Representation in Chemistry

By Roald Hoffmann* and Pierre Laszlo*

Modes of Representation

If you look in old chemistry books
you see
all those line cuts
of laboratory experiments
in cross-section.
The sign for water
is a containing line, the meniscus
(which rarely curls up the walls of the beaker),
and below it
a sea
of straight horizontal dashes
carefully unaligned vertically.
Every cork or rubber stopper
is cutaway.
You can see inside
every vessel
without reflections, without getting wet,
and explore every kink
in a copper condenser.
Flames are outlined cypresses
or a tulip at dawn,
and some Klee arrows
help to move gases and liquids the right way.
Sometimes a disembodied hand
holds up a flask.
Sometimes there is an unblinking observer's eye.

Around 1920
photoengraving
became economically feasible
and took over.
Seven-story distillation columns
(polished up for the occasion),
like giant clarinets,
rose in every text, along
with heaps of chemicals, eventually in color.
Suddenly
water and glass, all reflection
became difficult.
One had to worry about light,
about the sex
and length of dress or cut of suit
of the person sitting at the controls of this impressive
instrument.
Car models and hairstyles
dated the books more
than the chemistry in them.
Around that time
teachers noted a deterioration
in the students' ability to follow
a simple experimental procedure.

Roald Hoffmann[54]

1. Introduction

Chemical structures are among the trademarks of our profession, as surely chemical as flasks, beakers, and distillation columns. When someone sees one of us busily scribbling formulas or structures, he has no trouble identifying a chemist. Yet these familiar objects, which accompany our work from start to end, from the initial doodlings (Fig. 1) to the final polished artwork in a publication (Fig. 2), are deceptively simple. They raise interesting and difficult questions about representation. It is the intent of this article to reflect upon molecular graphics.

We are hooked on these little diagrams, aren't we? Yet what are they? Are they representations of reality, just a

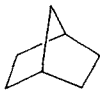
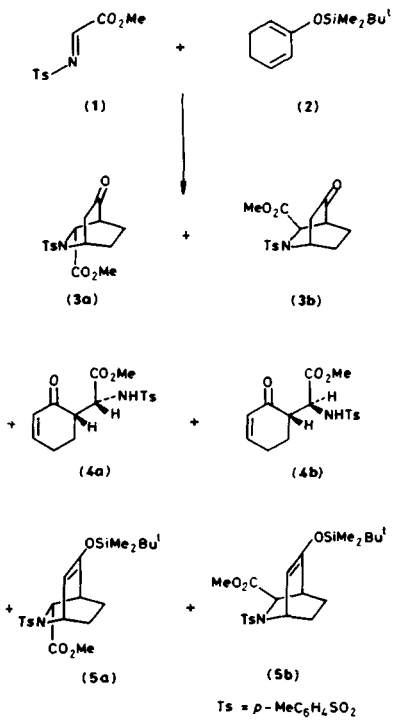
simplified two-dimensional version of the models that can be built from interpretation of X-ray diffraction patterns of a molecular crystal—in a word, are they *realistic*? A look at a few papers by others (not ours or yours, of course) will show how far short of realism these structures fall. They mix convention and realism in the most innocent manner. Take the case of the bicyclo[2.2.1]heptane skeleton (**1**).



1

Roald Hoffmann was born on July 18, 1937, in Zloczow, Poland. Having survived the war, he came to the U.S. in 1949, and studied chemistry at Columbia University and Harvard University (Ph.D. 1962). Since 1965 he has been at Cornell University, where he is now the John A. Newman Professor of Physical Science. He has received many of the honors of his profession, including the 1981 Nobel Prize in Chemistry (shared with Kenichi Fukui). "Applied theoretical chemistry" is the way Roald Hoffmann likes to characterize the particular blend of computations stimulated by experiment and the construction of generalized models, of frameworks for understanding, that is his contribution to chemistry. Roald Hoffmann also writes essays and poems. Two of his poetry collections, "The Metamict State" (1987) and "Gaps and Verges" (1990), have been published by the University Presses of Florida. He also is the presenter of a television course, "The World of Chemistry", which began to be aired on many U.S. educational television stations in the fall of 1990.

Pierre Laszlo was born on August 15, 1938, in Algiers. He went to school in Grenoble, Rio de Janeiro, and Paris and studied science at the Sorbonne (Ph.D. 1965 with E. Lederer) and Princeton (research associate, 1962–1963, with P. von R. Schleyer). After a postdoctoral appointment at Orsay, he became Assistant Professor at Princeton (1966–1970). Since 1970, he has been Professor of Physical Organic Chemistry at the Université de Liège (Belgium). In addition, he has been a professor at the Ecole Polytechnique in Palaiseau (France) since 1986. Pierre Laszlo has been a guest professor at numerous universities and has received a number of awards, including the Prix Biennal de la Sociéte Chimique de Belgique (1981). His main areas of research are NMR spectroscopy, carrier-bound reagents, and physical organic chemistry. He has published roughly 200 papers and is also the author or editor of seven books. His hobby is the translation of Petrarca's poems into French. In addition, he writes literary criticism.



The results of a systematic variation of solvent, temperature, and Lewis acid on the outcome of the reaction of (**1**) with (**2**) resemble the pattern reported for the trimethylsilyl analogue of (**2**), but with several important differences. Firstly, the *exo*/*endo* ratio of bicyclic adducts derived from (**2**) is greater than that for the trimethylsilyl analogue, and secondly, there is a corresponding greater preference for (**4a**) over (**4b**). Under certain low temperature conditions only cyclohexenone products (**4a,b**) and no bicyclic products were obtained. Hydrolysis of the hindered bicyclic silyl enol ether (**5a**) under relatively forcing conditions (AcOH–THF, 50 °C) barely produced any retro-Michael product (**4b**). These observations are consistent with (**3a**) and (**5a**) being derived from a [2 + 4] transition state in which the unfavourable steric interaction between the *N*-tosyl and t-butyldimethylsilyl groups is minimised,[5] while (**4a**) is derived from an open transition state in which the bulky silyl substituent avoids the steric clash with the ester group of the imine (**1**). Thus the proposed mechanism (c) in the previous paper,[1] involving a dual pathway explanation[6] for the origin of bicyclic and monocyclic products, seems to be supported in the present study.

We thank the S.E.R.C. for supporting this work, Merck, Sharp and Dohme, Harlow for a CASE award (A. B. T.), and Clare College for financial support (T. N. B.) and the award of the Denman Baynes Studentship (A. B. T.).

Received, 11th May 1988; Com. 8/01856A

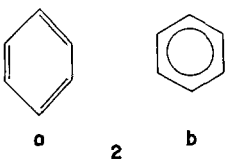
This commonly seen, supposedly three-dimensional representation actually sports an inverted perspective, the vanishing point being not in back, where it should be, but on the viewer's side. Most chemical drawings eschew obvious primitive artistic stratagems for communicating three-dimensionality; they float in a world of their own.

Perhaps they are "art", then, an abstraction from reality of the essence of norbornanes. If so, it's interesting to reflect on what kind of art they are. This is part of what we will do.

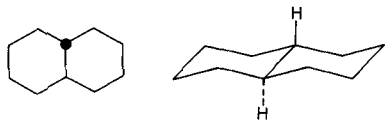
Perhaps chemical drawings do not need to be realistic representations because they are symbols, signs, that in a chemist's mind are reconstructed into the three-dimensional structure, or at least the ball-and-stick model. Chemical structures are then part of a chemical language. What is interesting about language (it doesn't matter whether it is German or English or ...) is that (1) despite its impreciseness, people communicate with it and (2) it, language, inevitably brings us complications, ambiguities and richnesses that we did not expect. Or perhaps that we subconsciously intended.

We both studied chemistry at a time when elongated benzene rings (**2a**) went out of fashion. Two arguments can be made about this iconic upheaval. True, the old way did not prevent incredible progress in synthetic organic chemistry, nor the perceptive theorizing of *Hückel*. On the other hand, the new and assuredly more accurate representation by a



regular hexagon (**2b**) did not serve only a cosmetic and PR purpose for the novel, powerful physical organic and theoretical chemistries associated with names such as *Saul Winstein* and *Charles Coulson*. It beaconed a change of focus, however subtle. This was the same time, remember, when conformational analysis came into general use. After decades of estrangement, structural chemistry and reactivity studies were coming back under the same roof. The writing of a structure is not innocent. It is ideology-laden. It carries, besides its face value, another message; in this case, the modern reunification of the theoretical and the experimental.

The ability to see a conformation behind a constitution, so that the set of symbols **3** is understood by an organic chemist as **4**, engages two types of skills. The imagination, the visual ability to perceive a shape in three-dimensional space runs second to *translation*. To go from the first, "flat" set of symbols, to the second, "skewed" set of symbols is equivalent to switching from one language (the word "science") to another



3 4

(the word "Wissenschaft"). This example drives home how much of a linguistic component there is in the thought processes of chemists, as activated by these small sketches that we call chemical structures. Part of our paper deals explicitly with chemical structures as constituting a language.

2. The Shapes of Molecules and How They Are Communicated

When we wish to probe something which is so ingrained in us that it is second nature (as the structural formula is), it is useful to put oneself outside. Imagine telling someone intelligent, attentive, and sympathetic, but someone who is not a chemist, about structure and its communication in our science. Here is what we might say:[1]

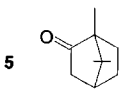
Shape matters in chemistry. Two molecules as subtly different from each other as a left hand is from a right, may have quite different physical, chemical, and biological properties. Thus, the mirror image of carvone, the main component of oil of spearmint, smells of caraway. The arrangement of atoms in space is not just a laboratory curiosity, it can be a matter of life or death. Thalidomide, a sedative of the early sixties, was responsible for thousands of fetal malformations in Europe. The pharmaceutical marketed was a mixture of left- and right-handed mirror image molecules. One form was teratogenic, causing malformation, its mirror image was not. Had this been known at the time, great anguish and human loss could have been prevented.[2]

Molecules are made up of atoms. (Forgive us, chemist friends; we're still continuing our hypothetical monologue directed at the nonchemist.) But molecular structure is not just the identity of the atoms. Or even how they are connected up, those elemental atomic building blocks within the molecule. At the operative level of modern chemistry, structure means the three-dimensional arrangement of atoms in space.[3] It is a graph, at the very least, a three-dimensional set of points connected by lines called bonds.

It is critical that chemists easily communicate this structural information among themselves. Via what's at hand, which are two-dimensional media—paper, a screen. The information is complex—many atoms, many bonds, a richness of geometrical structure. The information is at some important level inherently graphic—it is essentially a shape to be drawn. And now we come to the crux of the matter. The group of professionals to whom this visual, three-dimensional information is essential are not talented (any more, any less) at transmitting such information. Chemists are not selected, do not select themselves, for their profession on the basis of their artistic talents. Nor are they trained in basic art technique. The authors' ability to draw a face so that it looks like a face atrophied at age ten.

So how do they do it, how do we do it? With ease, almost without thinking, but, as we will see, with much more ambiguity than we, the chemists, think there is. The process is *representation*, a symbolic transformation of reality. It is both *graphic* and *linguistic*. It has a *historicity*. It is *artistic* and *scientific*. The representational process in chemistry is a shared code of this subculture.

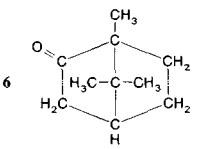
Let us begin our look at the process by a look at the outcome. This was shown in Figure 2, a typical page from a modern chemical article. The substantial amount of graphic content just stares one in the face. There are little pictures here. Lots of them. But the intelligent observer who is not a chemist is likely to be stymied. He finds himself in a situation analogous to that of *Roland Barthes* on his first visit to Japan, beautifully described in his "The Empire of Signs".[4] What do these signs mean? We know that molecules are made of atoms, but what is one to make of a polygon such as structure **5**, here representing a white, waxy medicinal



5

compound with a penetrating aroma, camphor?[*] Only one familiar atomic symbol, O for oxygen, emerges.

Well, it's a shorthand. Just as the military man gets tired of saying Commander in Chief, South Pacific Operations, and writes CICSPO, so the chemist tires of writing all those carbons and hydrogens, ubiquitous elements that they are, and draws the carbon skeleton. Every vertex and endpoint that is not specifically labeled otherwise in structural representation **5** of camphor is carbon. Since the valence of carbon (the number of bonds it forms) is typically four, chemists privy to the code will know how many hydrogens to put at each carbon. The polygon drawn above is in fact a graphic shorthand for structure **6**.

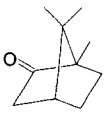


6

But is **6** the true structure of the molecule of camphor? Yes and no. At some level it is. At another level the chemist wants to see the three-dimensional picture, and so draws **7**. At still

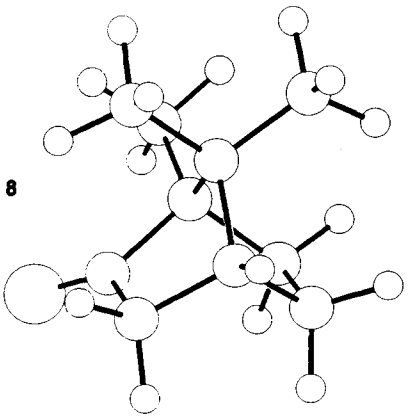
[*] A further story needs to be told of camphor. We picked this molecule as one recognizable to the public, but carrying within it minimal complexities of representation. One of us (*R. H.*), having forgotten its structure, checked it in a textbook, then specified to some friends the geometry needed to produce the beautiful drawings of camphor in this paper. Every one of them was the mirror image of what you see, which is the naturally occurring, dextrorotatory material (1*R*,4*R* in configuration)! That we had the wrong absolute configuration was pointed out to us by a careful reader, *Ryoji Noyori*, the 1990 Baker Lecturer at Cornell. A literature search then revealed the wrong configuration disported by many, if not most textbooks, the Merck Index, and numerous literature papers, such as the important one by *G. M. Whitesides* and *D. W. Lewis*, (*J. Am. Chem. Soc* 92 (1970) 6979) on the use of an NMR shift reagent to determine enantiomeric purity. The structure is correctly given in the Sigma, Aldrich, and Fluka catalogues and the references to the assignment may be found in the following handbook: W. Klyne, J. Buckingham: *Atlas of Stereochemistry, Vol. 1*, Chapman and Hall, London 1978, p. 85.

7

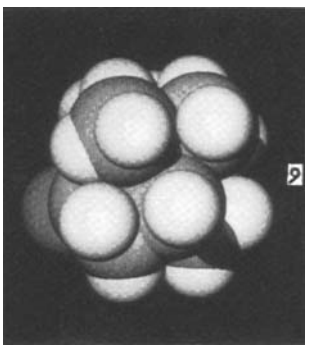


another level, he or she wants to see the "real" interatomic distances, that is, the molecule drawn in its correct proportions. Such critical details are available, with a little money, a little work, by a technique called X-ray crystallography. And so we have a drawing **8**, likely to have been produced by a computer.[5]

8



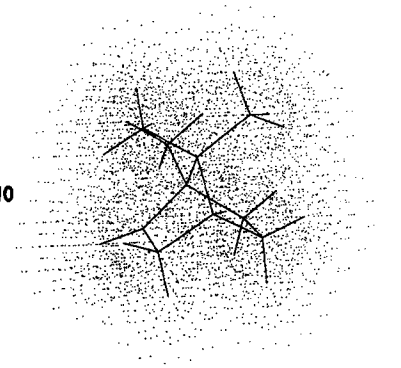
This is a view of a so-called ball-and-stick model, perhaps the most familiar representation of a molecule in this century. The sizes of the balls representing the carbon, hydrogen, and oxygen atoms are somewhat arbitrary. A more "realistic" representation of the volume that the atoms actually take up is given by the "space-filling" model **9**. Note that in



9 the positions of the atoms, better said of their nuclei, become obscured. And neither **8** or **9** is portable. It cannot be sketched by a chemist in the 20 seconds that a slide typically remains on a screen in the rapid-fire presentation of the new and intriguing by a visiting lecturer.

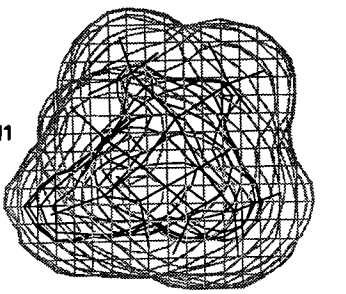
The ascending (descending?) ladder of complexity in representation hardly stops here. Along comes the physical chemist to remind his or her organic colleagues that the atoms are not nailed down in space, but moving in near harmonic motion around those sites. The molecule vibrates; it doesn't have a static structure. Another chemist comes and says: "You've just drawn the positions of the nuclei. But chemistry is in the electrons, you should draw out the chance of finding them at a certain place in space, the electronic distribution." As one tries to do in **10** and **11**.

10



We could go on. The literature of chemistry does. But let's stop and ask: Which of these representations, **5** through **11**, is right? Which *is* the molecule? Well, all are, and none is. Or, to be serious—all of them are models, representations suitable for some purposes, not for others.[6] Sometimes just the name "camphor" will do. Sometimes the formula, $C_{10}H_{16}O$, suffices. Often it's the structure that's desired, and something like **5** or **7** is fine. At other times one requires **8** or **9**, or even **10** or **11**.[7]

11



Naive realism asserts that chemical formulas resemble reality: they do. It is possible to obtain pictures of benzene rings by physical means. They look, sometimes, like the benzene rings of the chemist (**2**). Sometimes they don't. The scientist who thinks that now, with scanning tunneling microscopy (STM), one can finally see atoms in molecules, has a shock coming when he or she looks at an STM image of graphite.[8] Half the hexagonal lattice atoms are highlighted in the image, half not. For good reasons. Seeing and believing have a complex relationship to each other. These (the benzene rings of the chemist) are rough approximations. They stand not unlike a metaphor to the molecular object represented.

Let us fix on the *typical* level of presentation (of Figures 1 and 2), that of a polygon (**5**) or a three-dimensional idealization of it (**7**). But what *are* these curious constructions, these drawings, filling the pages of a scientific paper? We now ask the question from the point of view of an artist or draftsman. They're not isometric projections, certainly not photo-

graphs. Yet they're obviously attempts to represent in two dimensions a three-dimensional object for the purpose of communicating its essence to some remote reader.

The clues to three-dimensionality in these drawings are minimal. Some are conventional: here and there (one example in **7**), there is a line "cut" to establish that some piece of the structure is in front of another, that is, **12** instead of **13**.

12 **13**

This is hardly a modern invention, something that one must learn at the Ecole des Beaux Artes. Figure 3 shows one of the cave paintings from Lascaux.[9] Note the treatment of the legs of the bisons as they go into the body. Now smart chemists should be able to do what cavemen 15 000 years ago did, shouldn't they? Too often they don't bother.

Fig. 3. Two bisons from the Lascaux Cave. Reproduced from J. Vouvé, J. Brunet, P. Vidal, J. Marsal: *Lascaux en Périgord Noir*, Pierre Fanlac, Périgeux 1982, p. 31. Reproduced with permission of the publishers.

Scattered about in the drawings of Figures 1 and 2 are sundry wedges and dashed lines. These are pieces of a visual code, simple in conception: a solid line is in the plane of the paper, a wedge in front, a dashed line in back. Thus, **14**

14

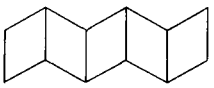
shows several views, all quite recognizable to chemists, of the tetrahedral methane molecule, CH_4. The tetrahedron is the single most important geometrical figure in chemistry. (Be patient, colleagues, think of telling your father-in-law about what you are doing.)

Describing this notation may be enough to make these structures rise from the page for some people, but the neural networks that control representation are effectively etched in, for life, when one handles (in human hands, not in a computer) a ball-and-stick model of the molecule while looking at its picture.

A glance at the more complicated molecules of Figure 2 shows that the wedge-dash convention is not applied consistently. Most compounds have more than a single plane of interest; what's behind one plane may be in front of another. So the convention is almost immediately used unsystematically, the author or lecturer choosing to emphasize the plane he or she thinks important. The result is a cubist perspective, a kind of Hockney photocollage.[10] The molecule is certainly seen, but may not be seen as the scientist thinks (in a dogmatic moment) that it is seen. It is represented as he chooses to see it, nicely superimposing a human illogic on top of an equally human logic.

They're floating in space, curiously unframed, these representations. You search in vain for a set of reference planes, a chair, a figure to orient you. But these are not given. The reader must decode the three-dimensionality with little help. Mind you it's not that difficult—there is an innate drive to see things as three-dimensional. Witness the difficulty we have in seeing the pattern of connected rhomboids, **15**, as flat.[11a]

15



Let us now come out of the didactic monologue. The hypothetical nonchemist, if he or she has persevered, has now partaken of the knowledge (prejudices?) that the chemist has about structures. We can proceed together.

The question remains: what do these chemical structures represent? How are they drawn and read? *Philostratus* tells, much mythologized, the story of *Apollonius of Tyana*, a Pythagorean who lived around the time of Christ. In a dialogue with a disciple *Apollonius* explores what painting is. It's done to make a likeness, to imitate. But what about cloud shapes in the sky, read by us as horses or bulls? Are those also imitations? *Apollonius* and his disciple agree that these are but chanced configurations, that it is we who interpret those shapes, give them meaning. He continues: "But does this not mean that the art of imitation is twofold? One aspect of it is the use of hands and mind in producing imitations, another aspect the producing of likenesses with the mind alone... I should say that those who look at works of painting and drawing must have the imitative faculty and that no one could understand the painted horse or bull unless he knew what such creatures are like."[11b]

Knowing is not an unproblematical concept. How does that three-dimensional structure unfold in its full glory in the mind of a chemist? As we said, the direct images produced by contemporary techniques such as scanning tunneling microscopy or electron microscopy (and these are not so "direct" on close examination) are few. Secondary knowledge, through X-ray crystallography, microwave spectroscopy, or electron diffraction, is experienced still by only a small number of specialists. For most of us it is the real, physical handling of models that sets the stage—the analogy to seeing *Apollonius*' bull or horse in the first place. Or looking at many pictures of molecules drawn by others, assimilating

thereby the set of conventions shared by chemists. It's much like art, and we will return to this below.

3. History, Media

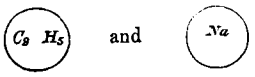
How did the chemists' way of seeing and drawing evolve? One can choose a starting point for chemistry almost at will, and ours will be *Lavoisier*. In his time, the end of the 18th century, there were no chemical structures of type **5–11**. The idea of an element was just taking form; the symbols for these elements were still not codified. The results of chemical experiments could be perfectly well communicated in words and, especially after *Lavoisier*, with numbers.

Illustrations figure importantly in *Lavoisier*'s work, nevertheless. They are often the illustrations of his experimental equipment, of glass and metal containers, gauges, barometers, all exquisitely detailed. A plate from *Lavoisier*'s 1789 classic "Traité Elementaire de Chimie" is shown in Figure 4.[12a] The appeal of these illustrations is in large part due to their creator: Mme. *Lavoisier, Marie Anne Pierrette Paulze*. Her original sketches, as well as her corrections of these engravings, are available. Mme. *Lavoisier* was an accomplished artist, a student of *David*.[12b]

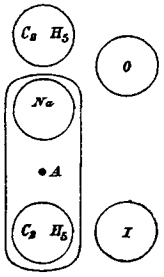
The media available to the scientific communication process of the time were quite circumscribed. In lecture presentations it was the voice, demonstrations,and blackboard and chalk. Illumination levels were low. In printed presentations one had, aside from normal typesetting possibilities, woodcuts and engravings, usually copperplate.

When did it become essential to communicate three-dimensional chemical information? By the middle of the 19th century there arose some pressure to represent the ways

The reaction is easily understood by the following diagram, in which the atoms



are supposed to be capable of changing places by turning round upon the central point A.



It is clear that we thus get $\begin{matrix}C_2H_5\\C_2H_5\end{matrix}$O and NaI. The circles are merely used to separate off the atoms or units of comparison. To express the corresponding decomposition of iodide of ethyle by hydrate of potash, forming alcohol, we should replace the ethyle of the sodium-compound by hydrogen, and the same change of place between sodium and ethyle forms $\begin{matrix}H\\C_2H_5\end{matrix}$O (alcohol) and Na I.

Fig. 5. An excerpt from an article by A. W. Williamson ("On Etherification"), *J. Chem. Soc. London 4* (1852) 229. The original runs across two pages.

atoms were linked to each other. Figure 5 shows a page from a crucial 1852 paper by *A. W. Williamson*.[13] Note the illustration, presumably engraved, and the way chemists of the time tried to represent, within the linear confines of a printed text, that in ordinary alcohol, ethanol, one has C_2H_5 group and H atom connected to an oxygen. We see here the beginnings of the tension between the medium and the content.

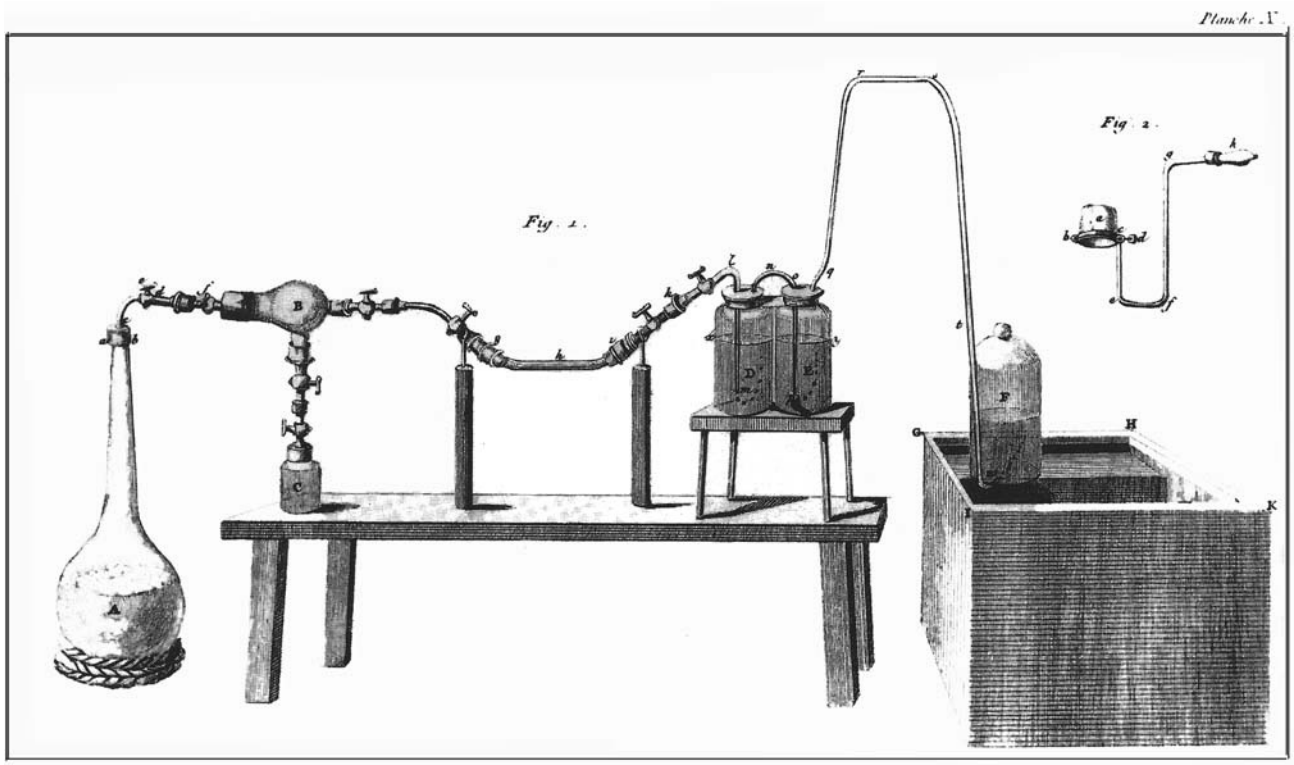


Fig. 4. Plate X from *A. Lavoisier*'s classic "Traité Elementaire de Chimie" (Cuchet, Paris 1789). The drawing is by Mme. *Lavoisier*.

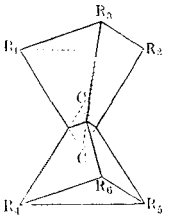
The content, incidentally, is fascinating, in that it reveals a struggle to give structure to and withhold it from the molecular formula.

The study of optical isomerism led *L. Pasteur* to the remarkable insight that the still unseen microscopic molecules must be in some way three-dimensional and left- or right-handed.[14] It seems in retrospect almost strange that it took another quarter of a century for a correct model to take shape. But so it did, in 1874, in the tetrahedral carbon atom of *J. H. van't Hoff* and *J. A. Le Bel*.[15] Structure **16** reproduces one of *van't Hoff*'s original drawings.



16

A carbon lies at the middle of each tetrahedron. *Van't Hoff* was led to this model some forty years before any one "saw", even indirectly, the disposition of atoms in space in a molecule. *N. J. Turro* in a perceptive article addressing some of the same issues discussed here, has aptly called the tetrahedral carbon atom "a triumph of topological thinking".[16]

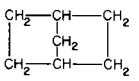
The increased reliance of chemists upon molecular formulas derived much from the example of another pivotal 19th-century figure, *Kekulé*. As a teenager, *Kekulé* had hesitated between two professions, architecture and chemistry. His strong leanings for the former showed up in his routine building of molecular models, which he would display in his lectures. He would make projections onto planar screens of these models and use these projections as graphic formulas in his publications.

With the contributions of *Kekulé*, *van't Hoff*, and many others, the structural theory of organic chemistry evolved apace, and by 1890, one hundred years ago, it was clear that one needed the capability to set in print quasi-three-dimensional drawings of type **7**.

There was no problem in doing so on a blackboard. But the printing media were not up to it, at least not at the budgetary levels appropriate to mass dissemination of a scientific journal. Photography had been around for a good part of the century, but it also had not yet affected the routine printing process. Nor did it *ever* subsequently make an impact on the communication of chemical structures. This is worth a digression relevant to the question of what one is trying to communicate in these drawings, which we will take later.

Engraving still remained the technique of choice in the printing process of a hundred years ago. It was expensive to set lines at an angle. So if a journal had to set the molecule of norbornane, C_7H_{12}, the "skeleton" of camphor, it was represented as **17** rather than **18**. This was done not only in 1890, but until 1950, even when engraving was replaced by photogravure.

The policies of journals, their economic limitations, and the available technology put constraints not only on what is printed, but also on how we *think* about molecules. Now everyone (in chemistry) knew since 1874 that carbon was "tetrahedral", that its four bonds pointed to the corners of tetrahedron. Molecular models were available or could be relatively easily built. Yet we suspect that the image or icon of norbornane that a typical chemist had in his mind around 1925 was **17** and not **18**. The chemist is conditioned by what



17

18

he or she sees in a journal or textbook—an image—and might have been moved to act, in synthesizing a derivative of this molecule, for instance, by that unrealistic image.[17] And yet *G. Komppa* did synthesize it![18]

Maybe it's not that different from the way we approach romance in our lives, equipped with a piecewise reliable set of images from novels and movies.

4. Chemical Representation as Language

Most, if not all, scientists make use of visual imagery for problem-solving, in order to sort out and organize information, to find analogies, to think.[19, 20] But chemists are unusual among scientists (though they share this with the architects) in having an iconic vernacular, that of the formulas.

A chemical formula is like a word. It purports to identify, to single out the chemical species it stands for. Chemical formulas embody the ancient dictum (going back, as far as teaching is concerned, to the Czech *Comenius* at the time of the Renaissance): "One thing, one word."[21] Indeed, chemical systematics takes great care to avoid ambiguous situations; we have nomenclatures that deal with every conceivable type of isomerism.

A first problem is easily discarded. When we refer to a familiar object in the outside world by its name, we project a measure of personal experience into the identification. If I say "dog", I cannot help forming a fleeting mental image of a furry or fiery quadruped, wagging its tail or baring its teeth, in between a friend and a threat.[22] The trivial names of chemicals, which often have been with us for centuries, are no different, even when imbued with outdated knowledge that has leached out: sulfuric acid, potash, albumin, *azote*, etc.

This brings up a second, more serious problem. Chemistry is a mature science. It has shed to a large extent its childhood habit of going no further than a phenomenological description of bulk properties, at the macroscopic level (that of sensory perceptions), accompanied by an apt denomination (such as "potash"—because the compound was first found, literally, in pot ash).

Chemistry has become a microscopic science. Explanations nowadays go routinely, paradigmatically from the microscopic scale to the observable: from the way the electrons are distributed in a dye molecule to its color; from the de-

tailed shape of a molecule and of the electrostatic potential around it to its pharmacological activity; from bond energies to the superior tensile strength of Kevlar.

Such a seminal characteristic of chemical sciences was noted already at the time of the Enlightenment. The entry for "chemistry" in the *Encyclopédie* by *Diderot* and *D'Alembert* points out that chemists (but not the Newtonian physicists of the time, who explained everything with central forces acting on material points) are wont to posit invisible and intangible entities or qualities to explain observations. They are forced to do so by the smallness of their particles. We are still under a similar constraint, even though "images" of some molecules and of some atoms have become available very recently. Indeed we know our building blocks, molecules, much better. But it remains a long, long way from the molecular scale to the macroscopic world of the senses. We still have to represent molecules, and chemists have to do so as much as other people. And we tend to represent to ourselves atoms *as if* they were normal objects in our everyday experience: with a size, with a certain hardness or softness, with measurable attractions to other atoms or to electrons, and so on. This is a little naive, unavoidable, and endearing—not unlike a belief in angels in past centuries.

We made earlier (last sentence in Section 3) the same point. Humans delude themselves with mental constructs projected upon reality, often deemed as "realism". Chemistry, in like manner, is a mix of a molecular engineering, based on extrapolations from the macroscopic to the microscopic, and a science, coming to grasp directly with the microscopic. The puritans among us wish to get rid of the former, and they push for our minds to handle abstractions only, as in mathematics. Thus, they tend to measure our understanding of the physical world by its secession from everyday experience. While we have a great deal of respect for such an inclination, a constant temptation to most scientists one would think, we are not such purists ourselves. The needs of communication and teaching are one, circumstantial, reason. A second, and more potent, reason is the centrality of semirealistic representations to chemical thought. This is the central theme in our discussion.

What we have is a fascinating philosophical quandary, and an instance of quasi-circular reasoning,[23] too. The above cited quantities—the size of an electronic cloud in an atom, the atom's *electronegativity*—are neither derivable from first principles[24] nor are they observables. They, these Platonic archetypes, have evolved slowly among chemists, in an inductive manner, from experimental determinations; and we attempt to *deduce* from them in turn consequences, for objects in the physical world only very slightly different from those that formed the basis for the formulation of these qualities. This feature is one of the major hurdles for students learning chemistry. Our discipline is a curious mix of empirical observation *and* abstract reasoning. This is not unlike music—but it parts chemistry from the rigor of pure mathematics. Students brought up on deductive logic have a hard time with chemistry!

True, chemical formulas have been severed from subjective life experiences to a considerable extent, much more so than words such as "dog", "automobile", or "contraception". Yet, despite such an excision, chemical structures retain a strong connection with sensory experiences; by contrast with such mundane words, they carry an essential *representational* component.

Let us elaborate some on this interesting paradox. As *Ferdinand de Saussure* pointed out, in one of his fundamental insights, the *word–thing* relationship is that of the *signifier* to the *signified*; and a key notion is that of the *arbitrariness* of the signifier.[25] When we say "dog" (or "Hund" or "cachorro"), each of these terms has been selected more or less randomly in the history of the language. It could have been a "snark" or a "livel" or a "rop" in English, who knows! The word "dog" has settled into its niche (forgive the pun) in the common language by way of the numerous cross-relations it bears with other words in the dictionary (such as "leash", "dogfood", "bitch", or "seeing eye"). We flesh out a word because we cannot help loading it with our private empirical experience, just as we do with atoms. But in actuality the word is a total fabrication. It could have been an entirely different choice.[26]

With this reminder, we return to this paradox: formulas forsake reality in a sense, and they aim to stand for reality in another. Indeed, chemical structures differ from words in the normal language because they combine symbolic and representational (iconic) values. Take the case of the molecule of natural gas, methane, drawn above in structure **14**. The various types of strokes in **14** indicate *both* connection of the carbon with the hydrogens via chemical bonds (the symbolic statement) and whether the bond butts out of the plane of the paper, or recedes from the viewer to the backside (the representational or geometric statement). The chemical formula is trying to signify a lot with the utmost economy in graphics. It aims at portraying accurately the connectivity of atoms—the nearest-neighbor relationships as stemming from chemical bonds—and the geometry.

Thus, we can state the second problem with chemical formulas: they are in between *symbols* and *models*. This hybrid status is an uneasy one. These two poles pull formulas toward opposite and sometimes incompatible requirements.

As models, chemical formulas ought to be reliable and accurate representations of what one might term "molecular reality" (we shall return to this useful figment of the collective psyche of chemists). As symbols, they ought to be arbitrary, to a large extent. This is reflected, to give an all-too-familiar example, in the use of a capital O to represent an oxygen atom: behind this universal convention, there is an assumption of transferability (an oxygen atom *here* is very much like an oxygen atom *there*) which is not that easy to put on a firm theoretical basis. An oxygen atom free of a molecule is indistinguishable from any other oxygen atom. But inside a molecule, a ketone oxygen is very different from an ether one.

Words of a common language are highly ambiguous. Take the word "representation" itself. It can mean either the act of representing or the result of such a mental or physical action. In the latter sense, a representation can be a description, according to this or that framework: representations are theory-laden. In a closely related sense a representation will refer to the worldview, to the *style* of whoever makes it; this is the more subjective meaning of representation. In yet another meaning (that of the poet, for instance), a representation is an epiphany; making the represented object be under our very eyes, whereas it truly is absent. This is representa-

tion as illusion. Not to mention yet other meanings, such as in the diplomatic lingo, where representations are a protest and a rebuke. Strings of words, as arranged in a poem, any text for that matter, have also a plurality of meanings. Hermeneutics strives to enrich the reading of a text by associating to the more obvious and mundane meaning a deeper meaning as well.[27]

Is the world of chemistry and chemical structures unambiguous, characterized by one drawing, one molecule? To some extent chemistry is such, because it is "a sign imprinted in matter", as *J.-M. Lehn* has called it.[28] The instructions for making aspirin work here as well as in Montevideo and Karaganda. The article reporting the synthesis of a new drug perhaps needs translation, but in another sense it doesn't, for it is understood around the world, it is infinitely paraphrasable. Chemical structures, chemical formulas are the signing tools of this language.

But in another way the graphic language of chemistry is quite ambiguous. We've seen clear evidence for this in the plurality of answers given for camphor to the simple question: What is the structure of the molecule? It could be argued that once drawn, no matter how drawn, the single molecule "camphor" enters the mind of the chemist. But as we will see later, how a molecule is thought about and subsequently manipulated in the material world is very much influenced by the way we carry it around in our minds.

A chemical formula is at once a metaphor, a model (in the sense of a technical diagram), and a theoretical construct. A chemical formula is part pure imagination, part inference. It is an attempt to depict the real by manipulation of symbols, just as language enables us to talk about the world and about ourselves by combining arbitrary utterances. The simile cannot be pushed too strongly. In a deep philosophical sense, calling something an "acid" and calling something else "red" are identical mental operations. Likewise, referring to "ethanol" or "reserpine" is akin to talking about "Rockefeller Center" or about the "Eiffel Tower".

"Acid" and "red" are ill-defined but most useful concepts relating to everyday experiences. Conversely, "ethanol" and "Eiffel Tower" are defined unambiguously, but they need not be commonplace objects, they are cultural objects in the widest sense.

One of the points *C. P. Snow* made in his "Two Cultures" lecture was precisely that we should give equal status—that the value judgments had to be either suspended or commensurate—for two cultural objects such as, say, the novels of *Jane Austen* on one hand and the structure of DNA or the second law of thermodynamics on the other.

If "ethanol" is in a similar mental category as "Eiffel Tower", the chemical formula of ethanol stands to it not unlike a dictionary definition for "Eiffel Tower": a chemical formula is a concise paraphrase, in a half-symbolical, half-iconic language, of some of the attributes of an object, so that the object can be properly and unambiguously identified, that is, differentiated from like objects (Eiffel Tower as distinguished from the Madeleine or the Centre Pompidou; ethanol as distinct from ethane or from acetic acid).

Language and chemical representation, besides their joint use of names, have other similarities. They share use of invariant elements. Many words and most chemical compounds are just that, compounds, put together by association of structural fragments. There is deep similarity between a word such as "one-upmanship" and a "chemical word" such as C_6H_5-CH_2-CO-OH. In the latter case, just as in the former, the structural fragments (phenyl, methylene, carbonyl, hydroxy) are stable semes: to a first approximation they retain their basic meaning whatever the nature of the other modules they are connected with.

Chemistry is the science of change, of transformations. Every science starts with axioms about the integrity of certain of its objects. The mechanical engineer believes in the integrity of a steel girder. The cell biologist believes in the integrity of chloroplasts or mitochondria: he or she is convinced that these organelles are interchangeable, playing identical roles in one cell or in another.

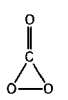
For chemistry, it is crucial to make sense of change by constraining it to occur between well-defined states. Invariance and its equivalent, transferability, are basic assumptions to chemistry. At each level of understanding (or complexity), the lower units are set as invariant: starting with atoms, going on to the simple structural fragments such as the above (C_6H_5, CH_2, CO, OH), on to simple molecules, further on to chains or polymers, the helices of proteins and nucleic acids, and so forth.

The concept of transferability goes back, beyond *Dalton*'s atoms, to the Lavoisier revolution: "Rien ne se perd, rien ne se crée." By a quirk of scientific history, his use of the balance made *Lavoisier* discover the physical law of mass conservation; but the linguistic bent he had inherited from *Condillac* made him give a *linguistic* expression to it. *Lavoisier* founded modern chemical language on the explicit analogy to natural language. No wonder that chemical formulas, to this day, retain an important linguistic component.

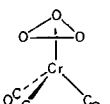
It is possible to set up a formal relationship between chemistry and language; an intriguing initial step in this direction has already been taken by *H. W. Whitlock, Jr.*[29] In the terminology of *Chomsky*, a language is defined by a set of symbols (a vocabulary) from which strings (sentences) may be generated by a set of productions or transformations (rules for making changes).[30] The identification of symbols with chemical elements or those simple structural fragments (CH_2, CO, OH) we have alluded to above, and of productions with chemical reactions, is obvious. *Whitlock* interestingly shows that a certain problem in organic synthesis may be approached by analyzing it in the context of formal language.[31]

The shared productivity of language, formal or natural, with chemistry applies also to the realm of what has not yet been said, or written, or synthesized. There exist rules, for instance such that we have the competence to pronounce a word that we have never heard: "a roor", "to roat", "the poot". Likewise, we can write utopian formulas for (so far) unknown chemical species (e.g., **19**–**21**). This serves quite often as an inducement to try and prepare them.

19



20



21

These structures, waiting impatiently to be made, have for chemists the incongruous look, both attractive and shocking, of a novel object deemed by some as an impossibility: not unlike a first look at a laser printer in action, or a monorail train levitating above its magnetized track, a Stealth bomber, or a town-size space station.

This is a strong analogy, that of language and chemistry. Its tiny area of invalidity is homonymies ("rapt" and "wrapped"). They don't occur in chemistry, or very seldom: "*periodic* table" and "*periodic* acid", linguistic look-alikes, in fact, are easily told apart from the context and pronunciation.

Thus both languages, the natural and the chemical, witness an evolution of meaning, from so-called nonsense to highly significant statements. Even though it does not build upon known ("domesticated") words, and it invents instead new ("wild") words, the "Jabberwocky" poem by *Lewis Carroll* makes sense because of its impeccable syntax, which lets the imagination of the reader both be charmed by the word-play and invests some of the words with meaning, by way of various associations. Chemistry has likewise its wild species (benzyne, tetrahedrane, or **19**–**21** above), besides its more usual bottled samples. In fact most of the molecules of chemistry, wild dreams or not, are invented, synthesized. They were not on earth before.

Chemical representation is also language-like when dealing with the class of transformations known as chemical reactions. In an important sense, chemistry is the skillful study of symbolic transformations applied to graphic objects, the formulas. There are one-to-one correspondences between compounds and formulas. Likewise, it is possible to specify unequivocally the transform from one compound to another. If one thinks of chemical compounds as nodes in an infinite and multidimensional grid, then the connecting lines in such a network are the transforms. Chemistry has thus two facets, structural when the focus is static, on the points in the grid; and dynamic when what is examined is the interconversion along the edges in the network. There are strict rules about *rewriting* formulas to express transforms; not unlike rules of musical composition.

Chemical transforms are the analogues of action sentences in natural language. The parallel is illustrated by **22**.

subject substrate	transitive verb reagent	object product

22

An example of the former is "John saws a log". An example of the latter is "the aldehyde is reduced by sodium borohydride to the alcohol".

Just as action sentences carry subordinates as modifiers, to provide information about time, location, quantity, manner, so the chemical equation is wont to specify the solvent, the reaction temperature, the reaction time, the yield of product, etc.

In another sense, this parallel is too general. The product molecules in a chemical reaction contain the same atoms as the reactants, but reconnected in a different way. The relationship of subject and object is different—except in a category of sentences having a pronominal (or reflexive) verb. Sentences such as "Jane washes herself" or "John admires himself in the mirror" are somewhat like statements about chemical transforms. Funny that chemical equations come so close to psychological statements!

In *Goethe*'s 1809 novel "Die Wahlverwandtschaften" (Elective Affinities), a by-then outdated theory of chemical combination powers a work of fiction.[32] The actions and emotions of the characters of this work embody (and probe critically) the way some people thought molecules behave. One wishes one were able to point today to a similarly inspired literary text. The closest one comes is *Primo Levi*'s remarkable memoir "The Periodic Table", or some chapters in his novel "The Monkey's Wrench". Nevertheless, it is interesting to reflect on the deep morphological resemblance of chemistry and, if not life, at least language.

In the foregoing, the parallel between chemical formulas and everyday language may have appeared rather artificial and a little forced. We can defend it nevertheless with an anecdote.

One of us was visiting recently the office of Professor *C. Tamm*, at the University of Basel. The conversation turned to a structure of a complex natural product, inscribed on the blackboard and recently elucidated in Professor *Tamm*'s laboratory. As an aside, one of us said: "The way I read this structure starts with the six-membered ring, goes on to the *spiro* junction with the five-membered ring, etc." Professor *Tamm* agreed. We discovered in this manner that we shared the same vision of this particular molecule. Both of us were going around this complex network (bonds and atoms) in well-nigh identical manners—obviously a result of our training.

It is thus our contention that chemical formulas are read according to conventional sequences. Recent research in neuropsychology teaches indeed that mental patterns do not spring up whole. They are built up gradually, a part at a time; and the parts, it is found, are visualized in roughly the same order as they are typically drawn. With respect to the two types of tasks (retrieval of archival shapes and coordination of shapes into a mental image), the two brain hemispheres play different roles.[33, 34]

The opposite viewpoint is a necessary complement. As *Verbrugge* indicates, discussing the example of *Kekulé*'s architectural formulas, his ring structure for benzene, and the oscillation of benzene between the two equivalent ring forms, "scientific understanding develops only when we are prepared to reshape our representation systems in fundamental ways."[35]

We submit that the combined pressures of (1) the learning, early on, of chemical nomenclature, (2) incessant on-the-job confrontations with formulas through seminars, the reading of publications, the handling of molecular models, and (3) the demands of communication with other chemists have built this largely unconscious and stereotyped collective way of seeing. Probably art historians act the same; it is quite possible, even likely that two specialists of Quattrocento painting will both scan a picture in much the same ways.

Let us now explore the opposite viewpoint. Because perception of chemical shapes is so stereotyped, conversely to be able to see a structure in a novel way can be extremely fruitful. Chemistry shares with poetry its notion of elegance, its mission so to say. This is to discover new relations between

objects. Very often, the elegance of a key step in a series of chemical transformations is rooted in the perception of a nonobvious connection between parts of the molecular object. More generally, it would repay the student of psychological invention to take a close look at flowsheets, the sequence of molecules made and transformed, in synthesis of natural products. Indeed, the synthetic elaboration of complex chemical structures offers fascinating glimpses into the creative process, in the doing. In the hands of a master craftsman such as *R. B. Woodward*, structural fragments experience what are to the mind—that of the conceiver as well as that of the reader—genuine *Gestalt* shifts, from one part of the synthesis to another. By studying the Woodward syntheses in detail, one can just see him turning a molecule over in this mind, and seeing some of its elements from new angles. The changes of the structures in the course of a Woodward synthesis are metaphors of creativity.[36] They exploit the plurality of meanings embodied in a chemical structure. We submit that it may be difficult to move closer to the creative imagination in action.[37]

A final point, made to us by *H. Hopf*.[38] Chemistry is full of representations other than graphic ones—take the various spectra, IR, NMR, photoelectron, all different (the medium is the message; in German the plotter is even called "Schreiber"). Their music (the tones, overtones and harmonics of spectroscopy) carry incredible dynamic detail far beyond the static structure. Some (NOESY plots) claim to embody the same informational content as conformational drawings. It's a wondrous multitude of representational imagery out there, artists/scientists working in so many media to capture the essence of the real.

5. But Is It Art...

Art or the reaction to it, the aesthetic response, has never been easy to define. There are so many forms of pleasing human creation, so many constructed objects or patterns evoking emotional reactions. Cognizant of the complexity and venerable history of aesthetics, let us hazard a definition.[39, 40] While it is one contestable in all of its parts, perhaps it touches on most of the qualities of what we've chosen to call art. Then we will examine representation in chemistry as it measures up against this definition.

Let's call Art those symbolic acts or creations of human beings which aspire to the extraction from the complex realm of Nature, or the equally involved world of the emotions, of some aspect of the essence of these worlds. Art functions by communication of a symbol, meant to convey information and/or evoke an emotional response.

The essential components of the aesthetic system are (1) the creator—painter, composer, photographer, writer, dancer, (2) the audience—both that perceived in the creator's mind and the real one, the viewers, (3) the set of symbols by which communication takes place—the watercolor, sound waves, and images evolving in time, a text, (4) the act of communication itself—to an audience that is present (watching a dance, listening to a cantata) or absent (reading a novel).

If this definition sounds too rational, too "scientific", devoid of the gut emotional response we should like good art to hit us with, so be it. *Nelson Goodman* argues persuasively that "in aesthetic experience the *emotions function cognitively*", that feeling is knowing. He goes on to examine the usual attributes of art (that the aesthetic is directed to no practical end, that it gives immediate satisfaction, that in art inquiry is a means of obtaining satisfaction, etc., all of these existing as marks of art mainly by contrasting them with an opposite attributed to science), and he finds them wanting. He says: "... the difference between art and science is not that between feeling and fact, intuition and inference, delight and deliberation, synthesis and analysis, sensation and cerebration, concreteness and abstraction, passion and action, mediacy and immediacy, or truth and beauty, but rather a difference in domination of certain specific characteristics of symbols."[41]

To return to the question heading this section: are chemical structures art? It seems clear that they possess all the components of the "aesthetic system". Structural formulas are symbols created by one chemist (or several) to communicate information to others. The drawing of the structure of camphor is certainly a symbolic motion, a communication of an essence—the arrangement in space of the atoms of this molecule. Some might call it just a sketch, an information-reducing stratagem by someone not able or willing to compute and show others the all-important electron density around the nuclei. *That* electron density is the real molecule; the structural formula—well, that's "just a poor representation".

Of course, that simple structural drawing is more. It is the appropriate tool, the model fitting the occasion. Indeed, it's the extraction from the complexity (of something so simple as a molecule!) of one aspect of its essence. It certainly conveys information, that structure. And, in the few careful readers of the paper, the structure may even evoke an emotional response, a wonder that it was made, jealousy of the man or woman who made it first.

Does it matter that the aesthetic response will be provoked instantly only in the minds of those initiated to the chemical structure code? We don't think so. To be sure one has to be taught to understand the chemists' ways of signing. But it's not that difficult. Responses of the population at large to abstract art, or some primitive tribal groups to realistic Western art, have not been, are not likely to be, immediately appreciative.

The chemical structure is an artistic construct because it is a transformation of a model of reality (note the secondhand if not nth-hand relationship to the real) for the purpose of communication. Neither chemistry texts nor anatomy books are much illustrated with photographs. There are some photographs, to be sure. But by and large a photograph (and we certainly don't wish to imply that photography is mere representation; it is far from that) contains too much detail. What one wants to communicate is the essence needed for the moment. One wants to teach, to evoke a response. Drawings, with their artistically selected detail, are much better for that purpose.[42]

The symbolic nature of the chemical formula, the fact that chemists know that a hexagon stands for a ring of carbon atoms that in turn is much, much smaller, the implicit knowledge that that hexagon is *not* an enlarged photograph of the ring, all that symbolic distancing of course enhances the

metaphorical nature of the chemical discourse. Structures are not what they stand for; they stand for what they are not.

But is it art? Having argued that chemical representations, such as structural formulas, share all the symptoms of art, let us take the opposite tack, at least for a while.

Just as it is impossible to ignore the artist and his audience, the mental set of both, so it is impossible to put out of mind the context of a picture or a scientific illustration. And chemical structures, in particular, are often really part of the text. Oh, they may have artistic value or expressive power on their own. One could mount a good art exhibit around them. But their function, their organizing referent, is the text.

By way of illustration, Figure 6 shows the beginning of a paper written by one of us.[43] Note four little drawings in the first two paragraphs. They are typically floating in midair, typically using the wedge–dash–line notation. The structures are numbered boldface, and referred to specifically in the text. In fact they are part of the text, and that they are referenced to (by their boldface numbers) even in the middle of a sentence, confirms this role. In one chain (labeled **2** in Fig. 6) the units of five telluriums are related by a so-called screw axis, whereas in another chain (labeled **3** in Fig. 6) they are simply translated, one relative to the other. All that could have been said in words. But it was easier to draw a picture. So a structure was born.

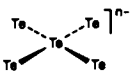
Actually, the motives of the representation are not so simple here. The authors use the pictures not only to save space. They are also plumbing strategies to capture their audience. These tellurium compounds are not immediately interesting to everyone in chemistry. Specialization is a plague in any field of scholarship. The geometries of the tellurium structures are difficult to see. Since in science, as everywhere else, what we do not understand we are afraid of, what we do not understand we find uninteresting, the authors are using the visual appeal (and density of explanatory power) of a drawing to inform, to pull in, to attract, to seduce. Still another motive: It is the "style" of one of the authors (*R. H.*) to decorate his papers with such drawings. He is establishing a visual signature.

Still another argument against assigning full artistic value to a chemical structure is that it is not, to use *Goodman*'s terminology, "replete".[44] Not every stroke in the representation matters; the lines could be a different color, the molecule readily recognizable as what it is even if drawn from a somewhat different viewpoint. This is in contrast to a Goya etching, which, were similar changes made in it, would be another Goya etching, a different work of art, or at the very least a different "êtat".[45] To put it in another way, the chemical structure addresses the inherent paraphrasability of scientific knowledge (paraphrase as one of the (few) differentiations of art and science has been persuasively forwarded by *G. Stent*[46]). It's the same molecule, intended to be the same, perceived to be the same. But what if the slightly different representation enters the unusual mind, prompting an experiment untried before? The icon powers the iconoclast.

Perhaps another way to approach the artistic content of chemical drawings is to think of their relationship to various visual art genres. For instance, we see a similarity between chemical structures and what has been called, not without controversy, primitive art. Tribal art, be it of Australian aborigines or an Eskimo clan, often appears schematic to us, deficient in perspective. That's our problem, for to the native group which shares the culture that informs that art, the representation may be highly accurate and perceptive. So it is with chemical drawings—their perspective may be inadequate, their representation artistically unsophisticated. But they tell a concise story to the chemical reader. Like primitive images or sculptures, chemical drawings will usually distort a view if the viewers' ability to clearly *classify* an object is enhanced by that distortion. So if it is important to show that someone owns six sheep, the sheep will be posed so that they are distinct, and clearly seen as sheep. A deity will be represented by its symbolic attributes so that we cannot confuse it with any other.

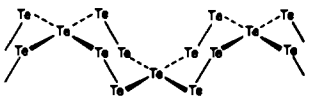
The iconic representation of camphor (see drawing **7**) is simplified and distorted (compare with **9** or **11**) so as to allow us to identify the molecule, to trigger a connection in the

The recent literature contains a number of examples of a square-planar tellurium structural unit which may formally be defined as Te_5^{n-} (1). In some cases such as Rb_2Te_5[1] and Cs_2Te_5[2]

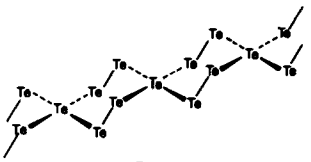


1

the stoichiometry clearly defines the cnarge on the unit as 2−. In these instances the unit is the basic building block of a one-dimensional anionic chain. In Cs_2Te_5 the Te_5^{n-} units are screw axis related (2) while in Rb_2Te_5 the Te_5^{n-} units are related by translation (3).



2



3

For most of the other cases in which the Te_5^{n-} unit appears, the attribution of a particular charge to the unit is more ambiguous. For instance, on K_2SnTe_5,[3] the unit again appears embedded in a one-dimensional chain (4) but the Te_5^{n-} units alternate

4

with tetrahedral Sn in making up the chain. Formally, at least, the square-planar units could still be considered Te_5^{2-} if the tin is Sn(0), but the Te–Sn bond length of 2.74 Å is almost identical with the sum of the tetrahedral covalent radii (2.72 Å) given by Pauling.[4] This suggests a formal oxidation state of 4+ for the Sn and a net charge of 6− on the Te_5^{n-} unit.

Fig. 6. The beginning of a paper, "Hypervalent Tellurium in One-dimensional Extended Structures Containing Te_5^{n-} Units": J. Bernstein, R. Hoffmann, *Inorg. Chem. 24* (1985) 4100. The original runs across three columns in the journal.

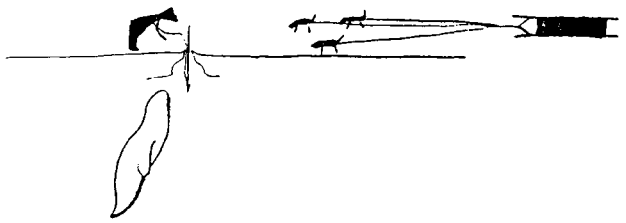


Fig. 7. An Aivilik drawing of a seal hunt. From E. Carpenter: *Eskimo Realities*, Holt, Rinehart and Winston, New York 1973, p. 117. Reproduced with permission of the publishers.

mind. The Aivilik drawing (Fig. 7[47]) of seal hunting through the ice rearranges space (top view of sled, side view, X-ray, of hunter, ice, and seal) and time (the seal approaching, the harpoon already thrown) so as to render visible, in all its richness, the hunt.

Something similar occurs in the pictorial language of chemists. If a piece of a molecule, some functionality such as an aldehyde group is essential, even if it is hidden behind another part of the molecule, it will be brought forward without much regard to faithfulness of representation.

There is still another anthropological point of contact. In some cultures knowing the true name of an object or a person forms a special bond, even gives power. So it is in chemistry. Knowing the "name" of a compound, which means its structure, gives the chemist tremendous power over the molecule. A range of its properties, its behavior are implied by that structure.

Guy Ourisson, in a perceptive article that deals with many of the same issues we have discussed, identified the chemical structure as an ideogram or pictogram, a symbol that represents an idea or object directly.[7] This point was also made by *R. Etiemble*. He makes the analogy to Chinese characters, and perhaps one could also do so productively to Egyptian hieroglyphs. Like the character, the chemical sign enters the conscience of a chemist directly. All its meanings are attached, and the chemist manipulates that little picture mentally in a multiplicity of ways. The chemical structure implies not only a molecule but its physical, chemical, even biological properties.

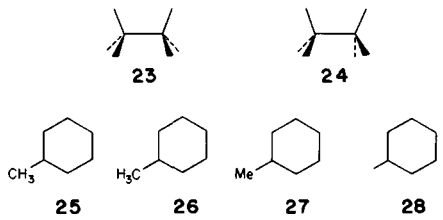
Rudolf Hoppe has prefaced one of his review articles with stimulating reflections on the symbolic language of the chemist; his graphics are admirably chosen; they more than hint at the convergence of *la pensée sauvage* and the language of chemistry.[48]

Fig. 8. An illustration from a book by *Tove Jansson* (Tove Jansson: *Moominsummer Madness*, Henry Z. Walck, New York 1955, p. 53). Reproduced with permission of the publishers.

The drawing of chemical structures also has a kinship with caricature and comic strips. If one examines a successful cartoon or schematic book illustration closely one finds that a wide spectrum of emotion—grief, terrible anger, ecstasy—is communicated in just a few strokes of a pen. Think of the Dr. Seuss books, *Jean de Brunhoff*'s Babar, *Hergé*'s Tintin books, *Tove Jansson*'s Moomintrolls (see Fig. 8[49]), or *Walt Disney*'s numerous cartoon characters. And not just for children. *Gombrich* discusses the effect of caricature perceptively, arguing that we "accept the grotesque and simplified partly because its lack of elaboration guarantees the absence of contradictory clues".[50] In examining a work of art we look at the information in it, and unconsciously seek relationships. It's not the absolute flux of light entering our eye from a painted white spot that makes us see it as brightly lit, it is its differentiation from neighboring patches of paint.

The act of viewing is collaborative (between painter and viewer) and forgiving. We always create space, in our minds, when we see a two-dimensional representation. And we elaborate the information, interpolating our experience to fill out what is omitted. At least providing there are no contradictory clues, no signals to tell us that we are wrong. Caricatures or cartoons (or if those are not "serious" enough, take a Goya or Picasso etching) work by providing the appropriate minimal information.

So do chemical structures. The chemist's mind is very tolerant. It will accept both **23** and **24** as representations of an eclipsed ethane. It will read the substituent attached at lower left to the six-membered ring in **25** through **28** as a methyl group. It will fill in the missing three-dimensional background required to make these molecules come to life; it will geometrize the floating world of these little symbols.



In any case, the drawing does not exist by itself, but is an integral part of the text. It is as if the chemist invented a new language, part text, part the tactile sense that is behind the model-building that is behind the ability of a chemist to reconstruct a molecule in his or her mind from such minimal information. We are pushed back to the logic of language. And in another way, to viewing the combined text–structure complex as an art form.

Note added in proof (July 1990): The reader's attention is directed to two recent contributions: *Stephen T. Weininger*, Worcester Polytechnic Institute, explores in an important, well-documented lecture-essay a semiotic perspective on chemistry.[51] And *Pier-Luigi Luisi* and *Richard M. Thomas*, ETH Zürich, make a number of comments similar to ours (and many original ones) in an article on pictographic communication in chemistry and biology.[52] There is also a beautiful discussion of the language of chemistry in two recently translated essays by *Primo Levi*.[53]

We've benefited much from the critical comments of Kurt Mislow, Hearne Pardee, Noel Carroll, Vivian Torrence, Gilles-Gaston Granger, and Henning Hopf. The assistance of Dennis Underwood, Donald Boyd, and Laura Linke is also gratefully acknowledged, as are the photographs of Stephen R. Singer, the drawings of Jane Jorgensen and Elisabeth Fields, and the typing of Joyce Barrows. A slightly different version of this essay has appeared in Diogène, Paris.

[17] The gift for seeing structures in space with one's eyes, and the cognate imaginative prowess of seeing them with the mind's eye, are important components of creativity for a chemist. And perhaps not only for chemists. For instance, mathematicians still discuss, since *Hadamard*'s pioneering study of mathematical creativity (K. Hadamard, *The Psychology of Invention in the Mathematical Field*, Princeton Univ. Press, Princeton 1945) whether iconic representations are involved in the thought processes of mathematicians (A. Muir, *the Mathematical Intelligencer 10* (1988) 33). If one were to rely on the example of chemists, the answer to this much-debated question would have to be "Yes, of course!".

[20] We take the view that such figures of speech as the metaphor, should be seen as cognitive tools, and not as deviations with respect to the prosaic norm. See D. Sperber, D. S. M. Wilson: *Relevance: Communication and Cognition*, Blackwell, Oxford/Harvard Univ. Press, Cambridge, MA, USA, 1986.

[21] J. A. Comenius: *Orbis Sensualium Pictus*, Michael Endter, Nüremberg 1658.

[22] We have not succumbed to the nominalist fallacy! We have elected our Fido example because the view, admittedly restricted and restrictive, of language as nomenclature is precisely that embodied in the language of chemistry. *Saussure*, with his idea of signs as uniting a signifier and a signified, swept off the illusory notion of language as nomenclature for objects. The word "dog" refers, not to a real object, but to an attribute shared by several different entities.

[23] Circular reasoning is not all bad. Elsewhere one of us makes a sort of a case for its utility in real chemistry: R. Hoffmann, *Amer. Sci. 75* (1988) 182.

Structure and Molecular Stacking of Anthocyanins—Flower Color Variation

By Toshio Goto and Tadao Kondo*

In 1913 *Willstätter* made the striking observation that the same pigment can give rise to different colors. Thus, the same pigment, cyanin, is found in the blue cornflower and in the red rose. *Willstätter* attributed the variety of flower colors to different pH values in solution. Indeed, anthocyanin changes its color with pH; it appears red in acidic, violet in neutral, and blue in basic aqueous solution. *Willstätter*'s pH-theory for explaining flower color variation is still to be found in major text books of organic chemistry. Very recently, however, reinvestigation has disclosed that the color variation and stabilization of anthocyanins in aqueous solution could have other causes, namely self-association, copigmentation and intramolecular sandwich-type stacking. The stacking would be mainly brought about by intermolecular or intramolecular hydrophobic interaction between aromatic nuclei such as anthocyanidins, flavones and aromatic acids. In addition, hydrogen bonds and charge transfer interactions may also be involved. The most interesting molecular complexes of anthocyanins are the metalloanthocyanins such as commelinin and protocyanin (blue cornflower pigment). These seemingly pure blue complexes each consist of six anthocyanin and six flavone molecules and two metal ions; their molecular weight is nearly 10000. A structure is proposed for commelinin.

1. Introduction[1-6]

1.1. Controversy about Blue Flower Colors

Beautiful flower colors are in greater part due to anthocyanins. Research into the chemistry of anthocyanins first began around 1913 with investigations by *Willstätter*, who had just finished his famous work on chlorophyll. He determined the structure of cyanin, which had been isolated from the blue cornflower, *Centaurea cyanus*.[7] Within a few years thereafter he had determined the structures of most of the important anthocyanin aglycons, the anthocyanidins, which are responsible for the color of the anthocyanins.

Like litmus, anthocyanin changes its color with changing pH: in strongly acidic medium it appears orange to red in color, whereas in weakly acidic to neutral solutions it appears purple to violet. The blue color can be produced only in alkaline solutions.

Willstätter attributed the variety of flower colors to variation in pH in the flower cell sap. Indeed, he had isolated cyanin[7] from blue cornflower as well as from red rose. *Shibata*,[8] a Japanese botanist, questioned this theory of pH-value for explaining the blue flower color, for it was hardly conceivable that flower cell sap could be alkaline.[9] Instead, he proposed, in 1919,[8] a metal-complex theory, according to which the blue color is produced by complexation of anthocyanins with metal ions such as magnesium ions. As experimental evidence he mentioned, inter alia, the reduction of flavones with magnesium and acid in non-aqueous media, which leads to a blue complex of anthocyanin and magnesium. *Everest*, one of *Willstätter*'s collaborators, strongly opposed this theory without offering any experimental evidence to the contrary. Since then the theory fell into oblivion, until it was resurrected in 1957 by *Hayashi*, a former co-worker of *Shibata*. *Hayashi* isolated[10,11] a blue-colored anthocyanin, commelinin, in crystalline form from deep-blue flower petals of *Commelina communis* (Fig. 1, left) and reported[7] that it consists of two molecules each of an anthocyanin (awobanin **A**), and a flavone (flavocommelin **F**),[12] and one atom each of magnesium[13,14] and potassium. This pigment is so stable that its blue color does not immediatly alter upon changing the pH from 7 to 1. *Hayashi* et al. explained its color and stability in terms of a 1:4 coordination complex of magnesium and flavonoids (**A** + **F**), as shown in Figure 2 (top).[15] He named such a metal complex of anthocyanin metalloanthocyanin. However, *Bayer*[16] opposed this explanation, since, in contrast to iron(III) or aluminum ions, magnesium ions generally do not form stable chelates with anthocyanins.

In 1958, *Bayer*[17] isolated another blue metalloanthocyanin named protocyanin from the blue cornflower *Centaurea cyanus* (Fig. 1, right). He reported that it contained 19.2% cyanin and about 80% of a polysaccharide as well as ferric and aluminum ions (MW ca. 6200). He proposed a structure for it in which the trivalent metal ions coordinatively bind two cyanin molecules and a polygalacturonic acid (Fig. 2, bottom).[16,18] *Hayashi* et al. reported[19] that the protocyanin that they had isolated, yielded, on hydrolysis, cyanin, a flavone, a polysaccharide, and a polypeptide, as well as iron, magnesium, and potassium ions, but not aluminum ions. *Asen* and *Jurd*[20] isolated from blue cornflower a blue pigment, which, according to their analysis, was an iron complex of four molecules of cyanin and three molecules of a flavone glucoside. Since they thought that it differed markedly from protocyanin they named it

cyanocentaurin, but *Osawa*[21] later concluded that it was identical with *Hayashi*'s protocyanin.

Commelinin and protocyanin show two surprising properties that distinguish them from other anthocyanin pigments; they are not dialyzable, and, upon electrophoresis at pH 4–6, they migrate to the anode, thus indicating that they are high molecular weight, negatively charged pigments.[22]

In 1931, *Robinson* et al.[23] suggested a "copigmentation effect" of flavones and tannins. The effect produces a bathochromic shift of the visible absorption band of anthocyanins. The copigmentation, however, occurs only in aqueous solutions, is nonstoichiometric, and gives, at most, a bluish-violet and never the pure blue color of commelinin and protocyanin.

1.2. Controversy about the Stabilization of Anthocyanins

Numerous anthocyanins have been isolated from flowers, fruits and leaves, but relatively few anthocyanidins, the, aglycons of anthocyanins, have been found. The main anthocyanidins found in nature are pelargonidin, cyanidin, peonidin, delphinidin, petunidin, and malvidin (Fig. 3). The most widely spread anthocyanins are anthocyanidin 3-glucosides and 3,5-diglucosides.[24] In strongly acidic media (pH below 2.5), anthocyanins form stable flavylium ions, whose color is usually orange or red. When an acidic solution of an anthocyanin is neutralized to pH 4 to 6, the violet anhydrobase is formed first, but it decolorizes rapidly to form a pseudobase by hydration (Fig. 4).[4, 25–29] Since

Toshio Goto was born in Gifu (Japan) in 1929. He graduated from Nagoya University in 1952 and became a member of the staff in the Department of Chemistry of the University in 1954. From 1957 through 1959 he worked with professor L. F. Fieser in the Department of Chemistry at Harvard University. He received his Ph.D. from Nagoya University in 1960 and was promoted to Associate Professor in 1961. In 1966 he transferred to the Department of Agricultural Chemistry as a Professor of Organic Chemistry. His main research interests included the determination of the structure of and total synthesis of biologically active or functionally interesting natural products such as marine toxins, nucleosides, and gangliosides, and the chemistry of bioluminescence and flower color variation. In August 1990 Professor Goto suffered a fatal heart attack.

Tadao Kondo was born in Nagoya (Japan) in 1941. He graduated from Gifu Pharmaceutical College in 1965 and continued his studies in the Department of Agricultural Chemistry of the University of Nagoya. After obtaining his M.Sc. and joining the teaching staff of the Department in 1969, he finally gained his Ph.D. in 1973. He then joined Professor R. U. Lemieux's group and worked as a post-doc in the Department of Chemistry at the University of Alberta, Canada, in the period 1973–1975. In 1979 he moved to the Chemical Instrument Center, Nagoya University, as a Research Associate. His major research fields are the synthesis of nucleosides and gangliosides, and the chemistry of flower color variation.

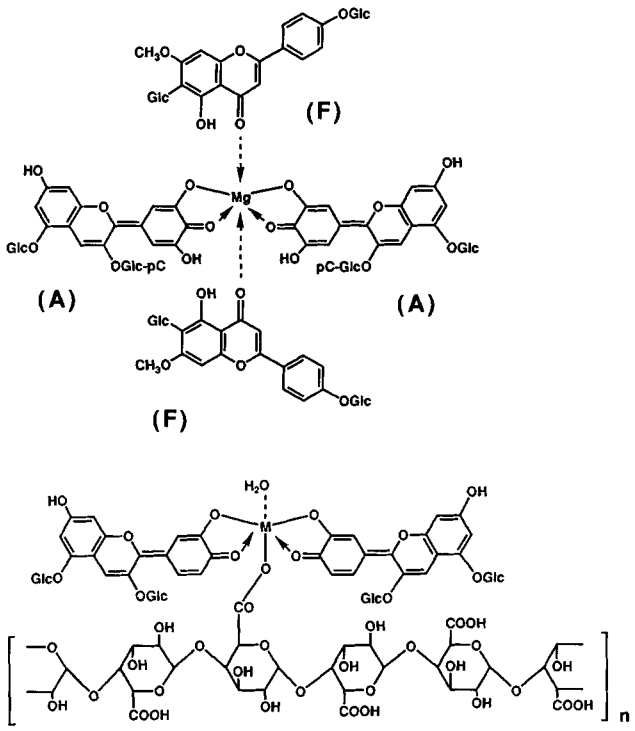

Fig. 2. Top: Structure of commelinin proposed by *Hayashi* et al. [15] (1970). A: awobanin 5; F: flavocommelin 3. Bottom: structure of protocyanin proposed by *Bayer* et al. [16] (1966). pC = *p*-hydroxycinnamoyl.

flower cell sap is usually weakly acidic, anthocyanins cannot be stable in the cell sap if there is no additional stabilizing effect.

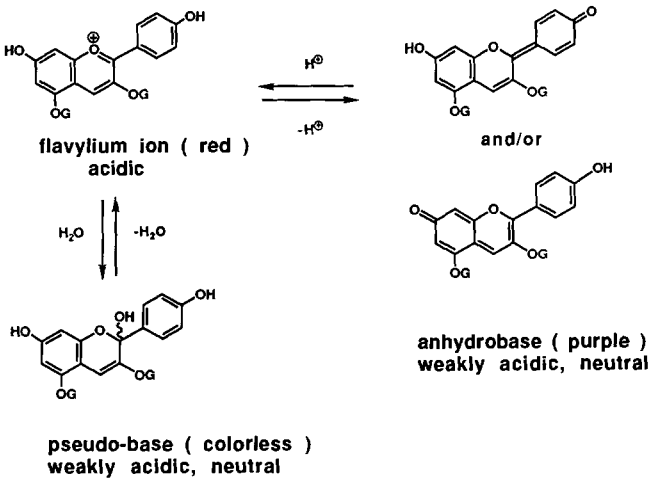
OCH_3	H	petunin	petunidin
OCH_3	OCH_3	malvin	malvidin

Fig. 3. Structure of common anthocyanins.

The copigmentation has some stabilizing effect as well as a bathochromic effect on anthocyanins. Polyphenols such as flavones and tannins have copigmentation effects, which have long been attributed to hydrogen bonding between the host compound and the copigment used.[30-32]

Another stabilizing mechanism was suggested by *Asen* et al.[30] in 1972: the self-association of anthocyanins. It was based on the observation that, at pH 3.16, the absorbance of cyanidin 3,5-diglucoside at λ_{max} increased 300 times when the concentration was increased from 10^{-4} M to 10^{-2} M (100 times), suggesting a self-association of the anthocyanin in the form of the flavylium ions.[6] Similarly, the shape of the visible absorption spectrum changed when a solution of a delphinidin derivative at pH 6.6 was diluted from 8×10^{-3} M to 8×10^{-5} M; the absorbance ratio $A_{624\ nm}/A_{540\ nm}$ changed from 0.58 to 1.10, i.e. the solution became intense blue.[33]



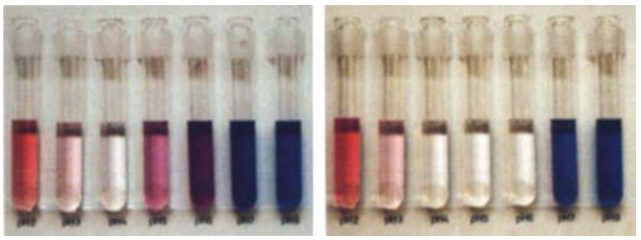


Fig. 4. Top: Change in structure of an anthocyanin in aqueous solution as a function of pH (G = sugar residue). Bottom left: Malvin in water (5×10^{-5} M) at several pH values; just after dissolving. Bottom right: Malvin in water (5×10^{-5} M) at several pH values; 2 hours after dissolving.

Raising the temperature produced a similar change. This suggested that dilution or heating caused dissociation of associated anthocyanins. Indeed, the concentration of anthocyanins in vivo reaches as high as 2.4×10^{-2} M.[34, 35]

1.3. Controversy about Horizontal Stacking (Hydrogen Bonding) and Vertical Stacking (Hydrophobic Interaction)

Numerous workers have considered self-association and copigmentation as being very likely; however, the association has in greater part been attributed to hydrogen bonding between hydroxy and carbonyl groups on the aromatic nuclei and sugar moieties to form horizontally stacked molecules.[30, 32, 36]

On studying the molecular assembly of commelinin, the blue pigment obtained from *Commelina communis*, we already alluded, as long ago as 1976,[37, 38] to a vertical stacking of anthocyanin and flavone molecules by hydrophobic interaction between the aromatic nuclei, a stacking which is further stabilized by superimposed hydrophilic sugar moieties. This concept was supported by *Sweeny* et al.[39] Then, convincing evidence was obtained for a vertical self-

association of anthocyanin anhydrobases in neutral solution by means of circular dichroism and ^{1}H-NMR spectroscopic measurements (Section 2). Copigmentation phenomena such as the association between anthocyanin and flavone were analyzed similarly (Section 4). Flavone itself was also found to self-stack vertically (Section 3). Although intermolecular associations such as self-association and copigmentation are destroyed by dilution, very stable anthocyanins have been found recently in dilute neutral aqueous solutions. All of these stable anthocyanins contain two or more aromatic acyl moieties in a molecule. We and *Brouillard* proposed a sandwich-type vertical stacking of an anthocyanidin nucleus and two aromatic acyl moieties, and have reported some experimental evidence supporting this mechanism (Section 7).

Metalloanthocyanins such as commelinin and protocyanin have proven to be very complicated molecules. We have shown that they consist of six molecules each of anthocyanin and flavone with two metal ions; their molecular weight is nearly 10000. Unlike in the case of copigmentation their molecular assembly is stoichiometric. We attribute this arrangement in the metalloanthocyanins to self-association and copigmentation as well as to the complexation of metal ions (Section 5).

Thus, the stability and color variation of anthocyanins in aqueous solutions is mainly due to vertical, hydrophobic stacking (and/or charge transfer interaction) of aromatic nuclei in flavonoids and aromatic acids. The stacking may be further assisted by hydrogen bonding in the hydrophilic sugar moieties superposed on the stacks.

2. Self-Association of Anthocyanins

Although some indications of a self-association of flavylium ions in acidic solutions had been reported before, it was *Hoshino, Matsumoto*, and *Goto* who were first able to demonstrate the self-association of anthocyanin anhydrobases in neutral solution, by means of circular dichroism[40-42] and ^{1}H-NMR measurements.[43] Thus, the CD curves of typical anthocyanidin 3,5-diglucosides were found to show a large negative exciton-type Cotton effect in the visible absorption band region when the anthocyanins (in the form of their flavylium chlorides) are dissolved in a neutral buffer (pH 7.0) in fairly high concentration (Fig. 5, top). At least two anthocyanidin chromophores must stack vertically in a left-handed screw axis to cause this type of split bands. This finding is supported by theoretical calculations using the method of CD exciton-type chirality.[44] The magnitudes of $[\theta]$ are strongly intensified when the concentration is increased, indicating enhanced formation of stacked molecules in the more concentrated solutions.

Shifting of the visible spectra towards shorter wavelengths due to formation of the chiral aggregates is also observed at pH 7.0. The self-association of the delphin anhydrobase produces a remarkable hypsochromic shift in the visible spectrum (Fig. 5, top) as well as a large Cotton effect.[42] This indicates that the stability and color variation of these anthocyanins in flower petals are derived at least in part from self-association. The vertical stacking was also supported by ^{1}H-NMR spectral analyses.[43] The hypsochromic shift of malvin in aqueous solution is not only due to simple self-association. At pH 7.0 the anhydrobase and its anion are in equilibrium, and self-association suppresses ionization of the anhydrobase, thus giving rise to a hypsochromic shift.[45]

Cyanin and pelargonin behave abnormally.[46] The negative exciton-type Cotton curve formed at first gradually transforms into a large positive exciton-type Cotton curve with an unsymmetrical shape (Fig. 5, bottom). It was concluded therefrom that these anthocyanins gradually form a suspension of insoluble particles, which are responsible for the curve. Since these anhydrobases are sparingly soluble in water, highly aggregated particles are expected to be formed. In some flowers, pigment crystals were detected in the cell sap.[33,47-49] An X-ray structure analysis showed that pelargonidin bromide stacks vertically.[50]

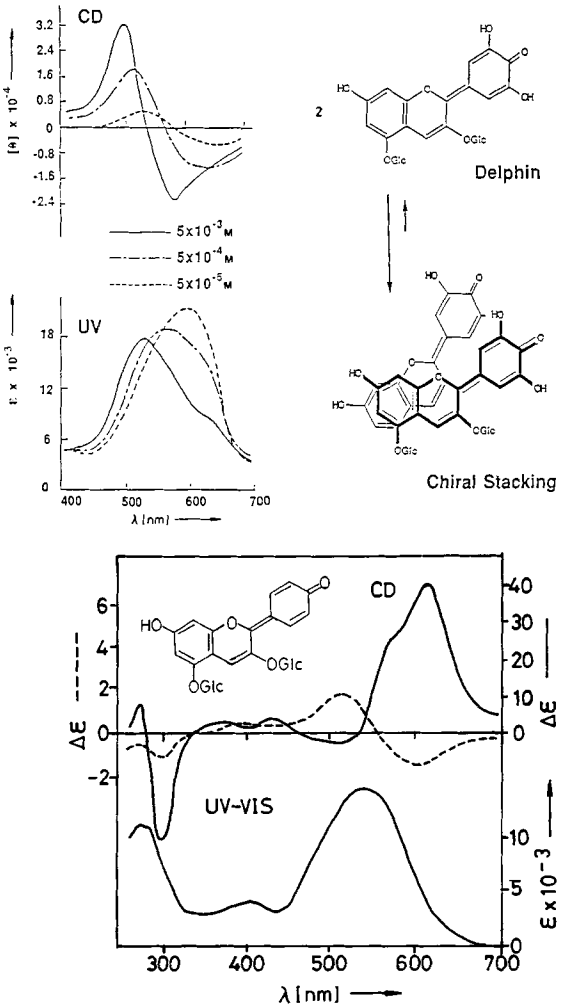

Fig. 5. Top: Dependence of CD and electronic spectra of delphin on concentration in water at pH 7.0. Bottom: UV/VIS and CD spectra of pelargonin (7×10^{-4} M) in 0.05 M phosphate buffer at pH 7.27. CD spectra: --- 2 min after dissolving; — insoluble particles formed by aging. Electronic spectrum: — 2 min after dissolving.

3. Self-Association of Flavones[51]

In aqueous solution, both the CD spectra and the UV spectra of the flavone flavocommelin depend on its concen-

tration (Figure 6, top). When the concentration increases to 5×10^{-3} M, fairly large exciton-type Cotton curves are observed, indicating that the flavone molecules are chirally self-associated in aqueous solutions at high concentrations. Such a stacking can also be supported by the decreasing absorbance in the UV spectrum and from the temperature dependence of CD and UV spectra. In contrast in DMSO solutions, no Cotton effect on the CD and no change in the

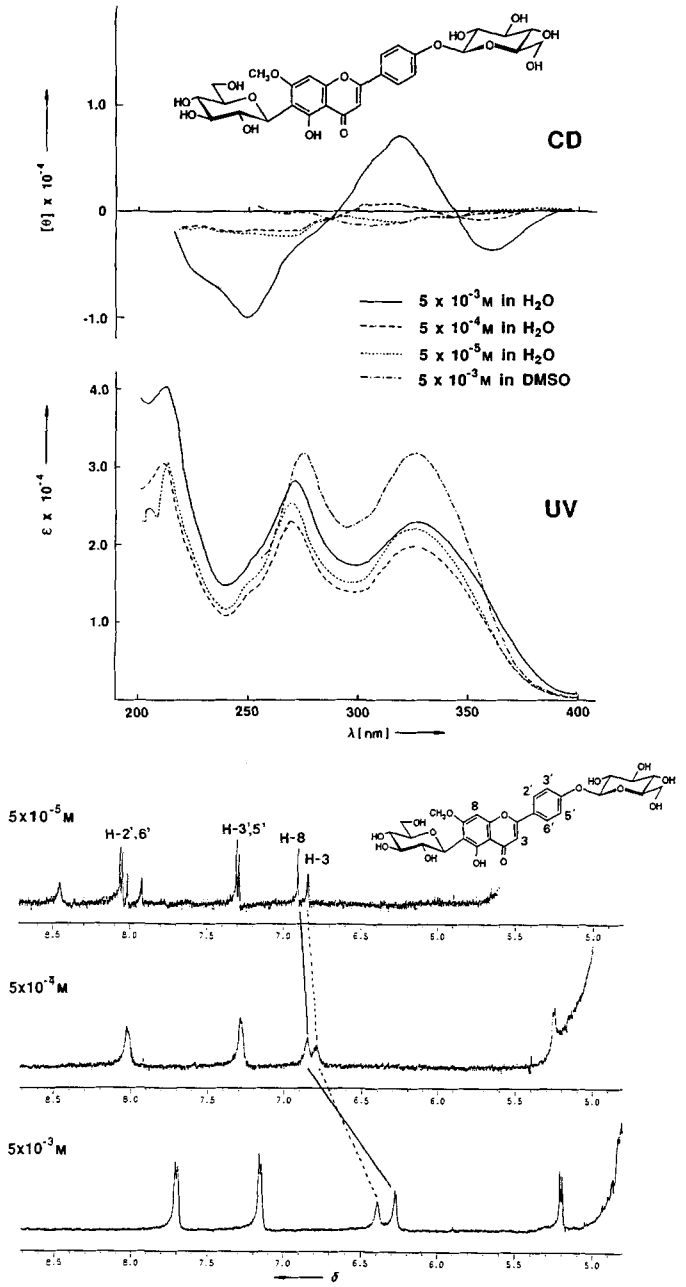

Fig. 6. Top: CD and UV spectra of flavocommelin **3** in water at pH 5.7 and in DMSO. Bottom: Concentration dependence on the ^{1}H-NMR signals of flavocommelin in D_2O at 30 °C.

UV spectra are observed at concentrations as high as 5×10^{-3} M. The NMR spectra also support assumption of such a stacking. The signals corresponding to the ring protons are all shifted toward higher fields when the concentration of the solution is increased (Fig. 6, bottom), whereas very little change is observed in the signal of the anomeric protons at $\delta = 0.04$, indicating that the aromatic rings are stacked vertically, so that the aromatic ring protons of a molecule are shielded by the aromatic rings of other molecules.

4. Copigmentation of Flavones with Anthocyanins

Since *Robinson* and *Robinson*[23] discovered the copigmentation effect in 1931 there have been many papers[6, 21, 27, 30, 33–35, 44, 52–62] reporting this phenomena between anthocyanin and flavone or other polyphenols. The copigmentation[21] depends on the type and concentration of the anthocyanin, on the type and concentration of the flavone, and on the pH and temperature of the solution. Anthocyanins which contain an aromatic acyl group form a much stabler copigmentation complex with flavones[53, 63] than unacylated anthocyanins, but anthocyanins having two or more aromatic acyl groups are stabilized by intramolecular sandwich-type stacking (Section 7) rather than by copigmentation. A copigmentation is possible both with the flavylium ion as well as the anhydrobase. It proceeds non-stoichiometrically only in solution, giving at best a bluish-purple color, and never producing a pure blue color.[44] Copigmentation not only causes a bathochromic shift of the visible absorption maximum of anthocyanin but also results in a large increase in absorptivity (stabilization) (Fig. 7, top).

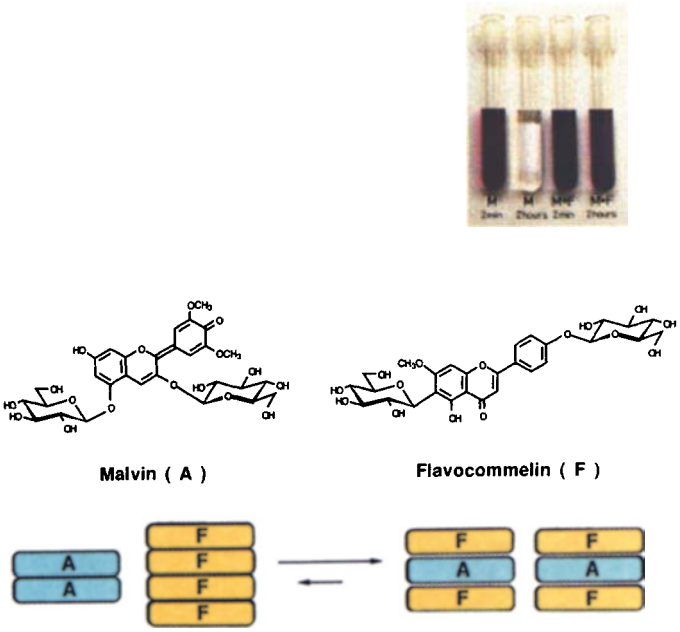

Fig. 7. Top: Copigmentation of flavocommelin and malvin in water at pH 6.0 (malvin: 5×10^{-5} M; flavocommelin: 5×10^{-4} M). Bottom: Copigmentation effect of flavocommelin on malvin.

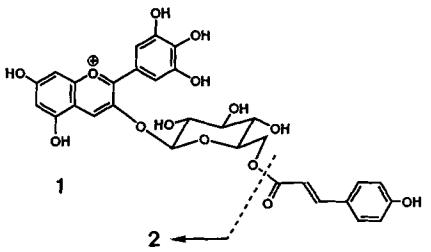
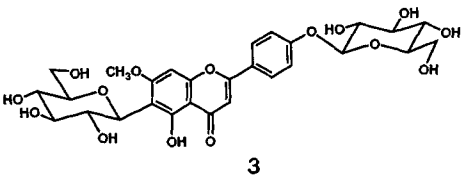
The copigmentation effect had long been explained in terms of hydrogen bonding between the host compound and the copigment used to produce horizontal stacking.[30–32, 36] We proposed[37, 38, 64] that copigmentation in aqueous solution arises from hydrophobic stacking between the aromatic nuclei of anthocyanin and flavone (vertical

stacking; charge transfer interaction[65] could also play a role) (Fig. 7, bottom). This hydrophobic stacking could be further stabilized by the hydrophilic sugar moieties covering them (hydrogen bonding). As an example, the mechanism of color development in the purple flower of *Commelina communis* is described.[66]

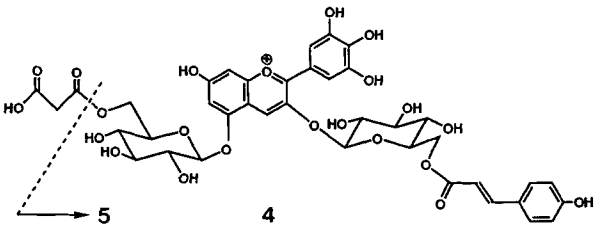
The purple flowering variant of *Commelina communis* (Fig. 1, middle) differs from the common blue flower (see Section 5).[67] The fact that also flowers with multicolored petals, e.g. half blue and half purple have been found, would indicate that a close relationship must exist between the blue and the purple pigments. Two anthocyanins, **1** and **2**, as well as flavocommelin **3** are found in the purple petals, whereas the blue petals contain malonylawobanin **4** and flavocommelin **3**.



3-*O*-[6-*O*-(*p*-hydroxycinnamoyl)-β-D-glucopyranosyl]delphinidin (**1**) and 3-*O*-(β-D-glucopyranosyl)delphinidin (**2**) from the purple flower of *Commelina communis*.



Flavocommelin (**3**) from *Commelina communis*.



Malonylawobanin **4** and awobanin **5** from the blue flower of *Commelina communis*.

Press juice from the purple petals has an absorption maximum in the visible range at 580 nm, while, at the same pH (pH 5.8) the absorption maxima of the anthocyanins **1** and **2** appear at 530 and 540 nm, respectively, suggesting copigmentation with the flavone, flavocommelin. The addition of three equivalents of flavocommelin **3** shifts the absorption maximum of **1** and **2**, about 30 and 40 nm to a longer wave lengths, respectively. The intensities of the absorptions are also increased considerably in the presence of the flavone, whereas Cotton effects in the CD spectrum of the anthocyanins are decreased. The visible spectrum of the press juice of purple petals coincides well with that of a mixture containing the anthocyanins, **1** and **2**, and the flavocommelin **3** (Fig. 8), thus indicating that the purple color of the

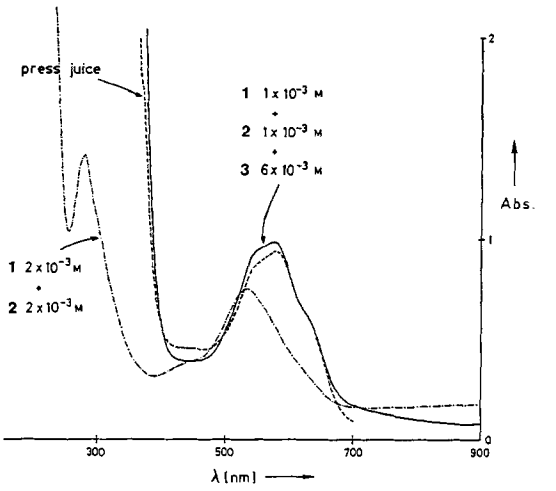


Fig. 8. Copigmentation effect of flavocommelin **3** on the anthocyanins **1** and **2**, to reproduce the in vivo purple color of *Commelina communis* variant. ---: press juice from purple petals, pH 5.8; -·-·-: **1** and **2** in 0.02 M acetate buffer, pH 5.8; ——: **1**, **2**, and **3** in 0.02 M acetate buffer, pH 5.8.

petals is produced by copigmentation of anthocyanins **1** and **2** and flavocommelin **3**. The disappearance of the Cotton effect in the visible region suggests a sandwich-type vertical stacking by hydrophobic interaction. A charge transfer interaction between the anthocyanin and the flavone could contribute to the bathochromic effect.

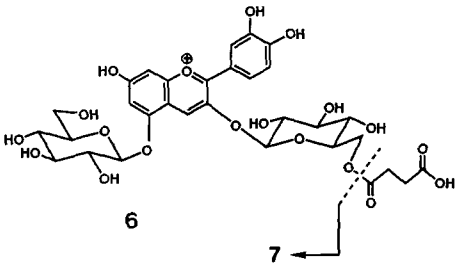
5. Metalloanthocyanins: Commelinin and Protocyanin[44]

5.1. Structure of Components

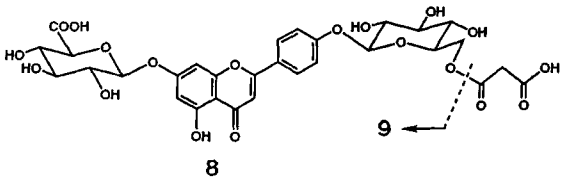
Up to now only two metalloanthocyanins have been isolated: commelinin and protocyanin. The pigment of the *Hydrangea* might also belong to this group.[59, 60]

Since commelinin moves towards the anode upon electrophoresis,[22, 68] it must have a negative charge. This was very difficult to explain, since neither awobanin (**A**) **5** nor flavocommelin (**F**) **3** has a negative charge, nor does the magnesium ion. The problem was finally solved, however, when it was discovered that the true anthocyanin present in the flower is malonylawobanin (**M**) **4**,[69, 70] which contains a malonic acid residue. Hence, awobanin (**A**) **5** is an artifact produced during extraction.

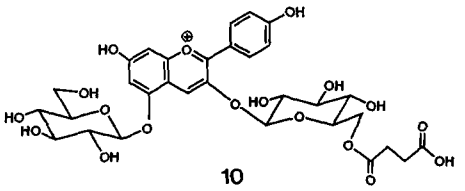
Willstätter et al. isolated cyanin **7** from cornflower petals.[7] It was believed to be the anthocyanin component of the blue pigment, protocyanin; however, we[71] and *Takeda*[72] found that the true anthocyanin is succinylcyanin **6**, which, similarly to malonylawobanin **4**, also contains a carboxy group. In 1974, *Asen* et al.[73] isolated a flavone from cornflower petals, and they established its structure as apigenin-4′-*O*-glucoside-7-*O*-glucuronide **9**, but it was also found to be an artifact. The true flavone **8** proved to have an additional malonic acid residue in the molecule.[72] Pink flowers of *C. cyanus* contain succinylpelargonin **10**,[74] while crimson flowers of the same species contain malonylcyanin **11** and succinylcyanin **6**[75] (Fig. 1, right).



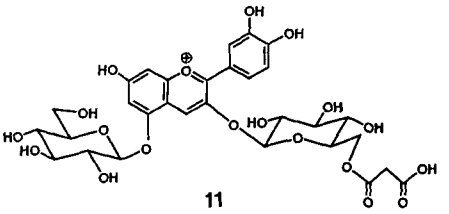
Succinylcyanin **6** and cyanin **7** from the blue flower of *Centaurea cyanus*.



The malonylflavone **8** and *Asen*'s flavone **9** from *Centaurea cyanus*.



Succinylpelargonin **10** from the pink flower of *Centaurea cyanus*.



Malonylcyanin **11** from the crimson flower of *Centaurea cyanus*.

5.2. Molecular Composition of the Metalloanthocyanins

Hayashi and *Takeda*[15] reported that commelinin consists of two molecules each of awobanin (**A**) **5** and flavocommelin (**F**) **3**, and one atom each of magnesium[76] and potassium; high molecular components such as polysaccharides and polypeptides could not be detected. These authors proposed a coordinated complex of magnesium and four flavonoid molecules (Fig. 2, top). Later, we[69] found that the actual anthocyanin involved is malonylawobanin (**M**) **4**.

On electrophoresis an aged commelinin sample mysteriously gave several blue spots (Fig. 9, right).[22,69] We found that commelinin obtained from fresh petals and that synthesized from **M**, **F** and magnesium ions produced only the spot that moved fastest, and that pigments prepared from **M**, **A**, **F**, and magnesium ions produced seven blue spots at the same intervals (Fig. 9, left). Commelinin synthesized from **A**, **F**, and magnesium ions gave only the spot that moved the slowest. This finding indicated that commelinin must contain six molecules each of **M** and **F** per molecule (MW about 9500).[77] The molecular weight determined by analytical ultracentrifugation was around 10 000.

Bayer et al.[16] and *Hayashi* et al.[19] independently described protocyanin as a complex of cyanin, a flavone, polysaccharides and/or polypeptides, and metal ions such as Fe and Al (*Bayer*), or Fe and Mg (*Hayashi*). *Bayer* proposed a structure containing polygalacturonic acid (Fig. 2, bottom), in which two anthocyanins and the polysaccharide chelate a metal ion.

We[44] obtained natural protocyanin free of macromolecular substances. It consisted of succinylcyanin **6**, the malonylflavone **8**, and Fe and Mg ions. A pigment reconstructed from the above components was identical with the natural pigment and contained about six molecules each of succinylcyanin **6** and the malonylflavone **8**, and one atom each of Fe and Mg; thus the composition is very similar to that of commelinin, suggesting a similar overall structure.

5.3. Evidence of Flavonoid Stacking in Commelinin

In commelinin, malonylawobanin molecules self-associate chirally, as is evident from the large exciton-type Cotton effect in the visible absorption band (Fig. 10, top).[44] Stacking between the anthocyanidin and flavone nuclei was apparent from ^{1}H-NMR spectrum of commelinin (Fig. 10, middle), in which some nuclear Overhauser effects were observed between protons of the anthocyanidin and the flavone, suggesting the crossing arrangement of **M** and **F** as shown in Fig. 10 (bottom).[78] The ^{1}H-NMR spectrum (Fig. 10, middle) reveals that six molecules each of **M** and **F** reside in the same environment, thus suggesting a cyclic arrangement such as cyclo(-**MMFFMMFFMMFF**-) of the twelve flavonoids. Strong evidence of vertical stacking of

Blue: malonylawobanin **4**; yellow: flavocommelin **3** (arrows indicate negative NOE observed between protons of **4** and **3**).

flavocommelin with other aromatic nuclei is obtained from the large high-field shifts of the aromatic proton signals of flavocommelin in commelin (Fig. 10, bottom).[78]

5.4. Gross Structure of Commelinin

It is well known that anthocyanins having *o*-dihydroxy groups on the B-ring form a blue chelate complex with trivalent metal ions such as iron(III) and aluminum(III); in contrast, divalent magnesium is not capable of forming such a complex.[16] *Hayshi* and *Takeda*[15] proposed, a priori, a structure for commelinin (Fig. 2, top) in which magnesium ion chelates with the *o*-dihydroxy group in the B-ring of awobanin (**A**) **5**. In order to establish the essential binding sites for the magnesium ions, we have examined whether commelinin-like pigment can be produced from modified components (Fig. 11, top left). Neither the malonyl and *p*-hydroxycinnamoyl groups of malonylawobanin (**M**) **4** nor the hydroxy group on C-5 of flavocommelin (**F**) **3** are essen-

tial. Since at least the *o*-dihydroxy group in the B-ring is necessary in order to obtain a similar type of complex, it could be that the metal ion chelates to this position.[44]

Crystals of commelinin[15] and the cadmium analogues of commelinin[13] have been prepared by *Hayashi* and *Takeda*, and subjected to X-ray crystallographic analyses by *Y. Saito* et al.[79] A complete structural analysis could not be accomplished, but the following crystal data were obtained: trigonal, space group $P321$, $a = 31.251$ Å, $c = 33.675$ Å, $Z = 12(?)$ (**AF** as one unit), $V = 28.529$ Å^3. This crystal has a threefold symmetry axis; the commelinin molecule must therefore have a three-fold symmetry.

6. Structure of Polyacylated Anthocyanins

6.1. General

Although numerous natural anthocyanins have been reported, little is yet known about their structures, since the structure determinations have thus far mainly been carried out by hydrolysis or oxidative degradation to fragments. Thus, as little is known about the configuration at the anomeric center and ring size of the sugar moieties as about the binding sites of the acyl groups in anthocyanins and the configuration of the double bond in the case of the cinnamic

Top right: A proposed gross structure of commelinin (another magnesium ion is under the magnesium ion shown, and two magnesium ions have an octahedral structure). **M**: malonylawobanin **4**; **F**: flavocommelin **3**. Bottom: Arrangement of six anthocyanidin skeletal frameworks, in the commelinin molecule. Left: View along the *c*-axis; right: view perpendicular to the c-axis. Based on a rough analysis of the X-ray crystallographic data.

Considering these crystal data and the above-mentioned findings, we proposed the structure shown in Figure 11 (top right) for commelinin.[1,44] The composition $[M_6F_6Mg_2]^{6\ominus}$ can be fulfilled by placing three M_2F_2 units around the *c*-axis and two magnesium atoms at the center. Two copigmented **MF** units are stacked chirally by hydrophobic interaction between the two anthocyanin molecules to form the **FMMF** unit; an intense exciton type Cotton band indicates chiral stacking of the two anthocyanins. Three **FMMF** units are doubly linked by chelation with two magnesium ions. A more detailed stacking form of the anthocyanidin nuclei is proposed in Figure 11 (bottom left and right), which we assumed from a very crude analysis[1] of the X-ray data recorded by *Y. Saito* et al.[79]

acid derivatives. ^{1}H-NMR and mass spectrometric analyses would seem most promising for elucidation of the structures of complex natural anthocyanins, but such investigations were not reported until 1978, when we first published the ^{1}H-NMR spectra of acylated anthocyanins.[70,80,81] The difficulty in obtaining analyzable NMR spectra may lie in the conventional purification method for anthocyanins.

Accurate molecular weight determination by mass spectrometry is also important for the elucidation of the structure of complex anthocyanins, since small components that show no NMR signals might be overlooked if the molecular weight is not known. Anthocyanin-flavylium salts are, however, highly polar compounds and do not readily give a molecular ion in their EI mass spectra. The molecular weight

(1113) of gentiodelphin was first determined by field desorption (FD) mass spectrometry in 1982.[82] Fast atom bombardment (FAB) mass spectrometry was then found best for observing the molecular ion, as reported by *N. Saito* et al.[83] and us[84] in the case of platyconin **13** (*m/z* 1421). Mass spectrometry enabled discovery of the presence of malonic acid in the anthocyanin **4** from *Commelina communis*.[69] The methylene protons in the malonic acid moiety are easily exchangeable with deuterium in acidic deuterium oxide or deuteriomethanol; hence the malonic acid moiety is difficult to detect by means of ^{1}H-NMR spectroscopy.[85]

In the conventional extraction method using methanolic hydrochloric acid the malonyl group in the anthocyanins is very likely to hydrolyze.[86] The finding of malonylawobanin **4** and succinylcyanin **6** discussed in Section 5.1 stimulated a reinvestigation of the structures of the natural anthocyanins that have so far been reported. *Harborne* reinvestigated natural anthocyanins by electrophoresis, since malonated anthocyanins exist as zwitterions at around pH 4.4. He and *Boardley*[87] (see also Ref. [88]) examined flowers of 81 species belonging to 27 plant families and found that zwitterionic anthocyanins occur in half of the samples; in particular, almost all species in the Compositae and the Labiatae gave a positive test. *Takeda* et al.[89] detected some dimalonated anthocyanins from Compositae by means of FAB mass spectrometry. Thus, zwitterionic anthocyanins widely occur in nature. Natural polyacylated anthocyanins, whose structure and stereochemistry have mainly been determined by us, are presented in the following sections.

6.2. Anthocyanins Polyacylated with Cinnamic Acid Derivatives

Cinnamic acid derivatives such as *p*-coumaric acid (4-hydroxycinnamic acid), caffeic acid (3,4-dihydroxycinnamic acid) and ferulic acid (4-hydroxy-3-methoxycinnamic acid) are very common in polyacylated anthocyanins. We have determined the complete structure of several such complex pigments as shown below.

Gentiodelphin **12**[82] obtained from *Gentiana makinoi* (Fig. 12, left) has two caffeylglucoside groups at the C-5 and C-3′ positions, while platyconin **13**[84] (for isolation, see Ref. [90, 91]) obtained from the Chinese bellflower *Platycodon grandiflorum* (Fig. 12, middle) has a long chain glucosylcaffeylglucosylcaffeylglucoside at the 7-position, which is a rare position to be glycosylated. Cinerarin **14**[92] (for isolation see Refs. [93–95]), obtained from the garden cineraria *Senecio cruentus* (Fig. 12, right), has a more complicated structure of this type; it has three caffeylglucosyl units in addition to a malonylglucosyl moiety at C-3. Heavenly blue anthocyanin (HBA) **15**, isolated[96,97] from blue flowers of a morning glory *Ipomoea tricolor* (Fig. 13, left), has a branched chain containing three glucosylcaffeic acid moieties at C-3; two moieties have a glucose unit in the *m*-position of the caffeic acid and one on the *p*-position.[98–101] The anthocyanins **16–18**, each with two cinnamic acid derivatives, have been found in the red cabbage, *Brassica oleracea*.[102,103] (see also Ref. [104]). Interestingly, one of the acids is attached at the 2-position of a glucose unit instead of

the usual 6-position, and anthocyanins containing one of three different acids—*p*-coumaric, ferulic, and sinapic acid—coexist.

Zebrinin **19**,[105] obtained from *Zebrina pendula* (Fig. 14, left), has four caffeyl groups; two groups are bound to an arabinose unit. It is interesting that lobelinin B **21**[106] (for isolation, see Ref. [107]) from *Lobelia erinus* (Fig. 14, right) has four different acyl glucosides on the cyanidin: *p*-coumaric, caffeic, ferulic, and malonic acids are bound to different sugar moieties (cf. lobelinin A **20**)! Recently, similar type

pigments, ternatin A1 **22** and ternatin B1 from *Clitoria ternatea*, were reported by *Terahara* et al.[108] and *Kondo* et al.,[109] respectively.

Curiously, the 3-phenylpropenoic acid derivatives in the anthocyanins are predominantly in the *E* configuration, i.e.

6.3. Anthocyanins Polyacylated with Benzoic Acid Derivatives

Delphinium flower is widely cultivated as one of the most famous horticultural plants in the world. In 1915, *Willstätter*[113] isolated a pigment, delphinin, from the petals of *Delphinium consolide* and suggested the structure as bis(*p*-hydroxybenzoyl)diglucosyldelphinidin. At that time very few anthocyanins with benzoic acid derivatives as acyl components were known. In 1964, however, *Harborne*[86] reported that the presence of a *p*-hydroxybenzoyl group in this molecule is doubtful. Later, *Asen* et al. reported an anthocyanin isolated from the larkspur "Dark Blue Supreme" to be delphinidin 3-[bis(*p*-hydroxybenzoyl)glucosylglucoside],[33] and an anthocyanin from flowers of the biennial bellflower, *Campanula sp.* "Rose" to be pelargonidin 3-[bis(*p*-hydroxybenzoyl)rutinoside-7-glucoside].[114] From violet flowers of

Fig. 14. Left: *Zebrina pendula*. Right: *Lobelia erinus*.

are present as cinnamic acid derivatives.[110, 111] The reason for this is still unclear. In the case of monoacylated anthocyanins, however, derivatives with *Z*-configuration may be formed.[111, 112]

the *Delphinium hybridum* "Black Night" (Fig. 15, left) we[115] isolated the anthocyanin violdelphin **23**. It contains two molecules of *p*-hydroxybenzoic acid, but has a structure completely different from those reported above. The

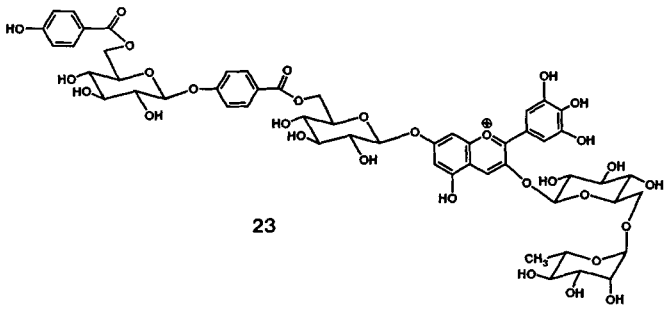
Fig. 15. Left: *Delphinium hybridum* 'Black Night'. Middle: *Salvia splendens*. Right: *Slavia farinacea*.

blue flowers of *Delphinium* furnished a more complicated anthocyanin which has two more *p*-hydroxybenzoylglucosyl units than **23**.



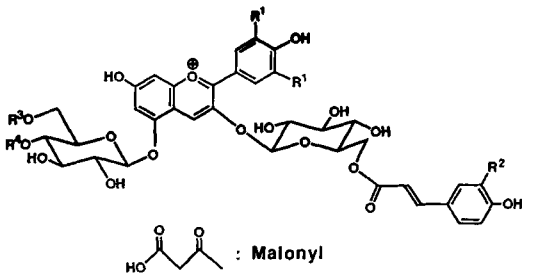
23

Violdelphin **23** from the violet flower of *Delphinium hybridum*.

6.4. Anthocyanins Polyacylated with Malonic Acid

Willstätter and *Bolton*[116] reported that salvianin isolated from *Salvia coccinea* consists of pelargonidin diglucoside acylated with malonic acid. *Karrer* and *Widmer*[117, 118] isolated monardaein from *Monarda didyma*, which they considered to be identical with salvianin and composed of pelargonidin diglucoside acylated with two molecules of malonic acid and one molecule of *p*-coumaric acid. Contrary to the above results neither *Harborne*[86] nor *Birkofer* et al.[119] could find malonic acid in any of these anthocyanins.

We found that monardaein (**30**)[120] indeed contains two molecules of malonic acid. We have also examined scarlet, purple, and blue flowers of *Salvia* (Fig. 15, middle).[121] In scarlet petals of *s. splendens* we found salvianin **24**,[122] monodemalonylsalvianin **25**, monardaein **30**, and monodemalonylmonardaein **31** (ratio of yields, 8:4:2:1). Purple petals of *s. splendens* gave salviadelphin (**26**), monodemalonylsalviadelphin (**27**), bisdemalonylsalviadelphin (**28**), and dimalonylawobanin (**32**) (5:4:1:1). Similarly, blue petals of *S. farinacea* (Fig. 15, right) gave malonylawobanin **4** and salviamalvin **29** (2:1).



: Malonyl

	R^1	R^2	R^3 [a]	R^4 [a]		Color
24	H	OH	Mal	Mal	salvianin	scarlet
25	H	OH	Mal	H		scarlet
26	OH	OH	Mal	Mal	salviadelphin	purple
27	OH	OH	Mal	H		purple
28	OH	OH	H	H		purple
29	OCH_3	H	Mal	H	salviamalvin	blue
30	H	H	Mal	Mal	monardaein	scarlet
31	H	H	Mal	H		scarlet
32	OH	H	Mal	Mal		purple
4	OH	H	Mal	H	malonylawobanin	blue

[a] Mal = Malonyl.

Anthocyanins **24**–**32** from scarlet, purple, and blue flowers of *Salvia*.

Very interestingly, the difference in color of the scarlet, purple, and blue petals of *Salvia* not only arises from the difference in the anthocyanidin nuclei (pelargonidin, delphinidin, and malvidin; cf. Fig. 3) but also from the difference in pH in the petals: pH 5.6 in scarlet petals, pH 6.1 in purple petals, and pH 7.0 in blue petals.

7. Intramolecular Sandwich-type Stacking of Polyacylated Anthocyanins

In 1971 *N. Saito* et al.[90] found that platyconin **13** is unusually stable in neutral or weakly acidic aqueous solu-

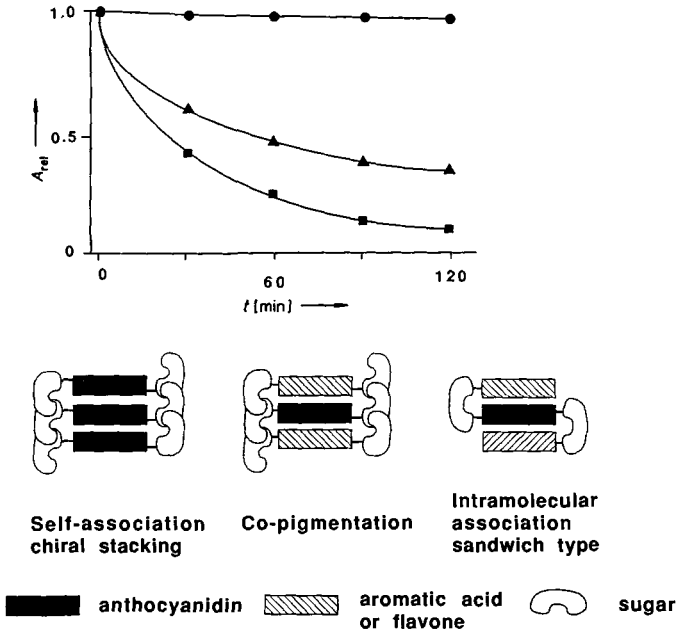


Fig. 16. Top: Approximate representation of the stability of anthocyanins (5×10^{-5} M) in water at pH 6.5. ●–●: Anthocyanins having two or more moieties of cinnamic acid derivative(s); ▲–▲: anthocyanins having one moiety of a cinnamic acid derivative; ■–■: anthocyanins having no acyl moiety. tions. Then, a few of the stable anthocyanins listed in Section 6.2 were found.[94, 107, 108] These anthocyanins contained two or more cinnamic acid derivatives. Removal of the acyl groups by hydrolysis made the anthocyanin unstable (Fig. 16, top). Such an effect had been attributed to hydrogen bonding between the phenolic hydroxyl groups in the anthocyanidin and the aromatic acids.[93] We[82, 84] and *Brouillard*,[27, 64, 123] on the other hand, were of the opinion that diacylated anthocyanins must be stabilized by a sandwich-type stacking (Fig. 16, bottom) caused by hydrophobic interaction between the anthocyanidin ring and the two aromatic acyl groups, as suggested in the case of copigmentation[37] and self-association.[40]

Evidence supporting this hypothesis has been obtained from ^{1}H-NMR spectra. Careful nuclear Overhauser effect (NOE) measurements on heavenly blue anthocyanin (HBA) **15** showed several long-range NOE's (Fig. 17, top), indicating a folded conformation for HBA.[44] A comparison of the ^{1}H-NMR data of HBA with those of methyl glucosylcaffeate showed that: the proton signals on the two caffeic acid residues, which are close to the anthocyanidin nucleus of HBA, exhibited large upfield shifts, whereas the signals of the third caffeic acid residue, which is distant from the anthocyanidin, showed only small shifts (Fig. 17, top). This indicates that two of the aromatic acyl groups are stacked parallel with the anthocyanidin nucleus. The CD curve showed a strong Cotton effect near the absorption of the acyl groups (ca. 349 nm), whereas no exciton-type splitting was observed in the visible region.

Figure 17 (bottom) shows an intramolecular sandwich-type stacking model of HBA **15**. Such stacking protects the HBA molecule from attack by water to form the pseudobase, thus stabilizing the flavylium ion as well as the anhydro base. The blue color of the petals is caused by an increase in the pH of the cell sap to 7.5,[124, 125] an unusually high pH (Fig. 18). The red morning glory, "Scarlet O'Hara" (*Ipomoea nil*) (Fig. 13, right), has an anthocyanin **33** that differs from HBA **15** only by lacking a methoxy group on the B-ring,[78] but the color is quite different because the pH of the cell sap is lower (pH 6.1).

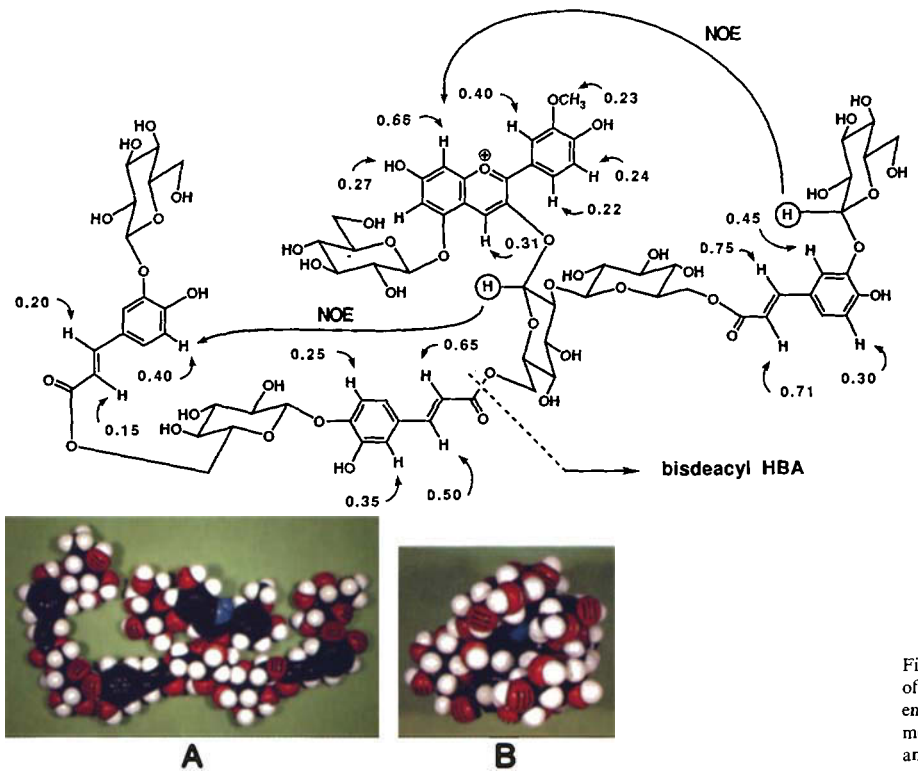

Fig. 17. Top: Long-range NOE's and upfield shifts of proton signals in the ^{1}H-NMR spectrum of heavenly blue anthocyanin **15** in acidic deuteriomethanol. Bottom: CPK models of heavenly blue anthocyanin **15**. A: extended form; B: stacked form.

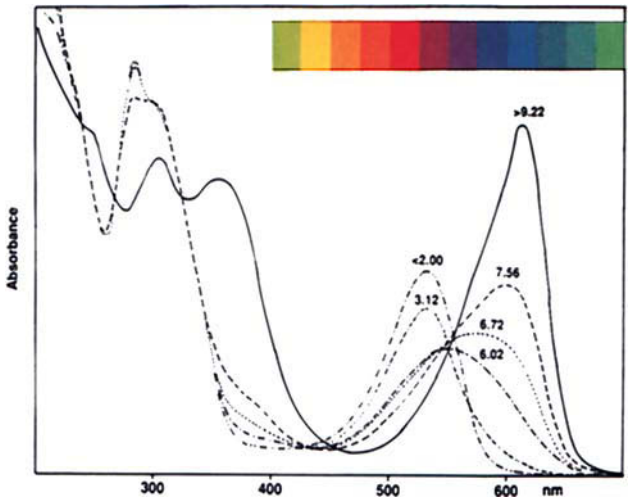

Fig. 18. Electronic spectra of heavenly blue anthocyanin **15** in aqueous solutions at several pH's (the rainbow colors show only approximate spectra).

A detailed conformational analysis of gentiodelphin **12** was carried out using the coupling constants and NOE data of the ^{1}H-NMR spectra (Figure 19, top). Unlike HBA, gentiodelphin does not assume a sandwich-type conformation (Fig. 19, bottom).[75] Despite this gentiodelphin **12** is fairly stable in aqueous solution (Fig. 20). The reason why gentiodelphin is so stable, however, awaits further clarification.

8. Summary and Outlook

Simple anthocyanins are not stable in dilute aqueous solutions; they are stabilized by vertical stacking of aromatic rings between anthocyanins (self-association), anthocyanins and phenols such as flavones (copigmentation), or intramolecularly between anthocyanidins and their aromatic acid residues (intramolecular sandwich-type stacking) by hydrophobic interactions (Fig. 21, top). Such stackings are further

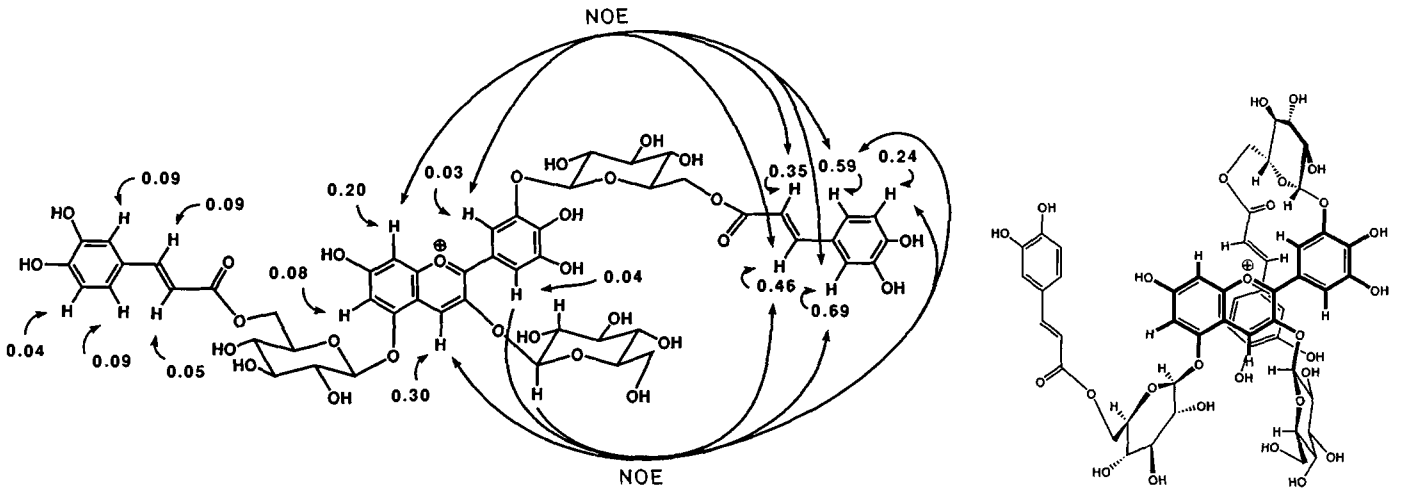

Fig. 19. Left: Long-range NOE's and upfield shifts of proton signals in the ^{1}H-NMR spectrum of gentiodelphin **12**. Right: A stacked conformation of gentiodelphin **12**.

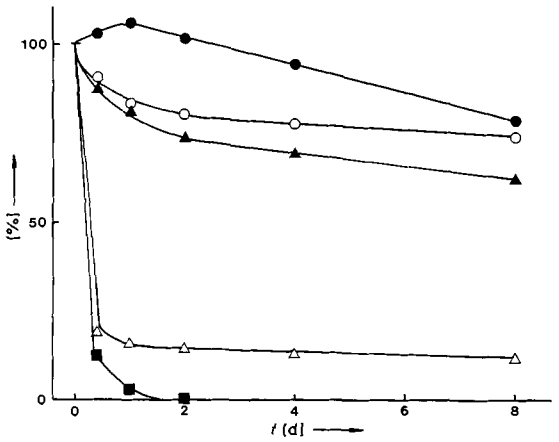

Fig. 20. Stability of acylated anthocyanins (5×10^{-5} M) in aqueous solutions at pH 6.5. ●–● lobelinin A **20**, ○–○ gentiodelphin **12**, ▲–▲ HBA **15**, △–△ bisdeacyl-HBA, ■–■ awobanin **5**.

stabilized by a superposed layer of hydrophilic sugar moieties (hydrogen bonding). Attack by a water molecule at C-2 of the anthoycanidin nucleus is prevented by the stacked moities since hydration would result in conversion of the sp^2-hybridized carbon atom C-2 into a sp^3-hybridized carbon atom (Fig. 21, bottom). The presence of such stackings has been detected in vivo by means of CD,[126] and resonance Raman spectra.[127, 128]

In the case of metalloanthocyanins, metal ions chelate with anthocyanin molecules, which, in turn, stack with flavone molecules. A cyclic arrangement of twelve flavonoids (six anthocyanins and six flavones) centered by metal ions has been proposed. Commelinin has two magnesium ions in the center of twelve flavonoid molecules arranged symmetrically, but, remarkably, two different metal ions are involved in protocyanin. Is it possible that two different metal ions exist in a symmetrical arrangement similar

to that of commelinin? This interesting problem will be solved only by X-ray analysis of the complex molecules. Now, the X-ray analysis of commelinin is in progress.

Polyacylated anthocyanins are suggested to be stabilized by sandwich-type stacking of two aromatic acyl moieties on and under the anthocyanidin nucleus, as is evident from the ^{1}H-NMR data of HBA **15**. In the case of gentiodelphin **12**, however, only one aromatic acyl group can be stacked on the anthocyanidin nucleus; nevertheless it shows a similar stability to that of HBA. Further studies, in particular a detailed analysis of the molecular recognition, are necessary in order to clarify these stabilization mechanisms.

Polyoxometalate Chemistry: An Old Field with New Dimensions in Several Disciplines

By Michael T. Pope* and Achim Müller*

Inorganic metal–oxygen cluster anions form a class of compounds that is unique in its topological and electronic versatility and is important in several disciplines. Names such as *Berzelius, Werner,* and *Pauling* appear in the early literature of the field. These clusters (so-called isopoly- and heteropolyanions) contain highly symmetrical core assemblies of MO_x units (M = V, Mo, W) and often adopt quasi-spherical structures based on Archimedean and Platonic solids of considerable topological interest. Understanding the driving force for the formation of high-nuclearity clusters is still a formidable challenge. Polyoxoanions are important models for elucidating the biological and catalytic action of metal–chalcogenide clusters, since metal–metal interactions in the oxo clusters range from very weak (virtually none) to strong (metal–metal bonding) and can be controlled by choice of metal (3d, 4d, 5d), electron population (degree of reduction), and extent of protonation. Mixed-valence vanadates, in particular, show novel capacities for unpaired electrons, and the magnetic properties of these complexes may be tuned in a stepwise manner. Many vanadates also act as cryptands and clathrate hosts not only for neutral molecules and cations but also for anions, whereby a remarkable "induced self-assembly process" often occurs. Polyoxometalates have found applications in analytical and clinical chemistry, catalysis (including photocatalysis), biochemistry (electron transport inhibition), medicine (antitumoral, antiviral, and even anti-HIV activity), and solid-state devices. These fields are the focus of much current research. Metal–oxygen clusters are also present in the geosphere and possibly in the biosphere. The mixed-valence vanadates contribute to an understanding of the extremely versatile geochemistry of the metal. The significant differences between the chemistry of the polyoxoanions and that of the thioanions of the same elements is of relevance to heterogeneous catalysis, bioinorganic chemistry, and veterinary medicine.

Ubi materia, ibi geometria.

Mundus participat quantitate, et mens hominis...
nihil rectius intelligit, quam ipsas quantitates, quibus percipiendis factus videri potest.[**]
Johannes Kepler

1. Introduction and Historical Background

The chemistry of molybdenum (VI), tungsten (VI), and vanadium (V) in aqueous solution is dominated by the formation of polyoxoanions,[1] as exemplified by Equations (a) and (b).

$$8\,H^{\oplus} + 7[WO_4]^{2\ominus} \longrightarrow [W_7O_{24}]^{6\ominus} + 4\,H_2O \quad (a)$$

$$23\,H^{\oplus} + [HPO_4]^{2\ominus} + 12[MoO_4]^{2\ominus} \longrightarrow [PMo_{12}O_{40}]^{3\ominus} + 12\,H_2O \quad (b)$$

This behavior has long been recognized; in the earliest systematic investigation of molybdenum chemistry, *Berzelius*[2] noted the formation of yellow (heteropolyanion) products from the reaction of molybdate with phosphate or arsenate and the subsequent ready formation (which has important consequences) of the blue (mixed-valence) derivatives. The first heteropolytungstates were discovered and characterized by *Marignac* in 1862. During the next 70 years, polyoxometalates were intensively investigated, and hundreds of such compounds are described in the Gmelin volumes published in the 1930s.[3, 4] In his famous book, *Neuere Anschauungen auf dem Gebiete der Anorganischen Chemie* (1909), *A. Werner* proposed structures for the species ("Iso- und Heteropolysäuren und Heteropolysalze"). A remarkable sentence is: "Wahrscheinlicher ist aber, daß die einzelnen Kerne der mehrkernigen Anionen viel inniger, d. h. nicht nur durch ein, sondern durch mehrere Sauerstoffatome miteinander verbunden sind"[***] (anticipation of edge- and face-sharing of polyhedra!). *Pauling,* with his instinct for an important class of compounds, proposed structures that were based on corner-sharing of MO_6 octahedra,[5] but it was not until 1933, when *Keggin* reported the structure of the heteropoly acid $[H_3PW_{12}O_{40}]\cdot 6\,H_2O$ (by analysis of 32 powder X-ray lines),[6] that the importance of more compact

edge-shared polyhedral arrangements was revealed. Further progress was slow; a review published in 1971[7] listed only 25 X-ray investigations, most of low quality. Subsequent developments in X-ray crystallographic hardware and software have altered this picture considerably; in 1987/88, for example, some 66 structures were published. During the last 20 years, spectroscopic methods such as Raman and one- and two-dimensional metal and ^{17}O NMR spectroscopy have flourished[8–14] and these, in combination with precise electrochemical measurements (see, for example, Refs. [15,16]) and new analytical techniques such as fast atom bombardment (FAB) mass spectrometry,[17] have enabled the important links between solid and solution structure to be established. New classes of structures with often unexpected reactivity and applications are still being characterized. The number of heteropolymolybdate and -tungstate anions is immense; more than 70 different heteroelements, with "coordination numbers" ranging from 3 to 12, have been confirmed and, for many of these (e.g., P/Mo pair species), dozens of stoichiometries and structures are known.

The present article aims to highlight some of the more interesting and important recent results and to indicate some of the directions and challenges of future research. Polyoxometalates form a class of inorganic compounds that is unmatched in terms of molecular and electronic structural versatility, reactivity, and relevance to analytical chemistry, catalysis, biology, medicine, geochemistry, materials science, and topology.

2. Problems of Nomenclature

The nomenclature of polyoxometalates involves two considerations: a name for the class as a whole and the systematic nomenclature of individual species.

The names "isopoly" and "heteropoly" for species such as those formed in Equations (a) and (b), respectively, are unsatisfactory for at least two reasons: not only is "homo" a more usual antonym for "hetero", but the distinction between the two groups is wholly artificial and could lead to solecisms such as "mixed isopolyanion" to describe species such as β-$[Mo_6V_2O_{26}]^{6\ominus}$ (isostructural with the isopolymolybdate β-$[Mo_8O_{26}]^{4\ominus}$) and the consideration of $[(H_2)W_{12}O_{40}]^{6\ominus}$ (which is chemically and structurally equivalent to a heteropolyanion like $[SiW_{12}O_{40}]^{4\ominus}$) as an isopolyanion. Names such as "polyoxoanions" and "polyoxometalates" have been used more recently, but it is important with a field as venerable as this, with a vast early literature, that changes in nomenclature not be made lightly. However, we favor the gradual introduction of a name such as "metal–oxygen clusters", which can be used for the field as a whole and which emphasizes the presence of *metal* centers. The word cluster in inorganic chemistry has hitherto been applied to species in which there are strong as well as weak metal–metal interactions (cf. "iron–sulfur clusters"). This seems appropriate for the present field, since, as we shall see, polyoxometalates exhibit the whole range of metal–metal interactions, from extremely weak to very strong.

The question of systematic nomenclature, which is important for information retrieval, has been addressed by IUPAC.[18] The names must take into account a labeling system for the metal atoms and may also require one for the oxygens if ambiguity is to be avoided in certain cases. The resulting names are almost never used in normal scientific intercourse, since they are very long and cumbersome—for example, 1.4,1.9,2.5,2.6,3.7,3.8,4.10,5.10,6.11,7.11,8.12,9.12-dodeca-μ-oxo-μ_{12}-(tetraoxophosphato-$O^{1,4,9}$,$O^{2,5,6}$,$O^{3,7,8}$,$O^{10,11,12}$)tetrakis[tri-μ-oxo-tris(oxomolybdate)](3−) for α-$[PMo_{12}O_{40}]^{3\ominus}$.

Michael T. Pope was born in Exeter, England, in 1933 and received B.A. and Ph.D. degrees in Chemistry at Oxford University in 1954 and 1957 under the supervision of R. J. P. Williams. He was introduced to the field of heteropolyanion chemistry during postdoctoral research with Louis C. W. Baker at Boston University. In 1962, following a three-year period with Laporte Industries in England, he went to Georgetown University as Assistant Professor. He has been Full Professor at Georgetown since 1973 and is currently Department Chairman. His research interests center around all aspects of the reactivity, structures, and applications of polyoxometal clusters.

Achim Müller was born in Detmold in 1938 and received the Ph.D. degree (1965) and habilitation (1967) at the University of Göttingen under the supervision of O. Glemser. He has worked on problems of molecular physics (theory of mass influence on molecular constants), vibrational spectroscopy (matrix isolation spectroscopy, band contour analysis, resonance Raman effect, metal isotope effects), bioinorganic chemistry (biological N_2 fixation by free-living microorganisms as well as model compounds), and molecular metal oxide and sulfide complexes and clusters (synthesis, geochemical relevance, electronic and molecular structure, topological aspects, and use in heterogeneous catalysis). He has published 30 reviews in these areas and is now Full Professor of Inorganic Chemistry at the University of Bielefeld.

3. Structures: Variety Based on Highly Symmetrical Core Assemblies

That molybdenum(VI) and tungsten(VI) are polyoxoanion formers par excellence is clearly the result both of a favorable combination of ionic radius and charge and of accessibility of empty d orbitals for metal–oxygen π bonding.[1b] Other elements and oxidation states possess these attributes to a greater or lesser degree. Polyoxoanions of vanadium (V), niobium (V), and tantalum (V) are also known. Other possibilities exist with hexavalent Tc, Re, Ru and Os, pentavalent Cr, Mo, W, Tc, and Re, and tetravalent Ti, V, Cr, Mo, and W.[1b] The extent to which some of these occur is discussed below. As we shall see, the relevant 3d-element chemistry is different, and the situation with vanadium is, so far, unique in the whole field of cluster chemistry. Structures may also include VO_5 units, and quite a number of paramagnetic fully reduced (V^{IV}) and mixed-valence species are known. These species are discussed in Section 7.

Rather than attempting to catalogue all known polyoxometalates, we illustrate here some of their major structural features and their architecture. We exclude the purely "tetrahedral" polyvanadates ($[V_2O_7]^{4\ominus}$, *cyclo*-$[V_4O_{12}]^{4\ominus}$, etc.), since their structural and acid-base chemistry is very similar to that of the corresponding phosphates, although we note in passing that such oligomers may play an important role in biochemical processes.[19] We also exclude, mainly for reasons of space, the emerging structural variety of oxo-alkoxo molybdate and vanadate oligomers.[20, 21]

Polyoxometalate structures are governed by two general principles:

1. Each metal atom occupies an MO_x coordination polyhedron (most commonly an octahedron or square pyramid) in which the metal atoms are displaced, as a result of M–O π bonding, towards those polyhedral vertices that form the surface of the structure.
2. Structures with MO_6 octahedra that contain three (or more) free vertices are, in general, not observed (*Lipscomb*[22]).

It follows from the first principle that the metal atoms M are never located at inversion centers, although other octahedrally coordinated *hetero*atoms may not be so restricted: contrast, for example, the isostructural anions $[W_7O_{24}]^{6\ominus}$ (C_{2v} symmetry with "central" W^{VI})[23] and $[MnW_6O_{24}]^{8\ominus}$ (D_{3d} symmetry with "central" Mn^{IV}).[24]

The second principle, the Lipscomb restriction, has been rationalized in terms of the strong *trans* influence of the terminal M–O bonds, which facilitates dissociation of neutral $\{MO_3\}$ from the cluster.[25] However, the stability of some mononuclear *fac*-trioxo complexes, such as $[MoO_3(tacn)]$ and $[WO_3(tacn)]$ (tacn = *N,N',N''*-triazacyclononane), in aqueous solution[26] suggests that this restriction is not absolute. Indeed, two anti-Lipscomb polyoxomolybdate structures have recently been characterized.[27, 28] Such structures are likely to remain uncommon, however, since the terminal oxygens of the $\{MoO_3\}$ groups are more strongly basic/nucleophilic[26] than those of $\{MoO_2\}$ and $\{MoO\}$ and will therefore offer sites for further polymerization.

3.1. Quasi-Spherical Structures Derived from Assemblies of MO_6 Octahedra and Based on Regular (Platonic) Solids

Three compact, highly symmetrical ("parent") clusters of MO_6 octahedra are shown in Figures 1–3. An important principle is that each cluster retains the symmetry of its central oxygen polyhedron: a tetrahedron (Fig. 1), an octahedron (Fig. 2), and an icosahedron (Fig. 3). The parent clusters form a convenient starting point for the discussion of many other polyoxometalate structures, which can be regarded as "derivatives".

The $\{(XO_4)(M_{12}O_{36})\}$ parent structure ("Keggin"; Fig. 1) is adopted by many polyoxometalates. Some of the possibilities for derivative structures are shown in Scheme 1. The very high formation tendency of Keggin fragments is particularly noteworthy: self-assembly of a cluster of T_d symmetry

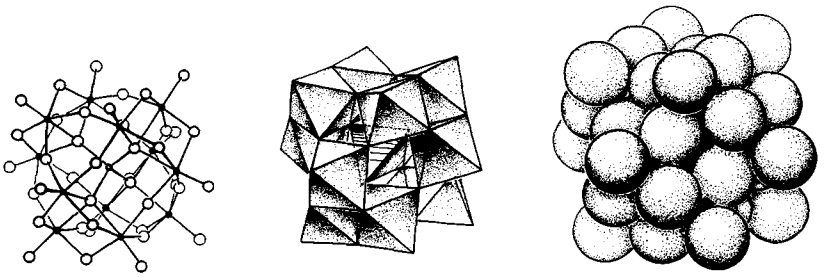

Fig. 1. $\{XM_{12}O_{40}\}$ (T_d) parent structure: the Keggin ion in bond, polyhedral, and space-filling representations.

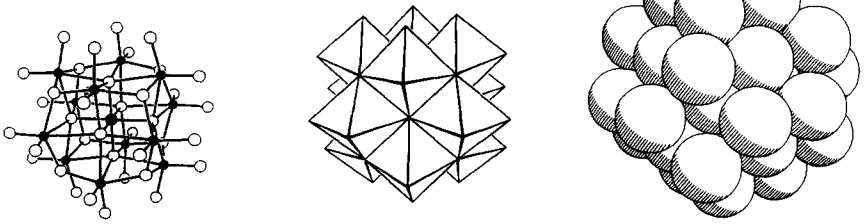

Fig. 2. $\{XM_{12}O_{38}\}$ (O_h) parent structure in bond, polyhedral, and space-filling representations.

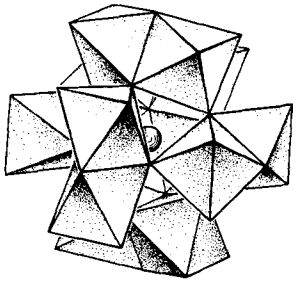

Fig. 3. $\{XM_{12}O_{42}\}$ (I_h) parent structure in polyhedral representation.

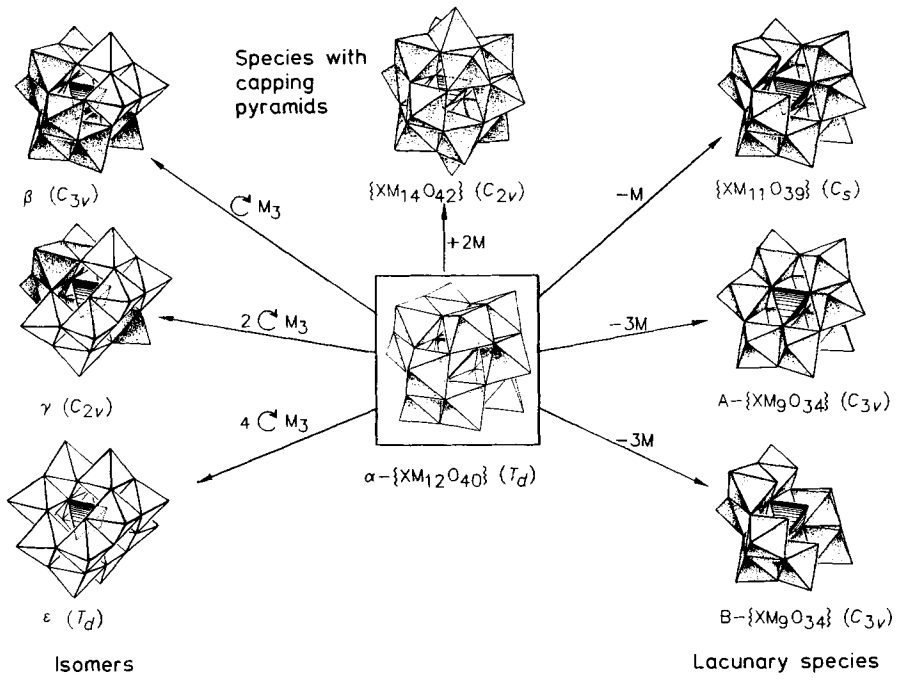
lanthanide and actinide cations. Although polyanions with this structure can function as ligands (see Section 6), no lacunary or capped versions have yet been reported.

3.2. Quasi-Cyclic Structures

Some polyoxometalates are topologically based on cyclic arrangements of polyhedra. Figure 5 shows a simple example. Such structures may be viewed as neutral rings of corner-sharing distorted MO_4 tetrahedra to which the heteroatom



Scheme 1. The $\{(XO_4)(M_{12}O_{36})\}$ parent ("Keggin") structure and its relationship to some known capped, deficient (lacunary), and isomeric versions. The three isomeric structures are obtained by rotation (C_6) of one, two, or four M_3 groups by 60°.

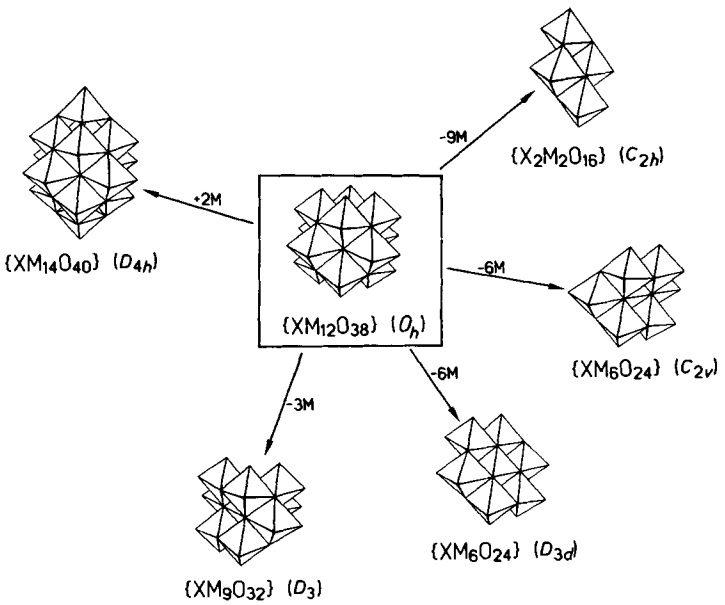
from 12 units of T_d symmetry occurs even when there is no central tetrahedral nucleus, as exemplified by Equation (c).

$$12[WO_4]^{2\ominus} + 18H^{\oplus} \longrightarrow [(H_2)W_{12}O_{40}]^{6\ominus} + 8H_2O \qquad (c)$$

For reasons that are not clear at present, but which are probably electrostatic in origin, the $\{(XO_6)(M_{12}O_{32})\}$ parent structure (Fig. 2), with O_h symmetry, has not yet been observed for a discrete polyoxometalate. However, as Scheme 2 shows, several derivatives, such as the mixed-valence mineral sherwoodite, $[AlV_{14}O_{40}]^{9\ominus}$ (compare also the relevant model in Section 7), are known. Note that all structures in this scheme are based entirely upon edge-sharing MO_6 octahedra and may be considered as fragments of a cubic closest packing of oxygen atoms.[29-31]

There are also other edge-shared clusters that are not, strictly speaking, pieces of the parent structure shown in Figure 2. An important example is the $\{M_6O_{19}\}$ unit, which has complete O_h symmetry (Fig. 4).

The $\{(XO_{12})(M_{12}O_{30})\}$ parent structure (Fig. 3) is known only for a handful of heteropolymolybdates of tetravalent



Scheme 2. The $\{(XO_6)(M_{12}O_{32})\}$ parent structure and its relationship to some known capped ("sherwoodite") and deficient versions.

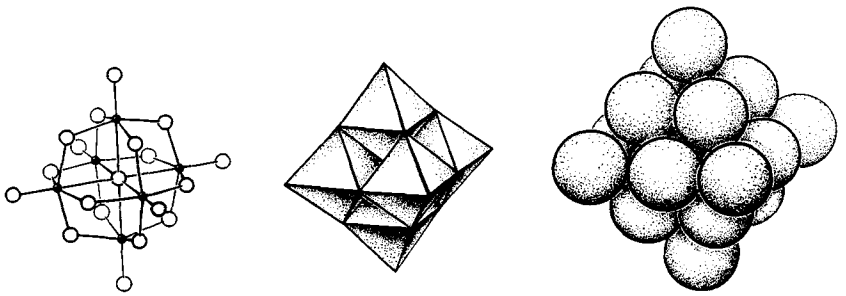


Fig. 4. $\{M_6O_{19}\}$ structure in bond, polyhedral, and space-filling representations. This structure is well-known for M = Mo, W, Nb, Ta, and recently, as bi- and tetracapped derivatives [32–34], for V.

tetrahedra are attached by additional, relatively weak bonds.[35] Much of the reactivity and fluxionality of these anions in solution is thereby understandable.[36–37]

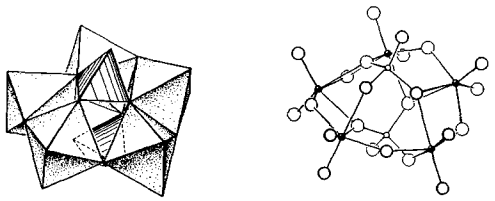

Fig. 6. Structure of $[(PO_4)_2Mo_5O_{15}]^{6\ominus}$ in polyhedral and bond representations

A more complex example of this type of structure is provided by the very large isopolymolybdate anion $[Mo_{36}O_{112}(H_2O)_{16}]^{8\ominus}$.[38] The structure consists of identical Mo_{17} "halves" linked by two MoO_6 octahedra. Each half may be viewed as an $\{Mo_7O_{24}\}$ unit (of C_{2v} symmetry, see Scheme 2) that is encircled by a ring of ten corner-sharing distorted MoO_4 tetrahedra. Relatively weak bonds to oxygens of the enclosed $\{Mo_7O_{24}\}$ units and to hydrate water molecules complete six-coordination for each of the exterior molybdenum atoms.

4. Formation and Solution Behavior

It is appropriate to consider formation and solution properties together, since these topics are intimately related. The majority of polyoxometalates have been formed and studied in aqueous solution[39a] and a recent compilation of typical syntheses is available.[39b] However, nonaqueous syntheses have also been developed.[8] Equations (a) and (b) (Section 1) show that aqueous solutions of these species can act as high-capacity buffers.

As shown in Figure 6, several species may be in equilibrium, depending on the pH. The compound isolated in crystalline form may not necessarily be the one with the highest abundance. In addition, as will be shown in Section 5, many polyoxometalates are unequaled in their "electron reservoir" properties. Coupled or uncoupled proton- and electron-transfer chemistry therefore underlies many realized and potential applications. A further significant general property of polyoxometalates is their solubility (in the presence of appropriate counterions) in solvents ranging in polarity from dimethyl sulfoxide to benzene.[40] The solubility of such complexes in anhydrous solvents extends their chemistry to include the reactions of organometallic species[11c,41,42] as well as other kinds of reactivity such as atom- and group-transfer processes.[43,44] Underlying all aspects of the chemistry of polyoxometalates is their extreme thermal robustness and stability against oxidants. In Section 9, we touch upon some of the diverse applications that have been reported; a complete survey is beyond the scope of the present article.

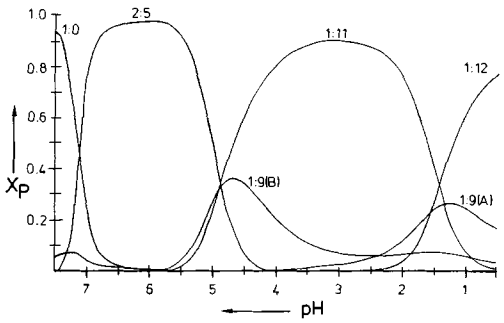

Fig. 6. Distribution diagram for species present in fresh solutions containing $[MoO_4]^{2\ominus}$ and $[HPO_4]^{2\ominus}$ in a molar ratio of 12:1 at different pH values (3.0 M $NaClO_4$ medium). Curves are labeled with the ratio of P:Mo in each complex. Differences in the extent of protonation of the complexes are not distinguished [15].

5. Electronic Structures: Mixed-Valence Species, Intramolecular Electron Transfer, Ring Currents, and Electron-Storage Properties

The electronic structures of "oxidized" (d^0) polymolybdates and polytungstates may to first order be extrapolated from those of the individual MO_6 octahedra from which they are constructed. Although the actual environment of the metal atoms is of lower symmetry in most cases, MO_6 octahedra in polyoxometalates fall into two classes, "mono-oxo" (C_{4v}) and "*cis* dioxo" (C_{2v}), based on the number of terminal M–O bonds. We earlier labeled these as types I and II, respectively.[45] In the absence of in-plane π bonding, the LUMO for type I octahedra is a nominally nonbonding, mainly metal-centered ("d_{xy}") orbital, whereas the LUMO for type II octahedra is strongly antibonding with respect to the terminal M–O bonds. Polyoxometalates constructed of type I octahedra, of which the Keggin structure is a prime example, are therefore easily reduced to mixed-valence species (heteropoly "blues" and "browns") which retain the overall architecture of the oxidized anions. This result can

also be understood from extended Hückel[46] and Xα[47] calculations, which show that, as expected, the density of states in the LUMO (a "d_{xy} band" that has some oxygen contribution and is responsible for the intervalence charge-transfer (IVCT) transitions) increases, and the HOMO-LUMO gap decreases, with aggregation of MO_6 octahedra. On the other hand, type II polyoxometalates are reduced irreversibly and with more difficulty to complexes that have not yet been identified. The following summary refers only to reductions of type I species.

Cyclic voltammograms of molybdate and tungstate Keggin anions, and indeed of all type I polyoxometalates, display sequences of reversible one- or two-electron reductions (see, for example, Fig. 7), which yield deeply colored mixed-valence species ("heteropoly blues"). Electronic spectra of the reduced polyoxometalates show intensity-enhanced d–d bands in the visible and IVCT bands in the near-IR regions. Depending on the acidity of the solution and the polyanion charge, the reductions involve addition either of single electrons or simultaneously of pairs of electrons and protons.[48]

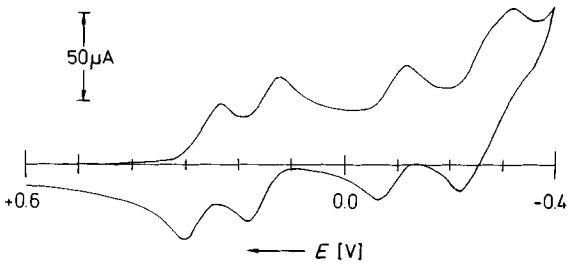

Fig. 7. Cyclic voltammogram of α-$[PMo_{12}O_{40}]^{3\ominus}$ in 0.1 M HCl (50% H_2O/EtOH) showing sequence of five reversible two-electron reductions.

For the paramagnetic one-electron-reduced anions, ESR and ^{17}O NMR spectroscopy demonstrate that the unpaired electron is weakly trapped at low temperatures, but undergoes rapid hopping (intramolecular electron transfer) at room temperature (class II mixed-valence behavior according to the well-known classification of *Robin* and *Day*;[49-52] see Fig. 8). Anions generated by two-electron (and four-electron) reduction are ESR-silent, but ^{17}O and ^{183}W NMR spectra show that the additional electrons are fully delocalized (on the NMR time scale) at room temperature and generate "ring currents" analogous to those produced by the π electrons of benzene.[55-58] Two structural studies of two-electron-reduced anions, α-$[H_2AsMo_{12}O_{40}]^{3\ominus}$[28] and α-$[H_2CoW_{12}O_{40}]^{6\ominus}$,[59] have been reported; both revealed crystallographically disordered anions of T_d symmetry, so that no conclusions about possible valence trapping could be drawn from interatomic distances.

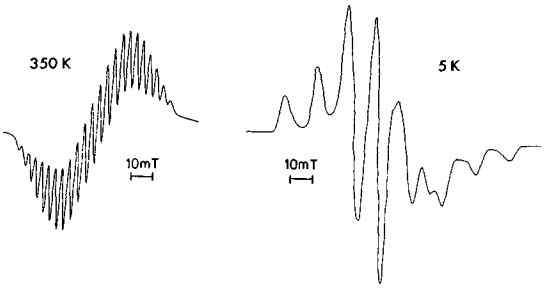

Fig. 8. ESR spectra of α-$[P_2W_{15}V^{IV,V}_3O_{62}]^{10\ominus}$ containing a trigonal "mixed-valence V_3 unit". Note the interaction of the unpaired electron with three equivalent V nuclei ($I = 7/2$, 22 hyperfine lines) at 350 K and with a single V nucleus (8 parallel and 8 perpendicular hyperfine lines) at 5 K [53, 54].

Reduction of Keggin anions beyond the two-electron stage leads to modest changes in electronic and molecular structure, although the reductions remain chemically reversible. For the molybdates, some of the bridging oxygens become protonated and a four-electron-reduced β-Keggin structure is stabilized [Eq. (d)]. Electronic and NMR spectra of these complexes, together with two X-ray structural determinations, suggest that complete valence averaging involving at least six of the Mo atoms has occurred.[28, 58, 60]

$$\alpha\text{-}[PMo_{12}O_{40}]^{3\ominus} + 4\,e + 3\,H^{\oplus} \longrightarrow \beta\text{-}[H_3PMo^{V}_{12}O_{40}]^{4\ominus} \quad (d)$$

With tungstates, on the other hand, protonated $W^V_6W^{VI}_6$ (blue) polyanions undergo intramolecular disproportionation to $W^{IV}_3W^{VI}_9$ (brown) species. In the latter, terminal oxygens have become protonated to form water molecules coordinated to W^{IV} atoms occcupying adjacent edge-sharing octahedra of the Keggin structure[61-63] (Fig. 9). The W^{IV} atoms are linked by metal–metal bonds as in the aqua cation $[W_3O_4(aq)]^{4\oplus}$. Subsequent reductions lead to conversion of the remaining W atoms to W^{IV} (for studies in solution, see Ref. [61]). According to the simple principles treating M_3 clusters of the early transition elements,[64, 65] each W^{IV}_3 triad (of C_{3v} symmetry) in the 24-electron-reduced cluster can formally accept an additional two electrons into a nonbonding a_1 orbital [Eq. (e)] (cf. Ref. [65]), so that an astonishing *32-electron reduction of the Keggin anion* can be demonstrated. The Keggin structure is completely restored upon reoxidation.[61]

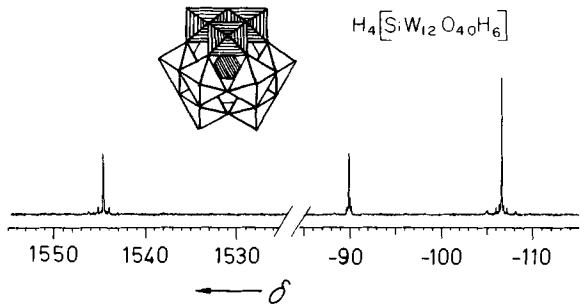

Fig. 9. ^{183}W NMR spectrum of $[SiW_{12}O_{40}H_6]^{4\ominus}$ showing resonances for W^{IV} ($\delta = +1545$) and W^{VI} ($\delta = -90, -107$). The magnitudes of the W···W coupling constants derived from the satellites at the base of each line establish that the W^{IV} atoms occupy an edge-shared triad (cross-hatched) [63].

$$(1a_1)^2(1e)^4(2a_1)^0 \longrightarrow (1a_1)^2(1e)^4(2a_1)^2 \quad (e)$$

6. Polyoxometal Systems as Unique Ligands: Multianion Clusters, Cryptates, and Clathrates

Polyoxometalate anions can act as ligands that are unique in two respects: topology and electron-acceptor ability due

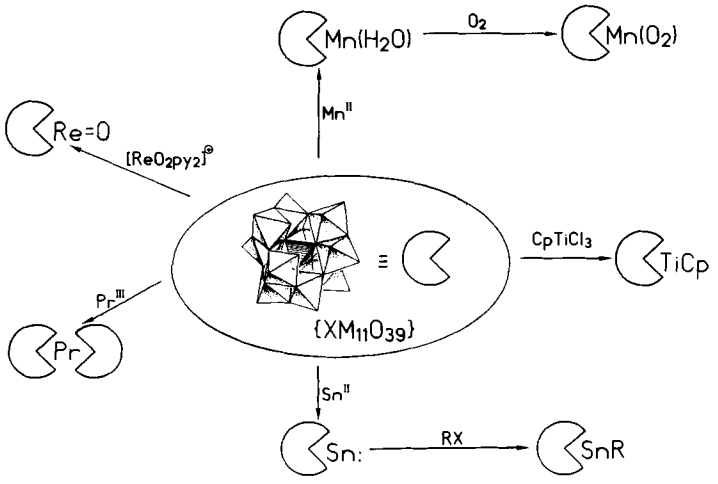
to the reducibility of the metal centers. Several types of physical measurements support the acceptor nature of polyoxometalate ligands:

1. Electrochemical investigations show that such "ligands" are easily reduced.
2. The electronic spectra contain low-energy metal-to-ligand absorption bands (e.g., for Cu^{I} in $[CuW_{12}O_{40}]^{7\ominus}$[66] and Ce^{III} in $[CeMo_{12}O_{42}]^{9\ominus}$[67]), comparable to the bands found for thiometalate complexes.
3. The ESR-derived value of the Fermi contact term for the unpaired electron of V^{IV} in $[XM_{11}VO_{40}]^{x\ominus}$ (M = W, Mo) is reduced (electron delocalization is greater in the molybdates[68]).
4. The ^{183}W NMR isotropic shifts reveal delocalization of unpaired spin density of Co^{II} onto W atoms in α-$[CoW_{12}O_{40}]^{6\ominus}$.[69]

Two modes of complex formation with polyoxometalate ligands can be distinguished: (1) "complete" (plenary) structures binding metal cations via surface terminal and bridging oxygen atoms; (2) "defect" (lacunary) structures enclosing cations in the vacancies.

Complexes of the first kind are favored if the polyoxometalate has a high charge, more than one oxygen atom is coordinated to the external cation, and the reactions are carried out in nonaqueous solutions. Examples of such complexes include the weak and labile complexes of Mn^{II} and Eu^{III} with $[(H_2)W_{12}O_{40}]^{6\ominus}$ acting as a monodentate ligand through a terminal oxygen atom,[70] species such as $[UMo_{12}O_{42}\{Ni(H_2O)_3\}_2]^{4\ominus}$[71] with the anion of Figure 3 acting as a tridentate ligand through three adjacent terminal oxygen atoms, and complexes like $[(CpTi(SiW_9V_3O_{40})]^{4\ominus}$[72] in which three adjacent bridging oxygen atoms of a Keggin anion function as donors to the Ti atom.

Complexes with lacunary polyoxometalate structures as ligands are of great variety and are exceedingly numerous.[1b, 73] The vacancy created by the nominal loss of an MO_6 octahedron (equivalent to stoichiometric loss of $MO^{n\oplus}$) from, for example, a Keggin anion, represents a binding site that is pentadentate, as in $[(SiW_{11}O_{39})Co(H_2O)]^{6\ominus}$ ("octahedral" Co^{II}), or tetradentate, as in $[(PW_{11}O_{39})Cu]^{5\ominus}$ ("square-planar" Cu^{II}) and $[(PW_{11}O_{39})_2Ce]^{10\ominus}$ ("square antiprismatic" Ce^{IV}). Some of the possible reactions of such complexes are summarized in Scheme 3.



Scheme 3. Some examples of the many possible reactions of lacunary Keggin anions [151–156].

Complex anions such as $[(SiW_{11}O_{39})M]^{n\ominus}$ have been viewed and used as inorganic analogues of metalloporphyrins,[43, 74] but with several differences and advantages. (1) The inorganic polyoxometalate ligand is not susceptible to oxidative degradation and is thermally more robust than porphin or other macrocyclic ligands. (2) Owing to the oxygen donor atoms, complexes of 3d cations are of high-spin type. (3) The acceptor properties of the oxometalate ligand are dependent on its reducibility and can be modified by metal replacement or by partial reduction. (4) In general, the electron population on metal and ligand is considerably more variable than for the metalloporphyrins.

Derivatives of lacunary polyoxometalates in which more than one metal atom has been lost, for example, the XM_9 complexes of Scheme 1 (three vacancies), present a range of structures, reactions, and potential applications. Their chemistry is still in the early stages of development.

Reconstituted Keggin-like structures are possible (e.g., β-$[SiW_9O_{37}\{Co(H_2O)\}_3]^{10\ominus}$[40] and γ-$[PW_{10}O_{38}(VO)_2]^{5\ominus}$.[75] These are soluble well-defined species, which serve as models of transition-metal oxide surfaces.

Alternatively, lacunary anion fragments may assemble into larger clusters, either directly [Eq. (f)] or, more commonly, with the incorporation of metal ion linkers. Three of the many possible examples are shown in Figure 10. Other compounds of this type include unusual groupings of adjacent paramagnetic metal centers (e.g., $Fe_4^{III}C_2^{II}$[78]).

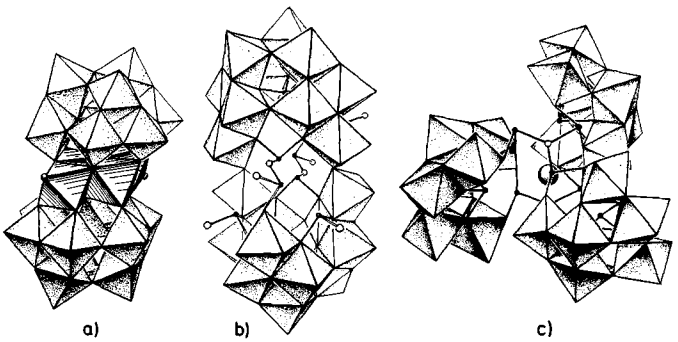


Fig. 10. Structures of three polyoxometalates assembled from Keggin fragments: a) $[Co_4(H_2O)_2(PW_9O_{34})_2]^{10\ominus}$ [79]; b) $[As_{10}Mo_{24}O_{90}]^{14\ominus}$ [28]; c) $[(Na)(Sb_3O_7)_2(SbW_7O_{24})_3]^{18\ominus}$ ("HPA-23") [80].

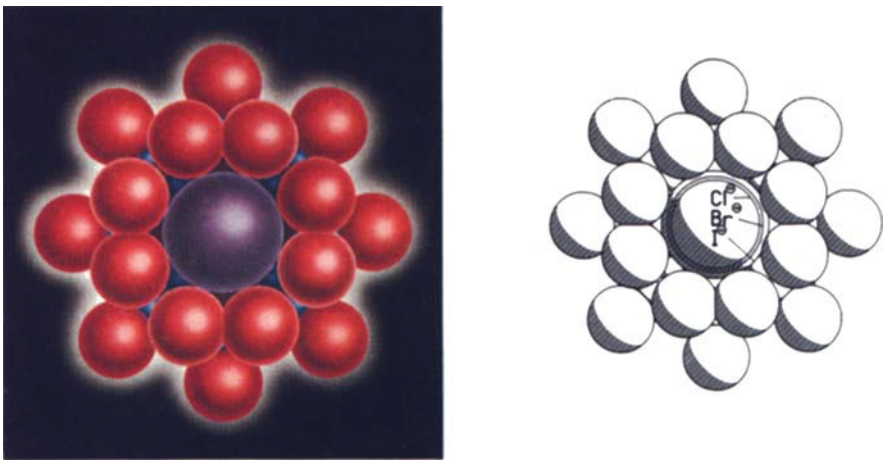
$$2\,[PMo_9O_{31}(H_2O)_3]^{3\ominus} \longrightarrow [P_2Mo_{18}O_{62}]^{6\ominus} + 6\,H_2O^{[15]} \qquad (f)$$

$[P_8W_{48}O_{184}]^{40\ominus}$ ($\triangleq$ 4 "P_2W_{12}" from $[P_2W_{18}O_{62}]^{6\ominus}$)[76]
$[P_5W_{30}O_{110}]^{15\ominus}$ ($\triangleq$ 5 "PW_6" from $[PW_{12}O_{40}]^{3\ominus}$)[77]

Many of the larger multianion clusters have structures that permit the inclusion of cations or anions. The central sodium ion in the tungstoantimonate of Figure 10 is readily exchangeable with other mono- or divalent cations (compare with crown ether complexes),[81] but in some other cases, such as $Na^{\oplus}$ in $[(Na)H_2W_{18}O_{56}F_6]^{7\ominus}$[82] and $NO_3^{\ominus}$ in



a) b)

Fig. 11. Structure of a hemisphere of a species containing the $\{V_{18}O_{42}\}$ shell viewed along the virtual S_8 axis: a) $I^{\ominus}$ (violet), V (blue), O (red); b) with $Cl^{\ominus}$, $Br^{\ominus}$, $I^{\ominus}$ [85].

$[(NO_3)Cu_3(PW_9O_{34})_2]^{13\ominus}$,[83] the encrypted ions are tightly bound and therefore inert.

There is a fine distinction between *cryptates* and *clathrates*. The examples given in the preceding paragraph are probably best thought of as cryptates, since the enclosed ions have reasonably well-defined bonding interactions with the polyanion. Recent work has identified polyoxometalate inclusion compounds or clathrates in which the host–guest interaction is much weaker: for example, $[V_{12}O_{32}(CH_3CN)]^{4\ominus}$[84] and $[H_4V_{18}O_{42}(X)]^{9\ominus}$ (X = I, Br, Cl[85]; see Fig. 11). These compounds demonstrate that charge, as well as shape- and size-selectivity, can be important factors in the synthesis and possible reactivity of polyoxometalates (for the template effect of the enclosed anion, see Ref. [87] and Section 7).

7. Reduced Polyoxovanadates: A New Class of Metal–Oxygen Clusters

Although only two large V^V isopolyanions, $[V_{10}O_{28}]^{6\ominus}$[86] and $[V_{12}O_{32}]^{4\ominus}$,[84] are known, several V^{IV}-containing species have been isolated recently (Table 1). Their chemistry is different from that of the Mo and W anions, since, for example, the metal–metal interactions are not very marked (in contrast, spin pairing is preferred in reduced clusters of the 4d and 5d metals[56, 58]). Nearly all ratios of V^{IV} to V^V can be observed: V–O clusters are possible with as few as *two* $V^{IV}(d^1)$ centers (uncoupled or very weakly coupled spins) to as many as *eighteen* V^{IV} (d^1) centers (antiferromagnetically coupled with no V–V bonds). In clusters with small numbers of spins, the spins are found as far apart as possible. The magnetic moment per V^{IV} center decreases (indicating that spin–spin coupling increases) with increasing numbers of spins or V^{IV} centers (which necessarily come into closer contact) in a nearly continuous manner, a unique situation for metal cluster compounds[87] (Table 1). The coordination geometries at the V centers are also highly variable (tetrahedral (V^V), square-pyramidal (V^{IV}, V^V), octahedral (V^{IV}, V^V), and trigonal-bipyramidal (V^V)) and lead to structures unknown for Mo and W.

"Hollow spheres" with "cryptand/clathrate" properties may be formed by linking VO_5 pyramids. The spherical cluster shells $\{V_{18}O_{42}\}$ and $\{V_{15}O_{36}\}$[88–90] have the hitherto virtually unknown property of encapsulating negatively charged ions, even those with significantly different radii (as in the species $[H_4V_{18}O_{42}(X)]^{9\ominus}$, X = I, Br, Cl[85]). The anion serves as a template for the cluster shell, which can be widely varied in an "induced self-assembly" manner. The template itself can be formed from the reaction solution, leading, for example, to the generation of a cluster ($\{V_4O_4\}O_4$ cube) inside a cluster ($V_{30}O_{74}$ shell; cf. synthesis of the unusual mixed-valence species $[V_{34}O_{82}]^{10\ominus}$).[87]

Table 1. Vanadium–oxygen clusters with varying numbers of V^{IV} d^1 centers and spin–spin coupling (most of them with the O_{24} rhombicuboctahedron of the Keggin structure) [87].

Anion	Structure	V^{IV} centers	μ [h]	Ref.
$[V_{14}AsO_{40}]^{7\ominus}$	[a]	2	1.77	[87]
$[V_{12}O_{36}(AsOH)_3(AsO_4)]^{7\ominus}$	[b]	4	1.75	[87]
$[V_{12}As_8O_{40}(HCO_2)]^{3\ominus}$	[c, g]	6	1.75	[87]
$[V_{12}As_8O_{40}(HCO_2)]^{5\ominus}$	[c, g]	8	1.39	[87]
$[V_{12}As_8O_{40}(H_2O)]^{4\ominus}$	[c, g]	8	1.38	[87]
$[V_{15}O_{36}(Cl)]^{6\ominus}$	[d]	8	1.38	[90]
$[V_{18}O_{42}(SO_4)]^{8\ominus}$	[e, g]	12	1.14	[89]
$[V_{14}As_8O_{42}(SO_3)]^{6\ominus}$	[f, g]	14	1.20	[87]
$[V_{15}As_6O_{42}(H_2O)]^{6\ominus}$	[f, g]	15	1.08	[157]
$[V_{18}O_{42}H_4(I)]^{9\ominus}$	[e, g]	18	1.06	[85]

[a] Sherwoodite type. [b] Three-fourths of an AsV_{12} ε-Keggin-type structure capped with three VO and three AsOH groups. [c] Derivative of the "extended Keggin" V_{18} species (Fig. 12) in which $As_2O^{4\oplus}$ groups have replaced some of the twelve "original" VO groups and two of the six "extra" VO groups are missing. [d] $\{V_{15}O_{36}\}$ shell illustrated in Figure 13. [e] Shown in Figure 14. [f] As [c] but with no missing VO groups. [g] Rhombicuboctahedron spanned by 24 oxygen atoms as in the Keggin structure. [h] Magnetic moment per V^{IV} center at room temperature in μ_B.

Starting with the hypothetical $\{V_{12}O_{36}\}$ "Keggin" shell of cubic symmetry, VO groups can be added (according to the capped species of Scheme 1) to the six equivalent (100) square faces of the rhombicuboctahedron formed by the 24 oxygen atoms (thereby generating the $\{V_{18}O_{42}\}$ structure), or $As_2O^{4\oplus}$ groups can replace some of the "original" VO groups above the other 12 equivalent (110) square faces[85]

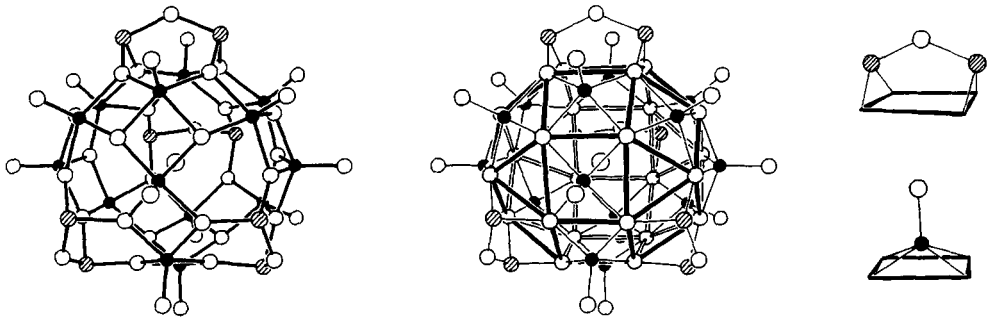


Fig. 12. Structure of $[V_{14}As_8O_{42}(H_2O)]^{4\ominus}$ and demonstration of the capping of the faces of the rhombicuboctahedron by VO and $As_2O^{4\oplus}$ groups [87].

(Fig. 12 and Table 1; see also Section 8). The complexation of, for example, $VO^{2\oplus}$, by a lacunary Keggin anion (Scheme 3), is analogous. Furthermore, binding of $(RX)_2O^{4\oplus}$ (X = Si, Ge) groups to (oxidized) lacunary Keggin anions was proposed[153] to occur in exactly the same fashion as that now demonstrated for $As_2O^{4\oplus}$ and the reduced vanadate clusters.

Other interesting and structurally unique mixed-valence species are the ellipsoidal cluster $[V_{19}O_{41}(OH)_9]^{8\ominus}$[91] (12 $V^{IV}O_6$ octahedra, 7 $V^{V}O_4$ tetrahedra, including a central group), $[AsV_{14}O_{40}]^{7\ominus}$[87] (12 $V^{V}O_6$ octahedra and 2 $V^{IV}O_5$ square pyramids, model for the mineral sherwoodite), $[V_{10}O_{26}]^{4\ominus}$[92] (8 $V^{V}O_4$ tetrahedra, 2 $V^{IV}O_5$ square pyramids), $[V_{15}As_6O_{42}(H_2O)]^{6\ominus}$ (which has D_3 symmetry and is a derivative of the V_{18} species, Table 1), and $[V_{15}O_{36}(CO_3)]^{7\ominus}$[85] (Fig. 13). The anion $[V_{19}O_{41}(OH)_9]^{8\ominus}$

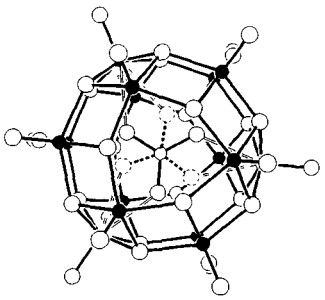

Fig. 13. Structure of $[V_{15}O_{36}(CO_3)]^{7\ominus}$ [85].

provides a molecular model for the magnetic properties of VO_2, since it contains six rather short V–V vectors and the singlet state is still highly populated at (for the magnetochemist) rather high temperatures.[87]

8. Topological Considerations

Egli è scritto in lingua matematica, e i caratteri son triangoli, cerchi, ed altre figure geometriche, senza i quali mezi è impossibile a intenderne umanamente parola...[*]

Galileo Galilei

Topology describes the properties of geometrical elements that are unchanged by reversible single-valued and continuous mappings.[93, 94] The most obvious connection to crystallography and chemistry is that crystals grow as convex polyhedra and that, in species of the type AX_n, the X atoms can form a (coordination) polyhedron. In addition, space-filling arrangements, in which small polyhedra are interconnected by vertex-, edge-, and face-sharing, are of importance for the subject considered here.

The important polyhedra are mostly *regular* (Platonic), with all vertices equivalent and all faces of the same type, and *semiregular* (Archimedean), where only the first condition is fulfilled.[95] Polyoxometalate chemistry is governed by these types of polyhedra, the vertices being defined by oxygen and/or metal atoms (Table 2; see also Section 3). Such "global" polyhedra may be distorted owing to the influence of a lower-symmetry central unit, as in the Keggin-type species.

The tendency of the oxygens to form space-filling assemblies (perhaps even closest-packed) of polyhedral domains, and of the metal atom centers to form polyhedra with mini-

[*] "[The greatest book of philosophy, which is the universe itself,] is written in the language of mathematics, and the letters are triangles, circles, and other geometrical figures, without whose help it is impossible for a human being to understand a single word."

Table 2. Polyhedra (M_x,O_y) spanned by metal and oxygen atoms of polyoxometalates.

x	Polyhedron	Point group [a]	y	Polyhedron	Point group [a]	Example	Ref.
6	octahedron	O_h	12	cuboctahedron	O_h	$[Mo_6O_{19}]^{2\ominus}$	[158]
12	icosahedron	I_h (T_h)	12 [b]	icosahedron	I_h	$[Mo_{12}O_{42}(Ce)]^{8\ominus}$	[159, 1b]
12	truncated tetrahedron	T_d	12 [b]	cuboctahedron	O_h (T_d)	$[Mo_{12}O_{34}(HOAsO_3)_4]^{4\ominus}$	[166]
12	cuboctahedron	O_h (T_d)	24	rhombicuboctahedron	O_h (T_d)	$[Mo_{12}O_{36}(PO_4)]^{3\ominus}$ (α-Keggin)	[161]
12	anticuboctahedron [c]	D_{3h} (C_{3v})				$[W_{12}O_{36}(SiO_4)]^{4\ominus}$ (β-Keggin [d])	[162]
12	truncated tetrahedron	T_d				$[V_{12}O_{40}Mn_3H_3]^{5\ominus}$ [e] (ε-Keggin [f])	[163]
12	cuboctahedron	O_h (D_{4h})				sherwoodite core [g] $[V_{14}O_{40}(Al)]^{9\ominus}$	[164]
			24	rhombicuboctahedron	O_h (T_d)	$[V_{18}O_{42}(SO_4)]^{8\ominus}$	[89]
			24	"14th Archimedean solid" [h]	D_{4d}	$[H_4V_{18}O_{42}(X)]^{9\ominus}$ (X = Cl, Br, I)	[85]

[a] Real symmetry due to systematic distortion in parentheses. [b] Inner shell of oxygen atoms. [c] Not an Archimedean solid; it can be derived from the cuboctahedron by a 60° rotation of one triangle (see [d]). [d] Derived from the α-Keggin isomer by a 60° rotation of one $\{M_3O_{13}\}$ unit (see Scheme 1). [e] Symmetry reduced to C_{3v} by Mn and H atoms. The polycation $[Al_{12}(OH)_{24}(H_2O)_{12}(AlO_4)]^{7\oplus}$ is a hydroxo cluster with this structure [165]. [f] Derived from the α-Keggin isomer by 60° rotations of all $\{M_3O_{13}\}$ units (see Scheme 1). [g] Figure 2. [h] Not an Archimedean solid; it can be derived from the rhombicuboctahedron by a 45° rotation of one hemisphere.

mization of Coulombic repulsions, seems obvious but is not completely understood.

Two compounds with the same $\{V_{18}O_{42}\}$ fragment form an illustrative example. The 24 oxygen atoms of the spherical shells of $[H_4V_{18}O_{42}(X)]^{9\ominus}$ and $[H_9V_{18}O_{42}(VO_4)]^{6\ominus}$ form corners of convex polyhedra (with idealized sides of equal length). The first structure forms the so-called 14th Archimedean solid[96] (also called pseudo-rhombicuboctahedron; its vertices are not equivalent, but each one is surrounded by three squares and one triangle in an equal way). This can be converted into the rhombicuboctahedron (one of the usual 13 Archimedean solids) by a 45° rotation of the upper hemisphere. The latter polyhedron (but with a tetrahedral distortion induced by the central VO_4 unit) is formed by the corresponding 24 oxygens of the second polyvanadate anion[85] (Fig. 14).

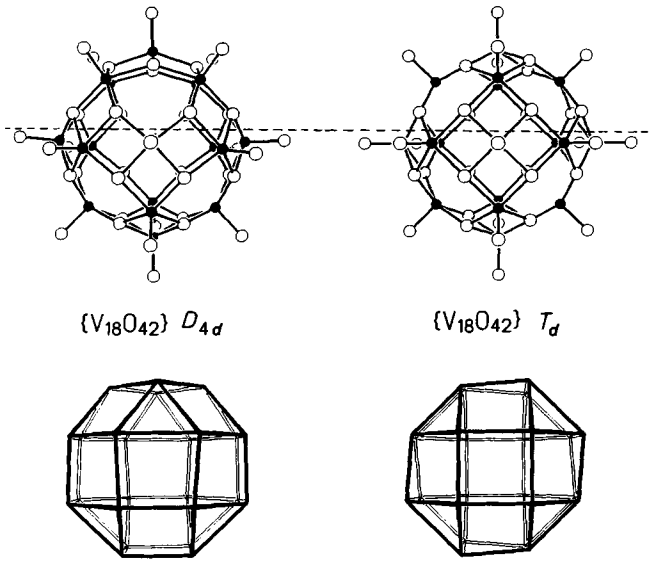

Fig. 14. Comparison of the structures of the $\{V_{18}O_{42}\}$ shells of $[H_4V_{18}O_{42}(X)]^{9\ominus}$ and $[H_9V_{18}O_{42}(VO_4)]^{6\ominus}$ (black = V, white = O), which can be interconverted by C_8 rotation of a hemisphere (marked by dotted line), and the demonstration of the so-called 14th Archimedean solid [96] and the rhombicuboctahedron, respectively, spanned by the 24 bridging oxygen atoms of these two anions [85].

An aspect relevant to chemistry and based on capping by VO or $As_2O^{4\oplus}$ groups of the two sets of O_4-square faces of the rhombicuboctahedron of the Keggin anion was mentioned in Section 7.

9. Applications

The applications of polyoxometalates are mainly based on their unique properties, including size, mass, electron- and proton-transfer/storage abilities, thermal stability, lability of "lattice oxygen", high Brønsted acidity of the corresponding acids. An additional advantage is the fact that heteropoly acids can be separated and enriched by extraction into organic solvents.

9.1. Analytical and Clinical Chemistry

Polyoxometalates have long been used for detection, separations, and quantitation, based particularly on properties such as (1) their high molecular weights, (2) their electrochemical activity and reducibility to form colored species, and (3) the variety of elements that can be incorporated. Consequently, many different types of analytical methods can be used for a variety of purposes. Some 26 elements can be determined through heteropolymolybdate formation alone.[97]

The earliest[98] and still probably the most widely used application has been the determination of P and Si either gravimetrically or by physical methods after reduction to heteropoly blues. Recent examples include simultaneous determination of P, Si, Ge, and As by differential-pulse anodic voltammetry,[99] chromatographic (HPLC) separations,[100] and measurement of nanomolar concentrations of silica in seawater.[101]

Many pharmaceuticals and biological samples are routinely determined using polyoxometalates.[102] The ability of polyoxometalates to coagulate proteins and to precipitate organic molecules like alkaloids is important in this connection. Their use in clinical chemistry and in the analysis of drug preparations, pesticides, and other biologically active molecules was reviewed recently.[102] Some examples are shown in Table 3. The methods involve reduction to mixed-valence blues (uric acid determination,[103] Lowry protein determination[104]) or selective precipitation (cholesterol, low-density (LDL) and high-density lipoprotein (HDL) separations[105]).

Table 3. Use of heteropolymolybdates to analyze biomaterials [a].

Sample	Substance	Polyanion used	Method [b]
Whole blood	Si	$SiMo_{12}$ blue	S
Blood serum	Si	$SiMo_{12}$ blue	S
Blood, urine	As	$AsMo_{12}$ blue	S, N
Biosolutions	uric acid	$SiMo_{12}$ blue	S
	uric acid	PMo_{12}	G
Cell nuclei	histones	PMo_{12} blue	S
Animal tissues	nialamide [c]	PMo_{12} in ethanol	TLC
	cocaine	PMo_{12} in ethanol	TLC
	amidopyrine	$SiMo_{12}$	G

[a] Abstracted from [102]. [b] S, spectrophotometry; N, nephelometry; G, gravimetry; TLC, thin layer chromatography. [c] Antidepressive.

The use of polytungstates, long employed as imaging agents, for electron microscopy has recently been improved with the development of organic derivatives of these anions[106, 107] that permit highly selective labeling.

9.2. Catalysis and Photocatalysis

Heteropolyanions are widely used as oxidation catalysts as well as acid catalysts. They are also excellent model systems for investigating several fundamental problems of catalysis.

The basic reversible redox reactions involved in substrate oxidations are shown in Equations (g) and (h), where

$[HPA]_{ox}$ and $[HPA]_{red}$ signify the oxidized and reduced forms of a heteropolyanion. Such catalysts can be used, for instance, in the formation of carboxylic acids from the corresponding aldehydes, as well as in the dehydrogenation of alcohols, aldehydes, and carboxylic acids to form C=C and C=O bonds.

$$[HPA]_{ox} + \text{substrate} + i\,H^{\oplus} \rightleftarrows H_i[HPA]_{red} + \text{oxidized substrate} \quad (g)$$

$$H_i[HPA]_{red} + i/4\,O_2 \rightleftarrows [HPA]_{ox} + i/2\,H_2O \quad (h)$$

Heterogeneous catalytic oxidation processes involving well-characterized polyoxometalates have been reviewed:[108-110] among the more important are the commercial vapor-phase oxidation of methacrolein to methacrylic acid (80000 tons per year)[111] and methane oxidation.[112] Synthesis of new bifunctional catalysts from polyoxometalates (e.g., $[(Ph_3P)_2Rh(CO)]_4[SiW_{12}O_{40}]$, which can be used for sequential hydroformylation and oxidation of olefins) is a recent development.[113]

Homogeneous oxidative catalytic activity[114] has been demonstrated for both thermal[115] and photochemical dehydrogenation and H_2 evolution from RX-type (e.g., X = CH_2OH, COOH) species, including water-splitting processes,[116-118] and for oxygen transfer to alkanes.[119] Polymolybdovanadates have been used as reoxidants in Wacker chemistry (oxidation of alkenes, coupling of aromatics) and may themselves be reoxidized with oxygen[120] [Eqs. (i) and (j)].

$$Pd^0 + [HPA]_{ox} + 2H^{\oplus} \longrightarrow Pd^{II} + H_2[HPA]_{red} \quad (i)$$

$$H_2[HPA]_{red} + 1/2\,O_2 \longrightarrow [HPA]_{ox} + H_2O \quad (j)$$

Use of the heteropolyanion instead of the normal $CuCl_2$ oxidant avoids corrosion by HCl. Table 4 summarizes some catalyzed oxidation reactions.

Table 4. Some oxidation reactions catalyzed by polyoxometalates [a].

Reaction	Catalyst [b]	T [°C]	Yield [%]
Isobutene → methacrylonitrile	"$Mo_{10}PBi_3Fe_6K_{0.06}$"	420	74
Butene → maleic anhydride	"$Mo_{12}PBi_{0.36}Mn_{0.52}$"	400	63
Butadiene → furan	$(NH_4)_3[PMo_{12}O_{40}]$	350	21
Crotonaldehyde → furan	$[PMo_{12}O_{40}]^{3\ominus}$	350	40
Methacrolein → methacrylic acid	Mo-P-V-Cu, As, Bi, Cs	280–340	70–80
Isobutyric acid → methacrylic acid	$[PMo_{10}V_2O_{40}]^{5\ominus}$	310	70
Phenol → catechol, hydroquinone	$[PW_{12}O_{40}]^{3\ominus}/H_2O_2$	80	82

[a] Abstracted from [108]. Examples mostly from the patent literature. [b] Formula or approximate composition of catalyst.

The $V^{IV}/V^V/O$ polyoxometalate system is important for understanding the "V_2O_5" Contact Process catalyst for oxidation of SO_2. The catalyst is a melt formed from V_2O_5 and $NaVO_3$ and, during turnover, contains V^{IV} centers according to ESR studies[121,122] and therefore very probably contains mixed-valence polyvanadates. Similar species should also be involved in the Stretford Process for removal of H_2S from fossil fuel gas[123] [Eq. (k)].

$$HS^{\ominus} + 2\,V^V \longrightarrow \{S\} + 2\,V^{IV} + H^{\oplus} \quad (k)$$
(overall reaction: $H_2S + 1/2\,O_2 \longrightarrow S + H_2O$)

Polyoxometalate surfaces are models for metal oxide surfaces and the oxidation activity can be understood in terms of the loss of surface oxygen atoms and delocalization of the remaining electrons over several metal atoms under relatively mild conditions [schematically according to [Eq. (l)].

$$\{M^{n\oplus}-O\} \longrightarrow \{M^{(n-2)\oplus} - \square\} + O \quad (l)$$

Acid catalysis by heteropoly acids can nicely be related to the known data on their acidity. Compounds of the type $H_x[XM_{12}O_{40}]$ with the Keggin structure are strong polybasic acids. In the crystal lattice there are nonlocalized protons that rapidly exchange with the protons of the crystal water molecules of the so-called secondary structure and with the protons localized on the μ_2-bridging oxygen atoms of the polyanions. In aqueous solution the compounds are strong acids, which are often completely dissociated. Upon reduction, the anion basicity increases and, consequently, the anion has a tendency to become protonated [see Eqs. (i) and (j)]. Although heteropoly acids are more expensive than mineral acids like sulfuric and hydrochloric acid, they have the advantages of being nonvolatile, odorless, and thermally stable. They can be used in homogeneous acid catalysis as well as in heterogeneous catalysis using supports like silica gel or activated charcoal at temperatures of approximately 300 °C.

Since the acid centers are considered to be at the bridging oxygens on the anion's surface, knowledge of the electronic structures, as well as electron density studies, are of critical importance (see Section 5).

Table 5. Heteropolyanion acid-catalyzed reactions [a].

Reaction	Catalyst [b]	T [°C]	Activity ratio [c]
Homogeneous			
Propene → isopropanol	PMo_{12}, PW_{12}	150	2–4
Phenylacetylene → acetophenone	PMo_{12}, PW_{12}	60	>10
Heterogeneous			
Isopropanol → propene	PW_{12}	150	100
2-methylpropene, methanol → methyl *tert*-butyl ether	PMo_{12}, PW_{12}/SiO_2	90	300
Methacrylic acid → propene	PW_{12}, SiW_{12}	240	4

[a] Abstracted from [108]. [b] $[H_nXM_{12}O_{40}]$ abbreviated as XM_{12}. [c] Ratio of the catalytic activity of the heteropoly acid to that of mineral acids and silica-alumina for homogeneous and heterogeneous systems, respectively.

Currently, in what is probably the most important catalytic application, industrial production of 2-propanol, 2-butanol, and *tert*-butanol by liquid-phase hydration of the corresponding olefins [e.g., Eq. (m)] is catalyzed by tungstophosphoric acid. Table 5 gives an overview of different acid-catalyzed reactions.

$$CH_2 = CHCH_3 + H_2O \longrightarrow CH_3CH(OH)CH_3 \quad (m)$$

The most widely used industrial catalysts are probably those for hydrodesulfurization (HDS), hydrodenitrification (HDN), and hydrodemetalation (HDM) of fossil fuels (see, e.g., Refs. [124–126]). In most cases these catalysts contain,

before promotion, polymolybdate species (probably heptamolybdates) on an alumina support[125] and, in the promoted form, a "cobalt polymolybdate". Catalytic activity has been related to the form of polymolybdate used in impregnation of the alumina support.[125]

9.3. Solid-State Applications: Electronic and Protonic Conductors

Many of the solution properties of polyoxometalates are also observed in the crystalline salts and free acids, since the large anions tend to have very weak attractions for countercations and solvate molecules. In particular, the electron- and proton-transfer characteristics are often retained in the solid state. Crystalline acids of Keggin anions such as $H_3[PW_{12}O_{40}]\cdot 21H_2O$ are protonic conductors,[127] and proton-conducting films have been described.[128] The same types of acids have been used as solid electrolytes for fuel cells.[129] Electrochromic[130] and ion-selective electrodes have also been reported. An example of the latter, sensitive to ammonium ions, is based on compressed pellets of ammonium 12-molybdophosphate in polystyrene.[131] Insoluble molybdophosphate salts have also long been used and are commercially available as cation-exchange materials.[132] They are especially valuable for highly radioactive solutions that destroy organic resins. The use of polyoxometalates as inorganic electron-acceptor components in charge-transfer salts[133a] and of polytungstates as sources of inorganic resist materials[133b] demonstrate other recent applications in materials science.

9.4. Medicine: Antitumoral, Antiviral, and Antiretroviral Activity

Many polyoxometalate salts have been shown to be biologically active. Such activity includes highly selective inhibition of enzyme function,[134-136] in vitro and in vivo antitumoral activity,[137] antiviral activity (e.g., against rabies[138] and scrapie, the sheep version of "mad cow disease"[139]), and antiretroviral activity (e.g., against HIV infections, connected with AIDS, SAIDS[134]). One particular heteropolytungstate (HPA-23, see Fig. 10) has been used for treatment of AIDS patients in France. Research in this field is particularly vigorous.

Reasons for biological activity may include ionic size and shape (blocking of the CD4 plasmamembrane receptors of T4 lymphocytes for the interaction with the gp 120 envelope glycoprotein of HIV?), electron-transfer and -reservoir properties (i.e., inhibition of biological electron transfer[140]), and stability (or nonlability) at micromolar concentrations and physiological pH (particularly true for large polytungstates, but also, surprisingly, for some molybdates and vanadates).

10. Occurrence in the Geo- and Biospheres

The geochemistry of vanadium is particularly diverse.[141-143] Three oxidation states are detectable, and two (IV, V) are stable in the normal range of geological environments. Consequently, a bewildering variety of interesting minerals, including many mixed-valence ones, are known (e.g., the heteropolyanion-containing sherwoodite;[142, 143] see Scheme 2). There are also several minerals (e.g., pascoite, hummerite) that contain the isopoly decavanadate anion, $[V_{10}O_{28}]^{6\ominus}$.[142, 143] The oxidized and mixed-valence minerals are presumably formed by weathering of the primary postmagmatic ore montroesite, (V,Fe)O(OH).[142, 143] The geochemical situation corresponds to the variety of mixed-valence vanadium clusters (Section 7).

As expected, molybdenum and tungsten do not form such a variety of mixed-valence minerals. There is only one known related (amorphous) oxidic species, ilsemannite, a blue mixed-valence molybdenum mineral.[142]

Little is known about the aggregation of $MO_4^{n\ominus}$ (M = V, Mo, W) anions in the biosphere, bearing in mind the low concentrations under physiological conditions. The mononuclear species are important for uptake and transport of the elements V, Mo, and W. Mo is an essential trace element for most, if not all, organisms, and V and Mo are involved in biological nitrogen fixation. The Mo storage protein[144] in *Azotobacter vinelandii* possibly contains an apoprotein with an isopolymolybdate core, since the release of Mo can easily be controlled by pH variation.

11. Thiometalates Are Different

The early transition elements discussed here also form thiometalates of the type $[MS_4]^{n\ominus}$ with d^0 configurations and polymeric species. Their chemistry is relevant for different biological processes (e.g., nitrogen fixation or the Cu–Mo antagonism of ruminants) and for their use as catalysts in industrial processes (e.g., HDS, see Section 9.2).

The very large differences in the chemistry between mononuclear oxo- and thioanions, $[MX_4]^{n\ominus}$, can be attributed to the following properties of the thioanions:[145-147]

1. The HOMO–LUMO difference is very small.
2. They are less basic than the oxoanions.
3. They exhibit strong electron-withdrawing properties as ligands.
4. They undergo intramolecular redox reactions ($S^{2\ominus}$ oxidation, M reduction) upon protonation [e.g., Eq. (n)] or heating [e.g., Eq. (o)]

$$[Mo^{VI}O_2S_2]^{2\ominus} \longrightarrow [Mo^{V}_2O_2S_2(S_2)_2]^{2\ominus} \quad (n)$$

$$[W^{VI}S_4]^{2\ominus} \longrightarrow [W^{IV}S(W^{VI}S_4)_2]^{2\ominus} \quad (o)$$

5. Metal sulfides, with reduced metal centers, are easily and irreversibly precipitated from aqueous solution.

The following differences in the chemistry of the polynuclear thioanions result:

1. Coordination numbers of the metal centers are in general smaller (4, 5) as a result of the larger S atom.
2. There is a tendency towards the formation of smaller aggregates.
3. Lower oxidation states of the metal atoms tend to be favored as a result of facile intramolecular redox pro-

cesses. Exceptions involve Nb and Ta, which are difficult to reduce (see, for example, the hexanuclear thioanions[148]).

4. $S_n^{2\ominus}$ (mainly $S_2^{2\ominus}$) ligands are frequently present.
5. Thiometalate complexes almost always exist with mononuclear ligands (e.g., $[Ni(WS_4)_2]^{2\ominus}$), although it has been possible to replace oxygen by sulfur to a very limited extent in polyoxometalates (e.g., $[NbW_5O_{18}S]^{3\ominus}$[149]).

12. Epilogue

Savoir pour prévoir[*]
Auguste Comte

The molecular metal–oxygen clusters of the early transition elements are remarkable for their topology and electronic structures (electron-, proton-, and oxygen-reservoir properties). Although the first compounds of this type were reported over 150 years ago, new types of clusters continue to be discovered.

It will be important to understand the high tendency for self-assembly of the "spherical" species in terms of close-packing of oxygens and minimal metal–metal repulsions. A predictable direction for future research will be exploitation of the unique property of these species, namely, that metal–metal interactions can be varied from extremely weak (but nonzero[150]), through weak (antiferromagnetic coupling), to strong (metal–metal bonding) by stepwise reduction of the cluster without changing its topology. It should be kept in mind that metal–oxygen, as well as metal–sulfur, clusters play an important role in the biosphere and in catalysis.

That some species may be used to model n-type semiconducting oxides and indeed other solid-state processes and that others display reactivity with respect to oxygen-transfer processes (e.g., those catalyzed by enzymes like the Mo-containing oxygen transferases, but also selective oxidation processes) are additional factors that have not gone unnoticed and will continue to stimulate research. The characterization of the different electron-transfer components in the photosynthesis system, for example, is of importance and heteropolyanions can be of help as artificial electron acceptors (see, for instance, Ref. [102]).

The possible impact for further medical applications is difficult to predict, and research in this area (e.g., related to HIV replication) is still being carried out in several institutions. The reasons for the versatile biological functions need further clarification.

Michael T. Pope thanks the Alexander von Humboldt Foundation for a Senior Scientist Award and Georgetown University for a sabbatical leave, during which this article was prepared, as well as the National Science Foundation, the Petroleum Research Fund, administered by the American Chemical Society, and ARCO Chemical Corporation for research support. Achim Müller thanks the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and the Westfälisch-Lippische Universitätsgesellschaft for financial support. We are both deeply indebted to our co-workers, whose names appear in the references, for their friendship, enthusiasm, hard work, and insights, and to our colleagues for valuable discussions. We particularly thank Dr. Howard T. Evans, Jr., for permission to use many of his structural illustrations, Michael Penk for his skills in preparing several polyhedral diagrams, and Chaoying Rong for recording the cyclic voltammogram shown in Figure 7.

Enantioselective Addition of Organometallic Reagents to Carbonyl Compounds: Chirality Transfer, Multiplication, and Amplification**

New Synthetic Methods (83)

By Ryoji Noyori* and Masato Kitamura

Nucleophilic addition of organometallic reagents to carbonyl substrates constitutes one of the most fundamental operations in organic synthesis. Modification of the organometallic compounds by chiral, nonracemic auxiliaries offers a general opportunity to create optically active alcohols, and the catalytic version in particular provides maximum synthetic efficiency. The use of organozinc chemistry, unlike conventional organolithium or -magnesium chemistry, has realized an ideal catalytic enantioselective alkylation of aldehydes leading to a diverse array of secondary alcohols of high optical purity. A combination of dialkylzinc compounds and certain sterically constrained β-dialkylamino alcohols, such as (−)-3-*exo*-dimethylaminoisoborneol [(−)-DAIB], as chiral inducers affords the best result (up to 99% *ee*). The alkyl transfer reaction occurs via a dinuclear Zn complex containing a chiral amino alkoxide, an aldehyde ligand, and three alkyl groups. The chiral multiplication method exhibits enormous chiral amplification: a high level of enantioselection (up to 98%) is attainable by use of DAIB in 14% *ee*. This unusual nonlinear effect is a result of a marked difference in chemical properties of the diastereomeric (homochiral and heterochiral) dinuclear complexes formed from the dialkylzinc and the DAIB auxiliary. This phenomenon may be the beginning of a new generation of enantioselective organic reactions.

1. Introduction

Chirality is a major phenomenon in Nature, and molecular asymmetry in particular is playing a crucial role in science and technology. A variety of significant biological functions emerge through molecular recognition, which requires strict matching of chirality. Nonracemic molecules will also contribute to the creation of advanced materials possessing unique physical properties. Accordingly enantioselective synthesis of chiral organic compounds is an important task allotted to synthetic chemists. Asymmetric catalysis using chiral metal complexes, among others, provides a general, powerful tool in this context.[1]

The carbon–carbon bond forming reaction, together with oxidation, reduction, and functional group transformation, is one of the most fundamental operations for constructing organic molecules. Addition of organometallic reagents to carbonyl compounds is among the most common reactions for this purpose, complementary to reduction of aldehydes or ketones, and provides a reliable way to form alcoholic products. Organometallic chemistry dates back to the discovery of organozinc compounds by *Frankland* in 1849.[2] Although this pioneering achievement was deeply appreciated, the significance of organozinc chemistry remained somewhat underestimated, at least in terms of synthetic utility. The Reformatsky reaction[3] and Simmons–Smith reaction[4] utilize Zn metal but, in simple alkylation to carbonyl compounds, organozinc compounds were replaced by Grignard reagents (discovered 50 years later)[5] and organolithium compounds (developed by *Wittig* and *Gilman*[6] among others), owing perhaps to their higher generality, higher reactivity, and easier manipulation. Recently, the chemistry of organoboron, -aluminum, -titanium, -lanthanide compounds, etc. has been further developed with the hope of obtaining high selectivities. The enantioselective version of the reaction between organometallic reagents and carbonyl compounds which leads to optically active alcohols is desirable because of its general synthetic importance.

A nonracemic, chiral environment can be introduced into organometallic compounds in two ways (Fig. 1). One is the coordination of aprotic chiral solvents or complexing agents to the metallic center, and the other is the modification of the organometallic reagent by protic chiral ancillaries, such as alcohols or amines, to give organometallic alkoxides or amides, respectively. The molecular structures of various main-group organometallic compounds having neutral and anionic ligands have been studied by X-ray crystallographic analysis and spectroscopic methods, revealing that the steric and electronic properties of the ligands significantly affect the structures, including configuration, metal coordination number, and bond polarity.[7–9] Many organometallic compounds form labile molecular associates, so the aggregation state responsible for the reaction may be different from that of the ground-state structure. The organometallic compounds are amphiphilic in nature: the nucleophilicity of the carbon moiety and Lewis acidity of the metallic center cooperate in the alkyl transfer reaction. Thus chiral ligands per-

turb the structure and stability of the transition state in many ways.

In the last two decades, a number of highly enantioselective alkylation reactions of carbonyl compounds have been developed by proper combination of organometallic reagents and well-designed chiral ancillaries. So far most selective reactions have used a chiral auxiliary in a stoichiometric or an excess amount, but it has been our hope to realize a catalytic asymmetric induction. In this respect, a number of unexpected, nonclassical aspects have been observed with the classical organozinc chemistry. This review describes the historical background and our personal account of this research.[10-13] The subject is limited to simple alkylation or arylation reactions. The chemistry using structurally more elaborate carbon nucleophiles, such as metal enolates or allylic metal compounds, is not included.

2. Stoichiometric Asymmetric Alkylation

2.1. Reaction with Organometallic Reagents Modified by Aprotic Chiral Ligands

The curtain on enantioselective alkylation of aldehydes was raised in 1940 by *Betti* and *Lucchi* who claimed the first successful use of Grignard reagents and a chiral tertiary amine.[14] The Bologna chemists reported that the reaction of benzaldehyde and methylmagnesium iodide in the presence of *N,N*-dimethylbornylamine gave, in 73% yield, 1-phenylethanol showing an optical rotation of 0.30°. However, two years later *Tarbell* and *Paulson*, who were unable to reproduce this result, concluded that the optically active alcohol had not been produced although a neutral optically active impurity was formed by the reaction.[15] The original concept remained valid, however: certain chiral complexing agents are able to effect enantioselective addition of organometallic compounds to aldehydes.

Cohen and *Wright* reported in 1953 that the reaction of ethyl 2-oxo-2-phenylacetate with 1.6 equivalents of ethylmagnesium chloride and (2*R*,3*R*)-dimethoxybutane in benzene yielded ethyl 2-hydroxy-2-phenylbutanoate in 5% *ee* and in 37% yield.[16] Multidentate ethers such as dimethoxybutane, hexa(*O*-methyl)mannitol, or penta(*O*-methyl)arabitol are more effective than unidentate chiral ethers.[17] Table 1 outlines the development of this type of chemistry.

In the late 1960's we became interested in the use of (−)-sparteine **1**, a naturally occurring tertiary diamine, and noticed a 22% *ee* in the reaction of benzaldehyde and ethylmagnesium bromide.[18] Organolithium reagents were less sensitive than Grignard reagents to the presence of this chiral ligand. *Seebach* studied systematically the effects of multidentate ligands[19] and attained 52% *ee* in the reaction of benzaldehyde and *n*-butyllithium aided by an amino ether **2**.[19d] Ultimately, *Mazaleylat* and *Cram* accomplished 95% *ee* in the same alkylation using the chiral diamine ligand **3** having three C_2 axes.[20] A strong solvent effect was observed and use of diethyl ether at −120°C gave the best *ee*

Ryoji Noyori, born in Kobe, Japan in 1938, completed his undergraduate study in 1961 and the Master's degree in 1963 at Kyoto University, and immediately became an instructor in Professor H. Nozaki's laboratory at the same university. While at Kyoto he earned his Ph.D. degree in 1967. Appointed as an associate professor at the Department of Chemistry of Nagoya University in 1968, he was promoted to his current position in 1972. Noyori did his postdoctoral work with Professor E. J. Corey at Harvard University in 1969–1970. His research interests have been mainly in the exploitation of new synthetic methods, particularly on the basis of organometallic chemistry and their application. Noyori discovered a variety of asymmetric syntheses including enantioselective catalyses using BINAP (p,p'-(1,1'-binaphthyl-2,2'-diyl)bis(diarylphosphane)) chemistry, which have enormous utility. His organometallic methodologies have opened truly efficient routes to terpenes, vitamins, β-lactam antibiotics, alkaloids, prostaglandins, carbohydrates, nucleic acids, etc. Noyori's contribution has been recognized by a number of awards and honors, which include the Chemical Society of Japan Award (1985), the Centenary Medal and Lectureship from the Royal Society of Chemistry (1989), the Fluka Prize (1989), the Naito Foundation Research Prize (1989), the Toray Science & Technology Prize (1990).

Masato Kitamura was born in Nagoya in 1956 and studied agricultural chemistry at Nagoya University where he completed his doctoral work on total synthesis of maytansine under the direction of Professors T. Goto and M. Isobe. In 1983 he was a postdoctoral fellow with Professor G. Stork (Columbia University) and then joined the Noyori group as an assistant professor. He is a recipient of the Chemical Society of Japan Award for Young Chemists (1989).

value. Similar diamine ligands, such as **4**, containing two *trans*-2,4-diarylpyrrolidine units were effective for asymmetric addition of arylmagnesium bromides to aldehydes, providing the corresponding alcohols in up to 75% *ee*.[21]

2.2. Reaction with Organometallic Reagents Modified by Protic Chiral Auxiliaries

This strategy, though now widely utilized, was found rather recently. Since the importance of molecular aggregates in organometallic reactions was not correctly recognized, most synthetic chemists considered that the reaction of organolithiums or Grignard reagents of type RMgX and protic compounds formed, by eliminating an alkane, metallic compounds with no alkylation ability. In 1969, however, *Inch* et al. demonstrated that, in the presence of an α-D-glucofuranose derivative **5** containing a free hydroxyl group (Table 2), methylmagnesium bromide reacts with cyclohexyl phenyl ketone (alcohol:CH_3MgBr:ketone = 1:1.75:0.5) to afford the corresponding alcohol in 70% *ee* and in 95% chemical yield.[24] This reaction probably involves a multi-

nuclear magnesium compound containing methyl group(s) and a sugar alkoxide.

Later, the influence of chiral amino alcohols such as *N*-methylephedrine **6**[25-27] and Darvon alcohol **8**[28] or chiral dihydrooxazoles such as **7**[29] was examined in alkylations using Grignard reagents, organocuprates, organoaluminates, etc. *Mukaiyama* attained 95% *ee* in the reaction of benzaldehyde and *n*-butyllithium in the presence of a proline-derived diamine, **9**, in a 1:1 mixture of dimethoxymethane and dimethyl ether at −123 °C.[30] The reaction using lithium trimethylsilylacetylide also proceeded in 92% optical yield and was used for the synthesis of corticoids.[31]

Chirally modified organotitanium compounds are also useful.[32] *Seebach* et al., after extensive experimentation, found that aromatic aldehydes are arylated with organotitanium compounds generated in situ from enantiomerically pure 2,2′-dihydroxy-1,1′-binaphthyl **11** (binaphthol), chlorotriisopropoxytitanium and aryl Grignard reagents in THF to give the diaryl alcohols in greater than 98% *ee* in some cases.[33] *Reetz* et al. noted that *N*-sulfonylated derivatives of norephedrine, such as **12**, are good chiral ligands for modification of methyltitanium reagents, which effect alkylation of aromatic aldehydes to form (*R*)-alcohols in ca. 90% *ee*.[34] ^{1}H and ^{13}C NMR spectra of the titanium reagent showed a multitude of peaks not in line with a single monomeric or dimeric species. The results of several representative examples of reactions with reagents modified by chiral ligands are given in Table 2.

2.3. Reaction with Lithium/Magnesium Binary Reagents Modified by Binaphthol

A high level of enantioselection, based on ligand-directed chirality transfer, is obtained by careful combination of chiral auxiliaries, carbonyl compounds, and organic groups (alkyl, aryl, etc.), as exemplified in Section 2.2. A general method did not exist. The chemical and optical yields of reactions using organolithium or -magnesium compounds often vary depending on the reaction conditions, the ratio chiral ligand: alkylmetal :substrate, the way the chiral reagents were prepared, etc.

The use of excess amounts of chiral sources (usually 4 equivalents or more) over carbonyl substrates is imperative in many cases in order to achieve a high level of enantioselective addition, although the titanium reagents were usually utilized with only 1 to 1.3 equivalents of chiral auxiliaries.[33] This can be a result of the competition between achiral and chiral alkylating agents present in the reaction system, leading to products with varying selectivities and at different rates. Therefore, the creation of a single highly reactive species possessing excellent chiral recognition ability is crucial in achieving a stereoselective reaction. A readily available Li/Mg binary organometallic agent **13** (Fig. 2, empirical formula) is advantageous for this purpose: coordinatively saturated tetrahedral lithium and magnesium can avoid the complication of reagents by polymerization or aggregation, and the C_2 chiral bidentate modifier can minimize the number of the reactive species.[33, 37] The two kinds of metals may play specific roles as alkyl donor and carbonyl activator, which results in high reactivity.

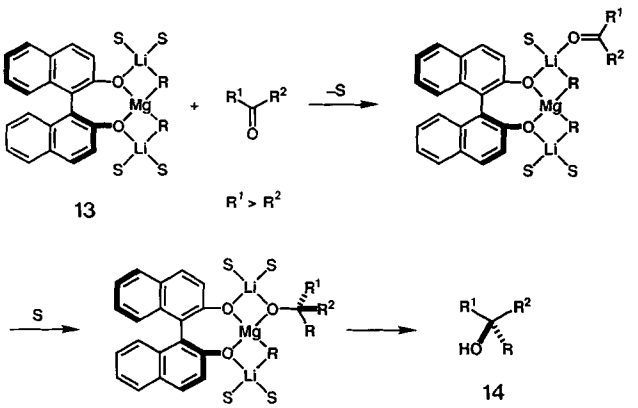

Fig. 2. Enantioselective addition of binaphthol modified Li/Mg binary organometallic agents to carbonyl compounds. S = solvent.

Thus the ethylating agent, (*S*)-**13** (R = ethyl), possessing two homotopic ethyl groups, was prepared by treatment of enantiomerically pure (*S*)-binaphthol (*S*)-**11** dissolved in THF with 2 equivalents of *n*-butyllithium, and then with 1 equivalent of diethylmagnesium at −78 °C. And indeed, the golden-yellow homogeneous reagent (0.074 M) reacted with 1 equivalent of benzaldehyde at −100 °C for 1 h in a 1:1 mixture of THF and dimethoxyethane (DME) to form (*S*)-1-phenyl-1-propanol (**14**, R = ethyl, R^1 = phenyl, R^2 = H) in 92% *ee* and 93% yield. As exemplified in Table 3, a variety of aromatic or aliphatic aldehydes were alkylated in greater than 80% optical yield with the alkyl or phenyl reagents using a 1:1 stoichiometry (not an excess).[11]

Table 3. Enantioselective reactions of the Li/Mg reagent, (*S*)-**13**, with carbonyl compounds $R^1R^2C{=}O$ [a].

Organometallic R in (*S*)-**13**	R^1	R^2	Product Yield [%]	*ee* [%]	Configuration

C_2H_5	p-$CH_3OC_6H_4$	H	98	83	*S*
C_2H_5	$C_6H_5CH_2CH_2$	H	40	85	*S*
C_2H_5	n-C_6H_{13}	H	86	85	*S*
C_2H_5	c-C_6H_{11}	H	68	84	[b]
n-C_4H_9	C_6H_5	H	98	88	[b]
C_6H_5	1-$C_{10}H_7$	H	89	82	[b]
C_2H_5	C_6H_5	CH_3	57	45	[b]

[a] The reaction was carried out at −100 °C in a 1:1 THF–DME mixture. [b] Not determined.

A 0.074 M [D_8]THF solution of di-*O*-lithiobinaphthol, prepared by mixing (*S*)-**11** and *n*-butyllithium in a 1:2 mole ratio followed by recrystallization from THF–hexane, exhibited a broad ^{7}Li NMR signal at $\delta = -0.25$ (LiCl in [D_8]THF as external reference, half-width $\nu_{1/2} = 14$ Hz at 20 °C). The aromatic protons also gave broad NMR signals. However, addition of 1 equivalent of diethylmagnesium to this solution sharpened the signals to a great extent (Fig. 3).

The ^{1}H NMR spectra of the ethylating agent **13** (R = ethyl) revealed a very sharp, single triplet and quartet due to the methyl and methylene protons at $\delta = 1.32$ and −0.92, respectively, at temperatures ranging from 20 to −50 °C.[38] The ^{7}Li NMR spectrum, measured at 20 °C,

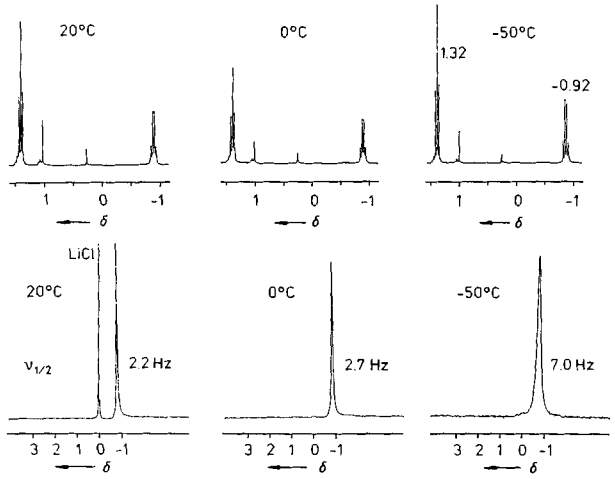

Fig. 3. ^{1}H (top, THF as internal standard) and ^{7}Li NMR spectra (bottom, LiCl in [D_8]THF as external standard) of the Li/Mg ethylating agent **13** (R = C_2H_5, S = [D_8]THF, 0.074 M [D_8]THF solution) at 20, 0, and -50 °C.

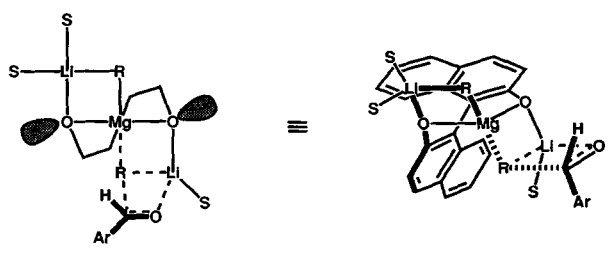
showed a single signal ($\nu_{1/2}$ = 2.2 Hz) at $\delta = -0.96$, and this signal was broadened at -50 °C ($\delta = -0.98$, $\nu_{1/2}$ = 7.0 Hz). Obviously some equilibration such as exchange of the coordinated THF molecules exists, but such a dynamic effect does not affect the magnetic environment of the ethyl protons to any great extent. Upon addition of benzaldehyde the spectrum became complicated, giving several new broad ^{7}Li signals at lower field. Notably, however, the original $\delta = -0.98$ signal due to **13** remained, though with decreased intensity, during the alkylation reaction.

The degree of enantioselection in alkylations with **13** was little affected by the extent of conversion of the starting materials. The ethylation of benzaldehyde using 4 equivalents of (*S*)-**13** (R = ethyl) afforded the same enantioselectivity (*S*/*R* = 96:4) as 1 equivalent, while the reaction with half an equivalent of the reagent resulted in decrease in the selectivity, *S*/*R* = 91:9 (90% yield). The resulting alkylmetal alkoxide products may cause adverse enantioselective alkylation.[39]

The enantioselectivity of the ethylation of benzaldehyde varies from 66% to 92% *ee* on changing the reaction temperature from 20 to -100 °C. Plotting of ln(*S*/*R*) as a function of $1/T$ shows direct proportionality, and from the line slope the difference in activation energy of the alkylation leading to the *S* and *R* alcohols is calculated to be 1.3 kcal/mol. This linearity suggests the participation of a single chiral reagent in the enantioselective alkylation over this temperature range. A further increase of enantioselectivity is expected by decreasing the reaction temperature, but the freezing of the reaction media prohibits such experiments. A possible transition state giving the *S* alkoxide product is illustrated by the structure **15** (naphthalene rings are omitted in **15a**).



15a **15b**

The reaction with (*S*)-**13** provides one of the most effective ways to alkylate carbonyl compounds in an enantioselective manner, but it is still based on stoichiometric chirality transfer; the preparation of optically active alcohols suffers from the necessity of using an equimolar amount of binaphthol.

3. Catalytic Enantioselective Alkylation

3.1. The Concept

Reactivity of organometallic compounds is profoundly affected by neutral or anionic heteroatom auxiliaries. In certain cases, addition of a chiral auxiliary could enhance the reactivity and at the same time control the stereochemical outcome in an absolute sense. Catalytic asymmetric alkylation is the obvious ideal and Figure 4 presents a possible pathway to this ultimate goal, where addition of dialkylmetal, R_2M, to a prochiral carbonyl substrate is achieved by a catalytic amount of protic chiral auxiliary, HX*. Actually the metallic compounds are not simple monomers as formulated but usually exist as aggregates or in forms associated with other molecules.[9]

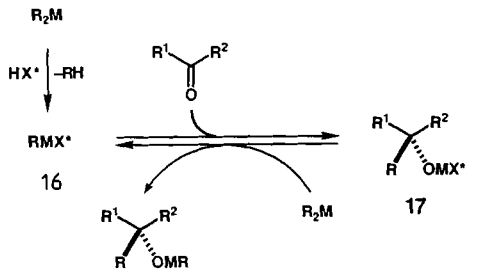


Fig. 4. Enantioselective alkylation catalyzed by protic auxiliary HX*. M = metallic species. X* = chiral heteroatom ligand.

In order to obtain a high degree of enantioselection in this scheme, the chiral anionic ligand X* must possess a suitable three-dimensional structure which clearly differentiates between the diastereomeric transition states of the alkyl delivery step, **16** → **17**. In addition, several kinetic conditions are to be satisfied to achieve catalytic asymmetric induction. First, the rate of the alkylation by the chirally modified organometallic **16** should substantially exceed that of the reaction of the original achiral reagent R_2M. Second, ligand X* must be readily detached from the initially formed metal alkoxide **17** by the action of the alkyl donor or carbonyl substrate to establish the catalytic cycle. These are key issues for obtaining a high turnover efficiency and an excellent chiral bias. These considerations also apply to the reaction using aprotic modifiers.

Although a wide array of well-shaped chiral auxiliaries or ligands are now accessible, the kinetic requirements described above are not easily secured by use of conventional organolithium or -magnesium compounds. *Cram* has found

that reaction of *n*-butyllithium and benzaldehyde in the presence of 0.77 mol% of a chiral diamine with binaphthyl skeleton gives 1-phenyl-1-pentanol in 7% *ee*.[20] *Hogeveen* has also observed a rate-enhancing effect in the same reaction system, resulting in production of 1-phenyl-1-pentanol in 19% *ee* by employing 2.4 mol% of the chiral lithium amide **10** prepared from (*S*)-α-methylbenzylamine (Table 2).[40] The rate of the catalyzed chiral reaction appears to exceed the uncatalyzed alkylation rate considerably, but the factor is too small to provide a synthetically useful turnover.

3.2. Amino Alcohol Promoted Alkylation with Diorganozinc Compounds

Among the various organometallic compounds diorganozinc acts as an ideal alkyl donor for catalytic asymmetric alkylation. In ordinary hydrocarbon or ethereal solvents, dialkylzinc compounds do not react with aldehydes. When dimethylzinc or diethylzinc, for instance, is mixed with benzaldehyde in toluene at or below room temperature, a yellow coloration occurs owing to reversible donor-acceptor complexation.[41] However, no chemical reaction, or even change in the ^{1}H NMR spectrum, is observed. At elevated temperatures ethylation does take place, but very slowly.

There have been several trials using dialkylzinc for the catalytic asymmetric alkylation of benzaldehyde. In the presence of Pd^{II} or Co^{II} complexes of (1*R*)-camphorquinone oxime, the reaction is accelerated to some extent and the ethylation product is obtained with 40–60% *ee*.[42a] In 1984 *Oguni* and *Omi* reported that certain β-amino alcohols also catalyze ethylation of benzaldehyde.[42b] For example, the reaction occurs in toluene at 24°C in the presence of 2 mol% of (*S*)-leucinol, giving after 48 h (*R*)-1-phenyl-1-propanol (*R*)-**18** in 48.8% *ee* and 96% yield. However, other simple amino alcohols are less efficient. In this first successful example, the *ee* value was not satisfactory and the reaction was slow.

In view of the prime significance of "ligand acceleration"[43] in the scenario outlined in Figure 4, we have screened a variety of bidentate protic auxiliaries and aprotic ligands in the hope of obtaining greater acceleration of the nucleophilic alkylation.[10, 13] Figure 5 illustrates the results of the reaction of benzaldehyde and diethylzinc in a

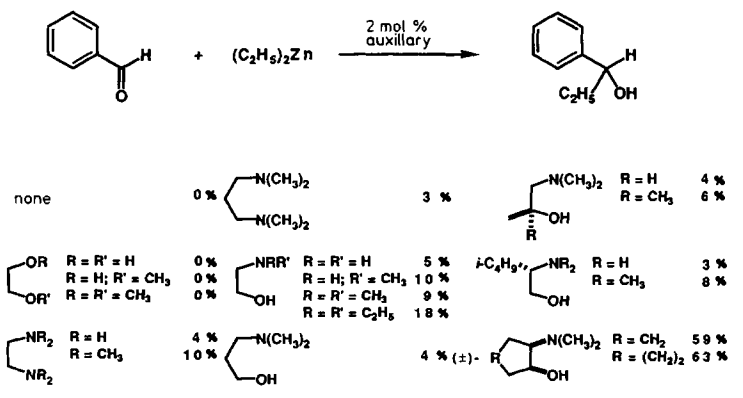

Fig. 5. Yields of ethylation of benzaldehyde with diethylzinc in the presence of 2 mol% of auxiliary in toluene at 0°C for 1 h.

1:1.2 mole ratio performed in toluene containing 2 mol% of various additives at 0°C for 1 h. Aprotic additives such as *N,N,N',N'*-tetramethylethylenediamine are also effective as promoters, and the efficiency appears highly dependent on the structures and substitution patterns. β-Dialkylamino alcohols act better than the corresponding *N*-monoalkyl or non-alkylated compounds. *N,N*-Dimethylleucinol is ca. three times more reactive than leucinol itself, where the acidic proton on the nitrogen may cause complications. Further impressive rate enhancement has been obtained with sterically constrained α,β-disubstituted β-dialkylamino alcohols: some cyclic compounds proved to be 10 to 100 times more effective than simple α-amino acid derived alcohols. Later, simple acyclic β-dialkylamino alcohols possessing a bulky α-substituent were found to be equally efficient.[13, 44]

In 1986 we reported for the first time a highly enantioselective alkylation[10] catalyzed by (−)-3-*exo*-(dimethylamino)isoborneol [(−)-DAIB **19**],[45] a camphor-derived, sterically congested, chiral β-dialkylamino alcohol (Fig. 6).

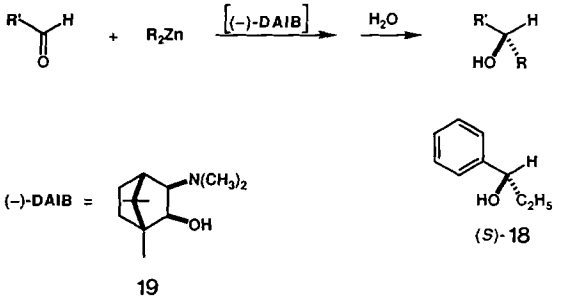

Fig. 6. DAIB-promoted enantioselective addition of dialkylzinc compounds to aldehydes. R = alkyl; R' = aryl, alkenyl, alkyl

In the presence of 2 mol% of (−)-DAIB, for example, the reaction of benzaldehyde and diethylzinc proceeds rapidly in toluene at 0°C, and after 6 h the alcohol (*S*)-**18** is obtained in 98% *ee* and in 97% yield. With the isomer of **19**, (+)-3-*endo*-(dimethylamino)borneol **20**, the *R* alcohol in 95% *ee* is obtained.[46]

A range of alkylating agents and aldehydes can be used for the DAIB-catalyzed enantioselective reaction. Dimethyl-, diethyl-, and other simple dialkylzinc agents are equally employable: methylation of benzaldehyde proceeds considerably more slowly than other alkylations, but gives an *ee* of greater than 90%; alcohols of type **21** are derived from substituted benzaldehydes; the reaction of furan-2-carbaldehyde and di-*n*-pentylzinc forms synthetically useful (*S*)-**22** in greater than 95% *ee*.[13, 47] Use of ferrocenecarbaldehyde leads to optically active **23**, a key compound for the synthesis of a wide range of chiral ferrocene derivatives.[13] Certain α,β-unsaturated or aliphatic aldehydes can also be alkylated in an enantioselective manner, in which case the *ee*'s of the products **24** are highly influenced by the substrate structures. Addition of di-*n*-pentylzinc to (*E*)-3-tributylstannylpropenal affords **25** with *S*/*R* = 93:7, a chiral building block of the three-component coupling prostaglandin synthesis.[48]

Thus DAIB satisfies the conditions of an ideal chiral auxiliary that results in high reactivity and excellent stereoselectivity. Our first report[10] was followed by publication of a

series of related work,[49-52] and now a number of chiral β-amino alcohols can be used for enantioselective alkylation. Some successful examples are compiled in Table 4. The reaction of racemic 2-phenylpropanal and diethylzinc in the presence of (2*R*)-(−)-1-diisopropylamino-3,3-dimethyl-2-butanol proceeds with 5.4:1 enantiomer discrimination.[53] We see a rather good correlation between reactivity and enantioselectivity: high enantioface selection is obtained with a fast reaction.[13] β-Dialkylamino alcohols **26**–**33**, among others, are highly effective catalysts. *Fréchet* et al. was able to immobilize DAIB on polystyrene supports to facilitate recovery and recycling of the chiral catalyst, although this lowered the reaction rate.[50a] Polymer-bound ephedrine acts similarly.[50a, 51j] Some immobilized β-imino alcohols also act as catalysts.[50b] Certain γ-dialkylamino alcohol derivatives such as **36**, as well as divinylzinc, can also be used (see Table 5).[54]

Reactivity is increased by some functional groups near to the carbonyl group, but enantioselectivity is often diminished, probably because heteroatom coordination to the Zn atom facilitates the uncatalyzed achiral pathway. For instance, benzyloxyacetaldehyde or propyl pyruvate is readily ethylated with diethylzinc, even without amino alcohols, but the product is racemic. *n*-Butyl acetoacetate and acetophenone are not alkylated under the standard conditions. However, alkylation of γ- or δ-keto esters proceeds to give the corresponding hydroxy esters in optically active form.[51l] *p*-Benzoylbenzaldehyde, a keto aldehyde, is ethylated chemoselectively giving the optically active secondary alcohol **21f** without alkylating the keto group.[51m]

The choice of solvents is important. In the DAIB-catalyzed ethylation of benzaldehyde, nonpolar solvents such as toluene, hexane, ether, or their mixtures give the most satisfactory results. The reaction in THF is sluggish and the *ee* of product **18** is only 91% (98% in toluene and 99% in a 1:1 mixture of toluene and ether). The enantioselectivity of the ethylation is virtually not affected by DAIB concentration. With regard to the temperature effect, the optical yield of **18** in toluene is decreased from 98% at −20 to 0 °C to less than 95% at 50 °C.[58] With some other amino alcohol catalysts, opposite temperature effects on the selectivity have been observed.[51d]

Some other active catalysts include certain tridentate diamino alcohols,[51b] amido alcohols,[54] γ-amino alcohols,[51d, 54] secondary amino alcohols,[55] and lithium,[51b, g, i] titanium,[56] and boron[57] salts of the appropriate amino alcohols, amines, or sulfonamides, etc. These examples are summarized in Table 5.

A major byproduct of the reaction of benzaldehyde and diethylzinc is benzyl alcohol, whose yield increases with increasing aldehyde/alkylzinc ratio. The ethylation product, ethylzinc 1-phenyl-1-propanoxide, tends to react slowly with benzaldehyde, forming propiophenone and ethylzinc benzyloxide. Alkyl–Zn moieties do reduce aldehydes but are not a main source of hydrides, since the reaction using dimethylzinc also forms benzyl alcohol after aqueous workup, together with acetophenone. Diisobutylzinc, however, reduces benzaldehyde, owing to the enhanced β-hydrogen reactivity.[50a]

3.3. Mechanism of the Amino Alcohol Catalyzed Alkylation

3.3.1. *Transition State Models*

It is worth pointing out that the stoichiometry of the aldehyde, dialkylzinc, and DAIB auxiliary has marked effects on the reactivity[10] (Table 6). The reaction of benzaldehyde and diethylzinc does not occur in toluene at 0 °C without DAIB and, notably, no alkylation takes place with *an equimolar amount* of DAIB either. Remarkably, however, *a catalytic quantity* of DAIB promotes smooth alkylation. In other words, a complex formed from equimolar amounts of a dialkylzinc and DAIB by elimination of an alkane can not alkylate benzaldehyde despite the presence of an alkyl–Zn bond, but nevertheless does catalyze alkylation with dialkylzinc present in excess. This phenomenon clearly indicates that two Zn atoms per aldehyde are responsible for the alkyl transfer reaction. This view is also consistent with the result of a matrix isolation experiment using polymer-bound DAIB as an auxiliary.[50a]

The exact mechanism of alkyl transfer from organometallic species to carbonyl compounds remains to be elucidated. However, various bimetallic transition state models such as **37**–**39** (see page 58) can explain why the highly enantioselective alkylation generates an *S* configuration.

The first is the bicyclic transition state **37**.[12] The reaction occurs from the mixed-ligand dinuclear zinc complex **40**, where DAIB structure is simplified. A number of positional isomers and stereoisomers are possible for the product-forming dinuclear complex, but the formulated structure **40** is appropriate from an electronic basis for the promotion of the alkyl transfer. In going from the ground state to the transition state, electrophilicity of the aldehyde and nucleophilicity of the alkyl group must be enhanced. As easily seen from the polar limiting structure **40b**, this electronic requirement is satisfied best by this molecular assembly. The more Lewis acidic DAIB-chelated Zn_A accommodates the aldehyde substrate, increasing the electrophilicity at the carbon atom, and the bridging alkyl rather than the terminal alkyls

acts as the migrating group. Although the electron density of the bridging R in the ground state is slightly lower than that of the terminal R, the $Zn-R_{bridging}$ bond is more polarizable than the $Zn-R_{terminal}$ linkage.

The folded bicyclic transition structure **37** features a tricoordinate structure of the migrating R group. This postulate is based on the ab initio molecular orbital calculations by *Schleyer, Houk*, and co-workers on the vapor-phase addition

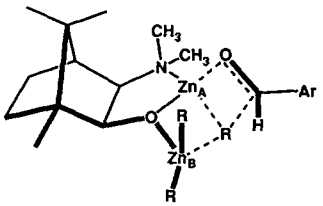
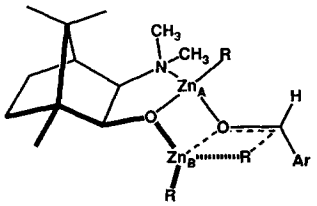
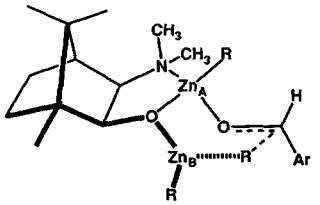
of dimeric methyllithium to formaldehyde.[59] The reaction is thought to involve transfer of a bridged methyl via a related planar bicyclic transition state **41**. This transition structure is considered to be very early on the reaction coordinate and the distance between the carbonyl carbon and the incoming methyl is quite large. The trajectory of attack by the carbon nucleophile is controlled by the lithium ion, and the reacting Li–CH_3 bond is elongated to a great extent. The aggregation state of the reactive alkyllithium species in solution has been a matter of controversy,[60] but it seems to be the consensus that dimers are the reacting entities in ethereal solvents. In THF *n*-butyllithium exists mainly as a tetramer, but the dimer is much more reactive.[61] Monomeric species are not detected in THF.



37

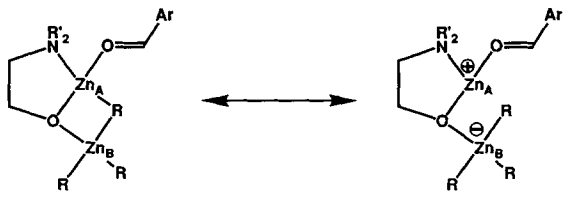


38

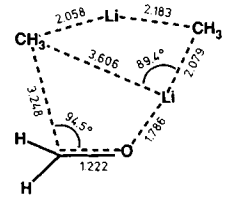


39

The bicyclic transition state **38** could give an alternative explanation for the stoichiometry and stereochemistry of the organozinc reaction.[50a] Such a mechanism involving transfer of a terminally located R to the electrophilically activated, bridged carbonyl carbon[62] was first suggested by *Mole* et al. for the reaction of trimethylaluminum and benzophenone.[63] The *Pasynkiewicz–Sliwa* type bimetallic assembly **39**, postulated by *Corey* and *Hannon*,[51c] is also in full accord with the experimental findings. This transition state model, originally proposed for the reaction of trimethylaluminum and propiophenone,[64] is characterized by the monocyclic, six-centered structure.



40a **40b**



41

3.3.2. The Sense of the Asymmetric Induction

A survey of the stereochemical outcome observed with a range of chiral β-amino alcohols as promoters (Table 4) is outlined in Figure 7.

The bicyclic transition state model of type **37** correctly predicts the absolute configuration of the products. The general sense of the asymmetric induction is controlled primarily by the chirality of the stereodetermining bicyclic intermediates, **42** and **43**.[12] The *S*-configurated Zn alkoxide is derived from **42** which possesses *S*-Zn and *S*-O bridgehead atoms, while the *R* alkoxide is obtained from the *R*-Zn, *R*-O enantiomer **43**. As illustrated by the diastereomeric transition structures **44** and **45** arising from **42**, the kinetic stereochemical bias is provided by a nonbonded repulsion between the carbonyl substituents, Ar and H, and a terminal R group attached to Zn_B. The *S*-generating geometry **44** is obviously preferable to the *R*-forming transition state **45**. The relative stabilities of the chiral bicyclic structures are influenced by substituents at the α and β positions, in accord with the general sense of Figure 7, as well as by the nitrogen substituents. The α*S* or β*R* configuration shows a preference for **42**, whereas **43** is stabilized by the enantiomeric α*R* or β*S* configuration of the auxiliary.

The degree of the enantioselection depends on the bulkiness of the substituents at the α carbon and, indeed, β-dialkyl-

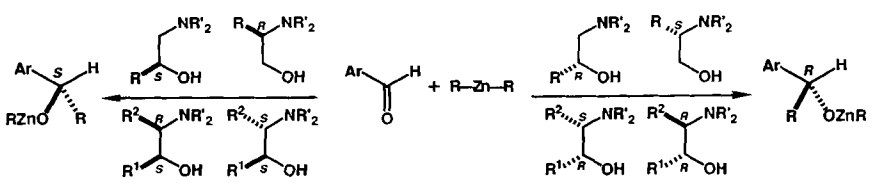


Fig. 7. General sense of asymmetric induction with a β-dialkylamino alcohol catalyst.

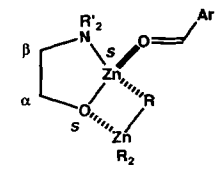
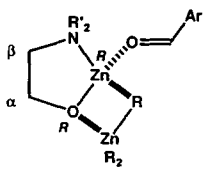
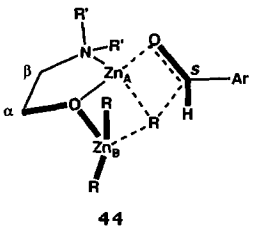
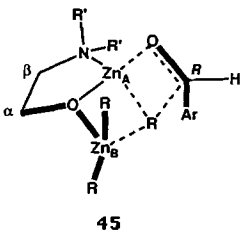
amino-α-*tert*-butylethanol **27** results in up to 98% *ee* in the ethylation of benzaldehyde.[113] As is seen in (−)-DAIB, the *αS, βR* (or *αR, βS*) configuration, generating *cis*-α,β-disubstitution in the five-membered chelate complexes, is the most desirable, because the directing effects of the vicinal substituents cooperate in keeping a single chiral integrity **42** (or **43**), which presents very clear facial bias in the alkyl transfer step. With *trans*-α,β-disubstitution in the Zn chelate, the directing effects offset each other, but the α stereogenic center is more influential than the β center. In the ethylation of benzaldehyde, the diastereomeric amino alcohols, **33** and **34**, deliver the same asymmetric orientation, with higher enantioselectivity in the case of **33** (94% *ee* vs 81% *ee*, see Table 4).[113] A similar tendency is observed with (1*R*,2*S*)-*N*-ethylephedrine and (1*R*,2*R*)-*N*-ethylpseudoephedrine (77% *ee* vs 72% *ee*).[65] In addition, bulky alkyl groups at the nitrogen atom tend to increase the enantioselectivity.[113]

With **35**, i.e., an (*S*)-binaphthyl moiety is the only chiral element, the ethylation of benzaldehyde proceeds in 49% optical yield (Table 4). Thus *αS* configurated β-dialkylamino alcohols always afford *S*-enriched alkylation products, while *αR* auxiliaries lead predominantly to *R* products. No exceptions have been seen in the enantioselective alkylation of benzaldehyde,[66] at least in those with a high level of stereoselection. The steric, not electronic, origin of the stereoselectivity agrees with the consistently high optical yields gained with a variety of benzaldehydes possessing electronically different substituents. Other aldehydes behave similarly. In summary, stereochemical information from the backbone of the chiral auxiliary defines the chirality of the bridgehead atoms in the stereodetermining bicyclic intermediates **42** and **43**, which in turn is transmitted to the aldehyde ligand by an alkyl transfer reaction (via **44** and **45**). Direct steric interaction between carbonyl substituents and α- or β-substituents of chiral auxiliaries is unimportant.

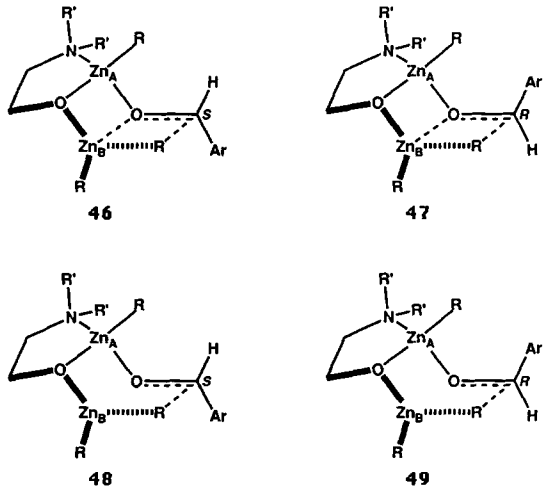








The same arguments on the substituent effects apply to the transition state models of the types **38**[50a] and **39**.[51c] Now with the *αS* configurated amino alcohol ancillaries, the *S*-generating transition states **46** and **48** are favored over the diastereomeric *R* transition states, **47** and **49**, which suffer



significant nonbonded repulsion between Ar and the Zn_A-linked R group.[67, 68]

3.3.3. The Reaction Pathway

On the basis of ^1H NMR studies, single-crystal X-ray analysis, molecular weight (MW) determination of certain key intermediates, alkyl scrambling experiments, kinetic measurement, etc., we have postulated the catalytic cycle of Figure 8 for the amino alcohol accelerated alkylation by dialkylzinc compounds.[112] The scheme has a soft energy surface and compounds **50**–**53** are in dynamic equilibrium.

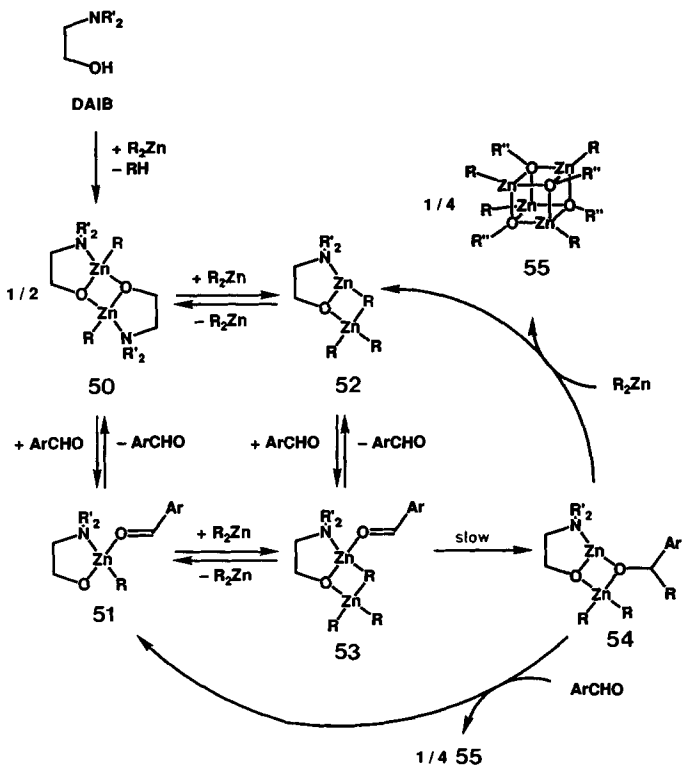


Fig. 8. Catalytic cycle of the DAIB-catalyzed enantioselective alkylation of benzaldehyde with dialkylzinc compounds R_2Zn. Ar = C_6H_5, R′ = CH_3, R″ = $CH(C_6H_5)R$.

In addition, alkylzinc compounds are generally flexible in nature and readily undergo interconversion with many other structural isomers by intra- or intermolecular processes: only entities with a significant contribution in the reaction are formulated in the scheme. The structural study has been done mainly by using dimethylzinc, because the methylzinc intermediates fluctuate less than the other alkyl analogues and are hence easier to monitor.

The proposed reaction pathways in Figure 8 are supported by many lines of structural information. The following phenomenona are to be noted:

1) The ^{1}H NMR spectrum of a 1:1 mixture of benzaldehyde and dimethyl- or diethylzinc in [D_8]toluene at room temperature gives only the independent signals of each component. The signals are sharp and no appreciable change in chemical shift is observed. No chemical reaction takes place under such conditions.

2) Reaction of (−)-DAIB and dimethylzinc in a 1:1 mole ratio in toluene evolves methane and produces only one dimeric compound, **50** (R = CH_3), among three possible stereoisomers. This complex possesses a dinuclear structure both in hydrocarbon solution and in the solid state, as substantiated by cryoscopic MW determination in benzene, ^{1}H and ^{13}C NMR measurements, and single-crystal X-ray analysis. The detailed structure will be given in Section 3.5 ((2*S*,2′*S*)-**50** (R = CH_3) in Fig. 11).

3) Complex **50** contains Zn–alkyl moieties but cannot alkylate aldehydes. However, the complex acts as a catalyst precursor. Such dimers are perhaps in equilibrium in toluene with a small amount of a coordinately unsaturated monomeric species **60**, which possesses a trigonal Zn atom, in accord with the fact that the MW decreases with decreasing concentration. This view is also supported by the results obtained with a polymer-bound DAIB **26**.[50a]

4) The dinuclear framework of **50** (R = CH_3) is ruptured spontaneously upon addition of 1 equivalent of benzaldehyde, leading to the mononuclear complex **51**. The ^{1}H NMR spectrum at 0 °C shows a broad aldehydic proton signal.[69] This process is reversible and would occur mainly via **60** by a dissociative mechanism. The unsaturated Zn atom in the trigonal monomer **60** accepts the donor aldehyde molecule to form a tetrahedral complex **51**.[68] MW measurement reveals that the position of the equilibrium is dependent on the **50**:aldehyde ratio.

5) The monomeric mixed ligand complex **51** is still unable to undergo alkyl transfer. The aldehyde ligand in **51** (R = C_2H_5; Ar = C_6H_5) is very slowly reduced, giving benzyl alcohol after hydrolysis. As noted in Section 3.2, only dialkylzinc compounds present in excess to DAIB or **50** can deliver alkyl groups to aldehydes.

6) Dimethylzinc also breaks the dimeric structure of **50** to give new fluctuant dimeric complexes such as **52**, exhibiting only one Zn–CH_3 signal in the ^{1}H NMR spectrum in a 25 to − 50 °C temperature range.

7) This process is also reversible as judged by MW measurement. The compound **52** (R = C_2H_5) and its isomers have dinuclear Zn structures and no sign of the occurrence of higher aggregates is observed in a 52 to 170 mM concentration range.

8) When 1 equivalent of benzaldehyde is introduced to the dinuclear complex **52** (R = CH_3) in toluene at 0 °C, a new dynamic system containing **53** is formed. The same equilibrating mixture is obtained by the reaction of the mononuclear complex **51** and dimethylzinc in a 1:1 ratio. The presence of a rapid equilibrium, **51**⇄**53**⇄**52**, is indicated by its broad ^{1}H NMR spectrum giving a single broad Zn–CH_3 signal.

9) The alkyl-transfer step, **53**→**54**, is slow. Upon standing, a 0.5:1:1 molar mixture of **50** (R = CH_3), dimethylzinc, and benzaldehyde at 20 °C slowly yields an alkoxide assignable to **54** (MW unknown). The ^{1}H NMR spectrum shows a doublet at δ = 1.93 and a quartet at δ = 5.36 due to methyl and methine protons of the bridged alkoxide, as well as a broad singlet at δ = − 0.17 due to Zn–CH_3.

10) The newly generated complex **54** (R = CH_3) is rather stable under these conditions and, over a period of several days, is converted slowly to the cubic Zn alkoxide tetramer **55** (R = CH_3) and catalyst precursor **50**. The tetrameric nature of **55** has been ascertained by cryoscopic MW measurement. Interestingly, **54** upon exposure to benzaldehyde or dimethylzinc undergoes instantaneous decomposition to **55**, completing the catalytic cycle.

Rates of the alkylation reaction are dependent on the nature of the alkyl groups. In accord with the fluctuating nature of the Zn intermediates, when two different dialkylzincs, R^1_2Zn and R^2_2Zn, are utilized in the DAIB-catalyzed reaction, a statistical distribution of the possible alkylation products, **56** and **57**, is observed (Fig. 9).[70]

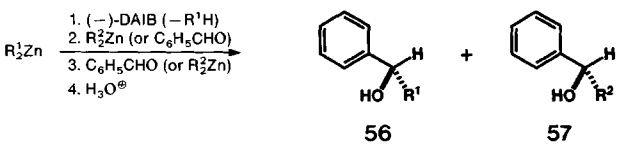

Fig. 9. Alkyl scrambling experiment.

As illustrated in Table 7, the product ratio **56**/**57** is determined only by the ratio of the two alkyl groups and their relative reactivities (CH_3:C_2H_5:*n*-C_4H_9 = 1:20:8). It is not

[a] R^1_2Zn was first added to a toluene solution of (−)-DAIB at 30 °C, and after 15 min R^2_2Zn was added. After the mixture was stirred for 10 min and cooled to 0 °C, benzaldehyde was added. The mixture was stirred at 0 °C for 6 h, quenched with water, and analyzed by high pressure liquid chromatography. All reactions produced 3–14% of benzyl alcohol. [b] (*S*)-Product in 98% *ee*. [c] (*S*)-Product in 94% *ee*. [d] R^2_2Zn was added to the initially formed R^1Zn complex and the mixture was stirred at −78 °C. Then benzaldehyde was added. [e] Benzaldehyde was added to the R^1Zn complex prior to addition of R^2_2Zn (see Fig. 9).

influenced by the order or conditions, such as temperature (30 to −78 °C), of the mixing of benzaldehyde and the second alkylzinc to the initially formed dimeric DAIB-chelated complex **50**. The low migratory aptitude of the methyl group is consistent with the slow reaction using dimethylzinc, which may be attributed to relatively high stability of the methyl bridged dinuclear intermediates. The sense and degree of asymmetric induction in the competitive experiments are also identical with those of the independent reactions.

The mechanism of Figure 8 fully agrees with the kinetic data obtained by the DAIB-aided ethylation of benzaldehyde in toluene at 0 °C. Under standard catalytic conditions, the reaction is first order in (−)-DAIB but zero-order in diethylzinc and benzaldehyde. The rate is only affected by aldehyde concentrations when they are lower than 0.3 M. The kinetic results also agree with the presence of the equilibrium described in Figure 8 (complexes **50**–**53**) and, importantly, indicate that the alkyl transfer is occurring intramolecularly from the dinuclear mixed-ligand complex **53**. The result convincingly dismisses the possibility of any bimolecular mechanisms such as a reaction between the DAIB-modified organozinc species and free benzaldehyde, or nucleophilic attack of a free dialkylzinc to benzaldehyde complexed with a DAIB-chelated Zn Lewis acid. The ^{1}H NMR study also supports this interpretation. Since the degree of enantioselection is decreased from $S:R = 99:1$ to less than 97.5:2.5[58] by raising the reaction temperature from −20 to 50 °C, the alkyl-transfer step **53**→**54** via **37** is the turnover-limiting, as well as the stereo-determining step.

3.4. Origin of the Catalyst Efficiency

The efficient catalytic enantioselective reaction is a result of the combination of the stereo-regulating ability of the well-shaped amino alcohols and the appropriate kinetics. At least three factors are suitably coupled to achieve the ideal catalytic system.

The first is the structure/reactivity profile of organozinc compounds. Monomeric dialkylzinc compounds which have an sp-hybridized linear geometry at Zn (**58**) are inert to aldehydes, because the alkyl–metal linkage is rather nonpolar.[71] However, the bond polarity can be enhanced by creating a bent geometry **59**, where the Zn atom uses orbitals having a higher p character. A coordinatively unsaturated

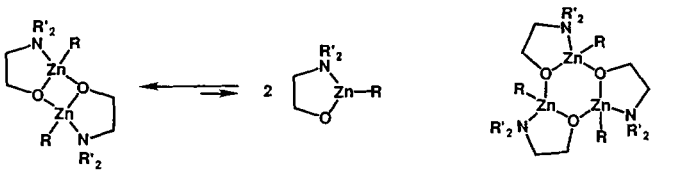
58 **59**

X = alkyl, N, O, halogen etc.

bent compound **59**, particularly with an electronegative substituent, has a strong donor character at the alkyl group and acceptor character at the Zn atom. Such auxiliary-induced structural perturbation increasing the reactivity toward carbonyl substrates is attained by amino alcohols such as DAIB (the argument is simplified because the actual reactive species has a dinuclear structure).

The second important factor is the tendency of the alkylzinc alkoxide product **54** to form the cubic tetrameric structure **55**, which is removed from the reaction system. The tetramer **55** neither alkylates aldehydes nor acts as a catalyst: The reaction of diethylzinc and benzaldehyde in the presence of the homologue of **55** formed from enantiomerically pure (*S*)-1-phenyl-1-ethanol gave, after 12 h at 0 °C, 1-phenyl-1-propanol in only 2.2% yield.[39] *Fréchet's* matrix isolation experiment, in which filtration of the DAIB-bound polymer before hydrolysis did not affect the yield of the alkylation product, demonstrates that the final Zn alkoxides, which are soluble in hydrocarbon, do not bind to the chiral ligands.[50a]

Third, the use of sterically congested chiral auxiliaries is essential for obtaining high reactivity. DAIB upon reaction with organozinc compounds forms the dimeric compound **50**. By contrast, 2-dimethylaminoethanol, which possesses a similar but sterically noncongested structure, is known to give trimeric alkylzinc alkoxides of type **61**.[72] This is the origin of the great rate enhancement for the congested compound, because the dimer dissociates more readily into the reactive monomer **60** than the trimer does. Furthermore,



50 **60** **61**, R = CH_3, C_2H_5; R' = CH_3

DAIB-derived **52** or its isomers are dinuclear in nature, whereas tetranuclear complexes are formed by mixing diethylzinc and less congested amino alcohols, such as 2-dimethylamino-3-methyl-1-butanol, 3-dicyclohexylamino-2-propanol, and 2-dimethylamino-1-phenylethanol, in a 2:1 molar ratio.[73]

3.5. Chiral Amplification

A number of nonclassical aspects have emerged in the amino alcohol aided enantioselective alkylation, but perhaps the most striking is the far from linear relationship between *ee* values of the chiral auxiliaries and the alcoholic products. The reaction catalyzed by DAIB[11] or *Oguni's* **27**[44] in a low *ee* leads to the alkylation products in *ee*'s which are very close to those obtained with the enantiomerically pure auxiliaries. The chirality amplifying phenomenon[74] is clearly seen in Figure 10, which shows the *ee*'s of the *S* alcohols as a function of the *ee* of DAIB auxiliary. Typically, the reaction of benzaldehyde and diethylzinc promoted by 8 mol% of (−)-DAIB in 15% *ee* in toluene at 0 °C gives rise to (*S*)-**18** in 95% *ee* and 92% yield.

We have disclosed that the extreme convex deviation from a linear correlation results from a marked difference in chemical properties of the diastereomeric dinuclear complexes of type **50** formed from dialkylzinc and the DAIB auxiliary.[12] When enantiomerically pure (−)-DAIB is mixed with a stoichiometric quantity of dimethylzinc in

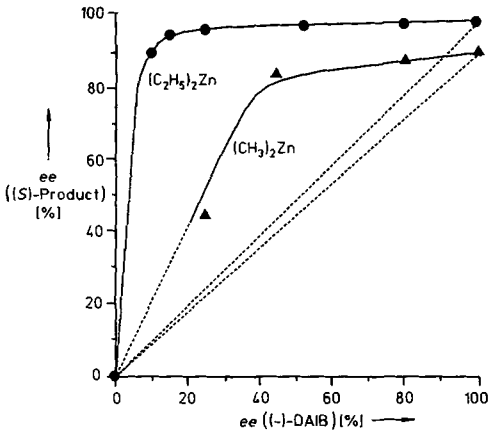


Fig. 10. The *ee* of the alkylation product as a function of the *ee* of DAIB. • 0.42 M $(C_2H_5)_2Zn$, 0.42 M C_6H_5CHO, 34 mM (−)-DAIB in toluene at 0 °C. ▲ 0.47 M $(CH_3)_2Zn$, 0.49 M C_6H_5CHO, 47 mM (−)-DAIB in [D_8]toluene at 32 °C.

toluene at room temperature, a single dimeric complex, (2*S*,2′*S*)-**50** (R = CH_3), is formed quantitatively. The stereochemistry elucidated by single crystal X-ray analysis is given in Figure 11 (top). The structure is characterized by chiral C_2 symmetry. The central Zn_2O_2 four-membered ring is "*endo*-fused" to the adjacent DAIB-Zn five-membered rings because of the sterically demanding bornane backbone. The central 5/4/5 tricyclic structure has *syn* geometry. The simple ^1H and ^{13}C NMR spectra indicate magnetic equivalency for the two DAIB moieties of the complex in solution. The cryoscopic MW measurement also suggests a dimeric structure in benzene, but the concentration effect indicates a tendency of (2*S*,2′*S*)-**50** (R = C_2H_5) to dissociate into the monomer (2*S*)-**60**.

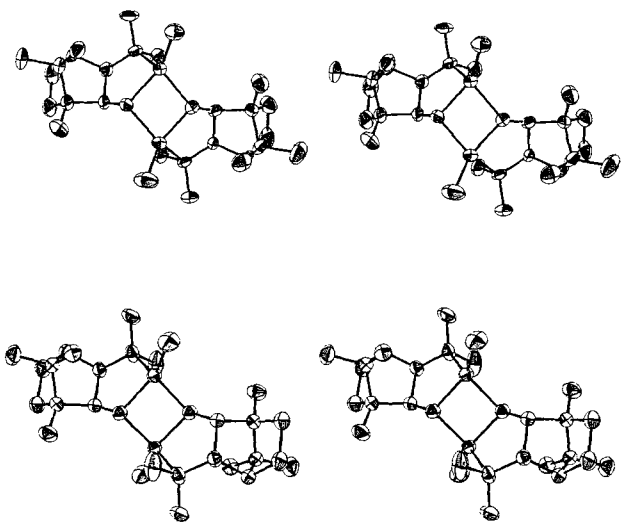

Fig. 11. Stereoview of (2*S*,2′*S*)-**50** (R = CH_3) (top) and (2*S*,2′*R*)-**50** (R = CH_3) (bottom).

Interestingly, an equimolar mixture of (2*S*,2′*S*)-**50** (R = CH_3) and the enantiomer (2*R*,2′*R*)-**50** in toluene is instantaneously converted to a new dinuclear Zn compound. The same complex is obtained by the reaction of racemic DAIB and dimethylzinc in a 1:1 mole ratio. This dinuclear complex, (2*S*,2′*R*)-**50** (R = CH_3), is a *meso* compound and possesses achiral C_i symmetry. The ^1H and ^{13}C NMR spectra are simple because of the degeneracy of the structure. The dimeric nature has been proven by MW measurement of the ethyl derivative, as the methylzinc complex has low solubility in aromatic hydrocarbons and hence MW measurement at high concentration is difficult. The single-crystal X-ray analysis (Fig. 11, bottom) of (2*S*,2′*R*)-**50** (R = CH_3) indicates that the Zn_2O_2 four-membered ring is *endo*-fused to the DAIB-Zn chelate rings, as in its chiral counterpart, but the central 5/4/5-fused tricyclic moiety has an *anti* configuration.

Thus what we have seen is strict matching of chirality or, in other words, accurate enantiomer recognition, leading to the thermodynamic situation outlined in Figure 12. Mono-

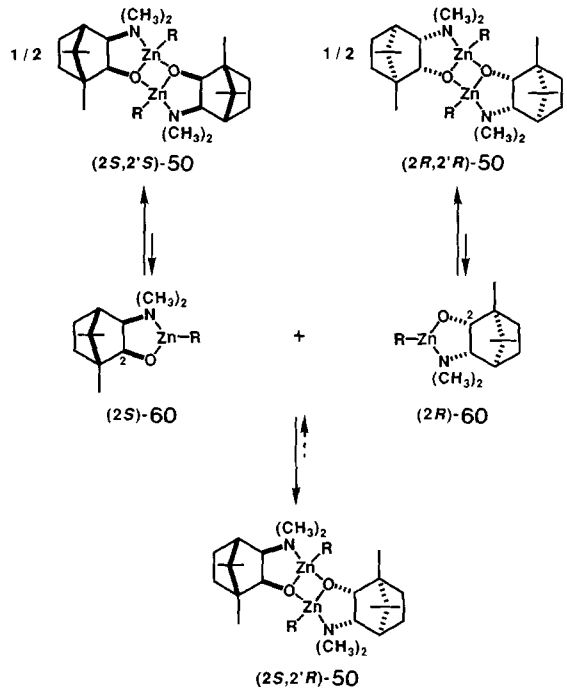

Fig. 12. Enantiomer recognition of the chiral trigonal Zn compounds **60**.

meric (2*S*)-**60** and (2*R*)-**60** are catalytically active chiral complexes derived from a dialkylzinc and (−)- or (+)-DAIB, respectively. Homochiral or heterochiral interaction between these monomers leads to the chiral dimeric complexes, (2*S*,2′*S*)-**50** and (2*R*,2′*R*)-**50**, or the *meso* dinuclear complex, (2*S*,2′*R*)-**50**, which is diastereomeric to the other two. In our system the heterochiral complex (2*S*,2′*R*)-**50** is overwhelmingly more stable than the homochiral dimers (2*S*,2′*S*)- and (2*R*,2′*R*)-**50**. When racemic DAIB is reacted with dimethylzinc in a 1:1 ratio in toluene, (2*S*,2′*R*)-**50** (R = CH_3) is produced exclusively, without forming diastereomer (2*S*,2′*S*)- and (2*R*,2′*R*)-**50**. A 1:1 mixture of (2*S*,2′*S*)- and (2*R*,2′*R*)-**50** (R = CH_3) in toluene is also instantaneously and quantitatively transformed to the more stable (2*S*,2′*R*)-**50** by way of the monomers, (2*S*)- and (2*R*)-**60**.

The chemical properties of the diastereomeric complexes, (2*S*,2′*R*)-**50** and (2*S*,2′*S*)- or (2*R*,2′*R*)-**50** are surprisingly different. The *meso* compound, (2*S*,2′*R*)-**50** (R = CH_3), is not

affected by the addition of 1 equivalent of dimethylzinc, benzaldehyde, or their mixtures. The ^{1}H NMR spectrum in toluene (Fig. 13b) exhibits only independent signals of these three components: the unchanged dinuclear complex and dimethylzinc afford separate Zn–CH_3 signals and benzaldehyde gives a sharp aldehyde signal.

The behavior of the chiral (2*S*,2′*S*)-**50** is, however, entirely different (Fig. 13c,d). As described in Section 3.3.3, the dimeric structure is ruptured instantaneously on exposure to equimolar amounts of dimethylzinc and benzaldehyde, establishing a dynamic equilibrium among complexes **50**–**53** (Fig. 8). In the ^{1}H NMR spectrum (Fig. 13d), a single Zn–CH_3 signal and a broad aldehydic proton are observed, consistent with this view. In addition, a small amount of **54** (R = CH_3) is starting to emerge.

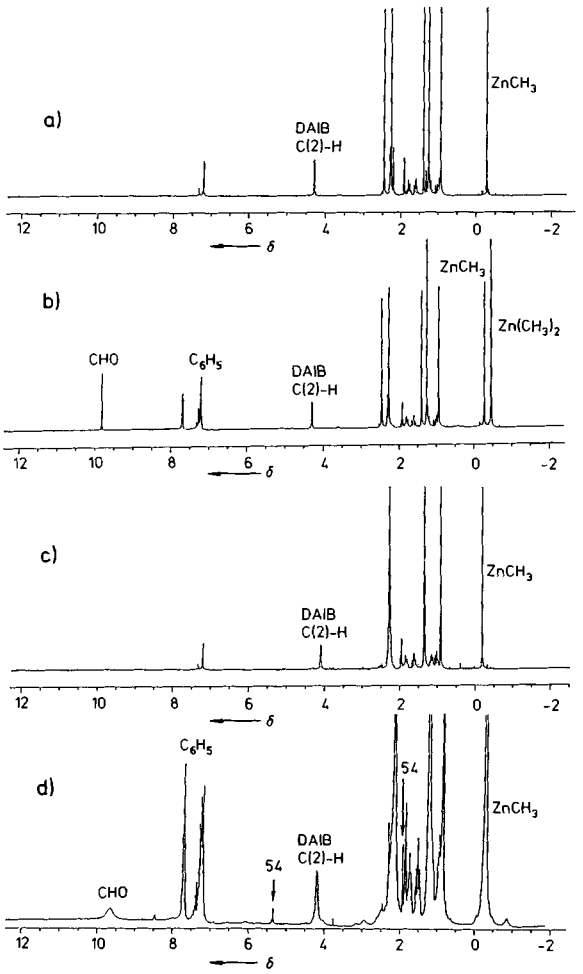

Fig. 13. ^{1}H NMR spectra of the dinuclear catalyst precursors and their mixtures with dimethylzinc and benzaldehyde in [D_8]toluene at 25 °C. a) (2*S*,2′*R*)-**50** (R = CH_3). b) 0.5:1:1 (2*S*,2′*R*)-**50**/$(CH_3)_2Zn$/C_6H_5CHO mixture. c) (2*S*,2′*S*)-**50** (R = CH_3). d) 0.5:1:1 (2*S*,2′*S*)-**50**/$(CH_3)_2Zn$/C_6H_5CHO mixture.

The ^{1}H NMR study using *stoichiometric* amounts of dimethylzinc, DAIB auxiliary, and benzaldehyde has thus shed light on the difference between the chiral and *meso* dinuclear complexes of type **50**: the homochiral complexes are very reactive in the presence of dialkylzincs and aldehydes, while the heterochiral isomer is unreactive. Notably, however, under the standard *catalytic* conditions, both enantiomerically pure DAIB and the racemate do promote alkylation, but the difference in rate of these independent reactions is not large enough to explain the great chiral amplification. For example, in the ethylation using 34 mM DAIB, 0.42 M diethylzinc, and 0.42 M benzaldehyde in toluene at 0 °C, the reaction with (−)-DAIB is merely 14-times faster than that with (±)-DAIB. On the other hand, the reaction catalyzed by (−)-DAIB in 15% *ee* under the same conditions affords the ethylation product in 95% *ee*, indicating the rate difference in the chiral and achiral pathways is about 171. The independent and competitive figures are not the same.

A refined explanation of such a phenomenon is provided by considering the difference in kinetic behavior. Figure 14 illustrates the kinetic profiles of the ethylation using (−)-DAIB and racemic DAIB. The rate of the reaction using

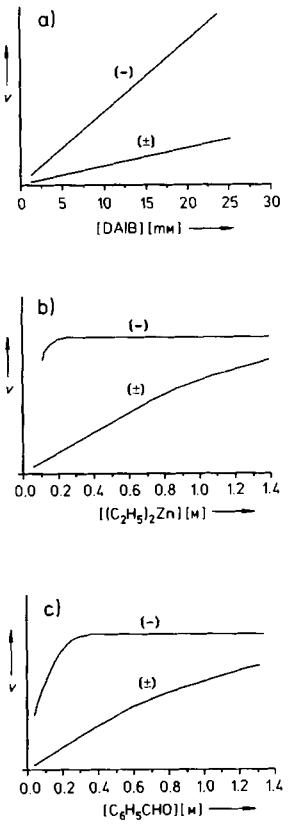

Fig. 14. Kinetic profiles of the reaction of benzaldehyde and diethylzinc catalyzed by (−)- and racemic DAIB. a) The plot of the initial rate as a function of DAIB concentration (0.41 M $(C_2H_5)_2Zn$, 0.41 M C_6H_5CHO). b) The plot of the initial rate as a function of $(C_2H_5)_2Zn$ concentration (2.1 mM DAIB, 0.33 M C_6H_5CHO). c) The plot of the initial rate as a function of C_6H_5CHO concentration (2.1 mM DAIB, 0.33 M $(C_2H_5)_2Zn$).

pure (−)-DAIB, as described above, is not affected by the concentration of diethylzinc and benzaldehyde under the ordinary conditions. By sharp contrast, the rate of the (±)-DAIB catalyzed reaction is profoundly influenced by the dialkylzinc and aldehyde concentrations, where some bimolecular reaction between (2*S*,2′*R*)-**50** and dialkylzinc or benzaldehyde may be involved. Therefore, the rate difference of the reaction with (−)- and (±)-DAIB becomes more

significant with lower concentrations of dialkylzincs and aldehyde substrates. In other words, with given concentrations of an organozinc and aldehyde, the larger rate difference is obtained with higher auxiliary concentration.

Such different kinetic behavior results in a marked dependence of the degree of nonlinearity on DAIB concentration. Figure 15 shows nonlinearity in the ethylation aided by (−)-DAIB in 14% *ee* [(−)/(+) = 57:43], where all reaction parameters except for DAIB concentration are fixed. Evi-

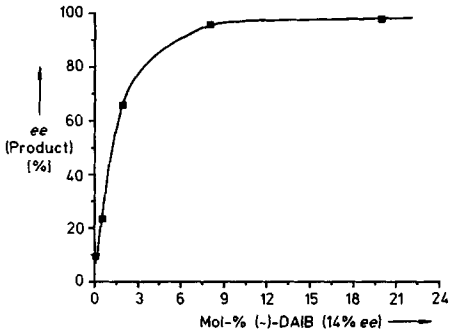

Fig. 15. Effect of auxiliary concentration on the nonlinearity in the ethylation of benzaldehyde aided by (−)-DAIB in 14% *ee* (0.42 M $(C_2H_5)_2Zn$, 0.42 M C_6H_5CHO, toluene, 0 °C).

dently, a chiral catalyst system and achiral one are working competitively in the alkylation. When the reaction is carried out with 0.5 mol% of the partially resolved DAIB, the turnover difference is only twofold, giving the alcohol in 24% *ee*, but with the use of 20 mol% of the catalyst, the product is obtained in 98% *ee*. In the latter case, the turnover efficiency of the chiral catalyst system becomes even more than 600 times greater than that of the coexisting achiral catalyst system.[75]

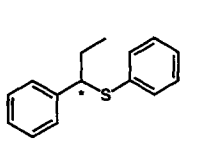
Thus we can conclude that the emergence of the intriguing nonlinearity is a result of conspicuous differences in the properties of the diastereomeric complexes, (2*S*,2′*S*)- or (2*R*,2′*R*)-**50** and (2*S*,2′*R*)-**50**. The origin of the nonlinear effect is basically the differences in the stability of these complexes, but the difference in the kinetic behavior is also important for evaluating the degree of chiral amplification. When partially resolved DAIB is employed as auxiliary, the chiral and achiral dinuclear complexes are generated in a thermodynamically controlled ratio. All the minor enantiomer, within the limit of NMR accuracy, is converted to the thermodynamically stable *meso* dinuclear complex, (2*S*,2′*R*)-**50**, while the major enantiomer, present in excess, forms the less stable chiral counterpart. The latter possesses a greater tendency to dissociate into the active monomer **60**, thereby exhibiting a much higher turnover efficiency. The difference in stability is understood by comparing the relative steric congestion of the central *syn* and *anti* 5/4/5 tricyclic ring systems. The crystalline structures of these complexes (Fig. 11) indicate that the dihedral angle of the five- and four-membered rings in the *syn* isomer, (2*S*,2′*S*)-**50** (R = CH_3), is substantially larger (ca. 20°) than in the less congested *anti* isomer, (2*S*,2′*R*)-**50** (R = CH_3).

4. Diastereomeric Interactions of Enantiomers

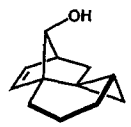
Diastereomeric interaction of the enantiomeric organozinc compounds has played a key role in the unusual chiral amplification. Although chirality recognition is a general phenomenon, a systematic investigation of interactions between *enantiomers* possessing an identical molecular constitution has not been made. This section deals with some examples related to this effect.

Enantiomer recognition is a fundamental principle in crystal lattice formation, giving racemates or conglomerates, and multilayer interactions.[76] Such effects are also noted during sublimation. *Kwart* and *Hoster* found that evacuation of partially resolved **62** causes loss of optical activity owing to sublimation of the enantiomorph in excess leaving behind the less volatile racemate.[77] Some samples represented enrichment from a starting level of 6% optical purity to 74%. Similarly optical purity of mandelic acid could be enhanced or reduced, depending on the optical purity of the starting material.[78]

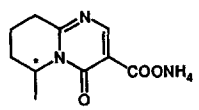
Paquette et al. found spontaneous resolution by sublimation of racemic chiral alcohol **63**.[79] Thus evacuation of **63** to 20 Torr at 20 °C for several days gave a crystal of the sublimed material, whose X-ray analysis confirmed its single mirror image form. Because the individual needles were clustered and never very large, several crystals were removed together for optical rotation measurements. Consequently there was some mixing of the two mirror image forms. Nevertheless, the sublimed crystals possessed optical activity, while the residual material did not. Interestingly, optical purity of the precipitates formed by titration of nonracemic **64** with hydrochloric acid was lower than that of original **64**.[80]



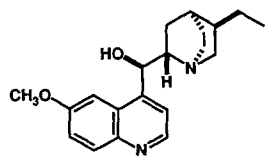
62



63



64



65

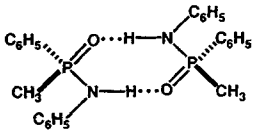
Liquid crystals are extremely sensitive to optically active compounds.[81] Upon mixing enantiomeric cholesteric liquid crystals, a nematic phase could form.

Enantiomer recognition in solution may be interpreted by a simple symmetry argument. Under certain conditions, enantiomers can form homochiral or heterochiral associates which can be differentiated by achiral methods. Although such associates in solution are usually labile, their presence was clearly shown by *Horeau* et al., who found that *ee* and optical purity determined by rotation value, in general, need not be in linear relationship.[82] The existence of such effects has also been suggested by slight differences in nonoptical

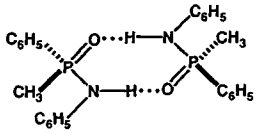
properties such as dielectric constants,[83] boiling points,[84] and IR spectra.[85]

Uskoković noted that the ^{1}H NMR spectra of optically pure dihydroquinine **65** and of its racemate are significantly different when taken at the same concentration in $CDCl_3$.[86] The spectrum of the partially resolved **65** affords two sets of peaks whose areas are proportional to the relative amount of each enantiomer. These facts can be rationalized by considering the solute-solute interactions of the enantiomers.

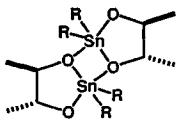
In a like manner, the ^{1}H NMR spectra of optically active, but optically impure, samples of methylphenylphosphinic anilide and related analogues exhibit distinct signals for the *P*-methyl groups in the *R* and *S* enantiomers, which may be ascribed to the molecular association through hydrogen bonding as illustrated by **66** (homochiral, favored) and **67** (heterochiral, unfavored).[87] Similar NMR nonequivalence of the enantiomers has been noted for some substituted succinic acids and rather complex compounds having both phosphorus and carbon chiral centers.[88] The organotin compounds derived from partially resolved 2,3-butanediol and dibutyltin oxide are shown by an ^{1}H NMR study to form a mixture composed of *meso* dimer **68** and chiral dimer **69**. This diastereomeric relationship may be used for the optical enrichment of the diol from 75% *ee* to 98% *ee*.[89]



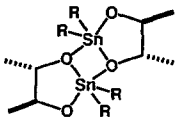
66



67



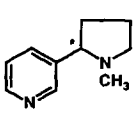
68



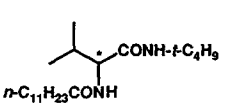
69

R = *n*-C_4H_9

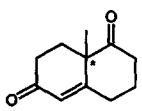
The diastereomeric self-assemblies are even separable in special environments. Thus chromatography of partially resolved enantiomers can cause depletion or enrichment in enantiomers on achiral stationary phases with an achiral mobile phase: *Cundy* and *Crooks* first resolved ^{14}C-labeled nicotine **70** into its enantiomers with high-performance liquid chromatography on Partisil ODS and SCX through coinjection with optically active nicotine.[90] When the diamide **71** (84% optical purity) was subjected to chromatography on Kieselgel 60 using a mixture of hexane and ethyl acetate as eluent, the elute had lower optical purity



70



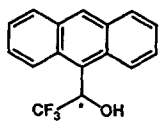
71



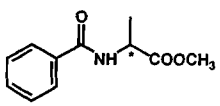
72

than the starting material (30% yield, 46% optical purity), and the latter fractions contained **71** with an average 90% optical purity.[91] Under some conditions, optical enrichment from 60% to greater than 99.8% was attained. *Dreiding* et al. found that chromatography of a nonracemic mixture of the enantiomeric diketone **72** with achiral stationary phase (silica gel) and mobile phase (4:1 hexane–ethyl acetate) furnishes fractions which differ in *ee*.[92]

By use of aminopropyl silica gel as the stationary phase and a hexane–2-propanol mixture as the mobile phase, chromatography of binaphthol **11** with only 33% *ee* leads to a distinct separation into two signals.[93] The excess enantiomer is eluted first and then the racemate. The separation factor is improved on increasing the *ee* and the amount loaded. In a like manner, excess enantiomers of the chiral NMR shift reagents **73** and **74**, the tranquilizer chloromezanone, and the benzodiazepine camazepane can be separated.



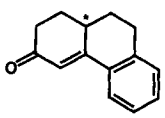
73



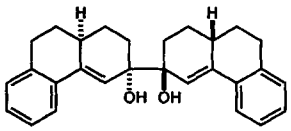
74

The solution-phase enantiomer recognition results in various intriguing stereochemical outcomes in organic reactions:

1) In 1974, *Touboul* and *Dana* reported an amazing selectivity in the controlled potential electrochemical reduction of the enone **75**.[94] While the dimerization of optically pure (+)-**75** or its enantiomer gave solely the *cis-threo-cis* diol (+)- and (−)-**76**, respectively, racemic **75** behaved similarly to lead to racemic **76** and to no other possible diastereomer.



75



76

2) Reductive dimerization of camphor **77** under McMurry's conditions gives the stereoisomers, **78**, **79** (and

their enantiomers), **80**, and **81**. *Wynberg* and *Feringa* noticed that the reaction of racemic camphor prefers homochiral dimerization (total 64.9%) over the diastereomeric heterochiral coupling (35.1%).[95]

3) Oxidative dimerization of the chiral phenol **82** affords the chiral dimers **83** and **84** (and their enantiomers) and the *meso* dimer **85**, whereby a significant difference in diastereoselectivity is seen between the reactions of the enantiomerically pure and racemic substrate.[95] The reaction of (*S*)-**82** produces (*S,S*)-**83** exclusively, while the dimerization of racemic **82** lacks stereoselectivity. In the latter case, some indirect enantiomer effect assists the production of **84**, which is absent in the former reaction.

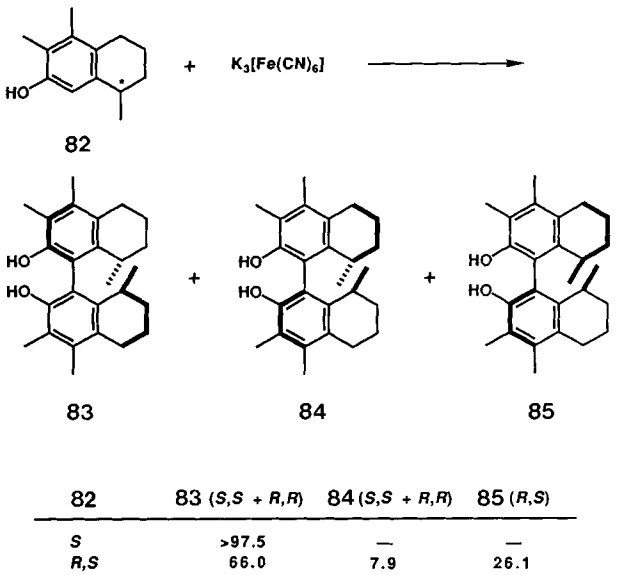

Fig. 17. Oxidative dimerization of the chiral phenol **82**. Yields in %.

4) A striking stereospecificity was observed by *Gladysz* et al. in the intermolecular coupling of a rhenium–carbene species.[96] Crossover experiments using the enantiomerically configurated metal complexes **86** and **87** showed that the reaction proceeds through strict enantiomer self-recognition to form only homochiral coupling products, **88** and **89** (Fig. 18).

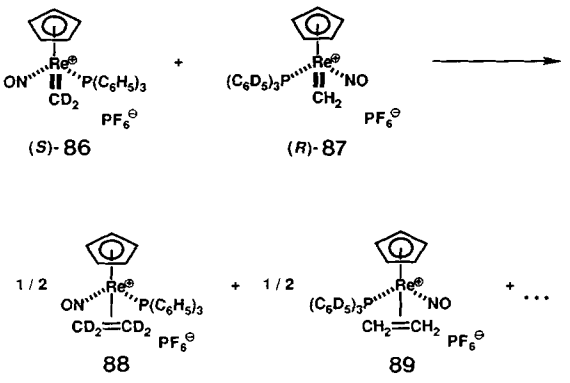

Fig. 18. Coupling of carbene ligands. The dots represent further rhenium complexes.

A considerable departure from the linear relationship between the *ee* of a chiral auxiliary and the extent of the asymmetric induction has also been observed in certain catalytic reactions:

1) *Kagan, Agami,* and their co-workers reported some interesting examples.[97] First, oxidation of *p*-tolyl methyl sulfide **90** with *tert*-butyl hydroperoxide was effected in the presence of titanium tetraisopropoxide modified with enantiomerically pure (+)-diethyl tartrate (DET) to afford the (*R*)-sulfoxide **91** in 85% *ee*, whereas use of tartrate ancillary in 50% *ee* gave the product not in 42.5% *ee* as expected when linearity is assumed, but in only 19% *ee* (catalytic conditions), or 33% *ee* (stoichiometric conditions).

2) The Sharpless oxidation of geraniol **92** using enantiomerically pure DET gave the epoxide **93** in 94% *ee*. The optical yield drops to 70% *ee* by using the auxiliary with 50% *ee*. This value is considerably higher than the *expected* 47% *ee* (Fig. 19, center).

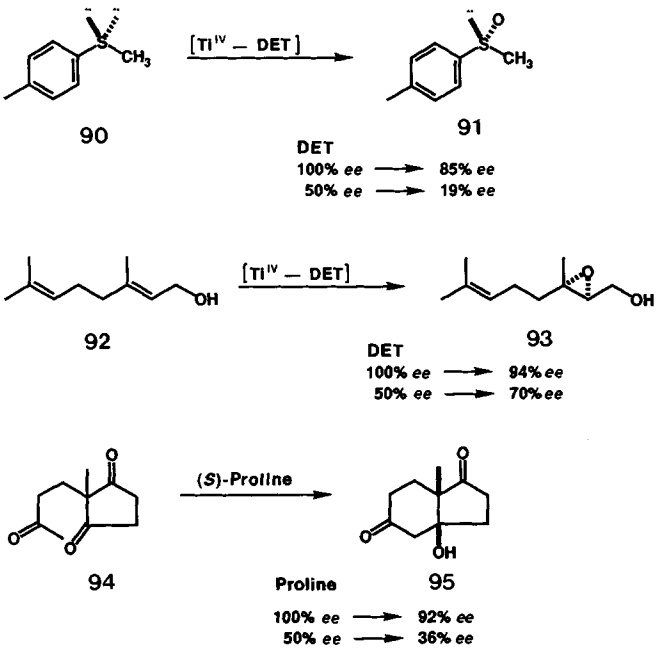

Fig. 19. Examples of the nonlinear effect in asymmetric catalysis.

3) The Hajos–Wiechert intramolecular aldol reaction of triketone **94** to **95** also exhibits a nonlinear relationship between the enantiomeric purity of the (*S*)-proline catalyst and the enantioselectivity.[98] With the partially resolved amino acid, the cyclization gave the product in an *ee* lower than the anticipated value. On the basis of the kinetic study, these results have been interpreted in terms of the involvement of two chiral auxiliary molecules in the stereodetermining steps.[98b]

The enantioselective addition of organozincs to prochiral aldehydes discussed in Sections 3.2 and 3.3 presents an extreme example of such a phenomenon. By virtue of the catalytic nature of the reaction together with the conspicuous difference in the chemical properties of the homochiral and heterochiral *catalyst dimers*, the nonlinear effect has led to unprecedentedly high chiral amplification. This molecular

mechanism may be related to the mechanism of chirality amplification in nature.[74]

5. Outlook

Since the discovery in 1966 of asymmetric cyclopropanation of olefines with diazoalkanes, catalyzed by a chiral Schiff base/Cu^{II} complex,[99] a variety of homogeneous asymmetric reactions using metal complex catalysts and prochiral substrates have been developed. Most of the enantioselective organometallic reactions (defined as transformations involving metal–carbon or –hydrogen bonds) rely on transition metal chemistry, but chiral multiplication can also be achieved by main group elements.[43a, 100] This article has presented some aspects of this subject. Addition of organometallic compounds to carbonyl substrates is one of the most fundamental synthetic reactions. Although asymmetric synthesis with chirally modified organomagnesium or lithium reagents has some 50 years of history, it was only 10 years ago when a level of enantioselection greater than 90% was accomplished on the basis of stoichiometric chirality transfer. Now this domain is growing continuously, and particularly over the last five years there has been great progress in the catalytic reaction. We have realized the highly stereoselective reaction (in some cases 99% *ee*) using organozinc compounds and a catalytic quantity of chiral auxiliary, which at the same time exhibits chiral amplification. The mechanism has now been elucidated at the molecular level. This achievement, however, marks only the beginning of this important area, which is yet to be fully explored. The organozinc chemistry is intriguing, but the scope of the reaction is still limited. The procedure can be applied to a variety of organozinc compounds having primary alkyl groups, but not to the secondary and tertiary compounds, which are too unstable because of alkene elimination. Furthermore, we have not looked closely at reactions using highly functionalized organometallic reagents or substrates, which might be useful for the synthesis of complex natural products or their artificial analogues. Thus a general method for enantiofacial and selective alkylation or arylation still remains elusive. Further development of versatile methods using other metal elements is strongly desired, and we hope that the principles described here will be helpful.

In scientific research a rational approach to problems is obviously ideal, although in reality major breakthroughs in this field have been obtained mainly by serendipity or through trial-and-error improvements of the existing systems. A large body of information has accumulated in organometallic chemistry, but the level of our structural and mechanistic understanding, particularly in the supramolecular chemistry,[9] still remains primitive. Unifying views on the structure-reactivity relationship or reliable selection rules have not appeared. However, we are quite optimistic: chemists' intuition coupled with logical designing and keen insight will continue to generate a series of versatile stereoselective organic reactions along this line.

Finally, we would emphasize that asymmetric catalysis is a four-dimensional chemistry. Stereochemical differentiation is crucially important but not enough. As illustrated above, high efficiency is obtained only by combining the ideal three-dimensional structure (x,y,z) and appropriate kinetics (t).

The author (R. N.) was exceedingly honored with the Merck-Schuchardt lectureship, (FRG), and indeed enjoyed the memorable lecture tour in May, 1989. We would like to thank Messrs. M. Okada, S. Suga, and K. Kawai, our students at Nagoya who made sustained intellectual and experimental efforts to elucidate the new chemistry described in this article. Valuable discussions with Professor N. Oguni at Yamaguchi University are also appreciated. This work was supported financially by Specially Promoted Research (No. 62065005) from the Japanese Government, the Ministry of Education, Science and Culture of Japan.

[58] Reaction of diethylzinc and benzaldehyde in toluene containing 2 mol% (−)-DAIB at 50 °C for 2 min gave the (*S*)-1-phenyl-1-propanol in 94.6% *ee* and 70.2% yield. The blank experiment without (−)-DAIB afforded the racemic alcohol in 0.3% yield, indicating that the *S*/*R* ratio in the DAIB catalyzed reaction at 50 °C was at most 97.5:2.5. The previously recorded value 94.5:5.5, obtained by the 1.5 h reaction [11–13], ignores the participation of the uncatalyzed reaction and hence should be revised.

[65] P. A. Chaloner (University of Sussex), personal communication.
[66] Certain γ-amino alcohols [54] or β-monoalkylamino alcohols showed opposite selectivities. For example, ethylation of benzaldehyde in the presence of **36**, gives (*S*)-1-phenyl-1-propanol in 92% *ee*. In *Chaloner*'s report [51a], the structure is not really meant to be a Fischer projection, and the results quoted there are indeed for (1*R*,2*S*)-ephedrines and not pseudoephedrine derivatives.

[69] ^{1}H NMR spectrum of **51** in [D$_8$]toluene at 0 °C gave a singlet at $\delta = 6.2$ with 10–20% intensity of aldehydic proton signal, which may be assignable to the hemiacetal proton of **I**. An analogous observation was made in the reaction of *n*-butyllithium with benzaldehyde at − 85 °C [61], giving compound **II** with the hemiacetal proton signal at $\delta = 5.74$, or in the reaction of tetrakis(dialkylamido)titanium with aldehydes at −78 °C [M. T. Reetz, B. Wenderoth, R. Peter, *J. Chem. Soc. Chem. Commun. 1983*, 406].

The Third Allotropic Form of Carbon

By *J. Fraser Stoddart**

From Fiction to Fact. Every so often something happens in science that is extremely simple and immensely satisfying. The harvesting of C_{60} in the late summer of last year by *Krätschmer* and his associates[1] from a rather special brew of soot has vindicated the inspired structural proposal—the celebrated truncated icosahedron with the ultimate symbol (I_h) in point group symmetry that also happens to grace the familiar pattern displayed on regulation soccer balls—advanced away back in the mid-80s by *Kroto* and his collaborators[2] for a compound they dubbed buckminsterfullerene, molecules of which they had clearly observed by time-of-flight mass spectrometry following vaporization of graphite by laser evaporation.

Prior knowledge by most in the field of the autumnal announcement[1] in *Nature* heralded a flurry of activity in numerous research laboratories around the world. Now that sample tube quantities of this new race of carbon compounds are available, this third allotropic form of carbon promises to create chemistry and aid and abet applications around it every bit as rich as those associated with the ubiquitous and rare allotropes—graphite and diamond, with their diversely distinctive properties and distinctly diverse uses.

Harvesting the Soot. At present, access to milligram quantities of C_{60}, and its rugby ball counterpart, C_{70} (Fig. 1) depends on perfecting simultaneously two separate arts—firstly, isolating fullerene-rich soot in gram quantities, apparently best achieved when graphite rods of uniform particle size are evaporated by resistive heating under a partial atmosphere of an inert gas like helium[1] or argon[3] and then, secondly, effecting the demanding chromatographic separation of C_{60} from C_{70}, both of which are to be found in boiling benzene extracts of the soot. The top yield reported for this harvest at the onset of winter was a remarkable 14% by *Diederich* and his team at UCLA[4] who have employed a battery of chromatographic and spectroscopic techniques to show that their soot is 85:15, C_{60}:C_{70}. Although chromatography has been executed with modest success using hexane as the eluant on both alumina[3,4] and silica gel,[5] fractional sublimation[1,6] at very high temperatures (ca. 600 °C) under vacuum from an inert atmophere should be amenable to the large scale manufacture of this new product line of carbon. It is surely only a matter of time until both physical and chemical means of isolation are perfected to a point where kilograms of C_{60}, C_{70}, and other homologues, can be stored in bottles. And there is promise[5] of even better things to come—the preparation of C_{60} and C_{70} starting from precursors other than graphite.

Believing is Seeing. Both C_{60} and C_{70} are highly colored crystalline solids that are sparingly soluble in common organic solvents, giving rise to solutions with pinkish-to-red hues to them. The UV-VIS spectra of C_{60} both neat[1] and in solution[3,4] reveal three, if not four, broad bands of considerable intensities in the UV that correspond roughly with the allowed transitions predicted by theory for the molecule.

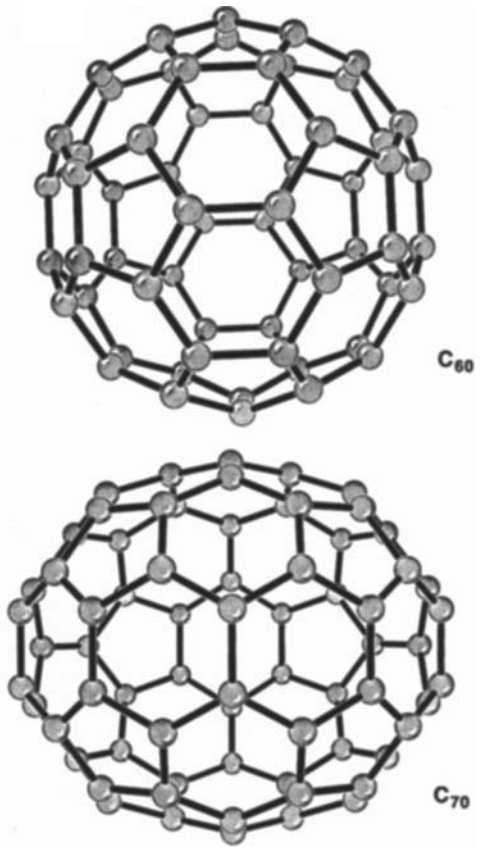

Fig. 1. Drawings of the proposed molecular structures for C_{60} (top) and C_{70} (bottom). Reproduced by permission of Professor *F. Diederich*, Los Angeles.

The chemical world awaits a detailed single crystal X-ray diffraction analysis of the structure of C_{60} or C_{70}, or more likely perhaps, of a derivative in the first instance. In the meantime, X-ray diffraction studies[1] on micrometer sized hexagonal platelets of C_{60}, with unit cell parameters of 10.02 and 16.36 Å, correspond closely to a simple hexagonal close packing of disordered spherical molecules.[7] These days STM is all the rage for seeing images of molecules very often sitting on a surface of graphite! Late in December two reports appeared in which the imaging of C_{60} and the slightly taller C_{70} with a scanning tunnelling microscope is described.[8]

Seeing is Believing. The weight of the spectroscopic evidence for the structures proposed[2] for C_{60} and C_{70} is overwhelming. There is agreement from at least four camps[1,3,5,9] that the four strongest bands for C_{60} in conventional KBr pellets of soot extracts in various states of purification appear at 1430, 1182, 577, and 527 cm^{-1}. Almost identical spectra were observed[9] from argon and krypton matrices deposited on gold substrates, indicating that the solid state absorptions are close to the gas phase ones.

The findings[1, 3, 5] of mass spectrometry are equally convincing. Both the EI and FAB methods reveal strong molecular ions at m/z 720 and 840 for C_{60} and C_{70}, respectively. The EIMS shows[5] the expected isotopic distribution patterns with the $[M+1]^{\oplus}$ intensities for C_{60} and C_{70}, 61% and 67%, respectively, of the $M^{\oplus}$ peak. Interestingly, the $C_{60}^{2\oplus}$ ion is detected[5] in appreciable quantities when EI spectra are run at high (70 eV) ionization energies, confirming the amazing stability of the C_{60} carbon cage.

Since C_{60} has I_h symmetry, all its carbon atoms are equivalent. Thus, the ^{13}C NMR spectrum should display one, and only one, signal. It does.[3-6] In a C_6D_6 solution, the single peak is observed at $\delta = 143.2$ (Fig. 2). For C_{70}, with its D_{5h}

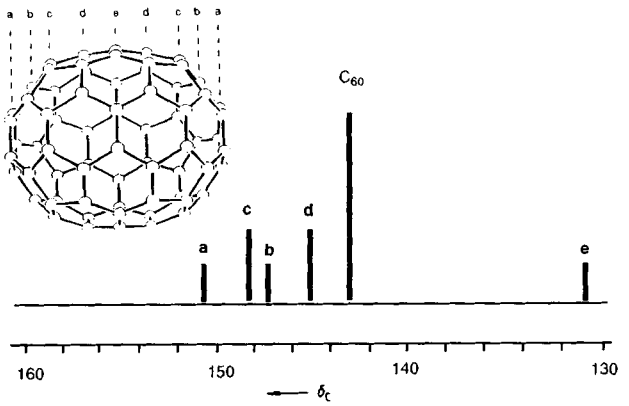

Fig. 2. A ^{13}C NMR line spectrum of a mixture of C_{60} and C_{70}. The five sets (a–e) of identical carbon atoms lie in the vertical planes as indicated on the inset schematic diagram of C_{70}. The assignments are those given in [3]. The schematic diagram is reproduced by permission of Professor *H. W. Kroto*, Brighton.

symmetry, we should observe five signals—two, both with twice the intensities of the other three. Indeed, when a long 20 second pulse delay was used[5] to make allowances for the relatively long T_1 values, the ^{13}C NMR spectrum, also recorded in a C_6D_6 solution (Fig. 2), revealed[5] peaks at $\delta = 150.7$ (a), 147.4 (b), 148.1 (c), 145.4 (d) and 130.9 (e) in the ratio of 10:10:20:20:10 as expected for C_{70}.

The Proof of the Pudding is in the Eating. Now that C_{60} and C_{70} exist as authentic crystalline samples, can any chemistry be done with them? The answer is yes according to *Smalley* et al.[9] They have found that C_{60} undergoes a Birch reduction [Eq. (a)] to give a product, which is a mixture of

$$C_{60} \underset{\text{DDQ/Toluene}}{\overset{\text{Li/liquid NH}_3\text{/tBuOH}}{\rightleftharpoons}} C_{60}H_{36} \qquad \text{(a)}$$

isomers with the molecular formula $C_{60}H_{36}$. The fact that treatment of this hydrogenated product with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) in toluene produces a substance indistinguishable from authentic buckminsterfullerene demonstrates that the reduction of C_{60} is fully reversible, indicating that no alteration occurs to the carbon skeleton of the molecule during its Birch reduction.

In CH_2Cl_2 with nBu$_4$NBF$_4$ as the supporting electrolyte, C_{60} undergoes electrochemical reduction in two waves at -610 mV and -1000 mV relative to the normal hydrogen electrode [Eq. (b)]. This electrochemical behavior[10] suggests that stable salts based on C_{60} as either an anion or dianion might be on the cards.

$$C_{60} \underset{-e}{\overset{+e}{\rightleftharpoons}} C_{60}^{\ominus} \underset{-e}{\overset{+e}{\rightleftharpoons}} C_{60}^{2\ominus} \qquad \text{(b)}$$

The photophysical properties of C_{60} have also been studied recently. It is a potential generator of singlet oxygen.[11]

From Fact to Fiction. Confronted with molecules as pretty and as fascinating as C_{60} and C_{70}, the human imagination starts to run riot. Will they behave as the ultimate in lubricants, i.e. as molecular ball-bearings? The materials science of carbon is on the move again.

Then, smaller molecules and ions, which can no doubt be trapped inside the carbon cages, are expected to have a rather unique chemistry. One can also envisage the introduction of holes and even trap doors into the surfaces of the carbon cages, leading to the possibility of dialysis at the molecular level or the controlled slow release of bioactive molecules. The pharmaceutical and agrochemical industries should not be disinterested in the post-Columbus chemistry of carbon.

And then, there is the prospect of doing outer and inner sphere chemistry, particularly with transition metals. To what extent can chemical species that are imprisoned, not only covalently but also mechanically inside fullerenes, influence their optical and redox properties? Can much larger fullerenes,[12] like C_{540}, be made and can one be assembled onion-like inside another? Surely the scientists who are fortunate enough to find themselves bang in the middle of this bonanza will be limited only by their imaginations for some considerable time to come.

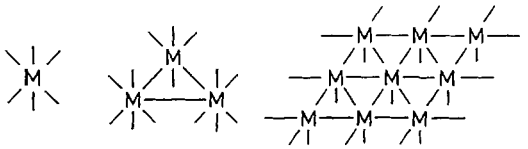
Molecular Systems with Perfect Metal Structure

By *Georg Süss-Fink* *

Lord Lewis and his research group at the University of Cambridge have taken a spectacular step on the road from molecular clusters to metallic structures. They have synthesized the dianionic transition-metal cluster $[Os_{20}(CO)_{40}]^{2\ominus}$, whose metal framework represents a perfect tetrahedral cubic-close-packed metal core. This cluster anion, crystallized as its tetrabutylphosphonium salt, is remarkable for the aesthetics of its molecular structure.

The last two decades have witnessed a very rapid expansion in the chemistry of transition-metal complexes containing more than two metal atoms. *F. A. Cotton* proposed that such complexes be termed "clusters".[1] They are oligonuclear systems generally consisting of a framework of metal atoms held together by intermetallic bonds and surrounded by a shell of terminal or bridging ligands.



mononuclear oligonuclear polynuclear

As oligonuclear species, metal clusters occupy a no-man's-land between mononuclear metal complexes on the one side and polynuclear metal surfaces on the other, and thus between typical homogeneous and typical heterogeneous catalysts. Starting from the notion of *P. Chini*[2] that clusters represent molecular metal fragments containing chemisorbed species on their peripheries, *J. Lewis* et al.[3] and *E. L. Muetterties*[4] related transition-metal clusters to catalysis: On the one hand, transition-metal clusters can serve as molecular models for poorly understood heterogeneous catalysts. On the other hand, they might function as unconventional homogeneous catalysts. Furthermore, the pioneering work of *G. Schmid*[5] on superclusters has awakened hope that they might allow metal particles of defined size to be prepared, a possibility of great interest not only for chemistry but also for physics and materials science. The chemistry of transition-metal clusters has received considerable impulse from these potential applications. A basic understanding of the formation and properties of metal cores is expected to emerge in this area of research.

The large transition-metal clusters—containing up to 42 metal atoms—observed during the last two decades exhibit diverse structures, which have been established by X-ray diffraction techniques.[6] For very large clusters with 55 or more metal atoms, electron microscopy has proved particularly useful.[5] Whereas the structures of smaller clusters can be explained largely in terms of electronic factors (i.e., they obey the noble-gas rule or the skeletal electron pair theory), the frameworks of larger metal clusters are governed primarily by geometric factors (i.e, their metal atoms are as close packed as possible).

Now, the research group of *Lord Lewis* has reported a new cluster that strikingly illustrates the transition from molecular structures to compact metal structures. The trinuclear cluster $[Os_3(CO)_{10}(NCCH_3)_2]$ decomposes in an unclear fashion upon vacuum pyrolysis at 300 °C and 10^{-3} Torr. Extraction of the decomposition residue affords the dianion $[Os_{20}(CO)_{40}]^{2\ominus}$, together with other lower-nuclearity clusters. The dianion can be crystallized as its tetrabutylammonium salt.[7]

A single-crystal X-ray analysis reveals that the dianion has a metal framework consisting of 20 cubic-close-packed osmium atoms arranged to form a perfect tetrahedron. The symmetry of the ligand shell, consisting of 40 terminal carbonyl groups, corresponds to that of the metal framework.

The new cluster $[Os_{20}(CO)_{40}]^{2\ominus}$ should be compared with the cluster $[HNi_{38}Pt_6(CO)_{48}]^{5\ominus}$, described in 1985 by *G. Longoni* et al.[8] (Fig. 1). Whereas the metal lattice of the

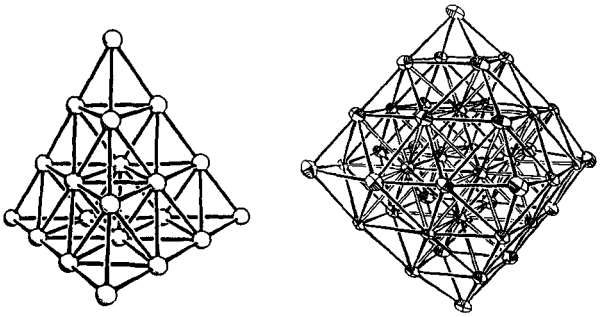


Fig. 1. Tetrahedral section of a cubic close packing (ccp) in $[Os_{20}(CO)_{40}]^{2\ominus}$ (left) and an octahedral section of a ccp in $[HNi_{38}Pt_6(CO)_{48}]^{5\ominus}$ (right).

latter corresponds to an octahedral section of a cubic-close-packed array of metal atoms, the osmium framework of the former represents a tetrahedral section. It should be noted, however, that metallic osmium crystallizes as a hexagonal-close-packed structure, whereas the osmium atoms in $[Os_{20}(CO)_{40}]^{2\ominus}$ are cubic close packed.

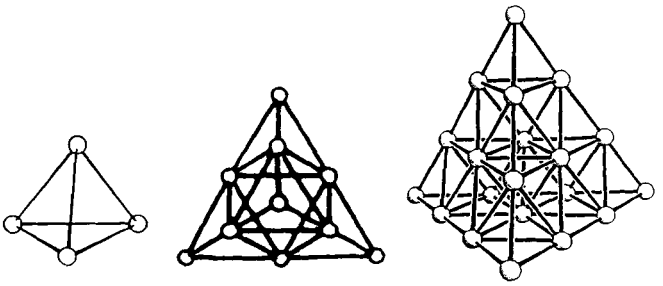

Fig. 2. Gradual growth of the tetrahedron on going from four ($[H_2Os_4(CO)_{12}]^{2\ominus}$) to ten ($[Os_{10}C(CO)_{24}]^{2\ominus}$) to twenty metal atoms ($[Os_{20}(CO)_{40}]^{2\ominus}$).

[*] Prof. Dr. G. Süss-Fink
Institut de Chimie, Université de Neuchâtel
Avenue de Bellevaux 51, CH-2000 Neuchâtel (Switzerland)

Still another comparison emerges: In the series of metal clusters with tetrahedral symmetry, $[H_2Os_4(CO)_{12}]^{2\ominus}$ [9] and $[Os_{10}C(CO)_{24}]^{2\ominus}$ [10] were the first two clusters containing two and three osmium atoms, respectively, on the edges of the tetrahedron. The new cluster $[Os_{20}(CO)_{40}]^{2\ominus}$, which has four osmium atoms on the edges of a face-centered tetrahedron, readily fits into this series (Fig. 2). Thus, gradual tetrahedral growth is possible on going from molecular clusters to metallic structures.

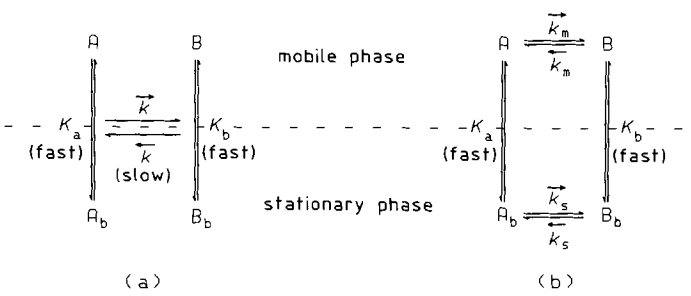
Dynamic HPLC: A Method for Determining Rate Constants, Energy Barriers, and Equilibrium Constants of Molecular Dynamic Processes**

By *Jaume Veciana** and *Maria I. Crespo*

Dynamic spectroscopic (NMR, ESR, IR) experiments are extensively used for the study of molecular dynamic processes and the determination of their kinetic parameters.[1] By contrast, such studies are rather uncommon in chromatography despite its importance in chemistry.[2-5] The simplest dynamic chromatographic experiment involves two resolvable species that are interconvertible on the separation time scale (minutes). In this case, the temperature and flow-rate dependence of the chromatographic profiles can be observed. Although various examples of such behavior have been reported[3-6] and the basic theory describing a dynamic chromatographic experiment has largely been developed,[3,4,7] a general method for evaluating the kinetic parameters of the molecular dynamic processes is still lacking. The methods so far reported either suffer from practical limitations[8] or are unrealistic.[9]

The method described here, based on a simulation procedure, permits the determination of the rate constants, energy barriers, and equilibrium constants of interconversion processes occurring during HPLC separation. This method, which is called D-HPLC (dynamic HPLC) in analogy to the well-known DNMR method, has proved effective and readily applicable to several kinds of interconversions (enantiomerizations, conformational changes), detectors (spectrophotometer, polarimeter), and stationary phases (reversed phases, chiral phases), including those giving rise to either linear (Gaussian or ideal peaks) or nonlinear (skewed peaks) chromatographic processes.

Using stochastic models, *Giddings* et al.[2] theoretically analyzed the spatial distribution of two species at a given time in a chromatographic separation (TLC), where the two species, A and B, undergo slow reversible first-order interconversions. In this analysis, the authors assumed that the apparent rate constants of the overall forward and reverse reactions, $\vec{k}$ and $\overleftarrow{k}$, respectively, are smaller than those of the purely chromatographic processes (partition, adsorption, etc.), so that the species in the mobile phase (A, B) are, at any time, in equilibrium with the bound species (A_b, B_b) in the stationary phase (Scheme 1a).



Scheme 1. Equilibria involved in the chromatographic separation of two interconverting species, A and B: a) simulated equilibria; b) actual equilibria.

The corresponding temporal distribution at the end of a chromatographic column (GC, HPLC) is readily obtainable from the spatial distribution by a simple mathematical transformation.[7b] An explicit function[10] describing the chromatographic profiles of a D-HPLC experiment may then be derived by determining the time dependence of the probability density functions of all the molecular dynamic events that occur during the chromatographic separation. This is done by using the proper temporal distribution function that takes into account the kinetics of mass transfer of the species between the mobile and the stationary phases. Depending on the degree of linearity of the chromatographic process, the temporal distribution function can be equated to either a normalized Gaussian function (for symmetric peaks in linear chromatography) or a normalized exponentially modified Gaussian function (for skewed peaks in nonlinear chromatography).[11] Figure 1 shows the time dependence of the probability density functions for all the molecular dynamic events occurring in a linear chromatographic process. Thus, simulation of the chromatograms of any D-HPLC experi-

[**] This work was supported by the C.I.C. y T. (Grant No. MAT 88-0268). We acknowledge Dr. *C. Rovira* (C.S.I.C) for her comments and Dr. *J. Badenas* for his computer assistance.

ment can be accomplished by using, as trial parameters, the apparent rate constants ($\vec{k}$ and $\overleftarrow{k}$) and the chromatographic parameters of the two interconverting species (retention times, t_A and t_B; theoretical plate numbers, N_A and N_B; and asymmetry factors, τ_A and τ_B[12]), provided that the injected molar ratio of the two species, C_B^0/C_A^0, and the relative response of the detector, $\varepsilon_B/\varepsilon_A$, are known. In such a way, the values of $\vec{k}$ and $\overleftarrow{k}$ best describing the dynamic behavior of the studied system can be determined.[13]

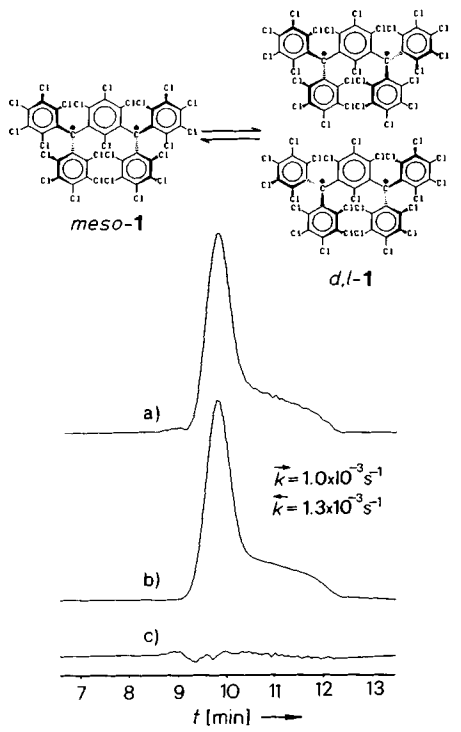

Fig. 2. Resolution versus diastereomerization in a D-HPLC experiment involving diradical **1**. a) Experimental chromatogram: C_{18} reversed-phase column, 12.5 cm × 0.46 cm (inner diameter); $T = 45\,^{\circ}C$; eluent CH_3CN/THF (88:12); flow rate 1 mL min^{-1}; dead time 1.07 min; UV detector at 383 nm; amount of sample, ca. 1 μg. b) Simulated chromatogram: $t_A = 9.8$ min, $t_B = 12.1$ min, $N_A = 1800$, $N_B = 3000$, $\varepsilon_B/\varepsilon_A = 1.0$, and $C_B^0/C_A^0 = 0.02$ [12] c) Residuals: (a) − (b).

Figures 2 and 3 show the excellent agreements achieved in the simulation of two representative examples of two series of D-HPLC experiments performed at different temperatures and using distinct eluent flow rates.[14] Although the apparent rate constants determined by this method need not be equal (see below) to the rate constants of the processes occurring in the mobile and the stationary phases (Scheme 1b), in practice we have found only small differences between them.[15] Therefore, the apparent rate constants may be used to determine the approximate energy barrier[16] for the molecular dynamic process in question. Using the apparent forward rate constants given in Figures 2 and 3, we have found $\Delta G^{\ddagger}_{317} = 96.0 \pm 0.2$ kJ mol^{-1} for **1** and $\Delta G^{\ddagger}_{268} = 80.4 \pm 0.2$ kJ mol^{-1} for **2**. These values are in agreement with those measured by independent techniques: $\Delta G^{\ddagger}_{317} = 97 \pm 2.5$ kJ mol^{-1} (direct equilibration of *meso*-**1** in CH_3CN/THF, 70/30[17]) and $\Delta G^{\ddagger}_{268} = 82 \pm 3$ kJ mol^{-1} (DNMR spectroscopy[18] of racemic **2**[19] in hexachlorobutadiene/$(CD_3)_2SO$, 1/1).

The apparent rate constants determined by the D-HPLC method are in fact related to those involved in the mobile

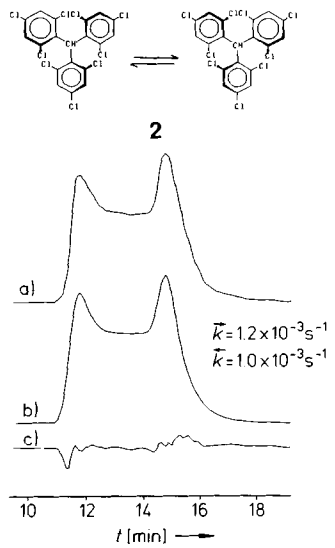

Fig. 3. Chiral resolution versus enantiomerization in a D-HPLC experiment involving racemic **2**. a) Experimental chromatogram: column, (+)-poly(triphenylmethylmethacrylate), 25 cm × 0.46 cm (inner diameter); $T = -5\,^{\circ}C$; eluent, methanol; flow rate, 0.5 mL min^{-1}; dead time 2.97 min; UV detector at 254 nm; amount of sample, ca. 1 μg. b) Simulated chromatogram: $t_A = 11.4$ min, $t_B = 14.7$ min, $N_A = 2300$, $N_B = 3400$, $\tau_A = 0.47$, $\tau_B = 0.60$, $\varepsilon_B/\varepsilon_A = 1.0$, and $C_B^0/C_A^0 = 1.0$ [12] (A = (−)-**2**, B = (+)-**2**). c) Residuals: (a) − (b).

phase ($\vec{k}_m$ and $\overleftarrow{k}_m$ and in the stationary phases ($\vec{k}_s$ and $\overleftarrow{k}_s$) by Equations (a) and (b), where k'_A and k'_B are the capacity

$$\vec{k} = (\vec{k}_m + k'_A\vec{k}_s)/(1 + k'_A) \quad \text{(a)}$$

$$\overleftarrow{k} = (\overleftarrow{k}_m + k'_B\overleftarrow{k}_s)/(1 + k'_B) \quad \text{(b)}$$

factors of the two species.[20] The principle of microscopic reversibility[21] and Equations (a) and (b) allow Equation (c) to be derived. Equation (c) relates the apparent rate con-

$$\vec{k}/\overleftarrow{k} = K_m t_B/t_A \quad \text{(c)}$$

stants to the equilibrium constant in the mobile phase, $K_m = \vec{k}_m/\overleftarrow{k}_m$. Therefore, this simulation method also allows a direct determination of the K_m constants. The equilibrium constants calculated from Equation (c) for compounds **1** and **2** are $K_m = 0.62 \pm 0.05$ and $K_m = 0.93 \pm 0.08$, respectively. These values agree with the experimentally determined equilibrium constant for **1**, $K_m = 0.66 \pm 0.04$,[17] and that expected for a chiral compound such as **2** in an achiral solvent, $K_m = 1$.[18]

The positive results described here validate the simulation method and also show that Scheme 1a does not violate the principle of microscopic reversibility. In addition, excellent results have also been obtained with this simulation method for other families of compounds (triarylmethyl radicals, helicenes, triptycenes, thioamides), chiral stationary phases (triacetylcellulose), and detectors (polarimeter).[22]

The D-HPLC method thus represents a new way to study molecular dynamic processes which has some limitations and advantages with respect to other classical methods. The main limitation arises from the use of apparent rate constants instead of those for the processes actually occurring in the chromatographic phases. However, such a limitation does not have a serious influence on the determination of precise energy barriers, which differ by less than 2 kJ mol^{-1} from those determined by independent techniques. The principal advantages of this method come from the versatility,

availability, and analytical scale of the HPLC technique. This method is especially suitable to the study of processes with activation energies ranging from 65 to 105 kJ mol^{-1}, since such processes are difficult to study by DNMR experiments and direct equilibration techniques. Furthermore, it also permits a complete kinetic study to be performed using insignificant amounts (nanograms) of samples without cumbersome previous enrichments being required.

[12] For the species with intermediate apparent retention times. ($t_A < t' < t_B$), the mean values $N' = (N_A + N_b)/2$ and $\tau' = (\tau_A + \tau_B)/2$ were used. Other kinds of dependence do not produce any significant change in the chromatographic profiles.

[13] The reproducibility of $\vec{k}$ and $\overleftarrow{k}$ values obtained with this simulation method is around 4%. This value was determined by studying the mutual influence of the chromatographic (t, N, and τ) and kinetic ($\vec{k}$ and $\overleftarrow{k}$) parameters on the agreement between the simulated and the experimental profiles.

[14] The apparent rate constants determined from the simulation of chromatograms for D-HPLC experiments performed at a constant temperature and using different eluent flow rates were always in agreement and showed a standard deviation of approximately 8%. This result, together with that described in [13], indicates that the precision of the simulation method is around 8%.

[15] The largest difference between $\vec{k}$ (or $\overleftarrow{k}$) and $\vec{k}_m$ (or $\overleftarrow{k}_m$) values observed for the diastereomerization of **1** corresponds to 35% of $\vec{k}_m$, which can be considered of small account; see [16]. Such close agreement is due to the presence of short-range and weak interactions between the species and the mobile and stationary phases.

[16] Deviations of the rate constant even larger than 50% of its exact value give rise to errors of approximately 2% in the associated energy barrier determined from the Eyring equation.

[17] This $\Delta G^{\neq}$ value was calculated from $\Delta H^{\neq}[meso \rightarrow d \text{ (or } l)] = 91 \pm 2.5$ kJ mol^{-1}, $\Delta S^{\neq}[meso \rightarrow d \text{ (or } l)] = -24 \pm 10$ J mol^{-1} K^{-1}, taking into account the statistical correction of the entropy by a factor of $R \ln 2$: J. Veciana, C. Rovira, M. I. Crespo, O. Armet, V. M. Domingo, F. Palacio, *J. Am. Chem. Soc.* in press.

[18] J. Veciana, M. I. Crespo, 1st Int. Symp. on Separation of Chiral Molecules, Paris 1988. This $\Delta G^{\neq}$ value was calculated from the thermodynamic parameters of the process determined by the simulation of ^{1}H NMR spectra (D-NMR 4, QCPE no. 466, University of Indiana) of **2** in the temperature range 335–383 K.

Thermally Irreversible Photochromic Liquid Crystal Polymers**

By *Ivan Cabrera, Achim Dittrich*, and *Helmut Ringsdorf**

Photochromism has always been something of a curiosity, while liquid crystals (LCs), though once mere chemical rarities, have already found widespread application in displays and many other electrical and electrooptical devices. Materials which combine both properties in a molecular entity should, therefore, be considered as chemical curiosities with many potential applications. Indeed, photochromic LC-polymers have already found use, e.g., as nonlinear optical materials[1] or for optical information storage.[2, 3] The holographic information storage in LC-polymers with azobenzene side groups[3] is based on the *trans-cis* isomerization of these groups. This tranformation causes a local reorientation of the mesogenic groups, which results in a variation of the refractive index. Thus a phase hologram can be formed. Photochromic LC-polymers containing spiropyran side groups have also been prepared.[4] Since these materials offer the possibility of controlling with light and temperature the formation of the three primary colors, they may be used in display and information storage technologies.

A disadvantage in all these polymers, however, is that the colored form of the photochrome is not thermally stable even at room temperature. Therefore, the color formation and related molecular reorientations upon which the recording of information is based are not permanent. In this communication, the first LC-polymers with thermally irreversible photochromic properties are reported. The materials are copolymers with mesogenic and photochromic fulgimide ((*E*)-2-[1-(2,5-dimethyl-3-furyl)ethylidene]-3-isopropylidenesuccinimide) side groups. They do not show any thermochromic behavior, in contrast to other photochromic compounds mentioned above, because their photochromic units are thermally stable up to 100 °C.

The synthesis, isomerization and electrocyclization of the photochromic (*E*)-2-[1-(2,5-dimethyl-3-furyl)ethylidene]-3-isopropylidenesuccinic anhydride (fulgide) have been studied in detail by *Heller* et al.[5] They have shown that its photochromic properties result from a conrotatory photocyclization to the 7,7a-dihydrobenzofuran (7,7a-DHBF) derivative, which undergoes the reverse process on exposure to visible light [Eq. (a)].

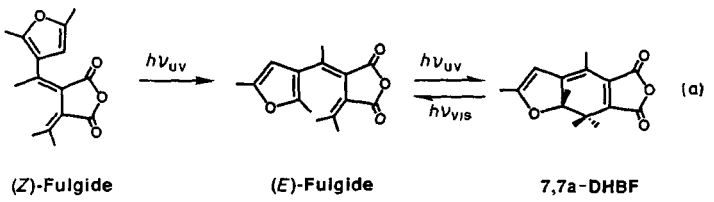
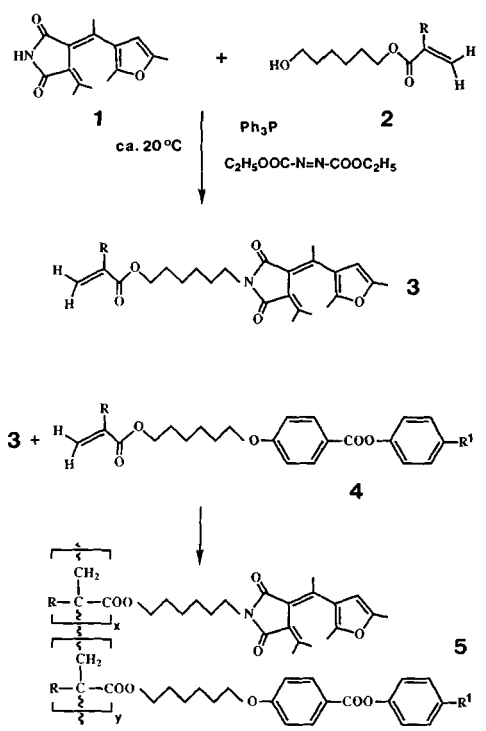
[**] This research was supported by the Alexander von Humboldt Foundation with a fellowship (*I.C.*) and by the NEDO project (*A.D.*) (NEDO = New Energy and Industrial Technology Development Organization).



Fulgimide-containing LC-polymers were synthesized according to Scheme 1. Furyl-fulgimide **1** was prepared by treatment of an *(E)*/*(Z)* fulgide mixture with ammonia in acetone solution.[6, 7] A Mitsunobu reaction[8] was used for



Scheme 1. Synthesis of LC-polymers with fulgimide side groups. Acrylate (**a**): R = H, R^1 = CN; methacrylate (**b**): R = CH_3, R^1 = OCH_3.

the preparation of the acrylate- and methacrylatefulgimide monomers **3** from **1**, which on radical copolymerization with the mesogenic monomers **4** led to the desired LC-copolymers **5**. For both the acrylate-(**5a**) and methacrylate-copolymers (**5b**) the clearing point of the mesophase decreases with increase of the fulgimide content. The phase diagrams are given in Figure 1.

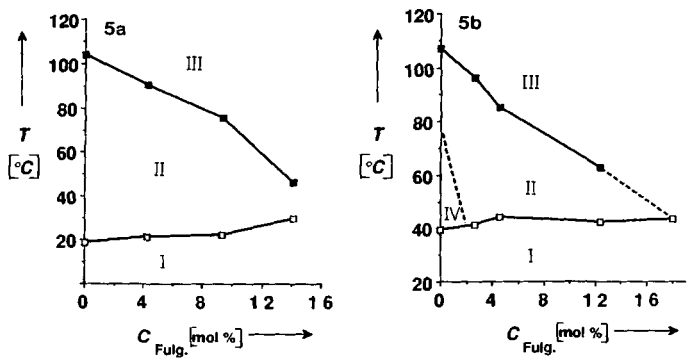


Fig. 1. Effect of the number of fulgimide side groups on the phase transitions of copolyacrylates **5a** and copolymethacrylates **5b**. I = glassy, II = nematic, III = isotropic, IV = smectic

The photochemical ring closure of the fulgimide groups on irradiation at λ = 366 nm and the reverse decoloration on irradiation with visible light (λ > 475 nm) can be clearly followed by UV-visible spectroscopy as a function of the time of irradiation. Characteristic changes in the absorption spectrum of the copolymers in solution and in an oriented filmare given in Figure 2. A homeotropically oriented film of a

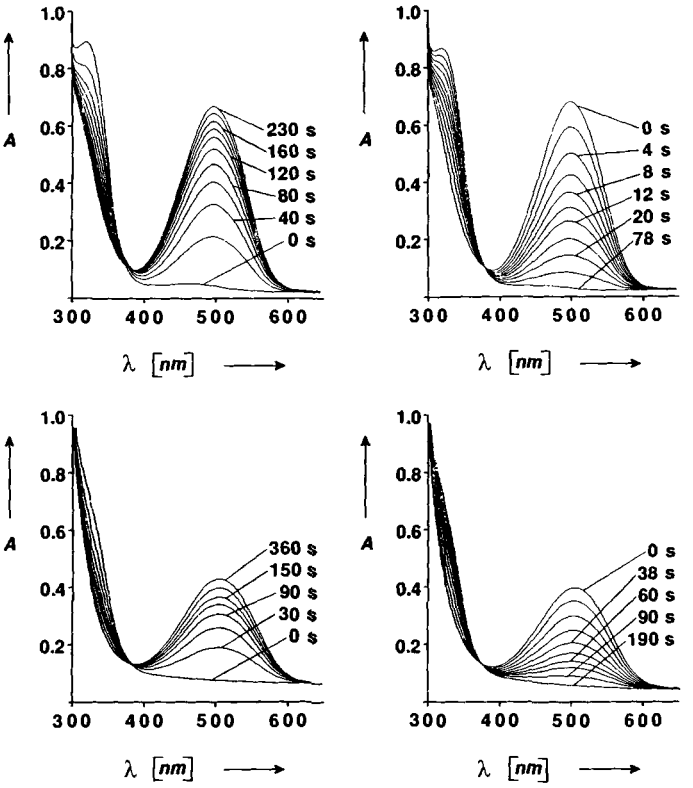

Fig. 2. Coloration on ring closure (λ = 366 nm) (left) and decoloration on ring opening (λ > 475 nm) (right) of a copolyacrylate **5a** (9.4 mol% of fulgimide groups) as a function of irradiation time *t*. Top: in toluene; bottom: homeotropically oriented film. *A* = Absorption in arbitrary units.

copolyacrylate was prepared by heating the polymer to the isotropic state followed by slow cooling of the material in an electric field.

Comparison of the spectra obtained in solution (Fig. 2 top) with those of the oriented film (Fig. 2 bottom) indicates that there is a bathochromic shift of the absorption maximum from 496 nm in solution to 506 nm in the film. In both cases, however, the existence of isosbestic points as well as exactly linear absorption difference diagrams[9] conclusively demonstrate the first-order character of the photoreactions (Fig. 3).

The photocolored form of the fulgimide side groups shows complete thermal stability at room temperature. Figure 4 demonstrates this for a copolymethacrylate **5b**. When a UV-irradiated film is kept in the dark, the absorption maximum in the visible does not change at all.

An interesting feature of the photochromic LC-polymers reported here, in contrast to the previously synthesized systems, is that one can clearly study the effect of each of the photochromic groups on the meso phase. In fact, polarizing

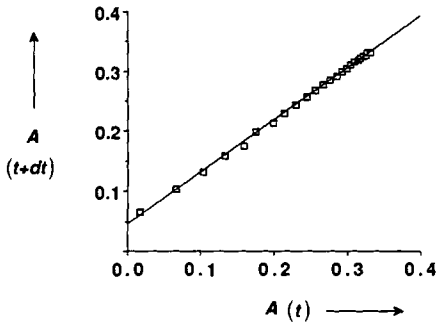

Fig. 3. Absorption at time $t + dt$ vs absorption at time t for the photoreaction from the open to the closed photochromic form in toluene (λ_{max} = 496 nm; copolyacrylate **5a** with 9.4 mol % fulgimide groups).

microscope observations have already revealed that irradiation of the materials with UV light leads to a higher clearing point of the meso phase. This suggests that the dihydrobenzofuran side groups (colored form) distort the parallel arrangement of the molecules in the meso phase less that the fulgimide groups.

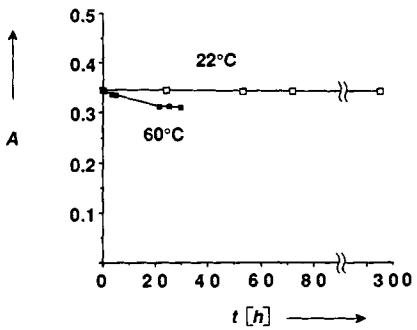

Fig. 4. Thermal stability of the colored form of the fulgimide groups in a copolymethacrylate **5b** with 2.5 mol % fulgimide content at 22 °C and 60 °C. A UV-irradiated film was used.

To test the possibility of recording optical information, a film of a photochromic polymer was covered with a standard photomask and irradiated with UV light (λ = 366 nm). The optically stored image of the mask could be observed with the polarizing microscope. Moreover, preliminary experiments have already shown that holographic patterns can be stored in the materials described here. The exact contribution of amplitude and phase effects is currently being investigated.

Experimental Procedure

1 was prepared by reaction of (*E*)/(*Z*)-2-[1-(2,5-dimethyl-3-furyl)ethylidene]-3-isopropylidenesuccinic anhydride with ammonia in acetone solution [6, 7]. 6-Hydroxyhexylacrylate **2a** (R = H) and 6-hydroxyhexylmethacrylate **2b** (R = CH_3) were synthesized as described in reference [10].

Typical example of the procedure for **3a** and **3b**: 0.115 g of **1**, 0.157 g of triphenylphosphane and 0.108 g of **2a** were dissolved in dry THF. To this a solution of azodicarboxylate (0.108 g) in dry THF was added. A trace of *p*-benzoquinone was also added to inhibit polymerization. The mixture was stirred for 14 hours in the dark. Afterwards the solvent was removed under vacuum and the product purified by flash chromatography (petrol ether: ethyl acetate 12:1). Yields: **3a** 40.4% **3b** 29.3% (based on **1**); oily compounds.

All compounds have been characterized by IR, ^{13}C and ^1H NMR spectroscopy. **3a**: ^1H NMR ($CDCl_3$, 400 MHz): δ = 6.33 (m; *Z*-H of CH_2=), 6.06 (t; H_2C=C*H*), 5.87 (s; furan-H), 5.78 (m; *E*-H of CH_2=), 4.11 (t; H_2C-OOC), 3.55 (t; CH_2-N), 2.54 (s; CH_3-C=), 2.28 (s; *Z*-CH_3 of $(CH_3)_2C$=), 2.20 (s; furan-5-CH_3), 1.94 (s; furan-2-CH_3), 1.64, 1.37 (m; N-CH_2-(CH_2)$_4$-CH_2-OOC), 1.28 (s; *E*-CH_3 of $(CH_3)_2C$=). **3b**: ^1H NMR ($CDCl_3$, 400 MHz): δ = 6.06 (m; *Z*-H of CH_2=), 5.88 (s; furan-*H*), 5.52 (m; *E*-H of CH_2=), 4.10 (t; CH_2-OOC), 3.55 (t; CH_2-N), 2.54 (s; CH_3-C=), 2.28 (s; *Z*-CH_3 of $(CH_3)_2C$=); 2.21 (s; furan-5-CH_3); 1.95 (s; furan-2-CH_3); 1.91 (t; H_2C=CCH_3), 1.64, 1.37 (m; N-CH_2-(CH_2)$_4$-CH_2-OOC), 1.28 (s; *E*-CH_3 of $(CH_3)_2C$=).

The mesogenic monomers **4** were prepared by standard methods [11, 12]. The copolymers **5** were prepared by polymerization of the monomer (20–30 percent in THF solution) with 1.2 mol % of 2,2'-azobis(isobutyronitrile) at 55 °C. The polymers were precipitated in methanol, purified by reprecipitation and dried under vacuum at room temperature. The yields of the polymers (20–70%) depended substantially on the concentration of fulgimide monomer. The higher the concentration the lower the polymer yield. The composition of the polymers was determined by NMR spectroscopy. Typical molecular weights, determined by gel permeation chromatography, are 5000 for copolyacrylates **5a** and 14000 for copolymethacrylates **5b**.

Selective Halogenation at Primary Positions of Cyclomaltooligosaccharides and a Synthesis of Per-3,6-anhydro Cyclomaltooligosaccharides

By *Andrée Gadelle* and *Jacques Defaye**

6-Deoxyhalo cyclomaltooligosaccharides are of interest as reactive intermediates for the modification of solubility and inclusion properties of cyclomaltooligosaccharides.[1, 2] A main route to these derivatives involves the displacement of acylated 6-sulfonates by a halide salt. However, the direct sulfonylation at primary positions of cyclomaltooligosaccharides, although well documented, does not usually proceed with high yield and selectivity,[1, 3, 4] and the displacement is furthermore not a quantitative process.[5] An improved access to such derivatives was introduced by *Takeo* et al.,[6] who obtained per-6-bromo-6-deoxy cyclomaltooligosaccharides by direct bromination of the cyclic oligosaccharides with methanesulfonyl bromide in DMF. This halogenation procedure, which presumably involves the in situ formation of a brominated dimethylammonium bromide and is then related to the more general activation process of alcohols toward nucleophilic displacements by

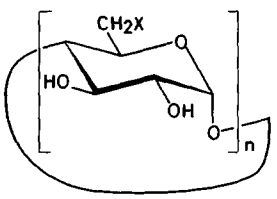
Vilsmeier–Haack complexes,[3, 7] was found, in our case, to result in some methanesulfonylation when applied to amylose.[8] Subsequent modification, which involved the use of pure crystalline Vilsmeier bromide, prepared from triphenylphosphane and bromine in DMF, resulted in the formation, in high yield and purity, of 6-bromo-6-deoxyamylose.[8] Extension of this reaction to the preparation of 6-deoxyhalo cyclomaltooligosaccharides and their conversion into per-3,6-anhydro derivatives is now described.

Isolation of a Vilsmeier iodide, from the reaction of iodine and triphenylphosphane in DMF does not proceed as easily as for the corresponding bromide,[8] and iodination reactions were conducted in situ. When either cyclomaltohexaamylose **1** or cyclomaltoheptaamylose **2** was allowed to react in DMF containing triphenylphosphane and iodine at 80 °C for 15 h and the solution further treated with sodium methoxide to destroy the formate esters formed in the reaction, per-6-deoxy-6-iodo cyclomaltooligosaccharides **3** and **4**, which were suitable for use without further purification, were obtained in 80% and 88% yields, respectively. Their structures were inferred from fast atom bombardment mass spectrometry (FABMS), which gave the expected protonated molecular ions at *m/z* 1633.6 (**3**) and 1904.7 (**4**) and which were shifted to 1671.5 by the addition of potassium iodide (**3**) and to 1926.7 with sodium iodide (**4**). Both compounds gave six signals in their ^{13}C NMR spectra. The C-6 signals were found at high field, in agreement with the inductive effect of the iodine atom. A further structural confirmation for **4** came from its conversion into its known tetradecaacetate.[5]

The versatility of the reagent for the preparation of 6-deoxyhalo cyclomaltooligosaccharides is further exemplified by the preparation of heptakis(6-bromo-6-deoxy)cyclomaltoheptaamylose[6] **5** by reaction of **2** with bromine and triphenylphosphane in DMF under similar conditions.



1 X = OH n = 6
2 X = OH n = 7

6 n = 6
7 n = 7

3,6-Anhydroamylose was previously obtained in high yield from the reaction of 6-bromo-6-deoxyamylose with base.[8] It is water-soluble and its ability to bind with fatty acids is attributed to a partial helical conformation.[8] It was then of interest to prepare, for comparison, closely related cyclic structures. Interestingly, although mono-[9], di-[10] and tri-3,6-anhydro[11] cyclomaltooligosaccharides were already described, per(3,6-anhydro)cyclomaltoheptaose **7** has only quite recently been reported from the corresponding heptakis(6-*O*-*p*-tosyl) derivative.[12] The ready availability of per-6-deoxyhalo derivatives **3** and **4** now makes the access to such structures quite easy. **6** and **7** were prepared by treatment of the respective 6-iodo derivatives **3** and **4** with aqueous sodium hydroxide in DMSO. Anhydro cyclomaltooligosaccharides were recovered from the reaction after partial neutralization by addition of dry ice, and ultrafiltration against water. Confirmation of the structures **6** and **7** came from FABMS, which gave signals at *m/z* 887 and 1031 for the sodium species. In the ^{13}C NMR spectra of **6** and **7**, the signal for C-3 was shielded in both derivatives by $\delta = 2.5$ relative to the unmodified cyclomaltooligosaccharide signal, whereas that of C-6 was deshielded by $\delta = 7.7-7.8$, in agreement with data found for methyl 3,6-anhydro-α-D-glucopyranoside.[13] The D-glucopyranose units in **6** and **7** must have the alternative $^1C_4$ conformation.

In preliminary experiments, the per-3,6-anhydro cyclomaltooligosaccharides **6** and **7** were more soluble in water than the corresponding cyclomaltooligosaccharides. They were also appreciably soluble in methanol.

Experimental Procedure

3 and **4**: To a stirred solution of triphenylphosphane (21 g, 80 mmol) and iodine (20.2 g, 80 mmol) in DMF (80 mL) was added either **1** or **2** (4.32 g, 26.6 mole equiv.) and the solution was stirred at 80 °C for 15 h. It was then concentrated under vacuum to half the volume and the pH adjusted to 9–10, by the addition of sodium methoxide in methanol (3 M, 30 mL), with simultaneous cooling. The solution was kept at room temperature for 30 min to destroy the formate esters formed in the reaction, after which it was poured into ice water (1.5 L). The precipitate was collected by filtration to yield either **3** (5.8 g, 80% from **1**) or **4** (6.41 g, 88% from **2**) [14].

3: m.p. 227 °C (dec.); $[\alpha]_D^{25} + 95°$ ($c = 1.3$, DMF); ^{13}C NMR (50 MHz, $(CD_3)_2SO$, DMSO): $\delta = 101.8$ (C-1), 86.3 (C-4), 72.3 (C-5), 71.8 (C-3), 70.8 (C-2), 9.3 (C-6); FABMS (VG-ZAB-SEQ, dithioerythritol–dithiothreitol 1:4 *p*/*p*–KI): *m/z* 1671.5 ([*M* + K]$^\oplus$, 90%), 1633.6 ([*M* + H]$^\oplus$, 24), 1545.6 ([*M*HK − I]$^\oplus$, 100), 1418.7 ([*M*H_2K − 2I]$^\oplus$, 95), 1292.8 ([*M*H_3K − 3I]$^\oplus$, 76). Correct elemental analysis (C,H,I).

4: m.p. 235 °C (dec.); $[\alpha]_D^{25} + 66.1°$ ($c = 1.15$, DMF); ^{13}C NMR (50 MHz, $(CD_3)_2SO$, DMSO): $\delta = 102.3$ (C-1), 86.1 (C-4), 72.3 (C-3, C-5), 71.2 (C-2), 9.6 (C-6); FABMS (glycerol–thioglycerol–NaI): *m/z* 1926.7 ([*M* + Na]$^\oplus$, 100%), 1904.7 ([*M* + H]$^\oplus$, 21), 1800.9 ([*M*HNa − I]$^\oplus$, 71). Correct elemental analysis (C,H,I). Pyridine–Ac_2O acetylation of **4** yielded crystalline peracetylated heptakis(6-deoxy-6-iodo)cyclomaltoheptaose (69%), m.p. 180 °C (from Me_2CO–EtOH), $[\alpha]_D^{25} + 83.3°$ (*c* 1.2, $CHCl_3$); from [5]: m.p. 172–177 °C, $[\alpha]_D^{24} + 84°$ ($c = 0.1$, MeOH).

5: The experimental description was analogous to that of **3** and **4** except that bromine (4 mL, 80 mmol) was used instead of iodine. Yield 5.57 g (93%) [14].

5: m.p. 214 °C (dec.); $[\alpha]_D^{25} + 78.1°$ ($c = 1.76$, DMF). Correct elemental analysis (C,H,Br). From [6]: m.p. 205–206 °C (dec.), $[\alpha]_D^{25} + 98°$ ($c = 1$, pyridine).

6 and **7**: To a stirred solution of either **3** or **4** (1 g) in DMSO (30 mL) at 60 °C, was added aqueous sodium hydroxide (M, 6 mL) and the mixture was stirred for 6 h at 60 °C. The solution was cooled, dry ice was added in small portions, and the solvent was removed under vacuum. The solid residue was dissolved in water (150 mL), purified by ultrafiltration (Amicon 8200 device fitted with an Amicon Diaflo YCO5 membrane) against water for 24 h, and freeze-dried. Yield: **6** (405 mg, 75% from **3**). **7**: (502 mg, 88% from **4**) [14, 15].

6: m.p. 258 °C (EtOH aq.); $[\alpha]_D^{25} + 13°$ ($c = 0.72$, H_2O); ^{13}C NMR (50 MHz, D_2O, Me_2CO): $\delta = 97.6$ (C-1), 77.2 (C-4), 73.7 (C-5), 71.0 (C-3), 68.5 (C-6), 68.2 (C-2); FABMS (dithioerythritol–dithiothreitol–NaI): *m/z* 887 ([*M* + Na]$^\oplus$, 100%). Correct elemental analysis (C,H).

7: m.p. 289 °C (EtOH aq.); $[\alpha]_D^{25} - 10°$ ($c = 0.76$, H_2O); ^{13}C NMR (50 MHz, $(CD_3)_2SO$, DMSO): $\delta = 97.7$ (C-1), 76.9 (C-4), 73.6 (C-5), 70.9 (C-3), 68.4 (C-2, C-6); FABMS (glycerol–thioglycerol–NaI): *m/z* 1031 ([*M* + Na]$^\oplus$, 100%), 1053 ([*M* + 2Na − H]$^\oplus$, 58%), 1075 ([*M* + 3Na − 2H]$^\oplus$, 12%). Correct elemental analysis (C,H).

Synthesis and Characterization of Per-3,6-anhydro Cyclodextrins**

By *Peter R. Ashton, Paul Ellwood, Ian Staton,* and *J. Fraser Stoddart**

Cyclodextrins (CDs) are a class of cyclic oligosaccharides composed commonly of 6 (α-CD), or 7 (β-CD), α(1 → 4)-linked D-(+)-glucopyranose units. They have been widely investigated on account of their ability to form inclusion complexes with a wide variety of substrates.[1] The structures of the CDs have been extensively studied both in the solid state[2] and in solution.[3, 4] These investigations have established unambiguously that the D-glucopyranose residues adopt the expected $^4C_1$ chair conformation and that the gross structures of the molecules are those of truncated cones.[2] All the hydroxyl groups are located on the exteriors of the cones, making them somewhat hydrophilic, whereas the interiors of the cavities are relatively hydrophobic because they are lined with the H-3 and H-5 methine protons.

Many researchers have sought to change the structures and properties of CDs by chemical modification.[5] Although this research has led to a great deal of extremely elegant work, the majority of the chemical modifications to date have not resulted in significant perturbations of the gross structural features of the CD molecules. As a consequence, CDs have become trapped in something of a "structural straightjacket". Recently, however, a number of chemical modifications which could release CDs from this "structural straightjacket" have been achieved.[6, 7] In this paper, we wish to report another key chemical modification, namely per-3,6-anhydration. Examination of space-filling molecular models of, for example, per(3,6-anhydro)-β-CD indicates that the cavity of this derivative is dominated by the glucosidic pyranose ring and free hydroxyl oxygen atoms. Thus, the per-3,6-anhydro CDs constitute, potentially, a completely new class of CD-derived molecular receptor.

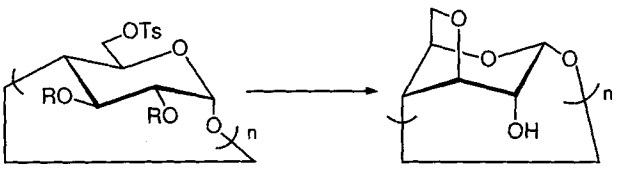
[**] Presented in part at the Royal Society of Chemistry Carbohydrate Group Spring Meeting, Cardiff, UK, 25–28 March 1990, at the Fifth International Symposium on Cyclodextrins, Paris, France, 27–30 March 1990, and at the Smith Kline Beecham Pharmaceutical Research Symposium on "Chirality in Drug Design and Synthesis", Cambridge, UK, 27–28 March 1990. This work was supported by the Science and Engineering Research Council and the Johnson Matthey Technology Centre in the United Kingdom.

Among carbohydrates in general, 3,6-anhydro derivatives of pyranose sugars are well known.[8] Usually, such derivatives are prepared by base treatment of pyranose derivatives carrying a good leaving group at C-6 and a *syn*-hydroxyl group at C-3. *Fujita* et al.[9] were the first to report 3,6-anhydration in CD systems. However, to date only partial anhydro ring formation has been achieved.[10]

Our initial attempt to synthesize the per-3,6-anhydro derivatives **3** and **4** of α-CD and β-CD involved (Scheme 1, R = H) the use of the per-6-*O*-tosyl derivatives **1** and **2**, respectively. These tosylates were first reported by *Lehmann* et al.[11] in 1954; since then, modifications to the original procedure have been reported by *Umezawa* et al.,[12] *Cramer* et al.,[13] and *Breslow* et al.[14] However, despite the extensive amount of research on **1** and **2**, analytical data for them are scarce.[15] In addition, only *Umezawa* et al.[12] give details of a chromatographic procedure for the purification of per(6-*O*-tosyl)-α-CD **1**. The other researchers[11, 13, 14] all used recrystallization as the means of purification. Thus, we suspected that the established literature procedures yield mixtures and not pure compounds. All the crude reaction products obtained in the present study were subjected to careful chromatography followed by a detailed analysis with a battery of physical methods.

Purification and analysis by HPLC, FABMS and NMR spectroscopy did indeed show that the reaction products of tosylations of both α-CD and β-CD contained mixtures of over- and under-tosylated derivatives, as well as the desired axially symmetrical derivatives **1** and **2**.[16] As expected[17] however, the reaction mixture obtained from α-CD was considerably more complicated than that obtained from β-CD: only sufficient pure **1** was isolated to permit its full characterization,[16] whereas sufficient pure **2** was isolated to allow the reaction illustrated in Scheme 1 (R = H) to be attempted. By

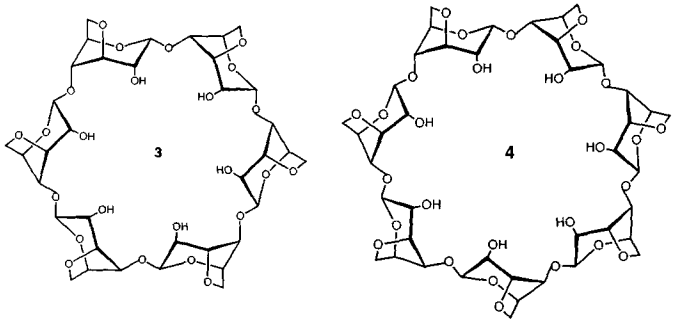


R = H, n = 6 **1** n = 6 **3**
R = H, n = 7 **2** n = 7 **4**
R = Bz, n = 6 **5**

Scheme 1. The synthesis of per-3,6-anhydro CDs **3** and **4** from the corresponding per-6-*O*-tosyl derivatives **1**, **2** and **5**. R = H: $NaOH/H_2O$; R = Bz: $Et_3N/CH_3OH/H_2O$

suspending the pure tosylate **2** in 1 M aqueous sodium hydroxide solution and stirring the reaction mixture for 2 days at 60 °C, per(3,6-anhydro)-β-CD **4** was isolated in 44% yield after reverse phase chromatography.[18] The ^1H and ^{13}C NMR spectra of the pure material were recorded in both D_2O and CD_2Cl_2 solutions. The vicinal H-H coupling constants obtained from the ^1H NMR spectra confirmed that the D-glucopyranose residues are locked in the $^1C_4$ chair conformation. However, the ^1H NMR chemical shifts and $[\alpha]_D$ values were different in the two solvents, which suggests that the gross conformation of the molecule is exhibiting some solvent dependence. In addition, a ^{13}C INEPT NMR spectrum was recorded in D_2O and an accurate value (164 Hz) of $^1J_{CH}$ was obtained for the anomeric position. This value is consistent[19] with an axial orientation for the

anomeric proton; thus the presence of the anhydro-D-glucose units with their $^1C_4$ chair conformation is confirmed (Scheme 2). The FABMS of pure per(3,6-anhydro)-β-CD **4** showed a pseudo molecular ion corresponding to a mono-



Scheme 2. Structures of **3** and **4**.

sodium adduct and further ions consistent with disodium and sodium/potassium adducts.[20] Single crystals suitable for X-ray crystallography were obtained by the vapor diffusion of methanol into an aqueous solution of **4**, and the full structural solution has not yet been achieved,[21] although a full set of X-ray data has been collected.

In view of the difficulties experienced in isolating large quantities of pure per(6-*O*-tosyl)-α-CD **1**, an alternative method of synthesizing per(3,6-anhydro)-α-CD **3** was developed using per (2,3-*O*-benzoyl-6-*O*-tosyl)-α-CD **5** as the key synthetic precursor (Scheme 1, R = Bz). This derivative was prepared according to the procedure described by *Lehn* et al.[17] Suspending **5** in $Et_3N/CH_3OH/H_2O$[22] and refluxing for 4 days gave eventually a clear solution. Neutralization with hydrochloric acid, followed by removal of the CH_3OH/H_2O under vacuum afforded a white solid. The FABMS of this white solid showed a base peak at *m/z* 966 corresponding to the triethylammonium adduct of **3**. Reverse phase chromatography with extensive recycling was necessary in order to isolate a small quantity of pure **3**. The ^1H and ^{13}C NMR spectra of this material were recorded in D_2O, and vicinal H-H coupling constants again indicate that the anhydro glucose residues were in the $^1C_4$ chair conformation (Scheme 2). The FABMS of the pure compound now showed molecular ion adducts corresponding to $[M + 2Na - H]^{\oplus}$ and $[M + K]^{\oplus}$, as well as the expected monosodium adduct.[20]

The development[23] of synthetic and chromatographic procedures for the preparation of the pure per-3,6-anhydro CDs **3** and **4** provides the opportunity to investigate their ability to form inclusion complexes.

Experimental Procedure

3: **5** [17] (50 mg, 0.016 mmol) was suspended in $Et_3N/CH_3OH/H_2O$ (1:5:1 v/v) (7 mL) and heated under reflux for 4 days. The resulting solution was then cooled and neutralized with hydrochloric acid (ca. 0.1 M). The solvents were removed under vacuum to give a white residue. HPLC using a Technicol Reverse Phase Column and CH_3OH/H_2O (1:4 v/v) as eluant afforded pure **3**. (3 mg, 22%); m.p. 236–237 °C; (Found: C 47.7; H 5.29% (material was very hygroscopic); *m/z* 887 $[M + Na]^{\oplus}$, 904 $[M + K]^{\oplus}$, 909 $[M + 2Na - H]^{\oplus}$. $(C_6H_8O_4)_6$ requires C 50.0; H 5.55%; *M* 864); $[\alpha]_D$ + 10 (*c* = 0.25, H_2O); δ_H (250 MHz, D_2O): 3.87 (6H, dd, $J_{1,2}$ = 4, $J_{2,3}$ = 5 Hz), 3.98 (6H, dd, $J_{5,6b}$ = 3, $J_{6a,6b}$ = 11.5 Hz), 4.24 (6H, d, $J_{6a,6b}$ = 11.5 Hz), 4.31 (6H, dd, $J_{3,4}$ = 5.5, $J_{4,5}$ = 2 Hz), 4.39 (6H, t, $J_{2,3}$, $J_{3,4}$ = 5 Hz), 4.56 (6H, m), 5.24 (6H, d, $J_{1,2}$ = 3 Hz). δ_C (63 MHz, D_2O): 68.4 (C-2), 68.8 (C-6), 71.3 (C-3), 74.0. (C-5), 77.5 (C-4), 98.0 (C-1).

4: **2** (20 mg, 0.009 mmol) was suspended in aqueous NaOH solution (2 mL of a 1 M solution) and the reaction mixture was stirred at 50 °C for 2 days. The clear solution was neutralized with hydrochloric acid (0.1 M) and the H_2O was removed under vacuum to leave a white residue. The desired compound was isolated by reverse phase HPLC. Thus, injecting a H_2O/CH_3OH (3:2 v/v) solution of the white residue onto a Dynamax C-18 Reverse Phase Preparative Column, and eluting with this solvent system afforded pure **4**. (4 mg, 44%); m.p. 226–227 °C; (Found: C 48.7; H 5.76% (material was very hygroscopic); *m/z* (positive ion FABMS) 1031 $[M + Na]^{\oplus}$, 1053 $[M + 2Na - H]^{\oplus}$, 1069 $[M + Na + K - H]^{\oplus}$. $(C_6H_8O_4)_7$ requires C 50.0; H 5.55%, *M* 1008). $[\alpha]_D$ 0 (*c* = 0.6, D_2O), $[\alpha]_D$ − 33 (*c* = 0.4, CH_2Cl_2); δ_H (250 MHz, D_2O): 3.94 (7H, br, dd, $J_{1,2}$ = 3.5, $J_{2,3}$ = 5 Hz), 4.03 (7H, dd, $J_{5,6b}$ = 3, $J_{6a,6b}$ = 11.5 Hz), 4.29 (7H, d, $J_{6a,6b}$ = 11.5 Hz), 4.36 (7H, dd, $J_{3,4}$ = 5, $J_{4,5}$ = 2 Hz), 4.46 (7H, t, $J_{2,3}$, $J_{3,4}$ = 5 Hz), 4.63 (7H, m), 5.31 (7H, d, $J_{1,2}$ = 3 Hz); δ_H (250 MHz, CD_2Cl_2): 3.89 (7H, br, dd, $J_{1,2}$ = 3.5, $J_{2,3}$ = 5 Hz), 3.95 (7H, dd, $J_{5,6b}$ = 2.5, $J_{6a,6b}$ = 11 Hz), 4.17 (7H, d, $J_{6a,6b}$ = 11 Hz), 4.19 (7H, dd, $J_{3,4}$ = 5, $J_{4,5}$ = 2.5 Hz), 4.38 (7H, t, $J_{2,3}$, $J_{3,4}$ = 5 Hz), 4.54 (7H, t, $J_{4,5}$, $J_{5,6b}$ = 2.5 Hz), 5.19 (7H, d, $J_{1,2}$ = 3 Hz). δ_C (63 MHz, D_2O): 68.0 (C-2), 68.6 (C-6), 71.0 (C-3), 73.8 (C-5), 76.5 (C-4), and 97.5 (C-1).

[18] The relative simplicity of the crude reaction mixture after the tosylation of β-CD led us to investigate the possibility of using the recrystallized but impure reaction product as the starting material for the per-3,6-anhydration. Such a procedure did indeed afford pure **4** because the subsequent chromatographic purification of the per(3,6-anhydro)-β-CD is straightforward. Therefore, we recommend using impure starting tosylate routinely to obtain large quantities of **4**. A similar investigation in the case of the α-CD derivatives was unsuccessful on account of the large number of asymmetrical 3,6-anhydro derivatives produced.

[20] In our experience (for example, see P. R. Ashton, J. F. Stoddart, R. Zarzycki, *Tetrahedron Lett. 29* (1988) 2103), the FABMS of chemically modified cyclodextrins with *m*-nitrobenzyl alcohol as matrix gives only one pseudomolecular ion—a sodium adduct. Unlike the parent CDs and the majority of chemically modified CDs, the per-3,6-anhydro CDs **3** and **4** have cavities dominated by oxygen atoms, and therefore constitute a better binding environment for metal ions.
[21] Crystal data: monoclinic, a = 10.223(3), b = 41.213(12), c = 13.738(4) Å, β = 111.54(2)°, V = 5284 Å^3, $P2_1$, Z = 4 (2 crystallographically independent molecules). Full three-dimensional diffraction data have been collected and the structural solution is being attempted currently (A. M. Z. Slawin, D. J. Williams, unpublished results).

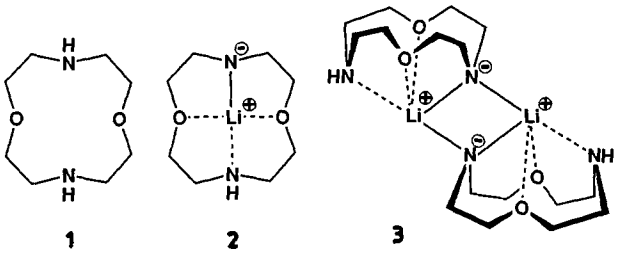
[23] When we had completed the research reported in this communication, we discovered that **3** and **4** had also been prepared by *J. Defaye* et al. at the same time using a slightly different synthetic procedure; see the preceeding communication: A. Gadelle, J. Defaye, *Angew. Chem. 103* (1991) 94; *Angew. Chem. Int. Ed. Engl. 30* (1991) 78.

Aggregation of Aza Crown Ethers by Metalation: Synthesis and Crystal Structure of 1-Lithio-1,7-diaza[12]crown-4—The First Lithiated Crown Ether**

By *Donald Barr, David J. Berrisford, Luis Méndez, Alexandra M. Z. Slawin, Ronald Snaith,* J. Fraser Stoddart,* David J. Williams,** and *Dominic S. Wright*

There is much current interest[1, 2] in lithium amide reagents whose $Li^{\oplus}$ centers are complexed by functional groups inherent to the amide residue, in contrast with the more usual "external" complexation provided by added Lewis bases. The interest is concerned mainly with the precise structures of these reagents both in the solid state and in solution as well as with how these structures govern their subsequent reactions with organic substrates. Elsewhere in alkali-metal chemistry, neutral macrocyclic ligands (crowns, cryptands, etc.) are widely used, normally to encapsulate $M^{\oplus}$ ions and to separate them from their anions.[3] Here, we report our first attempt at merging these two strands of alkali-metal coordination chemistry—namely, the results of monolithiating a diaza crown ether (**1**) containing NH units. The ensuing ligand must be both the anion and the complexant such that, taken together with the $Li^{\oplus}$ center, a single entity is formed. It seemed likely that the $Li^{\oplus}$ ion in the product, **2**, would be unusually accessible to added organic substrates. X-ray diffraction studies showed that the lithiation product **2** is present in the solid state as the dimeric structure **3**.[4–6]



1 **2** **3**

Reaction of macrocycle **1**[7, 8] with *n*BuLi (1 molar equivalent) in the presence of 1 molar equivalent of $OP(NMe_2)_3$ (HMPA) afforded a compound with the empirical formula **2**. (The bulk product contained only traces[9] of HMPA). The crystal structure reveals that **2** forms a dimer **3** (Fig. 1). In each monomeric unit, the $Li^{\oplus}$ ion is bonded to its $N^{\ominus}$ center (2.111(4) Å), to the intact NH center (2.186(4) Å), and to both O atoms (2.258(4), 2.327(3) Å). Dimerization is due to interaction of the $Li^{\oplus}$ ion of each monomer with the $N^{\ominus}$ center of the other monomer (N-Li, 1.996(4) Å). To accommodate this interaction, each $Li^{\oplus}$ ion is displaced markedly from its "own" crown ether (by 0.94 Å) and becomes five-coordinate; this is an unusual—but not unknown—coordination[2] for $Li^{\oplus}$. The four-membered Li_2N_2 ring is planar and rhombic with transannular Li···Li' and N(7)···N(7') distances of 2.476(6) and 3.28(1) Å, respectively. The Li–N(7)-Li' angle is 74.1(2)°. All the other angles at each N are close to tetrahedral. To our knowledge, **3** is the first example[10, 11] of an oligomeric $Li^{\oplus}$–crown ether complex, to be characterized fully in the solid state; **3** is atypical, however, since the crown ether is anionic.

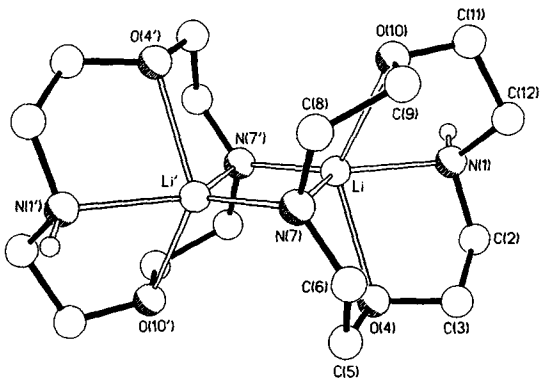


Fig. 1. The structure of **3** in the crystal. The hydrogen atoms, with the exception of those on N(1) and N(1'), have been omitted for clarity. The torsional angles in the macrocycle, starting with that about the N(1)–C(2) bond and proceeding clockwise, are 81, −167, 59, −160, 83, 59, −166, 78, 59, −161, 82, and 56° (average estimated standard deviation 0.2°).

MNDO calculations[12] have been used to probe the structural features of **3**. The results of calculations on four model species are summarized in Table 1. For monomeric **2**, it was assumed initially that the $Li^{\oplus}$ ion was in the heteroatom plane of the crown ether with the CH_2 units mutually eclipsed. The optimized geometry, freely refined, shows the $Li^{\oplus}$ ion bonded to all four heteroatoms. To achieve this situation, the $Li^{\oplus}$ ion is displaced 0.79 Å above the idealized N_2O_2 plane, the N–H bond is twisted away from the Li–N(H) bond, and the CH_2 groups become staggered. The $Li^{\oplus}$···crown ether displacement is typical for five-coordi-

Table 1. The results of MNDO calculations on monomeric **2**, on a model for HMPA-complexed monomeric **2**, and on two models for dimeric **3**.

nate $Li^{\oplus}$ complexes (i.e., ones with $Li^{\oplus}$–anion contacts; cf. 0.85 Å in the solid-state structure of ([12]crown-4)LiSCN[11] and 0.79 Å in that of (dibenzo[14]crown-4)LiSCN[13]).

A complex of the monomer, $2 \cdot OPH_3$, was also examined. Again the structure was freely refined, with no symmetry restrictions. The important findings are (1) that the complexation energy is rather small (-17.1 kcal mol^{-1}), (2) that all the bonds between $Li^{\oplus}$ and the heteroatoms of the crown ether lengthen as expected compared with the distances found in uncomplexed **2**, and (3) that the $Li^{\oplus}$ ion moves further out (to 0.99 Å) of the crown plane. As a preliminary model for dimeric **3**—the association state found by X-ray diffraction—an H_2N'-*Li'* unit was contacted with the $N^{\ominus}$–$Li^{\oplus}$ edge of monomeric **2**. After optimization, the resulting association energy (a mean of -21.9 kcal mol^{-1} expressed per mole of Li) is somewhat larger than the complexation energy found for the monomeric $2 \cdot OPH_3$ adduct. This implies that the $Li^{\oplus}$ ion in this system prefers to achieve fivefold coordination by such association rather than by bonding a complexant. This is perhaps relevant to the experimental observation that HMPA is not incorporated—at least, stoichiometrically—in the dimeric product **3**. In the calculated $2 \cdot H_2N'Li'$ structure, the $Li^{\oplus}$ ion of the crown ether is "lifted" even further out of the plane to 1.12 Å. In addition, the $N^{\ominus}$–Li distance lengthens markedly compared with the values in monomeric **2** and in $2 \cdot OPH_3$. Thus, the complexed $Li^{\oplus}$ ion moves to a much more central position above the crown ether. In a final calculation, an attempt was made to mimic a species more closely related to the dimeric structure found for **3** in the solid state. In this species, whose optimized structure is shown in Figure 2, one NH_3 and two H_2O ligands were attached to the $Li'^{\oplus}$ ion of $2 \cdot H_2N'Li'$. The

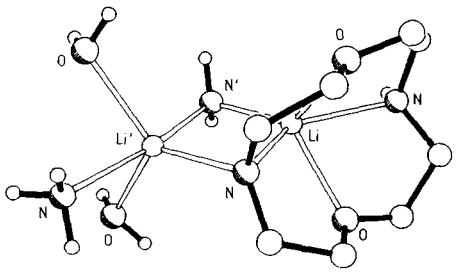

Fig. 2. The MNDO-optimized structure of $2 \cdot H_2N'Li' \cdot 2H_2O \cdot NH_3$ as viewed side-on.

calculated association energy of the two units (monomer **2** plus $H_2N'Li' \cdot NH_3 \cdot 2H_2O$) is a mean of -17.6 kcal mol^{-1} expressed per mole of Li. The $Li^{\oplus}$ ion of the crown ether is less central than in $2 \cdot H_2N'Li'$. The $N^{\ominus}$–*Li'* bond lengthens since the $Li'^{\oplus}$ ion now bears NH_3 and H_2O ligands, and thus the $N^{\ominus}$–Li bond shortens. Once more, however, the complexed $Li^{\oplus}$ ion is found to be raised markedly above the mean plane of the crown ether (by 1.11 Å). Thus, the results of the MNDO calculations agree reasonably well with the experimental findings principally in demonstrating (1) the deprotonation of a crown ether induces a strong preference for association of the metalated product and (2) that, to effect such association, the metal ion needs to move considerably further away from the plane of its "own" crown ether.

The results of this preliminary investigation raise several possibilities which are being explored: (1) Since **3** is still an amine containing an active NH function, further lithiation should be feasible, thus giving polymers,[14] or, by introduction of neutral donors to satisfy the extra metal ion, higher oligomers. (2) Although electronically well-satisfied, the five-coordinate $Li^{\oplus}$ centers in **3** remain sterically open to attack by added organic substrates (e.g., ketones). (3) The second metal[15] need not be a $Li^{\oplus}$ ion, so that mixed-metal $(crown)^{2\ominus}/Li^{\oplus} \cdot M^{\oplus}$ species could be synthesized. A particularly interesting aspect of the structure is that the dimerization caused by deprotonation requires additional displacement of the $Li^{\oplus}$ ion from the crown plane. A consequence of these structural features may be to allow incorporation of larger $M^{\oplus}$ ions (e.g., $Na^{\oplus}$, $K^{\oplus}$), which would normally not fit into the crown, or even of $M^{2\oplus}$ ions (e.g., $Mg^{2\oplus}$), possibly leading to cyclization products, "$(N \cdot crown \cdot N\text{-}Mg)_n$".

Experimental Procedure

2: The aza crown ether **1** [7, 8] (177 mg, 1.02 mmol), in a stirred solution of dry THF (3 mL), was lithiated under N_2 by addition of 1 molar equivalent of a 1.6 M solution of *n*BuLi in hexane (0.63 mL). This reaction yielded a white precipitate. *Addition of 1 molar equivalent of HMPA (0.18 mL) in THF* (3 mL), followed by heating under reflux, gave a clear solution from which crystals started to grow after 1 h at room temperature. The air-sensitive solid was filtered off, dried in vacuo, and transferred to a drybox under N_2. Yield (first batch of crystals) 71 mg, 39%; m.p. 105 °C (dec.). ^{1}H NMR (360.14 MHz, $C_6D_5CD_3$, 25 °C): $\delta = 2.13$ (1H, br. s, NH), 2.89 (8H, br. s, $4 \times CH_2$), 3.67 (8H, t, $4 \times CH_2$) [9]. ^{7}Li NMR (139.96 MHz, $C_6D_5CD_3$, δ relative to PhLi): δ (25 °C) = -0.54 (br. s), δ (-90 °C) = -0.50 (sharper s) (both ^{7}Li peaks have small shoulders, probably as a result of partial hydrolysis). Single crystals suitable for X-ray crystallography were sealed under N_2 in Lindemann tubes prior to data collection.

[8] Anhydrous **1** was purified by sublimation (90 °C, 0.05 Torr Hg), m.p. 88–88.5 °C (83–84 °C [7]). Analytical and spectroscopic data were in agreement with the literature information.

[9] ^{1}H NMR spectroscopic analysis indicates the presence of approximately one HMPA ligand per five $Li^{\oplus}$ ions in part of the bulk crystalline sample. However, there is no evidence that the single crystal used for structural analysis contains similar amounts of HMPA. The maximum residual electron density in the final ΔF map 0.14 e Å^{-3}.

[10] The monolithiation of **1** has been previously reported (P. L. Anelli, F. Montanari, S. Quici, *J. Org. Chem. 50* (1985) 3453) as an intermediate step in the synthesis of [1.1.1]cryptates, but no isolation or characterization of the lithium amide was mentioned. Treatment of monoaza[18]crown-6 with KH has been shown to afford a potassium amide which acts as a self-solvating base for a number of reactions, including 1,2-eliminations (G. W. Gokel, B. J. Garcia, *Tetrahedron Lett. 1977*, 317; R. A. Bartsch, D. K. Roberts, *ibid. 1977*, 321). Not unrelated structurally are the aminoalanes obtained on reaction of organoaluminum species with macrocycles (e.g., 1,4,8,11-tetraazacyclotetradecane, cyclam) and open-chain tetradentate

amines (G. H. Robinson, S. A. Sangokoya, *J. Am. Chem. Soc. 109* (1987) 6852; *Organometallics 7* (1988) 1453; G. H. Robinson, A. D. Rae, C. F. Campana, S. K. Byram, *ibid. 6* (1987) 1227; G. H. Robinson, S. A. Sangokoya, F. Moise, W. T. Pennington, *ibid. 7* (1988) 1887; S. A. Sangokoya, F. Moise, W. T. Pennington, M. F. Self, G. H. Robinson, *ibid. 8* (1989) 2584; G. H. Robinson, M. F. Self, S. A. Sangokoya, W. T. Pennington, *J. Am. Chem. Soc. 111* (1989) 1520).

[11] All the known complexes of $Li^{\oplus}$ with neutral crown ethers are monomers, usually with the $Li^{\oplus}$ ion separated from its anion, though occasionally with $Li^{\oplus}$–anion contacts (e.g., [12]crown-4-LiSCN; P. Groth, *Acta Chem. Scand. 35* (1981) 463). See also S. M. Doughty, J. F. Stoddart, H. M. Colquhoun, A. M. Z. Slawin, D. J. Williams, *Polyhedron 4* (1985) 567; I. Goldberg in S. Patai, Z. Rappoport (Eds.): *Crown Ethers and Analogs*, Wiley Interscience, Chichester 1989; p. 207]. Binuclear (as opposed to dimeric) complexes of dications with neutral crown ethers are known for the heavier alkali-metal cations and very large crown ethers (e.g., dibenzo[30]crown-10 · $(NaNCS)_2$, J. D. Owen, M. R. Truter, *J. Chem. Soc. Dalton Trans. 1979*, 183). In the context of metalated crown ethers, the closest analogies to **3** for which X-ray structural data are available are (1) a benzene sulfonate crown ether species containing a $C_6H_3SO_3^{\ominus}Li^{\oplus} \cdot H_2O$ unit wherein the $Li^{\oplus}$ ion is bonded to only two of the crown ether oxygens, with loose association being effected by intermolecular $SO_3^{\ominus} \cdots H_2O$ hydrogen bonding (J. van Eerden, M. Skowronska-Ptasinka, P. D. J. Grootenhuis, S. Harkema, D. N. Reinhoudt, *J. Am. Chem. Soc. 111* (1989) 700), and (2) a MgBr benzo crown ether containing a $C_6H_3^{\ominus}$ $(MgBr)^{\oplus}$ unit in which the $Mg^{2\oplus}$ ion is coordinated to all four oxygen centers, the complex remaining monomeric (P. R. Markies, O. S. Akkerman, F. Bickelhaupt, W. J. J. Smeets, A. L. Spek, *J. Am. Chem. Soc. 110* (1988) 4284).

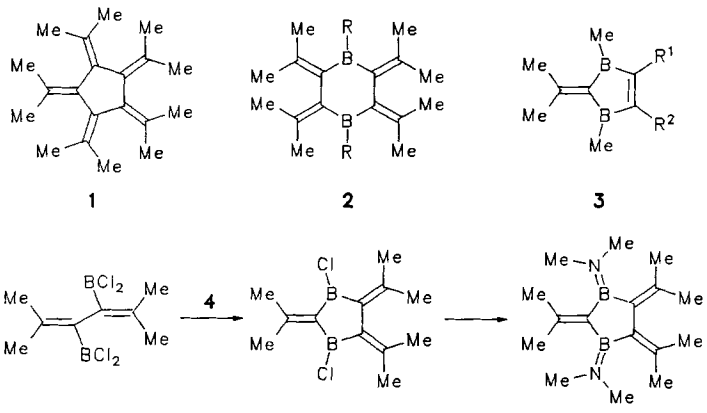
[14] Attempts to isolate a dilithiathed crown ether complex have, to date, invariably resulted in the rapid formation of insoluble oligomeric materials. Further studies are in progress.

[15] Mixed-metal crown ether complexes should have interesting properties as superbases (A. Mordini, E. Ben Rayana, C. Margot, M. Schlosser, *Tetrahedron 46* (1990) 2401; C. Margot, M. Rizzolio, M. Schlosser, *ibid. 46* (1990) 2411; C. Margot, H. Matsuda, M. Schlosser, *ibid. 46* (1990) 2425, and references therein).



Scheme 1. Synthesis of 1,3-dibora[5]radialenes **6** from 3,4-bis(dichlorboryl)-2,5-dimethyl-2,4-hexadiene **5** and 2-methyl-1,1-bis(trimethylstannyl)propene **4** [5]. **6a**: 3,4-dilithio-2,5-dimethyl-2,4-hexadiene [4], $B(OMe)_3$, TMEDA, 0 °C → 3,4-bis(dimethoxyboryl)-2,5-dimethyl-2,4-hexadiene, 48%, b.p. 85 °C/5 torr; OCH_3Cl exchange with BCl_3 → **5**, 72%, b.p. 65 °C/0.6 torr; ring closure of **5** with **4**, pentane → **6a**, 40%, b.p. 80 °C/10^{-3} torr. **6b**: **6a**, 2 MeLi, − 50 °C, pentane → **6b**, 90%, b.p. 70 °C/10^{-3} torr. **6c**: **6a**, 2 Me_3SiNMe_2, *n*-hexane, 70 °C → **6c**, 92%, b.p. 85 °C/10^{-3} torr, m.p. 75 °C (ether, − 20 °C).

Synthesis, Structure, and Rearrangement of 1,3-Dibora[5]radialenes**

By *Markus Enders, Albrecht Krämer, Hans Pritzkow*, and *Walter Siebert**

Dedicated to Professor Max Schmidt on the occasion of his 65th birthday

Radialenes are of interest in many respects because of their reactivity and electronic structure.[1] Metal-catalyzed oligomerizations of cumulenes on nickel(0)[1, 2] have recently enabled simple syntheses of [4]- and [6]radialenes, and the decamethyl[5]radialene **1** could be obtained for the first time via $(Me_2C=CBr)_2CuLi$.[3] Despite the numerous heteroradialenes reported in the literature, thus far only one boron-containing radialene has been documented. We report here the synthesis of the 1,3-dibora[5]radialene **6** from the versatile diene **5** (Scheme 1). Attempts to synthesize **6** from 3,4-dilithio-2,5-dimethyl-2,4-hexadiene and $Me_2CC=CC(BClR)_2$ analogously to the route leading to 1,4-dibora[6]radialene **2** ($R = CMe_3$, NPh_2) described by *Maercker* et al.[4] failed. We therefore examined the reaction of bis(trimethylstannyl)propene **4**[5] with 3,4-bis(dichloroboryl)-2,5-dimethyl-2,4-hexadiene **5**, and indeed obtained the dibora[5]radialene **6a** in 40% yield. Substitution of the chlorine atoms in the yellow distillable **6a** by methyllithium leads to the light yellow octamethyl derivative **6b**; with Me_3SiNMe_2 the bis(dimethylamino) compound **6c** isoelectronic with **1** is formed.

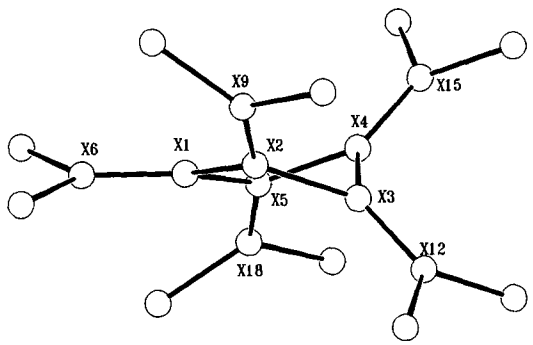


Fig. 1. Molecular structure of **6c**. The two independent molecules have approximately the same conformation, with a twofold axis through X1 and the midpoint of X3–X4. Averaged distances [Å] (standard deviation 0.005 Å): X1-X2(X5) 1.587, X1-X6 1.401, X3-X4 1.586, X3(X4)-X12(X15) 1.368, X2(X4)-X3(X5) 1.546 (individual values 1.522, 1.549, 1.566), X2(X5)-X9(X18) 1.353.

The constitution of **6a–c** follows from the spectroscopic data (Table 1); the X-ray structure analysis[6] of **6c** shows that the five-membered ring is not planar, but has the half-chair conformation (Fig. 1). The expected differences in the lengths of the C–C and B–C bonds in the ring and the exocyclic C=C and B=N bonds are small. According to MNDO calculations[7] several conformers are possible, all of which are half-chair shaped and thus have a similar struc-

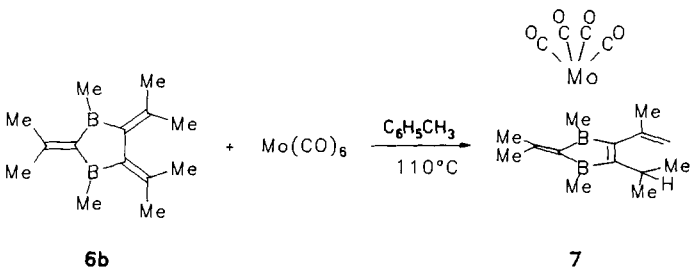
[**] This work was supported by the Deutsche Forschungsgemeinschaft (SFB 247), by the Fonds der Chemischen Industrie, and by BASF AG (Ludwigshafen).

ture and the same spatial demand. The result of the X-ray structure analysis can be explained in terms of a superposition of several conformers and therefore does not provide any accurate information about the bond lengths and angles.

Prolonged heating (10 d/110 °C) of **6b** in toluene leads, because of steric interaction of the neighboring dimethylmethylene groups, to a mixture of substances, from which the 1,3-diborafulvene **3b** (R^1 = MeC=CH_2, R^2 = $CHMe_2$) is isolated in 64% yield.[8] The formation of **3b** as a result of



6b **7**

Scheme 2. Synthesis of the tetracarbonyl(1,3-diborapentafulvene)molybdenum complex **7**: **6b** and $Mo(CO)_6$ in toluene, 110 °C, 4 h → orange **7**, column chromatography (SiO_2, hexane), 85%, m.p. 77 °C (hexane, − 20 °C).

a sigmatropic 1,5-H-shift proceeds much more rapidly in the presence of metal complex fragments: Reaction with hexacarbonylmolybdenum in toluene (110 °C) leads within a few hours to formation of the 1,3-diborafulvenemolybdenum complex **7** (Scheme 2), which was also characterized by an X-ray structure analysis.[9]

1,3-Dibora[5]radialenes **6** are thus excellent educts for the synthesis of unsymmetrically substituted 1,3-diborafulvenes **3**. Furthermore, they have great potential for the synthesis of novel carbaboranes (by hydroboration) and metallacarbaboranes (by hydrometalation).

Table 1. ^{1}H-, ^{11}B- and ^{13}C-NMR data of **6a**, **6b**, **6c** and **7**.

6a: ^{1}H NMR ($CDCl_3$): δ = 1.67 (s, 6H), 2.17 (s, 6H), 2.44 (s, 6H). ^{11}B NMR ($CDCl_3$): δ = 60.5. ^{13}C NMR (C_6D_6): δ = 23.4 (CH_3C), 25.7 (CH_3C), 28.5 (CH_3C), 146.1 (C_{exo}), 185.1 (C_{exo}), 153 (br, C_{ring})

Synthesis of a Novel Macrobicyclic Cavity Possessing Six Convergent Hydroxyl Groups and Acting as a Siderophore

By *Jean Louis Pierre*,* *Paul Baret* and *Giselle Gellon*

Naturally occurring and synthetic ferric ion chelators, like siderophores, are currently of great interest because of their biochemical role in microorganisms[1, 2] and plants,[2] their potential applications in the treatment of iron overload disease,[3, 4] and their use both as NMR contrast agents[5] for the imaging of organs and tumors in the human body[4] and as anticancer drugs.[1, 6] The natural and synthetic siderophores containing catecholate or hydroxamate donor groups are not ideal drugs (desferrioxamine B, for example, needs to be infused for 6–12 h per day because of its very short half-life in the body; catecholates are air sensitive); thus it is a stimulating challenge to synthesize new families of such molecules.

The pioneering work of *Vögtle* et al.,[7] *Raymond* et al.,[8] and *Martell* et al.[9] suggested to us the ultimately successful synthesis of macrobicyclic siderophores which contain 2,2'-dihydroxybiphenyl groups. Incorporation of three such subunits in a macrobicycle effectively produces six convergent phenolate groups as potential coordination sites; in addition, with such groups the often observed facile oxidation of the subunit (e.g. catechol group) may be attenuated.

The synthesis of the bicapped ligand **1a** was carried out by the high-dilution technique, as well as in high yield through a template reaction. The methyl-protected macrobicyclic derivative **1b** was obtained from the tripodal precursor **2b** by high-dilution (benzene) route in 25% yield. Removal of the

Université Joseph Fourier
B.P. 53X, F-38041 Grenoble Cédex (France)

methyl protecting groups (BBr_3, $CHCl_3$) then gave **1a** in 70% yield. The ^1H and ^{13}C NMR spectra of **1a** (in D_2O/NaOD) and of **1b** (in $CDCl_3$) reflect the symmetry of the molecules. The methoxyl groups are magnetically equivalent in **1b**, but in the open-chain triester precursor **2b**, two

4f: R = H; X = X′ = $N(Me)_2$

Scheme 1.

The template synthesis was performed through the key compound **4e** (Scheme 1) by using the elegant procedure of *Raymond*.[10] The template-reaction step (**4e**, $N(CH_2CH_2NH_2)_3$ (tren), $FeCl_3$, Et_3N, DMF, 4-dimethylaminopyridine) gave the red ferric complex of **1a** in nearly quantitative yield. The colorless product **1a** obtained on demetalation ($Na_2S_2O_4$, HCl, DMSO) was identical to that secured from the stepwise synthesis. The ferric complex could be prepared from **1a** through an exchange procedure involving ferric acetylacetonate;[11] this method avoided the initial basic conditions required for dissolving the chelator. The FAB mass spectrum of the complex corroborated the 1:1 stoichiometry $[M - 4H + Fe]$. The UV/VIS spectrum of the iron(III) complex of **1a** in acetonitrile solution showed an absorption ($\lambda_{max} = 464$ nm, $\varepsilon \approx 870$), similar to that observed with compound **4f**. Competition experiments in water at pH 11.5 between **1a** and either EDTA or desferrioxamine-B attest the great stability of the Fe^{III} complex with this new ligand. The UV/VIS absorption curve of a solution containing equimolecular amounts of EDTA and **1a** is similar to that of the pure Fe^{III} complex of **1a**. With desferrioxamine B, the absorption ($\lambda = 430$ nm) is shifted to longer wavelength ($\lambda = 460$ nm) upon addition of **1a**.

The determination of stability constants and protonation constants is in progress, as are electrochemical, biochemical and structural studies.

Experimental Procedure

The derivatives of **4** are defined in Scheme 1. **3** was obtained from dibenzofuran: a) *s*-BuLi, TMEDA, Et_2O; b) CO_2; c) $H_3O^{\oplus}$; d) NaOH/KOH fusion; e) $H_3O^{\oplus}$ (overall yield = 83%).

4e was obtained from **3**: a) $PhCH_2Br$, K_2CO_3, acetone; b) NaOH, methanol; c) $H_3O^{\oplus}$; d) *N*-hydroxysuccinimide, dicyclohexylcarbodiimide, dioxane; e) H_2/Pd-C, dichloromethane (overall yield = 41%).

The podand **2b** was prepared from **4b**: tren, Et_3N, THF; 76%; **4b** was obtained from **3** via **4a**: a) Me_2SO_4, K_2CO_3, acetone; b) NaOH 1 eq., methanol; c) $H_3O^{\oplus}$; d) $SOCl_2$ (overall yield = 45%).

The macrocycle **1a** was recrystallized from methanol/ether; **1b** was purified by chromatography (silica gel, CH_2Cl_2/$iPrNH_2$).

1a: ^1H NMR (300 MHz, D_2O, NaOD): $\delta = 8.02$ (d, $J = 7.4$ Hz, 6H, Ar-H4), 7.43 (d, $J = 7.4$ Hz, 6H, Ar-H6), 6.87 (t, $J = 7.4$ Hz, 6H, Ar-H5), 3.85 (m, br, 12H, CH_2NH), 3.26 (m, br, 12H, CH_2N); ^{13}C NMR (75 MHz, D_2O, NaOD): $\delta = 169.8$ (C = O), 159.5 (Ar-C2), 134.8, 130.6, 128.6, 119.7, 117.1 (Ar-C1, 3, 4, 5, 6), 51.1 (NHC), 37.0 (NC); MS(FAB): *m/z* 1007. Enzymatic Synthesis of Chiral C_4 Building Blocks from *meso*-Tartaric Acid

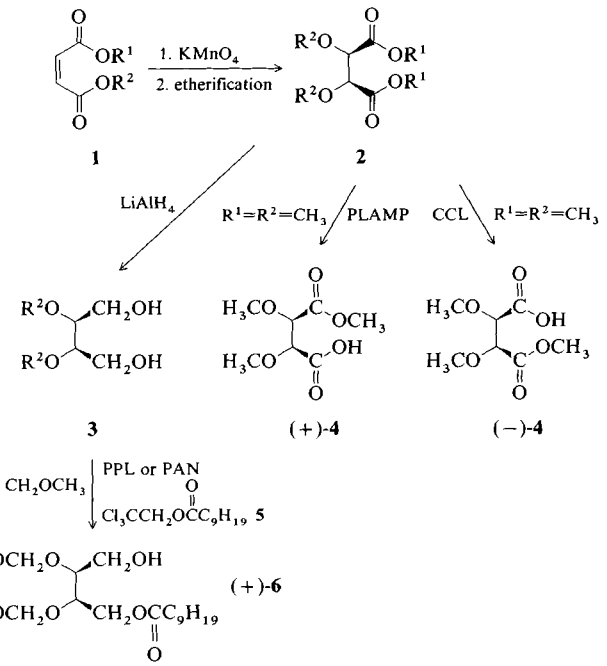
By *Hans Jürgen Bestmann** and *Ulrich Christian Philipp*

The use of optically active (*R,R*)- and (*S,S*)-tartaric acids as chiral starting compounds for a diversity of syntheses is well documented.[1] In contrast, the conversion of *meso*-tartaric acid into chiral building blocks has so far remained an unsolved problem, if one disregards an earlier resolution of the monomethyl ester with strychnine (without determination of the absolute configuration)[2] and an enzymatic hydrolysis of the dimethyl ester to the monomethyl ester with moderate *ee* value (48%).[3]

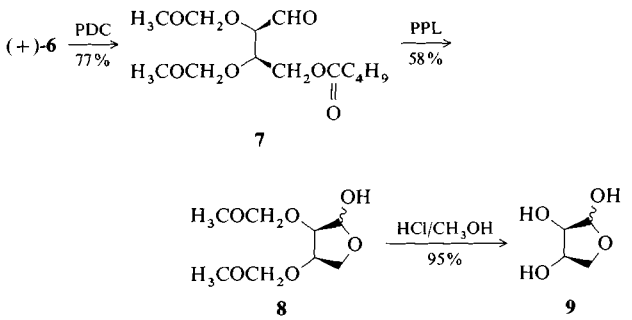
[*] Prof. Dr. H. J. Bestmann, Dr. U. C. Philipp
Institut für Organische Chemie der Universität Erlangen-Nürnberg
Henkestrasse 42, W-8520 Erlangen (FRG)

By reaction of maleic esters **1** with potassium permanganate in aqueous solution we have prepared isomer-free *meso*-tartaric acid ester, protected the OH groups in various ways, and subjected the compounds **2** so obtained to a screening with several enzymes. Of the results, we describe here only the most favorable.[4]

meso-Dimethoxysuccinic acid dimethyl ester **2** ($R^1 = R^2 = CH_3$) is hydrolyzed by porcine liver esterase [as porcine liver-acetone powder (PLAMP)[5, 6] in 0.1 N phosphate buffer at pH = 7 in the presence of 20% methanol] at the pro-*S* ester group to give (+)-**4** with an *ee* value of 90.5% and a chemical yield > 90%.[7] In contrast, lipase from *Candida cylindrecea* (CCL, sigma type VII), in the absence of methanol, attacks the pro-*R* ester group. (−)-**4** is obtained with an *ee* value of 92.5% in a yield of > 90%. The determination of the absolute configuration of (+)-**4** and (−)-**4** was accomplished by application of the Freudenberg shift principle[8] by comparison of the change in molecular rotation during the transition from *R,R*-2,3-dimethoxysuccinic acid dimethyl ester to the corresponding (*R,R*)-monoester with the signs of the rotation of (+)-**4** and (−)-**4**. The *ee* values were determined by gas chromatography of the diastereomeric (*S*)-1-phenylethylamides, which were prepared from (+)-**4** and (−)-**4** and (*S*)-1-phenylethylamine by reaction with propanephosphinic acid anhydride and *N*-methylmorpholine[9] in methylene chloride.



In addition, we have converted the diesters **2** with lithium aluminum hydride into the diols **3** and again carried out a screening—in this case of the enzymatic nonacylation—the following result being the most favorable: by reaction of the readily cleavable acetalic methoxymethyl protecting group in **3** ($R^2 = CH_2OCH_3$) with 2,2,2-trichloroethyl deconoylate **5** in the presence of PPL or pancreatin from porcine pancreas (PAN, Fluka), an acylation of the pro-*R*-CH_2OH group leads to (+)-**6**.[10] The *ee* value is 95% and the chemical yield 90%. The determination of the absolute configuration of (+)-**6** was achieved by conversion into D-(−)-erythrose in three steps: (+)-**6** was converted with pyridinium chromate (PDC) into the aldehyde **7** (brownish oil), which, without further purification was hydrolyzed with PPL at pH = 7 in phosphate buffer to the mixture of diastereomers **8** (colorless liquid, purified by chromatography on silica gel 60 with petroleum ether/ether 1:1, $[\alpha]_D = +9.00$, $c = 1.3$, in $CHCl_3$). Reaction of **8** with HCl/methanol afforded D-(−)-



erythrose, whose rotation, ^{1}H-NMR spectrum, and TLC retention time (mixed chromatogram) were identical with authentic material. The *ee* value of (+)-**6** was determined via the diastereomeric Mosher effect.[11]

Experimental Procedure

All experiments were carried out on the 10 mmol scale.

Enzymatic hydrolysis: The diester **2**, $R^1 = R^2 = CH_3$ (10 mmol) was dissolved, emulsified or suspended in 0.1 N phosphate buffer (pH = 7.0, 30 mmol) and treated with 500 U of the enzyme. During the reaction, the temperature and pH value were kept constant [thermostat and autotitrator (1.00 N NaOH), respectively]. The reaction mixture was worked-up when the reaction had come to a standstill, i.e. when no more sodium hydroxide was titrated. The mixture was first saturated with NaCl and continually extracted with ether at pH = 7.0 to remove any diester **2** that had been formed. The semiester was then continually extracted at pH = 4.0 (autotitrator, 2 N H_2SO_4). Finally, the organic phase was dried with $MgSO_4$ and freed from ether. The product could be used for further reactions without additional purification.

(+)-**6**: A mixture of 2.10 g of diol **3**, $R^2 = CH_2$-O-CH_3, 12 mL of 2,2,2-trichloroethyl decanoylate, and 2.0 g of PPL in 100 mL of anhydrous THF was stirred for 5 d at room temperature in the dark. The enzyme was then filtered off and the clear solution freed of THF. The residue was then subjected to column chromatography (silica gel 60; eluent: 1. petroleum ether/ether/triethylamine 200:100:1; 2. ether/triethylamine 200:1). Yield: 3.27 g (90%).

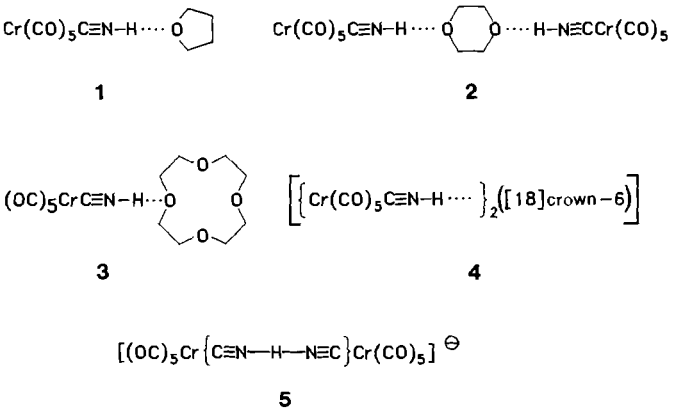
Molecular and Ionic Hydrogen Isocyanide (CNH) Adducts with N-H···O- and "Super-Short" N-H···N-Hydrogen Bridges: Metal-Stabilized Hydrogen Bisisocyanides**

By *Eberhard Bär, Joachim Fuchs, Dirk Rieger, Francisco Aguilar-Parrilla, Hans-Heinrich Limbach,* and *Wolf P. Fehlhammer**

Short and super-short hydrogen bonds, particularly as occur in homonuclear molecule-ion associates AHA$^{\ominus}$ (A$^{\ominus}$ = anion base, e.g. Hal$^{\ominus}$) and BHB$^{\oplus}$ (B = neutral base, e.g. N-heterocycle), are currently a subject of intensive theoretical and experimental investigations.[1] Interest in H-bridged *cyanide* and *hydrogen cyanide* systems[2] may well originate from their capability of spontaneous aggregation and self-condensation to give biologically relevant secondary products $[HCN]_n$ (n, e.g., 2, 5(adenine),[3] and greater) rather than from mere bonding aspects. This property is in turn closely coupled with the question of chemical evolution.[4, 5]

Hydrogen isocyanide (HNC), which has only recently been discovered in interstellar clouds, is also connected with prebiotic organic synthesis.[6] We discovered the marked tendency of this acid to form hydrogen bonds during an attempted preparation of $[Cr(CO)_5CNH]$ in THF, when instead the sublimable (!) etherate **1** was obtained. On the strength of this finding we carried out directed syntheses of further adducts with cyclic ethers (e.g. **2**) and crown ethers (**3**, **4**), which selectively take up one or two hydrogen isocyanide complex molecules, respectively.[7] In the case of **2** we determined X-ray crystallographically an N(H)···O distance of 2.877(11) Å,[8] whose very small difference from the sum of the van-der-Waals radii of nitrogen and oxygen (2.93 Å) is indicative of only a weak H bond. Due to the low quality of the intensity data, however, this value should be regarded with some reservation.

We expected to find stronger hydrogen bonding in adducts of the (at least formally) symmetric type AHA$^{\ominus}$ **5** (A$^{\ominus}$ = $[Cr(CN)(CO)_5]^{\ominus}$), which should be formed from pentacarbonyl(hydrogen isocyanide)chromium and its conjugate base. It has long been known that such structural units are present in the crystal lattice of "cyanometallic acids" and determine their coordination polymeric structure.[9] The N(H)···N distances in this type of bridge are very short; the shortest distance measured so far is that in the highly symmetric, three-dimensionally H-cross-linked $H_3[Co(CN)_6]$ (2.582(4) Å).[10] In this connection, the prediction of a surprisingly high stability for $[NCHCN]^{\ominus}$[2c] warrants attention, which might even be surpassed by the stability of the "iso form" $[CNHNC]^{\ominus}$.[11]



Indeed, yellow (**5a**, $ER_4 = NEt_4$) or colorless (**5b**, $ER_4 = AsPh_4$) products having all the properties required of the *metal-stabilized hydrogen bisisocyanide ion* **5** crystallize from ether-layered CH_2Cl_2-solutions of equimolar amounts of $[Cr(CO)_5CNH]$ and $(ER_4)[Cr(CN)(CO)_5]$. In the first place, the ν(NH) absorption bands are broadened and shifted to long wavelengths such as to develop an absorption continuum which superimposes the IR region from about 1800 to 300 cm^{-1}. Also the downfield shifts of the ^{1}H-NMR signals of the hydrogen bridge protons (δ = 11.2 (**5a**), 11.9 (**5b**)), which are larger than those of the NH···O adducts **1**–**4** by a good 2 ppm, point to strong hydrogen bonding. That the hydrogen bonds, moreover, are symmetrical, is indicated by the appearance of only one set of ^{13}C-NMR res-

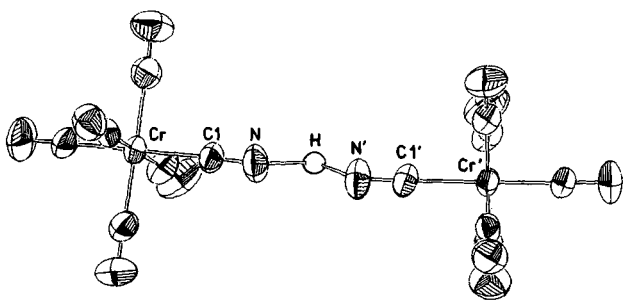


Fig. 1. Structure of **5** in crystals of **5b** (ORTEP, ellipsoids at the 50% probability level). Space group $P2/n$, a = 11.295(2), b = 6.817(1), c = 24.476(6) Å, β = 100.85(1)°, V = 1850.9 Å^3, Z = 2; 2824 measured reflections, 2552 observed ($I > 2\sigma(I)$), 271 refined parameters, R = 0.056 (R_w = 0.054). Selected bond lengths [Å] and angles [°]: Cr–C(O)$_{trans}$ 1.847(6), Cr–C(O)$_{cis}$ (average value) 1.894, Cr–C1 2.012(6), C1–N 1.167(8), N···N' 2.569(7); Cr–C1–N 178.8(5). The H position taken from the difference Fourier synthesis and refined (y coordinate) is associated with a high temperature factor and is therefore not reliable (cf. text).

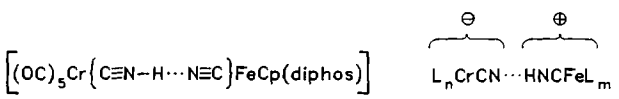
[**] Chemistry of Hydrogen Isocyanide, Part 7. This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and the Graduiertenkolleg "Synthese und Strukturaufklärung niedermolekularer Verbindungen.—Part 6: D. Rieger, F. E. Hahn, W. P. Fehlhammer, *J. Chem. Soc. Chem. Commun. 1990*, 285.

onance signals ($\delta = 157.4$ s (CN), 216.5 CO_{cis}), 219.1 (CO_{trans}) and by the band-deficient IR and Raman spectra.

The X-ray structure analysis of **5b** (Fig. 1)[12] confirms the strong bridge bond: the N(H)···N distance of 2.569(7) Å is even less than that in $H_3[Co(CN)_6]$. Since the bridge H-atom could not be localized with certainty, however, the question of its symmetrical arrangement had to remain open for the time being. In any case, no decision can be made as to whether the bridge H atom moves in a single or a double minimum potential, because of the crystallographic symmetry element (C_2) coinciding with the bridge midpoint.[13, 10b]

The method of choice for obtaining detailed information about proton motions in NH···N hydrogen bridges is currently high-resolution solid-state ^{15}N-CPMAS-NMR spectroscopy (^1H cross polarization (CP), sample rotation about the magic angle (MAS)) with ^1H decoupling.[14] The spectra[15] of the reference compounds $[Cr(CO)_5C^{15}NH]$ and $NnPr_4$ $[Cr(C^{15}N)(CO)_5]$ measured at 25 °C each show one singlet, at $\delta \approx 135$ and 273, respectively. In contrast, the two nitrogen atoms of ^{15}N-labeled **5b** (= **5b'**) give rise to only *one* line at $\delta = 193$ ($\nu_{1/2} = 38.5$ Hz), i.e. they are (as to be expected from the X-ray structure analysis of **5b**) chemically equivalent. The value of $\delta = 193$ is reconcilable both with a symmetrical double minimum potential with small energy barrier as well as with a single minimum potential for the proton motion. Surprisingly, however, two signals are observed at $\delta = 209$ ($\nu_{1/2} = 50.2$ Hz) and 178 ($\nu_{1/2} = 53.5$ Hz) in the case of **5a'** (= ^{15}N-labeled **5a**). This means that the established chemical equivalence of the two nitrogen atoms in **5b'** does not apply here due to interactions between the ions; the average distances between the bridge H-atom and the two nitrogen atoms are no longer identical. Measurements at several temperatures showed that the signal splitting observed in the case of **5a'**, in contrast to that of other NH···N hydrogen bridges perturbed by intermolecular interactions, is temperature independent. We regard this as a first indication that the proton motion in **5a** is a result of an unsymmetrical single minimum potential.

The handicap of an enforced crystal symmetry (see **5b**) does not apply in the heterodinuclear *neutral* adduct **6** (diphos = bis(diphenylphosphino)ethane, for which one



6 **7**

naturally does not expect an ideally symmetrical H-bridge either. Nevertheless, it is surprising at first sight, how asymmetrically the unequivocally established bridge H-atom here is located between the very close cyano N atoms (Fig. 2).[12] In view of the charge separation, which should effect a shift of the bridge H-atom in the direction of the iron atom (see **7**), the structural variety of the hydrogen bisisocyanide **6** contrary to **5** does not, however, seem unlikely. Both the asymmetry and the strength of this NH···N bond are also reflected in the IR and NMR spectra of **6**, which show markedly separated ν(CN) bands [(Nujol): $\tilde{\nu} = 2122$ s, 2070 w cm^{-1}] and CN signals [$\delta(^{13}C) = 156.9$ (s, CrCN), 161.7 (t, $J = 30.5$ Hz, FeCN)] besides the characteristic NHN absorption continuum ($\tilde{\nu} = 1300-300\ cm^{-1}$) and downfield shift ($\delta(^1H) = 11.4$).

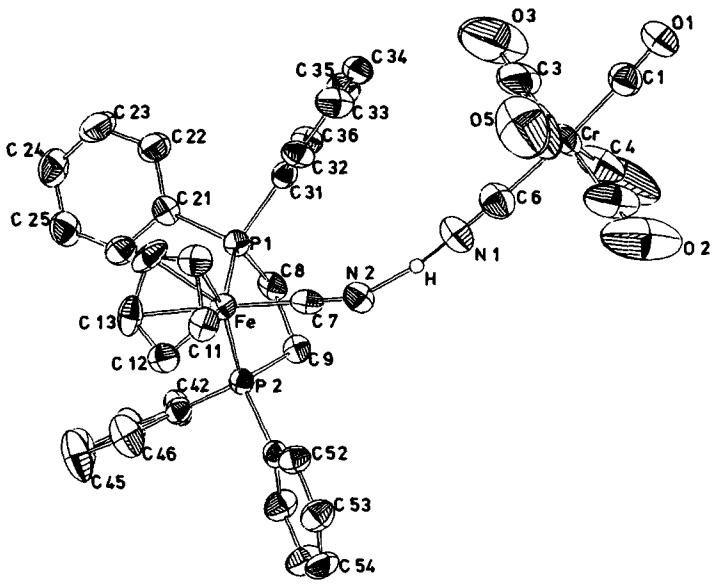


Fig. 2. Molecular structure of **6** (ORTEP), ellipsoids at the 50% probability level). Space group $P\bar{1}$, $a = 8.919(2)$, $b = 15.617(4)$, $c = 15.809(5)$ Å, $\alpha = 111.68(2)$, $\beta = 101.88(2)$, $\gamma = 96.49(2)°$, $V = 1958.65$ Å^3, $Z = 2$; 4950 measured reflections, 4188 observed ($I > 2\sigma(I)$), 593 refined parameters, $R = 0.062$ ($R_w = 0.064$). Selected bond lengths [Å] and angles [°]: Cr–C1 1.846(11), Cr–$C(O)_{cis}$ (mean value) 1.854, Cr–C6 2.025(12), C6-N1 1.155(15), N1-H 1.17(14), H-N2 1.40(14), N1···N2 2.557(12), N2-C7 1.164(11), C7-Fe 1.855(9); Fe-C7-N2 177.9(6), C7-N2-H 157(4), N2-H-N1 171(9), H-N1-C6 178(5), N1-C6-Cr 178.5(8).

Experimental Procedure

3: Freshly sublimed $[Cr(CO)_5CNH]$ [17] (0.22 g, 1.00 mmol) was dissolved in ca. 5 mL of [12]crown-4, the excess ether removed in a vacuum, and the residue reprecipitated from CH_2Cl_2/*n*-hexane at −20 °C. There remained 265 mg (67%) of colorless crystals which melt without decomposition at 50 °C. IR (polyoil): $\tilde{\nu}$ [cm^{-1}] = 3200–2400 s, br. (NH···O) 2123, 2077 m, 2053 m–s, 1946 vs, br. (ν(CN) + ν(CO)); Raman (CH_2Cl_2): $\tilde{\nu}$ [cm^{-1}] = 2094 m,sh,p, 2088 s,p, 2036 s,p, 1993 s,dp, 1943 m,br.,dp (ν(CN) + ν(CO)); 270-MHz ^1H NMR ($CDCl_3$, 25 °C): $\delta = 9.2$ (s, br., NH···O), 3.6 (s, 16H, CH_2). sh = shoulder, p = polarized, dp = depolarized.

5b: A solution of $AsPh_4[Cr(CN)(CO)_5]$ (0.60 g, 1.00 mmol) in CH_2Cl_2 (20 mL) was filtered through a cellulose filter and added dropwise to a solution of freshly sublimed $[Cr(CO)_5CNH]$ (0.22 g, 1.00 mL) in CH_2Cl_2 (20 mL). The reaction solution was then carefully layered with ca. 30 mL of diethyl ether and cooled to −78 °C. A pale yellow solid was formed (0.45 g, 55% yield; m.p. 103 °C (decomp.)), which was collected on a glass frit and dried in a stream of argon.

6: A solution of $[Cr(CO)_5CNH]$ (220 mg, 1.00 mmol) and [Fe(CN)(Cp)diphos] [18] (545 mg, 1.00 mmol) in CH_2Cl_2 (20 mL) was layered with petroleum ether (40–60 °C). On cooling to −20 °C orange-red crystals were formed in about 80% yield. M.p. 150 °C (decomp.).

All the new compounds gave correct elemental analyses.

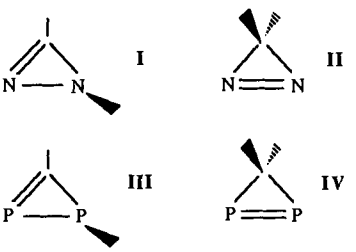
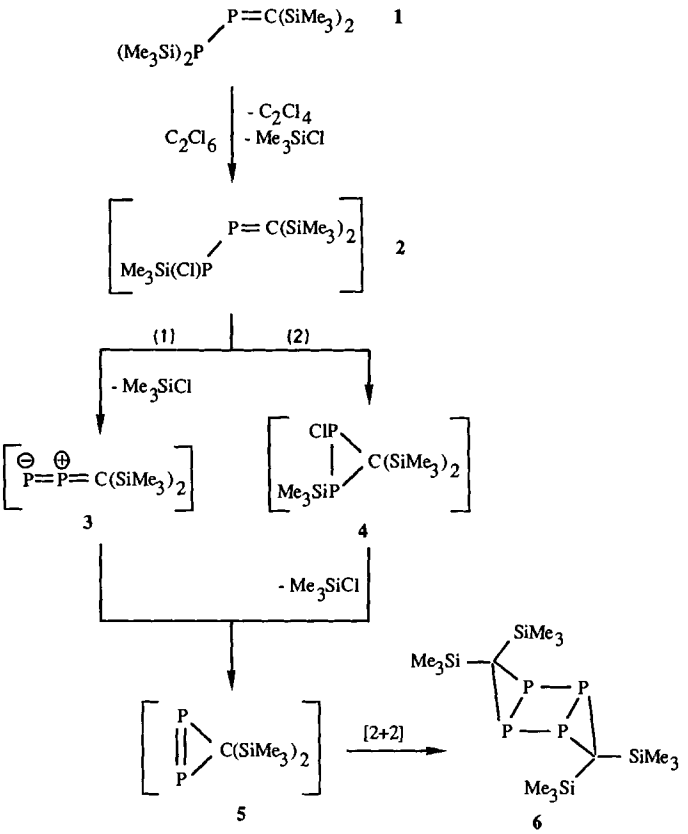
Formation of a *trans*-1,2,4,5-Tetraphosphatricyclo-[3.1.0.0^{2,4}]hexane by [2+2] Cyclodimerization of a 3*H*-Diphosphirene**

By *Edgar Niecke*,* *Rainer Streubel*, and *Martin Nieger*

Diazirines exist only in the 3*H* form **II** [1,2] and are widely used as precursors of electrophilic carbenes.[2] On the other hand, only the 1*H* isomer **III**, which corresponds to **I** and was recently obtained by phosphanediyl transfer starting from a halogen(silyl)phosphane and a phosphaalkyne,[3] is known for the homologous phosphorus compounds. Our investigations in this area were motivated by the possibility of preparing a 3*H*-diphosphirene **IV**, isomeric to **III**, in a corresponding way from an α-bifunctional 1,2-diphospha-2-propene(halogen(silyl)phosphinomethylenephosphane).



Reaction of the persilylated 1,2-diphospha-2-propene **1**[4] with hexachloroethane under mild conditions[5] results in elimination of chlorotrimethylsilane and formation of a product having the analytical composition of diphosphirene **5** but twice its molecular mass. The spectroscopic data all indicate the formation of the tricyclic system **6**, a cyclodimer of **5**.



Two pathways are conceivable for the formation of the diphosphirene intermediate **5**: (1) an α elimination of chlorotrimethylsilane from the 1,2-diphospha-2-propene intermediate **2** to give **3**, the diphospha analogue of a diazaalkane, followed by cycloisomerization of **3** to afford **5**—an isomerization similar to the vinylcarbene/cyclopropene rearrangement;[6] (2) a 1,2-chloro shift accompanied by cyclization to give the β-functional diphosphirane **4**, which subsequently loses chlorotrimethylsilane to yield **5**. The recently observed diphospha-2-propene/diphosphirane isomerization[7] makes the second pathway equally plausible. The reaction step leading from **5** to **6** is typical of diphosphenes with *Z* configurations;[8] for cyclopropene, this process is thermodynamically favored and can be initiated by catalysts.[9]

Anorganisch-chemisches Institut der Universität
Gerhard-Domagk-Strasse 1, W-5300 Bonn 1 (FRG)

[**] This work was supported by the Fonds der Chemischen Industrie.

The constitution of **6** was established by elemental analysis, the mass spectrum,[10] the relatively high-field position of the ^{31}P NMR signal ($\delta = -87.6$), and the appearance of two sets of pseudoquintets for the trimethylsilyl groups in the ^{1}H and ^{13}C NMR spectra.[11] The expected steric crowding of the molecule in *syn* form with two silyl groups in "flagpole" position, as well as the resulting repulsion between the lone pairs on the phosphorus atoms, favors an *anti* conformation for **6**. Its existence was confirmed by an X-ray structure analysis[12] (Fig. 1).

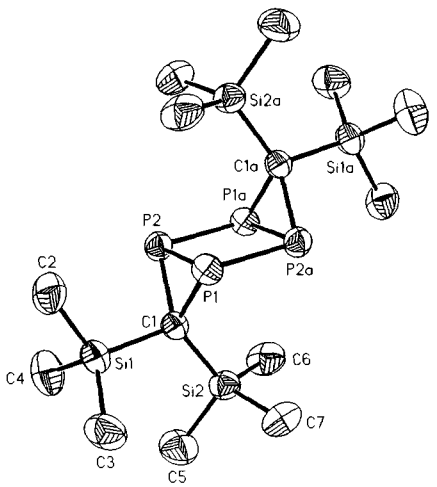

Fig. 1. Molecular structure of **6**. Important bond lengths [pm] and angles [°]: P1-P2 220.4(1), P1-P2a 224.5(1), P1-C1 187.1(3), P2-C1 187.3(3), C1-Si2 189.8(3), C1-Si1 192.4(3); P1-P2-P1a 90.2(1), P2-P1-P2a 89.8(1), P1-P2-C1, 53.9(1), P2-P1-C1 54.0(1), P1-C1-P2 72.1(1), C1-P1-P2a 102.0(1), C1-P2-P1a 102.3(1), P2-C1-Si1 104.8(1), P2-C1-Si2 129.0(1), P1-C1-Si1 106.3(1), P1-C1-Si2 121.4(1); Interplanar angle between the P1–P2–P1a–P2a and P1–P2–C1 planes 105°; angle between the P1–P2–C1 plane and the C1–Si2 bond 135°.

The molecule possesses C_1 symmetry in the solid state. The bonding in the diphosphirane framework, which exhibits an interplanar angle of 105° with respect to the planar P_4 framework,[13] is similar to that in the correspondingly substituted 1,2,3-triphosphabicyclo[1.1.0]butanes.[14] However, the two P–P distances (220.4(1) and 224.5(1) pm) are significantly different; the longer distance points to the formation of the cycloadduct from two molecules of **5**. Also noteworthy are the P–C–Si_{endo} angles (129.0(1) and 121.4(1)°), which are larger than the P–C–Si_{exo} angles (104.8(1) and 106.3(1)°). Two distinctly different C1–Si distances (192.4(3) and 189.8(3) pm) are therefore found.

Further investigations are necessary to determine to what extent this finding can be interpreted in terms of a polarization of the molecular structure toward formation of a diphosphiranylium ion in the solid state. The same holds true for the possible complex stabilization of the 3*H*-diphosphirene **5**.

Metal Carbonyl Complexes of Sapphyrins**

By *Anthony K. Burrell, Jonathan L. Sessler,* Michael J. Cyr, Ellen McGhee*, and *James A. Ibers**

Sapphyrin is a 22 π-electron pentapyrrolic "expanded porphyrin".[1] It has an N-center radius of about 2.7 Å. Consequently, one can anticipate a rich organometallic chemistry of sapphyrins, a chemistry that should differ from that of the smaller tetrapyrrolic porphyrins. Nevertheless, only a few metal complexes have been reported[1a] and these involve

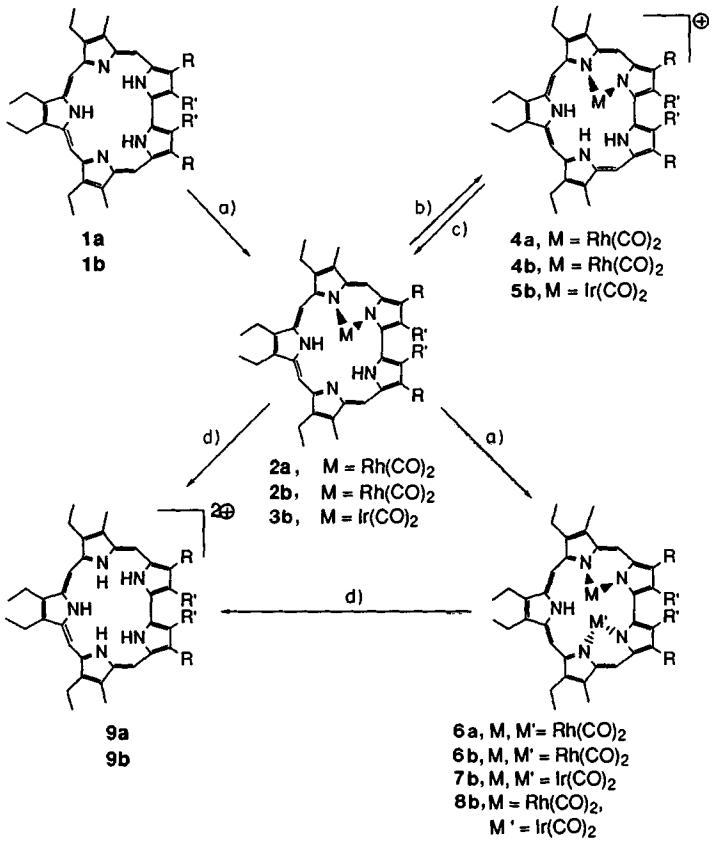
[**] This work was supported by the Texas Advanced Research Program (*J. L. S.*, grant number 1581) and by the NIH (*J. A. I.*, Grant HL 13157). *J. L. S.* also thanks the NSF for a Presidential Young Investigator Award (1986), the Alfred P. Sloan Foundation for a Research Fellowship (1989–1991), and the Camille and Henry Dreyfus Foundation for a Teacher-Scholar Award (1988–1922). *J. L. S., A. K. B.*, and *M. J. C.* are grateful to Prof. *E. Vogel*, Cologne, for the gift of a bipyrrole sample used to prepare sapphyrin **1a**.

primarily first-row transition metals with characterization limited to visible spectroscopy and mass spectrometry. The paucity of metal complexes of sapphyrin probably results from the difficulties associated with its preparation. We recently reported a convenient synthesis for sapphyrin,[2] which has enabled us to initiate studies of its organometallic chemistry. We expected second- and third-row transition metals to be the most promising for initial study, with metal carbonyls being particularly attractive owing to their successful use in the porphyrin series.[3]

When $[\{RhCl(CO)_2\}_2]$ and $[IrCl(CO)_2(py)]$ were allowed to react with the free-base sapphyrin macrocycles, H_3sap[4] (**1**), no evidence for "in-plane" products was obtained (Scheme 1). However, a wide variety of new complexes did result. For instance, addition of 0.5 equivalent of $[\{RhCl(CO)_2\}_2]$ or 1 equivalent of $[IrCl(CO)_2(py)]$ to a solution of **1** in CH_2Cl_2 containing a small amount of NEt_3[5] affords $[Rh(CO)_2(H_2sap)]$ (**2**) or $[Ir(CO)_2(H_2sap)]$ (**3b**).[6] During isolation and purification, **2** and **3b** are protonated to form the cationic complexes $[Rh(CO)_2(H_3sap)]^{\oplus}$ (**4**) and $[Ir(CO)_2(H_3sap)]^{\oplus}$ (**5b**).[6] The structures shown for **4** and **5b** (Scheme 1) were anticipated on spectroscopic grounds and were confirmed in a crystal structure determination of $[Ir(CO)_2(H_3sap)]Cl$[7] (Fig. 1). The ^1H NMR spectrum of **4**, for instance, indicates the presence of an unsymmetrical system. Four methyl signals along with four *meso*-proton signals are evident in the $\delta = 4.11-3.68$ and $\delta = 11.44-10.98$ regions, respectively. In addition, the three pyrrolic NH protons appear as three distinct signals at high field ($\delta = -2.60$, -2.71, -3.22), as would be expected for such an unsymmetrical protonated complex.



Scheme 1. Synthesis of sapphyrin complexes. a) $[\{RhCl(CO)_2\}_2]$, NEt_3 or $[IrCl(CO)_2(py)]$, NEt_3; b) silica gel; c) NEt_3; d) HCl. **a**, R = $CH_2CH_2CH_3$, R' = H; **b**, R = CH_2CH_3, R' = CH_3.

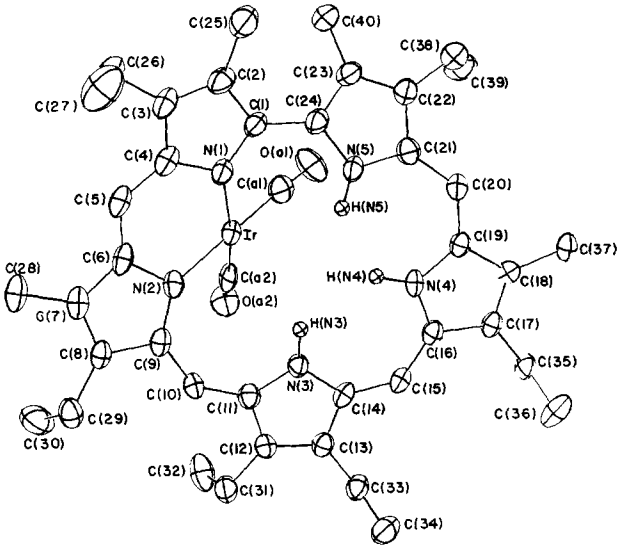


Fig. 1. Structure of $[Ir(CO)_2(H_3sap)]^{\oplus}$ (**5b**-Cl). The labeling scheme is shown. Here and in Figure 2 the 50% ellipsoids are shown, and all hydrogen atoms, save those in the core, are omitted for the sake of clarity.

Treatment of **2** with a further molar equivalent of $[\{RhCl(CO)_2\}_2]$ or reaction of **1** with an excess of $[\{RhCl(CO)_2\}_2]$ gives $[\{Rh(CO)_2\}_2(Hsap)]$ (**6**).[6] Similar chemistry in the iridium system leads to **7b**. An interesting feature of this step-by-step addition of metals is that the formation of a heterobimetallic complex is easily achieved. Either addition of $[IrCl(CO)_2(py)]$ to **2** or of $[\{RhCl(CO)_2\}_2]$ to **3b** results in the rapid formation of $[\{Ir(CO)_2\}\{Rh(CO)_2\}(Hsap)]$ (**8b**).[6] The structures shown for the complexes **6**–**8** (Scheme 1) were determined by spectroscopic means and were confirmed by a crystal structure determination of **6a** (Fig. 2).[8]

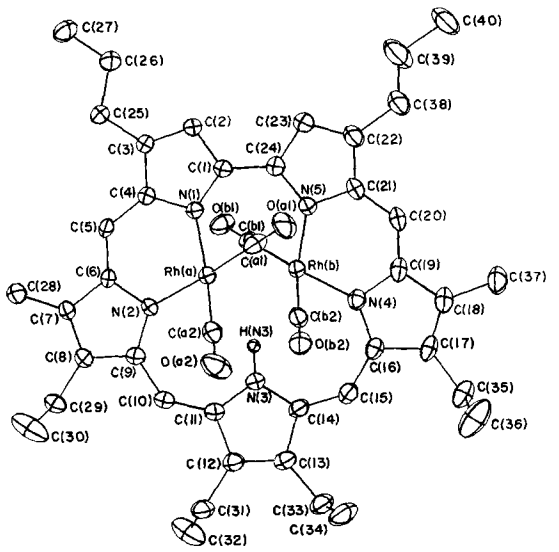

Fig. 2. Structure of $[\{Rh(CO)_2\}_2(Hsap)]$ (**6a**).

During the course of the reaction converting **1** into **4** via **2**, the position of the Soret-like band in the UV/VIS spectrum changes from approximately 450 nm to about 480 nm. The resultant changes in the ^1H NMR spectrum are again

consistent with the proposed structure, notably the return to C_2 symmetry. The addition of a second rhodium dicarbonyl fragment and formation of **6** causes this Soret-like band to shift still further to the red, to about 500 nm. The structures of **5b**-Cl and **6a** (Fig. 1 and 2, respectively) are similar to those of $[\{Rh(CO)_2\}_2(OEP)]$[9] and $[\{Rh(CO)_2\}_2(NMC)]$ (NMC = *N*-methylcorrole)[10] in that each metal center bridges an imine and an amine nitrogen atom. The Rh–N distances range from 2.061(4) to 2.081(4) Å, the Ir–N distances from 2.064(5) to 2.091(6) Å. The general geometry around the metal atoms is thus approximately square-planar, with the metal planes at an angle of roughly 47° to the plane of the sapphyrin. The sapphyrin plane is considerably ruffled, with the pyrrole rings distorted in such a way that the nitrogen atoms N1 and N2 are bent towards Rh(a) and Ir and the nitrogen atoms N4 and N5 are bent towards Rh(b). Maximum and average deviations from the N_5C_{24} plane are −0.425 and 0.264/0.054 Å, respectively, for Rh and −0.398(6) and 0.765(8)/0.206 Å, respectively, for Ir.

All of the sapphyrin complexes discussed here, with the exception of **2a** and **4a**,[6] show remarkable stability. The relatively high ν(CO) values indicate that at least one of the carbonyl groups bound to the rhodium center in either **4** or **6** should be easily displaced. To date, however, we have not seen any indication of either photolytic or thermal loss of CO from either **4** or **6**. Also, all of the coordination compounds reported here display much lower reactivity under oxidizing conditions (e.g., methyl iodide or acetic anhydride).[11] Reagents such as HCl cleave the metals to form protonated sapphyrins (**9**). Iodine reacts only slowly with **6** or **7**, removing one of the metal carbonyl moieties to afford **3** and **5b**, respectively. Furthermore, in preliminary studies we have found that complex **6** acts as an efficient homogeneous catalyst for the hydrogenation of alkenes.[12]

Experimental Procedure

5b: Sapphyrin **1b** (50 mg, 0.08 mmol) was dissolved in dichloromethane (15 mL) containing triethylamine (0.5 mL). $[IrCl(CO)_2(py)]$ (30 mg, 0.08 mmol) was added and the solution stirred at room temperature for 12 h. The solvent was removed in vacuo and the residue taken up in dichloromethane. Filtration through Celite, followed by chromatographic purification on silica gel using dichloromethane/methanol (9:1) as the eluent, gave the cationic iridium complex **5b** (62 mg) in 81% yield. Recrystallization from dichloromethane–methanol then gave analytically pure product (73% recovery). ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C, TMS): δ = 11.41 (s, 1H; *meso*), 11.15 (s, 1H; *meso*), 10.96 (s, 2H; *meso*), 4.55 (m, 8H; CH_2), 4.32 (m, 4H; CH_2), 4.09 (s, 3H; Me), 3.89 (s, 3H; Me), 3.83 (s, 3H; Me), 3.74 (s, 3H; Me), 2.16 (m, 12H; CH_3), 2.10 (m, 3H; CH_3), 1.74 (m, 3H; CH_3), −2.67 (s, 1H; NH), −2.96 (s, 1H; NH), −3.29 (s, 1H; NH). IR (KBr): ν[cm^{-1}] = 2044 (vs), 1967 (vs) (CO), 3156(w), 3100(w), 3114(w) (NH). MS (FAB): *m/z* 884 ($M^{\oplus}$), 819 ($M^{\oplus}$ − CO). VIS (CH_2Cl_2) λ_{max} (lgε) = 360 (4.23), 484 (5.62), 596 (3.00), 638 (3.60), 694 (3.96), 715 (3.94) nm. Correct elemental analysis (C,H,N).

6a: Sapphyrin **1a** (50 mg, 0.08 mmol) was dissolved in dichloromethane (15 mL) containing triethylamine (0.5 mL). $[\{RhCl(CO)_2\}_2]$ (40 mg, 0.1 mmol) was added and the solution stirred at room temperature for 12 h. The solvent was removed in vacuo and the residue taken up in dichloromethane. Filtration through Celite, followed by chromatographic purification on silica gel using dichloromethane as the eluent, afforded the dirodium complex **6a** (67 mg) in 88% yield. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C, TMS): δ = 11.34 (s, 2H; *meso*), 11.06 (s; 2H, *meso*), 10.20 (s, 2H; β-pyrrolic), 4.76 (m, 4H; CH_2), 4.65 (m, 4H; CH_2), 4.78 (m, 4H; CH_2), 4.04 (s, 6H; Me), 2.64 (m, 4H; CH_2), 2.24 (t, 12H; CH_3, J = 7.3) 1.37 (t, 12H; CH_3, J = 7.4), −3.54 (s, 1H; NH). IR (KBr): ν[cm^{-1}] = 2060, 1996 (CO), 3215 (NH), MS (FAB): *m/z* 917 ($M^{\oplus}$). VIS (CH_2Cl_2): λ_{max} (lgε) = 372 (4.65), 428 (4.68), 499 (5.32), 593 (3.08), 643 (3.74), 700 (5.74) nm. Correct elemental analyses (C,H,N)

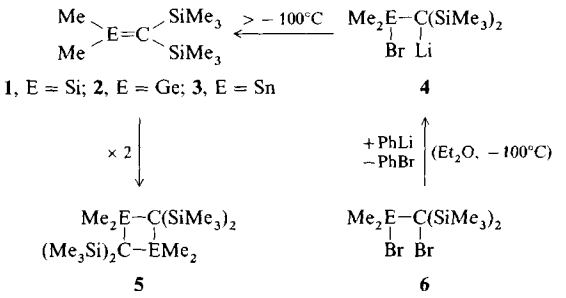
[**] Unsaturated Compounds of Silicon and Its Group Homologues, Part 37. Part 36: N. Wiberg, H. Schuster, *Chem. Ber. 124* (1991), in press.

to attempt the preparation of the stannaethene **3**, a further example of an unsaturated tin compound, by a corresponding route involving "thermal salt elimination" (the first stannaethene was synthesized by *A. Berndt* et al.[3]).

Indeed, **3** was generated similarly to **1** and **2** as shown in Scheme 1, via intermediate **4** (E = Sn), by dropwise addition of a solution of phenyllithium to a solution of the dibromo compound **6** (E = Sn) in diethyl ether at $-100\,^{\circ}C$; at low temperatures, **3** is a short-lived species that dimerizes to give **5** (E = Sn).

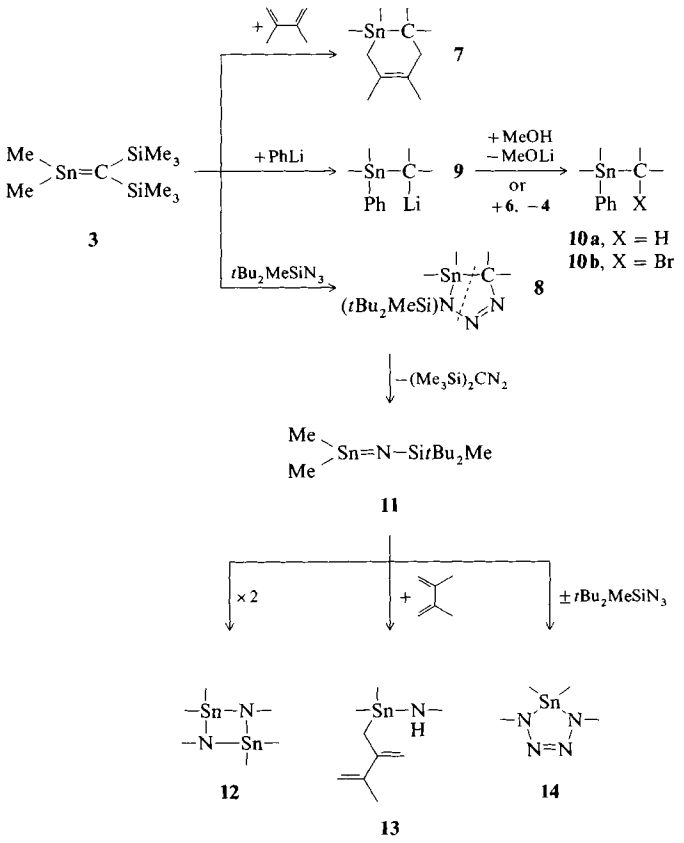


Scheme 1. Generation of sila-, germa-, and stannaethenes **1**–**3**.

The intermediacy of stannaethene **3** was established by trapping of the unsaturated compound. Addition of PhLi to a solution of **6** (E = Sn) in ether in the presence of 2,3-dimethylbutadiene (DMB) or azido(di-*tert*-butyl)methylsilane resulted in formation of the [2 + 4] cycloadduct **7** or the [2 + 3] cycloadduct **8**, respectively, of stannaethene **3** (Scheme 2). As already observed for **1** and **2**, the silyl azide is a better trapping reagent than DMB. This is shown by the following observations: (1) Dimer **5** is formed together with **7** even when a 20-fold excess of DMB is used, whereas [2 + 3] cycloaddition with the azide is quantitative.[4] (2) When PhLi is added dropwise to a solution of **6** (E = Sn) in the presence or absence of DMB (but not in the presence of tBu$_2$MeSiN$_3$), the addition product **9** (Scheme 2), formed from PhLi and **3**, is also obtained. This also means that **4** (Scheme 1) slowly decomposes even at $-100\,^{\circ}C$ to stannaethene **3**, which is trapped by PhLi (**9** was identified, after protolysis, as **10a** and, after bromination, as **10b**).

The [2 + 3] cycloadduct **8** formed from **3** and tBu$_2$MeSiN$_3$, undergoes [2 + 3] cycloreversion at slightly raised temperature to give stannanimine **11** and bis(trimethylsilyl)diazomethane. The intermediacy of imine **11**, which dimerizes to **12** in the absence of other reactants, was also shown by trapping reactions. In the presence of DMB in excess or of tBu$_2$MeSiN$_3$, the ene reaction product **13** or the [2 + 3] cycloadduct **14**, respectively, is formed. Compound **14**, in turn, is a precursor of **11** and decomposes upon warming in the presence of DMB to form **12** and **13**. Thus, trapping with tBu$_2$MeSiN$_3$ allows stannanimine **11** to be "stored".

The silaethene **1**[1] and the germaethene **2**,[2] generated by treatment of **6** with PhLi as shown in Scheme 1, as well as the silanimine and germanimine Me$_2$E = N(SiMetBu$_2$)[5] generated, via a [2 + 3] cycloadduct, by treatment of **1** and **2**, respectively, with tBu$_2$MeSiN$_3$, react with DMB and tBu$_2$MeSiN$_3$ in a basically analogous fashion to **3** and **11**, respectively.[6–8] Only gradual differences are observed. Thus, ethenes **1**–**3** and DMB undergo not only [2 + 4] cycloadditions but also ene reactions; however, the amount of Diels–Alder reaction product decreases from about 80% to practically 0% on going from **1** to **2** to **3**[9] (in the reaction of the imine Me$_2$E = N(SiMetBu$_2$) with DMB, only ene reaction occurs). Moreover, the metastability of the [2 + 3] cycloadducts of **1**–**3** with tBu$_2$MeSiN$_3$ with respect to first-order [2 + 3] cycloreversion increases in the series **1**-, **2**-, **3**-cycloadduct. This finding can be explained by, for example, an increase in the energy of the imine in the order silan-, german-, stannanimine. The fact that the chemical behavior of the unsaturated tin compounds **3** and **11** is analogous to that of the corresponding silicon and germanium compounds indicates that the bonding in these systems is similar.[10, 11]



Scheme 2. Generation of the stannanimine **11** as well as reactions of **3** and **11** (the Me, SiMe$_3$, and SiMetBu$_2$ groups on Sn, C, and N are partly omitted for clarity).

Experimental Procedure

The NMR spectra were recorded at the following frequencies: ^{1}H 89.55 and 270.166 MHz, ^{13}C 22.49 and 67.936 MHz, ^{29}Si 33.35 and 53.674 MHz, ^{119}Sn 33.35 and 100.682 MHz.

6 (E = Sn): BuLi (55.0 mmol) in 30 mL of hexane was added over 4 h to a solution of (Me$_3$Si)$_2$CBr$_2$ (17.27 g, 54.3 mmol) [12] in 80 mL of Et$_2$O at $-100\,^{\circ}C$. Me$_3$SnCl (11.00 g, 55.0 mmol) in 20 mL of Et$_2$O was then added over 1 h at $-78\,^{\circ}C$ (quantitative formation of (Me$_3$Si)$_2$(Me$_3$Sn)CBr. ^{1}H NMR: $\delta = 0.201$ (2 SiMe$_3$), 0.271 (SnMe$_3$)). LiBr was removed by filtration and Et$_2$O and hexane were replaced by 60 mL of CH$_2$Cl$_2$. The reaction mixture was then added dropwise at room temperature to a solution of Br$_2$ (54.0 mmol, 2.80 mL) in 20 mL of CH$_2$Cl$_2$. The reaction mixture was allowed to stand for 12 h and the CH$_2$Cl$_2$ and MeBr were then removed by distillation. Sublimation at 60–70 °C/10^{-4} mbar afforded 22.4 g (47.9 mmol; 89%) of colorless, crystalline **6** (E = Sn), m.p. 144 °C; correct elemental analysis (C, H). ^{1}H NMR (C$_6$D$_6$): $\delta = 0.248$ (2SiMe$_3$), 0.651 (SnMe$_2$). ^{13}C{^{1}H} NMR (C$_6$D$_6$): $\delta = 1.506$ (2SiMe$_3$), 1.923 (SnMe$_2$), 33.31 (CBr). ^{29}Si NMR (C$_6$D$_6$): $\delta = 7.45$. ^{119}Sn NMR (C$_6$D$_6$): $\delta = 58.82$. MS (70 eV): m/z 468 ($M^{\oplus}$).

5 (E = Sn), **7**, **10**: PhLi (3.30 mmol) in 1 mL of C$_6$H$_6$ and 6 mL of Et$_2$O was added over 3 h to a solution of **6** (E = Sn) (1.50 g, 3.20 mmol) in 25 mL of Et$_2$O ($-100\,^{\circ}C$) (A) or **6** (E = Sn) (1.50 g, 3.20 mmol) and DMB (32.0 mmol, 3.6 mL)

in 10 mL of Et_2O. After warming to room temperature and addition of MeOH, the solution contained—according to the ^1H NMR spectrum—90% **5** (E = Sn), 5% **10a** and 5% **10b** in case (A) and 60% **5** (E = Sn), 10% **7**, 5% **10a**, and 25% **10b** in case (B). The products were separated by preparative HPLC (retention times: **10a** < **10b** < **7** < **5**).

5 (E = Sn): Colorless crystals, characterized by comparison with an authentic sample [13]. **7**: Colorless crystals, correct elemental analysis (C, H). ^1H NMR (C_6H_6): $\delta = 0.125$ ($2SiMe_3$), 0.234 ($SnMe_2$), 1.400 (CH_2Sn), 1.696 ($2CH_3$), 2.453 (CH_2). $^{13}C\{^1H\}$ NMR (C_6D_6): $\delta = -5.780$ ($SnMe_2$), 2.015 ($2SiMe_3$), 9.719 (CSi_2), 17.11 (CH_2Sn), 22.83 ($2CH_3$), 36.09 (CH_2), 127.2/129.2 (C=C). ^{29}Si NMR (C_6D_6): $\delta = 3.358$. ^{119}Sn NMR (C_6D_6): $\delta = 5.271$. MS (70 eV): *m/z* 390 ($M^{\oplus}$).

10a: Colorless liquid. ^1H NMR (C_6D_6): $\delta = -0.458$ (CH), 0.084 ($2SiMe_3$), 0.364 ($SnMe_2$), phenyl multiplet. $^{13}C\{^1H\}$ NMR (C_6D_6): $\delta = -6.064$ ($SnMe_2$), 0.215 (CH), 3.349 ($2SiMe_3$), 136.2/143.8 (Ph). ^{29}Si NMR (C_6D_6): $\delta = 1.575$. ^{119}Sn NMR (C_6D_6): $\delta = -23.67$. MS (70 eV): *m/z* 371 ($M^{\oplus} - Me$).

10b: Colorless, liquid, correct elemental analysis (C, H). ^1H NMR (C_6D_6): $\delta = 0.137$ ($2SiMe_3$), 0.459 ($SnMe_2$), phenyl multiplet. $^{13}C\{^1H\}$ NMR (C_6D_6): $\delta = -5.485$ ($SnMe_2$), 1.587 ($2SiMe_3$), 30.58 (CBr), 136.8/142.8 (Ph). ^{29}Si NMR (C_6D_6): $\delta = 5.909$. ^{119}Sn NMR (C_6D_6): $\delta = -21.46$. MS (70 eV): *m/z* 464 ($M^{\oplus}$).

8: PhLi (4.36 mmol) in 2 mL of C_6H_6 and 10 mL of Et_2O was added dropwise over 3 h to a solution of **6** (E = Sn) (2.04 g, 4.36 mmol) and tBu_2MeSiN_3 (3.60 g, 17.6 mmol) in 15 mL of Et_2O at −78 °C. The reaction mixture was allowed to warm to room temperature and the LiBr and solvent were removed. Recrystallization of the reaction mixture from pentane afforded 1.80 g (3.50 mmol; 80%) of colorless, crystalline **8**. M.p. 116 °C. Correct elemental analysis (C, H). ^1H NMR (C_6D_6): $\delta = 0.068$ (SiMe), 0.112 ($2SiMe_3$), 0.359 ($SnMe_2$), 1.142 ($SitBu_2$). $^{13}C\{^1H\}$ NMR (C_6D_6): $\delta = -5.78$ ($SnMe_2$), −0.843 (SiMe), 1.140 ($2SiMe_3$), 15.54 (CSi_2), 21.11 ($2CMe_3$), 28.80 ($2CMe_3$). ^{29}Si NMR (C_6D_6): $\delta = 0.012$ ($2SiMe_3$), 12.77 ($SiMetBu_2$). ^{119}Sn NMR (C_6D_6): $\delta = 64.88$. MS (70 eV): *m/z* 450 ($M^{\oplus} - tBu$).

12, 13, 14: Compound **8** (0.25 g, 0.50 mmol) was heated in 0.5 mL of C_6D_6 (A), in 0.5 mL of C_6D_6 containing 5 mmol (0.6 mL) of DMB (B), or in 0.5 mL of C_6D_6 containing 0.63 g (3.36 mmol) of tBu_2MeSiN_3 (C) for 20 h at 60 °C. According to the ^1H NMR spectrum of the reaction solution, 100% **12** (A), 100% **13** (B), or 60% **14**/40% **12** (C) were present in addition to $(Me_3Si)_2CN_2$ (^1H NMR: $\delta = 0.074$) [14]. Compounds **12**, **13**, and **14**/**12** remain as residue after distillative removal of solvent and $(Me_3Si)_2CN_2$ under high vacuum. Compounds **14** and **12** can be separated by fractional crystallization from Et_2O (1st fraction: **14**). **12**: Colorless solid. ^1H NMR (C_6D_6): $\delta = -0.100$ ($2SiMe$), 0.545 ($2SnMe_2$), 1.040 ($2SitBu_2$). $^{13}C\{^1H\}$ NMR (C_6D_6): $\delta = -3.141$ ($2SiMe$), 5.018 ($2SnMe_2$), 21.01 ($4CMe_3$), 29.12 ($4CMe_3$). ^{29}Si NMR (C_6D_6): $\delta = 5.113$. ^{119}Sn NMR (C_6D_6): $\delta = 140.1$. MS (70 eV): *m/z* 583 ($M^{\oplus} - tBu$).

13: Colorless oil. ^1H NMR (C_6D_6): $\delta = 0.011$ (SiMe), 0.199 ($SnMe_2$), 1.055 ($SitBu_2$), 1.823 (CH_3), 2.054 (CH_2Sn), 4.900 ($2H_2C=$). $^{13}C\{^1H\}$ NMR (C_6D_6): $\delta = -5.969$ (SiMe), −4.824 ($SnMe_2$), 20.74 (CH_3), 22.94 (CMe_3), 28.53 (CH_2Sn), 28.60 (CMe_3), 109.7/113.4 ($2H_2C=$), 143.7/146.4 ($2C=$). ^{29}Si NMR (C_6D_6): $\delta = 10.71$. ^{119}Sn NMR (C_6D_6): $\delta = 42.60$. MS (70 eV): *m/z* 503 ($M^{\oplus}$).

14: Colorless crystals, decomposition at 160 °C. ^1H NMR (C_6D_6): $\delta = -0.021$ ($2SiMe$), 0.337 ($SnMe_2$), 1.121 ($2SitBu_2$). $^{13}C\{^1H\}$ NMR (C_6D_6): $\delta = -4.938$ ($2SiMe$), 0.001 ($SnMe_2$), 21.05 ($4CMe_3$), 28.70 ($4CMe_3$). ^{29}Si NMR (C_6D_6): $\delta = 11.75$. ^{119}Sn NMR (C_6D_6): $\delta = 41.50$. MS (70 eV): *m/z* 520 ($M^{\oplus}$).

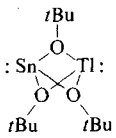
On the Differing Lewis Basicity of In^I Compared with Sn^{II} in Molecular Indium-Tin and Thallium-Tin Alkoxides**

By *Michael Veith** and *Klaus Kunze*

In the thallium-tin alkoxide **1**,[1] which we synthesized for the first time some years ago, each of the two metal atoms has a lone pair. Therefore, **1** could act as a double Lewis base toward electrophilic metal centers, whereby both Sn and Tl



1

can engage in bonding. When **1** is allowed to react thermally or photochemically with chromium or molybdenum hexacarbonyl in excess, however, only the monoadduct **2** or **3**, respectively, is obtained, as shown in Equation (a).

$$[Sn(OtBu)_3Tl] + [M(CO)_6] \xrightarrow[-CO]{\Delta T \text{ or } h\nu} [(CO)_5M-Sn(OtBu)_3Tl] \quad (a)$$

1 → **2**, M = Cr; **3**, M = Mo

An X-ray structure analysis (Fig. 1 and Table 1) confirms that the tin atom in **3** is bonded to the molybdenum atom.

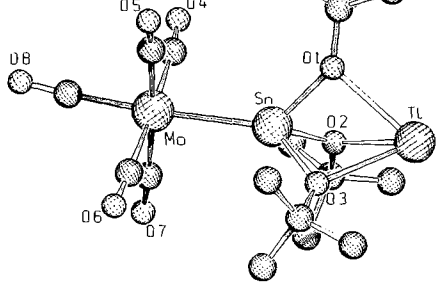


Fig. 1. Molecular structure of **3** [8] determined by X-ray analysis [2, 9]. The unlabeled spheres are carbon atoms; hydrogen atoms are omitted. The Mo-Sn···Tl angle is 178.9(1)°.

Sn-Cr [Å]	–	–	–	2.636(3)
In-Mo [Å]	–	–	2.742(1)	2.734(2)
O-In-O [°] (O-Tl-O)	66.7(1)	63.9(8)	73.2(3)	70.6(5)
O-Sn-O [°]	81.5(1)	84.2(9)	74.0(3)	76.6(5)
In···Sn [Å] (Tl)	3.200(3)	3.298(1)	3.078(1)	3.087(2)
R value	0.037	0.062	0.058	0.068

Compared with the starting compound **1** (Sn-O = 2.023(9), Tl-O = 2.595(7), and Tl···Sn = 3.306(2) Å[1]), all metal–oxygen distances are slightly shortened; the distance between thallium and tin is decreased. Characteristic of the monoadducts **2** and **3** are the high CO wave numbers ($\nu(A_1^{1b})$ bands) and a strong downfield shift of the ^{119}Sn NMR signals relative to those of compound **1** ($\Delta\delta = 97.04$; Table 2). Even under drastic conditions (large excess of metal carbonyl, higher temperature, longer reaction time), no complex fragment becomes bonded to the thallium atom of **2** or **3**.

We therefore attempted to replace thallium by its homologue indium. The desired compound **4** may be obtained starting either from **1** or from the sodium salt $[\{Na(OtBu)_3Sn\}_2]$[3] in a heterogeneous reaction with InBr [Eq. (b)].

$$\left.\begin{array}{l}[Tl(OtBu)_3Sn]\ \mathbf{1}\\ 1/2[\{Na(OtBu)_3Sn\}_2]\end{array}\right\} \xrightarrow[-TlBr/-NaBr]{+InBr} [In(OtBu)_3Sn]\ \mathbf{4} \qquad (b)$$

Toluene, used as solvent, apparently causes partial dissolution of InBr via formation of an arene complex.[4] The monomeric product **4**, like **1**, is soluble in nonpolar solvents, exhibits a similar ^{119}Sn absorption (Table 2), and forms isotypic crystals (Table 1). According to an X-ray structure analysis, **4** has a distorted bipyramidal InO_3Sn structure with In and Sn in apical positions and the three oxygens in equatorial positions. Compared with **1**, the indium atom is closer to the O_3 plane than the thallium atom, as expected; the distances to the oxygen atoms lie in the normal range (see also indium 2,4,6-tris(trifluoromethyl)phenoxide[5]).

Reaction of **4** with $[Cr(CO)_6]$ or $[Mo(CO)_6]$ in THF either thermally or photochemically in analogy to Equation (a) likewise results in formation of monoadducts **5** and **6**, respectively. Use of an excess of the metal carbonyl or longer reaction times results in further reaction to give the diadducts **7** and **8**, respectively [Eq. (c)].

$$[In(OtBu)_3Sn]\ \mathbf{4} \xrightarrow[-CO]{+[M(CO)_6]\ (\Delta T \text{ or } h\nu)} [Sn(OtBu)_3In-M(CO)_5]\ \begin{array}{l}\mathbf{5},\ M = Cr\\ \mathbf{6},\ M = Mo\end{array} \xrightarrow[-THF]{+[M(CO)_5(thf)]} [(CO)_5M-Sn(OtBu)_3In-M(CO)_5]\ \begin{array}{l}\mathbf{7},\ M = Cr\\ \mathbf{8},\ M = Mo\end{array} \qquad (c)$$

In contrast to **2** and **3**, the transition-metal atoms in **5** and **6** are not coordinated to the tin atom but rather to the indium atom. This is revealed by the upfield shift of the ^{119}Sn NMR signal (**6**: $\Delta\delta = -95.96$) compared with that of **4** and by the wave numbers of the $\nu(A_1^{1b})$ stretching band, which indicate a different electron density *trans* to the CO group (see Table 2).

This is shown especially clearly on going from the monoadducts **5** and **6** to the diadducts **7** and **8**. The second $\nu(A_1^{1b})$ bands due to the $M(CO)_5$ units on tin lie in the absorption region observed for compounds **2** and **3** (Table 2).

The result of an X-ray structure analysis of **8** is shown in Figure 2. The four metal atoms Mo, Sn, In, and Mo are

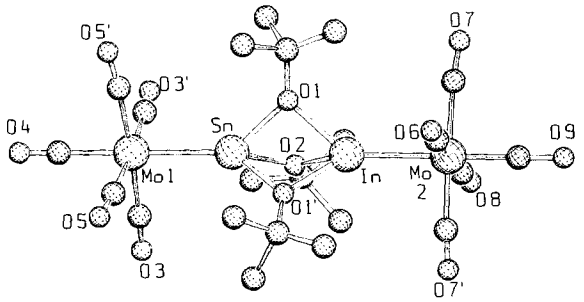

Fig. 2. Molecular structure of **8** [2] (atoms labeled as in Fig. 1). The stacked arrangement of the $Mo(CO)_5$ groups is clearly shown.

arranged nearly linearly (Mo-Sn-In = 174.2°, Mo-In-Sn = 178.8°), with metal single bonds between Mo and In and between Mo and Sn (distances in Table 1); as found in the starting compound **4**, In and Sn are bridged by three *tert*-butoxy groups. The coordination of $Mo(CO)_5$ units on indium and tin results in withdrawal of electron density from indium, so that the In–O distance is significantly less than that in **4**. The electron density on Sn is increased to a comparable extent; that is, the Sn–O distances are longer than those in free **4**. If the whole molecule is considered, however, **4** acts as an electron donor toward the $Mo(CO)_5$ units, since the In···Sn distance in **8** is less than that in **4** by 0.122 Å (Table 1).

The preferential coordination of the fragments $[Cr(CO)_5]$ and $[Mo(CO)_5]$ to indium in the monoadducts can be ex-

Table 2. ^{1}H and ^{119}Sn NMR data (δ values in benzene) and CO wave numbers [cm^{-1}] for compounds **1**–**10**.

[a] $J(^{205,203}Tl\text{-}Sn) = 1293$ Hz.

 © VCH Verlagsgesellschaft mbH, W-6940 Weinheim, 1991 0570-0833/91/0101-0096 $ 3.50+.25/0

ploited chemically. As shown in Equations (d) and (e) reaction of **5** and **6** with the THF adduct of the corresponding metal pentacarbonyl affords the positional isomers **9** and **10**, respectively, which contain four different metal atoms.

$$\underset{\mathbf{5}}{[(CO)_5Cr-In(OtBu)_3Sn]} + [Mo(CO)_5(thf)] \xrightarrow[-THF]{} \underset{\mathbf{9}}{[(CO)_5Cr-In(OtBu)_3Sn-Mo(CO)_5]} \quad (d)$$

$$\underset{\mathbf{6}}{[(CO)_5Mo-In(OtBu)_3Sn]} + [Cr(CO)_5(thf)] \xrightarrow[-THF]{} \underset{\mathbf{10}}{[(CO)_5Mo-In(OtBu)_3Sn-Cr(CO)_5]} \quad (e)$$

Compounds **9** and **10** are clearly distinguished by their CO wave numbers (Table 2) and crystal data (Table 1).[6] The X-ray structure analysis of **10** (Fig. 3, Table 1) again reveals

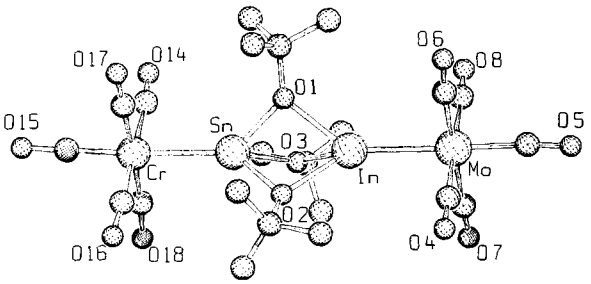

Fig. 3. Molecular structure of **10** [2]. In contrast to **8**, the $M(CO)_5$ groups are arranged in an eclipsed fashion.

an almost linear arrangement of the metal atoms (Mo-In···Sn = 178.1(1)°, Cr-Sn···In = 179.7(1)°). Interchange of the Sn and In positions in the structure analysis leads here and for **8** to poorer U values. As found for **8**, addition of $[M(CO)_5]$ fragments to **4** results in a decrease in the separation of the main-group metals (Δd = 0.113 Å) and a charge shift from indium to tin. However, owing to the shorter Cr–Sn bond compared with the Mo–Sn bond in **8**, the charge shift is less pronounced.

Experimental Procedure

4: $[Tl(OtBu)_3Sn]$ (1.0 mmol) [1] or $[\{Na(OtBu)_3Sn\}_2]$ (0.5 mmol) [3] was stirred with indium(I) bromide (1.4 mmol) in 15 mL of toluene at 110 °C for 5 or 40 h, respectively. The insoluble material, which may contain some indium, was removed by filtration and the filtrate was concentrated. Sublimation of the residue at 30 °C/10^{-2} Torr afforded 0.42 g (92%) or 0.41 g (90%), respectively, of **4**; m.p. 41 °C.

2, **3**, and **5**–**10**: A stirred solution of **1** or **4** and $[Cr(CO)_6]$ or $[Mo(CO)_6]$ in toluene was heated to reflux. Alternatively, the metal carbonyl was first photolyzed in THF and then allowed to react with **1** or **4** in toluene. Preparation of **9** and **10** starts with **5** and **6**, respectively, whose synthesis must be carried out with exact molar ratios of starting materials. All of the compounds were purified by sublimation or recrystallization and gave correct elemental analyses (C, H, metal).

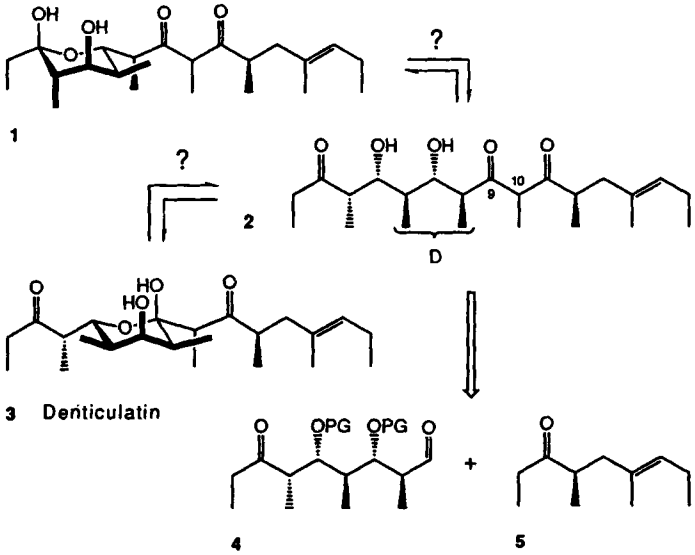
Efficient Stereoselective Total Synthesis of Denticulatins A and B**

By *Marc W. Andersen, Bernhard Hildebrandt,* and *Reinhard W. Hoffmann**

The stereoselective synthesis of natural products of polyketide origin, particularly those which contain the stereotriad D, remains a challenge to the preparative chemist.[1] Among such substances are the denticulatins **3**,[2] two polypropionates isolated from *Siphonaria*, whose biological significance remains unclear. Denticulatin is a polyhydroxy-polyketo compound and exists in the form of a semiacetal. For the synthesis of the denticulatins it is of interest whether open-chain precursors such as **2** cyclize to the correct denticulatin isomer **3**, as well as whether other semiacetals such as **1** isomerize to the desired product (Scheme 1).



Scheme 1. Possible synthetic routes to denticulatin. PG = protecting group.

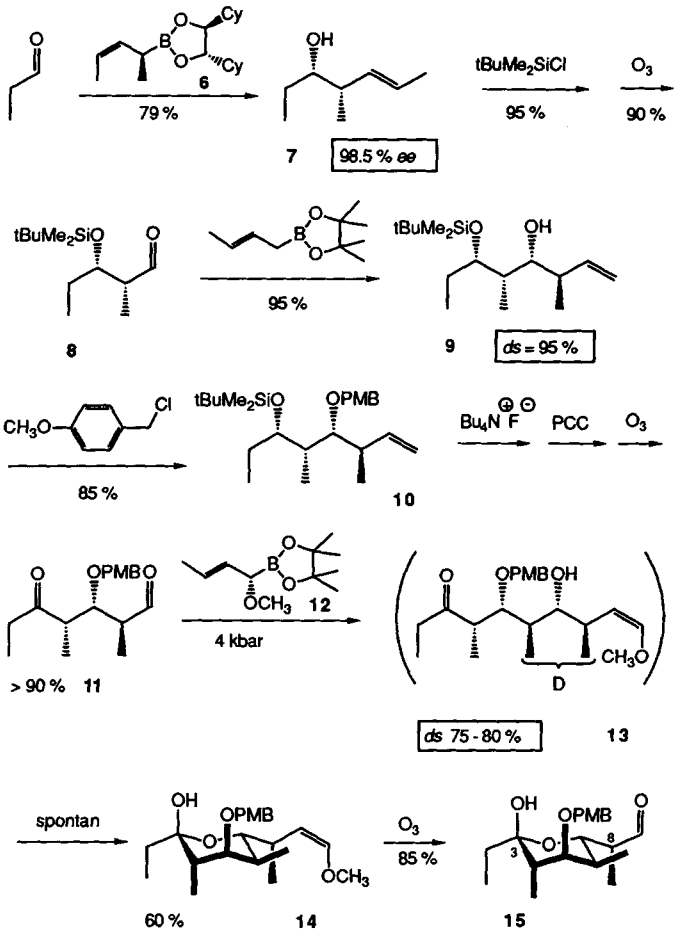
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank Prof. Dr. *J. Faulkner*, San Diego, USA, and Dr. *M. Garson*, Wollongong, Australia, for spectra and samples of natural denticulatin. Our thanks also go to Miss *Sonja Wissner*, Miss *Sabine Gärtner*, and Mr. *Georg Dahmann* for assistance with the experiments.



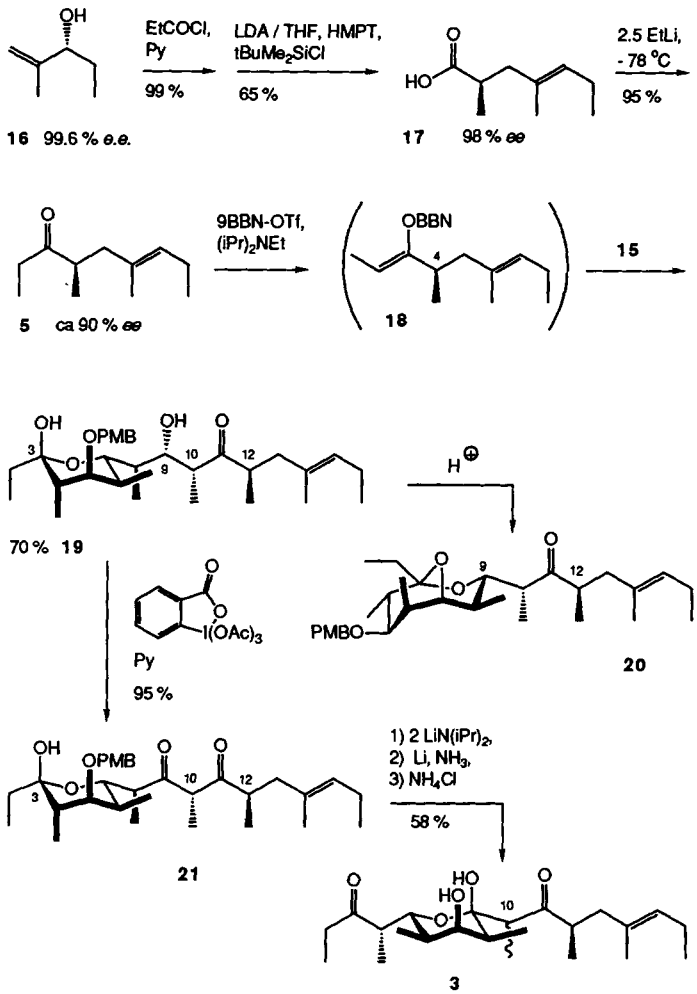
Scheme 2. Synthesis of the building block **15**, which serves as synthetic equivalent for **4** (Scheme 1). PMB = *para*-methoxybenzyl.

Ziegler and *Becker*[3] have recently synthesized **3** for the first time by cyclization of *open-chain* educts. We describe here a shorter route to the denticulatins via the semiacetal **1**.

The synthetic concept, like that of *Ziegler*'s, involves a coupling between C9 and C10. The actual improvement exemplified by our method, however, lies in the rapid synthesis of the building block **4** via three stereoselective allylboration reactions. The carbon chain from C1 to C9 is thereby synthesized, similarly as in the biogenesis, by linkage of propionaldehyde synthetic equivalents (Scheme 2). Accordingly, in the first step, propionaldehyde was extended with the reagent **6** providing the *syn*-alcohol **7** with high stereo- and enantioselectivity.[4] Protection of the OH group and subsequent ozonolysis furnished the aldehyde **8**, previously obtained via a more circuitous route.[5] We have already reported on the *anti*-diastereoselective chain extension of **8** by crotylboration, leading to **9** with substrate control of the diastereoselectivity, and on alcohol protection to give **10**.[5] Conversion of the C-3 alcohol function to the required ketone oxidation state was carried out by desilylation of **10** and oxidation with pyridinium chlorochromate (PCC). Ozonolysis then gave the ketoaldehyde **11**.

The next step was considered the most challenging aspect of the synthesis, namely, the chain extension with formation of the stereotriad D, a step which requires an effective reagent control of the diastereoselectivity. The α-methoxycrotylboronate reagent successfully used for this purpose in preliminary experiments[6] also proved useful here. In view of the high asymmetric induction originating from the aldehyde **11**, which actually favors formation of the undesired diastereomer, a selectivity of 75–80% in favor of the mismatched pair product **13** is still acceptable. The δ-hydroxyketone **13** cyclized spontaneously to the semiacetal **14**, ozonolysis of which led to the aldehyde **15**. This represents the key building block **4**, which can be prepared in 26% yield in ten steps by our synthesis.

The other required fragment, ketone **5**, was obtained from the allyl alcohol **16**[7] by Claisen rearrangement to the acid **17** and subsequent reaction with ethyllithium (Scheme 3). The constitution and configuration of **5** were checked by comparison with a sample prepared according to *Enders* et al.[3, 8] The ketone **5** was converted with Hünig base/9BBN-OTf into the enol borinate **18**. The (*Z*)-configuration of the enol double bond was verified by transformation[9] of **18** into the corresponding silyl enol ether, which showed the characteristic C4 signal at $\delta = 37.6$ in the ^{13}C-NMR spectrum. Addition of **18** to the aldehyde **15** gave, besides the



Scheme 3. Synthesis of the second building block **5** and subsequent reactions leading to denticulatin. Natural denticulatin also exists as a C10 epimer mixture. LDA = lithium diisopropylamide, HMPT = hexamethylphosphoric triamide, 9BBN = 9-borabicyclo[3.3.1]nonane, OTf = trifluoromethanesulfonate.

main product **19**, ca. 20% of another stereoisomer. This results from a partial racemization of the ketone **5** occurring during its distillation or during the formation of **18**. This follows from the condensation of racemic **5** with the aldehyde **15** affording with a 4:1 selectivity the above mentioned by-product, which must therefore be 12-*epi*-**19**.

Addition of **18** to **15** occurred with selective (>90%) formation of the *anti*-Cram isomers **19** (and 12-epi-**19**); this became clear after the bicyclization of **19** to **20** initiated by traces of acid: ^{1}H-NMR data (NOE values and coupling constants) of **20** confirm the chair/boat conformation of the bicycle and its relative configuration at C9. This also holds true for the product derived from 12-epi-**19**.

The completion of the synthesis had to take into account the sensitivity of **19** and the succeeding compounds towards acid. Oxidation of the C9 hydroxy group to give the latent triketone **21** was accomplished with the Dess-Martin periodinane[10] in the presence of pyridine. Compound **21** is thereby obtained as a stereoisomer that is uniform at C10 (cf. Ref. [3]).

Up to this reaction step a selective synthesis of the denticulatin A (with α-configuration at C10) seems possible. Numerous attempts to cleave the PMB group at C5 oxidatively or by hydrogenation failed because of the lability of the denticulatins. We therefore had to forfeit the stereochemistry at C10: after deprotonation at C10 the PMB group could be cleaved with lithium in ammonia, resulting in a 1:1 mixture of the denticulatins A and B. These were identified on the basis of their ^{13}C-NMR and ^{1}H-NMR spectra. The rotation $[\alpha]_D^{21} = -33.3$ ($c = 0.42$, $CHCl_3$) corresponds to that of the natural denticulatins [A = −30.7 ($c = 1.49$, $CHCl_3$); B = −26.4 ($c = 0.39$, $CHCl_3$)].[2] The spectroscopic data of the compounds **15**, **19** and **21** are summarized in Table 1.

The conversion of **21** into **3** confirms that the initially formed semiacetal **1** spontaneously isomerized to denticulatin **3**, whereby the number of axial residues on the respective semiacetal ring decreases.

Catalytic and Stoichiometric Enantioselective Addition of Diethylzinc to Aldehydes Using a Novel Chiral Spirotitanate **

By *Beat Schmidt* and *Dieter Seebach**

The enantioselective addition of diethylzinc to aldehydes, catalyzed by chiral amino alcohols, has become a sport in organic synthesis, generating a number of unusual achievements.[1-5] We report here another record: it is possible, with the same catalyst, to obtain either enantiomer in an excess of up to 99.5:0.5 by simply changing the reaction conditions.

In the course of our work on the use of chiral titanates[6-8] for the addition of nucleophiles to carbonyl groups, we have prepared the spirotitanate **1**. A colorless, spectroscopically and analytically pure, crystalline compound, **1** is stable in air for many hours and exists as a monomer in solution. This spirotitanate is prepared from the corresponding diol derived from (*R*,*R*)-tartaric acid[9-13] and tetraethyl titanate by azeotropic distillation of ethanol with toluene followed by removal of the solvent in vacuo. We

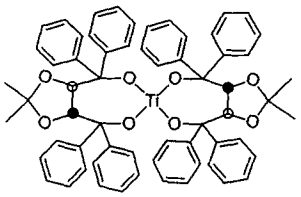
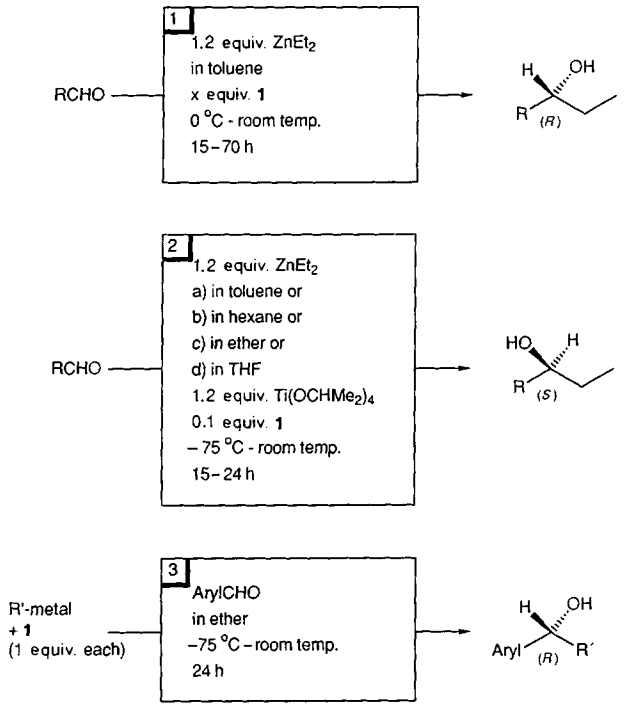
[**] The results described herein are part of the proposed dissertation of B. S.



1

tested **1** for the enantioselective activation of aldehydes on addition of diethylzinc. Details of the execution of the reaction and of the current results are shown in equations 1 and 2, as well as in Table 1. The enantiomeric ratios listed have been determined by ^{19}F NMR spectroscopy of the Mosher esters.



The addition of 0.05–2.0 equivalents of **1** to a mixture (1.2:1) of diethyzinc[14] and anisaldehyde in toluene leads to the (*R*)-alcohol (up to 99:1). However, if the concentration of **1** is held constant at 0.1 equivalents and an additional 1.2 equivalents of tetraisopropyl titanate are added at low temperature, the (*S*)-alcohol is formed in excess (97:3). Under these conditions (RCHO:Ti(O*i*Pr)$_4$:1 = 1:1.2:0.1) we have also tested some other aromatic, as well as saturated and α,β-unsaturated aliphatic aldehydes and have found that the (*S*)-alcohol always predominates (≥ 9:1). Moreover, unlike in the previously published enantioselective activations of Et_2Zn, the hydrocarbon solvent can be replaced by diethyl ether or even tetrahydrofuran. Finally we investigated whether titanate **1** can also be used for the enantioselective addition of methyllithium and Grignard reagents to aldehydes via a chiral ate-complex[10, 15] (see Equation 3 and Table 1). This is indeed possible and the stereochemical outcome is reversed again: the (*R*)-alcohol is formed from anisaldehyde with a selectivity of 96:4.

These findings are remarkable for the following reasons: a) the reaction is an exclusively Lewis acid mediated addition of diethylzinc to aldehydes (no amino alcohol or amide is added); b) the induction achieved by the use of the bulky chiral spirotitanate is reversed, rather than "diluted", by the addition of a tenfold excess of achiral titanate; c) donor solvents such as ether may be used without detrimental effects.

Table 1. Results of enantioselective alkyl transfer reactions mediated by the spirotitanate **1** as shown in equations 1–3.

Method		Aldehyde	Formula	Product Yield [%]	*R/S*
1	x = 0.05	Anisaldehyde		33	91:9
	x = 0.1			15	91:9
	x = 1.0			42	95:5
	x = 2.0			89	99:1
2	a	Heptanal		75	4:96
	a	3-Phenyl-propanal		85	9:91
	b	Isobutyr-aldehyde		44	3:97
	a	Cyclohexane carbaldehyde		67	9:91
	a	Cinnamic aldehyde		89	2:98
	a	Benzaldehyde		75	0.5:99.5
	c			62	1:99
	d			63	9:91
	a	Anisaldehyde		86	3:97
	a	*p*-Bromobenz-aldehyde		88	5:95
	a	Thiophene-1-carbaldehyde		75	3:97
3	MeLi	Benzaldehyde		65	95:5
	MeLi	Anisaldehyde		53	96:4
	MeMgI	Benzaldehyde		46	81:19
	MgBr	Benzaldehyde		50	80:20

These results are of general significance for enantioselective synthesis,[16] and we hope soon to be able to explain the observed effects.[17]

Experimental Procedure

Spirotitanate: The spirotitanate **1**, prepared as described above from highly pure starting materials, should not contain more than 10% of the free diol for use in the reactions. It is insoluble in ether and can be washed with this solvent.

Catalytic reactions: Upon completion of the reaction (20 mL solvent/10 mmol aldehyde/1 mmol **1**), 10 mL of saturated NH_4Cl and 30–50 mL Et_2O are added, and the solution is stirred for 30 min. The solution is then filtered through celite, dried (saturated NaCl solution, then Na_2SO_4), and concentrated. Low molecular weight products are purified by flash chromatography through a short column (hexane/Et_2O 3:1) to remove unreacted aldehyde, toluene, and

traces of a light yellow impurity. The alcohol is obtained from the resulting residue by kugelrohr vacuum distillation.

Stoichiometric reactions: The diol, prepared as above until after the drying stage, is precipitated by the addition of pentane to the ether solution and filtered (this may need to be repeated). The resulting solution is concentrated and the residue is distilled either directly, or after chromatography, as described above. Recovery of the diol (m.p. 190–192 °C, $[\alpha]_D^{20} = -68.5$ ($c = 1$, $CHCl_3$)) [6c]: By recrystallization from ether/pentane; hydrolysis of the dioxolane ring was not observed in the experiments described here.

[16] Other, more or less obvious applications and modifications of **1** are currently under intensive investigation in our laboratories.
[17] Until now, there has been no time for mechanistic studies; we know, however, from NMR studies, that mixing of a $CHCl_3$ solution of **1** with $Ti(OCHMe_2)_4$ at room temperature leads to exchange of the RO ligands, presumably with formation of a monocyclic titanate with two Me_2CHO groups on titanium! In other cases of enantioselectively catalyzed Et_2Zn additions, detailed mechanistic proposals have been made [2, 4, 5].

$Th_6Br_{15}H_7$—Stabilization of a Th_6Br_{12} Cluster by Seven Hydrogen Atoms

By *Arndt Simon*,* *Fred Böttcher*, and *Jeremy Karl Cockcroft*

The formation of cluster compounds of thorium was observed for the first time during attempts to prepare reduced thorium bromides. Their formation requires the presence of a third element, which, as interstitial atoms, stabilizes the cluster.[1] These compounds are, on the one hand, structurally closely related with corresponding compounds of zirconium[2, 3] and niobium,[4] and, on the other, they form hitherto unknown types of clusters. Thus, the compounds $Th_6Br_{14}C$ and $Th_6Br_{15}M$ with Th_6Br_{12} clusters were obtained, which are stabilized by a C or M atom (M = Mn, Fe,Co,Ni) in the center of the octahedral Th_6 unit.[5] In contrast, the central units in compounds of the type $Th_{12}Br_{29}N_6A_y$ (A = Li–Rb; $y = \leq 1$) consist of twelve closely packed Th atoms.[6]

The incorporation of an interstitial H atom in the M_6 octahedron was first demonstrated years ago in HNb_6I_{11}.[7] In a corresponding attempt to stabilize the Th_6Br_{12} cluster by hydrogen we obtained a remarkable result. The reaction of Th and $ThBr_4$ under H_2[8] led, inter alia, to black, cubic crystals, an X-ray structure analysis of which[10] revealed an arrangement of the Th and Br atoms as in Nb_6F_{15}.[11] Th_6Br_{12} clusters are linked to one another via Br atoms facing all six vertices of the octahedra according to $Th_6Br^i_{12}Br^{a-a}_{6/2}$ (via linear Br^{a-a} bridges!). Two such interpenetrating skeletons form a body-centered structure. Neutron diffraction diagrams of the deuteriated powder confirmed the analytically determined, surprisingly high hydrogen content of the compound.[10] Seven D atoms[12] are statistically distributed over the eight face centers of the Th octahedron. As shown in Figure 1 the D atoms do not lie in the interior of the octahedron but about 22 pm from the triangular faces. This displacement can easily be explained in terms of the electrostatic repulsion between the hydride-like bonded H atoms; the D–D distance (205.0 pm) is very short, comparable with the assumed shortest H–H distances in Th_4H_{15}.[13]

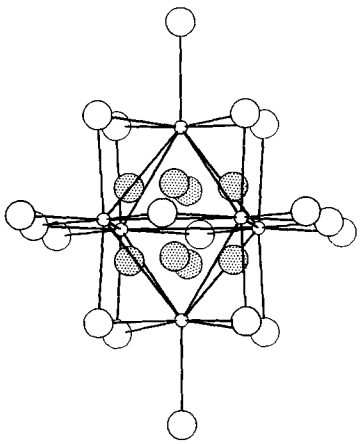

Fig. 1. Metal clusters in $Th_6Br_{15}D_7$ (small circles Th, large open circles Br, hatched circles D with 7/8 occupation). Shortest distances pm from neutron diffraction data: d(Th–Th) = 386.1(2), d(Th–D) = 223.8(2), octahedra edges $d(Th–Br^i) = 294.5(1)$, octahedra apices $d(Th–Br^{a-a}) = 295.8(1)$, d(D–D) = 205.0(3). The D atoms are surrounded by an almost trigonal planar array of Th atoms. The Th–Th distance is slightly shorter than in the compounds MTh_6Br_{15} with M = Fe, Co (d(Th–Th) = 391.8(2)).

Max-Planck-Institut für Festkörperforschung
Heisenbergstrasse 1, W-7000 Stuttgart 80 (FRG)

The additional occupation of the face centers of the M_6 octahedron of a M_6X_{12} cluster is observed for the first time in $Th_6Br_{15}H_7$; this type of occupation is already known for systems with condensed clusters. In the compounds ZrXH (X = Cl, Br)[14] and $LnXH_2$[15] two H atoms assume positions in opposite faces of elongated trigonal antiprisms of M atoms (d(D–D) = 220 pm in the case of ZrBrD and 298 pm in the case of $TbBrD_2$).

The number of bonding orbitals in the $Th_6Br_{12}H_7$ cluster is the same as in the hypothetical empty Th_6Br_{12} cluster: bonding H–Th interactions merely lead to a lowering of individual orbital energies; the antibonding combinations lie above the HOMO-LUMO gap. Thus, the electron balance for $Th_6Br_{15}H_7$ ($6\times4-15+7=16$) corresponds exactly to that for a complete occupation of all bonding cluster orbitals (for comparison Nb_6F_{15}: $6\times5-15=15$). The metal–metal bonding in the (empty) M_6X_{12} cluster is best described in terms of closed three-center two-electron bonds in all eight faces of the M_6 octahedron[16] and provides a clear picture of the bonding contribution of the H atoms. Seven of these multicenter bonds are reinforced by the mixing of the 1s function of the respective H atom in the center of the bond and by the additional electron of each H atom, so that finally there are seven four-center two-electron bonds and one three-center two-electron bond.

Since the electron balance already varies in the case of empty clusters (e.g. $Ta_6Cl_{12}^{n\oplus}$ with n = 2–4, corresponding to 16 to 14 electrons in M–M bonding states[17]) and can be further decreased in clusters with interstitial atoms (e.g. $Sc_7Cl_{12}B$ corresponding to 12 electrons[18]), it is to be expected that the hydrogen content in $Th_6Br_{15}H_7$ is variable. Further investigations are currently under way.

[8] Procedure: 708 mg of $ThBr_4$ and 182 mg of ThH_2 were heated in a sealed Ta capsule (protected by a quartz glass ampoule from oxidation) for 3 d at 100 °C. Finally the unopened Ta capsule was tempered for 1 d under 1 atm of H_2 at 680 °C. The X-ray diagram of the reaction product showed cubic symmetry of $Th_6Br_{15}H_x$ with a few very weak extraneous lines. The analytical determination of the H content (combustion in O_2, determination as H_2O) yielded $5.5 \le x \le 5.7$. For the neutron diffraction, a sample b was used which was originally prepared for other purposes (4320 mg $ThBr_4$, 687 mg Th, Ta capsule in quartz glass ampoule, 0.5 d 1000 °C, three weeks 640 °C, finally annealed in Ta capsule for 3 d at 680 °C in 1 atm D_2). The X-ray investigation showed the simple diagram of $Th_6Br_{15}D_x$ besides the line-rich (therefore weak) diagram of $ThBr_{3.5}D_{0.17}$ [9]. The analytical determination of the D content gave $x \approx 5.8$ for the corresponding portion of $Th_6Br_{15}D_x$.

The Reduction of the NbX_5/AlX_3 System with Aluminum in the Presence of Aromatic Hydrocarbons: An Approach to Niobium(II), Niobium(I), and Niobium(0) Organometallics**

By *Fausto Calderazzo*, Guido Pampaloni, Lucia Rocchi, Joachim Strähle* and *Klaus Wurst*

In memoriam Fausto Ungari

Since the pioneering work by *E. O. Fischer* and *F. Röhrscheid*,[1] who reported the isolation of the hexamethylbenzene (hmb) complexes $[Nb_3Cl_6(\eta^6\text{-hmb})_3]^{n\oplus}$ (n = 1,[1] n = 2[2]) and $Nb_2Cl_4(\eta^6\text{-hmb})_2$[1] by low temperature hydrolysis of the unknown primary reaction products of the $Al/AlX_3/NbX_5$/arene system, this method has seldom been used for the preparation of low-valent niobium organometallics. To the best of our knowledge, only the metal vapor technique is available[3] for the preparation of the bis-arene complexes of niobium(0). In this paper, we report the identification of the primary reaction products in the $Al/AlX_3/NbX_5$/arene system, the further reaction to bis(1,3,5-trimethylbenzene)niobium(0) ([Nb(mes)$_2$]), and some new chemistry of [Nb(mes)$_2$].

The synthesis of the primary reaction products (**1**) is summarized in Equation (a). Compounds **1** have been isolated in moderate yields (30–50%) as dark brown solids sensitive to oxygen and moisture. We assume for these niobium(II)

$$NbX_5 + Al + AlX_3 + \text{arene} \longrightarrow \underset{\mathbf{1}}{[Nb(\eta^6\text{-arene})(AlX_4)_2]} \qquad \text{(a)}$$

X = Cl, arene = benzene, hmb; X = Br, arene = hmb

derivatives a halo-bridged structure of the type already established by X-ray diffractometry for the corresponding titanium(II) complexes,[4] $[\eta^6\text{-arene})Ti\{(\mu\text{-}X)_2(AlX_2)\}_2]$, and by chemical and spectroscopic data for the similar zirconium(II) species.[5]

[**] This work was supported by the Consiglio Nazionale delle Ricerche (C.N.R. Roma) and by the Ministero dell'Università e della Ricerca Scientifica e Tecnologica (MURST).

Treatment of **1** (X = Br, arene = hmb) with tetrahydrofuran at room temperature gives compound **2** [Eq. (b)].

$$2[Nb(\eta^6\text{-hmb})(AlBr_4)_2] \xrightarrow[\sim 20\,^\circ C]{THF} \underset{\mathbf{2}}{[Nb_2Br_4(\eta^6\text{-hmb})_2]} + 4\,AlBr_3 \qquad (b)$$

Preliminary results of an X-ray diffractometric experiment on a single crystal of **2**, showed a dimeric centrosymmetric structure with four bridging bromides and a Nb–Nb distance of 2.760(2) Å, suggestive, together with the 18-electron count, of a single niobium–niobium bond.[6] Compound **1** (arene = hmb, X = Br) is oxidized by water at about $-30\,^\circ C$ giving a 50% yield of the trinuclear compound $[Nb_3Br_6(\eta^6\text{-hmb})_3]Br$.[2]

The primary reaction product of $Al/AlX_3/NbX_5$/1,3,5-trimethylbenzene (mes) system was not isolated; however, the crude reaction mixture, still containing unreacted aluminum, was treated with tetrahydrofuran (THF) or 1,2-dimethoxyethane (DME) at temperatures as low as $-15\,^\circ C$. Under these conditions, further reduction occurs and $Nb(mes)_2$ is obtained in 30–50% yields [see reaction sequence (c)]. This represents the first synthesis of a niobium(0) derivative which does not require the use of the vapor-metal technique.

$$NbCl_5 \xrightarrow[2)\ DME,\ -15\,^\circ C]{1)\ Al/AlCl_3/mes} [Nb(mes)_2] \qquad (c)$$

The redox reactivity of $[Nb(mes)_2]$ in the presence of carbon monoxide has been investigated in some detail. $[Nb(mes)_2]$ reacts with CO in *n*-heptane at room temperature, the reaction time depending on the pressure of carbon monoxide (48 h at atmospheric pressure, 24 h at 5 atm, 10 h at 50 atm), to give the green $[Nb(mes)_2(CO)][Nb(CO)_6]$ in substantially quantitative yields [Eq. (d)]. Thus, the chemistry of $[Nb(mes)_2]$ parallels that of the corresponding

$$2[Nb(mes)_2] + 7\,CO \longrightarrow [Nb(mes)_2(CO)][Nb(CO)_6] + 2\,mes \qquad (d)$$

vanadium(0) system,[7] except that vanadium requires more drastic conditions: $[V(mes)_2]$ does not react appreciably with CO under the conditions used for $[Nb(mes)_2]$. The hexacarbonylvanadate(−1) and the tetraphenylborate salts of the bis(mesitylene)carbonylniobium(I) cation have been obtained by oxidation of $[Nb(mes)_2]$ with $V((CO)_6$ and (N,N'-Me_2-4,4′-bipyridyl)$(BPh_4)_2$ under CO. When the oxidation of $[Nb(mes)_2]$ by (N,N'-Me_2-4,4′-bipyridyl)$(BPh_4)_2$ was performed under argon in THF, $[Nb(mes)_2(thf)]BPh_4$ was isolated in high yields.

$[Nb(mes)_2]$ has been reported[8] to be reduced to the $[Nb(mes)_2]^\ominus$ anion by potassium in DME. We have observed that $[Nb(mes)_2]$ is not affected by $[CoCp^*_2]$ ($Cp^* = (\eta^5$-$C_5Me_5)$) in toluene under argon, but it slowly reacts under CO at atmospheric pressure to give high yields of $[Co(Cp^*)_2][Nb(CO)_6]$ [Eq. (e)]. This suggests that the presumably fast electron transfer occurs on a partially carbonylated product of niobium(0).

$$[Nb(mes)_2] + 6\,CO + [CoCp^*_2] \longrightarrow [CoCp^*_2][Nb(CO)_6] + 2\,mes \qquad (e)$$

Experimental Procedure

$[Nb(mes)_2]$: A suspension of Al powder (5.7 g, 211 mmol), sublimed $AlCl_3$ (4.69 g, 35.2 mmol) and sublimed $NbCl_5$ (9.45 g, 35.0 mmol) in mesitylene (40 mL) was stirred at room temperature for 15 h and at 120–130 °C for 4 h. The reaction mixture consisted of two brown liquid layers. Under vigorous stirring. DME (50 mL) was slowly added (30 min) to the reaction mixture cooled to $-15\,^\circ C$. After the addition was complete, *n*-heptane (50 mL) was added and the deep red suspension was stirred at room temperature for 15 h. After filtration, the red filtrate was dried at 30–40 °C/10^{-2} torr and the residue treated with *n*-heptane (50 mL). The solution was filtered and evaporated to dryness under vacuum at room temperature, and the residue treated with *n*-heptane (5 mL) which partially dissolved the solid. After cooling to $-78\,^\circ C$, $[Nb(mes)_2]$ (5.03 g, 43% yield) was obtained as dark brown microcrystals.

$[Nb(mes)_2(CO)][Nb(CO)_6]$: A solution of $[Nb(mes)_2]$ (1.02 g, 3.1 mmol) in *n*-heptane (100 mL) was introduced into a glass autoclave (Büchi, Uster, Switzerland) and stirred for 24 h under CO at a pressure of 5 atm. The bright green solid was filtered, dried under vacuum at room temperature and identified as $[Nb(mes)_2(CO)][Nb(CO)_6]$ (0.64 g, 67% yield). Analysis: Found: CO 31.1, Nb 28.9; Calcd. for $C_{25}H_{24}Nb_2O_7$: CO 31.5, Nb 29.3. IR (THF): $\tilde{\nu}$ [cm^{-1}] = 1990 m, 1889 m(sh), 1859 vs.

Stereoselective Synthesis of Vicinal Diamines**

By *Manfred T. Reetz,* Ralf Jaeger, Ralf Drewlies,* and *Marcus Hübel*

Although vicinal diamines are a synthetically, biologically, and medicinally important class of compounds,[1] there is still no general procedure for diastereoselective synthesis of these compounds in enantiomerically pure form.[1, 2] Here we report on two methods that transform amino acids **1** selectively into either diamines **5** or **9**, having a new stereogenic center.

To synthesize diamines **5** of (*S,S*) configuration, the *N,N*-dibenzylamino aldehydes **2**,[3] readily accessible from amino acids **1**, were converted under standard conditions (benzylamine/CH_2Cl_2/$MgSO_4$, 0°, 4 h) into the corresponding *N*-benzyl aldimines **3** (90–95% yield). Because Grignard-like additions to simple aliphatic aldimines are notoriously difficult owing to competing α deprotonation,[4] such C–C bond

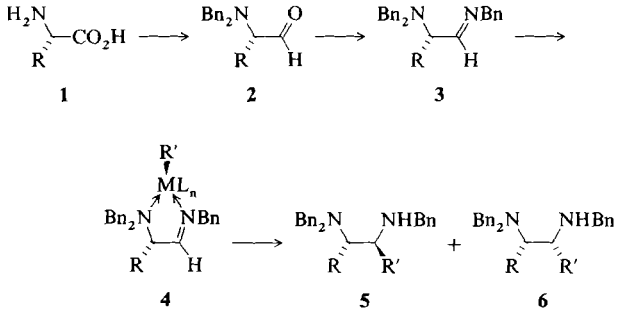
formation was not expected to be facile in the case of aldimines **3**. In fact, the method based on R_2CuLi in the presence of BF_3 failed[4g] (< 15% adducts), as did the use of Grignard reagents in several solvents and of alkyllithium compounds in THF. In *ether*, on the other hand, MeLi and *n*-BuLi add diastereoselectively with formation of the chelation-controlled[5] adducts **5** (Scheme 1, Table 1). The reason for the poor yield in the case of MeLi was unclear and led us to try the less basic organocerium reagents.[6] Indeed, acceptable results were obtained with the combination *n*BuLi/$CeCl_3$ (Table 1), but not with MeLi/$CeCl_3$! This problem was solved by use of the more reactive Me_3Ce.[7] Organolithium and -cerium reagents add without accompanying racemization.



Scheme 1. Bn = CH_2Ph.

Table 1. Stereoselective additions to aldimines **3**.

R	Reagent[a]	Yield [%]	**5**:**6**
Me	*n*BuLi	54	86: 14
Me	*n*BuLi/$CeCl_3$	71	88: 12
Bn	MeLi	40	>95: <5
Bn	MeLi/$CeCl_3$	28	>95: <5
Bn	3 MeLi/$CeCl_3$	78	>95: <5
Bn	3 MeLi/$LaCl_3$	63	>95: <5
Bn	3 MeLi/$YbCl_3$	40	>95: <5
Bn	*n*BuLi	80	93: 7
Bn	*n*BuLi/$CeCl_3$	84	93: 7
Me_2CH	*n*BuLi	85	93: 7
Me_2CH	*n*BuLi/$CeCl_3$	80	89: 11
Me_2CHCH_2	*n*BuLi	77	82: 18
Me_2CHCH_2	*n*BuLi/$CeCl_3$	86	82: 18
Me_2CHCH_2	*n*BuLi/$LaCl_3$	83	83: 17
$Bn_2N(CH_2)_3$	*n*BuLi	76	87: 13

[a] All reactions [14a] were carried out in ether at −78 °C with subsequent warming to room temperature.

We postulate the intermediacy of chelates **4**, which are attacked preferentially from the sterically less shielded side. This contrasts with addition of RLi and RLi/$CeCl_3$ to the corresponding aldehydes **2**, which undergo > 90% non-chelation-controlled reactions.[3] Thus, α-amino aldimines of type **3** are much better chelating agents than aldehydes **2**. This is presumably due to the stronger N–metal bond compared with an O–metal bond and to the (*E*) configuration of the C–N double bond, which makes only *syn* complexation possible.

In order to reverse the direction of diastereoselectivity, it seemed necessary to weaken the donor strength of the nitrogen atoms of the α-amino aldimines to the point where effective chelation no longer pertains. This was accomplished by the replacement of the benzyl group on the aldimine nitrogen by the electron-withdrawing tosyl group. The *N*-tosyl derivatives **7** were prepared by the Weinreb procedure[8] and allowed to react in situ with Grignard reagents. Indeed, the non-chelation-controlled adducts **9** were preferentially formed (Scheme 2, Table 2). This result is consistent with the Felkin–Anh model[5, 9a] or with possible ground-state phenomena.[9b]

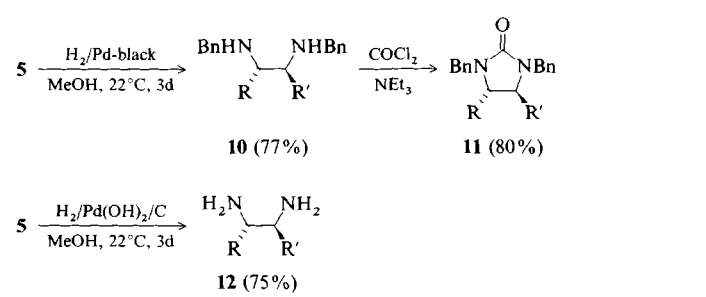
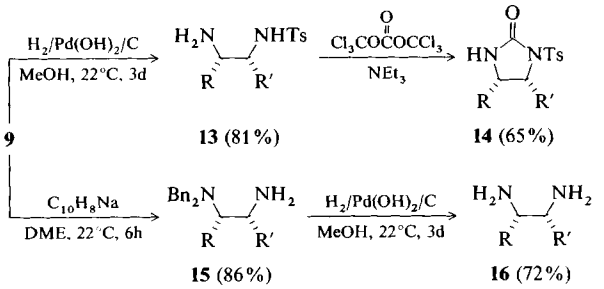
Me_2CHCH_2	PhMgCl	70	6: 94
Me_2CHCH_2	CH_2=$CHMgBr$	75	<5: >95

The assignment of the configuration of the adducts **5** was made possible by selective deprotection of **5** (R = Bn; R′ = *n*Bu) with H_2/Pd-black[3] to give **10** followed by cyclization to give the urea derivative **11**. The NOE difference spectrum indicated a *trans* arrangement of the two alkyl moieties at the stereogenic centers. Complete debenzylation—for example, to give the free diamine **12**—was accomplished with the Pearlman catalyst according to the method of *Yoshida* et al (Scheme 3).[10] Compound **12** was acylated on both amino groups by treating it with an excess of (+)-3,3,3-trifluoro-2-methoxy-2-phenylpropionyl chloride according to the method of *Mosher*.[11] The bis-acylated adduct shows a single set



Scheme 3. **10**, **11**, R = Bn, R′ = *n*Bu; **12**, R = Me_2CH, R′ = *n*Bu.

of signals in the ^1H, ^{13}C, and ^{19}F NMR spectra—proof that the synthesis and reactions of the aldimine proceed without racemization (*ee* > 98%). The *N*-tosylamine **9** could also be selectively deprotected. For example, **9** (R = Bn; R′ = Me) was transformed into **13** by treatment with Pearlman catalyst and then cyclized to give the urea derivative **14** having a *cis* arrangement of groups on the stereogenic centers (Scheme 4). Compound **13** was acylated on the NH_2 groups according to the Mosher method[11] and also proved to be optically pure (*ee* > 98%). The tosyl group in **9** was selectively removed by treatment with sodium naphthalide (dimethoxyethane (DME), 6 h, 22 °C)[12] or with sodium in liquid ammonia (−40 °C, 4 h)[13] (81–86% yields), affording product **15**. The free amine **16** was prepared by debenzylation. Such regioselective deprotection is of importance for further reactions at one or the other nitrogen atom.



Scheme 4. R = Bn, R′ = Me.

The reactions leading to vicinal diamines **5** and **12** or **9** and **16** are stereoselective, proceed without racemization, and are simple to carry out.[14] Since many amino acids are also accessible in the (*R*) form,[15] it is also possible to prepare the enantiomeric vicinal diamines.

[14] a) General procedure for additions to **3**: A solution containing 1 mmol of an aldimine **3** in 10 mL of anhydrous ether was allowed to react under an inert atmosphere with 1.3 mmol of an alkyllithium reagent at −78 °C. After 1 h, the reaction mixture was allowed to warm to room temperature and stirred for 1–2 h; in the case of the aldimine obtained from ornithine (R = $Bn_2N(CH_2)_3$), the reaction time was increased to 4 d. Aqueous workup and chromatography on silica gel (petroleum ether/ethyl acetate 2:1) afforded diamines **5** (Table 1); b) General procedure for additions to **7**: An aldehyde **2** (2 mmol) in 2 mL of anhydrous dichloromethane was added to a solution of *N*-sulfinyl-*p*-toluenesulfonamide (600 mg, 2.8 mmol) [8] in 10 mL of anhydrous dichloromethane at room temperature under an inert atmosphere. The reaction mixture was stirred for 2–3 h (exception: **7** (R = Me_2CH), 48 h) and 6 mmol of a Grignard reagent was

then added at 22–30 °C. After 1 h, the reaction mixture was worked up with 50 mL of saturated NaCl solution and extracted twice with ethyl acetate. The combined organic extracts were dried over $MgSO_4$ and evaporated. Chromatography on silica gel (petroleum ether/ethyl acetate 2:1) afforded adducts **9** (Table 2); c) General procedure for single debenzylation of **5**: Pd-black (ca. 50–100 mg) was added to a solution of 20 mL of methanol and 1 mL of formic acid. Diamine **5** (0.5–2 mmol) was dissolved in a small amount of methanol (2–5 mL) and added dropwise to the above solution. The reaction mixture was stirred for 1–3 d at room temperature under 1 atm of H_2. After filtration to remove Pd-black and removal of the solvent by distillation, a 75–85% yield of diamine **10** was obtained: d) General procedure for triple debenzylation of **5**: The catalyst [10] $Pd(OH)_2/C$ was dried for 24 h at 60 °C over P_2O_5 prior to use. $Pd(OH)_2/C$ (50–100 mg) was then added to a solution of diamine **5** (0.5–2 mmol) in anhydrous methanol and the mixture was stirred for 3 d under 1 atm of H_2. After filtration over Celite to remove the catalyst and removal of the solvent by distillation, a 70–90% yield of the completely debenzylated diamine **12** was obtained.

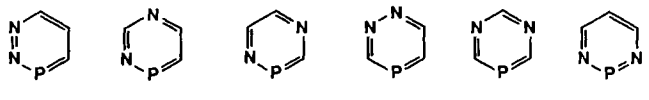
2,4,6-Triaryl-1,3,5λ^3-diazaphosphinines

By *Gottfried Märkl** and *Christian Dörges*

Dedicated to Professor Karl Dimroth on the occasion of his 80th birthday

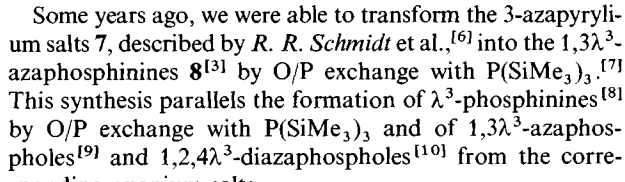
The N/P electronegativity difference causes a dramatic change in the reactivity of 1,2λ^3-[2] and 1,4λ^3-azaphosphinines[1] compared with that of λ^3-phosphinines. The 1,3λ^3-azaphosphinines,[3] for which a mesomeric interaction between the heteroatoms is not possible, have proven useful, for example, as building blocks for the synthesis of functionally substituted λ^3-phosphinines.[4] It therefore seemed especially interesting to investigate how the heteroatom effects in diaza-λ^3-phosphinines reinforce or compensate each other. Of the diaza-λ^3-phosphinines **1**–**6**, homologous to triazines, only a derivative of 1,2,4λ^3-diazaphosphinine **4** (see below) has been described.[5]



1 **2** **3** **4** **5** **6**

Some years ago, we were able to transform the 3-azapyrylium salts **7**, described by *R. R. Schmidt* et al.,[6] into the 1,3λ^3-azaphosphinines **8**[3] by O/P exchange with $P(SiMe_3)_3$.[7] This synthesis parallels the formation of λ^3-phosphinines[8] by O/P exchange with $P(SiMe_3)_3$ and of 1,3λ^3-azaphospholes[9] and 1,2,4λ^3-diazaphospholes[10] from the corresponding oxonium salts.

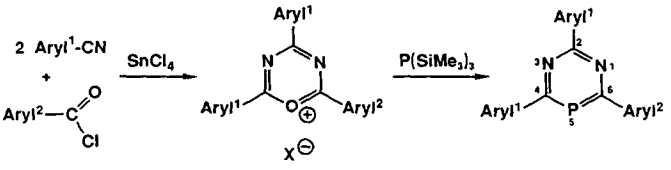
This O/P exchange was unsuccessful with the readily accessible 2,4,6-triaryl-3,5-diazapyrylium salts **9**, $X^{\ominus} = SnCl_5^{\ominus}$,



7

[*] Prof. Dr. G. Märkl, Dipl.-Chem. C. Dörges
Institut für Organische Chemie der Universität
Universitätsstrasse 31, W-8400 Regensburg (FRG)

which *R. R. Schmidt* et al. prepared in a straightforward and elegant fashion by reaction of aroyl chlorides and aryl nitriles with $SnCl_4$. The salts obtained by reaction of the $SnCl_5^{\ominus}$ salts with NH_4PF_6, NaI, or $NaClO_4$ in anhydrous acetonitrile also do not undergo O/P exchange either with $P(SiMe_3)_3$ or with $P(CH_2OH)_3$[11] or PH_3[12] (this behavior corresponds to that of the corrseponding azapyrylium salts **7**). Likewise, the fluoroborates **9**, $X = BF_4^{\ominus}$, obtained in 80–90% yield by reaction of **9**, $X = SnCl_5^{\ominus}$, with $AgBF_4$, react with $P(SiMe_3)_3$ in CH_3CN to give an undefined mixture of products. However, reaction in refluxing benzene for 24 h affords, after chromatographic workup (silica gel 60, toluene), pale yellow, crystalline products, which, according to the analytical and spectroscopic data, are the 1,3,5λ^3-diazaphosphinines **10** (Table 1).



9 **10**

9, **10**: **a**, $Aryl^1 = Aryl^2 = C_6H_5$; **b**, $Aryl^1 = Aryl^2 = 4\text{-}CH_3C_6H_4$; **c**, $Aryl^1 = Aryl^2 = 4\text{-}ClC_6H_4$; **d**, $Aryl^1 = C_6H_5$, $Aryl^2 = 4\text{-}ClC_6H_4$; **e**, $Aryl^1 = 4\text{-}ClC_6H_4$, $Aryl^2 = C_6H_5$; **f**, $Aryl^1 = 4\text{-}ClC_6H_4$, $Aryl^2 = 4\text{-}CH_3C_6H_4$; **g**, $Aryl^1 = 4\text{-}CH_3C_6H_4$, $Aryl^2 = 4\text{-}ClC_6H_4$; $X^{\ominus} = SnCl_5^{\ominus}$, $PF_6^{\ominus}$, $I^{\ominus}$, $ClO_4^{\ominus}$, $BF_4^{\ominus}$.

The mass spectra of diazaphosphinines **10** show that they decompose into their components R-C≡P and R-C≡N; the mass spectra of the unsymmetrically substituted derivatives indicate that scrambling of the radical cations occurs (for

Table 1. Yields and physical data for **10a**.

10a: Yield 6%; m.p. 146–147.5 °C, (CH_2Cl_2/EtOH), MS (70 eV): *m/z* 326 ($M^{\oplus}$, 10%), 223 ([*M*-PhCN]$^{\oplus}$, 1.3), 120 ([PhC≡P]$^{\oplus}$, 100%). ^{31}P NMR ($CDCl_3$): $\delta = 140.3$ [for comparison: 1,3λ^3-azaphosphinine **2**, Aryl = C_6H_5: $\delta = 163.0$[3]; 2,4,6-triphenyl-λ^3-phosphinine: $\delta = 172.0$[11]. example, the molecular ion peaks of **10b** and **10g** are also observed in the mass spectrum of **10f**).

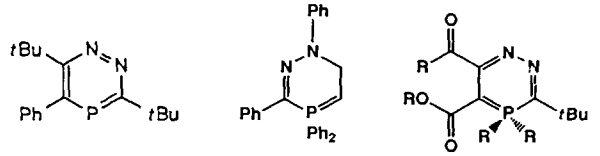
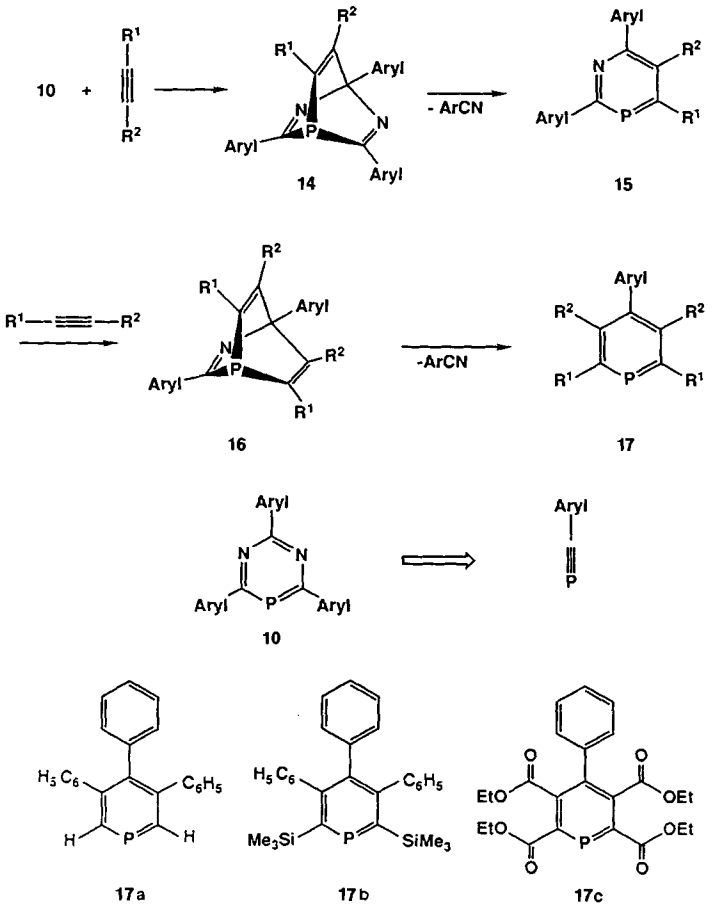
Besides the 1,2,4λ^3-diazaphosphinine **11**, obtained by reaction of 2-*tert*-butyl-1-chloro-3-phenylphosphirene with lithio-*tert*-butyldiazomethane, only the 1,2,4λ^5-diazadihydrophosphinine **12**[15] and several 1,2,4λ^5-diazaphosphinines of type **13**[16] have been described so far. The synthesis



11 **12** **13**

of the 1,3,5λ^3-diazaphosphinines **10** thus provides the first general route to λ^3-phosphinines containing two nitrogen atoms in the ring.

Preliminary investigations into the chemistry of the 1,3,5λ^3-diazaphosphinines **10** have revealed striking similarities with the reactivity of the 1,3λ^3-azaphosphinines **8**. In contrast to λ^3-phosphinines, which react only with highly reactive alkyne dienophiles (F_3C-C≡C-CF_3, NC-C≡C-CN) at 100 °C (sealed tube) to form heterobarrelenes,[17] diazaphosphinines **10** undergo a "domino" reaction in refluxing toluene with all alkyne dienophiles so far investigated to give the tri- and pentasubstituted λ^3-phosphinines **17** via the heterobarrelenes **14**, the 1,3λ^3-azaphosphinines **15**, and the heterobarrelenes **16**. Starting from **10**, only the fragments phosphorus and aryl-C^6 of the original diazaphosphinine are present in **17**. Thus, diazaphosphinines **10** can be formally regarded as synthons for P≡C-Aryl.



14 **15** **16** **17** **10** **17a** **17b** **17c**

In this way, the pentasubstituted λ^3-phosphinines **17a**–**17c** have so far been synthesized by reaction of **10a** with phenylacetylene, 1-phenyl-2-trimethylsilylacetylene, and diethyl acetylenedicarboxylate, respectively.

$(n\mathrm{Bu}_4\mathrm{P})_2[\mathrm{Os}_{20}(\mathrm{CO})_{40}]$, a Thermolytically Generated High-Nuclearity Cluster with a Tetrahedral Cubic-Close-Packed Metal Core**

By *Angelo J. Amoroso, Lutz H. Gade, Brian F. G. Johnson, Jack Lewis,* Paul R. Raithby,* and *Wing-Tak Wong*

The structures and properties of metal cores containing tens or hundreds of metal atoms are of considerable interest not only in their role as model systems in surface sciences[1] but also due to their postulated, and in some cases proven, unusual catalytic and physicochemical behavior.[2] However, little is known about the detailed kinetic and thermodynamic constraints that influence the buildup of either large clusters or small colloidal metal particles.[3]

[**] We acknowledge the financial support of the British Council (FCO-Kurt Hahn Scholarship to *L.H.G.*), the Royal Commission for the Exhibition of 1851, and the U.K. Committee of Vice Chancellors and Principals (*W.-T.W.*), and the SERC (*A.J.A.*).

A powerful method for the synthesis of binary high-nuclearity carbonyl clusters containing metals of the iron triad has been the thermolytic generation of metal carbonyl fragments which combine to generate an array of clusters containing between 4 and > 20 metal atoms.[4] In these thermolyses certain atom numbers are found to dominate the product distributions, thereby allowing highly selective syntheses of these species under the appropriate reaction conditions. For osmium clusters, the generation of metal cores containing 4, 6, 10, and, as reported here, 20 metal atoms appears to be particularly favored. With the exception of the hexaosmium clusters, these atom numbers correspond to the series of "magic" numbers 4, 10, and 20 associated with molecular tetrahedra of edge lengths 2 (atoms), 3, and 4 and therefore represent a gradual buildup of cubic-close-packed cores with an overall tetrahedral symmetry. While the structures and chemistry of the first two members of this series (e.g., $[H_2Os_4(CO)_{12}]^{2\ominus}$ [5] and $[Os_{10}C(CO)_{24}]^{2\ominus}$ [6]) have been extensively studied, it is only the recent reinvestigation of the vaccum pyrolysis (10^{-3} Torr, 300 °C) of the osmium cluster **1** that has led to the isolation of the dianion **2** and the characterization of the $Os_{20}^{\ominus}$ tetrahedron.

$[Os_3(CO)_{10}(NCCH_3)_2]$ **1**

$[Os_{20}(CO)_{40}]^{2\ominus}$ **2**

The cluster dianion **2**, which may be isolated as its $(Ph_3P)_2N^{\oplus}$, $(nBu_4P)^{\oplus}$, or $(Me_4N)^{\oplus}$ salt, is formed in 20% yield along with $[Os_{10}C(CO)_{24}]^{2\ominus}$, $[Os_{17}(CO)_{36}]^{2\ominus}$,[7] and a number of lower-nuclearity fractions (Os_4, Os_5). The stoichiometry of the compound was initially established by FAB mass spectrometry.[8] The simplicity of the ν(CO) absorption band pattern in the IR spectrum indicated a highly symmetrical cluster geometry.[9] This was confirmed by a single-crystal X-ray structure analysis of its $(nBu_4P)^{\oplus}$ salt (Fig. 1a), which established the hitherto unobserved metal core geometry (Fig. 1b).[10] The metal polyhedron may be derived from that of $[Os_{10}X(CO)_{24}]^{2\ominus}$ (X = H_4, C) by addition of a further planar triangular layer of ten osmium atoms. This kind of skeletal geometry has been the object of a number of theoretical studies related to the abundant M_{20} clusters in supersonic beams of alkali-metal vapors.[11] Simple electron-counting rules would demand a higher skeletal electron count for a tetrahedral Os_{20} species than that obtained on the basis of the formulation put forth in this paper. However, neither the crystal structure analysis nor IR, ^1H NMR or ^{13}C NMR spectroscopy[9] has revealed the presence of interstitial atoms (C,H) in the four octahedral or eleven tetrahedral cavities of the core. Moreover, for a molecular mass of this magnitude the FAB mass spectra obtained are not unambiguous in determining the presence of interstitial hydrogen or even carbon atoms.

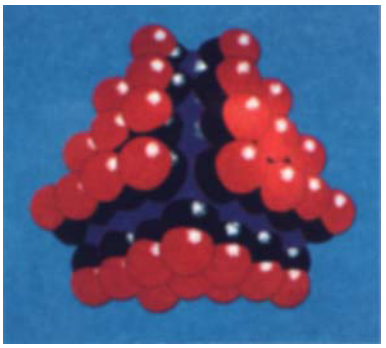

Fig. 2. Space-filling model of **2** showing the monolayer of CO on the surface of the metal core.

The mean metal–metal distances (2.786(5), 2.747(3), 2.678(8) Å for the Os atoms surrounding the three different types of tetrahedral cavities and 2.746(4) Å for the octahedral cavities) are similar to those in the recently characterized dianion $[Os_{17}(CO)_{36}]^{2\ominus}$, which is also a binary cluster with unoccupied interstitial sites.[7] The four Os atoms of the unique tetrahedron at the center of the cluster (shaded in Figure 1b) have the highest metal–metal connectivity and an

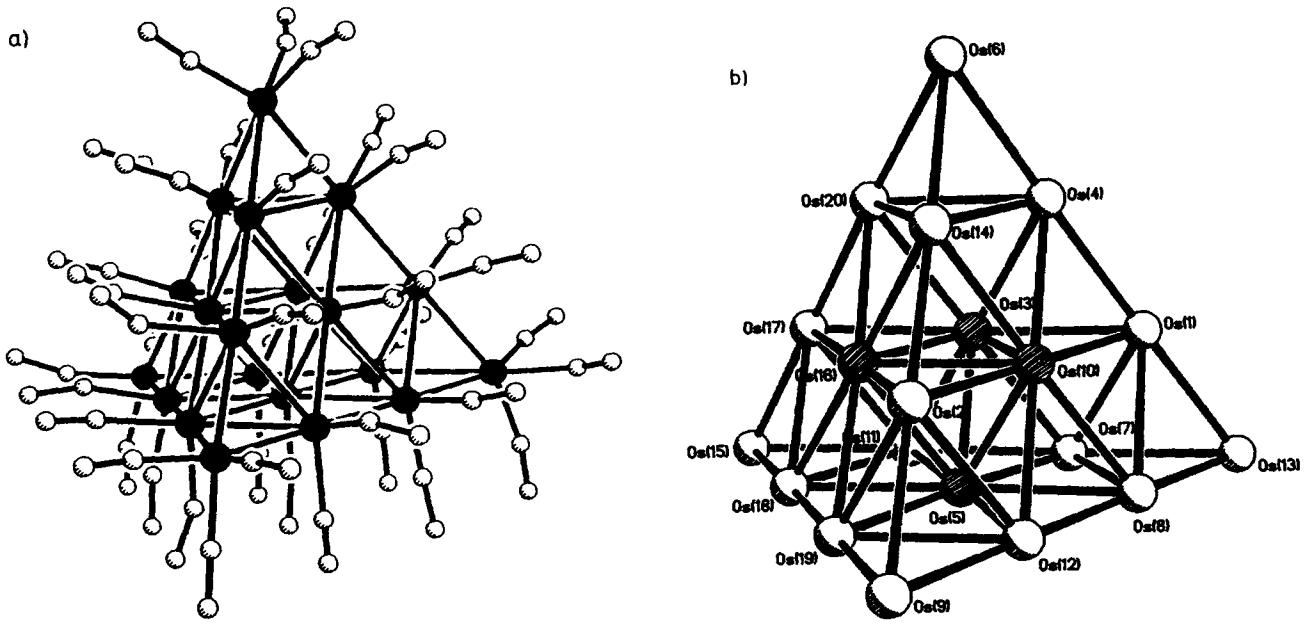

Fig. 1. a) Molecular structure of the dianion $[Os_{20}(CO)_{40}]^{2\ominus}$ (**2**). b) Structure of the Os_{20} metal core.

average bond distance of 2.678(8) Å, approaching that observed for the bulk metal (2.6754 Å).[12]

The symmetry of the core is matched by that of the CO ligand shell in which there are 40 terminal CO ligands in three chemically distinct environments (Fig. 2). The coordination of CO to the cluster surface is similar to that observed for chemisorbed carbon monoxide on the (111) surface of cubic-close-packed metals.

Preliminary cyclovoltammetric studies of the cluster have revealed a rich electrochemistry[13] which reflects the increased density of accessible oxidation states for large metal particles in comparison to the smaller clusters studied so far.[14]

Experimental Procedure

A 180-mL Carius tube was filled with a suspension of 1 g of **1** [15] in 30 mL of CH_2Cl_2. The solvent was evaporated under reduced pressure and the solid evenly distributed over the interior surface of the tube, which was then sealed at 10^{-3} Torr. The precursor compound was pyrolyzed at 300 °C for 70 h to yield a brown-black powder which was initially sparingly soluble in acetone. Heating under reflux in a mixture of 100 mL of acetone and 30 mL of methanol in the presence of $[(Ph_3P)_2N]Cl$ (1.2 g) for 20 h resulted in almost complete dissolution of the solid. The deep brown solution was filtered (ca. 100 mg of insoluble material) and the filtrate evaporated to dryness. After the removal of surplus $[(Ph_3P)_2N]Cl$ by extraction with methanol, the residue was redissolved in 25 mL of acetone and separated by thin layer chromatography (silica gel) using acetone/hexane (60/40) as eluent. Apart from the neutral low-nuclearity fractions moving near the solvent front ($R_f = 0.9$, ca. 100 mg of Os_4 and Os_5 clusters), the major fractions were $[(Ph_3P)_2NOs_{17}(CO)_{36}]$ ($R_f = 0.65$, brown, 73 mg (7%)), $[(Ph_3P)_2N]_2[Os_{10}C(CO)_{24}]$ ($R_f = 0.60$, red, 350 mg (29%)), and $[(Ph_3P)_2N]_2[Os_{20}(CO)_{40}]$ (**2**) ($R_f = 0.4$, brown-green, 200 mg (20%)). Other minor fractions, including the baseline, accounted for ca. 100 mg of material. The $(nBu_4P)^{\oplus}$ salt of **2** was obtained through cation metathesis with $(nBu_4P)Cl$ and crystallized by slow evaporation of a solution of the salt in acetone/methanol (2/1).

[8] The negative ion FAB mass spectra of the salts of dianionic clusters display a characteristic peak pattern: dianion, monoanion, (dianion + cation), and, in exceptional cases, (dianion + 2 × cation). For **2**, the most abundant isotopomers were found at *m/z* 2467 dianion; simulated 2464, 4937 (monoanion; simulated 4929), 5186 (dianion + $(nBu_4P)^{\oplus}$; simulated 5197), 5450 (dianion + 2 × $(nBu_4P)^{\oplus}$; simulated 5462).

[9] IR (CH_2Cl_2): $\tilde{\nu}$ [cm^{-1}] = 2045 (s), 2002 (s), 1955 (w); no absorption bands for an interstitial carbide observed between 500 and 800 cm^{-1} ($Me_4N^{\oplus}$ salt, CsI disk). ^{13}C NMR (100.6 MHz, [D_6] acetone, 295 K): $\delta = 158.0$ (12 CO), 179.5 (4 CO), 179.8 (24 CO); no carbide resonances observed between $\delta = 350$ and 480. A set of up to six paramagnetically shifted ^{13}CO signals may appear between $\delta = 55$ and 310, depending on the treatment of the sample before recording of the spectra.

[10] Crystal data for $(nBu_4P)_2[Os_{20}(CO)_{40}]$: triclinic, space group $P\bar{1}$, $a = 14.094(5)$, $b = 16.539(8)$, $c = 22.650(9)$ Å, $\alpha = 105.93(1)$, $\beta = 101.78(1)$, $\gamma = 90.21(1)°$, $M = 5443.2$, $V = 4960(4)$ Å^3, $Z = 2$, $\varrho_{calcd} = 3.645$ g cm^{-3}, $F(OOO) = 4748$, $Mo_{K\alpha}$ radiation, $\lambda = 0.71069$ Å, $\mu(Mo_{K\alpha}) = 256.47$ cm^{-1}. The structure was solved by a combination of direct methods and difference Fourier techniques and refined by the block-matrix least-squares method. All osmium atoms were refined anisotropically, while the carbonyl ligands were refined independently at a later stage. No attempt to refine the $(nBu_4P)^{\oplus}$ has been made. 6210 reflections (corrected for absorption and decay), 2891 observed reflections with $F > 3\sigma(F)$ with $5° < 2\theta < 38°$, $R = 0.072$, $R_w = 0.065$. Further details of the crystal structure investigation can be obtained from the Director of the Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Rd, Cambridge CB2 1EW (UK). Book Reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the following address: Redaktion Angewandte Chemie, Postfach 101161, W-6940 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

High Pressure Chemical Synthesis. Edited by *J. Jurczac* and *B. Baranowski*. Elsevier, Amsterdam 1989. x, 507 pp., hardcover DFl 320.00.—ISBN 0-444-88187-5

Formerly, in the good old days, when one believed that one had acquired sufficient knowledge it was usual to sit down and write a book. Nowadays, when it seems that there is no longer anyone who has a complete grasp of a subject unaided, one persuades one's scientific friends to write something for a field which has now reached an advanced stage of development and has great future potential (or alternatively, a publisher or a "series editor" organizes this). From this there then emerges a book, the parts of which are in many cases better than the whole.

"High Pressure Chemical Synthesis", edited by *J. Jurczac* and *B. Baranowski* of the Polish Academy of Sciences in Warsaw, is a multi-author book. In its 13 chapters (plus an introduction by the editors) the 18 authors report their experiences in the area of high pressure chemical (?) synthesis. The fact that more than half the authors (10) as well as the editors belong to the Polish Academy of Sciences is an indication of the importance attached there to the use of "pressure" to assist chemical reactions. There is certainly some justification for this, even though it remains true that the bunsen burner, compared with the high pressure autoclave or press, is a cheaper item of apparatus. The merit of the idea behind this book, and the achievement of its editors, is that it deals with such reactions (and processes) that require pressure to proceed usefully or even to occur at all.

In the introduction the editors point out that the earth itself is a unique high pressure laboratory for the synthesis of many inorganic substances (minerals). However, this is probably also true for the area of organic syntheses. Accordingly, the range of topics covered in this multi-author book is very wide.

Only four chapters are concerned with inorganic substances: ultrahard materials, diamond, cubic boron nitride (*O. Fukunaga*, Tokyo), metal nitrides, mainly III-V semiconductors, but also molybdenum nitrides (*S. Porowski, I. Grzegory* and *J. Jun*, Warsaw), (transition) metal hydrides (*B. Baranowski* and *S. M. Filipek*, Warsaw), oxides of iron, cobalt and nickel in higher oxidation states (*G. Demazeau*, Bordeaux). These chapters only deal with the classes of substances that are of technological interest; many aspects, such as fluorides, sulfides, and solid state reactions and phase transformations at high pressures are not covered at all.

The other nine chapters are concerned with organic chemistry (including biochemistry and biological chemistry). In the chapters on open-chain systems (*N. S. Isaacs*, Reading) and (carbo-)cyclic systems (*J. W. Scheeren*, Nijmegen), as also in the following chapters, the effects of pressure on the reaction rate are clearly seen as negative contributions to the activation volume and reaction volume. The contribution on monosaccharides (*A. Golebiowski, J. Jurczac* and *S. Pikul*, Warsaw) examines the effects of pressure on the regio- and stereoselectivity of organic reactions. The following chapters are concerned with β-lactams and other N-heterocycles prepared by cycloadditions and -condensations (*M. Chmielewski* and *J. Jurczak*, Warsaw), cryptands and other host molecules (*J. Jurczak* and *M. Pietraszkiewicz*, Warsaw), organic syntheses using organometallic reagents or catalysts (*J. Jurczak*, Warsaw and *A. Rahm*, Bordeaux), and materials of biological interest, amino acids and enzyme-catalyzed reactions (*Y. Taniguchi*, Kyoto). *G. Luft* (Darmstadt) then deals with polymers, an area of special technological importance in which the advantages of high pressures are particularly evident. Next *G. Jenner* (Strasbourg) discusses C_1 chemistry, i.e. the synthesis of basic chemicals from carbon monoxide and hydrogen, another area of great technological promise which is only accessible through the use of high pressures and catalysts.

Each chapter is constructed on the lines of a review article, and thus includes an adequate number of references to the original literature. The extensive author index (24 pp.) is an aid to finding relevant papers in cases where the names of the authors signify something to the reader. The subject index too is undoubtedly useful. The book contains a total of 507 pages, reproduced from many different typewriters and PC printers (a form which is not aesthetically appealing, and is also inappropriate in the age of compatible computers). It is definitely more in the nature of a volume of a review journal than a textbook, each chapter having been written for the specialist rather than for the reader seeking an overview of high pressure synthesis. Also, regrettably, the high price will be an obstacle to this very useful work reaching a wide readership; however, it can be recommended without reservation to well-funded libraries for their "progress reports" sections.

Sensors—A Comprehensive Survey. Series editors: *W. Göpel, J. Hesse* and *J. N. Zemel*. VCH Verlagsgesellschaft, Weinheim. **Vol. 1: Fundamentals and General Aspects.** Edited by *T. Grandke* and *W. H. Ko*. 1989. xxxiii, 641 pp., hardcover DM 350.00 (subscription price: DM 290.00).—ISBN 3-527-26767-0; **Vol. 5: Magnetic Sensors.** Edited by *R. Boll* and *K. J. Overshott*. 1989. xii, 513 pp., hardcover DM 350.00 (subscription price: DM 290.00).—ISBN 3-527-26771-9

If one can believe the forecasts of leading market research agencies, the field of sensors has an enormous development potential with annual growth rates running into two figures. Owing to the central importance of sensors in measurement and control and their vital role in automated processes, a new key technology has grown up in this area. The function of sensors in general is to provide information. The more information one has on the state of a system, the more precisely can one model the system and predict its behavior, and

 © VCH Verlagsgesellschaft mbH, W-6940 Weinheim, 1991 0570-0833/91/0101-0110 $ 3.50+.25/0

the more effectively control its operation. Without a highly developed sensor technology it is impossible to be at the forefront of measurement and control technology and to manufacture high-technology products. VCH has just published the first two volumes of an eight-volume handbook on sensors, which sets out to describe the most important types of sensors and to present a comprehensive survey of the latest developments in this fast-moving field. The handbook is thus very much in tune with current trends and with the economic importance of such measuring devices.

The eight volumes deal with the following topics: 1. Fundamentals and General Aspects, 2/3. Mechanical Sensors, 4. Thermal Sensors, 5. Magnetic Sensors, 6. Optical Sensors, 7/8. Chemical and Biochemical Sensors. Following the appearance of Volumes 1 and 5 the editors and publishers are to be congratulated on a series which is (up to now) turning out very well. The authors engaged for the work are acknowledged experts, and they have generally covered the literature up to 1988/89 in their respective special fields. Unnecessary overlapping of subject matter, which is often an annoying feature of multi-author works, has been largely avoided. Where overlapping does occur, a different point of view is presented, thereby adding significantly to the description.

The first chapter of Volume 1 deals with the general principles of sensors, definitions, sensor characteristics and models, and includes useful information on the design of integrated-circuit chips and their encapsulation. Chapter 2 is concerned with the basic technology used in manufacturing modern sensors. The practically-orientated descriptions of the manufacture of integrated circuit chips, of thin-film and thick-film technologies, and of integrated optics are impressively good, and will provide newcomers to the field with some detailed know-how. Chapter 3 deals with sensor interfaces, including signal processing and data treatment. The suggested approaches to sensors or sensor arrays that are self-correcting undoubtedly represent a good way of obtaining improved reliability in the measurement of physical quantities. However, in the field of trace analysis of gases by chemical sensors, a method which is only used in low concentration ranges and is therefore very susceptible to trouble, so that it is seldom possible to identify all trace substances or to rule out their presence, the computation method described as a way of correcting for inadequate chemical selectivity only works with a little luck on one's side, to use the words of one of the authors of this volume. The disastrous results obtained in comparative trace analysis trials on the same sample using instruments from different manufacturers or based on different principles speak for themselves, and regularly illustrate the dangers of underestimating the difficulties of trace analysis problems. The final chapter of Volume 1 describes some typical applications of sensors, including examples of their use in automobiles, in domestic equipment, for process control in the chemical industry and in power-station technology, for environmental protection purposes, for medical technology, and for aerospace applications, together with indications of other potential uses. Although some of the contributions here seem rather trivial from the analytical chemist's viewpoint, they will serve to impress on non-specialist readers the many different types of sensors that are still waiting to be developed.

Volume 5 contains twelve articles on magnetic sensors, starting from the basic physical principles and continuing through to trends for the future. The subjects of the individual articles are: magnetogalvanic, magnetoresistive and magnetoelastic sensors, fluxgate sensors, inductive loop sensors, Wiegand and pulse-wire sensors, superconducting quantum interference devices (SQUIDs), and applications for each of these types of devices.

This monograph, written by authors drawn from both industry and universities, is a highly informative work, even for the non-specialist. It describes in a compact form all the modern magnetic sensors that are of practical importance. It also makes easy reading, not least because of the excellent standard of presentation of this series, in which the numerous figures and tables greatly facilitate finding the required information. Also extremely useful are the references to the most recent published work, dissertations, company reports and other material.

If the remaining volumes turn out to be equally well edited and competently written, the result will be a series that no library should be without. This standard work can be recommended unreservedly for scientists in the fields of chemistry, electronics, process technology and measurement and control technology. A more up-to-date review of such quality in a rapidly developing field is unlikely to be found anywhere.

Photochemistry on Solid Surfaces. (Series: Studies in Surface Science and Catalysis, Vol. 47). Edited by *M. Anpo* and *T. Matsuura*. Elsevier, Amsterdam 1989. xx, 585 pp., hardcover DFl 360.00.—ISBN 0-444-87413-5

In the Elsevier series "Studies in Surface Science and Catalysis", which began in 1975, Volume 47 "Photochemistry on Solid Surfaces" has now appeared under the editorship of *M. Anpo* and *T. Matsuura*. This work must be compared with the review article "Radiation and Photoeffects at Gas/Solid Interfaces" by *J. Cunningham*, which appeared five years earlier in *Comprehensive Chemical Kinetics, Vol. 19* (also published by Elsevier). The present volume sets out to give a review of the latest developments in photochemistry on solid surfaces. This field is in fact developing very rapidly, especially with regard to high-technology industrial applications, which according to the editors are now profiting from a major governmental research project in Japan. To help stimulate further progress in this area, 69 authors have been engaged to report on this many-faceted field, which they have done in 35 articles grouped in 9 chapters with a total of 581 pages. The preponderance here of Japanese (52%) and North American (29%) authors should not be allowed to obscure the fact that European workers have made and continue to make fundamental contributions in this area; in many of the articles the European contributions are underrepresented in the literature citations, and of course this imbalance is not corrected when one refers back to the earlier review. Despite this, the volume is also of interest to European research workers as a means of keeping informed about work in Japan and North America, although more complete information is, of course, available from CAS-ONLINE and from data banks on patents.

Following a short introductory chapter (13 pages), Chapter 2 (104 pages) discusses time-resolved fluorescence spectroscopy, the spectroscopy of transient absorbed species, laser flash photolysis at solid surfaces, excimer formation on silica gel surfaces, and photoacoustic measurements on adsorbed species. The descriptions of the techniques and of the types of information that can be expected from them are elucidated by numerous block diagrams, by presentation of

the basic equations, and by diagrams which are mainly redrawn from earlier publications.

In Chapter 3 (77 pages) specific surface effects on photochemical reactions are discussed. Most of these are free radical reactions, which can be carried out on surfaces of glass, silica gel, semiconductors and metal oxides at various temperatures. The presence of defects with electron acceptor properties can cause chemiluminescence.

New developments in organic photochemistry at solid surfaces are described in Chapter 4 (57 pages). Surfaces that can function as electron transfer partners include those of zeolites, micelles and organic crystals.

Chapter 5 (62 pages) is devoted to inorganic photochemistry at solid surfaces. Metal complexes and metal carbonyls can be illuminated on low temperature matrices, crystal surfaces, porous Vycor glass or silica gel; metal oxides and metal carbonyl catalysts are prepared on supports.

Chapter 6 (36 pages) gives a short introduction to the industrially important processes of photodeposition and photoablation on solid surfaces (often using lasers). These high-technology applications (e.g. in microelectronics) have not been adequately covered here. In this area especially, extensive industrial research and development programs are under way in Europe, e.g. the ESPRIT project (European Strategic Programme for Research and Development in Information Technologies), which go far beyond those reported in this book.

Similarly in Chapter 7 (65 pages) on photochemistry at semiconductor surfaces, it is not possible in so few pages to do justice to the topic. Although the chapter offers some useful thoughts on fractal surfaces, area-selective illumination, photoluminescence of CdS and fluorescence of adsorbed dyes, it is advisable to first obtain an overview of the topic by looking through the published proceedings of major international conferences on photochemistry, which usually contain numerous contributions on photoelectrochemistry.

The application of photochemistry to optical information storage media such as laser-CDs is an area of great importance, which is treated in Chapter 8 (50 pages). The topics that are sketchily covered here include IR-absorbing dyes for DRAW disks, photoinduced phase transitions in liquid crystals, and the application of surface reactions of polymers in lithography. Here again it is regrettable that European laser research is not represented.

Finally Chapter 9 (97 pages) deals with photochemistry in crystals (very briefly, and restricted to ketones), liquid crystals, chiral crystals (absolute asymmetric syntheses), and proteins (picosecond dynamics, energy transfer). The book ends with a subject index (15 double-column pages).

Thus the book is a collection of short articles which exemplify most aspects of the field described by the title, but these are not of a genuine review character. In fact many of the individual topics are covered elsewhere in monographs.

The book is likely to be useful to libraries as an aid to the newcomer entering the field and as a source of ideas for the specialist in his more advanced research. Although it does not cover every topic, it provides an indication of the breadth of this rapidly developing field of research. Future publications of this type should have their subject matter more precisely defined, and should also include contributions from industry.

The economies made by the publishers through reproducing typescripts in (more or less) camera-ready form are unfortunately not reflected in the price; at DFl 360, despite the use of glossy paper, it is too expensive, especially for individual purchasers.

Towards the Chemical Synthesis of Proteins

By Ernst Bayer*

The chemical total synthesis of proteins using solid supports has made great progress. It is therefore becoming a reality what *E. Fischer* already predicted in 1902[**]: "I foresee the time when physiological chemistry... is able to prepare synthetic enzymes." The synthesis of peptides of up to 20 amino acids by the well-established solid-phase procedure on polymeric supports (SPPS) has made great progress through the development of newer supports. At the same time, methods have emerged which facilitate the separation and characterization of peptides, thus allowing optimization of the synthesis of pure materials. The new supports which enable one to synthesize peptides by a rapid continuous flow procedure are characterized by hydrophilicity, beads of approximately equal size, similar swelling properties in the solvents used for peptide synthesis, and stability at high pressure. With graft copolymers of weakly cross-linked polystyrene and linear polyethylene glycol (PEG), the synthetic cycle for coupling of one amino acid can routinely be reduced to 10–20 min with a concomitant higher yield. With beads of monodispersed graft copolymer of 10 μm diameter, a synthetic cycle can, in principle, be shortened to 1–5 min. By utilizing this high-speed solid-phase procedure, larger peptides up to the size of proteins could also be prepared in a few hours. With newer mass spectroscopic methods such as ion-spray mass spectrometry, peptides of up to a molecular mass of 100 kDa can be characterized, and with the advent of capillary electrophoresis, another very efficient separation tool, besides HPLC, is at our disposal.

1. Introduction

The chemical synthesis of peptides has made great progress in the last two decades. Peptide synthesis has proven indispensable for the structural elucidation of many recently isolated natural products having a peptide structure such as hormones, neuropeptides, and antibiotics, which very often could be isolated in only minute quantities. Investigation of the structure–activity relationships of biologically active peptides also demands the synthesis of many analogues of a given peptide. Peptide synthesis has moreover become an indispensable research tool in immunology. Thus, the synthesis of overlapping peptide sequences is essential for epitope characterization and antibody formation.

The advances made in the chemical synthesis of peptides would not have been possible without the availability of the method of solid-phase peptide synthesis (SPPS) introduced by *Merrifield*.[1–3] Experts outside the field of peptide chemistry erroneously gained the impression that every peptide could be synthesized on a routine basis in this way, yet this notion even gains more support when one considers the possibility of peptide synthesis using fully automated synthesizers. It is therefore not surprising that since the introduction of SPPS it has been predicted that the chemical synthesis of proteins would become a routine matter. Table 1 shows several selected examples of reports concerning the solid-phase synthesis of proteins in the last 20 years.

Table 1. Attempted syntheses of naturally occurring proteins by SPPS.

Protein	Number of amino-acid residues	Year	Authors
Ferredoxin	55	1968	*Bayer, Hagenmaier, Jung* [133]
Ribonuclease A	124	1969	*Gutte, Merrifield* [134]
Cytochrome c	104	1969	*Sano, Kurihara* [135]
Growth hormone	188	1970	*Li, Yamashiro* [136]
Ribonuclease T_1	104	1972	*Izumiya* [138]
Lysozyme	129	1973	*Sharp* et al. [137]

Considering the purity criteria which govern the areas of organic and pharmaceutical synthetic chemistry, it becomes obvious that none of the protein syntheses listed in Table 1 furnish, with certainty, a pure product. In the period 1969–1973 numerous publications appeared regarding protein synthesis, but the mere fact and the recognition that the purity criteria were often not fulfilled resulted in a large reduction of the number of publications appearing thereafter. The aim to achieve a reliable synthesis of long polypeptides has therefore still not been realized. Nonetheless, it is worthwhile aiming for this goal. After all, the synthesis of pure and biologically active small peptides by SPPS furnishes a lot of information regarding the structure-activity relationships of these compounds. Similar results could be expected from the same studies on proteins, if a reliable synthesis were possible.

One question that is often posed, is whether preparing proteins via gene technology renders their chemical synthesis superfluous. But as long as a reliable chemical synthesis is not possible this question remains purely hypothetical. It is also obvious that in the case of syntheses involving non-coded amino acids, or in the case of the subsequent derivatization of proteins, the chemical synthesis could represent an easier procedure. Substitution of genetically coded amino acids by non-protein amino acids in small peptides often produces surprising biological activities; the same effects can be expected in the case of proteins. Above all, specific introduction of ^{13}C-labeled amino acid residues in the active centers of proteins and subsequent NMR investigation regarding the mechanism of action is only possible by the chemical synthesis. The biotechnological and chemical syntheses can therefore supplement each other and the new science of protein engineering[4–6] could gain impetus by the successful synthesis of long chain peptides. It is therefore important to assess the state of the art of automated peptide synthesis and to survey the trends of future developments.

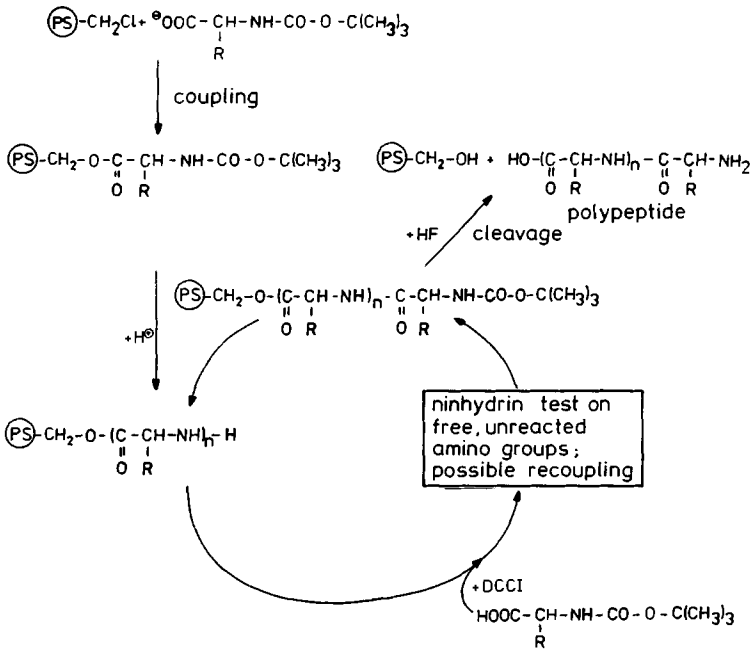
2. Principles of the Merrifield Peptide Synthesis

In principle, solid-phase peptide synthesis follows the strategy of the stepwise assembly of peptides by consecutive coupling of amino acids. This procedure, with the use of low molecular mass *C*-terminal carboxy protecting groups, has long been known in peptide chemistry,[7] but has found less widespread application than the classical coupling of fragments.[8–10] It has also long been known that the stepwise synthesis should be carried out from the *C*-terminal to the *N*-terminal end;[11,12] since only in this way can the danger of racemization be largely circumvented. Furthermore, the stepwise synthesis using low-molecular *C*-terminal protecting groups finds less application simply because the sparing solubility of one of the coupling partners does not permit a homogeneous reaction. Carrying out the synthesis as a heterogeneous reaction in such cases is also unpromising due to the poor filterability of the reaction mixture.

Merrifield's ingenious idea was to employ an insoluble and filterable polymeric support such as cross-linked polystyrene which functions at the same time as the carboxy protecting group for the *C*-terminal amino acid. Thus, the N^{α}-protected *C*-terminal amino acid is attached to the chloromethylated polystyrene-divinylbenzene as shown in Scheme 1. After removal of the N^{α}-protection, the next N^{α}-protected amino acid is coupled and the process is repeated until the entire desired peptide is assembled on the polymeric support. The advantage of this procedure is that a large excess of coupling components and additive reagents can be employed which will be easily separated from the polymer-bound peptide by simple filtration. Consequently, the laborious and cumbersome purification of intermediate peptides, a process typical of the classical solution synthesis, is avoided and results in a tremendous saving of time.

Originally, dicyclohexylcarbodiimide was proposed as the coupling reagent, but many other suitable coupling proce-

Ernst Bayer, born March 24, 1927 in Ludwigshafen/Rhein, studied chemistry at the Universities of Heidelberg and Freiburg. After completing his Diploma in 1952 he continued his studies at the Max-Planck-Institut für Medizinische Forschung, Heidelberg, where he gained his doctorate in 1954 for research on hemovanadium under the supervision of Richard Kuhn. After his habilitation in 1958 at Karlsruhe, he remained there as Dozent until 1962. In 1962 he was offered and accepted a Professorship at the University of Tübingen, and, except for a short spell as Robert A. Welch Professor at the University of Huston (February 1967–April 1970), has remained there ever since. In 1978 he received the Tswett medal of the Soviet Academy of Sciences and the British A.J.P. Martin award, in 1981 the Max Bergmann medal, in 1985 the American Tswett award, in 1989 the Distinguished Service Cross 1st Class of the Federal Republic of Germany, and in 1990 the Richard Kuhn medal of the German Chemical Society. Since 1982 he has been chairman of the advisory board for environmentally relevant existing chemicals. His scientific interests include natural products chemistry, peptide synthesis, separation methods, natural metal complexes, polymer chemistry, catalysis, and enantiomeric analysis.



Scheme 1. Standard cycle for solid phase peptide synthesis after *Merrifield*. PS = polystyrene cross-linked with 0.5–1% DVB; DCCI = dicyclohexylcarbodiimide.

dures, e.g. with active esters or anhydrides can also be used.[13 - 20] Besides the chloromethyl group originally proposed for the anchoring of the *C*-terminal amino acid on the polymer, in the meantime many other anchoring agents have been introduced.[13, 21 - 28]

Even today, *Merrifield*'s original strategy using the benzyl ester anchor and the acid labile *tert*-butyloxycarbonyl group for amino protection is widely employed. The protection of the trifunctional amino acids follows principally the known methods in peptide chemistry and is well-documented in the literature.[9, 13, 29 - 35]

After completion of the synthesis, the peptide is detached from the support. In the Merrifield strategy, strong acids or anhydrous HF are used for the cleavage of peptides from the polymer. Under these conditions the side-chain protecting groups are simultaneously removed and free peptides are obtained. Owing to standardization of the steps involved, the solid-phase synthesis can easily be automated. In fact automatic peptide synthesizers have already been developed and are commercially available.[31, 36 - 38]

3. Problems in the Synthesis of Pure Peptides

Like all other ingenious ideas, SPPS also has its short comings. Thus, it very soon became obvious that the fact that the growing peptide chain always remains on the polymer not only has advantages (facile separation), for, in principle, a multistep synthesis without purification of the intermediates can only yield a pure product if every reaction step proceeds unequivocally and quantitatively. However, which organic reaction can always be claimed to proceed quantitatively? Also in peptide synthesis the occurrence of some side reactions should be taken into account, such as, e.g., detachment of the protecting groups of trifunctional amino acids and additional reactions of the third functional groups (carboxy, amino and hydroxy), racemization, rearrangements, and cyclizations.

The by-products thus formed can then react further and remain together with the growing peptide chain on the polymeric support until the end of the synthesis. Yet even if the side reactions can be avoided, a complete peptide coupling and amino deprotection in every cycle is highly unlikely in the heterogeneous reactions that take place on polymeric beads. Polymer matrix effects as well as the formation of rigid conformations can also drastically lower the yield. The effects of these conformational changes are well documented in the literature.[38 - 46] Above all, the formation of β-folded structures in the case of peptides with 6–20 amino acid residues can often lead to an abrupt termination of the synthesis before the desirable end product is obtained. Even if a statistical yield of 99.5% is obtained in every coupling and deprotection reaction, the problem of the so-called truncated and failure sequences remains unresolved.[47 - 52] As an example the synthesis of a pentapeptide A–B–C–D–E is given in Figure 1. The truncated sequences arise if the polymer-

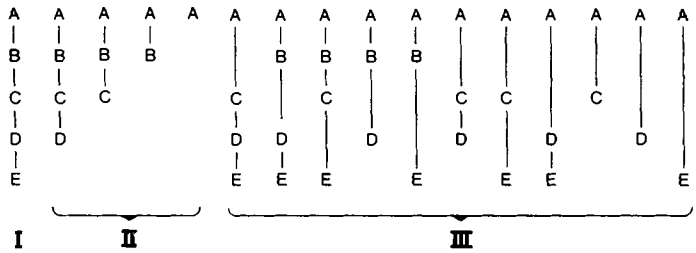


Fig. 1. Truncated **II** and failure sequences **III** obtained by solid-phase synthesis of a pentapeptide A-B-C-D-E **I**.

bound peptide no longer reacts in a synthetic step. They possess, in principle, the correct sequence. But because of conformational changes, an end group which has not reacted in one or several coupling steps can again become accessible at a later stage. Therefore as the peptide grows, a binominally increasing number of failure sequences will be produced. These peptides with failure sequences, which are chemically related to the desired end product, are extremely difficult to separate. It has been demonstrated that such failure sequences are also produced during otherwise successful syntheses.[47 - 54] Besides chromatographic procedures, the more recent spectroscopic methods such as FAB (fast atom bombardment) and ion-spray MS can also be used for the detection of failure sequences. Figure 2 shows the detection of such failure sequences of a synthetic heptadecapeptide, directly after its cleavage from a polymeric support.

Assuming a 95% yield in every coupling and amino deprotection step in the synthesis of ribonuclease with 124 amino acids, the product can only be obtained in 0.0002% yield, whereas, concomitantly a 15-fold amount of peptides containing one less amino acid is produced. It is therefore obvious that the synthesis of a peptide using the original conditions of SPPS would be possible only under very fortunate circumstances. Only if the yield is improved through optimization of the conditions, is there a chance to prepare

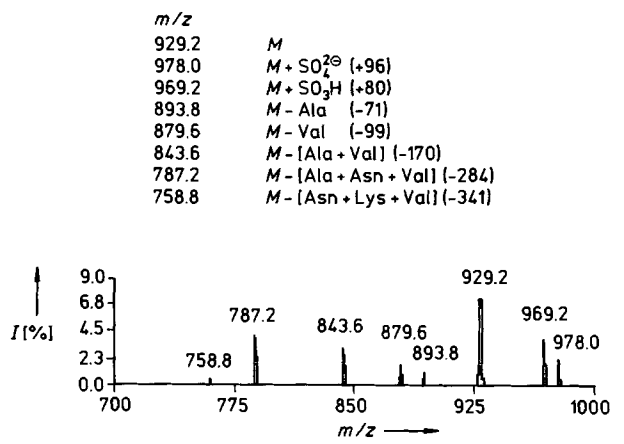

Fig. 2. Ion-spray mass spectrum of the 17-residue peptide H-Ala-Val-Leu-Gly-His-Asp-Glu-Ala-Ala-Tyr-Ser-Lys-Asn-Arg-Arg-Ala-Val-OH *M* directly after its cleavage from the polymeric support. Besides the heptadecapeptide, $m/z = 929.2$, there exist five peptides with failure sequences. The m/z values are valid for the ions of the composition given on the right, which, in each case were determined as diprotonated species.

a long chain peptide with the correct structure in high yield and in pure form. With a 99.5% yield in every step of a ribonuclease synthesis, the main product could be obtained in 29% yield, whereas the sequences with one less amino acid are produced in 36% yield. In the case of shorter peptides the percentage of failure sequences is lower and chromatographic separation is easier. Nevertheless, the synthesis of small peptides in pure form was a difficult task in the early days of SPPS. Only after the development of an efficient separation procedure by HPLC (high performance liquid chromatography) in the 1970s, did SPPS become so successful. The application of HPLC for the separation of peptides was first mentioned in the literature in 1973.[55, 56] Today there is rarely a publication in which HPLC is not used for the final purification of a peptide synthesized on a solid support. It was therefore essential to have access to a new reliable separation method in order to promote the polymer supported synthesis of peptides of up to about 20 amino acids.

The separation of proteins by conventional HPLC is far less feasible. On the one hand, in the case of long chain polypeptides the number and the amount of difficultly separable peptides with similar sequences increase exponentially, and, on the other, many stationary phases are not suitable for proteins. Therefore, the development of newer separation and characterization techniques is absolutely necessary to guarantee a reliable protein synthesis. The correlation between synthesis and separation methods will be discussed in more detail in Section 6.

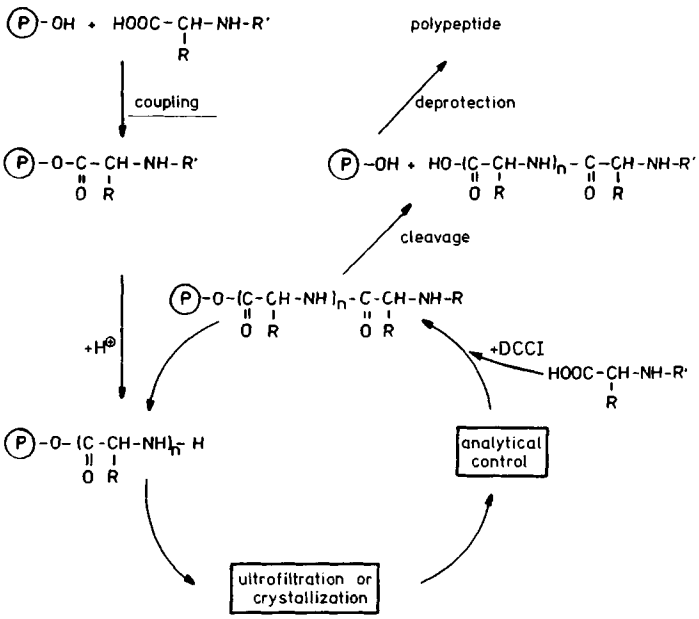
4. Optimization of the Polymeric Support

Without de-emphasizing the importance of optimizing SPPS by correct choice of the protecting groups, the anchor for binding the *C*-terminal amino acid, and the strategy of the synthesis, it is quite evident that an optimization of the polymeric support could contribute most fundamentally to the improvement of SPPS. Polystyrene is a relatively hydrophobic matrix and therefore not the best choice for the hydrophilic peptides. Furthermore, steric factors and a lack of kinetic equivalence of the functional groups play a certain role in the case of cross-linked polymers. Since SPPS involves heterogeneous reactions, lowering the dependence on diffusion is important. The varied reactivity of the functional groups in cross-linked polystyrene has been demonstrated by *Rudinger* et al. [57] as well as by *Andreatta* et al.[58]

4.1. Liquid Phase Synthesis

The matrix effect of the cross-linked polymer and the heterogeneous reaction can be avoided if a linear and soluble polymer is used. This goal was achieved by *Shemyakin, Ovchinnikov* et al.[59] who used linear polystyrene, and by *Bayer* and *Mutter* et al.[60, 66] who employed linear polyethylene glycol. Linear polystyrene is very easily cross-linked and difficult to handle. More suitable is polyethylene glycol (PEG), which, owing to its good solubility in many organic solvents, can solubilize even otherwise insoluble peptides.

A synthetic cycle using the liquid-phase procedure is shown in Scheme 2. The couplings are carried out in homogeneous solution. Kinetic investigations have shown[67] that amino acid-PEG esters have the same coupling rates as the low molecular mass amino acid esters (Table 3). Diffusion phenomena play no role in this technique. Instead of the simple filtration used in SPPS, membrane filtration is employed in this procedure. This is possible because polymer-bound peptides ($M_r = 3-20$ kDa) and the low molecular mass reagents show considerable differences in molecular size. Recrystallization of the peptide-PEGs can also be used as a valuable alternative procedure for purification purposes.[64]



Scheme 2. Standard cycle for liquid phase peptide synthesis [60–66].

A noticeable advantage of the liquid-phase method is the possibility of carrying out a better analytical control of the reaction, since now also spectroscopic methods such as

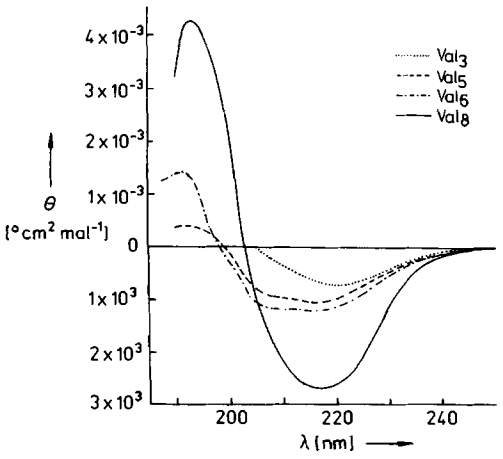


Fig. 3. CD Spectra of Boc-(L-Val)$_n$-Gly-PEG in trifluoroethanol. n = 3 and 5 (random coil); n = 6, 15% β-structure; n = 8, 100% β-structure.

NMR and CD can routinely be applied. This method has been employed the widest to study the changes in folding during the stepwise peptide synthesis.[65, 68 - 70] Figure 3 shows such an investigation by means of CD-spectroscopy during the stepwise synthesis of polyvaline.[71] Figure 4 presents the NMR spectrum of a PEG-bound sequence of insulin.[72]

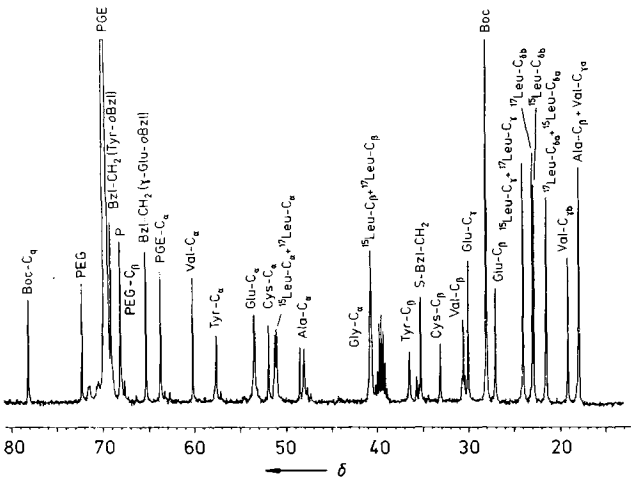

Fig. 4. Aliphatic region of the ^{13}C-NMR signals of the polyethylene glycol-bound octapeptide, which corresponds to the insulin B13–20 fragment. Measurement in suspension.

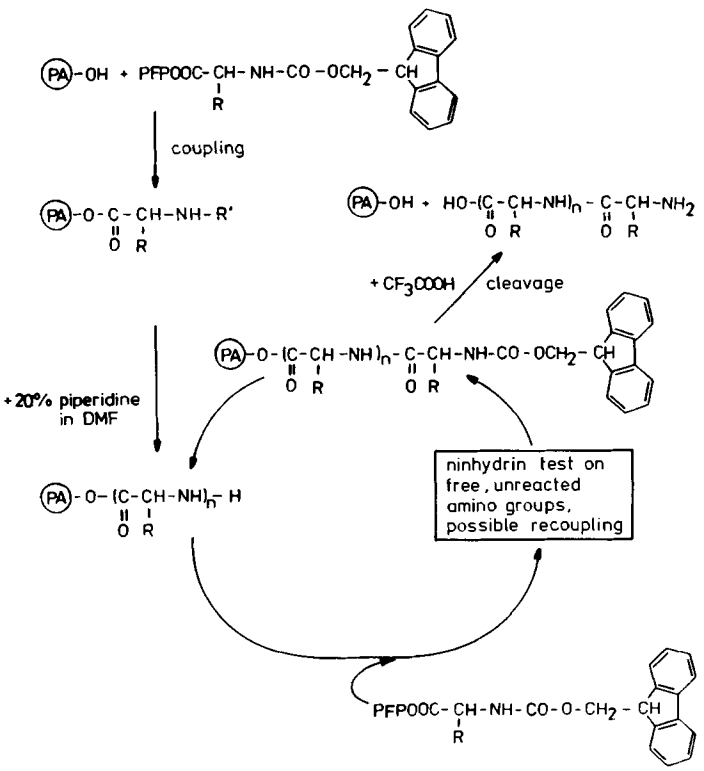
The disadvantages of liquid phase synthesis are, however, the problem of automation and the time-consuming operations.[73] Membrane filtration often takes very long, and for the crystallization process the product must be precipitated, washed, and redissolved. These operations practically render an untroublesome automation impossible. Moreover, the solubilization by PEG is unsatisfactory in the case of longer peptides.

4.2. Polyacrylamides as Polymeric Supports

Polyacrylamides, which are more hydrophilic than polystyrene, were introduced as polymeric supports in peptide syntheses by *Atherton* and *Sheppard* et al.[32, 74 - 76] Poly(*N*,*N*-dimethylacrylamide) has a polarity similar to peptides and swells much better than polystyrene in the solvents which are commonly used in peptide synthesis, e.g. dimethylformamide (DMF). A good swelling of the polymeric support is essential for the free access of functional groups to the polymer, specially to the micropores. The less the reaction space is restricted by the polymeric matrix, the more favorable become the reaction conditions. At about the same time, *Carpino* and *Han*[77] described the use of the fluorenylmethoxycarbonyl (Fmoc) group for protection of the amino function. The Fmoc group can be cleaved with alkalies such as piperidine and can therefore be used in conjunction with acid labile protecting groups. Compared to the solely acid labile Boc group, the Fmoc group furnishes decisive improvements. Its UV absorption also opens up the possibility of spectroscopically monitoring the peptide synthesis. Regarding corrosion of the automated peptide synthesizers, treatment with alkalies is more preferable than treatment with acids. The increased scope of the strategy in the case of the alkaline cleavage is also appreciable.



Scheme 3. Standard cycle for solid-phase method on polyacrylamide gel using Fmoc strategy. PA = copoly(dimethylacrylamidebis(acryloyl)ethylenediamine-acryloylsarcosine methyl ester) + linker. PFP = pentafluorophenyl.

For these reasons, the polyacrylamide gel and Fmoc strategy have found wider use in Europe than the original *Merrifield* strategy. Scheme 3 depicts a peptide synthesis on poly(*N*,*N*-dimethylacrylamide) using the Fmoc strategy.

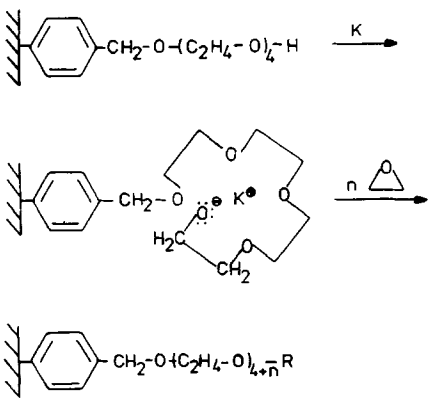
4.3. Hydrophilic Tentacle Polymers

As mentioned in Section 4.1, PEG is very compatible with peptides. It is soluble in water and in almost all organic

solvents with the exception of aliphatic hydrocarbons and diethyl ether. PEG was shown to be a valuable support for peptide syntheses using the liquid-phase method. The main difficulty encountered, however, was the separation of PEG-bound peptide from the reagents in the homogeneous phase. It was therefore justifiable to believe that this problem could be circumvented by immobilizing long chain PEGs on an insoluble polymer, thus combining the advantages of SPPS and the liquid phase method.

Since cross-linking of the linear polyethylene glycol would restrict the mobility of the polymer chains, an attempt was made to graft it on an insoluble matrix. Inorganic solids such as silica gels could not be considered, because modified silica gels are not stable enough under the conditions of repeated alkaline and acidic treatment which are usually employed during the peptide synthesis. The simplest immobilization procedure would be the coupling of one of the hydroxy groups of PEG to chloromethylated polystyrene according to a classical ether synthesis.[78, 79] The main problem of this procedure, however, is that when long PEG chains (>800 Da) are used, the yields are unsatisfactory. Moreover, both terminal hydroxy groups react with chloromethyl groups, so that the polystyrene is additionally cross-linked. Consequently, the number of free hydroxy groups will be reduced with concomitant lowering of the capacity of the graft copolymer for binding to peptides.

By means of anionic polymerization of ethylene oxide, PEG chains of unlimited size can be immobilized on cross-linked polystyrene beads containing hydroxy functional groups.[80 - 86] This article describes in summary the preparation, properties, and application of graft copolymers for the first time. Preferably the potassium salt of poly(styryl-methyltetraethylene glycol ether), which is present in the form of an open crown ether, is used for the synthesis (Scheme 4). When carrying out this grafting reaction, functionalized polystyrene beads of any degree of porosity can be employed. If nonporous beads are used, the ethylene oxide can only be grafted on the surface. In this case, the polyoxyethylene chains extend outwards from the matrixlike tentacles. Such polymers are of interest as stationary phases for HPLC; however, they are not suitable for peptide syntheses, since their peptide loading is too low. For peptide and nucleotide syntheses, graft copolymers based on porous polystyrene are more interesting.



Scheme 4. Synthesis of graft copolymers from cross-linked PS and linear PEG. R = H, K.

Graft copolymers with PEG chains of about 3000 Da have proven optimal. These copolymers contain about 70% of linear PEG and only about 30% of cross-linked polystyrene matrix. The properties of these polymers are therefore largely determined by the PEG portion of the molecules. This is demonstrated, in particular, by the swelling properties. Table 2 shows a comparison of the swelling factors of the polystyrene-polyethylene glycol graft copolymers and polystyrene in several solvents. The graft copolymers swell in all solvents which dissolve PEG.

Table 2. Comparison of the swelling factors of polystyrene (PS) cross-linked with 1% DVB with those of a graft copolymer of polyethylene glycol (M = 3300 Da) and PS (PS-PEG).

Solvent	PS	PS-PEG
Water	–	2.5
MeOH	0.95	2.5
EtOH	1.05	1.2
CH_2Cl_2	5.2	3.0
Toluene	5.3	3.1
DMF	3.5	3.2
CH_3CN	2.0	3.0
THF	5.5	3.4
Dioxane	4.8	3.7
Ether	2.5	1.1

A good solvation leads to a high degree of mobility of the PEG chains and the peptides bound to them. This mobility can be demonstrated by ^{13}C-NMR relaxation time measurements.[87] Figure 5 shows that the ^{13}C-NMR relaxation times T_1 of peptides which are bound to polystyrene are lower than those of peptides which are bound to PEG or to graft copolymers, whereas those of the peptides bound to the last two supports are about the same. Both the PEG chain as well as the peptides bound to it give rise to sharp NMR

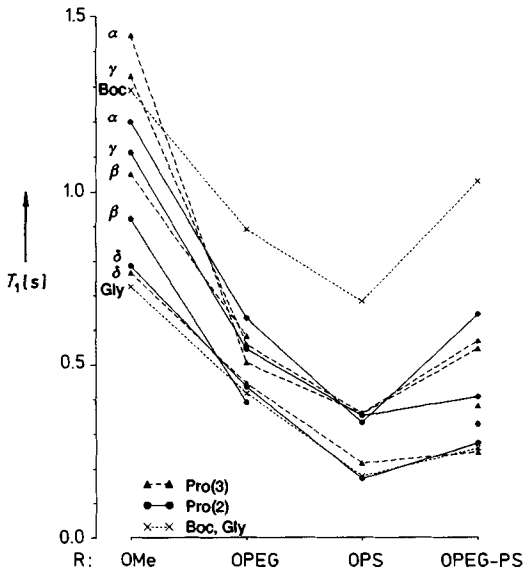


Fig. 5. ^{13}C-NMR relaxation time T_1 of the free (R = OMe) and of the polymer-bound tripeptides Boc-Gly-Pro(2)-Pro(3)-R.

signals such as are normally not expected from measurements on solid materials in suspensions. On the other hand, in solvents such as ether, which do not solvate PEG, wide NMR signals typical of the measurements on solids in suspensions are obtained.

We can therefore distinguish between a solvated tentacle conformation and a non-solvated knäuel conformation of the graft copolymer as shown schematically in Figure 6. For

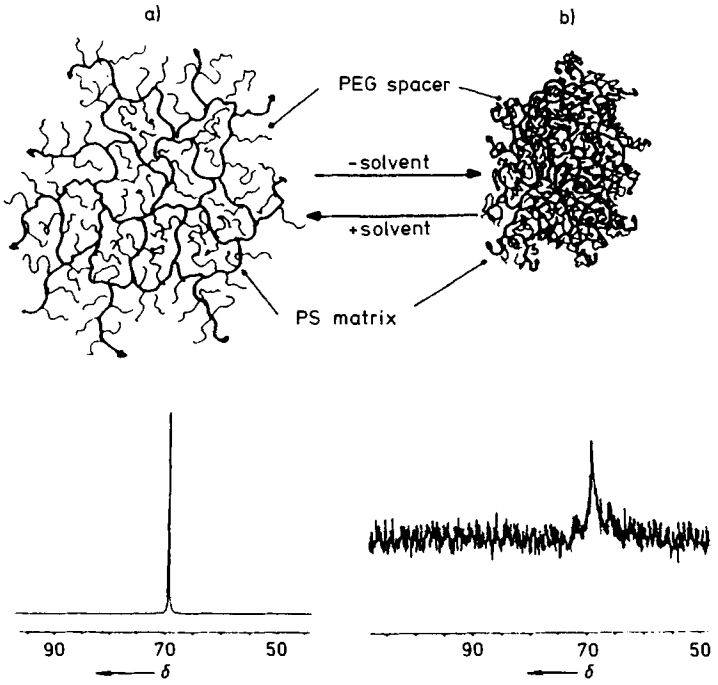

Fig. 6. Top: Conformations of the graft copolymers PS and PEG. Bottom: The respective ^{13}C-NMR spectra of a) folded and solvated form, sharp NMR signals in spite of the measurement in suspension; b) Knäuel conformation in contact with nonsolvating solvents; usual signal broadening of the solid state.

this reason, such polymers have received the trivial name tentacle polymers.[88] Figure 7 shows the homogeneous distribution of the PEG chains on the surface and in the interior of the polymer bead. Under the conditions used in the electron microscopic investigation, the graft copolymers exist in

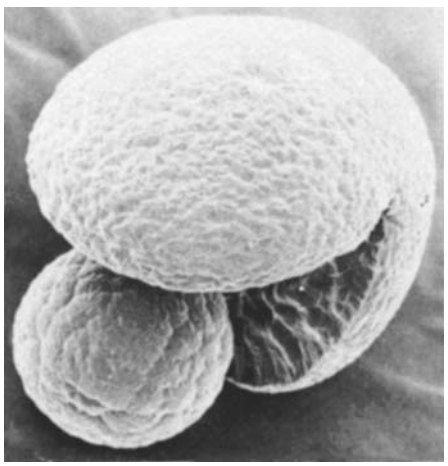

Fig. 7. Electron micrograph of the graft copolymer of PS and PEG 1 mm ≈ 3.227 μm.

the knäuel conformation. A remarkable feature is the observed comparable swelling factors of the tentacle polymers in different solvents (Table 2). This enables the packing of columns with the graft copolymer for continuous flow peptide syntheses in columns, since no change in the packing occurs on applying different solvents during the synthesis. The swelling factors also remain unchanged as the peptide chain grows.

A further property of the copolymer rarely observed in other polymers can promote its use in continuous flow peptide synthesis: due to the solvation, the PEG-PS beads are stable under pressures up to 200 bars, the condition under which relatively high flow rates can be achieved. This in turn shortens the time required for a coupling cycle. The advantages of the continuous flow synthesis will be discussed again in Section 5.

Since, according to NMR investigations, the mobility of the PEG chains of the graft copolymers is about the same as the mobility of free PEGs, it can be assumed that these copolymers after being solvated, behave like a homogeneous phase. The same conclusion can be reached by considering the rate constants of peptide coupling on the graft copolymer which have the same order of magnitude as those of the liquid phase synthesis (Table 3). According to these exami-

Table 3. Comparison of the rate constants k of coupling glycine active esters to polyethylene glycol glycine (PEG-Gly) in solution and to polystyrene-poly(ethyleneglycolglycine) graft copolymers (PS-PEG-Gly). The numbers represent M_r of the PEG chains.

Polymeric support	k[mol^{-1} · s^{-1}]	meq Gly/g polymer [a]
PS-PEG-2000-Gly	0.37	0.20
PS-PEG-3300-Gly	0.32	0.12
PS-PEG-5700-Gly	0.29	0.08
PEG-2000-Gly	0.16	0.49
PEG-4000-Gly	0.17	0.38
PEG-6000-Gly	0.13	0.27
Glycine ethyl ester	0.12

nations, tentacle polymers are suitable as hydrophilic supports for a rapid peptide synthesis.

4.4. Monodispersed Tentacle Polymers

So far, diffusion phenomena have not adequately been taken into account in the optimization of peptide syntheses, although they are of prime importance for shortening the duration of the synthetic cycles. Since the reactions are heterogeneous, the particle diameter plays a decisive role in all the diffusion processes. As the particle diameter gets larger, the contribution of diffusion becomes more extensive. The commercially available resins that are used for a Merrifield SPPS are polydispersed, i.e., they have a wide particle size distribution, e.g. 10–200 μm. It is obvious that the duration of the synthesis is determined by the largest particles. These also contain a relatively higher number of functional groups in comparison to the small particles, as shown in Figure 8. A

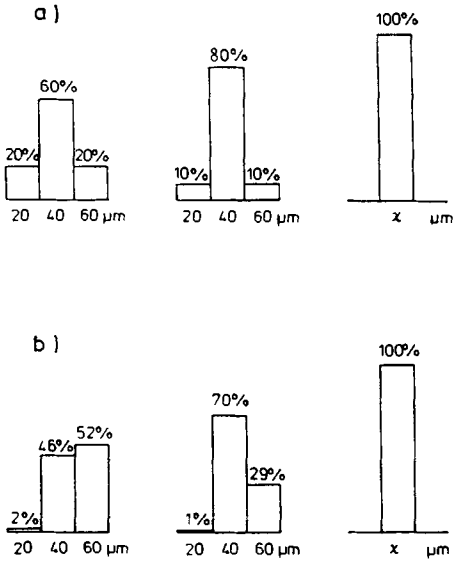

Fig. 8. Arbitrary size distributions of the polydispersed polymeric beads (a) and calculated percentage of the functional groups in the polymeric beads with different diameters (b). χ: arbitrary size of monodispersed beads.

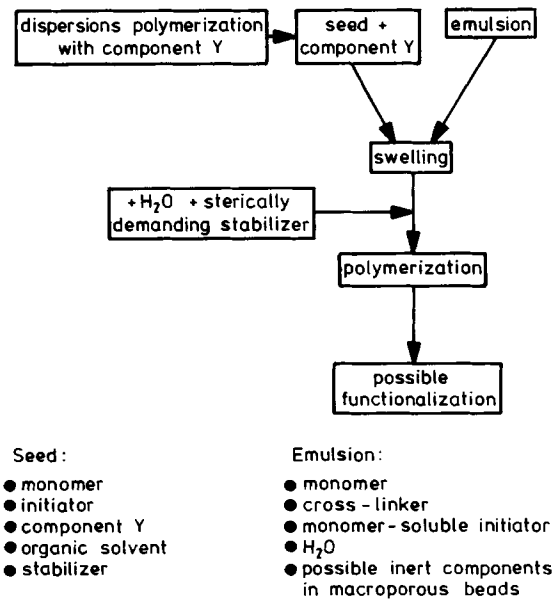
considerable shortening of the duration of a synthetic cycle would therefore be possible, if monodispersed and uniform particles with as small a diameter as possible were available. Most of the polymerization procedures, however, lead to polydispersed materials.

Following a detailed study of diffusion processes, *Ugelstad* et al.[89, 90] investigated the essential parameters for the preparation of monodispersed polystyrene beads. Using this as a basis, the preparation of monodispersed and cross-linked polystyrene beads with diameters of 5–20 µm was elaborated. First of all, a "seed" is prepared in a two-step reaction (Scheme 5) in a homogeneous solution using an initiator.[91] In order to obtain particles with equal diameters, it is important to produce the seed in a short time and



Scheme 5. Two-step process for the synthesis of monodispersed, cross-linked polystyrene.

to work in the presence of bulky stabilizers which suppress the formation of aggregations and micelles. The particles of the seed are still not cross-linked; they are then brought into an aqueous emulsion of the monomeric styrene, the cross-linker divinylbenzene, and the initiator. In a diffusion-controlled process in the presence of water-soluble and sterically hindered stabilizers, the seed becomes swollen and cross-linked (Figure 9). Figure 10 shows the monodispersed and

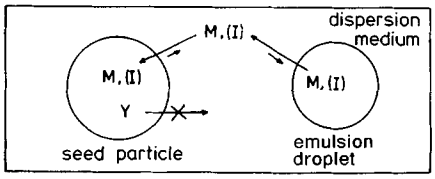


Fig. 9. Swelling of the monodispersed seed. M = monomer, I = initiator; Y = component Y.

cross-linked polystyrene beads thus obtained. The deviations in the diameters are less than 2%, e.g. 10 ± 0.02 µm. If one compares these polymers with the other customary resins with a broad distribution of molecular size, it is immediately evident that for the first time large molecules with such a uniform molecular structure and size can be prepared, which otherwise only nature is able to produce. These monodispersed and cross-linked polystyrene beads can now be functionalized and used as supports for peptide synthesis.

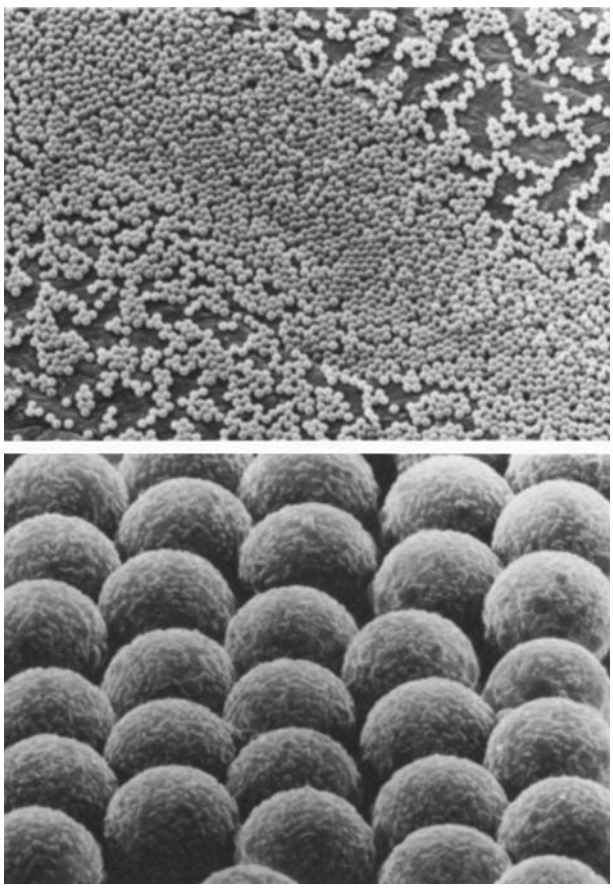

Fig. 10. Electron micrographs of the monodispersed polystyrene (top, 1 mm ≈ 1.424 µm) and of the graft copolymer of PS and PEG (bottom, 1 mm ≈ 0.420 µm).

It is also possible to graft PEG chains to these beads, as already described in Section 4.3. Figure 10 (bottom) shows an example of such monodispersed graft copolymers. Under the conditions used in the electron microscopic investigation the PEG chains of the above polymers exist in ordered spherical forms.

With these pressure-stable and hydrophilic polymeric supports, we can minimize the diffusion problems of the solid-phase synthesis. Moreover, the new supports cannot only be used for the synthesis of peptides and nucleotides, but also as stationary phase for HPLC.[92]

5. Continuous Flow Synthesis

Tentacle polymers are pressure stable and show almost equal swelling factors in different solvents. These two properties make them suitable for column packings and for carrying out continuous peptide syntheses with high flow rates. As a consequence, tentacle polymers distinguish themselves from all other polymers. A continuous flow synthesis has advantages over the batch synthesis recommended by *Merrifield. Bayer, Halasz* et al. already described the first continuous flow synthesis on chemically modified silica gel supports as long ago as 1970.[73] They demonstrated that a shorter time was required for a cycle and at the same time the peptide synthesized showed a higher purity. For the synthesis of longer peptide chains, however, the modified silica gels are not chemically stable enough.

Later, pellicular resins were used for the continuous synthesis.[94] Because of the low pressure-stability and different swelling factors, the usual supports cannot be used. Therefore, *Frank* and *Gausepohl* employed loosely packed cartridges of different polymeric gels for the continuous flow synthesis.[95] *Atherton, Sheppard* et al. polymerized polydimethylacrylamide gels on kieselguhr and successfully employed the material obtained for continuous flow syntheses using an automated synthesizer.[96, 97] Kieselguhr is, however, not a spherical support as can be seen from the electron micrograph of a polydimethylacrylamide polymerized in kieselguhr (Fig. 11), which in comparison to the graft copolymer in Figure 10, is clearly a characteristically more heterogeneously distributed polymer.

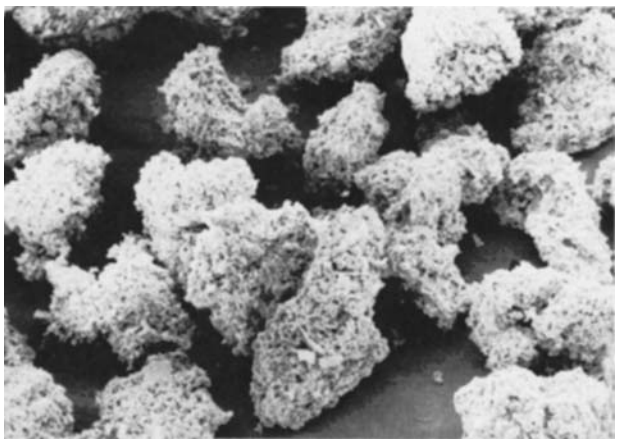

Fig. 11. Electron micrograph of polyacrylamide-kieselguhr supports.

The graft copolymers of cross-linked polystyrene and polyethylene glycol show pressure stability, similar swelling behavior in different solvents, chemical stability, spherical form, and equal bead size. All of these properties are prerequisite for a rapid peptide synthesis by the continuous flow method. Since its introduction, it has been shown on many occasions that this procedure is superior to the normal batch-wise synthesis.

An essential advantage of the continuous flow method is that the excess of coupling components and solvents normally used in SPPS can be drastically reduced. Moreover, the coupling and deprotection reactions can be monitored by UV measurements at the inlet and outlet of the column. In this respect the UV active protecting groups such as Fmoc are especially suitable.

The lowering of the excess of reagents compared to that in the batch-wise method results from carrying out the reaction in a continuous flow. When a relatively highly concentrated solution of the coupling components is allowed to pass through the column a concentration profile develops, as shown in Figure 12 (right). Since only a relatively small region of the functional polymer (support) comes in contact with the coupling components while the reagent flows through the column, the excess of reagents in every column segment is larger than would have been the case if the reagents had been in contact with the total support. The narrower the coupling components band, the larger the excess of reagents in a given column segment. Hence, the reaction can proceed more completely, and the content of peptides with statistical failure sequences will be lowered. A typical spectrophotometric monitoring of a synthetic cycle is shown in Figure 13a.

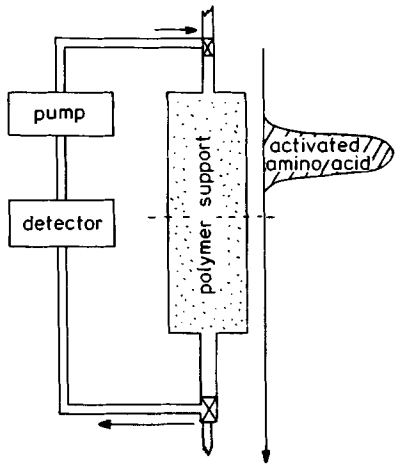

Fig. 12. Moving band of the coupling components in the reaction vessel during continuous flow synthesis.

When using polymeric beads having a diameter of about 80 μm, the cycle for coupling one amino acid lasts about 6–15 min. Even if double couplings are used, a peptide with 30 amino acid residues can be synthesized in a few hours. By employing the already available tentacle polymers with a diameter of 8 μm, the time required for the coupling cycle can be further reduced by a factor of ten, i.e. to 1–2 min. For

these short times, however, there are no synthesizers available. Continuous monitoring of the synthesis also allows the detection of difficult coupling steps, which for example are caused by conformational effects. This effect is specially evident during the cleavage of amino protecting groups, as it is symbolized by appearence of a strong tailing. Thus, it is possible to distinguish the difficult coupling steps which can be avoided in a subsequent optimized synthesis. Figure 13 shows the course of a synthetic cycle with the normal coupling time and another one which has been slowed down by such conformational influences (Fig. 13 b).[*] Therefore, before the actual synthesis is carried out, it is advisable to perform a so-called preview synthesis on a small scale and to follow the course of the reaction spectroscopically, and to investigate the peptide analytically.

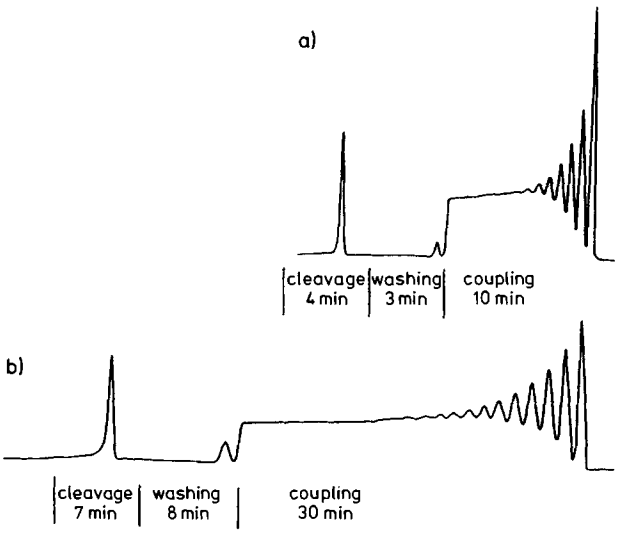

Fig. 13. Continuous UV spectroscopic monitoring of a) the coupling and cleavage reactions of a cycle of continuous flow synthesis on the tentacle polymeric support and b) of the slower reaction due to the formation of a β-folded structure.

Since the time required to perform a total synthesis with the new polymers is very short, it will be rewarding to spare the time for a preview synthesis. By performing a preview synthesis, the difficult coupling steps will be identified and the strategy for the main synthesis can accordingly be changed. This can be achieved, e.g., by changing the solvents, using a higher temperature, choosing other protecting groups or overcoming the difficult steps by coupling small peptides instead of single amino acids. Through further developments of the spectrophotometric control of the continuous flow synthesis, future synthesizers could eventually be able to determine the coupling time and the necessity of post-coupling reactions automatically, i.e. they could be intelligent and self-regulating machines.

[*] Note added in proof: *D. Seebach* has reported in a recent review (*Angew. Chem. 102* (1990) 1363; *Angew. Chem. Int. Ed. Engl. 29* (1990) 1320) (therein p. 1379 and 1337, respectively), that the synthesis of critical sequences proceeds with higher coupling yields on graft copolymers of polystyrene and polyethylene glycol in comparison to the classical polystyrene support using solvents containing LiX.

6. Analytical Control and Purification

The application of carrier-synthesis for the preparation of proteins is naturally dependent on reliable procedures to separate and characterize the synthesized products. Thus, SPPS became an established procedure only after the introduction of efficient HPLC.

The first applications of HPLC to the separation and characterization of synthetic peptides were reported at the 15th European Peptide Symposium in 1973.[55, 56] Since then, HPLC has been the main, and unfortunately also often the only, method of characterization. In the literature, the occurrence of a single HPLC peak is often uncritically interpreted as an indication of a single entity, and almost with no exception, the purity of a product is ascertained by a simple integration and comparison of the peak areas without considering the discrepancy between the specific UV extinction of different peptides. The possible error sources concerning the purity, which are due to neglecting the response factors of the UV detectors, should at least be mentioned.

Since the presence of impurities due to failure sequences can always be suspected, despite optimization of the synthetic methods, it does not suffice to carry out only HPLC and amino acid analysis to characterize the products. Reversed-phase HPLC characterizes peptides according to their hydrophobic interactions, whereby small parts of the peptides are often responsible for the interaction.[98 - 100] Reversed-phases are not suitable for differentiating peptides according to their different acidity, basicity, and molecular size. Therefore, for a complete characterization, an electrophoretic or ion-exchange chromatographic separation (characterization based on the charge) and a size exclusion chromatographic separation (characterization based on the molecular size) must also be carried out. Multidimensional chromatography enables optimal separations using different separation mechanisms.[101 - 103]

Besides employing chromatographic procedures, it is strongly recommended that spectroscopic methods such as mass spectrometry or NMR spectroscopy also be used for the characterization. In the field of synthetic peptide chemistry, for peptides up to 20 amino acids there is an arsenal of separation and characterization methods which one can draw on to ensure that the desired goal of the synthesis is attained.

However, in the case of large peptides and proteins, whose reliable chemical syntheses are still a thing of the future, many of the methods suitable for peptides, remain inapplicable. For example, during the HPLC of proteins on modified silica gels, the molecules are often denatured,[104, 105] and the mass spectroscopic characterization of proteins by the conventional methods (EI, FAB and CI) is not always possible.

With respect to the synthesis of proteins, and parallel to the continuing developments of support (carrier) synthesis, new methods have fortunately been introduced for the separation and mass spectroscopic identification of large peptides. These methods are expected to give the same impetus to the support synthesis of proteins as was given by HPLC to the synthesis of peptides via SPPS.

Numerous new stationary phases have now been developed for the rapid separation of proteins, and they show a

higher mechanical and chemical stability than the ordinary reversed-phase materials. Particularly worth mentioning are: the pellicular resins, in which a functionalized monomer is polymerized on a solid inorganic support such as silica gel,[106-109] and the tentacle polymers described in Sections 4.3 and 4.4, which are also pressure stable.[110] Figure 14 shows a rapid separation of proteins on such supports. A further automated separation procedure which has appeared on the horizon is capillary electrophoresis.[111-118] This method matches HPLC with regard to

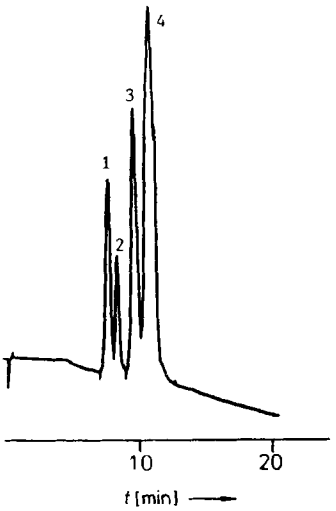

Fig. 14. Fast separation of proteins on monodispersed TentaGel (13 μm); 1 = ribonuclease, 2 = insulin, 3 = lysozyme, 4 = albumin. Gradient from 0.1% trifluoroacetic acid (TFA) in H_2O to 0.1% TFA in H_2O: acetonitrile 20:80 in 20 min; 1.5 mL min^{-1}, column 60 × 4.6 mm, UV detection at λ = 210 nm.

separation efficiency, speed, and ease of handling, and will certainly find a similarly broad spectrum of applications. Capillary zone electrophoresis (CZE) in open capillaries with diameters of 40–100 μm, and lengths of 20–80 cm can easily attain theoretical plates of 100 000, which is normally achieved by capillary gas chromatography. Since in essence, capillary zone electrophoresis separates molecules according to their charges it will complement reversed-phase HPLC, which is based on hydrophobic interaction.

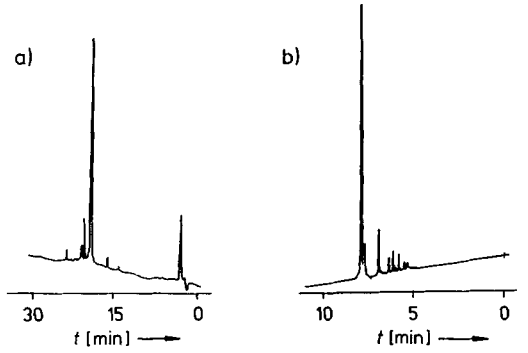

Fig. 15. Separation of a peptide a) using HPLC and b) capillary electrophoresis CE. HPLC: reversed-phase C_{18} column 250 × 4.6 mm, gradient water/acetonitrile. CE: quartz capillary, chemically modified with Chirasil-Val, 500 μm × 400 mm, 100 mM phosphate buffer, pH = 2.5; 15 kV. UV detection at λ = 200 nm (a and b).

Peptides which appear to be pure according to HPLC, show further impurities upon subjection to capillary electrophoresis, as shown in Figure 15.[116] Now it becomes apparent that "orthogonal" separation techniques, and not only reversed-phase HPLC, must be applied to establish the purity of peptides. For nucleotide separation, CZE is already a well-established method. In the case of protein separation, unmodified capillaries are not suitable; this is due to the adsorption of proteins on the quartz surface, a problem that can be circumvented by deactivating the surface with a coating of polymer. Sharp peaks as in Figure 16 are then obtained for the separation on quartz capillary inactivated by a coating of PEG.[118]

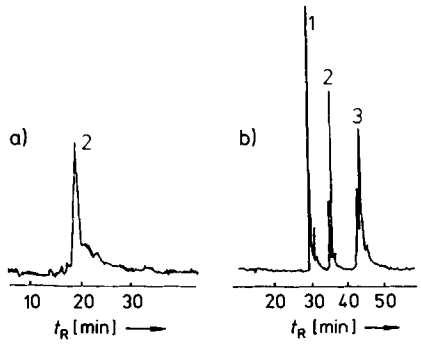

Fig. 16. CE-separation of a protein mixture (1 = lysozyme, 2 = trypsin, 3 = chymotrypsinogen) a) on an unmodified capillary, b) on a PEG-impregnated capillary. a) 0.01 M KH_2PO_4 buffer, pH = 6.8. b) 0.05 M KH_2PO_4 buffer, pH = 4.1 (after Ref. [118]).

Parallel to the development of these new separation methods, mass spectroscopy has penetrated into the field of protein chemistry, but so far only for proteins with molecular masses of up to 120 000 Da. Besides FAB and plasma desorption ionization, the ion-spray method should be mentioned.[119, 120, 127, 128] In this method, the solution containing the sample to be analyzed is pumped through a sprayer which is kept at high voltage in order to form a mist of highly charged droplets. The droplets contain both positive and

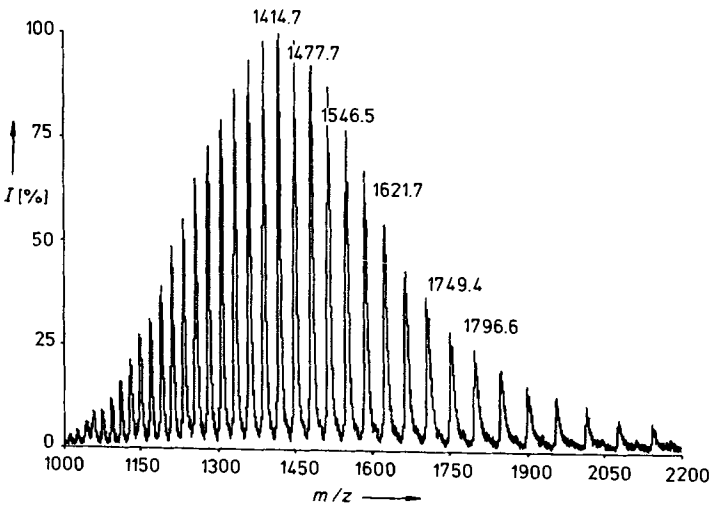

Fig. 17. Ion-spray mass spectrum of pig serum albumin, M = 66 439 Da. The peak at m/z = 1796.6 corresponds to 37 times positively charged protein (SCIEX mass spectrometer).

negative ions with ions of one polarity being predominant. As the solvent evaporates, the electrical field at the surface of the droplets increases due to the decreasing radius. If the droplets evaporate far enough, a critical field is reached at which ions are emitted from the surface, ejected into a gas phase and enter the mass analyzer. Since peptides and proteins contain basic amino acids such as arginine and lysine, they can develop multiple charges. The m/z values of these multiply charged ions lie, even in the case of proteins, in the range of a quadrupole mass spectrometer. Figure 17 shows, e.g., the mass spectrum of a protein recorded by this method.[116] Since the first step of ion-spray mass spectroscopy is the formation of a mist of the substance to be analyzed from the solution under atmospheric pressure, it is possible to couple an ion-spray MS to a HPLC or a CZE instrument. With such an arrangement, a new dimension for the investigation of macromolecular natural products is obtained.[116, 121, 122] Figure 18 shows the separation of

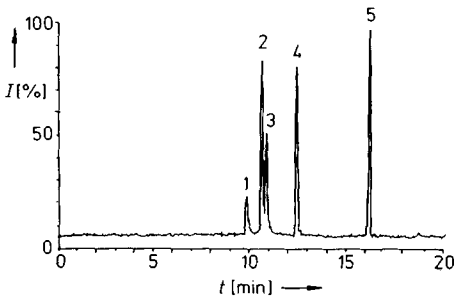

Fig. 18. Coupled capillary electrophoresis/ion-spray mass spectrometry of dynorphins [121]: 1 = Tyr-Gly-Gly-Phe-Leu-Arg-Arg-Ile-Arg, 2 = Tyr-Gly-Gly-Phe-Leu-Arg-Arg, 3 = Tyr-Gly-Gly-Phe-Leu-Arg-Arg-Ile, 4 = Tyr-Gly-Gly-Phe-Leu-Arg, 5 = Tyr-Gly-Gly-Phe-Leu. Quartz capillary 100 μm × 100 cm. Buffer: acetonitrile/30 mM ammonium acetat = 50/50, pH = 4.8; SCIEX mass spectrometer, total ion stream.

dynorphins by coupled CZE/ion-spray MS. For peak 5 in Figure 18 a separation efficiency of about 250 000 theoretical plates could be calculated. Figure 19a shows the ion-spray mass spectrum of the dynorphin giving rise to peak 5 in Figure 18.[121] Using tandem mass spectrometry, it is possible to determine the peptide sequence from the $(M + H)^{\oplus}$ peak (Fig. 19b).

7. Examples of Syntheses on the Tentacle Polymers

The practical application of tentacle polymers will be illustrated by way of example with the synthesis of two polypeptides, and the importance of the novel analytical procedures for the control and optimization of the synthesis will be dealt with in detail. As a model, a rapid preview synthesis of the HIV-1 protease sequence 59–99 is described. The course of the synthesis was monitored by analytical methods.

7.1. Tentacle Polymer-Peptides for the in vivo Formation of Antibodies

The prediction of epitopes for the formation of antibodies and the synthesis of these epitopes are nowadays indispens-

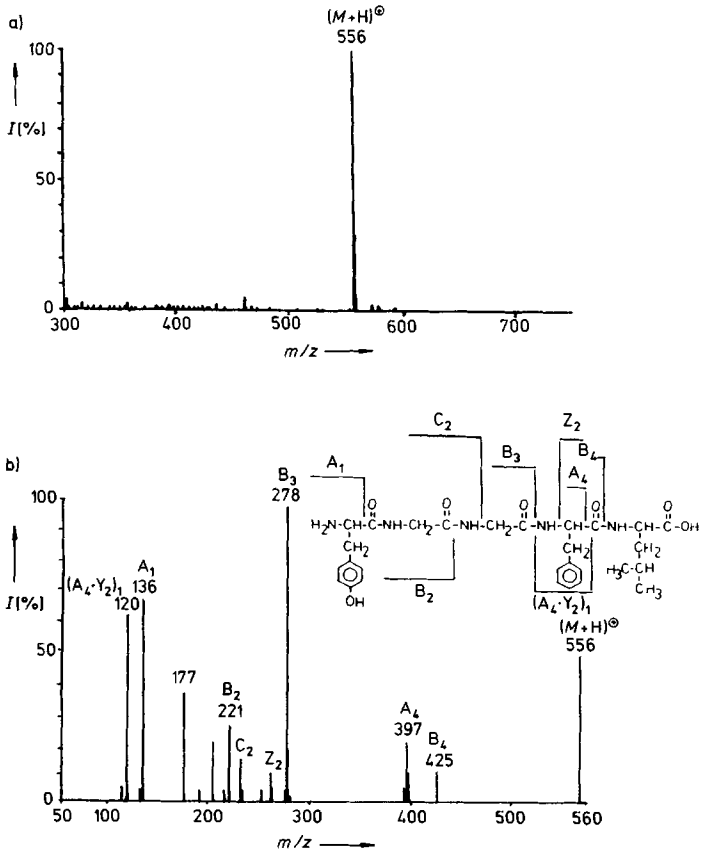

Fig. 19. Mass spectra to peak 5 in Figure 18. a) Ion-spray MS. b) Daughter ion spectrum to peak in (a) [121] for sequence analysis.

able tools in immunology. A multitude of overlapping peptides is required for a dependable prediction. Conjugates of peptides with carriers such as serum albumin or lipopeptides are employed in immunization.[123–125] It would now constitute a tremendous step forward methodologically, if the peptides did not need to be cleaved from the polymeric support, and in place of a conjugate, they could be directly applied for the in vivo and in vitro immunization and production of antibodies. Owing to the compatibility of the PEG chains with biological systems, the tentacle polymers are said to be suitable in this respect.

In order to verify this hypothesis, an epitope region of the hemophilus influenzae P6 protein, corresponding to the sequence 115–131, was synthesized on TentaGel, and for comparison, also on PEG.[126] The synthesis of the sequence H_2N-Ala-Val-Leu-Gly-His-Asp-Glu-Ala-Ala-Tyr-Ser-Lys-Asn-Arg-Ala-Val-OH was carried out according to the Fmoc strategy with the following side-chain protecting groups: Mtr for Arg, Boc for Lys, Trt for His, *t*Bu for Ser, O*t*Bu for Glu, O*t*Bu for Asp, and ONp for Asn (Mtr = 4-methoxy-2,3,6-trimethylbenzylsulfonyl, Trt = triphenylmethyl, *t*Bu = *tert*-butyl, O*t*Bu = *tert*-butyl ester, ONp = nitrophenyl ester).

Figure 20 shows the ion-spray mass spectrum of the PEG peptide. It is interesting to note that the exact molecular mass distribution of the peptide-polymer can be determined with a single mass spectrum, whereas otherwise it could be achieved only indirectly by means of exclusion chromatography and standard substances. The difference in the individual peaks of the mass spectrum of the fourfold protonated polymer-peptide $(M + 4H)^{3\oplus}$ with an average molecular

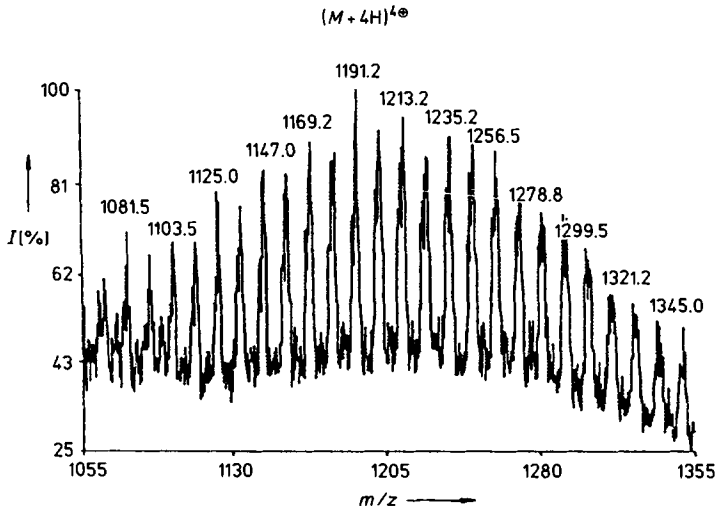

Fig. 20. Ion-spray mass spectrum of the $(M + 4H)^{4\oplus}$ peak of the PEG peptide A-V-L-G-H-D-E-A-A-Y-S-K-N-R-R-A-V-PEG_{3000}. The peptide was synthesized by the liquid-phase procedure. Average molecular mass 4850.9 (SCIEX mass spectrometer).

mass of 4850 corresponds exactly to one fourth of the molecular mass of the CH_2-CH_2-O-monomeric unit.

For immunization, the soluble PEG peptide as well as the immobilized PEG peptide were administered to mice, and, after four weeks, serum samples were taken for the determination of antibodies, using the ELISA test. The titers of the ELISA in Figure 21 show that the polymer peptides form

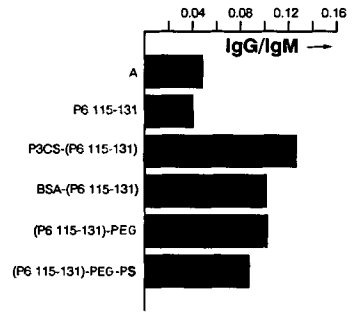

Fig. 21. ELISA titers of the serums after immunization with different conjugates of the sequence 115–131 of hemophilus influenza P6 protein [126]. G = goat; M = mouse; A = negative control.

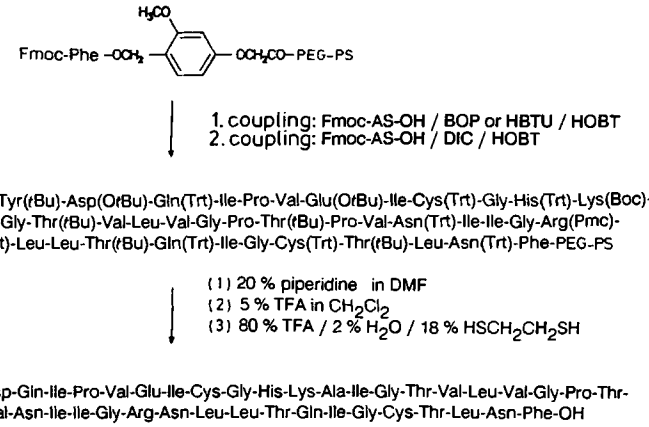
antibodies as nicely as the serum albumin conjugate BSA-(PG 115–131).[126]

7.2. Preview-Synthesis of the Sequence 59–99 of HIV-1 Protease

It is interesting to carry out the chemical synthesis of HIV-1 protease, which is required for activation of the aids virus, since the amino acids of the active center can be specifically labeled with ^{13}C and inhibition studies can be carried out using NMR. The two critical cysteine residues, which have been substituted by less critical ones in an attempted synthesis by *Kent* et al.[131] are located at positions 67 and 95.

Sequence 59–99 of the HIV-1 protease was synthesized on a TentaGel support using the rapid continuous flow procedure (Scheme 6). By applying the preview-synthesis mode and subsequent characterization of the by-products, it could easily be established which couplings presented difficulties and the synthetic strategy could be optimized according to these



Scheme 6. Scheme of the synthesis of the HIV-1 protease sequence. BOP = benzotriazol-1-yloxytris(dimethylamino)phosphonium hexafluorophosphate; HOBT = hydroxybenzotriazole; HBTU = *O*-benzotriazol-1-yl-*N*,*N*,*N*',*N*'-tetramethyluronium hexafluorophosphate; DIC = diisopropylcarbodiimide; AA = amino acid.

findings. This synthesis furnished a crude material with a complex composition as shown by the chromatogram in Figure 22. The structures of the major by-products could be assigned on the basis of their molecular masses obtained on

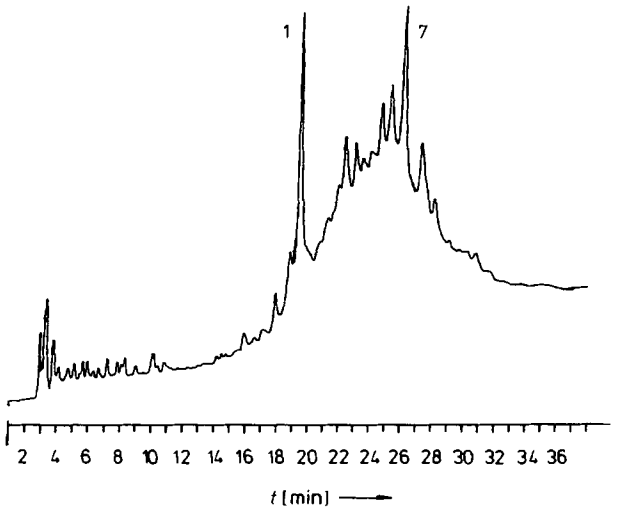


Fig. 22. HPL chromatogram of the crude product of sequence 59–99 of HIV-1 protease after its cleavage from the polymeric support. Column 250 × 4.6 mm, Nucleosil 100 C18, 5 µm. Mobile phase water/acetonitrile/0.1% TFA. Gradient, acetonitrile from 25% to 50%. 1 = failure sequence; 7 = HIV protease sequence 59–99.

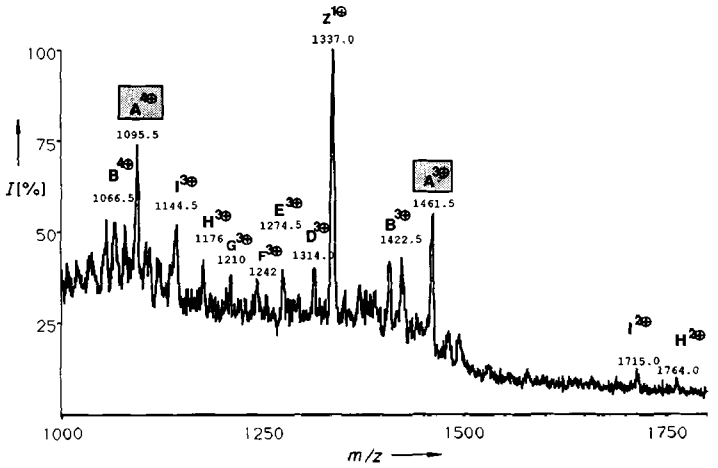
direct injection into an ion-spray spectrometer and without any previous separation (Fig. 23). The retention times of the desired main product and of the by-products could be ascertained exactly by HPLC with single-ion monitoring



(Fig. 24). Thus, the fraction of the HIV-1 protease sequence (A) could be isolated in the pure form by HPLC, as is shown by the mass spectrum in Figure 25.

The by-products were identified using a coupled HPLC/tandem mass spectrometer. By this means, the structural elucidation of the by-products requires only as much time as running a HPLC chromatogram, i.e., about 30 min. Figure 26 shows the fragmentation scheme of a by-product determined by tandem mass spectrometry; the structure of the by-product could be assigned unequivocally. The most important by-products are shown in Figure 27. From this synthesis it was learned that, due to the formation of rigid conformations, the couplings of the residue 91 (Thr) up to the residue 82 (Val) took place in low yields. In the subsequent couplings, the reactions were complete and no failure sequences were observed. It is interesting to note that failure sequences are formed in which up to nine amino acids are missing in a chain. Even though the aim of the synthesis, i.e., preparation of pure HIV-1 protease sequence, was already achieved in this preview synthesis, a larger amount of the peptide for the inhibition studies could be obtained by opti-

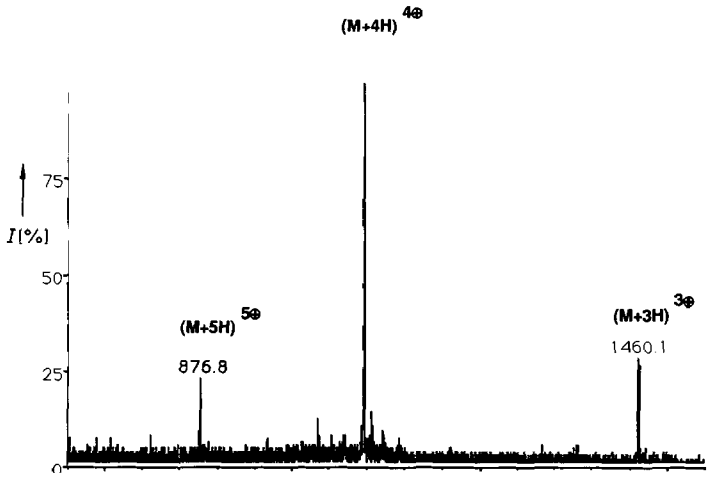


Fig. 25. Ion-spray mass spectrum of the isolated pure HIV-1 protease sequence 59–99. Molecular mass was found to be 4377.8 ± 1.

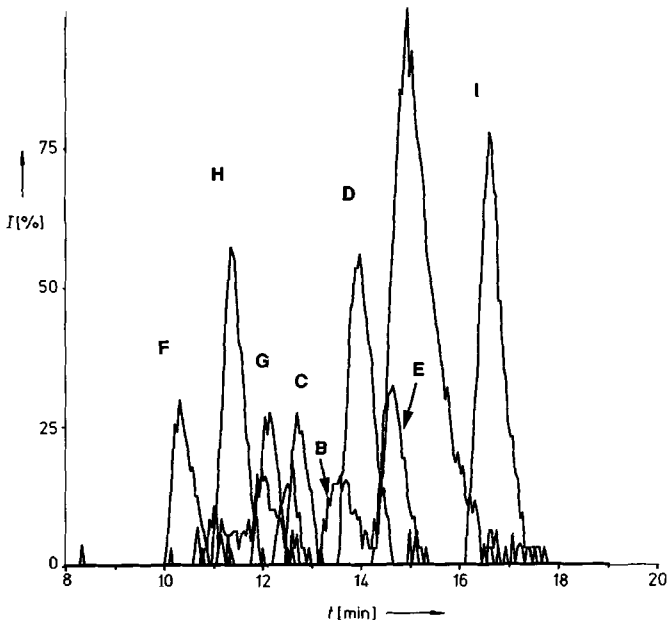

8. Outlook

By employing new polymeric supports for peptide synthesis under the conditions of continuous flow, it became possible to synthesize long chain polypeptides in a matter of a few days. As shown, the required time to carry out a cycle can even be shortened further to 1–2 min by using 8 μm supports.

New analytical methods such as capillary electrophoresis and ion-spray mass spectroscopy as well as continuous monitoring of the synthesis by means of UV spectroscopy allow one to recognize the difficult sequences and failures likely to be encountered in the course of synthesis. Hence the hitherto "black box" of the support synthesis becomes fully transparent and permits optimization of the critical steps. By judicially sparing a little time, one can carry out a small scale preview synthesis. Exact analytical investigations enable the problems of a synthesis to be recognized and thus help in choosing the strategy to be adopted in the main synthesis. In this way a purer peptide can be assembled on the polymer and the unsuccessful or troublesome final purifications which frequently are encountered can be circumvented. The

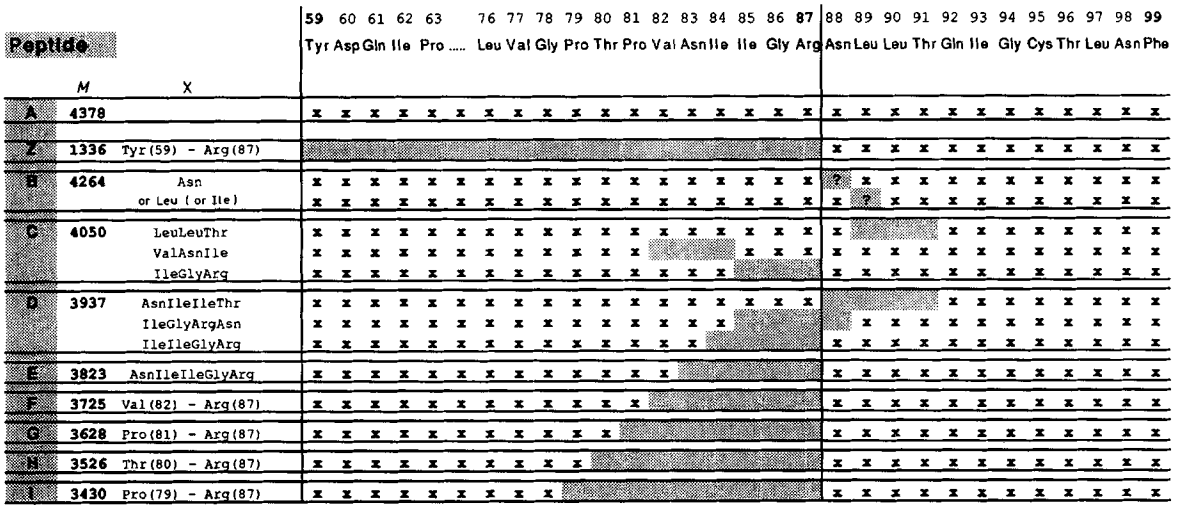

Fig. 27. Failure sequence peptides of the crude product in the synthesis of the HIV-1 protease sequence 59–99 A. X = deleted amino acids.

continuous flow procedure can also be carried out more easily than the normal batch procedure on a large scale. By carrying out pilot syntheses, we have prepared proteins with up to 120 amino acid residues such as HIV-1 protease, [129, 130] human insulin, metallothionein, [129] as well as cardiodilatin [132] on the tentacle polymers. Through these syntheses, the critical steps were analytically ascertained, and the strategy for the optimized syntheses were established.

These investigations show unambiguously that proteins up to a molecular mass of over 10000 Da can be prepared synthetically, and that analytical methods for purity verification are at our disposal. It depends primarily on future developments of the supports and the analytical methods as to whether it will be possible to use this procedure for the synthesis of even larger proteins. For an understanding of the biological activities of proteins, the already accessible synthetic fields provide valuable information and consequently contribute to resolving the remaining secret correlations of structure and biological activity in nature.

The work presented in this article and carried out in the laboratory at Tübingen could never have been achieved without the committed collaboration of many generations of young chemists. That the names of merely a few may be emphasized in no way detracts from the significance of the accomplishments of the other co-workers mentioned in the literature section. To be mentioned here are Professors G. Jung, H. Hagenmaier, W. Voelter, W. Parr, H. Eckstein, and Dr. B. Hemmasi, who in the years 1966–1973, above all, contributed to the first attempt to synthesize peptides up to the size of apoferrodoxin on a solid support. They also carried out investigations regarding the problem of failure sequences. The liquid-phase method was developed between 1971 and 1976 in collaboration with Professor M. Mutter. All the above associates now command

their own fields of peptide chemistry and have successfully accomplished outstanding works. Dr. Uhmann, Dr. Frank, Dr. Hupe and Mr. Nicholson have contributed to the development of HPLC and the gas chromatographic detection of racemization. Recently, the development of monodispersed and of polyethyleneglycol-polystyrene supports was realized in association with Dr. W. Rapp. The syntheses of longer polypeptides were performed in collaboration with Mr. Zhang.

Thanks are due to all the sponsors of this work: The State of Baden-Württemberg, the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie; the Bundesminister für Forschung und Technologie; Hoffmann La Roche, Basel, Hoechst AG (Frankfurt) Diamalt AG (München) and BACHEM USA.

Bryophytes, a Source of Biologically Active, Naturally Occurring Material?

By Hans Dietmar Zinsmeister*, Hans Becker, and Theophil Eicher.

Chemical studies of the plant category of mosses (bryophytes) were neglected for a long time. They have now been shown to be a storehouse of naturally occurring materials, including some with novel chemical structures. Many of these materials display considerable biological activity. Investigations are hampered frequently by too small amounts of plant material. The resulting low yields of components are then generally inadequate to permit testing for biological activity. In vitro culture and appropriate chemical synthesis on a preparative scale are being undertaken to overcome this difficulty.

1. Introduction

Many bioactive substances from bacteria, fungi, lichens, and plants are invaluable to humanity and are sometimes used extensively in medicine. Thus a large proportion of medicaments on the German market are genuine or modified naturally occurring compounds.[1] It is tacitly assumed that plant compounds are derived almost entirely from higher plants, without questioning whether components of lower plants, such as bryophytes, could also serve as sources of bioactive material. The foreword of a textbook of pharmacy published in 1985[2] contains the quotation "only few types of living material have been excluded from procedures providing medicaments and other products of pharmaceutical interest—the bryophytes are an example of these". This appears to give a clear answer to the above question. Closer examination of this plant group reveals, however, that this statement will have to be revised in the future.

The plant group of the bryophytes is first considered briefly here: They represent an independent branch of the plant world, with about 20000 species, mostly terrestrial. This is about five percent of the estimated total of 400000 plant species in the world. Morphologically they occupy a position intermediate between the thallophytes and the cormophytes. From the taxonomic point of view they are divided into three classes:[3b, 4]

- Hornworts (Anthocerotae)
- Liverworts (Hepaticae)
- Mosses (Musci or Bryatae)

The hornworts always adopt simple thallus forms, that is, with little differentiation into distinct tissue systems, but there are liverworts with ground-hugging, thallus vegetation forms, as well as those with a small stem, prostrate or erect, bearing simple leaves without midrib. Almost without exception the mosses fall into the small stem and small leaf types, often with notable morphological differentiation.

The bryophytes[5] are in general prostrate but can become somewhat conspicuous through the formation of green "mats", as encountered in moorland and woods. The largest moss, up to 70 cm tall, is a species of *Dawsonia*; the smallest, sometimes not even half a millimeter in height, is an *Ephemerum* species. A so-called generation change occurs in the development cycle of a bryophyte. The bryophyte plant itself, as encountered in nature, is the haploid gametophyte, providing masculine and feminine sexual cells. These fuse to the zygote, which develops into the sporophyte, the second generation. The sporophyte is, however, not an individual in the full sense but remains attached to the gametophyte during its life and is represented by the often clearly visible spore capsule. Haploid spores develop in it through meiosis (reductive division). They germinate to green thallus protonema on which "buds" form, which grow into new, haploid bryophytes. The bryophytes are a group of plants which appeared very early in the earth's history. Fossilized bryophytes have been found from the Upper Devonian period, about 300 million years ago. In contrast, flowering plants can be traced back only to the Cretaceous time, about 100 million years ago.

Bryophytes grow predominantly in relatively shady and moist places, even though there are "wizards of survival" among them as far as the ability to withstand drying out is concerned. Such bryophytes are termed xerophytic (xeros = dry; phytein = grow). They can keep alive for a very long time in the air-dried state. It was possible to "reawaken" the moss *Anoectangium compactum* after 19 years in a herbarium! Some bryophytes also set up records in resistance to extremes of temperature. For example, some species are found at high altitudes where ground temperatures of 70 °C have been measured. Their demands for light are far more modest than those of flowering plants, whose limits for propagation lie at about 2% of full daylight. Bryophytes tolerate down to 0.1% and are thus able to penetrate into deep recesses.

Bryophytes are found everywhere except in the oceans and regions of extreme desert. Their species are most prevalent in tropical mountain and rain forests (Fig. 1). There they prefer the epiphytic form of life, that is, they grow on other plants, such as trees, covering trunks and branches with a smooth layer or hanging down from them in meter lengths. Even leaves can be covered with moss growth.

Biomasses of up to 100 g dry weight per square meter can be attained in such biotopes. They profit there from their

Fig. 1. Epiphytic mosses and liverworts in tropical mountain forest (2800 m altitude) near Quito, Ecuador. Left: *Macromitrium guatemalense*; right (hanging): *Frullania brasiliense*. Photography: Prof. R. Mues.

general ability to take up water and nutrients with the whole vegetation body and to store considerable amounts of water. Some liverworts have developed parts of their leaves into water sacs; others, for example the peat mosses which form the peat moors, possess special cells for water storage. Measurements on various bryophytes have shown that they are able to store water in amounts up to eight times their dry weight. Their important regulatory function in the water cycle in nature depends mainly on this.

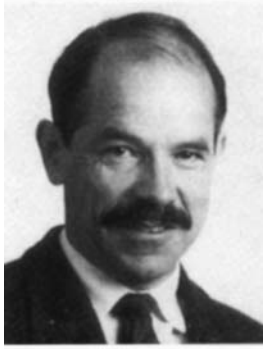
2. Components of Bryophytes

2.1. General Remarks

The chemical analysis of bryophytes was neglected for a long time. Even though analyses were performed in the previous century,[6, 7] it was not until the last two decades that biologists, chemists and pharmacists began to take an interest in the chemistry of this fascinating group of plants. This long period of neglect can be attributed principally to the difficulties of acquiring larger amounts of bryophyte material and the laborious workup procedures for obtaining the pure substances. The bryophyte plants, often only a few centimeters large, have to be cleaned with great care to avoid a mixture of species and to prevent extracting parts of higher plants embedded in the moss cushions. A stereomicroscope frequently has to be used for this.

In the last twenty years rapid and unexpected progress has been made in the chemical investigation of bryophyte com-

Hans Dietmar Zinsmeister was born in Munich in 1935, studied biology there at the Ludwig Maximilian University from 1954–1959, completing his doctorate with L. Brauner. After an assistantship at the Botanical Institute of the University of Munich and a research year as NATO-fellow with L. J. Audus in London, he obtained his 'Habilitation' in Botany in 1965. He was guest professor at the Munich Campus of the University of Maryland until 1968 and has been Professor of Botany at the University of the Saarland since 1972 and also Director of the Botanical Garden there since 1982. His main research fields are the phytochemistry of bryophytes and the cyanogenesis of nutritional plants, including the physiological and chemotaxonomic aspects.

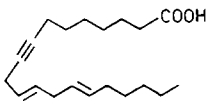


Hans Becker was born in Neustadt/W in 1940, studied pharmacy from 1961 to 1964 in Mainz and obtained his doctorate in 1970 at the Botanical Institute in Karlsruhe under E. Sprecher with a comparative work on the secondary metabolism of plants and callus cultures. He acquired his 'Habilitation' in 1973 in Pharmaceutical Biology and was professor from 1973–1986 at the Institute of Pharmaceutical Biology in Heidelberg. He has been professor of Pharmacognosy and Analytical Phytochemistry at the University of the Saarland since 1987. His fields of work concern secondary metabolism in callus cultures and bryophytes. Besides his research activities he is co-author of several books.

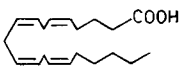
Theophil Eicher was born in Heidelberg in 1932, studied chemistry at the University of Heidelberg from 1952–1957 and received his doctorate there under G. Wittig. After a postdoctoral year in R. Breslow's group at Columbia University in New York, he worked as research assistant in Heidelberg and Würzburg, where he obtained his 'Habilitation' in 1967. In 1974 he was appointed associate professor at the Institute of Organic Chemistry of the University of Hamburg and in 1976 full professor at the Department of Chemistry of the University of Dortmund. Since 1982 he has been professor at the Department of Chemistry of the University of the Saarland. His research activities include the synthetic aspects of the chemistry of cyclopropenones and triafulvenes, and natural products. He is co-author of several books and received the literature award of the Fonds der Chemischen Industrie in 1982 together with L.-F. Tietze.

ponents, especially the secondary metabolites.[8] This has been helped by the progressive refinement of analytical techniques, so that today only a few milligrams substance suffice for characterization of the structures of natural products. Nevertheless, the components of, at the most, only 5% of known species have been studied. The results obtained up to now reveal an astonishing, latent store of new and rare, naturally occurring compounds, including new structural types. Compared to the other bryophyte categories, the liverworts are the best investigated.

The basic compound classes found, such as minerals, carbohydrates, proteins, nucleic acids, lipids, and the organic acids which participate in fundamental metabolic processes, admittedly show close similarities to those in other, in particular higher, plants, but distinct differences have also been found. For instance, polyunsaturated C-20 and C-22 fatty acids are widely found in bryophytes. Although they also occur in algae and ferns, they are absent from seed plants.[9, 10] Fatty acids containing an acetylenic bond (e.g. eicosa-11,14-dien-8-inoic acid, **1**) have also been isolated from liverworts and mosses.[11–13] The high content of arachidonic acid (**2**), found in some bryophyte species, also deserve mention. Thus the total lipid fraction of cell cultures of the moss *Leptobryum pyriforme* was reported to contain 20% arachidonic acid.[14] Another interesting report is of the discovery in some moss species of substances similar to prostaglandins.[15]

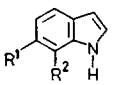


1



2

Numerous secondary metabolites have been isolated from mosses recently. The results have been summarized in various review articles.[9, 16, 17] Table 1 contains a survey of the classes of secondary metabolites found so far in bryophytes; distinct differences between liverworts, hornworts and mosses are evident. According to our present state of knowledge, phenolic and isoprenoid components predominate in all bryophytes. It is striking that nitrogen-containing secondary products have been found only occasionally, for example, two prenylated indole derivatives from *Riccardia* species (liverwort), namely the 6- and 7-(3-methyl-2-butenyl)indoles, **3** and **4**.[18]



3: R^1 = , R^2 = H

4: R^1 = H, R^2 =

Cyanoglucosides, common in higher plants, occur only rarely in bryophytes. Hydrocyanic acid could be identified unequivocally in only one (*Dicranum scoparium*) of 80 investigated moss and liverwort species.[19]

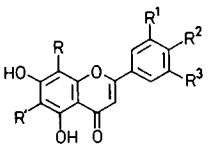
2.2. Phenolic Components

Flavonoids dominate at present among the phenolic compounds. They have been found in just about half of the liverwort and moss species hitherto examined for their presence (600 and 300 species, respectively).[20]

2.2.1. Flavonoids

This compound class is represented by an especially high number of flavones. They are often present as *C*-glycosides, e.g. tricetin-6,8-di-*C*-glucopyranoside (**5**), tricetin-6-arabino-8-glucopyranoside (**6**), apometzgerin-6,8-di-*C*-arabinopyranoside (**7**), and tricin-6,8-di-*C*-arabinopyranoside (**8**).



5: R^1–R^3 = OH; R,R′ = β-D-glucopyranosyl
6: R^1–R^3 = OH; R = β-D-glucopyranosyl; R′ = α-L-arabinopyranosyl
7: R^1, R^2 = OCH_3; R^3 = OH; R,R′ = α-L-arabinopyranosyl
8: R^1, R^3 = OCH_3; R^2 = OH; R,R′ = α-L-arabinopyranosyl
9: R^1, R^3 = H; R^2 = OH; R = β-D-(2-*O*-ferulyl)glucopyranosyl; R′ = α-L-arabinopyranosyl

Mention should be made also of some *O*- and *O,C*-glucosides, such as apometzgerin-7-*O*-glucuronide (**10**),[21] iso-

furcatain-7-*O*-β-D-glucopyranoside (**11**),[22] isoorientin-3′-*O*-sophoroside (**12**),[23] and the flavonoid-*O*-triglycoside, diosmetin-7-*O*-(2,4-di-*O*-α-L-rhamnopyranosyl)-β-D-glu-

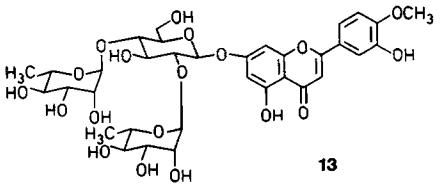
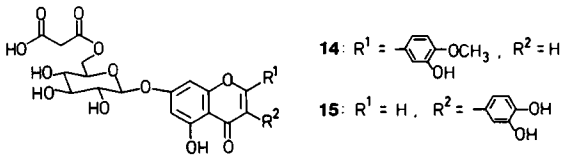
12: R^1 = *O*-sophorosyl; R^2 = OH; R^3,R,R′ = H

copyranoside (**13**), of unusually branched structure and isolated from two moss species.[24, 25] Acylated flavonoids are not rarely encountered in bryophytes, for example, feruloylisoschaftoside (**9**), diosmetin-7-*O*-glucoside-6″-malonyl ester (**14**), and orobol-7-*O*-glucoside-6″-malonyl ester (**15**).[26, 27]

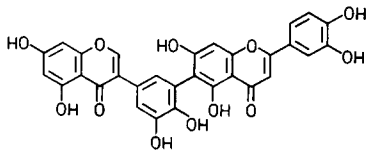


13

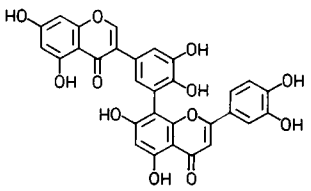


14: R^1 = , R^2 = H
15: R^1 = H , R^2 =

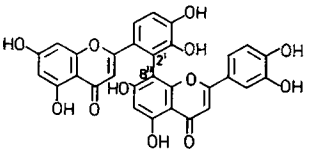
Biflavonoids appear to be restricted to mosses but are widespread there. New types of compound are, for example, bryoflavone (**16**), heterobryoflavone (**17**), philonotisflavone (**18**), and dicranolomin (**19**); the first two contain one flavone and one isoflavone unit.[28–30]



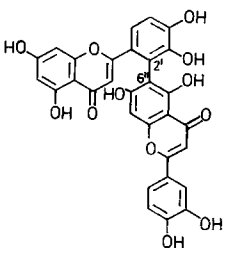
16



17



18

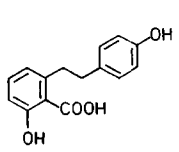


19

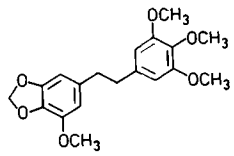
Flavonols and particularly anthocyanidins seem to be rarer. So far, the only representatives of the latter which have been isolated are the two 3-deoxyanthocyans of the luteolinidin type, from *Bryum* species (Musci),[31] although red to violet coloured bryophyte organs are encountered.

2.2.2. *Other Phenolic Components*

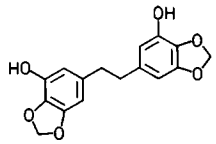
The structural variants of bibenzyl and bis(bibenzyl) in liverworts are especially remarkable in this connection.[16, 32] Examples of the former are lunularic acid (**20**), brittonin (**21**) and the related system **22**, prenylbibenzyl (**23**) and its geranyl analogue (**24**), and the radulanins A and F (**25** and **26**).



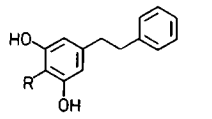
20



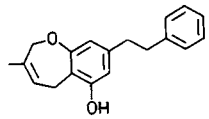
21



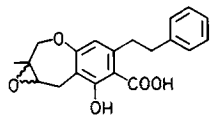
22



23: R =
24: R = 

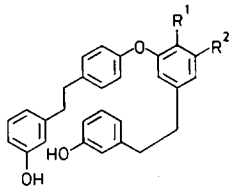


25

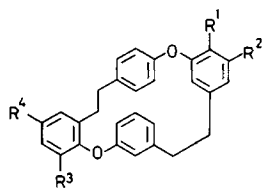


26

Examples of the bis(bibenzyl) compounds are the perrottetins E–G (**27**–**29**), the marchantins A, C and I (**30**–**32**), the riccardins B and C (**33** and **34**), and plagiochin D (**35**).



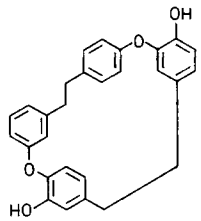
27: R^1 = OH; R^2 = H
28: R^1,R^2 = OH
29: R^1 = OCH_3, R^2 = OH



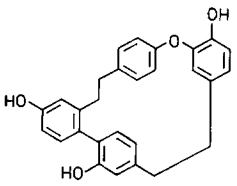
30: R^1–R^3 = OH; R^4 = H
31: R^1,R^3 = OH; R^2,R^4 = H
32: R^1–R^3 = H; R^4 = OCH_3

No examples of structures of these types are yet known in the other bryophyte classes. The sphagnorubins A–C (**36**–**38**), red cell wall coloring materials containing a phenanthrene nucleus, have been found in peat mosses (Musci).[33]

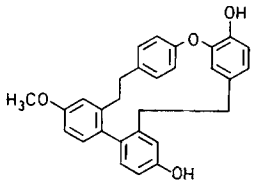
Two new types of naphthalene derivative have recently been discovered: 6,7-dihydroxy-4-(3,4-dihydroxyphenyl)-



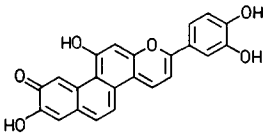
33



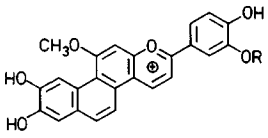
34



35

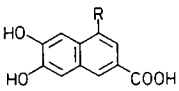


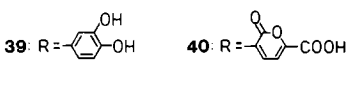
36



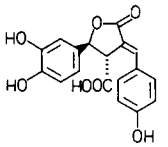
37 : R=H
38 : R=CH_3

naphthalene-2-carboxylic acid (**39**) in *Pellia*,[34] and scapaniapyrone (**40**) in *Scapania undulata*.[35] The first lignanes to be discovered in bryophytes, megacerosic and anthocerosic acids (**41**, **42**), were from hornwort species which, in contrast to the mosses and liverworts, appear to produce no flavonoids.[36] The occurrence of rosmarinic acid (**43**), built up from two caffeic acid units, also deserves mention. It is found widely in higher plants and has pharmacological significance.[36]

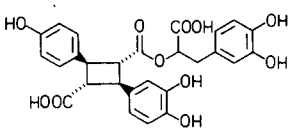




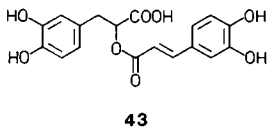
39: R= 40: R=



41



42



43

Although many intermediate and end products of the secondary metabolism of bryophytes are known, only very meagre information is available about their biogenesis and the enzyme systems involved. For example, in phenylpropane metabolism only three enzymes have up to now been reported. They are phenylalanine ammoniumylase (Hepaticae, Musci), cinnamic acid 4-hydroxylase (*trans* cinnamic acid 4-monoxygenase; Hepaticae), and cinnamyl alcohol dehydrogenase (Musci).[37]

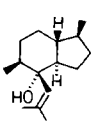
2.3. Isoprenoids

Especially interesting in this compound class are the terpenes, which are numerous especially in liverworts and occur in many structural variants. They constitute an important part of the essential oils, which are contained in their own individual oil bodies (Fig. 2).

Fig. 2. Oil bodies in cells of *Jungermannia obovata* Nees (Hepaticae), ca. 1000 x. Photography: Prof. R. Mues.

2.3.1. Monoterpenes

Many liverworts have a characteristic, strong odour, due mainly to very volatile monoterpenes. By 1983, 25 different monoterpenes had been detected.[17] These are almost entirely compounds known also in higher plants. They have mostly been identified through GC–MS, so that their optical rotations are known in only a few cases. (+)-Bornyl acetate and (−)-β-sabinene have been isolated from *Wiesnerella denudata* and *Conocephalum conicum*.[38] (+)-Bornyl ferulate and (−)-limonene have also been isolated from the latter as optically active components.[39] Recently we succeeded in isolating (−)-limonene from *Ricciocarpos natans*.[40] A substance with intense fragrance has been isolated from *Lophocolea heterophylla*.[41] A mossy scent was still clearly noticeable when 0.05–0.08 mg of it, eluted from the GC column, was expanded into a volume of about 40 m^3. Its empirical formula was given as $C_{12}H_{20}O$;[41] the structural elucidation has not yet been carried out. *Lophocolea cuspidata* also contains a powerful fragrance similar to pine needles, which can still be detected even when the culture preparation vessel is closed with a cottonwool plug.[42] Tamariscol (**44**), a sesquiterpene from *Frullania tamarisci*[43]



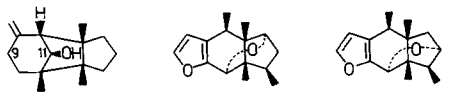
44

and other liverwort species, has a "mysterious, sweet-mossy and woody" fragrant note and has been patented as a perfume.[44]

2.3.2. *Sesquiterpenes*

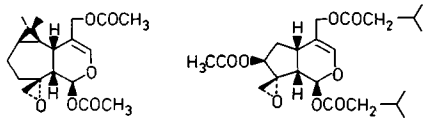
The sesquiterpenes form the largest group of terpenes hitherto found in liverworts.[16,17] Of the approximately 50 different types found in the liverworts, some have been isolated only from this plant class. These include the barbatanes (gymnomitranes), pinguisanes, the 2,3-secoaromadendranes, myltaylanes and vitranes. Some of these typical liverwort components are described briefly here. Gymnomitrol (**45**) was first detected in 1972 in *Gymnomitrion obtusum*.[45] Derivatives have been subsequently found which contain a hydroxyl group exclusively or additionally in the 9-position.[46,47]

Pinguisanes are widely distributed in species of the liverwort genera *Porella, Lejeunea, Ptilidium*, and *Aneura*. It may be necessary to revise some pinguisane structures, because the structure of one of the reference compounds, pinguisanin, has been altered from **46** to **47**, after comprehensive experimental work on the nuclear Overhauser effect (NOE).[48]



45 **46** **47**

Some 2,3-secoalloaromadendranes, such as plagiochilin A (**48**)[49] show a striking similarity to the monoterpenoid valepotriates; for example, valtrate (**49**),[50] isolated from Valerianaceae and discussed as the potential active substance of valerian. The ^{13}C NMR data of some of the 2,3-secoalloaromadendranes were tabulated in 1981.[51] Two sesquiterpene alcohols with a hitherto unknown carbon skeleton, myltaylenol and cyclomyltaylenol (**50** and **51**), have been isolated from *Mylia taylorii*.[52,53]

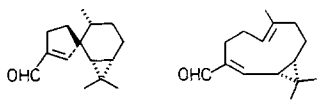


48 **49**

50 **51**

A crystalline derivative could be prepared from **50** for X-ray structure analysis by oxidizing the exomethylene to a keto group and esterifying the alcohol. With the aid of the circular dichroism (CD) spectrum, the absolute configuration of this norbornan-2-one derivative could be elucidated. The same liverwort contained many additional unusual sesquiterpenes.[54]

Vitrenal (**52**), from the liverwort *Lepidozia vitrea*, is a spiro compound, which could have been formed by ring-closure of isobicyclogermacrenal (**53**) found in the same species.[55]



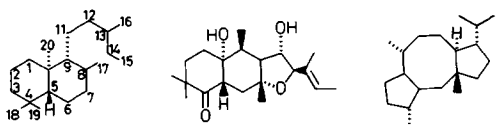
52 **53**

Many sesquiterpenes found in liverworts are enantiomers of the corresponding compounds from higher plants (see table in [17]). Any potential biological activity of these compounds can therefore be tested with both enantiomers.

2.3.3. *Diterpenes*

In contrast to mono- and sesquiterpenes, diterpenes occur in both mosses and liverworts, although more frequently in the latter.[17,56] Phytol has been found relatively frequently in open-chain diterpenes.[57,40] It is, however, unclear whether this is a real component or an artifact from chlorophyll during workup. Isophytol[58] and geranylgeraniol[59] are further aliphatic diterpenes.

Carbocyclic diterpenes from bryophytes can, for the most part, be classified with the carbon skeletons described for compounds found in plants and marine organisms. Some examples of each basic skeleton type are presented here. Further examples can be found in review articles.[16,17,56] Diterpenes with carbon skeletons hitherto not encountered elsewhere have also been detected in bryophytes. Labdane derivatives (basic skeleton **54**) have been isolated from various liverwort species. *Jungermannia rosulans* yielded 3-oxolabda-8,14-dien-13-ol and its isomer, 3-oxolabda-8(17),14-dien-13-ol,[60] and the liverwort *Porella perrottetiana*, trans-(5*R*,7*S*,8*S*,9*S*,10*S*)-labda-12,14-diene-7,8-diol.[61] A series of further labdane derivatives has been described more recently.[62-64] Among the different structures, which are remarkable for their variety of oxidation states, is the new compound **55**, described by the authors as a "novel rearranged labdane".[62] Its angular methyl groups and the C-6 side chain are each displaced by one C-atom in the labdane ring structure.

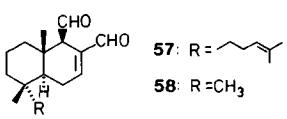


54 **55** **56**

Dolabellanes (basic structure **56**) are diterpenes with a tricyclic carbon skeleton. They were first isolated in 1971, from species of the liverwort genus *Barbilophozia*.[65] Their structure, established through spectroscopic data and chemical reactions, has been confirmed by X-ray structure analysis.[66] Dolabellanes have since also been found in the liver-

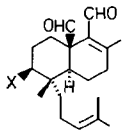
worts *Chandonanthus setiformis*[67] and *Odontoschisma denudatum*.[68]

The carbon skeleton of the sacculatanes has so far been found only in liverworts. It is closely similar to the drimane skeleton of the sesquiterpenes. Both these compound classes display similar substitution patterns. Thus, sacculatal (**57**), isolated from various liverworts, corresponds formally to polygodial (**58**), shortened by one isoprene unit. It is interesting that sacculatal has a pungent taste, whereas the 9-epimer, isosacculatal, does not possess this property.[16] Altogether, four perrottetianal derivatives from various liverwort species have been described.[69, 70] We were recently able to isolate from cultures of *Fossombronia pusilla* the derivative 8-hydroxy-8,9-dihydroperrottetianal A (**61**), in addition to the perrottetianals A and B (**59** and **60**).[71]



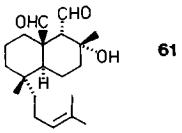
57: R =

58: R = CH_3

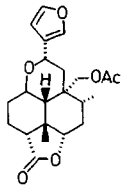


59: X = H

60: X = OH



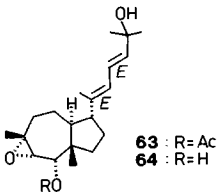
61



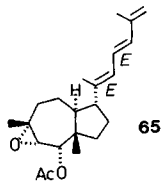
62

Gymnocolin (**62**), a bitter-tasting diterpenoid, has been isolated from *Gymnocolea inflata*.[72] This was the first example in liverworts of a clerodane, known from higher plants. Further examples of this diterpene class have been detected in, among others, *Anastrepta orcadensis*,[73] *Scapania bolanderi*,[74] and *Pleurozia acinosa*.[75]

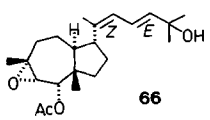
A short time ago we were able to isolate from *Anastrophyllum minutum* six diterpenes (**63**–**68**) belonging to a new structural type, sphenolobane.[76]



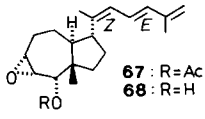
63: R = Ac
64: R = H



65

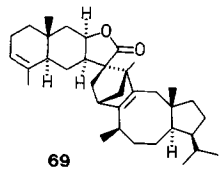


66

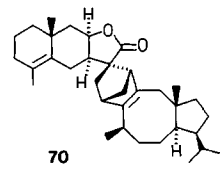


67: R = Ac
68: R = H

Tricyclic diterpenes from liverworts can contain four different carbon skeletons: *ent*-pimarane, pimarane, abietane and fusicoccane.[56] The fusicoccane type had been found only in microorganisms[78] before its discovery in *Plagiochila acanthophylla japonica*.[77] Recently we detected two new spiro compounds, plagiospirolides A and B (**69** and **70**), in *Plagiochila moritziana*. These are derived formally through



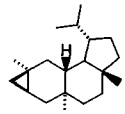
69



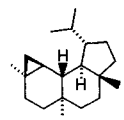
70

Diels–Alder cycloaddition of a fusicoccane with a sesquiterpene methylenelactone of the eudesmane type.[79]

Tetracyclic diterpenes encountered have been of the *ent*-kaurane structural type, widespread in higher plants, and the verrucosanes and neoverrucosanes (basic structures **71** and **72**) detected so far only in liverworts. The verrucosanes were



71

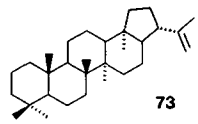


72

first isolated from *Mylia verrucosa*[80] and subsequently also from other liverworts;[56] the neoverrucosanes were found only associated with verrucosanes in *Mylia verrucosa*[80] and *Scapania bolanderi*.[74]

2.3.4. Triterpenes and Phytosterols

The triterpenoids found in bryophytes can be subdivided into the following carbon skeletal types:[17] α-amyrane, fernane, friedelane, D-friedooleanane, hopane, lupane, neohopane, and serratane. The most frequently encountered triterpene is 22(29)-hopene (**73**).



73

Exhaustive investigation has been made of the configuration at C-24 of the 24-methyl- and 24-ethylsterols in mosses.[81] Evidently 24β-alkylsterols dominate in algae and fungi but 24α-alkylsterols in higher plants. Bryophytes appear to take an intermediate position; the two epimeric 24-methylcholesterols occur in bryophytes in an α:β ratio ranging from 1:4 to 4:1.

3. Biologically Active Substances from Bryophytes

Even though bryophytes have not yet formally become important as medicinal or toxic plants,[82] preparations from them have indeed been used, notably in the Chinese and North American Indian folk medicine.[83] For example, as long ago as 1590 the Chinese *Ri* reported the diuretic properties of two mosses and the hair-growth-stimulating action of the ash of the maidenhair moss. North American Indians made use of pastes and ointments derived from mosses for treating wounds. During the first World War both the Ger-

mans and the Allies apparently took advantage of the special absorptive and antibiotic properties of *Sphagnum* species (peat mosses) for making bandage material. Furthermore, forest workers in Canada, North America and Europe have been known for a long time to be susceptible to contact dermatitis, which could be traced to epiphytically growing liverworts of the genus *Frullania*. The observation that many bryophytes are neither eaten by animals nor attacked by pest organisms has led to speculation about endogenous protective agents. It is also noteworthy that viruses have not yet been found in bryophytes.[84]

Nowadays many moss components are known to be responsible for various biological activities (Table 2). Several of these display many quite different bioactivities. A small selection of bioactive compounds produced by bryophytes is given here.

Table 2. Biological activities of bryophyte components.

1. Allergenic effect
2. Cytotoxic and cytostatic action
3. Cardiotonic activity
4. Carcinogenic action
5. Anti-inflammatory action
6. Vasopressin antagonism
7. Liberation of peroxide
8. Antibacterial activity
9. Toxicity toward fungi
10. Antifeedant activity
11. Prophylaxis against pest organisms
12. Toxicity toward molluscs
13. Toxicity toward molluscs
14. Growth regulation and plant development
15. Enzyme inhibition

Some sesquiterpene lactones, such as the two frullanolide enantiomers (**74** and *epi*-**74**) are the compounds from *Frullania* species which cause the contact dermatitis.[85-87] The allergenic action has been traced to the α-methylene-γ-butyrolactone ring. A series of new, naturally occurring compounds from bryophytes show appreciable cytotoxic and cytostatic properties (Table 3); examples are: 4-epiarbusculin (**75**), oxyfrullanolide (**76**), 8α-acetoxyzaluzanin C (**77**), diplophyllin (**78**) and (+)-epoxyfrullanolide (**79**). The

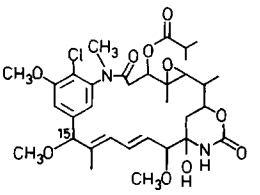
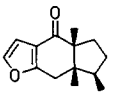
(IC_{50}: 2×10^{-5} ppm[87]). Its activity exceeds by a factor of 100 that of doxorubicin (formerly adriamycin), which has been employed successfully in various cancer cases.[89] However, only microgram amounts of this compound have been isolated so far from 20 kilograms of bryophyte sample. The furanosesquiterpene norpinguisone (**81**), from species of the liverwort genus *Porella*,[116] is toxic toward the mould *Aspergillus niger*.



80



81

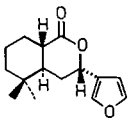
The sesquiterpene aldehyde (−)-isobicyclogermacrenal (**53**), from *Lepidozea vitrea* (Hepaticae), inhibits the growth of roots and leaves of rice seedlings in the concentration range from 1.1×10^{-3} M to 2.3×10^{-4} M.[90] In contrast, the diterpene acetate gymnocolin (**62**), from *Gymnocolea inflata* (Hepaticae), promotes the germination of wheat seeds in 10^{-6} to 10^{-7} M concentration.[91] The bibenzyl derivative lunularic acid (**20**), found in all liverworts subsequently studied (about 80)[92] very probably plays a decisive role in growth regulation and development in this class of bryophyte. The information about the occurrence of this substance in algae in the relevant literature is conflicting; it has been sought in vain in hornworts, mosses, and lichens, and there is only one example as yet of a seed plant containing it. Some of its derivatives (esters, amides) show molluscicidal activity.[93]

Sacculatal (**57**) possesses a potent piscicidal activity. Individual killie fish (a carplike species), *Orizia latipes*, are killed within two hours by solutions of 0.4 ppm.[94] The same compound is also highly active as a tumor provoker.[95] The sesquiterpene hemiacetal, plagiochilin A (**48**), from various *Plagiochila* species (Hepaticae) is a most powerful antifeedant. Concentrations of only 1–10 ng cm^{-2} were sufficient in the „Choice-Test" for the cotton plant pest, a butterfly species called the „African army worm". This is about 10 to 100 times more active than similarly functioning substances from higher plants.[116] The bis(bibenzyl), marchantin A (**30**), isolated from various *Marchantia* species,[116] shows

Table 4. Antibacterial activity of marchantin A (**30**) (according to[32], modified).

Bacterial species	Min. inhibiting concentration (ppm)
Acinetobacter calcoaceticus	6.25
Alcaligenes faecalis	100
Bacillus cereus	12.5
Bacillus megaterium	25
Bacillus subtilis	25
Cryptococcus neoformans	12.5
Enterobacter cloacae	100
Escherichia coli	100
Proteus mirabilis	100
Pseudomonas aeruginosa	100
Salmonella typhimurium	100
Staphylococcus aureus	3.13–25

distinct antibacterial activity toward some types of bacteria (Table 4). The furanosesquiterpene ricciocarpin A (**82**), from *Ricciocarpos natans*, is strongly toxic toward the water snail, *Biomphalaria glabrata*, known to be a bilharzia carrier.[93]



82

4. In Vitro Culture of Bryophytes

In addition to the difficulties of acquiring large amounts of bryophytes, there is the problem that many of them are spread over wide areas and occur only in small populations. The bryophyte growth sites, especially in the tropics, are often accessible only with difficulty. This frequently impedes the collection of a particular species in amounts sufficient for isolating and testing components for potential biological and pharmacological activity. Field cultivation of bryophytes similar to that of useful and medicinal plants is not practicable; even if the required ecological conditions were created, mixed populations would result.

A highly promising way out of this impasse is the use of in vitro culture of the bryophytes. They can be grown in vitro on suitable nutrient media, under aseptic conditions, as surface or submersed cultures. Although this technique has been known for higher plants since 1939, it was first employed relatively late for bryophytes (for a review, see [96]). Originally the cultures were used to answer morphological and physiological questions, but since the beginning of the eighties also to test for the possible formation of secondary metabolites.[14, 97–102]

Bryophyte cultures offer effectively the same advantages as in vitro cultures of higher plants.[103] Plants from all climatic zones can be grown in cultures. A comparatively constant production of material can be achieved through controlled culture conditions. Herbicides and insecticides are not needed, so that it is in general an environmentally favorable method.

Bryophyte cultures have additional advantages: The plants, often only a few millimeters large, can be cultivated easily, even in differentiated form, in fermenters. Since the bryophyte plant itself is haploid, it is possible to select mutants relatively rapidly.[104] Many bryophyte species are available in nature in such tiny amounts that in vitro culture is the only way of obtaining larger quantities of plant material. An example of this is the liverwort *Fossombronia pusilla*, which is just a few millimeters in size; a brief description is given here of its in vitro culture: A small cushion (about 5 g fresh material weight) with spore capsules was collected in August 1987. Starting with these spore capsules, an in vitro culture was set up according to the general plan (Fig. 3) on a mineral salt medium,[105] 2% in sugar, at 23 °C, and in permanent illumination (4500 Lux) (stages e–g in Fig. 3). The liverwort can be cultivated also in a liquid medium.

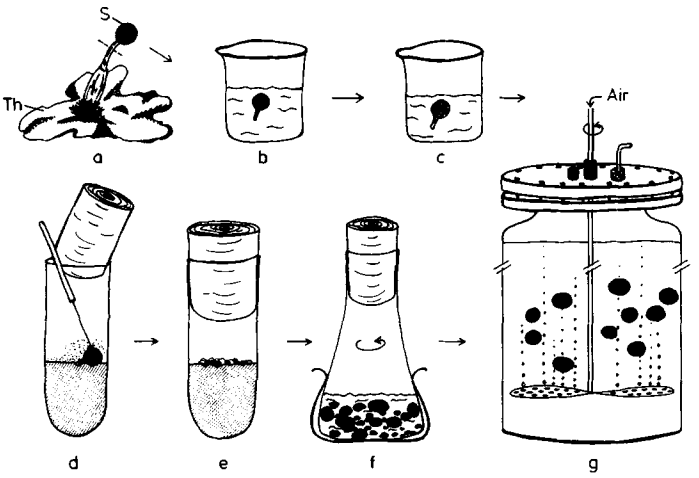


Fig. 3. Sketch of the layout of a liverwort in vitro culture:
a) liverwort with spore capsule (S = spore capsule, Th = thallus)
b) surface sterilization of the capsule
c) washing with sterilized water
d) placing the spores on the sterile agar medium
e) preliminary culture on agar medium of the small liverwort plants formed
f) "liquid culture" in an erlenmeyer flask (220 ml)
g) culture in 5-L fermenters

However, these cultures grew only when 12.5 μg L^{-1} vitamin B_{12} were introduced. A nutrition experiment with ^{57}Co-tagged B_{12} showed that a considerable fraction of the vitamin was taken up by the cultures.[71] Starting from two spores and after only one year, 1 kg *F. pusilla* plant was harvested (Fig. 4). The cultures also grow in 5-L fermenters. The cultures yield the same substances (see Section 2.3.3) as the plants in nature, as shown by a qualitative TLC and GC comparison.[14, 97–102]

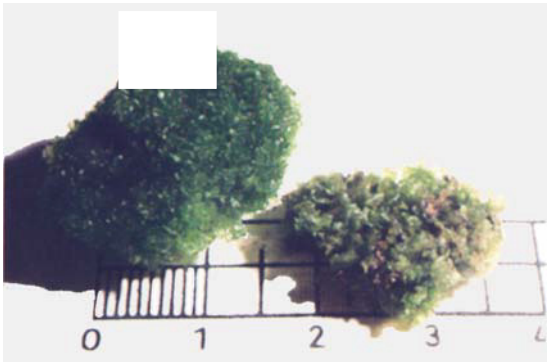

Fig. 4. *Fossombronia pusilla* (L). Nees, left: grown in an in vitro culture; right: grown under natural conditions. Photography: Prof. R. Mues.

Another good example of the efficacy of in vitro culture of bryophytes is certainly *Ricciocarpos natans*, a thallus liverwort of amphibious life mode. The thalli float like duckweed on the surface of ponds, ditches, and stagnant water stretches. The species is rare in Central Europe and is dying out as a result of water pollution. Consequently this bryophyte cannot be collected in adequate amounts; furthermore, it is usually contaminated with algae, a grave handicap to the isolation of material. In vitro cultures of *Ricciocarpos natans* on a mineral salt nutrient medium, 1% in sucrose, show the sigmoid growth curve, typical for microorganisms (see Fig. 5). The weight of fresh material increased eightfold

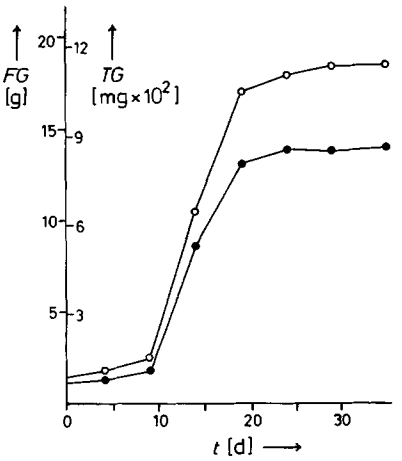

Fig. 5. Growth of the sterile culture of *Ricciocarpos natans*. Nutrient medium: modified B5 medium according to *Gamborg*: 1% sucrose, permanent irradiation of 2000 Lux; 22 °C. ○ fresh weight (g/flask); ● dry weight (mg/flask). Each point is the mean of five parallel culture preparations.

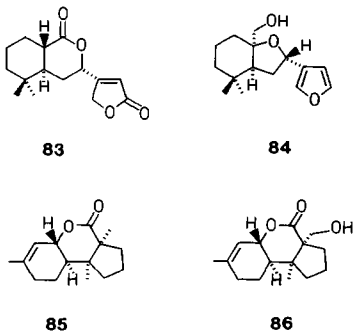
during 10 days of this logarithmic growth phase. This clearly surpasses the growth under natural conditions. A chromatographic comparison showed that the same pattern of components was produced both under natural conditions and in the in vitro culture.[40] Ricciocarpins A and B (**82** and **83**), ricciofuranol (**84**), cuprenolide (**85**), and cuprenolidol (**86**), all hitherto unknown structures, were isolated from the cultures.[40]



These two examples show that in vitro cultures furnish bryophytes in amounts sufficient to permit isolation of the components. Up to now, the chromatograms of the components from the plants in the cultures agree with those from the plants growing freely in nature.

5. Syntheses of Bryophyte Components

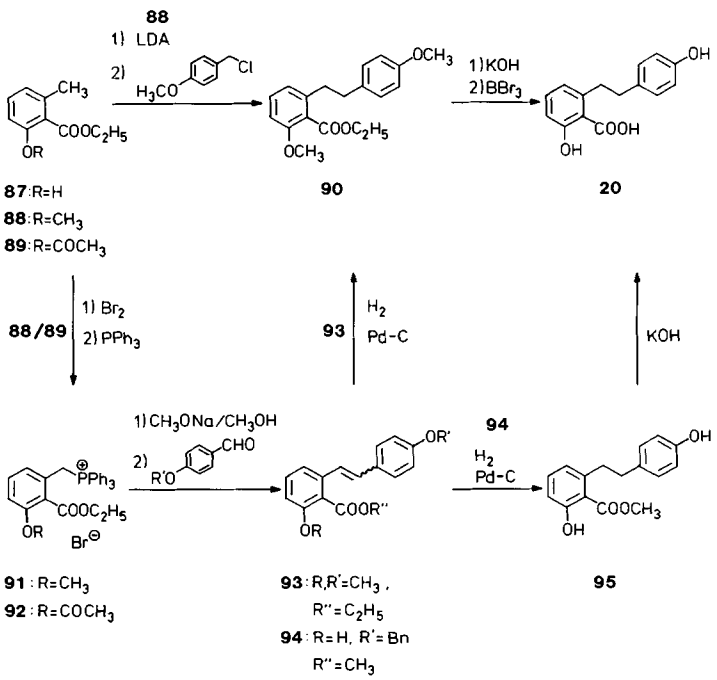
5.1. General Remarks

Chemical synthesis is very important for acquiring the natural products on a larger scale and for independent elucidation of structures. Despite the large number and variety of the bryophyte components hitherto isolated and structurally classified, comparatively little is known about syntheses of these naturally occurring compound classes. The investigations undertaken on representative examples in the domains of the phenolic and the nonphenolic components have centered on new types of structure and stereochemical aspects and, above all, on important biological activities. The aim of our own work is primarily the development of efficient and versatile syntheses on preparative scale.

5.2. Phenolic Components

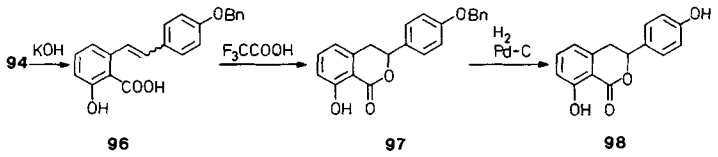
5.2.1. Bibenzyl Derivatives

Lunularic acid (**20**) has been synthesized in a number of ways.[106] Syntheses with good yields[107] start from 6-methylsalicylate (**87**)[108], whereby the 6-methyl group is converted into the bibenzyl unit by either metalation/alkylation or bromination/Wittig reaction/hydrogenation via the methyl ether (**88**), or acetate (**89**). The organometallic route (**88** → **90** → **20**) gives a total yield of 50% of lunularic acid in three stages and on a 5–10 g scale, the Wittig reaction route (**89** → **92** → **94** → **95** → **20**), 75% acid in five stages and on a 100 g scale. The Wittig reaction of **92** with *p*-benzyloxy-



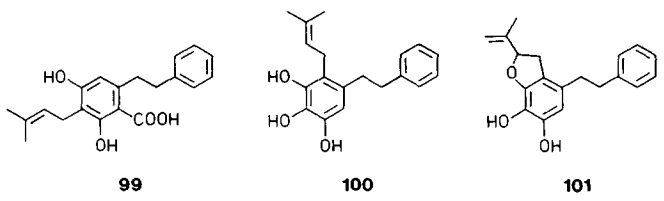
benzaldehyde to **94** is accompanied by transesterification and deacetylation and is virtually quantitative.

The stilbene-*o*-carboxylate esters (**93**/**94**) are useful intermediates for synthesizing hydrangenol derivatives. Thus the *rac*-hydrangenol (**98**) is obtained in an overall yield of 70% from the ester (**94**) by hydrolysis, acid-catalyzed cyclization of the carboxylic acid (**96**) and catalytic debenzylation of the lactone (**97**).[109]

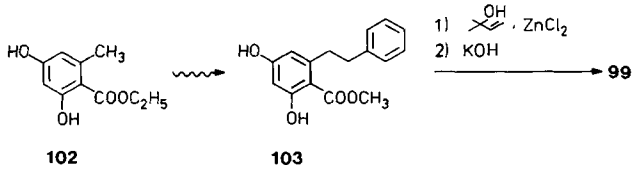


96 **97** **98**

The prenylbibenzyl derivative (**99**),[110] its (decarboxylated) analogues (**23** and **24**), and the perrottetins A and D (**100** and **101**) are related structurally to lunularic acid (**20**). Starting material for the synthesis of **99**[111] is the bis-*O*-acetylated ester of orsellinic acid (**102**). It is converted to the bibenzyl intermediate **103** in a reaction sequence analogous to that for lunularic acid (see above); the prenylbibenzyl derivative **99** is obtained by prenylation with α,α-dimethylallyl alcohol in the presence of $ZnCl_2$ as catalyst, followed by saponification of the ester.



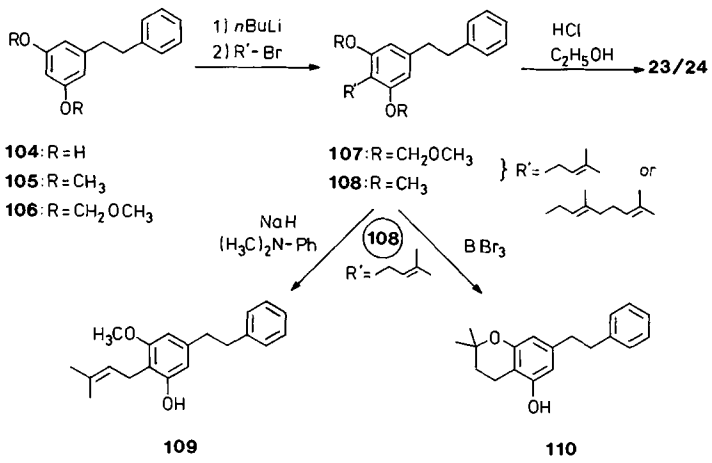
99 **100** **101**



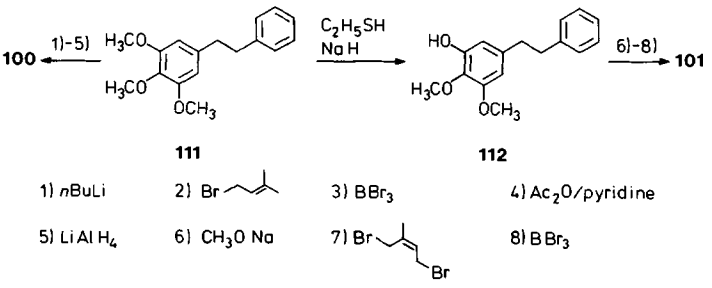
102 **103**

The key compound for synthesis of the amorfrutin analogues **23** and **24**[112] is 5-(β-phenylethyl)resorcinol (**104**). It is easily available in the methyl- or methoxymethyl(MOM)-protected form (**105** or **106**) from β-resorcylaldehyde.[113] The γ,γ-dimethylallyl or geranyl side chain is introduced by regioselective metalation of the 2-position with n-butyllithium and alkylation with the appropriate bromides. Removal of the blocking group (3% HCl in ethanol) from the MOM compound (**107**) leads to **23** or **24**, whereas deprotection of the dimethyl ether (**108**, R′ =) by means of BBr_3 and cyclization via the allyl side chain (forming **110**) using NaH/*N*,*N*-dimethylaniline splits off only one methyl group (forming **109**).

The perrottetins A and D (**100** and **101**) can be obtained in analogous reaction sequences from the dibenzyl derivatives **111** and **112**, accessible from 3,4,5-trimethoxybenzaldehyde.[114]

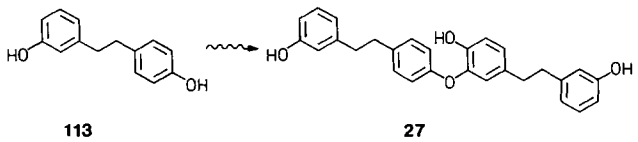


109 **110**



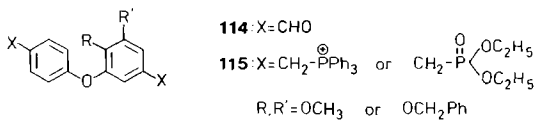
5.2.2. *Bis(bibenzyl) Derivatives*

The perrottetins E, F and G (**27**–**29**) are acyclic bis(bibenzyl) derivatives. Perrottetin E (**27**) is derived formally—perhaps also biogenetically[16]—from lunularin (**113**), the decarboxylation product of lunularic acid (**20**), through oxidative O–C coupling of the *p*-substituted hydroxyphenyl radicals.

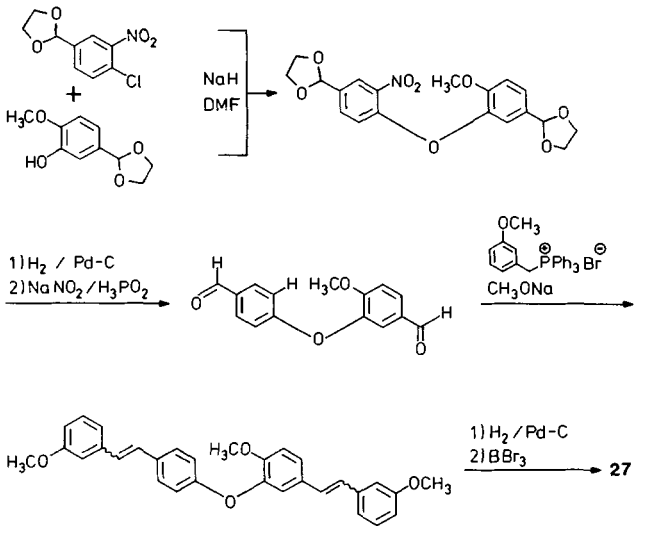


113 **27**

Several syntheses are known for the perrottetins E–G.[115–117] The usual principle is to construct suitably substituted 4,3′-diphenyl ether derivatives such as **114** and **115**. These are subjected to double Wittig or Horner reactions and subsequent hydrogenation which permits formation of the *m*-hydroxyphenyl side chain in OH-protected form; the perrottetins **27**–**29** are then obtained on removing the blocking group.

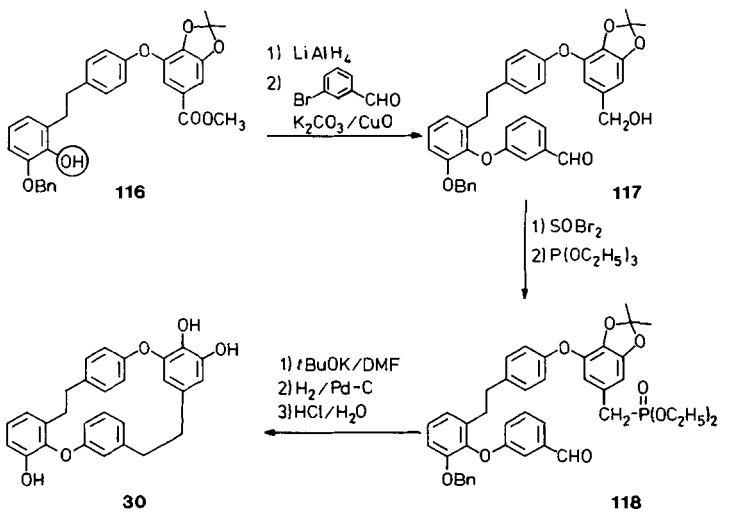


The compounds **114** and **115** can be synthesized by first forming the diphenyl ether through an S_NAr reaction of phenolates with aromatic halides activated by *o*-NO_2, and then transforming -NO_2 to -H; this has proved to be superior preparatively to direct Ullmann coupling. The example of the synthesis of perrottetin E (**27**) may be taken, in which the desired molecule is obtained in 35% overall yield in six stages.[117]



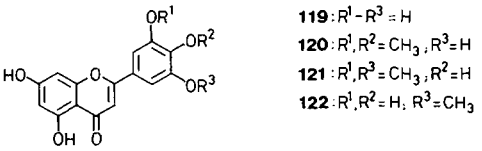
The cyclic bis(bibenzyl) derivatives of the marchantin, riccardin and plagiochin types deserve special mention. They can occur in many forms with a variety of substituents on both the benzene nucleus and ethylidene bridge.[114] A plausible hypothesis for their biogenesis considers cyclization of open-ring precursors, such as perrottetins, through intramolecular phenol oxidation, accompanied by C–O or C–C linkage of the terminal *m*-hydroxyphenyl units.[16] In this way the macrocyclic diphenyl ethers, marchantin C, riccardins B and C, and plagiochin D can be correlated biogenetically with perrottetin E (**27**).

Syntheses of the marchantins A (**30**)[118,119] and I (**32**)[120] and the riccardins B (**33**)[119,121] and C (**34**)[122] have been described. The synthesis of marchantin A (**30**), given below, illustrates the possibility of building up the cyclic bis(bibenzyl) compounds via the scheme developed for perrottetin synthesis. This makes use of a selectively protected (β-phenylethyl)-substituted diphenyl ether unit containing a free phenolic OH group (such as **116**), which is coupled with another diphenyl ether unit through an S_NAr reaction (**116** → **117**); the macrocycle is then closed by an intramolecular Horner reaction (**118** → **30**).[123]

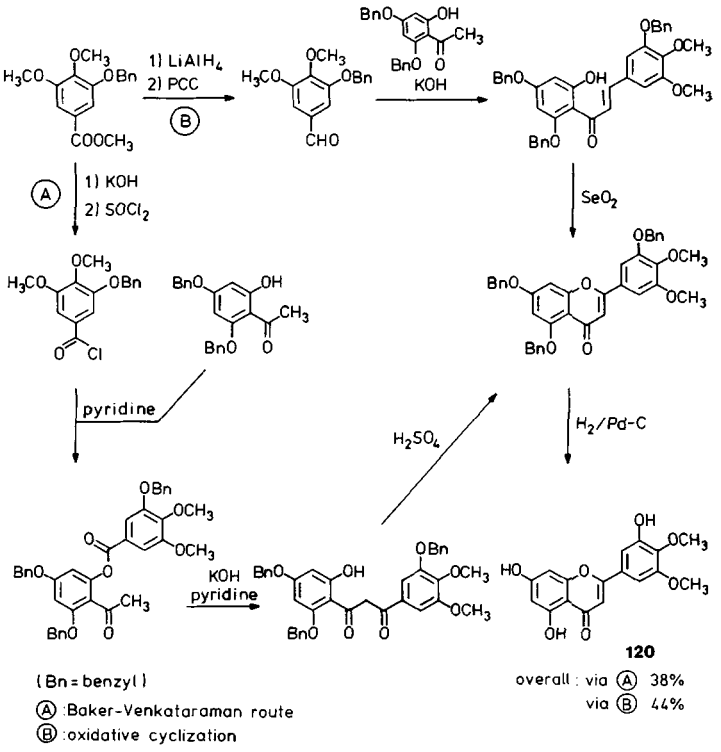


5.2.3. *Flavonoids*

Tricetin (**119**) and its *O*-methylated derivatives apometzgerin (**120**), tricin (**121**) and selgin (**122**), which occur in bryophytes as aglycones of *O*- and *C*-glycosides, can be synthesized on the preparative scale in good yields.[124,125]

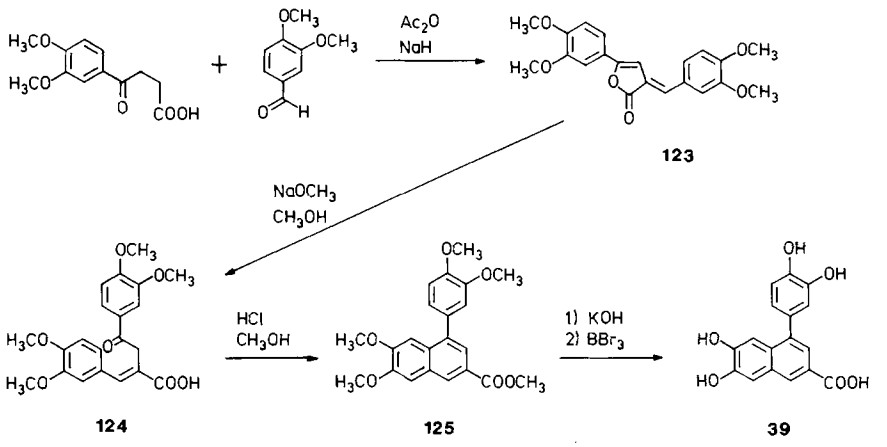


One route is via a Baker–Venkataraman transformation of protected *o*-aroyloxyacetophenones to *o*-hydroxydibenzoylmethanes, followed by acid-catalyzed cyclization; the other involves direct oxidative (with selenium dioxide) ring closure of chalcones to yield flavones, as illustrated in the following synthesis of apometzgerin (**120**).[125]



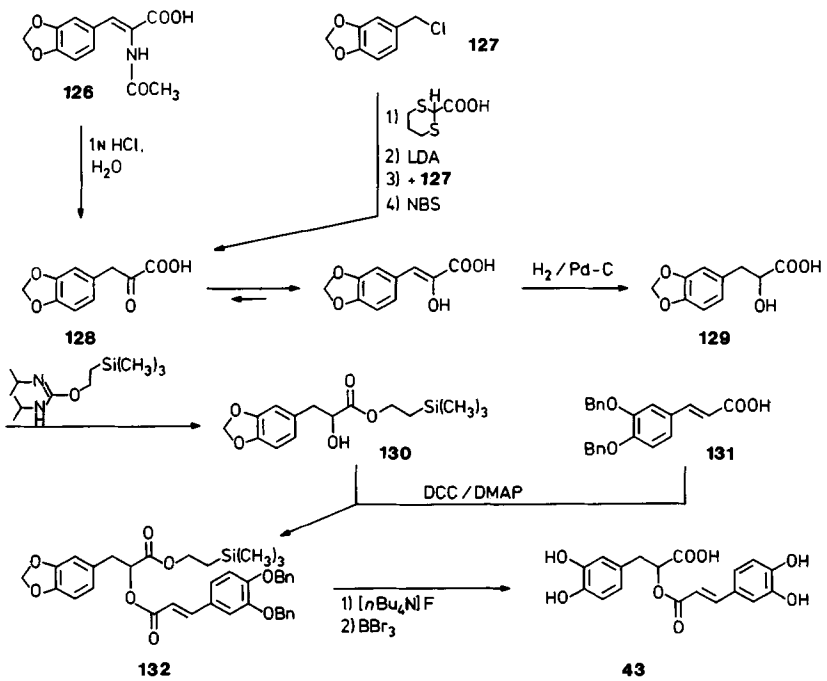
5.2.4. *Other Phenolic Components*

The 6,7-dihydroxy-4-(3,4-dihydroxyphenyl)naphthalene-3-carboxylic acid (**39**) is a representative of a new class of



phenolic bryophyte components (see Section 2.2.2). Its structure has been confirmed by independent synthesis: The butenolide (**123**) was converted by base into the open-chain α,β-unsaturated acid (**124**), which was then cyclized through an intramolecular S_EAr reaction to the ester (**125**); the acid (**39**) was obtained by hydrolysis of the ester and demethylation with BBr_3.

The starting material for the synthesis of rosmarinic acid (**43**) (Scheme 1, first carried out by us[126]) is β-(3,4-methylenedioxy)-α-acetamidocinnamic acid (**126**), which is conveniently available from piperonal through azlactone synthesis and subsequent partial hydrolysis. Further hydrolysis with 1 N HCl converts **126** (present almost entirely in the enol form) to the α-ketoacid (**128**), which is hydrogenated to piperonyllactic acid (**129**). *N,N'*-Diisopropyl-*O*-(β-trimethylsilylethyl)isourea transforms **129** into the β-trimethylsilyl ester (**130**), the free hydroxyl function of which is esterified with *O,O*-dibenzylcaffeic acid (**131**) according to the DCC (dicyclohexylcarbodiimide) method. The silylated ester group in (**132**) is split off using tetra-*n*-butylammonium fluoride, and the phenol protective group removed by BBr_3. Alternatively the α-ketoacid (**128**) can be obtained by the Corey–Seebach method[127] from **127**, through an alkylation reaction with 1,3-dithiane-2-carboxylic acid.



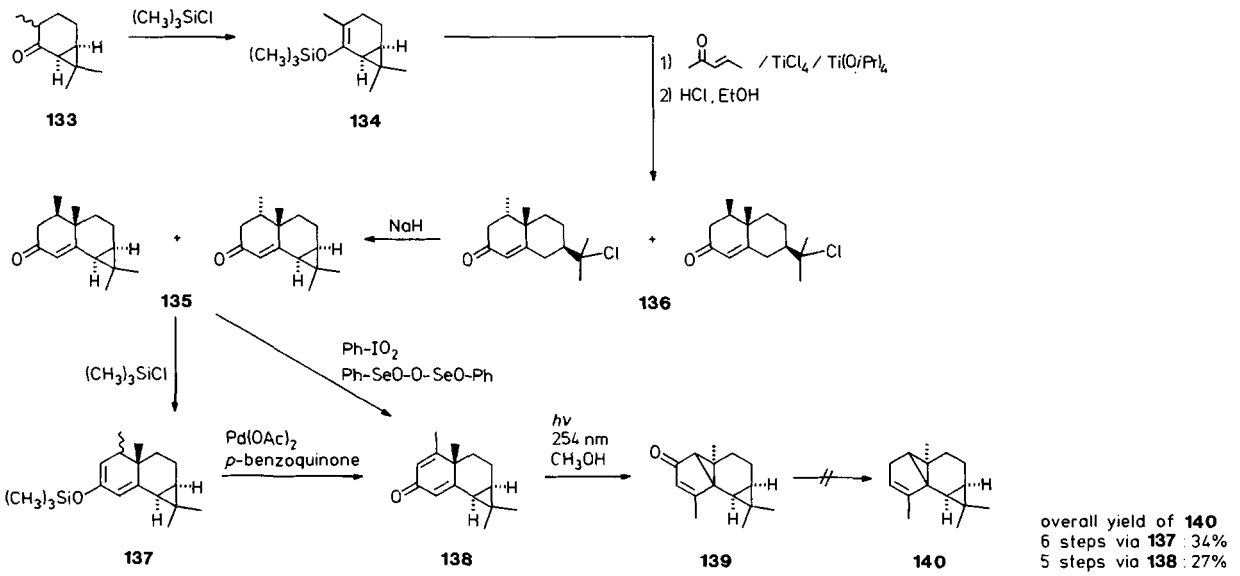
Scheme 1. NBS = *N*-bromosuccinimide, LDA = lithium diisopropylamide, DCC = dicyclohexylcarbodiimide, DMAP = 4-dimethylaminopyridine.

5.3. Isoprenoids

Numerous sesquiterpene and diterpene systems isolated from bryophytes have special structural or stereochemical features, or biological activities. This has attracted the attention of chemists interested in syntheses. Examples are the sesquiterpenes anastreptene (**140**), taylorione (**145**), chiloscyphone (**155**), ricciocarpin A (**82**), and the diterpenes sacculatal (**57**) and perrottetianal A (**59**).

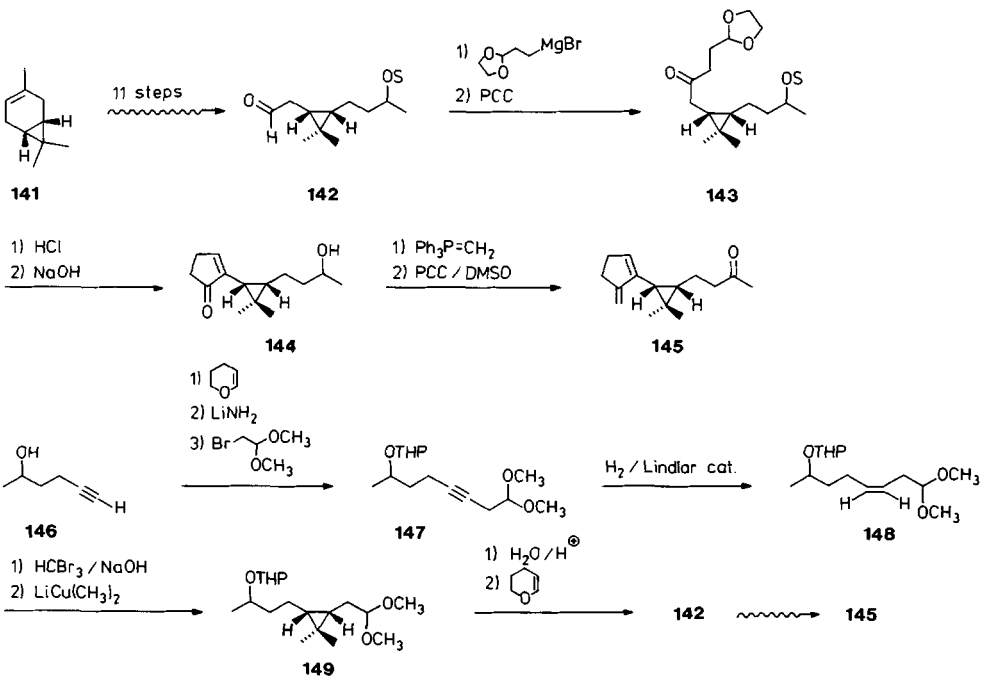
5.3.1. *Sesquiterpenes*

(−)-9-Anastreptone (**139**) can be built up from the starting material, (−)-carone (**133**).[128] The silylenol ether of the carone (**134**) is subjected to Robinson annulation with 3-penten-2-one, using $TiCl_4/Ti(OiPr)_4$ as catalyst. Subsequent treatment with HCl/ethanol opens the three-membered ring to yield an epimeric mixture of chloroenones (**136**) (76:24 mixture, separable by fractional crystallization). Restoring the ring with NaH yields the epimeric enones **135**, which can be transformed into the dienone **138** in two ways, namely, oxidation of the dienol silyl ether **137** with $Pd(OAc)_2$/*p*-benzoquinone, or direct dehydrogenation with $C_6H_5IO_2$/phenylseleninic anhydride. Irradiation in methanol leads via a stereoselective di-π-methane rearrangement to a single product, (−)-9-anastreptenone (**139**) ($[\alpha]_D^{20} = -235$ (c = 0.11 in $CHCl_3$)). A similar reaction sequence converts (+)-carone into the (+)-enantiomer of **139**. So far it has not been possible to reduce the anastreptenones to the hydrocarbons.



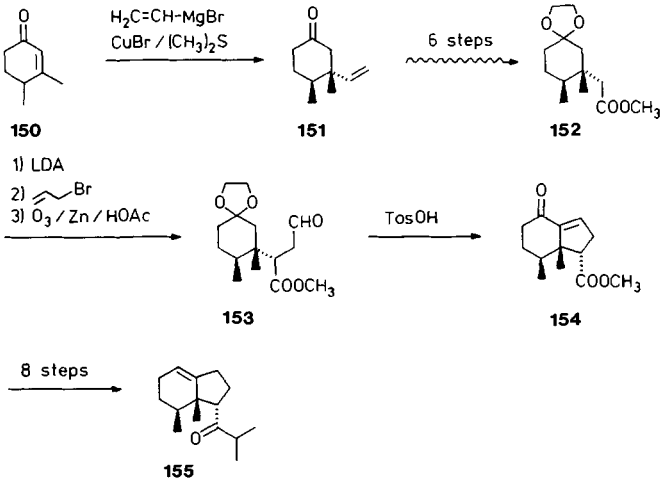
(−)-Taylorione (**145**) has been obtained in a 17-stage partial synthesis, starting from (−)-Δ^3-carene (**141**).[129] The key compound is the chiral aldehyde **142** (S = MOM). This yields the desired product **145** via chain lengthening (to **143**), intramolecular aldol condensation (to **144**), and finally Wittig olefination and oxidation.

The racemic aldehyde **142** (S = tetrahydropyran, THP)[130] can be obtained in 15% overall yield in a simple sequence of six stages, beginning with 5-hexin-2-ol **146** (**146** → **142**, S = THP). This represents a total synthesis of the racemic naturally occurring compound **145**. The route to total synthesis of the chiral natural product can be accomplished via diazoacetic ester reactions[132] of the *cis* olefin



148, analogously to the synthesis of the *ent*-chrysanthemic acid.[131]

The bicyclic α-methylene ketone chiloscyphone (**155**)[133] has been built up in a multistage reaction sequence, beginning with 3,4-dimethyl-2-cyclohexen-1-one (**150**).[134] 1,4-Addition of vinyl cuprate to **150** furnishes the cyclohexanone **151** with the desired *cis* stereochemistry of the vicinal



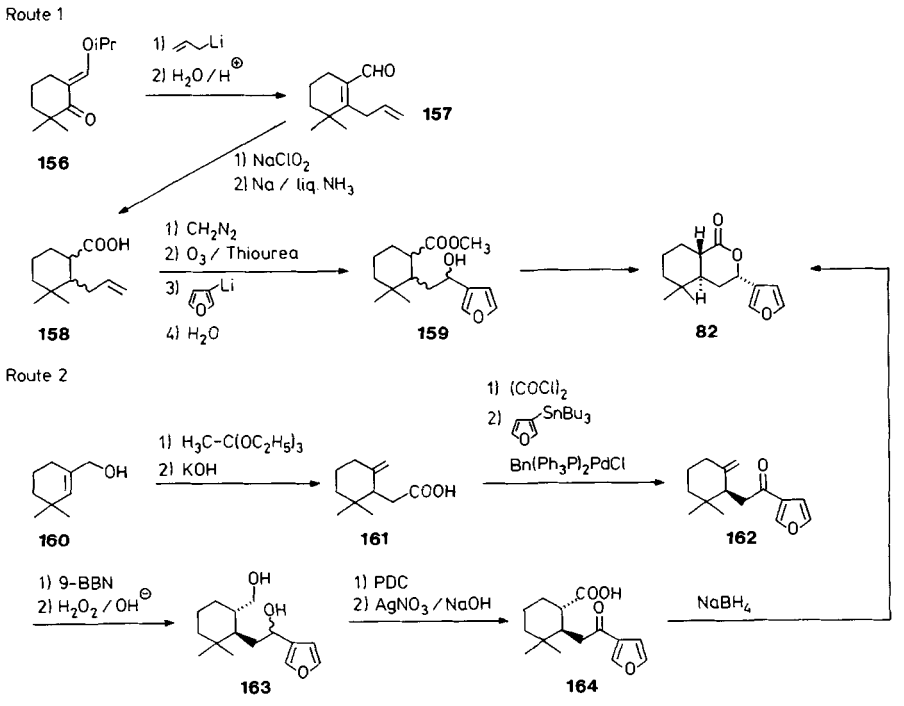
methyl groups. The vinyl group in **151** is converted into $-CH_2COOCH_3$ (→**152**) and then a C^2 aldehyde side chain is introduced into the α-position to the ester function by alkylation with allyl bromide/lithium diisopropylamide (LDA) and subsequent ozonolysis. After deprotection, the aldehyde **153** undergoes an intramolecular aldol condensation to the bicycloenone **154**. This can be separated from its C-6 epimer and yields the naturally occurring compound **155** after further conventional transformations.

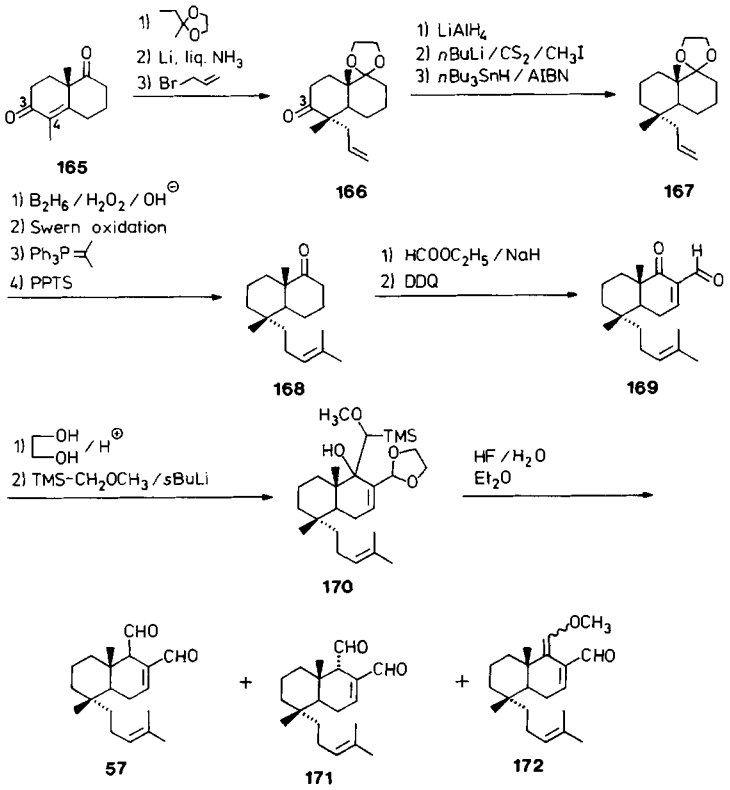
Ricciocarpin A (**82**) has been obtained as racemate via two synthetic routes. In route 1[135] allyllithium is added to the enol ether of 6,6-dimethyl-2-formylcyclohexanone (**156**). Hydrolysis of the product yields the 2-allyl-substituted cyclohexenaldehyde (**157**), which is oxidized with $NaClO_2$ to the corresponding carboxylic acid. Its conjugated double bond is then selectively reduced with sodium in liquid ammonia. The saturated acid **158** is esterified with diazomethane, and subsequent ozonolysis converts it into the ester aldehyde, to which β-furyllithium is added to give the carbinol ester epimers **159**. Subsequent hydrolysis in a basic medium yields a mixture of lactone stereoisomers, from which *rac*-ricciocarpin A (**82**) can be isolated as the main product.

In route 2[136] dimethylcyclohexenylmethanol (**160**) is converted into the acid (**161**) by a [3,3]-sigmatropic Claisen orthoester reaction, followed by saponification. The acid chloride derivative is treated with tris-*n*-butyl-β-furylstannane in the presence of benzylchlorobis(triphenylphosphine)palladium in hexamethylphosphoric triamide to yield the furylketone **162** (pallescensone, natural product from *Pictyodendrilla cavernosa*[137]). Hydroboration/reduction with 9-borabicyclo[3.3.1]nonane (9-BBN) gives the diol **163** in a stereocontrolled way. Its oxidation by pyridinium dichromate (PDC) yields the ketocarboxylic acid **164** of *trans* configuration. The sterically uniform *trans* form of *rac*-ricciocarpin A (**82**) is furnished by reducing the acid **164** with sodium borohydride.

5.3.2. *Diterpenes*

(−)-Sacculatal (**57**) has been synthesized from the chiral dione **165** as starting material.[138]. The saturated carbonyl function of **165** is first converted selectively into a ketal and an allyl side chain introduced at C-4 by reductive alkylation (→**166**). Oxygen removal at C-3 (**166** → **167**) is accomplished by reducing the carbonyl group, converting the secondary alcohol into the dithiocarbonate and performing radical fission of the dithiocarbonate with tributyl stannane according





to the method of *Barton*. The decalone (**168**) is the key compound for the synthesis. It is derived from **167** by building up the C-4 homoprenyl side chain (through hydroboration, Swern oxidation and a Wittig reaction of the aldehyde thus obtained with $Ph_3P{=}CH(CH_3)_2$ and ketal fission with pyridinium *p*-toluenesulphonate (PPTS). The two formyl groups of sacculatal are introduced by Claisen condensation with formate, dehydrogenation with 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (DDQ), protection of the aldehyde function in **169** and addition of methoxy-(trimethylsilyl)-methyllithium. The intermediate **170** thereby attained is hydrolysed, but not selectively. In addition to sacculatal (**57**, 26%), isosacculatal **171** (16%) and the *E*/*Z*-isomeric enol ethers **172** (20%) are obtained.

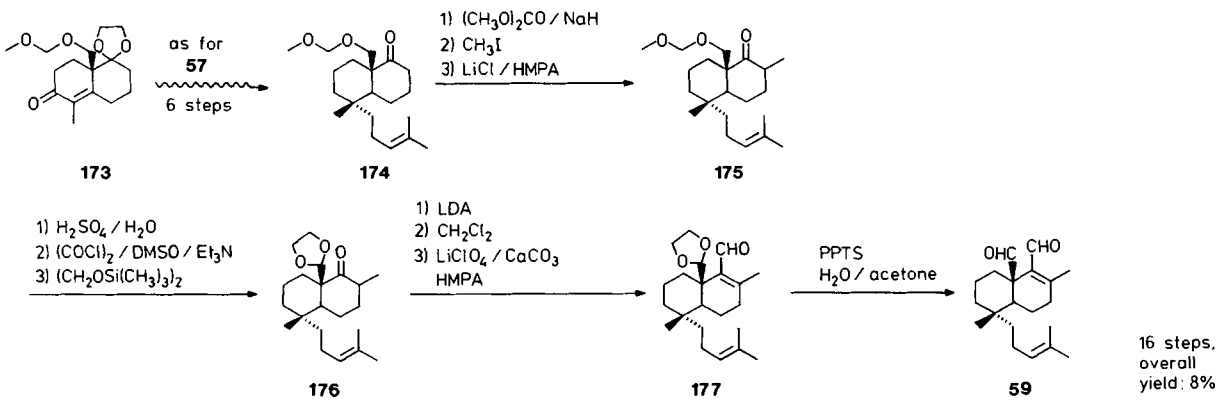
latal synthesis, into the decalone **174**, functionalized at the angular substituent. Compound **174** is then α-methylated conventionally (Claisen condensation with diethyl carbonate, and Krapcho fission of the methylated β-ketoester) and the angular CH_2OR group oxidized to the protected aldehyde group (**175** → **176**). The second aldehyde group is introduced by adding dichloromethyllithium to **176**, eliminating water and hydrolyzing to **177**. The desired end product **59** is then obtained by deblocking with pyridinium *p*-toluenesulphonate.

6. Résumé and Further Prospects

The present state of research in the chemistry of bryophytes can be summarized as follows:

1. Bryophytes constitute a notable reserve of rare and structurally new natural products.
2. Many such substances display marked biological activity.
3. In vitro cultures of bryophytes produce numerous secondary metabolites. They thus offer promising possibilities of providing larger amounts of plant material and also of components.
4. Chemical syntheses enable many bryophyte constituents to be obtained on a preparative scale. This is essential for broad biological screening. Furthermore, interesting biological activities may be shown by synthesized modified natural products and intermediates.

The question posed in the title "are bryophytes a source of biologically active material?" can consequently be answered with a clear "yes". It appears quite possible that, in the future, bryophyte components or products derived from them, can be used in pharmacological and agricultural chemical domains, or in food technology and the cosmetic industry. In our experience bryophyte constituents offer a rich field for combined research by biologists, pharmacists and chemists. This has led to the foundation in Saarbrücken of an interdisciplinary working group, "Chemistry and Biology of the Bryophytes", and also to close cooperation with BASF in Ludwigshafen on a project supported by the Bun-



The synthesis of (+)-perrottetianal A (**59**)[139] follows the same scheme. The protected chiral dione **173**, obtainable in a multistage synthesis,[140] is transformed, as in the sacculatal synthesis, into the decalone **174**, functionalized at the angular substituent. Compound **174** is then α-methylated conventionally (Claisen condensation with diethyl carbonate, and Krapcho fission of the methylated β-ketoester) and the angular CH_2OR group oxidized to the protected aldehyde group (**175** → **176**). The second aldehyde group is introduced by adding dichloromethyllithium to **176**, eliminating water and hydrolyzing to **177**. The desired end product **59** is then obtained by deblocking with pyridinium *p*-toluenesulphonate.

desministerium für Forschung und Technologie (BMFT, Federal Ministry for Research and Technology). The main points of future research are, in addition to present aims,

principally the preparation of auto- and heterotrophic tissue cultures up to the technical scale, and research on the biogenesis of bryophyte component compounds.

Our sincere thanks are due to all scientific co-workers in the participating research groups for their dedicated experimental work. Further, we wish to thank Mrs. Christine Zehren, Mrs. Uta Krienke, and Mr. Alois Etringer for their work on the figures. We are grateful also to Mrs. Christel Allmann for preparing the manuscript, to Prof. Dr. R. Mues for the use of his colour photographs and to Prof. M. Ashworth for undertaking the translation into English.

We are especially indebted to the BASF Agricultural Field Station in Limburgerhof for their effective cooperation and energetic encouragement. For financial support we thank the BMFT.

The Bioinorganic Chemistry of Vanadium

By Dieter Rehder*

Vanadium is a trace element that plays an important, perhaps essential and general role in the regulation of enzymatic phosphorylations. Several forms of life, including the fly agaric toadstool (*Amanita muscaria*) and certain sea squirts (ascidians), are able to concentrate vanadium. In other organisms vanadium is part of the active site of some enzymes. Well-studied examples are the nitrogen-fixing bacterium *Azotobacter* and various seaweeds that use vanadate-dependent peroxidases to synthesize halogenated organic compounds. Despite its importance as a "biometal" both in primitive, prokaryotic organisms (*Azotobacter*) and in the highly organized ascidians, which represent an early stage in the evolution of vertebrates, the bioinorganic chemistry of vanadium is still in its infancy. Just as young, but undergoing explosive development, is the chemistry of model compounds for vanadium-containing biomolecules, a domain of the bioinorganic coordination chemist, who almost daily discovers compounds with new and surprising structural features. This article reviews this fascinating area of bioinorganic chemistry.

1. Introduction

Vanadium occurs with an abundance of 0.014% in the earth's crust and thus, though more widely dispersed, is as common as zinc, whose extensive biological function has been known much longer. The vanadium concentration in the oceans, where life evolved, is only 50 nM. However, some groups of aquatic organisms can accumulate vanadium. Among these are many members of an order of tunicates, the Ascidiacea (sea squirts), which concentrate vanadium to 0.15 M in specialized blood cells.[1] The first specific vanadate-dependent enzyme, a haloperoxidase, was isolated from the knobbed wrack (a marine brown alga).[2] The ability to accumulate vanadium is not restricted to marine life, however, as is shown by the discovery in lichen of a haloperoxidase with vanadium at the active site[3] and by the isolation of a vanadium compound of low molecular weight (amavadin) in the toadstool *Amanita muscaria* and other species of the genus *Amanita*.[4, 5] Above-average vanadium content is found in fossil matter[6a] such as crude oil, coal, and carbonaceous fossils, in bituminous rock, and in limestone sediments (cf. Table 1). The early work of *Treibs* showed[6b] that the vanadium found there is mostly in the form of vanadium porphyrins, which probably arose through secondary processes.

The biological significance of vanadium was recognized as early as 1904 through its fungostatic effect on yeasts.[7] The significant concentrations of vanadium in ascidians led shortly thereafter to the first proposals for its biological function.[8] *Henze*, who published his studies of vanadium in the blood of ascidians in 1911, assumed that "Hämovanadin" had an oxygen transport function. Although such a function was later refuted, there is still no consensus on the actual role of vanadium in ascidians. During the following decades, sporadic reports of possible biochemical functions for vanadium appeared. That vanadium is essential in chlorophyll synthesis[9] and in the growth of rats and chickens[10, 11] has been known since the beginning of the seventies. The inhibition of ribonuclease by vanadium was also reported during this period.[12] General acceptance of vanadium as a biometal was assisted by the discovery in 1977 that it inhibited the Na,K ATPase (sodium-potassium pump).[13] Since then several reviews on the "new biochemistry of vanadium" have appeared.[14–20] Only in recent years did vanadium become interesting to bioinorganic chemistry, when it became clear that this element is present at the active site of enzymes. Two such enzymes are known today: the above-mentioned haloperoxidases in sea algae and lichens[2, 3, 21] and the nitrogenases in the nitrogen-fixing bacterium *Azotobacter*, which incorporates vanadium only (instead of molybdenum) into the corresponding cofactor when molybdenum is deficient or after genetic manipulation.[22] Besides a Mo and V nitrogenase, an iron nitrogenase, free of these two metals, is often—but not always[23a]—coded in the nitrogen-fixing microorganism.[23b–d] The significant role that vanadium can play in the reduction of N_2 to NH_3 was already proved half a century ago by *Bortels'* comprehensive series of investigations into *Azotobacter*,[24] but was apparently forgotten thereafter.

Similar to molybdenum, vanadium assumes an exceptional position among the biometals in that both its anionic and

Table 1. Distribution of vanadium [a].

Sample	Concentration	Ref.
Seawater (Pacific)	1.6 $\mu g L^{-1}$; 35 nM	[27]
Fresh water	1.3 $\mu g L^{-1}$	[27a]
Carbon-containing sediments of marine origin (e.g., shale, limestone)	up to 100 $mg kg^{-1}$	[28a, b]
Basalt and igneous rock	150 $mg kg^{-1}$	[28c]
Coal, crude oil	up to 1 $g kg^{-1}$ [b]	[30]
Ascidians	up to 2 $g kg^{-1}$	
Other vertebrates	0.4 $mg kg^{-1}$	[32]
Cow's milk	0.2–10 $\mu g L^{-1}$	[33b]
Tissue (human)	0.1–1 μM	[34]
Invertebrates	0.5–2.5 $mg kg^{-1}$	[32]
Fly agaric (*Amanita muscaria*)	up to 1 $g kg^{-1}$	[4b]
Brown algae	2 $mg kg^{-1}$	[32a]
Other plant material	0.1–5 $mg kg^{-1}$	[28c, 32, 33a]

[a] Average values relative to dry weight (whenever applicable). [b] Some crude oils (e.g., Venezuelan petroleum) contain significantly more vanadium.

W-2000 Hamburg 13 (FRG)

cationic forms can participate in biological processes. The anionic form, vanadate(v), strongly resembles phosphate; the inhibitory, stimulatory, and regulatory functions with respect to phosphohydrolases and phosphotransferases, as well as the interesting toxicological and pharmacological effects of vanadate, are probably attributable to this similarity. In three fundamental points, however, vanadate differs from phosphate: (1) At physiological pH values monovanadate exists in the diprotonated form, $H_2VO_4^{\ominus}$, in contrast to the monoprotonated form of phosphate, $HPO_4^{2\ominus}$, which has two negative charges. Furthermore, vanadate tends to form oligovanadates, although not at the usual physiological concentrations. (2) Vanadium shows a pronounced tendency to use its energetically favorable d orbitals to form compounds with coordination numbers 5, 6, and 7. With diols, for example, vanadium undergoes not only esterification but can also—in contrast to phosphate—extend its coordination geometry from a tetrahedron to a tetragonal pyramid or trigonal bipyramid.[25] (3) Vanadate is easily reduced under physiological conditions. In the oxidation states III and IV, cationic species are preferentially formed. Thus, vanadium can behave as a transition metal and, as such, replaces other metal ions in enzymes and enters into complex reactions with potential ligand systems. The formation of vanadyl porphyrins during the generation of fossil matter from plants and animals is an example of this; vanadyl porphyrins have also been identified in vivo.[26]

The biological function of vanadium is a result of these features, which I shall expand upon individually in Section 3. Besides the ability of vanadium to assume various oxidation states, its coordination chemistry plays a central role in the interaction with biomolecules. The challenge to the bioinorganic chemist lies in preparing model compounds and in characterizing both biogenetic and biomimetic vanadium compounds; this area will be covered in greater detail in Section 4. First, however, a few aspects of the aqueous chemistry of vanadium will be addressed in order to provide the prerequisites for understanding the role of vanadium in biological processes.

2. The Aqueous Chemistry of Vanadium

Of the common oxidation states of vanadium, only V^{III}, V^{IV}, and V^{V} are involved in physiological systems; V^{II} reduces water to hydrogen, as the compilation of standard electrochemical potentials[29] in Table 2 shows. V^{IV} is easily oxidized to V^{V} under aerobic conditions, possibly according to Equation (a).

$$4\,VO^{2\oplus} + O_2 + 2\,H_2O \longrightarrow 4\,VO_2^{\oplus} + 4\,H^{\oplus} \qquad (a)$$

More recent investigations indicate that autoxidation and formation of $O_2^{\ominus}$ (hyperoxide) must also be considered in neutral medium. Hyperoxide either exists alongside vanadate(v) or reacts further to give peroxovanadyl, $V(O_2)^{2\oplus}$.[31] On the other hand, V^{V} is easily reduced by organic matter to V^{IV}. V^{III} and V^{IV} are found in the vanadocytes of certain tunicates[35a,b] and V^{IV} is found in amavadin in *Amanita muscaria*.[4,36] XANES (X-ray absorption near edge structure) data suggest an oxidation state of between II and IV for vanadate-containing nitrogenases.[37] V^{V} is present in seawater, in the exoplasm of tunicates, and in vanadate-dependent peroxidases. The action of vanadium as a phosphate antagonist is directly attributable to V^{V} and probably also indirectly to the facile change to V^{IV}. The ions listed in Table 2, with the exception of $H_2VO_4^{\ominus}$, exist only in strongly acidic media; however, they can be stabilized by complexation even under physiological conditions. This is particularly true for $VO^{2\oplus}$; its stable complexes with proteins, for example, have formation constants of $10^7-10^9\ M^{-1}$.[38]

Table 2. Electrochemical potentials [a].

Redox pair	Standard potential [V]
$H_2VO_4^{\ominus} + 4H^{\oplus} + e \rightleftarrows VO^{2\oplus} + 3H_2O$	1.31
$O_2 + 4H^{\oplus} + 4e \rightleftarrows 2H_2O$	1.23
$VO_2^{\oplus} + 2H^{\oplus} + e \rightleftarrows VO^{2\oplus} + H_2O$	0.99; 1.016(2) [b]
$VO^{2\oplus} + 2H^{\oplus} + e \rightleftarrows V^{3\oplus} + H_2O$	0.34; 0.309(2) [b]
$V^{3\oplus} + e \rightleftarrows V^{2\oplus}$	−0.25
$NAD^{\oplus} + 2H^{\oplus} + 2e \rightleftarrows NADH + H^{\oplus}$ [c]	−0.34
$2H^{\oplus} + 2e \rightleftarrows H_2$; pH 7	−0.42

[a] If not otherwise indicated, the data are taken from standard tables. [b] In 1 M NaCl [30]. [c] NAD = nicotine adenine dinucleotide.

The V^{V} species present in aqueous medium, which depend on both the pH and the vanadium concentration, have been largely identified by potentiometric[39,40] and combined potentiometric/^{51}V NMR spectroscopic studies.[41] The regions in which the different vanadates exist within the pH interval 5–9 and at two total-vanadate concentrations, c(V),

Dieter Rehder, born in 1941 in Hamburg, studied chemistry in Hamburg from 1961 to 1967 (Ph.D. thesis, 1970, under the supervision of R. Nast). After a stay in Kingston, Jamaica (1972–1975; with the German Volunteer Service), he returned to Hamburg as "Hochschulassistent" and attained his Habilitation in 1979. He has been a full professor since 1984. His research programs encompass organometallic and hydrido compounds of the (early) transition metals, the inorganic biochemistry of vanadium, and magnetic resonance spectroscopy of metal nuclei.

are shown in Figure 1, together with the ^{51}V NMR spectrum at pH 7.6. In the more restricted physiological range (pH $= 7 \pm 1$) and at high enough $c(V)$, the species found are dihydrogen orthovanadate (V_1''), dihydrogen divanadate (V_2''), and *cyclo*-tetravanadate (V_4), -pentavanadate (V_5), and (at higher ionic strengths) -hexavanadate (V_6). A trivanadate appears not to be present.[41] At pH 6.3, the orange or yellow

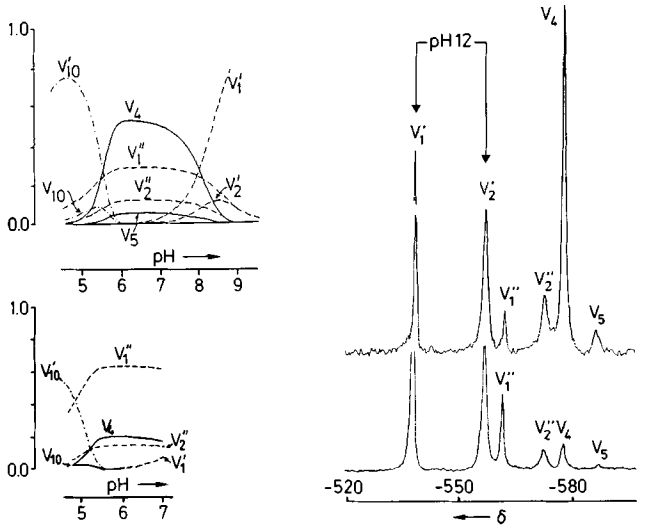

Fig. 1. Left: Regions in which vanadates exist in physiological pH range when the total concentration $c(V)$ is 1.25 mM (top) and 0.31 mM (bottom). In the former case the dominant species is $V_4O_{12}^{4\ominus}$ (V_4), in the latter $H_2VO_4^{\ominus}$ (V_1''). Right: This also becomes clear from the relative integral intensities of the ^{51}V NMR signals of the vanadates. The spectra were recorded at 94.7 MHz in H_2O/D_2O 2/1 (internal standard vanadate ($c(V) = 0.74$ M) at pH 12; 0.17 M NaCl (physiological ionic strength); 0.1 M Hepes buffer, pH = 7.6) for $c(V) = 1.5$ mM (top) or $c(V) = 0.37$ mM (bottom). At pH 12 and $c(V) = 0.74$ M, only V_1' and V_2' are observed. $V_1' = HVO_4^{2\ominus}$, $V_2' = HV_2O_7^{3\ominus}$, $V_2'' = H_2V_2O_7^{2\ominus}$, $V_5 = V_5O_{15}^{5\ominus}$, $V_{10} = V_{10}O_{28}^{6\ominus}$, $V_{10}' = HV_{10}O_{28}^{5\ominus}$. For further details on the left side of the figure, see [41a] and [41c].

(depending on the dilution) monohydrogen decavanadate (V_{10}') also occurs. This mixture of vanadates is often named metavanadate. At $c(V) < 10^{-4}$ M (e.g., in seawater), virtually the only species present is monovanadate, which undergoes a rapid protonation equilibrium [Eq. (b)].

$$H_2VO_4^{\ominus} \rightleftharpoons HVO_4^{2\ominus} + H^{\oplus} \qquad (b)$$

In contrast, exchange between vanadates of differing nuclearity is slow. The chemical shift of the ^{51}V NMR signal, $\delta(^{51}V)$, is dependent on the position of the equilibrium and therefore on pH according to Equation (c), which may be

$$pH = pK_a + \log(\delta_2 - \delta_{obs})/(\delta_{obs} - \delta_1) \qquad (c)$$

used to determine the pH of, for instance, biological systems [$\delta_1 = \delta(HVO_4^{2\ominus}) = -537.7$, $\delta_2 = \delta(H_2VO_4^{\ominus}) = -561.7$ (relative to $VOCl_3$), $pK_a(H_2VO_4^{\ominus}) = 8.16$[42]]. V^V occurs as orthovanadate, $VO_4^{3\ominus}$, above pH 12. (For information on the oxosulfidovanadates(V), which are of potential interest for the genesis of vanadium-containing nitrogenases, see Ref. [43].)

Peroxovanadate(V) has been mentioned in connection with therapies for cancer[44] and diabetes (see Section 3.1); furthermore, such species possibly play a role in the halogenation of organic compounds by vanadate-dependent peroxidases. In the pH range 5–9 the following anions were identified by Raman,[45a] ^{17}O NMR,[45b] and ^{51}V NMR[45] spectroscopy: *cis*-$[VO_2(O_2)_2(H_2O)]^{3\ominus}$, $[V_2O_3(O_2)_4]^{4\ominus}$ (or its protonated form), $[VO(OH)(O_2)_2(H_2O)]^{2\ominus}$, and $[VO(O_2)_2(H_2O)]^{\ominus}$ (formulated as in Ref. [45a]). The $\delta(^{51}V)$ values of the peroxo compounds lie between $\delta = -690$ and -760 and are thus clearly higher than those of the simple vanadates; all these compounds may therefore easily be observed in the same solution after it has been treated with H_2O_2.

Of special relevance to the phosphate/vanadate antagonism is the formation of the anions $H_xPVO_7^{(4-x)\ominus}$ ($x = 1,2$) and $HVP_2O_{10}^{4\ominus}$, which are analogous to pyro- and triphosphate. These mixed anhydrides have been identified in the pH range 6.7–8.0 by ^{51}V NMR spectroscopy and are more susceptible to hydrolysis into the individual components than divanadate by a factor of 10; however, they are 10^6 times more stable than pyrophosphate.[42a] The formation constant for the formation of $H_2PVO_7^{2\ominus}$ from hydrogen vanadate and hydrogen phosphate is 25 M^{-1}. In acid medium, furthermore, several "triphosphate complexes" of $VO_2^{\oplus}$ (e.g., $[VO_2(HP_3O_{10})]^{3\ominus}$) have been identified by spectroscopic means.[42b]

The free cations $[V(H_2O)_6]^{3\oplus}$, $[VO(H_2O)_5]^{2\oplus}$, and $[VO_2(H_2O)_4]^{\oplus}$ are of lesser importance, as they exist only in more strongly acidic medium. V^{III} forms a sparingly soluble precipitate of vanadium oxide at pH > 2.2. The blue cation $[VO(H_2O)_5]^{2\oplus}$ is in equilibrium with its deprotonated form $[VO(OH)(H_2O)_4]^{\oplus}$, which becomes the dominant species around pH 6. In addition, a dimer, probably $[\{VO(H_2O)_4\}_2(\mu\text{-}OH)_2]^{2\oplus}$, can be observed. In this pH range, however, the precipitation of sparingly soluble vanadyl hydroxide, $VO(OH)_2$, begins. Vanadate(IV) forms in strongly alkaline solution.

3. The Biological Role of Vanadium

3.1. Physiological Effects and Medical Applications

Vanadium poisoning is known to occur in particular by inhalation of vanadium-rich dust and its symptoms resemble those of influenza.[33b] But an etiological role in manic-depressive psychosis has also been attributed to vanadium.[33c] The MAK value (maximum workplace concentration—German standard) for V_2O_5 dust, which can occur especially in the vicinity of large-scale furnaces and has a direct toxicological effect on lung parenchyma, is 0.01 mg m^{-3}.[46] When vanadium is administered intravenously, the tolerance level is very low: although 5.6 mg kg^{-1} body weight can be well tolerated, 11.2 mg kg^{-1}, for example, leads to serious health disorders.[33b] The LD_{50} value in animal experiments is a few milligrams per kilogram.[47] Oral intake is less hazardous, mainly because only 2% of the vanadium is resorbed. Vanadium levels of 1 mg kg^{-1} in food are considered acceptable.[19] The bones, liver, and kidneys retain vanadium with a biological half-life of 20–100 h. The excretion takes place mainly through the urine,[33b] probably as V^{IV} coordinated, for example, to transferrin.

Many of the effects of vanadium are due to inhibition or stimulation of enzymes that participate in phosphate metabolism. This subject has been reviewed several times[15-19] and selected examples will be treated below. Not only monovanadate but also decavanadate and the oligovanadates which exist at physiological pH (Fig. 1) can bind to tissue, as is shown, for example, by the binding of vanadate to the Ca ATPase of the sarcoplasmic reticulum (SR).[48b] As a rule, the regulatory effect of vanadium slowly diminishes owing to its reduction to $VO^{2\oplus}$. V^{V} and V^{IV} (for which the effect is more pronounced) form complexes with a large number of biogenic ligands.[54a, b] Table 3 lists some formation constants. Some of these complexes can be reduced or oxidized reversibly. The redox potentials for selected examples show (Table 4) that a reduction from V^{V} to V^{IV} can take place under physiological conditions with, for example, NADH ($E^{\circ} = -0.34$ V) or glutathione ($E^{\circ} = -0.23$ V). Under aerobic conditions, $VO^{2\oplus}$ catalyzes the oxidation of NADH and NADPH via vanadium(v) intermediates and $O_2^{\ominus}$.[31] In oxidation state V or IV, vanadium binds to serum albumin[53b, 64-66] and, more efficiently, to transferrin[53, 67, 68] (the latter also coordinates V^{III}[69]). Vanadotransferrin probably is the actual form in which vanadium is transported in the more highly organized organisms. Vanadium enters into the cell cytoplasm as vanadate via the same channels through which phosphate is translocated; in erythrocytes the transport paths are the same as those for chloride and hydrogen carbonate.[70] Inside the cell, vanadate is slowly reduced by glutathione to $VO^{2\oplus}$, which can bind to the protein mantle of ferritins and thereby be temporarily "stored".[67]

Table 3. Formation constants $K[M^{-1}]$ of selected V^{IV} and V^{V} complexes with biogenic or related ligands.

Ligand	K [a]	Ref.
V^{V} (as $HVO_4^{2\ominus}$)		
Oxalate	13	[49a]

[a] The boldface letters refer to the structures shown above the table. Rhodotorulic acid is a naturally occurring dihydroxamic acid. Abbreviations: ehgs = *N*-[2-(*o*-salicylideneamino)ethyl](*o*-hydroxyphenyl)glycine; acac = acetylacetonate (1−); H_2shed = *N*-salicylidene-*N*'-(2-hydroxyethyl)ethylenediamine; tcad(2−) = 1,4,7-triazacyclononane-*N*,*N*'-diacetate; docda(2−) = 1-oxa-4,7-diazacyclononane-*N*,*N*'-diacetate; dcdt(2−) = 1,2-dicyanoethylene-1,2-dithiolate.

Vanadium compounds of therapeutic importance are listed in Figure 2. The unspecific, pharmacological effects of vanadium compounds include the lowering of cholesterol and glucose levels, a diuretic and natriuretic[71a] (weight-reducing) effect, the contraction of blood vessels, and the enhancement of the oxygen affinity of hemoglobin and myoglobin.[71b, c] The latter effect is probably due to the decrease in the concentration of 2,3-diphosphoglycerate in erythrocytes, a result of the vanadium-mediated stimulation of the 2,3-diphosphoglycerate phosphatase activity of phosphoglycerate mutase. This has led to the suggestion that vanadate be used for the symptomatic treatment of sickle-cell anemia.[71c]

Vanadium (e.g., vanadate, **1**, in Fig. 2) has a direct cardial effect, similar to digitalis. Possible reasons include the inhibition of the Na,K ATPase and the stimulation of adenylate cyclase[72] in particular, as well as the inhibition of the Ca ATPase of the sarcoplasmic reticulum.[17a] The mechanism

of inhibition of ATPases by vanadium is explained in Section 3.2. Noteworthy is the insulin-mimetic effect of **1**[73] and peroxovanadate(v)[74] (**2**), which is reminiscent of the role of chromium and the chromium-containing glucose tolerance factor. A corresponding effect of $VO^{2\oplus}$[75] is disputed.[17a] Diabetic rats which were fed vanadate in drinking water displayed a normal glucose concentration in the blood.[73c] The arguments for and against the various hypotheses for the insulin-like action of vanadate have been summarized.[76a] A plausible mechanism assumes that vanadate activates the phosphorylation of a tyrosine group of the insulin receptor (a tyrosine kinase). Recently an unspecific increase in the phosphorylation of protein tyrosine in the presence of vanadate was reported.[76b] But even a vanadylation of this tyrosine kinase by vanadate has been implicated in the insulin-mimetic effect. The observation that phenol and *N*-acetyltyrosine ethyl ester form esters with vanadate that are several orders of magnitude more stable than those with phosphate supports this hypothesis.[76c]

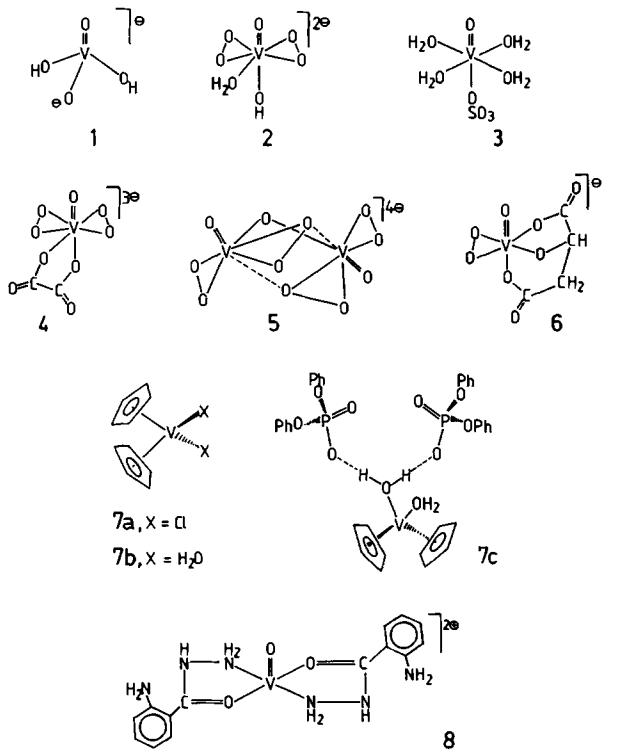

Fig. 2. Vanadium compounds which have been discussed in connection with therapeutic applications and have already proved to be active in animal tests. Compound **1** is a vasocontractor, lowers the cholesterol level, and has a diuretic and natriuretic effect; **1**, **2**, and **3** have insulin-mimicking functions; **3**–**7** show a carcinoma-inhibitive effect (**7a** is the administered and **7b** the active form). Compound **7c** is a model compound (simplified sketch) for the interaction of **7** with nucleotides. The hydrazine complex **8** has a higher activity against tuberculosis mycobacteria than the ligand itself, which is used in therapy [78d]. Compounds **1**, **3**–**5**, **6**, **7a**, and **7b** are also structurally characterized.

Several vanadium compounds have been studied with respect to their cytostatic activity. The peroxovanadate(v) complexes **4**–**6** show antitumor activity in certain forms of leukemia when administered at doses of 4.5–11.5 mg kg^{-1} body weight (i.e., just below the toxic level). An internal redox process in which V^{IV} and $O_2^{\ominus}$ are formed has been held responsible for this activity.[44] V^{IV}, administered as vanadyl sulfate (**3**) in the diet, inhibits in rats the formation of mammary carcinoma induced by methyl nitrosourea.[77a] This is interesting inasmuch as $VO^{2\oplus}$ is distinctly less toxic than V^{V}. The first step in the inhibition of carcinogenesis by vanadium could be its transfer as $VO^{2\oplus}$-transferrin to the neoplastic tissue, which is particularly rich in transferrin receptors.[67] Another interesting fact is that with bleomycin, an antibiotic used in cancer chemotherapy, $VO^{2\oplus}$ forms a stable complex,[77b] which may be considered a "supercancerostatic" agent.

A bifunctional complex is also formed between the antitumor antibiotic anthracycline and vanadocene dichloride (**7a**).[77c] Complex **7a**, like other cyclopentadienyl complexes of transition metals, has long been regarded as a potential cytostatic.[78a,b] Under physiological conditions, **7a** forms the aqua complex **7b**, analogous to cisplatin. With the phosphate groups of nucleotides it forms labile outer-sphere complexes with V–P distances of around 600 pm (calculated from ^{31}P NMR data), in good agreement with the results from the X-ray diffraction analysis of the model compound **7c** (Fig. 2).[78c] The formation of a labile complex between the stable complex **7b** and nucleotides contrasts with the behavior of cisplatin, which forms a stable bond to the endocyclic N atoms of the nucleotide bases. Moreover, cisplatin influences the hydrogen bonding between base pairs of DNA, whereas **7b** does not.

3.2. Functional, Unspecific Vanadium Compounds

3.2.1. The Interaction between Vanadate and Enzymes

Inorganic vanadate ($V_i = H_2VO_4^{\ominus}$) can probably be assigned an exogenic regulatory function with respect to enzymes that are involved in the widest sense in phosphorylations. In the previous sections this aspect has been mentioned repeatedly; I intend now to examine well-studied examples more closely. At the available concentrations of 10^{-6} to 10^{-7} M, both exogenic vanadate(v) and intracellular $VO^{2\oplus}$ are able to enter into bonding interactions with numerous biological molecules. Examples are phosphoglucomutase,[54c] alkaline and acid phosphatase, oligopeptides, and enzyme substrates such as citrate, malate, and glycerate.[54a] Reports have also appeared on the in vitro inhibition of enzymes by di-[79a] and tetravanadate[79b] at higher (toxic) concentrations. V^{IV} can also function as an inhibitor of, for example, glucose-6-phosphate dehydrogenase from baker's yeast[79c] and the ATPases of skeletal muscle membrane.[79d] As a rule, however, the slow reduction of V^{V} to V^{IV} in cells, which *Willsky* et al. studied in vivo for *Saccharomyces cerevisiae* (brewer's yeast) using ^{51}V NMR and ESR spectroscopy,[80a–c] is regarded as a detoxification process.

A long-known and thoroughly studied example of enzyme inhibition is the blocking of the Na-K pump (Na,K ATPase) by vanadate.[13, 16, 79e–g, 81] The Na-K pump transports $Na^{\oplus}$ out of and $K^{\oplus}$ into cells. This is an active translocation; the energy required is provided by the hydrolysis of ATP to ADP and phosphate ($P_i = HPO_4^{2\ominus}$). The bond breaking (and the accompanying ion transport) is catalyzed by an

ATPase that is an integral part of the cell membrane and that is active only in the presence of $Mg^{2\oplus}$. The ATPase can exist in two different conformations, E_1 and E_2, which are sensitized for the acceptance of $Na^{\oplus}$ and $K^{\oplus}$, respectively. These processes are represented in Figure 3. During the change from E_1 to E_2 the enzyme is phosphorylated [E_1(P)]. After the release of P_i, vanadate inhibits the enzyme by bonding to the vacated pocket to give [E_2(K, V, Mg)]. Vanadate is very tightly bound: the reverse reaction, [E_2(V)]$\rightarrow E_2 + V_i$, takes place at a rate of 0.32 h^{-1}.[81a, b] The complex formation constant K is 2.4×10^8 M^{-1}.[81c] There exists another coordination possibility with lower affinity ($K = 1.9 \times 10^6$ M^{-1}), which plays no role in inhibition. The reason for the tight bond may be that vanadate forms, in contrast to phosphate, stable five-coordinate complexes, in this case a bidentate coordination with the carboxylate group of an aspartate residue. $H^{\oplus}$-translocating ATPases for which no E(P) transition state has been found are insensitive to vanadate. Desferrioxamine B, a tris(hydroxamate), can rapidly reactivate vanadium-inhibited ATPases; vanadate forms a stable complex with this siderophore.[80d]

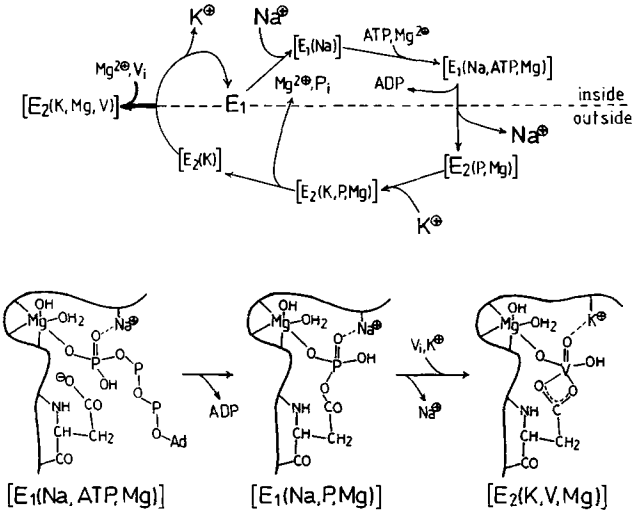

Fig. 3. Top: Schematic representation of the transport of $Na^{\oplus}$ and $K^{\oplus}$ (coupled to the hydrolysis of ATP) through the cell membrane and the inhibition of this process by vanadate(v). E represents the enzyme ATPase. The scheme is based on [80c]. Bottom: The inclusion of vanadate into the enzyme is represented in a simplified manner insofar as the binding site for vanadate is not identical with that of highest affinity for ATP. $V_i = H_2VO_4^{\ominus}$, $P_i = HPO_4^{2\ominus}$.

Vanadate(v) is also an effective inhibitor of ribonucleases. Well-investigated examples include RNase A from bovine pancreas[82] and RNase T_1 from the mold *Aspergillus oryzae*.[52a, 83, 84] RNase T_1 catalyzes the specific hydrolysis of the phosphodiester bonds of RNA at the 3′ position of guanosine. As in other enzymatic cleavages of the P–O bond, the transition state postulated is a pentavalent phosphorus in trigonal-bipyramidal geometry (cf. Fig. 4a).[83] The function of vanadate in this inhibition has been traced to the blocking of the recognition site of the enzyme for the substrate (RNA). In the case of RNase T_1, this site contains histidine, arginine, and glutamate. Model studies on histidine and glutamate with di- and tripeptides showed that an interaction between vanadate and the peptide bond occurs.[52] RNase T_1

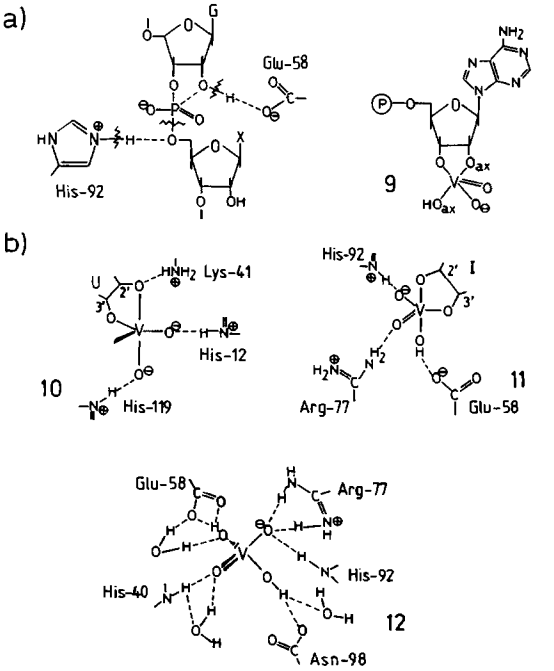

Fig. 4. Coordination of vanadate to ribonucleases. **a)** The (postulated) transition state for the enzymatic phosphodiester cleavage [83b]. The cleavage occurs at the sites marked with zigzag lines. Dashed lines are bonds after cleavage. Compound **9** is a vanadate–AMP complex that models the transition state [50, 51]. **b)** Schematic representation of the complexes formed from vanadate and RNase A + uridine (**10**) [82b], RNase T_1 + inosine (**11**) [52a], and RNase T_1 (**12**) [84].

forms a relatively weak complex ($K = 145(30)$ M^{-1}) with vanadate. An increase in the stability is observed in the ternary complex, not only for RNase T_1/vanadate/inosine ($K = 1.5 \times 10^5$ M^{-2}),[52a] but also for RNase A/vanadate/

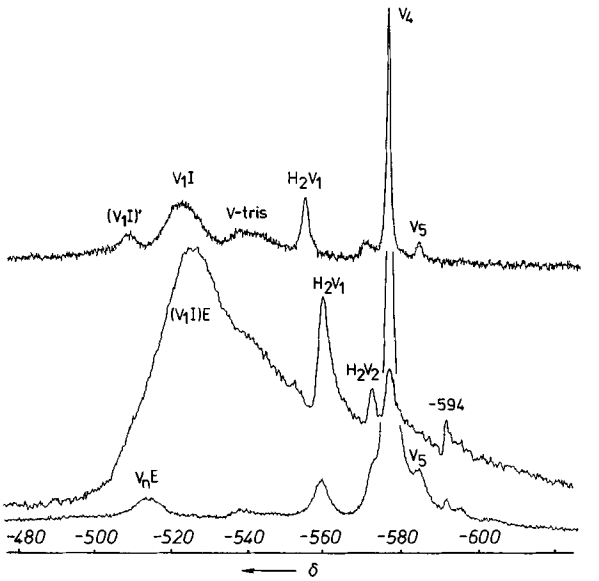

Fig. 5. 94.7-MHz ^{51}V NMR spectra of vanadate in ribonuclease-containing solutions (Tris buffer, pH 7.8; Tris = tris(hydroxymethyl)aminomethane). The broad signals are from the complexes vanadate/RNase T_1 (V_1E; cf. **12** in Fig. 4), and inosine/vanadate/RNase T_1 ($(V_1I)E$; cf. **11** in Fig. 4); the signal at $\delta = -541$ is from a complex of vanadate and Tris. $(V_1I)'$ is a ternary complex formed between vanadate, inosine, and Tris [184]. The middle spectrum reflects the significant increase in complexation of monovanadate in ternary compared with binary systems (cf. [52a]). For the abbreviations for the sharp resonances, which correspond to free vanadates, see the legend of Fig. 1. Concentrations: $c(V) = 12.8$ mM, c(enzyme) $= 5.5$ mM, c(inosine) $= 10.9$ mM.

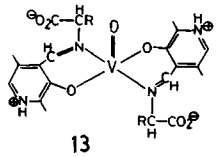
uridine.[82] The characteristics of these complexes correspond to those of binary complexes of vanadate with nucleosides or nucleotides (compare compound **9** in Fig. 4 and the ^{51}V NMR spectra in Fig. 5), for which it is assumed that cyclic ester formation involves coordination of vanadate across the 2′ and 3′ positions of ribose with formation of a trigonal-bipyramidal environment about V^V.[50, 51] That this coordination geometry also occurs in the case of ternary complexes with RNase A and RNase T_1 (Fig. 4b, **10** and **11**) is supported by neutron diffraction[82b] and ^{51}V NMR studies.[52a] Recently an X-ray diffraction analysis of the binary complex of vanadate with RNase T_1 showed that tetrahedral $H_2VO_4^{\ominus}$ is hydrogen-bonded into the active site of the enzyme.[84]

3.2.2. Vanadium in Photosynthesis

That vanadium is also an essential trace element for green plants was known as early as 1953.[85] Vanadate increases oxygen production by stimulating photosystem I in the chloroplasts of single-cell green algae (*Chlorella, Scenedesmus*).[85, 86a] Simultaneously, the production of biomass and chlorophyll (and other leaf pigments) increases.[9b, 14, 86] It is particularly noticeable that the stress symptoms in algae cultivated under iron-deficiency conditions can be suppressed completely by vanadate. This led to the suggestion that vanadium centers might be involved in redox catalysts.[86a] Better documented is the function of vanadium in chlorophyll production: vanadate and V^{IV} (perhaps only the latter, since reduction of vanadium is probable) are capable of a nonenzymatic catalysis of the formation of δ-aminolevulinic acid (ALA).[86b] ALA plays a central role as a precursor in the biosynthesis of chlorophyll. It is formed from 4,5-dioxyvaleric acid (DOVA) and alanine (Ala) by transamination in the presence of pyridoxal phosphate (PLP). Alanine is transformed into pyruvate (PA) [Eq. (d)]. A Schiff base acts as

$$\text{Ala} + \text{DOVA} \xrightarrow{\text{PLP, } V_i} \text{ALA} + \text{PA} \qquad \text{(d)}$$

intermediate in this transamination and the formation of a complex at least with V^{IV} of type **13** is considered responsible for the efficacy of vanadium.[86b]

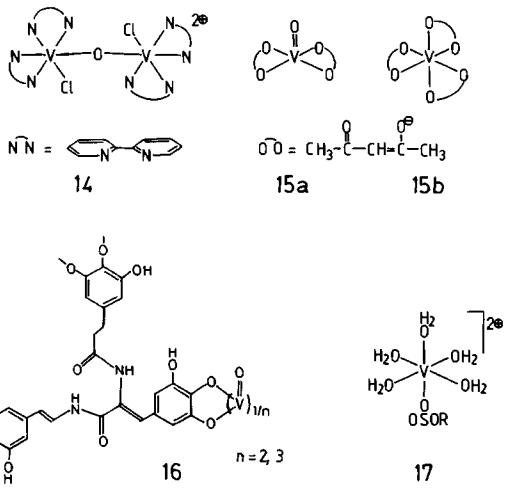


13

Besides stimulation of photosynthesis, vanadium can also inhibit it under certain circumstances. This is suggested by studies on the deactivation of the carboxylase activity of ribulose-1,5-diphosphate carboxylase/oxygenase in the presence of vanadium during irradiation.[87a] The enzymatic carboxylation of ribulose-1,5-diphosphate is the initial step in carbon fixation. The deactivation is attributed to photooxidation of serine by vanadium in the active site of the enzyme.

3.2.3. Vanadium in the Blood of Ascidians

Ascidians (sea squirts), which are sessile organisms belonging to the tunicates (Urochorda), are found worldwide in the tidal zones of oceans. Many of them are capable of concentrating vanadium to 10^7 times the level in seawater in specialized blood cells, the vanadocytes. Other types accumulate iron instead of vanadium. The vanadium concentration in the vanadocytes is 0.15 M; in special vanadium-containing vacuoles in the vanadocytes, the vanadophores, it can reach 1 M. The vanadium is absorbed as vanadate(v) into the exoplasm. There are at least five morphologically distinguishable types of vanadocytes, which correspond to different maturation stages and take up vanadium to different extents (the highest concentration of V is found in the so-called signet-ring cells). Depending on the ascidian suborder, chiefly V^{IV} (Aplousobranchia) or V^{III} (Phleobranchia) is present.[35a, c] This view is supported by both magnetic[87b] and chemical evidence. For instance, complexes **14**[35a] and **15**[35c] (Fig. 6) have been identified after external application of bipyridine or acetylacetonate.



14 15a 15b 16 17

Fig. 6. Vanadium complexes considered in connection with the vanadocytes of ascidians. Compounds **14** and **15** could be identified when the vanadocytes were exposed externally to bipyridine or acetylacetonate [35a]. The V–O–V angle in **14** is 173.5°; the two halves of the molecule are twisted 61.6° relative to one another [35c]. Compound **16** possibly plays a decisive role in the construction of the tunicae of ascidians [1] (for catecholate complexes as models, see **58** and **59** in Fig. 13, Section 4.2). Compound **17** can occur in concentrated sulfuric acid [89b].

Even the more recent investigations on ascidians[35, 88, 89a] have not been able to answer two of the most interesting questions on the biochemistry of vanadium. They involve, on the one hand, the function of vanadium and, on the other, its coordination environment and the closely related question of the pH within the vanadophores. Among the functions mentioned are participation in the construction of the tunica, toxicity for foraging enemies, a store for redox equivalents, and an antidote against oxygen starvation.[88a] At present the most popular is the first function, according to which vanadium acts as a mediator (in the sense of a template effect) in the construction of the polymeric structure of the material of the tunica. This thesis is supported by the fact that the pigments (the so-called tunichromes)[89a, b] in certain

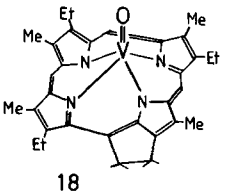
vanadocytes (the morula cells) also participate in the construction of the tunica. Tunichromes are hydroxy-DOPA-containing di- and tripeptides (DOPA = 3,4-dihydroxyphenylalanine) that form very stable complexes such as **16** with $VO^{2\oplus}$.[11] Another $VO^{2\oplus}$-coordinating compound isolated from the vanadocytes, vanadobin, contains a reducing sugar, but is otherwise not further characterized.[88b, 89c] A further possibility is the coordination of $VO^{2\oplus}$ or V^{III} to a glycoprotein that corresponds to ferreascidin. Ferreascidin (M = 10000 g mol^{-1}) contains a high percentage of tyrosine and DOPA, which complex Fe^{III} in iron-accumulating ascidians[90] and are also good ligands for vanadium.

Whether vanadium in the vanadocytes or vanadophores is in fact bonded to tunichrome, vanadobin, or another organic ligand is not definite and is tied up with the unsolved problem of pH within the cell structures, pH values of between 1.8 and 7.2 have been measured by diverse methods and in a great variety of cell fractions. Only with reference to the literature (e.g., Refs. [35a, b] and [88b]) can one sift through the data. Naked vanadium(III) can exist only below pH 3 (cf. Section 2); when the acid medium is sulfuric acid it occurs as $[V(H_2O)_5OSO_3]^{\oplus}$ (perhaps also as $[V(H_2O)_5OSO_2R]^{2\oplus}$;[89b] **17** in Fig. 6). This is the form postulated on the grounds of, among others, EXAFS (extended X-ray absorption fine structure)[91] and ESR studies.[92a, b] Recent experiments[92c] on *Ascidia ceratodes*, in which the distribution of ^{14}C-labeled dimethylamine and the acid 5,5-dimethyloxazolidine-2,4-dione between the intra- and extracellular blood-cell matter was analyzed, gave a pH of 7.1(2) for the cytoplasm of morula cells and 5.0(2) for the vacuoles. Since between 50 and 90% of vanadium is present as V^{III} in these cases, a stabilization by complexation must take place.

3.3. Coordination Compounds with Biogenic Ligands

3.3.1. Vanadyl Porphyrins in Fossil Matter

The high vanadium content (up to 4%) in petroleum, oil shales, bituminous limestone, and similar materials of marine origin,[28a, b, 93a, 94, 95] in which the organic fractions arise as a rule from the fossilization of planktonic organisms and/or bacterial activity in the initial stages of fossilization, raised early on the question of the source of the vanadium.[6] Quite high vanadium contents are also measured in fossilized terrestrial plants (e.g., between 0.4 and 0.7% in fossilized mosses[95a]). Regardless of the origin, vanadium occurs in such material chiefly in the form of vanadyl ($VO^{2\oplus}$) porphyrins,[38, 93a, 94b] which only occur in the smallest quantities in living organisms.[26b, 96] Consequently, vanadium must have been incorporated into the porphyrins through secondary processes (transmetalation). Although the so-called geoporphyrins bear, in the main, no simple biosynthetic relationship to the naturally occurring porphyrins, chlorophyll (e.g., from green algae and chlorophyll-containing bacteria) was presumably the original porphyrin compound.[93a, 97] This assumption is supported by the isolation and structural characterization of vanadyl porphyrin **18**.[93b] Whether the vanadium is of biotic or abiotic origin is an open question. In view of the information in the previous section, a biotic origin for at least part of the vanadium may be considered likely. But plausible arguments have also been aired for abiotic sources, especially from volcanic ashes.[94a]



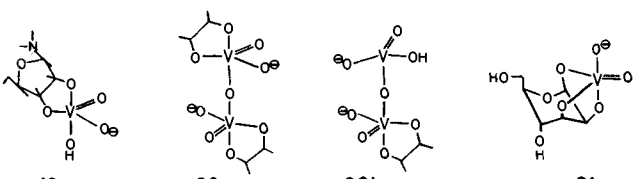
18

The generally accepted assumption that vanadyl porphyrins are indigenous components of petroleum has recently been opposed by the suggestion that these pigments were extracted out of the sedimentary stratum (e.g., shaley limestone) by the percolation of younger petroleum fractions and thereby concentrated in the petroleum.[95b] This migration theory was also advanced earlier by *Goldschmidt*.[6a]

3.3.2. Nucleotides, Nucleosides, Sugar, and Phosphate

The coordination behavior of vanadium with respect to these molecules has potential significance in connection with competitive processes in the regulation of the activity of, for example, the ATPases and ribonucleases (Section 3.2.1) as well as with regard to the cancerostatic action of vanadate (Section 3.1). Both V^{V} and V^{IV} are capable of reacting with the phosphate groups and/or the sugar alcohol groups of nucleotides. The complexes formed with vanadate(v) may be conceived as mixed anhydrides or esters of the hypothetical orthovanadic acid. The nitrogen functions of the bases are coordinated only in exceptional cases.

Sugars and nucleosides react with vanadate(v) to form cyclic esters, which are derived from mono- and divanadate and in which the vanadium is probably coordinated in a trigonal-bipyramidal fashion. With nucleosides, bonding takes place with the hydroxyl groups at C2′ and C3′ of ribose and leads to stable five-membered ring chelates. Examples are the esters **19** and **20**.[50a, 51, 52a, 82b] β-Mannopyranoside forms the bicyclic ester **21** with vanadate.[50a]

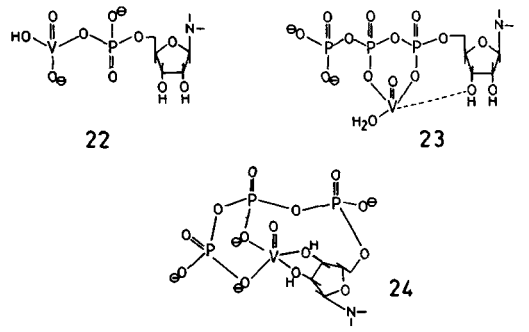


19 20a 20b 21

Nucleotides can also bind to vanadate through their phosphate residues. AMP reacts in this way with $H_2VO_4^{\ominus}$. In addition to compounds of type **19** (cf. also **9** of Fig. 4) and **20a**,[51] principally the mixed anhydrides "AVP" (**22**) and "AV_2P",[50a, 51] analogous to ADP and ATP, are formed. These undergo rapid exchange equilibria with their components AMP, $H_2VO_4^{\ominus}$, and $H_2V_2O_7^{2\ominus}$.[51] Similar mixed anhy-

drides are also formed with ribose 5-phosphate[50b] and phosphate itself[42] (Section 2).

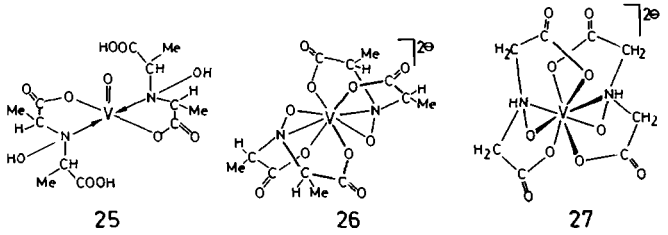
The formation constants for 1:1 complexes of V^V with nucleotides are of an order of magnitude between 1 and $10^3\ M^{-1}$; their existence has been established chiefly by spectrophotometric, potentiometric, and ^{51}V NMR spectroscopic techniques. $VO^{2\oplus}$ shows a more pronounced tendency to coordinate such ligands (cf. Table 3), so that in many cases complexes could be isolated,[57, 98a-c] even if not characterized by X-ray structure determination. Structure proposals in



these cases are also based on spectroscopic data.[57, 98c, d, 99] $VO^{2\oplus}$ forms 1:1 compounds[57] in acid medium with triphosphate and a blue 1:1 complex in the acidic to neutral region with ATP, in which the vanadyl ion probably bonds to two oxygen atoms of the triphosphate residue as well as to one or two hydroxyl groups of ribose (**23** and **24**).[99]

3.3.3. Amavadin—a Vanadium Compound from Fly Agaric

The concentrations of vanadium in some types of *Amanita* and related fungi[5] are remarkably high, whereby fly agaric (*Amanita muscaria*) contains by far the highest concentration (up to $325\ mg\,kg^{-1}$ dry weight), mainly in the bulb. Isolated from this toadstool is a vanadium(IV) compound of exceptional stability, amavadin, for which no biological function is known. As the compound is reversibly oxidizable (E° in $H_2O = 0.78$ V), a function as redox catalyst is conceivable.[36b] Amavadin was originally formulated as the pentacoordinate vanadyl complex $[VO(H_2L)_2]$ (**25**) with H_3L = *N*-hydroxy-2,2′-iminodipropionic acid.[100a] Recently the composition $[VL_2]^{2\ominus}$ (**26**) was assigned to it, where L



is coordinated through the hydroxylamido function and both carboxylate functions according to spectroscopic evidence.[36c] The argument presented for structure **26** rests partly on the lack of a short V=O bond in the EXAFS spectrum.[100b] The bond lengths for the V=O group lie typically between 155 and 165 pm, but can also be stretched up to 180 pm as in complex **61a** (Fig. 13).[101] The structure proposal **26** is supported by X-ray diffraction analysis of the complex **27**, which contains the very similar ligand *N*-hydroxyiminodiacetate.[102]

3.3.4. Vanadate-Dependent Haloperoxidases from Sea Algae and Lichen

Vanadate-dependent nonheme bromo/iodoperoxidases (V-PO) were discovered in 1983 by *Vilter* in the knobbed wrack (*Ascophyllum nodosum*)[2] and later, especially by the research group of *Wever* in Amsterdam, not only in *Ascophyllum*[21a, 103a, b] but also in other marine brown algae (*Laminaria* and *Chorda*),[21b, c] in marine red algae (*Ceramium, Corallina*),[21d, 103c, d] and in a terrestrial lichen (*Xanthoria parietina*).[3] An overview of the state of the investigations to 1987 is given in Ref. [104]. The best-studied isoenzyme from *A. nodosum* has a molecular mass of $105\,000\ g\,mol^{-1}$. Conspicuously high (ca. 25%) is the content of acidic amino acids. In its active state V-PO contains two V^V per molecule.[66] It is not known whether the two vanadium centers cooperate. The holoenzyme can be rendered inactive by dialysis against EDTA/citrate buffer (EDTA = ethylenediaminetetraacetate(2−)) and the activity restored with $H_2VO_4^\ominus$. Reduction of V^V to V^{IV} by dithionite also diminishes the enzyme activity. V-PO catalyzes the bromination and iodination of organic substrates by H_2O_2 (or peroxides) in the presence of inorganic bromide or iodide according to Equation (e).

$$RH + X^\ominus + H_2O_2 + H^\oplus \longrightarrow RX + 2H_2O \qquad \text{(e)}$$

The process possibly involves a hypohalite intermediate, which acts either directly or via HOX as the actual halogenating agent.[103e, f] In favor of such a mechanism is the V-PO-catalyzed, in vitro bromination of barbituric acid[103g] and the in vitro formation of hypoiodite from iodide and peroxovanadium(V).[105] A hypohalite intermediate is also likely when one considers that disproportionation of H_2O_2 to O_2 and H_2O is catalyzed by V-PO only in the presence of $Br^\ominus$ or $I^\ominus$.[106]

As many of the often quite complicated organic halogen compounds found in seaweeds exhibit antibiotic activity, it is generally suspected that vanadate-dependent peroxidases (and also their "normal" companion peroxidases) from the algae have a function, among others, in counteracting bacterial attack. As sea algae also produce considerable amounts of simple, volatile brominated hydrocarbons (e.g., $CHBr_3$), and indeed in quantities equal to the industrial production (ca. 10^4 tons per year), a geological and topically significant role in the regulation of the stratospheric ozone layer may be attributed to them.[108]

Ideas about the coordination environment around vanadium have been deduced from ^{51}V NMR,[66, 107] X-ray absorption (XAS),[109, 110] ESR,[111] and electron spin echo envelope modulation (ESEEM) spectra,[112] both on the native V^V-PO (XAS, Fig. 7, top, and NMR) and on the species obtained by reduction with dithionite, V^{IV}-PO (XAS, ESR,

ESEEM). Common to all suggestions (**A**, **B**, and **C** in Fig. 7, bottom) is a coordination number of at least 5 for vanadium, the presence of a vanadyl group, and an environment of ligands with mainly *O*-ligands as donor groups. Substrates such as halide ($Br^{\ominus}$, $I^{\ominus}$) probably cause an increase in coordination number,[66, 107] while reduction causes a decrease.[110] Candidates for oxygen-containing functional groups are carboxylate residues of glutamate or aspartate and OH groups of tyrosine or serine. The participation of esterlike bonds is suggested by the short V–O bond length of 172 pm, which was found by XAS in the EXAFS region for one of the V–O bonds in native V-PO[109a] (**A** in Fig. 7).

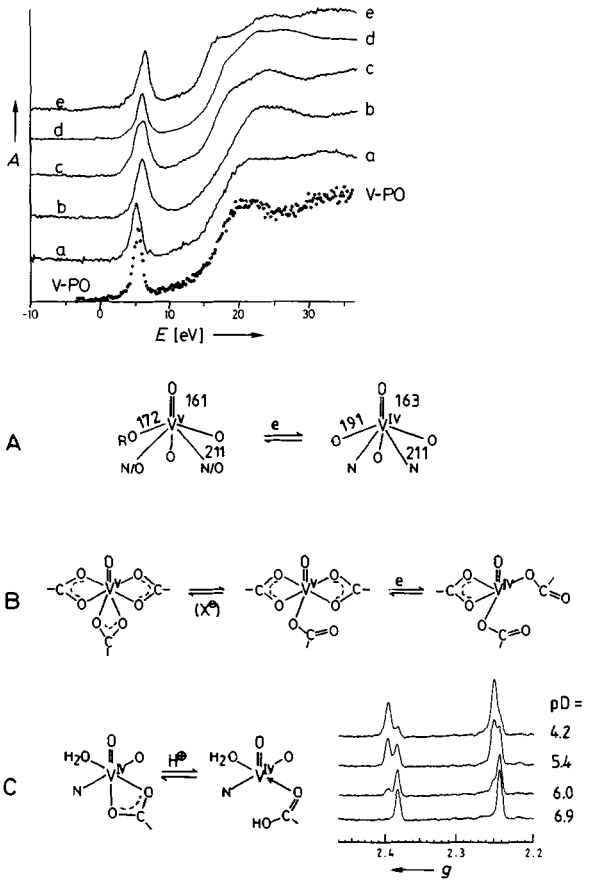


Fig. 7. Top: 2.5-GeV XAS spectra (XANES region) of vanadate(v) haloperoxidase (V-PO) from *Ascophyllum nodosum* (bottom spectrum) and some model compounds ($a = [VO(O_2)_2(oxalate)]^{3\ominus}$, $b = [VO(O_2)(oxalate)_2]^{3\ominus}$, $c = [VO_2(oxalate)_2]^{3\ominus}$, $d = [VO(O_2)(H_2O)dipicolinate]^{\ominus}$, $e = [VO_2(edta)_2]^{3\ominus}$ [110]. The zero of the energy scale is defined by vanadium metal (5465 eV absolute). The position and half-height width of the white band ("1s→3d"), the uniformity of the rise in the absorption edge, and the position of the K edge (1s→4p) of the spectrum of V-PO agree well with the corresponding characteristics of the oxo-peroxo-oxalato complexes. Bottom: Structural proposals for the prosthetic group in vanadate-dependent peroxidases, deduced from spectroscopic investigations. **A** based on EXAFS [109], **B** on XANES [110] and ^{51}V NMR [66, 107], and **C** on ESR [111] and electron spin echo [112] investigations on reduced peroxidase. The pD dependence for the $m_I = -7/2$ and 5/2 lines of the ESR signal for the holoenzyme in D_2O reveals a change in the coordination sphere of vanadium, which can be traced to a protonation/deprotonation equilibrium. The spectrum is reproduced from [111] with permission. With regard to **B**, compare also the model compound **48** in Fig. 12, Section 4.2.

Such a short single bond length is typical for vanadyl esters.[113] Furthermore, ESR studies of reduced V-PO show that both a protonatable ligand (Glu, Asp, or His) and H_2O are involved in the coordination to vanadium[111] (compare the pH dependence of the *g* value for the $m_I = -7/2$ resonance in the ESR spectrum, Fig. 7, **C**). The coordination of an *N*-donor ligand (histidine), at least in V^{IV}-PO, is suggested in particular by an ESEEM study.[112]

3.3.5. *Vanadium Nitrogenase*

Besides the usual molybdenum nitrogenase (Mo-Nase), another with vanadium as active center (V-Nase) was discovered only a few years ago in the nitrogen-fixing bacteria *Azotobacter chroococcum* and *A. vinelandii*. It is activated by molybdenum deficiency.[22] Also, certain mutants of *Azotobacter*, in which the genetic information for encoding Mo-Nase is missing, can reduce atmospheric nitrogen with V-Nase.[23a, 114, 115] Other microorganisms besides *Azotobacter* are capable of synthesizing the alternative nitrogenase, namely the cyanobacterium *Anabaena variabilis*[116] and probably also *Clostridium pasteurianum*.[117] It is interesting that, when it grows in Mo-deficient media, the hydrogen bacterium *Xanthobacter autotrophicus* accumulates vanadium as well. As the ESR spectra show, however, V^{IV} is not a component of a nitrogenase in this microorganism.[118]

The progress of the research into V-Nase has been summarized recently in two review articles.[119] The enzyme resembles its Mo analogue in the construction and structure of the prosthetic groups, as well as in its functions: It consists of a FeV protein with a molecular mass of 240 000 g mol^{-1} (six subunits as against four in the Mo-Nase)[23a, 115] and an

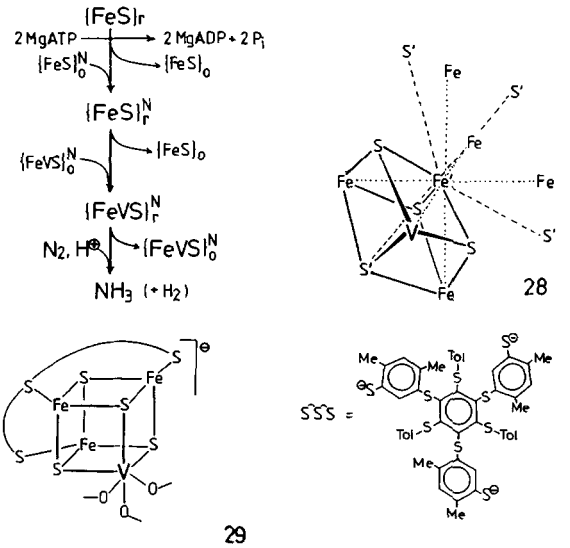

Fig. 8. Simplified representation of the electron-transfer processes during nitrogen fixation by vanadate nitrogenase (top left) as well as of the FeV cofactor (**28**, according to [124a]) and of the model compound **29** for the VFe_3S_4 cluster in the cofactor [125]. {FeS} is an iron protein of the type [4Fe-4S]-ferredoxin; $\{FeS\}^N$ and $\{FeVS\}^N$ are components of the FeV protein. The indices "r" and "o" refer to the reduced and oxidized forms, respectively. In the case of **28**, the cubane-like VFe_3S_4 unit (solid lines) is represented as part of a larger metal-sulfur cluster, a "superstructure" deduced from EXAFS data; Fe', in a corner position of the cubane, is octahedrally surrounded by five Fe and one V (dotted lines). All iron ions are tetrahedrally coordinated by sulfur; this is indicated by dashed lines for $Fe'(S')_4$. V can achieve octahedral coordination through two ligand functions not belonging to the cluster. In model **29**, V carries, in addition to the three $S^{2\ominus}$ ligands, three O ligands (e.g., DMSO or DMF) or N ligands. Tol = p-$CH_3C_6H_4$.

iron protein (a 4Fe-4S ferredoxin). From the FeV protein, which contains 2 V, about 23 Fe, and 20 sulfide S atoms,[114] the actual iron-vanadium (FeV) cofactor can by extracted with dimethylformamide (DMF). It contains V, Fe, and sulfide S atoms in the ratio 1:6:5.[120]

The mechanistic route of nitrogen fixation is shown in abbreviated form in Fig. 8 (top left). At each electron-transfer process from Fe to the FeV protein, two molecules of Mg-ATP are hydrolyzed.[121a] In contrast to the Mo-Nase, which uses 25% of the electron flux to reduce two $H^{\oplus}$ to H_2, the enzymatic reduction by V-Nase requires about 50% of the reduction equivalents in this side reaction.[121b] Another difference is that the reduction of C_2H_2 by Mo-Nase stops at C_2H_4, whereas the reduction by V-Nase can proceed to C_2H_6.[117]

According to data from the XANES region of the XAS spectrum, the oxidation number of V lies between II and IV.[37] (See Ref. [122] for the general problem of determining the oxidation number from XANES parameters.) From the ESR spectrum of the reduced form of V-Nase, a spin state of $S = 3/2$ is determined for vanadium.[123] The weak intensity of the white band in the XANES range suggests a (distorted) octahedral rather than a tetrahedral environment for vanadium. These results are corroborated by EXAFS studies, which yield the parameters in Table 5.

Table 5. EXAFS data for the FeV cofactor in the vanadium nitrogenase.

Ligand atom (V-XAS) [a]	Number		Distance [pm]	
S	3(1)	3–4	231(3)	233(3)
Fe	3(1)	3(1)	275(3)	276(3)
O or N	ca. 3	2–3	215(3)	215(3)
(Fe-XAS) [b]				
S	3		224	
V	1		290	
Fe	2		265	

[a] The values for number and distance were taken from [124a, b] (left column) and [124c] (right column). [b] Values from [127d].

This data indicates that a VFe_3S_4 cluster is part of the FeV cofactor. Furthermore, a long Fe–Fe distance of 369 pm[124d] reveals an additional long-range order in the cluster. The structure proposal **28** (Fig. 8) follows from these results. It may be compared with the corresponding FeMo cofactor and also, according to the XAS data, with the VFe_3S_4 cluster in the model compound **29**.[128]

3.3.6. *Transferrin and Related Proteins*

Already in Section 3.1 the significance of the transferrins (Tf) in the transport of V^V, V^{IV}, and also V^{III} was mentioned (see also Ref. [126]). At this point, details about the coordination of vanadium to these and related proteins will be presented. The reader is referred to the review by *Chasteen*[38] for studies of further vanadium–protein complexes and, for other selected examples of proteins with enzyme character, to the previous sections. In addition, Table 3 includes several formation constants of V–protein complexes.

Vanadium is present in blood serum as V^V and also as V^{IV} and bonds tightly to Tf in both oxidation states (complex formation constants are around $10^{6.5}$ M^{-1} [127]). The affinity of serum albumin for V^{IV} is comparable;[53b] V^V, on the other hand, is bonded only weakly to albumin. A maximum of two V per Tf are taken up; the two not quite equivalent binding sites on the C and N termini of human apo-Tf could be distinguished using both ^{51}V NMR (for V^V)[68] and ESR (for V^{IV}) techniques.[67]

As a result of coupling of an unpaired electron with the nuclear spin of ^{51}V (7/2), either an eight-line system or, for axial symmetry (which occurs as a rule in $VO^{2\oplus}$ complexes), two sets of overlapping eight-line systems appear in the ESR spectrum. As example, Figure 9 (top) shows the X-band

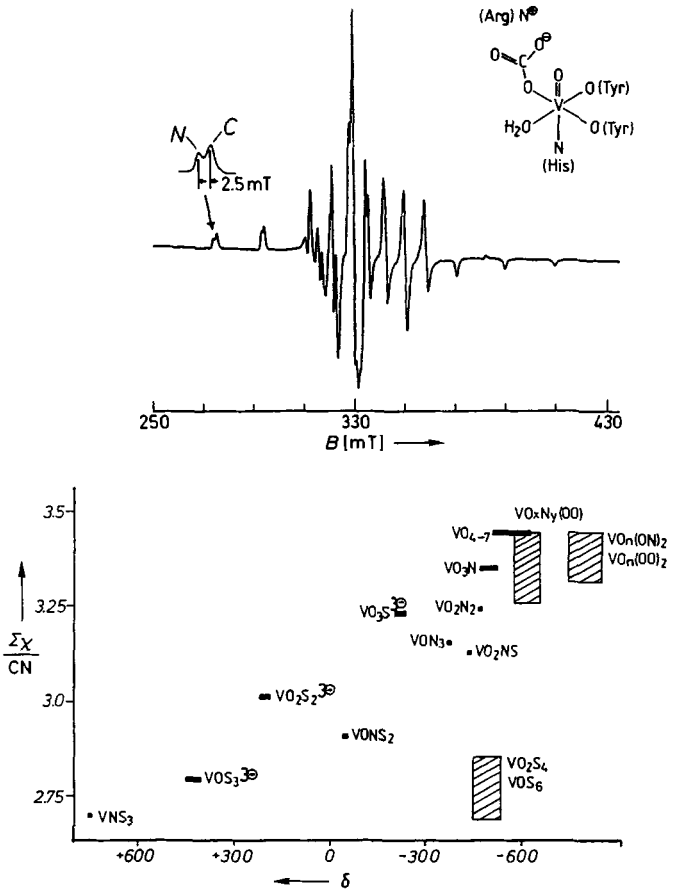

Fig. 9. Top: The X-band ESR spectrum of the divanadyl complex of human serum transferrin [$(VO^{2\oplus})_2$-Tf] at 77 K and pH 7.4 (Hepes/hydrogen carbonate buffer). $c(V) = 0.36$ mM, c(protein) = 0.18 mM. The expanded signal ($m_I = -7/2$) shows a splitting due to the different binding centers for $VO^{2\oplus}$ (N or C terminus). The structure proposal (top right) corresponds to the present state of knowledge for the coordination sphere of a Tf-bonded metal ion and is consistent with ESR data. The spectrum is reproduced from [67] with permission. Bottom: Relationship between $\delta(^{51}V)$ (standard $VOCl_3$) and the sum of the electronegativities of the ligand functions coordinated to V, Σ_χ, divided by the coordination number CN [107]. Shaded columns indicate complexes that contain strained ring structures ($OO^{2\ominus}$, $R_2NO^{\ominus}$, $CO_2^{\ominus}$, $CS_2^{\ominus}$). O, N, and S represent ligands which coordinate via these ligands to the vanadium. (OO) and (ON) are peroxo or hydroxylamido ligands.

ESR spectrum of the complex which is formed from $VO^{2\oplus}$ and human serum transferrin and in which such anisotropy is clearly observed. It is interesting that the $m_I = -7/2$ resonance reveals a further splitting, which is attributed to the two slightly different binding centers (N and C termini).[67]

In Table 5 are listed the ESR parameters (g factors and hyperfine coupling constants A) of some vanadyl compounds; they show that at least the differentiation between N- and O-coordination can become problematic. The ESR spectrum of $(VO_2^{\oplus})_C$-Tf (C-terminal attachment) corresponds to a vanadyl complex with octahedral geometry and is consistent with the ligand sphere sketched in Figure 9.[67] The participation of tyrosine in the coordination is confirmed by the appearance of a corresponding charge-transfer (CT) band in V^{III}-Tf, a compound which is surprisingly stable (e.g., towards atmospheric oxygen).[69]

Table 6. ESR parameters of selected vanadyl complexes.

Ligand	Coordination [a]	$g_{\parallel}/g_{\perp}$ [b]	$A_{\parallel}/A_{\perp}$ [c]	Ref.

[a] In some cases the number of donor O- and N-ligands is assumed from preliminary structures. [b] $g_{\parallel}$ refers to the axis in which the vanadyl oxygen is found. [c] Hyperfine coupling constants in 10^{-4} cm^{-1}. [d] Isotropic factor $g_o = 1/3(g_{\parallel} + 2g_{\perp})$. [e] Isotropic hyperfine coupling constant $A_0 = 1/3(A_{\parallel} + 2A_{\perp})$. [f] The spectrum is not strictly axial. The deviation for $g_{\perp}$ (1.979), $g_{xx} - g_{yy}$, is 0.01. [g] The rhombic distortion in the tetragonal plane of this complex is reflected in $g_{xx} - g_{yy} = 0.005$ and $A_{xx} - A_{yy} = 4.2 \times 10^{-4}$ cm^{-1}. [h] Cf. **76** in Fig. 15. [i] The complex has, according to [128f], the composition $[VO(im)_3(H_2O)]^{2\oplus}$ and tetragonal-pyramidyl geometry.

^{51}V NMR spectroscopy has shown itself to be a useful method of characterizing V^V-containing biological and biomimetic systems.[129a, b] The chemical shifts of V^V-Tf ($\delta = -529.5$ and -531.5 relative to $VOCl_3$)[68] correspond to a complex with a coordination number of 5 or 6 and O/N-coordination with oxygen ligand dominance.[107, 129c] As in all d^0 systems, the δ values of V^V complexes also show an "inverse dependence" on the electronegativity χ for the ligand function bonded to vanadium; that is, the shielding of the ^{51}V nucleus increases with increasing χ and decreases with increasing polarizability α. The δ/χ correlation is shown in Figure 9 (bottom) for biorelevant ligand functions (S,N,O). Furthermore, the V^V compounds show a dependence of the δ values on steric factors, in that the shielding also increases with increasing bulkiness of the ligands and with any ring strain in chelate systems (three- and four-membered rings). We have systematically examined the steric effect, which can also be used, for example, to distinguish diastereomers, in the complexes $[VO(oxine)_2OR]$[101] (oxine = 8-hydroxyquinoline).

The transferrin-related proteins in milk (lactoferrin) and in the whites of bird eggs (ovotransferrin, conalbumin) also coordinate vanadium.[130] In the case of human lactoferrin, two $VO^{2\oplus}$ (at the C- and N-terminal ends) are taken up. Moreover, the coordination of a third vanadyl ion to an unspecific binding site on the surface of the protein close to the C terminus can be identified.[130a] Polarographic investigations on conalbumin similarly show two distinguishable binding sites with a coordination capacity of 1 and 16 V per molecule and formation constants of $10^{5.5}$ and $10^{3.1}$. The bonding to vanadate(v) is presumably due to the ion-pair interactions between vanadate and protonated nitrogen functions of amino acid side chains (histidine or arginine).[130c]

4. Model Complexes

In biological systems the available ligand atoms are sulfur (sulfide, thiolate), nitrogen (amide and amine), and oxygen (oxide, hydroxide, water, alcoholate, phenolate, carboxylate, hydroxamate, hydroxylamide). In the case of vanadium there are examples of all above-mentioned ligand types. Thus, vanadium is bonded to, among others, sulfide in vanadium nitrogenase and probably to carboxylate and $OR^{\ominus}$ (perhaps also to histidine) in vanadate-dependent haloperoxidase. For amavadin the coordination to the O atoms of carboxylate and hydroxylamide groups may be considered proven. The bonding to proteins like transferrin and ATPase occurs through O- and N-functions from side chains, but possibly also involves peptide bonds. Vanadium can adopt the coordination number (CN) 4–8 and thus form tetrahedral (CN = 4), tetragonal-pyramidal or trigonal-bipyramidal (CN = 5), octahedral or trigonal-prismatic (CN = 6), pentagonal-bipyramidal or capped trigonal-prismatic (CN = 7), and dodecahedral (CN = 8) complexes. In the selection of model compounds I have restricted myself to "modern" bioinorganic aspects of the coordination chemistry of vanadium: (1) systems with S-ligands as well as ligands with N_2 groups (nitrogenase models), (2) complexes with carboxylate, alcoholate, phenolate, and hydroxamate ligands, and (3) histidine-modeling ligands. Some of the complexes described in the following discussion (e.g., the polynuclear carboxylato complexes or compounds with tridentate nitrogen ligands) have—as yet—no immediate relevance to biomolecules; nevertheless, they are considered here to illustrate, among other features, the parallels to the bioinorganic chemistry of iron[131a] and of manganese.[131b]

4.1. Model Compounds for Vanadium Nitrogenase

One should distinguish here between compounds which approximate the structure of the vanadium center of the FeV cofactor, in that sulfur ligands are involved in the construction of the coordination sphere (structural models), and those which contain N_2 and ligands derived therefrom and as such have potential functional character. The following vanadium complexes containing S-ligands do not only have the character of model compounds for nitrogenase; they are, like the cysteine-ester complex **35a** (Fig. 10), also of interest in improving the understanding of the role of vanadate in the activation of the serine sulfhydrase (enzymatic transformation of cysteine into serine + H_2S).[132a]

Counted among the structural models is the cubane cluster **29** already introduced in Figure 9a, which probably reproduces the central component of the FeV cofactor fairly accurately and is related to corresponding models for the FeMo cofactor. The compounds in Figure 10 (ordered according to decreasing oxidation number for vanadium) reflect the variety with respect to oxidation number, coordination geometry, and nuclearity that one also meets in the still young field of vanadium-sulfur coordination chemistry. Particularly interesting in the light of the possible function of vanadium in the nitrogenase as electron-transfer agent are the mixed-valence complexes **33** (V^{V}/V^{IV}) and **38a** (V^{IV}/V^{III}). Complex **38a** contains in the V_3S_4 nucleus a *nido* cluster, which is derived from the corresponding *closo* structure of a V_4S_4 cubane like **38b**. Complex **38a** can be reversibly reduced and oxidized in MeCN in a one-electron process [Eq. (f), edt = ethanedithiolate (2−)].[136b] The one-electron oxidation of **36** and **39** in MeCN yields mixed-valence complexes too.

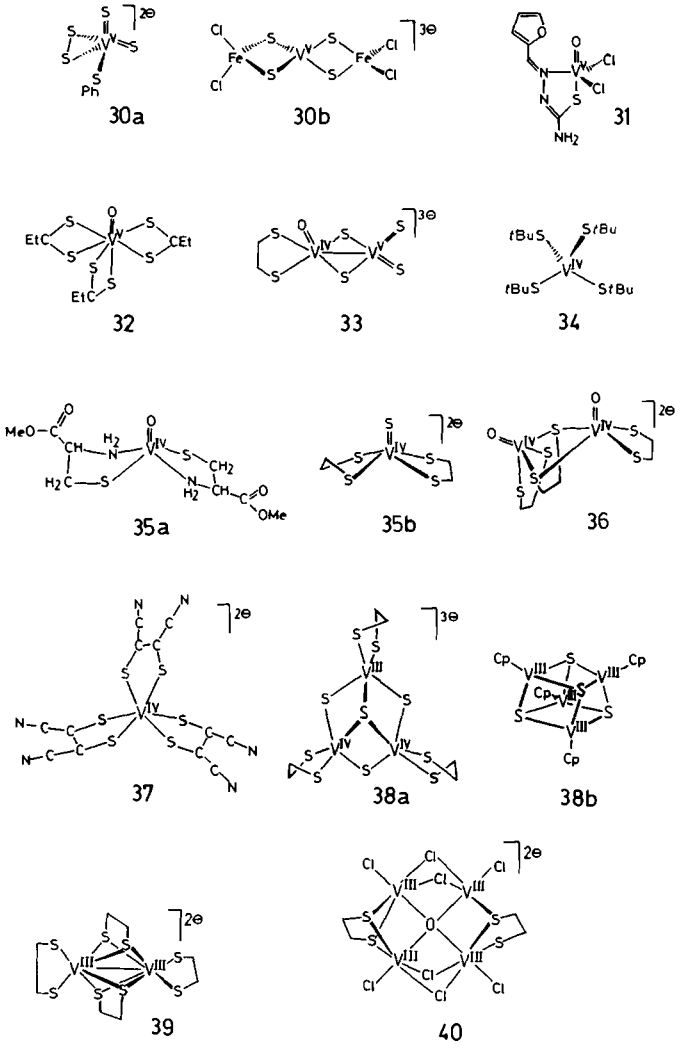

Fig. 10. Coordination compounds of vanadium with sulfur ligands as structural models for the iron-vanadium cofactor of vanadium nitrogenases. The molecular structures were, with the exception of **31**, determined by X-ray diffraction analysis. For clarity some structures have been reproduced somewhat idealized from the original literature. Sources: **30a** and **33** [132c], **30b** [132d], **31** [133], **32** [134], **34** and **36** [135], **35a** [132b], **35b** [136a], **37** [63], **38a** [136b], **38b** [136d], **39** [137], **40** [137c]. Compounds **37** and **39** show an arrangement for the VS_6 unit that lies between a trigonal prism and an antiprism (= octahedron).

$$[V_3S_4(edt)_3]^{4\ominus} \overset{-1.51\ V}{\rightleftharpoons} [V_3S_4(edt)_3]^{3\ominus} \overset{-0.63\ V}{\rightleftharpoons} [V_3S_4(edt)_3]^{2\ominus} \quad (f)$$

38a

Potential functional models are collected in Figure 11. The series **41** and **42** describe both the dinitrogen complexes (**41a** exists only in gas matrix[138a]) and the complexes with reduced ligands (hydrazine and ammonia); nothing is known about a direct transformation of **41a**/**42a** into **41b**/**42b** or **41c**/**42c**. In contrast, it was already shown almost two decades ago that N_2 is reduced in alkaline solutions containing $V^{2\oplus}$ and $Mg^{2\oplus}$, depending on the conditions, either to N_2H_4 (100 bar, 293 K) or to NH_3 (0.9 bar, 343 K).[141a] At pH values around 4.5, N_2 is reduced to N_2H_4 by the system $V^{2\oplus}/HO_2C(CH_2)_nCO_2H$ (n = 5, 6). The postulated intermediate, a binuclear complex with bridging carboxylate, keeps the two V centers together and thus allows the end-on bridging coordination of N_2.[141b] A binuclear μ-N_2 complex of V^{II}, **43**,[142] has recently been characterized structurally.

	d(NN) [pm]	d(VN) [pm]	(VNN) [°]

46	140.0(12)	201.9(5)	

Fig. 11. Vanadium complexes with N_2 and other *N-N* ligands; potential functional models for vanadium nitrogenases. Sources: **41a** [138a], **41b** [140a], **41c** [139a], **42a** [138b], **42b** [140b], **42c** [139b, c], **43** [142], **44** [143], **45** [144], **46** [140b].

Bond lengths approach that of a formulation with the hydrazido(4−) ligand; the magnetic behavior of the compound and the easy exchange of N_2 for CO and alkyne suggest a N_2 complex. As a first reduction step in the nitrogen fixation, intermediates with diimide, isodiimide/hydrazide(2−), and hydrazine are discussed. To the rare examples of such complexes belong **44**, **45**, and also the diazine complex **46**. The bond lengths and angles listed below indicate that the end-on-bonded ligands in complexes **44** and **45** are isodiimine and hydrazido(2−) ligands, respectively.

4.2. Carboxylato, Hydroxamato, Alkoxo, and Aryloxo Complexes

Mono-, di-, hydroxo-, and aminocarboxylates form, in the main, weak complexes with vanadate(v) and $VO^{2\oplus}$ in aqueous systems (see Table 3). Isolation is often only possible from organic solvents. Complexes of V^V with carboxylates that have no other functional groups available are generally mononuclear (**47** and **48** in Fig. 12) and have typical coordination numbers of 6 or 7. As was shown in example **48** with η^2 coordination of the pivalate ligand (for the model character of this compound for vanadate-dependent peroxidases, compare with **B** in Fig. 7), CN 7 is only partly achieved in solution.[147] When a binuclear V^V carboxylate is formed, as in the case of the citrate complex **49**, the vanadium centers are connected by an additional function, here the deprotonated hydroxyl group of citric acid. The bridging by $O^{2\ominus}$, known from the oligovanadates(v), appears to be reserved for the mixed-valence carboxylato complexes (**50**, V_5^V/V^{IV}; **51**, V^V/V_4^{IV}) and species with vanadium(IV) (**52**). *Casey* et al. referred early on to the "polymeric" nature of $VO^{2\oplus}$ carboxylates;[152] their "island" structures could only be unraveled by X-ray analyses. A further characteristic of these complexes is the bidentate bridging function of the carboxylato ligands. With multifunctional ligands such as tartrate, oxalate, and malonate, V^{IV} can form both bi- (**53**) and mononuclear (**54**) complexes. Carboxylate functions operate here as in the V^V complex **49** only in a monodentate fashion. The cluster **51** can undergo irreversible and reversible redox processes [Eq. (g)].[149]

$$V_5^{IV} \xleftarrow{+e} V^V V_4^{IV} \underset{}{\overset{-e,\ 0.68\ V}{\rightleftharpoons}} V_2^V V_3^{IV} \xrightarrow{-e} V_3^V V_2^{IV} \qquad \text{(g)}$$

The investigation of $VO^{2\oplus}$ complexes in solution has also been successfully performed by ^1H ENDOR spectroscopy (ENDOR = electron nuclear double resonance). This method, in which the frequencies of irradiation are those of selected transitions in the ESR spectrum of an axial molecule (e.g., the components at $m(I)_{\parallel} = -5/2$ and $m(I)_{\perp} = -3/2$), enables, through the determination of hyperfine coupling constants A_H, conclusions to be drawn about the distance d(H-V) of the ligand proton coupled with the unpaired electron on the vanadium center and therefore also about the mode of coordination of the ligand. In this manner it could be shown, for example, that galacturonic acid coordinates at pH < 4 via the carboxylate group (Fig. 12, bottom, **55a**), in the physiological pH range via carboxylate and the deprotonated OH group on C4 (**55b**), and in strongly alkaline medium via two alkoxy oxygens (**55c**).[154a] Some data are listed in Figure 12. For comparison, ENDOR data for $[VO(H_2O)_5]^{2\oplus}$ [154c] and the V^{IV}–catecholate complex **58** (Fig. 13) have been included. These data agree well with those based on the bonding parameters from X-ray structure determinations.

In connection with the inhibition of enzymes (e.g., ribonucleases, ATPases), the CN 5 of vanadium is of interest, because vanadate, in contrast to its antagonist phosphate, forms stable complexes after expansion of its coordination sphere (from a tetrahedral geometry). These complexes are models for the transition state in phosphodiester hydrolysis.

Fig. 12. Top: Complexes of V^V and V^{IV} with carboxylato ligands, in which exclusively *O*-donation occurs (**47**–**54b**). Sources: **47** [145], **48** and **50** [= $V^{IV}V_5^VO_4(\mu\text{-}O)_4(\mu_3\text{-}O)_2(\mu\text{-}O_2Ph)_8$] [147], **49** [148], **51** [= $V_3^{IV}V_2^VO_5(\mu_3\text{-}O)_4\mu_4\text{-}Cl(\mu\text{-}tca)_4$; Htca = thiophene-2-carboxylic acid] [149], **52a** [150a], **52b** (with THF twisted 90° relative to the O = V-O axis) [150b], **53** [151], **54a** [146a], **54b** [146b]. Bottom: ^1H ENDOR results and structure proposals for complexes of $VO^{2\oplus}$ with galacturonic acid (**55** [154a]), catechol (**58** [154b]), and water (VO-aq = $[VO(H_2O)_5]^{2\oplus}$ [154c]. For the structure of **58**, see Fig. 13. Coupling constant data $A(H)$ in MHz.

CN 5 is achieved in **53** (trigonal bipyramidal), in the apical vanadium of complex **51** (tetragonal pyramidal), and in the V_4 subunit of complex **50** (between trigonal bipyramidal and tetragonal pyramidal). Further examples may be found in the previous sections and in Figures 13 (**56**–**58**) and 14 (**64a**). Compounds **56** and **57** are the only structurally well-characterized triesters $VO(OR)_3$ of tetraoxovanadic (orthovanadic) acid. They occur as dimers for R = Me and as monomers for R = C_2H_4Cl (and probably for all other R), which however associate into larger aggregates in the solid state and also in solution[113] (in Fig. 13 this is indicated by dashed lines). The V–OR bond in these two esters and the

ester bond in **60** are conspicuously short (175–186 pm; V–O single bonds otherwise lie around 200 pm, V=O double bonds between 155 and 165 pm), which has been discussed as evidence for an ester bond in native vanadate-dependent peroxidase (Fig. 7, **A**). The catecholate complexes **58** and **59**, as well as the hydroxamate complexes **60**–**62**, are noteworthy in that catecholates and hydroxamates are the most important function carriers of the siderophores produced by bacteria and fungi and are possibly also active in the mobilization of vanadium, similar to that of $Fe^{3\oplus}$, out of inorganic extracellular depots. Kinetic investigations into complexation of aromatic diols by vanadate(v) and its reduction to V^{IV} were performed by *Ferguson* and *Kustin*.[156]

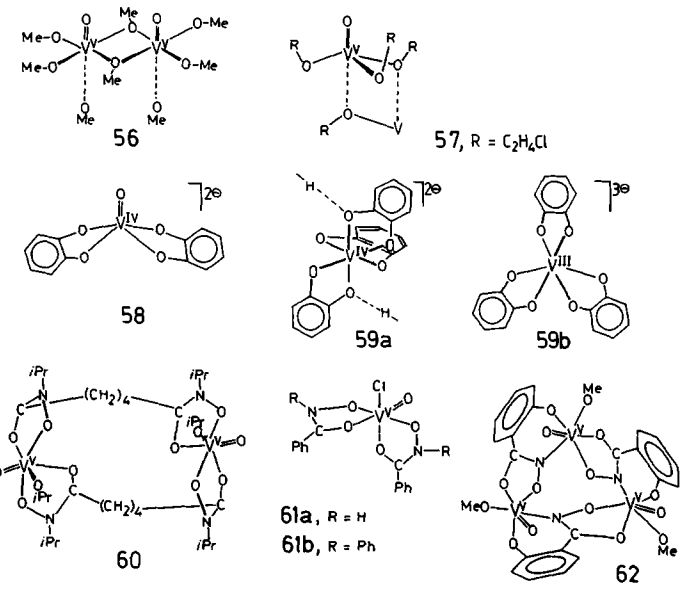

Fig. 13. Vanadium complexes with alkoxo, aryloxo, and hydroxamato ligands. Sources: **56** [153], **57** [113], **58** and **59** [128b], **60** and **61a** [58], **61b** [101], **62** [155]. The dashed lines in **56** and **57** imply bonding interactions with neighboring molecules. **59a** is octahedral, but shows considerable distortions from ideal octahedral geometry, for which hydrogen bonds (dashed lines) from the counterion $HNEt_3^{\oplus}$ to the phenolate oxygens may be held responsible. In the potassium salt of complex **59b** the trigonal torsion angle is 45.6°. The V=O double bond in **61a** is normal at 159.1 pm; in **61b**, however, it is unusually long (180.1(4) pm).

Structurally characterized complexes of vanadium with simple amino acids appear not to exist. Cysteine methyl ester forms with $VO^{2\oplus}$ the complex **35a** (Fig. 10) with *N,S*-coordination. Histidine (in connection with $VO^{2\oplus}$)[158] and various dipeptides studied by us (in connection with $H_2VO_4^{\ominus}$; see, for instance, **63** in Fig. 14), which contain freely available carboxylate groups, tend to avoid the coordination with the carboxylate oxygen. In contrast, *N,O*-coordination occurs with more complex aminocarboxylates and related ligands. Examples are the complexes with picolinate (1–) **64a**, dipicolinate(2–) **64b**, nicotinate(1–) **65**, EDTA **66** and **67**, and triazacyclononane-*N,N*-diacetate(2–/1–) **68**, shown in Figure 14. Compound **68a** can be reversibly oxidized to **68b** (Table 4).

N,O-coordination of a different kind, namely exclusively or additionally from Schiff base functions plus $OR^{\ominus}$, is displayed by the complexes **69** (here, an acetate group of EDTA is replaced by the hydroxyethyl group), as well as by **70**–**74**.

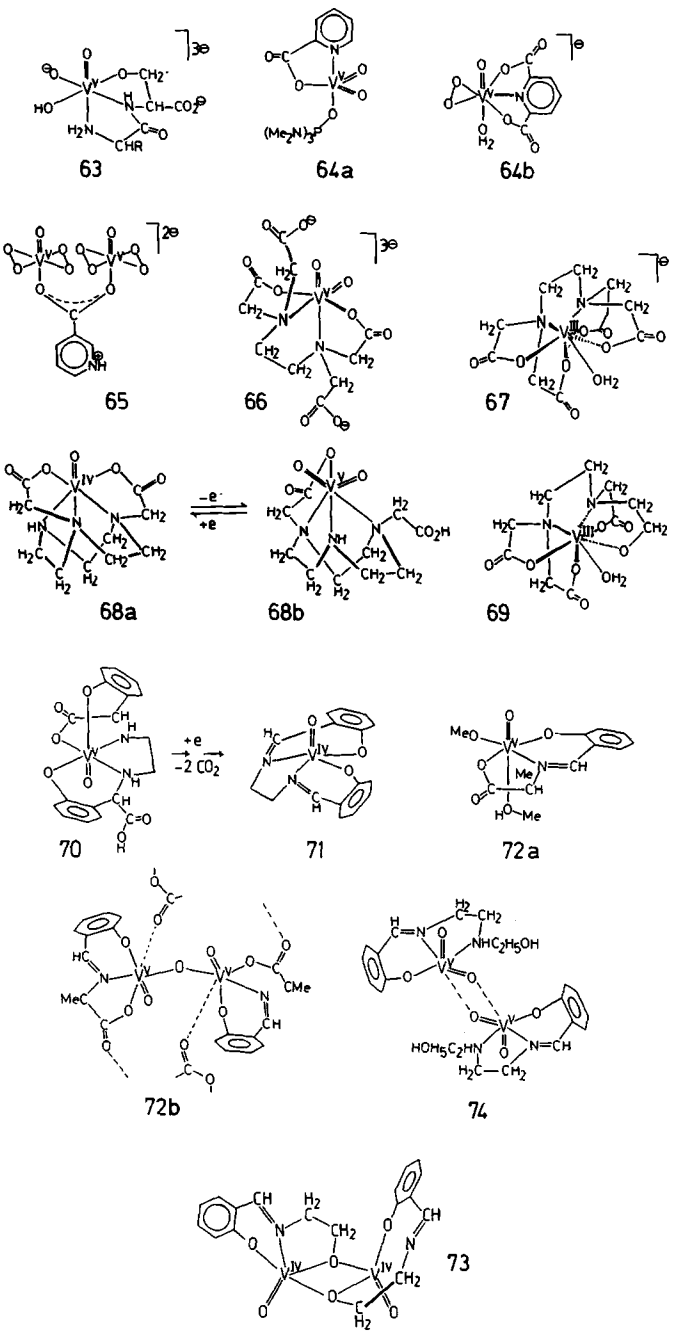

Fig. 14. Complexes with *O,N*-donor ligands. Sources: **63** [52], **64a** [157a], **64b** [157b], **65** [159], **66** [160], **67** [161], **68** [62], **69** [162], **70** [60, 163b], **71** [163a], **72a** and **72b** [165a], **73** [165b], **63**, **65**, and **70** are structure proposals. Compounds **67** and **69** have the geometry of twisted trigonal prisms with the aqua ligands in capping positions. The decarboxylation of **70** takes place in two steps and with the participation of an intermediate with V^{III}. Compound **72b** is, as the dashed lines (= weak bonding interactions) show, associated with a second dimeric unit to form a tetranuclear complex.

Complex **70**, which contains the ligand ethylenebis(hydroxyphenyl)glycine, decarboxylates under suitable conditions to the salen complex **71**[60, 163b, c] (salen is the double Schiff base formed from two molecules of salicylaldehyde and ethylenediamine). This unusual oxidative (with respect to the ligand) decarboxylation is a notable model for the decarboxylation of *S*-adenosylmethionine by vanadate(v), a reaction that takes place in the presence of pyridoxal phosphate at vanadate concentrations as low as 10^{-7} M via the formation of a Schiff base complex[164] (see also Section 3.2.2).

The ligand in **72a** and **72b** is the Schiff base formed from salicylaldehyde and alanine. The low magnetic moment of **73** (1.53 μ_B) allows conclusions to be drawn about the antiferromagnetic interaction between the two-alkoxo-bridged V centers (d(V-V) = 306.8(4) pm). Oxidation by air transforms **73** into a dimeric V^V complex.

4.3. Histidine-Modeling Ligands

Histidine (imidazolylalanine) as component of a protein matrix is capable of coordinating biometals such as $Zn^{2\oplus}$, $Cu^{\oplus/2\oplus}$, $Fe^{2\oplus/3\oplus}$, and $Mn^{2\oplus/3\oplus/4\oplus}$ and is also mentioned in connection with the coordination of $VO^{2\oplus}$ in transferrin and (reduced) vanadate-dependent haloperoxidase (V^{IV}-PO). Histidine itself complexes vanadate(v) only weakly.[52a, 158] ESR spectra of model compounds such as **75** and **76** (Fig. 15) show a similarity to that of V^{IV}-PO (compare also the data in Table 6, Section 3.3.6) inasmuch as they give similar g factors and hyperfine coupling constants and furthermore correspond to the total habitus (i.e., they display in principle an axial spectrum), but they reveal the significant rhombic distortion in the plane (splitting of $g_{\|}$) as well.

The coordination of three histidine residues in Fe-hemerythrin and Cu-hemocyanin, for example, has stimulated the recent development of the coordination chemistry with suitable tridentate *N*-ligands, and vanadium is no exception. Particularly noteworthy are 1,4,7-triazacyclononane and its derivatives[62] (cf. **68** in Fig. 14, **80** and **81** in Fig. 15), hydrotris(3,5-dimethylpyrazolyl)borate[167, 168] (pz; **77** and **78** in Fig. 15), the hexadentate tetrakis(2-pyridylmethyl)ethylenediamine, which additionally joins doubly OH-bridged $VO^{2\oplus}$ centers with one another (**79** in Fig. 15), and the Schiff base in **82**, which also presents six *N*-functions in a binuclear, OR-bridged complex. Compound **77** is formed by oxidation with air (and other reactions) from a precursor containing V^{III} and can be reversibly oxidized in DMF to a species containing V^V [Eq. (h)].

$$[pzV^{III}Cl_2(dmf)] \xrightarrow{O_2} \underset{\mathbf{77}}{[pzV^{IV}OCl(dmf)]} \underset{+e,\ 1.18\ V}{\overset{-e}{\rightleftharpoons}} \text{"p-}V^{V}\text{"} \qquad \text{(h)}$$

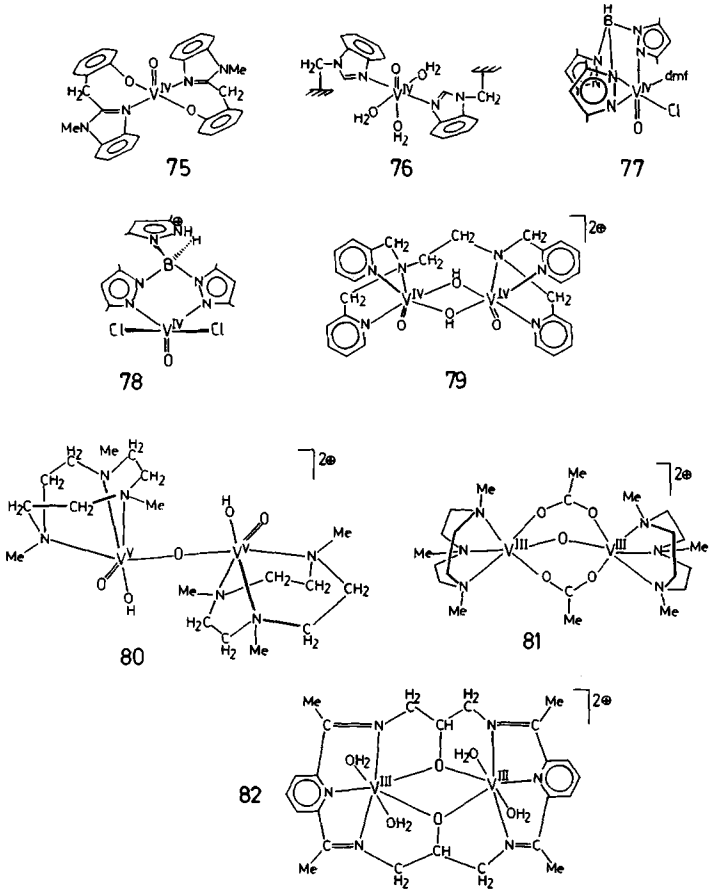

Fig. 15. Vanadium complexes with ligands that model the coordination to histidine. Compare also **68** in Fig. 14. Sources: **75** [166], **76** [128e] (benzimidazole is bonded to a support), **77** and **78** [167], **79** [169], **80** [170], **81** [171], **82** [172]. Compounds **75** and **76** are preliminary structure proposals. In **81** the V–O–V angle is 130.2° (usually the V–O–V unit is approximately linear; see, e.g., **14** in Fig. 6). The aqua ligands in **82** are in apical positions, the O of the μ-alkoxo group in trigonal-planar surroundings.

Addendum

Section 2: The kinetic exchange pathways between monovanadate and oligovanadates have been studied at pH 8.6 by ^{51}V–^{51}V exchange spectroscopy (EXSY). The dimer is mainly formed from two monomers, and dimer–monomer exchange is fast. The main pathway for tetramer formation is the reaction between two monomers and a dimer (a labile linear trimer may be involved); the pentamer forms either from tetramer and monomer (low c(V)) or from two tetramers.[174]

Sections 3.1 and 3.2: Several recent experiments cast new light on the vanadate species responsible for enzyme inhibition. Oligomers probably have a more potential role in this respect than recognized previously.[175, 176] Monovanadate *and* oligovanadates coordinate to myosin and its subfragment 1, and it has been suggested that photocleavage of the subfragment occurs only when tetravanadate is bound.[177] New results are also available on the metabolism of vanadate(v) (mainly detoxification through reduction to V^{IV}): Vanadate(v) is reduced by nonprotein thiols related to glutathione[178] and by dihydroxyacetone.[179] In the latter case, the half-life of $H_2VO_4^{\ominus}$ is 20 min. Reduction is about 75 times slower than ester formation (between vanadate and dihydroxyacetone). V^V is restored on contact with O_2.[179] $VO^{2\oplus}$ has been shown to stimulate O_2 evolution by photosystem II particles inactivated by removal of $Ca^{2\oplus}$.[180]

The use of appropriate ^{48}V complexes (such as [^{48}V]vanadylpheophorbide[181]) for tumor imaging by positron emission tomography (PET) is a promising new development in the medical application of vanadium.

Section 3.3: $VO^{2\oplus}$ complexed to ribonucleic acid reacts with hydrogen peroxide in a Fenton-like manner to produce OH radicals.[182] The interaction of vanadate with mononucleosides, ADP, and ATP was investigated by multinuclear NMR spectroscopy. Among the compounds formed are the mixed anhydrides AMPV, $AMPV_2$, and ADPV.[183] The main component of the complexes generated from vanadate(v) and inosine (and other nucleosides) in aqueous solution is binuclear and contains two ligands, with the vanadium centers in a trigonal-bipyramidal array.[184]

The accumulation and chemistry of vanadium (in the form of amavadin) in the fly agaric toadstool has been reviewed.[185] Electrochemical data suggest that the role of

amavadin is that of an electron-transfer catalyst or mediator. A plausible, though hypothetical, assumption is that amavadin is a component of a primitive oxidase.[185]

A ^{51}V NMR study on vanadate-dependent bromo/iodoperoxidase from *Ascophyllum nodosum* has revealed that, in addition to the active site (where V^V is tightly bound), there are unspecific, low-affinity binding sites on the protein for vanadate. These have been modeled with Gly-Tyr and Phe-Glu.[186] While vanadate-dependent peroxidases are usually found in the cell wall (between cortex and medulla) of the algae, peroxidases have now also been isolated from the protoplasts of seaweeds belonging to the genus *Laminaria*.[187] Vanadium and iron are constituents of a nonheme peroxidase from the marine red alga *Corallina vancouveriensis*.[188] In the absence of substrate, the system peroxidase/H_2O_2/$Br^{\ominus}$ evolves singlet oxygen.[188]

A supplementary EXAFS study of the FeV cofactor in vanadium nitrogenase, employing Fe as the back-scatterer, supports the view that the structural similarity of FeV and FeMo cofactors includes the long-range order and a mixed Fe/M second shell.[189]

Section 4: V^{IV} in an environment of eight sulfur functions is present in the binuclear (d(V-V) = 280 pm) and diamagnetic complex $\{V(S_2CMe)_2\}(\mu\text{-}S_2)_2$.[190] Functional models for vanadium nitrogenase, *cis*/*trans*-$[V(N_2)_2p_4]^{\ominus}$ and $[V(N_2)p_5]^{\ominus}$ (the p_n are oligodentate phosphane ligands), have been characterized by ^{51}V and ^{15}N NMR and by IR. The compounds are stable at ambient temperatures; part of the N_2 is reductively protonated to $NH_4^{\oplus}$ in the presence of HCl.[191]

Several new vanadium complexes serving as potential models for vanadium binding in biological systems have been reported. Among these are the pseudo-octahedral "bare" (i.e., without the V=O group) complexes $V^{III}L$, $[V^{IV}L]^{\oplus}$, and $[V^{V}L]^{2\oplus}$, with L a triazacyclononane derivative carrying phenoxy groups at the nitrogens and coordinating through three N and three O atoms. The three complexes can be reversibly interconverted by cyclovoltammetry.[192] Other complexes of interest that have been structurally characterized are $[V^{V}O(N,N')$-(pentane-3-ol)bis(salicylaldimine)][193] and $[V^{V}OCl(pinacolate)]_2$.[194] An ENDOR investigation into the systems $VO^{2\oplus}$/salicylic acid and $VO^{2\oplus}$/2,3-dihydroxybenzoic acid has shown that dihydroxybenzoic acid behaves, depending on the pH, either as a catecholic or as a salicylic ligand.[195] An EPR study of the aqueous $VO^{2\oplus}$/catecholate system has revealed the formation of 1:1, 1:2, and 1:3 (metal:ligand) complexes.[196]

The first comprehensive book on vanadium in biological systems has appeared, covering biochemical, chemical, and methodological aspects of the biochemistry of vanadium (cf. Ref. [129b]). In two additional reviews, emphasis is laid on V-PO and vanadium in ascidians[197] and on the latter aspect only.[198]

5. Concluding Remarks

The high abundance of vanadium in fossil matter of animal and plant origin as against its comparatively low concentration in most organisms today (Table 1) prompts the question whether vanadium was formerly more intensively used and whether the present groups of organisms which still accumulate vanadium (Ascidiacea, *Amanita*) are not in a certain sense living fossils. Similarly, the question arises whether those enzymes which still contain vanadium in the active site (haloperoxidases, nitrogenases) are not in fact handed-down function carriers which have not bowed to evolutionary pressure. In this regard, it is interesting to note that only the phylogenetically older subdivisions of the Ascidiacea show high vanadium contents, while the younger take up preferentially or exclusively iron.[88c, 188] Furthermore, peroxidases containing iron are more wide-spread than vanadate-dependent peroxidases and even among these there are apparently examples which contain iron besides vanadium[103d] or which conduct their enzymatic activity with iron as well as vanadium.[173] Points of intersection in the vanadium and iron metabolisms are probable.[18, 86a] After all, nitrogen-fixing organisms fall back on vanadium (or iron), only when no molybdenum is available. All this appears to indicate that, in the course of evolution, nature has found better solutions with other metals for many types of functions. Considering these premises, the chances of discovering further vanadium compounds with specific functions in nature should be judged with skepticism (possibly the search for such compounds among the geologically oldest groups of organisms such as the archaebacteria and the zymogenic species of the genus *Clostridium* would be successful). Undisputed is the fact that the dual nature of vanadium—on the one hand, in anionic form (as vanadate(v)) a competitor of phosphate in its metabolism and, on the other, in cationic form (as $VO^{3\oplus}$, $VO_2^{\oplus}$, $VO^{2\oplus}$, and $V^{3\oplus}$) a transition-metal ion which can interact with biogenic ligands (including proteins)—enables this element to serve many regulatory tasks in the organism.

The work of my own group, cited in the list of references, would not have been possible without the dedicated assistance of my co-workers, whom I would like to thank. The Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and the Freie und Hansestadt Hamburg have been generous in supporting this research. My particular thanks are due to those colleagues whose cooperation made the joint work on enzymes possible. These are above all Dr. Vilter, Institut für Pharmazeutische Biologie der Universität Bonn (work on peroxidase) and Prof. Saenger and his group, Institut für Kristallographie der Freien Universität Berlin (work on ribonuclease). I thank Prof. Achim Müller, Universität Bielefeld, for the critical perusal of the manuscript and lively discussions.

[122] C. Weidemann, D. Rehder, U. Kuetgens, J. Hormes, H. Vilter, *Chem. Phys. 136* (1989) 405. The energy of the white band, a pre-edge structure, (the so-called 1s → 3d transition), is generally correlated with the coordination charge, which is made up of the oxidation number of V and the ionicities of the V–L bonds. This association suggests that, for vanadium complexes with the same or a similar construction for the coordination sphere, the K → 3d transitions for V^V lie at higher energies than those for V^{IV}. The trend indeed confirms this. [J. Wong, F. W. Lytle, R. P. Messmer, H. D. Maylotte, *Phys. Rev. B: Condens. Matter 30* (1984) 5596; K.-H. Hallmeier, R. Szargan, G. Werner, R. Meier, N. A. Sheromov, *Spectrochim. Acta Part A42* (1986) 841]. Nevertheless, geometric factors such as distortions in octahedral complexes (bent octahedral axis, unequal bond lengths in the octahedral plane, vanadium outside the octahedral plane) can have distinctly greater effects than differences in oxidation number. For V^{IV} complexes, we have found energies of the white band between 4.3 and 5.8 eV, for V^V complexes between 4.6 and 6.2.

Highly-Reduced Metal Carbonyls

By *Wolfgang Beck* *

Anionic carbonyl complexes (carbonylmetalates) contain metals with formal negative oxidation numbers and constitute one of the most important classes of compounds in organometallic chemistry. Since the first systematic studies of carbonylmetalates by *Hieber* et al.[1] these compounds have proven to be valuable starting compounds for the synthesis of a variety of—even multinuclear—metal carbonyls and their derivatives.[2] They are also used in organic synthesis.[3]

The first anionic carbonyl complexes $[HFe(CO)_4]^{\ominus}$ and $Fe(CO)_4^{2\ominus}$ were obtained by reaction of $Fe(CO)_5$ with alkaline hydroxide solutions[4] (Hieber base reaction).

$$Fe(CO)_5 + 3\,OH^{\ominus} \longrightarrow [HFe(CO)_4]^{\ominus} + CO_3^{2\ominus} + H_2O$$

Kruck et al.[5] interpreted the mechanism of this reaction in terms of an attack by hydroxide at the C atom of a CO ligand with elimination of carbon dioxide.

The simplest and most straightforward entry to carbonylmetalates is via the reduction of metal carbonyls, usually with alkali metals, whereby a CO-ligand (two-electron donor) is formally replaced by two electrons or a metal–metal bond is reductively cleaved.

$$Fe(CO)_5 + 2\,Na \longrightarrow Na_2[Fe(CO)_4] + CO$$

$$[(OC)_5Re\text{–}Re(CO)_5] + 2\,Na \longrightarrow 2\,Na[Re(CO)_5]$$

Pioneering work by *Behrens*[6] in 1941 already showed that this reduction is effectively carried out in liquid ammonia. Using the 18e rule a series of mononuclear neutral and anionic carbonyl complexes results in which the central atom in each case has a noble gas electron configuration (Table 1).

Table 1. Mononuclear neutral and anionic carbonyl complexes with noble gas electron configuration [a].

Metal		Structure: tetrahedral	trigonal-bipyramidal	octahedral
Ni		$Ni(CO)_4$		
Co,Rh,Ir	$M(CO)_3^{3\ominus}$	$M(CO)_4^{\ominus}$		
Fe,Ru,Os		$M(CO)_4^{2\ominus}$	$M(CO)_5$	
Mn,Re		$M(CO)_4^{3\ominus}$	$M(CO)_5^{\ominus}$	$M(CO)_6^{\oplus}$
Cr,Mo,W	$(M(CO)_3^{6\ominus}$	$M(CO)_4^{4\ominus}$	$M(CO)_5^{2\ominus}$	$M(CO)_6$
V,Nb,Ta		$(M(CO)_4^{5\ominus})$	$M(CO)_5^{3\ominus}$	$M(CO)_6^{\ominus}$
Ti,Zr,Hf		$(M(CO)_4^{6\ominus})$	$(M(CO)_5^{4\ominus})$	$M(CO)_6^{2\ominus}$

[a] Derivatives of the compounds quoted in parentheses are known.

The compounds within a column are iso-structural. The anions in the same row are each derived from the one on the right by replacement of a CO-ligand by two electrons.

Recently, *Ellis* et al.[7] were able to prepare new, highly reduced, i.e. three- and four-fold negatively charged metal carbonyls ("Ellis compounds") by a series of impressive experimentally demanding and systematically planned studies. A few years ago one would scarcely have thought of the existence of anions such as $Cr(CO)_4^{4\ominus}$!

Synthesis: Highly-reduced metal carbonyls and their derivatives were prepared by *Ellis* et al. with alkali metals or alkali metal naphthalenides as reducing agents in liquid ammonia, in hexamethylphosphoric triamide, or even in THF. Singly charged anions or metal carbonyls with donor ligands (amines, phosphanes) were employed as starting compounds (see, e.g., Ref. [8,9]).

$$Na[M(CO)_6] + 2\,Na \longrightarrow Na_3[M(CO)_5] + CO \quad (M = V,Nb,Ta)$$

$$[M(CO)_4(tmeda)] + 4\,Na \longrightarrow Na_4[M(CO)_4] \quad (M = Cr,Mo,W)$$

$$Na[M(CO)_5] + 2\,Na \longrightarrow Na_3[M(CO)_4] + CO \quad (M = Mn,Re)$$

$$Na[Co(CO)_4] + 2\,Na \longrightarrow Na_3[Co(CO)_3] + CO$$

The synthesis of hexacarbonyltitanate, -zirconate, and -hafnate(− II), the first stable binary carbonyls of elements of group 4, was achieved, inter alia, by reductive carbonylation of $[M(CO)_4L]$ with potassium naphthalenide as reducing agent in the presence of cryptands:[10]

$$[M(CO)_4L] + 2\,KC_8H_{10} \xrightarrow{\text{cryptand, CO}} [K(\text{cryptand})]_2[M(CO)_6] + 2\,C_8H_{10} + L$$

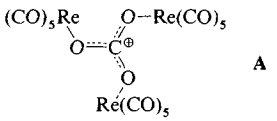
$(L = H_3CC(CH_2PMe_2)_3,\ M = Ti, Zr, Hf)$

The titanium and zirconium compounds are also accessible under similar conditions directly from the metal tetrachlorides. The "exhaustively" reduced carbonylmetalates $M(CO)_4^{5\ominus}$ (M = V,Nb,Ta), $M(CO)_4^{6\ominus}$ (M = Ti,Zr,Hf) and $M(CO)_3^{6\ominus}$ (M = Cr,Mo,W) have not yet been characterized; *Ellis* et al., however, have been able to isolate their corresponding triphenylstannyl derivatives (see below).

Properties and reactivity: The solvent-free salts of the tri- and tetraanionic carbonylmetalates are, as expected, strong reducing agents; they are extremely pyrophoric. The isolated salts $Na_4[M(CO)_4]$ (M = Cr,Mo,W) or $Cs_3[Ta(CO)_5]$ can explode under argon (!), even without external interference. The extremely sensitive compounds were therefore mostly employed in situ.

Carbonylmetalates, e.g. $Cr(CO)_5^{2\ominus}$ can reduce CO_2.[11]

$$Cr(CO)_5^{2\ominus} + 2\,CO_2 \longrightarrow Cr(CO)_6 + CO_3^{2\ominus}$$



A

Such a reaction is possibly responsible for the unexpected formation of the novel μ_3-carbonato-bridged complex **A**, which is formed along with the hydride $[(OC)_5ReIr(H)(CO)_3Re(CO)_5]$ from $Ir(CO)_3^{3\ominus}$ and $[(C_2H_4)Re(CO)_5]^{\oplus}$ on exposing the reaction solution to air.[12]

The protonation of carbonylmetalates is one of their most important reactions and usually leads to hydrido complexes.

$$Fe(CO)_4^{2\ominus} + 2H^{\oplus} \longrightarrow [H_2Fe(CO)_4]$$

$$Re(CO)_4^{3\ominus} + 2H^{\oplus} \longrightarrow [H_2Re(CO)_4]^{\ominus}$$

$V(CO)_5^{3\ominus}$ reacts with NH_4Cl in liquid ammonia with H_2-elimination ($H^{\oplus}$ as oxidizing agent) and formation of $[V(CO)_5NH_3]^{\ominus}$; the ammonia in this anion can be readily replaced by stronger donor ligands L (isocyanide, phosphane).

$$V(CO)_5^{3\ominus} + 2H^{\oplus} \xrightarrow[-H_2]{NH_3} [V(CO)_5NH_3]^{\ominus} \xrightarrow[-NH_3]{+L} [V(CO)_5L]^{\ominus}$$

Carbonylmetalates react as nucleophiles with alkyl and aryl halides, affording access to the important class of organometallic complexes containing a metal–carbon σ-bond.

$$Re(CO)_5^{\ominus} + CH_3I \xrightarrow[-I^{\ominus}]{} [(OC)_5Re-CH_3]$$

Corresponding reactions can also be carried out with the highly reduced $Re(CO)_4^{3\ominus}$ anion (H_3COTos = methyl *p*-toluenesulfonate:[8]

$$Re(CO)_4^{3\ominus} + CH_3OTos \xrightarrow[-OTos^{\ominus}]{} [H_3CRe(CO)_4]^{2\ominus} \longrightarrow [(H_3C)_2Re(CO)_4]^{\ominus}$$

As we have already been able to show, protonation of $[(H_3C)_2Re(CO)_4]^{\ominus}$ with tetrafluoroboric acid affords the doubly coordinatively unsaturated $Re(CO)_4^{\oplus}$,[13a] a useful organometallic Lewis acid[13b] for reactions with nucleophiles.

$$[(H_3C)_2Re(CO)_4]^{\ominus} + 2H^{\oplus} \longrightarrow Re(CO)_4^{\oplus} + 2CH_4$$

In our studies we have used carbonylmetalates as nucleophiles for additions to coordinated unsaturated hydrocarbons. The addition of carbonylmetalates to unsaturated hydrocarbons in cationic complexes has proven to be a direct and rational method for the synthesis of numerous hydrocarbon-bridged complexes.[14]

$$[(OC)_5Re(C_2H_4)]^{\oplus} + Os(CO)_4^{2\ominus} + [(C_2H_4)Re(CO)_5]^{\oplus} \xrightarrow{(CO)_4} (OC)_5Re(CH_2)_2Os(CH_2)_2Re(CO)_5$$

Highly reduced metal carbonyls are especially useful for the synthesis of multinuclear complexes with metal–metal bonds between main-group and subgroup elements, which, e.g., are formed by reaction with chlorotriphenylstannane or chlorotriphenylphosphinegold.

$$Cr(CO)_4^{4\ominus} + 3ClSnPh_3 \xrightarrow[-3Cl^{\ominus}]{} [(OC)_4Cr(SnPh_3)_3]^{\ominus}$$

$$V(CO)_5^{3\ominus} + 3ClAuPPh_3 \xrightarrow[-3Cl^{\ominus}]{} (OC)_5V(AuPPh_3)_3$$

According to the studies of *Ellis* et al. triphenylstannyl derivatives of almost all highly reduced metal carbonyls are known.

$[Co(CO)_3(SnPh_3)_2]^{\ominus}$ ($\triangleq Co(CO)_3^{3\ominus}$), $[W(CO)_3(SnPh_3)_4]^{2\ominus}$ ($\triangleq W(CO)_3^{6\ominus}$),

$(OC)_4Zr(SnPh_3)_4]^{2\ominus}$ ($\triangleq Zr(CO)_4^{6\ominus}$), $[Ti(CO)_5(SnPh_3)_2]^{2\ominus}$ ($\triangleq Ti(CO)_5^{4\ominus}$).

The multinuclear complexes have interesting structures containing transition metals with high coordination numbers. The synthesis, structure, and dynamic behavior of $(Ph_3Sn)_4M(CO)_4^{2\ominus}$ (M = Zr, Hf) in solution is described in this issue of "Angewandte Chemie".[7]

Investigations on highly reduced metal carbonyls also led *Ellis* et al. to novel carbonyl compounds of the early transition metals.[15] Thus, the CO-richest derivative of the hitherto unknown $Ti(CO)_7$ could be synthesized with the structurally characterized $[Ti(CO)_5(Me_2PCH_2CH_2PMe_2)]$.

Finally, the bonding situation in these unusual carbonylmetalates should be briefly discussed. The high negative charge leads to strong metal–CO π-backbonding; the negative charge is distributed over the antibonding π^*-CO orbitals corresponding to $M=C=O \leftrightarrow {}^{\oplus}M\equiv C-O^{\ominus}$.

With increasing negative charge the C-O bond is weakened, as shown by the wave numbers of the CO vibrations (Table 2).

Table 2. CO vibration frequencies of binary metal carbonyls.

Metal carbonyl	$\tilde{\nu}$ (CO) [cm^{-1}]	Metal carbonyl	$\tilde{\nu}$ (CO) [cm^{-1}]
$Mn(CO)_6^{\oplus}$	2090	$Ni(CO)_4$	2050
$Cr(CO)_6$	1980	$Co(CO)_4^{\ominus}$	1890
$V(CO)_6^{\ominus}$	1860	$Fe(CO)_4^{2\ominus}$	1790
$Ti(CO)_6^{2\ominus}$	1750	$Mn(CO)_4^{3\ominus}$	1670
		$Cr(CO)_4^{4\ominus}$	1460

The position of the CO bands of tetracarbonylchromate(– IV) corresponds almost to that of a C–O single bond, i.e. the CO group can be formulated as a carbyne ligand.

Summarizing, it can be stated that these remarkable compounds with metal atoms in the lowest known oxidation states have enriched the chemistry of metal carbonyls considerably.[16] Further interesting results can be expected.

Ultramicroelectrodes—a New Dimension in Electrochemistry?

By *Jürgen Heinze**

Metal electrodes with extremely small dimensions, in the μm range, have been used for voltammetric and polarographic measurements for some time now. They were originally developed for biological and medical research.[1] The electrochemists initially paid little attention to ultramicroelectrodes, in the firm belief not only that the current would diminish with decreasing electrode surface area and thus present measurement problems, but also that no significant differences would exist between the properties of large and small electrodes. Only through the works of *M. Fleischmann* et al. at the beginning of the eighties was it finally clear that a decrease in the surface area of the electrode not only effects quantitative changes, but also results in unusual qualitative effects. In 1981 *R. M. Wightman* reported, in one of the first comprehensive reviews, on the properties and perspectives of microvoltammetric electrodes.[2] The steadily growing interest in ultramicroelectrodes since that time primarily results from the fact that their employment based on well-established measuring principles (as apply in voltammetry or chronoamperometry) opens up new possibilities for the investigation of electrode reactions and electron transfer processes.

Which then are the new properties that make this type of electrode so attractive? One generally speaks of ultramicroelectrodes when the expansion of the inherently small diffusion layer on the time scale of the experiment is "greater" than the characteristic dimensions of the electrode. In the case of a spherical electrode such a characteristic is its radius or diameter, in the case of a band electrode the width, and in the case of the frequently employed disk electrodes, again the radius. Relatively large diffusion layers develop a few seconds after current starts passing through electrodes with characteristic dimensions below 20 μm. The originally planar diffusion field transforms into a (hemi)cylindrical or a (hemi)spherical diffusion field (see Fig. 1 bottom). As a consequence substantially more electroactative particles reach the electrode per unit time and surface area than in the case of a pure planar diffusion. On the other hand, the ever-increasing volume in a prescribed solid angle dictates that in time the flow of particles in and out of unit volume becomes stationary. The mass transport coefficient m, which is a measure of the rate of transport of particles in the stationary diffusion layer is, in a spherical field, inversely proportional to the radius of the electrode ($m = D/r$[cm s^{-1}], D = diffusion coefficient, r = electrode radius); as a result the diffusion rate at extremely small electrodes can be unusually large.

In practice this means, in the case of ultramicroelectrodes, that despite overall decreasing currents, the current densities increase by several orders of magnitudes compared to those in the case of a conventional large-surface-area electrode. The ratio between faradaic and capacitive current is drastically improved and opens up interesting analytical applications. Current densities of up to 70 A cm^{-2} have been reported. Moreover, in contrast to cyclic voltammetry (CV) (Fig. 1, left), one observes the formation of stationary current-voltage curves analogous to the *polarograms* obtained with the dropping mercury electrode or the rotating electrode (Fig. 1, right). Theoretical studies confirm that the transition from the transient state to the stationary state can be described by a parameter $\sigma = (Da^{-1}r^{-2})^{1/2}$, where $a = vRT\,n^{-1}\,F^{-1}$ is the normalized scan rate in the CV experiment. At $\sigma = 0$ the limiting case for normal planar diffusion ($r \rightarrow \infty$) is given by the typical transient voltammogram (Fig. 1, top left), whereas above $\sigma > 1$ the stationary state develops (Fig. 1, top right). Large σ values, usually coupled with small electrode radii, imply high transport coefficients m and thus also high current densities. Since the rate of transport of the electroactive particles in the diffusion layer increases with decreasing electrode radius, this process in the case of extremely small electrodes is as rapid, or more rapid, than heterogeneous charge transfer, i.e. a change from a diffusion-controlled to a kinetically-controlled process occurs. The resulting stationary current-voltage curves shift and change their shape compared to those for a diffusion-controlled process, which indicates thermodynamic (Nernst) equilibrium at the electrodes (Fig. 1). Ultramicroelectrodes are therefore a very elegant new tool for the determination of kinetic parameters in fast heterogeneous charge-transfer reactions. Kinetic data for rapid homogeneous chemical processes can also be determined thus, but, owing to the number of electrons transferred, only if the diffusion-limited current is dependent on the homogeneous kinetics e.g. in three-step *e*lectrochemical, *c*hemical, *e*lectrochemical (ECE) but not in EC processes.[3]

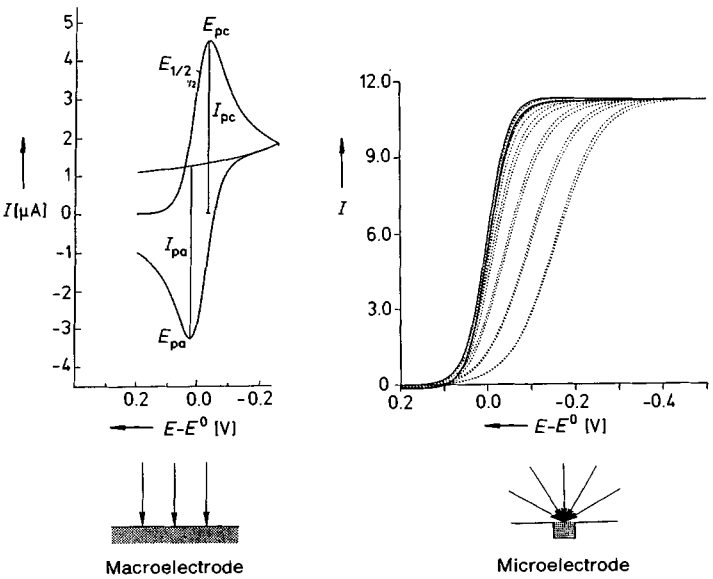

Fig. 1. Left: conventional cyclic voltammogram during measurements with macroelectrodes ($\sigma = 0$, planar diffusion field); right: steady-state cyclic voltammograms for a spherical ultramicroelectrode ($\sigma = 11.1$, $D = 1 \times 10^{-6}$ cm^2 s^{-1}, $r = 0.5$ μm, (hemi)spherical diffusion field); k_s^0: (—) > 100, (– – –) 1.1, 0.35, 0.11, 0.035, 0.011, 0.0035, 0.0011 cm s^{-1}. At $k_2^0 > 100$ cm s^{-1} and a mass transport coefficient of $m = 0.2$ cm s^{-1} the electrode process is diffusion-controlled. For $k_2^0 \leq 0.2$ cm s^{-1} the process switches to kinetic control and the steady-state voltammograms shift on the potential axis with a small change in shape. k_s^0 can be determined with the aid of theory from the shift of the curves. [11]

[*] Prof. Dr. J. Heinze
Institut für Physikalische Chemie der Universität
Alberstrasse 21, W-7800 Freiburg (FRG)

The unusually small currents from ultramicroelectrodes in the nA and pA range means that largely undistorted current-voltage curves can be measured, even at the high electrolyte resistances met with in almost electrolyte-free or in poorly conducting media, e.g. in benzene, in the solid or in the gas phase. Thus, for the first time electrochemical data can be obtained under the conditions common in spectroscopy.[4] Moreover, in cyclic voltammetry the small *IR* effect for current passage through microelectrodes permits the use of extremely high scan rates. In standard experiments with normal electrodes, scanning rates of between 0.05 $V s^{-1}$ and 0.2 $V s^{-1}$ are the rule, whereas with the new technique values of over 1 000 000 $V s^{-1}$ are achieved.[5] This means that in a voltammetric experiment, rate constants of electron-transfer-induced chemical reactions of up to 10^7 s^{-1} (1st order) or 10^9 $M^{-1} s^{-1}$ (2nd order) and heterogeneous standard rate constants of up to ca. 1 $cm s^{-1}$ can be measured. In this connection fast-sweep cyclic voltammetry can be regarded as an alternative to steady-state voltammetry, the former being preferred for mechanistic investigations.

Aside from the novel methodological aspects which ultramicroelectrodes offer, their size is a further argument in favor of their exploitation. In neurophysiology they are used for voltammetric in vivo measurements in single cells; in lithography they serve for the generation of microstructures in the nm range. Further applications are seen in electrochemical scanning tunneling microscopy and in sensors.[6]

Theoretical and experimental studies have shown that the specific qualities of ultramicroelectrodes improve only with decreasing electrode radii. Nevertheless, it has so far not been possible to utilize the full potential of such electrodes. This is primarily due to the fact that only shielded electrodes with radii of down to 5 μm were commercially available. Electrodes with radii down to 0.1 μm were produced exclusively by a few specialists and only in small numbers worldwide.

A group of scientists at CALTEC under the leadership of *N. S. Lewis* has now apparently made a breakthrough in the further miniaturization of microelectrodes.[7] They have succeeded in preparing ultramicroelectrodes (the authors speak of *nanodes*) with radii of 1 nm (= 10 Å). The procedure comprises two steps: Pt wires with a diameter of 0.5 mm were first electrochemically etched and then drawn at a precisely prescribed rate through a glass melt, the temperature of which was adjusted exactly to within 10 °C between 1250 and 1370 °C. During the drawing process the etched Pt tip was drawn out and simultaneously covered with glass. Of 200 electrodes prepared in this way 50% had radii of less than 0.1 μm, and some 10% of even 1–10 nm. With a radius of 1 nm the platinum surface is formed from ca. only 40 Pt atoms.

The extremely small surface areas of such "disk" electrodes ensure that within a few μ seconds a hemispherical diffusion field is formed in which the transport coefficients m of the diffusion can be up to 100 $cm s^{-1}$. Thus, for the first time, there is the possibility of determining heterogeneous diffusion rate constants whose values are orders of magnitude greater than 1 $cm s^{-1}$ from the shift and change of shape of steady-state voltammograms (cf. Fig. 1). Indeed, in measurements with nanodes ($r = 1-2$ nm) the authors could determine k_s^0 values of 79 ± 44 cm^{-1} and 220 ± 120 $cm s^{-1}$ for a series of redox pairs, e.g. $[Ru(NH_3)_6^{\ominus}]^{2/3\oplus}$ (H_2O, 0.5 M KCl) and ferrocene ($Fc^{0/\oplus}$) (CH_3CN, 0.3 M nBu_4NClO_4). For the reduction of methylviologen ($MV^{2\oplus/\oplus}$), even fully reversible steady-state curves were obtained with nanodes (= 2.2 nm). This confirms that the total electrode reaction is diffusion-controlled, despite the high transport rates, and that Nernst equilibrium must exist at the electrodes. An estimation of the heterogeneous rate constant gave a minimum value of over 170 ± 80 $cm s^{-1}$. Such high standard rate constants have never been measured. A comparison of this value with the values predicted by the electron transfer theory of *Marcus*[7] shows surprisingly good agreement. Measurements of heterogeneous rate constants by classical electrochemical methods had hitherto mostly furnished significantly lower values, which threw doubt on the reliability of the theoretical predictions. Apparently the high-transport rates hinder the formation of passivating films, which thwart reproducible measurements of heterogeneous rate constants considerably, and naturally lead to low values depending upon the thickness of the passivation layer. The authors have several arguments against objections and criticisms. The assumption that quantum or double-layer effects and migration effects already lead to the observed signals with a 1 nm electrode, is refuted by the fact that Nernst behavior is always observed independently of the electrode size in very rapid redox reactions, whereas, in the case of slow electron transfer, kinetic waves are obtained as expected, already with "larger" electrodes (1 nm $\leqq r \leqq$ 5 nm). Also the assumption that several domains one underneath the other are formed with metallic surfaces during the preparation of the electrodes cannot apply, since the electrode radii in the individual domains would then have to be even smaller than 1 nm. Finally, as always with new methods, good agreement with the results of other methods of measurements is quoted.

Nevertheless, the measuring technique, about which information is only indirectly accessible in the publication, cannot be problem-free. Especially critical in the case of small currents (ca. 1–2 pA) are ripple and noise effects, which cannot be eliminated with standard measuring equipment. Finally, the theory of diffusion at these electrodes is complicated and has been worked out in detail only for simple redox processes not complicated by homogeneous reactions. However, the development of efficient numerical methods[9] also promises remedies here, so that no major hurdles should stand in the way of a routine application of this new dimension in electrochemistry.

Synthesis of a Highly Amphoteric *s*-Indaceno[1,2,3-*cd*:5,6,7-*c'd'*]diphenalene: Switching between Diatropism and Paratropism Due to Changes in Oxidation Level**

By *Ichiro Murata,* Shigeru Sasaki, Kay-Uwe Klabunde, Jiro Toyoda,* and *Kazuhiro Nakasuji*

Dedicated to Professor Tetsuo Nozoe on the occasion of his 88th (Beiju) birthday

We have successfully used the phenalenyl group as a crucial unit for the construction of highly amphoteric hydrocarbons such as 1,2-bis(phenalen-1-ylidene)ethane,[1] 1,2-bis(phenalen-1-ylidene)ethene,[2] and pentaleno[1,2,3-*cd*:4,5,6-*c'd'*]diphenalene (PDPL).[3] In addition to these hydrocarbons, *s*-indaceno[1,2,3-*cd*:5,6,7-*c'd'*]diphenalene (IDPL, **1**) is also expected to be a highly amphoteric hydrocarbon, since the neutral state of **1** will be destabilized by the unfavorable electronic contribution of a nonaromatic *s*-indacene system[4] and the redox states $\mathbf{1}^{2\oplus}$, $\mathbf{1}^{\bullet\oplus}$, $\mathbf{1}^{\bullet\ominus}$, and $\mathbf{1}^{2\ominus}$ will be substantially stabilized by the formation not only of two terminal phenalenyl segments but also of a central benzene structure with loss of the *s*-indacene conjugation (Fig. 1). We now report the synthesis of **12**, a diisopropyl derivative of **1**, and switching between diatropism and paratropism due to changes in oxidation level.

We chose dibromoacenaphthyleno[1,2-*k*]fluoranthene (**4**) as a key intermediate which might be converted in a straightforward fashion into the final skeleton. Diels–Alder reaction of 5-bromoacenaphthylene (**2**)[5] and 3-bromo-7,9-diisopropylcyclopent[*a*]acenaphthylen-8-one (**3**),[6] followed by decarbonylation and aromatization with *p*-chloranil, afforded an isomeric mixture of the 3,10- and 3,11-dibromo compounds **4**.[7] The formation of two regioisomeric dibromides at this stage was not of long-range consequence, since they converged to a single symmetrical product in the final stage

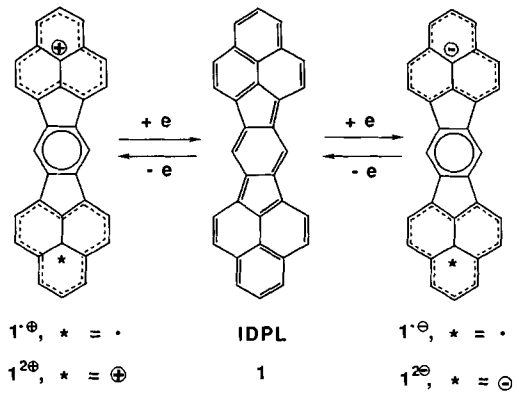

Fig. 1. Expected redox behavior of **1**.

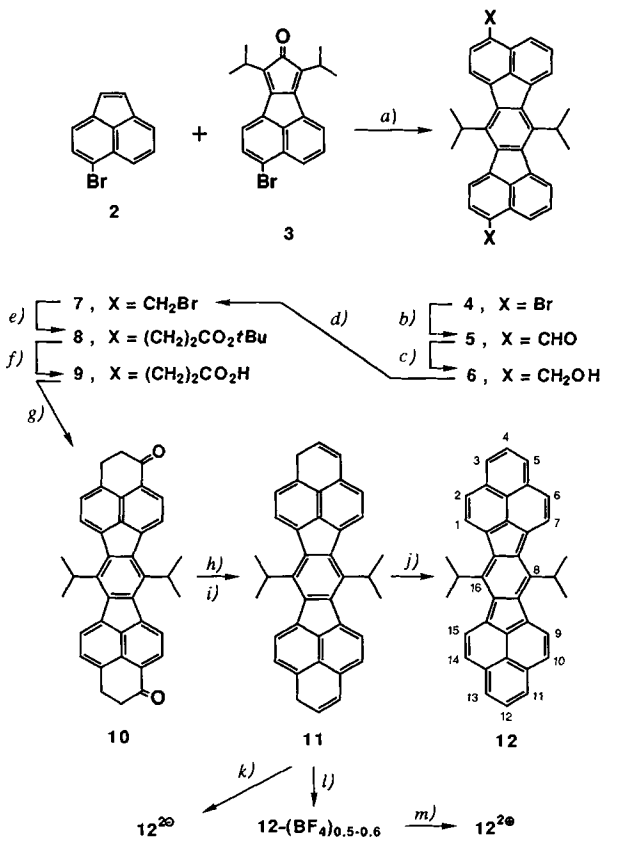
(**11**→**12**). Conversion of dibromide **4** to the bis(bromomethyl) derivative **7** was performed by the usual method. Compound **7** was transformed into the bispropionic acid **9** by the Schlessinger two-carbon elongation procedure.[8]



Scheme 1. Synthesis of **12**, $\mathbf{12}^{2\oplus}$, and $\mathbf{12}^{2\ominus}$. Reaction conditions: a) **2** (1.4 equiv.) + **3** (1 equiv.), reflux, xylene, 3 h, then *p*-chloranil (1.2 equiv.), xylene, reflux 2 h, 74%. b) *n*BuLi (2.8 equiv.), DME, −60 °C, 1.5 h, then PhN(CH$_3$)CHO (4.9 equiv.), −50 → −40 °C, 1.5 h, 49%. c) NaBH$_4$ (2.2 equiv.), EtOH, reflux 2 h, 96%. d) PBr$_3$ (2.5 equiv.), benzene, reflux, 15 min, 80%. e) *n*BuLi, (CH$_3$)$_2$CHNH$_2$ (1.2 equiv.), CH$_3$CO$_2$*t*Bu (1.6 equiv.), THF, −78 °C, then **7** (0.34 equiv.), 2 h, 93%. f) Cat. *p*-TosOH, benzene, 1.5 h, 97%. g) Excess SOCl$_2$, reflux, 40 min, then AlCl$_3$ (9 equiv.), CH$_2$Cl$_2$, −78 → −40 °C, 5 h, 78%. h) NaBH$_4$ (3 equiv.), CH$_2$Cl$_2$ + EtOH, room temperature, 2 h. i) Cat. β-C$_{10}$H$_7$SO$_3$H, benzene, reflux, 15 min, 55%. j) *p*-Chloranil (1.14 equiv.), benzene, room temperature, 20 min, then reflux 25 min, 81%. k) K mirror, under vacuum, [D$_8$]THF, −78 °C, 1 week. l) Ph$_3$CBF$_4$ (4.5 equiv.), CH$_2$Cl$_2$, 74%. m) Conc. D$_2$SO$_4$.

[**] This work was supported by a Grant-in-Aid for Scientific Research on Priority Areas (No. 01648003) from the Ministry of Education, Science and Culture, Japan. We thank Professor *Jun-ichi Aihara* for the ring current calculations. *K.-U. K.* thanks the Japan Society for the Promotion of Science for a postdoctoral fellowship.

Friedel–Crafts cyclization of **9** gave the diketone **10**, which was converted into the dihydro compound **11** through a reduction–dehydration sequence. Dehydrogenation of **11** with *p*-chloranil in benzene provided the desired **12** as a green crystalline solid.[9]

Investigation of the electrochemical behavior of **12** by cyclic voltammetry[10] revealed two reversible reduction waves ($E_1^{red} = -0.48$ V, $E_2^{red} = -1.07$ V) and two irreversible oxidation waves ($E_1^{ox} = 0.62$ V, $E_2^{ox} = 0.84$ V). If we adopt the span of the oxidation and reduction potentials, $E^{sum} = E^{ox} + (-E^{red})$, as an experimental measure of the amphotericity of a molecule, diisopropyl-IDPL **12** may be considered a highly amphoteric hydrocarbon,[11] although $E_1^{sum} = 1.10$ V observed for **12** is slightly greater than that of PDPL ($E_1^{sum} = 0.99$ V).[3] Interestingly, the E_2^{sum} value (1.91 V for **12**) is smaller than that of PDPL (2.19 V).[3] This finding suggests substantial stabilities for both the doubly charged species $\mathbf{12}^{2\oplus}$ and $\mathbf{12}^{2\ominus}$.

Unexpectedly, treatment of the dihydro compound **11** with excess trityl tetrafluoroborate in dichloromethane afforded, instead of the mono- or dication salts, a radical-cation salt with nonstoichiometric composition, **12**-$(BF_4)_{0.5-0.6}$[12] in 74% yield, which, on dissolution in concentrated D_2SO_4, gave the dication $\mathbf{12}^{2\oplus}$ as a dark blue solution. On the other hand, the dianion $\mathbf{12}^{2\ominus}$ could be generated as a bluish purple solution when **11** was treated with potassium mirror[13] under vacuum at −78 °C for a week. The ^{1}H NMR chemical shifts for the three redox states $\mathbf{12}^{2\oplus}$, **12**, and $\mathbf{12}^{2\ominus}$ are compared in Table 1.[14] The most striking

Table 1. ^{1}H NMR chemical shifts for $\mathbf{12}^{2\oplus}$, **12**, and $\mathbf{12}^{2\ominus}$.

Proton	$\mathbf{12}^{2\oplus}$ [a]	**12** [b]	$\mathbf{12}^{2\ominus}$ [c]
CH_3	1.47	1.49 1.50 [d]	2.09
CH	3.40	3.67	5.45
H-1, 7, 9, 15	7.60	7.11 7.20 [d]	8.39
H-2, 6, 10, 14	8.22	6.99 7.01 [d]	6.95
H-3, 5, 11, 13	8.25	7.09	7.01
H-4, 12	7.50	6.95	7.14

[a] Measured in D_2SO_4 at 60 °C, 400 MHz. [b] Measured in CS_2 + [D_6]acetone (4:1) at −80 °C, 500 MHz. [c] Measured in [D_8]THF at 0 °C, 400 MHz. [d] Nonequivalence of these protons is presumably due to the restricted rotation of two isopropyl groups. Indeed, the spectra of $\mathbf{12}^{2\oplus}$, **12**, and $\mathbf{12}^{2\ominus}$ are temperature-dependent.

feature is that, despite the shielding caused by the two negative charges, the isopropyl protons (both CH_3 and CH), as well as the protons at the 1-, 7-, 9-, and 15-positions of $\mathbf{12}^{2\ominus}$, unexpectedly appear at lower field than those of the corresponding protons in the dication $\mathbf{12}^{2\oplus}$. Nevertheless, the chemical shifts of the remaining ring protons of $\mathbf{12}^{2\ominus}$ are comparable to those of the neutral species **12**. These findings clearly suggest the effect of a diamagnetic ring current in the dianion $\mathbf{12}^{2\ominus}$, which possesses a conjugated periphery of 30 π electrons. This aromatic system is only weakly perturbed by the inner two double bonds.[15] In contrast, the dication $\mathbf{12}^{2\oplus}$, which corresponds to a two-electron oxidation state of the highly amphoteric hydrocarbon **12**, exhibits paratropism, even though it has 4n + 2 π electrons both in the whole molecule (30 π) and in the periphery (26 π).

London–McWeeny ring current calculations,[16] based on the Hückel approximation, were performed on the parent systems $\mathbf{1}^{2\oplus}$, **1**, and $\mathbf{1}^{2\ominus}$. They suggest that the IDPL dianion $\mathbf{1}^{2\ominus}$ should have pronounced diamagnetic ring currents mainly along the periphery of the molecule,[15] whereas the IDPL dication $\mathbf{1}^{2\oplus}$ should show strong and weak paratropism at the central *s*-indacene and the terminal benzene rings, respectively. Currently, we are studying the intriguing solid-state properties of **12** and **12**-$(BF_4)_{0.5-0.6}$.

Tetra-*tert*-butyltetraboratetrahedrane

By Theo Mennekes, Peter Paetzold, Roland Boese,* and Dieter Bläser*

Davan and *Morrison*[1] obtained the glassy compound B_4R_4 (R = *t*Bu), which contains extremely deshielded boron

[*] Prof. Dr. P. Paetzold, T. Mennekes

atoms ($\delta(^{11}B) = 135.1$),[2] by reaction of LiR with tetrachlorotetraboratetrahedrane, B_4Cl_4. *Klusik* and *Berndt*[3] reduced di-*tert*-butyldichlorodiborane(4), Cl–B(R)–B(R)–Cl, with Na/K alloy to generate mostly a radical anion, $[B_4R_4]^{\cdot\ominus}$, which they investigated by ESR spectroscopy and to which they assigned a four-membered ring structure. The reaction solution showed a ^{11}B NMR signal at $\delta = 135.7$, presumably due to the uncharged molecule B_4R_4. The structure of B_4R_4 was previously unknown, although its formation from the tetrahedrane B_4Cl_4 points to a tetrahedral structure; however, the interconvertibility of the tetrahedrane and cyclobutadiene structures of the carbon analogues C_4R_4[4] made the cyclobutadiene structure a possibility for B_4R_4 as well.

We have now reduced RBF_2 in pentane with Na/K alloy (M) and thereby obtained B_4R_4 as a yellow solid in 79% yield [(Eq. (a)].

$$12\,RBF_2 + 8\,M \rightarrow B_4R_4 + 8\,M[RBF_3] \qquad (a)$$

The NMR spectra of our product in $CDCl_3$ display only one NMR signal for each element: $\delta(^1H) = 1.00$ (s), $\delta(^{11}B) = 135.4$, $\delta(^{13}C) = 28.2$ (q); the NMR signal of the B-bonded ^{13}C atom, which, as expected, is very broad, could not be resolved. A broad UV absorption with a maximum at 282.8 nm ($\varepsilon = 5012$, in isooctane) is responsible for the yellow color.

The X-ray structure analysis (Fig. 1) revealed that B_4R_4 is indeed a tetrahedrane.[5] The molecular symmetry C_2 of the central B_4C_4 framework deviates only slightly from the ideal T_d symmetry: the values for the B–B bond lengths (1.699(6)–1.714(4) Å) the angles in the cluster triangles (59.5(2)–60.4(2)°), and the angles between the edges of the polyhedron and the B–C bonds (143.5(2)–146.8(1)°, ideal value 144.74°) lie within narrow ranges. In the tetrahedrane B_4Cl_4 (point group in the crystal: D_{2d}), the two different B–B distances (1.69(4) and 1.71(4) Å) lie in the same range as those in B_4R_4.[6] The molecules B_4R_4 and C_4R_4,[7] which certainly are structurally analogous in the gas phase, also exhibit similarities in the crystalline modifications isolated and characterized in each case.[8] Thus, the vibrational amplitudes in the central B_4C_4 and C_4C_4 frameworks are relatively small and nearly isotropic, whereas they are large and strongly anisotropic for the twelve peripheral C atoms. Conformational interactions between the *t*Bu groups are less important in B_4R_4, since the mean B–B distance of 1.707 Å is significantly larger than the mean C–C distance of 1.485 Å in the C_4 tetrahedron. We therefore ascribe the anisotropic vibrations of the methyl groups of B_4R_4 to normal torsional vibrations around the B–C axis. In our opinion, an "enantiomeric disorder", which, in the case of C_4R_4, could change a structure of near T symmetry to one of near T_d symmetry, is ruled out for B_4R_4.

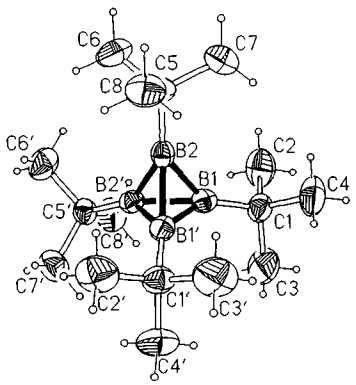

Fig. 1. Molecular structure of B_4tBu_4. The C_2 axis is perpendicular to the B1–B1′ and B2–B2′ bonds. Selected distances [Å] and angles [°] (standard deviations in parentheses): B1-B1′ 1.699(6), B2-B2′ 1.705(6), B1-B2 1.708(4), B1-B2′ 1.714(4), B1-C1 1.570(4), C1-C2 1.537(4), C1-C3 1.538(4), C1-C4 1.536(4), B2-C5 1.576(4), C5-C6 1.543(4), C5-C7 1.527(4), C5-C8 1.530(4); B2-B1-B1′ 60.4(2), B2-B1-B2′ 59.8(2), B1′-B1-B2′ 60.1(2), B1-B2-B1′ 59.5(2), B1-B2-B2′ 60.3(2), B1′-B2-B2′ 59.9(2), B2-B1-C1 145.0(2), B1′-B1-C1 143.9(1), B2′-B1-C1 145.2(2), B1-B2-C5 143.9(2), B1′-B2-C5 143.5(2), B2′-B2-C5 146.8(1).

Although the B_4 framework of B_4R_4 is less shielded than the smaller C_4 framework of C_4R_4, B_4R_4 is unusually inert for an organoboron compound with strained B–B bonds. It may be handled for short periods in the air without decomposition, it is insoluble in water and is not attacked by water at the surface, it cannot be hydrogenated with H_2 in the presence of Pd on carbon in toluene, and it does not react with CO or 3-hexyne in toluene, nor with PMe_3 in hexane.

B_4R_4 crystallizes from toluene, but the single crystals decompose when the mother liquor is removed. The structure analysis could be carried out, however, with a crystal embedded in toluene. A so-called diamond–square–diamond rearrangement, in which opposite edges of the tetrahedron undergo planarization to form a square followed by the reverse process from the opposite edges of the square, can hardly be the cause of the instability of the crystal. This planarization involves a HOMO–LUMO crossing, which, according to an ab initio calculation for the parent B_4H_4 exhibits an activation energy of 85 kcal mol^{-1}.[9]

The formation of B_4R_4 according to Equation (a) probably proceeds via an intermediate, F–B(R)–B(R)–F, which gives either a diborane(2), RB=BR, or a longer-chained compound $F-(BR)_n-F$ (n = 3,4) and then the product. If, instead of RBF_2, $R'BCl_2$, containing the extremely bulky group $R' = (Me_3Si)_3C$, is treated with Na/K alloy, then R′B = BR′ is presumably formed as intermediate. This species does not dimerize, but rather is stabilized by double C–H insertion into the B–B bond.[10]

Experimental Procedure

Tetra-*tert*-butyltetraboratetrahedrane: Na/K alloy (1/3; 9.50 g) was added at room temperature to a solution of *tert*-butyldifluoroborane (15.0 g) [11] in 50 mL of pentane. The resulting exothermic reaction caused the mixture to reflux for 10 min. The precipitated salts were collected by filtration at room temperature and washed with 2 × 5 mL of pentane. The filtrate was evaporated to dryness and the residue sublimed at 80 °C/0.005 Torr into a receptacle cooled with liquid nitrogen to afford 2.52 g of pure product.

closo-Azadodecaborane, $NB_{11}H_{12}$ **

By *Jens Müller, Jan Runsink*, and *Peter Paetzold**

Rhombohedrally distorted B_{12} icosahedra are the building blocks of elemental boron, anions with exact icosahedral symmetry are found in solutions of $Na_2[B_{12}H_{12}]$, and well-known examples of the three isomeric dicarbadodecaboranes $C_2B_{10}H_{12}$ are heterododecaboranes containing discrete neutral icosahedral units. The carbon atoms in the latter compounds represent the most electronegative element of coordination number 6 found in molecules. Is it possible to incorporate the still more electronegative element nitrogen as a heteroatom into an icosahedral framework isoelectronic to $C_2B_{10}H_{12}$ and $B_{12}H_{12}^{2\ominus}$ to give a compound with the composition $NB_{11}H_{12}$?

We have repeatedly attempted to carry out such a synthesis in analogy to that of 1,2-$C_2B_{10}H_{12}$, which involves closure of the open *arachno* structure of $B_{10}H_{12}L_2$ (L = Lewis base) by incorporation of the two C atoms of acetylene. Unfortunately, use of iminoboranes[1] such as MeB≡NMe, isoelectronic to acetylene, has been unsuccessful. The iminoboranes undergo oligomerization more rapidly than reaction with $B_{10}H_{12}L_2$. However, our recent preparation of *nido*-$NB_{10}H_{13}$ (**1**)[2] opened up the possibility of closing the *nido* framework of **1** with a BH fragment.[3] Addition of BH_3 to **1** should result in comproportionation of two of the hydridic H atoms of BH_3 with the two protonic bridging H atoms of **1** to give H_2.

Indeed, the open cluster borane **1** can be closed by treatment with an excess of $Et_3N{\cdot}BH_3$ at 140 °C [Eq. (1)]. The initial product was the ionogenic compound **2**, however, formed in quantitative yield.[4] Reaction of **2** with HBF_4 affords the corresponding acid **3**, our target molecule, as a sublimable, colorless solid[5] [Eq. (2)].

The constitution of **3** was established by NMR spectroscopy. Three ^{11}B NMR doublets in a ratio of 5:5:1[5] are indicative of a B_{11} framework with fivefold symmetry and 11 terminal H atoms. The 2D ^{11}B–^{11}B NMR spectrum confirms that a set of five equivalent B atoms (B7 to B11) is bonded to a second such set (B2 to B6) as well as to a single B atom (B12) on the C_5 axis. Moreover, no cross-peak, which would have indicated a bond between B12 and the atoms B2 to B6, is observed. The coupling constants $J_{BH} = 177$, 147, and 150 Hz for B2 to B6, B7 to B11, and B12, respectively, reveal that the B–H bonds in proximity to the N atom are stronger than the others. For *closo*-1-methyl-1-phosphadodecaborane, $MePB_{11}H_{11}$, which is comparable to **3**, the corresponding coupling constants (164, 150, and 150 Hz)[6] show the same trend. The overlapping quartets for the three kinds of H atoms cannot be resolved in the ^1H NMR spectrum; however, their chemical shifts[5] may be determined from the three cross-peaks in the 2D ^{11}B-^1H NMR spectrum. The *N*-bonded H atom gives rise to a 1:1:1 triplet in the ^1H NMR spectrum with $J_{NH} = 62.5$ Hz, a consequence of the symmetrical charge distribution around the ^{14}N atom on the C_5 axis.

The title compound is thus the first cluster molecule containing a sixfold coordinated N atom in the framework.

Experimental Procedure

3: Compound **1** (0.50 g) [2] was dissolved in triethylamine-borane (1.00 g) and the resulting solution was heated at 140 °C for 3.5 h. Removal of the excess $Et_3N{\cdot}BH_3$ in vacuum affords the NMR-spectroscopically pure product **2**, which was dissolved in 5 mL of a 54% solution of HBF_4 in diethyl ether. The solution was extracted with 5 × 20 mL of toluene and the combined toluene extracts were evaporated to dryness. Sublimation of the residue at 50 °C/0.001 Torr gave 0.25 g (47%) of **3**.

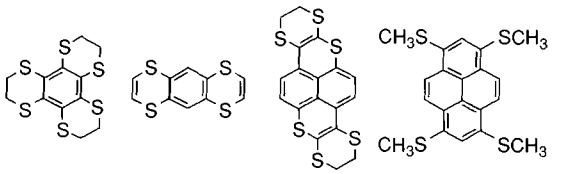
Radical Cation Salts of 1,3,6,8-Tetrakis(methylthio)-pyrene—New Easily Accessible Compounds with High Electrical Conductivity and Excellent Stability**

By *Gerhard Heywang** and *Sigmar Roth*

Dedicated to Professor Rudolf Gompper on the occasion of his 65th birthday

The discovery of the charge-transfer complex formed from tetracyanoquinodimethane (TCNQ) and tetrathiafulvalene (TTF)[1] gave new impetus to the studies begun in the fifties[2] on electrically conducting radical cation salts, which led to the superconducting complexes of bis(ethylenedithio)tetrathiafulvalene (BEDT-TTF).[3] Disadvantages are the long-winded syntheses of the donor molecules (TTF, five steps with overall yield of 55%;[4,5] BEDT-TTF, five steps with overall yield of 35%[6]), and the low stability of the radical cation salts (for example, the halogen complexes of pyrene and perylene cannot be stored[7]).

The search for novel sulfur-containing donor components led to the compounds **1**–**3**.[8–10] The overall yield of the many-step synthesis lies here, as in most cases, below 12%. We now report the title compound, donor ligand **4**, a component easily accessible in large quantities. The radical cation salts from **4** are characterized by a high electrical conductivity and good thermal stability.

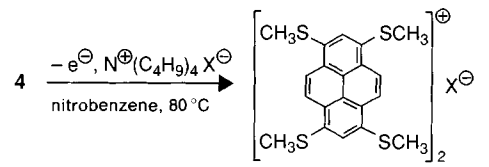


1 **2** **3** **4**

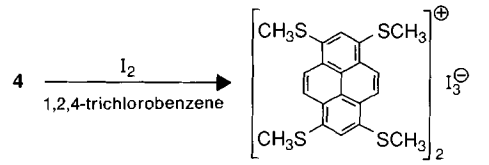
The halogenation of pyrene leads in quantitative yield to 1,3,6,8-tetrahalopyrene,[11] which reacts with sodium methyl sulfide in aprotic solvents to tetrakis(methylthio)pyrene (**4**) with optimal yields of 98%. Electrocrystallization of **4** in the presence of suitable electrolytes gives the radical cation salts **5a**–**c**, with powder conductivities between 10^{-1} and 10^{-2} S cm^{-1}.

Compound **5a** shows single crystal conductivities of 300 to 677 S cm^{-1}, which increase with decreasing temperature. Because of the high mechanical stress of the four point probe, the temperature dependence of the conductivity measurements could only be followed to 260 K.

The reaction of **4** with iodine affords **5d** (pressed pellet, without pressure 5–10 S cm^{-1}). The temperature dependence of the single crystal conductivity is shown in Figure 1. The conductivity increases continually with decreasing temperature till $T = 46$ K, even though a steplike function, in which the conductivity of each successive step is lower than the previous step, is obtained. Our interpretation is that these steps result from microcracks in the crystal, because in one particular crystal the original room-temperature conductivity was reproducible in spite of many such steps in the temperature dependence curve.



5a X = ClO_4 [4.7 × 10^{-2} S cm^{-1}]
5b X = BF_4 [2.5 × 10^{-2} S cm^{-1}]
5c X = PF_6 [3.7 × 10^{-2} S cm^{-1}]



5d

The function of ln σ vs $1/T$ between 46 K and 10 K is strictly linear. The activation energy calculated from such a plot is $kT_0 = 0.011$ eV at $T_0 = 130$ K. For most transitions induced by an electron–phonon interaction, the temperature condition $T_0 = 3.5\ T_1$ holds.[12] This requirement is satisfied relatively well for **5d**.

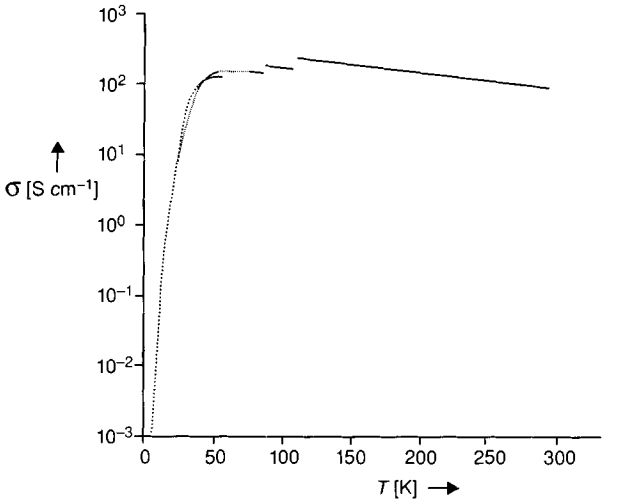


Fig. 1. Temperature dependence of the electrical conductivity of the complex **5d**, measured on a crystal (needle) 0.4 mm long. The crystal broke at 60 K on repetition. Where fewer measurements were made, the line is dotted.

Whereas the TTF–iodine complex decomposes at 180 °C and the corresponding BEDT–TTF complex at 220 °C through reaction of the iodine ion with the donor component, compound **5d** reacts back to **4** above 245 °C by loss of iodine. That the four methylthio substituents are responsible for this stabilizing effect is confirmed by comparison with the iodine complex of the 1,6-bis(methylthio)pyrene described earlier[13] (halfwave potential: 0.96 V[14]), which loses about 1% iodine per day at room temperature (initial conductivity of a pressed pellet is 10^{-2} S cm^{-1}). Cyclovoltammetry yields a potential of $E_1 = 0.65$ V vs Ag/AgCl for **4**.[15] The new radical cation salts probably owe their high stability to the favorable redox potential as well as to the symmetry of **4**.

Diverse radical cation salts of **4** may also be prepared with oxidizing agents such as H_2O_2 and $KMnO_4$ in the presence of suitable anions in aqueous medium to which small amounts of tetrahydrofuran and sulfuric acid have been added. Compound **5a** prepared in the presence of $NaClO_4$ with these oxidizing agents shows the same powder conductivity as the electrochemically prepared sample. Table 1 shows that

Table 1. Comparison of the single crystal conductivities σ [S cm^{-1}] of radical cation salts.

Anion	Cation			
	TTF	BEDT-TTF	**3**	**4**
$I_3^{\ominus}$	100–450 [16]	60–250 [17, 18] 10–50 [20] [a]	42 [19]	110

[a] First values represent the α modification, second values the β modification. [b] Conductivity of a pressed pellet.

the radical cation salts of the donor components **4** have the highest single crystal conductivities.

Experimental Procedure

4: 46.6 g of 1,3,6,8-tetrabromopyrene[11] was added in small portions to 29 g of sodium methyl sulfide in 800 mL dimethylformamide in a 2-L three-necked flask and allowed to react for 15 h at 100 °C. Thereafter 800 mL of water was added, and the yellow precipitate was filtered, washed with methanol and dried under vacuum. Yield: 31.5 g (91%). In *N,N'*-dimethyl-2-imidazolidinone at room temperature the yield of **4** is 98%. M.p. 270 °C; IR (KBr): ν[cm^{-1}]: 1595, 1484, 1440, 1280, 1225, 1096, 1008, 968, 848, 819; satisfactory elemental analysis (C,H,S); ^{1}H NMR (200 MHz, D_2SO_4, 20 °C, TMS): δ = 2.60 (s, 12H, S-CH_3), 6.90 (s, 2H, -CH=), 8.36 (s, 4H, -HC=CH-).

5a: In a 100-mL electrolysis cell with two platinum electrodes one centimeter apart, a solution of 386 mg (1 mmol) **4** and 1.71 g (5 mmol) tetrabutylammonium perchlorate in 100 mL nitrobenzene was electroyzed at 80 °C for 24 h with a current of 1.5 mA. A cell potential of 1.6 V was observed. At the anode 186 mg of up to 1 mm long, black, lustrous crystals of **5a** form (42.5% yield, current efficiency 16%). M.p. 230° (decomp); satisfactory elemental analysis (C, H, S, Cl); IR (KBr): ν[cm^{-1}]: 1095 ($ClO_4^{\ominus}$); ESR: g = 2.0094 ($\nu_{1/2}$ = 14.5 G), 0.004 spins per complex (reference: "strong pitch" from Bruker). The X-ray structure of **5a** was determined [23].

5d: To a solution of 772 mg (2 mmol) of **4** in 10 mL of 1,2,4-trichlorobenzene at 120 °C was added a solution of 508 mg (2 mmol) iodine in 10 mL of 1,2,4-trichlorobenzene. Black crystals with a golden luster separated immediately. The solution was cooled and filtered by suction. The crystals were washed with methylene chloride. The quantitative yield (1.15 g) was obtained. Satisfactory elemental analysis (C, H, S, I); IR (KBr): no bands; ESR: g = 2.0054 ($\nu_{1/2}$ = 14 G), 0.007 spins per complex (reference "strong pitch" from Bruker); for X-ray structure of **5d** see [23].

β-Lithio Ketone Enolates: Generation and Reactions with Electrophiles**

By *Hiroyuki Nakahira, Ilhyong Ryu,* Masanobu Ikebe, Nobuaki Kambe*, and *Noboru Sonoda**

It is known that β-lithio ketones (**1**) are hardly any use in C–C bond-forming reactions because of their ready isomerization to the more stable lithium cyclopropoxides **2** (eq. 1).[1] Thus, synthetic equivalents of **1**, the β-acyl carbanion, have been extensively studied.[2] We suspected that such a bond-forming process could be more conveniently performed with the enolate form (**3**) of β-lithio ketones (**1**). Reaction via intermediate **3** has the added advantage that a nucleophilic site at the α-position is available, which would allow the sequential β- and α-dialkylation of ketones (eq. 2). Although several dilithio species related to **3** having anion-stabilizing substituents in the β-position have been reported to date,[3] the simplest, unfunctionalized dilithio species **3** itself has remained unexplored.[4, 5] We now report an efficient method for the generation of β-lithio ketone enolates (**3**) from β-trialkylstannyl ketones (**5**)[6] and their use as α,β-acyl dicarbanions (eq. 3).

Deprotonation of β-stannyl ketone (**5a**) by lithium diisopropylamide (LDA) in THF afforded the *Z*-form enolate selectively. The subsequent treatment of the enolate with *n*BuLi at −78 to 0 °C for 30 min resulted in Li-Sn exchange to furnish β-lithio ketone enolate **3a** with complete retention of the stereochemistry. Further reaction with Me_3SiCl provided **6a** in 91% yield (*E*/*Z* = 0/100, see also Table 1). On the other hand, enolate formation on deprotonation of **5b** by LDA lacked both regio- and stereoselectivity. However, the use of lithium bis(trimethylsilyl)amide led to selective gener-

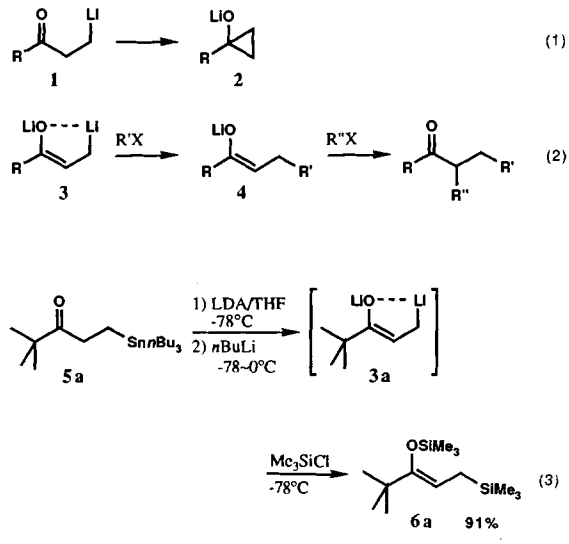
Suita, Osaka 565 (Japan)

[**] This work was supported in part by Grant in Aid for Scientific Research from the Japanese Ministry of Education, Science, and Culture.



ation of (*Z*)-enolate, which was then subjected to Li-Sn exchange to give β-lithio ketone (*Z*)-enolate **3b** (Table 1, entry 4). As shown in Table 1 entry 8, β-lithio ketone enolate **3d**, which has a homoallyl structure, could also be generated by regioselective deprotonation of **5d** with LDA followed by Li-Sn exchange. In this case, however, a prolonged time (3 h) was required for the complete conversion to **3d**. Li-Sn exchange in the (*E*)-enolate of β-stannyl ketone was extremely slow, which suggests that stabilization arising from intramolecular five-membered ring complexation is a crucial factor for this exchange.

In accord with our premise (eq. 2) β-alkylation of **3** with alkyl bromides took place more rapidly than α-alkylation, allowing the direct conversion to β-alkylated enolates (**4**). Thus, treatment of **3a** with 1-bromopentane at −78 to −20 °C for 1 h followed by proton quenching gave the β-alkylated ketone **7** in 71% yield (entry 2). Similarly, the β-allylated ketone **9** was prepared by treatment with prenyl bromide (−78 °C, 5 min) in 53% yield (entry 5). β-Alkylated enolates (**4**) can undergo a number of useful transformations developed for metal enolates.[7] Further treatment with Me_3SiCl after β-alkylation of **3b** provided β-alkylated (*Z*)-enol silyl ether **10** in 68% yield (entry 6). The β-alkylation/α-allylation sequence leading to **8** was also successful (entry 3). Important spectroscopic data for compounds **6**–**10** are collated in Table 2.

Table 1. Generation of β-lithio ketone enolates (**3**) and their reactions with electrophiles[a].

Entry	Substrate **5**	β-Lithio ketone enolate **3**	Electrophile (equiv.) conditions	Product (yield [%]) [b]

[a] Elemental analyses or high-resolution mass spectra were obtained for all new compounds.

The high efficiency of the synthesis steps via the β-lithio ketone enolates (**3**), coupled with the simplicity of the experimental procedure, makes this reaction route a promising tool for α,β-functionalization of ketones.

Experimental

Typical procedure (Table 1, entry 2): **5a** (403 mg, 1.0 mmol) was added to a cooled solution (−78 °C) of LDA—prepared from diisopropylamine (0.184 mL, 1.3 mmol) and *n*BuLi (1.58 M hexane solution, 0.76 mL, 1.2 mmol)—in THF (5 mL), and the solution was stirred for 2 h at −78 °C. *n*BuLi (1.58 mL, 2.5 mmol) was added by syringe. The reaction mixture was allowed to warm to 0 °C and stirred for 30 min. Thereafter it was cooled again to −78 °C, and 1-bromopentane (453 mg, 3.0 mmol) was added. The mixture was allowed to warm to −20 °C and stirred for 1 h. Dilution with ether followed by washing with water, drying ($MgSO_4$), concentration, and flash chromatography (SiO_2, *10% ether in pentane*) gave **7** *(130 mg, 71%)*.

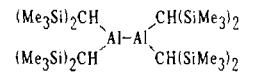
$K_2[Al_{12}iBu_{12}]$, a Compound with Al_{12} Icosahedra**

By *Wolfgang Hiller, Karl-Wilhelm Klinkhammer, Werner Uhl,** and *Jürgen Wagner*

The reduction of chlorodiisobutylaluminum with potassium to give the corresponding tetraisobutyldialuminum(*Al-Al*) was first described in 1976.[1, 2] However, the proposed structure was essentially based on only a deuterolysis experiment in which the amount of liberated D_2 was measured; isolation of the pure compound has not yet been achieved. The only compound with an Al–Al bond so far characterized spectroscopically and by crystal structure analysis is tetrakis[bis(trimethylsilyl)methyl]dialuminum(*Al-Al*) (**1**).[3]



1

The reaction mentioned above, which was carried out in *n*-hexane, results in formation of a brown precipitate consisting mostly of potassium chloride. Extraction of this precipitate with toluene, however, gives a low but reproducible yield of a further product, which crystallizes at −30 °C as dark red octahedra. The crystal structure determination showed that this product was dipotassium *closo*-dodecaisobutyldodecaaluminate, $K_2[Al_{12}iBu_{12}]$ (**2**), in which Al_{12} icosahedra are present (Fig. 1). The crystals of **2** contain toluene, which is completely removed over several hours under vacuum (10^{-3} Torr) at room temperature. However, the crystals thereby become brittle and break upon even gentle handling. We obtained single crystals suitable for X-ray diffraction analysis by drying the crystals under vacuum at −30 °C; their composition was approximately $K_2Al_{12}iBu_{12} \cdot 1.2\ C_7H_8$ according to integration of the ^1H NMR spectrum. Whereas, under normal conditions, **2** completely decomposes within 30 min upon exposure to an X-ray beam, the diffraction pattern can be measured at −65 °C without any significant change in the intensities of the control reflections.

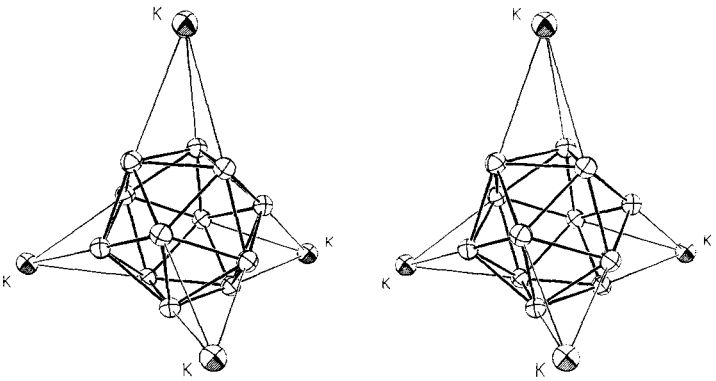


Fig. 1. Stereoscopic drawing of the Al_{12} icosahedron (thermal ellipsoids at 30% probability). For clarity, only the Al and K atoms are shown. Selected bond lengths [pm] and angles [°]: Al-Al 267.9(5), 268.0(4), 269.6(5), K-Al 400.4(3); Al-Al-Al 59.8(1), 60.0, 60.4(2).

Compound **2** crystallizes in the centrosymmetric cubic space group $Fd\bar{3}$ with eight formula units per unit cell.[4] There are three slightly different bond lengths between the aluminum atoms of the icosahedron (267.9(5), 268.0(4), and 269.6(5) pm). Moreover, the bond angles between the triangular sides, which exhibit a maximum deviation of 0.4° from the ideal value of 60°, are consistent with nearly undistorted icosahedral symmetry. The Al–Al bonds are only slightly longer than that in the Al_2 compound **1** (266.0 pm).[3]

A potassium atom lies on a threefold axis above each of four faces of the icosahedron and is coordinated by three α-C atoms of isobutyl groups. As shown in Figure 2, each potas-

sium atom bridges two icosahedra, so that its coordination number is six with respect to carbon (C1), resulting in formation of a trigonal antiprism. Thus, the solid-state structure consists of a three-dimensional network in which the icosahedral centers are surrounded tetrahedrally by potassium atoms and the cations are coordinated by the Al_{12} clusters in a linear fashion in analogy to a part structure of Cu_2O.[5] The K–C distance (323 pm) is consistent with the standard value reported in the literature.[6] Two values can be distin-

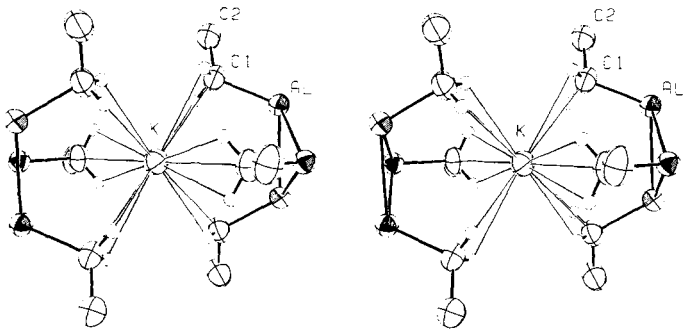

Fig. 2. Stereoscopic drawing of the environment of the potassium ions (thermal ellipsoids at 30% probability). For clarity, the methyl groups (C21 and C22) and the hydrogen atom H21 on C2 are omitted. Important distances [pm] and angles K-Cl 322.6(9), Al-C1 199.9(9), C1-C2 153(1); C1-K-C1 180.0, 86.8(2) (2×), 93.2(2) (2×), Al-C1-K 97.3(3), Al-C1-C2 117.5(7).

guished in crystalline methylpotassium:[7] short contacts with a mean value of 298.5 pm, where the lone pair of the carbanion is directed toward the cations, and longer contacts of 337 pm through C–H σ bonds, which correspond more closely to the bonding in **2**. Shorter distances between potassium and carbon than those in **2** are also observed from the powder data for the structure of potassium tetramethylaluminate (315, 348 pm) and -gallate (294, 352 pm).[8] The hydrogen atoms on the bridging C1 are 272 and 296 pm from the potassium atom. A comparable interaction between potassium and C-H σ bonds was recently found in potassium{dichlorobis[bis(trimethylsilyl)methyl]aluminate}.[9] The Al–C bond length (199.9 pm) is considerably shorter than that usually found for bridged systems and lies in the widespread region of Al–C single bonds. In agreement with the K–C–Al bridge discussed here, the IR spectrum exhibits broad bands for the Al–C and C–C stretching modes.

In the framework made up of potassium atoms and Al_{12} icosahedra, channels extending parallel to the face diagonals are formed and incorporate crystal toluene. However, the toluene molecules are so strongly disordered that their positions cannot be completely determined. For a maximum residual electron density of 0.5 $eÅ^{-3}$, only the position of a six-membered ring fragment could be determined and then refined by restriction of the bond lengths. Its influence on the *R* value and standard deviation is small, however. We are currently attempting to obtain a derivative of **2** that allows us to circumvent this disorder.

Compound **2** is surprisingly stable in air; it remains crystalline for about 2 h without noticeable change, but then a colorless substance, presumably $Al(OH)_3$, begins to grow on the crystal. Under inert atmosphere, **2** is thermally stable to about 150 °C, above which rapid decomposition occurs with deposition of aluminum.

Compound **2** corresponds to $[B_{12}H_{12}]^{2\ominus}$ in its cluster structure and number of valence electrons and, like that compound, obeys the Wade rules for a *closo* structure. $K_2[B_{12}H_{12}]$ crystallizes in the cubic space group $Fm\bar{3}$, but displays a different arrangement of anions and cations with a potassium ion coordinated by 24 hydrogen atoms.[10]

Experimental Procedure

All operations were carried out under purified argon in dry solvents. Chlorodiisobutylaluminum (8.5 g, 48 mmol) was dissolved in 40 mL of *n*-hexane and treated with potassium (1.9 g, 48 mmol). The resulting reaction mixture was stirred for three days at 0 °C and for one day at room temperature. It was then filtered and the residue was treated with 40 mL of toluene. Concentration of the solution thereby obtained to roughly one-third of its initial volume and cooling to −30 °C resulted in formation of dark red crystals of **2**, which were dried under 10^{-3} Torr at room temperature. Yield: 62 mg (1.5% based on Al). Dec. (under argon) at 150 °C. ^1H NMR (60 MHz, C_6D_6): δ = 2.35 (m; CH), 1.40 (d, *J* (H,H) = 6.2 Hz; CH_3), 0.60 (d, *J* (H,H) = 6.4 Hz; CH_2). $^{13}C\{^1H\}$ NMR (62.896 MHz, C_6D_6): δ = 30.9 (CH), 28.8 (CH_3), 17.1 (CH_2). IR (Nujol; CsBr disc) [cm^{-1}]: $\tilde{\nu}$ = 1330 (s), 1315 (s, δCH_3), 1250 (w), 1210 (m), 1165 (s, br., ϱCH_3), 1070 (w), 1045 (w), 1020 (s ν(as)CC), 950 (m), 920 (m), 840 (m), 820 (s, br.), 780 (sh, ν(s)CC), 730 (s), 700 (s), 670 (s, br.), 610 (s, br. νAlC), 560 (w), 490 (w), 470 (m), 440 (m), 400 (m), 375 (m δCC, δAlC (νAlAl?)). A Raman spectrum could not be recorded.

Double Stereodifferentiation in Carbohydrate Coupling Reactions: The Mismatched Interaction of Donor and Acceptor as an Unprecedented Factor Governing the α/β Ratio of Glycoside Formation**

By *Nynke M. Spijker* and *Constant A. A. van Boeckel**

One century after the first glycoside syntheses of *Michael*[1] and *Fischer*,[2] the stereochemical outcome (α/β ratio) of carbohydrate coupling reactions is still difficult to control. The best-established method for stereoselective car-

[**] We wish to thank Mr. *G. N. Wagenaars* for recording the NMR spectra

bohydrate coupling reactions, the Koenigs–Knorr procedure (1901),[3] is based on the participation of a group at C-2 of the glycosyl donor to direct the 1,2-*trans* glycosidic bond formation. Although the experimental conditions of this procedure have been revised progressively,[4] the basic principle of neighboring group participation has not been obliterated.[5]

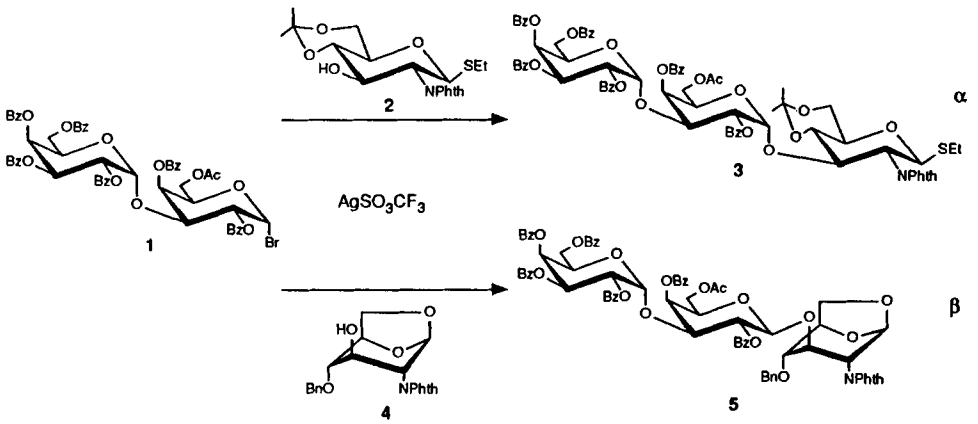
Another breakthrough was realized by *Lemieux* et al.[6] and *Paulsen* et al.[7] in the seventies. They demonstrated that coupling reactions of various glycopyranoside donors under "in situ anomerization" conditions lead to 1,2-*cis*-glycosidic bonds. Furthermore, for the preparation of 1,2-*cis* glycosidic bonds in D-manno- and L-rhamnopyranosides other methods[8] have been introduced which use insoluble silver salt promoters.

The yield and the stereochemical outcome of the coupling strategies outlined above are frequently unsatisfactory. For this reason much attention has been paid to additional factors that may act on glycosylations, such as the type of the leaving group at the anomeric center (e.g. bromide,[7] fluoride,[9] thioether,[10] imidate,[11] or pentenyl ether[12]), the promoter,[7] the substituents at the carbohydrates,[7, 13] the solvent, and the temperature. Although these studies provided much empirical knowledge to improve glycosylations, carbohydrate chemists are still confronted with coupling reactions that proceed in low yields and give poor α/β ratios.

leading to the α-bond. That the stereochemical outcome (α/β ratio) of an interglycosidic bond formation may be affected by unfavorable steric interactions in either the α- or β-transition state, can be corroborated by applying the principle of double stereodifferentiation.[15] When stereochemical interactions between a chiral carbohydrate donor and a chiral carbohydrate acceptor are a dominant factor during the formation of the interglycosidic bond, we expect different α/β ratios in coupling reactions of L- and D-donors with a D- or L-acceptor respectively, because sterically matched and sterically mismatched pairs are possible in the individual transition states (i.e. L-α-D, L-β-D/D-α-D, D-β-D and their mirror images).

To substantiate this hypothesis we performed coupling reactions of the easily accessible 2,3,4-tri-*O*-benzoyl-6-deoxy-α-D-galactopyranosyl bromide (**6**)[16] and its L-isomer (**7**) (derived from L-fucose) with glycosyl acceptor **2** (Scheme 2).

Reaction of the D-glycopyranosyl bromide **6** with **2** in the presence of silver trifluoromethanesulfonate and 2,6-di-*tert*-butylpyridine, under the conditions described above, afforded the α-coupled disaccharide **8α** in 58% yield and the β-coupled product **8β** in 29% yield (α/β ratio: 2/1), whereas the coupling of the L-glycopyranosyl bromide (**7**) with **2** under the same conditions gave only 7% yield of **9α** and 61% of **9β** (α/β ratio: 1/8.4).[17]



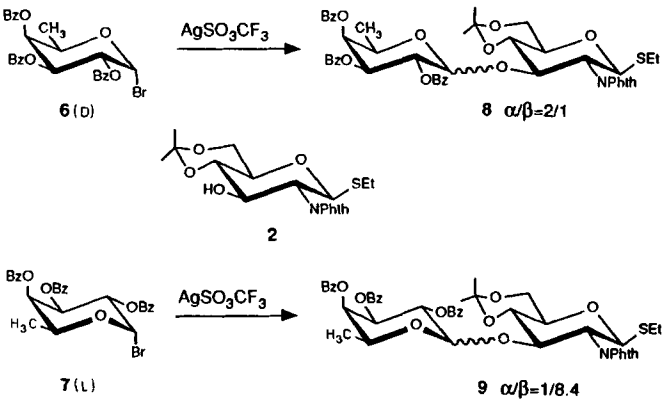
Scheme 1. Bz = benzoyl, Bn = benzyl, Ac = acetyl, Phth = phthaloyl, Et = ethyl.

We now report a most intriguing example of a carbohydrate coupling with an unexpected stereochemical outcome. The coupling between donor **1** and acceptor **2** in dichloromethane in the presence of silver trifluoromethanesulfonate, 2,6-di-*tert*-butylpyridine (0.8 equiv) and molecular sieves 4 Å gave after 20 minutes at − 50 °C *exclusively* α-coupled product **3**[14] in 23% yield (Scheme 1). Thus, although a participating group is present at C-2 of donor **1** to direct the β-glycoside formation in the synthesis of the oligosaccharide Galα(1-3)Galβ(1-3)GlcNAc, only the α-interglycosidic bond was formed.

Which factor outweighs the well-established β-directing effect of the benzoyl participating group? Even other activating groups at the anomeric center of **1** (e.g. fluoride, imidate), and different promoters (e.g. silver silicate) did not lead to the expected β-glycoside formation.

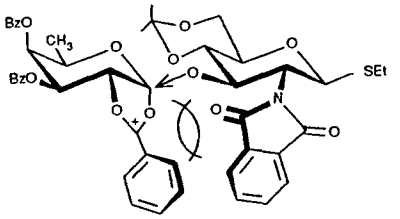
We reasoned that severe steric hindrance between the donor **1** and acceptor **2** occurs in the transition state leading to the β-interglycosidic bond, but not in the transition state

These results clearly demonstrate the influence of double stereodifferentiation on the α/β ratio of this coupling reac-

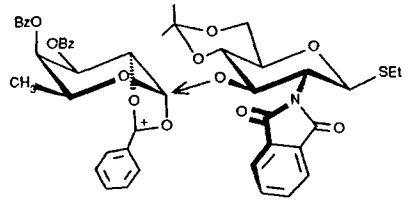


Scheme 2.

tion. Furthermore the glycosidic bonds of the products do not isomerize (anomerization) under the applied reaction conditions (the solution may become slightly acidic). Thus donor **6** and acceptor **2** apparently form a mismatched pair in the transition state leading to the β-glycoside because of disfavorable steric interactions, whereas donor **7** and acceptor **2** form a matched pair during the formation of the β-coupled product. Molecular modeling shows (Fig. 1) that during the formation of the β-glycoside considerable steric hindrance arises between the phthalimido group of **2** and the benzoyl ester at C-2 of **6** (D), but not between the phtalimido group of **2** and **7** (L). On contemplating these results we can explain the unexpected stereochemical outcome of the coupling reaction between **1** and **2** in terms of a mismatched pair for the β-glycoside transition state. The undesired α-glycoside **3** is then formed through an intermediate oxocarbenium ion[6, 7] in which the benzoyl group does not participate.



6(D)+**2**
mismatched pair

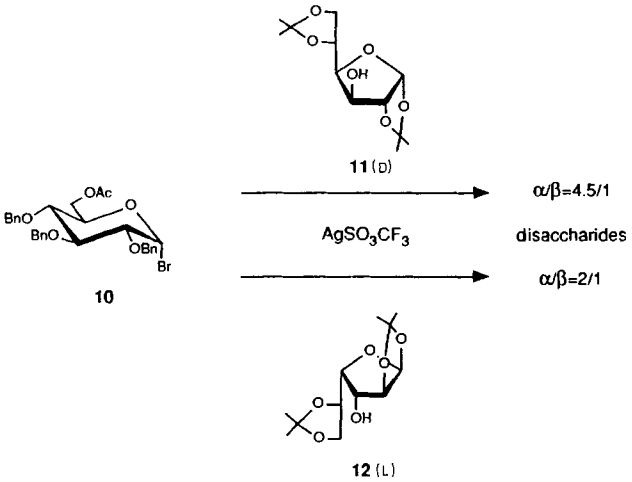


7(L)+**2**
matched pair

Fig. 1. During the formation of the β-glycoside, considerable steric hindrance arises between the phthalimido group of **2** and the benzoyl ester of **6**(D), but not between **2** and **7**(L).

We now reasoned that to synthesize the β-glycosidic bond of the oligosaccharide Galα(1-3)Galβ(1-3)GlcNAc a glycosyl acceptor has to be used that does not form a sterically mismatched pair during β-coupling with donor **1**. To this end, we used 1,6-anhydrosugar **4**[18] as glycosyl acceptor, because its hydroxyl group is oriented differently towards the bulky protecting groups than the hydroxyl group of **2**. Thus, **1** was coupled with **4** in the presence of silver trifluoromethanesulfonate and 2,6-di-*tert*-butylpyridine (Scheme 1). Indeed, in this glycosylation only β-coupled trisaccharide **5**[19] was formed, in 75% yield. Since the hydroxyl group of **4** is not intrinsically more reactive than that of **2**,[20] the difference in yield and α/β ratio of the two coupling reactions has to be attributed to the fact that a mismatched pair is formed in the transition state of the β-coupling between **2** and **1**, but not in the β-coupling of **4** with **1**.

To get more insight into the influence of double stereodifferentiation on α/β ratios of carbohydrate coupling reactions, we performed a glycosylation in which two *enantiomeric* glycosyl acceptors are individually coupled with a D-glycosyl donor. Thus, reaction of 6-*O*-acetyl-2,3,4-tri-*O*-benzyl-α-D-glucopyranosyl bromide (**10**)[21] with 1,2:5,6-di-*O*-isopropylidene-D-glucofuranose (**11**) in the presence of silver trifluoromethanesulfonate and 2,6-di-*tert*-butylpyridine (in situ anomerization conditions) afforded the α- and β-coupled disaccharides in 70% and 16% yield respectively (α/β ratio: 4.5/1), while coupling of the same donor (**10**) with the L-acceptor (**12**)[22] under the same conditions gave the α- and β-coupled products in 47% and 24% yield respectively (α/β ratio: 2/1) (Scheme 3).



Scheme 3.

In another example the effect of double stereodifferentiation was less pronounced. Coupling of 2,3,4-tri-*O*-benzyl-6-deoxy-α-D-galactopyranosyl bromide[23] with 1,6-anhydro-2,4-di-*O*-benzyl-β-D-galactopyranose[24] in the presence of silver silicate aluminate[25] gave the α- and β-coupled disaccharides in 12% and 75% yield respectively (α/β ratio: 1/6.5), while coupling of the L-glycosyl bromide with the same aglycon afforded the α- and β-coupled dimers in 14% and 57% yield respectively (α/β ratio: 1/4). Apparently in this example other factors, like the substituents at the donor and type of promoter, play a more important role.

In conclusion, the unfavorable steric interaction between a glycosyl donor and acceptor in the transition state leading to either the α- or β-interglycosidic bond may strongly influence the stereochemical outcome (α/β ratio) of glycosylations. When unexpected α/β ratios in glycosylations are obtained, a sterically mismatched interaction in the transition state leading to the desired glycosidic bond has to be considered. These interactions may be foreseen by molecular modeling studies of the α- and β-glycosides. To reduce unfavorable steric interactions, protecting groups can be replaced by sterically less demanding ones, the conformation of the carbohydrate unit (mostly the aglycon) may be altered (e.g. through the formation of anhydro sugars), and in oligosaccharide synthesis the building block strategies can be adapted. A more systematic study of matched and mismatched pairs during interglycosidic bond formation will improve our understanding of oligosaccharide synthesis, which still relies on trial and error.

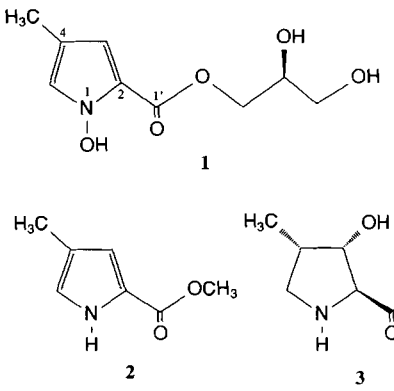
Biogenesis of the Carbon Skeleton of Glycerinopyrin: A New Biosynthetic Pathway for Pyrroles**

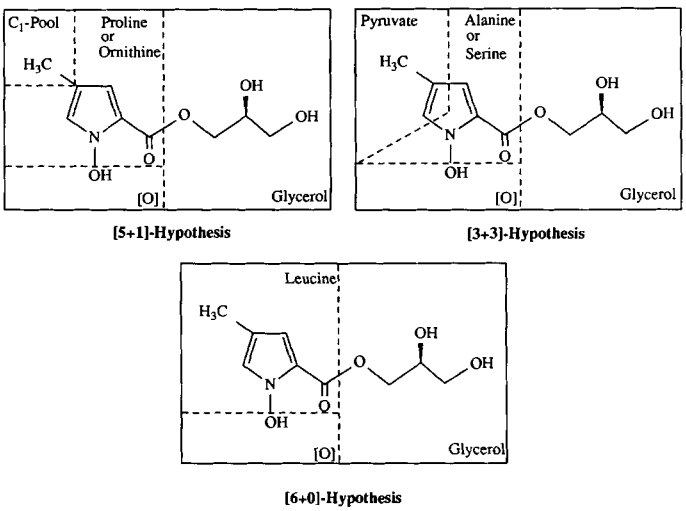
By *Monika Schönewolf* and *Jürgen Rohr**

The structure of glycerinopyrin **1**, a metabolite of *Streptomyces violaceus* (strain FH-S 1081), was recently elucidated.[11] The small natural product attracted our interest in particular regarding the biosynthesis of its methyl-branched five-membered nitrogen heterocycle. This structural element has been found in nature only once before, namely in the trail marker pheromone **2** of the Texan leaf-cutting ant *Atta texana* (Buckley),[2, 3] which also is the closest natural relative of **1**. A saturated compound of this structural type, 3-hydroxy-4-methylproline[4–6] (HMP) **3**, occurs in some cyclopeptide antibiotics including echinocandin B[7, 8] and mulundocandin.[9] Herein we report for the first time the biogenesis of such a type of nitrogen heterocycle from which emerges a novel biosynthetic pathway of general significance.



That the side chain of **1** derives from glycerol (the major source of carbon of the fermentation medium) seemed to be obvious and could be demonstrated by a feeding experiment with 0.144 mol L^{-1} [1,1,3,3-$^2H_4$]-glycerol, which resulted in an approximately 20% incorporation into **1** (Table 1).[10]

Three biogenetic hypotheses were considered for synthesis of the methyl-substituted 2-pyrrolecarboxylic acid moiety (Fig. 1): 1) a [5 + 1] assemblage of proline, hydroxyproline or ornithine and one carbon from the C_1-pool (usually the *S*-CH_3 group of methionine), 2) a [3 + 3] condensation of a metabolite of the glycolysis cascade and an amino acid derived therefrom, e.g. pyruvate and alanine (or serine), and 3) a [6 + 0] formation from leucine.



Scheme 1. Biogenesis hypotheses for glycerinopyrin **1**

Feeding experiments with [S^{13}CH$_3$]methionine and [1-^{13}C]alanine (also convertible into pyruvate by transamination) did not result in remarkable incorporations into **1** (Table 1). Hence the first hypothesis was considered unlikely, and the second one was ruled out. Administration of [1-^{13}C]acetate showed a 1.4% specific enrichment[10] of the

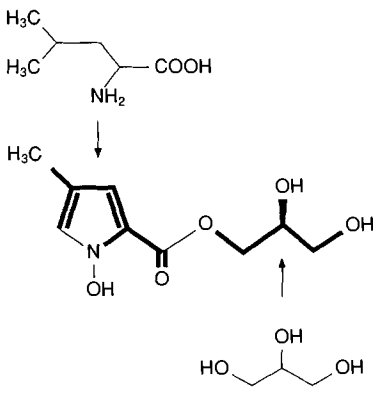
1′-position of glycerinopyrin **1** (Table 1), a result which also ruled out the first hypothesis: If ornithine or proline were the precursor of the 2-pyrrolecarboxylic acid building block of **1**, an enrichment of C-5 in **1** would have been expected according to the metabolization of [1-^{13}C]acetate via the citric acid cycle into [5-^{13}C]α-ketoglutaric acid (precursor of ornithine and proline).[11, 12] The acetate feeding experiment also could be interpreted as an indication of the leucine hypothesis, i.e. the third hypothesis, since acetate is the source of C-1 and C-2 of leucine during its biosynthesis,[12] which is in accordance with the enrichment of C-1′ found in **1**. Finally, the third hypothesis could be proven correct by a feeding experiment with D,L-[1-^{13}C]leucine: 99% specific incorporation[10] into glycerinopyrin **1** (enrichment of C-1′, Table 1) shows leucine to be an immediate precursor of its 4-methyl-2-pyrrolecarboxylate moiety.

Table 1: Incorporation experiments with *Streptomyces violaceus*.

Precursor[a]	Amount [mmol]	Time[b] [h]	Incorporation[10] in **1** [%]	Labeled atom(s) in **1**
[1,1,3,3-$^{2}H_4$]glycerol, 99% ^{2}H	144	41	20	3′-H_2, 5′-H_2
L-[*S*-$^{13}CH_3$]methionine, 97% ^{13}C	1.005	46, 52	–	–
[1-^{13}C]D,L-alanine, 99% ^{13}C	5.612	45, 52	–	–
sodium[1-^{13}C]acetate, 99% ^{13}C	6.095	12–48, every 3	1.4	C-1′
D,L-[1-^{13}C]leucine, 99% ^{13}C	6.984	42, 46, 52	99[c]	C-1′

[a] See experimental. [b] After inoculation. [c] As a reason for this unusually high specific incorporation of leucine it is probable that the liberation of this amino acid from the fermentation medium (caseine peptone) and/or its endogenous de novo synthesis, respectively, is shut off due to the large amount of added leucine.

Our findings revealed that the biogenetic source of the entire carbon skeleton derives from only two building blocks, namely glycerol as precursor of the alcohol component of the natural ester, and—as an interesting and novel result—the amino acid leucine as precursor of the 4-methyl-2-pyrrolecarboxylic acid component (Scheme 2). The latter



Scheme 2. Biogenesis of the carbon skeleton of glycerinopyrin **1** from leucine and glycerol

constitutes a new biosynthetic pathway for natural pyrroles in addition to the known laevulinic acid pathway, which leads to porphobilinogen (precursor of all porphyrin systems), the formation of the antibiotic pyrrolnitrin from tryptophan, and the synthesis from proline/hydroxyproline.[13–16] The novel pathway described here is probably also responsible for the formation of the pheromone **2**[2, 3] and of the amino acid HMP **3**.[4–6] Furthermore, it is an extension of nature to chemical syntheses of HMP **3** and to recently published pyrrole syntheses.[5, 6, 17–19] The two alternative mechanisms which are plausible for the formation of the pyrrole ring require a diastereoselective derivatization of one of the methyl groups of leucine. This could be achieved by an oxidation to the aldehyde or epoxide, which can be nucleophilically attacked by the α-amino group. There is a certain parallel to an oxidation in the recently discovered interconversion of leucine into hydroxymethylglutaryl(HMG)-CoA, where an oxidation of one of the methyl groups of leucine to a carboxyl group (though after its conversion into isovaleric acid via transamination and decarboxylation) is an essential initiation reaction.[20, 21] A terminal functionalization of intact leucine is so far unknown. The other alternative would be an amination (in the manner of the ornithine biosynthesis[12]) followed by a ring closure reaction of the generated amino group with the 2-keto group of the (earlier) transaminated leucine, in analogy with the biosynthesis of the 2-piperidinecarboxylic acid moiety of virginiamycin from lysine.[22] Investigation of the ring closure mechanism of the 4-methyl-2-pyrrolecarboxylate residue of **1** requires the synthesis of several postulated labeled intermediates.

Experimental

General: see Ref. [1]. Feeding experiments: The labeled compounds were dissolved in sterile water and added (in one or more equal portions) to the growing 1L-culture (1L-fermentor, type Biostat M, B. Braun, Melsungen, Germany) of *Streptomyces violaceus*[1]; pH changes were immediately corrected by addition of sterile 0.5 M HCl and 0.5 M NaOH, respectively (see also Table 1). In the case of the feeding experiment with [1,1,3,3-$^{2}H_4$]glycerol; the initial fermentation was carried out with 2% instead of 3% glycerol; the decrease in amount of unlabeled glycerol until the feeding was estimated by the dry cell weight.

Labeled compounds: The ^{13}C-labeled compounds were obtained from CIL (Cambridge Isotope Laboratories, Cambridge, Mass., USA), the deuterated glycerol was synthesized [23] via oxidation of diethyl malonate with lead tetraacetate ($PbOAc_4$) and reduction of the diethyl-2-*O*-acetylmalonate with lithium aluminum deuteride ($LiAlD_4$, 99% D, obtained from Zentralinstitut für Isotopen- und Strahlenforschung, Akademie der Wissenschaften, Leipzig, Germany).

Alkyl- and Arylrhenium Trioxides**

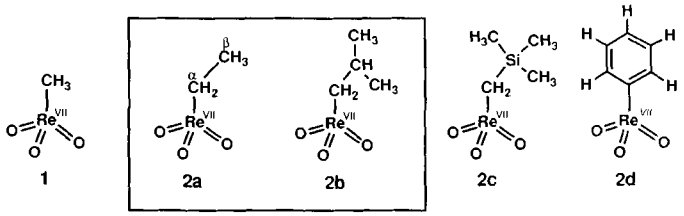
By *Wolfgang A. Herrmann,* Carlos C. Romao, Richard W. Fischer, Paul Kiprof,* and *Claude de Méric de Bellefon*

The β-hydrogen elimination is a preferred pathway for the decomposition of metal alkyls and accounts for the notorious instability of ethyl complexes and other complexes containing β-hydrogen atoms.[1, 2] Although a voluminous ligand sphere often guarantees kinetic stability,[3] little was previously known about its effect on the chemistry of hypervalent metals.[4] In particular, coordinatively unsaturated alkyl complexes (alkyl $\neq$ methyl) were not expected to be isolable.

Here we show that this assumption is wrong by describing well-characterized derivatives of the 14-electron complex methylrhenium trioxide (**1**).[5] Whereas reactions of rhenium oxides with tin, mercury, and aluminum alkyls led to decomposition, treatment of dirhenium heptaoxide with diethylzinc resulted in formation of ethylrhenium trioxide (**2a**) in over 60% yield [Eq. (a)]. However, maintaining an exact stoichiometry and suitable temperature is crucial to the success of the reaction.[6] The reaction proceeds quantitatively with precipitation of pure white zinc perrhenate from the THF solution.

$$2\,Re_2O_7 + ZnR_2 \xrightarrow{THF} \underset{\mathbf{2a-d}}{2[R\text{-}ReO_3]} + [Zn(ReO_4)_2(thf)_2] \qquad (a)$$

Ethylrhenium trioxide forms colorless crystals, which melt at $-21\,^{\circ}C$ to give a clear, air- and moisture-stable liquid. Since **2a** vaporizes rapidly at room temperature, isolation and handling require low temperatures. The complex survives the conditions of conventional gas chromatography. It exhibits an unexpectedly high thermal stability. Even in the absence of coordinating solvents, **2a** is stable at room temperature, only decomposing slowly at about 60 °C. However, β-hydrogen elimination is not the major pathway of decomposition. Instead, the spectrum of products determined by GC/MS analysis indicates that the decomposition occurs via radical pathways (comparable amounts of ethylene, ethane, and butene isomers; Re–C bond cleavage). The considerably better stability in solvents such as benzene and THF points to the involvement of intermolecular processes in the decomposition.



Isobutylrhenium trioxide (**2b**) and trimethylsilylmethylrhenium trioxide (**2c**) may be obtained similarly. They, too, are characterized by high volatility and thermal stability. The decomposition of the isobutyl derivative **2b** at 120 °C affords mainly isobutenes together with a small amount of isobutane. The silaneopentyl complex **2c** melts at 30 °C without decomposition, but then decomposes—surprisingly faster than **2a**!—with preferential loss of tetramethylsilane and formation of much ethylene and propene (!) along with a small amount of methane.

The likewise new phenylrhenium trioxide (**2d**) is formed according to Equation (a) as a colorless substance,[6] which decomposes slowly at room temperature, but rapidly and quantitatively at higher temperatures, to give biphenyl. Solutions of **2d** in solvents such as hexane are more stable (in the dark) than in the solid state, but readily decompose upon exposure to light with formation of a deep blue precipitate (presumably rhenium oxides) and biphenyl.

The organic rhenium oxides **2a–d** were characterized by complete elemental analysis and by IR and NMR (^1H, ^{13}C, ^{17}O) spectroscopy as well as mass spectrometry.[6] The ^{17}O NMR spectra, in particular, reveal the electron-shifting effects of the groups in **2a–c** compared with the parent compound **1**. The synthetic route is generalizable and exploits the formation of sparingly soluble zinc perrhenate via dismutation of Re_2O_7 to "$[ReO_3]^{\oplus}$" and $[ReO_4]^{\ominus}$ [Eq. (a)].

Since crystals of the solvent-free complexes **2a–d** were not suitable for X-ray structure analyses (soft consistency), we synthesized the quinuclidine adducts of ethyl- and silaneopentylrhenium trioxide[7] and characterized them structurally (Fig. 1).[8]

These base adducts **3a** and **3c** form quantitatively upon mixing of the components, thereby revealing the pronounced Lewis acidity of the coordinatively unsaturated rhenium(VII) centers in **2**. The framework geometry in both cases is nearly undistorted trigonal-bipyramidal (D_{3h} symmetry distorted toward C_{3v} symmetry) with unusual bond lengths between the metal center and the neighboring atoms. Neither the X-ray structure nor the spectroscopic data provide evidence for the interaction of β- or γ-hydrogen atoms with the metal centers or with the oxo ligands (e.g., hydrogen bridges), as observed, for example, in the complex $[(C_2H_5)TiCl_3(dmpe)]$,

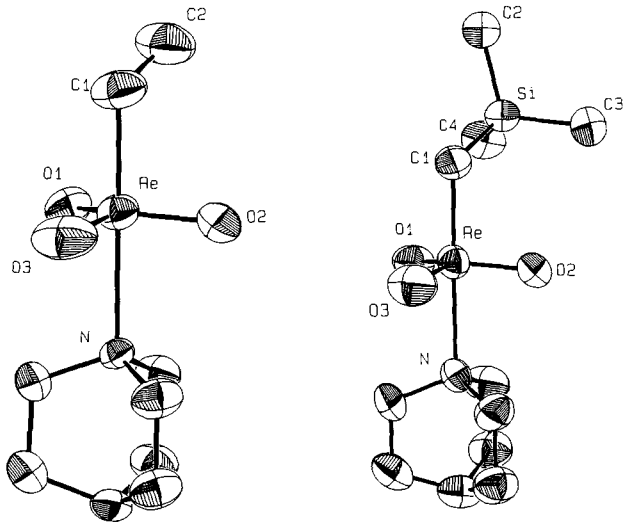

Fig. 1. Molecular structures of the quinuclidine adducts of **2a** (left) and **2c** (right) (ORTEP drawings). Selected bond lengths [pm] and angles [°]: **3a:** Re-C1 210.5(4), Re-O1 170.7(3), Re-O2 169.6(3), Re-O3 170.3(4), Re-N 240.7(3), C1-C2 151.3(6); Re-C1-C2 112.5(4), O1-Re-O2 118.1(1), C1-Re-N 179.5(2), O1-Re-N 84.4 (1). **3c:** Re-C1 209.2(4), Re-O1 168.8(3), Re-O2 169.4(3), Re-O3 169.8(4), Re-N 243.2(3), C1-Si 190.0(5); C1-Re-N 178.1(1), C1-Re-O1 98.4(1), C1-Re-O2 96.1(1), C1-Re-O3 97.2(2), O1-Re-O2 119.7(2), O1-Re-O3 118.2(2), O1-Re-N 83.4(1), Re-C1-Si 117.7(3). Further details of the crystal structure investigations may be obtained from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, W-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-54943, the names of the authors, and the journal citation.

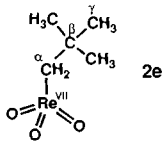
dmpe = bis(dimethylphosphino)ethane (agostic interactions).[2b, d]

Sixfold coordination can be achieved by reaction of **2a–c** with ethylenediamine and analogous chelating ligands. For example, **2c**·$H_2NCH_2CH_2NH_2$ forms air- and moisture-stable yellow crystals [$\tilde{\nu}$(ReO) = 924 (vs), 911 (vs) cm^{-1} (KBr)], which, as expected, are thermally more stable than base-free **2c**. Treatment of **2a** with *diethylzinc in excess* results in smooth formation of the new Re^{VI} binuclear complex $[\{(\sigma\text{-}C_2H_5)_2ReO_2\}_2]$.[9]

The synthesis of the neopentyl complex **2e** proved extremely difficult according to the method described above.



2e

Although the compound is indeed formed at −60 °C, it decomposes with loss of neopentane upon warming above −40 °C and, especially rapidly, at room temperature (solvent participation). Finally, we obtained only indirect evidence for the existence of the *tert*-butyl complex **2f**: Even at −90 °C, reaction of Re_2O_7 and $Zn(t\text{-}C_4H_9)_2$ in THF solution gives a mixture of products that indicates the formation and decomposition of **2f** according to Equation (b).[12]

$$2\,[(CH_3)_3C\text{-}ReO_3] \longrightarrow 2\,ReO_3 + H_2C{=}C(CH_3)_2 + HC(CH_3)_3 \qquad (b)$$

2f

The results described here counter the widespread and well-supported notion that coordinatively unsaturated alkyl complexes containing β-hydrogen atoms readily decompose. Furthermore, ethyl- and isobutylrhenium trioxide are the first examples of coordinatively unsaturated alkyl complexes of the oxo series with β-H atoms. Reaction (a) should also allow functionalized groups R to be attached to highly oxidized metal centers to give compounds such as $C_6H_5C{\equiv}C\text{-}ReO_3$,[10] which provide the prerequisites for the direct control of metal oxide reactivity for catalytic purposes.[11] Furthermore, these results clearly reveal once more how little we know about stability and decomposition pathways of hypervalent organometallic compounds.

[6] *Experimental Procedure:* A solution of sublimed Re_2O_7 (489 mg, 1 mmol) in 15 mL of THF (< 1 ppm H_2O) was treated at dry-ice temperature with exactly 0.5 mmol of ZnR_2 (1 M solution in THF). The colorless stirred solution was warmed to −5 °C (R = C_2H_5), −30 °C (R = *i*-C_4H_9), or 20 °C (R = $CH_2Si(CH_3)_3$, C_6H_5). The THF was evaporated in vacuo, and the residue was extracted with cold (!) *n*-pentane. The yellow extract was filtered through a cannula and concentrated to about 10 mL at −30 °C under vacuum. Cooling the solution to dry-ice temperature afforded colorless crystals, which were dried under high vacuum at −30 °C. Yield 60–70%. Gas chromatogram (HP A-5890): fused silica, HP-1, 50 m, 200 kPa He, 120/180 °C 20° C/min, 180/200 °C 40° C/min: t_R = 7.23 min. **2a**: Colorless crystals from *n*-pentane, m.p. −21 °C. [12] Note added in proof (Jan. 15, 1991): Further studies have shown that radical-type degradation pathways (e.g., Re–C bond cleavage) are of importance and are connected with the stability of the radicals R·; for example, **2f** eliminates butene and isobutane [Eq. (b)], but also large amounts of 2.2.3.3-tetramethylbutane. The system $Re_2O_7/Zn(CH_2C_6H_5)_2$ yields a little toluene and much bibenzyl at −80°C (compare decomposition of **2d**). Cyclopentadienylrhenium trioxide, $[(C_5H_5)ReO_3]$, is stable under ordinary conditions, representing the first C_5H_5 complex of a metal in an oxidation state greater than 5 (W. A. Herrmann, M. Taillefer, C. de Méric de Bellefon, unpublished results, 1990).

Triisopropylamine: A Sterically Overcrowded Molecule with a Flattened NC_3 Pyramid and a "p-Type" Nitrogen Electron Pair**

By *Hans Bock,** *Ilka Goebel, Zdenek Havlas, Siegfried Liedle,* and *Heinz Oberhammer*

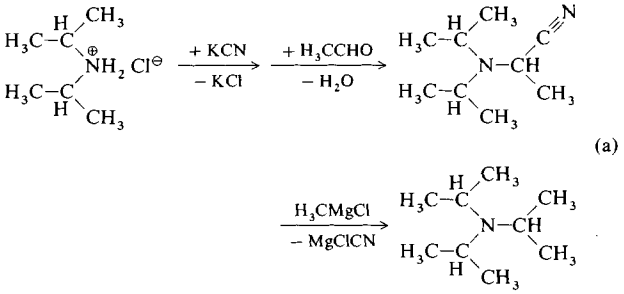
Dedicated to Jean-Marie Lehn

The "ammonia clock", the time standard based on the flip-flop of the 37-pm-high NH_3 pyramid within 4.2×10^{-11} s, is a textbook example of molecular dynamics[1a] and especially of nonclassical tunneling in a double minimum potential.[1b, c] The gas-phase structure and other characteristic molecular properties of NH_3, such as its enthalpy of inversion $\Delta H^{\ddagger}_{inv}$ and its first vertical ionization energy IE^{v}_{1}, are dramatically changed on substitution (Table 1).

Table 1. X–N–X bond angle α, inversion enthalpy $\Delta H^{\ddagger}_{inv}$, and vertical first ionization energy IE^{v}_{1} of ammonia and selected derivatives NX_3 [3].

X =	H	CH_3	CF_3	F
α [°]	106.6	110.9	117.9	102
$\Delta H^{\ddagger}_{inv}$ [kJ mol^{-1}]	24.5	31.4	?	ca. 250
IE^{v}_{1} [eV]	10.85	8.44	12.52	13.83

Considerable flattening or even planarity is observed when X = SF_5, C_3F_7, SiH_3, $Si(CH_3)_3$, GeH_3, or SCF_3;[2] the smallest inversion barriers are found in derivatives H_2NX containing a π-acceptor substituent like X = CHO, CN, or NO_2 ($\Delta H^{\ddagger}_{inv} = 4.6$, 8.5, or 11.3 kJ mol^{-1}, respectively[1b]) and the lowest ionization potentials are measured for the fluctuating amine $N(CH_2SiR_3)_3$ (R = CH_3; 7.66 eV)[3f] and the rigid molecule azabicyclo[3.3.3]dodecane (7.13 eV[3g]). These tremendous electronic ($\Delta IE^{v}_{1} = 6.6$ eV) and/or steric ($\Delta\alpha = 18°$) substitution effects (Table 1) on a dynamic center with an electron pair, as well as supporting quantum-chemical calculations,[4] have aroused our curiosity concerning the molecular properties of triisopropylamine, which is accessible by a three-step synthesis[5] [Eq. (a)].



(a)

The expectations are fulfilled (Fig. 1A). The photoelectron spectrum exhibits a "lone" ionization band at only 7.18 eV, which is assigned by MNDO calculations[4c, d] to a flattened radical-cation ground state, $\tilde{X}(^2A)$, with dominant N-electron-pair contribution.[6] The cyclovoltammogram (Fig. 1B) in aprotic THF solution ($c_{H^{\oplus}} < 1$ ppm) indicates a reversible one-electron oxidation at +0.71 V;[7] that is, the usual oxidative cleavage of the α hydrogens of trialkylamines to give the respective immonium ions $R_2\overset{\oplus}{N}{=}CR'_2$ takes place not at all or only slowly. The ESR signal pattern of the radical cation (Fig. 1C), generated with SbF_5/CH_2Cl_2, consists of an ^{14}N triplet with $a_N = 1.946$ mT and an intensity of 1:1:1, centered around g = 2.0035;[8] possible couplings have to be confined within the line width of 0.367 mT. These experimental findings are in satisfactory agreement with MNDO open-shell calculations,[4d] which predict as global minimum for $((H_3C)_2HC)_3N^{\cdot\oplus}$ a C_{3h} structure with the H–C bonds in the NC_3 plane.

The surprising molecular properties of triisopropylamine (Fig. 1),[6-8] as well as the geometry-optimized approxima-

B) Cyclovoltammograms in THF/0.1 M $Bu_4N^{\oplus}ClO_4^{\ominus}$ at 243 K (glassy carbon electrode) vs. Ag/AgCl; scan rate $\nu = 50$ to 500 mV s^{-1}). C) ESR spectrum of the radical cation generated by SbF_5/CH_2Cl_2, at 180 K (cf. [5]).

tive calculations,[4] suggest a molecular structure with a flattened NC_3 skeleton, which can be experimentally verified by gas-phase electron diffraction[9] (Fig. 2).

Analysis of the radial distribution function (Fig. 2), calculated by Fourier transformation of the diffraction intensities,[9a] results in a molecular structure of approximate C_3 symmetry. For the "least-squares" analysis of the diffraction intensities, local C_{3v} symmetry for all methyl groups and C_s symmetry for the isopropyl groups, as well as equal C–H bond distances, were assumed. The experimental values for the C–N–C bond angles 119.2(3)°, which correspond to a tilting of 5.2(11)° out of the NC_3 plane, and for the C–N–C′–H′ dihedral angles (5.0(18)°) exhibit only small deviations from a planar C_{3h} configuration of the $N(CH)_3$ unit with C-N-C = 120° and C-N-C′-H′ = 0°. Because deviations of this magnitude are typically caused by both low-frequency "out-of-plane" vibrations of the NC_3 skeleton and torsional vibrations of the isopropyl groups around the N–C bonds, the result of the gas-phase electron diffraction study (cf. Ref. [9c]) corresponds to an equilibrium structure of triisopropylamine with a trigonal-planar amino nitrogen (Fig. 2). Surprisingly, moreover, the C–N bond distance of 146 pm is comparable to that in trimethylamine, which is pyramidal.[3a] Obviously, and in agreement with quantum-chemical calculations,[4] a bond lengthening requires higher energies than the flattening of the molecular skeleton.

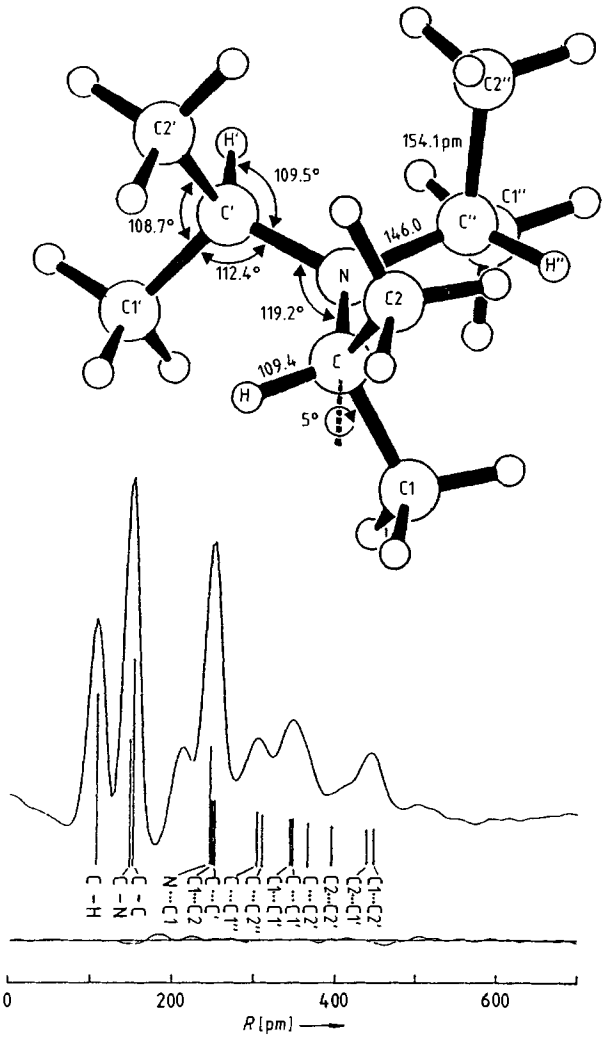

Fig. 2. Gas-phase structure of triisopropylamine and the respective radial distribution function from the electron diffraction.

According to a careful literature search,[2] triisopropylamine is thus the first trialkylamine for which a flattening of the NC_3 pyramid and, concomitantly, the formation of a p-type nitrogen electron pair could be verified by structure determination. This experimental finding not only allows the

rationalization of all measurement data (Fig. 1),[5-8] but is additionally supported by approximative quantum-chemical calculations using different methods[4a] (Table 2).

The experimentally determined structure parameters are satisfactorily embraced by the calculated approximative values.[4b,c] The dipole moment μ should be only small and the charge distribution (q_μ values, compare formula in Table 2) is polarized, according to the differing effective nuclear charges, from the rather negative nitrogen center to the positive isopropyl groups. The low inversion enthalpies[4f] estimated by MNDO FORCE and AM1 calculations for different C–N–C angles, however, suggest a rather weakly pronounced double minimum potential for triisopropylamine.[1]

Table 2. Experimental and calculated molecular properties of triisopropylamine (square brackets: charges q_μ according to AM 1).

	Experiment	MM3	MNDO	AM1
α [°]	119.2	117.9	120.0	116.3
δ [°]	5.0	4.8	0	6.7
d_{CN} [pm]	146.0	145.8	147.4	145.7
μ [D]		0.02	0	0.76
ΔH_{inv} [kJ mol^{-1}]				9.6

In the meantime, the salt $[(H_3C)_2HC)_3N^{\oplus}H][SbCl_6^{\ominus}]$ has been prepared.[10a] Its structural characterization is planned, as are also the measurement of the proton affinity of triisopropylamine[10b] and single-crystal structure determinations of other sterically overcrowded alkylamino derivatives.[10c]

[4] a) The molecule $C_9H_{21}N$ possesses 31 atoms and, accordingly, 87 degrees of freedom (C_1). In order to avoid an expensive ab initio calculation employing a basis set sufficient to cover the rather small energy differences, therefore, the force field program MM2 and the semiempirical SCF programs closed and open shell MNDO, as well as AM1, have been used as different or differently parametrized calculation procedures. b) The approximative results obtained for the structural data of the almost—or according to MNDO—planar triisopropylamine, as well as its small dipole moment and its low inversion enthalpy (Table 2), are comparable. For the steric repulsion component, a value of 93 kJ mol^{-1} was estimated by MM2. c) The first vertical ionization energy was calculated to be 9.08 eV by MNDO and 8.83 eV by AM 1, corresponding to deviations from Koopmans' theorem ($IE_i^v = -\varepsilon_i^{SCF}$) of 1.9 and 1.65 eV, respectively. These, values are larger than usual and demonstrate, together with the more closely corresponding values for the pyramidal NH_3 ($IE_1^v = 10.85$ eV [3c]; MNDO, 11.91 eV; AM1, 10.42 eV) that trigonal-planar nitrogen centers are less well covered by the parametrization (cf., e.g., M. J. S. Dewar, W. Thiel, *J. Am. Chem. Soc. 99* (1977) 4970). With respect to the charge of the radical cation ground state, predominantly located at the N center ($[c_{1,N}^{MNDO}]^2 = 0.7$), however, also the electronic relaxation on electron expulsion should be rather small. d) Concomitantly, a MNDO open-shell calculation predicts a planar radical cation with spin populations $\varrho_N = 0.082$, $\varrho_{C,\alpha} = 0.009$, and $\varrho_{C,\beta} = 0.019$. e) According to MNDO FORCE calculations, the IR spectrum should show the following intense bands ($\tilde{\nu}$ [cm^{-1}] for $\langle\mu\rangle^2 > 0.25$; vibrational mode in square brackets; irreducible representation for C_3 in parentheses): 3274 [80,81] (e) and 3260 [74,73] (e), CH_3 stretch; 1535 [66,65] (e), N(CH) in-plane bending; 1494 [61] (a), CCH bending; 1369 [44,45] (e), $N(CH)_3$ in-plane bending; 1348 [41] (a), $N(CH)_3$ out-of-plane bending and 480 [18] (a), NC_3 out-of-plane. For the rotation of the isopropyl groups around the N-C bonds, a barrier of comparable height (523 cm^{-1} ≙ 6.5 kJ mol^{-1}) as that for the inversion, was calculated. f) The inversion enthalpies (Table 2) were estimated either from the N inversion vibration or from the difference in the AM 1 enthalpies of formation for the C–N–C angles of 116.3° and 120°. Accordingly, and with the necessary caution with respect to the approximation used, triisopropylamine should possess a shallow double minimum potential, each minimum corresponding to 116.3°. The barrier of 9.6 kJ mol^{-1} calculated for the saddle point at 120° would then be above the inversion mode of 480 cm^{-1} ≙ 5.9 kJ mol^{-1} and below most of the other vibrational modes ($\tilde{\nu} > 780$ cm^{-1}). g) In the meantime, *R. Ahlrichs* (Universität Karlsruhe) has begun performing ab initio calculations with increasingly improved basis sets, which so far confirm most of the above results and especially a zero-point mode in the region of the double minimum saddle point.

[5] F. Kuffner, W. Koechlin, *Monatsh. Chemie 93* (1962) 476. Synthesis (cf. *I. Göbel, Diplomarbeit*, Universität Frankfurt 1989): Diisopropylamine (4.25 mL, 0.3 mol) was neutralized with concentrated HCl and the resulting, stirred solution was then treated dropwise with a saturated aqueous solution of KCN (0.3 mol) and, after coooling to 0 °C, acetaldehyde (16.9 mL, 0.3 mol). The organic phase, as well as the ether extracts of the aqueous phase saturated with K_2CO_3, were dried over Na_2SO_4 and fractionally distilled at about 10 Torr. At a column head temperature of 58 °C, 17.4 g (37.6%) of α-diisopropylaminopropionitrile was isolated. The product (9 g, 58 mmol) was dissolved in 25 mL of dry ether at 25 °C and treated dropwise under Ar with an ether solution (100 mL) of H_3CMgCl (prepared from 4.9 g of Mg and gaseous CH_3Cl with addition of five drops of 1,2-dibromoethane). After 30-min reflux, the solution was poured on ice and neutralized with aqueous NaOH. Fractional distillation in vacuo (b.p. 47 °C/14 Torr) of the ether phase, dried over Na_2SO_4, yielded 3.74 g (45%) of $N(CH(CH_3)_2)_3$ ($n^{20} = 1.4141$) ^{1}H NMR (270 MHz, $CDCl_3$, 25 °C, TMS): $\delta = 0.9$–1.04 (d, 18H, CH_3), 2.96–3.4 (sept, m 3H, CH). MS: *m/z* 143 ($M^{\oplus}$), 128 ($M^{\oplus}$ – Me), 100 ($M^{\oplus}$ – *i*Pr), 86–84 ($M^{\oplus}$ – *i*Pr – Me), 70 ($M^{\oplus}$ – *i*Pr – 2 Me), 57 ($M^{\oplus}$ – 2 *i*Pr)). UV (diethyl ether): $\tilde{\nu}_m = 41\,670$ and $47\,900$ cm^{-1}.

[6] The known [3g] regression $IE_1^v(NR_3) = 8.92 - 0.129\,\Sigma n_{eff}$, on inserting n_{eff} (R = Me) = 1 and n_{eff} (R = *i*Pr) = 2.87, yields the following differences between estimated and experimental vertical first n_N ionization energies: Me_3N 0.09 eV, Me_2NiPr 0.09 eV, $MeiPr_2N$ 0.17 eV, $NiPr_3$ 0.62 eV. The latter value is found to be outside the regression line and in accord with a flattening of the NC_3 skeleton [4].

[7] All reversibility criteria are largely fulfilled: $\Delta E = 66$ mV, $i_{pa}/i_{pc} = 1.08$, "steady state" cycles (Abb. 1B). Trialkylamines without α hydrogens, such as 9-*tert*-butyl-9-azabicyclo[3.3.1]nonane, are also reversibly oxidized (S. F. Nelsen, C. R. Kessel, *J. Chem. Soc. Chem. Commun. 1977*, 490). These results suggest that the three C–H bonds of the title compound are located in the NC_3 skeletal plane (symmetry C_{3h}).

[8] Radical cations of amines $R^3N^{\cdot\oplus}$ are often generated by γ-irradiation of their perchlorates $(H_4N^{\oplus}ClO_4^{\ominus})$: T.Cole, *J. Chem. Phys. 35* (1961) 1169;

J. S. Hydet, E. S. Freeman, *J. Phys. Chem. 65* (1961) 1636) or by UV photolysis of suitable adducts ($(H_3C)_3N{\cdot}Cl_2$: Y. L. Chow, W. C. Danen, S. F. Nelsen, D. H. Rosenblatt, *Chem. Rev. 78* (1978) 244) and are usually short-lived. An exception is again 9-*tert*-butyl-9-azabicyclo[3.3.1]nonane, the radical cation of which in CH_2Cl_2, like that of trisopropylamine, is persistent over hours. The skilled help of Dr. *R. Baur* (Universität Frankfurt) in recording the ESR spectrum (Abb. 1 C) is gratefully acknowledged.

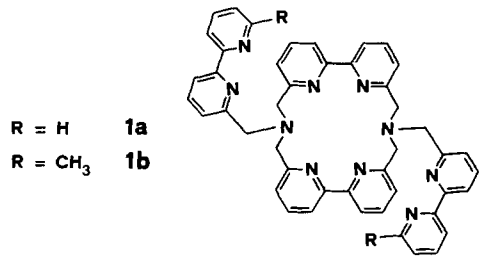
[9] a) The diffraction intensities were determined using a KD-GZ gas diffractograph at camera distances of 25 and 50 cm and an acceleration voltage of 60 kV. Temperature of the sample and the inlet nozzle were 25 °C; the camera pressure was 1.5×10^{-5} mbar. The photo plates were evaluated by the usual methods (H. Oberhammer, W. Gombler, H. Willner, *J. Mol. Struct. 70* (1981) 273) and the diffraction intensities in the s regions (20–180 nm^{-1} as well as 80–350 nm^{-1}) were used for the structure determination. b) The intensities were multiplied by a diagonal weight matrix and literature scattering amplitudes and phases applied (J. Haase, *Z. Naturforsch. 25A* (1970) 936). c) The following geometry parameters were obtained from the diffraction analysis (cf. Fig. 2) ([pm] and [°]; error tolerances, 3σ values with possible scaling error of 0.1% for bond lengths): C–N 146.0(5), C–C 154.1(3), C–H 109.4(4); C–N–C 119.2(3), C–C–C 108.7(12), C–C–N 112.4, C–C–H 109.0(6), N–C–H 109.5 (not refined), C–N–C′–H′ 5.0(18). The following interatomic distances (cf. Fig. 2) and vibrational amplitudes (without nonbonding distances to hydrogens) were determined: C–H 109 and 7.9(3), C–N 146 and 4.9 (not refined), C–C 154 and 5.9(3); N···C1 249, C1···C2 250, C···C′ 252 and each 8.2(2), C···C1″ 305, C···C2″ 312 and each 12.1(11), C1···C1′ 346, C···C1′ 349 and each 12.2(11), C···C2′ 370 and 9.5(19), C2···C2′ 396 and 16.9(38), C2···C1′ 441, C1···C2′ 452 and each 10.6(25).

[10] a) H. Bock, I. Göbel, unpublished. In 1-azabicyclo[3.3.3]undecane hydrochloride, the C–N–C angle is still 116° (A. H.-J. Wang, R. J. Missavage, S. R. Byrn, I. C. Paul, *J. Am. Chem. Soc. 94* (1972) 7100). b) The proton affinities for tri(*n*-propyl)amine and 1-azabicyclo[3.3.3]undecane of 988 and 977 kJ mol^{-1} differ only slightly [3g]. c) A single-crystal structure determination of tetrakis(dimethylamino)ethene at −30 °C (H. Bock, H. Borrmann, K. Ruppert, A. Simon, unpublished) also verifies largely flattened NC_3 pyramids.

Luminescence Properties of $Eu^{3\oplus}$ and $Tb^{3\oplus}$ Complexes of Branched Macrocyclic Ligands Containing Four 2,2′-Bipyridine Units**

By *Vincenzo Balzani,* Jean-Marie Lehn,* Jan van de Loosdrecht, Andrea Mecati, Nanda Sabbatini,* and *Raymond Ziessel*

An important research theme in the field of macrocyclic chemistry is the design of ligands capable of forming stable and strongly luminescent lanthanide complexes to be used as new luminescent materials and as labels for biological applications.[1–10] In such complexes the ligands must play three important roles: they must absorb light, transfer excitation energy to the lanthanide ion, and shield the lanthanide ion from interaction with solvent (water) molecules which deactivate the luminescent excited state. Previous investigations[1–4, 8] have shown that the 2,2′-bipyridine (bpy) chromophoric group may be used as a building block to design multidentate ligands which satisfy the above requirements. The synthesis of the branched macrocyclic ligands **1a** and **1b**, which contain four bpy units, has been reported recently.[11] Here we describe the luminescent properties of the novel $Eu^{3\oplus}$ and $Tb^{3\oplus}$ complexes of **1a** and the $Eu^{3\oplus}$ complex of **1b**.



[Eu-**1a**]$Cl_3 \cdot 2H_2O$ was prepared by mixing equimolar amounts of **1a** (suspension in CH_2Cl_2/MeOH 5:1) and $EuCl_3 \cdot 6H_2O$ (solution in MeOH). Heating the mixture at 80 °C for one hour caused the solid to dissolve. The solvent was then removed under vacuum and the pale yellow residue was dissolved in MeOH. Slow diffusion of Et_2O resulted in precipitation of the complex. The same experimental procedure was used to prepare [Tb-**1a**]$Cl_3 \cdot 2H_2O$ and [Eu-**1b**]$Cl_3 \cdot 2H_2O$. The complexes were characterized by elemental analysis, NMR spectroscopy, and FAB mass spectrometry.[12] Absorption spectra, luminescence spectra, and luminescence lifetimes were measured as previously described.[8]

Solutions of [Eu-**1a**]$Cl_3 \cdot 2H_2O$ in methanol or water exhibited identical absorption spectra, which did not change even after several days. For [Tb-**1a**]$Cl_3 \cdot 2H_2O$ and [Eu-**1b**]$Cl_3 \cdot 2H_2O$, the absorption spectra in methanol solution were different from those in aqueous solution. Furthermore, in methanol solution no spectral change was observed, whereas in water the absorption spectra changed with time for a few hours until they became similar to those obtained for methanol solution. The reason why [Tb-**1a**]$Cl_3 \cdot 2H_2O$ and [Eu-**1b**]$Cl_3 \cdot 2H_2O$ are unstable in aqueous solution was not investigated, and the luminescence properties of these two complexes have only been studied in methanol solutions.

The absorption spectra of the complexes are characterized by the high-intensity ligand-centered (LC) bands of the coordinated bpy units. The wavelengths and molar absorption coefficients of the most intense band are as follows: [Eu-**1a**]$^{3\oplus}$, $\lambda_{max} = 312$ nm, $\varepsilon = 36\,000\ M^{-1}cm^{-1}$ (in H_2O) and $38\,000\ M^{-1}cm^{-1}$ (in CH_3OH); [Eu-**1b**]$^{3\oplus}$, $\lambda_{max} = 299$ nm, $\varepsilon \approx 39\,000\ M^{-1}cm^{-1}$, with another peak of comparable intensity present at 292 nm (CH_3OH); [Tb-**1a**]$^{3\oplus}$, $\lambda_{max} = 312$ nm, $\varepsilon \approx 44\,000\ M^{-1}cm^{-1}$ (CH_3OH). The molar absorption coefficients of the LC bands in these complexes are thus higher than those of the previously studied [Eu ⊂ bpy · bpy · bpy]$^{3\oplus}$ and [Tb ⊂ bpy · bpy · bpy]$^{3\oplus}$ cryptates,[3, 8] because of the presence of one more bpy unit.

Excitation of the complexes in their LC absorption bands resulted in the well-known, structured luminescence of the lanthanide ion, with the highest energy peak at 17 300 cm^{-1} for $Eu^{3\oplus}$ ($^5D_0 \rightarrow {}^7F_0$ transition) and 20 490 cm^{-1} for $Tb^{3\oplus}$ ($^5D_4 \rightarrow {}^7F_6$ transition). Corrected excitation spectra in the near-UV region closely matched the absorption spectra.

Luminescence lifetimes and quantum yields obtained under various experimental conditions are gathered in Table 1, where analogous data concerning the bpy · bpy · bpy cryptates[3, 8] are also shown for comparison purposes.

The luminescence lifetime of [Eu-**1a**]$^{3\oplus}$ in H_2O is much higher than that of [Eu ⊂ bpy · bpy · bpy]$^{3\oplus}$, whereas the lifetime in D_2O is almost the same for the two complexes.

[Tb-**1a**]$^{3\oplus}$	CH_3OH	1.1	2.0	0.14
	CH_3OD	1.2	2.9	0.35
[Tb ⊂ bpy · bpy · bpy]$^{3\oplus}$ [d]	H_2O	0.33	1.7	0.03
	D_2O	0.43	3.8	–

[a] Excitation in the ligand-centered band at approximately 300 nm. [b] Experimental error ≤ 10%. [c] Experimental error ≈ 30%. [d] From [3] and [8].

This shows that the $Eu^{3\oplus}$ ion is much better protected by **1a** towards the interaction with water molecules. Use of the empirical equation proposed by *Horrocks*[13] and the experimental lifetimes at 300 K in H_2O and D_2O solutions revealed that no water molecule is present in the first coordination sphere of the metal ion in [Eu-**1a**]$^{3\oplus}$, whereas about 2.5 water molecules are present in the case of [Eu ⊂ bpy · bpy · bpy]$^{3\oplus}$.[3] The efficient shielding offered by **1a** to the metal ion towards solvent interaction is also shown by the lifetime data of [Eu-**1a**]$^{3\oplus}$ in CH_3OH and CH_3OD. These results indicate that, as expected from the examination of space-filling models, the metal ion can be enclosed in the macrocyclic ring of **1a** and then encapsulated by the two branches of the ligand. This shielding effect is most likely present also in [Tb-**1a**]$^{3\oplus}$, but for this complex fast metal-to-ligand back energy transfer could explain why the lifetime is practically the same in CH_3OH and CH_3OD.[14]

Comparison of the lifetime values for [Eu-**1a**]$^{3\oplus}$ and [Eu-**1b**]$^{3\oplus}$ in methanol shows that the metal ion is almost equally shielded by the two ligands. However, the luminescence quantum yield is much smaller for [Eu-**1b**]$^{3\oplus}$, probably because the two methyl substituents in **1b** prevent a close approach of some bpy units to the metal and therefore reduce the energy-transfer efficiency from the ligand-centered to the metal-centered excited states. This hypothesis is supported by the presence of a residual ligand-centered phosphorescence (λ_{max} = 470 nm, 77 K) for [Eu-**1b**]$^{3\oplus}$.

The higher luminescence quantum yield exhibited by [Eu-**1a**]$^{3\oplus}$ compared with [Eu ⊂ bpy · bpy · bpy)]$^{3\oplus}$ in H_2O at 300 K cannot be entirely accounted for by the better shielding offered in **1a** towards interaction of the excited metal ion with solvent molecules. In fact, the quantum yield is higher by a factor of 5 whereas the lifetime is higher only by a factor of about 2. Furthermore, the quantum yield is higher also in D_2O, where the shielding effect does not play any role. These results show that the energy-transfer efficiency from the ligand-centered to the luminescent metal-centered level is larger (approximately by a factor of 2) for [Eu-**1a**]$^{3\oplus}$. For the analogous $Tb^{3\oplus}$ complexes no conclusion can be drawn in this regard because of the lack of directly comparable data and the presence of metal-to-ligand back energy transfer.[14]

In conclusion, in the $Eu^{3\oplus}$ and $Tb^{3\oplus}$ complexes of **1a** the presence of four bpy units provides a very high molar absorption coefficient and an excellent protection towards the deactivating action of water on the luminescent excited state. Furthermore, in [Eu-**1a**]$^{3\oplus}$ the ligand-to-metal energy-transfer efficiency is higher than in [Eu ⊂ bpy · bpy · bpy]$^{3\oplus}$. For these reasons, the $Eu^{3\oplus}$ and $Tb^{3\oplus}$ complexes of **1a** are strongly luminescent species, superior to the previously investigated[1–3, 8] bpy · bpy · bpy cryptates. Thus, [Eu-**1a**]$^{3\oplus}$ is a promising luminescent label even in aqueous solution. Functionalization of the bpy units[15] should make possible the coupling of this complex to biological substrates.

A Short and Flexible Enantioselective Synthesis of the Didemnenones**

By *Heike Bauermeister, Hartmut Riechers, Dietmar Schomburg, Peter Washausen,* and *Ekkehard Winterfeldt**

Till now Caribbean tunicates have primarily been a source of cyclic peptide derivatives, but recently *Lindquist* et al. described the isolation and structure elucidation of a cyclopentenone derivative with tumor-inhibiting properties.[1] This material proved to be a mixture of the epimeric lactols

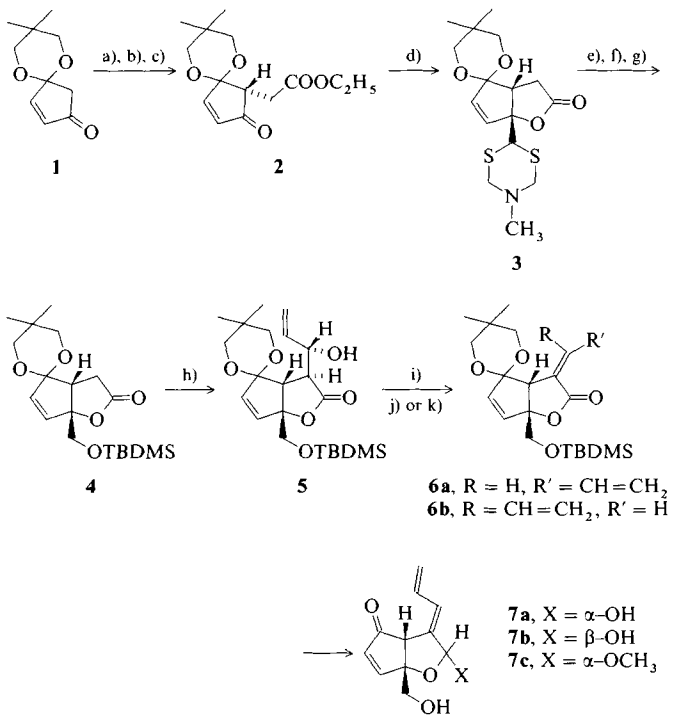
[**] Financial support by the Deutsche Forschungsgemeinschaft is gratefully acknowledged. Abbreviations used: LDA = Li*N*iPr_2, TBDMS = Si*t*BuMe_2, DBU = 1,8-diazabicyclo[5.4.0]undec-7-ene, NOE = nuclear Overhauser enhancement, DIBAH = Al*i*Bu_2H.

7a and **7b**, which could, however, be converted into the nicely crystalline α methyl ether **7c** for characterization and comparison.[1, 2] Although these are comparatively small molecules they are packed with functionality and contain two functional groups that are both considered to be responsible for biological activity: the cyclopentenone moiety, which is a strong acceptor group, and the unsaturated lactol, which under slightly acidic conditions, for instance in tumor cells, could give rise to an oxonium derivative, or on oxidation could yield the corresponding unsaturated lactone with well-established acceptor properties. These are certainly the main reasons for the present synthetic interest in this field.[2, 3] In both the known syntheses of the didemnenones the stereoselective construction of the exocyclic butadiene system represents the crucial and complicated step. We now report a flexible, stereoselective synthesis in which the unsaturated lactone **6** is an important intermediate.



Scheme 1. Reagents and conditions: a) THF, LDA, −78 °C, 30 min; b) THF, ICH_2COOEt, −78 °C, 30 min (a + b 65%); c) Lipomod PC, H_2O, phosphate buffer (pH = 7), 27 °C, 32 h (17%, 91% *ee*); d) THF, dithiazine, *n*BuLi, −78 °C, 1 h (55%); e) $MeCN/H_2O$, HgO, $HgO/HgCl_2$, room temperature, 30 min; f) MeOH, $NaBH_4$, 0 °C, 10 min; g) CH_2Cl_2, TBDMSCl/imidazole, 1–2 h (e + f + g 65%); h) THF, LDA, acrolein, −78 °C, 45 min (73%); i) CH_2Cl_2, CH_3SO_2Cl, Et_3N, room temperature, 15 min (100%); j) THF, $KN(SiMe_3)_2$, −78 °C, 15 min (50%); k) CH_2Cl_2, DBU, room temperature, 1 h (100%).

Starting from monoketal **1**, which is easily prepared from the corresponding diketone[4] by conventional techniques, we obtained *rac*-ketoester **2** on alkylation with ethyl iodoacetate. A subsequent kinetic resolution with the commercially available lipase Lipomod PC[5] led to pure (*R*)-ester **2** in 35% yield. Thioketal **3** was generated from this ketone with high diastereoselectivity (exclusive β approach), and served extremely well for an X-ray structure determination, as the sulfur atoms allowed the determination of the absolute configuration by computational techniques.[6]

Subsequent oxidative hydrolysis, borohydride reduction, and conventional silylether formation gave rise to lactone **4**, which underwent aldol addition with high diastereoselectivity. The configuration of **5** was assigned on the basis of the *Zimmerman–Traxler* transition state. As expected for this set of configurations, mesylate elimination with DBU in dichloromethane (E_2 type, *anti* elimination) gave rise to **6a** as the main reaction product (**6a**:**6b** = 10:1). For E_{1cB} elimination conditions (*syn* elimination) we chose $KN(SiMe_3)_2$ as a strong base at low temperature and indeed obtained mainly **6b** (**6b**:**6a** = 3:1). The configuration of both lactones could easily be assigned by conventional NMR chemical shift observations (influence of the carbonyl group) and NOE experiments. DIBAH reduction and deprotection gave rise to the *iso*didemnenones from **6a**, while **6b** generated the mixture of the epimeric didemnenones, which as reported by *Lindquist* et al.[1] could be transformed into the stable α methyl ether **7c**. This was identical to the natural product derivative.[7]

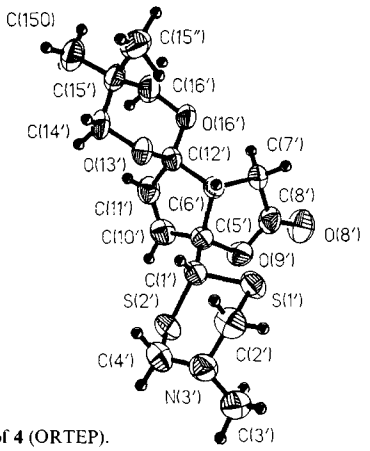


Fig. 1. X-ray crystal structure of **4** (ORTEP).

Our synthesis leads to both stereoisomers at the exocyclic double bond from a common homochiral intermediate (**5**) by simply changing the conditions of the elimination process. As this leads to the lactones, which are then reduced to the corresponding lactols, four stereoisomers are available for testing the biological activity. The influence of the double bond configuration as well as of the oxidation status of the lactone moiety on the biological activity can thus be determined.

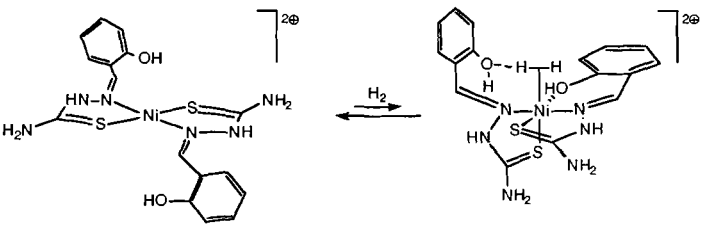
Functional Modeling of Ni,Fe Hydrogenases: A Nickel Complex in an *N,O,S* Environment.**

By *Marc Zimmer**, *Gayle Schulte*, *Xiao-Liang Luo*, and *Robert H. Crabtree**

Hydrogenases containing both nickel and iron[1] catalyze H_2/D exchange,[2] but their physiological role is H_2 oxidation.[1] There is circumstantial evidence in favor of a Ni site for H_2 binding.[2c] Various ESR signals coupled to ^{61}Ni ($I = \frac{3}{2}$) are found for ^{61}Ni, Fe hydrogenases,[2a,c] but the oxidation state assignment for some of these (nickel(I) or (III)) is controversial.[2,c-e] Exposure to O_2 deactivates the enzymes, but they may be reductively activated to give the 'ready' form.[2c] Little is known about the ligand environment, but extended X-ray absorption fine structure (EXAFS) data suggest that three[3] to four[4] sulfurs are coordinated to Ni, while ESR data only show one.[5] Very few Ni^I or Ni^{III} *S*-donor complexes are known;[6,7] most Ni^{III} species have highly noninnocent ligands,[8,9] form dimers,[10,11] or decompose to disulfides.[12,13] Recently some interesting Ni^{III} thiolates were isolated.[14] We now report an *N,O,S*-donor Ni^{II} complex that is octahedral in the solid state but square planar in solution, can be reduced to an air-stable Ni^I form, and, like hydrogenase itself, catalyzes H_2/D exchange. This is the first nickel-containing hydrogenase model system which is functional for isotopic exchange. The previous ones, the Os and Ru porphyrins of *Collman* et al.,[15a] and the Pd(salen) (salen = bis(salicylidene)ethylenediamine) systems of *Olivé* et al.[15b] did not contain physiologically relevant metals.

We screened a large number of *S*-donor Ni complexes for activity and find H/D exchange only for $[NiL_2]Cl_2$ (**1**) (L = *o*-C_6H_4(OH)CH=N-NHCSNH_2) which is formed by refluxing $NiCl_2$ with L[16,17] in ethanol for two hours and crystallizes as dark green plates in 81% yield. An X-ray crystal structure of **1** · EtOH (Fig. 1) shows a pseudooctahedral dicationic complex.[18] Both ligands are in the phenol, rather than the phenolate form. The magnetic moment in the solid state is 1.98 B.M. (1.83×10^{-23} J T^{-1}), significantly lower than the spin-only value.[19a] The Ni–S bonds are short (2.386(3) Å and 2.362(3) Å vs. 2.45–2.55 Å in typical Ni^{II} octahedral species[19b]), consistent with significant $R_2N^{\oplus}$=C–$S^{\ominus}$ character for the ligand. The long Ni–O(Aryl) bonds (2.143(6) and 2.091(6) Å), are further evidence for protonated phenols.[19b]

In solution the complex is diamagnetic, as shown by the Evans method[20] and the normal ^1H NMR spectrum. This suggests that the complex has lost one or two ligands. Similar behavior has been observed for Ni^{II} complexes of thiourea.[21] The long Ni–O(Aryl) bond and the position of the phenol resonances (intensity: 2) almost unshifted from the free ligand (-O*H* at $\delta = 9.90$) suggest that both phenol groups dissociate (Scheme 1).



3

Scheme 1. Probable structure of the dication **1** in solution. **3**: Proposed catalytic intermediate for hydrogen activation.

Reduction of **1** electrochemically ($E > -1.05$ V, scan speed = 100 mV s^{-1}; $I_a/I_c = 1.64$; $\Delta E = 0.098$ V, quasi reversible)[22] or with $NaBH_4$ (irreversible) produces a Ni^I species (**2**) which is stable in air (ESR) for hours. Ni^I is unusual in an S environment and no air-stable examples are known. Neither the ligand itself nor $[ZnL_2]SO_4$ reacts with $NaBH_4$, suggesting that ligand L is not reduced under these conditions. Nickel is the predominant site of reduction as shown by the ESR spectrum in dimethylformamide (DMF) (Fig. 2,

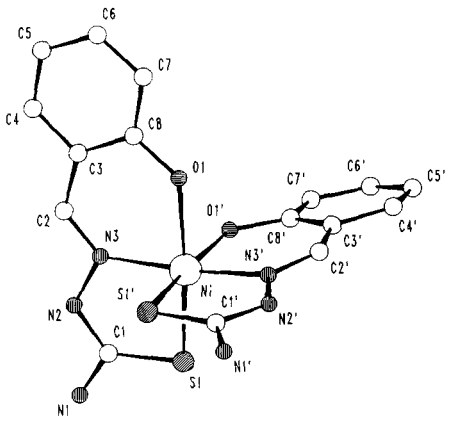


Figure 1. Structure of the Ni-salicylaldehyde thiosemicarbazone cation [18] (selected Ni–L bond lengths [Å]: S1, 2.39; S1', 2.36; N3, 2.02; N3', 2.01; O1, 2.14; O1', 2.09).

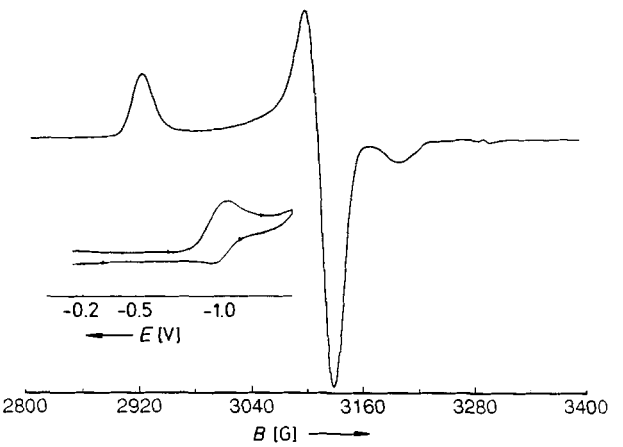

Figure 2. Frozen solution (7 K) of X band ESR spectrum ($\nu = 9.0519$ GHz) of **2**. Insert: Cyclic Voltammogram of **1** [22].

$g = 2.25$, 2.12, and 2.06),[23] which is consistent with an axially distorted Ni^I species. The reduced forms of the analogous Ni complexes which lack the phenol groups,[24]

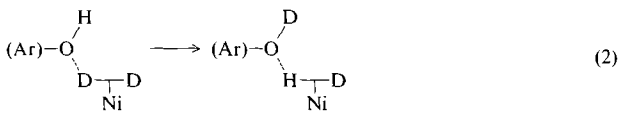
[**] This research was supported by the National Institutes of Health. We thank Prof. *G. W. Brudvig* for discussions, and Ms. *C. A. Buser* and Dr. *J. Bocarsly* for obtaining ESR spectra.

four coordinate **4**, and five coordinate **5** have identical $g_\perp$ and $g_\parallel$ to **2**. UV-vis spectra show that **5** does not disproportionate to **1** and **4**. The Ni^I complexes are therefore four-coordinate with an N_2S_2 environment.

$[Ni(C_6H_5CH{=}N\text{-}NHCSNH_2)_2]Cl_2$ **4**

$[Ni(C_6H_4OHCH{=}N\text{-}NHCSNH_2)(C_6H_5CH{=}N\text{-}NHCSNH_2)]Cl_2$ **5**

We looked at D_2/H exchange with ethanol-OH protons catalyzed by **1**. Exposure to D_2 (1 atm) gave H/D exchange, especially in the presence of promoters like HI or HBF_4. A 0.1 M solution of **1** in a dimethyl sulfoxide/ethanol mixture (90:10) gave 7.5 turnovers[25] of H/D exchange after five minutes at 25 °C and 1 atm pressure of D_2. Deuteriation of the EtOH proton was followed by ^2D NMR by monitoring the EtO*D* resonance at $\delta = 4.15$ versus C_6D_6 as standard. The catalytic activity disappeared after 7.5 turnovers. Neither **4** nor **5** promotes H/D exchange, so both phenolic OH groups are required for activity. A possible catalytic intermediate is **3**,[26] in which one phenol group is bound to the nickel, and the other forms a hydrogen bond with H_2 (Scheme 1). Hydrogen bonding may increase the affinity of the complex for H_2 and promote exchange (Scheme 2).



(2)

Scheme 2.

This work reveals some unusual features of Ni chemistry in an *S*-donor environment. A stable Ni^I species is formed from **1** on reduction. In solution, ligand dissociation leads to a species which interacts with D_2 and promotes H/D exchange. Compound **1** is thus a functional model for hydrogenases.

[**] Highly Reduced Organometallics, Part 29. This work was supported by the U.S. National Science Foundation and the Petroleum Research Fund administered by the American Chemical Society. Part 28: [1].

such as η^2-1,2-bis(dimethylphosphino)ethane[6] and η^3-1,1,1-tris(dimethylphosphinomethyl)ethane[7] were known to stabilize carbonyls of these elements. We now wish to report on an unprecedented class of carbonyls of Zr and Hf which contain only the triphenylstannyl ligand as the stabilizing group. These complexes, which formally contain divalent zirconium or hafnium, are dianions of the composition $[(Ph_3Sn)_4M(CO)_4]^{2\ominus}$ (**1**, M = Zr; **2**, M = Hf). They are the first examples of eight-coordinate metal carbonyls containing only monodentate ligands.

The synthetic procedure is summarized in Equation (a) ($C_{10}H_8$ = naphthalene; further details are given under *Experimental Procedure*). Trimethylphosphane must be present

$$MCl_4 \cdot 2THF + 2NaC_{10}H_8 \xrightarrow{4PMe_3,\ 4Ph_3SnNa,\ CO} Na_2[(Ph_3Sn)_4M(CO)_4] + 2C_{10}H_8 \quad (a)$$

M = Zr, Hf.

during these reductions or the carbonylation step fails. Although the exact role of the phosphane in this synthesis is not understood, *Cloke* and *Green* previously established that PMe_3 was crucial in the synthesis and stabilization of the first bis-arene compounds of Zr^0 and Hf^0.[8] Attempts to prepare $[(Ph_3Sn)_4Ti(CO)_4]^{2\ominus}$ by this procedure resulted instead in the formation of the known Ti^0 species $Na_2[(Ph_3Sn)_2Ti(CO)_5]$[9] and Ph_6Sn_2. Cation exchange with Et_4NBr and $n Pr_4NCl$ provided salts which could easily be crystallized in pure form.

IR spectra of the tetraalkylammonium salts in CH_3CN or as mineral oil mulls of crystalline solids displayed one intense band in the ν(CO) region at about 1880 cm^{-1}.[10] ^1H, ^{13}C, and ^{119}Sn NMR spectra of the anions were independent of the counterion and in accord with the assigned compositions.[11] Corresponding ^{13}C and ^{119}Sn NMR spectra of the 99% enriched ^{13}CO compounds established that they were fluxional tetrastannyl tetracarbonyls.[12] Independent evidence for the presence of four equivalent tin atoms in **2** in solution was obtained from the ^{119}Sn NMR spectrum of the unenriched hafnium dianion, which showed, after prolonged spectral acquisition time (ca. 12 h) at 50 °C, a 1:10:1 apparent triplet with $J(^{117}Sn\text{-}^{119}Sn) = 1100 \pm 50$ Hz.[13]

The molecular structure of **1** is shown in Figure 1 and has a metal–ligand coordination core ($ZrSn_4C_4$) consisting of a dodecahedron of D_{2d} symmetry, characterized by interpenetrating tetrahedra of carbonyl and triphenylstannyl groups.[14] The Ph_3Sn units form an elongated tetrahedron (A sites), while the carbonyl groups form a substantially flattened tetrahedron (B sites) to minimize interligand repulsions.[15] A stereoview of the isostructural hafnium complex **2** emphasizes the relatively high symmetry of these dodecahedral species (Fig. 2). Selected interatomic distances

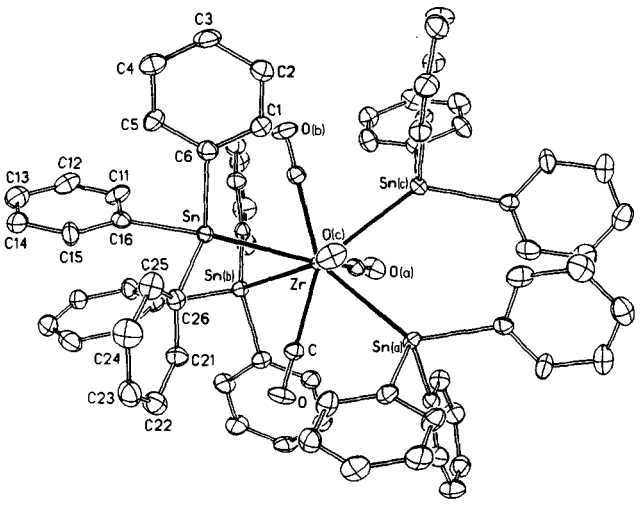

Fig. 1. Molecular structure of **1**. For important bond lengths and angles, see Table 1.

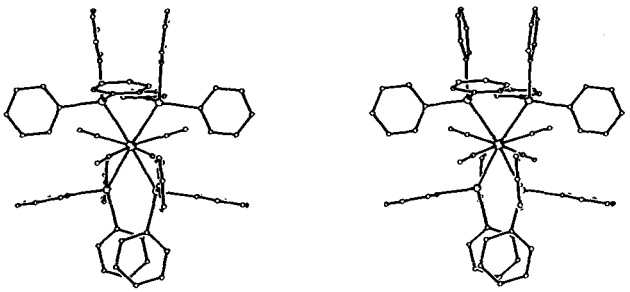

Fig. 2. Stereoview of **2** looking down the $S_4(\bar{4})$ axis.

and angles for **1** and **2** are shown in Table 1 and appear to be within normal limits. Also, cations are well separated from anions in the crystalline lattice. As expected on the basis of previous studies on isostructural zirconium and hafnium complexes,[16] the carbon and tin bonds to hafnium are somewhat shorter than corresponding bonds to zirconium. Prior to this work, $[(\eta\text{-toluene})_2Hf(SnMe_3)_2]$[17] was the only example of a structurally characterized compound containing heavier group 4 metal–tin bonds. These Hf–Sn bonds

Table 1. Selected bond lengths [Å] and angles [°] for **1** and **2**.

	Zr (**1**)	Hf (**2**)
Bond lengths		
M-C	2.232(5)	2.162(12)
M-Sn	3.086(1)	3.063(1)
C-O	1.155(6)	1.189(16)
Sn-(*ipso*)C (mean)	2.22(2)	2.22(1)
Bond angles		
M-C-O	177.9(4)	176.8(4)
Sn-M-Sn(a)	125.7(1)	125.6(1)
Sn-M-Sn(b)	80.3(1)	80.5(1)
C-M-C(a)	93.6(1)	94.0(2)
C-M-C(b)	151.1(3)	149.2(6)
C-M-Sn	89.4(1)	88.1(3)
C-M-Sn(a)	66.0(1)	66.6(3)
C-M-Sn(b)	68.2(1)	68.2(3)
C-M-Sn(c)	142.0(1)	143.3(3)

are appreciably shorter (2.953(1) Å) than those in **2**, perhaps due to a less crowded environment about hafnium in the bis-arene complex. Although the M–C bonds in **1** and **2** are somewhat longer than corresponding ones found in $[(C_5Me_5)_2M(CO)_2]$ (Zr-C = 2.145(9), Hf-C = 2.14(2) Å),[18] they are quite similar in length to those observed recently for the octahedral $[M(CO)_6]^{2\ominus}$ (Zr-C = 2.210(4), Hf-C = 2.178(3) Å).[1] The metal carbonyl units are close to being linear. Average Sn–M–Sn(b) and C–M–C(b) angles for **1** and **2** are 80.4(2) and 150(1)°, respectively, giving dodecahedral shape parameters of 40.2° for θ_A(Sn) and 75° for θ_B(C).[15] These data are typical of dodecahedral geometries.[19]

Whether similar carbonyl complexes of the group 3 metals can be prepared and isolated is currently under investigation.

Experimental Procedure

In a typical synthesis of **2**, a cold solution (−60 °C) of $NaC_{10}H_8$ (1.30 g, 8.6 mmol) in 80 mL of 1,2-dimethoxyethane (DME) was added by cannula to a mechanically stirred solution/slurry of $HfCl_4 \cdot 2THF$ (2.0 g, 4.3 mmol) and PMe_3 (1.8 mL, 18 mmol) in 70 mL of DME at −60 °C. Addition of a cold solution (−60 °C) of $NaSnPh_3$ (6.42 g, 17.2 mmol) in 100 mL of DME to the resulting red-brown solution caused the color to change rapidly to a deep green. Argon was replaced by CO (1 atm) and the reaction mixture was stirred under CO for 12 h, while slowly warming to room temperature, to give a deep red solution. After filtration and cation exchange (with Et_4NBr), a red solid was obtained upon addition of excess ethanol. Recrystallization of the product from CH_3CN–toluene provided deep purple crystals (5.1 g, 61%), which gave satisfactory analyses (C, H, Sn) for **2** as a bis-tetraethylammonium salt. Similar yields (50–60%) were obtained for the $n Pr_4N^{\oplus}$ salt (correct C, H analyses). The same procedure consistently provided lower yields (25–45%) of satisfactorily pure **1** as $Et_4N^{\oplus}$ and $nPr_4N^{\oplus}$ salts (C, H, Sn analyses). These substances are stable indefinitely under nitrogen at room temperature and decompose without melting above 150 °C. Spectroscopic data for the anions as $Et_4N^{\oplus}$ or $nPr_4N^{\oplus}$ salts are essentially identical and are shown only for the $Et_4N^{\oplus}$ compounds [10–12]. The 99% enriched ^{13}CO complexes were prepared by the same procedure with suitably enriched CO. X-ray quality crystals were obtained by slow diffusion of diethyl ether into an acetonitrile solution of the $nPr_4N^{\oplus}$ salts at 0 °C over a 3–5-day period. Suitable crystals could not be obtained with the less soluble $Et_4N^{\oplus}$ salts.

[12] Signals due to cations are not given. $^{13}C\{^1H\}$ NMR (75 MHz, CD_3CN, 50 °C, TMS): **1**: δ = 242.0 (pseudoquintet, CO, $^2J(^{119}Sn, ^{117}Sn\text{-}^{13}C)$ = 100 Hz); **1**: δ = 239.7 (pseudoquintet, CO, $^2J(^{119}Sn, ^{117}Sn\text{-}^{13}C)$ = 93 Hz). The pseudoquintet has relative intensities of approximately 1:6:16:6:1. These relative intensities are in satisfactory agreement with the calculated ones of 1:7:19:7:1 for the most intense five lines of nonets arising from four magnetically equivalent tin groups coupled to ^{13}C, assuming identical $J(^{115,117,119}Sn\text{-}^{13}C)$ values and a total relative abundance of NMR-active Sn nuclei of 16.54%. The outermost four lines of the nonets were too low in intensity for detection. $^{119}Sn\{^1H\}$ NMR (112 MHz, CD_3CN, 50 °C, Me_4Sn): **1**: δ = 337 (binomial quintet, $^2J(^{119}Sn\text{-}^{13}C)$ = 102 Hz); **2**: δ = 300 (binomial quintet, $^2J(^{119}Sn\text{-}^{13}C)$ = 93 Hz). Below 40 °C (**1**) or 50 °C (**2**), the ^{13}C and ^{119}Sn NMR signals broaden and become strongly temperature-dependent. For further details see K.-M. Chi, *Ph.D. Thesis*, University of Minnesota, 1988.
[13] *Rudolph* et al. previously established that "triplet" ^{119}Sn resonances with relative intensities of 1:6.25:1, 1:8.3:1, or 1:12.5:1 are expected from ^{117}Sn–^{119}Sn coupling for a cluster containing five, four, or three equivalent tin atoms, respectively. The observed $J(^{117}Sn\text{-}^{119}Sn)$ value of 1224 Hz for the naked metal cluster $Sn_4^{2\ominus}$ is very similar to the corresponding value we observed for $[(Ph_3Sn)_4Hf(CO)_4]^{2\ominus}$. Synthesis of Nonstabilized Phosphaalkynes by Vacuum Gas-Solid HCl Elimination

By *J. C. Guillemin, T. Janati, P. Guenot, P. Savignac,* and *J. M. Denis**

Phosphaalkynes have recently proved useful as building blocks in synthesis.[1] The stabilized derivatives bearing tertiary or secondary alkyl groups are efficiently prepared by base-induced elimination of hexamethyldisiloxane from the corresponding α-trimethylsiloxy *P*-trimethylsilylphosphaalkenes.[2] However, with the exception of $HC{\equiv}P$ and $CH_3C{\equiv}P$, which are obtained in low yield by flash vacuum thermolysis of the corresponding dichlorophosphanes,[3] no efficient method is available to synthesize other nonstabilized phosphaalkynes. Recently we have shown that (dichloromethyl)phosphane can be regarded as a synthetic equivalent of $HC{\equiv}P$.[4] We now report that $HC{\equiv}P$ and other nonstabilized phosphaalkynes can be easily synthesized from the corresponding (dichloroalkyl)phosphanes by vacuum gas-solid HCl elimination (VGSR).[5]

Halogen–metal exchange between **1** and *n*BuLi in the presence of LiCl and subsequent acid hydrolysis or alkylation led to (dichloroalkyl)phosphonates **2**.[6] We observed a cleaner reaction and better yields with diisopropyl ester **1** in place of the diethyl ester **1** (R = Et) used previously.

$$Cl_3CP(O)(OR)_2 \xrightarrow[2)\ R^1X,\ THF,\ -80°C]{1)\ n\text{BuLi/LiCl, THF, } -85°C} R^1Cl_2CP(O)(OR)_2$$

The chemoselective reduction of phosphonate **2** to **3** was critical: the best results were obtained with $AlHCl_2$ as an electrophilic reducing agent in diethyl ether at low temperature.[7] To avoid polymerization, phosphane **3** must be quickly purified by distillation. Phosphonate **1** could also be reduced in this way to give **3f** (R^1 = Cl).

$$\underset{\textbf{2a–2e}}{R^1Cl_2CP(O)(OR)_2} \xrightarrow[Et_2O,\ -80°C]{AlHCl_2} \underset{\textbf{3a–3e}}{R^1Cl_2CPH_2}$$

Purified (dichloroalkyl)phosphanes **3** can be stored for several weeks in a refrigerator (5 °C) in the presence of a small amount of hydroquinone. The stability of **3** at room temperature depends on the substituents: **3e** and **3f** decompose in a few hours, but **3b**–**3d** can be kept for several days. The parent compound **3a** cleanly isomerized, probably via a twofold HCl elimination/addition, into the corresponding dichlorophosphane CH_3PCl_2. Phosphanes **3** were characterized by ^1H, ^{13}C, and ^{31}P NMR spectroscopy as well as by high-resolution mass spectrometry (HRMS) (Table 1).

Table 1. Selected spectroscopic data for (dichloroalkyl)phosphanes **3** (*J* in Hz).

3	R^1	δ^1H [a]	$\delta^{31}P$ (^1J(PH)) [a]	$\delta^{13}C$ (^1J(CP)) [a]	*m/z* of $M^{\oplus}$ found (calcd)

f	Cl		−12 (200)	89.8 (42)	149.895 (149.8960)

[a] $CDCl_3$, TMS, room temperature. [b] $(M-Cl)^{\oplus}$

Owing to the acidity of the two hydrogens bonded to the phosphorus atom, dehydrochlorination of **3** readily occurred in a VGSR sequence using K_2CO_3 as a solid base.[5] The first HCl elimination was performed at 200 °C, but the transient chlorophosphaalkenes **4** polymerized even at low temperature. Complete HCl elimination takes place at 350 °C.[8] The phosphaalkynes **5** were collected by a standard procedure[5] and characterized by NMR and IR spectroscopy and by mass spectrometry (Table 2). As an example, compound **5b** was obtained from 0.018 mol of **3b** in 60% yield (see *Experimental Procedure*).

$$\underset{\textbf{3}}{R^1Cl_2CPH_2} \xrightarrow[VGSR]{K_2CO_3} \underset{\textbf{4}}{\left[\begin{array}{c} R^1 \\ \diagdown \\ Cl \end{array} C{=}P{\sim}H\right]} \xrightarrow[VGSR,\ 350°C]{K_2CO_3} \underset{\textbf{5}}{R^1{-}C{\equiv}P}$$

For **5a**, **5b**, and **5e**, the NMR data are in good agreement with the reported values;[3b, 11] for the new compounds **5c**, **5d**, and **5f**, the data are consistent with the structures. A ^{31}P NMR high-field signal for **5f** was also observed for $FC{\equiv}P$ ($\delta = -205$).[12] Phosphaalkynes **5** can be kept for several hours or days under neutral atmosphere in a dilute THF solution (see Table 2). This stability, higher than previously reported, can be explained by their good purity. We have also obtained in low yield the chlorophosphaalkyne **5f** in the flash vacuum thermolysis products of $ClCH_2PCl_2$ heated at 850 °C.[13]

Experimental Procedure

Caution: All the reactions were carried out under nitrogen in a well-ventilated hood, since (dichloroalkyl)phosphanes and phosphaalkynes are pyrophoric compounds.

3a–3d, 3f: $LiAlH_4$ (1.33 g, 3.5×10^{-2} mol) in freshly distilled diethyl ether (100 mL) was introduced into a 250-mL three-necked flask. The mixture was cooled to −80 °C and $AlCl_3$ (14.0 g, 1.05×10^{-1} mol) quickly added. The suspension was allowed to warm to 10 °C, then cooled again to −80 °C. The phosphonate (2.5×10^{-2} mol) in diethyl ether (25 mL) was added dropwise at a rate to maintain the temperature under −70 °C. At the end of the addition, the mixture was allowed to warm to 10 °C. The volatile products were condensed into a cold trap. Most of the ether was then distilled off at atmospheric pressure (the oil bath temperature must be maintained below 70 °C). The flask containing the concentrated solution (about 10 mL) was cooled to −67 °C and evacuated for 20 min (10^{-2} mbar) to remove traces of solvent. Distillation of the residue in vacuo led to the pure phosphane (yield ca. 50%).

3e: The reduction was performed under the conditions reported above. To avoid polymerization of **3e** on heating, $NaHCO_3$ (5 g) was added at room temperature to the stirred decanted solution. After 5 min, the solution was filtered under nitrogen and distilled in vacuo. Compound **3e** was condensed as a white solid into a cold trap (−40 °C) while diethyl ether was removed (yield 70%, mp > 60 °C (dec.)).

5b *(VGSR)* [5]: Dried K_2CO_3 (150 g), ground into a fine powder with a laboratory mill, was introduced into a VGSR reactor (pyrex tube, l = 80 cm, inner diameter 4.0 cm), then horizontally distributed between two pads of glass wool separated by 60 cm. The reactor, fitted to a cold trap (77 K) bearing a Schlenk flask at the bottom, was heated to 350 °C [8]. Dichlorophosphane **3b** (2.4 g, 1.83×10^{-2} mol) was then slowly vaporized in vacuo (1 g per hour) through the reactor. The trap was disconnected from the reactor and vacuum pump by closing stopcocks and allowed to warm to room temperature while phosphaalkyne **5b** (0.64 g, 1.1×10^{-2} mol) was condensed into the Schlenk flask previously cooled to 77 K (yield 60%).

Analytical samples of phosphaalkynes **5a–5f**:

The general procedure described above was modified: the solvent (THF or $CDCl_3$), introduced between reactor and trap, was condensed with **5** (ca. 1.4×10^{-3} mol) into the cold trap. Transfer of the solution into the Schlenk flask was performed at atmospheric pressure under dry nitrogen.

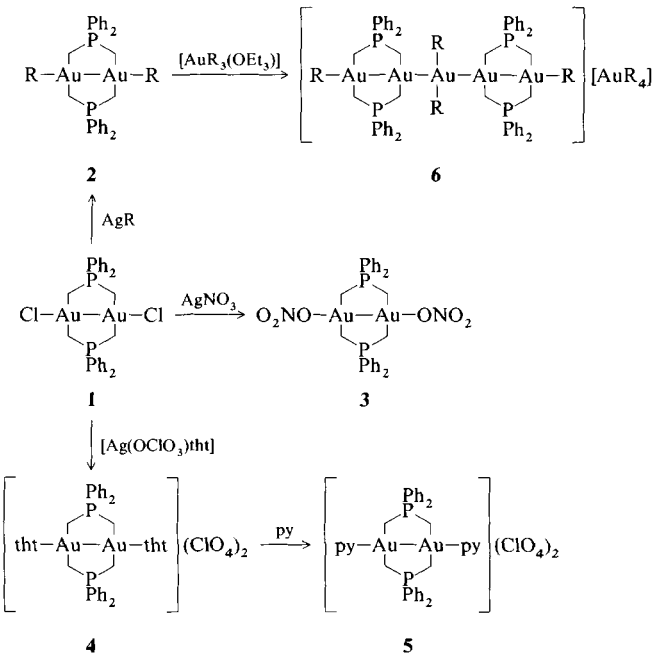
The reaction of **1** with the silver complex $Ag(OClO_3)(tht)$ (tht = tetrahydrothiophene) leads to the cationic complex **4**. Since tht is a readily displaceable ligand in gold complexes, **4** is a precursor for other cationic gold(II) complexes. For example, the cationic **5** is formed on addition of pyridine. Complexes **4** and **5** are the first cationic binuclear gold(II) complexes.



Scheme 1. Reactions of the binuclear gold(II) complex **1**. R = C_6F_5; tht = tetrahydrothiophene.

A Mixed-Valent Pentanuclear Gold Complex Containing a Linear $Au_5^{9\oplus}$ Chain**

By *Rafael Usón,* Antonio Laguna, Mariano Laguna, Josefina Jiménez* and *Peter G. Jones**

In 1988 we reported $[\{Au(CH_2)_2PPh_2\}_2Au(C_6F_5)_3]$,[1] the first oligonuclear gold complex with a gold(I)-gold(III) bond unsupported by covalent bridges. Here we report the synthesis and structure of a pentanuclear gold complex that has a linear chain of gold atoms in different oxidation states, $[Au^{III}]_2$-Au^{I}-$[Au^{III}]_2$. The central gold(I) atom, also unsupported by any covalent bridges, is linked to two gold(II) atoms.

Our starting complex is binuclear bridged **1** (Scheme 1), which is a good precursor for cationic and neutral binuclear gold(II) complexes. Complex **1** reacts with silver salts $Ag(C_6F_5)$ or $AgNO_3$ to afford the neutral complexes **2** (80% yield) or **3**[2] respectively. Complex **2** has been prepared by *Fackler* et al.[3] by a different method in slightly lower yield (62%).

The reaction of **2** with $[Au(C_6F_5)_3(OEt_2)]$ in the ratio 1:1 in dichloromethane led surprisingly to the pentanuclear cationic complex **6**, which possesses very unusual features. A stoichiometric formulation for the process is given in equation (a). The mother liquor after crystallization of **6** contains $C_{12}F_{10}$ (by ^{19}F NMR spectroscopy) together with unidentified products.

$$2\,\mathbf{2} + 2[AuR_3(OEt_2)] \longrightarrow \mathbf{6} + C_{12}F_{10} + 2\,Et_2O \qquad \text{(a)}$$
$$R = C_6F_5$$

Crystals of **6** suitable for X-ray studies were obtained from dichloromethane/petroleum ether as equidimensional red prisms. The crystals contain solvent, and thus had to be handled under inert oil to prevent cracking. The structure[4] of the cation of **6** is shown in Figure 1. Its backbone is a linear chain of five gold atoms (Au–Au–Au bond angles 176.3(1), 180°), all of which have square planar coordination geometry (maximum deviation from ideal angles 5.7°). The central atom Au1 lies on the symmetry centre $\frac{1}{4},\frac{1}{4},0$; the bond lengths are Au1–Au2 2.755(1), Au2–Au3 2.640(1) Å (cf. 2.769(1) Å across the eight-membered ring, 2.572(1) Å terminal in $[\{Au(CH_2)_2PPh_2\}_2Au(C_6F_5)_3]$).[1] The $[Au(C_6F_5)_4]^{\ominus}$ anion (not shown) lies with its Au atom (Au4) on the twofold axis $0,y,\frac{1}{4}$.

The assignment of oxidation states to the gold atoms of the pentanuclear cation is problematic. If the central atom Au1 is regarded as gold(I) in an anionic $[Au(C_6F_5)_2]^{\ominus}$ moiety, formed by reduction of the original gold(III) in $[Au(C_6F_5)_3(OEt_2)]$ by the two of $C_6F_5^{\ominus}$ leaving groups (one

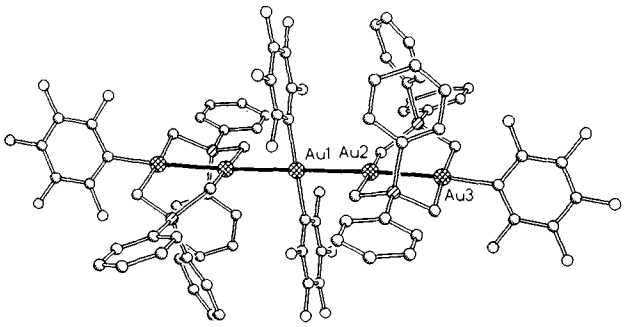

Fig. 1. The centrosymmetric cation of **6** in the crystal. Radii are arbitrary; H atoms omitted for clarity. Au–C bond lengths: at Au1 2.07 Å; Au2 2.10,2.10 Å; Au3 2.10,2.10 Å; and Au4 (not shown) 2.06,2.06 Å (estimated standard deviations 0.01 Å).

from each original gold(II) atom in **2**), then complex **6** is the first example of square planar gold(I). We prefer this description, but there is an alternative possibility: if Au1 is gold(III), part of a cationic $[Au(C_6F_5)_2]^{\oplus}$ moiety, then Au2 should be gold(I) and Au3 gold(II), again an unprecedented situation.

$Li_4[FeN_2]$: A Nitridoferrate(II) with Anions Isosteric with CO_2. A Defect Variant of the Li_3N Type Structure.**

By *Axel Gudat, Rüdiger Kniep** and *Albrecht Rabenau*

Nitridoferrates were not well known up to now. Although *Frankenberger* et al.[1] prepared Li_3FeN_2 already in 1928 from Li_3N and elemental iron in a nitrogen atmosphere, the crystal structure was only determined in 1990 and proved to be a nitridoferrate(III), with infinite one-dimensional chains of tetrahedral $[FeN_2]^{3\ominus}$ units ($^1_\infty[FeN_{4/2}]^{3\ominus}$) isosteric with SiS_2.[2] Only recently nitridoferrates(III) with the anions $[FeN_3]^{6\ominus}$ isosteric with $[CO_3]^{2\ominus}$ were found in the ternary systems Ca-Fe-N and Ba-Fe-N:[3] $(Ca_3N)_2[FeN_3]$[4] and $Ba_3[FeN_3]$.[5] Now we report the synthesis of a nitridoferrate(II), which contains $[FeN_2]^{4\ominus}$ units isosteric with CO_2.

Nitridoferrates are a structural link in the series of lithium and alkali earth nitridometalates of transition metals studied thus far. Nitridometalates of transition metals with group numbers smaller than eight contain isolated tetrahedral anions, $[MN_4]^{n\ominus}$, where the metal is in its highest, or at least a high, oxidation state, for example $Li_7[V^VN_4]$,[6] $Li_6[Cr^{VI}N_4]$,[7] $Li_7[Mn^VN_4]$,[8] $Ba_3[Mo^{VI}N_4]$ and $Ba_3[W^{VI}N_4]$.[9] As 32-electron systems the tetrahedral anions $[MN_4]^{n\ominus}$ are related to the ortho acid anions (oxo anions). The partial anion structures of the nitridoferrates also satisfy isosteric principles; however, the transition metal frequently shows a tendency to form smaller coordination numbers (CN): CN = 4 for Fe^{III} in $Li_3[FeN_2]$, CN = 3 for Fe^{III} in $Ba_3[FeN_3]$ and CN = 2 for Fe^{II} in $Li_4[FeN_2]$. The low oxidation state and the linear coordination of iron in the anions $[FeN_2]^{4\ominus}$ establishes the bridge to the low valent nitridoniccolates, which also have a coordination number of two and anion structures $^1_\infty[NiN^{n\ominus}_{2/2}]$ (for example, $Ba[NiN]$,[10] $Sr_3[Li_3(NiN)_4]$[11] and $(Ba_8N)[NiN]_6$[12]).

Besides the thermodynamically stable $Li_3[FeN_2]$,[2] the ternary Li-Fe-N system also incorporates metastable phases[13, 14] formed by fast cooling or quenching the melt. In order to prepare $Li_4[FeN_2]$ we melted lithium (99%; Ventron; cut under argon) in an iron crucible (ST 37 K) under vacuum and allowed it to react with nitrogen (5.0; Oxysorb, $p(N_2) = 100-800$ mbar), while continually increasing the temperature to 900 °C. The melt was kept at this temperature for 5 h and then shocked into a water-cooled iron crucible inverted shortly before over the reaction vessel. The products obtained thus are sensitive to hydrolysis and have a dark metallic luster. Besides Li_3N, $Li_3[FeN_2]$, and amorphous phases, they consist of up to 80% of metastable mixed crystal phases of the Li_3N structure type[15–17] and its superstructure variants. The composition of the mixed crystal phases lies between $Li_2[(Li_{1-x}Fe_x)N]$ $(0 \le x \le 1)$ and $Li_2[(Li_{1-3x}Fe_x)N]$ $(0 \le x \le 0.33)$; that of the superstructure variants is $Li_4Fe_xN_2$ $(x = 1.0-1.04)$. Single crystals of $Li_4[FeN_2]$ were isolated under dry paraffin as orthogonal prisms from the quenched reguli.

The crystal structure of $Li_4[FeN_2]$[18] (Fig. 1) may be described as a defect type of the Li_3N-type structure[15, 16] $(Li_2Fe_{0.5}\square_{0.5}N)$, in which the Li_2N layers are linked by linearly coordinated iron(II). The orthorhombic unit cell results from the ordered distribution of Fe^{II} between the Li_2N layers. The identity period along [001] is twice as big as that of Li_3N. The anion partial structure of $Li_4[FeN_2]$ consists of isolated, CO_2-isosteric $[FeN_2]^{4\ominus}$ dumb-bells (16-electron system) with Fe–N bond lengths of 186(1) pm (Li–N bond lengths within the $^1_\infty[LiN_{2/2}]$ chains in Li_3N: 193.8(1) pm[16]). These bond lengths are longer than Fe^{III}–N bonds where CN = 3 (in $(Ca_3N)_2[FeN_3]$,[4] 177 (2) and in $Ba_3[FeN_3]$,[5] 173 (1) pm) and clearly shorter where CN = 4 ($Li_3[FeN_2]$,[2] 195 (1) pm). The shortest known Fe–N bond (166.1(1) pm) occurs in the tetraphenylporphyrinato complex $[(tpp)Fe]_2N$ within the linear Fe-N-Fe bridges.[19] In contrast to Li_3N the Li_2N layers in $Li_4[FeN_2]$ are slightly corrigated (deviation from an ideal plane ± 2.05 (5) pm). The average Li–N distance within the layers is 214 (2) pm and is only slightly

longer than 210.6 (1) pm for the Li_3N structure[16]; the lithium ions within these planar layers are responsible for the remarkably high ion conductivity of Li_3N[20].

The formation of $Li_4[FeN_2]$ by quenching or rapid cooling from the melt is consistent with a metastable character at least under normal conditions. Already in 1949 *Sachsze* and *Juza*[17] noticed that mixed crystal phases of the Li_3N type $(Li_{1-x}M_x)$ $[Li_2N]$ are obtained from Li_3N and the transition metals M = Co, Ni, Cu under nitrogen at temperatures between 500 and 600 °C (i.e. probably from solid–gas reactions), but only $Li_3[FeN_2]$ when M = Fe.[1, 2] By quenching the melt such mixed crystal phases for M = Fe are formed besides primary crystallization products with an orthorhombic superstructure of the Li_3N type (*Cmmm*; $a = 741.3$ (2), $b = 1283.4$ (4), $c = 753.7$ (2) pm) in which the Li_2N layers are linked exclusively via iron–nitrogen contacts. In contrast to $Li_4[FeN_2]$ (Fig. 1), the iron positions are only partly occupied, so that besides isolated FeN_2 dumb-bells, chains of $^1_\infty[Fe_xN_{2/2}]$ $(x < 1)$ are also formed, which run parallel to the [001] direction. Several room-temperature structure investigations performed on one of the orthorhombic crystals (chemical composition from the first crystal structure analysis: $Li_4Fe_{1.04}N_2$) revealed continual place-changing of the iron atoms while the Li_2N layers were preserved. Over a long period this topotactic reaction leads finally to the formation of $Li_4[FeN_2]$ under polysynthetic twinning and secretion of the minimal excess of iron at the grain boundaries. Thus no single crystals of $Li_4[FeN_2]$ could be isolated and the crystal structure determination was carried out with a triplet crystal.[18–20]

Synthesis of the 2,3-Epoxy-2,3-dihydro-2,3-dimethylbenzo[*b*]furan, the Proposed Ultimate Mutagen of the Benzofuran Dioxetanes**

By *Waldemar Adam,* Lazaros Hadjiarapoglou, Thomas Mosandl, Chantu R. Saha-Möller*, and *Dieter Wild*

Furans can be metabolized by mixed function oxidases[1] into epoxides and these in turn are usually responsible for cellular damage. A well-known case is the potent mutagen and carcinogen aflatoxin B_1, a 2,3-dihydrofuran derivative, whose ultimate DNA-binding metabolite is the epoxide. The latter was recently prepared and shown to be a potent mutagen[2]. Since 2,3-dimethylbenzo[*b*]furan is used as a flavoring ingredient in foods,[3] we have been concerned with the possibility that its epoxide may induce DNA damage. In contrast to the reasonably stable 2,3-dihydrofuran epoxides,[2, 4] to date no furan epoxides have been isolated or detected; attempted epoxidation, even at low temperatures, afforded complex product mixtures.[5] Herein, we report the synthesis of the first benzofuran epoxides **2** by two independent routes (Scheme 1), one involving epoxidation of the benzofurans **1** with dimethyldioxirane and the other involving deoxygenation of the benzofuran dioxetane **3a** with dimethyl sulfide. Moreover, we implicate the benzofuran epoxides **2** as the ultimate compounds responsible for the high mutagenic activity in the *Salmonella typhimurium* strain TA 100 observed with benzofuran dioxetanes **3**;[6] these are the first dioxetanes which exhibit potent mutagenicity. We postulate that

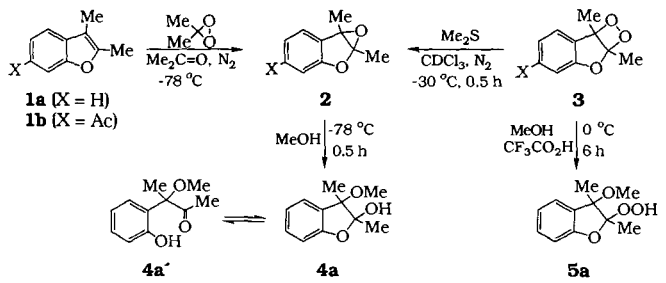
the in situ deoxygenation of polycyclic arene and heteroarene dioxetanes with formation of reactive epoxides may contribute significantly to cellular DNA damage.[7]



Scheme 1.

On treatment of a 0.22 M solution of benzofuran **1a** with stoichiometric amounts of a 0.05 M solution of [D_6]dimethyldioxirane in [D_6]acetone at $-78\,^{\circ}C$,[8] ^{13}C-NMR monitoring revealed after 0.5 h that the olefinic resonances of **1a** at $\delta = 109.7$(s) and 150.3(s) were replaced by the characteristic epoxide resonances for **2a** at $\delta = 66.9$(s) and 95.1(s). Analogous results were observed on reaction of the benzofuran **1b** with dimethyldioxirane to give the corresponding epoxide **2b** [^{13}C NMR ([D_6]acetone): $\delta = 66.5$ (s, C-3), 95.9 (s, C-2)]. The epoxide **2a** was also obtained on treatment of a 0.337 M solution of benzofuran dioxetane **3a** with stoichiometric amounts of a 0.337 M solution of dimethyl sulfide in $CDCl_3$ at $-30\,^{\circ}C$.[9] On warming the epoxide solutions above $0\,^{\circ}C$, complete decomposition resulted within 0.5 h.

The chemical reactivity of the epoxide **2a** manifested itself in the formation of the adduct **4a** (Scheme 1); complete conversion was observable 0.5 h after addition of methanol at $-78\,^{\circ}C$ (Scheme 1). The semiacetal **4a** was isolated in 95% yield as a *cis/trans* mixture; present in tautomeric equilibrium with the hydroxyketone (**4a**:**4a'** = 87:13).[10] In contrast, the dioxetane **3a** was stable towards methanol under these conditions; however, in the presence of traces of CF_3COOH complete methanolysis took place within 6 h at ca. $0\,^{\circ}C$ to give hydroperoxide **5a**[10] (Scheme 1). Similar reactivity differences were observed towards water as nucleophile.

These chemical transformations illustrate the labile character of the novel benzofuran epoxides **2**, and particularly their propensity to serve as alkylating agents. As expected, they also induced mutations in *Salmonella typhimurium* strain TA 100, a strain mutating especially in response to alkylation and pyrimidine dimerization in DNA. Incubation of Salmonella bacteria with epoxide **2a** (0.1–1 mM for 0.5 h) led to a linear, dose-dependent increase of revertants; the specific mutagenic activity was calculated to be ca. 1800 revertants per µmol. Treatment of acetone solutions of epoxide **2a** with aqueous phosphate buffer prior to incubation of the bacteria revealed decreased mutagenic activity with increasing pretreatment time. Apparently most of the labile benzofuran epoxide **2a** was hydrolyzed in the aqueous solution prior to reaching the DNA target.

Significant in this respect is the potent mutagenicity of the corresponding benzofuran dioxetanes **3a**.[6] Employing the standard procedure of the Ames test[11] (*Salmonella typhimurium* strain TA 100), **3a** induced ca. 117 000 and dioxetane **3b** ca. 370 000 revertants per µmol; these compounds are the first potent mutagens possessing the dioxetane structure; in the strain TA 2638, these dioxetanes were not mutagenic. This suggests that the damage is not due to active oxygen species which are generally involved in the genotoxicity of peroxides.[12] Furthermore, the damage in strain TA 100 could not be photoreactivated; it is, therefore, unlikely that the observed mutagenicity is of photochemical origin, e.g. due to pyrimidine dimerization,[12, 13] despite the fact that the strain TA 100 responds to such DNA damage.

In view of the similarity in the mutagenic action of the benzofuran epoxides **2** and dioxetanes **3**, we propose that the former are the ultimate mutagens of the latter. It is unlikely that the dioxetanes **3** are directly alkylating the DNA, because nucleophilic addition of methanol to the dioxetane **3a** requires acid catalysis and is slow compared to that for the epoxide **2** (Scheme 1). Since the dioxetanes **3** can be efficiently deoxygenated by sulfides to the corresponding epoxides **2**, an attractive chemical pathway is available for in situ generation of such reactive heteroarene oxides from the corresponding dioxetanes. Indeed, a model experiment showed that an aqueous solution of the biologically pertinent sulfide L-methionine effected the deoxygenation of the benzofuran dioxetane **3a** to the epoxide **2a** at $0\,^{\circ}C$, as confirmed by isolation of its hydrolysis product 2,3-dihydro-2,3-dimethylbenzo[*b*]furan-2,3-diol[10] in over 90% yield. Consequently, such deoxygenations of dioxetanes into epoxides by biological sulfides are feasible in cellular systems.

The provocative hypothesis put forth presently, that appropriate dioxetanes such as those derived from benzofurans may serve as precursors of mutagenic epoxides, constitutes an unusual and hitherto unrecognized mode for the induction of mutations. This novel mutagenic mechanism rests on the following key facts: the labile benzofuran epoxides **2** could be isolated for the first time, the benzofuran dioxetanes **3** could be deoxygenated with sulfides to these epoxides **2**, and finally mutagenic activity, similar in quality, could be demonstrated for the epoxides **2** and dioxetanes **3** in *Salmonella typhimurium* strain TA 100. We speculate that this new mutagenicity route may potentially possess wide scope, in that quite generally polycyclic arenes, such as benzo[a]pyrene, or polycyclic heteroarenes, such as furocoumarins, may be oxygenated to epoxides via the corresponding dioxetanes. In fact, in the mutagenic activity of benzo[a]pyrene a dioxetane has been implicated previously[7a, b], but the possibility that the dioxetane might serve also as precursor of its epoxide, analogous to the route **1** → **3** → **2**, has not yet been considered.

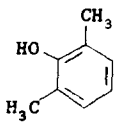
The Diels–Alder Dimer of 6-Hydroxy-2,6-dimethylcyclohexa-2,4-dienone, an Unusual Metabolite in the Bacterial Degradation of 2,6-Xylenol**

By *Helmut Kneifel, Carmen Poszich-Buscher, Susanne Rittich,* and *Eberhard Breitmaier**

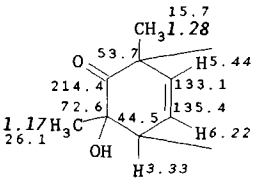
The pathways of the microbial degradation of most phenols which occur, e.g., in soils polluted with waste materials from former coke ovens, are well known.[1] Only 2,6-xylenol **1** was for a long time considered as biologically non-degradable; a possible degradation route was first proposed as late as 1987.[2, 3] The special feature of **1** in comparison to other phenols is that its two methyl groups *ortho* to the OH group block *ortho*-hydroxylation of the aromatic ring.



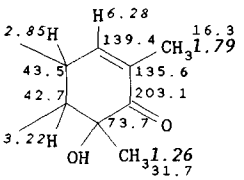
1

A complete degradation of 2,6-xylenol **1** via a hydroxylation in the 3- or 4-position with subsequent ring cleavage was achieved with a mixed culture, which besides containing pseudomonads also contains other still unidentified bacteria. When this mixed culture, however, is allowed to propagate over a long period of time on a mixed substrate of cresol isomers and phenol and **1** is added as further source of carbon and energy at high biomass concentration during the logarithmic growth phase, not only the oxidation products 2,6-dimethylhydroquinone, 2,6-dimethyl-1,4-benzoquinone, and 2-hydroxy-3,5-dimethyl-1,4-benzoquinone but also a new metabolite accumulates in the culture medium. This dead-end metabolite can be extracted with ethyl acetate and purified by preparative reversed-phase HPLC ($k' = 2.8$ upon HPLC on ODS-1 with acetonitrile/0.1% aqueous phosphoric acid 35/65 as eluent). The product absorbs strongly in the UV (λ_{max} = 242, 308 nm, lg ε_{max} = 3.84, 2.38); the GC-MS spectrum of the trimethylsilyl derivative shows peaks at m/z = 210 ($M^{\oplus}$), 195, 180, 167, 75, and 73 (100%).

Elucidation of the structure was accomplished, using 2 mg of substance, by ^{1}H- and ^{13}C-NMR methods. The ^{13}C-NMR spectrum of the metabolite shows 16 signals, yet the mass spectrum of the trimethylsilyl derivative indicates an empirical formula $C_8H_{10}O_2$ for the metabolite. H,H-COSY, C,H-COSY, and C,H-COLOC experiments identified the partial structures **2** and **3** ($\delta(^1H)$ italic figures, $\delta(^{13}C)$ upright figures in the formulas).

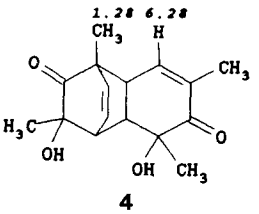


2

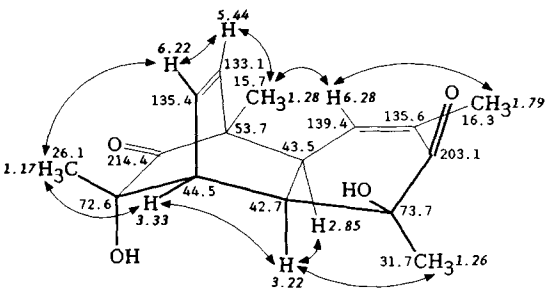


3

The coupling of the fragments **2** and **3** is possible in two ways; realized is the constitution **4**, as follows from the NOE difference spectra, which show a strong NOE between the methyl protons of **2** at δ = 1.28 and the alkene proton of **3** at δ = 6.28 (Scheme 1).



4



Scheme 1. NMR spectroscopic characterization of the 2,6-xylenol oxidation product **4**. The arrows link the H atoms between which a NOE occurs.

An NOE between the alkene proton of **2** at δ = 6.22 and the methyl protons of **2** at δ = 1.17 establishes the relative configuration of the respective methyl group (*exo*). The *exo* coupling of the six-membered ring follows, in particular, from the NOE between the methyl protons of **3** at δ = 1.26 and the bridgehead proton of **3** at δ = 3.22 as well as the absence of effects between the alkenyl proton pair with δ = 5.44/6.22 (**2**) and the bridgehead proton pair with δ = 2.85/3.22 (**3**). Also the mirror image of the structure shown in Scheme 1 would be possible, since, as a rule, enantiomers are not differentiated by NMR spectroscopy. That no corresponding peak for **4** appears in the mass spectrum can be explained in terms of a retro-Diels-Alder reaction of **4** in the GC-MS apparatus.

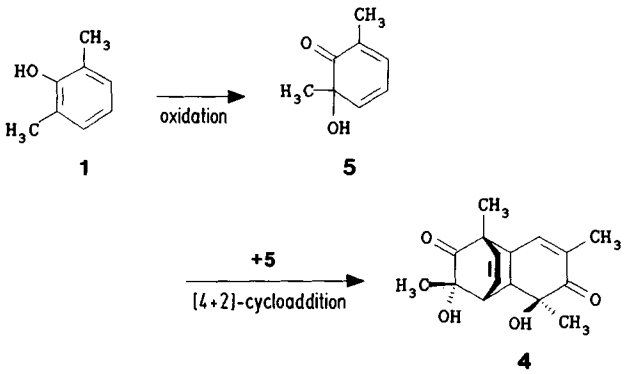
[**] This work was supported by the Bundesminister für Forschung und Technologie and by Biodetox, Ahnsen.

The metabolite **4**, which must be formulated as *exo*-3,10-dihydroxy-3,5,8,10-tetramethyltricyclo[6.2.2.$0^{2,7}$]dodeca-5,11-diene-4,9-dione, has already been described in the literature as a product of the oxidation of 2,6-xylenol **1** with sodium periodate.[4] As optically active natural product ($[\alpha]_D^{20} = -39.6°$, $c = 2.6$, $CHCl_3$), in contrast to the synthetic product, it is nevertheless new, as shown by a CAS on-line search. Metabolite and authentic substance prepared by the method described in Ref. [4] have identical HPLC retention times, IR, UV, and NMR spectra.

The metabolite **4** could be formed by Diels-Alder dimerization of the cyclohexadienone **5**, which is formed from **1** by oxidation. The methyl groups prevent a tautomerization of the dienone **5** to a pyrocatechol derivative.



1 **5** **4**

The formation of a 6-hydroxy-2,4-cyclohexadienone such as **6** in biological transformations of phenols has until now never been observed. Since there are numerous naturally occurring phenols with substituents in the 2- and 6-position—in particular methoxy groups are frequent, e.g. in syringic acid—*ortho*-hydroxylations of the type **1** → **5** could be of general importance.

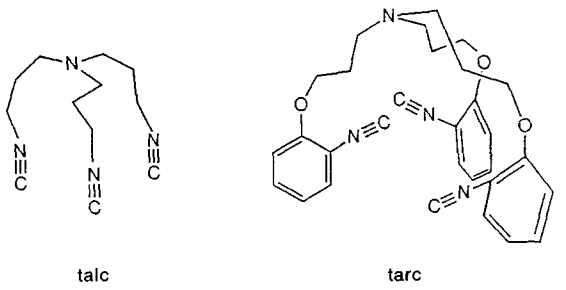
Chelate Complexes with Triisocyanide Ligands**

By *F. Ekkehardt Hahn** and *Matthias Tamm*

Isocyanide ligands form stable complexes of the type $[^{99m}Tc(CNR)_6]^{\oplus}$, which find application in the scintographic myocardium imaging[1] because of excellent radiophysical properties of the metastable isotope ^{99m}Tc.[2] During the search for particularly stable isocyanide complexes we prepared the potentially chelating triisocyanide ligands talc (3,3′,3″-nitrilotripropylisocyanide) and tarc (2,2′,2″-[nitrilotris(trimethyleneoxy)]triphenylisocyanide) (Fig. 1) and studied their coordination chemistry paying particular attention to chelate formation.

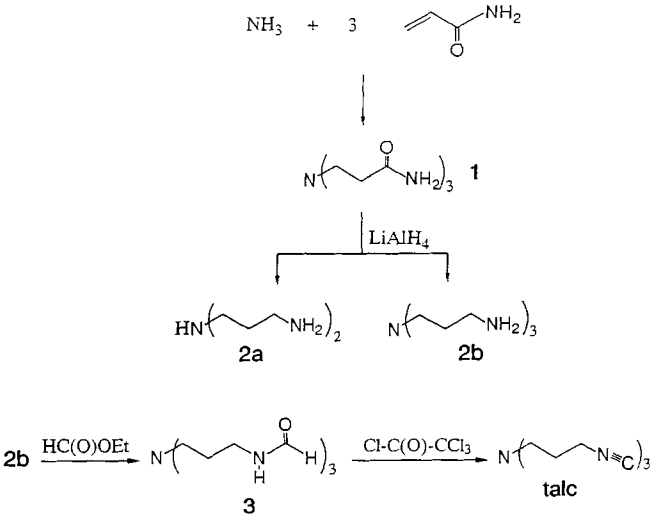


talc tarc

Fig. 1. Structural formulas for the ligands talc and tarc.

Little is known about the coordination chemistry of multidentate isocyanide ligands. The near linearity of the M–C≡N–R unit in metal complexes normally prevents the formation of chelate complexes analogous to those of diphosphanes and diamines. The known bridging di-[3] and triisocyanide ligands[4] do not form chelate complexes where one or more of the isocyanide functions coordinate to the same metal. Triisocyanide ligands which have isocyanide functions linked through longer alkyl chains could, however, act as chelating ligands. Talc and tarc are such examples.

The talc ligand was synthesized according to Scheme 1. We were surprised at the formation of bis(3-aminopropyl)amine



Scheme 1. Synthesis of talc.

(**2a**)[6] besides the desired tris(3-aminopropyl)amine (**2b**)[6] on reduction of **1**.[5] Reaction of **2b** with ethyl formate yields N,N′,N″-[nitrilotris(trimethylene)]triformamide quantitatively. The isocyanide functions of talc were introduced using the method of *Ugi* et al.[7] Talc is a yellow liquid that freezes at −20 °C and is soluble in alcohols, and aromatic and chlorinated hydrocarbons. The ^1H NMR spectrum shows the typical isocyanide[8] ^1H–^{14}N long-range coupling (H_y in Fig. 2);[6] different values for the two ^{13}C–^{14}N coupling constants are observed in the ^{13}C NMR spectrum.[6]

Talc crystallizes from ethanol at −78 °C. The X-ray structure (Fig. 3)[9] shows that talc is monomeric and gives

[**] Metal Chelates with Medical Implications, Part 4. Part 3: [12]

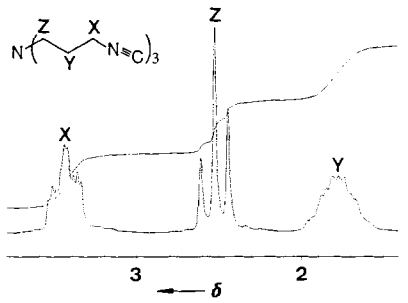

Fig. 2. ^{1}H NMR spectrum of talc.

an accurate N≡C distance for aliphatic isocyanides (1.135(3) Å) which is significantly shorter than the N≡C length determined by electron diffraction for CF_3NC (1.1726(2) Å)[10] or CH_3NC (1.166(1) Å).[11]

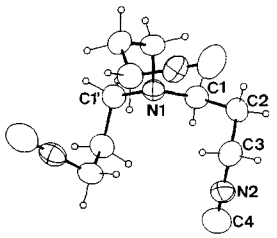

Fig. 3. Structure of talc in the crystal (ORTEP). Selected bond lengths [Å] and bond angles [°]: N2-C3 1.429(3), N2-C4 1.135(3); C3-N2-C4 176.6(2).

The ligand tarc is formed by Williamson etherification of tris(3-chloropropyl)amine[12] with three equivalents of *o*-nitrophenol, reduction of the nitro groups (analogous to reaction **1** → **2b**), formylation of the phenylamine functions with formic acid (analogous to the reaction **2b**→**3**) and the transformation of the thus formed formamide functions into isocyanide functions by the method of *Ugi* et al.[7] The yellow crystalline solid could be completely characterized.[6] Tarc is soluble in THF, CH_2Cl_2 and $CHCl_3$, but only slightly soluble in toluene and benzene.

To test the chelating ability of the new ligands we reacted them with $[(C_7H_8)M(CO)_3]$ (M = Cr, Mo, W) in dichloromethane[13] and examined the products by IR spectroscopy (Table 1) and in part by X-ray crystallography. The IR spectra show that octahedral, facial complexes with C_{3v} symmetry were formed. Whereas no significant shift in frequency for NC and CO absorptions occurs within the series *fac*-[(tarc)M(CO)$_3$], M = Cr, Mo, W, a comparison of the IR spectra of *fac*-[(talc)W(CO)$_3$] and *fac*-[(tarc)W(CO)$_3$] reveals that the aromatic isocyanide, tarc, is a weaker σ donor and a better π acceptor than talc, since the CO stretching frequencies appear at higher and the NC frequencies at lower wavenumbers than for *fac*-[(talc)W(CO)$_3$].

Table 1. IR data of talc, tarc, *fac*-[(talc)W(CO)$_3$], and *fac*-[(tarc)M(CO)$_3$] (M = Cr, Mo, W).

Compound	ν(NC) [cm^{-1}]		ν(CO) [cm^{-1}]	
	A_1	E	A_1	E
talc	2148			
fac-[(talc)W(CO)$_3$]	2160	2115	1932	1854
tarc	2118

fac-[(tarc)W(CO)$_3$]	2137	2068	1933	1878

On crystallization from dichloromethane *fac*-[(tarc)-W(CO)$_3$ · HCl] forms with 2.5 molecules of solvent per formula unit (Fig. 4). The X-ray structure[9] shows that tarc is

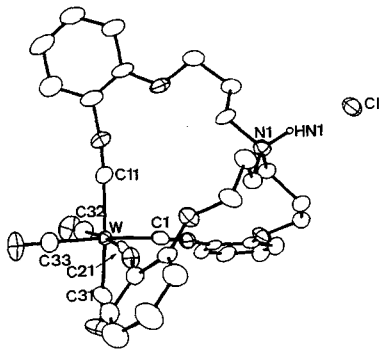

Fig. 4. Structure of *fac*-[(tarc)W(CO)$_3$ · HCl] in the crystal (ORTEP). Selected bond lengths [Å] and bond angles [°]: W-C1 2.109(7), W-C11 2.107(4), W-C21 2.126(7), W-C31 1.988(4), W-C32 1.965(5), W-C33 1.995(7), N1-HN1 0.74(7), HN1 · · · Cl 2.27(7); C1-W-C11 93.6(2), C1-W-C21 98.6(2), C1-W-C31 87.7(2), C1-W-C32 87.6(2), C1-W-C33 174.9(2), C11-W-C21 93.3(2), C11-W-C31 175.4(2), C11-W-C32 88.6(2), C11-W-C33 91.1(2), C21-W-C31 90.8(2), C21-W-C32 173.3(2), C21-W-C33 83.2(2), C31-W-C32 87.1(2), C31-W-C33 87.5(2), C32-W-C33 90.4(2).

indeed a chelating ligand occupying the three facial positions with only slight distortion of the octahedron. Thus the ability of tripodal polyisocyanide ligands to form chelate complexes has been demonstrated unequivocally for the first time.

In *fac*-[(tarc)W(CO)$_3$] the tungsten atoms forms three 18-membered rings with the ligand. These belong among the largest chelate rings known in organometallic compounds. The central nitrogen atom is in the "out" conformation. This is extremely rare for chelating tripodal ligands, as may be seen by comparison with the structures of the tricatechol complexes K_3[V(trencam)][14] and Na_3[Fe(L)] (L = macrocyclic bicapped trencam derivative).[15] The reason for the protonation is unclear. The reaction of the complexed tarc with HCl impurities in solution is improbable, as the free ligand does not form a hydrochloride adduct in dichloromethane. More likely is that the inversion of the central nitrogen atom is hindered by complexation and thus is a strong enough base to react with dichloromethane with concomitant HCl formation.

Structure determinations on aromatic W^0 isocyanides have not yet been undertaken. The W–C bond lengths are, however, in good agreement with values for a W^{II}-*tert*-butylisocyanide.[16]

[13] [(tarc)W(CO)$_3$] as typical example of the synthesis of the complexes: Two solutions of 0.33 g (0.67 mmol) tarc in 10 mL CH_2Cl_2 and 0.24 g (0.67 mmol) [(C_7H_8)W(CO)$_3$] in 10 mL CH_2Cl_2 were prepared. These solutions were added dropwise under argon, simultaneously and within half an hour, to 10 mL CH_2Cl_2. The deep red [(C_7H_8)W(CO)$_3$] decolorized in the process. The solvent was removed in vacuum and the yellow residue was washed several times with hexane to remove C_7H_8. The yield was 0.35 g (86%) of the analytically pure product. Correct elemental analysis was obtained for the solvent free *fac*-[(tarc)W(CO)$_3$ · HCl].

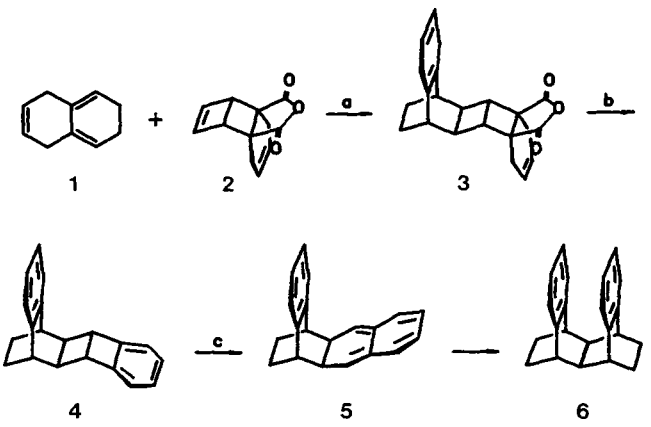
syn-Sesqui- and -Sesterbenzobicyclo[2.2.2]octene, Molecules with Stacked Benzene Rings**

By *Wolfram Grimme**, *Heinz Theo Kämmerling*, *Johann Lex*, *Rolf Gleiter**, *Jürgen Heinze** and *Michael Dietrich*

Dedicated to Wolfgang R. Roth on the occasion of his 60th birthday.

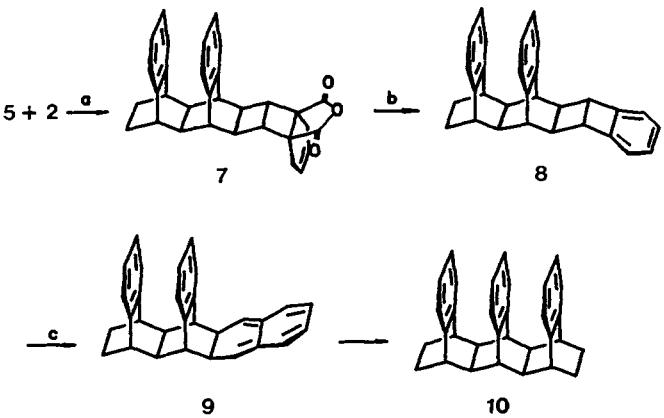
Uniform stacking of planar π systems is the basic principle for the construction of conducting organic *crystals*, in which overlap of frontier molecular orbitals forms conducting bands. *Molecules* with stacked π systems are scarce and the number of their layers is limited. In the multidecker cyclophanes,[1] the π systems are twisted relative to one another to reduce strain, which distinguishes them from conducting molecular crystals. Another type of stacking occurs in sesquibenzonorbornene; here a rigid tetracycle holds two benzene rings facing each other but tilts them at an angle of 18.6° from each other.[2] We now report our first attempts at constructing analogous multilayers by stacking benzobicyclo[2.2.2]octene units.

The anhydride **2**, a masked napthalene, reacts as dienophile and was used to synthesize Diels–Alder adducts to the b side of naphthalene.[3] With the isotetralin **1** it forms the *endo* adduct **3**, which is oxidized in two steps to the dibenzotetracycle **4** (Scheme 1). The thermal opening of its



Scheme 1. a: Xylene, 140 °C, 19 h, 60%; b: 1) NEt_3 0.03 M in 90% hydrous pyridine, 20 °C, 3 h, 30 mA cm^{-2}; 2) DDQ in CCl_4, 20 °C, 12 h, 53%; c: 1) CH_2 = CH-COCl 0.8 M in xylene, 120 °C, 4 h; 2) *N*-hydroxy-2-thiapyridone 0.8 M in toluene, 20°, 15 min; 3) *t*BuSH 0.35 M in toluene, reflux 3.5 h, 62%, 0.51 g.

benzobicyclo[2.2.0]hexene unit leads to the 2,3-dihydronaphthalene derivative **5**, which readily adds a dienophile on its convex side. With acrylic acid chloride it forms the *syn*-sesquibenzobicyclo[2.2.2.]octene-5-carbonic acid chloride, which is degraded to the parent compound **6** by the method of *Barton*.



Scheme 2. a: Toluene, reflux, 5 h, 93%; b: 1) NEt_3 0.02 M in 90% hydrous pyridine, 20 °C, 3 h, 20 mA cm^{-2}; 2) DDQ in CCl_4, 20 °C, 12 h, 21%; c: 1) CH_2=CH-COCl 0.3 M in xylene, 120 °C, 3 h; 2) *t*BuOOH 5 M in $CHCl_3$, 20 °C, 2 h; 3) cumene, reflux, 2 h, 43%, 40 mg.

[**] This work was supported by the Deutsche Forschungsgemeinschaft within the program for "Noncovalent Interactions".

2,3-Dihydronaphthalene (**5**) also adds the anhydride **2** to its convex side yielding *syn*-sesquibicyclooctene (**7**) (Scheme 2). Electrolysis and subsequent oxidation with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) affords the tribenzohexacycle **8**, which opens thermally to form 2,3-dihydronaphthalene (**9**). Cycloaddition of acrylic acid chloride to the free side of **9** and subsequent decarboxylation via the *tert*-butyl perester yields the all-*syn*-sesterbenzobicyclo[2.2.2]-octene **10**. Important physical data of the new compounds are given in Table 1.

Table 1. Important physical data of **3**, **4**, **6**–**8**, and **10**. ^{1}H NMR spectra were obtained at 90 (**3**, **4**) or 300 MHz, in CCl_4 (**4**) or $CDCl_3$. ^{13}C NMR spectra at 75.5 MHz in $CDCl_3$ with TMS as standard. Satisfactory elemental analyses of **4** and **6** were obtained.

10: M.p. 292 °C; ^{1}H NMR: δ = 6.41 (AA'XX', $J + J'$ = 8.6 Hz, $\Delta\nu$ = 59.2 Hz, 8H), 5.98 (AA'XX', $J + J'$ = 8.6 Hz, $\Delta\nu$ = 58.4 Hz, 4H), 2.73 (s, 2H), 2.69 (s, 4H), 2.37 (s, 4H), 1.26 (AA'XX', $\Delta\nu$ = 200 Hz, 4H); ^{13}C NMR: δ = 140.66, 136.60, 126.71, 125.51, 124.92, 124.26, 45.32, 44.68, 38.93, 28.22; UV (*n*-hexane): λ_{max} [nm] (ε) = 250 (840, sh), 258 (980), 264 (750, sh), 272 (540, sh); MS (70 eV): *m/z* 414 ($M^{\oplus}$, 28%), 130 ($C_{10}H_{10}^{\oplus}$, 100), 128 ($C_{10}H_8^{\oplus}$, 70), 115 ($C_9H_7^{\oplus}$, 22)

The X-ray structure shows that **6** closely approximates C_{2v} symmetry (Fig. 1).[4, 5] The benzene rings tilt 21.1° away from each other; at the base their separation is 3.04 and at the upper edge 3.84 Å. This distance is smaller than that of graphite and comparable with that of the partially charged tetrathiafulvalene (TTF) stacks (3.47 Å) in the conducting tetracyanoquinonedimethane (TCNQ)-TTF crystal.[6] MMX force field calculations predict a structure with very similar alignment (18.6°, 3.02 Å) for the benzene rings; we suspect that the strain energy of 41.3 kcal mol^{-1} (merely 1.6 kcal mol^{-1} higher than that of two separate benzobicyclooctene units) is underestimated.

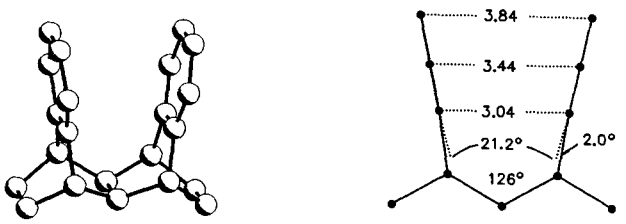

Fig. 1. Structure of **6** in the crystal (hydrogen atoms omitted) as PLUTO drawing and projection in σ_v (dihedral angles [°], distances [Å]).

Compound **10** also has approximate C_{2v} symmetry according to X-ray structure analysis (Fig. 2).[7] The angle between the planes of neighboring benzene rings increases to 21.7° and their distance apart at the base to 3.09 Å. These larger values are surprising at first, because the force field calculations predict 16.9° and 3.01 Å. The wrong trend in the calculated data can be explained by a quantum mechanical effect not considered in the force field: repulsion increases with the number of overlapping, fully occupied orbitals (here HOMOs from benzene).

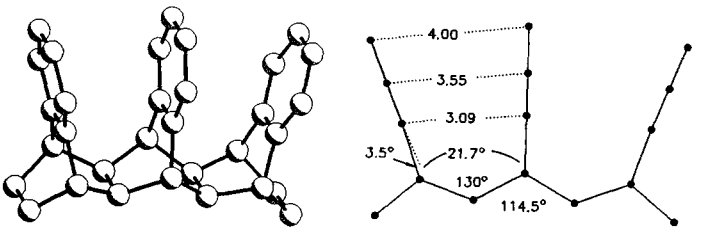

Fig. 2. Structure of **10** in the crystal (hydrogen atoms omitted) as PLUTO drawing and projection in σ_v (dihedral angles [°], distances [Å]).

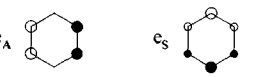
The photoelectron (PE) spectra of **6** and **10** reveal a large splitting of the orbitals of the stacked benzene rings. The first four (or six for **10**) ionic states (Table 2) arise from the ionization of the π MOs of the two (or three) benzene rings. Each ring contributes two no longer degenerate MOs (e_A, e_S, Scheme 3).



Scheme 3. Benzene π molecular orbitals with e_A and e_S symmetry.

In the case of **6**, the first two PE bands, which are separated by 0.4 eV, may be assigned to the ionization of the bonding and antibonding linear combination of e_A MOs. Bands 3 and 4 result from the corresponding linear combinations of the e_S. The assignment of the PE bands for **10** is similar (Table 2): a strong splitting is observed (0.4 eV) for the e_A molecular orbitals and a weak splitting for e_S.

Table 2. Ionization energies E_v [eV] in the gas phase of **6** and **10** and their assignments.

6: 7.8 ($15b_1$); 8.2 ($17a_1$); 8.8, 8.9 ($11a_2$, $12b_2$)

10: 7.4 ($20b_1$); 7.89 ($26a_1$); 8.2 ($19b_1$); 8.5, 8.8 ($14a_2$, $19b_2$, $13a_2$)

The relatively small ionization energy of **10** suggested that the compound could be oxidized in solution. Indeed, the cyclovoltammogram in CH_2Cl_2/0.1 M Bu_4NPF_6, −20 °C shows the reversible, stepwise formation of the mono- and

dication at $E_1 = 1.280$ V and $E_2 = 1.738$ V (Fig. 3). The unusual occurrence of a stable mono- and dication can be explained by the ionization from energy-rich MOs spread across the whole π system, which delocalizes the positive charges over three benzene rings. The Coulomb repulsion is also thereby decreased. The oxidation of **10** is facilitated by more than 1.2 V compared with the oxidation of benzene ($E^\circ > 2.4$ V).[7] Compound **10** is, to our knowledge, the first reversibly oxidizable hydrocarbon that consists of only benzene π systems.[8]

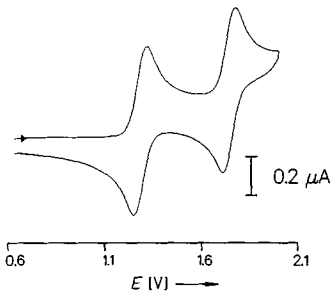


Fig. 3. Cyclovoltammogram of the oxidation of **10** in CH_2Cl_2/0.1 M Bu_4NPF_6. Conditions: $c = 4 \times 10^{-4}$ M, $T = -20$ °C, $V = 100$ mV s^{-1}, E vs. Ag/AgCl.

Further stacking of *syn*-oriented benzobicyclooctenes using the building block **2** is possible, so that the formation of extended MOs from the HOMOs of benzene can be studied in homologues of **6** and **10**.

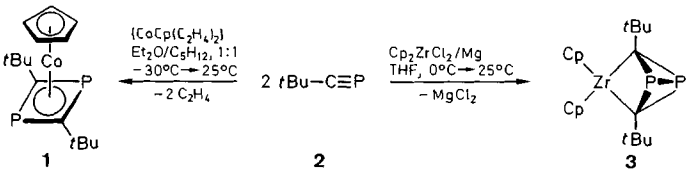
A Cp_2Zr Complex of a Phosphaalkyne Dimer as Educt in the Synthesis of Cyclic Phosphorus Compounds**

By *Paul Binger, Thomas Wettling, Ronald Schneider, Frank Zurmühlen, Uwe Bergsträsser, Jürgen Hoffmann, Gerhard Maas*, and *Manfred Regitz**

Dedicated to Professor Karl Dimroth on the occasion of his 80th birthday

Phosphaalkynes can be cyclooligomerized in the coordination sphere of metal atoms.[1] Thus, for example, the 1,3-diphosphacyclobutadiene complex **1**[2,3] is obtained regiospecifically from the *tert*-butyl-substituted phosphaalkyne **2** and $[CoCp(C_2H_4)_2]$, Cp = η^5-(C_5H_5). However, despite numerous attempts, we have so far been unable to remove the CpCo fragment from the complex **1**.

In contrast, the Cp_2Zr residue in the 1,3-diphosphabicyclo[1.1.0]butane complex **3** can be substituted or eliminated by a series of reaction partners, a finding which we exploited for the synthesis of bi- and tricyclic organophosphorus compounds as well as of 1,3-diphosphetanes and 1,2-dihydro-1,2-diphosphetes. The zirconium complex **3** is readily accessible from Cp_2ZrCl_2/Mg or Cp_2ZrCl_2/BuLi and **2**.[4]



When **3** is heated in the presence of dichloro(phenyl)borane the Cp_2Zr fragment is replaced by the PhB unit with formation of Cp_2ZrCl_2; that is, the tricyclic molecular skeleton remains intact in the product **4** (yield 46%).[5] Germanium tetrachloride reacts in the same way under milder conditions.[6] The boradiphospha-heterocycle **4** has two mirror planes (P–B–P and C–B–C), so that the framework carbon atoms (and also the *t*Bu groups) as well as the two phosphorus atoms are magnetically equivalent (Table 1). The high-field position of the signals in the ^{31}P-NMR spectrum are comparable with those of diphosphabicyclobutanes[7] and those of the educt **3**.[4]

Addition of bromine to the tricycle **4** leads to cleavage of the P–P bond with formation of the boradiphosphabicycle **6** (43%) and **8b** (11%). The NMR spectroscopic non-equivalence of the two phosphorus atoms of the brominated bicycle **6** (Table 1) is consistent with the postulated stereochemistry. In the ^{11}B-NMR spectra, **6** and **4** show similar resonance signals at $\delta = 33.3$ and $\delta = 30.8$, respectively, a confirmation that the environs of the boron change only negligibly during the transition from **4** to **6**. The ^{13}C-NMR spectra are

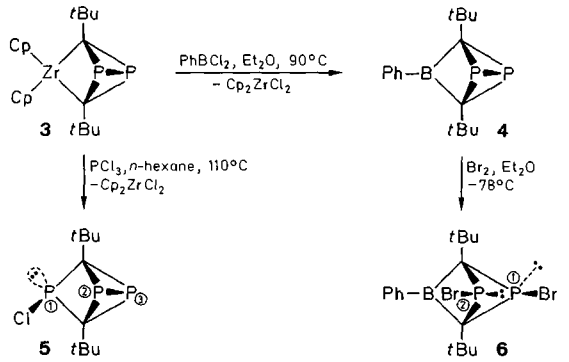
[**] Organophosphorus Compounds, Part 47. This work was supported by the Volkswagen-Stiftung and the Fonds der Chemischen Industrie.—Part 46: T. Wettling, G. Wolmershäuser, P. Binger, M. Regitz, *J. Chem. Soc. Chem. Commun. 1990*, 1541.



characterized by pseudotriplets, both for the framework carbon atoms as well as for the *t*Bu carbon atoms (Table 1).

Table 1. Some physical data of the cyclic phosphorus compounds **4**–**9** and **11** [a].

4: colorless [b] (after Kugelrohr distillation at 170 °C/10^{-2} torr); ^{1}H NMR: δ = 0.95 (s, 18H, *t*Bu), 7.2–7.6 (m, 5H, aromat. H); ^{13}C NMR: δ = 31.8 (t, ^3J(P,C) = 3.2 Hz, C(CH_3)$_3$), 31.3 (t, ^2J(P,C) = 4.2 Hz, C(CH_3)$_3$), 72.6 (m, br., C-skeleton); ^{31}P NMR: δ = − 341.3; MS (70 eV): *m/z* 288 ($M^{\oplus}$, 82%), 157 ($M^{\oplus}$ − *t*BuCP_2, 86), 131 ($M^{\oplus}$ − PhB*t*Bu, 59), 103 (100).

5: colorless [b] (after Kugelrohr distillation at 130 °C/10^{-2} torr); ^{1}H NMR: δ = 0.84 (s, 18H, *t*Bu); ^{13}C NMR: δ = 29.4 (m, C(CH_3)$_3$, 31.8 (m, C(CH_3)$_3$), 52.6 (m, C-skeleton); ^{31}P NMR: δ = 234.4 (pseudo-t, ^2J(P-1, P-2) = ^2J(P-1, P-3) = 58 Hz, P-1), − 121.4 (dd, ^2J(P-1, P-2) = 58 Hz, ^1J(P-2, P-3) = 146 Hz, P-2), − 306.0 (dd, ^2J(P-1, P-3) = 58 Hz, ^1J(P-2, P-3) = 146 Hz, P-3).

6: colorless [c] (from *n*-pentane/ether at − 20 °C); ^{1}H NMR: δ = 1.19 (s, 18H, *t*Bu), 7.1–8.2 (m, 5H, aromat. H); ^{13}C NMR: δ = 31.5 (t, ^3J(P,C) = 4.0 Hz, C(CH_3)$_3$), 34.8 (t, ^2J(P,C) = 4.2 Hz, C(CH_3)$_3$), 94.7 (t, br., ^1J(P,C) = 57 Hz); ^{31}P NMR: δ = 16.1 (P-2), − 106.9 (P-1); MS(70 eV): *m/z* 448 ($M^{\oplus}$, 96%), 371 ($M^{\oplus}$ − C_6H_5, 74), 368 ($M^{\oplus}$ − Br, 91), 288 ($M^{\oplus}$ − 2 Br, 100).

7a: colorless [b] (after Kugelrohr distillation at 120 °C/10^{-2} mbar); ^{1}H NMR: δ = 1.30 (s, 18H, *t*Bu); ^{13}C NMR: δ = 31.2 (q, ^3J(P,C) = 3.6 Hz, C(CH_3)$_3$), 35.2 (q, ^2J(P,C) = 5.2 Hz, C(CH_3)$_3$), 77.7 (q, ^1J(P,C) = 52.4 Hz, C-skeleton); ^{31}P NMR: δ = 42.9.

7b: yellow [b] (after Kugelrohr distillation at 180 °C/10^{-2} mbar); ^{1}H NMR: δ = 1.23 (s, 18H, *t*Bu); ^{13}C NMR: δ = 30.6 (s, C(CH_3)$_3$), 35.2 (q, ^2J(P,C) = 4.3 Hz, C(CH_3)$_3$), 67.0 (q, ^1J(P,C) = 53.2 Hz, C-skeleton); ^{31}P NMR: δ = 49.7.

7c: yellow [b] (Kugelrohr distillation at 190 °C/10^{-1} mbar); ^{1}H NMR: δ = 1.17 (s, 18H, *t*Bu); ^{13}C NMR: δ = 29.8 (s, C(CH_3)$_3$), 35.4 (q, ^2J(P,C) = 4.4 Hz, C(CH_3)$_3$), 46.5 (q, ^1J(P,C) = 52.6 Hz, C-skeleton); ^{31}P NMR: δ = 77.2.

8a: colorless [b] (Kugelrohr distillation at 120 °C/10^{-2} mbar); ^{1}H NMR: δ = 1.10 (s, 18H, *t*Bu), 3.00 (t, ^2J(P,H) = 12.0 Hz, 2H, CH); ^{13}C NMR: δ = 28.6 (t, ^3J(P,C) = 6.8 Hz, C(CH_3)$_3$), 33.1 (t, ^2J(P,C) = 14.5 Hz, C(CH_3)$_3$), 62.4 (t, ^1J(P,C) = 28.8 Hz, C-skeleton); ^{31}P NMR: δ = 105.5.

8b: colorless [b] (Kugelrohr distillation at 100 °C/10^{-2} mbar); ^{1}H NMR: δ = 1.00 (s, 18H, *t*Bu), 3.55 (t, ^2J(P,H) = 13.5 Hz, 2H, CH); ^{13}C NMR: δ = 28.4 (t, ^3J(P,C) = 7.3 Hz, C(CH_3)$_3$), 33.9 (t, ^2J(P,C) = 13.3 Hz, C(CH_3)$_3$), 57.8 (t, ^1J(P,C) = 29.1 Hz, ^1J(C,H) = 141.2, C-skeleton); ^{31}P NMR: δ = 92.8.

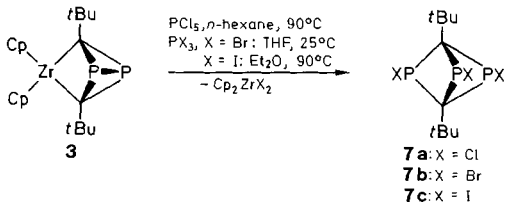
10: colorless crystals m.p. 33 °C (from *n*-pentane at − 20 °C); ^{1}H NMR: δ = 0.90 (s, 18H, *t*Bu), 1.56 (ddd, ^2J(P,H) = 12.5 and 6.2 Hz, ^3J(H,H) = 16.7 Hz, 2H, C*H*-*t*Bu), 2.56 (ddt, ^1J(P1,H) = 171.6 Hz, ^3J(P2,H) = 24.8 Hz, ^3J(H,H) = 16.7 Hz, 1H, PH); ^{13}C NMR: δ = 29.6 (pseudo-t, ^3J(P,C) = 3.2 Hz, C(CH_3)$_3$), 31.8 (d, ^2J(P,C) = 9.7 Hz, C(CH_3)$_3$), 46.4 (dd, ^1J(P,C) = 31.9 and 12.5 Hz, ring-C); ^{31}P NMR: δ = 24.1 (d, ^2J(P,P) = 22.8 Hz, P2), − 133.6 (d, ^2J(P,P) = 22.8 Hz, P1); MS (70 eV): *m/z* 238 ($M^{\oplus}$, 21%), 181 [$M^{\oplus}$ − $(CH_3)_3C$, 43], 70 ($(CH_3)_3CCH^{\oplus}$, 100), 55 ($C_4H_7^{\oplus}$, 18).

11: yellow crystals, m.p. 149 °C (from *n*-pentane at − 20 °C); ^{1}H NMR: δ = 1.30 (s, 18H, *t*Bu); ^{13}C NMR: δ = 30.4 (pseudo-t, X-part of an ABX system, J(P-1, C) + J(P-2,C) = 8.5 Hz, C(CH_3)$_3$), 39.4 (pseudo-t, X-part of an ABX system, J(P-1,C) + J(P-2,C) = 11.2 Hz, C(CH_3)$_3$), 162.5 (pseudo-t, X-part of an ABX system, J(P-1,C) + J(P-2,C) = 22.3 Hz, ring-C); ^{31}P NMR: δ = − 21.5; MS(70 eV): *m/z* 454 ($M^{\oplus}$, 16%), 327 ($M^{\oplus}$ − I, 90), 227 ($M^{\oplus}$ − C_4H_9CP, 38), 169 ($M^{\oplus}$ − PI_2, 58), 57 ($C_4H_9^{\oplus}$, 56).

[a] ^{1}H- (90 or 400 MHz, TMS), ^{13}C- (100.6 MHz, TMS), and ^{31}P-NMR spectra (80.0 MHz, 85% H_3PO_4) in C_6D_6; only **7a** and **c** were measured in $CDCl_3$. [b] The oils obtained on Kugelrohr distillation crystallized from ether or *n*-pentane between − 20 and − 78 °C; the crystals deliquesce between + 10 and + 30 °C. [c] Deliquesce on warming to room temperature.

The reaction of **3** with phosphorus trichloride also proceeds without alteration of the tricyclic framework, smoothly affording **5** in 75% yield. The triphosphatricyclopentane **5** is fully characterized NMR spectroscopically (Table 1). Special attention need only be drawn to the phosphorus atoms, which absorb at very different field strengths (δ = 234.4 P1, − 121.4 P2, − 306.0 P3). As expected, the chlorine can undergo nucleophilic substitution with *tert*-butyllithium in ether at − 78 °C.[8]

In contrast to the reaction of **3** with PCl_3 leading to **5**, the zirconium exchange upon reaction of **3** with phosphorus pentachloride (large excess), phosphorus tribromide (already at room temperature) and phosphorus triiodide under otherwise comparable conditions is accompanied by a halogen cleavage of the P–P bridge. Thus, the final products are the trihalogenotriphosphabicyclo[1.1.1]pentane derivatives **7a** (40%), **7b** (91%)[9] and **7c** (61%), respectively. When the reaction of **3** with PCl_5 is carried out in the molar ratio 1:1, a 1:1 mixture of **5** and **7a** is formed. This means that the tricycle **5** is apparently formed as intermediate in the reaction **3** → **7a**. However, the tricyclic system of **5** is recovered again via a P-P coupling when **7a** is treated with two equivalents of *tert*-butyllithium (ether, − 78 °C); concomitantly, an additional Cl/*t*Bu exchange takes place.



The appearance of only one resonance for the three phosphorus atoms in the ^{31}P-NMR spectra of **7a**–**c** and the quartet splitting of all ^{13}C-NMR signals indicate a highly symmetric structure, which has been confirmed by a crystal structure analysis of **7a**.[10] **7a** has C_3 symmetry both in

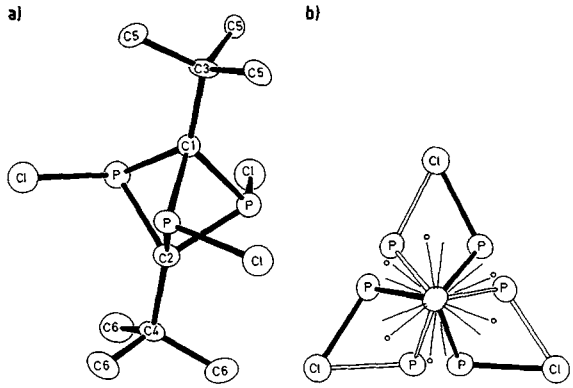


Fig. 1. a) Structure of **7a** in the crystal. Bond lengths [Å]: P-Cl 2.078(2), P-Cl 1.861(5), P-C2 1.860(7), C1-C3 1.558(11), C2-C4 1.539(11), C3-C5 1.561(7), C4-C6 1.536(17). Bond angles [°]: Cl-P-C1 109.6(1), Cl-P-C2 107.0(1), C1-P-C2 74.1(3), P-C1-P′ 87.5(3), P-C1-C3 127.1(3), C1-C3-C5 107.7(4), P-C2-P′ 87.5(3), P-C2-C4 127.0(2), C2-C4-C6 108.2(4). b) Disorder of **7a** in the crystal; view along the C3-C1-C2-C4 axis (3*m* symmetry). The chlorine atoms (shown here isotropically) are fixed on a mirror plane; probably the mirror symmetrically related positions Cl and Cl′ deviate only slightly, however, from this plane (cf. the somewhat too large a value for *d*(P–Cl)). The molecule with the bold printed bonds and with methyl groups shown as open circles O corresponds to that presented in Figure 1 a; assignment of methyl groups on the basis of the smallest *gauche* interactions.

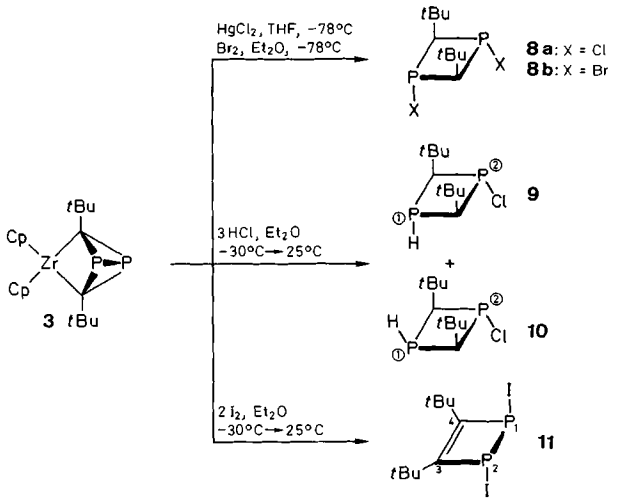
solution (cf. Table 1) and in the crystal (Fig. 1a); in the crystal the molecule is also disordered (Fig. 1b).

When the Cp_2Zr fragment is removed from **3** with mercury(II) chloride or bromine at low temperature, the polycyclic structure of the educt is completely lost: the *P*-halogenated 1,3-diphosphetanes **8a** (14%) and **8b** (73%), respectively, are formed. The incorporated hydrogen can only come from the solvent, indicating a radical reaction. Each of the ^{1}H-NMR spectra of the two compounds shows a triplet with typical ^2J(P,H) coupling. The stereochemistry of **8b** (1,3-substituents always *cis*) follows unequivocally from its crystal structure analysis.[11]



A 1,3-diphosphetane, which has only one P-halogen function, is formed in the reaction of the zirconium complex **3** with hydrogen chloride. It precipitates as a *cis*/*trans* isomeric mixture **9**/**10** (60%), whereby the presumed *trans* isomer **10** apparently dominates in the ratio 2:1 and can be obtained in pure form by fractional crystallization (Table 1). Since both the *t*Bu residues as well as the framework carbons of this isomer each give rise to only one signal in the ^{1}H- and ^{13}C-NMR spectra, both substituents have *cis* arrangement. The 1,3 arrangement of the two P nuclei follows from the comparatively small P,P coupling of 22.8 Hz. P1 is recognizable by the high field position of its NMR signal as well as by the P-H coupling of 171.6 Hz, P2 by the downfield shift of its NMR signal by the chlorine substituents (Table 1).

Reaction of **3** with iodine proceeds differently from that with bromine. Although the Cp_2Zr fragment is likewise cleaved from **3**, in this case the P–P bond remains intact. Both here, and in the case of the reaction of **3** with the interhalogen compounds ClI (70%) and BrI (65%), the 1,2-dihydro-1,2-diphosphete **11** is formed.[12]

In the respective NMR spectra the two ring carbon atoms as well as the two phosphorus atoms are equivalent (Table 1). The crystal structure analysis[10] affords unequivocal proof of the *trans* arrangement of the two iodine atoms as well as of the C_2 symmetry of the molecule (Fig. 2).

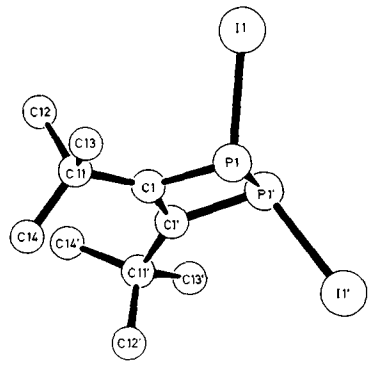


Fig. 2. Structure of **11** in the crystal. Bond lengths [Å]: P1-I1 2.484(2), P1-P1′ = 2.192(4), P1-C1 1.827(6), C1-C1′ 1.334(12) Å. Bond angles [°]:C1-P1-P1′ 75.5(2), C1-P1-I1 106.9(2), P1′-P1-I1 100.5(1), P1-C1-C1′ 102.1(4), C1′-C1-C11 136.4(6)°. Folding angle in the four-membered ring: P1-C1-C1′/P1-P1′-C1′ 12.8°, C1-P1-P1′/C1-C1′-P1′ 20.8°.

Experimental

5: A solution of **3** (0.40 g, 0.95 mmol) in *n*-hexane (10 mL) was heated together with phosphorus trichloride (2 mL, excess) for 2.5 h at 110 °C (Schlenck tube). After cooling, the solution was pipetted from the precipitated Cp_2ZrCl_2, evaporated down at 25 °C/10^{-2} mbar, and the residue distilled at 130 °C/10^{-2} mbar (Kugelrohr). Yield 0.19 g (75%) of a pale yellow oil, which crystallized from *n*-pentane at −78 °C; m.p. ≈ 30 °C.

11: After cooling to −30 °C, the solution of **3** (0.61 g, 1.4 mmol) in ether (30 mL) was treated dropwise with stirring with a 0.5 M ethereal iodine (5.8 mL). The mixture was allowed to warm to room temperature and then evaporated down at 25 °C/2×10^{-2} mbar. The residue was taken up in pentane (20 mL) and filtered free of Cp_2ZrI_2. Evaporation of the filtrate and cooling to −20 °C furnished 0.43 g (65%) of yellow crystals; m.p. 149 °C.

$[As^{V}V^{V}_{12}V^{IV}_{2}O_{40}]^{7\ominus}$, a Topologically Interesting, Mixed Valence Cluster as Model for Vanadium Minerals Formed by Weathering **

By *Achim Müller,* Joachim Döring, M. Ishaque Khan,* and *Volker Wittneben*

The geochemistry of basaltophilic vanadium, which occurs in high abundance, for example, in biogenic deposits, is "peculiar and complex",[1a] but also of considerable importance. "Important" vanadium sulfide minerals are relatively rare (patronite VS_4), whereas the number of oxidic species formed by the weathering of magmatic and postmagmatic rocks is very large[1b,c] due to the high affinity of vanadium for oxygen.[2] The easy change of oxidation states, which is characteristic for vanadium (V^{V} to V^{III} in aqueous solution, whereby V^{V} and V^{IV} are stable and can be easily interconverted), has consequences for catalysis (e.g. "V_2O_5" catalyst for the production of sulfuric acid[3]), biochemistry (all the valence states mentioned have been found in V-proteins[4]), and geochemistry[5] owing to the unusual variety of mixed valence minerals (e.g. bluish-green sherwoodite with discrete anion[6]).

We have now been able to synthesize the first cluster which is similar to the anion in sherwoodite. Reduction of V^{V} with $SCN^{\ominus}$ in the presence of As^{V} in acidic aqueous solution leads to formation of bluish-black **1**.

$K_7[As^{V}V^{V}_{12}V^{IV}_{2}O_{40}] \cdot 12H_2O$ **1**

Compound **1** was characterized by elemental analysis (including manganometric determination of the amount of V^{IV} and thermogravimetry (water of crystallization)), IR, Raman (and pre-resonance Raman), UV/VIS/NIR, and ESR spectroscopy, magnetochemical measurements (see *Experimental*), MO calculations, as well as by a single-crystal X-ray structure analysis.[7]

Whereas we have previously found a distinct preference for the formation of V^{IV}/V^{V} clusters with a higher number of V^{IV} centers, we have now also succeeded in preparing species with a lower number of V^{IV} centers by using the weak reducing agent $SCN^{\ominus}$ ($2\,SCN^{\ominus} \rightleftarrows (CNS)_2 + 2e^{\ominus}$) in acidic medium.

The cluster anion in **1** is structurally very interesting (Fig. 1): the $\{AsV_{12}O_{38}\}$ basic unit with O_h symmetry is formed from twelve edge-sharing VO_6 octahedra, which also share faces with a central AsO_6 octahedron. Two additional

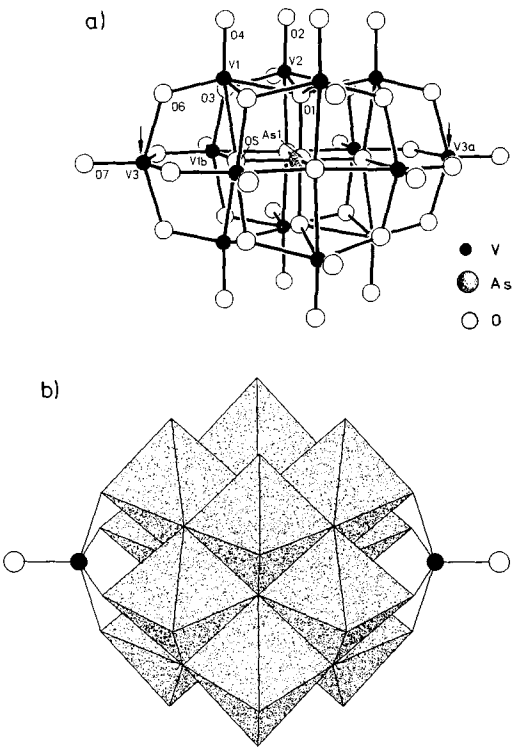

Fig. 1 a) Structure of the anion $[As^{V}V^{V}_{12}V^{IV}_{2}O_{40}]^{7\ominus}$ in crystals of **1**. b) Polyhedral representation of the central $\{AsV_{12}O_{38}\}$ unit with two attached V-O vectors. Distances [pm]: As1-O1 183.9(4), As1-O5 180.4(5), V1-O1 220.2(1), V1-O3 194.7(1), V1-O4 160.6(3), V1-O5 230.9(1), V1-O6 170.4(3), V2-O1 239.2(1), V2-O2 163.1(3), V2-O3 194.5(3), V3-O5 255.7(3) (sherwoodite: 236 (5)), V3-O6 195.9 (3), V3-O7 158.1(6), V1-V1b 322.7(1), V1-V2 318.3(1), V1-V3 317.2(1). V^{IV} centers marked by arrows.

(oppositely disposed) V=O groups are located on the C_4 axis, above the apices of the AsO_6 octahedron, whereby the symmetry is reduced to D_{4h}. The four vanadium atoms (V2) on the *h* mirror plane have two, the remaining ones (V1, V3) only one terminally bound oxygen atom. There are also μ_2-, μ_3-, and μ_5-oxygen atoms, whereby the V–O distances understandably increase with increasing coordination number of the oxygen. The coordination polyhedron of V3 can be described as a square pyramid; the V3–O5 distance (255.7 (3) pm) is too large to count O5 in the polyhedron. The calculated V–O bond valence sums[8] show that the two manganometrically determined V^{IV} centers are located in these two pyramids. The number of $\nu_s(V=O_{term})$ bands (A_{1g}) in the pre-resonance Raman spectrum is, as expected, identical with the number of non-equivalent V atoms (see *Experimental*).

The $\{V_{12}O_{38}\}$-unit in **1** is also topologically remarkable: the V atoms form a cuboctahedron, i.e. one of the 13 Archimedean solids. The unusual octahedral environment of the As atom is enforced by the "hollow" $\{V_{12}O_{38}\}$-aggre-

[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and the Westfälisch-Lippische Universitätsgesellschaft. We thank Prof. Dr. *K. Wieghardt* for magnetic measurements and Dr. *H. Bögge* for his help with the X-ray structure analysis.

gate. The basic species $[(X)V_{12}O_{38}]^{n\ominus}$, of fundamental importance for the structure of metal-oxygen clusters, has so far not been isolated.

Replacement of a "lower valence" heteroatom center Z such as $Al^{3\oplus}$ or $Fe^{3\oplus}$ (in sherwoodite) by the $As^{5\oplus}$ center remarkably leads to a shortening of the two Z–O5 distances, and thus to a significant lengthening of the V3–O5 distances (cf. caption to Fig. 1). The resulting change in the coordination (possibly) leads to a predominant localization of the two V^{IV}-3d-electrons in **1**. At room temperature, a magnetism corresponding to the spin-only value is measured (see *Experimental*). Since the two V^{IV} centers are intramolecularly 872 pm and intermolecularly 813 pm apart, detailed information on the magnetism can only be obtained by susceptibility measurements at very low temperatures. An SCCC-EH calculation[9] confirms that the two unpaired electrons are localized with more than 50% probability in the d_{xy} orbitals of V3. The 3d functions of these two atoms show a splitting almost undisturbed by the remaining metal atoms, as is expected for isolated, square-pyramidally coordinated vanadyl ions.[10] Also other physical data (e.g. the Raman spectrum with $\lambda_e = 647.1$ nm) are consistent with a mixed valence cluster, which does not belong to class III (delocalized electron ground state; after *Robin* and *Day*[11]).

The E_h(redox potential)–pH diagram, which is of importance for the geochemist,[1c, 1d, 12] demonstrates qualitatively the formation of the mixed valence vanadate minerals from magmatic and post-magmatic primary rocks [Eqs. (a) and (b)]. With the exception of sherwoodite, the vanadium minerals have a three-dimensional network structure.

$$V^{III} \xrightarrow[H_2O]{(O_2)} \{V^{IV}/V^{V}\} \qquad (a)$$

$$V^{III} \xrightarrow[H_2O]{O_2} V^{V} \xrightarrow[H_2O]{\text{weak reducing agent [13]}} \{V^{IV}/V^{V}\} \qquad (b)$$

It appears to be important that mixed valence polyoxovanadates are formed [cf. Eq. (a), (b)], and not, as is fundamentally possible, a mixture of V^{IV} and V^{V} species. In the case of chromium, for example, there are either Cr^{III}- or Cr^{VI}-minerals; mixed valence minerals in a similar abundance as in the case of vanadium are only found with iron.[11] In the formation of the polyoxovanadates, not only the stabilization of V^{IV} centers in a "V^{V}/O matrix" plays a decisive role, but also changes in solubility during the redox processes and easier reduction after a condensation. In the case of molybdenum, often the element most similar to vanadium, the above-mentioned characteristics do not apply, so that besides the primary mineral MoS_2 (in pre-cambrian granites) practically only completely oxidized weathering minerals are found (exception: ilsemannite[1b]).

An understanding of the geochemistry and biogeochemistry of vanadium is important in many respects: 1) In all workable deposits the vanadium concentration is extremely low. 2) Vanadium is frequently associated with uranium (cf. E_h–pH diagram for the U/V mineral system with broad (average) range of existence in the case of the economically interesting carnotite $K_2[(UO_2)_2(V_2O_8)] \cdot 3H_2O$;[1b] extensive exploration in the framework of the Colorado Plateau project[1d, 5]). 3) So far, it is still unclear how the high V-content comes about in fossil fuels in the form of VO-porphyrins (in extreme cases up to 70% V_2O_5 in petroleum ashes),[1e, 14] i.e. whether it is both of biogenic as well as abiogenic origin. The possible origin and importance of these geoporphyrins have been discussed in the literature.[15]

Experimental

Synthesis of **1**: A stirred solution of KVO_3 (1.93 g, 14 mmol), $As_2O_5 \cdot 5/3\,H_2O$ [16] (0.39 g, 1.5 mmol), and KSCN (0.97 g, 10 mmol) in H_2O (50 mL) in a 100 mL Erlenmeyer flask was adjusted to a pH value of ca. 2.0 at 90 °C with 0.5 M H_2SO_4 and the mixture stirred for a further 10 min at this temperature (color change from orange to greenish-brown). The stirred mixture was then adjusted to about pH 4.6 with 10% KOH solution (color change to dark green) and allowed to stand for 16 h (covered with a watch glass) on a hot plate at 70–75 °C. The precipitated dark blue crystals of **1** were filtered off from the hot solution, washed several times with 50% aqueous methanol and pure methanol, and dried on a filter paper. Yield 1 g.

Characterization of **1**: IR (KBr, main absorption bands): $\tilde{\nu}$ [cm^{-1}] = ca. 3400 (vs, ν(OH)), 1624 (s, δ(HOH)), 1010 (m, $\nu(V^{IV}=O_{term})$), 965 (vs, $\nu(V^{V}=O_{term})$), 913 (m, $\nu_{as}(O_{term}=V^{V}=O_{term})$), 774 (s, ν_{as}(V-O-M, M = V, As)), 678 (m), 624 (s), 564 (s). Raman (solid state, main absorption bands of the A_{1g} vibrations. (D_{4h})): 1012 (vw, $\nu(V^{IV}=O_{term})$), 987 (vw, $\nu(V^{V}=O_{term})$), 785 (s, ν_s), 748 (m) (λ_e = 647.1 nm); 1012 (s, $\nu(V^{IV}=O_{term})$), 987 (s, $\nu(V^{V}=O_{term})$), 943 (s, $\nu_s(O_{term}=V^{V}=O_{term})$), 785 (s), 750 (sh), ($\lambda_e$ = 488.0 nm): pre-resonance Raman effect, "active" for ν ($V=O_{term}$) stretching vibrations, since $\pi(O) \rightarrow d(V)$ type charge transfer (CT) involved. UV/VIS/NIR (KBr, in transmission): 14.9, 11.8 (sh) kK (1 kK = 10^3 cm^{-1}; similarity with spectra of $V^{IV}=O(d^1)$ complexes, therefore approximate assignment: d → d transitions in a tetragonal-pyramidal field), 30.8 kK ($\pi(O) \rightarrow d(V)$-CT). ESR (solid state, X band, 9.4351 GHz): g = 1.98 (broad signal with rough indication of structure due to hyperfine interaction (^{51}V: $I = 7/2$) at 10 K). Magnetism: $\mu_{eff} = 1.77\,\mu_B$ (per V^{IV} center, at room temperature). The Curie-Weiss law is only *approximately* fulfilled between room temperature and 80 K.

[5] Practically no pure vanadium minerals occur in primary magmatic rocks (e.g. magnetite), but only compounds in which Fe^{III} is isomorphically replaced by V^{III}. Weathering processes (also of postmagmatic rocks such as montroseite) lead to formation of an unusually large number of vanadate minerals, e.g. the decavanadates in the minerals pascoite, hummerite and huemulite, but also the yellow, uranium-containing carnotite [1d] and diverse mixed valence species (V^{IV}/V^{V}) [1b, c]. All V-minerals are described in a recent work with numerous figures, including one of sherwoodite: H. T. Evans, Jr., J. S. White, Jr.: "The Colorful Vanadium Minerals", *Mineral. Rec. 18* (1987) 333.

[6] The results of the X-ray structure analysis of sherwoodite (R = 0.22, cf. H. T. Evans, Jr., J. A. Konnert, *Am. Mineral. 63* (1978) 863) are best reconciled with the formula $Ca_{4.5}[AlV_{14}O_{40}] \cdot 28H_2O$, whereby Al is apparently isomorphically replaceable by Fe and Ca by Mg in the minerals [1b]. The structure of the anion can be compared with that of the anion in **1**; it is likewise present in reduced form in the mineral. $K_7[MnV_{13}O_{38}] \cdot 18H_2O$ is a related species with smaller number of V atoms and exclusively oxidation state five (M. T. Pope, *Heteropoly and Isopoly Oxometalates (Inorg. Chem. Concepts 8)*, Springer, Berlin 1983; M. T. Pope, A. Müller, *Angew. Chem. 103* (1991) 56; *Angew. Chem. Int. Ed. Engl. 30* (1991) 34).

[7] *I4/mmm*; a = 1135.7 (2), b = 2002.8 (5) pm, $V = 2583.2 \times 10^6$ pm^3; μ = 3.64 mm^{-1}, $Z = 2$, R = 0.040 for 791 independent reflections ($F_o > 3.92\,\sigma(F_o)$), Siemens R3m/V diffractometer, $Mo_{K\alpha}$ radiation (graphite monochromator). The powder diffractogram calculated from single crystal data agrees with the measured diagram (most intense Bragg reflections: d = 994, 804, 313, 284, 226 pm; Phillips PW1050/70 diffractometer, $Cu_{K\alpha}$ radiation). The reflection profiles in the X-ray structure analysis indicate a weak asymmetry, so that twinning cannot be ruled out. The potassium ions

appear strongly disordered; however, upon long irradiation (>3 days) Bürger precession photographs gave no indication of a "resolvable twinning" or the presence of a superstructure. The R value of 0.04 also indicates that the anion structure, which is lattice determining, was correctly found. Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, W-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-54906, the names of the authors, and the journal citation.

[8] The bond valence sums for the V^V centers according to $\sum_i (d(V\text{-}O_i)/179.1\ pm)^{-5.1}$ are 4.98 (V2) and 4.91 (V1) and those for the V^{IV} centers according to $\sum_i (d(V\text{-}O_i)/177.0\ pm)^{-5.2}$ are 4.02 (V3) (after I. D. Brown, K. K. Wu, *Acta Crystallogr. Sect. B32* (1976) 1957). The "primary" V^{IV}/V^V distinction is based on the averaged summation $\sum_i (d(V\text{-}O_i)/178.0\ pm)^{-5.15}$.

BOOK REVIEWS

Book Reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the following address: Redaktion Angewandte Chemie, Postfach 101161, W-6940 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

Protein Purification. Principles, High Resolution Methods and Applications. Edited by *J.-C. Janson* and *L. Rydén*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York 1989. xi, 502 pp., hardcover, DM 124.00.—ISBN 3-527-26184-2/0-89573-122-3

Genetic engineering has made a wide variety of proteins available for pharmaceutical use. An important aspect of this technology is the maintenance of high standards of quality by efficient methods of purification and analysis. This has given a new impetus to the further development of separation techniques, especially from the standpoint of industrial applications.

This book describes the present state of development of all the most important chromatographic and electrophoretic methods for separating proteins. The aspects covered are well defined by the book's subtitle: it is mainly concerned with high resolution methods of purification, with less emphasis on the early stages of an isolation procedure. The procedures of cell breakdown, extraction, separation from other cell constituents, precipitation methods or ultrafiltration, which can have a crucial effect on the success of the stages that follow, are only briefly summarized in an introductory chapter, as also are the associated analyses by protein determination and enzyme tests. For planning a complete work-up process, other sources of information must be called on; however, the reader is greatly helped in this by well-chosen literature references.

The introduction is followed by ten chapters on chromatography: introduction, gel filtration, ion-exchange chromatography, chromatographic focussing, reversed phase HPLC, hydrophobic interactions, separation on immobilized metal ions, "covalent" chromatography, affinity chromatography, and partition in two-phase systems. Whereas here the emphasis is firmly on the preparative applications, the part dealing with electrophoresis goes beyond the book's title by emphasizing the analytical aspects; this consists of six chapters, on gel electrophoresis, isoelectric focussing, immuno-electrophoresis, protein mapping in 2D gels, recovery of proteins and blotting, and capillary electrophoresis, comprising together a third of the contents.

Each chapter consists of an introduction including theory and a description of the available separating media, followed by a section devoted to methods and lastly a number of examples of applications. The references, whose number varies between 30 and 100, enable the reader to study each method in greater depth if required. With regard to the applications described, differences in quality between the chapters become clearly apparent, ranging from only sparse descriptions (e.g. for RP-HPLC) to detailed accounts of experimental procedures (e.g. for affinity chromatography). As suppliers of separating media usually provide detailed instructions along with their products, the absence of laboratory recipes of this kind from the articles is a problem that can certainly be overcome. In other respects the individual contributions are well matched in style and structure. This consistency and the excellent quality of the text and figures combine to make the book very satisfying to use. The fact that most of the 17 coauthors, as well as the editors themselves, belong to either the research department of Pharmacia LKB or the University of Uppsala was a distinct advantage from the standpoint of editorial efficiency. Although this has no doubt influenced the choice of applications examples, it has not detracted from the value of the rest of the texts of the contributions

from a general use standpoint; these have all benefited from a high level of expertise and the authors' practical experience.

The book offers a wealth of useful information not only for newcomers but also for "insiders", who certainly are not equally familiar with every one of the separation methods, and will find here a valuable overview of the current state of the art (the one exception to this is capillary electrophoresis, which has made a huge step forward in the past year). The book can therefore be recommended for buying not only by libraries but also by everyone working in this field.

Gerhard Seipke [NB 1079 IE]
Pharma Forschung
Hoechst AG, Frankfurt/Main (FRG)

Advanced Practical Organic Chemistry. By *M. Casey, J. Leonard, B. Lygo* and *G. Procter*. Blackie, Glasgow 1990. xii, 264 pp., paperback, £ 14.95.—ISBN 0-216-92796-X

This book is concerned solely with the practical side of preparative organic chemistry. The groups of readers for whom it is intended include not only undergraduates and graduate students of organic chemistry, but also particularly those "non-specialists", such as biologists, biochemists, materials scientists and polymer chemists, for whom, according to the authors, the book can serve as a useful information source.

A general introduction in Chapter 1 is followed by a second chapter which describes in detail how to keep a laboratory notebook (experiment number, date, reaction scheme, references to relevant literature, etc.). Here, as also in other parts of the book, the text seems to be aimed more at the "non-specialists" than at organic chemistry undergraduates and graduate students, who should already have learned these procedures in their elementary practical work.

Chapter 3 describes in detail the fitting out of an individual work-bench station and of the laboratory as a whole. It is of particular interest to anyone who needs to set up a new organic chemistry laboratory. He or she will find here a useful survey of general laboratory equipment (rotary evaporators, balances, vacuum pumps, drying ovens etc.) and a detailed list of all the items required at the laboratory bench (numbers and sizes of flasks, and so forth). There is also a good description of modern vacuum systems which have additional facilities for working under inert gases.

Chapter 4 deals with the purification and drying of solvents, and Chapter 5 with the purification and handling of reagents (e.g. transfering liquids under an inert gas, and the preparation of diazomethane). There then follows a chapter on working with gases and another on the various types of vacuum pumps and their capabilities.

Chapter 8 describes how one carries out an organic reaction. Special attention is devoted to reactions using air-sensitive reagents, and there is a very good account of various techniques for working under inert gases. Some simple methods that the organic chemist can use to monitor the progress of a reaction are also described. The following chapter then deals with the work-up of a reaction mixture, including the various methods available for purifying reaction products. The next two chapters are concerned with special points that arise when carrying out reactions on either a very small or a very large scale.

The chapter on methods of characterization deals with the various spectroscopic techniques (NMR, IR, UV, MS), but unfortunately only very superficially. One must ask whether, instead of this really very scanty treatment of such an important subject, it would not have been more useful to refer the reader to appropriate books on spectroscopic methods where these matters are covered in detail.

Towards the end of the book, in a sequence which seems to make little sense, come chapters on the chemical literature (Chemical Abstracts, Beilstein, computer databases), special techniques (photolysis, ozonolysis, vacuum flash pyrolysis etc.), advice on what to do when a reaction goes wrong, examples of particular reactions (the preparation of *n*-butyllithium, the aldol reaction, Claisen rearrangements etc.), and lastly—incredibly placed at the end of the book—a chapter on safety. Especially in view of the authors' claim, referred to earlier, to have addressed the book in part to a readership less familiar with preparative organic chemistry, the placing of the chapter on safety at the end strikes this reviewer as highly questionable. Paradoxically, this chapter begins by stating that "safety is your primary responsibility".

Despite the criticisms made here concerning a few points, the book as a whole provides a very useful survey of modern preparative techniques used in the organic chemistry laboratory. It can be recommended for advanced students, who should be able to afford it in view of the low price.

Hans-Joachim Knölker [NB 1082 IE]
Institut für Organische Chemie
der Universität Hannover (FRG)

Chemically Modified Carbon Fibers and their Applications. By *I. N. Ermolenko, I. P. Lyubliner* and *N. V. Gulko*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York 1990. x, 304 pp., hardcover, DM 184.00.—ISBN 3-527-26027-4/0-89573-873-2

This monograph summarizes in about 300 pages the considerable amount of knowledge gained during the last two decades on carbon fibers (C-fibers). In 1982 the authors published in book form in the USSR a summary of research on doped C-fibers. The present book is an English translation of a revised and considerably enlarged edition of the earlier work. This review of a specialized field is intended not only for specialists but also for graduate students and scientists who wish to become involved in the area of modern fibers.

The introduction describes the various types of C-fibers and classifies them on the basis of their heat treatment and mechanical properties. Here the authors explain that the emphasis in the chapters that follow is on doped C-fibers, which they call "element-carbon-fibers"; for information on undoped C-fibers the reader is referred to other reviews.

In Chapter 2 the structures of C-fibers are discussed with the help of models and experimental results. The pyrolysis process which is an essential part of the preparation of the fibers can be considerably influenced by elements and compounds introduced as dopants, and this causes variations in the (supermolecular) structure of the resulting fibers and in the distribution and chemical form of the dopants in the matrix. Chapter 3 deals with mechanical, thermal and electrical properties of C-fibers and their chemical stabilities. In particular the relationship between microscopic ordering and mechanical strength is discussed. Two special sections are devoted to the activation of adsorption and desorption and that of ion-exchange processes by chemical modification of the C-fibers.

Chapter 4 deals with the pyrolysis of cellulose fibers as a four-stage process. For each temperature range in the process the characteristic chemical changes undergone by the

cellulose, up to its complete carbonization, are discussed in the light of spectroscopic and chromatographic evidence. However, the number of different variables involved in the pyrolysis process is so great that it is probably not realistic to expect a clear relationship between chemical changes of the fiber matrix and the structural and mechanical properties to emerge here.

Chapter 5 is the longest and the most important as regards detailed information content; it deals with the preparation of doped C-fiber materials, with special attention to the effects of different additives on the pyrolysis process. Although the effects occurring during the different stages of the process are many and varied, the authors succeed very well in deriving a systematic relationship between the chemical properties of the additives and their effects on the pyrolysis process.

Chapter 6 is entitled "Surface Modification of C-Fibers". The main emphasis is on the introduction of ionic groups in relation to ion-exchange applications, and on chemical and thermal methods for increasing the adsorptivity of C-fibers.

Compared with this, the surface modification of C-fibers to improve their adhesion properties in polymer and metal fiber-reinforced composites is treated rather too briefly. Also in the applications described in Chapter 7 the authors limit their account mainly to low-modulus fibers and their typical applications in the areas of adsorption, catalysis and medical science. Uses of C-fibers in composite materials are treated briefly, and for applications of high-modulus fibers the reader is referred to already existing reviews.

Although this monograph does not cover all aspects of the chemical modification of C-fibers, it is a useful survey within this specialized field. The qualities of the book that impress are its high information content and the many literature references, which in some parts raise it to the standard of a handbook. It can be strongly recommended for the readership intended by the authors.

Wolfgang Meyer [NB 1085 IE]
Max-Planck-Institut für Polymerforschung,
Mainz (FRG)

Mycotoxins. Chemical, Biological and Environmental Aspects. (Series: Bioactive Molecules, Vol. 9). By *V. Betina*. Elsevier, Amsterdam 1989. 438 pp., hardcover, HFl 295.00.—ISBN 0-444-98885-8

The book gives an overview of the most important mycotoxins, their occurrence, their structures and physicochemical properties, the fungi that produce them, their biosyntheses and their biological activities.

Chapter 1 covers very briefly, but also in a way understandable even to non-microbiologists, some aspects of the taxonomy and chemotaxonomy of mycotoxin-producing fungi. Mycotoxins and their producers are summarized very clearly in four tables, with indications of the chapters in which they are treated more thoroughly.

Chapter 2 covers general aspects of secondary metabolites, which include mycotoxins. The most important topics and theories are introduced and discussed.

Chapter 3 summarizes the most important biological effects of mycotoxins. In addition to the toxic effects on man and mammals, their effects on insects, plants and other microorganisms are discussed. The relevance of biological screening is also discussed. Chapter 4, on modes of action, describes many different sites of action and metabolic pathways that are affected by mycotoxins. Unfortunately there is not much critical evaluation of published results. A distinction between primary and secondary effects would have been helpful to the non-specialist. Chapter 6 briefly describes some ecological aspects of toxins and the organisms that produce them. With regard to methods of detection, biological tests are described in most detail.

In the second half of the book, covering 12 chapters, the most important mycotoxins are described, and arranged by chemical structure or biological action. The aflatoxins, sterigmatocystins and versicolorins, the ochratoxins and related compounds, citrinin, the tricothecenes, patulin and other small lactones (penicillic acid, mycophenolic acid, butenolide, citreoviridin), zearalenone, the cytochalasans, rubratoxins, anthraquinones, tremorgenic mycotoxins (including penitrems and paspaline) and epipolythiopiperazine-3,6-diones such as gliotoxins and chaetocins, are all comprehensively described.

The chapter "Miscellaneous Toxins" deals very briefly with PR toxin, secalonic acid D, viridicatum toxin, cyclochlorotine, cyclopiazonic acid, moniliformin and fusarin C. For each mycotoxin, information on the organism that produces it, its occurrence, the biosynthesis of the toxin, its isolation and physicochemical characterization, its structure, biological activity, mode of action and ecological aspects is set out very clearly.

The book has several merits; it is easy to follow, well-organized, and contains essential information for all the toxins listed, covering the literature up to 1988 inclusive. The mycotoxin producing organisms are listed separately in the index. It is almost unavoidable for a book of this size to also contain some flaws. The formula of one of the tautomeric forms of mycophenolic acid (p. 244) is incorrect. Beside the formula for moniliformin there is an extra unrelated group.

Overall, this book serves as an up-to-date compilation of the most important mycotoxins. It can be recommended as a reference work, as an introduction to the subject, or as an accompaniment to lectures. Unfortunately the variety of biological effects are often only listed but not evaluated, which reduces the value of the book for the non-biological reader.

Timm Anke [NB 1094 IE]
Lehrbereich Biotechnologie
der Universität Kaiserslautern (FRG)

Biomineralization, Chemical and Biochemical Perspectives. Edited by *S. Mann, J. Webb* and *R. J. P. Williams*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York 1989. xiv, 541 pp., hardcover, DM 274.00.—ISBN 3-527-26750-6/0-89573-672-1

Reports on international conferences about aspects of biomineralization appear at nearly regular intervals of four to five years. A particularly important contribution on this topic was that of the 1981 Dahlem conferences (*Life Science Research Report 23*). Up to then biomineralization had been understood to be a process involving the formation of insoluble calcium compounds. In addition biomineralization had come to be regarded as a biological phenomenon that also includes pathological aspects such as the formation of stones in the body, and demineralization processes (osteoporosis, caries). Since 1983, however, the term biomineralization has started to undergo a change of meaning to include the area of "biological metal accumulation", and appears to be becoming a part of "bioinorganic chemistry". Thus the original meanings of the terms are gradually becoming blurred.

The bood reviewed here is well produced and appears at an opportune time, especially in view of the fact that, in addition to the emergence of the aspects mentioned above,

new developments in techniques now necessitate an updated treatment of the subject. The material is divided into 15 chapters which are written in the style of review papers. The topics covered are as follows: the functional forms of biominerals; crystallographic strategies of biomineralization; the carbonate calcification of algae, matrix-crystal interactions in $CaCO_3$ biomineralization; stereochemical and structural relationships between macromolecules and crystals in biomineralization; in vitro studies of calcium phosphate crystallization; biochemical studies of teeth mineralization in vertebrates, chemical studies of biogenic silicates; function and structure of ferritin and hemosiderin, biomineralization of iron in the teeth of molluscs; mineralization of magnetite in unicellular organisms; structural and analytical studies of metal ion-containing granules; the use of proton beam analysis in studies of mixed biominerals; the significance of studies on biomineralizates for materials technology.

The contents are, without exception, good and the treatment of the subject matter is impeccable. For the specialist the book offers a rich source of ideas and suggestions. However, only three of the articles are concerned with matrix-crystal interactions, which is the central topic of biomineralization. Moreover, two articles on this subject put forward controversial views, giving the impression that the role of the organic matrix is questionable, or at least unimportant (see also the preface). The reader is left alone with this problem, without being given a clear answer. Some time ago *S. Mann*, in his article "Biomineralisation" (*Chem. Unserer Zeit 20* (1986) 69), gave a much better, unambiguous and impressive statement of his position on this question. There he clearly and unequivocally explained the difference between geological minerals and biomineralizates. The fundamentals of techniques and theory are certainly a part of this question. Here an unusually large amount of space is devoted to these aspects and to crystal structure studies. Moreover, of the total of about 500 pages of text, almost 200 are devoted solely to iron, resulting in a serious imbalance. Lengthy discussions about ferritin structures have very little to do with biomineralization. Alongside these chapters the more biologically orientated articles give the impression of having been grafted on. Only one page is given to pathological biomineralization processes. However, apart from these few inconsistencies, the book opens up some useful chemical and biochemical perspectives.

Reizvolle Moleküle der Organischen Chemie. (Series: Teubner Studienbücher Chemie). By *F. Vögtle*. Teubner, Stuttgart 1989. 402 pp., paperback, DM 39.80.—ISBN 3-519-03503-0

Each volume in the series "Teubner Studienbücher Chemie" deals with fundamental and more advanced aspects of a particular field of chemistry. The books do not aim at the breadth of coverage of a textbook, nor at the depth of treatment of a comprehensive monograph; instead they are intended only to give the student of chemistry an *introduction* to specialized topics that are of current interest, and which are therefore undergoing rapid development.

In the volume "Reizvolle Molecüle der Organischen Chemie" published in 1989 (and also in the following volume "Supramolekulare Chemie – Eine Einführung",[*] which appeared almost simultaneously), *Fritz Vögtle* presents a survey of "attractive molecules" relevant to his field of study. His starting point is a wish to open up to the reader, in a way that is both instructive and entertaining, the great variety of organic chemistry, by taking him or her on a journey of discovery through the field of unusual molecules and all that relates to them (their history, synthesis, chemical and spectroscopic properties, and applications). In the resulting thoroughly readable organic chemistry book, the appeal of the "attractive molecules" referred to in the title is revealed not least through the many lavish stereoscopic illustrations which provide three-dimensional views; *Vögtle*'s artwork studio has already set a high standard of quality with illustrations such as these in numerous publications. They are a delight to the eye! Or, as the author himself puts it on page 23: not least of the aimes was that merely looking at the structures shown here should bring joy to the heart of every chemist!

Among the most notable of the "attractive molecules" that *Vögtle* has in mind in the title of the book are hydrocarbons that are to some degree exotic. Accordingly, the introduction (19 pp.) is followed by detailed excursions into the chemistry of interesting aliphatic hydrocarbons (Chapter 2, 56 pp.), arenes (Chapter 3, 115 pp.), and "araliphatics" (Chapter 4, 65 pp.). It is evident that deciding what to include or leave out must have been a painful choice. Some of the interesting molecules that were filtered out are the following: tetra-*tert*-butyltetrahedrane, cubane, dodecahedrane, adamantane, pagodane, and [1.1.1]propellane (Chapter 2); the triphenylcyclopropenyl cation, azulene, biphenylene, circulene, and [7]helicene (Chapter 3); triptycene, iptycene, 1,8-methanonaphthalene, [2.2.2]cyclophane, and superphane (Chapter 4). As one can see from the restrictions placed on the material included, no attempt has been made in *Vögtle*'s book to cover the *entire* field of exotic hydrocarbons. Instead, rigorously limiting the coverage to just a *few* candidates has made enough space available to allow a satisfying breadth and depth in the treatment of the material.

The meticulous care that *Vögtle* has brought to the task of doing justice to the title of the book is evident from the lengths of the bibliographies to the chapters, which amount to a total of 31 pages! In a literature study of such a high standard as this, it is not surprising to find that only a few years ago it would not have been possible to write this particular book, despite the fact that the topic of exotic hydrocarbons is far from new. Among the recent reactions included are the synthesis of cubene (October 1988), *Prinzbach*'s second-generation syntheses of dodecahedrane (March 1989) and the anionic polymerization of [1.1.1]propellane (May 1989).

Whether one's interest lies mainly in deeper subjects such as a comparison of azulene syntheses, in relationships between structure and color in azulenes, in the regioselectivity of electrophilic substitutions of biphenylenes, of 1,8-methanonaphthalene or of cyclophanes, whether one wishes to become enmeshed in the three-dimensional structural formulas of the helicenes, heterohelicenes or helicenophanes, or goes in search of curiosities such as information about adamantane chemistry being carried out *on a tonnage scale* in Japan with the aim of treating Parkinson's disease, or about evidence for the presence of the cyclopropenylium ion in Halley's comet, *Vögtle*'s book offers something for everyone who enjoys browsing among topics in organic chemistry that

[*] Review: *Angew. Chem. 102* (1990) 112.

are off the well-trodden track of textbooks. Moreover, the reader who has become tired of hydrocarbons will welcome the relief of Chapter 5 on heterocycles and compounds with pharmacological activity, dealing with Tröger's base, acetylsalicylic acid, vitamin B_6 and phthalocyanines. In this reviewer's opinion the chapter might also have very usefully combined the pharmacologically active with the exotic by giving a glimpse into the fascinating chemistry of antitumor antibiotics of the enediyne type (Neocarzinostatin, Esperamycin, Calichemicin), which currently are possibly the "hottest" of all classes of biological substances.

The formula schemes are clear and visually pleasing throughout (some minor exceptions: the undecipherable trishomocubyl moieties on page 65, the nearly invisible C = C bonds in the intermediates **8** and **9** on page 72, and the representation of phthalocyanine on page 332 which seems more like a puzzle. The very small number of errors in the structural formulas include a missing carbonyl oxygen in **8** on page 35, the omission of the second regioisomer of the bis(diazoketone) in the formula on page 72, three missing double bonds in **10** on page 189, and $(CH_2CO)_2O$ instead of $(CH_3CO)_2O$ on page 293. A few of the synthesis schemes (pages 60, 72, 140, 174, 211, 268, 305) could have been made even more informative by inserting the reagents (although these are, of course, referred to in the text).

The text is written in a flowing style, and covers the subject matter with a breadth and depth that are appropriate to the book. The few minor errors are unlikely to lead the reader astray; for example, HCl elimination reactions are described as being base-catalyzed instead of being carried out with stoichiometric quantities of base (pp. 86, 87), "Retro-Alder-Reaktion" appears instead of Retro-Aldol-Reaktion (p. 51), and reference is made to planar conformation instead of configuration (p. 67). On page 61 the Wagner-Meerwein rearrangement does not start out from the adamantyl cation but leads to it. On page 72 the word "Diazotierung" is used to describe the transfer of a diazo group, and on page 122 an azo coupling reaction is wrongly described by the word "Azotierung". "Benzofulvalen" on page 100 should read Benzofulven, on page 264 "*o*-Xylen" appears instead of *o*-Xylylen, on page 266 "Propionsäureester" instead of Propiolsäureester, and on page 269 "Ethyldiazotat" instead of Ethyldiazoacetate. On page 218 it is evident from the structural formula that a "Carbeniat" here means a carbanion. The NMR spectrum described on page 136 is of the AA'BB' type, not A_2B_2. In the chapter on azulenes Figures 7 and 9 show the formulas of intermediates in reactions that are probably better described as concerted processes (an electrocyclic ring-opening and a [2 + 8]-cycloaddition). Occasionally the term mesomerism is used in an unfortunate way which could lead to confusion for beginners in organic chemistry. References such as those to "Einfluß hyperkonjugativer Grenzformen" (effects of hyperconjugated canonical forms, p. 66), or to discontinuance of a "Möglichkeit zur Ausbildung mesomerer Grenzformen" (possibility of formation of mesomeric canonical forms, p. 126), the showing of a mesomerism arrow *between structural isomers* (p. 130), or the analysis of the possible canonical structures for a carbenium *transition state* (p. 137) imply a degree of reality for canonical forms which is of questionable validity.

The preface contains an assurance that *large* portions of the book assume only knowledge of an undergraduate level, but perhaps one should not take this quite literally. In fact, in *many* parts of the book the treatment is of a breadth and depth (as already commended above) such that only very advanced undergraduate or rather graduate students are likely to benefit from reading "Reizvolle Moleküle". However, those at the latter stage of their studies who wish to gain a deeper knowledge of organic chemistry through reading of a less formal kind are assured that, by buying *Vögtle*'s book, they will obtain pleasure from it without undue pain (at a price of only DM 39.80 for 402 pages).

Iminophosphanes: Unconventional Compounds of Main Group Elements

By Edgar Niecke* and Dietrich Gudat

Dedicated to Professor Rolf Appel on the occasion of his 70th birthday

The large number of known stable compounds in which phosphorus has a low coordination number makes it clear that such compounds can no longer be regarded as "exotic" in main group chemistry. While the rich chemistry of P–C multiply bonded systems makes clear their affinity to their organic congeners, iminophosphanes in particular are also of increasing importance. The linkage of a phosphinidine fragment with an imine fragment via a multiple bond gives rise to a class of compounds with an unusually wide range of structural types. This in turn leads to a broad spectrum of chemical behavior which makes iminophosphanes extremely useful synthetic building blocks in organoelement chemistry.

1. Introduction

The development of the chemistry of multiply bonded systems involving elements in higher periods is generally regarded as a renaissance of main group chemistry. An extremely important role in this chemistry has been played by phosphorus compounds with low coordination numbers; although the first of these were discovered in the 1960's, either little notice was taken of them because of their low stability ($P{\equiv}CH$[1]) or they were regarded sceptically because of the nature of their bonding (phosphacyanine) cations[2]). The discovery of arenes of the phosphabenzene type[3] led to a more intensive study of compounds with such "exotic" bonding systems. The preparation of acyclic imino-[4] and methylenephosphanes[5] marked the beginning of a rapid phase of development, in the course of which a number of compounds were prepared which are both synthetically useful and also interesting because of their bonding properties.[6] This work culminated in the 1980's in the inclusion of heavier elements of the fourth[7] and fifth main groups[8] and of boron[9] in a stable (p–p)π-bonding system involving phosphorus.

The (3p–2p)π-P–N bonding system occupies a special place among the known compounds with twofold coordinated phosphorus because of the presence of a π-bonded fragment of high electronegativity with a "lone pair". In contrast to the phosphorus atom, the imine nitrogen can vary its bonding state within wide limits by means of formal electron release or acceptance ("isovalent hybridization"[10]); this manifests itself in a series of unconventional structures and gives rise to unusual reactivity patterns. The application of this potential made possible the first successful synthesis of bis(imino)phosphoranes from iminophosphanes; it has also led to the generation of a large number of new heterocycles, so that today the iminophosphanes can be regarded as important synthetic building blocks in organoelement chemistry.

The present account will attempt to provide a critical overview of the chemistry of the P=N double bond, particular attention being paid to structural and bond-theoretical aspects. We have attempted to prepare a comprehensive survey, including more recent work. As experience has shown, systems such as aminophosphenium cations[11] or resonance-stabilized five-membered PN heterocycles of the aza-

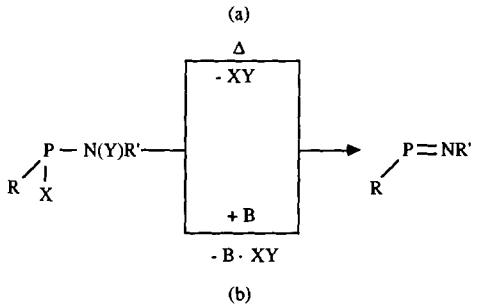
[*] Prof. Dr. E. Niecke, Dr. D. Gudat
Institut für Anorganische Chemie, Universität Bonn
Gerhard-Domagk-Strasse 1, W-5300 Bonn 1 (FRG)

phosphole type[12] (in which P–N bonds with (p–p)π-interactions are also present) exhibit a quite different chemical behavior. These classes of compounds will thus not be included in the present discussion, and we refer the reader to relevant reviews.[11, 12] The coordination chemistry of iminophosphanes has also not been included, since it has been covered in detail in a recent survey.[13] We should mention that some aspects of the subject matter covered here have been discussed in earlier reviews.[14, 15]

2. Synthetic Methods

2.1. Elimination Reactions

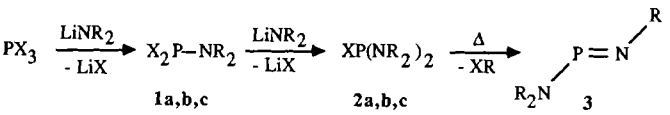
In analogy to the normal methods for the formation of olefins or heteroolefins (e.g. phosphaalkenes, silaalkenes),



Scheme 1. Formation of the double bond in iminophosphanes by thermally-induced (a) or base-induced elimination (b).

1,2-elimination reactions form by far the most important synthetic route to iminophosphanes. The formation of the double bond by elimination of a molecule XY from aminophosphanes R(X)P–N(Y)R′ can be carried out either thermally or under the influence of a base (Scheme 1). The preparatively most valuable methods involve thermal elimination of organohalogenosilanes (X = F, Cl, Br; $Y = SiMe_3$)[16–40] or lithium halides (X = F, Cl; Y = Li)[24, 36, 41–45] and base-induced dehydrohalogenation reactions (X = Cl, Y = H).[38, 46–47]

The thermal elimination of trimethylchlorosilane from the *N*-silylated diaminohalogenophosphanes **2a–2c**, which were prepared from PX_3 via **1**, provided the first route to an isolable aminoiminophosphane **3** with a P–N-(p–p)π-bonding system[4, 17] (Scheme 2). The synthesis of a variety of



Scheme 2. R = $SiMe_3$; X = F (**a**), Cl (**b**), Br (**c**).

iminophosphanes has been carried out in an analogous manner via thermolysis of suitably substituted precursors; apart from *P*-alkyl or *P*-aryl substituents,[24, 29] these can contain *P*-amino,[16–18, 21–23, 39] *P*-hydrazino,[19, 29, 40] *P*-diorganophosphino[36, 37] or *P*-aryloxy substituents[32] as well as *N*-phosphino[26, 30] or *N*-amino[20, 27, 28] residues. In spite of the versatility of this synthetic principle, it is limited in its generality, as the thermal stability of the precursors requires extremely drastic reaction conditions. The high temperatures required lead to the occurrence of side reactions: for example the thermolysis of diaminofluorophosphanes $R_2N(F)P–N(SiMe_3)tBu$ with sterically undemanding R_2N ligands (**4e–h**) leads to elimination of R_2NSiMe_3 with formation of 1,3-di-*tert*-butyl-2,4-difluoro-1,3,2,4-diazaphosphetidine **6** rather than the expected iminophosphanes **5**[27, 48] (Scheme 3). It is generally necessary to remove the

Edgar Niecke, born 1939 in Berlin, studied chemistry at the University of Göttingen, where he received his doctorate under the supervision of O. Glemser. After his habilitation in 1976 in Göttingen, he took up an appointment as Professor of Inorganic Chemistry at the University of Bielefeld, and in 1986 he was offered and accepted a professorial chair at the University of Bonn. His main fields of interest are the synthesis, structure, and reactivity of compounds of phosphorus with lower coordination numbers (phosphorus-element (p-p)π bond systems), but also phosphorus heterocycles, phosphanediyls and organometallic compounds with novel phosphorus ligands.

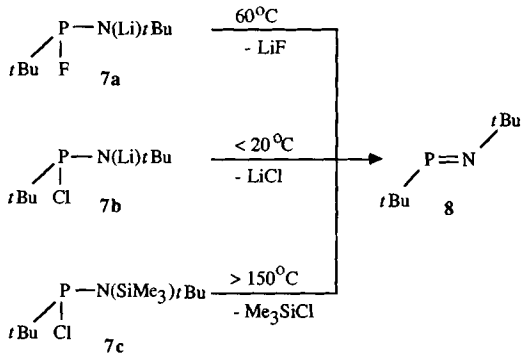
Dietrich Gudat, born 1957 in Düsseldorf, studied chemistry at the University of Düsseldorf and then at the University of Bielefeld, where he gained is doctorate under the supervision of E. Niecke. After Postdoc research at the University of Sussex (with J. F. Nixon) and at the Iowa State University (with J. G. Verkade) he accepted a post at the University of Bonn, where he has been working for his habilitation since 1989. His research interests focus on investigations of the coordination chemistry and redox properties of novel podand-like and macrocyclic phosphorus compounds as well as the applications of NMR spectroscopy, particularly for the monitoring of dynamic processes.

iminophosphanes continually from the reaction mixture in order to avoid the occurrence of further reactions, so that this method is only suited for the preparation of volatile compounds which distil without decomposition.

	a	b	c	d	e	f	g	h
R	$SiMe_3$	*t*Bu	*i*Pr	*s*Bu	*n*Bu	*n*Pr	Et	Me
(a)	+	+	+	+	+	+		
(b)					(+)	(+)	+	+

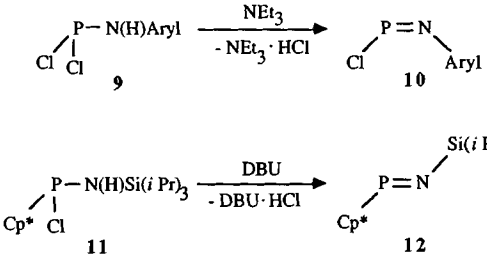
Scheme 3. Product formation in the thermolysis of diaminophosphanes in dependence of residue R.

It is possible to avoid high temperatures in the synthesis of iminophosphanes by using a procedure involving thermal salt elimination, since the decomposition temperature of the *N*-lithiated aminohalogenophosphane precursors is much lower than that of the *N*-silylated derivatives. Thus, the formation of **8** via elimination of LiX from **7a,b** occurs at below 20 °C (X = Cl) or at 60 °C (X = F), while the elimination of Me_3SiCl from *N*-silylated **7c** only occurs at above 150 °C[24] (Scheme 4). The *N*-lithiated aminohalogenophosphanes can readily be prepared from the corresponding NH-substituted derivatives via Li/H exchange. Lithium amides ($LiN(SiMe_3)_2$, $LiN(SiMe_3)$*t*Bu,[41–44] lithium di-*tert*-butylphospide[36,45] or *tert*-butyllithium[24] have been found to be particularly advantageous, as they combine a considerable basicity with a steric demand which suffices to suppress side reactions such as substitution at the phosphorus atom or addition of the organo-H compounds formed to the P=N double bond. In general, as can be seen from the examples **7a,b**, the thermal stability of *N*-lithiated phosphanes decreases on going from fluoro-substituted derivatives (which are in some cases isolable and stable at room temperature) to the chloro- or bromo-substituted derivatives, so that the salt elimination can often be carried out below room temperature.



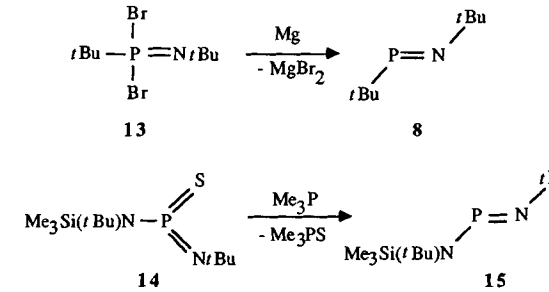
Scheme 4. Variation of reaction conditions by using lithiated aminohalogenphosphanes.

In contrast to the thermal elimination reactions, the amine-induced dehydrohalogenation of NH-substituted aminohalogenophosphanes normally leads to the formation of 1,3,2,4-diazadiphosphetidines (cf.**6**)[49–51] or higher P,N oligomers.[51] It has not yet been demonstrated unequivocally that unsaturated intermediates are formed.[50] Only in a few cases has the formation of isolable P=N double bond systems in such elimination reactions been reported: thus the reaction of the aminochlorophosphanes **9** and **11** with triethylamine and DBU (1,8-diazabicyclo[5.4.0]under-7ene) respectively yields the *P*-functionalized iminophosphanes **10**[46,47] and **12**[38] (Scheme 5), the formation of which is apparently favored by the high steric demand of the substituents at nitrogen.



Scheme 5. Aryl = 2,4,6-tri-*tert*-butylphenyl, Cp* = pentamethylcyclopentadienyl.

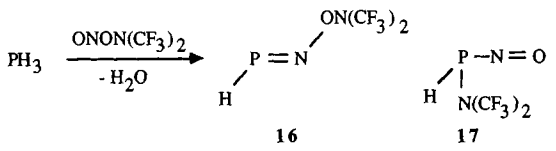
The synthesis of iminophosphanes is in principle also feasible via 1,1-elimination reactions starting from iminophosphorane precursors, as has been shown for the reductive debromination of the dibromoiminophosphorane **13**[52] and the desulfurization of iminothiophosphoranes such as **14** to **15** (Scheme 6).[50,53] Although this reaction is of theoretical interest, its preparative use has so far been only very limited, as the synthesis of the precursors was carried out starting from iminophosphanes.



Scheme 6. Synthesis of iminophosphanes by 1,1-elimination.

A recent report[54] has described the preparation of the *N*-aminooxy-substituted iminophosphane **16** via an elimination of water in the course of the reaction between PH_3 and

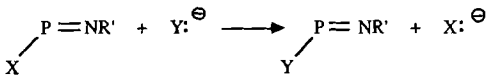
O-nitroso-*N*,*N*-bis(trifluoromethyl)hydroxylamine.[54] However, the suggested structure **16** involving a P=N double bond does not follow with certainty from the spectroscopic data presented; the IR spectrum in particular supports the isomeric structure **17**.



It has in several cases been possible to use the synthetic principles described above for the preparation of homologous molecules with As=N double bonds.[40, 42]

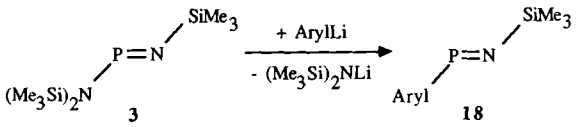
2.2. Substitution Reactions

Iminophosphanes with a nucleofugal leaving group at phosphorus can react with nucleophiles via ligand substitution, the double bond remaining unchanged (Scheme 7). The



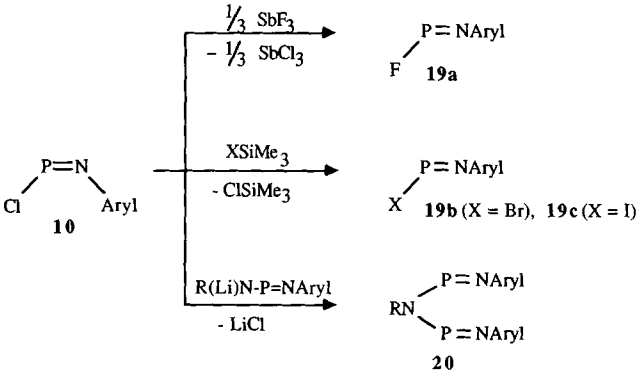
Scheme 7. Synthesis of iminophosphanes by nucleophilic substitution.

first reported preparative applications of this synthetic method involved the transamination of bis(trimethylsilyl)-aminoiminophosphanes with dialkylamides[55] and the preparation of the aryliminophosphane **18** from **3** and 2,4,6-tri-*tert*-butyllithiobenzene[53, 56] (Scheme 8). However, only the



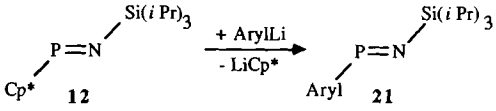
Scheme 8. Aryl = 2,4,6-tri-*tert*-butylphenyl.

recent preparations of stable *P*-chloro[47] and *P*-phenoxy derivatives[32] have permitted such substitution reactions to become of more general importance.[46, 57–61] The chloroiminophosphane **10** in particular has been shown to be a key intermediate in the preparation of a large variety of new *P*-functionalized iminophosphanes[46, 47, 58–60, 62–64] (Scheme 9). Reactions of **10** with *N*-lithiated aminoiminophosphanes should also be mentioned: these afford 1,3,5-triaza-2,4-diphosphapenta-1,4-dienes **20**[61] (Scheme 9), which as heteroanalogues of pentadienyl anions are expected to exhibit interesting coordination properties. While in general *P*-alkyl- or *P*-aryl-substituted iminophosphanes do not undergo ligand substitution reactions, pentamethylcyclopentadienyl-substituted compounds such as **12** are a special case, as the five-membered ring can readily be exchanged in a nucleophilic manner for amino or aryl substituents (e.g. synthesis of **21**, aryl = 2,4,6-tri-*tert*-butylphenyl.[38] An unex-



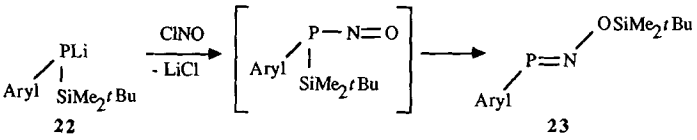
Scheme 9. Aryl = 2,4,6-tri-*tert*-butylphenyl. X can, apart from being F, Br, I also be tBu$_2$As, tBu$_2$P, R'RN, RO, tBuS, R$_2$C=N, Cp*, tBuC≡C, R$_3$P=N. **20a**, R = tBu; **20b**, R = Aryl; **20c**, R = 2,4,6-iPr$_3$C$_6$H$_2$).

pected substitution of the tBu residue (rather than an oxidative addition at phosphorus) was also observed in the reaction of tBuP=NAryl with sterically demanding halogenoamines.[32]

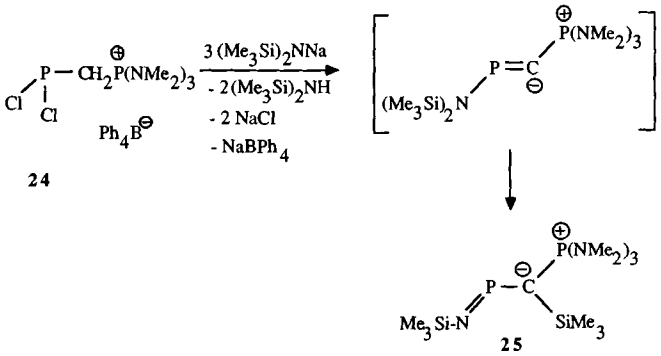


2.3. Rearrangement Reactions

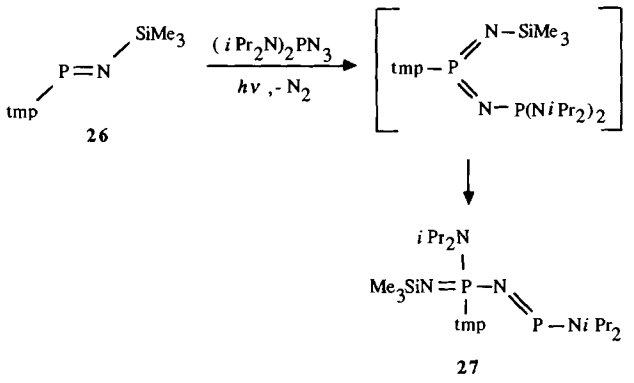
Only a few examples of syntheses of iminophosphanes via rearrangement reactions have so far been described. The formation of a P=N double bond via a [1,3] shift of a silyl group bonded to phosphorus to a doubly bonded oxygen in the α-position, a standard synthetic principle in phosphaalkene chemistry, has only been verified in the preparation of the *N*-silyloxy-substituted iminophosphanes **23**.[65] A



[1,3] silyl shift is also assumed to occur during the reaction of the phosphonium salt **24** with three equivalents of sodium bis(trimethylsilyl)amide, which affords the phosphoranylidenemethyl-substituted iminophosphane **25**.[66] The [1,3]

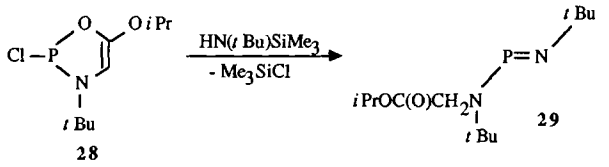


shift of a dialkylamino group has been suggested to occur in the formation of **27** by photolysis of azidobis(diisopropylamino)phosphane in the presence of the iminophosphane **26**[67] (Scheme 10). The reaction of the 2,3-dihydro-1,3,2-



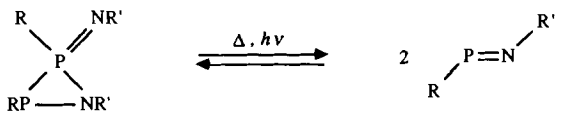
Scheme 10. tmp = 2,2,6,6-tetramethylpiperidyl.

oxazaphosphole **28** with *tert*-butyl(trimethylsilyl)amine leads via elimination of trimethylchlorosilane and [1,5] hydrogen shift to the functionalized aminoiminophosphane **29**.[68]



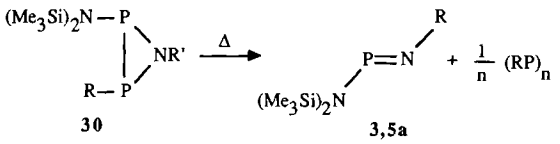
2.4. Cycloreversion Reactions

Because of the reversibility of the [2 + 1] cyclodimerization of iminophosphanes, the λ^3,λ^5-azadiphosphiridines formed in the reverse reaction can in turn be used as precursors for iminophosphanes (Scheme 11). It is thus possible,



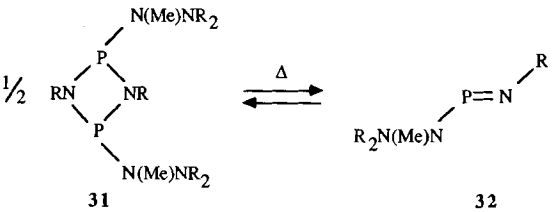
Scheme 11. Azadiphosphiridines as sources of iminophosphanes.

starting from solutions of *P*-alkyl-*N*-alkyl/aryl-substituted $\lambda^3\lambda^5$-azadiphosphiridines to generate the corresponding monomers thermally or photochemically and to characterize them spectroscopically, even though they are not stable in the pure state.[24, 42, 44] The cycloreversion of *N*-silyl-substituted $\lambda^3\lambda^5$-azadiphosphiridines requires considerably higher temperatures; under such conditions the monomers cannot be characterized spectroscopically, but their presence has been detected by means of trapping reactions (see Section 4.3). Thermal [2 + 1] cycloreversion reactions of $\lambda^3\lambda^3$-azadiphosphiridines have been observed in the case of **30**; they lead to the formation of the aminoiminophosphanes **3** and **5** as well as to cyclopolyphosphanes $(RP)_n$[69, 70] (Scheme 12).

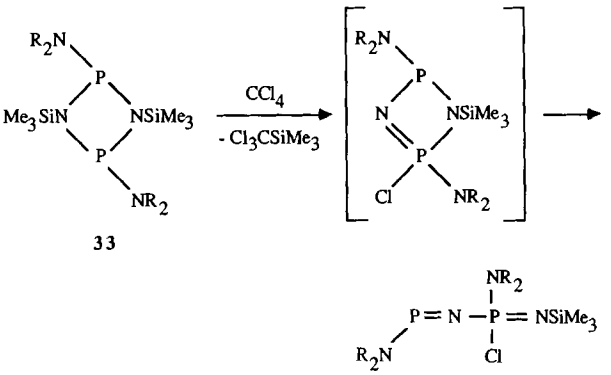


Scheme 12. R = iPr$_2$N, tBu; R' = SiMe$_3$, tBu.

There are very few examples of the formation of iminophosphanes via retroreactions starting from four-membered or larger rings. The diazadiphosphetidine **31** (R = SiMe$_3$) is in equilibrium with the aminoiminophosphane **32** (R = SiMe$_3$),[20] while the formation of iminophosphoranes and alkoxyphosphanes in the course of reactions of the cyclotetramers $(Me_3C_6H_2PNtBu)_4$ with diethylamine and alcohols respectively has been explained as resulting from reactions of the iminophosphane formed from the eight-membered ring by cycloreversion.[51] Electro-



cyclic ring-opening of an intermediate didehydrodiazadiphosphetidine has been postulated to be involved in the formation of the phosphoranyl-substituted iminophosphanes **34** via oxidation of the diazadiphosphetidine **33** with CCl_4[67, 71] (Scheme 13).



Scheme 13. R = iPr, SiMe$_3$.

3. Structural and Bonding Considerations

3.1. Theoretical Studies

According to ab initio calculations the parent system HP=NH resembles diimine in having a planar bent structure, the (*E*)-conformation being slightly more stable than the (*Z*)-conformation.[72–79] Participation of d orbitals in the double bond system can be neglected.[80] The comparison with structural parameters calculated at the SCF level[76]

(see Fig. 1) shows that the transition from (*E*)- to (*Z*)-HP=NH is accompanied by a shortening of the P–N bond and an increase in the bond angles P and N. The inversion barrier at the nitrogen atom is considerably lower than that in diimine and corresponds to approximately one-third of the activation energy for a rotation about the π bond. According to these calculations, the (*E*)/(*Z*)-isomerization involves a transition state in which the PNH geometry is almost linear[73, 76] (Fig. 1). The low value of the nitrogen inversion barrier can be regarded as the reason why it has so far not been possible to detect the existence of (*E*)/(*Z*) isomer pairs in iminophosphanes.

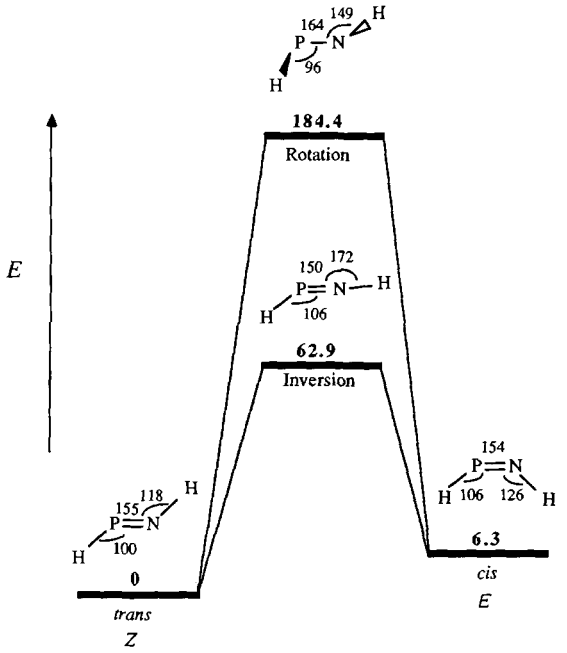


Fig. 1. SCF equilibrium geometries and relative energies for HP=NH (bond lengths in pm, bond angles in degrees, energies in kJ mol^{-1}; after[76]).

Replacement of the hydrogen atom at phosphorus in HP=NH by either more electronegative or more electropositive substituents (π-acceptors/donors) results in the former case in an appreciable strengthening and in the latter in a corresponding weakening of the double bond. At the same time the (*Z*)-configuration becomes more stable with respect to the (*E*)-configuration, while the inversion barrier is decreased.[81] Exactly opposite effects have been forecast for the influence of corresponding substituents at nitrogen,[81] the greatest changes being observed for donor-acceptor ("push-pull")-substituted model compounds.[37, 81] A weakening of the double bond with concomitant formation of a delocalized 4-electron-3-center π-bond system is caused by the introduction of substituents with pronounced π-donor properties (e.g. NH_2) at the phosphorus or nitrogen atoms.[72, 81, 82] The inductive effect of the ligands is either weakened (by *P*-substitution) or strengthened (by *N*-substitution).[81]

An analysis of the frontier orbitals of (*E*)-HP=NH shows that the HOMO is a non-bonding orbital which is mainly localized at phosphorus, while the LUMO is an antibonding π^* orbital. The π(P=N) orbital lies directly below the HOMO in energy.[72, 83–85] The formation of a delocalized π-bonding system in H_2N–P=NH is accompanied by a strong destabilization of the π(P=N) energy level, so that the energy difference between the two highest occupied orbitals is minimal in this case.[72, 82] On the basis of these calculations it was predicted that HP=NH would preferentially undergo [n + 1] addition reactions[86] (oxidative addition at phosphorus, "carbene-analogous reaction behavior"), while in the case of H_2N–P=NH [n + 2] additions to the double bond should be favored[72] (see Section 4.3).

3.2. Electron Spectroscopic and Electrical Measurements

The UV/visible spectra of iminophosphanes show two characteristic absorption bands, which can be identified on the basis of their differing intensities as arising from the expected n–π^* and π–π^* transitions of the P/N chromophore.[87, 88] In the He(I) photoelectron (PE) spectra the double bond system manifests itself in the form of a series of ionization bands at low energies in addition to the undifferentiated bands which result from the ionization of the skeletal MO's.[84, 87, 88] An assignment of these bands to ionization from n(P) or π(P=N) orbitals can be made on the basis of the observed linear correlation (Fig. 2) between the

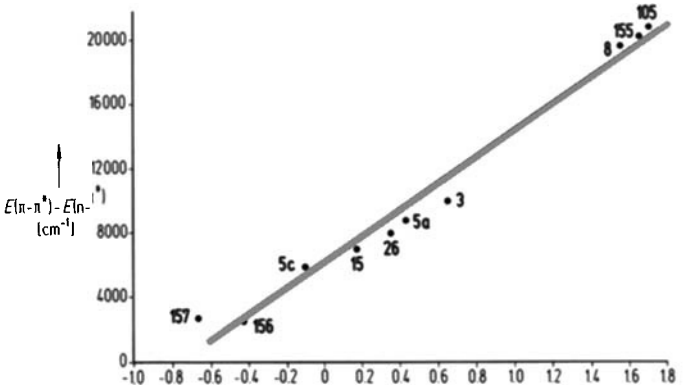

Fig. 2. Correlation between the difference in electron excitation energies $[(\Delta E(\pi\text{-}\pi^*) - \Delta E(\text{n-}\pi^*)]$ and vertical ionization potentials $[I_v(\pi) - I_v(\text{n})]$ for alkyl- and amino-substituted iminophosphanes (after [88], **155**: *t*BuP=$NCEt_3$, **156**: *t*BuP=N–TMP; **157**: *t*Bu-P=N–NMe_2).

ionization energy differences and the corresponding optical excitation energies[27, 87] and is further supported by the comparison with calculated adiabatic ionization potentials.[88] In the case of *P*-alkyl substituted iminophosphanes the first ionization potential corresponds to an ionization from the n orbital, while for *N*-aminoiminophosphanes and *P*-(dialkylamino)iminophosphanes it involves an ionization from the π-orbital. Assuming the validity of *Koopmans'* theorem[89] the bonding situation corresponds in the first case to that of the parent system (*E*)-HP=NH [ε(np) > $\varepsilon(\pi_{P=N})$], while in the second case there is a crossover of the orbital sequence [$\varepsilon(n_P) < \varepsilon(\pi_{P=N})$].

The measurement of dipole moments for iminophosphanes and a comparison with those measured for other P–E multiply bonded systems made possible the determination of

a double bond increment ($p_{P=N} = 2.2 \pm 0.2$ D) and thus demonstrates the high polarity of the double bond.[90] Electrooptical measurements with the help of the Kerr effect made it possible to determine the anisotropy of the polarizability of the P–N bond (3.5–4.0 A^3) as well as to carry out studies on the geometrical orientation of substituents.[91]

3.3. Molecular Structures

A large number of crystallographic investigations on iminophosphanes have been carried out recently (Table 1). While in most cases the double bond was found to have an (*E*)-configuration, a (*Z*)-configuration or even a nearly linear P–N–R geometry was observed in a few cases. Thus, it is now possible to discuss the nature of the P–N bond not only on a theoretical but also on an experimental basis.

Structural studies on iminophosphanes with a C–P=N–C skeleton, which can be considered as homologues of the unknown parent compound (*E*)-HP=NH, have so far been limited to two examples. The experimentally determined double bond distances in **44**[97] and **47**[96] agree well with the results of SCF calculations for (*E*)-HP=NH, while the relative increases in the bond angles at phosphorus and nitrogen are apparently due to the steric bulk of the substituents.

Aminoiminophosphanes have been the subject of intensive study, and in almost all cases an (*E*)-configuration at the double bond was determined. The amine nitrogen generally has a planar coordination geometry, while the R_2N and the PNR′ units are coplanar; this indicates the formation of a delocalized π-electron system. The P–N bond distances lie within the expected ranges: 167 ± 3 pm ($P–N_{amine}$) and 156 ± 2 pm ($P–N_{imine}$). In the azomethine-substituted derivatives **45** and **51** the large values for the bond angles at the azomethine nitrogen (∢ PN′C, **45**: 167.5°, **51**: 165°) and the short $P–N_{azomethine}$ bond distances ($r_{P-N'}$; **45**: 159.5 pm, **51**: 161.4 pm) indicate the existence of a high degree of s-character in this P–N′ bond. The $R_2C=N$- and Aryl N=P- units exhibit an almost orthogonal arrangement (∢ N′PNC/NCR_2, **45**: 87.5°, **51**: 87.9°), also indicating the formation of a 4π-electron system delocalized across the N–P–N sequence rather than of a theoretically possible heterobutadiene system.

A surprisingly short P–N bond distance of 153.7 pm and a torsion of 26° about the double bond have been observed for the sterically hindered derivative **49**. The expected weakening of the π bond caused by the twisting is apparently more than compensated by the considerable increase of the bond angle at the imine nitrogen (152°).[96] The comparatively long $P-N_{amine}$ and short $P-N_{imine}$ distances in the 1,3,5-triaza-2,4-diphosphapenta-1,4 diene **20a**, the P/N skeleton of which is (*S*)-configurated, can be explained in terms of a delocalized 5-center-6-electron π system.[61] The *N,P*-diaminoiminophosphane **36** has two amine ligands in 1,2-position: only the amine residue at nitrogen has the geometry necessary for an effective π conjugation. The $(SiMe_3)_2N$ residue at the imine nitrogen is in contrast orthogonal to the plane of the π system; this leads to a decrease of the angle at the imine nitrogen (107.1°) and an increase in the P–N bond length to 159.8 pm.[28]

An almost planar P–N–NR_2 arrangement, which indicates a conjugation between the double bond and an $(SiMe_3)_2N$ group at nitrogen, has been found for the *N*-amino-*P*-phosphinoiminophosphane **35**. The π-electron delocalization makes itself apparent in the short N–N bond distance (138.1 pm) and the particularly long P–N bond (161.9 pm).[37]

Until now a (*Z*)-configuration of the double bond has only been found for iminophosphanes which bear a tris(*tert*-butyl)phenyl group at nitrogen. The aryl ligand is orthogonal to the plane of the P=N double bond, due no doubt to steric effects. In the pairs of compounds (*E*)-tBu_2C=N-P=N-Aryl (**45**)/(*Z*)-Fl=N-P=N-Aryl (**51**),[59] and (*E*)-iPr_2N-P=N-Aryl (**46**)/(*Z*)-Me_2N-P=N-Aryl (**53**),[98] which contain substituents with comparable steric and electronic properties, a comparison of the bonding parameters confirms the expected larger bond angles and shortening of the P–N bond distances in the (*Z*)-isomers. The observed correlation between the P–N bond length and the valence angle at nitrogen is remarkable: in the halogen-, aryloxy-, or alkoxy-substituted iminophosphanes **10**, **19c**, **56**–**58** in particular it is found that extremely short P–N bond distances (148–151 pm) are accompanied by an almost linear arrangement of the P–N–C_{aryl} fragment (Table 1). The P–O bonds in **54**–**58**, which vary between 159 pm (**54**)[96] and 166 pm (**55**),[104] lie within the range expected for single bonds (164 pm[107]).

Interesting structural effects are shown by the *P*-halogenoiminophosphanes **10** and **19b,c**, the bis(chalcogeno)-phosphinato-substituted derivatives **59** and **60**, and the (C_5Me_5)-substituted derivative **12**. In those modifications of **10** which have been studied there is a significant difference in the valence angle at the imine nitrogen, although the other bonding parameters remain almost unchanged (Table 1). This indicates that the P–N–R unit can very readily undergo deformation, a fact which can be interpreted in terms of the prediction of a low inversion barrier at nitrogen.[81]

The phosphorus–halogen bonds in **10** (r_{P-Cl} = 214.2 pm,[46] 212.7 pm[105]) and **19b** (r_{P-Br} = 233.5 pm[96]) are significantly longer than in the trihalides PX_3 (r_{P-X}[107]: 204 pm (X = Cl); 222 pm (X = Br)); this can be interpreted in terms of an n(N)→σ*(PX) charge transfer.[108] This effect is even more pronounced in the iodo compound **19c** (r_{P-I} = 289.5 pm[96] vs. 252 pm in PI_3[107]). In this case the increasing polarization of the *P*–halogen bond is accompanied by the presence of a short intermolecular P–I contact

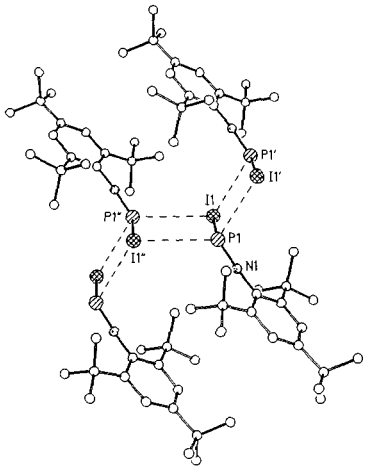

Fig. 3. Crystal structure of **19c**. Bond lengths: P1–I1 289.5(1) pm, P1–I1' 322.4 pm. The additional intermolecular contact P1–I1" (360.5 pm) lies within the range of the sum of the van der Waals' radii and does not correspond to a bonding interaction (after [46]).

(322 pm), so that a transition to a biomolecular donor-acceptor complex is already indicated in the crystal (Fig. 3).

A bonding situation comparable to that in **19c**, in this case in the form of an intramolecular donor-acceptor interaction, can be found in **59**, which has two weak phosphorus–sulfur bonds of different lengths (r_{P-S} 244.2 and 273.9 pm).[96] The two phosphorus–chalcogen bond lengths are less divergent in the selenium derivative **60** (r_{P-Se} 263.6 and 278.8 pm), so that in this case a description of the bonding situation can include the participation of a contact ion pair of the type $[R_2PSe_2]^{\ominus}[PNAryl]^{\oplus}$ as a resonance hybrid.[106] Complete separation into a cation and an anion is realized in the case of **61**, where the extremely short P–N bond distance and the almost linear arrangement of the P–N–C_{Aryl} fragment justify a description in terms of a phosphanetriylammonium ion with partial triple bonding between P and N.[46]

The molecular structure of the iminophosphane **12** can be interpreted as an intramolecular π-complex between $[Me_5C_5]^{\ominus}$ and $[R_3SiNP]^{\oplus}$ (Fig. 4); in contrast to **47** the

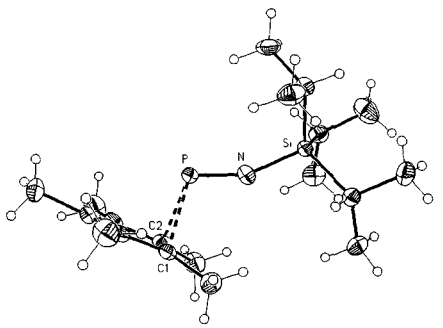

Fig. 4. Crystal structure of **12**. Bond lengths: P–Cl 216.8(4) pm, P–C2 212.2(4) pm, P–N 153.3(3) pm; bond angle P–N–Si 153.3(2)° (after [38]).

cyclopentadienyl ligand is coordinated in a "non-classical" η^2 manner. Important arguments for this description are provided by the almost equal bond distances, the (pseudo)-planar geometry in the five-membered ring, the increase in the length of the P–C bonds (r_{P-C} = 212.2 and 216.8 pm)

and in the valence angle at the imine nitrogen, and the shortening of the P–N bond (see Table 1) in comparison to that in **47**.[38]

3.4. NMR Spectroscopic Investigations

The chemical shift range for the ^{31}P resonance of iminophosphanes covers the wide range between $\delta = 87$ for **19a** and $\delta = 787$ for **42** (see Table 2). The ^{31}P-NMR data

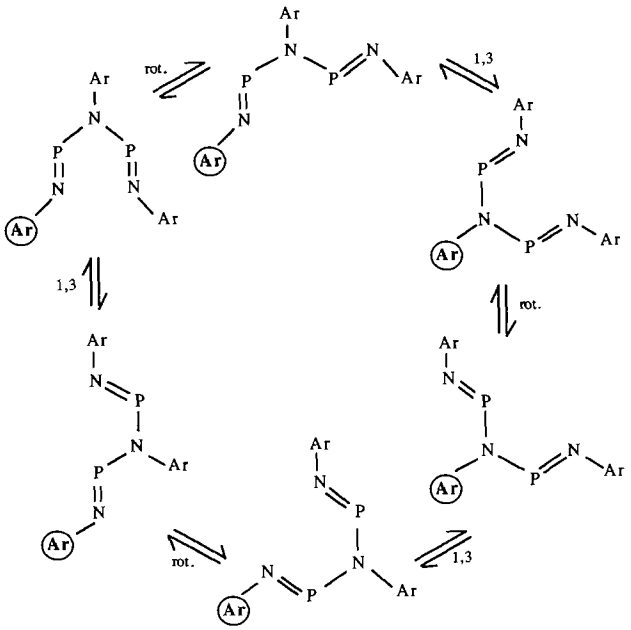
published up to mid-1985 have been reviewed.[15] Although a theoretical or empirical treatment of the large chemical shift differences generally observed for compounds in which phosphorus has a coordination number of two is extremely difficult,[109] the shifts in iminophosphanes can be explained to a good approximation in terms of the stereoelectronic effects of the substituents at phosphorus and nitrogen. Thus, for a series of compounds of the type R–P=NAryl there is a linear correlation between $\delta^{31}P$ and the n–π^* electron excitation energy; this indicates that the paramagnetic term makes a dominant contribution to the shielding tensor.[88] According to this postulate, substituents R with strong σ-donor properties ($C_5Me_5(CO)_2Fe$, *t*Bu$_2$As, *t*Bu$_2$P) which cause a red shift of the n-π^* band will lead to deshielding, while ligands with π-donor and/or σ-acceptor properties ($R_2C=N$, R_2N, RO, halogen) will induce a shielding of the phosphorus nucleus. A geometrical effect on the chemical shift, which is well documented for (*E*)/(*Z*) isomer pairs of diphosphenes or phosphaalkenes, is also apparent in the iminophosphane system. Thus, in the pairs **45**/**51**, **40**/**52**, and **46**/**53**, for which the substituents at phosphorus have comparable steric and electronic effects, the (*E*)-configured iminophosphanes **45**, **40** and **46** show a significant deshielding ($\Delta\delta^{31}P$ 60 ± 5 ppm, see Table 2).

Although in the case of phosphaalkenes ^{13}C-NMR spectroscopy acts as an additional probe for studying the nature of the double bond, the unfavorable magnetic properties of the isotopes ^{14}N and ^{15}N are an extreme handicap to such studies on iminophosphanes. $^{14}N/^{15}N$-NMR studies on iminophosphanes have thus so far been carried out in only a few cases,[110] so that it is not at present possible to discuss the data in a systematic manner.

Apart from the interpretation of chemical shifts and coupling constants, NMR can be used for studying dynamic processes and thus provides a further tool for probing the nature of the P=N double bond. Thus in a series of aminoiminophosphanes R'(R)N–P=NR' (R = SiMe$_3$, R' = SiMe$_3$ (**3**), *t*Bu (**15**); R = H, R' = Aryl (**40**)) it has been possible to detect degenerate sigmatropic [1,3] shifts involving either protons or trimethylsilyl groups; these correspond to chemical exchange between the amino and imino positions in the molecule.[4, 17, 43] The 1,3,5-triaza-2,4-diphosphapenta-1,4-diene **20b** undergoes an analogous rearrangement in which the shift of a P=NAryl group and a P–N bond rotation lead to a complete equilibration of all three nitrogen positions[61] (Scheme 14).



Scheme 14. Schematic representation of the dynamic structure of **20b**; labeled aryl residue passes through all possible positions (after [61]). rot. = rotation about a P–N single bond, 1,3 = [1,3] shift of an arylN=P group. Ar = Aryl.

"Ring whizzing", i.e. a series of very fast [1,5] sigmatropic ring shifts, is observed for *P*-(pentamethylcyclopentadienyl)-substituted iminophosphanes. Since the observed processes are still fast with respect to the NMR time scale even at low temperatures, it can be concluded that the activation energy is considerably lower than in the corresponding $\lambda^3\sigma^3$ phosphorus compounds.[38, 41]

A remarkable temperature dependence is observed in the ^{31}P- and ^{77}Se-NMR spectra of the iminophosphane *t*Bu$_2$P^{A}Se$_2$P^{B}NAryl **60**. While the coupling constants $^2J(P^A, P^B)$ and $^1J(P^B, Se)$ are detectable at −80 °C, they disappear when the temperature is raised, although $^1J(P^A, Se)$ remains almost unchanged. At the same time the signal correspond-

ing to the phosphorus atom of the double bond undergoes a significant low-field shift. An explanation of these results is possible on the basis that the structure in the crystalline state (see Section 3.3), which involves the presence of contact ion pairs $[R_2PSe_2]^{\ominus}[PNAryl]^{\oplus}$, is maintained at low temperatures in solution; the partial disappearance of the couplings when the temperature is increased corresponds to an increasing dissociation into single ions.[47, 106]

4. Reactivity

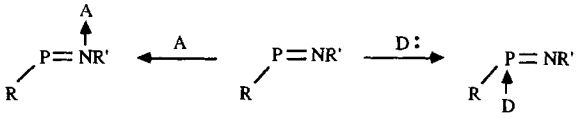
4.1. Addition Reactions

Product formation in many reactions of iminophosphanes can be understood on the basis of a complex reaction mechanism whose first step is an addition to the P=N double bond. Such an addition can in principle involve either an increase of the coordination number of phosphorus (oxidative 1,1 addition) or a 1,2 addition; the observed regioselectivities indicate a complex dependence on the nature of the substrate. Thus 1,1 additions at phosphorus are preferred in reactions of halogens and halogen derivatives of electronegative elements, while the alkyl and halogen derivatives of electropositive elements undergo 1,2 addition with the formation of a very stable element–nitrogen bond.

Because of the high polarity of the P–N bond we can assume that most addition reactions occur via a two-step mechanism, the initial step of which involves attack of a Lewis acid or base at the double bond. The interaction of iminophosphanes with Lewis acids/bases, which can in this sense be regarded as "incomplete additions", is thus of great importance in understanding the reactivity of these compounds.

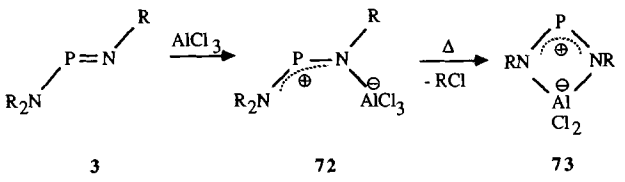
4.1.1. Attack by Lewis Acids and Bases

Theoretical treatments of the electron density distribution in the P=N double bond of iminophosphanes lead us to expect that Lewis acids will attack preferably at nitrogen and Lewis bases at phosphorus[74] (Scheme 15). Although such



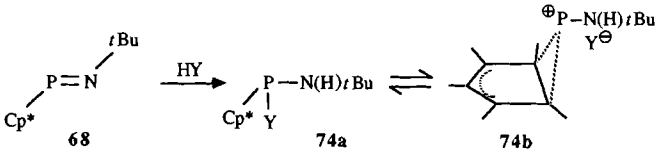
Scheme 15. A = Lewis acid, D = Lewis base.

acid/base adducts are very difficult to study because of their extreme readiness to undergo further reactions, an experimental confirmation of the expected behavior was possible in several cases. Thus the complex **72** was isolated from the reaction of **3** with aluminum trichloride; on raising the temperature this complex decomposed with the formation of the heterocyclic product **73**[111] (Scheme 16). Addition of trifluoroacetic acid to the iminophosphane **68** yielded a product which according to NMR studies is the phosphenium ion **74b** (formed via *N*-protonation of **68**) in dynamic equilibri-



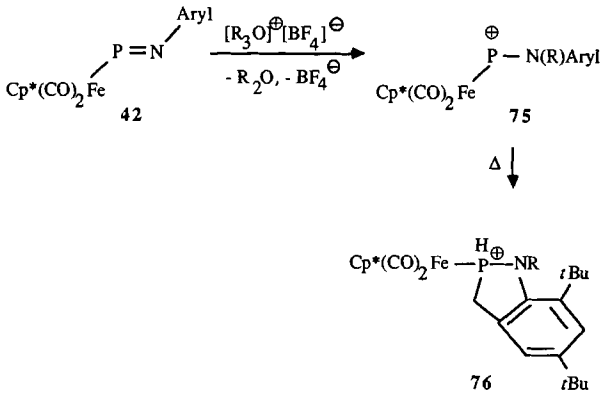
Scheme 16. R = $SiMe_3$.

um with the aminophosphane **74a**[112] (Scheme 17). In an analogous reaction, treatment of the ferrioiminophosphane **42** with Meerwein's salt initially yields an isolable cationic



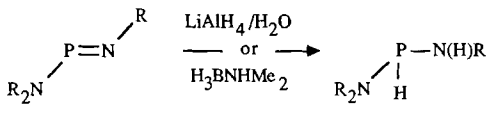
Scheme 17. Y = CF_3SO_3.

phosphinidene complex **75**, which undergoes thermal rearrangement to give the phosphane complex **76** (Scheme 18).[113]

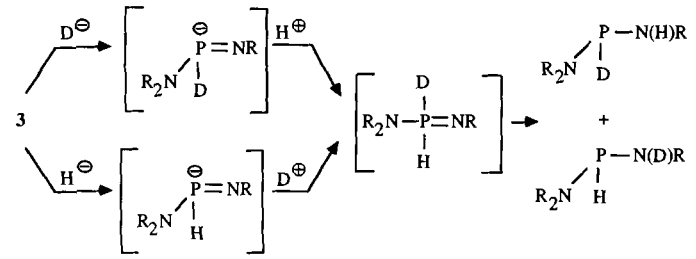


Scheme 18. R = Me, Et; Aryl = 2,4-di-*tert*-butylphenyl.

The intermediate formation of iminophosphoranide anions in the course of the formation of **77** (R = $SiMe_3$) from **3** (R = $SiMe_3$) and $LiAlH_4$ (after hydrolysis) was confirmed

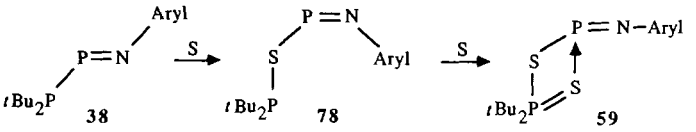


by means of isotopic labeling studies (Schema 19).[114] A similar process has been suggested for the analogous methylation with MeLi/MeI;[114] however, the mechanism of formation of **77** (R = $SiMe_3$) in the reaction of **3** (R = $SiMe_3$) with H_3BNHME_2, which formally involves the transfer of both a hydride ion and a proton, could not be clarified.[115] The dithiophosphinic acid derivative **59**, which was formed

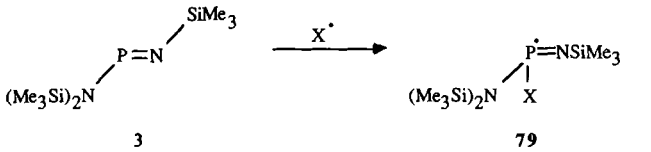


Scheme 19. Isotope labeling experiments for the reduction of **3**. R = $SiMe_3$.

by double sulfurization from **38** via **78**, has the structure of an *intra*molecular iminophosphane/Lewis base complex.[47] Similar *inter*molecular donor-acceptor interactions in the solid state have been detected in the case of the

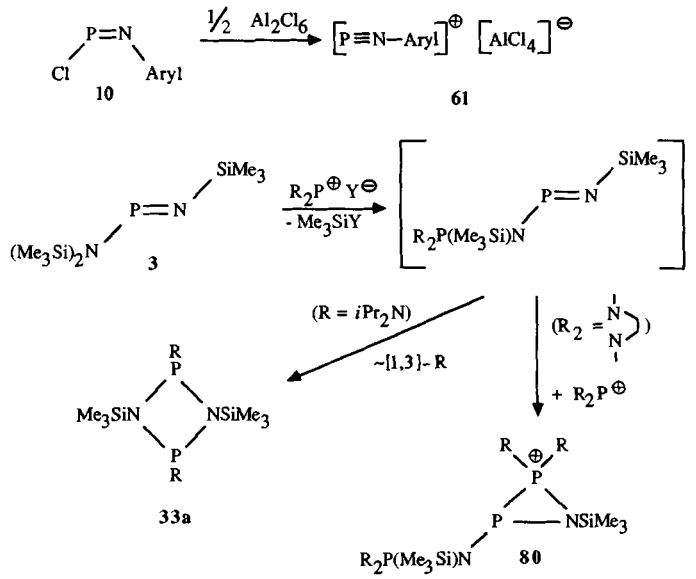


halogenoiminophosphane **19c**.[106] The formation of iminophosphoranyl radicals **79** from **3** and suitable alkyl, alkoxy or acyl radicals can also be considered as an attack of a Lewis base at twofold coordinated phosphorus[116] (Scheme 20).



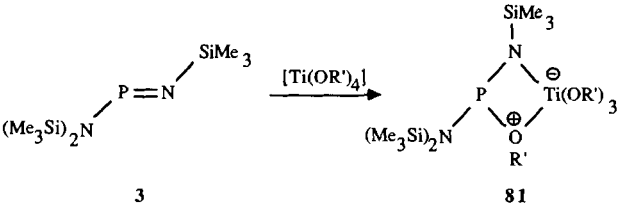
Scheme 20. X = R, RO, RCO.

An alternative mechanism for the interaction of an iminophosphane with a Lewis acid was observed in the reaction of the *P*-chloroiminophosphane **10** with aluminum



Scheme 21. Y = CF_3SO_3.

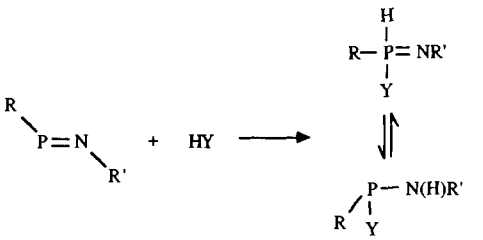
trichloride. Attack of the Lewis acid at the chlorine atom, followed by ligand abstraction, led to formation of the first known phosphanetriylammonium ion[46]. In contrast, the reaction of diaminophosphenium ions with **3** occurred in the expected manner; the formation of the final products **33a** and **80** was explained on the basis of an undetectable iminophosphane/Lewis acid complex[117] (Scheme 21). Treatment of the aminoiminophosphane **3** with titanium



alkoxides led to the occurrence of double Lewis acid/base reactions, giving heterocyclic products which contain two donor–acceptor bonds.[118]

4.1.2. *Addition of Reagents with Acidic Hydrogens*

The relatively polar iminophosphane double bond reacts readily with compounds containing acidic hydrogens to form either correspondingly substituted aminophosphanes (formal 1,2 addition) or the tautomeric iminophosphoranes (formal 1,1 addition) (Scheme 22). Since the tautomeric equi-



Scheme 22. Reactions of iminophosphanes with H-acidic compounds.

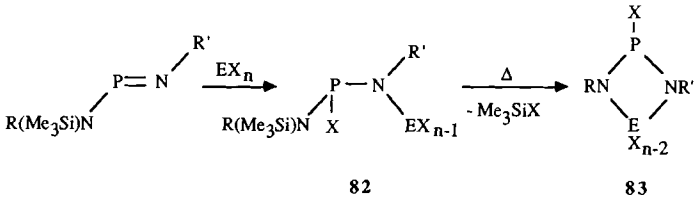
librium reaction must be assumed to be fast,[119] the observed constitution of the reaction products, and not the differing regioselectivities for the two addition reactions, will reflect the relative thermodynamic stabilities of the two forms. The phosphane form is generally found to be of lower energy, so that additions of hydrogen halides[47], alcohols,[30, 31, 120, 121] thiols,[120, 121] amines,[30, 122] phosphanes,[123] and some other compounds with acidic hydrogens[36] to P=N double bond systems lead in most cases to the formation of the corresponding aminophosphanes as the sole products. Stabilization of the hydridophosphorane form requires not only the presence of a trimethylsilyl group at the imino position but also further substituents at phosphorus which increase its basicity. Thus, reactions of $(Me_3Si)_2N$–P=$NSiMe_3$ with sterically less demanding alkyl alcohols and amines lead to the selective formation of the corresponding iminophosphoranes[120–122] while in the reactions with phenol, *tert*-butyl alcohol, and adamantanol the

products are in each case an equilibrium mixture of the two tautomers.[120, 121]

The addition of substrates with acidic hydrogens to iminophosphanes occurs even in the absence of additional bases; however, asymmetric induction was recently observed during the addition of achiral alcohols to iminophosphanes in the presence of chiral tertiary amines, thus indicating a possible base catalysis of the addition reaction.[124]

4.1.3. Halometalation and Organometalation Reactions

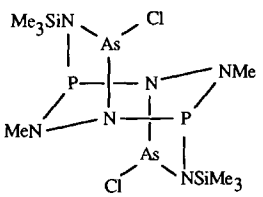
The readiness of phosphorus halides and redox-stable halides of more electropositive elements to react with iminophosphanes depends on their Lewis acidity; the initial formation of Lewis acid–iminophosphane adducts (see Section 4.1.1) is followed by a 1,2 shift of a halogen to give aminohalogenophosphanes **82** (Scheme 23). While such



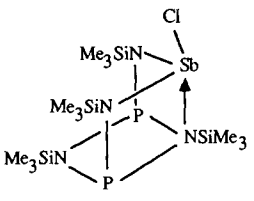
82 83

Scheme 23. E = B, Si, P, As; R, R' = $SiMe_3$, *t*Bu.

products are stable in the case of complete alkyl substitution (R = R^1 = R^2 = alkyl),[23] *N*-silylated derivatives are subject to further reaction steps; the most favored of these is an intramolecular 1,3 elimination of halogenosilanes to give the four-membered heterocycles **83**.[125–129] However, an intermolecular condensation reaction has also been detected in a few cases, for example in the formation of the hexaazadiphosphadiarsatricyclodecane derivative **84** from arsenic trichloride and the iminophosphane $(Me_3Si)_2N$–N(Me)–P=N$SiMe_3$.[130] Multiple addition of an iminophosphane to an element halide was observed in the reaction of **3** with antimony trichloride, which affords the tricyclic compound **85**.[131]

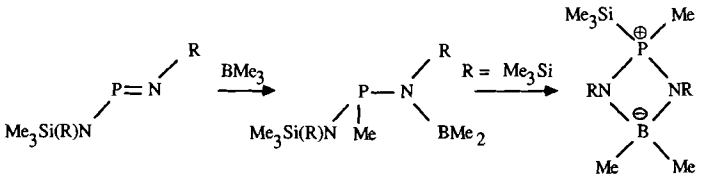


84



85

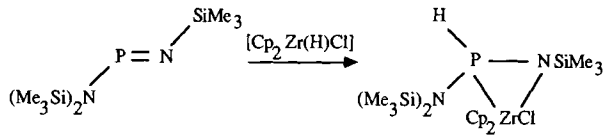
In analogy to the halides, alkyl compounds of electropositive elements also add at the P=N double bond. Thus, reaction of **3** with BMe_3 smoothly affords the 1,2-addition product **86**, while the partly alkylated aminoiminophosphane **15** reacts further via a [1,2] trimethylsilyl shift and ring closure to give the heterocycle **87** (Scheme 24). Analogous products are also formed on reaction of **3** or **15** with Al_2Me_6.[132] An unstable organometallic compound which decomposes with



3,15 86 87

Scheme 24. R = $SiMe_3$, *t*Bu.

reductive elimination of mercury can be assumed as intermediate in the formation of diamino(silyl)phosphanes by reaction of aminoiminophosphanes with bis(trimethylsilyl)-mercury.[133] A reaction similar to the hydrozirconation of

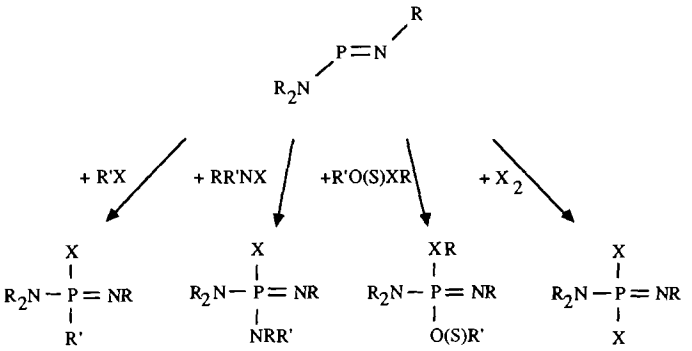


3 88

olefins was observed in the reaction of **3** with $[Cp_2Zr(H)Cl]$, which affords, via 1,2 addition and subsequent intramolecular complexation, the heterocycle **88**.[134]

4.1.4. Oxidative Additions

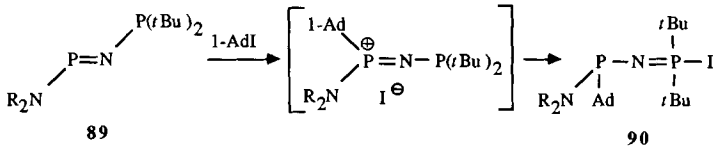
In contrast to the types of reaction discussed above, iminophosphanes react with alkyl halides and halogen derivatives of electronegative elements such as halogenoamines, alkyl hypohalites, arylchlorosulfanes or with halogens themselves via 1,1 addition to give the corresponding iminophosphoranes[4, 25, 31, 125, 126, 135–141] (Scheme 25). The addition products thus obtained from reactions of



Scheme 25. R = $SiMe_3$; X = Cl, Br.

aminoiminophosphanes with (*N*-trimethylsilyl)halogenoamines are important intermediates in the synthesis of aminobis(imino)phosphoranes (see Section 4.2). A free radical mechanism has been suggested for most of the oxidative addition reactions which have been studied,[126] although an alternative ionic mechanism has been discussed for the addition of CCl_3Br to aminoiminophosphanes.[25] An interesting special case is provided by the reaction of the *N*-phosphi-

noiminophosphane **89** with iodoadamantane; in this case a 1,3 addition of the alkyl halides with concomitant 1,2 shift of the double bond is observed, apparently as the result of steric effects[142] (Scheme 26). Oxidative chlorination with the for



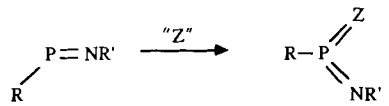
Scheme 26. R = $SiMe_3$; Ad = adamantyl.

mation of a dihalogenophosphorane and an element subhalide was found to occur when tin tetrachloride was allowed to react with **3**.[126]

4.2. Reactions involving the Formation of Diylides R–P(=Z)=NR'

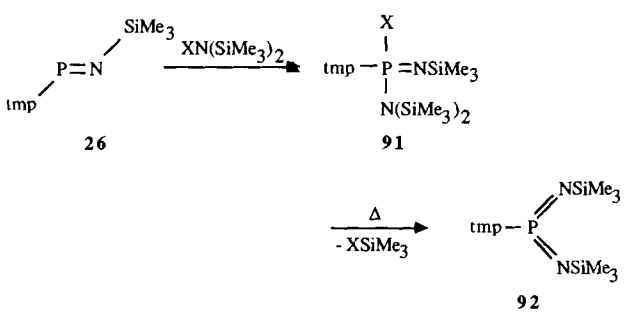
Iminophosphanes play a central role in the preparation of diylidic iminophosphoranes R–P(=Z)=NR' (Z = O, S, Se, "PR"). Systems of this type, in which a trigonal planar coordinated phosphorus(v) atom forms part of a delocalized (p–p)π-bond system, are not only of considerable theoretical interest but also offer interesting synthetic possibilities. Although the formation of these products can formally be regarded as an oxidative addition to iminophosphanes, experimental studies have shown that various reaction mechanisms are in fact involved.

Thus reactions of iminophosphanes with ozone, sulfur or selenium appear to involve a direct oxidative addition; no intermediates could be detected in the formation of either the iminochalcogenophosphoranes (Scheme 27) or the [2 + 2] cyclodimerization products resulting from them.[17, 18, 143–145] Evidence for a formal oxidative trans-



Scheme 27. Z = O, S, Se, "PR".

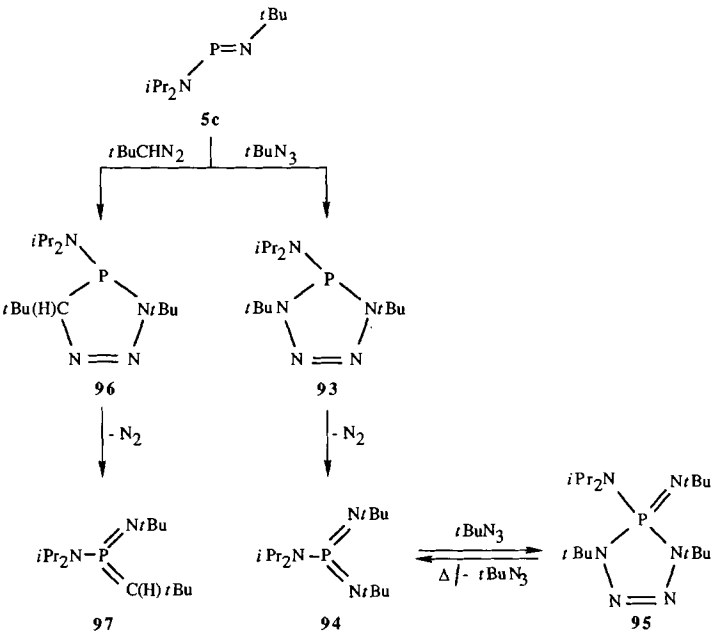
fer of a phosphanediyl "RP" to an iminophosphane with formation of an imino-λ^3,λ^5-diphosphene was recently presented.[146] Bis(imino)phosphoranes such as **92** can be ob-



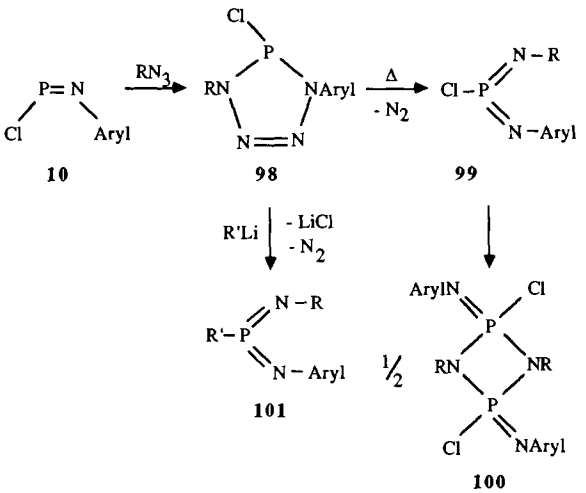
Scheme 28. X = Cl, Br; tmp = 2,2,6,6-tetramethylpiperidyl.

tained in good yields via oxidative addition of chloro(silyl)-amines to iminophosphanes such as **26** to **91** with subsequent chlorosilane elimination[25, 135] (Scheme 28).

In contrast to chalcogenation, alternative reaction mechanisms have been detected in some cases in reactions of iminophosphanes with azides or diazoalkanes, which lead to the formation of iminomethylene- or bis(imino)phosphoranes via a formal oxidative addition of a carbene or a nitrene.[25, 44, 47, 67, 147–154] Thus reaction of the aminoiminophosphane **5c** with alkyl *tert*-butylazide and diazoneopentane led via [2 + 3] cycloaddition to formation of the heterocycles **93**[155] and **96** respectively; these underwent thermal or photolytic elimination of nitrogen to give the corresponding diylides **94** and **97** respectively.[149–151] Un-

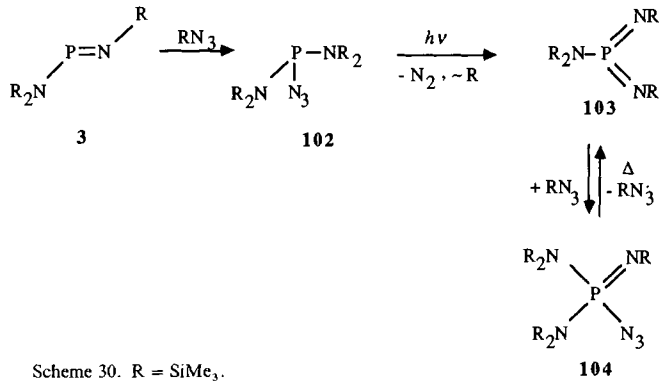


der the reaction conditions the bis(imino)phosphorane **94** can add excess azide to give **95**, from which the diylide can be re-formed by vacuum thermolysis.[151] The chloroiminophosphane **10** reacts in a similar manner via [2 + 3]



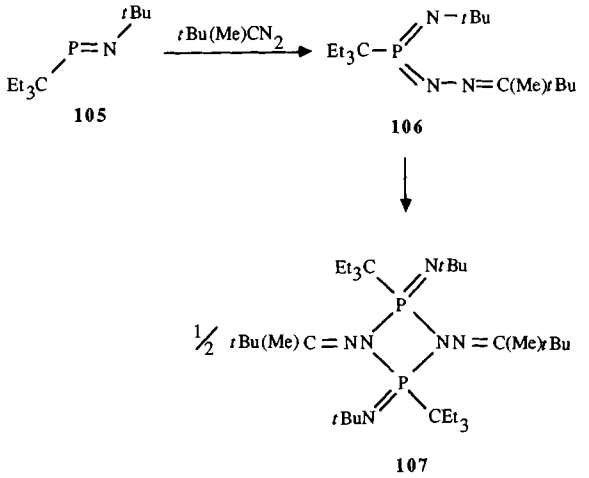
Scheme 29. R = *t*Bu, Et_3C, 1-adamantyl; R' = *n*-Bu, C_5Me_5, Aryl NH, Aryl O, *t*BuS.

cycloaddition to afford the heterocycles **98**; thermolysis of the latter leads to elimination of nitrogen to give the diazadiphosphetidines **100** via the unstable bis(imino)phosphoranes **99**. In the presence of suitable organolithium derivatives, **98** undergoes nucleophilic substitution to give the stable bis(imino)phosphoranes **101** (Scheme 29).[154] A 1,2 addition analogous to the halometalation was observed in the reaction of **3** with trimethylsilyl azide; the unstable azidophosphane **102** thus formed undergoes nitrogen elimination and a Curtius-type rearrangement to afford the bis(imino)phosphorane **103**, which can add reversibly to excess azide to form **104**[149] (Scheme 30).



Scheme 30. R = $SiMe_3$.

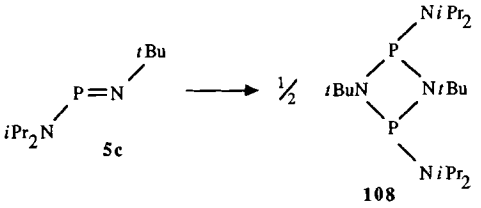
It was possible to detect an oxidative addition of an azoalkane to the P=N double bond in the reaction of the *P*-alkylated iminophosphane **105** with 2-diazobutane-3,3-dimethyl. In analogy to the Staudinger reaction between tertiary phosphanes and azides, the primary product is the spectroscopically detectable adduct **106**, which undergoes stabilization via a [2 + 2] cycloaddition to give the isolable diazadiphosphetidine **107**.[44] In contrast, the reaction of



$(Me_3Si)_2N$–P=$NSiMe_3$ **3** with diazomethane occurs spontaneously with the uptake of two methylene groups to give the corresponding λ^5-iminophosphirane; in this case it was not possible to observe the formation of a diylide intermediate.[156]

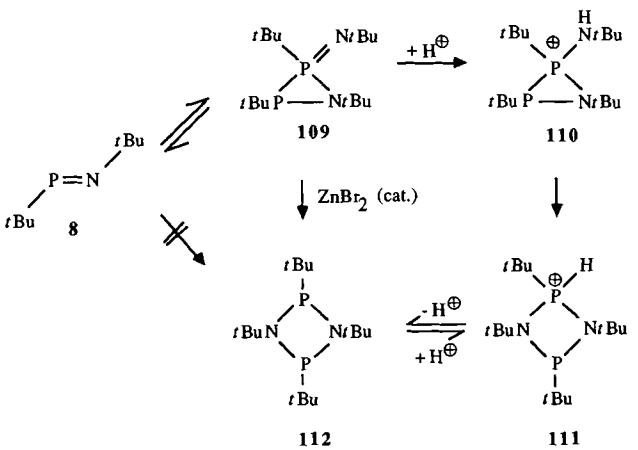
4.3. Oligomerization Reactions

The low kinetic stability of the double bond in iminophosphanes causes them to undergo cyclodimerization, a reaction typical of other "non-classical" double bond systems. However, in the case of the iminophosphanes a structure-dependent regioselectivity is observed, a phenomenon which is unknown for other heteroolefin systems. Thus *P*-alkyl- and *P*-aryl-substituted iminophosphanes react via a reversible [2 + 1] cycloaddition to give λ^3,λ^5-azaphosphiridines[24, 43–45] (see Scheme 11), while π-donor-substituted aminoiminophosphanes and (*N*-amino)iminophosphanes undergo (with one known exception) irreversible [2 + 2] cyclodimerization with the formation of 1,3,2,4-diazadiphosphetidines **5c** → **108**[20, 23, 38] (for exception see Section 2.3). This observed duality correlates well with theoretical predictions, according to which the reactivity is due to different frontier orbital interactions between the reactants[45, 72, 87] (see Section 3.1).



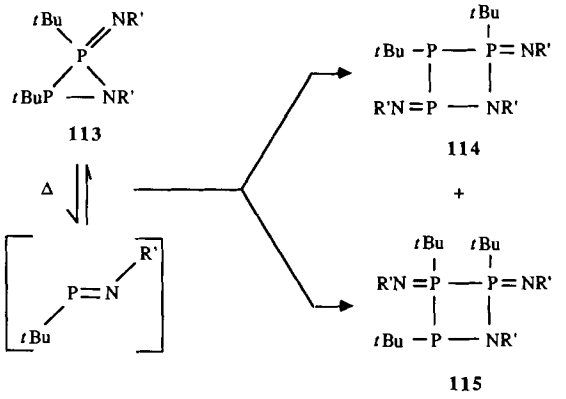
The factors which determine the course of the [2 + 1]-cyclodimerization are the degree of kinetic stability and the temperature. Thus metastable iminophosphanes have a significantly longer lifetime at lower temperatures,[24, 42] while for derivates of the type $Me_{3-n}Et_nC$–P=N*t*Bu (n = 0–3) the dimerization rate decreases with increasing steric demand of the substituent at phosphorus.[33]

Apart from these effects, there is also a remarkable susceptibility of the self-addition to the influence of Lewis acids. For example $(Me_3Si)_2N$–P=$NSiMe_3$, which dimerizes only very slowly in the pure state, undergoes a fast [2 + 2] cyclodimerization in the presence of catalytic amounts of Lewis acid.[157] An apparent change in the regioselectivity was observed in the case of **8**; under the influence of Lewis or Brønsted acids the azadiphosphiridine **109** formed in a reversible [2 + 1] cycloaddition underwent rearrangement to



give the diazadiphosphetidine **112**, which is formally the product of a [2 + 2] cycloaddition. The course of the reaction of **109** with trifluoromethanesulfonic acid could be confirmed by isolation of the intermediates **110** and **111**.[52]

An interesting special case of an iminophosphane oligomerization is the thermolysis reaction of the azadiphosphiridine **113**, which affords a mixture of the isomeric azatriphosphetidines **114** and **115**. The reaction has been postulated to involve an oxidative insertion of monomeric iminophosphane, formed in an initial [2 + 1] cycloreversion of **113**, into the P–N single bonds of excess starting material (Scheme 31).[158]

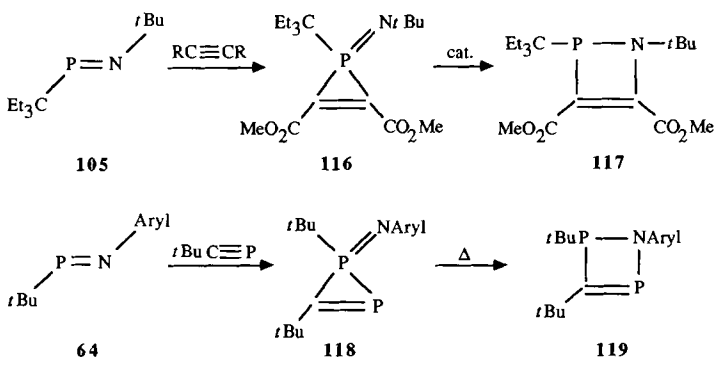


Scheme 31. R′ = $SiMe_3$.

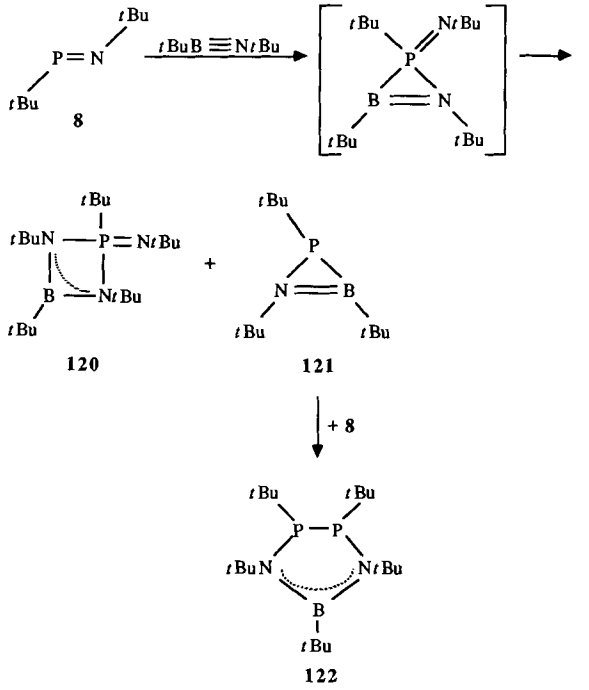
4.4. Cycloaddition Reactions

4.4.1. [2 + 1] Cycloadditions

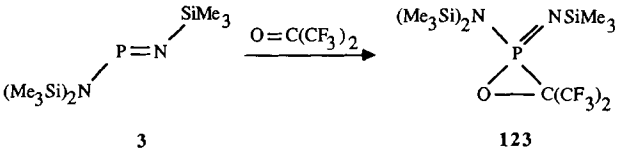
The *P*-alkylated or arylated iminophosphanes **64** and **105** react readily with activated alkynes or *tert*-butylphosphaalkyne via a [2 + 1] cycloaddition to give the corresponding λ^5-phosphirenes **116** or the λ^3, λ^5-diphosphirenes **118** respectively (Scheme 32); in the presence of Lewis acids (and in the case of **118** also on heating) these undergo a rearrangement similar to the ring expansion reaction of λ^3,λ^5-azadiphosphiridines to form the four-membered heterocycles **117** and **119** respectively.[44, 159, 160] A [2 + 1] cycloaddition leading to an azaphosphaboridine isoelectronic to **116** was postulated as the initial step of the reaction of **8** with the acetylene isostere *tert*-butyl(*tert*-butylimino)borane. However, the product cannot be detected and undergoes a spontaneous disproportionation to give the 1,3,2,4-diazadiphosphaboretidine **120** and the azaphosphaborirene **121**, which in turn reacts via the insertion of a further molecule of **8** to form the final product **122**.[161]



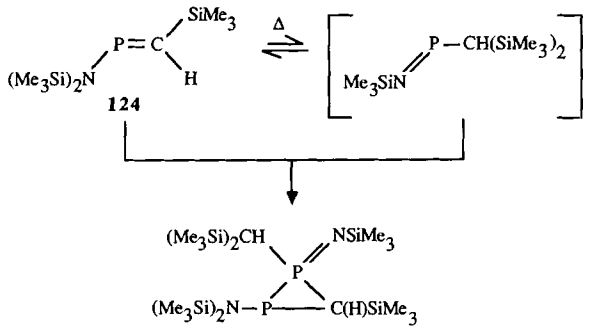
Scheme 32. [2 + 1] Cycloadditionen. R = CO_2Me, Aryl = tri-*tert*-butylphenyl.



The silyl-substituted aminoiminophosphane **3** reacts very readily with hexafluoroacetone via a [2 + 1] addition to give the 1,2λ^5-oxazaphosphirane **123**.[162] The unusual regioselectivity observed – reactions of aminoiminophosphanes with double-bond systems normally occur via a [2 + 2] cycloaddition (see Section 4.4.2) – can be understood in terms of the frontier orbital model if a crossover between the n(PN) and π(P=N) energy levels is assumed; such a crossover is predicted by quantum-mechanical calculations and confirmed by spectroscopic studies.[72, 87]



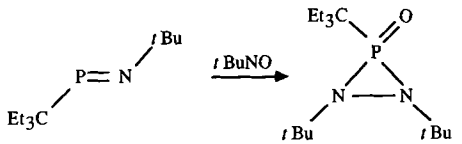
The formation of the λ^5,λ^3-iminodiphosphirane **125** in the thermolysis of from **124**[163] can also be explained on the basis of a [2 + 1] cycloaddition of an iminophosphane to the P=C double bond of excess starting material; the iminophosphane, the existence of which could not be detected, is formed from **124** via a [1,3] silyl shift. The λ^3,λ^3-azadiphosphiridines obtained in the reaction of aminoiminophosphanes with iPr_2NPCl_2 and magnesium can also formally be regarded as products of a [2 + 1] cycloaddition of a phosphanediyl at a P=N double bond; in this case the reaction mechanism is



124

125

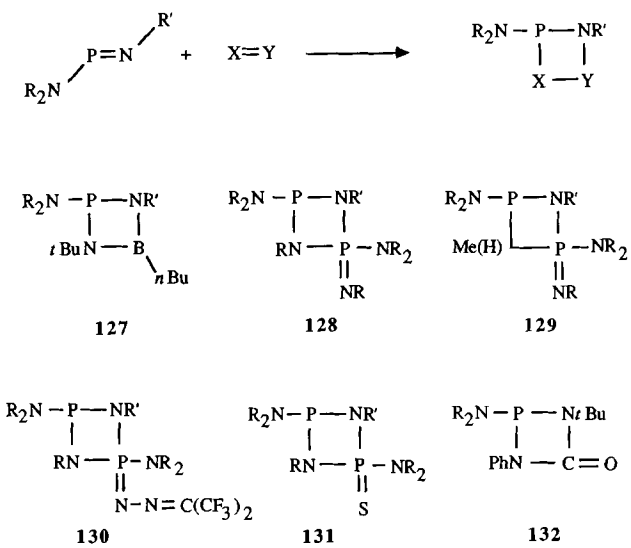
unknown.[170] The reaction between *t*BuNO and the iminophosphane **105** to give the diazaphosphinidine **126**[164] involves [2 + 1] cycloaddition with subsequent isomerization.



105 126

4.4.2. [2 + 2] Cycloadditions

Theoretical studies (see Section 3.1) have led to the predicition that reactions of aminoiminophosphanes with polar multiple bond systems should occur preferentially via [2 + 2] cycloaddition;[172] they should thus differ from reactions of *P*-alkyl- and *P*-aryl-substituted derivatives. The synthesis of a large number of four-membered heterocycles such as **127–129**, **132**, **133** was indeed possible by reacting **3** or **5a, c** with multiply-bonded systems such as butyl(*tert*-butylimino)borane,[165] phenyl isocyanate,[166] substituted λ^5-azaphospholes[167] or diylides $(Me_3Si)_2N$-P(=Z)=NSiMe$_3$, (Z = NSiMe$_3$, CHMe)[148, 168] (Scheme 33). In analogy, the formation of **130**, **131** and **134** was postulated to involve the trapping of unstable bis(imino)phosphorane, iminothiophosphorane or silandiylamine intermediates via a [2 + 2] cycloaddition with **3**,[169, 170] while [2 + 2] cycloaddition of the iminophosphane and an RBS unit has been suggested to be the key step in the synthesis of **135** from **3** (or **5a, c**) and trithiaborolanes[171] (Scheme 34).

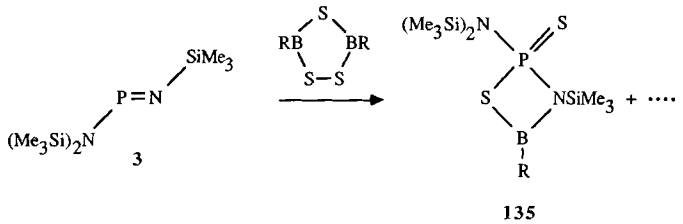


127 128 129

130 131 132

133 134

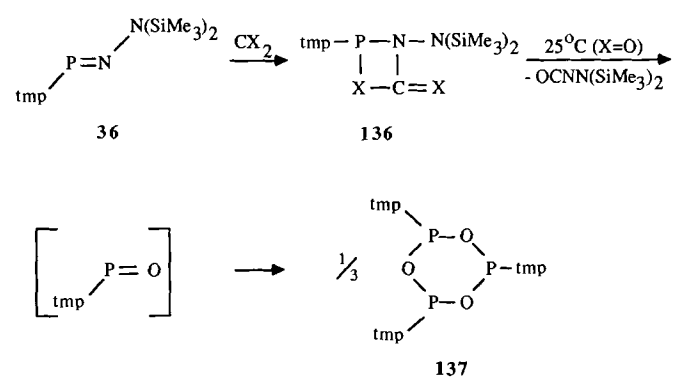
Scheme 33. R = SiMe$_3$, *i*Pr; R′ = SiMe$_3$, *t*Bu.



3 135

Scheme 34. R = Me, Et, Bu, Ph, Mes, Me$_2$N, Et$_2$N; the dots denote oligocondensates.

Fast [2 + 2] cycloaddition of the 2-phosphatetrazene **36** to CO_2 or CS_2 afforded the heterocycles **136a, b**, of which **136a** decomposes at room temperature to give the oxaphosphinane **137**.[28] The formation of the latter (and the generation of $(iPr_2NPO)_3$ from **5c** and SO_2[172]) has been suggested to involve a retroreaction of the original cycloadduct with the formation of an unstable oxophosphane, which then trimerizes (Scheme 35).



36 136 137

Scheme 35. X = O (**a**), S (**b**).

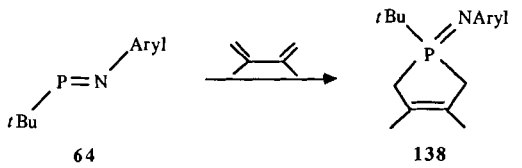
4.4.3. [2 + 3] Cycloadditions

The importance of this reaction type has already been referred to in the discussion of the reaction between iminophosphanes and alkyl azides or diazoalkanes (see Section 4.3).

4.4.4. [4 + 1] Cycloadditions

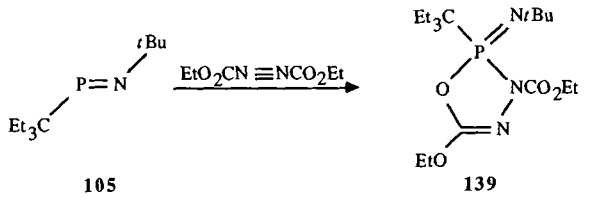
Whereas phosphaalkenes react cleanly with butadiene derivatives to give products formed in [4 + 2] cycloadditions

of the Diels-Alder type,[5] *P*-alkyl-*N*-aryl-substituted iminophosphanes react under comparable conditions via oxidative [4 + 1] cycloaddition with formation of dihydro-λ^5-phospholenes such as **138**[159, 173]; they react with 1,2-



64 **138**

diketones to give analogous dihydro-1,3,2-dioxaphospholes.[44, 162] The dihydrooxadiazaphosphole **139**, which results from the reaction of **105** with diethyl azodicarboxylate, can also formally be regarded as deriving from a [4 + 1]

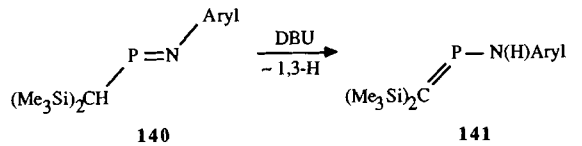


105 **139**

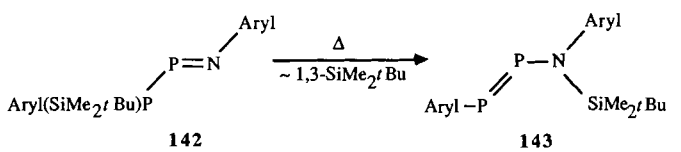
cycloaddition; however, a multistep reaction mechanism cannot be excluded with certainty in this case.[44]

4.5. Rearrangement Reactions

A 1,3 Shift of an α-hydrogen or of a trimethylsilyl group with the formation of a new phosphorus-element double bond was observed in the thermal or base-catalyzed isomerization of the iminophosphanes **140** and **142** to the phosphaalkene **141** and the diphosphene **143** respectively[36, 60].

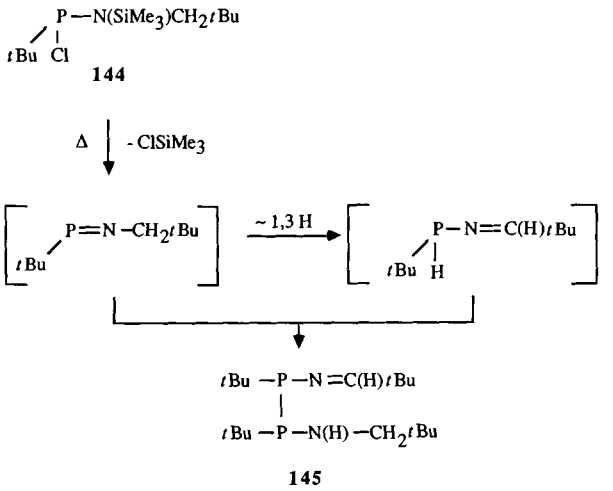


140 **141**

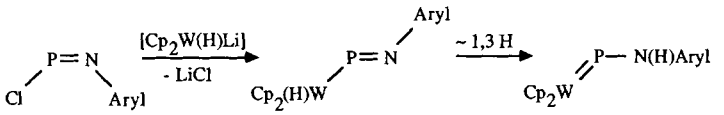


142 **143**

A rearrangement of this type has also been suggested to occur in the synthesis of aminophosphaalkenes and -diphosphenes via the reaction of suitable iminophosphanes with either alkyllithiums[174, 175] or trimethylsilyl-[176] and lithio(tri-*tert*-butylphenyl)phosphane[177] and for the formation of the diphosphane **145** in the thermolysis of **144**;[42] however, it was not possible to detect the corresponding



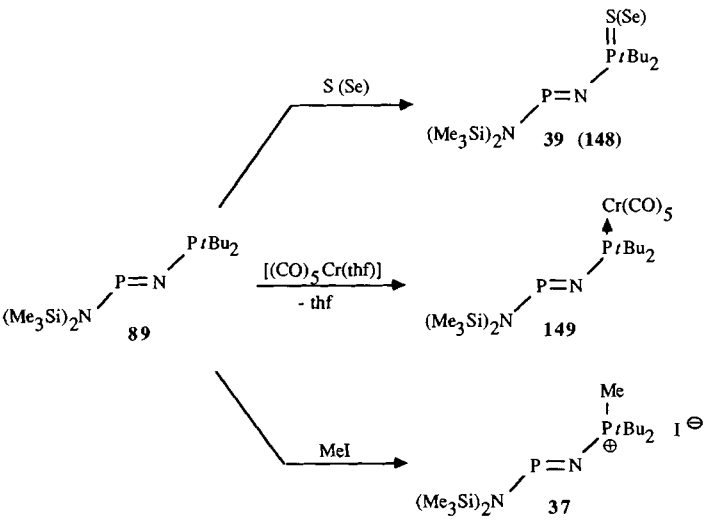
iminophosphane intermediates in these cases. The formation of the terminal phosphinidene complex **147** from **146** via a 1,3 hydrogen shift can be followed spectroscopically.[95]



10 **146** **147**

4.6. Reactions at Peripheral Groups

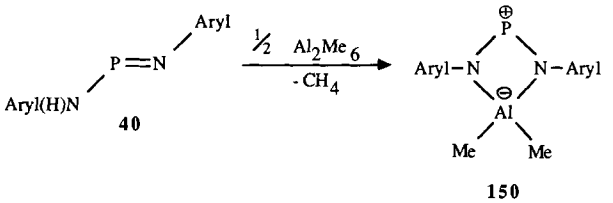
Although a number of iminophosphanes are known which contain further functional groups the extreme reactivity of the latter has so far prevented the discovery of many examples of reactions in which the former underwent transformations while the P=N double bond remained unchanged. Reactions of **89** with chalcogens (**38**, **148**) methyl iodide (**37**) and [$(CO)_5Cr(thf)$] lead to selective derivatization of the



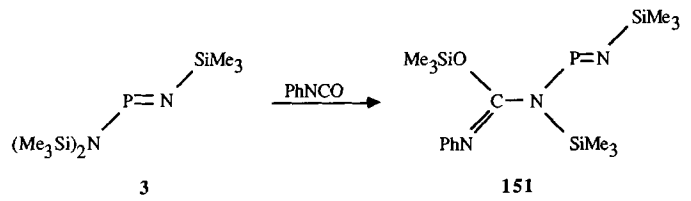
89

threefold coordinated phosphorus with retention of the iminophosphane structure; this indicates that the twofold coordinated phosphorus atom has a relatively low basicity in these cases[26, 142]. The NH-functionalized compound **40**

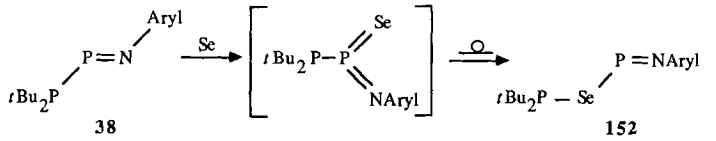
and Al_2Me_6 do not give the expected organometalation but rather a condensation product in which the low coordination number remains unchanged; the zwitterionic structure of the product **150** results from a nucleophilic attack of the imine nitrogen at aluminum.[178]



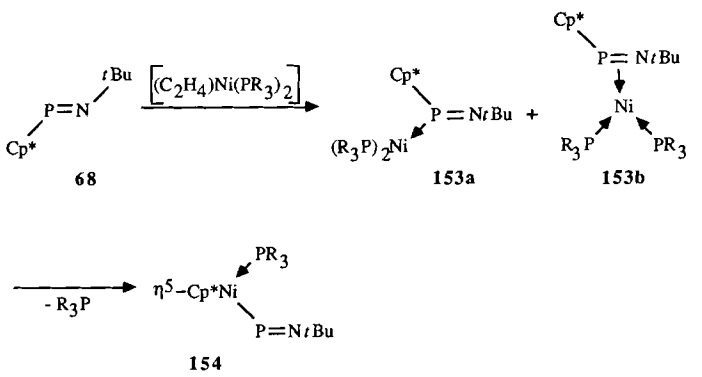
The formation of functionalized iminophosphanes such as **151** via insertion of phenyl isocyanate or tetrafluoropropyl cyanate into an Si–N bond of **3** occurs without formal participation of the double bond.[179, 180] However, a more exact



study of the reaction with phenyl isocyanate indicated the presence of a multi-step reaction in which the product is generated via an electrophilic addition of the substrate at the imine nitrogen followed by a 1,5 silyl shift.[166] Participation of the double bond has also been suggested for the selenation of **38**; the formation of the *P*-selenoiminophosphane **152** was explained on the basis of rearrangement of a selenoiminophosphorane intermediate arising from oxidative selenation.[106]



The reactions of **68** with nickel complexes of the type [(olefin)Ni(PR_3)$_2$] to give the metal-substituted derivatives **154** (Scheme 36) are related to nucleophilic substitution reactions. The detection of the intermediates **153a, b**, from which **154** is generated via a 1,2 shift of the cyclopentadienyl residue, also indicates that the double bond system is involved in the reaction. The analogous generation of a metalloiminophosphane and its subsequent [2 + 1] addition to excess starting material was formulated to explain the formation of a spirocyclic $\lambda^3\lambda^5$-azadiphosphiridine from Me_5C_5–P=N*t*Bu and $(MeCN)_3Mo(CO)_3$.[41]



Scheme 36. Bu (**a**), Et (**b**), Ph (**c**).

5. Future Prospects

The present survey shows that the chemistry of the iminophosphanes has undergone a very rapid development in the last few years; the mutual stimulation of theory and experiment has played an important role in making possible such rapid progress. In the initial phase the synthesis of aminoiminophosphanes and their transformation into (from the point of view of bonding theory) "unusual" compounds with $\sigma^3\lambda^5$-phosphorus formed the focus of interest; new applications in catalysis have very recently been reported for the latter.[182] Later studies dealt with "carbene-like" properties of the *P*-alkylated derivatives, which afforded routes to new types of phosphorus heterocycles. The recent synthesis of *P*-halogenated derivatives has made possible the preparation of a broad spectrum of functionalized iminophosphanes, including metalloiminophosphanes and a phosphanetriylammonium ion; the extreme bonding situation in the latter compounds is made clear by their in part extremely unusual crystal structures.

What can we expect in the future? Since the parent system (*E*)–HP=NH has so far resisted all attempts at its detection, one important goal is the generation of further small, highly reactive iminophosphanes and the study of their reactivity in the gas phase or in a matrix. New phospha-analogs of cumulene systems, such as diazo- and azido-compounds, are of both theoretical and synthetic interest. A further aspect which will certainly continue to be of great interest is the study of the coordination chemistry of known or still unknown phosphorus–nitrogen systems; the synthesis of phospha-analogs of pentadiazenes mentioned above (Section 2.2) has certainly provided an initial impulse in this direction. The generation of optically active iminophosphanes and products derived from them, and a study of their chemistry, would certainly be of great promise both from the synthetic point of view and as a tool for carrying out detailed mechanisitic studies.

While until now all attempts have been directed towards the study of monomeric products, the high reaction potential of the double bond of iminophosphanes suggests that the latter are capable of serving as useful precursors in polymer chemistry. In this respect it would be extremely attractive to verify the existence of a phosphandiylimide [RP=N]$^{\ominus}$; such a system could be used in the construction of poly-iminophosphanes $(PN)_xR_y$, and together with the known iminophosphane system RP=NR′ could also serve as a model compound for the study of ionic polymerization and the generation of "living polymers". The possible role of iminophosphanes as precursors for an as yet unknown $(PN)_x$ polymer or corresponding copolymers formed from

iminophosphane and phosphazene units also remains to be studied.

My grateful thanks go to all those co-workers whose enthusiastic collaboration has contributed to the advancement of this area of chemistry, from the initial phase to the present time; many of the most recent results can as yet only be found in doctoral theses, but the names of all involved can be found in the list of references. Thanks are also due to Prof. Dr. W. W. Schoeller (Bielefeld) for many intensive and fruitful discussions, and to Mrs. D. Purschke for her skilful and patient help in the preparation of this manuscript. Much of the work cited here was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie and the Minister für Wissenschaft und Forschung des Landes Nordrhein-Westfalen.

3-Amino-2*H*-Azirines. Synthons for α,α-Disubstituted α-Amino Acids in Heterocycle and Peptide Synthesis.

New Synthetic Methods (84)

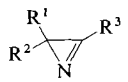
By Heinz Heimgartner*

The recent upswing in peptide chemistry has been accompanied by an increasing interest in nonproteinogenic amino acids. These include the α,α-disubstituted glycines, the best known of which is Aib (2-aminoisobutyric acid, 2-methylalanine). These α-amino acids occur in natural oligopeptides such as the peptaibols, a class of membrane-active ionophores that has been isolated from fungal cultures. The twofold substitution at the α-C atom of the amino acids severely restricts the conformational freedom of the peptides and causes particular secondary structures to be favored; thus, α,α-disubstituted α-amino acids induce the formation of β turns or helices. 3-Amino-2*H*-azirines are ideal synthons for the construction of oligopeptides, cyclic peptides and depsipeptides (peptolides) containing such α,α-disubstituted α-amino acids. The presence of the ring strain in these molecules means that they can be used in peptide coupling without the need for additional activating reagents. Using 3-amino-2*H*-azirines a large array of heterocycles containing α,α-disubstituted α-amino acids as structural elements within their skeleton can be synthesized. The driving force in these reactions is the release of the strain on the three-membered ring, which usually takes place in a ring-expansion reaction. The mechanistic elucidation of these reactions, which can be quite complex, contains some surprises.

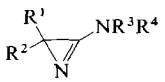
1. Introduction

Molecules with strained, three-membered rings have been arousing the interest of chemists for more than 100 years. At first it was denied that such organic compounds could exist at all,[1] but in 1885 *A. von Baeyer* presented the first theoretical basis for their consideration, with his strain theory.[2] The prediction that three- and four-membered rings would be unstable compounds, and difficult to prepare, proved extremely stimulating for both theoretical and preparative organic chemistry.[3] Today the exclusion of three-membered carbo- and heterocycles from the arsenal of the organic chemist is inconceivable.[4, 5]

One well-studied class of unsaturated, three-membered heterocycles that has found synthetic application comprises the 2*H*-azirines (**1**), whose synthesis and reactivity have been the object of numerous investigations in the past twenty years (cf. [6, 7]). In the course of these studies it has been shown that numerous nitrogen-containing heterocycles can be synthesized using **1**, both by thermal,[8-11] and by photo-



1



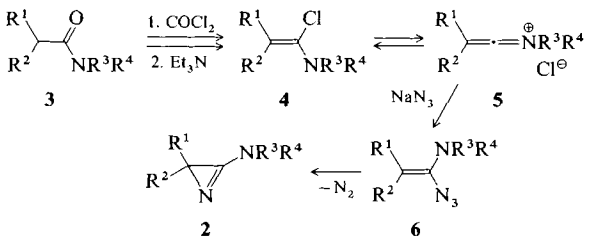
2

chemical[12-16] and metal-catalyzed processes.[17, 18] Remarkably, in different types of reaction, 2*H*-azirines can react by cleavage of the N(1)–C(2), N(1)–C(3), or C(2)–C(3) bonds (for typical examples see [19–21]).

In contrast to the 2*H*-azirines **1**, which are cyclic imines, the 3-amino-2*H*-azirines **2** are cyclic, three-membered amidines with a C–N double bond in an endocyclic position. The first examples of this class of compounds were described by *Rens* and *Ghosez* in 1970.[22] The presence of a nucleophilic amidine group that is at the same time part of the strained azirine structure (with an estimated ring strain of 200 kJ mol^{-1} [23]) is responsible for the varied reactivity of these heterocycles.[25] Since 3-amino-2*H*-azirines are easily accessible via the reactions described below, they are very valuable starting materials for organic synthesis.

2. Synthesis and Structure of 3-Amino-2*H*-Azirines

The most general synthesis is based on the procedure of *Rens* and *Ghosez*[22] already mentioned (Scheme 1). *N,N*-Disubstituted carboxylic amides (**3**) are treated with phosgene, followed by base-catalyzed HCl elimination to yield α-chloroenamines (**4**). These react with sodium azide via



Scheme 1.

keteniminium salts (**5**) to give α-azidoenamines (**6**), which eliminate N_2 in situ to afford **2**.[26] The [1-^{15}N]-labeled azirine **2a*** (R^1–R^4 = Me) used for mechanistic studies was also synthesized in this manner,[27] using sodium [1-^{15}N]azide. In the case of 2,2-dialkyl-3-(dimethylamino)-2*H*-azirines (**2**; R^1, R^2 = alkyl; R^3, R^4 = Me), reaction with phosgene in dichloromethane and with sodium azide in ether

[*] Prof. Dr. H. Heimgartner
Organisch-chemisches Institut der Universität
Winterthurerstrasse 190, CH-8057 Zürich (Switzerland)

or dimethylformamide leads to azirines in yields of ca. 70%. However for slower reacting amides (**3**, R^1 and/or R^3 = aryl), modified conditions are required. For example, if ca. 5% dimethylformamide is added to the reaction with phosgene, the chloroenamine **4** is formed spontaneously.[28,29] A second possibility is provided by a route via the corresponding thioamide,[30,31] where HCl elimination occurs even without addition of base. A slightly modified route has also been used to synthesize C(2)-monosubstituted 3-amino-2*H*-azirines[26,32] (Table 1, **2v–y**). In several cases, reaction of the chloroenamine with sodium azide led to isolable 5-amino-4*H*-1,2,3-triazoles, which could then be transformed into the 3-amino-2*H*-azirines by photochemical N_2 elimination.[33]

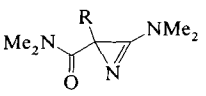
Other approaches lead to 3-amino-2*H*-azirines **2za–2zd**,[42–45] though these are far less general. The azirines synthesized by these routes contain substituents that are incompatible with the *Ghosez* synthesis.[26] The reaction sequence leading to azirines of type **2zc**[44] is remarkable, because the otherwise short-lived α-azidoenamines are isolable. Compounds **2zd**,[45] which are obtained via a Neber rearrangement, are distinguished by the presence of an unsubstituted amino group on C(3). Hardly any reactions have yet been carried out with azirines **2za–2zd**.



2za (R = H, Et, PhO, Cl[42a])

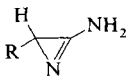
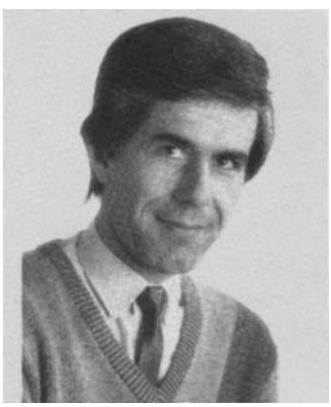
2zc [44]



2zd (R = $PhSO_2$, $C_6H_2Cl_3$-NHCO[45])

The 3-amino-2*H*-azirines **2** are generally stable liquids or solids which may be kept for years at 0 °C if moisture and acids are excluded. The vinyl-substituted compounds **2f** and **2g** are exceptions, as they decompose slowly even at 0 °C. Suitable reaction solvents are ether, tetrahydrofuran (THF), dichloromethane, acetonitrile, and dimethylformamide (DMF), i.e. polar aprotic solvents, but also, for example, toluene and 2-propanol.

The structure of the 3-amino-2*H*-azirines has been determined by X-ray crystallography (Table 2). All of them display, besides a relatively short C(2)–C(3) single bond and a long N(1)–C(2) single bond, a lengthened N(1)–C(3) double bond and a shortened C(3)–N(4) single bond. This demonstrates a pronounced delocalization of the N(4) electron pair



Heinz Heimgartner was born in Münsterlingen, Switzerland in 1941. He completed his doctorate in chemistry at Zürich University in 1972 under Professor Hans Schmid, with distinction for his dissertation on the photochemical and thermal aromatic sigmatropic rearrangements in hydrocarbons. While working on his "habilitation" in the position of chief assistant in 1976, he took over the responsibility for the research groups, "Reaction mechanisms" and "Photochemistry", on the death of Professor Schmid. In 1978 he received the award of the Swiss Chemical Society and the Werner medal for research into the chemistry of the aminoazirines and their application in organic synthesis. Since his habilitation in 1980 he leads his own research group. His particular fields of activity are heterocyclic chemistry, the chemistry of small rings, reaction mechanisms, organic photochemistry and peptide chemistry. In 1987 he become a titular professor.

into the π-system of the C–N double bond[42b, 46–48] (for comparison see [49]). Figure 1 shows the structure of **2ag** in the crystal.

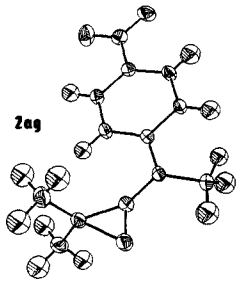

Fig. 1. Structure of 2,2-dimethyl-3-[*N*-methyl-*N*-(4-nitrophenyl)amino]-2*H*-azirin, **2ag**, in the crystal.

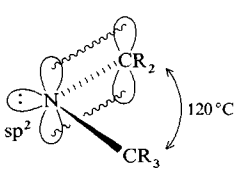
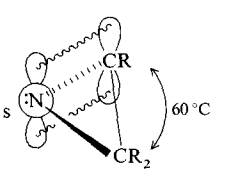
As in most amidines, the N(1) atom is the most nucleophilic and presumably also the most basic center in 3-amino-2*H*-azirines (**2**).[50] However, the basicity of **2a** (R^1–R^4 = methyl, $pK_b = 7.1$[54]) is significantly less than that of the comparable *N,N,N'*-trimethylisobutyramidine (pK_b = 3.0[54]).[55] The reduced basicity of 2*H*-azirines compared with noncyclic amidines or imines can be explained by a model with variable hybridization at the N atom. Open-chain (C=N)-containing compounds display sp^2 hybridization and have interorbital angles of ca. 120°, but in the three-membered rings a nonhybridized N atom with interorbital angles of ca. 90° is energetically more favorable. The free pair of electrons is therefore localized in an sp^2 orbital (**7**) in the first case, and in an s orbital (**8**) in the second.



7



8

The effects of ring strain in 3-amino-2*H*-azirines (**2**) can be seen in the IR, ^{13}C NMR and ^{15}N NMR spectra. The ν(C=N) vibrational absorption in chloroform lies in the 1760–1805 cm^{-1} region; nonstrained amidines absorb at 1590–1680 cm^{-1}.[57] In the ^{13}C NMR spectrum (in $CDCl_3$), the signals for C(2) and C(3) of 3-(dimethylamino)-2,2-dimethyl-2*H*-azirine (**2a**) appear at δ = 39.8 and 168.1, while the corresponding signals in 3,6-bis(dimethylamino)-2,2,5,5-tetramethyl-2,5-dihydropyrazine are found at δ = 54.5 and 162.6, respectively.[58] The ^{15}N NMR spectrum (in $CDCl_3$) of **2a** shows absorptions for N(1) and Me_2N at δ = – 179.7 and – 326.4, respectively ($\delta(CH_3NO_2) = 0$);[27] in comparable amidines without ring strain, the N atoms display shifts of δ ≈ – 155 and ≈ – 312, respectively.[27, 59]

3. Reactions of 3-Amino-2*H*-Azirines

Practically all of the reactions of 3-amino-2*H*-azirines (**2**) known today proceed by opening of the three-membered ring. The only exceptions are reactions with palladium complexes[52] or with transition metal halides,[53] which lead to complexes of the type $(azirine)_2MX_2$ (e.g. **9**, **10**, Fig. 2) and reactions with trimethylsilyltriflate or trityltetrafluoroborate.[51] The latter yield aziridinium salts, which react with nucleophiles to give 2-aminoaziridines or further open-chain products.

10

It is especially interesting that—as for 3-phenyl-2*H*-azirines—in reactions that proceed via ring opening, each bond of the three-membered ring may be selectively cleaved, depending on the reaction conditions.[25, 60, 61] Reactive intermediates, which may be used in the construction of new *N*-heterocycles, are formed in the process (Scheme 2).

3.1. Reactions with Cleavage of the C(2)–C(3) Bond

Irradiation of 3-(*N*-methyl-*N*-phenylamino)-2*H*-azirines (**2**, R^3 = Me, R^4 = Ph) in dimethoxyethane with UV light (λ = 254 nm), in the presence of dipolarophiles, affords five-membered heterocycles such as **11** (Scheme 3).[30] Here it is clear that the C–C bond of the azirine ring has been broken.

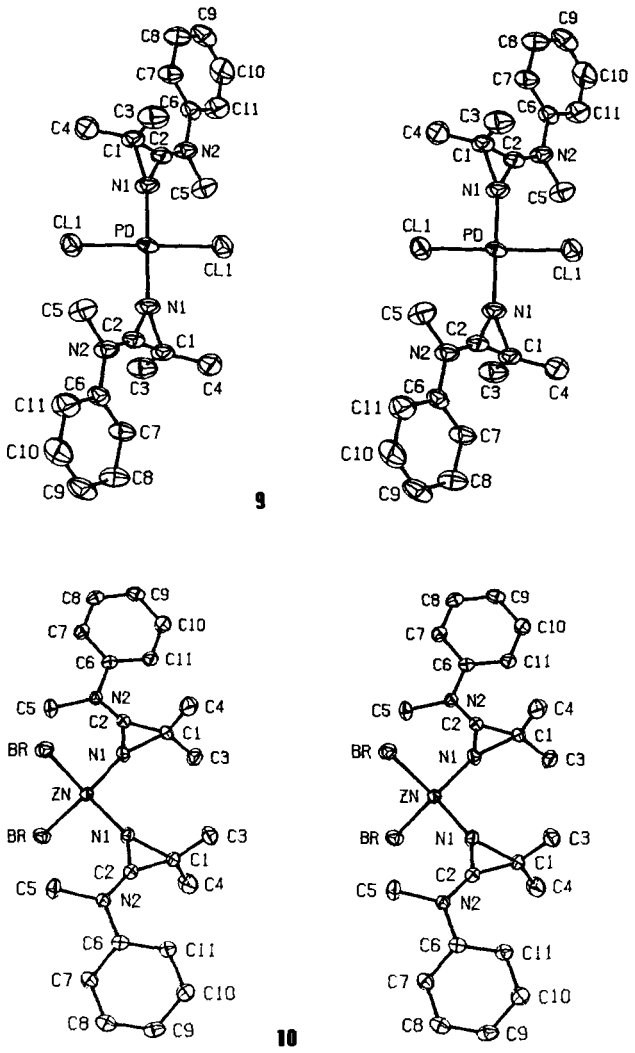

Fig. 2. Stereodrawings of the crystal structures of azirine-metal complexes **9** and **10**.

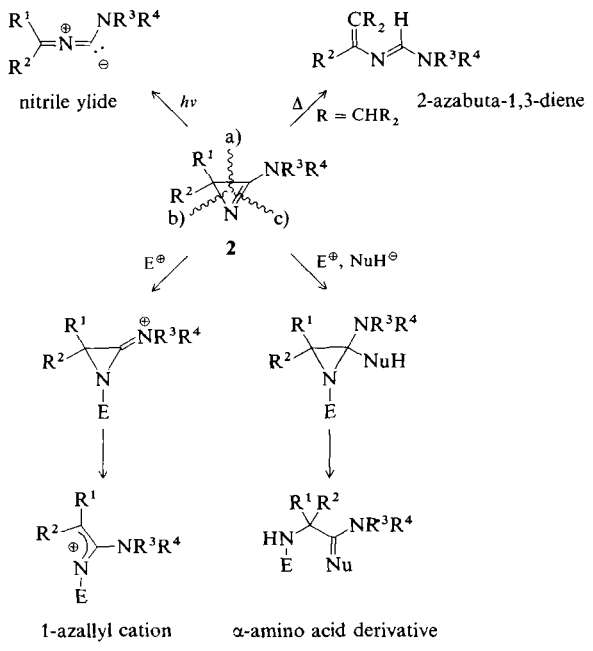
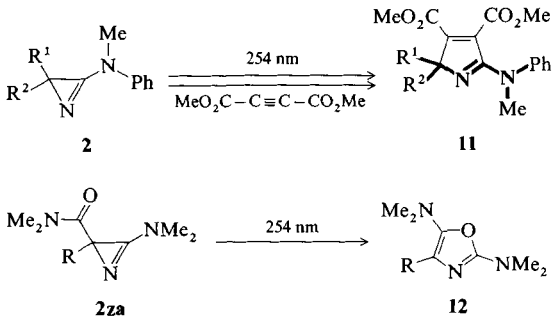


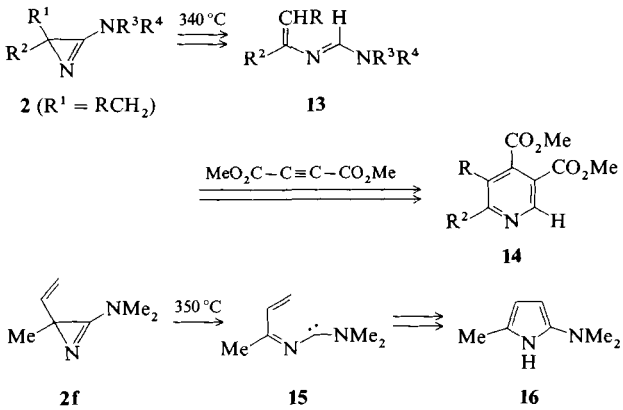
Scheme 2.

This ring-opening mode has been studied in detail for the photolysis of 3-phenyl-2*H*-azirines,[116] and takes place via a 1,3-dipolar intermediate, a nitrile ylide. Since 3-amino-2*H*-azirines (**2**) absorb at shorter wavelengths than the corresponding 3-phenyl-2*H*-azirines, their excitation requires short-wave UV light and their photolysis is therefore of less preparative importance. The photochemical isomerization of azirine **2za** to the 1,3-oxazole **12** also proceeds via cleavage of the C–C bond (Scheme 3).[62a] Analogous thermal oxazole-forming reactions have been described only recently.[62b]



Scheme 3.

The C(2)–C(3) bond of 3-amino-2*H*-azirines can also be cleaved by pyrolysis at 340–400 °C.[30,63] The 2-azabuta-1,3-dienes of type **13** that are formed are useful heterodienes, which can, for instance, be utilized in the synthesis of pyridines (**14**) via *Diels–Alder* reactions (Scheme 4). Ring-expansion of **2f** to pyrrole **16**, observed on thermolysis, also occurs by breakage of the C–C bond.[37] A carbene of type **15** is a likely intermediate, as in the formation of **13**.

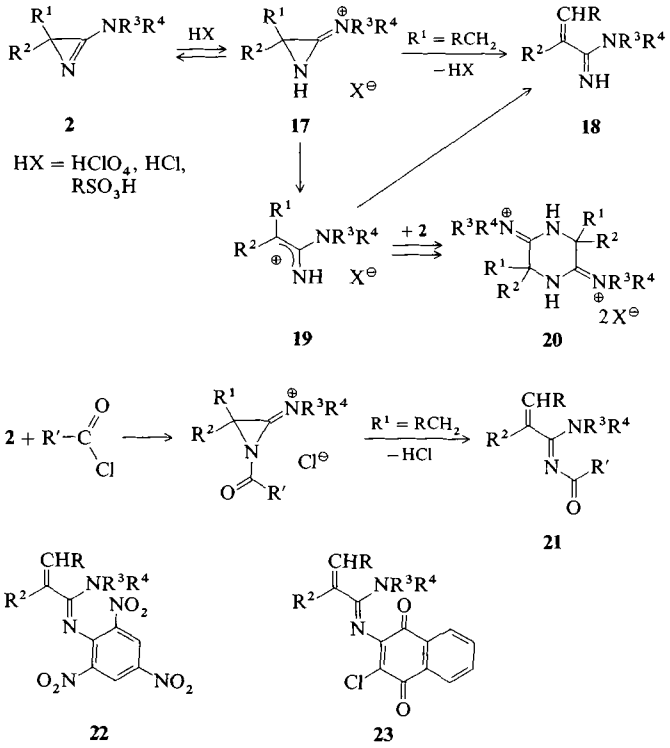


Scheme 4.

3.2. Reactions with Cleavage of the N(1)–C(2) Bond

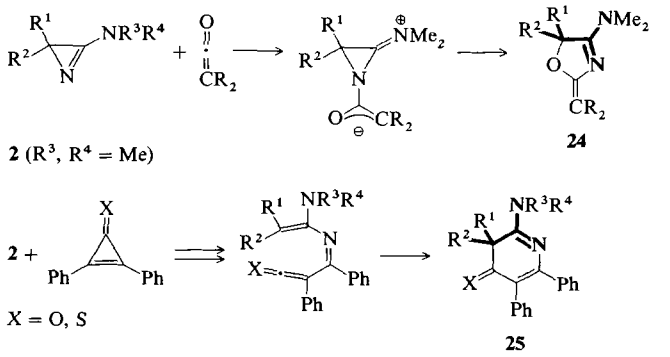
Once again, analogously to the chemistry of the 3-phenyl- and 3-alkylsubstituted 2*H*-azirines, the 3-amino-2*H*-azirines **2** undergo a ring-opening reaction with very strong protic acids such as $HClO_4$, HCl, RSO_3H, under non-nucleophilic conditions. Here the N–C single bond is broken, and the major products isolated are acrylamidines (**18**) and pi-

perazine-2,5-bis(*N*,*N*-dialkyliminium) salts (**20**) (Scheme 5).[22, 54, 64] An azallyl cation of type **19** probably occurs as an intermediate, by ring-opening of **17**. Reaction of **2** with carboxylic acid chlorides,[65, 66] chloroarenes or chloroquinones[67] also leads to acrylamidines of types **21**, **22** and **23** respectively.



Scheme 5.

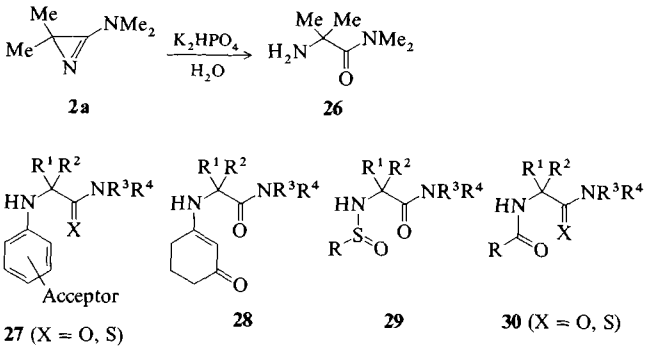
The reactions of **2** with electrophiles, leading to new heterocycles, are of special interest. Only two of the known examples will be mentioned here: 2,2-dialkyl-3-(dimethylamino)-2*H*-azirines (**2**; R^1, R^2 = alkyl; R^3, R^4 = Me) react with ketenes to yield 2,5-dihydro-4-(dimethylamino)-2,3-oxazoles **24**,[68, 69] and with cyclopropenones or cyclopropenethiones to afford good yields of the corresponding pyridin-4(3*H*)-one or -thione **25** (Scheme 6).[70]



Scheme 6.

3.3. Reactions with Cleavage of the N(1)–C(3) Bond

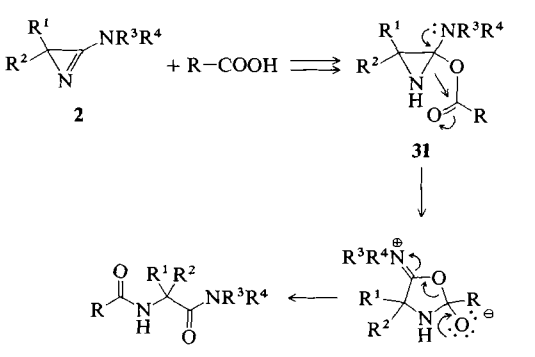
Cleavage of the N–C double bond of 3-amino-2*H*-azirines (**2**) occurs, for example, on hydrolysis with potassium hydrogen phosphate in water,[54] and leads to an amide of an α,α-disubstituted α-amino acid (e.g. **26**, Scheme 7), as for all examples of this type. Products **27**–**30** are formed on reaction of **2** with activated phenols or thiophenols,[71] with cyclic, enolizable 1,3-diketones,[72] with sulfinic acids,[64] and with carboxylic[72] and thiocarboxylic acids[38, 73] respectively. All of these reactions proceed smoothly, generally even at temperatures around 0 °C.



Scheme 7.

Variation of the substrate in reactions with phenols and 1,3-dicarbonyl compounds demonstrated that the initial step in all these reactions is an activation of the 3-amino-2*H*-azirine **2** by protonation, since for substrates with $pK_a > 8$, the reaction no longer occurs. On the other hand, if the reagent is a very strong acid (e.g. HCl, RSO_3H), the N(1)–C(2) bond is cleaved (see Section 3.2). This is explained by the absence of a good nucleophile capable of trapping the iminium aziridine arising from the protonation step before ring-opening takes place.

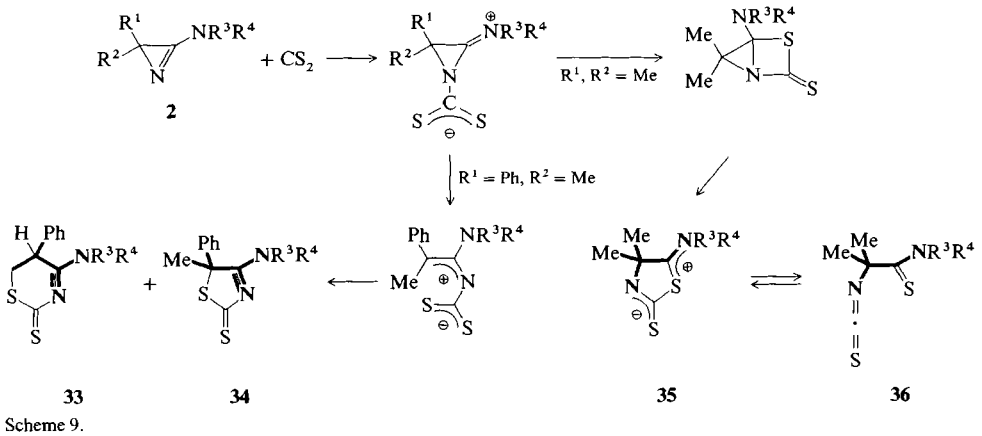
From these considerations, the following mechanism for the production of diamides **30** in the reaction with carboxylic acids may be proposed (Scheme 8): The aziridine intermediate **31** is formed by protonation of the ring-N atom and nucleophilic carboxylate addition. This then undergoes intramolecular nucleophilic attack by the aziridine-N atom on the carboxyl group, and a ring-expansion to zwitterion **32**. Ring-opening, with concomitant formation of two amide



Scheme 8.

groups, leads to the product **30**. The driving force behind the reaction is the ring strain of **2** on the one hand, and the formation of a diamide on the other.

N(1)–C(3) ring openings of **2** are also frequently observed in reactions with NH-acidic compounds[74] and with heterocumulenes such as carbon disulfide,[75–77] isocyanates,[69, 78, 79] isothiocyanates,[78, 80, 81] and ketenimines.[82] Whereas with ketenes the N(1)–C(2) cleavage is the only reaction observed, (as mentioned above), with the other heterocumulenes the mode of ring-opening also depends on the nature of the C(2)-substituent on **2** (e.g., products **33** and **34**, or **35** and **36** are formed with CS_2, depending on the substituent; Scheme 9). A phenyl group at C(2) promotes cleavage of the N(1)–C(2) bond.



33 **34** **35** **36**

Scheme 9.

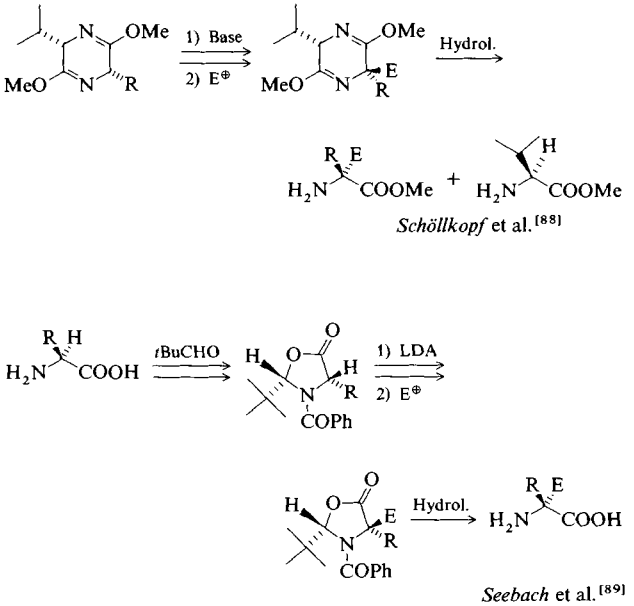
In summary, it can be said that on reaction of **2** with moderately strong protic acids ($pK_a \approx 3$–8) and with various heterocumulenes, the C–N double bond is cleaved to afford derivatives of α,α-disubstituted α-amino acids. 3-amino-2*H*-azirines can therefore clearly be regarded as synthetic equivalents of α,α-disubstituted α-amino acids.

4. Occurrence and Importance of α,α-Disubstituted α-Amino Acids

α,α-Disubstituted α-amino acids belong to the group of nonproteinogenic peptide components. As early as 1872, *Urech* synthesized the first member of this class, 2-methylalanine (2-aminoisobutyric acid, Aib), by hydrolysis of 5,5-dimethylhydantoin.[83] Later, *Tiemann* et al. made use of the Strecker synthesis to prepare various α-alkylated α-amino acids, including unsymmetrically-substituted (racemic) examples.[84] The first optically active α,α-disubstituted α-amino acid, (−)-(*R*)-2-ethylalanine (D-isovaline, D-Iva), was obtained by *Ehrlich* and *Wendel* in 1908, by means of microbiological racemate resolution.[85] This method was later replaced by other means of enantiomer separation (mainly by crystallization[86] and chromatographic methods[87]). Today, various enantioselective syntheses of α,α-disubstituted α-amino acids are known, such as the "bislactim ether method" of *Schöllkopf* et al.,[88] the "self-reproduction of the chiral center" of *Seebach* et al.[89] (Scheme 10), enzymatic[90] and other procedures.[91]

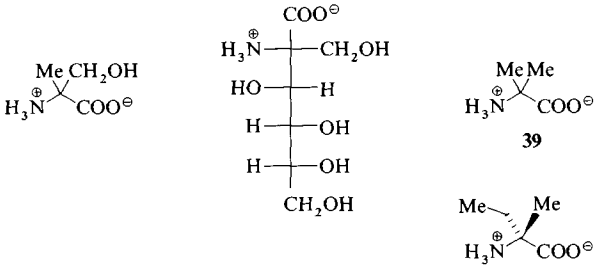
The continuing search for new synthetic methods to prepare α,α-disubstituted α-amino acids (see, for example, [92]) demonstrates the current interest in these compounds, due above all to their proven or potential biological activity. In particular, α-methyl α-amino acids and their derivatives can act as inhibitors of enzymes that metabolize the corresponding proteinogenic amino acids.[93] Some well-known examples include 2-methyl-3(3,4-dihydroxyphenyl)alanine (2-methyl dopa; antihypertensive activity by inhibition of dopa-carboxylase[94]), 2-methylaspartic acid (inhibits the corresponding transaminase[95]), and 2-ethylphenylalanine (bacteriostatic activity[96]).

In Nature one finds primarily 2-methylalanine (**39**, Aib)[99] and D-2-ethylalanine (**40**, D-Iva),[100] but various branched serine derivatives such as α-methylserine (**37**, in the antibiotic Amicetin)[97] or 2-amino-2-deoxy-2-hydroxymethyl-D-mannonic acid (**38**, a synthetic intermediate for the



Scheme 10. LDA = lithium diisopropylamide.

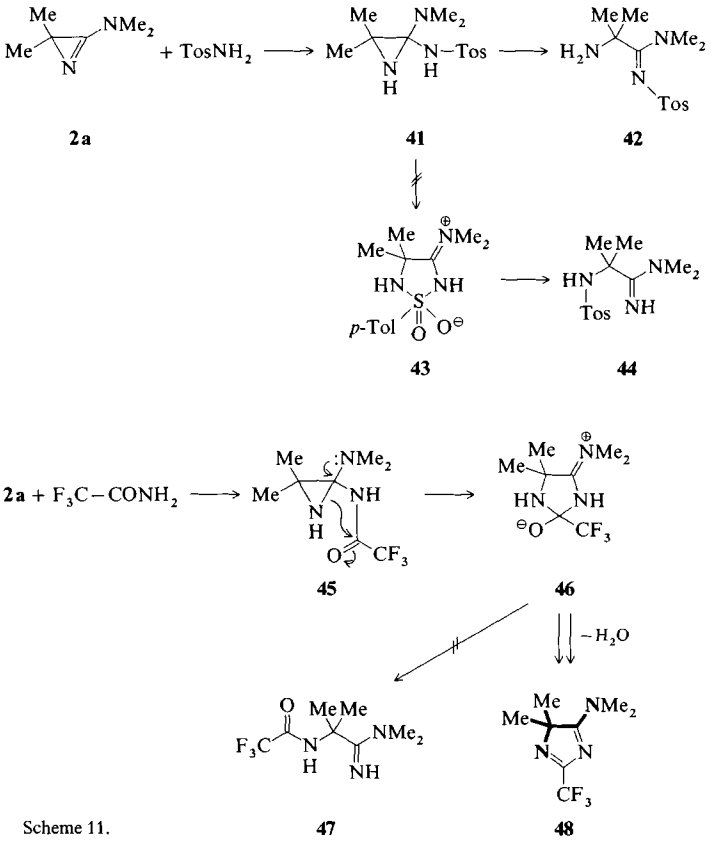
antibiotic Thermozymocidin)[98] also occur. Aib and D-Iva make up a high proportion (up to 50%) of natural polypeptide antibiotics and amphiphilic ionophores, the so-called peptaibols.[101, 102]



37 38 39 40

Since Aib is not incorporated into proteins, it has been used as a model substance in studies of amino acid transport.[103] However, α-methyl α-amino acids are also employed in modification of peptide hormone sequences, in order to make these more resistant to enzymatic degradation,[104] to stabilize preferred conformations of the peptide backbone,[105–107] or in studies of the factors affecting the biological activity of a peptide (e.g. [116–118]). Because of conformational restrictions, incorporation of α,α-disubstituted α-amino acids into a peptide chain leads to an increase in the helix content,[99b, 119] or the formation of specific β turns,[120–122] and is therefore useful in the synthesis of oligopeptide segments with stable secondary structures.[112] For example, the solubility of hydrophobic peptides in polar solvents can be increased.[99b, 119] As the peptaibols demonstrate, these peptides are also capable of modifying the ion permeability of membranes (see e.g. [102]). In studies of structure-activity relationships, too, the reduced flexibility of the peptide backbone facilitates the search for the "active conformation" recognized by a physiological receptor.[123]

In the equivalent reaction of **2a** with trifluoroacetamide, however, the 4*H*-imidazole **48** is formed even at 0 °C, in 80% yield (Scheme 11, bottom).[124] In this case, intramolecular attack of the aziridine-N atom of **45** on the trifluoroacetamide group obviously takes place, giving rise to zwitterion **46**, which can generate **48** by H_2O elimination. However, the ring-opening analogous to the reactions with carboxylic acids, from **46** to the amide-amidine **47** (cf. Scheme 8), was not observed.



Scheme 11.

5. Synthesis of Heterocycles by Ring-Expansions of 3-Amino-2*H*-Azirines

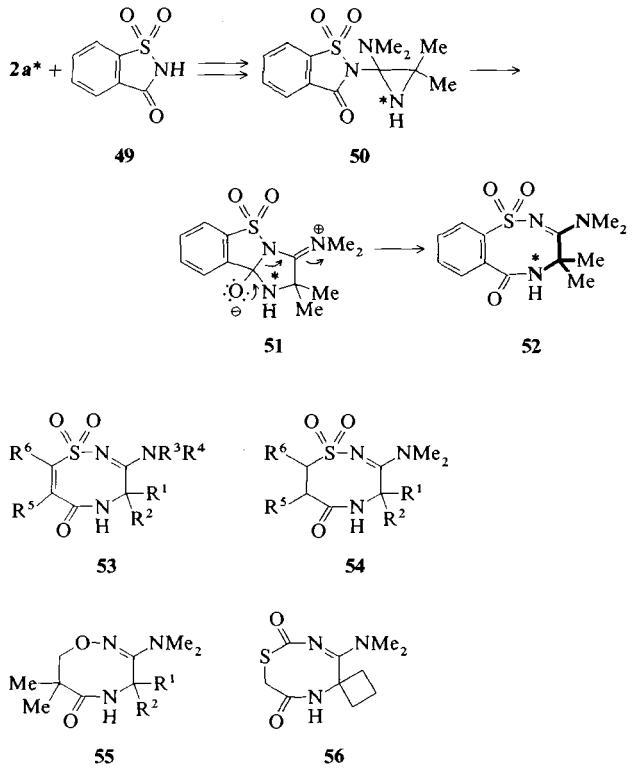
5.1. Reactions of 3-Amino-2*H*-Azirines with NH-Acidic Heterocycles

As mentioned in Section 3.3, 3-amino-2*H*-azirines react not only with OH-acids, but also with NH-acidic compounds, with cleavage of the N(1)–C(3) bond (see review [74]). For instance, if a 1:1 mixture of 4-toluene-sulfonamide and 3-(dimethylamino)-2,2-dimethyl-2*H*-azirine (**2a**) is heated at reflux in 2-propanol, a single 1:1 adduct **42**[124] is isolated in ca. 60% yield. This adduct is thought to be formed via the aziridine **41** (Scheme 11, top). Remarkably, no products arising from nucleophilic attack on the sulfonamide group are observed.[125] In particular, one does not find **44**, which might be formed in a reaction analogous to that with carboxylic acids, via **43**. Nucleophilic attack on the S atom by the aziridine-N atom of **41** clearly cannot compete with the ring-opening.

5.1.1. Ring Expansions to Seven- to Nine-Membered Heterocycles

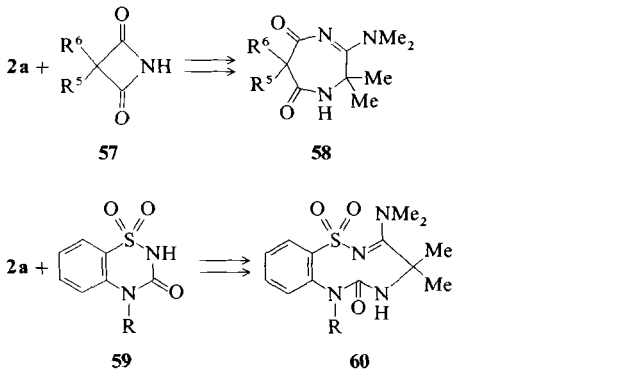
The results described above demonstrate that although a sulfonamide reacts with **2** to give aziridines of type **41**, ring-expansion to a zwitterion of type **46** can only occur with neighboring carbonyl groups. The combination of these two groups in the same molecule, e.g. in saccharin, (1,2-benzoisothiazol-3(2*H*)-one-1,1-dioxide, **49**) makes possible an interesting ring-expansion to 4,5-dihydro-1,2,5-benzothiadiazocin-6-one-1,1-dioxide **52** (Scheme 12).[126] The reaction mechanism, via aziridine **50** and ring-expansion to zwitterion **51** and to the product, corresponds to that formulated in Scheme 8 for the reaction with carboxylic acids. The key step in the reaction is the cleavage of the central C–N bond in **51**. Using [1-^{15}N]-labeled **2a*** it has been proved that N(5) of **52** derives from the azirine,[27] and that the latter is therefore built into the ring as an α-amino acid unit.

The same reaction sequence has been realized with a series of isothiazol-3(2*H*)-one- and isothiazolidin-3-one-1,1-diox-



Scheme 12.

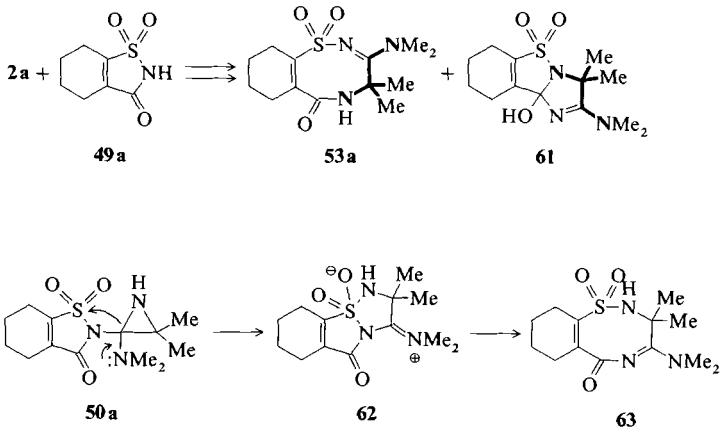
ides,[127] with 4,4-dimethylisoxazolidin-3-one,[128] and with 1,3-thiazolidine-2,4-dione,[31, 129] yielding the eight-membered heterocycles **53**–**56** in generally good yields. In selected cases the seven-membered and nine-membered heterocycles are also obtainable. For example, malonimides **57** afford 1,4-diazepine-5,7-dione derivatives **58**[130] and the 2*H*-1,2,4-benzothiadiazin-3(4*H*)-one-1,1-dioxides **59** give 4,5-dihydro-1,2,5,7-benzothiatriazonine-6(7*H*)-1,1-dioxides **60**,[59, 131] as shown in Scheme 13. Except for the seven-



Scheme 13.

membered **58**, the structures of these ring-expansion products are all distinguished by the presence of a *trans*-amide group in the ring.

The reaction of **2a** with **49a** needs special mention. This reaction produces 88% of **53a**, as well as ca. 1% of the isomeric compound **61** (Scheme 14).[127] The crystal structures of this byproduct and **53a** are shown in Figure 3. Compound **61** presumably arises via zwitterion **62**, which is formed by nucleophilic attack of the aziridine-N atom of **50a** on the sulfone group. Ring-expansion to **63**, followed by transannular ring closure, leads to **61**. The occurrence of this



Scheme 14.

byproduct shows that although nucleophilic attack on the SO_2 group is much less efficient than attack on the CO group, it is not impossible. A corresponding nucleophilic attack of azirine **2a** is also observed in the smooth reaction with 4-toluenesulfonic acid chloride, yielding N^1,N^1-dimethyl-N^2-(4-toluenesulfonyl)methacrylamidine,[65] analogously to reactions with carboxylic acid chlorides (Scheme 5).

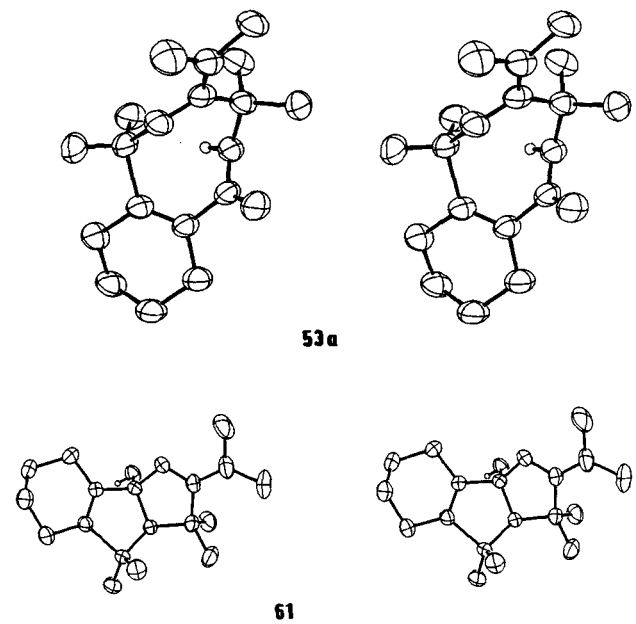


Fig. 3. Stereodrawings of the crystal structures of **53a** (top) and **61** (bottom).

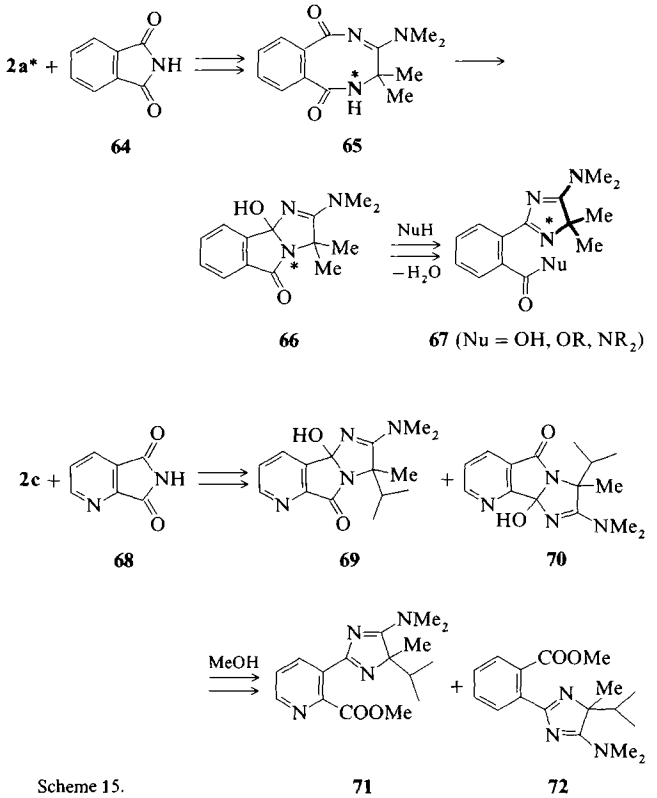
Several reactions of 3-amino-2*H*-azirines (**2**) with NH-acidic heterocycles lead to products which can be explained by a ring-expansion followed by a transannular ring-closure. Thus, for example, a 1:1 adduct is formed from **2a** and

phthalimide in acetonitrile or chloroform at room temperature. On the basis of spectral data, this adduct is assigned the structure 2,3-dihydro-2,5-benzodiazocine-1,6-dione **65** (Scheme 15).[126] Purification of the rather unstable crude product by recrystallization from DMF leads to the tricyclic azacyclol **66**, whose structure has been proven by X-ray crystallography.[132] The same product is obtained directly when the reaction of **2a** and phthalimide is carried out in DMF as solvent.

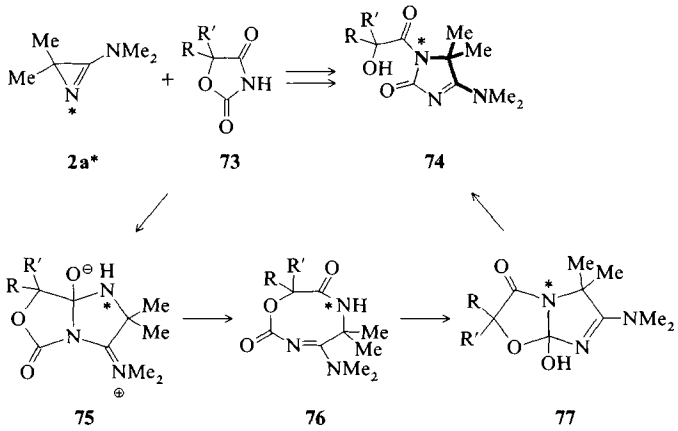


Scheme 15.

This reaction also proceeds via cleavage of the N(1)–C(3) bond of **2**, as is clear from the position of the label after reaction of [1-^{15}N]-labeled **2a***. In azacyclol **66**, only N(4) is labeled (^{15}N NMR).[27] Treatment of **65** or **66** with nucleophilic solvents such as water, alcohols or amines affords 2-(4*H*-imidazol-2-yl)benzoic acid derivatives of type **67**, in good yields. These products are of interest because they are structurally closely related to potent herbicides.[133] The major product isolated from the reaction of 3-(dimethylamino)-2-isopropyl-2-methyl-2*H*-azirine (**2c**) and pyridine-2,3-dicarboxylic acid imide (**68**), after methanolysis, is **72**,[134] which differs from the most biologically active derivative really only in an amidine instead of the corresponding five-membered lactam function. Unfortunately, the hydrolysis to the lactam has not yet been satisfactorily achieved.

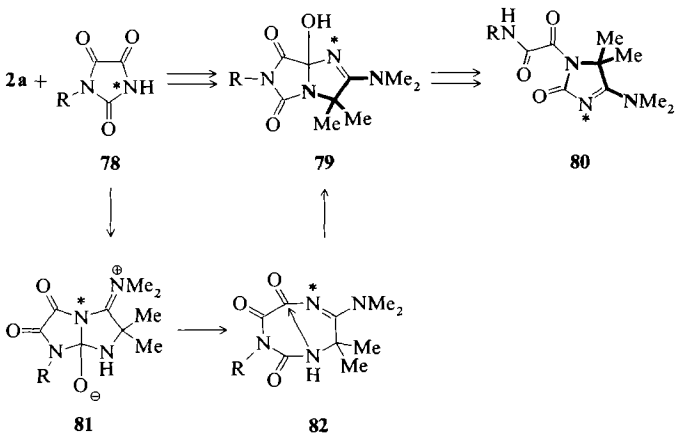
Since the synthesis was carried out with racemic **2c**, **71** and **72** were also obtained in their racemic form. It is also worth mentioning that azacyclol formation does not take place regioselectively, but that **69** and **70** are found in approximately equal proportions. Amazingly, both azlactones afford a mixture of **71** and **72** on methanolysis, so that separation of the isomers is only reasonable at this step. A mechanism for this behavior has been formulated.[134]

3-Amino-2*H*-azirines (**2**) react smoothly with 1,3-oxazolidine-2,4-diones **73** in acetonitrile at room temperature to give 3,4-dihydro-2*H*-imidazol-2-ones **74** (Scheme 16).[27, 31, 129] The analogous reaction with 1,3-thiazolidine-2,4-dione is more complex and gives rise not only to the mercapto analogue of **74**, but also to products of further reactions. The result of reaction of **73** with [1-^{15}N]-labeled **2a*** is surprising, since the **74** that is produced is labeled exclusively at the substituted N(3) atom. This finding can be easily explained by the reaction mechanism outlined in Scheme 16, via zwitterion **75**, ring-expansion to the 1,3,6-oxadiazocine derivative **76**, transannular ring-closure to **77**, and a second ring-opening. Further support for this reaction pathway comes from the isolation of **56**, the product analogous to **76** (Scheme 12), from the reaction of **2r** with 1,3-thiazolidine-2,4-dione.



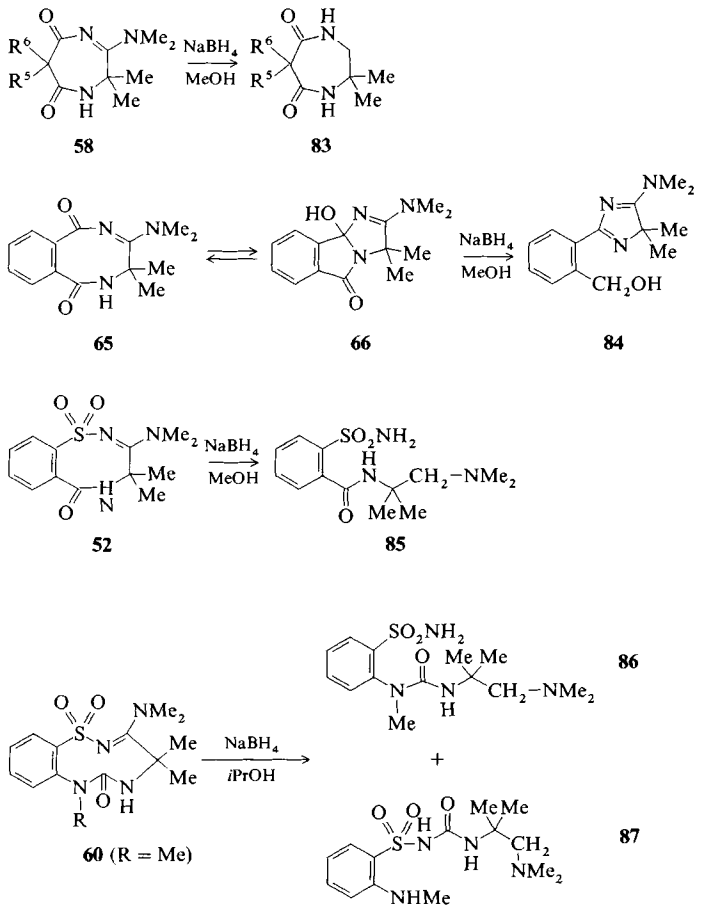
Scheme 16.

The quantitative formation of azacyclol **79** from **2a** and monosubstituted parabanic acids (imidazolidine-2,4,5-triones) **78** in 2-propanol at room temperature also follows a complex reaction mechanism (Scheme 17).[135] If the [3-^{15}N]-labeled N-methyl derivative of **78** is used, in the ^{15}N NMR spectrum of **79** all of the label is found at the amidine-N atom.[59] Zwitterion **81** and the 1,3,6-triazocine-2,4,5-trione **82** are therefore very likely intermediates in the



Scheme 17.

reaction. On warming **79** in acetonitrile, a further rearrangement to 3,4-dihydroimidazol-2-one **80** takes place, but the mechanism is not yet clear in all its details.



Scheme 18.

The novel seven- to nine-membered heterocycles formed in these reactions show surprising behavior, even in such simple reactions as hydrolysis or reduction. This makes structure determination by classical methods difficult, and in many cases X-ray structures have been determined for key compounds.

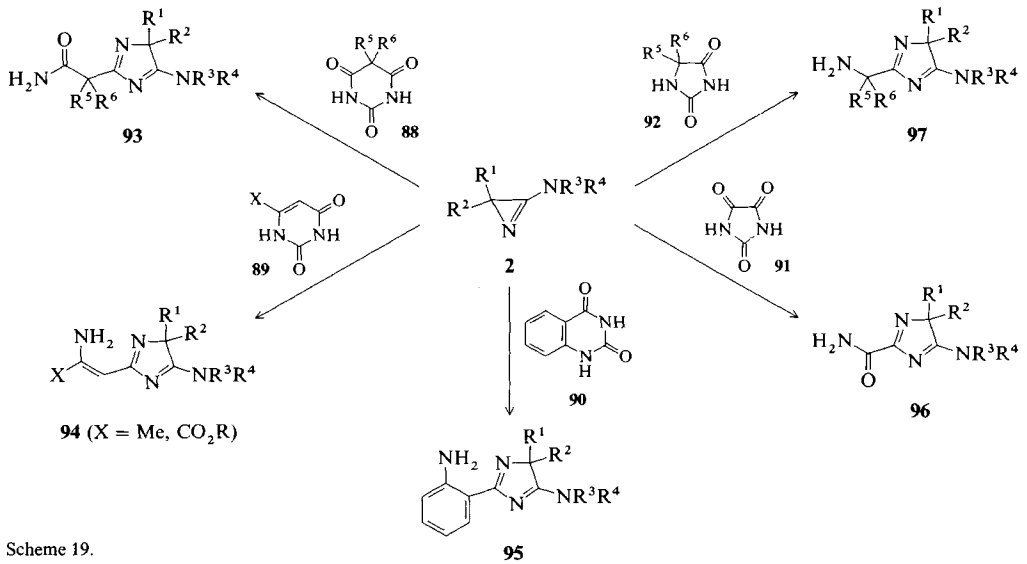
To illustrate this, Scheme 18 shows some results of $NaBH_4$ reductions. The diazepine derivative **58** is reduced to **83**, retaining the ring structure,[130] while for **65** ⇄ **66**, the azacyclol is reduced to **84**.[126] In cyclic sulfonamidines **52** and **60**, on the other hand, reduction occurs with ring-opening,[126, 136] whereby in the case of the nine-membered **60**, two isomeric products **86** and **87** are formed. The appearance of the latter requires a transannular ring-closure of **60**.

5.1.2. *Formation of 4H-Imidazoles*

As emerges from the reactions of **2** with NH-acidic compounds described above, there is clearly a great tendency to form imidazole derivatives (Schemes 11 and 15–18). This is confirmed in many further reactions with NH-acidic heterocycles ($pK_a < 8$). Thus, five- and six-membered heterocycles containing the structural element NH–CO–NH–CO (**88**–**92**) are without exception converted by **2** to 4*H*-imidazoles (**93**–**97**, Scheme 19). This reaction is independent of the solvent, though in some cases temperatures of up to 80 °C are required.[59, 137, 138]

Some of the products thus formed readily undergo subsequent reactions. For example, thermolysis of **93** with elimination of HNCO leads to the corresponding 2-alkyl derivative (phenyl groups at C(α) accelerate the fragmentation)[59], and the enamine side chain of derivative **94** is hydrolyzed to the carbonyl compound even on merely standing in air.[138]

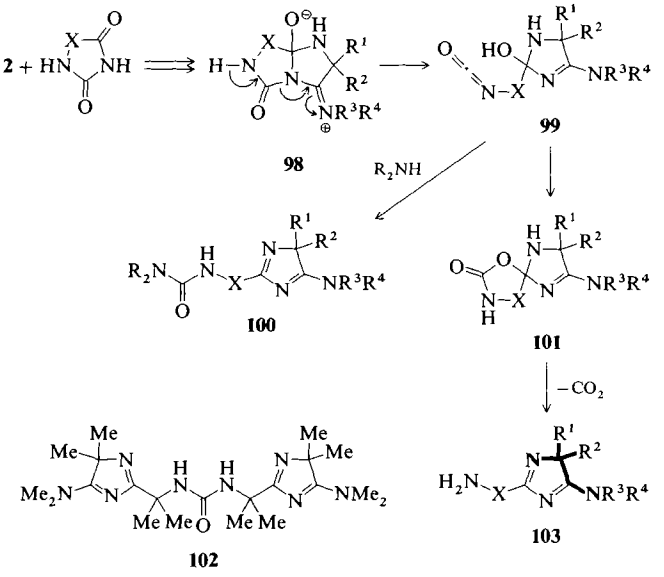
The question of reaction mechanism for the formation of 4*H*-imidazoles is an interesting one. These compounds are decarboxylated 1:1 adducts, and clearly, in the course of the reaction, the urea carbonyl group of the NH-acidic heterocycle is eliminated as CO_2. A mechanism that accounts for the findings to date is formulated in Scheme 20. The zwitterion **98**, which arises as usual, has a new reaction pathway open to it, leading via the cyclic urethane **101** and fragmentation to the 4*H*-imidazole **103**. However, an alternative mechanism involving elimination of water from **99** and sub-



Scheme 19.

sequent hydrolysis of the isocyanate function cannot be ruled out.

Two pieces of evidence that argue for the existence of **99** as an intermediate are the formation of urea derivatives of type **100** in the presence of secondary amines (e.g. morpholine), and the isolation of **102** as a byproduct from the reaction of **2a** and 4,4-dimethylhydantoin (**92**, $R^5 = R^6 = Me$)[59] (see also [74]). In addition, the inhibition of the reaction by the presence of a substituent at N(1) or N(3) of **88**, **90** or **92** supports the proposal in Scheme 20.



Scheme 20.

Since **2** reacts both with 1,3-benzoxazine-2,4-dione,[27, 139] and with 1,3-oxazolidine-2,4-diones (**73**)[27] and 1,3-thiazolidine-2,4-diones[129] (1-oxa and 1-thia analogues of **90** and **92**), the lack of reaction with the 1-alkyl derivatives of barbituric acids **88**, quinazoline-2,4-dione (**90**) and hydantoins **92** requires an explanation. By introducing an alkyl substituent at N(1), the acidity of the *N*-heterocycle is somewhat reduced (e.g. pK_a of 5,5-diethylbarbituric acid = 7.8, pK_a of 5,5-diethyl-1-methyl-barbituric acid = 8.2–8.4[1401]). Hence, the first step of the reaction, protonation of **2**, probably fails to take place. In accordance with this, the more acidic 1-alkyl parabanic acids **78** (Scheme 17) again react with **2**.

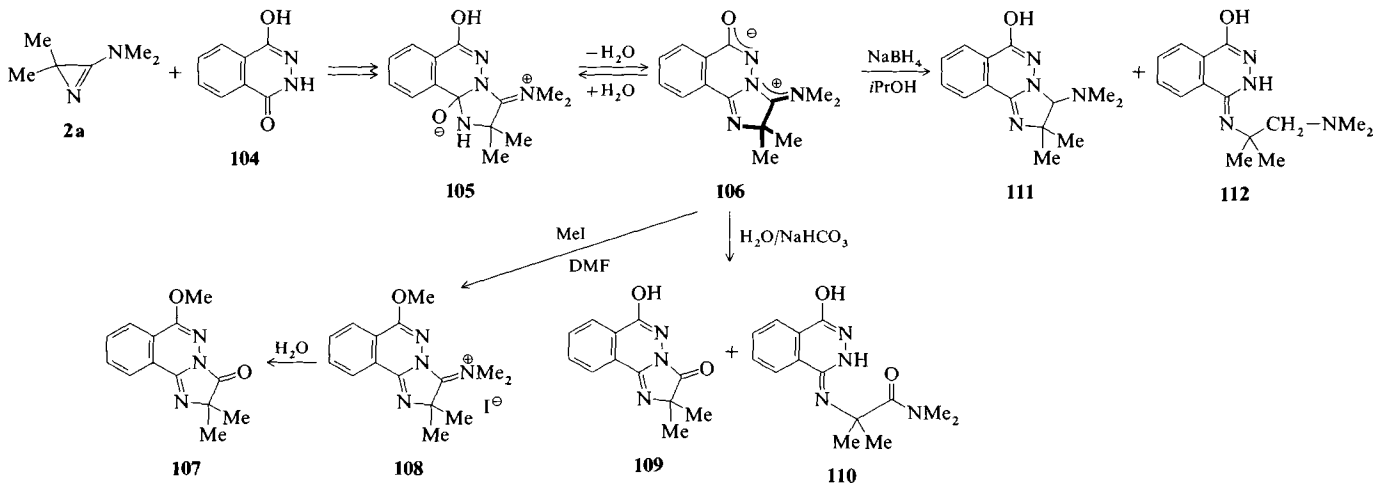
5.1.3. *Synthesis of Polycyclic Compounds*

The reactions of NH-acidic compounds with **2** that lead to polycyclic compounds are largely of mechanistic interest, since they allow conclusions regarding nonisolable intermediates. Phthalic acid hydrazide (2,3-dihydrophthalazine-1,4-dione, **104**) reacts with **2a** in DMF analogously to the corresponding imide **64** (Scheme 15), and yields the dehydrated 1:1 adduct **106**, a direct product of the zwitterion **105** with an intact ring system (Scheme 21).[141] The same reaction also occurs between maleic acid hydrazide (1,2-dihydropyridazine-3,6-dione) and **2a**.

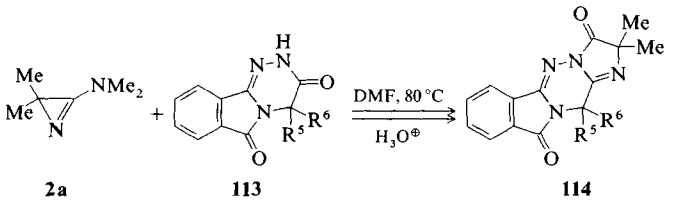
Hydrolysis of **106** with saturated $NaHCO_3$ solution yields a mixture of the tri- and bicyclic compounds **109** and **110** in 35% and 57% yield respectively, while treatment with water/triethylamine affords exclusively **110**. The iminium iodide **108** obtained by methylation of **106** is hydrolyzed by water to **107**, the *O*-methyl derivative of **109**. Reduction of the zwitterion **106** with $NaBH_4$ also leads to two products, **111** and **112** (Scheme 21).

To elucidate the structure of the 6-6-5 ring system **109**, compounds of type **113** (R^5, R^6 = Me, H) have been synthesized for comparison purposes.[142, 143] The monomethyl derivative displays a typical NH signal for an NH-acidic compound in the ^1H NMR spectrum ([D_6]DMSO) at $\delta = 11.2$, and it therefore seemed likely that it would react with **2a**. Indeed, heterocycles of type **113** do react with **2a**, to give a somewhat unstable initial product. After hydrolytic workup, the tetracyclic **114** is obtained (Scheme 22), which contains the intact ring skeleton of the zwitterion postulated as an intermediate.

Reactions of 3-amino-2*H*-azirines **2** with 1,3-thiazolidine- and 1,3-oxazolidine-2-thiones (**115**) also lead to heterobicycles containing α,α-disubstituted α-amino acids, as do reactions with 1,3-benzoxazole-2(3*H*)-thione (**122**). While **115** (X = S) in acetonitrile affords a mixture of the bicyclic **119**

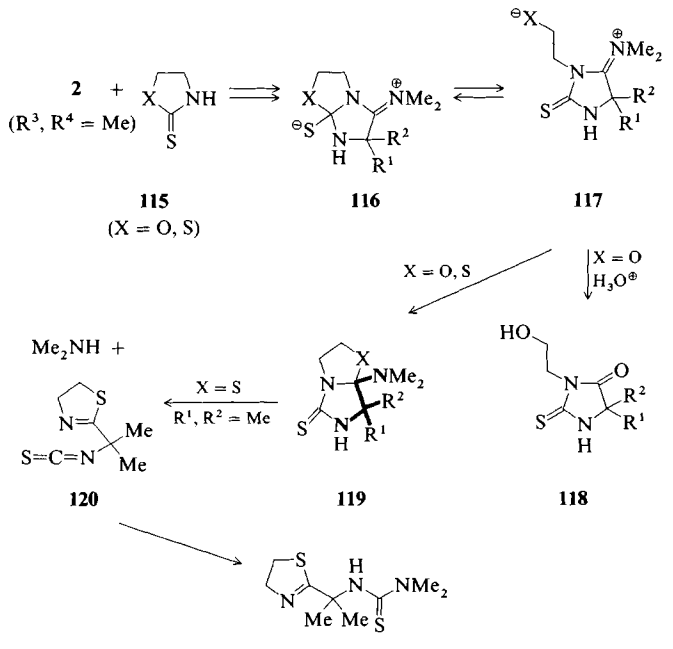


Scheme 21.



Scheme 22.

and the thiourea **121**, in 2-propanol **121** is formed exclusively (Scheme 23).[144] Control experiments show that the latter is a reaction product from **119**. Under the same conditions, a salt-like, unstable compound is formed in the reaction with **115** (X = O), which on chromatography afforded a small amount of **118**.[145] Compound **118** is obtained in good yields after hydrolytic workup of the crude product. In a few cases direct evaporation of the solvent and recrystallization allowed isolation of **119** (X = O).

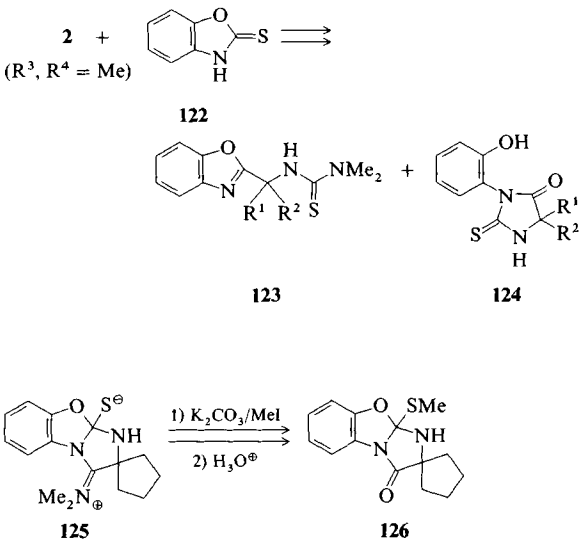


Scheme 23.

These results agree with the reaction mechanism proposed in Scheme 23. In contrast to the ring-expansions described in Section 5.1.1, it is not the central C(2)–N bond of zwitterion **116** that is broken, but the C(2)–X bond. In the thiolate product, **117** (X = S), nucleophilic ring closure occurs to give **119**, whereas for the less nucleophilic alcoholate, **117** (X = O), the reaction largely stops at this stage.

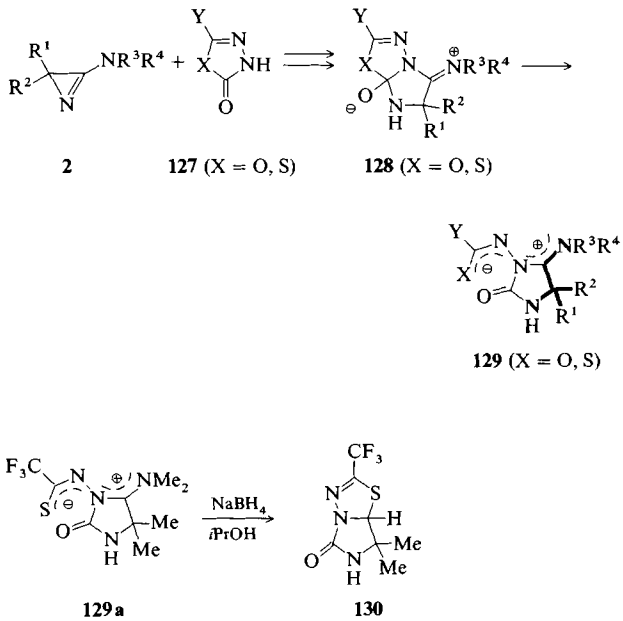
The course of the reaction of **2** with 1,3-benzoxazole-2(3*H*)-thione (**122**) in acetonitrile is as expected; the thiourea **123** and the thiohydantoin **124** are obtained as the major products, each in about 30% yield (Scheme 24).[146] The ring-closure corresponding to **117** → **119** presumably fails to take place because the anion is stabilized as the phenolate.

In the case of spirocyclic **2s**, it was possible to prove that these reactions also proceed via a zwitterion, **125**. Treatment of the reaction mixture with methyl iodide and K_2CO_3, followed by hydrolysis, gives a 38% yield of **126**. The isothiocyanate intermediate postulated for formation of thioureas **121** and **123** can also be trapped in both cases, by addition of morpholine.[144, 146] However, nucleophilic attack of the amine on the C = S group of **119** would also explain the formation of **121**, so that **120** must not necessarily be an intermediate.



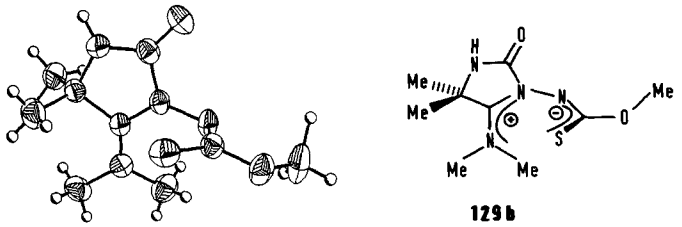
Scheme 24.

Further support for the suggested mechanisms for the reactions of NH-acidic heterocycles with **2** derives from the formation of zwitterionic 1:1 adducts **129**, which correspond to the nonisolable intermediates **117**. 3-Amino-2*H*-azirines (**2**) react at room temperature with 5-substituted 1,3,4-oxadiazol- and 1,3,4-thiadiazol-2(3*H*)-ones (**127**) to yield compounds of type **129** (Scheme 25). These are isolated in very good yields, as astonishingly stable, crystalline substances.[147] The structures of several members of this novel



Scheme 25.

class of substances have been determined by X-ray crystallography. In connection with the absence of a ring-closure reaction corresponding to **117** → **119**, it is worth mentioning that the two planes of the delocalized anion and cation lie orthogonal to one another (see **129b** in Fig. 4). In contrast, ring-closure to the bicyclic compound **130** was achieved in the reduction of **129a** by $NaBH_4$.[143]

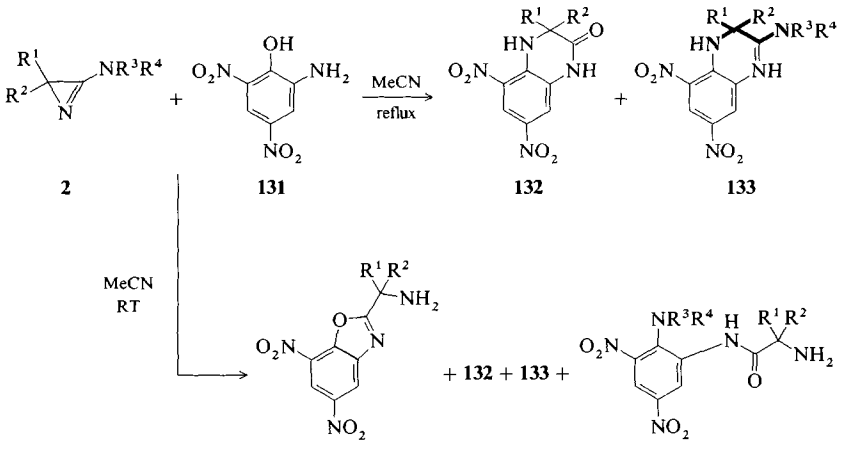


129b

Fig. 4. Structure of the zwitterion **129b** in the crystal.

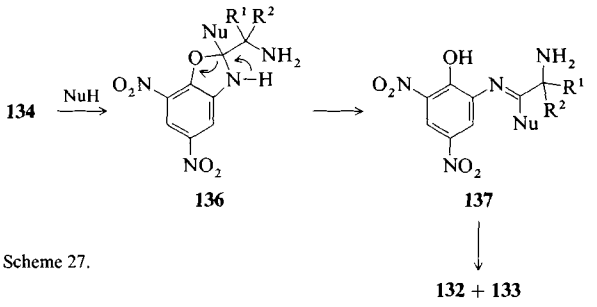
5.2. Reactions with Phenols

As mentioned in Section 3.3, 3-amino-2*H*-azirines (**2**) react with activated phenols to give *N*-phenylamino acid derivatives (**27**, Scheme 7). With a suitably positioned nucleophilic group, these products ought to provide starting materials for cyclizations. Indeed, reaction of **2** with picramic acid (2-amino-4,6-dinitrophenol, **131**) in boiling acetonitrile yielded the quinazoline derivatives **132** and **133** as the only isolable products, in 10% and 25% yield, respectively (Scheme 26).[67, 74]



Scheme 26.

The formation of these products is interpreted as occurring via cyclization (transamidation) of an intermediate corresponding to **27**. Attempts to isolate this intermediate at low reaction temperatures (0–25 °C) gave surprising results.[148] The major product, and in some cases (**2**, R^3 = Ph, R^4 = Me) the only one, in yields of up to 83%, was the 1,3-benzoxazole derivative **134**. Byproducts included **135**, and **132** and **133**. The latter two were obtained in high yields on basic hydrolysis of **134**, or on reaction with secondary amines. For these ring-transformations of **134**, a mechanism involving formation of **136** by nucleophilic addition (H_2O, ROH, RNH_2), rearrangement to **137**, and intramolecular, nucleophilic aromatic substitution of the OH group at C(1) by the NH_2 group seems plausible (Scheme 27).

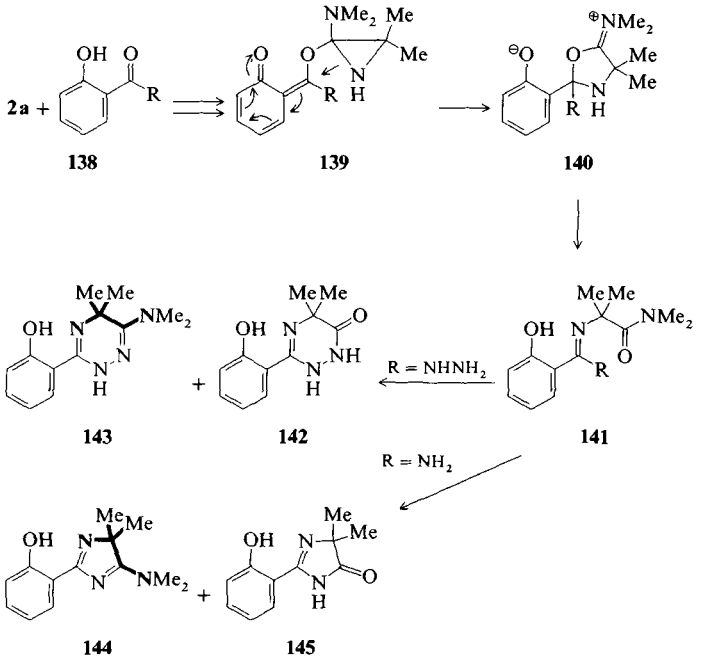


Scheme 27.

Phenolic substrates of the salicylic acid type (**138**) no longer react with **2** by aromatic substitution. Rather, the oxygen atom of the side chain is exchanged by the α,α-disubstituted α-amino acid, similarly to the reaction observed for enolized, cyclic 1,3-diketones[72] and 2-formylcycloalkanones.[64] If R is a nucleophilic group such as NH_2NH or NH_2, the initially formed **141** cyclizes on warming to give 1,2,4-triazine derivatives (**142** and **143**) or imidazole derivatives (**144** and **145**) respectively (Scheme 28). Reaction of **2a** with salicylic acid hydrazide (**138**, R = NH_2NH) in boiling benzene affords a 45% yield of **142** and **143**, in a ratio of ca. 3:2,[74, 149] while in acetonitrile at room temperature the intermediate **141** is obtained in 80% yield. Cyclization to **143** occurs spontaneously in methanolic solution; at 50 °C it proceeds quantitatively with a half time of ca. 45 min. In DMSO, too, the cyclization proceeds quantitatively, but **142** and **143** are produced in a ratio of ca. 1:2.

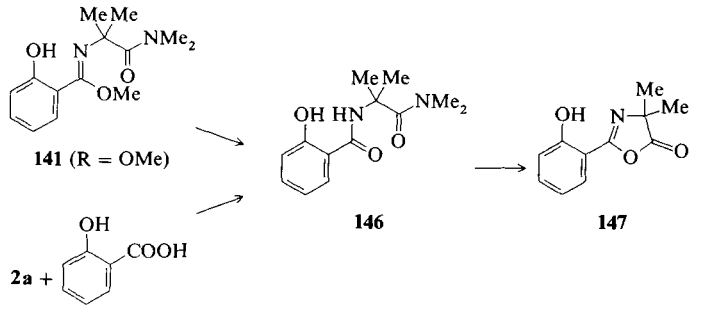
Salicylamide (**138**, R = NH_2) reacts with **2a** in an analogous manner. Here the products are the 4*H*-imidazole **144** and the 4,5-dihydroimidazol-5-one **145**. However, the ratio of the two is very solvent-dependent (Scheme 28).[74]

Methyl salicylate (**138**, R = OMe) reacts with **2a** to give the iminoester **141** (R = OMe, Scheme 29).[124] Spontaneous cyclization of the product is impossible in this case. Mild



Scheme 28.

hydrolysis gives the diamide **146**, which can be cyclized by heating in toluene in the presence of HCl to give 1,3-oxazol-4(5*H*)-one (**147**, Scheme 29). Products **146** and **147** are also



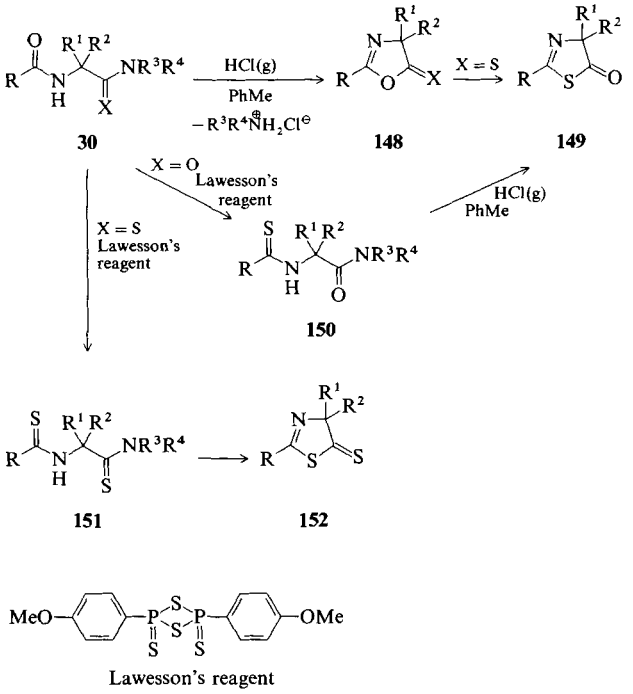
Scheme 29.

obtained from the reaction of **2a** with salicylic acid. This reaction will be discussed in more detail in Sections 5.3 and 6 (see also Scheme 8).

5.3. Reactions with Carboxylic Acids and Carboxylic Acid Derivatives

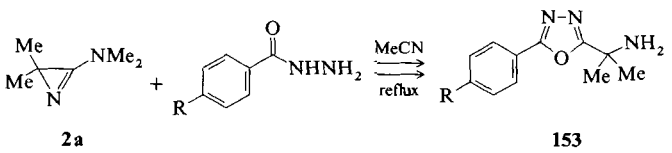
The diamides **30** (X = O, see Scheme 7) formed from carboxylic acids and the 3-amino-2*H*-azirines **2** are, as already mentioned, suitable substrates for the synthesis of 4,4-disubstituted 1,3-oxazol-5(4*H*)-ones (azlactones, **148** (X = O), Scheme 30). Cyclization with HCl gas in toluene proceeds quantitatively, and the sole byproduct is the hydrochloride of the secondary amine, which can be removed by filtration.[73, 150]

The analogous cyclization of monothioamides (**30**, X = S) does not, however, yield the expected 1,3-oxazole-5(4*H*)-thiones (**148**, X = S), but the isomeric 1,3-thiazol-5(4*H*)-ones (**149**, Scheme 30). Trapping reactions with amines show that the thiazolones **149** arise by a rearrangement of the initially formed, unstable **148** (X = S).[150] Thionation of diamide **30** (X = O) with Lawesson's reagent, for example, constitutes another route to **149**; cyclization of the selectively formed **150** proceeds smoothly under acid catalysis. Thionation of **30** (X = S) to the dithioamides **151** occurs in an analogous manner, and the products then cyclize spontaneously under the reaction conditions to the 1,3-thiazole-5(4*H*)-thiones **152**.[28, 38] These dithio analogous of azlactones have been little known until now and undergo a number of addition reactions.[151] They can also be synthesized by double O/S exchange of **30** (X = O),[152] or directly, by reaction of the 3-amino-2*H*-azirines **2** with dithio acids at − 60 °C.[38]



Scheme 30.

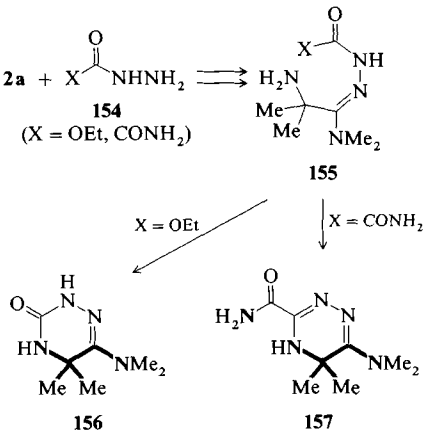
Aromatic hydrazides not bearing an OH group in the *ortho* position (cf. Section 5.2) do not react with **2a** at room temperature. However, under more drastic conditions (acetonitrile/reflux; DMF/60 °C), good yields of 1,3,4-oxadiazoles of type **153** (Scheme 31) are obtained.[149, 153] These reactions can proceed either via nucleophilic attack of azirine **2a** on the hydrazide group, or via an initial protonation of **2a**. Both mechanisms are in accord with the finding that acceptor substituents at C(4) accelerate the reaction,



Scheme 31.

while donors retard it ($v_{rel} \approx 7$ (R = NO_2), 1 (R = H), 0.7 (R = MeO)).

1,2,4-Triazine derivatives **156** and **157** (Scheme 32) may be successfully prepared by reaction of **2a** with ethyl hydrazinecarboxylate or oxamic acid hydrazide (**154**, X = EtO or H_2NCO respectively), in 2-propanol at 70 °C[153] (cf. also



Scheme 32.

[147]). When the reaction with **154** (X = EtO) is performed at room temperature, the open chain intermediate **155** can be isolated as an *E*/*Z* mixture, which cyclizes in the melt or in DMF at 70 °C.

6. Application of the Azirine/Oxazolone Method in Peptide Synthesis

6.1. Construction of Linear Peptides with α,α-Disubstituted α-Amino Acid

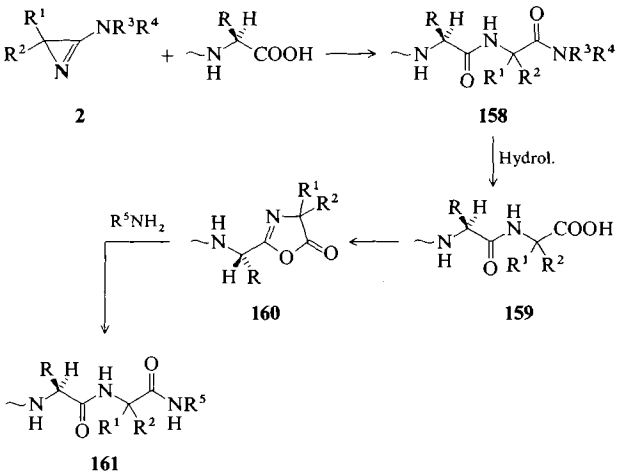
Conventional chain elongation techniques either fail completely for peptides containing α,α-disubstituted α-amino acids or suffer from extreme difficulties.[103, 106, 154–157] Apart from low yields, especially in the Merrifield procedure,[158] and cleavage of the acid-labile Aib-peptide bond on removal of the protecting group,[159] problems arise in particular because of racemization (or epimerization) of the carboxyl component, which occurs partly as a result of the necessarily long reaction times.[157, 160] The main reason for the low reactivity of α,α-disubstituted α-amino acids is probably the steric hindrance of the two α-substituents, which is large even for Aib. Various synthetic approaches to larger Aib-containing polypeptides (e.g. alamethicin) failed initially,[161] before they were eventually successful.[157]

Since the difficulties described are attributable to the activation of the carboxyl component in coupling of sterically hindered amino acids, the alternative activation of the amino component should offer great advantages. Donor substituents (alkyl or trialkylsilyl) on the amino group increase the nucleophilicity, but because of the increased steric hindrance they also lower the coupling rate. Use of the *tert*-butyl ester leads to a slight increase in the reactivity of the amino group,[162] but no satisfactory solution for amino group activation has yet been found.[163]

The application of the 3-amino-2*H*-azirines **2** as amino acid synthons in peptide synthesis is thus especially interesting, since it realizes the idea of amino group activation. The formal *N*-activation by the ring strain is so significant that no further activation of the acyl component is required at all; 3-amino-2*H*-azirines are highly reactive synthons for α,α-disubstituted α-amino acids (see reviews [61, 164, 165]).

6.1.1. Principle and Mechanism of Chain Elongation with 3-Amino-2H-Azirines

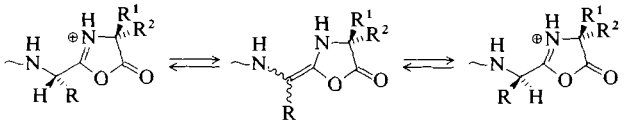
The principle behind chain elongation with the 3-amino-2*H*-azirines **2** is largely apparent from the transformations described in Sections 3.3 and 5.3. Reaction of carboxylic acids with **2** leads to diamides of type **30** (first coupling step); the acid-catalyzed cyclization to 1,3-oxazol-5(4*H*)-ones **148** (X = O) can be regarded as the activation step for coupling to a further amino component. It should be pointed out that no additional reagents are required under the very mild conditions needed for the coupling with **2**, and no byproducts are observed. This makes workup of the products very simple and also allows the use of bifunctional carboxylic acids (hydroxy, mercapto and amino acids) in unprotected form.[166]



Scheme 33.

The principle of the procedure for incorporation of α,α-disubstituted α-amino acids into peptides by our "azirine/oxazolone method" is described in Scheme 33. In general, reactions of *N*-protected amino acids or peptides with **2** proceed quantitatively at 0–25 °C. The new amide bond is formed in a very rapid, intramolecular rearrangement (**31** → **32** → **30**, Scheme 8), with minimal risk of racemization. An intermediate analogous to **31** is also found in the "four-component condensation" of *Ugi* et al.,[167] where less than 0.01 % racemization is observed. The critical step is the hydrolysis of the peptide amide **158** to the acid **159**. This refunctionalization of the terminal amide group in **158** occurs with a very high selectivity as long as the terminal acid is disubstituted (R^1, $R^2 \neq H$), and an *N*,*N*-disubstituted amide is present (R^3, $R^4 \neq H$), that is, for the products of

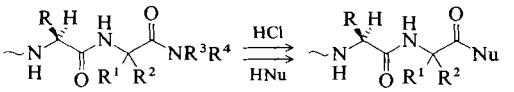
coupling to **2**.[29, 150, 166] Treatment of a suspension or solution of **158** (R^3, R^4 = Me) in acetonitrile/water with HCl gas at ca. 60 °C affords **159** in yields higher than 95%. A 1,3-oxazol-5(4*H*)-one occurs as an intermediate in this reaction. This is presumably the reason for the partial epimerization of the penultimate amino acid, which can take place via the intermediate shown in Scheme 34.[168] This epimerization can be completely suppressed if the *N*-methyl anilide **158** (R^3 = Ph, R^4 = Me) is used; this compound can be hydrolyzed under even milder conditions (3 N HCl, THF/H_2O, 25 °C).[168]



160a **162** **160b**

Scheme 34.

Refunctionalization to esters and thioesters **163** occurs analogously (Scheme 35).[166] Here, **158** is either treated with HCl gas directly in the required alcohol, or in a solution of the phenol or thiophenol in acetonitrile at ca. 70 °C. After evaporation of the solvent, the product is recrystallized or purified by chromatography.

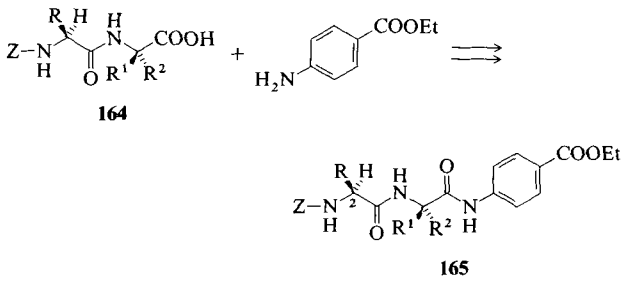


158 **163** (Nu = RO, ArO, PhS)

Scheme 35.

The difficulties that are encountered in the coupling of peptides with *C*-terminal α,α-disubstituted α-amino acids have already been mentioned. Nevertheless, the formation of peptide bonds between Aib and amino components, via 4,4-dimethyl-1,3-oxazol-5(4*H*)-one (**160**, R^1, R^2 = Me), yields encouraging results.[169, 170] However, the high temperatures required greatly restrict the applicability of this method; significant amounts of epimerization are observed,[171] again due to the equilibrium formulated in Scheme 34. Thus, on coupling of Z-Ile-Aib-OH (**164**, R = $CH_3CH_2CH(CH_3)$, R^1 = R^2 = Me) with the slow-reacting amino compound ethyl 4-aminobenzoate by the DCC(dicyclohexylcarbodiimide)/*t*BuOH method,[155] one obtains **165** which is nearly 50% epimerized at the C(2) center of Ile (Scheme 36). Even coupling with isobutyl chloroformate via the mixed anhydride, under Anderson conditions,[172] a method which is recommended for coupling of Aib,[102] gives ca. 5% epimerized **165**. Furthermore, the yield of the reaction is very modest.[171]

The difficulties of epimerization and low yields may be circumvented by catalysis of the coupling reaction. Suitable catalysts have proved to be camphor-10-sulfonic acid (CSA) and zinc chloride. In both cases, **165** forms with DCC even at 0 °C, in yields of 80–95% and without epimerization at



164 **165**

Scheme 36. Z = Benzyloxycarbonyl ($PhCH_2OCO$)

C(2) of Ile.[171] Clearly, both protonation and complexation with the Lewis acid accelerate the ring opening of the 1,3-oxazol-5(4*H*)-one intermediate, and hence reduce the tendency to epimerize.[29] Similar effects have already been reported using $CuCl_2$ as the Lewis acid[173] (see also [174]).

In summary, it can be stated that the reaction of peptides with the 3-amino-2*H*-azirines **2**, together with selective hydrolysis of the terminal amide group and efficient, epimerization-free DCC-coupling via 1,3-oxazol-5(4*H*)-ones, constitutes an attractive method for insertion of α,α-disubstituted α-amino acids into peptides.

6.1.2. Synthesis of Oligopeptides with α,α-Disubstituted α-Amino Acids

To demonstrate the scope of the "azirine/oxazolone" method, several dipeptides,[150, 166] a number of tripeptide analogues of type **165** (Table 3)[175] and tetrapeptides **170** (Scheme 37, Table 4)[122] have been synthesized. These mod-

el peptides were selected as target structures with a view to studying the dependence of their conformations on the nature of the α,α-disubstituted α-amino acids.[121, 122] The tripeptide sequence **165** is also interesting because *Šorm* et al.[176] have shown that peptide derivatives such as ethyl isoleucylalanyl-4-aminobenzoate (Ile-Ala-Benzocain) show structural similarities to certain juvenile hormone analogues (cf. [177, 178]).

Coupling of Z-Ile to the racemic azirines **2b**, **2c** and **2e**, which are asymmetrically substituted at C(2), leads to 1:1 mixtures of diastereomeric dipeptides. These are separated by HPLC before proceeding further. The synthesis of tetrapeptides **170** (Scheme 37) also proceeds in very good yields for the coupling and hydrolysis steps up to tripeptide **169**; the final coupling to Val-OCH_2Ph using a water-soluble carbodiimide still needs improvement (Table 4).

Conformational studies of tripeptides **165**[29, 121] and tetrapeptides **170**[40, 122] demonstrate the pronounced tendency of oligopeptides containing α,α-disubstituted α-amino acids to adopt β turns. That these appear so clearly even in tri- and tetrapeptides is surprising. Another remarkable finding is that α,α-disubstituted α-amino acids with a branched side chain are particularly able to stabilize β turns or helical conformations, while extended forms are increasingly stabilized by longer side chains.

Coupling reactions with **2a** are ideal for the synthesis of poly-Aib peptides, since they can be carried out iteratively; the peptide amide formed with **2a** in each step is hydrolyzed and reacted once more with **2a**. In this way, $PhCH_2CO$-$(Aib)_3$-OMe,[166] PhCH(OH)CO-Aib-OH,[179] H-$(Aib)_4$-OMe[166] and Z-$(Aib)_6$-N(Ph)Me (**171**)[36] (Fig. 5) have been synthesized, amongst others. The selectivity of the hydrolysis step must be specially emphasized; the terminal *N*,*N*-disubstituted amide group is cleaved exclusively.

The Aib-containing peptide Z-$(Aib)_3$-Pro-$(Aib)_3$-N(Ph)-Me has been obtained by coupling the segments Z-$(Aib)_3$-OH and Pro-$(Aib)_3$-N(Ph)Me, using DCC/$ZnCl_2$.[36] The segments themselves were synthesized via the azirine/oxazolone method.

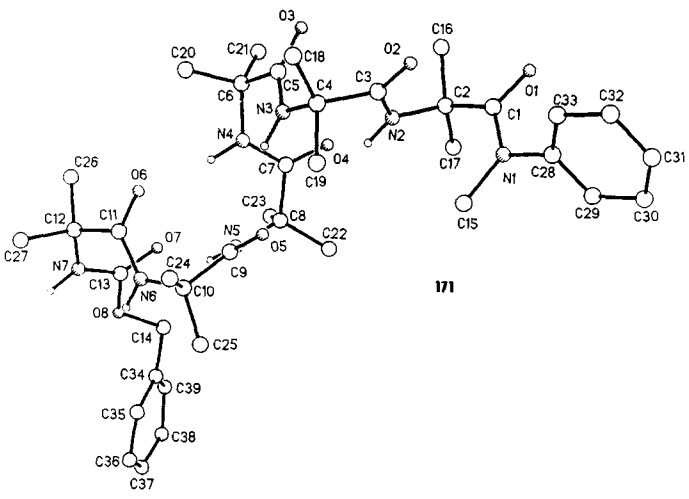

Fig. 5. Structure of Z-$(Aib)_6$-N(Ph)Me (**171**) in the crystal.

6.1.3. *Synthesis of Peptaibol Fragments*

The peptaibols are amphiphilic polypeptide antibiotics and ionophores[180] with a high proportion (up to 50%) of

nonproteinogenic 2-aminoisobutyric acid (Aib) and occasional D-isovaline residues (D-Iva). Further characteristics are an aminoalcohol at the C terminus and an *N*-terminal acetyl group. The peptaibols can be divided into two groups:[181] those with 18–20 amino acids which contain no hydroxyproline (Hyp), and those with 15–16 amino acids, including Hyp (Table 5). Physiologically, the peptaibols are distinguished by their membrane-modifying qualities. They induce a potential-dependent ionic conductance in lipid bilayers, and therefore serve as model systems for studies of the synaptic transfer of nerve impulses.[189–191]

Table 5. Examples of Peptaibols.

Peptaibol	No. of amino acids total	α,α-disubst.	*C*-terminal aminoalcohol	Ref.
Alamethicin F-30	20	8	Pheol	[102,182,183]
Antiamoebin I	16	8	Pheol	[100,184]
Emerimicin IV	15	6	Pheol	[185]
Hypelcin A	20	10	Leuol	[186]
Paracelsin A	20	9	Pheol	[182]
Suzukacillin A	20	9	Pheol	[187]
Trichorzianin A IIIc	19	8	Trpol	[188]
Trichotoxin A-40	18	9	Valol	[100,102,182]
Trichotoxin A-50	18	9	Valol	[182]

It is striking that when the peptaibols are isolated from fungal cultures (e.g. *Trichoderma viride* → Almethicin, Trichotoxin; *Emericellopsis poonensis thirum* → Antiamoebin), each major compound is found along with several sequence isomers, whose preparative separation is most difficult. This microheterogeneity can be traced back to the nonribosomal biosynthesis with low-specificity multienzyme complexes.[192] For some time now, attempts have therefore been made to synthesize chemically homogeneous compounds. Four different syntheses of the best known member of this group, Alamethicin F-30, have been published, in 1981 and 1985.[157, 193]

Ac-Aib-Pro-Aib-Ala-Aib-Ala-Gln-Aib-Val-Aib-Gly-Leu-Aib-Pro-Val-Aib-Aib-Glu-Gln-Pheol.

Alamethicin F-30

The azirine/oxazolone method now constitutes an ideal method for the synthesis of peptaibol fragments. The Z-protected (12–20) nonapeptide Z-Leu-Aib-Pro-Val-Aib-Aib-Glu(OCH_2Ph)-Gln-Pheol, which was also used in the total synthesis reported by *Schmitt* and *Jung*,[157] is obtained by the route outlined in Scheme 38, in 29% yield.[29, 194] A comparison of this yield with that obtained by the classical route (12%) clearly shows the advantages of the new methodology. In particular, the synthesis of the tripeptide segment Z-Val-Aib-Aib-N(Ph)Me, using the 3-amino-2*H*-azirine **2a** as an Aib synthon (95% yield), is vastly superior to previous techniques.

As further attractive target molecules, we selected fragments of Trichotoxin A-50 (G) and of Antiamoebin I.

Ac-Aib-Gly-Aib-Leu-Aib-Gln-Aib-Aib-Aib-Ala-Ala-Aib-Pro-Leu-Aib-D-Iva-Gln-Valol

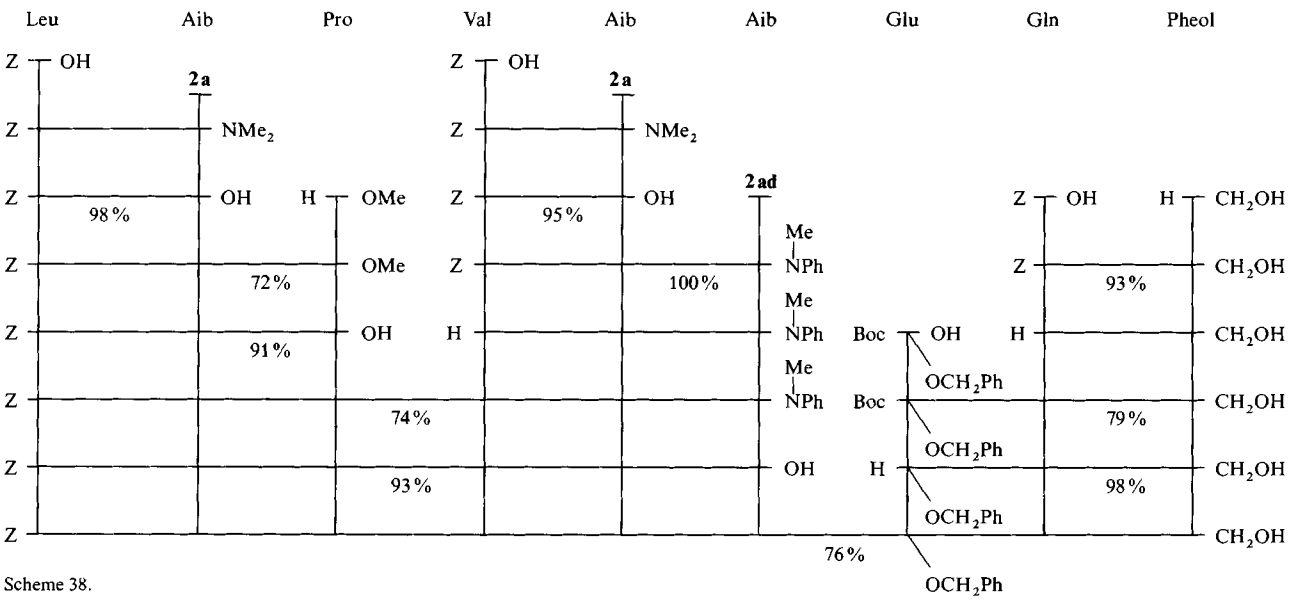
Ac-Phe-Aib-Aib-Aib-D-Iva-Gly-Leu-Aib-Aib-Hyp-Gln-D-Iva-Hyp-Aib-Pro-Pheol

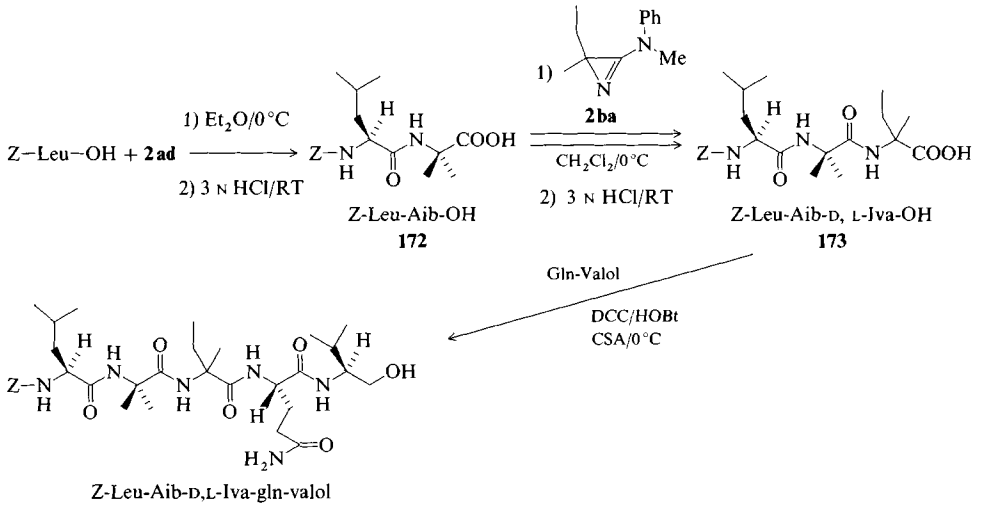
Antiamoebin I

The synthesis of the (10–13) segment of Trichotoxin A-50 (G), Z-Ala-Ala-Aib-Pro-OMe, proceeds in 60% yield,[165, 195] including a yield of 92% for the coupling of Z-Ala-Ala with **2ad** and subsequent hydrolysis with 3 N HCl (THF/H_2O) to Z-Ala-Ala-Aib-OH. The synthesis of Z-Leu-Aib-Iva-Gln-Valol **174** is outlined in Scheme 39. The tripeptide **173** was obtained as an epimeric mixture (ca. 7:5), since racemic **2ba** was used.[196] Separation of the epimers at the tripeptide amide stage is more difficult than for the dipeptide amides of type **165**. Using HPLC, the (+)-epimer was obtained in pure form, but the (−)-isomer still contained ca. 12% of its epimer.[195]

A further problem appeared while constructing the (6–9) segment. When the peptide amides Z-Gln-$(Aib)_n$-N(Ph)Me are hydrolyzed, even under the mildest conditions, the amide group in the Gln side chain is also partially hydrolyzed (→ Glu). Similar difficulties also appear in the synthesis of



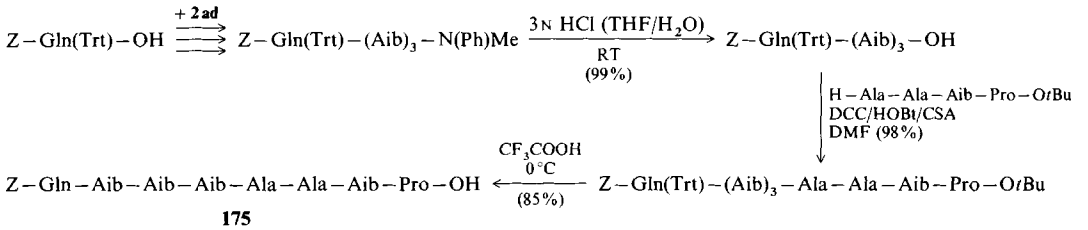
Scheme 38.



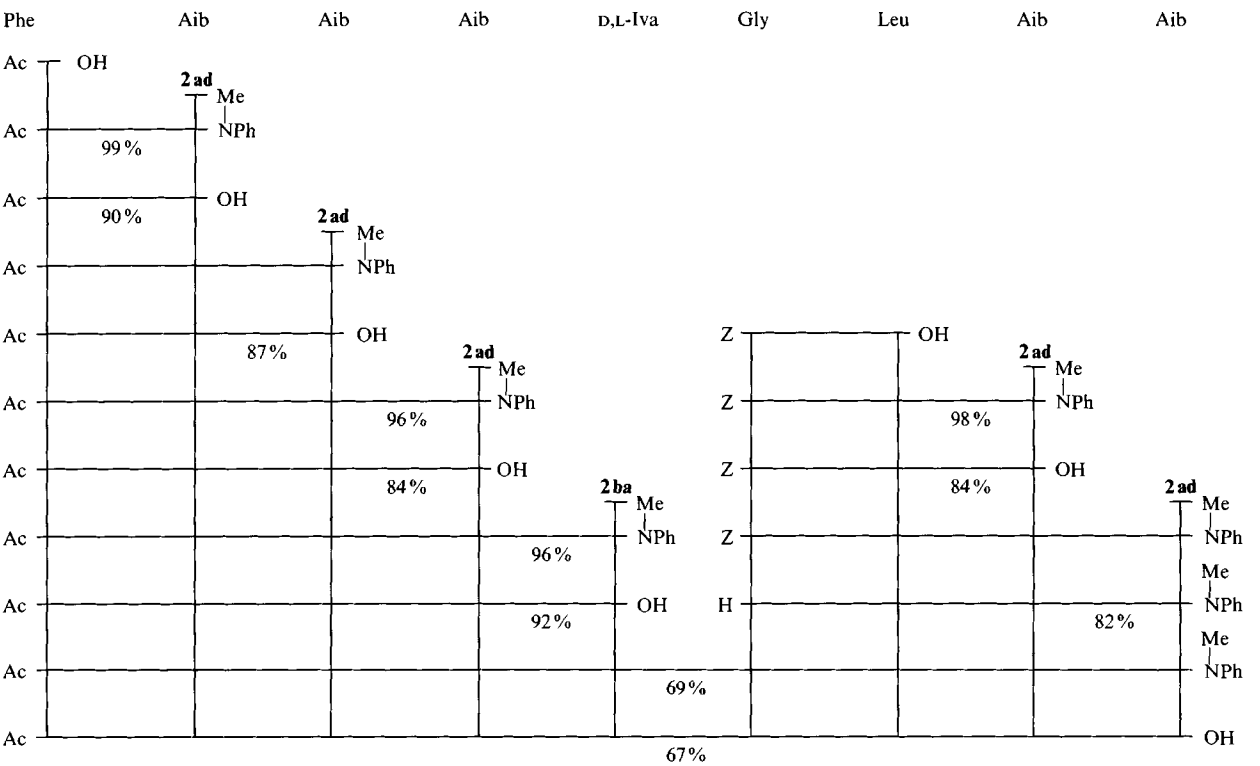
Scheme 39. DCC = dicyclohexylcarbodiimide; CSA = camphor-10-sulfonic acid.

Z-Asn-Aib segments (→Asp). This can only be avoided by introducing a suitable protecting group. The trityl group has proved its worth here; it allows the synthesis of **175**, as shown in Scheme 40, in an overall yield of ca. 60%.[35]

The synthesis of the *N*-terminal nonapeptide of Antiamoebin is presented in Scheme 41. Successive construction of Ac-Phe-Aib-Aib-Aib-D,L-Iva-OH using the 3-amino-2*H*-azirines **2ad** and **2bd** afforded very good yields of an epimer-



Scheme 40.



Scheme 41.

ic mixture, which could again be separated by HPLC. Coupling of segments (1–5) and (6–9) has so far only been performed with the epimeric mixture (ca. 4:7), and gives best results via the mixed anhydride with isobutyl chloroformate.[198] The crude yield for the coupling with DCC/CSA via the 1,3-oxazol-5(4*H*)-one is actually higher (92%), but on chromatography to remove the urea produced in the reaction, this falls to ca. 52%.

The X-ray crystal structure of the analogously prepared segment Z-Gly-Leu-Aib-Aib-OH (Fig. 6) shows not only intermolecular hydrogen bonds, but also an intramolecular one between NH(1) and O(4), which stabilizes formation of a β turn.

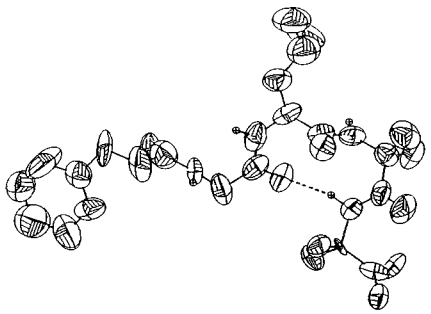


Fig. 6. Structure of Z-Gly-Leu-Aib-Aib-OH in the crystal.

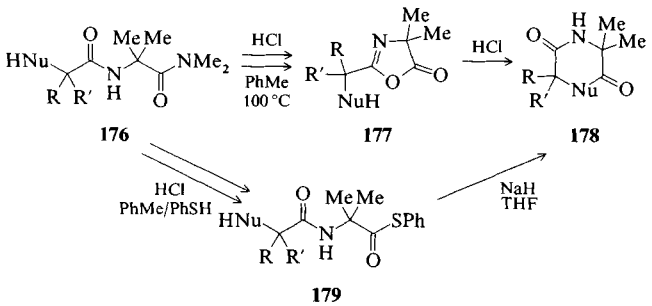
6.2. Direct Amide Cyclization to Cyclic Depsipeptides

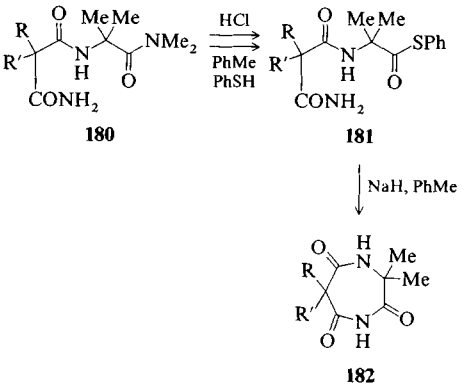
As has been discussed in the previous sections, diamides and peptides of type **158** (Scheme 33) are selectively transformed into acids or esters under acidic conditions. The 1,3-oxazol-5(4*H*)-one formed as an intermediate is attacked by a nucleophile in an intermolecular reaction, with ring-opening. In the absence of an external nucleophile, substrates of type **176** undergo an intramolecular reaction with the nucleophilic group they carry, giving rise to cyclic products. Thus, for example, on treatment of a suspension of **176** (Nu = O, R,R′ = Me) in toluene with HCl gas at 100 °C, the morpholine-2,5-dione **178** (Nu = O, R,R′ = Me) is obtained in 87% yield (Scheme 42).[179] However, the success of the cyclization depends greatly on the substituents R and R′. For R,R′ = Ph, for example, the reaction comes to a halt at the level of the 1,3-oxazol-5(4*H*)-one **177**.



Scheme 42.

One alternative to the "direct amide cyclization" (e.g. **176** → **178**) is the route via the corresponding phenyl thioester **179**. Cyclization is then brought about with sodium hydride in THF. Using this route, the cyclization of **176** (Nu = NH) to piperazine-2,5-diones is also possible; these compounds are only accessible via acid-catalyzed ring closure in exceptional cases.[164]

Base-catalyzed cyclization of phenyl thioesters can also be used to obtain 1,4-diazepine-2,5,7-triones **182** (Scheme 43).[199] The required triamides **180** are usually synthesized by reaction of malonic acid monoamides with the 3-amino-2*H*-azirines **2a** and subsequent acid-catalyzed refunctionalization of the dimethylamide group.

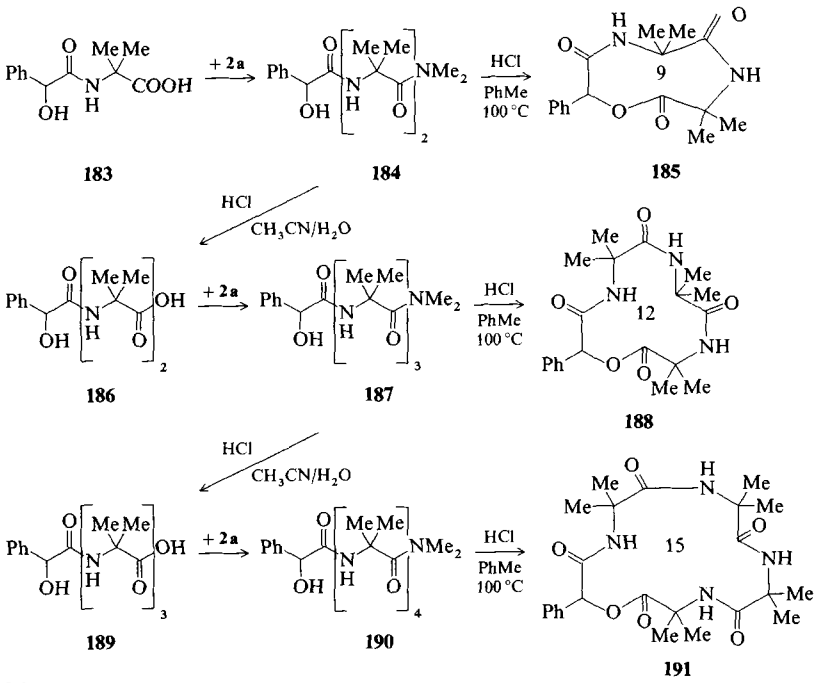


Scheme 43.

"Direct amide cyclization" under acid catalysis is especially well-suited for the synthesis of cyclic depsipeptides (cyclopeptolides) of medium ring size. In Scheme 44 one example of peptide chain extension with aminoazirines and amide cyclization starting from (±)-mandelic acid is presented.[179] Cyclization takes place at ca. 100 °C by bubbling HCl gas through a suspension of the peptide in toluene. During workup the solvent is evaporated, the residue is suspended in THF/ether, and the dimethylamine hydrochloride produced in the reaction is filtered off. This gentle procedure allows the isolation of the 9-, 12- and 15-membered depsipeptides **185**, **188** and **191** in 85%, 90% and 86% yield respectively.[179] The most surprising of these is the easy formation of the nine-membered **185**, since it is known that, with very few exceptions (e.g. cyclotriprolyl[200]), cyclic tripeptides are very difficult to synthesize.[201] Under conventional cyclization conditions, the main products are cyclodimers of *N*-substituted piperazine-2,5-diones. The high ring strain in **185** is obvious in its sensitivity to hydrolysis: while **188** and **191** are stable compounds, **185** is hydrolyzed to the open-chain acid PhCH(OH)CO-Aib-Aib-OH even with only traces of water.

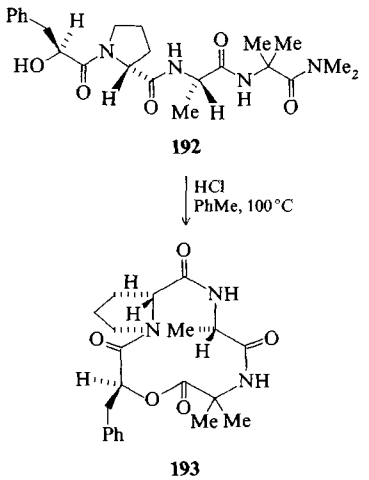
The selectivity of ring closure to the terminal amide group must be specially mentioned. In no case does cyclization occur with cleavage of the peptide chain[179] (cf. [161]). In these model compounds containing only Aib-units within the peptide chains, this selectivity is explained by preferential formation of the 1,3-oxazol-5(4*H*)-one via protonation of the *N*,*N*-dimethylamide group.

The general significance of these new cyclization methods is apparent from the successful syntheses of the 12-mem-



Scheme 44.

bered cyclodepsipeptides **193** (Scheme 45) and **197** (Scheme 46). Cyclo[(*S*)-Pms-(*R*)-Pro-(*S*)-Ala-Aib] (**193**, Pms = phenyl lactic acid) is a lactone analogue of the tetrapeptide cyclo-[(*S*)-Phe-(*R*)-Pro-(*S*)-Ala-Aib] studied by *Rich* et al.,[202] which served as a model compound for optimization of the cyclization to *Chlamydocin*.[203] In the case of the peptide, the ring closure between Phe and Aib proceeded very slowly and in only 2% yield; the corresponding cyclization **192** → **193** took place with a yield of 72% (Scheme 45).[204]



Scheme 45.

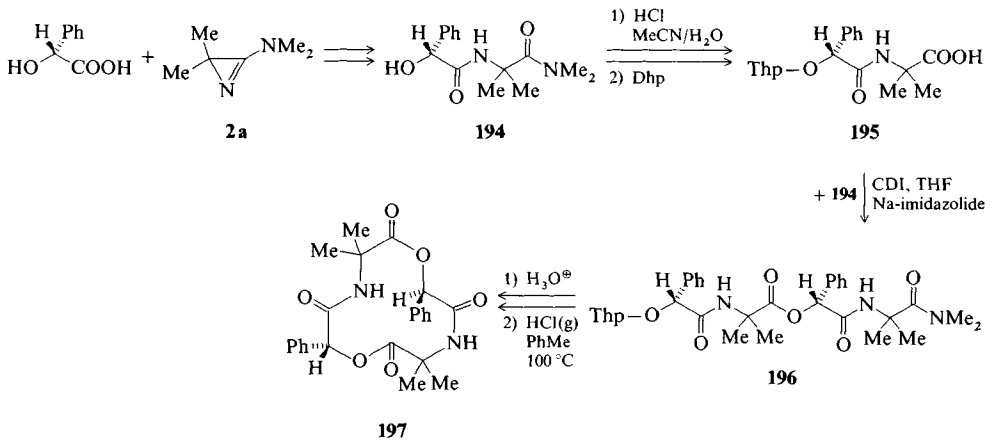
Compound **197** displays an alternating sequence of (*R*)-mandelic acid and Aib residues, and therefore serves as a model compound for the cyclization of enniatins.[180, 205, 206] These are natural ionophores containing alternating (*R*)-α-hydroxy- and (*S*)-α-amino acids. In the antibiotic Enniatin B, for example, the 18-membered ring is built up of three identical [(*R*)-2-hydroxy-3-methylbutanoyl-N^{α}-methyl-L-valyl] units. In enniatin syntheses, cyclization is usually carried out by formation of a lactam bond; for model compounds of type **197**, ring closure occurs via amide cyclization and lactone formation.[207]

The linear precursor **196** is easily synthesized by coupling **194**, available from (*R*)-mandelic acid and **2a**, with **195**, in 66% yield. A modified carbonyldiimidazole (CDI) procedure[208] has proved useful for coupling the two fragments, using sodium imidazolide as base. Cyclization with HCl in toluene at 100 °C leads to **197** in 88% yield. No cleavage of the ester group is observed under these conditions.

In summary, acid-catalyzed amide cyclization is ideally suited for lactone ring-closures (cf. also [209]), and hence for the synthesis of cyclic depsipeptides. No dimerization occurs, even when only small solvent volumes are used. Because of the heterogeneous nature of the reaction, the "dilution principle"[210] is probably obeyed nonetheless, since only a small proportion of the reactant is actually present in solution in the toluene. The high yields obtained are also due to the irreversible nature of the activation step (i.e. 1,3-oxazol-5(4*H*)-one formation), to precipitation as its hydrochloride of the dimethylamine produced, and to the gentle workup procedure by filtration and evaporation of the solvent.

6.3. Synthesis of Cyclic Aib-Containing Peptides

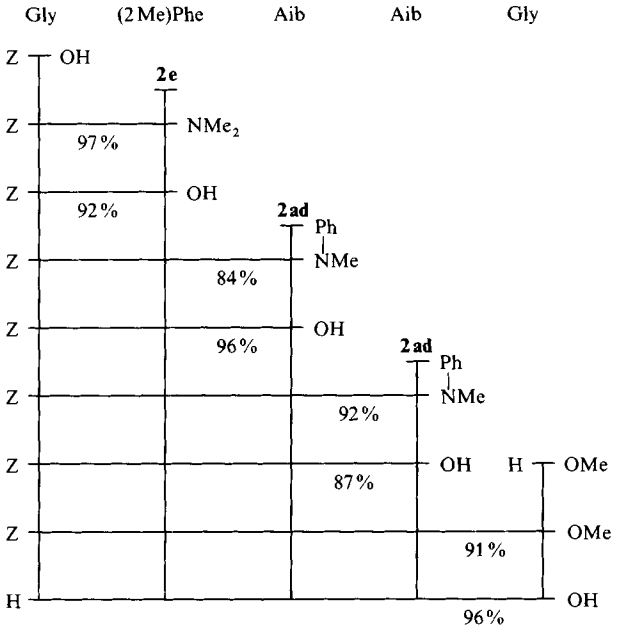
The synthesis of cyclic peptides continues to arouse great interest.[211–214] Unfortunately, acid-catalyzed amide cyclization (Section 6.2) cannot be applied to the formation of cyclic peptides. As for the depsipeptide derivatives of type **176** (Nu = NH, Scheme 42), the method fails for longer peptides, since the free amino group is completely protonated under the reaction conditions. Therefore for the synthesis of



2a 194 195 196 197

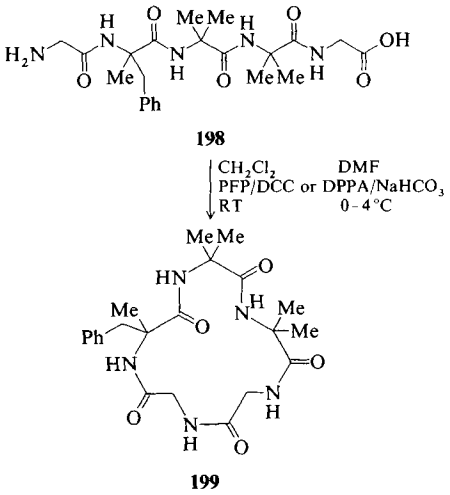
Scheme 46. Dhp = dihydropyran, Thp = tetrahydropyranyl, CDI = carbonyldiimidazole.

cyclic, Aib-containing peptides, a combination of the "azirine/oxazolone method" with a conventional cyclization is called for. The pentapeptide **198** was chosen as a model compound and was synthesized from Z-glycine according to the synthetic plan given in Scheme 47, by reactions with 3-amino-2*H*-azirines **2e** and **2ad**, followed by coupling to glycine methyl ester via the 1,3-oxazol-5(4*H*)-one (DCC/$ZnCl_2$). The protecting groups were removed as usual by hydrogenolysis and saponification.[36]



Scheme 47.

Several procedures have been tried out for the cyclization of **198** to the 15-membered **199** (Scheme 48). The pentafluorophenol/DCC method[215] yields **199** in 25% yield. In this procedure, a 10^{-4} M solution of **198** is stirred with 2 equivalents of pentafluorophenol and 1 equivalent of DCC for 30 hr at room temperature, and the cyclized product **199** is purified by HPLC. The highest yield of crystallized product (60%) was obtained by the procedure of *Brady* et al.[216] Compound **198** was stirred in anhydrous DMF (10^{-4} M) with diphenylphosphorylazide (DPPA) and $NaHCO_3$ at 0–4 °C.



198 199

Scheme 48. PFP = pentafluorophenol, DPPA = diphenylphosphorylazide.

The latter method also allows cyclization of the tetrapeptide H-Gly-(2Me)Phe-Aib-Gly-OH to the 12-membered cyclo[Gly-(2Me)Phe-Aib-Gly]. In this case, however, the yields achieved till now were only 20–25%. The major side reaction is cyclodimerization, which could not be completely suppressed even on dilution to 10^{-5} M.

The structures of the linear and cyclic pentapeptides **198** and **199** have been determined by X-ray crystallography (Fig. 7).[217] The linear compound **198** occurs in the crystalline state as a left-handed 3_{10}-helix, stabilized by two intramolecular hydrogen bonds (N(4)H···O(1) and N(5)H···O(2)).

The relatively rigid conformation of the cyclic compound **199** also shows two intramolecular hydrogen bonds, one of which is comparatively strong (N(1)H···O(3)), while the other appears to be relatively weak (N(3)H···O(3)).

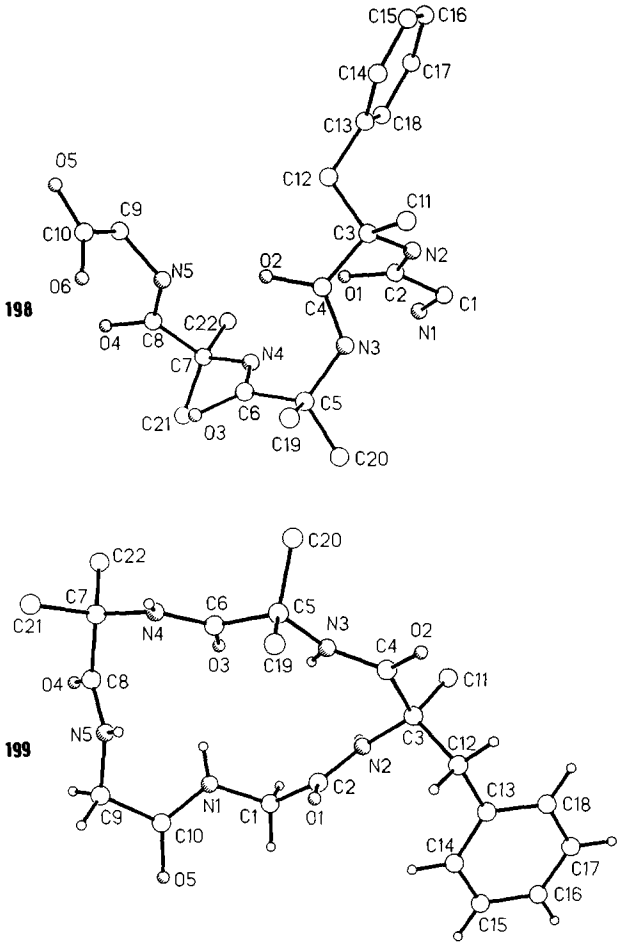


Fig. 7. Structures of the linear pentapeptide **198** (top) and the cyclic pentapeptide **199** (bottom) in the crystal.

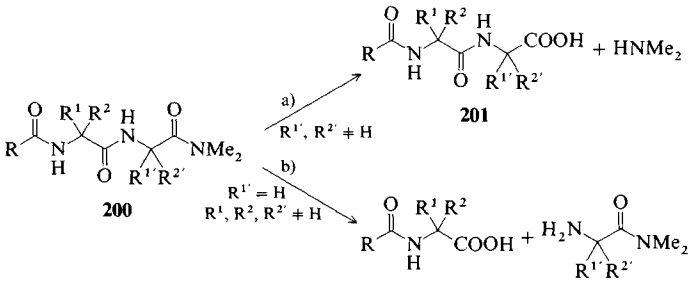
6.4. Resolution of Racemic α,α-Disubstituted α-Amino Acids via Diastereomeric Dipeptides

For the dipeptides **200**, the selective amide cleavage (HCl/$MeCN/H_2O$) described in Section 6.1.1 leads to the dipeptide acids **201** if the *C*-terminal amino acid is α,α-disubstituted ($R^{1'}$, $R^{2'} \neq H$; Scheme 49, path a). On the other hand, if

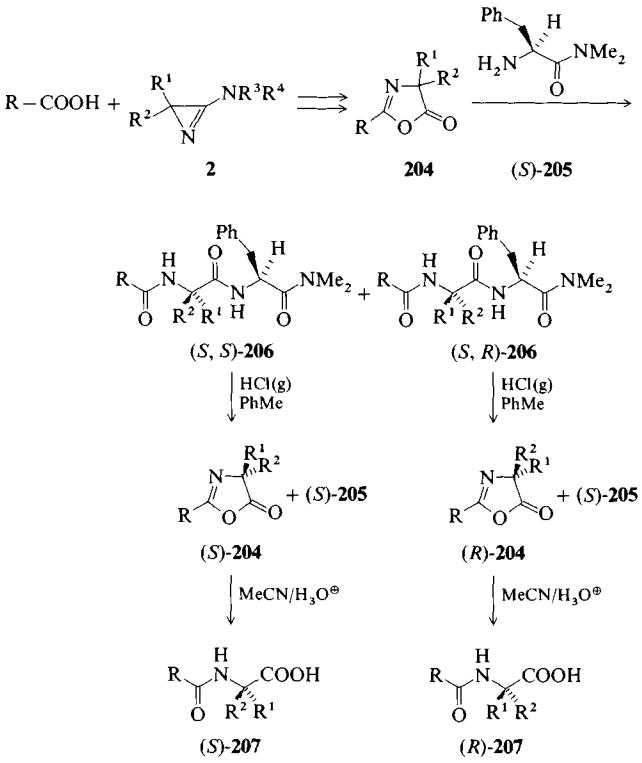


Scheme 49.

the terminal amino acid is monosubstituted and the penultimate one is disubstituted (R^1, R^2, $R^{1'} \neq H$), a selective cleavage of the *C*-terminal amino acid **203** is observed under the same conditions (path b).[73, 150, 166]

On the basis of type b selective cleavage, a resolution of racemic α,α-disubstituted α-amino acids has been developed, following the sequence below:

1. The racemic, *N*-acylated, α,α-disubstituted α-amino acid (in the form of the oxalone **204**) is coupled to the *N*,*N*-dimethylamide of an enantiomerically pure, monosubstituted α-amino acid (e.g. Phe-NMe_2, (*S*)-**205**).
2. The diastereomeric dipeptides thus formed (e.g. (*S*, *S*)- and (*S*, *R*)-**206**) are separated by chromatography.
3. The separated diastereomeric dipeptides are degraded by means of selective amide cleavage into the enantiomerically pure α,α-disubstituted α-amino acids (e.g. (*S*)- and (*R*)-**207**) and the unchanged chiral auxiliary.



Scheme 50. R^1, R^2 = alkyl; $R^1 > R^2$

This concept has been tested successfully with *N*,*N*-dimethylphenylalanine amide (Phe-NMe_2) and *N*,*N*-dimethyl-N^{α}-phenylalanylphenylalanine amide (Phe-Phe-NMe_2) as chiral auxiliaries, and a series of different α,α-disubstituted α-amino acids (Scheme 50).[218, 219] The 4,4-disubstituted 1,3-oxazol-5(4*H*)-ones **204** used for coupling with the chiral auxiliary were synthesized via the 3-amino-2*H*-azirines **2**, from ketones via hydantoins, or by alkylation of 4-monosubstituted 1,3-oxazol-5(4*H*)-ones. In most cases, separation of diastereomers (*S*, *S*)-**206** and (*S*, *R*)-**206** can be effected by "flash chromatography" on silica gel.[220] Thus, for example, the dipeptides **206** with R^1, R^2 = $PhCH_2$, Me were isolated in 42% and 40% yield, based on **204**. Hydrolysis to the enantiomerically pure *N*-acyl amino acids (*S*)-**207** (R^1 = $PhCH_2$, R^2 = Me; 89%) and (*R*)-**207** (85%) proceeds smoothly at 70 °C, and ca. 80% of the chiral auxiliary can be recovered. The enantiomeric methyl esters, for example, can be obtained in a similar manner if one treats the

separated dipeptides in methanol with HCl gas. With a suspension of (*S*,*S*)- or (*R*, *S*)-**206** in toluene, bubbling HCl gas affords the enantiomeric 4,4-disubstituted 1,3-oxazol-5(4*H*)-ones.

7. Summary and Outlook

The 3-amino-2*H*-azirines **2** have proved themselves to be reactive synthetic intermediates suited for a wide variety of uses. The reactions that they undergo with carboxylic acids, NH-acidic heterocycles and other protic acids proceed with cleavage of the C–N double bond to give α,α-disubstituted α-amino acid derivatives. Nonproteinogenic amino acids of this nature occur in several biologically active heterocycles such as herbicides, and the chemistry of 3-amino-2*H*-azirines offers a convenient pathway for building these amino acid fragments into known and novel heterocycles. However, some of the transformations with the NH-acidic heterocycles studied have led to surprising results. The elucidation of the mechanisms of these reactions, which all proceed via a zwitterion as the key intermediate, has contributed greatly to the understanding of the reactivity of three-membered, cyclic amidines. In certain cases, however, a confident prediction of the course of a reaction is still difficult.

This is not the case, however, for the use of 3-amino-2*H*-azirines as synthons for α,α-disubstituted α-amino acids in the synthesis of peptides and peptidelike compounds. Reactions with amino acids or peptides generally lead to coupling products, that is, to the peptide extended by one α,α-disubstituted α-amino acid. This coupling takes place under very mild conditions, with no additional reagents, and affords high yields. Together with the selective hydrolysis to the peptide acid and Lewis acid catalyzed coupling via 1,3-oxazol-5(4*H*)-ones (also under mild conditions, and without epimerization), this reaction makes a very useful extension to the repertoire of peptide synthesis. This procedure, described by us as the "azirine/oxazolone method", is especially attractive for the synthesis of peptaibols, cyclic depsipeptides (peptolides) and oligopeptides that occur in relatively rigid conformations.

This last aspect is of particular importance, since as well as studies of the relationship between structure, conformation and biological activity, one of the most ambitious aims in peptide chemistry is the construction of artificial proteins with "tailormade" physical and chemical characteristics. One prerequisite for the synthesis of such proteins is the availability of oligopeptide fragments with "stable secondary structure" as building blocks. The α,α-disubstituted α-amino acids strongly induce β turns, and could be suitable for constructing β-turn subunits, which serve as recognition patterns for triggering immunological, endocrine and metabolic reactions. The "azirine/oxazolone method" can play a significant role in constructing such compounds. This synthetic strategy will gain greatly in importance as soon as enantiomerically pure 3-amino-2*H*-azirines become available.

My thanks are due to Zürich University, the Swiss National Science Foundation, F. Hoffmann–La Roche AG, Basel, the Prof.-Hans-E.-Schmid-Stiftung, the Anna-Feddersen-Wagner-Fonds and the Stipendienfonds der Basler Chemischen Industrie for financial support of our research and the doctoral students involved with it. In particular I would like to thank my committed and talented co-workers, whose names appear in the list of references. Their many ideas and their tireless efforts to realize these ideas experimentally, mainly as doctoral and diploma students, have produced the results that are described in this article.

[107] The twofold substitution at C(2) severely restricts the conformational freedom of these amino acids and their derivatives [101, 108–113]. While the conformationally allowed areas for Ala in the Ramachandran diagram [114] still make up ~ 15% of the total area, for Aib this value is below 0.5% [115].

[125] However, such an attack on the S atom is observed in the smooth reaction of **2a** with tosyl chloride, which, in analogy to the reactions with carboxylic acid chlorides, affords N^1,N^1,2-trimethyl-N^2-tosylacrylamidine [65].

Pulsed Electron Spin Resonance Spectroscopy: Basic Principles, Techniques, and Examples of Applications

New Analytical Methods (43)

By Arthur Schweiger*

Electron spin resonance (ESR) spectroscopy has recently undergone a major innovative advance, which is described by the magical phrase *pulsed ESR*. To the spectroscopist who rubs this Aladdin's lamp there now opens up the mysterious world of spin acrobatics with its many novel and surprising phenomena. The use of pulse techniques makes it possible to reduce measurement times, increase sensitivity, improve resolution and simplify spectra. This article describes the most important pulse techniques used in ESR spectroscopy. Mathematical descriptions are kept to a minimum, space being devoted instead to examples of applications in various areas of chemical research.

1. Introduction

Today, ESR spectroscopy counts among the most important methods for investigating the structure and dynamics of paramagnetic compounds.[1-4] It is very sensitive and specific and has therefore been used with great success for many years in chemistry, physics, biology, and mineralogy.

Until recently the conventional CW (continuous wave) methods of measurement prevailed in ESR spectroscopy. This contrasts with the situation in applied NMR spectroscopy, where the CW methods have been almost entirely superseded by an impressive variety of elegant pulse methods.[5,6] Although pulse methods were introduced in ESR spectroscopy at about the same time as in NMR, for nearly thirty years this field of work has only been seriously followed by a very small number of research groups.[7,8] This initial reluctance is probably explained by the expensive instrumentation needed and the lack of sufficiently fast digital electronics. However, the situation has changed radically within the last few years. Pulsed ESR spectroscopy is a field of research which has now emerged from its former shadowy existence and is undergoing extraordinarily rapid development.[9-22] One can now build a pulsed ESR spectrometer using components that are mostly commercially available.[10,23-29] A fully developed commercial instrument has recently come onto the market.[30]

There is now scarcely a single topic area of ESR spectroscopy that is not ripe for being permanently affected by the various pulse methods. Techniques of particular importance include time-resolved ESR spectroscopy,[31-33] methods for measuring relaxation times,[9,13,34,35] techniques for studying molecular motions,[9] electron-electron double resonance,[36-41] electron-nuclear double resonance,[42-45] and ESR imaging.[46-49]

This account begins with a short description of CW ESR spectroscopy (Section 2). It aims to remind the reader of the physical basis of electron spin resonance and to provide the background knowledge needed for the sections that follow. The next two sections give a systematic survey of the most important pulsed ESR methods. Section 3 introduces the basic features of pulsed ESR spectroscopy and explains these principles in greater detail with the help of some examples of applications. Section 4 describes a number of pulsed ESR techniques that have been developed only recently, and whose applications potential has not yet been fully exploited. These include both methods that have been adapted from nuclear magnetic resonance and others that specifically take into account the special requirements of ESR.

2. CW Methods in Electron Spin Resonance

2.1. Conventional ESR Spectroscopy

The ESR spectrum of a paramagnetic compound in an external magnetic field B_0 can be described by a Hamiltonian of the form (1).[1-4] The electronic Zeeman operator $\mathcal{H}_{EZ}$

$$\mathcal{H} = \mathcal{H}_{EZ} + \mathcal{H}_F + \mathcal{H}_{HFS} + \mathcal{H}_Q + \mathcal{H}_{NZ} \quad (1)$$

includes the interaction of the electron spin with the external field $\boldsymbol{B}_0$. As the Zeeman energy can also be affected by orbital magnetic moments, the term $\mathcal{H}_{EZ}$ often yields information about excited electronic states and about the symmetry of the environment of a paramagnetic center. The fine structure term $\mathcal{H}_F$ describes the interaction between two or more electron spins, e.g. in triplet states or in compounds containing transition metal ions. The term $\mathcal{H}_{HFS}$ describes the hyperfine interaction between the electron spin and the nuclear spins. Here a distinction is made between the isotropic coupling (Fermi contact term), which arises from the finite probability of the electron being located at the position of the nucleus, and the anisotropic dipolar coupling, which includes the interaction between the magnetic moments of the electron and of the nucleus. The terms $\mathcal{H}_Q$ and $\mathcal{H}_{NZ}$ describe the nuclear quadrupolar energy and the nuclear Zeeman energy respectively. These two quantities are of secondary importance in ESR spectroscopy, since they generally cause only very small shifts in the resonance frequencies.

The static variables specified in Equation (1) contain a wealth of information about the geometrical and electronic structure of a paramagnetic compound.

In the following we consider a simple model system consisting only of one electron spin and one nucleus with spin

$I = 1/2$. The distance between the nucleus and the electron, which is regarded as a point charge, is assumed to be $r = 0.26$ nm, the isotropic coupling is given by $a_{iso}/2\pi = 6$ MHz, and the line joining the electron and the nucleus is assumed to be inclined at an angle θ to the direction of the external field $\boldsymbol{B}_0$ (Fig. 1a). We can further assume, without loss of generality, that the nucleus lies in the xz plane of the laboratory coordinate system. In this article we shall return frequently to this model system in explaining the various techniques.

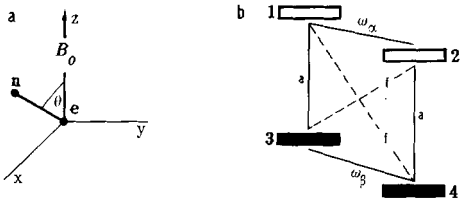

Fig. 1. a) Parameters describing the model system used frequently in this article, consisting of an electron spin (e) and a nucleus with spin $I = 1/2$ (n). x, y, z is the laboratory coordinate system. b) Four-level scheme showing the two allowed ESR transitions (a) and the two forbidden ESR transitions (f), and the NMR (ENDOR) frequencies ω_α and ω_β.

The Hamiltonian for an isotropic g-tensor (expressed in angular frequencies) then has the form (2) in which the elec-

$$\begin{aligned}\mathcal{H} &= \mathcal{H}_{EZ} + \mathcal{H}_{HFS} + \mathcal{H}_{NZ} \\ &= \omega_S S_z + A S_z I_z + B S_z I_x - \omega_I I_z,\end{aligned} \tag{2}$$

tron and nuclear Zeeman frequencies are $\omega_s = g_e\beta_e B_0/\hbar$ and $\omega_I = g_n\beta_n B_0/\hbar$ respectively, and the quantities A and B are defined as in (3).

$$A = A_\parallel \cos^2\theta + A_\perp \sin^2\theta, \quad B = (A_\parallel - A_\perp)\sin\theta\cos\theta \tag{3}$$

The quantities $A_\parallel = A_\parallel^d + a_{iso}$ and $A_\perp = A_\perp^d + a_{iso}$ in (3) describe the principal axis values of the axially symmetric hyperfine tensor with the dipolar components $A_\parallel^d$ and $A_\perp^d$.

In the corresponding energy level scheme (Fig. 1b) four ESR transitions can be distinguished: two "allowed" transitions (ω_{13}, ω_{24}) in which only the magnetic quantum number m_S changes ($\Delta m_S = \pm 1$, $\Delta m_I = 0$), and two "forbidden" transitions (ω_{23}, ω_{14}) for which $\Delta m_S = \pm 1$ and $\Delta m_I = \pm 1$. The corresponding ESR frequencies are collected in (4),[50]

$$\begin{aligned}\omega_{13} &= \omega_S - \omega_-/2 \\ \omega_{24} &= \omega_S + \omega_-/2 \\ \omega_{23} &= \omega_S - \omega_+/2 \\ \omega_{14} &= \omega_S + \omega_+/2\end{aligned} \tag{4}$$

in which $\omega_+ = \omega_\alpha + \omega_\beta$, $\omega_- = \omega_\alpha - \omega_\beta$, the nuclear frequencies ω_α and ω_β being given by:

$$\begin{aligned}\omega_\alpha &= \left[\left(\frac{A}{2} - \omega_I\right)^2 + \left(\frac{B}{2}\right)^2\right]^{1/2} \\ \omega_\beta &= \left[\left(\frac{A}{2} + \omega_I\right)^2 + \left(\frac{B}{2}\right)^2\right]^{1/2}\end{aligned} \tag{5}$$

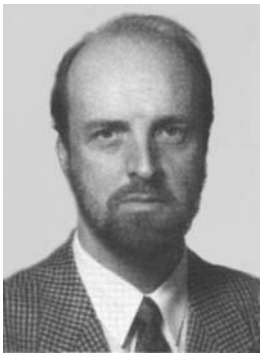
From the transition probabilities for the allowed (I_a) and forbidden (I_f) ESR transitions, which are given by the expressions in (6) with $\sin\varphi_\alpha = B/\omega_\alpha$ and $\sin\varphi_\beta = B/\omega_\beta$, it follows that the "forbidden" transitions can only take place if the quantity B [see (3)] differs from zero.

$$\begin{aligned}I_a &= \cos^2[(\varphi_\alpha + \varphi_\beta)/2] \\ I_f &= \sin^2[(\varphi_\alpha + \varphi_\beta)/2]\end{aligned} \tag{6}$$

The ESR spectrum of our model system with $\theta = 45°$ is shown in Figure 2a. Here it is assumed, as is usual in ESR spectroscopy, that the field B_0 is varied while the frequency ω_{mw} of the irradiating field, which lies in the microwave (mw) region, is held constant ($\omega_{mw}/2\pi = 9.2$ GHz). The hyperfine splitting[*] $a = \omega_-$ of the two allowed transitions, expressed in frequency units, is 8 MHz for the chosen geometry, whereas the frequency difference between the two forbidden lines is about $2\omega_I/2\pi = 28$ MHz. Owing to the large line widths it is seldom possible to observe forbidden transitions in an ESR spectrum; however, they provide the basis for several important pulsed ESR techniques.

In a disordered system such as a powder or a frozen solution, the ESR spectrum consists of a superposition of the spectra arising from all possible orientations of the electron-

[*] The splitting of ESR signals caused by the hyperfine coupling is customarily referred to as the hyperfine splitting, despite the fact that in the solid phase the quantity a also includes a contribution from the nuclear Zeeman interaction.



Arthur Schweiger was born in Zürich, Switzerland, in 1946 and studied physics at the Swiss Federal Institute of Technology (ETH) in Zürich. He received his Ph.D. under the guidance of Hans Günthard at the ETH in 1976. From 1976 he was Oberassistent in the Laboratory of Physical Chemistry at ETH, where he habilitated in 1982. In 1985, he was awarded the Werner Prize of the Swiss Chemical Society. His major fields of interest are the development of new methods in ESR spectroscopy and the application of ESR in coordination chemistry.

nucleus axis relative to the field vector B_0. In calculating the powder spectrum shown in Figure 2b an axially symmetric g-tensor was used. The hyperfine coupling is only resolved in the case where B_0 is along the direction of the principal axis $A_{\parallel}$. Furthermore, in Figure 2b the ESR spectrum is shown as the first derivative of the absorption signal, which is the usual convention with the CW method of recording.

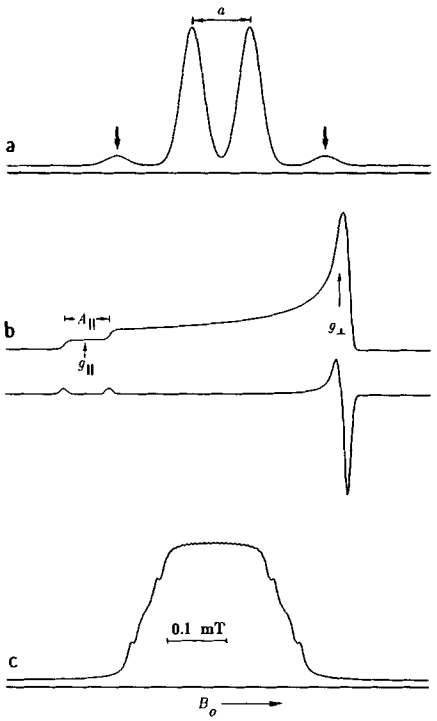


Fig. 2. Typical ESR spectra. a) Single crystal ESR spectrum with two allowed and two forbidden transitions (the two forbidden transitions are indicated by arrows). b) Powder ESR spectrum (absorption spectrum (top) and first derivative (bottom)) of the model system (Fig. 1a) with an axially symmetric g-tensor ($g_{\parallel} = 2.02, g_{\perp} = 2.00$; the g-tensor and the hyperfine tensor are coaxial, the rest of the parameters are as in the model system). c) ESR spectrum of an isotropic system (e.g. in solution), consisting of six nuclei with spin $I = 1/2$ and hyperfine coupling constants $a = 1$, 1.5, 2, 3, 4 and 8 MHz. The 64 signals are not resolved.

Usually the unpaired electron is surrounded by a large number of magnetic nuclei. Since the number of lines increases multiplicatively with the number of magnetic nuclei as a consequence of the ESR selection rules, usually only a small number of hyperfine interactions are resolved in the ESR spectrum. This is illustrated in Figure 2c for the example of a spin system with six nuclei each with $I = 1/2$ (number of lines $= 2^6 = 64$). The spectrum consists of one peak with almost no structure. Inhomogeneously broadened spectra of this sort are, unfortunately, the general rule in solids. This unsatisfactory situation is often made even worse by additional broadening mechanisms, for example the so-called strain effect.[51]

2.2. Electron-Nuclear Double Resonance Spectroscopy

Electron-nuclear double resonance (ENDOR) spectroscopy offers a way around this problem by giving a dramatic increase in resolution.[52-59] The success of the ENDOR method depends on being able to saturate one of the ESR lines with an intense MW field. A second irradiating field in the radiofrequency region induces nuclear spin transitions, thereby altering the populations of the energy levels, and this change is detected by observing changes in the polarization of the saturated ESR transition. Thus, in the ENDOR technique the NMR spectrum in the two m_S states of a paramagnetic compound is measured indirectly via the electron spin. The ENDOR spectrum of our model system with $\theta = 45°$ is shown in Figure 3a. The two resonance lines at ω_{α} and ω_{β} again show a splitting of $a = \omega_{-}$.

As a result of the different selection rules the number of lines now only increases in an additive (linear) way with the number of nuclei. This means that even in complex spin systems with many nuclei the ENDOR spectrum is usually still quite simple. For example, the ENDOR spectrum of the spin system with six nuclei consists of only $2 \times 6 = 12$ lines (Fig. 3b). Moreover, in the solid phase the quadrupolar couplings for nuclei with spin $I \geq 1$, i.e. those described by the operator $\mathcal{H}_Q$, are observed directly as splittings of the lines. It is therefore hardly surprising that ENDOR spectroscopy, with its extensive armory of special techniques,[54-56, 60] has developed into one of the most important methods of electron spin resonance. This method is always used in cases where poor resolution makes it impossible to determine the magnetic parameters from the ESR spectrum.

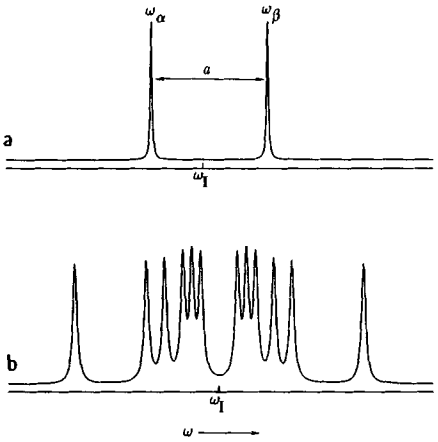

Fig. 3. a) Single crystal ENDOR spectrum of the model system (Fig. 1a). b) ENDOR spectrum of the system defined in Figure 2c. All six hyperfine couplings are resolved.

3. Summary of the Standard Procedures Used in Pulsed ESR Spectroscopy

In this section the standard techniques of pulsed ESR spectroscopy are described with the help of clear and simple vector diagrams. For a more rigorous mathematical description the reader is referred to several review articles and monographs.[5, 7, 9, 12]

3.1. Fourier Transform ESR Spectroscopy

3.1.1. Basic Principles

In an external magnetic field electron spins can assume either a parallel orientation (α state) or an antiparallel orientation (β state). The β state, which is lower in energy, has a larger population than the α state as a consequence of the equilibrium distribution, and this causes a macroscopic magnetization M_z to become established in the direction parallel to B_0. The behavior of this magnetization during a pulsed ESR experiment can be most easily described using a coordinate system which rotates with the frequency ω_{mw}. For this purpose the linearly polarized MW field is decomposed into two circularly polarized components. The component with the same direction of rotation as the coordinate system becomes time-independent as a result of this transformation; in the following discussion we assume that it is parallel to the x-axis of the rotating coordinate system. The effect of the other component which rotates with the frequency $(-2\omega_{mw})$ is in general negligible.

The result of applying a short intense MW pulse is to rotate the magnetization M_z through the flip angle $\beta = \gamma_e B_1 t_p = \omega_1 t_p$ in the plane perpendicular to the x-axis. Here γ_e is the gyromagnetic ratio of the electron spin, B_1 (ω_1) is the field intensity of the MW pulse, and t_p is the pulse duration. In the simplest type of pulsed ESR experiment a single pulse with a flip angle $\beta = 90°$ (called a 90° pulse) transforms the original longitudinal magnetization M_z into a transverse y-magnetization[*] (see also Fig. 4). If the resonance condition $\omega_{mw} = \gamma_e B_0$ is exactly fulfilled, the magnetization stays along the direction of the y-axis after the pulse. However, if the Larmor frequency $\omega = \gamma_e B_0$ does not exactly match the microwave frequency ω_{mw}, the magnetization starts to precess about the z-axis with the frequency $\Omega = \omega - \omega_{mw}$. Since the observer (i.e. the detection system) is aligned in the direction of the y-axis in the rotating coordinate system, the difference frequency Ω is measured directly. The oscillating signal, which decays owing to transverse relaxation or inhomogeneous line broadening, is called the free induction decay (FID). By performing a Fourier transformation (FT) into the frequency domain one obtains the spectrum, consisting of a peak at the frequency Ω.

This FT-ESR method[61-63] becomes of particular interest in a case where magnetic nuclei interact with the electron spin. To understand this we consider our simple model system in the liquid phase, which has a spectrum consisting of two resonance lines with a splitting a_{iso}. Here again a 90° pulse converts M_z into a y-magnetization. Immediately after the pulse the two magnetization vectors begin to precess about the z-axis with their different respective frequencies. Figure 4 shows the behavior of the magnetization in the rotating coordinate system, together with the resulting FID and the FT-ESR spectrum, which is identical to the CW ESR spectrum.

[*] The flip angle is always specified with reference to the on-resonance magnetization. Thus a 90° pulse turns M_z through exactly 90° into the y-direction. Off-resonance magnetization vectors, on the other hand, also contain x- and z-components after the 90° pulse. However, these additional components are irrelevant as regards the basic principles of pulsed ESR spectroscopy.

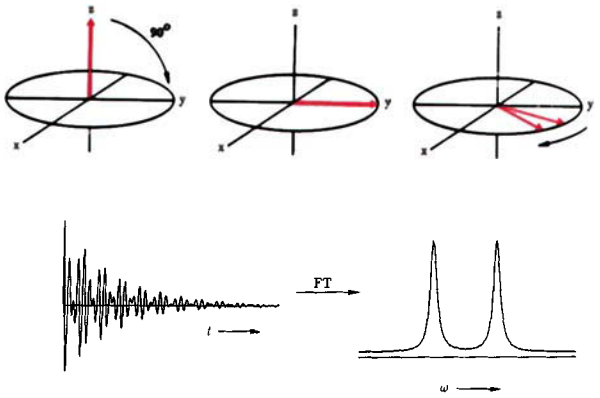

Fig. 4. Top: Evolution of the magnetization during an FT-ESR experiment on a system with $S = 1/2$ and $I = 1/2$. Bottom: FID and corresponding FT-ESR spectrum.

In principle, therefore, the FT-ESR method makes it possible to record the entire ESR spectrum within a few microseconds, whereas in the continuous wave (CW) method the spectrum has to be recorded by slow passage through the resonances.

In nuclear magnetic resonance it is usually possible to achieve complete and simultaneous excitation of the entire spectrum using a single short pulse. In the corresponding ESR experiment, however, this is only possible for a rather limited class of paramagnetic compounds. Problems arise in generating the short MW pulse, and from the limited bandwidth of the detection system and the necessity for very rapid data acquisition. To rotate the magnetization of a sample through 90° about the x-axis the MW field strength must satisfy the condition $B_1 \gg \Omega/\gamma_e$. However, this condition cannot be attained in practice for the majority of spin systems. Often instead only a portion of the spectrum is excited, and even within this partial spectrum there are x- and y-components in the magnetization, and consequently large distortions of intensity and phase. This unsatisfactory situation can be improved to some extent by using quadrature detection.[5,6] In this technique one measures both transverse components of the magnetization, thereby increasing the detector bandwidth by a factor of two. A further problem is that the dead time τ_D of the pulsed ESR spectrometer prevents one from observing the FID during the first 50–100 ns after the 90° pulse. It is therefore not possible to measure broad resonance lines. Consequently it is unlikely in the foreseeable future that FT-ESR could be used to study compounds containing transition metal ions.

The current state of the art in the FT-ESR method is illustrated in Figure 5a by the example of the three-line spectrum of a nitroxide radical in solution at room temperature.[61] The bandwidth of about 200 MHz needed to obtain this spectrum was made possible by using a special probe head known as a bridged loop-gap resonator.[28]

3.1.2. Example of an Application

FT-ESR spectroscopy has now reached a stage of development such as to make it an important research tool for many investigators working in the area of free radical chemistry.

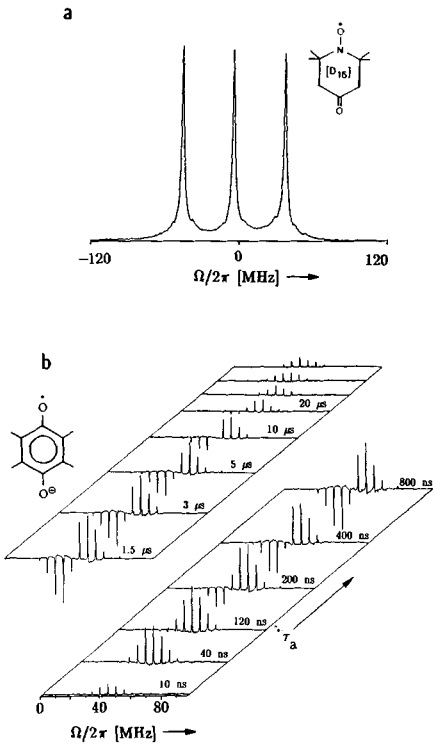

Fig. 5. a) FT-ESR spectrum of perdeuterated tempone in [D_8]toluene (1.5×10^{-4} M) at 22 °C. Duration of the 90° pulse: 6.7 ns; quadrature detection (Ref. [61]). b) FT-ESR spectra of $DQ^{\ominus}$ at 245 K as a function of the interval τ_a between the laser pulse and the 90° MW pulse (upper peaks: absorption; lower peaks: emission) (Ref. [65]).

This applies especially to studies of short-lived paramagnetic species.[64–66] To illustrate this we choose as an example an FT-ESR study of the spin dynamics of the duroquinone radical ion ($DQ^{\ominus}$), which is formed by electron transfer from photoexcited tetraphenylporphyrinatozinc (ZnTPP).[65, 66] Figure 5b shows FT-ESR spectra of $DQ^{\ominus}$ as a function of the time τ_a between a short laser pulse (15 ns), which excites the ZnTPP into the triplet state, and the 90° MW pulse. Up to a τ_a value of about 1 μs the intensities of the peaks continue to increase and the lines on the low-field side become emissive to an increasing extent. Between 1 and 10 μs the signal intensity decreases while the population distribution remains approximately constant, then for greater values of τ_a the emission peaks finally change again into absorption peaks. Detailed information of this kind about the intensity profiles and time variation of the different hyperfine lines makes it possible to seperate the various spin polarization mechanisms, thereby providing a basis for a better understanding of the underlying electron transfer process.

Some alternative FT-ESR spectroscopic techniques, as well as their extension into two dimensions, will be described in Section 4.

3.2. Electron Spin-Echoes

3.2.1. *Basic Principles*

The rapid decay of the FID caused by inhomogeneous broadening can be reversed by performing a spin-echo experiment. This phenomenon, which was first described by *Hahn*[67] for the nuclear spin case, depends on the non-linear behavior of an ensemble of (classical or quantum-mechanical) oscillators with different frequencies. The sequence of events leading to the appearance of an electron spin-echo is shown in Figure 6a. In order to simplify the explanation of the spin-echo phenomenon we assume idealized MW pulses (infinitesimally short and of infinitely high intensity) which give complete and simultaneous excitation of the entire ESR spectrum.

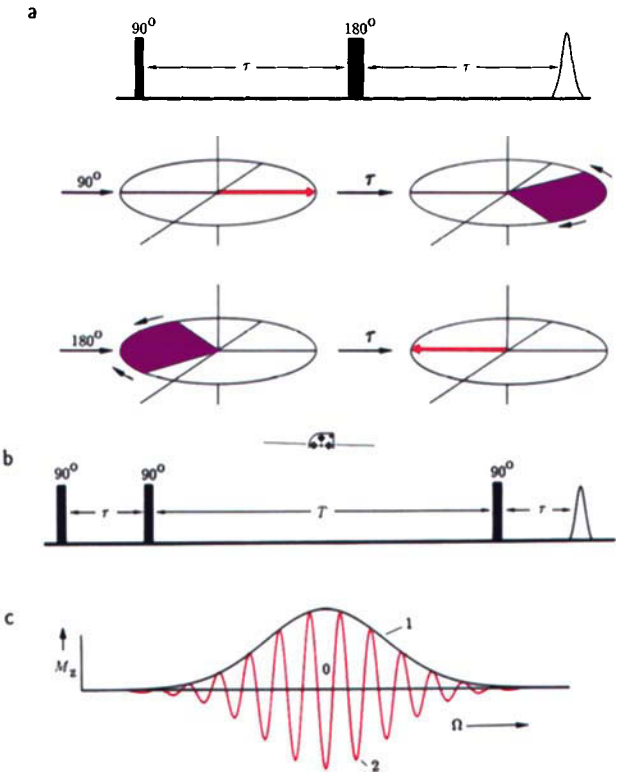

Fig. 6. a) Two-pulse echo sequence and evolution of the magnetization. b) Three-pulse sequence for producing a stimulated echo. c) Inhomogeneous ESR signal; 1: equilibrium condition, 2: z-magnetization pattern after the second 90° pulse.

As before, a magnetization along the y-direction is produced by a 90° pulse. Immediately after this pulse the different transverse magnetization vectors start to precess with their individual frequencies $\Omega_i = \omega_i - \omega_{mw}$, so that the FID decays rapidly, and after a short time there is no detectable signal. After a time interval τ a second MW pulse turns the magnetization vectors through 180° about the x-axis. Since the directions of rotation of the individual components remain unaltered after this refocussing pulse, after a further time interval τ all the vectors are aligned along the $(-y)$-direction. The resulting $(-y)$-magnetization, which builds up and decays again within a short time, is called a spin-echo. The amplitude of this two-pulse echo is a function of the pulse interval τ, and its rate of decay is described by the phase memory time T_M.[*] In solids T_M is usually only a few microseconds, even at low temperatures.

[*] The phase memory time T_M is defined as the time taken for the echo amplitude to decay to $1/e$ of its initial value. In a case where the echo amplitude decays exponentially, T_M corresponds to the transverse relaxation time T_2.

The pulse sequence $90°-\tau-180°-\tau$ is the simplest one that can be used to generate an echo. A second pulse sequence which is often used consists of three 90° pulses (Fig. 6b). In this three-pulse sequence with pulse intervals τ and T a so-called *stimulated* echo is formed after an interval τ following the third pulse. The rather complicated mechanism by which this echo is formed can be best understood if we begin by considering more closely the effects of the first two 90° pulses on the spin system.[68] During the dephasing period which follows the first pulse the transverse magnetization again spreads out in the xy-plane. After the time τ the on-resonance magnetization, and also all the magnetization vectors with off-resonance frequencies $\Omega = 2\pi n/\tau$, are aligned along the y-direction. These are then turned through a further 90° by the second 90° pulse, so that the overall effect on these vectors is an inversion. Magnetization vectors with off-resonance frequencies $\Omega = (2n-1)\pi/\tau$ precess through an angle of $\pm(2n-1)\pi$ during the time τ, and are turned back into the z-direction by the second pulse. Magnetization vectors with $\Omega = (2n-1)\pi/2\tau$ are oriented along the $(\pm x)$-direction after the time τ, and cannot be affected by a second x-pulse. Thus, the sequence $90°-\tau-90°$ generates from the inhomogeneous ESR line an M_Z pattern in the frequency domain which oscillates with the period $2\pi/\tau$ (Fig. 6c). The lifetime of this periodic pattern is determined by the longitudinal relaxation time T_1 of the electron spin, which can be as much as several hundred microseconds at low temperatures. A third 90° pulse applied after a time $T \leq T_1$ generates the FID of this M_Z pattern; it consists of a single peak at a time τ after the pulse and is called a stimulated echo.

The three-pulse sequence also generates several two-pulse echoes, but these can be eliminated by means of a phase cycle.[69] In this procedure the phases of the MW pulses are varied systematically in a succession of experiments and the data from the individual measurements are suitably combined.[5, 6] Just as in nuclear magnetic resonance, such phase cycles are very important in pulsed ESR as a way of suppressing unwanted contributions to the time-domain signal.[70]

Since ESR spectra are often poorly resolved, the FID, and therefore also the spin echo, shows little structure in these cases. For this reason the *amplitude* of the echo is used as the main source of information in spin-echo experiments. This amplitude depends on a number of variables such as the static field strength B_0, the time interval between the MW pulses, or the time between generating a paramagnetic species and applying the pulse sequence. Modulation effects on the amplitudes of the echoes are specifically treated in Section 3.3.

Echo-Detected ESR Spectroscopy

Measuring the intensity of the two-pulse or three-pulse echo as a function of B_0 can be used as an alternative to CW ESR spectroscopy. There are two ways whereby such an echo-detected ESR spectrum can be recorded free from distorting effects. One either measures the maximum echo amplitude using pulses whose duration t_p is larger than the reciprocal resolution $2\pi/\Delta\omega$, or alternatively one measures the integral over the echo (without restriction as to the pulse duration), using an integration window t_i which satisfies the condition $t_i > 2\pi/\Delta\omega$.[30] Figure 7 shows an echo-detected ESR spectrum of a sample of the one-dimensional organic conductor $[(\text{fluoranthene})_2]^{\oplus}PF_6^{\ominus}$ in powder form, recorded at a microwave frequency of 95 GHz (corresponding to a field strength $B_0 = 3.4$ T).[71] The unusually high resonance frequency makes it possible to easily resolve the very small anisotropy of the g-tensor in this compound ($g_\perp/g_\parallel = 1.00018$).[72]

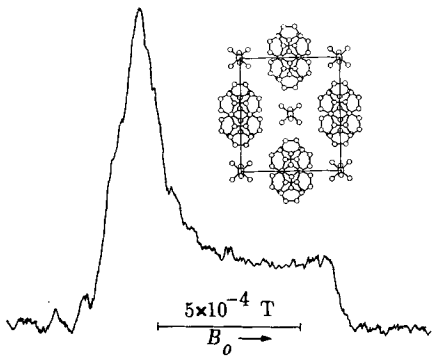

Fig. 7. Echo-detected ESR spectrum of the one-dimensional conductor $[(\text{fluoranthene})_2]^{\oplus}PF_6^{\ominus}$, measured at a microwave frequency of 95 GHz (Ref. [71]).

Echo-detected ESR spectroscopy has some advantages compared with the more usual CW ESR method. This is seen in a particularly impressive way in investigations of short-lived free radicals such as those generated by a laser pulse. The time resolution achieved by this method is determined solely by the interval τ_a between the laser pulse and the first MW pulse. Thus the echo-detected ESR spectrum gives an instantaneous snapshot of the state of a spin system at any instant $t_a \geq 0$.

Measuring the ESR spectrum by means of the echo amplitude is also superior to the usual CW method for stable paramagnetic compounds with very broad ESR lines, such as often occur with polycrystalline samples of compounds containing transition metal ions. This is due to the fact that in the CW method a field modulation is used to generate the first derivative of the absorption spectrum. The available modulation amplitude is often too small compared with the width of the ESR line to measure small changes in the gradient of the absorption spectrum with adequate sensitivity. In contrast to this, the echo method enables one to directly measure the z-magnetization at each point in the spectrum. However, the interaction between the electron spin and the nuclear spins can affect the amplitude of the echo (Section 3.3), and consequently there is a possibility that the line shape may be distorted when measuring powder ESR spectra by the echo-detection method.[73, 74]

Measuring Rates of Chemical Reactions

To obtain data on the kinetics of a short-lived free radical one measures the intensity of an individual ESR line as a function of the time τ_a between the formation of the radical and the first MW pulse. This time profile not only describes the formation and decay of a radical, but also contains information about transient phenomena, for example effects

caused by chemically induced dynamic electron spin polarization (CIDEP).

The Determination of Relaxation Times

The most direct way of measuring relaxation times is that based on echo methods, since in this procedure all the types of interactions that can cause inhomogeneous broadening undergo refocussing. This makes it easy to separate static inhomogeneous contributions to the line width from homogeneous broadening caused by dynamic effects.

The phase memory time T_M is usually determined by measuring the decay of the two-pulse echo as a function of the pulse interval τ. Figure 8a shows the result of such a T_M measurement on a coal sample.[30] If the MW pulse is only capable of exciting a portion of the ESR spectrum, it is possible for some of the transverse magnetization to be lost through spectral diffusion, i.e. as a result of a "leakage" of magnetization into adjacent parts of the spectrum that have not been excited by the MW pulse. This spectral diffusion can be prevented by using a pulse sequence consisting of a 90° pulse followed by a periodic refocussing pulse pattern of the form $(\tau - 180° - \tau)n$; this generates a series of echoes at the times $2m\tau$ ($m = 1,2,\ldots n$).[75] However, with this sequence even small deviations from the optimal setting of the flip angle cause an additional damping of the echo. So as to minimize the cumulative effect of these errors, it is usual to shift the phase of the 180° pulse sequence through 90° relative to that of the 90° pulse.[76] In the case of the coal sample the phase memory time measured using this *Carr-Purcell-Meiboom-Gill* pulse sequence (Fig. 8b) was found to be considerably greater than the value obtained with the simple two-pulse sequence.

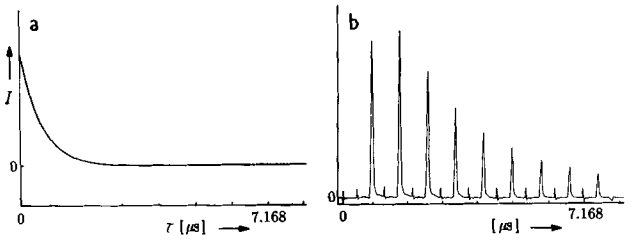

Fig. 8. a) Decay of the two-pulse echo from a coal sample at room temperature as a function of the pulse interval τ. b) Carr-Purcell-Meiboom-Gill multiple echo pattern of the same coal sample (Ref. [30]). I = echo intensity.

For measuring the spin-lattice relaxation time T_1 a number of pulse methods are available. In principle T_1 can be determined from the amplitude of the stimulated echo, as the z-magnetization relaxes towards thermal equilibrium during the variable time T. However, it must be remembered that the first two 90° pulses produce an M_Z pattern (Fig. 6b) with an oscillation frequency which increases with increasing τ. As a result of this, portions of the ESR spectrum with inverted magnetization are immediately adjacent to portions with an unaltered equilibrium magnetization. Consequently the measurement of T_1 is again subject to errors caused by spectral diffusion, since any loss of polarization via non-resonating spins causes the echo amplitude to decay more rapidly.[13]

To avoid spectral diffusion when measuring T_1, the entire ESR spectrum must be saturated ($M_Z = 0$) or inverted ($M_Z = -M_0$), or the width of the excited portion of the ESR spectrum must be greater than the excitation width of the reading pulses that are applied after the time T. Several T_1-measuring pulse sequences whereby spectral diffusion can be partially or completely suppressed are compared in Figure 9. A long pulse or a succession of many short 90° pulses saturates a broad region of the ESR spectrum, as there is then sufficient time for the spectral diffusion to reach adjacent non-resonating parts of the spectrum (Fig. 9a). In the ideal case this results in complete saturation of the ESR signal (saturation recovery method). The measurement of the z-magnetization after the time T is achieved either by a two-pulse echo or by recording the FID, whose duration for broad ESR lines corresponds to the duration of the reading pulse.[77]

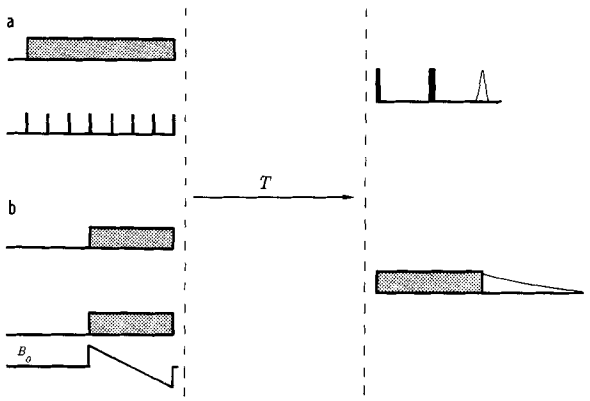

Fig. 9. Pulse sequences for measuring the spin-lattice relaxation time T_1. Left: preparation sequence; right: detection sequence. a) Saturation. b) Inversion.

An alternative method (inversion recovery) uses a 180° excitation pulse. To avoid spectral diffusion in this case one should either use a 180° pulse that is appreciably harder (i.e. of higher intensity and shorter duration) than the reading pulses, or rapidly sweep the field B_0 through a broad spectral range so as to increase the width of the excited region (Fig. 9b).

Other methods in which a weak CW microwave field is used to monitor the recovery from saturation are described in the literature.[78]

3.2.2. *Examples of Applications*

Figure 10 shows an example of the use of electron spin-echoes to observe very rapid processes.[79] The echo-detected ESR spectrum of the benzosemiquinone radical in isopropanol shows a strong emission signal 80 ns after the radical is generated by a laser pulse (Fig. 10a); the appearance of this signal can be attributed to a triplet CIDEP mechanism. Its decay, measured as a function of the time interval τ_a, is mainly caused by spin-lattice relaxation (Fig. 10b).

Relaxation times form an important source of information on the dynamic behavior of a spin system. For example,

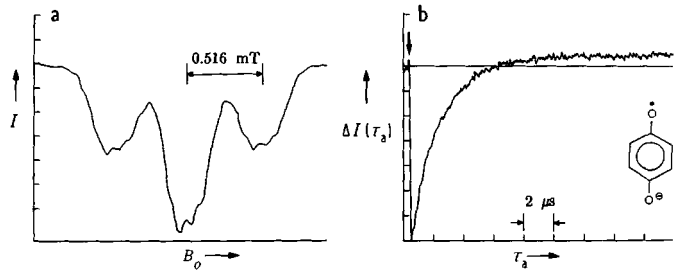

Fig. 10. Photolytically generated benzosemiquinone in 2-propanol. a) Echo-detected ESR spectrum, recorded 80 ns after the laser pulse. b) Decay of the central peak of the ESR spectrum as a function of the interval τ_a between the laser pulse and the first MW pulse; the arrow indicates the position of the laser pulse (Ref. [79]).

they can lead to conclusions about the nature of molecular motions in viscous solutions, characteristic phase transitions in solids, or the distances between paramagnetic centers. The importance of such measurements is illustrated here by three examples.

Crystals of triglycine sulfate (TGS) undergo a ferroelectric phase transition at the Curie temperature $T_C = 47\,^{\circ}C$. To study the dynamics of this transition in greater detail, stable free radicals produced by X-irradiation were used as paramagnetic probes and the relaxation times T_M and T_1 were measured in the region of T_C.[80] Both the longitudinal and transverse relaxation times show critical behavior near the Curie point (Fig. 11). The shortening of T_M can be explained in terms of fluctuations of the order parameter at the ferroelectric phase transition, while the increase of T_1 at the Curie point is due to coupling of the acoustic lattice modes to the ferroelectric relaxational mode.

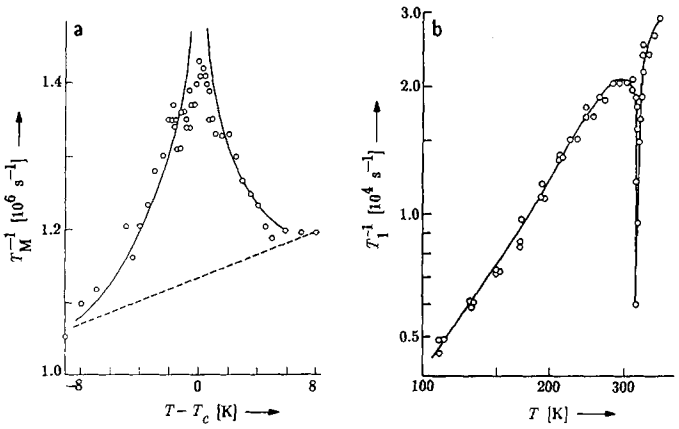

Fig. 11. Temperature anomaly near the Curie temperature T_c in the relaxation times of free radicals in irradiated triglycine sulfate (circles: experimental data, broken line: calculated dependence). a) Phase memory time T_M. b) Spin-lattice relaxation time T_1 (Ref. [80]).

Labeling large molecules with spin probes is a well-established ESR technique for investigating the dynamics of diamagnetic compounds.[81] It has recently been found[82] that the curve of the phase memory time T_M (or of the homogeneous line broadening T_M^{-1}) as a function of B_0 is characteristic of the type of reorientation process occurring.[83-85] The data are easiest to interpret in the form of normalized contour plots in which the shape of the homogeneously broadened line is represented as a function of B_0.

Figure 12 shows two such plots obtained from a model membrane labeled with cholestane as a spin probe.[83] These were produced by measuring the echo-detected two-pulse ESR spectra of the labeled multilayers for two different orientations and 50–60 different τ-values, and applying a Fourier transformation of the data with respect to τ for each field position. A comparison of the experimental data with model calculations shows that the dynamic behavior of this smectic phase can be described in terms of Brownian motion and a high degree of ordering.

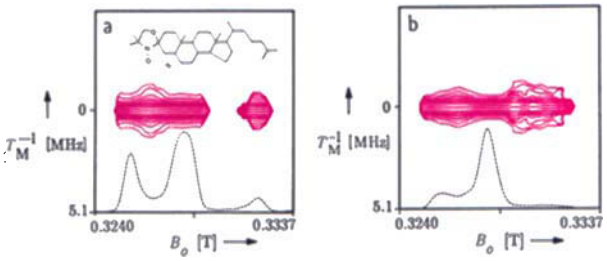

Fig. 12. Experimental contour diagrams of the homogeneous line broadening T_M^{-1} for the spin probe cholestane in orientated dipalmitoylphosphatidylcholine multilayers at $-20\,^{\circ}C$; broken line: spectrum at 0 MHz. Angle between B_0 and the direction of orientation of the multilayers was a) $\theta = 90°$, b) $\theta = 45°$ (Ref. [83]).

If the relaxation times of two paramagnetic centers are sufficiently different, their spectra can be easily separated using the echo-detected ESR method. Figure 13 illustrates this for the example of an undoped *cis/trans*-polyacetylene.[86] With a pulse interval of $\tau = 0.7$ μs the two-pulse ESR spectrum consists of a single structureless line with a width of 1.45 mT (Fig. 13a). For larger values of τ the intensity of this line diminishes rapidly, leaving behind a doublet with a splitting of 2.3 mT (Fig. 13b). The broad

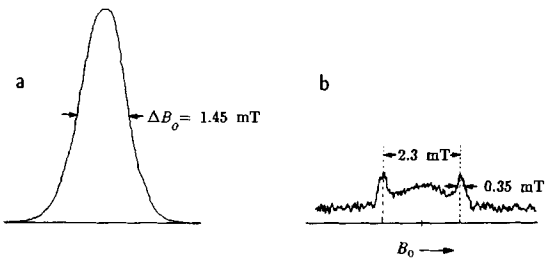

Fig. 13. Separation of overlapping ESR spectra using echo-detected ESR spectroscopy: the example is *cis/trans*-polyacetylene. a) Pulse interval $\tau = 0.7$ μs. b) $\tau = 1.82$ μs (Ref. [86]).

single-line spectrum (relaxation time $T_M = 0.425$ μs) is assigned to trapped solitons whose spin density is distributed over several CH units (Section 3.3.4). On the other hand, the doublet spectrum (with $T_M = 1.6$ μs) arises from a localized defect with a hyperfine coupling characteristic of a proton with sp^2 hybridization.

3.3. The Nuclear Modulation Effect

3.3.1. *Two-Pulse Echo Modulation*

In a two-pulse or three-pulse experiment in which τ or T is varied, the couplings between the electron spin and the nuclear spins can cause a modulation of the echo intensity.[87, 88] As this electron spin echo envelope modulation (ESEEM) can only occur if anisotropic interactions are present, it is only found in the solid phase. For the semiclassical description of the nuclear modulation effect which follows, we return again to our model system (Fig. 1a). The ESR spectrum, with lines corresponding to the two allowed transitions and the two forbidden transitions, is again shown schematically in Figure 14a. By applying sufficiently short MW pulses all four transitions are excited simultaneously, and in particular this includes pairs of transitions that originate from a common energy level.

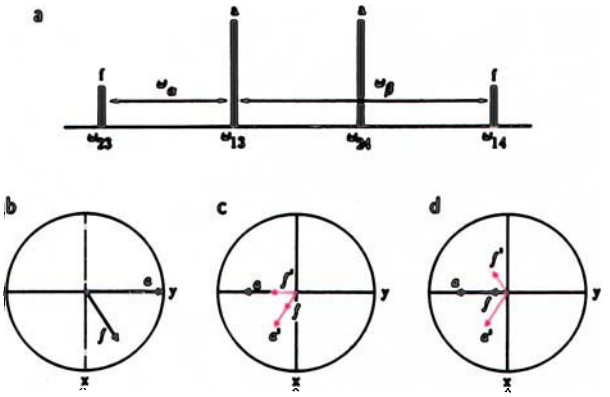

Fig. 14. Diagram illustrating the ESEEM effect. a) Schematic ESR spectrum for a spin system with $S = 1/2$ and $I = 1/2$ showing the two allowed transitions (a) and the two forbidden transitions (f). b) to d) Behavior of the magnetization of an allowed transition (ω_{13}) and of a forbidden transition (ω_{23}) during the two-pulse experiment with $\omega_{mw} = \omega_{13}$.

The way in which the echo modulation arises can easily be shown by means of vector diagrams (Fig. 14b–d).[89] To see this we will follow the behavior of the allowed a-transition ω_{13} and the forbidden f-transition ω_{23}, which both involve a common energy level 3, in a two-pulse experiment. We also assume that the resonance frequency of the allowed transition matches the MW frequency, i.e. $\omega_{13} = \omega_{mw}$. Immediately after the 90° pulse along the x-axis, the magnetization vectors corresponding to these two transitions are parallel to the y-axis. During the first evolution period the orientation of the vector $\boldsymbol{a}$ remains unaltered, whereas the vector $\boldsymbol{f}$ precesses with the frequency $\omega_\alpha = (\omega_{23} - \omega_{13})$ (Fig. 14b). After the time τ the 180° pulse turns the vector $\boldsymbol{a}$ into the $(-y)$-direction, and at the same time gives rise to a new component $\boldsymbol{f}'$. The vector $\boldsymbol{f}$ behaves in an analogous way (Fig. 14c). In the second evolution period the orientation of the vectors $\boldsymbol{a}$ and $\boldsymbol{a}'$ remains unaltered, whereas the two vectors $\boldsymbol{f}$ and $\boldsymbol{f}'$ continue to precess with the frequency ω_α. Thus the vectors $\boldsymbol{a}'$ and $\boldsymbol{f}'$ are no longer orientated along the $(-y)$-direction, and this results in a reduction in the intensity of the echo (Fig. 14d). Since the orientations of these two vectors depend on τ, and their contribution to the echo becomes a maximum when $\omega_\alpha \tau = 2\pi n$, the echo amplitude oscillates in proportion to $\cos(\omega_\alpha \tau)$. This applies for any combination of transitions with a common energy level. The complete modulation formula for the two-pulse experiment is given in (7).

$$E_{mod}(2\tau) = 1 - \frac{k}{4}[2 - 2\cos(\omega_\alpha \tau) - 2\cos(\omega_\beta \tau) + \cos(\omega_+ \tau) + \cos(\omega_- \tau)] \quad (7)$$

This expression, which can be evaluated with the help of the spin density operator formalism,[88] contains not only the two nuclear frequencies but also their sum ω_+ and difference ω_-. The amplitudes of the four modulations with different frequencies are given by the modulation depth parameter $k = 4I_aI_f = (\omega_I B/\omega_\alpha\omega_\beta)^2$. For the case of an isotropic hyperfine interaction a_{iso}, or if $\boldsymbol{B}_0$ is orientated along one of the principal axes of the hyperfine tensor, the echo modulation disappears, since in either of these cases the quantity B in the expression for the modulation depth parameter becomes zero.

Figure 15a shows the modulation pattern for our model compound with $\theta = 45°$. After eliminating the zero frequency component and carrying out a Fourier transformation in the frequency domain, one obtains either the cosine or the magnitude spectrum containing the two nuclear resonance frequencies ω_α and ω_β and their sum and difference frequencies ω_+ and ω_-.

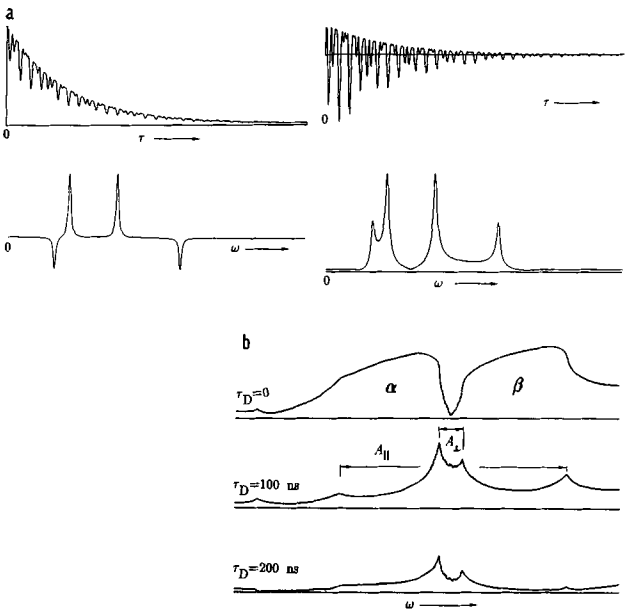

Fig. 15. Two-pulse echo modulation (for parameters see model system). a) upper plots: ESEEM pattern before (left) and after (right) elimination of the constant term; lower plots: cosine spectrum (left) and magnitude spectrum (right) for a particular orientation ($\theta = 45°$). b) Effect of the dead time τ_D on the line shape and intensity in the powder spectrum (sum-frequency peak not shown).

If several nuclear spins are involved in the ESEEM effect, the echo modulation is given by the product rule (8).[88] Thus

$$E^n_{mod}(2\tau) = \prod_i^n E^{(i)}_{mod}(2\tau) \quad (8)$$

the spectrum contains, in addition to the four main frequencies, some combination frequencies. However, as the modulation depth parameters k_i appear as squared or higher order terms in the amplitudes of these modulations, the intensities of the combination peaks are generally small.

Apart from these combination frequencies and the sum and difference frequencies the positions of the lines in the ESEEM spectrum correspond to those in the ENDOR spectrum. The nuclear modulation effect, which arises solely from the interplay of allowed and forbidden transitions without the need for a radiofrequency field, therefore ranks alongside ENDOR spectroscopy as one of the most important tools that can be used for elucidating the structures of paramagnetic compounds.

In studies on disordered systems it is often difficult to determine the magnetic parameters from an ESEEM spectrum, since the broad lines are associated with a rapid decay of the modulation pattern in the time domain, and for short τ-values the observation of the echo modulation is limited by the dead-time of the spectrometer. Despite the use of some clever experimental tricks, this problem cannot be entirely solved.[30, 90, 91]

Figure 15b illustrates how seriously the dead time τ_D can affect a two-pulse ESEEM spectrum. This again uses our model system as an example, by assuming a powder sample which gives averaging over all possible orientations. For the ideal case where $\tau_D = 0$ (which cannot be realized experimentally) one obtains the true spectrum with undistorted line shapes. However, if the dead time is such that data acquisition can only start at $\tau = 100$ ns, the α and β hyperfine lines both split into doublets, due to the fact that steep gradients in the spectrum (corresponding to high frequencies in the frequency domain) are more efficiently detected. The peak maxima of these doublets are directly related to the hyperfine components $A_\perp$ and $A_\parallel$, which means that in simple cases the interpretation of the spectrum can even be made easier by the dead time effect.[92] However, with a dead time $\tau_D = 200$ ns the intensities of the peaks are already reduced by a factor of 10, which often means that they are comparable with the noise level. Often in practice the modulations decay to such an extent during the time τ_D that the weak oscillations still detectable are insufficient to allow reconstruction of the spectrum. Techniques for avoiding this dead-time problem will be discussed in Section 4.

3.3.2. Three-Pulse Echo Modulation

The stimulated echo too shows a nuclear modulation effect. However, whereas in the two-pulse experiment only *electron* spin coherences are produced and mixed, in the three-pulse experiment the second 90° pulse transfers the electron spin coherence into *nuclear* spin coherence.[*] This nuclear spin coherence develops during the evolution time T and decays with the transverse nuclear relaxation time T_{2n} (or T_1 in cases where $T_1 < T_{2n}$), which is usually much longer than the corresponding relaxation time T_M of the electrons. The third 90° pulse transfers the nuclear spin coherence back to observable electron spin coherence. For the stimulated echo of a spin system with $S = 1/2$ and $I = 1/2$, the modulation at the time $\tau + \tau'$ (where $\tau' = \tau + T$) is given by Equation (9).[88]

$$E_{mod}(\tau + \tau') = 1 - \frac{k}{4}\{[1 - \cos(\omega_\alpha \tau)][1 - \cos(\omega_\beta \tau')] + [1 - \cos(\omega_\beta \tau)][1 - \cos(\omega_\alpha \tau')]\} \quad (9)$$

When τ' (T) is varied the echo envelope is modulated only by the two basic frequencies ω_α and ω_β; the sum and difference frequencies do not appear. However, according to Equation (9) the amplitudes at the two frequencies ω_α and ω_β depend on $\omega_\beta \tau$ and $\omega_\alpha \tau$ respectively. Due to this suppression effect individual peaks in the spectrum can disappear completely. These "blind spots" occur for the α peak when $\tau = 2\pi n/\omega_\beta$, with a corresponding condition for the β peak.

For several nuclear spins the product rule (10) applies.[93]

$$E^n_{mod}(\tau + \tau') = \tfrac{1}{2}\left[\prod_i^n E^{(i)}_\alpha(\tau, \tau') + \prod_i^n E^{(i)}_\beta(\tau, \tau')\right] \quad (10)$$

In contrast to the two-pulse experiment, combinations of the nuclear frequencies only occur within the *same* m_S state.

The great advantage of the three-pulse ESEEM experiment lies in the slow decay of the echo modulation, whose duration is no longer limited by a short phase memory time T_M as in the two-pulse experiment. Moreover, there are fewer peaks than in the two-pulse ESEEM spectrum, as the sum and difference frequencies do not appear. The three-pulse method is therefore often preferred in single crystal investigations.

A different situation exists in disordered systems. In powder samples or frozen solutions the modulation pattern usually decays very much faster than the overall amplitude of the echo, owing to destructive interference of the different resonance frequencies. Moreover, the line-shape distortions caused by the suppression effect make the interpretation more difficult. Because of these two effects the two-pulse echo modulation method often gives better results for such systems.

3.3.3. Effect of the Microwave Frequency

The MW frequency can affect the ESEEM pattern in several different ways. According to Equation (7) the modulation depth parameter k depends not only on ω_α and ω_β but also on the Zeeman frequency of the nucleus concerned, and therefore on the field B_0 or the microwave frequency. For small hyperfine couplings the condition $\omega_I \simeq \omega_\alpha \simeq \omega_\beta$ holds, with the result that the modulation depth parameter k is approximately equal to B^2/ω_I^2, and is thus inversely proportional to the square of the nuclear Zeeman frequency. In compounds with small hyperfine couplings a reduction in the microwave frequency therefore causes a considerable increase in the modulation amplitudes. Figure 16a compares the two-pulse ESEEM patterns of vitrinite measured at 3 GHz (S-band) and 9 GHz (X-band).[94] The amplitude of the echo modulation at the lower MW frequency is about ten

[*] A transition between any two arbitrary eigenstates is described as a coherence. This term therefore has a wider meaning than the expression "transverse magnetization", which refers only to allowed transitions. A coherence corresponds to an off-diagonal element in the spin density matrix.

times larger than at the commonly used frequency of 9 GHz, in agreement with the above approximation. However, at low MW frequencies the combination lines also appear more strongly, and for strongly coupled nuclei this can lead to very confused ESEEM spectra.

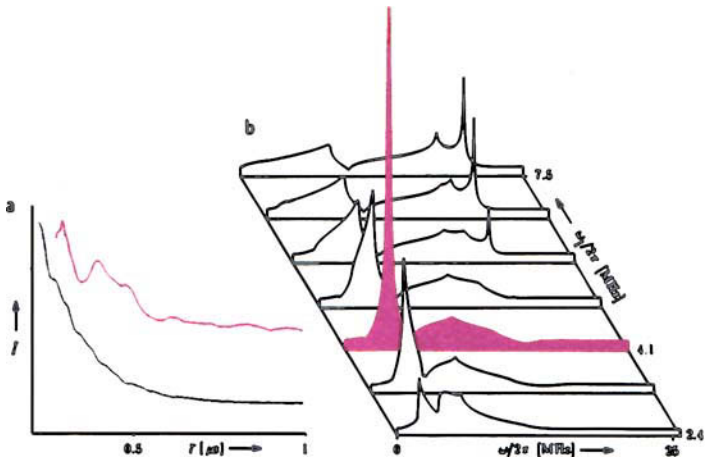

Fig. 16. a) Effect of the microwave frequency on the two-pulse modulation patterns for a vitrinite sample at 298 K. Upper trace: MW frequency = 3 GHz (S-band); lower trace: MW frequency = 9 GHz (X-band) (Ref. [94]). b) Effect of the microwave frequency on the shapes and intensities of the lines in a powder ESEEM spectrum (for parameters see model system, Fig. 1a). At a nuclear Zeeman frequency of $\omega_I/2\pi = 4.1$ MHz the α-transition becomes dispersion-free (spectrum in red).

The microwave frequency affects not only the depth of modulation but other parameters too. For example, in disordered systems the line shape is greatly affected by, among other factors, the choice of MW frequency.[95, 96] As a result it is even possible for individual hyperfine lines to become dispersion-free. For an axially symmetric spin system with $S = 1/2$ and $I = 1/2$ this condition is reached for the α-line at a nuclear resonance frequency given by $\omega_I = A_{||}^d/8 + a_{iso}/2$.[96] The α-line then consists of an intense narrow peak at the frequency $\omega_\alpha = 3A_{||}^d/8$, whereas the β-transitions remain distributed over a wide frequency range, and thus manifest in weak and broad features. It is therefore possible, by varying the MW frequency, to determine the dipolar hyperfine coupling $A_{||}^d$ directly from the ESEEM spectrum. Figure 16b shows a series of powder spectra of our model system for different MW frequencies. In this numerical example the α-peak becomes dispersion-free for $\omega_{mw}/2\pi = 2.7$ GHz ($\omega_I/2\pi = 4.1$ MHz).

A similar narrowing of particular lines can be achieved for quadrupolar nuclei with spin $I = 1$. Especially in the case of weakly coupled ^{14}N nuclei with a nearly isotropic hyperfine tensor, the nuclear Zeeman interaction and the hyperfine interaction cancel each other for $m_S = 1/2$ at a microwave frequency $\omega_{mw} = a_{iso}g_e\beta_e/2g_n\beta_n$.[68, 97, 98] Choosing this particular value for ω_{mw} has the effect of reducing the Hamiltonian for this m_S subsystem to one that contains only the quadrupolar interaction. Since the corresponding transitions are independent of the field B_0, and therefore of the orientation, the ESEEM spectrum consists essentially only of narrow lines which correspond to pure quadrupole frequencies.

3.3.4. *Examples of Applications*

With the limited selection of two-pulse and three-pulse experiments that are discussed in this section, only a rough indication can be given of the wide variety of applications of the nuclear modulation effect. These examples are designed to convince the reader of the usefulness of the method, and at the same time to draw attention to some special aspects of ESEEM spectroscopy.

Surface Complexes

In natural bodies of water the phosphate cycle plays an important role and affects, among other things, the adsorption behavior of heavy metal ions. ESR spectra yield little information about the nature of the bonding between metal ions and hydrated metal oxide surfaces in the presence of phosphates. In particular it is not possible to determine from the spectra whether or not ternary surface complexes are formed, nor whether the bonding of the metal ions at the oxide surfaces involves inner- or outer-sphere coordination. In contrast to CW ESR spectroscopy the ESEEM technique makes it possible to observe the weak interactions between the metal ion and the magnetic nuclei in the immediate environment (ligands, metal oxides). We take as our example Cu^{II} ions, which become adsorbed on δ-Al_2O_3 in the presence of various phosphates.[99]

Figure 17a shows the ESR spectrum of Cu^{II}(pyrophosphate)$_2$ in a frozen aqueous solution, showing very little spectral structure. The only effect of adsorption of the Cu^{II}

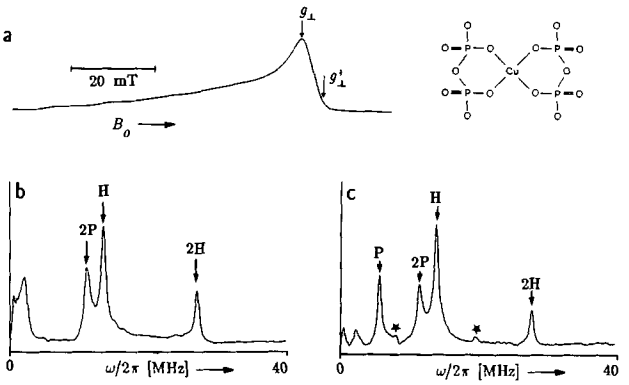

Fig. 17. Two-pulse echo modulation pattern from Cu^{II}(pyrophosphate)$_2$ in frozen aqueous solution. a) CW ESR spectrum (integrated) at 90 K. The arrows indicate the two field positions used for the ESEEM experiment. b) Two-pulse ESEEM magnitude spectrum at 10 K, measured at $g_\perp$. c) Measured under the same conditions at $g'_\perp$; asterisks mark combination signals at $\omega_H \pm \omega_P$ (Ref. [99]).

ions on the δ-Al_2O_3 surface is a further broadening of the ESR lines. Owing to the large anisotropy of the g-tensor and of the copper hyperfine tensor, the ESR spectrum is smeared out over a range of about 80 mT. The high field region of the spectrum is produced by orientations of the magnetic field $\boldsymbol{B}_0$ that lie close to the plane of the complex ($\boldsymbol{B}_0$ parallel to the principal axis direction $g_\perp$). An ESEEM experiment in this field region therefore corresponds to a powder-type averaging over two dimensions. Two such "powder" ESEEM spec-

tra of Cu^{II}(pyrophosphate)$_2$ in frozen solution, for different measuring positions in the neighborhood of $g_\perp$, are shown in Figure 17b,c; both spectra show proton and phosphorus resonances.

As the short MW pulses excite a spectral region corresponding to a field range of about 3 mT, orientations out of the plane of the complex are also observed, and in general this causes a broadening of the lines in the ESEEM spectrum. By shifting the detection window towards the high field end of the spectrum ($g'_\perp$ in Fig. 17a) the orientational selectivity can be considerably improved. This is illustrated by the ESEEM spectrum in Figure 17c, in which additional peaks appear at the Zeeman frequency ω_P of the phosphorus nucleus and at the combination frequencies $\omega_H - \omega_P$ and $\omega_H + \omega_P$.

Figure 18 shows ESEEM spectra of Cu^{II} ions adsorbed on δ-Al_2O_3. The strong aluminum peaks confirm that a surface complex has been formed. Figure 18a shows the spectrum obtained in the presence of orthophosphate, pyrophosphate and tripolyphosphate. The absence of phosphate peaks indicates that in all these frozen solutions the phosphates are no longer coordinated to the copper in the presence of δ-Al_2O_3. This is further confirmed by the doublet structure of the sum peaks of the protons, which results from the binding of water at the remaining free equatorial coordination sites of the copper (Section 4.3).

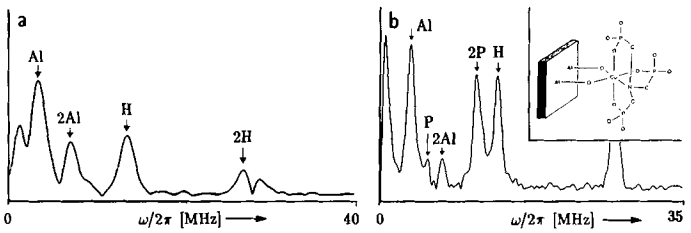

Fig. 18. a) Two-pulse ESEEM magnitude spectrum of Cu^{II} ions adsorbed on the hydrated oxide surface δ-Al_2O_3 at 10 K. b) Two-pulse ESEEM magnitude spectrum of Cu^{II}(NTP) adsorbed on δ-Al_2O_3, measured at 10 K. In both cases the data were apodized before Fourier transformation (Ref. [99]).

In the case of Cu^{II}NTP (NTP = nitrilotrismethylenephosphonate) we find a spectrum which contains not only aluminum peaks but also phosphorus peaks (Fig. 18b). Therefore Cu^{II}NTP is the only one of the phosphates investigated that forms a ternary surface complex when adsorbed on the oxide surface.

Coordination of Water in Metmyoglobin

A number of studies have led to the conclusion that in metmyoglobin (oxidized myoglobin containing $Fe^{3\oplus}$) a water molecule is bonded to the heme iron ion. ESEEM spectroscopy has provided direct evidence for this coordination.[100] For this purpose three-pulse experiments were carried out on metmyoglobin in both H_2O and D_2O and one ESEEM pattern was divided by the other. As a consequence of the product rule, forming this quotient eliminates the oscillations of those nuclei that are present in both samples. However, this suppression is only complete in ordered systems and when using the two pulse sequence [cf. Eqs. (8) and (10)]. Nevertheless, it has been found in practice that even for powder samples and three-pulse sequences the quotient method is very effective in reducing unwanted modulation components due to protons and nitrogen nuclei.

In metmyoglobin the modulation pattern after carrying out the division essentially contains only the frequencies of those deuterium nuclei that belong to exchangeable water molecules. The corresponding ESEEM spectrum is shown in Figure 19a. Positioned symmetrically with respect to the peak (b) of the more distant deuterium nuclei at the nuclear Zeeman frequency ω_D of the deuterons, there appear two further lines (a and c) with a separation of 0.8 MHz. Since

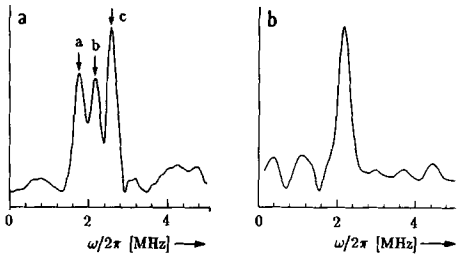

Fig. 19. Deuterium signals in the ESEEM quotient spectra of heme proteins. a) Metmyoglobin, $B_0 = 0.3384$ T. b) Methemoglobin, $B_0 = 0.3330$ T (Ref. [100]).

the only exchangeable protons near the heme group are those of water, the hyperfine splitting observed in the ESEEM spectrum of metmyoglobin proves that a water molecule is coordinated directly to the iron ion. In contrast the spectrum of methemoglobin (Fig. 19b) shows no splitting of this kind, showing that in this protein the bonding of water to the iron ion is much weaker.

Determination of the Structures of the Ligands in a Copper Protein

The ESEEM method ranks with EXAFS (extended X-ray absorption fine structure) as one of the most important tools for determining the structures of active centers in metalloproteins.[18, 68] The ESEEM spectra of these not only contain information about magnetic parameters but often also enable conclusions to be drawn about the number and identities of the ligands. This will be illustrated by the example of the copper protein phenylalanine hydroxylase obtained from *Chromobacterium violaceum*.[101]

Here again it is found that the CW ESR spectrum yields no direct information about the nature of the ligands. Figure 20a shows the three-pulse echo modulation measured at $g_\perp$ and the corresponding ESEEM spectrum of the nitrogen nuclei that are not directly coordinated to the copper ion. As the condition for observing pure quadrupole resonances for the $m_S = 1/2$ state is nearly fulfilled (Section 3.3.3), the ^{14}N spectrum consists of narrow lines at the quadrupolar frequencies $\nu_0 = 0.55$ MHz, $\nu_- = 1$ MHz, and $\nu_+ = 1.55$ MHz ($\nu_0 + \nu_- = \nu_+$). The somewhat broader peak at 4.1 MHz is assigned to the $\Delta m_I = \pm 2$ transition of the $m_S = -1/2$ state, which is also independent of the orientation to a first approx-

imation. A comparison with the data for Cu^{II} complexes with 2-methylimidazole ligands suggests that in the case of phenylalanine hydroxylase the compound histidylimidazole coordinates to the Cu^{II} ion.

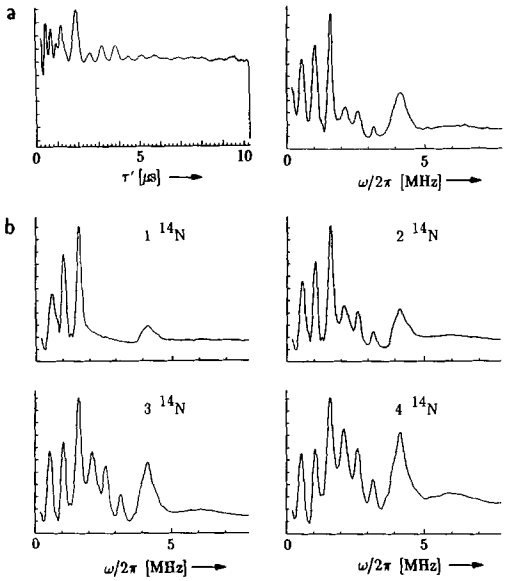

Fig. 20. Determination of the structures of the ligands on the Cu^{II} ion in the protein phenylalanine hydroxylase. a) Three-pulse modulation pattern (left) and ESEEM spectrum (right), measured at $g_\perp$, $\tau = 152$ ns, $T = 4.2$ K. b) Simulated three-pulse ESEEM spectra calculated for one to four nitrogen atoms, using experimental data from Figure 20a as parameters (Ref. [101]).

In the ESEEM spectrum of phenylalanine there are, in addition to the main peaks, three further weak ones. As their positions correspond to the frequencies for combination lines, there must be more than one imidazole ligand coordinated to the copper ion. Figure 20 b shows the corresponding simulated spectra for one to four nitrogen nuclei. These show that the intensities of the combination lines and of the $\Delta m_I = \pm 2$ peaks are strongly dependent on the number of coupled ^{14}N nuclei. Comparing these plots with the experimental spectrum in Figure 20 a leads to the conclusion that the protein studied here must have *two* histidylimidazole groups equatorially coordinated to the Cu^{II} ion.

Magnetic Properties of Triplet States

Magnetic resonance methods such as CW ESR spectroscopy, optically detected magnetic resonance, and ENDOR and ESEEM spectroscopy, have made great contributions to the understanding of triplet states in organic molecules and biological systems. The ESEEM technique in particular is ideally suited for determining small hyperfine couplings in short-lived triplet states.[22, 102–105] For a spin system with $S = 1$ and $I = 1/2$ the two-pulse modulation formula is:

$$E_{mod}(2\tau) = 1 - \frac{k'}{4}[2 - 2\cos(\omega_T\tau) + 2\cos(\omega_I\tau) - \cos(\omega_T + \omega_I)\tau - \cos(\omega_T - \omega_I)\tau] \quad (11)$$

with the modulation depth parameter k' given by the expression (12).

$$k' = [(2B(\omega_T + \omega_I + A))/(B^2 + (\omega_T + \omega_I + A)^2)]^2 \quad (12)$$

In observing the ESR transition $|m_S = 0\rangle \rightarrow |m_S = 1\rangle$ one measures the nuclear frequencies ω_I and

$$\omega_T = \omega_{+1} = [(A - \omega_I)^2 + B^2]^{1/2} \quad (13)$$

whereas for the transition $|m_S = -1\rangle \rightarrow |m_S = 0\rangle$ one measures the frequencies ω_I and

$$\omega_T = \omega_{-1} = [(A + \omega_I)^2 + B^2]^{1/2} \quad (14)$$

As an example of an ESEEM study of a triplet state we may take the determination of the magnetic parameters of anthracene in a single crystal of *p*-terphenyl, which was excited into the triplet state at room temperature by a laser pulse of 40 μs duration.[105] Figure 21 shows the echo modulation patterns of the low field transition with $\boldsymbol{B}_0$ along each of the three principal axes of the fine structure tensor, together with the corresponding ESEEM spectra. With the field along the *x*-axis the spectrum contains four peaks at the two fundamental frequencies $\omega_{-1}/2\pi = 1.73$ MHz and $\omega_I/2\pi = 11.71$ MHz and at the sum and difference frequencies. The peak at 1.73 MHz is assigned to the α-protons (positions 1, 4, 5 and 8). In the spectrum for the *y*-direction the fundamental frequency $\omega_{-1}/2\pi = 7.96$ MHz corresponds to the coupling of the β-protons (2, 3, 6 and 7). From these ESEEM data one can determine the elements of the hyperfine tensor and hence the corresponding spin densities.[105]

Solitons in Polyacetylene

Polyacetylene, $(CH)_x$, exhibits many unusual physical properties. Of particular interest is the behavior of the soli-

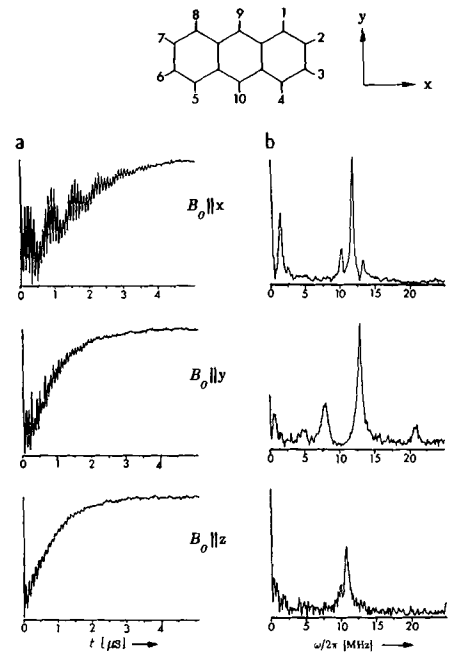

Fig. 21. Two-pulse echo modulation results from photoexcited anthracene in a single crystal of *p*-terphenyl, measured at room temperature. a) Modulation patterns for the low-field transition $|m_S = -1\rangle \rightarrow |m_S = 0\rangle$ with $\boldsymbol{B}_0$ along the *x*, *y* and *z* molecular axes. b) The corresponding ESEEM magnitude spectra (Ref. [105]).

tons which are present in the undoped polymer with a typical concentration of one spin per 2000–3000 carbon atoms. Solitons are neutral π-radicals which arise from defects in the conjugated π-bond system of the polyene chains. Since a delocalization of the electron lowers the energy of the defect, it becomes distributed over about fifty C–C bonds.

The three-pulse ^{13}C-ESEEM spectra of *trans*- and *cis*-polyacetylene (with 99% ^{13}C enrichment) are identical and are independent of temperature between 4 and 300 K.[106] The spectra consist of one peak at the Zeeman frequency ω_C of the ^{13}C nucleus together with a large number of combination lines or multiple-quantum transitions at frequencies $n\omega_C$ (Fig. 22). It is very unusual to find such strong combination

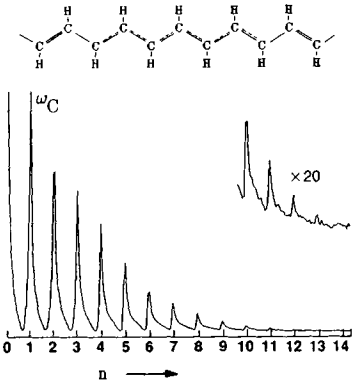

Fig. 22. Solitons in polyacetylene. ^{13}C multiple quantum transitions in *trans*-$(CH)_x$ (three-pulse ESEEM magnitude spectrum, compound 99% ^{13}C enriched) (Ref. [106]).

lines in an ESEEM spectrum measured in the X-band. Since a diffusion of the solitons along the $(CH)_x$ chains would destroy the multi-quantum coherence, it must be concluded from the modulation pattern that the defect structures remain at fixed positions even at room temperature. Attempts have been made to describe the multiple-quantum pattern on the basis of various models. It was found that the experimental results could only be explained by assuming that the delocalized electron interacts with a large number of ^{13}C nuclei in *neighboring* polyacetylene chains.[107]

3.4. Pulsed ENDOR Spectroscopy

3.4.1. Basic Principles

ENDOR spectroscopy is a long-established magnetic resonance technique. The CW ENDOR method, which is still the most commonly used form of ENDOR, has a serious disadvantage in that the signals observed with this technique depend very critically on the balance between the various relaxation times and the MW and RF pumping fields. Moreover, even when the experimental variables are optimized, the signal intensities in ENDOR are only a few percent of those with ESR.

Along with the rapid developments occurring in pulsed ESR spectroscopy, there has recently also been a growing interest in pulsed ENDOR techniques.[42–45] One of the advantages of these methods compared with the CW ENDOR method is that the entire pulse sequence can usually be made short enough to exclude unwanted relaxation effects. This means that the pulsed ENDOR technique can be used at any desired temperature, provided that an electron spin-echo can be detected. The two standard methods used in pulsed ENDOR spectroscopy are described below and illustrated by several examples. Some special pulsed ENDOR techniques are discussed in Section 4.6.

Figure 23 shows the two pulse sequences used, which were introduced a considerable time ago by *Davies*[108] and *Mims*[109] respectively. Both are based on a transfer of spin polarization. The Davies ENDOR experiment (Fig. 23a) starts by inverting the polarization of one of the ESR transitions by means of *selective* 180° MW pulse. As the spin-lattice relaxation time T_1 in the solid phase can be as much as several hundred microseconds, depending on the temperature, this allows enough time to apply a selective 180° RF pulse so as to invert the polarization of a nuclear spin transition in one of the two m_S states. This causes the population difference in the ESR transition that was first excited to disappear (Fig. 23b), and consequently the echo also disappears.

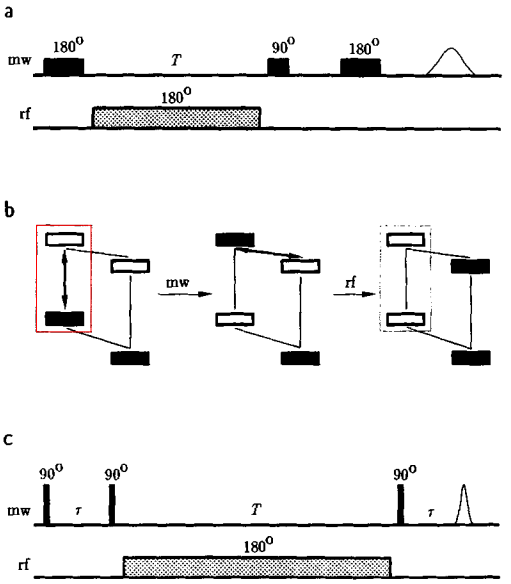

Fig. 23. Standard pulsed ENDOR sequences. a) Davies ENDOR sequence. b) Changes in populations of states in the Davies experiment. c) Mims ENDOR sequence.

Figure 24a shows the Davies ENDOR spectrum of a single crystal of $Mg(NH_4)_2(SO_4)_2 \cdot 6H_2O$ doped with Cu^{II} ions. It consists of proton resonances from water coordinated directly to the copper ion, together with some resonance lines of other nearby protons. A noticeable feature of this spectrum is that the broad matrix line near the nuclear Zeeman frequency of $\omega_H/2\pi = 11.8$ MHz is considerably weaker than the lines of the more strongly coupled protons. This arises from the inadequate selectivity of the first MW pulse, which can therefore excite both ESR transitions in the case of weakly coupled nuclei. This can reduce, or even eliminate altogether, the transfer of polarization by the RF pulse.

Unlike the Davies pulse sequence the pulsed ENDOR technique introduced by *Mims*[109] does not require selective MW pulses. The Mims ENDOR method is based on measuring the stimulated echo as a function of the frequency of a 180° RF pulse applied between the second and third MW pulses (Fig. 23c). The duration of th RF pulse is again limited by the relaxation time T_1. However, the polarization transfer is less transparent than in the Davies experiment, as the first two MW pulses impose a complicated magnetization pattern on the ESR line. As a result of this there are blind spots in the ENDOR spectrum for pulse intervals given by $\tau = 2\,\pi n/a$ ($n = 1,2,\ldots$), similar to those in the three-pulse ESEEM experiment. To avoid the possibility of missing individual lines it is therefore essential to repeat the experiment with different τ-values. For $\tau = 2\pi(2\,n - 1)/a$ the echo intensity is again reduced to zero in the Mims ENDOR experiment (maximum ENDOR effect).

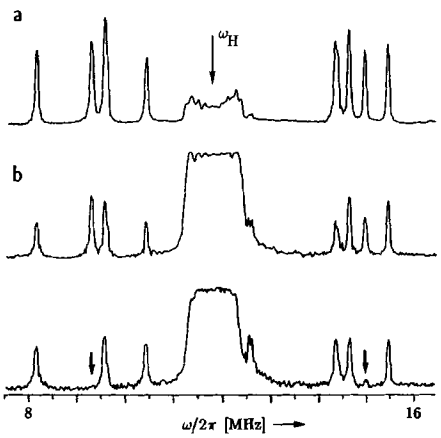

Fig. 24. Pulsed ENDOR single crystal spectra of Cu^{II}-doped $Mg(NH_4)_2(SO_4)_2 \cdot 6H_2O$ at 10 K; ω_H is the nuclear Zeeman frequency of the protons. a) Davies ENDOR spectrum. b) top: Mims ENDOR spectra with $\tau = 430$ ns, bottom: with $\tau = 800$ ns; the arrows mark blind spots in the spectrum.

An important feature of the Mims ENDOR sequence compared with the Davies method is that it gives a greater echo amplitude, since more electron spins are involved in the experiment. Figure 24b shows Mims ENDOR single crystal spectra for two different τ-values. The arrows indicate blind spots.

3.4.2. *Examples of Applications*

An example from the literature will be described here, and the pulsed ENDOR method will be compared with the ESEEM technique.

Pulsed ENDOR Spectroscopy of Free Porphyrin Bases

In order to determine the hyperfine tensor for the two inner protons of the [D_{12}]porphyrin, the compound was incorporated into a single crystal matrix consisting of perdeuterated *n*-octane.[110] The deuteration achieves two objectives: in the first place it increases the sensitivity, as the hyperfine couplings for deuterium are smaller than those for protons and a microwave pulse of a given duration can therefore excite more spins, and secondly it increases the phase memory time T_M. Photoexcitation into the lowest-lying triplet state is achieved at a temperature of 1.4 K by applying a laser pulse 1 μs before the start of the ENDOR pulse sequence. The ENDOR frequencies for the ESR transition $|m_S = 0\rangle \rightarrow |m_S = 1\rangle$, measured in the plane of the porphyrin ring, are shown in Figure 25. As the two inner

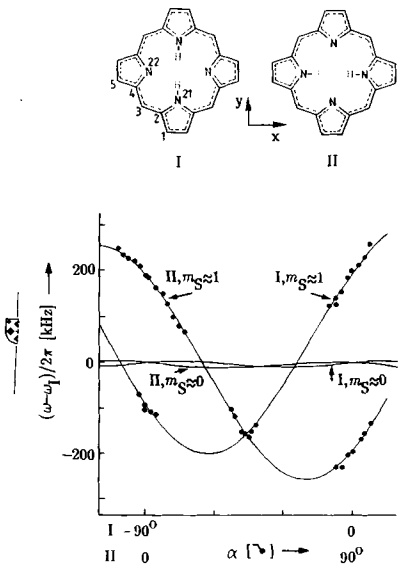

Fig. 25. ENDOR frequencies $(\omega - \omega_I)/2\,\pi$ for the two tautomers I and II in the porphyrin free base, with B_0 in the plane of the porphyrin ring, at 1.4 K (Ref. [110]).

protons can occupy two alternative positions, which can be interchanged by a 90° rotation of the molecule about the *z*-axis, the ENDOR spectra consist of four lines. Although the sample contained only about 10^{13} triplet spins, it was possible by spectrum accumulation to completely determine the hyperfine tensors for the two magnetically equivalent protons from the angular dependence of the nuclear frequencies ω_{+1} [Eq. (13)]. The ENDOR data show that the molecular symmetry departs considerably from D_{2h}. From the values of the tensor components it was also possible to determine the positions of the protons and the spin densities on the porphyrin nitrogen atoms.

ESEEM and Pulsed ENDOR Spectroscopy of ^{14}N nuclei in a Disordered System

Hyperfine couplings of nuclei with small magnetic moments are in general difficult to observe, owing to the fact that the nuclear transition probabilities are small with the ENDOR technique. Furthermore, the electron spin, whose direction of quantization alternates at the radiofrequency, can cause a considerable reduction in the effective RF field at the position of the nucleus (the so-called hyperfine enhancement).[*] An alternative is to use ESEEM spectrosco-

[*] The hyperfine enhancement can cause either an increase or a reduction of the effective RF field experienced by the nuclear spin, depending on the m_S state that is observed. For a spin system with $S = 1/2$ and $I = 1/2$ the RF field strength must be multiplied by the factor $(1 - m_S a_{iso}/\omega_I)$[53].

py, since with this method the relationships that determine the modulation amplitudes, and therefore also the line intensities, are different.

It will now be shown, by taking as an example a copper complex with ^{14}N hyperfine couplings below 4 MHz, that the two methods are often complementary.[111] In Figure 26 two sets of simulated powder spectra are compared, one for ESEEM (a) and the other for ENDOR (b). For a pair of magnetically equivalent nuclei with spin $I = 1$ we expect six transitions altogether, three for each m_S-state ($|-1\rangle \rightarrow |0\rangle$, $|0\rangle \rightarrow |1\rangle$ and $|-1\rangle \rightarrow |1\rangle$), with a corresponding broadening due to powder averaging.

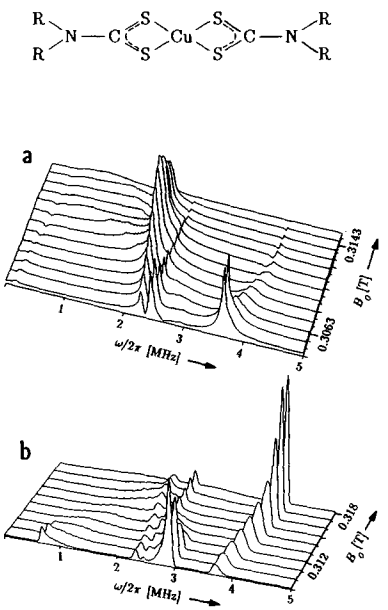

Fig. 26. Comparison of the ESEEM and pulsed ENDOR techniques for the example of ^{14}N powder spectra. The data shown are for $[Cu^{II}(Et_2dtc)_2]$ (Et_2dtc = *N*,*N*-diethyldithiocarbamate). The spectra were calculated for $m_I^{Cu} = 3/2$ with directions of B_0 between $g_{\parallel}$ and $g_{\perp}$. a) ESEEM spectra, τ_D = 800 ns. b) Pulsed ENDOR spectra (Ref. [111]).

The two plots complement each other in a near-ideal fashion. Peaks that are weak or not detectable at all in the ENDOR spectra appear as intense lines in the ESEEM spectra, and vice versa. This example illustrates the fact that in many cases a complete determination of the hyperfine and quadrupolar couplings of nuclei with small magnetic moments is only possible by combining data from ESEEM and pulsed ENDOR.

4. New Techniques in Pulsed ESR Spectroscopy

Following the description of the basic types of experiments of pulsed ESR spectroscopy in Section 3, we now turn to some new developments in techniques.

4.1. Two-Dimensional FT-ESR Spectroscopy

Two-dimensional nuclear magnetic resonance (2D NMR) is now well recognized as one of the most important spectroscopic methods for obtaining detailed information about the structure and dynamics of molecules in solution.[5,6] It is only quite recently that some of the 2D NMR techniques have been successfully carried over into ESR spectroscopy.[61,63,112-114] Two-dimensional ESR methods are essentially subject to the same restrictions as were described for one-dimensional ESR spectroscopy in Section 3.1. As before, the MW pulse must excite the whole of the ESR spectrum, and the line widths must be small enough to ensure that the FID does not die away before the dead time has elapsed.

4.1.1. 2D Correlation Spectroscopy (COSY)

In nuclear magnetic resonance, COSY experiments are used to study the transfer of coherence between coupled nuclear spins.[5,6] Analogous procedures can also be carried out with electron spins. In the simplest form of COSY (Fig. 27a) the preparation stage consists of a 90° pulse.[5,112] The transverse magnetization thus produced is allowed to develop during the evolution period t_1, and thereby becomes labeled according to the precession frequencies present. A second 90° pulse then generates the FID, which is measured during the acquisition period t_2. In the 2D experiment the evolution time t_1 is increased in a stepwise fashion, and a separate FID is recorded for each t_1-value. After shifting the phase of the first pulse by 90° this measurement cycle is then repeated. The two sets of FIDs, whose amplitudes oscillate as functions of t_1, then undergo a two-dimensional complex Fourier transformation, yielding a 2D ESR spectrum in which the variable frequencies are ω_1 and ω_2. In a 2D plot of this kind the diagonal peaks ($\omega_1 = \omega_2$) represent the uncorrelated ESR spectrum, whereas the cross-peaks (off-diagonal peaks) provide evidence of cross-correlations.

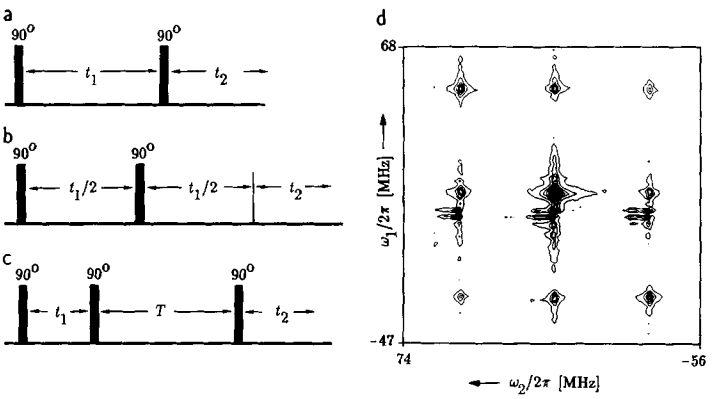

Fig. 27. a) to c) 2D FT-ESR pulse sequences, COSY (a), SECSY (b), EXSY (c). d) EXSY contour line diagram for perdeuterated tempone (for structure see Fig. 5a) in [D_8]toluene (1.17×10^{-3} M), 21 °C, mixing time 310 ns (the doublets at $\omega_1 = 0$ are caused by artefacts) (Ref. [112]).

4.1.2. 2D Spin-Echo Correlation Spectroscopy (SECSY)

In the SECSY experiment (Fig. 27b) the shape of the echo is recorded as a function of the pulse separation $\tau =$

$t_1/2$.[5, 112] The time interval between the first pulse and the echo maximum is equal to the evolution period, whereas the time following the echo maximum corresponds to the detection period. The two-dimensional Fourier transformation gives a SECSY plot with the ESR spectrum along the ω_2-axis and the homogeneous line shape along the ω_1-axis. Provided that the MW pulses are short enough to excite the entire ESR spectrum, one SECSY spectrum contains the same information as a series of echo-detected ESR spectra (Section 3.2.2.). The advantage of SECSY compared with the field sweep method is that the time needed for data acquisition is shortened by an order of magnitude.

4.1.3. 2D Exchange Spectroscopy (EXSY)

EXSY (Fig. 27c) is a 2D technique for monitoring the transfer of magnetization between hyperfine lines.[5, 112] In this the COSY sequence is extended by the addition of a further 90° pulse and a mixing period of constant duration T, during which an exchange of magnetization between individual hyperfine lines can take place. The magnetization of a hyperfine line 'a', which precesses during the evolution period with the frequency $\omega_1 = \omega_a$, acquires a new precession frequency $\omega_2 = \omega_b$ after the transfer of polarization, which corresponds to the frequency of the hyperfine line 'b'.

Figure 27d shows the EXSY spectrum of perdeuterated tempone (contour plot).[112] The transfer of polarization which occurs during the mixing period as a result of Heisenberg spin exchange[*] causes cross-peaks to appear. The Heisenberg exchange rate ω_{HE} can be determined directly from the ratio of the intensities of the diagonal and cross-peaks.

4.2. Special Nuclear Modulation Effects

The nuclear modulation effect is of central importance in pulsed ESR spectroscopy. For this reason a number of techniques have recently been developed for improving resolution and sensitivity, separating overlapping ESEEM spectra, and overcoming various types of instrumental distortions by either eliminating them or taking them into account in the processing of the data.[50, 115]

4.2.1. Eliminating Dead-Time Effects in ESEEM Spectroscopy

It was shown in Section 3.3 that the spectrometer dead time can cause unacceptable distortions of the ESEEM spectrum. A pulse technique which gives results that are completely unaffected by the spectrometer dead time is described below.[116]

The pulse sequence for this is shown in Figure 28a. The first two pulses, separated by the interval τ_i, generate the usual two-pulse echo at a time τ_i after the 180° pulse. However, in contrast to the usual procedure this short-lived transverse magnetization is not recorded, but is instead converted into a longitudinal magnetization by a further 90° pulse, so that it can be "stored" there for a time interval of the order of T_1. After a fixed time delay $\tau_1 < T_1$ the stored z-magnetization can be "read out" by means of a further two-pulse experiment with a pulse interval $\tau_2 > \tau_D$. *Increasing* τ_i in a series of steps gives an ESEEM pattern which corresponds to the usual two-pulse echo modulation, but with the important difference that the dead time after the first two pulses can no longer have any effect on the acquisition of the echo amplitude data.

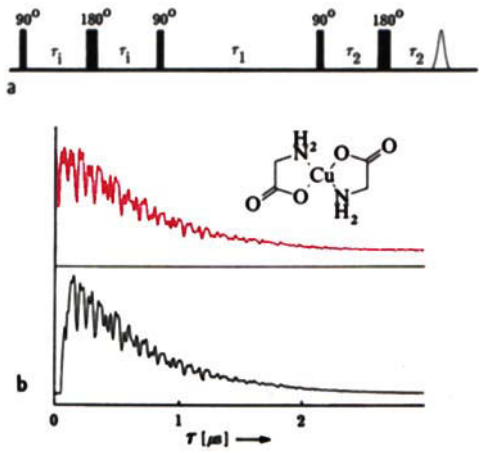

Fig. 28 ESEEM experiment unaffected by the dead time. a) Five-pulse sequence in which the third pulse stores the echo magnetization along the z-direction. b) Comparison of the five-pulse and two-pulse echo modulation patterns from a Cu^{II}-doped single crystal of TGS at 10 K (Ref. [116]).

Introducing these additional storing and reading pulses thus completely eliminates the dead-time problem. However, some sacrifice of signal intensity due to relaxation effects and the finite durations of the pulses is unavoidable. Also the two extra pulses generate further echoes, which can overlap with the echo in which we are interested for certain combinations of τ_i, τ_1 and τ_2. However, unwanted echoes of this kind can in turn be eliminated by suitable phase cycles.[116]

Figure 28b shows a five-pulse and a two-pulse ESEEM pattern from a Cu^{II}-doped single crystal of TGS. The two modulation patterns are practically identical except for the first 120 ns, which is lost in the two-pulse experiment owing to the dead time.

4.2.2. Reconstruction of Broad Hyperfine Lines

It was mentioned in Section 3.3.1 that in three-pulse experiments on powder samples the line shapes can be badly distorted by the suppression effect and by the dead time. However, since the rapid decay of the echo modulation in disordered systems is caused by destructive interference, the original information can be reconstructed by means of a suitable pulse sequence.[117]

The reconstruction method is based on a three-pulse sequence with specially chosen time intervals. According to Equation (9) the intensities at the two modulation frequencies ω_α and ω_β depend on the amplitudes $(1 - \cos(\omega_\beta\tau))$ and

[*] Heisenberg spin exchange is a spin-spin exchange process between pairs of free radicals. This relaxation mechanism is mainly important at high radical concentrations.

$1 - \cos(\omega_a \tau)$) respectively. Consequently, if the time interval τ is several microseconds this causes a rapid modulation of the amplitudes of the hyperfine lines (Fig. 29a). If now the time τ' is varied and the stimulated echo is measured, this amplitude-modulated spectrum corresponds in the time domain to an oscillating pattern consisting of two parts, a signal $f_1(\tau')$ which appears at small values of τ' and rapidly decays, and a signal $f_2(\tau')$ in the region near $\tau' = \tau$ (Fig. 29b).

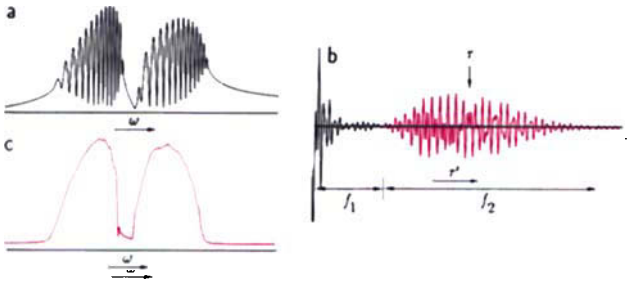

Fig. 29. Reconstruction of broad hyperfine signals in powder samples. a) Magnitude spectrum of the complete modulation pattern with $\tau = 2$ µs. b) Modulation pattern for $\tau = 2$ µs. c) Magnitude spectrum of f_2 (for parameters see model system, Fig. 1a) (Ref. [117]).

The second signal lies well outside the dead time, and is formed by the refocussing of the amplitude modulation; it is therefore called the *echo-modulation echo*. It can be shown that the magnitude spectrum of this echo-modulation echo corresponds to the undistorted hyperfine spectrum (Fig. 29c).[117]

4.2.3. Extended-Time Excitation

In the usual ESEEM methods only the amplitude of the electron spin-echo is measured. To record a modulation pattern one therefore has to increase one of the time intervals in the pulse sequence in a stepwise manner from experiment to experiment, which can be a very time-consuming procedure. However, by using a suitable pulse sequence it is possible to prepare the spin system in such a way that it responds by producing a long transient signal whose variation with time is identical to the echo modulation.[118] It is then possible to measure the complete modulation pattern in a single experiment, similar to the recording of an FID. Extended time excitation can be achieved using coherent microwave radiation of a constant amplitude, or a picket fence consisting of a succession of many short weak pulses, followed in either case by a single hard 180° refocussing pulse (Fig. 30). Stochastic excitation also gives the correct modulation pattern, but only after adding together data from many individual measurements, which is necessary because of the random nature of this form of excitation.

The extended time excitation effect relies on a continuous refocussing of the electron-nuclear interactions due to the special manner of preparation of the spin system. For an infinitely broad inhomogeneous ESR line the duration of the transient signal is exactly equal to that of the excitation pulse.[77] For weak preparation pulses (flip angle $\beta_{tot} \leq 30°$) the modulation phenomenon is easy to understand from a

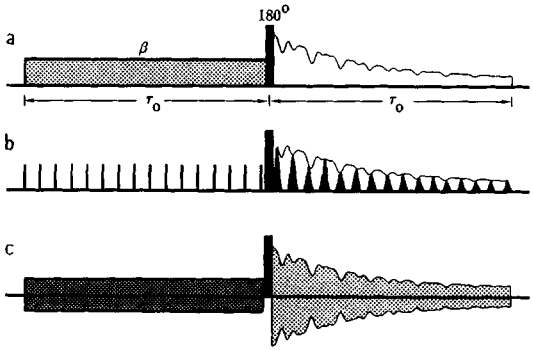

Fig. 30. Pulse sequences for extended time excitation. a) Weak coherent preparation pulse. b) Preparation using a picket fence of short weak pulses. c) Stochastic excitation.

qualitative standpoint, as the behavior of the spin system is then linear. Each brief element of the time interval τ_0 gives rise to a two-pulse echo positioned symmetrically relative to the 180° pulse (Fig. 30b). In the case of a continuous extended time excitation the superposition of all these echoes produces a continuous transient signal, which corresponds to the ESEEM pattern of a two-pulse experiment. In Figure 31a results from the two-pulse echo modulation method and the extended time excitation experiment are compared. In the two-pulse ESEEM experiment (Fig. 31a, top) the individual echoes from a cobalt complex show deep modulations at frequencies below 7 MHz, which are caused by hyperfine and nuclear quadrupolar couplings of the nitrogen-containing ligands (200 echoes recorded by multiple exposure). The same modulation pattern can be obtained by a single experiment using coherent extended time excitation with a duration of $\tau_0 = 2$ µs (Fig. 31a, bottom).

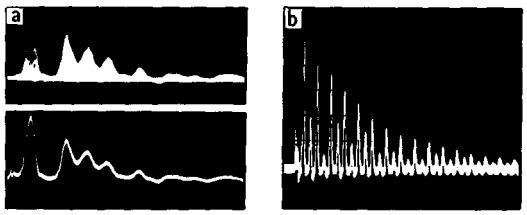

Fig. 31. a) Comparison of transient signals from [Co^{II}(acacen)] (H_2acacen = *N*,*N'*-bis(acetylacetone)ethylenediamine), measured by the standard two-pulse experiment (top) and by extended time excitation with $\tau_0 = 2$ µs (bottom). b) Modulation pattern from [Cu^{II}(bipyam)(dien)] (bipyam = 2,2-bipyridylamine, dien = diethylenetriamine), obtained using a picket fence of 16 weak short pulses. First-order and second-order contributions are separated in time (Refs. [118, 50]).

However, the extended time excitation method only gives a correct echo modulation pattern if the requirements for linear system theory are satisfied. For flip angles $\beta > 30°$ distortions appear in the modulation pattern, and the method can then no longer be used. Nevertheless, since the signal intensities increase with increasing flip angle, variants have been proposed whereby extended time excitation can give correct modulation patterns well into the non-linear region.[50]

A simple example is shown in Figure 31b. The pulse sequence used consists of 16 weak pulses, each with a duration of 10 ns, a flip angle $\beta_b \simeq 7°$, and a pulse interval $\Delta\tau =$

100 ns. The 180° refocussing pulse follows the last of the 16 pulses after an interval $\Delta\tau/2 = 50$ ns. This choice of time intervals results in a time separation of all the unwanted second-order interpulse echoes (stimulated or refocussed echoes formed from two weak pulses and the 180° pulse). In this way the total flip angle $\beta_{tot} = 16\beta_b$ of the extended time excitation period can considerably exceed the linear region without introducing serious distortions into the modulation pattern. In practice this gives an increase of about an order of magnitude in sensitivity.

4.2.4. Soft ESEEM Spectroscopy

A common feature of all the pulse sequences for producing echo modulations that have been described so far is that they make use of at least one intense MW pulse, which is capable of exciting the allowed and forbidden transitions simultaneously. In the technique now to be discussed the allowed and forbidden transitions are excited separately by weak selective pulses.[119] A soft ESEEM experiment of this kind can be achieved in two ways: by using pulses with two different MW frequencies, or by including within the pulse sequence a sudden change of the field strength B_0 (Fig. 32). Since these two procedures are equivalent, only the soft ESEEM technique based on two frequencies will be described.

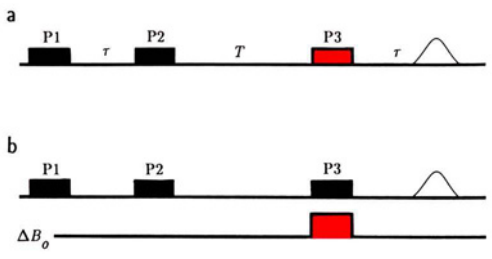

Fig. 32. Soft ESEEM pulse sequences. a) Two-frequency soft ESEEM. b) Two-field soft ESEEM.

The soft ESEEM method consists of a two-pulse echo sequence in which the 180° refocussing pulse is split into two 90° pulses separated by a time interval T. The first pulse of the sequence, with a flip angle of 90° and a frequency $\omega_{mw}^{(1)}$, selectively excites one of the four ESR transitions (allowed or forbidden), thereby producing an electron spin coherence which begins to dephase after the pulse. After a time interval τ the 90° pulse P2 with the same frequency stores a fraction of this coherence in the form of longitudinal magnetization along the $(-z)$-direction. The third pulse P3, with the new frequency $\omega_{mw}^{(2)}$, is applied after a time delay $T > \tau$, so as to avoid distortion by overlapping with the echo generated by the first two pulses. If the frequency of the third pulse is close to an ESR transition which shares a common energy level with the first transition, the stored longitudinal magnetization is converted back into electron spin coherence. During the subsequent evolution period this coherence precesses and produces a stimulated echo after a time τ. In analogy with nuclear magnetic resonance we call this transient signal a *coherence transfer echo*,[120] since it involves dephasing and refocussing processes for different ESR transitions.

Figure 33 (a and b) compares two-pulse and soft ESEEM patterns from a Cu^{II}-doped single TGS crystal. The spectrum of the two-pulse modulation (pulse durations 20 ns and 40 ns) contains essentially three fundamental frequencies and the sum frequency (Fig. 33c). If the durations of both pulses are increased by a factor of ten, while keeping the flip angle unchanged, the modulation almost completely disappears. A similar behavior is observed for the corresponding soft ESEEM pattern using three pulses of the same frequency and $t_{90°} = 300$ ns. However, if the frequency of the pulse P3 differs by an amount $\Delta\omega$ from the frequency of pulses P1 and P2, and if this frequency difference is close to one of the modulation frequencies ω_m, the echo intensity oscillates about the time-axis with the frequency ω_m (Fig. 33b).

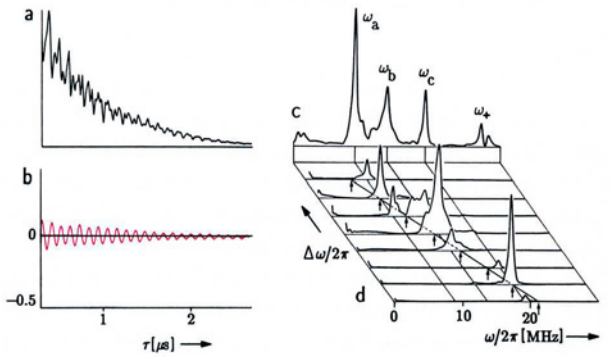

Fig. 33. Two-pulse and soft ESEEM patterns from a Cu^{II}-doped single crystal of TGS at 10 K. a) Two-pulse ESEEM experiment with pulse durations $t_{90°} = 20$ ns and $t_{180°} = 40$ ns. b) Two-frequency soft ESEEM experiment with pulse duration $t_p = 300$ ns and $\Delta\omega/2\pi = 19$ MHz; observed modulation frequency $\omega_m/2\pi = \omega_c/2\pi = 18.9$ MHz. c) Two-pulse ESEEM spectrum. d) Series of soft ESEEM spectra recorded at $\Delta\omega/2\pi$-steps of 2 MHz (Ref. [119]).

As the long excitation pulses cover only a narrow frequency window in the ESEEM spectrum, it is necessary to repeat the experiment with a range of different frequencies $\omega_{mw}^{(2)}$. The spectra obtained by Fourier transformation of a series of soft ESEEM patterns are shown in Figure 33d. To obtain these results the difference frequency $\Delta\omega/2\pi$ was increased from 7 to 21 MHz in 2 MHz steps. From this two-dimensional representation it can be seen that the soft ESEEM method correctly reproduces all the fundamental frequencies in the spectrum. The sum and difference frequencies do not appear, provided that each of the three selective pulses excites only one allowed and one forbidden ESR transition.

The soft ESEEM method has several advantages compared with the standard two-pulse method. The experiment can be performed with a microwave power level two to three orders of magnitude smaller than that for a two-pulse experiment with hard pulses ($P_{mw} \simeq B_2^2$). Also the soft ESEEM method makes it possible to observe modulation frequencies well above 100 MHz.

4.2.5. Increasing the Modulation Amplitude

In a normal three-pulse ESEEM experiment the first two pulses produce nuclear spin coherence, which then evolves during the evolution time T, and is converted by the third

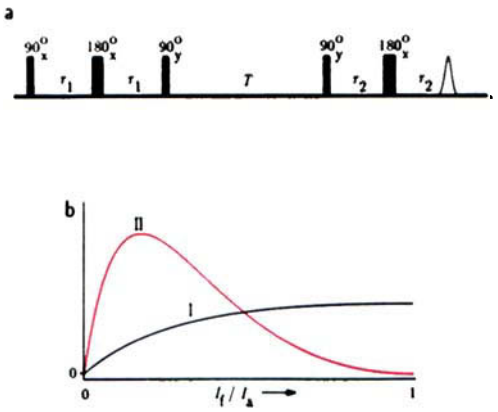

Fig. 34. Five-pulse ESEEM experiment for increasing the modulation amplitude. a) Pulse sequence. b) Amplitude of the echo modulation in the three-pulse (I) and five-pulse experiments (II) as a function of the ratio I_f/I_a of the transition probabilities for forbidden and allowed transitions (Ref. [121]).

pulse into electron spin coherence which can be observed. However, at the same time the three pulses also generate the stimulated echo. Thus, the formation of the echo and the transfer of coherence are closely linked together in the three-pulse experiment, and the experimenter can only influence them by the choice of the time interval τ.

However, by arranging for the formation of the echo and the production of nuclear spin coherence to be separated in time, it becomes possible to control the modulation amplitude over a much wider range.[121] This can be achieved, for example, by a five-pulse sequence (Fig. 34a), in which the first three pulses with a fixed time interval τ_1 are used only to produce the nuclear spin coherence. The nuclear spin coherence is maximized if the phase of the third pulse is shifted by 90° relative to that of the first two pulses. After a variable evolution time T the nuclear spin coherence is measured by a two-pulse echo sequence. To maximize the transfer of nuclear spin coherence back into electron spin coherence the fourth pulse, which comes at the end of the evolution period, should have the same phase as the detector.

With this five-pulse sequence it is theoretically possible, in the case of a small I_f/I_a ratio (or a small modulation depth parameter $k = 4I_aI_f$) to obtain a modulation amplitude up to eight times greater than in the three-pulse experiment, while at the same time keeping the unmodulated component of the echo intensity close to zero. In Figure 34b the modulation amplitudes for the five-pulse and three-pulse experiments are plotted as functions of I_f/I_a, the ratio of the intensities of the forbidden and allowed transitions. In the five-pulse experiment the modulation amplitude reaches a maximum at $I_f/I_a = 0.17$, whereas in the three-pulse experiment the maximum is not reached until $I_f/I_a = 1$, and it is only half that in the five-pulse experiment. Since I_f/I_a is usually small in practice, the increase in modulation obtained by using the five-pulse sequence can be quite considerable.

4.2.6. *Structural Information from the Sum-Frequency Peak*

In two-pulse experiments one observes, for each nucleus with spin $I = 1/2$, not only the fundamental frequencies ω_α and ω_β but also the sum frequency $\omega_+ = \omega_\alpha + \omega_\beta$. Expanding these sum frequencies as power series in A/ω_I and B/ω_I with $A, B < \omega_I$ gives (15).

$$\omega_+ \simeq 2\omega_I + B^2/4\omega_I + (4B^2A^2 - B^4)/64\omega_I^3 \qquad (15)$$

Equation 15 contains only terms of the second and higher orders in A and B. Because of this partial refocussing of the hyperfine interactions, the sum peaks appear as narrow lines in the neighborhood of $2\omega_I$, i.e. twice the nuclear Zeeman frequency.

The sum frequency takes its lower limiting value of exactly $2\omega_I$ when $\boldsymbol{B}_0$ is parallel or perpendicular to the line joining the electron and the nucleus. For all other directions of $\boldsymbol{B}_0$ the sum frequency is greater than $2\omega_I$. When it reaches its maximum value $\omega_{max} = 2\omega_I + \Delta$ the intensity of the sum peak is also at its maximum. Consequently, in a powder sample the sum peak extends over the frequency range from $2\omega_I$ to ω_{max}. As the intensity is reduced in regions where the gradient changes only slightly (i.e. near $2\omega_I$) due to the effect of the dead time, the sum peak spectrum for each nucleus usually appears as only a narrow line at the frequency ω_{max}. The frequency shift Δ is closely related to the dipolar part of the hyperfine coupling, and it contains important information about the positions of the nuclei.[122, 123]

In most cases the widths of the individual sum-frequency peaks are determined by the phase memory time T_M, which is relatively short. To improve the resolution one must therefore use a pulse sequence which allows a nuclear spin coherence to evolve during the variable time interval.[122] However, it is well known that sum frequencies do not appear in the three-pulse ESEEM experiment [Eq. (9)]. On the other hand, if in such a pulse sequence one inserts a 180° pulse at a time $T/2$ after the second 90° pulse (Fig. 35a) and increases T in a stepwise manner, sum frequencies again appear. The appearance of these sum frequencies (and also of the corresponding difference frequencies) is due to a transfer of nuclear spin coherence between the different m_S-states, which is induced by the additional 180° pulse. The slow decay of the echo intensity (determined by T_1) during the evolution time T usually results in a greatly improved resolution of the sum-frequency peaks.

Figure 35b shows such a sum peak spectrum obtained with a powder sample of Cu^{II}-glycine. So as to eliminate the dependence of the individual peak intensities on the value chosen for the time interval τ, several spectra with different τ-values were added together. In addition to the dominant peak at $2\omega_I$, which is caused by the large number of more

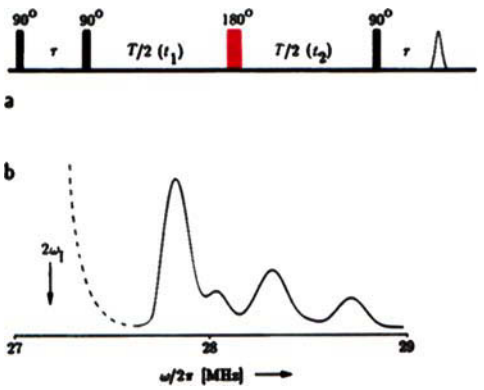

Fig. 35. Four-pulse ESEEM experiment for producing well-resolved sum-peak spectra. a) Pulse sequence. b) Sum-peak spectrum of Cu^{II}-glycine (see Fig. 28b) (cf. Ref. [122]).

distant, and therefore weakly coupled, protons, the sum frequencies of the four protons of the amino and methylene groups of the glycine ligands are clearly resolved. From the dependence of these sum frequencies on the position of the B_0 observing field in the ESR spectrum it is possible to determine the copper-proton distances and the positions of the protons. Thus, it is seen that sum peak spectra can provide valuable additional information about a spin system, especially when the hyperfine lines are broad and show little structure.

4.2.7. *Two-Dimensional ESEEM Techniques*

Two-dimensional echo modulation techniques (2D ESEEM) can often make ESEEM spectra easier to interpret. For example, in overlapping spectra they make it possible to assign the lines to individual paramagnetic centers and to determine the relative signs of the hyperfine couplings.

The 2D Three-Pulse ESEEM Technique

In this experiment both the time intervals $t_1 = \tau$ and $t_2 = \tau'$ in a stimulated echo sequence are independently increased in steps.[124] For a spin system with $S = 1/2$ and $I = 1/2$ the resulting 2D spectrum consists of six lines. Two pairs of axial peaks, one with the frequencies $(\omega_\alpha, 0)$, $(\omega_\beta, 0)$ and the other with the frequencies $(0, \omega_\alpha)$, $(0, \omega_\beta)$, form two identical 1D spectra along the ω_1 and ω_2 axes respectively, while the two cross-peaks at $(\omega_\alpha, \omega_\beta)$ and $(\omega_\beta, \omega_\alpha)$ are positioned symmetrically on either side of the diagonal $\omega_1 = \omega_2$ (Fig. 36a). In the magnitude spectrum all these peaks have the same intensity; blind spots, which caused difficulties in 1D spectra, therefore do not arise in this 2D ESEEM method.

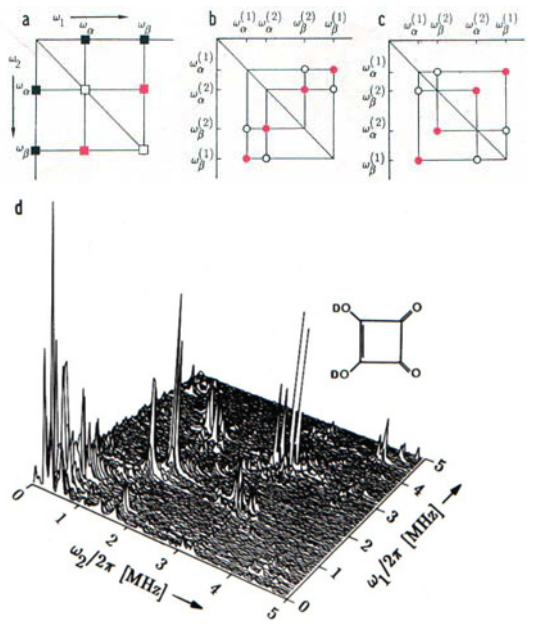

Fig. 36. a) Schematic 2D ESEEM spectrum for a spin system with $S = 1/2$ and $I = 1/2$; ■: peaks observed in both the three-pulse and in the four-pulse spectra, □: diagonal peaks arising from incomplete excitation in the HYSCORE method. b) Schematic 2D ESEEM spectrum for a three-spin system with $S = 1/2$ and $I_1 = I_2 = 1/2$. The two hyperfine coupling constants a_1 and a_2 have the same sign; ○: cross-peaks $(\omega_\alpha^{(i)}, \omega_\beta^{(j)})$ with $i \neq j$, ●: cross-peaks $(\omega_\alpha^{(i)}, \omega_\beta^{(j)})$ with $i = j$ (Ref. [70]). c) Corresponding situation where the hyperfine coupling constants a_1 and a_2 have opposite signs. d) HYSCORE single crystal spectrum at 295 K of deuterated squaric acid irradiated with 2 MeV electrons (Ref. [125]).

In systems with several spins and sufficiently large modulation depth parameters k_i, combination cross-peaks also appear, and these can be used to determine the relative signs of the hyperfine couplings. This is shown in Figure 36 (b and c) for the example of two nuclei with spin $I = 1/2$ and frequencies $\omega_\alpha^{(1)}$, $\omega_\beta^{(1)}$, $\omega_\alpha^{(2)}$ and $\omega_\beta^{(2)}$. In Figure 36b the two hyperfine coupling constants a_1 and a_2 have the same sign, whereas in Figure 36c they have opposite signs.

A disadvantage of the 2D three-pulse ESEEM technique is that the echo intensities decay at different rates along the two time axes, with T_M-relaxation along the t_1-axis and T_1-relaxation along the t_2-axis. As a result the line widths in the two frequency dimensions can differ by orders of magnitude.

The 2D Four-Pulse ESEEM Technique

Undesirable line-width effects of the kind just described do not arise in the HYSCORE (hyperfine sublevel correlation) experiment.[125] The HYSCORE technique is a 2D version of the four-pulse sequence mentioned in Section 4.2.6 (Fig. 35a), with an evolution period t_1, a 180° mixing pulse, and a second evolution period t_2. As nuclear spin coherence evolves during both these evolution periods, the line widths also are determined in both frequency dimensions by T_1 (or T_{2n}). This is illustrated in Figure 36d, which shows the HYSCORE spectrum of an electron-irradiated single crystal of deuterated squaric acid.[125]

When the modulation formulas of the three-pulse and four-pulse 2D ESEEM techniques are compared, it becomes clear that the same six frequencies occur in both experiments. However, in the HYSCORE plot the amplitudes for the different frequencies depend in a complicated way on ω_α, ω_β and τ. In particular, for certain values of these parameters (blind spots) the two cross-peaks can disappear.[70] Moreover, if the MW pulses in a HYSCORE experiment are not sufficiently hard to fully excite the spin system, new peaks appear along the diagonals of the 2D plot at the frequencies $(\omega_\alpha, \omega_\alpha)$ and $(\omega_\beta, \omega_\beta)$ (Fig. 36a). These correspond to the 1D three-pulse ESEEM spectrum, and are produced by components of the magnetization that cannot be completely refocussed by the 180° pulse. As the HYSCORE experiment involves four pulses, up to 13 unwanted echoes can result when the excitation is incomplete; however, all these can be eliminated by suitable phase cycles.[70] In the HYSCORE experiment too the positions of the cross-peaks can be used to determine the relative signs of hyperfine coupling constants (Fig. 36b, c).

4.3. Improving the Resolution of Powder ESR Spectra

Improving resolution is a subject of central importance for the spectroscopist. In ESR the spectra of disordered systems especially are lacking in structure. In this section we consider pulse techniques which suppress parts of the spectrum corresponding to particular orientations, thereby making it possible to greatly improve the resolution of the entire powder ESR spectrum.

The method is based on an echo-detected ESR experiment in which the orientation of the sample relative to the magnetic field vector $\boldsymbol{B}_0$ is altered during the pulse sequence.[126] To understand how this change of orientation affects the powder spectrum we will consider an axially symmetric spin system with $S = 1/2$. The resonance surface has the form of an ellipsoid of rotation B_{res}, the dimensions of the axes being $B_{\parallel} = \hbar\omega_{mw}/\beta g_{\parallel}$ and $B_{\perp} = \hbar\omega_{mw}/\beta g_{\perp}$ where $g_{\parallel}$ and $g_{\perp}$ are the principal values of the g-tensor (Fig. 37). For a given orientation of the magnetic field (defined by the angle θ) the resonance field strength is given by $B_{res}(\theta) = \hbar\omega_{mw}/\beta g(\theta)$, with $g(\theta) = (g_{\parallel}^2 \cos^2\theta + g_{\perp}^2 \sin^2\theta)^{1/2}$. Evidently the directions $B_{\parallel}$ and $B_{\perp}$ correspond to stationary points on the ellipsoid surface (i.e. points at which $dg(\theta)/d(\theta) = 0$), and near these directions the resonance condition remains unchanged when the magnetic field is rotated.

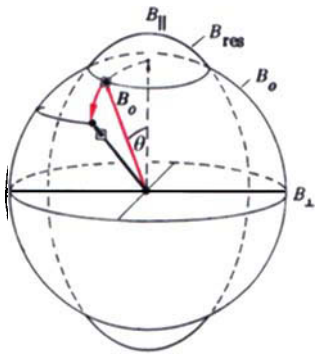

Fig. 37. Diagram to explain the experiment in which the orientation of $\boldsymbol{B}_0$ is changed during the pulse sequence. B_{res}-ELLIPSOID is the ellipsoidal resonance surface for an axially symmetric g-tensor with $g_{\perp} > g_{\parallel}$; B_0-SPHERE is a sphere with radius B_0 (Ref. [126]).

In this experiment the first 90° pulse of a three-pulse sequence excites those centers which satisfy the resonance condition $B_0 = B_{res}(\theta)$. For a given magnetic field strength B_0 this condition is satisfied for all the field vectors $\boldsymbol{B}_0$ that lie along the surface of a cone whose apex angle is 2θ. A change in the orientation of the sample relative to $\boldsymbol{B}_0$ in general alters the angle θ, and therefore also the resonance condition. The two 90° pulses, which are applied following such a reorientation, are unable to generate a stimulated echo because of the change in the resonance condition (Fig. 38a). This applies for all orientations except in the case of those sites for which the principal axes of the g-tensor are parallel or perpendicular to $\boldsymbol{B}_0$ ($\theta = 0$ or 90°), or for which a reorientation does not alter the angle θ (i.e. $\boldsymbol{B}_0$ lies on the same conical surface for both orientations).

Therefore in a powder sample any rotation between the molecular and the laboratory coordinate systems reduces all the contributions for $\theta \neq 0,90°$. If also all the other unwanted components in the spectrum are to be suppressed, the change of orientation during the pulse sequence must occur in two mutually perpendicular directions (Fig. 38b).[126] The spectrum then essentially consists only of contributions from the orientations $\theta = 0$ and $\theta = 90°$. From an experimental standpoint the necessary reorientation can be achieved either by rotating the field vector $\boldsymbol{B}_0$ or by rotating the sample.

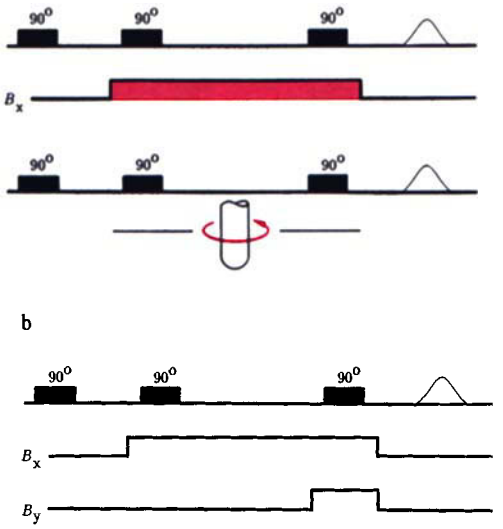

Fig. 38. Three-pulse sequences with orientational changes. a) One reorientation (top: field jump, bottom: sample rotation). b) Two reorientations (two field jumps in mutually perpendicular directions) (Ref. [126]).

Rotation of the Field Vector $\boldsymbol{B}_0$

Deflecting the field vector $\boldsymbol{B}_0$ is most easily achieved by switching on an additional field component perpendicular to the z-axis of the laboratory coordinate system (Fig. 38a, top). By using suitable auxiliary coils close to the resonator a transverse field of up to 10 mT can be established within 300 ns. For a longitudinal field B_0 of 0.3 T this corresponds to a deflection angle δ of about 1°, which is sufficient to give a considerable improvement in resolution for many compounds containing transition metal ions. Figure 39 shows echo-detected powder ESR spectra of a copper complex, measured both with and without a field jump.

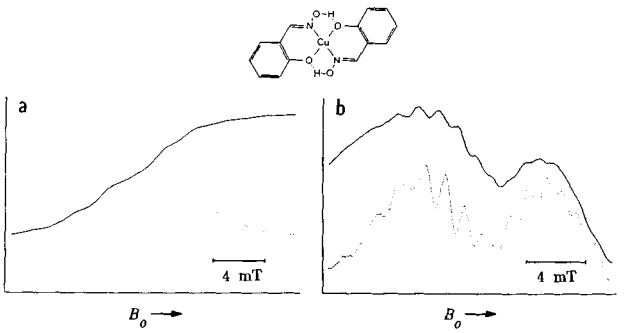

Fig. 39. Improvement in the resolution of powder ESR spectra of [Cu(sal)$_2$] (sal = salicylaldoxime) in [Ni(sal)$_2$] at 10 K using the field jump technique. a) Top: echo-detected three-pulse ESR spectrum, low-field region, bottom: corresponding ESR spectrum with one field jump. b) Top: echo-detected three-pulse ESR spectrum, low-field region, bottom: corresponding ESR spectrum with two field jumps (Ref. [126]).

Rotation of the Sample

Rotating the sample about an axis perpendicular to $\boldsymbol{B}_0$ is exactly equivalent to the experiment in which one of the field directions is altered (Fig. 38a, bottom). So as to be able to

work with low rotation frequencies, it is again preferable to use the three-pulse sequence, in which the decay of the echo intensity is determined by the spin-lattice relaxation time T_1. At sufficiently low temperatures a rotation frequency of a few hundred Hz is usually sufficient to suppress unwanted orientations from the spectrum. For example, with $T = 20\,\mu s$ and a rotation frequency of 200 Hz the sample rotates through an angle of about 1.5° between the second and third MW pulses.

4.4. The Electric Field Effect

The crystal field parameters of a paramagnetic center can be affected by an external electric field. Two mechanisms are mainly responsible for this effect. Firstly the electric field, by shifting the positions of ions, induces electric dipole moments, and secondly the wave functions of the ions become polarized. Since this effect is seen as a shift of the ESR lines which is approximately proportional to the electric field, it is referred to as a "linear" electric field effect (LEFE).[127] However, not all paramagnetic centers show an LEFE. For example, the magnetic parameters of free radicals are insensitive to electric fields. Also metal ions at sites with inversion symmmetry are to a first-order approximation unaffected by an external electric field.

As the local electric fields present are often greater by several orders of magnitude than the highest experimentally attainable fields that can be applied externally, the shifts of the resonance lines are often small, even in compounds without inversion symmetry, and in a CW ESR experiment they are only observable in rare cases. This is especially true of disordered systems. However, the difficulty of measuring small changes in the position of an inhomogeneously broadened line with a width of typically 1 mT or more can be avoided by pulse methods.[128]

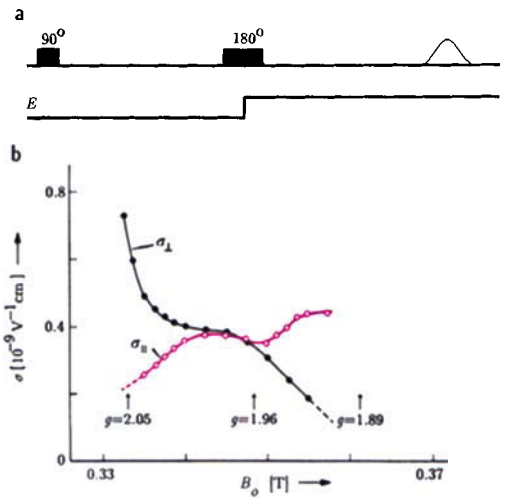

Fig. 40. Linear electric field effect (LEFE). a) Pulse sequence. b) LEFE shift parameters for spinach ferredoxin as a function of the magnetic field B_0 (Ref. [129]). $\sigma_\parallel : E \parallel B_0$, $\sigma_\perp : E \perp B_0$.

The pulsed LEFE experiment is shown in Figure 40a. In a two-pulse sequence an electric field jump is applied at the same time as the 180° pulse. This changes the precession frequency of the magnetization generated by the first pulse by an amount $\Delta\omega$, so that the echo formed at the time 2τ has a phase shift $\Delta\Phi = \tau\Delta\omega$. Since in a disordered system there exists, for every site with a positive $\Delta\Phi$, another site with an equal and opposite negative $\Delta\Phi$, the phase information is lost, and the effect must be detected by measuring a change in the intensity of the echo. For comparison purposes it is usual to define a shift parameter σ,[68] which is the electric field strength for which the echo amplitude is reduced by 50%.

As well as the simple test of whether or not there is inversion symmetry, paramagnetic compounds can also be identified and classified according to the curves of the shift parameters $\sigma_\parallel$ (E parallel to B_0) and $\sigma_\perp$ (E perpendicular to B_0) as functions of B_0.[68] As an example Figure 40b shows the result of an LEFE measurement on spinach ferredoxin, an iron-sulfur protein with two iron atoms.[129] The curves of $\sigma_\parallel$ and $\sigma_\perp$ as functions of B_0 show that the two iron atoms in this complex are non-equivalent.

4.5. Longitudinal Detection

In most pulsed ESR experiments one measures a transverse magnetization during the acquisition period, whether this takes the form of an FID, an echo, or some other transient signal. As well as this normal procedure, however, some other methods of observation can be used. These have been developed for special fields of application, where in many cases they have advantages over the conventional method of observation. One such method is optically detected magnetic resonance, whose most striking feature is its extremely high sensitivity.[130]

The technique that will be described here is a less well-known one, in which one measures the rapid change in the z-magnetization during the short microwave pulses.[73] In the simplest version of such a longitudinal detection (LOD) experiment, a 180° pulse of duration t_p inverts the on-resonance component of an inhomogeneous ESR line. This causes a hole of depth $2\,Mz$ and width $2/t_p$ to appear in the ESR line, and after the pulse this begins to fill up again with the time-constant T_1. The time-derivative $\dot{M}_Z$ of the z-magnetization induces an e.m.f. $U \cong \dot{M}_Z$ in a pick-up coil which has its axis *parallel* to B_0 and is connected to a capacitance C to form a resonant circuit (Fig. 41). This oscillatory circuit, whose resonance frequency $\omega_{res}/2\pi$ is in the range 1–

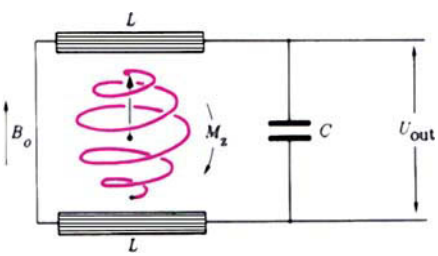

Fig. 41. Schematic arrangement for a pulsed ESR experiment with longitudinal detection (Ref. [73]). L (inductance) indicates the position of the pick-up coils.

100 kHz, acts as a band-pass filter and selects one Fourier component of the signal. Usually the resonance frequency of the oscillatory circuit is chosen to be equal to the repetition rate of the pulse (or of the pulse sequence). The periodic excitation by the pulses builds up an e.m.f. $U_{out}(t) = U \sin(\omega_{res}t + \varphi)$ across the resonant circuit, and after suitable filtering this can be recorded by an RMS voltmeter. As the detection frequency and the microwave frequency differ by many orders of magnitude, the excitation and the detection are completely decoupled from each other. Dead-time effects caused by the microwave pulses do not arise in the LOD method.

Figure 42 shows three alternative LOD sequences, together with the corresponding curves of z-magnetization vs. time. The sequence consisting of a single 180° pulse (Fig. 42a) allows one to measure an ESR spectrum by slowly changing the field B_0. An example of an application for which this

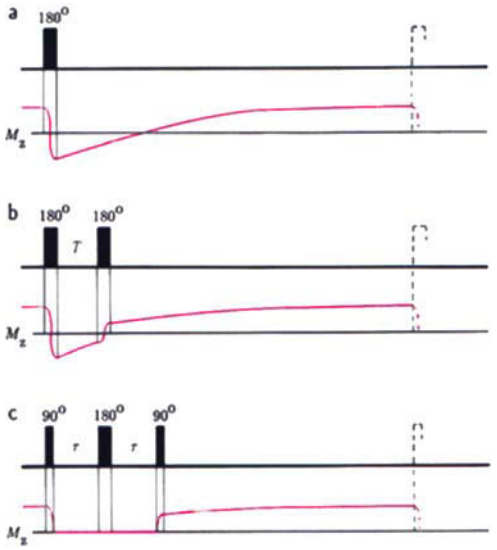

Fig. 42. LOD pulse sequences. a) One-pulse sequence for measuring ESR spectra. b) Two-pulse sequence for measuring T_1. c) Three-pulse sequence for measuring T_M and recording echo modulation patterns (Ref. [73]).

LOD sequence can be used is in detecting short-lived radicals that are produced immediately before the 180° pulse, e.g. by a laser pulse. It is also used for measuring ESR spectra with very broad lines, since the signal intensity is not limited by the amplitude of the modulation as it is in a CW ESR experiment.

The LOD sequence 180°–T–180° (Fig. 42b) is useful for measuring short longitudinal relaxation times. The inverted z-magnetization produced by the first 180° pulse relaxes during the interval T and is measured during the second 180° pulse.

Lastly, in the LOD sequence 90°–τ–180°–τ–90° (Fig. 42c) the third pulse turns the echo magnetization produced by the first two pulses out of the xy-plane. This again constitutes a rapid change of the z-magnetization, which is detected by the pick-up coil. This sequence is suitable for measuring short transverse relaxation times or for recording the rapidly decaying ESEEM patterns of disordered systems, since the data acquisition is then no longer limited by the dead time.

4.6. Special Pulsed ENDOR Techniques

This section describes a number of new pulsed ENDOR methods that have been developed to optimize the ENDOR effect, to determine the number of equivalent nuclei, or to simplify complex ENDOR spectra. All these techniques are based on the transfer and subsequent detection of polarization. Recently also some pulse sequences based on the indirect observation of nuclear spin coherence have been proposed. For double resonance methods in which the ENDOR effect is observed through a change in the electron spin coherence, the reader is referred to the literature.[131, 132]

4.6.1. Optimizing the ENDOR Effect

With the Mims and Davies ENDOR sequences (see Fig. 23) it is possible in the most favorable cases to obtain an ENDOR effect of 50% (disappearance of the echo intensity).[133] If one replaces the RF pulse by a sandwich consisting of a 180° MW pulse flanked by two 180° RF pulses, this increases the ENDOR effect to 100% in both cases (inversion of the echo).[134] The pulse sequence that gives this optimum polarization transfer in the case of the Davies ENDOR experiment is shown in Figure 43a.

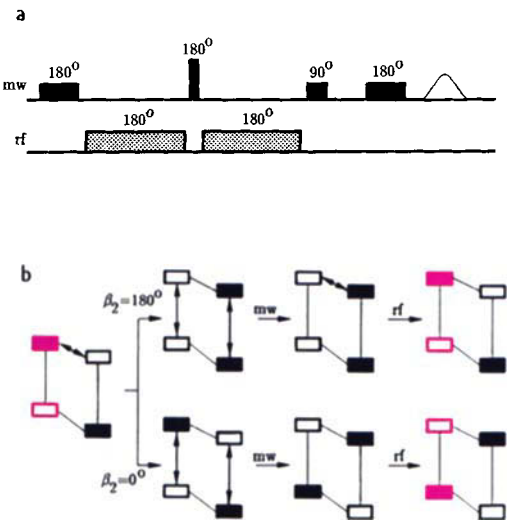

Fig. 43. a) Davies ENDOR with optimized polarization transfer. b) Corresponding changes in populations of states (Ref. [134]).

The transfer of polarization in this extended Davies ENDOR scheme can be followed without difficulty (Fig. 43b). After the first MW pulse, which inverts the polarization of a particular ESR transition, we consider separately the polarization patterns for one on-resonance radiofrequency ($\beta_2 = 180°$) and for one off-resonance radiofrequency ($\beta_2 = 0$). From the diagrams it is evident that for the off-resonance case the polarization of the observed ESR transition at the end of the mixing period has returned to the original equilibrium condition (positive echo amplitude). However, if the frequency of the two RF pulses coincides with that of an ENDOR transition, the polarization remains inverted after the sandwich pulse (negative echo amplitude), which corresponds to an ENDOR effect of 100%.

4.6.2. *Hyperfine-Selective ENDOR Spectroscopy*

Although the double resonance effect usually gives an enormous reduction in the number of lines in an ENDOR spectrum (Section 2.2), it is often difficult in complicated spin systems to assign the transitions to individual nuclei. The pulse sequence used in the hyperfine-selective ENDOR technique (HF-ENDOR) enables one to select from a complex ENDOR spectrum only those lines that belong to a nucleus with a particular hyperfine coupling whose value can be varied at will.[135] Thus an ENDOR spectrum can be decomposed into a number of partial spectra, each of which describes a separate electron-nucleus subsystem.

The HF-ENDOR technique is based on the Davies ENDOR scheme (Section 3.4), but in this case the echo is detected at a position of the magnetic field which is shifted from the preparation stage by an amount equal to the hyperfine coupling (Fig. 44a, b). The change of position in the ESR spectrum is achieved either by a jump in the field strength, B_0[135] or by a change in the MW frequency.[136] Thus the HF-ENDOR technique is an electron-electron-nuclear triple resonance experiment.

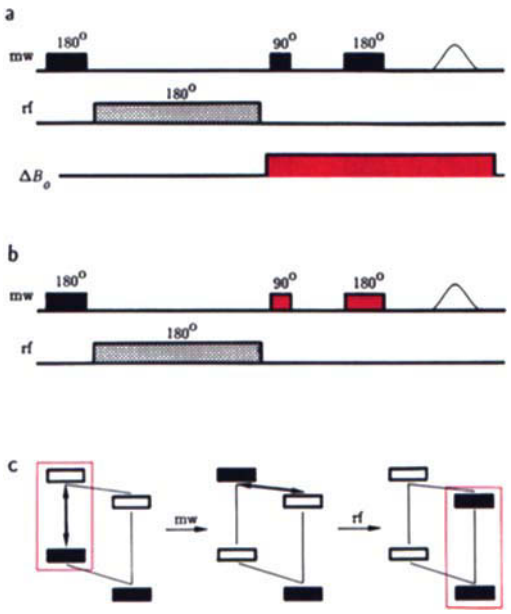

Fig. 44. Hyperfine-selective ENDOR (HF-ENDOR). a) HF-ENDOR with field jump ΔB_0. b) HF-ENDOR with two microwave frequencies. c) Corresponding changes in populations of states (Refs. [135, 136]).

If, in a complicated multilevel system, we consider a subsystem which describes the interaction between the electron spin and one nucleus with spin $I = 1/2$, the selective 180° MW pulse inverts the polarization of one of the two (allowed) ESR transitions of this subsystem (Fig. 44c). It thus "burns a hole" in the ESR line at the existing field position B_0. The selective 180° RF pulse then inverts the polarization of one of the two nuclear spin transitions. This transfers part of the polarization and forms a secondary hole in the ESR line at the position $B_0 + a$, since the two ESR transitions of the subsystem under consideration are at field positions separated by the hyperfine coupling constant a.

In the normal Davies ENDOR experiment the change which the RF pulse induces in the polarization at the field position B_0 is detected by a two-pulse echo sequence. However, since now all the ENDOR transitions can originate from any arbitrary energy level, all the ENDOR lines can be observed by using a variable radiofrequency at the field B_0. But for an observer at the field position $B_0 + \Delta B_0$, the situation appears differently. At this position in the spectrum a transfer of magnetization only occurs if one of the nuclei has a hyperfine coupling constant equal to ΔB_0. Therefore at $B_0 + \Delta B_0$ one observes only the spectrum of this nucleus. This selection principle remains valid for any value of the nuclear spin quantum number I.

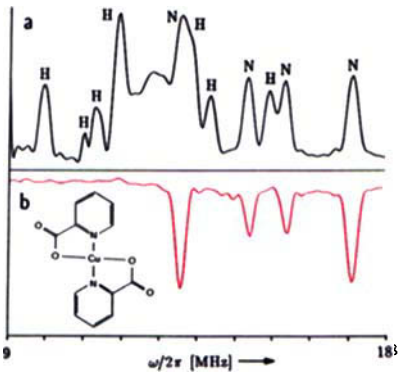

Fig. 45. ENDOR and HF-ENDOR spectra of Cu^{II}-picolinate at 10 K. a) Portion of Davies ENDOR spectrum. b) Hyperfine-selective ENDOR spectrum of the two magnetically equivalent ^{14}N nuclei; the field jump ΔB_0 between excitation and acquisition was 1.1 mT (Ref. [135]).

Figure 45 shows a portion of the ENDOR spectrum of a single crystal of Cu^{II}-picolinate, containing both proton and nitrogen lines, together with an HF-ENDOR spectrum recorded at a field position shifted by an amount equal to the hyperfine coupling constant a_N of the nitrogen nuclei.[135] This selection procedure can be repeated for each set of equivalent nuclei, thereby giving a complete breakdown of the ENDOR spectrum into its components.

4.6.3. *ESR-Detected Nuclear Transient Nutations (Multiple-Quantum ENDOR Spectroscopy)*

An RF pulse can generate nuclear transient nutations[*] within an m_S-state. Various sequences consisting of combinations of MW and RF pulses have been proposed for generating and detecting such nuclear nutations.[44, 137–139] Figure 46a shows two methods, both based on the Davies ENDOR scheme and differing only in their RF pulse sequences. In both cases the first 180° MW pulse serves to generate nuclear spin polarization. The first sequence involves a stepwise increase in the length of the RF pulse, whereas the second method uses a 180° RF pulse which is divided into two 90° pulses and the phase φ of the first 90° pulse is advanced in a

[*] Transient nutations (or Torrey oscillations) are precessions of the on-resonance magnetization in the plane perpendicular to the applied alternating field.

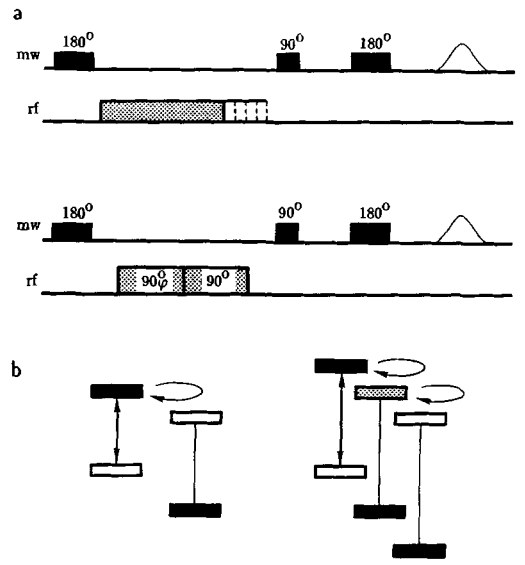

Fig. 46. Indirectly detected nuclear transient nutation. a) Pulse sequence for inducing multiple-quantum nuclear transitions. b) Nuclear nutation within an m_S spin state; left: one $I = 1/2$ nucleus, right: two $I = 1/2$ nuclei (Refs. [137, 138]).

stepwise fashion. For a spin system having a single nucleus with spin $I = 1/2$, this means that the nuclear spin polarization of the observed transition oscillates sinusoidally. These oscillations are then recorded indirectly via the electron spin-echo.

In spin systems with several equivalent nuclei a complicated nutation pattern is produced, as the RF pulse also affects the polarizations of ENDOR transitions whose energy levels have not been involved in the MW preparation pulse. This is shown schematically in Figure 46 b for the case of two nuclei with spin $I = 1/2$. Experimental techniques whereby such transitions become excited are often referred to as multiple-quantum ENDOR spectroscopy (MQ-ENDOR). The Fourier transformation of the nutation pattern yields the MQ-ENDOR spectrum. The particularly interesting feature of such spectra is that the number and intensities of the lines are characteristic of the number of equivalent nuclei in the spin system. This important item of information cannot be obtained from the ENDOR spectrum. Figure 47a shows a series of calculated MQ-ENDOR spectra for one to four equivalent nuclei with spin $I = 1/2$.

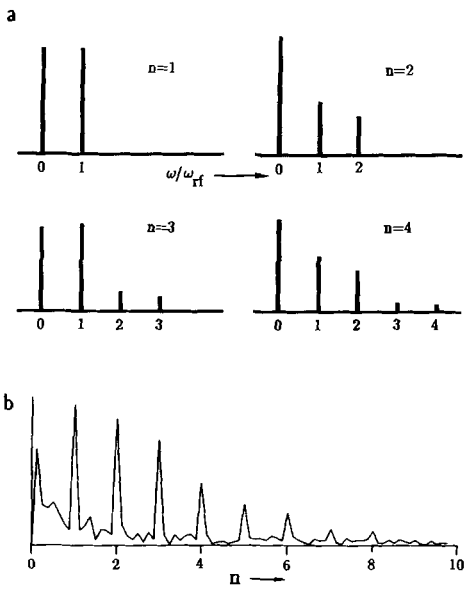

Fig. 47. a) Multiple-quantum patterns for $n = 1$, 2, 3 and 4 equivalent nuclei with spin $I = 1/2$. b) MQ-ENDOR spectrum of the protons of *trans*-polyacetylene with $\omega_{RF} = \omega_H$ (Refs. [137, 138]).

If the field intensity of the RF pulse is greater than the difference between the hyperfine coupling constants, it is also possible to induce MQ-ENDOR transitions of non-equivalent nuclei. The number of MQ transitions observed then provides a measure of the density of the spectral distribution of the hyperfine couplings. An example of such an *n*-quantum spectrum for solitons in *trans*-polyacetylene (Section 3.3.4) is shown in Figure 47b.[138]

4.6.4. *Pulsed ENDOR Spectroscopy in the Time Domain*

In all the ENDOR experiments described above, the RF pulse causes a transfer of nuclear spin *polarization*. However, a disadvantage of these techniques is that if the RF pulses are too short the ENDOR lines can be broadened. This broadening can be avoided by measuring the ENDOR spectrum in the time domain. Two possible pulse sequences for this, based again on the Mims and the Davies ENDOR schemes, are shown in Figure 48 a, b.[140, 141] After generating nuclear spin polarization, an intense 90° RF pulse is used to produce nuclear spin *coherence*. However, the spectral range that can be excited by the RF pulse is only about 1 MHz wide. After a time T the nuclear spin coherence is converted back into electron spin polarization by a further 90° RF pulse, and this is then measured by recording an echo. Measuring the echoes

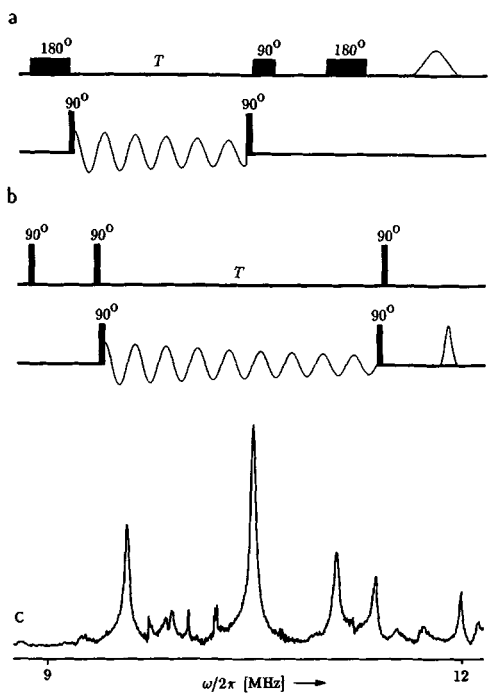

Fig. 48. ENDOR in the time domain. a) and b) Pulse sequences for measuring ENDOR spectra in the time domain. c) ENDOR spectrum of a Cu^{II}-doped single crystal of TGS reconstructed from segments. Magnitude spectra, each 1 MHz in width, with center frequencies 9.2, 9.7, 10.2, 10.7, 11.2, 11.7, and 12.2 MHz (Refs. [139, 140]).

as a function of T and performing a Fourier transformation on the data yields a portion of the ENDOR spectrum with natural line widths determined by the transverse relaxation time T_{2_n} of the nuclei. Thus the FID of the excited nuclear spins is observed indirectly via the electron spin. The entire ENDOR spectrum can be obtained by repeating the experiment with different frequencies of the RF pumping field. Figure 48c shows an ENDOR spectrum obtained by fitting together such spectral segments recorded by the stimulated echo sequence.[141]

5. Summary and Outlook

There can be no doubt that pulsed electron spin resonance techniques open up new and previously undreamed of prospects in ESR spectroscopy. Of the many different pulsed ESR methods that are described in this article, those that appear to be finding the widest application are the ESEEM technique, the FT-ESR method, and the various pulsed ENDOR methods. Since there are in most cases no real alternatives to these methods, i.e. the spectroscopic data of interest cannot be obtained in any other way, the additional cost of the equipment needed can be justified. Furthermore, the pulsed ESR instruments that are now commercially available are remarkably user-friendly, and therefore advanced knowledge of microwave electronics is not required. Moreover, the cost of a pulsed ESR spectrometer is considerably less than that of a modern NMR spectrometer.

Only the future will tell which of the sophisticated pulse techniques described here have the potential for becoming established in the long term. Some methods will undoubtedly soon become part of the everyday repertoire of pulsed ESR spectroscopy, whereas others will perhaps be only of historical interest a few years from now. Whatever the outcome, there are certain to be rapid advances in the development of pulsed ESR techniques. Also new methods will find their way into practical use, filling in gaps in the armory of pulsed ESR spectroscopic techniques.

The theoretical description of these pulsed experiments using the density operator formalism may be unfamiliar to many CW ESR spectroscopists. However, users whose interest is confined to magnetic parameters such as the nuclear resonance frequencies can safely ignore the complications of the spin dynamics on which the experiments are based.

To forecast the future of pulsed ESR spectroscopy is a risky undertaking. It seems unlikely that, as has happened in nuclear magnetic resonance, pulse methods will replace CW spectroscopy or make it obsolete within the foreseeable future. It is much more probable that pulsed ESR spectroscopy will become one of the cornerstones of ESR spectroscopy.

I thank my departmental colleagues for many useful suggestions and discussions during the preparation of this article. Furthermore, I am grateful to Bruker GmbH (Karlsruhe) for their financial support enabling the use of color printing. The support of our research by the Swiss National Science Foundation over a numbers of years is acknowledged.

Spontaneous Resolution by Stirred Crystallization**

By *J. Michael McBride** and *Randall L. Carter*

It does not take long for a beginning chemist to develop a naive trust in predictions based on probability. Unlike a physician, who deals with a handful of cases, or an epidemiologist, who deals with hundreds of thousands, a chemist has the luxury of dealing with samples that contain more than 10^{20} molecules. For such large samples, predictions based on probability verge on certainty. Chemists are not disturbed that quantum mechanics precludes strict determinism in the behavior of an individual molecule, because it supplies reliable probabilities, and for macroscopic chemical samples molecular probability amounts to collective determinism. A chemist who has difficulty repeating a literature experiment may attribute the problem to unobserved or unreported differences in procedure or materials, or to error in measurement, but not to sampling error. The precise reproducibility from experiment to experiment that is the hallmark of good chemistry depends on having samples with enormous numbers of molecules.

Because of their training, chemists are particularly intrigued by phenomena that seem improbable. Several such cases involve chirality. A familiar and profound example is the occurrence in nature of only one enantiomer of complex biological molecules. How did living systems become resolved? Does biological handedness result from some weak interaction that provided a tiny evolutionary bias in favor of one set of enantiomers, or from one single molecular event that occurred at random but was destined to become a sort of molecular "Adam" by being multiplied into the whole kingdom of living things?

Crystallization provides a more homely example of curious statistics involving chirality. Although growth of a macroscopic crystal involves a large number of molecular events, formation of the original nucleus occurs but once per crystal. It is not uncommon for a solution to deposit only one crystal. Even if 100 or 1000 crystals grow, the number of nucleation events is small by chemical standards, and they differ from most chemical phenomena in that they can often be counted individually as well as measured collectively. Recently, *Dilip Kondepudi* et al. of Wake Forest University (USA) have reported results from counting chiral crystals that provide new insights into the mechanism of nucleation.[1]

Their interest in the role of competition and autocatalysis in breaking chiral symmetry in the biosphere,[2] led *Kondepudi* et al. to repeat 19th Century work by *Kipping* and *Pope* on the crystallization of $NaClO_3$.[3] This salt is particularly well suited for such experimentation because aqueous solutions of its achiral ions produce beautiful rectangular prisms in the *chiral* cubic space group $P2_13$. Since the individual ions are achiral, they can join either enantiomeric lattice. Thus, in contrast to the situation for a racemic solution of intrinsically chiral molecules, there is no necessity that complete crystallization give equal amounts of the two enantiomeric solids. Furthermore, because of their cubic symmetry crystals of $NaClO_3$ are not birefringent, so that one may easily identify an individual crystal's handedness by its rotation of linearly polarized light ($3.6° \text{ mm}^{-1}$ at 546 nm).

In 1898 *Kipping* and *Pope* measured the handedness of 3137 $NaClO_3$ crystals from 46 separate crystallizations in order to test surprising reports that crystallization of analogous substances had shown strong bias toward formation of one enantiomorphic form. They were pleased to find that among 3137 crystals 1571 (50.08%) were dextrorotatory. This fell well within statistical error of the unbiased 50:50 distribution they anticipated.[4]

Kondepudi et al. confirmed these results by counting 525 dextrorotatory crystals in a sample of 1000. But when they tried stirring the solutions (ca. 100 rpm) to remove the concentration gradients that favor nucleation at the air–liquid interface, they found that each beaker gave a predominance of one enantiomer. There was no systematic bias in favor of one of the enantiomers (dextrorotatory crystals predominated in 18 batches, levorotatory in 14), but the bias within each batch was remarkably strong. Of the 32 batches, 23 formed *only* crystals of one enantiomer, for example one batch consisted of 865 levorotatory crystals and no dextrorotatory crystals. Among 11 829 crystals counted, only 33 had the minority configuration for their respective batch, and 15 of these were formed in one particular crystallization.

In a stirred beaker a single nucleation event apparently gives rise to most or all of the hundreds of crystals formed. The most likely mechanism of this "Adam" effect is that crystals begin nucleating at random, but the first crystal to be struck by the stirrer clones hundreds or thousands of new nuclei. Growth of so many nuclei soon lowers the concentration of the solute below the threshold for spontaneous formation of primary nuclei, so there is no way to begin crystallization of the enantiomer.[5]

We have confirmed this mechanism by video recording a number of stirred crystallizations. Figure 1 presents three stages during crystallization of a supersaturated $NaClO_3$ solution that had been prepared by heating near the boiling point, degassing under vacuum, filtering through glass wool, and reheating to near the boiling point. After about an hour of stirring at room temperature,[6] a single crystal had formed on the bottom of the vial and was growing toward the stirrer at 0.2 mm min^{-1}. Figure 1a shows the first collision of the stirrer with the tip of the crystal. After 20 seconds and 35 collisions stirring was stopped. Within another 30 seconds more than 5000 tiny crystals became visible (Fig. 1b). A minute and a half after the first collision these crystals had grown into beautiful small prisms with dimensions of 0.1 to 0.2 mm (Fig. 1c). The speed with which the new crystals developed leaves no doubt that they grew from

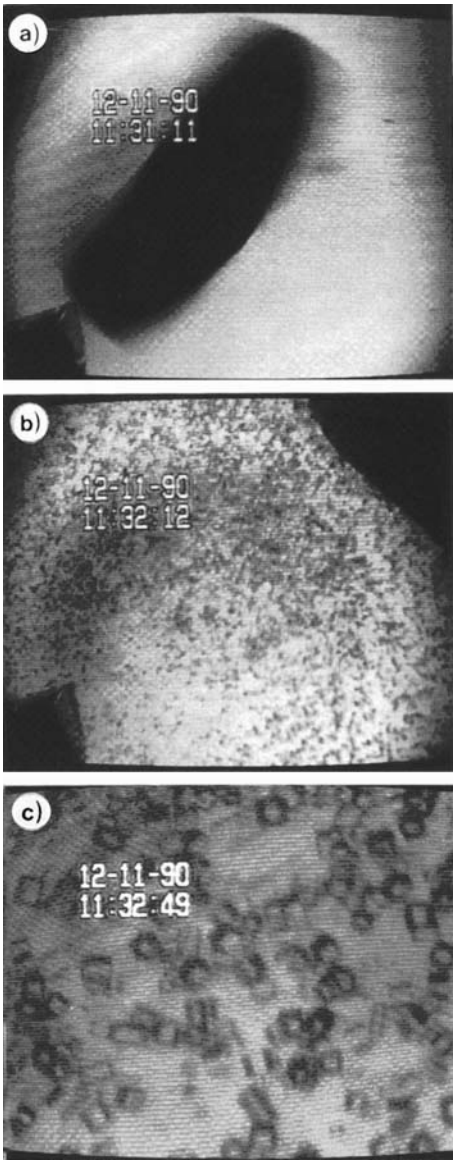

Fig. 1. Figures from a video recording of magnetically stirred crystallization of $NaClO_3$ solution: a) first contact between 10×3 mm stirrer and tip of primary crystal; b) within 1 min stirring has been stopped (stirrer at top right) and solution is filled with new crystals; c) sevenfold increase in magnification shows that new crystals are 0.1 to 0.2 mm prisms. Note in Figure (b) that the tip of the primary crystal was not visibly damaged by spawning thousands of secondary nuclei.

nuclei struck from the tip of the single crystal by these few contacts with the stirrer.[7] Subsequent examination of 48 daughter crystals with a polarizing microscope showed that every one was levorotatory, as was the initial crystal.

Like many other phenomena with such a reasonable explanation, the results of *Kondepudi* et al. may not be surprising, in retrospect. As they point out, the idea of cloning crystals during stirred crystallization is familiar to chemical engineers as secondary nucleation.[8] Their novel contribution has been to study an achiral solute that gives chiral crystals and thus to provide a powerful new tool for demonstrating and studying secondary nucleation. For example, it has been suggested that secondary nuclei arise from an hypothetical layer of adsorbed molecular aggregates that have not yet been incorporated into the crystal lattice,[8] but *Kondepudi's* results show that these nuclei had been incorporated at least enough to acquire the absolute configuration of the bulk crystal.

There have been several previous reports of less dramatic resolutions in *unstirred* solutions. In 1954 *Havinga* gave a clear discussion of "spontaneous asymmetric synthesis" in crystallizing the salt of a slowly racemizing allyl ammonium ion.[9] In 1971 *Pincock* et al. reported spontaneous resolution during crystallization of melted 1,1'-binaphthyl at 150 °C, at which temperature conformational racemization of the molecule in solution is rapid.[10] Like *Havinga*, they measured resolution by optical rotation after dissolving the crystals at room temperature, where molecular racemization is slow. In 1982 *Addadi*, van *Mil*, and *Lahav* reported spontaneous resolution during crystallization of a substituted divinylbenzene from ethanol, but not from other solvents.[11] They measured resolution using optical rotation of the cyclobutane formed by solid-state [2 + 2] photocycloaddition. In seven crystallizations the enantiomeric excess ranged from 46% to "ca. 100%". In 1986 *Evans* et al. reported that solid-state photolysis of chiral crystals of an achiral dibenzobarrelene gave levorotatory product from all eight crystals formed in one batch.[12] In 1990 *Feng* and *McBride* reported that each of the 11 crystals from small-scale crystallization of a diacyl peroxide was of the same chirality.[13]

For achieving practical resolutions *Kondepudi*'s approach of stirring during crystallization has the advantages of reproducibly giving very high enantiomeric excess and of not requiring the growth and separation of large single crystals. Intentional seeding with dust from a single crystal might be equally effective, but cloning nuclei from the first spontaneously nucleated crystal to strike the stirrer automatically introduces a shower of nuclei at an appropriate level of supersaturation. Intentional seeding has the advantage that the chirality of a given batch is predictable. Either technique should work best when applied to a solution of achiral or rapidly racemizing species that form chiral crystals.

Determining resolution by counting individual crystals has an obvious advantage in precision over the previous approach of measuring optical rotations in solution. It would be very difficult by solution rotation to distinguish 99 from 100% purity, but *Kondepudi* had no difficulty in counting ratios of 781:0 or 841:2. Thus his work may form the basis for a new way of studying crystallization; one in which statistical analysis plays an important role. One may now reevaluate previous studies statistically and carry out new studies to look for the contribution of cloning in unstirred systems. It seems clearly to have played a role in *Kipping* and *Pope*'s early work. Their data show that 5 of the 46 batches had distributions that departed from 50:50 by more than 2.3 standard deviations (σ), where only 1 in 50 would be expected to do so. The most dramatic had 24 dextrorotatory crystals and 68 levorotatory crystals, thus deviating from expectation by more that 4σ, an event that should occur only one time in 5000. At the other extreme, where 11 of the batches should have departed from 50:50 by *less* than 0.32σ, in fact only three did so. This suggests that cloning occurred in most, if not all, of their crystallizations.

The role that stirred crystallization may have played in the origin of biological chirality is not clear, but the surprise that many chemists (including the present authors) experienced

on learning of *Kondepudi*'s results shows clearly that mental adjustments are required in order to deal intuitively with "improbable" solid-state phenomena.

The Rationality of Random Screening— Efficient Methods of Selection of Peptides and Oligonucleotide Ligands

By *Andreas Plückthun** and *Liming Ge*

Words like "random" and "screening" imply ignorance about a system, and, to some, an inefficient, inelegant, and irrational method of research. This article will highlight some examples from the recent literature, where random mutagenesis and screening approaches have been used very elegantly to remove ignorance. Such strategies may, in some cases, contribute to a much faster gain of information than any testing of preconceived theories. They have also been instrumental in gaining insight into evolutionary processes at the molecular level.

To chemists, random screening is entirely familiar. In pharmacological research, "lead"-compounds have traditionally been found by screening natural products from organisms with names often refractory to memorization. The "refinement" of such compounds by the sometimes sarcastically called "methyl-, ethyl-, futile" chemistry is initially a random-walk probing the binding pocket of the affected enzyme or receptor. Quantitative structure–activity relationships can only be derived and applied after enough initial data have been accumulated. Although tremendous progress is being made in various aspects of theoretical chemistry and many facets of molecular modeling (not to be reviewed here), a breakthrough completely obviating empirical approaches is still not in sight.

Much of this reseach ultimately deals with the binding of ligand molecules to proteins: the ligands may be small organic molecules, other proteins, peptides, DNA or RNA. However, the prediction of the magnitude of such binding interactions is in most cases still close to impossible, even if the structures of *both* the proteins *and* the ligand are known. In many cases of interest to the researcher, the structure of the receptor protein will be unknown, and it cannot be predicted from the amino acid sequence. Furthermore, flexible ligands such as peptides have an enormous number of accessible conformations, and it is generally not clear, in which conformation such flexible ligands are bound.

The substances for which very large numbers of variants can be most easily obtained are peptides, proteins and nucleic acids. "Dirty" oligonucleotides can be synthesized by mixing a certain percentage of the "wrong" bases at each position with the correct one, or even with a complete random assortment of bases at predefined positions.[1] Such oligonucleotide mixtures may themselves constitute the ligand mixture, out of which the most efficient binding species can be searched or selected if the ligand or the receptor is DNA (see below). Alternatively, these oligonucleotides may be used to randomize a certain portion of the gene encoding the protein or peptide of interest.

Pioneering work in this area was performed by *J. R. Knowles* et al. Triose phosphate isomerase is an enzyme that may be regarded as having reached its endpoint in evolution.[2] The rate of the reaction it catalyzes is only limited by diffusion of the substrate. This means that the cell producing the enzyme does not gain anything from modifying the enzyme to accelerate the rate of the chemical reaction further, as the turnover will not get any faster. A single mutation in the catalytic base of the enzyme (changing its orientation and distance from the substrate) decreases this rate enough that the reaction is no longer diffusion controlled. Then, there is motivation again for the cell to improve the enzyme. *Knowles* et al. used "dirty" oligonucleotides to create a collection of genes with random mutations and introduced these genes into an *E. coli* strain devoid of its own triose phosphate isomerase. In the presence of appropriate precursors, the cells would grow if and only if a functional isomerase was present. The lower the level of the enzyme present in the cell, the higher the rate of the enzyme-catalyzed reaction had to be to support the growth of the bacterial cell. With this strategy, the research group found enzymes with activities much improved from the starting mutant, but different in amino-acid sequence from the wild-type.[3] This work shows that there are alternative solutions to the design of an efficient catalyst. It is rather unlikely that, with the present low level of understanding of protein structures, these alternative, efficient enzyme variants would have been found by any other way.

The elegance of this approach is its use of a positive in vivo selection. This, however, is also its limitation, as it requires both turnover and a suitable metabolic pathway in the host cell. More general solutions of finding the optimal ligand or the optimal receptor will therefore have to be carried out *outside* of the cell. In the work on triose phosphate isomerase, the underlying question was, which active sites would be most suitable for the catalytic task. In the other examples discussed, the question was which ligand would best fit a certain protein binding site.

Three groups[4–6] devised a rather efficient strategy to investigate which peptide would best fit a given binding site. In this "protein strategy" (Fig. 1) the peptides were, however, not tested as such, but were instead presented on the surface of a protein of bacteriophage M13. The essence of the experiments was to create a collection of phages (a so-called epitope library), retain those on a filter that bind to the given binding protein and amplify them by infecting *E. coli* cells. This example illustrates the basic features that any kind of screening system of binding must have, be it for the ligand or the receptor: a selection step, which separates the functional receptor or ligand molecules from the non-functional ones, and an amplification step. As a very large number of candidates are to be screened, very few molecules of each individual molecular species will be present, making this amplification step necessary for subsequent selection. Also, the manipulation must be facile enough to allow the enrichment to be carried out through various cycles.

Scott and *Smith*[4] inserted the epitopes to be tested into the pIII protein of bacteriophage M13. Apparently, foreign inserts at the chosen position did not prevent the phage from infection. The phage carries a tetracycline resistance gene so

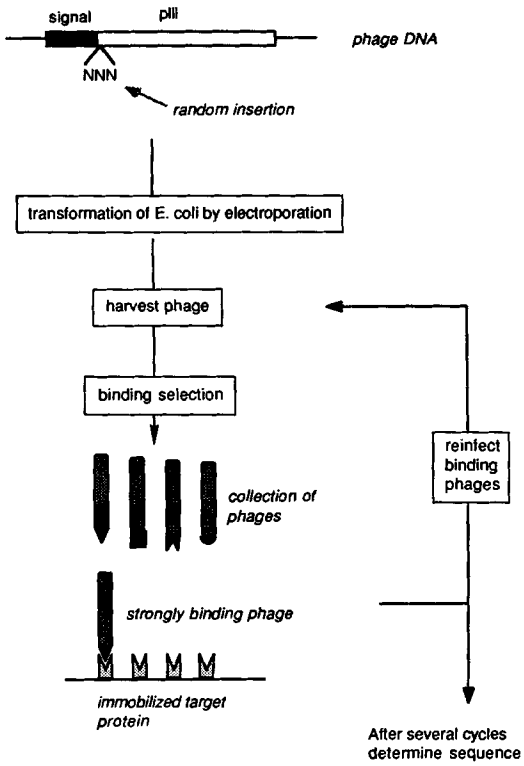

Fig. 1. The protein strategy of random screening.

that only one infection is necessary to propagate the DNA. Phage-carrying bacteria were not recognized as plaques but as colonies on selective medium. Since non-functional frame shift mutants in this protein could be propagated as well, the ability to infect could be used as a selection for epitope inserts which restored the reading frame. The authors tested the system with two monoclonal antibodies specific for a known hexapeptide, an epitope from hemerythrin. The antibodies were biotinylated and mixed with the phage. The antibodies and antibody-phage complexes were then adsorbed to a streptavidin-coated surface—streptavidin forms extremely tight complexes with biotin. Non-adsorbed phages were washed off, while bound phages were eluted with acid and amplified after infection. After several rounds, the DNA of a number of phages encoding the epitopes in protein pIII were sequenced. Reassuringly, sequences very similar to the known epitope were found. A very similar approach was also reported by *Cwirla* et al.[5]

Also using the pIII protein of bacteriophage M13, 15-residue-streches of inserted peptides were randomized by *Devlin* et al.[6] However, mutants that would directly bind to streptavidin were searched. Interestingly, all of the peptides found contained a core consensus sequence. This shows that the approach can be used to detect peptide ligands even for proteins that have no known affinity for any peptides. It will now be necessary to quantify some of the binding constants in order to estimate the minimal affinities that still can be detected.

A related concept has been used to find DNA sequences that bind to a DNA binding protein of unknown specificity. In this case, the random oligonucleotides can either be used directly or be introduced into a larger plasmid ("oligonucleotide strategy") (Fig. 2). In the most general case, the mixture of ligands is incubated with the protein in question and binding species are either physically separated by adsorbing the protein to a solid phase or functionally enriched, e.g. by their ability to function as primer. The polymerase chain reaction

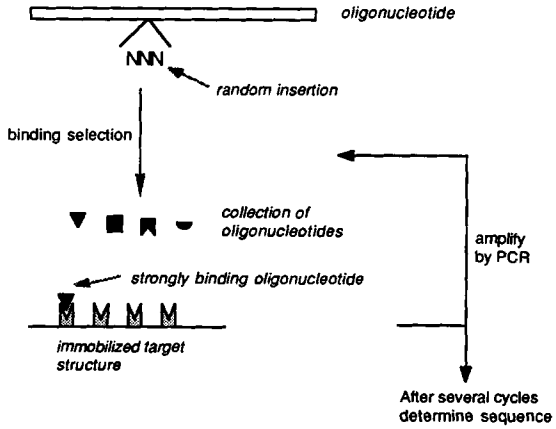

Fig. 2. The oligonucleotide strategy of random screening.

(PCR)[7] is then used to amplify those sequences that are bound by the protein in vitro. The availability of this in vitro exponential amplification method sets DNA and RNA apart from all other ligands.

Thiesen and *Bach*[8] used this strategy to determine the binding sites on DNA recognized by the human transcription factor SP1. The consensus binding site was known from previous work, thus allowing the method to be validated. The template oligonucleotides were designed to contain a defined region of 22 nucleotides on both ends, which served as the hybridization sites for PCR primers of 22 nucleotides in length. The central regions of the double stranded template oligonucleotides were twelve completely random nucleotides. The SP1 protein was incubated with the mixture and protein-DNA complexes were then bound to a nitrocellulose filter. Non-binding DNA was washed off and bound DNA was eluted and amplified by PCR. Further enrichment of binding sequences was achieved by the so-called band-shift electrophoresis: the migration of the functional oligonucleotides in a polyacrylamide gel is retarded by bound proteins. When oligonucleotides from the retarded bands were cloned and sequenced, sequences rather similar to the known consensus sequences of transcription factor SP1 were retrieved.

Tuerk and *Gold*[9] used an in vitro selection and amplification method to determine sequences crucial for the binding of T4 DNA polymerase to the 5′ leader sequences of its own mRNA; they speak of "systematic evolution of ligands by exponential enrichment" (SELEX). The binding of T4 DNA polymerase to a 36-nucleotide (nt) fragment (in which a 5-bp helix with an 8-nt loop is found) of its own mRNA prevents translational initiation. Thus, an autogenous regulation of the gene is achieved. The sequences of these eight crucial nucleotides from bacteriophage T4 and a distantly related bacteriophage RB69 are identical. The question investigated by these authors was whether other sequences besides the one found in T4 and RB69 could give rise to functional interactions. *Tuerk* and *Gold* randomized the sequence of these eight bases in single-stranded DNA templates. They

then transcribed these templates in vitro, and the excess amount of RNA transcripts was mixed with the T4 DNA polymerase. The RNAs retained by the polymerase bound to a nitrocellular filter were used as templates for reverse transcriptase and the resulting cDNAs were amplified by PCR. These template DNAs were again transcribed in vitro and the RNA transcripts were subjected to the next round of competitive binding selection. After the fourth round of selection and amplification, two sequences with equal affinity to the polymerase were predominant. One of them was the wild-type sequence and the other one differed in four bases from the wild-type, giving rise to two new base pairs in the loop. The existence of another sequence with equal binding affinity as the wild-type, but which is not found in nature, strongly suggests that there are other crucial roles played by the wild-type sequence, in addition to the binding of the polymerase.

A similar approach has been used by *Ellington* and *Szostak*[10] to enrich the RNA molecules that bind to dyes resembling a redox cofactor, nicotinamide adenine dinucleotide (NAD), from a random RNA pool. From an initial pool of 10^{13} different sequences, 10^2 to 10^3 were found to bind to the dye, immobilized to a column, after 6 cycles of selection. This implies that there are many different solutions to the binding of a ligand by RNA, and it fuels speculations about wider roles of RNA-based catalysts in prebiotic life.

Also developed in *Szostak*'s laboratory[11] as well as by *Robertson* and *Joyce*,[12] an in vitro method was used to select variants of the *Tetrahymena* self-splicing intron that had ligase activity. The system was designed such that only the active intron variants could be amplified and propagated. The "ribozyme" ligated itself to an RNA oligonucleotide complementary to the internal guide sequence. Both ligated (long) and non-ligated (short) ribozyme molecules were converted to cDNA with reverse transcriptase using a primer complementary to its 3′ end. A second primer then hybridized exclusively with the added sequence resulting from ligation. With these two primers, PCR could be used to selectively amplify those molecules which had undergone the RNA-catalyzed ligation reaction. New RNAs could be transcribed from the DNA templates, and the cycle could then be repeated. Randomization was carried out at several positions in this case. The wild-type was found to be the most active of all.

These examples illustrate the rapid progress being made in the development of new techniques for random screening. It may be useful to summarize again the molecular features and techniques that make these approaches possible: a) the rapid automatic synthesis of oligonucleotides (and to a lesser degree, peptides) can generate an enormous number of variants in a single step; b) the random oligonucleotides may themselves serve as ligands or receptors, or encode peptide ligands or protein receptors; c) the desired molecular species can be multiplied from virtually single molecules either in vivo (by transfection or transformation of bacteria with this DNA) or in vitro by the polymerase chain reaction. It remains to be seen whether analogous strategies can be developed for investigating ligands other than DNA, RNA or proteins. The present strategies will play, however, an increasingly important role in the investigation of molecular interactions of biochemical relevance. For some questions, random screening may be the most rational approach.

Novel Strategies for the Construction of Complex Polycyclic Ether Frameworks. Stereocontrolled Synthesis of the FGHIJ Ring System of Brevetoxin A**

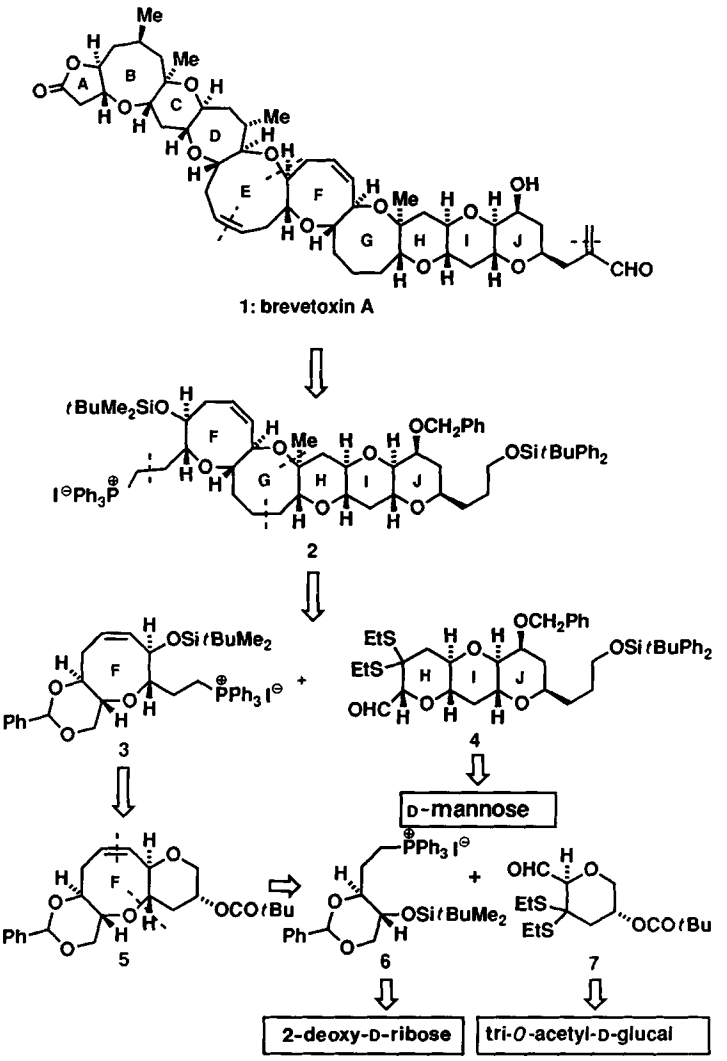
By *K. C. Nicolaou,* C. A. Veale, C.-K. Hwang, J. Hutchinson, C. V. C. Prasad* and *W. W. Ogilvie*

Dedicated to Professor Hans Jürgen Bestmann on the occasion of his 65th birthday

Recent reports from these laboratories described new synthetic technologies and strategies for the construction of the ABCD[1] and E[2] ring systems of brevetoxin A (**1**).[3] In this communication we describe an efficient and stereocontrolled synthesis of the FGHIJ ring framework (**2**) of this novel neurotoxin.

An attractive retrosynthetic analysis of brevetoxin A (**1**) with a high degree of convergency is shown in Scheme 1. Thus initial disconnection of the indicated strategic bonds of **1** (dotted lines) leads to the appropriately functionalized intermediate **2** containing the FGHIJ ring framework of the target molecule. Further disconnection of the G ring of the newly generated intermediate **2** as shown leads to compounds **3** and **4** as potential precursors. In order to ensure a high yielding formation of the 8-membered ring system in **3**, an additional ring was temporarily installed in its pregenitor (**5**) (to decrease number of rotations and facilitate ring closure). Finally, disconnection of **6**, **7**, and **4** led to enantiomerically pure precursors of the correct stereogenicity, namely 2-deoxy-D-ribose, tri-*O*-acetyl-D-glucal, and D-mannose, respectively. The successful execution of the designed strategy for reaching **2** is described below.

Syntheses of key intermediates **6** and **7** are briefly summarized in Scheme 2. Thus, 2-deoxy-D-ribose was converted



Scheme 1. Retrosynthetic analysis of brevetoxin A (**1**).

into olefin **9** (65% overall yield) by a Wittig reaction followed by sequential and selective protection involving 1,3-benzylidene formation and silylation. Subsequent ozonolysis–reduction led to alcohol **10**, which was then converted into phosphonium salt **6** via iodide **11** by standard chemistry (68% overall yield). For the synthesis of **7**, tri-*O*-acetyl-D-glucal (Scheme 2) was converted into **12** by methods previously described from these laboratories[4] followed by selective monosilylation. Epoxidation with mCPBA gave the α-epoxide **13** as a single product (75%), which was transformed into epoxyketone **14** by PDC treatment (86%). Reductive opening of **14** to **15** (88%) occurred smoothly upon treatment with NaI, whilst transformations **15** → **16** → **17** → **18** → **7**

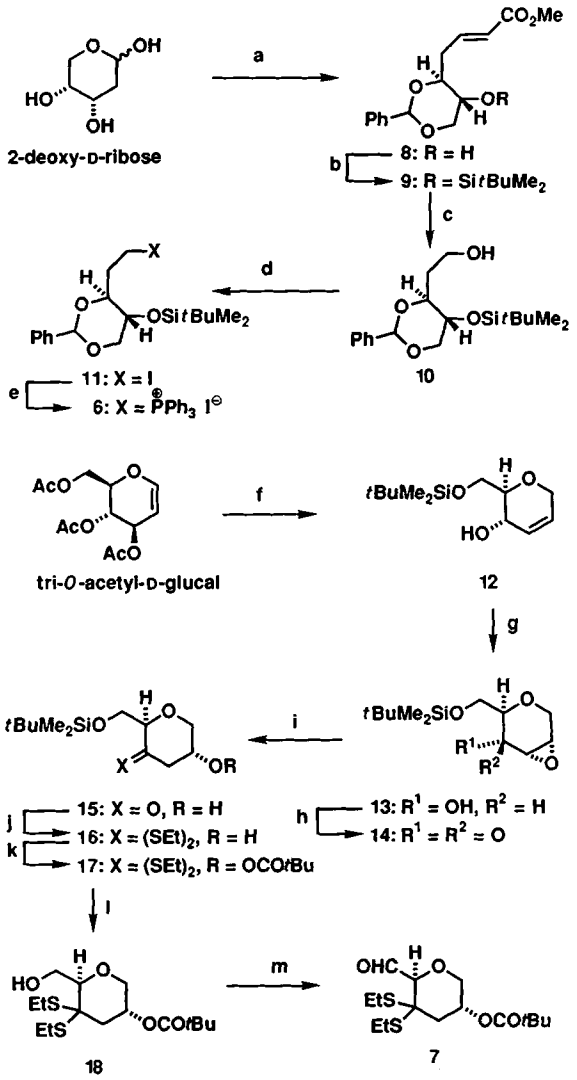
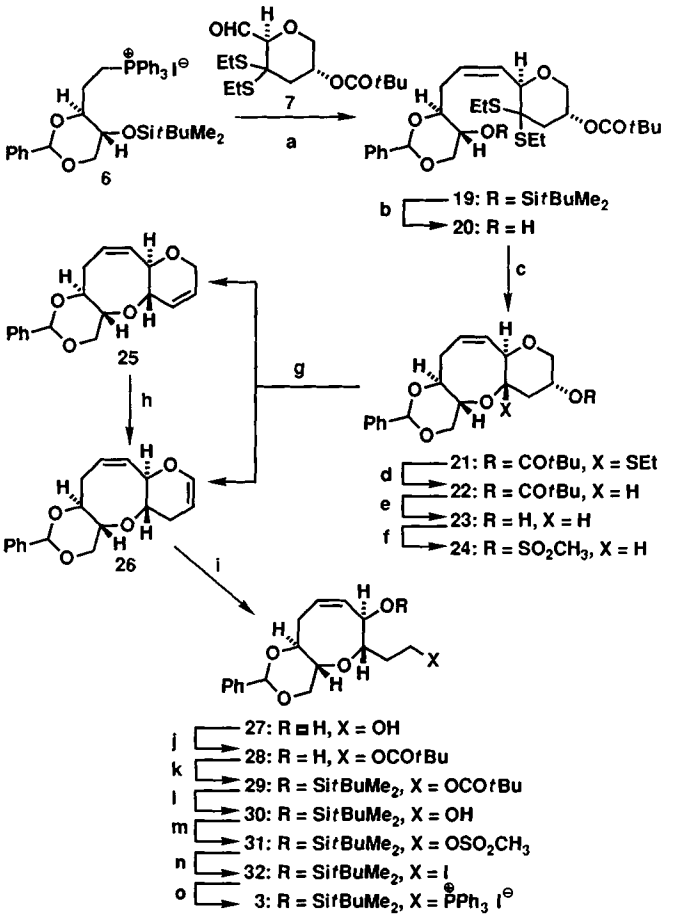
[**] This work was financially supported by the National Institutes of Health (USA), the National Science Foundation (USA), Merck Sharp and Dohme (USA) and Hoffmann LaRoche (USA) and was partially carried out at the University of Pennsylvania. Abbreviations used: mCPBA = *meta*-chloroperbenzoic acid, PDC = pyridinium dichromate, CSA = camphorsulfonic acid, HMPA = hexamethylphosphoric acid triamide, Tf = trifluormethanesulfonate, TBAF = tetrabutylammonium fluoride, DIBAH = diisobutylaluminum hydride, DBU = diazabicyclo[5,4,0]undec-7-ene, py = pyridine, DET = diethyltartrate, 9-BBN = 9-borabicyclo[3,3,1]nonane.



Scheme 2. Preparation of key intermediates **6** and **7**. Reagents and conditions: a) 1: 1.1 equiv of $Ph_3PCHCOOMe$, THF, 80 °C, 4 h, 100%; 2: 1.5 equiv of $PhCH(OMe)_2$, 0.1 equiv of CSA, CH_2Cl_2, 25 °C, 12 h, 65%; b) 1.1 equiv of $tBuMe_2SiOTf$, 1.5 equiv of 2,6-lutidine, CH_2Cl_2, 0 °C, 30 min, 100% c) O_3, CH_2Cl_2, −78 °C, 2 h, then 3.5 equiv of $NaBH_4$, MeOH, 0 °C, 2 h, 90%; d) 1.4 equiv of I_2, 1.4 equiv of PPh_3, 1.4 equiv of imidazole, CH_3CN, 25 °C, 30 min, 84%; e) 1.1 equiv of PPh_3, CH_3CN, 80 °C, 48 h, 90%; f) 1: see ref. [4]; 2: 1.5 equiv of $tBuMe_2SiCl$, 2.0 equiv of imidazole, DMF, 0 °C, 1 h, 94%; g) 1.2 equiv of mCPBA, CH_2Cl_2, 0–25 °C, 12 h, 75%; h) 2.0 equiv of PDC, CH_2Cl_2, 25 °C, 6 h, 86%; i) 5.0 equiv of NaI, 0.5 equiv of NaOAc, 5.0 equiv of HOAc, acetone, 25 °C, 1 h, 88%; j) 4.0 equiv of EtSH, 2.5 equiv of $BF_3{\cdot}OEt_2$, CH_2Cl_2, −40 °C, 1 h, 74%; k) 1.5 equiv of $(CH_3)_3CCOCl$, Et_3N, CH_2Cl_2, 25 °C, 18 h, 84%; l) 1.5 equiv of TBAF, THF, 0 °C, 3 h, 95%; m) 5.0 equiv of $SO_3{\cdot}py$, 5.0 equiv of Et_3N, DMSO, CH_2Cl_2, 0 °C, 1 h, 75%.

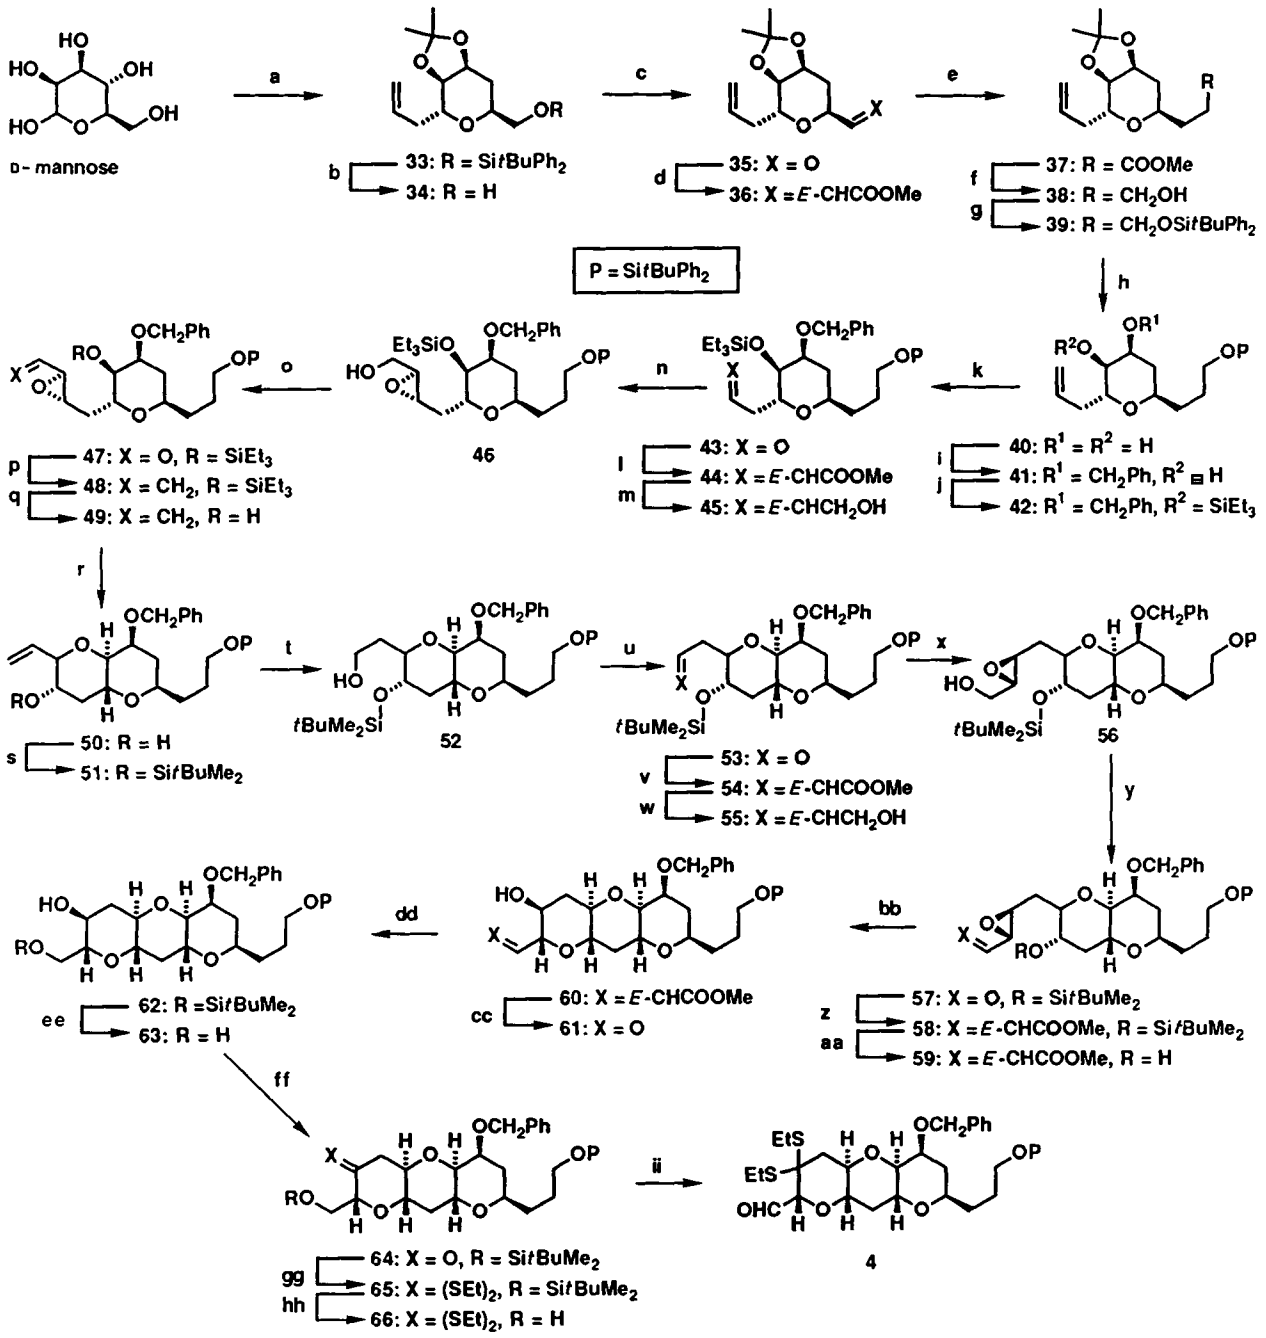


Scheme 3. Synthesis of key intermediate **3**. Reagents and conditions: a) 0.9 equiv of *n*BuLi, THF, −78 °C, 1 h, then 4.0 equiv of HMPA, 1.0 equiv of **7**, −78–25 °C, 18 h, 75%; b) 1.5 equiv of TBAF, THF, 25 °C, 12 h, 98%; c) 4.0 equiv of $AgClO_4$, 5.0 equiv of $NaHCO_3$, 4 Å molecular sieves, silica gel, CH_3NO_2, 25 °C, 4 h, 74%; d) 4.0 equiv of Ph_3SnH, 0.1 equiv of AIBN, toluene, 110 °C, 2 h, 95%; e) 2.5 equiv of DIBAH, CH_2Cl_2. −78 °C, 1 h, 85%; f) 1.5 equiv of CH_3SO_2Cl, 3.0 equiv of Et_3N, CH_2Cl_2. 0 °C, 1 h; g) 5.0 equiv of DBU, DMF, 145 °C, 2 h; 84% from **23** (**25**:**26** = 4.6:1); h) 1.0 equiv of KO*t*Bu, DMSO, THF, 50 °C, 3 h, 60%; i) 1: 1.1 equiv of mCPBA, THF, H_2O, 0–25 °C, 1 h; 2: 10.0 equiv of $NaBH_4$, MeOH, 0 °C, 1 h; 3: excess $NaIO_4$, EtOH, H_2O, 25 °C, 1 h; 4: 3.0 equiv of $NaBH_4$, MeOH, 0 °C, 1 h, 85% from **26**; j) 1.1 equiv of $(CH_3)_3CCOCl$, py, −20–0 °C, 4 h, 82%; k) 1.5 equiv of $tBuMe_2SiCl$, 5.0 equiv of imidazole, DMF, 25 °C, 12 h, 97%; l) 2.7 equiv of DIBAH, CH_2Cl_2, −78 °C, 1 h, 98%; m) 1.4 equiv of CH_3SO_2Cl, 3.0 equiv of Et_3N, CH_2Cl_2, 0 °C, 1 h; n) 10 equiv of NaI, acetone, 56 °C, 2 h, 84% from **30**; o) 1.0 equiv of I_2, 1.0 equiv of PPh_3, CH_3CN, 60 °C, 48 h, 92%.

proceeded uneventfully affording the requisite aldehyde (**7**) in high overall yield.

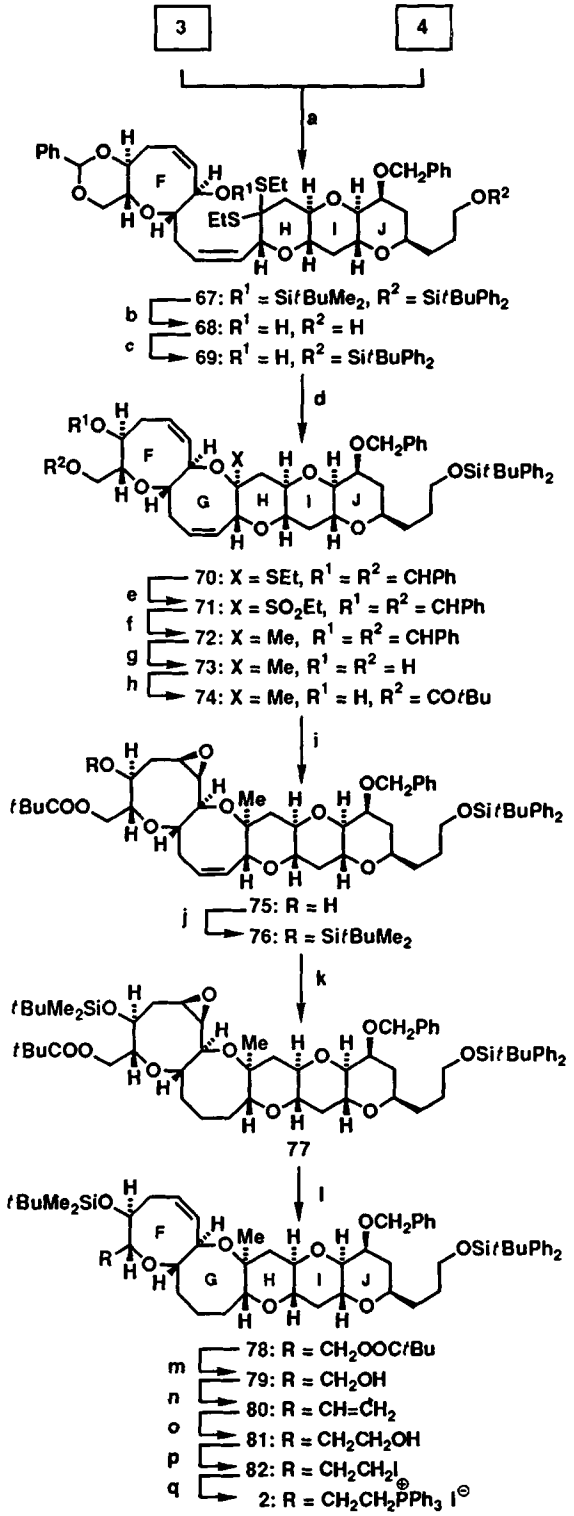
The coupling of intermediates **6** and **7** and elaboration of the resulting product to compound **3** is summarized in Scheme 3. Generation of the phosphorane from **6** followed by reaction with aldehyde **7** gave selectively the *cis* olefin **19** (75%), which was converted into hydroxydithioketal **20** and then cyclized[5] by the action of $AgClO_4$ to afford oxocene derivative **21** (74%). Desulfurization of **21** (95%) followed by standard manipulations led to methanesulfonate **24** in high overall yield. Base-induced elimination converted **24** into a mixture of **25** and **26** (84%, **25**:**26** ca 4.6:1). The undesired isomer **25** was isomerized to the desired enol ether **26** (60%) under basic conditions. Transformation of **26** to **27** (85% overall yield) required three steps: mCPBA epoxidation of the enol ether in the presence of H_2O leading to a hydroxy lactol, $NaBH_4$ reduction forming a triol, and $NaIO_4$ cleavage of the 1,2-diol system. Compound **27** was converted into phosphonium salt **3** by conventional methods via intermediates **28**–**32** as summarized in Scheme 3 (77% overall yield).

Scheme 4 outlines the construction of the key intermediate **4** from D-mannose. This synthesis was based on synthetic technology for the regio- and stereoselective synthesis of cyclic ethers from hydroxy epoxides previously described from these laboratories[6] and applied[7] to the construction of brevetoxin B intermediates. The highlights of this sequence were the two ring forming reactions **49** → **50** (CSA, 80%) and **59** → **60** (CSA, 80%).



Scheme 4. Reagents and conditions: a) see ref. [7]; b) 1.5 equiv of TBAF, THF, 25 °C, 2 h, 95%; c) 1.5 equiv of $(COCl)_2$, 2.0 equiv of DMSO, 5.0 equiv of Et_3N, CH_2Cl_2, −78 °C, 1 h; d) 1.2 equiv of $Ph_3PCHCOOMe$, CH_2Cl_2, 25 °C, 18 h, 90% from **34**; e) 2.0 equiv of L-selectride, 2.5 equiv of *t*BuOH, THF, −78 °C, 1 h, then 3 equiv of NaOH, 3 equiv of H_2O_2, 0 °C, 1 h; f) 2.5 equiv of DIBAH, CH_2Cl_2, −78 °C, 1 h, 78% from **36**; g) 1.1 equiv of *t*BuPh$_2$SiCl, 3.0 equiv of imidazole, DMF, 0–25 °C, 2 h, 95%; h) 0.1 equiv of CSA, MeOH, 25 °C, 4 h, 90%; i) 1.04 equiv of *n*Bu$_2$SnO, MeOH, 65 °C, 1 h, then 1.2 equiv of CsF, 1.2 eqiv of $PhCH_2Br$, DMF, 25 °C, 18 h, 87%; j) 1.2 equiv of Et_3SiCl, 2.0 equiv of imidazole, DMF, 25 °C, 12 h, 96%; k) excess O_3, CH_2Cl_2, −78 °C, then 1.5 equiv of Ph_3P; l) 1.1 equiv of $Ph_3PCHCOOMe$, benzene, 25 °C, 12 h, 78% from **42**; m) 2.5 equiv of DIBAH, CH_2Cl_2, −78 °C, 1 h, 96%; n) 0.075 equiv of (+)-DET, 0.05 equiv of Ti(*i*OPr)$_4$, 1.3 equiv of *t*BuOOH, 4 Å molecular sieves, CH_2Cl_2, −20 °C, 48 h, 92%; o) 5.0 equiv of SO_3·py, 5.0 equiv of Et_3N, CH_2Cl_2, DMSO, 0 °C, 1 h; p) 1.5 equiv of Ph_3PCH_2Br, 1.4 equiv of NaN(TMS)$_2$, THF, 0 °C, 1 h, 76% from **46**; q) 1.1 equiv of TBAF, THF, −20–0 °C, 3 h, 92%; r) 0.1 equiv of CSA, CH_2Cl_2, 0 °C, 2 h, 80%; s) 1.5 equiv of *t*BuMe$_2$SiCl, 3.0 equiv of imidazole, DMF, 25 °C, 12 h, 99%; t) 2.0 equiv of 9-BBN, THF, 0 °C, 2 h, then excess NaOH, excess H_2O_2, 0 °C, 1 h, 92%; u) 1.5 equiv $(COCl)_2$, 2.0 equiv of DMSO, 5.0 equiv of Et_3N, CH_2Cl_2, −78 °C, 1 h; v) 1.0 equiv of $Ph_3PCHCOOMe$, benzene, 25 °C, 12 h, 86% from **52**, w) 2.5 equiv of DIBAH, CH_2Cl_2, −78 °C, 1 h, 96%; x) 0.075 equiv of (+)-DET, 0.05 equiv of Ti(*i*OPr)$_4$, 1.3 equiv of *t*BuOOH, 4 Å molecular sieves, CH_2Cl_2, −20 °C, 12 h, 92%; y) 5.0 equiv of SO_3·py, 5.0 equiv of Et_3N, DMSO, CH_2Cl_2, 0 °C, 2 h; z) 1.5 equiv of $Ph_3PCHCOOMe$, benzene, 25 °C, 12 h, 78% from **56**; aa) 1.03 equiv of TBAF, THF, 0 °C, 3 h, 87%; bb) 0.2 equiv of CSA, CH_2Cl_2, 0–25 °C, 80%; cc) excess O_3, CH_2Cl_2, −78 °C, then 1.5 equiv of Ph_3P, 25 °C, 3 h; dd) 4.0 equiv of $NaBH_4$, MeOH, 0 °C, 96% from **60**; ee) 1.5 equiv of *t*BuMe$_2$SiCl, 3.0 equiv of imidazole, DMF, 0 °C, 1 h, 93%; ff) 1.5 equiv of $(COCl)_2$, 2.0 equiv of DMSO, 5.0 equiv of Et_3N, CH_2Cl_2, −78 °C, 1 h, 93%; gg) 5.0 equiv of EtSH, 3.0 equiv of $Zn(OTf)_2$, CH_2Cl_2, 25 °C, 5 h; hh) 0.01 equiv of CSA, MeOH, 0 °C, 83% from **64**; ii) 4.0 equiv of SO_3·py, 4.0 equiv of Et_3N, DMSO, CH_2Cl_2, 0 °C, 1 h, 92%.

Scheme 5 outlines the synthesis of the targeted intermediate **2** starting with the coupling of **3** and **4** (*n*BuLi, HMPA) to afford predominantly the *cis* olefin **67**[8] (*cis*:*trans* ca 3:1, 88% total yield).[9] Desilylation of both oxygens in **67** followed by selective monosilylation with *Hanessian*'s[10] more robust and UV-active protecting group gave **69** via diol **68**



Scheme 5. Synthesis of **2**. Reagents and conditions: a) 0.97 equiv of *n*BuLi, THF, −78–0 °C, 20 min, then 4.0 equiv of HMPA, 0.8 equiv of **4**, −78–25 °C, 3 h, 88%; b) 3.0 equiv of TBAF, THF, 25 °C, 3 h; c) 1.02 equiv of $BuPh_2SiCl$, 3.0 equiv of imidazole, DMF, 0 °C, 3 h, 72% from **67**; d) 8.0 equiv of $AgClO_4$, 10 equiv of $NaHCO_3$, 3 Å molecular sieves, silicagel, CH_3NO_2, 25 °C, 3 h, 87%; e) 2.0 equiv of mCPBA, 3.0 equiv of $NaHCO_3$, CH_2Cl_2, 0 °C; f) 3.0 equiv of $AlMe_3$, CH_2Cl_2, −78 °C, 30 min, 94% from **70**; g) 5.0 equiv of EtSH, 10 equiv of $NaHCO_3$, 3.0 equiv of $Zn(OTf)_2$, CH_2Cl_2, 25 °C, 5 h, 90%; h) 1.05 equiv of $(CH_3)_3CCOCl$, py, 0 °C, 12 h, 86%; i) 1.0 equiv of mCPBA, CH_2Cl_2, 0 °C, 3 h, 75%; j) 1.5 equiv of $tBuMe_2SiOTf$, 3.0 equiv of 2,6-lutidine, CH_2Cl_2, 0 °C, 20 min, 82%; k) 10 equiv of $KO_2CN = NCO_2K$, 20 equiv of HOAc, py, 0 °C, 18 h, 83%; l) 10 equiv of WCl_6, 20 equiv of *n*-BuLi, THF, −78–25 °C, 4 h, 92%; m) 3.0 equiv of DIBAH, CH_2Cl_2, −78 °C, 20 min, 95%; n) 5.0 equiv of SO_3·py, 5.0 equiv of Et_3N, DMSO, CH_2Cl_2, 0 °C, 2 h, then 3.0 equiv of Ph_3PCH_3Br, 2.0 equiv of $NaN(TMS)_2$, THF, 0 °C, 1 h, 83%; o) 1.2 equiv of 9-BBN, THF, 0 °C, 2 h, then excess NaOH, excess H_2O_2, 0 °C, 1 h, 73%; p) 2.0 equiv of CH_3SO_2Cl, 5.0 equiv of Et_3N, CH_2Cl_2, 0 °C, 20 min, then 10 equiv of NaI, acetone, 50 °C, 12 h, 75%; q) 10 equiv of PPh_3, CH_3CN, 60 °C, 24 h, 80%.

(72% overall from **67**). Cyclization[5] of hydroxy dithioketal **69** induced by $AgClO_4$ led to **70** in 87% yield. Application of previously described technology[5] allowed us to replace the ethylthio group in **70** with a methyl group with retention of stereochemistry to give **72** via intermediate **71** (mCPBA oxidation, followed by treatment with $AlMe_3$, 94% overall yield). The benzylidene protecting group was then removed by exposure to $Zn(OTf)_2$·EtSH followed by selective monopivaloate formation to give sequentially **73** (90%) and **74** (86%). At this juncture the double bond in ring G, which assisted in its high-yield formation, was to be hydrogenated to reach the desired goal. To do this it was found necessary to block temporarily and selectively the double bond of the F ring, a task that became possible by utilizing the directing effect of the homoallylic hydroxyl group. Thus, **74** reacted smoothly with stoichiometric amounts of mCPBA to furnish epoxide **75**[11] (75%), which was then protected as the silyl ether **76** (82%). Diimide reduction of **76** proceeded smoothly to afford the saturated system **77** (83%) and deoxygenation by the method of Sharpless[12] (WCl_6-*n*BuLi) led to the desired compound **78** in excellent yield (92%). Finally, the required chain extention and conversion into the phosphonium salt proceeded with standard chemistry and through intermediates **79** (95%), **80** (83%), **81** (73%), and **82** (75%) to afford the targeted FGHIJ ring framework **2** (80% from **82**).

Similar chemistry was carried out with intermediates carrying a one-carbon substituent on ring J. An X-ray crystallographic analysis of the crystalline compound **74a** (Fig. 1), related to **74** (Scheme 2), was performed[13] (see ORTEP drawing, Fig. 1) and confirmed the stereochemical assignments shown in all structures.

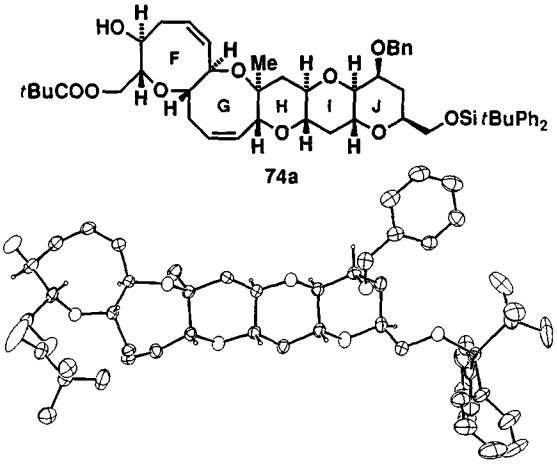


Fig. 1. Structural formula and ORTEP drawing of **74a**.

The described chemistry provides practical and efficient access to the advanced intermediate **2** and related compounds representing the FGHIJ ring assembly of brevetoxin A (**1**). The complexity of the systems and the high yields in which they are obtained demonstrates the power of new synthetic technology and strategies developed in this program for the construction of complex polycyclic frameworks containing medium-size cyclic ethers. Studies towards the total synthesis of brevetoxin A (**1**) are continuing.

Intermediates in Nitrogenase Models: N_2H_3 and N_2H_4 as η^2-Coordinated Ligands**

By *Sabine Vogel, Annette Barth, Gottfried Huttner,* Thomas Klein, Laszlo Zsolnai,* and *Reinhard Kremer*

Dedicated to Professor Dieter Sellmann on the occasion of his 50th brithday

Dinitrogen ligands of the type N_2H_x are important intermediates in all models which attempt to explain the activity of nitrogenase.[1] The hydrazido(1-) ligand, $N_2H_3^{\ominus}$, plays a key role. Only in one case recently was it possible to stabilize this ligand on a organometallic complex fragment.[2] Organoderivatives $R_mN_2H_{(3-m)}$ ($m \geq 1$) of the parent compound N_2H_3, however, have been known as ligands for some time.[3] We report here the synthesis and properties of $[(tripod)Co(\eta^2\text{-}N_2H_3)]^{\oplus}$ (tripod = $CH_3C(CH_2PPh_2)_3$), **1**, the first non-organometallic N_2H_3 complex. The protonation of **1** led to $[(tripod)Co(\eta^2\text{-}N_2H_4)]^{2\oplus}$, **2**. The η^2-coordination of the N_2H_4 ligand, which is as important in the interpretation of nitrogenase activity, could be proven for the first time by the X-ray structure analysis of this complex.

In the presence of tripod, $[Co(BF_4)_2 \cdot 6H_2O]$ reacted with $N_2H_{4\ aq}$ to cation **1** (Fig. 1), which precipitated as the dark green, air-sensitive BPh_4 salt. The analytically pure, crystalline salt **1**-$(BPh_4) \cdot 2THF$ has a magnetic moment of 1.8 μ_B, corresponding to a low spin d^7 configuration at $Co^{2\oplus}$. Figure 1 shows the results of the X-ray structure analysis of this salt.

The coordination geometry of cobalt lies between the two extremes of square pyramid and trigonal bipyramid. The best description of the geometry of **1** is as an ideal tetrahedron around the cobalt atom, where the N_2H_3 unit, as a whole, occupies one tetrahedral site.[4]

The only moderate quality of the crystals[5] did not permit the crystallographic location of the hydrogen atoms attached to nitrogen. The identification of the ligand as an N_2H_3 unit is, however, unambiguous: in the IR spectrum three NH stretching frequencies are observed ($\tilde{\nu}$ = 3290, 3217, 3130 cm^{-1}) as expected for N_2H_3; these bands do not appear when deuterated reagents are used for the synthesis.

The magnetism of **1** mentioned above corresponds to one unpaired electron per cobalt atom. This only allows the formulation of **1** as $[(tripod)Co(N_2H_x)]^{\oplus}$, where $x = 2n + 1$. Furthermore, the structure of **1** points to the existence of the N_2H_3 unit: the N–N distance of 138.4(14) pm lies in the range observed for the N–N bond lengths of η^2-organohydrazido ligands in $R_mN_2H_{(3-m)}$.[3]

Similarly the different Co–N distances (Fig. 1) reflect the familiar pattern[3] of the η^2-coordinated $R_mN_2H_{(3-m)}$ ligands. The shorter metal–N distance agrees with those for the nitrogen atoms which carry only one substituent (H or R).[3] The same pattern is also observed for $[(tripod)Co(\eta^2\text{-}NHNMe_2][BPh_4] \cdot 1.5THF$: $Co\text{–}N_{NMe_2}$ = 205(2), $Co\text{–}N_{NH}$ = 196(2) pm.[7]

Further evidence for the identity of **1** is provided by its protonation to **2**. The dark green BPh_4 salt of **1** is converted into the light green hydrazine complex **2** in THF with 40% $HBF_{4\ aq}$, which is obtained as the analytically pure, crystalline salt $[(tripod)Co(N_2H_4)][(BPh_4)(BF_4)] \cdot THF$.

According to the X-ray analysis, the best description of the coordination geometry around the cobalt atom of **2** is a distorted square pyramid (Fig. 1) in which the phosphorus atoms P1 and P2, and the two nitrogen atoms of the hydrazine ligand form the base of the idealised square pyramid. In agreement with this geometry, the Co-P bond to the apical phosphorus atom P3 is margianally longer than the other Co-P bonds. The magnetism of **2**-$(BPh_4)(BF_4) \cdot THF$ (solid state) of 3.84 μ_B corresponds with the spin-only value for three unpaired electrons.[8] Compound **2** may therefore be described formally as a high spin d^7 $Co^{2\oplus}$ complex.

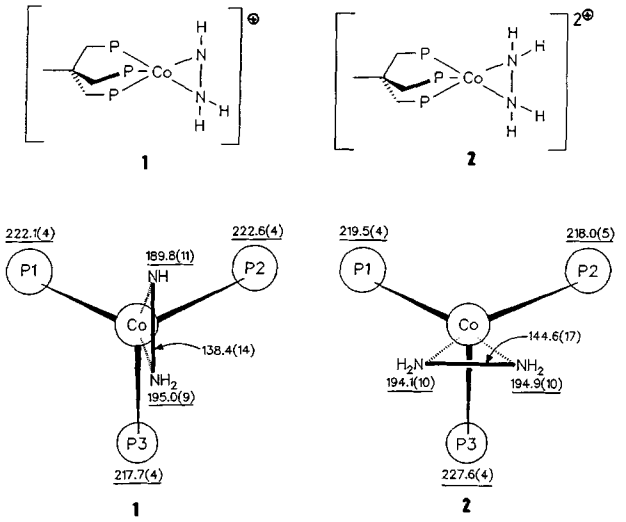

Fig. 1. η^2-Bonding (top) and structure characterization (bottom) of the cations **1** and **2** (phenyl groups of the tripod ligands omitted). Numerical data: distances in pm; underlined values: distances to cobalt; values in parentheses: standard deviations of the last decimal place.

The experimentally determined magnetism of three unpaired electrons confirms the N_2H_x, x = 2n, ligand composition for the dication **2**. The bond lengths suggest a formulation with x = 4: the N–N bond distance of 144.6(17) pm falls into the range found for η^2-coordinated organohydrazines $R_mN_2H_{(4-m)}$ $(m \geq 1)$[9] and precludes the formulation N_2H_2 or N_2[10] as ligand unit for **2**.

The Co–N distances in **2** are equal within experimental error, which confirms that both nitrogen atoms have the same substitution pattern (in contrast to **1**). In the NH stretching region of the IR spectrum, **2**-$(BPh_4)(BF_4) \cdot THF$ shows a broad band at 3229 cm^{-1} with shoulders at 3310 and 3275 cm^{-1}, and a sharp band at 3148 cm^{-1}. These four IR-active NH valence frequencies are expected for a N_2H_4 ligand in **2**.

In nature phosphane ligands do not form part of enzymes, neither does cobalt occur as the active metal center in the known nitrogenases. Nevertheless, the hypothesis that the specific coordination geometry imposed by the tripod ligand stabilizes the elusive N_2H_x intermediates in complexes **1** and **2**, possibly throws some light on the subject.

Experimental Procedure

All work was performed under argon to exclude air and moisture. Before use all glassware was heated with a hot-air blower, evacuated several times on a vacuum line (oil pump) and flushed with inert gas. Solvents were dried under inert gas and freshly distilled. The IR spectra were taken as Nujol mulls.

1: Equimolar amounts of the tripod ligand (624 mg, 1 mmol) in 15 mL THF and carefully dried (over P_2O_5 in a desiccator) $Co(BF_4)_2 \cdot 6H_2O$ [11] (340 mg, 1 mmol) in 15 mL ethanol were mixed at 20 °C. To the orange-red solution was added dropwise 0.5 mL (1 mmol) 64% N_2H_4 (immediate color change to dark green). After addition of 342 mg (1 mmol) sodium tetraphenylborate in 5 mL ethanol, the mixture was stirred for 2 h at 20 °C and then filtered through a G4 frit. Concentration to half the volume (10^{-1} mbar, 20 °C) caused black-green crystals of **1**-$BF_4 \cdot THF$ to separate within 24 h. Decantation, washing of the crystalline product with ethanol till the washings were colorless and then with petroleum ether, and drying under high vacuum gave an analytically pure product. Yield: 435 mg (42%, based on $Co^{2\oplus}$ salt); correct C,H,N,P analyses.

2: To an equimolar mixture of the tripod ligand (624 mg, 1 mmol) in 15 mL THF and $Co(BF_4)_2 \cdot 6H_2O$ [11] (340 mg, 1 mmol) in 15 mL ethanol is added dropwise 0.05 mL (1 mmol) 64% N_2H_4 at 20 °C. The solution is stirred for 1 h (20 °C), after which 4 drops of 40% HBF_4 (ca. 1 mmol) is added to the dark green reaction mixture (no color change); addition of a solution of 684 mg (2 mmol) sodium tetraphenylborate in 10 mL ethanol, 1 h stirring at 20 °C and filtration (G4) gives, after workup as for **1**, dark green crystals of **2**-$(BPh_4)(BF_4) \cdot THF$. Yield: 450 mg (40%, based on $Co^{2\oplus}$ salt); correct elemental analyses (C,H,N,P,Co,F,B).

Chloride-Induced Conversion of $[Mn_4O_2(OAc)_6(py)_2(dbm)_2]$ to $[Mn_4O_3Cl(OAc)_3(dbm)_3]$: Potential Relevance to Photosynthetic Water Oxidation**

By *Sheyi Wang, Kirsten Folting, William E. Streib, Edward A. Schmitt, James K. McCusker, David N. Hendrickson,** and *George Christou**

We are currently seeking models for the various oxidation levels (S_n states; n = −1 through 4) of the photosynthetic water oxidation center (WOC), to assist in the elucidation of its nature and mode of action.[1] The WOC requires four Mn atoms for activity, and these are oxo-bridged and ligated by O- and perhaps N-based groups, primarily of aspartate and glutamate carboxylates in the protein matrix; recent reports suggest[2] the nitrogen ligation to be minimal, at the level of 1 ± 1 per four Mn centers. The WOC also requires $Cl^{\ominus}$ for activity, and it has been suggested, for example, that the $Cl^{\ominus}$ is a ligand of the Mn atoms, or that it is involved in acid/base chemistry at the polypeptides.[1-3] The $Cl^{\ominus}$ is an essential cofactor for the WOC; in the absence of $Cl^{\ominus}$, an abnormal S_2 state is formed and advancement to S_3 is blocked.[3e, 4] Whatever its precise role, $Cl^{\ominus}$ thus seems to be important at the higher S_n states.

We recently described the preparation of various Mn complexes that were proposed as potential models of certain S_n states.[5, 6] The complexes $[Mn_4O_2(O_2CR)_6(bpy)_2]$ and $[Mn_4O_2(O_2CR)_7(bpy)_2]^{0,\oplus}$ (bpy = 2,2'-bipyridine), whose $[Mn_4O_2]^{Z\oplus}$ core contains a Mn_4 unit that is either planar or nonplanar ("butterfly" structure), were proposed as models for S_{-1}, S_0 and S_1.[5, 7] In addition, the complexes $[Mn_4O_3Cl_6(OAc)_3(HIm)]^{2\ominus}$, (HIm = imidazole) and $[Mn_4O_3Cl_4(OAc)_3(py)_3]$, which contain three Mn^{III} and one Mn^{IV} in a distorted Mn_4O_3Cl cubane core, were proposed as S_2 models.[6, 7] Obviously, the coordination spheres of the Mn_4O_2 and Mn_4O_3Cl complexes are not equivalent. Furthermore, the bpy and terminal $Cl^{\ominus}$ ligands are inconsistent with current WOC data,[8] and we were unable to convert Mn_4O_2- into Mn_4O_3Cl-containing species, which must be possible for potential S_1 and S_2 models. We report herein that all of the above shortcomings have now been redressed and, in addition, that a remarkable influence of $Cl^{\ominus}$ has been observed that may be of significant biological relevance.

Treatment of $[Mn_3O(OAc)_6(py)_3](ClO_4)$ in MeCN with ca. 1.5 equiv. of dibenzoylmethane slowly gives red microcrystals that can be recrystallized from hot MeCN to give red-black crystals in 45–55% overall yield. The product, the Mn_4^{III} complex **1**,[9] has crystallographically imposed C_i symmetry (Fig. 1) with chelating dbm ligands occupying the bpy positions of the previous complexes, and with six bridging $AcO^{\ominus}$ and two terminal py ligands.

$[Mn_4O_2(OAc)_6(py)_2(dbm)_2]$ **1**

Complex **1** displays remarkable reactivity with $Cl^{\ominus}$. If 1 equiv of nBu_4NCl is added to the hot MeCN recrystallization medium, **1** is not recovered; the product on cooling is instead the $Mn_3^{III}Mn^{IV}$ complex **2** in 20–25% nonoptimized yield. Based on the precedence of other systems,[5, 6] we

$[Mn_4O_3Cl(OAc)_3(dbm)_3]$ **2**

believe that **2** is formed from **1** by disproportionation and ligand redistribution. The structure[10] of **2** (Fig. 2) consists of a $[Mn_4O_3Cl]^{6\oplus}$ core with three bridging $AcO^{\ominus}$ and three chelating dbm groups. To emphasize the change that has occurred during the transformation of **1** into **2**, their central

portions are shown below in diagrammatic form. The Mn_4O_3Cl core of **2** is essentially superimposable on those of other Mn_4O_3Cl complexes, showing that the complete exchange of oxygen-ligating ligands (dbm) for the previously present peripheral ligands (py, HIm, $Cl^{\ominus}$) has little structural effect. It does, however, have a small effect on the magnetic exchange interactions within **2**. The effective magnetic moment, μ_{eff}/Mn_4, steadily rises from 8.49 μ_B at 381.5 K to 10.42 μ_B at 10.0 K. Fitting of the data to the theoretical susceptibility equation derived previously[6b] gave J_1 (Mn^{III}–Mn^{IV}) = − 33.4 cm^{-1} and J_2 (Mn^{III}–Mn^{III}) = + 5.1 cm^{-1}; these values are similar to those for $[Mn_4O_3Cl_4(OAc)_3(py)_3]$ for which J_1 = − 26.8 cm^{-1} and J_2 = + 12.1 cm^{-1}.[6b] For complex **1**, the exchange interactions are similar in sign and magnitude to those in $[Mn_4O_2(OAc)_7(bpy)_2]^{\oplus}$, even though the latter has a butterfly rather than a planar disposition of the four Mn ions.[5b]

2

The described results represent important progress in our WOC modeling efforts. The predominantly oxygen ligation in **1** is now much more consistent with WOC data,[8] and not only does the S_2 model complex **2** have equivalent ligation, but also an Mn_4O_2 (S_1 model) complex has been directly converted into an Mn_4O_3Cl (S_2 model) complex for the first time, paralleling the native $S_1 \rightarrow S_2$ conversion. In addition, the $Cl^{\ominus}$-dependent nature of the model conversion perhaps sheds light on the $Cl^{\ominus}$-dependence of water oxidation and on why an abnormal S_2 state is formed in the absence of $Cl^{\ominus}$. Finally, we have previously hypothesized,[7] based merely on the structures of Mn_4O_2 and Mn_4O_3Cl materials, that substrate (H_2O) incorporation into the WOC Mn_4 aggregate may occur stepwise as bridging oxides during the $S_1 \rightarrow S_2 \rightarrow S_3$ transitions, and that this may be how H_2O is activated to oxidation to O_2 (eq. a). The conversion of **1** to **2**, while mechanistically unclear, does involve an increase in the number of

$$\underset{S_1}{Mn_4O_2} \xrightarrow[-e^{\ominus},\,-2H^{\oplus}]{+H_2O} \underset{S_2}{Mn_4O_3Cl} \xrightarrow[-e^{\ominus},\,-2H^{\oplus}]{+H_2O} \underset{S_3}{Mn_4O_4} \qquad \text{(a)}$$

oxide bridges, as in eq. (a), emphasizing the feasibility of this suggestion. We are currently investigating whether the Mn_4O_3Cl to Mn_4O_4 conversion can be accomplished. Of course, in the absence of X-ray structural data on the WOC, it is uncertain to what extent these model complexes reproduce the actual structure and transformations of the WOC Mn site. Nevertheless, we believe that the chemistry observed with synthetic complexes may parallel that of the native site and, therefore, at the very least, provide insights into the functioning of the WOC.

1,3-(C → O) Silyl Shift in α-Diazo α-Silyl Ketones: Cycloaddition Reactions and Kinetic Proof for the β-Siloxydiazoalkene Intermediate**

By *Rainer Munschauer* and *Gerhard Maas**

The thermal treatment of α-diazo α-silyl ketones **1** at temperatures up to 80 °C leads by nitrogen elimination to products which are derived from alkylidenecarbenes (**3**).[1] We have suggested that the carbenes **3** are formed from diazoalkenes (**2**) which in turn result from a 1,3-(C → O) silyl migration in **1**. Diazoalkenes have as yet not been isolated. Recently the first low-temperature matrix isolation of a diazoethene derivative was reported;[2] furthermore, there are indications that diazoalkenes are formed in solution as reactive intermediates, which spontaneously eliminate N_2 to yield unsaturated carbenes.[3] In spite of these experimentally documented (and for the parent compound, diazoethene, even calculated[4]) high thermal lability, there are results which can be interpreted as trapping of intermediate diazoalkenes.[5–8]

In particular, the suggestion of 1,3-dipolar cycloadditions of diazoalkenes[5, 6] prompted us to study the thermolysis of the diazo compound **1** in the presence of dipolarophilic alkenes.

Indeed, **1a** and **1b** react with *N*-phenylmaleimide (NPM) and norbornene already at room temperature, or just above, to give the 1:1 cycloadducts **6a**, **6b** and **7a**, **7b** respectively,[9] which can be interpreted as direct trapping products of the diazoalkenes **2a** and **b**. (For reaction conditions and physical data, see Scheme 1 and Table 1). Silyl enol ethers **7** readily isomerize thermally to *N*-silyl-pyrazolines **8**; with **7b** this reaction takes place in the solid state as well as during the attempt to purify it by column chromatography (silica gel/petroleum ether).

Table 1. Selected physical and spectroscopic data of **6**, **7**, and **8** [a].

6a: colorless solid; m.p. 106 °C; ^{1}H NMR: δ = 1.05 (d, CHMe_2), 1.31 (sept, SiCH), 1.46 (s, *t*Bu), 4.42 (d, ^3J = 8.3, =CCH), 5.66 (d, ^3J = 8.3, NCH); ^{13}C NMR: δ = 14.5 (d, SiCH), 18.1 (q, CHMe_2), 28.4 (q, CMe_3), 39.2 (s, CMe$_3$), 41.6 (d, =CCH), 89.0 (d, NCH), 140.6 (s, O-C=C), 169.3 (s, C=O), 171.6 (s, O-C=C, 174.1 (s, C=O); IR (KBr): $\tilde{\nu}$ = 1592 cm^{-1} (C=C-OSi).

6b: Bright yellow solid; m.p. 100–102 °C; ^{1}H NMR: δ = 1.09 (d, CHMe_2) 1.38 (sept, SiCH), 4.11 (d, ^3J = 7.7, =CCH), 5.72 (d, ^3J = 7.7, NCH); ^{13}C NMR: δ = 13.5 (d, SiCH), 17.9 (q, SiCHMe), 41.9 (d, =CCH), 89.3 (d, NCH), 143.9 (s, O-C=C), 155.5 (s, O-C=C), 168.4 (s, C=O), 173.0 (s, C=O); IR (KBr): $\tilde{\nu}$ = 1618 cm^{-1} (C=C-OSi).

7a: colorless oil; ^{1}H NMR: δ = 0.5–1.5 (m, Si*i*Pr$_3$ und 3 CH$_2$), 1.32 (s, *t*Bu), 2.20 (s, CH), 2.65 (d, ^3J = 7.2, =CCH), 2.80 (s, CH), 4.45 (d, ^3J = 7.2, NCH); ^{13}C NMR: δ = 14.9 (d, SiCH), 18.2 (q, CHMe_2), 26.2(t), 28.0(t), 29.0 (q, CMe_3), 31.8(t), 38.2 (s, CMe$_3$), 39.5(d), 42.9(d), 44.0(d), 93.2 (d, NCH), 146.4 (s, O-C=C), 163.7 (s, O-C=C); IR (Film): $\tilde{\nu}$ = 1608 cm^{-1} (C=COSi).

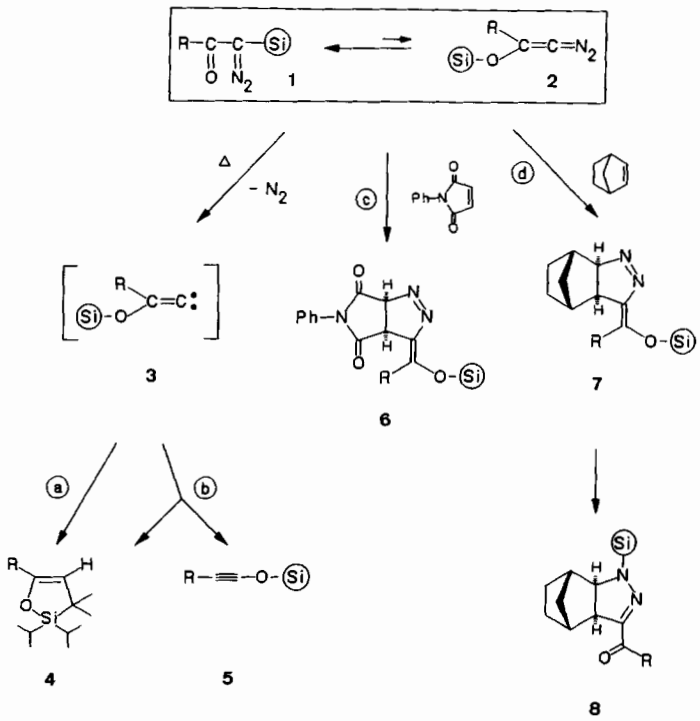
8b: Yellow crystals; m.p. = 80–81 °C; ^{1}H NMR: δ = 1.0–1.6 (m, Si*i*Pr$_3$ and 3 CH$_2$), 2.48 (s, CH), 2.73 (s, CH), 3.46 (d, ^3J = 10.2, =CCH), 3.98 (d, ^3J = 10.2, NCH); ^{13}C NMR: δ = 12.2 (d, SiCH), 18.2 (q, CHMe_2), 25.1(t), 28.0(t), 33.2(t), 39.8(d), 45.6(d), 52.9(d), 72.2 (d, NCH), 150.7 (s, C=N), 184.9 (s, C=O); IR (KBr): $\tilde{\nu}$ = 1615 cm^{-1} (s, C=O).

[a] NMR spectra in $CDCl_3$, TMS as standard, ^{1}H NMR at 90 and 400 MHz, ^{13}C NMR at 50.3 and 100.6 MHz, *J* in Hz.

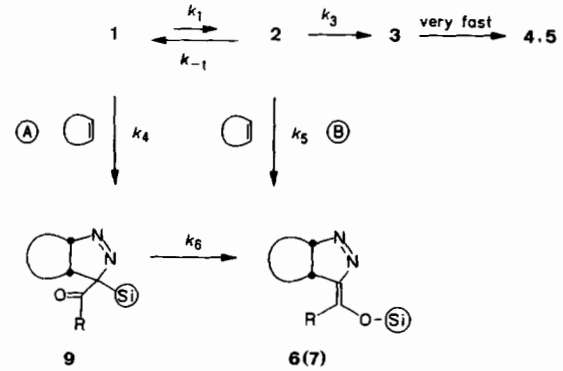


Scheme 1. Ⓢi = Si*i*Pr$_3$, **1a**–**8a**: R = *t*Bu, **1b**–**8b**: R = *p*-NO$_2$C$_6$H$_4$. ⓐ Benzene, 80 °C, 5 h, 57% **4a** [1c]. ⓑ **1b**, benzene, 80 °C, 2 h, 47% **4b**, 34% **5b** ([1a]; the formation of **4b** is not mentioned in this reference). ⓒ *N*-phenylmaleimide (1 equiv), ether, Schlenk pressure tube; for **1a**: 40 °C, 2 h, 79% **6a**; for **1b**: 40 °C, 2 h, 67% **6b**. ⓓ norbornene (20 equiv), ether, Schlenk pressure tube; for **1a**: 60 °C, 19 h, 78% **7a**, 13% **8a**, 5% **4a**; for **1b**: 50 °C, 18 h, 55% **7b** (before column chromatography of the product mixture), 18% **8b**, 16% **4b** + **5b** (or 20 °C, 5 days, 43% **8b** (after column chromatography)).

When the cycloadditions leading to **6** and **7** are carried out at temperatures $\leq$ 40 °C, the thermal decomposition of **1** mentioned in the introduction, which leads via **2** and **3** to **4** and/or **5**, is completely suppressed.

The question remains whether the cycloadducts **6** and **7** are direct trapping products of the diazoalkene **2** or whether they result from a [3 + 2] cycloaddition of the diazoketone **1**, followed by spontaneous silyl ketone to silyl enol ether isomerization (**1** → **9** → **6(7)**, Scheme 2).

Arguments against the route via **9** are first that unimolecular thermal isomerization of simple α-silyl ketones to silyl enol ethers occur typically only above 130 °C.[10, 11] There is no reason why silyl ketones of type **2** should rearrange already between 30 and 60 °C. Further, ethyl diazo(triisopropylsilyl)acetate (**10**) does not form cycloaddition products even under forcing conditions with *N*-phenylmaleimide (36 °C, 10 days) or with norbornene (100 °C, 72 h). Since **10** and also other diazosilylacetates are thermally very stable[12] and show even at 100 °C no tendency to decompose via diazoalkenes as proposed above for the diazosilyl ketones, one may conclude that **6** and **7** are indeed trapping products of the diazoalkenes **2**. Steric influences probably are an important factor causing the diazoalkenes **2** to undergo cycloaddition reactions more readily than the diazo ketones **1**. Similarly, the exclusive formation of (*Z*)-silyl enol ethers, **6** and **7**, is probably due largely to the sterically more favorable arrangement of the space-filling Si*i*Pr$_3$ group.



Scheme 2. Possible routes to **6** and **7**.

The diazoalkenes **2** cannot be detected in solution at 30–45 °C by IR or NMR spectroscopy (limit of detection in the ^{1}H NMR spectrum is ca. 1%). A kinetic analysis can, however, distinguish between the formation of cycloadducts **6** and **7** via route Ⓐ or Ⓑ[13] (Scheme 2). In the presence of a large excess of alkene and at temperatures at which the thermal decomposition of **1** is negligible ($k_3 \approx 0$), the decrease in the concentration of **1** is described by a pseudo-first-order

rate law with rate constant k_{obs} (equations (a)–(d)). For route Ⓐ where $k_6 \geq k_4$, equation (a) applies.

$$k_{obs} = k_4[\text{alkene}] \quad (a)$$

For route Ⓑ with d[**2**]/dt = 0, the observed rate constant is described by equation (b),

$$k_{obs} = (k_1 k_5\,[\text{alkene}])/(k_{-1} + k_5[\text{alkene}]), \quad (b)$$

which reduces to equation (c) or (d).

$$k_{obs} = k_1, \text{ when } k_5[\text{alkene}] \gg k_{-1} \quad (c)$$

$$k_{obs} = (k_1 k_5/k_{-1})\,[\text{alkene}], \text{ when } k_5\,[\text{alkene}] \ll k_{-1} \quad (d)$$

We followed the decrease in concentration of **1a** in benzene in the presence of excess NPM by analytical HPLC.[14, 15] The dependence of the k_{obs} values obtained from the function $\ln [\mathbf{1}] = \ln [\mathbf{1}]_0 - k_{obs}\, t$ (correlation coefficient $r \geq 0.999$) on [NPM] at T = 303 K is plotted in Figure 1. Already at relatively low excess of NPM a plateau is reached, that is the condition, k_5[alkene] $\gg k_{-1}$, of Eq. (c) is satisfied. Thus route Ⓑ, via the diazoalkene intermediate **2a**, is confirmed by the kinetic study. From the temperature dependence of the limiting rate constant k_1 for T = 293–303 K, the following activation parameters were calculated: $E_a = 21.6 \pm 0.4$ kcal mol^{-1}, $\Delta H^{\neq} = 21.0 \pm 0.4$ kcal mol^{-1}, $\Delta S^{\neq} = -3.4 \pm 1.2$ cal K^{-1} mol^{-1}. In an analogous study with norbornadiene as trapping agent,[16] a plot of the dependence of rate on concentration of norbornadiene yields a line through the origin. This relationship is described by equations (a) and (d) and no distinction between routes Ⓐ and Ⓑ can be made.

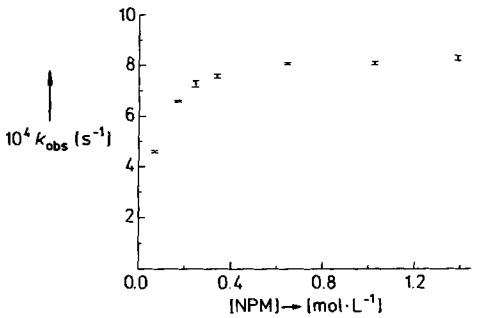


Fig. 1. $k_{obs} = -$ d[**1a**]/dt as a function of [NPM]; see text. Conditions: T = 303 K, solvent benzene, [**1a**] = 0.035 mol L^{-1}, 2.5- to 39.9-fold excess of NPM.

[14] Merck/Hitachi LiChrograph, LiChrospher RP-18 (125 × 4 mm), eluant acetonitrile (1.25 mL min^{-1}); detection at λ = 254 nm, 1,4-diiodobenzene as internal standard; no further absorptions between λ = 254 and 300 nm.

[15] The k_{obs} values were determined for the decrease in the concentration of **1a**, because the calculation of the concentration of **6a** involves larger errors (partial overlapping of peaks, lability of **6a** under HPLC conditions). For comparison one example run under optimal conditions for the detection of **6a** (acetonitrile/water, 95/5 (v/v); 1.25 mL min^{-1}, λ = 290 nm) at 290 K yielded for the decrease in [**1a**] $k_{obs} = (2.692 \pm 0.005) \times 10^{-2}$ min^{-1} (correlation coefficient r = 0.99998), and for the increase in [**6a**], $k_{obs} = (2.77 \pm 0.13) \times 10^{-2}$ min^{-1} (r = 0.9906).

[16] Norbornadiene yields cycloadducts (*endo* and *exo* isomers) with **1a**, which are analogous in structure to **7a**. In contrast to norbornene, norbornadiene is a liquid at room temperature and thus suitable for kinetic studies undiluted.

Diphosphonio Isophosphindoles, Phospholes with a Planar Phosphorus**

By *Alfred Schmidpeter*,* and *Martin Thiele*

Dedicated to Professor Rolf Appel on the occasion of his 70th birthday

Phosphole is an exception among the quartet of heterocycles, pyrrole, phosphole, furan, and thiophene, because it lacks aromaticity:[1, 2] The expected energy gain from cyclic delocalization is too small to meet the energy demand for a planar coordination for the phosphorus atom (inversion barrier for phospholane: 36 kcal mol^{-1}[3]). Thus in all the *P*-substituted phospholes as yet studied, phosphorus is pyramidal; the known phospholes unsubstituted at phosphorus are unstable at room temperature.[1] Their phosphorus atom is also pyramidal, but in one phosphole the inversion barrier is at least reduced to 16 kcal mol^{-1}.[2, 3] A planar environment for phosphorus in the ground state is conceivable when electron-withdrawing substituents occupy 2,5 positions. In fact, this was achieved in the 1,3-bis(triphenylphosphonio)isophosphindoles **6** and **7**.

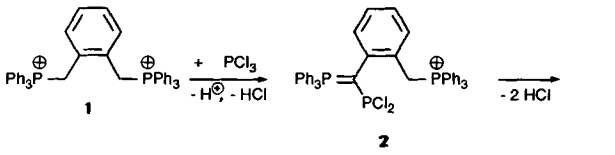
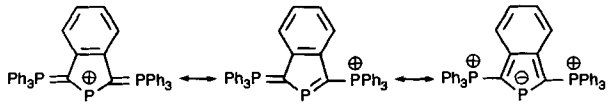
[**] Four- and five-membered phosphorus heterocycles, Part 76. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. part 75: K.-H. Zirzow, A. Schmidpeter, *Z. Naturforsch. B43* (1988) 1475.

The *o*-xylylenebis(triphenylphosphonium) ion (**1**),[4] which is easily prepared from α,α-dibromo-*o*-xylene and triphenylphosphane, undergoes cyclocondensation with phosphorus trichloride[5] and triethylamine to form the 1,3-bis(triphenylphosphonio)isophosphindole cation (**3**). As intermediate only the PCl_2-substituted ylide cation **2**[6] can be detected spectroscopically and also isolated. Cation **3** is obtained as the bromide; the counterion can be exchanged for $BPh_4^{\ominus}$, $SbCl_6^{\ominus}$, or $HgI_3^{\ominus}$ by precipitating the respective salts from a methanol solution.



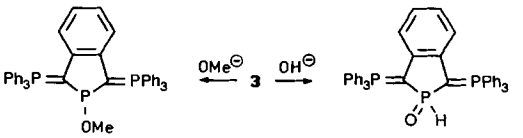
1 **2**



3a **3b** **3c**

The resonance formulas **3a**, **3b**, and **3c** can be written for **3**. Formula **3a** presents the cation as a phosphenium ion stabilized by two methylenephosphorane groups (whose ylide nature is not reflected in the formula), **3b** as a phosphonio-substituted phosphaalkene,[7] and in **3c** a phospholide anion modified by two phosphonio substituents. In fact **3** proves to be more thoroughly "ambiphilic" than other compounds with two-coordinate phosphorus. The ^{31}P NMR shift in **3**, however, ($\delta = 242$) corresponds to a *C*-substituted phosphenium ion (range: $\delta = 168-266$)[8] rather than a phospholide ion ($\delta = 40-103$).[1,9] This suggests that forms **3a** and **3b** predominate.

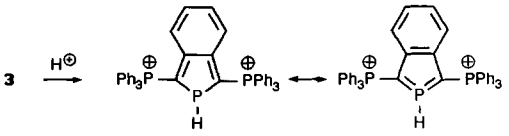
The Lewis acidity of **3** is small in comparison with other phosphenium ions.[8b] Thus the cyclic chlorophosphane which probably forms en route from **2** to **3** spontaneously loses a chloride ion. Furthermore, cation **3** does not react with water, although it adds the more strongly basic anions $MeO^{\ominus}$ and $HO^{\ominus}$ to form **4** and **5**, respectively.[10]



4 **5**

Cation **3**, on the other hand, is more basic than otherwise found for phosphenium ions, which can be neither protonated nor alkylated. Cation **3** is protonated by strong acids like HBF_4 and CF_3SO_3H. Formula **3b** would suggest a protonation at the ylide carbon, **3c** at the two-coordinate phosphorus atom. In fact, the symmetric dication **6** is formed and can be isolated as, for example, the tetrafluoroborate salt. Its formation corresponds to the protonation of phospholide ions to 1*H*-phospholes at low temperature,[11] which are, in contrast to **6**, unstable at room temperature and isomerize to 2*H*-phospholes, which promptly dimerize. Thus **6** is the first stable phosphole not substituted at phosphorus.

The decreasing negative charge on atoms C1 and C3 in the series **4**, **3**, and **6** is reflected in the ^{31}P NMR spectrum by an increase in the deshielding of the onium phosphorus. In particular the P–H coupling of 586 Hz for the isophosphindol **6** is significant: it is extremely high for a three-coordinate phosphorus atom, and far larger than for any other phosphane, in particular, for all known phospholes (217–234 Hz[11]). As the s character of the bond is reflected in the coupling constant, the phosphorus atom in **6** must be sp^2 hybridized and is thus in a planar environment. This bonding, best expressed by formula **6b**, corresponds to that of the bismethylenephosphoranes[11], which have been shown to be planar by X-ray crystallography. Till now for the only existing, but unstable, hydrobismethylenephosphorane $HP[=C(SiMe_3)_2]_2$, $^1J_{PH}$ was found to be 406 Hz.[11b] The distinctly higher value of $^1J_{PH}$ for **6** probably results from the CPC angle, which must be much smaller in the five-membered ring of **6** than in acyclic bismethylenephosphoranes (ca. 130°). With the exception of some azaphosphole transition metal complexes, **6** is the first phosphole or heterophosphole with phosphorus in a planar environment.[12]



6a **6b**

Cation **3** can be alkylated by Me_3OBF_4 to the methyl derivative of **6**, the dication **7**, which also has a planar phosphorus atom in the ring. The coupling constant between phosphorus and the methyl carbon atom is 14 Hz in trimethyl phosphane, around 19 Hz in 1-methylphospholes,[13] but 98 Hz in **7**. Again this value is far greater than the corresponding coupling in alkylbismethylene phosphoranes (33–44 Hz[14]).

Besides the phosphonio substituents, the condensed benzene ring probably also favors the planar structure of **6**. The planarity of phosphorus in a phosphindole ([2.3]-annelation) demands about 8 kcal mol^{-1} more energy[3] than in a phosphole; it should demand less energy in an isophosphindole. The resonance formula **6b** gains in importance through the [3.4]-annelation.

Earlier attempts to prepare isophosphindoles were unsuccessful and even their oxides proved to be too reactive for isolation.[15]

The arsenic cations analogous to **3** and **6** can also be prepared and other heteroatoms may be stabilized in unusual coordination environments in the same position.

Experimental Procedure

3-Br: 40.2 g (51 mmol) **1**-Br_2 and 7.0 g (51 mmol) PCl_3 were heated under reflux in 100 mL Et_3N and 50 mL CH_2Cl_2 for 48 h. More CH_2Cl_2 was added and the ammonium halides were separated by shaking with water. The organic phase was concentrated and **3**-Br separated on addition of THF. After drying, digestion in THF, and recrystallization from ethanol, the yield of pale yellow crystals was 29.8 g (80%). M.p. 302°C (decomp.); ^{31}P NMR (AB_2 spin system): $\delta(A) = 241.8$, $\delta(B) = 16.8$ ($J(AB) = 91.4$ Hz); $^{13}C\{^1H\}$NMR (ABB'*X* spinsystem): $\delta = 109.0$ ($J(AX) = 56.0$ Hz, $J(BX) = 96.6$ Hz, $J(B'X) = 14.0$ Hz).

6-$(BF_4)_2$: A solution of 1.48 g (2.0 mmol) **3**-Br in 5 mL CH_2Cl_2 was mixed with 0.65 mL of a 6.15 M HBF_4 solution in Et_2O and allowed to stand for 30 min. On addition of 10 mL Et_2O, the product precipitated. Recrystallization from CH_2Cl_2 yielded 0.80 g (48%) colorless, extremely moisture-sensitive crystals. ^{31}P NMR (AB_2 spin system): $\delta(A) = 41.7$, $\delta(B) = 23.1$ ($J(AB) = 12.3$ Hz,

^1J(PH) = 586.2 Hz); $^{13}C\{^1H\}$NMR: δ = 110.1 (dd, ^1J(PC) = 52.7, 38.4 Hz, C1).

7-$(BF_4)_2$: 30 min after the preparation of a solution of 2.50 g (3.4 mmol) **3**-Br and 1.01 g (6.8 mmol) Me_3OBF_4 in 10 mL CH_2Cl_2, the volume was reduced to half. A colorless, very moisture-sensitive powder (1.75 g, 61%) precipitated on addition of 10 mL Et_2O and was recrystallized from CH_2Cl_2/Et_2O. ^{31}P NMR (AB_2 spin system): δ(A) = 69.3, δ(B) = 22.4 (J(AB) = 11.0 Hz, ^2J(PH) = 12.8 Hz; $^{13}C\{^1H\}$NMR: δ = 116.9 (dd, ^1J(PC) = 49.0, 36.4 Hz, C1), 43.0 (d, ^1J(PC) = 97.5 Hz, CH_3).

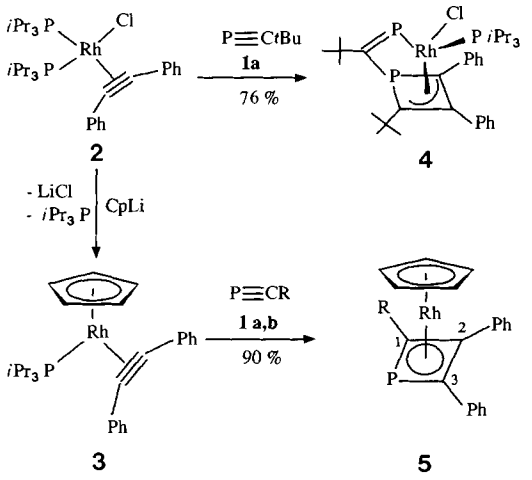
Cooligomerization of Phosphaalkynes and Alkynes in the Coordination Sphere of Rhodium Complexes**

By *Paul Binger,* Josef Haas, Albert T. Herrmann, Franz Langhauser*, and *Carl Krüger*

Dedicated to Professor Rolf Appel on the occasion of his 70th birthday

Cyclizations of phosphaalkynes,[1] especially of the kinetically stable, readily accessible *tert*-butylphosphaacetylene (**1a**), in the coordination sphere of transition-metal complexes have attracted increasing interest in recent years. For example, long-sought phosphorus heterocycles such as 1,3-diphosphacyclobutadiene and 1,3,5-triphospha-Dewar-benzene are now accessible via this route.[1] Cooligomerizations between phosphaalkynes and other unsaturated systems (e.g., alkynes), however, are very rare. So far only one monophosphacyclobutadiene complex, formed from 1,2-bis(trimethylsilyl)acetylene and **1a** has been described.[2]

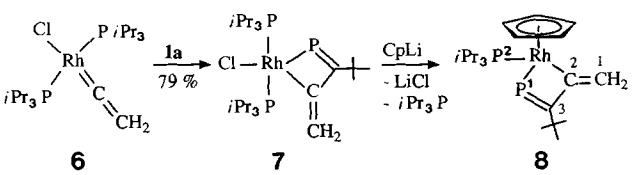
We now report the cooligomerizations of *tert*-butylphosphaacetylene (**1a**)[3] and of *N*-isopropyl-*N*-trimethylsilyl-2-aminophosphaacetylene (**1b**)[4] with tolane or acetylene in the coordination sphere of rhodium(I) complexes. The starting point for the syntheses described here was provided by the rhodium(I) complexes of tolane, **2** and **3**, first synthesized by *H. Werner* et al.,[5] as well as of the vinylidene **6**.[6]



a, R = *t*Bu; **b**, R = N*i*Pr(SiMe$_3$)

The rhodium tolane complex **2** reacts at $-20\,^{\circ}C$ with two equivalents of **1a** to give the cotrimer **4** (yield 76%), in which a monophosphacyclobutenyl group, formed from one molecule of **1a** and the tolane ligand, is bonded as η^3 ligand to rhodium. The second molecule of **1a** is bonded to the P atom of the phosphacyclobutenyl ligand and to the rhodium center in a σ fashion.[7] On the other hand, the rhodium (η^5-cyclopentadienyl)tolane complex **3** reacts with the two phosphaalkynes **1a** and **1b** in refluxing THF to give the two rhodium η^4-monophosphacyclobutadiene complexes **5a** and **5b**, respectively, in 90% yield; that is, complex **3** undergoes codimerization with only one molecule of the phosphaalkyne.

Complex **7**, the first 1-phospha-2-rhodacyclobutene, is formed upon reaction of the rhodium vinylidene complex **6** with **1a** in a [2+2] cycloaddition as yellow needles (79%).[7] The regiochemistry of this cycloaddition indicates that the carbene carbon of **6** has electrophilic character.[8] Replacement of the chloro ligand in **7** by a cyclopentadienyl ligand results in smooth formation of the 1-phospha-2-rhoda-3-methylenecyclobutene **8**.



The crystal structure analyses of the rhodium complexes **4** and **7** reveal several structural features.[9] The rhodium atom in **4** is coordinated in a distorted tetrahedral fashion; the corners of the tetrahedron are occupied by Cl, P2, P3, and

[**] This work was supported by the Volkswagen-Stiftung.

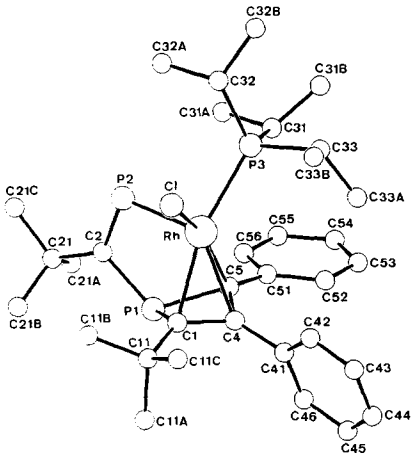

Fig. 1. Molecular structure of **4** (crystallographic numbering). Selected distances [Å] and angles [°]: P1-C1 1.860(3), P1-C5 1.875(2), C1-C4 1.434(4), C4-C5 1.443(4), Rh-P1 2.745(1), Rh-P2 2.226(1), Rh-P3 2.364(1), Rh-C1 2.235(3) Rh-C4 2.276(3), Rh-C5 2.152(3), Rh-Cl 2.409(1), P1-C2 1.813(3), P2-C2 1.657(3); C4-C5-P1 89.0(2), C5-C4-C1 100.7(2), C4-C1-P1 89.8(2), C5-P1-C1 72.8(1), P2-C2-P1 108.4(2).

the η^3-bonded allyl part of the phosphacyclobutenyl ligand (Fig. 1). The phosphacyclobutenyl ring is folded; the angle between the planes C1/P1/C5 and C1/C4/C5 is 29.7°. The η^3-allyl partial structure of this ring is characterized by the nearly equal C1–C4 and C4–C5 distances (1.434(4) and 1.443(4) Å, respectively) and the corresponding Rh–C distances (see caption to Figure 1), which correlate with those of known Rh-η^3-allyl compounds.[10] The P1–C1 and P1–C5 distances (1.860(3) and 1.875(3) Å) are consistent with P–C single bonds, whereas the P1–C2 distance is slightly shortened (1.813(3) Å); there is no bonding interaction between P1 and rhodium (2.745(1) Å). The P2–C2 distance in the phosphaethylene bridge (1.657(3) Å) corresponds to a P–C double bond, and the P2–Rh distance (2.226(1) Å) is typical of a Rh–P single bond.

The rhodium coordination in **7** consists of a slightly distorted tetragonal bipyramid (Fig. 2) with the two triisopropylphosphane ligands in axial positions and P2, C1, and Cl, together with a free coordination site, in equatorial positions. The heterocycle is planar and, along with C31 and the Cl atom, lies in the crystallographic mirror plane of the molecule. The P2–C2 and C1–C11 distances (1.699(9) and 1.32(1) Å, respectively) are in the range of P–C and C–C double bond lengths, respectively; the C1–C2 single bond (1.48(1) Å) is slightly shortened. The Rh–P2 and Rh–C1 distances (2.241(2) and 2.057(9) Å, respectively), as well as the C1–Rh–P2 angle (68.0(2)°), are as expected. The latter agrees with the values found in rhodacyclobutanes.[11]

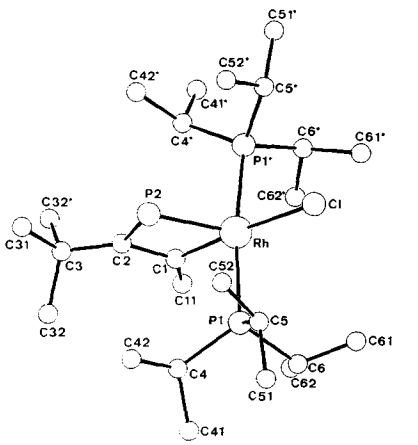

Fig. 2. Molecular structure of **7** (crystallographic numbering). Selected bond distances [Å] and angles [°]: Rh-Cl 2.436(2), Rh-P1 2.399(1), Rh-P2 2.241(2), Rh-C1 2.057(9), P2-C2 1.699(9), C1-C2 1.48(1) C1-C11 1.32(1); P1-Rh-P1* 172.1(1), C1-Rh-Cl 174.7(2), C1-Rh-P2 68.0(2), C2-P2-Rh 89.8(3), C1-C2-P2 98.3(6), C2-C1-Rh 103.9(6).

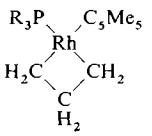
The structures of the rhodium complexes **5** and **8** were derived from their spectroscopic data (mass spectrum, ^{31}P and ^{13}C NMR spectra). The monophosphacyclobutadiene complexes **5a, b** exhibit the molecular-ion peak as most intense peak; the ^{31}P NMR spectrum contains a doublet at $\delta = -48.75$ ($J_{PRh} = 37.3$ Hz) for **5a** and -26.45 ($J_{PRh} = 36.5$ Hz) for **5b**. In the ^{13}C NMR spectrum, the characteristic signals for the C atoms of the four-membered ring of **5a** lie (see formula for numbering) at $\delta = 85.1$ (C1, $J_{C1P} = 42.3$, $J_{C1Rh} = 13.3$ Hz), 103.9 (C2, $J_{C2P} = 3.9$, $J_{C2Rh} = 9.4$ Hz), and 105.2 (C3, $J_{C3P} = 45.7$, $J_{C3Rh} = 13.5$ Hz). The structure has meanwhile been confirmed by a crystal structure analysis.[12] The values for **5b** are similar to those for **5a**.

In the ^{31}P NMR spectrum of the rhodium complex **8** (see formula for numbering), the signal for the Rh–P single bond ($\delta = 344.71$, $J_{P1Rh} = 35.1$ Hz, $J_{P1P2} = 12.1$ Hz) shows the characteristic low-field shift. The ^{13}C NMR spectrum contains signals at $\delta = 235.1$ (C3, $J_{C3P1} = 55$ Hz) and 124.4 (C2, J_{C2P1} and $J_{C2Rh} = 24.4$, 11.2 Hz) for the C atoms of the four-membered ring; the C atom of the terminal methylene group gives rise to a signal at $\delta = 104.4$ (C1, $J_{CH} = 150.5/160.1$, $J_{C1P1} = 23.7$, $J_{C1Rh} = 1.9$ Hz). Overall, the structure of **8** corresponds to that of known compounds of type **9**.[11]



9

We are currently exploring the use of other alkynes and phosphaalkynes in the syntheses describe here and are investigating the properties of the metal-free phosphorus heterocycles released from the complexes.

Experimental Procedure

4: Compound **1a** (2.5 g, 25 mmol) was added to **2** (0.55 g, 0.86 mmol) in 50 mL of diethyl ether at -30 °C. The resulting dark red solution was stirred for 12 h at 20 °C and then concentrated to 10 mL. After cooling for 2 d at -78 °C, the solution afforded **4** as dark red, nearly black crystals; 0.44 g (76%) of **4** was obtained after filtration and drying at 0.5 Torr; m.p. = 155 °C (dec.).

5a: Compound **1a** (0.08 g, 0.8 mmol) was added to a solution of **3** (0.35 g, 0.69 mmol) in 40 mL of THF and the reaction mixture was refluxed for 3 d. The THF was then removed by distillation at 0.5 Torr, the residue was dissolved in 5 mL of pentane, and the resulting solution was cooled to -78 °C. The yellow crystals formed after 3 d were freed of mother liquor and dried at 0.5 Torr; 0.28 g (90%) **5a**, m.p. 95 °C.

7: Compound **6** (0.65 g, 1.3 mmol) was dissolved in 40 mL of THF at 0 °C and **1a** (0.18 g, 1.8 mmol) was then added, resulting in an immediate change in color from yellow to red. The reaction mixture was stirred for 12 h at 20 °C, the volatiles were then removed at 0.5 Torr, and the oily residue was dissolved in 25 mL of diethyl ether; **7** precipitated at -78 °C as a microcrystalline yellow solid. A single recrystallization gave 0.63 g (79%) of yellow needles (m.p. 111 °C).

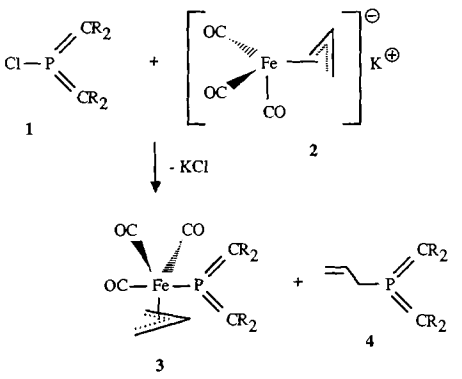
The First Metallobis(methylene)phosphoranes—Unexpected Isomerization to a Phosphaferrocene

By *Hans Jürgen Metternich* and *Edgar Niecke**

Dedicated to Professor Rolf Appel on the occasion of his 70th birthday

The synthesis of bis[bis(trimethylsilyl)methylene]chlorophosphorane (**1**), the first *P*-functionalized $\sigma^3\lambda^5$-phosphorane, by *Appel* et al.[1] led to an intensive investigation of this class of compounds.[2] The focus of this work has been the preparation of compounds with bonds between phosphorus and other main-group elements. However, nothing is known about the relevance of this class of compounds to coordination chemistry and organometallic synthesis. The related bis(imino)phosphoranes,[3] on the other hand, have found applications in catalysis.[4] We report here the synthesis of the first metallobis(methylene)phosphorane as well as the products of its cyclization.

Reaction of the reactive potassium metalate **2**,[5] obtainable from η^3-allyl(tricarbonyl)iodoiron and K/Hg, with the chlorobis(methylene)phosphorane **1** led to substitution of chlorine and formation of **3**, as the main product,[6] together with bis(methylene)propenylphosphorane[7] (**4**), which results from extrusion of the carbonyl fragment.[8]



Recently, a transition-metal-substituted bis(methylene)-phosphorane was also assumed to be the product obtained from the reaction of K[(η^5-C_5H_5)Fe(CO)$_2$] (**5**) with **1**.[9] However, the ^{31}P NMR signal ($\delta = -81.6$), which is found at unusually high field for a $\sigma^3\lambda^5$-phosphorus atom, especially compared with the signal for **3** ($\delta = 331.8$), indicates that, instead of the postulated "open" form of a metallobis-(methylene)phosphorane, a cyclic isomer was obtained.

By varying the reaction conditions,[10] we have now succeeded in synthesizing the metallobis(methylene)phosphorane **6** and its rearrangement product, the phosphaferrocene **7**, from **1** and **5**. Both isomers were separated by column chromatography and isolated as pure compounds. The isomerization of **6** and **7** can be regarded as a coupling of the phosphorane fragment with the two carbonyl groups of the Fe fragment. Thus, the rearrangement does not lead to the isomeric metallo- λ^3-phosphirane **8**,[13] as so often observed

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

with alkyl-substituted bis(methylene)phosphoranes,[12] but results in the formation of a phospholyl ligand in the coordination sphere of the transition metal.

The composition and constitution of compounds **3**, **4**, **6**, and **7** was established by elemental analysis and high-resolution mass spectrometry as well as by IR and NMR spectroscopy.

Like the metallomethylenephosphanes,[14] the metallobis(methylene)phosphoranes **3** and **6** have more strongly deshielded ^{31}P (**6**: $\delta = 347.1$) and ^{13}C nuclei than those of the corresponding organosubstituted compounds.[12] In the phospholyl complex **7**, on the other hand, the ^{31}P nucleus is strongly shielded[15] ($\delta = -83.5$), as expected. The ^{13}C resonances of the ring carbon atoms lie in the usual range.[15] The mass spectrum, which is characteristic for phosphaferrocenes,[15] and the absence of CO vibrational bands in the IR spectrum are additional evidence for a sandwich structure of **7**.[16] Further investigations of the organometallic chemistry of *P*-functionalized phosphoranes with $\sigma^3\lambda^5$-phosphorus are in progress.[17]

Experimental Procedure

3: A freshly prepared solution of $Na[(\eta^3\text{-}C_3H_5)Fe(CO)_3]$ in 40 mL of THF was treated at $-10\,^{\circ}C$ with **1** (1.53 g, 4 mmol) dissolved in 20 mL of toluene. The reaction mixture was allowed to warm to room temperature and then stirred for 3 h. The solvents were removed at 30 °C under vacuum, the residue was dissolved in 60 mL of pentane, and the solution was filtered. Of the reaction products **3**, $Fe_3(CO)_{12}$, **4** [7], and two dihydrophosphole complexes, three were isolated by column chromatography (silica gel, 30×200 mm, pentane, 10 °C). Crystallization of the first, red fraction at 6 °C afforded **3** in 36–49% yield, m.p. 111 °C. ^{31}P NMR (C_6D_6, 25 °C): $\delta = 331.8$ (br). ^{13}C NMR (C_6D_6, 25 °C): $\delta = 220.1$ (s, CO), 219.9 (d, $J = 1.0$ Hz, CO), 137.6 (d, $J = 55.8$ Hz, P = C), 86.4 (d, $J = 3.0$ Hz, C2 (Allyl)), 47.1 (d, $J = 1.9$ Hz, C1,3 (Allyl)), 5.5 (d, $J = 2.6$ Hz, $SiCH_3$), 3.4 (d, $J = 10.2$ Hz, $SiCH_3$), 3.1 (d, $J = 7.0$ Hz, $SiCH_3$). MS (60 eV): $m/z = 528$ (1%) [$M^{\oplus}$], 500 (1) [$M^{\oplus} - CO$], 472 (2) [$M^{\oplus} - 2CO$], 444 (69) [$M^{\oplus} - 3CO$], 429 (2) [$M^{\oplus} - 3CO - Me$], 403 (11) [$M^{\oplus} - 3CO - C_3H_6$], 348 (10) [$M^{\oplus} - Fe(CO)_3C_3H_5$], 73 (100) [$SiMe_3^{\oplus}$], and other fragments. IR (pentane) $\tilde{\nu}$[cm^{-1}] = 2020 w, 1990 vs, 1940 vs (C = O).

4 [8]: Compound **1** (1.15 g, 3 mmol) in diethyl ether (20 mL) was treated at 10 °C with 6 mL of a freshly distilled 0.5 M solution of allylmagnesium iodide in diethyl ether. The reaction mixture was allowed to warm to 22 °C and then stirred for 2 h. The solvent was removed under high vacuum and the orange residue was dissolved in 30 mL of pentane. After filtration of the solution, **4** was crystallized from diethyl ether at $-30\,^{\circ}C$ (yield 93%, m.p. 58 °C). ^{31}P NMR (C_6D_6, 25 °C): $\delta = 177.9$ (dt, $J = 12.9$ Hz and 14.1 Hz. ^{13}C NMR (C_6D_6, 25 °C): $\delta = 132.1$ (d, $J = 8.6$ Hz, $= CH_2$), 119.3 (d, $J = 13.6$ Hz, $-CH =$), 82.6 (d, $J = 41.1$ Hz, P = C), 43.7 (d, $J = 37.9$ Hz, P–CH_2), 4.1 (s, $SiCH_3$), 3.8 (s, $SiCH_3$). MS (60 eV): $m/z = 388$ (16%) [$M^{\oplus}$], 373 (29) [$M^{\oplus} - CH_3$], 347 (46) [$M^{\oplus} - C_3H_5$], 315 (41) [$M^{\oplus} - SiMe_3$], 259 (37) [$M^{\oplus} - SiMe_4 - C_3H_5$], 73 (100) [$SiMe_3^{\oplus}$], and other fragments.

6 and **7**: Compound **1** (1.15 g, 3 mmol), dissolved in 90 mL of toluene, was added dropwise over 4 h to a solution of $K[(\eta^5\text{-}C_5H_5)Fe(CO)_2]$ in 50 mL of THF at 75 °C. After the addition was completed, the reaction mixture was stirred for 1 h and the solvents were then removed under vacuum. The dark brown residue was extracted into 40 mL of pentane and insoluble material was removed. Workup by column chromatography (Florisil, 30×200 mm, pentane, 10 °C) afforded **6** in 39% yield; m.p. 104 °C. ^{31}P NMR (C_6D_6, 25 °C): $\delta = 347.1$ (s). ^{13}C NMR (C_6D_6, 25 °C): $\delta = 221.1$ (s, CO), 219.0 (s, CO), 140.6 (d, $J = 50.1$ Hz, P = C), 81.6 (s, C_5H_5), 6.0 (d, $J = 1.8$ Hz, $SiCH_3$), 4.8 (d, $J = 3.5$ Hz, $SiCH_3$), 3.7 (d, $J = 8.6$ Hz, $SiCH_3$), 3.1 (d, $J = 5.1$ Hz, $SiCH_3$). MS (50 eV): $m/z = 496$ (4%) [$M^{\oplus} - CO$], 468 (69) [$M^{\oplus} - 2CO$], 348 (12) [$(Me_3Si)_2C = P = C(SiMe_3)_2^{\oplus}$], 73 (100) [$SiMe_3^{\oplus}$], and other fragments. IR (pentane) $\tilde{\nu}$[cm^{-1}] = 2021 w, 1938 vs (C = O).

Crystallization of the second fraction at $-80\,^{\circ}C$ afforded bright orange crystals of **7** (in 34–72% yield, depending on the reaction time); m.p. 99–101 °C. ^{31}P NMR (C_6D_6, 25 °C): $\delta = -83.5$ (s). ^{13}C NMR (C_6D_6, 25 °C): $\delta = 126.6$ (d, $J = 28.5$ Hz, P-*C*-COSi), 82.1 (d, $J = 52.9$ Hz, P–C–*C*OSi), 71.9 (d, $J = 2.5$ Hz, C_5H_5), 2.6 (s, $OSiCH_3$), 1.8 (d, $J = 5.9$ Hz, $SiCH_3$). MS (50 eV): $m/z = 524$ (100%) [$M^{\oplus}$], 436 (8) [$M^{\oplus} - SiMe_4$], 73 (36) [$SiMe_3^{\oplus}$].

A Cluster with the Triply Facially Bridging Trimethylenemethane Ligand: Structure and Bonding of $[\{Rh(cod)\}_3(\mu_3\text{-}H)\{\mu_3\text{-}C(CH_2)_3\}]$ **

By *Gerhard E. Herberich,* Ulli Englert, Lars Wesemann,* and *Peter Hofmann**

A great variety of trimethylenemethane (TMM) complexes are known,[1] some of which are important intermediates in organic synthesis.[1, 2] They are almost always mononuclear, as exemplified by $[(\eta^4\text{-tmm})Fe(CO)_3]$.[3] The TMM ligand is seldom bonded in a bridging fashion as in the binuclear complex $[(\mu\text{-}\eta^1\text{:}\eta^3\text{-tmm})Ru_2(CO)(\mu\text{-}CO)Cp_2]$(*Ru–Ru*).[4] Here we report the first example of a facially bridging coordination to a *triangulo* trimetal cluster.

Complexation of $Li_2[TMM] \cdot 2TMEDA$[5] with $[RhCl(cod)]_2$ yields a labile primary product, presumably **1**, which decomposes in solution to form the novel trinuclear complex **2**.

$[\{Rh(cod)\}_2(tmm)]$ **1** $[\{Rh(cod)\}_3(\mu_3\text{-}H)(\mu_3\text{-}tmm)]$ **2**

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

Complex **2** (Fig. 1)[6] contains an equilateral Rh_3 triangle ($d_{Rh\text{-}Rh}$ = 298 pm[7]) capped on one side by a nearly planar TMM ligand; CO lies 5.4 pm above the plane C1, C2, C3. A triply bridging hydrido ligand was localized on the other side of the Rh_3 triangle.[8] Owing to coupling with the Rh nuclei, this μ_3-H ligand gives rise to a quartet at $\delta = -13.4$ in the ^1H NMR spectrum. Complex **2** deviates significantly from idealized C_{3v} symmetry. The TMM ligand does not eclipse the Rh_3 triangle but is rotated by 19°. With respect to the Rh_3 plane, the COD rings are tilted by 34° away from the TMM ligand and rotated by 21° around their C_2 axis.

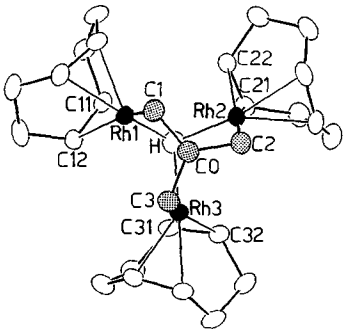

Fig. 1. Molecular structure of **2**. Selected distances [pm] and bond angles [°]: Rh1-Rh2 297.7(1), Rh2-Rh3 298.1(1), Rh3-Rh1 297.7(1), Rh1-H 167(3), Rh2-H 187(3), Rh3-H 196(3), Rh1-C1 213.2(3), Rh2-C2 212.8(2), Rh3-C3 213.8(3), C0-C1 142.2(4), C0-C2 143.2(4), C0-C3 143.0(4); Rh2-Rh1-Rh3 60.08(1), Rh1-Rh2-Rh3 59.96(1), Rh1-Rh3-Rh2 59.96(1), C1-Rh1-H 101(1), C2-Rh2-H 99.5(9), C3-Rh3-H 97.8(9), C1-C0-C2 120.5(2), C1-C0-C3 119.2(2), C2-C0-C3 119.9(2), Rh1-C1-C0 97.7(2), Rh2-C2-C0 98.0(2), Rh3-C3-C0 96.1(2).

Complex **2** is a diamagnetic 44-electron cluster; a 48-electron configuration would have been expected according to the 18-electron rule. In terms of the fragment frontier orbital formalism,[9] **2** can be regarded as a trinuclear metal complex fragment, $[Rh(cod)]_3^{\oplus}$ with a total of 26 d valence electrons, which interacts with both the 6π ligand $TMM^{2\ominus}$ and a μ_3-bridging $H^{\oplus}$.[10] The frontier orbitals of the $[Rh(cod)]_3^{\oplus}$ fragment can be traced back to the characteristic ML_2 orbitals[11] of three [Rh(cod)] units. This is shown for the simplified model $[Rh(C_2H_4)_2]$ (**3**) with C_{2v} symmetry (MO scheme **A** in Fig. 2).

Combination of the MOs of three $[Rh(C_2H_4)_2]$ units (**3**)[12] leads to the MO scheme **B** for $[Rh(C_2H_4)_2]_3^{\oplus}$ (**4**), as derived from extended Hückel (EH) model calculations.[13] Both **4** and the complete model cluster **5** (Fig. 2, MO scheme **C**) adopt C_{3v} symmetry; the $[Rh(C_2H_4)_2]$ fragments, like the

$[\{Rh(C_2H_4)_2\}_3(\mu_3\text{-}H)(\mu_3\text{-}tmm)]$ **5**

[Rh(cod)] units of **2**, are tilted toward the side of the metal triangle opposite to the TMM ligand, but the double bonds are still parallel to the Rh_3 plane. The frontier orbitals b_2 (xz, z) and $3a_1$ (sp hybrid) of the $[Rh(C_2H_4)_2]$ units (**3**) give rise to the valence MOs $1a_1$, 1e, $2a_1$, and 2e of **4**.[12] Owing to their relative energies and symmetry properties, four of these, namely, $1a_1$ (HOMO of **4**) and the empty MOs $1e_s$, $1e_a$, and $2a_1$, are ideally suited for interaction with the occupied π MOs π_1, π_{2s}, and π_{2a} of $TMM^{2\ominus}$ and the empty 1s AO of an $H^{\oplus}$ (**D** in Fig. 2).[14] For **5**, the resulting MO scheme **C** has a HOMO–LUMO separation of more than 1.7 eV and thus reflects the stable, diamagnetic closed-shell electron configuration of **2**, which, for the electron count given, is only made possible by the additional μ_3-H bridging.[15] The three lowest unoccupied orbitals of **5** are linear combinations of 5p AOs of the Rh centers in the Rh_3 plane. At each Rh atom, these orbitals are comparable to the LUMO of mononuclear, square-planar d^8 complexes with usually 16 instead of 18 valence electrons. For clusters **5** and **2**, the appropriate number is already reached at 44 (instead of 48).[16]

The distortion and symmetry reduction to C_3 found in **2**, in contrast to **5**, does not play a crucial role for the electron configuration of this type of TMM cluster. C_{3v} symmetry in **5** (TMM eclipsing the Rh_3 triangle) would have caused too short H–H distances especially between the *endo* H atoms of the C = C units on the hydride side. The same holds for complex **2**. A geometry optimization for **5**, represented by **6** in Scheme 1,[17] results in a ground-state geometry almost identical to that of the real structure. The distortion of the $[\{Rh(cod)\}_3(\mu_3\text{-}H)]$ fragment to C_3 symmetry, in turn, is responsible for the 19° rotation of the planar TMM ligand above the Rh_3 triangle; this rotation restores optimal overlap between the Rh atoms and the C atoms of the TMM ligand. According to the calculation for **5**, a complete rota-

tion of the TMM ligand would be hampered by a rotation barrier of about 50 kcal mol^{-1}. This high barrier is a consequence of the bonding situation (MO scheme **C** in Fig. 2), which can be represented for **5** by three degenerate ground-state structures of type **7**.

Related *triangulo* clusters (e.g., of heteroanalogues of TMM or complexes containing other ML_2 fragments) can be derived from the electron configuration of **2**. Their synthesis poses an interesting challenge.

Experimental Procedure

1: $Li_2[C(CH_2)_3] \cdot 2TMEDA$ (0.625 g, 3.39 mmol) [5] was allowed to react in THF at −78 °C with $[RhCl(cod)]_2$ (1.67 g, 3.39 mmol). The temperature was allowed to warm to 20 °C and the reaction mixture was stirred for 1 h. The THF was then removed and the residue was dissolved in toluene. Filtration of the solution through a small amount of kieselgur gave a dark red solution of **1**. Complex **1**, which was crystallized at −20 °C from toluene/hexane, is not stable upon storage and decomposes in solution within 10 h at 20 °C (^{1}H NMR). ^{1}H NMR (60 MHz, C_6D_6, TMS int.): δ = 4.6 (s, br, 8HC =), 2.0 (s, br, $8CH_2$), 1.6 (s, TMM).

2: Complex **2** crystallized within 24 h from solutions of **1** in toluene/hexane at 20 °C. The dark red crystals are air-stable. Complex **2** decomposes in solution within 50 h (^{1}H NMR). ^{1}H NMR (80 MHz, [D_8]toluene, int. TMS, not completely assignable owing to low solubility): δ = 4.6 (s, br, 12HC =), 2.1 (s, br, $12CH_2$ from COD), 2.2–0.9 (several signals, TMM not assignable), −13.4 (q, $^1J(^{103}Rh\text{-}^1H)$ = 14 Hz, μ_3-H).

Model geometries: adapted from the structure of **2**.
[14] The π_3 and 2e MOs of TMM and **3**, respectively, do not play a dominant role for bonding in **5** and **2**.
[15] Without attachment of μ_3-$H^{\oplus}$, that is, formally without the transfer of two electrons of the cluster framework to the μ_3-H atom (hydridic in **2**), a doubly reduced **4** or an isoelectronic system, even though also isoelectronic to **5**, would have two electrons in twofold degenerate LUMO (MO scheme **B**). This would correspond to an open-shell triplet or to a Jahn–Teller-unstable singlet state.
[16] A stable electron configuration should even result for full occupation of the two LUMO levels in the MO scheme **C** (48 VE) owing to their Rh–Rh bonding character and the large separation from the next-highest MO (Rh–Rh antibonding).
[17] In the model calculations the three $[Rh(C_2H_4)_2]$ units of **5** relax with retention of C_3 symmetry for the complete cluster (corresponding to the arrows in **6**) by (1) tilting toward the hydride and (2) sideways displacement in the same direction and rotation around their local C_2 axes, which causes the rotation of the TMM ligand around the C_3 axis. The geometry-optimized structure of **5** corresponds to the geometry of **2**.

Interaction of Hydrophobically-Modified Poly-*N*-isopropylacrylamides with Model Membranes – or Playing a Molecular Accordion **

By *Helmut Ringsdorf*,* *Joachim Venzmer*, and *Françoise M. Winnik*

One stabilizing element of cell membranes is the cytoskeleton. In the case of the red blood cell this is a two-dimensional protein network which is coupled to the membrane via anchor proteins.[1] Through lateral contractions and expansions the cytoskeleton participates in the cell overall motion and in membrane processes such as protrusions.[2] Simple model membranes such as monolayers[3] and liposomes[4] are lipid assemblies which lack the stabilizing elements present in natural membranes. Approaches to improve the mechanical stability of lipid membranes with the help of polymer science involve either chemical cross-linking of the membrane by use of polymerizable lipids,[5] or fixation onto a lipid bilayer of water-soluble polymers which carry lipid-

compatible anchor groups[6] (Fig. 1). These concepts mostly neglect the dynamical aspect of membranes. If, however, the adsorbed polymer responds by some physical change to an external stimulus, such as a pulse of light or changes in pH, it can be used to modulate the systems properties.[7] This communication describes model membranes which simulate the dynamics of the cytoskeleton by a thermoreversible contraction/expansion of a polymer anchored to a lipid bilayer.

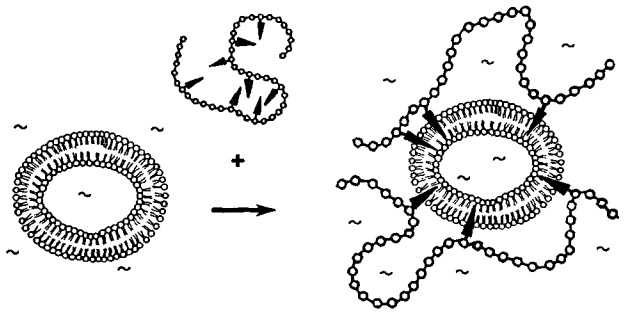

Fig. 1. Schematic drawing of the interaction of a liposome with a water-soluble polymer bearing hydrophobic anchor groups.

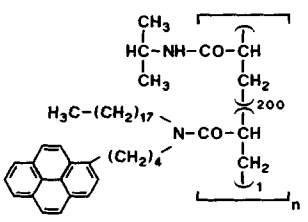
To play such a "molecular accordion" the water-soluble polymer must satisfy the following requirements: 1) it must anchor itself tightly onto the lipid bilayer and 2) its dimensions must undergo thermoreversible expansion and contraction. The second feature is characteristic for polymers which form solutions that are clear in cold water, but become turbid upon heating. One example of a polymer exhibiting such a lower critical solution temperature (LCST)[8] is poly-*N*-isopropylacrylamide (PNIPAM).[9] It was selected in this study for the following reasons: 1) its LCST is 32 °C, a temperature convenient for working with membranes; 2) the incorporation of a few anchor groups can easily be achieved by radical copolymerization; 3) investigations of the molecular aspects of the LCST phenomena have confirmed that the hydrodynamic radius of single PNIPAM macromolecules decreases upon precipitation at the LCST.[10] In addition, a suitable detection system is needed to follow the conformational changes of the polymer. Fluorescence spectroscopy of a pyrene-labeled polymer was chosen since pyrene has two distinct emissions: an isolated pyrene exhibits a structured "monomer" emission but if an excited pyrene group comes into close contact with a ground state pyrene, an excimer will form and emit light as a broad featureless band centered at 485 nm.[11] Thus, the changes in the relative intensity of the monomer and excimer emissions constitute a measure of the changes in the number of isolated pyrenes to that of pairs of pyrenes in close proximity.



1

The functional labeled polymer **1** used here is a random copolymer of *N*-isopropylacrylamide and *N*-[4-(1′-pyrenyl)-butyl]-*N*-*n*-octadecylacrylamide in a molar ratio of ca. 200/1.[12] In water at 20 °C **1** exhibits an emission due to locally excited pyrene (intensity I_M) and a broad featureless emission centered at 480 nm (intensity I_E) due to pyrene excimer emission (Fig. 2A). The large contribution of excimer

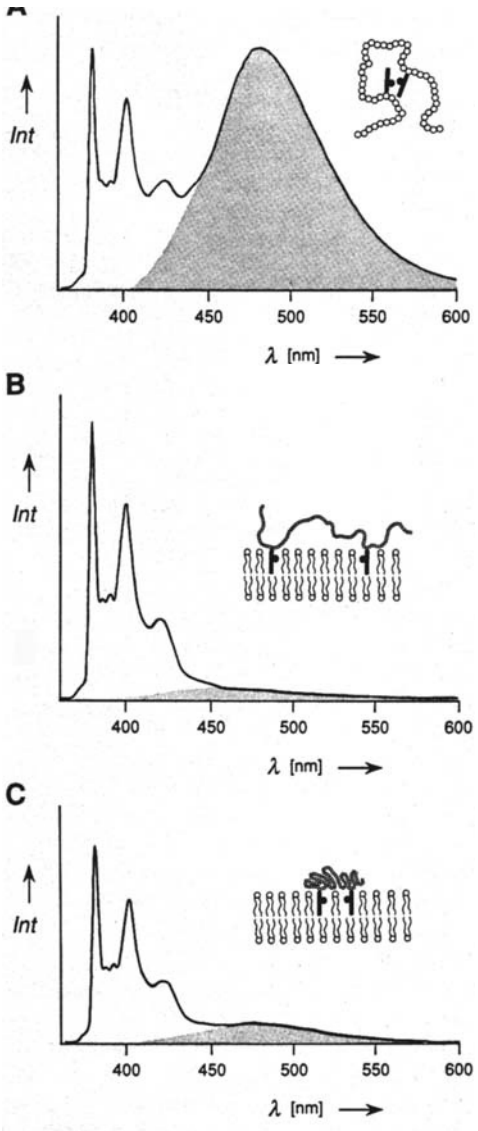


Fig. 2. Fluorescence spectra and schematic representations of the interactions of **1** with liposomes of DMPC (λ_{exc} = 347 nm): (**A**) polymer without liposomes (I_E/I_M = 1.10); (**B**) polymer with DMPC liposomes at 26 °C (I_E/I_M = 0.04); (**C**) same system at 34 °C (I_E/I_M = 0.12).

emission to the total fluorescence of **1** (I_E/I_M = 1.10) is indicative of the existence in the solution of microdomains with high local pyrene concentration. These have been identified as the inner core of unimolecular polymeric micelles, consisting of a hydrophobic domain formed by the octadecyl chains and the pyrene groups, surrounded by the more polar PNIPAM backbone, which lends to the polymer its solubility in water.[12] Solutions of **1** heated above their LCST present a much altered emission. Most notable is the large increase of the monomer emission at the expense of the excimer emission (I_E/I_M = 0.45), signaling heat-induced disruption of the hydrophobic microdomains. Above the LCST the pyrene groups are solubilized largely as isolated species in the separated polymer-rich phase.

Addition of small unilamellar liposomes of dimyristoyllecithin (DMPC, 1 gL^{-1}) to a solution of **1** (20 ppm) at 26 °C has a dramatic effect on the structure of this polymer in water, as evidenced by a remarkable decrease in the pyrene excimer emission ($I_E/I_M = 0.04$, Fig. 2B). This decrease indicates that the octadecyl/pyrene-anchor groups are inserted into the lipid bilayer. Among the lipidic alkyl chains they experience a hydrophobic environment such that the driving force for micellar aggregation is lost. The pyrene groups are separated from each other among the lipidic chains and excimer formation is almost entirely precluded.[13] This effect depends on the relative concentrations of liposomes and **1**. When increasing amounts of polymer are added to a liposome solution, a polymer concentration is reached at which I_E/I_M increases again. This signals the point at which the surface of the liposomes is covered entirely with polymer (35 macromolecules per liposome or 1 pyrene per 110 lipids). The excess polymer adopts a micellar structure identical to that of pure **1** in water, characterized by a strong excimer emission.

When the temperature of a solution of functionalized liposomes is raised to 34 °C, i.e. above the LCST of PNIPAM, there results a small, but significant increase in the excimer emission ($I_E/I_M = 0.12$, Fig. 2C). This effect is reversible: upon cooling the solution I_E/I_M fell to its original value (0.04). The increase in excimer emission upon application of heat can be explained by the following sequence of events. At the LCST the PNIPAM loops in the aqueous environment collapse. The anchor groups attached to the polymer are forced to move closer together by lateral diffusion within the membrane. The number of pyrene pairs close enough to form excimers increases, resulting in an enhanced excimer emission. Upon cooling the polymer loops in water expand forcing the anchor groups to move apart from each other. Hence the excimer emission all but vanishes. There is however another scenario to account for the heat-induced increase in excimer emission: a small number of anchor groups might be pulled out of the membrane. Thus, free polymer would exist in solution and adopt a conformation typical of pure **1** solution above its LCST. This mechanism too would account for the observed increase in I_E/I_M. A control experiment is needed to distinguish between these two mechanisms. This experiment, carried out with liposomes made with a lipid of a higher phase transition, provided the proof that the "molecular accordion" was indeed playing our tune.

Structure and fluidity of liposomes are temperature dependent.[14] Above a characteristic transition temperature liposomes exist in the liquid-analogous phase, in which the lipid alkyl chains are molten. In this phase lateral diffusion within the plane of the membrane is permitted. Below the phase transition temperature liposomes exist in the solid-analogous phase, in which the alkyl chains of the lipids are crystallized in all-*trans* configuration. There is practically no lateral diffusion within the membrane in this phase. In the experiment described above, the DMPC liposomes (phase transition temperature 23 °C)[15] were in the liquid-analogous phase in the entire temperature range probed. The next set of experiments was carried out with liposomes made from distearoyllecithin (DSPC). Their phase transition temperature is 54 °C,[15] a temperature well above the LCST of PNIPAM. Therefore, by scanning temperatures from 26 °C to 56 °C one can observe separately the events occurring at the LCST of PNIPAM and at the liposome phase transition temperature. Figure 3 illustrates the results of a temperature scan performed with DSPC liposomes (1 gL^{-1}) and **1** (20 ppm). Fluorescence of this solution at 26 °C (Fig. 3A) consists almost entirely of pyrene monomer emission

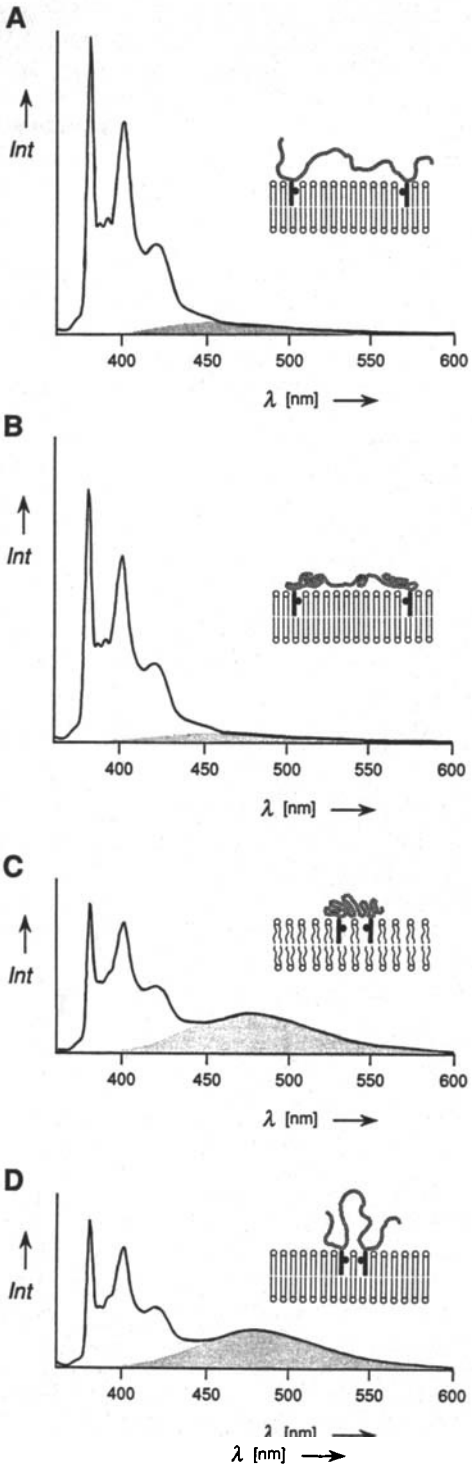

Fig. 3. Fluorescence spectra and schematic representations of the interactions of **1** with liposomes of DSPC (λ_{exc} = 347 nm): (**A**) polymer with DSPC liposomes at 26 °C ($I_E/I_M = 0.03$); (**B**) same system at 34 °C ($I_E/I_M = 0.03$); (**C**) same system at 56 °C ($I_E/I_M = 0.28$); (**D**) same system cooled to 26 °C ($I_E/I_M = 0.28$).

($I_E/I_M = 0.03$), indicating that the polymer anchor groups are inserted in the liposomes in their solid-analogous phase, as they were in the liquid-analogous phase of DMPC liposomes. At 34 °C, a temperature higher than the LCST of PNIPAM but lower than the liposome phase transition, the pyrene emission still originates almost entirely from isolated chromophores ($I_E/I_M = 0.03$, Fig. 3B). Therefore, even though the PNIPAM loops are collapsed, the pyrene groups are still unable to get in close proximity. This observation is consistent with the fact that in the solid-analogous phase

 © VCH Verlagsgesellschaft mbH, W-6940 Weinheim, 1991 0570-0833/91/0303-0317 $ 3.50+.25/0

lateral diffusion within the membrane is precluded. Finally at 56 °C, a temperature above the DSPC phase transition, pyrene excimer emission accounts for a significant part of the total emission ($I_E/I_M = 0.28$, Fig. 3C). At this temperature the anchor groups are free to diffuse within the membrane. They move closer together, presumably to relieve some of the strain caused by the collapse of the PNIPAM loops.

Next, the system was cooled to 26 °C. No change occurred in the fluorescence of the system: the ratio I_E/I_M retained its large value of 0.28 (Fig. 3D). Again the membrane has lost its fluidity and, even though the polymer dimensions are expanded, the anchor groups unable to move within the membrane cannot be pulled apart from each other. Therefore this heating/cooling cycle has left the DSPC liposome/**1** system in a state different from the original one. While initially the anchor groups were separated from each other within the membrane, at the end of the experiment they are locked in the configuration reached in the liquid-analogous phase of the liposome. This observation constitutes the ultimate proof that the "molecular accordion" is playing its tune: if the anchor groups had been pulled out of the membrane at any stage of the cycle, their re-insertion within the membrane below the LCST of PNIPAM would lead to the configuration depicted in Figure 3A, with separated anchor groups and hence drastically reduced pyrene excimer emission.

One may wonder whether the contractions of the anchored PNIPAM described here lead to a change in the shape of the liposomes, thus simulating the effects of the cytoskeleton contractions in the case of erythrocytes. This seems unlikely for two reasons. First, small unilamellar liposomes are not form-flexible. For a given surface to volume ratio the sphere is the only shape possible. Second, an anchored linear macromolecule capable of lateral diffusion cannot be expected to cause protrusions. Such changes in shape may possibly be achievable with a cross-linked polymeric network. This may be the next step towards a more advanced simulation of the natural process.

Experimental

The synthesis and characterization of **1** (LCST = 30.6 °C, M_V = 360 000, on average 16 octadecyl/pyrene groups per macromolecule) have been described in detail elsewhere [12]. The liposomes ($d \approx 100$ nm, BI 90 Particle Sizer, Brookhaven Instrument Corp.) were prepared by sonication of the lipids in deionized water (1 gL^{-1}, 40 W, Ultrasonic Homogenizer, Series 4710, Cole and Parmer Instrument Corp.) above the phase transition temperature of the lipid. Solutions for fluorescence measurements were prepared by addition of a polymer stock solution (50 µL, 1 gL^{-1}) to a liposome solution (2.5 mL). Fluorescence spectra were recorded with a SPEX spectrometer as described previously [12]. The excimer to monomer ratios (I_E/I_M) were calculated by taking the ratio of the emission intensity at 480 nm to the mean of the emission intensities at 379 nm and 399 nm. For measurements at different temperatures the samples were heated at a rate of 0.2 K min^{-1}.

[13] Addition of **1** to liposomes did not lead to a complete vanishing of the excimer emission with all liposomes tested. For example with liposomes composed of lecithin from egg yolk (high degree of unsaturation in the lipid chains) the system reached an equilibrium state at 26 °C where $I_E/I_M = 0.43$. Compatibility of the anchor groups with the lipid chains plays an important role in controlling the distribution of the anchor groups within the membrane.

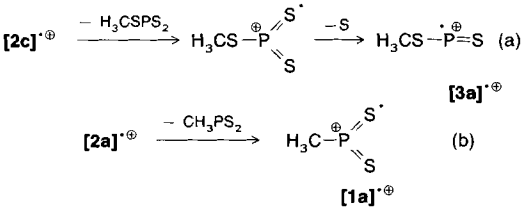
To our knowledge nothing has so far been reported in the literature about the existence of the (organothio)thioxophosphanes **3** isomeric with **1** and containing trivalent phosphorus of coordination number two. We have now been able to show that stable (organothio)thioxophosphanes RS–P=S **3a** and **3b** can be generated under unimolecular conditions by neutralization-reionization mass spectrometry (NRMS).[5]

Radical cations of the composition "$[RPS_2]^{\cdot\oplus}$" are formed upon mass spectrometric decomposition [electron impact ionization (EI): 70 eV] of the molecular ions of the dithiadiphosphetane disulfides **2a**–**2c**.[6]

Intense signals are observed for ions of the composition $[CH_3PS_2]^{\cdot\oplus}$ (m/z = 110) in both the EI mass spectrum of **2c** and of **2a**. These radical cations are formed from **[2c]**$^{\cdot\oplus}$ by ring cleavage, loss of CH_3SPS_2, and subsequent elimination of sulfur [Eq. (a)], and from **[2a]**$^{\cdot\oplus}$ by loss of CH_3PS_2 after ring opening [Eq. (b)]. It can be assumed that, depending on



their origin, ions of composition $[CH_3PS_2]^{\cdot\oplus}$ (m/z = 110) have a different structure, which can be derived either from a (methylthio)thioxophosphane **[3a]**$^{\cdot\oplus}$ or from a dithioxophosphorane **[1a]**$^{\cdot\oplus}$. To check this, the ions with m/z = 110 were mass selected and collisional activation (CA) mass spectra recorded;[7, 8] these differ from one another depending on the origin of the ions: in the case of the ions generated from **2c**, intense signals are observed for $PS^{\oplus}$ (m/z = 63) and $[CH_3S]^{\oplus}$ (m/z = 47) (Fig. 1a). Loss of an intact methyl group confirms that no isomerization reaction with participation of the methyl group, such as H-migration from C to S, has taken place. It can therefore be concluded that, in this case, the ions with m/z = 110 indeed have the structure **[3a]**$^{\cdot\oplus}$ containing a C–S bond. The NR mass spectrum (neutralization with Xe; reionization with O_2)[8] (Fig. 1b) shows

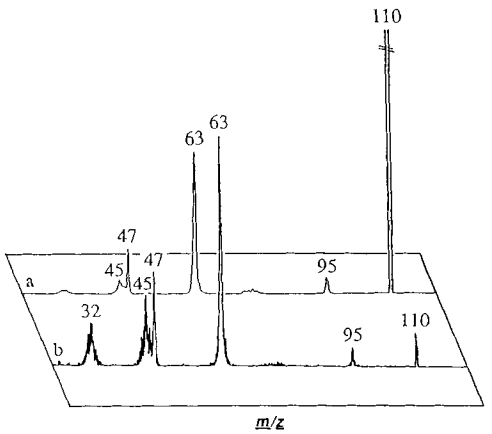


Fig. 1. CA- (a) and NR-mass spectrum (b) of "$[CH_3PS_2]^{\cdot\oplus}$" (m/z 110) (generated from **2c**).

that the neutral (methylthio)thioxophosphane **3a** (C_s) is really able to exist: for not only a "survivor signal" m/z = 110 is observed, but also the characteristics of the CA and NR mass spectra correlate well.

On the other hand, the CA mass spectrum (Fig. 2a) of the ions with m/z = 110 generated from **2a** according to Equation (b) differs from that of the ions that have been generated from **2c** according to Equation (a) (Fig. 1a). The most striking difference is the high intensity of the signal for $[PS_2]^{\oplus}$ (m/z = 95; base peak). Most likely the latter is formed by cleavage of a methyl group from **[1a]**$^{\cdot\oplus}$. Signals also appear, however, for $[CH_3S]^{\oplus}$ (m/z = 47), and these can only arise from **[3a]**$^{\cdot\oplus}$.

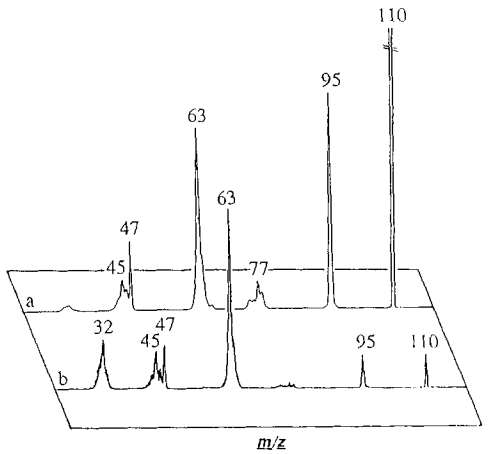

Fig. 2. CA- (a) and NR-mass spectrum (b) of "$[CH_3PS_2]^{\cdot\oplus}$" (m/z = 110) (generated from **2a**).

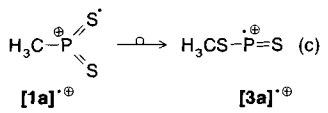
Apparently the methyl group in **[1a]**$^{\cdot\oplus}$ undergoes a [1, 2]-shift from P to S with formation of **[3a]**$^{\cdot\oplus}$ and lowering of the coordination number of the P from three to two [Eq. (c)].



In this case the ions with m/z = 110 should be coextisting in the structures **[3a]**$^{\cdot\oplus}$ and **[1a]**$^{\cdot\oplus}$. The respective NR mass spectrum (Fig. 2b) is consistent with that of **[3a]**$^{\cdot\oplus}$ (Fig. 1b), so that there is no evidence for decomposition of **1a**. It can be assumed that only neutral molecules of the structure **3a** are formed in the neutralization, since the **1a** formed in a highly excited state immediately before the reionization completely isomerizes to **3a** in the second collision cell.

Semiempirical MO calculations (MNDO)[9] confirm the experimental findings. It should be noted that according to such calculations the ionized (methylthio)thioxophosphane **[3a]**$^{\cdot\oplus}$ (ΔH_f^0 = 219 kcal mol^{-1}) is thermodynamically more stable than the ionized isomeric methyldithioxophosphorane **[1a]**$^{\cdot\oplus}$ (ΔH_f^0 = 242 kcal mol^{-1}). A standard enthalpy of formation of $\Delta H_f^0 = -9$ kcal mol^{-1} was found for **3a** and of ΔH_f^0 = 21 kcal mol^{-1} for **1a**.

In the EI mass spectrum of the 2,4-diphenyl-1,3,2,4-dithiadiphosphetane 2,4-disulfide **2b**, an intense signal is observed for ions of the composition "$[C_6H_5PS_2]^{\cdot\oplus}$" ($m/z$ = 172), which are formed directly from the molecular ions

 © VCH Verlagsgesellschaft mbH, W-6940 Weinheim, 1991 0570-0833/91/0303-0319 $ 3.50+.25/0

$[2b]^{\bullet\oplus}$, and for which likewise the structure of a phenyldithioxophosphorane $[1b]^{\bullet\oplus}$ or of a (phenylthio)thioxophosphane $[3b]^{\bullet\oplus}$ is open to discussion.

Signals at $m/z = 77$ ($[C_6H_5]^{\oplus}$) and $m/z = 51$ ($[C_4H_3]^{\oplus}$) in the CA mass spectrum (Fig. 3a) of "$[C_6H_5PS_2]^{\bullet\oplus}$" confirm that it contains an intact phenyl group. Consecutive elimination of S to $m/z = 140$ and $m/z = 108$ is an indication of the presence of the structure $[1b]^{\bullet\oplus}$. The ions $[C_6H_5S]^{\oplus}$ ($m/z = 109$), which can only be formed from $[3b]^{\bullet\oplus}$, and $[C_6H_5P]^{\bullet\oplus}$ ($m/z = 108$), which can only come from $[1b]^{\bullet\oplus}$ lead to the conclusion that radical cations "$[C_6H_5PS_2]^{\bullet\oplus}$" in the form of $[1b]^{\bullet\oplus}$ and $[3b]^{\bullet\oplus}$ exist alongside each other. Analogously to the ions that stem from **2a**, here also it follows from the NR mass spectrum that only neutral **3b** (C_s) is formed from both components of the ionic mixture. That is, neutral **1b** must have rearranged into the (phenylthio)-thioxophosphane **3b**. Figure 3b shows namely a "survivor

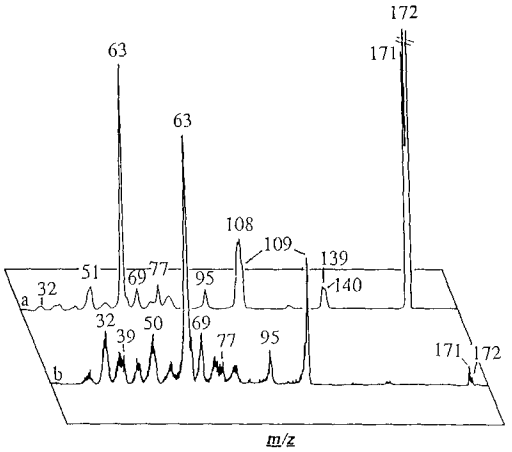


Fig. 3. CA- (a) and NR-mass spectrum (b) of "$[C_6H_5PS_2]^{\bullet\oplus}$" ($m/z$ 172) (generated from **2b**).

signal" at $m/z = 172$, which is only of small intensity. The spectral characteristic of the NR mass spectrum, however, differs from that of the CA mass spectrum. In the former, only an intense signal for $[C_6H_5S]^{\bullet\oplus}$ ($m/z = 109$) is still observed, which can be reconciled only with the thioxophosphane structure $[3b]^{\bullet\oplus}$, whereas the signal for $[C_6H_5P]^{\bullet\oplus}$ ($m/z = 108$) in the CA mass spectrum, which can be regarded as characteristic for the presence of $[1b]^{\bullet\oplus}$, is no longer present.

The results show that both the neutral molecules $RP(=S)_2$ **1a** and **1b** as well as their singly positively charged ions isomerize to (organothio)thioxophosphanes RS–P=S **3a** and **3b** and to the corresponding ions, respectively. Thus, NRMS[10] proves once again to be an effective method for the generation of highly reactive phosphorus compounds of low coordination number, for which there is so far no other synthetic route.

Enantioselective Metabolism of (±)-α-1,2,3,4,5,6-Hexachlorocyclohexane in Organs of the Eider Duck **

By *Roland Kallenborn, Heinrich Hühnerfuss,** and *Wilfried A. König*

Many investigations are being carried out on the fate of organic pollutants in marine and terrestrial ecosystems. Of primary interest are the questions of stability, degradation, and enrichment of anthropogenic organic compounds in the food chain. A problem has long been the differentiation between enzymatic and nonenzymatic degradation processes. Only the recently developed cyclodextrin phases,[1] which very quickly found application as chiral stationary phases in gas chromatography, made it possible to distinguish between the two degradation processes for very small concentrations of pollutants. Applying this new method to environmental analysis, *Faller* et al.[2] were able to study the microbial degradation of α-1,2,3,4,5,6-hexachlorocyclohexane (HCH), the only chiral isomer of the eight conceivable HCH isomers (Fig. 1), in the North Sea, where it is present at concentrations of several nanograms per dm^3 of seawater. For this low trophic stage of the marine ecosystem, the enantiomeric ratio (+)-α-HCH/(−)-α-HCH, which is 1 for technical α-HCH, was found to vary from 0.85 in the eastern North Sea to about 1.15 in the western North Sea. Using liver, kidney, and muscle tissue of the eider duck (*Somateria mollissima L.*), we have now examined whether comparable enantiomeric ratios are found for a considerably higher

[**] Gas-Chromatographic Separation of the Enantiomers of Organic Marine Pollutants, Part 2. This work was supported by the Bundesministerium für Forschung und Technologie (MFU 0620). Part 1: [2].

trophic stage in the marine ecosystem or whether enantioselective degradation processes lead to even more pronounced shifts. The eider duck was chosen because it largely favors mussels (*Mytilus edulis*) in its diet. Mussels, in turn, are capable of strongly enriching pollutants and thus serve as "indicator organisms" to provide insight into the state of an aquatic environment.

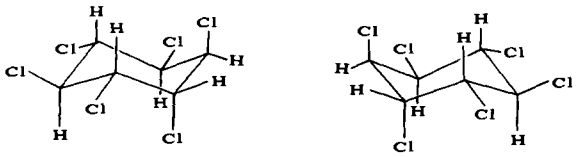

Fig. 1. The two enantiomers of α-HCH. The absolute configuration of the (+) and (−) enantiomers have not yet been determined.

Typical chromatograms of liver, kidney, and muscle extracts are shown in Figure 2. In all three extracts, (+)-α-HCH is clearly enriched; almost enantiomerically pure (+)-α-HCH is present in liver extracts. The enantiomeric purity of (+)-α-HCH isolated from liver extract is so high that, after purification by HPLC, it can be used directly in model experiments. By contrast, the enantiomeric ratio (+)-α-HCH/(−)-α-HCH was about 7.0 in muscle samples and about 1.6 in kidney extracts, whereby the values for these organs are slightly larger or smaller for different eider ducks.

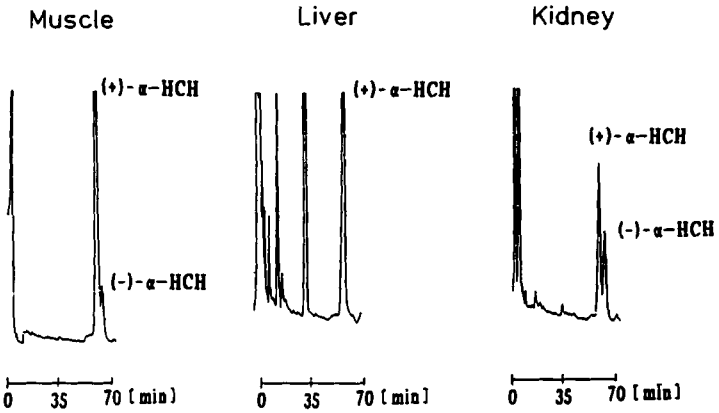

Fig. 2. Comparison of the chromatograms of extracts from the muscle, liver, and kidney of eider ducks (60-m glass capillary with heptakis(3-*O*-butyryl-2,6-di-*O*-pentyl)-β-cyclodextrin as chiral stationary phase, columns temperature 423 K (isothermal); carrier gas, 100 kPa helium, on-column injection, electrochemical detection).

An exact explanation for the appearance of different enantiomeric ratios of α-HCH in the organs of eider ducks cannot be given at the present time. It may be assumed, however, that the reason lies in the different physiological functions of the organs. For muscle and kidney, whose main functions are locomotion and excretion, respectively, the content of extractable lipids is about 2%; these organs can therefore store lipophilic pollutants. Liver, which contains about 2.5% of extractable matrix, serves as a "detoxification organ" and therefore is not only capable of storing toxic compounds but can also metabolize them to substances that the body can tolerate or excrete. Since the (+)-α-HCH found in the liver of eider duck is almost enantiomerically pure, (−)-α-HCH is presumably more readily degraded enzymatically than the (+) isomer in the liver. Although such a nearly enantioselective degradation has already been observed for biogenic organic compounds, this study represents the first demonstration for synthetic substances.

Experimental Procedure

Animals from the Oehe/Schleimünde wildlife refuge on the Baltic coast of Germany were investigated. Organ samples were taken only from healthy animals that, upon diving, had become trapped in the fishing nets of local fishermen and were thereby drowned. The tissue samples were homogenized with a threefold amount of anhydrous sodium sulfate; 60 g of the resulting powder was treated with 80 ng of the internal standard ε-HCH and then extracted in a Soxhlet apparatus for 8 h with 100 mL of ultrapure *n*-hexane. The extract was concentrated to 5 mL at 360 mbar and 313.2 K and then placed on a colums of partially deactivated alumina (5% water). The column was eluted with 70 mL of ultrapure *n*-hexane and the eluate was concentrated to 0.4 mL. Of this solution, 0.2 mL was separated on a LiChrosorb 100 Si column (Merck) by HPLC and the α-HCH fraction was measured by gas chromatography (Carlo Erba Vega gas chromatograph, 60-m glass capillary column with heptakis-(3-*O*-butyryl-2,6-di-*O*-pentyl)-β-cyclodextrin as chiral stationary phase, oven temperature 423 K (isothermal); carrier gas, 100 kPa helium, "on-column" injection, electrochemical detection). The organs from a total of six eider ducks were investigated, so that these results can be considered sufficiently reliable.

η^1-(1*S*, 2*E*)-1-(*N*,*N*-diisopropylcarbamoyloxy)-3-trimethylsilylallyllithium·(−)-Sparteine: Structure of a Chiral, Carbamoyloxy-substituted Allyllithium Compound**

By *Michael Marsch, Klaus Harms, Oliver Zschage, Dieter Hoppe* and *Gernot Boche**

Organolithium compounds bearing an oxygen substituent in the α position play an important role in organic synthesis.[1-3] Especially important is the discovery by *Still* et al. that the aliphatic derivatives are configurationally stable.[2] *Hoppe* et al. found that the carbamoyloxy-substituted allyllithium compounds **1** are useful reagents for the stereoselective synthesis of homoallyl alcohols.[3] (*S*)-**1a**, obtainable by deprotonation with retention of configuration, is configurationally stable at −70 °C on a preparative scale. Use of a chiral diamine allows (*R*)-**1b** to be isolated: in the presence of (−)-sparteine (**2**),[4] only (*R*)-**1b** crystallizes from the racemic mixture of the corresponding allyllithium compounds and is thus likewise accessible for enantioselective reactions.[3b] In a similar way we obtained (*S*)-**1c**[5] and

(*S*)-**1a**, $R^1 = R^2 = CH_3$, R^3 = Li · TMEDA
(*R*)-**1b**, $R^1 = CH_3$, R^2 = H, R^3 = Li · **2**
(*S*)-**1c**, $R^1 = SiMe_3$, R^2 = Li · **2**, R^3 = H

As revealed in Figure 1, sparteine-coordinated Li1 is bonded only to C1 (Li1-C1 220.7(8) pm) of the anionic allyl unit: the Li1–C2 distance is 293.2(8) pm. This structural feature is due to intramolecular chelate formation with the O atom of the carbamoyl group (Li1-O2 189.7(8) pm) to form a stable five-membered ring and is favored over η^3 coordination of the Li atom to the allyl unit.[10] The C1–C2–C3

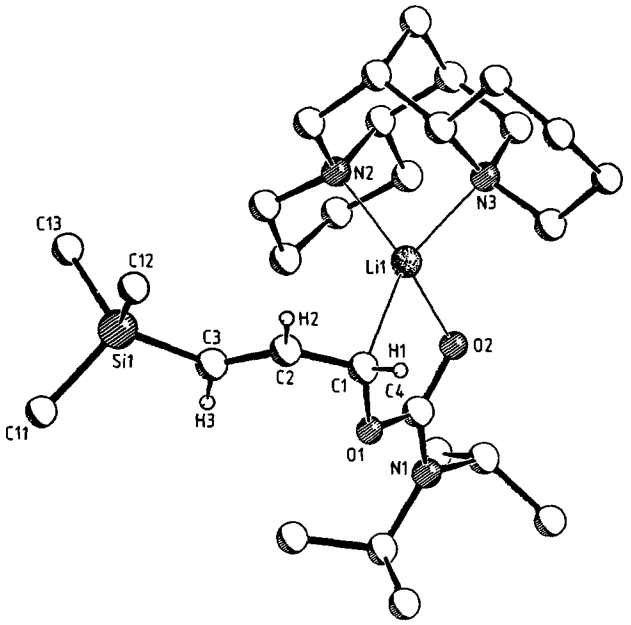

Fig. 1. Molecular structure of (*S*)-**1c**. [6] Important bond lengths [pm] as well as bond and torsional angles [°]: C1-C2 139.2(6), C2-C3 136.2(6), C3-Si1 182.0(5), C13-Si1 187.3(6), Li1-C1 220.7(9), Li1-O2 189.8(8), Li1-O1 284.0(8), Li1-N2 207.5(8), Li1-N3 201.7(8), C1-O1 147.6(6), C4-O1 133.8(6), C4-O2 123.9(5); C1-C2-C3 133.4(4); Li1-C1-C2-C3 91.7(6), Li1-C1-C2-H2 – 88(2), O1-C1-C2-C3 – 17.1(8); O1-C1-C2-H2 163(2), H1-C1-C2-C3 – 157(3), H1-C1-C2-H2 23(3).

angle is very strongly increased (133.4(4)°). Whereas the bonding geometry at C3 and C2 is nearly planar (sum of angles 359.7 and 360.4°, respectively), that at C1 is pyramidal. Thus, the sum of the angles at C1 is decreased to 347°, and the C1–H1 and C1–O1 bonds point away from Li1 and form angles of 23 and 17°, respectively, with the plane of the substituents at C2. The Li1–C1 bond is nearly perpendicular (Li1-C1-C2-C3 91.7°) to this plane. The preferential silylation at C1 and the stereoselective reaction with aldehydes at C3 (after complexation of the O atom of the aldehyde group by Li1[3]) are in agreement with the solid-state structure of (*S*)-**1c**.

It is remarkable that the structures of a *tert*-butylthio-[10b] and an (*S*)-2-(methoxymethyl)pyrrolidine-substituted[11] homoenolate equivalent are so clearly different from that of (*S*)-**1c**. In dimeric, intramolecularly chelated (3*S*)-3-lithio-1-[(*S*)-2-(methoxymethyl)pyrrolidino]-1,3-diphenylpropene,[11] each of the two Li atoms is bonded to the C3 atoms of both anionic allyl units as well as to the N and O atoms of a methoxymethylpyrrolidine substituent; the C1–C2 and C2–C3 bonds are 136(1) and 140(1) pm long, respectively. This is indicative of a strongly delocalized 3-metalated enamine system, which corresponds to the high C3 regioselectivity in reactions with electrophiles. In *tert*-butylthiobutenyllithium[10b] the Li atom is coordinated in an η^3 fashion to the anionic allyl unit (C1-Li 218, C3-Li 238 pm), whereby the C1–C2 distance (147 pm) is considerably longer than the C2–C3 distance (134 pm). In agreement with experimental observations, a metal-controlled regioselectivity of electrophilic attack is more difficult to establish here.[10b]

What can be said about the C1–O1 distance in (*S*)-**1c**? A search of the Cambridge Structural Database, as well as of published structures of carbamoyloxy-substituted compounds,[12] revealed the following average values: C_{sp2}–OCb = 139.9 pm (six values) and C_{sp3}–OCb = 143.6 pm (eleven values). Since the hybridization of C1 lies between sp^2 and sp^3 owing to pyramidalization, the C1–O1 distance found (147.6 pm) is markedly longer than the distance expected at least for a neutral molecule. A Li1–O1 interaction is not observed for (*S*)-**1c** (Li1-O1 284.0(8) pm). In ab initio studies on the structure of α-lithiomethanol, four different minima were found; the structure of (*S*)-**1c** corresponds to the "classical" structure in which the C–O bond is also lengthened compared with that in methanol.[13] The situation is exactly the opposite in α-lithiated thioethers owing to the different stabilization of a negative charge by an RS substituent (polarization and negative hyperconjugation versus induction by oxygen): the C_α–S bond is consistently shorter than that in the corresponding thioethers.[14]

The C4–O1 distance in (*S*)-**1c** (133.8(6) pm) is shorter than the mean value of the corresponding distances in neutral carbamoyloxy-substituted compounds (136.0 pm[12]), whereas C4–O2 (123.9(5) pm) is longer (mean value 120.5 pm[12]). This can be visualized as "dipole-stabilization" of the negative charge at C1.[15]

The Structure of $IF_6^{\ominus}$ **

By *Ali Reza Mahjoub* and *Konrad Seppelt**

The $BrF_6^{\ominus}$ ion has an octahedral structure in solution[1] and in the crystal.[2] This finding contradicts the electron-pair repulsion model as well as the often discussed fact that the structure of xenon hexafluoride in the gas phase,[3] in solution,[4] and in the crystal[5] deviates strongly from octahedral symmetry. The recently proposed octahedral symmetry of the very unstable species $ClF_6^{\ominus}$ in solution[6] thus makes the unknown structure of the $IF_6^{\ominus}$ ion especially interesting.

The structural information so far reported for the $IF_6^{\ominus}$ ion is dubious, since it was established in 1971 that $I_3F_{16}^{\ominus}$ is the initial product of the reaction of $F^{\ominus}$ with IF_5. Pure $IF_6^{\ominus}$ is only formed when $I_3F_{16}^{\ominus}$, whose structure is now known,[2] is subjected to vacuum pumping over a long period.[7] Earlier investigations (e.g., vibrational[8] or ^{129}I-Mössbauer spectroscopy[9]) were possibly carried out with samples of unclear composition. Moreover, the vibrational spectra and X-ray powder data of pure $IF_6^{\ominus}$ salts do not lead to unequivocal conclusions about the structure.[7]

Attempts to grow single crytals of pure $Cs^{\oplus}IF_6^{\ominus}$ from, for example, BrF_5 or CH_3CN solutions failed. Either the solvent still contains some HF, which leads to interesting cocrystallizations (e.g., $IF_5 \cdot HF_2^{\ominus}$, $2IF_5 \cdot HF_2^{\ominus}$, and $3IF_5 \cdot H_3F_4^{\ominus}$,[10] or it causes solvolysis [Eq. (a)].

$$3IF_6^{\ominus} + 2BrF_5 \longrightarrow I_3F_{16}^{\ominus} + 2BrF_6^{\ominus} \qquad (a)$$

On the other hand, the preparation of $(CH_3)_4N^{\oplus}IF_6^{\ominus}$ and its recrystallization from CH_3CN gave crystals of an $IF_6^{\ominus}$ salt which were suitable for structure analysis.

At room temperature, the crystals appear to be monoclinic. However, a structure analysis could only be performed by assuming a disorder or a merohedral twin and, even then, the positions of the fluorine atoms were very inexact. At lower temperatures, the crystals become triclinic and are always twinned ($a' = -a$, $b' = -c$, $c' = -b$). Extrapolation of the reflection splitting versus temperature gave a value of about 60 °C where $b = c$ and $\beta = \gamma$. Differential thermal analysis (DTA) revealed a first-order phase transition at 51.2 °C. The X-ray data were collected at the lowest temperature possible (−163 °C), since overlap of the reflections is thereby minimized. The structure of the $IF_6^{\ominus}$ ion can be described as a distorted octahedron of near C_{3v} symmetry (Fig. 1). Three

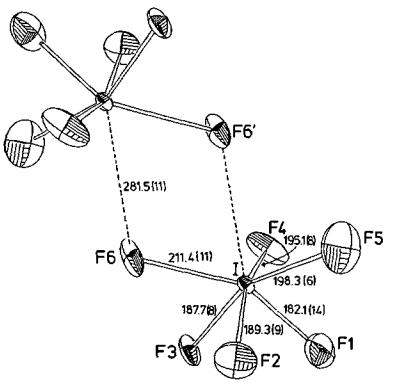

Fig. 1. The structure of the $IF_6^{\ominus}$ ion in crystals of $(CH_3)_4N^{\oplus}IF_6^{\ominus}$ (ORTEP, 50% thermal ellipsoids at −163 °C). Angles [°]: F1-I-F2 81.0(4), F1-I-F3 80.6(5), F2-I-F3 85.0(3), F4-I-F5 99.6(4), F4-I-F6 111.1(4),F5-I-F6 123.8(5), F1-I-F6 152.0(3), F2-I-F5 156.6(5), F3-I-F4 158.9(6).

fluorine atoms (F1, F2, F3) have shorter bonds that form angles of $< 90°$ with each other. There are three longer bonds with angles of $> 90°$. The bonds to fluorine atoms lying on opposite sides of the molecule have angles of about

150–160°. Current knowledge suggests that the sterically active electron pair occupies the cone between fluorine atoms F4, F5, and F6. This finding confirms the most recent theoretical prediction for the "free" $IF_6^\ominus$ ion, according to which C_{3v} symmetry is favored by 23 kcal mol^{-1} over O_h symmetry.[11]

Fluorine atom F6′, which occupies a seventh coordination site, is 281.5 pm from bromine in the direction of the nonbonding electron pair. A weakly bonded dimer with a center of symmetry is thereby formed. Thus, the $IF_6^\ominus$ ion may also be described as an adduct consisting of two IF_5 units and two $F^\ominus$ ions, the latter of which roughly lie opposite the apical positions of the $IF_5^\ominus$ square pyramids.

The intergrowth of the twins to form merohedral twins or a disordered single crystal when the temperature is increased corresponds to the pairwise exchange of F6 and F6′ between the two iodine atoms of the dimer, whereby the positions of these fluorine atoms change by only 110 pm. The other fluorine atoms follow this motion. In the crystal structure measured at room temperature (pseudo-monoclinic symmetry), therefore, the fluorine atoms have extremely large vibrational amplitudes. However, the cations are not measurably involved in this motion. In solution, on the other hand, rapid exchange of all of the fluorine atoms occurs (^{19}F NMR (0 °C, CH_3CN, $CFCl_3$ ext.): singlet at $\delta = -19$).

The analogy of the $IF_6^\ominus$ partial structure to the crystal structure of XeF_6 is even more apparent when a salt with a smaller counterion is investigated: in contrast to $(CH_3)_4N^\oplus IF_6^\ominus$, $NO^\oplus IF_6^\ominus$ crystallizes as a tetramer (Fig. 2) whose structure is qualitatively the same as that of the tetrameric unit $(XeF_5^\oplus F^\ominus)_4$ in crystalline XeF_6.[5] The small

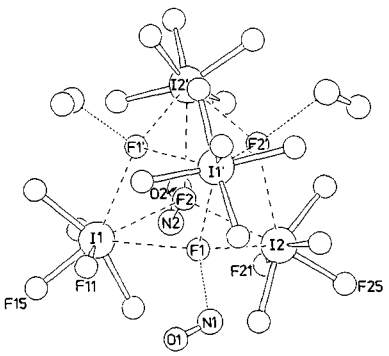

Fig. 2. The tetrameric structural unit in crystalline $NO^\oplus IF_6^\ominus$. A nearly regular $(IF_5)_4$ tetrahedron is held together by triply bridging fluoride ions, so that a cubane structure results. The bridging fluorine atoms originate from NOF (synthesis of the salt from NOF and IF_5): N(1) ··· F(1) = 197.2(9), N(2) ··· F(2) = 208.3(8) pm. The distances and angles of the IF_5 units are similar to those in free IF_5 [12]. The F–I distances in the cubane framework lie between 260.9(4) and 276.9(6) pm.

difference is only the highly symmetric bridging by the fluorine atoms F1 and F2 in the iodine tetramer. The three contacts of these atoms to the iodine atom are almost equal (260.9, 267.9, 274.9, and 262.3, 265.1, 276.9(4) pm), whereas one shorter and two longer contacts (223, 260, 283(3) pm) are present in $(XeF_5^\oplus F^\ominus)_4$.

XeF_6 and $IF_6^\ominus$ are not yet fully analogous, since the iodine system lacks an octahedral hexamer such as $(XeF_5^\oplus F^\ominus)_6$ in the crystalline state[5] as well as a nonrigid analogue to Xe_4F_{24} in solution.[4]

Experimental Procedure

$(CH_3)_4N^\oplus IF_6^\ominus$: IF_5 and $(CH_3)_4N^\oplus F^\ominus$ were combined in an FEP tube equipped with a valve (FEP = tetrafluoroethylene-hexafluoropropylene copolymer) under moisture-free conditions [13]. After completion of the reaction, the mixture was subjected to vacuum pumping. CH_3CN was then condensed into the tube to dissolve the product. Cooling to 0 °C resulted in formation of large, colorless crystals. The X-ray structure analysis at room temperature gave the following structural data: $a = 1126.6(5)$, $b = 1359.7(7)$, $c = 649.0(3)$ pm, $\beta = 93.73(3)°$, $C2/m$ (No. 12). The primitive unit cell has the parameters $a = 649.0$, $b = c = 883.0$ pm, $\alpha = 100.72$, $\beta = \gamma = 92.380$; cooling results in formation of a triclinic twin with ($T = -163$ °C): $a = 656.2(1)$, $b = 838.9(1)$, $c = 873.5(1)$ pm, $\alpha = 100.1(1)$, $\beta = 93.5(1)$, $\gamma = 91.8(1)°$, twinned according to $(-1\,0\,0)$, $(0\,0\,-1)$, $(0\,-1\,0)$, $P\bar{1}$. The Gemini program [14] was used to show that 1468 of 2882 measured reflections are nonoverlapping. Of these, 1384 are unique and 1273 have $I \geq 3\sigma(I)$ at $2° \leq \theta \leq 30°$, $\omega - 2\theta$ scan. Enraf–Nonius CAD4 diffractometer, $Mo_{K\alpha}$ radiation, $\mu = 34.28$ cm^{-1}, full matrix, SHELXTL plus, $R = 0.066$, $R_w = 0.056$. $NO^\oplus IF_6^\ominus$: Equimolar amounts of IF_5 and NOF were condensed into an FEP tube connected to a metal vacuum line and the tube was sealed under vacuum. At −20 °C, millimeter-size, colorless crystals formed spontaneously by sublimation. Great care must be taken to avoid the presence of HF, which leads to the formation of $NO^\oplus HF_2^\ominus \cdot IF_5$ (known crystal structure [10]). X-ray structure analysis at −157 °C gave the following structural data: $a = 1752.9(6)$, $b = 814.6(2)$, $c = 1588.1(6)$ pm, $\beta = 116.83(3)°$, $C2/c$, (No. 15), $Z = 8$. $R = 0.045$, $R_w = 0.041$. Further details of the crystal structure investigations may be obtained from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, W-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-55031, the names of the authors, and the journal citation.

Solvent-free Tris(trimethylsilyl)methyllithium**

By *Wolfgang Hiller, Marcus Layh,* and *Werner Uhl**

Bulky substituents stabilize compounds with unusual structural elements and properties. Recently we used this

Pfaffenwaldring 55, W-7000 Stuttgart 80 (FRG)
Dr. W. Hiller
Institut für Anorganische Chemie der Universität Tübingen

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

principle to synthesize a dialane(**4**) with aluminum-aluminum bond,[1] which was protected from disproportionation by the very large bis(trimethylsilyl)methyl substituent. Tris(trimethylsilyl)methyl analogues could not be prepared before, because the starting compound, tris(trimethylsilyl)-methyllithium,[2] was hitherto described as an ether or amine adduct, which in the presence of aluminum halides gave decomposition products formed by ether fission.[3] The boron halides behave similarly; however, these difficulties are overcome by using trimethoxyborane instead of halide.[4] The application of this variation to aluminum compounds was not successful. We hoped to find a route to the desired organoaluminum compounds through solvent-free tris(trimethylsilyl)methyllithium **1**.

Usually solvent-free lithium compounds are obtained by the reaction of the corresponding organomercury compounds with elemental lithium. Because of the high steric shielding in bis[tris(trimethylsilyl)methyl]mercury,[5] the compound reacted only on treatment with ultrasound and UV radiation: the attack of the very stable tris(trimethylsilyl)methyl radical[6] on the solvent, *n*-hexane, yielded quantitatively tris(trimethylsilyl)methane [eq. (a)]. Bromotris(trimethylsilyl)methylmercury (**2**), readily available from equivalent amounts of mercury dibromide and alkyllithium, reacted with lithium without further activation at room temperature [eq. (b)]; again only the formation of trisilylmethane and an equal quantity of the dialkylmercury derivative was observed [Eq. (c)].

$$Hg[C(SiMe_3)_3]_2 + Li \xrightarrow[2.\ h\nu]{1.\ \text{ultrasound}} Li/Hg + 2\,HC(SiMe_3)_3 \quad (a)$$

$$HgBr_2 + LiC(SiMe_3)_3 \cdot 2\,THF \xrightarrow[-THF]{} \underset{\mathbf{2}}{Br{-}Hg{-}C(SiMe_3)_3} + LiBr \quad (b)$$

$$\underset{\mathbf{2}}{Br{-}Hg{-}C(SiMe_3)_3} + Li \longrightarrow LiBr + HC(SiMe_3)_3 + Hg[C(SiMe_3)_3]_2 \quad (c)$$

Finally a method described by *Bickelhaupt* et al. for the synthesis of 1,3-dilithiopropanes[7] from 1,3-HgBr derivatives and *tert*-butyllithium was successful. Probably for steric reasons the reaction of this organolithium compound with **2** stopped at *tert*-butyltris(trimethylsilyl)methylmercury, so we had to use the less voluminous *n*-butyllithium. Equation (d) shows the reaction steps for the synthesis of **1**; the isolable intermediate with mixed substituents, a dialkylmercury compound, reacted with excess *n*-butyllithium at 65–70 °C in the melt over a period of 15 h to afford the desired product, which was easily separated from the organomercury compound by recrystallization from *n*-pentane.

$$\underset{\mathbf{2}}{Br{-}Hg{-}C(SiMe_3)_3} + n\text{BuLi} \longrightarrow n\text{Bu}{-}Hg{-}C(SiMe_3)_3 + LiBr$$

$$n\text{Bu}{-}Hg{-}C(SiMe_3)_3 + n\text{BuLi} \xrightarrow{65-70\,^\circ C} \underset{\mathbf{1}}{LiC(SiMe_3)_3} + n\text{Bu}_2Hg \quad (d)$$

Compound **1** ignites spontaneously in air and with traces of oxygen characteristic red intermediates are formed. It may be kept under argon at room temperature, however, and is thermally very stable. Although cryoscopic molecular mass determination shows that **1** is monomeric in benzene, a low-intensity dimer peak is detected in the mass spectrum but only at low vaporization temperature and ionization energy (340 K, 20 eV). The monomer is not observed and appears only under more drastic conditions (380 K, 70 eV).

Crystals of **1** suitable for a single crystal X-ray structure determination were obtained by recrystallization from cyclopentane. Compound **1** crystallizes in the centrosymmetric space group $P\bar{1}$ with a Li_2C_2 dimer in the unit cell.[8] The Li_2C_2 four-membered ring includes a crystallographic inversion center (Fig. 1). The Li–C distances (average 230 pm) are almost identical and over 10 pm longer than in the THF adduct of **1**, which has linear C–Li–C bridges,[2] but lie well within the range expected for Li–C bonds.[9–11] The angles within the heterocycle are very different and the Li–C–Li angle of 61.6° is what is expected for a three-center geometry.[12] Interestingly the Si–C bonds to the anionic C atom (on average 185.8 pm) are significantly shorter than the bonds to the methyl groups (on average 188.0 pm); this is possibly caused by an interaction between the anionic C atoms and the silicon atoms.

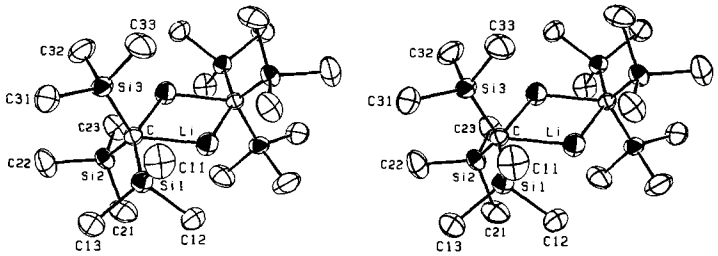

Fig. 1. Stereoview of **1** in the crystal (ORTEP, ellipses with 40% probability, hydrogen atoms omitted for clarity). Important distances [pm] and angles [°]: Li-C 229.1(6), Li'-C 230.3(6), C···C 394.6(5), Li···Li 235.3(9), C-Si1 185.7(3), C-Si2 184.4(3), C1-Si3 186.4(3), Si-C_{Me} 187.2(3)–189.4(4), C-Li-C 118.4(3), Li-C-Li 61.6(2).

In addition to the two bonds to the inner carbon atoms, every lithium atom shows close interaction with two C–H σ bonds (agostic interactions[13]), so that it is surrounded by four ligands in a distorted tetrahedral environment (Fig. 2).

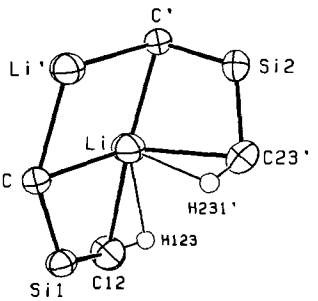

Fig. 2. Environment of the lithium atom. The primed atoms were found by reflection across the crystallographic symmetry center. Important distances [pm] and angles [°] not given in Fig. 1: C12-Li 254.1(7), H123-Li 224(4), C23'-Li 246.6(6), H231'-Li 219(4), C'···C-Si1 114.8(1), C'···C-Si2 98.5(1), C'···C-Si3 111.3(1).

Similar structural elements have been found in many organolithium compounds,[9, 10] including for example, the adduct of *n*-butyllithium and lithium-*tert*-butanolate,[14] lithium tetramethylboranate,[15] and lithium(μ-hydrido)tri(*tert*-butyl)alanate.[16]

Thus, besides the tetrameric structure for methyl- and ethyllithium,[9] the hexameric for (trimethylsilyl)methyl- and

cyclohexyllithium,[10] and the polymeric for bis(trimethylsilyl)methyllithium,[11] in dimeric tris(trimethylsilyl)methyllithium (**1**) a fourth structural type for alkyllithium derivatives occurs. Hitherto only in the presence of donor atoms could dimeric organolithium compounds be detected.[17]

The reaction of **1** with aluminum halides leads to crystalline products which are at present under investigation.

Experimental Procedure

2: 7.53 g (0.0209 mol) $HgBr_2$ was suspended in 125 mL diethyl ether and allowed to react slowly at 0 °C with a solution of 7.57 g (0.0198 mol) tris(trimethylsilyl)methyllithium · 2THF in 55 mL diethyl ether, which was added in two equal portions separated by 30 min of stirring. The reaction mixture was stirred for 3 h at room temperature; then the solvent was removed under vacuum, the residue taken up in 30 mL *n*-pentane and separated from LiBr by filtration. Colorless crystals of **2** precipitated from the filtrate at − 60 °C. Yield: 7.4 g (73%); m.p. (under Ar) 229 °C; molecular mass (cryoscopic, in benzene) found: 514, calc. 512.1 g mol^{-1}. ^1H NMR (60 MHz, C_6D_6): $\delta = 0.07$; IR (Nujol, CsBr plates): $\nu[cm^{-1}] = 1295$ w, 1265 s, 1255 s (δCH_3); 845 vs, 840 sh, 780 m (ϱCH_3); 675 s, 660 m, 615 m (νSiC); 460 vw, 360 vw, 310 (δSiC).

1: 11.82 g (0.0231 mol) **2** dissolved in 50 mL *n*-pentane was mixed at 0 °C with 18.5 mL (2.5M, 0.0462 mol) *n*-butyllithium in *n*-hexane, diluted with 50 mL *n*-pentane. The mixture was warmed to room temperature and stirred for 15 min, before the solvent was distilled off under vacuum and the highly viscous residue allowed to stand with stirring for 15 h at 65–70 °C. On cooling, the mixture crystallized. It was treated with 180 mL *n*-pentane and LiBr was filtered off. Colorless crystals of **1** precipitated from the filtrate at − 60 °C. Yield 4.43 g (81%); m.p. (under Ar) 214–215 °C (decomp.); mol. mass (cryoscopic, in benzene) found 242, calc. 238.2 g mol^{-1}; mass spectrum (340 K, 20 eV): 476.2 (1.6%) [$M^{\oplus}$], 245.2 (2.8) [$Li_2C(SiMe_3)_3$]; (385 K, 70 eV): 245.2 (1.7%) [$Li_2C(SiMe_3)_3$], 238.2 (12.4) 1/2 [$M^{\oplus}$]. ^1H-NMR (60 MHz, C_6D_6): $\delta = 0.22$; ^{13}C-NMR (62.896 MHz, C_6D_6): $\delta = 7.7$ ($SiMe_3$), central C atom not observed. IR (Nujol, CsBr plates): $\tilde{\nu}[cm^{-1}] = 1250$ vs (δCH_3), 1105 vw, 1000 w; 875 vs, 845 vs, 825 vs, 760 m (ϱCH_3); 715 w, 655 sh, 650 m, 600 m (νSiC); 522 m,br. (νLiC); 365 w,br., 320 w,br., 310 sh (δSiC + δLiC).

$[InAs_3]^{6\ominus}$ and $[AlSb_3]^{6\ominus}$, Trigonal Planar Anions in Cs_6InAs_3 and Cs_6AlSb_3**

By *Wolfgang Blase, Gerhard Cordier, Karl Peters, Mehmet Somer*, and *Hans Georg von Schnering**

In the series of oxoanions of the earth metals, anions with trigonal-planar coordination are so far known only in the case of borates. If the $O^{2\ominus}$ ligands are replaced by isoelectronic $As^{3\ominus}$ or $Sb^{3\ominus}$ ligands also the homologues of boron can be trigonal-planar coordinated. Hitherto, only compounds were known in which such AX_3 units are condensed to form large anionic assemblies. Thus, in the crystal structures of K_2GaSb_2 or Cs_2GaSb_2,[1] $GaSb_3$ units are coupled via common antimony atoms and antimony-antimony bonds into chains, which are isostructural with BS_2.[2]

The crystal structures of $K_{20}Ga_6Sb_{12.66}$ and $K_{20}Ga_6As_{12.66}$[3] contain the corner-sharing trinuclear anions $[Ga_3Sb_6]^{9\ominus}$ and $[Ga_3As_6]^{9\ominus}$, respectively, and those of Cs_3AlP_2 and Cs_3GaP_2 the dinuclear edge-sharing moieties $[Al_2P_4]^{6\ominus}$ and $[Ga_2P_4]^{6\ominus}$.[4]

With the synthesis of Cs_6InAs_3 and Cs_6AlSb_3 we have now also succeeded in characterizing for the first time compounds containing the units $[InAs_3]^{6\ominus}$ and $[AlSb_3]^{6\ominus}$, respectively. Both compounds are formed as shiny metallic crystals from the elements at 950 K.[5] In the planar anions[6] (Fig. 1) the deviation from D_{3h} symmetry is only slight ($119.0 < \beta < 121.8°$). The bond lengths $d_{Al-Sb} = 261.8(3)$, 262.3(3) and 267.0(4) pm and $d_{In-As} = 258.6(3)$, 261.4(3) and 264.5(3) pm, respectively, lie, according to the *Pauling*[7] bond order, in the range of single bond lengths.

In the crystal the Cs atoms form chains of elongated trigonal prisms, condensed in bundles of four along [010]. The atoms of the trigonal-planar anions $[InAs_3]^{6\ominus}$ and $[AlSb_3]^{6\ominus}$ align the bundles of four Cs_6-prisms centrally to give the polymeric structure $^1_\infty\{Cs_{12/2}[MX_3]\}$. The packing of these bundles essentially corresponds to a unidimensional hexagonal rod packing. The periphery of the bundles consists of six elongated rectangular faces. The space between the rods consists of empty half-cubes (partition along the (110) face of

the cube), and empty doubly capped trigonal prisms. The half-cubes are each bounded by two prism bundels, while the capped prisms are each bounded by four prism bundles. The stacking of the trigonal prisms extends the coordination between Cs and As(Sb) atoms.

The X atoms are each bound to an M atom and are coordinated by seven Cs atoms (d_{Sb-Cs} = 380.4–443.7, d_{As-Cs} = 358.7–427.6 pm). The Cs atoms exhibit 5- and 6-coordination towards X.

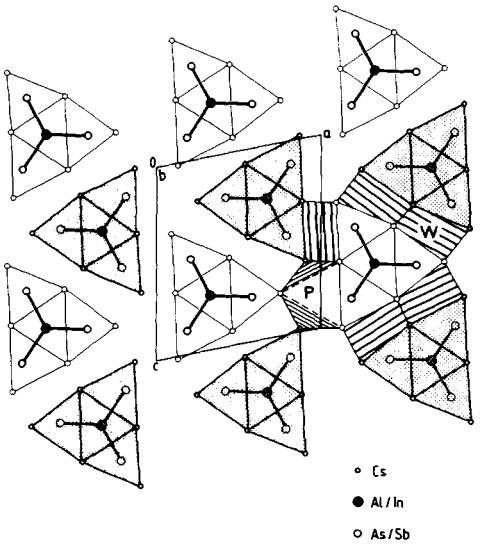

Fig. 1. Projection of the crystal structure of the compounds Cs_6InAs_3 and Cs_6AlSb_3 on (010). Lines of different thickness mark the positions of the atoms with $y = 0$ and $y = 1/2$; the upper prism bundles are shaded. The empty halves of cubes W and the empty capped prisms P on the right-hand side are emphasized by hatching.

The anions $[AlSb_3]^{6\ominus}$ and $[InAs_3]^{6\ominus}$ are members of an isosteric series with 24 valence electrons, which extends via $[SiP_3]^{5\ominus}$ in Cs_5SiP_3 or $[SiAs_3]^{5\ominus}$ in Cs_5SiAs_3[8] through to the oxoanions $[BO_3]^{3\ominus}$, $[CO_3]^{2\ominus}$ and $[NO_3]^{\ominus}$. Starting with the D_{3h} symmetry of an isolated $[MX_3]^{6\ominus}$ unit, the vibration analysis yields $\Gamma_{vib} = A_1' + A_2'' + 2E'$, whereby A_1' is only Raman active and A_2'' only IR-active. Vibrations of type E′ are both IR-active and Raman-active.

In the crystal (factor group C_{2h}, point group Cs) the symmetry of the planar $[MX_3]^{6\ominus}$-group is perturbed. This leads to splitting of the degenerated vibrations of type E′ and partial removal of the inactivity of the A_1' and A_2'' vibrations in the Raman or IR spectrum. The effects are, however, small, but allow interpretation in terms of an only slightly distorted D_{3h} symmetry.

In accord with the reduction in symmetry four bands are observed above 100 cm^{-1} in the IR spectra[9]; these can be assigned to the three fundamental vibrations $A_1' + A_2'' + E'$ (Fig. 2). The antisymmetric valence vibration ν_3 (E′) splits, and in each case two separate, very strong bands are observed at 318 and 293 ($[AlSb_3]^{6\ominus}$) and 215 and 197 cm^{-1} ($[InAs_3]^{6\ominus}$), respectively. The moderately strong bands at 181 cm^{-1} ($[AlSb_3]^{6\ominus}$) and 99 cm^{-1} ($[InAs_3]^{6\ominus}$) are assigned to the non-planar vibration A_2''. The IR inactive vibration $\nu_1(A')$ observed in the case of D_{3h} symmetry appears, as expected, in each case as weak intensity band at 132 cm^{-1} ($[AlSb_3]^{6\ominus}$) and 171 cm^{-1} ($[InAs_3]^{6\ominus}$), respectively. The observed wave numbers are comparable with the corresponding valence vibrations ν_1 of the isosteric molecules AlI_3 ($\tilde{\nu}$ = 156 cm^{-1})[10] and $InBr_3$ ($\tilde{\nu}$ = 212 cm^{-1}).[11] The weak intensity deformation vibration ν_4 (E′) could not be localized because of complete superposition with lattice vibrations. From the frequencies[12] one obtains, after using an approximation procedure,[13] values of 0.99 and 1.07 N cm^{-1} for the valence force constants f, 0.13 and 0.15 N cm^{-1} for the interaction constants f', and 0.16 and 0.15 N cm^{-1} for the force constants of the non-planar vibration f_γ' of $[AlSb_3]^{6\ominus}$ and $[InAs_3]^{6\ominus}$, respectively. Interesting is a comparison of

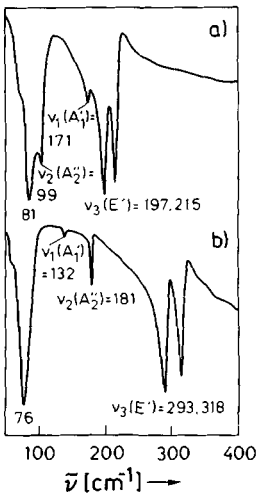

Fig. 2. FIR spectra of Cs_6InAs_3 (a) and Cs_6AlSb_3 (b).

these values with the f values 1.74 and 1.91 N cm^{-1} of the isosteric molecules AlI_3[10] and $InBr_3$.[14] The marked decrease in the valence force constants (ca. 45%) for the anions is consistent with previous observations, according to which an increase in formal ionic charge weakens the bonds and thus reduces the frequencies and force constants. Raman spectra could not be obtained because of ready decomposition in laser light.

Synthesis and Crystal Structure of $Br_5^{\oplus}MF_6^{\ominus}$ (M = As, Sb)**

By *Hans Hartl,** *Joachim Nowicki,* and *Rolf Minkwitz*

Homonuclear iodine cations $I_n^{\oplus}$ (n = 2,3,5,7)[1] have already been the subject of numerous investigations; in contrast little is known about the analogous bromine ions. Only the crystal structure of $Br_2^{\oplus}Sb_3F_{16}^{\ominus}$[2] and the syntheses of $Br_3^{\oplus}X^{\ominus}$ ($X^{\ominus} = AsF_6^{\ominus}$,[3] $SO_3F^{\ominus}$,[4] $[Au(SO_3F)_4]^{\ominus}$)[5] and $Br_5^{\oplus}[Au(SO_3F)_4]^{\ominus}$[5] have been reported.

Liquid bromine reacts with the extremely mild and selective fluorinating reagent $XeF^{\oplus}MF_6^{\ominus}$ (M = As, Sb) at room temperature in a complex reaction sequence to give $Br_5^{\oplus}MF_6^{\ominus}$ [Eq. (a)].

$$3\,XeF^{\oplus}MF_6^{\ominus} + 8\,Br_2 \xrightarrow{\text{room temperature}} 3\,Br_5^{\oplus}MF_6^{\ominus} + 3\,Xe + BrF_3 \quad (a)$$

In this reaction $Br_3^{\oplus}$ can be detected as intermediate by vibration spectroscopy[6] and BrF_3 as by-product by ^{19}F-NMR spectroscopy.[7] Only three lines (272, 220, 170 cm^{-1}) are observed in the Raman spectrum of $Br_5^{\oplus}AsF_6^{\ominus}$, consistent with the C_{2h} symmetry of the $BR_5^{\oplus}$ ion, and in the IR spectrum only three (290, 275, 185 cm^{-1}) of the expected six bands are unequivocally assignable.

In the pentahalides $I_5^{\ominus}$, $[I_3Cl_2]^{\ominus}$ and $[I_3Br_2]^{\ominus}$[8] the halogen atoms form V-shaped anions, whereas the centrosymmetric pentabromonium ion $Br_5^{\oplus}$ has a Z-shaped structure analogous to the cations $I_5^{\oplus}$, $[I_3Cl_2]^{\oplus}$ and $[I_3Br_2]^{\oplus}$[1a, 9] (Fig. 1). In all ions there are two short bonds between the external halogen atoms and two longer bonds to the central halogen atom. Thus, the array of halogen atoms can formally be described as an adduct of two halogen or interhalogen molecules with a central halide or halonium ion. In accord with the electron pair repulsion model (VSEPR)[10] the central halogen atom in the pentahalide(− 1) has an AX_2E_2 coordination with bent structure, whereas that in the pentahalogen(+ 1) ion shows an AX_2E_3 coordination with formation of a linear 3c,4e bond. The Br2–Br3 bond lengths (2.275(1) Å in $Br_5^{\oplus}AsF_6^{\ominus}$ and 2.268(2) Å in $Br_5^{\oplus}SbF_6^{\ominus}$) are somewhat shorter than in crystalline bromine (2.289(3) Å at − 100 °C[11]). The bond lengths to the central Br1 on the other hand (2.514(1) and 2.512(1) Å) are larger, and are comparable with those in linear anionic $Br_3^{\ominus}$ with 3c,4e bonding (e.g. $[Cs(AuBr_4)_2]Br_3$ (2.540(2) and 2.562(1) Å[12]).

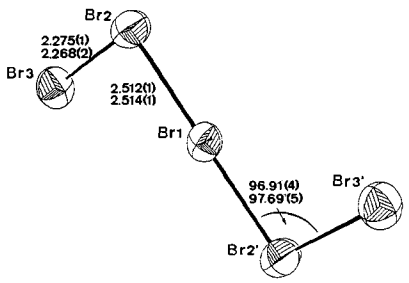

Fig. 1. ORTEP plot of the $Br_5^{\oplus}$ ion [13]. Bond lengths [Å] and bond angles [°]: top row of figures refer to $Br_5^{\oplus}AsF_6^{\ominus}$, bottom row of figures to $Br_5^{\oplus}SbF_6^{\ominus}$.

The most stable geometry for $X_5^{\oplus}$ cations seems to be the planar *trans*-configuration as found in $I_5^{\oplus}$ and $Br_5^{\oplus}$. This is consistent with STO-3G calculations, which show that all other rotamers are energetically unfavorable.[1a] In analogy to $[I_3Cl_2]^{\oplus}$, however, the energy differences are so small that

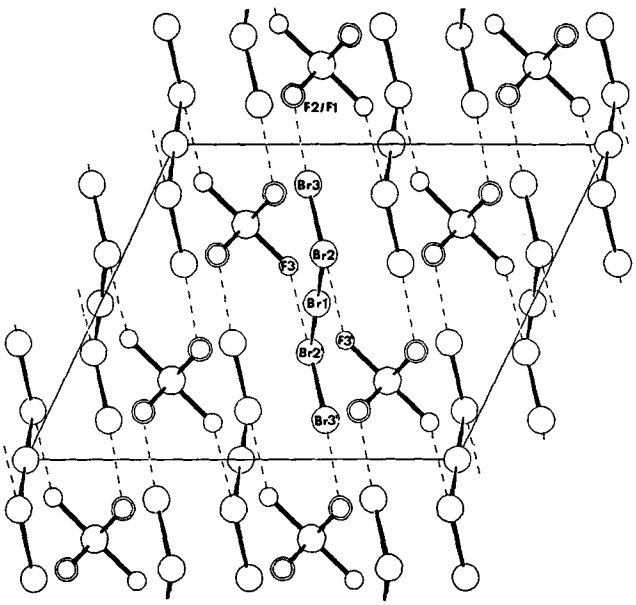

Fig. 2. Structure of $Br_5^{\oplus}MF_6^{\ominus}$ (M = As, Sb) in the crystal (projection in the [010] direction). The fluorine atoms F1 and F2 of the $MF_6^{\ominus}$ octahedron are superposed in this projection; bond lengths [Å], bond angles [°]: As-F1 = 1.727(7), As-F2 = 1.699(8), As-F3 = 1.730(5), Br2-F3 = 2.847(6), Br3-F1 = 2.782; F-As-F = 88.85–91.00° and 177.5–179.2, Br2-Br3-F1 = 173.5(2), Br3-Br2-F3 = 178.0(2); Sb-F1 = 1.879(8), Sb-F2 = 1.857(9), Sb-F3 = 1.874(6), Br2-F3 = 2.768(7), Br3-F1 = 2.767(7); Br2-Br3-F1 = 174.5(2), Br3-Br2-F3 = 178.1(2).

in the presence of a suitable counterion,[9] deviations from the planar arrangement are expected.

In $Br_5^{\oplus}AsF_6^{\ominus}$ and $Br_5^{\oplus}SbF_6^{\ominus}$ the anions and cations are, in each case, coupled by four fluorine atoms of the $MF_6^{\ominus}$ octahedron to form layers (Fig. 2). The Br–Br···F moieties are approximately linear, the fluorine atoms participating in the anion–cation contacts have As–F and Sb–F distances ca. 0.03 Å longer than those not participating in the contacts. Comparable interionic contacts also occur in other polyhalogen cations.[1a, 1c, 2b]

Experimental

Br_2 (ca. 5 mL) was distilled under an inert gas onto $XeF^{\oplus}MF_6^{\ominus}$ (M = As, Sb) in a two-limbed ampule. After ca. 3–4 hours at room temperature a brown solid of $Br_3^{\oplus}MF_6^{\ominus}$ separated, which, within two days, formed rectangular dark brown crystals. After decanting off the liquid Br_2, the solid was pumped dry.

$(I_3O_6)^{\oplus}$, a Novel Polyoxo Cation of Iodine**

By *Anette Rehr* and *Martin Jansen**

Dedicated to Professor Rolf Appel on the occasion of his 70th birthday

More on the basis of speculation than on unequivocal structural and analytical data, I_4O_9 and I_2O_4 are usually described as $I(IO_3)_3$[1] and $(IO)IO_3$.[1a, b, 2] Equally vague is the situation regarding the ternary derivatives of these pseudobinary oxides, which are sometimes formulated as adducts, e.g. $I_2O_4 \cdot 3SO_3$,[3] and sometimes as salts, like $(IO_2)_2(S_2O_7)$.[4] So far only the existence and structure of the polymeric iodosyl cation $(IO)_n^{n\oplus}$[5] have been established. In all other cases it was at best possible to deduce the common structural units for the first time from vibration spectra.[2, 4a, 6] In connection with our studies on halogen-oxygen compounds[7] we have now also directed our attention to the frequently mixed valence, iodine compounds. Because of the complex phase relationships and structures it was essential to prepare the compounds in the crystalline state and as pure phases.

By thermal decomposition of H_5IO_6 in conc. phosphoric acid and subsequent addition of pure sulfuric acid we not only succeeded in growing single crystals, but also in synthesizing preparative amounts of the previously unknown $(I_3O_6)(HSO_4)$. Not unexpectedly, with the numerous neighboring phases in the system investigated, a precise control of the reaction conditions (temperature, atmosphere, time) is absolutely necessary for reproducibility of the experiments. We achieved the best results using a metal bath as source of heat.[8]

The crystal structure[9] consists of two clearly separable moieties, a cationic one of the composition $(I_3O_6)_n^{n\oplus}$ and an anionic one ($HSO_4^{\ominus}$), between which there exist predominantly electrostatic interactions; the novel isopolycation $(I_3O_6)_n^{n\oplus}$ contains mixed-valence iodine. The pyramidal (pseudotetrahedral) environment of the crystallographically independent iodine atoms I1–I4 with distances and angles as found in numerous other iodates(v),[10] clearly points to I^V, while the square planar (double pseudooctahedral) coordination of I5 and I6 by oxygen characterizes these iodine atoms as I^{III}. Since this is, to our knowledge, the first reported planar IO_4 structure group, and since no structural data for other analogous species such as $IF_4^{\ominus}$ in KIF_4 are available, a categorizing of the distances found is not possible. Although the O–I–O bond angles in particular deviate considerably from the ideal geometry, the IO_4 unit deviates at a maximum of only 4 pm in each case from the best plane through the five atoms. The structural groups described here are coupled via all four corners of the polyhedron around I^{III} and two of the three oxygen atoms around I^V to give a $^1_\infty$ ribbon (Fig. 1). The structural groups in this network, which are identifiable as typical for tri- and pentavalent iodine respectively, could mislead one to formulate the cationic moiety of the structure as $[I^{3\oplus}(IO_3^{\ominus})_2]^{\oplus}$ or $[(IO^{3\oplus})_2IO_4^{5\ominus}]^{\oplus}$. This would indeed furnish a perfectly clear interpretation of the make-up of the cation, but would not account for the bonding properly. The I–O bond lengths and the pronounced steric effect of the free electron pair point to a dominant covalent bonding in the I–O structural moiety.

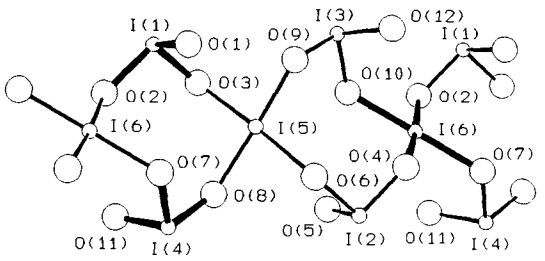

Fig. 1. Crystal structure of the isopolycation $(I_3O_6)_n^{n\oplus}$. Bond lengths [pm] around I^V: I1-O1 179.3, I1-O2 186.7, I1-O3 182.4, I2-O4 182.4, I2-O5 176.8, I2-O6 186.9, I3-O9 185.0, I3-O10 184.1, I3-O12 177.0, I4-O7 182.3, I4-O8 182.5, I4-O11 177.2; about I^{III}: I5-O3 211.2, I5-O6 217.8, I5-O8 215.6, I5-O9 209.7, I6-O2 212.8, I6-O4 213.2, I6-O7 212.1, I6-O10 214.1; angles [°] about I^V 94.0–105.0, mean value 98.5; about I^{III} 83.9–97.5, mean value 90.0 and 175.1–179.3, mean value 176.9; about I^{III}-O-I^V 122.8–133.2, mean value 126.2.

Although, as expected, the positions of the hydrogen atoms next to the strongly scattering iodine atoms could not be determined, the oxygen atoms which participate in H-bridge bonding can be identified on the basis of crystallochemical considerations: from the S–O and "intermolecular" O–O distances it follows that H-bridge bonding only occurs between the sulfate anions, never in (or to) the $(I_3O_6)^{\oplus}$ polycation. The SO_4 anions are in each case coupled by H-bridges one-dimensionally along [100]. The cationic and anionic structural moieties are arranged in layers parallel to (010) (Fig. 2).

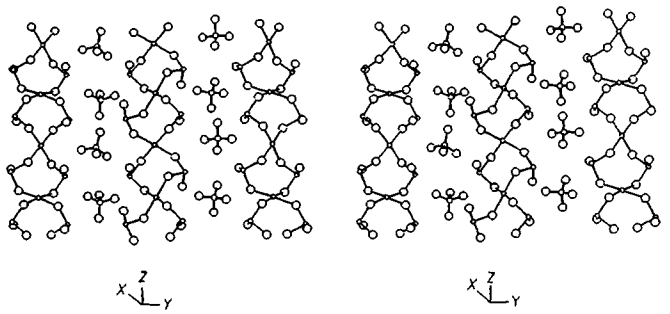

Fig. 2. Stereodiagram of $(I_3O_6)(HSO_4)$ in the crystal.

The possible existence of an iodyl cation $(IO_2)^{\oplus}$ has been discussed by several authors,[1a, 4a, 6a, 11] but in no case has it been confirmed. The X-ray powder data and vibration spectra reported in previous cases give no indication that the compound described here is identical with any of those investigated earlier.

The structure and existence of $(I_3O_6)HSO_4 \triangleq I(IO_3)_2HSO_4$ can be regarded as supporting evidence for the constitution postulated for $I_4O_9 \triangleq I(IO_3)_3$.

[8] 10 mL of conc. phosphoric acid contained in a glass beaker was dehydrated for 1/2 h in a metal bath at 270–280 °C. After cooling, 3 g of pulverized H_5IO_6 were admixed and heating continued at 310–330 °C until the first appearance of iodine vapor (duration about 10 min). The mixture was then cooled under vacuum in a desiccator and was allowed to stand for a few hours. Subsequently, the mixture was treated with 50 mL of pure H_2SO_4, stirred, transferred to an ampoule, and the ampoule and contents tempered for a week at 60 °C in a resistance furnace. After pouring off the supernatant acid mixture, the residue was dried on a porous plate over conc. H_2SO_4 in a desiccator. The crystals are hygrosyopic; they were sealed under argon in a capillary for the X-ray structure investigations.

The Neutral Transition Metal Thiolates $[M(SAr)_2]_2$ (M = Mn, Fe or Co, Ar = 2,4,6-*t*-$Bu_3C_6H_2$)**

By *Philip P. Power** and *Steven C. Shoner*

The chemistry of transition metal thiolate complexes constitutes a large and rapidly expanding area of chemistry.[1, 2] The relevance of such complexes to the structure, bonding and function of biologically active reaction centers in metalloproteins such as ferredoxins, nitrogenases, blue copper proteins and metallothioneins has provided a significant portion of the impetus for their study.[3] A characteristic feature of the vast majority of well-characterized homoleptic transition metal thiolates is that they are ionic.[1–3] Most typically, the transition metal is surrounded by four thiolate ligands, and it has approximately tetrahedral coordination. This unit may be a mononuclear complex or form part of a multinuclear aggregate. The anionic nature of the complexes is of fundamental importance since it plays an important role in the prevention of polymer formation. In contrast, neutral

University of California
Davis, CA 95616 (USA)

[**] This work was supported by the donors of the Petroleum Research Fund administered by the American Chemical Society.

homoleptic transition metal thiolates are normally found as insoluble polymers which are not well characterized. Exceptions to this involve the structures of a small number of neutral, open-shell transition metal thiolate complexes. Some examples are $[Mo(SR)_4]$ or $[Mo_2(SR)_6]$ (R = *t*Bu,[4] 2,4,6-$Me_3C_6H_2$,[5] 2,4,6-*i*$Pr_3C_6H_2$),[4,5] $[Ni_4(SR)_8]$ (R = C_5H_9NMe,[6] C_6H_{11},[7] C_3H_7[8], $[Ni_5(SEt)_{10}]$,[9] $[Ni_5(SCH_2SiMe_3)_{10}]$,[9] $[Ni_6(SR)_{12}]$ (R = Et,[9] C_2H_4OH[10]) or $[Ni_8(SCH_2COO\text{-}Et)_{16}]$[11] and $[Pd_6(SR)_{12}]$ (R = *i*Pr, CH_2CH_2OH)[10] or $[Pd_8\{S(nPr)\}_{16}]$.[12] All of these complexes involve four-coordinate metals and the aggregated structures of the nickel and palladium species illustrate the tendency of these complexes to associate. No open-shell transition metal thiolate complexes with low (3 or less) coordination numbers have been reported.[14] In this paper the syntheses and structures of the first well-characterized neutral thiolate complexes of Mn, Fe, and Co are now described.

The title compounds $[\{M(SAr)_2\}_2]$ (M = Mn, **1**; Fe, **2**; Co, **3**; Ar = 2,4,6-*t*$Bu_3C_6H_2$) were synthesized as described below by the treatment of $[M\{N(SiMe_3)_2\}_2]$ (M = Mn,[15] Fe,[16] or Co[17]) with two equivalents of HSAr.[18] The X-ray crystal structures[19] of **1**–**3** may be illustrated by the iron complex **2** in Figure 1. Important structural features are

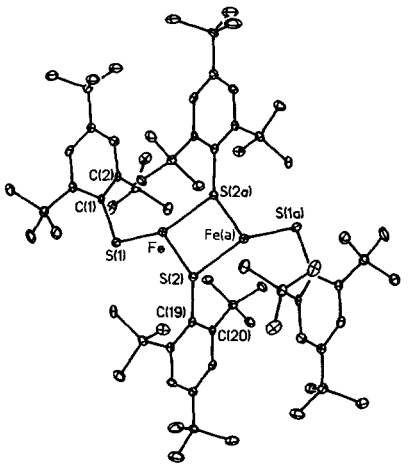

Fig. 1. Computer generated thermal ellipsoidal plot (H atoms omitted) of $[\{Fe(SAr)_2\}_2]$ **2**. The structures of **1** and **3** in the crystal are similar, bond distances and angles for **1**, **2** and **3** are listed in Table 1.

listed in Table 1. The complexes, which are isomorphous, consist of well-separated dimers that have a crystallographically imposed center of inversion. The $[M_2S_2]$ cores are therefore planar as required by symmetry. The metal centers have either planar or nearly planar coordination. The sulfur atoms of the thiolato bridges are all pyramidally coordinated with the pyramidicity increasing in the sequence **3** > **2** > **1**. Although the coordination of each metal atom is roughly trigonal planar, the angles at the metal center are very irregular (Table 1). The degree of angular irregularity decreases in the sequence Mn > Fe > Co. The M–S bridging distances are, as expected, longer than the M–S terminal bond lengths but the difference becomes progressively less on going from Mn to Co and in complex **3** the difference is only 0.04 Å. The M–S bond lengths in **1**–**3** appear to be about 0.03 Å–0.09 Å shorter than the distances found in four-coordinate complexes. This is in keeping with the lower coordination number of these metals. The M ··· M distance decreases steadily on going from Mn to Co until in **3** it is only 2.818 Å.

Table 1. Important bond distances [Å] and angles [°] for **1**–**3**.

	1 $[Mn(SAr)_2]_2$	**2** $[Fe(SAr)_2]_2$	**3** $[Co(SAr)_2]_2$

M ··· M	3.554	3.262	2.818

The compounds **1**–**3** are the first well-characterized, neutral, homoleptic thiolates of Mn, Fe and Co. In addition, they are the first three-coordinate open-shell transition metal thiolate complexes to be structurally characterized.[14] The low-coordination of the metal atoms and the low degree of aggregation of the $[M(SAr)_2]$ moieties are due to steric crowding by the bulky aryl groups. The utility of the 2,4,6-*t*$Bu_3C_6H_2S$ ligand in preventing association has been demonstrated in the main group elements[20,21] and, most recently, in the case of a cadmium complex.[22] The dimeric bridged structures of **1**–**3** bear a resemblance to that of the cadmium complex and to those of the amides $[M\{N(SiMe_3)_2\}_2]$ (M = Mn,[23,24] Fe[26] or Co[24]). Unlike the latter, the complexes **1**–**3** do not apparently dissociate to monomers in solution. Presumably, the amido complexes dissociate more readily because they are more crowded owing to the shorter M–N distance and the presence of two substituents on nitrogen. Preliminary magnetic data on **1**–**3** indicate magnetic moments that are marginally higher than those of the complex $[M\{N(SiMe_3)_2\}_2]$,[16] which indicates the presence of two high-spin, antiferomagnetically coupled metal centers. This is in harmony with the low coordination number and consequently low overall ligand field strength of the coordinating ligands. All complexes decompose above 140 °C and a white crystalline substance (thought to be SAr_2) is formed.[26] Presumably, the other product of this decomposition is the metal sulfide.

Experimental

Synthesis of $[Fe\{(2,4,6\text{-}tBu_3C_6H_2)S\}_2]_2$ **2**: 1.11 g (4 mmol) of 2,4,6-*t*$Bu_3C_6H_2SH$ [18] was dissolved in ca. 20 mL of pentane. To this was added 0.753 g (2 mmol) of $[Fe\{N(SiMe_3)_2\}_2]$ [16] via a solid addition funnel. The solution immediately turned dark red with the formation of an orange microcrystalline precipitate. After the addition was completed, the solution was stirred for an additional hour, and filtered to give a quantitative yield of **2**. To obtain crystals suitable enough for an X-ray structure analysis the reactions were carried out in 80 mL of toluene (Mn,Fe) or diethylether (Co), heated until the precipitate dissolved, and allowed to cool slowly to room temperature to give almost colorless (Mn), dark red (Fe) or metallic green (Co) crystals of the title compounds in moderate yield (40–50%). The compounds display very low solubility in hydrocarbons such as hexane, benzene or toluene. Greater solubility was observed in donor solvents but it is not clear, at present, if this is due to solvation of the low-coordinate metals.

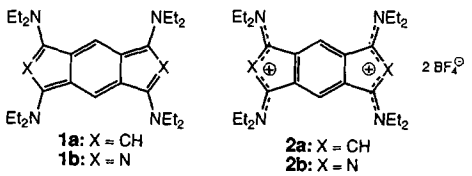
1,3,5,7-Tetrakis(diethylamino)-*s*-indacenediylium-bis(tetrafluoroborate)—a Stable *s*-Indacene Dication**

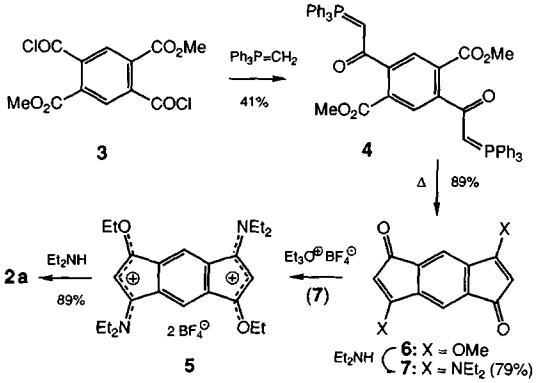
By *Rudolf Gompper,* Kurt Polborn, Christian Seifert,* and *Hans-Ulrich Wagner*

As a 12π-electron system *s*-indacene should formally be classed with the antiaromatic compounds. According to the largest eigenvalue of the bond–bond polarizability matrix "λ_{max}" = 1.57 ($\lambda_{crit} \approx 1.7$)[1] and the resonance energy per electron (REPE = 0.0092 β),[2] *s*-indacene lies in the transition region between aromatic and antiaromatic compounds. The parent compound was isolated as an unstable air-sensitive oil;[3,4] 1,3,5,7-tetra-*tert*-butyl-*s*-indacene[5] ("λ_{max}" = 1.38[11]) and 4,8-bis(dimethylamino)-*s*-indacene[6] ("λ_{max}" = 1.03[11]), on the other hand, are stable. The frontier orbitals indicate that *s*-indacene should be stabilized by donor moieties in the 4,8 position and acceptor moieties in the 2,6 position. Compounds with this substitution pattern include 4,8-bis(dimethylamino)-*s*-indacene,[6] hexamethyl 4,8-dihydroxy-*s*-indacene-1,2,3,5,6,7-hexacarboxylate,[7] and 1,3,5,7-tetrakis(diethylamino)-2,6-diaza-*s*-indacene[8] **1b**, which, with "λ_{max}" = 1.22, has a delocalized π-electron system and accordingly must be described as an aromatic (4n)π-system.[9]

With "λ_{max}" = 1.18, a 1,3,5,7-tetraamino-*s*-indacene, e.g. **1a**, should also still show double bond delocalization, but, owing to its wealth of electrons should be more difficult to handle than **1b**. Analogously to the preparation of **1b** from **2b**, **1a** ought to be accessible by reduction of **2a**. Compound



2a is a derivative of the *s*-indacene dication, which, although a 10π-electron system, has thus far never been reported. On the basis of calculated bond orders,[10] *s*-indacene dications should be composed of an aromatic sextet and two annelated alkyl cation units (in contrast, according to calculated bond orders and the measured ^{1}H-NMR spectra, *s*-indacene dianions possess a delocalized 14π-electron system[10–12]). The only derivative of an *s*-indacene dication reported so far[13] carries a partial positive charge on C-2,6 and is therefore not comparable with **2a**. We have now synthesized **2a**, investigated its properties, and shown that it can be reduced to **1a**.



Transylidation[15–17] of dimethyl 2,5-bis(chlorocarbonyl)terephthalate[14] **3** with methylenetriphenylphosphorane affords the ylide **4**, which can be cyclized by double intramolecular Wittig reaction at the ester groups (cf. Refs. [18–20]) to give **6**. Reaction of **7**, obtained from **6** and diethylamine, with triethyloxonium tetrafluoroborate leads to

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

the dicationic salt **5**, which can be converted directly, i.e. without prior isolation, into **2a** by reaction with diethylamine (cf. Table 1).

Table 1. Yields, physical and spectroscopic data of compounds **2a**, **2a'**, **2b**, **4**, **6**, **7**, **8a**, **8b**, and of 3-dimethylamino-*N*,*N*-dimethylpropeniminium tetrafluoroborate [a].

2a: Yield 89%; blue cyrystals, m.p. > 300 °C (from CH_3CN/ether), UV/VIS (CH_3CN): λ_{max} [nm] (ε) = 303 (sh), 312 (74100), 340 (sh), 597 (5890), 630 (5880), 710 (sh); ^1H NMR (80 MHz, CD_3CN): δ = 5.40 (s, 2H, $C^{2,6}H$), 7.70 (s, 2H, $C^{4,8}$-H); ^{13}C NMR (100 MHz, CH_3CN): δ = 92.5 (s, $C^{2,6}$), 121.6 (s, $C^{4,8}$), 139.0 ($C^{3a,4a,7a,8a}$), 164.8 (s, $C^{1,3,5,7}$).

2a': Yield 81%; deep-violet rectangles, m.p. 202–203 °C (from CH_3CN/ethyl acetate), UV/VIS ($CHCl_3$): λ_{max} [nm] (ε) = 593 nm (4786), 630 (4266)

2b: UV/VIS ($CHCl_3$): λ_{max} [nm] (ε) = 440 (9770))[8]

4: Yield 41%; colorless crystals, m.p. > 180 °C (decomp.) (from $CHCl_3$/ether)

6 (Yield 89%; red leaflets, m.p. > 300 °C (from DMF), UV (DMSO): λ_{max} [nm] (ε) = 465 (540)

7: Yield 79%; shiny metallic needles, m.p. 246–247 °C (from ethyl acetate), UV/VIS ($CHCl_3$): λ_{max} [nm] (ε) = 545 (2800)

8a[21]: UV/VIS (CH_2Cl_2): λ_{max} [nm] (ε) = 476 (7080); ^1H NMR (CD_3CN): δ = 5.28 (s, C^2H); ^{13}C NMR (CH_3CN): δ = 89.9 (s, C^2), 165.6 (s, C^1/C^2)

8b[22]: UV/VIS (CH_2Cl_2): λ_{max} [nm] (ε) = 375 (6920)
3-dimethylamino-*N*,*N*-diemethylpropeniminium tetrafluoroborat[24]: ^1H NMR ([D_6]DMSO): δ = 5.37 (s, C^2H); ^{13}C NMR (DMSO): δ = 90.8 (s, C^2), 163.7 (s, C^1/C^2)

[a] $[(CH_3)_2N{=}CH{-}CH{=}CH{-}N(CH_3)_2](BF_4)$

Especially striking is the blue color of **2a** (**2b**[8] is only yellow). The great difference in color ($\Delta\lambda_{2a/2b}$ = 190 nm, $\Delta\nu_{2a/2b}$ = 6854 cm^{-1}) can be explained qualitatively on the basis of the frontier orbitals (Fig. 1). PPP-π-SCF calculations show that the longest wavelength band of **2a** corresponds to the extent of 85% to a HOMO-LUMO transition; the calculated spectrum is in good agreement with the measured spectrum. In positions 2 and 6 the HOMO has very large coefficients, whereas the LUMO shows nodes in these positions. It follows, therefore, that the HUMO-LUMO gap is very much greater in the case of **2b** (0.684 β) than in the case of **2a** (0.256 β). The same substituent effect is observed with the indenylium salts **8a**[21] ($\Delta E_{HOMO-LUMO}$ = 0.697 β) and **8b**[22] ($\Delta E_{HOMO-LUMO}$ = 0.921 β) but is less pronounced ($\Delta\lambda_{max\ 8a/8b}$ = 101 nm, $\Delta\nu_{max\ 8a/8b}$ = 5658 cm^{-1}). Remarkably, the difference in color between **2a** and **8a** ($\Delta\lambda_{max}$ = 154 nm, $\Delta\nu_{max}$ = 5135 cm^{-1}) is substantially greater than that between **2b** and **8b** ($\Delta\lambda$ = 65 nm, $\Delta\nu$ = 3939 cm^{-1}). Also interesting is that 1,5-bis(1-methyl-4-pyridino)-3,7-bis(1-methyl-4-pyridylene)-3,7-dihydro-*s*-indacene diiodide (UV/VIS (CH_3OH): λ_{max} [nm] = 586;[13] $\Delta E_{HOMO/LUMO}$ = 0.642 β [calculated without Cl]), in contrast to **2**, absorbs at shorter wavelength than corresponding indene derivatives (UV/VIS (CH_3OH): λ_{max} [nm] = 584/607/601;[13] $\Delta E_{HOMO/LUNO}$ = 0.843 β [calculated without Cl]).

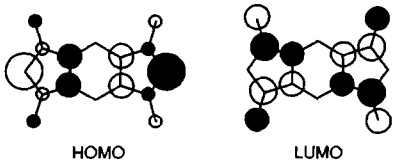

Fig. 1. Frontier orbitals of **2a**.

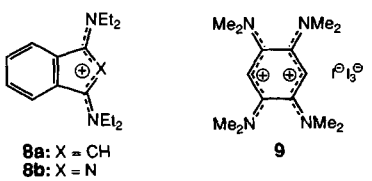

From the calculated π-bond orders of the ground state (p_{3a-8a} = 0.597, p_{1-8a} = 0.313) and the first excited state (p_{3a-8a} = 0.429, p_{1-8a} = 0.447) of **2a** it can be deduced that the excited state approximates a delocalized 10π-electron system.

The crystal structure analysis of **2a'** ($[(NC)_2C{=}CH{-}C(CN)_2]^{\ominus}$ instead of $BF_4^{\ominus}$ in **2a**, prepared by reaction of **2a** with $K[(NC)_2C = CH{-}C(CN)_2]$ in H_2O) shows (Fig. 2) that the dication of **2a'** (and **2a**) can, in accordance with theoretical predictions, be best described as a benzene ring with two annelated trimethinecyanine units. This is further supported

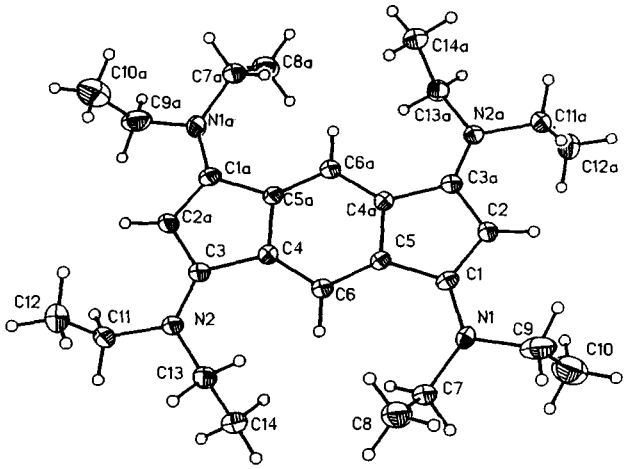

Fig. 2. Structure of **2** in the crystal (ORTEP)[23]: selected bond lengths [pm] and angles [°]:C1-C2 138.4(4), C2-C3a 139.1(4), C5-C4a 139.5(4), C5-C6 137.7(4), C4-C6 139.0(4), C1-N1 132.0(4); C2-C1-C5 108.2(2), C1-C2-C3a 110.1(2), C1-C4-C5a 106.9(2), C1-C5-C6 132.1(3), C6-C5C4a 120.8(2), N1-C1-C5 125.4(2), N2-C3-C2a 125.7(2), C1-N1-C7 125.5(2), C1-N1-C9 119.3(2).

by a comparison of the ^1H- and ^{13}C-NMR data of **2a** with those of **8a** and 3-dimethylamino-*N*,*N*-dimethylpropeniminium tetrafluoroborate.[24] Also informative is a comparison of **2a** with **9**.[25] An X-ray structure analysis has confirmed that **9** contains two vinamidinium units which are coupled by single bonds. That is, **2a** can be regarded as a phenylogous derivative of **9**; in contrast to **9**, however, **2a** is completely planar. The ring-proton signals of **9** (^1H NMR ($CDCl_3$): δ = 5.85) are shifted downfield compared to the corresponding C^2H-proton signals of **2a** and **8a**, probably as a result of the acceptor effect of the second vinamidinium unit. The large dication–dication distance in the crystal of **2a'** (890 pm) rules out an interaction of the indacene dication moieties.

The cyclic voltammogram of **2a** ($CH_3CN/Bu_4N^{\oplus}BF_6^{\ominus}$, Pt-electrode versus $Ag/Ag^{\oplus}$) shows two reversible reduction steps at -0.38 V (formation of the radical cation) and -0.81 V (formation of the *s*-indacene **1a**). **2b** is reduced reversibly to the radical cation (-0.11 V) and to **1b** (-0.56 V) more readily than **2a**.

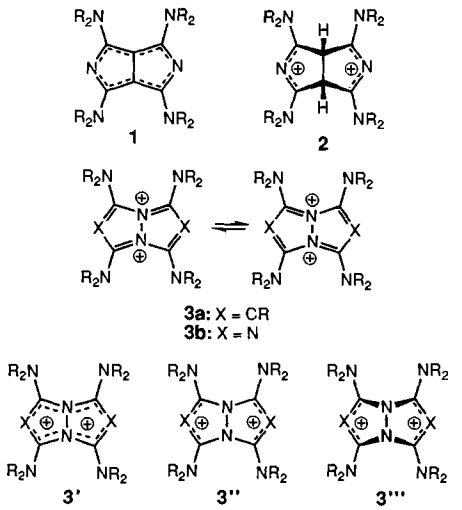
2,3a,5,6a-Tetrapentalene Dications and Tetraamino-1,3,5,7-tetrazocine **

By *Stefan Ehrenberg, Rudolf Gompper,* Kurt Polborn,* and *Hans-Ulrich Wagner*

Pentalene can be stabilized sterically and electronically;[1] using 1,3,4,6-tetrakis(dimethylamino)-2,5-diazapentalene **1**, R = Me, as example we have been able to show[2] that donor-acceptor-substituted pentalenes exhibit double-bond delocalization and accordingly are to be classed as "aromatic (4n)π-electron systems".[1] The question arises, however, whether also the pentalene derivatives **3**, which have N atoms in positions 3a and 6a, and thus are doubly positively charged (3a,6a-diazapentalene dications), show such a double bond delocalization corresponding to **3'** or whether they are valence tautomeric systems. As 8π-electron systems the dications **3** are related with bimanes[3] (partly planar, partly non-planar):[3–5] anhydro-1-hydroxy-3-oxo-pyrazalo[1,2-*a*]-pyrazolium hydroxides[6, 7] (planar), 1,3,5,7-tetraaza-2,4,6,8-tetraborabicyclo[3.3.0]octanes[8] and 3,7-dithia-1,5-diaza-2,4,6,8-tetraborabicyclo[3.3.0]octanes[9] (non-planar). In contrast to these compounds, however, the dications **3** can exist not only as planar, but, moreover, also as delocalized "aromatic" 8π-electron ring systems **3'** (cf. Gimarcs rule of "topological charge stabilization"[10]). And, as further partially localized planar structures **3''** and the folded structures **3'''** must be taken into consideration (compound **2**, which was obtained by protonation of **1**, can serve as model for **3'''**[2]).



An indication of whether **3** or **3'** is likely to be present is provided by Hückel molecular orbital (MO) calculations (see Table 1). Nitrogen atoms in the positions 3a and 6a give rise to a greater decrease in the energy of the HOMO than N-

Table 1. Effect of substituents on the double-bond delocalization in pentalenes (ring N-atoms are counted as substituents here). HMO frontier orbital energies (β) and largest eigenvalues of the bond–bond polarizability matrix ("λ_{max}"[11, 12]) [$\alpha_X = \alpha_C + h_X\beta_{CC}$; $h_{NR}2 = 1.5$; $h_N = 0.5$].

9b: m.p. 275–280°C; UV/VIS (CH_3CN): λ_{max} [nm] (ε) = 240 (16200), 366 (33900, 453 (sh); ^1H NMR (80 MHz, CD_3CN): δ = 2.79 (s, 12H, NCH_3), 7.25 (m, 5H, phenyl-H); ^{13}C NMR (100 MHz, CD_3CN): δ = 43.1 (NCH_3), 107.7 (C-2,6), 128.4 (Ph-*ipso*), 130.1 (Ph-*m*), 131.2 (Ph-*p*), 133.7 (Ph-*o*), 154.4 (C-1,3,5,7); IR (KBr): $\tilde{\nu}$[cm^{-1}] = 1594, 1510, 1422, 1332, 1061.

10a: Yield 8%; m.p. 96°C; ^1H NMR (80 MHz, $CDCl_3$): δ = 2.94 (s, 6H, NCH_3), 3.55 (AA'BB', 8H, NC_2H_4O); ^{13}C NMR (100 MHz, CD_3CN): δ = 37.3 (NCH_3), 45.1 (NCH_2), 66.7 (OCH_2), 162.0, 162.4 (C-2,4,6,8); IR (KBr): $\tilde{\nu}$[cm^{-1}] = 2855, 1578, 1399, 1378.

10b: Yield 28%; m.p. 197–199°C; UV/VIS (CH_2Cl_2): λ_{max} [nm] (ε) = 233 (27500), 248 (sh); ^1H NMR (80 MHz, $CDCl_3$): δ = 3.57 (AA'BB'); ^{13}C NMR (100 MHz, $CDCl_3$): δ = 45.0 (NCH_2), 66.5 (OCH_2), 162.1 (C-2,4,6,8); IR (KBr): $\tilde{\nu}$[cm^{-1}] = 2965, 2899, 2851, 1578, 1310.

The crystal structure analysis (Fig. 1) of **6a'**, $[(NC)_2C{=}CH\text{-}C(CN)_2]^{\ominus}$ instead of $BF_4^{\ominus}$ in **6a** (prepared by reaction of **6a** with $K[(NC)_2C{=}CH\text{-}C(CN)_2]$ in water) revealed a slightly bent ring system; the angle between the N1–N2–N3 and N1–N2–N4 planes is 159.2° (in the case of urazourazole 156°[16]; 1,5-diazabicyclo[3.3.0]octane-2,4,6,8-tetrone is planar[17]). In addition, **6a'** (torsional angles C2–N1–N2–C1 and C3–N1–N2–C4 17.8(3)° and 18.5(3)° respectively), as also 2,4,6,8-tetramethyl-3,7-dithia-1,5-diaza-2,4,6,8-tetraborabicyclo[3.3.0]octane[9] (torsion angle 18°), is twisted.

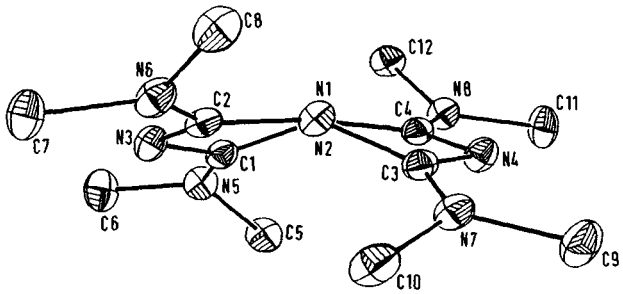

Fig. 1. Structure of **6a'** in the crystal (ORTEP)[18]: selected bond lengths [pm] and angles [°]: N1-N2 141.8(4), C1-N3 133.3(5), C1-N2 139.4(5), C2-N3 132.3(5), C2-N1 141.3(5), C3-N1 140.6(5), C3-N4 134.4(4), C4-N4 132.1(5), C4-N2 140.4(5), C1-N5 130.6(5), C2-N6 131.3(5); C1-N3-C2 106.6(3), N3-C1-N2 110.3(3), C1-N2-N1 104.7(3), C2-N1-N2 102.9(3), N3-C1-N5 123.4(4), C1-N2-C4 141.7(3), C2-N1-C3 142.5(3).

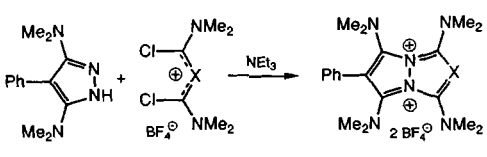
The sums of the angles at N1 and N2 (349.2 and 350.1°, respectively, hydrazine 324°[19]) are consistent with a marked sp^2 hybridization corresponding to the formulas **3b** and **3b'** (in the case of **6b** the sums of the angles at N1 and N2 are even 358.1° and 358.5 respectively). The N1–N2 bond (141.8 pm) is only slightly shorter than the N–N bonds in hydrazine[19] and in the dimethylhydrazines,[20] and comes close to that in 2,4,6,8-tetramethyl-3,7-dithia-1,5-diaza-2,4,6,8-tetraborabicyclo[3.3.0]octane[9] (144.9 pm); *in* contrast, the N–N bond in anhydro-1-hydroxy-3-oxopyrazolo[1,2-*a*]pyrazolium hydroxide[6] (134 pm) is distinctly shorter.

The C1–N3 bond (133.3 pm) and C1–N5 bond (130.6 pm) have ca. 50% double bond character,[21] indicating a larger share of structure **3b''** in the ground state. However, the C1–N2 bond (139.4 pm) is likewise significantly shorter than a $C(sp^2)$–$N(sp^2)$ bond (147 pm, 0% double bond character[21]), so that **3b** and **3b'** must also participate in the ground state. A certain delocalization of **6b, c** in keeping with **3b** and **3b'** also follows from the electron spectra of **6b, c** and 1,2-dimethyl-3,5-dimorpholino-1,2,4-triazolium tetrafluoroborate (prepared by reaction of **5b** with 1,2-dimethylhydrazine); the compounds **6b, c** absorb at significantly longer wavelength.

An MNDO calculation for **6a**, NH_2 instead of NMe_2, indicated a very flat double minimum between the dihedral angles (N1–N2–N3 and N1–N2–N4 planes) 148° and −148°. The energy barrier of ca. 1 kcal mol^{-1} lies within the limits of error of the method, so that a distortion of the molecule could be primarily caused by the spatial interactions of the large dimethylamino groups. The calculated bond lengths correlate well with the measured bond lengths.

Indeed, 3,5-bis(dimethylamino)-4-phenylpyrazole[22] **7** can be converted by reaction with **5a** and **8** into the triazapentalenediylium salt pyrazolo[1,2-*a*]triazoldiylium salt) **9a** and



7 **5a**: X = N **9a**: X = N
8: X = C-Ph **9b**: X = C-Ph

diazapentalenediylium salt (pyrazolo[1,2-*a*]pyrazoldiylium salt) **9b**, respectively.

The dication salts **6b, c** can be reduced with zinc in acetonitrile to give the tetraaminotetrazocines **10**, i.e. the first fourfold donor-substituted 1,3,5,7-tetrazocines. On the basis of the donor-acceptor pattern one could expect an almost planar structure for **10**. However, as the crystal structure analysis of **10b** (Fig. 2) shows, it has a boat-shaped configu-

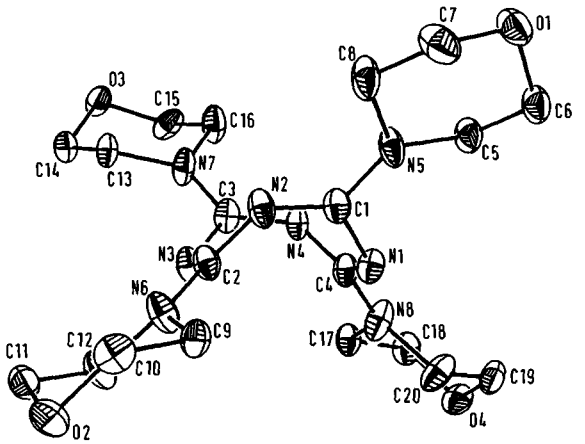


Fig. 2. Structure of **10b** in the crystal (ORTEP)[18]: selected bond lengths [pm] and angles [°]: N1-C1 139.6(10), N2-C1 130.1(9), N2-C2 136.9(10), N3-C2 130.2(9), N3-C3 138.7(10), N4-C3 132.0(9), N4-C4 135.0(10), N1-C4 130.9(9), C1-N5 135.2(10); C1-N1-C4 116.6(6), C2-N3-C3 118.8(6), N1-C1-N2 124.5(7), N3-C3-N4 124.4(7), C1-N2-C2 119.7(7), C3-N4-C4 119.2(6), N2-C2-N3 126.0(7), N1-C4-N4 127.2(7), N1-C1-N5 114.5(6), N2-C1-N5 119.9(7).

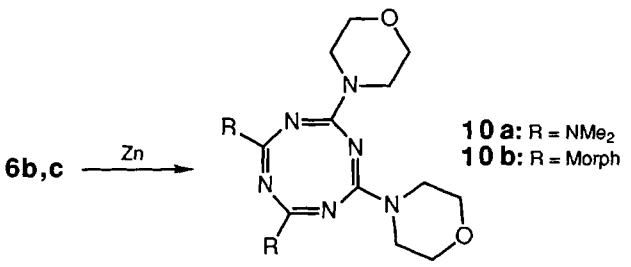
ration, like 2,6-diethoxy-4,8-diphenyl-1,3,5,7-tetrazocine.[23] Similarly to octamethylcyclooctatetraene,[24] however, **10b** is somewhat more planar than cyclooctatetraene. The mean of the internal bond angles is 121.6° and that of the torsion



angles 66.7° (in the case of octamethylcyclooctatetraene[24] the corresponding values are 122.2° and 66.6°, respectively, in the case of cyclooctatetraene (cf. Ref. [24]) 126.8° and 55.7°, respectively).

Book Reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the following address: Redaktion Angewandte Chemie, Postfach 101161, D-6940 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

Electrophilic Aromatic Substitution. By *R. Taylor*. Wiley, Chichester 1990. xvi, 513 pp., hardcover £ 85.00. – ISBN 0-471-92482-2

Twenty-five years ago this same author (in collaboration with *R. O. C. Norman*) wrote the highly regarded monograph "Electrophilic Substitution in Benzenoid Compounds". The present state of knowledge on electrophilic substitution in arenes has now been systematically and comprehensively covered in an almost completely rewritten book of eleven chapters. Heteroarenes are not included here, but benzenoid compounds such as annulenes, metallocenes and carboranes are. (Electrophilic substitutions in heteroarenes are soon to be treated by this author in collaboration with *A. R. Katritzky* in Volume 47 of the series *Advances in Heterocyclic Chemistry*.)

Electrophilic substitutions in arenes are among the classical reactions of organic chemistry that students have always been introduced to early in their courses. The book's preface tells us that about one third of world chemical production consists of arenes and substituted arenes. So, one might ask, in a field that has been so widely studied and worked over, is there much that is new to be reported? Indeed there is, as this book proves.

The first two chapters ("Introduction" and "The Mechanism of Electrophilic Aromatic Substitution") give a brief but adequate account of the theoretical and mechanistic basis needed to understand the chapters that follow (the theory of aromaticity; inductive, mesomeric and steric effects of substituents; possible mechanisms of S_EAr reactions, such as S_E1, B-S_E1, S_E3, S_E2 and A-S_E2). Chapter 3 ("Hydrogen Exchange") deals with the simplest types of electrophilic aromatic substitutions: deuteriodeprotonation (H/D exchange), tritiodeprotonation (H/T exchange), protiodedeuteriation (D/H exchange), protiodetritiation (T/H exchange) and deuteriodetritiation (T/D exchange) – all of which are reactions of special interest from a mechanistic standpoint. Chapter 4 ("The Replacement of a Substituent by Hydrogen") discusses fourteen reactions in which a substituent already present in the arene ring undergoes electrophilic replacement by a proton, ranging from protiodeauration through protiodealkylation to protiodesilylation. Also included in this group of reactions from a mechanistic standpoint is the hydrolysis of arylmagnesium halide Grignard reagents (protiodemagnesiation). Chapter 5 ("Metallation") deals with the replacement of hydrogen atoms in arenes by metals (Li, Au, Hg, B, Tl, Si, Pb, Sb, Te, Rh, Pd); however, the only one of these that has so far been categorized unequivocally as an electrophilic aromatic substitution is mercuration. Nevertheless, the author describes all the known arene metallation reactions, and invites further experimental investigations to remedy this gap in mechanistic knowledge. In Chapters 6 to 9 we find descriptions of electrophilic aromatic substitution reactions that are more familiar to the average chemist, with the various electrophiles arranged according to the periodic system. Thus Chapter 6 describes reactions using carbon electrophiles (e.g. Friedel-Crafts alkylations and acylations), Chapter 7 describes reactions using nitrogen electrophiles (e.g. azo couplings and nitrations), Chapter 8 deals with reactions involving oxygen, sulfur and selenium electrophiles (e.g. sulfonations), and Chapter 9 covers electrophilic halogenations. Chapter 10 ("The Replacement of a Substituent X by a Substituent Y") deals with 63 known *ipso*-substitution reactions, ranging from silyldelithiation through sulfodealkylation to halogen exchange. Lastly, in Chapter 11 ("Quantitative Evaluation of Electronic and Steric Effects in Electrophilic Aromatic Substitution") we learn something about quantitative relationships between structure and reactivity in electrophilic substitutions of arenes, about suitably modified Hammett equations with detailed tables of substituent constants and reaction constants, and about the factors that determine the *ortho/para* ratio in the product. A subject index completes this comprehensive work; however, there is no index of authors.

There is scarcely any aspect of electrophilic substitution of arenes that is not covered in this book, as can be judged from the inclusion of about 2700 literature references and 127 tables. The clear and attractive typography and lucid formula schemes make the book easy to read, and one quickly becomes absorbed. In doing so one comes across unexpected recent results, even concerning named reactions that have long been familiar. Anyone who seeks comprehensive and reliable information about electrophilic substitution in arenes would be well advised to borrow this book from the nearest library, which certainly ought to have it in its collection. However, the comparatively high price means that not many readers are likely to have their own copy for reference.

The Chemistry of Metal Cluster Complexes. Edited by *D. F. Shriver, H. D. Kaesz* and *R. D. Adams*. VCH Verlagsgesellschaft, Weinheim 1990. 439 pp., hardcover DM 164.00. – ISBN 3-527-28047-2

Not surprisingly for such a rapidly expanding field of research, another monograph on the chemistry of metal clusters has now appeared; it is certainly the most up-to-date and well presented. This is not least because of the publishers' attractive production of the book. Like its predecessors (B. F. G. Johnson (Ed.): *Transition Metal Clusters*, Wiley, Chichester 1980; M. Moskovits (Ed.): *Metal Clusters*, Wiley, New York 1986; B. C. Gates, L. Guczi, H. Knözinger (Eds.): *Metal Clusters in Catalysis*, Elsevier, Amsterdam 1986) this monograph edited by acknowledged experts is a collection of individual contributions by well-known authors, some of whom have published similar articles elsewhere. This naturally means that the book does not have the character of a unified whole. Despite the evident efforts by the editors to achieve some unity, it remains true that the chapters of this book are independent articles; in this situa-

tion instances of overlapping and conflicting descriptions are unavoidable. The reader should therefore not expect to be given an overall view of cluster chemistry; instead he or she is presented with a collection of independent progress reports on different aspects of cluster chemistry, all of which are of a high standard.

A brief introduction by *H. D. Kaesz* and *D. F. Shriver* explaining the layout of the subject matter is followed by a detailed chapter on structures and bonding theories which is very useful for the reader who seeks a systematic treatment; what is especially impressive is the strict separation of facts from interpretations. The types of structures that are observed, the rules regarding numbers of electrons and their theoretical basis are kept clearly separate. In the following chapter *R. D. Adams* sets out to bring some systematic order into the synthesis of metal clusters, a very difficult task in view of the many facets of their chemistry and the random nature of the preparative methods used. More amenable to classification are ligand substitution reactions and ligand transformations in metal clusters, which are treated in two chapters by *D. J. Darensbourg* and *G. Lavigne* respectively, though with some overlapping. Despite the very compressed style, the article by *Lavigne* is undoubtedly of great importance for the synthetic chemist. The chapter by *B. F. G. Johnson* and *A. Rodgers* on polyhedral rearrangements and fragmentations of metal clusters, unlike the rest of the chapters in the book, does not aim to systematically treat a large amount of information; instead it consists of a fundamental discussion of the energetic aspects of metal clusters. In the chapter on metal clusters as homogeneous catalysts and catalyst precursors *W. L. Gladfelter* and *K. J. Roesselet* give an up-to-date though not exhaustive review of the state of knowledge in this area. The book ends with a very useful literature survey by *M. I. Bruce* listing review articles on cluster chemistry, covering the period from 1965 to 1988.

Among the faults noted are a number of inconsistencies in formulas which are rather more serious than isolated printing errors. There are arbitrary differences in the sequence of the ligands in the formulas of analogous complexes, as in $[HRu_3(CO)_{11}]^{\ominus}$ (p. 230) and $[Fe_3(\mu\text{-}H)(CO)_{11}]^{\ominus}$ (p. 239). Ionic complexes mentioned in the same context are written in one case with square brackets and in another case without: $Co_6(CO)_{15}^{2\ominus}$ (p. 310) and $[H_3Os_4(CO)_{12}]^{\oplus}$ (p. 311). Then neutral clusters too are shown in square brackets, though again not in all cases: $[Au_{11}(PPh_3)_7(SCN)_3]$ (p. 65) in contrast to $Au_{11}(PPh_3)_7(SCN)_3$ (p. 67). The representation of ionic complexes generally is very confused: thus on page 222 the cation $[Co_3Cp_3(\mu\text{-}H)(\mu_3\text{-}\eta^2\text{-}CH_2]^{\oplus}$ is identified as **[75]**, whereas in the figure on the same page the formula shows no charge but has the symbol **[75]**$^{\oplus}$. Furthermore, the coordination number assigned to a complex in the ionic complexes relates in one case to the cluster ion alone but in another to the salt as a whole, **[83b]** (p. 223). Also the coordination numbers are written, apparently arbitrarily, in one case in square brackets and in another case in curved brackets: **[179]** and **(179)** on page 250. In the reaction schemes the formulas are occasionally printed without the subscript or superscript forms of the numbers: e.g. PR3 and BuCHN2 (p. 210). Naturally all these errors in the formulas cause difficulties in reading the book.

Lastly there is the question of the choice of material. It is unpardonable that the superclusters discovered recently by *G. Schmid* and the concept of the "magic numbers" are nowhere mentioned. This very important discovery, which fills the much discussed gap between "molecular" and "metallic" metal clusters, should certainly be included in an up-to-date monograph on metal clusters. There is also no mention (even in the bibliography) of one of the best introductory review articles on metal cluster compounds, the three-part review by *B. Walther* in *Zeitschrift für Chemie (Leipzig)*; the first two parts of this appeared in 1986 and 1988. These two examples show once again that even important publications in German journals become known to only a limited extent, or very late, in the English language science world.

Summary: A book which is indispensable to the cluster chemist, and is very useful despite its shortcomings.

Georg Süss-Fink [NB 1106 IE]
Institut de Chimie
Université de Neuchâtel (Switzerland)

Lectins. By *N. Sharon* and *H. Lis*. Chapman and Hall, London 1989. vii, 127 pp., hardcover £ 19.50. – ISBN 0-412-27380-2

Anyone who looks up the keyword "Lectin" in a textbook of biochemistry will find little space devoted to this topic. Although one can certainly justify an individual treatment of a special field of study, the question arises as to whether such a book is likely to find a readership beyond the narrow confines of the specialist discipline. To assess how useful reading this book is likely to prove, the main factors to be considered are the degree of importance of the research topic in relation to other areas, and the didactic quality of the presentation.

The coining of expressions such as glycobiology or tumor lectinology, and the considerable increase in the last few years in the number of papers on lectins that appear in journals dealing with remarkably varied fields of work, are evidence of a growing interest in this topic, and especially in the function of the interaction between the sugar part of the cellular glycoconjugate and the specific binding proteins. Proteins that have the capacity to recognize sugar structures of this type therefore constitute an essential link in this form of biological information transfer; our present state of knowledge concerning these is merely the tip of the iceberg. This class of sugar receptors, which according to their definition are distinct from enzymes and antibodies, includes the lectins. To isolate them, to determine their sugar specificity, and to localize them, one requires sugar structures that are coupled to suitable carriers. To produce these represents a challenge for organic chemists and biochemists. The fact that lectins can be localized using suitable sugar ligands, and the availability of the lectins as sugar-specific laboratory agents, leads to uses in cell biology, immunology and histochemistry. Our present understanding of the way in which they function, which is still only in its infancy, indicates a great potential for clinical applications, the exploitation of which can indicate ways of overcoming infections, of achieving therapeutically advantageous immune modulation, and of extending the armory of agents for labeling tumors.

N. Sharon and *H. Lis* are therefore to be commended on having emphasized in their book on lectins the inherently interdisciplinary nature of the subject, in a presentation that is consistently lucid and comprehensible. For this reason interested students can benefit from using the book as an extension to textbooks, by working through seminar topics with the help of relevant individual chapters. In a clearly arranged sequence the authors describe the occurrence of lectins, their biological activities and functions insofar as these have been measured up to now, their sugar specificities, structural and biosynthetic aspects, and the many different ways in which they are used as a laboratory tool.

The book includes an excellent and entertaining outline of the history of the scientific study of lectins, which goes back more than a hundred years. Every chapter makes it clear, even to the non-specialist reader, that this history will be enriched by further additions as a result of studies that are now in progress or will be carried out in the future. This gives one an extra incentive to absorb the information presented here, so as to provide a basis for following and understanding such future developments as they occur. Therefore it is to be hoped that the book will be widely read, and that it will not be too long before a new updated edition appears. However, the reader interested in this topic is not advised to wait for such a new edition. It is to be hoped, and is indeed likely in view of the quality and presentation of the material in this well set out and easily digestible survey, that readers—especially those who are not lectins specialists—will be motivated to keep informed about progress in relevant sectors of the field of lectins. Finally, it can be assumed that some of the information that this book contains, such as the role of lectins in viral and bacterial infections or in transport of glycoproteins, will also in due course find its way into the standard textbooks.

A Random Walk Through Fractal Dimensions. By *B. H. Kaye*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York 1989. xxv, 421 pp., hardcover DM 138.00 (paperback DM 64.00).—ISBN 3-527-26468-X/0-89573-496-6

The concept of fractals, invented by *Benoît B. Mandelbrot*, has by its vivid imagery altered ways of scientific thought to an extent that is perhaps greater than that caused by the second law of thermodynamics. It is doubtless also because of this graphic quality that a large number of scientists have already become involved with this new tool. Publications reviewing this subject are therefore to be welcomed. The book by *B. H. Kaye* is neither a handbook nor a work of reference; instead it contains exactly what its title promises: a random walk through fractal dimensions, confined to the scientific and mathematical aspects. The mathematical procedure of fractals is likewise a random one, but it certainly does not lack a plan. Its basic operations are governed by strict rules, but these are then applied to random numbers. Although fractals are ultimately a mathematical device, formulas are avoided in the book. Regrettably, this is taken so far that one is not even given a mathematical definition of the term "fractal". An extreme case is the chapter entitled "Mathematical Description of Fractal Clusters", which contains only two quite unimportant formulas. The vague references in the text to "famous" names in the field are rather annoying; for more detailed information one has to refer to the bibliography.

The value of the book lies in its plentiful illustrations and the directness of its style, together with the fact that, due to the absence of mathematical detail, it is very easy to read. It is therefore very suitable as a first introduction to the topic. It can be used as a supplement to basic treatments of the subject, in particular to those by *Mandelbrot* or to those that deal with special aspects. It offers a wealth of new examples drawn from mathematics, scientific statistics and various fields of science. The main emphasis of the application examples is in the author's special field of dispersed phases. The book also serves as a stimulus for further research.

Structure and Reactivity in Reverse Micelles. (Series: Studies in Physical and Theoretical Chemistry, Vol. 65). Edited by *M. P. Pileni*. Elsevier, Amsterdam 1989. xviii, 379 pp., hardcover, HFl 285.00.—ISBN 0-444-88166-2

This book, which is published as Volume 65 in the series "Studies in Physical and Theoretical Chemistry", is concerened with topical problems in the field of reverse micelles. It consists of 21 individual contributions by different authors, most of whom do not confine themselves to a narrow definition of reverse micelles but also include microemulsions in this class. The aspects emphasized in the articles fall under three headings: the applications of various analytical techniques, solubilization, and chemical reactions in reverse micelles and microemulsions. The treatment of structural problems which is promised in the book's title is limited to that arising in the chapters on analytical techniques and solubilization, and is mainly restricted to "classical" reverse micelles.

The analytical techniques that are described include methods of investigating structure, such as light-, X-ray- and neutron-scattering measurements, as well as electron microscopy and various spectroscopic methods. First the applicability of each individual technique to the study of structure and reactions in reverse micelles is discussed, then particular types of reverse micelles are used as examples to illustrate the capabilities and limitations of the various analytical methods.

In the articles on solubilization in reverse micelles and microemulsions the main emphasis is on discussions concerning the site of the preferential solubilization and the associated structural changes. Also the various solubilization techniques and their advantages and disadvantages are discussed in detail.

The reactions that can be carried out in reverse micelles and microemulsions include such widely different processes as pulse radiolysis, electron transfer, photoreactions, the preparation of clusters of metallic and semiconducting elements, polymerizations and enzymic catalysis. Although here too the reactions are in some cases used to gain more detailed knowledge about the structures of reverse micelles, the dominant theme is the idea of using reverse micelles as variable microreactors.

The form of the book, consisting of separate individual contributions, has made it possible to present a very wide range of topics within the overall theme of reverse micelles. The articles provide the reader with numerous up-to-date references to original papers on each of the topics treated. Representatives of widely differing schools of thought such as *P. L. Luisi* and *K. Martinek* have an opportunity to put their views; this area of research is thereby presented, with its attendant controversies, as one that is active and exciting, and in which one can still expect many interesting developments.

Although good use has been made of the opportunities presented by a book made up of separate contributions, one is left with the usual problems of this format: the following of a central theme is sacrificed in favor of breadth of subject matter. The attempt by *P. L. Luisi* to provide an aid to orientation alongside the contributions dealing with their

special topics is a very good idea, even though it is not ideally placed in the book. In their efforts to convey their special interests the authors of the individual articles have tended to neglect the treatment of the fundamentals, and they often assume that the reader has an extensive knowledge of colloid chemistry. In many cases it is difficult to relate the individual contributions to each other, especially as their subject matter is not always well harmonized: many points are explained several times, others not at all, so that parts of the book are quite laborious to read. Also some expressions are used with different meanings in different chapters, and no consistent notation is used for the mathematical equations.

One has a general impression that the proofreading has been rather perfunctory. Often one comes across errors that might be excused as mere blemishes in the main text, but which cause problems when they occur in keywords (e.g. "Stibene" frequently instead of "Stilbene") or in literature references. There are other minor errors which cause annoyance, such as missing chapter numbers (which frustrate the laudable attempts of some of the authors to refer to "Chapter X" by one of the others), or gaps in the subject index: for example, one searches in vain for "NMR" under the letter N – instead it appears under R with just one entry (!) as "Reversed micelle, NMR in".

Despite its shortcomings the book can definitely be recommended as a source of more advanced information on the field of reverse micelles, not least because of its references to recent literature for further reading. However, as a first introduction to this field the book is of only limited suitability. Some of the many review articles that are available on this subject offer better introductions.

André Laschewsky [NB 1090 IE]

Organic Chemistry in Action. The Design of Organic Synthesis. (Series: Studies in Organic Chemistry 41). By *F. Serratosa*. Elsevier, Amsterdam 1990. xxi, 395 pp., hardcover HFl. 290.00.—ISBN 0-444-88345-2

Synthesis is still the main occupation of many organic chemists. The systematic development of retrosynthesis by *Corey* has contributed to the "renaissance" of synthetic chemistry as a whole. The large number of recently published natural products syntheses are a lively proof of this fact. In spite of the large efforts in synthesis relatively few books are available to introduce synthesis and synthesis planning to students. The book "Organic Chemistry in Action" by *F. Serratosa* together with a copy of the program CHAOS aims to provide such an introduction to organic synthesis. The combination of a book with a computer program is new and should hopefully facilitate the learning process for beginners.

Serratosa's book can be divided into four parts. Chapters 1 to 4 present the basic concepts of synthesis planning. After a short introduction to the history of synthesis the criteria for evaluating synthetic schemes are introduced. The next chapter treats the systematic analysis of reactivity according to *Evans*. A short introduction to retrosynthesis follows. In the second part specific synthetic problems are treated. The first problem is the synthesis of "dissonant" systems or, according to *Seebach*'s more familiar nomenclature, the application of the "Umpolung" concept. Next a series of synthetic methods for synthesizing rings are presented. Strategies for synthesizing structures with quaternary carbon atoms and bridged systems are described in Chapter 7. *Corey*'s rules for finding strategic bonds are nicely introduced using patchouli alcohol as an example. This part concludes with a discussion of how to achieve stereochemical control in ring and acyclic systems. In Chapter 9 on diastereoselectivity in reactions of acyclic compounds, several variations of the aldol reaction are treated followed by a short overview on Sharpless epoxidation. A recapitulation of the heuristic rules and their application, illustrated by a series of examples taken from the literature, forms the third part, which concludes the main text. The last part is unfortunately arranged in a rather fragmented way, consisting of Chapter 11, Appendices 2 to 4, and the diskette containing a copy of the program CHAOS (Computerisation and Heuristics Applied to Organic Synthesis). Appendix 2 is a tutorial for the use of CHAOS. In addition there is a list of the retrosynthetic steps used by CHAOS and some suggestions for exercises. Chapter 11, which is a description of CHAOS, fits uneasily into the book's text.

To try to combine a textbook on organic synthesis and planning with a computer program is certainly a good idea. Unfortunately the present publication cannot be considered to be a good combination of the two media. The program is not polished enough to be a valuable help in the learning process. CHAOS certainly cannot be used as an alternative to other synthesis programs or reaction data bases. Looking at the price the purchase of this book can only be recommended for libraries or for lecturers preparing courses on organic synthesis. It only can be hoped that a much cheaper version without the diskette will appear soon, thus enabling students to profit from the nicely chosen examples; at the same time the numerous printing mistakes could be eliminated.

EPR of Exchange Coupled Systems. By *A. Bencini* and *D. Gatteschi*. Springer, Berlin 1990. x, 287 pp., hardcover DM 178.00.—ISBN 3-540-50944-6

This book is concerned with the theory of electron paramagnetic resonance spectroscopy (EPR) and magnetic properties for systems containing two or more magnetically coupled paramagnetic centers (transition metal ions and/or free radicals). A knowledge of the basic theory of EPR spectra of isolated centers is an essential prerequisite for understanding this monograph.

After discussing the exchange and superexchange interaction mechanisms, including an explanation of the empirical rules established by *Goodenough* and *Kanamori* for the occurrence of ferromagnetic and antiferromagnetic exchange in magnetically coupled systems, the authors discuss in detail the spin Hamiltonian operator for such systems. Chapter 3 then deals with the spin levels and EPR spectra of magnetically coupled pairs and their dependence on the exchange interaction. The spin Hamiltonian operators of the isolated centers and the interaction operator are then used as the basis for deviving the spin Hamiltonian operator for the coupled system, by using irreducible tensor operators. From this one obtains the relationship between the parameters in the spin Hamiltonian for the individual centers (g-tensor, fine structure tensor D and hyperfine structure tensor A) and those for the coupled system. Following this, the spin Hamiltonian operators and EPR spectra of clusters of paramagnetic species are analyzed, with the emphasis on treating systems with strong exchange interactions (triads and tetrads). For

these systems too the relationships between the spin Hamiltonian parameters for the individual centers and those for the coupled system are derived; the matrix elements needed for this derivation are set out in the form of clear tables. Chapter 5 deals with spin-lattice relaxation processes in magnetically coupled spin systems; the authors limit their discussion almost exclusively to the relaxation behavior of paramagnetic ion pairs (dimers of Ir^{4+}, Fe^{3+} and Cu^{2+}).

The chapters that follow provide a good review of experimental EPR studies on model systems with magnetically coupled centers that are of importance in physics, chemistry and biology. Chapter 7 discusses EPR spectra of paramagnetic ion pairs and of diradicals, and Chapter 8 deals with spectra of systems in which paramagnetic ions and free radicals are magnetically coupled. The application of EPR spectroscopy to studies of magnetically coupled species in biological materials is currently a topic of great importance, and Chapter 9 therefore deals with EPR spectra and the structural information that they yield for copper and iron proteins and for exchange coupled species in complexes that are important for photosynthesis. Chapter 10 describes the magnetic properties and EPR spectra of low-dimensional spin systems consisting of a large number of magnetically coupled paramagnetic ions. One- and two-dimensional structures are considered in detail. The final chapter describes the application of EPR spectroscopy to studies of excitons and their motions in diamagnetic solids.

The book is intended for advanced students and for scientists (physicists, chemists and biologists) involved in work in the area of EPR spectroscopy or on the magnetic properties of materials. For these readers the monograph provides a speedy and thorough introduction to studies of the magnetic properties and EPR spectroscopy of magnetically coupled systems, without having to read the widely scattered original publications. However, in order to understand the theories treated in the book one must have a knowledge of certain aspects of quantum mechanics (second-order quantization, properties of angular momentum operators, irreducible tensor operators). The book concludes with an appendix on second-order quantization and the properties of the angular momentum and irreducible tensor operators.

Chemical Reactions of Natural and Synthetic Polymers. (Ellis Horwood Series in Polymer Science and Technology). By *M. Lazár, T. Bleha* and *J. Rychlý*. Ellis Horwood, Chichester 1989. 250 pp., hardcover, £ 35.00.—ISBN 0-7458-0193-5

Previous titles in the "Polymer Science and Technology" series have included "Chromatography of Synthetic and Biological Polymers", "Polymers and their Properties", "Cellulose and its Derivatives", "Wood and Cellulosics", "Chemical Reactions of Natural and Synthetic Polymers", "Cellulose Chemistry and its Applications", "Polymers as Materials for Packaging" and "Styrene-Based Plastics and their Modifications". The declared aim of this series is to cover the field of natural and synthetic polymers, including the latest developments in basic research and in industry. It is against this claim that the quality of the present book must be evaluated. A further question that seems important to me is whether there is a need for monographs of this kind, which have recently been published in increasing numbers. In principle I welcome books of this type, in which experts provide the reader with an introduction to a specialized field. There is hardly a better way of familiarizing oneself with a specialist topic.

The monograph consists of ten chapters. Chapter 1 discusses the most important aspects of chemical reactions of polymers, such as the effects of neighboring groups, the influence of the medium, and intra- and intermolecular reactions. These effects are treated in textbook style with well-chosen examples. It is annoying to find it stated (pp. 14, 27) that the functional groups in a polymer react at rates equal to those for the same groups in small molecules. If that were so one would have no need for this monograph. A few lines later the authors contradict the statement by pointing out that it is only *very rarely* the case. The authors' arguments are in most cases easy to follow. However, the generalization that in carrying out reactions on polymers one should choose a solvent such that the product is precipitated (p. 21) seems ill-conceived; in many cases the opposite course is more sensible. Apart from these points the chapter is clearly presented, leaving aside the microdiagrams and especially the microcaptions.

The next chapter describes ways of modifying structural units that are also used in technological applications. These include fluorinations and chlorinations of hydrocarbon polymers, reactions at double bonds and cyclizations. In each case there is a very detailed discussion of mechanisms. The doping of polymers to increase the electrical conductivity is also described. Three pages are devoted to the many different reactions of polymers containing aromatic structural units. This section is rather too short in view of importance of such reactions, e.g. for synthesizing ion-exchange media. In this chapter, of course, one should not omit to describe such technologically important reactions as the hydrolysis of polyvinylacetates or the modification of natural polymers, e.g. in the xanthane reaction of cellulose. The rearrangement reaction described on pages 71–72 is due to *A. W. von Hofmann*, not to a man named *Hoffman*.

Chapter 3 deals with branched polymers, and especially with grafting. Regrettably, the section on "Macromolecular Initiators" deals only with peroxides and redox systems; there is no mention of the more than twenty publications on polymeric azo initiators that have come from the *Kerber* and *Heitz* groups.

Another polymer modification reaction that is certainly of great importance is crosslinking. Chapter 4 describes the main methods used for synthesizing network structures. These are presented very clearly, including modern approaches such as ionomers and the principle of physical crosslinking. A description of the general principles is followed by detailed accounts of particular systems and the crosslinking methods that can be used in each case. Interpenetrating networks are also briefly touched on. The very short Chapter 5 deals with polymer-polymer exchange reactions. Unfortunately the important "urethane exchange" class of reactions is not mentioned here. However, this chapter does to some extent live up to the book's title, as it deals with the interactions between dissimilar DNA molecules which can be used, for example, to study genetic defects.

The next chapter, on polymer degradation, is much more comprehensive; this deals with photooxidative degradation, thermolysis, thermooxidative degradation, and also the burning of polymers. Further sections on mechanochemical degradation, ozonolysis, and radiolytic, ionic and biological degradation complete this chapter.

The protection of polymers from degradation is an important prerequisite to allow their use as constructional materials. Chapter 7 deals with additives that confer this protec-

tion. These include UV stabilizers, antioxidants, quenching agents and fire-retardants. These are all substances designed to prevent or hinder reactions of the polymer. In my view, therefore, this chapter does not quite fit into the overall theme of the book. Moreover, there exists a considerable number of fundamental monographs and review articles on the subject which are not mentioned in the bibliography of this chapter.

One of the most important aims of polymer modification is to obtain materials with new combinations of properties, and to synthesize structures that cannot be obtained in other ways. This topic is covered in Chapter 8. Methods are described that can be used to alter the crystallinity, solubility, permeability, and also the mechanical and electrical properties.

The next chapter is concerned with present and future applications of materials produced by modifying polymers. Included here are, of course, the cellulose derivatives, crosslinked polyethylene, crosslinked casein, polyisobutylene copolymers, and various other types of elastomers such as modified PVC. The principles of manufacturing and using semipermeable membranes, functionalized polymers, polymeric reagents and polymeric catalysts are also described.

The final chapter describes recent developments such as the measurement of molecular motions in polymers by introducing fluorescence probes. Theoretical models for energy conversion processes such as thermal to mechanical, chemical to mechanical and light to chemical energy are at least briefly mentioned.

This book offers interesting reading both for experts and for those wishing to begin work in this area. Despite the weaknesses mentioned, the different aspects of the subject are covered in a way which gives an impression of uniformity. The book is fluently written and deals with all the important aspects of this highly complex area of polymer research. In view of the increasing level of activity in the area of polymer modification I consider this to be a useful book.

Ribonuclease T1: Structure, Function, and Stability**

By C. Nick Pace, Udo Heinemann, Ulrich Hahn, and Wolfram Saenger*

Proteins carry out the most important and difficult tasks in all living organisms. To do so, they must often interact specifically with other small and large molecules. This requires that they fold to a globular conformation with a unique active site that is used for the specific interaction. Consequently, protein folding can be regarded as the "secret of life". Biochemists and chemists have a great interest in elucidating the mechanism by which proteins fold and in predicting the folded conformation and its stability given just the amino acid sequence. This challenge is sometimes called the "protein folding problem". The ability to construct proteins differing in sequence by one or more amino acids and to analyze their three-dimensional structures by X-ray crystallography and NMR spectroscopy is a powerful tool for investigating the conformational stability and folding of proteins. Several proteins are now under intensive study by this approach. One of these is ribonuclease T1.

1. Introduction

Studies of the ribonucleases have made a major contribution to our understanding of the structure, function, and stability of enzymes.[1–5] Ribonuclease A (RNase A), the best-studied mammalian enzyme, and ribonuclease T1 (RNase T1), the best-studied microbial enzyme, resemble each other in function and small size, but are not homologous in amino acid sequence or three-dimensional structure.[1, 4] Detailed crystallographic studies of RNase A and its derivatives and complexes have been published by over 12 laboratories,[2] and 9 crystal structures have been determined for RNase T1. This wealth of structural information and the small size of these enzymes ensure that future studies of the ribonucleases will continue to improve our understanding of enzymes.

The active center of the ribonucleases is clearly divided into a substrate recognition site, which is specific for certain nucleic acid bases, and a catalytic site, where cleavage of the phosphodiester bond takes place.[2, 5] RNase A recognizes the pyrimidine bases uracil and cytidine, whereas the microbial RNases are specific for guanine or for guanine and adenine, or they are nonspecific. Due to its high specificity for guanine in single-stranded RNA, RNase T1 has found wide application as a tool in RNA sequencing and mapping studies.[6–8] RNase A and the microbial RNases act on RNA in a similar acid/base-catalyzed two-step mechanism, which first involves a transesterification to produce a 2′,3′-cyclic phosphate and then hydrolysis to the 3′-phosphate.

Originally, RNase T1 was isolated from Takadiastase, a commercial preparation of the culture medium of the mold fungus *Aspergillus oryzae*, in two isoforms with either Gln or Lys at position 25 (Gln25-RNase T1 or Lys25-RNase T1,

Fig. 1).[5, 9] More recently, the gene for RNase T1 was cloned in *Escherichia coli* by genetic engineering methods using three strategies.[10–13] In one, RNase T1 was expressed as a fusion protein and cleaved by cyanogen bromide to produce RNase T1 in modest quantities;[10] in the other two, the gene was cloned downstream from a gene for a transmembrane signal peptide and active RNase T1 was excreted into the periplasm, from which it could be isolated in quantities of up to 50 mg per liter of culture medium.[11–13] This work has provided access to RNase T1 molecules specifically altered at any desired amino acid residue by site-directed mutagenesis. In the discussion that follows, mutant ribonucleases will be designated XnY to show that amino acid X at position n has been replaced by amino acid Y.

In this review, we first describe the structure of RNase T1 bound to various ligands and inhibitors, next we summarize a series of experimental studies of the conformational stability of RNase T1, and, finally, we consider the conformational stability of RNase T1 in terms of the three-dimensional structure. These studies are helping us gain a better understanding of the forces that stabilize the folded, biologically active conformations of proteins and should eventually contribute to a solution of the protein folding problem.

2. Three-Dimensional Structure of RNase T1 Complexed with Different Ligands

Several crystal structures of RNase T1 have been determined at medium to high resolution (Table 1). They often contain derivatives of guanosine bound to the enzyme recognition site, but crystal structures of wild-type and mutant

C. Nick Pace was born in 1940 in Delta, Utah (USA). He studied chemistry at the University of Utah (B.S., 1962) and biochemistry at Duke University (Ph.D., 1966). After working as a postdoctoral fellow in the chemistry department at Cornell University, he became Professor in the Biochemistry Department at Texas A & M University in 1968. His main research interest is the conformational stability and mechanism of folding of globular proteins.

Udo Heinemann was born in 1953 in Bebra-Iba, Hessen (FRG) and studied chemistry at the Universität Göttingen, where he received his Ph.D. in 1982 for work done at the Max-Planck-Institut für experimentelle Medizin in Göttingen. He then worked as a postdoctoral fellow at the Molecular Biology Institute, University of California at Los Angeles. From 1985 to 1991, he was an "Assistent" at the Institut für Kristallographie der Freien Universität Berlin, where he became a Privatdozent in 1989 and a Heisenberg fellow of the Deutsche Forschungsgemeinschaft in 1991. Crystallographic and biochemical studies of nucleic acid and protein structure are his major fields of interest.

Ulrich Hahn was born in 1950 in Kassel (FRG). He studied agricultural sciences and biology at the Universität Göttingen, where he received his Ph.D. in 1980 for work done at the Max-Planck-Institut für experimentelle Medizin in Göttingen. After working as a postdoctoral fellow at this institute, he moved to the Institut für Kristallographie der Freien Universität Berlin in 1982 as a staff scientist (Akademischer Rat). Since 1989, he has been a Privatdozent. Gene technology and protein engineering of nucleic acid binding proteins are his fields of interest.
