0.54 g, 45%) were separated by decantation and dried for 1 h in vacuo. Decomposition point: 76 to 154 °C. Correct C, H, N analysis. IR (CsI): $\tilde{\nu}$ [cm^{-1}] = 3060 (m), 1580 (s), 1460 (s), 1250 (s), 1040 (s), 930 (m), 870 (m), 780 (s), 750 (s), 690 (s).

Facile Synthesis of Si-Functional Silacyclobutenes**

By *Norbert Auner,* Claudia Seidenschwarz,* and *Eberhardt Herdtweck*

The synthesis, structure, and reactions of monosilacyclobutanes have been the subject of numerous investigations in the last thirty years.[1, 2] In comparison, very little has been reported about silacyclobutenes;[3] the reason for this obviously being their poor accessibility. They can be prepared on a laboratory scale, but only with great effort and in low yield by multistep organosilicon synthesis[4] or by gas-phase pyrolysis of suitable Si-precursors.[5] This is also true in the case of cycloaddition reactions of silenes with acetylenic derivatives.[6] Moreover, Si-halogenated silacyclobutenes, from which substituted derivatives are accessible by simple reaction sequences, are unknown.

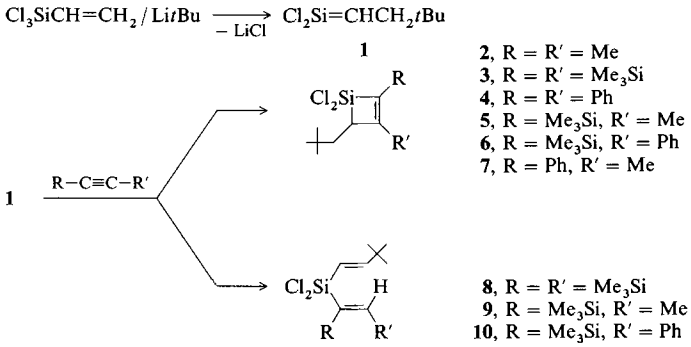
In earlier work, *Jones*[7] reported on the cycloaddition reactions of dimethylneopentylsilene. In our studies, however, we used the combination vinyltrichlorosilane/Li*t*Bu for the regioselective synthesis of [2 + 2] cycloadducts of dichloroneopentylsilene **1**, and for the preparation of Diels-Alder adducts with dienes of low activity.[8, 9] The unusually high synthetic potential of this silene has now manifested itself also in its reactivity towards 1,2-disubstituted acetylene derivatives.

By reaction of equimolar amounts of $Cl_3SiCH{=}CH_2$ and Li*t*Bu in the presence of acetylene derivatives R−C≡C−R′ the silacyclobutenes **2**–**7** can be prepared in 50–80% yield (Scheme 1). The spectroscopic data are in good agreement with those reported in the literature.[10]

Surprisingly, the silacyclobutenes are thermally very stable; they do not decompose even on heating for several days at 200 °C. Upon synthesis the derivatives **2**–**5** and **7** are obtained as viscous, colorless liquids, whereas **6** is isolated as a sublimable, crystalline compound. The colorless, almost slightly air-sensitive crystals are readily soluble in nonpolar solvents, and a suitable single crystal could be investigated by X-ray crystallography (Fig. 1).[11]

The central, markedly distorted SiC four-membered ring is almost planar, the bond lengths and angles are largely determined by the influence of the two chlorine substituents at the Si atom and the shortness of the endocyclic C=C double bond. Due to the chlorine substituents the Si1–C1 and Si1–C3 bond lengths—in comparison to the structural parameters of other silacyclobutenes[10]—are clearly shortened to 182.8(1) and 186.4(1) pm, respectively, and consequently the endocyclic angle at Si1 is widened to 80.7(1)°, whereas the C=C bond distorts the angle Si1–C1–C2 to 87.8(1)°. As a result there are two external angles of 134.7(1) and 137.5(1)° at C1. The C1=C2 double bond with a length of 135.4(1) pm is slightly stretched.

The [2 + 2] cycloaddition most likely proceeds in two steps via 1,4-dipoles $[Cl_2Si(\overset{\ominus}{\underset{\cdot\cdot}{C}}HCH_2tBu)C(R){=}\overset{\oplus}{C}(R')]$, and is impressively regioselective (Scheme 1); in no case can isomeric products $Cl_2SiC(R'){=}C(R)CHCH_2tBu$ be detected. This finding suggests a polarization in the silene **1**, with the positive partial charge localized at the Si atom, and the negative partial charge at the C atom. The strong electrophilic character of **1** can be attributed to the influence of the two chlorine substituents on the Si atom.[8, 12] The three reactions leading to formation of the silacyclobutenes **3**, **5** and **6** also yield the *trans*-ethene compounds **8**–**10** (*cis*-orientation of R,R′) in amounts between 10 and 30% (Scheme 1).[13]



Scheme 1.

Their formation can be explained in terms of an ene reaction, in which **1** as ene reacts with the acetylenes as enophile.[14]

If the electrophilicity of neopentylsilenes of type **1** is reduced by substituent effects at the Si or α-C atom, the [2 + 2]

[**] Silaheterocycles, Part 12. This work was supported by the Volkswagen-Stiftung, the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie.—Part 11: [15].

cycloaddition does not take place: $R_2Si{=}CHCH_2tBu$ (R = Me or Ph)[15] and $Cl_2Si{=}C(SiMe_3)CH_2tBu$[16] do not react with the acetylenes mentioned here.

The facile entry to Si-dichlorinated silacyclobutenes opens up further synthetic possibilities through their derivatization; this is exemplified by the preparation of the H- and F-substituted derivatives **11** and **12** in good yields by reaction of **6** with $LiAlH_4$ and of **3** with SbF_3, respectively.

12

Experimental

General procedure for **2**–**7**: A mixture of 15 mmol of $Cl_3SiCH{=}CH_2$ and 45 mmol of acetylene derivative in *n*-pentane at −78 °C (for the synthesis of **5**: 0 °C) was treated with 15 mmol of Li*t*Bu in *n*-pentane (1.4 mmol mL^{-1}) and slowly warmed to room temperature, whereupon LiCl precipitated. For completion of reaction the mixture was stirred for a further 12 h at 20 °C, and then filtered. After removal of pentane by distillation, the residue was subjected to short path distillation at 10^{-2} mbar (b.p. [°C]/yield [%]: **2**: 52/46; **3**: 87/55; **4**: 200/85; **5**: 70/60; **7**: 116/65; **6**: 56 (m.p.)/78) or, for the isolation of pure **6**, recrystallized from pentane or ether.

For the preparation of **11**, **6** (3 mmol) was allowed to react with $LiAlH_4$ in ether at 0 °C according to the procedure described in Ref. [17]; for the synthesis of **12**, a solution of **3** (5 mmol) in toluene was allowed to react with SbF_3 at 0 °C and the mixture was then warmed to 60 °C for 6 h[18]. B.p./*p*/yield: **11**: 100 °C/10^{-2} mbar/60%; **12**: 40 °C/10^{-2} mbar/80%.

The purity of the four-membered ring compounds **2**–**7** and **11**, **12** was checked by elemental analysis; their mass spectroscopic fragmentation (70 eV) was as expected.

NMR data of the silacyclobutenes: ^{1}H NMR (100 MHz, $CDCl_3$, 25 °C, TMS) of **6**: δ = 7.25 (m, 5H; Ph), 3.20 (m, 1H; CH), 1.40 (m, 2H; CH_2), 0.84 (s, 9H; *t*Bu), 0.02 (s, 9H; $SiMe_3$); δ(*t*Bu and CH_2) of **2**–**5**, **7**, **11** and **12** are very similar to the parameters of **6**, the δ values of R and R′ lie in the expected ranges. Merely, δ(CH) varies between 2.30 (in **2**) and 3.20 (in **6** and **7**); ^{13}C- and ^{29}Si-NMR data (^{13}C NMR: 90.6 MHz, $CDCl_3$, DEPT, TMS; ^{29}Si NMR: 79.4 MHz, $CDCl_3$, TMS); assignment: $\overset{1}{>}Si\overset{2}{C}(R){=}\overset{3}{C}(R')\overset{4}{C}H_2tBu$; **6**: δ = 173.0 (C^2), 149.5 (C^3), 46.3 (C^4), 40.8 (CH_2), 30.5 ($C(CH_3)_3$), 29.3 ($C(CH_3)_3$), −0.2 ($SiMe_3$), 137.2 (=*C*(Ph)), 129.2 (*CH*(Ph)), 127.6, 128.3 (each 2 *CH*(Ph)); ^{29}Si NMR: δ = −1.4 (Cl_2Si), −12.4 (Me_3Si). [11] P. Kiprof, E. Herdtweck, R. E. Schmidt, M. Birkhahn, W. Massa: STRUX-III program system for refinement of X-ray data, Technische Universität München/Universität Marburg, 1989/1985. **6** crystallizes as colorless platelets from *n*-pentane. The extinctions ($h01$: $1 = 2n + 1$; $0k0$: $k = 2n + 1$) are consistent with the monoclinic space group $P2_1/c$. The lattice constants are refined on the basis of 25 reflection positions ($\theta > 39.8°$; $\pm h$, $\pm k$, $\pm l$) to a = 963.2(4), b = 1178.9(2), c = 1777.9(6) pm, β = 78.04(2)°; $V = 1975 \times 10^6$ pm^3; $C_{17}H_{26}Cl_2Si_2$; $Z = 4$; ϱ_{calcd} = 1.202 g cm^{-3}. The collection of the intensities was carried out at 193 K on an automatic four-circle diffractometer (CAD4-Enraf-Nonius; λ = 71.073 pm; graphite monochromator) in the measuring range $1.0° \le \theta \le 25.0°$ in the ω-scan at variable width and maximum measuring time t_{max} = 60 s. Of 3856 measured intensities (477 with $I < 0$ were classed as unobserved), after averaging 3178 (NO) independent reflections with $I > 0$ and 291 (NV) parameters were refined by full matrix least squares. $R = \sum(||F_o|-|F_c||)/\sum|F_o| = 0.037$; $R\omega = [\sum\omega(|F_o|-|F_c|)^2/\sum\omega F_o^2]^{1/2} = 0.032$; GOF = $[\sum\omega(|F_o|-|F_c|)^2/(NO-NV)]^{1/2} = 3.423$. The solution of the structure was carried out by direct methods and difference Fourier technique. The positions of the hydrogen atoms were refined free (only the hydrogens on C3 and C4 were given a fixed, collective deviation parameter). Anomalous dispersion was taken into account. After the last refinement cycle (shift error < 0.001) the maximum/minimum residual electron density was + 0.31/−0.27 e_0 Å^{-3}. Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, W-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-55625, the names of the authors, and the journal citation.
[12] An alternative reaction path for the formation of the silacyclobutenes involves a carbanionic attack of the α-lithioadduct $Cl_3Si\overset{\ominus}{\underset{\cdot\cdot}{C}}HCH_2tBuLi^{\oplus}$ on the acetylenes followed by cyclization with elimination of LiCl. However, an addition of Me_3SiOMe to the reaction mixture leads to preferential formation of the Si=C trapping product $Cl_2Si(OMe)CH(SiMe_3)CH_2tBu$ (a reaction which proceeds quantitatively in the absence of acetylenes); moreover, $F_3Si\overset{\ominus}{\underset{\cdot\cdot}{C}}HCH_2tBuLi^{\oplus}$, which is markedly more stable in comparison to the chlorine analogue, does not react with dienes and acetylenes: N. Auner, C. Seidenschwarz, A. Wolff, unpublished results.

$BPh_4^{\ominus}$ as a Ligand in Cationic Zirconium Complexes: Novel Bonding Mode and Fluxionality

By *Andrew D. Horton** and *John H. G. Frijns*

It is now fairly well established that a cationic complex, $[Cp_2MR]^{\oplus}$, is the active species of Group 4 metallocene/alkylaluminoxane catalysts and related systems in alkene polymerization.[1] The excess alkylaluminoxane presumably functions partly as a Lewis acidic precursor of a poorly coordinating anion, and so alternative anions are of interest for one-component catalysts.[2, 3] Although Lewis base adducts,

P.O. Box 3003, NL-1003 AA Amsterdam (The Netherlands)

$[Cp_2MR(L)][BPh_4]$, have been extensively studied,[2] attempts to synthesize more reactive base-free complexes have led to phenyl metalation giving $[(C_5Me_5)_2Zr(C_6H_4BPh_3)]$.[3] *Bochmann* et al. recently generated the complexes $[Cp_2MMe][BPh_4]$ at low temperature in dichloromethane, and provided evidence for solvent coordination.[4] In contrast, in the new complexes presented here, coordination of the tetraphenylborate anion occurs. Like the alkylaluminoxane systems, the complexes are soluble in aromatic solvents and catalyze the isotactic polymerization of propene.

Attempted isolation of $[Cp'_2ZrMe][BPh_4]$ in aromatic solvents has previously led either to phenyl transfer (non-crowded system, $Cp' = C_5H_5$)[5] or to anion metalation (crowded system, $Cp' = C_5Me_5$).[3] Cyclopentadienyl ligands of intermediate steric bulk were expected to stabilize complexes by allowing anion coordination as an alternative to the sterically less demanding C–H activation,[6] whilst hindering the sterically more demanding phenyl transfer. Complexes with chiral ligands were of relevance to stereospecific polymerization catalysis.[1a, 2b] The new complexes **1**–**4** were synthesized by protonolysis of Cp'_2ZrMe_2 between -30 and 25 °C [Eq. (a)] and were obtained as orange (**1**) or yellow (**2**–**4**), THInd = tetrahydroindenyl) precipitates, indefinitely stable in the solid state at -40 °C.[7] The stability in bromobenzene decreases in the order: **2** (40 h) > **1** (20 h) >> **3** (90 min) > **4** (50 min) ($t_{1/2}$ at 25 °C).

$$Cp'_2ZrMe_2 \xrightarrow[C_6H_5Br]{[PhNMe_2H][BPh_4]} Cp'_2ZrMe(BPh_4) + CH_4 + PhNMe_2 \quad (a)$$

1: $Cp'_2 = rac\text{-}C_2H_4(Ind)_2$
2: $Cp'_2 = rac\text{-}C_2H_4(THInd)_2$
3: $Cp' = (Me_3C)C_5H_4$
4: $Cp' = (Me_3Si)C_5H_4$

Low temperature ^{1}H-NMR studies in aromatic solvents showed that the tetraphenylborate anion is coordinated to the central zirconium. The proton chemical shifts for the coordinated phenyl ring and the three equivalent non-coordinated rings of $[BPh_4]^{\ominus}$ are compared in Table 1 with the "free" anion resonances. Complexes **3** and **4** possess an

[a] Coordinated phenyl ring. [b] **1** was measured in C_7D_8/C_6D_5Cl.

equatorial plane of symmetry, as shown by the observation of equivalent cyclopentadienyl groups and of three resonances in the ratio 2:2:1 for the coordinated phenyl group. The *ortho*-protons of the coordinated phenyl ring are shifted ca. $\delta = 0.15$ further downfield than those of the three non-coordinated Ph groups, whereas the signals of the *meta*- and *para*-protons are detected ca. $\delta = 0.75$ and 1.05, respectively, further upfield. Complexes **1** and **2**, with a chiral zirconium center, show five signals for the coodinated phenyl ring. The average chemical shifts for the *ortho*-, *meta*- and *para*-hydrogens of the tetrahydroindenyl complex **2** are similar to those for complexes **3** and **4** with C_s symmetry, suggesting similar interactions between the *meta*- and *para*-carbon atoms and the zirconium atom. The extreme upfield location of the signals for H_{o2}, H_{m2} and H_p in **1** are due to the ring-current effect of an indenyl six-membered ring on part of the adjacent phenyl ring (Fig. 1).

The upfield shifts of the *meta*- and *para*-hydrogens and downfield shifts of the *ortho*-hydrogens are consistent either with unusual $\eta^3(m,p)$-coordination of the phenyl ring (Fig. 1),[8] or with the rapid equilibration of two enantiomers (**3**, **4**) or diasteroisomers (**1**, **2**) with $\eta^2(m,p)$-coordinated

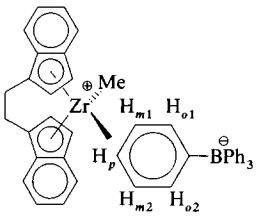

Fig. 1. $[\{rac\text{-}C_2H_4(Ind)_2\}ZrMe(BPh_4)]$ **4**.

phenyl rings. The average structure, in which the B–C_{ipso}–C_p axis of the phenyl ring lies in the equatorial plane with BPh_3 pointing away from the cyclopentadienyl rings, is the same in either case. Interconversion of two η^2-coordinated aromatics can be a low-energy process.[9] Broadening of the cyclopentadienyl and anion ^{1}H-NMR signals of **3** and **4** observed at -70 °C may well be due to restricted rotation of the RC_5H_4 ligand. The fact that resonances due to a static "η^2-"structure for **3** or **4** are not observed, even at -70 °C, and that sharp resonances due to only one (rather than the expected two) diastereoisomer(s) of **2** are seen at -65 °C, does not allow us to entirely rule out the presence of two rapidly intercoverting η^2-forms. Coordination of $[BPh_4]^{\ominus}$ in the η^6-[10] and η^2-models[11] has been observed previously, especially in the case of late transition metal complexes.

Two novel fluxional processes have been observed. The chiral environment at zirconium in the thermally stable complex **2** allows exchange of the hydrogens of the unique phenyl ring above and below the equatorial plane to be probed. Each of the two *ortho*- and two *meta*-H resonances for the unique phenyl group is sharp at -65 °C, but broadens at -30 °C and coalesces at -10 to -5 °C. At 25 °C two relatively sharp resonances (relative intensity 2) are obtained. This lower energy process ($\Delta G^{\neq} \cong 12.1$ kcal mol^{-1}) leaves the *p*-Ph and the BPh_3 resonances unchanged between -65 and 25 °C. Above 25 °C broadening and partial collapse of all Ph and BPh_3 resonances occur, but decomposition is evident above 75 °C, before the high temperature limit is reached. This apparent exchange of all anion phenyl groups leaves the tetrahydroindenyl resonances unchanged.

The NMR results show that in **2** the environments of each of two *ortho*- as well as of the two *meta*-hydrogens exchange more rapidly than phenyl exchange. Since oxidative addition to Zr^{IV} of the phenyl *para*-C–H bond is not possible, a remarkable fluxional process appears to be operative, involving flipping of the coordinated face of the unique phenyl ring, whilst the ring remains coordinated to zirconium, perhaps via a Zr-H-C interaction involving H_p (Fig. 2) or H_m. Such an electrostatically assisted "intermolecular" interaction is known in the structure of $[(EtC_5Me_4)_2ZrMe(C_2B_9H_{12})]$,[3] in which a carborane anion is coordinated solely via a Zr–H–B bond. That ring flipping in **2** occurs

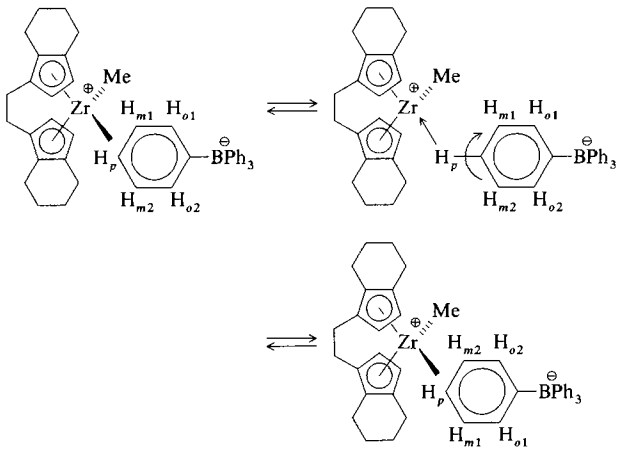

Fig. 2. A possible mechanism of phenyl-group flipping in complex **2**.

faster than ring exchange is surprising, but may be due to the steric crowding at zirconium, which disfavors simultaneous coordination of two phenyl groups.

Use of the good polar solvent 1,1,2,2-tetrachloroethane[12] allows observation of the anion ^{13}C-NMR resonances which are partially obscured or weak in C_6D_5Br. The downfield *ipso*- and *ortho*-resonances and (generally) upfield *meta*- and *para*-resonances of the anion coordinated ring in **1**–**4** are again consistent with η^3- or (fluxional) η^2-coordination of a phenyl ring. However, additional resonances due to the "free" anion are also observed in this solvent. The "free" anion (**1**: *ca.* 35%; **2**: *ca.* 25%; **3**: *ca.* 20%; **4**: *ca.* 10%) gives resonances identical to those of the anion in Lewis base adducts of the type $[Cp'_2ZrMe(L)][BPh_4]$ (formed, e.g., on addition of THF to the complexes). Resonances due to the corresponding cation cannot be unambiguously identified, but the cation is presumably $[Cp'_2ZrMe(C_2D_2Cl_4)]^{\oplus}$, containing η^1- or η^2-coordinated solvent. Previous studies of related metallocene cations, generated *in situ* in CD_2Cl_2, suggested that the anion is not coordinated to the metal, but instead is present as a mixture of "solvated" and "ion paired" species;[4] in contrast, the fluxional anion in $[Zr(CH_2Ph)_3(\eta^6\text{-}PhBPh_3]$ apparently remains coordinated to the Zr atom in CD_2Cl_2.[10c]

Complexes **1** and **2** react with propene at 15°C to give isotactic polypropylene with melting points (**1**: 142°C, **2**: 143°C) comparable to that of polymer formed using methylaluminoxane as cocatalyst.[13] The modest polymerization rate is explained by the difficulty of anion displacement by the weakly coordinating alkene. The electrostatic attraction between anion and cation clearly compensates for the loss of aromatic stabilization on coordination of the anion. High-activity one-component catalysts will require more poorly coordinating anions.

Experimental

C_6H_5Br (4 mL) was added to a mixture of *rac*-$[C_2H_4(Ind)_2ZrMe_2]$ (150 mg; 0.40 mmol) and $[PhMe_2NH][BPh_4]$ (172 mg; 0.39 mmol) at −30°C; the mixture was then warmed to 25°C and stirred for ten minutes. Filtration and addition of hexane gave an orange oil, which was washed twice with hexane, with vigorous stirring, to give **1** as an orange solid (280 mg; 77%). Complexes **2**–**4** were obtained similarly, except that **4** was precipitated at 10°C. A trace impurity of $PhNMe_2$ was removed by re-precipitation. ^{1}H-NMR resonances for **1** and **2** have been assigned using 2D-COSY-NMR techniques. Selected ^{1}H NMR for cations (1:1 C_6D_5Cl:C_7D_8, −30°C): **1**: δ = 6.22, 5.05, 4.83, 3.52 (d, 1H; Ind-C_5), −0.70 (s, 3H; Zr-*Me*); (C_7D_8, −30°C): **2**: δ = 5.72, 4.36, 4.32, 3.26 (d, 1H; THind-C_5), 0.18 (s, 3H; Zr-*Me*); **3**: δ = 5.82, 5.18, 4.95, 4.64 (br, 2H; $(Me_3C)C_5H_4$), 0.88 (s, 18H; $(Me_3C)C_5H_4$), 0.33 (s, 3H; Zr-*Me*); **4**: δ = 5.98, 5.26, 5.17, 5.03 (br, 2H; $(Me_3Si)C_5H_4$), 0.32 (s, 3H; Zr-*Me*), 0.02 (s, 18H; $(Me_3Si)C_5H_4$). Selected ^{13}C-NMR data for the anions ($C_2D_2Cl_4$, −35°C): free $BPh_4^{\ominus}$: δ = 164.5 (*ipso*-C), 136.5 (*o*-C), 126.3 (*m*-C), 122.0 (*p*-C); **2**: δ = 180.8 (*ipso*-Ph), 161.7 (*ipso*-BPh_3), 144.8, 139.7 (*o*-Ph), 136.1 (*o*-BPh_3), 133.1 (*m*-Ph), 127.0 (*m*-BPh_3), 123.1 (*p*-BPh_3), 120.4 (*m*-Ph), 116.0 (*p*-Ph), 46.9 (Zr-*Me*); **4**: δ = 181.0 (*ipso*-Ph), 161.3 (*ipso*-BPh_3), 141.5 (*o*-Ph), 136.0 (*o*-BPh_3), 126.9 (*m*-BPh_3), 123.6 (*m*-Ph), 123.1 (*p*-BPh_3), 120.0 (*p*-Ph), 44.9 (Zr-*Me*). The anion in **1** and **3** gives similar resonances to **2** and **4**, respectively.

Polymerization experiments: A solution of complex **1** (100 mg) in C_6H_5Br/toluene (20 ml, 1/4) was added to toluene (150 ml) and propene (*ca.* 6 atm) in a steel autoclave at 15°C. After 1.9 h, the propene was removed and isooctane (150 ml) and MeOH (100 ml) were added to give a fine precipitate of polypropylene (3.6 g). Similarly, complex **2** (2.6 h) gave 7.2 g of polypropylene. Polymer **1**: M_n = 25,500; M_w = 45,600; M_z = 63,500; M_w/M_n = 1.8. Polymer **2**: M_n = 10,900; M_w = 28,600; M_z = 43,800; M_w/M_n = 2.6.

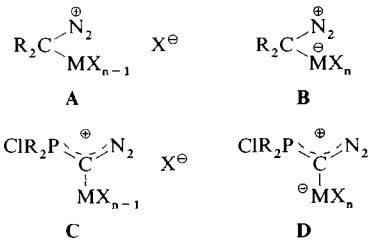
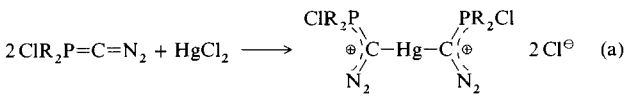
interaction between catalyst and diazo derivatives has been postulated to be initiated by electrophilic attack of the Lewis acid MX_n at the diazo carbon, with simultaneous or subsequent loss of N_2. None of the postulated primary adducts **A** or **B** has so far been isolated. Thus, it was of interest to study the reactivity of the stable bis(diisopropylamino)chlorodiazomethylenephosphorane **1**[2] towards Lewis acids and alkylating agents, in the hope of obtaining **A**- and **B**-type complexes **C** and **D**, which should be stable due to the possible π electron delocalization.[3, 4]



A **B**

C **D**

Among the possible Lewis acids, we first chose mercury dichloride, which is known to be moderately reactive toward diazo decomposition.[5] In toluene at room temperature it reacts smoothly with the (diazomethylene)phosphorane **1** to give the bis{[chlorobis(diisopropylamino)phosphonio]diazomethyl}mercury salt **2** [Eq. (a)]. The ionic nature of **2** was



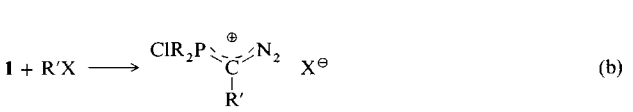
(a)

1 **2**

R = iPr$_2$N

demonstrated by anion exchange with potassium hexafluorophosphate. The PF_6 salt formed could be isolated as a solid (m.p. 130 °C (decomp.)) in 90% yield. The presence of diazo groups was confirmed by an IR absorption at 2083 cm^{-1} and the $[P-C(N_2)]_2Hg$ skeleton was apparent from the ^{31}P-NMR ($\delta = +61.7$, $^2J_{^{199}Hg^{31}P} = 181.3$ Hz) and ^{199}Hg-NMR[6] ($\delta = +1234$, t) spectra. Since Lewis acids are known to react with phosphorus ylides at carbon,[7] it is reasonable to postulate the primary formation of a transient adduct $ClR_2P(N_2)CHgCl_2$, which would rearrange into a salt $[ClR_2P(N_2)CHgCl]Cl$. Repetition of this reaction sequence could explain the formation of **2**.

The alkylation of **1** was then investigated. With methyl trifluoromethanesulfonate and triphenylcarbenium hexafluorophosphate clean reactions occurred, leading to the expected salts **3** (m.p. 135 °C decomp.)) and **4** (m.p. 180 °C (decomp.)) in 85 and 70% isolated yield, respectively [Eq. (b)].



(b)

3: R′ = Me, X = F_3CSO_3
4: R′ = Ph_3C, X = PF_6

R = iPr$_2$N

These compounds were fully characterized by spectroscopic methods (Table 1) and in the case of **4**, by an X-ray crystal study (Fig. 1).[8] The molecular structure of **4** is illustrated in Figure 1, together with the atom numbering scheme

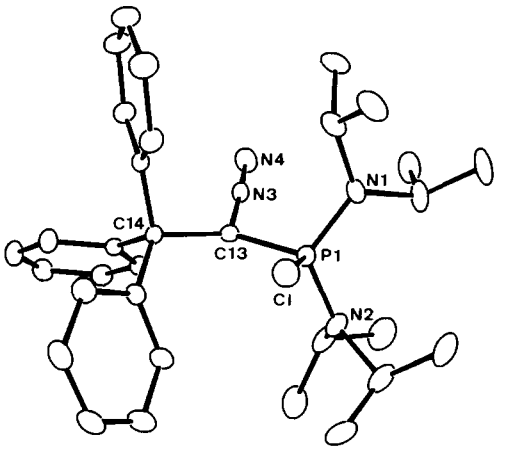


Fig. 1. Molecular structure of **4** (ORTEP, ellipsoids at the 25% probability level. Selected bond lengths [Å] and angles [°]: P1-N1 1.622(4), P1-N2 1.607(3), P1-C1 2.006(2), P1-C13 1.763(4), C13-C14 1.567(5), C13-N3 1.332(4), N3-N4 1.124(4), P1-C13-C14 135.1(2), P1-C13-N3 110.0(3), C14-C13-N3 111.8(3), C13-N3-N4 176.2(4).

and the pertinent metric parameters. Interestingly, the C13–N3 bond length (1.332 Å) is at the upper limit (1.28–1.32 Å) and the N3–N4 bond length (1.124 Å) is at the lower limit (1.12–1.14 Å) for a diazo compound, but they are shorter and longer, respectively, than those observed for diazonium salts (C–N 1.38–1.43; N–N 1.09–1.11 Å).[1b] From the structural data-available,[9] a $P-C_{ylide}$ bond length of 1.63–1.64 Å can be estimated, which is much shorter than the P–C bond length observed for **6** (1.763 Å). These data indicate that in the ground state, although the diazonium form is not negligible, the phosphonium form clearly predominates. This assumption is confirmed by the rather low IR frequency (2090 cm^{-1}).

Table 1. Selected spectroscopic data of **3**–**8**. [a]

3: ^{31}P NMR ($CDCl_3$): $\delta = +60.6$. ^1H NMR ($CDCl_3$): $\delta = 2.17$ (12.9) (d, 3H, $C(N_2)CH_3$). ^{13}C NMR ($CDCl_3$): $\delta = 11.8$ (10.8) (d, $C(N_2)CH_3$), 43.8 (202.0) (d, CN_2), 120.5 (q, $^1J(^{19}F^{13}C) = 320.4$ Hz, CF_3). IR ($CDCl_3$): $\tilde{\nu}$ [cm^{-1}] = 1740 cm^{-1} (CO).

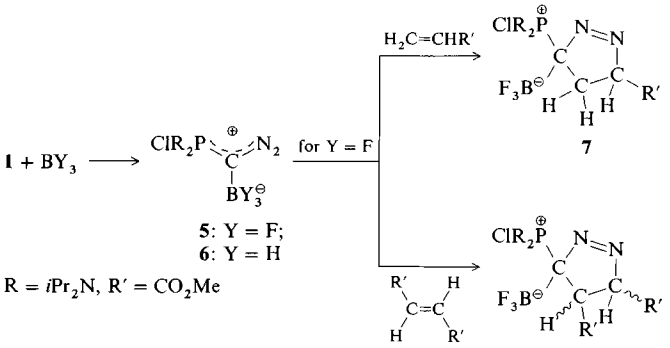
[a] Numbers given in round brackets after the δ values are coupling constants of the respective nucleus from couplings with ^{31}P.

The formation of stable compounds of type **C** prompted us to attempt the synthesis of derivatives of type **D**. Indeed, the reaction of **1** with diethylether-trifluoroborane led to the desired adduct **5** in 83% yield as a water-sensitive reddish orange oil. The presence of the diazo group was confirmed by an IR absorption at 2080 cm^{-1}, the P–C–B skeleton was shown to be present by a 1:1:1:1 quartet at $\delta = +63.4$ ($^1J_{^{31}P^{11}B} = 9$ Hz) in the ^{31}P-NMR spectrum, and the BF_3

moiety gave typical ^{11}B- ($\delta = +0.9$, q, $^1J_{^{19}F^{11}B} = 32$ Hz) and ^{19}F-NMR ($\delta = +38$, q) signals. Similarly, addition of tetrahydrofurane-borane complex to **1** furnished the adduct **6** as a yellow oil in 87% yield. Note that only one example



of an isolated α-diazoalkylborane is known,[10, 11] and that compounds **5** and **6** are the first α-diazoalkylborates. Compound **5** undergoes a regiospecific but also stereospecific [2 + 3] cycloaddition with methylacrylate, leading to **7** (m.p. 155°C, 70% yield) in the form of only one of the diastereoisomers (according to NMR data). With dimethyl fumarate, the *trans* geometry is maintained but two diastereoisomers **8** are formed in a 70/30 ratio (Table 1).

Experimental

Diazomethylenephosphorane adducts **2**–**6** were prepared by adding the Lewis acid or alkylating agent to a toluene solution of **1**, at room temperature for $HgCl_2$, Ph_3CPF_6, $BF_3{\cdot}OEt_2$ and $BH_3{\cdot}THF$, and at 0°C for $MeOSO_2CF_3$. After stirring for 1 h at room temperature, the solvent was removed in vacuo and the residue was washed several times with pentane. Adduct **2** was recrystallized from acetonitrile, **3** from 1,2-dichloroethane/ether, and **4** from toluene/acetonitrile, while adducts **5** and **6** were obtained as oils. Cycloadducts **7** and **8** were obtained by adding the stoichiometric amount of the corresponding alkene to a toluene solution of **5** at −80°C. After stirring for 1 h at room temperature, the solvent was removed and **7** was recrystallized from 1,2-dichloroethane/ether, while **8**, owing to its instability, was spectroscopically characterized in solution.

Structure of an Organometallic Intercalate: Single Crystal X-Ray and Powder Neutron Diffraction Study of $[SnS_2\{Co(\eta\text{-}C_5H_5)_2\}_{0.31}]$ and $[SnS_2\{Co(\eta\text{-}C_5D_5)_2\}_{0.31}]$**

By *Dermot O'Hare,* John S. O. Evans, Philip J. Wiseman* and *Keith Prout*

Since the intercalation of an organometallic species into a layered host lattice was first reported by *Dines*[1] in 1975, there has been considerable interest in the intercalation of organometallic guests, e.g. $[Co(\eta\text{-}C_5H_5)_2]$, $[Cr(\eta\text{-}C_5H_5)_2]$, $[Zr(\eta\text{-}C_7H_7)(\eta\text{-}C_5H_5)]$, into layered host lattices, such as MS_2 (M = Nb, Ta, Ti, Mo), MPS_3 (M = Cd, Mn, Fe, Ni) and FeOCl.[2] In particular, the intercalation of electron-rich organometallic guests has been shown to greatly enhance the conductivity of the host lattice through guest-host electron transfer, and in the case of intercalation of $[Cr(\eta\text{-}C_5H_5)_2]$ or $[Co(\eta\text{-}C_5H_5)_2]$ into TaS_2 the superconducting critical temperature (T_c) of the host material was significantly increased.[3] We have also recently reported that the intercalation of $[Co(\eta\text{-}C_5H_5)_2]$ into $SnSe_2$ converts the host lattice, a semiconductor with a relatively large band gap, into a type II superconductor with $T_c = 6.1$ K.[4]

Whilst there has been a considerable amount of research into the physical properties of metallocene intercalates, the inherent disorder of these materials, problems due to extreme preferred-orientation effects, and the difficulty of synthesizing crystals of a suitable quality for conventional diffraction methods have severely limited work on structural determination. Fundamental questions such as the orientation of the guest molecule remain unanswered, as due to the almost spherical van der Waals surface of the unsubstituted metallocenes, little can be deduced from lattice expansion measurements alone (Fig. 1).

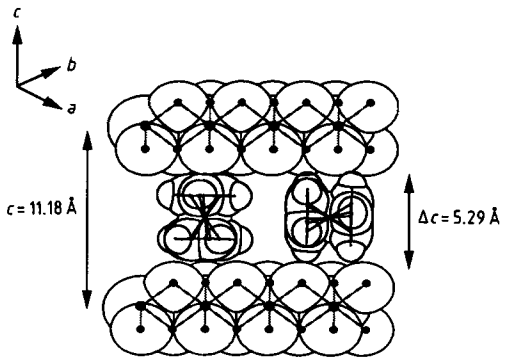

Fig. 1. Intercalated metallocene molecules could adopt two extreme orientations, with their principle axis either perpendicular or parallel to the host lattice planes.

Recently, variable-temperature solid-state ^2H NMR investigations on microcrystalline samples of $[TaS_2\{Co(\eta\text{-}C_5H_5)_2\}_{0.33}]$ have indicated that the guest molecules may be dynamically exchanging between a range of extreme orientations.[5] In this communication we describe the first three-dimensional structure determination of an organometallic intercalate, namely $[SnS_2\{Co(\eta\text{-}C_5H_5)_2\}_{0.31}]$, using single-crystal X-ray film techniques and neutron diffraction studies of both powdered and aligned samples.

Single crystals of phosphorus-doped (1%) 2H-SnS_2 were grown by vapor-phase transport methods using bromine as a transporting agent (5 mg per cm^3).[6] We found that relatively large single crystals of SnS_2 (typically 2 mm × 2 mm × 0.1 mm) could be intercalated with $[Co(\eta\text{-}C_5H_5)_2]$ in 4–5 days by heating the crystals to 60 °C in a concentrated solution of $[Co(\eta\text{-}C_5H_5)_2]$ in dimethoxyethane. The elemental composition was found by microanalysis to be $[SnS_2\{Co(\eta\text{-}C_5H_5)_2\}_{0.31}]$.[1]

Preliminary X-ray photographs of single crystals of this compound indicated that the diffraction patterns obtained were not of a suitable quality to use conventional 4-circle automated diffractometers. For this reason we employed more traditional Weissenberg film methods to record the diffraction pattern. By mounting the crystal along its *a* axis it was possible to record *hkl* reflections for $h = 0$, 1 and 2. A total of 21 photographs of different exposure times were taken to obtain a reasonable intensity range, and the relative intensities of the diffraction peaks were then estimated using the intensity strip method.[7] It proved possible to index and obtain the relative intensities of a total of 177 reflections.

From the photographs obtained it is clear that these materials retain a remarkable degree of order on intercalation. The diffraction "spots" remain sharp in θ, but are up to 30° wide in ω. This suggests that the structural integrity of the host remains essentially intact during intercalation. The fact that the diffraction spots are sharp in θ indicates that the layer sequence, ABABAB, where A and B represent individual SnS_2 layers, is well preserved on intercalation. If the layers were to stack randomly, the diffraction peaks would be diffuse in θ as well as ω. The diffuseness of the spots in the ω direction indicates that the layers show some rotational disorder about the *c* axis. That the lines remain sharp in θ indicates that this diffuseness is more due to increased mosaic spread than to the rotation of individual layers. We therefore conclude that the crystal is made up of relatively well-ordered slabs, which are ca. 200 Å thick and prone to periodic stacking faults along the *c* axis. The total "smeared" pattern is then made up of many sharp patterns, due to the individual mosaics, superposed with different ω translations.

From the systematic absences observed on the films (00*l*, $l = 2n + 1$) it was apparent that as well as the documented increase of the interlamellar distance from 5.89 to 11.18 Å ($\Delta c = 5.29$ Å) on intercalation, there is also a doubling along the *c* axis. The unit cell parameters, measured from Weissenberg and oscillation photographs, are $3.62 \times 3.62 \times 22.36$ Å. The inherent accuracy of the intensity measurements, due to factors such as reflection overlap and absorption, was $00l > 0kl > hkl$; therefore the analysis of the X-ray data was performed in three stages. Initially the estimated intensities of the ten observed 00*l* reflections from the zero-level Weissenberg were used to perform a one-dimensional Fourier synthesis phased on approximate tin and sulfur positions. Least-squares refinement was then used to optimize the sulfur *z* coordinate.

Inclusion of all the intensity information derived from the zero-level photograph enabled two-dimensional Patterson and Fourier maps to be computed. From this tin, sulfur, and cobalt positions could be clearly resolved. We also observed a doubling along the *c* axis caused by a relative shift of adjacent tin disulfide layers along the crystallographic *b* axis.

When we included intensity information from all three Weissenberg photographs, we concluded that consecutive tin disulfide layers are shifted in both the *a* and *b* directions relative to pure SnS_2. This shift necessarily leads to the destruction of the threefold symmetry of the host lattice, and the loss of crystallographic symmetry was confirmed by a series of Laue and Precession photographs.

When the heavy atoms were located satisfactorily, we attempted to determine the relative orientation of the guest molecules between the layers. Initially using the one-dimensional data we compared the observed and calculated electron densities for both the parallel and perpendicular arrangements of the cyclopentadienyl rings relative to the SnS_2 layers (see Fig. 1). The scattering of X-rays from a cyclopentadienyl ring undergoing rapid rotation around the metallocene C_5 axis was described using an appropriate Bessel function. Agreement factors for the two extreme orientations of $R_{I(\text{parallel})} = 0.137$ and $R_{I(\text{perpendicular})} = 0.347$ indicated that the parallel model gives much better agreement with the experimental data. Refinement of a model in which the occupancy of the two extreme orientations is allowed to vary converged to a parallel occupancy of 0.33(5) cobaltocenes per half unit cell and perpendicular of −0.02(5); this agrees

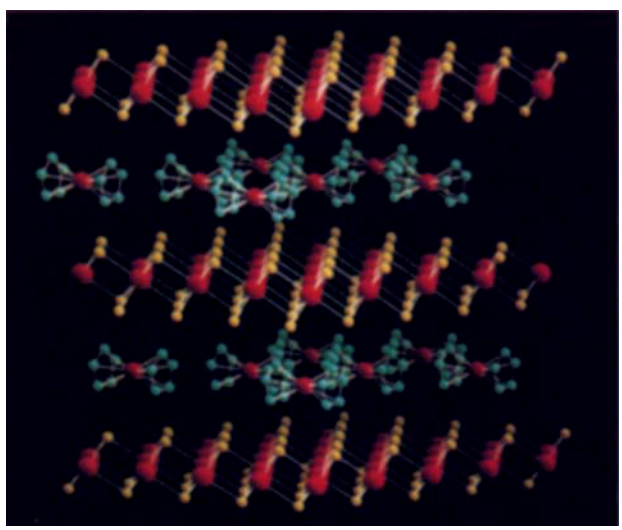

Fig. 2. A view of the three dimensional structure of $[SnS_2\{Co(\eta\text{-}C_5H_5)_2\}_{0.31}]$.

 © VCH Verlagsgesellschaft mbH, W-6940 Weinheim, 1991 0570-0833/91/0909-1157 $ 3.50+.25/0

well with the experimentally observed occupancy of 0.31 molecules per SnS_2.

The parallel orientation of the $[Co(\eta\text{-}C_5H_5)_2]$ was confirmed by analysis of the time-of-flight neutron diffraction pattern of an aligned sample of single crystals of $[SnS_2\{Co(\eta\text{-}C_5D_5)_2\}_{0.31}]$, recorded at the Rutherford Appleton Laboratory. Using the neutron data we calculated an agreement factor for the parallel orientations of $R_{I(\text{parallel})} = 0.106$. The occupancies of an initial model containing both extreme orientations refined to a parallel occupancy of 0.302(5) and a perpendicular of 0.008(5). Attempts to refine a model containing solely the perpendicular orientation failed to produce good agreement with the observed data.

Figure 2 shows the final structure based on refinement of both the X-ray and neutron data. Since both sets of data were collected at room temperature, the carbon atoms of the cyclopentadienyl ring have large thermal parameters to account for the undoubtedly large degree of cyclopentadienyl ring disorder in the *a,b* plane. However, we can conclude from our data that the metallocene molecules all adopt the parallel orientation. We also have preliminary evidence that the guests are ordered in the *a,b* plane of SnS_2 layers which have commensurate interlayer spacing.

Pressure-Assisted Formation of a Cobalt–Carbon σ Bond: A High-Pressure Pulse Radiolysis Study**

By *Rudi van Eldik, Haim Cohen,* and *Dan Meyerstein**

The study of the kinetics of formation of transient complexes with metal–carbon σ bonds through the reaction of aliphatic free radicals with transition metal complexes, and of the homolysis of the metal–carbon σ bond, is of interest due to the role of these processes in a variety of catalytic and biological processes.[1, 2] Of particular significance is the study of the reaction mechanisms of the formation and decomposition of complexes with cobalt–carbon bonds due to the biological role of the homolysis of cobalt–carbon bonds in vitamin B_{12} catalyzed reactions.[1a–c, e, 3] It is therefore not surprising that the kinetics of the reaction of a variety of free radicals with several cobalt complexes [k_1 in Eq. (1)] has been studied.[4–6] The detailed mechanisms of these reactions, that is, whether interchange or dissociative, have not been resolved.[7] The kinetics of the homolysis of cobalt–carbon σ bonds [k_{-1} in (1)] was also studied in a series of investigations,[1e, 2, 3a, 6, 8, 9] partly in order to determine the

$$[L_mCo^{II}] + {}^{\bullet}R \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} [L_mCo^{III}\text{-}\langle c^- \rangle R^-] \quad (1)$$

cobalt–carbon bond dissociation energy. It was suggested that this energy equals $\Delta H^{\neq}$ (k_{-1}) as the bond formation step in reaction (1) approaches the diffusion controlled limit, i.e. has a small activation barrier.[1e, 2, 3a, 9] However, it should be noted that this assignment will depend on the intimate nature of the bond breakage process.

The application of high-pressure kinetic techniques to the study of inorganic, organometallic, and bioinorganic reactions has greatly assisted the elucidation of the underlying mechanisms in recent years.[10] Furthermore, pulse radiolysis techniques enable the study of metal–carbon bond formation in a direct way.[4–6] We have therefore combined both techniques and performed pulse radiolysis studies at high pressure (up to 150 MPa)[11] in order to study the interaction of methyl radicals with $[Co^{II}(nta)(H_2O)_2]^-$ (nta = nitrilotriacetate) during which $[Co^{III}(nta)(H_2O)(CH_3)]^-$ is produced. The results reported here enable us to comment on the mechanism of the cobalt–carbon bond-formation and homolysis reactions and clearly demonstrate that pressure assists the formation of this bond.

Irradiation of a N_2O saturated (0.011 M) solution containing $(1-5)\times10^{-3}$ M $CoSO_4$, 6×10^{-3} M nta, 0.1 M DMSO, and 1.2×10^{-4} M O_2 at pH 6.5, results in the following sequence of reactions:[6, 13]

$$e_{aq}^- + N_2O \xrightarrow{H^+} {}^{\bullet}OH + N_2 \quad k_2 = 8.7\times10^9\ M^{-1}s^{-1}\ [14] \quad (2)$$

$${}^{\bullet}OH + (CH_3)_2SO \longrightarrow (CH_3)_2\dot{S}OOH \quad k_3 = 7.0\times10^9\ M^{-1}s^{-1}\ [15] \quad (3)$$

$$(CH_3)_2\dot{S}OOH \longrightarrow {}^{\bullet}CH_3 + CH_3SOOH \quad k_4 = 1.5\times10^7\ s^{-1}\ [15] \quad (4)$$

$$[Co^{II}(nta)(H_2O)_2]^- + {}^{\bullet}CH_3 \rightleftharpoons [Co^{III}(nta)(H_2O)(CH_3)]^- + H_2O \quad (5)$$
$$k_5 = 1.6\times10^8\ M^{-1}s^{-1}\ [6]$$
$$K_5 = k_5/k_{-5} = 2.7\times10^6\ M^{-1}\ [6]$$

$$[Co^{III}(nta)(H_2O)(CH_3)]^- + {}^{\bullet}CH_3 \xrightarrow{H_2O} [Co^{II}(nta)(H_2O)_2]^- + C_2H_6 \quad (6)$$
$$2k_6 = 7.5\times10^7\ M^{-1}s^{-1}\ [6]$$

$${}^{\bullet}CH_3 + O_2 \longrightarrow {}^{\bullet}O_2CH_3 \quad k_7 = 4.7\times10^9\ M^{-1}s^{-1}\ [6] \quad (7)$$

$${}^{\bullet}O_2CH_3 + [Co^{II}(nta)(H_2O)_2]^- \longrightarrow [Co^{III}(nta)(H_2O)(O_2CH_3)]^- + H_2O$$
$$k_8 = 1.0\times10^8\ M^{-1}s^{-1}\ [6] \quad (8)$$

The kinetics of formation of $[Co^{III}(nta)(H_2O)(O_2CH_3)]^-$ under the selected experimental conditions obey the rate law in (9),[6, 13] from which it follows that K_5 and k_{-5} can be

calculated from a plot of k_{obs}^{-1} versus the concentration of Co^{II} at constant O_2 concentration as indicated in (10). Thus

$$-\frac{dc([Co^{III}(nta)(H_2O)(CH_3)]^-)}{dt} = \frac{k_7 k_{-5}\, c(O_2) c([Co^{III}(nta)(H_2O)(CH_3)]^-)}{k_5 c([Co^{II}(nta)(H_2O)_2]^-) + k_7 c(O_2)} \quad (9)$$

$$k_{obs}^{-1} = \frac{K_5 c([Co^{II}(nta)(H_2O)_2]^-)}{k_7 c(O_2)} + k_{-5}^{-1} \quad (10)$$

by repeating such experiments as a function of pressure, it is in principle possible to measure the pressure dependence of K_5 and k_{-5},[16] from which the reaction volume for equilibrium (5) and the activation volume for both the formation and homolysis of the Co^{III}–CH_3^--bond, can be calculated.

The experimental data in Figure 1 depict the relationship suggested by Equation (10). The pressure dependence

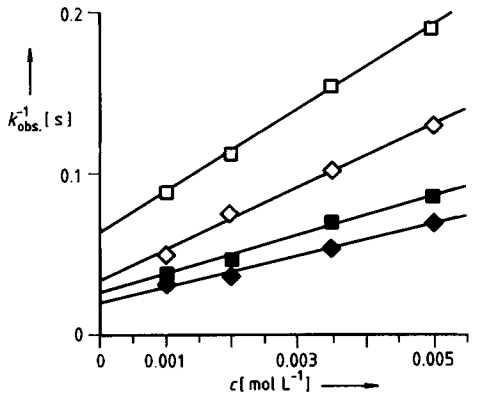

Fig. 1. Plots of k_{obs}^{-1} vs. concentration c of $[Co(nta)(H_2O)_2]^-$ at different pressures: □ p = 150 MPa, ◇ p = 100 MPa, ■ p = 50 MPa, ● p = 0.1 MPa.

of K_5 and k_{-5} is presented in Figure 2, from which it follows that $\Delta\bar{V}(K_5) = -16.4 \pm 1.6\ cm^3\,mol^{-1}$ and $\Delta V^{\neq}(k_{-5}) = +18.6 \pm 2.0\ cm^3\,mol^{-1}$. A combination of these values results in $\Delta V^{\neq}(k_5) = +2 \pm 4\ cm^3\,mol^{-1}$. In order to corroborate the latter value, the pressure dependence of k_5 was measured directly by observing the rate of formation of $[Co^{III}(nta)(H_2O)(CH_3)]^-$ at 264 nm.[17] The observed rate data are $(1.9 \pm 0.1) \times 10^8$ and $(1.3 \pm 0.1) \times 10^8\ M^{-1}s^{-1}$ at 0.1 and 150 MPa, respectively, which result in a $\Delta V^{\neq}(k_5)$ value of $+6.0 \pm 2.5\ cm^3\,mol^{-1}$. The latter value is in good agreement with that calculated in an indirect way (see above).

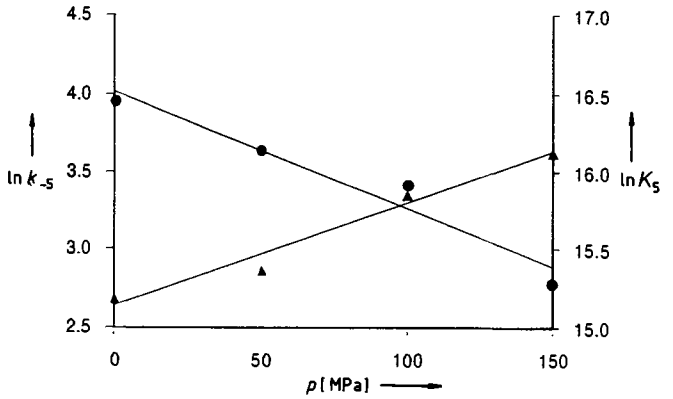

Fig. 2. Pressure dependence of ln k_{-5} (●) and ln K_5 (△).

The effect of pressure on reaction (8) was measured in a similar way,[18] and the results are $k_8 = (1.00 \pm 0.12) \times 10^8$, $(0.96 \pm 0.06) \times 10^8$, $(0.80 \pm 0.10) \times 10^8$, and $(0.68 \pm 0.06) \times 10^8\ M^{-1}s^{-1}$ at 0.5, 50, 100, and 150 MPa, respectively. From these data it follows that $\Delta V^{\neq}(k_8) = +6.0 \pm 1.0\ cm^3\,mol^{-1}$, which is very close to that reported above for k_5.

As reflected by the significantly negative value of $\Delta\bar{V}(K_5)$ (see Equation 5), pressure strongly assists the formation of the cobalt–carbon bond. This value indicates that the product state is considerably more compressed than the reactant state, from which we conclude that the hydrophobic methyl radical has a considerably larger solvation sphere than the water molecule that is released during the bond-formation process. In addition, cobalt–carbon bond formation can be considered an oxidative addition reaction since Co^{II} is oxidized to Co^{III}, which will also result in a significant decrease in volume. The measured activation volumes for k_5, k_{-5} and k_8 are all in line with a dissociative reaction mode. The largest effect ($+18.6 \pm 2.0\ cm^3\,mol^{-1}$) was observed for k_{-5}, which is in good agreement with data reported in the literature for homolysis reactions of the metal–carbon bond.[12a, 19, 20] The observed effect can partly be ascribed to the desolvation of the aliphatic free radicals formed in this process.[9, 20] The observed volumes of activation for k_5 and k_8 are very similar to those generally reported for solvent-exchange and complex-formation reactions of aquated Co^{II} ions[9, 21] and are characterisitc for a dissociative interchange (I_d) mechanism. This conclusion is further underlined by the insensitivity of $\Delta V^{\neq}$ to the nature of the binding radical. From these results we conclude that metal–carbon bond formation is very similar to a ligand-exchange process in terms of volume changes, and follows an I_d mechanism in the case of cobalt(II). Homolysis of the cobalt–carbon bond is presumably accompanied by an additional contribution arising from the breakup of the solvent cage. It is questionable whether this reaction can be considered a limiting dissociative mechanism whose activation enthalpy corresponds to the bond dissociation energy, as suggested previously.[1e, 2, 3a, 9]

We conclude that through a unique combination of pulse radiolysis and high-pressure techniques it was possible to gain insight into the mechanism of metal–carbon bond formation and homolysis. In addition, it is clear that the formation of the cobalt–carbon bond is assisted by pressure since the homolysis reaction exhibits a much larger activation volume than the bond-formation reaction, resulting in a significantly negative overall reaction volume.

[11] Details of the experimental setup are given elsewhere [10, 12]. A further modification of the high-pressure cell was undertaken. The sapphire window through which the radiation entered the cell was replaced with a 10 mm thick steel window into which a hole (9 mm deep, 8 mm diameter) was drilled. In this way sufficient radiation for accurate experiments could penetrate the cell. A Xe–Hg arc lamp was used to follow the reaction at 313 nm. the high light intensity of this lamp helped to increase the signal-to-noise ratio of the kinetic traces. All experiments were performed at 17 °C.

[16] According to equation (10) the slope of the plot of k_{obs}^{-1} versus c (Co^{II}) equals $K_5/k_7\, c\,(O_2)$; thus the pressure dependence of the slope arises from the pressure dependence of K_5 and k_7. Fortunately, reaction (7) is diffusion-controlled and k_7 will therefore vary with pressure in the same way as the viscosity of the solvent. Over the investigated pressure range the variation in the viscosity of water is negligible and the pressure dependence of the slope must reflect the pressure dependence of K_5.
[17] This wavelength is near the absorption maximum of the product [6a] and is a line of the Xe–Hg arc lamp used to study the reaction. The light intensity at this wavelength is considerably lower than at 313 nm, and the error limit is therefore larger.
[18] For this purpose N_2O saturated solutions containing 2×10^{-4} M $CoSO_4$, 4×10^{-4} M nta, 0.1 M DMSO and 1.2×10^{-4} M O_2 at pH 6.5 were irradiated. Under these conditions k_8 can be measured directly.

Solvation Effects on Geometry and Chemical Shifts. An Ab Initio/IGLO Reconciliation of Apparent Experimental Inconsistencies on $H_3B\cdot NH_3$ **

By *Michael Bühl, Thomas Steinke, Paul von Ragué Schleyer,** and *Roland Boese*

Redetermination of the X-ray structure of the parent borane-ammonia complex $H_3B\cdot NH_3$ **1**[1] confirms the B–N separation of 1.564 Å,[2] which is surprisingly short for such a dative complex.[3] In contrast, the B–N distance determined in the gas phase by microwave spectroscopy (r_0 = 1.672 Å)[4] is more than 0.1 Å longer. The MW value is reproduced quite accurately by ab initio calculations at various levels[5] (cf. our MP2(Full)/6-31G* data,[6] Fig. 1). While some longer B–N separations in the 1.64–1.67 Å range are found in the crystal structure (and by ab initio calculations) of substituted borane-amine complexes,[7] a recent review recommended 1.58 Å as the reference value.[8] However, the potential energy surface of **1** is quite flat. When the X-ray B–N distance is employed (and the other parameters fully optimized), the energy is only ca. 1.5 kcal/mol higher (Fig. 1).

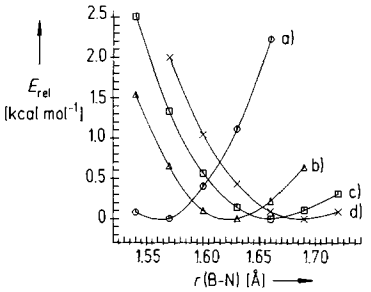

Fig. 1. Relative energy E_{rel} of $H_3B\cdot NH_3$ as a function of the B–N distance r computed with the 6-31G* basis set and various procedures: for the isolated molecule at the SCF (d) and MP2 levels (c), all other parameters optimized; with the SCRF continuum method in the solvents hexane (b) and water (a), single point calculations on the MP2 geometries. Note the pronounced bond-shortening in the polar solvent, water.

There is also a discrepancy between the experimentally determined chemical shift $\delta(^{11}B)$ for **1**, measured in water solution,[9] and the value calculated (IGLO[10]) for the isolated molecule. As shown in Figure 2, the correlation between measured and IGLO $\delta(^{11}B)$ chemical shifts for a large series of borane complexes is generally quite satisfactory (correlation coefficient 0.991, standard deviation δ = 2.0). The ^{11}B IGLO chemical shift for **1**, calculated using the

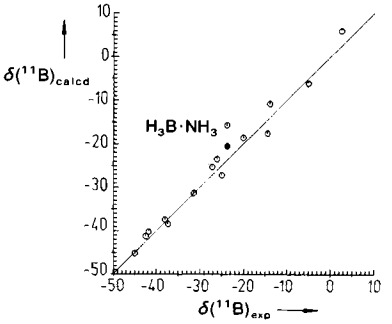

Fig. 2. Plot of the calculated (IGLO) vs. experimentally determined chemical shifts $\delta(^{11}B)$ of borane-adducts H_3B-L (L = CO, PH_3, $CN^{\ominus}$, PMe_3, $PH_2^{\ominus}$, $CH_3^{\ominus}$, $NC^{\ominus}$, $NCS^{\ominus}$, NH_3, $SH^{\ominus}$, SMe_2, $N_3^{\ominus}$, $OH^{\ominus}$, NMe_3, OMe_2 [11]). The theoretical values were computed employing a TZP basis (denoted II') and MP2/6-31G* fully optimized geometries. Without **1**, the standard deviation is δ = 2.0 (correlation coefficient 0.991). The ideal slope = 1 is shown. Blackened point: $H_3B\cdot NH_3$ **1** employing a B–N distance of 1.57 Å according to the SCRF calculations (see Fig. 1).

MP2(Full)/6-31G* B–N distance of 1.66 Å, deviates from the experimental value in water by $\Delta\delta = 8.1$ (Fig. 1, Table 1). However, if the X-ray separation, 1.57 Å, is used instead, the IGLO error is only 3.3. The experimental $\delta(^{11}B)$ value can be matched if a B–N distance of ca. 1.50 Å is assumed.

Table 1. Dependence of the calculated (IGLO) chemical shift $\delta(^{11}B)$ of $H_3B \cdot NH_3$ **1** on the B–N distance; in italics: experimentally determined values.

r (B–N) [Å]	μ [D] [a]	$\delta(^{11}B)$ [b]
1.66 [c]	5.67	– 15.7
1.63	5.73	– 17.5
1.60	5.79	– 19.1
1.57	5.84	– 20.5
1.54	5.90	– 21.8
1.51	5.93	– 23.0
Experiment	*5.22* [d]	*– 23.8* [e]

[a] Dipole moment, calculated at the HF/6-31G*//MP2/6-31G* level; note that the high dipole moment does not change to a great extent with the B–N distance. [b] IGLO basis II': B,N 9s5p1d {51111,2111,1}, H 3s {21} (cf. Ref. [10c]); the geometric parameters (except the B–N distance) were optimized at the MP2/6-31G* level. [c] Fully optimized. [d] Gas phase (Ref. [3]). [e] Ref. [6].

These data suggest that the geometry of **1** (and to a lesser extent of other borane-amine complexes) may depend on the environment. We investigated this possibility for **1** by means of self-consistent reaction field (SCRF) calculations,[12, 13] a modern adaption to the ab initio framework of the Onsager-Kirkwood-Westheimer ellipsoidal cavity model for medium effects.[14] As implemented by *Tomasi* and his group,[12] SCRF provides a means for modeling continuum effects. Simulations can be carried out with parameters for various solvents; those for hexane and for water were employed here.[13] (It should be noted that hydrogen bonding effects for water are not included specifically in this treatment.[15]) The results, summarized in Figure 1, are quite significant. Reoptimization of the B–N distance of **1** in the SCRF field simulated for hexane (6-31G* basis set) results in a reduction of the B–N bond length to 1.62 Å; for water the reduction is even more dramatic (1.57 Å, Fig. 1). As the B–N distance decreases with increasing solvent polarity, we suggest that the dipolar field in the crystal (like the dielectric reaction field of water) may be responsible for the B–N bond shortening. This conclusion is supported by additional findings. In the weaker dipolar crystal fields of more voluminous complexes, the B–N distance is substantially longer, e.g. 1.60 Å in the $H_3B \cdot NH_3 \cdot$ 18-crown-6 complex.[16] Longer B–N separations are also found in complexes of substituted boranes and/or substituted amines in the solid state, e.g. 1.656, 1.648 and 1.616 Å for $Me_3B \cdot NHMe_2$, $Me_3B \cdot NH_3$ and $H_3B \cdot NMe_3$, respectively.[7] For the latter, the B–N bond shortening with respect to the gas phase ($r_0 = 1.637$ Å,[17] MP2/6-31G* value 1.645 Å[18]) is less pronounced than for **1**.

Several important inferences follow. Medium effects on NMR chemical shifts, which occasionally are observed, may be indirect. Solvent molecules are too remote to influence nuclear shielding directly.[15, 18] Instead, solvation may change the geometry (and the electronic structure), and this influences the chemical shifts. Particularly for systems with flat potential energy surfaces, even highly accurate X-ray structures may provide misleading information concerning geometrical parameters, if these are considered to be characterized by the equilibrium values in isolated, unperturbed systems.

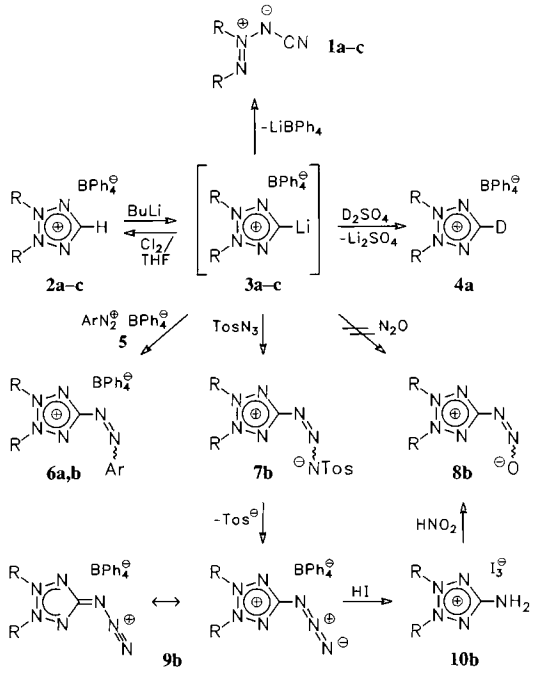
5-Lithio-2*H*-tetrazolium Carbenoids: NMR Spectroscopic Detection and Reactions with Nitrogen Electrophiles**

By *Robert Weiss** and *Rainer H. Lowack*

2*H*-Tetrazolium ions of type **2** are part of the tetrazolium/formazanide redox system, which is distinguished by an excellent charge stabilization within both the cationic and the anionic oxidation state. As a consequence, the 2*H*-tetrazolio substituent should facilitate redox umpolung.[1] We have examined nucleophilic reagents for the introduction of the 2*H*-tetrazolio group into electrophilic substrates[2] and report trapping reactions of the 5-lithiotetrazolium ion **3** and its spectroscopic detection by ^{13}C NMR spectroscopy.



Scheme 1. **a**: R = *p*-tolyl, **b**: R = *p*-anisyl, **c**: R = *p*-dimethylaminophenyl, Tos = *p*-toluenesulfonyl, Ar = *p*-dimethylaminophenyl.

^1H NMR spectra show that tetrazolium salts **2**, dissolved in tetrahydrofuran, are deprotonated quantitatively at − 90 °C by *n*- or *tert*-butyllithium. The 5-lithiotetrazolium salts **3** thus formed can be considered as carbenoids.[3] At − 100 °C they are sufficiently stable for their ^{13}C NMR spectra to be recorded.[4] The ^{13}C NMR spectrum of **2b** had no signals between $\delta = 165$ and 250, whereas, after lithiation, a single unstructured multiplet appeared at $\delta = 202.4$ and vanished when the solution was heated up to room temperature. IGLO/DZ//6-31G* calculations[5] indicate that this multiplet is the ^{13}C NMR signal of the solvated carbenoid's tetrazolium ring.[6] According to the calculations, this shift of 48 ppm to lower field upon lithiation of **2b** can be explained mainly by the decrease of π-electron density at the tetrazolium C atom and by the weakening of the two N–C σ bonds to this atom.[7] Corresponding changes in the chemical shift have been observed upon deprotonation of an imidazolium salt[3] and lithiation of benzene[7] or halogen alkanes.[8]

Above ca. − 60 °C the 5-lithiotetrazolium salts **3** open up by an intramolecular E_{1cB} elimination to yield the (2*Z*)-1-cyano-2,3-diaryltriaz-2-en-2-ium-1-idenes **1**.[1] Nevertheless, **3** could be trapped at − 90 °C with either D_2SO_4, aryldiazonium tetraphenylborate **5**,[9] or tosyl azide in good yields.[10] The new tetrazolium salts **6** and **9b** thus formed had not been accessible before, among other reasons because the reactivity[11] of 1,5-diarylformazans towards **5** is too low. On the other hand, this sole method to derivatize tetrazolium ions of type **2** failed when strongly oxidizing electrophiles like chlorine (or bromine) were used. In this case not the desired product but ion **2** as its chloride (bromide) was isolated in a yield of 67% (79%). We assume that **3** was oxidized by the halogen to the corresponding radical cation which abstracted an H atom from the solvent THF to re-form **2**.[12]

The azide **9b** was identified spectroscopically[13] and by its reduction with iodide to amine **10b** and subsequent diazotization to the known[14] tetrazolium-5-diazotate **8b**. Reduction of **9b** with triphenylphosphane/water led to fission of the C–N bond. In contrast to *Balli's* azidinium salts,[15] **9b** did not react with azide ions. Thus, from the intensely yellow, shock-insensitive tetraphenylborate salt **9b**, the corresponding colorless chloride or azide salt could be prepared with tetrabutylammonium chloride or azide, respectively.

Experimental Procedure

9b: To **2b** (4.64 mmol) dissolved in 50 mL of THF, *n*-butyllithium (5.1 mmol, 1.6 molar in hexane) and then tosyl azide (10 mmol) were added dropwise at − 90 °C. The initially dark brown solution turned dark red within a few minutes. After warming to 20 °C over 10 h the solvent was evaporated. The green brown residue, which contained a small amount of **7b** according to mass spectrometry, was chromatographed with dichloromethane/methanol (1 : 0 to 10 : 1) on silica gel. From acetonitrile/ether or dichloromethane/ether 2.00 mmol (43%) of yellow air-stable crystals were obtained.

6b: As above, from **2b** (1.44 mmol) in 30 mL of THF, *n*-butyllithium (1.50 mmol) and **5** (1.87 mmol, added undissolved in portions). After chromatography and hydrolysis of the anion in hydrochloric acid, the product was precipitated as its tetrafluoroborate from water/methanol (2 : 1) with $LiBF_4$. Recrystallization from dichloromethane/ether yielded 0.81 mmol (56%) of an oxygen-sensitive, dark red crystalline powder.

10b: To **9b** (0.688 mmol) in 2 mL of acetonitrile, an HI solution (3.5 mmol, 50% in H_2O) was added dropwise at − 40 °C. The solution turned dark brown with strong evolution of gas. After slow warming to 20 °C the solvent was evaporated. The residue was dissolved in 3 mL of dichloromethane and filtered. Concentrated aqueous hydrochloric acid (4 mL) was added, followed by titration with H_2O_2 solution (30%) till the color changed from brown to purple. The organic layer was chromatographed with dichloromethane/methanol (1 : 0 to 10 : 1) on silica gel. From methanol, 0.608 mmol (88%) of the colorless chloride crystallized.

Galactosyltransferase-Catalyzed Synthesis of 2′-Deoxy-*N*-acetyllactosamine **

By *Joachim Thiem** and *Torsten Wiemann*

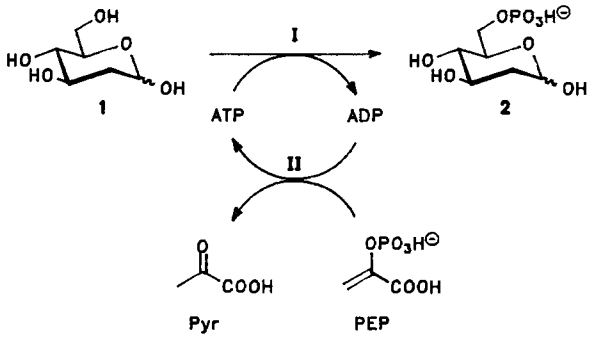
Dedicated to Professor Burchard Franck on the occasion of his 65th birthday

2-Deoxy sugars are components of cardiac glycosides[1a] and many antibiotics.[1b] The synthesis of their glycosides and the use of these in medicine and as enzyme inhibitors has attracted great interest.[1c] Since a neighboring group capable of directing the reaction is absent, the stereoselective synthesis of 2-deoxyglycosides poses problems. Several methods have been proposed to solve them.

Whereas 2-deoxy α-glycosides are still obtainable with good results by using the *N*-iodosuccinimide (NIS) method[2a–c] or analogous procedures,[2d–f] 2-deoxy β-glycosides are especially difficult to synthesize owing to the anomeric effect. Here, an auxiliary substituent is usually employed, such as in the dibromomethyl methyl ether method[3a] (DBE method) and other procedures,[3b–e] or, after glycosylation, the 2′-OH function is removed by reduction.[4] To the best of our knowledge, there is only one reported example of an enzymatic synthesis of a 2-deoxy sugar. *Lehmann* et al.[5] observed that D-glucal is accepted by β-glucosidase and were able to isolate a 2′-deoxy-β-disaccharide in 8% yield.

We have used galactosyltransferase (EC 2.4.1.22) for the synthesis of a 2′-deoxy β-D-disaccharide. The galactosyltransferase catalyzes the in vivo transfer of galactose from uridine 5′-diphosphate galactose to terminal *N*-acetylglucosamine residues. The acceptor substrate has been successfully varied in numerous preparative syntheses.[6] However, an example of the synthetic application of a modified donor substrate in not yet known. We have now found that the galactosyltransferase accepts uridine diphosphate (UDP) 2-deoxygalactose, whereby 2-deoxygalactose is transferred to *N*-acetylglucosamine both stereo- and regiospecifically to form a β(1-4) glycosidic bond.

The starting material, 2-deoxy-D-*arabino*-hexose 6-phosphate (**2**), was synthesized by enzymatic phosphorylation of 2-deoxy-*arabino*-hexose (**1**) with in situ regeneration of adenosine triphosphate (ATP) (Scheme 1). Both the hexokinase and the pyruvate kinase had been immobilized on VA-epoxy.[7] The 6-phosphate **2** was isolated by chromatography on DEAE cellulose (80% yield).



Scheme 1. Synthesis of 2-deoxyglucose-6-phosphate (enzymes: I hexokinase on VA-epoxy, II pyruvate kinase on VA-epoxy).

The reactions were performed in a one-pot synthesis using immobilized enzymes (Scheme 2). The reaction cycle results in constant regeneration of the cofactor uridine triphosphate (UTP), thereby minimizing inhibition effects and costs. Such a cycle—with a different support and different substrates—was first employed by *Whitesides* et al.[8a] and later by other research groups as well.[8b,c] Phosphoglucomutase (**III**) establishes an equilibrium between the 6-phosphate **2** and the 1-phosphate **3**, which is shifted toward **3** by UDP-glucose pyrophosphorylase (**IV**) and inorganic pyrophosphatase (**V**). In this way, *Withers* et al.[9] were able to isolate the extremely hydrolysis-sensitive 2-deoxy 1-phosphate **3**. UDP-galactose-4-epimerase (**VI**) then establishes an equilibrium between the UDP 2-deoxyglucose (**4**) thus synthesized and UDP 2-deoxygalactose (**5**). The kinetic parameters for this reaction have already been determined by *Kochetkov* et al.[10] Compound **5** is accepted as a donor substrate by galactosyltransferase (**VII**), resulting in transfer of 2-deoxygalactose to *N*-acetylglucosamine (**6**). The product, 2′-deoxy-*N*-acetyllactosamine (**7**), was obtained in 40% yield (150-μmol scale). The structure was established by ^1H NMR and ^{13}C NMR spectroscopy as well as by FAB mass spectroscopy (Table 1). The UDP formed as side product is phosphorylated to UTP with phosphoenolpyruvate (PEP) as phosphate donor in a reaction catalyzed by pyruvate kinase (**VIII**). UTP can then

FAB-MS (free sugar 7): $M^{\oplus}$ + 1 = 368, $M^{\oplus}$ + Na = 390

reenter the reaction to form UDP 2-deoxyglucose. The amount of conversion in the reaction can be quantified by using the Fiske–Subbarov method for photometric determination of phosphate.[11] All enzymes used in the cycle are immobilized on activated CH-sepharose and can be employed repeatedly.

Experimental Procedure

The reaction was carried out in Tris buffer (100 mM, pH 7.5, 9 mL). The buffer contained $MgCl_2$ (10 mM), $MnCl_2$ (5 mM), KCl (40 mM), NaN_3 (0.02%), and bovine serum albumin (0.5%). After addition of 2-deoxy-D-*arabino*-hexose 6-phosphate (**2**, $NH_4^{\oplus}$ salt, 100 mg, 40 mM), *N*-acetylglucosamine (**6**, 120 mg, 60 mM), PEP (82 mg, 44 mM), glucose 1,6-diphosphate (0.1 mg, catalytic), and UTP (11 mg, 2 mM), adjustment of the pH value, and deoxygenation with helium, the immobilized enzymes were added (phosphoglucomutase (rabbit muscle), 20 U; UDP-glucose-pyrophosphorylase (bovine liver), 10 U; inorganic pyrophosphatase (yeast), 20 U; UDP-galactose-4-epimerase (yeast), 5 U; galactosyltransferase (cow's milk), 2 U; pyruvate kinase (rabbit muscle), 50 U). The mixture was incubated in a shaking apparatus for two weeks at 30 °C. The enzyme, after collection by filtration and washing, could be reused. After removal of phosphate on an ion-exchange column (Dowex 1 × 8, $H^{\oplus}$ form), the product was isolated by gel permeation chromatography (Fractogel TSK HW-40 (S), 2 × 110 cm) (53 mg, 144 μmol, 40% yield).

tion of a "synthesis gas" on the surface of bulk metals or colloidal particles.[1] Several decanuclear hydrido clusters of osmium and ruthenium have been structurally characterized by X-ray diffraction,[2-4] and most exhibit tetracapped octahedral metal cores with what appear to be closed-packed arrays of carbonyl ligands approximately perpendicular to the four six-metal atom surfaces of the core. None of these clusters shows the marked displacement of carbonyl ligands invariably associated with surface-bonded hydride ligands in smaller clusters,[5-8] and it has therefore been thought, until now, that the hydride ligands were probably all located in interstitial sites. A neutron diffraction study of one of these

$[H_4Os_{10}(CO)_{24}]^{2-}$ **1**

decametal clusters, the dianion **1**, has now established that all four hydride ligands are located on the surface of the metal framework.

Single crystal X-ray studies do not allow direct location of H atoms in polynuclear carbonyls of the third-row transition metals, but they often lead to successful deduction of hydrogen sites using indirect methods based on detecting 'gaps' in the carbonyl ligands,[5-8] or on determination of potential energy minima.[9] For example, a μ_3 site on the surface of the octahedral cluster monoanion **2** was deduced from the surface ligand distribution observed in the X-ray analysis,[6] and was later confirmed by neutron diffraction studies.[10] The first interstitial H atom to be reported in a carbonyl cluster

$[HOs_6(CO)_{18}]^-$ **2** $[HRu_6(CO)_{18}]^-$ **3**

was sited in the octahedral cavity of **3**, the ruthenium analogue of **2**.[11] The unexpected location was originally deduced indirectly from the extremely compact arrangement of the carbonyl ligands which left no space for a surface H atom and from the NMR data. This structural assignment initially proved controversial,[12] but was vindicated by later neutron diffraction studies.[13] A similar octahedral hydride environment was revealed in neutron diffraction studies of the hexacobalt cluster $[HCo_6(CO)_{15}]^-$.[14]

Analogous observations in X-ray studies of the decanuclear monoanion **4**[2] were also consistent with an interstitial location for the H atom, because they showed a complete coverage of the metal core by carbonyl ligands very similar to that of the corresponding non-hydrido dianion **5**.[15]

$[HOs_{10}C(CO)_{24}]^-$ **4** $[Os_{10}C(CO)_{24}]^{2-}$ **5**

As the only octahedral site in **4** is occupied by the carbido atom, the possible location of a hydrido ligand in a slightly enlarged tetrahedral cavity of the cluster was proposed, and the ^{187}Os satellite pattern associated with the hydride signal in the ^1H NMR spectrum was consistent with this assignment.[16]

Carbide formation during formation of these high nuclearity clusters is suppressed by thermolyzing the Os_3 precursors in high boiling protic solvents. The X-ray study of **1**,[3] originally obtained in low yield from the reaction of $Os_3(CO)_{12}$ with *i*BuOH,[17] again showed an overall structure almost indistinguishable from that of the carbido dianion **5** but without the central C atom. It was formulated as $[H_4Os_{10}(CO)_{24}]^{2-}$ because the hydrides were essential to give the 134 cluster valence electrons required for the observed tetracapped octahedral geometry,[15, 18] and the presence of hydrido ligands was confirmed by ^1H NMR spectroscopy. The close similarity of the carbonyl distribution in **1** to that of the non-hydrido dianion **5** was consistent with an interstitial location of the four hydrogen ligands. The cluster also showed significant lengthening of a number of metal–metal distances which were attributed to the cavity expansion produced by internal hydrides. Variable-temperature ^1H and ^{13}C NMR studies showed a high degree of ligand fluctionality in solution at ambient temperatures (CD_2Cl_2, 295 K). On cooling to 198 K the single broad hydride reso-

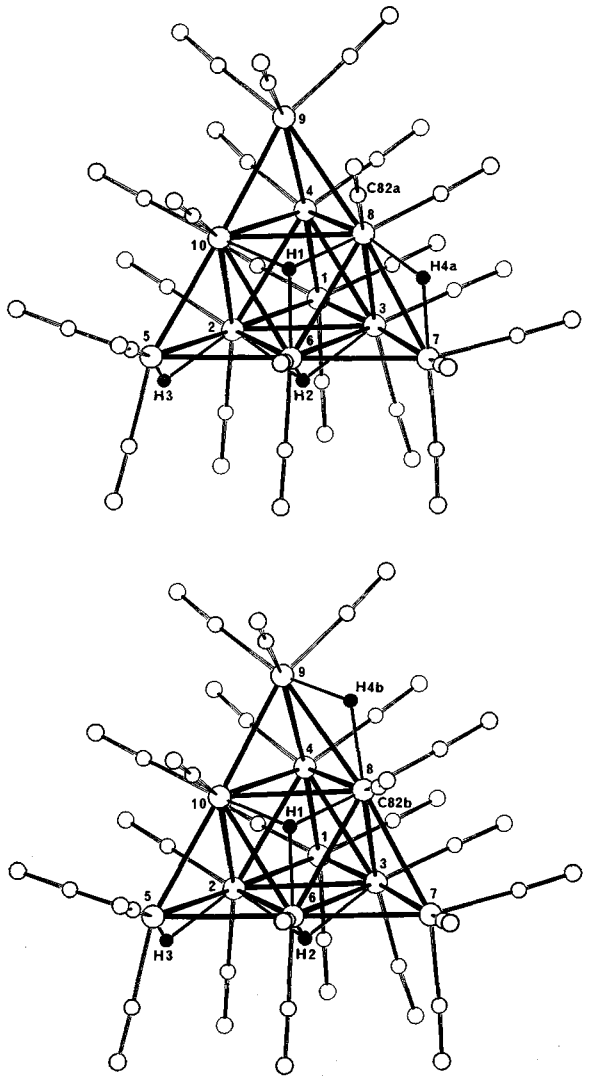

Fig. 1. Perspective views of the structures of the two isomers of the tetrahydrido dianion **1**, showing the surface location of the hydrogen ligands; for clarity only the numbers of the osmium atoms are shown: Top: isomer **1a** which has a virtual C_2 axis through Os6 and Os4; bottom: isomer **1b** which has no symmetry. Principal bond lengths [Å] and angles [°]: (estimated standard deviations in parantheses): Os1-Os2 2.801(8); Os1-Os3 2.772(8); Os1-Os4 2.745(9); Os2-Os3 2.868(7); Os2-Os4 2.816(8); Os2-Os5 2.862(8); Os2-Os6 2.900(8); Os2-Os10 2.805(9); Os3-Os4 2.755(8); Os3-Os6 2.881(8); Os3-Os7 2.733(8); Os3-Os8 2.815(9); Os4-Os8 2.798(8); Os4-Os9 2.739(9); Os4-Os10 2.789(8); Os5-Os6 2.793(7); Os5-Os10 2.778(8); Os6-Os7 2.779(7); Os6-Os8 2.910(8); Os6-Os10 2.858(8); Os7-Os8 2.855(8); Os8-Os9 2.888(8); Os8-Os10 2.894(7); Os9-Os10 2.754(8); Os2-H2 1.87(2); Os2-H3 1.82(3); Os3-H2 1.89(2); Os5-H3 1.81(4); Os6-H1 1.88(3); Os6-H2 1.85(3); Os7-H4a 1.80(5); Os8-H1 1.82(2); Os8-H4a 1.70(4); Os8-H4b 1.77(6); Os9-H4b 1.82(5); Os10-H1 1.89(2); Os6-H1-Os8 104(2); Os10-H1-Os6 99(1); Os10-H1-Os8 103(1); Os3-H2-Os2 100(1); Os6-H2-Os2 103(1); Os6-H2-Os3 101(1); Os5-H3-Os2 104(2); Os8-H4a-Os7 109(2); Os9-H4b-Os8 107(3).

nance at $\delta = -16.48$ split into two signals of equal intensity at -14.70 and -19.08.[19] This signal pattern could not be be explained in terms of a model in which the four hydride ligands occupy interstitial sites (four tetrahedral, one octahedral) within the cluster; therefore their location on the cluster surface, though not apparent from the X-ray study could not be ruled out. Despite persistent attempts to grow crystals of a decanuclear hydrido species suitable for neutron studies using a range of different counterions, none has been obtained until now.

In the present neutron study of the $[(Ph_3P)_2N)]^+$ salt of **1** at 20 K, the hydrido H atoms were directly located in a difference-Fourier synthesis, and were found to be on the cluster surface, two in μ_3 and two in μ_2 sites.[20] The four hydride ligands gave rise to five negative peaks, three of approximately equal height and two of half height. These were attributed to two isomers of the tetrahydrido dianion **1a** and **1b**, differing in the position of the fourth H ligand, and distributed randomly through the crystal. The first isomer **1a** has virtual C_2 symmetry (Fig. 1 top) and the fourth H ligand, H4a, bridges the edge Os7–Os8; in isomer **1b** the corresponding hydride, H4b, bridges Os8–Os9 (Fig. 1 bottom). Significantly, two alternative orientations for a carbonyl ligand on Os8 were resolved and the two components, CO82a and CO82b, were assigned to isomers **1a** and **1b**, respectively.[21] The bridged Os–Os distances show the characteristic lengthening associated with hydrogen ligands (range for H-bridged 2.855 to 2.910(8); for unbridged 2.733 to 2.816 Å). The results from this study demonstrate an essential role for neutron diffraction in full characterization of large hydrido metal clusters.[22] Preliminary results with neutron data collected for **1** at 295 K show a similar hydride distribution to that in the low-temperature study.

The two μ_3 sites occupied by the H ligands in **1** are the first examples of cluster hydrides located in the center of a large planar array of surface metal atoms. Their very congested locations correspond to potential energy minima which are an order of magnitude greater than that associated with the μ_3 H site in the hexanuclear cluster **2** (calculated using the HYDEX programme written by *Orpen*[9]). Computed space filling models[23] (Fig. **2**) show that the H atoms are partially

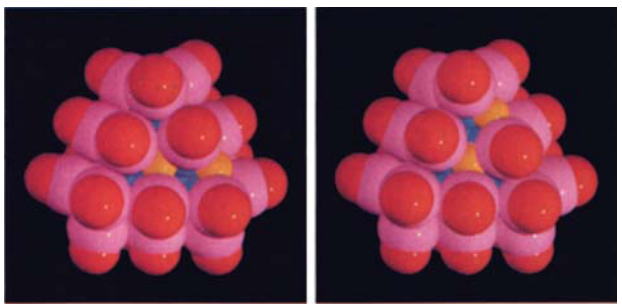

Fig. 2. Computed space-filling models of the two isomers viewed perpendicular to the faces at the front of the views in Fig. 1, that is onto the H1 μ_3 site defined by Os6, Os8, and Os10: (a) isomer **1a** showing the μ_2 H atom H4a; (b) isomer **1b** showing the μ_2 H atom H4b.

submerged under the van der Waals spheres of the three nearest CO ligands in a completely different arrangement from that observed on the surface of smaller clusters.[6, 8, 10] The nearly close-packed distribution of the carbonyl ligands round the μ_3 H atoms in **1** gives rise to some remarkably short C···H contact distances (2.23 to 2.35 Å), compared to a range of 2.48 to 2.70 Å for the three shortest C···H contacts in the neutron study of $[HOs_6(CO)_{18}]^-$ at 20 K.[10] Incipient C···H interaction between the CO ligands and the H atoms on the faces may be deduced from the concerted slight displacement of the oxygen atoms of the carbonyl ligands away from the occupied μ_3 sites which can be seen in Figure 2; this feature is absent in the two unbridged faces of the cluster. These results provide the best molecular model so far for chemisorption at high density of carbon monoxide and hydrogen on (111) or (001) surfaces of metals.

[19] The ^{13}C NMR spectrum of **1** recorded in CD_2Cl_2 at 295 K consists of two (exchange-broadened) carbonyl resonance signals at $\delta = 175.8$ and 192.9 which coalesce at 230 K. Below that temperature the spectra display a complicated pattern of exchange processes which have to date not been fully understood. It proved impossible to obtain a low temperature limit spectrum even at 170 K.
[20] Crystal data for $[(PPh_3)_2N]$-**1** (neutron, 20 K): $C_{96}H_{64}N_2O_{24}P_4Os_{10}$, $M_r = 3655.5$, triclinic, space group $P\bar{1}$ (No. 2), $a = 26.641(1)$, $b = 17.234(1)$, $c = 10.428(1)$ Å, $\alpha = 96.701(2)$, $\beta = 100.672(3)$, $\gamma = 86.148(3)°$, $Z = 2$, $V = 4667.75$ Å^3, ϱ_{calcd} (20 K) = 2.600 g cm^{-3}, $\lambda = 1.3150(2)$ Å (Ge(115) monochromatic thermal neutrons), $T = 20$ K (Displex cryorefrigerator), $\mu = 1.25$ cm^{-1}. Crystal size ca. $0.15 \times 0.20 \times 0.35$ cm; four-circle neutron diffractometer D19, equipped with a position-sensitive detector. A total of 8125 data were recorded, of which 4875 were unique. 4131 absorption corrected data [$I/\sigma(I) > 2.0$] were used in full-matrix refinement of the atomic parameters obtained previously from X-ray data [2] together with those located from this study ($R = 0.0897$; $R_w = 0.0941$). Further details of the crystal structure investigation are available on request from the Director of the Cambridge Crystallographic Data Centre,

University Chemical Laboratory, Lensfield road, GB-Cambridge CB2 1EW (UK), on quoting the full journal citation.

[21] After inclusion of the hydrido H atoms in the model, the highest residual peak was positive (of height approximately 0.2 that of a C atom) and very close to the center of the Os_6 octahedron. The ^{13}C NMR spectra of **1** from the batch used in the neutron study indicated the presence of ca. 20% of the carbido dianion, (**5**) (known to be isomorphous with **1** as its $[(Ph_3P)_2N]^+$ salt). The residual density was therefore interpreted as due to a random 20% occupation of the cluster site by the virtually isostructural carbido dianion. The parameters of the carbido C atom (occupancy 0.2) refined satisfactorily, and the hydrido H atoms and the disordered carbonyl ligand CO82 were therefore assigned overall 0.8 total occupancy.

[22] This study clearly demonstrates that negative evidence for surface location of H ligands in large clusters is unreliable, and the question of the exact location of all the H atoms formerly assigned to interstitial tetrahedral sites must be re-examined. For example the X-ray evidence for the interstitial nature of the H ligand in $[HOs_{10}C(CO)_{24}]^-$ can, with hindsight, be explained by an external μ_2 H and threefold disorder of the cluster anion in the Ph_4As^+ salt and sixfold disorder in the Ph_3PMe^+ salt [2]. Significantly, preliminary X-ray results for the dihydride $[H_2Os_{10}C(CO)_{24}]$ show a similar disorder of two carbonyl ligands to that observed in **1** and have been interpreted as indicating two μ_2 H ligands on the surface (D. Braga, University of Bologna, personal communication).

[23] Calculated using a molecular graphics programme CHEM-RAY: J. W. Lauher, *J. Mol. Graphics 8* (1990) 34. The osmium atoms were assigned covalent radii of 1.5 Å to give a clearer view of the surface ligands. All other atoms have spheres of van der Waals radii [8].

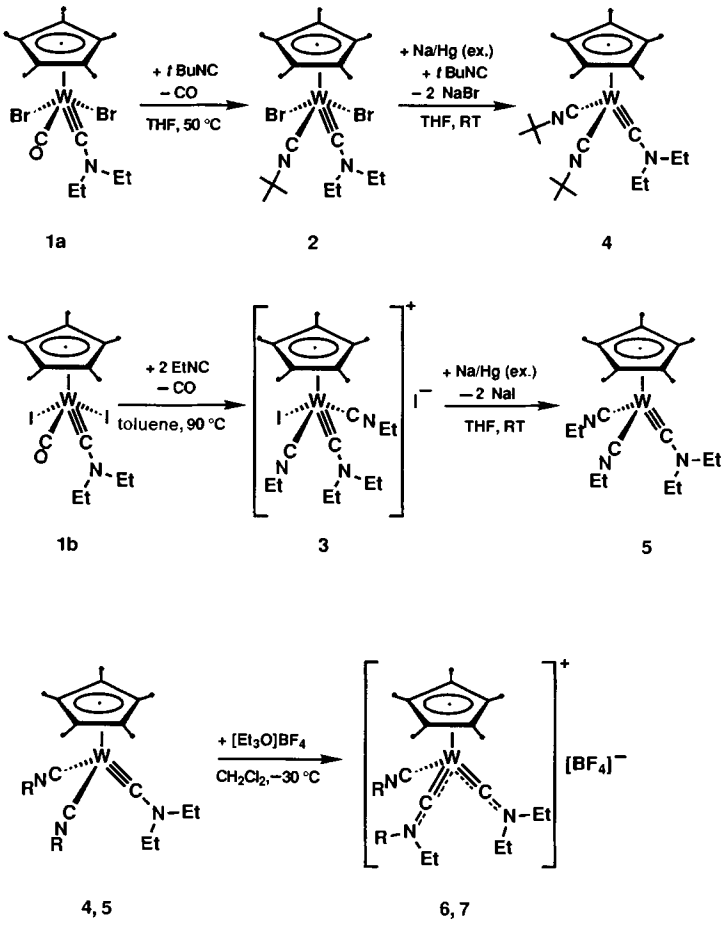
Metal-Centered Coupling of Two Carbyne Ligands To Form an Alkyne Ligand**

By *Alexander Constantin Filippou,* Walter Grünleitner, Christian Völkl,* and *Paul Kiprof*

The coupling of two carbyne ligands to form an acetylene ligand according to $M(CH)_2 \rightarrow M(C_2H_2)$ is symmetry-allowed for d^4 metal centers.[1a] In fact, MO calculations [1b] on the hypothetical 18-electron d^4 complexes $[W(CH)_2Cl_2(CO)_2]$ and $[W(CH)_2Cp(CO)]^+$[2] predict a spontaneous rearrangement to the 16-electron acetylene complexes $[W(\eta^2\text{-}HC{\equiv}CH)Cl_2(CO)_2]$ and $[W(\eta^2\text{-}HC{\equiv}CH)Cp(CO)]^+$, which may be stabilized by complexation with further ligands. However, these calculations also indicate that π-donor substituents on the carbyne carbon stabilize the bis(carbyne) form relative to the alkyne complex. Mononuclear bis(carbyne) complexes are extremely rare, but are often postulated as intermediates in C–C coupling reactions that form alkyne complexes from carbyne precursors.[3]

We have now prepared the first bis(carbyne) complexes of tungsten and selectively converted them into alkyne complexes. The starting materials for the three-stage synthesis are the η^5-C_5Me_5 tungsten complexes **1a** and **1b**[4] (Scheme 1). Treatment of **1a** with *t*BuNC leads to the displacement of the CO ligand to form **2**, which is then reduced to **4** with sodium amalgam in the presence of *t*BuNC. A similar reaction sequence for **1b** leads via **3** to the ethyl isocyanide derivative **5**. The monocarbyne complexes **4** and **5** are finally alkylated with $[Et_3O]BF_4$ to yield selectively the yellow bis(carbyne) derivatives **6** and **7**, respectively.

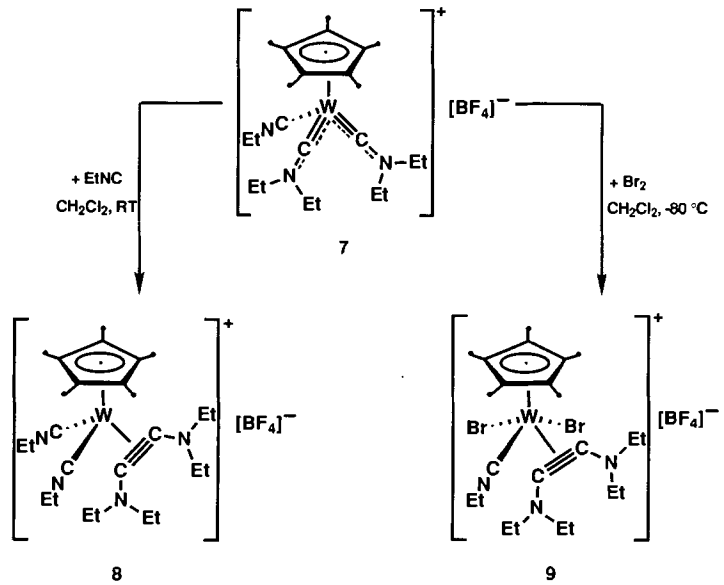
Nucleophilic reagents induce coupling of the two carbyne ligands in **7** to form an alkyne unit. Thus reaction of **7** with



Scheme 1. RT = room temperature, ex. = excess.

ethyl isocyanide yields the W^{II} complex **8** (Scheme 2). A coupling of the two carbyne ligands is also induced by oxidizing agents, as shown by the reaction of **7** with Br_2 which affords the W^{IV}-alkyne complex **9** (Scheme 2).

The bis(carbyne) complexes **6** and **7**[2] are unusually thermally stable: compound **6** decomposes only after several



Scheme 2.

hours in CH_2Cl_2 at room temperature and **7** in the solid state only above 63 °C. In contrast to the IR spectra of the monocarbyne precursors **4** and **5**, two characteristic absorption bands at ca. 1530 and 1600 cm^{-1} for the stretching vibration ν(CN) of the aminocarbyne ligands are found for both **6** and **7** (Table 1).[4] Furthermore, the ^{13}C NMR spectrum of **6** shows two characteristic resonance signals for the carbyne-C atoms at low field, and that of **7** one ($\delta \approx 280$). The $^1J_{WC}$ coupling constants for **6** and **7** (ca. 230 Hz) lie within the expected range for a W–C triple bond.[5a] In the ^{13}C NMR spectra of the coupling products **8** and **9**, however, resonance signals are observed at $\delta \approx 200$, which is typical of a 4-electron alkyne ligand (see also the alkyne-C resonance signals of **12**–**14**).[3c, d, 5b] Evidence of the formation of another W^{II}-bis(carbyne) complex (**11**) in the reaction of the carbyne complex **10** (accessible from $[W(EtNC)_6]$)[3e] with $[Et_3O]BF_4$ is found in the IR spectrum (Scheme 3). Further experimental proof for the formation of **11** is provided by its nucleophile-induced carbyne–carbyne coupling reaction with NEt_4Br to yield the alkyne complex **13** (W^{II}), by the alternative synthesis of **13** from $W(CO)_6$ and $Et_2NC{\equiv}CNEt_2$ (Scheme 4, DME = dimethoxyethane), and by the X-ray structure of the analogous coupling product **14** (Fig. 1).[6]

$[W(\eta^2\text{-}Et_2NC{\equiv}CNEt_2)Br(t\text{BuNC})_4]PF_6$ **14**

Outstanding features of **14**, the first structurally characterized complex of bis(diethylamino)acetylene, are the bond distances and angles in the alkyne ligand, which suggest strong π-bond delocalization.[5b] The octahedral geometry of the cation is distorted: the four equatorial isocyanide groups tilt toward the bromine ligand (Fig. 1).

These results support our hypothesis[3c–e] that bis(carbyne) complexes are key intermediates in the electrophilically induced carbyne–isocyanide coupling reaction of electron-rich carbyne complexes and in the reductive isocyanide–isocyanide coupling reaction of $[M(RNC)_6X]^+$ complexes (X = halogen) to form the alkyne complexes, $[M\{\eta^2\text{-}R(H)NC{\equiv}CN(H)R\}X(RNC)_4]^+$. This new mechanistic information is particularly important with respect to the stoichiometric reductive coupling of CO ligands in low-valent niobium and tantalum complexes[3g] and the catalytic hydrogenation of carbon monoxide (Fischer–Tropsch synthe-

sis),[7] since the factors promoting such processes are now better understood.

Experimental Procedure

2: A solution of **1a** (0.28 g, 0.47 mmol) in THF (50 mL) was treated with *t*BuNC (0.044 g, 0.06 mL, 0.53 mmol) and heated for 3 h at 50 °C. Evaporation of the solvent yielded the product as a red-violet solid. Yield: 0.30 g (98%); m.p. 148 °C.

4: A solution of **2** (0.35 g, 0.54 mmol) in THF (50 mL) was treated with *t*BuNC (0.052 g, 0.07 mL, 0.62 mmol) and Na/Hg (0.40 mL, 0.85% w/w, 1.99 mmol Na) and stirred at room temperature for 5 h. Thereafter, the red solution was filtered to remove the amalgam and precipitated NaBr, the filtrate evaporated to dryness, and the residue purified by chromatography on neutral alumina (45 × 1.5 cm; eluant pentane/Et_2O, 1/1) at 0 °C. Yield: 0.185 g (60%) of a yellow microcrystalline solid; m.p. 35 °C.

7: A solution of **5** (0.13 g, 0.25 mmol) in CH_2Cl_2 (30 mL) was treated at −78 °C with a solution of $[Et_3O]BF_4$ (0.048 g, 0.25 mmol) in CH_2Cl_2 (5 mL), warmed to −30 °C, and stirred for 2 h. After removal of the solvent at −30 °C, complex **7** was isolated as a yellow solid. Yield: 0.16 g (quantitative); m.p. 63 °C (dec.).

9: A solution of **7** (0.18 g, 0.29 mmol) in CH_2Cl_2 (25 mL) was treated at −78 °C with a solution of Br_2 (0.046 g, 0.015 mL, 0.29 mmol) in CH_2Cl_2 (10 mL), warmed to room temperature, and stirred for 1 h. The lilac solution was then evaporated to dryness, and the residue recrystallized from CH_2Cl_2/pentane. Yield: 0.22 g (97%); m.p. 135 °C.

13: A solution of **12** (0.36 g, 0.51 mmol) in dimethoxyethane (80 mL) was treated with EtNC (0.031 g, 0.042 mL, 0.56 mmol), heated for 5 h under reflux, and thereafter evaporated to dryness. The residue was recrystallized from THF/Et_2O. Yield: 0.34 g (91%) of a lilac solid; m.p. 136 °C.

The Synthesis and Structure of Some New Sodalites: The Lithium Haloberyllophosphates and -Arsenates**

By *Thurman E. Gier, William T. A. Harrison,* and *Galen D. Stucky**

The arrangement of atoms in the sodalite structure, first elucidated in 1930 by *Pauling*[1] for its mineral namesake, $Na_8Cl_2(Al_6Si_6O_{24})$, is a remarkably versatile one. The sodalite cage occurs as a building block in the commercially important zeolites X, Y, A, and related zeolite structures such as "hexagonal Y",[2] and may occur in other aluminosilicates whose structures have not yet been determined. Since the first structure determination, several elements (other than the Al/Si pair) have been found to be capable (along with oxygen) of forming sodalite-like structures: $(B_{12}O_{24})$,[3] $(Si_{12}O_{24})$,[4] $(Al_{12}O_{24})$,[5] $(Al_6P_6O_{24})$,[6] $(Be_6Si_6O_{24})$,[7] $(Be_6Ge_6O_{24})$,[8] $(Al_2Be_2Si_8O_{24})$,[9] $(Ga_6Si_6O_{24})$,[10] and more recently, $(Zn_6(P,As)_6O_{24})$.[11] Substitutions on the extra-framework sites are also possible; at least some of the cage centers tolerate all of the chalcogenides[3, 8, 9] including polysulfides and selenides,[12] the larger halides,[14] and oxyanions such as SO_4^{2-} and WO_4^{2-}.[5] The sodium sites may be fully or partially occupied by Li^+, K^+, Rb^+, or Ag^+[15] and Zn^{2+}, Mn^{2+}, Co^{2+}, and Cd^{2+}.

In the course of exploring new molecular sieves and open framework structures based on $(MXO_4)^-$ framework units, including $BePO_4^-$,[16–18] $BeAsO_4^-$,[13] $ZnPO_4^-$,[11, 13] and $ZnAsO_4^-$[11, 13] which have the same net framework charge

as the well-known aluminosilicates, analogues of zeolite X, Li–A(BW) and Rho as well as the zincophosphate and zincoarsenate sodalite have been prepared.[13] Here we report the synthesis and structure of the lithium haloberyllophosphates and -arsenates as additions to the sodalite family.

Microcrystalline powders suitable for Rietveld structure determination were prepared hydrothermally in sealed gold capsules at elevated temperatures and pressures; for instance, $Li_8Br_2(Be_6P_6O_{24})$ was prepared from $LiBePO_4$ and LiBr (see *Experimental Procedure*). If LiCl or LiI are substituted for the bromide salt under the same conditions, the corresponding chloro- (a = 8.025(2) Å) or iodo- (a = 8.162(2) Å) congeners are formed. Similarly, if $LiBeAsO_4$ is used, the corresponding chloro- or bromoarsenates result. (a = 8.238(2) Å and 8.286(2) Å respectively). One species, the iodoarsenate, could not be prepared in this fashion, because the iodide ion was extensively oxidized to free iodine by As^V. For reasons not presently known, the hydroxo hydrate analogues, commonly known in the aluminosilicate structure field, have also resisted synthesis.

Only the boralite sodalites (e.g. $Zn_8O_2(B_{12}O_{24})$, a = 7.4659(3) Å) have a smaller unit cell than these new phases, and the corresponding small size of the 6-ring "windows" militates against ion exchange. Apparently no sodium will exchange for the lithium in the lithium bromoberyllophosphate (molten $NaNO_3$, 325 °C, 3 days), but silver exchanges very slowly (molten $AgNO_3$, 265 °C, 5 days) and the cell edge increases to 8.350(3) Å. The extent of silver exchange is unknown, but under these conditions of "stuffing", the structure is marginally stable since traces of AgBr and Ag_3PO_4 appear among the products.

The second harmonic generation (Nd: YAG laser) of these materials was measured and a small but distinct response found (about three times as intense as that of quartz) confirming the acentric space group. Final observed, calculated and difference profile plots for Li/Br-BePO are illustrated in Figure 1.

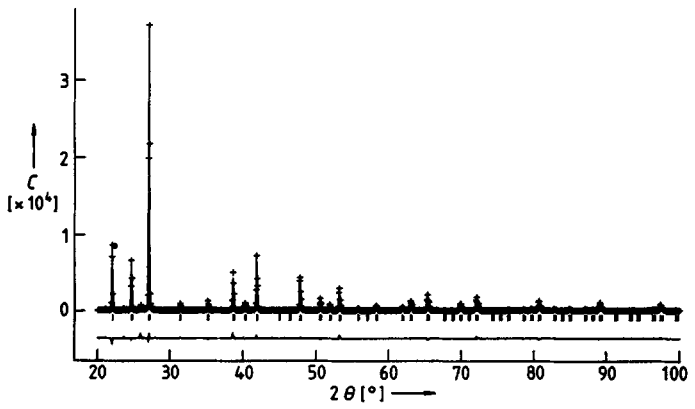

Fig. 1. Structure determination of $Li_8Br_2(Be_6P_6O_{24})$: Final observed (+), calculated (−), and difference profile plots. Allowed reflection positions are indicated by tick marks (|). C = count rate.

The new composition (see *Experimental Procedure*) of the sodalite framework[21] of $[Li_8Br_2(Be_6P_6O_{24})]$ consists of face-sharing truncated octahedra, built up from ordered BeO_4 and PO_4 tetrahedral units. The Be : P ratio is 1 : 1 and the BeO_4 and PO_4 units alternate throughout the structure, as indicated by the bond-distance results (see legend of Fig. 2). Consequently, no refinements of a disordered framework model were attempted. This Be/P/O topology results in spherical cavities (β cages) of approximate diameter 5.5 Å,

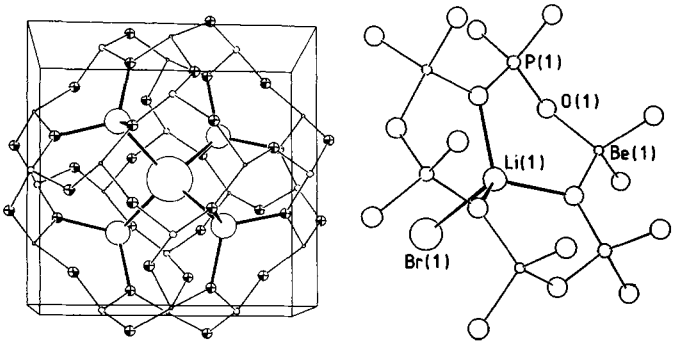

Fig. 2. Left: ORTEP view of the Be/P/O sodalite cage framework, enclosing the tetrahedral Li_4Br unit. For the framework, Be atoms are small circles, P atoms medium circles, and O atoms shaded circles. The large bromide anion is tetrahedrally surrounded by four lithium cations, which in turn make three bonds to the oxygen atoms of the framework. Right: Environment of the Li cation. Selected bond lengths [Å] (standard deviations in parentheses): Be(1)-O(1) 1.620(3), P(1)-O(1) 1.548(3); Li(1)-O(1) 1.923(6); Li(1)-Br(1), 2.685(18).

interconnected via six-rings of approximate diameter 2.2 Å. The $(BePO_4)_6$ framework has an overall negative charge which is compensated by the positive charge of the two $(Li_4Br)^{3+}$ units which reside in the β cages, giving an overall unit cell stoichiometry of $Li_8Br_2(Be_6P_6O_{24})$.

The lithium cations approximately occupy the sodalite 6-ring windows (site symmetry .3.), and are threefold coordinated by framework oxygens. Each also sees the bromine anion at the center of the β cage resulting in distorted tetrahedral geometry (Fig. 2). The bromine anion sees a regular tetrahedron of four lithium cations (23. symmetry). The closest lithium–lithium contact between cages is 4.255(9) Å. The average O–Be–O and O–P–O tetrahedral angles are 110.3(3)° and 110.7(3)° respectively. The Be–O–P framework bond angle is 128.9(2)°, compared with an average of 136(2)° in the zeolite-X analogue, BePO-X,[18] and 134.2(6)° in the zeolite rho analogue, pahasapaite.[16]

By using low temperature synthesis (< 80 °C) the sodalite cage structure was previously found in structures of zeolite X-analogues containing only either Group 2 or Group 12 metal atoms (beryllium and zinc).[18] The synthesis of zinc[11] and beryllium phosphate/arsenate structures analogous to sodalite is further evidence for the existence of an extensive field of molecular-sieve structures based on Group 2 and 12 metals.

Experimental Procedure

A typical preparation may be carried out as follows: for $Li_8Br_2(Be_6P_6O_{24})$, 2.664 g (24 mmol) of $LiBePO_4$ (prepared by standard solid-state techniques) and 2.084 g (24 mmol) of LiBr were sealed in a gold tube (9.5 mm diameter, 102 mm long) with 1.7 ml of H_2O. The tube was then heated in a commercial Tem-Pres (LECO) apparatus to 550 °C (3723 bar–54000 psi) for 36 h and the furnace cooled to ambient over 6 h. After thorough washing and drying of the white microcrystals, 3.305 g (yield = 98.5%) of material exhibiting the powder diffraction pattern of a clean primitive cube (a = 8.081(2) Å) was recovered.

Structure Determination: The crystal structure of $[Li_8Br_2(Be_6P_6O_{24})]$ was established by Rietveld refinement of X-ray powder data (Scintag automated powder diffractometer, θ–θ geometry, flat-plate sample, $Cu_{K\alpha}$ radiation, λ = 1.54178 Å, 20° < 2θ < 100°, step size = 0.02°, T = 25(1) °C). All data analysis was carried out using the program GSAS[19] on a DEC μVAX-II computer. The structure[20] of aluminosilicate hydroxy sodalite $[Na_8(OH)_2(Si_6Al_6O_{24})]$ was used as the starting model for this new $[M_8X_2(A_6B_6O_{24})]$-type sodalite, in space group $P\bar{4}3n$ (No. 218). The usual profile (scale factor, lattice parameter (refined value = 8.0823(4) Å), zero-point error, Voigtian peak-shape-width variation coefficients), atomic positions and isotropic thermal parameters were optimized to convergence, resulting in final agreement factors of R = 0.0867, R_w = 0.1449 and χ^2 = 5.9 for 21 variables and 1998 parameters, largest atomic Δ/σ < 0.01. Difference Fourier syntheses at the end of the refinement revealed no significant regions of extra-atomic electron density, and joint site–population refinements

for Li and Br, constrained to maintain charge neutrality, revealed no significant difference from full occupation. No corrections for preferred orientation or absorption were considered. Final observed, calculated, and difference profile plots for the Li/Br-BePO are illustrated in Figure 1. Further details of the crystal structure investigation my be obtained from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, W-7514 Eggenstein-Leopoldshafen 2 (FRG) on quoting the depository number CSD-55624, the names of the authors and the journal citation.

Reversible Isomerization of the Dinuclear Complex $[(\eta^6\text{-}p\text{-cymene})RuCl(\mu\text{-pz})_2Ir(CO)_2]$ with Formation of a Ruthenium–Iridium Bond**

By *Daniel Carmona, Joaquina Ferrer, Ana Mendoza, Fernando J. Lahoz, Josefa Reyes*, and *Luis A. Oro**

Pyrazoles have been actively investigated as versatile ligands that can yield dinuclear homo- or heterometallic, homo- or heterovalent complexes with interesting photochemical, redox, and catalytic properties.[1] These dinuclear complexes often contain two bridging pyrazolyl ligands forming a six-membered MN_4M' ring in a boat conformation. The unusual flexibility of this ring permits a wide range of intermetallic separations.[2]

[**] This work was supported by the Dirección General de Investigación Científica y Técnica. pz = pyrazolyl.

The reversible cleavage and formation of a metal–metal bond usually implies the addition or removal of small molecules.[3] Nevertheless, Jones *et al.* have recently reported the synthesis of $[(CO)_2Rh(\mu\text{-}t\text{Bu}_2P)_2Rh(CO)_2]$, a unique system in which simple geometrical isomerism occurs with reversible formation and cleavage of a metal–metal bond.[4] Here we describe a double-bridged Ru-Ir pyrazolyl system which easily isomerizes with reversible metal–metal bond formation accompanied by halide migration. The analogous Ru-Rh system was also analyzed for comparison.

Carbonylation of the complexes $[(\eta^6\text{-}p\text{-cymene})RuCl(\mu\text{-pz})_2M(cod)]$ (M = Ir, Rh; cod = 1,5-cyclooctadiene)[5] proceeds rapidly at room temperature when CO is bubbled through dichloromethane or THF solutions. The products are the dicarbonyl complexes **1** and **2**. Complex **1** was ob-

$[(\eta^6\text{-}p\text{-cymene})RuCl(\mu\text{-pz})_2M(CO)_2]$ **1**, M = Ir; **2**, M = Rh

$[(\eta^6\text{-}p\text{-cymene})RuCl(\mu\text{-pz})_2Ir(CO)_2]$ **1a** $[(\eta^6\text{-}p\text{-cymene})\overline{RuCl(\mu\text{-pz})_2}Ir(CO)_2]$ **1b**

tained as a mixture of two isomers, **1a** and **1b**, according to spectroscopic and analytical data.[6] The relative amount of each isomer isolated from solution is variable from one preparation to another and sometimes pure **1a** was obtained. Pure **1b** spontaneously precipitates from methanolic solutions of mixtures of **1a** and **1b**. According to ^1H NMR measurements, an equilibrium between **1a** and **1b** is reached in solution. The K value at room temperature for the process **1a** $\rightleftharpoons$ **1b** is 2.4 ± 0.1 in $CDCl_3$. The isomerization **1b** $\rightarrow$ **1a** was monitored by ^1H NMR spectroscopy. The reaction obeys a second-order rate law in **1b** ($k = 3 \times 10^{-3}$ mol^{-1} dm^3 min^{-1}) and was inhibited by addition of benzyltriphenylphosphonium chloride. These findings support an ionic mechanism for the isomerization.

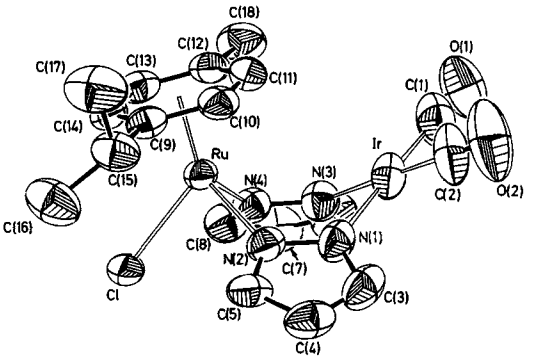

Fig. 1. Molecular structure (ORTEP) of **1a**. Selected bond lengths [Å] and angles [°]: Ru-N(4) 2.079(4), Ru-N(2) 2.088(4), Ru-Cl 2.403(1), Ru-CY 1.678(2), Ir-N(3) 2.062(4), Ir-N(1) 2.062(4), Ir-C(1) 1.872(8), Ir-C(2) 1.838(7), C(1)-O(1) 1.129(10), C(2)-O(2) 1.148(10); N(2)-Ru-N(4) 85.0(1), N(2)-Ru-Cl 86.9(1), N(4)-Ru-Cl 85.1(1), N(1)-Ir-N(3) 89.3(1), N(3)-Ir-C(1) 90.5(3), C(1)-Ir-C(2) 90.2(3), N(1)-Ir-C(2) 90.0(2). CY represents the centroid of the arene ligand.

Both isomers of complex **1** have been completely characterized by X-ray diffraction (Figs. 1, 2).[7] Only one isomer of the related Ru-Rh complex **2** could be detected and was also characterized by X-ray crystallography (Fig. 3).[8] There are no significant structural differences between **1a** and **2**. In both cases the molecular structure of the dinuclear complex consists of a pseudooctahedral ruthenium(II) atom and a square-planar iridium(I) (**1a**) or rhodium(I) (**2**) atom connected by two bridging pyrazolyl ligands. The resulting six-

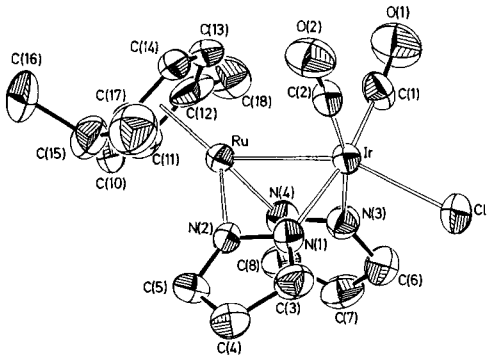

Fig. 2. Molecular structure (ORTEP) of **1b**. Selected bond lengths [Å] and angles [°]: Ru-Ir 2.6962(6), Ru-N(4) 2.075(6), Ru-N(2) 2.083(5), Ru-CY 1.675(3), Ir-N(3) 2.059(5), Ir-N(1) 2.069(5), Ir-Cl 2.517(2), Ir-C(1) 1.844(6), Ir-C(2) 1.831(8), C(1)-O(1) 1.169(8), C(2)-O(2), 1.178(10); Ir-Ru-CY 139.4(1), N(2)-Ru-N(4) 82.9(2), Ir-Ru-N(2) 70.6(2), Ir-Ru-N(4) 70.6(1), N(1)-Ir-N(3) 83.7(2), N(3)-Ir-C(1) 90.3(3), C(1)-Ir-C(2) 92.4(3), N(1)-Ir-C(2) 90.7(3), Ru-Ir-Cl 154.77(3). CY represents the centroid of the arene ligand.

membered RuN_4M ring adopts a boat conformation. The Ru–M distance excludes any significant metal–metal interaction. (Ru-Ir = 3.6636(4), Ru-Rh = 3.6153(5) Å). In particular, the Ru–Cl distance is similar for both complexes (**1a**, Ru-Cl = 2.403(1); **2**, 2.397(1) Å). Isomer **1b** has a dinuclear structure with a metal–metal bond (Ru-Ir = 2.6962(6) Å) bridged by two pyrazolyl ligands. If we consider the metal–metal bond as a coordination position, the pseudooctahedral coordination of the ruthenium metal is completed by an η^6-coordinated *p*-cymene ligand. The distorted octahedral coordination of iridium is completed by two terminal CO ligands and a chlorine atom *trans* to the metal–metal bond

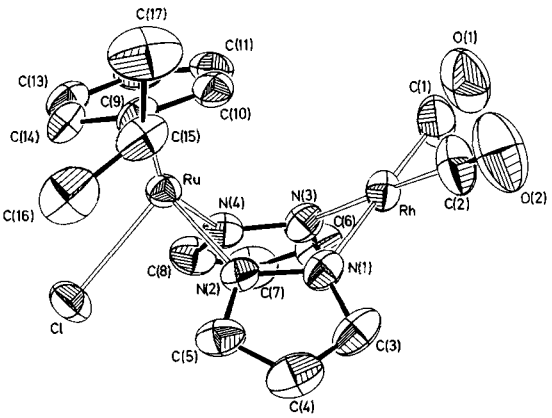

Fig. 3. Molecular structure (ORTEP) of **2**. Selected bond lengths [Å] and angles [°]: Ru-N(4) 2.086(3), Ru-N(2) 2.086(3), Ru-Cl 2.397(1), Ru-CY 1.668(2), Rh-N(3) 2.068(4), Rh-N(1) 2.056(4), Rh-C(1) 1.875(5), Rh-C(2) 1.847(5), C(1)-O(1) 1.108(7), C(2)-O(2) 1.127(7); N(2)-Ru-N(4) 84.5(1), N(2)-Ru-Cl 87.0(1), N(4)-Ru-Cl 87.1(1), N(1)-Rh-N(3) 89.1(1), N(3)-Rh-C(1) 90.5(2), C(1)-Rh-C(2) 91.7(2), N(1)-Rh-C(2) 88.8(2). CY represents the centroid of the arene ligand.

(Ru-Ir-Cl 154.77(3)°). The long Ir–Cl bond 2.517(2) Å) can be explained by the high *trans* influence of the metal–metal bond.[9] From a structural point of view, the isomerization **1a** → **1b** formally implies the migration of the chloride ligand from the ruthenium to the iridium accompanied by a strong compression along the Ru–Ir vector of about 1 Å.

Mixtures of both isomers of **1** react with NaX (X = Br, I) in methanol to give the corresponding bromide and iodide complexes **3** and **4**. From their spectroscopic properties,[10]

$[(\eta^6\text{-}p\text{-cymene})\overline{Ru(\mu\text{-pz})_2}IrX(CO)_2]$ **3**, X = Br; **4**, X = I

we assume that **3** and **4** have similar structures to **1b** with a Ru–Ir metal–metal bond.

The ν(CO) bands of **1b**, **3**, and **4** are shifted to slightly higher wave numbers than the corresponding vibrations of the related compound **1a**. Although a partial oxidation of Ir in the former complexes is thereby implied and a covalent M–M′ bond between d^7 Ru^I and d^7 Ir^{II} centers cannot be ruled out, the most reasonable formulation of these metal–metal complexes involves d^6 Ru^{II} and d^8 Ir^I centers with a polar donor–acceptor bond from the iridium to the ruthenium.

It is noteworthy that only in the Ru-Ir chloride system does the isomerization equilibrium **1a** ⇌ **1b** take place. Neither the homologous bromide or iodide complex nor the Ru-Rh chloride analogue exhibits such reactivity, even under more drastic conditions (reflux in toluene).

Experimental Procedure

1 and **2**: Carbon monoxide (1 atm) was bubbled through a solution of $[(\eta^6\text{-}p\text{-cymene})RuCl(\mu\text{-pz})_2M(cod)]$ (M = Ir, Rh) (2.5 mmol) in 25 mL of THF or CH_2Cl_2 over 3 h. The solution was concentrated under vacuum to about 3 mL and the complex was precipitated by addition of hexane. Yields: **1**, 75%; **2**: 90%.

3: NaBr (131.4 mg, 1.277 mmol) was added to a solution of **1** (278.0 mg, 0.426 mmol) in 25 mL of methanol. After 10 min of stirring an orange solid slowly precipitates. The suspension was stirred for 1 day. The solid was filtered off, washed with methanol and diethyl ether, and air-dried. Yield: 225.0 mg (76%). Complex **4** was prepared analogously. Yield: 73%.

[7.7]Circulene, a Molecule Shaped Like a Figure of Eight**

By *Koji Yamamoto,* Yasuhiro Saitho, Daisuke Iwaki,* and *Takayuki Ooka*

We have been interested in the synthetic studies of twisted π-electron systems,[1] and previous papers described the synthesis of the saddle-shaped [7]circulene (**1**), which has a circular arrangement of seven benzene rings.[2] An obvious extension of our interests in these studies directed our efforts to the preparation of the unique 8-shaped and saddle-shaped [7.7]circulene (**2**)[3, 4] with contiguous benzoannelated rings around a central bicyclo[5.5.0]dodecane framework. This molecule consists of ten fused benzene rings and has a total of forty π electrons. However, the canonical structure **2b** suggests that the molecule might behave as a heptalene[5] with a 28 π-electron periphery. The canonical form **2b** is unique for it can in principle, be converted into an aromatic system by the addition or removal of electrons. The consideration of these structural factors led us to synthesize the novel 8-shaped [7.7]circulene (**2**) and its quinonoid derivative (**3**), which has revealed the strained nonplanar and unusual saddle-shaped geometry anticipated from the examination of its molecular model.

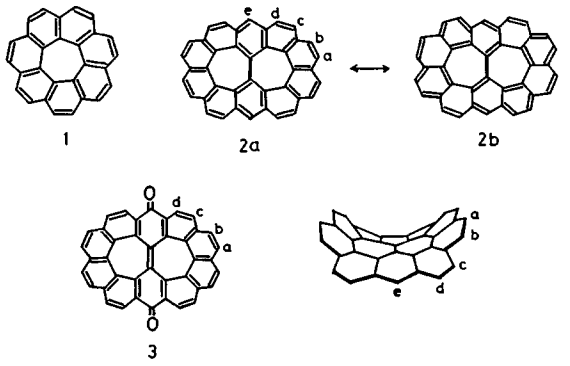
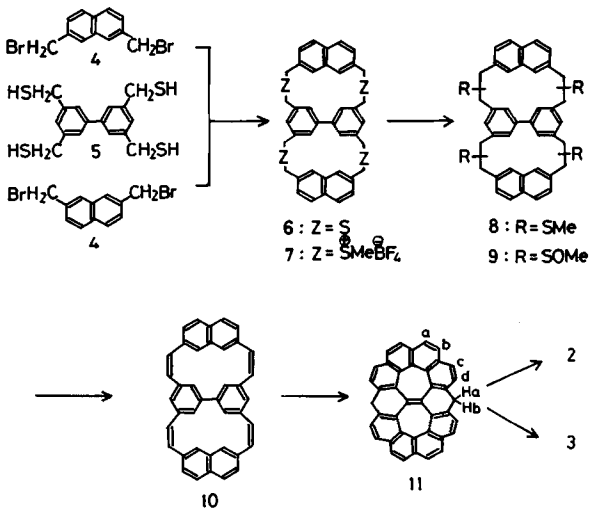
[**] This work was supported by a Grant-in-Aid for Scientific Research (No. 01540424) from Japanese Ministry of Education, Science, and Culture.



The termolecular coupling of the tetrathiol **5**[6] and two equivalents of 2,7-bis(bromomethyl)naphthalene (**4**)[7] was carried out in dimethylformamide with cesium carbonate[8] to give the tetrathiacyclophane **6**,[9] (m.p. > 300 °C, 40% yield). Reaction of **6** with dimethoxycarbenium tetrafluoroborate in dichloromethane yielded the tetrasulfonium salt **7**. Subsequent Stevens rearrangement mediated by sodium hydride provided a 21% yield of the tetrasulfide **8** as a yellow oil. Oxidation of **8** with *m*-chloroperbenzoic acid gave the tetrasulfoxide **9** whose pyrolysis at 300 °C (0.001 mm) produced the unsaturated cyclophane **10** (yellow prisms, m.p. 176–178 °C, 16% yield from **8**). A cyclohexane solution of **10**



containing a trace amount of iodine was irradiated using a high-pressure mercury lamp[10] for 2 h to afford the dihydro[7.7]-circulene (**11**)[11] (yellow prisms, m.p. 350 °C, 12% yield), which was isolated by chromatography on silicagel. The ^{1}H NMR ($CDCl_3$) revealed that two methylene groups showed an AB quartet at $\delta = 4.50$ (4H) and two sets of AB quartet aromatic resonances (H^a, H^b and H^c, H^d). This evidence, supported by its mass spectrum and its correct elemental analysis, pointed to dihydro[7.7]circulene (**11**) as the product, which seems to be a saddle-shaped nonplanar molecule.[12]

The existence of two methylene groups of **11** was also confirmed by its oxidation with selenium oxide in dioxane which gave the novel quinonoid derivative **3** in 21% yield (as well as 14% of the monoketone, m.p. 210–212 °C)[13] stable orange prisms (from benzene) m.p. > 300 °C).[16]

For the introduction of the final two benzene rings into the circular arrangement, we found that dehydrogenation of **11** with triphenylmethyl perchlorate[14] in acetic acid afforded

a 25% yield of [7.7]circulene (**2**; stable pale orange prisms, m.p. > 300 °C; from benzene).[17] The NMR data are characteristic: The ^{1}H NMR spectrum has a single peak at $\delta = 7.61$ and two sets of AB systems and the ^{13}C NMR spectrum exhibits twelve peaks. These spectral properties of **2** and its thermal stability indicate that this molecule is best represented by the structure **2a** consisting of two hexa[7]circulene units.[15]

We are at present investigating the chemical and physical properties of [7.7]circulene (**2**) and its derivatives.

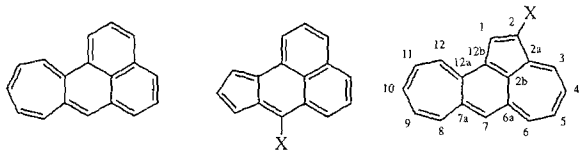
2-Triphenylmethyldicyclohept[*cd,g*]indene: A Novel *cata-peri* Condensed Nonalternant Hydrocarbon**

By *Yoshikazu Sugihara,* Junji Saito*, and *Ichiro Murata**

Due to the unique annelation mode, the *cata-peri*-condensed nonalternant hydrocarbons are endowed with intriguing properties.[1] Our recent studies on cyclohepta[*a*]phenalene **1**[2] and 7-methoxycyclopenta[*a*]phenalene **2b**[3] have been concerned with their high electron donating and accepting properties as a function of their molecular orbital characteristics.[4] Dicyclohept[*cd,g*]indene **3a**, an isomer of **1**, is a new class of compound in the series, since **3** is formally composed of two prototype nonalternant hydrocarbons, azulene and heptafulvene. We report herein the first synthesis of a derivative, **3b**, of this ring system and on its physical properties, which may illustrate the intrinsic character of the parent hydrocarbon **3a**.



1 **2a**, X = H; **2b**, X = OCH_3 **3a**, X = H; **3b**, X = CPh_3

4-Methylazulene **4**[5] was deprotonated with lithium dicyclohexylamide (LDCHA) in ether (Scheme 1) and the resulting carbanion was quenched with diphenyl disulfide to give 4-phenylthiomethylazulene **5** in 66% yield.[6] The cycloheptatrienyl group could effectively be introduced at the desired position by deprotonation of **5** with lithium diisopropylamide (LDA) in ether followed by treatment with tropylium tetrafluoroborate to afford **6**, which was oxidized with *meta*-chloroperbenzoic acid (MCPBA) to give a mixture of diastereoisomeric sulfoxides **7**. To our surprise, upon thermolysis in a degassed benzene solution at 55 °C, sulfoxides **7** were transformed into a tetracyclic azulene derivative **10**, which consists of the desired carbon skeleton. Although no information could be obtained from ^{1}H-NMR monitoring of the thermolysis (in [D_6]benzene), the formation of **10** was rationalized as shown in Scheme 1. Thus, the heptafulvene

[**] This work was supported by a Grant-in-Aid for Scientific Research on Priority Areas (No. 02230103) from the Ministry of Education, Science and Culture, Japan.

chromophore, initially formed by elimination of sulfenic acid, collapses to the tetracyclic intermediate **9** by a facile electrocyclic 14π reaction.[7] This undergoes a preferential [1,7]-hydride shift with formation of the stable, conjugated azulene **10**. To abstract hydride ion from **10**,[8] this was treated with trityl tetrafluoroborate; however, the product obtained was a triphenylmethyl-substituted derivative **11**,[9] since a reactive site of the azulene skeletal framework in **10** remains free to attack by electrophiles. Finally, **11** was dehydrogenated[10] by sequential treatment with trityl tetrafluoroborate and diethyl ether to afford **3b** as black needles (m.p. = 200 °C (decomp.)).[11]

The UV/VIS spectrum of **3b** in benzene exhibits a long wavelength absorption up to 750 nm, and moderate hypsochromic shifts of 2–6 nm were observed for all the maxima above 300 nm upon using acetonitrile instead of benzene as solvent. The ^{1}H-NMR chemical shifts and the vicinal coupling constants of the skeletal hydrogens (Fig. 1) indicate

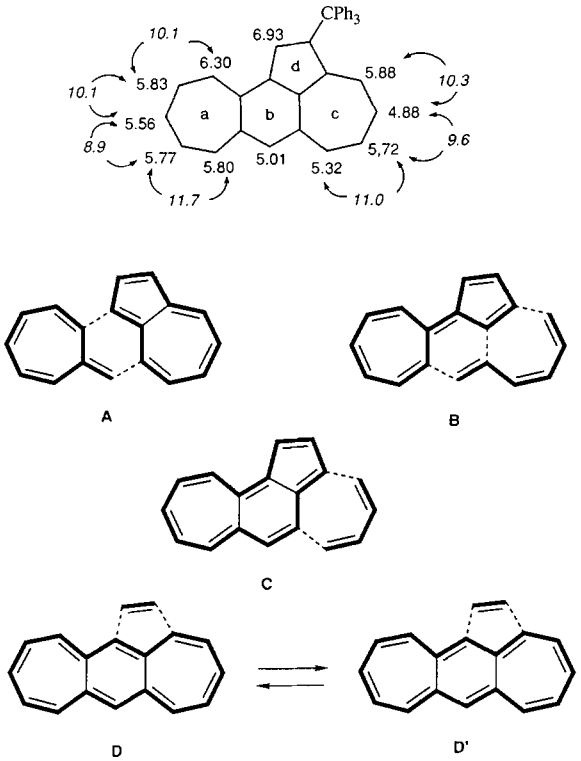

Fig. 1. Above: ^{1}H-NMR data (500 MHz, $CDCl_3$, TMS) of **3b**: chemical shifts (δ values) and vicinal coupling constants [Hz] (in italics). Below: possible bonding structure of **3b**.

some interesting properties: as far as the chemical shifts (δ = 5.56–6.30) and the coupling constants (J_{vic} = 8.9–11.7 Hz) of the ring a are concerned, these NMR parameters are quite similar to those of 8-phenyl-[12] and 8,8-diphenylheptafulvenes.[12] However, the chemical shift of the hydrogens attached to the ring c and ring d, which constitute formally an azulene chromophore, are substantially higher than those of azulene itself. This means that the bonding structure of **3b** cannot be described in terms of a simple composite of azulene and heptafulvene (model **A**). Other possible descriptions are as sesquifulvalene/hexatriene (model **B**) or a cyclohept[*e*]indene/butadiene system (model **C**). However, these models are also unsuitable for a description the real structure of **3b**, since the seven-membered ring hydrogens of sesquifulvalene (δ = 6.2–7.05)[13a] and 4-phenyl-

11: blue columnar crystals, m.p. = 210 °C (decomp.); MS: m/z 472 ($M^{\oplus}$, 12%), 395 ($M^{\oplus}$ − Ph, 17), 229 ($M^{\oplus}$ − CPh_3, 4); ^{1}H NMR (400 MHz, $CDCl_3$, TMS): δ = 7.63 (d, J = 9.9 Hz, 1H, H-3), 7.58 (s, 1H, H-1), 7.35 (t, J = 9.9 Hz, 1H, H-5), 7.14–7.26 (m, 15H, trityl), 6.88 (d, J = 9.9 Hz, 1H, H-6), 6.66–6.74 (m, 2H, H-9, 10), 6.58 (t, J = 9.9 Hz, 1H, H-4), 6.37 (d-like, J = 4.2 Hz, 1H, H-8), 6.23 (dd, J = 9.0, 4.8 Hz, 1H, H-11), 5.37 (dd, J = 9.0, 5.9 Hz, 1H, H-12), 4.29 (d, J = 21.8 Hz, 1H, H-7), 4.04 (d, J = 21.8 Hz, 1H, H-7'), 3.01 (d, J = 5.9 Hz, 1H, H-12a).

3b: black crystals, m.p. = 200 °C (decomp.); exact mass, calcd for $C_{37}H_{26}$, 470.2036, found 470.2043; UV/VIS (CH_3CN): λ_{max} [nm] (lg ε) = 268 (4.04), 307 (4.44), 391 (3.89), 412 (3.91), 437 (3.97), 474 (sh, 3.20), 518 (sh, 3.17), 616 (sh, 3.37), 668 (3.63); ^{1}H NMR (500 MHz, $CDCl_3$, TMS): see Fig. 1. ^{13}C-NMR (125.8 MHz, $CDCl_3$, TMS): δ = 130.9, 127.3, 125.8 (phenyl), 142.6 (C-3), 140.6 (C-5), 137.9 (C-8), 136.4 (C-11), 134.7 (C-9), 130.2 (C-10), 129.4 (C-6), 128.2 (C-12), 123.9 (C-1), 122.0 (C-4), 121.1 (C-7).

cyclohept[*e*]indene-2,3-dicarbonitrile (δ = 7.85–9.5)[13b] resonate at substantially lower field than those of the ring a hydrogens of **3b**. A most likely possibility would be a bond shift equilibrium between two Kekulé structures of the hitherto unknown dicyclohepta[*a*,*d*]benzene,[14] which should sustain a paramagnetic ring current associated with its peripheral 16π elelctrons, perturbed by an external double bond (model **D** ⇄ **D'**).[15]

The redox properties of **3b** were examined by cyclic voltammetry,[16] and are characterized by two oxidation waves at 0.43 and 1.10 V as well as a reduction wave at − 1.18 V. As expected from its high Hückel HOMO level (0.1778 β), the first oxidation potential of **3b** is close to that of **1** (E^{ox} = 0.39 V; HOMO = 0.1055 β).[2] Furthermore, the reduction potential of **3b** is clearly more positive than that of **2b** (E^{red} = − 1.27 V) suggesting that the hydrocarbon **3b** is seemingly amphoteric (E^{sum} = 1.61 V).[17]

Since the electronic perturbation caused by the triphenylmethyl substituent in **3b** is presumably small, the physical properties of the unknown parent compound **3a** could be similar to those of **3b**.[18]

[8] Generally, hydride abstraction from a tertiary center as in **10** is an unfavorable process under normal conditions and therefore the hydrogen to be eliminated has to be moved thermally or photochemically. In the present case, attempts to migrate a hydrogen atom in **10** resulted in the formation of a tarry material.
[9] K. Hafner, A. Stephan, C. Bernhard, *Justus Liebigs Ann. Chem. 650* (1961) 42–62.
[10] For the conversion **10** → **3a**, we examined dehydrogenation with either *p*-chloranil or 2,3-dichloro-5,6-dicyano-1,4-benzoquinone. An unstable

greenish product was obtained which showed a similar UV/VIS spectrum to that of **3b**; however, its structure could not be characterized due to the low yield.

[11] All the new compounds were fully characterized by spectral data together with satisfactory elemental analyses.

Alkane Cascade Polymers Possessing Micellar Topology: Micellanoic Acid Derivatives**

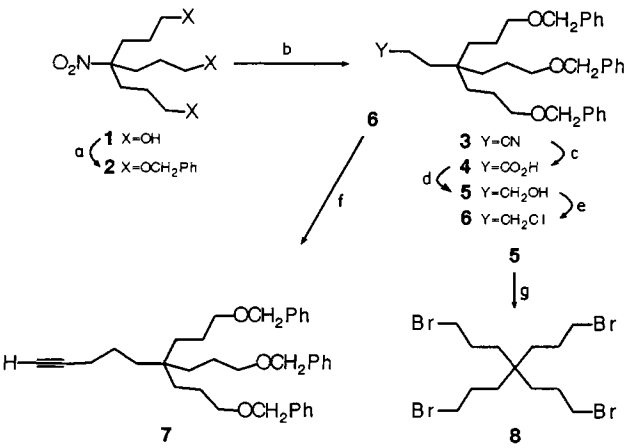
By *George R. Newkome,* Charles N. Moorefield, Gregory R. Baker, Andrew L. Johnson,* and *Rajani K. Behera*

The synthesis of high molecular weight, highly branched, multifunctional molecules possessing a predetermined three-dimensional morphology has been the focus of a growing number of research groups.[1] To develop synthetic strategies for such cascade polymers, diverse factors must be considered; these include the initial core, building blocks (or repeat units), spacers, branching integers, dense packing limits, and porosity. Selection of the appropriate building block(s) is governed by the type of branching desired (e.g., carbon vs. heteroatom) as well as the technology used to attach each successive layer (or tier). Thus far, building-block units have relied predominantly on heteroatom chemistry for either a center of branching or attachment of additional building blocks. We herein report the first example of an alkyl carbon cascade polymer, a derivatized "micellane" possessing the characteristics of a globular micelle.

Our interest[2] in the design and application of cascade polymers initially led us to synthesize high molecular weight molecules containing quaternary carbon branching points and a maximum number of terminal functional groups, and focused on the formation of the amide bond. Work revolved around a multiplicative approach utilizing two building blocks, a trialkyl methanetricarboxylate[3] and 2-amino-2-hydroxymethyl-1,3-propanediol (tris(hydroxymethyl)-aminomethane, "tris"). The inertness of nucleophilic substitution at the neopentyl carbons required the incorporation of spacer moieties; these extraneous steps were circumvented by the preparation of "bis-homotris".[4] Subsequently it was determined that in general, three carbon atoms are necessary to ensure an appropriate distance to minimize the reaction retardation caused by an adjacent quaternary center. Therefore, $C[(CH_2)_3Br]_4$ and $XC[(CH_2)_3Y]_3$ were selected as the ideal alkyl core[5] and building blocks, respectively, for iterative cascade polymer construction.

Since nitrotriol **1**[6] was pivotal to the preparation of bis-homotris,[4] it was chosen as the starting point for construction of the desired reagents (core and building blocks). Application of an unexploited procedure[7] provided the three-carbon homologation[8] from a quaternary center by addition of a tertiary radical to an electron-deficient alkene, such as acrylonitrile or methyl acrylate. Although the yields associated with this reaction are moderate (30–65%), a novel series of tetra(bis-homologated) analogues of pentaerythritol was readily prepared.

The triol **1** (Scheme 1) was treated[9] with benzyl chloride to give (78%) the trisether **2**, which was subsequently cyanoethylated[7] affording (61%) the nitrile **3**. The characteristic ^{13}C NMR chemical shifts for the quaternary carbon ($\delta = 36.5$), cyano moiety ($\delta = 120$), and CH_2CN ($\delta = 11.6$) and loss of the peak at $\delta = 94.0$ for the nitro-substituted carbon support the assignment.



Scheme 1. a) $PhCH_2Cl$, Me_2SO, KOH; b) acrylonitrile, nBu$_3$SnH, azobisisobutyronitrile, $PhCH_3$, 110°C; c) KOH, EtOH/H_2O, H_2O_2, Δ; d) $BH_3 \cdot THF$, THF, Δ; e) $SOCl_2$, CH_2Cl_2, pyridine; f) HC≡CLi · en, Me_2SO, 40°C; g) HBr, H_2SO_4, 100°C.

Hydrolysis[10] of nitrile **3** proceeded cleanly to give (92%) carboxylic acid **4**, as indicated by the appearance (^{13}C NMR) of a peak at $\delta = 179.8$ (CO_2H). Conversion of acid **4** into alcohol **5** proceeded quantitatively with excess 1.0 M $BH_3 \cdot THF$ solution (>95%; ^{13}C NMR: $\delta(CH_2OH) = 63.3$). Transformation into chloride **6** was smoothly achieved in CH_2Cl_2 with excess $SOCl_2$ and a catalytic amount of pyridine[11] (92%; ^{13}C NMR: $\delta(CH_2Cl) = 45.6$). Reaction of lithium acetylide ethylenediamine complex[12] in dimethylsulfoxide with **6** gave the terminal alkyne **7** (87%;

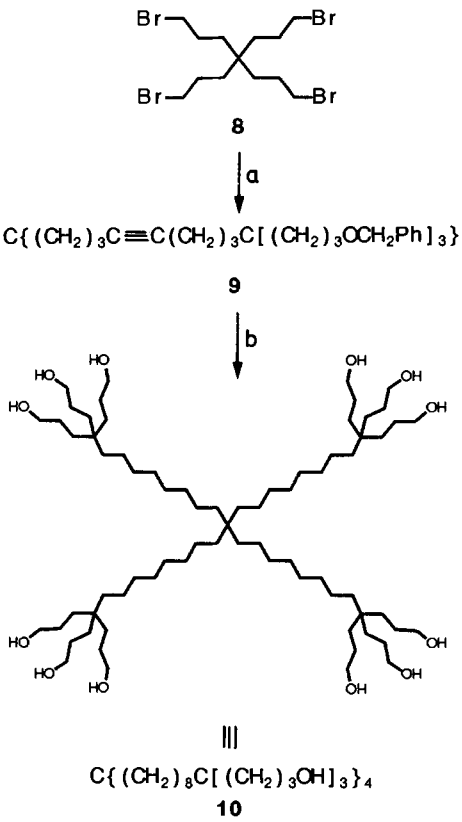
[**] Chemistry of Micelles, Part 11. The results were first presented at the Symposium on Self-Assembling Structures (by *G. R. N.*) at the 199th National Meeting of the American Chemical Society, Boston, MA, USA, April 1990 (Abstracts ORGN 317). This work was supported by the Petroleum Research Fund, administered by the American Chemical Society, and the National Science Foundation (DMR-86-00929; 89-06792). For Part 10 see: C. D. Weis, G. R. Newkome, *J. Org. Chem. 55* (1990) 5801.

^{13}C NMR: $\delta(CH_2C{\equiv}CH) = 84.0$ and $\delta(CH_2C{\equiv}CH) = 68.1$).

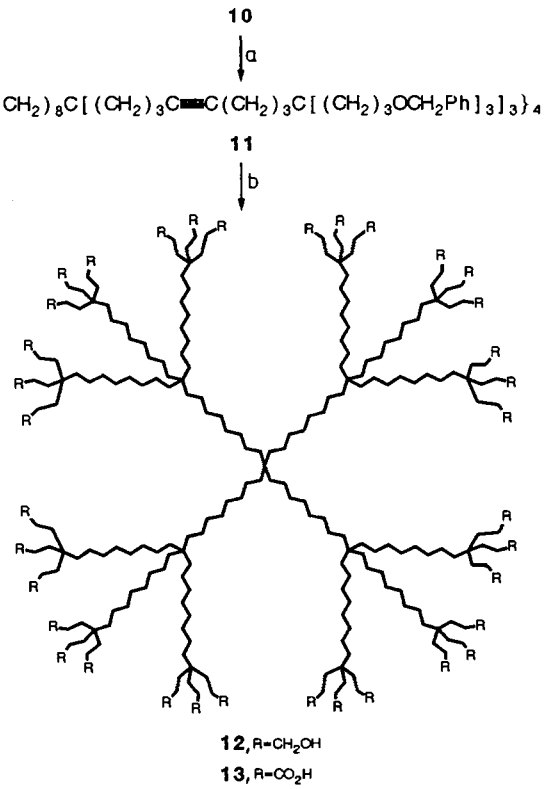
An improved synthesis of the core tetrabromide **8** from alcohol **5** was achieved by bromination with HBr/H_2SO_4; thus, **8** was obtained in eight steps from nitromethane (24% overall yield) versus 17 steps from citric acid[13] (<2% overall yield) or 12 steps from tetrahydropyran-4-one[5] (<5% overall yield).

Alkylation of the four-directional core **8** with 6 equivalents of terminal alkyne building block **7** (Scheme 2) gave the purified dodecabenzyl ether **9** (67%),[14] as evidenced by the disappearance of the terminal alkyne absorptions and the appearance of a peak $\delta = 80.9$ (C≡C).



Scheme 2. a) Hexamethylphosphoric triamide (HMPA), lithium diisopropylamide (LDA), 6 equiv alkyne **1**, tetramethylethylenediamine (TMED), 0–40 °C, 1.5 h; b) EtOH, THF, 10% Pd-C/H_2 (4 atm), 60 °C, 4 d.

The dodecabenzyl ether (**9**) was soluble in $CHCl_3$ and CH_2Cl_2 and insoluble in CH_3CN and EtOH. Simultaneous reduction of the triple bonds and deprotection of **9** with Pd–C/H_2 afforded (91%) dodecaalcohol **10**, as indicated in the ^{13}C NMR spectrum by the disappearance of resonances assigned to the alkyne carbons and to their α-carbon atoms ($\delta = 19.8$), as well as the appearance of a peak at $\delta = 64.1$ (CH_2OH). Alcohol **10**, which is slightly soluble in $CHCl_3$ or H_2O but very soluble in EtOH or MeOH, was smoothly converted (53%) into the dodecabromide (^{13}C NMR: $\delta(CH_2Br) = 34.8$) employing $SOBr_2$ at 40 °C for 12 h. A second tier (Scheme 3) was readily obtained by alkylation of the dodecabromide[15] with 18 equivalents of alkyne **7** to give 49% of hexatricontabenzyl ether **11**, which was similarly reduced and deprotected in one step yielding 89% of hexatricontaalcohol **12**, an [$8^2 \cdot 3$]micellanol.[16] Both polyether **11** and polyol **12** exhibited the same solubilities and many of the same ^{13}C and ^1H NMR signals as their lower analogues (**9** and **10**). Aqueous solubility was increased by RuO_4 oxidation[17] of **12** affording 85% of hexatricontacarboxylic acid **13** ([$8^2 \cdot 3$]micellanoic acid), followed by treatment with NH_4OH or $(CH_3)_4NOH$. Disappearance of the ^{13}C NMR signal for the hydroxymethyl moiety at $\delta = 64.0$ and the appearance of the carboxylate signal at $\delta = 187.4$, as well as the high water solubility of its ammonium salt confirm that the transformation has occurred. The micellar properties of **13** have been investigated and will be reported in the following communication.[18]



Scheme 3. a) 1. CH_2Cl_2, $SOBr_2$, pyridine; 2. 18 equiv alkyne **1**; b) EtOH/THF, 10% Pd-C/H_2 (4 atm), 60 °C, 4 d.

In view of the diversity of these reagents, we are continuing our efforts towards the synthesis of related macromolecules based on this cascade technology.

[14] ^{13}C NMR was extremely useful because of the characteristic chemical shifts of the interior carbons and the expected T_1 increases [19] of the quaternary carbons. All "cascade" compounds were purified by non-aqueous, reverse-phase flash column chromatography. Correct elemental analyses were obtained for all new compounds. ^{13}C NMR assignments are based on calculated values, signal intensities, and DEPT NMR experiments; consecutive numbering beginning at the central quaternary carbon simplifies description due to symmetry. Selected physical data for **9**–**13**: **9**: ^1H NMR (360 MHz, $CDCl_3$): δ = 1.10–1.65 (m, 80H), 2.00–2.21 (m, 16H), 3.35 (br t, 24H), 4.45 (s, 24H), 7.28 (s, 60H); ^{13}C NMR (360 MHz, $CDCl_3$): δ = 19.3 (C4, C7), 22.8 (C3, C8), 23.3 (C12), 32.4 (C11), 35.6 (C2, C9), 36.4 (C10), 36.7 (C1), 71.1 (C13), 72.6 (C14), 80.1 (C5, C6), 127.2, 127.3, 128.1, 138.4 (C_6H_5); IR (neat): $\tilde{\nu}$ = 3080, 3030, 2925, 2860, 1100, 745, 699 cm^{-1}. **10**: ^1H NMR (CD_3OD): δ = 1.08–1.32 (m, 112H), 3.37 (t, 24H, J = 6.5 Hz); ^{13}C NMR (CD_3OD): δ = 23.9, 24.1 (C3, C8), 27.4 (C12), 30.8 (C5, C6), 31.7, 31.8 (C4, C7), 33.6 (C11), 37.5 (C10), 37.8, 37.9 (C2, C9), 38.1 (C1), 63.8 (C13); IR (neat): $\tilde{\nu}$ = 3700–3000, 2850, 2920, 1480, 1575, 1065 cm^{-1}. **11**: ^1H NMR ($CDCl_3$): δ = 1.05–1.70 (m, 300H), 2.00–2.22 (m, 48H), 3.36 (br t, 72H), 4.43 (s, 72H), 7.27 (s, 180H); ^{13}C NMR ($CDCl_3$): δ = 19.3 (C13, C16), 22.8 (C12, C17), 23.2 (C3, C8, C21), 29.0 (C5, C6), 32.0 (C4, C7), 32.3 (C20), 35.5 (C11, C18), 35.8 (C2, C9), 36.3 (C19), 36.4 (C10), 36.5 (C1), 71.0 (C22), 72.6 (C23), 80.1 (C14, C15), 127.2, 127.3, 128.0, 138.3 (C_6H_5); IR (neat): $\tilde{\nu}$ = 3080, 3030, 2925, 2860, 1100, 745, 700 cm^{-1}. **12**: ^1H NMR (CD_3OD): δ = 1.15–1.87 (m, 400H), 3.50 (t, 72H, J = 6.5 Hz); ^{13}C NMR (CD_3OD): δ = 23.8 (C3, C8), 24.7 (C12, C17), 27.4 (C21), 29.5 (C5, C6), 30.7, (C14, C15), 30.8 (C4, C7), 31.6 (C13, C16), 33.6 (C20), 37.5 (C11, C18), 37.6 (C2, C9), 37.7 (C1, C10, C19), 63.9 (C22); IR (neat): $\tilde{\nu}$ = 3700–3000, 2850, 2920, 1480, 1575, 1065 cm^{-1}. **13**: ^1H NMR ($NaOD/D_2O$): δ = 1.11–1.70 (m, 328H), 2.05–2.20 (m, 72H); ^{13}C NMR ($NaOD/D_2O$): δ = 24.9 (C3, C8), 25.3 (C12, C17), 28.5 (C5, C6), 32.1 (C4, C7), 32.9, (C14, C15), 33.0 (C13, C16), 34.8 (C21), 35.2 (C20), 38.0 (C2, C9), 38.3 (C11, C18), 39.2 (C1, C10, C19), 187.4 (C22); IR (neat): $\tilde{\nu}$ = 3400–2700, 2920, 2850, 1715 cm^{-1}.
[15] Alkylation [12] of the corresponding chloro and iodo derivatives was equally effective.
[16] [$8^2 \cdot 3$]-nomenclature: 8 denotes the number of carbons between each branching locus, 2 denotes tiers, and 3 denotes the carbons after the outermost branching center; micellanol denotes a hydrocarbon infrastructure and hydroxylic terminal moieties.

structures depend not only on the molecular architecture of the amphiphile, but also on diverse factors such as temperature and concentration.[2] Based on work by *Shinkai* et al.[3] and *Menger* et al.[4] who synthesized water-soluble calixarenes and "hexapus", respectively, which possess micellar characteristics, our investigations[5] as well as others,[6] concerning the design and synthesis of cascade polymers, seemed well suited for the control of molecular topology, stability, and the associated micellar properties. In particular, we have prepared the first, symmetrical, four-directional, saturated hydrocarbon cascade polymer ([$8^2 \cdot 3$]micellanoic acid)[7] containing 36 carboxylic acid moieties equidistant from a central neopentyl core. Due to the obvious micellar topology, the acid groups were converted into their corresponding ammonium (**1**) and tetramethylammonium (**2**) carboxylate derivatives (see Fig. 1) to facilitate the study of their properties.

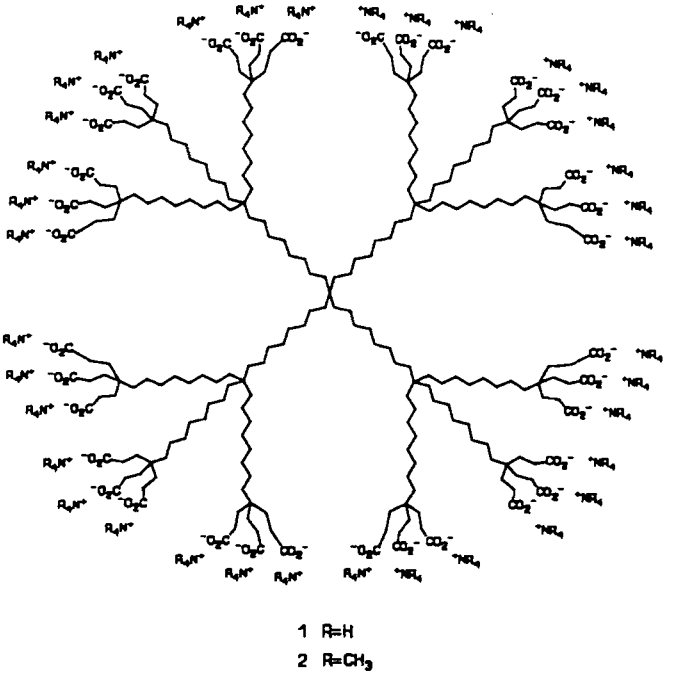

Fig. 1. Two-tier cascade polymer.

Unimolecular Micelles**

By *George R. Newkome,* Charles N. Moorefield, Gregory R. Baker, Mary J. Saunders,* and *Steven H. Grossman*

Aggregation phenomena of amphiphiles and their resultant micellar chemistry are well documented.[1] Micelle

Investigation of possible aggregation was initially facilitated by electron microscopy (EM) of unstained samples of **1** and **2**.[8] Examination of **1** revealed a range of particle sizes; the majority (monomers) were 30 to 50 Å in diameter and the largest (aggregates) were ca. 1000 Å. We attribute the aggregation of **1** to intermolecular H-bonding promoted by solution evaporation on the EM grid, since the size distribution and pattern reflect concentration increases during evaporation. The $Me_4N^{\oplus}$ analogue (**2**), however, exhibited no aggregation (see Fig. 2), but rather the entire field of view consisted of uniform particles (30 Å ± 5 Å). Since the $Me_4N^{\oplus}$ cation is known to reduce H-bonding significantly,[9] aggregation was minimized or totally circumvented during evaporation. Observed diameters agree well with calculated diameters[10] (see Fig. 3), which indicated a minimum of 30 Å and a maximum of 48 Å corresponding to contracted and extended conformations, respectively. This physical observation supports the following spectral evidence that polycarboxylate **2** exists as single molecules.

Phase-resolved anisotropy values for lipophilic probes such as diphenylhexatriene (DPH) in micelles provide a mea-

[**] Chemistry of Micelles, Part 13. The results were first presented at the Symposium on Self-Assembling Structures at the 199th National Meeting of the American Chemical Society, Boston, MA, USA, April 1990 (Abstracts ORGN 317). This work was supported by the Petroleum Research Fund, administered by the American Chemical Society, and the National Science (*G. R. N* Grant Nos. DMR 86-00929 & 89-06792; *M. J. S.* Grant No. DCB 88-02011) as well as the Florida High Technology and Industrial Council. We also thank Professors *J. Rebek, Jr.* (MIT), *P. S. Russo* (LSU), and *R. Potter* (USF) for their invaluable discussions. Part 12: G. R. Newkome, Y. Hu, M. J. Saunders, F. R. Fronczek, *Tetrahedron Lett. 32* (1991) 1133.

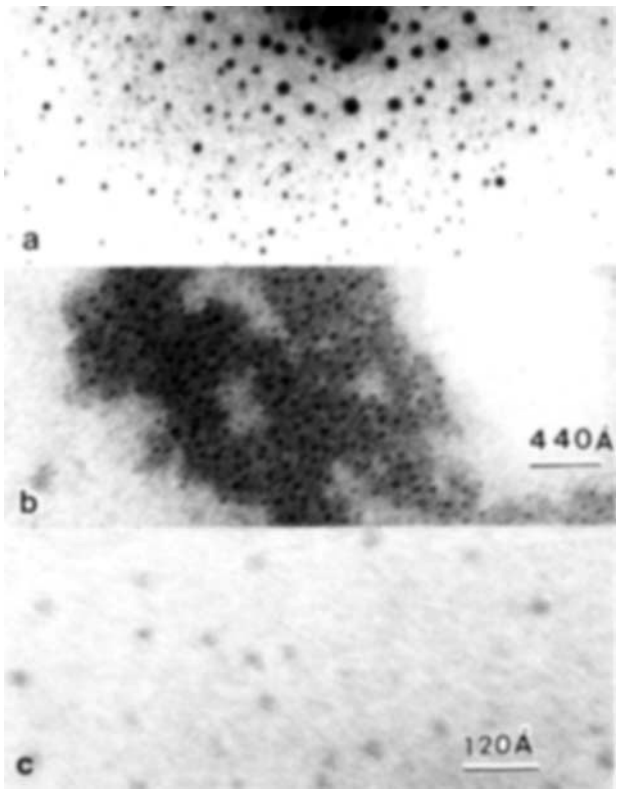

Fig. 2. Electron micrographs of **1** (a) and **2** (b, c). Note aggregation of **1** after solvent evaporation in (a) whereas **2** [(b) and (c)] remains dispersed (darkened background is caused by excess salt). Final magnification for (a) and (b) is 225000× and (c) 820000×.

sure of internal rotational freedom.[11] Models used to describe the data[12] correspond to an isotropic rotator, a two-component anisotropic rotator, and to restricted or hindered rotation. In an independent experiment,[13] the fluorescence lifetime of DPH with **2** was determined to be 1.2 ns (17%) and 6.9 ns (83%) ($\chi^2 = 1.30$). The single-term decay law

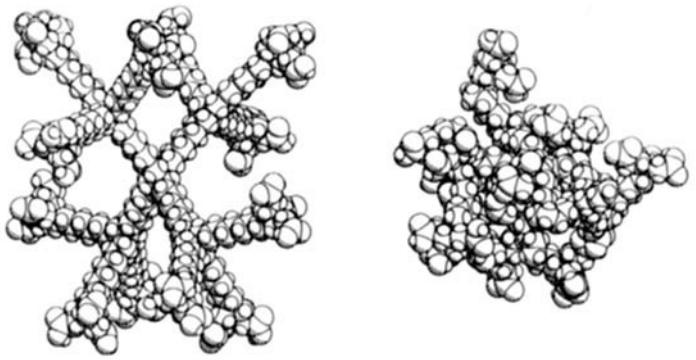

Fig. 3. Idealized representations of the 36-carboxylic acid in extended (left) and contracted (right) conformations, respectively.

was inadequate and the three-term discrete exponential and single-term Lorentzian distribution decay laws were not a significant improvement on the two-term discrete decay law. Anisotropy data were fit to a one-term (θ_1), a two-term (θ_1, θ_2; f_1, f_2), or a single-term decay law with a hindered anisotropy component (θ_1, r_∞). The results are shown in Table 1.

Table 1. Phase-resolved anisotropy values for DPH and micellanoate **2**. θ is the rotational correlation time, f the fractional contribution, and r_∞ the limiting anisotropy for the hindered rotation model. χ^2 is based on the standard deviation for a phase and demodulation ratio of 0.5° and 0.005°, respectively. Data obtained for the a) single discrete anisotropy decay model, b) double discrete anisotropy decay model, and c) hindered rotation model.

	θ_1	f_1	θ_2	f_2	r_∞	χ^2
a	2.90					102.
b	0.23	0.57	4.67	0.43		2.31
c	2.21				0.018	2.51

The values obtained in the two-term lifetime decay law indicate that DPH molecules are predominately associated within the lipophilic interior of the polycarboxylate microenvironment. The fast component could arise from distribution of some DPH near the surface of the micellanoate or more likely, some DPH not embraced by the micellanoate yet and still in the aqueous phase. The differential phase and demodulation ratio data could be equally well fitted to a two-term discrete exponential decay or a single-term decay with hindered rotation. Restricted motion by the probe molecule is insignificant as suggested by the magnitude of the hindered anisotropy. The two-term discrete model shows the presence of two distinct modes of rotational motion. The fast correlation time is similar to that previously observed with DPH in mineral oil (0.76) or dioleoyl-L-α-phosphatidylcholine (DOPC) vesicles (0.8) above the transition temperature,[11] as is the correlation time for the slower rotation (3.9). In fact, both the lifetime and anisotropy decay laws for DPH with micellanoate **2** and DOPC vesicles are remarkably similar[11] demonstrating the host–guest relationship between **2** and DPH.

The commonly employed techniques of optical fluorescence microscopy and photometry revealed the absorption and subsequent fluorescence (at 520 nm) of chlortetracycline (CTC, 5 mM, pH 11),[14] in an aqueous solution of **2**. There was no detectable fluorescence from aqueous solutions of CTC or the spherical polymer **2** alone. When combined, the fluorescence intensity increased linearly with increasing concentrations of **2**.[15] Since CTC fluoresces only in lipophilic environments,[16] this fluorescent probe must be interacting within the infrastructure of the cascade polymer.

Phenol blue (PB),[3, 17] and pinacyanol chloride (PC)[4] have more traditionally been used as spectrophotometric probes to study micellar properties: PB as a solvent property indicator (λ_{max} ranges from 658 nm in water to 552 nm in cyclohexane), and PC as a probe for aggregation. A deep violet aqueous solution of PB (5.5×10^{-6} M) changed to light blue upon addition of micellanoate **1** (3.1×10^{-4} M). The UV spectrum of this solution displayed only a slight frequency shift ($\Delta\lambda_{max} = 5$ nm) for the absorption band, which decreased in intensity, and broadened markedly.

In the presence of anionic micelles, the color of an aqueous solution of PC changes from pink to blue;[18] in the absence of amphiphiles, an aqueous solution of PC (3.9×10^{-6} M) has absorptions at 554 and 600 (λ_{max}) nm. In solutions of PC (3.9×10^{-6} M) and of sodium dodecylsulfate (NaDS) at concentrations above the critical micelle concentration (cmc, $>10^{-2}$ M) these absorptions shift to 564 and 610 nm; NaDS solutions at concentrations below 10^{-2} M show an absorption at 478 nm. Upon addition of micellanoate **1** or **2** (6.8×10^{-4} M and 3.3×10^{-4} M, respectively) to an aqueous solution of PC (3.9×10^{-6} M, pH 10.0), λ_{max} shifts to 610 nm and the absorption becomes more intense and narrowed. In both cases, this absorbance ($\lambda_{max} = 610$ nm) gradually shifts

(toward $\lambda_{max} = 600$ nm) as the concentration of either decreases to 1.6×10^{-6} M; absorptions appear at 478 nm when concentrations fall below 3.9×10^{-7} M. These results are consistent with those of *Shinkai* et al.[3] and *Menger* et al.[4] Furthermore, if a cmc exists, it must be $< 3.9 \times 10^{-7}$ M.

Added evidence of molecular inclusion[4] was provided by the resultant UV spectrum ($\lambda = 214$, 276 nm) of an aqueous solution of micellanoate **2** (2.3×10^{-4} M) with naphthalene ($\lambda = 214$, 276 nm; 3:1 H_2O/EtOH). Also, the intensity of the absorbance for **2** and naphthalene at 276 nm is ca. four times greater (3.35) than that observed for naphthalene in a 2:1 mixture of water and ethanol (0.844).

The interactions of these novel cascade polymers with CTC, PC, DPH, and naphthalene demonstrated the inclusion of these guest molecules within the lipophilic infrastructures of micellanoates **1** and **2**. The interaction of PC with **1** or **2** indicated the formation of 1:1 complexes. In addition, the tetramethylammonium salt **2** was shown not to aggregate in basic solution. The data strongly suggest that these spherical polymers ([$8^2 \cdot 3$]micellanoates) exist as single molecules[19] capable of molecular inclusion and therefore act as unimolecular micelles.

[13] Phase-resolved lifetimes and anisotropies were determined with an SLM Model 48000s spectrofluorometer equipped with two frequency synthesizers capable of attaining 200 MHz. The excitation was a Liconix HeCd laser operated at 325 nm. The emission was collected through a Schott 408 nm cuton filter. The lifetime standard was POPOP (1.32 ns). The samples were stirred continuously during data acquisition and temperature was maintained at 30°C using thermostatted water. The estimated error used in the decay law fittings (SLM Instrument software, Urbana, IL) was 0.005 in the demodulation and 0.4° in the phase shift. Each sample was read three times at each of 22 frequencies (3–70 MHz for lifetime and 10–140 MHz (12 frequencies) for anisotropy determinations). In the minimization used to establish the anisotropy decay law, either the lifetime or the limiting anisotropy (0.38), or for DPH both, were fixed parameters. The sample was prepared by sonicating excess DPH in a 1.76×10^{-4} M aqueous solution of tetramethylammonium carboxylate for 10 min. Excess DPH was removed by filtration through glass wool.

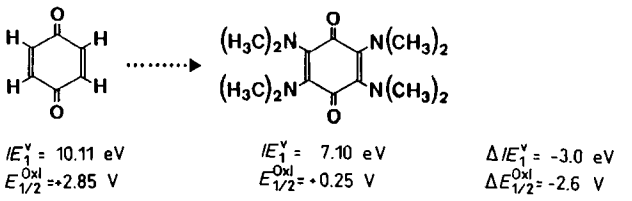
Structural Changes on Twofold Oxidation of Tetrakis(dimethylamino)-*p*-benzoquinone: A Sterically Overcrowded Electron-Rich "Chair" Compound Turns into a "Twist" Dicyanine Salt**

By *Hans Bock,* Klaus Ruppert, Christian Näther,* and *Zdenek Havlas*

Dedicated to Kurt Dehnicke on the occasion of his 60th birthday

The textbook example[1a] for a reversible one-electron reduction[1b] of organic π systems, *p*-benzoquinone, can be "umgepolt" by four dimethylamino substituents[1c] (Scheme 1). Tetrakis(dimethylamino)-*p*-benzoquinone, therefore, can be both reduced to its semiquinone radical anion[1c]—and oxidized to its semiquinone radical cation.[1c,d] This extraordinary redox behavior of the sterically overcrowded and electron-rich compound, which can stabilize positive charges by delocalization into the dimethylamino substituents, stimulated us to determine the structures of both the black neutral molecule[2,3] and its black dication salt, which can be prepared by $SbCl_5/CH_2Cl_2$ oxidation (Fig. 1).



Scheme 1.

[**] Structures of Sterically Overcrowded or Charge-Perturbed Molecules, Part 8. This work was supported by the State of Hesse, the Fonds der Chemischen Industrie, and the Alexander von Humboldt Foundation (*Z. H.*). Part 7: [11a].

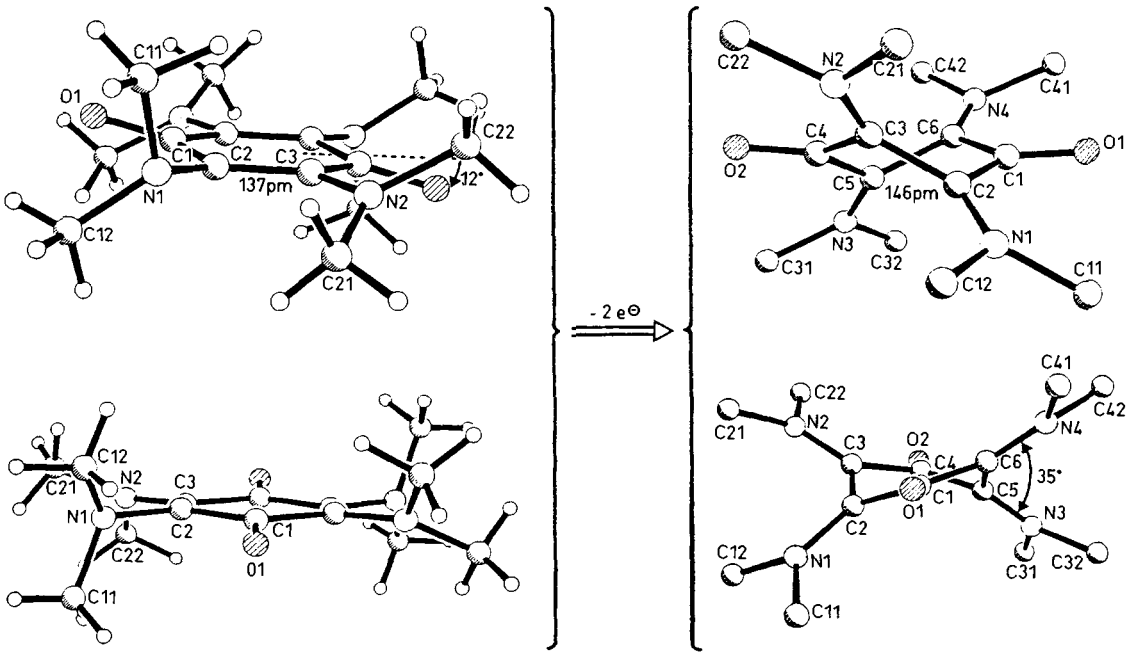

Fig. 1. Left: Crystal structure of tetrakis(dimethylamino)-*p*-benzoquinone [3]. Important distances [pm] (±0.5) and angles [°] (±0.5) (average values): C1-O 123, C1-C2 145, C1'-C3 151, C2-C3 137, C2-N1 142, C3-N2 137, N1-C12 146; O1-C1-C2 120, C1-C2-C3 119; torsion angles, C1C2-N1C11 84, C1'C3-N2C22 45, OC1(C2C3')-C2C3/C2'C3' 12. Right: Crystal structure of tetrakis(dimethylamino)-*p*-benzoquinone bis(hexachloroantimonate) [5]. Important distances [pm] (±1) and angles [°] (±1) (average values): C1-O 123, C1-C2 148, C1-C6 148, C2-C3 146, C2-N1 132, C3-N2 132; O1-C1-C2 123, C2-C1-C6 114; torsion angles, C1C2-N1C11 10, C4C3-N2C22 8, O1C1(C2C6)-O2C4(C3C5) 35.

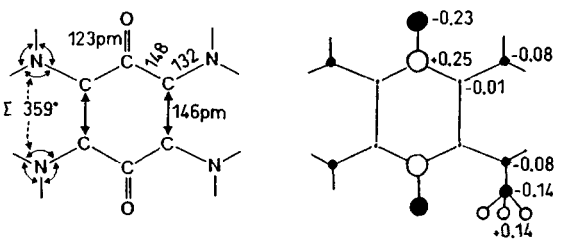
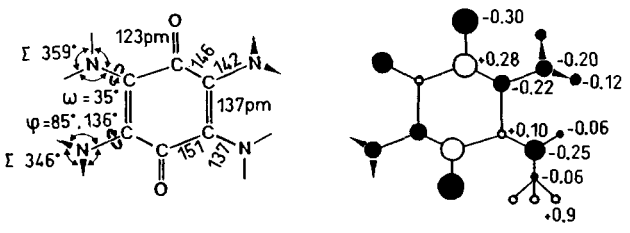
The steric overcrowding in molecules containing vicinal $(H_3C)_2N$ substituents at a C=C bond,[6] which can be traced to the van der Waals radii of about 200 pm for each of the methyl groups, is also pronounced in the title compound (Fig. 1, left). The space-filling $(H_3C)_2N$ molecular subunits press the C=O groups between them from above and below the central C_4 quinone skeletal plane at interplanar angles of 12° and, in addition, they are either partly or even completely planarized (sums of angles around N1 and N1′ 346° and around N2 and N2′ 359°). This energetically preferred angle distortion is further emphasized by the C=C and C=O bond lengths, $d_{C=C}$ = 137 pm and $d_{C=O}$ = 123 pm, which remain within the usual range.[7] Exciting are the deformations of the quinone skeleton, caused by the different n/π and σ_{CN} interactions of the differently twisted (dihedral angle ω(CC-NC) = 35°, torsion angles φ(CC-NC) = 85°, 136°) and differently planarized dimethylamino substituents (sum of angles C–N–C = 346° and 359°), which are connected by C–N bonds of different lengths (Scheme 1).

The lengths of the C–C bonds on both sides of the C=O groups differ by 5 pm. Analogous "mericyanine"-like[8a] distortions are well-known for 2,5-dialkylamino substituted quinones[8] and can be rationalized by MO perturbation arguments.[8a] The special feature of the structure presented here (see Scheme 2), which can be satisfactorily reproduced quantum-chemically by AM1 energy hypersurface calculations[9] and whose calculated charge distribution q_μ^{AM1} is also displayed in Scheme 2, therefore, consists in the skeletal deformation of tetrakis(dimethylamino)-*p*-benzoquinone structurally "frozen" in its single crystal[1c] and caused by the steric overcrowding of conformationally different $(H_3C)_2N$ substituents.

Oxidation of tetrakis(dimethylamino)-*p*-benzoquinone by $SbCl_5$ in CH_2Cl_2[4] under aprotic conditions yields black crystals of the bis(hexachloroantimonate) salt. Its structure determination (Fig. 1, right) proves that the molecular skeleton remains intact in the dication and that the removal of two electrons produces the two six-electron five-center cyanine chains hoped for, which by their twisting of 35° relative to each other rather elegantly relieve the steric overcrowding in the neutral molecule (Scheme 3).



Scheme 3.

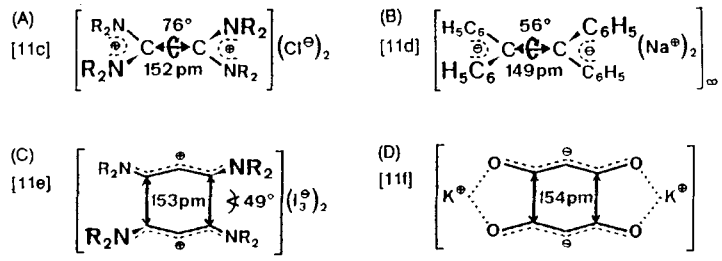


Scheme 2.

The two C=C bonds in tetrakis(dimethylamino)-*p*-benzoquinone, each 137 pm in length, are thus stretched in the dication by 9 pm(!); the CC bonds on either side of the C=O groups become more equal in length, the C–N bonds of 142 and 137 pm are shortened to 132 pm, and all dimethylamino groups become planar (sum of CNC angles 359° to 360°). The ring centers remain planar and the $(H_3C)_2N$ substituents

are only slightly twisted, with dihedral angles between 1 and 10°. The calculated charge distribution q_μ^{AM1} (Scheme 3) for the quantum-chemically reproducible, geometry-optimized structure[10] is in accord with the delocalization of the positive charges along the two N-C-C(O)-C-N$^\oplus$ chains and their considerable transfer to the peripheral methyl groups.

The general and powerful "cyanine" structure perturbation principle[11b] has been pointed out already in the discussion of the 2,4,6,7-tetramethoxythianthrene dication, the structure of which—despite the same number of 14 π electrons as in anthracene—does not exhibit an increased charge delocalization over the three annelated six-membered rings, but rather prefers stretching perpendicular to its long molecular axis with formation of two H_3CO-CCC-S$^\oplus$-CCC-OCH_3 chains.[11a] Of the numerous examples, in which an even number of π electrons are distributed over an odd number of π centers, the following structural changes shown in Scheme 4 are particularly spectacular.[11c-f]



Scheme 4.

The bond skeletons of the starting compounds are always considerably deformed—independent of the formal number of π centers (Scheme 4: three in A and B, five in C and D), the resulting chains and the π electrons delocalized in them (Scheme 4: four in A and B, six in C and D), the type of compounds (Scheme 4: open-chain ethene derivatives such as A and B, those containing six-membered rings such as the dication of tetrakis(dimethylamino)benzene, C, or the dianion of 2,5-dihydroxy-*p*-benzoquinone, D) and independent of their method of preparation (Scheme 4: A, C, oxidation; B, reduction; D, salt formation). Conversely, these deformations permit an energetically favorable "cyanine" charge delocalization.[12] This rationalization can be straightforwardly extended to both structures presented here, the chairlike one of the tetrakis(dimethylamino)-*p*-benzoquinone with differently rotated $(H_3C)_2N$ groups (Scheme 2) and, especially, the one of its dication exhibiting a "twist" conformation and elongated C=C bonds.

In general, a change in the electron distribution and, unalterably, the energy of a compound has to be accompanied by structural changes—as required even in a simplified consideration of the individual states of a molecule,[13a] which always will be superior to the many and misleading so-called bond models. These structural distortions can be surprisingly severe especially on two-electron redox reactions (cf. Fig. 1 as well as Scheme 4; A–D) and, therefore, a search for other striking examples should be quite rewarding.[13b]

Engl. 28* (1989) 1646, and references cited therein; c) H. Bock, P. Hänel, W. Kaim, U. Lechner-Knoblauch, *Tetrahedron Lett. 26* (1985) 42. The reversible half-wave reduction potentials of *p*-benzoquinones, O=C(RC=CR)$_2$C=O, are −0.40 V (R = H) and −1.07 V (R = NMe_2); according to its ENDOR spectrum, the Me_2N-substituted radical anion, generated at a sodium mirror, is stabilized in THF solutions as a Na$^\oplus$ contact-ion pair; d) The first dications of tetraamino-*p*-benzoquinone derivatives (1,4,5,8-tetramethylbis(ethylene)- and tetrapiperidino-*p*-benzoquinone, have been prepared and isolated by *R. Gompper, R. Binder*, and *H. U. Wagner, Tetrahedron Lett. 27* (1986) 691.

[2] Tetrakis(dimethylamino)-*p*-benzoquinone was prepared as described by *K. Wallenfels* and *W. Draber* (*Justus Liebigs Ann. Chem. 667* (1963) 55) from tetrafluoro-*p*-benzoquinone and dimethylamine as follows (P. Hänel, *Dissertation*, Universität Frankfurt am Main 1987): A 30% aqueous dimethylamine solution (7 mL) was added dropwise to fluoranil (1 g, 5.56 mmol) (Aldrich) in 40 mL of diethyl ether at 300 K. After stirring for 1 h, the precipitated solid was filtered off, washed with water, and recrystallized from benzene/petroleum ether; yield 0.8 g (63%) 2,5-difluoro-3,6-bis-(dimethylamino)-*p*-benzoquinone. This (3.5 mmol) was heated in a mixture of a 30% aqueous solution of dimethylamine (10 mL), triethylamine (4 mL), and methanol (16 mL) for 4 h to about 350 K. The reaction mixture was poured into 80 mL of water and the precipitated solid filtered off. Sublimation at 10^{-2} mbar yielded 0.45 g (92%) of black crystals (m.p. 378–379 K); ^{1}H NMR ($CDCl_3$, TMS): δ = 2.85 (s, CH_3).

[3] a) Crystal structure analysis: $C_{14}H_{24}N_4O_2$, black crystals by sublimation at 368 K and 10^{-2} mbar; a = 1760.65(9), b = 1075.32(5), c = 832.09(4) pm, $\alpha = \beta = \gamma = 90°$, $V = 1575.36 \times 10^6$ pm^3 (200 K), orthorhombic, space group P_{bca} (No. 61), Z = 4, Siemens AED II four-circle diffractometer, $Mo_{K\alpha}$, graphite monochromator, 3038 measured reflections in the range $3 < 2\theta < 50°$, of which 952 were independent with $I > 1.5\sigma(I)$, $\mu(Mo_{K\alpha}) = 0.8$ cm^{-1}; structure determination by direct methods (SHELXTL-Plus), N = 952, NP = 140, R = 0.039, R_w = 0.035, $w = 1/\sigma^2(F) + 0.000106\,F^2$. All C,N, and O atoms were refined anisotropically, all H atoms were found and refined isotropically. The molecule is situated around a crystallographic inversion center. Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, W-7514 Eggenstein-Leopoldshafen 2 (FRG), by quoting the depository number CSD-55493, the names of the authors and, the journal citation.

[4] The oxidizing agent is presumably the chloromethyl carbocation formed by the reaction $SbCl_5 + CH_2Cl_2 \rightarrow SbCl_6^\ominus + CH_2Cl^\oplus$, oxidation potential $E_{1/2}^{ox} \approx +1.6$ V (H. Bock, U. Lechner-Knoblauch, *J. Organomet. Chem. 294* (1985) 295). *Experimental procedure*: Tetrakis(dimethylamino)-*p*-benzoquinone (160 mg) were dissolved in 20 mL of dry CH_2Cl_2 and $SbCl_5$ (1 g) was added dropwise under argon. After 2 d of reaction at room temperature, the solvent was removed from the resulting suspension in vacuo. The violet residue was dissolved in 5 mL of dry CH_3CN; after addition of 10 mL of dry CH_2Cl_2, black needles with a metallic luster began to grow within 12 h.

[5] Crystal structure analysis: $[C_{14}H_{24}N_4O_2]^{\oplus\oplus}[SbCl_6^\ominus]_2 \cdot [CH_3CN] \cdot [CH_2Cl_2]_x$, black needles with a metallic luster from CH_3CN/CH_2Cl_2; a = 1248.4(10), b = 1977.3(5), c = 1566.6(3) pm, β = 97.71(4)°, $V = 3832.29 \times 10^6$ pm^3 (room temperature), monoclinic, space group $P2_1/c$ (No. 14), Z = 4, Siemens AED II four-circle diffractometer, $Mo_{K\alpha}$, graphite monochromator, 8816 measured reflections in the range $3° < 2\theta < 50°$, of which 4135 were independent with $I > 2\sigma(I)$, $\mu(Mo_{K\alpha}) = 22.9$ cm^{-1}. Structure determination by Patterson methods (SHELXTL-Plus), N = 4135, NP = 352, R = 0.059, R_w = 0.06, $w = 1/\sigma(F) + 0.001999\,F^2$; empirical absorption correction; C,N,O,Cl, and Sb atoms refined anisotropically, H atoms at calculated positions (d_{CH} = 96 pm) refined isotropically using a common temperature factor. Dichloromethane molecules statistically disordered [3b].

[6] Cf., e.g., the extreme case of tetrakis(dimethylamino)ethene, which, according to its −30 °C single-crystal structure analysis, exhibits a rather twisted bond as well as largely planarized $(H_3C)_2N$ groups (H. Bock, H. Borrmann, Z. Havlas, K. Ruppert, A. Simon, unpublished results).

[7] Electron diffraction in the gas phase (K. Hagen, K. Hedberg, *J. Chem. Phys. 59* (1973) 158) yields, for example, for the unsubstituted parent molecule *p*-benzoquinone $d_{C=O}$ = 122.5 pm, $d_{C=C}$ = 134.4 pm, d_{C-C} = 148.1 pm, CCC = 118°. Single-crystal structure analysis (I. Bolhius, C. T. Kiers, *Acta Crystallogr. Sect. B34* (1978) 1015) yields $d_{C=O}$ = 133.4 pm, d_{C-C} = 147.0 pm, CCC = 120.9°.

[8] Examples given: a) 2,5-diamino-3,6-dichloro-*p*-benzoquinone (S. Kulpe, D. Leupold, S. Dähne, *Angew. Chem. 78* (1966) 639; *Angew. Chem. Int. Ed. Engl. 5* (1966) 599) with $d_{C(N)/C(O)}$ = 150 pm and $d_{C(Cl)/C(O)}$ = 141 pm; b) 2,5-diaziridino-*p*-benzoquinone (T. Ito, T. Sakurai, *Acta Crystallogr. Sect. B29* (1973) 1594) with $d_{C(N)/C(O)}$ = 152 pm and $d_{C(H)/C(O)}$ = 146 pm.

[9] Geometry-optimized AM1 calculations yield for the energy minimum (ΔH_f°(AM1) = +13.5 kcal mol^{-1}) the following selected structure parameters (distances in pm, angles in °; experimental data in parentheses; cf. Fig. 1, left, as well as Scheme 2): C=O 124 (123), C=C 138 (137), C1-C2 148 (146), C1'-C3 152 (151), C2-N1 143 (142), C3-N2 138 (137), sum of angles CN1C 339 (346), sum of angles CN2C 359 (359), ω_1(C1C2-N1C11) 76 (84), ω_2(C1'C3-N2C22) 29 (45), bending angle OC1(C2C3')-C2-C3/C2'-

C3') 32 (12). Obviously, a satisfactory agreement results; nevertheless, the minimum of the total energy calculated for a "boat" conformation is 6 kcal mol^{-1} below that of the "chair" conformation.

[10] For the dication, a complete geometry optimization also yields a twist conformation with an enthalpy of formation ΔH_f°(AM1) = + 424 kcal mol^{-1}; the resulting structure parameters for the planarized dication skeleton agree largely with the experimental data (cf. Fig. 1 right, as well as Scheme 3): C=O 123 (123), C=C 147 (146), C-C 149 (148), C-N 134 (132), sum of angles CNC 360 (359).

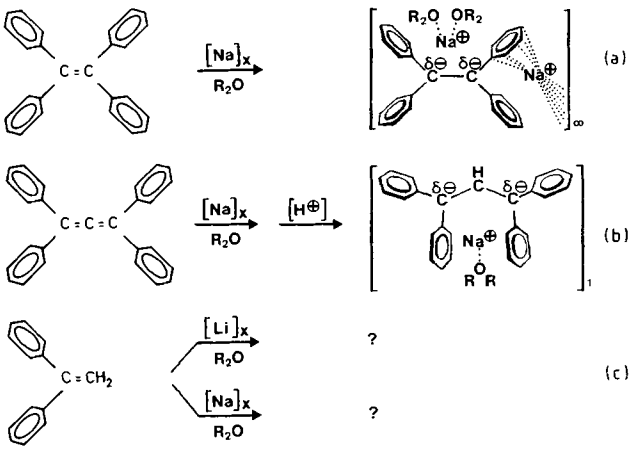
What will be formed on reduction of 1,1'-diphenylethene [Eq. (c)], which contains an $(H_5C_6)_2C$ unit only on one side, by lithium and sodium metal under comparable aprotic conditions? Isolated in each case are orange, air-sensitive crystals of the title compounds.



The Two-Electron Reduction of 1,1'-Diphenylethene by Lithium or Sodium to Different 1,1,4,4-Tetraphenylbutane-1,4-diide Salts via C–C Bond Formation— A Monomeric Dilithium Contact Ion Triple and a Polymer String of "Hydrocarbon Oysters Containing Solvated Sodium Pearls"**

By *Hans Bock,* Klaus Ruppert, Zdenek Havlas, Wolfgang Bensch, Wolfgang Hönle,* and *Hans Georg von Schnering*

Dedicated to Professor Hanskarl Müller-Buschbaum on the occasion of his 60th birthday

The "ocean" of known alkali-metal organic compounds with often surprising structures[1] hides numerous details in its "dark depths". Thus, their preparation involves largely unknown redox processes, which include both solvation and contact-ion pair formation. Also unknown is the influence of the respective countercation and its solvation on the crystallization of the reduction product.[3, 4] On allowing unsaturated hydrocarbons containing twofold phenyl-substituted π centers to react with sodium mirrors [Eqs. (a) and (b)], we discovered that Na countercations[5] repeatedly preferred an inter- or intramolecular six-membered-ring sandwich coordination.[3d–f]

The structures (Fig. 1) suggest that both reactions involve two-electron reduction to a 1,1,4,4-tetraphenylbutane-1,4-diide via C–C bond formation,[10, 11] because this dianion is the hydrolysis-sensitive intermediate of a 1,1,4,4-tetraphenylbutane synthesis. The dilithium and disodium salts, although prepared under nearly identical reduction conditions,[6, 7] display rather large structural differences. The monomeric dilithium contact ion triple (Fig. 1 A) contains doubly ether-solvated $Li^{\delta\oplus}$ countercations, which are π-coordinated to the almost trigonal-planar C1 anion centers as well as to adjacent centers of the less twisted ($\omega = 8°$) phenyl ring. Its butane-1,4-diide chain shows an antiperiplanar conformation and contains a central C–C bond of 156 pm length. In contrast, the sodium salt (Fig. 1 B) consists of contact-ion aggregates, the ether-solvated $Na^{\delta\oplus}$ countercations of which (Na1 and Na3) are partly encapsulated as a π sandwich between two phenyl rings, inclined towards each other owing to the synclinal conformation ($\omega = 69°$) of the butane-1,4-diide chain. The central C2–C3 bond of the latter is lengthened to 158 pm presumably because of the decreased $Na^{\oplus} \leftarrow C^{\ominus}$ delocalization of the negative charges. The resulting "hydrocarbon oysters with solvated $Na^{\oplus}$ pearls" are threaded together on crystallization by π-allyl coordination through additional $(R_2O)Na^{\delta\oplus}$ centers (Na2 and Na4) to form an infinite string. Taking into account contact distances up to 300 pm, the coordination numbers are 11 and 12 for the sandwich centers Na1 and Na3 and 8 for the chain-connecting centers Na2 and Na4.[9] The crystal structures of both salts show additional remarkable features. The angles around the nearly planar anion centers C1 and C4 range from 116 to 125°; that is, they differ by up to 9°. The torsion angles of the differently twisted planar phenyl rings are between 9 and 35°. Especially on countercation contact, they are severely distorted; for example the *ipso* angles at the anion substitution centers are decreased to values as low as 112° (cf. Ref. [4c]) and the ring CC bonds vary in length from 136 to 146 pm (Fig. 1 B). For some of the $Li^{\oplus}$ and $Na^{\oplus}$ countercation-solvating diethyl ethers, a bending of one of their external C–C bonds out of the W conformation is observed with torsion angles up to 79° (Fig. 1 B).

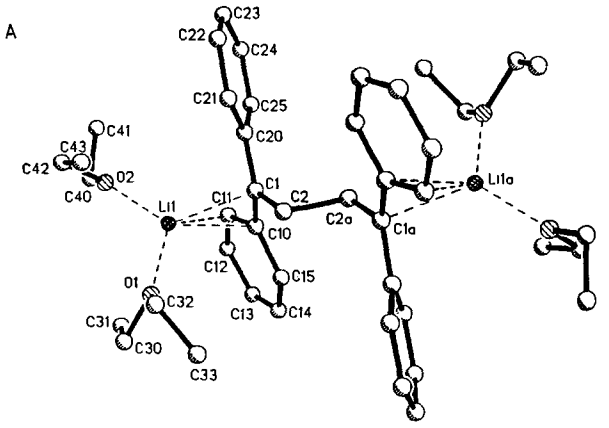
[**] Structures of Sterically Overcrowed and Charge-Perturbed Molecules, Part 9. This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and the State of Hesse. Part 8: H. Bock, K. Ruppert, D. Fenske, H. Goesmann, *Z. Anorg. Allg. Chem. 595* (1991) 275.



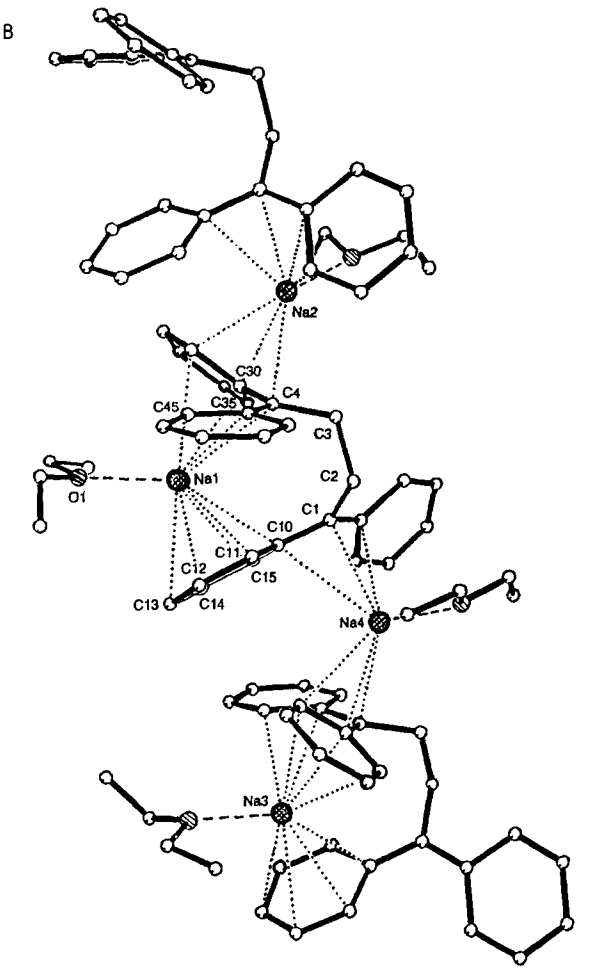


Fig. 1. A) Crystal structure of dilithium 1,1,4,4-tetraphenylbutane-1,4-diide tetrakis(diethylether) [8]. Important distances [pm] (± 0.8) and angles [°] (± 0.5) of the salt, which exhibits a center of inversion: C2-C2a 156, C1-C2 151, C1-C10 144, C1-C20 146, C1-Li1 228, C10-Li1 232, C11-Li1 258, Li1-O1 193, Li1-O2 193; C2a-C2-C1 114, C2-C1-C10 118, C10-C1-C20 123, C1-C10-C11 125, C11-C10-C15 113, C10-C11-C12 124; torsion angles C1C2-C2aC1a 180, C2C1-C10C11 172, C2C1-C20C21 143, C30O1-C32C33 70, C42O2-C40C41 79. B) Crystal structure of disodium 1,1,4,4-tetraphenylbutane-1,4-diide bis-(diethylether) [9]: section of the infinite chain in which the contact ion pairs containing Na1 and Na2 are connected through the likewise solvated centers Na2 and Na4. The tetraphenylbutane-1,4-diide contains a rather long central C2–C3 bond of 158.4 pm, torsion angles ω(C1C2-C3C4) = 69° and ω(CC-phenyl) = 9°–29° a well as partly rather distorted, planar benzene rings (e.g., C10-C11 146 pm versus C12-C13 136 pm or C11-C10-C15 = 112°). The coordination of the Na1 center comprises the sandwich Na1-C10 to Na1-C15 with contact distances of 284, 273, 276, 289, 289 and 279 pm, an allyl unit with Na–C distances of Na1-C35 = 300 pm, Na1-C30 = 267 pm and Na1-C4 = 303 pm, and the single bonds Na1-C45 (305 pm) and Na1-O1 (235 pm).

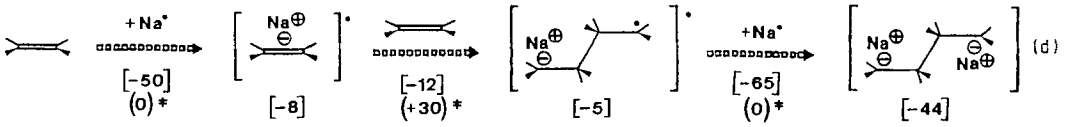
On viewing the different structures of the tetraphenylbutane-1,4-diide salts, which we have isolated here for the first time as single crystals, it is especially striking that the $Na^{\oplus}$ countercations partly prefer to complex in *intra*molecular sandwiches as observed before in tetraphenylallylsodium diethyl ether.[3e] This obviously renders possible the optimum charge distribution for the formation of contact-ion aggregates. For this reason and starting from the experimentally determined structure (Fig. 1 B), we have approximatively calculated the differences in the enthalpies of formation $\Delta(\Delta H_f^{MNDO})$ and in the charge distributions q_μ^{MNDO} between the 1,1,4,4-tetraphenylbutane-1,4-diide $M^{\ominus\ominus}$, its—for the sake of computing time—"hydrated" sodium contact-ion-pair anion $[M^{\ominus\ominus}Na^{\oplus}(OH_2)_2]^{\ominus}$, and the chain structure unit $\{Na^{\oplus}\cdots[M^{\ominus\ominus}Na^{\oplus}(OH_2)_2]^{\ominus}\cdots Na^{\oplus}\}$ (Scheme 1).

	$M^{\ominus\ominus}$	$[M^{\ominus\ominus}Na^{\oplus}(OH_2)]^{\ominus}$	$\{Na^{\oplus}\cdots[M^{\ominus\ominus}Na^{\oplus}(OH_2)]\cdots Na^{\oplus}\}$
$\Delta(\Delta H_f^{MNDO})$ [kcal mol^{-1}]	0	−269	−471
$\sum q^{MNDO}(M)$	−2	−1.53	−1.15
ring A	−0.30	−0.27	−0.12
ring B	−0.30	−0.21	−0.06
ring C	−0.36	−0.19	−0.13
ring D	−0.36	−0.23	−0.09
q_{C1}	−0.37	−0.34	−0.41

Scheme 1.

The calculated enthalpy of formation for the dianion $M^{\ominus\ominus}$ decreases considerably on additional contact-ion interaction. Simultaneously, the charges $\sum q_\mu^{MNDO}$ of the individual $M^{\ominus\ominus}$ phenyl rings also decrease rather strongly, especially within the simulated chain structure unit $(Na^{\oplus}\cdots[]^{\ominus}\cdots Na^{\oplus})$, whereas q_{C1} of the butane-1,4-diide centers remains approximately constant. The preferred formation of an intramolecular $(R_2O)Na^{\delta\oplus}$ sandwich,[3e] therefore, is supported quantum-chemically for tetraphenylbutane-1,4-diide as well.

Again, there remains the open question concerning the pathway of the two-electron reduction of 1,1′-diphenylethene in ether solutions by the alkali metals lithium and sodium,[6, 7] which presumably starts heterogeneously. Of special interest is the C–C bond formation, for which speculative possibilities range from a surface reaction at the bare metal to a dimerization within a solvent cage. ESR/ENDOR spectroscopic investigations in aprotic ether solutions[2b, 3a–c, 13] confirm that $Li^{\oplus}$ or $Na^{\oplus}$ contact-ion pairs of radical anions $M^{\bullet\ominus}$ of suitable molecules M can be generated by their alkali-metal reduction and identified beyond doubt by their ^7Li or ^{23}Na couplings. The aggregation, possibly required for dimerization of sodium contact-ion pairs via C–C bond for-



mation, is supported, for example, by the structure determination of the dimer salt [fluorenone$^{\bullet\ominus}$Na$^{\oplus}$(dme)$_2$]$_2$ (dme = dimethoxyethane).[3c] Because of the analogy to anionic styrene copolymerization,[11] we have performed extensive MNDO/CI hypersurface calculations[13] for the network of imaginable reaction steps involved in the C–C bond formation. Equation (d) shows the most probable pathway with the lowest enthalpy differences ($\Delta(\Delta H_f^{MNDO})$) and enthalpies of activation ($\Delta(\Delta H_f^{\neq(MNDO)})$) (all values in kcal mol^{-1}).

Accordingly, the energetically preferred contact-ion-pair radical $\{[H_2C=CH_2]^{\bullet\ominus}Na^{\oplus}\}$ should first form at the sodium metal mirror; addition of excess ethene then leads to the $Na^{\oplus}$ butanyl-4-ide, which is further reduced to the diamagnetic triple ion $[Na^{\oplus}H_2C^{\ominus}\text{-}CH_2\text{-}CH_2\text{-}CH_2^{\ominus}Na^{\oplus}]$. Phenyl substituents lower all enthalpy values.[14]

Thus, despite increasing detailed preparative and quantum-chemical knowledge, a full understanding of contact-ion crystals and their formation is—as emphasized at the beginning—still far away and additional investigations with selected model compounds like the analogous 1,1,4,4-tetraphenylbutadiene, in which the negative charges can be additionally stabilized within the unsaturated C4 chain,[15] are needed.

[4] Among the remarkable exceptions are (1) all alkali methyls (E. Weiss, S. Corbelin, J. K. Cockroff, A. N. Fitch, *Angew. Chem. 102* (1990) 728; *Angew. Chem. Int. Ed. Engl. 29* (1990) 650 and references cited therein; cf. also [1]), (2) the $Li^{\oplus}$, $Na^{\oplus}$, $K^{\oplus}$, and $Rb^{\oplus}$ acetylides [1], (3) $Li^{\oplus}$ and $Na^{\oplus}$ phenyls (T. Maezke, D. Seebach, *Helv. Chim. Acta 72* (1989) 624 and [1] and references cited therein, as well as $Li^{\oplus}$ and $Na^{\oplus}$ cyclopentadienyls [1], and the tetracyanoethene anion salts with $Na^{\oplus}$, $K^{\oplus}$, and $Cs^{\oplus}$ countercations (H. Bock, K. Ruppert, D. Fenske, H. Goesmann, *Z. Anorg. Allg. Chem. 595* (1991) 275, as well as H. Bock, C. Näther, K. Ruppert, unpublished; cf. also D. A. Dixon, J. S. Miller, *J. Am. Chem. Soc. 109* (1987) 3656).

[5] The preferred formation of $Na^{\oplus}$ sandwich-structure subunits may be caused by (1) a favorable average solvation energy of $Na^{\oplus}$ cations, also in diethyl ether (cf., e.g., $\Delta H_{hydr.}$ [kJ mol^{-1}]: $[Li(OH_2)_{25}]^{\oplus}$ −499,5; $[Na(OH_2)_{17}]^{\oplus}$ −390; $[K(OH)_2)_{11}]^{\oplus}$ −306; N. Wiberg: *Hollemann-Wiberg Lehrbuch der Anorganischen Chemie*, 91st–100th ed., de Gruyter, Berlin 1985, p. 954) and (2) possibly also by favorable radii ratios. For the latter, ab initio SCF calculations using 6-31* basis sets are quoted, which suggest an 80% ionic character and yield radii estimates for the countercations of $Li^{\delta\oplus} \approx 75$ pm and $Na^{\delta\oplus} \approx 115$ pm (see [1a], Table on p. 174). The inner circle radius of a hexagon with edge length d amounts to $r_{inside} = d\sqrt{3}/2$; thus, for benzene ($d_{CC} = 139$ pm), about 120 pm should result for the maximum π charge density.

[6] Preparation of the dilithium salt: anhydrous degassed diethyl ether (15 mL) and degassed 1,1'-diphenylethene (310 mg) were placed in a Schlenk trap (preheated under vacuum) under argon and Li powder (100 mg) was added. After 1 d, the reaction solution had turned red and, after 3 d, orange, air- and moisture-sensitive crystals had grown.

[7] Preparation of the sodium salt: A metal mirror was generated in a Schlenk trap, preheated under vacuum, by vacuum distillation of sodium (170 mg). Anhydrous diethyl ether (30 mL) and degassed 1,1'-diphenylethene (500 mg) were then added under argon. After 1 h, the reaction solution had turned red and, after 24 h, the metal mirror had largely vanished. On slow cooling (1 K h^{-1}) from 293 K to 263 K, orange, air- and moisture-sensitive crystals grew.

[8] a) Crystal structure analysis: $[(H_5C_6)_2CCH_2CH_2C(C_6H_5)_2]^{\ominus\ominus}2Li^{\oplus}\cdot 4Et_2O$, $a = 833.4(4)$, $b = 1109.5(6)$, $c = 1194.9(9)$ pm, $\alpha = 79.45(5)$, $\beta = 87.25(5)$, $\gamma = 71.92(4)°$, $V = 1032.54 \times 10^6$ pm^3 (170 K), $Z = 1$, $\varrho_{calcd} = 1.079$ g cm^{-3}, $\mu(Mo_{K\alpha}) = 0.6$ cm^{-1}, triclinic, space group $P\bar{1}$, Siemens AED II four circle diffractometer, 3492 measured reflections within $3° < 2\theta < 48°$, of which 1795 are independent with $I > 1\sigma(I)$. Structure determination by direct methods (SHELXTL-PLUS), $N = 1795$, $NP = 351$, $R = 0.087$, $R_w = 0.061$, $w = 1/\sigma^2(F) + 0.000715\,F^2$. C, O, and Li atoms found anisotropically; H atoms refined isotropically. Insufficient scattering of the single crystal subjected to measurement leads to an unfavorable N/NP ratio. The dianion is centered around a crystallographic inversion center. b) Further details of the crystal structure determination are available on request from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, W-7514 Eggenstein-Leopoldshafen 2 (FRG), by quoting the depository number CSD-55492, the names of the authors, and the journal citation.

[9] Crystal structure analysis: $[(H_5C_6)_2CCH_2CH_2C(C_6H_5)_2]^{\ominus\ominus}2Na^{\oplus}\cdot 2Et_2O$, $a = 1653.1(2)$, $b = 1126.9(4)$, $c = 1762.8(7)$ pm, $\beta = 104.99(5)°$, $V = 3172.03 \times 106$ pm^3 (200 K), $Z = 8$, $\varrho_{calcd} = 1.161$ g cm^{-3}, $\mu(Mo_{K\alpha}) = 0.9$ cm^{-1}, monoclinic, space group $P2_1$, Siemens AED II four-circle diffractometer, 5461 measured reflections within $3° < 2\theta < 48°$, of which 4918 are independent with $I > 1\sigma(I)$. Structure determination by direct methods (SHELXTL-PLUS), $N = 4918$, $Np = 622$, $R = 0.097$, $R_w = 0.093$, $w = 1/\sigma^2(F) + 0.004844\,F^2$. Na and C atoms of the tetraphenylbutane-diide skeleton refined anisotropically; O and C atoms of the ether molecules refined isotropically. Hydrogen atoms are isotropically refined groupwise, each with a fixed temperature factor. The crystal structure (Fig. 1B) shows four different $Na^{\oplus}$ centers, all of which are solvated by one diethyl ether molecule with Na–O contact distances between 229 and 235 pm, and which can be formally characterized by the following four types of bonding: a one-sided phenyl sandwich (Na1 and Na3), coordination to four adjacent C centers (Na2 and Na3), allyl-anion-type interactions (Na1 and Na4), and single $Na^{\oplus}$–C bonds (Na1, Na3, and Na4). Thus, the four different $(R_2O)Na^{\oplus}$ centers are surrounded as follows: Na1 by one C_6 sandwich, one C_3 chain, and one Na–C single bond; Na2 by one C_4 and one C_3 chain; Na3 by one C_6 sandwich, one C_4 chain, and one Na–C single bond; Na4 by two allyl subsystems and one Na–C single bond [8b].

[10] The reductive C–C bond formation of ethenes by reaction with alkali metals has been reported, for example, for $Ph_3SiHC=CH_2$ (J. J. Eisch, R. J. Beuhler, *J. Org. Chem. 28* (1963) 2876) and for $(Me_3Si)_2C=CH_2$ (M. Kira, T. Hino, Y. Kubota, N. Matsuyama, H. Sakurai, *Tetrahedron Lett. 29* (1988) 6939). A literature search produced no known crystal structures; the course of the reaction has been deduced from deuterolysis, reoxidation, and ring closure by R_2SiCl_2 to yield silacyclopentane derivatives.

[11] Cf., e.g., M. Swarć (Ed.): *Carbanions, Living Polymers and Electron Transfer Processes*, Wiley-Interscience, New York 1968, p. 367f. Contrary to the thermally initiated industrial-scale polymerization of styrene, styrene/butadiene copolymerisates are prepared using lithium alkyl compounds; also, sodium naphthalide is applicable (Dr. Brandstetter (BASF, Ludwigshafen), personal communication).

[12] For some organolithium compounds, $Li^{\oplus}$ six-membered-ring sandwiches have also been structurally proven [1b]: for example, on both sides in lithium-7*bH*-indeno[1,2,3-*j*,*k*]fluorenide (D. Bladauski, W. Broser, H. J. Hecht, D. Rewicki, H. Dietrich. *Chem. Ber. 112* (1979) 1380) or one-sided in bis[(tetramethylethenediamine)lithium]naphthalene and -anthracene salts (J. J. Brooks, W. Rhine, G. D. Stucky, *J. Am. Chem. Soc. 94* (1972) 7346; W. E. Rhine, J. Davis, G. D. Stucky, *ibid. 97* (1975) 2079). Die $Li^{\oplus}$–C_6 contact distances are between 228 and 266 pm; in the double sandwich structure, the planes of the six-membered rings are only 386 pm apart. In

the disodium salt presented here, the $Na^{\oplus}$–C_6 distances are between 265 pm and 305 pm and the ones between the nearest-neighbor phenyl rings within the contact-ion-pair subunit are about 470 pm.

B46* (1991) 326; c) H. Bock, H.-F. Herrmann, *J. Nouv. Chim.*, in press. Cf. also the *Dissertations* of P. Hänel, B. Hierholzer, H.-F. Herrmann, and R. Baur (Universität Frankfurt 1987, 1988, 1989, and 1990, respectively).

[14] All quantum-chemical calculations have been performed using the MNDO program SCAMP and the parameters given in [3e]. For disodium tetraphenylbutane-1,4-diide, the experimental structure has served as the starting point and all ether ethyl groups have been substituted by H to save computing time. The energy hypersurface calculations for the anionic ethene dimerization have been carried out with all configurations resulting from the six inner and partly occupied molecular orbitals. The C···C distance between the C-connecting centers has been chosen as reaction coordinate and every point of it has been completely geometry-optimized.

SiI_2—A Novel Triatomic Molecule with a Relativistic Touch**

By *Hans Bock,* Matthias Kremer, Michael Dolg,** and *Heinz-Werner Preuß*

Dedicated to Don Weyenberg on the occasion of his 60th birthday

Combination of the 13 most important nonmetal elements (H, B, C, Si, N, P, O, S, F, Cl, Br, I, Xe) allows the construction of 1638 triatomic molecules, of which 1183 are linear and 455 are cyclic. With rather few exceptions—including the title compound—they are already known; thus the other dihalogen silanediyls (silylenes), too, are accessible via different routes[1] (Fig. 1).

The still-unpublished He(I) photoelectron (PE) spectrum of $SiBr_2$,[1g] which exhibits a Br–Si–Br angle of 103° and Si–Br bond lengths of 224 pm,[1f] will be discussed by way of introduction without considering relativistic effects, which probably can no longer be neglected for SiI_2. According to a useful rule of thumb,[3] six radical-cation states of low energy are expected for the altogether twelve $3p_{Si}$ and $4p_{Br}$ valence electrons; the additional band at 15.3 eV, therefore, results from a $3s_{Si}$ ionization (Fig. 1, bottom: $2a_1$). As the MNDO diagrams illustrate (Fig. 1, bottom), the following straightforward and plausible assignment results: the $M^{\cdot\oplus}$ ground state $\tilde{X}(^2A_1)$ is generated by electron expulsion from the silicon electron pair (Fig. 1: $4a_1$) followed by four n_{Br} bromine-electron-pair (Fig. 1: $3b_2$, $1a_2$, and $3a_1$) and two σ_{SiBr} ionizations (Fig. 1: $2b_2$ und $2a_1$), the latter with a dominant 3 s_{Si} contribution. On PE spectroscopic comparison of SiF_2, $SiCl_2$, and $SiBr_2$ (Fig. 1), especially striking is the lowering of the halogen-electron-pair ionizations $n_F > n_{Cl} > n_{Br}$, which reflects the tremendous influence of the decreasing effective nuclear charge of the halogen substituents[3] and their increasingly smaller difference from that of the Si center. What additional information will be supplied by the PES band pattern of SiI_2, the preparation of which is best accomplished by the reaction of SiI_4 with elemental silicon?[4]

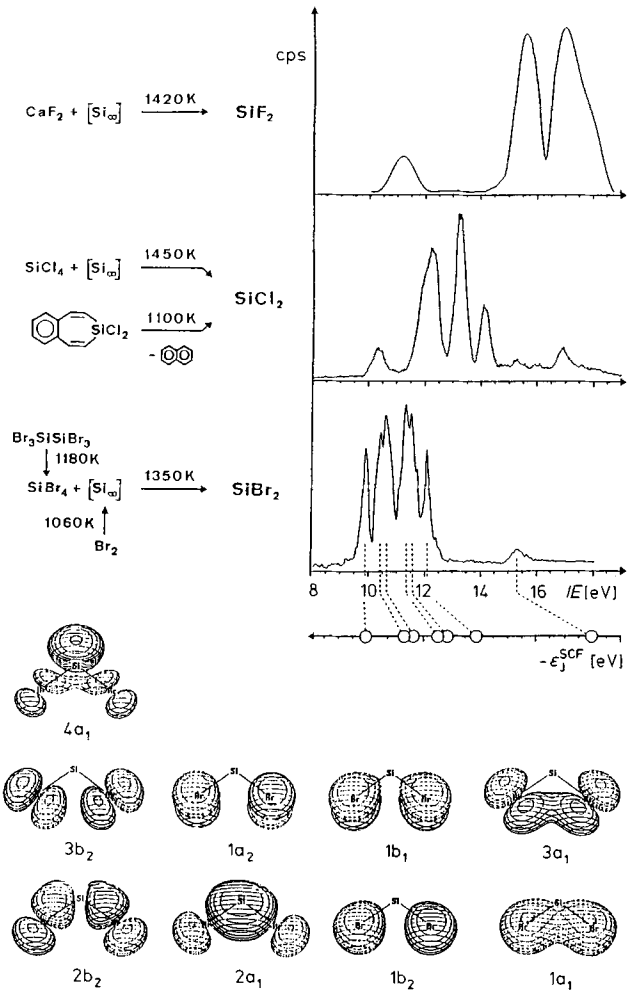

Fig. 1. Preparation and PE spectroscopic characterization of SiF_2 [1c], $SiCl_2$ [1d, e], and $SiBr_2$ [1f, g] (top) as well as Koopmans' assignment of the radical-cation states of $SiBr_2$ based on MNDO eigenvalues and eigenfunctions (bottom) [2].

The comparison of the radical-cation-state pattern of SiI_2 (Fig. 2) with those of the other dihalogen silylenes (Fig. 1) shows that only the $3s_{Si}$ ionization has shifted significantly to lower energies, but a distinct spread to largely isolated bands can be recognized, which now are $\Delta IE^{v}_{n,m} = 0.4$ to 0.7 eV apart (Table 1). For the assignment of the vertical ionization energies IE^{v}_{n} of SiI_2 via Koopmans' correlation, $IE^{v}_{n} = -\varepsilon^{SCF}_{j}$, based on SCF eigenvalues (Table 1), therefore, the relativistic effects caused by the two heavy-atom substituents I necessarily have to be taken into account. The relativistic influence comprises direct effects through the mass/velocity term, the Darwin term, and the spin/orbit term, as well as indirect ones through the relativistic changes in the electron distribution within the core electron system and thus in the field for the valence electrons. In comparison to nonrelativistic Hartree–Fock calculations, the effects for relativistic Dirac–Fock calculations lead to a contraction of the 5s and $5p_{1/2}$ orbitals by 3.9 and 4.0%, whereas the $5p_{3/2}$ orbital expands relative to radii expectation values only slightly by 0.6%. Energetically, the 5s and $5p_{1/2}$ orbitals are stabilized

Cederbaum, W. von Niessen, P. Paetzold, P. Rosmus, B. Solouki, *Angew. Chem. 101* (1989) 77, *Angew. Chem. Int. Ed. Engl. 28* (1989) 88 and H. Bock, M. Bankmann, *Phosphorus, Sulfur Silicon Relat. Elements 53* (1990) 167.

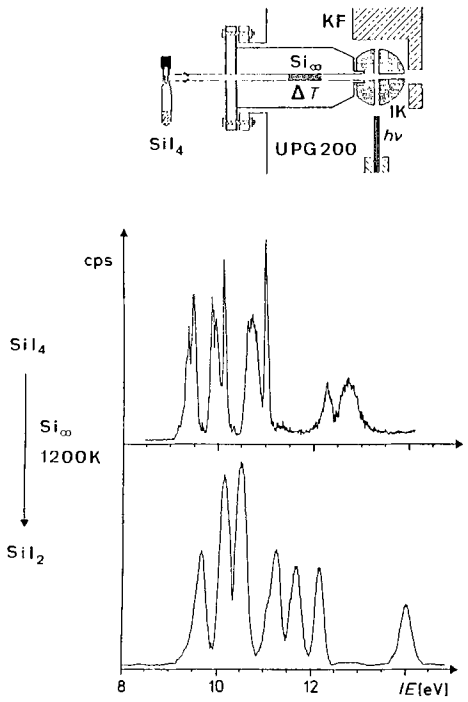

Fig. 2. Short-path apparatus (schematic) for the gas-phase preparation of SiI_2 in the electron-bombardment oven (ΔT) of the Leybold Heraeus UPG 200 PE spectrometer ($h\nu$, He(I) lamp; IK, ionization chamber; KF, cooling trap) as well as He(I) PE spectra of SiI_4 and SiI_2.

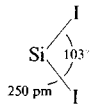
by 1.52 and 0.7 eV, whereas the $5p_{3/2}$ orbital is destabilized by 0.39 eV.[7] The experimentally observed hyperfine structure splitting of the ($5s^2$, $5p^5$) states of the iodine atom, $^2P_{3/2}$ and $^2P_{1/2}$, amounts to 0.94 eV.[3b] These relativistic effects can be successfully incorporated into quantum-chemical investigations—as demonstrated by a test calculation for HI (exp./calcd: $IE_1^v(^2P_{3/2})$ = 10.38/10.14 eV; $IE_2^v(^2P_{1/2})$ = 11.05/10.86 eV; $\Delta IE_{1/2}^v$ = 0.67/0.73 eV[3b, 6])—by using a quasi-relativistic two-component pseudopotential SCF method and a double zeta (DZ) polarization function (p) basis set[6] (Table 1).



1

Table 1. Experimental and calculated data for SiI_2.

IE_n^v [eV]	C_{2v}^*/C_{2v}	$-\varepsilon_j^{SCF}$ [eV]	$\Delta\varepsilon_j^{SCF}$ (rel.) [eV]
9.70	$9e_{1/2}/4a_1$	9.37	0.02
10.16	$8e_{1/2}/3b_2$	10.00	−0.07
10.54	$7e_{1/2}/1a_2$	10.31	−0.05
11.25	$6e_{1/2}/1b_1$	11.30	0.05
11.70	$5e_{1/2}/3a_1$	11.72	0.06
12.18	$4e_{1/2}/2b_2$	12.37	0.02
14.10	$3e_{1/2}/2a_1$	17.67	0.05

Obviously, the Koopmans' defects amount—with the exception of the $2a_1(3s_{Si})$ ionization—to a maximum deviation of only 0.33 eV. In contrast, the first SiI_2 ionization energy predicted by semiempirical MNDO calculations is too low by 1.1 eV and that predicted by relativistic EHMO calculations using the program ITEREX 85 is even 1.6 eV too low.[1g] Eye-catching is the rather small effect of spin/orbit coupling within the C_{2v} molecular symmetry (**1**, $\Delta\varepsilon_j^{SCF}$ (rel.)) of only at most 0.07 eV, whereas, in the analogous GeI_2, the relativistic effects increase to 0.3 eV and thus can no longer be neglected. The SiI_2 structural parameters from the geometry-optimized DZP-SCF calculation[7] are supported by the satisfactory agreement between the values also calculated for the other dihalogen silylenes and their known experimental values (exp./calcd, e.g., for $SiBr_2$: Si–Br = 224/221 pm, Br–Si–Br = 103/106°[1d, 7]). The population analysis for SiI_2 based on the optimized structure yields for the Si center a charge of + 0.54 and, correspondingly, for each of the I centers − 0.27. Comparison with the values obtained for the Si centers of the other dihalogen silylenes (SiF_2, + 0.91; $SiCl_2$, + 0.78, $SiBr_2$, + 0.66[7]) further supports the assumption that the steady decrease in the valence-electron ionization energies, clearly visible in their PE spectra (Figs. 1 and 2), can be traced back to the effective nuclear charges of halogen substituents, which decrease from F to I.

Could the novel molecule SiI_2 be of some use? Speculations range from the oligomerization of the species, generated here thermally under unimolecular conditions, to give compounds $(SiI_2)_n$ with $n < 6$,[1a, 9] for example, which are stable at room temperature and under normal pressure and which would further enlarge polysilane chemistry, to known silylene additions to unsaturated hydrocarbons[10] as well as subsequent products. More technologically minded proposals[11] concern uses in chemical vapor deposition (CVD), surface etching, or Si_x transport reactions, because the generation temperature for SiI_2 from SiI_4 and Si_x requires only 1200 K (Fig. 2), which is considerably below those necessary for the other dihalogen silylenes, and also because Si–I bonds are supposedly easier to split. Until such proposals are realized for SiI_2, however, its charm consists in being one of the few still unknown triatomic main-group-element molecules.

Rappoport (Eds.): *The Chemistry of Functional Groups, Supplement D*, Wiley, Chichester 1983, pp. 1499–1603; cf. also [1b].

[4] a) Pure SiI_4 is an absolute necessity. Therefore, the brownish, waxy raw material obtained from reaction of the elements (G. Brauer: *Handbuch der Präparativen Anorganischen Chemie*, de Gruyter, Berlin 1985) is twice distilled at 500 K after adding 10 wt% of copper powder before each distilla-

tion. The resulting, slightly violet solid can be sublimed under 10^{-3} mbar pressure at 370 K to yield white crystalline needles, which have to been stored in sealed ampoules at low temperature and under exclusion of light. b) Reaction of the silicon tetrahalides SiI_4 and $SiBr_4$ with silicon powder: An 8-mm-long layer of Si powder dispersed in quartz wool was placed into the heatable molybdenum tube (inner diameter 4 mm) of the electron-bombardment oven in the PE spectrometer between two quartz-wool stoppers. After removal of surface water by heating to 370 K under 10^{-5} mbar pressure, the silicon tetrahalides were evaporated from either a trap with a Teflon stopcock ($SiBr_4$, twice distilled at 427 K/1 bar) or from the heatable solid evaporator of the PE spectrometer (SiI_4); the pressure in the inlet system remained below 10^{-4} mbar. After recording of the SiX_4 PE spectra, the reaction zone was heated in 50 K steps until the SiX_4 ionization patterns disappear.

[7] The one- and two-component ab initio pseudopotential calculations are performed using the programs TURBOMOLE (R. Ahlrichs, M. Bär, M. Häser, H. Horn, C. Kölmel, *Chem. Phys. Lett. 162* (1989) 165) or UHREL (P. Hafner, W. H. E. Schwarz, *Chem. Phys. Lett. 65* (1979) 537). The energy-adjusted quasi-relativistic pseudopotentials used comprise in satisfying approximation the most essential relativistic effects resulting from the Dirac equation (mass/velocity term, Darwin term, and spin/orbit term of the Pauli equation). Si and I are treated as systems of four and seven valence electrons and for both atoms energy-optimized (4s4p)GTO-valence basis sets of double zeta quality are employed. The geometry optimizations have been performed within one-component SCF calculations using the program TURBOMOLE and applying a gradient procedure. The effects of spin/orbit interactions were subsequently investigated by two-component SCF calculations using the program UHREL starting from the equilibrium geometries determined.

Superconductivity in Layered Structures of Rare-Earth Carbide Halides

By *Arndt Simon,* Hansjürgen Mattausch, Roland Eger,* and *Reinhard K. Kremer*

The structures of superconducting oxocuprates contain without exception CuO_2 layers.[1] For $YBa_2Cu_3O_{6.6}$ (transition temperature $T_c \approx 60$ K), the anisotropy of the decrease of T_c in a magnetic field corresponds to the behavior of two-dimensionally metallic, and at low temperatures superconducting, niobium and tantalum dichalcogenides.[3] Crystals of these phases consist of MX_2 planes, connected by van der Waals bonds. TaS_2 is superconducting at $T_c = 1.8$ K;[4] the highest transition temperature in dichalcogenides (T_c = 7.3 K) is found for $NbSe_2$.[5] Since these systems are two-dimensional and can be modified by intercalation reactions, extensive investigations on superconducting dichalcogenides have been undertaken.[6, 7]

We now report on the superconductivity of similar layered compounds of the composition $Y_2C_2Br_2$, $Y_2C_2I_2$, $La_2C_2Br_2$, and $Lu_2C_{2-x}Cl_2$. Monophasic samples are prepared like $Gd_2C_2Br_2$[8, 9] as moisture-sensitive, microcrystalline, bronze-colored platelets by heating stoichiometric quantities of trihalide, metal, and graphite powder in gas-tight, welded tantalum ampules for several days at ca. 1300 K.[10] The phase analysis[11, 12] was performed with the modified Guinier technique.[13] As Figure 1 shows, the structures of the crystals, which cleave like graphite, are characterized by close-packed double sheets of metal atoms (M). The octahedral interstices are occupied by C_2 units and the metal double layers are sandwiched by layers of halogen atoms (X). Such XMC_2MX slabs are joined together by van der Waals forces.[8, 9] The crystals show good metallic conductivity within the layers. The conductivity is orders of magnitude smaller in the perpendicular direction.[15]

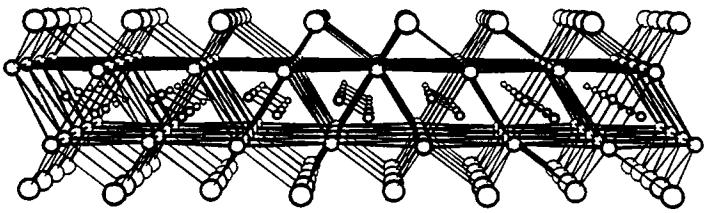

Fig. 1. Central projection of a slab of $M_2C_2X_2$ along [010] of the monoclinic structure (X, M, and C atoms are drawn in decreasing size; the diagram is based on the positional parameters of $Gd_2C_2Br_2$).

Figure 2 shows the onset of superconductivity for $Y_2C_2Br_2$ as indicated by resistance measurements; the diamagnetic shielding[16] displayed in Figure 3 confirms the

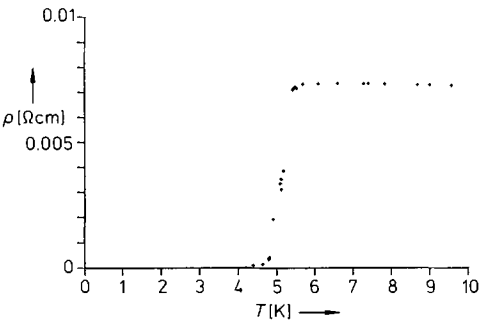

Fig. 2. Dependence of the electrical resistance ϱ of $Y_2C_2Br_2$ on temperature [16].

superconducting state of all four phases. The carbide halides are interesting not only because superconductivity is observed in a two-dimensionally delocalized electronic system. An analysis of their very special electronic structure and bonding could also contribute to the understanding of the chemical prerequisites for the phenomenon of superconductivity.

Extending an earlier idea about high-temperature superconductors,[17, 18] we attribute the attractive interaction between conducting electrons through electron–phonon coupling[19] to a tendency toward localization of the electrons in pairs in special band states. These band states may be bonding (covalent M–M bonds, for example in Nb, Nb_3Sn, $NbSe_2$), nonbonding (lone pairs in Sn, Pb, $(Ba,K)(Bi,Pb)O_3$) or antibonding in character (d states in oxocuprates). The carbide halides described here fall into the last category.

Heisenbergstrasse 1, W-7000 Stuttgart 80 (FRG)

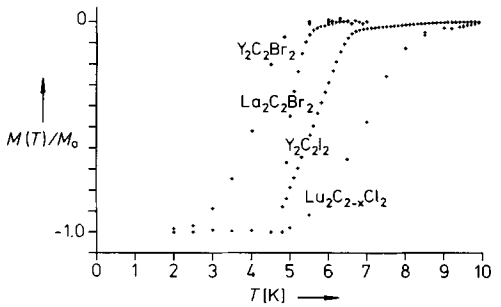

Fig. 3. Magnetization measurements on rare-earth carbide halides. All data points are normalized in such a way that at the lowest temperature the maximal diamagnetic shielding is achieved. For $Y_2C_2Br_2$ it is 40% of the ideal value.

The C–C distance of 127 pm[8] and 130 pm[9] in $Gd_2C_2Br_2$ determined by X-ray crystallography on single crystals—neutron diffraction on a powder sample of $Tb_2C_2Br_2$ gives a C–C distance of 129 pm[20]—corresponds approximately to a double bond and leads to a formal bond description[21] as $(M^{3+})_2C_2^{4-}(X^-)_2$ for the phases $M_2C_2X_2$. Semiconductor behavior is therefore expected unless a strong overlap of M-d and C-p states closes the band gap. Metallic behavior results, in terms of molecular chemistry, from the backbonding of occupied π^* states of the C_2 groups into empty d states on the M atom. This backbonding is already indicated by shortened C–C distances. Such a view of the bonding in $Gd_2C_2Cl_2$ was substantiated by calculations of the band structure using the Extended Hückel method.[23] They led to a density of states at the Fermi edge, and their COOP (*c*rystal *o*rbital *o*verlap *p*opulation)[24] confirmed the C–C antibonding ($C\pi^*$) and the Gd–C bonding character of these states.

Thus, a picture of the pairwise attractive interaction between the conduction electrons in the compounds $M_2C_2X_2$ results. The electrons are delocalized in covalently mixed p-d band states and have a tendency to pairwise occupation of the molecular π^* states of the C_2 units. In this sense, the stretching and wagging vibrations of the C_2 unit should promote an effective electron–phonon coupling through variations of the energy of the π^* level or variation of the p-d overlap. The parallels to other superconducting systems such as, for instance, type $BaBiO_3$ are obvious.[25, 26] Here too, the electrons are delocalized in a band of covalently mixed O–Bi states and have a tendency to occupy in pairs the (in this case nonbonding and metal-centered) lone-pair states.

As anticipated, superconductivity in $M_2C_2X_2$ phases does not occur with magnetic lanthanoid ions; the corresponding, similarly metallic compounds of Gd and Tb undergo magnetic ordering at temperatures around 28 and 78 K respectively, but show no superconductivity. The lowering of the valence electron concentration in $Y_2C_2Br_2$ by replacing 10% of the Y atoms by calcium atoms lowers T_c to 4 K. The particular halogen involved is critical: T_c is ca. 1 K higher for $Y_2C_2I_2$ than for $Y_2C_2Br_2$; however, $Y_2C_2Cl_2$, $La_2C_2I_2$, and $Lu_2C_{2-x}Br_2$ are not superconducting.

For completeness we add that superconductivity also occurs in binary rare-earth metal carbides of the composition M_2C_3 and MC_2.[6] For example, a transition temperature of 17 K is observed for $C_{1.55}Th_{0.3}Y_{0.7}$.[27] Their structures also contain C_2 units as is required for this composition, and the observed C–C distances suggest strong p-d mixing.[28]

[28] The idea mentioned here of pairwise attraction of conducting electrons in systems with C_2 units is naturally not applicable to all carbides. Transition-metal carbides like NbC belong in our opinion to the first category.

Book Reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the following address: Redaktion Angewandte Chemie, Postfach 101161, D-6940 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

Profiles, Pathways and Dreams. Autobiographies of Eminent Chemists. Edited by *J. I. Seeman*. American Chemical Society, Washington, D. C. 1990. **D. J. Cram. From Design to Discovery.** xxi, 146 pp., hardcover $ 24.85.—ISBN 0-8412-1768-8; **C. Djerassi. Steroids Made it Possible.** xxiv, 205 pp., hardcover $ 24.85.—ISBN 0-8412-1773-4; **E. L. Eliel. From Cologne to Chapel Hill.** xxxi, 138 pp., hardcover $ 24.95.—ISBN 0-8412-1767-X; **J. D. Roberts. The Right Place at the Right Time.** xix, 299 pp., hardcover $ 24.95.—ISBN 0-8412-1766-1

Jeffrey I. Seeman, an American industrial chemist who tells us that he has always been interested in the human side of scientific developments, suggested to the books department of the American Chemical Society (ACS) in 1986 that they should publish a volume of autobiographical essays by eminent chemists. The ACS took up this idea, but both they and the editor soon found that the project began to develop a life of its own, so that by the time it is finished (at least for the time being!) there will be no less than 22 individual volumes. The series has now been given the general title "Profiles, Pathways and Dreams", and the first four autobiographies (consisting of nearly 800 pages altogether!) have appeared and are reviewed here. My verdict can be summarized in one sentence: please let us have more soon! (Since this was written the number of volumes has in fact grown to ten).

The clever and carefully-considered choice of authors means that the level of interest in the series is unlikely to fade soon. As well as applying the criterion that each author must have made fundamental contributions to organic chemistry over a long period, much importance has also been placed on maintaining the international quality of the project. The authors eventually enlisted (ominously, it is stated in the preface that "Not all who were invited chose to participate, and not all who should have been invited could be asked") represent experiences of teaching and research in thirteen countries altogether.

These first volumes of the series can be read at several quite different levels, and this is likely to be true also of later volumes. In the first place, of course, they are the life stories of the authors, in which the human dimension and the dreams come out to a varying degree depending on temperament and frankness, sometimes strongly (*Djerassi*) and sometimes with more reserve (*Cram*). Here each reader will develop his or her own particular affinities. For me it was *Roberts*' autobiography that pleased most: his sober style and absence of illusions, his modesty ("Memory of the titans of any given era of modern chemistry tends to fade rapidly from generation to generation"), the humor, both overt and veiled, and the occasional adverse comments about colleagues.

Secondly, these "blue volumes" (each with a profile on the cover in gold of the author portrayed therein!) are also excellent textbooks of chemistry, since their authors describe in detail how their research aims have developed over the decades: by studying the classic examples one gains mastery of a science. In this connection it is also interesting to note at how early a stage each author discovered his (scientific) leitmotif in every case, and how steadfastly he continued to pursue it over a very long period and developed it further using the latest techniques. This possibly characterizes one of the main differences compared with present-day research in organic chemistry: the research of the fifties to seventies which is described in these autobiographies (the average age of the authors being around seventy) was more noticeably "inner-directed" (to use a term coined by *David Riesman*, a sociologist of that period), in contrast to the strongly "outer-directed" research of today. The main reason for this could be the considerable changes that have occurred in the system of supporting and rewarding research. The scarcity of financial support and of material resources in general in those earlier years forced researchers to be more self-reliant. Here again *Roberts* provides a good example, constructing his own glass apparatus, and later his own NMR spectrometers which he continued to develop. In those days there was no talk of creativity prizes, reagents of the year, or other such gimmicks originating from the world of scientific marketing.

Thirdly, these volumes are a tribute to the American university system. This is at the same time both very elitist and democratic in character, has a strong internationalist tradition, as is clearly shown by the experiences of the immigrants *Djerassi* and *Eliel* during their first years in American universities, and provides academic freedom (researchers remain almost exclusively researchers, rather than administrators as tends to happen in Germany).

This series of volumes will not add up to a history of modern organic chemistry; that purpose cannot be achieved through autobiographies, and it will certainly not be attempted. On the other hand, when the series is complete we shall have a very rich and colorful patchwork of chemistry, made up additionally of many interesting and sometimes amusing snapshots, together with many brilliant highlights.

Heteroatom Chemistry. Edited by *E. Block*. VCH Publishers, New York 1990. xii, 376 pp., hardcover DM 178.00.–ISBN 0-89573-743-4

"Heteroatom chemistry" is usually understood to mean the organoelement chemistry of the elements in main-groups 3 to 7 of the Periodic Table (i.e. the 13th to 17th groups). This book is based on twenty plenary lectures delivered at the International Conference on Heteroatom Chemistry (ICHAC) held in Albany, NY, in 1989. The presentation of this material in book form is almost beyond reproach.

This very extensive subject could not be covered in a mere 376 pages; the editor has therefore limited the contents to an overview of the current situation regarding the applications of heteroatom compounds (excluding those of nitrogen and

 © VCH Verlagsgesellschaft mbH, W-6940 Weinheim, 1991 0570-0833/91/0909-1190 $ 3.50+.25/0

oxygen), mainly in synthetic organic chemistry. In addition a few articles are devoted to unusual types of bonding in compounds of main-group elements. The choice of eminent authors has ensured that the book is successful in meeting these aims.

Y. Apeloig deals with bonding and structure in some unusual silicon compounds. This article is a good summary of the same author's contribution to "The Chemistry of Organic Silicon Compounds" (edited by *S. Patai* and *Z. Rappoport*), which appeared in 1989. *A. J. Arduengo III* and *D. A. Dixon* present experimental and theoretical evidence showing that trivalently bonded compounds of the "pnictogen" elements can undergo not only the familiar textbook vertex inversion process (tetrahedron–trigonal-planar intermediate–tetrahedron), but also an "edge inversion process" (tetrahedron–square-planar intermediate–tetrahedron). This new process is illustrated by the example of *Arduengo*'s T-shaped compounds of main-group elements. In discussing the problem of color in pentaarylbismuth compounds *K. Seppelt* draws attention to the unusual bismuth-carbon bonding in these hypervalent species; relativistic effects must be invoked to account for the phenomena that are observed. This group of contributions dealing mainly with theoretical and physical chemical aspects ends with an article by *J. B. Lambert, G. Wang* and *E. C. Chelius* in which they discuss the β-effect of trimethylsilyl, -germyl and -stannyl groups in the solvolysis of cyclohexyl and cyclopentyl derivatives.

Four articles are devoted to the reactivity and synthetic applications of sulfoxides. Those by *H. B. Kagan* and *A. Ohno* are concerned with chiral sulfoxides, whereas *O. De Lucchi* et al. discuss atropisomeric binaphthylsulfones and -sulfoxides as chiral auxiliaries. *N. Furukawa* describes an investigation into the question of whether sulfuranes are formed as intermediates in the reaction of sulfoxides with organometallic reagents, and considers the possible synthetic applications of these experiments.

A further contribution on the chemistry of hypervalent heteroatoms is provided by *D. H. R. Barton*, who describes ligand coupling reactions applied to pentacoordinated bismuth compounds. *Y.-Z. Huang* et al. give an impressive account of the use of arsene ylides in synthesizing polyenes and sensitive natural products. Some insights into the chemistry of organoselenium compounds are provided by *W. Ando* and *N. Tokitoh*, who describe the photolysis and pyrolysis of selenium- and sulfur-containing heterocycles to form highly reactive intermediates. The section on polyselenium and polysulfur heterocycles is especially interesting, and includes some hitherto unpublished results. *T. G. Back* et al. report on the selenosulfonation of alkenes and alkynes and some applications of this method in steroid chemistry. *A. Krief* et al. have succeeded in synthesizing molecules in which quaternary carbon atoms are linked together, by proceeding via α-lithioselenides.

Two articles deal with the chemistry of low-valency compounds of main-group elements. In the first of these *M. Regitz* discusses the synthesis of phosphaalkynes and the chemistry based on these. Although detailed and up-to-date reviews of this topic already exist,[*] the fascinating possibilities opened up by this chemistry simply had to be included in this book. The second article is an updated survey of the chemistry of siloxy-substituted silenes, an area which is the specialty of *A. G. Brook*. *T. Cohen* describes the use of phenylthioethers to synthesize carbanions which would otherwise be accessible only with great difficulty or not at all. The sections on the preparation of dianions from epoxides and dioxetanes are particularly interesting. These anions are very useful building blocks, for example in synthesizing spiroketals.

Some results obtained in the very promising field of polydentate Lewis acids, which in contrast to that of polydentate Lewis bases is still only in its infancy, are described with the help of examples by *H. G. Kuivala*. Some new sterically strained boron compounds are described by *M. Lappert* et al. Nearly all these results are previously unpublished; however, the coverage is rather too brief for my taste (9 pages), especially as this is the only article dealing with boron chemistry. *H. Sakurai* gives a brief account of some interesting metal-induced cyclooligomerizations of silylated cyclic polyalkynes, and of the synthesis and structure of hexakis(trimethylsilyl)benzene. The book ends with an article by *K. Tang* on copper and silver complexes with sulfur ligands, which is certainly worth reading, although it does not really fit into the subject of the book.

The literature citations in all the articles are, without exception, fairly recent or very recent; references to reviews are also included. The choice of topics and their treatment give no cause for criticism. As the book is essentially a conference proceedings report, it provides insights into the current state of research in selected areas rather than comprehensive reviews. In so doing it succeeds, briefly but succinctly, in conveying an appreciation of the principles underlying the reactivity of each element or molecule discussed. In general it is exactly the personal points of view expressed in the treatment of the topics that give the book its appeal, and the authors' love of their special fields of research is evident between the lines. The fact that the dominant heteroatom elements are sulfur and selenium (at least in nine of the twenty articles), may be a consequence of the editor's area of interest. This excellent book can be recommended to anyone who wants a rapid survey of the currently "hot" topics in main-group chemistry. However, the price is already approaching the "pain threshold" (and is well above it for students), which means that for future volumes, if the basic concept is to be maintained, the possibility of paperback editions should be considered.

Chemistry of Alicyclic Compounds. Structure and Chemical Transformations. (Series: Studies in Organic Chemistry, Vol. 38). By *G. Haufe* and *G. Mann*. Elsevier, Amsterdam 1989. 468 pp., hardcover DFl 350.00.—ISBN 0-444-98878-5

This book lives up to the authors' claim: it is suitable as a standard text and guide for the student, and it can be used by a practising chemist to increase the depth of his knowledge of alicyclic compounds. Obviously, the chemistry of alicyclic compounds is so large a subject that it is not possible for the authors to cover it completely. Their treatment is therefore concentrated mainly on small to medium-sized ring systems.

The book, which is practically free of errors that affect the meaning, is divided into six self-contained chapters. The first chapter, and also the two that follow it, are written in textbook style and should therefore be easily understandable even by second-year chemistry undergraduates. Chapter 1 deals with the systematic description of the structures of alicyclic compounds. The topological and topographical as-

pects of alicyclic structures are explained with the help of examples (although the diagrams in Figure 1.11 on page 41 are mirror images of the correct structures). The chapter is completed by detailed tables of compounds arranged according to increasing numbers and sizes of rings, including structural formulas and literature references.

In Chapter 2, after explaining kinetic and thermodynamic stability, results of theoretical calculations on alicyclic compounds by ab initio, semiempirical and force field methods are presented, and their structure-energy relationships are discussed. Unfortunately the treatment in this chapter is very superficial and uncritical. For example, it is wrongly stated on page 84 that in organic chemistry compounds with exceptionally high energies are described as being strained, and molecules with distorted structures are described as being sterically hindered. Also one would expect to find more than is offered here under the title "Relationships Between Strain and Reactivity"; there are no mentions or citations of pioneering studies such as those by *P. von R. Schleyer* (1961), *C. S. Foote* (1964) or *C. J. M. Stirling* (1985).

Chapter 3 is concerned with dynamic processes in alicyclic compounds, such as intramolecular motions, vibrations, internal rotations and ring inversions, conformational transformations (e.g. pseudorotation) and configurational transformations (double-bond isomerizations and inversions), as well as valence isomerizations (π-bond shifts).

The remaining three chapters (4–6) contain detailed discussions of a wide variety of ring-reducing, ring-enlarging and transannular reactions of alicyclic compounds, together with their energetic and stereochemical aspects. Regrettably, one searches in vain in this part of the book for information or literature references concerning modern free radical cyclization chemistry. The structural formulas, which are clearly drawn and also include perspective views where necessary, enable the reader to easily find his or her way around the text, despite the very high information density. This is further helped by the detailed contents list and the 33-page subject index. For those who wish to read up special topics in greater depth there is a bibliography at the end of each chapter, containing between 110 and 430 citations including recently published work.

The printing quality is unsatisfactory. For example, the reproduction of some of the figures is incomplete or of very poor quality (pages 56, 147, 315 and 319), and several pages are marred by blotches. Moreover, owing to the poor quality of the paper the book is not well suited for use in the laboratory.

To summarize, the first three chapters contain stimulating treatments of structural and energetic aspects of alicyclic compounds. This is followed by a compilation of a wide variety of ring-reducing, ring-enlarging and transannular reactions, illustrated by many examples, which should be a useful source, mainly for the synthetic chemist.

Chirality and Crop Protection

By Gerardo M. Ramos Tombo* and Daniel Belluš*

Dedicated to Professor Kurt Schaffner on the occasion of his 60th birthday

The modern agrochemical industry is searching, more intensively than ever, for new substances to combat pests (weeds, deleterious insects, plant pathogens, etc.). In the complex and costly selection and optimization process, state-of-the-art scientific methods are always needed. The aims of the interdisciplinary optimization are mainly the reduction of the rate of application of the new substance, an increase in the selectivity against the target organism, and the optimal ecological profile. If a promising crop protection compound is a racemate or a diastereoisomeric mixture, the chemist has a unique opportunity to contribute to this optimization process through the synthesis of enantiomerically pure isomers for testing purposes. If the single isomer proves to be biologically superior to the racemate, the development of an economical and ecologically sound process for the production of the single isomer presents an even greater challenge. The average price of a crop protection compound is much lower than that for a pharmaceutical product, and this fact imposes a severe limitation upon the flexibility of the chemist who is concerned with the synthesis and production of a stereochemically pure agrochemical. This forces the crop protection chemist to make full use of both his scientific and creative capabilities. Fortunately, parallel to the development of the above optimization aims of a modern and ecologically sound crop protection research, there has been a continuous and worldwide advance in the area of asymmetric synthesis. Due to the interplay of these two parallel efforts there has been a great accumulation of chemical, biological, and agronomical knowledge in recent years, which should have implications beyond merely the synthesis of enantiomerically pure agrochemicals.

1. Introduction

The pioneering work on the resolution of racemic tartaric acid by *Louis Pasteur* in the middle of the 19th century allowed chemists to realize that optical activity is a result of molecular asymmetry. Since then, the significance of stereoisomerism, not only in relation to physicochemical but also to biological properties, has been gradually recognized by scientists.[1] Chirality is not a requirement for biological activity, but in those cases in which the bioactive molecule contains one or more stereogenic centres, the desired biological property is often strongly related to a given absolute configuration.[2, 3]

Besides this so-called principal activity[4] of stereoisomers, there are often differences in their uptake, transportation, metabolic behavior, elimination, and toxicological properties. Accordingly, the advantages of using stereochemically pure compounds have been recognized for many years, first for pharmaceuticals[2] and later for agrochemicals.[3] However, due to practical limitations, only a few substances, mainly of natural origin, have been developed as single stereoisomers.

For a long time, there were no general methodologies for the synthesis of enantiomerically pure compounds, and the separation of racemates on an industrial scale was, in gener-

al, difficult, inefficient, and expensive. Over the past 15 years, however, significant advances have been made in both these fields.[5] *Seebach*[6] recently stated that almost no aspect of organic synthesis is generating as many publications as the preparation of enantiomerically pure compounds.

The dramatic improvements in synthesis and analysis have provided the scientific basis for a systematic investigation of the implications of stereoisomerism as one of the many determinant factors of biological properties. Not surprisingly, the industries involved in the synthesis, development, and marketing of biologically active compounds are becoming more and more active in this area. Many examples of the successful development of economically feasible industrial syntheses of enantiomerically pure compounds are now known, and catalytic processes are likely to emerge as a major focus for research in this field in the near future.[8]

In modern agrochemical R & D all four principal methods of introducing chirality (Fig. 1) are now used for obtaining small samples of pure stereoisomers for testing purposes, as well as for commercial-scale syntheses. In many cases the development and use of enantiomerically pure compounds can bring great economic and environmental advantage over the use of a racemate or a diastereoisomeric mixture: for example, lower application rates, and fewer or no side effects or phytotoxicity; the possibility of precise mode of action studies; reduced capital requirements for production, transportation, storage. In addition, this represents an exciting and motivating research field!

It is difficult to obtain precise data on the number of chiral synthetic agrochemicals which are at present used in enantiomerically pure form, but from various sources it can be estimated that approximately 10% for the presently marketed agrochemicals,[3, 9] and 20–30% of the compounds in the development pipelines of leading agrochemical companies[10] contain one or more stereogenic centres. Although the majority of these products will presumably be marketed as a single isomer, examples in this paper will show convincingly that the real situation in crop protection is far from black-and-white ("good enantiomer, bad racemate"). Six principal possibilities are frequently met in agrochemical research and development:

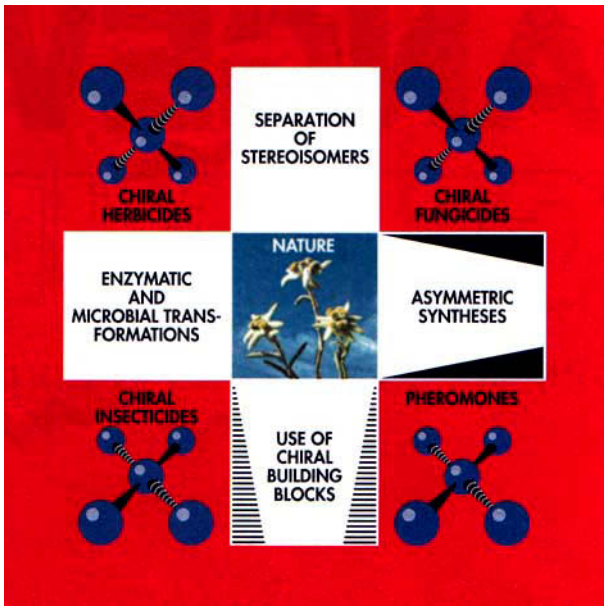

Fig. 1. A chiral Swiss tetrahedron containing Nature in the center as the sole source of chirality for four principal approaches (inside the cross) to enantiomerically pure compounds of importance for crop protection (outside the cross). For 700 years now (1291–1991), the absolute configuration of the Swiss cross is determined regularly by voting, either by a show of hands or by ballot; it is clearly the *R* one (*right*: dextrorotatory) [7]. The centerpiece as well as the overall design is a tribute to the origins of *Kurt Schaffner*.

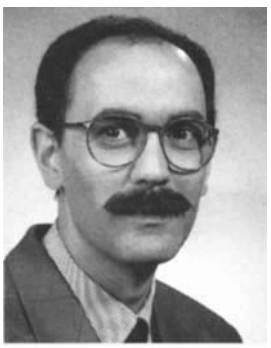


Gerardo M. Ramos Tombo was born in 1952 in Rosario, Uruguay. He studied chemistry in Montevideo (B. Sc., 1976) and at the ETH, Zürich (Diploma, 1979), where he completed his dissertation entitled "Intramolecular additions to isolated C–C double bonds in sterically compressed olefin-alcohols and amines" in 1983 under the guidance of Professors O. Jeger and C. Ganter. This work was honoured with the Silver Medal of the ETH. In 1983 he joined the Central Research Laboratories of Ciba-Geigy Ltd. in Basel and in 1987 he transferred to the Agrochemical Division where he leads the Basic Synthesis Research section. His research interests lie in the conception and development of industrially useful synthetic methods and asymmetric syntheses.

Daniel Belluš was born in 1938 in Trnava, Czechoslovakia and studied chemistry at the Slovak Technical University in Bratislava. He obtained his Dipl. Ing. in 1960 and completed his Ph. D. in 1967 in the area of the photochemistry of polymers. In the same year, he went as a postdoctoral fellow to the ETH Zürich to work with O. Jeger and K. Schaffner. Since 1969 he has been with Ciba-Geigy Ltd. in Basel, 1985–1991 as head of Plant Protection R & D and currently as head of the Corporate Research Units. From 1980 he has lectured at the University of Freiburg (Switzerland). His research interests lie in the reactions of small rings, photochemistry, cycloadditions and rearrangements (reactions without reagents), heterocyclic and metal-catalyzed reactions, and crop protection chemicals (1985–1991). Amongst his honours he prizes the Scientific Award of the City of Basel (1982) and an honorary doctorate (Dr. sc. techn. h.c.) from his Alma Mater (1991) the highest.

1. The stereoisomers have complementary biological acitvity (a common case within the triazole fungicides, e.g. propiconazole **25** and **34**–**37**).
2. All stereoisomers possess nearly identical qualitative and quantitative biological activity (i.e., the fragment containing the chiral center does not interact with the receptor, e.g. **62**).
3. The stereoisomers have qualitatively similar but quantitatively different potencies (a common case, e.g., within pyrethroids containing two or three chiral centers, Section 4.5).
4. Several stereoisomers are equally active (e.g., O.D.P. **125**).
5. The stereoisomers have qualitatively different biological activities (e.g. (*R*)- and (*S*)-**22**).
6. All the biological activity resides in one stereoisomer (e.g., **63**, (*R*)-**78**).

However, in the modern agrochemical industry it is no longer enough to pursue biological activity only. In order to make the very costly decision whether or not to develop a single stereoisomer, it is necessary to adopt a multidisciplinary approach by investigating the translocation, mode of action, nontarget toxicity, crop safety, and environmental behavior of each specific substance. If, for insurmountable economic reasons, a racemate or a mixture of diastereoisomers is chosen for further development, they must exhibit a clean toxicological and environmental record and offer solutions to specific agronomical problems which are clearly superior to the existing ones.[10]

The complexity of the synthetic route to a given stereoisomer and its amenability to scale-up will also play a central role in this decision-making process. Our purpose is to illustrate, for the chemistry of crop protection, the activities in this very dynamic field by means of examples critically selected from recent publications and patents. Apart from a few important examples from the older literature, only structures, syntheses, and activities of chiral herbicides, fungicides, and insecticides which have been published in the last four to five years will be considered. Rich sources of very recent results were the Brighton Crop Protection Conference 1990[11] and the 7th IUPAC International Conference of Pesticide Chemistry, Hamburg, 1990.[12] We have tried to include only compounds with rigorously proven biological activities. The enormous number of chiral natural products with potential usefulness for crop protection are not described,[13] as such a task would exceed the scope of this review.

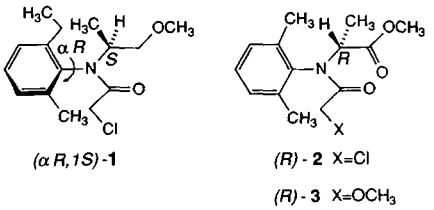
2. Disease Control

The implications of stereoisomerism for the biological activity of fungicides[14] are difficult to characterize, since the system involved is a complex one. Receptors and metabolic pathways must be considered in both the pathogen and the host plant.

2.1. Acylalanines and Related Acylanilides

The origin of the acylanilide fungicides is closely linked with research in the herbicide field of the chloroacetanilides such as metolachlor **1**, the most active stereoisomer of which has the (αR, 1 *S*) absolute configuration (Scheme 1).[15]

Replacement of the alkoxyalkyl substituent in **1** by an ester group led to the prototype racemic compound (**2**) with the code number CGA 29212, which exhibited curative and systemic activity against *Phytophtora infestans*.[16] Resolution



Scheme 1. The most active stereoisomers of the herbicide metolachlor ((α*R*, 1*S*)-**1**) and the structurally related fungicides CGA 29212 ((*R*)-**2**) and metalaxyl ((*R*)-**3**).

and biological testing of the single isomers showed that (*R*)-**2** was an excellent fungicide with low herbicidal activity, whilst its enantiomer (*S*)-**2** exhibited high herbicidal but no fungicidal activity (Fig. 2).[16]

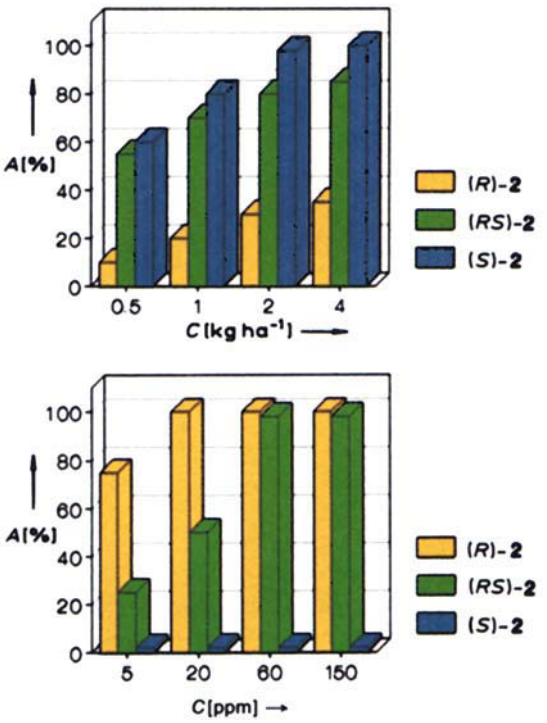


Fig. 2. Biological activity *A* (% relative to untreated control samples) of the stereoisomers of CGA 29212(**2**) [16]. Top: mean herbicidal activity on eight grassy weeds with pre-emergent application. *C* = herbicide concentration. Bottom: fungicidal activity against grape downy mildew. *C* = concentration of the fungicide in the spray solution.

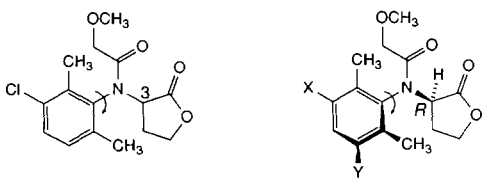
First attempts at a technically feasible large-scale separation of the racemate CGA 29212 (**2**) or an enantioselective synthesis of (*R*)-**2** were unsuccessful. Further work in this direction was discontinued once the biologically more powerful analogue metalaxyl (*rac*-**3**) was discovered, as a result of an intensive optimization program.[17]

In this case the enantiomerically pure stereoisomers of **3** were obtained by the resolution of a racemic precursor through diastereoisomeric salt crystallization.[17] In vitro biological testing against *Phytophthora infestans* and *Phytium ultimum* showed that (*R*)-**3** was approximately 1000 times more active than (*S*)-**3**. However, in vivo trials revealed smaller differences in activity: (*R*)-**3** was 3–10 times more active than (*S*)-**3**, depending on the pathogens tested.[16, 18] Unlike **2**, metalaxyl (*rac*-**3**) shows no phytotoxic effects, and therefore a separation of the single enantiomers was not necessary.

As indicated by a range of biological studies,[14] it seems that a dual mode of action is associated with the acylanilide fungicides. The effects on fungal growth appear to be dependent on the stereochemistry of the agent; however, the effects on the plasma membrane and germination are independent of stereochemical homogeneity.[16] Furthermore, a comparative study of the biochemical and physiological effects of the stereoisomers of **3** indicated that (*R*)- and (*S*)-**3** have the same mode of action but show considerable differences in their effectiveness in reaching, or binding to, the receptor.[19]

Clozylacon (**4**)[20] is a new experimental acylanilide fungicide especially suited for soil application against *Oomycetes*,[21] where protection from these pathogens is required for relatively long periods.

Because of the stereogenic centre at C3 and the atropisomerism due to hindered rotation around the aryl carbon–nitrogen bond (marked with an arrow in Scheme 2), **4** consists of four stereoisomers. These stereoisomers have been separated by several methods.[22]



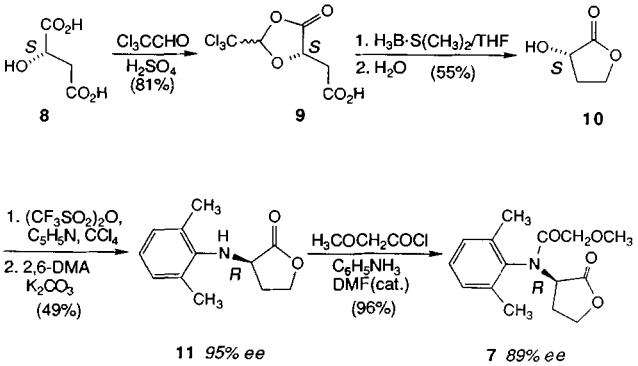
Scheme 2. Stereoisomerism in the experimental fungicide clozylacon (**4**) and its precursor **7**.

The diastereoisomeric pairs of enantiomers **5**, *ent*-**5** and **6**, *ent*-**6** were separated either by crystallization or chromatography on silica gel, and the resulting racemates were subsequently separated on an MPLC column packed with triacetyl cellulose. A more efficient, one-step analytical separation was possible on an HPLC column packed with tris(3-methylbenzoyl) cellulose.[22]

Biological tests showed that the desired fungicidal activity arises mainly from **5**, the isomer with the absolute configuration α *S*, 3 *R*.[22] Work towards an economically feasible process for the stereoselective synthesis of **5** focused on developing enantioselective access to precursor **7**. It was known that **7** is easily chlorinated to afford a diastereoisomeric mixture of **5** and **6**, which can be separated by crystallization. Furthermore, a method had been established to epimerize compound **6** to a mixture of **5** and **6**, thus allowing a recycling of the undesired isomer.[22]

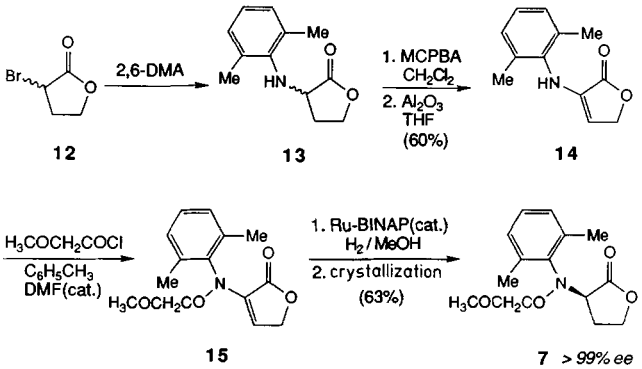
Two conceptionally different synthetic routes to the target molecule **7** were developed:[23]

a) using (*S*)-malic acid (**8**) from the "chiral pool", which provides both the required absolute configuration and the correct number of C atoms for the lactone ring of **7** via the hydroxylactone (*S*)-**10** (Scheme 3).



Scheme 3. Synthesis of **7** starting from (*S*)-malic acid (**8**). 2,6-DMA = 2,6-dimethylaniline, DMF = dimethylformamide.

b) in an enantioselective modification of the existing pilot plant synthesis of **4**,[22] introducing the chiral information in a key Rh- or Ru-catalyzed asymmetric hydrogenation of the prochiral enamide intermediate **15** (Scheme 4).[15]



Scheme 4. Syntheses of **7** by catalytic homogeneous hydrogenation of **15**. MCPBA = *meta*-chloroperbenzoic acid.

The key intermediate in route a) is the (*S*)-3-hydroxybutyrolactone **10**, which has the opposite absolute configuration to the target molecule **7**. A nucleophilic subsitution at the activated 3-position, with inversion of the configuration, provides the correct stereochemistry. The final acylation step (→**7**) was accompanied by some racemization. One single recrystallization from a 1:1 mixture of hexane and ethyl methyl ketone (MEK) provided optically pure **7**.

Route b) presents, as a key step, the enantioselective hydrogenation of the enamide **15**. This type of *N*-acyl substituted enamide has never been hydrogenated before. Therefore, several chiral Rh- and Ru-catalysts were tested and an extensive screening of experimental conditions carried out. The best results were obtained with the [Ru(OAc)$_2$(*S*)-BINAP]

catalyst (BINAP = 2,2'-bis(diphenylphosphino)-1,1'-binaphthyl; 95% yield, 66% *ee*). As before, optically pure **7** was obtained by a single recrystallization of the crude hydrogenation product. Since no deactivation, even at a substrate/catalyst ratio of 4000:1, was observed for this system, it was well-suited for industrial production. This fact made [$Ru(OAc)_2$–(*S*)-BINAP] the catalyst of choice for this synthesis.

2.2. Triazole Fungicides

The triazole fungicides are the most important group amongst the ergosterol biosynthesis inhibitors (EBI).[14] The primary mode of action of the 1,2,4-triazole fungicides is the inhibition of the cytochrome P-450 dependent C14-demethylation of lanosterol (**16**, Fig. 3) or 24-methylene-24,25-dihydrolanosterol, which are intermediates in fungal sterol biosynthesis.[24] Besides their fungicidal activity, some of these compounds also show plant growth regulating activity. This can often be explained by the inhibition of the cytochrome P-450 dependent oxidation of the methyl group at C4 of *ent*-kaurene (**17**, Fig. 3), an intermediate in the biosynthesis of gibberellin, and was used for the development of several triazole-containing plant growth regulators.[24]

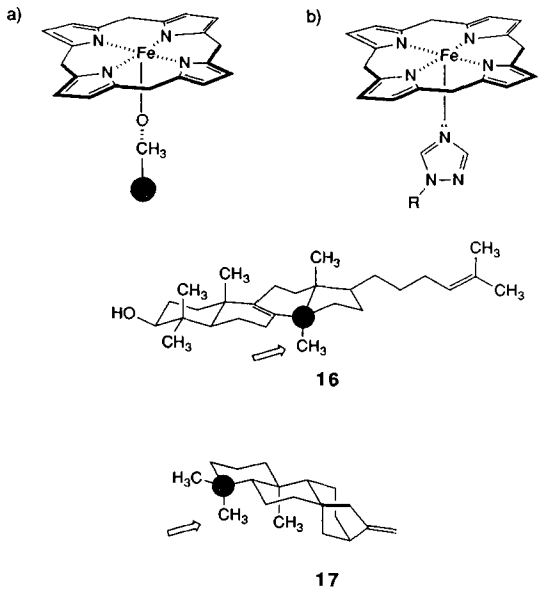


Fig. 3. Hypothetical inhibition model for the system trizaole–cytochrome P-450 [24]: a) normal oxidative process for the C14-demethylation of lanosterol (**16**) (EBI) or C4-oxidation of *ent*-kaurene (**17**) (PGR); b) strong binding of a 1,2,4-triazole moiety, inhibiting oxidation.

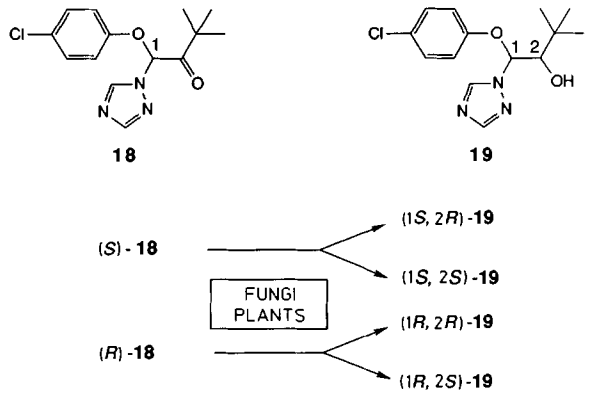
Among the 1,2,4-triazole fungicides most extensively investigated with respect to implications of stereoisomerism in their biological activity are triadimefon (**18**) and triadimenol (**19**).

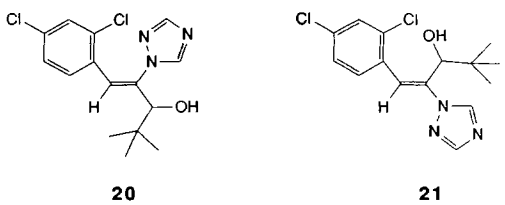
Triadimefon (**18**) is a very weak fungicide for which no significant activity differences have been found between the enantiomers (*S*)- and (*R*)-**18**.[25] The carbonyl group in **18** is reduced to afford **19**, in fungi as well as in plants. This reduction is accompanied by a considerable increase in the fungicidal potency—triadimenol **19** is the active principle.

In contrast to **18**, the fungicidal activity of the resulting triadimenol (**19**) can clearly be attributed to the (1*S*, 2*R*)-**19** isomer. The stereochemical outcome of the reduction, **18** → **19**, and therefore also the resulting biological activity, are highly dependent on the fungal organism involved. The experimental work regarding the relationship between fungitoxicity and the nature and rate of the stereoselective metabolic transformation of **18** into **19** has been recently reviewed.[14, 24]



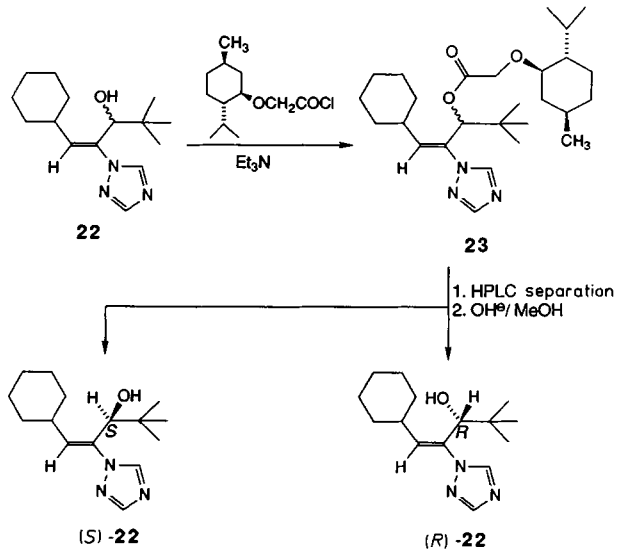
Scheme 5. The isomers of triadimefon (**18**) and triadimenol (**19**).

The 1-vinyltriazoles are a group of compounds which has also been developed as fungicides or plant growth regulation agents. The influence of stereoisomerism on both activities has been thoroughly investigated for the compounds **20** and **21**.[26] The biological activity is concentrated in the *E* isomer (**21**). For the racemate **21** (diniconazole), the fungicidal activity is restricted to the *R* isomer, whilst the *S* isomer is a plant growth regulator, which acts by inhibiting gibberellin biosynthesis.

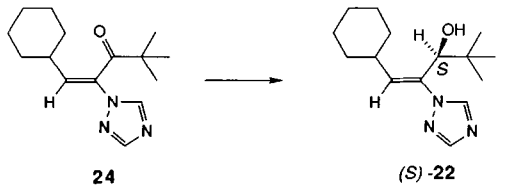


Scheme 6. Isomeric 1-vinyltriazoles: the biological activity is concentrated in the *E* isomer **21** (diniconazole).

Very recently, the synthesis and biological properties of the isomers of a related vinyltriazole, triapentenol (**22**) have been reported (Scheme 7).[27] Small quantities of both enantiomers (*S*)- and (*R*)-**22** were obtained by the chromatographic separation of the diastereoisomeric ester mixture **23**. The synthesis of (*S*)- and (*R*)-**22** was based on enantioselective reduction of the corresponding enone **24** by metal hydrides in the presence of chiral amino alcohols (Scheme 8). In the case of **22**, the fungicidal activity was again restricted to the isomer (*R*)-**22**, whereas (*S*)-**22** was responsible for the plant growth regulating effect.[27]

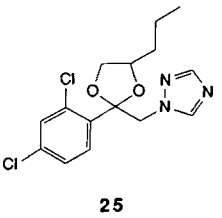


Scheme 7. Small-scale separation of the enantiomers of triapentenol (**22**).



Scheme 8. Enantioselective reduction of **24** to (*S*)-**22** [27]. With $LiAlH_4$/(−)-*N*-methylephedrine the yield is 85% (*ee* > 95%) with $BH_3 \cdot THF$/(*S*)-diphenylprolinol 87% (*ee* = 83%).

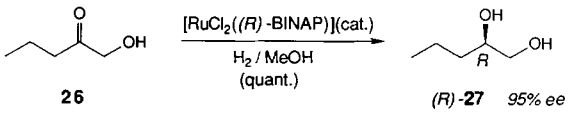
Very remarkable differences in the in vitro activity against *Ustilago madis* were recently reported for the stereoisomers of the dioxolano-1,2,4-triazole fungicide propiconazole (**25**).[28] The isomers with the 2*S* absolute configuration were shown to be more efficient inhibitors of ergosterol biosynthesis.



Scheme 9. The broad-spectrum fungicide propiconazole (**25**). See also Scheme 12.

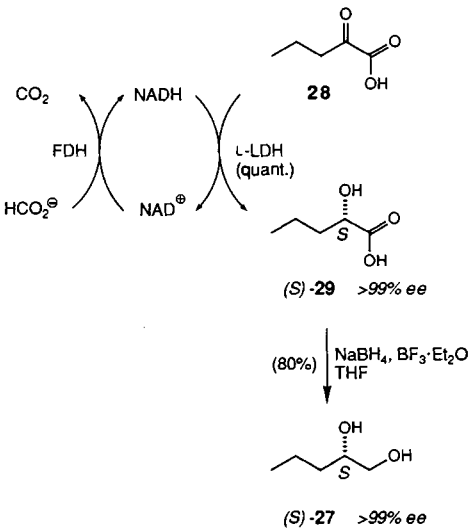
Since the described synthesis of all stereoisomers of **25** included an inefficient preparation of enantiomerically pure (*R*)- and (*S*)-1,2-pentanediol (**27**) starting from the corresponding 2-aminovaleric acid, and a subsequent chromatographic separation of the diastereoisomeric products,[28] a synthesis more amenable to scale-up was needed. A novel stereoselective synthesis of all four stereoisomers **34**–**37** of propiconazole (**25**) was therefore developed.[29] A key step in this process is the catalytic enantioselective preparation of pentanediol ((*R*)-**27** and (*S*)-**27**) from a common achiral precursor. Two different approaches were investigated, both of them returning encouraging results:

a) the hydrogenation of 1-hydroxypentan-2-one (**26**) catalyzed by a Ru–BINAP complex (Scheme 10).
b) the enzymatic reduction of 2-oxopentanoic acid (**28**) using L-lactate dehydrogenase (Scheme 11).



Scheme 10. Enantioselective catalytic homogeneous hydrogenation of 1-hydroxypentan-2-one (**26**).

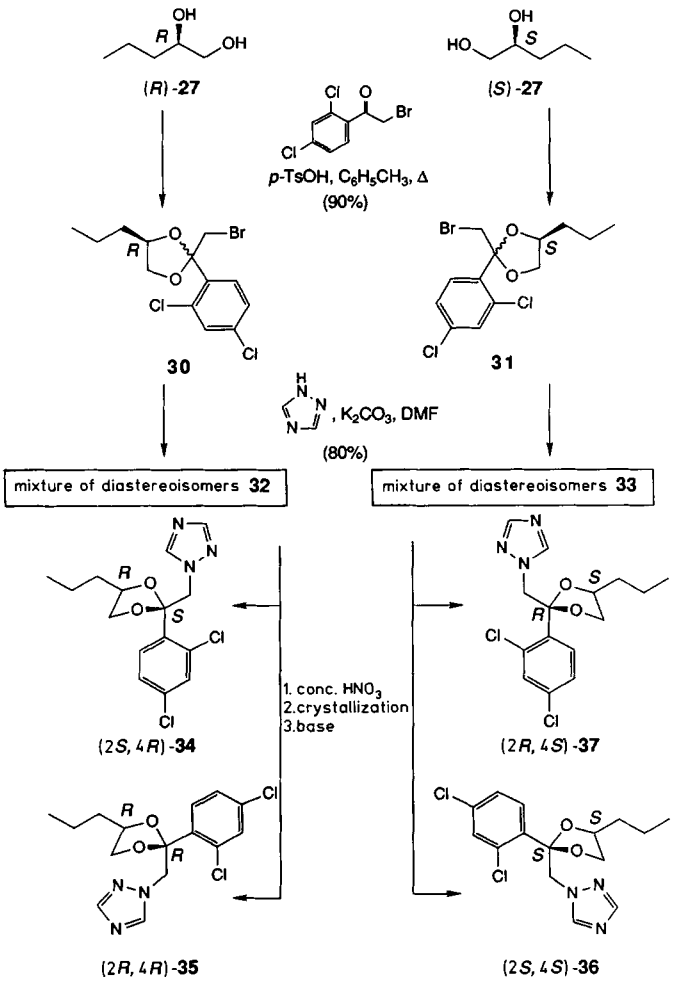
The enantioselective hydrogenation of **26** using a Ru–BINAP[30] complex as a catalyst proceeds with excellent enantioselectivity and efficiency. The high dilution of the catalyst relative to the substrate makes this process very attractive for the large-scale production of (*R*)- or (*S*)-**27**.[31] The use of [$RuCl_2${(*S*)–BINAP}] affords quantitatively (2*S*)-pentanediol ((*S*)-**27**) with 95% *ee*. (*R*)-**27** can be obtained in similar optical and chemical yields by using the Ru complex with the enantiomeric ligand (*R*)-BINAP.



Scheme 11. Enantioselective enzymatic reduction of 2-oxopentanoic acid (**28**). L-LHD = lactate dehydrogenase from bovine heart; FDH = formate dehydrogenase from yeast.

The enantioselective reduction of α-keto acids by means of L-lactate dehydrogenase (L-LDH) is a well-known process.[32] For the synthesis of (*S*)-**29** from **28**, the required NADH cofactor was recycled using formate dehydrogenase (FDH) (Scheme 11). The process was performed either batchwise, or continuously in an enzyme membrane reactor.[33] The enantiomerically pure (*S*)-hydroxy acid **29** was obtained quantitatively and was subsequently reduced, in high yield, to (*S*)-**27** with borane generated in situ. Similarly, by using D-LDH (obtained from yeast) the enantiomeric (*R*)-**27** was produced from the same precursor **27**, again with high optical and chemical yields.

The synthesis of the diastereoisomeric mixtures **32** and **33** was carried out using standard procedures (Scheme 12).[28] The separation of the mixtures of **32** and **33** into the single isomers **34**, **35** and **36**, **37**, respectively, was performed by crystallization of the corresponding nitrates. Field trials of the thus available large quantities of the individual stereoisomers **34**–**37** have shown that the different pathogen species discriminate between each stereoisomer. However, the fungicidal activity as well as the small plant growth regulating effect were not constant across the spectrum of target organisms (Fig. 4). Consequently, the mixture of all four stereoisomers was the prerequisite for the extraordinary commercial success of propiconazole (**25**), which demonstrates strong activity across a broad spectrum of pathogens.



Scheme 12. The stereoisomers (**34**–**37**) of propiconazole (**25**). *p*-TsOH = *p*-toluenesulfonic acid.

Triazole fungicides with novel structures continue to be developed and in some cases the fungicidal activity is clearly connected with a single isomer. For example, the *R* enantiomer of tetraconazole (**41**) has been found to be clearly more fungitoxic than the corresponding *S* enantiomer. Both compounds, (*R*)-**41** and (*S*)-**41**, were prepared with *ee* > 95% by hydrolysis of the racemate **38**, catalyzed by procine pancreas lipase (PPL), or by PPL-catalyzed monoacetylation of the prochiral precursor **42** (Scheme 13).[34]

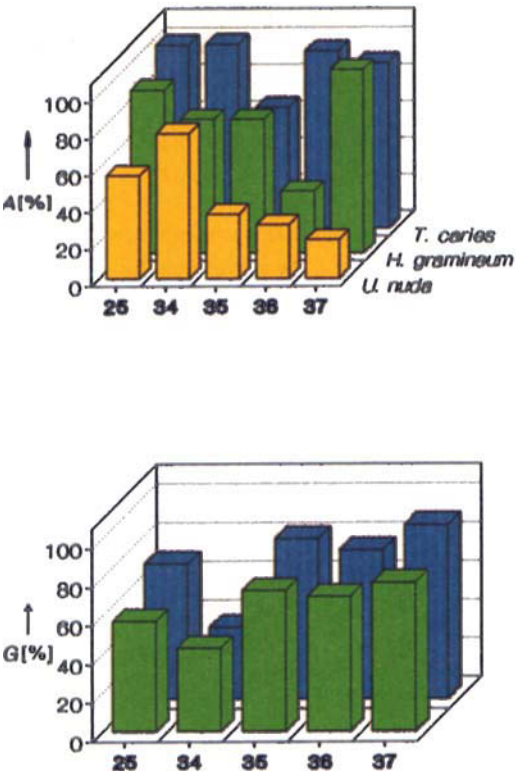


Fig. 4. Biological activity of propiconazole (**25**) and its stereoisomers (**34**–**37**) on seed treatment (rates: 2.5 g a.i. per 100 kg seed). Top: fungicidal activity *A* against *Ustilago nuda, Helminthosporium, and Tilletia caries* as percentage relative to the untreated control sample. Bottom: plant growth regulating effect on barley (green) and wheat (blue) as growth (*G*) relative to the untreated sample [%] at growth stage 11–12.

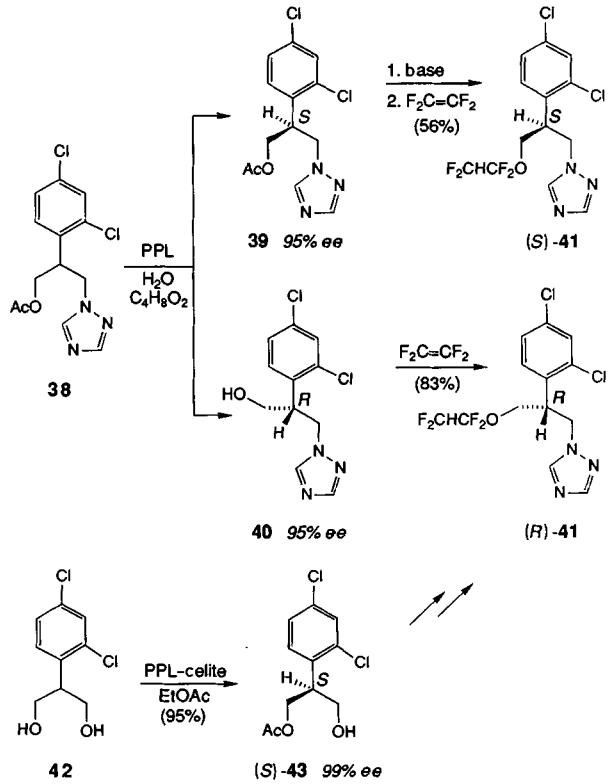
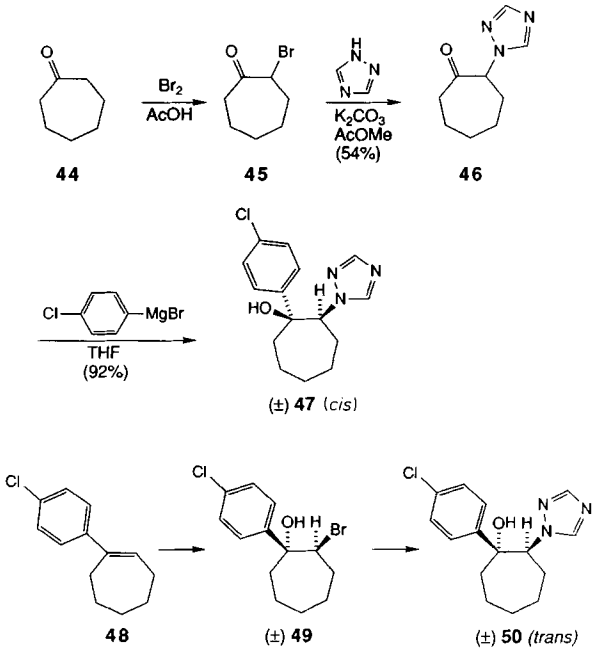


Scheme 13. Chemoenzymatic synthesis of both enantiomers of tetraconazole (**41**).

The new triazole fungicide **47** with the code number SSF-109 contains a cycloheptane ring, which is a unique substructure within the biologically active 1,2,4-triazole fungicides. The *cis* compound **47** exhibited generally stronger in vitro and in vivo fungicidal activity than its *trans* isomer **50**. The latter, on the other hand, showed a much stronger plant growth regulating effect.[35]

This *cis* compound **47** was synthesized by a chelation-controlled addition of the corresponding Grignard compound to the triazolylcycloheptanone **46** (Scheme 14). The *trans* isomer **50** was prepared in poor yield from the bromohydrin **48** via an oxirane intermediate.[36]



Scheme 14. Synthesis of *cis*- and *trans*-triazolylcycloheptanols **47** and **50**.

This *cis*-racemate **47** was resolved by separation of the corresponding diastereoisomeric L-menthoxyacetates using column chromatography. The absolute configuration of the individual enantiomers has not yet been reported. Nevertheless, biological tests revealed that the enantiomer (−)-**47** was 2–4 times more active than the (+)-enantiomer, curiously both as a fungicide and as a plant growth regulator.[35]

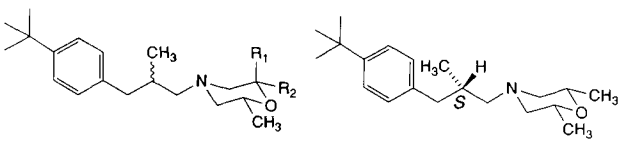
On considering the diversity of structures discussed above, a rather high structural flexibility of the sterol binding site at the cytochrome P-450 oxygenase involved in C14-demethylation is evident. This flexibility in the chemical structure of the inhibitor is generally accompanied by a remarkable stereochemical selectivity. At the moment, conclusions or generalizations on structural or stereochemical requirements for activity must remain tentative, since detailed substrate–receptor studies are lacking.

2.3. Morpholine Derivatives

Whereas triazole fungicides (see Section 2.2) disturb sterol biosynthesis in fungi by inhibition of the C14-demethylation of lanosterol or 24-methylene-24,25-dihydrolanosterol, the morpholine fungicides inhibit sterol biosynthesis at two different sites of the same pathway, namely the Δ^{14}-reductase and the $\Delta^8 \rightarrow \Delta^7$-isomerase enzymes.[37]

Because of their high activity against cereal powdery mildew and rusts, the morpholine fungicides were mainly developed for use in cereals. Due to their different mode of action they also evolved as valuable mixing partners for triazole fungicides. Thus, the morpholine fungicides are able to control strains of cereal powdery mildew which have become less sensitive to triazole fungicides.[38] This mixing of fungicides, each acting by inhibition of different enzymes of the same biochemical pathway, proved to be a very successful antiresistance concept. The most important representative of this class is fenpropimorph (**51**), which was selected from a great number of *p*-alkyl substituted 3-phenyl propylamines for further development as a fungicide for use in cereals.[39]

It was shown earlier that the racemic compound **51**, with a *cis*-2,6-dimethylmorpholine moiety, has a clearly superior fungicidal activity to the corresponding **52**, which contains a *trans*-2,6-dimethylmorpholine substituent.[39] The *cis* and



51 $R_1 = H$, $R_2 = CH_3$ *(S)*-**51**

52 $R_1 = CH_3$, $R_2 = H$

Scheme 15. The stereoisomers of fenpropimorph (**51**).

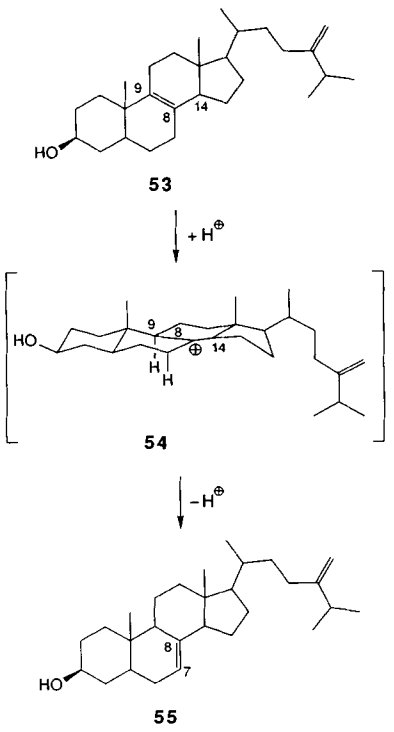
trans isomers **51** and **52** are separable by distillation. Also the transformation of **52** into the thermodynamically more stable **51** could be achieved by using Pd-containing catalysts at high temperatures.[40] Hence, the production of the *cis* stereoisomer **51** of a purity higher than 98% is possible on a large scale.

The *cis* racemate **51** was resolved by crystallization of the diastereoisomeric salts formed with (−)-camphorsulfonic acid.[41] The absolute configuration of the single isomers was determined by X-ray structural analysis.[39]

Extensive biological testing showed that the *S* enantiomer of **51** is equivalent to racemic **51** in its effect against barley mildew and is superior to racemic **51** against mildew and brown rust of wheat. On the other hand the *R* enantiomer of **51** is comparable to *rac*-**51** in its effect against barley mildew, but clearly inferior against mildew and wheat brown rust.[39,42]

Recently the design of new putative inhibitors of the $\Delta^8 \rightarrow \Delta^7$ sterol isomerase in the fungal ergosterol biosynthesis pathway was reported.[43] As neither the fungal nor the yeast $\Delta^8 \rightarrow \Delta^7$ isomerase have been purified to homogeneity or crystallized, this approach was based upon the assumed mechanism of the enzymic transformation and on the structure of the natural substrate.

The proposed detailed mechanism of the $\Delta^8 \rightarrow \Delta^7$ isomerization is depicted in Scheme 16. The process starts with protonation of **53** from the α face, which generates an unstable carbocation at C8 (**54**). This is followed by removal of the α hydrogen at C7, to produce episterol (**55**).

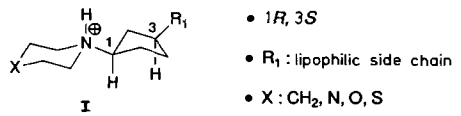


Scheme 16. Conversion of fecosterol (**53**) into episterol (**55**) catalyzed by the enzyme $\Delta^8 \rightarrow \Delta^7$ sterol isomerase.

On this basis, the working hypothesis originally outlined by *Benveniste*[44] included the following points:

a) mimicry of the C8 carbocation by a positively charged nitrogen, despite the resulting different geometries;
b) use of tertiary amines with p*K*a values which allow them to be applied as free bases (advantageous for their permeability through biological membranes) and, on the other hand, to be protonated at the N atom under physiological p*H* to develop the positive charge on the nitrogen atom;
c) simulation of structural elements of the steroid, e.g., rings B and D, including stereochemistry and lipophilicity.

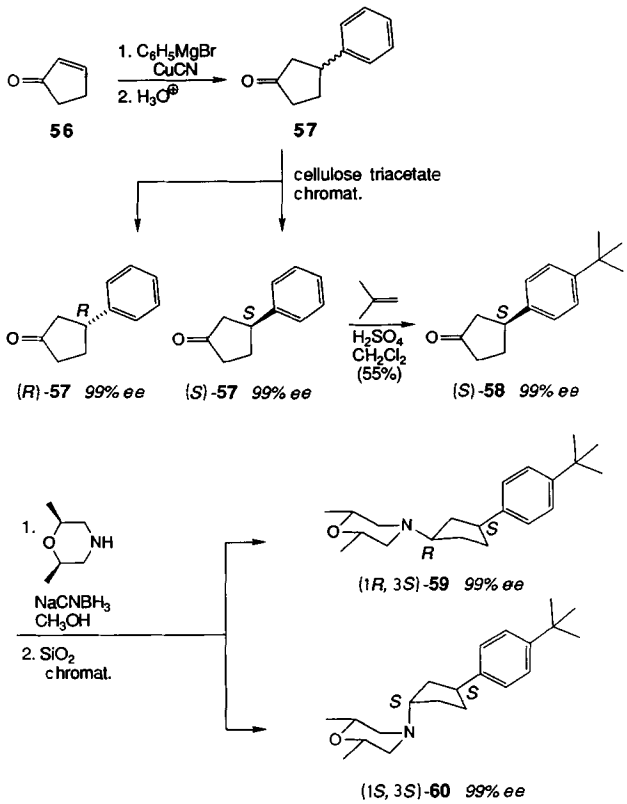
Based on these three principles *Huxley-Tencer* et al.[43a] designed the perceived transition state analogues of the general structure **I** (Scheme 17) and synthesized many compounds. Maximum fungicidal activity was found when the



Scheme 17. General structure of an inhibitor of the enzyme $\Delta^8 \rightarrow \Delta^7$ sterol isomerase.

amine moiety was *cis*-2,6-dimethylmorpholine and the substituent at C3 was a *para-tert*-butylphenyl group. The compounds were first synthesized in a nonstereoselective way, with the aim of obtaining, after separation, all possible stereoisomers (Scheme 18).

The absolute configuration of this series was assigned by comparison of the optical rotations of the enantiomeric ketones (*R*)- and (*S*)-**57** with known values.[45] The latter were obtained by preparative chromatographic (HPLC) on triacetyl cellulose. The introduction of the *tert*-butyl group into the *para* position of the phenyl ring of (*R*)- and (*S*)-**57** was achieved regioselectively and without racemization. Reductive amination of the enantiomerically pure ketones (*R*)- and (*S*)-**58** produced the desired compounds **59** and **60** as a diastereoisomeric mixture, which could be separated by chromatography on silica gel. In each case the relative *cis* or *trans* stereochemistry of the cyclopentane rings was assessed from the ^{1}H NMR data (NOE).[43a]



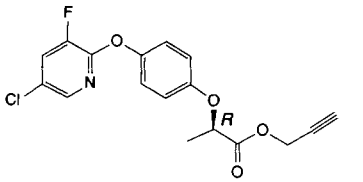
Scheme 18. Stereoselective synthesis of $\Delta^8 \rightarrow \Delta^7$ sterol isomerase inhibitors (1*R*, 3*S*)-**59** and (1*S*, 3*S*)-**60**. The corresponding compounds with the opposite absolute configuration at C3 were obtained analogously from (*R*)-**57**. Chromat. = Chromatography.

In vitro and in vivo tests showed that (1*R*, 3*S*)-**59** was the most potent compound, as expected from the natural absolute configuration of the steroidal ring D. In greenhouse tests against *Erisyphe graminis* on barley, the compound (1*R*, 3*S*)-**59** showed an ED_{50-85} value[46] which was approximately 20 times lower than that of fenpropimorph (**51**). The fungicidal activity in this series (in vitro and in vivo) followed the sequence: (1*R*, 3*S*) > (1*R*, 3*R*) > (1*S*, 3*S*) > (1*S*, 3*R*).[43a]

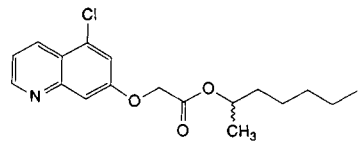
The *R* absolute configuration at C1 of the designed inhibitor, which corresponds to the stereochemistry at C14 of the natural substrate, seems more important for the inhibitory activity of **59** than the absolute configuration at C3. The latter should simulate the rather flexible side chain in **54**.

3. Weed Control

The structural variability of compounds having herbicidal activity is large. For many of the herbicidal compounds which have sterogenic centers the relationship between stereoisomerism and biological activity is generally not well understood. The stereoselectivity of herbicides interfering with auxin activity, for example 2-aryloxypropionic acid derivatives, has been recently reviewed.[47] A very interesting example within this class of compounds was presented by *Amrein* et al. and *Cornes* et al. in 1989.[48] The combination of the compounds **61** and **62**, with the code numbers CGA 184927 and CGA 185072, respectively, in a ratio of 4:1, is a herbicide(**61**)–safener(**62**) mixture for the selective postemergence control of annual grass weeds in wheat, rye, and triticale. The herbicidal activity of **61** is concentrated in its *R* enantiomer, whereas the enantiomers of the safener showed practically no differences in activity.[48] It was shown that the ability of **62** to protect wheat from injury by the herbicide **61**, and to confer partial protection to barley, is related to the ability of the safener to stimulate herbicide metabolism in these crop species.[49]



61



62

Scheme 19. A 4:1 mixture of the herbicide **61** and the safener **62** exhibits excellent postemergence control of annual grass weeds in wheat, rye, and triticale.

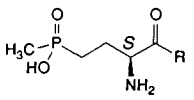
Reseach work on the stereoselectivity of the few older chiral compounds belonging to the important group of the photosynthesis inhibitors (mainly ureas and cyanoacrylate derivates) has been the subject of a recent review.[50]

In the following section we shall concentrate on a few new chiral herbicides with high biological potential and whose enantioselective synthesis was accomplished after a great deal of effort.

3.1. (*S*)-Phosphinotricin

(*S*)-Phosphinotricin (**63**) is a naturally occurring phosphorus-containing amino acid. It was first obtained by hydrolysis of the antibiotic tripeptide bialaphos (**64**).[51]

Racemic phosphinotricin is the active component of the broad-spectrum nonselective herbicide with the common name glufosinate ammonium. Its herbicidal action is apparently due to the inhibition of the ammonia-fixing enzyme



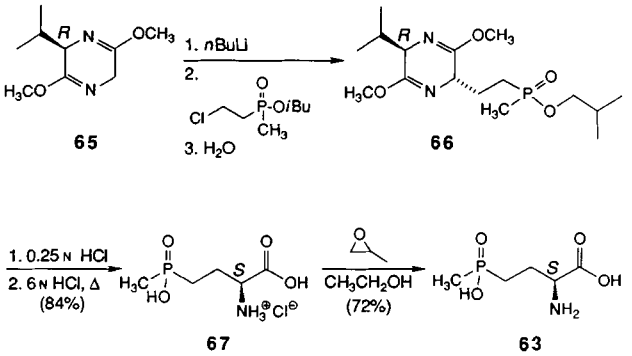
63 R = OH

64 R = Ala-Ala-OH

Scheme 20. (*S*)-Phosphinotricin (**63**), a naturally occurring phosphorus-containing amino acid, was first isolated from the antibiotic tripeptide **64**.

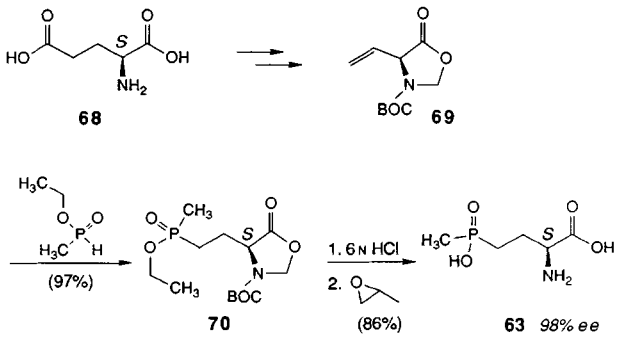
glutamine synthetase.[52] This activity is associated with the isomer (*S*)-**63**.[53]

Besides the synthetic approaches through chiral imine alkylation[54] and enzyme-catalyzed racemate resolution,[55] there are recent reports on the enantioselective syntheses of **63** that use methods with preparative potential. For example, alkylation of the enantiomerically pure Schöllkopf's bislactime ether **65** obtained from (*R*)-valine afforded, after a standard two-step hydrolysis and recovery of (*R*)-methylvalinate, (*S*)-phosphinotricin **63** with 93% *ee* (Scheme 21).[56, 58]



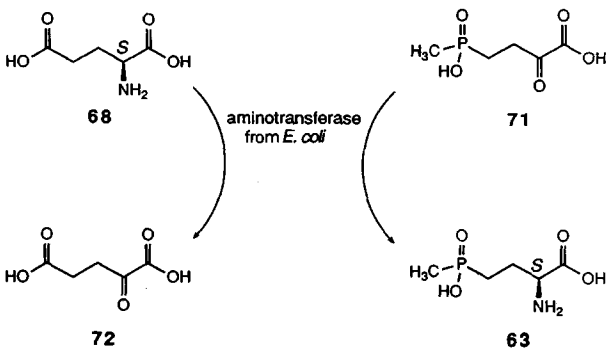
Scheme 21. The bislactime ether route to phosphinotricin (**63**).

Another approach takes advantage of the accessibility of the chiral pool substance (*S*)-glutamic acid (**68**). The conversion of **68** into the protected (*S*)-vinylglycine derivate **69** can be accomplished in three steps according to a known procedure.[59] Regioselective addition of ethyl methyl phosphonite to **69** gives, after deprotection, (*S*)-**63** in high yields with 98% *ee* (Scheme 22).[56]



Scheme 22. A chiral-pool approach to phosphinotricin (**63**). BOC = *tert*-butoxycarbonyl.

Finally, an alternative enzymatic process with better prospects for large-scale production of **63** (Scheme 23) was described recently.[57] An aminotransferase capable of transaminating the α-keto acid **71** to **63** was isolated from *Escherichia coli K-12*. Substrate-specific studies suggest that this enzyme is identical with the 4-aminobutyrate–2-ketoglutarate transaminase (EC 2.6.1.19). The transaminase was immobilized by coupling to an epoxide-activated carrier and was used in a column enzyme reactor for the continuous production of **63**. A fourfold molar excess of glutamate over the

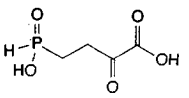


68 **71** **72** **63**

Scheme 23. Enzymatic synthesis of phosphinotricin (**63**).

α-keto acid **71** was used to shift the reaction equilibrium to the desired product **63**. Yields of more than 90% of **51** with production rates of 50 g L^{-1} h^{-1} were then achieved. The unreacted glutamate could be recycled.[57a]

Furthermore, the gene encoding the transaminase was cloned and expressed in *E. coli*. The transaminase expression in transformants of *E. coli* could be increased up to 80-fold compared with that of a wild-type control. The expressed transaminase consituted up to 20% of the total protein of the bacteria. The protein crude extract of the transformants was used, after a heat precipitation step, as described above for the production of **63** in an enzyme reactor.[57b]



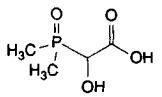
73

Scheme 24. The biosynthetic precursor of phosphinotricin (**63**).

Interestingly, the amino acid forming step in the biosynthesis of bialaphos (**64**) is the transamination of **73** (Scheme 24), which in a later step is methylated at phosphorus.[60]

3.2. 2-Dimethylphosphinoyl-2-hydroxyacetic Acid

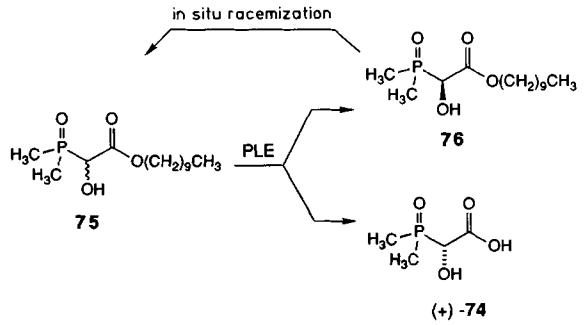
A new, interesting phosphorus-containing experimental nonselective herbicide is racemic 2-dimethylphosphinoyl-2-hydroxyacetic acid (**74**), code number HOE 063 704.[61] The herbicidal activity of **74** comes from the inhibition of acetolactate reductoisomerase, an important enzyme in the biosynthesis of branched-chain acids.[62]



74

Scheme 25. The experimental herbicide HOE 063 704 (**74**).

The racemic ester **75** was enantioselectively hydrolyzed by porcine liver esterase (PLE) to (+)-**74**. The remaining ester **76** racemized spontaneously under the reaction conditions, thus attaining a conversion rate of 95% (→ (+)-**65**).[61] The absolute configurations shown in Scheme 26 are assumed in analogy to (*R*)-acetolactate, but are not yet experimentally determined.



75 **76** (+)-**74**

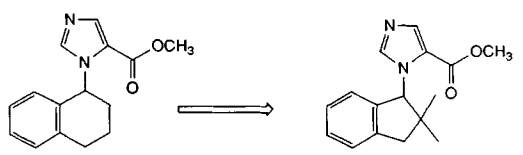
Scheme 26. Enzymatic resolution of **75**. Absolute configurations and *ee*'s have not yet been reported.

The isolated (+)-**74** is the biologically active isomer, as demonstrated by in vivo studies. Also in vitro experiments with isolated acetolactate reductoisomerase from *Daucus carota* and *Escherichia coli*, indicated that (+)-**74** is twice as active as the racemic compound **74**.[61]

3.3. Imidazole-5-carboxylic Esters

In the course of a standard herbicide screening program, unexpected activity was found in compound **77**, which belongs to a group of imidazole-5-carboxylic esters with hypnotic and antimycotic activity.[63]

As a result of the synthetic work to optimize the herbicidal activity of **77**, a sterol biosynthesis inhibitor, the compound **78** (Scheme 27) was found to be the most active substance in

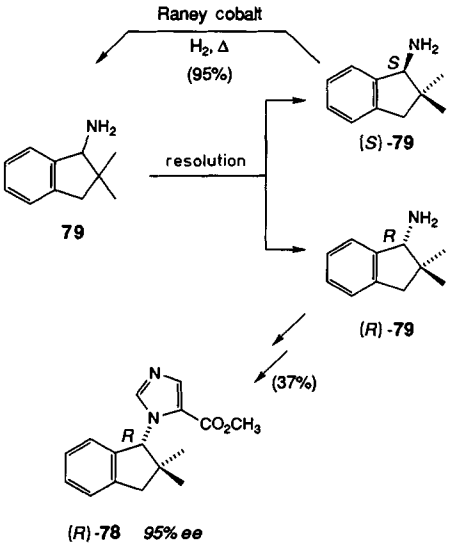


77 **78**

Scheme 27. The herbicide **78**, the result of intensive synthetic work to optimize the herbicidal activity of **77** [62].

this series. In the standard test (against *Digitaria sanguinalis*) **78** was four times more active than **77**.

The stereoisomers of **78** were synthesized in enantiomerically pure form starting from the corresponding amines, (*R*)- or (*S*)-**79**, in a multistep synthesis using either a Thorpe[64] or a Jones[65] cyclization procedure to construct the imidazole moiety. The required enantiomerically pure amines were prepared by resolution of the racemic compound **79** with L-*N*-benzoylglutamic acid.[63] A method of recycling of the undesired isomer in high yields (> 90%) was also developed,[66] based on treatment of the latter with Raney cobalt catalyst at 190 °C without added solvent (Scheme 28). The



Scheme 28. Stereoselective synthesis of (*R*)-**78** via racemate resolution with (*S*)-*N*-benzoylglutamic acid and recycling of the undesired stereoisomer (*S*)-**79**.

compound (*R*)-**78** proved to be twice as active as the racemate **78**. Its enantiomer (*S*)-**78** was completely inactive in the *D. sanguinalis* test. Similar results were obtained with the stereoisomers of **77**, although in this case the *S*-isomer exhibited a measurable activity (Fig. 5).

A herbicidal pharmacophore structure was proposed based on conformational analysis, force field and MO calculations, and CAMM (*C*omputer-*A*ssisted-*M*olecular *M*odeling) superpositioning studies of **77** with sets of analogues of high activities and low or zero activity.[63]

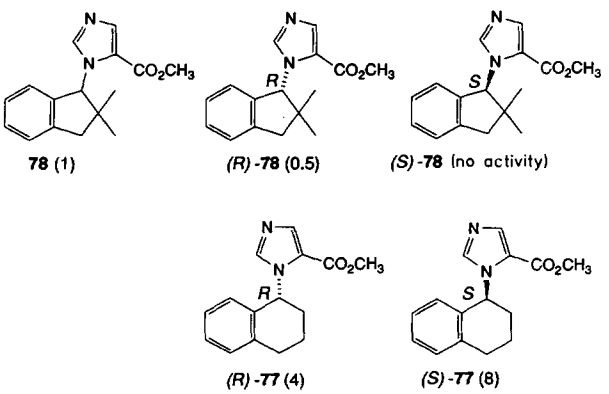


Fig. 5. Activities of some imidazole-5-carboxylic acid derivatives expressed as relative application rates (in parantheses) against *Digitaria sanguinalis*.

Consideration of an optimized orientation of the phenyl ring with respect to the imidazole moiety revealed a lipophilic pocket which seems to be relevant for activity. The methyl ester group points away from the lipohilic groups and the region below the phenyl ring must remain unoccupied (Fig. 6).[63]

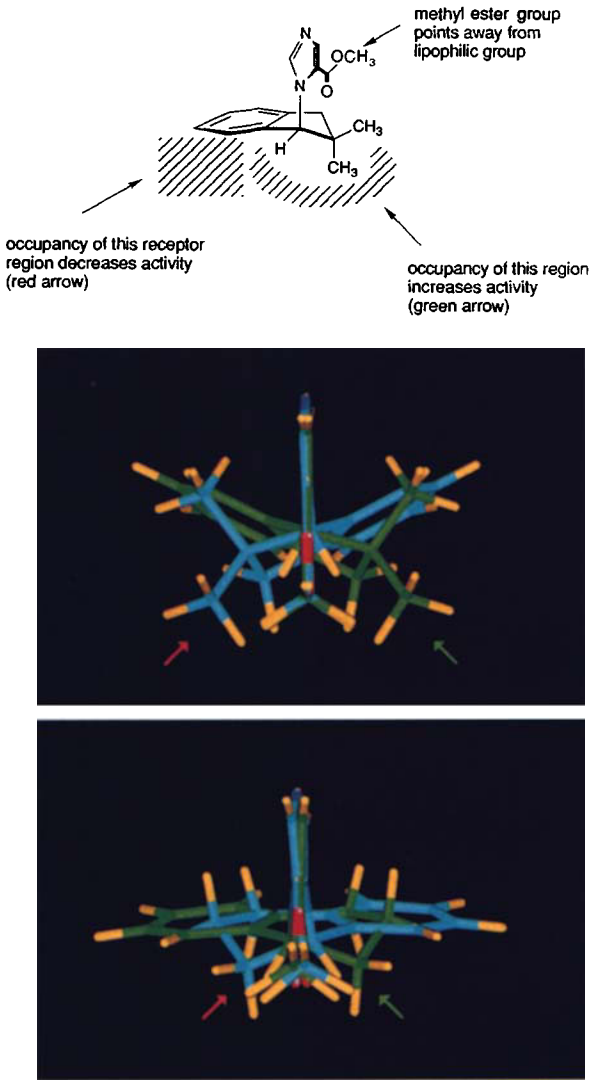

Fig. 6. CAMM studies of **77** and **78**. a) Proposed herbicidal pharmacophore structure, illustrated with the compound (*R*)-**78**. b) Superposition of the imidazole rings of (*R*)-**78** (green) and (*S*)-**78** (blue). c) Superposition of the imidazole rings of (*R*)-**77** (green) and (*S*)-**77** (blue).

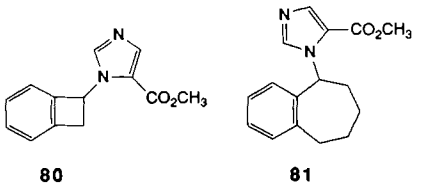
The differences in biological activity observed for the stereoisomers of **77** and **78** fit this model. Superposition of the completely inactive (*S*)-**78** with the active (*R*)-**78** shows that the methyl group *trans* to the imidazole ring occupies the region below the phenyl plane in (*S*)-**78**. On the other hand, although (*R*)-**77** is twice as active as (*S*)-**77**, the latter exhibits some activity. In this case, superpositioning studies show that the less active stereoisomer does not occupy the receptor's forbidden region, but that the lipophilic pocket is less occupied. Superposition studies were also used to predict the inactivity of the racemic compounds **80** and **81**. Neither four- nor seven-membered rings were able to provide the



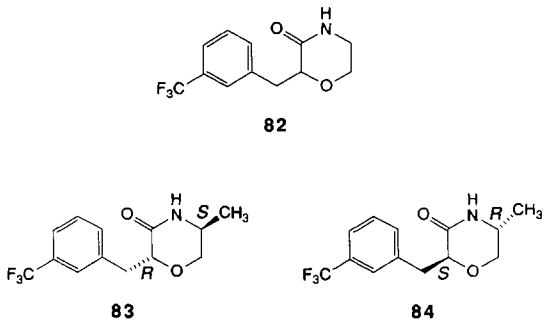
Scheme 29. Imidazole-5-carboxylic acid derivatives which are inactive as herbicides.

correct orientation of the phenyl ring plane relative to the imidazole moiety (Scheme 29).[63]

3.4. Further Structural Types

An interesting example of the optimization of in vitro activity using computer modelling was recently reported by *Mitchell* and *Bartlett*.[67]

The ketomorpholine **82** (Scheme 30) is a newly discovered inhibitor of phytoene desaturase, and shows pre-emergence herbicidal activity. A structural model was constructed by studying the overlap of a number of structurally diverse inhibitors for which structure–activity relationships were available. By comparing **82** with the model, a pseudoaxial orientation of the benzylic substituent at C2 was postulated. The model also predicted that a methyl substituent at C5, *trans* to the benzyl group, should be tolerated. The two *trans* stereoisomers **83** and **84** were prepared selectively, and in an in vitro test the activity was found to reside solely in the (2*R*, 5*S*)-isomer **83** (Scheme 30).[67]

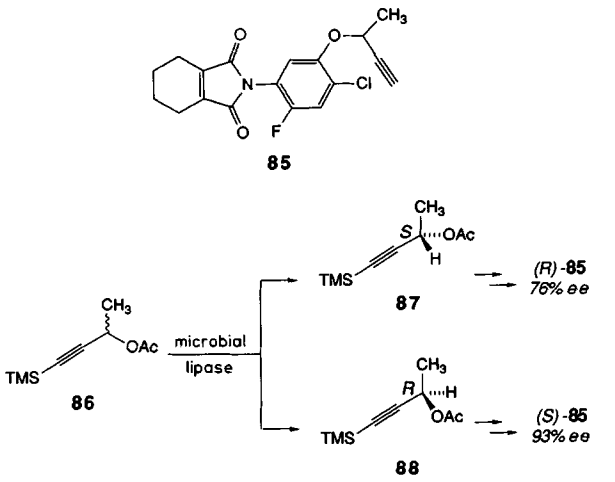


Scheme 30. The herbicidal active ketomorpholine **82** and structural analogues **83** and **84**. Only the stereoisomer **83** shows herbicidal activity.

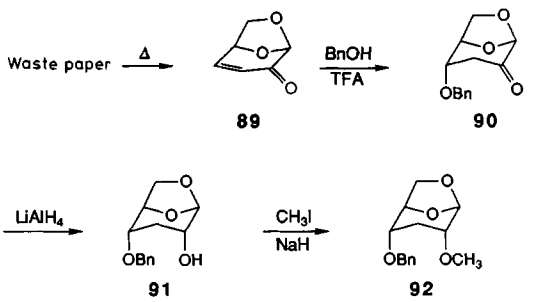
The *N*-phenyltetrahydrophthalimides are a known class of pre- and postemergence herbicides now experiencing a renaissance. Within this class, the compound **85**, (code number S 23121) is a potent postemergence herbicide for cereals.[68] The selectivity of this compound is apparently related to the 1-methyl-2-propynyloxy substituent.

The stereoisomers of **85** have been prepared enantioselectively from the precursors **87** and **88** (Scheme 31).[69] The single isomers (*S*)- and (*R*)-**85** exhibited no selectivity in the inhibition of protoporphyrin IX synthesis.[68]

The bicyclic compounds **92** is a potent herbicide of a new structural class with an as yet undetermined mode of action.[70] It can be ingeniously synthesized in stereoisomerically pure form from waste paper in four steps, starting with a pyrolysis at 350 °C (Scheme 32).[70]

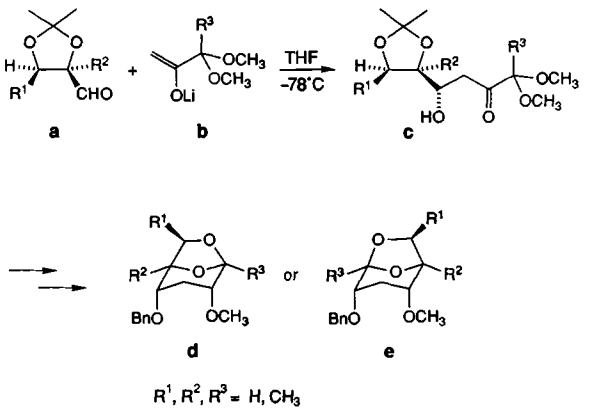


Scheme 31. Chemoenzymatic approach to the stereoisomers of **85**.



Scheme 32. Stereoselective synthesis of the 6,8-dioxabicyclo[3.2.1]octane derivative **92**. The starting material **89** is obtained from cellulose by pyrolysis. Bn = benzyl; TFA = trifluoroacetic acid.

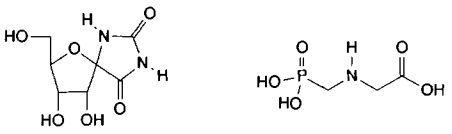
A number of structural analogues, mainly of the types **d** and **e**, and also some with different configurations as C2 and C4, were prepared stereoselectively.[71] The key step was an aldol reaction between a chiral aldehyde of type **a** and an enolate of type **b** (Scheme 33). In spite of considerable synthetic work, compound **92** remained the most potent in this series.



Scheme 33. Aldol approach to polysubstituted 6,8-dioxabicyclo[3.2.1]octane derivatives.

The newly described herbicide hydantocidin (**93**) possesses an unique structural feature, namely a spiro hydantoin ring at C1 of D-ribofuranose.[72]

The compound **93** was isolated from a *Streptomyces hygroscopicus* (SANK 63584) culture. Interesting properties were described for **93**: very low toxicity, systemic mode of action, broad spectrum, and low selectivity. Its weed-control activity is similar to that of glyphosate (**94**).[72, 73]



93 **94**

Scheme 34. Two herbicides with similar weed control activity: hydantocidin (**93**) and glyphosate (**94**).

Hydantocidin (**93**) and all its 15 stereoisomers were synthesized starting from derivatives of tartaric acid. The synthesis of the D series, starting from ethyl D-tartrate is described in Scheme 35.[73]

The L series was synthesized analogously, starting from ethyl L-tartrate.[73] Not only the preparative effort of *S. Sugai* et al., but also the stereoselectivity of the biological activity is impressive: only the N^1-β-D isomer **93**, and to a much lesser extent the N^1-α-D isomer **108**, exhibit herbicidal properties.[73]

4. Insect Control

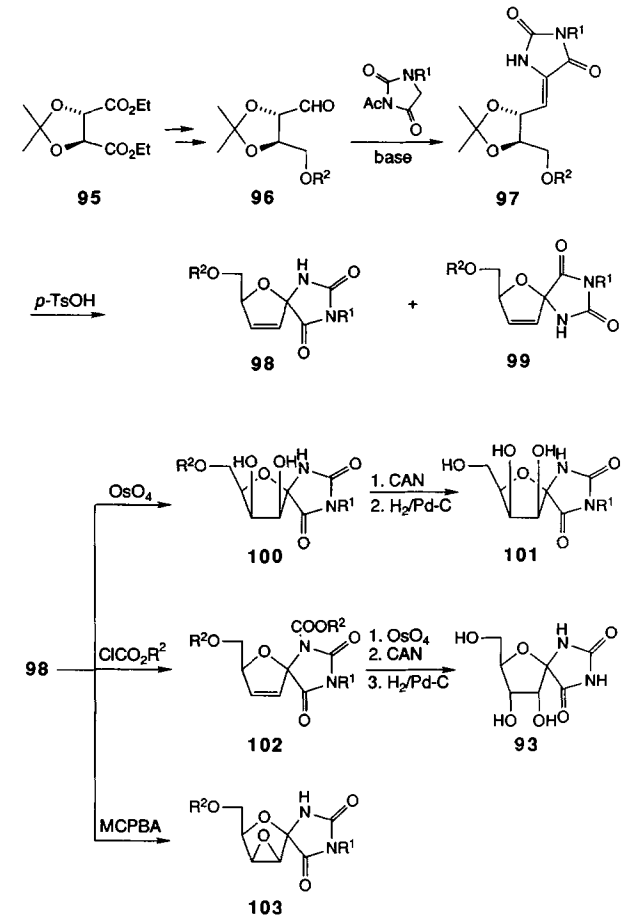
Much work has been done over the past years trying to understand the interrelation of stereochemistry and biological activity of synthetic and natural insect controlling agents. The topic has been recently reviewed for most of the important classes of insecticides.[3]

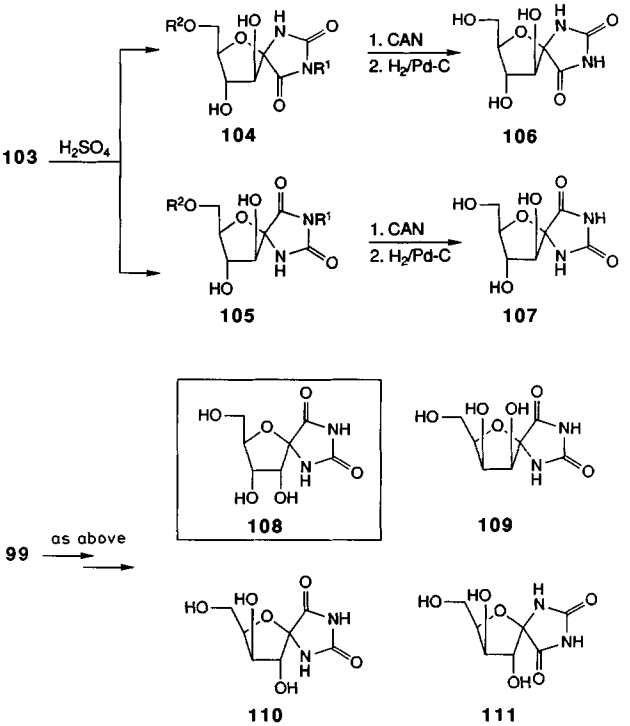
4.1. Organophosphates

The biochemical and toxicological properties of chiral organophosphate enantiomers differ widely.[74] A very recent study from *Hirashima* et al.[75] illustrates the complex interplay of stereochemical, toxicological, and metabolic factors for the insecticide salithion (**112**) and its oxidation product salioxon (**113**) (Scheme 36).

Enantiomerically pure (*S*)- and (*R*)-**112** was obtained via (*S*)-proline methyl ester derivatives; the diastereomers were separated by crystallization and subsequent acid catalyzed methanolysis.[75a] The corresponding salioxon enantiomers (*R*)- and (*S*)-**113** were obtained from the salithion enantiomers by *meta*-chloroperbenzoic acid (MCPBA) oxidation as shown in Scheme 36.[75b]

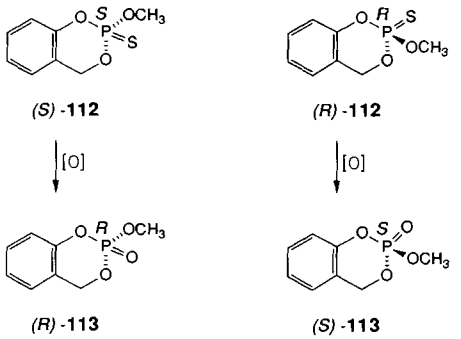
(*S*)-**112** was a more potent insecticide by topical application than (*R*)-**112** on *Musca domestica* female adults correlating with the acetylcholine esterase (AChE) inhibition in vivo. However, against *Tribolium castaneum* the *R* enantiomer of **112** had a stronger larvicidal activity than the *S* enantiomer three days after treatment.





Scheme 35. Stereoselective synthesis of hydantocidin (**93**) and all its 15 stereoisomers. CAN = cerium(IV) ammonium nitrate.

On the other hand, (*R*)-**113** was a stronger house fly AChE inhibitor in vitro than the *S* enantiomer, whereas the latter ((*S*)-**113**) was a more potent *T. castaneum* larval AChE inhibitor than the *R* enantiomer. In all the discussed cases, the oxidized form **113** occurs during metabolism in the insect. The

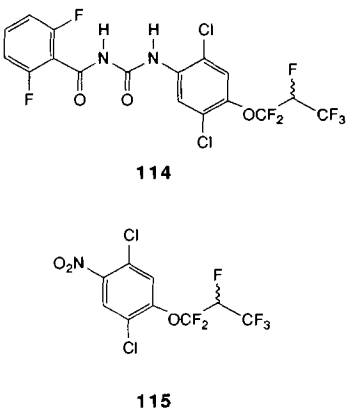


Scheme 36. The stereoisomers of salithion (**112**) and salioxon (**113**).

reversed stereospecificity between *M. domestica* insecticidal and *T. castaneum* larvicidal activity of salithion enantiomers ((*R*)- and (*S*)-**112**) might be a result of a stereospecific difference in the intrinsic potency of salioxon enantiomers ((*S*)- and (*R*)-**113**) as AChE inhibitors of the two species.[75c]

4.2. Benzoylureas

Benzoylureas are insect growth regulators, acting by inhibition of chitin synthesis and so interfering with the formation of the cuticle.[76] An interesting example of a compound of this class possessing stereoisomerism was recently reported by *Drabek* et al. (Scheme 37).[77]



Scheme 37. The benzoylurea insecticide **114**. Its precursor **115** was resolved by chromatography on a tribenzoyl cellulose column.

The compound **114** with the code number CGA 184699 is a benzoylurea with good environmental behavior and interesting activity. Both enantiomers of compound **114** were obtained in pure form from the corresponding intermediates (+)- and (−)-**115**, which were obtained by chromatographic separation of the racemic **115** on a tribenzoyl cellulose column.[77] The absolute configuration could not be determined for this series.

The enantiomers of **114** showed a different insecticidal activity in laboratory trials against *Heliothis virescens L-1*. The (+)-isomer was a factor of 1.7 better than the racemate **114** and 2.2 times better than the (−)-enantiomer. However, the differences in the biological activities of the enantiomers of **114** were practically nonexistent in field trials and did not justify the very expensive and tedious chromatographic separation. As a consequence, compound **114** will be developed as a racemate.

4.3. Pheromones

Pheromones are semiochemicals (*semion* (greek) = a mark or signal) which act between members of the same species. Since the first isolation of a pheromone from the silkworm moth by *Butenand* et al. in 1959,[78] over 100 chiral pheromones have been isolated and identified. Outstanding synthetic work has been performed to obtain enantiomerically pure pheromones, mainly aimed at the determination of the absolute configuration of the natural products. An excellent review of this topic was published recently by *Mori*.[79]

Pheromones are very often blends, the components of which may act synergically and should be present in a definite ratio. This synergism frequently relates double-bond isomers and/or isomerism due to the presence of one or more stereogenic centers in the molecule. The interrelation between stereoisomerism and biological activity can be manifold. In some cases only one isomer is active, in others both, either as synergist, inhibitor, or independently active compounds.[80]

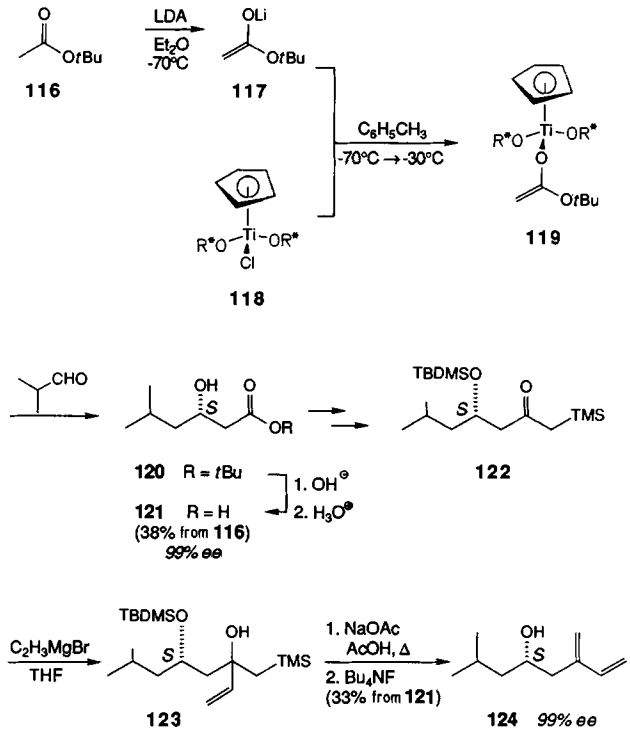
4.3.1. (*S*)-*Ipsenol*

Various species of bark beetles are dangerous pests for coniferous forests throughout the world. Among these are beetles of the genus *Ips* and *Pityokteinus*. (*S*)-ipsenol (**124**) is an aggregation pheromone of several species belonging to these genera.[81] The absolute configuration was established by *Mori* in 1976 by chemical correlation.[82]

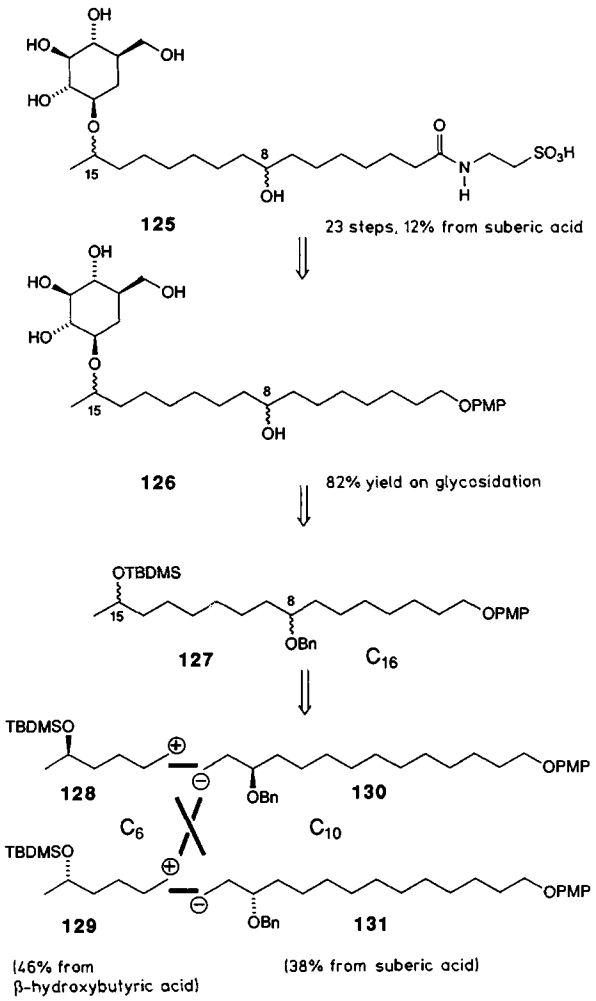
The enantioselective synthesis of large amounts (50 g) of (*S*)-ipsenol (**124**) was recently reported by *Oertle* et al.[83] (Schema 38). The material was used for extended field trials to control the population of *Pityokteinus curvidens*. The key hydroxyacid intermediate **121** was obtained in enantiomerically pure form (*ee* > 99%) by an enantioselective aldol reaction using the chiral titanium complex **118**.[85] The subsequent transformation of the carboxy group of **121** followed, with some modifications on the silicon directed diene synthesis described by *Jenkins* et al.[86] In this way 56 g of enantiomerically pure (*ee* > 99%) (*S*)-ipsenol (**124**) has been prepared in one batch, starting from 160 g of β-hydroxyacid **121**.

4.3.2. *The Oviposition-Deterring Pheromone (ODP) in Rhagoletis cerasi*

The cherry fruit fly (*R. cerasi*) lays one single egg into halfripe cherries. It was demonstrated in field tests that double or



Scheme 38. Enantioselective synthesis of (*S*)-ipsenol (**124**) on a large scale (2 mol). LDA = Lithium diisopropylamide, OR* = 1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranos-3-*O*-yl, TBDMS = *tert*-butyldimethylsilyl.



Scheme 39. Retrosynthetic concept of an enantioselective synthesis of all four stereoisomers C8/C15 of **125**. PMP = *p*-methoxyphenyl.

triple oviposition into the same fruit occurred with a much lower frequency than would be expected if deposition had taken place randomly.[87] Consequently, the hypothesis was put forward that the females mark the fruit.[88] Since fruits infested by maggots are not accepted by the consumer, cherries have to be protected against the oviposition of fruit flies.

Isolation and purification of the active component from the faeces made possible a partial structural analysis of the ODP (**125**).[89] ODP contains two stereogenic centres at C8 and C15 besides the sugar moiety. Since the assignment of the absolute configuration was not possible by spectroscopic means, an enantioselective synthesis of all four stereoisomers at C8/C15 was carried out.[90] The general retrosynthetic concept is illustrated in Scheme 39.

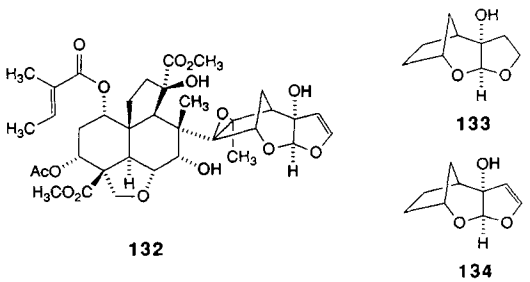
As anticipated, the glycosidation to a β-glycoside derivative proved to be an extremely difficult step. Finally, an excellent and highly stereoselective glycosidation was achieved by using tetra-*O*-pivaloylglucopyranosyl fluoride according to *Kunz* et al.[91] The absolute stereochemistry of the natural ODP was assigned by employing both spectroscopic methods and comparative studies of the biological activity. It was demonstrated that the natural ODP is a diastereomeric mixture, namely, (8 *RS*, 15 *R*)-**125**.[92] Since the stereochemistry at C8 need not be controlled, a much shorter synthesis, suitable for large-scale production of "natural" ODP could be developed.[92]

By spraying (8 *RS*, 15 *R*)-**127** (10 mg L^{-1}) on cherry trees, the infestation rate of cherry fruit fly eggs was reduced (i.e., 1.85–2.5% infestation of treated trees against 21.4–23.35% infestation of untreated trees) in summer field trials in Switzerland in 1989.[92]

4.4. Insect Antifeedants

Insect antifeedants are currently attracting much research interest owing to their effect on a range of major crop pests.[93] An antifeedant is a chemical which inhibits feeding but does not kill the insect directly.[94] The insect often remains near the antifeedant source and possibly dies through starvation. The limited information presently known does not allow generalizations on the mode of action of antifeedants.[95]

Considerable attention has been focused recently on the extremely potent natural antifeedant azadirachtin (**132**, Scheme 40).[96]



Scheme 40. Azadirachtin **132** and two synthetic substructures with similar antifeedant activity against *S. littoralis*.

The high level of interest in **132**, which has been isolated from the neem tree *Azadirachta indica*, stems from its exceptional biological activity. Compound **132** is the most potent antifeedant against *Lepidopterus* species isolated to date. It is 100 per cent lethal at only 10 ppm concentration through a variety of processes including antifeedancy, growth disruption, and moulting inhibition. Despite such high toxicity towards certain insects, azadirachtin is apparently harmless to higher forms of life and exhibits no phytotoxicity.[94b]

Although it is possible to use extracts of neem seeds for crop protection, **132** itself is quite unstable and its low abundance in the plant makes it difficult to obtain pure **132** for agricultural use. Efforts are being made to synthesize **132**;[97] however, any synthesis of such a structurally complex and chemically unstable molecule containing 16 chiral centers is not going to be amenable to commercial development. In an alternative approach, substructures of **132**, for example **133** and **134**, were synthesized and screened for antifeedant activity.[97a] Both of these compounds were found to be active against *Spodoptera littoralis* and **134** was almost as potent as the natural product **132** at 10 ppm concentration.

4.5. Pyrethroids

The insecticidal properties of the pyrethrum powder extract from the flower heads of *Chrysanthemum cinerariefolium* have been well documented for over 100 years. A few years ago about 23000 tons were produced annually.[98a] The flowers, grown in Kenya, contain on average 1.3% of enantiomerically pure esters of (1 *R*)-*trans*-chrysanthemic acid **135**–**137** and (1 *R*)-*trans*-*E*-pyrethric acid **138**–**140** (Table 1).[99]

Table 1. The mixture of natural enantiomerically pure insecticides present in *Chrysanthemum cinerariefolium* flower heads.

No.	structure	name (% in mixture) stereochemistry [98]
135		pyrethrin I (35) 1*R trans*; α*S*
136		cinerin I (10) 1*R trans*; α*S*
137		jasmolin I (5) 1*R trans*; α*S*
138		pyrethrin II (32) 1*R trans*, *E*; α*S*
139		cinerin II (14) 1*R trans*, *E*; α*S*
140		jasmolin II (4) 1*R trans*; *E*; α*S*

The mixture of compounds shown in Table 1 is responsible for their remarkable and rapid action on a wide range of insects. Pyrethrin I (**135**) is especially effective for kill and pyrethrin II (**138**) for the rapid knockdown of flying insects.

Early attempts at synthesizing compounds similar to the natural pyrethrins produced a range of products which, although having an inherent problem of instability to light, did find significant success as insecticides in the household sector. Whereas **141**–**143** (Table 2) are esters of chrysanthemic acid and have the natural (1 *R*)-*trans* configuration (which is conferred on its precursor by the chiral enzymatic microenvironment in the flower heads, Fig. 7), the majority of commercial household chrysanthemates are racemic and take advantage of the elegant and simple access to the racemic chrysanthemic esters (Scheme 41).

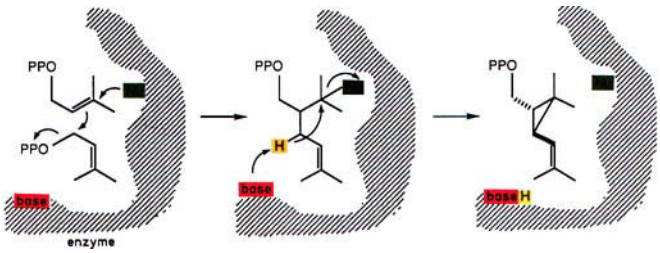


Fig. 7. 1,3-Cycloelimination in nature: suggested enantioselective pathway for (1 *R*)-*trans*-chrysanthemol pyrophosphate formation from isopentenol pyrophosphate in the flower heads of *Chrysanthemum cin.*, according to *Naumann* [98b] and *Crombie* [100].

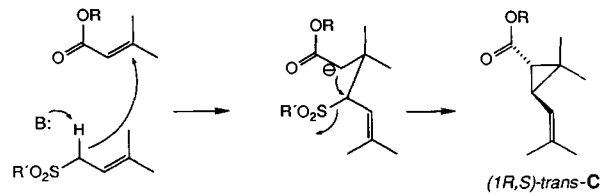

Scheme 41. 1,3-Cycloelimination in the chemical industry: Synthesis of racemic *trans*-chrysanthemic ester **C** according to *Martell* [101], ingeniously utilising the simplest starting materials, and the arylsulfonyl group as both an activating and a leaving group.

However, the pyrethroids started to gain commercial importance as agricultural insecticides only when at the beginning of the 1970's *Elliot*[102] combined phenoxybenzyl alcohols with photostable derivatives of chrysanthemic acid, containing dihalovinyl moieties instead of the dimethylvinyl substituent on C3, thus creating the very potent insecticides permethrin **155** (4 stereoisomers), cypermethrin **156** (8 stereo-

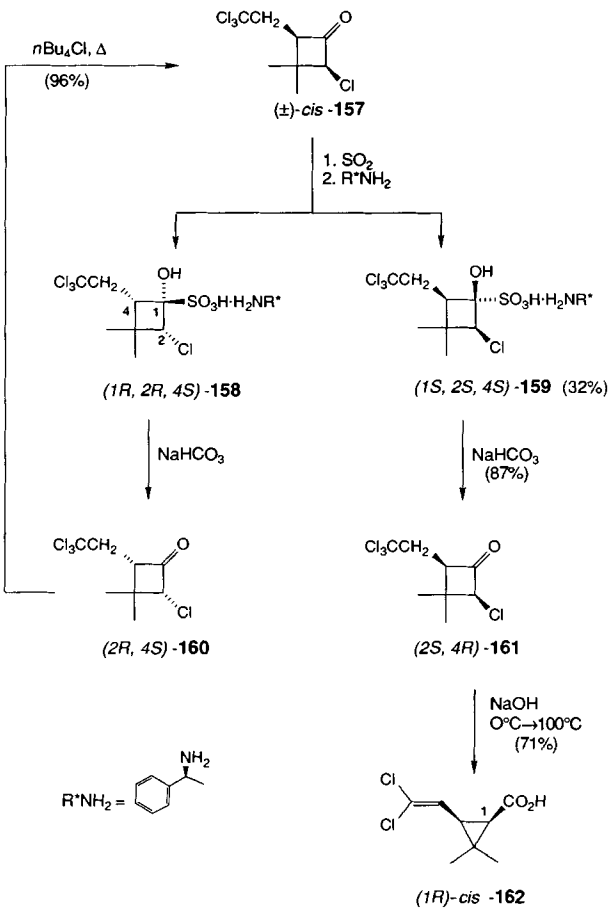
isomers) and especially the enantiomerically pure ester deltamethrin **146** (Table 2). *Elliot's* discovery triggered an enormous synthetic activity all over the world, aiming in the 1970's mainly at the search for new, improved derivatives and analogues of the archetypal esters **135** and **155**, as well as on the circumvention of existing patents. The emphasis in the 1980's shifted to the cost-effective and enantioselective synthesis of selected leading compounds, as well as to the fine-tuning of their biological and ecotoxicological properties, for example, to decrease their toxicity to fish.

An excellent overview of the wealth of splendid pyrethroid chemistry, performed mostly by industrial chemists, was published in 1990 by *Naumann*.[98] He critically evaluated about 2600 references from the scientific patent literature published until 1987. Therefore we selected only a few recent examples with an emphasis on enantioselective synthesis.

Complete transformation of racemic constituents into a single enantiomer or diastereoisomer without loss of any material, requires refinement of many resolution methods and their adaptation to industrial scale. The underlying principle of all industrially successful separations of stereoisomers is the removal of the target product (or its diastereomeric salt or chiral precursor) in crystalline state from the reaction mixture, on the basis of its relative insolubility. This is accompanied by a continuous epimerization of the undesired stereoisomer in the solution, utilizing the mobility of an activated hydrogen. A striking example of the application of this methodology is the preparation of deltamethrin **146**: the most active, enantiomerically pure (1 *R*)-*cis*-α*S* isomer is now produced at a rate of 200 t per annum from the eight possible isomers, despite of the involvement of two racemates (racemic *trans*-chrysanthemic acid and racemic cyanhydrine).[109]

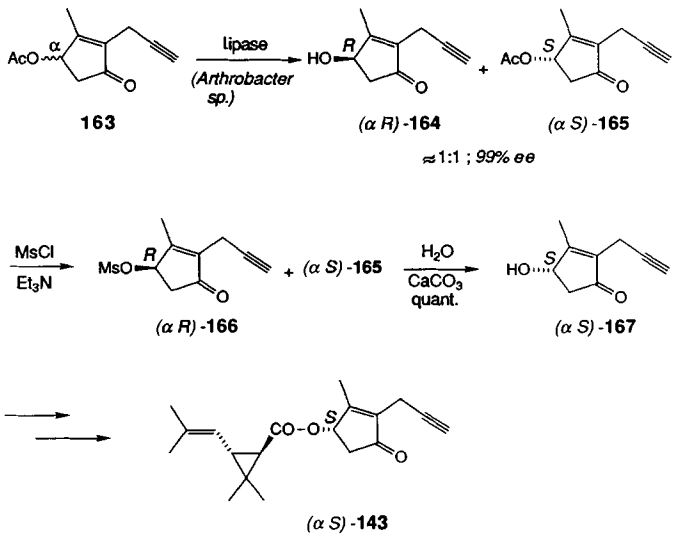
Eight diastereoisomerically and enantiomerically related isomers of **156** have different biological properties, the (1 *R*)-*cis*-α*S* being the most active.[110] To achieve an economic synthesis of its consituent (1 *R*)-*cis*-**162**, a cost-effective resolution of a cyclobutanone derivative into pure enantiomers had to be accomplished on an industrial scale for the first time (Scheme 43).[111] The easily available racemic cyclobutanone



Scheme 43. A "cyclobutanone" route to (1 *R*)-*cis*-permethric acid (**162**).

157 was converted into the bisulfite adducts.[112] Fortunately, by using the cheap auxiliary (1 *S*)-phenylethylamine only two of the four possible diastereomeric salts were formed. Isomers **158** and **159** could be readily separated by fractional crystallization. The mild hydrolysis liberated the properly configurated (2 *S*, 4 *R*)-cyclobutanone **161** for the subsequent enantioselective Favorskii rearrangement to (1 *R*)-*cis*-**162**. The unwanted enantiomer (2 *R*, 4 *S*)-**160** could be readily racemized with Bu_4NCl to (±)-*cis*-**157** and utilized again in the separation steps. Thus, the whole procedure represents a chirally economic synthesis of (1 *R*)-*cis*-**162** (permethric acid).

An approach incorporating an inversion of configuration by an S_N2 substitution of C-α of the undesired alcohol enantiomer was chosen in the industrial synthesis of the new household insecticide (*S*)-prallethrin **143**.[104] Principally, it represents a combination of an enzyme-catalyzed reaction and a chemical reaction, which ensures no loss of valuable starting material (Scheme 44). At a substrate concentration



Scheme 44. A complete conversion of a racemic acetate **163** into the enantiomerically pure alcohol **167** by a chemoenzymatic approach.

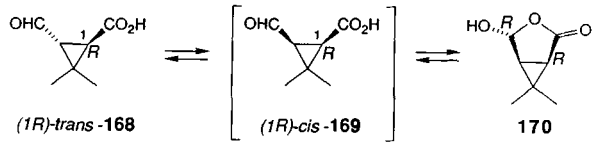
of 8.8 w/v % (α *R*, *S*)-**163**, an enzyme concentration of 3 mg L^{-1}, pH 7.0, and 40 °C, a lipase from *Arthrobacter* species yielded enantiomerically pure (α *R*)-**164** and the (α *S*)-acetate **165**. This mixture of products was then esterified with methanesulfonyl chloride to afford a mixture of the corresponding (α *R*)-sulfonate **166** along with unaffected (α *S*)-**165** acetate. Both esters were hydrolyzed in the presence of a small amount of $CaCO_3$. The (α *R*)-sulfonate **166** was converted into the desired (α *S*)-cyclopentenolone **167** with inversion of configuration, while (α *S*)-**165** was hydrolyzed with retention of configuration. Consequently, all the racemic acetate was converted with maximum efficiency into (α *S*)-**167**.

A similar chemoenzymatic approach was recently applied to the complete transformation of racemic α-cyano-3-phenoxybenzyl alcohol into the (α *S*) enantiomer.[104]

(1 *R*)-*trans*-caronaldehyde **168** can be prepared by ozonolysis of chrysanthemic acid. Compound **168** and its (1 *R*)-*cis*-isomer **169**, or, more precisely, the lactolic form **170**, are mutually interconvertible.

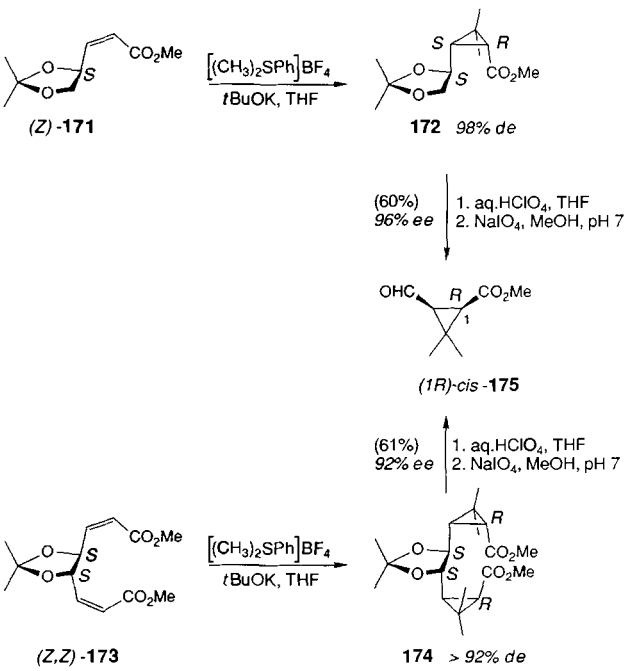
Both caronaldehyde isomers are extremely valuable chiral building blocks, because many versatile transformations, especially olefinations of the Wittig type, lead ultimately to a variety of interesting pyrethroid acids.[98b] For this reason, new synthesis of caronaldehydes **168** and **169** from natural

compounds like (+)-α-pinene, α-limonene, and (+)-Δ-3-carene are frequently reported. None of them seem to be technically attractive as yet, because several more or less laborious degradation steps are necessary in each case to remove one or more supernumerary atoms of the carbon skeleton.



Scheme 45. Interconversion of (1 *R*)-*trans*-caronaldehyde (**168**) and its (1 *R*)-*cis*-lactolic isomer **170**.

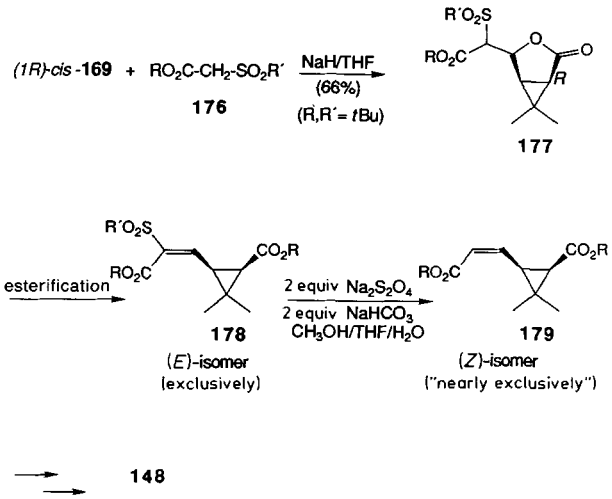
Recent syntheses by *Krief* of (1 *R*)-*cis*-**175** lack this disadvantage,[113] as shown in Scheme 46. The optically active unsaturated esters **171** and **173** are derived from easily available (*S*)-2,3-*O*-isopropylidene glyceraldehyde and (*R*,*R*)-2,3-*O*-isopropylidene tartaric acid.



Scheme 46. Synthesis of (1 *R*)-*cis*-caronaldehyde methyl ester **175**.

Very recently, the *tert*-butyl ester of (1 *R*)-*cis*-caronaldehyde **169** was used for the synthesis of the new pyrethroid acrinathrin (**148**) according to Scheme 47.[107]

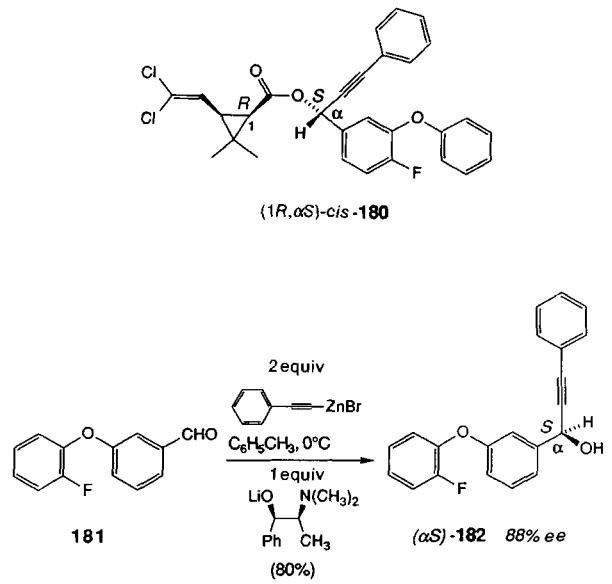
Finally, the successful preparation of the alcohol constituent of the enantiomerically pure experimental pyrethroid CGA 221 869 (**180**) which has diminished fish toxicity[114] is worth mentioning for at least two reasons.[115] Firstly, 2-phenylethynylzinc bromide was applied for the first time in an asymmetric addition to an aldehyde in the presence of a chiral amino alcohol, the lithium salt of (−)-*N*-methylephedrine (Scheme 48). Secondly, the optical induction (88% *ee*) in this easy addition reaction, **181** → **182**, is considerably higher than the enantioselectivities usually reported for the



Scheme 47. Enantioselective synthesis of the acid part of acrinathrin (**148**) from the caronaldehyde derivative (1 *R*)-*cis*-**169**.

addition of dialkynyl zinc reagents to aldehydes in the presence of chiral amino alcohols.[116]

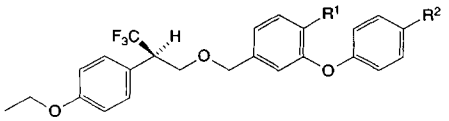
Pyrethroid insecticides have achieved a high share (19.4% in 1989) of the total insecticide world market, which amounted to 9.6 billion Swiss Francs in 1989.[117] Alongside the



Scheme 48. The use of 2-phenylethylzinc bromide as alkynyl-delivering reagent in asymmetric synthesis of experimental pyrethroid **180**.

natural mixture of esters **135**–**140** and the enantiomerically pure synthetic esters **141**–**154**, there are more than 15 other, constitutionally uniform although stereochemically heterogeneous, pyrethroids on the market. As the wealth of products brought to the market by two decades of synthetic efforts is impressively large, suggestive of exhaustiveness, the impression may arise that there is no longer anything new to discover in this area, either in terms of structure or activity. This is probably largely true. At the same time, however, investigations are being undertaken to overcome some of the deficiencies of the current products and explore new market niches.

For example, the new pyrethroids which have neither an ester group nor a cyclopropane residue (their low fish toxicity makes them appropriate for use in rice fields) have nothing in common structurally with the archetypal pyrethrin **135**, except the outer surface of the molecules which is important for recognition by the binding site.[118]



183 $R^1 = R^2 = H$

184 $R^1 = F, R^2 = H$

185 $R^1 = H, R^2 = Br$

Scheme 49. Pyrethroids containing neither ester nor cyclopropane groups.

The only enantiomerically pure derivatives **183**–**185** are missing even the usual geminal methyl group![119] (See Scheme 48; (2 *R*) enantiomers are more active than (2 *S*) ones.)

5. Conclusions and Outlook

As the above results indicate, the syntheses and investigations of enantiomerically pure agrochemicals have developed from isolated curiosities to become serious aims of modern agrochemical research and development. Clearly, the phenomenon of chirality will play an increasingly important role in crop protection by influencing both the thinking and the direction of the research programs of the scientists involved.

From an *agrochemist's* point of view, it is still an important and rewarding task to discover and develop new and inexpensive methods of introducing chirality which are a) applicable not only to model substances, but b) also take account of the chiral-economic requirements of both industry and environment (for instance, by the recycling of unwanted stereoisomers or by using catalytic reactions whenever possible). The examples shown above have been selected to demonstrate what has been achieved to date in this respect.

From an *agrobiologist's* point of view, performing mode-of-action studies with pure stereoisomers improves the understanding of the factors that influence biological activity, and hence enables the best compounds to be discovered more rapidly. The complex interaction of chiral substrates with natural chiral receptors, as well as their uptake, transportation, metabolism, etc., inside the chiral constituents of target organisms (e.g., peptides, polysaccharides, polynucleotides) may frequently lead to surprising insights and stimulate synthetic chemistry by the design of bioactive substances.

From an *agronomist's* point of view, the use of a single stereoisomer may offer an additional possibility for the solution of certain agronomical problems (e.g., reduction in phytotoxicity, fewer effects on beneficial insects and other non-target organisms, etc.). First and foremost, however, one principal question has always to be answered: To which of the six principal categories (see Section 1) does the investigated crop protection product containing one or more centers of chirality belong? Thus, the increasing flow of racemic and diastereoisomeric experimental compounds as well as their enantiomerically pure constituents from chemical laboratories will assist the agronomists in the refinement of their greenhouse and field testing evaluations.

Thanks to these interdisciplinary interactions, further exciting scientific progress, as well as economical and ecological benefits, can be expected in the fledging area of "Chirality in Crop Protection" in the near future.

The authors would like to thank heartily their colleagues Drs. Urs Burckhardt, Hans-Peter Buser, Philippe Chemla, John Dingwall, Hanspeter Fischer, Robert Nyfeler and David Wadsworth, who critically read this article, and Christa Fletcher and Dr. Victor Flück who helped to prepare the manuscript, drawings, and figures.

[1] The discipline of understanding the interplay of chiral substrates with living matter has a long history. For fascinating reading see: B. Holmstedt in H. Frank, B. Holmstedt, B. Testa (Eds.): *Chirality and biological activity*, H. R. Liss Inc., New York, 1990, pp. 1–14.

[6] D. Seebach, *Angew. Chem. 102* (1990) 1363; *Angew. Chem. Int. Ed. Engl. 29* (1990) 1320.

[7] To the best of our knowledge, *A. Eschenmoser's* suggestion (*Lectures on Organic Synthesis*, Technion, Haifa, 1969) to synthesize the highly strained and delightfully symmetric "helvetane" represents the only attempt to deplanarize the Swiss cross so far. It is cited and depicted in G. Dinsburg (for D. Ginsburg), *Nachr. Chem. Tech. Lab. 30* (1982) 289, as well as *Nouveau J. Chim. 6* (1982) 175. *A. Nickon* and *E. F. Silversmith* write in *Organic Chemistry: The Name Game*, Pergamon, New York 1987, pp. 87–88: "If you read his delightful article, you will go to bed chuckling—and feeling good about chemists."

[98] Two outstanding new books, treating all aspects of pyrethroid chemistry and neurotoxic activity against insects, appeared in the series *Chemistry of Plant Protection* (W. S. Bowers, W. Ebing, D. Martin, R. Wegler (Eds.), Springer, Berlin 1990: a) *Vol. 4* by K. Naumann: *Synthetic Pyrethroid Insecticides: Structures and Properties;* b) *Vol. 5* by K. Naumann: *Synthetic Pyrethroid Insecticides: Chemistry and Patents.*
[99] For the most part we follow in this paper the unambiguous designation of chiral pyrethroids proposed by N. F. Janes (*Pestic Sci. 18* (1987) 149). The "1 *R*, *cis*" system of designation of stereochemistry of the cyclopropane ring substituents, avoids a confusing *R* vs. *S* change at C3,

required by Cahn–Ingold–Prelog convention, when priority orders of the side-chain substituents are changed.

[102] M. Elliott, *Pestic. Sci. 27* (1989) 337 and references cited therein.
[103] There are, however, four exceptions in this table: three non-cyclopropane pyrethroids (**152**–**154**) are marketed apparently as esters containing racemic 3-phenoxybenzaldehyde cyanohydrin [98a], whereas commercial tralomethrin **147** is a 60:40 mixture of two diastereoisomers arising from the brominated side chain at C 3. In contrast to other cases, the two diastereoisomers of **147** are about equally effective because they act first by losing bromine, thus behaving as 'propyrethroids' for **146**.

Phytochrome, the Visual Pigment of Plants

By Wolfhart Rüdiger* and Fritz Thümmler

Dedicated to Professor Kurt Schaffner on his 60th birthday

Plants require light for photosynthesis. In order to adapt to the light conditions in their particular habitat, they have developed various photoreceptor systems. Of these, phytochrome allows even two-color vision in the red/far-red region. The photoreceptor phytochrome is of interest not only to botanists, but also to natural product chemists, photochemists, biochemists, photobiologists, and recently molecular biologists. Despite numerous studies, there are still considerable gaps in our knowledge of this photoreceptor. This article first describes the basic structural studies of the tetrapyrrole chromophore and its photochemical *cis–trans* isomerization, which is the source of the chromoprotein's photochromism. In the section on the protein moiety, beside other topics, the domain structure of phytochrome and the conformational changes during phototransformation are discussed. Finally, the known phytochrome genes are used to derive phylogenetic relationships, and possible structure-function relationships are discussed.

1. Introduction

After germination, higher plants remain firmly rooted in one place. They have therefore developed strategies to adapt themselves to their particular environmental surroundings. One important environmental factor is light, which is required for photosynthesis. The adaptation of the photosynthetic apparatus to light quality is well known ("light" and "shade" plants or leaves). Many other processes in the life of the plant are also controlled by light, from germination, growth, and greening to flower formation. These may be collected under the term photomorphogenesis.[1] Photomorphogenesis is regulated by photoreceptors. The effective spectral region can be measured as an action spectrum corresponding to the absorption of the particular photoreceptor; by this means at least three photoreceptors may be distinguished in plants. These are active in the UV-B, UV-A/blue, and red/far-red regions. The first two of these photoreceptors have been only poorly characterized to date, but the red/far-red receptor, "phytochrome", has been identified and already studied in detail.

Phytochrome was discovered forty years ago in Beltsville (Maryland).[2] *Borthwick*, *Hendricks*, and their colleagues were interested in the photoperiodic control of flower formation and the light regulation of seed germination. The decisive discovery was that in both cases—with an almost identical action spectrum—red light (λ_{max} = 660 nm) displayed an induction effect which could be abolished by subsequent far-red illumination (λ_{max} = 730 nm).[3,4] A photochromic photoreceptor was postulated, which was thought to exist in a physiologically inactive, red-absorbing form (Pr) and in a physiologically active, far-red absorbing form (Pfr). This was subsequently confirmed by isolation of the photoreceptor. The substance is a chromoprotein which is present in only very low levels in plants; even in seedlings grown in the dark and therefore free of chlorophyll, the photoreceptor cannot be seen with the naked eye. On the other hand, because of its photochromic nature it can readily be detected in such tissue with sensitive spectroscopic methods.

$$\mathrm{Pr} \underset{730\ \mathrm{nm}}{\overset{660\ \mathrm{nm}}{\rightleftharpoons}} \mathrm{Pfr} \rightarrow \text{physiological reaction}$$

The preferred starting material for isolation of phytochrome was dark-grown ("etiolated") oat seedlings, which contain relatively high levels of this photoreceptor in the tips of the coleoptiles (seed leaf sheaths). Because of proteases, which act when the plant cell is broken open, for many years only proteolysis products of the native photoreceptor were isolated ("small phytochrome", 60 kDa; "large phytochrome", 114–118 kDa). Not until 1982 was it possible to determine the size of the intact molecule (monomer size of oat phytochrome, 124 kDa), and to isolate it successfully.[5,6] The photochromic properties are retained on isolation; saturating illumination with far-red light (λ_{max} = 730 nm) transforms 99% of the phytochrome into the Pr form, while saturating illumination with red light yields about 85% Pfr with 15% Pr. Figure 1 shows the absorption spectra of the two

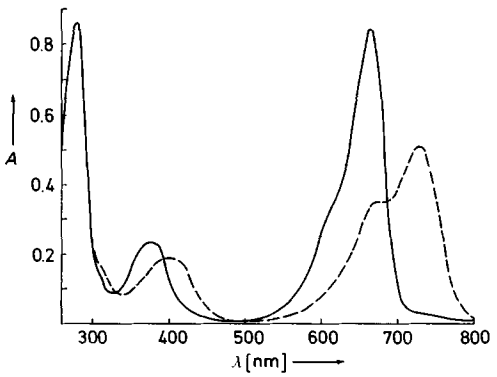

Fig. 1. Absorption spectra of 124 kDa phytochrome from etiolated oat in 10 mM phosphate buffer, pH 7.8 (from ref. [7]). The spectra were determined at 4°C after saturating illumination with far-red (—) and red (– – –) light. The A_{667}/A_{280} ratio of the Pr form (here 0.99) is a measure of the purity of the isolated phytochrome.

forms. Native phytochrome is a dimer consisting of two identical subunits. Each subunit is made up of an *N*-terminal domain containing the chromophore (N in Fig. 2) and a *C*-terminal domain (C in Fig. 2). The quaternary structure of

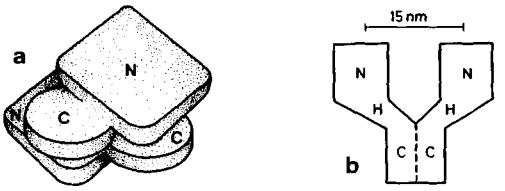

Fig. 2. Model of the dimeric phytochrome molecule, derived from a) small-angle X-ray scattering and electron microscopy (redrawn from ref. [8]) and b) electron microscopy (from ref. [9]).

pea phytochrome has been derived from small-angle X-ray scattering and electron microscopy[8] (cf. Fig. 2). For oat phytochrome, a very similar Y form has also been established by electron microscopy.[9]

2. The Tetrapyrrole Chromophore

2.1. The Structure of Phytochromobilin

The absorption of visible light was an early indication of a nonprotein chromophore in phytochrome, but for a long time there was only speculation about its chemical nature. An open-chain tetrapyrrole structure was not demonstrated until 1969,[10] by oxidative degradation and identification of the products.

Oxidative degradation with chromic acid or dichromate had already been developed as a simple, analytical micromethod for the determination of bile pigment structures, and requires no more than 1 nmol of a tetrapyrrole.[11] This method measures the kinetics of pigment decolorization, which proceeds considerably more rapidly for open-chain tetrapyrroles (bile pigments) than for porphyrins and chlorophyll derivatives. In addition, characteristic degradation products were identified (e.g. by thin-layer chromatography and specific staining), and consisted of β-substituted pyrroledialdehydes, maleimides, and succinimides. The original β-substituents of the tetrapyrrole are retained in the degradation products. Many tetrapyrroles have been studied by this method.[12]

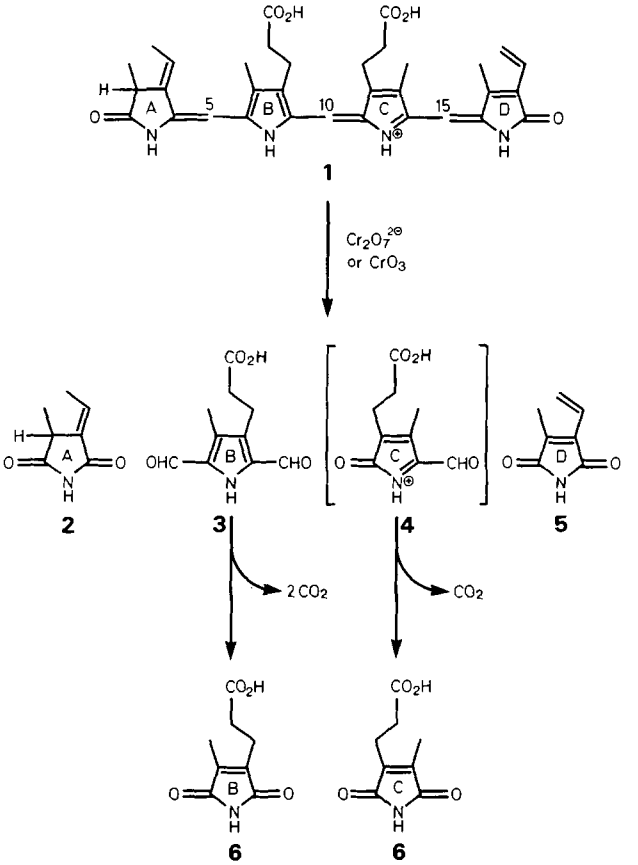

Fig. 3. Chromic acid and dichromate degradation of phytochromobilin (**1**). The degradation is shown here for synthetic **1**. The reactions for the analytical studies are shown in Fig. 4.

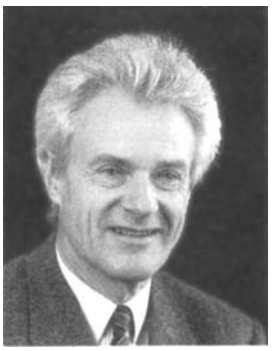

Wolfhart Rüdiger was born in 1933 in Stolp/Pommern, and studied chemistry from 1953 to 1959 at the University of Würzburg. He obtained his doctorate in 1961 under F. G. Fischer on a chlorophyll-related subject and then spent two years at the Max-Planck-Institut for Medicinal Research, Heidelberg, and at the marine biological station in Naples. His work there concerned the biochemistry of vanadium, in particular hemovanadium, in a group of marine animals (tunicates). From 1963 he was a postdoctoral research assistant at the Institute of Biochemistry at Saarbrücken University, where he habilitated in 1969 with a study on open-chain tetrapyrroles in animals and plants. Since 1971 he has been Professor for Phytochemistry and Chairman of the Institute of Botany at Munich University. Besides phytochrome his interests include the regulation of chlorophyll biosynthesis and the structure and function of novel plant germination inhibitors.

Fritz Thümmler was born in 1953 in Rosenheim, and studied biology from 1975 to 1981 at Munich University. After obtaining his doctorate in 1984 on a subject from the phytochrome field under Professor Rüdiger, he went for two years to Professor D. P. S. Verma at the McGill University, Montreal. There he worked on nodulins (plant proteins which are induced on symbiosis with rhizobial bacteria). Since 1987 he has been a postdoctoral assistant at the Institute of Botany, Munich University.

The oxidative degradation of the phytochrome chromophore was first carried out without cleaving the covalent bond to the protein.[10] The only products identified were **3** and **6**, derived from rings B and C (Fig. 3). In order to study the covalent bond to Ring A, thioethers (e.g. **7**) were synthesized as model substances[13] (Fig. 4a). Alkaline cleavage of these thioethers, or of their sulfone products from chromic acid degradation, was optimized.[14] Thus, degradation product **2** from Ring A of the tetrapyrrole was released and identified in a two-step reaction (Fig. 4b). The configurations of

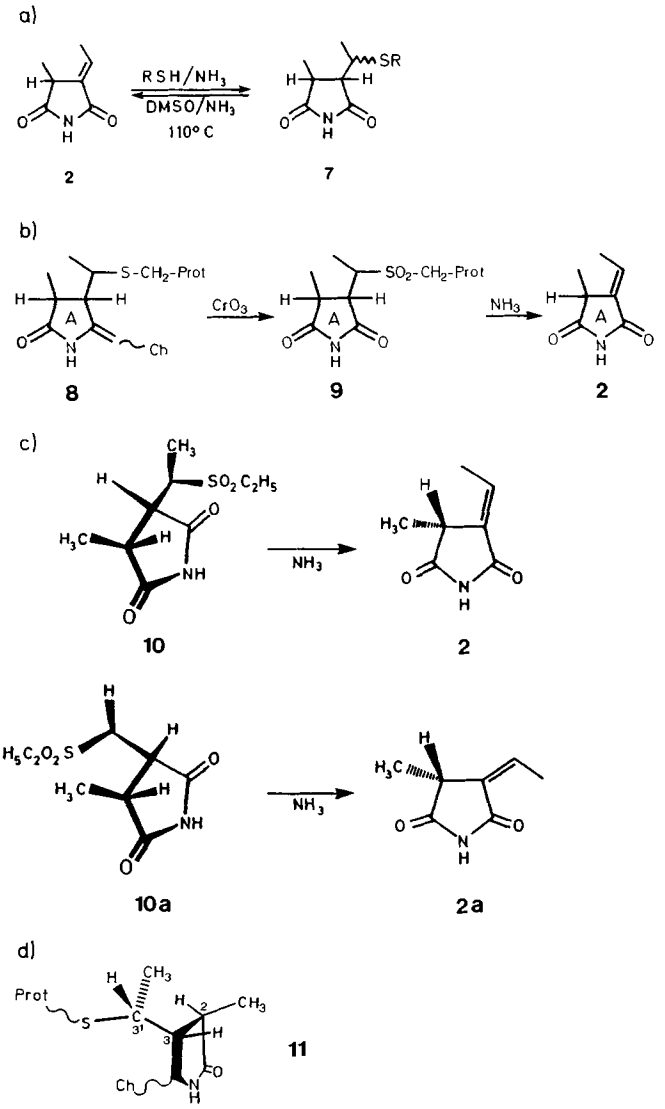

Fig. 4. Model experiments and degradation reactions for structure determination of ring A of phytochromobilin. a) Model synthesis of **7** from **2** and elimination of the thiol [13]. b) Isolation of **2** from phytochrome **8** via the protein-bound **9** [16]. c) Stereoselectivity of the elimination reaction of sulfones **10** or **10a** to olefins **2** or **2a** [14,15]. d) Derived configuration of ring A of the tetrapyrrole chromophore [16]. DMSO = dimethyl sulfoxide, Prot = protein, Ch = chromophore.

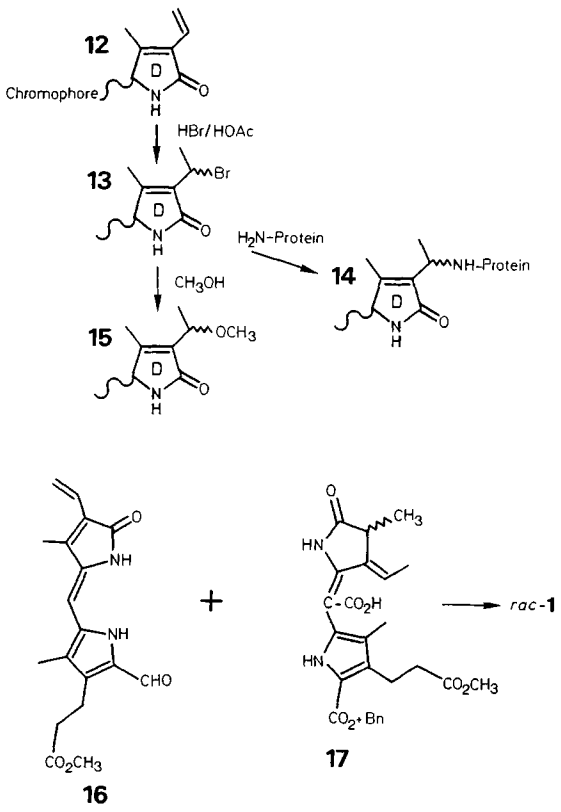
the model sulfones **10** and **10a** (determined by X-ray crystallography)[15] and the appearance of *Z,E*-isomeric degradation products **2** and **2a** (Fig. 4c) even yielded some evidence for the absolute configuration of the thioether bond in phytochrome. Stereoselective elimination from phytochrome affords only **2** and not **2a**; from this a 2*R*,3*R*,3*R'* configuration was deduced for Ring A and its substituents in phytochrome (Fig. 4d).[16]

The intact tetrapyrrole chromophore is not cleaved from the protein under the alkaline conditions described in Figure 4b. Clearly, oxidation to the succinimide and, in particular, oxidation of the thioether to the sulfone are required for a facile elimination. In contrast, the thioether was successfully cleaved, while retaining the tetrapyrrole, by using HBr in glacial acetic acid (Scheme 1).[17] However, a complication



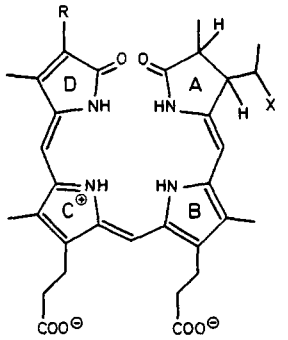
Scheme 1.

arose at Ring D (**12** in Scheme 1); HBr obviously adds very readily to the vinyl group, and the resulting bromo derivative **13** then reacts with nucleophilic groups on the protein to give **14**. This difficulty was avoided by not using the intact chromoprotein for cleavage of the chromophore, but only a chromopeptide obtained by proteolysis, consisting of eight to eleven amino acids in addition to the chromophore. Workup with methanol yielded mainly methanol adducts of the chromophore (**15**). The reaction steps from **12** to **15** were repeated with synthetic **1**.[17,18] This sequence of reactions, together with the total synthesis of **1** from **16** and **17**,[18] can be regarded as a "classical chemical" structure determination of the phytochrome chromophore.

Independently of these studies in Munich, *J. C. Lagarias* in Berkeley has investigated chromopeptides from phycocyanin and phytochrome by ^{1}H NMR spectroscopy. The chromoprotein phycocyanin is a light-harvesting pigment in cyanobacterial photosynthesis.[19] It contains several phycocyanobilin chromophores (one in the α subunit, two in the β subunit), which are closely related to phytochromobilin. Since phycocyanin is easily obtained in large quantities, it

has been used by several groups as a model for studies on phytochrome. *Lagarias* et al. made use of synthetic peptides and in order to assign the amino acid signals synthesized the sequence of one chromopeptide from phytochrome, Leu-Arg-Ala-Pro-His-(Ser,Cys)-His-Leu-Gln-Tyr, which had already been reported in 1971.[20] They also made a heptapeptide corresponding to a chromopeptide from phycocyanin.

By comparison with the known ^{1}H NMR spectrum of free phycocyanobilin, the structure of the bound phycocyanobilin was confirmed to be **18**, thus localizing the thioether bond.[21] A subsequent study of the phytochromopeptide **19**[22] showed that the only structural difference in the chromophore was in the substituents of Ring D: in phytochromobilin, a vinyl group replaces the ethyl group of phycocyanobilin.



18 R = Ethyl X = Ala-Ala-Cys-Leu-Arg-Asp-Hsl
19 R = Vinyl X = Leu-Arg-Ala-Pro-His-Ser-Cys-His-Leu-Gln-Tyr

2.2. The Chromophore Structure in the Pfr Form

The interaction of the chromophore with the native protein is essential for the photochemistry of phytochrome, since neither free phytochromobilin nor denatured phytochrome in the Pr form show any spectral changes on illumination. Several authors have suggested[22, 23] that photoconversion of phytochrome does not represent a permanent change in the chemical structure of the chromophore, but that only protein interactions or binding to amino acids are altered. This was disproved, however, by our observation that when the reactions were performed in the dark, denaturation with urea[24] or proteolysis with pepsin[25] led to products with different spectral properties from the Pr and Pfr forms (Fig. 5). The products from Pfr are light-sensitive; on illumination they are immediately converted into the products that are obtained from the Pr form. This light-sensitivity could be the reason why other authors[20] have failed to observe the difference between Pr and Pfr peptides. The difference is not limited to spectral properties—Pr and Pfr peptides can be separated by chromatography, even though they have the same amino acid composition. The difference must therefore lie in the chromophore. Since the same tetrapyrrole oxidation products are obtained from the Pr and Pfr

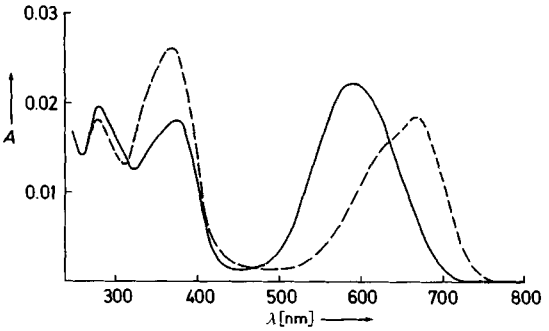

Fig. 5. Absorption spectrum of the Pfr chromopeptide in 1% aqueous formic acid. The spectrum was recorded first after isolation of the peptide by chromatography in the dark (—) and then after illumination with white light for 10 s (– – –). The second spectrum is identical to that of the Pr peptide (from ref. [28]).

peptides,[25] the difference must be located in the methine bridges, which are destroyed on chromic acid oxidation. Various model compounds[26] had to be rejected, since they did not display the light-sensitivity of the Pfr peptide. Eventually, the *Z,E* isomerization of tetrapyrroles proved to be a suitable model reaction; by using a method of *Falk* and co-workers[27] (Fig. 6a), this isomerization can also be carried out on chromopeptides from phycocyanin and phytochrome.[28] The position of the isomerization in the Pfr peptide was then traced to the C15–C16 double bond by ^{1}H NMR spectroscopy[29] (Fig. 6b). Hence, the Pr chromophore is in the 15*Z*,*syn*-form and the Pfr chromophore in the 15*E*,*anti*-form.

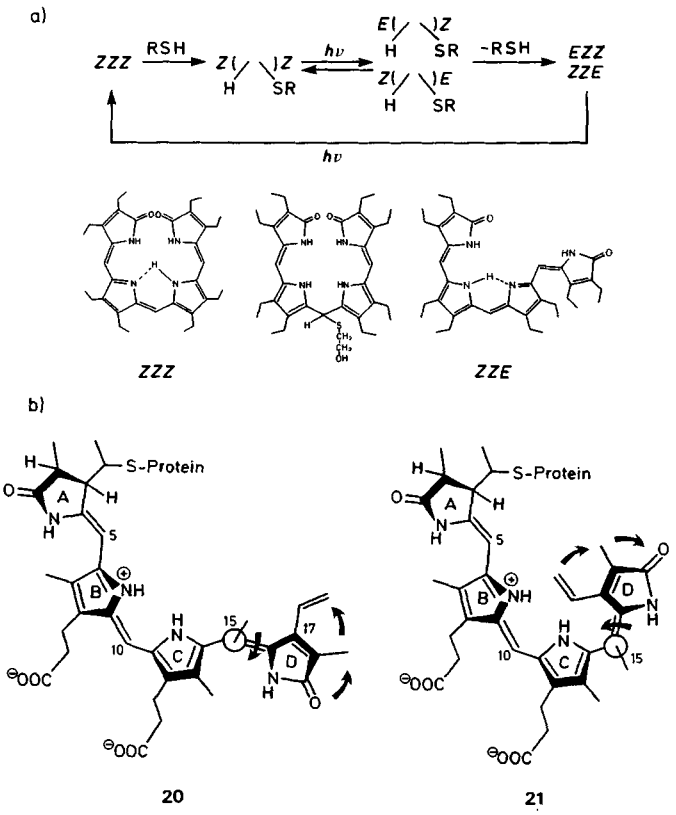

Fig. 6. *Z,E* isomerism in open-chain tetrapyrroles. a) Octaethylbiliverdin as example of the preparation of a bilatriene with *E* configuration according to ref. [27]. b) Structure of phytochromobilin in the Pr form **20** and the Pfr form **21**. Conformation **20** corresponds to the configuration of phycocyanobilin in native phycocyanin, as determined by X-ray analysis [54]. The arrows show the displacement of ring D on conrotation of the C14–C15 and C15–C16 bonds from **20** (*Z,syn*) to **21** (*E,anti*) and vice versa (cf. Section 2.3).

phore can be assigned the 5*Z*,10*Z*,15*Z* configuration **20**, and the Pfr chromophore the 5*Z*,10*Z*,15*E* configuration **21**.

One possible objection to this conclusion is that the 15*E* configuration might arise merely as an artifact of the proteolysis of Pfr. The reasoning behind this objection is, for example, the marked shift in the long-wavelength absorption maximum from 730 nm to 600 nm on proteolysis (cf. Figs. 1 and 5). This spectral shift will be discussed in Section 2.3. The objection ignores the fact that the 15*E* isomer is converted into the 15*Z* isomer in an exergonic reaction (ΔG° is at least $-20\ kJ\,mol^{-1}$).[30] The reverse reaction is not possible with free phytochromobilin. This is related to the steric requirements of the β substituent. Only for the *E* isomer does a significant torsion angle arise, leading to partial decoupling of the π system and a hypsochromic shift in the absorption bands. In bilatrienes methylated at N21 and N24, similar steric hindrance yields a torsion in both the *Z* and the *E* configurations. Correspondingly, the photoisomerization ($Z \rightleftharpoons E$) occurs in both directions here, to give a measurable equilibrium; for example, for a 21,24-dimethyl bilatriene to $Z,Z,Z \rightleftharpoons E,Z,Z \rightleftharpoons E,Z,E$.[31]

Differences between native Pr and Pfr have since been measured by resonance Raman spectroscopy[32] and by SERSS (Surface-Enhanced Resonance Raman Scattering Spectroscopy).[33] In both cases, the differences measured were interpreted in the sense of a 15*Z* configuration for the chromophore in the Pr form and a 15*E* configuration for the Pfr form. This confirmed the data and conclusions from the chromopeptides. Fourier transform difference infrared spectroscopy[34] shows similarities, at least, between *Z*,*E*-isomeric model chromophores and the two phytochrome forms. According to the infrared spectra, the chromophore is protonated in both the Pr and the Pfr forms.

We discussed the *Z*,*E* isomerization of the chromophore as a candidate for the primary photochemical reaction of phytochrome as early as 1985.[35] A *Z*,*E* isomerization of the chromophore retinal is believed to be the primary photoreaction in the visual pigment of humans and mammals. By convergent evolution, the same principle thus seems to be realized in chemically quite divergent chromophores (a tetrapyrrole for phytochrome, an isoprenoid for rhodopsin). The actual photoconversion consists of the isomerization of a C–C double bond, which requires only minimal activation energy from an excited state. The reverse reaction in the dark is blocked because of the higher thermal activation energy for the isomerization (ca. $108\ kJ\,mol^{-1}$ for the tetrapyrrole[30]), and a stable photoproduct is generated. Stepwise dark reactions then take place through interactions with the protein. Both in rhodopsin and in phytochrome, the intermediates of these reactions can be observed in the phototransformation.

2.3. Intermediates

Relaxation products on the pathways Pr → Pfr or Pfr → Pr, which differ from one another in their absorption spectra, are described as intermediates. The absorption spectra of linear tetrapyrroles can be affected by very many factors;[36] for phytochrome, interactions of the apoprotein with phytochromobilin must be taken into consideration. Both for phytochrome and for rhodopsin, discontinuous spectral changes are noticeable; the individual intermediates are hence clearly distinct from one another. On the pathway from Pr to Pfr at least four intermediates can be distinguished,[37] while at least two can be seen on the way from Pfr to Pr.[38] The scheme of intermediates (Fig. 7) was initially derived from absorption measurements at low temperatures, where the individual intermediates are "frozen". The

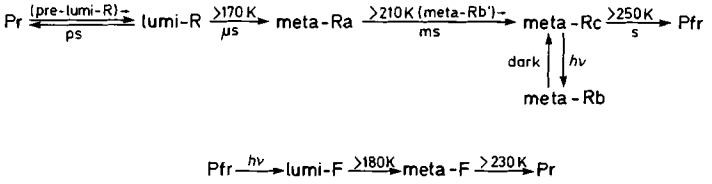

Fig. 7. Schematic diagram of the photointerconversion of the two phytochrome forms via several intermediates (from ref. [38], expanded). The temperatures given are the minimum values for the individual relaxation steps; the times indicate the order of magnitude of the relaxation times at room temperature.

absorption measurements required a clear glass, which was obtained in buffer with 66% glycerine. All the data in Figure 7 and Table 1 refer to this solvent mixture. Thus, below 170 K illumination of Pr affords only lumi-R as intermediate (since $\lambda_{max} \approx 700$ nm it is called I_{700} by some authors), which on warming without further illumination is gradually transformed into Pfr, via the subsequent intermediates. At suitable higher temperatures, the intermediates meta-Ra or meta-Rc are obtained immediately; meta-Rb is formed only in native phytochrome under constant illumination, and relaxes in the dark to meta-Rc. With progressive proteolysis to phytochrome fragments of size 114/118 kDa, 60 kDa, and 39 kDa, the proportion of meta-Rb increases steadily. Many authors combine the products meta-Ra, meta-Rb, and meta-Rc into the intermediate Ibl (= bleached phytochrome), but different absorption spectra are quite distinguishable (Table 1).

Table 1. Spectroscopic data for the phytochrome forms, measured at −140 °C in glycerine buffer solution (from ref. [38]). f_1 and f_2 = relative oscillator strength of the first and second absorption bands.

phytochrome form	first absorption band λ_{max} [nm]	ε [$dm^3mol^{-1}cm^{-1}$]	second absorption band λ_{max} [nm]	ε [$dm^3mol^{-1}cm^{-1}$]	f_2/f_1
Pr	667	140000	380	50000	1.10
Pfr	741	119000	403	41000	1.10
a) path Pr → Pfr					
lumi-R	693	190000	384	47000	0.86
meta-Ra	663	86000	386	52000	1.37
meta-Rb (P_{bl})	665	40000	380	57000	2.29
meta-Rc	725	80000	387	50000	1.45
b) path Pfr → Pr					
lumi-F	673	105000	388	44000	1.02
meta-F	660	133000	381	55000	1.15

The same (or at least very similar) intermediates also occur at room temperature, and can be studied by time-resolved spectroscopy.[39] The intermediates pre-lumi-R[40] and meta-R'b[37] have been described, which had not been found previously by other authors. The times given in Figure 7 only

show the order of magnitude of the duration of intermediate transitions. Both Pr fluorescence[41,42] and absorption changes for the early intermediates[43] can only be explained by at least two parallel but kinetically distinct components. However, complex kinetics can also appear in absorption measurements when intermediates that follow one another overlap strongly in their absorption.[37,44]

Up till now, no direct experimental data is available on the chemistry of the intermediates. The following general observations can be made. The primary photochemical reaction, which is possible even in an ice matrix at temperatures below 170 K, must take place in a protein pocket which protects the chromophore from outside. The chromophore is better protected from attack by chemical agents in the Pr form than in the Pfr form.[45] The protein pocket must be large enough to allow, for example, the *Z,E* isomerization of the chromophore, but not so large that the isomerization can occur quite freely, without any interaction with the protein environment. A complete rotation of Ring D, which also requires temporarily a large space at right angles to the plane of the ring is very hard to imagine—at least not on the picosecond time scale. Conrotation of the C14/C15 single bond with the C15/C16 double bond (Fig. 6) would require the least space. Ring D is thereby displaced with respect to the rest of the molecule only within the plane of the ring, and does not rotate. This model was proposed by us in 1985[35] and is supported by recent resonance-Raman studies,[32] which show that the chromophore possesses a C15-*Z,syn* conformation in the Pr form, and a C15-*E,anti* conformation in the Pfr form.

In the picosecond range this movement only has to reach the activation threshold for the *Z,E* isomerization; the tetrapyrrole will then continue to relax in the direction given by the arrow. If the protein pocket is small enough, the protein must follow this relaxation. The consequence of this would be the conformational changes which eventually lead, via the intermediates, to physiologically active Pfr. As well as these purely steric interactions, however, ionic interactions between the protonated, positively charged chromophore and the charged amino acid residues could well play a part in the conformational changes enforced by the chromophore, as could hydrogen bond interactions.

Comparing the oscillator strengths (Table 1) reveals that the ratio f2/f1 has a particularly high value for the intermediate meta-Rb. This high value corresponds to a protein-free tetrapyrrole in a cyclic–helical conformation, while Pr, Pfr, and the other intermediates appear from the oscillator strengths to be present in a more extended conformation, brought about by interactions with the protein. *H. Falk*[36] has pointed out that because of the many different influences on the electronic spectra of open-chain tetrapyrroles, such data cannot be used alone to draw conclusions on conformation. However, there is other evidence for a particularly small interaction between chromophore and protein in illuminated phytochrome, where meta-Rb is preferentially accumulated; the chromophore and its binding site are more accessible to chemical agents during illumination than in the dark for the Pr or the Pfr form.[45,46]

The data in Table 1 also indicates that the characteristic long-wavelength absorption band of the Pfr form appears only during the last relaxation steps, and thus is not directly associated with the primary photoreaction. By acid denaturation of the meta-Rb intermediate and spectral measurements, we have been able to show that the *Z,E* isomerization takes place before the Pfr band appears.[47] In a 39 kDa fragment, which is still photoreversible and in principle forms the same intermediate as Pr, the long-wavelength absorption is completely absent.[48] Clearly, this fragment is lacking the portion of the peptide chain which needs to interact with the chromophore in order to generate the long-wavelength absorption band. A possible candidate for such an interaction is a point charge, which can effect a bathochromic shift if it is placed in a defined spatial position relative to the π system.[49]

3. Studies of the Protein

3.1. Domain Structure

Electron microscopy and small-angle X-ray scattering studies can only reveal the rough outlines of the shape of the phytochrome molecule (Fig. 2). Biochemical studies, however, have yielded information on the domain structure of phytochrome. Partial proteolysis, electrophoretic separation of the fragments, and studies with monoclonal antibodies or monospecific antisera[50,51] have yielded a picture of a relatively compact chromophore-containing 64 kDa domain which is relatively inert to further proteolytic digestion. This domain lies in the *N*-terminal half of the peptide chain (Fig. 8a), and corresponds to the "small" phytochrome iso-

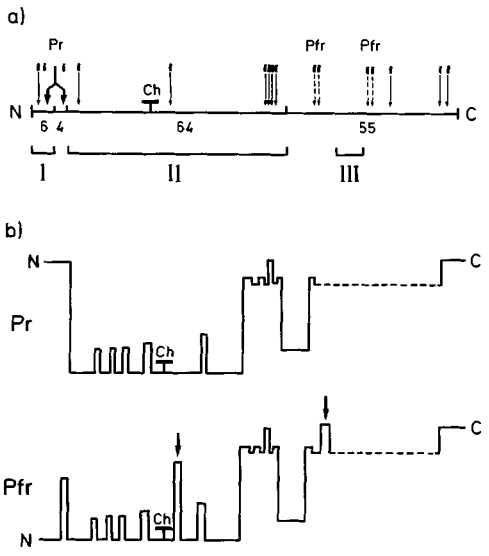

Fig. 8. Domain structure of phytochrome A from etiolated oat. The peptide chain is indicated by a continuous line from the *N*-terminus (N) to the *C*-terminus (C). Ch = tetrapyrrole chromophore. a) The roman numerals refer to three classes of antibodies, whose epitopes have been localized in the regions indicated. The arabic numerals indicate the size of the corresponding domains in kDa (from ref. [50]). The arrows mark sites of proteolytic attack on partial proteolysis: Pfr = preferred attack in the Pfr form, Pr = preferred attack in the Pr form (from ref. [51]). b) Schematic diagram of the conformation of the peptide chain in the Pr and Pfr forms, obtained from kinetic partial proteolysis experiments. Exposed parts of the peptide chain, which contain early proteolytic cleavage sites, are raised. Regions drawn lowered, which are in the interior of the globular protein, contain potential proteolytic cleavage sites which are only attacked later. The dashed region of the peptide chain is cleaved rapidly and often, and therefore yields no defined fragments. Two regions that are only exposed in the Pfr form are marked with arrows (from ref. [54]).

lated at the beginning of phytochrome research. The peptide regions responsible for direct interactions with the chromophore and hence for photochromism are localized here. The area between amino acids 65 and 400, or 200 and 400,[52, 53] is essential for the spectral properties of the Pr chromophore, while the region from 420 to 600[53] is required for the long-wave absorption of the Pfr chromophore. Of all the amino acids essential for interaction with tetrapyrrole in this region, arginine-316 (five residues *N*-terminal to the chromophore-binding site cysteine-321) should be specially mentioned, as it is conserved in all known phytochrome sequences and is also found in the corresponding position in all phycocyanin sequences. Through electrostatic interaction with a propionic acid side chain on the chromophore, this arginine (together with the chromophore-binding cysteine) is responsible for the extended conformation of the tetrapyrrole in phycocyanin.[54] We also assume a similar extended conformation for the phytochrome-chromophore (Fig. 6b). In contrast, the *C*-terminal chromophore-free domain (ca. 55 kDa in size) is readily attacked by proteases, and is therefore rapidly degraded to small, poorly defined peptides. The connection between the chromophore-containing domain and the chromophore-free domain ("hinge region") is attacked particularly rapidly by proteases. Similarly, a proteolytic attack can occur at a series of sites in the extreme *N*-terminal region (ca. 10 kDa) of phytochrome (Fig. 8a).

After elucidation of the primary structure of oat phytochrome (cf. Section 4.1) the *N*-terminal sequences of the peptide fragments were determined and then assigned within the total sequence. The points of protease attack on the amino acids could then be determined precisely.[53, 55] Since the *N*-terminus of the entire peptide chain is blocked, the phytochrome sequence cannot be determined by the Edman method. Mass spectrometry of the *N*-terminal peptides showed acetylserine to be the *N*-terminus of oat phytochrome; the methionine situated immediately before the serine in the DNA sequence is obviously removed before acetylation.[56] By following the kinetics of proteolytic attack at given sites, highly exposed regions of the peptide chain can be distinguished from those situated within the molecule in regions better shielded from proteolytic attack (Fig. 8b). Preferential protease attack is observed in the "hinge region", close to the *C*-terminus and—only in the Pr form—close to the *N*-terminus.

The 6–10 kDa *N*-terminal region of the peptide chain plays a special role. If it is removed by proteolysis[57] or blocked by antibody binding,[58] the absorption maximum of the Pfr form is shifted from 730 to ca. 722 nm, the rate of dark reversion of Pfr to Pr is increased by a factor of at least 10, the chromophore in the Pfr form is more accessible to external chemical agents, and the circular dichroism (CD) spectrum of Pfr in the 200–230 nm region approaches that of the Pr form. This all suggests that there is a direct interaction between this part of the peptide chain and the chromophore in the Pfr form;[59] however, an indirect influence of this region on the protein–chromophore interaction cannot be ruled out.

The *C*-terminal 55 kDa domain does not take part in chromophore–protein interactions. Instead it is responsible for dimerization of phytochrome. On gel chromatography, phytochrome displays an apparent molecular mass of 320–360 kDa;[51] equilibrium centrifugation gives a value of 253 kDa.[60] The data suggest a dimer of nonglobular nature (cf. Fig. 2). After partial proteolysis, only the fragments containing the *C*-terminal domain migrate on gel chromatography at 2–3 times the value of their molecular mass determined by sodium dodecyl sulfate (SDS)-gel chromatography; *N*-terminal, chromophore-containing fragments show the same molecular mass on gel chromatography and SDS-gel chromatography.[60] Experiments on cross-linking the peptide chains with glutaraldehyde or "dimethyl suberimidate" (dimethyl octanediimidate)[60] also suggest contact sites in the *C*-terminal domain for the phytochrome dimer. The schematic diagram of phytochrome dimers (Fig. 2) was partly derived from these experiments.

3.2. Differences between Pr and Pfr

Although conformational effects in the protein as a result of phototransformation have long been postulated, clear changes in shape[8] or protein conformation[61, 62] have not been found. Even the 3% increase in α-helix content,[58 or 59] which was determined from the circular dichroism spectrum in the UV, could not be confirmed by Fourier transform difference-IR spectroscopy.[34] Presumably the tetrapyrrole chromophore also contributes to the CD spectrum in the UV region. The differences between Pr and Pfr in retention time on gel chromatography, which were at first interpreted as a change in shape of the molecule,[51] can also be traced to other causes, presumably a change in the surface charge.[63]

In contrast, local changes in the surface structure of phytochrome on phototransformation have been demonstrated by various methods. Among these are, for example, preferential phosphorylation of the Pr form in the *N*-terminal region,[64] a more negative surface charge on the Pfr form (associated with the exposed site of the aspartate and glutamate residues in the region between amino acids 340–355),[63] better accessibility of the chromophore in the Pfr form,[45] differences in the affinity of various antibodies to Pr and Pfr,[58, 65] differences in the exposure of aromatic amino acids,[66] and differences in partial proteolysis, as discussed above. As can be seen in Figure 8b, the *N*-terminal region (ca. 10 kDa) is easily accessible to proteolysis in the Pr form, but not in the Pfr form. Two regions around amino acids 354 and 753 are especially conspicuous, and are attacked preferentially in the Pfr form.[55] Such regions are of interest as potential components of an "active site" on the surface of the Pfr form; however, neither an active site nor a function associated with one has yet been demonstrated.

3.3. Studies with Antibodies

Phytochrome is probably the plant protein that has been explored most thoroughly with monoclonal antibodies.[67] Of these investigations just a few are presented here.

Phytochrome can be measured quantitatively with the help of antibodies. One application is the measurement of phytochrome distribution within a seedling (Fig. 9).[67, 68] The concentration of the photoreceptor is highest in the

coleoptile tip, the shoot tip, and the root tip. This distribution had also been found by using spectroscopy[69] and immunocyto-chemistry.[70] When the intracellular localization in etiolated seedlings was studied, the Pr form was found to be evenly distributed in the cytoplasm. On conversion into the Pfr form, however, it is rapidly bound to discrete, as yet unidentified sites in the plasma membrane (plasmalemma).[71] In green, lower plants (e.g. the fern *Adiantum*[72] and the alga *Mougeotia*[73]), however, phytochrome appears to be permanently localized, in a dichroic conformation, in or near the plasma membrane.

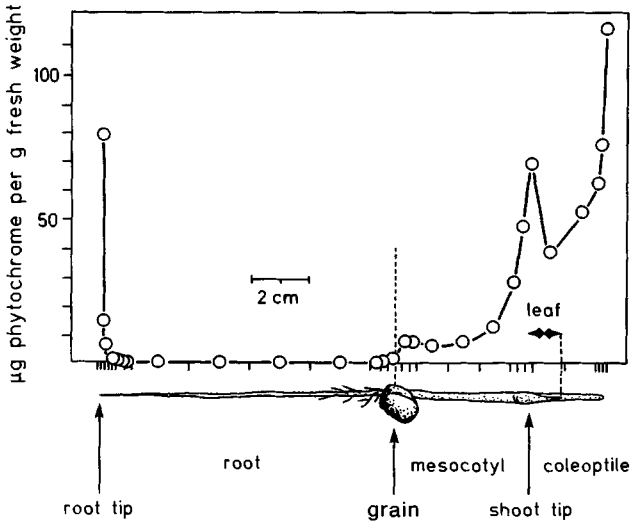

Fig. 9. Distribution of phytochrome in an etiolated, 5-day old maize seedling. The plant was cut into sections, which were then each extracted, and the phytochrome content of the extracts measured using antibodies. The divisions on the abscissa indicate the length of each section analyzed (from ref. [68]).

It has long been known that the photoreversible phytochrome of etiolated plants disappears on illumination, leaving only a small residue (1–5% of the initial amount).[1] Studies with antibodies also showed that not only the chromophore is degraded, but also the phytochrome-protein.[74] The remaining phytochrome proved to be immunologically heterogeneous.[75–78] The dominant photoreceptor in etiolated plants was originally called phytochrome type I; in the meantime, the term used by molecular biologists, type A (*phy*A), has become usual. The dominant phytochrome in light-grown, green plants (originally called type II[79]) is also heterogeneous.[80] It is probably a product of genes *phy*B and *phy*C (cf. Section 4), although differences due to post-translational modifications cannot yet be ruled out.

3.4. Distribution of Phytochrome in the Plant Kingdom

The operational criterion for the presence of phytochrome is a physiological effect inducible by red light which can be reversed by far-red light. From observations in many plants, it is assumed that phytochrome is generally present in higher plants (seed plants). In contrast, for lower plants (ferns, mosses, algae), the evidence indicates only sporadic occurrence. Identification of phytochrome by isolation or partial purification and identification of the protein band has only been possible for a few species; for example, for etiolated seedlings of oat, rye, pea, zucchini, rice,[81, 82] and for several green plants (oat;[75, 78] pea,[76] the moss *Atrichum undulatum*,[83] the green algae *Mesotaenium caldariorum*[84] and *Chaetomorpha linum*[85]).

Table 2. Identification of phytochrome by Western blotting [a].

Type of plant	N [b]	ref.
seed plants		
monocotyledons	17	[86–89]
dicotyledons	21	[86–89]
ferns	3	[89]
mosses	5	[83, 86, 89]
red algae	2	[85, 90]
brown algae	2	[85, 90]
green algae	7	[83, 85, 86, 90]

[a] Plant extracts were separated by SDS gel electrophoresis. The proteins were transferred to a suitable membrane (usually nitrocellulose) and treated with cross-reacting monoclonal antibodies. Specific reaction of a protein band in the size range 120–130 kDa was regarded as a positive result. The monoclonal antibodies were directed against phytochrome from oat [85–87, 89, 90], maize [83, 85, 89, 90], rye [88], or pea [86, 88]. Epitopes of the cross-reacting antibodies lie either in the *N*- or *C*-terminal region of the peptide chain for all examples studied so far. [b] Number of species in which phytochrome has been detected to date.

The distribution of phytochrome has been studied with the aid of monoclonal antibodies directed against phytochrome from etiolated oat,[65, 87] maize,[65] rye, or pea,[86, 88] which show a good cross-reaction with phytochrome from other plants (Table 2). Here, too, the higher plants studied showed a generally broad distribution, while many of the lower plants gave a negative result. This need not necessarily imply the absence of phytochrome. If phytochrome is present, however, the peptide chain must be so different from that in phytochrome of higher plants that it contains no epitope recognizable by the antibodies used. Interestingly, phytochrome is present in several algae where no phytochrome-dependent reaction was previously known. For the green alga *Ulva rigida* we subsequently found phytochrome-dependent protein synthesis, probably associated with the phytochrome-regulated uptake and reduction of nitrate.[91, 92]

4. Phytochrome Genes

4.1. Structure of the Phytochrome Genes, Phylogeny

Information about the primary structure of large protein molecules can be obtained most simply by analyzing the genes coding for the corresponding proteins. The *phy*A protein from oat was the first phytochrome molecule whose primary structure was elucidated in this way by the group of *Quail*.[93, 94]

With the information from this fundamental paper, it was now possible to isolate and characterize other phytochrome genes. By heterologous screening, cDNA clones were identified that code for *phy*A in zucchini,[95] maize,[96] and *Arabidopsis thaliana*.[97] With the help of synthetic oligonucleotide primers, *Kay* et al.[98] were able to isolate cDNA clones coding for rice phytochrome. Independently, *Tomizawa* et al.[99] identified a cDNA clone for pea *phy*A in an expression bank by immunoscreening with a specific antibody.

Once again, it was *Quail* and co-workers who were the first to elucidate the primary structure of the light-stable, "green" phytochrome of higher plants. Using a *phy*A DNA probe from zucchini, they screened a cDNA bank constructed from poly(A)$^{\oplus}$-RNA from green *A. thaliana* leaves, at low stringency, and were thus able to isolate the corresponding cDNA clones (*phy*B and *phy*C).[97] Further genes coding for light-stable phytochrome have since been isolated from rice, pea, and tobacco.[100] A fragment of a fourth phytochrome gene from *A. thaliana* (*phy*D) has also been cloned and sequenced.[101, 102]

Recently, *Thümmler* et al.[103a] have for the first time obtained phytochrome sequences (*phy*Cer) from a lower plant, the moss *Ceratodon purpureus*, using the polymerase chain reaction. The Pfr-dependent phototropism of this plant has been well studied.[103b] The oligonucleotide primers used were directed against conserved DNA sequences in the chromophore-binding region of phytochrome genes of higher plants (see Table 3). Since then, a phytochrome cDNA clone has also been isolated from the fern *Selaginella martensii*, by immunoscreening a λgt11-expression bank with the cross-reacting antibody Z3B1, which is directed against maize phytochrome.[104]

The primary structure of the corresponding genes was determined for *phy*A from oat,[107] rice,[98] maize,[96] and pea,[105] and for *phy*Cer from the moss *Ceratodon*.[106, 108] In Figure 10, the organization of these genes is presented

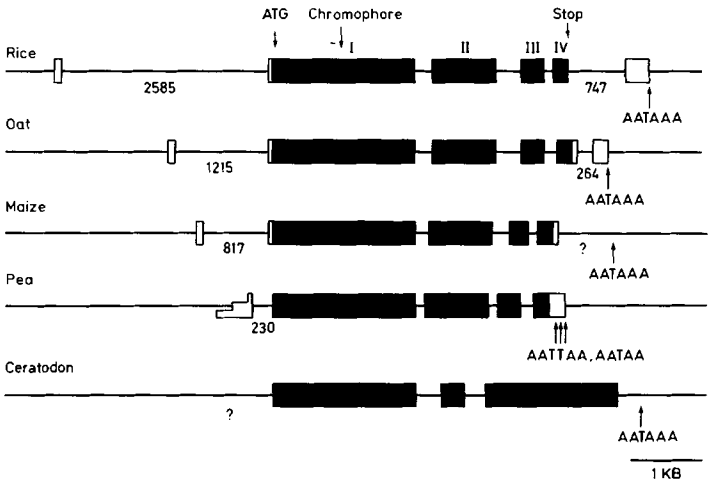

Fig. 10. Comparative schematic diagram of the phytochrome genes of rice, oat, maize, pea, and *C. purpureus*. (—) represents intron and flanking sequences; the numbers indicate the length of the introns in the untranslated exons, in base-pairs (Bp); □ untranslated exon sequences; ■ translated exon sequences I, II, III, IV; references for the corresponding genes: rice [98], oat [107], maize [96], pea [105], and *C. purpureus* [108].

[a] Comparison of pairwise homology was carried out with the FASTA program [119]. Abbreviations: Selag = *S.martensii*, Cerat = *C.purpureus*, Ara = *Arabidopsis thaliana*. [b] The derived polypeptide sequences do not overlap in the correspondig regions. [c] The FASTA program finds no homology between the given amino acid sequences within the prescibed cut-off range. [d] For *phy*D, only a ca. 500 Bp DNA fragment is known, which is located in exon I. [e] The phytochrome gene from *S. martensii* has only been sequenced in the 3'-terminal region, from ca. 130 base pairs after the start of exon II. References for the phytochrome genes: maize [96], pea [105], Ara A,B,C = *A. thaliana phy*A, *phy*B, and *phy*C [97], Ara D = *A. thaliana phyD* [102], Selag = *S. martensii* [104], Cerat = *C. purpureus* [108].

schematically. For zucchini phytochrome, and for the two light-stable phytochrome types *phy*B and *phy*C from *A. thaliana*, only the cDNA sequence is known, while for *S. martensii* only a partial, 3'-terminal cDNA sequence has yet been published.

As Figure 10 shows, the phytochrome genes illustrated consist of several exons interspersed by shorter introns. The oat *phy*A gene, for example, is 5.94 kilobases (KB) long and consists of six exons and five introns. The *phy*A genes also show unusual, long intron sequences in the 5'- and 3'-flanking, untranslated regions of the gene. In rice, the 5'-terminal intron is 2585 base pairs (Bp) in length, and is therefore one of the longest introns yet found in a plant gene. In contrast to the phytochrome genes of monocotyledonous plants, the pea phytochrome gene lacks the 3'-terminal intron entirely and is made up of only five exons and four short introns. For the maize phytochrome gene, the existence of a 3'-terminal gene was not investigated. In the *phy*A genes of rice and oat, the nucleotide sequence at the boundary between exon 5 and intron 5 (5'TCAAATG/gtat3') is conserved, and the existence of this sequence at a corresponding site in the maize phytochrome gene is strong evidence for the presence of the intron in the maize gene as well. The organization of the *phy*Cer gene differs clearly from the pattern of the *phy*A genes. Unlike the latter, the *phy*Cer gene comprises just two large coding exons, on either side of a short, central exon. It is not known whether the 5'- and 3'-flanking, untranslated regions also contain introns in *phy*Cer. The *phy*A genes in oat, maize, rice, and pea contain sequence motifs which are found in the promoter region of many eukaryotic genes, and which play an important role in regulation of their expression. These include a TATA-motif, a CCAAT-motif, and a GC-element.[109] These genes (including the *S. martensii* and

C. purpureus genes) also reveal AATAAA or related motifs in the 3′-untranslated region, which are responsible for polyadenylation of the corresponding transcripts.

Genes for multidomain proteins are, without exception, built up of several exons. The sites corresponding to the exon–intron boundaries often appear to lie at the surface of the protein, and are hence especially sensitive to protease attack.[110] In phytochrome A, coding exon I corresponds to the chromophore-containing, *N*-terminal domain, probably including the "hinge region", so that several "early cleavage sites" (amino acid residues 600–700) fall into this region of the sequence (cf. Fig. 8). Exons II, III, and IV code for the *C*-terminal, chromophore-free domain. Perhaps the preferential proteolytic cleavage of these domains (cf. Section 3.1) is related to the many exon–intron transitions in this region. It is not known whether the 3′-exons code for different functional subdomains in the *C*-terminus of the phytochrome proteins. Interestingly, *Schneider-Poetsch* et al.[111] have found structural homologies to bacterial sensor proteins in the 250-amino acid, *C*-terminal polypeptide part of *Selaginella* phytochrome; in the oat *phy*A gene this part is encoded in the last two exons.

In Table 3, sequence homologies for phytochrome proteins are presented, divided according to the individual exons. Figure 11 shows the amino acid sequences at the exon–intron boundaries. The high amino acid sequence homology at

4.2. Expression of Phytochrome Genes

The expression of many light-regulated genes is modulated by phytochrome.[112] For most of these genes, expression is stimulated by light, but in the case of protochlorophyllide reductase[113] and the *phy*A genes themselves[114, 115, 98] expression is negatively influenced by Pfr. The point of regulatory action is primarily transcription. In the case of monocotyledonous plants such as oat[114, 115] and rice,[98] this negative control is very dramatic, while in maize and dicotyledonous plants it is much less pronounced. In oat or rice, the *phy*A transcription is suppressed within five minutes of Pfr formation, even in the absence of protein synthesis; hence all the necessary factors for the signal transduction must already be present.[115] In *Arabidopsis* the down-regulation of *phy*A–mRNA is only seen in continuous white light,[97] while in oat or rice a short, inductive period of red light suffices.

Compared to monocotyledonous plants, the Pfr-dependent *phy*A expression is complex in dicotyledonous plants. In *Arabidopsis*, gene probes specific to *phy*A hybridize to two *phy*A transcripts of different length, and in pea to three different species. This is caused by the presence of several transcription start sites within the complex *phy*-promoter (see Fig. 10).[105, 116] Transcription from one of these sites is strongly light-dependent, while the others are expressed in a

Fig. 11. Comparison of the amino acid sequences from the known exon–intron boundaries in *phy*A from oat, rice, maize, and pea with the amino acid sequences from the presumed exon–intron boundaries in *phy*A from zucchini and *A. thaliana*, *phy*B and *phy*C from *A. thaliana*, and with phytochrome from *C. purpureus* and *S. martensii*. AS = number of amino acids coded for by exons I, II, III, and IV, or the number of amino acids in the entire phytochrome polypeptide; Bp = length of the corresponding intron in basepairs; references for the phytochrome genes: oat [107], rice [98], maize [96], pea [105], zucc = zucchini [95], Ara A,B,C = *A. thaliana phy*A, *phy*B, and *phy*C [97], Selag = *S. martensii* [104], Cer = *C. purpureus* [108]

the transition from exon to intron suggests that the phytochrome genes of higher plants and of the fern show the exon–intron structure illustrated in Figure 10. In the *Arabidopsis phy*B gene, this has been confirmed for the transition from Exon I to Exon II.[108]

In this context, the phytochrome gene from the moss *Ceratodon* is an exception. As in all other *phy* genes, the transition from Exon I to Exon II is conserved. Exon II, however, which in this region shows high homology to the other phytochromes, breaks off after about 100 amino acids; it is followed by an intron of unknown length (probably 300 Bp). This is followed by a long open reading frame of some 530 amino acids.[108] This presumed protein shows no homology at all to the *C*-terminal peptide sequences of the known phytochrome proteins.

more or less light-independent manner.[97, 105, 116] A further peculiarity of dicotyledonous plants is the unidentified open reading frames (URF's), which are oriented "in frame" to the long reading frame of the phytochrome polypeptides. These URF's also exist in *phy*B and *phy*C of *Arabidopsis*, and their function is unknown.[97, 105] In contrast to *phy*A, *phy*B and *phy*C are only expressed very weakly in *Arabidopsis*, in a practically light-independent manner.[97] It is unclear which phytochrome type controls the expression of *phy*A, but in pea the light-stable phytochrome type is certainly also involved in this effect.[117] Conserved sequence motifs have been found in various *phy*A promoters from higher plants.[112] These motifs presumably play a functional role in the expression of the *phy*A genes and are currently the subject of intensive research.[112, 118]

4.3. Possible Structure–Function Relationships

Since biochemical methods have not yet yielded any detailed knowledge of the function of phytochrome or of the signal transduction sequence leading from it, a few considerations based on the structure of known phytochrome genes are in order. All the known phytochrome genes can be traced back to a common "primeval" phytochrome gene, which at least in the 5'-terminal region displayed a similar structure to that shown in Figure 10. In the chromophore domain (Exon I), all the phytochromes (*phy*A, *phy*B, *phy*C, *phy*D, *phy*Cer) show 50–60% homology to one another (the *phy*A types display 70–90% homology; see Table 3). This shows that the light-regulatory domain of the phytochrome molecule is subject to strong evolutionary pressure. The function of this domain, namely reversible photoconversion by interaction with the tetrapyrrole chromophore, should be the same in all phytochromes.

The similarity in the hydropathy profiles (which are a measure of the hydrophobicity of the individual amino acids along the sequence) of *phy*A, *phy*B, *phy*C, and *Selaginella*-phytochrome[97, 111] also suggests general similarity in the *C*-terminal region. Of the exons coding for the *C*-terminal domain of phytochrome, Exons II and IV are somewhat more highly conserved; Exon III is the most variable. In contrast, the phytochrome from *Ceratodon* is strongly divergent from this group of phytochromes. The lack of obvious homology in the *C*-terminal half of the protein and the divergent gene structure in this region are evidence for a different mode of regulatory function for the phytochrome in moss. However, a related phytochrome type has perhaps not yet been discovered either in higher plants or in ferns.

The existence of many phytochrome-dependent reactions, which include examples as varied as the rapid changes in membrane properties and the complex regulation of gene expression, as well as the occurrence of different phytochrome types suggest that there are different signal transduction chains for a single light stimulus.

Signal transduction in animal cells has been thoroughly studied. Many animal hormone functions depend on the binding of the hormone molecule to hormone receptors in the plasma membrane, which causes an activation of G-proteins. The G-proteins activate enzymes such as the phospholipase C, an effector enzyme of the phosphoinosite cascade, or the adenylate cyclase. This activation finally causes the opening of calcium channels and a temporary increase in the cytosolic calcium concentration, which is, however, immediately decreased again by a calcium/calmodulin-dependent calcium-ATPase to the initial concentration. The transient changes in calcium concentration then coupled to a phosphorylation cascade initiated by calcium-regulated kinases bound to the membrane. The signal chain leads to the corresponding answer of the target cells. An increasing number of indications suggest that analogous signal transduction chains also exist in plant cells. The participation of calcium has been proved for many phytochrome-dependent reactions;[125] thus, for example, the calcium/calmodulin system plays a role in the light-dependent expression of the chlorophyll a/b-binding proteins[122] as well as in the Pfr-dependent chloroplast rotation in the alga *Mougeotia*.[73, 120] Similarly red/far red-dependent phosphorylation processes and changes in the cellular concentrations of phosphatidyl inositols have been observed.[126, 123] Experiments with specific inhibitors and activators suggest that regulatory proteins like G-proteins, calmodulin, phospholipase C, protein kinase C, or adenylate cyclase are also involved in the phytochrome-dependent swelling of wheat protoplasts.[121] A phytochrome-dependent phospholipase C has been found in mosses,[123] and a protein kinase C is suspected to be involved in the protein phosphorylation in oat protoplasts that is dependent on red light.[127] Receptor molecules with tyrosine kinase activity play a central role in growth regulation of animal tissue. The participation of similar signal chains in the transmission of phytochrome-dependent stimulation in plant cells has not yet been studied.

Hormone function in the animal kingdom depends without exception on transmission of signals through membranes. As in plants the activated phytochrome is formed in the target cells themselves, such transmission across membrane barriers is not necessary. Thus applying animal signal paths noncritically to plant cells is extremely problematic. The phytochrome-dependent signal transmission should be considered in the light of intracellular signal transmission. *Schneider-Poetsch* et al. established a homology between *phy*A, *phy*B, *phy*C, and *Selaginella*-phytochrome and bacterial sensor proteins, which is interesting.[111] It implies that signal chains for phytochrome reactions exist that are similar to those for the signal transduction for chemical stimulation in bacteria.[128] There is, however, no experimental evidence for the existence of such signal chains in plants. One indication that the regulation of the gene expression by phytochrome is based on different paths is found in the experiments of *Lam* et al.[129] They showed that cycloplasmatic protein synthesis is essential for the Pfr-dependent expression of the genes for the chlorophyll a/b-binding protein and the genes for the small subunit of ribulose-1,5-biphosphate carboxylase, whereas no protein synthesis is required for the Pfr-dependent inhibition of the expression of protochlorophyllide reductase gene and the *phy*A gene. Hints that different phytochromes may have different functions come from experiments with phytochrome mutants.[124] Continuation and extension of these experiments are especially promising directions for further work.

5. Summary and Outlook

The plant photoreceptor phytochrome has proved a rewarding subject for interdisciplinary research in the fields of chemistry, physics, and biology. For natural product chemists, structure and synthesis of the tetrapyrrole chromophore are at the fore. Whether the interactions with the protein can be simulated by coupling the tetrapyrrole to suitable model structures is still an interesting question. Photochromism and the fixing of certain conformations of the flexible tetrapyrrole can be invoked as important criteria for such interactions. For the biochemist, the defined conformational changes in the protein, induced quite reversibly by specific illumination, are of interest. Phytochrome is a suitable model for studying certain aspects of the folding process in proteins. The discovery of various phytochrome genes and the possibility of reconstituting the chromoprotein from the

apoprotein and the chromophore have raised new questions for spectroscopists and biologists. The recently discovered phytochromes have not yet been studied in detail either spectroscopically or with regard to their specific biological effects. The signal transduction sequence induced by phytochrome is still unknown. The old question of whether phytochrome exerts a single primary effect or undergoes a multitude of direct reactions with other components of the plant cell must be reinvestigated with regard to the various phytochromes.

Without the trusting cooperation of colleagues and the committed efforts of the numerous co-workers who are named as coauthors in the original papers, the authors could never have achieved the results cited. We thank all of those who have taken part in the study of phytochrome. The research was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

The Elucidation of Peroxyl Radical Reactions in Aqueous Solution with the Help of Radiation-Chemical Methods

By Clemens von Sonntag* and Heinz-Peter Schuchmann

Dedicated to Professor Kurt Schaffner on the occasion of his 60th birthday

Whenever free radicals are formed, independent of whether this occurs thermally, is induced by UV or ionizing irradiation, or takes place in redox reactions, they are converted rapidly into the corresponding peroxyl radicals in the presence of oxygen. Peroxyl radical reactions in aqueous environments are observed not only in aquatic systems (e.g., rivers, lakes and oceans) but also in the living cell and to a considerable degree even in the atmosphere (in water droplets). The peroxyl radical chemistry occurring in this medium is often very different from that observed in the gas phase or in organic solvents. In spite of the great importance of these reactions in medicine (for example in anti-cancer irradiation therapy and ischaemia) there have been comparatively few studies of peroxyl reactions in aqueous media. Radiation-chemical techniques such as pulse radiolysis offer the best means for carrying out such studies, so that it is not surprising that the majority of the information available in this area has been obtained with the help of radiation-chemical methods. The radiation chemistry of water can be controlled in such a manner that the main products are $^{\bullet}OH$ radicals (90% yield), which react with substrate molecules to give substrate radicals and in the presence of oxygen to give substrate peroxyl radicals. The experimental conditions can also be varied in such a way that $HO_2^{\bullet}/O_2^{\bullet\ominus}$ radicals can be formed in 100% yield and caused to react with substrates. We therefore have a simple access to these intermediates, which are extremely important in biological systems. A detailed product analysis, supported by kinetic studies carried out with the help of pulse radiolysis, has been used to clarify the chemistry of a series of peroxyl radicals, so that sufficient material is now available to justify a review of the variety of the peroxyl radical reactions studied by means of radiation-chemical methods. A more general survey of the physical properties of the peroxyl radicals and their unimolecular and bimolecular reactions will be followed by a discussion of selected examples of various classes of substance. Because of the great biological importance of radical-induced DNA damage this area will also be treated briefly.

1. Introduction

Peroxyl radicals play an important role in many naturally occurring processes, since almost all free radicals which are formed thermally, photochemically, by ionizing radiation or in the course of oxidation processes react rapidly with oxygen to form the corresponding peroxyl radicals. In addition, many processes which are vital for life as we know it occur in aqueous media, as the living cell consists of ca. 70% water. It is thus particularly surprising that the chemistry of free radical reactions has been studied almost solely under artificial conditions in which oxygen is absent, while that of peroxyl radicals has been studied almost exclusively in organic solvents.[1-3] This became clear to us some years ago when we began to concern ourselves with radical-induced damage to DNA caused by ionizing radiation. The destruction of the cells, which is the required effect in anti-cancer radiation therapy, is intensified by oxygen.[4-8] This means that peroxyl radicals must play a decisive role in those processes occurring in living organisms which are induced by ionizing radiation.

It is becoming ever more clear that some illnesses, even ageing, involve peroxyl radicals.[9] This is true in particular for the effects of ischaemia,[10] where oxygen impoverishment due to blockage of a blood vessel is followed by the development of a high reductive potential as a result of the anaerobic cell metabolism. If the cells are reoxygenated after removal of the blockage, electron transfer leads to the formation of the superoxide radical anion, $O_2^{\bullet\ominus}$, in such a high concentration, physiologically speaking, that the cells are damaged by products formed from it, particularly by the $^{\bullet}OH$ radical; this cell damage involves both the DNA and radical peroxidation of the lipids contained in the cell membranes.[10] $O_2^{\bullet\ominus}$, the smallest of all the peroxyl radicals, also plays a part in inflammatory processes,[10] while it is also an important intermediate in the formation of hypochloric acid, one of the chemical weapons used by the cells of our immune system.[10-12]

Our biological existence is indeed a finely tuned compromise. We need oxygen in order to be able to live, but an increase in its concentration by only a factor of five (pure oxygen rather than air) renders it toxic.[10] Thus animals used for experimental purposes die after a few days in an oxygen atmosphere as a result of peroxyl radical reactions which cannot be compensated for.[13]

Some types of forest damage have also been suggested to be due in part to reactions of $O_2^{\bullet\ominus}$ occurring subsequent to initial damage caused by other agents.[10] The phenolic species found in plant cells, in particular α-tocopherol, act as antioxidants; this is also true for ascorbic acid and glutathione.[10, 14] These antioxidants are also found in animal cells.

Peroxyl radicals also play an important part in environmental processes, which often involve an initial photochemical step or a reaction of an ·OH radical. This applies to atmospheric chemistry,[15] where reactions occurring in an aqueous phase (clouds, fog, precipitation) are the subject of increasing interest.[16, 17] The nitrate photolysis induced in surface waters by the UV component of sunlight, which leads to ·OH radicals as well as other species, can play a role in self-cleansing; the sequence of reactions involved naturally proceeds via peroxyl radicals.[18]

·OH radicals are also formed in the course of ozone treatment of drinking water;[19, 20] they attack organic substances in the water, and are also formed under the influence of ultrasound, the application of which leads to the formation of microscopic bubbles (cavitation). Their collapse leads to intense local heating, temperatures of ca. 4000 K being reached, so that water molecules are split into H· atoms and ·OH radicals.[21, 22]

Attack by ·OH radicals also represents the main source in the radiation-chemical formation of organic radicals, and thus of peroxyl radicals, in aqueous solution. The advantages of the radiation-chemical method for the investigation of peroxyl radicals in comparison with other techniques will be discussed in the following section.

2. Radiation-chemical Formation of Peroxyl Radicals

A conventional method of forming peroxyl radicals in aqueous solution makes use of the Fenton reaction,[23, 24] in which $Fe^{2\oplus}$ or $Ti^{3\oplus}$ ions react with H_2O_2 to give ·OH radicals, which in turn react with substrates RH via H-abstraction or add to C=C double bonds to yield substrate radicals (reaction rates for the ·OH radicals are collected in Ref. [25], and unless otherwise stated are taken from this source). The substrate radicals are converted into peroxyl radicals in the presence of O_2 [reactions (1)–(3)]. This simple reaction,

$$Fe^{2\oplus} + H_2O_2 \longrightarrow Fe^{3\oplus} + {}^{\cdot}OH + OH^{\ominus} \quad (1)$$

$$^{\cdot}OH + RH \longrightarrow H_2O + R^{\cdot} \quad (2)$$

$$R^{\cdot} + O_2 \longrightarrow RO_2^{\cdot} \quad (3)$$

which can be carried out in any laboratory, does however have a number of drawbacks. Product analysis is often complicated, as apart from an excess of the substrate $Fe^{2\oplus}$, $Fe^{3\oplus}$, H_2O_2 and frequently additives such as EDTA are present. More serious is the fact that $Fe^{2\oplus}$, $Fe^{3\oplus}$ and H_2O_2 can react with intermediate radicals and reactive products, often in an unclear manner. ·OH radicals can also react with H_2O_2 to give $HO_2^{\cdot}/O_2^{\cdot\ominus}$ radicals [reaction (4), $k_4 = 10^7\ dm^3\ mol^{-1}\ s^{-1}$], so that larger amounts of the latter may also be present and may in turn interfere in the reaction pathways. Examples are known which show clearly that the products can be very

$$^{\cdot}OH + H_2O_2 \longrightarrow H_2O + HO_2^{\cdot} \quad (4)$$

different depending on whether Fenton's reagent or "cleanly" radiation-chemically produced ·OH radicals are used.[26, 27] A further disadvantage of Fenton's reagent is that kinetic studies can only be carried out in exceptional circumstances.

A clean generation of ·OH is in principle possible via a flash-photolytic cleavage of H_2O_2 [reaction (5)]. The disad-

$$H_2O_2 \xrightarrow{h\nu} 2\ ^{\cdot}OH \quad (5)$$

Clemens von Sonntag, born 1936 in Stuttgart, studied Chemistry in Heidelberg, Vienna, and Karlsruhe, where he was awarded his doctorate for research carried out at the Kernforschungszentrum Karlsruhe. After a spell at the University of Leeds, England, doing postdoctoral work with Professor F. S. Dainton, he returned to Karlsruhe where he took up a post as group leader at the Institut für Strahlenchemie des Kernforschungszentrums. In 1970 he habilitated at the Universität Karlsruhe and was appointed professor in 1977. Since 1970 Clemens von Sonntag has been group leader at the Max-Planck-Institut (MPI) for Kohlenforschung, Abteilung Strahlenchemie, today MPI für Strahlenchemie, Mülheim an der Ruhr. In 1984 he was awarded the Weiss Medal of the Association for Radiation Research for his studies on the radiation chemistry of DNA. His main interests center on the radiation chemistry of biologically relevant compounds and photochemistry, especially in vacuum-UV.

Heinz-Peter Schuchmann, born 1937 in Darmstadt, studied Chemistry in Darmstadt and Ottawa, Canada (doctorate 1970 in Ottawa for research in gas kinetics). Since 1971 he has worked at the Max-Planck-Institut für Strahlenchemie, Mülheim an der Ruhr. His fields of interest include the radiation chemistry of aqueous solutions and photochemistry in the far UV.

vantage of this procedure is that the absorption coefficient of H_2O_2 is very low (e.g., only 20 $dm^3\ mol^{-1}\ cm^{-1}$ at 254 nm); thus the concentration of H_2O_2 must be high in order that a sufficient amount of UV light can be absorbed. This however means that reaction (4) can gain in importance. A further problem is caused by substrates which absorb UV light and thus protect the H_2O_2 against decomposition by acting as an inner filter. If, however, (in the absence of H_2O_2) UV-sensitive substrates are to be used as the source of radicals, the substrate-specific photochemistry is accompanied by further problems caused by laser excitation. In aqueous solution the ionization potential is ca. 3 eV lower than in the gas phase,[28, 29] so that the biphotonic photoionization process becomes very important. The spectra of the radical cations, which often react slowly or not at all with oxygen, can then make the kinetic evaluation of the parallel reactions of the peroxyl radicals more difficult.

The above discussion leads us to expect that the radiation-chemical method of production will in many ways be superior to both the Fenton reaction and the photolytic method. In a typical radiation-chemical experiment[7, 30–34] dilute aqueous solutions of a substrate ([substrate] $\approx 10^{-3}$ mol dm^{-3}) is irradiated with ^{60}Co-γ-radiation or with fast electrons from an electron accelerator. The irradiation energy is almost entirely absorbed by the solvent. In contrast to the radiolysis of organic solvents, water provides only a small number of extremely reactive free radical intermediates, which thus generally react rapidly with substrates. This makes it possible to carry out kinetic studies even in the submicrosecond range (pulse radiolysis). A further advantage of water as a solvent is that it is not attacked by organic radicals. Its radiation chemistry is simple: ionization and electronic excitation lead to the formation of solvated electrons $e_{aq}^{\ominus}$, $^{\bullet}OH$ radicals and $^{\bullet}H$ atoms as the primary radicals[35] [reactions (6)–(10)]. In addition, small amounts of H_2 and H_2O_2 are formed in centers of high radical density (the so-called "spurs") [reactions (11)–(13)]. In the

$$H_2O \xrightarrow[\text{radiation}]{\text{ionizing}} H_2O^{\bullet\oplus} + e^{\ominus} \quad (6)$$

$$H_2O \xrightarrow[\text{radiation}]{\text{ionizing}} H_2O^{*} \quad (7)$$

$$H_2O^{\bullet\oplus} \longrightarrow {}^{\bullet}OH + H^{\oplus} \quad (8)$$

$$e^{\ominus} \xrightarrow{H_2O} e_{aq}^{\ominus} \quad (9)$$

$$H_2O^{*} \longrightarrow H^{\bullet} + {}^{\bullet}OH \quad (10)$$

$$H^{\bullet} + H^{\bullet} \longrightarrow H_2 \quad (11)$$

$$e_{aq}^{\ominus} + e_{aq}^{\ominus} \longrightarrow H_2 + 2\,OH^{\ominus} \quad (12)$$

$$^{\bullet}OH + {}^{\bullet}OH \longrightarrow H_2O_2 \quad (13)$$

$$e_{aq}^{\ominus} + O_2 \longrightarrow O_2^{\bullet\ominus} \quad (14)$$

$$H^{\bullet} + O_2 \longrightarrow HO_2^{\bullet} \quad (15)$$

presence of O_2 the solvated electrons and the $^{\bullet}H$ atoms react rapidly with the former to give $O_2^{\bullet\ominus}/HO_2^{\bullet}$ radicals [reactions (14) and (15), $k_{14} = 1.9 \times 10^{10}$ $dm^3\ mol^{-1}\ s^{-1}$, $k_{15} = 2.1 \times 10^{10}$ $dm^3\ mol^{-1}\ s^{-1}$], which are in equilibrium [$pK_a(HO_2^{\bullet}) = 4.8$].[36]

The $^{\bullet}OH$ radicals do not react with O_2 but normally with added organic substrates, as indicated above. The reaction of the $H^{\bullet}$ atoms and in many cases also of the solvated electrons with organic substrates is slower (see Ref. [25]). Thus, in oxygen-saturated solutions the reactions (14) and (15) lead to approximately equal amounts of organic peroxyl radicals and $HO_2^{\bullet}/O_2^{\bullet\ominus}$ radicals. This high proportion of $HO_2^{\bullet}/O_2^{\bullet\ominus}$ radicals is advantageous when the reactions of $RO_2^{\bullet}$ radicals with $HO_2^{\bullet}/O_2^{\bullet\ominus}$ are to be studied, although this is not normally the primary subject of interest. When the solvated electrons are to be converted into $^{\bullet}OH$ radicals their

$$e_{aq}^{\ominus} + N_2O \longrightarrow {}^{\bullet}OH + N_2 + OH^{\ominus} \quad (16)$$

rapid reaction with N_2O can utilized [reaction (16), $k_{16} = 9.8 \times 10^9$ $dm^3\ mol^{-1}\ s^{-1}$]. Because of the much higher solubility of N_2O (2.4×10^{-2} mol dm^{-3} at 1 atm) compared to O_2 (1.3×10^{-3} mol dm^{-3}) the conversion of $e_{aq}^{\ominus}$ into $^{\bullet}OH$ radicals is almost complete when a 4:1 mixture of these gases is used, and reaction (14) can be neglected. Thus, the system now consists of ca. 90% $^{\bullet}OH$ radicals and ca. 10% $HO_2^{\bullet}/O_2^{\bullet\ominus}$ radicals.

It will be shown (Section 5.1) that a series of peroxyl radicals eliminate $HO_2^{\bullet}/O_2^{\bullet\ominus}$. This elimination is fast and quantitative in the case of the reaction of the $CO_2^{\bullet\ominus}$ radical with O_2, so that the system formate/N_2O/O_2 provides a source of 100% $HO_2^{\bullet}/O_2^{\bullet\ominus}$ radicals [reactions (17) and (18)].[37] The

$$HCO_2^{\ominus} + {}^{\bullet}OH \longrightarrow CO_2^{\bullet\ominus} + H_2O \quad (17)$$

$$CO_2^{\bullet\ominus} + O_2 \longrightarrow CO_2 + O_2^{\bullet\ominus} \quad (18)$$

$HO_2^{\bullet}/O_2^{\bullet\ominus}$ radicals thus produced can be caused to react with organic and inorganic substrates in an unambiguous manner when suitable experimental conditions are used. $HO_2^{\bullet}/O_2^{\bullet\ominus}$ radicals are prepared conventionally by enzymatic action of xanthine oxidase on xanthine in the presence of oxygen.[38, 39] In this system other reactive species are formed apart from $HO_2^{\bullet}/O_2^{\bullet\ominus}$. The nature of these is much less well understood than that of the radiation-chemical system; thus use of the xanthine/xanthine oxidase system can under certain conditions simulate a nonexistent high $HO_2^{\bullet}/O_2^{\bullet\ominus}$ reactivity (cf. Ref. [40] with Ref. [41, 42]).

The G-values[**] of the primary radicals are well known ($G(^{\bullet}OH) = 2.9 \times 10^7$ mol J^{-1}; $G(e_{aq}^{\ominus}) = 2.9 \times 10^{-7}$ mol J^{-1}; $G(H^{\bullet}) = 0.6 \times 10^{-7}$ mol J^{-1}; $G(H_2) = 0.45 \times 10^7$ mol J^{-1}; $G(H_2O_2) = 0.8 \times 10^{-7}$ mol J^{-1}). The dose rate [unit of dose: 1 Gray (Gy) = 1 J kg^{-1}] of a radiation source can be determined very simply and rapidly[30] (in the case of a ^{60}Co-γ source this must in principle be done only once, since the decay constant of the nuclide is known). Since the yields of primary radicals, and thus also of primarily formed peroxyl radicals, are known from the dose rate and the irradiation time, it is possible to obtain a material balance subsequent to product analysis. Apart from the formation of the products the oxygen consumption can also be measured. The data thus obtained provide important information: a) when in an

[**] The G value is a measure of the radiation-chemical yield. It was originally defined as the number of molecules formed (consumed) per 100 eV absorbed energy. Since the eV is a non-SI unit, the G value is now given in units of mol J^{-1}. In the older literature the G values are always given in units of molecules/100 eV, but in this review the new SI units will be used.

N_2O/O_2-saturated solution (taking the stoichiometry into account) G(products) is lower than the G value of their primary radical precursors [$G(^{\bullet}OH + H^{\bullet}) \approx 6 \times 10^{-7}$ mol J^{-1}], it is clear that not all the products have been accounted for; b) when the value of G(products) is considerably greater than this value a free-radical chain reaction is involved.

The pulse radiolysis method makes it possible to impart the irradiation energy within less than 1 μs. The reactions (2), (3) and (5)–(15) leading to the peroxyl radicals are often nearly diffusion-controlled ($k \geq 10^9$ dm^3 mol^{-1} s^{-1}), so that at oxygen concentrations of $\geq 10^{-4}$ mol dm^{-3} the organic peroxyl radicals are formed within 2–3 microseconds. Several methods are available for following the kinetics of the subsequent peroxyl radical reactions. In some cases UV/VIS spectroscopy can be used; however, peroxyl radicals generally do not have particularly characteristic absorption spectra but typically exhibit only broad absorptions at $\lambda < 300$ nm.[43] The products formed from them may in some cases show characteristic spectra.

Many peroxyl radicals are uncharged but are converted into charged particles by unimolecular and bimolecular processes; thus for example the elimination of $HO_2^{\bullet}$ leads to $H^{\oplus}$ and $O_2^{\bullet\ominus}$. Since these reactions involve a conductivity change they can be followed by conductometric methods. The range of measurement lies between the submicrosecond and the minute domains, i.e. more than eight powers of ten on the time scale.[44] The conductivity signal at weakly acidic pH is positive when acids are formed (increase in conductivity because of additional $H^{\oplus} + A^{\ominus}$) but negative in alkaline solution (replacement of $OH^{\ominus}$ by $A^{\ominus}$ because of the neutralization of $OH^{\ominus}$ by $H^{\oplus}$; the equivalent conductivity of $OH^{\ominus}$, $\lambda^0(OH^{\ominus}) = 180$ dm^3 val^{-1} Ω^{-1} cm^{-1}, is greater than that of other monoanions, $\lambda^0(A^{\ominus}) = 40$–$60$ dm^3 val^{-1} Ω^{-1} cm^{-1}). The increase in conductivity is reduced parallel to the suppression of the dissociation when the pH of the solution falls below the pK_a of the intermediate.

Studies of polymers in solution can be carried out when the pulse radiolysis apparatus is combined with a light-scattering measurement device[45] (if possible a low-angle laser light-scattering apparatus[46, 47]) in order to carry out a kinetic resolution of the peroxyl radical-induced change (lowering) of the molecular weight. In the case of charged polymers, e.g. polynucleotides, single-stranded DNA or hyaluronic acid the formation of breaks in the strand can also be followed by the change in the conductivity.[48] Because of the high charge density a large proportion of the counterions are condensed on the polyanionic species and play no part in determining the conductivity. When strand cleavage occurs the charge density in the neighborhood of the break is lowered and counterions are set free. When, for example, the counterion is $Na^{\oplus}$, the formation of breaks leads to an increase in conductivity in both acidic and basic solutions (in contrast to the formation of an acid).

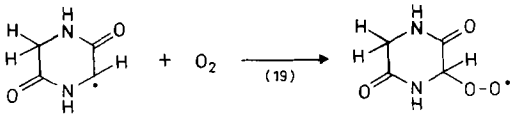
The radiation-chemical techniques thus provide us with two complementary tools: a quantitative product analysis and a good set of kinetic data. The use of ^{60}Co-γ radiolysis (and, in a completely different dose rate range, of pulse radiolysis) permits the variation of the dose rate by several orders of magnitude. This is important for studies of chain reactions, and can also provide information on whether particular radicals undergo reactions which are first or second order (in radicals) and which products are formed in the various reaction pathways. The influence of the temperature on the reactions can be studied relatively easily across the temperature range 0–80 °C, while the use of pressure cells allows us to work at higher temperatures;[49, 50] however, this latter possibility has so far been used only rarely.

Having discussed the advantages of the radiation-chemical methods for the study of peroxyl radical reactions, we must now turn to their limitations. Such studies are in general restricted to dilute solutions (typically $\leq 10^{-3}$ mol dm^{-3}), since only under these conditions can we be sure that a conversion of the solvated electrons subsequent to saturation with N_2O into $^{\bullet}OH$ radicals or with O_2 into $O_2^{\bullet\ominus}$ is quantitative. At higher concentrations reactions of the electrons with the substrates are often observed. In addition, at substrate concentrations above 0.1 mol dm^{-3} a *direct* absorption of the ionizing radiation by the substrate is detectable (approximately in proportion to its weight percentage), while in the molar concentration range the formation of products from this source becomes so important that it is no longer possible to obtain a clear interpretation of the data. This, however, means that important processes that can only be reliably measured at substrate concentrations in the molar range (i.e., at concentrations higher by a factor of 1000) because of their low rate constants cannot be studied using radiation-chemical methods or can be studied only in a limited manner. Such processes include the extensive and important area of autoxidation reactions (H transfer reactions and intermolecular addition of peroxyl radicals to double bonds). This subject will thus be referred to only occasionally in the present account. Reactions which occur subsequently to oxidation processes will also not be discussed, as radiation-chemical methods have (until now) not been used to study them. This article is intended to make the reader familiar with the possibilities offered by radiation-chemical methods and with the results obtained so far. A general acount of the chemistry of peroxyl radicals would exceed the scope of the present report.

3. Peroxyl Radicals: Formation and Properties

3.1. Formation of Peroxyl Radicals and the Reversibility of the O_2 Addition

Radicals formed via an attack by $^{\bullet}OH$ radicals often have high absorption coefficients in the UV-visible range, while the peroxyl radicals formed from them absorb only slightly or not at all in this wavelength range.[43] The radical **1** formed from glycine anhydride is a typical example, being formed in virtually quantitative yield in the reaction between an $^{\bullet}OH$ radical and glycine anhydride (see also Section 6.3);



1 **2**

its spectrum shows clear maxima at 270 and 360 nm (Fig. 1). The peroxyl radical **2** formed in reaction (19) shows practically no absorption in this range. If the observed first order rate constant for the decomposition of the radical **1** is plotted as a function of the oxygen concentration the result is a straight line (insert in Fig. 1), the slope of which gives the bimolecular rate constant ($k_{19} = 2 \times 10^9$ dm^3 mol^{-1} s^{-1}).[51]

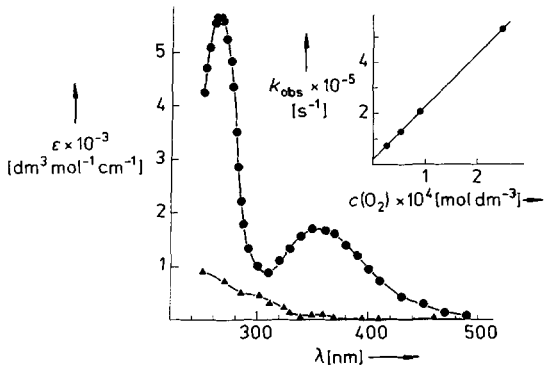


Fig. 1. Pulse radiolysis of glycine anhydride in aqueous solution [51] (10^{-3} mol dm^{-3}, pH 6.5). (●) UV/VIS spectrum of the glycine anhydride radical **1** 6.5 μs after the pulse (N_2O-saturation). (△) spectrum of the glycine anhydride peroxyl radical **2** 15 μs after the pulse (N_2O/O_2-(4:1)-saturation). *Inset:* observed rate constant k_{19} of the disappearance of **1** as a function of the oxygen concentration measured at 360 nm.

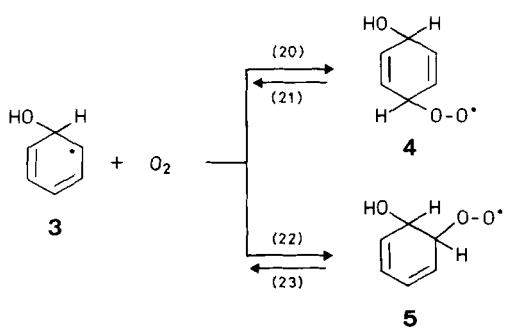
Experiments of this type have provided rate constants for reactions of a large variety of radicals with O_2 (a survey can be found in Ref. [43]). These rate constants often lie close to 2×10^9 dm^3 mol^{-1} s^{-1}, i.e., the reaction is virtually diffusion-controlled, and the formation of peroxyl radicals is practically irreversible.[52] There are however also cases in which the formation of the peroxyl radicals is noticeably reversible even at room temperature.[53] Such a reversibility in the gas phase has long been discussed for the hydroxycyclohexadienyl radical **3** which is formed from benzene and ·OH radicals,[15] and has also been demonstrated recently for aqueous solutions.[54]

The spectrum of the radical **3** is shown in Figure 2 (right-hand scale), and shows a clear maximum at 310 nm. This absorption disappears rapidly in the presence of O_2 ($k_{20/22} = 3.1 \times 10^8$ dm^3 mol^{-1} s^{-1}), though it does not disappear completely. A residual absorption dependent on the oxygen concentration is approached at ca. 30 μs; afterwards this disappears only very slowly (Fig. 2). A kinetic evaluation gives a value of $k_{21/23} = 1.2 \times 10^4$ s^{-1} for the back reac-



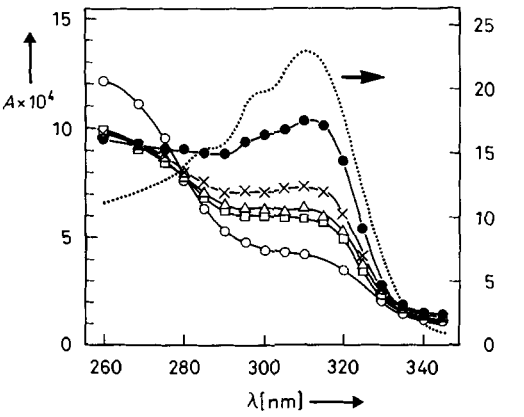


Fig. 2. Pulse radiolysis of benzene in aqueous solution [54] (2×10^{-3} mol dm^{-3}). Right-hand scale: (...) absorption 2 μs after the pulse (N_2-saturation). Left-hand scale: (●) 10 μs, (×) 20 μs, (△) 30 μs, (□) 40 μs and (○) 170 μs after the pulse (N_2O/O_2-4:1-saturation).

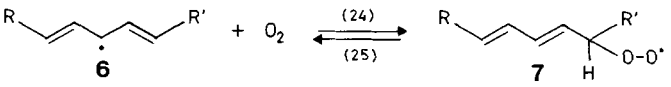
tion. There are clear indications that the peroxyl radical with the 1,4-cyclohexadiene structure **4** is dominant and that only a small amount of **5** is present in the equilibrium mixture.[54] This is surprising, since in the case of the open-chain pentadienyl radicals **6** formed from unsaturated fatty acids, which are also in equilibrium with their peroxyl radicals in the presence of O_2 [reactions (24) and (25)],[55, 56] conjugation of the double bonds is observed: thus the peroxyl radical **7** is formed preferentially and nonterminal peroxyl radicals with isolated double bonds appear to be of no importance.[57]



When a hydroxycyclohexadienyl radical contains a strongly electron-attracting group (as for example in the case of the adduct between benzonitrile and an ·OH radical) it is no longer possible to detect the formation of peroxyl radicals, perhaps because of a high rate of the back reaction.[58]

Further examples of oxygen addition which is reversible at room temperature are provided by benzyl[59] and thiyl radicals.[60] In the case of less strongly labilized peroxyl radicals, such as the allylperoxyl radical[61] or the trichloromethylperoxyl radical[62] (in the gas phase) the equilibrium becomes measurable only at higher temperatures.

3.2. Taft Constant σ^*, Dipole Moment and Spin Distribution of the Peroxyl Radical Group

The charge state of an —OH or —NHR group at a position next to the peroxyl radical function is of great importance in aqueous solution, since it has a considerable influence on the rate of the $HO_2^{\cdot}/O_2^{\cdot\ominus}$ elimination (see Section 5.1). The acidity (pK_a value) of these neighboring groups can be calculated for a large number of peroxyl radicals on the basis of increments if the Taft constant σ^* of the peroxyl radical group is known.[63] This constant was measured for the acetic acid system by means of pulse radiolysis; it could

be shown that the pK_a value of the peroxyl radical derived from acetic acid is 2.1 [equilibrium (28/29)],[64] i.e., considerably lower than that of acetic acid itself ([equilibrium (26/27)], $pK_a = 4.8$). The σ^* value for $-CH_2O_2^\bullet$ calculated from

$$CH_3CO_2H \underset{(27)}{\overset{(26)}{\rightleftharpoons}} CH_3CO_2^\ominus + H^\oplus \qquad pK_a = 4.8$$

$$^\bullet O_2CH_2CO_2H \underset{(29)}{\overset{(28)}{\rightleftharpoons}} {}^\bullet O_2CH_2CO_2^\ominus + H^\oplus \qquad pK_a = 2.1$$

these figures is 1.55, which is higher than the σ^* values for $-CH_2F$ (1.10) and $-CH_2CN$ (1.30). The peroxyl radical group is thus a strongly electron-attracting group. A σ^* value of 1.55 for $-CH_2O_2^\bullet$ corresponds to a σ^* value of 3.88 for the $^\bullet O_2$ increment. The pK_a values calculated for the peroxyl radicals derived from malonic acid and glycine anhydride using this increment do indeed agree well with the experimental values.[65]

As expected on the basis of the high σ^* value of the $^\bullet O_2CH_2$ group the alkylperoxyl radicals have a large dipole moment;[66] a value of 2.6 Debye has been estimated.[67]

No data from experiments in aqueous solution are available which would give us information on the spin distribution in peroxyl radicals; it is however known from other measurements that the spin density is not concentrated on the terminal oxygen atom but that a considerable spin density is found at the internal oxygen atom.[67-70] This is also the case for thiylperoxyl radicals $RSOO^\bullet$.[71]

3.3. Redox and Hydrogen Transfer Reactions of Peroxyl Radicals

Peroxyl radicals generally possess oxidizing properties. They thus react rapidly with good electron donors such as *N,N,N',N'*-tetramethylphenylenediamine (TMPD) or ascorbic acid via electron transfer [e.g., reaction (30)].[43, 72-79] Electron-attracting substituents at the peroxyl radical accelerate the electron transfer, so that $CCl_3O_2^\bullet$,[79] and $CH_3C(O)O_2^\bullet$.[77] are reduced by TMPD in a practically diffusion-controlled manner. The redox potential of the $CH_3O_2^\bullet$

$$RO_2^\bullet + TMPD \longrightarrow RO_2^\ominus + TMPD^{\bullet\oplus} \qquad (30)$$

radical has been estimated to be 0.6–0.7 V; $CCl_3O_2^\bullet$ must have a redox potential which is above 1.0 V.[75] The living cell contains two important antioxidants, the C and E vitamins. The rather unreactive radicals formed from these by oxidation have much lower redox potentials (0.28 and 0.48 V respectively[76]) than the peroxyl radicals, so that the latter can be deactivated by the two vitamins. While vitamin C is found in the aqueous phase, vitamin E is localized in the lipid phase. The concentration of vitamin E in the cell is generally much lower than that of vitamin C (in liver cells 2×10^{-5} mol dm^{-3} compared with 2×10^{-3} mol dm^{-3}).

The phenoxyl radical of vitamin E formed by attack of peroxyl radicals is rapidly repaired in vitro by vitamin C ($k = 1.6 \times 10^6$ dm^3 mol^{-1} s^{-1}),[80] and it had thus always been assumed that the latter would also have a protecting effect on vitamin E in vivo. Surprisingly, however, this is not the case.[81].

Halogenated peroxyl radicals react with dimethyl sulfide via electron transfer,[82] but in addition considerable amounts of dimethyl sulfoxide are also formed [reaction (31)].[83] The ROO–H bond energy (ΔH(HOO–H) = 376 ± 5 kJ mol^{-1}[84])

$$R(Hal)COO^\bullet + (CH_3)_2S \longrightarrow R(Hal)CO^\bullet + (CH_3)_2SO \qquad (31)$$

is comparable with the C–H bond energy of compounds which have only weakly bonded hydrogen atoms. For this reason peroxyl radicals can undergo hydrogen abstraction reactions [reaction (32)]. This reaction is one of the steps in

$$RO_2^\bullet + RH \longrightarrow RO_2H + R^\bullet \qquad (32)$$

the well-known chain reactions which play an important part in the autoxidation of, for example, unsaturated fatty acids[55] and ethers.[85, 86]. The increase of the chain length with increasing temperature is due to acceleration of reaction (32). Almost no data have been published for aqueous systems. This is understandable, since reaction (32) is in general slow and concentrations in the molar range are necessary for a proper kinetic analysis; such concentrations are three orders of magnitude greater than those used for typical radiation-chemical studies in aqueous solution. A comparison with data from experiments in organic solvents (hydrogen donors) is thus not possible; however, the data in Ref. [87] allow us to estimate an activation energy of ca. 55 kJ mol^{-1} for the 2-methyltetrahydrofuran system. Similar activation energies were found in organic solvents for a series of readily oxidizable compounds;[88] however, the kinetic parameters depend on the polarity of the medium because of the highly polar structure of the peroxyl radicals[57] and thus cannot simply be transferred uncritically from the organic phase to aqueous solutions.

The $HO_2^\bullet/O_2^{\bullet\ominus}$ radicals occupy a special place within the family of peroxyl radicals, since they have not only oxidizing properties but also, in the case of $O_2^{\bullet\ominus}$ in particular, reducing ones. Their reactions in aqueous solutions will be discussed in the next section. A comparison with the radical chemistry of $O_2^{\bullet\ominus}$ in organic solvents, which is different from that in aqueous media[89-91] cannot be treated here for lack of space.

4. The $HO_2^\bullet/O_2^{\bullet\ominus}$ System, a Special Case

There are hardly any peroxyl radical systems in aqueous solution in which $HO_2^\bullet/O_2^{\bullet\ominus}$ radicals do not play a part, since many peroxyl radicals decompose unimolecularly with formation of $HO_2^\bullet/O_2^{\bullet\ominus}$, or the latter are formed by bimolecular reactions of the peroxyl radicals. Thus, before the reactions of organic peroxyl radicals are covered it is necessary to discuss the properties of $HO_2^\bullet/O_2^{\bullet\ominus}$. A recently published review article surveys this area in detail;[92] here we shall only emphasize some important aspects and refer to some facts not mentioned in that article.

The hydroperoxyl radical $HO_2^\bullet$ has a pK_a value of 4.8 [reactions (33/34)] (the best value,[36] based on a series of radiation-chemical studies.[93-98]). Thus, the superoxide radical $O_2^\bullet$ predominates in neutral solution.

$$HO_2^{\bullet} \underset{(34)}{\overset{(33)}{\rightleftharpoons}} O_2^{\bullet\ominus} + H^{\oplus} \quad pK_a = 4.8$$

$O_2^{\bullet\ominus}$ absorbs much more strongly in the UV ($\lambda_{max} = 243$ nm; $\varepsilon = 2350\ dm^3\ mol^{-1}\ cm^{-1}$) than does $HO_2^{\bullet}$ ($\lambda_{max} = 228$ nm; $\varepsilon = 1400\ dm^3\ mol^{-1}\ cm^{-1}$); this difference can be put to use for the detection of $HO_2^{\bullet}/O_2^{\bullet\ominus}$, for example by following the pH-dependence of the absorption at 260 nm.[36, 92]

The $HO_2^{\bullet}$ radical is an acid, so that its formation can be followed in weakly acid media (pH > 4.8, the pK_a of $HO_2^{\bullet}$) by measuring the increase in conductivity, in alkaline solution, by following the decrease in conductivity. Since these conductivity changes are only observed for short periods of time because of the bimolecular termination of $HO_2^{\bullet}/O_2^{\bullet\ominus}$ they must be followed by the pulse radiolysis technique; an example is shown in Figure 3.

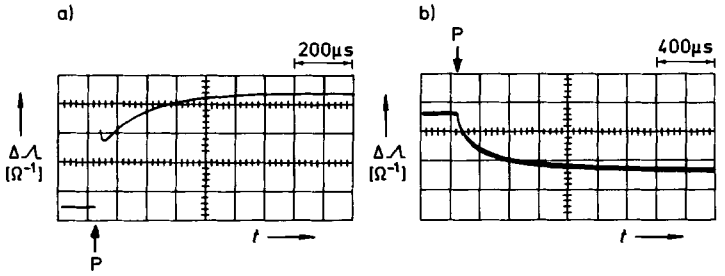


Fig. 3. Pulse radiolysis of diethyl ether in aqueous solution; diagram from Ref. [149] (10^{-3} mol dm^{-3}, N_2O/O_2-(4:1)-saturation). Conductivity change $\Delta\Lambda$ as a function of time. A: pH 6.5, dose 15 Gy, 100 µs/division. B: ph 9.8, dose 10 Gy, 200 µs/division.

This bimolecular termination involves a disproportionation of $HO_2^{\bullet}$ and $O_2^{\bullet\ominus}$ to give hydrogen peroxide and oxygen [reactions (35) and (36); $k_{35} = 8.6 \times 10^5\ dm^3\ mol^{-1}\ s^{-1}$; $k_{36} = 1.0 \times 10^8\ dm^3\ mol^{-1} s^{-1}$]. No reaction (37) between two $O_2^{\bullet\ominus}$ radicals is observed, so that such a reaction must be slower than $0.35\ dm^3\ mol^{-1}\ s^{-1}$.[36] The rate constant of

$$HO_2^{\bullet} + HO_2^{\bullet} \longrightarrow H_2O_2 + O_2 \quad (35)$$
$$HO_2^{\bullet} + O_2^{\bullet\ominus} \longrightarrow HO_2^{\ominus} + O_2 \quad (36)$$
$$2\,O_2^{\bullet\ominus} \longrightarrow O_2^{2\ominus} + O_2 \quad (37)$$

bimolecular disproportionation of the $HO_2^{\bullet}/O_2^{\bullet\ominus}$ radicals is plotted in Figure 4 in logarithmic units against the pH value. Under strongly acid conditions the reaction is controlled by the $HO_2^{\bullet}$ radical. As long as this is virtually the only species present, the observed rate constant (k_{obs}) has the value of

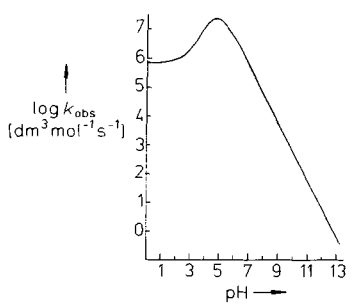

Fig. 4. Observed rate constant (second order) of the decay of $HO_2^{\bullet}/O_2^{\bullet\ominus}$ as a function of pH (after Ref. [36]).

k_{35}. Reaction (36) becomes more important as the pH increases, and k_{obs} also increases. The large linear decrease at high pH reflects the fact that $O_2^{\bullet\ominus}$, which is now dominant, can only react with the $HO_2^{\bullet}$ radicals which are present in ever decreasing quantities in the equilibrium mixture. If a reaction between two $O_2^{\bullet\ominus}$ radicals (37) were of importance then a plateau would be observed at high pH values, as is the case in strongly acid conditions for the disproportionation of two $HO_2^{\bullet}$ radicals.

The question whether singlet oxygen is formed in the disproportionation of $HO_2^{\bullet}/O_2^{\bullet\ominus}$ radicals (e.g., Ref. [99]; a survey given in Ref. [100]) must, according to recent results,[101, 102] be answered in the negative.

In contrast to organic peroxyl radicals, which have only oxidizing properties, the $HO_2^{\bullet}/O_2^{\bullet\ominus}$ radical can both be reduced to hydrogen peroxide and oxidized to oxygen. Tetranitromethane is rapidly reduced by $O_2^{\bullet\ominus}$ to the nitroform anion [reaction (38); $k_{38} = 1.9 \times 10^9\ dm^3\ mol^{-1}\ s^{-1}$], while the reaction of the $HO_2^{\bullet}$ radical is slower by more than five orders of magnitude.[103]

$$O_2^{\bullet\ominus} + C(NO_2)_4 \longrightarrow O_2 + C(NO_2)_3^{\ominus} + NO_2^{\bullet} \quad (38)$$

Since $O_2^{\bullet\ominus}$ is the only peroxyl radical which can reduce tetranitromethane, reaction (38) provides us with a clear proof of the existence of $O_2^{\bullet\ominus}$ in pure peroxyl radical systems (i.e., when no other reducing radicals are present). The nitroform anion is stable and absorbs strongly at 350 nm (ε(350 nm) = $15000\ dm^3\ mol^{-1}\ cm^{-1}$[104]), a wavelength at which peroxyl radicals normally absorb hardly at all. Thus, reaction (38) is suitable for the quantitative determination of $O_2^{\bullet\ominus}$ both in pulse-radiolytic experiments and during continuous γ-irradiation.

The $O_2^{\bullet\ominus}$ radical makes its reducing properties felt in its reactions with other peroxyl radicals, with which it reacts via electron transfer to give hydroperoxides [reaction (39)]. The

$$RO_2^{\bullet} + O_2^{\bullet\ominus} + H^{\oplus} \longrightarrow RO_2H + O_2 \quad (39)$$

rate constant of this reaction depends strongly on the redox potential of the peroxyl radical. The strongly oxidizing acetylperoxyl radical reacts at a rate of $10^9\ dm^3\ mol^{-1}\ s^{-1}$,[77] for the $HO_2^{\bullet}$ radical the rate is $10^8\ dm^3\ mol^{-1}\ s^{-1}$ [reaction (36)], while for the more weakly oxidizing α-hydroxyethylperoxyl radical the rate was estimated to be only $10^7\ dm^3\ mol^{-1}\ s^{-1}$.[105]

Ozone reacts with $O_2^{\bullet\ominus}$ according to reaction (40) via electron transfer to give $^{\bullet}OH$ radicals;[106, 107] this reaction plays a very important role in the purification of drinking water by ozone.[20] The self-exchange reaction (41) of $O_2^{\bullet\ominus}$ is also an

$$O_3 + O_2^{\bullet\ominus} + H_2O \longrightarrow {}^{\bullet}OH + 2\,O_2 + OH^{\ominus} \quad (40)$$

electron transfer reaction. An attempt to estimate its rate using available data and the Marcus theory led to an uncertainty of almost 14 orders of magnitude (10^{-8}–$10^{5.7}\ dm^3\ mol^{-1}\ s^{-1}$).[108] Radiation-chemical techniques have recent-

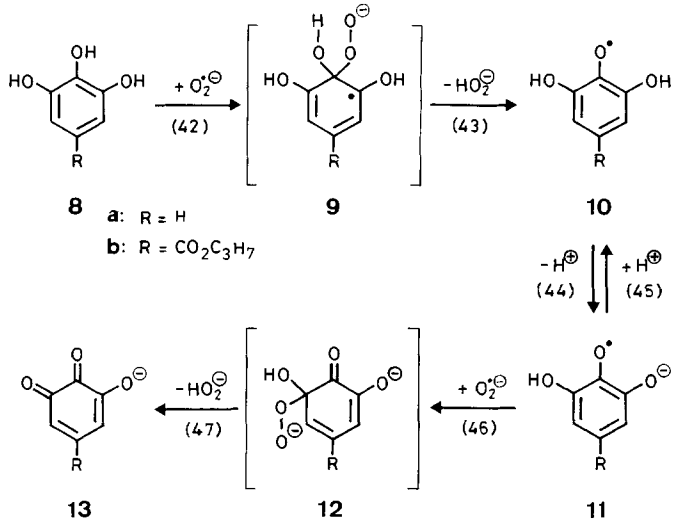
ly been used to determine this value more exactly, the result being $450 \pm 160\,dm^3\,mol^{-1}\,s^{-1}$.[109]

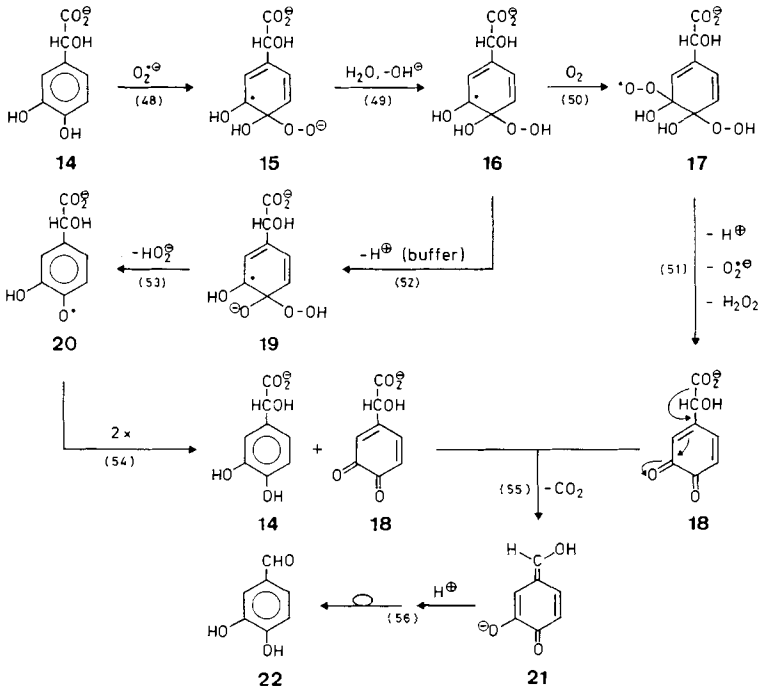
$$O_2^{\bullet\ominus} + O_2 \longrightarrow O_2 + O_2^{\bullet\ominus} \quad (41)$$

In contrast to $O_2^{\bullet\ominus}$, which undergoes no hydrogen abstraction reactions,[87,91,110] the $HO_2^{\bullet}$ radical behaves like a "normal" peroxyl radical. For example, it reacts with linoleic acid[110] to give radicals of the pentadienyl type ($k \approx 300\,dm^3\,mol^{-1}\,s^{-1}$) with a rate constant very similar to that found for 1,4-cyclohexadiene in acetonitrile ($k = 160\,dm^3\,mol^{-1}\,s^{-1}$).[111]

It is thus particularly surprising that $O_2^{\bullet\ominus}$ reacts relatively rapidly with phenolic antioxidants such as pyrogallol **8a** or the propyl ester of gallic acid **8b** ($k = 3.4 \times 10^5$ and $2.6 \times 10^5\,dm^3\,mol^{-1}\,s^{-1}$ respectively) to give the phenoxyl radicals **10** and **11**.[112] For energetic reasons[113–115] the latter cannot be formed via a hydrogen transfer reaction. It must be assumed that $O_2^{\bullet\ominus}$ adds to the benzene ring and that the adduct radical **9** splits off $HO_2^{\ominus}$ or H_2O_2 subsequent to protonation at the peroxyl function [reactions (42) and (43)]. Moreover, the $HO_2^{\bullet}$ radical reacts much more slowly with such phenolic antioxidants.[112] This observation supports the suggested mechanism, since the $HO_2^{\bullet}$ radical should be the more reactive in a hydrogen transfer reaction. Furthermore $O_2^{\bullet\ominus}$ is also able to oxidize the phenoxyl radical **11** (probably via **12**) to the quinone **13** [reactions (46) and (47)].

Phenols which contain two rather than three OH groups react noticeably slower with $O_2^{\bullet\ominus}$. Thus, for example, the rate constant k for catechol was found to be $< 8 \times 10^4\,dm^3\,mol^{-1}\,s^{-1}$.[112] The oxidation of 3,4-dihydroxymandelic acid **14** by $O_2^{\bullet\ominus}$ leads via decarboxylation to 3,4-dihydroxybenzaldehyde **22**.[116] In this case again, the initial step is presumably an addition of $O_2^{\bullet\ominus}$ [reaction (48)]. The adduct radical **16** must have a high pK_a value, and **15** will thus undergo rapid protonation of the peroxylate function [reaction (49)]. At high oxygen concentration (i.e., in O_2-saturated solution) **16** will be converted into the peroxyl radical **17**; this type of peroxyl radical rapidly splits off $HO_2^{\bullet}$. Loss of H_2O_2 then gives the quinone **18** [reactions (50) and (51)]. $O_2^{\bullet\ominus}$ is reformed, and a chain reaction occurs. In competition with reaction (50) **16** can split off H_2O_2 (via **19**) to give the phenoxyl radical **20** [reactions (52) and (53)]. This does not react with O_2, but disproportionates with a second radical to give 3,4-dihydroxymandelic acid **14** and its quinone **18** [reaction (54)]. The latter can now undergo decarboxylation and forms the final product 3,4-dihydroxybenzaldehyde **22** via the enol **21**. The reation steps from **20** to **22** were established by means of pulse radiolysis.[117] The reaction scheme makes clear that at the stage of intermediate **16** a branching occurs, which allows a chain reaction via reaction (50). Reaction (52) does not lead to a chain reaction; it can be accelerated by the





addition of a borate buffer to such an extent that the chain reaction is suppressed.

Adrenalin belongs to the same class of compounds, so that it is not surprising that $O_2^{\bullet\ominus}$ also causes its oxidation.[116, 118]

A remarkable process is the cleavage of the ketomalonate anion **23** by $O_2^{\bullet\ominus}$ to give CO_2 and monoperoxalic acid **25**.[119] The dependence of $G(CO_2)$ on the reciprocal square root of the dose rate shown in Figure 5 (left) and the dependence on the concentration of ketomalonic acid (right) [$G(CO_2) > 200 \times 10^{-7}$ mol J^{-1} can be achieved!] are good indications for the occurrence of a chain reaction.

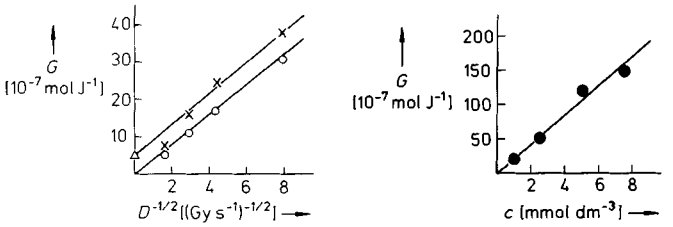


Fig. 5. γ-Radiolysis of ketomalonate [119] (10^{-3} mol dm^{-3}) in the presence of sodium formate (10^{-2} mol dm^{-3}) in aqueous solution (pH 10, N_2O/O_2-4:1-saturation). G Values of CO_2 (×) and monoperoxalic acid (o) as a function of (dose rate)$^{-1/2}$. The zero value for CO_2 (Δ) is the value from the radiolysis of formate in the absence of ketomalonate. *Inset:* G value of monoperoxalic acid as a function of ketomalonate concentration.

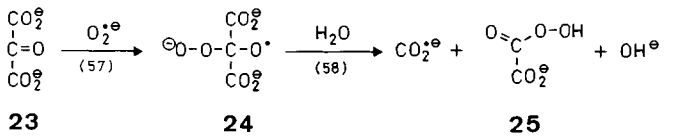
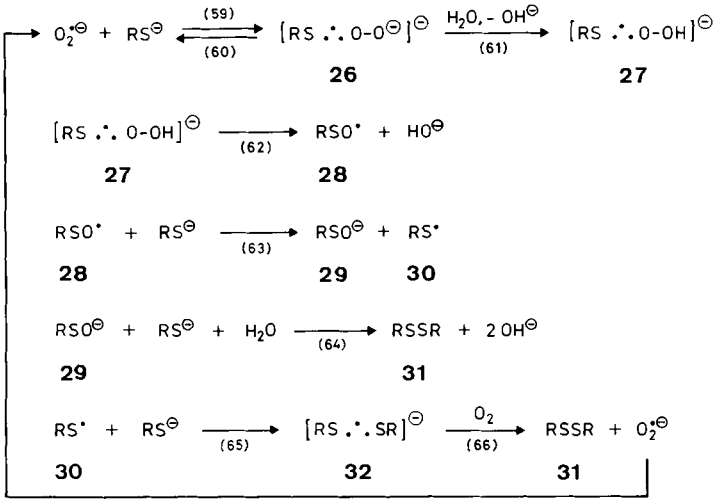
This reaction was unexpected; it may perhaps involve the adduct **24**, which is subject to the β-cleavage typical of oxyl radicals [reaction (58)]. The $CO_2^{\bullet\ominus}$ thus formed propagates the chain by means of its rapid reaction with oxygen to give $O_2^{\bullet\ominus}$ [reaction (18)]. It is not known with certainty how the adduct **24** is formed. The rate constant for the propagation is ca. 150 dm^3 mol^{-1} s^{-1}.



The reaction of $O_2^{\bullet\ominus}$ with thiolate ions, studied for the example of 1,4-dithiothreitol, is also a chain reaction;[42] its final products are water and the disulfide **31**. Since $O_2^{\bullet\ominus}$ can neither abstract a hydrogen atom from the thiol (present in equilibrium) nor accept an electron from the thiolate anion, another mechanism must be involved. Thiolate ions readily form complexes with radicals (e.g. **32** with its three-electron bond typical of complex sulfur radicals[120]). The formation of **26** is thus probably the initial step [reaction (59)]. Rapid protonation of **26** at the peroxylate function would be followed by decomposition of the adduct radical **27** to give the sulfinyl radical **28** and hydroxide ion [reaction (62)]. Chain propagation occurs via reactions (64)–(66); sulfenate ions **29** and thiyl radicals **30** are also intermediates in the reaction.

It was mentioned in the Introduction that the $O_2^{\bullet\ominus}$ radical is a dangerous poison for the living cell. The concentration in the cell of $O_2^{\bullet\ominus}$, which is continually formed in a number of reactions, is therefore kept low by special enzymes, the superoxide dismutases (SOD).[121, 122] The SODs are metal-



loenzymes which can contain Cu/Zn, Fe or Mn.[122, 123] Common to all these enzymes is that the oxidation state of the metal can change, as in the two reactions (67) and (68).

$$SOD\text{–}Cu^{2\oplus} + O_2^{\bullet\ominus} \longrightarrow SOD\text{–}Cu^{\oplus} + O_2 \quad (67)$$

$$SOD\text{–}Cu^{\oplus} + O_2^{\bullet\ominus} + 2H^{\oplus} \longrightarrow SOD\text{–}Cu^{2\oplus} + H_2O_2 \quad (68)$$

This is not the place to discuss the interesting chemistry of the SODs, but it should be pointed out that pulse radiolytic methods have played an important part in understanding the kinetics of the $O_2^{\bullet\ominus}$/SOD reactions (e.g., Refs. [124–135]).

As is so often the case for electron transfer processes, the transition metal/$O_2^{\bullet\ominus}$ reaction generally involves adducts. As a result of the reactions of such transition metal ion/$O_2^{\bullet\ominus}$ complexes reactive intermediates (or •OH radicals) can be formed, which are able for example to induce damage to DNA.[136] They could be a cause of the toxicity of $O_2^{\bullet\ominus}$. Such intermediates have been well characterized in many cases.[92]

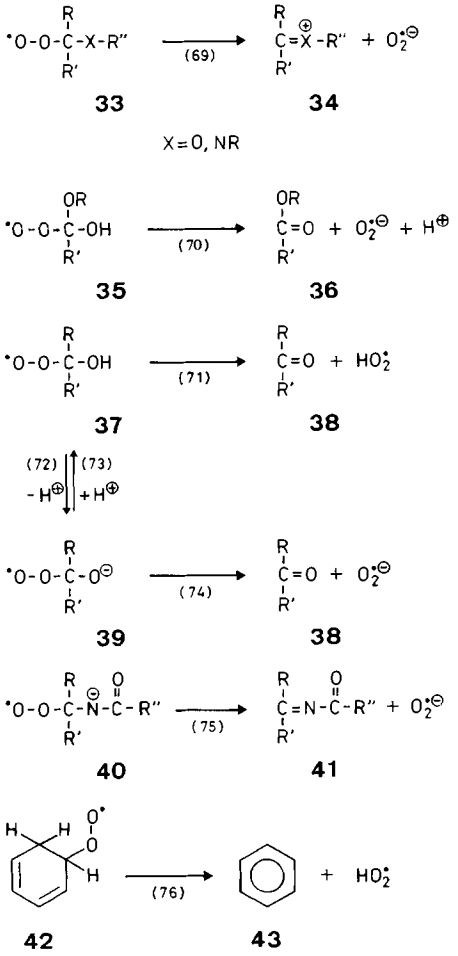
5. Reactions of Peroxyl Radicals: a Survey

Studies of the reactions of peroxyl radicals in aqueous solution have made clear that a series of reaction pathways are possible which do not occur, or if so only very slowly, in the gas phase and in nonpolar solutions. This also applies to some secondary reactions, for example those of oxyl radicals. The two following sections will provide a brief survey of the various types of reaction, while Section 6 will be concerned with particular aspects of the peroxyl radical chemistry of certain classes of compound.

5.1. Monomolecular Reactions

A number of peroxyl radicals are able to eliminate $O_2^{\bullet\ominus}$. In order for the rate of this reaction to be measurable the positive charge must be stabilized by a heteroatom [reaction (69)]. The influence of the substituents is much more pronounced in charge stabilization than in the stabilization of radical centers.[137] An alkoxy group situated next to the

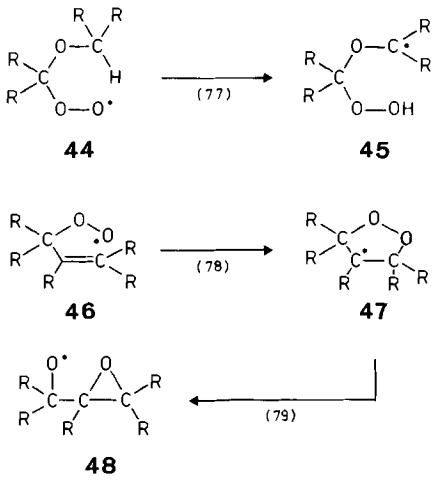
peroxyl radical function (**33**, X = O) does not suffice to make the reaction much faster than 1 s^{-1},[138] while two alkoxy groups (**33**, X = O, R′ = OR) accelerate the reaction to almost 10^5 s^{-1};[139] with a dimethylamino group as the stabilizer of the positive charge (**34**, X = NR) the reaction is so fast that an intermediate peroxyl radical (**33**, X = NR) can no longer be detected.[140] The rapid formation of $HO_2^{\bullet}/O_2^{\bullet\ominus}$ from the peroxyl radicals of aldehyde hydrates (**35**, R = H) and hemiacetals **35**[77, 141, 142] may also involve an elimination of $O_2^{\bullet\ominus}$, although in these cases the proton is split off in a concerted manner together with $O_2^{\bullet\ominus}$ [reaction (70)]. The $HO_2^{\bullet\ominus}$-elimination reactions starting from α-hydroxyalkylperoxyl radicals **37** [reaction (71)] are mechanistically different, and a five-membered transition state has been assumed to be involved.[143] This type of reaction possibly also includes the formation of $HO_2^{\bullet}$ from cyclohexadienylperoxyl radicals **42** [reaction (76)].[27, 144] In this case the driving force would



33 **34** **35** **36** **37** **38** **39** **38** **40** **41** **42** **43**

be the increase in conjugation energy as the aromatic product **43** is formed. A deprotonation of the α-hydroxyalkylperoxyl radicals **37** leads to their anions **39**, which very rapidly eliminate $O_2^{\bullet\ominus}$ [reaction (74); $k_{74} > 10^6 s^{-1}$].[105, 145, 146] This is also true for the peroxyl radical anions derived from the peptides **40**, which are however noticeably more stable ($k_{75} < 3.7 \times 10^6$ s^{-1})[147] than the peroxyl radical anions of the alcohols **39**.

If weakly bonded hydrogen atoms are in a suitable position (**44**, six-membered ring as the transition state) intramolecular hydrogen transfer reactions can become more important at low dose rates (i.e., long lifetime of the peroxyl radical with respect to termination reactions [reaction (77)].[138, 148, 149] Peroxyl radicals of type **46** can also add intramolecularly to double bonds[150] [reaction (78)]; in the benzene system this reaction leads to endoperoxide radicals



44 **45** **46** **47** **48**

(Section 6.7). The peroxyadduct radicals can decompose with formation of the epoxides **48** [reaction (79)].[150, 151]

5.2. Bimolecular Reactions

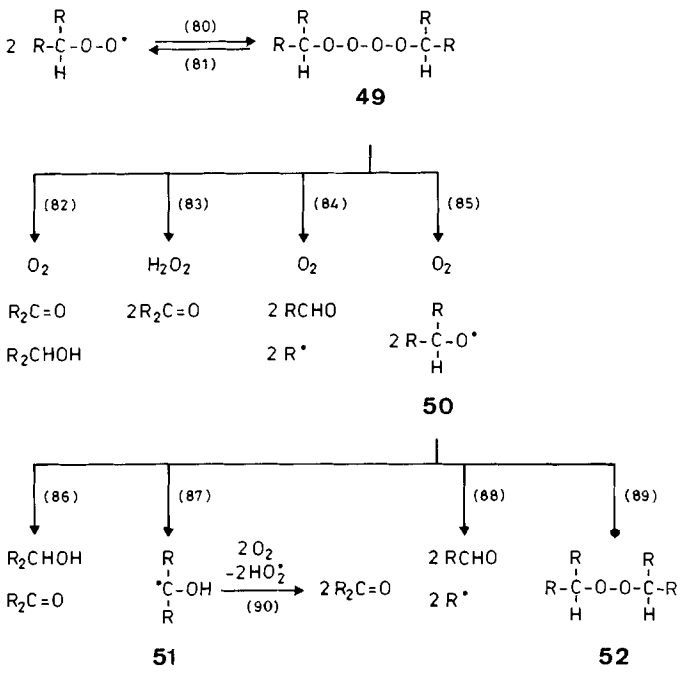
Peroxyl radicals undergo a head-to-head termination reaction[152] to form intermediate tetroxides **49**, which are in equilibrium with the peroxyl radicals at low temperatures in organic solvents [reactions (80) and (81)].[153–158]

An equilibrium is possible because the decomposition of the tetroxide **49** to form products [reactions (82)–(85)] has a higher activation energy than decomposition to give two peroxyl radicals [reaction (81)].[*] At higher temperatures the decomposition of the tetroxide to form products becomes more important. Tetroxides **49** have so far not been observed during pulse radiolysis experiments in aqueous solution [$c(RO_2^{\bullet}) < 5 \times 10^{-5}$ mol dm^{-3}], and under these conditions the formation of products always shows second-order kinetics.[149] The formation of tetroxides in higher concentrations would have made itself felt by the presence of a noticeable first-order component.

Bimolecular rate constants for product formation of $> 10^9$ dm^3 mol^{-1} s^{-1} were determined in water for a series of primary ($RCH_2O_2^{\bullet}$) and secondary ($R_2CHO_2^{\bullet}$) peroxyl radicals.[149, 159] This indicates that in these cases the rate of decomposition of **49** to give products must be comparable with that of the back reaction to give two peroxyl radicals. This is however not the case for all primary and secondary peroxyl radicals and in particular not for tertiary peroxy radicals ($R_3CO_2^{\bullet}$). Thus the rate constant for the bimolecular

[*] *Note added in proof* (September 5, 1991): It has recently been proposed [S. L. Khursan, V. S. Martem'yanov, E. T. Denisov, *Kinetics Catalysis (Engl. Transl.) 31* (1990) 899–907] that the product-forming reactions of the tetroxide have their origin in the asymmetric homolysis ROOOOR → RO• + •OOOR

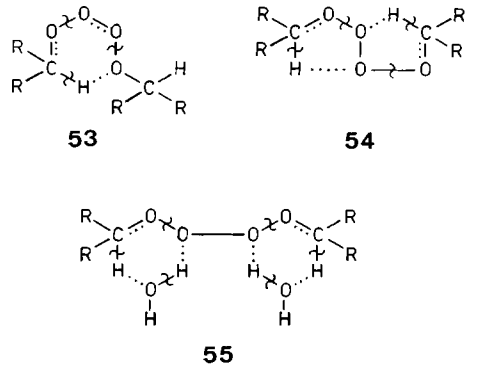
termination of the tertiary peroxyl radical derived from diisopropyl ether has been estimated as $2k \leqq 2\times10^7\ dm^3\,mol^{-1}\,s^{-1}$.[138] The tert-butylperoxyl radical reacts even more slowly ($2k = 2\times10^4\ dm^3\,mol^{-1}\,s^{-1}$).[160] A smaller number of reaction pathways is available to tertiary peroxyl radicals than to primary or secondary radicals [reactions (82) and (83) are not possible]; this may be *one* reason for their slow bimolecular decay. It has recently been demonstrated for certain organic solvents that the rate of bimolecular recombination of tertiary[161] and secondary[162] peroxyl radicals increases when the Taft σ^* constants of their substituents increase. A similar systematic dependence was however not found for primary peroxyl radicals.[162]



The fact that primary and secondary peroxyl radicals generally terminate several orders of magnitude faster than tertiary radicals has been explained in terms of the ability of the former to disproportionate to the hydroperoxide and the Criegee intermediate RR'COO (R' = H, R),[163], one of these species then being responsible for a chain reaction.[164]. In the case of the methylperoxyl radical it was possible to show that in aqueous solution such a reaction cannot play an important role under these conditions.[165]

The best known reaction is the Russell reaction, in which two primary or secondary peroxyl radicals undergo an electrocyclic reaction (i.e., without the formation of free radicals as intermediates) to give molecular oxygen, a product with a C=O function and one with an OH function [reaction (82)].[166] A six-membered transition state **53** has been postulated. Two decomposition pathways are possible, which both obey the spin conservation postulate: either decomposition into a singlet carbonyl compound, an alcohol and singlet oxygen ($^1O_2$), or into a triplet carbonyl compound,[167] alcohol and triplet (ground state) oxygen. In organic solvents $^1O_2$ could be detected in peroxyl reactions,[168, 169] but not in aqueous solution. The short lifetime of $^1O_2$ in aqueous solutions makes such experiments more difficult.

A further electrocyclic process leads to the formation of H_2O_2 and two carbonyl compounds [reaction (83)]. The transition state could involve two five-membered rings as in **54**, while in water the inclusion of two water molecules to form two six-membered rings as in **55** is also possible. This interesting reaction was first described for the reaction of two cyclopentylperoxyl radicals in cyclopentane at low temperatures,[170] while it is of general importance in aqueous solution. In the case of the bimolecular decay of the hydroxymethylperoxyl radicals this reaction is in fact the major one.[143]



The decomposition of peroxyl radicals to give molecular oxygen and two oxyl radicals **50** [reaction (85)] is a further well-known reaction pathway.[1] A disproportionation of the oxyl radicals in the solvent cage (reaction (86); see Ref. [171]) leads to the same products as the Russell mechanism, so that these two processes cannot be clearly separated. A recombination of two oxyl radicals to give peroxides **52** [reaction (89)] is not of great importance in aqueous solution,[160, 172] since reaction (85) probably leads preferentially to $^3O_2$ and a triplet oxyl radical pair and to only a small degree to $^1O_2$ and a singlet radical pair. Thus the probability of recombination in the solvent cage is reduced and the probability that the oxyl radicals **50** can leave it is high.

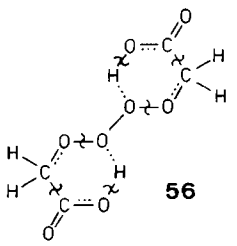
A further reaction thus gains in importance, i.e. the water-catalyzed rearrangement of an oxyl radical **50** to the tautomeric α-hydroxyalkyl radical **51** [reaction (87)].[173–176] Hydrogen shifts of this type have not been observed in the gas phase or in organic solvents;[177] this is in agreement with theoretical predictions[178] which indicate it to have an activation energy that is too high. In water the reaction is, however, very fast ($t_{1/2}$ < several μs). Mechanistic details have not so far been elucidated. Reaction (87) is of particular interest, since $HO_2^•/O_2^{•\ominus}$ is formed in the subsequent reaction (90). Since the latter can be very fast, the rate of formation of $HO_2^•/O_2^{•\ominus}$ is in this case determined by the bimolecular termination reaction (80).

In the case of primary and secondary oxyl radicals **50** the 1,2-H shift is generally so fast that it can take precedence over the long-known β-fragmentation of the oxyl radicals **50** [reaction (88)]. In the case of tertiary oxyl radicals the latter is however the typical decomposition pathway. The solvent water also has a considerable influence here. Thus, in the gas phase the decay constant of the *tert*-butoxy radical $k = 10^3\ s^{-1}$;[179] it increases in solution with increasing polarity of the solvent[180] and in water reaches a value of $k >$

$10^6\ s^{-1}$.[181] For this reason H-abstraction reactions [reaction (91)], which are typical of oxyl radicals in organic solvents, do not take place in dilute aqueous solution. Frag-

$$RO^{\bullet} + RH \longrightarrow ROH + R^{\bullet} \quad (91)$$

mentation products such as those shown in the sequence of reaction (85) followed by reaction (88) could perhaps also be formed via a "zipper" mechanism [reaction (84)]; evidence for this will be discussed in Section 6.2.



56

A further electrocyclic fragmentation reaction was observed in the acetate system.[182] It leads to formaldehyde and CO_2, perhaps via the transition state **56** (or ionized analogues).

6. The Peroxyl Radical Chemistry of Individual Classes of Compound

In any real system it is never the case that merely one of the possible processes discussed above is observed; various processes always occur in parallel. It would exceed the limits of the present article to give a detailed account of the decomposition pathways followed in each of the cases studied together with their percentage contributions. Such figures, as far as they have been measured, can be found in the original literature. In the following sections we shall attempt to emphasize particular aspects as well as to make the reader acquainted with the scope of the material available.

The manner in which we have ordered the following sections may appear arbitrary; we have however attempted to group together compounds with functions that are structurally related and which thus often induce a similar peroxyl radical chemistry. The sections bear the names of the substrate molecules involved. We have devoted a section to DNA and its model systems because of their importance for radiation biology and cancer radiation therapy.

6.1. Alkanes

The only unsubstituted alkylperoxyl radicals which have so far been studied are the methylperoxyl[165] and the cyclopentyl- and cyclohexylperoxyl radicals.[183] The alkanes from which these are derived have only one type of hydrogen atom, so that ·OH-radical-induced hydrogen abstraction leads to only one single alkyl radical species.

The low solubility of the alkanes in water plays a not unimportant part in these studies, since product analysis

Table 1. Products of methane radiolysis in aqueous solution [165] ($c(CH_4)$ = 0.08 mol dm^{-3}, $c(N_2O)$ = 0.1 mol dm^{-3}, $c(O_2) = 1.3 \times 10^{-3}$ mol dm^{-3}) and their G values in units of 10^{-7} mol J^{-1}.

Product	G (pH ≤ 6)	G (pH 8)[a]	Product	G (pH ≤ 6)	G (pH 8) [a]
CH_2O	2.9	3.3	HCOOH	0.3	0.0 5
CH_3OH	1.6	–	CH_3OOCH_3	0.1	–
CH_3OOH	0.8	0.7	H_2O_2	2.2	2.4

[a] Buffered.

requires that the radiation-chemically produced ·OH radicals do not react with the products but only with the alkanes even at higher doses. This is a particular problem in the case of methane, which is only slightly soluble at atmospheric pressure. Since it must also be mixed with N_2O/O_2, its concentration in water is reduced accordingly. In addition methane reacts relatively slowly with ·OH radicals ($k = 1.1 \times 10^8$ $dm^3\ mol^{-1}\ s^{-1}$) while the products derived from it react an order of magnitude faster. For this reason the γ-radiolysis was carried out in an autoclave at a methane pressure of 50 bar.[165] The products are listed in Table 1.

This method is less suitable for pulse radiolysis studies, for which it is possible to make use of the reaction of the ·OH radical with dimethyl sulfoxide;[184] this produces methyl radicals (and methylsulfinic acid) in 92% yield[172] [reaction (92), $k_{92} = 6.6 \times 10^9\ dm^3\ mol^{-1}\ s^{-1}$]. This methyl radical

$$^{\bullet}OH + (CH_3)_2SO \longrightarrow [(CH_3)_2S(O^{\bullet})OH] \longrightarrow {}^{\bullet}CH_3 + CH_3SO_2H \quad (92)$$

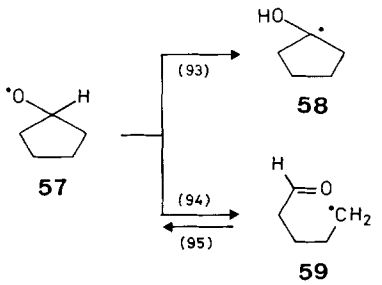
source was used to measure the rate constants $k(^{\bullet}CH_3 + O_2 \rightarrow CH_3O_2^{\bullet}) = 1.7 \times 10^9\ dm^3\ mol^{-1}\ s^{-1}$ and $2k(2\ CH_3O_2^{\bullet} \rightarrow \text{products}) = 1.8 \times 10^8\ dm^3\ mol^{-1}\ s^{-1}$.[185] Since the methylperoxyl radical is only a weak oxidizing agent[75] the reaction with $O_2^{\bullet\ominus}$ is slow and the rate constant cannot be measured by means of pulse radiolysis; however, the value for the bimolecular termination of the methylperoxyl radicals and the data from the product analysis (Table 1) lead to an estimated value for $k(CH_3O_2^{\bullet} + O_2^{\bullet\ominus} + H^{\oplus} \rightarrow CH_3O_2H)$ of $2.5 \times 10^7\ dm^3\ mol^{-1}\ s^{-1}$.[185]

The formation of the products listed in Table 1 can readily be explained on the basis of the general reaction scheme given above [reactions (80)–(90)], the methoxyl/hydroxymethyl rearrangement[176] playing an important role. The hydroxymethylperoxyl radicals undergo spontaneous elimination of $HO_2^{\bullet}$ (see Section 6.2) only slowly, so that they are also subject to bimolecular termination reactions which lead to the production of formic acid. If the solution is buffered at pH 8, the elimination of $HO_2^{\bullet}/O_2^{\bullet\ominus}$ is accelerated by reactions (72) and (74). Thus G(formaldehyde) increases while G(formic acid) decreases correspondingly (Table 1).

The peroxides **52** formed according to reaction (89) are generally not detected, since they are often formed in low yields, their detection is difficult, and in the main no material is available for comparison in order to confirm their identity. In the case of methane radiolysis the yield of dimethyl peroxide is less than 4% of the methylperoxyl radicals originally formed, which demonstrates that this reaction pathway is indeed unimportant. The peroxide yield is comparably low for the termination of *tert*-butylperoxyl radicals.[160]

The cyclopentylperoxyl radical in cyclopentane decomposes to give only cyclopentanone and cyclopentanol.[170] In

aqueous solution, however, various reactions occur in parallel; the most important single process (40%) is ring cleavage.[183] Cyclohexylperoxyl radicals also decompose in aqueous solution with ring cleavage, though since the cyclohexane system is less strained the contribution of this pathway is only 15%.[183] This ring cleavage is particularly interesting; were intermediate oxyl radicals **57** to be formed, these would rapidly rearrange to give α-hydroxycyclopentyl radicals **58** [reaction (93)], so that β-fragmentation [reaction (94)] would not be able to compete.[175] The formation of fragmentation products in such a high yield has been explained on the basis of the "zipper mechanism" [reaction (84)].[183] The sole formation of α-hydroxycyclopentyl radicals **58** as established by ESR spectroscopy could be an artefact[186], since the reversibility of reaction (94) [reaction (95)][187] with a subsequent fast and irreversible 1,2-H shift [reaction (93)] should make the detection of the intermediate ring-opened radical **59** impossible. This indicates that further evidence for the suggested zipper mechanism is required.



6.2. Alcohols, Ethers, Acetals, Aldehyde Hydrates and Carbohydrates

Attack of •OH radicals on the alcohols methanol, ethanol and 2-propanol lead to the preferential formation of α-hydroxyalkyl radicals.[188] It has already been mentioned that the peroxyl radicals derived from the latter eliminate $HO_2^{\bullet}$[105, 145, 146, 189] [reaction (71)] or split off $O_2^{\bullet\ominus}$ subsequent to deprotonation of the OH function [reaction (74)].

The elimination of $O_2^{\bullet\ominus}$ from the radical anion must occur very rapidly ($k > 5 \times 10^5\ s^{-1}$; the temporal resolution is limited by the rate of the O_2-addition), since a pre-equilibrium has not so far been observed (but compare the analogous peptide-peroxyl radicals, Section 6.3). The spontaneous $HO_2^{\bullet}$ elimination depends to a large extent on the neighboring substituents; thus it cannot be measured for the peroxyl radical $HOCH_2O_2^{\bullet}$ derived from methanol ($k < 3\ s^{-1}$), while that derived from ethanol, $CH_3CH(OH)O_2^{\bullet}$, eliminates $HO_2^{\bullet}$ at a rate of $50\ s^{-1}$ and that from 2-propanol at a rate of $650\ s^{-1}$.[146] $HO_2^{\bullet}/O_2^{\bullet\ominus}$ is formed within 10 μs from the peroxyl radicals $(HO)_2CHO_2^{\bullet}$ derived from formaldehyde hydrate and $CH_3C(OH)_2O_2^{\bullet}$ derived from acetaldehyde hydrate.[77, 141]

Since the $HO_2^{\bullet}$ elimination from hydroxymethylperoxyl radicals is so slow in neutral solution, the latter react with one another at the high dose rate of a pulse radiolysis experiment to give two molecules of formic acid and one of hydrogen peroxide [reaction (83)].[143] This type of reaction is also observed in the ethanol system, though other processes (such as the Russell mechanism) occur here as well.[105]

β-Hydroxyalkylperoxyl radicals are formed to the extent of about 15% in the ethanol and 2-propanol systems.[188] Their chemisty can be studied separately, as •OH radicals react quantitatively with ethylene to give β-hydroxyethyl radicals,[190] and in the presence of oxygen to give the corresponding peroxyl radicals **60** [reactions (96) and (97)].[191] Radicals of this type are also formed from *tert*-butanol [reactions (98) and (99), 95% yield,[188, 192] $k_{99} = 1.8 \times 10^9\ dm^3\ mol^{-1}\ s^{-1}$.[193] The chemistry of the peroxyl radicals **60** and

$$\bullet OH + H_2C{=}CH_2 \longrightarrow HOCH_2CH_2^{\bullet} \xrightarrow{O_2} \underset{\mathbf{60}}{HOCH_2CH_2O_2^{\bullet}} \quad (96/97)$$

$$\bullet OH + (CH_3)_3COH \xrightarrow{-H_2O} {}^{\bullet}CH_2C(CH_3)_2OH \xrightarrow{O_2} \underset{\mathbf{61}}{{}^{\bullet}O_2CH_2C(CH_3)_2OH} \quad (98/99)$$

61 has been cleared up in detail by means of product analysis, and their reaction kinetics determined by means of pulse radiolysis.[159, 191] A series of reactions occur via an undetected tetroxide [see the general scheme, reactions (80)–(90)]. The fragmentation reaction observed in both systems [e.g. reaction (100)] is noteworthy: it leads to α-hydroxyalkylperoxyl radicals (•CH_2OH or •$C(CH_3)_2OH$), which eliminate $HO_2^{\bullet}/O_2^{\bullet\ominus}$ subsequent to oxygen addition. Thus, the β-hydroxyalkylperoxyl radicals also produce superoxide radicals in considerable amounts, though in contrast to the α-hydroxyalkylperoxyl radicals this occurs according to second order rather than first order kinetics. The formation of $HO_2^{\bullet}$ subsequent to bimolecular termination is also important in the case of ethers [reactions (101)–(103)].[149] It can be estimated from the data available that in the case of the oxyl radical **62** the 1,2-H shift [reaction (102)] occurs at about double the rate at which the methyl group is cleaved [reaction (104)]. In the case of the polymeric ether polyethylene oxide the bimolecular decay of the peroxyl radicals leads to rupture of the polymer chain.[194] Since no oxyl/α-hydroxyalkyl rearrangement was observed here[149] the C–C fragmentation [analoguous to reaction (104)] must be much faster. This is understandable, as the fragmentation of poly(ethylene oxide) leads to an alkoxymethyl radical which is more stable than the methyl radical. At lower dose rates the bimolecular disappearance of these peroxyl radicals must compete with an intramolecular hydrogen transfer, which can take place via a

$$\underset{\mathbf{60}}{2\ HOCH_2CH_2O_2^{\bullet}} \longrightarrow 2\ {}^{\bullet}CH_2OH + O_2 + 2\ CH_2O \quad (100)$$

$$2\ CH_3CH(O_2^{\bullet})OEt \longrightarrow \underset{\mathbf{62}}{2\ CH_3CH(O^{\bullet})OEt} + O_2 \quad (101)$$

$$\underset{\mathbf{62}}{CH_3CH(O^{\bullet})OEt} \longrightarrow CH_3C^{\bullet}(OH)OEt \xrightarrow{O_2} CH_3CO_2Et + HO_2^{\bullet} \quad (102/103)$$

$$\underset{\mathbf{62}}{CH_3CH(O^{\bullet})OEt} \longrightarrow {}^{\bullet}CH_3 + HCO_2Et \quad (104)$$

sterically more favored six-membered transition state [reaction (77)].[138, 149] The rate constant of this reaction is of the order of magnitude of $1\ s^{-1}$;[138] since it is a genuine unimolecular reaction it is independent of the ether concentration in the dilute solutions studied.[149, 195] Only at higher ether concentrations do the known intermolecular hydrogen transfer reactions (ether autoxidation) become important.

The tertiary peroxyl radical derived from diisopropyl ether also seems to be able to eliminate $HO_2^{\bullet\ominus}$ at a rate similar to that of the slow intramolecular hydrogen transfer (and thus not amenable to kinetic study). This reaction is presumably so slow because of the low stabilization energy of the ether carbocation: the introduction of a second ether function as in the tertiary peroxyl radical **63** derived from acetaldehyde dimethyl acetal causes this reaction to become very fast [reaction (105), $k_{105} = 6.5 \times 10^4\ s^{-1}$].[139] The relatively high stabilization energy of this acetal carbocation **64** is demonstrated by its easily measurable reaction with water [reaction (106)], the rate k_{106} of which was determined by pulse radiolysis to be $1.3 \times 10^5\ s^{-1}$.[196]

$$\underset{\mathbf{63}}{CH_3C(OCH_3)_2O_2^{\bullet}} \longrightarrow O_2^{\bullet\ominus} + \underset{\mathbf{64}}{CH_3C(OCH_3)_2^{\oplus}} \qquad (105)$$

$$\underset{\mathbf{64}}{CH_3C(OCH_3)_2^{\oplus}} + H_2O \longrightarrow CH_3C(OCH_3)_2OH + H^{\oplus} \qquad (106)$$

•OH radicals are unselective in their reactions with carbohydrates, and abstract hydrogen atoms bonded to carbon in an almost statistical manner; reactions with OH groups are observed hardly at all.[197] Thus the reaction with D-glucose leads to six different radicals in similar yields. Five of the latter lead to α-hydroxyalkylperoxyl radicals and thus to elimination of $HO_2^{\bullet}$. The elimination rates are different, but the various processes can be only partially resolved kinetically.[142] The elimination of $HO_2^{\bullet}$ from the C(1)-peroxyl radical is an extremely rapid process ($k > 10^5\ s^{-1}$), in agreement with the reactions of aldehyde hydrates reported above. Not all types of glucose peroxyl radical eliminate $HO_2^{\bullet}$ within 10 ms.[198] It appears that the C(5)-peroxyl radical can eliminate $HO_2^{\bullet}$ either only slowly (after or concertedly with a ring-opening) or not at all. It is thus capable of bimolecular termination, a reaction which leads to the fragment products glycolic acid and L-*threo*-tetrodialdose as well as *xylo*-pentodialdose and formaldehyde (Table 2).

The C(5)-peroxyl radical can also be reduced by $HO_2^{\bullet}$ to the corresponding hydroperoxide. This is possible because in neutral solution the stationary concentration of $O_2^{\bullet\ominus}$ can be relatively high. After ring opening the C(5)-hydroperoxide should split off H_2O_2, a reaction typical of α-hydroxyhydroperoxides.[105, 141, 199, 200] The fact that no organic hydroperoxides can be detected after irradiation[87] thus does not necessarily contradict the suggested reaction pathway.

It was mentioned in the introduction that •OH radicals are formed in the ultrasound irradiation of aqueous solutions and that they are also formed in the decomposition of ozone in this medium. Thus ultrasound[201, 202] and ozone treatment[198] of aqueous glucose solutions should yield the same products as γ-irradiation, and this is indeed the case.

The reactions of peroxyl radicals which lead to the cleavage of the glycosidic linkage in di- and poly-saccharides are much less well understood. In the case of polysaccharides this reaction leads to a lowering of the molecular weight; thus ca. 22% of the peroxyl radicals induced in alginic acid lead to chain rupture.[203] The polysaccharide hyaluronic acid is of great biological importance, being present in many types of tissue. It is also converted into low molecular weight fragments by free-radical attack,[47, 204–206] so that the viscosity of its aqueous solutions undergoes a considerable decrease; this effect could lead to an impairment of its biological function. The kinetics of strand rupture were followed by pulse radiolysis[47] and are basically second order. They are however not yet understood in detail, particularly since no product analysis has been carried out. Equally in the case of cellobiose, mechanistic details are not yet fully clear even though a product analysis exists.[207]

Carbohydrates contain a set of relatively weak C–H bonds, as do aldehydes and ethers, and should thus also undergo autoxidation in aqueous solution. This is however not the case,[87] because most sugar peroxyl radicals readily split off $HO_2^{\bullet}/O_2^{\bullet\ominus}$. The $O_2^{\bullet\ominus}$ does not undergo hydrogen abstraction reactions, so that no chain reaction takes place, and autoxidation is prevented.

6.3. Amines, Amino Acids, and Peptides

The free-radical chemistry of such simple amines as trimethylamine is surprisingly complex. In aqueous solution three

radicals are in equilibrium, the neutral radical $^{\bullet}CH_2N(CH_3)_2$ **65** and the two protonated forms $(CH_3)_3N^{\bullet\oplus}$ **66** and $^{\bullet}CH_2N(CH_3)_2H^{\oplus}$ **67**.[208] In neutral and acid conditions **66** predominates, as its pK_a lies above that of **67** [pK_a(**66**) = 8, pK_a(**67**) = 3.6]. The neutral form **65** dominant in alkaline conditions reacts rapidly with O_2 to give the immonium ion **68** and $O_2^{\bullet\ominus}$ [$k_{107} = 3.5 \times 10^9$ dm^3 mol^{-1} s^{-1}), apparently without the formation of an intermediate peroxyl radical.[140] The formation of $O_2^{\bullet\ominus}$ is accompanied by a change in

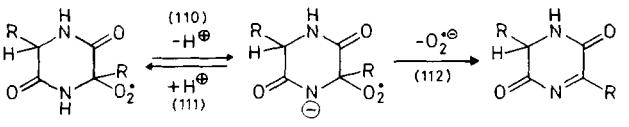
$$^{\bullet}CH_2N(CH_3)_2 + O_2 \longrightarrow CH_2{=}N(CH_3)_2^{\oplus} + O_2^{\bullet\ominus} \quad (107)$$
65 **68**

the conductivity of the solution. The subsequent reactions can also easily be followed by pulse radiolysis using conductometry [reactions (108/109)], $k_{108} = 2.8 \times 10^8$ dm^3 mol^{-1} s^{-1}; $k_{109} = 4$ s^{-1}). Reaction (109) is of more general interest because this type of reaction plays a part in the condensation of aldehydes with amines, which is an equilibrium reaction.

$$CH_2{=}N(CH_3)_2^{\oplus} \xrightarrow{OH^{\ominus}} HOCH_2N(CH_3)_2 \longrightarrow CH_2O + HN(CH_3)_2 \quad (108/109)$$

Peroxyl radicals derived from amino acids also eliminate $HO_2^{\bullet}/O_2^{\bullet\ominus}$. In the case of the peroxyl radical of the glycine zwitterion the elimination rate is 1.5×10^5 s^{-1} at pH 7.9.[209]

The only peptides which have so far been studied in detail are glycine anhydride, alanine anhydride and sarcosine anhydride.[65, 147, 210, 211] In these compounds hydroxyl radicals abstract a hydrogen atom bonded to a ring carbon atom; sarcosine anhydride also undergoes abstraction of a hydrogen from the exocyclic methyl group (20%). The pK_a-values of the corresponding peroxyl radicals are 10.7 and 11.2 in the case of glycine anhydride **69a** and alanine anhydride **69b** [equilibrium (110/111)]; these agree very well with the values calculated using the σ^* value of the peroxyl increment. An elimination of $HO_2^{\bullet}$, which has been demonstrated for the corresponding α-hydroxylalkylperoxyl radicals [reaction (71)] is not observed here ($k < 0.1$ s^{-1}). However, the perox-



69 **70** **71**

a: R = H, **b**: R = CH$_3$

yl radical anions **70** eliminate $O_2^{\bullet\ominus}$; $k_{112} = 1.6 \times 10^5$ s^{-1} for the anion derived from glycine anhydride **70a** and 3.7×10^6 s^{-1} for that from alanine anhydride **70b**. The electron-donating effect of the methyl group thus makes itself felt both in the pK_a value and in the rate of elimination of $O_2^{\bullet\ominus}$. This elimination leads to the formation of unstable 3,4-dehydro-2,5-diketopiperazines **71**; these undergo $H^{\oplus}$- and $OH^{\ominus}$-catalyzed addition of water, a process which has also been studied by means of pulse radiolysis.[212]

The peroxyl radicals derived from sarcosine anhydride cannot eliminate $HO_2^{\bullet}/O_2^{\bullet\ominus}$, so that their disappearance is described by a second-order rate law; the products were determined both qualitatively and quantitatively.[65]

In the case of proteins the $^{\bullet}OH$ radical-induced peroxyl radical formation is followed by chain rupture. It is interesting to note that predetermined fracture points apparently exist; these are responsible for a nonstatistical distribution of the possible fragments.[213] The reasons for this behavior are as yet unknown.

6.4. Aldehydes and Ketones

Aldehydes such as formaldehyde and acetaldehyde are hydrated to a considerable extent in aqueous solution. In the case of formaldehyde the equilibrium lies almost completely on the side of the hydrate, and its peroxyl radical chemistry is thus described in Section 6.2. The hydrate **73** of acetaldehyde **72** is also very important; at 20 °C, 56% of the total aldehyde exists in the form of the hydrate [equilibrium (113/114)]. Reaction (113) is relatively slow ($k = 9 \times 10^{-3}$ s^{-1}). If the acetyl radical **74** is formed via hydrogen abstraction the rate of hydration is increased by many orders of magnitude ($k_{115} = 2 \times 10^4$ s^{-1}), but the dehydration reaction (116) may also be accelerated.[77, 214]

$$CH_3CHO + H_2O \underset{(114)}{\overset{(113)}{\rightleftharpoons}} CH_3CH(OH)_2$$
72 **73**

$$CH_3C(O)^{\bullet} + H_2O \underset{(116)}{\overset{(115)}{\rightleftharpoons}} CH_3C(OH)_2^{\bullet}$$
74 **75**

The reaction with oxygen leads to the formation of a mixture of acetylperoxyl radicals **76** and acetylhydrate peroxyl radicals. The latter rapidly eliminate $HO_2^{\bullet}$ (Section 6.2), so that after a few microseconds $O_2^{\bullet\ominus}$ radicals are present as well as **76**. Since **76** is one of the strongest oxidizing agents in the peroxyl radical family, it reacts rapidly with $O_2^{\bullet\ominus}$ to give the peracetate ion **77** ($k_{117} = 10^9$ dm^3 mol^{-1} s^{-1}). Peracetic acid **78** reacts with the acetaldehyde to give two molecules of acetic acid ($k_{118} = 1.2 \times 10^{-2}$ dm^3 mol^{-1} s^{-1}[215]). The value of 1.5×10^{-2} dm^3 mol^{-1} s^{-1} obtained from the radiation-chemical experiment is in good agreement with the literature.[77]

$$CH_3C(O)O_2^{\bullet} + O_2^{\bullet\ominus} \longrightarrow CH_3C(O)O_2^{\ominus} + O_2 \quad (117)$$
76 **77**

$$CH_3C(O)OOH + CH_3CHO \longrightarrow 2\,CH_3CO_2H \quad (118)$$
78

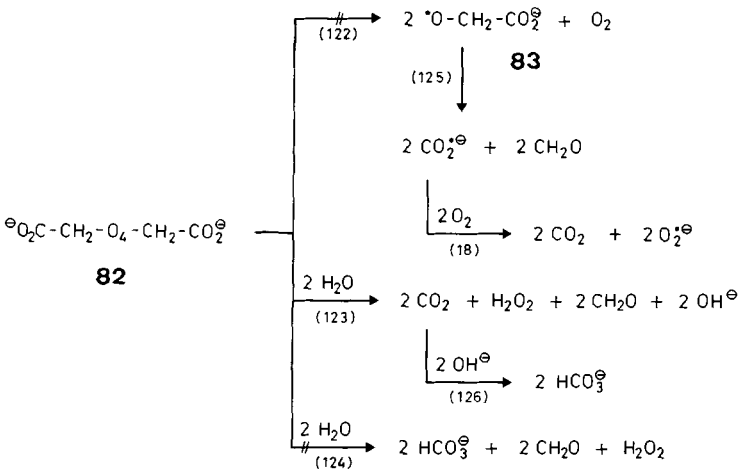
The isomer of the acetyl radical **74** is the formylmethyl radical **80**, which is formed by elimination of water from the 1,2-dihydroxyethyl radical **79** [reaction (120)].[216–219] The

$$^{\bullet}OH + HOCH_2CH_2OH \xrightarrow{(119)} H_2O + {}^{\bullet}CH(OH)CH_2OH$$
79

$$\mathbf{79} \xrightarrow[(120)]{-H_2O} {}^{\bullet}CH_2CHO \xrightarrow[(121)]{O_2} {}^{\bullet}O_2CH_2CHO$$
80 **81**

water elimination is acid- and base-catalyzed.[220-222] Under alkaline conditions (pH $\geq$ 12) the 1,2-dihydroxyethyl radical anion (the anion of **79**) rapidly eliminates $OH^{\ominus}$ ($3.1 \times 10^6\ s^{-1}$),[221] so that at low O_2 concentrations only formylmethylperoxyl radicals **81** are formed. These decompose bimolecularly, the main products being formaldehyde and formic acid.[116]

A detailed study of the acetonylperoxyl radical (from acetone and $^{\bullet}OH$) has been carried out.[223] Apart from other reactions, fragmentation following a bimolecular reaction occurs to give formaldehyde and the acetyl radical mentioned above. The latter is the precursor of the carbon dioxide also observed.[77].



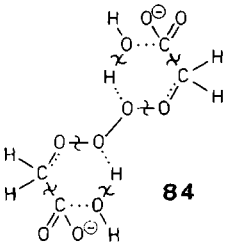
6.5. Carboxylic Acids

The radical $CO_2^{\bullet\ominus}$ derived from formic acid ($pK_a(^{\bullet}CO_2H) = 1.4$[224]) reacts rapidly to give CO_2 and $O_2^{\bullet\ominus}$;[37] an intermediate peroxyl radical has so far not been detected [reaction (18)]. The latter could perhaps be observed through pulse radiolysis if high oxygen pressure (in a pressure cell) were used to accelerate the reaction between $CO_2^{\bullet\ominus}$ and O_2, so that a high concentration of the intermediate could be built up; under such conditions the decay would perhaps be observable in the nanosecond range.

The main products derived from the peroxyl radicals of the acetate ion are glyoxylic acid, glycolic acid, formaldehyde and CO_2[64, 182, 209, 225-228] (Table 3). It is noticeable that much more glyoxylic acid is formed than glycolic acid, i.e. the Russell mechanism [reaction (82)] is unimportant in comparison with reaction (83); this is also confirmed by the high yield of H_2O_2. The reaction pathway to give formaldehyde and CO_2 is however surprising. "Classically" one could formulate the decomposition of the assumed tetroxide intermediate **82** to give O_2 and two oxyl radicals **83** [reaction (122)], and **83** should rapidly decompose into $CO_2^{\bullet\ominus}$ and formaldehyde [reaction (125)]. The $CO_2^{\bullet\ominus}$ reacts immediately according to reaction (18) to give CO_2 and $O_2^{\bullet\ominus}$. However, it was shown by pulse radiolysis that this reaction pathway is not the main one,[182] since although some $O_2^{\bullet\ominus}$ is formed in the course of the bimolecular decay of the acetate peroxyl radicals, its yield is much too small to explain the production of formaldehyde and CO_2 as being due to this process. It is probable that the reaction is a concerted one [reaction (123)]. One of the possible transition states has been indicated above (formula **56**), while deprotonated analogues and multistep processes could also be involved. The process certainly involves the formation of CO_2, which is only slowly[229] converted into bicarbonate according to reaction (126). Reaction (124) can thus be excluded. This possibility had to be checked, since this reaction pathway would involve the presence of a transition state (**84**) similar to that of (**56**) postulated for pathway (123).

Table 3. γ-Radiolysis products of sodium acetate [182] (0.01 mol dm^{-3}, pH 7.8) in N_2O/O_2-(4:1)-saturated solution and their G values (in units of 10^{-7} mol J^{-1}).

Product	G	Product	G
Glyoxylic acid	2.8	Organic (hydro)peroxides	0.7
Glycolic acid	0.7	Hydrogen peroxide	2.6
Formaldehyde	1.4	Oxygen uptake	5.5
Carbon dioxide	1.4		



The acetate peroxyl radical reacts with $O_2^{\bullet\ominus}$ via electron transfer, while the reaction with the $HO_2^{\bullet}$ radical leads via a tetroxide to C—C fragmentation.[64]

As expected the peroxyl radical derived from malonic acid ($pK_a(HCO_2CH(O_2^{\bullet})CO_2^{\ominus}) \leq 3$) has a pK_a much lower than that of the parent compound ($pK_a(HCO_2CH_2CO_2^{\ominus}) = 5.7$);[62] this behavior parallels that of acetic acid (see Section 3.2). The pK_a-value agrees well with that of 2.9 calculated from the σ^* value of the peroxyl group.

6.6. Lipids

The radical-induced lipid peroxidation (oxidation of polyunsaturated fatty acids) has mainly been studied in organic solvents,[56] but aqueous solutions have also provided interesting results. In very dilute solutions the salts of fatty acids are predominantly homogeneously dissolved; however, above the critical micelle concentration[230] (which, for example, in the case of linoleic acid lies at 2.3×10^{-3} mol dm^{-3}) the fatty acids begin to form aggregates; at higher concentration rod-shaped micelles are formed, this second transition occurring at ca. 1.2×10^{-2} mol dm^{-3} for linoleic acid.[231]

Only relatively few radicals of the pentadienyl type **6** (10%[232]) are formed primarily as a result of initiation by $^{\bullet}OH$ radicals (see Section 3.1); most of the $^{\bullet}OH$ radicals react

by addition to a double bond. These radicals generate (intramolecularly if the geometry is favorable) pentadienyl-type radicals. Within the micelles the rate of this conversion is slower because of the lower mobility of the radicals in such a matrix; however, the conversion is almost quantitative because of the intermolecular hydrogen transfer reaction which now takes place.[232–234] This should also be true for the corresponding peroxyl radicals.

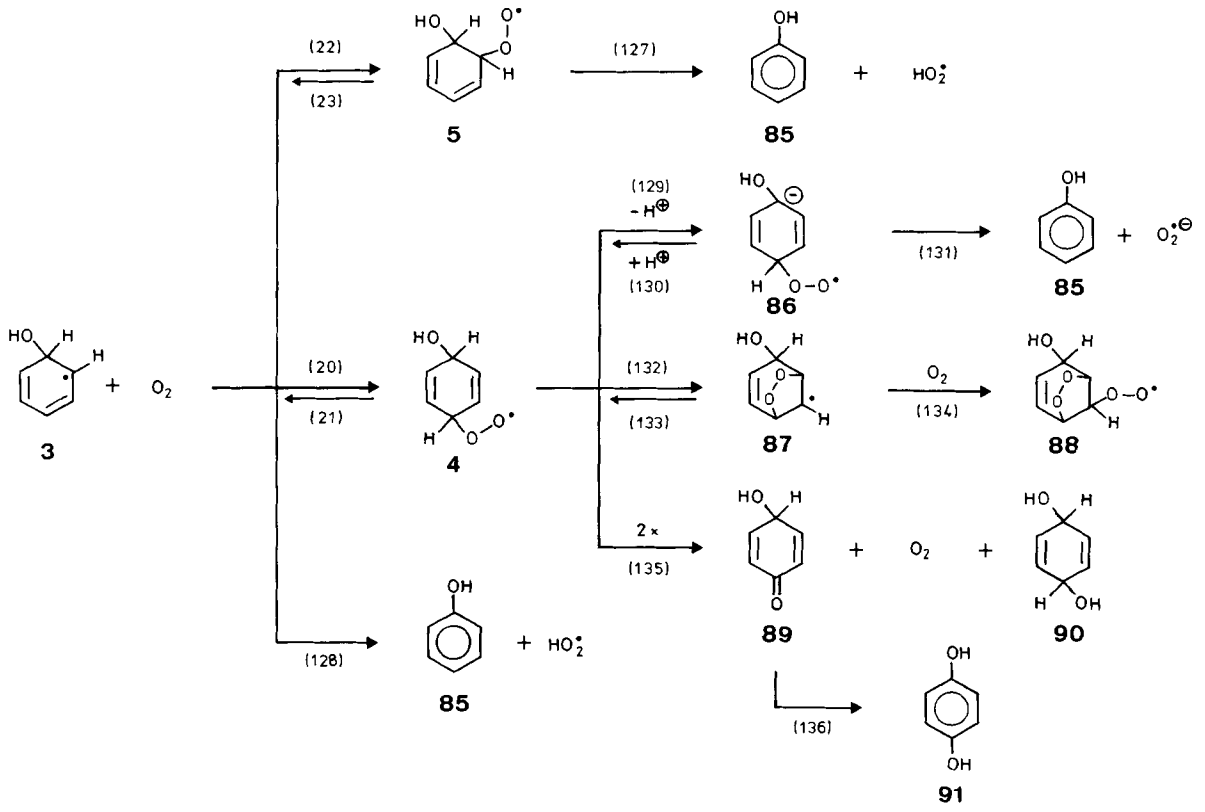
The lipid peroxidation is a radical chain reaction, the rate-limiting step being a hydrogen transfer reaction which has a considerable energy of activation [reaction (26)]. Oxygen addition to the pentadienyl radicals **6** is however fast ($k_{24} = 3 \times 10^8$ dm^3 mol^{-1} s^{-1}), as is the bimolecular termination of the lipid peroxyl radicals **7** ($2k \approx 10^7$ dm^3 mol^{-1} s^{-1}).[233] As expected, it is found that the chain length increases both with increasing temperature and with a decrease in the steady-state concentration of the radicals, i.e. if the radicals are formed by irradiation it is proportional to (dose rate)$^{-1/2}$.[231, 235]

As long as the fatty acids are not aggregated the chain length is short and the peroxidation ineffective. The chain length increases drastically when the critical micelle concentration is exceeded.[231, 236] A second increase is observed at the transition to rod-shaped micelles.[231] On the basis of the postulate that bimolecular termination occurs mainly via two monomeric peroxyl radicals or via the reaction of a monomer with a micellar peroxyl radical, while a termination via two micellar peroxyl radicals is improbable, it was possible from pulse radiolysis data to estimate that the monomeric peroxyl radicals are incorporated into the micelles with a rate constant $k = 8 \times 10^8$ dm^3 mol^{-1} s^{-1} but that they also leave the micelles at a rate of 1.6×10^5 s^{-1}.[232]

Little is known about the products of radiation-induced lipid peroxidation in aqueous solution. Material balances have not yet been established. The oxygen consumption is much higher than that expected for the formation of organic hydroperoxides and "malondialdehyde".[238] It is not known which reaction is responsible for the formation of $HO_2^{\bullet}/O_2^{\bullet\ominus}$ in the decomposition of fatty aid peroxyl radicals [$G \approx (2.2–4.7) \times 10^{-7}$ mol J^{-1}].[239]

6.7. Benzene and its Derivatives

Benzene and its derivatives rapidly add $^{\bullet}$OH radicals and hydrogen atoms to give cyclohexadienyl-type radicals such as **3**. As described in Section 3.1, addition of oxygen to these radicals can be reversible [reactions (20)–(23)]. In the case of the unsubstituted cyclohexadienyl radical (formed from the reaction of $^{\bullet}$OH radicals with 1,4-cyclohexadiene[240]) a subsequent $HO_2^{\bullet}$ elimination analogous to reaction (127) or the direct hydrogen transfer from this radical to O_2 with direct formation of $HO_2^{\bullet}$ [reaction (128)] is so fast ($k > 8 \times 10^5$ s^{-1}[58]) that a back reaction can no longer be detected. These reactions have been discussed for the autoxidation of cyclohexadiene.[241, 242] In the polar solvent water a decomposition to give an $O_2^{\bullet\ominus}$ radical and a cyclohexadienyl cation could provide a possible alternative to an electrocyclic $HO_2^{\bullet}$ elimination; however, this pathway has been excluded.[58] The $HO_2^{\bullet}$ elimination must involve a transition state in which the hydrogen to be eliminated and the terminal oxygen of the peroxyl radical function can approach very closely. Of the two possible peroxyl radicals **4** and **5**, only **5** with its 1,3-cyclohexadiene structure permits this (distance ca. 1.8 A); for **4**, which has a 1,4-cyclohexadiene structure, the distance is ca. 3.9 A. The yield of $HO_2^{\bullet}$ elimination product (benzene from the cyclohexadienylperoxyl radicals, phenol **85** from



the hydroxycyclohexadienylperoxyl radicals **5**) reaches only about 60% of the expected value[27] (see also earlier radiation-chemical studies of this system[243-251]). The $HO_2^•$ elimination is thus not the only unimolecular reaction. In Table 4, the presence of fragment products (altogether about thirty) with one to six carbon atoms is indicated. They are thought to derive from intermediate endoperoxides **87** and **88** [reactions (132)–(134)].

Table 4. γ-Radiolysis of benzene in aqueous solution [27] (pH 6.5), c (benzene) = 2×10^{-3} mol dm^{-3}, c (N_2O) = 1.8×10^{-2} mol dm^{-3}, c (O_2) = 2.6×10^{-4} mol dm^{-3}, dose rate 0.14 Gy s^{-1}. Products and their G values (in units of 10^{-7} mol J^{-1}).

Hydrogen peroxide	1.7	1.4
$HO_2^•$	4.0[b]	[a]

[a] Not determined. [b] Determined by the TNM method (see Section 4).

In the system hydroxycyclohexadienyl radical/O_2 the observed $HO_2^•$ elimination is much slower than in the unsubstituted case ($k \approx 800$ s^{-1}).[27, 144] Because of the occurrence of reactions (20)–(23) the observed decay constant is smaller than the rate constant which corresponds to reaction (127). When reaction (128) is neglected, a value of ca. 4×10^4 s^{-1} can be estimated for k_{127}, showing that after this correction the rate of elimination of $HO_2^•$ from **5** approaches the value found for the unsubstituted peroxyl radical.

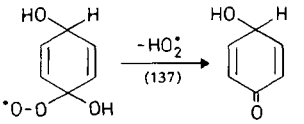
Pathway (127) via equilibrium (22)/(23) could not be distinguished from a slow reaction (128) which might proceed alongside processes (20)/(21) and (22)/(23), and the question as to which of these constitutes the route to phenol must remain open. The fact that perdeuterated benzene gives a smaller phenol yield than the undeuterated compound, and that at the same time the oxygen consumption is higher, may be attributed to the isotope effect that is expected for reactions (127) and (128). In the case of the deuterated benzene this will lead to a longer lifetime of peroxyl radical **5** with respect to reaction (127), and thus will favor the reaction sequence (20 → 132 → 134), causing the oxygen consumption to be higher.

At high pH the yield of phenol approaches the G value of the primarily attacking $^•OH$ radical. It thus follows that the 4-hydroxy-2,5-cyclohexadienylperoxyl radical **86** deprotonated at C4 can also eliminate $O_2^{•\ominus}$ [reactions (129) and (131)].

Further reactions may be involved at the high dose rate of pulse radiolysis. The peroxyl radical **4**, which is by far the dominant one, is now also subject to bimolecular termination [reaction (135)]. Important products are then 3,6-dihydroxy-1,4-cyclohexadiene **90** and hydroquinone **91**, which is formed via the short-lived (see below) 4-hydroxy-2,5-cyclohexadienone **89** [reaction (136)].

It is noteworthy that muconaldehyde is a prominent product when the $^•OH$ radicals are formed via a Fenton reagent,[252] while in the radiolytic system no muconaldehyde is formed (< 0.5%).[27] The use of $^{36}O_2$ does not lead to incorporation of ^{18}O into the phenol in the radiolytic system, though this is the case of the Fenton system.[253] This is a further indication of the problems which can occur in the interpretation of results obtained with Fenton systems.

The amino acid phenylalanine behaves similarly to benzene, its radiation chemistry being dominated by the phenyl group.[254] The system phenol/$^•OH$/O_2 has also been studied by pulse radiolysis.[255] It was reported that the peroxyl radicals **92** formed in this system eliminate $HO_2^•$. An undefined non-radical intermediate is postulated; this rearranges to give hydroquinone and could be 4-hydroxy-2,5-cyclohexadienone **89** [reaction (137)]. Cyclohexadienones are indeed short-lived in water and rearrange rapidly to give the corresponding phenols [reaction (136)].[256, 257]



92 **89**

It was mentioned above that the hydroxycyclohexadienyl radicals derived from some benzene derivatives, e.g. benzonitrile, show only a slight reaction or even no reaction at all with oxygen. This has been confirmed by oxygen consumption measurements at low dose rates (^{60}Co-γ-radiolysis).[58]

6.8. Sulfur Compounds

The simplest sulfur radicals, the thiyl radicals, react very rapidly with oxygen; the RS–$O_2^•$ bond is however very weak, so that an equilibrium is set up at room temperature [reactions (138) and (139)];[60] this equilibrium does not lie completely on the side of the thiylperoxyl radicals **93** even under the conditions of air saturation [$c(O_2) = 2.5 \times 10^{-4}$ mol dm^{-3}].[258] The latter exhibit a definite absorption at ca. 540 nm[259] which permits their observation; they have very recently also been observed by ESR spectroscopy.[71] The

$$RS^• + O_2 \underset{(139)}{\overset{(138)}{\rightleftharpoons}} RSOO^• \quad \mathbf{93}$$

isomeric sulfonyl radical RS(O)O$^•$ **94** is however much more stable than **93**, the calculated energy difference being about 210 kJ mol^{-1}.[260] It can thus be assumed that **93** should rearrange to **94**. This can easily be achieved under photolytic conditions;[261, 262] the thermal rearrangement is however slowed to such an extent by the activation energy (calc. 105 kJ[260]) that the rate of this strongly exothermic reaction (140) can no longer be measured with certainty at room temperature by pulse radiolysis ($k_{140} < 10^4$ s^{-1}[258]). The

measurement of this unimolecular reaction is made more difficult by bimolecular termination processes (**93** + **93**; **93** + RS$^{\bullet}$; RS$^{\bullet}$ + RS$^{\bullet}$) and by a reaction with the thiol which can lead to sulfinyl radicals **28** [reaction (141)]. ESR measurements at low temperatures have provided good evidence for the occurrence of **28** in irradiated thiol/O_2 systems.[71, 262–265] This reaction also cannot be very fast; a first estimate for a value of $k_{141} \approx 5 \times 10^5$ dm^3 mol^{-1} s^{-1} was obtained for the 2-mercaptoethanol system.[266] As is to

$$\underset{\mathbf{93}}{\text{RSOO}^{\bullet}} \longrightarrow \underset{\mathbf{94}}{\text{RS(O)O}^{\bullet}} \qquad (140)$$

$$\underset{\mathbf{93}}{\text{RSOO}^{\bullet}} + \text{RSH} \longrightarrow \text{RSOH} + \underset{\mathbf{28}}{\text{RSO}^{\bullet}} \qquad (141)$$

be expected for such a complex mechanism, the yields of the products in the 2-mercaptoethanol system depend strongly on the concentrations of the thiol and of oxygen (Table 5 and Fig. 6).

Table 5. γ-Radiolysis of 2-mercaptoethanol in aqueous solution at different concentrations [258] (c (N_2O) = 1.8×10^{-2} mol dm^{-3}, c (O_2) = 2.6×10^{-4} mol dm^{-3}, pH 5.7). Dose rate 0.3 Gy s^{-1}. G values in units of 10^{-7} mol J^{-1}.

Products	G at 2.8×10^{-4} M	G at 1.12×10^{-2} M	Products	G at 2.8×10^{-4} M	G at 1.12×10^{-2} M
RSO_3H	3.7	1.2	HCHO	0.7	0.97
RSSR	1.2	4.9	CH_3CHO	0.2	0.27
RSO_2H	0.09	0.08	$HOCH_2CHO$	0.12	0.48
H_2SO_4	0.79	0.65	OHCCHO	0.10	0.04
HCOOH	0.10	0.15			

Two main products are noteworthy, the disulfide and the sulfonic acid. However, almost no sulfinic acid is formed. This indicates that a further oxygenation beyond the $RSO_2^{\bullet}$ stage must take place. ESR measurements at low temperatures provide evidence for a reaction of the RS(O)O$^{\bullet}$ radicals with oxygen to give $RSO_4^{\bullet}$ radicals.[262] This intermediate could be the precursor for the sulfonic acid and the sulfuric acid, but details are still obscure.

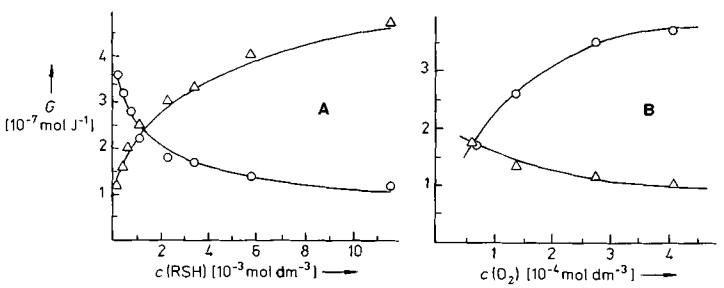


Fig. 6. γ-Radiolysis of 2-mercaptoethanol in aqueous solution [258] (pH 5.6, N_2O/O_2, dose rate 0.3 Gy s^{-1}). Concentration dependence of the G values of disulfide (△) and sulfonic acid (○). A: as a function of the thiol concentration; c (O_2) = 2.6×10^{-4} mol dm^{-3}. B: as a function of the oxygen concentration; c (RSH) = 2.8×10^{-4} mol dm^{-3}.

In alkaline solution, when sufficient thiolate anions are present in equilibrium, the disulfide radical anion and its reaction with oxygen [reactions (65)[267] and (66)[268, 269] become important. The $O_2^{\bullet\ominus}$ radical can then enter into a chain reaction with the thiolate ion (see Section 4).

Radical cations ($R_2S^{\bullet\oplus}$, $(R_2S)_2^{\bullet\oplus}$, $RSSR^{\bullet\oplus}$) play an important role in the radical chemistry of sulfur; just as for other radical cations,[270–272] these are unreactive or only slightly reactive towards oxygen.[273]

6.9. Halogen Compounds

The peroxyl radical chemistry of the halogens has attracted particular interest for two reasons. The well-known liver toxicity of this class of compounds, which also includes some anaesthetics such as halothane, is suggested to be due in part to reactions of intermediate peroxyl radicals.[74] Secondly they are intermediates in the ozone-induced decomposition (in aqueous media by the $^{\bullet}$OH radical route) of the haloethenes, which are nowadays omnipresent in ground-water.[274, 275] The addition of $^{\bullet}$OH radicals to halogenated ethenes gives $^{\bullet}$OH adduct radicals **95** which rearrange rapid-

$$^{\bullet}\text{OH} + \text{Cl}_2\text{C}{=}\text{CCl}_2 \xrightarrow{(142)} \underset{\mathbf{95}}{\text{HOCCl}_2\text{CCl}_2^{\bullet}} \underset{(144)}{\overset{(143)}{\rightleftharpoons}} \underset{\mathbf{96}}{^{\bullet}\text{C(OH)ClCCl}_3}$$

$$\underset{\mathbf{96}}{^{\bullet}\text{C(OH)ClCCl}_3} \xrightarrow[(145)]{\text{O}_2,\ -\text{HO}_2^{\bullet}} \underset{\mathbf{97}}{\text{CCl}_3\text{COCl}} \xrightarrow[(146)]{\text{H}_2\text{O}} \underset{\mathbf{98}}{\text{CCl}_3\text{CO}_2\text{H}} + \text{HCl}$$

$$\text{HOC(Cl)}_2\text{CCl}_2^{\bullet} \xrightarrow{(147)} \text{HCl} + \text{OCClCCl}_2^{\bullet}$$

ly [reaction (143)]. This rearrangement has been postulated because of the formation (via **96** and **97** as intermediates) of trichloroacetic acid **98** [reactions (145) and (146)].[275] **95** can split off HCl rather than undergoing rearrangement and addition of O_2 [reaction (147)]. According to pulse radiolysis measurements the latter reaction is very fast ($k_{147} > 7 \times 10^5$ s^{-1}).[276]

Halogenated peroxyl radicals are also formed from the reaction of $^{\bullet}$OH radicals with partially halogenated ethanes.[277] Another route to these intermediates is provided by solvated electrons,[74, 78, 277, 278] which react with halogen compounds via dissociative electron capture [e.g. reaction (148)]. The

$$\text{HCCl}_3 + \text{e}_{\text{aq}}^{\ominus} \xrightarrow{(148)} {^{\bullet}\text{CHCl}_2} + \text{Cl}^{\ominus}$$

oxyl radicals **99** formed in the bimolecular termination reactions can undergo decomposition via two routes, i.e., 1,2-H shift and β-fragmentation [reactions (149) and (152)]. In bro-

$$\cdot OCHCl_2 \xrightarrow[(149)]{} HOC\cdot Cl_2 \xrightarrow{-HCl} ClC\cdot=O \xrightarrow[(151)]{} Cl\cdot + CO$$
99

$$\cdot OCHCl_2 \xrightarrow{(152)} HCOCl + Cl\cdot$$
99

mine-containing oxyl radicals the β-fragmentation is the only decomposition route observed because the C–Br bond is considerably weaker than the C–Cl bond.[278, 279] C–C bond cleavage has also been observed in the peroxyl radical chemistry of halogenated ethanes, though this reaction is not yet understood in detail.[280]

6.10. Nucleic Acids and Their Building Blocks

Radical-induced changes in the DNA of the living cell can trigger mutations and carcinogenesis and even lead to reproductive cell death. The latter is the goal of cancer therapy, since the actual danger is the uncontrolled growth of cancer cells and not their presence as such. For this reason the field of radical-induced DNA modifications has been the subject of much research.[7]

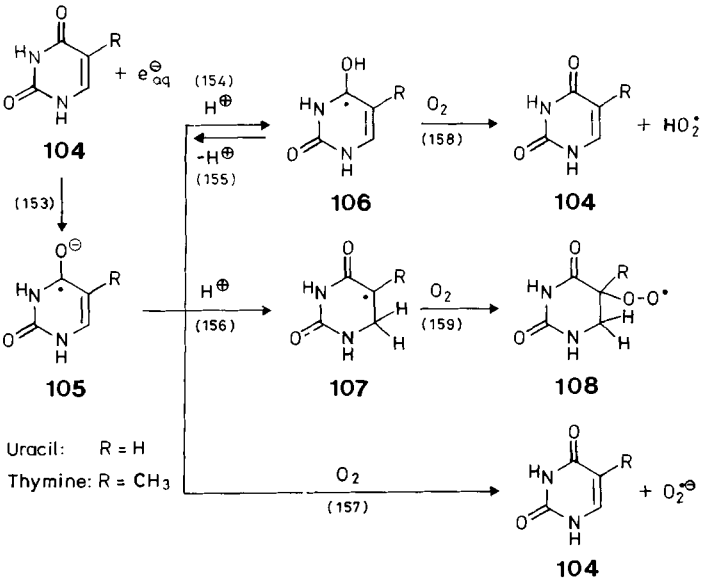
In the cell most DNA damage can be repaired enzymatically. However, an unrepaired break in the DNA double helix prevents the transmission of the complete information to the daughter cells, which generally in turn prevents cell multiplication. Unrepaired base changes can in principle lead to a point mutation. In the cell the radiation energy can either be absorbed by the DNA (*direct* effect), or by the water surrounding it (*indirect* effect) whereby the 'OH radicals, solvated electrons and 'H atoms formed in reactions (6)–(10) react with the DNA. The direct effect has so far been little studied, while a good deal more is known about the indirect effect.[7]

The solvated electrons (and also the H' atoms) react only with the nucleobases. The 'OH radicals react preferentially with these as well, though about 10–20% of them also react at the sugar component (in poly(U) 7%[282]). The sugar radicals are then the precursors for the strand breaks and for unchanged free nucleobases. A small proportion of the sugar radicals which cause a single strand rupture can subsequently react with the complementary strand and thus lead to a double-strand break.[283] In the absence of O_2 the strand breakage in DNA is mainly due to a β-elimination of the phosphate groups from the C4' radical[284, 285] (see also Refs. [286–288]). This process is however so slow that the corresponding peroxyl radical is formed in the presence of O_2.

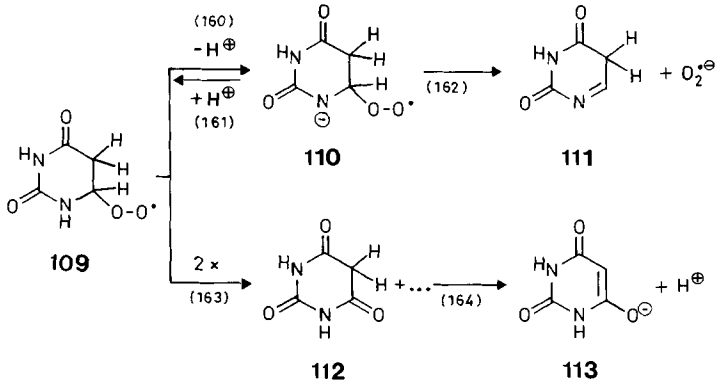
A radical-induced chain rupture is of necessity accompanied by a chemical change in the sugar component. A set of such sugar products has been identified in irradiated DNA (**100**–**103**).[289–292] It is by no means easy to generate one single sugar radical selectively.[293] It is not possible here to discuss mechanistic suggestions regarding the formation of these products in DNA (for the reactions of the peroxyl radicals of the alkyl phosphates see Refs. [294, 295]).

The base-derived radicals can be studied in much more detail in model systems, e.g. DNA subunits; however, the results thus obtained cannot be transferred with complete confidence to DNA itself. We know for example from the poly(U) system that base radicals react with the sugar component both in the presence and in the absence of oxygen, these reactions leading to strand rupture and the liberation of unchanged bases.[282, 296–304] Hydrogen transfer reactions of this type are less efficient in DNA. However, the often extremely detailed model studies are also very relevant to the chemistry of DNA peroxyl radicals.

The reaction of a solvated electron with a nucleobase leads to the formation of the electron adduct. In the case of derivatives of cytosine, adenine and guanine these electron adducts are rapidly protonated by water.[305–308] The subsequent reactions with oxygen are not yet well understood.[305, 309] In the uracil/thymine system **104** the electron adduct **105** reacts more slowly with water [pK_a (**106**) $\approx$ 7[310, 311]], initial protonation occurring at the heteroatom [reaction (154)]. A protonation at C6 [reaction (156)] is slower, but at the same time the deprotonation is much more difficult (pK_a (**107**) $\gg$ 7).[312–314] As a result **107** eventually dominates. The electron adduct **105** itself and its *O*-protonated form **106** react rapidly with oxygen, resulting in the formation of $O_2^{\cdot\ominus}/HO_2^{\cdot}$ and restitution of the base **104** [reactions (157) and (158)], no intermediate peroxyl radical being observed. The C-protonation [reaction (156)] can be accelerated by phosphate catalysis.[313] The resultant radicals **107** react with O_2 [reaction (159)] without regeneration of the pyrimidine chromophore.[315]



The C6-yl radicals isomeric to **107** are formed via addition of an ·H atom;[316] they are also formed when ·OH radicals are allowed to react with dihydrouracil.[317] The addition of ·OH radicals to the pyrimidines also leads preferentially to this type of radical.[318, 319] The reaction of the latter with O_2 leads to peroxyl radicals **109**, the structure of which is similar to that of the peptide peroxyl radicals (Section 6.3) and which behave in a similar manner. As in the case of the latter these peroxyl radicals eliminate $O_2^{\cdot\ominus}$ from their anion **110** with the formation of very short-lived isopyrimidines **111** [reactions (160)–(162)], the reactions of which with water have been established by means of product analysis and pulse radiolysis.[320, 321] Since the $O_2^{\cdot\ominus}$ elimination occurs only from the anion **110**, while elimination of $HO_2^{\cdot}$ from the neutral form **109** is very slow, the peroxyl radicals **109** decompose under acid conditions according to a second-order rate law, which leads to a different product distribution. Thus, one of the products formed from **109** is the keto form of barbituric acid **112** [reaction (163)]. As the latter is a C–H acid it dissociates only relatively slowly in spite of its low pK_a of 4.0 [reaction (164)];[322, 323] this reaction can be followed very readily by pulse radiolysis.[229]



The ·OH radical-induced radical chemistry of the purines leads to conjugated radicals with a high spin density at the heteroatom.[324] Such radicals are often (but not always) unreactive towards oxygen. It is thus not surprising that a fraction of the purine radicals does not react with oxygen, as could be shown both by pulse radiolysis[195, 325] and by measurement of the O_2 uptake during the irradiation.[195]

In the cells, aside from the enzymatic repair of the damaged DNA, a faster "chemical" repair of the DNA radicals via thiols/thiolate ions plays an important role (the glutathione concentration in the cell can be as high as 10^{-2} mol dm^{-3}), by suppressing the dangerous formation of DNA peroxyl radicals.[6, 8, 326] The latter can however also react with thiols, as was recently shown by means of kinetic ESR spectroscopy for the DNA (polynucleotide)/thiol system.[301, 304, 327] Since the peroxyl radicals derived from polymers, e.g. the DNA peroxyl radicals, have a very long lifetime (with respect to a bimolecular termination) their reaction with glutathione in the cell must be of great importance because of its high concentration. Thus the final products of the peroxyl radicals would in the main be determined by this reaction. In Sections 4 and 6.8 we referred to the very complex sulfur/peroxyl radical chemistry. The question of the $RO_2^{\cdot}$/thiol(thiolate) reaction requires further study because of its great biological significance which is becoming apparent.

7. Future Prospects

The present survey is intended to provide an impression of the possibilities afforded by radiation-chemical techniques in the field of peroxyl radical chemistry. The fact that these studies have been carried out mostly using *dilute aqueous solutions* is due to the method used. The radiolysis of water is a simple process chemically which provides only three radicals, ·OH, ·H and the solvated electron; the reactions of these can be carried out in such a way that either $RO_2^{\cdot}$ radicals are formed in 90% yield or $O_2^{\cdot\ominus}$ radicals formed quantitatively. The possibility of using very dilute solutions has the advantage that even many hydrocarbons dissolve at the concentrations required; if not, derivatives are often available which are sufficiently water-soluble. One example is Trolox C, a functionalized water-soluble analogue of vitamin E.

There is certainly no better method for studying $O_2^{\cdot\ominus}$, which is so important in biological systems. The variety of reactions which have recently been uncovered indicates that we are entering a very interesting area of chemistry, interesting in particular because $O_2^{\cdot\ominus}$ forms very reactive complexes with a series of transition metal ions. A better understanding of the chemistry of antioxidants is also important, not only for elucidating the processes occurring in the living cell but also for technical processes, e.g. food technology.

In spite of the considerable progress so far made in studies of radical-induced DNA damage, which could be referred to only briefly here, this area will be the subject of further research. Because of their long lifetimes these polymer radicals can be subject to a number of unimolecular reactions which are not observed clearly in low molecular weight model systems[138, 300, 303] as their peroxyl radicals undergo much faster bimolecular termination. Synthetic polymers will be of use in investigating this point. An exact understanding of their peroxyl radical chemistry is certainly of technical interest.[45, 328]

In environmental technology radical-forming agents such as ozone are increasingly being used in the rehabilitation of former industrial sites to remove unwanted pollutants from both the soil and the ground-water. Here as well, radiation-chemical techniques provide the best method for mechanistic studies.

VCH Index Library

The electronic index comes with the search module of the literature-management program, VCH Biblio. You can use this index on all PCs running with MS-DOS.

ANGEWANDTE CHEMIE
International Edition in English

Soon available

At the press of a button

The annual index of "Angewandte" is soon available on 5 1/4" and 3 1/2" diskettes.

Yearly updates will keep this invaluable electronic library complete. You can search the cumulative contents in mere seconds.

Price: ca. DM 34.00 plus shipping and handling.

Special news! In honor of the 30th anniversary of "Angewandte Chemie I.E." the cumulative index will also be available on diskette.

Single-Crystal X-Ray Diffraction Studies of Oligonucleotides and Oligonucleotide–Drug Complexes

By Olga Kennard* and William N. Hunter

Nucleic acids constitute the library of genetic information for all living organisms. They also play a regulatory role in many biological events concerned with the utilization of genetic information. The double-helical model of DNA, proposed by *Watson* and *Crick* in 1953, suggested the structural basis for its biological role, but this insight into nucleic acid structures seems to have generated as many questions as it has provided answers. Experimental studies, in particular fiber diffraction work, yielded a wealth of information on the conformational flexibility of nucleic acids and on the importance of interactions with water and cations. Major advances in synthetic organic chemistry, with implications for molecular biology, propelled nucleic acid research forward in the late 1970s. The availability of milligram quantities of synthetic oligonucleotides of defined sequence and high purity paved the way for detailed and accurate structural analysis using single-crystal X-ray diffraction methods and, in more recent times, NMR spectroscopy. This article is a detailed survey of the structural results generated by crystallographic techniques as applied to DNA, RNA, and nucleic acid–drug complexes over the period 1979–1990. The appendix lists important definitions used in the characterization of oligonucleotide structures.

1. Introduction

The aim of a review is not only to present a factual survey of a field but to try and define the fundamental problems which are being tackled, to indicate how far these have yielded to solutions, and to discuss the possibilities opened up for future research. While factual aspects can be presented with relatively little bias, the definition of the field and the relative importance attached to the various results is necessarily colored by the reviewer's interests and prejudices, to say nothing of the very human tendency of attaching too much significance to the results from the reviewer's own laboratory. Striving for impartiality, on the other hand, produces a bland review far removed from the rough and tumble of the actual research.

In this review we present a factual account of some of the results which seem to us of crucial importance to the role of DNA and RNA structure in biological systems and discuss how far these have helped us to understand the fundamental mechanisms which are being investigated. Areas highlighted include a variety of sequence-specific model structures, RNA helices, hydration patterns, and the continuum of right-handed DNA conformation. We present detailed models for DNA with base-pair mismatches and other errors and review the interactions of a variety of drugs and antibiotics with oligonucleotides.

This is admittedly a very personal and ephemeral view of what we find of greatest interest in looking back over the work of the past decade and the way we see the success and failure of prodigious work in a score of laboratories in answering some fundamental questions about oligonucleotide structure and function. Other, possibly equally personal, views can be found in some of the reviews cited and we hope that readers will be encouraged to consult them and thus gain a more rounded view of the field. We also present a brief nontechnical account of the experimental and computational techniques used in the single-crystal X-ray determinations of oligonucleotides, as well as their scope and limitations. There is a comprehensive list of references to individual structure determinations, to complementary studies where appropriate, and to reviews and textbooks. To help the general reader to evaluate our review and the detail given in the references, we have compiled an appendix with numeric tables summarizing the main crystallographic results. For the same reason the important definitions of geometric features used to describe oligonucleotide structure are given and are translated into visual terms through a variety of diagrams. We include references to some recent conference abstracts to alert readers to important work in progress which is likely to be published in the near future.

2. The Single-Crystal X-Ray Structure Determination of Oligonucleotides

The principal references to structure determinations of oligonucleotide fragments containing four or more bases, published in the last decade or so, are given in Tables 1–3. Tables 1–3 are fairly comprehensive, although in isolated cases several structure determinations were reported for the same molecule, but carried out at different temperatures, with different counterions, or with oligonucleotides containing some brominated, methylated, or otherwise modified bases. Because the essential findings of such multiple determinations are very similar, not all references are cited.

Oligonucleotide structures fall into three main categories: the right-handed A and B forms and the left-handed Z form. Figures 1–3 show examples of each family based on a single-crystal structure determination. Throughout this article we will use global conformation to designate the helix type (e.g.,

A-DNA, B-DNA, or Z-DNA). These polymorphic forms are quite distinct.

The A form (Fig. 1) has 11 base pairs per turn of helix with 32.7° twist between adjacent base pairs. The rise per base pair is 2.9 Å. The bases are oriented *anti* about the glycosidic bond and the furanose ring adopts C3′-*endo* conformation. The global helix axis lies in the major groove with the bases displaced some distance away. The overall effect is that of a ribbonlike structure wrapped around a pole. The structure has a wide and shallow minor groove and a narrow, deep major groove.

Olga Kennard was born in Budapest, Hungary, in 1924. She was educated at the University of Cambridge (B.A., 1944; M.A., 1948; Sc.D. 1973) She was the recipient of the Royal Society of Chemistry Prize in 1980, was elected a Fellow of the Royal Society in 1987, and was awarded the Order of the British Empire in 1988. She has been a member of the scientific staff of the Medical Research Council since 1948 and worked until 1961 in London at the Institute of Ophthalmology and the National Institute for Medical Research. In 1961 she was seconded to the University of Cambridge to set up a laboratory of Crystallographic Chemistry to study the structure of molecules of biological interest, which, over the years, increased in complexity from simple steroids to large antibiotics. Since the early 1970s her laboratory has focused on the analysis of DNA fragments and DNA–drug complexes. She also pioneered the compilation and utilization of scientific data through the establishment, in 1965, of the Cambridge Crystallographic Data Centre. Currently she is Scientific Director of the Centre and Visiting Professor of University of London and is working on the structure of oligonucleotides, particularly RNA fragments.

William N. Hunter was born in Greenock, Scotland, in 1958. He studied Chemistry at Paisley College (B.Sc., 1979). Further research in synthetic inorganic chemistry and crystallography at the University of Glasgow with Prof. D. W. A. Sharp and Dr. K. W. Muir led to the award of a Ph.D. in 1982. For the next two years he was Henry Bertie and Florence Mabel Gritton fellow at the University of Sydney, working in protein crystallography in Prof. H. C. Freeman's laboratory. From 1985 to 1989 he was a research associate with Olga Kennard in Cambridge studying nucleic acid structure. He is now a lecturer in the Structural Chemistry section in Manchester with research interests centered on macromolecular crystallography.

[a] FU = 5-fluorouridine, D = 2-aminoadenine, X = N4-methoxycytosine.

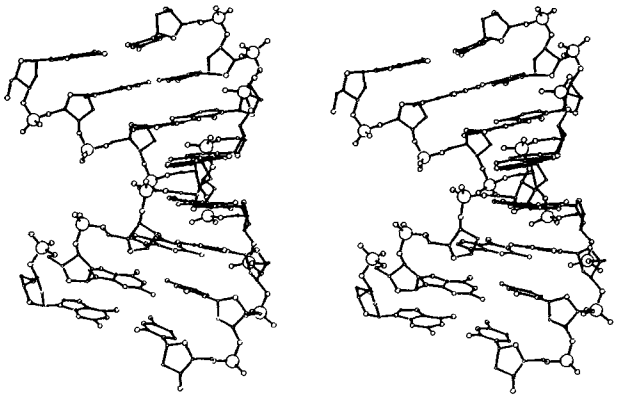

Fig. 1. Stereoview illustrating the A-form DNA as represented by the octamer d(GGGGCCCC) [9]. In this view the shallow but wide minor groove is seen at the bottom and the narrow, deep major groove above.

The B form (Fig. 2) has 10 base pairs per turn, a helix twist of 36.0° and a rise per base pair of 3.4 Å. The glycosidic orientation is *anti* and the sugar conformation tends to C2′-*endo*. The global helix axis is through the base pairs. The minor groove tends to be narrow and deep, the major groove much more open in comparison to the A form.

The Z form (Fig. 3) is a left-handed helix with a zigzag sugar-phosphate backbone, hence the name. The Z form is mostly adopted by alternating cytosine/guanine sequences and can be considered as a repeat of d(CpG) steps. There are 12 base pairs per turn and a rise of 3.7 Å. The helix twist, glycosidic orientation, and sugar conformation depend on whether the pyrimidine or purine is being considered or whether it is the first or second base pair of the dinucleotide step.

Within each family there are a number of structural subsets, denoted by A′, B′, etc. These conformations depend on small structural differences. Comparative values are presented in Table 11 in the appendix.

The number of distinct structures that have been successfully crystallized and analyzed during the past decade is still relatively limited. There are several types of B-DNA structures,

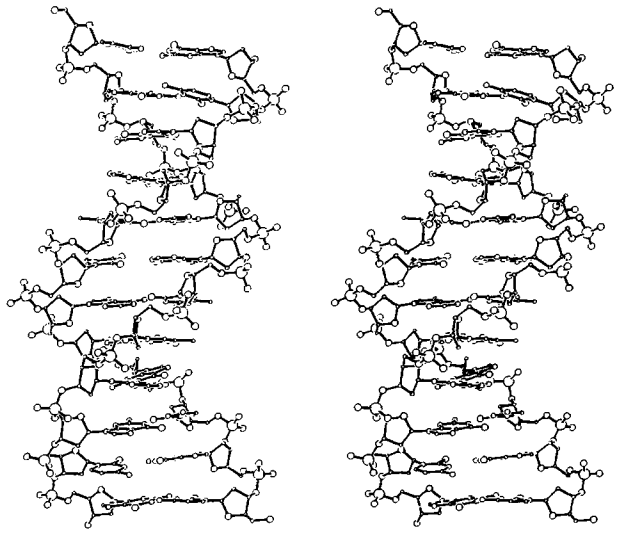

Fig. 2. Stereoview of B-form DNA as depicted by the Drew–Dickerson dodecamer d(CGCGAATTCGCG). Numerous references to this structure are given in the text.

represented by two dodecamers, d(CGCGAATTCGCG)[26] and d(ACCGGCGCCACA),[33] a hexamer d(GpsCpGpsCpGpsC),[24] decamers, d(CCAGGCCTGG)[30] and d(CGATCGATCG)[34] (Table 1), and two sequences with extra adenines[70, 71] (Table 3). These structure types make use of different interactions between adjacent double helices to create the regular crystal lattice. In contrast, all the A-

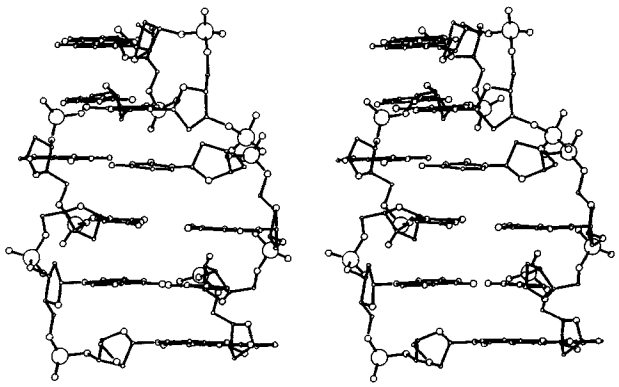

Fig. 3. The left-handed polymorph, Z-DNA, formed by the hexamer d(CGCGCG) [40, 41, 150]. Note the zigzag appearance of the phosphate-sugar backbone, from which the name is derived.

DNA helices that have been crystallized utilize a very similar packing motif involving hydrogen bonding and van der Waals contacts in the flat minor grooves. Such interactions can be accommodated in unit cells with a variety of symmetry operators, including sixfold, fourfold, and twofold screw axes. The same packing motif is utilized by a hybrid DNA–RNA decamer which forms an orthorhombic crystal.[22] Left-handed Z-DNA helices crystallize in essentially the same way, with end-to-end contacts between the helices in an orthorhombic space group (hexanucleotides) and two other closely related space groups (tetranucleotides). Selected references to deoxyoligonucleotides containing mismatched

(non-Watson–Crick) base pairs and extra bases, all utilizing the various crystal packing arrangements discussed above, are listed in Table 3. Table 4 (Section 8) gives selected references to deoxyoligonucleotide–drug complexes.

The limited number of crystal types has raised some fundamental questions about the relationship between the length of the sequence, the base composition, and the influence of crystal lattice forces in determining the type of global conformation adopted and whether or not the global conformation is identical in the crystal structures and in solution. We shall discuss these questions and some relevant experimental findings later in this review.

3. Techniques of X-Ray Analysis

3.1. Synthesis, Purification, Crystallization, and Data Collection

Techniques of synthesizing deoxyoligonucleotides in the milligram quantities required for X-ray analysis have greatly advanced since the original solution methods,[72, 73] which yielded large quantities, but which were very labor-intensive. Modern automatic solid-phase equipment based on the phosphoramidite technique[74] allows for the rapid synthesis of deoxyoligonucleotides up to 20–24 base pairs in length and of reasonable homogeneity. Stringent purification appears to be an essential prerequisite for successful crystallization. Generally, the deprotected oligonucleotide is subjected to high-pressure liquid chromatography on a strong anion-exchange resin and eluted with a phosphate buffer gradient at neutral pH. This process separates uncharged molecules from DNA and removes the shorter DNA fragments, which are by-products of the synthesis, from the main fragment by charge-based separation. A second HPLC run on C18-reverse-phase material and elution with an acetonitrile gradient separates the partially protected DNA segments of the same lengths as the target molecule from the main deprotected product, utilizing the differences in hydrophobicity. This second HPLC step also removes the phosphate salts. The pure oligonucleotide is then lypohilized to give typically 5–15 milligrams of the ammonium salt of the target DNA.

Anion-exchange separation on a preparative scale, however, is not ideal for purification of oligonucleotides longer than 10–12 nucleotides. Instead, the "trityl on" procedure is used. The acid-labile and highly lipophilic dimethoxytrityl protecting group at the 5′ terminus is left intact on the crude sample and is used to differentiate between the target sequence and the shorter sequences, where the protecting group has already been removed. A high degree of purification is achieved during the first HPLC run on a C18-reverse-phase column with acetonitrile elution. After detritylation with aqueous acetic acid and lyophilization, the sample is further purified by HPLC on an anion-exchange resin. The entire process takes about three to four days, most of which is spent on purification. Problems often arise with purification of self-complementary sequences by anion-exchange chromatography due to the formation of secondary structures such as DNA duplexes or hairpin loops, which elute at different rates. In such cases, heat and/or the use of phosphate buffer solutions, containing 20 % acetonitrile, helps to generate and maintain single strands only.

This rather detailed description of purification procedures is included to give chemists (and crystallographers) a better perspective of the problems involved in the preparation of the quantities of ultrapure compounds needed for crystallization. Even so, we would also like to note that the chances of obtaining diffraction-quality crystals on any sequence is generally less than 10 %, and crystallization remains the rate-determining step in many structure analyses.

The most common method of crystallization is to diffuse a precipitating agent into a solution containing the DNA, an associated cation, a buffer, and in many cases, spermine. Alternatively, water is diffused out of the solution by a desiccant such as hexane-1-6-diol or 2-methyl-2,4-pentanediol. In either method approximately 5- to 10-μL droplets of the oligonucleotide solution are suspended as hanging drops over a reservoir or up to 50-μL droplets are placed as "sitting drops" in hollowed-out glass plates. A wide range of conditions are commonly set up with variations in oligonucleotide concentration, the nature and concentration of the counterions, and pH, at either room temperature or at 4 °C. Remarkably, the only RNA fragment so far analyzed was crystallized at 37 °C![23] Once the approximate conditions are determined, they are refined until diffraction-quality crystals are obtained. With care, reproducible conditions are found, and more crystals can generally be grown.

The success rate of crystallization, as discussed above, is very low. Disordered crystals are often formed or none at all. Even crystals with good optical order, as indicated by sharp extinction when viewed with a polarized light source, may only give poor-quality X-ray diffraction patterns. This is most likely a consequence of rotational disorder of the cylindrical DNA helixes in the adjacent unit cells which form the crystal. The problem is further exacerbated by the extensive hydration of the crystals, which commonly contain about 50 % solvent. The limited diffracting power of many of the oligonucleotides, discussed in the next section, is the consequence of both solvent and DNA disorder.

Certain crystals are unstable at room temperature and diffraction measurements are frequently carried out at 4 °C on samples sealed in glass capillary tubes to prevent loss of solvent. Recently, several structures were measured at 115 K without a capillary, using a fast-freezing technique.[75, 76] Although this technique does not improve the diffracting resolution, it stabilizes the crystals and allows data collection from a single crystal.

The quality of the diffraction data and the attainable resolution are determined by the size and, most importantly, by the perfection of the crystals used for measurements. The Z hexamers form the most perfect crystals, often diffracting to 1 Å or better. Shorter or longer Z-forming sequences tend to be disordered. In general, the right-handed deoxyoligonucleotide crystals diffract in the range of 1.7- to 2.5-Å resolution except for the B-DNA decamer,[60] which diffracts to 1.3-Å resolution. The use of synchrotron radiation can lead to improvements in effective resolution[7] and is likely to be used more frequently in the future to aid structure solution by anomalous dispersion methods.[77, 152] A typical data collection on a diffractometer would result in some 2500 reflections to a resolution of about 2.0 Å, which would be used in

the structure analysis. The recent availability of area detectors designed for the simultaneous measurement of very large numbers of reflections is revolutionizing this aspect of the subject.[78, 79]

3.2. Structure Solution and Refinement

A variety of experimental and computational techniques can be applied to solve oligonucleotide structures, such as molecular replacement, multiple isomorphous replacement, and anomalous dispersion (see *Blundell* and *Johnson*[80]). The object is to find the correct model for the fundamental structural motif: the asymmetric unit. In many cases this motif consists of two independent oligonucleotide strands which coil about each other to form a duplex. Less frequently, the motif is a single strand and the double helix is formed by a twofold symmetry operation. Occasionally, the asymmetric unit contains four or more strands which may complicate the structure solution.[152]

Most of the successful structure determinations to date have employed the molecular replacement method with a model based on fiber diffraction coordinates or on coordinates from a related crystal structure.[4, 81] A notable exception is the use of maximum entropy methods for a 15-mer containing an extra base.[70]

Once the phase problem is solved, the refinement process begins. This procedure is directed towards reducing discrepancies between structure amplitudes calculated from the model and the experimentally determined values derived from intensity measurements. When a crystal does not diffract to atomic resolution, the number of measurements is small compared to the number of variables. In such cases constrained/restrained methods of refinement are employed and certain variables such as bond lengths and angles are held constant in an attempt to make the best use of the experimental observations.

Solvent molcules are an essential part of the oligonucleotide crystal structures. Refinement will, if the resolution warrants, include the location of solvent molecules from various electron density maps, often with the aid of computer graphics. Usually around three to eight solvent molecules are found for each nucleotide in the molecule. Counterions have only been positively identified in the Z-DNA hexamers, the B-DNA decamers, and some of the DNA–drug complexes. It is common practice to assign solvent positions as water oxygen atoms. The refinement process is terminated when there is optimal fit of the model structure with the electron density maps, when no further solvent molecules can be located, and when there is no further improvement in the crystallographic residual R. This residual is defined as $R = \sum(|F_o| - |F_c|)/\sum|F_o|$, where F_o is the observed and F_c the calculated structure amplitude. Most oligonucleotide structures are refined to an R factor of between 0.12 for well-resolved structures and 0.25 for poorly resolved structures.

The effective resolution limits the degree of structural detail that can be accurately determined. Coordinates for individual atoms can only be determined reliably for structures which diffract close to 1 Å. For most oligonucleotide structures, resolution limits the analysis to the accurate determination of structural features such as sugar conformation, orientation of bases, and the principal torsion angles. Information about the position of solvent molecules, particularly in the first hydration shell, is sufficiently reliable to allow for some generalizations of the role of hydration and its relation to global conformations.

A variant of the techniques described above has been used to analyze structures with base-pair mismatches. In these structures the contributions of the atoms of the mismatched bases were initially omitted from the calculations. At an intermediate stage in the refinement the positions of the atoms in the mismatched base pairs were located from electron density maps and their contributions were included in the calculations. In this way the analysis is not biased by a preconceived model of the base-pair mismatch. Similar techniques were used for several other structures, including some oligonucleotide–drug complexes and have led to the discovery of novel features such as Hoogsteen base-pairing in DNA fragments complexed with bifunctional intercalators.[82, 83]

4. Sequence-Specific Model Structures

4.1. Alternating B-DNA

The relation between sequence and variations in local helical parameters was analyzed in detail by *Calladine* and *Drew*[84–86] and by *Shakked* and *Rabinovich*[87] and some tentative "rules" were proposed. The rules, which relate variations in helix twist and roll angles to steric clash between base pairs, proved to be too simple and were contradicted by later X-ray structures.

An interesting generalization that has emerged, however, is the existence of regular alternation in the local helical parameters of d(AT) tracts. Such alternations, first observed in the tetramer d(pTATA),[1, 2, 89] led to the proposal of an alternating B-DNA helix for poly d(AT). In such a model the helix twist angle is smaller at the ApT step than at the TpA step. Similar alternation was reported in the central AT region of d(CGCATATATGCG).[29] Alternating backbone conformation was also observed in the phosphorothioate analogue of d(GCGCGC)[24] and, when examined closely, in the CGCG segments of the dodecamer d(CGCGAATTCGCG). DNAse footprinting experiments give good correlation with the notion that this nuclease is able to cut preferentially at ApT and GpC steps (low twist) rather than at TpA and CpG steps (high twist), suggesting that modulations of the backbone conformation may act as recognition signals, directing interactions with proteins.

4.2. Homopolymer d(A)–d(T) Tracts

The special characteristics of d(A)–d(T) tracts were first demonstrated crystallographically by *Nelson* et al.[28] who analyzed the duplex formed by d(CGCAAAAAAGCG) and d(CGCTTTTTTGCG). Although the crystals are isomorphous with the Dickerson–Drew dodecamer, the double helix has some interesting structural variations. The A·T base pairs of the central region have unusually large propeller twists (approximately 25°), which permit the formation of a three-centered hydrogen-bonding network in the

major groove between the N6 atoms of adenines and the O4 atoms of two thymines, one the Watson–Crick partner and the other the base in the 3′ direction of the opposing strand. Similar three-centered bonds were subsequently observed in d(CGCAAATTTGCG), both when crystallized by itself and when complexed with distamycin.[27] The presence of such interstrand hydrogen bonds, in addition to a marked purine–purine base overlap, confers a certain rigidity to the homopolymer tract and could well provide an explanation as to why long runs of adenines are not located in the more sharply curved tracks of chromosomes, but are found at the end of the nucleosomal DNA with decreased supercoiling.[90] The rigidity and mode of bending of DNA is a highly controversial subject and a number of different theories have been proposed to account for the many experimental observations. For a recent discussion see *Calladine* et al.[91]

4.3. Ribonucleotide Double Helices

Structural studies on transfer-RNA have been detailed elsewhere (see *Saenger*[92]), and our review is restricted to duplex RNA. There are only two examples of well-characterized crystals containing RNA double helices. They are the hybrid decamer r(GCG)d(TATACGC) studied by *Wang* et al.[22] and the 14-mer r(UUAUAUAUAUAUAA).[23, 88] Stereoviews of these structures are given in Figures 4 and 5, respectively. In both cases the major groove is narrow and deep, the minor groove broad and shallow. RNA adopts conformations similar to those observed for A-form DNA. The hydroxyl substituent on the furanose ring is implicated in restricting the sugar conformation to C3′-*endo*.

The decamer structure (Fig. 4) consists of two hybrid DNA–RNA segments on either side of duplex DNA. All three sections display a conformation similar to the fiber-based model for the 11-fold RNA duplex. Water molecules bridge the ribose O2′-hydroxyl group and the cytosine O2 group on the minor-groove side of the base pair and may contribute to the particular ribo conformation. The 14-mer RNA duplex (Fig. 5) allows for the most detailed analysis of an RNA helix. This structure can be treated as three segments separated by kinks in the sugar-phosphate backbone. The kinks influence the major-groove dimensions and result in a structure quite distinct from the fiber models. The O2′-hydroxyl group, while playing a structural role, is directed towards the minor groove and thus provides a functional group able to interact with proteins. The access to this functional group is facilitated by the relatively open minor groove in the A-form structures.

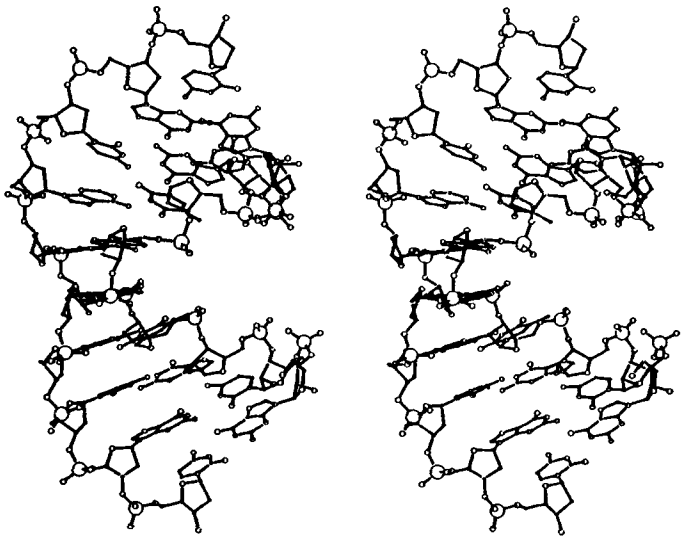

Fig. 4. A stereoview of the RNA–DNA hybrid decamer r(CGC)-d(TATAGCG), analyzed by *Wang* et al. [22].

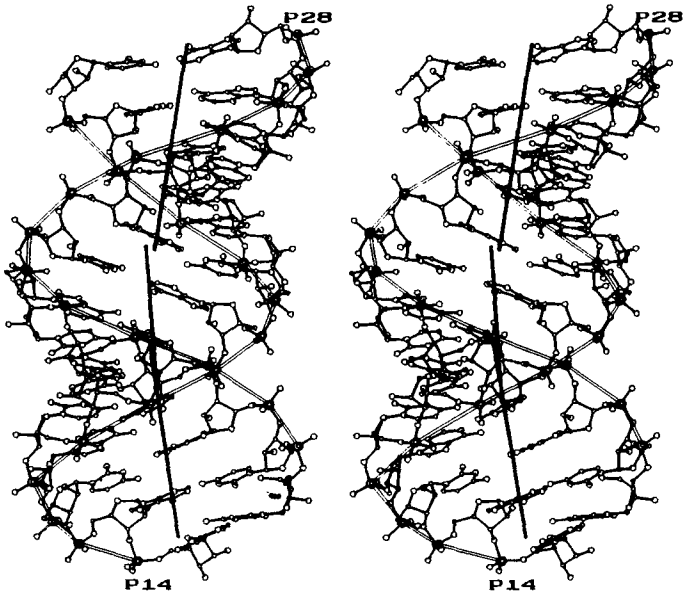

Fig. 5. A stereoview of the RNA structure r(UUAUAUAUAUAUAA), studied by *Dock-Bregeon* et al. [23]. Phosphorus atoms 14 and 28 are labeled. This structure can be considered as consisting of three segments and the three optimal helix axes corresponding to each section are drawn. Note the A form and how the bases tend to wrap around these helical axes. We thank Prof. *D. Moras* for providing this diagram.

5. Hydration

DNA crystals, as already mentioned, contain around 50 % solvent. The extensive hydration contributes to the difficulties of obtaining well-ordered crystals and precise X-ray diffraction data. It does, however, allow for the experimental study of nucleic acid hydration and extrapolation from the crystal-structure results to in vivo structures, in much the same way as is common for protein structures.

In DNA, distinct hydration patterns are observed around the sugar-phosphate backbone as well as in the major and minor grooves. An examination by *Saenger* et al.[93] of the water structure reported in numerous DNA fragments led to the proposal that in mixed-sequence DNA the hydration of the backbone is related to the global conformation. The typical backbone hydration patterns of A-, B-, and Z-DNA helices are illustrated in Figures 6–8. As can be seen, in both A- and Z-DNA a continuous chain of water molecules links the phosphate oxygens along the backbone. The water molecules are shared between adjacent phosphate groups, result-

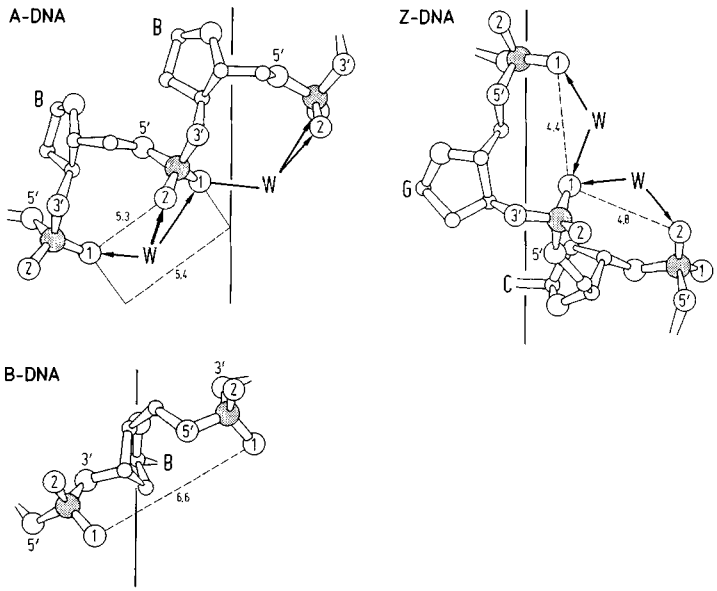

Fig. 6. A comparison of deoxyribose 3',5'-diphosphate fragments in A-form, B-form, and Z-form DNA. Phosphorus atoms are shaded, phosphate oxygens are numbered. The vertical line is a representation of the helix axis calculated for each polymorph, the dashed lines and distances [Å] represent the shortest separations between free phosphate oxygen atoms. The base position for the right-handed forms is indicated by "B" and by "G" and "C" for Z-DNA. "W" represents water molecules able to bridge free phosphate oxygens in A- and Z-form DNA [93].

ing in an effectively greater economy of hydration. In the B form there are more water molecules around each phosphate group and virtually no water bridges between adjacent phosphate oxygens. These observations can be rationalized very

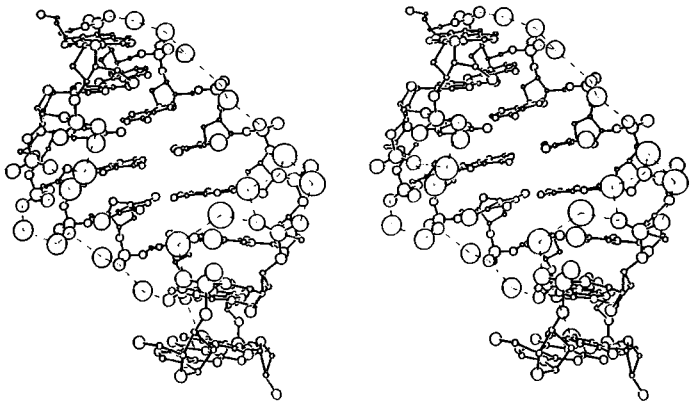

Fig. 7. The hydration of phosphate groups in the A-form fragment d(GGBrUABrUACC). This stereoview shows a view into the major groove. Waters are represented by the largest spheres with possible hydrogen bonds as dashed lines. Note that there is an almost continuous linking of phosphate groups by water molecules [93].

simply by considering the O1P/O2P···O1P/O2P distances in the three global conformations. In A- and Z-DNA the distances are about 5.4 Å and 4.6 Å, respectively, short enough to be bridged by a single water molecule. The pattern of backbone hydration in A-DNA can be affected by local changes, which appear to be related to specific sequences. In two octamers with global A conformations the backbone hydration pattern was found to be discontinuous at the central pyrimidine–purine step.[11, 14] At this step the structures deviate most markedly from standard "textbook" A-DNA. In B-DNA the corresponding phosphate oxygen distances are 6.5 Å or more, too great for a single water bridge to form. The extended sugar-phosphate backbone of the B form is either responsible for or a direct consequence of the more variable hydration under high water activity.

The hydration of the grooves appears more sequence-dependent than the hydration of the backbone. *Dickerson* and colleagues were the first to observe a regular pattern of hydration in the central AATT segment of the dodecamer d(CGCGAATTCGCG). A string of well-ordered water molecules is hydrogen-bonded to nitrogen and oxygen atoms

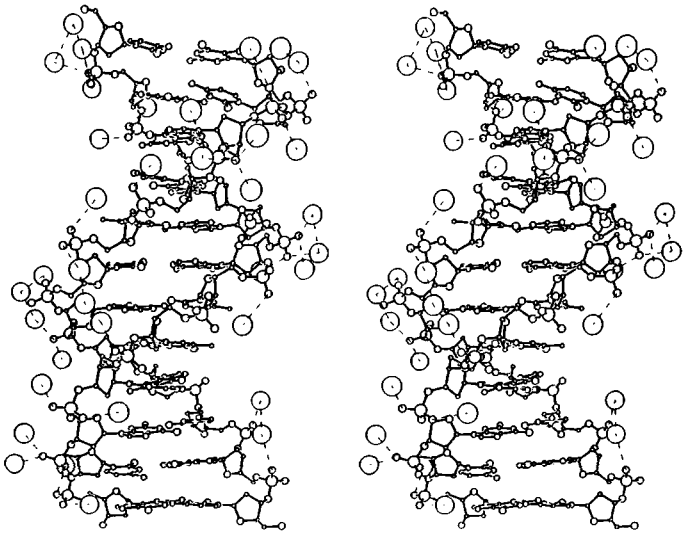

Fig. 8. Hydration of phosphate groups in the B-form dodecamer d(CGCGAATTCGCG). As in Fig. 7, the waters are the largest spheres and attendant hydrogen bonds are shown as dashed lines. The phosphate groups tend to have clusters of water molecules around them rather than bridging waters [93].

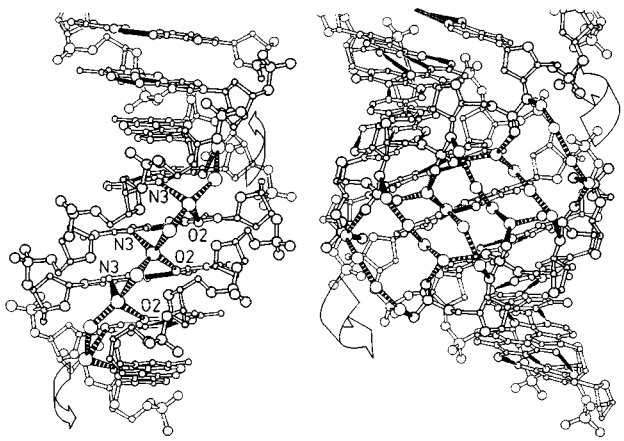

Fig. 9. Schematic illustration of the minor-groove hydration, the "spine of hydration" observed in the narrow AATT section of the B-form dodecamer (left), and the major-groove hydration observed in A-form d(loCCGG) (right). Broken lines show possible water–water hydrogen bonds, filled lines show hydrogen bonds between atoms on the DNA bases and the water molecules. Note that in the B-form the purine N3 and pyrimidine O2 atoms form the hydrophilic attachments [92].

lining the minor groove, which is very narrow in this region.[94, 95] As the groove widens at the CGCG ends, the regular arrangement of water molecules is disrupted (Fig. 9, left). This so-called spine of hydration probably plays a significant role in stabilizing the B-DNA conformation, particularly of this AT-rich region.

In A-DNA structures some sequence-specific hydration patterns were observed in the major groove . In d(IoCCGG) there are strings of water molecules across the groove linking the phosphates of each strand (Fig. 9, right).[3] The hydration pattern in the major groove of the octamer d(GGBrUABrUACC) and in d(GGTATACC)[7] consists of a series of fused pentagons involving hydrogen bonds between water oxygen atoms and the functional groups of the bases (Fig. 10). This pattern is related to the base sequence

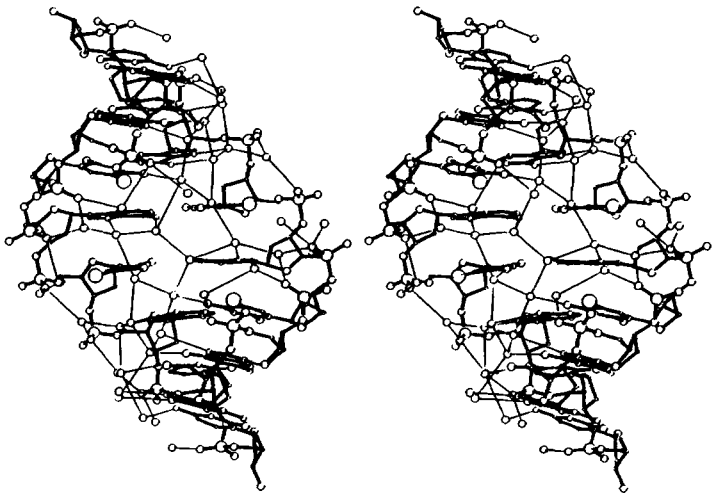

Fig. 10. The major-groove hydration of d(GGBrUABrUACC). Hydrogen bonds are shown as thin lines. Note the series of fused pentagons which fill the major groove of this A-DNA fragment.

and is disrupted in octamers with different sequences. The diagrams depicting the fused pentagons and the role of water in stabilizing non-Watson–Crick base pairs are given in Figures 13 and 14. More detailed accounts of hydration are given by *Saenger*[92, 96] and *Westhof*.[97, 98]

6. The Continuum of Right-Handed DNA Conformation

The archetypal concept that the various global conformations of right-handed DNA represent discontinuous states, which are only stable in very different environments, has undergone a marked change. Single-crystal studies have shown that the global characteristics of individual sequences are more variable than indicated by fiber diffraction studies. Refer, for example, to Table 10 in the appendix, which shows that in A-type helices the minor-groove width can vary from 10.2 to 8.7 Å and that of the major groove from 10.1 to 3.2 Å. Extrapolations from the single-crystal studies of short fragments such as d(GGGGCCCC) to models of poly(dG)·poly(dC) led to the suggestion that the homopolymer utilizes the preferred stacking of the purines and adopts a double-helical form which resembles the A form[9] even in environmental conditions where the classical B form may be expected. Preferred stacking of purines was also observed in the crystal structure formed by the nonamer d(GGATGGGAG) and its complementary strand d(CTCCCATCC).[19] This oligonucleotide structure, which represents the essential DNA binding site of the transcription factor TF III A of *Xenopus*, adopts an A-type conformation. It is worth noting that TF III A is a protein able to bind both DNA and RNA.

The question arises as to whether these structures are an artifact of the crystalline state induced by lattice forces which distort the DNA structure from the solution equilibrium conformation. For a number of years the global conformations observed in the solid state and solution could not be reconciled. For example, when sequences known to adopt an A-type conformation in the crystal were examined by NMR or CD spectroscopy, the spectra could only be interpreted as arising from the B form.[99] An important study was published by *Fairall* et al.[100] comparing the CD spectra of a number of short DNA fragments of known solid-state conformation. In these experiments carefully selected reference spectra were used and the variations in conformation in relation to the solution conditions were monitored. The results show clearly that in solution there is a continuum of helix conformations which is sequence-dependent. The CD experiments find that the complete TF III A binding site of 54 base pairs, as well as the 9-mer fragment examined crystallographically,[19] adopt a conformation which is intermediate between the canonical A- and B-DNA conformations. In addition, the study successfully correlates the CD spectra, which range from the B form, represented by the Dickerson–Drew dodecamer, to the A form characterized by calf thymus DNA in 80 % ethanol, with the experimentally determined helix parameters such as groove width, base-pair tilt, rise, and displacement.

6.1. The Coexistence of A and B Conformations

A new twist was given to the question of the influence of the environment on the stabilization of the various global forms of DNA by the observation[101] that the crystal structure of d(GGBrUABrUACC) contains double helices of both the A and B forms. The crystal lattice of this sequence is built up from A-DNA double helices which form a helical arrangement about the crystallographic sixfold screw axes and enclose a large channel approximately 26 Å in diameter (Fig. 11). The presence of DNA double helices in these channels was indicated by diffuse reflections observed on some high-intensity synchrotron photographs (Fig. 12) which are reminiscent of fiber patterns. The diffuse reflections were interpreted as originating from disordered B-form DNA helices and were successfully modeled by computer simulation experiments. The coexistence of these two DNA polymorphs of the same sequence in the same crystal structure confirms, if such confirmation is required, that the two conformations are near equivalent in energy. It further shows that different global conformations can be adequately stabilized by intramolecular interactions, such as stacking forces between bases and hydrogen bonding of base pairs as well as first- and possibly second-order hydration effects already discussed.

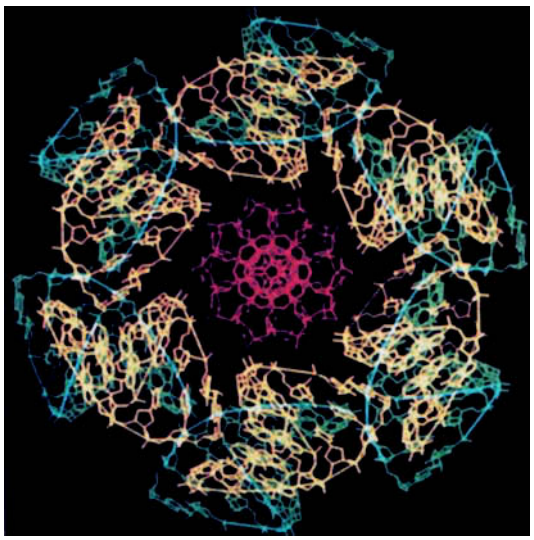

Fig. 11. A view down the 6_1 screw axis in the crystal structure of d(GGBrUABrUACC) showing the channel filled with B-form DNA (in red) and six surrounding A-form helices (in yellow and green). There are no unacceptable intermolecular contacts between the A- and B-form helices.

On the basis of this observation it is possible to conceive that in the biological situation adjacent stretches of DNA might adopt different global conformations or structures of intermediate conformation in response to the mutual adaptation between a protein and the DNA base sequence at the appropriate recognition site. Conformational shifts could occur without the drastic change of environment needed in fiber transformations. One such situation might arise at the

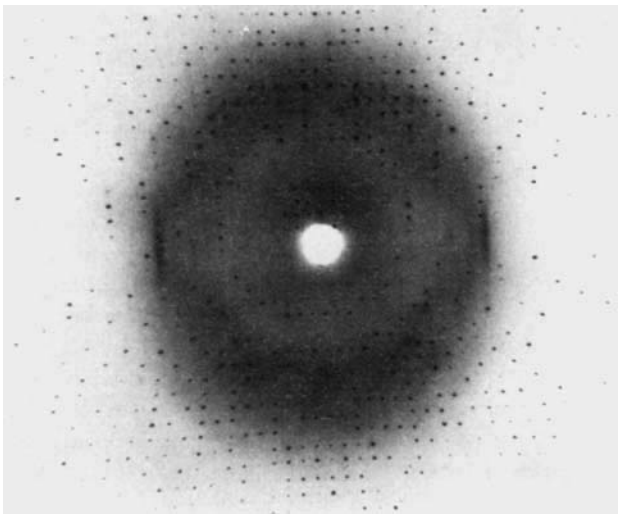

Fig. 12. A 2° oscillation photograph from a single crystal of d(GGBrUABrUACC) [101]. Discrete Bragg reflections give rise to well-defined spots. The streaks are representative of B-DNA fiber patterns. The darkening due to diffuse scattering from the glass capillary and bulk solvent is evident.

TFIIIA binding site discussed previously, which shows a strong tendency to adopt an A-type structure both in solution and in the crystal structure. A further example is the similarity between the structure of d(CTCTAGAG), the central part of which forms an important section of the *trp* repressor site[111] and the *trp* repressor/operator complex analyzed by *Sigler* and co-workers.[102]

7. Errors in the DNA Duplex

The genetic code as encapsulated in the sequence and structure of DNA is constantly under attack from chemical and physical forces present in our environment. Carcinogenic materials, ultraviolet light, and ionizing radiation, to quote but a few examples, can directly damage nucleic acid structures or induce biosynthetic errors during replication or genetic recombination. Such errors include strand breaks, missing or additional bases, chemically modified bases, or the formation of base pairs which are not complementary in the Watson–Crick sense. Biosynthetic errors may also occur as a random event even in the absence of external factors.

While modifications to DNA may provide a useful evolutionary adaptation, the mutagenic process, if unchecked, may run out of control, reduce the fidelity of replication and produce unacceptably high rates of point mutations with deleterious consequences for a given organism. Nature has evolved a complicated and as yet poorly understood recognition and repair system to process errors in DNA.[103] In recent years X-ray diffraction analyses of synthetic deoxyoligonucleotides containing a variety of errors have contributed important structural information to aid our understanding of the nature of these errors and the implication for error recognition and processing. We detail the various "error" studies in this section.

7.1. Base-Pair Mismatches

The incorporation of non-Watson–Crick base pairs in the double helix is the most common error occurring on replication. The classical theory of such mispair formation, initially proposed by *Watson* and *Crick*[140] and subsequently extended by *Topal* and *Fresco*,[104, 105] postulated the involvement of rare tautomer forms of the bases. The resultant mispairs are sterically equivalent to Watson–Crick base pairs and thought unlikely to destabilize the double helix to any significant extent. The rare tautomer hypothesis is the subject of a recent review by *Strazewski* and *Tamm*.[106]

The X-ray analysis of DNA fragments with potential mispairs cannot give any information about the transient occurrence of rare tautomer forms at the time of replication. It can, however, define the structure of a DNA double helix which incorporates mismatched base pairs and provide details concerning the nature of the hydrogen-bonding scheme between noncomplementary bases, the manner in which such base pairs are accommodated in the duplex, the influence of neighboring sequences on the structure and stability of the mispairs, and the effect of global conformation on the mispair as well as, most importantly, provide clues about the way mismatches might be recognized by proteins which constitute the enzyme repair systems.

Table 8 in the appendix presents details of the various mispair-containing structures that have been characterized. Consideration of Tables 1–3 indicates that in each case a

corresponding Watson–Crick structure is available for comparative purposes.

The purine–pyrimidine G·T, and A·C mismatches form "wobble" base pairs with hydrogen bonding between the functional groups on the bases. For the G·T mispair there is no need to invoke the presence of minor tautomer forms to explain this pairing. Two of the three functional groups of guanine that are involved in hydrogen-bonded G·C pairs are utilized. The third functional group, N2, is free and projects into the minor groove. The thymine is displaced towards the major grove, bringing the O2 group within hydrogen-bonding distance of N1 of guanine. The free functional groups are hydrogen-bonded to solvent molecules. The pattern of solvation around the G·T mispair is remarkably similar in the various G·T-containing structures which have been analyzed. These include exampes of A-, B-, and Z-form helices. These solvent molecules are likely to play an important role in stabilizing certain base-pair mismatches. The global conformation adopted by the double helix appears to have little influence on mispair formation. The G·T pair can be accommodated with minimal distortion in any of the helices studied.

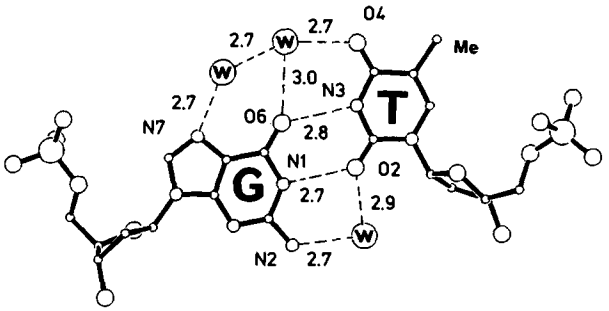

Fig. 13. One of the G·T mispairs observed in d(CGCGAATTTGCG). Distances are given in Å, hydrogen bonds are shown as dashed lines. Note the water molecules which bridge the mispaired bases in both the major and minor grooves [62].

The A·C wobble mismatch shows a close contact between two hydrogen-bond accepting groups, namely, the O2 of cytosine and the N1 of adenine. There are a variety of hydrogen-bonding schemes which can be constructed utilizing minor tautomeric forms of the bases. Because of the high-energy requirements for tautomerization, it was thought that the most likely formation of the A·C mispair involves the protonation of the adenine at the N1.[65, 66] This suggestion was later substantiated by NMR studies.[107] A bridging water, such as observed in the G·T pair, was found in the major groove of the A·C mispair. Figures 13 and 14 show these mispairs as determined in the crystal structures; Figure 15 gives the structural formulae.

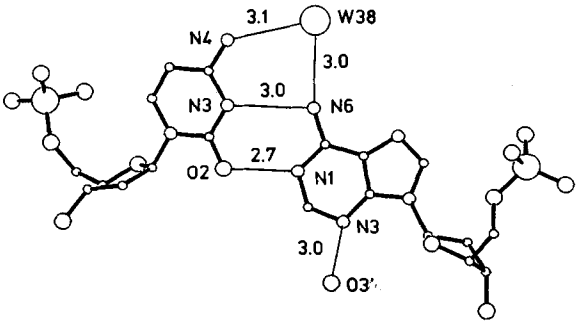

Fig. 14. One of the C·A mispairs observed in d(CGCCAATTAGCG). For comparison see Figure 13. In this case there is only bridging water molecule between the functional groups of the base in the major groove [65, 66].

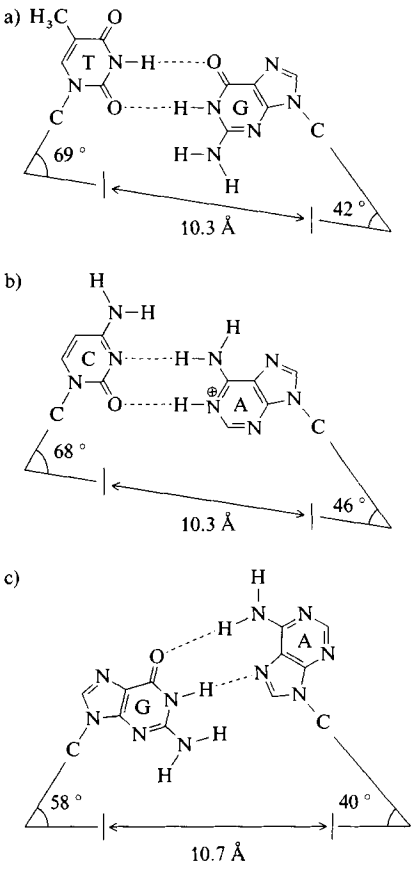

Fig. 15. Structural formulae and geometric details of three mispairs analyzed in the same crystallographic environment, namely, positions four and nine of the dodecamer sequence d(CGC_AATT_GCG). a) T·G; b) C·A; c) the G·A (*syn*). Distances [Å] represent the C1′–C1′ separation, the angles represent the N(base)–C1′–C1′ angle and highlight the asymmetry of the mispairs. Compiled from references [62–67].

The purine–purine G·A pair is more variable than the G·T and A·C mismatches. This is interesting in view of what we know about mutational hot spots and the variability of G·A mismatch repair. It was *Fresht* et al.[108] who showed that G·A was the most likely mismatch to escape detection by polymerase III. This mispair has been observed in three different hydrogen-bonding arangements (Scheme 1).

G(*anti*)·A(*syn*) in d(CGCGAATTAGCG)[63, 64]
G(*syn*)·A(*anti*) in d(CGCAAATTGGCG)[68]
G(*anti*)·A(*anti*) in d(CCAAGATTGG)[60, 61]

Scheme 1. Hydrogen-bonding arrangements in G·A mispairs.

The structural formulae for these purine–purine pairs are illustrated in Figure 16. The G(*anti*)·A(*syn*) base pair is illustrated in Figure 17. All three types of base pairs can be accommodated in the B-DNA double helix with the G(*anti*)·A(*anti*) pair causing the largest distortions to the sugar-phosphate backbone. The variation in the mutual

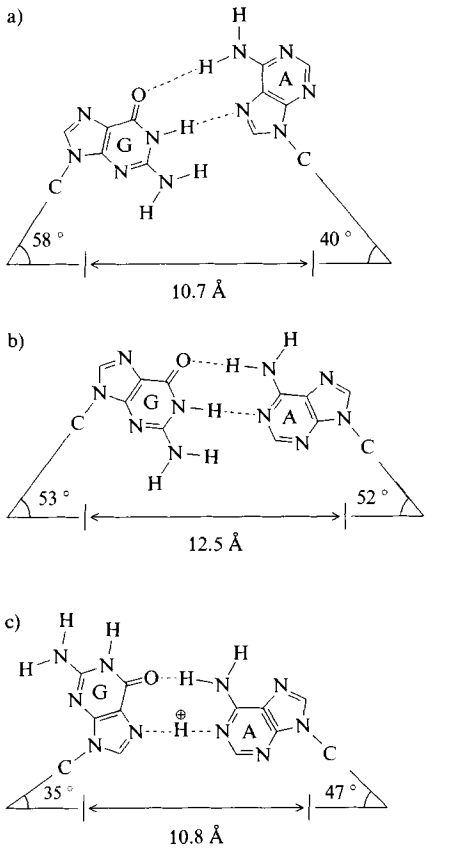

Fig. 16. Structural formulae and geometric details of three types of G·A pairing with the attendant C1′–C1′ distances and N(base)–C1′–C1′ angles. a) G(*anti*)·A(*syn*); b) G(*anti*)·A(*anti*); c) protonated G(*syn*)·A(*anti*). The largest distortions of the sugar-phosphate backbone are observed for the G(*anti*)·A(*anti*) pairing where the C1′–C1′ separation increases by almost 2 Å. Compiled from references [60, 61, 63, 68].

orientation of the bases appears to be related to both the sequence environment of the mispair and to pH. In solution the G(*anti*)·A(*anti*) pair is observed at neutral pH[109] whereas the G(*syn*)·A(*anti*) base pair with a protonated adenine is the dominant form at pH values of 4.0 to 5.5.[110]

The neighbor dependence can to some extent be rationalized by the hypothesis that this purine–purine mispair formation is strongly influenced by dipole–dipole interactions with the adjacent bases.[68] The importance of sequence environment is clearest for the G(*anti*)·A(*anti*) pair, which is stabilized by an inter-base-pair hydrogen bond from the amino N2 of the guanine to the O2 of thymine in the base pair above on the opposing strand (Fig. 18). Without a thymine in this position the mismatch stability would be lowered and another orientation could be adopted.

There is evidence[111] of differential recognition of the G·A mispair in vivo in different sequence environments. This may well be a consequence of the very different functional groups which are free to interact with polymerase or a repair enzyme in the different structural arrangements of the G·A pair. Given this variability it is perhaps not so surprising that G·A is the least well corrected mismatch.

These structural studies of mismatches have been extended to include the base inosine. This base occurs at the 5′-hydroxyl end of some tRNA anticodons, where it can pair with adenine, cytosine, or uracil. Despite the absence of the N2 amino group, this base behaves very like guanine and forms wobble pairs with thymine[60] and an I(*anti*)·A(*syn*) base pair with adenine.[67]

Extensive efforts to crystallize fragments that contain the other mismatches, A·A, G·G, C·C, C·T, or T·T, have so far met with little success. The T·T pairing has been observed

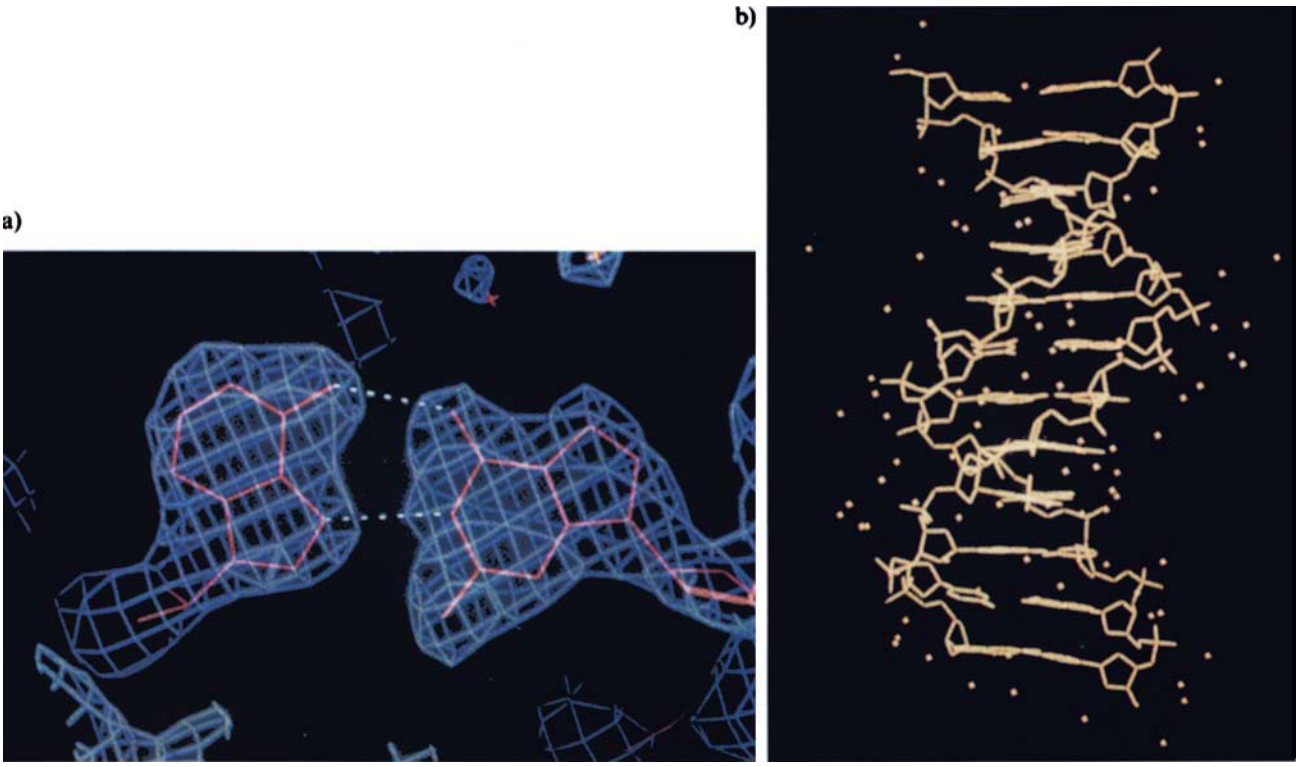

Fig. 17. The G(*anti*)·A(*syn*) base pair in the B-DNA dodecamer [63, 64]. a) The G(*anti*)·A(*syn*) mismatch viewed perpendicular to the plane of the bases G(04) and A(21), together with the electron density in the plane of the base pairs (calculated from a $2F_o-F_c$ map). b) A view of the double helix and associated solvent positions. Note that there is no distortion of the sugar-phosphate backbone in the region of the mismatch.

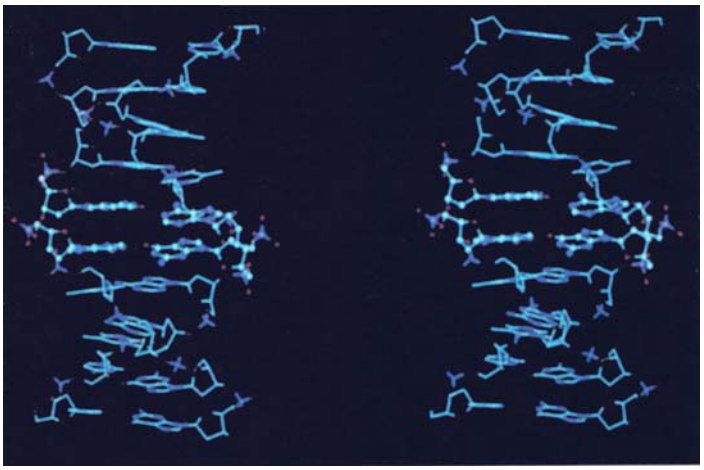

Fig. 18. The B-form decamer d(CCAAGATTGG) with the G(*anti*)·A(*anti*) base pairs [60, 61]. The mispairs in the center of the helix are highlighted. Note the cross-strand interactions of thymines in adjacent base pairs.

not in a duplex base pair but in intermolecular interactions in the sequence d(CGCGCGTTTTCGCGCG).[71] A symmetry-related molecule is positioned so that two thymines are brought into a pairing arrangement in a manner which could represent the non-Watson–Crick pair. In this structure the T·T pairing is such that the enol tautomeric form may be present for one of these bases. There is more information on mispairs from NMR experiments and readers are referred to reviews by *Patel* et al.[112] and to *van der Ven* and *Hilbers*.[160]

7.2. Extra-helical Bases and Mutation Hotspots

Three structures of oligonucleotide fragments that contain extra-helical bases have been published. Two of these were the sequences d(CGCGAAATTTACGCG)[70] and d(CGCAGAATTCGCG).[69] In both structures B-form double helices with 14 and 12 base pairs, respectively, were formed with adenines looped out from the helices. Crystal packing forces have been identified as playing a role in determining the positions of these extra-helical adenines. Nevertheless, despite the prominent role attributed to crystal packing forces, these studies illustrate how unpaired bases can be associated with a stable duplex and may give clues to the relevant properties of certain sequences that undergo frameshift mutations.

The sequence d(CGCGCGTTTTCGCGCG) referred to above was studied by *Chattopadhyaya* et al.[71] It adopts a monomeric hairpin conformation with a six-base-pair Z-DNA stem. The extra thymines form a loop which caps the left-handed helical section. A study by *Timsit* et al.[33] on the nonpalindromic sequence d(ACCGGCGCCACA) showed a structure where the crystal lattice contacts involve groove–backbone interactions which are responsible for a partial opening of G·C base pairs. This structure may be a valid model for the DNA–DNA interactions associated with such processes as genetic recombination. The partial opening of the G·C base pairs promotes a high propeller twist and sequence-dependent three-center hydrogen bonds. We would expect this section of the duplex to be less stable and this may explain the propensity of the sequence to be a hotspot for frameshift mutagenesis. Perhaps more than anything else it may highlight the importance of proteins such as recombinases in maintaining the fidelity of the genetic code.

7.3. Recognition of Mistakes in DNA

It appears from the crystallographic analysis that the DNA duplex has sufficient flexibility to incorporate mispairs or extra-helical bases in a stable duplex where the conformation of the sugar–phosphate backbone remains essentially indistinguishable from that of the native helix with no mispairs. Any distortions are highly localized. The structural studies suggest that the recognition of mispairs is likely to occur at the level of the bases. One aspect of such recognition is the distribution of donor and acceptor groups in the major and minor grooves of the helix. The discrimination of the G·C and A·T base pairs by such a mechanism was suggested by *Seeman* et al.[113] and has been supported by a number of recent crystallographic studies on DNA–protein complexes. This mechanism is likely to play a role in mismatch recognition since the functional group disposition is characteristic of the different mismatches (Fig. 19).

A second recognition feature may be the asymmetry of the glycosyl angles between the bases and the sugar on each side

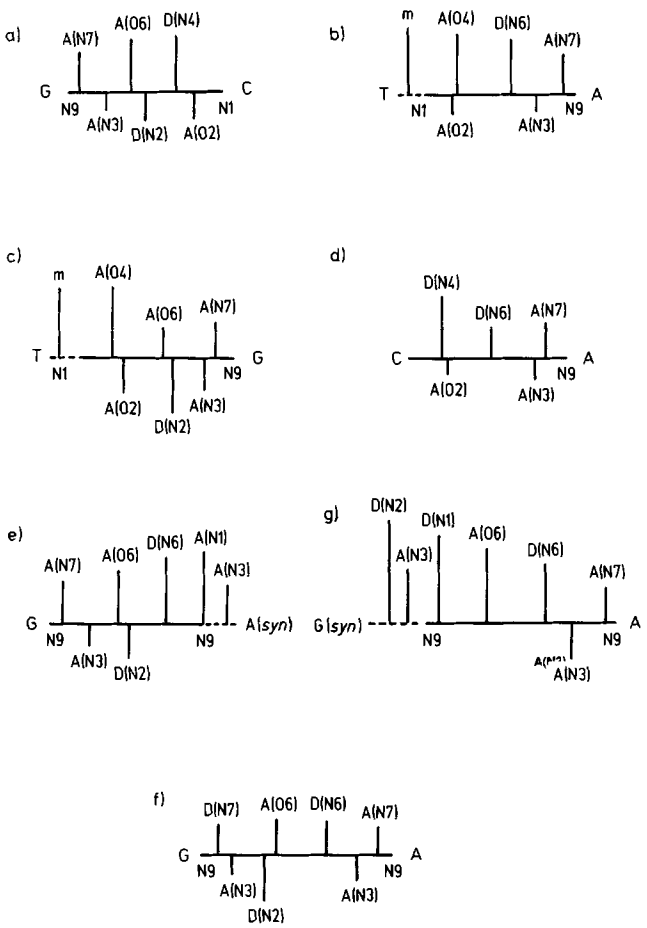

Fig. 19. Stick representations, as given in Figure 28, of the Watson–Crick base pairs G·C (a) and A·T (b) and mispairs G·T (c), C·A (d), G(*anti*)·A(*syn*) (e), G(*anti*)·A(*anti*) (f), and G(*syn*)·A(*anti*) (g). Note the varied positions of the donor and acceptor groups. Compiled from references [60–67].

of a base pair. The glycosyl angles in Watson–Crick base pairs are symmetrical but they become increasingly asymmetrical as we examine the A·G, A·C, and G·T mispairs (see Fig. 15 and 16). This asymmetry is paralleled by the repair efficiencies for these mismatches. Whether such a structural-biological correlation is significant or not will become clearer when more mispairs in different sequence environments are characterized and when there is more information about the mismatch repair enzymes and their complexes with oligonucleotide fragments containing mispairs.

8. DNA–Drug Complexes

DNA is a logical target for chemotherapy. The binding of peptides, as well as small organic and inorganic molecules, to DNA can interfere with the numerous processes, including transcription and replication, in which DNA participates. Such interference can retard or prevent cell growth. There is an extensive literature on the chemical and biochemical studies of molecules able to bind to DNA and numerous antibiotics of this type have been characterized.[114] Some of these molecules have clinical applications but most have toxic side effects.

With an increasing knowledge of the detailed structure of DNA at the molecular level, derived from X-ray and NMR studies, the challenge now is to obtain similar information about drug–DNA complexes. The hope is that such studies will lead to an improved understanding of the rules governing sequence-specific binding and an insight into the correlation between DNA structure, sequence, and activity. Such information is important for rational drug design[115] and may well lead to more useful antibiotics and antitumor agents. One must, however, beware of too simplistic a belief in structural studies. The delivery of a drug to the target site, and only the target site, is a complex problem which calls for solution studies, biological experiments, and a different type of insight into drug design requirements.

The X-ray structure analysis of DNA–drug complexes made a slow start. Up to 1984 the structure of only one complex was published, as a preliminary report,[116] but increasingly (as shown in Table 4) the crystal structures of more complexes have been solved. Progress was particularly rapid in 1988/89 when the number of papers more than doubled. Many of these have only appeared in conference reports but the main results from the studies are included here.

8.1. Drug Categories

Three categories of drugs have been studied crystallographically, intercalators, minor-groove binders, and an inorganic compound which coordinates to DNA. All these drugs can

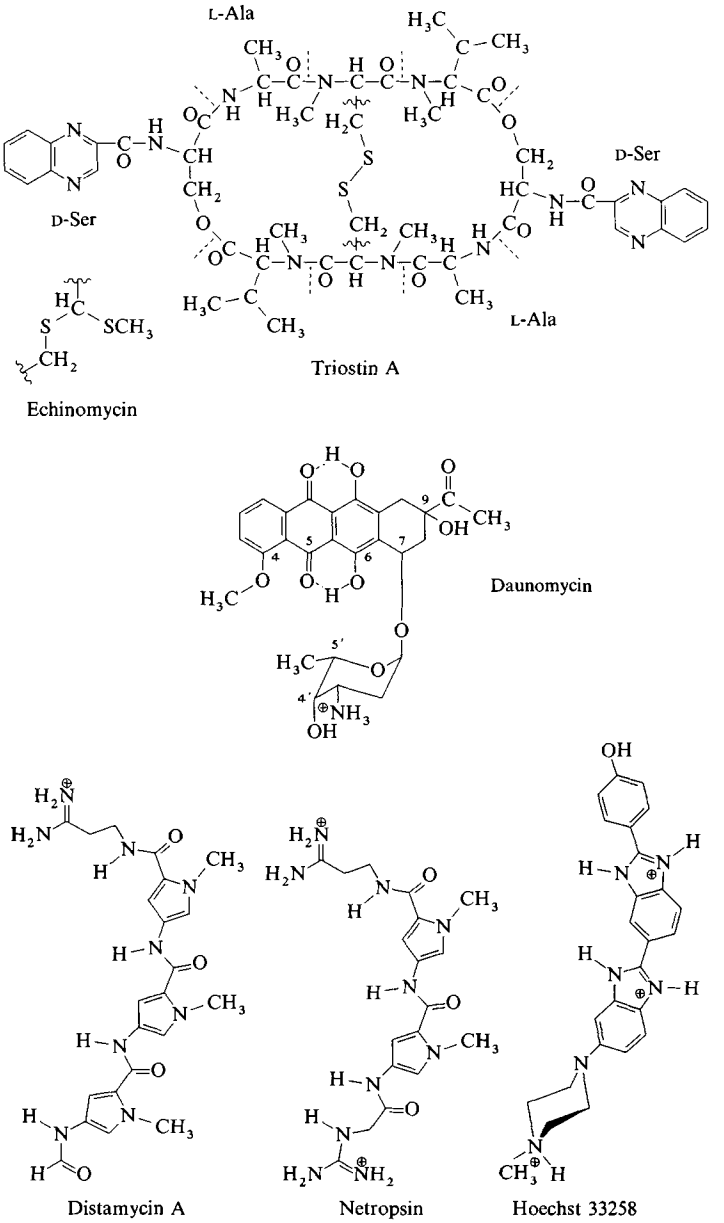

Fig. 20. Structural formulae for selected DNA-binding antibiotics which have been studied complexed to oligonucleotides. (a) shows the intercalators, (b) the minor-groove binders. The groove binders are arranged with the left side as the one which interacts with the minor-groove side of the bases while the right side is directed away from the duplex. Reference [151] contains further information concerning nucleic acid–antibiotic interactions.

bind to double-stranded DNA. The structural formulae of selected antibiotics is given in Figure 20.

Prior to describing the results of the X-ray analyses, it may be useful to recall the structural features of the DNA duplex which may be important in sequence-specific recognition by other molecules, be they large or small. They include the negatively charged phosphate backbone, the hydrogen-bond-accepting and -donating functional groups in the major and minor grooves, and aromatic, hydrophobic components able to promote van der Waals and hydrophobic interactions. There are additional structural aspects to be considered: the physical shapes and dimensions of the minor and major grooves, which are to some extent sequence-dependent, the hydration patterns, and the extreme structural flexibility of the double helix.

8.2. Intercalators

The phenomena of intercalation was first described by *Lerman*.[117] It involves the aromatic portion of a drug molecule positioning itself between base pairs. Intercalation increases the separation of adjacent base pairs and the resultant helix distortion is compensated for by adjustments in the sugar-phosphate backbone and an unwinding of the duplex. Aromatic stacking interactions between the bases and the intercalating molecule are the major stabilizing feature of the complexes formed.

Simple mono-intercalators like acridine have only been examined crystallographically in dinucleoside phosphates, which are too short for reliable extrapolation to intercalation of the double helix. More complex monofunctional intercalators, such as daunomycin, adriamycin, and their derivatives, which have a planar chromophore and a sugar residue, have been successfully cocrystallized with hexanucleotides, principally d(CGTACG), d(CGATCG), and variants of d(CGTACG) with methylated cytosines and/or a phosphorothioate linkage. Table 4 lists selected references to some of the structure determinations, Table 13 (appendix) to crystallographic details. In all these structures two drug molecules are intercalated, one at each CpG step. The chromophores are inserted in a "head-on" fashion with the long axis of the aglyclone moiety oriented at right angles to the long axis of adjacent base pairs and with the cyclohexene ring A protruding into the major groove. The amino sugar lies in the minor groove. Within this general pattern the individual contacts between drug and DNA depend both on the sequence of the bases adjacent to the intercalation site and on the chemical modifications of the intercalating drug.

The studies already reported give us an opportunity of evaluating these various factors, since we have, as indicated in Table 4, examples of complexes between different drugs and the same sequence, such as the sequence d(CGATCG) complexed to daunomycin, 4'-deoxyadriamycin, and adriamycin and the same drug analyzed in different sequence environments—for example, daunomycin complexed to d(CGTACG) and d(CGATCG). We even have two independent analyses of the same complex, daunomycin–d(CGATCG).[118, 119] It is reassuring that these two determinations led to the same structure within the relatively small experimental errors expected at the resolution of the studies.

We also have data on the X-ray structures of many of the uncomplexed drugs themselves, but as yet no structural information on the hexamers used in these studies. Figure 21 shows a daunomycin hexamer structure and Figure 22 the hydrogen-bonding system between the DNA and daunomycin, observed in the d(CGATCG) and the d(CGTACG) complexes.[118] This latter diagram emphasizes the flexibility

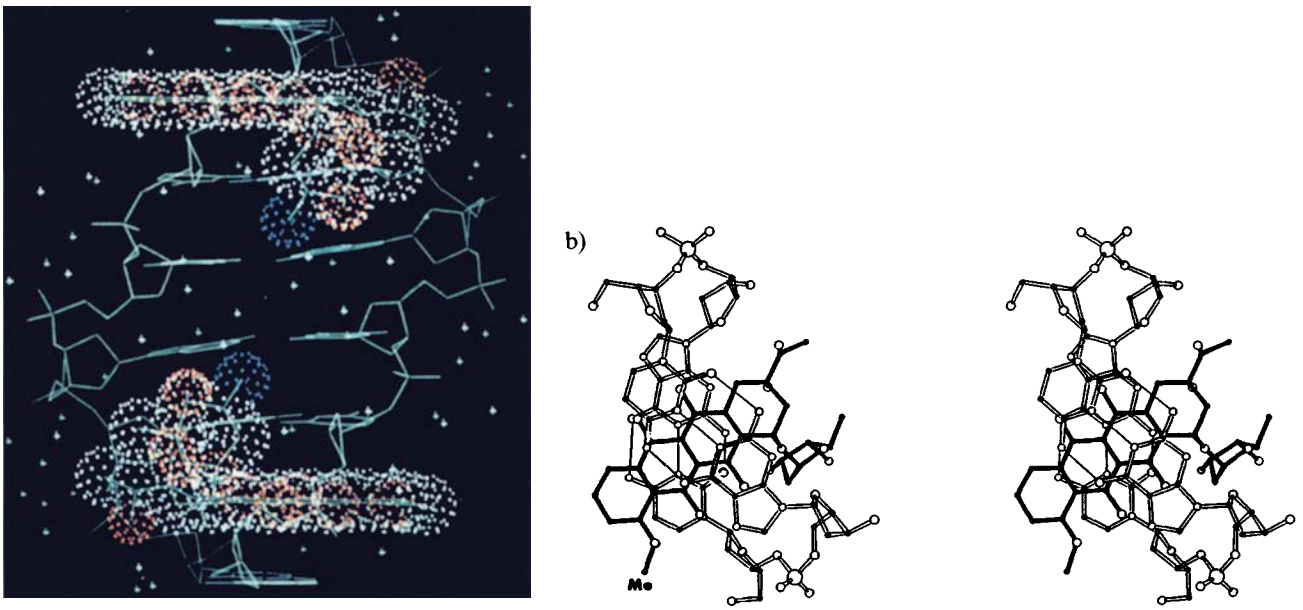

Fig. 21. The d(CGATCG)–daunomycin complex studied by *Moore* et al. [118]. (a) is a view from the minor-groove side of the complex. The drug is depicted with a dot surface representing 50 % van der Waals area. Note how the daunosamine moiety covers a large section of the minor groove. (b) is a view perpendicular to the chromophore of the drug and includes the CpG intercalation site. The drug is shown with dark bonds. This diagram illustrates the "head on" intercalation.

of the hydrogen-bonding arrangements in these complexes. Hydrogen-bond interactions can be directly between the functional groups of the drug and the DNA as, for example, between the hydroxyl group of ring A (essential for drug action) and the functional groups N2 and N3 of guanine at the intercalation site.

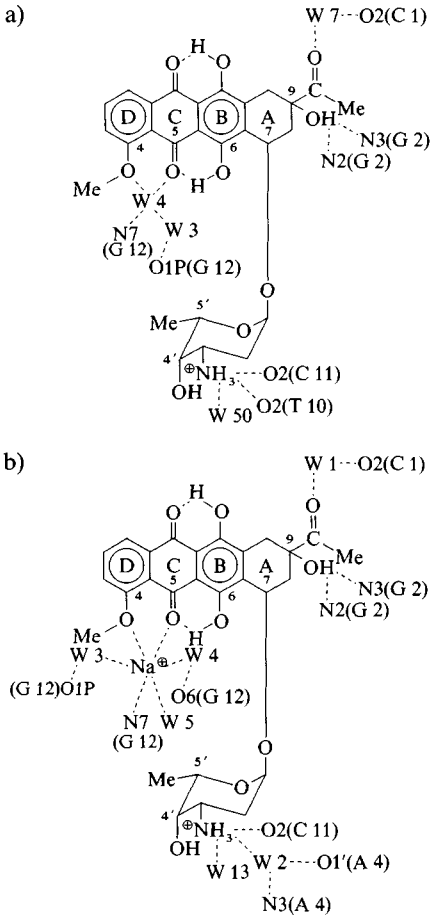

Fig. 22. Schematics of the hydrogen-bonding systems observed in a) the d(CGATCG)–daunomycin complex and (b) the d(CGTACG)–daunomycin complex [118]. The nucleobases belonging to the coordinated atoms are given in parentheses.

There is also hydrogen-bond interaction between the $NH_3^{\oplus}$ group and O2 of cytidine. The inversion of the base sequence adjacent to the intercalation site is accommodated by having a water-mediated rather than a direct hydrogen-bond interaction of the appropriate base with the $NH_3^{\oplus}$ group. Daunomycin also interacts with DNA in the major groove through water or through sodium-mediated interactions involving O4 and O5 of the chromophore substituents.

The two structure determinations show clearly why d(CpG) is the observed intercalation site for this drug and suggest that only the d(TpG) step could provide a similar hydrogen-bonding environment on intercalation.[118] Such a step has been identified as a possible binding site by *Chaires* et al.[120] and is being characterized crystallographically (*Kennard*, private communication). In addition to the hydrogen-bonding and stacking interactions at the intercalation site, the complex is further stabilized by a number of van der Waals contacts of less than 3.4 Å. These contacts are more numerous in the d(CGATCG) complex than in the d(CGTACG) complex and may possibly compensate for the somewhat weaker hydrogen-bond interactions mediated through water instead of the direct $NH_3^{\oplus}$ contact observed in the AT complex. Predictions about the importance of electrostatic interactions between the negatively charged phosphates and positively charged sugar substituent have not been substantiated by the results of the crystal structure analyses.

Two other aspects of these high-resolution studies are worthy of mention; changes in the drug structure and the distortion of the DNA double helix. Daunomycin and related molecules consist of a rigid aromatic system and a flexible sugar substituent. Comparison of the crystal structures of free and complexed drug molecules show that alterations in the structure are almost exclusively localized on the sugar moiety. The comparisons between daunomycin complexed to the two DNA hexamers show that structural differences are minimal but again localized on the flexible sugar. The distortion of the DNA can only be estimated indirectly since the structures of the uncomplexed hexamers are not yet known. There are marked asymmetric distortions of the double helix and it is possible to estimate the total unwinding angle, which is approximately 8° per daunomycin molecule. It is not yet possible to detail the effect of different drugs bound to the same oligomer since only preliminary reports of the other structures are available.

Recently, a complex between d(CGTpsACG) and the mono-intercalator nogalamycin has been reported.[121, 122] This drug has two sugars attached to the aglycone chromophore with the nogalose substituent in the minor groove and an aminoglucose in the major groove. In common with the daunomycin family there are extensive hydrophobic interactions to stabilize the complex. A close inspection of the aglycone rings of the nogalamycin and the daunomycin reveals that in the former the drug is positioned more towards the minor groove side of the duplex. This can perhaps be rationalized by the need to accommodate a section of the nogalamycin in the major groove. The shift thus enhances hydrophobic interactions on that side of the molecule and the flexible sugar on the minor-groove side is able to adjust once again to maximize interactions with the DNA.

The principal features of the DNA–drug structures discussed above are substantiated and extended in studies of complexes with the bifunctional intercalators triostin A and echinomycin (Fig. 20).[83, 123, 124] These molecules, illustrated in Figure 20, have two planar quinoxaline groups separated by a fairly rigid cyclic depsipeptide system. The two chromophores are optimally aligned (with the aid of a D-serine) to intercalate and bracket two adjacent base pairs from the minor-groove side of the B-DNA helix. Two views of an octamer bis-intercalator complex are given in Figure 23. In this complex the unwinding of the double helix is much more drastic than in the complexes with monofunctional intercalators. The DNA now resembles a ladder more closely than a double helix. As with the monofunctional intercalators, there are specific hydrogen bonds between the functional groups of the drug, the alanine amide groups, and the nucleotide bases (guanines) at the intercalation site, which account for the specificity of the drug. The most surprising feature of these structures, and one which was not predicted by the numerous theoretical studies of bifunctional interca-

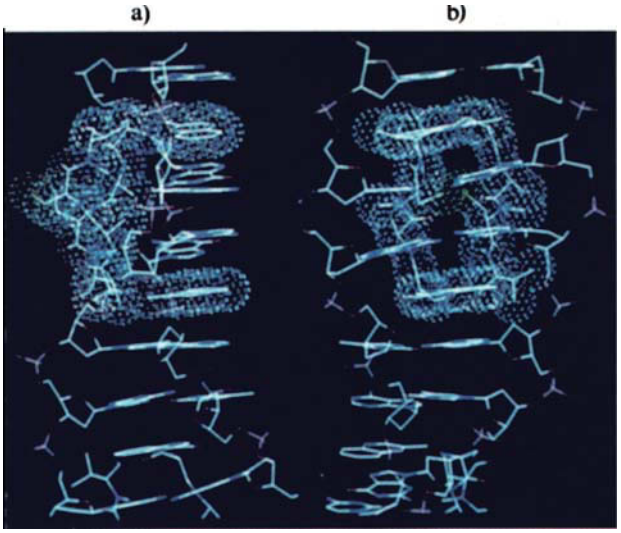

Fig. 23. Views of the d(GCGTACGC)–triostin complex characterizd by *Quigley* et al. [83]. The high degree of distortion of the DNA produces a ladder-like duplex. a) Side view of the drug highlighting the bis-intercalation. b) View from the major-groove side of the DNA. In both cases the drug is depicted with a dot surface representing a 50 % van der Waals area.

lation, is the disruption of the Watson–Crick hydrogen bonding of the base pairs adjacent to the intercalated quinoxaline rings. The central A·T base pair and the G·C pairs at each end now adopt Hoogsteen geometry.[125] This pairing arises when the purines adopt a *syn* orientation about the glycosidic bond as opposed to the normal *anti* orientation. The altered base-pairing allows the DNA to approach the drug more closely and results in extensive van der Waals interactions. Such interactions appear to be the dominant forces in the stabilization of these DNA–drug complexes.

8.3. Minor-Groove Binders

A number of studies have been reported on the structure of minor-groove binders, notably distamycin, netropsin, Hoechst 33258 (see Fig. 20), DAP1 (4′,6-diamidine-2-phenylindole),

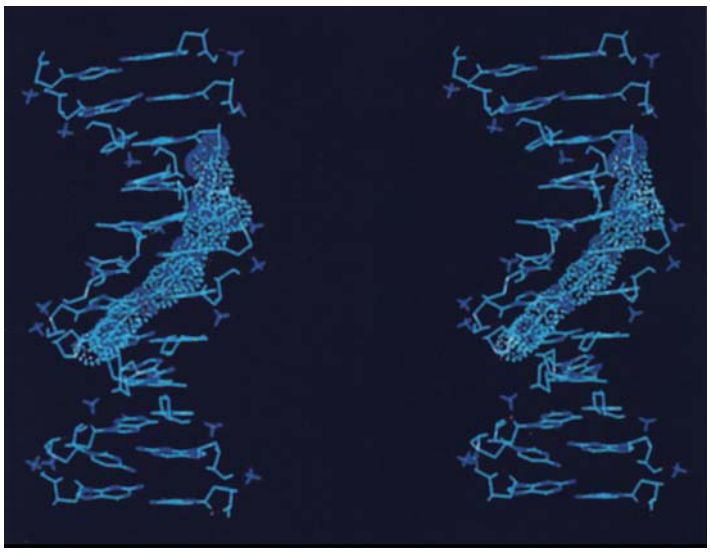

Fig. 24. A view of the d(CGCAAATTTGCG)–distamycin complex [27]. The overall B form of the DNA is retained and the drug highlighted with a dot surface representing a 50 % van der Waals area fits into the minor groove.

and, most recently, berenil, all of them complexed to either to the Dickerson–Drew dodecamer d(CGCGAATTCGCG) or one of its variants. The formulae of three of the groove binders are given in Figure 20. The diagrams presented in Figures 24 and 25 shows how this class of drugs interact with DNA. References and crystallographic constants are listed in Table 13 in the appendix. Unlike the complexes discussed in the previous section, the structure determinations were carried out at a lower resolution of between 2.2 and 2.4 Å, and thus some of the details and conclusions need to be treated with caution. In the case of one oligomer, d(CGCGAATTCGCG) complexed to Hoechst 33258, two independent determinations gave different results. In one determination[126] the drug was found to bind to the central four AATT base pairs, while in the other determination[127] the drug bound asymmetrically to the ATTC region. Only the symmetric AATT binding mode was observed in NMR studies.[128]

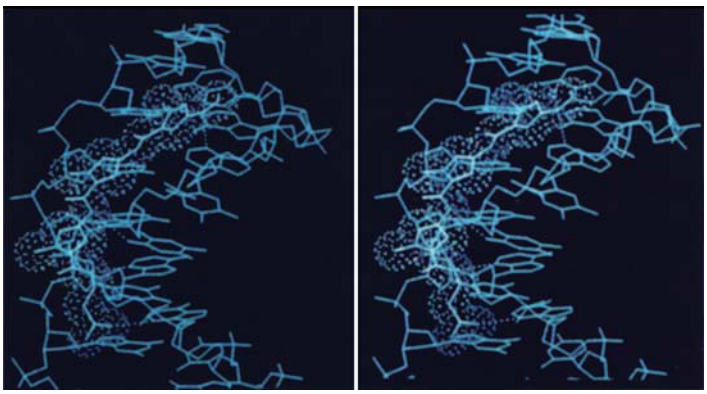

Fig. 25. A closeup view of the distamycin–d(CGCAAATTTGCG) interactions. Dashed bonds show the hydrogen bonds between the drug and the DNA.

Interestingly, the same drug, when complexed with the modified DNA dodecamer d(CGCGATATCGCG), binds in the opposite orientation and covers the GATAT region.[129] This study also contradicts previous findings that groove binders have little influence on the DNA structure itself and merely displace the so-called spine of hydration in the minor groove. In the d(CGCGATATCGCG) complex the helical twist between the ApT and the TpA steps is reversed from that described in the section on alternating DNA. An additional change involves the rotation of a thymine to facilitate hydrogen bonding to the drug.

Changes induced in the conformation of some of the groove-binding drugs themselves are surprisingly large. They include changes in the dihedral angles between the four rigid units of the Hoechst compound. It may well be that, while in some complexes the drug is a passive replacement for the ordered water structure in the narrow minor groove, in other sequences the narrow minor groove is not a feature of the native solvated sequences but is induced through an active interaction with the appropriate drug.

8.4. Cisplatin

The fortuitous discovery that *cis*-diamminedichloroplatinum(II) interacts with DNA[130] has produced one of the

most successful drugs for the treatment of cancer, albeit with serious side effects. The platinum coordinates to purines, especially adjacent guanines. Heavy-atom soaking experiments with d(CGCGAATTCGCG) produced evidence that the platinum atom was coordinating to the N7 atom of guanines.[131] Work on the drug interacting with pGpG has indicated the large degree of local distortion that this drug is likely to induce in duplex DNA.[132, 133]

8.5. General Principles of DNA–Drug Interactions

The drugs in the DNA–antibiotic complexes so far examined have all interacted mainly in the minor groove of B-DNA but have also, to some extent, perturbed the major groove. No direct electrostatic contacts have so far been observed between charged portions of a drug and the negatively charged sugar-phosphate backbone. Interactions between the drug and DNA generally involve direct hydrogen bonds linking the functional groups of the two components and hydrogen-bond contacts between such groups mediated by water molecules or by counterions. van der Waals forces contribute significantly to the stabilization of the complexes and may lead to serious perturbations of the DNA helix from the normal Watson–Crick geometry. At their most extreme, such perturbations can lead to the formation of Hoogsteen base pairs instead of the normal Watson–Crick pairs. Interaction with the DNA also induces some changes in the conformation of the drugs themselves.

Intercalation at specific base steps can be rationalized in terms of the hydrogen-bond interactions. The preference of minor-groove binders for A·T-rich regions seems to be related to the need to maximize van der Waals contacts. In some sequences the minor grooves in this region are intrinsically narrow. This produces a narrow canyon with hydrophobic walls and a polar floor which is well-suited to interaction with the types of organic molecules being discussed. In other sequences the drug itself induces the narrowing of the minor groove in the A·T-rich region to allow for close van der Waals contacts. It would be very much more difficult to induce a narrowing of a groove in a region containing guanines since the N2 group of guanine would hinder the entry of the drug into the minor groove.[134, 135] These general principles, deduced from structural studies, provide useful guidelines to synthetic chemists developing more effective and sequence-specific DNA-binding drugs.

9. Future Directions

Crystallographers, unlike other crystal gazers, claim no insight into the future. However, the upsurge of successful structure determinations in the past few years and the spread of work among a larger number of laboratories suggests that the next decade will bring a multitude of new results. We anticipate that a wealth of data will accumulate on the conformation of the various base steps in different sequence and crystal environments. It is possible that some rules characterizing the conformation of various steps will emerge, but we should not be too disappointed if, because of the extreme flexibility of the DNA double helix, there are no simple deductions. The range of oligonucleotide structures which can successfully be analyzed by X-ray diffraction methods will be extended by the development of synthetic techniques which will facilitate the preparation of much larger quantities of pure oligomers, the improved technology of X-ray data collection (synchrotron sources, area detectors, etc.), and the use of anomalous dispersion methods for structure solution.

There will undoubtedly be increased activity on the structure analysis of DNA–drug complexes with the major types of antibiotics and antitumor agents. Work on other classes of drugs such as those which form covalent or cross-strand linkages is already underway in a number of laboratories. Such studies will certainly lead to a much better understanding of the interaction between DNA and various drugs and possibly inspire the development of new anticancer agents.

Attempts may also be made at synthesizing novel molecules which would interact in the major rather than the minor groove. Ideas for such new compounds may arise from studies such as the analysis of drugs like nogalomycin, which affect the major groove and through a better characterization of DNA–protein interactions, which primarily occur in the major groove. We foresee an explosion in the number of protein–DNA complexes analyzed.

One of the largest growth areas is likely to be in the field of RNA structures. After years of mostly unsuccessful endeavors the synthesis of RNA fragments has now become a practical proposition and further developments in RNA chemistry hold out the bright hope of a similar review listing scores of RNA structures in 10 years time.

Close collaboration between workers from many disciplines using different approaches and techniques will be an essential prerequisite for all these studies if we are to gain an improved understanding of the structural basis of DNA and RNA function in the myriad biological events in which these unique polymers participate.

10. Appendix

Tables 5–13 give numeric information derived from X-ray diffraction analyses of selected oligonucleotide fragments, published between 1980 and 1990.

Tables 5–7 give selected data for DNA fragments crystallizing as A, B, or Z helices. For each crystal structure the following information is quoted: temperature of X-ray measurement, space group, cell dimensions, the resolution of the analysis, R factor, the number of solvent molecules located in the analysis, $N_{solv.}$ and the volume per base pair. The volume per base pair is calculated by dividing the asymmetric unit volume by the number of base pairs. In all these crystals two strands of the oligomer form the double helix and in many cases the double helix has no imposed crystallographic symmetry.

Table 8 lists similar data for DNA fragments containing mispairs. Comparison of Table 8 with Tables 5–7 shows that within each conformation type (A, B, or Z) the structures containing mismatches crystallize isomorphously with the native structures containing Watson–Crick complementary base pairs only. Table 9 gives data for three structures with extra bases.

[a] mC = 5-methylcytosine, araC = arabinose cytosine.

Table 10 contains the global helical parameters for A- and B-type helices observed in typical single-crystal studies and, for comparison, values derived from fiber diffraction. Table 10 is restricted to helices with Watson–Crick base pairs only. The parameters include the helix twist, rise per base pair, x, base-pair tilt, propeller twist groove width, and the displacement of the base pairs from the helix axis, D. These parameters can best be understood by reference to Figures 26–32 and the definitions given in Section 10.1. Note that there are quite substantial variations for each of these parameters in the different DNA fragments analyzed. These variations can be attributed to differences in base sequence, particularly when oligonucleotides crystallizing with the same structural motif are compared. The groove width is one of the parameters particularly affected. In A-type crystals the width of the minor groove ranges from 10.2 to 8.7 Å compared to the fiber value of 11.0 Å and the width of the major groove from 10.1 to 3.2 Å compared to the fiber value of 2.4 Å. Recently, two accounts[13, 18] have appeared on variations in the global and local parameters of the same sequence when crystal-

tures. They include the IUPAC-IUB recommendations,[136] the definitions introduced by *Dickerson* and co-workers,[137, 38] and implemented in the widely used HELIB/NEWHELIX suite of computer programs. The major groups engaged in developing algorithms for the analysis of oligonucleotide structures have recently agreed on a revised nomenclature.[139] We use the new terms in this text.

10.2. The Single Oligonucleotide Strand

Figure 26 illustrates a fragment of DNA with the sequence adenosine (A), guanosine (G), cytosine (C), and thymine (T). The bases are linked by 3′,5′-phosphodiester bonds. The fragment can be written as d(5′ApGpCpT3′) or, more usually, d(AGCT). Note that the fragment is self-complementary in the Watson–Crick sense. Figure 27 shows the atomic-numbering scheme and the definition of the torsion angles. Figure 28 illustrates aspects of nucleoside geometry with the purines in two alternative orientations, *syn* and *anti*, and also the intermolecular phosphorus distances associated with the two sugar conformations.

10.3. The Base Pairs

The Watson–Crick base pairs[140] are illustrated in Figure 29. Figures 30 and 31 illustrate the definitions associated

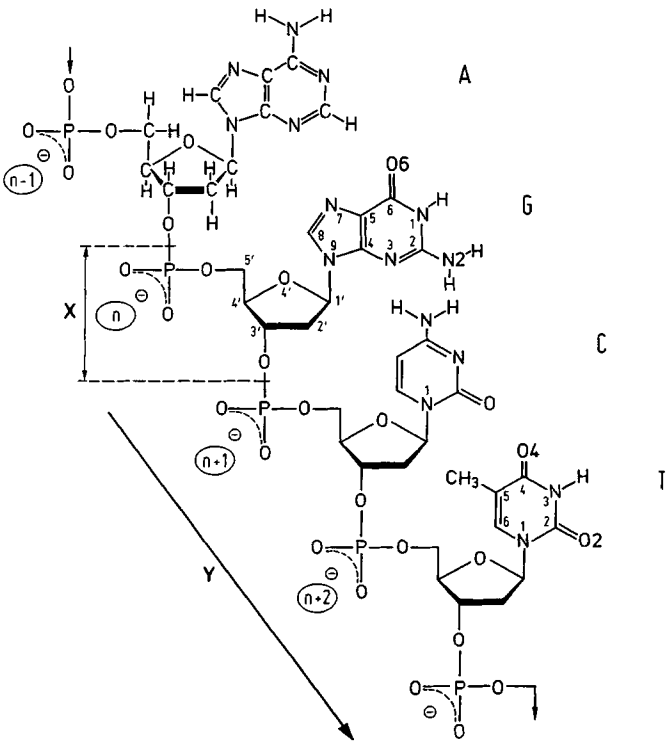

Fig. 26. The formula for a fragment of DNA with sequence adenosine (A), guanosine (G), cytosine (C), and thymidine (T) linked by 3′,5′-phosphodiester bonds [92, 136]. X indicates a nucleotide residue, Y the direction of the chain.

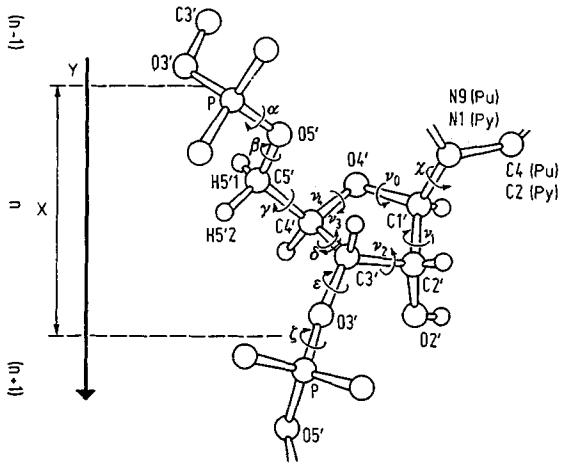

Fig. 27. An illustration of the sugar-phosphate backbone with the atomic-numbering scheme and definition of the torsion angles [92, 136] (for X and Y see Fig. 26). Pu = purine, Py = pyrimidine.

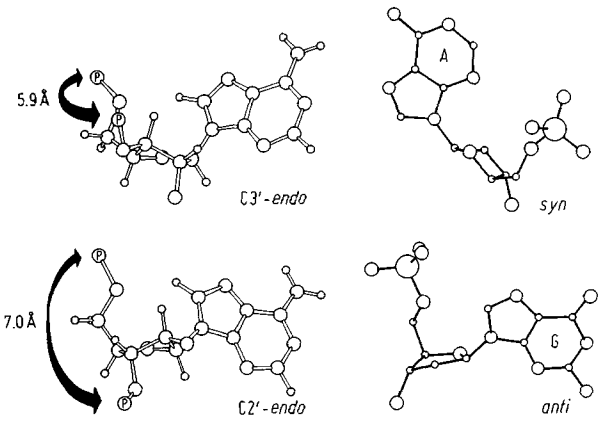

Fig. 28. Nucleoside geometry. Left: Drawings to show the two major furanose conformations encountered in structural studies and the effect each has on the phosphorus–phosphorus distances. Right: The *syn* and *anti* conformations of purines with respect to the furanose rings [92, 136].

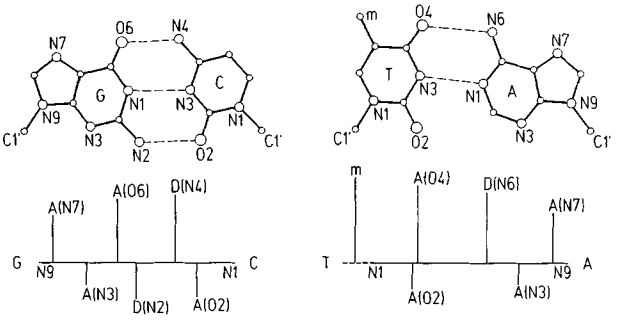

Fig. 29. The Watson–Crick base pairs G·C and A·T. Stick representations are used to convey some idea about the displacement of the functional groups of the bases. D indicates a hydrogen-bond donor and A a possible acceptor group. Base pairs are represented by a line parallel to the N9–N1 vector. The major groove is above this vector, the minor groove below.

with individual base pairs, Figure 32 with successive base pairs. These parameters are as follows:

Displacement represents the perpendicular displacement of the C6(pyrimidine–C8(purine) vector from the helix axis.

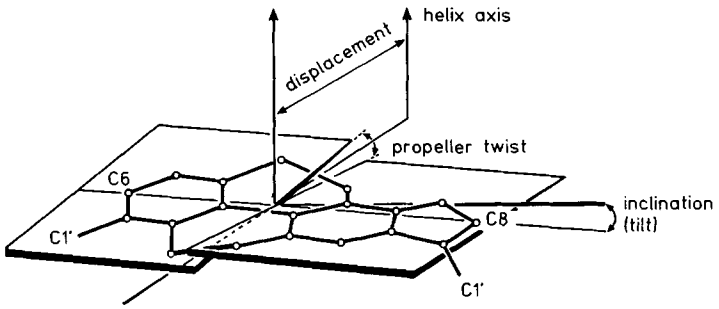

Fig. 30. Schematic drawing to show displacement, propeller twist, and inclination (formerly tilt) for a G·C base pair. The C6(pyrimidine–C8(purine) vector is drawn. This is often used as a point of reference.

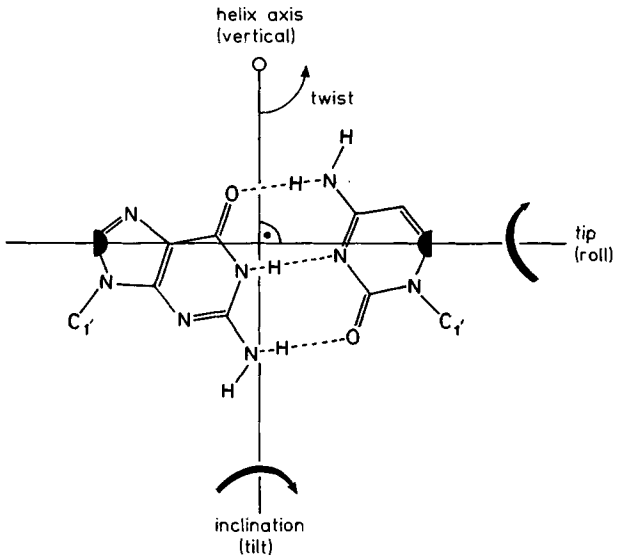

Fig. 31. An illustration of twist, inclination (formerly tilt), and tip (formerly roll) for a G·C base pair. The dark semicircles represent the positions of the C6 and C8 atoms of the pyrimidine and purine, respectively.

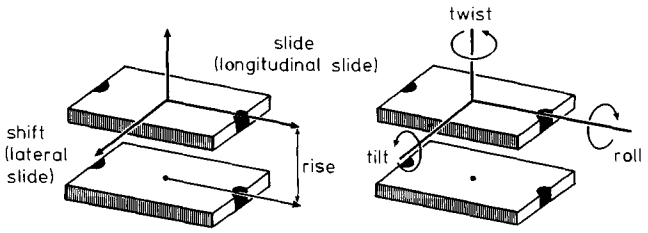

Fig. 32. Definitions for successive base pairs. This drawing shows slide, shift (formerly named lateral slide), twist, tilt, and roll. The base pairs are represented by blocks with the minor-groove side shaded and the C6(pyrimidine)/C8(purine) atoms depicted as dark semicircles on the short edges.

Propeller twist is the dihedral angle formed between individual base planes when viewed along the C6–C8 vector of the base pair.

Inclination (formerly base-pair tilt) defines the orientation of a base pair relative to the helix axis. It represents a rotation of the base-pair plane about the pseudodyad axis.

Tip (formerly base-pair roll) is used to define the orientation of a base pair relative to the helix axis and is denoted by a rotation of the base-pair plane about a line approximated

by the C6–C8 vector. This vector is perpendicular to both the helix axis and pseudodyad.

Helix twist also defines orientation of the base pair with respect to the helix axis. It is calculated by projecting successive C1′–C1′ vectors down a plane normal to the helix axis and measuring the angle between the two vectors. Alternatively, a local helix axis can be determined and by projecting the C6–C8 vectors in a similar fashion the local helix twist can be calculated.

Properties of successive base pairs

Roll and tilt define the angles between successive base pairs in the directions of the short and long axes, respectively.

Rise is the distance between successive base pairs along the helix axis.

Shift (formerly lateral slide) is the relative displacement of the C6–C8 vector midpoints of successive base pairs perpendicular to the long axis of the base pair.

Slide is the relative displacement of the C6–C8 vector midpoints of successive base pairs parallel to the long axis of the base pair.

Analytical expressions are given in Refs. [137, 138 141]. For calculations of the global helix axis the reader is directed to Ref. [6].

10.4. Properties of Grooves

Characterization of the shape of the major and minor grooves of the double helix is important since in many cases it will influence access to the functional groups of the bases by some sequence-specific agent such as a drug or protein. Shape will also influence the pattern of hydration. It is generally presented in terms of groove width and depth. The groove width can be estimated as the shortest phosphorus–phosphorus distance across a groove less 5.8 Å to compensate for the van der Waals radii of two phosphate groups Minor-groove depth is determined by the distance between phosphorus and the N2 of guanine, N3 of adenine, or O2 of either cytosine and thymine, less the sum of the van der Waals radii. The major-groove depth is quoted as the direct distance between the phosphorus and O6 atoms of guanine, N6 of adenine, O4 of thymine, and N4 of cytosine less the sum of their respective van der Waals radii. The van der Waals radii of oxygen and nitrogen atoms are generally taken as 1.4 and 1.5 Å, respectively.

We thank our colleagues, past and present, who worked in the crystallographic chemistry group, University Chemical Laboratory, Cambridge, and contributed to many of the studies cited in this review and to our friends in various laboratories who made their papers available to us prior to publication. We thank Springer-Verlag for permission to use diagrams from the Landolt-Bornstein Tables. The studies in Cambridge have been funded by the Medical Research Council. W.N.H. gratefully acknowledges the support of the Department of Chemistry at the University of Manchester, the Science and Engineering Research Council, and the Wellcome Trust.

Medicinal Chemistry in the Golden Age of Biology: Lessons from Steroid and Peptide Research**

By Ralph Hirschmann*

In memory of Max Tishler (1906–1989), mentor and longtime friend

Collaboration between biologists and chemists has generated medicines of enormous benefit to society. The dynamics of this synergistic interaction combines two strengths: the rigor of chemistry and the ability of biologists to construct unifying concepts from diverse fields of investigation. The resulting contributions to the practice of medicine have reduced morbidity and mortality while increasing the quality of life. Building on the work of chemists such as *Robinson, Prelog, Woodward,* and *Pauling*, medicinal chemists have advanced rational drug discovery, especially of enzyme inhibitors, to a degree unthinkable even twenty years ago. Some of the major contributions of medicinal chemistry to human and animal health stem directly from the creative application of structural and electronic reasoning, from advances in instrumentation, and from spectacular progress in biology. However, medicinal chemists have only begun to scratch the surface of the opportunities made possible by the impact of the "double-helix revolution" of the 1950s.

The most fundamental and lasting objective of synthesis
is not production of new compounds,
but production of properties.

George S. Hammond
Norris Award Lecture, 1968

1. Introduction

That effective collaboration between biologists and chemists fuels the drug discovery process is the underlying assumption of this article. To optimize this collaboration, it is desirable that chemists identify problems in biology that can be effectively and seminally solved through chemistry—which, as the molecular science, is in a position to play a central role in our understanding of biological events at the molecular level. Suffice it to say that the names of over forty biological journals include the word "Molecular". I will use the term *medicinal chemistry* to encompass whatever is of interest to those leading chemists in academia, at research institutes, and in industry who contribute to the biomedical sciences and/or drug discovery. I believe that chemists, though properly awed by developments in molecular biology stemming from the discovery of the double helix, have not, in their own minds, enjoyed the pride and self-esteem fully justified by their remarkable contributions to medicine and by their critical role in bringing about the "double-helix revolution" in biology.

This article is intended as a review of selected lessons in biomedicine-related chemistry that have been learned during the past 40 years. The items selected are developments that were of particular interest to the author. Thus, the examples are chosen subjectively and are based for the most part on research with the anti-inflammatory steroids (glucocorticoids) and with a small number of both large and small peptides.

Philadelphia, PA 19104-6323 (USA)

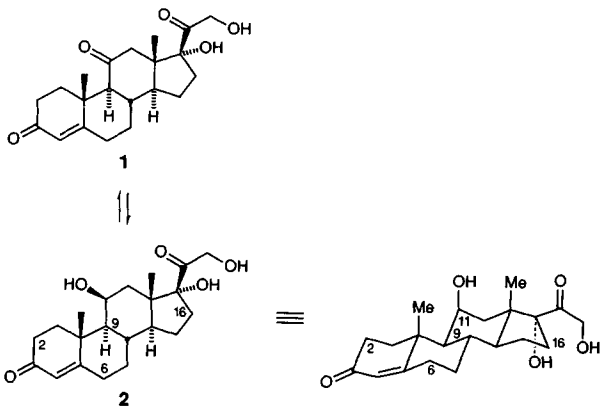
[**] This paper is based, in part, on the 1986 ACS Medicinal Chemistry Award Lecture and the 1988 Nichols Award Lecture of the New York Section of the American Chemical Society.

Three landmarks of the late 1940s and early 1950s make the past four decades a suitable time frame for review. First, *Sir Robert Robinson*'s electronic interpretation of organic chemistry, already the basis for the mechanistic thinking of the organic chemist, was introduced to medicinal chemistry. Secondly, the 1950s saw the application to medicinal chemistry of what was to become another of its major pillars, *structural chemistry*, resulting from the pivotal work of *Pauling, Prelog,* and *Woodward*. Had I chosen to view the past 40 years through a different glass (e.g., β-lactam antibiotics rather than the glucocorticoids), the same principles and strategies—electronic and structural—would still have been cited, but I would also be discussing the discoveries of *Fleming, Florey, Chain*, and *Abraham* and the synthetic contributions of *Woodward, Sheehan, Christensen, Morin*, and many others. Thirdly, the past forty years coincided with unprecedented developments in physical methods of characterization. As exemplified by steroid research, medicinal chemistry benefited enormously from the expanding applications of ultraviolet spectroscopy (*Dannenberg, Dorfman, Gillam, Woodward*), molecular rotation relationships (*Barton, Braude, Djerassi, Wallis, Young*), and mass spectroscopy (*Djerassi*), from the developing application of rotatory dispersions (*Djerassi*) and infrared spectroscopy (*Cookson, R. N. Jones, Dobriner, E. R. Katzenellenbogen*), and, finally, from the nuclear magnetic resonance technique (*Shoolery*).

2. The Cortisone Era

The discovery by *Hench* et al.[1] of the dramatic effect of cortisone (**1**) on patients incapacitated by rheumatoid arthritis opened the door to the cortisone era of the 1950s. Besides its great importance in physiology and medicine,

cortisone had an enormous impact on chemistry, both medicinal and otherwise. The isolation and characterization of this glucocorticoid steroid hormone—with which we associate the names of *Wintersteiner*, *Reichstein*, and *Kendall*—were remarkable achievements. Later on, it was recognized

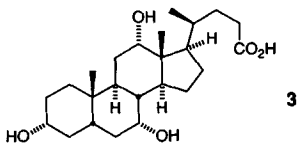


1 ⇌ **2**

that cortisone (**1**) and cortisol (**2**) are interconvertible in vivo and that the latter is the biologically active compound.[2a]

2.1. Synthetic Challenges

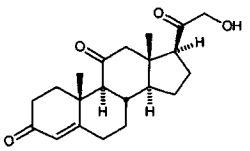
Cortisone was first synthesized by *Sarett*.[2b] To make the 37-step conversion of cholic acid (**3**) to cortisone practical on a commercial scale, *Tishler* at Merck introduced process re-



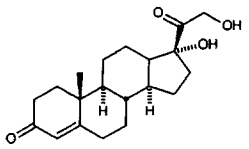
3

search as a sophisticated form of organic chemistry. He proved that esoteric reactions discovered in university laboratories can be reproduced effectively on a pilot-plant or even factory scale to manufacture molecules that possess medical and thus social value. Thereby he expanded enormously the horizons of the pharmaceutical industry.

The partial synthesis of **1** incorporated advances from the laboratories of many distinguished synthetic organic chemists of the international steroid community, including *Bergmann, Djerassi, Fieser, Gallagher, Julian, van de Kamp, Kendall, Marker, Mattox, Meystre, Miescher, Reichstein, Riegel, Robinson, Rosenkranz, Ruzicka, Sarett, Schwenk, Turner, Wallis, Wettstein, Woodward*, and their collaborators. As reported by *Fieser* and *Fieser*[3] in their well-known 1959 treatise *Steroids*, the research conferences sponsored by the National Research Council helped assure collaboration between many of the principal participants. The synthesis of **1** was preceded by that of *Kendall*'s Compound A (**4**). *Tishler*



4



5

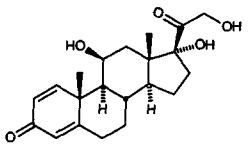
and three associates undertook the production of **4** in February 1944. By the summer of 1945, about 100 g had been prepared. In collaboration with *Kendall* and *Turner*, the laboratory production of cortisone was begun in March 1946 by three chemists and a technician, with early steps supported by the pilot plant. A total of 576 kg of the bile acid starting material **3** was processed. The hormone became available about two years later (April 1948), and the classic clinical study by *Hench*[1] at the Mayo Clinic began that same month. The original plan had been to assess the potential of cortisone by making 25 g available for testing. Fortunately, the highly successful process research, which raised the yield by more than two orders of magnitude, provided more than the targeted 25 g. This proved to be very important, because—as reported by *Tishler*—about 100 g was required to demonstrate the hormone's usefulness. Ultimately, 938 g of cortisone was produced! The production of the first 1000 kg of cortisone from bile acid was completed in about 30 months in the pilot plant. The extraordinary chemical and engineering accomplishments aside, it seems remarkable in retrospect—the interest of the Air Force in the adrenal steroids notwithstanding—that Merck undertook this task even prior to the first clinical success in arthritic patients and despite the fact that neither *Kendall*'s Compound A (**4**) nor *Reichstein*'s Substance S (**5**), which between them contain all of the oxygenated functions of **1**, possessed noteworthy biological activity. Indeed, the absence of such activity in the

Ralph Hirschmann is Research Professor of Chemistry at the University of Pennsylvania in Philadelphia. He has a concurrent appointment as University Professor of Biomedical Research at the Medical University of South Carolina in Charleston. Born in Germany in 1922, he came to the United States in 1937 and received an A. B. degree from Oberlin College in 1943. After three years of service in the U. S. Army during World War II, he began graduate studies at the University of Wisconsin in Madison, receiving a Ph.D. degree with William S. Johnson in 1950. He joined Merck & Co. that year and retired as a Senior Vice President in 1987.

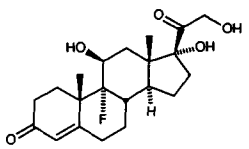
former compound had been a source of profound disappointment to those involved in the program.

The complexity of the synthesis of cortisone sparked an intensive search by many of the leading chemists in industry and in universities to discover alternative starting materials, and thus simpler routes and, later on, safer analogues. This interest generated novel chemistry in many laboratories principally in Switzerland, the United Kingdom, the United States, and Mexico. During the early and mid 1950s, at Gordon Research Conferences on the Chemistry of Steroids (now the Conference on Natural Products), investigations by many other organic chemists were also discussed—among them *Bernstein, Bowers, Chemerda, Fried, Henbest, Hershberg, Heusser, Herzog, H. Hirschmann, Hogg, Johnson, Laubach, Oliveto, Ringold, Schneider, Sondheimer, Stork, Taub*, and *Wendler*. It was an unusually exciting time, when one was always apprehensive about the competition's latest advances.

The complexity of the conversion of the bile acids to cortisone produced still another fringe benefit, in that the search for alternative starting materials and shorter routes enabled microbiologists—principally at Upjohn, Squibb, and Pfizer—to demonstrate that microbial transformations



6



7

can be invaluable adjuncts to the repertoire of the chemist. Two of the important early synthetic analogues, prednisolone (**6**) and 9α-fluorocortisol (**7**), stemmed from serendipitous observations resulting from microbial transformations.

2.2. Electronic and Structural Issues

During the 1950s, *Sir Derek Barton*,[4] building on *Hassel*'s[5] analysis of the stereochemistry of cyclohexane with its interconverting boat and chair forms, contributed uniquely to our understanding of the chemical behavior of the steroids as it is affected by the geometry of the molecule with its axial, equatorial, and pseudoequatorial substituents. Steroids, with their rigid backbones, became a proving ground for conformational analysis. Earlier, *Reichstein* had observed that there are two kinds of α and two kinds of β substituents. Almost overnight, *Barton*'s insights systematized a multitude of seemingly unrelated observations, such as the fact that a 3β-hydroxyl substituent in the allopregnane series (A/B rings *trans*) behaves chemically like a 3α-hydroxyl in the pregnane series (A/B rings *cis*). Both are equatorial substituents (Fig. 1). Building on *Barton*'s concepts, *Hirschmann* and co-workers[6] were able to explain their unexpected observation that solvolysis of the equatorial 12β-mesylate of rockogenin led to the unprecedented rearrangement to a C- nor D-homo ring system, rather than to methyl migration or to dehydration without rearrangement (Fig. 2). It was one

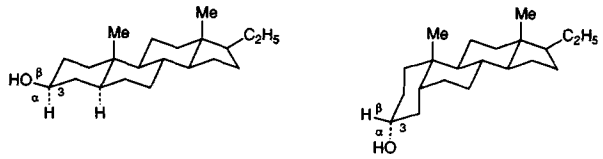


Fig. 1. The 3β-hydroxyl of the allopregnanes (left) and the 3α-hydroxyl of the pregnanes (right) are equatorial.

of the first, if not *the* first, rearrangement explicitly[6a] recognized to be under stereoelectronic control; it also allowed us to propose a pathway for the biosynthesis of the alkaloid jervine (**8**).

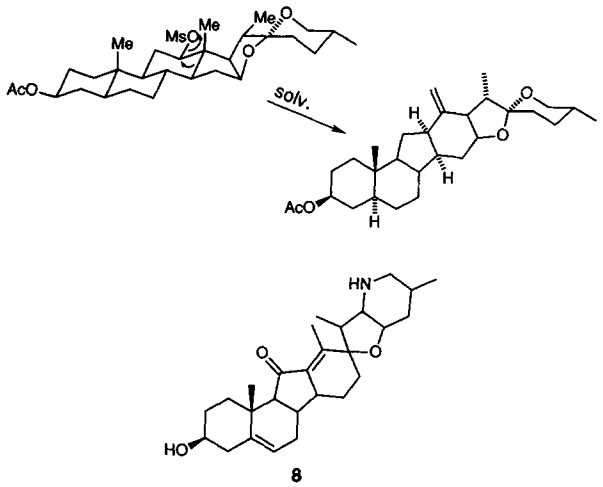

Fig. 2. The solvolytic rearrangement of the 12β-mesylate of rockogenin is under stereoelectronic control[6a] and suggested a biosynthetic route to jervine (**8**).

Barton's and *Robinson*'s insights, combined with the understanding of steric hindrance effects, studied especially by *M. Newman* and *H. C. Brown*, enabled chemists to rationalize steroidal structure–activity relationships (SARs). It became understandable why equatorial 2α-, 6α-, and 16α-methyl substituents enhanced the biological activity of cortisol, whereas the axial 2β and 6β substituents decreased such activity (for numbering, see **2**). Activity enhancement by the 2α and 6α substituents was thought to be due to decreased metabolism of the α,β-unsaturated 3-ketone, whereas the axial 2β- and 6β-methyls interfered with the binding of the 11β-hydroxyl to the glucocorticoid receptor. That both the 16α- and the 16β-methyl groups enhanced potency came as no surprise to anyone cognizant of the fact that, because the D ring is five-membered, both methyls occupy quasi-equatorial positions, thus protecting the C-17 side chain from metabolism without interfering with the binding of the 11β-hydroxyl to the receptor. *Fried* at Squibb explained the SARs of 9α-halogen substitution on the basis of electronic effects;[7] steric effects of large 9α substituents may also play a role. That 9α-fluorocortisol (**7**) is ten times more potent than cortisol (**2**) was attributed[7] to the increased acidity of the important 11β-hydroxyl. As electronegativity decreased and the size of the halogen increased, potency decreased: 9α-chloro, 4.7; 9α-bromo, 0.28; 9α-iodo, 0.1 (cortisol = 1). It is interesting that crystallographic

analysis of **7** by *Weeks* et al.[8] revealed that the 9α-fluorine substituent also has a structural effect on the A ring.

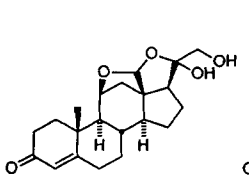
The creative application of electronic and steric concepts enabled the chemist in the pharmaceutical industry to reduce the number of compounds which had to be synthesized and tested in going from a lead to a candidate for clinical trial. *Sarett* referred to this as the "minimum systematic approach" to drug discovery.

2.3. Biological Issues

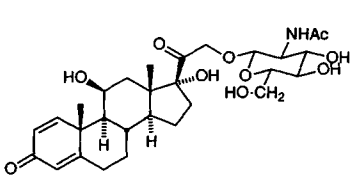
It soon became clear that cortisone caused multiple side effects, such as loss of calcium, a negative nitrogen balance, renal salt and water retention, and occasionally adverse mental effects. Initially this came as a surprise, since in the 1940s several vitamin-deficiency diseases had been cured—without side effects—by giving pharmacologic doses of the deficient vitamins. At first biologists and chemists hoped that enhancing potency would improve the therapeutic index (T. I.) of cortisol. They hoped that enhanced potency, by allowing one to lower dosage, would thereby reduce side effects. Unfortunately, this proved to be illusory, as shown by the fact that such early synthetic analogues as 2α-methyl and 9α-fluorocortisol (**7**), though more potent anti-inflammatory compounds than cortisol, did not possess an improved T. I. On the contrary, the unwanted salt retention had increased even more than the desired anti-inflammatory activity.

On the other hand, *Hershberg, Herzog,* and their associates at Schering discovered prednisolone (**6**) in 1955,[9] the first clinically important glucocorticoid that combined enhanced anti-inflammatory activity with a T. I. superior to that of cortisone/cortisol, in that prednisolone caused less salt retention.

Taken together, these results taught the medicinal chemists and the biologists two important lessons: first, that treating a patient with a pharmacologic dose of a hormone is likely to cause side effects when the disease is not due to a deficiency of that hormone; second, that the synthesis of analogues of a natural product such as cortisol, or of any other drug or potential drug, has a chance of improving the therapeutic index only if the receptor that mediates the desired effect is not the same as the receptor that causes a side effect.[10] The observation that the 2α-methyl and the 9α-fluoro substituents as well as the 1,2 double bond of **6** affected anti-inflammatory potency differently from salt retention potency suggested that this particular side effect of cortisol might be due to a receptor that is not the same as the receptor that results in anti-inflammatory activity. The biologists were able to make this important discovery because of the chemists' ability to produce molecules with novel properties. At about the same time (1955), *Reichstein*'s isolation and characterization of aldosterone (**9**),[11] the steroid hormone that regulates salt metabolism, lent further support to this idea.



9



10

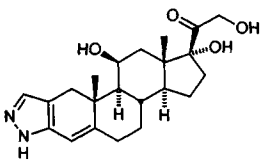
The term *receptor*[12a] had been defined in pharmacologic terms by *Langley*.[12b] At the molecular level, however, it was a black box. When there was some molecular understanding, a proper name such as trypsin was used rather than a term such as "the receptor for lysine-containing peptides".

A great many potent analogues were synthesized by industrial laboratories, and several of them became clinically important products. That no progress could be made in separating the remaining side effects of cortisone made it likely that these side effects were mediated via the same receptor that mediated the desired anti-inflammatory activity, though this interpretation was not, to my knowledge, explicitly stated at the time. In the 1950s, therefore, *Hirschmann, Sarett* et al. applied *drug latentiation* as a novel and "rational" approach toward a safer glucocorticoid.[13] We sought to design and synthesize a biologically inactive steroid (a prodrug), which would be *selectively*, or at least *preferentially*, converted into the active steroid at the site of inflammation. The 21-*N*-acetylglucosamide of prednisolone, **10**, was synthesized with the presumption that it would be biologically inactive and also with the anticipation that it would be *preferentially* converted into the active compound **6** in inflamed joints by *N*-acetylglucosaminidase. The basis for these expectations was the knowledge that the 21-ethers of the glucocorticoids are inactive and that the levels of *N*-acetylglucosaminidase are higher in inflamed joint fluids than in normal joints or in plasma. Our hope was at least partially borne out, because in animals the glycoside **10** has a better T. I. than prednisolone (**6**). Lack of oral bioavailability, however, led to the decision that the compound did not justify a clinical trial in humans. Still, the concept of drug latentiation—that is, *selective* conversion at a target of a prodrug to a drug—has been repeatedly explored since then.

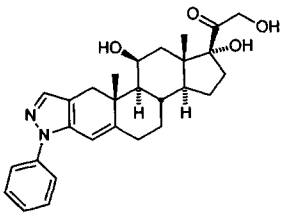
The successful synthesis of the medically important water-soluble 21-phosphate ester of cortisol for use in intravenous administration and ophthalmic formulations was reported by *Chemerda, Poos, Hirschmann* et al.[14] The synthesis proved to be nontrivial, because the presence of the 17α-hydroxyl group in potential precursors resulted in a propensity to give the unwanted 17α,21-epoxides.[15]

By 1963 it had been established that an oxygen at C-3 is not required for steroidal anabolic-androgenic or progestational activity. Indeed *Clinton* et al. at the Sterling-Winthrop Research Institute had reported in 1959 that androst-4-eno- and androstano[3,2-*c*]pyrazoles are potent anabolic compounds.

On the other hand, a wide body of data seemed to support the belief that a C-3 oxo group is required for the anti-inflammatory activity. Nevertheless, *Hirschmann, Steinberg, Tishler* et al.[16] undertook the synthesis of pregnadiene derivatives containing a fused pyrazole ring, such as **11** and **12**, and found them to be highly active. Indeed, the phenylpyrazoles, typified by **12**, proved to be the most powerful activity-enhancing pharmacophores discovered to date for steroidal anti-inflammatory compounds. Because one of these phenylpyrazoles was marketed by Roussel-Uclaf in France, the discovery of this class of compounds may either be regarded as "irrational-though-successful drug discovery" or as a reminder that at times it is desirable to question



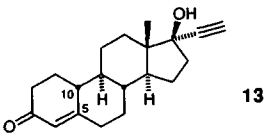
11



12

accepted but unproven dogma. Initially we[17] interpreted the high activity of the pyrazoles in terms of electron distribution around the 3-position, but later it appeared more likely to us that the observed potency was an early example of the existence of alternative or accessory binding sites. The latter has been a recurring theme in medicinal chemistry during the past twenty years, although, to my knowledge, it has been principally applied in the discussion of antagonists. The concept suggests that a function believed to be required for biological activity, such as the 3-oxo group of a glucocorticoid, may in fact not be needed if some other substituent, such as an aromatic ring, introduced elsewhere in the molecule, is complementary to the receptor. In general, then, novel structures have provided new insights into steroid interactions with receptors.

During the mid-fifties, the work of the Syntex and the Searle groups under the leadership of *Djerassi* and *Rosenkranz*[18] and *Colton* and *Riegel*,[19] respectively, with the progestins 17α-ethynyl-19-nortestosterone (**13**) and its isomer with a 5(10) double bond, was to become of great importance because these compounds can serve as orally effective anovulatory agents. Pharmaceutical preparations



13

used in the United States combine a progestin with an estrogen. This work serves as a persuasive reminder, if any is needed, that medicinal chemists are in a position to synthesize molecules with properties that profoundly affect not only medicine, but also societal behavior.

2.4. Recent Developments

By the early 1960s, the chemistry of the anti-inflammatory steroids appeared to have largely realized its potential. Clinically, the nonsteroidal anti-inflammatory drugs replaced the steroids as the treatment of choice for most inflammatory diseases. However, other aspects of steroid chemistry and medicinal chemistry continued to flourish. For example, *W. S. Johnson*'s brilliant biomimetic cyclizations are already regarded as classics.[20] Another noteworthy example, which generated great interest in the 1970s, is research related to vitamin D. Studies in several laboratories, including those of *Haussler*,[21] *Kodicek* and *Lawson*,[22] *DeLuca*,[23] and *Norman*,[24] culminated in the recognition that vitamin D_3 (**14**), after absorption from the gut, is hydroxylated in position 25 by a liver enzyme to give **15** and then in position 1α by a kidney enzyme to afford **16**. It is this latter dihydroxylated metabolite of vitamin D_3 that initiates calcium absorption. Subsequent to these biochemical accomplishments, which resulted in the characterization of **16**, organic chemists contributed elegantly to the solution of the resulting synthetic challenges as exemplified by the work of the laboratories of *Hesse*,[25] *DeClerq*,[26] *Dauben*,[27] *Mazur*,[28] *Uskovic*,[29] and others. These workers, as well as *Seki*[30] and others, have also helped to clarify the role of 1α,14(*R*),25-trihydroxyvitamin D_3 (**17**).

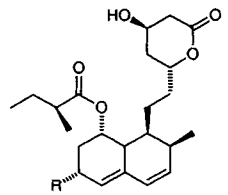
17

Steroid hormone antagonists and steroid-related enzyme inhibitors remain of the greatest interest today. Further, the understanding of cholesterol biosynthesis from acetate has recently led to one of the most important drugs approved during the 1980s, lovastatin (**18a**), which inhibits cholesterol biosynthesis. Its introduction in 1987[31] was hailed as a significant advance in the treatment of hypercholesterolemia (see Section 5, where **18b** is also discussed).

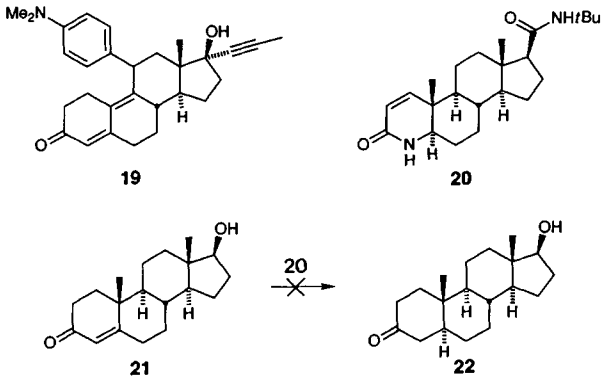


18a, R = Me
18b, R = H

Mifepristone (**19**)[32] is a progesterone antagonist developed by Roussel-Uclaf. Administration of this steroid, followed by a small amount of prostaglandin, has been found to be a safe and effective method for the early termination of pregnancy. It has been approved for distribution in France as a tightly controlled prescription drug.

Among the promising drugs currently in advanced clinical trials is Proscar (**20**), an inhibitor of the enzyme human pro-

static 5α-reductase. Proscar was designed and synthesized by *Rasmusson* et al.[33] to block the conversion of testosterone (**21**) to dihydrotestosterone (**22**). Unlike **21**, compound **22** stimulates prostate hyperplasia, but serves no known desirable purpose in the adult male. This eminently "rational" approach to the discovery of a drug for reducing the size of an enlarged prostate was first suggested in the 1950s by the late *Glen Arth* at Merck.



Other steroids of current interest include inhibitors of human placental aromatase, antiestrogens devoid of agonism, and compounds (21-amino steroids) with the potential to protect against central nervous system trauma, or amino steroids with the potential to be of benefit in adult-onset diabetics.

Finally, molecular biology has opened an important and fruitful new direction in steroid-related research, designed to gain an understanding of the molecular basis for the ability of intracellular steroid receptor proteins and their hormonal ligands to alter the transcriptional efficiency of networks of specific genes.[34] It will be interesting to see to what extent such investigations will add to our understanding of the SARs of steroid hormones and their antagonists, especially if crystalline receptors become available. At present it is interesting, but not surprising, that the cDNAs of diverse steroid receptors reveal three highly conserved regions.[35a] The structural unity in nuclear hormone receptors has been reviewed recently.[35b]

3. Peptides Large (Proteins) and Small (Hormones)

Steroids and peptides share an importance in both physiology and medicine. The peptide field had its inception about ninety years ago, when *Franz Hofmeister* and *Emil Fischer* (who was to receive a Nobel Prize that year for his work with sugars and purines) reported independently at a meeting in Karlsbad in 1902 that proteins are made up of amino acids linked via "peptide bonds" (*Fischer*'s term). *Fruton* has provided an interesting account of these scientists and of this event.[36] Yet despite *Fischer*'s reputation, this field of study did not quickly "catch on". Indeed, many hard-core organic and medicinal chemists continued to hold peptide research in low esteem well beyond the 1950s. In recent years, peptide research has enjoyed an explosive growth, but why did it have a relatively slow beginning? I believe several factors contributed to this.

One is that organic chemists considered peptide chemistry boring, largely because of the repetitious pattern of the amide backbone. In addition, most organic chemists tend to be uncomfortable with water-soluble organic molecules, because normally the aqueous layer is the one they discard. The pharmaceutical industry was also not sanguine about peptides, because peptides lack adequate oral bioavailability and often possess unacceptably short biological half-lives. Another deterrent was the suspicion that peptide hormones are a *Gemisch* of chemically related substances. *Sanger*'s elucidation of the sequence of bovine insulin[37] was a major milestone, in part because it drove home the fact that bovine insulin is as well-defined a chemical entity as are benzoic acid and cholesterol.

In spite of the reluctance of organic chemists to regard peptide chemists as bona fide members of their discipline, the early history of peptide research testifies to the extraordinary creativity and skill of such pioneers as *Fischer*, *Bergmann*, *Zervas*, and *Curtius*. Indeed, the history of peptide research abounds with the elegant contributions to organic chemistry by many peptide chemists whose names could not be cited herein because of the limited nature of this review.[*]

3.1. Structure Determination and Synthesis of Peptide Hormones

The isolation, characterization, and synthesis of the peptide hormones oxytocin (**23**)[38] and vasopressin (**24**)[39] was reported in 1953 by *du Vigneaud*, who was awarded a Nobel Prize for this achievement. The characterization of these two

23, X = Ile, Y = Leu
24, X = Phe, Y = Arg

hormones was an impressive accomplishment if we consider that both are cyclic peptides and that the structures had to be determined without benefit of Edman[40] degradation. The syntheses of these hormones in pure form was an equally noteworthy achievement, since it was not until later on that *Wieland*'s mixed anhydride method, the use of active esters pioneered by *Wieland*, *Schwyzer*, *Bodanszky*, *G. Anderson*, and others, as well as *Sheehan*'s carbodiimide method, really came into their own.

The oxytocin/vasopressin research by *du Vigneaud* and his collaborators provided an enormous impetus to peptide research (see Section 3.3 for medicinal chemical studies on oxytocin and vasopressin). By 1963 advances in synthesis enabled *Schwyzer* and *Sieber*[41] to announce the total synthesis of a chemically homogeneous peptide with the sequence proposed[42] for porcine ACTH (**25**), a hormone containing 39 amino acids. This synthesis was carried out by the stepwise method from the C-terminus to the N-terminus,

[*] An excellent survey of this area is given in a recent book: T. Wieland, H. Bodanszky: *The World of Peptides. A Brief History of Peptide Chemistry*, Springer, Heidelberg 1991. See also [36] and [151].

with purification at each step and without recourse to fragment condensation. Each amino acid was protected by the benzyloxycarbonyl protecting group, which could be removed by catalytic hydrogenation since ACTH has only one sulfur-containing amino acid, a methionine, near the N-terminus. The synthesis of the pure peptide of 39 amino acids remains a major milestone to this day.

H-Ser-Tyr-Ser-Met-Glu-His-Phe-Arg-Trp-Gly-Lys-Pro-Val-Gly-Lys-Lys-Arg-Arg-Pro-Val—
—Lys-Val-Tyr-Pro-Asp^{25}-Gly-Ala-Glu-Asp^{30}-Gln-Leu-Ala-Glu-Ala-Phe-Pro-Leu-Glu-Phe-OH

25

It was discovered later[43] that the synthetic peptide with the C-terminal amino acid sequence of **25** does not undergo deamidation under weakly alkaline conditions where natural porcine ACTH is completely deamidated. Further, this rapid deamidation was not satisfactorily explained by structure **25**. These observations led to a revision[43] of the structure originally assigned[42] to porcine ACTH, with Asn replacing Asp in position 25 and Glu replacing Gln in position 30. The revised structure explains the loss of ammonia under mild conditions, because the Asn–Gly bond is known[44] to undergo succinimide formation (Fig. 3).

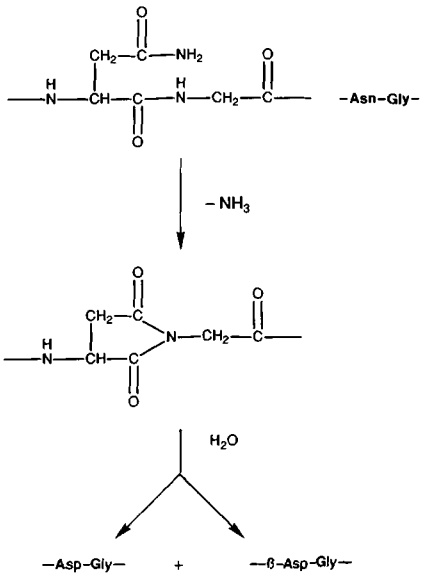


Fig. 3. The instability of the Asn–Gly bond, a pitfall in peptide chemistry. The dipeptide is present, for example, in ACTH, ribonuclease A, and secretin.

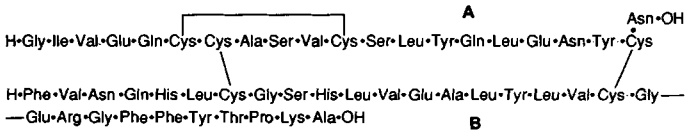
ACTH has found clinical use in treating inflammatory disease and as a diagnostic agent. It was found that the tetracosapeptidoamide lacking the amino acid sequence 25–39 possesses approximately 75% of the steroidogenic potency of the native hormone, demonstrating that drastic deletion of amino acids is sometimes permissible with little or no loss of biological activity.

Schwyzer's synthetic achievement notwithstanding, important and formidable problems still awaited solutions in the mid-1960s. Insulin (**26**) remained a challenge. The elucidation of the structure of bovine insulin by *Sanger*[37] had been completed in 1955. It had required the determination of



26

the linear sequences of its two chains, utilizing partial acid hydrolysates and partial enzyme digests to generate overlapping fragments. It was also necessary to distinguish Asn from Asp, and Gln from Glu, and to locate the one intrachain and the two interchain disulfide bonds.

Announcements of the total chemical synthesis of insulin were made in Germany by *Zahn* et al.[45] in 1963, in the United States by *Katsoyannis* et al.[46] in 1964, and in China by *Wang, Du* et al.[47] in 1965. The yields were low, however. This was attributed to the fact that the final step involved the uncontrolled formation of the three disulfide bridges, leading to the formation of undesired isomers and polymers. Interestingly, however, *Katsoyannis* et al.,[48] using an excess of A chain, were eventually able to obtain a yield of 60–80% for the simultaneous formation of the three cystine bridges. High yields were obtained later on also by investigators at Eli Lilly[49] and Genentech[50] for the combination of the A and B chains prepared by biotechnology. In 1974, *Sieber, Kamber* et al.[51] at Ciba attained another milestone in chemical design with a total synthesis of crystalline human insulin, in which the correctly paired disulfide bonds were formed in a controlled manner. This accomplishment was made possible through techniques developed by *Zervas* and *Photaki*[52] in Greece, by *Hirschmann, Veber* et al.[53] at Merck, and especially by *Hiskey* and his associates at Chapel Hill.[54]

The low yield (less than 4%) of insulin initially obtained in the "uncontrolled" oxidation of its reduced A and B chains proved to be a blessing in disguise. Because the low yield was contrary to *Anfinsen*'s principle of self-assembly (see Section 3.2), which states that a peptide sequence encodes proper folding, *Steiner* and his co-workers[55] considered the possibility that the biosynthesis of insulin might proceed via a *single-chain* hexahydro precursor, a prohormone. Indeed, *Steiner* was able to isolate a single-chain proinsulin in 1967 and to show that a fragment consisting of 29–35 amino acids (depending on the species) connects the A and B chains. He also demonstrated that fully reduced proinsulin can be oxidized to proinsulin in high yield and that proinsulin is convertible into insulin in vitro. The successful search for a prohormone exemplifies again the impact of chemical experimentation (in this instance, low yields in the combination of the two chains) on biological understanding (the discovery of prohormones). *Steiner*'s discovery of proinsulin started peptide research on the road to prohormones generally, and later to the preprohormones, which molecular biologists like to call the "gene products". Scientists at Eli Lilly and Genentech have synthesized insulin via proinsulin prepared by biotechnology. Studies by *Brandenburg* et al.[229] and by *Markussen*[230] with "miniproinsulins" led to the suggestion that the role of the connecting peptide of proinsulin in biosynthesis is simply to render the formation of the first interchain disulfide bridge a monomolecular process.

A profound contribution of molecular biology was the isolation, cloning, and expression of the insulin receptor and the recognition that it possesses kinase activity.

Insulin holds a very special place in the annals of peptide research. It was the first complex peptide of profound importance in medicine (life-saving in the case of the juvenile diabetic) to be sequenced.[56] Insulin played a central role in numerous other scientific discoveries as well. It established that peptide hormones are pure chemical entities and showed that a peptide lacking a prosthetic group can still generate biological activity.[57] Insulin was also the first peptide hormone to be crystallized (*Abel*, 1926);[58] in 1969, *D. C. Hodgkin* et al.[59a] reported its X-ray structure (see Ref. [215]). *Blundell*, *Hodgkin* et al.[59b] used X-ray crystallography to show that replacement of the B10-histidine can have a pronounced effect on the tertiary structure of the hormone, thus providing an explanation for the low potency of guinea-pig insulin in rodents or rodent tissues. Human insulin of porcine insulin origin became the first naturally occurring protein to be manufactured by semisynthesis.[231] Insulin became the first clinically significant product to be prepared by recombinant DNA technology.[50]

3.2. Chemical Syntheses of Enzymes

The first total syntheses of an enzyme (ribonuclease) were simultaneously but independently announced by *Merrifield* and *Gutte*[60] and by our group at *Merck*.[61] *Merrifield* and *Gutte* used the new solid-phase technique,[62] while we employed the fragment condensation method,[63–67] extensively utilizing the *N*-carboxyanhydrides[68] as building blocks. Selecting ribonuclease as the synthetic target, rather than seeking to improve the synthesis of insulin, had been a very deliberate choice for both groups. Insulin was the smaller molecule and thus presumably the less difficult to synthesize, and for that reason it appeared to be the more obvious one to pursue. However, the lure of an enzyme synthesis vis-à-vis a hormone synthesis proved decisive.

The de novo chemical syntheses of enzymes[160, 161] with good specific activity from their amino acid building blocks was highly satisfying in two respects (though it failed to fulfill its promise in a third). First, despite the brilliant demonstration by *Anfinsen* and *Haber* that a protein's *primary* sequence also contains the information for its *tertiary* structure,[69] many scientists in the mid-1960s still believed that the total chemical synthesis of an enzyme would prove impossible in the absence of some form of a template. A linear peptide containing eight cysteine residues can, on oxidation, form theoretically as many as 105 isomers, each possessing four cystine bridges. The two successful total chemical syntheses of the right isomer thus provided powerful affirmation of the Anfinsen/Haber principle of self-assembly.

Second, it was highly satisfying to know that the combined efforts of the international community of peptide chemists had made it possible by 1968 to synthesize an enzyme, a longtime goal of synthetic organic chemistry. Twelve years later *Yajima* et al.[70] were able to report the total synthesis of crystalline ribonuclease A by solution chemistry; they introduced trifluoromethanesulfonic acid as a deprotecting agent.

The unfulfilled promise relates to the fact that the total chemical syntheses of enzymes remained an arduous undertaking. Except for *Yajima*'s synthesis of crystalline ribonuclease A[70a] in 1981, no successful enzyme synthesis was announced between 1969 and 1988, notable efforts in the United States and abroad notwithstanding. It had been our hope, and also *Merrifield*'s, that the synthesis of ribonuclease would be followed by the syntheses of analogues of enzymes not found in nature, and that this would contribute to the understanding of protein structure and function. Unfortunately, the synthesis of an analogue of a protein can be an even more challenging task than that of the natural product itself, because there is no reference sample with which one can compare the physical, chemical, and biological properties of the synthetic product. Thus, criteria of purity are even harder to establish.[71] In addition, purification procedures developed for the natural substance, including, importantly, affinity chromatographic techniques, may not be applicable to the analogue. It remained for biotechnology to make site-directed mutagenesis into the powerful tool for protein analogue synthesis that we know it to be today. Reports by, for example, *Benkovic*,[72] *Fersht*,[73] *Knowles*,[74] and *Wells*[75] and their associates elegantly exemplify that enzyme analogue synthesis does indeed extend our understanding of enzyme mechanisms and of protein folding. In retrospect, *Anfinsen*'s pioneering work proved to be as important to biotechnology as it had been to the chemical enzyme syntheses of the 1960s.[75, 232]

In 1988, *Nutt*, *Veber* et al.[76a] described the total chemical synthesis of a 99-residue peptide with the sequence proposed by *Ratner* et al. at the NIH for the AIDS-related HIV protease. At the same time, *Schneider* and *Kent*[76b] reported the synthesis of an analogue of this enzyme in which L-α-aminobutyric acid replaced the two cysteine residues.

When *Merrifield* and *Gutte*, as well as we at Merck, selected protecting groups for our proposed enzyme syntheses, really general orthogonal protection had not been worked out. In particular, the then-current literature notwithstanding, the all-important acid-labile *tert*-butyloxycarbonyl (Boc)[77–79] protecting group could not be removed from an α-amino group without partial loss of the carbobenzoxy group (Cbz) from the ε-position of lysine. Even a partial loss of Cbz protection from any of the multiple lysine side chains of ribonuclease can lead to unwanted branching in the next coupling step. General orthogonality was subsequently achieved through the combined contributions of chemists such as *Carpino*, who introduced the acid-stable, piperidine-labile 9-fluorenylmethoxycarbonyl (Fmoc) group,[80] *Sieber* and *Iselin*, who used the biphenylisopropyloxycarbonyl (Bpoc) group,[81] and *Hiskey*, who employed selective cystine-bridge formation,[82] as well as through the work of *Barany*.[83]

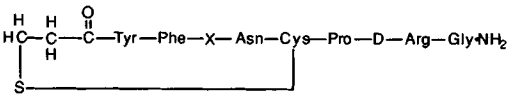
3.3. More Recent Chemical and Biological Developments

The most notable advance in peptide synthesis since the introduction of the benzyloxycarbonyl protecting group by *Bergmann* and *Zervas*, and of the azide coupling reaction by *Curtius*, was *Merrifield*'s invention of solid-phase peptide

synthesis.[62] Subsequent improvements in this new technique, in *Merrifield*'s laboratory and by countless investigators worldwide, and improvements in the fragment-condensation method[61,67] in combination with the introduction of the HF reaction by *Sakakibara* and co-workers[84] and the application of HPLC to peptide synthesis, principally by *Rivier*, have brought peptide synthesis to a point where, in the late 1980s, the peptide chemists possessed the techniques to synthesize complex peptides/proteins of about 100 amino acids quite rapidly. For example, *Sakakibara* et al. used the fragment condensation method to synthesize both human parathyroid hormone, hPTH(1–84),[84b] and angiogenin, which contains 123 amino acids.[84c] The HIV protease mentioned above became available[76] in sufficient quantity by total chemical synthesis for urgently needed inhibitor screening at a time when the viral enzyme had not yet been provided by biotechnology. Similarly, *Garsky* et al.[85] accomplished the chemical synthesis of echistatin, a potent inhibitor of platelet aggregation, composed of 49 amino acids, including four cystine bridges. These authors were, in addition, able to draw meaningful conclusions about SARs for novel analogues of this peptide. These advances, made possible by the research over a period of time of physical organic chemists such as *Kemp*,[86], *Benoiton*,[87] and *Tam*,[88] led to many of our current procedures that permit racemization-free, high-yield coupling reactions and the high-yield removal of protecting groups with minimal side reactions. Advances in the chemical syntheses of peptides and proteins remain of great importance, in part because biotechnology has so far been confined to use of the 20 coded amino acids, although recent work, especially by *Schultz*, suggests that this limitation will eventually be overcome.

In the 1960s, electronic theory and structural chemical concepts were having a marked effect on peptide chemistry. The impact of conformational analysis was to be as great on peptide research as it had been on steroid research. Gaining insight into peptide conformation was complicated by the greater flexibility of peptides and their greater structural diversity. Thus, whereas steroid conformational analysis is restricted to the relatively[89] rigid cyclopentanoperhydrophenanthrene skeleton, peptide conformations include helices, extended structures, turns, and other chain foldings less readily classified. The basis for peptide conformational analysis was provided by the seminal work of *Ramachandran*,[90] *Scheraga*,[91] and *Blout*,[92] who set forth many exciting ideas about solutions to problems in peptide conformation and protein folding. Using a range of physical methods, *Goodman*[93] initiated studies of conformational transitions in polypeptide systems. *Schwyzer* pointed out that cyclic peptides might have conformation-defining secondary structure,[94] opening a fertile field for conformational study of cyclic oligopeptides, exploited by *Blout*,[95a] *Kopple*,[95b] *Prelog*,[95c] *Ovchinnikov*,[95d] and others. The increasing capability of nuclear magnetic resonance spectroscopy to investigate peptide conformation was important to this effort. It has been reviewed by *Kessler*.[96] *Marshall*[97] pointed out the value of conformation-restricting amino acid residues in identifying biologically important peptide conformations. One of the first applications of cyclic peptide conformational analysis to problems in medicinal chemistry was made by *Urry, Ohnishi,* and *Walter*[98] in the oxytocin series. More recent elegant examples of conformational study of biologically active cyclic peptides come from the laboratories of *Hruby*,[99] *Kessler*,[100] and *Fesik* and *Rich*.[101] The classic review by *Rose, Gierasch,* and *Smith*[102] examines conformation from the perspective of "Turns in Peptides and Proteins". This review has recently been updated.[103]

As pointed out earlier (see ACTH and insulin, Section 3.1), the peptide hormones, like their steroidal counterparts, proved important in biology and in medicine. Oxytocin has been used widely for the induction of labor. *du Vigneaud* himself followed his synthesis of the neurohypophyseal hormones with medicinal chemical investigations into the importance of their side chains for biological activity. *Rudinger* and *Jost* in Czechoslovakia, in seminal studies,[104] showed that a monocarba (i.e., methylene) analogue of oxytocin is biologically active, proving that neither a sulfur–sulfur bond per se nor a *reducible* cyclic structure is required for activity. These empirical investigations laid the foundation for the subsequent, elegant medicinal chemical research by the Prague group,[105] by *Walter*,[106] by *Manning*,[107] and by *Hruby*.[108] Of clinical interest is the vasopressin analogue [1-deamino, D-Arg[8]]vasopressin (DDAVP, **27**), synthesized by *Huguenin* and *Boissonas*[109] and also by *Zaoral* et al.[110] as a potent, *selective*, long-lasting antidiuretic, of value in the treatment of diabetes insipidus. It is selective for the V_2 (kidney) receptor. It is interesting in terms of the molecular mechanisms of hormone action that *Manning*'s Val[4] analogue[111] (**28**), a potent V_2 agonist, is also a weak V_1 (vasopressor receptor) antagonist. *Berde, Huguenin*, and *Boissonas* at Sandoz in Basel prepared vasopressin analogues that are preponderantly either vasopressors or antidiuretics. The chemists' ability to generate new molecules again promoted the biologists' understanding of receptor subclasses. It is important to stress that by generating molecules possessing greater selectivity and potency, chemists have also provided the clinicians with better medicines and the biologists with more useful *labeled* ligands.



27, X = Gln
28, X = Val

In 1971, *Urry* and *Walter*[112] proposed a three-dimensional solution structure for oxytocin, thus applying structural thinking to this peptide hormone. They made several insightful observations, including the statement that there is no evidence that the amide backbone of peptide hormones participates directly in receptor occupation and activation. They recognized the importance of specific conformational assignments of structured sequences and the consequence of such assignments to side-chain conformations. Building on *Ramachandran*'s theoretical calculations of the early 1960s[90] and the later work by *Geddes* et al.,[113] *Walter* and *Urry* brought to medicinal chemistry an understanding of the effects of different types of turns on the conformation (equatorial, pseudoequatorial, axial, etc.) of substituents at

the α carbons in the $i + 1$ and $i + 2$ positions of such turns (Fig. 4).

Hruby, Manning, Walter, and others have called attention to the important fact that there can be considerable divergence in the SARs of hormone agonists and their antagonists. This is consistent with *Jencks'* insightful analysis of the "economics of binding energies",[114a] which states that agonists bind tightly to the receptor in its activated conformation, whereas antagonists bind tightly to the receptor in the ground state. In his commentary on "Binding Energy and the Activation of Hormone Receptors", *Franklin*[114b] built on and expanded these concepts.

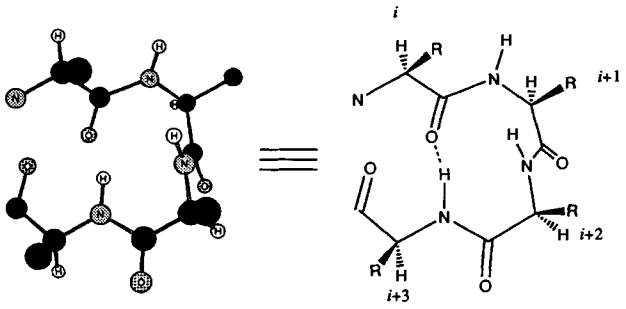


Fig. 4. Orientation of side chains in a type I β-turn.

At about the same time when *Urry* and *Walter* questioned the importance of hydrogen bonding between the amide backbone of the peptide hormones and their receptors, *Rudinger*[105] called attention to the crystallographic evidence for just such an interaction between proteolytic enzymes and their substrates/inhibitors. This distinction first became clear to me during a conversation with *D. Rich.*

The research in the 1960s and 1970s by *Guillemin*,[115, 116] *Rivier*,[117] *Schally*,[118, 119] and their collaborators typifies the ever-growing impact of peptide research on physiology and medicine. Their investigations culminated in the isolation, characterization, and synthesis of three hypothalamic hormones: gonadoliberin (GnRH, **29**), somatostatin (SRIF, **30**), and thyroliberin (TRH, **31**). These achievements were recognized by the award of a Nobel Prize to *Guillemin* and *Schally*. Equally significant were the subsequent isolation, characterization, and synthesis by *Rivier, Spiess, Thorner,* and *Vale*[120] and by *Guillemin* et al.[121] of growth-hormone-releasing factor (GHRF, **32**) and of the long-sought corticotropin-releasing hormone (CRF, **33**) by *Vale, Spiess, Rivier,* and *Rivier*.[122] Studies in humans have demonstrated that GnRH is useful in both the diagnosis and treatment of infertility, since it stimulates the release of luteinizing hormone (LH) and of follicle-stimulating hormone (FSH). As is so frequently the case, the discovery of a pure antagonist, in this case a GnRH antagonist, proved at least as significant as the discovery of novel agonists. GnRH antagonists are being tested clinically as antifertility agents.[123] Biologists also made the interesting discovery that, whereas superagonist analogues of GnRH initially act (as expected) as potent agonists, superagonism then results in downregulation of the receptors, and thus the long-term effect is to *prevent* the release of LH and of FSH, an effect of interest in the treatment of prostate cancer. Superagonists like ICI's Zoladex have been approved in certain markets.

A major development of the 1970s was the report in 1975 by *Hughes, Kosterlitz,* and their collaborators[124] of the isolation of two related pentapeptides, the now well-known enkephalins, Met-enkephalin (**34**) and Leu-enkephalin (**35**).

H•Tyr–Gly–Gly–Phe–Met•OH

34

H•Tyr–Gly–Gly–Phe–Leu•OH

35

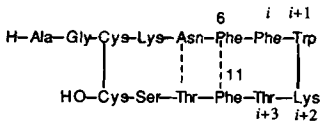
Their discovery attracted much attention because the enkephalins are the long-sought endogenous ligands for the "morphine receptor". The presence of a tyrosine in the enkephalins prompted peptide chemists to do the "logical" thing, that is, to superimpose the phenolic hydroxyls of morphine and of the enkephalins. Unhappily, as is so often the case, the receptors lack the chemists' "insights"; that is, the overlap of the two acidic hydroxyls does not appear to explain why morphine and the enkephalins bind to the same receptor. The question still remains unanswered.

The hope of finding a nonaddicting analgesic led to an intensive effort to find enkephalin analogues that are more selective, bioavailable, and biostable. Indeed, Sandoz's FK 33-824[125] and Lilly's methkephamid[126] possess improved in vivo stability, but these early compounds were nonselective and caused side effects. Enkephalin-related research, notably by *Schiller*,[127] *Hruby*,[128] and their collaborators, employed the principles of conformational restriction in an effort to achieve receptor selectivity. Taken together, studies with classical opiates, and with synthetic enkephalin analogues, have demonstrated the existence of several subclasses of opiate receptors, but the physiological function of these receptors is not yet understood.

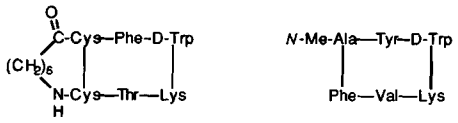
In Section 1, I referred to the subjective scope of this article. Suffice it to mention here that in his excellent 1980 review[129] of peptide and protein hormones, *Meienhofer* provides valuable information about such additional compounds as the endorphins, melanostatin, melanoliberin, Substance P, neurotensin, lipotropin, melanotropin, prolactin, growth hormone, parathyrin, calcitonin, thymic factors, glucagon, gastric inhibitory polypeptides, vasointestinal polypeptides, motilin, the placental hormones, relaxin, angiotensin, the kinins, and the growth factors. A more recent review was provided by *Schmidt*.[123] I cite these here to provide a better sense of the ever-expanding scope of peptide research.

As pointed out by *Reichlin*,[237] SRIF (**30**) is a major regulatory peptide with an extraordinary range of actions. A possible clinical application is acromegaly. Another was suggested by an early observation at the Karolinska Institute by *Luft* et al. that growth hormone (GH) may play a permissive role in the development of retinopathy in diabetes. Later, *Unger* pointed out that inappropriately high levels of glucagon may contribute to the complications of diabetes.[130] Because **30** suppresses both glucagon and GH release, I sought to discover an analogue of SRIF with a half-life suitable for the evaluation of such an agent in the treatment of juvenile diabetes. This was not possible with the short-lived **30**.

Veber and his collaborators approached this problem by seeking to gain insight into the conformation of **30** at its receptor. Building on the observation by *Rivier* et al.[131] that an analogue of somatostatin in which Trp^8 is replaced by D-Trp is significantly more potent than the hormone, and on *Ramachandran*'s[132] theoretical studies, suggesting that D-amino acids in the $i+1$ position stabilize β-turns, *Veber* et al.[133] proposed a model wherein Trp occupies an $i+1$ position (**36**, Fig. 5). This model resembled in several respects the solution conformation of SRIF that had been proposed earlier by *Holladay* and Puett,[134] but differed from it in other details, in that the Merck model suggested that the side chains of Asn^5 and Thr^{12}, as well as those of Phe^6 and Phe^{11}, are within bonding distance. In a systematic approach, these proposed relationships were then tested via the design, synthesis, and biological testing of relevant bicyclic compounds in which cystine bridges replaced Asn^5/Thr^{12} or Phe^6/Phe^{11}. An even greater conformational constraint was incorporated into a third bicyclic compound, **37**.



36



37

38

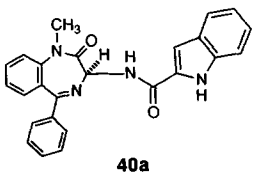
Fig. 5. The conformation proposed [133] for **30** at its receptor includes a β-turn, shown in **36**. This turn is supported by the fact that Asn^5/Thr^{12} or Phe^6/Phe^{11} may be replaced by cystine bridges, indicated by the dotted lines. The most compact bicyclic analogue is **37**. The correctness of the model is convincingly supported by the high activity of the cyclic hexapeptide **38**.

That high activity was retained in all three bicyclic structures strongly supported the proposed model. This led ultimately to the design and synthesis by *Freidinger*, *Veber*, *Nutt*, *Hirschmann* et al.[135] of the cyclic hexapeptide **38**, which contains only 2 of the 14 amino acids found in **30** but which is nevertheless 50 to 100 times more potent than the hormone. That the replacement of Phe^6 and Phe^{11} by a cystine bridge in **30** resulted in an analogue more potent than SRIF is of interest because *Rivier* and *Vale* had shown that replacement of either Phe^6 or Phe^{11} led to the loss of 97–99% of activity. Taken together, these paradoxical findings suggested that the two phenyalanines may stabilize the β-turn via a "herringbone" stacking of two phenyl rings. Presumably, the β-turn that is stabilized in SRIF by Phe^6 and Phe^{11} is stabilized by the cystine bridge of **37**. Clinical trials with **38** were terminated because, after short-term administration to humans, steatorrhea (fat malabsorption) was observed. In addition, when the drug was given to patients at bedtime, the insulin requirements the following morning were not lowered as much as had been hoped. This account reminds us that in drug discovery it is often easier to achieve scientific success, including encouraging results in model animal experiments, than to prevail in the clinic. On the other hand, *Bauer* et al.[136a,b] at Sandoz designed and synthesized octreotide (**39**)[136c], a cyclic octapeptide. The Swiss investigators found that the initial steatorrhea disappeared on continued administration of **39**. Octreotide was approved by the FDA for treatment of acromegalics and for use in patients with metastatic carcinoid and vasoactive intestinal-peptide-secreting tumors.

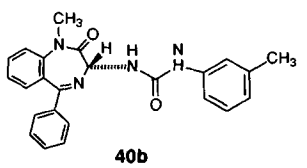
39

3.4. Peptidomimetics

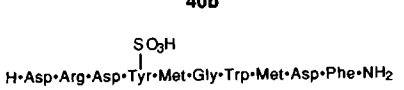
A remarkable achievement in medicinal chemistry was the work by *Evans*, *Anderson*, *Bock*, *Freidinger*, *Veber*, and their collaborators[137] which led to the design and synthesis of



40a



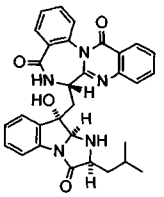
40b



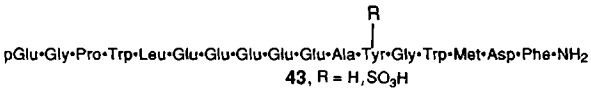
41

40a, a selective, potent, orally effective, peptidomimetic antagonist of the peptide hormone cholecystokinin (CCK, shown as the highly active decapeptide **41**).

Building on an astute analysis[137b] of the structure of the cholecystokinin antagonist and fungal screening lead asperlicin (**42**),[137c] these workers were successful in improving on its properties. They reasoned that a structure combining the elements of diazepam with D-tryptophan might bind to the CCK receptor. Given the similarities between the structures of CCK and gastrin (**43**), it is pleasing that they were subsequently able to design and synthesize selective gastrin antagonists as well,[138] typified by **40b**. It appears to be an important and generally valid concept that if two distinct hormones or neurotransmitters have structural similarities, their receptors are also likely to resemble each other (see also Section 2.3).



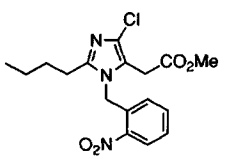
42



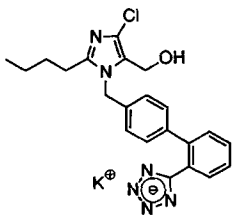
43, R = H, SO_3H

The discovery of asperlicin (**42**) falls into the realm of one of the most active areas of current peptide research, peptidomimetics. Peptidomimetic research owes its impetus to the desire to discover nonpeptides that bind to peptide receptors, but which have better bioavailability, biostability, and possibly greater selectivity than endogenous or synthetic peptide ligands.

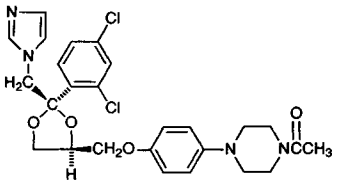
Discovery of peptidomimetics falls into one of two broad categories. They may be discovered either via broad screening of chemical sample collections, microbial broths, fungal metabolites, etc., or via design. Peptidomimetics discovered by screening include the above-mentioned fungal product, asperlicin (**42**), and compounds from chemical sample collections such as the 1-benzylimidazoles, typified by S-8308 (**44**),



44



45



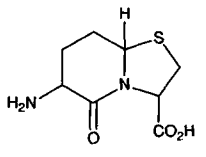
46

reported by *Furukawa* et al.[139] in Japan to be an angiotensin-II antagonist. At du Pont, *Chiu, Duncia, Timmermans et al.*,[140] in a series of important medicinal chemical studies, explored this peptidomimetic screening lead and were able to achieve increased potency (IC_{50} in the nM range) without loss of specificity. (The IC_{50} value denotes the concentration of an antagonist at which the maximal effect of the agonist is reduced by 50%.) DuP 753 (**45**), now in clinical trial, is orally active and devoid of any agonistic activity. It will be interesting to learn the clinical effects of renin inhibitors and of angiotensin II antagonists (see Fig. 6, Section 4.2) and to compare them with those of the established angiotensin-converting enzyme (ACE) inhibitors.

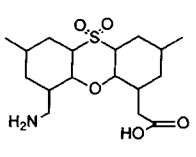
Another example of a screening lead is the antifungal drug ketoconazole (**46**), which was reported by *Biswanath* et al.[141] to be a GnRH antagonist. Compounds **44** and **45** are devoid of any amide bond, and **46** contains but one. All are orally bioavailable. The number of such nonpeptide antagonists of peptide hormones/neurotransmitters is steadily increasing.

In designing peptidomimetics, many laboratories have investigated the replacement of one amide bond at a time by such amide look-alikes as the ketomethylene isosteres, amines, ethylene bonds, α-difluoro ketones, cyclopropane isosteres, and many others. Stabilization of bioactive conformations via cyclization[97, 142] can also fall into the category of amide bond modification. The isostere approach has indeed succeeded in generating compounds with significantly greater biostability. Notable contributions have been made by *Barany, Bradbury, Coy, Goodman, Hoover, Martin, Morgan, Nagel, Rich, Rodriguez, Rosen, Sato, Spatola, Szelke, Thorsett, Wyvratt,* and others. *Spatola* has reviewed this field.[143] The isosteric replacement approach has generally not allowed one to predict which particular peptide bond might be replaceable by what mimetic as one goes from one peptide to the next. Few active compounds with more than two amide replacements have been reported.

A complementary approach involves the design of new scaffolding. Thus, *Nagai* and *Sato* described the synthesis of a bicyclic dipeptide derivative, **47**, mimicking the *i* and *i* + 1 positions of a β-turn, without including side chains at these positions. Compounds **47**–**52** do, however, contain handles for incorporation of the β-turn mimics into antiparallel β-pleated sheets. *Feigel*[144a] used the rigid tricycle **48** as well as the biphenyl derivative **49** to simulate a β-turn, again with-



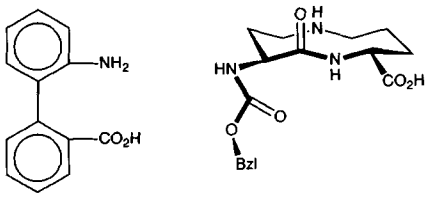
47



48

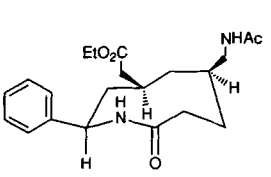
out incorporation of side chains. Similarly, *Kemp* et al.[145] described the synthesis of mimetic **50**, *Olson* et al.[146] of **51**, and *Kahn* et al.[147] of **52**. Both **51** and **52** incorporate a phenyl side chain.

Nicolaou, Hirschmann et al.[148] reported the *design* of a peptidomimetic, **53**, in which a β-D-glucose scaffolding re-

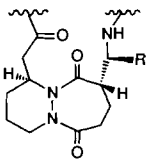


49

50

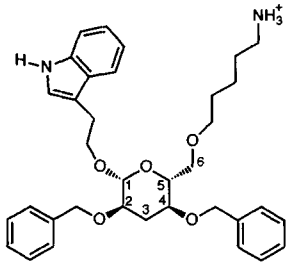


51

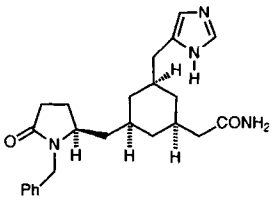


52

placed a β-turn and which incorporates the three critical side chains (i, $i+1$, and $i+2$) of the β-turn of a highly active cyclic hexapeptide analogue (**38**) of SRIF. Compound **53** was found by *Reisine* and *Raynor*[148] to bind to an endocrine (pituitary) SRIF receptor with an IC_{50} of 1 μM. However, **53** does not provide handles for the incorporation of the β-turn mimetic into a pleated sheet. Conceptually, the design of **53** resembles that of **54**, reported at about the same time by *Olson* et al.[149a] at Hoffmann-La Roche (Nutley), who at-



53



54

tached the side chains of the tripeptide thyrotropin-releasing hormone (TRH) to a cyclohexane scaffolding. The Roche compound is devoid of endocrine activity, but it exhibits oral activity in animal models of cognitive dysfunction. Consistent with these results, **54** bound to the low-affinity TRH receptors in the CNS but not to the high-affinity *endocrine* receptors of the pituitary brain stem.[149b]

Throughout the past 40 years, both biologists and organic chemists contributed to the biomedical sciences not by only advancing their respective fields of research but also by interacting with each other. For example, the structure determination and the total syntheses of the steroid and peptide hormones could not have been achieved without the prior isolation of these molecules, which was often guided by *biological* assays. Thus, biologists have prepared the ground for some of the great achievements in natural product synthesis by chemists such as *Corey*, *Danishefsky*, *du Vigneaud*, *Eschenmoser*, *W. S. Johnson*, *Kishi*, *Masamune*, *Stork*, and *Woodward*. These chemists, in turn, through their profound impact on synthetic methods and structural thinking, have helped to set the stage for many of the medicinal chemical achievements mentioned in this article. The award of the Nobel Prize to *Corey* in 1990[150] provides satisfying recognition of the importance of chemical methodology and synthesis to, inter alia, the biomedical sciences.

The spectacular, technological-intensive achievements of the recent past should not cause us to forget the extraordinary accomplishments of earlier workers, who solved problems of great complexity without access to modern techniques. Many examples may be found in *Fruton's* essays describing the interplay of chemistry and biology between 1800 and 1950.[151] Consider, for example, the elucidation of the molecular basis of sickle-cell anemia. As early as 1910, *James B. Herrick*[152] had surmised some connection between this disease and a peculiar, elongated form of red blood cells. In 1949, *Linus Pauling*[153] described a difference in electrophoretic mobilities between normal and sickle-cell hemoglobin and suggested a difference in ionizable groups as the cause. By 1957, *V. M. Ingram*[154] had found the molecular explanation by comparing trypsin digests of normal and abnormal hemoglobin: out of nearly 300 amino acids, one glutamic acid residue is replaced by a valine, a discovery well ahead of its time.

4. Drug Discovery in the Golden Age of Biology

It is desirable to define the word "drug" as used herein. Activity in relevant in vitro and in vivo assays does not mean that a compound is a drug. A drug is a substance approved by a regulatory agency in a medically sophisticated country. Many a promising compound has failed in safety studies, or in the clinic, because of poor bioavailability, rapid metabolism, species differences, and so forth. Discovering an active compound is relatively easy, discovering an important new drug remains unbelievably difficult.

The exciting recent developments in receptor research to be discussed below were made possible by two major discoveries that, in 1953, ushered in the modern era of biology. Of foremost significance, it was the year in which *James D. Watson* and *Francis Crick* proposed the double-helical structure of DNA and suggested that the sequence of nucleotide units in DNA carries encoded genetic information. It was also the year in which *Frederick Sanger* announced the structure of insulin. Taken together, these two discoveries suggested[155] that there is a connection between nucleotide and peptide sequences. These discoveries led within a decade to our understanding of the genetic code words that determine the amino acid sequence of proteins. Thus, the discovery of the double-helical structure of DNA became a revolutionary event in biology, with a profound impact on the vitality of all biomedical research.

It is difficult to overstate the impact of the double helix on the biomedical sciences. The dynamics between molecular biology and chemistry may be summarized rather simply: the discovery of the double helix was principally an accomplishment of the physical sciences. The roles played by X-ray crystallography, by chemical analyses (which provided information about the ratios of the building blocks of DNA), and by the chemical concept of complementarity are well known. Biochemists had to play a further role before biotechnology could come into its own. They discovered many

of the enzymes now taken for granted in the practice of genetic engineering, such as restriction endonucleases, ligases, polymerases, transcriptases, and reverse transcriptases. Similarly, chemists provided the techniques for the microsequencing of peptides and proteins and for the syntheses of nucleic acids. These operations are all taken for granted today. Having said all this, I hasten to add that molecular biologists are well on the road to repaying the biologically oriented chemists for their services, in that medicinal chemists are only beginning to build on the opportunities generated by molecular biology. The ability of biotechnology to facilitate the discovery and synthesis of proteins such as receptors and receptor subclasses can be cited as an illustration.

4.1. Complementarity and Rational Drug Design

The term *complementarity*, meaning molecular recognition, has already been used twice in this article. As *Arnett, Harvey,* and *Rose*[156] pointed out recently, "... molecular recognition has become one of the most evocative buzz terms in the chemistry of the late 1980s, with enzymes as the model of perfection for catalytic efficiency and specificity." They go on to list enzyme mimetic systems such as *Cram*'s crown ethers, *Lehn*'s cryptands, *Breslow*'s cyclodextrins, and *Rebek*'s convergent cleft molecules as designed artificial receptor sites. Simply put, molecular recognition is what biochemistry and bioorganic chemistry are all about. Therefore, it seems to me more noteworthy when molecular recognition is not involved, than when it is. There is even reason to expect that in the not-too-distant future the concept of complementarity will allow one to predict from the analysis of sequence data made possible by the polymerase chain reaction that a certain gene may be regulated by a given protein.

Another popular, and possibly overworked, buzzword is *rational drug design. Patchett* has drawn a useful distinction between rational drug discovery and rational drug design. Screening, often thought of as the antithesis of the rational approach, continues to play a very productive role in drug *discovery*, as is repeatedly illustrated throughout this review. On the other hand, the identification of the target enzymes, receptors, transport proteins, etc., for such screening has become much more mechanism-based, more sophisticated, and thus more "rational". In addition, the introduction of receptor displacement assays has dramatically increased the scope of screening. Mixtures of microbial and fungal products can be screened today as readily for central nervous system (CNS) or anti-inflammatory activity as they could be used forty years ago for the sole purpose of discovering new antibiotics. Another recent development with great potential stems from the ability of chemists and of molecular biologists readily to generate large libraries of polypeptides and of polynucleotides. These libraries can be quickly evaluated by sophisticated screening techniques. It remains the task of medicinal chemists to transform screening leads into candidates for clinical trial. Today they benefit enormously from computer-based molecular modeling in these endeavors.

Examples of rational drug discovery are typified by *D. Wood*'s observation in 1940 that the inhibition of bacterial growth by sulfonamide is competitively overcome by *p*-aminobenzoic acid. This observation established the latter as a growth factor and led to the synthesis of many structurally related antimetabolites. The synthesis in 1947 of aminopterin (4-aminopteroylglutamic acid) by *Seeger, Smith,* and *Hultquist* as an antimetabolite of folic acid, the structure of which had just been elucidated, serves as another example of rational drug discovery. Aminopterin was later found effective in inhibiting the growth of certain tumors. The synthesis of methyldopa, one of the most widely prescribed antihypertensives during the past 40 years, exemplifies both a reasoned choice of a synthetic target by *Pfister* and *Stein* and of rational drug testing by *Udenfriend* and *Sjoerdsma* at the NIH. The discovery of the thiazide diuretics by *Beyer, Novello,* and *Sprague*, a milestone in the treatment of hypertension, is another notable illustration. Many of the analogues of steroid and peptide hormones cited above serve as additional examples.

Rational drug *design*, on the other hand, implies that an enzyme or other receptor target has been identified in sufficient structural or mechanistic detail that a chemist can use such information to perfect a screening lead or to design de novo molecules that uniquely bind to and inhibit (or activate) the target protein. Such design from first principles, based solely on structural information about the macromolecule, is today a goal for the future, not as yet a reality. Therefore, research directors in the pharmaceutical industry with responsibility for keeping "pipelines" filled with product candidates, still do not commit a significant share of their resources to de novo design.

4.2. Enzyme Inhibitors

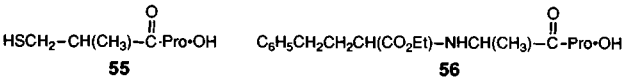
Enzyme inhibitors represent the area of medicinal chemistry where drug discovery has approached rational design most successfully. Research in laboratories such as those of *Abeles, Benkovic, Bloch, Bruice, Cleland, Fersht, Jencks, Knowles, Rose, Santi, Walsh,* and *Westheimer* has greatly increased our understanding of enzyme mechanisms. Central is the concept that an enzyme is able to enhance reaction rates by lowering the energy of the transition state of the reaction that it catalyzes. Enzyme-inhibitor design has been more successful than hormone-antagonist design because the former can take advantage of the transition-state analogue (TSA) concept. *Pauling* described the application of the TSA concept to enzyme-inhibitor design more than 50 years ago:[157]

> This picture of the nature of enzymes may well make us optimistic about the future of chemotherapeutics, for it predicts that for every enzyme... it would be possible to find an inhibiting molecule that is more closely complementary in structure to the enzyme than is the substrate itself, and which would accordingly be an effective inhibitor. The picture even presents us with ideas as to the nature of substances that would be effective inhibitors—they should resemble the activated complex.

Wolfenden, recognizing the importance of *Pauling*'s teachings, successfully explored its promise. *Byers* and *Wolfenden* pointed out[158] that "unusual potency is expected of inhibitors bearing a structural resemblance to chemically acti-

vated intermediates in catalysis or incorporating the binding characteristics of several reactants in a single inhibitor molecule." He designed and synthesized (*R*)-2-benzyl-3-carboxypropionic acid, which proved to be a potent inhibitor of carboxypeptidase A. He concluded that the inhibitor resembles the collected substrates for the reverse reaction, that is, the collected products. Taken together, the concepts of collected substrates, collected products, and transition-state analogues have proven to be exceptionally useful in the discovery of potent enzyme inhibitors. Examples of potent TSA inhibitors of enzymes include the fermentation product pepstatin (see below) and phosphorus-containing inhibitors described by several laboratories, including those of *Bartlett, Patchett* and *Thorsett, Portoghese, Petrillo,* and *Walsh.*

The design of the angiotensin-converting enzyme (ACE) inhibitors captopril (**55**) and enalapril (**56**) represents the most notable contribution to date of the Pauling–Wolfenden concepts to the practice of medicine. These ACE inhibitors



have revolutionized the treatment of hypertension and congestive heart failure. The achievements that they represent climaxed a series of worldwide investigations over a period of about 30 years, which included the isolation in the United States of the biologically inactive decapeptide angiotensin I (Fig. 6) and of the potent pressor substance angiotensin II, an octapeptide. It was shown[159] that a mammalian enzyme can convert angiotensin I to angiotensin II (Fig. 6).

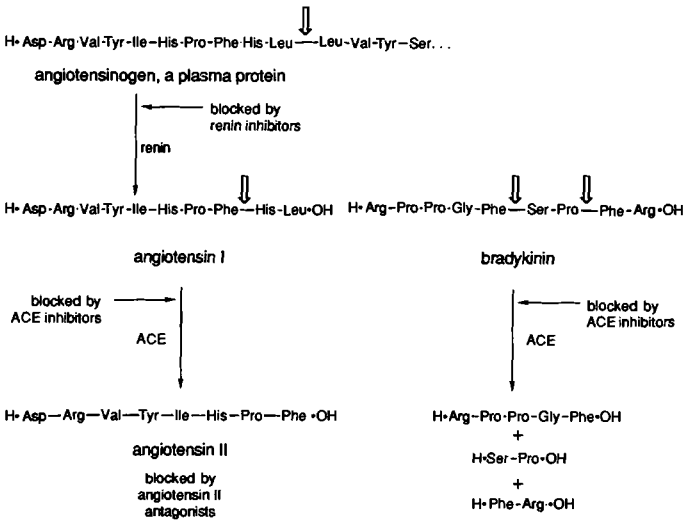


Fig. 6. ACE inhibitors, including the "bradykinin potentiating peptides", block formation of the pressor substance angiotensin II. ACE inhibitors also block the metabolism of bradykinin, a hypotensive peptide. The double arrow denotes site of enzymatic cleavage. Renin inhibitors block the formation of angiotensin I and thus, indirectly, of angiotensin II.

Later, scientists in Brazil discovered a series of peptides in snake venom, which potentiated the ability of a plasma nonapeptide, bradykinin, to lower blood pressure by inhibiting kininase I.[238] The seemingly unrelated studies in the United States and Brazil were linked when biochemists at Tulane University and the Albert Einstein College of Medicine purified and characterized ACE, and when studies at American, Brazilian, and British universities demonstrated that ACE is identical with kininase II and that it both inactivates (cleaves) the hypotensive bradykinin, and cleaves angiotensin I to give the hypertensive angiotensin II (Fig. 6).

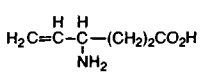
Early studies by *Skeggs* had suggested that ACE is a metalloprotease. *Ferreira* and *Rocha Silva*, as well as *Erdös* and *Whales*, had therefore employed sulfhydryl compounds to potentiate bradykinin. In an important advance, *Lipscomb* and co-workers were able to identify precisely the groups of the above-mentioned carboxypeptidase A which interact directly with zinc(II). Astutely recognizing the relevance of *Wolfenden*'s carboxypeptidase A inhibitor to the design of an inhibitor of the carboxydipeptidase ACE, and being aware of the snake venom inhibitors with their C-terminal prolines, *Ondetti, Cushman* et al.[160] at Squibb designed and synthesized captopril (**55**) and demonstrated its ability to lower blood pressure in animals. It was the beginning of a new era for the treatment of hypertension. Side effects seen in a small number of patients after administration of captopril, such as development of a rash and loss of taste, were reminiscent of side effects seen with penicillamine and made it appear reasonable to attribute these side effects to the mercapto groups common to **55** and penicillamine. A worldwide effort ensued to find a mercaptomimetic that would retain the ability of the mercapto group to bind zinc effectively without loss of oral bioavailability. No such mimetic has been found. However, *Patchett* et al.[161] ingeniously finessed the problem. They accepted partial loss of potency (three orders of magnitude) by replacing sulfhydryl with carboxyl, but gained potency (three orders of magnitude) by introducing phenethyl, which presumably recognizes the S_1 binding site. Monoesterification led to the prodrug **56**, which exhibits good bioavailability.

All in all, the ACE story is a beautiful illustration of successful interaction on an international scale between chemists, biochemists, X-ray crystallographers, and biologists in both academic and industrial environments. It is one of innumerable examples of the critical need for high quality, long-term basic research by individual academic investigators and for industry's ability, practicing research of equal excellence, to convert such basic research into products of societal value.

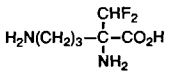
The contrasting clinical status of renin inhibitors is instructive. Renin is a mammalian aspartate protease that cleaves the protein angiotensinogen to generate angiotensin I (Fig. 6). As expected, renin inhibitors are effective in lowering blood pressure. In both academia and industry, the quality of the search for renin inhibitors has been superb. Of fundamental importance in this research was the recognition, which occurred almost concurrently in the laboratories of *Marciniszyn*,[162] *Marshall*,[163] and *Rich*,[164] that the statine residue, (3*S*,4*S*)-4-amino-3-hydroxy-6-methylheptanoic acid (Sta), in inhibitors of mammalian aspartic proteases such as pepstatin, functions as a transition-state bioisostere. *Boger* et al.[165] recognized that the statine residue replaces a dipeptide unit. Medicinal chemists in many laboratories have succeeded in designing and synthesizing a host of potent inhibitors of *human* renin based on

this understanding, yet to date there is no approved renin inhibitor, because the dual problems of oral bioavailability and adequate biological half-life have not been solved. This reminds us that bioavailability can remain a formidable obstacle to drug discovery even today.

The design of mechanism-based enzyme inhibitors,[166] pioneered by *Bloch*, *Abeles*, *Rando*, and *Walsh*, represents an intellectually highly satisfying achievement. Generally, but not necessarily, they lead to covalent bond formation. Two such inhibitors have recently become drugs, that is, approved for use in therapy. One is vigabatim (**57**), a selective, enzyme-activated, irreversible inhibitor of γ-aminobutyric acid (GABA) transaminase, for treatment of epilepsy. The other is ornidyl (**58**), which is used for the treatment of sleep-



57



58

ing sickness. It acts by blocking enzymes essential for the proliferation of trypanosome peptides transmitted by tsetse flies. In addition, a number of drugs have been determined retrospectively to belong in the category of mechanism-based enzyme inhibitors.[166]

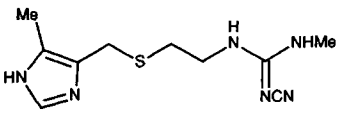
5. What Has Chemistry Done for Us Lately?

I shall restrict myself to first-generation compounds discovered during the past 20 years that are widely considered to represent milestones in therapy.

(1) I have already mentioned the discovery of captopril (**55**) (Section 4.2) and that its antihypertensive effect is mediated via a novel biochemical mechanism. Captopril provides effective treatment for a significantly broader patient population than prior antihypertensive therapy, suggesting that it treats a basic pathophysiology. In addition, its relative freedom from side effects, as well as its potential to reduce the incidence of strokes and the recurrence of heart attacks, makes its discovery an outstanding advance in medicine.

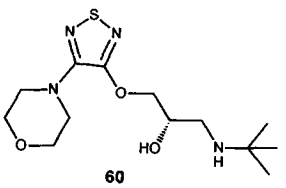
(2) Of equal importance was the isolation and the chemical and biochemical characterization of the fungal metabolite lovastatin (**18a**) by *Alberts*, *Patchett*, *Monaghan*, *Albers-Schonberg* et al.[31a] It is an inhibitor of HMG-CoA reductase and therefore blocks the conversion of 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) to mevalonate, the first committed intermediate in cholesterol biosynthesis. Importantly, it dramatically lowers the plasma levels of the cholesterol associated with the low-density lipoprotein (LDL), the principal contributor to atherosclerosis, the underlying condition responsible for coronary heart disease. A 1% decrease in the LDL cholesterol levels decreases the risk of coronary heart disease by 2%. Lovastatin was the first such enzyme inhibitor to be approved by a sophisticated regulatory agency. It is interesting that *Brown*, *Goldstein* et al. were able to show that the mechanism of **18b** is indirect, in that it stimulates, at the transcription level, the synthesis of the LDL cholesterol receptors.[31b] Mevastatin (**18b**, compactin) had actually been described before **18a** by *Endo* et al.[167] at Sankyo, who had built on the same biochemical rationale. Mevastatin, however, had encountered problems in safety assessment, another reminder that the road from a potent compound that is active both in vitro and in vivo to an approved drug is a hazardous one.

(3) The discovery of cimetidine (**59**) for the safe treatment of duodenal and gastric ulcers culminated research carried out at SKF (UK), to discover compounds which would block the histamine receptor subtype (H_2) involved in gastric acid secretion. Its discovery by *Black*[168] and by *Ganellin*,[239] pharmacologist and chemist, respectively, followed the prototypes burimamide and metiamide, discovered earlier by the same team. Cimetidine greatly reduces ulcer-related morbidity, pain, and the need for expensive hospitalization. Cimetidine and second-generation compounds are thus of great benefit to both the patient and society. In 1988, *Black* was awarded a Nobel Prize for his role in the discovery of cimetidine and for his earlier discovery of the β-adrenergic blocking agent propranolol.



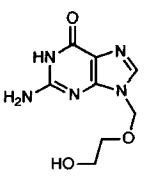
59

(4) Synthetic β-adrenergic blocking agents have long been established as cardiovascular drugs. The more recent discovery that one of them, timolol (**60**, blocadren),[169] synthesized by *B. K. Wasson* et al. at Merck (Canada), is a safe and effective agent for the topical treatment of glaucoma, represented another breakthrough in therapy. The compound has fulfilled its promise to revolutionize the management of open angle glaucoma because it can slow the progression of the disease.



60

(5) The discovery of acyclovir (**61**), an effective antiherpes drug, by *H. J. Schaeffer*, *G. Elion* et al.[170a] at the Wellcome Research Laboratories (USA) provided a potent inhibitor of the replication of the herpes simplex virus. Acyclovir is a prodrug that is monophosphorylated at the primary alcohol, but only by the viral thymidine kinase, not by human kinases. The triphosphate derived from this monophosphate

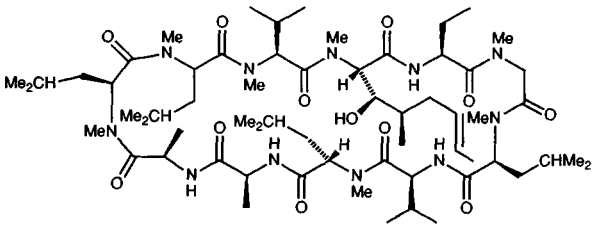


61

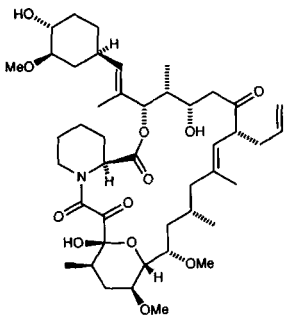
by host-cell enzymes inhibits the viral DNA polymerase more effectively than it inhibits the host polymerase. This twofold specificity apparently ensured a favorable T. I. The discovery of acyclovir built on the earlier antimetabolite research of *Elion* and *Hitchings*, which was recognized with the award of a Nobel Prize in 1988.[170b,c]

(6) The fungal metabolite cyclosporin (**62**)[171,172] has had a remarkable impact on the survival rates after organ and bone marrow transplants, because it greatly reduces the likelihood of near-term rejection induced by T cells. Isolated and chemically characterized by *Rüegger* et al. at Sandoz (Basel), this cyclic peptide has been adopted as the immunosuppressive agent of choice at a growing number of treatment centers worldwide.

Later, another more potent immunosuppressant, *Fujisawa*'s FK-506 (**63**), a 23-membered macrolide lactone, also discovered via the screening of fungal metabolites, was isolated and characterized by *Tanaka* et al.[173] Although it has not yet been approved for therapy by a regulatory agency, it is appropriate to discuss it here. Both **62** and **63** inhibit T-cell activation mediated by the T-cell receptor and, at the cellular level, inhibit remarkably similar steps in signal transduction.



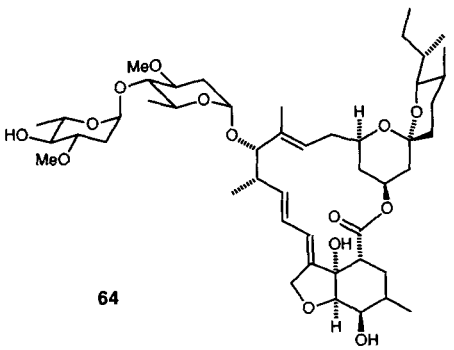
62



63

They hold promise for the treatment of a variety of diseases with an immunological etiology. Thus, an intensive effort is underway to find safer analogues and to identify biochemical mechanisms. Both immunosuppressants have been synthesized.[174,175] Cyclophilin has been shown[176] to be a receptor for cyclosporin. Cyclophilin was recognized to be identical to peptidyl-prolyl *cis-trans* isomerase by *Takahashi* et al.[177a] and by *G. Fischer* et al.[177b] *Fischer* et al. had also been the first[177c] to isolate that enzyme, which is now under investigation also by the groups of *Stein*,[178] *Schreiber*,[179] *Rich*,[181] and *Walsh*.[180] Through synthesis of cyclosporin analogues, *Rich*[181a] and also *Sigal* et al.[181b] have sought to determine the relevance of this receptor to the immunosuppressant activity of cyclosporin. Interestingly, an FK-506 binding protein called FKBP, under investigation by the groups of *Siekierka*,[182] *Schreiber*,[183a-c] and *Tropschug*,[184] is also a proline isomerase. Cyclosporin inhibits the isomerase activity of cyclophilin, and FK-506 that of FKBP. However, these inhibitory activities do not appear to be the full explanation of the immunosuppressant effects[181a,183a,c] of these compounds. Very recently, *Moore* et al.[240] and *Michnick* et al.[183d] have investigated the solution structure of FKBP and *Van Duyne* et al.[241] have succeeded in elucidating by X-ray crystallography the FKBP/FK-506 complex. The latter revealed a striking difference in conformation between FK-506 determined earlier[173] and bound FK-506. Very recently, *Schreiber* et al. have shown that cyclophilin and FKBP complexed with their respective ligands inhibit calcineurin. Taken together, these studies strikingly exemplify the ability of chemists to address problems of the greatest importance in biology and medicine.

(7) Mankind is also benefiting enormously from the discovery at Merck[185] of the avermectins in a broth produced by a culture of streptomyces originating from a Kitasato Institute actinomycete. They represent a family of compounds exhibiting a broad spectrum of potent antiparasitic properties. Chemically, they are related to the milbemycins discovered earlier in a search for pesticidal fermentation products at Sankyo. The Merck research involved fermentation and isolation, structure determination, parasitology, and synthetic organic chemistry. Under the leadership of *Chabala, M. H. Fischer,* and *Mrozik*, the medicinal chemistry program culminated in the further remarkable discovery that both the potency and the T. I. could be improved by the selective reduction of the single disubstituted, isolated *cis* double bond of the avermectins A/B to give the semisynthetic 22,23-dihydroavermectin B (**64**) containing some dihydroavermectin A. A mixture thereof, with a prescribed



64

composition, is known as ivermectin.[185] The screening at Merck of a novel broth generated at the Kitasato Institute has thus led to molecules which are safe and effective not only against endoparasites such as roundworms, but also against ectoparasites such as ticks, lice, mites, and insects.

Best of all, in addition to their value in veterinary medicine, these compounds hold the exciting promise of eradicating river blindness, one of the most dreaded diseases in certain countries of the Third World. This latter fact alone should make every medicinal chemist feel proud of his profession, as should the fact that Merck & Co., Inc. is making the drug available to the Third World without charge.

Chemists, collaborating with biologists and physicians, have played a critical role in bringing about these breakthrough discoveries, either by isolation chemistry, by design and synthesis, or by contributing to the design of sophisticated screening assays and by analogue synthesis. These achievements of the last 20 years follow such earlier milestones as the discovery of the antibiotics, antiasthmatics, antidepressants, anti-Parkinson drugs, antipsychotics, antitumor drugs, anxiolytics, diuretics, steroids, peptides, and the nonsteroidal anti-inflammatory agents. Taken together, these discoveries represent a sustained record of service to the practice of medicine and to scientific progress.

6. Summary and Outlook

It is tempting to speculate about the future, although it is the unexpected discoveries that often have the greatest impact. Nevertheless, certain recent developments may foreshadow advances. I shall cite two examples to illustrate the potential of molecular biology to provide new opportunities for medicinal chemists to intervene in pathophysiology. Until recently we had no understanding at all about cancer at the molecular level. Discoveries[186] in the laboratories of *Weinberg* at MIT, *Scolnick* at the NIH, and later *Sigal, Gibbs*, and *Scolnick* at Merck have opened the door to new approaches to cancer therapy. These workers determined the amino acid sequences of ras proteins in human tumors and showed how such sequences differ from the sequences in the normal protein. They found, for example, that a mutation causing Gly^{12} to be replaced by Val^{12} in the p-21 protein generates a mutant with the capacity to transform normal colon cells into malignant ones. Since both Gly and Pro are α-helix breakers, conformational analysis predicted[187] that only Pro would fail to convert the normal ras gene into an active oncogene. Experimental results were in good agreement with this prediction, but X-ray crystallography revealed later that helix-breaking is not involved. It was found by biochemists that the p-21 proteins are monomeric G-proteins, enzymes which are known to bind guanine nucleotides and to hydrolyze GTP to GDP, especially in the presence of GAP.[186] In the oncogenic mutants, the ratio of bound GTP to bound GDP is greater than in the normal protein, either because of a slower rate of enzymatic hydrolysis of GTP by the transformed G-protein or because of an increased exchange of GDP by GTP.[188, 189] Either way, these defective molecular switches cause the transformed cells to be "turned on" to an inappropriate degree. It has not yet been possible to apply this new understanding, but several approaches can now be contemplated. In this context it is particularly interesting that the processing of ras proteins has recently been found to involve the addition of a farnesyl residue.[190] This post-translational event is proving to be of great importance generally for membrane association. In the case of the monomeric ras G-proteins discussed above, such farnesylation appears to be required before their transforming properties can come into play. *Reiss* et al.[191] have recently defined the sequence requirements for peptide recognition by rat brain $p21^{ras}$ protein transferase. Inhibition of the farnesylation reaction thus offers a further potential target for intervention. It remains to be determined whether this particular post-translational event can be inhibited selectively.

At the DNA/RNA level, the application of the so-called antisense technology[192, 193] and the related "triple helix" approach[194a] have great potential,[194b] but also pose a profound challenge to chemists. This approach to drug design seeks to prevent the expression of unwanted proteins, rather than to inhibit their actions. This is also true of the strategies to deliver oxidative cleaving agents selectively to the unwanted DNA sequence, typified by the work of *Dervan*.[195] *Hurley*[196] has recently reviewed other opportunities provided by DNA-associated drug targets, which are by no means restricted to cancer.

An equally spectacular example of new understanding at the molecular level made possible by biotechnology is the work of *Lefkowitz* and his co-workers and that of *Dixon, Sigal, Strader*, and their co-workers, who have rescued the adrenergic receptors from the status of a black box. The work with the β-adrenergic receptors (βARs) at Duke University and at Merck built on the earlier investigations into visual pigments and into the far-more-accessible bacteriorhodopsin, which mediates light-driven proton transport across the purple membrane from *Halobacterium halobium*. These studies have taken place over a 100-year period, but significant advances into the structures of these proteins occurred only since the 1970s when *Henderson* and *Unwin*[197] used electron microscopy to show that the protein in the purple membrane contains seven closely packed, α-helical segments that extend roughly perpendicular to the plane of the membrane and that the lipid bilayer fills the spaces around the protein segments. The structure of this membrane protein in atomic detail was recently reported by *Henderson* et al.[198] Studies by *Ovchinnikov*,[199] *Hargrave*,[200] *Khorana*,[201] *Crouch*,[202] *Nakanishi*,[203] and their co-workers, as well as investigations in other laboratories,[243] established that the pathway of visual excitation in vertebrate retina involves the protein opsin, which is linked through a Schiff base derived from a lysine side chain and the aldehyde of 11-*cis*-retinal (rhodopsin). The presence of the seven-helix motif in rhodopsin was inferred by *Hargrave* et al.[243] through hydrophobic matching and other physical measurements. A photon induces a conformational change in rhodopsin via isomerization of 11-*cis*- to 11-*trans*-retinal. This isomerization in the photoreceptor results in binding of the hetero-trimeric G-protein (G_t, t = transducing; see Fig. 7 and below), initiating a series of events that ultimately affect the intracellular levels of the second messenger, cyclic AMP (cAMP).

The cloning of the gene and cDNA for a mammalian β_2 AR enabled *Dixon, Sigal, Strader* et al.[204] to discern that the amino acid sequence predicted for the receptor had significant homology with bovine rhodopsin, and to suggest that, like rhodopsin, the β_2 AR possesses multiple membrane-spanning regions. Application of the concept of hydrophobic matching led to a proposed structure for the β_2 AR which thus also contains seven transmembrane α-helical segments composing a single peptide chain. In this proposed structure, the seven hydrophobic domains are again connected by short hydrophilic segments, forming extramembranous loops. These structural similarities suggested also functional similarities between rhodopsin and the β_2 AR; that is,

both are linked to their G-proteins (G_t and G_s, respectively), with a photon serving as the agonist for rhodopsin and adrenaline for the β_2 AR.

An impressive subsequent accomplishment, made possible by site-directed mutagenesis, was the identification by *Dixon, Sigal, Strader* et al.[205] of aspartate-113 in transmembrane helix 3 as the amine binding site for β-adrenergic agonists and antagonists.[205] Later on, it was shown[206] that hydrogen bonding between the *m*-hydroxyl of the catecholamine adrenaline with Ser^{204} of the receptor and the *p*-hydroxyl of adrenaline with Ser^{207}, both in helix 5, is required for the expression of agonism.

Lefkowitz et al.[207] have deduced the complete primary amino acid sequences of mammalian β_1 ARs and of α ARs. It should be remembered, however, that medicinal chemists had discovered selective ligands for ARs long before the amino acid sequences of the relevant receptors had become known. The cardioselective (β_1) adrenergic blocking agents atenolol and metoprolol, which have greater affinity for the cardiac (β_1) receptors than for the bronchial (β_2) receptors, are well-known examples. At present, the new knowledge about the sequences and probable structures of both the cardiac (β_1) and bronchial (β_2) β receptors, however satisfying, does not yet allow us to explain the selectivity of these adrenergic blocking drugs, let alone to design, for example, a new cardioselective β blocker or a selective β_2-receptor agonist. This represents a significant challenge for the future. On the other hand, the work by *Strader* et al.[206] allows one to speculate why β-adrenergic blocking agents such as propranolol, pronethalol, and atenolol are β-blockers devoid of the so-called "intrinsic sympathomimetic activity (ISA)", that is, of β-adrenergic agonism, whereas β-blockers such as pindolol, dichloroisoprenaline, and practolol do possess ISA. The latter contain heteroatoms that may be able to mimic one of the phenolic hydroxyls of adrenaline and may thus hydrogen-bond with a serine hydroxyl in helix 5. Admittedly, one would have to invoke alternative explanations, such as allosteric effects, to explain why compounds such as alprenolol exhibit ISA.

The β ARs are among the best-characterized members of a family of receptors which mediate their actions through signal transduction pathways involving guanine nucleotide regulatory proteins (G-proteins; Fig. 7). In a series of elegant studies, which built on *Rodbell*'s suggestions of the transducer concept,[208] *A. G. Gilman*[209] and *Stryer* and *Bourne*[210] showed that receptors do not directly activate the effector enzymes or ion channels, but that G-proteins act as transducers of information across cell membranes, by coupling receptors with effectors inside the cell. These effectors thus respond to the original stimulation of the receptors (R) by hormones, neurotransmitters, and other agonists (H) via the intervention of the hetero-trimeric G-proteins. For example, after adrenaline binds to a β-adrenergic receptor, the conformational change thereby induced causes the H·R complex to become associated with the appropriate G·GDP complex. In the case of the β receptor, G is the so-called stimulatory G-protein (G_s). This interaction with the receptor causes GTP to replace GDP on the H·G·G_s complex, generating H·R·G_s·GTP. Formation of the latter complex triggers two further events. First, the G_s loses its affinity for H·R, regenerating free hormone and unoccupied receptor, and, second,

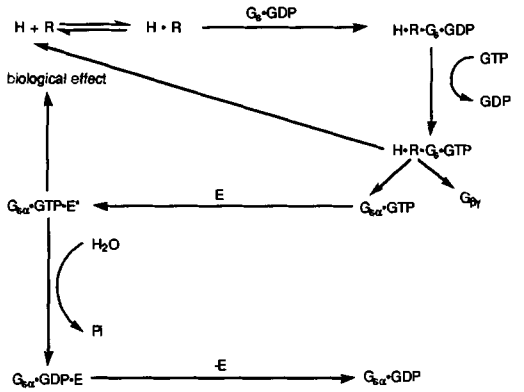


Fig. 7. The signal transduction pathway whereby stimulated membrane receptors are coupled to intracellular receptors via hetero-trimeric G-proteins, composed of α,β, and, γ subunits. For the β-adrenergic receptor, the relevant G-protein is the stimulatory G-protein G_s, and the enzyme (E) is adenylate cyclase. For the visual receptor rhodopsin, the G protein is transducin (G_t), and E is phosphodiesterase. E* denotes an activated enzyme, R a receptor, and H a hormone, neurotransmitter, or other agonist.

the β,γ subunits of the G_s·GTP complex dissociate from $G_{s\alpha}$·GTP.

It is this remaining complex between GTP and the α subunit of G_s that now binds and activates the relevant enzyme (E), which for the β ARs is adenylate cyclase, the enzyme that generates the "second messenger" cAMP. At this point another control mechanism intervenes. The $G_{s\alpha}$ protein is also an enzyme, irreversibly hydrolyzing GTP to GDP. The resulting $G_{s\alpha}$·GDP lacks affinity for the enzyme E, which is thus deactivated. As pointed out by *Jencks*,[114a] the system works because an effective agonist is complementary to the active conformation of the receptor, thus pulling the system forward. By analogy the system can be "cooled off" because the enzyme E is not complementary to the $G_{s\alpha}$ when the latter is bound to GDP. It has recently been shown[211] that farnesylation of γ subunits of G-proteins is required for GTP binding. Such farnesylation, and the opportunity for its selective inhibition was already mentioned above as a goal for the medicinal chemist in the case of the monomeric ras p21 protein.

In the case of the visual pigments, the G-protein is G_t (transducin), and the enzyme that it activates is a phosphodiesterase rather than adenylate cyclase. As pointed out by *Applebury* and *Hargrave*, nature has thus capitalized on a general biochemical mechanism for control of second messengers in the cytoplasm of cells. The diversity of the known ligands for cloned G-protein-linked receptors has been found to be remarkable.

These advances in our molecular understanding of the G-protein-linked receptors—typified above by the β_2-adrenergic receptor, like the advances in our understanding of the ras oncogenes—were made possible by biotechnology. In neither case has the medicinal chemist as yet used this information to design a new drug, but the opportunities are there. Specificity may well prove to be the critical requirement for success.

Rational drug design (in contrast to rational drug discovery) will have come fully into its own when the structural information about enzymes or other receptors permits the discovery of a new drug that would not have been possible without such structural information about the macro-

molecule. Analysis of X-ray crystal structures, in combination with other physical measurements, molecular modeling, and chemical intuition, will play a major role in this process in the years ahead. Biotechnology greatly increases the likelihood that the relevant crystalline protein will be available to the crystallographer at the right time, helping to connect the biochemistry and structural biology of a system. The initial success stories may well come from X-ray information about enzymes with a bound inhibitor. Promising advances include inhibitors of the enzyme dihydrofolate reductase.[212] The ability to make correct predictions continues to be the critical measure of success. Indeed, the design by *Baldwin, Navia, Anderson* et al.[213] of MK-927, a novel, topically active, carbonic anhydrase inhibitor for the treatment of glaucoma, represents an important step in that direction.

One well-recognized problem in such endeavors was cited by *Beddell, Goodford* et al.[214] in their search for substituted benzaldehydes designed to increase the oxygen affinity for human hemoglobin: "the structure of the receptor site is not rigid and it is often difficult to take account of the flexibility of both the designed ligands and the receptor site itself in predicting the properties of the ligand-receptor complex." The problem is compounded by the fact that the conformation of a ligand on its receptor may not correspond to a minimum-energy conformation of the ligand in solution. This was the situation reported by *Baldwin, Navia, Anderson* et al.[213] for their most potent inhibitor of carbonic anhydrase and for its optical antipode. Thus, the conformation of the receptor–ligand complex will minimize the energy of the complex, but not necessarily that of its components. This analysis suggests that it will, at times, prove undesirable to impose a conformational constraint on the solution minimum-energy conformation or on the conformation revealed by X-ray analysis of the small molecule. For example,[215] a recent X-ray study of an isomorphic, but completely inactive insulin analogue, miniproinsulin,[230] has led to the conclusion that insulin crystals can represent inactive conformers. Thus, 2 D NMR is emerging as a valuable, complementary technique to X-ray crystallography. Yet imposing a constraint on a minimum-energy conformation of a small molecule has often proved fruitful. In a recent review, *Schiller*[216] addresses some of these and related problems. *Knowles*[217] concluded from his studies with the enzyme triosephosphate isomerase that there are important "elements of precision" beyond the well-known[157, 218] fit of the transition state into the active site of an enzyme. For the interactions of hormones/neurotransmitters, such elements of precision are suggested by the finding of *Strader* et al.[219] that the replacement of Asp^{113} of the β_2-adrenergic receptor by Glu results in a mutant receptor which now recognizes several known β-adrenergic antagonists (β-blockers) as partial agonists.

An early example of chemical site-directed mutagenesis[220] was described by *Polger* and *Bender* in 1966, who converted the enzyme subtilisin into thiosubtilisin, containing a thiol group rather than a hydroxyl group as the essential nucleophile of the active site. This protein still hydrolyzes nitrophenyl acetate but fails to react with any of the classical substrates of subtilisin.[220, 221] These results can serve as a reminder that a de novo design might be creative to the point of being inspired, and yet miss the mark.

These difficulties notwithstanding, there is no doubt that the information provided by X-ray crystallography about receptor–ligand complexes is already proving invaluable to drug discovery. The same can be said about site-directed mutagenesis. One has every reason to expect that the combination of these techniques will prove to be synergistic. The studies of the interaction of human GH with its receptor by *Cunningham, Wells*, and their associates[222] at Genentech are of great current interest in this regard, since the atomic structure of the complex between GH and its binding protein (receptor) has just been solved.[223] It will be a major event when the information provided by X-ray crystallography and 2 D NMR, combined with site-directed mutagenesis, will permit, for example, the de novo design of an allosteric GH mimetic, or a novel inhibitor of FKBP, or an erythropoietin (EPO) mimetic. Such achievements would indeed represent rational drug design.

One can have the greatest expectations for the discoveries in biomedical science that will be made during the last decade of this century and during the 21st century. The challenges are formidable, and too many to enumerate, but they include autoimmune diseases, mental health, cancer, geriatric medicine, diabetes, and viral infections. And no challenge is greater than that posed by the clear and present danger of AIDS, where a formidable, multipronged attack is underway. For the time being the reverse transcriptase inhibitor 3′-azido-3′-deoxythymidine (AZT)[170d, 224] represents a welcome first step.

The staple of basic research discoveries that are waiting to be applied to the solution of these problems is impressive. In addition to the examples of advances in our understanding of cell signaling already mentioned, the elegant research of the phosphatidylinositol system, notably by the laboratories of *Berridge*[225] and *Irvine*[226] in Cambridge (UK) with IP_3 (based on observations made by *Mitchell*[227]) and by *Nishizuka*'s[228] laboratory in Japan with protein kinase C, provide opportunities for the medicinal chemist.

Small molecules are certain to continue to play a very important role among the drugs of the future. The new class of therapeutic small molecules might include, for example, compounds of value in the treatment of asthma, such as inhibitors of enzymes involved in leukotriene synthesis and antagonists of the leukotrienes. Success with any such compounds would bring to fruition years of long-term basic research in academia and industry. Promising results are also being reported with compounds for the treatment of migraine and osteoporosis. Selective inhibitors of reverse transcription, of phospholipase A_2, and of enzymes regulating lymphokine biosynthesis are other promising active research areas. This is also true of compounds with the potential to regulate thrombosis and clot lysis.

On the other hand, biotechnology is also certain to continue to add macromolecules to the armamentarium of the physician. As we approach the 21st century, there is the expectation of a growing list of proteins for use in therapy and the hope that gene therapy will also become a reality. At the present it seems likely to this reviewer that biotechnology will contribute to therapy at least as much by facilitating the discovery of small molecules as through the therapeutic use of macromolecules themselves.

Promises for the future are most likely to be fulfilled if neither biologists, nor chemists, nor molecular biologists view the other disciplines as a mere handmaiden of their own. As this article makes evident, we need each other.

The author is deeply grateful to the many colleagues who have read either sections of this manuscript or the entire paper. Their suggestions have truly been invaluable. It is also a pleasure to thank Paul Friese and Key Payton for their technical expertise in the typing of the manuscript and for the patience and good humor with which they accepted one revision after another. I am particularly indebted to Dr. Andreas Lender for his insightful and careful checking of the German and English versions of the galley proofs of this manuscript.

[142] The earliest examples of the employment of the concept of conformational constraint in peptide medicinal chemistry are probably the synthesis of carba analogues of oxytocin [104], and, more explicitly, the synthesis of a biscarba analogue of SRIF [133b]. The synthesis of bicyclic analogues of SRIF [133a] again employed conformational constraints to help elucidate bioactive conformations. The seminal work by *Freidinger* and *Veber* [see R. M. Freidinger, D. F. Veber, *Science (Washington, D. C.) 210* (1980) 656] and later by *Hruby*'s group [see T. K. Sawyer, W. L. Cody, J. J. Knittel, V. J. Hruby, M. E. Hadley, M. D. Hirsch, T. L. O'Donohue, *Pept. Struct. Funct. Proc. Am. Pept. Symp. 8th 1984*, 323] and by P. W. Schiller and J. DiMaio [*ibid.*, p. 269] are excellent examples of a different approach to conformational constraint. An early example of the use of conformational constraint in enzyme inhibitor design is the work of *Thorsett* und *Patchett* et al. [E. D. Thorsett, E. E. Harris, S. Aster, E. R. Peterson, D. Taub, A. A. Patchett, E. H. Ulm, T. C. Vassil, *Biochem. Biophys. Res. Commun. 111* (1983) 166].

The Extraordinary Enzymes Involved in Erythromycin Biosynthesis

By *James Staunton* *

The polyketides form a family of compounds which have very diverse structures and no obvious structural relationship, at least on superficial examination. Representatives of some of the main classes are presented in Scheme 1. Many of these compounds are of great commercial interest. For example, erythromycin, tetronasin, and oxytetracycline are all antibiotics which are used in medical practice and in animal husbandry. Another polyketide metabolite, FK 506 (not shown), is currently causing great excitement for its ability to act as an immunosuppressant following organ transplant surgery.[**]

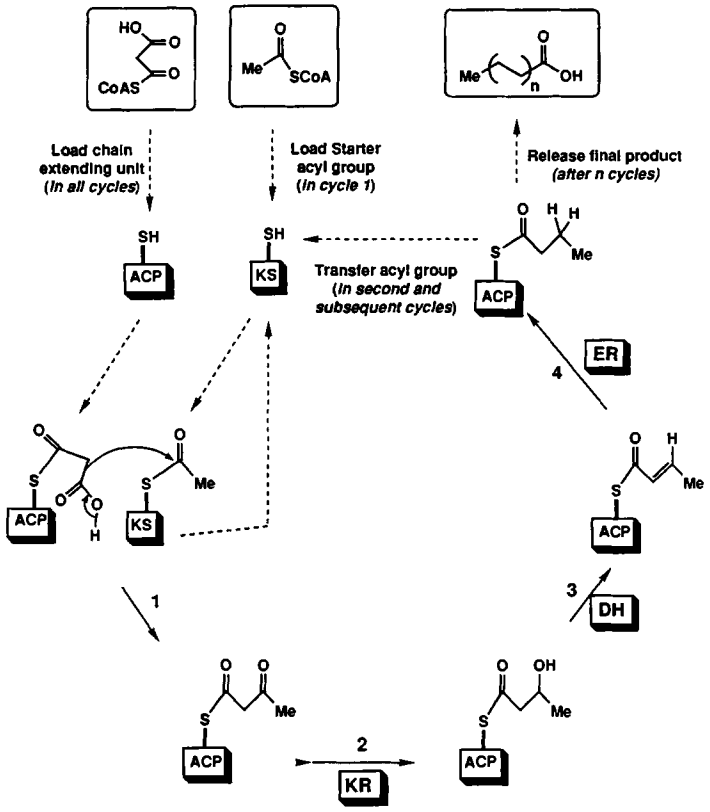
Actinorhodin

Scheme 1. Types of polyketide metabolites. 6-MSA = 6-methylsalicylic acid.

Despite their structural diversity the polyketides are thought to be related in biosynthesis, at least in the early steps of the pathways in which the essential core of the structure is assembled. This assembly process is thought to involve a variation of the standard biosynthetic cycle by which fatty acids are produced. In this cycle the growing fatty acyl chain is extended by the repeated addition of two methylene groups.[1] A representative reaction sequence is shown in Scheme 2. Initially, acetate is condensed with malonate to give acetoacetate with simultaneous loss of CO_2. Steps 2, 3, and 4 follow an unexceptional strategy to convert the ketone carbonyl to a methylene. The resulting extended acyl group then reenters at the starting point, and the cycle is repeated until the appropriate length of chain is reached. A special characteristic of these systems is that the growing chain is bonded via a thioester link to a protein thiol group at all stages, until the final product is released. The system of enzymes which carries out these steps is known as the fatty acid synthase (FAS) system.



Scheme 2. Reactions and enzymes of fatty acid biosynthesis. KS = ketoacyl-synthetase; KR = ketoreductase; DH = dehydratase; ER = enoylreductase; ACP = acyl-carrier protein; CoA = Coenzyme A.

On casual inspection it may seem improbable that any of the polyketides of Scheme 1 is related to the simple fatty acids, but ample evidence has been accumulated to support this proposition. Studies with mutants have provided important though indirect evidence. When a mutant of a polyketide-producing organism lacks the ability to produce one of the biosynthetic enzymes, the preceding intermediate may accumulate in sufficient quantities for it to be isolated and identified. Such experiments with the erythromycin producer, *Saccharopolyspora erythraea* (formerly *Streptomyces erythraea*), led to the identification of several late intermediates of the biosynthetic pathway.[2] These compounds lacked some of the features of the erythromycin A structure, but nothing simpler than the macrocyclic lactone 6-deoxyerythronolide B was discovered. These experiments therefore indicate that the biosynthesis of erythromycin takes place in two phases, as is shown in Scheme 3, linked by the pivotal first enzyme-free intermediate, 6-deoxyerythronolide B. Al-

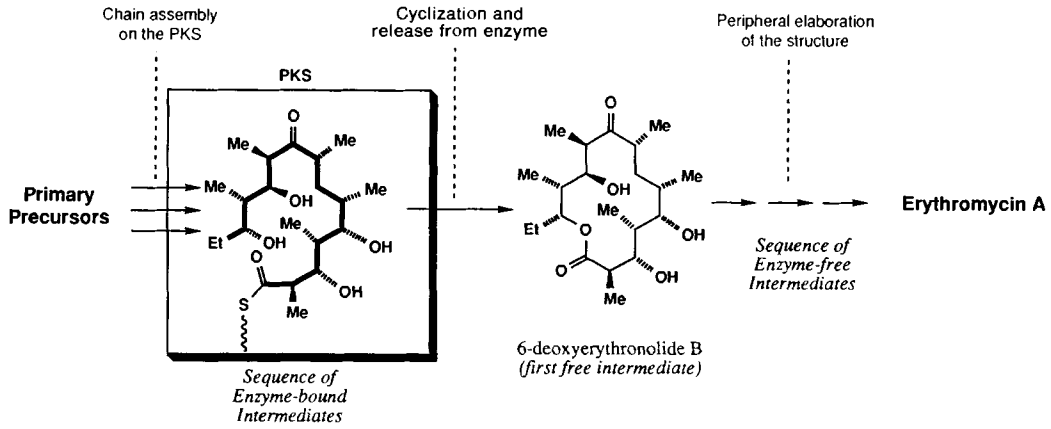
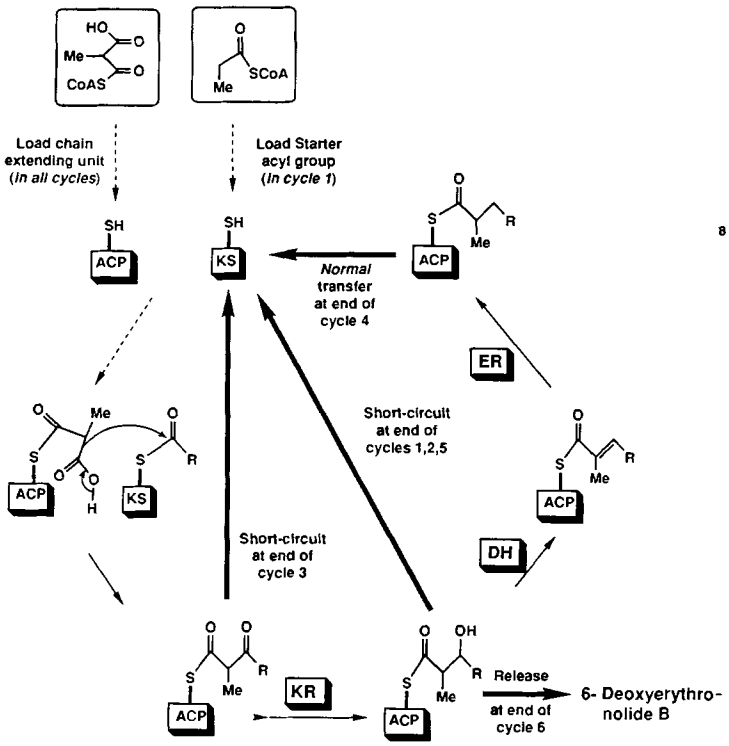


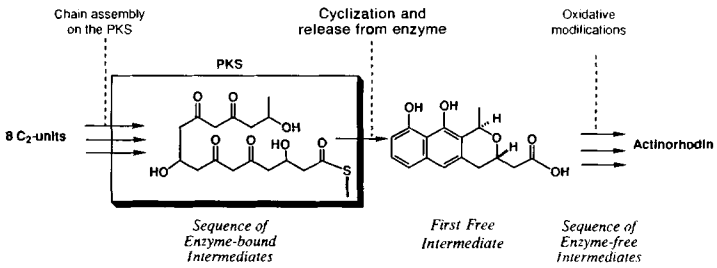
Scheme 3. Overview of the erythromycin A biosynthetic pathway. PKS = polyketide synthetase system.

though they throw no light on the mode of assembly of the key macrolide core of the molecule, these results support the idea that the early intermediates remain enzyme-bond, and so cannot accumulate in sufficient quantities for detection. By analogy with FAS systems, the enzymes involved in the chain assembly stage of a polyketide biosynthetic pathway are collectively known as the polyketide synthase (PKS) system.

The structure of the proposed final intermediate bound to the PKS in Scheme 3 is highlighted with heavy lines to emphasize that it contains a chain of carbons terminating in a carboxyl residue, and so has some structural resemblance to a simple fatty acid. Greater structural complexity is conferred on the antibiotic precursor by a series of branching methyl groups and by oxygen substituents. Both of these structural features can easily be introduced by a variation of the fatty acid biosynthetic cycle. The use of propionate rather than acetate as the chain starter acyl, and methyl malonate instead of malonate for the chain extension steps in Scheme 2 results in the formation of a carbon skeleton with methyl branching. Hydroxyl or ketone substituents could be left at the appropriate sites by omitting some or all of the steps normally used to convert each new ketone group to a methylene. In the case of 6-deoxyerythronolide B, the sequence of reactions catalyzed by the PKS would then take the form outlined in Scheme 4. The heavy arrows indicate where acyl groups need to be transferred in the various cycles, in order to leave the appropriate array of oxygen functions in the final enzyme-bound intermediate. Subsequent lactonization, perhaps catalyzed by a component of PKS, would then lead to the release of 6-deoxyerythronolide B. There are many classical biosynthetic incorporation studies using simple primary precursors variously labeled with isotopes of carbon, hydrogen, and oxygen in support of this scheme, and more recent incorporation studies with 'partly formed' chains, corresponding to enzyme-bound intermediates, have provided added insights.[3]



Scheme 4. Proposed mode of operation of the erythromycin PKS.



Scheme 5. Proposed biosynthesis pathway for actinorhodin.

Encouraged by progress made in studies of the genetics of the actinorhodin pathway by the Hopwood group in Norwich, many groups engaged in studies of polyketide biosynthesis have recently turned to a genetic approach in an effort to gain a clearer understanding of the molecular basis of chain assembly.[4] Actinorhodin has a structure consistent with a derivation from C_2-units via the enzyme-bound polyketide intermediate shown in Scheme 5. Since most of the ketone residues of this chain have been left unmodified by PKS, subsequent cyclization and dehydration reactions could take place to form the second intermediate shown. The

proposed pathway leads to actinorhodin by further oxidative steps involving other enzymes.

Many genes coding for proteins involved in this biosynthesis pathway have now been identified. Of particular interest here are a set of four which code for proteins having a strong sequence homology with protein components of various fatty acid synthases, and a fifth which is thought to be the cyclase responsible for the process of aromatization. These proteins are very probably the components of PKS. Interestingly, the individual genes are discrete and therefore the corresponding enzyme activities are not covalently linked to each other as they are formed. The actinorhodin PKS therefore probably resembles the FAS systems of most bacteria in consisting of a dissociable set of cooperating enzymes. Several other PKS gene clusters associated with the generation of polyacetate aromatic compounds in various *Streptomyces* species show a similar organization.[4] In contrast, the PKS for biosynthesis of 6-methylsalicylic acid (6-MSA), which has been isolated, is composed of a similar set of enzymes activities, linked covalently to form a large multifunctional protein.[5] The active form of the PKS is formed by the aggregation of four such multifunctional proteins. This more elaborate molecular architecture, which has precedents in the FAS systems of yeasts, mammals, and certain bacteria, probably leads to a more efficient and possibly more robust catalytic apparatus. In all of these polyacetate PKS systems, only one gene codes for each catalytic activity in the FAS cycle, which means that individual active sites in the PKS complex participate in successive cycles of chain extension.

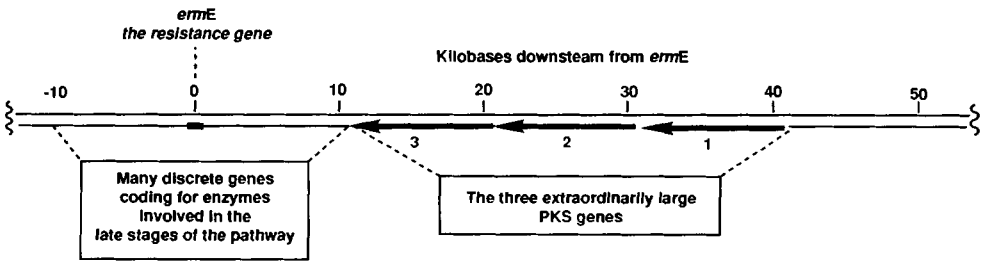
The breakthrough in locating the actinorhodin PKS genes has stimulated a search for PKS genes in other organisms. In one approach genetic probes based on the actinorhodin genes were used with considerable success to locate the PKS genes for various aromatic polyacetate metabolites.[4] A second approach, also based on the pioneering work of the Norwich group, proved successful with the erythromycin genes, although the size of the task proved much greater than anyone imagined at the outset.[6, 7] Firstly, the gene coding for erythromycin resistance in the producing organism was located. By working initially on the assumption that the biosynthetic genes would be clustered in the vicinity of the resistance gene, as had been observed for the actinorhodin genes, the neighboring DNA was sequenced in a search for genes coding for FAS type proteins. This search was encouraged by the finding stemming from the Abbott laboratories in Chicago that mutations that prevented synthesis of 6-deoxyerythronolide B could all be localized to near the resistance gene.

The resulting picture which has emerged for the gene structure of the enzyme system for erythromycin biosynthesis is outlined in Scheme 6. On both sides of the resistance gene there are regions containing about 10000 pairs (10 kbp) of DNA which contain genes thought to code for proteins involved in the late stages of the pathway, in which 6-deoxyerythronolide B is converted into the erythromycin A. In confirmation, deletion of individual genes in these regions produced mutant organisms from which late intermediates have been isolated.

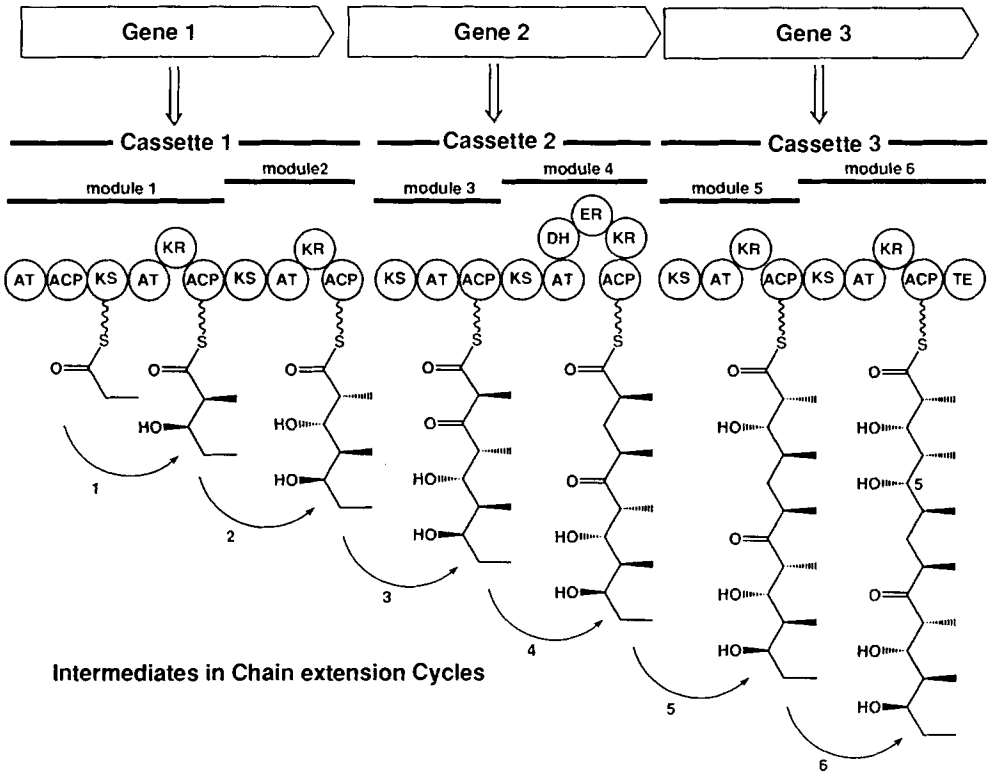
Sequencing further away from the resistance gene has subsequently revealed a region of DNA which contains sections corresponding to the elusive PKS gene cluster (Scheme 6). It became clear that the erythromycin PKS is much more elaborate than that associated with the biosynthesis of actinorhodin and other polyacetate aromatic compounds. The first indication of this extra complexity came with the discovery that there are several different genes coding for specific components of the PKS (e.g., there is more than one acyl-carrier protein (ACP) gene). This suggested that different cycles of chain extension might employ different versions of specific component enzymes.

What is perhaps even more surprising is the complexity of the organization of the enzyme activities. This was first revealed when a group from Cambridge published the complete sequence of one of the open reading frames (i.e., a potential gene) coding for part of the erythromycin PKS.[6] This exceptionally large open reading frame, containing more than 10 kbp of DNA, codes for a single giant protein of molecular weight 332472 Da, particular segments of which show sequence homology with individual FAS proteins. In all there are eight catalytic activities, corresponding to two different sets of the enzymes required for chain extension, together with a thioesterase.

More recently the complete sequence of the erythromycin PKS genes has been published by *Katz* and co-workers from the Abbott Laboratories.[7] It consists of three large open reading frames each coding for a large multifunctional protein having sufficient catalytic sites to carry out two chain extension cycles. It would appear, therefore, that there is an individual enzyme for each and every step carried out by the erythromycin PKS. The activities seem to be organized in six "modules", all of which contain the active sites for a condensation step, and all but one contain some or all of the active sites associated with conversion of the ketone group into a methylene in the fatty acid biosynthetic cycle. These modules are further linked in pairs, for which I suggest the term cassette. Three such cassettes collaborate in some undefined way to produce the first enzyme-free-intermediate, 6-de-



Scheme 6. Outline map of the cluster of genes coding for enzymes involved in erythromycin biosynthesis.



Scheme 7. The erythromycin polyketide synthetase system (PKS): primary organization of the genes and their corresponding protein cassettes. Examples of intermediates in the chain extension cycles are given. However, see caveat in text.

oxyerythronolide B, from one unit of propionate and six of methylmalonate.

Scheme 7 shows in more detail how the PKS genes are arranged on the genome, and how the catalytic sites are ordered in the primary structure of the protein chain in each corresponding cassette. A ligand is shown attached to each module to indicate how the modules may operate in assembling the polyketide chain. It should be stressed, however, that there are many possible ways for the cassettes to fold, possibly bringing complementary activities sited in different modules close together. In the functioning of the cassettes, therefore, the various activities which cooperate in a particular chain extension cycle may be drawn from different modules. Consequently, individual active sites with a particular function (e.g., the ACP's) need not necessarily come into play in the order in which they appear in the primary sequence of the protein, as is assumed in Scheme 7. At this time only one catalytic site, the ketone reductase (KR) site in module 5, has been firmly linked to a specific role in the elaboration of the erythromycin chain.[7] This was achieved by selective disruption of the DNA coding for this activity. The resulting mutant organism generated, instead of erythromycin, an analogue carrying a keto group at C5 of the macrolide ring. It is safe to conclude, therefore, that this reductase operates in the fifth cycle of chain extension, but not that its nearest neighbors in the primary sequence of the protein are its functioning partners.

In its size and sheer complexity this extraordinary PKS system breaks new ground, although in passing it should be mentioned that giant multifunctional proteins have also been implicated in the nonribosomal biosynthesis of some peptide secondary metabolites, and further examples may emerge as efforts to identify enzymes involved in other pathways of secondary metabolism gather pace.[8] The information obtained from sequencing the genes gives a fascinating insight into the primary organization of the PKS proteins, and some indication of how they function. An enormous multidisciplinary effort is required, however, to uncover fully the molecular basis of their action, and this will have to include direct studies of the proteins themselves. Encouraging progress on the isolation of PKS proteins from the erythromycin PKS has been reported from Cambridge.[9] A section of the open reading frame for cassette 3, corresponding to the thioesterase (TE) and ACP activities at the C-terminus, has been expressed at high levels in *Escherichia coli*. The resulting protein had the expected molecular mass (38019 Da), according to the electrospray mass spectrum, and it showed an ability to bind a standard inhibitor (phenylmethylsulphonyl fluoride) in a manner consistent with its expected thioesterase activity. More recently, the complete open reading frame coding for cassette 3 has been expressed in *E. coli* as a single protein with a molecular weight in the required range (ca 300 kDa by electrophoresis), confirming that these large genes are capable of expression as large single proteins.[10] Now that PKS proteins are becoming available, there is the exciting prospect that the activity of the constituent active sites may be demonstrated in vitro. The Cambridge group has already succeeded with a FAS ACP derived from the erythromycin producer, and in doing so has developed methodology appropriate to studying the PKS system.[11]

What other developments should we look for in the near future? It will be interesting to see if the organization of the erythromycin PKS as a series of modules arranged in cas-

settes holds good for other macrolide PKS's, and also possibly for ionophore-producing PKS's. This ordering of proteins in cassettes, which need not be exclusively bimodular, may hold the key to the precise control exercised by the synthase as a whole in carrying out its synthetic operations. It would, for example, help rationalize both the early observations of *Celmer* et al. on the common patterns of structure and stereochemistry which run through families of macrolides,[12, 13] and more recent related analyses of ionophore structures.[14] Perhaps regions with common structure in diverse metabolites are produced in different organisms by closely related cassettes derived from a common ancestral protein. Looking ahead, it may be possible to engineer organisms to produce novel chimeric metabolites by switching genes coding for specific cassettes from one producer to another.

If substantial amounts of active PKS proteins can be isolated by overexpression, it will be possible to investigate the molecular mechanisms by which the cassettes carry out their specific tasks. The protein–protein interactions which must play a major part in the collaboration between cassettes will make a fascinating study. Equally interesting are the molecular interactions which occur between protein components and substrates, which presumably help define the substrate specificity of the enzymic reactions. Progress in such studies could be of particular significance to synthetic chemists who have made great efforts in recent years to develop new methodology for macrolide synthesis.[15] Isolated PKS cassettes used in vitro may well prove to be convenient and efficient alternative synthetic tools for carrying out limited transformations on natural substrates and substrate analogues. In the longer term, it may be feasible to employ different combinations of cassettes in vitro, to generate complex chimeric products with greater control than would be possible in vivo. Chemists as well as biologists have reason to watch developments in this field.

$LiClO_4$ in Ether—an Unusual Solvent

By *Herbert Waldmann**

Many reactions can be influenced in a variety of ways by the solvent employed. This is especially the case when polarized transition states or ionic intermediates are involved in the reaction and when the solvent is nucleophilic or electrophilic. A case to the contrary is the Diels-Alder reaction, which remains largely unaffected by the surrounding organic medium. In the mid-eighties, however, *Breslow* et al.[1] and *Grieco* et al.[2] demonstrated that Diels-Alder reactions proceed with increased reaction rate and with improved *endo-exo* selectivity when they are carried out, not in organic solvents but in aqueous solutions. The effect is further enhanced by salts such as LiCl (salting-in effect), whereas the addition of guanidinium chloride has the opposite effect (salting-out effect). The use of water as solvent for such cycloadditions had already been described earlier by *Alder* et al.[3a] and later by *Koch* et al.[3b] The accelerating effect of this reaction medium is also manifested in many other reactions,[4] e.g. asymmetric hetero-Diels-Alder reactions[4b] and asymmetric nonhetero-Diels-Alder reactions,[4c, d] nucleophilic additions to iminium ions[4e] and carbonyl compounds,[4f] Claisen rearrangements,[4g] the benzoin condensation,[1b] and aldol reactions.[4h] It is attributed to the fact that a suitable aggregation is generated by hydrophobic interactions between the reaction partners (hydrophobic effect), and so exercises an "internal pressure" on the reactants encapsulated in "solvent cavities" whose effects are, in turn, comparable with a high external pressure, at least in the case of the Diels-Alder reaction.

Last year, *Grieco* et al.[5] described a solvent system, namely a 5 M solution of $LiClO_4$ in diethyl ether, which has a comparable, if not greater accelerating effect on Diels-Alder reactions. Already in 1986 *Sauer* et al.[6] investigated the steric course of Diels-Alder reactions in such solvent systems in order to determine the polarity of ethereal $LiClO_4$ solutions, and had already recommended them as polar solvents for organic chemical reactions. *Grieco* et al. then demonstrated the astounding properties of these solutions (see Scheme 1), which according to *Pocker* et al.[7] must be regarded as mixtures of the mono- and diether adduct of $LiClO_4$. The reaction of cyclopentadiene **1** with ethyl acrylate **2**

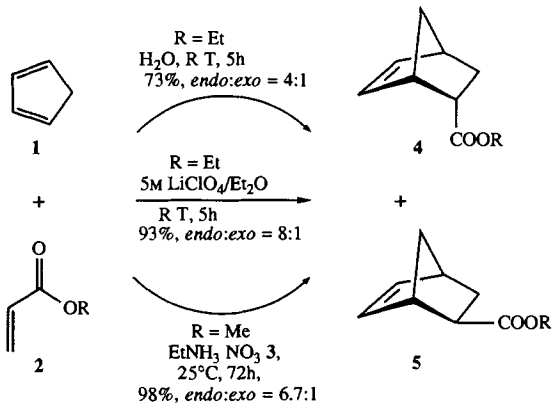
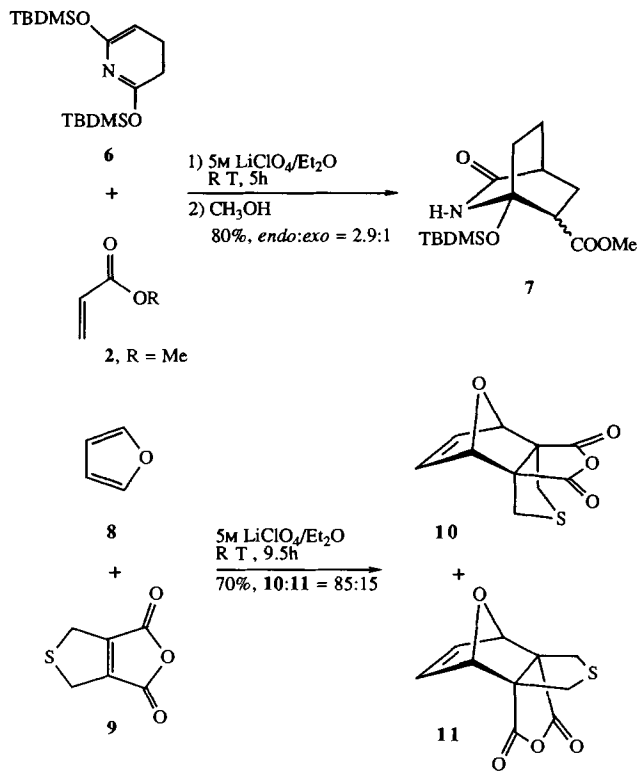


Scheme 1.

(R = Et) to give the bicycloheptenes **4** and **5** proceeds more rapidly and with higher *endo*-selectivity in 5 M $LiClO_4$/diethyl ether (*endo*:*exo* = 8:1) than in water (Scheme 1). Particularly advantageous is the compatibility of the $LiClO_4$/ether system with substances sensitive to hydrolysis. Thus, the azadiene **6** reacts with methyl acrylate at room temperature in the presence of the Li-salt to give the desired cycloadduct **7** in 80% yield in 5 h, whereas the same reaction in benzene affords **7** in 75% yield only after 72 h at 60 °C (Scheme 2). Particularly impressive is the reaction of furan **8**, which, owing to its aromaticity does not react with the thiophene derivative **9** under normal conditions (Scheme 2). In $LiClO_4$/ether,

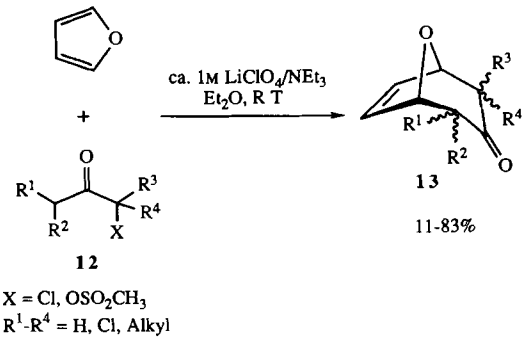


Scheme 2. RT = room temperature.

however, the cycloadducts **10** and **11** are formed in 70% yield in the ratio 85:15 after 9.5 h at room temperature and under atmospheric pressure. These values must be compared with those reported by *Dauben* et al.,[8] who required 6 h and 15 kbar in order to achieve the same product ratio in their synthesis of cantharidin by the same reaction in CH_2Cl_2. To explain their results *Grieco* et al. assume that $LiClO_4$/ether solutions, in analogy to water, generate an internal pressure and press the reactants together. However, the stabilization of a polarized transition state by the salt is not ruled out.

The latter possibility is not improbable, since, on the one hand, the rate- and selectivity-enhancing effect of Lewis acids on Diels-Alder reactions is well known, so that such an effect could be attributed to the presence of Li^+ ions in higher concentration. On the other hand, it has already been possible, with ethereal solutions of $LiClO_4$, to accelerate a number of reactions which proceed via polarized intermediates. Thus, *Winstein* et al.[9] found that the ionization of *p*-methoxyneophyl tosylate and a *p*-nitrobenzoate in a 0.1 M solution of $LiClO_4$ in ether is respectively 10^5 and 10^6 times faster than in ether itself. *Pocker* et al.[7] have investigated the properties of concentrated solutions of $LiClO_4$ in ether, developed concepts about their structure, showed that the ionization of *tert*-butyl chloride in 5.5 M $LiClO_4$/diethyl ether occurs about 10^6 times more rapidly than in ether, and found that the rearrangement of 1-phenylallyl chloride to 3-phenylallyl chloride takes place 85600 times more rapidly in a 3.39 M solution than without added salt ("electrostatic catalysis").

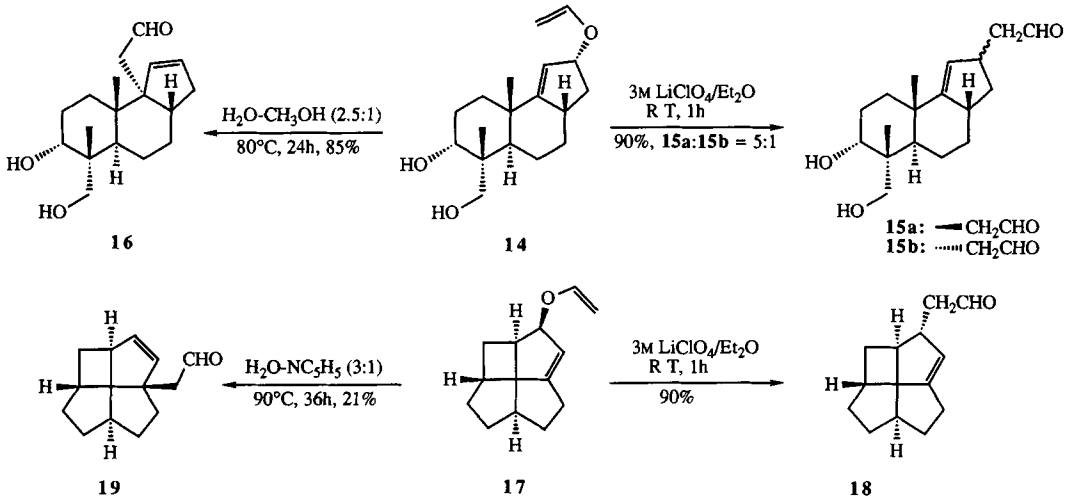
Already in the early eighties *B. Föhlisch* et al.[10] exploited the advantageous effects of the medium presented here in their detailed investigations of the [4 + 3] cycloadditions of α-halogeno- or α-sulfonyloxy-substituted ketones **12** to 1,3-dienes, in particular to furan (Scheme 3). The 8-oxabicy-



Scheme 3.

clo[3.2.1]oct-6-en-3-ones **13** formed thereby are of interest, inter alia, as starting materials for the synthesis of tropones and other natural products. For the cycloadditions with the α-halogeno- or the α-mesyloxyketones **12**, room temperature suffices, and inter- and intramolecular reactions can be carried out in satisfactory to good yields. A possible use of this method for the synthesis of natural terpenes, e.g. of the guajanolide, azulene, and hydroazulene type, seems very promising.

The favored acceleration of ionic conversions and reactions with polarized transition states by the system $LiClO_4$/diethyl ether also follows from the surprising observation made by *Grieco* et al.[11] that allyl vinyl ethers, contrary to expectation, do not undergo [3,3]-sigmatropic rearrange-



Scheme 4.

ments in 3 M $LiClO_4$/diethyl ether solutions, but give aldehydes in [1,3]-sigmatropic rearrangements (Scheme 4). Thus, e.g., **14** reacts under these conditions to give **15** in 90% yield within 1 h at room temperature (in 5 M salt solution the reaction is already complete after 10 min), and also the fenestrane **17** is transformed into the aldehyde **18** in high yield. These observations, particularly the steric course of the rearrangements, are in sharp contrast to the findings that **14** undergoes the expected Claisen rearrangement to **16** in water-methanol (2.5:1) at 80 °C and that also the fenestrane **17** rearranges to **19** in water-pyridine (3:1) at 90 °C.

In all cases the [1,3]-sigmatropic rearrangements take place at room temperature and make the products available in high yields under the mildest conditions. The authors demonstrate on the basis of crossover experiments that ionic intermediates must indeed be involved, and they verify the importance of Li^+ ions being present: the use of a 1.8 M tetrabutylammonium perchlorate solution as solvent has no advantageous effect on the rearrangement.

The solvent system $LiClO_4$/diethyl ether has already proven to be an excellent medium for diverse reactions. It is to be expected that further uses will be found. The fantasy of the experimentalist must not be confined to the concentrated solutions of $LiClO_4$ in ether, which also can be regarded as a salt with little ether additive.[7] Thus, *Jaeger* et al.[12] have recently reported that the low-melting (m.p. $\approx$ 12 °C) ethylammonium nitrate **3** (Scheme 1) likewise offers advantages as solvent; Diels-Alder reactions are considerably accelerated and proceed more selectively in this salt than in organic solvents. The effect is, however, less pronounced than on changing over to water or $LiClO_4$/ether.

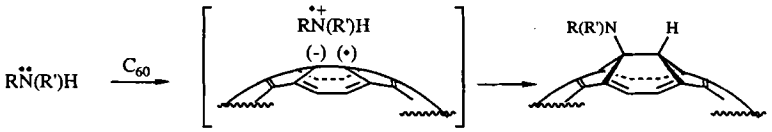
Globe-trotting Hydrogens on the Surface of the Fullerene Compound $C_{60}H_6(N(CH_2CH_2)_2O)_6$**

By *Andreas Hirsch, Qiaoying Li,* and *Fred Wudl**

Dedicated to Professor Michael Hanack on the occasion of his 60th birthday

We discovered recently that a variety of dienes, dipoles, and a number of nucleophiles react with buckminsterfullerene (C_{60}) to yield adducts.[1] Among the nucleophiles, primary and secondary amines such as *n*-propylamine, *n*-dodecylamine, *tert*-butylamine, ethylenediamine, and morpholine (H morph) readily react with C_{60} to give the amino addition compounds $C_{60}H_n(NRR')_n$ (predominantly $n = 6$ as determined by elemental analysis and titration experiments with 0.1 N HCl).[1] This might be due to the fact that C_{60} consists of six independent pyracyclene units to which the amines can be added most easily. In the case of the reaction with *n*-propylamine, however, also minor amounts of higher addition products (up to twelve amino groups) have been found by FAB mass spectrometry.[1] Whereas the other amino adducts of C_{60} are soluble in the neat amine, $C_{60}H_6(morph)_6$ precipitates from the solution and therefore evades further additions. All those carbon atoms in these "hairy balls" to which either a hydrogen or a nitrogen atom has been added change their state of hybridization from pseudo-sp^2 to pseudo-sp^3. The mechanism of the amino addition is stepwise (Scheme 1). A single electron transfer (SET) precedes the covalent bond formation and proton transfer, as determined by UV/VIS and ESR spectroscopy.[1]



Scheme 1. Proposed mechanism of amine addition to C_{60}.

In this paper we report the remarkable dynamic behavior of the morpholine adduct $C_{60}H_6(morph)_6$, which has been studied by ^1H NMR spectroscopy and deuterium exchange experiments. This compound was prepared by stirring C_{60} in neat morpholine for 2 days, whereupon it precipitated as an orange-brown solid from the red-brown solution. The $C_{60}H_6(morph)_6$ composition of this solid has been confirmed by elemental analysis and thermogravimetric analysis.[2] The IR spectrum[3] of $C_{60}H_6(morph)_6$ shows complete substitution of the NH by CH hydrogens (C_{60}–H, no NH vibrations) and is typical for *N*-substituted morpholine compounds.[4] Two broad peaks in the room-temperature ^1H NMR spectrum (relative to TMS) at $\delta = 3.84$ and 3.27, which are not resolved as triplets, are due to the methylene groups of the morpholine substituent. The attachment of the morpholine unit to C_{60} causes a downfield shift from $\delta = 2.87$ (free morpholine) to 3.27 for the CH_2 protons α to nitrogen, whereas the CH_2 protons α to oxygen are affected to a smaller extent ($\Delta\delta = 0.2$). This behavior demonstrates clearly the electron-withdrawing influence of the C_{60} core. The signal for the "bucky ball" protons is very broad and symmetrical at $\delta = 1.84$, indicating already a rapid exchange of these hydrogens. The ^1H NMR spectrum (in $CDCl_3$, δ relative to TMS), as a function of temperature, shows very interesting features (Fig. 1). Upon cooling, the signals of the

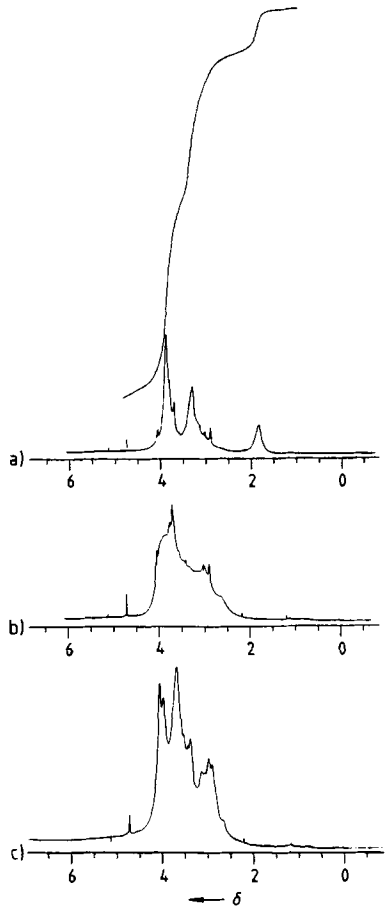


Fig. 1. Temperatur-dependent ^1H NMR spectra (500 MHz) of $C_{60}H_6(morph)_6$ in $CDCl_3$. a) 25 °C, b) −25 °C, c) −60 °C.

CH_2 groups of the morpholine substituents become broader, and at the same time the signals of the "bucky ball" protons shift downfield from $\delta = 1.84$ at room temperature to about 2.6 at −20 °C. At −25 °C only one broad and little struc-

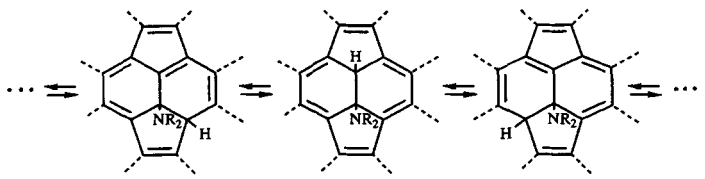
tured resonance region reaching from $\delta = 2.5$ to 4.2 appears in the spectrum. Further stepwise cooling down to $-60\,^{\circ}C$ results in a sharpening and formation of new signals. The main peaks appear at $\delta = 4.04$, 3.97, 3.96, 3.38, and 3.15. This relatively complex spectrum shows that $C_{60}H_6(morph)_6$ at $-60\,^{\circ}C$ consists of a mixture of constitutional and, perhaps, conformational isomers; different arrangements of the morpholine groups and "bucky ball" protons cause slightly different chemical shifts. At $-90\,^{\circ}C$ in CD_2Cl_2 even individual triplets between $\delta = 2.7$ and 3.4 can be resolved (CH_2 α to N). Heating up to $50\,^{\circ}C$ leads just to a small extent of further line sharpening compared to the spectrum at room temperature, but the chemical shift of the fullerene protons remains constant.

Whereas the observed dynamic phenomenon of the morpholine units can be conformational in character (ring inversion), the reversible shift of the "bucky ball" protons shows their very high mobility on the surface of the fullerene. The dynamic effect is independent of concentration (in the range 1×10^{-2}–8×10^{-4} M), indicating that it is an intramolecular process. It is possible, as suggested by a referee, that the process is assisted by the basic N atoms, particularly since the pK_a of the C_{60} surface C–H bonds is rather low (see below the discussion on H–D exchange). Therefore the spherical structure and the remaining conjugated π system of the C_{60} core is expected to allow multiple, almost degenerate [1,5]-sigmatropic hydrogen shifts (Scheme 2) which make these hydrogens on fullerene "globe trotters".[5]



Scheme 2. [1,5] sigmatropic hydrogen shift in $C_{60}H_6(N(CH_2CH_2)_2O)_6$.

In typical cases of [1,5]-sigmatropic hydrogen shifts the activation enthalpies $\Delta H^{\neq}$ are in the neighborhood of 30 kcal mol^{-1} but ca. 10 kcal mol^{-1} for cyclopentadiene, whereas the entropies $\Delta S^{\neq}$ are[6] -5 to -10 cal mol^{-1} K^{-1}. Although the activation entropies $\Delta S^{\neq}$ for [1,5]-sigmatropic shifts on the surface of C_{60} are expected to be very low (preorganized arrangement), the activation enthalpies $\Delta H^{\neq}$ must be extraordinarily low and lie below 10 kcal mol^{-1} since a rapid exchange is occurring above $-25\,^{\circ}C$. This result is puzzling, because considerable geometric changes must accompany the hydrogen motion; the carbon atom bearing the migrating hydrogen must move back down to the sphere's surface while a new carbon atom must rise to meet the incoming atom.

The reaction of C_{60} with *N*-deuterated morpholine leads to $C_{60}D_6(morph)_6$. The ^1H NMR spectrum of this compound shows just the CH_2 signals at $\delta = 3.9$ and 3.3. The deuterium on the C_{60}, however, can be easily exchanged by addition of methanol to the chloroform solution resulting in the formation of $C_{60}H_6(morph)_6$. Conversely, $C_{60}D_6(morph)_6$ has also been prepared by treatment of $C_{60}H_6(morph)_6$ with CH_3OD.[7] This behavior is in accordance with the line shape of the C_{60}-bound protons in the ^1H NMR spectrum and also supports the low $\Delta H^{\neq}$ values for [1,5]-sigmatropic hydrogen shifts. With the deuterated product in hand, we found that within experimental error there is no measurable deuterium isotope effect in this dynamic process.

That the CH bond in $C_{60}H_6(morph)_6$ is still covalent in character is shown by cyclic voltammetry in CH_2Cl_2. Two reversible reduction peaks at high scan rates (1 V s^{-1}) can be observed at 880 and 1319 mV vs. commercial Ag/AgCl (Fig. 2). Dissociated protons would have been reduced to H_2

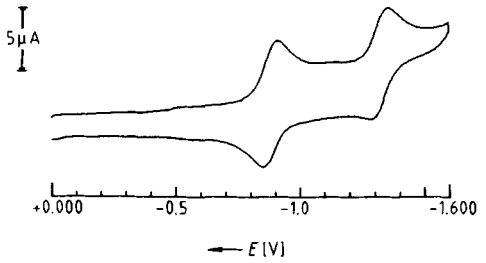


Fig. 2. Cyclic voltammogram of $C_{60}H_6(N(CH_2CH_2)_2O)_6$ at a platinum electrode in CH_2Cl_2; supporting electrolyte, 0.1 M Bu_4NBF_4; scan rate, 1 V s^{-1}; reference electrode, Ag/AgCl.

and at least one peak would have been irreversible. Although the reduction potentials are much higher than those for natural C_{60},[8] the cyclic voltammogram of $C_{60}H_6(morph)_6$ demonstrates that there is still a large amount of π conjugation of a substantially *electronegative* set of carbon atoms. The sharpness of the cyclic voltammogram waves shows also that a fairly uniform compound is present at room temperature; the substituents are very likely regularly distributed (one can postulate that the six morpholine substituents, due to steric requirements, are as far from each other as possible) or averaged through the globe-trotting hydrogens.

In summary, we report the discovery of a novel, facile dynamic process, very likely characteristic of C_{60} addition products where the elements of R_2N and **H** are added across the pyracyclene units. The scope and generality [R_nX–**H**, X = N, O, S, C(?), etc] of this phenomenon remain to be determined.

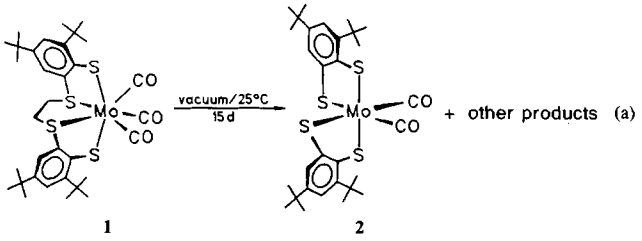
$[Mo(CO)_2(^{tbu}S'_2)_2]$ and $[MoCO(PPh_3)(^{tbu}S'_2)_2]$: CO Coordination at [Mo–S] Centers Where Mo Is in a High Oxidation State**

By *Dieter Sellmann,* Franz Grasser, Falk Knoch,* and *Matthias Moll*

Carbonyl complexes of metals in high oxidation states are usually unstable[1] and therefore rare.[2] Can such species occur in nitrogenases? The sulfur-coordinated Mo atoms of the active centers of Fe/Mo nitrogenases are probably in the high oxidation state + IV.[3] Nevertheless, they are postulated as coordination sites for the nitrogen molecule and the nitrogenase inhibitor CO.[4] In order to obtain model compounds for Fe/Mo nitrogenases, attempts have often been made to bind N_2 or CO to high-valent [Mo–S] centers.[5]

We have now obtained such a CO complex [see Eq. (a)]. In an unusual redox elimination the Mo^{II} complex $[Mo(CO)_3(^{tbu}S'_4)_2]$ (**1**, $^{tbu}S'^{2\ominus}_4$ = 1,2-bis(3,5-di-*tert*-butyl-2-mercaptophenylthio)ethane(2 −))[6] loses CO and C_2H_4 under high vacuum conditions to form $[Mo(CO)_2(^{tbu}S'_2)_2]$ (**2**). Complex **2** has a Mo^{IV} center; the only other ligands besides CO which are bound to the metal are biologically relevant dithiolato donors.



1 **2**

The bright blue-violet **2** is stable at room temperature and its IR spectrum in *n*-pentane shows two intense high-frequency CO bands at $\tilde{\nu}$ = 2041 and 2006 cm^{-1}. The number of bands, their absolute position, and their significant shift to higher frequency relative to the bands of **1** (for which $\tilde{\nu}$ = 2028, 1951 cm^{-1} in *n*-pentane) indicate that in **2** *cis* CO ligands are bound to an electron-deficient, high-valent [Mo–S] center.

^1H and $^{13}C\{^1H\}$ NMR spectra show that the $^{tbu}S'_2$ ligands are symmetry-equivalent, as are the CO ligands. The four *tert*-butyl groups give rise to only two sharp singlets in the ^1H NMR spectrum; the CO ligands show one signal and the C atoms of the $^{tbu}S'_2$ ligands ten in the $^{13}C\{^1H\}$ NMR spectrum. The IR and NMR data therefore confirm that **2** has a C_2 axis as indicated in Equation (a).

From the PPh_3 derivative $[Mo(CO)(PPh_3)(^{tbu}S'_2)_2]$ (**3**) we obtained single crystals, which enabled a molybdenum–sulfur–carbon monoxide complex in a high oxidation state to be characterized not only by spectroscopic methods, but for the first time also by X-ray crystallography.[7] Compound **3** forms in a similar way to **2** from $[Mo(CO)_2(PPh_3)(^{tbu}S'_2)]$ (**4**) ($\tilde{\nu}$(CO) = 1939(sh), 1930, 1882(sh), 1864 cm^{-1} in KBr)[6] and also shows a high-frequency CO band (1978 cm^{-1} in KBr). The released C_2H_4 was detected directly by NMR spectroscopy.

$$[Mo(CO)_2(PPh_3)(^{tbu}S'_4)] \xrightarrow[75\ min]{THF/65°C} [Mo(CO)(PPh_3)(^{tbu}S'_2)_2] + C_2H_4 + CO \quad (b)$$

4 **3**

As shown in Figure 1a, the C_1-symmetrical structure of compound **3** exhibits almost ideal pseudo-trigonal-prismatic coordination at the molybdenum center (Fig. 1b).[7] The average deviations of the atoms from tetragonal planes lie between 2.0 and 6.7 pm, the trigonal planes P1-S2-S3 and C1-S1-S4 are practically parallel (dihedral angle 2.1°), and the torsion angle between them is close to the limiting value of 0° for an ideal trigonal prism. The *tert*-butyl groups are as far apart as possible, giving rise to C_2 symmetry for the $[Mo(^{tbu}S'_2)_2]$ framework of **3**.

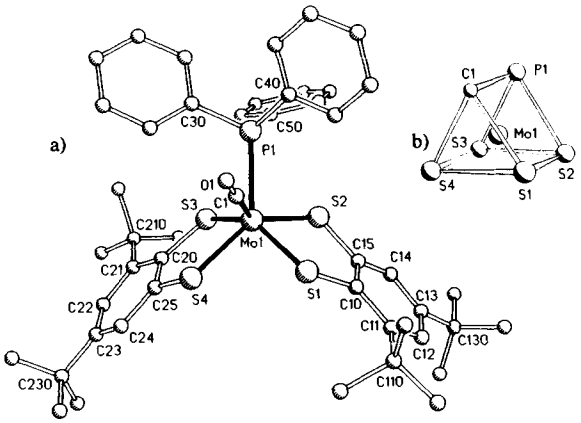


Fig. 1. a) Structure of **3** in the crystal (H atoms omitted); b) pseudo-trigonal-prismatic coordination at the molybdenum center. Important bond lengths [pm] and angles [°]: Mo1-C1 204.2(6), Mo1-S1 234.9(2), Mo1-S2 235.8(2), Mo1-S3 236.4(2), Mo1-S4 235.0(2), Mo1-P1 251.7(2), S1-C10 173.8(5), S2-C15 173.6(6), S3-C20 174.5(5), S4-C25 172.9(6), C1-O1 113.4(7); C1-Mo1-S1 79.0(2), S1-Mo1-S2 81.4(1), S2-Mo1-S3 86.8(1), S3-Mo1-S4 80.8(1), S1-Mo1-S4 84.2(1), C1-Mo1-P1 82.3(2), Mo1-C1-O1 178.8(5).

Not only the high-frequency CO absorptions of **2** and **3**, but also the interatomic distances of **3** indicate a high oxidation state for the Mo center and exclude an oxidation of the benzenedithiolato ligands to dithioketones according to Equation (c). Such ligand-centered redox steps are often discussed in connection with compounds containing dithioethylene ligands of the type $S_2C_2R_2$ and are deduced from bond shortening.[8] The relevant C–S distances in **3** and related $^tS'_4$ ($^tS'^{2\ominus}_4$ = 1,2-bis(2-mercaptophenylthio)ethane(2 −)) and $^{tbu}S'_4$ complexes with metals in low oxidation states, such as $[Mo(CO)_2(PMe_3)(^tS'_4)]$ (**5**), $[Mo(NO)(NH_2O)(^tS'_4)]$ (**6**), $[Mo(NO)_2(^tS'_4)]$ (**7**),[9] and $[Fe(CO)_2(^{tbu}S'_4)]$ (**8**),[10] all lie within the range 172.9(6) to 176.2(6), and no shortening of the C–S bond in **3** is evident. The same holds for the C–C distances in the C_6 rings. These findings are supported by calculations which indicate that 1,2-benzenedithiolate(2 −) also functions as dianion on coordination to high-valent metal centers,[11] by our results for Fe^{IV}–benzenedithiolato complexes,[12] and last but not least by the expectation that

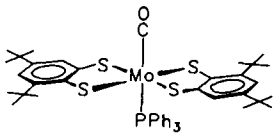
the resonance stabilization energy of the aromatic system would hinder a reaction such as described in Equation (c).[8] The Mo^{IV} centers of **2** and **3** thus have formal 14e configurations.

What stabilizes these electronically highly unsaturated metal centers? One answer is found in the comparison of the Mo–S distances in **3** and the previously mentioned complexes. The average Mo–S distances in **3** (235.5 pm) are significantly shorter than the average Mo–S(thiolato) distances in, for example, **5** (250.6 pm), **6** (247.8 pm), and **7** (245.1 pm).[9] They indicate that S → Mo π-donor bonds between occupied p orbitals of the thiolato ligands and empty Mo d orbitals decrease the electron deficit at the Mo center in **3**.

The ^1H and $^{13}C\{^1H\}$ NMR spectra of **3** each show exactly half the number of signals anticipated from the C_1 symmetry of the solid. Thus, in solution **3** has firstly a different structure than in the solid, and secondly a C_2 axis (as, for instance, in the *trans* structure of **3**.)



trans-**3**

$[Mo(CO)_2(^{tbu}S'_2)_2]$ shows that CO can indeed coordinate to Mo^{IV} centers that are surrounded exclusively by (biologically relevant) dithiolato donors. Do the Mo^{IV} centers in Fe/Mo nitrogenases have accordingly to be the coordination sites for the nitrogenase inhibitor CO as well as for the N_2 molecule? Even after the discovery of nitrogenases containing only iron as metal centers,[13] this possibility cannot be entirely ruled out. It is, however, also possible that N_2 is bound to the Fe center and CO to the Mo center. This arrangement could primarily impede the electron flow within the Fe–Mo clusters and as a result prevent the reduction of the N_2 molecule that becomes cut off from a further supply of electrons, although it is already bound. So the role of molybdenum in Fe/Mo nitrogenases can remain a topic of speculation!

Experimental Procedure

All operations were carried out under a nitrogen atmosphere in anhydrous, N_2-saturated solvents. **2**: Solid **1** (100 mg, 0.14 mmol) was decomposed at room temperature under high vacuum over 15 days. The resulting deep violet solid was purified by chromatography on SiO_2 (ICN Silica 100–200 60A) at 15 °C (eluant *n*-pentane/CH_2Cl_2, 19:1). Compound **2** is eluted as a blue-violet zone. Yield: 60%; IR(KBr): $\tilde{\nu}$(CO) [cm^{-1}] = 2035, 1997; ^1H NMR (270 MHz, $CDCl_3$, TMS): δ = 8.30 (d, 2H; C_6H_2), 7.64 (d, 2H; C_6H_2), 1.77 (s, 18H; C_4H_9), 1.42 (s, 18H; C_4H_9); $^{13}C\{^1H\}$ NMR (67.94 MHz, $CDCl_3$, TMS): δ = 222.04 (CO), 160.84, 153.26, 149.67 (2 peaks overlap), 125.63, 122.47 (C_{Aryl}), 38.39, 35.61, 32.02, 31.24 (C_{Alkyl}); FD-MS: *m/z* 658 ($M^{\oplus}$).

3: Compound **4** (950 mg, 1.0 mmol) was heated in THF (75 mL) for 75 min at boiling point, during which time the color changed from orange to red-violet. Evaporation of all volatile components afforded a violet-red solid, which was dried for 12 h and then redissolved in CH_2Cl_2 (10 mL). Filtration over SiO_2, evaporation of the filtrate to dryness and subsequent recrystallization from CH_2Cl_2/MeOH (1:1.5, 25 mL, 25– – 30 °C) yielded a deep red microcrystalline solid. Yield:44%; IR(KBr):$\tilde{\nu}$(CO) [cm^{-1}] = 1978; ^1H NMR (270 MHz, $CDCl_3$, TMS): δ = 8.16 (d, 2H; C_6H_2), 8.0–6.9 (br. s, 12H; C_6H_5), 7.45 (d, 2H; C_6H_2), 6.9–6.3 (br. s, 3H; C_6H_5), 1.61 (s, 18H; C_4H_9), 1.36 (s, 18H; C_4H_9); $^{31}P\{^1H\}$-NMR (109.38 MHz, $CDCl_3$, H_3PO_4): δ = 55.56 (*s*; PPh_3); $^{13}C\{^1H\}$-NMR (67.94 MHz, $CDCl_3$, TMS): δ = 231.73 (d, $^2J(^{31}P,^{13}C)$ = 11.5 Hz; CO), 159.39, 152.05, 147.63, 135.30 (d, $^2J(^{31}P,^{13}C)$ = 8.6 Hz), 130.95, 129.06, 128.91, 125.10, 120.83 (C_{Aryl}), 38.08, 35.43, 32.17, 31.21 (C_{Alkyl}); FD-MS: *m/z* 892 ($M^{\oplus}$).

lytic processes in homogeneous and heterogeneous phase to be studied on largely uniform metal particles.[1] The formation and stabilization of noble metal colloids in water is widely known[2] and was recently improved substantially by the use of special complex ligands.[3] Here we report on a general method for the preparation of metal colloids of elements of Groups 6–11 in the organic phase. The metal salts were suspended in THF and treated with tetraalkylammonium hydrotriorganoborates [Eq. (a)], which is readily accessible from ammonium halides and alkali-metal hydroorganoborates.[4] Brown-red metal colloid solutions are generated with hydrogen evolution, from which only a small proportion of the reduced metal precipitates. The ammonium salt that forms in the process functions as a protective atmosphere for the metal particles obviating the need for external stabilizers. The filtered colloid solutions are stable for months.

$$MX_n + nNR_4BEt_3H \xrightarrow{THF} M_{colloid} + nNR_4X + nBEt_3 + n/2\,H_2 \quad (a)$$

M: metal of groups 6–11; X: Cl, Br; n: 2, 3; R: alkyl, C_4–C_{20}.

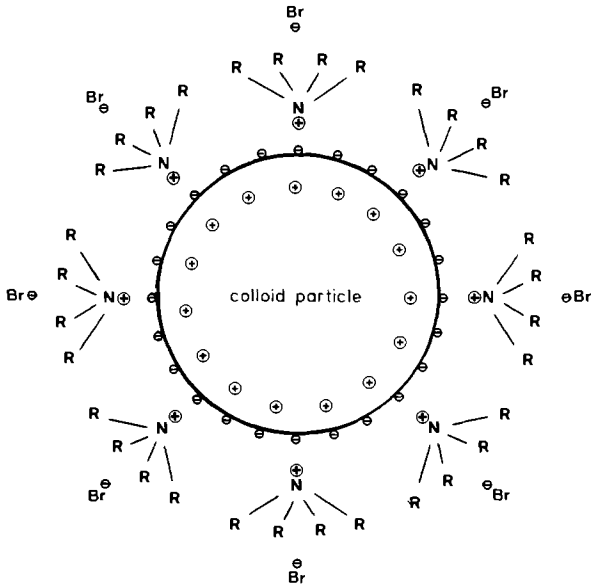

Fig. 1. Stabilization of the metal nucleus with NR_4Br.

In some cases we were able to isolate the metal colloids in powder form. The solution was evaporated to dryness under high vacuum, the waxy residue was taken up in ether or ethanol, and the colloid precipitated by addition of a third solvent (for particulars see Table 1 and Experimental Procedure). The gray-black metal colloid powder is very soluble in THF and other organic solvents (up to 1 g at metal L^{-1}). Elemental analysis of the isolated metal colloid and results from mass spectrometry indicate that NR_4X is present. The results hitherto suggest that tetraalkylammonium ions surround the presumably negatively charged metal nucleus (Fig. 1). The screening of the metal nucleus by large lipophilic alkyl groups explains the remarkable solubility of the metal colloids in organic solvents and their extraordinary stability.

The isolated metal colloids were examined by electron microscopy and preliminary results for Ru, Co, Rh, Pd, and Pt colloids and the coreduction product Pt/Rh are available. An estimation of the size of particle from transmission electron spectroscopy (TEM) pictures of the isolated colloids (at a magnification of 2.5×10^5:1, 3.6×10^5:1, and 1.2×10^6:1) revealed a narrow particle range (Table 1). With rhodium and ruthenium the size distribution maximum indicates that relatively small metal aggregates are formed, while for platinum and palladium they are larger. TEM photographs of the Pt/Rh coreduction product show a colloid with a narrow particle size distribution and a maximum size of approximately 2 nm. Whether this colloid is a Pt/Rh alloy must still

be determined by X-ray diffraction and electron spectroscopy (ESCA) studies.

The metal colloids can be adsorbed on the surface of supports. The metal aggregates do not coalesce during the process: electron microscope investigations show that the particle size remains the same and a very uniform distribution of the metal particles on the support is achieved. The supported metal colloids are effective catalysts for the hydrogenation of unsaturated compounds such as CO and C–C, C–O, C–N multiple bond systems, as well as for the hydrogenation of aromatic compounds. Furthermore, the free Pd and Ni colloids are suitable for the selective hydrogenation of naturally occurring products and product mixtures such as soya bean oil. The activity a of the rhodium colloid on an activated carbon support for the hydrogenation of *n*-butyronitrile, determined under controlled conditions[5] and quoted as volume H_2 taken up per g catalyst and per minute, was compared in a series of experiments with the activity of a conventionally prepared rhodium catalyst. Both systems contained 5% Rh on activated carbon from the same batch. The average activity of the Rh colloid catalyst (a = 140 N mL) exceeded the technical standard (a = 80 N mL) by a factor of 1.75. If the activated carbon support is doped with 0.2% titanium by initial treatment with bis(η-toluene)titanium[6] in THF and then covered with 5% Rh colloid, the measured hydrogenation activity (a = 195 N mL) of the Rh colloid catalyst on the support increases to a factor of 2.4 higher than that of the technical standard catalyst. A palladium colloid catalyst doped with 1% Ti (5% on activated carbon) surpasses the corresponding technical standard for the hydrogenation of cinnamic acid by a factor of 1.7 (a = 600 N mL). The corresponding Pt colloid catalyst (1% Ti, 5% Pt on activated carbon; a = 810 N mL) is a factor 2.1 better than the technical standard for the hydrogenation of crotonic acid. Attempts to isolate and characterize further colloid catalysts, to apply them in catalysis, and to determine the doping effects of low-valent early transition metals are in progress.

Experimental Procedure

Tetraoctylammonium triethylhydroborate: To a solution of $N(C_8H_{17})_4Br$ (160.04 g, 292.67 mmol) in THF (350 mL) under an inert atmosphere, was added a solution of $K[BEt_3H]$ in THF (250 mL, 1.17 M) within 30 min at room temperature and with constant stirring. KBr precipitated. After 1 h the reaction mixture was cooled for 16 h at 0°C. The bulky white precipitate was filtered off on a glass frit and washed with ca. 150 mL THF. The tetraoctylammonium hydridotriethylborate was obtained as colorless solution (0.371 M), which was stored below 0°C.

Rhodium colloid: To a suspension of $RhCl_3$ (2.79 g, 13.33 mmol) in THF (500 mL) was added a solution of $N(C_8H_{17})_4BEt_3H$ in THF (0.4 M, 100 mL) within 1 h at 40°C under an inert atmosphere and with stirring. The $RhCl_3$ dissolved completely within 2 h at 40°C. After 15 h at room temperature, the dark red-black solution was completely clear. The volatile components were removed by evaporation, and the black-brown, waxy residue was dried for 3 h at 40°C and 10^{-3} mbar. The product (22.3 g) was soluble in THF, ether, toluene, and acetone, but insoluble in ethanol, and contained 6.1% Rh. The residue was dissolved (in air) in 500 mL technical quality ether. Addition of 50 mL pure ethanol causes a gray-brown precipitate to form. It was left to stand for 1 h, before removing the clear supernatant solution by pressure of inert gas on the liquid surface. The precipitate was washed twice with a mixture of 90 mL ether/10 mL ethanol. Drying in vacuum (10^{-3} mbar, 20 min, 25°C) yields a gray rhodium colloidal powder (1.24 g), very soluble in THF, soluble in acetone, less soluble in toluene, and insoluble in ether. Elemental analysis: Rh: 73.40%, N: 0.30%, C: 16.57%, H: 3.13%; mass spectrum: characteristic ions at 36 (HCl, cleavage at high temperature); 353 ($N(C_8H_{17})_3$, major peak).

Charging of activated carbon with rhodium colloid: activated carbon (3.0 g) was pretreated under argon with bis(η^6-toluene)titanium (30.6 mg) in pentane (50 mL), dried, and suspended in dry THF (ca. 50 mL). Rhodium colloid (234 mg) in THF (50 mL) is added over 30 min with vigorous stirring. The completely metal-free, colorless solution is filtered through a D4 glass frit and the rhodium covered activated carbon is dried under high vacuum (10^{-3} mbar) for 16 h at room temperature. Approximately 10% of the solvent remains adsorbed. The activated carbon so charged contains 5% Rh and 0.2% titanium (relative to the solvent-free product). The catalyst is ready for use after treatment with inert gas that contains 0.2 vol% O_2 for 2 h.

Herbicide Resistance in Transgenic Plants through Degradation of the Phytotoxin to Urea**

By *Ursula H. Maier-Greiner, Christian B. A. Klaus, Lydia M. Estermaier, Guido R. Hartmann**

Herbicide resistance in transgenic plants has been achieved by three approaches:[1] 1) overproduction of the target protein, 2) expression of a mutant target protein that is resistant to the herbicidal action and 3) expression of an enzyme which inactivates the herbicide by modification. In each case residues of the phytotoxin or derivatives of it remain in the plant, causing possible drawbacks in its use as a nutrient. We describe here a new method of engineering resistance by converting the herbicide into an innocuous physiological compound. The relevant herbicide is cyanamide which is degraded to urea in transgenic tobacco.

In the soil fungus *Myrothecium verrucaria* an inducible enzyme was discovered which hydrates the herbicide cyanamide (brand name alzodef®) quantitatively to urea.[2, 3] This cyanamide hydratase (EC 4.2.1.69) is encoded by the 732 base-pair *cah* gene which is located on a 900 base-pair *Eco*RI fragment isolated from a cDNA gene bank of *Myrothecium verrucaria*.[3]

For expression in plants, a gene cassette was constructed by placing this *Eco*RI fragment between the 35S promoter of cauliflower mosaic virus and the polyA signal of the nopaline synthetase gene. The vector pRT101[4] may be used for this purpose. Two constructs were obtained, one with the gene in correct orientation with respect to the promoter (designated cah^+), the other with the gene in opposite orientation (cah^-). Transfer into plants was achieved by using standard binary vector systems, for example, pBin19[5] containing the cah^+ or cah^- gene cassette and *Agrobacterium tumefaciens* strain LBA4404[6] (Clontech Laboratories, Palo Alto, CA, USA). Triparental mating, transformation, and

regeneration were carried out as described.[7, 8] Developing shoots were selected on 100 $\mu g\,mL^{-1}$ kanamycin.

Fifteen kanamycin resistant plants were tested for cyanamide hydratase activity.[3] Enzyme activity was found in all plants, the level of expression ranging from 0.03 to 0.79 units per mg protein in the cell extract. The highest value corresponds to about a fifth of the specific activity measured in induced *Myrothecium verrucaria* extracts. Although the specific activity was highest in the roots, the total enzyme activity per gram fresh weight was distinctly higher in the leaves than in the other plant organs (Table 1). No activity was found in plants transgenic for *cah*$^-$.

Table 1. Activity of cyanamide hydratase in extracts of various organs of tobacco plants transgenic for *cah*$^+$. The organs were frozen in liquid nitrogen, pulverized, and then extracted with 5 mM phosphate buffer pH 8 (1 $mL\,g^{-1}$ fresh weight) (specific enzymatic activity in the extract of the total plant: 0.276 $U\,mg^{-1}$). No activity above background could be measured in *cah*$^-$ transgenic plants.

plant organ	activity [units per g fresh weight]	specific activity [units mg^{-1} protein]
cah$^+$ roots	0.073	0.660
cah$^+$ stem	0.437	0.469
cah$^+$ leaves	0.643	0.202

Rooting of wild type or *cah*$^-$ transgenic tobacco shoots is completely depressed with 1.2 mM cyanamide in the medium. In contrast, root formation of *cah*$^+$ transgenic axillary shoots was observed even when the growth medium was supplemented with 12 mM cyanamide. Thus in respect to root formation, the tolerance to cyanamide is increased at least by a factor 10. Rooted *cah*$^+$ transgenic plants grow well on at least 2.4 mM cyanamide, a concentration that kills nontransformed or *cah*$^-$ transgenic plants within six weeks. Plants nontransformed or transgenic only for the vector pBin19 are completely bleached within 15 days after being sprayed once with 0.5% cyanamide solution. In contrast *cah*$^+$ transgenic plants tolerate distinctly higher concentrations, which correlate with the level of *cah*$^+$ gene expression. For example, a plant with a specific enzymatic activity of 0.58 units per mg protein in the cell extract showed no necrosis after being sprayed once with 5% cyanamide solution, which is the herbizide concentration recommended for use in agriculture (Fig. 1). Additional evidence for the expressed cyanamide hydratase activity being responsible for the increased tolerance is the formation of urea in the plant. Extracts from leaves of *cah*$^+$ transgenic plants grown for several weeks in the presence of 2.4 mM cyanamide contain 10–32 μmol urea per g leaves (fresh weight), which is absent in controls grown without cyanamide.

Fig. 1. Cyanamide tolerance in transgenic tobacco. *Nicotiana tabacum* SR1 plants transgenic for *cah*$^+$ or pBin19 with 6–8 leaves were sprayed once with 5% cyanamide solution. The plants were maintained under sterile conditions in a growth chamber (16 h photo-period, 25/18°C). The photographs were taken after 15 days. Left: plant transgenic for pBin19; right: plant transgenic for *cah*$^+$.

These results clearly demonstrate that expression of cyanamide hydratase confers tolerance to cyanamide in transgenic tobacco by its degradation to urea. In the presence of the urea-degrading enzyme urease found in many plants,[9–12] the subsequent product of hydrolysis NH_4^+ may be used by the plant as a nitrogen source.

On the Enigma of Chlorophyll Degradation: The Constitution of a Secoporphinoid Catabolite**

By *Bernhard Kräutler,* Bernhard Jaun, Karlheinz Bortlik, Maja Schellenberg,* and *Philippe Matile*

Dedicated to Professor Vladimir Prelog on the occasion of his 85th birthday

The degradation of the green plant pigment chlorophyll, which lies behind the impressive natural phenomenon of fall colors of trees and shrubs, is still not understood.[1, 2] This gap in our knowledge[3] exists because the degradation of chlorophyll "apparently takes place without leaving any traces",[1a] although annually on earth probably over 10^9 t of chlorophyll is catabolized.[3] Only lately did the prospect of gaining insights into the chlorophyll metabolism arise out of the discovery of almost colorless plant metabolites, the most important of which were characterized as tetrapyrrole

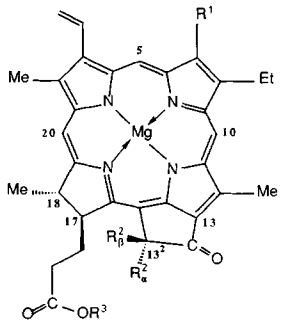
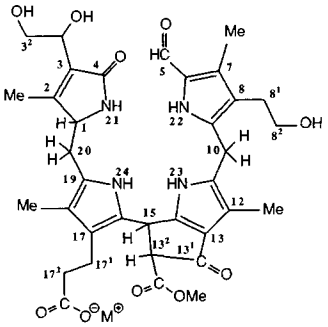
derivatives by isotope labeling.[1, 4–6] Among these metabolites the "fluorescent compounds" ("FC's") were suggested as precursors of the "rusty pigments" ("RP's"),[4] based on their appearance first in the chloroplasts and then in the vacuoles of yellowing barley primary leaves. The RP's owe their name (and their discovery) to the observation that on isolation in air and in the presence of acid they are transformed into easily visible, rust-colored secondary products.[1, 4, 5] We report here on the research resulting from cooperation between a botanical and a chemical laboratory, which led to the elucidation of the constitution of "RP-14",[5] the major representative of the rusty pigments from senescent barley primary leaves. The proposed constitution of RP-14 as the 1-formyl-19-oxobilane (**3**)[7] substantiates its relationship with chlorophyll a (**1**) and provides the first structural guideline which may help to unravel the mystery of how chlorophyll is catabolized.





1 (Chlorophyll a): R^1 = Me, R^2_α = C(O)OMe, R^2_β = H, R^3 = phytyl
2 (Chlorophyll b): R^1 = CH(O), R^2_α = C(O)OMe, R^2_β = H, R^3 = phytyl,
4 (Chlorophyllide a, Na salt): R^1 = Me, R^2_α = C(O)OMe, R^2_β = H, R^3 = Na
5 (13-Hydroxychlorophyll a): R^1 = Me, R^2_α = C(O)OMe, R^2_β = OH, R^3 = phytyl
6 (Pyrochlorophyllide a, Na salt): R^1 = Me, R^2_α = H, R^2_β = H, R^3 = Na

3-K: "RP-14" (K salt): $M^\oplus = K^\oplus$

To obtain a sample of the plant metabolite RP-14 (**3**), the primary leaves of the barley mutant *Hordeum vulgare* cv. Gerbel were aged in the dark as described before[4a, 5] (Fig. 1), and the cryosap isolated from it was separated by HPLC. The eluate that contained the potassium salt **3**-K as major component (94%, HPLC analysis) was lyophilized, and the salts removed from the residue on C-18 cartridges. The metabolite **3**-K was isolated as a powdery lyophilization residue (see *Experimental Procedure*).

The constitution of RP-14 (1-formyl-19-oxobilane, **3**) was deduced from MS, ^{1}H and ^{13}C NMR, UV/VIS, CD, and IR spectra: the molecular formula of **3**-K was given as $C_{35}H_{41}N_4O_{10}K$ in the FAB mass spectrum[8a] in positive-ion mode: molecular ion at *m/z* 717.266 ($C_{35}H_{42}N_4O_{10}K$ 717.254); base peak at *m/z* 679.287 ($C_{35}H_{43}N_4O_{10}$ 679.298); in negative-ion mode the base peak was at *m/z* 677.4. The absorption maximum of the longest wavelenth band in the UV/VIS spectrum of **3**-K (cf. ref. [5]) at 315 nm is consistent with an α-formylpyrrole unit, but not with an extended, conjugated chromophore. In the ^{1}H NMR (400 MHz) spectrum of **3**-K in D_2O ([D_6]DMSO), the signals of 33 (40) of the 41 protons can be seen (Figs. 2 and 3a): a singlet for the formyl proton and five singlets for methyl protons, including, according to the chemical shift, an ester methyl group; signals due to unsubstituted ethyl and vinyl groups are not observed. The signal at higher field of an AX system in the

Fig. 1. Primary leaves of barley (*Hordeum vulgare* cv. Gerbel and the structural formulas for chlorophyll a (**1**) and for the catabolite "RP-14" (**3**); left: freshly cut; right: as left, after 7 days aging in darkness [4a, 5]).

spectrum in [D_6]DMSO ($\delta_A = 4.63$, $\delta_X = 3.91$, $J_{A,X} = 3.3$ Hz, assigned to H-C15 and H-C13^2) is missing in the D_2O system as a result of H/D exchange. Of the 35 carbon atoms, signals for 33 are resolved in the ^{13}C NMR spectrum (100 MHz) of **3**-K in D_2O: the signal of C13^2, deuterated in D_2O, cannot be found; the spectrum in [D_6]DMSO shows 32 signals including that for C13^2 at $\delta = 64.99$.

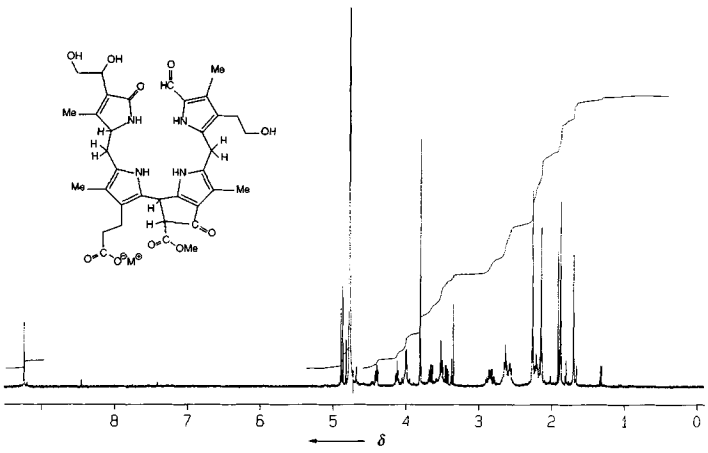


Fig. 2. ^{1}H NMR spectrum (400 MHz) of **3**-K in D_2O at 25 °C. (δ_{HDO} 4.72, *c* = ca. 3.5 mM): The signal of H-C13^2 is missing because of H–D exchange; the signal of H-C15 at $\delta = 4.83$ is therefore a singlet.

In addition to the five methyl groups, the H atoms bound to O and N atoms, and the formyl-H atom, six isolated spin systems of **3**-K are recognized on applying homonuclear ^{1}H chemical shift correlation (DFQ-COSY, TOSCY[8b–e]). The corresponding ^{13}C NMR signals were identified by ^{1}H,^{13}C–$^1J_{H,C}$ chemical shift correlation.[8f, g] Through information about the spatial neighborhoods from ^{1}H nuclear Overhauser measurements (NOESY,[8b, h, i] Fig. 3a) and support-

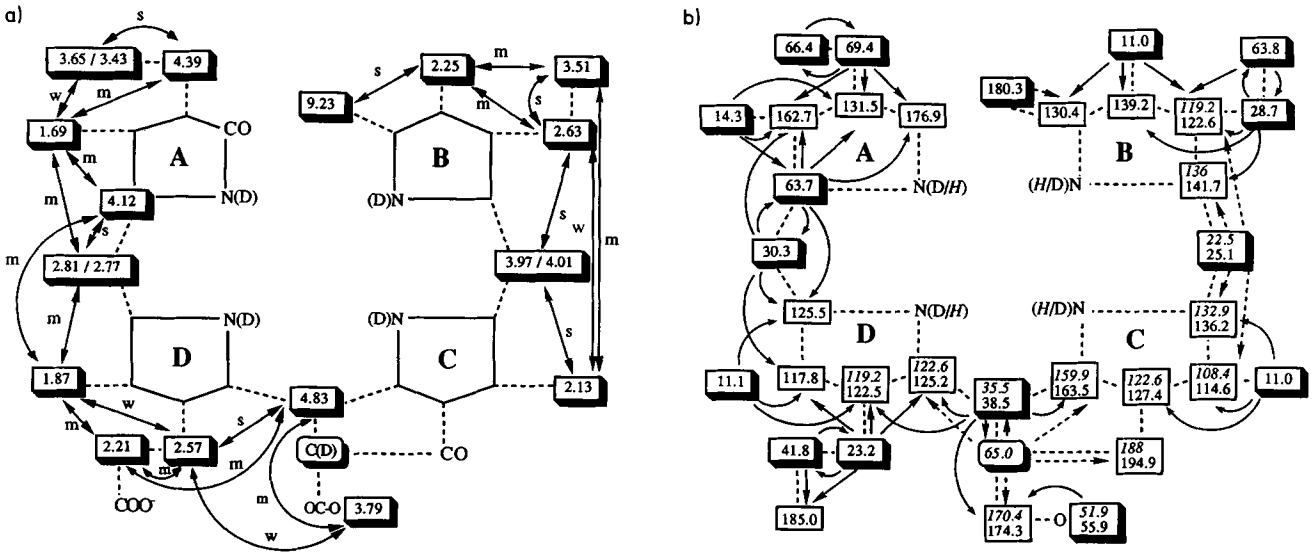

Fig. 3. a) Assignments and chemical shifts of the proton signals of **3**-K (D_2O, 25 °C, N_2) and NOE correlations observed in the NOESY spectrum [8b] (D_2O/MeOH 1:1, −7.5 °C, N_2; w = weak, m = medium, s = strong); b) assignments and chemical shifts of the ^{13}C NMR signals of **3**-K (D_2O, 25 °C, N_2; additional values in italics are for those signals in the spectrum of **3**-K in [D_6]DMSO that show additional correlations to those in D_2O in the HMBC spectrum [8i, j]). $^{2/3}J$(C,H) correlations are represented as arrows that start at protons and point to the correlated ^{13}C atoms (solid for D_2O, dashed for [D_6]DMSO). In the [D_6]DMSO spectrum the H-N21 and H-N24 show additional $^{2/3}J$(C,H) correlations to all four C atoms of the corresponding pyrrole rings A and D.

ed by H–C long-range connectivities from HMBC spectra (HMBC = Heteronucluear Multiple-Bond Connectivity,[8j] Fig. 3b), the connectivities of the C-centers and the *C*- and *N*-bonded H atoms of the B–C part (C5 to C13) and the A–D region (C14 to C4, including $C13^1$ and $C13^2$) of **3**-K were deduced, to which the four pyrrole N atoms could be fitted in a satisfactory way. The three O atoms which were not already assigned to carbonyl, ester, or carboxylato groups could be identified as hydroxy substituents at positions 3^1, 3^2, and 8^2 from FAB-MS, ^{13}C, and ^1H NMR data. The coupling of the A–D and B–C halves through an annelated cyclopentanone ring was concluded from the following: a) The molecular formular of **3**-K implies 17 double-bond equivalents, of which three are involved in the coupling in question. b) The ^{13}C chemical shifts of the three C atoms involved (δ = 127.4, 163.5, and 194.9) indicate that two are olefin (arene) atoms for which two σ bonds are observed and another is a ketone C atom for which the second C–C bond is missing. The exclusion of highly strained systems leads to the coupling through the cyclopentanone annelated to the pyrrole ring C, and the three C atoms are identified as C13, C14, and $C13^1$. (A related structural problem has been described.[10])

The analysis of all the spectroscopic data suggests that the constitution of **3**-K is that of a potassium-4,5-seco-4,5-dioxo-3^1,3^2,8^2-trihydroxy-13^2-methoxycarbonyl-1,4,5,10,15,20-(22H,24H)-octahydrophytoporphyrinate. The configuration of the four stereogenic centers, which apparently are largely uniform in optically active **3**-K, has still not been ascertained. However, from ^1H NMR data the methoxycarbonyl group at the 13^2-position of the cyclopentanone ring is *trans* to the AD half. Thus **3**-K presumably is the thermodynamically more stable diastereomer with respect to this part of the molecule (but it possibly forms in vitro on H exchange in a protic milieu).

A feature of **3** is the methoxycarbonyl-substituted cyclopentanone ring, which is a structural characteristic of the chlorophyll derivatives such as **1** and **2**. This and the occurrence of four methyl groups bonded to the chromophore in **3** shows a close structural correspondence between **3** and **1** (and less so with **2**), but not with the chlorins **5**[11a] and **6**[11b] suspected to be chlorophyll catabolites: compound **3** is formally accessible from chlorophyllide a (**4**), which has been postulated as the first degradation product of chlorophyll a (**1**),[1a, 12, 13] by demetalation and addition of one oxygen molecule and three water molecules; its chiroptic properties suggest an enzyme-controlled formation (cf. the current speculations on chlorophyll degradation[3, 14]).

Recently the light-emitting substance of krill (a part of the sea plankton) and luciferin from dinoflagellates have been characterized as the first examples of naturally occurring "bile pigments" structurally derived from chlorophyll.[10] In these substances the chlorin macrocycle is interrupted at the *meso* position C20, a site of the chlorin ring which is readily attacked by electrophilic reagents.[15] In contrast, the macrocycle in **3** is opened at the *meso* position C5, which recalls the oxygenolytic degradation of the iron porphyrin heme [7b, 16] to bile pigments.

The constitution of the 4,5-seco-4,5-dioxophytoporphyrinate **3**-K provides for the first time a structural guideline which may contribute to the understanding of the apparently complex process of chlorophyll degradation.

Experimental Procedure

For the cultivation of *Hordeum vulgare* cv. Gerbel and the conditions of the senescence induced in the dark, see [4a, 5]: 115 g of leaves were aged in continuous darkness for 7 d; the cryosap from 5 g batches of leaf material (ca. 4 mL) was treated with acetone (ca. 16 mL) and centrifuged to separate the protein material (5 min per 2300 g). The supernatant was treated with chloroform (20 mL), briefly shaken, and the aqueous phase separated into two portions (HPLC column, Stagroma, Wallisellen, Switzerland): Nucleosil RP-8, 10 μm, 20 × 250 mm; eluant: 27 vol% methanol/73 vol% 50 mM potassium phosphate pH 7; flow rate 14.6 mL min^{-1}; detection at 320 nm. The fraction with a retention of ca. 17.3 min was collected at 0 °C under an inert atmosphere (N_2). The crude fractions of **3**-K were lyophilized in three portions at room temperature, the residue extracted three times with ca. 3 ml portions 20 vol% aqueous methanol and the extracts purified in five portions by HPLC as described. The HPLC eluates were stored for 3–8 days under nitrogen at −20 °C and then lyophilized in two portions at $T < 0$ °C; the pale yellow residue of each batch was placed on a Waters C_{18} Sep-pak cartridge with ca. 2 mL destilled water and washed with ca. 25 mL destilled water. A pale yellow fraction was eluted with ca. 20 mL 20 vol% aqueous methanol and the eluate lyophilized under high vacuum at $T < 0$ °C. The light yellow residue of powdery **3**-K was dried under high vacuum at room temperature for ca. 4 h. Yield 13 mg (> 94%; analytical HPLC, cf. [5]).

Spectroscopic data: (NMR: Bruker AMX-400, ^{1}H NMR in D_2O: cf. Fig. 2 and 3a, ^{13}C NMR in D_2O: cf. Fig. 3b). ^{1}H NMR (400 MHz, ca. 4 mM solution under N_2, [D_6]DMSO): δ = 1.84, 1.85 (2s, H_3C (2^1 and 18^1)), 2.00, 2.17 (2s, H_3C (12^1, 7^1)), overlapping with 2.0–2.2 (m, H_2C (17^2)), 2.31 (dd, J(H,H) = 8.7/14.5 Hz, $H_aC(20)$), 2.4–2.6 (m, $H_2C(8^2)$ and $H_aC(17^1)$), 2.6–2.7 (m, $H_bC(17^1)$), 2.72 (dd, J(H,H) = 4.9/14.5 Hz, $H_bC(20)$), 3.2–3.3 (m, $H_2C(8^2)$), 3.3–3.5 (m, $H_2C(3^2)$), 3.62 (s, ester CH_3), 3.70/3.79 (AB spin system, J(H,H) = 15.8, $H_2C(10)$), 3.91 (d, J(H,H) = ca. 3.5 Hz, $HC(13^2)$) overlapping with 3.94 (dd, J(H,H) = 4.9/8.7 Hz, HC(1)), 4.33 (t, J(H,H) ca. 5.6 Hz, $HC(3^1)$), 4.63 (d, J(H,H) = 3.3 Hz, HC(15)), overlapping with 4.6–4.7 (br, 1H), 4.7–5.0 (br, 1H), 7.79 (s, HN(21)), 9.49 (s, HC(5)), 9.85 (s, HN(24)), 11–13 (br, ca. 1H), 13.0–13.2 (br, 1H)); ^{13}C NMR (100 MHz, ca. 15 mM solution under N_2, [D_6]DMSO): δ = 9.04(7^1,12^1), 9.30(18^1), 12.20(2^1), 21.68(17^1), 22.47(10), 27.35(8^1), 29.66(20), 35.52(15), 39.6(17^2), 51.92 (ester CH_3), 60.15(1), 61.01(8^2), 64.63(3^2), 64.99(13^2), 67.64(3^1), 108.42(12), 113.25(18), 119.20(8,17), 122.54, 122.62(13,16), 122.99(19), 127.9 (br, 6), 130.86(3), 132.95(11), 136 (br, 9), 154.94(2), 159.86(14), 170.43(13^3), 172.52(4), 177.30(17^3), 178 (br, 5), 188.15(13^1). UV/VIS and CD (0.02 M sodium phosphate, pH 7, $c = 8.10^{-5}$ M): λ_{max}[nm] (rel. ε) = 243 (0.83), 272 (sh, 0.59), 315 (1.0, log ε = 4.2); λ_{max}[nm]($\Delta\varepsilon$) = 223 (15), 247 (– 4), 282 (– 14), 317 (4). Anti-Selective and Diastereofacially Selective Aldol Reactions with (*R*)-2-Siloxy-1,2,2-triphenylethyl propionate**

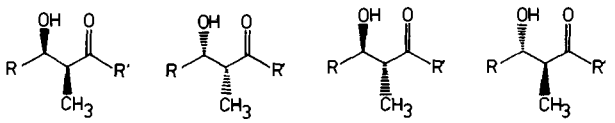
By *Manfred Braun** and *Hubert Sacha*

Dedicated to Professor Leonhard Birkofer on the occasion of his 80th birthday

The directed synthesis of the enantiomeric *syn*-β-hydroxycarbonyl compounds **1** and *ent*-**1** is achieved today with highly efficient variants of the aldol reaction, mostly starting from chiral propionamides. In contrast, *anti*-selective aldol reactions, based on the addition of chiral propionic acid esters to aldehydes RCHO, are known to be problematic partly because of poor simple diastereoselectivity (*anti*-**1** versus *syn*-**1**) and partly unsatisfactory diastereofacial selectivity (**2** versus *ent*-**2**).[1] Lately more effective enolates and silyl



1 *ent*-**1** **2** *ent*-**2**

ketene acetals have been developed as starting materials, but their synthesis has been hampered by the difficult access to the required chiral auxiliaries.[2] We now report the first *anti*-selective and diastereofacially selective aldol additions of the propionate **4b**; its chiral building block, triphenylglycol, is easily accessible in both enantiomeric forms (**3** and *ent*-**3**) and it has repeatedly proved its worth as the acetate.[3]

The esterification of the (*R*)-diol **3** with propionyl chloride took place as anticipated, exclusively at the secondary hydroxy group, and afforded the propionate **4a**, which was transformed into the propionate **4b** by *O*-silylation[4] in 90% total yield (Scheme 1, Table 1). The lithium enolate **5a**, formed in situ from 2-siloxy-1,2,2-triphenylethyl propionate (**4b**) deprotonated by lithium cyclohexylisopropylamide, undergoes transmetalation with [Cp_2ZrCl_2] to form **5b**. Subsequent addition of an aldehyde yields predominantly the *anti* diastereomers **6**/**7** (Table 1). Their contribution to the product distribution was determined by NMR spectroscopy (Table 2). At the same time this aldol addition shows a high diastereofacial selectivity: the diastereomeric ratio of **6**:**7** lies between 97:3 and > 98:2.

Table 1. Adducts **6**/**7**, formed by addition of the enolate **5b** to an aldehyde RCHO.

R		**6**–**9** Yield [a]	**6**/**7**:**8**/**9** (*anti*:*syn*)	**6**/**7**
Ph	**a**	90	89:11	97.5:2.5
$(CH_3)_2CH$	**b**	82	>98:2	97:3
$(CH_3)_3C$	**c**	75	>98:2	>98:2

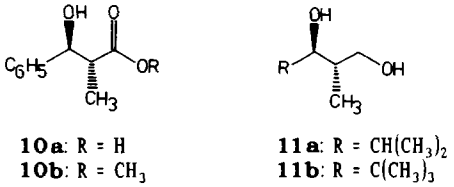
Table 2. Physical and spectroscopic data of compounds **4** and **6**.

4a: m.p. = 208–209 °C; $[\alpha]_D^{25}$ (c = 1.5, $CHCl_3$) = 199.8; ^{1}H NMR (60 MHz, $CDCl_3$, TMS int.): δ = 0.97 (t, J = 7.4 Hz, 3H), 2.18 (q, J = 7.4 Hz, 2H), 2.78 (s, 1H), 6.62 (s, 1H), 6.87–7.60 (m, 15H). – **4b**: m.p. = 77–79 °C; $[\alpha]_D^{25}$ (c = 1.15, $CHCl_3$) = 39.3; ^{1}H NMR (300 MHz, $CDCl_3$, TMS int.): δ = – 0.13 (s, 9H), 1.04 (t, J = 7.6 Hz, 3H), 2.27 (q, J = 7.3 Hz, 2H), 6.60 (s, 1H), 6.8–7.3 (m, 15H). – **6a**: ^{1}H NMR (300 MHz, $CDCl_3$, TMS int.): δ = – 0.13 (s, 9H), 0.88 (d, J = 7.3 Hz, 3H), 2.79 (m, 1H), 2.94 (d, J = 4.8 Hz, 1H), 4.66 (dd, J = 8.2, 4.8 Hz, 1H), 6.59 (s, 1H), 6.79–7.33 (m, 20H). – **6b**: ^{1}H NMR (300 MHz, $CDCl_3$, TMS int.): δ = – 0.15 (s, 9H), 0.77 (d, J = 6.6 Hz, 3H), 0.90 (d, J = 6.8 Hz, 3H), 1.08 (d, J = 7.3 Hz, 3H), 1.62 (m, 1H), 2.51 (d, J = 8.4 Hz, 1H), 2.63 (dq, J = 7.3, 5.5 Hz, 1H), 3.19 (m, 1H), 3.19 (m, 1H), 6.60 (s, 1H), 6.77–7.33 (m, 15H). – **6c**: ^{1}H NMR (300 MHz, $CDCl_3$, TMS int.): δ = – 0.13 (s, 9H), 0.84 (s, 9H), 1.17 (d, J = 7.3 Hz, 3H), 2.67 (dq, J = 7.3, 1.9 Hz, 1H), 3.11 (dd, J = 9.8, 1.9 Hz, 1H), 3.75 (d, J = 9.9 Hz, 1H), 6.55 (s, 1H), 6.78–7.31 (m, 15H).

The alkaline hydrolysis of the adduct mixture **6a**/**7a**/**8a**/**9a** obtained with benzaldehyde yields carboxylic acid **10a**, and subsequent treatment with diazomethane affords after purification by column chromatography (to separate off the *syn* isomer) the methyl ester **10b** (85% yield) in 96% *ee*. Comparison of the optical rotation[5] reveals the (2*R*,3*S*) configuration for **10b** and its optical purity was confirmed by ^{1}H NMR measurements with the shift reagent $[Eu(hfc)_3]$.[6] The reduction by $LiAlH_4$ of the crude products **6b**/**7b**/**8b**/**9b** and **6c**/**7c**/**8c**/**9c** which are formed by addition of the zirconium enolate **5b** to isobutyraldehyde or pivalaldehyde, respectively, affords the diols **11a** and **11b** (chemical yields: 63% and 68% respectively) in diastereomeric purity of 98% *de* after column chromatography on silica gel (to separate off both **3** and the *syn* isomer in each case); the enantiomeric excess is 94% and > 97%, respectively. The (2*S*,3*R*) configuration for 2,4-dimethylpentane-1,3-diol (**11a**) and (2*S*,3*S*) for 2,4,4-trimethylpentane-1,3-diol (**11b**)[7] are assigned by comparison of optical rotations.[8] Confirmation of the *ee* values is achieved by esterification of both the hydroxy groups with Mosher's reagent[9] and subsequent ^{19}F NMR spectroscopy.



Although the zirconium enolate **5b** of the (*R*)-propionate **4b** always shows a large preference to attack the *Si* side of the aldehyde, the opposite topicity results from addition of the silyl ketene acetal **5** (M = $SiMe_3$) under Mukaiyama conditions.[10] However, the diastereofacial selectivity is smaller than with zirconium enolate (**5b**). The lithium enolate also affords predominantly *anti* adducts, but shows almost no diastereofacial selectivity. The highly stereoselective *anti* addition of **5b**[11] is all the more astounding, because the zirconium enolates used so far, sometimes independent of their configuration (*E* or *Z*), have reacted with *syn* selectivity.[12] The chiral auxiliary triphenylglycol (**3**) is recovered without racemization after both the hydrolysis to carboxylic acid **10a** and the reduction to the diols **11**, and is reusable. Access from (*S*)-**3**[13] to the enantiomeric products is possible as well.

Experimental Procedure

6c: A solution of lithium isopropylcyclohexylamide generated from isopropylcyclohexylamine (0.36 mL, 2.1 mmol) and butyllithium (2.1 mmol, 1.6 M in hexane) in THF (10 mL) was treated under an inert atmosphere of nitrogen with **4b** (0.84 g, 2.0 mmol) in THF (10 mL) and stirred for 90 min at – 105 °C to – 78 °C. The mixture was cooled to – 105 °C, and $[Cp_2ZrCl_2]$ (1.84 g, 6.3 mmol) in THF (26 mL), precooled to – 78 °C, was added dropwise. The resulting mixture was stirred for 2 h at – 60 °C, again cooled to – 105 °C, whereupon a solution of 2,2-dimethylpropanal (0.33 mL, 3.0 mmol) in THF (10 mL) was added dropwise. After stirring for 1 h at – 100 °C and 3 h at – 78 °C, the solution was treated successively with hydrochloric acid (15 mL, 1 M), saturated NH_4Cl solution (10 mL), and water (40 mL), stirred for 1 h at 25 °C, and worked up with ethyl acetate. Removal of the solvent gave crude **6c** (0.76 g, 75%), which according to the 300 MHz ^{1}H NMR spectrum was still contaminated with ca. 1% of **7c** and ca. 1% of the *syn* isomers **8c**/**9c**.

11b: The crude product **6c** was treated for 20 h at 25 °C with $LiAlH_4$ (1.15 g, 30.0 mmol) in diethyl ether. After aqueous workup and separation from **3** by column chromatography (silica gel, ethyl acetate/*n*-hexane 3:2; R_f of **3** = 0.38), **11b** (0.18 g, 80%) is eluted. $[\alpha]_D^{25}$ = – 5.1 (c = 1.78, $CHCl_3$).

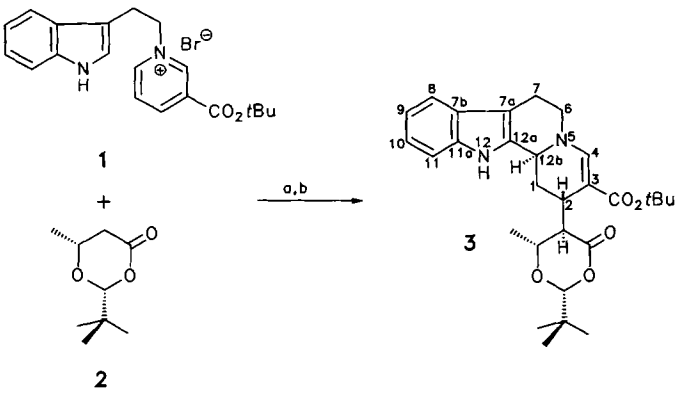
Addition of Chiral Nucleophiles to Pyridine Compounds: Total Synthesis of (−)-Isovallesiachotamine and (+)-Vallesiachotamine**

By *Robert Amann* and *Dietrich Spitzner**

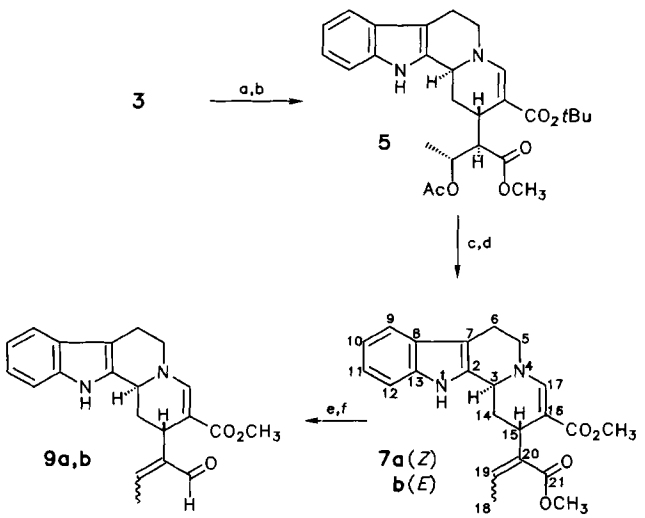
In the syntheses of indole alkaloids of the yohimbane, heteroyohimbane, or corynanthe type, the procedure of *Wenkert* (addition of a nucleophile—preferably malonate—to an *N*-tryptophylpyridinium derivative, protonation of the intermediate 1,4-dihydropyridine, and Pictet–Spengler ring closure) has proved its worth.[1] This reaction sequence generates two chiral centers in the prochiral pyridine residue. Stereoelectronic effects control the relative configuration of these centers.

We can now demonstrate that enantiomerically pure frameworks of indole alkaloids can be constructed with this reaction cascade when chiral nucleophiles are added to the pyridinium compound **1** and the Pictet–Spengler ring closure is performed according to *Wenkert*'s one-pot procedure in benzene with dry hydrogen bromide.[2] The (−)-(2*R*,6*R*)-2-*tert*-butyl-6-methyl-1,3-dioxan-4-one (**2**), formed from poly-(*R*)-3-hydroxybutyric acid according to *Seebach* et al.,[3] is particularly suitable as chiral nucleophile. The reaction procedure to form hexahydroindolo[2,3-*a*]quinolizine (**3**) is very simple, and also in this case no protecting group is required on the indole nitrogen. However, **2**-Li must be added in excess so that the indole is also deprotonated. As the addition proceeds, the reaction mixture, which is at first heterogeneous at −78 °C, becomes homogeneous.[4]



Scheme 1. Synthesis of **3**. Reagents and conditions: a) 2.2 equiv lithium diisopropylamide (LDA) and **2**, THF, −78 °C to 0 °C, 3.0 h; b) HBr(g), benzene, pH 6.5, 0 °C, 0.5 h, 27%.

Nonreacted pyridinium salt **1** can be recovered to a large extent. Analysis by chromatography (DC, silica gel 60, petroleum ether:ethyl acetate 4:1) and by ^{1}H NMR spectroscopy (250 MHz) of the chromatographed components of the crude product show that only one diastereomer (> 95%) is formed. It is remarkable that the chiral nucleophile is directed exclusively to C4 of **1**. This addition can be formulated by ionic as well as by radical steps (Single Electron Transfer, SET). To establish the stereochemical course (*lk* or *ul* addi-



Scheme 2. Synthesis of **9a, b**. Reagents and conditions: a) 4 equiv $NaOCH_3$, CH_3OH, 20 °C, 0.5 h, 98%, **4**; b) 1.5 equiv Ac_2O, pyridine, 120 °C, 30 h, argon, 88%, **5**; c) 6 equiv 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU), toluene, 115 °C, 1.5 h, argon, 88%, **6a, b**; d) 1 N HCl, CH_3OH, 20 °C, 2.5 h, 100%, **7a, b**; e) 4 equiv $LiAlH_4$, THF, 0 °C, 2.0 h, 78%, **8a, b**; f) 4 equiv MnO_2, CH_2Cl_2, 20 °C, 6.0 h, 60%, **9a, b**.

tion) of the reaction, the biosynthetically "early" alkaloids (−)-isovallesiachotamine (**9a**) and (+)-vallesiachotamine (**9b**), which can be isolated from *Vallesia*, *Rhazia*, and *Strychnos* species or obtained by mild hydrolysis from the alkaloid strictosidine,[5] were synthesized in few steps, starting from hexahydroquinolizine **3**. These natural products are formed along known biosynthetic pathways from tryptamine and secologanin.[6]

Compound **3** reacts with sodium methoxide in methanol by loss of pivalaldehyde to form the hydroxyester **4**, which is subsequently acylated. Acetate **5** forms the croton esters **6a, b** (3:1 *Z*/*E* mixture) by β elimination in toluene. Transesterification (MeOH/HCl) to **7a, b**[7] and selective reduction yield the alcohols **8a, b**, which are oxidized with MnO_2 to form the natural products **9a, b**. The proportion of the major isomer is increased by fractional crystallization.[8] These chemically very labile compounds isomerize on attempts to separate them by chromatography on silica gel.

The multifunctional hexahydroindolo[2,3-*a*]quinolizine **3** can be transformed in such a way that other enantiomerically pure indole alkaloids can also be prepared from it. Particularly attractive, however, are the homologous hexahydroindolo[2,3-*a*]quinolizines, which are derived from 2-methylnicotinic acid esters, since for these compounds the C_2 side chain typical of many indole alkaloids can be introduced very directly by a Winterfeldt lactam rearrangement.[9]

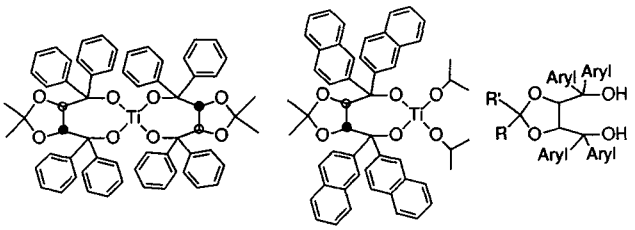
2,2-Dimethyl-α,α,α′,α′-tetrakis(β-naphthyl)-1,3-dioxolan-4,5-dimethanol (DINOL) for the Titanate-Mediated Enantioselective Addition of Diethylzinc to Aldehydes**

By *Beat Schmidt* and *Dieter Seebach**

We reported recently[1a] that addition of diethylzinc to aldehydes in the presence of 1 equivalent $Ti(OCHMe_2)_4$ and 0.1 equivalents spirotitanate **1** is highly enantioselective.[2] The compatibility of this Lewis acid mediated process with the donor solvent diethylether[3] allowed us to use dialkylzinc compounds which had been generated in situ from conventionally prepared primary Grignard reagents.[1b] With aliphatic aldehydes the selectivity was rather below 90% *ee* while it reached 99% with aromatic ones. We have now found that the monocyclic naphthyl-substituted titanate **2** is a far more effective catalyst.[4,5]



1 **2** (M_r = 830.87) **3**

In the course of mechanistic studies of the reaction carried out with $Ti(OCHMe_2)_4$/**1**, we noticed that simply adding diols **3** to the achiral titanate led to appreciable enantioselectivities and that a seven-membered ring titanate was formed upon mixing these components (NMR spectroscopy). Tetraaryldioxolanedimethanol (TADDOL) derivatives of titanium such as **2** can be isolated as colorless solids.[4]

The procedure using **2** and the product analysis followed those described for the spirotitanate[1] (see Eq. (a) and Table 1). The *Si* selectivity of Et_2Zn addition to benzaldehyde is > 99:1 with 0.2 equivalents of **2**; the product **4** is still formed with a 96:4 preference, when 5 mol% of **2** and

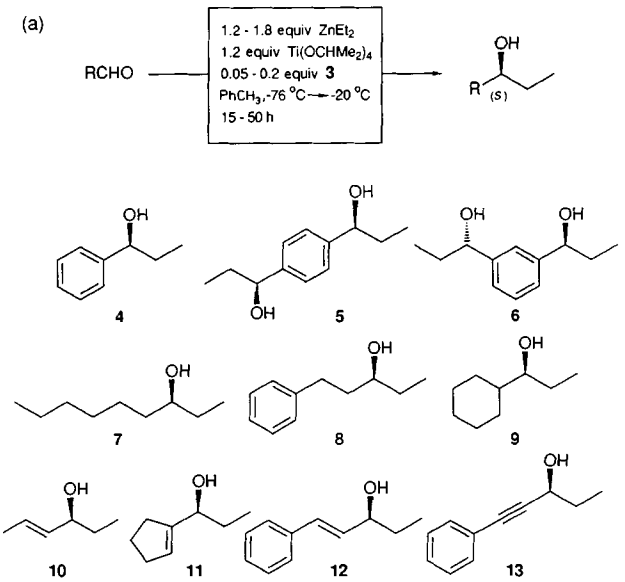
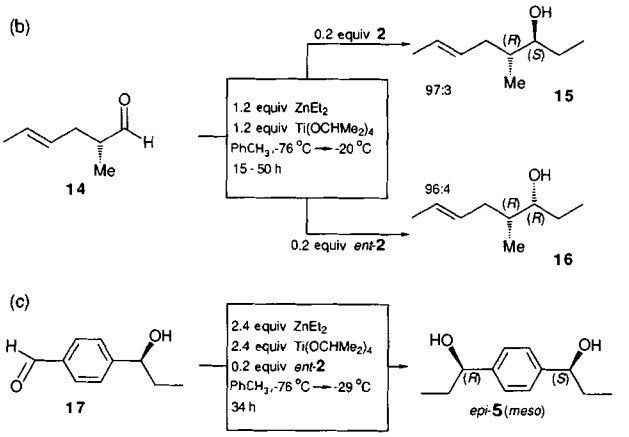
ETH-Zentrum, Universitätstrasse 16, CH-8092 Zürich (Switzerland)
[**] Part of the projected Ph. D. thesis of *B. Schmidt*. We thank *Y. Wang* for carrying out some experiments and *D. Felix* for assistance with *ee* determinations by gas chromatography. Financial support and gifts of chemicals by the Sandoz AG (CH-Basel), Dynamit-Nobel, Hüls Troisdorf (Bergkamen, FRG) are gratefully acknowledged.

an excess of Et_2Zn is used.[8] With terephthalic aldehyde one of the four possibilities, the (*S,S*) stereoisomer **5**, is obtained exclusively (>99% *ds*, 98% *ee*), while the reaction with isophthalic aldehyde is a little less selective, furnishing the (*S,S*) diol **6** with 93% *ds* and > 99% *ee* (see Fig. 1). Especially with saturated (→ **7**–**9**), olefinic (→ **10**–**12**), and acetylenic (→ **13**) aliphatic aldehydes the improvement obtained with **2** over the reagent with the tetraphenyl-substituted ligand is essentially an order of magnitude. The highest selectivity was observed with phenylpropinal: the (*R*) enantiomer was not detectable by gas chromatography (see Fig. 1), a promising result if one considers the multitude of interesting conversions that propargyl alcohols are capable of undergoing.

To test the influence of a stereogenic center in the α-carbonyl position of the aldehyde we added diethylzinc to (*R*)-2-methyl-4-hexenal (**14**). [Equation (b)]:[10] with the catalyst **2** a 97 : 3 *Si* addition ensued, with *ent*-**2** a > 96 : 4 *Re* addition. The assignment of configuration to the epimers **15** and **16**[11]





that formed is based on the sign of optical rotations and in analogy to the other reactions carried out.[12] The high selectivity of addition allowed us to construct the two centers of opposite sense of chirality in the *meso* diol *epi*-**5**[9] by first using the (*R/R*) ligand (→ **17**; *S/R* = 98.2 : 1.8) and then the (*S/S*) ligand (*ent*-**2**) on terephthalic aldehyde (see Fig. 1).

Table 1. Reactions of benzaldehyde, phthalic aldehydes, heptanal, 3-phenylpropanal, cyclohexanecarbaldehyde, crotonaldehyde, cyclopentene-1-carbaldehyde, cinnamaldehyde, and 3-phenylpropanal (5–10 mmolar runs). All secondary alcohols, except **5**, **6**, and **11**, have been previously described, and their configurations assigned; the sense of chirality follows from comparison of the sense of optical rotation with literature data [6]. Thus, we assign all alcohols the (*S*), and the diols **5** and **6** the (*S,S*) configuration. The ratios of enantiomers were determined by GC (cf. the specifications in [1b], for which the trifluoroacetates of **6**, **7** and **8** had to be prepared [7]).

[a] 2.4 equiv of $Ti(OCHMe_2)_4$ were used. [b] Only one diastereoisomer detectable. [c] See Fig. 1. [d] Racemate in GC not quite baseline separated. [e] The amount of the enantiomer lies below GC detection limits.

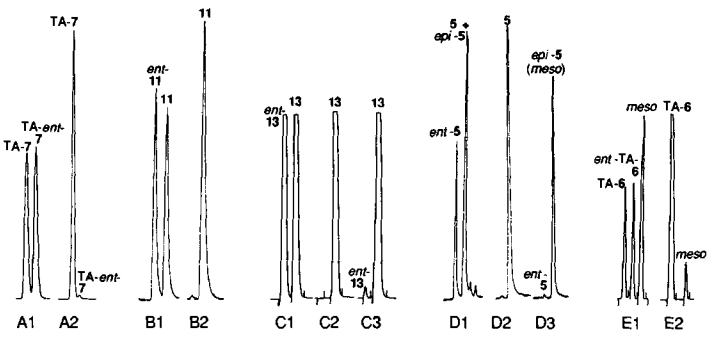

Fig. 1. Gas chromatograms for determination of the enantiomer ratios [1b]. A (**7**, trifluoroacetate); A1: racemic mixture; A2: product from reaction Eq. (a). B (**11**); B1: racemic mixture; B2: product from reaction. C (**13**); C1: racemic mixture; C2: product from reaction; C3: product "diluted" with ca. 3% *rac*. **13** (integration 1.5 : 98.5). D (**5**) [9]; D1: *meso*/*rac* mixture from terephthalic aldehyde and EtMgBr (integration ratio 22.9/58.0; on an achiral GC column a 29.1 : 38.0 *meso*/*dl* ratio was determined in this sample); D2: product from reaction; D3: *meso* product from **17**, Equation (c). E (**6**, bistrifluoroacetates) [9]; E1: *meso*/*rac* mixture from isophthalic aldehyde and EtMgBr (integration ratio 22.2/21.1/45.0); E2: product from reaction.

As can be seen from the diagram in Figure 2, the Lewis acid cocktail **2**/$(Me_2CHO)_4Ti$ provides the first case of a linear correlation between the enantiopurity of the catalyst and of the product in a Et_2Zn addition to an aldehyde, suggesting that a single DINOL ligand is involved in the rate-determining step.[13]

We are confident that organozinc compounds other than Et_2Zn will give similar results[1b] with the DINOL titanate **2**.

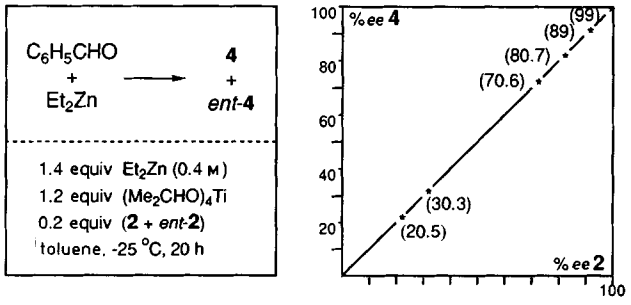

Fig. 2. Reactions of benzaldehyde with the DINOL derivative **2** of different enantiopurity. The molarity of Et_2Zn refers to the reaction mixture. Aliquots of (*R,R*)- and (*S,S*)-**3**, aryl = 2-$C_{10}H_7$, R = R′ = CH_3 were mixed for the preparation of **2** (see procedure). The numbers in brackets in the diagram were calculated from GC integrations measured with the samples of **4** obtained.

Experiments with aldehydes and zinc derivatives containing additional functional groups are under way.

Typical Procedure

8: Diol **3** (aryl = 2-$C_{10}H_7$, R = R′ = Me)[4], 0.933 g (1.4 mmol) is placed under argon in a dry 100 mL flask with side arm (serum cap). $Ti(OCHMe_2)_4$ (0.48 g, 1.7 mmol) and $PhCH_3$ (10 mL) are added by syringe, and after stirring at room temperature for 5 h the $PhCH_3$ and isopropanol are removed (40 °C/100–3×10^{-2} Torr). The solid residue is combined at room temperature with $PhCH_3$ (20 mL) and $Ti(OCHMe_2)_4$ (2.5 mL, 2.4 g, 8.4 mmol), and the solution cooled to − 25 °C (cryostat). Et_2Zn (4.2 mL, 8.4 mmol, 2 M in $PhCH_3$), and then 3-phenylpropanal (0.92 mL, 0.94 g, 7.0 mmol) are added dropwise. After 15 h at − 22 °C (TLC sampling) the reaction mixture is quenched with saturated aqueous NH_4Cl (10 mL), and Et_2O (40 mL) is added. Stirring for 30 min is followed by filtration through Celite, washing with saturated aqueous NaCl, drying over Na_2SO_4, and removal of the solvent. The residue is chromatographed through a short SiO_2 column (C_6H_{14}/Et_2O 3:1), and the resulting mixture of **3** and **8** heated in a Kugelrohr oven (100 °C air temp./0.3 mbar) to expel the alcohol **8**, the absence of which in the residue [14] is ascertained by NMR spectroscopy: 1.0 g colorless crystals, m.p. 40 °C.

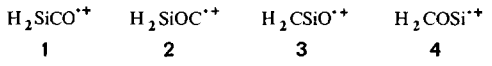
The Radical Cations of Silaketene and Several Isomers of $[C,H_2,Si,O]^{\cdot\oplus}$: An Ab Initio MO Investigation**

By *Jan Hrušák, Ragampeta Srinivas, Diethard K. Böhme,* and *Helmut Schwarz**

Recently, during systematic studies of the gas-phase chemistry of unsaturated silicon molecules,[1] we produced a radical cation with the elemental composition $[C,H_2,Si,O]^{\cdot\oplus}$ by the electron-impact ionization of $Si(OCH_3)_4$.[2] Although it was possible in analogous cases to establish ion connectivities by using tandem mass spectrometry,[1] the $[C,H_2,Si,O]^{\cdot\oplus}$ ion derived from $Si(OCH_3)_4$ could not be characterized in this way with certainty. The analysis of the collisional-activation spectra pointed toward the presence of several structures such as **1** and **4**, and ab initio calculations revealed an



energy surface rich in isomers. Here we present structures **1** to **4** which exhibit unusual structural features and show differences in geometry, symmetry, electronic structure, and order of stability from the "analogous" radical cations $CH_2{=}C{=}O^{\cdot\oplus}$ and $CH_2{=}O{=}C^{\cdot\oplus}$. These differences are also seen for the corresponding neutral molecules, and are much more pronounced than is implied by the similarities in Lewis structures.[3, 4]

All MO calculations were carried out with the GAUSSIAN 88 program package[5] within the unrestricted Hartree–Fock (UHF) formalism.[6] Stationary points were characterized by analyzing the force constant matrix. Complete geometry optimizations were accomplished with a 6-31G** basis set[7] and second-order Møller-Plesset perturbation theory (MP2).[8] Zero-point vibrational energies (ZPVE) were derived from harmonic frequencies calculated at the MP2/6-31G** level. The ZPVE were scaled by a factor of 0.89. The data for the energies obtained in this way (MP2/6-31G**//MP2/6-31** + ZPVE) for **1** to **4** are summarized in Table 1, and the geometric and electronic structures, as well as the relative stabilities of the $[C,H_2,Si,O]^{\bullet\oplus}$ radical ions, are adequately described[9] at this level of theory. This also follows from a comparison of calculated bond dissociation energies with experimentally available data.[2] Inconsistent results are obtained with smaller basis sets or when correlation effects are not included. On the other hand, an increase in the basis sets beyond 6-31G** does not seem necessary.

Table 1. Absolute [in Hartree] and relative energies [kcal mol^{-1}] for isomers of $[C, H_2, Si, O]^{\bullet\oplus}$ [a].

[a] For structural details see text and Scheme 1. [b] ZPVE: Zero-point vibrational energy. [c] The planar structure **1'** corrsponds to a transition state (one imaginary frequency) for the degenerate transformation **1** ⇄ **1'*** ⇄ **1**.

From many points of view, the radical cation of 1-silaketene ($H_2SiCO^{\bullet\oplus}$, **1**) is related to the neutral silaketene recently calculated by *Hamilton* and *Schaefer*.[10] The ketene-like *planar* C_{2v} structure **1'** (Scheme 1) is in both cases not a minimum but corresponds to a transition state of the degenerate isomerization **1** ⇄ **1'** ⇄ **1**. While for the neutral species an activation energy of 18.5 kcal mol^{-1} was calculated,[10] for the radical cations the energy difference between **1'** and **1** amounts to 9.0 kcal mol^{-1} (see Table 1). The imaginary frequency of the out-of-plane deformation is 598 cm^{-1} for the radical cation **1'** (Table 2) and 592 cm^{-1} for the neutral molecule.[10] Both the radical cation and the neutral form of **1** have a nonplanar C_s structure at the minimum. From a comparison of the vibrational frequencies (Table 2), the formal charges derived from the Mulliken population analysis and the geometrical details (Scheme 1) it follows that **1** corresponds to a complex of $SiH_2^{\bullet\oplus}$ and a largely "unperturbed" CO molecule. As is the case for the neutral species,[11] the Si–C bond can be understood in terms of an interaction between the empty p orbital of the silicon that is perpendicular to the SiH_2 plane and the pair of electrons on the carbon. A relatively long Si–C bond (1.979 Å) results. As expected, the unpaired electron occupies the sp^2-hybridized orbital of $SiH_2^{\bullet\oplus}$. In **1** Si is both the radical site (spin density ϱ = 1.01 e) and the center of charge (q = 0.78 e). The changes in structure which result as a consequence of the "complexation" of the $SiH_2^{\bullet\oplus}$ and CO parts are quite small compared with the structures of the separate building blocks: the C–O bond distance of 1.138 Å in **1** is not significantly shorter than that of the free CO (1.150 Å), and the Si–H bond is shortened by 0.008 Å and the HSiH angle is opened by 0.56 degrees. The vibrational frequencies summarized in Table 2 are also consistent with these changes in geometry. The energy for the dissociation of **1** into $SiH_2^{\bullet\oplus}$ and CO is 41.1 kcal mol^{-1}.

Table 2. Comparison of the vibrational frequencies of the planar and nonplanar silaketene radical cations (**1**) calculated at the MP2/6-31G**//MP2/6-31G** level with the CCSD results [10] for the neutral system [a].

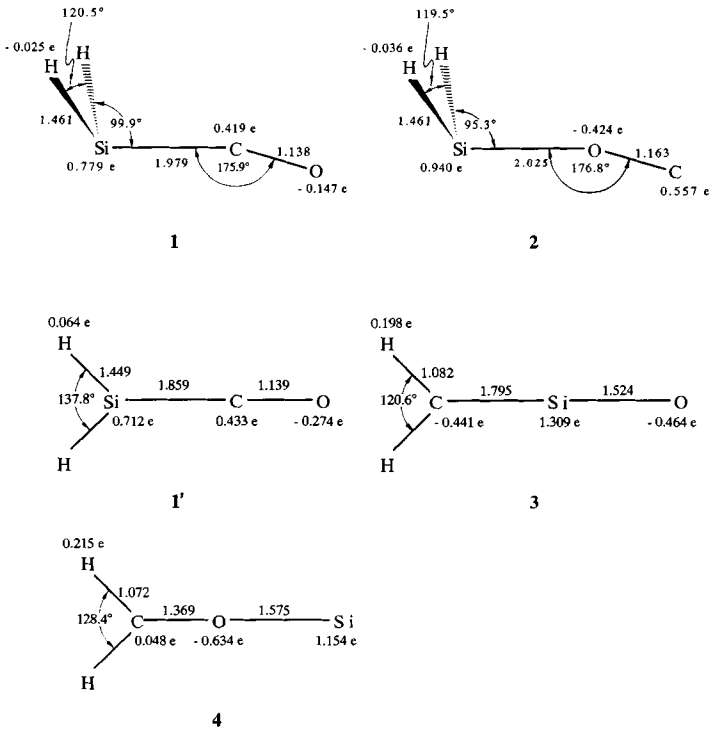
[a] For structural details see text and Scheme 1. [b] Calculated for the isolated cation and neutral species, respectively.



Scheme 1. The structural parameters and charge distribution calculated for the $[C, H_2, Si, O]^{\bullet\oplus}$ isomers **1**–**4**.

The coordination of $SiH_2^{\bullet\oplus}$ with the oxygen end of CO also results in a minimum in the energy surface for a nonplanar structure **2**. Although the isomer **2** is 23.4 kcal mol^{-1} less stable than **1**, the bond relationships and the geometries are

quite similar. The radical site and the charge are again mainly localized on the silicon ($\varrho = 0.98$ e; $q = 0.94$ e). The $SiH_2^{\bullet\oplus}$ segment is strongly bent (95.3°), and the Si–H and C–O bond lengths of 1.461 and 1.163 Å, respectively, are very similar to those found for **1**. Furthermore, the analysis of the vibrational frequencies supports a description of **2** as a complex of $SiH_2^{\bullet\oplus}$ and OC. The normal vibration of CO for **2** (2047 cm^{-1}) points towards an "unperturbed" CO bond, which is also consistent with the observed increase in the C–O bond length in **2** by 0.025 Å compared to **1**. The long Si–O separation of 2.025 Å and the low-lying frequency of 298 cm^{-1} for the SiO vibration correspond to a small perturbation. The symmetric and asymmetric SiH vibrations of 2383 and 2454 cm^{-1}, respectively, for **2** are very close to the vibrations of the free $SiH_2^{\bullet\oplus}$ (2334 and 2414 cm^{-1}, respectively). We obtain a value for the energy of dissociation of **2** into $SiH_2^{\bullet\oplus}$ and CO of 17.7 kcal mol^{-1}. As expected, the interaction of the empty p orbital of the $SiH_2^{\bullet\oplus}$ fragment with a free electron pair on the oxygen is energetically less attractive than the interaction with the electron pair on the carbon atom of CO.

The radical cation of 2-silaketene ($H_2CSiO^{\bullet\oplus}$, **3**) is a minimum on the energy surface. The energy of **3** is comparable to that of **2**. Several structural details deserve to be emphasized: 1) In contrast to **1** and **2**, the minimum in **3** can be described by a *planar* form with C_{2v} symmetry. 2) The Si–O bond in **3** of 1.524 Å is somewhat shorter than in the isolated $^2\Sigma^+$ $SiO^{\bullet\oplus}$ (1.542 Å). This corresponds to an increase in the SiO vibrational frequency (1321 cm^{-1}) of 271 cm^{-1} compared to $SiO^{\bullet\oplus}$. 3) The Si–C distance in **3**, 1.795 Å, lies between those of a Si–C bond in methylsilane (1.867 Å) and a Si–C double bond in silavinylidene (1.709 Å).[12] All of these data indicate that **3** formally corresponds to a silaketene derivative in which an electron has been removed from the Si–C double bond. The centers of spin and charge are formally separated in the resulting radical ion (a "distonic" ion[13]). The carbon atom carries the unpaired electron ($\varrho = 1.08$ e) and the silicon the charge (q = 1.30 e).

That the global minimum on the $[C,H_2,Si,O]^{\bullet\oplus}$ energy surface corresponds to a planar C_{2v} structure $H_2COSi^{\bullet\oplus}$ (**4**) is surprising, because in the ketene analogue the $H_2COC^{\bullet\oplus}$ structure is about 63 kcal mol^{-1} more energetic than $H_2CCO^{\bullet\oplus}$.[4c] It follows from the analysis of the geometry data and the charge distribution that **4** is not really a complex of $CH_2O/Si^{\bullet\oplus}$ but a combination of $CH_2/OSi^{\bullet\oplus}$. For example, the C–O separation in **4** of 1.369 Å clearly is larger than in a typical C–O double bond (H_2CO: 1.208 Å), while the Si–O bond in **4** is only 0.033 Å longer than in isolated $^2\Sigma^+$ $SiO^{\bullet\oplus}$. The C–H bond length and the HCH angle are also much closer to the parameters calculated for $^3CH_2$ (1.073 Å and 131°, respectively). Like **3**, structure **4** represents a distonic ion. The carbon carries the spin (1.292 e) and the silicon the charge ($q = 1.154$ e). Attempts to localize a bent form for **4** were unsuccessful; the C_s structure found at the UHF level does not correspond to a stationary point at the MP2/6-31G** level.

$K_2Cu_5Te_5$, a Novel Mixed-Valence Layered Compound with Metallic Properties**

By *Younbong Park, Donald C. Degroot, Jon Schindler, Carl R. Kannewurf,* and *Mercouri G. Kanatzidis**

Since the discovery of high temperature superconductivity, mixed-valence Cu compounds have received considerable attention with the aim of discovering related materials with even higher transition temperatures. Although mixed-valence solid state Cu–chalcogenide compounds have been known for some time, they remain relatively rare. For example, the only mixed-valence compounds known so far are $Na_3Cu_4S_4$,[1] ACu_4Q_3 (A = K, Rb, Cs, Tl; Q = S, Se),[2] $A_3Cu_8S_6$ (A = K, Rb),[3] $A_3Cu_8Se_6$ (A = Rb, Cs),[4] $Cs_2Cu_5Se_4$,[5] $TlCu_2Q_2$ (Q = S, Se),[6] $TlCu_6S_4$,[7] $Tl_5Cu_{14}Se_{10}$.[8] Even though the a priori design of a superconducting material that has a high T_c is not yet possible, it is still worthwhile to pursue the synthesis of mixed-valence Cu compounds, since their electronic features generally play an important role for high electrical conductivity. Furthermore, compared with ternary sulfides and selenides, tellurides are even rarer. To the best of our knowledge, there are

[**] Financial support from the Center for Fundamental Materials Research (CFMR) Michigan State University and the National Science Foundation (Presidential Young Investigator Award CHE-8958451) is gratefully acknowledged. The X-ray instrumentation was purchased in part with funds from the National Science Foundation (grant no. CHE-8908088). This work made use of the scanning electron microscope facilities of the Center for Electron Optics at Michigan State University.

only four known phases ($NaCu_3Te_2$,[9] KCu_3Te_2,[10] KCuTe,[11] and NaCuTe[11]) in the ternary A/Cu/Te (A = alkali metal) system, none of which have mixed Cu oxidation states. With these ideas in mind, we decided to use the now proven polychalcogenide flux method (150–450 °C)[12, 13] to explore similar new compounds. In our hands, this synthetic method has been quite successful in preparing novel structural types of (poly)sulfides and (poly)selenides of various transition metals.[12] Thus, we extended it to the telluride systems and report here the synthesis of a novel layered material, $K_2Cu_5Te_5$, the first mixed-valence Cu/Te compound, which possesses high metallic conductivity.

The reaction of K_2Te (0.309 g, 1.5 mmol), Cu (0.032 g, 0.5 mmol), and Te (0.508 g, 4.0 mmol) in an evacuated pyrex tube at 350 °C for three days followed by cooling (2 °C/h) afforded black parallelepiped crystals of $K_2Cu_5Te_5$ in 77% yield.[14] A quantitative microprobe analysis performed on a large number of crystals with a scanning electron microscope/EDS system gave the composition as $KCu_{2.4}Te_{2.6}$.[15] The product was isolated by removing the excess K_2Te_x with dimethylformamide (DMF) under inert atmosphere and is insoluble in all common organic solvents and stable in water and air. The nature of $K_2Cu_5Te_5$ was established by a single-crystal X-ray diffraction study.[16]

The structure of $K_2Cu_5Te_5$ is anisotropic. Anionic $[Cu_5Te_5]_n^{2n-}$ corrugated layers alternate with charge compensating K^+ ions (Fig. 1). The $[Cu_5Te_5]_n^{2n-}$ layers are

formed by edge-sharing rhombic $[Cu_2Te_2]$ units to form a distorted anti-PbO type structure. The structure of $[Cu_5Te_5]_n^{2n-}$ can also be viewed as a derivative of the CuTe lattice,[17] into which K^+ ions have been inserted and the electrons absorbed into the lattice. Based on the formula $K_2Cu_5Te_5$ and on the assumption that the oxidation state on each Te atom is −2, the formal oxidation state on copper would be +1 (two atoms) and +2 (three atoms). However, the coexistence of Cu^{2+} and Te^{2-} is most likely thermodynamically unstable with respect to electron transfer from the reducing Te^{2-} to the oxidizing Cu^{2+}. If all copper atoms are assigned the +1 oxidation state, the average oxidation state of Te is −1.4. This electron deficiency (holes) at Te can be either delocalized in the valence band, or localized through a structural distortion as ditelluride, or both. This situation is reminiscent of that found in CuS, a known metallic mixed-valence compound formulated as $(Cu^+)_2Cu^{2+}(S_2)^{2-}S^{2-}$ or as $(Cu^+)_3(S_2)^{2-}S^{-}$.[18] In $K_2Cu_5Te_5$ there are three crystallographically independent copper atoms, each of which possess a distorted tetrahedral geometry. The average Cu–Te distances for Cu1, Cu2, and Cu3 are 2.69(3) Å, 2.64(7) Å, and 2.58(4) Å respectively, which compare favorably with those found in KCu_3Te_2,[10] NaCuTe,[11] and CuTe.[17] However, the Cu2–Te1 and Cu3–Te3 distances (along the crystallographic *a* axis) are short at 2.582(1) Å and 2.540(2) Å respectively, suggesting that the holes might be constrained but delocalized on rows made from these atoms parallel to the *a* axis. Based on the +1 oxidation state for Cu, three electron vacancies exist per five Te. As a result, a structural distortion from the ideal anti-PbO structure occurs in which two vicinal Te2 atoms move closer together along the *c* axis to form a bond. Structural distortions in the electronegative element network as a response to changes in electronic structure of the electropositive metal are at the core of the Zintl concept[19] and are found in other ternary chalcogenide and pnictide systems.[20] The short Te2–Te2 bonds of 2.960(1) Å are formed by localizing two holes. In the absence of an additional distortion we can expect the remaining electron vacancy to be delocalized in the valence

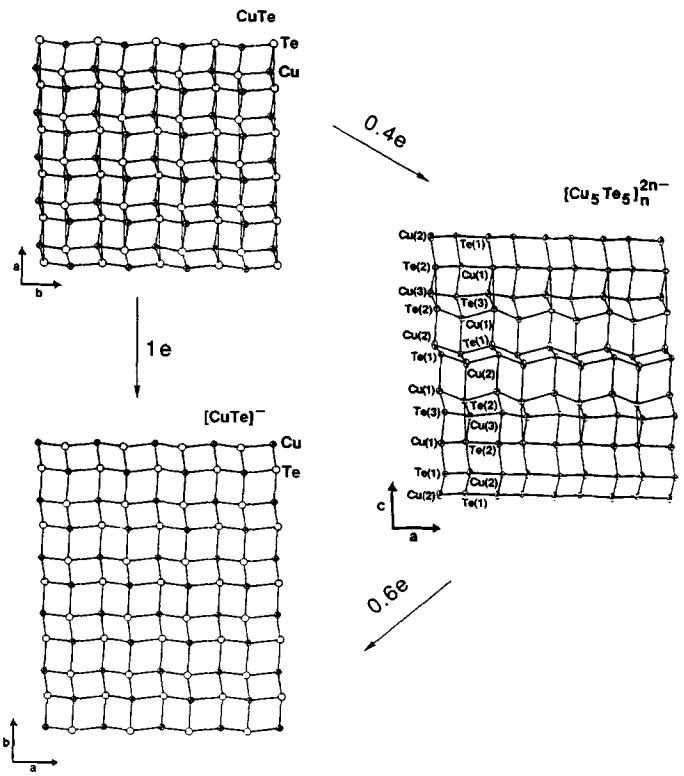

Fig. 2. Structural relationship of the $[Cu_5Te_5]_n^{2n-}$ layers (viewed down the (010) direction) to those of CuTe (above) and $[CuTe]_n^{n-}$ (below), as a function of oxidation state.

band, which consists mainly of p orbitals of the remaining three Te atoms, giving rise to a partially empty band. The Te2–Te2 bond is longer than normal Te–Te single bonds found in known polytellurides[21] by ca. 0.20 Å due to the multibonded nature of the Te2–Te2 unit. Each Te atom binds four Cu atoms which pull a significant fraction of the electron density from the Te–Te bond. The next shortest distance is between Te2 and Te1 and is in the nonbonding range of 3.667(1) Å. Te–Te bonds exist in the related layered structure of CuTe, which formally is better described as $(Cu^{+})_n(Te_n^{n-})$ rather than $(Cu^{2+})(Te^{2-})$. The structure of the $[Cu_5Te_5]_n^{2n-}$ layers can be rationalized as being derived from that of CuTe by reduction with 0.4 electrons. This reduction breaks some of the Te–Te bonds in CuTe. Further reduction by one electron breaks all the Te–Te bonds and gives rise to the ideal anti-PbO structure type found in NaCuTe.[11] Thus, $[Cu_5Te_5]_n^{2n-}$ is a true intermediate oxidation state compound between CuTe and $[CuTe]_n^{n-}$ (Fig. 2). The square-pyramidal geometry around Te1 and Te3 in $K_2Cu_5Te_5$ and their comparable average Cu–Te distances (2.61(3) Å for Te1, 2.63(9) Å for Te3) suggest indistinguishable oxidation states on Te1 and Te3 even though they are crystallographically distinct atoms. $K_2Cu_5Te_5$ can therefore be reasonably formulated as $(K^{+})_2(Cu^{+})_5(Te_2^{2-})_2(Te^{-1.67})_3$. Of course these are only formal oxidation states. The actual description is more complex due to the small electronegativity difference between the Cu and Te atoms. The geometry around K1 is square prismatic and the average K–Te distance is 3.63(5) Å.

Electrical conductivity and thermopower measurements on several single crystals of $K_2Cu_5Te_5$ show that it is a p-type metallic conductor within the temperature range 5–300 K (Fig. 3). The conductivity increases from 1.5×10^4 Scm^{-1} at room temperature to 3.2×10^5 Scm^{-1} at 5 K. The p-type conductivity is expected in view of the band filling argument advanced above.

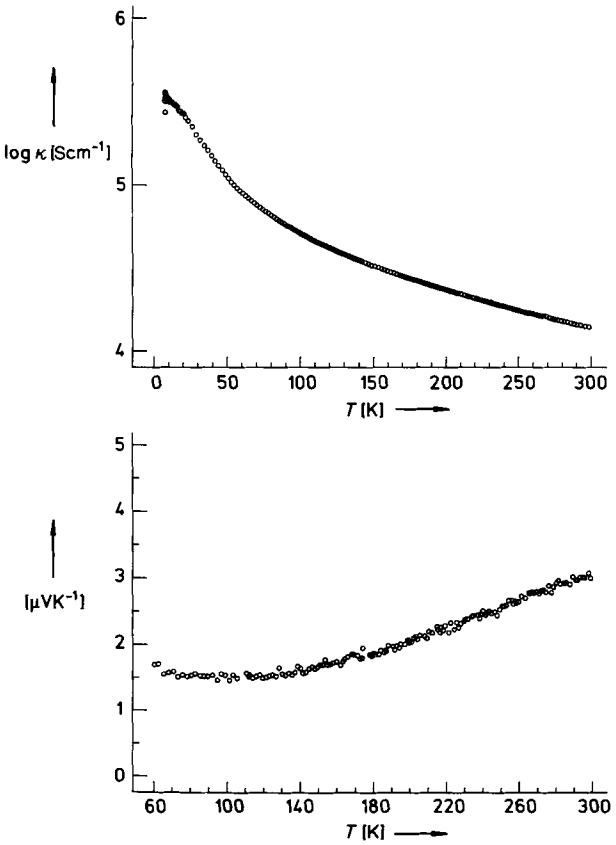

Fig. 3. Top: Four probe electrical conductivity (Scm^{-1}) data as a function of temperature for a single crystal of $K_2Cu_5Te_5$. Bottom: Thermoelectric power data as a function of temperature for a single crystal of $K_2Cu_5Te_5$. The measurements were made parallel to the *ac* plane.

Magnetic susceptibility data for $K_2Cu_5Te_5$ in the temperature range 2–300 K are shown in Figure 4. When plotted as

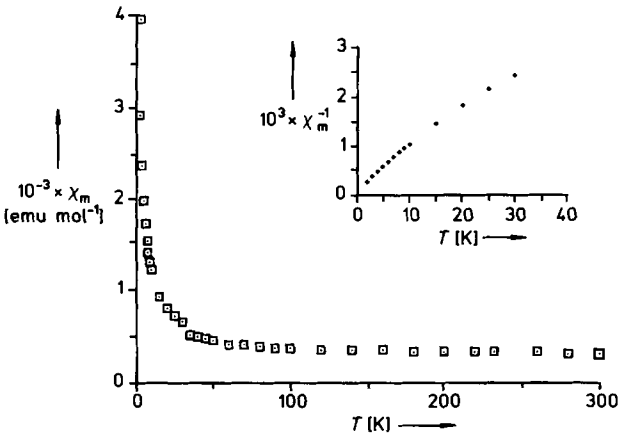

Fig. 4. Variable-temperature magnetic susceptibility data χ_m for polycrystalline $K_2Cu_5Te_5$. Insert: χ_m^{-1} [molemu^{-1}] vs. T.

χ^{-1} vs temperature (see insert), the data above 30 K show temperature-independent paramagnetism, while below 30 K the data follow a Curie–Weiss Law. This behavior is characteristic of metals (Pauli paramagnetism) containing a low concentration of paramagnetic impurities. The calculated Pauli paramagnetism is 25.6×10^{-5} emu mol^{-1}.[22]

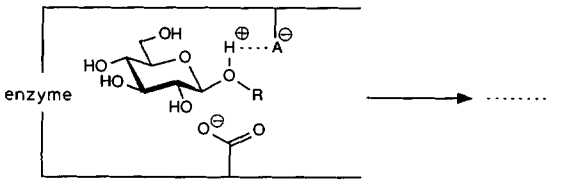
Amino-substituted β-Benzyl-*C*-glycosides; Novel β-Glycosidase Inhibitors

By *Richard R. Schmidt** and *Hansjörg Dietrich*

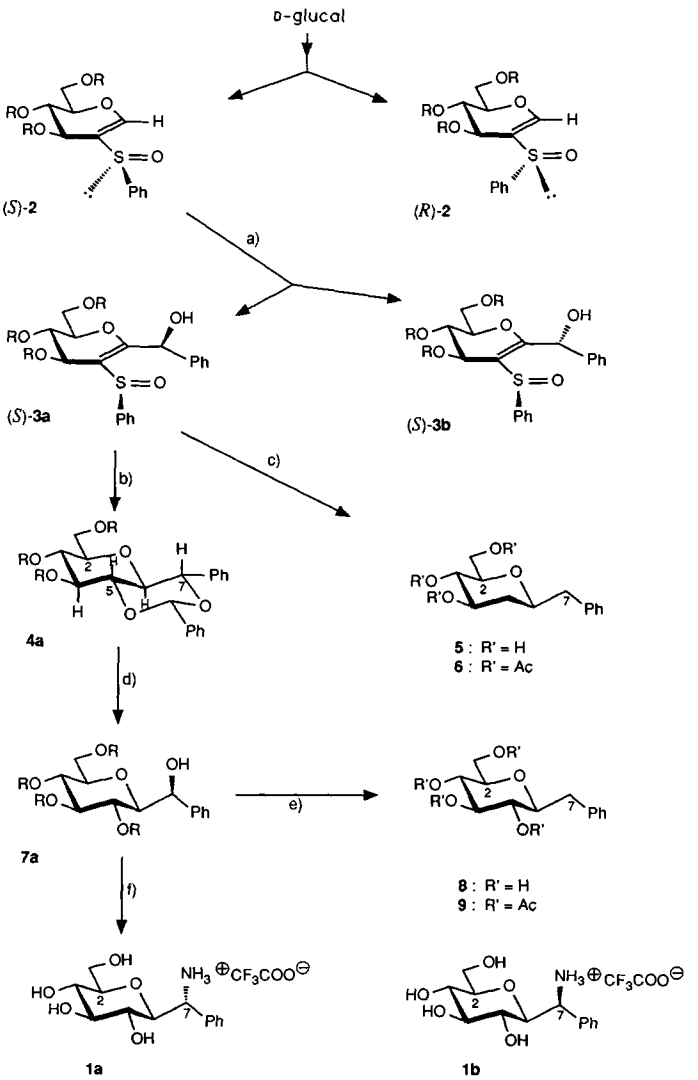
Glycosides and saccharides fulfill many biological functions; they serve as protective and skeletal substances, and as nutritional and reserve foodstuffs, they are components of nucleic acids, and they occur on the surfaces of cell membranes in the form of complex glycoconjugates.[1, 2] Biosynthesis and degradation of the saccharide chain are accomplished by complicated enzyme systems. Interference of the glycosidase-catalyzed degradation by specific enzyme inhibitors therefore allows conclusions to be drawn about the function of the carbohydrates and a planned modification of this function. High and low molecular weight glycosidase inhibitors have been found.[3] The low molecular weight inhibitors such as cyclites, mono- and oligosaccharides, and alkaloids provide a wide field of interest for chemistry, biology, and medicine, because α-glycosidase inhibitors might be effective against virus diseases. For instance, activity against HIV viruses has been found for the very potent glycosidase inhibitors, 1-deoxynojirimycin and castanospermine.[4, 5] Another excellent glycosidase inhibitor is acarbose, which is used in the treatment of diabetes.[3, 6]

The inhibitory action of these substances, which are similar to substrates or intermediates, respectively, is attributed particularly to the interaction of the amine nitrogen atom of the inhibitor with the acid groups AH of the active site of the enzyme, which initiates the hydrolysis of the glycoside bond of the substrate or (as carboxylate anion) stabilizes the glycosyl cation (Scheme 1).[7] Because phenylglycosides are often



Scheme 1.

accepted as substrates by glycosidases, we planned to prepare novel amino-substituted β-benzyl-*C*-glycosides of the structure **1a, b** (Scheme 2) as potential β-glucosidase inhibitors. Their inhibitory action should be compared with



Scheme 2. R = Benzyl. a) LDA, THF/hexamethylphosphoric triamide (HMPT), −100 °C; PhCHO (86%); (*S*)-**3a**:(*S*)-**3b** ≈ 4:1. b) 1. that of the *C*-glucoside derivatives not substituted at the benzyl group.

The direct C1 lithiation of the 2-phenylsulfinyl substituted glycals (**2**, readily obtained from D-glucal,[8, 9] Scheme 2) was used to synthesize the *C*-glucosides. Thus the C1-lithiated species was formed from the *S* isomer, (*S*)-**2**, with lithium diisopropylamide (LDA) in THF/HMPT at $-100\,^{\circ}C$ and subsequent reaction with benzaldehyde afforded an easily separable mixture of diastereomers, (*S*)-**3a** and (*S*)-**3b** (ca. 4:1, 86%) (Table 1). Treatment of the major product (*S*)-**3a** with Raney nickel W II and thereafter with hydrogen in the presence of Pd/C as catalyst yielded directly, through loss of the *O*-benzyl protecting groups and the benzylic hydroxy group, the dideoxy derivative **5**, whose structure was ascertained by *O*-acetylation to form **6**. If borane addition and alkaline oxidation with hydrogen peroxide followed the Raney nickel treatment, which causes the cleavage of the phenylsulfinyl group, a 5,7-dihydroxy derivative was obtained stereoselectively. Its structure was determined by ^1H NMR spectroscopy after transformation into the benzylidene derivative **4a** ($J_{4,5} = J_{5,6} = J_{6,7} = 9$ Hz. The reductive opening of the benzylidene group with $LiAlH_4/AlCl_3$ proceeded chemoselectively and afforded the 1,3,4,5-tetra-*O*-benzyl derivative **7a**. Here the hydrogenolytic *O*-debenzylation yielded the deoxy compound **8** directly and the derivative **9** on *O*-acetylation. The target molecule **1a** was obtained in good yield from **7a** by 7-*O*-mesylation, introduction of azide with tetrabutylammonium azide, release of the amino group by reduction with $LiAlH_4$, introduction of a *tert*-butoxycarbonyl(Boc) protecting group, hydrogenolytic *O*-debenzylation, and acid-catalyzed cleavage of the Boc protecting group. Compound **1a** was isolated as trifluoroacetate. The diastereoisomer **1b** was synthesized analogously from (*R*)-**2** via (*R*)-**3b** (the transformation with benzaldehyde afforded (*R*)-**3a** and (*R*)-**3b** in a 1:4 ratio and 94% yield) and the intermediates **4b** and **7b** (diastereomeric to **4a** and **7a**).

Table 1. Selected physical data of the compounds **4a**, **6**, **9**, and **1a**, **b** [a].

4a: $[\alpha]_D + 22.5$ ($c = 1.0$, $CHCl_3$); $\delta_H = 3.28$ (dd, $J_{5,6} = J_{6,7} = 9.0$ Hz; H-6), 3.77 (dd, $J_{2,3} = J_{3,4} = 9.5$ Hz; H-3), 3.86 (dd, $J_{4,5} = 9.0$ Hz; H-4), 3.92 (dd, $J_{4,5} = J_{5,6} = 9.0$ Hz; H-5), 4.79 (d, $J_{1,2} = 9.0$ Hz; H-7).
6: $[\alpha]_D + 10.1$ ($c = 1.0$, $CHCl_3$); $\delta_H = 2.72$ (dd, $J_{6,7'} = 6$, $J_{7,7'} = 13.8$ Hz; H-7'), 2.98 (dd, $J_{6,7} = 6$, $J_{7,7'} = 13.8$ Hz; H-7), 3.56 (ddd, $J_{1,2} = 5.2$, $J_{1',2} = 2.3$, $J_{2,3} = 9.6$ Hz; H-2), 3.68 (dddd, $J_{5a,6} = 11.4$, $J_{5e,6} = 1.9$, $J_{6,7} = 6$, $J_{6,7'} = 6$ Hz; H-6); 4.07 (dd, $J_{1,1'} = 12.1$, $J_{1',2} = 2.3$ Hz; H-1'), 4.26 (dd, $J_{1,1'} = 12.1$, $J_{1,2} = 5.2$ Hz; H-1), 4.90–4.98 (m; H-3,4).
9: $[\alpha]_D - 4.6$ ($c = 1.0$, $CHCl_3$); $\delta_H = 3.59$ (ddd, $J_{1,2} = 5.2$, $J_{1,2} = 2.4$, J_2,3 = 9.9 Hz; H-2), 3.66 (ddd, $J_{5,6} = 9.8$, $J_{6,7} = 6.5$, $J_{6,7'} = 5.6$ Hz; H-6), 4.95 (dd, $J_{4,5} = J_{5,6} = 9.4$ Hz; H-5), 5.04 (dd, $J_{2,3} = J_{3,4} = 9.4$ Hz; H-3), 5.18 (dd, $J_{3,4} = J_{4,5} = 9.4$ Hz; H-4).
1a: $[\alpha]_D - 9.4$ ($c = 1.0$, H_2O); $\delta_H = 3.27$–3.31 (m, 4H; H-2,3,4,5), 3.56–3.68 (m, 2 H; H-1',6), 3.74 (d, $J_{1,1'} = 12.0$ Hz; H-1), 4.49 (d, $J_{6,7} = 4.5$ Hz; H-7), 7.27–7.33 (m, 5H; C_6H_5).
1b: $[\alpha]_D + 20.8$ ($c = 1.0$, H_2O); $\delta_H = 2.63$ (dd, $J_{4,5} = J_{5,6} = 9.5$ Hz; H-5), 2.88 (dd, $J_{2,3} = J_{3,4} = 9.5$ Hz; H-3), 3.24–3.32 (m, 2H; H-2, 4), 3.48 (dd, $J_{1,1'} = 12.1$, $J_{1,2} = 7.5$ Hz; H-1), 3.64 (dd, $J_{5,6} = 9.5$, $J_{6,7} = 3.2$ Hz; H-6), 3.76 (dd, $J_{1,1'} = 12.1$, $J_{1',2} = 1.9$ Hz; H-1'), 4.56 (d, $J_{6,7} = 3.1$ Hz; H-7), 7.24–7.34 (m, 5H; C_6H_5).

[a] Optical rotations recorded at 20 °C, ^1H NMR spectra at 250 MHz in $CDCl_3$ (**4a**, **6**, **9**) or D_2O (**1a**, **b**).

For the inhibition studies, the cleavage of *O*-nitrophenyl-β-D-glucoside with β-glucosidase (cellobiase) from sweet almonds[10] was employed.[11] The resulting types of inhibition and the inhibition constants (K_i) are listed in Table 2. It is remarkable that the amino compound **1a** yields a K_i value similar to that of 1-deoxynojirimycin. The diastereomer **1b**, however, has an enzyme affinity two orders of magnitude smaller. This observation gives an indication of the relative position of the acid groups (AH) of the active site of the enzyme which participate in the glycoside cleavage. The K_i values of the deoxy compounds **5** and **8** lie in the same region as that of **1b**.

Table 2. Type of inhibition and inhibition constants (K_i) [a].

compound	pH	T [°C]	inhibition type	K_i [M]
1-deoxynojirimycin	6.8	27	competitive	1.8×10^{-5} [b]
1a	6.8	30	competitive	7.0×10^{-5} [c]
δ-gluconolactone	6.2	27	competitive	2.0×10^{-4} [b]
5	6.8	30	competitive	2.6×10^{-3}
8	6.8	30	mixed	6.1×10^{-3}
1b	6.8	30	competitive	7.6×10^{-3}
D-glucal	6.2	27	competitive	2.0×10^{-2} [b]
cellobiose	6.2	27	(substrate)	6.3×10^{-1} [b]

HETLOC, an Efficient Method for Determining Heteronuclear Long-Range Couplings with Heteronuclei in Natural Abundance**

By *Michael Kurz*, *Peter Schmieder*, and *Horst Kessler**

Heteronuclear long-range couplings such as $^3J(C,H)$ and $^3J(N,H)$ are among the most important NMR parameters

[*] Prof. Dr. H. Kessler, Dipl.-Chem. M. Kurz, Dipl.-Chem. P. Schmieder Organisch-Chemisches Institut der Technischen Universität München Lichtenbergstrasse 4, W-8046 Garching (FRG)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. *Peter Schmieder* thanks the Fonds der Chemischen Industrie for a fellowship.

for determining conformation and configuration.[1] However, their intensive use has been hindered by the difficulty in measuring them. Either the sensitivity of the existing methods of determination[2] is too low or the methods are limited to well-resolved proton spectra. Here we propose a procedure that can be used to determine the couplings to proton-bearing heteroatoms without the disadvantages mentioned above and without the necessity of a cumbersome enrichment of the heteronucleus (^{13}C, ^{15}N).

An efficient method for determining these long-range couplings should meet the following requirements: highest sensitivity, applicability to overlapped proton and carbon signals, and measurement of the coupling constants within the detection time (dimension with the better resolution). All of these conditions are fulfilled by the method of *Montelione* et al.,[3] in which an E. COSY pattern[4] is obtained in the conventional TOCSY or NOESY spectra of *isotopically enriched* proteins. In the incremented dimension ($F1$ in 2D spectra, $F2$ in 3D spectra), the cross peaks show the direct, large coupling to the heteronucleus ($^1J(C,H)$, $^1J(N,H)$) and, in the detected dimension ($F2$ in 2D spectra, $F3$ in 3D spectra), they show the desired heteronuclear long-range coupling to the same heteronucleus through the shift of the multiplet. In this way, coupling constants smaller than the line widths may be measured.

In order to determine couplings to nuclei in *natural abundance*, it is necessary to suppress the signals of protons that are not bonded to a magnetically active heteronucleus. We suggest the use of a ω_1 hetero half-filter,[5] which selects for such nuclei in $F1$ via the phase cycle. The pulse sequences are shown in Figure 1. BIRD presaturation[6] of the protons bonded to ^{12}C allows a rapid pulse sequence[7] (ca. two scans per second). The resulting 2D spectra are TOCSY spectra in which the cross peaks show the desired "E. COSY" pattern. The pulse sequence b in Figure 1 is the three-dimensional variant[8] in which the chemical shift is allowed to evolve

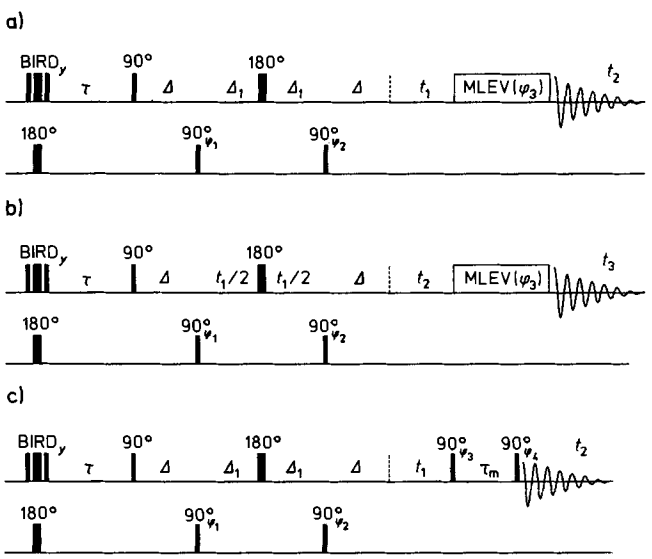

Fig. 1. Pulse sequences of the NMR experiments discussed in the text. a) ω_1 hetero half-filtered TOCSY without heteronuclear decoupling (HETLOC, determination of *het*eronuclear *l*ong-range *c*ouplings). b) 3D HMQC-TOCSY without heteronuclear decoupling. c) ω_1-filtered NOESY without heteronuclear decoupling. In all sequences, the BIRD pulse serves to suppress the signals of C^{12}-bonded protons and makes it possible to perform the experiment rapidly with two repetitions per second. The delay times are $\Delta = 3.57$ ms, $\Delta_1 = 3$ μs; τ has to be optimized for each compound. The phase cycle is $\Phi_1 = x, -x, x, -x$, $\Phi_2 = x,x, -x, -x$, receiver = +,−,−,+. In (c), the phase cycle corresponds to the phases Φ_3 and Φ_4 in the usual NOESY experiment. In the case of TOCSY transfer, MLEV-17 was used as mixing sequence.

further. This technique is especially applicable for overlapping signals. However, the method proposed here is restricted to systems in which the heteronucleus is bonded to a proton belonging to the same spin system as the $^nJ(H,X)$-coupled proton. If this is not the case, then the NOE cross peaks obtained with the pulse sequence shown in Figure 1 can be used: for example, between the amide proton of an amino acid and H^α of the preceding amino acid. For small molecules, however, the sensitivity is limited by the efficiency of the NOE mixing process.

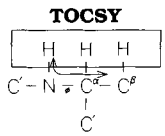

Fig. 2. Schematic representation of the determination of $^3J(H^N,C^\beta)$ in a peptide. H^N is linked to H^β through the TOCSY transfer. If ^{13}C-bonded H^β is selected for in the experiment, the H^N show long-range coupling to C^β.

The method to obtain $^nJ_{AX}$ is illustrated here to determine the Φ angle in peptides, the dihedral angle between the two carbonyl C atoms along the peptide chain. Figure 2 shows that the $^3J(H^N,C^\beta)$ coupling, just like the homonuclear $^3J(H^N,H^\alpha)$ coupling, is correlated with the angle Φ through a Karplus relation. The relevant Karplus–Bystrov relations

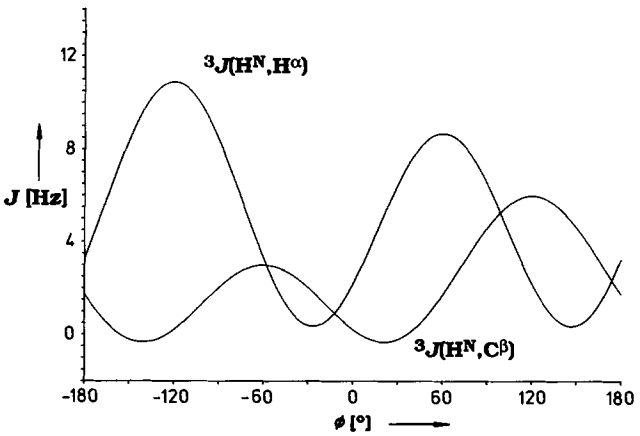

Fig. 3. Graphical representation of the Karplus–Bystrov relations (a) and (b). The curves shown pertain to the middle of an allowed range.

are given in Equations (a) and (b).[9] A graphical representation is shown in Figure 3.

$$^3J(H^N,H^\alpha) = 9.4\cos^2(\phi - 60) - 1.1\cos(\phi - 60) + 0.4 \quad \text{(a)}$$

$$^3J(H^N,C^\beta) = 4.7\cos^2(\phi + 60) - 1.5\cos(\phi + 60) - 0.2 \quad \text{(b)}$$

This approach will be exemplified with the cyclic pentapeptide *cyclo*(-Ala^1-Ala^2-Ala^3-Pro^4-Pro^5-), which exists in two conformations (53 and 47 %). Figure 4a shows the H^N, H^β region of the ω_1 hetero half-filtered TOCSY (HETLOC) spectrum. The cross peak of Ala^2-H^N in Figure 4a clearly reveals the E. COSY pattern.[4] Coupling constants can be determined either directly from the cross peak or, analogously to the DISCO procedure,[10] from slices through the spectrum (Fig. 4c).

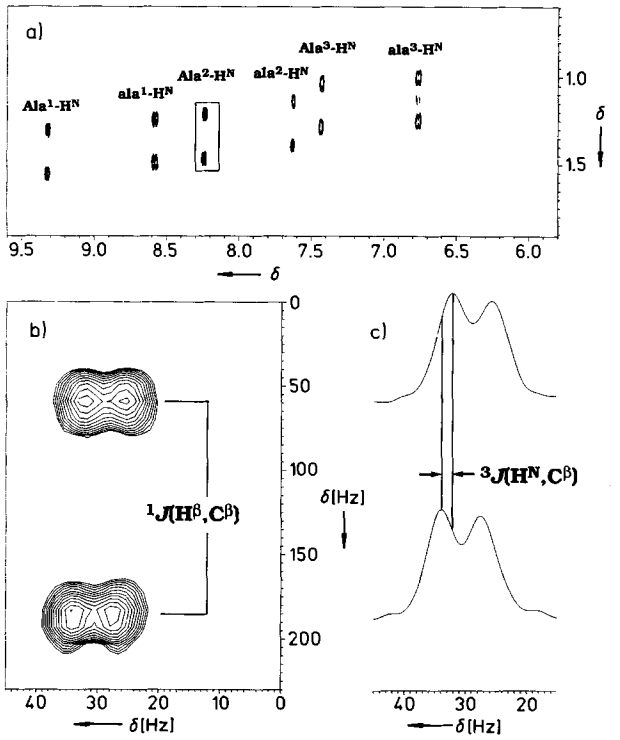

Fig. 4. Application of the pulse sequence shown in Figure 1a to the cyclic pentapeptide *cyclo*(-Ala[1]-Ala[2]-Ala[3]-Pro[4]-Pro[5]-). The sample contains 10 mg of peptide in 0.5 mL of [D_6]DMSO (ca. 25 mM per conformation); the measurements were carried out at 300 K with a Bruker AMX-500 spectrometer. 512 t_1 increments with 128 repetitions each were carried out ($\tau = 198$ ms, $\Phi_3 = x$); the total measuring time was 9.5 hours. 4096 points were recorded in the acquisition dimension; the spectrum was apodized in both dimensions with a 90°-shifted quadratic sine function and, after the calculation, had a size of 8192 × 1024 real points. a) Region of the H^N, H^β cross peaks of the ^{13}C ω_1-filtered TOCSY spectrum. b) Cross peaks of Ala[2]; the E. COSY pattern is clearly evident. c) Two slices through the cross peak of (b); the slices were inverse Fourier transformed, zero-filled, and Fourier transformed once again. The shift of the signals with respect to one another gives the long-range coupling.

Table 1 compares the angles obtained from both couplings. Combination of the two relations allows the number of possible angles to be reduced to one or two. The final determination can be made by using two additional long-range couplings, $^3J(H^N, C'_{(i)})$ and $^3J(H^\alpha, C'_{(i-1)})$, which need to be determined only qualitatively from a selective HMBC experiment.[11] The possible angles thus determined are given in boldface in Table 1; they are in good agreement with those obtained from MD simulations.

The experiment presented here provides a simple method for determining heteronuclear coupling constants. For the determination of structures in solution by NMR spectroscopy, these coupling constants are a valuable adjunct to the distances obtained from NOESY spectra.

Table 1. Coupling constants [Hz] and corresponding angles [°] for the three alanines in *cyclo*(-Ala[1]-Ala[2]-Ala[3]-Pro[4]-Pro[5]-) for the major and minor conformers (Ala and ala, respectively).

	$^3J(H^N,H^\alpha)$	→ angle	$^3J(H^N,C^\beta)$	→ angle	MD angle [a]
Ala[1]	8.0	−153, −87, 44, **76**	2.0	−90, −30, **63**, 177 [b]	63
Ala[2]	6.7	−160, −**80**, 32, 88	3.0	−**60**, 73, 167 [c]	−99
Ala[3]	6.6	−161, −**79**, 31, 89	2.5	−**81**, −39, 68, 172 [c]	−67
ala[1]	9.6	−**141**, −**99** [d]	0.2	−160, −**120**, 0, 40	−95
ala[2]	5.6	−167, −**73**, 24, 96	2.6	−**79**, −41, 69, 171 [c],	−51
ala[3]	10.0	−**137**, −**103** [d]	0.4	−163, −**117**, −3, 43	−100

[a] From restrained MD simulation with GROMOS [12] over 100 ps in vacuum. Eighteen and seventeen distances were used for the major and minor conformer, respectively. [b] Because of a very intense cross peak between the carbonyl C atom of the preceding amino acid and Ala[1] H^α, the alternative (−87°/90°) can be ruled out. [c] Owing to the weak or absent cross peak between the carbonyl C atom of the preceding amino acid and H^α of the amino acid being considered, the alternative with positive Φ angle (88°/73°, 89°/68°, or 96°/69°) can be ruled out. [d] Both angles determined from the $^3J(H^N, H^\alpha)$ coupling constants are consistent with the angles in boldface determined from the $^3J(H^N, C^\beta)$ relation. A more precise distinction is not possible, not even by using the other two long-range couplings, $^3J(H^N, C'_{(i)})$ and $^3J(H^\alpha, C'_{(i-1)})$.

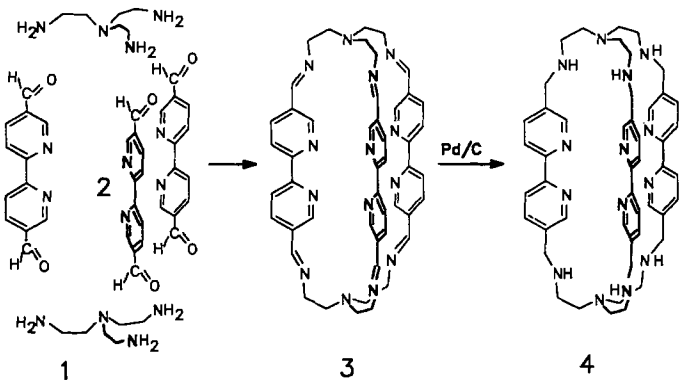
[**] This work was supported by Comisión Interministerial de Ciencia y Tecnologia (CICYT PB87-0109), by the Bundesministerium für Forschung und Technologie (BMFT-0329120A), by the CNRS (URA422) and by the Academy of Finland (No. 1031002). Since our three groups in Madrid, Bonn, and Strasbourg, supplemented by a Finnish group, had been working independently on this same topic, we decided to publish our results jointly, in a European spirit!

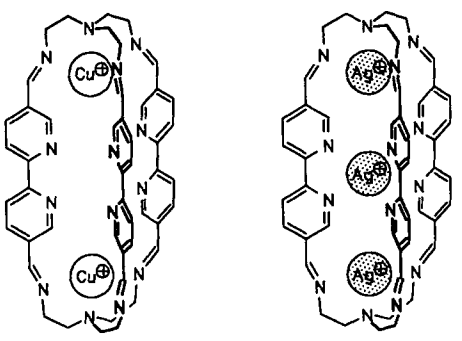
raised an interest in cryptands containing such binding subunits, and several were prepared during the past decade.[2] More recently, an efficient synthetic alternative, based on the high-yield, one-step Schiff base condensation of **1** with suitable dicarbonyl compounds, has been developed.[3] The importance of 2,2′-bipyridine metal complexes in photochemistry, photophysics, and in the splitting of water[4] led us to investigate the synthesis and properties of the cryptand **3**, which incorporates three such subunits and is derived form Tren (**1**) and 5,5′-diformyl-2,2′-bipyridine (**2**).



1 3 4

The dialdehyde **2** was obtained in 50% yield from 5,5′-bis(bromomethyl)-2,2′-bipyridine[5] by a Sommelet reaction or in 93% yield by Swern oxidation[6] of the corresponding dialcohol. Condensation of **2** with **1** under mild conditions gave the macrobicycle **3** in 78% yield. This one-pot cyclization, in which six new bonds are created in a single step to give a cage containing up to 14 nitrogen-donor centers, does not need high-dilution conditions. The cryptand **3** precipitates from the reaction mixture as soon as it is formed. Reduction of **3** with Pd/H_2 afforded the macrobicyclic polyamine **4** (>50% yield).

The dinuclear bis-Cu^I and trinuclear tris-Ag^I complexes **5** (78% yield) and **6** (67% yield) were prepared readily from **3** and two- or threefold molar amounts of $[Cu\text{-}(CH_3CN)_4BF_4$[7] or $AgBF_4$, respectively. The ^1H NMR spectra of these complexes were markedly different from those of the free ligand **3**, all signals being shifted downfield. The strongest effect ($\Delta\delta = 1.23$) was observed for the bipyridine C6 proton in complex **6** (anisotropic effect).



5 6

Crystal structure analyses of the free ligand **3** and its tris-Ag^I complex **6** showed *endo-endo*[8] conformations for the capping Tren units (Fig. 1).

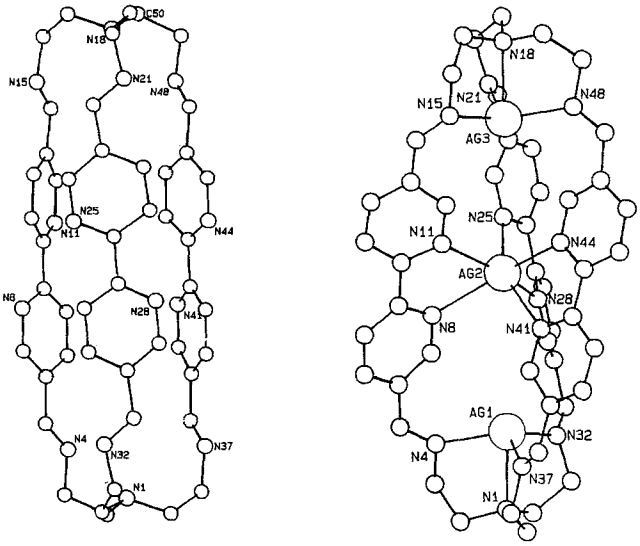


Fig. 1. Crystal structures of ligand **3** (left) and the Ag^I_3 cryptate **6** (right). Bond distances [pm] and bond angles [°] for the trinuclear Ag^I centers of **6**: Ag1-N1 244.6(7), Ag1-N4 231.6(8), Ag1-N32 229.0(9), Ag1-N37 228.0(8), Ag2-N8 250.4(7), Ag2-N11 248.1(6), Ag2-N25 244.4(6), Ag2-N28 250.6(7), Ag2-N41 248.9(6), Ag2-N44 247.7(7), Ag3-N15 229.3(8), Ag3-N18 243.1(7), Ag3-N21 229.9(7), Ag3-N48 229.3(9); Ag3-Ag2-Ag1 176.43(4); N4-Ag1-N1 76.5(3), N32-Ag1-N1 76.2(3), N32-Ag1-N4 113.3(3), N37-Ag1-N1 77.9(3), N37-Ag1-N4 112.2(3), N37-Ag1-N32 119.5(3), N11-Ag2-N8 66.3(2), N25-Ag2-N8 107.6(2), N25-Ag2-N11 99.3(2), N28-Ag2-N8 97.5(2), N28-Ag2-N11 155.7(2), N28-Ag2-N25 67.4(2), N41-Ag2-N8 96.3(2), N41-Ag2-N11 106.0(2), N41-Ag2-N25 150.6(2), N41-Ag2-N28 93.2(2), N44-Ag2-N8 149.1(2), N44-Ag2-N11 93.7(2), N44-Ag2-N25 98.5(2), N44-Ag2-N28 107.9(2), N44-Ag2-N41 65.5(2), N18-Ag3-N15 77.4(3), N21-Ag3-N15 116.1(3), N21-Ag3-N18 76.9(3), N48-Ag3-N15 115.2(3), N48-Ag3-N18 76.4(3), N48-Ag3-N21 113.7(3).

The distances between the bridgehead nitrogen atoms of **3** and **6** are about the same (1470 and 1466 pm, respectively). Similar donor distances in the cryptand and the cryptate (1550 pm) have also been reported for the tris(diphenylmethane) macrobicycle and its dinuclear Cu^I complex.[3a] The C_3 symmetry of the free ligand **3** changes to nearly D_3 symmetry in complex **6** (Fig. 2.). Whereas in **3** the bipyridine

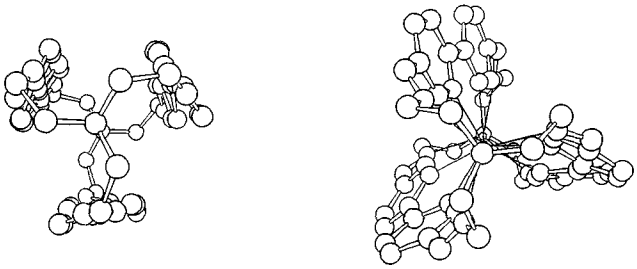

Fig. 2. Crystal structures of **3** (left) and **6** (right) projected along the bridgehead N–N axis.

subunits show the most favored *anti* conformation, which minimizes lone-pair repulsion, all nitrogen atoms are turned inside in **6** for complexing the central Ag^I ion in an almost octahedral way.[9] The torsion angles of the bipyridine units in **3** and **6** are changed from −163.3°, −160.9°, and −166.9° to −21.9°, −27.7°, and 1.0°, respectively. The imino nitrogen atoms are complexed by the Ag^I ions, so that their average N–N distance decreases from 443–452 pm in the free ligand **3** to 382–394 pm in complex **6**. The N–Ag^I distances to the bridgehead centers are 244 and 243 pm, and

the Ag^I–Ag^I distances are 493 and 490 pm. Finally, the N–Ag^I distances to the bipyridine N atoms are 244–251 pm. The coordination sphere around the central Ag^I ion can be regarded as a distorted octahedron, that around each of the two other Ag^I ions as a heavily distorted trigonal pyramid.

A mononuclear[10] and two dinuclear[3a] Ag^I complexes of related macrobicyclic ligands have been reported earlier. The cryptate **6** constitutes the first trinuclear Ag^I complex. The three metal ions are arranged in a row, held at well-defined distances, and bound in two different environments, the central one being a tris-bipyridine Ag^I site. Cryptand **3** offers the possibility of preparing homo- or heterometallic trinuclear metal cryptates that should display different binding, electrochemical, and photophysical properties for the terminal and the central metal ions, making available a range of novel features. For instance, a Cu^I-Ag^I-Cu^I heterodinuclear complex has already been prepared. Further development of the present work will also include the encapsulation of organic substrates inside the cavities of macrobicycles **3** and **4** either as free bases or as protonated and alkylated derivatives.

Experimental Procedures
