Wolfram Saenger was born in 1939 in Höchst/Main (FRG). He studied chemistry in Darmstadt and Heidelberg and received his Ph.D. in 1965 at the Technische Hochschule Darmstadt for work done at the Max-Planck-Institut für experimentelle Medizin in Göttingen. After working as a postdoctoral fellow at Harvard University, he served as head of the X-ray crystallography group at the Max-Planck-Institut für experimentelle Medizin from 1967 to 1981. He was also a Privatdozent (1971–77) and Professor (1977–81) at the Universität Göttingen. Since 1981, he has been a full professor at the Institut für Kristallographie der Freien Universität Berlin. In 1987 he received the Leibniz award of the Deutsche Forschungsgemeinschaft and in 1988 the Humboldt award. His interests focus on structural chemistry and structure–function relationships of biological macromolecules.

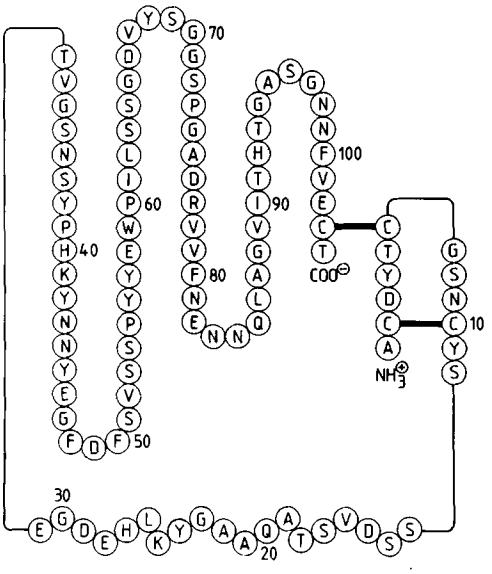

Fig. 1. Amino acid sequence of RNase T1 [5, 9] drawn in a way that emphasizes the secondary structure of the protein. Standard one-letter code has been used to denote amino acid residues.

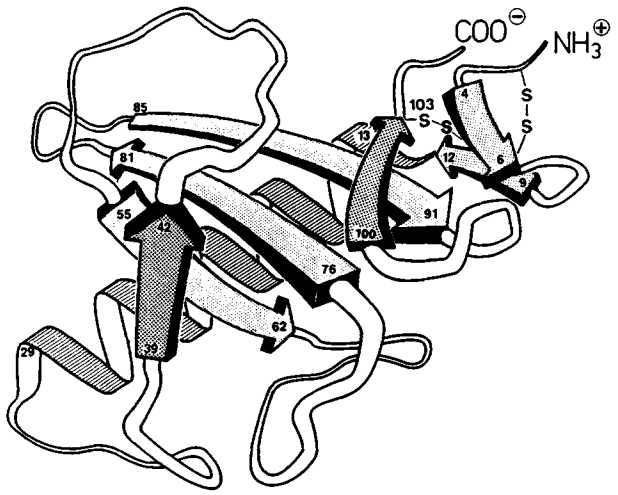

Fig. 2. Three-dimensional structure of RNase T1. The α-helix is shown as a wound ribbon; arrows mark the strands of the pleated sheets. Numbers indicate beginning and end of secondary structure elements, and the disulfide bonds are shown.

RNase T1 where this site is free have also been described. In all the crystal structures, RNase T1 adopts essentially the same three-dimensional polypeptide folding as displayed in Figure 2.

The polypeptide chain is cross-linked by two disulfide bonds from Cys 2 and Cys 10 and from Cys 6 to Cys 103. The

[a] Lys 25-RNase T1 and Gln 25-RNase T1 are the two isoforms of the protein; mutations are given in parentheses when appropriate. The crystal structures of the 2′-GMP complexes of both Lys 25-RNase T1 and Gln 25-RNase T1 were solved by multiple isomorphous replacement [14, 17]; all other crystal structures were either isomorphous with known structures of RNase T1 or solved by molecular replacement [25] using a known three-dimensional structure as start. All crystal structures were refined using stereochemical restraints [26] and routinely checked by computer graphics [27]. [b] 2′-GMP, 2′-guanylic acid; 3′-GMP, 3′-guanylic acid; 2′,5′-GpG, guanylyl-2′,5′-guanosine; vanadate, $[H_2VO_4]^{\ominus}$; 3′,5′-GDP, guanosine-3′,5′-diphosphate. [c] d_{min} is the maximum resolution of the diffraction data used. [d] The crystallographic residual is $R = \sum_h (F_o - F_c)/\sum_h F_o$, where F_o and F_c are observed and calculated structure amplitudes, respectively, and the summation is over all h reflections. [e] For structures that have an identifier, coordinates are available from the Brookhaven Protein Data Bank upon request. [f] In preparation.

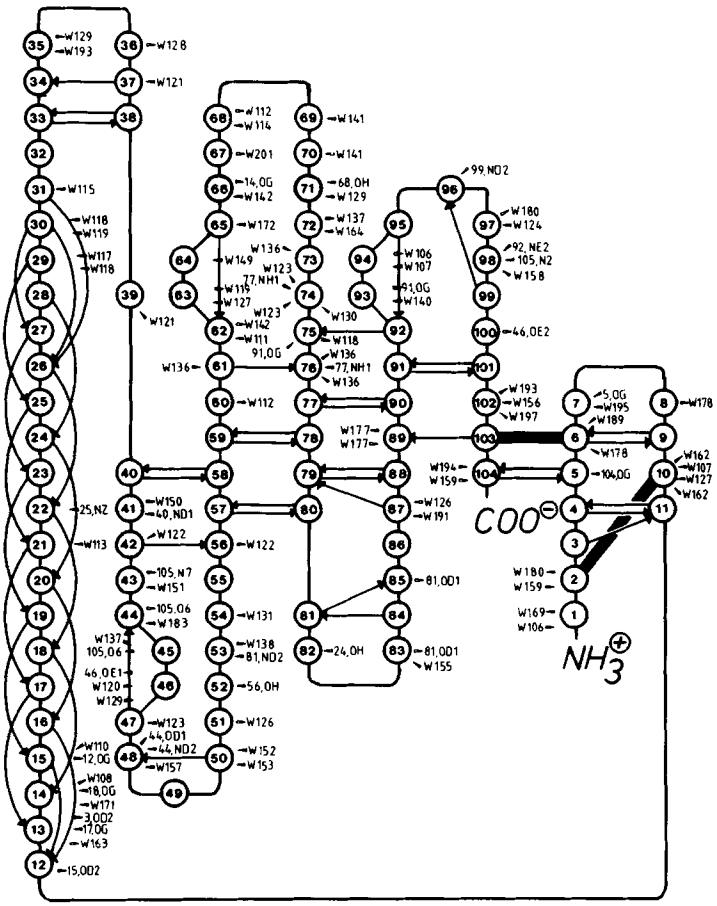

Fig. 3. Main-chain hydrogen bonding of RNase T1. Solvent sites are given the letter W and numbered (e.g., W129), and protein side chain atoms are indicated with sequence number and atom name (e.g., 77NH1). Arrows and arrowheads indicate the hydrogen bonds. The bold lines connecting residues 2 and 10 and residues 6 and 103 represent disulfide bonds. All hydrogen bonds discussed in this article are assigned according to the geometric criteria of *Baker* and *Hubbard* [28].

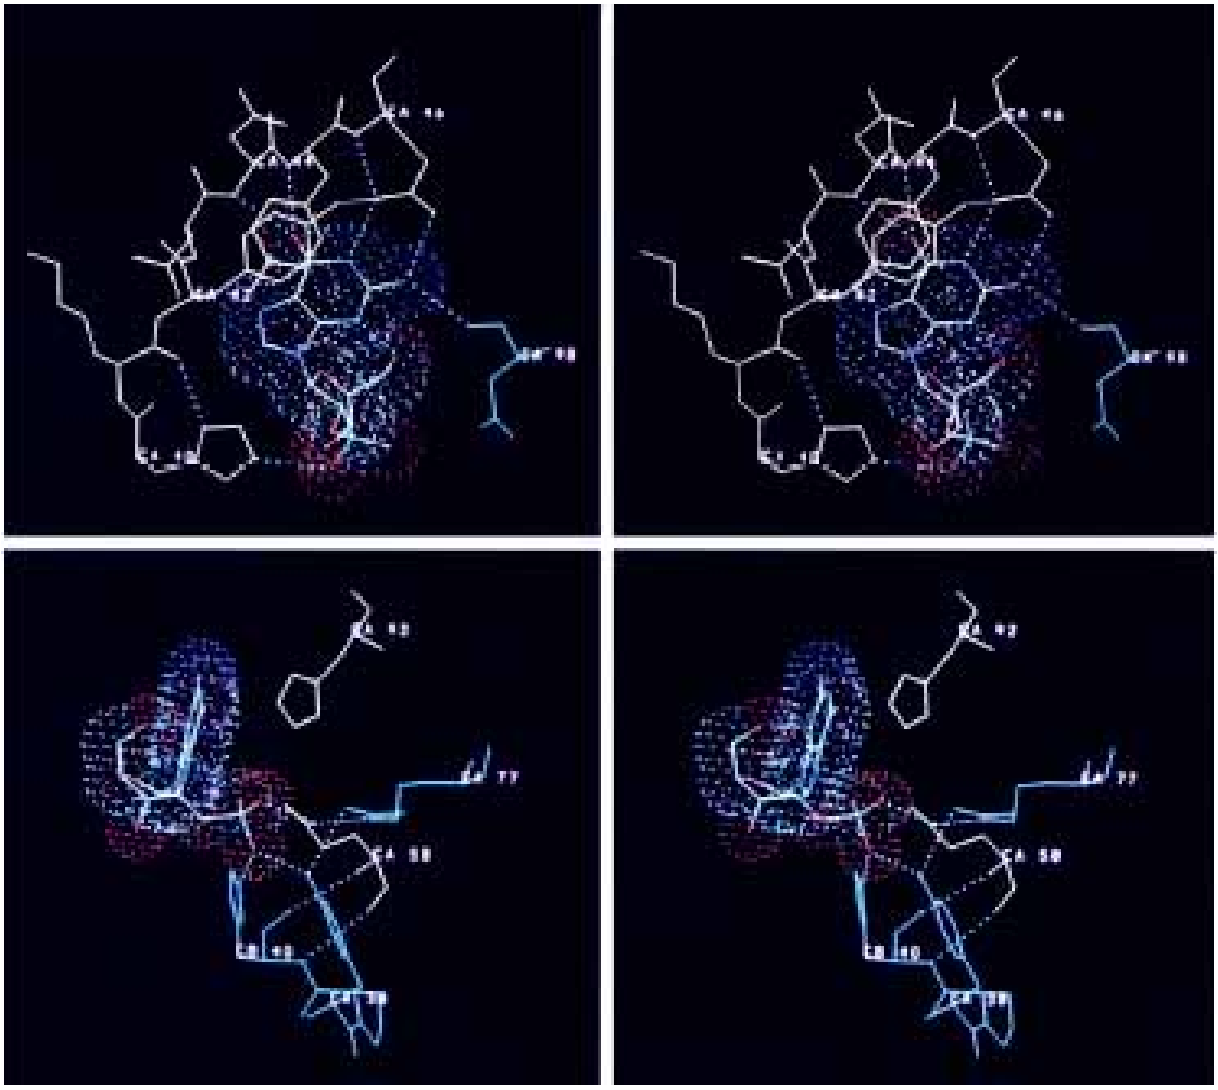

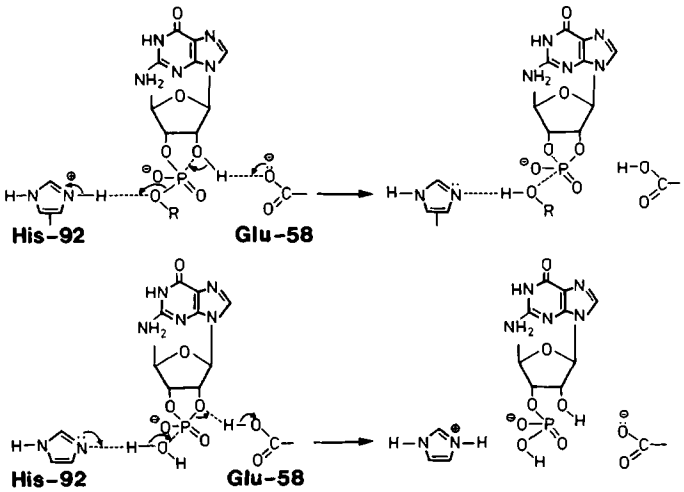

Fig. 4. Top and middle: Stereoview of the active site of RNase T1. The bound inhibitor, 2′-guanylic acid, is drawn with its van der Waals surface: white, carbon; blue, nitrogen; red, oxygen; light blue, phosphorus. The protein atoms are light blue and yellow; α-carbon positions are labeled, and hydrogen bonds are shown as dashed lines. Top: Base recognition site: the polypeptide stretch His40 to Glu46 is shown in yellow; Asn98 is blue. Middle: Catalytic site: Glu58 and His92, which are implicated in catalysis by RNase T1, are drawn in yellow; the other amino acids interacting with the phosphate group are blue. Bottom: In the reaction scheme the most probable mechanism for phosphodiester bond hydrolysis by RNase T1 [31] is outlined.

secondary structure is stabilized by 51 N–H···O=C hydrogen bonds (Fig. 3). It consists of a short two-stranded antiparallel β-sheet followed by a 4.5-turn α-helix and a second antiparallel β-sheet composed of five strands. The connections between the secondary-structure elements are more or less extended loops incorporating several β-turns. The five-stranded sheet is strongly twisted to form a barrel-like structure. If an enzyme–substrate complex is formed, the bound RNA single strand represents the missing sixth strand to complete the barrel.

The tertiary structure is stabilized by burying about 80% of the nonpolar side chains in a hydrophobic core and thereby removing them from contact with water. In addition to the hydrogen bonds in the α-helix and β-sheets, 31 hydrogen bonds between the main chain and the side chains and 14 hydrogen bonds between the side chains[16] help to stabilize the folded conformation of RNase T1.

2.1. The Guanine-Binding Site of RNase T1

Specific binding of guanine occurs through the polypeptide segment Tyr42 to Glu46 and the peptide C=O group of Asn98 (Fig. 4). Guanine N(7) and O(6) accept hydrogen

bonds from the peptide N-H groups of Asn43, Asn44, and Tyr45; guanine N(1)-H, and N(2)-H donate hydrogen bonds to the side chain of Glu46, and the second N(2)-H hydrogen bonds to the carbonyl oxygen of Asn98. Moreover, the carbonyl group at the 6-position of the guanine moiety is sandwiched between the phenolic side chains of Tyr42 and Tyr45, so that the hydrogen bonds are shielded from competition with bulk water and consequently stabilized.

In the crystal structures of RNase T1 with guanosine 2′-phosphate and guanosine,[14-18, 20, 22] the guanosine moiety is in the *syn* conformation, which permits an intranucleoside O(5′)-H ··· N(3) hydrogen bond to be formed. X-ray crystallography has revealed no hydrogen-bonding interaction between the ribose and the enzyme in any complex between RNase T1 and a substrate analogue. The phosphate group of guanosine 2′-phosphate is hydrogen-bonded to the side chains of Tyr38 (O_η), His40 (N_ε), and Glu58 (O_ε) (see Fig. 4), but not to the side chain of Arg77. Comparable interactions were also found with the phosphate group in guanylyl-2′,5′-guanosine, for which the phosphate group and the 3′-terminal guanosine are seen in twofold disordered positions.[20] The reason is that there are only a few interactions between RNase T1 and the 3′-terminal guanosine and there are some additional contacts to a symmetry-related RNase T1 molecule.

In the adduct between RNase T1 and vanadate, the anion $[H_2VO_4]^\ominus$ binds to the site where the phosphate group is bound in the complex with guanosine 2′-phosphate.[21] In the base recognition site, there is a water molecule close to the position where O(6) of guanine would be. The Glu46 side chain is rotated away from the guanine binding site, the side chain of Tyr45 is in a different position, and the Asn43–Asn44 peptide link is flipped by nearly 180° with respect to the other crystal structures which contain a bound guanine. This suggests that the guanine binding site is to a certain extent flexible to facilitate the binding of the substrate and the expulsion of the product.

The specificity of RNase T1 for guanosine has been investigated in a free-energy perturbation study,[29] which arrived at approximately the same difference between the free energies of binding of guanosine and adenosine as experimental studies. The simulation suggested that removal of the Glu46 carboxylate group should render RNase T1 an adenosine-specific ribonuclease. This conclusion, however, is not supported by biochemical studies of the RNase T1 Glu46Ala mutant.[30]

2.2. The Catalytic Site of RNase T1

The catalytic site of RNase T1 is defined by the environment of the phosphate group in the complexes with guanosine 2′-phosphate and guanylyl-2′,5′-guanosine (Fig. 4). Since the ligands contain phosphate in the 2′ position so that the phosphodiester link cannot be hydrolyzed, model building studies have been performed to construct the corresponding 3′-phosphate.[31] These suggest that the hydrogen-bonding scheme is different, as it is now possible to form a hydrogen bond between one of the phosphate oxygens and the imidazole of His92 and between the ribose O(2′)-H and the carboxylate of Glu58. The imidazole group of His40 is nearby, but probably not involved in hydrogen bonding to the ribose.

Based on this geometry and on the information known from numerous biochemical studies,[4, 32, 33] a reaction mechanism of RNase T1 (Fig. 4, bottom) was proposed where Glu58, possibly activated by His40, acts as a base and abstracts the proton from O(2′)-H; the $O(2')^\ominus$ then attacks the phosphodiester bond and O(5′) of the next nucleotide receives a proton from the protonated His92. The newly formed terminal guanylyl-2′,3′-cyclic phosphate is hydrolyzed by a water molecule activated by His92, to which it donates a proton, the leaving O(2′) receives a proton from Glu58, and the terminal guanosine 3′-phosphate product is formed.[14, 31]

Whereas the stereochemistry of this reaction[33] and the proposed role of His92 in catalysis are nearly universally accepted, site-directed mutagenesis of active-site residues has fueled a dispute about the function of Glu58 and His40. Removal of either residue preserves significant residual ribonuclease activity.[34-36] Support for the proposed action of Glu58 (and not His40) on guanosine O(2′)-H comes mainly from an analysis of the pH profiles of dinucleotide hydrolysis for wild-type RNase T1 and several single-site mutants by *Steyaert* et al.[36] Mutants lacking His40 display the same pH profiles as the wild type, while replacement of Glu58 leads to a change in pH dependence.

To date, two mutants of RNase T1 have been studied by crystallographic methods, His92Ala and His40Lys.[23, 24] The former is inactive because the catalytically important His92 is replaced by Ala,[34, 35] but the latter is still 13% active relative to the wild-type enzyme.[13, 36] In His92Ala, the replacement of the imidazole group by a hydrogen atom results in some major structural changes, because a hydrogen bond between the histidine side chain and the main-chain Asn99 C = O group is no longer possible and the loop formed by segment Ile90 to Asn99 thereby is destabilized. Similarly, the His40Lys mutant displays some local structural changes in this loop region; however, these changes are not as severe as in case of the His92Ala mutant.

2.3. The Distribution of Thermal Parameters Suggests Segmental Flexibility

In the course of refinement of an X-ray crystal structure, the atomic thermal parameters are refined as well as the atomic coordinates. They are indicative of the vibrations of the atoms in the crystal lattice. The thermal parameters of the main-chain and side-chain atoms are shown as a function of sequence number in Figure 5. Amino acids incorporated into β-sheets are more "rigid" than those in the α-helix; those in the loop structures vibrate the most. This is in line with our understanding of the stabilization of secondary structure by N–H ··· O=C hydrogen bonds between main-chain peptide groups; this hydrogen bonding also affects the thermal vibration of the associated side chains. Molecular dynamics studies based on the X-ray crystal structure atomic coordinates[37] also show the same tendency in the positional fluctuations of the main-chain and side-chain atoms illustrated in Figure 5.

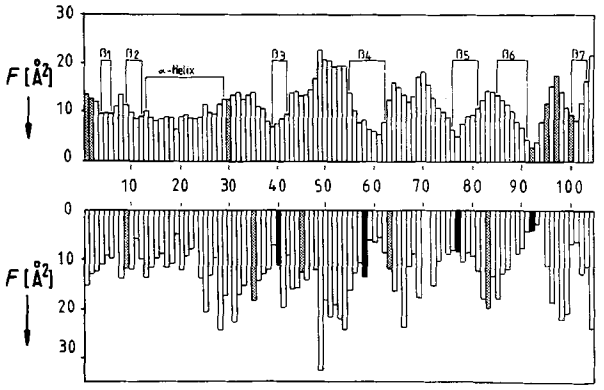

Fig. 5. Local mobility within the RNase T1 molecule represented by the mean crystallographic temperature factors of backbone (top) and side-chain atoms (bottom). Solid histogram bars mark the catalytically important residues His40, Glu58, Arg77, and His92, which are located near mobility minima. Amino acid side chains and main-chain portions involved in crystal lattice contacts have stippled bars.

The solution structure of RNase T1 has been investigated by 2D NMR techniques in the laboratory of *H. Rüterjans*.[38] There is no significant difference between the solid-state and solution-state structures of the wild-type enzyme, and the NMR data are also consistent with the X-ray structure for the His92 Ala mutant. In the low-resolution tertiary structure derived from NMR spectroscopy, especially the secondary structure of RNase T1 agrees well with that determined in the crystalline state. In addition, since the interpretation of the NMR data relies strongly on molecular dynamics methods, the distribution of thermally more rigid and more flexible sections of the RNase T1 structure in solution is also consistent with Figure 5.

2.4. Conserved Water Molecules and a Bound Metal Ion Are Integral Parts of the RNase T1 Structure

In the complex between RNase T1 and 2′-GMP, about 90 water molecules were located in the asymmetric unit and, after generation of symmetry-related water molecules, about 150 water molecules surround each RNase T1 molecule.[16] Comparison of hydrated RNase T1 molecules observed in four different crystal structures showed that about 30 water molecules are in the "same" position, that is, within 0.5 Å of the mean position. These water molecules are considered as conserved and integral parts of the RNase T1 molecular structure.[39]

Some of the conserved water molecules cross-link different parts of the RNase T1 polypeptide chain and help to stabilize its three-dimensional folding. One water molecule is simultaneously hydrogen-bonded to Tyr68 (O_η) and the peptide N–H groups of Ser35 and Asn36; one is in a strategic position and coordinates Cys6 (O), Ser8 (N), Asn9 (N_δ), Asp76 (O_δ), and Thr93 (O_γ); one connects the C-terminal carboxylate of Thr104 with the N-terminal Cys2 (O); three water molecules stabilize the loop structure at the C-terminus of the α-helix. Most notable is a chain of ten hydrogen-bonded water molecules. Waters 1 to 5 of this chain are anchored at the indole N atom of Trp59 and stitch together the narrow loop, residues 60 to 68 (Fig. 2); they are buried between this loop and the α-helix and inaccessible to solvent. Waters 5 to 8 of the chain coordinate to the metal ion ($Ca^{2\oplus}$ in the investigated structures), and waters 9 and 10 are hydrogen-bonded to side chains at the N-terminus of the α-helix.

The $Ca^{2\oplus}$ ion is eightfold coordinated in the form of a dodecahedron with trigonal faces[20,21] (Fig. 6). Its ligands

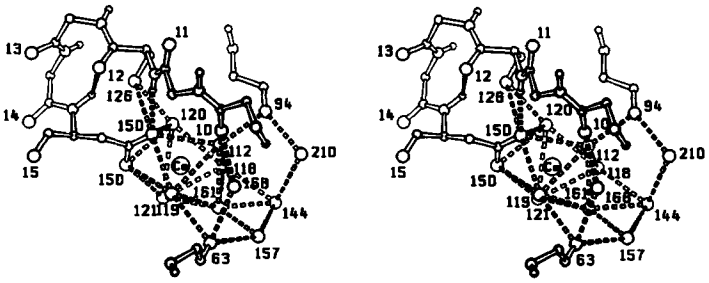

Fig. 6. Stereoview of the calcium binding site of RNase T1.

are the two carboxylate oxygens of Asp15 and six water molecules, four of which belong to the ten-water chain. The water molecules of the dodecahedron are additonally hydrogen-bonded to the main-chain C=O groups of residues 10, 12, and 63. The spatial arrangement of these carbonyl oxygen atoms and of the ten-water chain appears to be suitable to support the formation of a cation coordination site since, besides $Ca^{2\oplus}$, other cations bind to and structurally stabilize the RNase T1 molecule (see Section 3.5).

3. Experimental Studies of the Conformational Stability

The conformational stability of a globular protein, $\Delta G(H_2O)$, is defined as the difference in free energy between the folded and unfolded conformations under physiological conditions. In Section 3.1 we briefly describe how the conformational stability is measured,[40,41] and in the following sections we discuss experimental studies of the conformational stability of RNase T1 as a function of the variables of most interest to biochemists: temperature, pH, salt concentration, disulfide bond content, and amino acid sequence. The results provide insight into the structural features and forces that stabilize this small globular protein.

3.1. Measuring the Conformational Stability

When a protein unfolds, the unique three-dimensional structure, such as that shown in Figure 2, is disrupted and the protein approaches a randomly coiled conformation (see Section 3.6).[41–45] This is such a dramatic conformational change that it can be followed by almost any physical technique. For example, the near-UV absorption spectra of folded and unfolded RNase T1 are shown in Figure 7 (top). RNase T1 contains a single tryptophan residue that is completely buried and nine tyrosine residues that are, on the average, 82% buried in the interior of the folded protein.

The exposure of these residues to solvent on unfolding is the major factor that contributes to the observed blueshift in the absorption spectrum.[46] The intrinsic fluorescence spectra of folded and unfolded RNase T1 are shown in Figure 7 (bottom). The decrease in the fluorescence intensity arises because the buried Trp side chain is transferred from a nonpolar to a polar environment by unfolding and also because energy transfer from the nine Tyr residues to the Trp residue is less efficient after unfolding.[47]

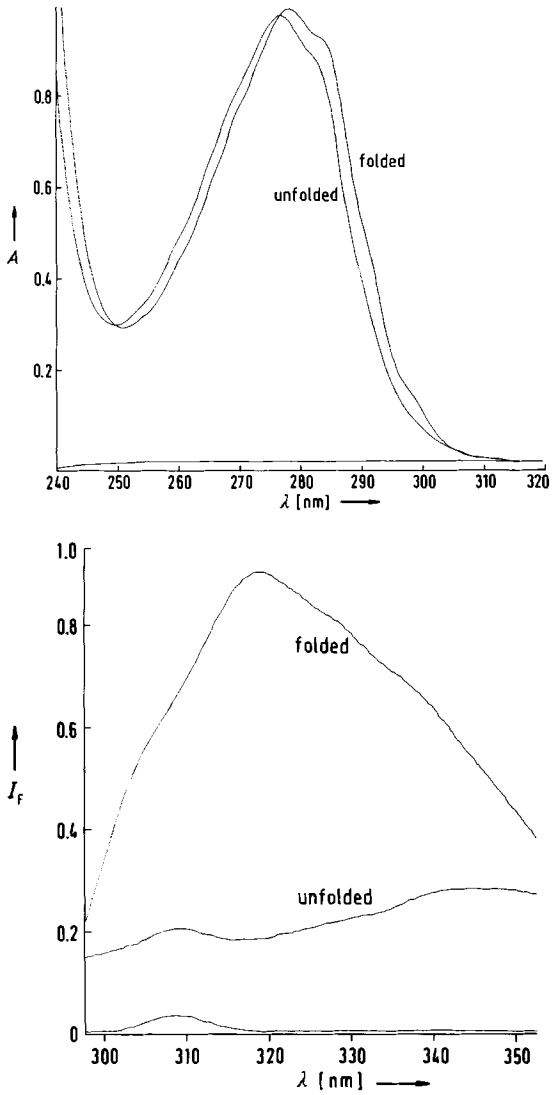

Fig. 7. Top: Absorption spectra of folded and unfolded (8 M urea) RNaseT1 (0.52 mg mL^{-1}) [41]. Bottom: Fluorescence emission spectra for folded and unfolded (8 M urea) RNase T1 (278-nm excitation wavelength, 0.01 mg mL^{-1} RNase T1) [40].

Two typical urea unfolding curves determined using fluorescence measurements are shown in Figure 8 (top), and two typical thermal unfolding curves determined using UV absorption measurements are shown in Figure 8 (bottom). Note that unfolding occurs as a steep, single step reflecting the cooperativity of this process. To analyze these curves, we assume a two-state folding mechanism [Eq. (a)], where only

folded (native) $\rightleftharpoons$ unfolded (denatured) (a)

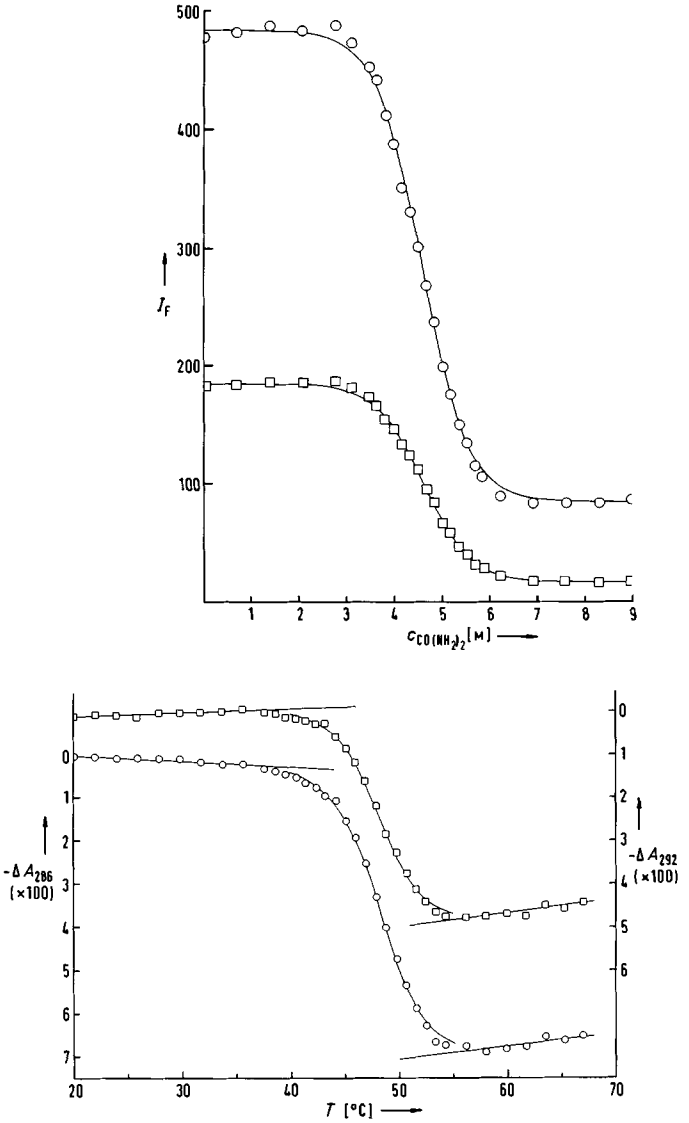

Fig. 8. Top: Urea unfolding curves for RNase T1 as a function of urea concentration $c_{CO(NH_2)_2}$ at 25 °C and pH 7 in 30 mM MOPS buffer (MOPS = 3-*N*-morpholinopropanesulfonic acid, sodium salt), monitored by measuring the fluorescence intensity at 320 nm after excitation at 278 nm (○) or 295 nm (□). Bottom: Thermal unfolding curves for RNase T1 as a function of temperature at pH 7 in 30 mM MOPS buffer, monitored by measuring the absorbance difference at 286 nm (○) or 292 nm (□) [41].

the folded and unfolded conformations are present at significant concentrations at equilibrium. This allows us to calculate the fraction of unfolded molecules, F_u, in the transition region with Equation (b), where y is the parameter used to follow unfolding, and y_f and y_u are the values of y characteristic of the folded and unfolded conformations. The values y_f

$$F_u = (y_f - y)/(y_f - y_u) \quad \text{(b)}$$

and y_u are obtained by extrapolating the pre- und post-transition baselines into the transition region. Figure 9 shows F_u values as a function of urea concentration derived from measurements made by four experimental techniques. The agreement of these measurements indicates that the concentration of partially folded intermediates present at equilibrium is low. This and other evidence supports the analysis of equilibrium data with a two-state folding mechanism.[41, 48]

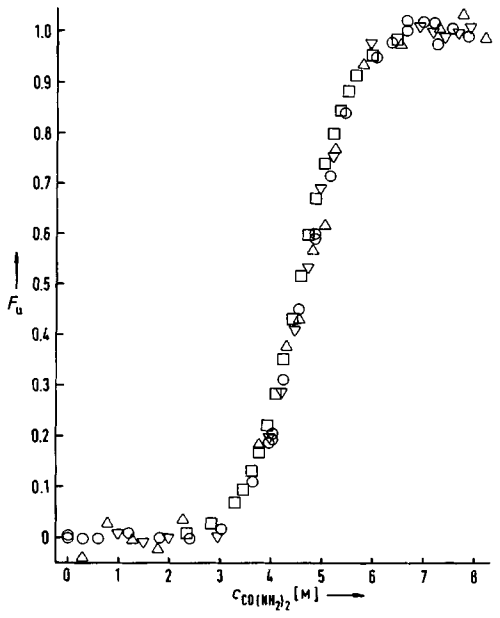

Fig. 9. Fraction unfolded RNase T1 as a function of urea concentration calculated with Equation (b). The following techniques were used to follow unfolding [41]: △, circular dichroism (CD) at 238 nm; ▽, UV absorption at 287 nm; ○, optical rotary dispersion (ORD) at 295 nm; □, fluorescence intensity at 320 nm.

Using kinetic methods, *Schmid*'s group has shown, in contrast, that partially folded intermediates can be detected during the transient phase of refolding.[48] (The unfolding of RNase T1 by urea or guanidine hydrochloride is a completely reversible reaction.) The intermediates formed very early during folding have extensive secondary structure, and there is great interest in characterizing these intermediates since this will give us a better understanding of the mechanism of protein folding.[49] RNase T1 refolds in three major phases: a fast phase that is completed in less than a second, and two slow phases that require minutes to hours.[48] As with many other proteins, the slow phases can be explained by the proline model:[50] the configuration of the Tyr 38–Pro 39 and Ser 54–Pro 55 peptide bonds is *cis* in folded RNase T1, but will be predominantly *trans* in the unfolded state; the *trans*/*cis* isomerization of these bonds gives rise to the slow folding phases. This was confirmed by replacing Ser 54–Pro 55 with Gly 54–Asn 55.[51] The conformational stability of this mutant is only about 0.9 kcal mol^{-1} less than that of wild-type RNase T1, but one of the two slow phases of folding is now absent, and the mechanism of folding is much simpler since there is now only one slow folding species rather than three.[51]

Equation (c) can be used to calculate the free energy of unfolding, ΔG, as a function of urea concentration or temperature from results such as those shown in Figure 8; R is the gas constant and T is the absolute temperature. ΔG is

$$\Delta G = -RT\ln[F_u/(1-F_u)] = -RT\ln[(y_f - y)/(y - y_u)] \quad (c)$$

found to vary linearly with urea concentration (Fig. 10), and $\Delta G(H_2O)$ is obtained by extrapolating to zero concentration of urea.[40] Recent theoretical[52] and experimental studies[53, 54] support the use of a linear extrapolation, but other means of extrapolation have been used in the past.[40, 44, 55]

Estimates of ΔG at 25 °C can also be obtained from thermal unfolding curves (see Section 3.3) or from calorimetric data.[45]

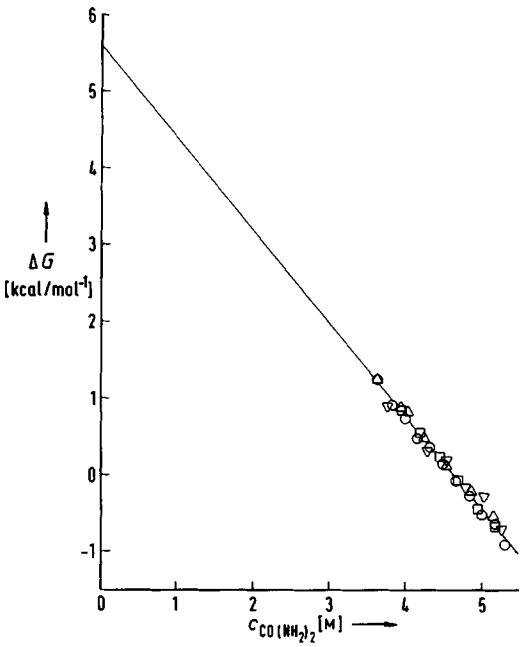

Fig. 10. ΔG as a function of urea concentration. The ΔG values were calculated with Equation (c) using data obtained by the techniques shown in Figure 9. The solid line was calculated with the following equation [41]: $\Delta G = \Delta G(H_2O) - m(CO(NH_2)_2)$, where $m = 1.21$ kcal mol^{-1} M^{-1} and $\Delta G(H_2O) = 5.6$ kcal mol^{-1}.

3.2. The Conformational Stability of Globular Proteins Is Surprisingly Low

"The tendency to assume a unique stable conformation in a 'physiological' medium is characteristic of the globular proteins . . . it is probably not a property of polypeptide chains in general. The natural proteins, numerous as they are, represent only a tiny fraction of the vast number of possible combinations of amino acid residues. The great majority of these possible sequences may have no tendency, in any solvent medium whatever, to assume a unique conformation."

J. T. Edsall[56]

"The stability must be great enough for the protein to find and maintain its native conformation relative to other conformations, but not so great that conformational changes or adjustments, considered an integral part of many protein functions, are precluded."

W. J. Becktel, J. A. Schellman[57]

Estimates of the conformational stability, $\Delta G(H_2O)$, as well as some pertinent structural information for RNase T1 and a number of other proteins, are given in Table 2. The conformational stability of almost all naturally occurring globular proteins lies between 5 and 15 kcal mol^{-1}. It appears to be advantageous to living organisms to have proteins in which the folded, biologically active conformation is only marginally more stable than an unfolded, inac-

For each protein, the identification code of the atomic coordinate set from the Protein Data Bank at Brookhaven National Laboratories is given in parentheses, followed by the reference for the estimate of $\Delta G(H_2O)$. [b] Number of amino acid residues. [c] Number of disulfide bonds. [d] Percentage content of different classes of amino acid side chains: c = charged side chains (Asp, Glu, Lys, Arg); p = polar side chains (Tyr, Ser, Thr, Asn, Gln, His); np = nonpolar side chains (Gly, Ala, Pro, Val, Ile, Leu, Cys, Met, Phe, Trp). [e] The percentage of the nonpolar side chains which are buried. For each side chain the accessibility was determined according to the program developed by *Lee* and *Richards* [66]. [f] The number of intramolecular hydrogen bonds for each protein was estimated as described by *Presta* and *Rose* [67].

tive conformation. The reasons for this are not clear. It may be important to the function of a protein as *Becktel* and *Schellman* suggest,[57] or it may play a role in metabolic regulation by influencing the levels of key enzymes through protein turnover.[68] Extending *Edsall*'s thoughts,[56] it might be argued that it is not possible to make the globular conformation of a protein significantly more stable through changes in the amino acid sequence. However, a protein based on a four-helix bundle has been constructed with a conformational stability of 22.5 kcal mol^{-1},[69] and single amino acid substitutions have been found that increase the conformational stability of globular proteins by 4.2,[70] 4.8,[71] and 9.7[72] kcal mol^{-1} (see Section 3.7). Thus, it seems likely that evolution could have generated more stable proteins if they were desired.

3.3. RNase T1 Can Be Unfolded by Heating or Cooling

At pH 7, RNase T1 is most stable at $-5\,^{\circ}C$ (≈ 8 kcal mol^{-1}); the stability decreases at both higher and lower temperatures, as indicated by the protein stability curve (Fig. 11)[57]. The interesting temperature dependence is described by a form of the Gibbs–Helmholtz equation [Eq. (d)], where $\Delta G(T)$ is ΔG at temperature T, T_m is the midpoint

$$\Delta G(T) = \Delta H_m(1 - T/T_m) - \Delta C_p[(T_m - T) + T\ln(T/T_m)] \quad (d)$$

of the thermal unfolding curve, ΔH_m is the enthalpy change for unfolding measured at T_m, and ΔC_p is the difference in heat capacity between the unfolded and folded conformations.[57] All of these parameters can be determined from either thermal unfolding curves[40] or from data obtained with a differential scanning calorimeter (DSC).[73] In Figure 11, the ΔG values below 40 °C are $\Delta G(H_2O)$ values from urea unfolding curves and they were used to estimate ΔC_p.[53] The ΔG values above 40 °C were obtained from thermal unfolding curves. The temperature of maximum stability, T_s,

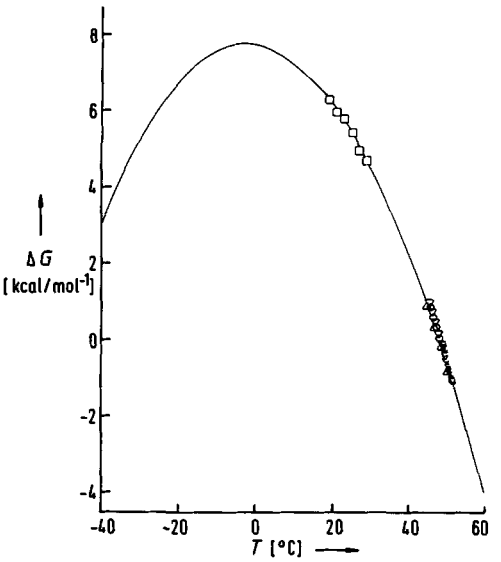

Fig. 11. ΔG as a function of temperature for the unfolding of RNase T1 at pH 7. The data points below 30 °C are from urea unfolding curves, and those above 40 °C are from thermal unfolding curves. The solid line was calculated with Equation (d) using the following thermodynamic parameters [53]: T_m = 48.1 °C, ΔH_m = 97.1 kcal mol^{-1}, ΔC_p = 1.65 kcal mol^{-1} K^{-1}, $\Delta G(25\,^{\circ}C)$ = 5.6 kcal mol^{-1}.

occurs at the temperature where $\Delta S = 0$ and is given by Equation (e). T_s is $-5\,^{\circ}C$ for RNase T1 and lies between

$$T_s = T_m \exp(-\Delta H_m/(T_m \Delta C_p)) \quad (e)$$

-10 and 35 °C for the proteins that have been studied to date. *Brandts* was the first to recognize the importance of ΔC_p in the thermodynamics of proteins folding,[74] and cold denaturation was first observed directly by *Pace* and *Tanford*[75] with β-lactoglobulin. Recent studies of T4 lysozyme,[64] myoglobin,[76] and staphylococcal nuclease[77] have shown that, for these proteins, T_s occurs above 0 °C, so that both low- and high-temperature unfolding can be observed directly.

The large positive value of ΔC_p for protein unfolding gives rise to a strong temperature dependence for ΔH and ΔS. In this case, Kirchhoff's law is given by Equation (f), where

$$\Delta C_p = C_p(u) - C_p(f) = d(\Delta H)/d(T) \quad (f)$$

$C_p(u)$ and $C_p(f)$ are the heat capacities of the unfolded and folded conformations, respectively. Thus at pH 7, ΔH increases from ≈ 18 kcal mol^{-1} at 0 °C to 97 kcal mol^{-1} at T_m (48.1 °C) for the unfolding of RNase T1. This thermodynamic behavior is observed for any reaction in which hydrophobic interactions are important. When a protein unfolds, the buried nonpolar side chains are brought into contact with water. (As shown in Table 2, 80–85% of the nonpolar side chains are buried in the folded conformation of all but the smallest globular proteins.) In the unfolded state these side

chains are clathrated by water molecules. The heat capacity of the unfolded protein is greater than that of the folded protein, because now these clathrates must melt in order to raise the temperature. Thus, the same effect that gives rise to hydrophobic interactions also gives rise to the large ΔC_p value that dominates the thermodynamics of protein folding.[73, 78–80]

3.4. RNase T1 Is Most Stable Near the Isoelectric Point

At 25 °C, RNase T1 is most stable ($\Delta G(H_2O) \approx 8.9$ kcal mol^{-1}) near pH 4.5, where the net charge is close to zero (Fig. 12). The pH dependence of the conformational stability of a globular protein will depend mainly on two related factors: (1) electrostatic interactions due to the charged groups and (2) differences between the pK values of the ionizable groups in the folded and unfolded conformations.[43, 81–84] The locations of the charged groups on the surface of RNase T1 at pH 7 are shown in Figure 13. At zero net charge, RNase T1 has seven positive charges (3 His, 2 Lys, 1 Arg, and 1 α-amino) and a total of seven negative charges from the 13 carboxylate groups (6 Asp, 6 Glu, and 1 α-carboxyl).

The charges on the surface of globular proteins are generally arranged so that a preponderance of favorable over unfavorable electrostatic interactions among the charged groups contributes favorably to the conformational stability.[85] When the protein unfolds, the charges will be further apart and the effective dielectric constant increased; consequently, electrostatic interactions will be substantially reduced, especially at moderate salt concentrations. There has been considerable interest recently in theoretical calculations of electrostatic effects in proteins.[86] These calculations are fraught with problems. For example, it is very difficult to represent the effective dielectric constant[87, 88] and to take into account solvation.[89] In addition, reliable experimental data with proteins to test the models are scarce. Calculations of the electrostatic interactions for RNase T1 by *Wodak*'s group[88] are discussed in Section 4.4.

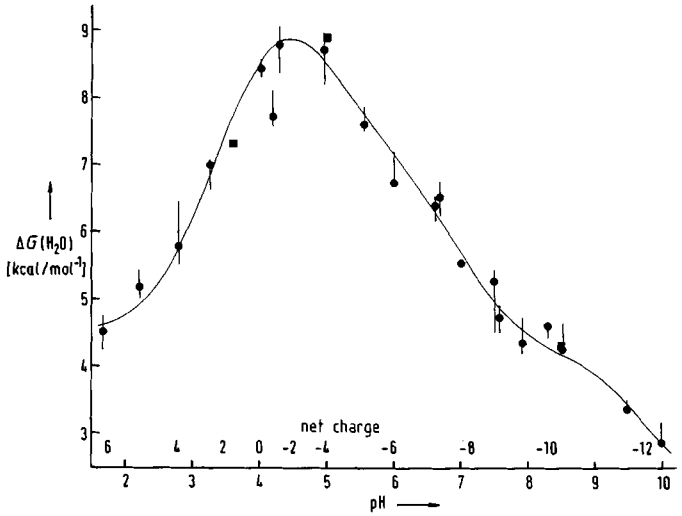

Fig. 12. $\Delta G(H_2O)$ as a function of pH for the unfolding of RNase T1 at 25 °C. The approximate net charge given is based on the titration curve for RNase T1 [84]. The solid curve was calculated using the following pK values for the folded conformation, pK_f, and unfolded conformations, pK_u: 3 Asp, pK_f = 2.7, pK_u = 4.1; 2 Glu, pK_f = 5.5 and 5.7, pK_u = 4.5; 2 His, pK_f = 7.2 and 7.8, pK_u = 6.4; 5 Tyr, pK_f = 9.9, pK_u = 9.6 [60].

The results in Figure 12 do allow one conclusion that also applies to RNase A.[60] The conformational stability of RNase T1 is reduced by about 6 kcal mol^{-1} at pH 10, where the net charge on the molecule is about −12 and repulsive electrostatic interactions should predominate. This suggests that electrostatic interactions involving the charges on globular proteins make a relatively small contribution to their conformational stability, probably much less than hydrogen bonding and hydrophobic interactions (see Sections 4.2 and 4.3).

Another important contribution to the pH dependence of $\Delta G(H_2O)$ results from differences between the pK's of groups in the folded and unfolded conformations.[43, 90] For RNase T1, the 6-kcal mol^{-1} increase in $\Delta G(H_2O)$ on going from pH 10 to 5 results mainly from the presence of groups that bind protons more tightly (higher pK's) in the folded

Fig. 13. Stereoview of RNase T1 showing the location of the basic side chains in blue and the acidic side chains in red.

than in the unfolded conformations and thereby shift the equilibrium toward the folded conformation and increase the stability. NMR titrations have shown that the pK's of the His residues are 7.9 (His92), 7.8 (His40), and 7.3 (His27) in folded RNase T1,[91] and a pK of about 6.6 would be expected for the His residues in the unfolded conformations. This alone would account for a change of over 4 kcal mol^{-1} in $\Delta G(H_2O)$ with pH.[60] Higher pK's are expected when the net charge on the molecule is negative, and lower pK's are expected when the net charge is positive. Thus, the entire decrease in $\Delta G(H_2O)$ at low pH can be explained by the presence of three Asp residues with pK's of 2.7 in the folded and 4.1 in the unfolded conformations. A set of pK's that gives the pH dependence shown by the solid line in Figure 12 is given in the figure legend. This set of pK's has been chosen arbitrarily to fit the observed data and is obviously not the only possible combination of pK differences that would account for the observed dependence of $\Delta G(H_2O)$ on pH.

Thus, both pK differences and electrostatic interactions among the charged groups will tend to favor the maximum conformational stability of ribonuclease T1 near the isoelectric pH, as is generally observed with globular proteins.

3.5. Specific Binding to the Folded Conformation Stabilizes RNase T1

The conformational stability of RNase T1 is increased by salts and can be almost doubled by adding 0.2 M Na_2HPO_4 (Fig. 14). This remarkable increase in the conformational

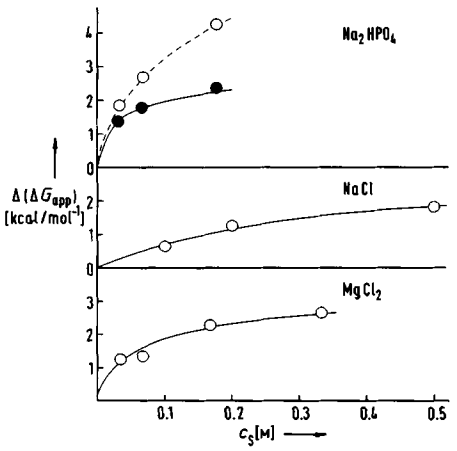

Fig. 14. Change in ΔG, $\Delta(\Delta G)$, for the unfolding of RNase T1 as a function of salt concentration. For Na_2HPO_4, the contribution of the $Na^{\oplus}$ ions was substracted from the $\Delta(\Delta G)$ values for Na_2HPO_4 to give the contribution of $[HPO_4]^{2\ominus}$ to $\Delta(\Delta G)$ (●). The solid lines were calculated with Equation (g) using the following binding constants: 155 M^{-1} for $MgCl_2$, 6.2 M^{-1} for NaCl, and 282 M^{-1} for Na_2HPO_4 [92].

stability results primarily from the preferential binding to folded RNase T1 of one divalent cation or two monovalent cations at a cation binding site involving Asp 15, or the binding of one $[HPO_4]^{2\ominus}$ ion at an anion binding site (the active site)[92] (see Figs. 4 (middle) and 6). The relationship between the increase in the conformational stability, $\Delta(\Delta G)$, the free concentration of the compound bound, [L], and the binding constant, K, is given by Equation (g).[43, 93, 94] Only

$$\Delta(\Delta G) = \Delta G(L) - \Delta G(L = 0) = RT \ln(1 + K[L]) \qquad (g)$$

modest binding constants, 6.2 ($Na^{\oplus}$), 155 ($Mg^{2\oplus}$), and 282 M^{-1} ($[HPO_4]^{2\ominus}$), are required to account for the enhanced stability.[92] One important goal of the modification of proteins through genetic engineering is to increase their stability. Our results suggest that the creation of specific cation and anion binding sites on the surface of a protein through amino acid substitutions might be a generally useful way of increasing their conformational stability. The design of these sites will be aided by the recent availability of detailed structural information on cation and anion binding sites in proteins.[20, 21, 95]

The use of specific ligand binding to stabilize a protein is not a new idea. In 1890, *O'Sullivan* and *Thomson* reported:[96] ". . . we have shown that invertase when in the presence of cane sugar will stand without injury a temperature fully 25 °C higher than in its absence. This is a striking fact, and as far as we can see, there is only one explanation of it, namely, the invertase enters into combination with the sugar." Since then, many aspects of the stabilization of enzymes by substrates and inhibitors have been studied.[97] For example, we have measured the stabilization of lysozyme by tri-*N*-acetylglucosamine[94] and the stabilization of RNase T1 by the inhibitor 2'-GMP. The presence of just 80 μM 2'-GMP increases the conformational stability of RNase T1 by over 0.5 kcal mol^{-1}. An obvious advantage of using ion binding for stabilization, rather than an inhibitor, is that it need not interfere with the functioning of the active site of the enzyme.

3.6. Disulfide Bonds Stabilize RNase T1 by Raising the Free Energy of the Unfolded Conformations

The 2–10 disulfide bond in RNase T1 is about 90% accessible to solvent, but the 6–103 disulfide bond is completely buried (Fig. 2). Thus, it is not surprising that the 2–10 disulfide bond is reduced more rapidly than the 6–103 disulfide bond, so that a derivative can be prepared with just the 2–10 disulfide bond broken.[98] To investigate the contribution of the disulfide bonds to the conformational stability of RNase T1, derivatives with one or both disulfide bonds broken have been prepared.[99] The activity, melting temperature, and conformational stability of these derivatives are listed in Table 3. Breaking the 2–10 disulfide bond lowers the conformational stability by over 3 kcal mol^{-1}, and breaking both disulfide bonds lowers the stability by 7–9 kcal mol^{-1} depending on the blocking group. Thus, disulfide bonds make a significant contribution to the stability of RNase T1. This is particularly interesting because barnase, a homologous ribonuclease with a similar folded conformation,[100, 101] is more stable than RNase T1, yet it contains no disulfide bonds.[71, 102]

The five proteins in Table 2 that contain disulfide bonds all unfold when the disulfide bonds are broken. Only RNase T1 refolds and functions with both disulfide bonds broken and the cysteine residues carboxymethylated. The results with RNase T1 are not unique. For both RNase A[103] and

lysozyme,[104] enzymatically active derivatives have been prepared in which two of the four disulfide bonds that are largely buried are broken and the cysteine residues blocked. These studies indicate that the folded conformations of proteins are to some extent flexible,[105] as also suggested by H–D exchange experiments in the crystalline state.[106]

Table 3. Activity, melting temperature, and conformational stability of RNase T1 and derivatives with one or both disulfide bonds broken [a] [99].

Protein	Activity [b] [%]	T_m [c] [°C]	$\Delta G(H_2O)$ [d] [kcal mol^{-1}]	$\Delta(\Delta G)$ [kcal mol^{-1}]
RNase T1	100	59.3	10.2	
(2–10)-RCM-T1	86	53.5	6.8	3.4
R-T1	53	27.2	3.0	7.2
RCAM-T1	43	21.2	1.5	8.7
RCM-T1	35	16.6	0.9	9.3

[a] (2–10)-RCM-T1 = RNase T1 with the 2–10 disulfide bond broken and the cysteine residues carboxymethylated; R-T1 = reduced RNase T1; RCAM-T1 = reduced carboxamidomethylated RNase T1; RCM-T1 = reduced carboxymethylated RNase T1. All of the experiments were done in 0.1 M sodium formate buffer, pH 5.0, containing 0.25 M NaCl. [b] RNA hydrolysis at 5 °C. [c] Midpoint of the thermal unfolding curve. [d] Conformational stability at 12.5 °C.

The notion that proteins with their disulfide bonds broken approach a randomly coiled conformation in 6 M guanidine hydrochloride (GdnHCl) or 8 M urea[42] may be incorrect. Recent studies on wild-type and mutant staphylococcal nuclease[107] and on several other proteins without disulfide bonds whose unfolded states differ significantly in their interaction with denaturants[60] suggest that the conformations assumed by unfolded proteins are not "random" and depend to at least some extent on the amino acid sequence of the protein. This suggests that the unfolded states of proteins may have a larger effect on the conformational stability of globular proteins than had been generally thought.[107] Since RCM- and RCAM-RNase T1 (Table 3) have melting temperatures below 25 °C, the unfolded states existing under physiological conditions can be compared with the unfolded states existing at higher temperatures and in the presence of GdnHCl or urea. Thus, RNase T1 provides a good model for reaching a better understanding of the unfolded states of proteins.

Disulfide bonds increase the conformational stability mainly by constraining the unfolded conformations of the protein and thereby decreasing their conformational entropy. Based on our results and other experimental evidence, we have proposed Equation (h) for predicting the effect of a cross-link on the conformational entropy of a protein, where n is the number of residues in the loop forming the cross-link.[99] Equation (h) predicts that the conformational stability of a protein will be raised by 3, 4, and 5 kcal mol^{-1} by adding loops of 15, 45, and 135 residues, respectively. In globular proteins, 49% of the disulfide bonds are separated by less than 24 residues and the average separation is 15 residues.[108]

$$\Delta S_{conf} = -2.1 - (3/2)R \ln n \qquad \text{(h)}$$

These results suggest that adding disulfide bonds would be a good means of making proteins more stable, but the first results have been discouraging. Seven different disulfide bonds were added to subtilisin, and none of the resulting proteins was more stable than wild type.[109] This indicates that it is difficult to add a disulfide bond to a protein without introducing some strain in the folded conformation and thereby destabilizing the protein. Recent results with T4 lysozyme were more encouraging.[110] Three different disulfides have been added and they raise the T_m's of the resulting proteins by 5, 6, and 11 °C. When all of the disulfides were incorporated in the same protein, T_m was increased by 23 °C.

3.7. RNase T1 Can Be Stabilized or Destabilized by Amino Acid Substitutions

We are using mutants prepared by site-directed mutagenesis to learn more about the forces that contribute to the conformational stability of RNase T1.[5, 111] Some of our first results with a mutant of RNase T1 that increases the conformational stability by about 0.9 kcal mol^{-1} and one that decreases the stability by about 0.8 kcal mol^{-1} are presented in Table 4. In the double mutant, these two contributions cancel and the stability does not differ significantly from that of wild-type RNase T1.

Table 4. Parameters characterizing the "urea and thermal unfolding" of RNase T1 and three mutants at pH 7.0 in 30 mM MOPS buffer [111].

	Urea unfolding			
Protein [a]	$\Delta G(H_2O)$ [b] [kcal mol^{-1}]	m [b] [cal mol^{-1} M^{-1}]	$[urea]_{1/2}$ [b] [M]	$\Delta(\Delta G)$ [c] [kcal mol^{-1}]
Wild type (*A. oryzae*)	5.62	1240	4.53	
Wild type (clone)	5.61	1235	4.54	
Gln25 → Lys	6.39	1210	5.30	0.94
Glu58 → Ala	4.72	1200	3.92	−0.77
Double mutant	6.29	1360	4.58	0.05

	Thermal unfolding				
Protein [a]	ΔS_m [d] [cal mol^{-1} K^{-1}]	ΔH_m [d] [kcal mol^{-1}]	T_m [d] [°C]	$\Delta G(25)$ [e] [kcal mol^{-1}]	$\Delta(\Delta G)$ [f] [kcal mol^{-1}]
Wild type (*A. oryzae*)	298	96	48.3	5.5	
Wild type (clone)	288	93	49.3	5.5	
Gln25 → Lys	330	107	51.7	6.9	0.93
Glu58 → Ala	270	86	46.0	4.5	−0.78
Double mutant	299	93	48.8	5.4	0.06

[a] The naturally occurring RNase T1 isoform Lys25-RNase T1 is here referred to as mutant Gln25 → Lys. [b] A least-squares analysis was used to fit plots of ΔG vs. urea molarity to the following equation: $\Delta G = \Delta G(H_2O) - m(\text{urea})$. $[urea]_{1/2}$ = midpoint of the urea unfolding curve. [c] $\Delta(\Delta G) = \Delta([urea]_{1/2}) \times m(\text{wild type})$. This equation gives $\Delta(\Delta G)$ at a urea concentration between the respective $[urea]_{1/2}$ values. [d] T_m = midpoint of the thermal unfolding curve; ΔS_m and ΔH_m are the entropy and enthalpy change at T_m. [e] ΔG at 25 °C, $\Delta G(25)$, was calculated using Equation (d) with ΔC_p = 1650 cal mol^{-1} K^{-1} [53]. [f] $\Delta(\Delta G) = \Delta(T_m) \times \Delta S_m(\text{wild type})$. This equation gives $\Delta(G)$ at a temperature between the respective T_m values.

The Gln25Lys mutation occurs in the α-helix of RNase T1 at a site that is largely exposed to solvent (Fig. 2). It is encouraging that this substitution increases the conformational stability by almost 1 kcal mol^{-1} without changing the activity. The Glu58Ala mutant was of interest because Glu58 is a central residue at the active site of RNase T1 (Fig. 4, middle) and has a unique chemical reactivity.[4] More recent studies of this mutant have shown an interesting pH dependence: wild-type RNase T1 is more stable than the

mutant below pH 7.5 and less stable above pH 7.5.[60b] This results because the average pK of the His residues is reduced from 7.6 in wild-type RNase T1 (see Section 3.4) to 7.1 in the mutant. The major effect is on His 40, whose pK is reduced from 7.9 in wild-type RNase T1 to 7.1 in the mutant. This confirms a suggestion by *Rüterjans* and *Pongs*[39c] made long before the structure of RNase T1 was known that the high pK results because His 40 ". . . is interacting with a carboxylate anion of an acidic amino acid residue . . ." Both of these mutations are complex, and changes in conformational entropy, hydrogen bonding, electrostatic interactions, and hydrophobic bonding probably all contribute to the observed differences in conformational stability.

Genetically engineered or natural mutations generally decrease the stability of a protein, but some single amino acid substitutions have been found to give large increases in the conformational stability. This is of great interest in biotechnological applications where the goal is often to make a protein as stable as possible.[112–115] In barnase, T_m is increased by 12 °C and $\Delta G(H_2O)$ by 4.8 kcal mol^{-1} in the Ala 14 Leu mutant,[71] and in cytochrome c, T_m is increased by 17 °C and $\Delta G(H_2O)$ by 4.8 kcal mol^{-1} in the Asn 57 Ile mutant.[70] The conformational stability of tryptophan synthase has been measured with every amino acid except Arg at position 49, where Glu is present in the wild-type enzyme.[72] For the Glu 49 Ile mutant, $\Delta G(H_2O)$ is increased by 9.7 kcal mol^{-1}. This is the largest increase in conformational stability reported for a single change in amino acid sequence. Several studies have shown that the effects of amino acid substitution are often localized, so that their effects on stability are additive. For example, six amino acid substitutions that each increase the stability by from 0.3 to 1.3 kcal mol^{-1} have been made in subtilisin; when they are all incorporated in the same molecule, the stability is increased by 3.8 kcal mol^{-1}.[115] So far, nature and random mutagenesis have proven better at finding stable mutants than biochemists working from the three-dimensional structures of folded proteins.

4. Theoretical Studies of the Conformational Stability

In this section, we will use the information available at present about conformational entropy, hydrophobic interactions, and hydrogen bonding and other electrostatic interactions to estimate the contribution of the most important forces to the conformational stability of RNase T1. These should be regarded as order of magnitude estimates, but they serve to point out that the fragile conformational stability of RNase T1 is the result of opposing forces of much larger magnitude.

4.1. Conformational Entropy

The conformation of the backbone of a folded protein can be specified by giving the angle of rotation at each N–C_α bond, φ, and each C_α–C_{CO} bond, ψ.[116] The fact that the conformation of the backbone and most of the side chains can be determined by X-ray diffraction studies indicates that rotation around these bonds is limited in the folded protein. When the protein unfolds, rotation about these bonds will be less restricted and many more conformations will be accessible to the polypeptide chain. As a consequence, the unfolded states will have a much greater conformational entropy than the folded states, and this is the major force that favors unfolding.

In 1954, *Kauzmann*[117] suggested that a randomly coiled polypeptide chain would be able to assume z^x conformations, where x is the number of bonds about which rotation can occur and z is the number of rotational states of equal energy per bond. As a first approximation, he assumed $x = 3.33$ and $z = 2$ for each amino acid residue in a polypeptide chain. If the folded protein had only one allowed conformation, the conformational entropy, ΔS_{conf}, [Eq. (i)], would

$$\Delta S_{conf} = R \ln z^x \qquad \text{(i)}$$

favor the unfolded conformations by 4.1 cal mol^{-1} K^{-1}, or 1.2 kcal mol^{-1} per amino acid at 25 °C. This question has been considered from a different point of view by *Dill*.[118]

Privalov[45] showed that for several small compact globular proteins, the specific enthalpy of unfolding converges to a value of about 13 cal g^{-1} near 110 °C. He argued that ". . . at 110 °C, the contribution of water to the entropy of unfolding is small, and the observed effects can be attributed to the increase in configurational freedom of polypeptides on unfolding." The average value observed was 4.2 cal mol^{-1} K^{-1} for each amino acid, a value remarkably close to that *Kauzmann* proposed.

Since the folded conformations of globular proteins are not rigid structures,[105] it is surely not reasonable to assume that they can be represented by a single conformation. On the basis of theoretical calculations, *Karplus* et al.[119] suggested that the conformational entropy of a folded protein is large ($\approx$ 35 cal mol^{-1} K^{-1} per residue), but about the same as it would be for a given unfolded conformer of the same protein. Thus, perhaps just counting the number of unfolded conformations by the simple approach suggested more than thirty years ago by *Kauzmann* does provide at least a rough estimate for ΔS_{conf}, and we have used this in Table 5 to estimate the contribution of conformational entropy to the stability of RNase T1.

Disulfide bonds will limit the conformations accessible to a randomly coiled polypeptide chain and thereby reduce the conformational entropy. *Schellman*[120] and *Flory*[121] and, more recently, *Chan* and *Dill*[122] derived equations based on polymer theory[123] to estimate the magnitude of this effect in proteins. We have used Equation (h) (Section 3.6) to correct ΔS_{conf} for the restraints imposed on the unfolded conformations by the two disulfide bonds in RNase T1. This seems reasonable since Equation (h) is an empirical equation based on experimental results including those for RNase T1.[99]

4.2. Hydrophobic Interactions

In order to estimate the contribution of hydrophobic interactions to the stability of globular proteins, two pieces of information are needed. First, we need to know which nonpolar groups are removed from contact with solvent when

Table 5. Estimating the contributions of conformational entropy, hydrophobic interactions, and hydrogen bonding to the conformational stability of RNase T1.

A. *Conformational entropy*

Rotation about φ, ψ, and χ:
104 residues × − 1.2 kcal per residue [a] = − 124 kcal mol^{-1}.

Disulfide bond restraints:
$T\Delta S(-\text{SS}-) = T(2.1 - (3/2)R\ln n)$, where n is the number of amino acid residues in the loop formed by the disulfide bond [b].

RNase T1 disulfides: 2 to 10 ($n = 9$) and 6 to 103 ($n = 98$).

$T\Delta S(-\text{SS}-) = 2.6 + 4.7 \approx 7.3$ kcal mol^{-1}.

Net: $T\Delta S_{conf} = -124 + 7 = -117$ kcal mol^{-1}.

B. *Hydrophobic interactions*:

Side chain	Number present	Number buried [c]	ΔG_{tr} [d]	Number buried [c] × ΔG_{tr}
Trp	1	1.0	3.1	3.1
Phe	4	3.7	2.4	8.9
Ile + Leu	5	4.4	2.4	10.6
Val	8	6.7	1.7	11.4
Tyr	9	8.9	1.3	11.6
Cys	4	3.3	1.3	4.3
Pro	4	3.4	1.0	3.4
Thr	6	3.3	0.4	1.3
Ala	7	4.7	0.4	1.9
His	3	2.3	0.2	0.5
Ser	15	3.5	0.0	0.0
Gln	3	2.4	−0.3	−0.7
Asn	9	5.0	−0.8	−4.1
-CH_2- [e]	23	16.6	0.7	11.6

Net: Hydrophobic interactions = 64 kcal mol^{-1}.

C. *Hydrogen bonding*
Folded RNase T1 contains 96 marginal to good hydrogen bonds [f].
96 H bonds × 0.76 kcal per H bond [g] = 73 kcal mol^{-1}.

Folded RNase T1 has four peptide NH and two peptide C=O groups that are not hydrogen-bonded and are completely buried [h]. All side-chain oxygen atoms are hydrogen-bonded.

4 × 1.4 kcal per NH H bond [h] + 2 × 2.8 kcal per C=O H bond [h] = − 11 kcal mol^{-1}.

Net: H bonding = 73 − 11 = 62 kcal mol^{-1}.

D. *Sum*
$\Delta G(H_2O) = T\Delta S_{conf}$ + hydrophobic interactions + H bonds
$\Delta G(H_2O) = -117 + 64 + 62 = 9$ kcal mol^{-1}.

[a] Based on a theoretical guess of 4.1 cal mol^{-1} K^{-1} per residue by *Kauzmann* [117] and an experimental guess of 4.2 cal mol^{-1} K^{-1} per residue by *Privalov* [45]. [b] See [99]. [c] See [66]. [d] ΔG_{tr} is the free energy change for transfer of amino acid side chains from a nonpolar medium (*n*-octanol) to water [126]. [e] The CH_2 groups in the side chains of Asp, Glu, Arg, and Lys. [f] See [16]. [g] *Fersht* [125] suggests 0.5 to 1.8 kcal mol^{-1}. 0.76 kcal mol^{-1} was chosen so that $\Delta G(H_2O)$ (experimental) = $\Delta G(H_2O)$ (theoretical). [h] *N. Pace, R. Erickson*, unpublished observations.

the protein folds, and second, we need to know the free energy change for the transfer of a given nonpolar group from water to the interior of a globular protein.

The accessibility to water of the amino acid residues in 37 monomeric globular proteins whose crystal structures have been determined at high resolution has been analyzed recently.[124] The amino acid side chains can be subdivided on the basis of their properties into charged, polar, and nonpolar side chains (Table 2). According to this classification, the solvent-accessible portion of an average globular protein contains comparable amounts of the three classes of side chains, but the buried portion contains mainly nonpolar side chains and very few charged side chains. Note that the content of nonpolar residues varies from 42 to 55% for the proteins in Table 2 and that the percentage of buried nonpolar residues increases with increasing size, as expected, reaching 86% for α-chymotrypsin.

For RNase T1, 70% of the peptide groups and 79% of the nonpolar side chains are inaccessible to water in the folded protein. Figure 15 shows which of the peptide groups and which of the side chains are at least 50% buried in folded RNase T1. The accessibility of each type of polar and nonpolar side chain is given in Table 5. For the calculations, we assume that all of these buried side chains will become fully accessible when the protein unfolds. This is probably not the case (see Section 3.6), but we have no other choice at present because our understanding of the solvent accessibility of unfolded proteins is still limited. Consequently, our estimate of the contribution of hydrophobic interactions to the stability of RNase T1 should be regarded as an upper limit.

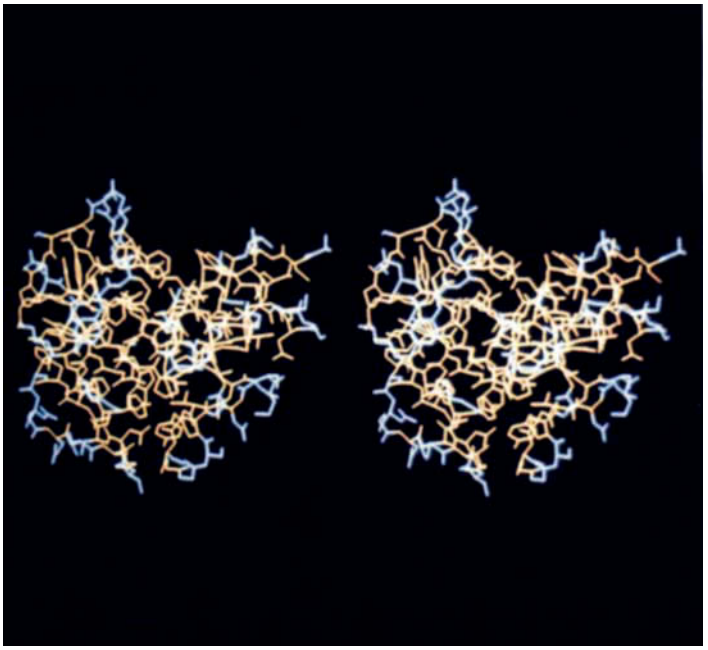

Fig. 15. Stereoview showing the buried and accessible peptide groups and side chains of RNase T1. All groups that are 50% or more accessible are shown in light blue; the remaining groups are yellow.

The free energy change for the transfer of the amino acid side chains from nonpolar environments such as *n*-octanol, hexane, or *N*-methylacetamide to water, ΔG_{tr}, has been determined experimentally in a series of studies since 1962.[126–132] No single solvent system can represent the heterogeneous interior of a globular protein, but *n*-octanol is probably a better model than more nonpolar solvents such as cyclohexane. In Table 5, we have therefore used ΔG_{tr} values for *n*-octanol for estimating the contribution of hydrophobic interactions to the stability of RNase T1.

The contribution of the hydrophobic interactions of a Val side chain to the conformational stability of a protein is illustrated in Table 6. The stability of the folded conformation is increased by 1.7 kcal mol^{-1} for each Val side chain that is buried on folding. This approach is used in Table 5 to estimate the contribution of all the polar and nonpolar side chains plus the CH_2 groups from the charged side chains to the conformational stability of RNase T1. It suggests that hydrophobic interactions restore over half of the free energy lost to conformational entropy. Some of the drawbacks of

Table 6. Contributions of hydrogen bonding and hydrophobic interactions to the conformational stability.

Interaction	ΔG [kcal mol^{-1}]
Hydrophobic interactions	
	1.7 [a]
Hydrogen bonding	
	0.5–1.8 [b]
	−4.2 [c]
	−5.8 [c]
	−3.3 [c]

[a] See [126]. ΔG_{tr} (*n*-octanol to water) values for the other side chains are given in Table 5. [b] See [125]. [c] *N. Pace*, unpublished results. The ΔG value for the OH of Tyr is 2.2 kcal mol^{-1}.

this general approach have been discussed,[71, 133–135] and a related approach that uses different model compound data has been described.[80]

4.3. Hydrogen Bonding

In an unfolded protein, the groups capable of hydrogen bonding will generally be completely hydrogen-bonded to water molecules. When a protein folds, about half of the groups form intramolecular hydrogen bonds,[136, 137] most of the rest will remain hydrogen-bonded to water, and only a few or none will be left with unsaturated hydrogen-bond donors or acceptors.[28, 136–138] The groups that are hydrogen-bonded to water in both states will not contribute significantly to the conformational stability. However, for the groups that form intramolecular hydrogen bonds and those that form no hydrogen bonds, we need to know the energetics for the hydrogen-bonding reactions and we need to know the number of groups in each category.

On the basis of experimental studies, *Fersht*[125] has suggested that intramolecular hydrogen bonds between uncharged groups will be favored over hydrogen bonds to water by from 0.5 to 1.8 kcal mol^{-1}. In a folded protein there will surely be a range of values for the contribution of individual hydrogen bonds because of differences in geometry and environment. It is reassuring that experimental studies by *Turner*'s group[139] have suggested that the net gain in stability per hydrogen bond in DNA double helices is very similar (0.5 to 2.0 kcal mol^{-1}).

The groups that do not form hydrogen bonds on folding will favor the unfolded state, where they will be able to hydrogen-bond to water. Estimates of ΔG for this process are given in Table 6. Note that the gain in stability from the formation of an intramolecular hydrogen bond between the groups in a peptide bond, 0.5 to 1.8 kcal mol^{-1}, is considerably less than the loss in stability, −4.2 kcal mol^{-1}, when the same groups fail to form a hydrogen bond when a protein folds. This is surely why the extent of hydrogen bonding in globular proteins is so high and why they have such a high content of secondary structures like α-helices and β-sheets in which the peptide N–H and C=O groups are completely hydrogen-bonded.

RNase T1 contains 293 nitrogen and oxygen atoms capable of accepting or donating hydrogen bonds, 205 backbone and 88 side-chain atoms. These atoms can form a total of 503 hydrogen bonds, 312 by the backbone and 191 by the side chains,[140] according to the hydrogen-bonding capabilities given by *Baker* and *Hubbard*.[28] Using the geometrical criteria suggested by these authors, we find that RNase T1 contains 96 marginal to good hydrogen bonds with an average N···O length of 2.98 Å.[16] Fifty-one of these hydrogen bonds are between the peptide groups in the polypeptide backbone, most of which occur in the secondary structure of RNase T1, as shown in Figure 3.

A sample of ten well-refined protein structures gave the following percentages of non-hydrogen-bonded groups: for peptide groups, 11.2% >C=O and 12.4% >N–H; for the uncharged, polar side chains, 22% Tyr, 18% Ser, 16% Thr, 17% Gln, 17% Asn; for the charged side chains, 3% Asp, 5% Glu, 2% His, 11% Arg, and 24% Lys (the value for Lys is high because this side chain wiggles more than the others and makes it difficult to assess the hydrogen bonding).[28] These percentages should be regarded as upper limits for the content of non-hydrogen-bonded groups: less tightly bound water molecules will not be seen so that some of these groups are sure to be partially hydrogen-bonded to water.

For RNase T1, we have counted the groups that are both not hydrogen-bonded and completely buried in the folded protein. No side-chain hydrogen-bonding groups meet these criteria, but four N–H groups and two C=O groups from peptide bonds do. These are the groups we have included in Table 5 to calculate the unfavorable contribution of unsaturated hydrogen-bond donors and acceptors to the conformational stability of RNase T1.

In order to estimate the contribution of hydrogen bonding to the conformational stability of RNase T1 in Table 5, we need to choose an average value for the contribution of each intramolecular hydrogen bond. We have chosen a value of 0.76 kcal mol^{-1} simply because this leads to agreement between the experimentally determined value of $\Delta G(H_2O)$ and the estimate from the analysis given Table 5. This is in the range of 0.5 to 1.8 kcal mol^{-1} suggested by *Fersht*.[125] Thus, the analysis in Table 5 suggests that the net contribution of hydrogen bonding to $\Delta G(H_2O)$ for RNase T1 is similar in magnitude to the contribution from hydrophobic interactions.

4.4. Electrostatic Interactions

"The general electrostatic interaction between the charged groups on the surface of these proteins appears not to be

energetically important for stability of the folded conformations. All of the 11 amino groups of ribonuclease A, 18 of the 19 of cytochrome c, and up to 10 of β-lactoglobulin were converted to acidic residues with only marginal changes in net stability."

Hollecker and *Creighton*[141]

The results presented in Section 3.4 suggest that electrostatic interactions among the charged groups contribute less than 6 kcal mol^{-1} to the conformational stability of RNase T1 and consequently are not a major factor. It is considerably more difficult to experimentally probe the contributions of permanent dipoles and induced dipoles to the conformational stability. Theoretical calculations by *Wodak*'s group[88] suggest that electrostatic interactions involving both the charged groups and all of the permanent dipoles destabilize the folded conformation of RNase T1. However, this may be more than offset by the favorable contribution of interactions involving induced dipoles, so that the net contribution of all of the electrostatic interactions to the conformational stability is favorable. The model of *Wodak* and colleagues attempts to take into account dielectric effects due to the protein matrix, but effects from the surrounding solvent have not yet been included.

The approach we have taken above in estimating the contribution of hydrogen bonding will take into account some, but certainly not all, of the electrostatic interactions between the permanent dipoles. Likewise, the approach used to estimate the contribution of hydrophobic interactions will account for some, but certainly not all, of the contributions of induced dipoles (London dispersion forces) to the conformational stability. The availability of experimental results on proteins in which local changes in the electrostatic interactions have been made by point mutations will allow refinement of the theoretical models so that we can reach a better understanding of the contribution of electrostatic interactions to the stability of globular proteins.

5. Summary and Outlook

RNase T1 is surely one of the most suitable proteins available for investigating the relationship between the structure of a protein and its chemical, physical, and functional properties. In this article we have summarized what is known about the structure of RNase T1 based on several high-resolution structure analyses by X-ray crystallography. We have also summarized results from a series of experimental studies of the conformational stability of RNase T1. In the final section of the article we have used the structural information and model compound data to guess at the contribution of hydrogen bonding, hydrophobic interactions, and conformational entropy to the conformational stability of RNase T1. We have discussed some of our initial results with site-directed mutants of RNase T1 that illustrate the enormous power of this technology for improving our understanding of all aspects of proteins and their function. Similar results with other proteins have been summarized in several recent reviews.[142]

The combination of structural studies in both the crystal and solution states with biophysical investigations of RNase T1 and selected mutant molecules is expected to yield insight to the structure and function of proteins in general. A very high resolution crystal structure analysis is under way and will provide the still missing fine details concerning side-chain orientations, solvation, and intramolecular hydrogen bonding. Along with kinetic studies of mutants, these structural data will help to clarify the still controversial mechanism of RNA hydrolysis by RNase T1. Similar studies of related microbial ribonucleases are in progress.[143] Further theoretical studies of RNase T1 structure, stability, dynamics, and ligand binding should be designed such that direct experimental testing of the results is possible. Very encouraging in this respect are recently developed spectroscopic methods that yield information about protein motions on a time scale accessible to molecular dynamics simulations.[144] It may be possible to identify intermediates on the folding pathway of RNase T1, as has recently been achieved for the related bacterial ribonuclease barnase.[145] Finally, it is hoped that the biology of the microbial ribonucleases will be investigated to answer obvious but entirely open questions regarding their role in nucleic acid metabolism and the origin of base specificity in these enzymes.

Fluorine-Stabilized Sulfur–Carbon Multiple Bonds

By Konrad Seppelt*

Alkylidene and alkylidyne sulfur fluorides contain sulfur–carbon multiple bonds. In contrast to the sulfur ylides, alkylidene sulfur fluorides fulfill all the criteria for double bonds, i.e. they have short bond lengths, strong anisotropic distribution of electron density, and rotation about the C–S bond is restricted. Alkylidyne sulfur fluorides have especially short bond distances and, due to a high amplitude bending motion, appear to be more or less linear, depending on the physical state. The advantage of the C–S multiple bond systems in contrast with numerous others, e.g. those of phosphorus and silicon, is that they exist without steric stabilization. Moreover, the limits of the triple-bond principle are outlined: the prognosis for triple bonds between two elements of higher periods is poor, because carbene-like or fully bridged structures win in terms of stability.

1. Introduction

In the last decade there has been a rapid development in the preparation of double bond systems with heavy main group elements which contradict the predictions of the Double Bond Rule. This development followed the investigations of compounds with metal–metal and metal–carbon multiple bonds. Among the main group elements, silicon and phosphorus have attracted most attention. The number of review articles on multiple bond systems of these elements is considerable.[1–10] Meanwhile, interest in the heavier homologues of the fourth and fifth main groups has also been aroused.[4, 5]

Independently of these developments, there has concomitantly been increased activity in the area of sulfur–carbon multiple bonds in the last few years, particularly regarding the compounds to be discussed herein with sulfur in higher oxidation states. On the one hand, the element sulfur has, until now, stood somewhat in the shadow of the elements phosphorus and silicon, not only because one always conceded that sulfur readily forms double bonds (SO_2, CS_2, and others), but also because the synthetic methods are more limited and often much more specific. On the other hand, the peculiarity of sulfur to have available three easily accessible oxidation states (II, IV, VI) can stimulate the imagination of the preparative chemist.

No compound is so unique that parallels or comparisons with other compounds or classes of compounds cannot be drawn. A new substance, which alone through its existence or its structure first causes great astonishment, after some time falls into the general picture of chemistry. Double bond systems of the type $R_2C{=}SF_4$, $R_2C{=}SF_2$, $R_2C{=}SF_2{=}O$, $R_2C{=}S{=}O$, and $R_2C{=}SO_2$ will be discussed herein and compared with the sulfur ylides $R_2\overset{\ominus}{C}{-}\overset{\oplus}{S}R'_2$ and oxosulfur ylides $R_2\overset{\ominus}{C}{-}\overset{\oplus}{S}OR'_2$. As a result, a discussion of the double bond becomes of central importance. Criteria which are measurable, or at least in principle measurable, will be drawn into the discussion: atomic spacings, electron densities, charge distribution, potentials such as vibrational energies and particularly torsional energies. MO models or their simplifications serve only occasionally to make the results plausible.

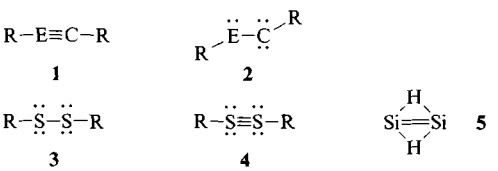
In spite of all of the remarkable success with the synthesis of such compounds, the fact remains that these double bonds still form, in the final analysis, more unfavorable bonding systems than those of elements of the second period. There is no lack of possible explanations.[11–13] A constantly repeated, simplified argument in the discussion is the increasing size of the elements, and the resulting "poor π-overlap". One can subdivide the bond energy of a double bond into a σ- and a π-increment, provided that the thermodynamic data of a large number of comparable compounds are known. Thus, one comes to the conclusion that the π increment in N=N and O=O double bonds is greater than the σ increment; in C=C double bonds both are about the same, and in all other multiple bonds the π increment is smaller.

Compounds with sulfur–carbon triple bonds of the type $R{-}C{\equiv}SF_3$ will be compared, for want of a better possibility, with the few known triple bond systems in which an element of the third or higher period takes part in the triple bond. This class of compound (R–C≡P, R–C≡As, R–N≡Si, $R_2P{\equiv}N$, $R{-}N{\equiv}P^{\oplus}$, $R_2P{\equiv}C{-}R$, $F_3S{\equiv}N$, $FS{\equiv}N$) is very heterogenous. Generally speaking triple bonds of this type are always a novelty. Naturally, the steric protection of the linear grouping of atoms of triple bond systems is much less possible than in the case of double bond systems so that the syntheses are very problematical. There are also indications that the range of existence for such triple bond systems is in principle limited. It will be shown that compound **1**



1 **2** **3** **4** **5**

offers little resistance to a sharp bending to give **2**. If one binds together two elements of the third period with a triple bond, then in these systems the "dicarbene structure" **3** will be more stable than **4**.

Even a doubly bridged structure **5** is theoretically predicted for disilaethyne.[14–19] The limitations of a bonding principle can be probed here, a particularly attractive challenge for the synthetic chemist.

2. Sulfur–Carbon Double Bonds

Sulfur–carbon double bonds have been known for some time in the form of carbon disulfide and its homologues O=C=S and S=C=Se. Subsequent findings prompted the question of why these compounds are so stable towards polymerization. The same applies here as with the outstanding stability of CO_2: The average C–O bond energy of CO_2 is clearly greater than the bond increment C–O in ketones. This is a result of the symmetry of the CO_2 molecule, in which according to a simple HMO model, each C–O bond has a bond order of 2.4.[20] CS_2 is an analogus special case.

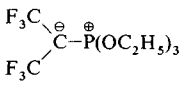
The simplest conceivable molecule with a C–S double bond $H_2C{=}S$, on the other hand, behaves "normally". This can be prepared by the elimination of HCl from $H_3C{-}S{-}Cl$, but is stable against polymerization only under reduced pressure.[21–24] Thus, thioformaldehyde was also discovered as a component of interstellar matter by means of its microwave spectrum.[25] The polymerization can be hindered by substitution at carbon, $(C_6H_5)_2C{=}S$ is already stable. Thioketones react preferably at the sulfur atom, which means indirectly that the double bond character of the C–S bond is less than in ketones. The color can also be interpreted in this way.

Sulfur ylides are also often stable in the conventional sense,[27] and even the simplest compounds $H_2\overset{\ominus}{C}{-}\overset{\oplus}{S}(CH_3)_2$ and $H_2\overset{\ominus}{C}{-}\overset{\oplus}{S}O(CH_3)_2$ are easily prepared.[28] The ylidic bond in the sulfur ylides (171–174 pm)[29] is indeed somewhat shorter than a C–S single bond ($\simeq$ 180 pm), but up to now there is no indication of a hindered rotation about the C–S bond.[30] Therefore, the conventional description as a single bond with zwitterionic bond strengthening is justifiable here.[31]

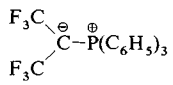
In order to strengthen the double bond character of the C–S bond, it was necessary to increase the electronegativity of the sulfur atom. This can best be achieved by means of the highest possible fluorine substitution at sulfur. Hence the preparation of $H_2C{=}SF_4$ **11** was considered possible, and in fact was achieved. Carbon bound fluorine has a similar influence on C–S double bonds. For the sake of simplicity, only α- and β-fluorinated molecules will be considered here.

Fluorine substitution in the α-position weakens the double bond. This can go so far that even no bond exists any more. Thus according to calculations the molecule $F_2\overset{\ominus}{C}{-}\overset{\oplus}{P}H_3$ does not exist, except possibly as a van der Waals adduct (354 ppm) between F_2C and PH_3.[32] Yet according to corresponding calculations, $HF\overset{\ominus}{C}{-}\overset{\oplus}{P}H_3$ is a chemically bound state with a P–C distance of 172.3 pm (for comparison $H_2\overset{\ominus}{C}{-}\overset{\oplus}{P}H_3$ calcd. 167.5 pm). This destabilization by an α fluorine obviously has several reasons: the carbene fragmentation is favored by the stability of the fluorinated carbene, and the strong interaction of the carbon's p-orbitals with the neighboring fluorine substituents weakens π bonds in general (fluoro effect in olefins). However, α-fluoro and α-difluoro phosphorus ylides have been successfully detected by trapping reactions.[33–39] Among sulfur compounds there is with few exceptions ($CF_3{-}CF{=}S{=}O$, $F_2C{=}S{=}O$, $F_2C{=}SF_2$) only sparse information available (see Section 5 and 7, compounds **27**, **35** and **39**).

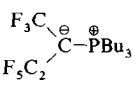
According to all previous findings, the role of a β-fluorine substituent is stabilizing. Examples in the series of phosphorus ylides are **6**,[40] **7**,[41] **8**,[42] and **9** (with crystal structure



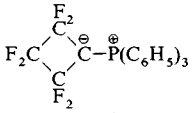
6



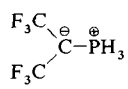
7



8



9



10

analysis[43]), and calculations on **10**.[32] With the sulfur compounds to be discussed herein, this stabilization by β-fluorine substitution can be decisive in actually obtaining a desired compound, for example $F_3C{-}C{\equiv}SF_3$, Firstly, a CF_3 group already exerts a certain steric protection, but also the acceptance of partial charge from the multiple bonded carbon atom can occur in the sense of a negative hyperconjugation.

The carbene-metal complexes, which were first prepared approximately fifteen years earlier,[44,45] were one other model for the synthesis of $R_2C{=}SF_4$. Without pushing the analogy too far, these classes of substances are similar in the coordinative saturation of the heavy atom (metal or sulfur), in the significance of the substituents on the carbon for stability, in certain structural principles, and in molecular dynamics (see Section 3).

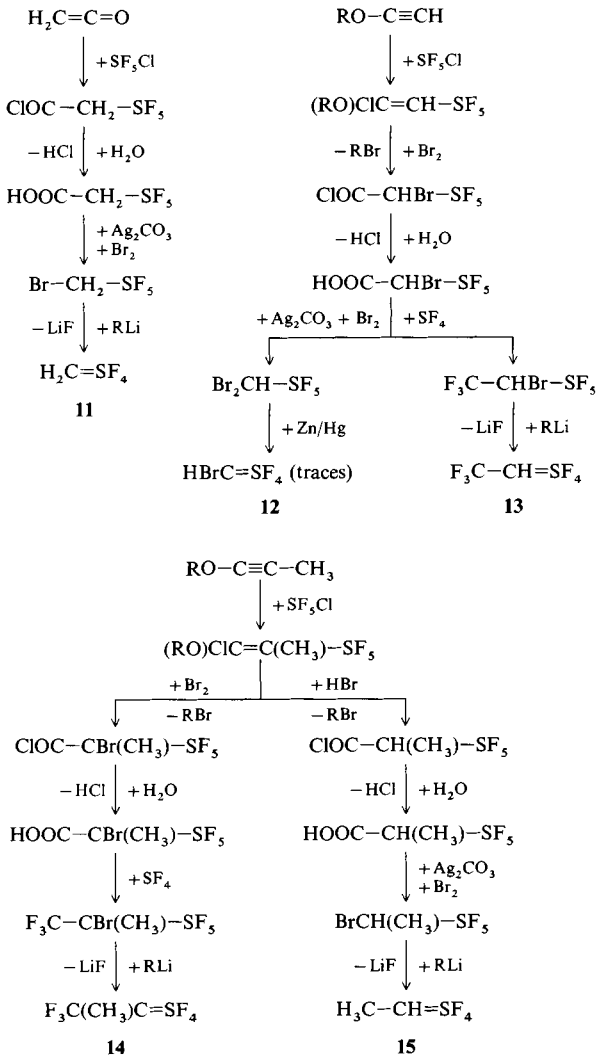
One sees with the molecule $H_2C{=}SF_4$ that here the double bond problem can be genuinely studied free of steric effects. The amazing success in the synthesis of Si=Si, P=P, and other double bonds rests ultimately on the success of the steric shielding of the unstable part of the molecule against

Konrad Seppelt, born in Leipzig in 1944, studied chemistry in Hamburg and Heidelberg, where he gained his doctorate in 1970 under the supervision of Professor W. Sundermeyer. After his habilitation in Heidelberg with work on selenium-fluorine compounds he joined Professor N. Bartlett at the University of California at Berkeley for one year. Following his appointment as Heisenberg Professor at the University of Heidelberg he accepted a post as professor at the Freie Universität Berlin. His research activities center on the chemistry of electronegative elements. He was awarded a Karl-Winnacker fellowship and the Chemistry Prize of the Akademie der Wissenschaften zu Göttingen.

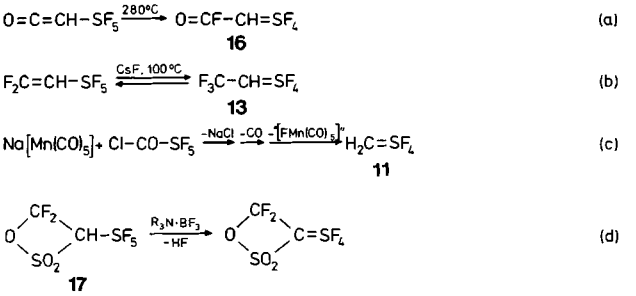
polymerization and/or oxidation. This steric shielding will influence the structure. Thereby the length of the double bond might be afflicted least, but the angle deformations (twist angle, pyramidalization) to a great extent.[3]

3. Alkylidene Sulfur Tetrafluoride

As long ago as 1972 *J. I. Musher* predicted the possible existence of compounds of the type $R_2C{=}SR'_4$ and had designated them as persulfuronium ylides,[46] however, they have so far never been synthesized. It is also questionable whether these compounds would be stable against ligand elimination (R'–R) with the simultaneous formation of normal sulfur ylides $R_2\overset{\ominus}{C}{-}\overset{\oplus}{S}R'_2$. The corresponding decomposition reaction is not expected for R'=F. So the first alkylidene sulfur tetrafluoride, $H_2C{=}SF_4$, was prepared by *G. Kleemann* and *K. Seppelt* in 1978 by a tedious synthetic route.[47, 48]



The substituted alkylidene sulfur tetrafluorides **12**,[51] **13**, **14**,[50] and **15**[49] could be prepared in a similar way. The long reaction route resulted in these compounds always being available in only small amounts. **13** and **14** had in addition to be separated from isomers. This difficult situation changed when **13**[52] and **16**[53] became easily accessible [Eq. (a) and (b)] with the accidental discovery of rearrangement reactions. An elegant method for small amounts of **11** is the decarbonylation by means of $Na[Mn(CO)_5]$[54] [Eq. (c)]. An HF elimination succeeds especially easily if the proton is a strongly acidic, as in the sultone **17**[55] [Eq. (d)].

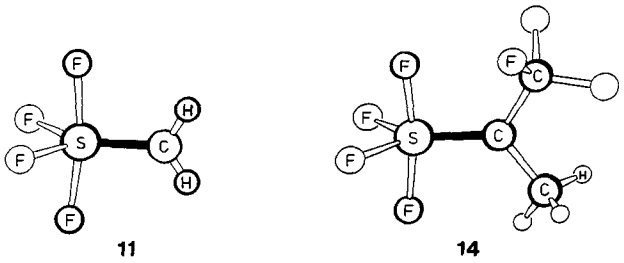


All alkylidene sulfur tetrafluorides are colorless liquids or gases with — in part — remarkable stability. Thus, **13** can be stored at room temperature for months without decomposition; **14** does not react with water. **11**,[56] **14**,[57] and **16**[53] have been characterized by X-ray structural analyses, **11** also by electron diffraction,[58] a normal coordinate analysis,[59] and an ab initio calculation[58] (Table 1).

Table 1. Bond lengths [pm] and bond angles [°] of alkylidene sulfur tetrafluorides in the crystal (low-temperature measurements) in comparison with structurally related compounds.

	C–S	F_{ax}-S-F_{ax}	F_{eq}-S-F_{eq}	Ref.
$H_2C{=}SF_4$ **11**	155.3	170.44	96.44	[56]
F_3C-C(CH_3)=SF_4 **14**	159.9(3)	170.40(5)	98.4(2)	[57]
O=CF-CH=SF_4 **16**	160.2(2)	172.19(9)	101.72(7)	[53]
$O{=}SF_4$		164.4(6)	114.9(34)	[60–63]
SF_4		173.1(5)	101.6(5)	[62, 64]
$H_2C{=}S$	161.1(2)			[22]
S=C=S	155.3			[65, 66]
R_2C-SR'_2	170–175			[67, 70]

Typical structural features, which are found in all alkylidene sulfur tetrafluorides include: the planarity of the $C_2C{=}SD_2^{ax}$ framework, the short C–S bond length, typical sp^2 bond angles at carbon, almost linear arrangement of the axial fluorine atoms, but a relatively small angle between the equatorial fluorine atoms (Table 1 and Fig. 1). The most exact structure is doubtlessly that of **14**, because no inaccurately determined hydrogen atoms exist on the double bonded carbon as in **11** (here, even hydrogen–fluorine bridges could exist, but evidently do not), and because the crystal structure is not predestined by the lattice symmetry on account of the low molecular symmetry (as is the case in **16**,[53] where eight of the ten atoms lie in a mirror plane). Not one of the six skeletal atoms in **14** is removed more than 3.5 pm from the principle plane. The C–S bond length (159.9(4) pm) is very much shorter than in the sulfur ylides (170–175 pm).[67–70] The slight bending from ideal angles of the axial fluorine atoms [F_{ax}–S–F_{ax} = 170.40(5)°] is far less than that of the equatorial fluorine atoms [F_{eq}–S–F_{eq} = 98.4(2)°].



11 14

Fig. 1. Structures of **11** and **14** from low-temperature X-ray measurements and electron diffraction. Double bonds are drawn darkened in. The carbon substituents as well as the carbon, sulfur, and axial fluorine atoms always lie in a plane which is symbolized by boldface type. In the case of the very accurately determined structure of **14**, the planes $F_2^{ax}S=C$ and $S=CC_2$ have a torsion angle of 2–3°, presumably caused by repulsion between the (C)-F and (S)-F^{ax} atoms. The slightly distorted trigonal bipyramidal geometry around sulfur is typical [56, 57].

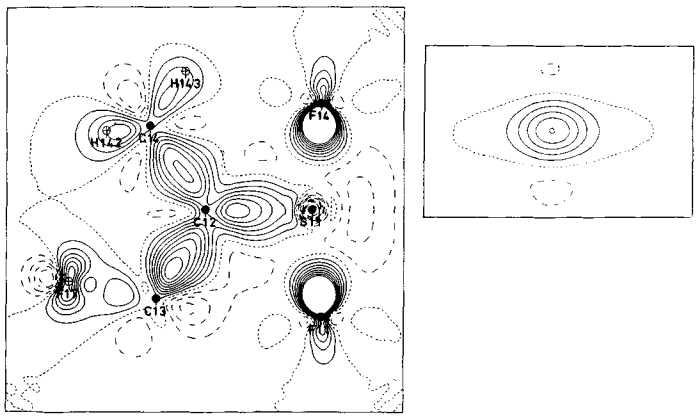


Fig. 3. X-X-Electron density contour lines of **14**. Left: All measurable details of our bonding concepts are reproduced in this diagram: largely nonpolar C–CH_3 and C–H bonds, semipolar C–S and C–CF_3 bonds, and strongly polar C–F and S–F bonds. Right: Cross-section perpendicular to the double bond, in the middle between C and S. The greater extension in the equatorial plane, typical for a double bond, is easily recognized. For the specific experimental and mathematical details of such high quality electron density analyses see Ref. [57]. Reproduced by kind permission of the American Chemical Society.

There are conceptional models which make these characteristic structures plausible. Use of the electron pair repulsion model yields a trigonal bipyramidal molecular shape at the sulfur with carbon as an equatorial ligand and preferably an equatorial position for the electron density of the double bond. Simpler yet is the representation of the molecule through connecting the edges of an octahedron (SF_6) with a tetrahedron (CH_4) (Fig. 2). Calculated π-electron density is

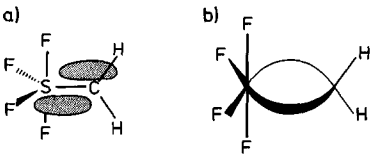

Fig. 2. Molecular models for alkylidene sulfur tetrafluorides with **11** as example. a) Electron pair replusion model; b) bent-bond model. In the final analysis, both models are identical, but they both depend on the existence of a double bond.

found predominately in the equatorial plane.[71] The experimental determination of the electron density distribution of the C=S double bond in **14** shows the typical anisotropy for double bonds, that is, the greater expansion of the electron density is found in the equatorial plane (Fig. 3).[57]

This structure is also in accord with the findings from vibrational spectroscopy.[59] The photoelectron (PE) spectrum of **11** is strikingly similar to that of SF_4.[58] However the lowest band doubtlessly corresponds to the π_{CS} ionization, which at 10.7 eV lies almost 4 eV higher than the comparable ionization in phosphorus ylides,[72] whereby the chemical difference becomes very clear: the π_{CS} electrons are found in a strongly bonding orbital. **16** is a special case in that the C=S double bond is evidently conjugated with the C=O double bond, and thereby somewhat lengthened[53] (see Figure 4).

The C=S double bond also has the most typical property of double bonds, namely to be rigid against torsion. This is easy to discern from the ^{19}F-NMR resonances, in that even at the highest experimentally obtainable temperatures the different fluorine atoms do not coalesce. Since an axial-equatorial fluorine exchange by the Berry mechanism[73] must be coupled to a 90° rotation of the double bond, the torsional barrier can be estimated to be at least 103 kJ mol^{-1}. From mass spectrometric and thermodynamic data, one comes to similar values for the double bond portion.[52] This torsional barrier of the methylene group is therefore high, but by no means as high as in ethene (267 kJ mol^{-1}).

The structures of the alkylidene sulfur tetrafluorides are comparable with those of similar classes of compounds. The cylindrically symmetrical S–O bond in $O=SF_4$ does not define a plane, thus the F_{ax}-F_{eq} exchange processes are very fast. It also happens that the bond angles and distances of the axial and equatorial fluorine atom are much more similar than in comparable molecules.[61–64] The *N*-alkyl sulfur

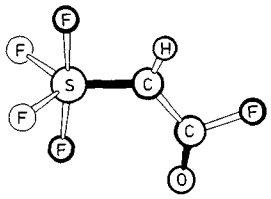

Fig. 4. Structure of **16** in the crystal (low-temperature measurements) [53]. The molecule is completely planar (bold-face type) except for the equatorial fluorine atoms. The conjugation of both double bonds (darkened in) as far as a lengthening of the C=S and a shortening of the C–C bond lengths is also discernible. The preference of the *cis*- over the *trans*-conjugation probably has only steric grounds.

imide tetrafluorides R–N=SF_4 are already much more similar to the alkylidene sulfur tetrafluorides. According to structural investigations the alkyl ligand is also found in the axial plane,[74] the π-electron density mostly in the equatorial plane, but not so pronounced as in the alkylidene sulfur tetrafluorides.[71] *N*-alkyl sulfur imide tetrafluorides are, depending on the residue R (R = CF_3,[75] CH_3,[76] and F[77, 78]) and temperature, no longer rigid. Aminophosphorus tetrafluorides R_2N–PF_4 are isoelectronic with $R_2C=SF_4$ and evidently have the same molecular geometry. The double bond character of the strongly polar N–P bond is never-

theless decreased so much that rotation, and therewith the axial–equatorial equilibrium of the fluorine atoms, is observed at about room temperature (depending on R).[75, 79, 80]

The carbene complexes **18**[81, 82]–**20**[81] and the corresponding ruthenium complexes[83] (Scheme 1) all have a comparable trigonal bipyramidal structure with the phos-

$[(PPh_3)_2Cl(NO)Os{=}CHR]$ **18**

$[(PPh_3)_2Cl(NO)Os{=}CF_2]$ **19**

$[(PPh_3)_3(CO)_2Os{=}CF_2]$ **20**

Scheme 1. Carbene complexes **18**–**20**. Compound **18**: R = H,CH_3, C_6H_5, C_2H_5COO.

phorus ligands in the axial positions and the carbon substituents in the equatorial plane. Complexes of the type $L_4(\eta^2$-alkene)M are the best analyzed examples for the coupling of axial-equatorial ligand exchange (Berry mechanism) with the torsion of the alkene (Fig. 5). Always, as also in the

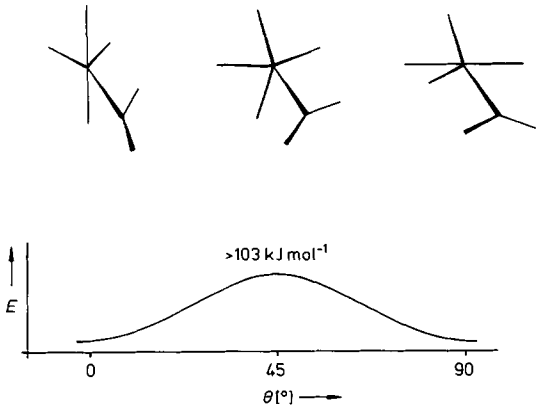

Fig. 5. Coupling of the torsion of the substituents with the axial-equatorial ligand exchange in **11**. This coupling makes it possible to reach the ground state again after a torsion of 90°. The same mechanism holds for the rotation of the ethylene ligand in $(CO)_4(\eta^2$-$C_2H_4)Fe$ though the barrier is much smaller here.

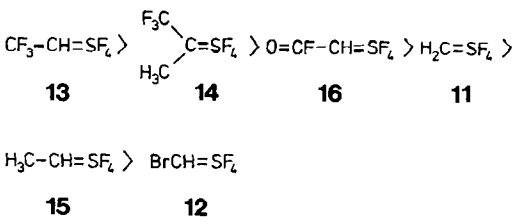
simplest case $[(CO)_4(\eta^2$-$C_2H_4)Fe]$, the ethylene ligand occupies an equatorial position of a trigonal bipyramid and is aligned in the equatorial plane.[84] According to calculations, rotation of the ethylene ligand through 90° requires 134 kJ mol^{-1}.[85] The torsional barrier of the ethylene rotation is in reality, however, less than 40 kJ mol^{-1} and thereby not freezable because it is coupled to the Berry mechanism of the carbonyl groups.[86] If the complex is modified by alkyl ligands,[87] carbonyl ligands,[88] and/or central atom (Ru,[89] Os[90]), this mechanism becomes freezable and therefore observable NMR spectroscopically.

4. Chemistry of the Alkylidene Sulfur Tetrafluorides

The stability of the alkylidene sulfur tetrafluorides varies strongly with the nature of substituents on the carbon (Scheme 2).



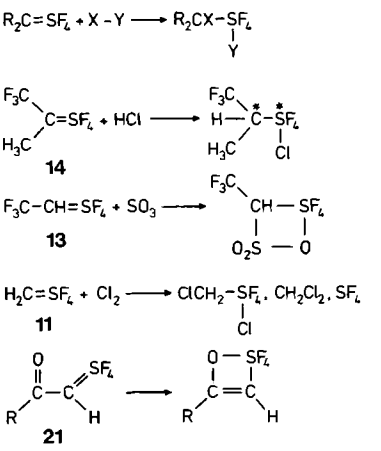
Scheme 2. Stability of the alkylidene sulfur tetrafluorides **11**–**16**.

13 is storable at room temperature in a sealed capillary tube for months without decomposition, while **12** is completely decomposed after a few hours. As decomposition products SF_4 is observed, in the pyrolysis of **11** in vacuum also ethylene, and in the thermal decomposition of **15**, inter alia 1,1-difluoroethane. These results indicate a carbene decomposition according to Equation (e), whereby the stabi-

$$R_2C{=}SF_4 \longrightarrow R_2C{:} + SF_4 \qquad (e)$$

lized carbene is formed easier than the electron-poor carbene. The prognosis for $F_2C{=}SF_4$ and $O{=}C{=}SF_4$ is poor in this respect, since the fragments CF_2 and $C{\equiv}O$ are especially stable. This prediction is in unison with the aforementioned calculations on the ylides $H_3\overset{\oplus}{P}{-}\overset{\ominus}{C}PR$ (R = R′: H,F,CF_3; R = H, R′ = F). It was calculated that the difluorinated ylide is not a bound state and that the trifluoromethyl-substituted ylide should be especially stable against carbene decomposition.[32]

The preparative use of alkylidene sulfur tetrafluorides as carbene sources is thwarted by the simultaneous formation of reactive SF_4. Addition reactions at the double bond are more clear.[48] Polar agents (HF, HCl, HBr, ICl, $BrOSeF_5$, HgF_2, AsF_5) add quickly. SO_3 adds with ring formation (Scheme 3).[91] The direction of the reaction is uniform so



Scheme 3. Addition reactions of alkylidene sulfur tetrafluorides.

that the partial positive part of the reactant approaches the carbon. This reveals the polarity of the C=S double bond in the sense of the ylidic formula. The addition yields always and exclusively *cis*-products concerning the substitution on the sulfur atom.

cis-Addition products are immediately recognizable by the characteristic AB_2C spectra of the fluorine atoms at sulfur.

A four-membered ring addition mechanism can be inferred from the uniformity of the direction of the addition (> 99%) and the rapidity (see at −78 °C). If one adds to a prochiral alkylidene sulfur tetrafluoride, then the chirality of the product becomes immediately recognizable from the ABCD spectrum (instead of AB_2C) of the fluorine atoms on the sulfur. Unpolar reagents yield larger amounts of side products, which often point to a carbene intermediate. Besides the expected addition product, CH_2Cl_2 is formed in the reaction of **11** with chlorine (Scheme 3). Thus far the alkylidene sulfur tetrafluorides show no reactivity as dienophiles in Diels-Alder reactions or as olefin-ligands in metal complexes. The oxidation or fluorination potential is too great for the latter.[92] Also, the reaction with carbonyl compounds does not yield products corresponding to the Wittig reaction. Fluorination of the carbonyl is observed, which could also be traced back to SF_4 which is formed as an intermediate.[48] Carbonyl-substituted alkylidene sulfur tetrafluorides such as **21** with R = C_6H_5 are subject to an irreversible isomerization to oxathietanes,[93] with R = F, on the other hand, the compound is stable. In contrast to the simple addition reactions, this cyclization requires a breaking up of the special molecular geometry for the transition state. A dimerization of an alkylidene sulfur tetrafluoride to an octa-*S*-fluorodithietane $F_4S(\mu\text{-}CR_2)_2SF_4$ in the sense of a [2 + 2] cycloaddition has as yet never been observed.

5. Alkylidene Sulfur Difluorides $R_2C{=}SF_2$

If one compares the alkylidene sulfur difluorides, $R_2C{=}SF_2$, with well-known analogues such as sulfur ylides $R_2\overset{\ominus}{C}\text{–}\overset{\oplus}{S}R'_2$, thionyl fluoride $O{=}SF_2$, or sulfur difluoride imides $R\text{–}N{=}SF_2$, it is certainly a wonder that this class of compounds was first discovered only in 1989. By chance an addition-elimination reaction was observed with the highly fluorinated olefin **22** which could thereafter be carried out with **23**[94] [Eq. (f) and (g)]. The method fails to work with all

$$\underset{\mathbf{22}}{F_5S\text{–}CH{=}CF_2} + SF_4 \xrightarrow[-HF]{CsF} \underset{\mathbf{24}}{F_5S(F_3C)C{=}SF_2} \quad (E \text{ and } Z) \qquad \text{(f)}$$

$$\underset{\mathbf{23}}{F_3C\text{–}CH{=}CF_2} + SF_4 \xrightarrow[-HF]{CsF} \underset{\mathbf{25}}{(F_3C)_2C{=}SF_2} \qquad \text{(g)}$$

other olefins which were tested. In some cases no reaction takes place or the intermediate alkylidene sulfur difluoride rapidly reacts further.

The geometry of the alkylidene sulfur difluorides arises immediately from the fact that **24** appears as two isomers and the CF_3 groups in **25** are not equivalent. The plane formed by the carbon substituents bisects the SF_2 angle (Fig. 6). This was not absolutely predictable, even though sulfur imide fluorides such as $Cl\text{–}N{=}SF_2$ and others show a comparable structure.[95] The C=S double bond is so torsionally stable that no interconversion of the isomers occurs up to 100 °C. The experimentally determined structure was confirmed by ab initio calculations.[94] However, these calculations gave a second structure for **25** with somewhat higher energy, which has a completely planar molecular framework as well as an almost linear SF_2 geometry (Fig. 6). This particular molecular geometry turns out to be the more stable one for the hypothetical compound **27**, so that here the realization of a non-Gillespie configuration, one which grossly violates the electron pair repulsion model, could succeed.

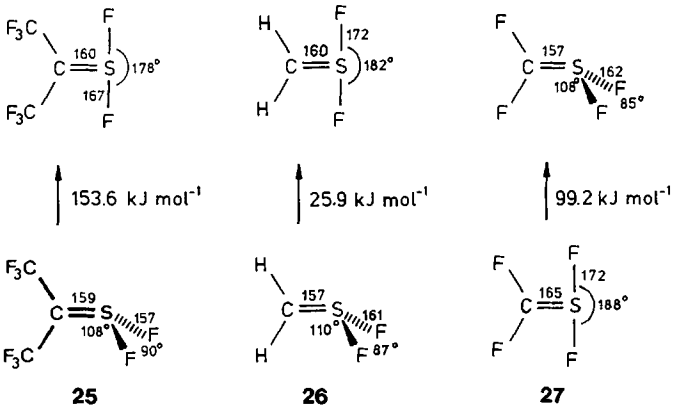


Fig. 6. Calculated structures of alkylidene sulfur difluorides [94]; bold-faced: known **25**. **26** and **27** have a completely different ground state structure. The pyramidal structures of **25** and **26** are as expected. In the case of **24**, the pyramidal structure gives rise to the appearance of two isomers. The planar T-shaped ground state structure of **27** has not yet been confirmed experimentally.

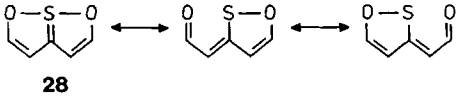
At this point a comparison with the structures of 1,6,4a-λ^4-trithiapentalene and 1,6-dioxa-6a-λ^4-thiapentalene **28** should be possible. These compounds have a planar T-shaped coordination at the sulfur. The question of whether "hypervalency" or "bond tautomerism" is involved has already been discussed in detail.[96, 97] The majority of the facts speak in favor of the symmetrical structure,[98–108] but probably with a decidedly flat potential for the back and forth motion of the central sulfur atom. Here the geometry might be enforced through the chelating ring, but in the theoretically postulated $F_2C{=}SF_2$ it is the ground state. Afterall, the same phenomenon was also found in the chemistry of phosphorus[109] with a larger group of calculated "non-Gillespie" structures. This T-shaped geometry can be important as a transition state for intramolecular ligand exchange in pyramidal molecules.[110–112] (This transition state corresponds to a planar transition state for a tetrahedral molecule.)



28

The investigation of the alkylidene sulfur difluorides showed that they rearrange easily. Thus, it is understandable why only decomposition products were observed earlier.[113] This instability corresponds to a [1,2]-fluoride migration with formation of the rare sulfenyl fluorides[114–116] [Eq. (h)].

The direction of this isomerization is opposite to that of the $F_2S{=}S/F\text{–}S\text{–}S\text{–}F$ isomers [Eq. (i)] and is largely caused by the energy gain of a C–F bond versus the energy cost of

a S–F bond. These experimental results are also supported by calculations.[94, 117]

The 1,2 fluoride migration in **24** is strongly accelerated by Lewis acids (BF_3, AsF_5). However, with BI_3 a dehalogena-

$$R_2C{=}SF_2 \xrightarrow{(BF_3)} R_2FC{-}S{-}F \qquad (h)$$

$$F_2S{=}S \longleftarrow F{-}S{-}S{-}F \qquad (i)$$

$$\underset{\mathbf{24}}{F_5S(F_3C)C{=}SF_2} \xrightarrow[-BF_3,-I_2]{+BI_3} \underset{\mathbf{29}}{F_5S(F_3C)C{=}S} \qquad (j)$$

tion occurs with formation of **29** as a stable, deep violet liquid[118] [Eq. (j)].

6. Alkylidene Sulfur Difluoride Oxides $R_2C{=}SF_2{=}O$

The first preparation of an alkylidene sulfur difluoride oxide was reported in 1988.[30] This is again remarkable because analogues such as sulfuryl halides, sulfur difluoride imide oxides $R{-}N{=}SF_2{=}O$, and oxosulfur ylides have been known for a long time. After the discovery of the alkylidene sulfur tetrafluorides, the discovery of the alkylidene sulfur difluoride oxides could essentially be reckoned with at any time, because it required only a simple hydrolysis. It is true though, that up to now, the desired reaction has succeeded in only one case[30] [Eq. (k)].

$$\underset{\mathbf{16}}{O{=}CF{-}CH{=}SF_4} \xrightarrow[-2HF]{H_2O} \underset{\mathbf{30}}{O{=}CF{-}CH{=}SF_2{=}O} \qquad (k)$$

$$\xrightarrow[-HF]{HgF_2} \underset{\mathbf{31}}{Hg[C(COF){=}SF_2{=}O]_2} \qquad (l)$$

Structurally, alkylidene sulfur difluoride oxides should not display any peculiarities, for they are derived from such well-known compounds as sulfones, etc. Nevertheless, the presently known species **30** shows a complicated dynamic behavior that can only be satisfactorily explained with the help of several assumptions. The environment of the sulfur atom is assumed to be quasi-tetrahedral. The temperature-dependent NMR spectra show three different isomers, all of which have equivalent fluorine atoms on the sulfur. It is clear therefore that the plane of the substituents on carbon bisects the SF_2 angle, as in the alkylidene sulfur difluorides. The two isomers observed at $-70\,^{\circ}C$ were interpreted as *E,Z* isomers. The third isomer results from the freezing of the conjugation. The still to be expected fourth isomer is not observed, perhaps for lack of intensity[30] (Fig. 7). Ab initio calculations yielded slightly different energies for these four isomers, so that one can tentatively assign the NMR resonances.[119] The question remains open why here for the first time the torsion of the C=S double bond freezes only at $-70\,^{\circ}C$, quite unlike all other C=S double bond systems discussed herein. A possible explanation could be: The approximate "three-fold" symmetry of the $\approx SOF_2$ group places less resistance on the torsion of the C=S double bond in contrast to the two-fold symmetry of the SF_4, SF_2, and S=O groups. In

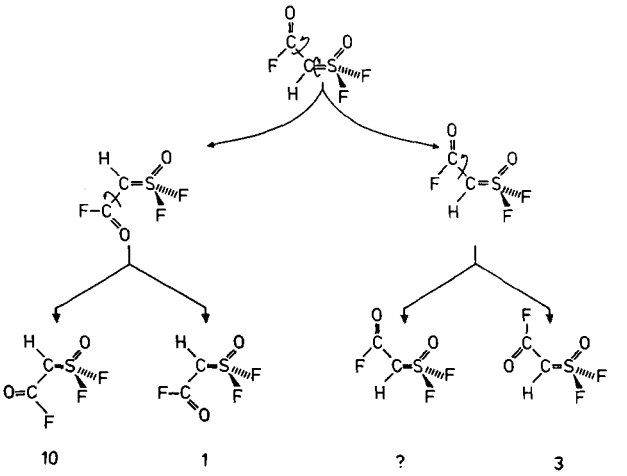


Fig. 7. Structural dynamics of **30**. The C=S double bond is freely rotating above room temperature, the C–C single bond above $-70\,^{\circ}C$. Three of the four possible isomers are observed at $-136\,^{\circ}C$ [30]. The numerical values indicate the quantitative relationship. The slight energy differences and thereby the concentrations of the isomers depend possibly on the number of weak intramolecular hydrogen-oxygen contacts.

this respect **30** resembles the sulfur and phosphorus ylides. In these, the ylidic bond is (with one exception, which can have steric reasons[121]) always freely rotating. This is also confirmed by calculations.[122, 123] The torsion angle of the ylidic P–C bond takes on entirely different values in crystal structures.[43, 124, 125] In the four published cases of crystal structures of sulfur ylides, the plane of the carbon substituents is found in the vicinity of the bisector of the SF_2 angle (variations up to 9.8°).[67–70] The appearance of isomers has not been observed up to now.[126] Accurate structural investigations of oxosulfur ylides, which are related the closest to **30**, are not known. But there is a parallel to the hindered rotation of the conjugated system: $H_2C{=}CH{-}CF{=}O$ appears as two isomers at $-140\,^{\circ}C$.[127]

30 can be derivatized to give the mercury compound **31** [Eq. (l)] which exists in solution as only one isomer. In the crystal structure of **31** the central mercury atom clearly fixes the C=S double bond in a definite way through oxygen-mercury contacts (Fig. 8). It is probably no coincidence that the

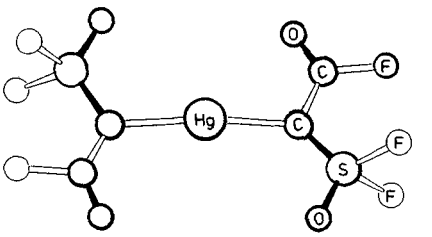

Fig. 8. Crystal structure of **31**. The molecule is largely planar except for the fluorine atoms (bold-face type, double bonds darkened in). Hg···O contacts fix the ligands in this configuration [120].

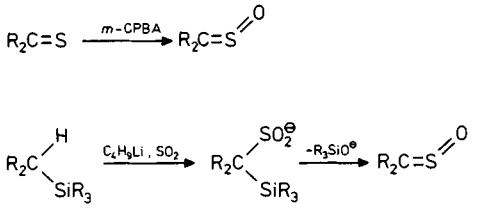
lowest energy form for **30** is calculated in the corresponding configuration: maximalization of hydrogen-oxygen contacts.[119] The C–S bond length (155(3) pm) is very short, as in the alkylidene sulfur tetrafluorides. In any case, the easy rotation of the double bond cannot be interpreted as weak bonding.

At this point it becomes recognizable that the behavior of a class of compounds is difficult to study from one or two cases. The synthesis, especially of nonfunctional and nonconjugated alkylidene sulfur difluoride oxides, would be desirable before generally valid conclusions can be drawn. A complex synthesis of $FSO_2(COF)C{=}SF_2{=}O$ was reported quite recently,[128] but no structural dynamics were observed.

7. Fluorine-Substituted Sulfines, R–CX=S=O

Interestingly enough the first sulfine resulted from an attempt to prepare a sulfene.[129] Its identity was first clarified in 1963. It has been known since the middle of the sixties, that sulfines occur in stable *E* and *Z* isomers as a consequence of the nonlinearity of the C–S–O system ($\sphericalangle$ CSO $\approx$ 114°). Besides several special cases, their production results from the oxidation of thioketones by means of *meta*-chloroperbenzoic acid or through a variant of the Peterson olefination (Scheme 4).



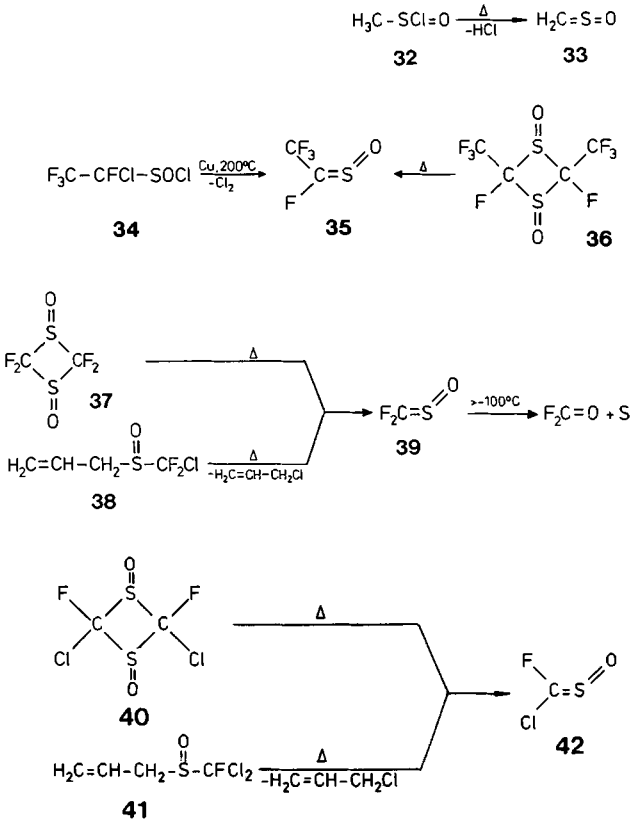
Scheme 4. General reactions for the preparation of sulfines.

The parent substance **33** could be prepared through the pyrolytic elimination of HCl from **32** and was identified spectroscopically as an unstable particle (Scheme 5).[131, 132] The first perfluorinated sulfine **35** resulted from dechlorination of **34** or better of late through thermal decomposition of the *S,S'*-dioxodithietane.[133, 134]

Thus far it is not clear which of the two possible isomers is formed here. The thermal decomposition of *S,S'*-dioxodithietanes has proven to be a productive synthetic method for fluorinated (and other) sulfines.[135–139] **39** could be obtained by this and by another route, and it turns out to be unstable above $-100\,^{\circ}C$.[140–142] However, it could be unequivocally identified both spectroscopically and through trapping reactions.

The only other α-fluorinated sulfine is **42**, which was also obtained through the cleavage of a four-membered ring or from the pyrolysis of **41**. It is only slightly more stable than **39**, so that again it could only be identified spectroscopically and through trapping reactions. But at least *E* and *Z* isomers could be assigned here.[141–143] Only $X_2C{=}S{=}O$[142–145] (X = Cl,Br) show moderate thermal stability at room temperature.

As expected β-fluorination shows a drastic effect: $(CF_3)_2C{=}S{=}O$ is a stable liquid capable of being produced by different methods of four-membered ring cleavage. The structure, though still not investigated in detail, results easily from the fact that the CF_3 groups are different according to NMR spectroscopy. Because of the stability of this special

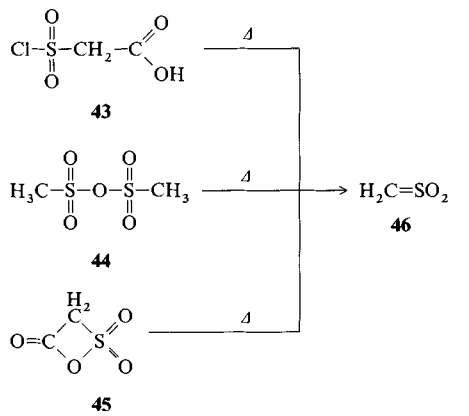


Scheme 5. Preparation of fluorine-substituted sulfines.

sulfine, it could be subjected to numerous chemical reactions. Particularly important are the addition reactions to the C=S double bonds which, in the case of the Diels-Alder reaction with anthracene, is reversible.[135–137]

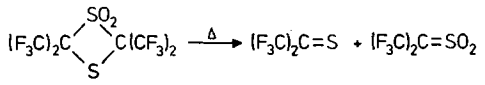
8. Fluorine-Substituted Sulfenes $R_2C{=}SO_2$

Our knowledge of sulfenes is by far worse than our knowledge of sulfines.[146] Sulfenes are prepared by elimination upon sulfonic acid compounds. They can be identified through trapping reactions or stabilized through reaction with bases in the "normal" ($R_3N^{\oplus}$–$SO_2{=}\overset{\ominus}{C}R'_2$) or the "reversed"[147, 148] ($R_3N^{\oplus}$–CR'_2-$SO_2^{\ominus}$) way. Reports about free sulfenes are incomplete. **46** could be identified spectroscopi-



cally (IR) among many other products from the thermolysis of **43**–**45**.[149–151] In this way a C–S double bond energy of 150 ± 20 kJ mol^{-1} was estimated.[152] It is predicted on the basis of calculations that electron-donating groups on carbon will stabilize sulfenes.[153] Diaminosulfenes (thiourea *S*,*S*-dioxides) actually exist in the sulfene form, but with strong hydrogen bridges.[154–157] The framework N_2C–SO_2 is not planar, but twisted through 68°, whereas planarity is predicted for $H_2C{=}SO_2$.[153]

The perfluorinated sulfene **48** has up to now only been detected as an unstable intermediate. It is formed in solution from $[(CH_3)_2N]_3S^{\oplus}(CF_3)_2C{-}SO_2F^{\ominus}$ by reaction with BF_3, BF_3-etherate or SiF_4.[158] If it is not trapped, it rearranges to $F_2C{=}C(CF_3){-}SO_2F$. An alternative method of preparation is again four-membered ring cleavage (cf. Section 7).



47 **48**

1,1-Dioxo-2,2,4,4-tetrakis(trifluoromethyl)1,3-dithietane **47** can be cleaved with quinuclidine, and isolation as the "normal" base adduct **48** was thus successful.[159]

This sulfene adds to moderately electron-rich olefins. The reactions are to some extent regio- and stereospecific. Diels-Alder reactions succeed in the same way. There are also hints of an electron transfer mechanism prior to the loss of SO_2.[158]

There are few materials comparable with sulfenes. Other derivatives with hexavalent sulfur in trigonal planar geometries are the sulfur triimides $(RN{=})_3S$[160–164] and sulfur diimide oxides $(RN{=})_2S{=}O$.[165] These have a completely planar molecular framework including the nitrogen ligands, which still requires a satisfactory theoretical explanation. Altogether our knowledge of this class of molecules is still seen as very incomplete.

9. Sulfur–Carbon Triple Bonds

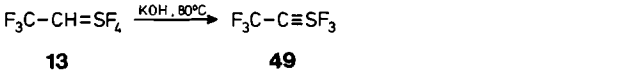
The two known compounds with sulfur–carbon triple bonds, $F_3C{-}C{\equiv}SF_3$ (**49**) and $F_5S{-}C{\equiv}SF_3$ (**51**), are special cases in which the triple bond is formed between an element of the second and one of a higher period. The total number of these compounds is still easily surveyable. Long ago this class of substances aroused interest when *Glemser* et al. discovered N≡SR compounds (R = F_3,F,Cl).[166–168] In the meantime, a few derivatives and their organic and organometallic chemistry have been reported.[169] Since then phosphaalkynes R–C≡P (R = H[170]; F[171,172], CH_3[173,174], CN[175]) have been detected as unstable molecules against polymerization. In 1981 *Becker*, *Gresser*, and *Uhl* succeeded in synthesizing phosphaalkynes with R = $(CH_3)_3C$ as a stable, colorless liquid.[176] Since then, numerous additional phosphaalkynes have been prepared with R = C_6H_5,[177] $(CH_3)_3Si$[178], 2,4,6-$(C_4H_9)_3C_6H_2$,[178,179] tripticyl,[180] adamantyl,[181] and others.[182] Predominately $(H_3C)_3C$–C≡P has become a versatile reaction partner in cycloaddition reactions as well as in organometallic syntheses.[182] Recently, the phosphadiazonium cation 2,4,6-(t-$C_4H_9)_3C_6H_2$–$N{\equiv}P)^{\oplus}$ was reported.[183] In 1986 *G. Märkl* and *H. Sepjpka* succeeded in synthesizing 2,4,6-(t-$C_4H_9)_3C_6H_2$–C≡As as a pale yellow, crystalline solid.[184]

Known compounds which contain λ^5-phosphorus are: $(C_6H_5)_2P{\equiv}C{-}Si(CH_3)_3$,[185] and $[(i\text{-}C_3H_7)_2N]_2P{\equiv}E$ (E=N,[186] C–$Si(CH_3)_3$[187]). The latter result from photolysis or thermolysis of azide- or diazo-precursors. Ab initio calculations show that in the phosphinonitrene H_2P–N the bond length (152 pm) is so shortened that it can be formulated as $H_2P{\equiv}N$[188] or $H_2\overset{\oplus}{P}{=}\overset{\ominus}{N}$.[189] Compounds with triply bonded silicon are thus far unstable. H–N≡Si has been isolated in a matrix from the decomposition of H_3Si–N_3, and C_6H_5–N≡Si was detected by photoelectron spectroscopy in the pyrolytic decomposition of $C_6H_5Si(N_3)_3$.[190,191]

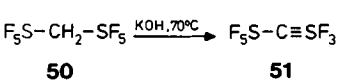
It is conspicuous that the heavier element prefers the terminal position (coordination number 1) in R–C≡P, R–N≡Si and R–$N{\equiv}P^{\oplus}$. It emerges from calculations that H–N≡Si is approximately 372 kJ mol^{-1} more stable than the isomer H–Si≡N[192] with only a small activation barrier of 55 kJ mol^{-1}.[193] An electrostatic consideration presents itself as a simple explanation. The proton (or the organic substituent) will bond to the hypothetical dipole $N{\equiv}Si^{\ominus}$ at the negative position. If such a simple consideration is reasonable, then F–Si≡N should be more stable than F–N≡Si. Similar comparisons are applicable for example to F–N=O and F–S≡N.

The success with the preparation of stable alkylidene sulfur tetrafluorides gave rise to the hope that compounds of the type R–$C{\equiv}SF_3$ should be capable of being synthesized too. This was first successful in 1984 when **49** and later **51** were prepared from **13** and **50** respectively.[194,195] The critical reactions are HF eliminations under basic conditions.

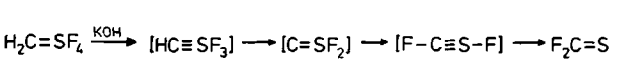
11 can also be forced to eliminate HF, but the intermediate **52** is not isolable, and **53**, formed through fluoride rearrangement, is obtained. **49** and **51** occupy a middle position with regard to their stability. They neither remain unchanged at room temperature (like some phosphalkynes with large R), nor are they very short-lived molecules (as C_6H_5–N≡Si, for example). They have half-lives of minutes at room temperature, and are almost indefinitely stable at −78 °C.



13 **49**



50 **51**



11 **52** **53**

In the following, this C≡S triple bond should be measured against the standard criteria, such as short bond length, linearity of the molecular framework, and strong electron density (so far as measurable) between the atoms bound by the triple bond. In all cases enumerated here, the triple-bond length is found to be very short (Table 2 and Fig. 9). Table 2

contains only experimentally determined values. Numerous calculated values exist for comparable systems.

These triple bonds are ca. 9% shorter than a comparable double bond and ca. 20% shorter than a comparable single bond. Consequently, the distance criterion is met. Bond contractions in C–C double and triple bonds amount to 13 and 22%, respectively.

Table 2. Triple bond lengths [d] of R–C≡SF_3 and comparable heteroalkynes.

Compound	d [pm]	Method [a]	Ref.

[a] MW = microwave spectroscopy, XR = X-ray structure analysis, ED = electron diffraction

Information about the electron density is at present only very limited. Only the X-ray structure analysis of **51** has such quality that a preliminary statement about the electron density can be made. Here a maximum of electron density in the shape of a little disk can be made out. It stands perpendicular to the bond axis between C and S, somewhat closer to C than to S (Fig. 9). The clover-leaf contour of this electron density

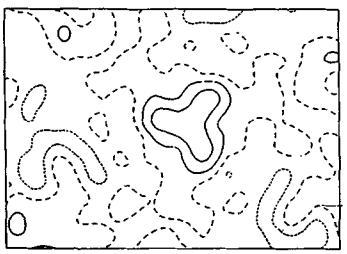

Fig. 9. Electron density perpendicular to the C≡S triple bond in **51**, approximately 60% of the bond length away from sulfur. The little disk-shaped area of electron density is typical for triple bonds. The clover-leaf form is enforced by the three-fold symmetry of the ≡SF_3 group and the crystal symmetry. Normally, a cylindrically symmetrical distribution of electron density is found in alkynes. That this measurement is much less informative in comparison to Figure 3 is due to poorer crystal quality, the disorder of the molecule, and insufficient measurement time.

is a result of a three-fold axis of rotation of the cubic crystal system, which coincides with the three-fold axis of the SF_3 part of the molecule. Whether this, in fact, indicates a deviation from the typical cylindrically symmetrical electron density in alkynes can at present not yet be stated with certainty. But such a trefoil distribution of electron density is essentially expected for R–C≡SF_3, since generally the atomic symmetry dominates the electronic symmetry, and in **51** no cylindrical symmetry exists as in acetylene. A cylindrically symmetrical distribution of electron density is in fact found experimentally in acetylene itself.[206]

The question of linearity of the bonding system is more complex. This question did not present itself for F_3S≡N and FS≡N since the terminal nitrogen cannot coordinate an additional atom. The phosphaalkynes R–C≡P in Table 2 are linear, 2,4,6-(t-C_4H_9)$_3C_6H_2$–C≡P[179] and 2,4,6-(t-C_4H_9)$_3C_6H_2$–N≡$P^{\oplus}$[183] deviate (177°) only slightly from the linear arrangement.

But **49** is already distinctly bent in the cystalline state: 171.5° (2.0).[196] In the gaseous state this deviation is very much larger: 155°(3).[197] These conflicting results first led to

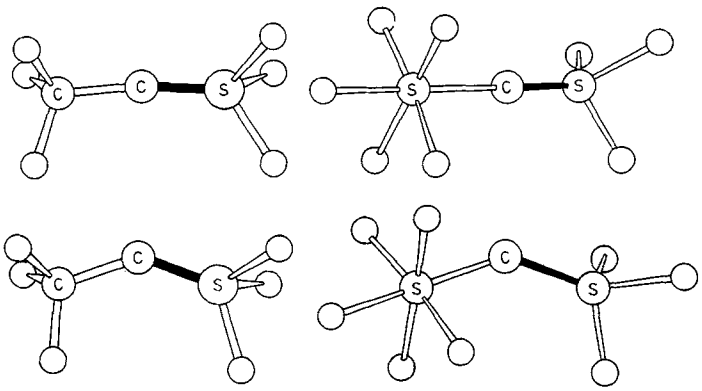

Fig. 10. Crystal structures of **49** and **51** (above) in comparison to the gas structures (below). The C≡S triple bond is darkened. In both cases one observes a strong bending of the molecule in the gas phase.

considerable confusion, especially since ab initio calculations initially predicted linearity, then perhaps a slight deviation from linearity, and finally a value of even 130°.[32, 197, 207] But these calculations are qualitatively in agreement that the bending requires only minimal energy (Fig. 11).

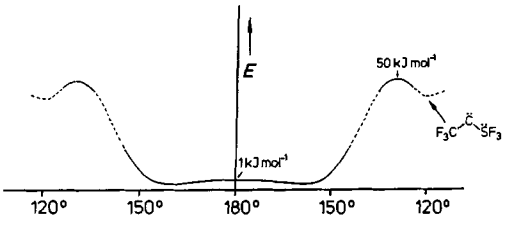

Fig. 11. Dependence of the energy from the C–C–S angle in **49**. The flatness of the potential, even at considerable bending angles, is remarkable. At still stronger bending angles the molecule transforms into the carbene state, F_3C-C̈-S̈F_3. Solid lines represent measured or calculated states, dashed lines denote interpolation and extrapolation. In particular, the energy level of the carbene F_3C-C̈-S̈F_3 with respect to the ground state is unknown. The energetic proximity of the strongly angled carbene state gives rise to the flatness of the potential.

The most sophisticated calculation at present is the geometry optimization by means of the 3-21G* basis set with stepwise bending of the angle by 0, 5, 10, 15, 20, 30, 40, 50, and 60° and the respective energy calculation with inclusion of electron correlation (MP4SDQ).[197] A bond angle of 130° emerges from this with a still small energy difference of 0.92 kJ mol^{-1} when compared with linearity (exp. > 2.0 kJ mol^{-1}).

This structural discrepancy is even more serious for the second compound of this class of substances, namely **51**. The solid structure shows a linear S–C–S framework prescribed by the cubic crystal symmetry. Even under the most optimistic assumptions (disorder!), the deviation from linearity cannot be greater than 4°.[195] But this molecule is also bent in the gas phase (*159*(3)°).[198]

In addition to the above-mentioned crystal structure analysis, electron diffraction, and ab initio calculations, the nonlinearity of **49** is based upon the interpretation of band broadening in the matrix IR spectrum and upon the broad band microwave spectrum and can thus be considered as certain.[197] In any case the small energy barrier for a bending motion made the development of a static model impossible here. The bending motion is much more a two-dimensional large amplitude motion. The linear case lies at a (quite weak) energy maximum, and the crystal lattice forces can vary the angle within certain limits. This accounts for the paradox that lattice forces have had to serve first of all as the explanation for a deviation from linearity and later as the explanation for not large enough a deviation from linearity.[208] These structural circumstances are thus far unprecedented for a triply-bonded carbon atom. But there are parallels among the cumulenes. For example, propadienone $H_2C{=}C{=}C{=}O$ and $(C_6H_5)_3P{=}C{=}P(C_6H_5)_3$ are both distinctly bent at the central carbon atom.[209, 210] Instructive is the case of $H_2C{=}C{=}C{=}O$, in which only the consideration of electron correlation in the ab initio calculation confirmed the previous experimentally determined nonlinearity.[211, 212]

The comparison of alkylidyne sulfur trifluorides with carbyne complexes is interesting. The metal–C triple-bond lengths are short (165–175 pm), as expected for metals of the first row of transition metals and 175–190 pm for the heavier homologues. Historically, it is noteworthy that the first carbyne complex $[(CO)_4IW{\equiv}C{-}C_6H_5]$ was also distinctly nonlinear (162).[214] However, after the crystal structures of many more compounds became known, linearity at the carbyne carbon dominated more and more.[215] Larger deviations can likewise be brought about by lattice forces when one assumes that the bending motion has a very flat potential as in **49**. Seen altogether, these considerations have, nevertheless, played no great role in the chemistry of the carbyne-metal complexes.

How can this nonlinearity of the $R{-}C{\equiv}SF_3$ molecules be plausibly explained? The bond is certainly polar. This emerges not only from the calculated charge distribution of the bond according to $F_3C{-}C{\equiv}SF_3 \leftrightarrow CF_3{-}\overset{\ominus}{C}{=}\overset{\oplus}{S}F_3$, $(C^{-0.7}\,S^{+1.6})$ and the surprisingly high ^{13}C-NMR resonance[196] (almost identical to $F_3C{-}CH_2{-}SF_5$), but also from the fact that in **51** the maximum of the electron density is clearly shifted towards the carbon.[195] On the other hand, the substituents F_3C or F_5S are not large enough to enforce linearity through the repulsive forces. If this qualitative consideration is supposed to hold true, it remains incomprehensible why the criteria for a double bond are fully preserved with the alkylidene sulfur tetrafluorides $R_2C{=}SF_4$ ($\leftrightarrow R_2\overset{\ominus}{C}{-}\overset{\oplus}{S}F_4$).

Trinquier and *Malrieu* have theoretically investigated such nonclassical distortions at multiple bonds more carefully, and thereby developed a semi-quantitative relationship[217] based upon earlier recommendations.[216] A (hetero)ethene will be planar only if the energy sum of the singlet–triplet separations of the carbene fragments R_2X: and R_2Y: does not exceed a certain value. Otherwise the molecular geometry will become distorted, for example pyramidal. Since the singlet–triplet separation for $:CH_2$ is quite negative, C=C double bonds are planar. This is the reason for there being so-called nonclassical distortions with groupings such as $:GeR_2$, $:SiF_2$, and others. Likewise, the bending in cumulenes such as $H_2C{=}C{=}C{=}O$ and $O{=}C{=}C{=}C{=}O$ is semi-quantitatively predictable with this method.[217] The extension of this model to triple bonds requires that the energy sum of the doublet-quartet separations of the carbyne fragments R–X and Y–R′ of the (hetero)acetylene $R{-}X{\equiv}Y{-}R'$ not be permitted to be too large. CH is a doublet in the ground state, but the quartet lies only 70 kJ mol^{-1} higher. The SF_3 radical also has a doublet ground state,[218] but nothing is known about the energy level of the quartet state. However, since paired electronic states of heavy elements are generally stabilized, and even more so through fluorine substitution, the case of a nonclassical distortion is already predictable for **52**. The prognosis is similar for $H_3C{-}C{\equiv}SF_3$ and **49**. The unknown $F{-}C{\equiv}SF_3$ is certainly very strongly bent.[219] This is consistant with the SCF-MP4 ab initio calculation, which predicts a very low energy minimum of 55 kJ mol^{-1} with an angle of only ca. 113°.[197] The calculated geometry at the sulfur atom can also be described only with the formula $F{-}\ddot{C}{-}\ddot{S}F_3$. Also the very unstable difluoroacetylene[220] could be subject to a nonclassical distortion, and the hypothetical $F{-}C{\equiv}Si{-}F$ by all means.[221]

Even if the ground state is linear as in acetylene, the *trans*-bent form occurs in the excited state.[222, 223] But the energy difference might be considerable. Qualitatively, in the case of **49** the situation is the same, except that the excited state $F_3C{-}\ddot{C}{-}\ddot{S}F_3$ is separated from the ground state by a barrier of only ca. 50 kJ mol^{-1}, (Fig. 11). In short, it is the energetically close lying, certainly strongly bent dicarbene state which causes the weak bending potential.

The conclusion may be drawn from this result that real triple bonds between two elements of the third or higher periods should be observed only in exceptional cases, because the carbene state should definitely be more stable. Thus one limitation of a bond principle emerges for which nature is responsible, and which cannot be overcome no matter how refined the experimental technique might be.

Interesting transitions are possible: F–S–S–F should possess a normal S–S single bond like H–S–S–H. However the S–S bond length corresponds to that of a double bond (188.8(15) pm),[224] as is found, for example, in the isomer $F_2S{=}S$ with 186.0(20) pm[224, 225] or in the S_2 molecule with 188.9 pm.[226] If one extrapolates the bond characteristics in the series $N{\equiv}N$, $N{\equiv}S{-}F$ to $F{-}S{\equiv}S{-}F$, then one could have quite naively expected a triple bond. In any case, one must assume that the so-called free electron pairs on the sulfur in F–S–S–F have partial bonding character as is symbolized, but not explained, by the manner of writing $F{-}S{-}S{-}F \leftrightarrow {}^{-}F{-}S{=}S^{\oplus}{-}F \leftrightarrow F{-}{}^{\oplus}S{=}S{-}F^{\ominus}$ (cf. structure of O_2F_2).

Similarities hold for $F_3S{-}SF$: the molecule has a structure in which the nonbonding electron pairs on both sulfur atoms are in the eclipsed position, and at the same time the torsion

about the S–S bond is hindered.[227] Calculations show that the S–S bond has 20% π-character.

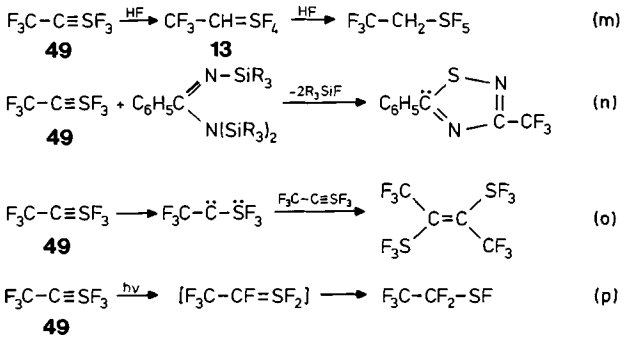
Also with the double bond principle there seems to be a limit lower in the Periodic Table. It has already been pointed out that the bond lengths in C=C, Si=Si, Ge=Ge and Sn=Sn containing compounds approach more and more the single bond lengths (a bond contraction of only 2% is observed for the Sn=Sn double bond[5]). This has been symbolized by the formulas $R_2Sn{=}SnR_2 \leftrightarrow R_2\overset{\oplus}{S}n{-}\overset{\ominus}{S}nR_2$, and with this also the nonplanarity at the Sn atoms has been "explained". Naturally, the description of a nonpolar bond with two polar boundary structures is not elegant, but this is the weakness of the method. The MO model is more elegant here: in the transition from C=C to Sn=Sn double bonds, the bonding π electron pair becomes increasingly a nonbonding electron pair localized on both Sn atoms.

10. Reactions of $F_3C{-}C{\equiv}SF_3$

The facts that **49** cannot be readily prepared in amounts greater than 1 g and that it is not stable at room temperature have thus far largely restricted chemical investigations. No chemical reactivity whatever has yet been described for **51**. The addition of HF to the triple bond in two steps is the most predictable reaction, but also the only one thus far in which the compound reacts as a triple bond.

In numerous attempts, the triple bond failed in every case to coordinate to metal complexes because **49** is too strong an oxidation and fluorination reagent. Likewise all attempts to carry out cycloaddition reactions have thus far met without success. These negative results are in complete contrast to the extensive complex chemisty of $t\text{-}C_4H_9{-}C{\equiv}P$[182] and $N{\equiv}SF$[169] and to some results of Diels-Alder reactions which these undergo.

The mechanism for the reaction of **49** with amidines to give thiadiazolines remains unclear.[92]



In all reactions, spontaneous dimerization is always observed, a remarkable reaction for a triple bond. The thermal tetramerization of $(H_3C)_3C{-}C{\equiv}P$, however, leads to a cubane.[230] Corresponding to the crystal structure analysis,[196] the geometry of the sulfur environment in the dimer indicates an oxidation state 4 for the sulfur atoms. From kinetic measurements it emerges that a first order reaction with $\Delta H^{*} = 50\ kJ\ mol^{-1}$ is the rate determining step of the dimerization reaction, which is attributed to the transformation of $F_3C{-}C{\equiv}SF_3$ into the carbene-like intermediate. A more rigorous proof for the intermediate existence of the carbene state would be a carbene trapping reaction, which nevertheless has failed thus far. The recently discovered $[(iC_3H_7)_2N]_2P{\equiv}C{-}Si(CH_3)_3$, which according to NMR data likewise contains a triple bond reacts as a heteroalkyne and also as a dicarbene.[231]

Upon irradiation in a matrix **49** is converted into $CF_3CF_2{-}SF$.[232] It must be assumed that the intermediate stage of an alkylidene sulfur difluoride is passed through (see Section 5).

11. Outlook

Often only a few examples are known of the novel bonding systems described herein, of the alkylidene sulfur difluorides and the alkylidyne sulfur trifluorides only two of each, of the alkylidene sulfur difluoride oxides only three. So it happens that the answers to the questions with regard to structure and bonding must be tentative, and particular so because the current representations serving as models cannot be applied completely unconstrained.

However, such simple new compounds are interesting for they often illustratively elucidate theoretical problems of bonding.

I would like to thank my co-workers Dr. J. Bittner, Dr. R. Damerius, R. Gerhardt, T. Grelbig, T. Henkel, Dr. G. Kleemann, Dr. T. Krügerke, R. Kuschel, and Dr. B. Pötter for their commitment to this area of research. Only through world wide cooperation, e.g. with H. Bock, J. Boggs, D. Dixon, H. Oberhammer, C. Marsden, A. Simon, J. Thrasher, have we been able to make any advance in this difficult field. Thanks are also due to the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie for the continuous financial support.

Metallomesogens: Metal Complexes in Organized Fluid Phases

By Anne-Marie Giroud-Godquin and Peter M. Maitlis*

Metallomesogens, metal complexes of organic ligands which exhibit liquid crystalline (mesomorphic) character, combine the variety and range of metal-based coordination chemistry with the extraordinary physical properties exhibited by liquid crystals. Thermotropic metallomesogens have been made incorporating many metals, including representatives of s-, p-, d- and even f-block elements. Both rodlike (calamitic) and disklike (discotic) thermotropic metallomesogens are known, and examples of all the main mesophase types are found. Many different varieties of ligand can be used: monodentate (4-substituted pyridines), bidentate (β-diketonates, dithiolenes, carboxylates, cyclometalated aromatic amines), or polydentate (phthalocyanines, porphyrins). As with organic mesogens, molecular shape and intermolecular forces play an important role, i.e. the ligands are important in determining mesophase character. The chief requirement for a metallomesogen is a rigid core, usually unsaturated and either rod- or disklike in shape, bearing several long hydrocarbon tails. The metal atom is usually at or near the center of gravity of the molecule. In some cases the ligands are themselves mesogenic, but this is not a requirement. The presence of one or more metals opens many exciting possibilities: new shapes, not easily generated by organic compounds, and hence new properties are then accessible. The incorporation of d-block metals brings with it features such as color and paramagnetism. Profound effects arise from the large and polarizable concentration of electron density that every metal atom possesses, since the molecular polarizability is a key factor in determining whether a molecule will form liquid crystals. Enhanced physical properties (e.g. high birefringencies), as well as new and unexpected ones, will result. A major requirement for metallomesogens to find applications in new device technology is that the metal–ligand bonds are strong and inert and the complexes stable; this can be accomplished with, for example, chelating ligands and the 5d metals.

1. Introduction

Scientific advances frequently take place at the interfaces between disciplines. *Metallomesogens* introduce to metal-based coordination chemistry the unusual physical properties exhibited by liquid crystals, so useful in electronic devices and elsewhere. Although metallomesogens have been known for some eighty years, only now is this area, which we have had the pleasure of helping to develop, springing into prominence.

Most work has concentrated on organic materials, but recent developments have highlighted the many new possibilities which can result from the introduction of one or more metal atoms into a liquid crystal; there are, after all, some sixty metals which can in principle be coordinated.

Reasons for putting a metal into a liquid crystal range from satisfying intellectual curiosity (it's an intriguing combination: what will the properties be?) through to the severely practical (novel substances for molecular electronics, new electrical or magnetic switches, conductors, new optical devices). Geometries and hence shapes not easily found in organic chemistry can result from coordinating a metal; metals show square planar, square pyramidal, trigonal bipyramidal, octahedral, and a remarkable variety of geometries for coordination numbers ≥ 7.

Many of the d- and f-block transition metal complexes are in oxidation states which give colored compounds, and many of them have unpaired electrons and exhibit paramagnetism, further extending the range of potentially useful physical properties.

But perhaps the most important effects arise from the large and polarizable electron density which is a feature of every metal atom. Polarizability is one of the most important attributes of molecules which form liquid crystals and any increase will have very profound effects on the physical characteristics, with the possibility of a useful but unexpected macroscopic property resulting.

1.1. What are Liquid Crystals?

Liquid crystals form a state of matter intermediate between the solid and the liquid. The terms *mesomorph* (Greek, *mesos morphe*, between two states, forms) and *mesophase* are also used; a *mesogen* is the molecule which gives rise to a mesophase. Organic liquid crystals have been known for over a century.[1] They can be divided into two broad families, the *thermotropics*[2] and the *lyotropics*.[3] Thermotropic liquid crystals change phase on heating or cooling; the crystal phase melts to the mesophase, which then clears to the isotropic liquid at a higher temperature. Some exhibit poly-

[*] The terms "dithiolenes" and "dithiolene complexes" introduced here are treated as trivial names. Strictly speaking these compounds should be called "enedithiols" and "enedithiolate complexes", respectively.

morphism: they show several mesophases. Lyotropic phases are formed by molecules in a solvent (generally water) and the appearance of the mesophase is controlled by the concentration.

A crystal (denoted by K or C) has defined shape, and most of its physical properties are anisotropic because the constituent molecules or ions are ordered in position and orientation. By contrast, the component molecules (or ions) of a fluid lack positional and orientational ordering; hence the physical properties are isotropic (I) and a fluid takes up the shape of the container. In a thermotropic mesophase the positional order is largely absent, giving a fluidity, while some orientational order is retained, giving the anisotropy. The transition from the crystal to the mesophase is often termed the *melting point*, and that from the highest mesophase to the isotropic, the *clearing point*, reflecting the fact that mesophases often appear turbid while the isotropic liquid is clear.

One consequence of this anisotropy is that mesophases can have two (or even three) different refractive indices, magnetic susceptibilities, and electric permittivities. As a result, some thermotropic molecules can be oriented by applied electric fields.

Thermotropics can be further sub-divided into *calamitic* (reed- or rodlike) and *discotic* (disklike, denoted by D);[4] *polymeric*[5] liquid crystals are also known. Rodlike thermotropics form two broad classes [*nematics* (N) and *smectics* (S)] and several subgroups of discotics are also known.

In the least ordered phase, the nematic, the rodlike molecules line up approximately parallel to each other (Fig. 1); this direction is known as the *director*. The transition from the crystalline to the nematic phase (K → N) is usually associated with an enthalpy change about ten times higher than the nematic to isotropic (N → I) transition.

A very useful characteristic of nematic mesophases is the ease with which they are reoriented by a magnetic or electric field. This has found practical application in electronic display devices. Nematic molecules are achiral (or racemic); the introduction of a chiral center into such a molecule gives rise to cholesteric behavior, where the director is now helical.

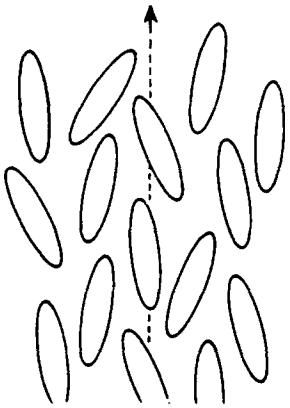

Fig. 1. Schematic representation of a calamitic nematic phase.

Smectic liquid crystals form a variety of layered phases, which offer additional order over that found for nematics; some have phases with the molecules perpendicular to the layers (e.g. S_A; Fig. 2, top), in others they are inclined to them (e.g. S_C; Fig. 2, bottom).

Discotic liquid crystalline phases are obtained with disklike molecules where the director is perpendicular to the molecular plane; columnar and nematic (Fig. 3) as well as

Peter Maitlis is Professor of Inorganic Chemistry at Sheffield University. He was educated in England (PhD with Professor M. J. S. Dewar in London, in 1956), and then spent twelve years in North America where he was Professor at McMaster University in Canada before returning to England and taking up the Chair in Sheffield in 1972. His research interests include organotransition metal chemistry and homogeneous catalysis. During the last five years he has become increasingly involved in the design of coordination complexes as Advanced Materials, in particular as liquid crystals, where he has developed the study of metallomesogens with his group. In 1984 he was elected to the Royal Society, and in 1986 he received the Sir Edward Frankland Prize Lectureship of the RSC for his work in organometallic chemistry. He has also been President of the Dalton Division of the RSC and was Chairman of the Chemistry Committee of the Science and Engineering Research Council.

Anne-Marie Giroud-Godquin was born in Casablanca (Morocco). After secondary school (Lycée de Casablanca) she completed her undergraduate studies in physics and chemistry at La Sorbonne (University of Paris). She discovered the excitement of chemical research with Dr. J. Jacques at the Collège de France during her Thèse troisième cyle in 1961. She then entered the Centre National de la Recherche Scientifique, where she gained her PhD (in steroid chemistry) from the University of Grenoble with Professor A. Rassat. After postdoctoral work with Professor G. Luckhurst at the University of Southampton, she returned to Grenoble to develop her original research on metal-containing liquid crystals. Later she spent some months at IBM in California with Professor U. Müller-Westerhoff. She is now Directeur de Recherche at the CNRS Chemistry Laboratory of the Centre d'Etudes Nucléaires at Grenoble, where she pursues her researches on metallomesogens.

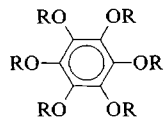
other types are known. Typical organic discotics are benzene derivatives with six long *n*-alkyloxy tails, **1**; many metallo-



1

mesogens (such as those based on phthalocyanine, porphyrin, or even β-diketonate ligands) also form discotic phases. The two-dimensional network of such a columnar

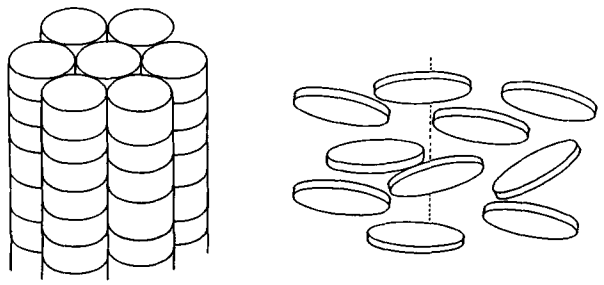


Fig. 3. Schematic representations of columnar-discotic (left) and nematic-discotic phases (right).

mesophase can be hexagonal, rectangular, or oblique, and the molecules can be either ordered or disordered along the long axes of the columns (Fig. 4).

Thermotropics are held together by weak dipole-dipole and dispersion forces. Their magnitude is critical: when they are too weak or when they are too strong, the liquid crys-

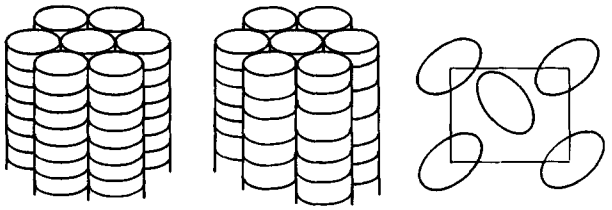

Fig. 4. Schematic representations of columnar-discotic phases. Left: ordered hexagonal, D_{ho}; center: disordered hexagonal D_{hd}; right: rectangular, D_r.

talline character is lost. Hence the molecular features which optimize thermotropic behavior are very important.

To exhibit liquid crystalline properties organic compounds require strongly polarizable groups, such as aromatic rings (A, B in Fig. 5), esters, or other oxy- (X, Y) or nitrile-functions. Rodlike thermotropic mesogens also require a long rigid group (often phenyl rings which form a core), while a rigid conjugated platelike grouping is usually associated with the core of a discotic mesogen. Both types need several long flexible *n*-alkyl- (or *n*-alkyloxy-) tails (R). The rod- or disklike shapes, together with the polarizable groups, increase the molecular anisotropy and facilitate formation of liquid crystal phases.

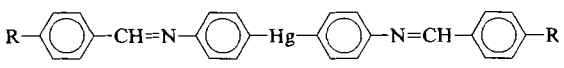
Fig. 5. Schematic representation of a rodlike, thermotropic, organic mesogen.

It is important to note that none of the mesophase structures illustrated is static; each representation is a snapshot; for example, smectic layers can be described by one-dimensional density waves.

The characterization of thermotropic mesophases relies first, on optical microscopy, where the different phases show characteristic textures when viewed between crossed polarizers, as the temperature is changed. Mixing with a known mesophase is widely used to confirm the observations, since two identical mesophases are frequently miscible. These optical methods are complemented by Differential Scanning Calorimetry (DSC), and by low angle X-ray scattering in the mesophase.

1.2. Early Work on Metallomesogens

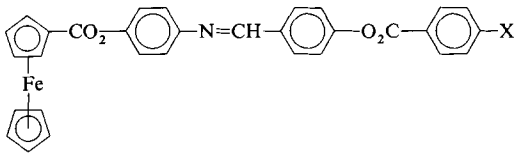
The first thermotropic metal-containing liquid crystals were reported by *Vorländer* in 1910.[6] He discovered that the alkali-metal carboxylates, $R(CH_2)_nCOONa$, formed classical lamellar phases characteristic of soaps. In 1923 *Vorländer* also found that the diarylmercurials **2** form smectic phases.[7]



2

Between 1959 and 1961 *Skoulios* et al. characterized alkali and alkaline earth salts of carboxylic acids and showed them

to possess a large variety of organizational types: lamellar, ribbonlike, and cylindrical.[8] The smectic ferrocenyl Schiff bases **3**, the first well-characterized organotransition metallomesogens, were synthesized by *Malthête* and *Billard* in 1976.[9]



3, X = C_nH_{2n+1} (n = 5, 6, 8); OC_nH_{2n+1}(n = 8, 10)

The first to seek advanced materials in this area were *Giroud* and *Müller-Westerhoff*, who in 1977 reported the mesogenic nickel and platinum dithiolenes.[10] This work laid the foundations for the study of mesogens containing d-block elements and marked the practical beginnings of interest in the subject. Since then many researchers have entered the field, and many new types of metallomesogen have been synthesized.

This article reviews progress, developments, and problems in the field up to early 1990, and offers indicators to the principles by which new representatives may be constructed, and to the relations between mesomorphism and structure at the molecular level, as they appear at the moment.

Because mesophase formation depends on intermolecular forces and because much of the space around the metal is occupied by the ligand, the properties of metallomesogens are, to a first approximation, dominated by the ligands and their arrangement, in other words by the overall shape of the molecule. Thus, for example, long monodentate ligands will tend to give rodlike nematics and smectics, while flat, disklike polydentate ligands (for example, macrocycles) will give discotics. For this reason the material in this review is arranged by ligand type.

This organization also brings out the exceptions—for example molecules which one might expect to show discotic phases but which have been reported as smectics—and shows how critical the substituents on the *perimeter* of the ligand to the type of mesophase behavior are. Where X-ray data are available on the single crystals, it also becomes clear that many metallomesogens have interactions which enable the metal to interact axially (though weakly) with a donor atom on a neighboring molecule. Examples of this are found in the dimetal tetracarboxylates, in copper β-diketonates, in zinc, mercury, and palladium dithiocarboxylates, in salicylaldimines and, in a modified sense, in the metallophthalocyanines. This feature appears to have an important, if as yet unquantified, bearing on mesophase formation.

The metallomesogens have therefore been arranged by ligand, starting with the simplest, monodentate, and progressing to more complex bidentate and polydentate types: carboxylates, β-diketonates, dithiolenes, and dithiocarboxylates, polyamines (phthalocyanines, etc), salicylaldimines (Schiff bases with *N-O* chelate formation), and cyclometalated mesogens.

2. Metallomesogens with Monodentate Ligands

2.1. Nitrile Complexes

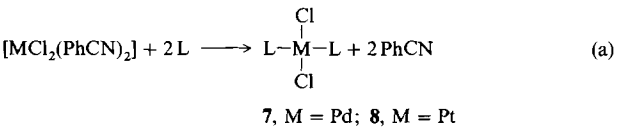
Nitriles bind readily to a variety of metals. The commercially available thermotropic CN-substituted biphenyls **4** and **5** and the bicyclohexyl derivative **6** analogous to **4** (**4** = n-CB, **5** n-OCB, **6** = n-CCH; n is the C number of the alkyl or alkoxy substituents) were first used by *Maitlis* and the Sheffield Liquid Crystal group for the synthesis of metallomesogens with a linear geometry. The (D_{2h}) *trans*-bis (neutral) ligand complexes **7**, **8** (L = n-CB and n-OCB), as well as

4 (n-CB)

5 (n-OCB)

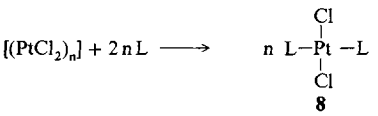
6 (n-CCH)

the monoligand complexes, **9** (L = n-OCB), were synthesized.[11] Synthetic routes were by displacement of one nitrile by another for **7** [Eq. (a)], by direct reaction, for **8** [Eq. (b)] or by bridge-splitting, for **9** [Eq. (c)].



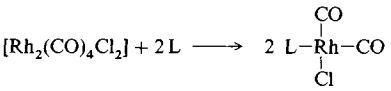
(a)

7, M = Pd; **8**, M = Pt



(b)

8



(c)

9

The palladium *alkyl* complexes **7** (L = n-CB) showed nematic *monotropic* behavior (thermodynamically unstable mesophases, which appear only on cooling). Lower homologues of the *alkyloxy* ligand complexes **7** (L = n-OCB, n = 4–7) showed nematic phases while the higher ones (n = 9) showed *enantiotropic* (thermodynamically stable) S_A and S_C phases.[12, 13] By contrast, platinum complexes, with both n-OCB and n-CB, showed enantiotropic phases.

Detailed comparisons are instructive (Table 1). Thus, while the ligand **4** (n = 5) has a nematic phase (24–35 °C) before clearing, and its $PtCl_2$ complex **8** behaves similarly, but at much higher temperature (K → N 189 °C, N → I 208 °C), the $PdCl_2$ complex shows only a monotropic nematic (I → N 92 °C). The ligand **5** (n = 9) shows an S_A phase (64–77 °C) and a nematic phase (77–80 °C) before clearing. The $PtCl_2$ complex shows an N and an S_C phase, but at higher temperatures (K → S_C 172 °C; S_C → N 183 °C; N → I

206 °C), whereas the $PdCl_2$ complex just shows smectic phases (K → S_C 119; S_C → S_A 122; S_A → I 146 °C).[12, 13] In some cases the complexes decompose close to the (rather high) clearing temperatures.

The structures of the Pd^{II} complex **7** (L = 5-CB) and the Pt^{II} complexes **8** (L = 5-CB and 8-CB) were confirmed by single crystal X-ray determinations (Fig. 6).[13] Since Pd and Pt are nearly equal in size, the 5-CB complexes are virtually identical, even with similar inter- as well as intramolecular dimensions. The ground state structures offer no immediate explanation for the differences in mesophase behavior, which may therefore be due to the generally higher lability of Pd^{II} complexes compared to their Pt^{II} analogs.

Although the bicyclohexylcyanopalladium complex **7** (L = 5-CCH), in contrast to the non-mesomorphic 3-CCH analogue, forms monotropic nematic phases (shown in Color figure 1 for L = 7-CCH), enantiotropic materials with a nematic range of ca. 5 °C can be prepared if the two complexes are mixed in a 1:1 ratio (Fig. 7).[12] This illustrates an important aspect of mesogens: even when the correct molecular shape does not produce the desired properties directly, they can often be induced by judicious mixing.

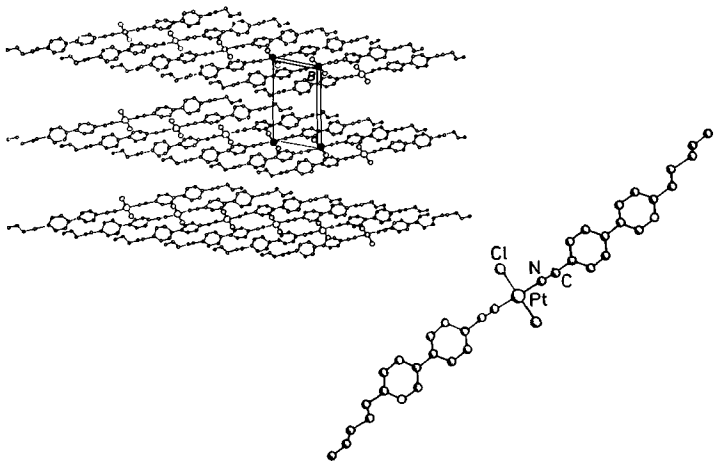

Fig. 6. Crystal structure of **8** (L = 5-CB) (after Ref. [13]).

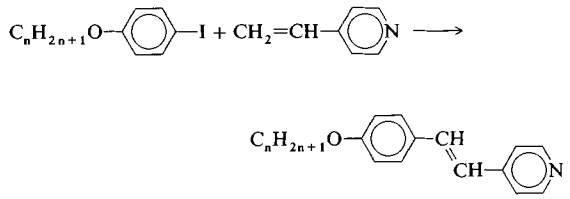
An unanticipated benefit of complexing to a metal is the sharp increase in the birefringence, Δn, the difference between the parallel and the perpendicular refractive indices. Thus, while Δn for the ligands **4**–**6** is around 0.18, a mixture of $PdCl_2$ complexes of 2-OCB, 4-OCB and 6-OCB ligands gave a birefringence, $\Delta n \approx 0.45$ (at room temperature, by extrapolation).[14]

Mesogenic rhodium complexes with one cyanobiphenyl ligand, e.g. **9**, (L = 9-OCB) have also been made, but show very short nematic ranges and decompose close to their clearing temperatures.[13]

2.2. *n*-Alkyloxystilbazole Ligands

The 4′-alkyloxy-4-stilbazoles **10** (n-OST) are 4-substituted pyridines with extra polarizable functions (conjugation) and

a flexible tail. Since pyridines complex well to a large number of transition metals, the stilbazoles have been widely used by the Sheffield group as ligands for metallomesogen formation.



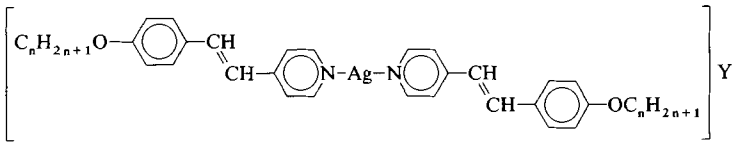
(d)

10 (n-OST)

The stilbazoles are made by a Heck reaction (palladium acetate and triethylamine in acetonitrile) between the 4-(alkyloxy)iodobenzene and 4-vinylpyridine [Eq. (d)]. The C=C double bond is *trans* in the ligand and in all the complexes examined. The ligands themselves show monotropic S_E and S_B phases for 3- and 4-OST, and enantiotropic S_E and S_B phases for $n > 5$, with clearing points around 85–90 °C.[15]

2.2.1. *Distilbazole Complexes*

Reaction of the stilbazoles with silver salts, AgY, led to a quite unexpected series of mesogenic materials, the ionic bis-ligand silver salts, $[Ag(n\text{-}OST)_2]Y$ **11** (**11a**: $Y = BF_4^{\ominus}$, **11b**: $Y = NO_3^{\ominus}$, **11c**: $Y = C_{12}H_{25}SO_4^{\ominus}$, **11d**: $Y = CF_3SO_3^{\ominus}$). The tetrafluoroborates **11a** were very sensitive to light, hygroscopic, and showed high transition temperatures.[16]



11

However, the dodecyl sulfate salts **11c** formed mesophases at lower temperatures and showed quite unusual behavior; for example, **11c** (n = 3) gave a *nematic* phase 146–159 °C before clearing.[17] Salts with longer alkyloxy chains exhibited complex behavior; for example, **11c** (n = 12) showed a lamellar (S_C) phase (108–132 °C), as well as a cubic (M_I) and an S_A phase before clearing at 178 °C to the isotropic liquid.[17, 18] Figure 8 shows a typical phase diagram relating transition temperatures to alkyl chain length. Phase identification was assisted by simultaneous X-ray diffraction and differential scanning calorimetry (XDDSC). The nitrate and triflate salts **11b** and **11d** are broadly similar to the dodecyl sulfates, but do not show such a variety of mesophases.

The existence of ionic nematics among the salts with shorter alkyloxy tails is quite unexpected, given the conflicting presence of both strong isotropic ionic forces and weak, anisotropic dispersion forces which stabilize the liquid crystal phases. The rich and varied polymorphism in these ionic systems may have some electrochemical applications.

A gold complex, [AuCl(8-OST)], which showed a mesophase between 120 and 200 °C,[12] and some very high melting palladium and platinum complexes, $[MCl_2$-

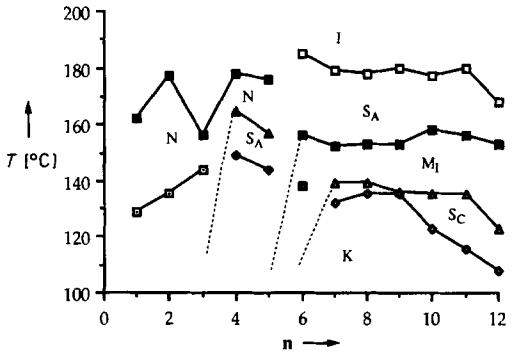


Fig. 8. Phase diagrams of $[Ag(n\text{-}OST)_2]C_{12}H_{25}OSO_3$ showing the extensive polymorphism of this system. ⊡ K → N, ◆ K → S_A, □ K → M_I, ◇ K → S_C, ■ N → I, □ S_A → I, ▲ S_A → N, △ S → M_I, ■ M_I → S_A (after Ref. [18]).

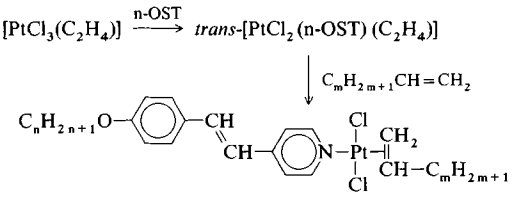
$(n\text{-}OST)_2]$ have also been prepared. Only $[PdCl_2(12\text{-}OST)_2]$ showed any mesophases (K → S 280 °C; S → N 290 °C; N → I 315 °C).

However, the related carboxylato complexes, prepared by reaction of $[Pd_2(O_2CR)_4]$ with the n-OST ligand, formed mesophases at much lower temperatures, for example $[Pd(O_2CC_9H_{19})_2(12\text{-}OST)_2]$, K → N 144 °C; N → I 151 °C.[19, 20] *Maitlis* et al. have found that the replacement of "hard" anions or ligands by softer organic amphiphilic anions or ligands is a generally useful strategy for lowering transition temperatures.

2.2.2. Monostilbazole Complexes

Another way to achieve lower transition temperatures is to incorporate some asymmetry. Since such complexes tend to disproportionate, this may not always be straightforward, but their synthesis has been accomplished in the case of the platinum complexes **12** which have one stilbazole and one η^2-olefin ("π-bonded") in the *trans* position. The complexes were prepared from Zeise's salt, $K[PtCl_3(C_2H_4)]$ by reaction with n-OST; the ethene can be readily displaced by other α-olefins [Eq. (e)].[20]



(e)

12

The chain lengths n and m were systematically varied (n = 3–12; m = 0–8) and it was found that mesophase behavior (all S_A) occurred for those with longer chains (Fig. 9). Complexes with $m + n \approx 8$–11 showed monotropic behavior (S_A); those with $m + n \gtrsim 11$–13 showed enantiotropic S_A phases (Color figure 2), while those with $m + n \lesssim 8$ were non-mesomorphic.[20]

The mesogenic complexes **12** had transition temperatures below 100 °C; these were further reduced on mixing. Thus, a 70:30 mixture of the pentene complex **12** (n = 12, m = 3)

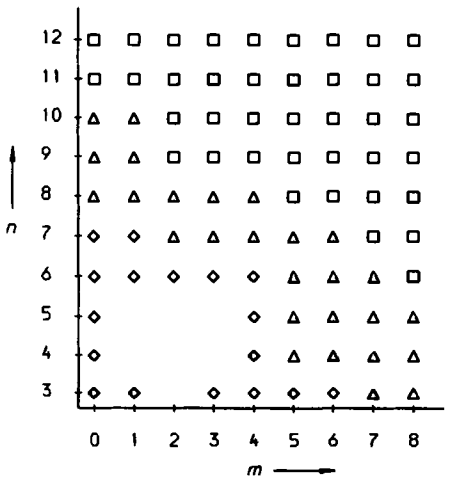


Fig. 9. The properties of the mesophases of *trans*-[$PtCl_2$(n-OST)-(CH_2=CHC_mH_{2m+1})] 12 as a function of n and m. ◇ non-mesogenic, △ monotropic, ◻ enantiotropic (after Ref. [20]).

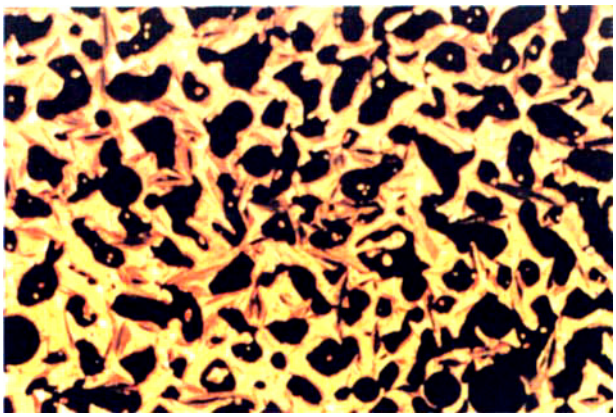

Color figure 2. Polarization microscopic photograph of the octene complex **12** during the transition from the isotropic liquid phase into the S_A mesophase.

and the related octene complex **12** (n = 12, m = 6) showed a much lower melting temperature (45 °C) than either component, while the clearing temperature (91 °C) remained unaffected (Fig. 10).

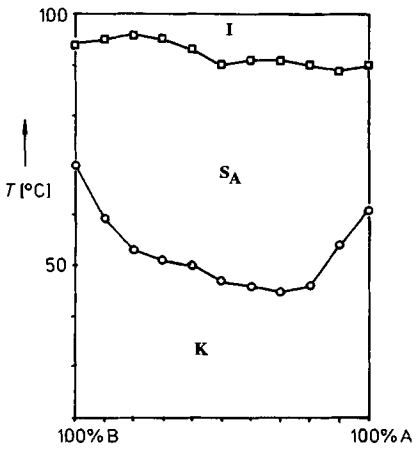

Fig. 10. Phase behavior of a mixture of the complex A (**12**; n = 12, m = 3) and B (**12**; n = 12, m = 6) (after Ref. [20]).

A series of unsymmetric stilbazole rhodium and iridium complexes **13** and **14** were prepared by the route shown in Equation (f). The burgundy iridium complexes **14** became yellow, both in solution and on melting, and showed nematic phases for n = 5–8, and S_A phases for n = 7–12, in the temperature range 80–130 °C (Table 2).[21] The rhodium com-

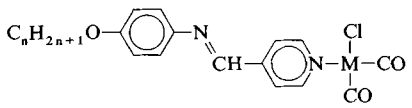
13, M = Rh; **14**, M = Ir

The mean electronic polarizabilities of the iridium complexes **14** (n = 5–12) were very substantially enhanced by comparison with those of the free ligands **10**.[22]

2.3. Complexes with Other Pyridine Ligands

Serrano et al. in Zaragoza have used other substituted pyridines as ligands for metallomesogen formation. Thus the *cis*-iridium complexes **16** containing the short-chain, non-



15, M = Rh; **16**, M = Ir

mesomorphic iminopyridine ligand (n-OIP, 4-alkoxy-*N*-(4-methylpyridine)aniline) formed nematic phases (mostly monotropic), while those with longer chains ($n \geq 9$) formed S_A phases.[23] These again had low transition temperatures, e.g. **16**, (n = 10, K→S_A 63 °C; S_A→I 85 °C) (Table 3). The related rhodium complexes **16** ($n \geq 8$) are also mesogenic;[24] e.g. **15**, (n = 9, K → S_A 76 °C; S_A→I 83 °C). It is quite remarkable that mesogenic complexes are formed here with a single organic ligand which is itself non-mesogenic. Further, and quite surprisingly, the *trans*-[Rh(n-OIP)$_2$(CO)Cl] complexes (n = 4, 8) were very high melting and showed no mesogenic character.[24]

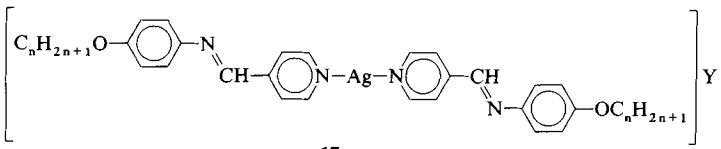
The silver(I) complexes with n-OIP, [Ag(n-OIP)$_2$]Y **17** (Y = $BF_4^\ominus$, $CF_3SO_3^\ominus$, $NO_3^\ominus$, and $PF_6^\ominus$) and with the pyridine carboxylate ligand n-OCP [Ag(n-OCP)$_2$]Y **18**, also showed mesogenic behavior.[25] Only one salt, **17** (Y = $BF_4^\ominus$, n = 2), was nematic (194.9–223.8 °C); all the others showed S_A or S_C phases (for example, **17**, Y = $BF_4^\ominus$, n = 12, K→S 104 °C; S→N 195 °C; N→I 211 °C, with decomposition).



17

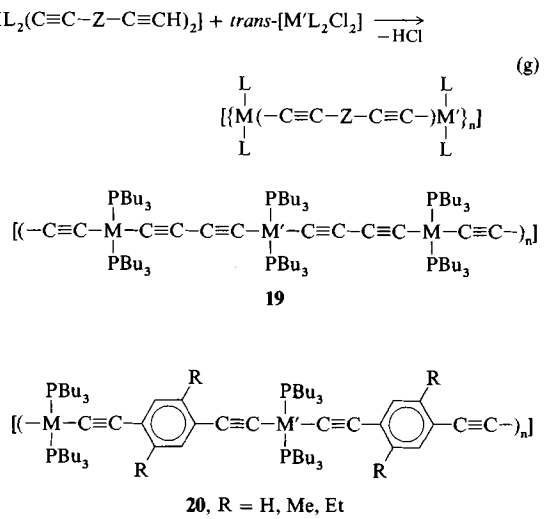
18

The ester salts **18** showed somewhat wider mesophase ranges and greater smectic polymorphism than the imino salts **17**, and smaller anions gave wider mesophases and lower melting points. Low angle X-ray data for four complexes with n = 10 showed the layer thickness in the mesophase to be 41–42 Å, i.e. shorter than the fully stretched linear cations (48 Å in **17**, 53 Å in **18**).[25]

2.4. Organometallic Complexes with $\eta^1(\sigma)$-Bonded Ligands

The first thermotropic metallomesogens were the smectic organomercury compounds **2**, described by *Vorländer* in 1923;[7] they were prepared by the condensation of bis(4-aminophenyl)mercury with aromatic aldehydes, RCHO, R = PhCH=CH, *p*-tolyl, or *p*-alkyloxyphenyl. All the compounds gave mesophases, and even those from benzaldehyde, R = Ph (mesophase 180–184 °C), as well as *p*-$MeOC_6H_4CH{=}NC_6H_4HgX$ (X = OAc, Cl) showed small mesogenic ranges. Unfortunately all these organomercury compounds are thermally unstable.

The very unusual organometallic liquid crystals **19** and **20** (M,M′ = Pd, Pt or Ni; M = M′ or M ≠ M′) have been made by *Takahashi* et al,[26] by a copper chloride–triethylamine coupling of the appropriate metal halide with an alkyne [Eq. (g)]. A wide variety of such compounds have been



19

20, R = H, Me, Et

made. These materials are very high melting and do not show thermotropic properties; however, they are *lyotropic nematic* in trichloroethylene solution, and can be aligned in a magnetic field. Whether the particular polymer aligns perpendicular to the magnetic field or parallel to it is determined by its diamagnetic anisotropy $\Delta\chi'$, which in turn is dependent on the $\Delta\chi$'s of the components of the polymer. Thus, for example, $\Delta\chi$ for acetylene is negative, while it is positive for benzene and *p*-xylene.

2.5. Ferrocenes

A series of mesogenic ferrocenes **3** (which have an overall shape not too dissimilar to the mercury compounds **2**) were made by *Malthête* and *Billard* in 1976,[9] by condensation of the appropriate benzaldehyde derivative with 4-aminophenyl ferrocene carboxylate. Recently, it was shown with the ferrocene carboxylic acid building block that the bis-substituted ferrocene [Fe(C_5H_4–COO–C_6H_4–C_6H_4–X)$_2$] gave monotropic S_C phases for X = $C_5H_{11}O$, and C_6H_{13}, whereas the monosubstituted [Fe(C_5H_5)(C_5H_4–COO–C_6H_4–C_6H_4–X)] was non-mesogenic.[27]

3. Metallomesogens with Carboxylato ligands

Metal soaps have long been known to have mesogenic properties. Thus, in 1910 *Vorländer* reported the existence of

lamellar phases in the anhydrous salts of alkali carboxylates,[6] and in 1938 *Lawrence* noted that copper stearate, for example, melted from a hard crystalline solid to a plastic fluid, which then transformed into a clear liquid.[28]

3.1. Alkali and Alkaline Earth Carboxylates

Structural data, indicating the existence of columnar and even disklike mesophases for the anhydrous alkali, alkaline earth, and cadmium salts of long-chain fatty acids ($C_nH_{2n+1}COOH$, n = 9, 11, 13, 15, 17, 19), were first reported by *Skoulios* et al.[29] The transition temperatures increased with increasing chain length, and several types of structure were found, depending on the metal (Fig. 11).

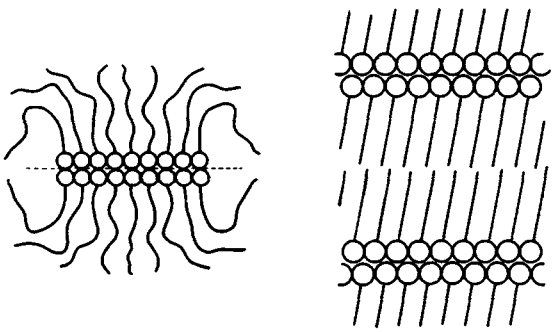


Fig. 11. Structures found in the mesophases of anhydrous alkali-metal carboxylates (after Ref. [29]).

Thus, the potassium salts can be: 1) lamellar, with ordered polar groups and alkyl chains; 2) lamellar with disordered polar groups and alkyl chains; 3) ribbonlike; or 4) disklike in a three-dimensional lattice. In the latter two, the polar groups are ordered while the alkyl chains are disordered.[30] As well as exhibiting thermotropic properties the alkali metal soaps also show lyotropic behavior with solvents.

The calcium carboxylates, for example, showed a lamellar phase below 110 °C with the paraffin chains perpendicular to the lamellae; between 120 and 180 °C the structure becomes disklike, while above 180 °C it consists of cylinders in a two-dimensional hexagonal array (Fig. 12). This last mesophase is also found for the cadmium soaps.

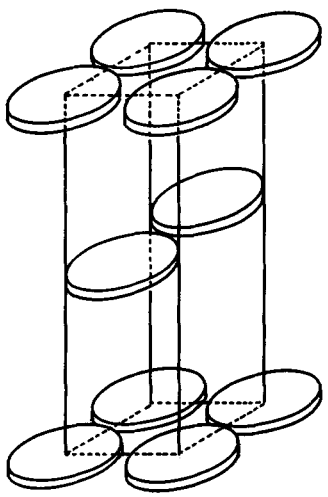

Fig. 12. Disklike structure adopted by anhydrous calcium carboxylate (after Ref. [30]).

3.2. Lead, Mercury and Thallium Carboxylates

S_C phases have been reported for the lead(II) carboxylates, $[Pb(C_nH_{2n+1}COO)_2]$ where n = 5, 7, 9 and 11.[31] The compounds (with n = 7, 9, 11, 13, 15, and 17) investigated further by DSC, optical microscopy, X-ray diffraction and various spectroscopic techniques, were found to transform from a lamellar crystalline to another lamellar highly ordered phase (between 80–100 °C, depending on chain length) and then to melt (at ca. 100 °C) to S_A phases (for n = 7, 9, 11). The alkyl chains melt in more than one step and, on recooling, a crystalline phase different from the original results.[32] The mercury carboxylates, $[Hg(O_2CC_nH_{2n+1})_2]$ (n = 7–17), are not mesogenic, but $[Tl(O_2CR)]$ with branched alkyls R, gave stable lamellar phases.[33]

3.3. Discotic Dinuclear Copper Carboxylates

The liquid crystalline phase obtained on heating copper stearate $[Cu_2(\mu\text{-}O_2CC_{17}H_{35})_4]$ was reinvestigated in 1964;[34] but it was not until considerably later that it was definitively characterized.[35] *Giroud-Godquin* et al.[36] identified the mesophase of copper laurate as hexagonal columnar (Fig. 13) by DSC, optical microscopy, and X-ray diffraction. This was the first example of a thermotropic hexagonal

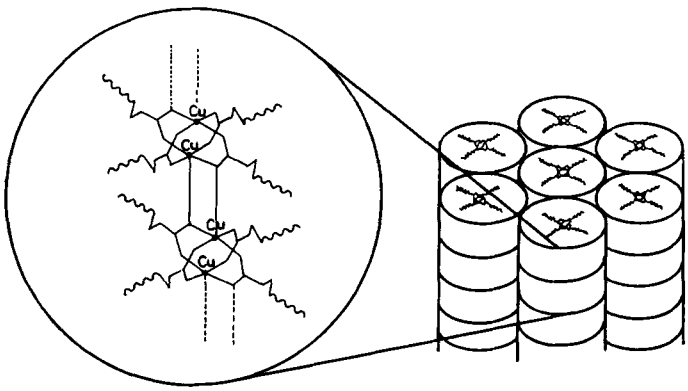

Fig. 13. Schematic view of the columnar mesophase of a copper(II) soap. Each column is made of stacked dicopper tetracarboxylate units. The polar "inorganic" cores are surrounded by disordered alkyl chains. The column axes define a two-dimensional hexagonal lattice (after Ref. [41]).

discotic mesophase bearing only four alkyl chains. The other carboxylates, $[Cu_2(\mu\text{-}O_2CC_nH_{2n+1})_4]$ (n = 4–24), showed the same structures. The X-ray studies showed that the complexes crystallize in lamellar structures, in which planes of polar copper carboxylate groups are separated by a double layer of aliphatic chains, slightly tilted with respect to the perpendicular of the plane. The lamellar spacing is a function of chain length. Above 120 °C there exists a columnar two-dimensional hexagonal structure in which columns of polar groups are surrounded by disordered alkyl chains. The dinuclear

$[Cu_2(\mu\text{-}O_2CC_nH_{2n+1})_4]$ unit is repeated along the column, with a stacking period of 4.7 Å independent of chain length, n; the columns are 15–25 Å apart, depending on n. A sharp increase in the molar volume at the transition temperature, consistent with a first order phase transition, was observed in dilatometric studies of $[Cu_2(\mu\text{-}O_2CC_nH_{2n+1})_4]$ (n = 18, 22, 24).[37]

X-ray single crystal data of copper carboxylates show them to be dinuclear (Fig. 14) with each copper surrounded by five oxygen atoms at a mean distance of 2.01 Å, one copper atom at a distance of 2.59 Å (its neighbor within a dimer), and another copper atom at 3.19 Å, belonging to the closest neighboring dimer.[38] The Cu-K edge EXAFS (*E*xtended *X*-ray *A*bsorbtion *F*ine *S*tructure) data on $[Cu_2(\mu\text{-}O_2CC_nH_{2n+1})_4]$ (n = 6, 7, 12, 18 and 22) confirmed this and also showed that the bond lengths of the dinuclear core remained the same at 20, 70, and 120 °C; i.e., no change was detectable on going from the solid to the mesophase.[39] Magnetic susceptibility measurements showed a small but sharp decrease in the magnetic moment of the dicopper unit at the transition temperature ($\Delta\mu_{eff} \approx -0.04\ \mu_B$). This was ascribed to a structural deformation of the dinuclear core, as a consequence of which the singlet–triplet gap is higher in the columnar mesophase ($-2J = 310-330\ cm^{-1}$) than in the crystal ($290-300\ cm^{-1}$).[40] Since the EXAFS data indicate no change in bond lengths, the phase change probably affects only the bond angles.[41]

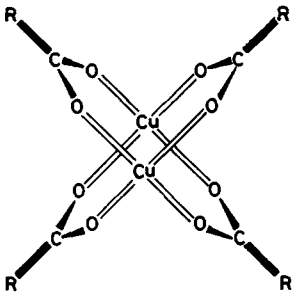

Fig. 14. Crystal structure of a dinuclear copper carboxylate.

Isotopic labeling has facilitated band assignments in the IR spectra of these complexes, allowing the detection of structural variants from changes in the methylene stretching frequency.[42] The dynamic behavior of the alkyl chains in copper carboxylates has been studied by incoherent quasielastic neutron scattering.[43]

Copper laurate has also been melt spun into fibers in its mesophase by the Grenoble group;[44] electron microscopy and X-ray diffraction measurements indicate that the fibers have high degrees of orientation both in the crystalline and the columnar phases.

3.4 Discotic Dinuclear Rhodium, Ruthenium, and Molybdenum Carboxylates

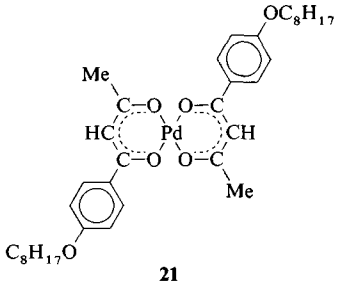
The rhodium(II) carboxylates, $[Rh_2(\mu\text{-}O_2CC_nH_{2n+1})_4]$, behave very similarly to the copper complexes,[45] and form columnar thermotropic mesophases of the same structures. Rh K-edge EXAFS measurements of $[Rh_2(\mu\text{-}O_2CC_7H_{15})_4]$ again show negligible differences between the dimensions in the crystal and in the mesophase [intramolecular, metal–metal bonded, Rh–Rh 2.38 (20 °C), 2.37 Å (120 °C); intermolecular Rh···Rh 3.16 Å (20 and 120 °C)]. A band at 350 cm^{-1} has been assigned to ν(Rh–Rh) in the Raman spectrum; these are the first metal–metal bonded compounds which show a two-dimensional hexagonal columnar lattice.[41]

The Grenoble group has also shown that the air-sensitive dinuclear Ru^{II} and the mixed valence Ru^{II}–Ru^{III} carboxylates, $[Ru_2(\mu\text{-}O_2CC_nH_{2n+1})_m]$ (m = 4 or 5), form thermotropic columnar mesophases.[41, 46] They are prepared by Cr^{II} reduction of the mixed valence (and non-mesogenic) $[Ru_2Cl(O_2CC_3H_7)_4]$, followed by carboxylate exchange. The magnetic moment of $[Ru_2(\mu\text{-}O_2CC_{15}H_{31})_4]$ increased sharply at ca. 100 °C, and a change, corresponding to the transition to the columnar mesophase, was also detected by DSC and X-ray diffraction. The quadruply bonded Mo≡Mo carboxylates $[Mo_2(O_2CC_nH_{2n+1})_4]$ form analogous discotic mesophases.[46b]

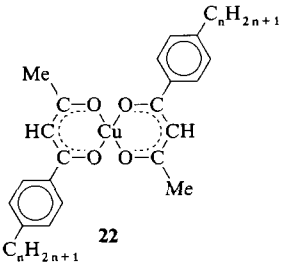
4. Mesogenic β-Diketonato Complexes

β-Diketonates form flat bis-ligand complexes with a variety of metals that can take up square planar geometries (including Ni, Pd, and Cu). When appropriate substituents are present, copper(II) diketonate complexes can give rise to discotic mesophases; nematic and occasionally lamellar mesophases have also been found. Mesogenic behavior seems to be optimized when the molecules have two pairs of *p*-substituted phenyls, situated 1,3 on each diketone. Some other variations are also tolerated. The complexes are easily made by reaction of the β-diketone with the appropriate copper salt.[47] Mesogenic β-diketones of other metals appear, so far, to have largely eluded workers in the field, though the synthesis of a discotic vanadyl β-diketonate analogous to **26** has recently been accomplished.[47b]

The first β-diketonate to be examined for mesophase behavior was the palladium(II) complex, **21**. *Bulkin* et al.[48] reported that DSC data for this complex indicated potential mesomorphism, but were unable to confirm this optically because the complex darkened on heating.



21

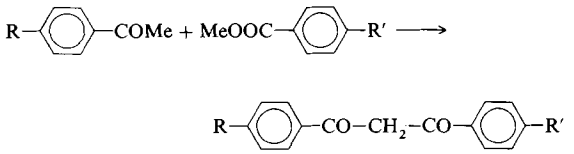


22

No liquid crystal properties were found for the copper(II) complexes **22** either.[49, 50] Only crystal-crystal transitions were observed; the polymorphism in the solid depended on chain length and showed an odd–even effect, but involved no change in coordination geometry.[51]

4.1. Copper Complexes of 1,3-Bis(*p*-substituted-phenyl)-*β*-diketones

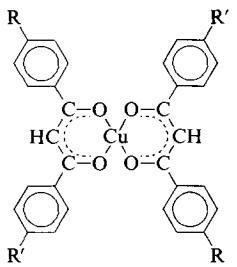
The 1,3-bis(*p*-substituted-phenyl)-*β*-diketones **23** and **24** are prepared by a standard condensation of the *p*-substituted acetophenone with the corresponding *p*-substituted methyl benzoate [Eq. (h)].[52] Ligands **23** with $m + n \geq 18$ exhibit smectic E phases, and show the unusual feature that the enthalpy changes observed on clearing are larger than those found on melting.[53] This situation is frequently observed for discotics but is exceptional for rodlike mesogens.[54]



(h)

23, $R = C_mH_{2m+1}$, $R' = C_nH_{2n+1}$
24, $R = C_mH_{2m+1}O$, $R' = C_nH_{2n+1}O$

The mesogenic copper(II) *β*-diketonates **25**, first described by *Giroud-Godquin* et al.[53, 55] in 1981, have a square planar geometry about the metal[56] and a d^9 configuration (one unpaired electron).[47] Both the symmetrically and the unsymmetrically substituted complexes **25** ($m = n$ or $m \neq n$) exhibit very organized discotic mesophases. The more symmetric have the higher melting and clearing temperatures and the larger molar enthalpy changes, for example **25** ($m = 7$ and $n = 13$; 71–122 °C) and **25** ($m = n = 10$; 85.5–128.5 °C).[53] Later work on these complexes, particularly NMR investigations of the spin-lattice relaxation time T_1,[57]



25, $R = C_mH_{2m+1}$, $R' = C_nH_{2n+1}$
26, $R = C_mH_{2m+1}O$, $R' = C_nH_{2n+1}O$
27, $R = C_mH_{2m+1}$, $R' = C_nH_{2n+1}O$

suggested that a lamellar phase is present, where the disklike molecules are organized in columns as shown in Figure 15. The complexes **25** ($m = n = 7-12$) and **26** ($m = n = 8$) also showed discotic mesophases;[53, 58, 59] the mesophase range for the alkyloxy ligand **24** with $m = n = 8$ was narrower than that for the alkyl ligand **23** with $m = n = 8$, but the opposite was true for the copper complexes **25** and **26** derived from them. Nickel analogs of **25** showed no mesogenic character.[53]

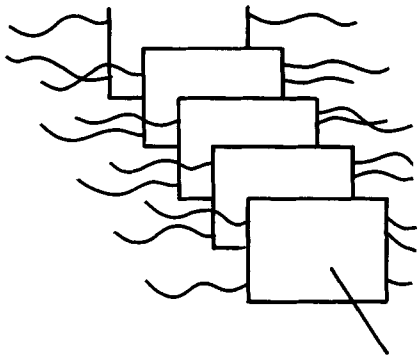


Fig. 15. Schematic representation of the tilted discotic lamellar phase of **25** ($n = 12$) (after Ref. [53]).

Eastman et al.[60] have found that the ESR spectra of single crystals of the symmetrical copper complex **25**, ($m = n = 8$) show features at 298 K associated with a one-dimensional Heisenberg antiferromagnet, while those of complex **26** do not. These workers also followed the phase changes by ESR spectroscopy, and in both cases detected a crystalline to discotic transition. The ESR spectra of complex **25** have been interpreted as showing that exchange interactions are significant and that a degree of long range order is maintained in the discotic phase.

The ligand *β*-diketones **24**, ($m = n$) showed triple melting behavior for $n = 1$, double melting for $n = 2-7$, and were mesogenic (smectic) only for $n = 8-12$,[61] but each of the copper complexes **26** derived from them ($m = n = 3-12$) had only one discotic mesophase. X-ray diffraction established that the mesophase in complex **25** ($n = 12$) is discotic lamellar, characterized by a tilt of the molecule to the layer and by a random positioning of the molecules within the layer (Fig. 16); there was no columnar structure.[62]

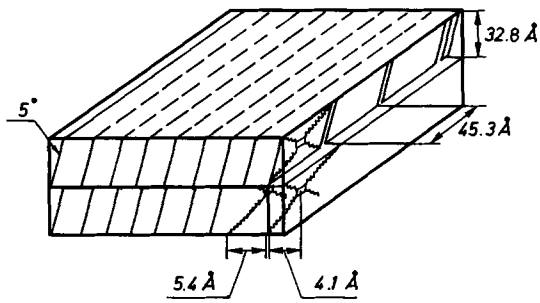

Fig. 16: Schematic representation of the structure of the discotic lamellar phase (D_L) of **25** ($n = 12$) (after Ref. [53]).

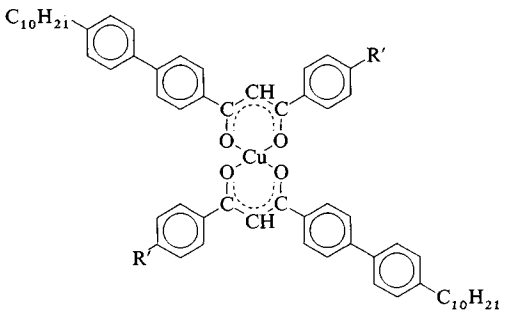
A reinvestigation of the mesophase originally identified for the unsymmetrical complexes **27** has shown that it is lamellar when $m = n = 5-12$).[63]

A very interesting discovery, by *Chandrasekhar* et al.[64, 65] is that the mesophases of the copper(II) complexes of the

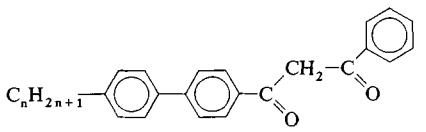
dialkyl- and of the alkyl,alkyloxy-substituted β-diketonates **28** (R′ = Me, Et, OMe, OEt, and OPr) are monotropic nematic, and are miscible with a nematic organic compound, 4″-*n*-pentyl-4-cyano-*p*-terphenyl (5-CT). These complexes incorporate features of both rodlike and disklike molecules,



28

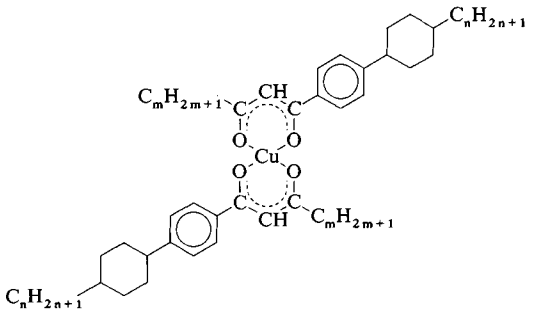
and are claimed to be the first examples of biaxial nematic metallomesogens.[66, 67] On addition of small quantities of the uniaxial nematic 5-CT, the sequence of transitions, isotropic → $N_{uniaxial}$ → $N_{biaxial}$, was observed on cooling. Magnetic, dielectric, and ESR measurements indicated the existence of antiparallel correlations in the nematic phase.

The biphenylylphenyl-substituted 1,3-propanediones **29**, the parent diketones of this series, also showed mesomorphic character.[68] Those with n = 4–7 showed both S_A and N phases, the higher ones only S_A phases.



29

X-ray studies of the 4″-alkylcyclohexylphenylalkyl analogs **30** of the Chandrasekhar complexes **28** by *Mühlberger* and *Haase*[69] showed that the β-diketonate ring was planar and that identical substitutents were *trans* to each



30

other (Fig. 17). These complexes only gave monotropic nematic phases, but an enantiotropic nematic phase was obtained by mixing **30** (n = 3, m = 8) and the organic nematic 5-CT.

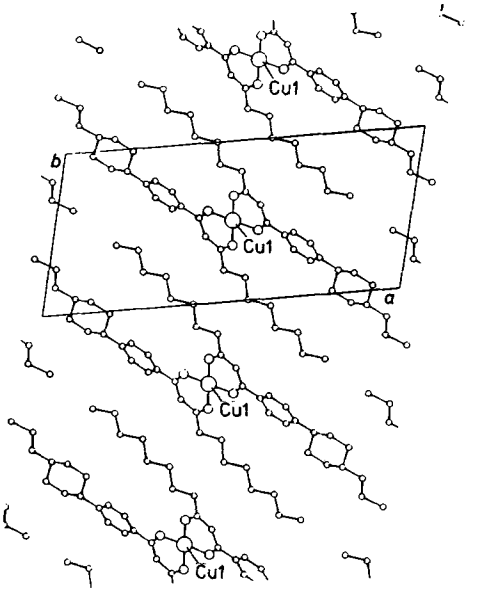


Fig. 17. Crystal structure of **30** (n = 3, m = 8). Projection along the lattice plane (001) (after Ref. [69]).

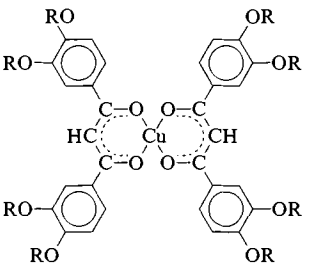
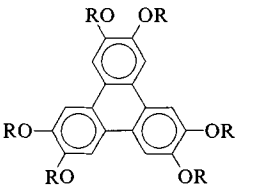
4.2. Copper Complexes of 1,3-Bis(3,4-disubstituted-phenyl)-β-diketones

Early studies had indicated that at least six *n*-alkyl tails were needed on a disklike core in order to obtain a columnar mesophase.[70] *Giroud-Godquin* et al.[71, 72] reported four columnar copper β-diketonate complexes **31**; the phenyls at the ends of the β-diketonate were each substituted (3,4) by two alkyloxy substituents, giving a total of eight tails. These complexes were shown to have a hexagonal columnar (D_h) mesophase by miscibility studies with the triphenylene



31

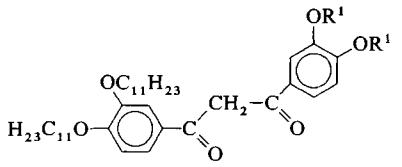


32

hexadecylalkanoate **32** (R = $C_{15}H_{31}CO$), an organic disklike molecule.[73] X-ray diffraction of the complex **31**, (R = C_9H_{19}) showed neighboring columns to be 29 Å apart in the mesophase; this value is substantially smaller than the molecular diameter with stretched conformation of the aliphatic chains (42 Å).[71]

The nickel complex corresponding to **31** showed no mesophase, neither did the copper complexes in which the phenyl was substituted in the 3,5 rather than 3,4 positions. The copper complex of the asymmetric β-diketonato ligand **29′** with R^1 = C_9H_{19} also showed a D_h mesophase, but those with R^1 = C_3H_7 or C_7H_{15} were not mesogenic.[72] Similar complexes were studied by *Ohta*[74] who found (by optical and DSC measurements) that the β-diketonates with four

pairs of OC_8H_{17} substituents in the 3,4 positions of the phenyl rings showed discotic mesophases. However the corresponding complex with four pairs of n-C_8H_{17} tails was not discotic.

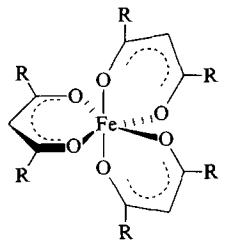


29'

Preliminary measurements suggested that the presence of a transition metal in a discotic mesogen such as **31**, (R = C_9H_{19}) may enhance the electrical conductivity in the uniaxial columnar (D_h) mesophase; the complex also gels in cyclohexane.[71]

4.3. Other Metal β-Diketonates

The octahedral iron(III) tris-β-diketonate Fe(RCOCHCOR)$_3$ **33** (R = $C_{10}H_{21}C_6H_4$) shows endothermic transitions at −10.5 °C (ΔH = 13.7 kJ mol^{-1}) and 37 °C (ΔH = 40.0 kJ mol^{-1}), and a birefringent structure within this range.[75] If confirmed, this would be the first octahedral metallomesogen.



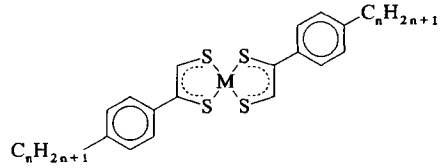
33

5. Metallomesogens with Sulfur-containing Ligands

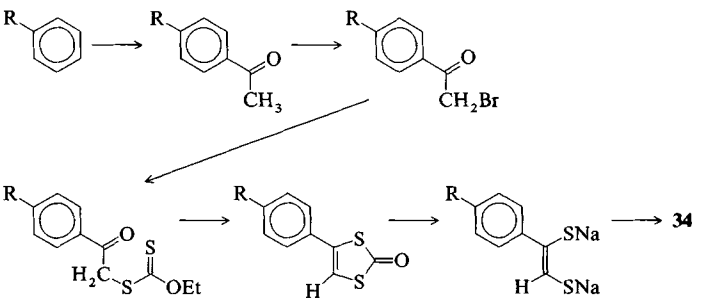
5.1. Dithiolene Complexes

The first systematic study of d-block metallomesogens was carried out by *Giroud* and *Müller-Westerhoff* on dithiolene complexes of Ni^{II}, Pd^{II}, and Pt^{II} (d^8 electron configuration).

The main series investigated, complexes **34** with two *p*-alkylphenyl substituents, were synthesized by the route outlined in Scheme 1.[10, 76–78] A single crystal X-ray diffraction of the nickel complex **34**, (M = Ni, n = 8) showed the expected M^{II} square planar geometry, with the substituents in a *trans*-conformation. The molecules are arranged zig-zag in layers in the unit cell (Fig. 18); this is the arrangement which would be anticipated as the precursor to a smectic C phase.[79]



34, M = Ni, Pd, Pt



Scheme 1. Synthetic route for the bis(alkylphenyl)dithiolene metal complexes **34**.

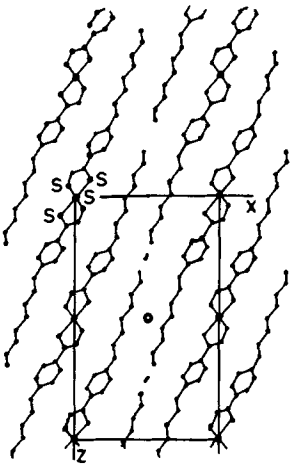


Fig. 18. The packing of a complex **34** (n = 8) in the unit cell (after Ref. [79]).

The Ni and Pt complexes **34** (M = Ni, Pt; n > 6) formed nematic and smectic mesophases (Table 4); those with n = 4,5 showed nematic and those with n > 6 showed only

Table 4. Transition temperatures [°C] for mesomorphic bis(alkylphenyl)dithiolene nickel and platinum complexes [78].

[a] Clears with (some) decomposition.

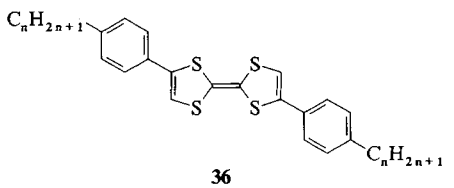
smectic phases. The platinum complexes had significantly higher melting and clearing temperatures than the nickel analogs, but the clearing temperatures became more similar with larger n. The reason why the palladium analogs do not possess any mesomorphic properties is not clear.

The overall molecular structure of **34** is reminiscent of the organic 4,4″-dialkylterphenyls **35**, which form smectic mesophases when n = 3–18.[80] The melting points and the mesophase ranges of **35** are higher than those of the corresponding complex; for example, the smectic range is 161–181 °C for **35**, (n = 10), 103–189 °C for the nickel complex **34**, (M = Ni, n = 10), and 140–202 °C for the platinum complex **34**, (M = Pt, n = 10).

35

The dithiolenes have interesting electron acceptor properties and unusual electronic structures, with strong absorption bands ($\lambda_{max} > 750$ nm, $\varepsilon > 25\,000$). Smectic and nematic derivatives of the nickel dithiolenes **34** with a strong electron donor, tetrathiafulvalenes **36**, were synthesized, but no charge transfer complex resulted.[81]

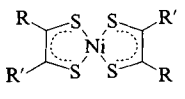
The complex **34** (M = Ni, n = 4), dissolved in the cyanobiphenyl **4** (n = 5), has been shown to be useful as a near-infrared dichroic dye in active and passive devices for lasers operating near 800 nm. The solubility and blocking



36

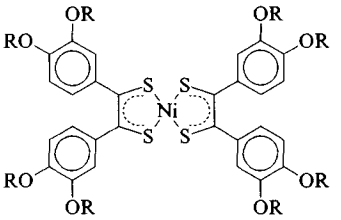
extinction of this complex were considerably superior to the structurally similar but non-mesogenic laser dye, [Ni-(3-$Me_2NC_6H_3CSCSC_6H_5)_2$].[82]

Analogous di- and tetrasubstituted nickel dithiolenes **37** (R = *p*-$C_{12}H_{25}OC_6H_4$; R′ = H or R′) prepared by *Strzelecka* et al.[83] were originally tentatively described as discotic mesogens. However, recent X-ray data for **37** (R = R′ = *p*-$C_nH_{2n+1}OC_6H_4$, n = 9, 11, and 13) showed that the phase changes were between different crystal forms



37

(K → K′) and that these compounds were not mesogenic.[84] In 1986 *Ohta* et al. reported that the tetraalkoxyphenyl compounds **37** (R = R′ = *p*-$C_9H_{19}OC_6H_4$, and R = R′ *p*-$C_{11}H_{23}OC_6H_4$) also formed discotic mesophases; this report was based on the miscibility of the two compounds giving a eutectic, and other optical observations.[85] No X-ray data are yet available to confirm the claim. However, the related nickel dithiolene **38** with four 3,4-bis(dodecyloxy)phenyl substituents was shown by X-ray diffraction to give rise to a hexagonal disordered columnar (discotic) mesophase (D_{hd}).[86]



38, R = $C_{12}H_{25}$

5.2. Dithiocarboxylates

Dithiocarboxylates ($RCS_2^{\ominus}$) and xanthates ($ROCS_2^{\ominus}$), which react with metals to give MS_2C four-membered rings, are related to the dithiolenes, which form five-membered MS_2C_2 rings.

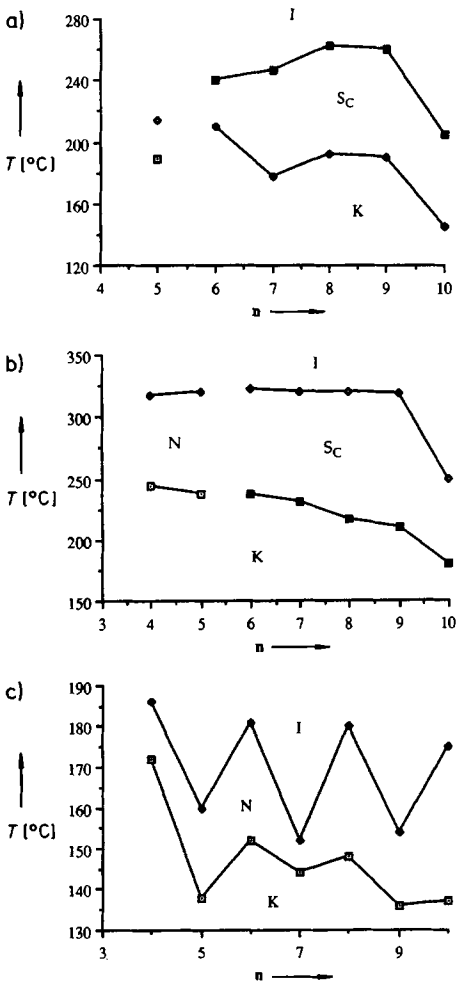


Fig. 19. Phase diagrams of complexes of the type **39**. a) M = Ni; □ K → N, ● K → S_C, ■ S_C → I, ◇ N → I. b) M = Pd; □ K → N, ◆ N → I, □ K → S_C, ◇ S_C → I. c) M = Zn; ⊡ K → N, ◆ N → I. Various mesophases occur depending on the metal (after Ref. [87]).

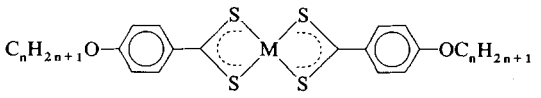
Studies by the Sheffield group on the bis(4-alkyloxydithiobenzoato) complexes showed that the Ni^{II} and Pd^{II} complexes **39** (M = Ni, Pd) were mesogenic (Fig. 19a, 19b).[87, 88] Optical microscopy, combined with an X-ray diffraction and DSC (XDDSC) study, confirmed the occurrence of S_C mesophases for palladium complexes **39** with longer-chain ligands (e.g. n = 8; 214–320 °C) and of N phases in the case of shorter-chain ligands (n = 4,5).[118] Similar results were obtained for the nickel complexes, **39**, (M = Ni).



39

The single crystal X-ray structure analysis of the palladium complex **39** (M = Pd, n = 8; Fig. 20) showed it to be composed of monomeric species, with square-planar coordinated Pd centers (four Pd–S bonds with bond lengths of 2.29–2.35 Å), loosely associated into dimers via long intermolecular Pd···S contacts (≥ 3.38 Å).[88]

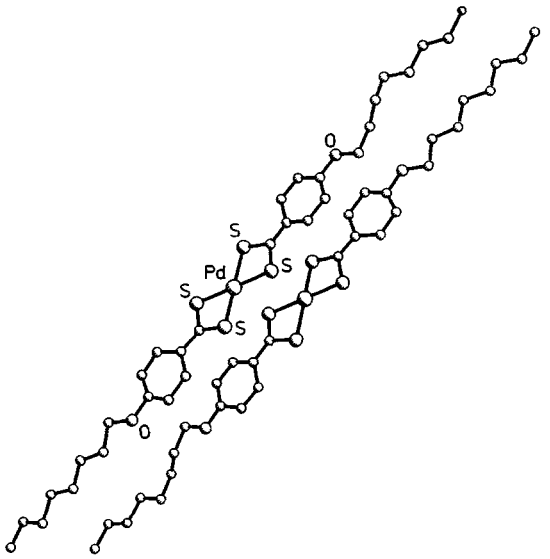


Fig. 20. Crystal structure of a complex **39** (M = Pd, n = 8) (after Ref. [88]).

The molecular structure of the unsubstituted bis (dithiobenzoato) zinc complex (Fig. 21)[89] suggested that even a tetrahedrally coordinated metal center would induce such compounds to form rodlike mesogens. Mesophases were indeed observed for the dialkyloxy-substituted zinc complexes **39** (Fig. 19c). However, although monomeric in solution, single crystal X-ray diffraction studies showed that in the solid the molecules are dinuclear with an eight-membered $Zn_2S_4C_2$ ring, making each zinc effectively five-coordinate (Zn–S 2.22–2.77 Å, Fig. 22).[87, 88]

Recent single crystal X-ray data on the related bis(4-alkyloxydithiobenzoato)mercury complexes $Hg(S_2CC_6H_4OR)_2$ (R = C_4H_9 and C_8H_{17}; nematic phases at 178–192 °C and 137–200 °C, respectively), indicate that these too have a

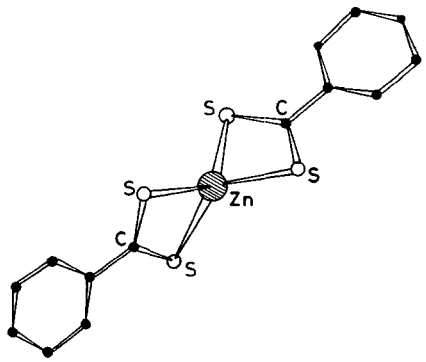

Fig. 21. Structure of $[Zn(S_2CPh)_2]$ (after Ref. [89]).

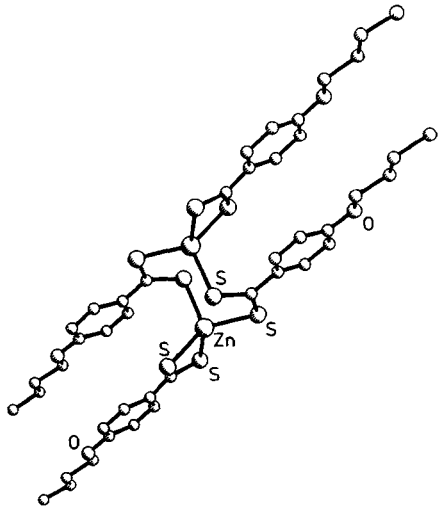

Fig. 22. Crystal structure of a complex **39** (M = Zn, n = 4) (after Ref. [88]).

more complex coordination geometry than might be expected: two shorter *trans* Hg–S bonds (2.41 Å) and two longer *trans* Hg–S bonds (2.96 Å) in the same plane, with two additional axial intermolecular Hg···S contacts (3.36 Å, Fig. 23).[90]

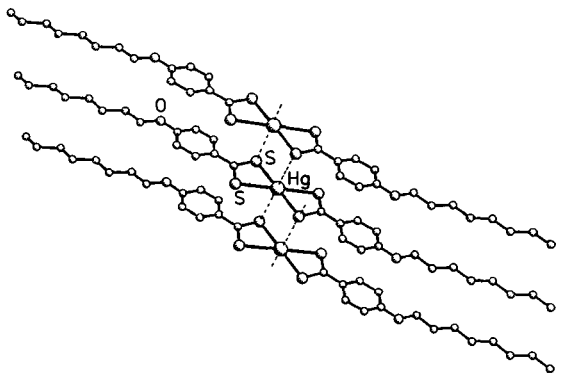

Fig. 23. Crystal structure of a complex **39** (M = Hg, n = 8).

Again, the metal center, as in the Pd complex (Fig. 20), is planar and not tetrahedrally coordinated. An effect of the alkyloxy chains, which confer mesomorphism, also appears to be to reduce the tendency towards tetrahedral geometry at the metal center.

The use of **39** (M = Ni, Pd) in display and thermal recording materials has in the meantime been patented.[91]

The dimeric tetrakis(*n*-alkyldithiocarboxylato)dinickel complexes **40** (R = C_5H_{11} to $C_{12}H_{25}$) have been described; they show monotropic lamellar mesophases with broken fan textures. Identification of the phases has been checked by

41

X-ray measurements. The corresponding monomeric xanthates, [Ni($ROCS_2$)$_2$] **41** (R = CH_3 to $C_{12}H_{25}$) exhibit complex double- and triple-melting behavior.[92]

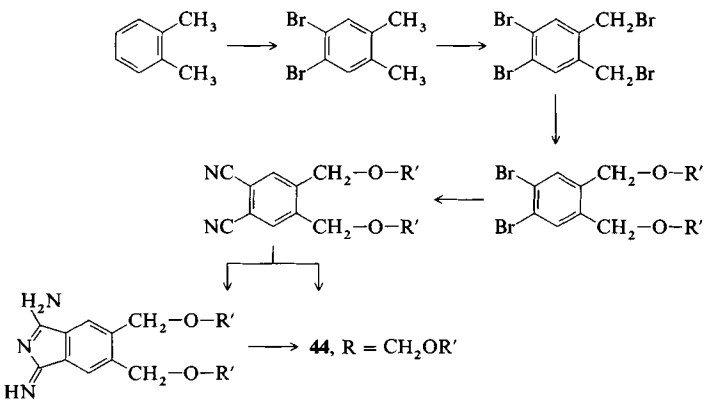
6. N_4-Macrocycles and Other Polyamine ligands

In view of the range of polyamine ligands, it is not surprising that they also occur as components of metallomesogens. The discotic metallophthalocyanines, first studied by *Simon* et al. in Paris,[93] are especially interesting.

6.1. Phthalocyanine Complexes

6.1.1. Copper Complexes

Discotic metallophthalocyanines **42** (M often Cu) were originally envisaged as one-dimensional conductors, but also have other potential applications.[93] A typical synthetic path to such compounds is presented in Scheme 2. The copper phthalocyanine **42** with eight dodecyloxymethylene substituents (R = $CH_2OC_{12}H_{25}$) gave a stable mesophase be-



Scheme 2. Synthetic route for octakis(alkoxymethylene)phthalocyanine (after Ref. [100]).

tween 53 and ca. 300 °C; X-ray data indicated that the macrocycles are stacked at a distance of 4.5 Å in columns, with the columns ca. 31 Å apart (Fig. 24).[93]

Discotic columnar mesophases (D_{ho}) were also found in the case of complexes **42** (R = $CH_2OC_nH_{2n+1}$, and

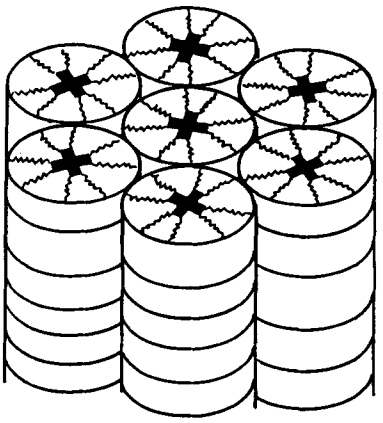


Fig. 24. Structure of the discotic mesophase of **42** (R = $CH_2OC_{12}H_{25}$). The zig zag tails from the central unit symbolize the substituents on the phthalocyanine ring.

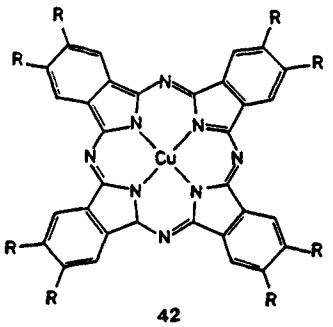
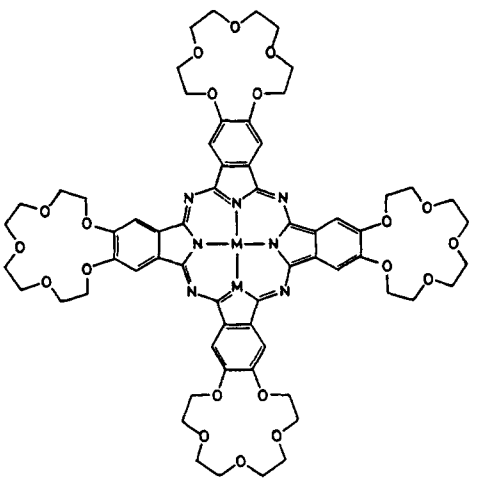
OC_nH_{2n+1}, n = 6–11) by *van der Pol* et al.[94] The transition temperatures (as well as the related enthalpies and entropies) are only slightly different from those of the corresponding metal-free molecules. X-ray data showed inter-disk distances



42

within one stack of 3.4 Å. Copper phthalocyanines **43** bearing four benzo[15]crown-5 substituents have also been made; they stack to give channels through which ions may be transported.[95]

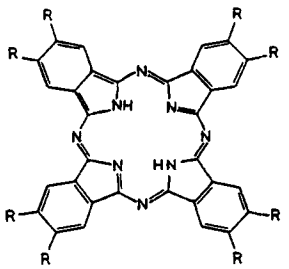


43

Although ESR spectra indicated good electron mobility in **42** (R = $CH_2OC_{12}H_{25}$),[93] the complexes are semiconductors with mesophase conductivities very similar to that of the unsubstituted and non-mesogenic copper phthalocyanine itself ($\sigma = 6 \times 10^{-8}\,S\,m^{-1}$ at 175 °C);[94] a slight decrease in conductivity was found on going from the solid to the mesophase. As is very often found with insulating or semiconducting materials, the conductivity increased by several orders of magnitude on doping with I_2.[94, 96]

Van der Pol et al. examined the luminescence properties of **42** (R = $CH_2OC_{12}H_{25}$) as a function of temperature, and found a sharp drop in intensity at the melting point.[97]

Interestingly, many of the metal-free phthalocyanines themselves are discotic, for example **44** (R = $CH_2OC_{12}H_{25}$) has a structure very similar to that of its copper complex.



44

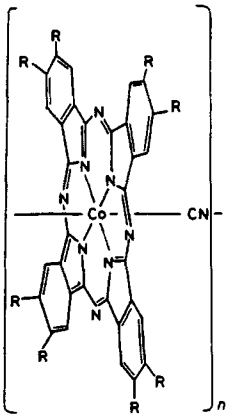
The stacking distance here is 4.5 Å and the columns form a hexagonal lattice with the columns 31.2 Å apart; X-ray diffraction measurements on the phthalocyanine **44** (R = 2-$EtC_6H_{12}OCH_2$) show a nematic phase.[93] Many other discotic metal-free phthalocyanines have also been made.[98]

A cholesteric columnar copper complex **42** (R = $C_{12}H_{25}OC^*H(Me)CH_2OCH_2CH_2$), with eight optically active substituents on the phthalocyanine ring, has been reported.[99] Differences in mesophase behavior between the chiral material and its achiral analog (with racemic $C_{12}H_{25}OCH(Me)CH_2OCH_2CH_2$ substituents) were found; the chiral material showed polymorphism, while the achiral analog showed only one mesophase.

6.1.2. *Mn, Co, Ni, and Zn Phthalocyanines*

Complexes of Co, Ni, and Pb with the phthalocyanine **44** (R = $CH_2OC_8H_{17}$) exhibit mesophases below 100 °C;[100] the cobalt compound reacts with NaCN to give a polymeric material, thought to be **45**. Discotic zinc and manganese complexes of **44** (R = $CH_2OC_{12}H_{25}$) have also been reported.[101]

The use of liquid crystalline host materials containing colored compounds, which absorb laser light and cause local heating, has been considered for laser addressed devices.[102] The brightly colored phthalocyanines, their benzo-homologues (the naphthalocynines), and eight complexes with Cu, and one each with Ni and Zn, have been investigated for this purpose. Major changes in spectra are achieved by introduction of nuclear alkyloxy substituents; changing the metals offers the opportunity for further spectral fine tuning. Moreover, the parent compounds and the metal complexes with

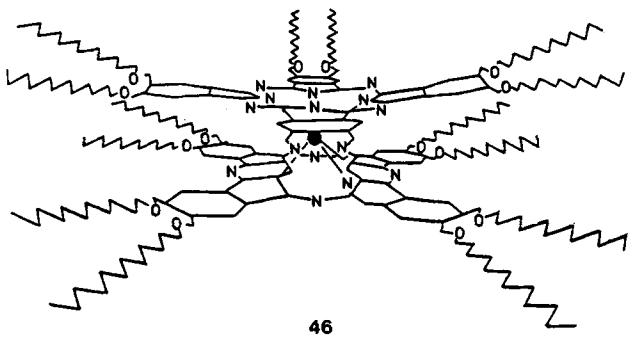


45

long chain alkyls dissolve in nematic liquid crystals, which is also useful. A variety of mesophases was found, again below 100 °C for longer chain substituents. The textures of one mesophase are consistent with hexagonal columnar, and those of another, with a rectangular columnar discotic phase.

6.1.3. *Lutetium Phthalocyanines*

Simon et al. found that bis(phthalocyanine)lutetium is a molecular semiconductor. Discotic mesophases were found for the complexes of the subtstituted phthalocyanines [Lu{$(ROCH_2)_8C_{32}H_8N_8$}$_2$] **46** (R = $C_{12}H_{25}$).[103] Both the



46

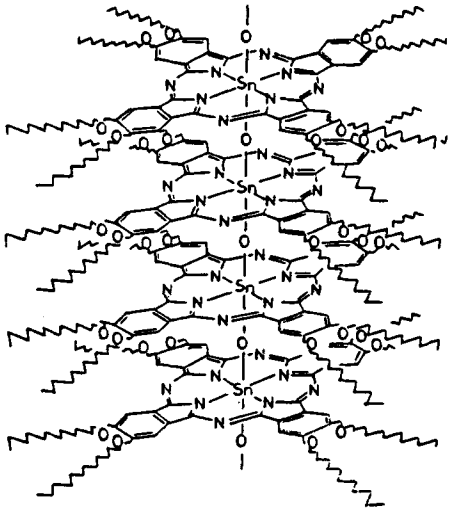
green neutral form and the red oxidized form, as the $SbCl_6^{\ominus}$ salts, were prepared. The ionic compounds formed the more stable mesophases. X-ray data for the mesophase of **46** (R = $C_{18}H_{37}$) indicated an intercolumnar distance of 37 Å and a repeating unit of 7.3 Å, twice the thickness of the phthalocyanine ring, as expected (Fig. 25). The X-ray pat-

Fig. 25. Schematic representation of the repeat units of the bis(phthalocyaninato)lutetium derivatives **46**.

tern remains unchanged on going from ambient temperature to the temperature where the isotropic phase appears, indicating that the mesophase and the solid have similar structures. The ESR spectrum of the neutral species shows broadening in the mesophase; there is some uncertainty about the magnetic state of the oxidized form. The electrical properties of the neutral form of **46** (R = $C_{18}H_{37}$) are also very similar in the solid and in the mesophase (conductivity $1.8 \times 10^{-9}\,\Omega^{-1}\,cm^{-1}$ at 10^4 Hz), but the conductivity increases on oxidation. It was estimated that the hopping probability of an electron is 10^7 greater within a column than between columns for the same activation energy.

6.1.4. Si, Sn and Pb Phthalocyanines

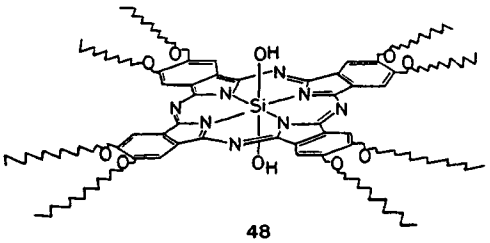
Columnar phthalocyanines linked by O–Si–O[104] or O–Sn–O[105] spacers have also been described. The tin complex **47** shows a columnar mesophase between 59 and 114 °C,



47

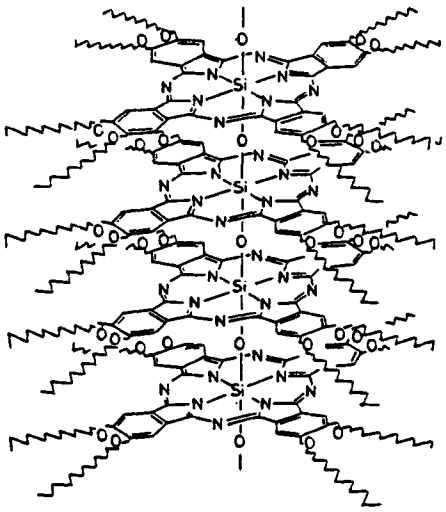
characterized by X-ray diffraction measurements as a rectangular packing of columns (column separation 25.2 and 30.7 Å), and with a probable intermetallic spacing of 3.85 Å.[105] The fluid isotropic phase is slowly transformed into a highly viscous anisotropic material, which has a polymeric {–O–Sn–}$_n$ backbone; this in turn becomes isotropic at 290 °C.

The silicon-containing phthalocyanine **48** showed hexagonal-columnar mesophases (D_{hd}) between ambient and 300 °C



48

for n ≥ 4. On heating in air at 180 °C loss of water occurred, accompanied by oligomerization to dimers, trimers, and some higher oligomers, e.g. **49**.[104]



49

Also Sn^{II} and Pb^{II}, form a series of complexes of the type just outlined.[106] The Sn^{II} complex is readily oxidized to the Sn^{IV} complex **47**. The lead complex forms columnar discotic liquid crystals, with intercolumnar spacings of 26.9, 31 and 36 Å for the $C_8H_{17}OCH_2$, $C_{12}H_{25}OCH_2$, and $C_{18}H_{37}OCH_2$ chains respectively. The mesophase was stable down to

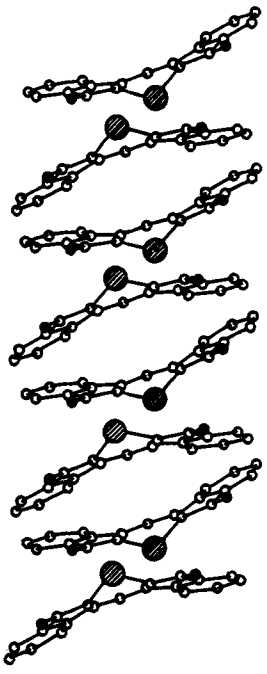


Fig. 26. Side-view of the proposed structure of Pb (phthalocyanine) illustrating the antiferroelectric coupling of the Pb atoms (⊘) (after Ref. [107]).

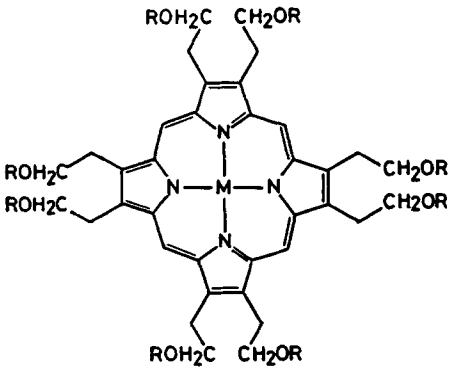
– 45 °C; the X-ray data have been interpreted in terms of dimers (Fig. 26) which exhibit antiferroelectric coupling.[107]

6.2. Other N_4 Macrocycles

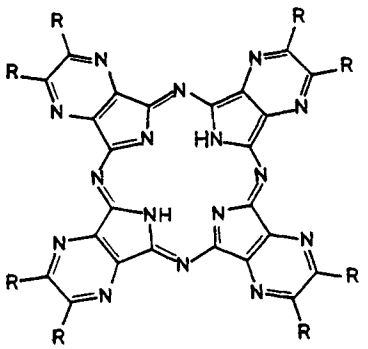
Mesogenic metal-containing prophyrin complexes **50** (R = CH_2OH, M = Cu, Cd, Zn, and Pd) have been reported, as well as some which are not mesogenic but which, on



50

mixing with long-chain alkanes or *n*-alkyl halides, form monotropic mesophases.[108]

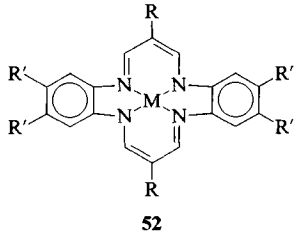
The disklike octadodecyltetrapyrazinoporphyrazine **51** (R = $C_{12}H_{25}$) and its copper complex show discotic mesophases (by X-ray).[109] Although the structure of this



51

ligand differs little from that of its copper complex, there is still a change of mesomorphic character. The former shows a hexagonal disordered columnar mesophase (D_{hd}) between 118 and 238 °C, the decomposition temperature, while the copper complex has a rectangular disordered columnar mesophase (D_{rd}) between 114 °C and the decomposition temperature 288 °C.

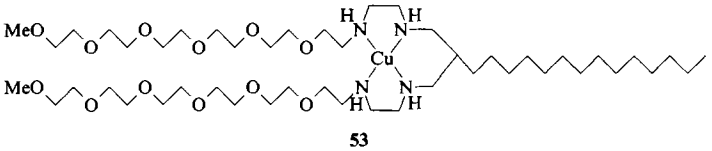
Discotic phases have been reported in a patent for a series of substituted dibenzotetraza[14]annulenes **52** containing divalent Ni, Pd, Pt, Co, or Cu. The complexes have been considered for use in electro- or thermooptical displays.[110]



52

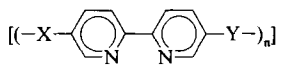
6.3. Other Amine Complexes

The "annelides" $C_{16}H_{33}CH\{CH_2NHCH_2CH_2NH(CH_2CH_2O)_6Me\}_2$ form mesogenic copper complexes such as **53**.[111] Between 77 and 95 °C, both the hydrophilic and the hydrocarbon chains are in a quasi-liquid state, whereas the polar head groups remain in a two-dimensional crystalline array. These lamellar phases, intermediate between



53

crystalline solids and liquid crystals, have been termed tegma crystals. The ESR spectra of the complex in the mesophase, in the solid, and in solution point in each case to a weak magnetic coupling between the copper atoms.[112]

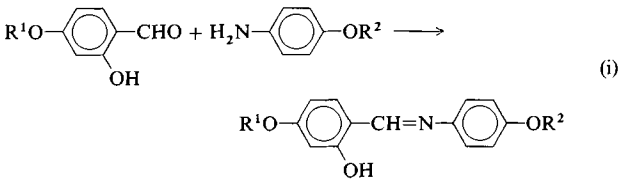


54, X, Y, = CO, CO_2CH_2, $CO_2(CH_2)_{10}O$

The 5,5′-linked 2,2′-bipyridyls **54** constitute an unusual series of thermotropic polymers; they complex metals such as Fe^{II}, Cu^{I} or Cu^{II} to give metallomesogenic materials.[113]

7. Salicylaldimine Complexes

Schiff bases derived from substituted salicylaldehydes are very versatile ligands which form (*N–O*) chelates with many metals. Ligands for thermotropic liquid crystals are usually made by condensing the appropriate 4-substituted ether of 2,4-hydroxybenzaldehyde with a 4-substituted aniline or other primary amine [Eq. (i)]; many of these ligands are

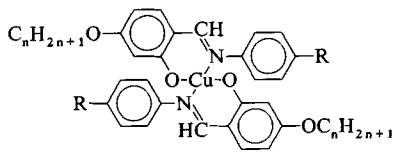


(i)

themselves mesogenic (nematic). Metal complexes can be prepared in good yield when the salicylaldimine is refluxed in ethanol in the presence of (for example) copper(II) acetate.

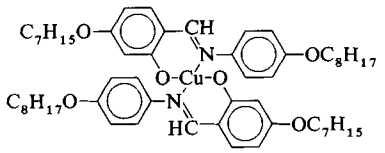
7.1. Copper, Nickel, and Palladium [$M(N_1O_1)_2$] and [$M(N_2O_2)$] Complexes

Most of the paramagnetic salicylaldimine copper(II) complexes **55** [n = 1, 3, 5–8; R = C_mH_{2m+1} (m = 2, 8, 12), F, $O_2CC_6H_4OC_{12}H_{25}$], first reported by *Ovchinnikov* et al. in 1984, showed smectic mesophases.[114, 115] However, nematic behavior was observed by *Galyametdinov* et al. for **55** (n = 7; R = $O_2CC_6H_4OC_{12}H_{25}$).[116]



55

Calorimetric and microscopic investigations revealed that the complex **56** forms S_A (142–157 °C) and S_C (157–165 °C) mesophases. ESR spectra showed that it was a slightly distorted square planar complex with *trans* conformation, both in dilute toluene solution and in the isotropic liquid phase,[117] but that some of the planar molecules had undergone tetrahedral distortion in the mesophase. The data were interpreted as indicating that the planar molecules formed the smectic phase while the tetrahedral ones were concentrated in microscopic isotropic droplets, i.e. that the mesophase was heterogeneous.



56

The X-ray single crystal structure of mesogenic **57** (n = 4, R = *p*-$C_6H_4C_6H_{13}$) showed that, owing to a twist of the *N*-phenyl and the benzoyl moieties relative to each other, the molecule adopts a lathlike rather than a disklike structure (Fig. 27).[118] The coordination about copper is distorted square-pyramidally, with a torsion angle of 22° between the two Cu–N–O chelate planes, and a weak axial interaction with the ester carbonyl group of the adjacent molecule

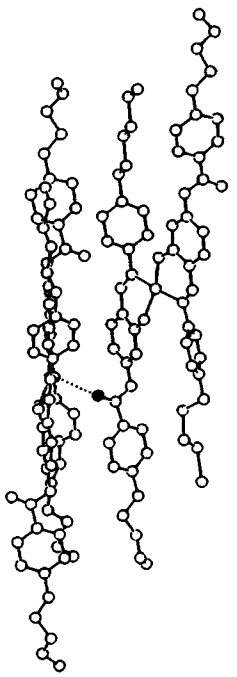


Fig. 27. Crystal structure of a complex **57** (n = 4, R = *p*-$C_6H_4C_6H_{13}$) showing weak axial coordination (dotted line) of the carbonyl O-atom (black) to the neighboring copper center (after Ref. [118]).

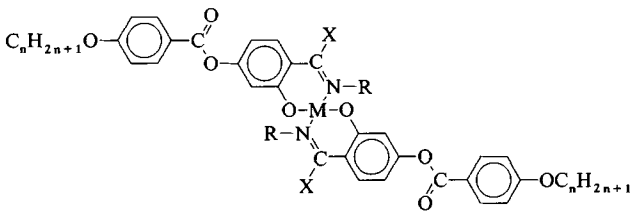

57, M = Cu, X = H

59, M = Cu, X = Me

(Cu···O 3.04 Å). This compound shows a nematic phase above 223 °C and is also a model for a series of complexes of the type **57** (R = 4-C_6H_4OEt), which show S_C and N phases (Table 5). Again, in this series, complexes with smaller n (6–10) form nematic, those with n = 11, 12, 14 form both nematic and S_C phases, while those with n = 16, 18 form only S_C phases.

Table 5. Transition temperatures [°C] of the mesomorphic copper(II) complex **57** (R = 4'-$EtOC_6H_4$)[118].

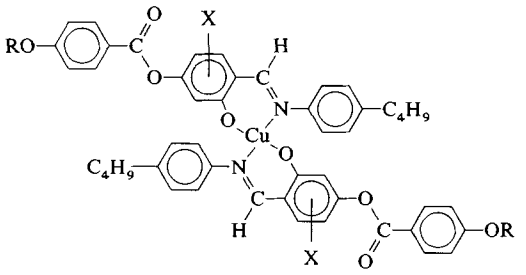
[a] Clears with (some) decomposition.

Both copper(II) and nickel(II) complexes **57** and **58** (R = 4-$C_6H_4OC_nH_{2n+1}$; n = 1–6; 8, 10, 14, and R = C_mH_{2m+1}; m = 1–10) derived from the *n*-alkylamines ($C_mH_{2m+1}NH_2$) show mainly nematic mesophases, while those derived from arylamines show largely smectic mesophases.[119, 120] The nickel complexes were more stable thermally but the copper complexes had lower melting points. The nickel complexes were diamagnetic, and hence square planar.

All the copper complexes **57** (X = H, Me; R' = Me, *n*-$C_{10}H_{21}$, *p*-$C_6H_4OC_{10}H_{21}$) derived from 2,4-dihydroxybenzaldehyde showed nematic or S_C phases, whereas those from 2,5-dihydroxybenzaldehyde were only mesogenic when the imine (R'N=) was derived from methylamine.[121] The stability of the nematic phase of **57** (R = Me) was found to decrease with increasing n, until, for n = 14, only an S_C phase is observed.[122] Nematic mesophases have also been reported for complexes of type **57'**.[123]

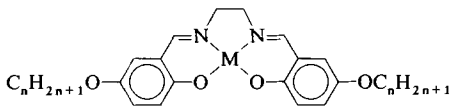
X-ray studies on the mesophase have been carried out for **55** (R = C_4H_9, *n* = 7, 12); the complexes show smectic phases, whereas the free ligands form only nematic phases.[124] There is also evidence favoring the presence of interdigitated layers of partially melted chains, and a pos-

sible coupling of copper atoms in pairs inside the smectic layers. X-ray studies of the nematic and smectic phases of **57** (R = Me, $C_{10}H_{21}$, and $C_{10}H_{21}OC_6H_4$) have also been carried out.[125]



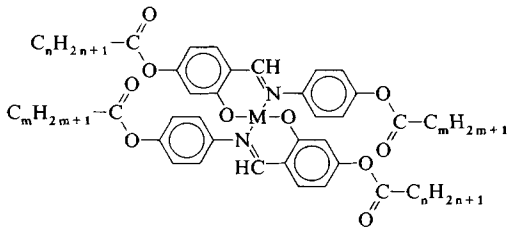
57'

Other salicylaldimines have also been used for the synthesis of mesogenic copper and nickel complexes. Thus, the bis(salicylidene)ethylenediamine (H_2salen) ligands (derived from 5-alkoxy-2-hydroxybenzaldehydes), form complexes **60** (M = Cu, Ni, n = 4–8), all of which show highmelting S_A phases.[126] By contrast, related complexes with the *N*-methylalkyloxysalicylaldimine ligands, $[M\{ROC_6H_3(O)CH{=}NMe\}_2]$ were not mesogenic.



60

The copper and palladium complexes **61** have also been shown to exhibit smectic mesomorphism, forming mainly S_C phases.[127] The palladium complexes have much higher melting and clearing temperatures than the corresponding copper complexes. The crystal structures of representatives



61

of each series have been determined; both in the case of Pd^{II} as well as in the case of Cu^{II}, the coordination is square planar (Fig. 28).[128] The prosmectic packing of the copper complexes in the crystal (in layers with their major axes inclined at ca. 60° to the layer plane) explains why these complexes do not show discotic behavior. Copper, nickel, and palladium complexes **57** and **58** have been compared. None of the nickel complexes show mesomorphic behavior, whereas the corresponding copper complexes show nematic (and some smectic) phases, and the two palladium complexes synthesized show both smectic and nematic phases.[127]

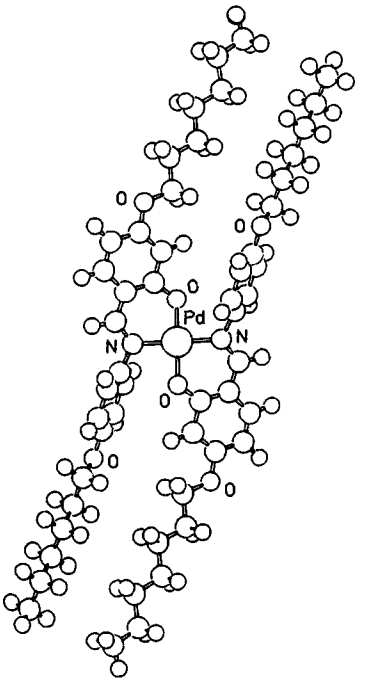


Fig. 28. Molecular structure of the palladium salicylaldimine complex **61** (m = 6, n = 7) (according to [128]).

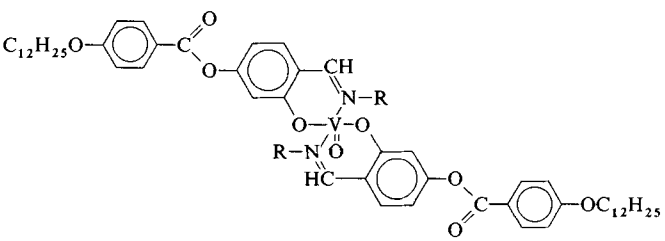
7.2. Vanadyl and Iron $[M(N_1O_1)_2]$ Complexes

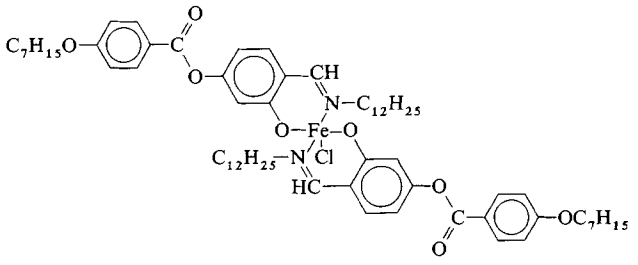
Of the complexes of type **61** with esterified salicylaldiminatoligands (M = Zn, Co, Ni, Cu, VO, and Pd)[129] the zinc, the cobalt, and the nickel complexes showed no mesomorphic behavior, but the copper, the vanadyl, and the palladium complexes (m = 8, n = 7) all showed smectic mesophases: S_C phases (Cu: 142–156; VO: 151.8–170; Pd: 164.5–198 °C) and S_A phases (Cu: 156–165; VO: 170–179.8; and Pd: 198–209 °C). The absence of mesophases for the nickel and the cobalt complexes was ascribed to the tetrahedral geometry about the metal, as shown by ESR and electronic spectroscopy; the copper and the palladium centers are square planar, while the vanadyl unit is square pyramidal.[130]



62

The first mesogenic Schiff base-vanadyl complex was reported in 1984.[130] The complexes **62** (R = Me, *n*-C_5H_{11}, $C_{10}H_{21}$, and *p*-alkylOC_6H_4), form nematic (e.g. for R = *n*-C_5H_{11} 109–131 °C) as well as smectic mesophases.[131] The low viscosity of the mesophases allowed easy orientation of the molecules by a magnetic field; the orientation remained unaltered in the solid state.

The mesogenic iron(III) complex **63**, recently reported by *Galyametdinov* et al.[132] is paramagnetic (ESR parameters, $g_1 = 2.096$, $g_2 = 4.30$), and forms an S_A phase (85–151 °C).

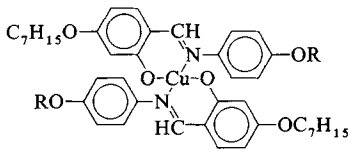


63

Although the available data are still patchy, it appears that mesophases are formed when the molecular geometry of the salicylaldimine moiety of the ligand about the metal atom is planar or planar with an axial interaction (square pyramidal), but not for tetrahedral geometries. Within the series most closely examined, those of Cu^{II}, nematic phases tend to be favored with short alkyloxy chains, and smectic phases with longer ones.

7.3. Polymeric Liquid Crystals Based on Salicylaldimine Ligands

Carfagna et al.[133] reported the synthesis and properties of mixed ethylene oxide-dodecanediol-Schiff base polymers of the type **64**, as well as of the monomeric complex **65**. Complex **65** forms a clear S_A phase, the polymers, on the other hand, are monotropic, and presumably show S_A phases. However, in solution there is some evidence for de-



64, R = $[\{(CH_2)_{12}O\}_x\{(CH_2CH_2O)_3\}_{110-x})_2]_n$
65, R = C_6H_{13}

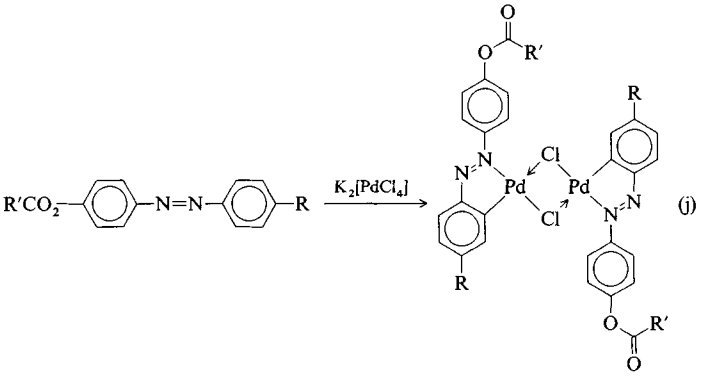
polymerization. Related polymeric copper complexes based on salen-type units have also been found to be mesogenic.[134]

8. Cyclometalated Mesogens

Up to now, only palladium-containing cyclometalated mesogens have been reported. However, since many other metals form stable cyclometalates this is likely to be a fruitful area for future development.

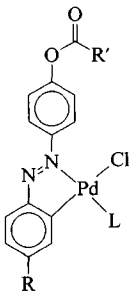
8.1. Complexes Derived from Azobenzenes

Ghedini et al. in Calabria prepared the first cyclopalladated liquid crystals **66**; (R = EtO or Et; R′ = C_4H_9, C_5H_{11}, C_6H_{13}, and $(CH_2)_8CH = CH_2$), by cyclopalladation of the appropriate 4,4′-substituted azobenzene derivative with K_2PdCl_4 in aqueous dioxane (25 °C, one week) [Eq. (j)].[135] These dinuclear chloro-bridged complexes formed nematic phases on melting, typically at ca. 200 °C, i.e. at much higher



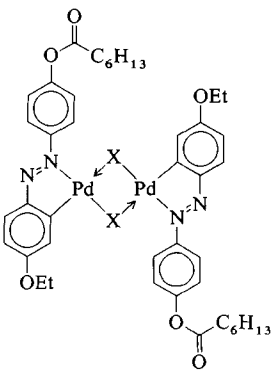
66

temperature and in a narrower range than the free ligands; for example, while the nematic range for the ligand $EtOC_6H_4N = NC_6H_4O_2CC_6H_{13}$ was 59–112 °C, that for the complex derived from it was 190–205 °C. The monomeric complexes **67** (L = PPh_3) obtained by cleaving **66** with PPh_3 are not esogenic; however, the amine adducts **67** (L = pyridine, or quinoline) form smectic and nematic



67

mesophases.[136] The adduct with the planar quinoline showed an S_A phase already at 136–151 °C, and a nematic phase from 151–180 °C; the importance of the geometry of the added ligand L was reinforced by the observation that the aniline adduct is not mesogenic and simply decomposes



68

at 173–175 °C. The dimeric complexes **66** show a high birefringence in the mesophase.[135]

All three μ-halogeno-complexes **68** show similar nematic phases, but the melting temperatures decrease in the sequence X = I > Br > Cl.[136] The chloride showed only a nematic phase (190–205 °C), while the bromide showed enantiotropic S_A (210–215 °C) and N (215–250 °C) phases as well as a monotropic S_B phase, and the iodide showed enantiotropic S_A (220–225 °C) and nematic (225–230 °C) phases.

The Calabria group also found that mesogenic azobenzene ligands were not essential for the synthesis of mesogenic complexes; however, in this case only monotropic materials are formed.[137] Thus, the complex derived from $C_{12}H_{25}OC_6H_4N = NC_6H_5$ showed a smectic phase (150–136 °C) on cooling the isotropic liquid.

Other nematogenic cyclopalladated 4,4′-azobenzenes have been reported;[138] and a non-mesogenic complex derived from 4,4′-dimethoxyazobenzene has been characterized by a single-crystal X-ray structure determination (Fig. 29).[139]

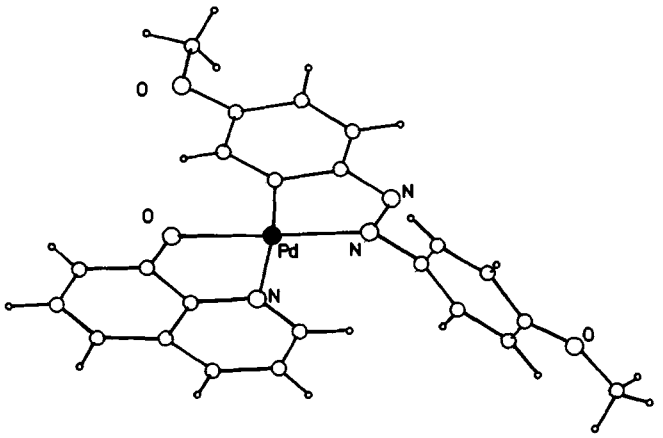


Fig. 29. Structure of the non-mesomorphic, cyclopalladated complex formed from the PdCl adduct of 4,4′-dimethoxyazobenzene and 8-hydroxyquinoline (after Ref. [139]).

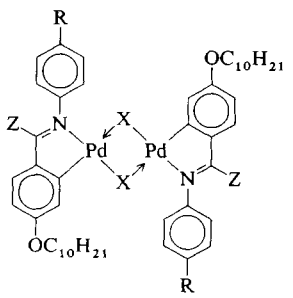
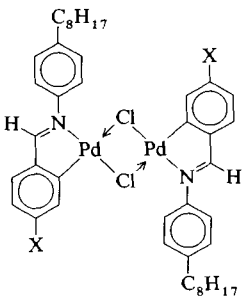
8.2. Complexes Derived from Arylimines

Espinet et al. in Spain have prepared the mesogenic complexes **69** and **70** from the corresponding Schiff bases and $Pd_3(OAc)_6$ (Z = H, R = $C_{10}H_{21}$ or $C_{10}H_{21}O$; Z = Me, R = $C_{10}H_{21}$ for **69**, and X = H, halide, OCOR, CN, NO_2, CF_3, etc for **70**)[140]



69



70

The complexes **69** showed smectic phases (usually S_A) when X = Cl, Br, and SCN, (Table 6) but the acetato-bridged complexes were generally non-mesogenic. It was suggested that this was due to the nonplanarity usually found for complexes with di-μ-acetato bridges in contrast to the planar arrangements with other bridging ligands. Again for this series, the

Table 6. Transition temperatures [°C] for mesomorphic *ortho*palladated iminoarenes **69** (R = $C_{10}H_{21}$, Z = Me)[140].

Komplex	Mesophases		
69	S_C	S_A	I

X = SCN	–	166.6	219.6
X = OAc		(160.0) [a]	169.9

[a] Monotropic mesophase. [b] Clears with (some) decomposition.

melting and especially the clearing temperatures of the complexes are very significantly higher than those of the free ligands; e.g. in the case of $C_{10}H_{21}OC_6H_3CH = NC_6H_4C_{10}H_{21}$ the phase changes occur at 53.3 (K→S_F), 84.4 (S_F→S_A), and 89.1 °C (S_A→I), while the corresponding di-μ-chloro complex showed phase changes at 112.4 (K′→S_C), 135.0 (S_C→S_A), and 237.6 °C (S_A→I, decomposition; Table 6). The chloro complexes **70** showed similar behavior; again the acetates were non-mesogenic.

8.3. Complexes Derived from Diarylazines

In contrast to the above-mentioned compounds the di-μ-acetato complexes **71** (X = $MeCO_2$) derived from the symmetrical 4,4′-bis(alkyloxybenzylidene)azines $C_nH_{2n+1}OC_6H_4CH = N–N = CHC_6H_4OC_nH_{2n+1}$ (n = 7–10, 12, 14) showed S_C (and in two cases, also N) mesophases. The μ-acetato ligands constrain the complexes to be nonplanar, and a novel type of structure based upon "open-book"-shaped molecules (Fig. 30) has been proposed.[141]

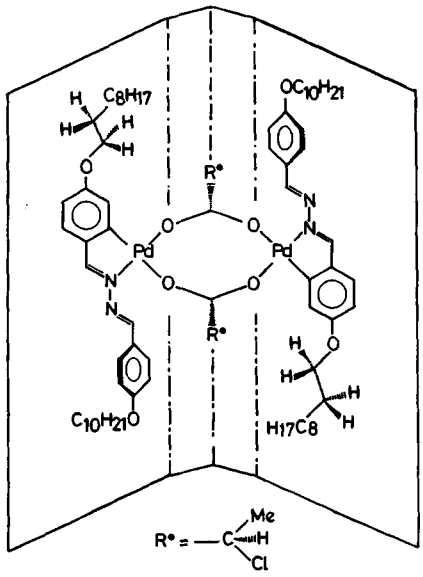

Fig. 30. The proposed structure of the optically active complex **71** reminiscent of an "open book". The complex exhibits a ferroelectric phase (after Ref. [142]).

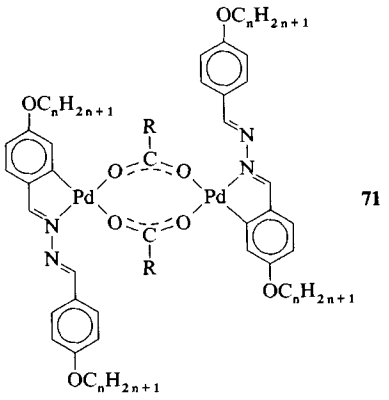
Reaction of **71**, (n = 10, X = Cl) with (R)-MeCH-$ClCO_2Na$ furnished the optically active complex **71** (n = 10, R = C*Me(H)Cl), which was shown by NMR spectroscopy to contain a mixture of the *trans-ΔR,R*, *trans-ΔR,R* and *cis-R,R* isomers.[142] The complex showed an enantiotropic S_C phase (102–119 °C), making it the first organometallic ferroelectric. However, the electrooptic response is substantially slower than for organic calamitic S_C^* phases, due to the high viscosity of the material. The high viscosity may be due to the bulkiness of the open-book molecular shape.



71

Further μ-carboxylato-complexes of the type **71**, (n = 10, $R = C_mH_{2m+1}$) have been studied.[143] It was found that short chains (m = 1–3) gave rise to S_C (and N) mesophases, while for m = 4–6 enantiotropic N and for m = 7–9 monotropic N mesophases are observed. A more complex behavior was found with m ≥ 10: monotropic S_C and N as well as enantiotropic N mesophases were formed. It is argued that these effects arise from a perturbation of the molecular packing, a point which is reinforced by X-ray data.

9. Structure–Property Relationships

The study of metallomesogens is very much in its infancy and considerable information must still be accumulated before relationships similar to those now available for organic mesogens can be drawn. Many metallomesogens are colored and this, together with their somewhat high melting temperatures, can make optical phase identification difficult. Owing to their high viscosity, smectic, discotic, and disordered crystal phases can sometimes be confused; this makes the use of additional techniques for mesophase identification imperative. Phase behavior needs to be definitively established, and this will require more low angle X-ray determinations in the mesophases.

Further, the detailed molecular geometries of many quite simple metal complexes are not yet known, and single crystal X-ray structures are also necessary. The assignment of structures by spectroscopy, extrapolation and analogy, so widely used in both organic and inorganic chemistry, may not always be reliable for metallomesogens.

The information gathered in this review allows the following generalizations to be made.

Both disk- and rodlike metallomesogens of many different types are known. Most of the mononuclear systems have the metal at or near the center of gravity of the molecule; this is true of the discotic mesogens (e.g. phthalocyanines, β-diketonates, and of the dinuclear carboxylates) as well as for the nematic and smectic calamitic mesogens.

The basic requirements for a metal complex to show mesomorphism are not dissimilar to those for many organics. Thus, a calamitic mesogen will typically have a long rigid group, which, frequently, but not essentially, corresponds to the core of the molecule containing the metal atom and two *trans*-ligands containing aromatic rings, carrying *n*-alkyl (or *n*-alkyloxy) tails in the *p*-positions. Shorter tails tend to give rise to nematic mesogens, longer ones to smectic mesogens, while the stretched S-shape with the "outboard dipoles" characteristic of many organic compounds forming S_C phases (Fig. 31) is also found in many S_C metallomesogens with *n*-alkyloxyphenyl tails. In some cases it is possible to construct calamitic mesogens with only one long organic ligand; these often show S_A phases (e.g. **12**–**16**).

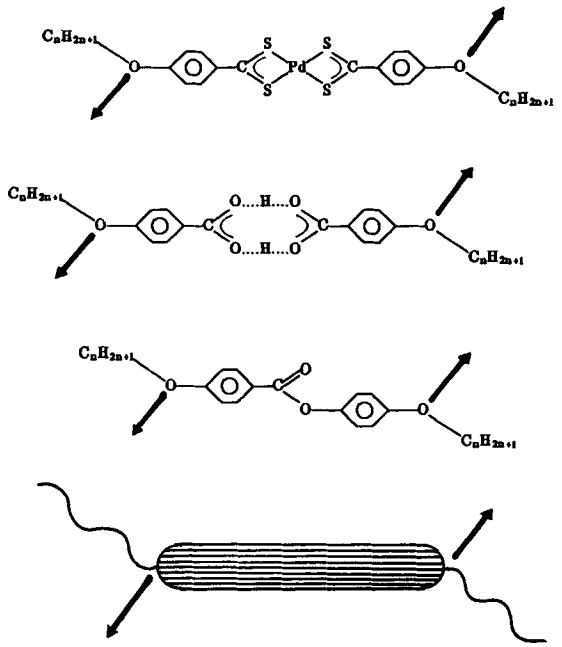


Fig. 31. Molecules forming S_C phases with S shape.

A discotic molecule will usually have a flattish platelike form with the metal in the center surrounded by a highly unsaturated organic ligand bearing at least four and preferably six or eight *n*-alkyl (or *n*-alkyloxy) substituents. A great many of the metallomesogens known to date are of the columnar discotic type, including carboxylates, β-diketonates, and phthalocyanines (cf. Sections 3.3, 4 and 6.1). By contrast, the complexes of salicylaldiminato ligands (Section 7), especially those with longer hydrocarbon tails, tend to give smectic phases. Both for calmitic compounds as well as for discotic compounds, the tails usually need to be at least five atoms long to show mesomorphism; and the presence of an extra phenyl in the tail is often advantageous.

Many metallomesogens are composed of ligands which are *not* mesomorphic. When the free ligands *are* themselves

mesomorphic, the derived metallomesogens show similar phase behavior when incorporation of the metal changes the molecular shape to only a small extent, for example in the phthalocyanines (Section 6.1). In other cases, the considerable difference in structure which the organization of ligands by the metal makes to the overall molecular shape ensures quite different mesophase behavior, for example in the copper β-diketonates.

Thermotropic metallomesogens have been made which incorporate alkali metals, alkaline earths, many 3d metals (V, Mn, Fe, Co, Ni, Cu), some 4d and 5d metals (Mo, Rh, Pd, Ag, Ir, Pt, Au), several p-block metals (Zn, Cd, Hg, Pb, Tl), and the lanthanide Lu.

Linear, square planar, and 5-coordinate (usually distorted square pyramidal) geometries have so far been found for the metals in mesogenic complexes. It seems that most metallomesogens need at least one "vacant" coordination site on the metal, which, in the crystal, loosely associates with a donor atom in a neighboring molecule. Thus, for example, the X-ray single crystal data of mesogenic square planar complexes show such axial interactions between the metal (M) and a liganding atom (X) on a neighboring molecule (cf. e.g., the structures in Figures 13, 20, 22, 23, 24, 27 and in Section 6.1). No complexes having an unequivocal tetrahedral geometry about the central metal have yet been found to be mesomorphic. This *may* be because intermolecular M···X interactions are not compatible with a tetrahedral geometry, but that they are needed to confer mesomorphism. Furthermore, for dithiobenzoate or salicylaldimine mesogens (Sections 5.2 and 7.1) it appears that attempts to impose a tetrahedral geometry lead to distortion.

The tails needed to confer mesomorphism on a complex may even be able to change the structure subtly, at least in the solid-state. For example, in the bis(dithiobenzoato) zinc complex (Section 5.2): while the unsubstituted complex shows a clear tetrahedral geometry about the zinc, the 4-octyloxy and the 4-butyloxy complexes have a loose dinuclear structure with a 5-coordinated metal.

Only one possible molecular metallomesogen with a presumed octahedral arrangement of six oxygen ligand atoms about the metal has so far been reported (see **33**). It is important to confirm this and to make other similar molecules.

These generalizations all depend on the assumption that the structure in the crystal is closely related to that in the mesophase, but this may not always be valid. In a few cases it has been checked: thus, in the columnar discotic dicopper and dirhodium tetracarboxylates there is no detectable change in bond lengths (by EXAFS) on going from the crystal to the mesophase (Section 3.3).

It is found that ligands with *n*-alk*oxy* tails often have beneficial effects in stabilizing mesophases; for example while the palladium alkoxy-CB complexes **7** show thermodynamically stable (enantiotropic) phases, the closely related alkyl-CB complexes at best only form the unstable (monotropic) phases (Section 2.1). Similarly, whereas the copper β-diketonates with 1,3-phenyls bearing p-$C_8H_{17}O$ substituents gave discotic mesophases, those where the phenyls had p-C_8H_{17} substituents did not (Section 4.2).

The introduction of a metal can lead to rather high-melting mesophases, perhaps due to strong axial (M···X) intermolecular interactions. This can be counteracted i) by introducing asymmetry into the molecule (Sections 2.2.2 and 2.3), which makes the molecular packing more difficult; ii) by introducing more amphiphilic coligands (e.g. carboxylate in place of halide, Section 2.2.1); or iii) by mixing two or more related complexes (this lowers the melting point without seriously affecting the clearing temperature, Figs. 7 and 10). These methods have been used to bring transition temperatures close to ambient, and further decreases are certainly possible.

In order to be useful as *advanced materials*, metallomesogens must be reasonably *inert* and quite thermally robust. Since complexes often have the metal as center of reactivity, for example towards air or moisture, inertness and stability must be added. This can be done by using very strongly binding ligands or by incorporating the heavier 5d metals, or both. Suitable ligands are those with donor atoms having large stability constants (e.g. S or P in compounds of the heavy Group VIII metals) and especially chelates.

Apart from those needed to characterize the materials, rather few serious physical measurements have yet been undertaken on metallomesogens. However, considerable increases in polarizability have been found (as expected),[22] as well as (unanticipated) high birefringences.[14, 135] This latter observation parallels the use of heavy metal oxides in high refractive index glasses.

Currently available metallomesogens may have long electrooptic response times (see Ref. [142]), which could be a disadvantage for some electronic displays. However, there are many other potential applications and their uses as passive NIR blockers[82] in laser addressable or thermal recording materials[91, 110] have already been proposed. New and interesting is the suggestion that, since the incorporation of alkali-metal cations into cholesteric crown ethers causes a change in the helical pitch, this can be made the basis of an alkali-metal sensor.[144] Another is the observation by scientists at the 3M-Company in the USA that salts such as the fluorescent pink compounds $[Pt(RNC)_4][Pd(CN)_4]$ (RNC, e.g., decylphenyl isocyanide), turn blue when exposed to the vapors of many hydro- or fluorocarbons.[145] Although not specifically identified as liquid crystals, such materials must at least be closely related to metallomesogens.

10. Outlook

Metallomesogens now form a viable and challenging interdisciplinary topic which offers much scope to the imagination of both the synthetic chemist, for the design of new ligands and their metal complexes, and the materials scientist and engineer for new uses for these advanced materials. The knowledge is now at hand to design complexes offering rod-like nematic or smectic mesophases or, by suitably modifying the ligands, a variety of discotic phases. Colors can be incorporated by the use of suitable metals and ligands, as can magnetic, ferroelectric, and many more exotic properties The organized stacks of some of the metallomesogens, for example the dimetal tetracarboxylates, suggest that, with suitable manipulation, electrically conducting materials may result.[71, 94, 103]

Although a substantial number of metals have already been incorporated into metallomesogens, many still remain to be explored. The design of ligands for metallomesogen character is also in its infancy and new applications will require new types of complexes. This is one challenge to workers in the field.

Possible device applications for metallomesogens, which may presently be anticipated, are as new thermal or nonlinear optical materials, and in electrochemistry and sensors.

The effects of organic mesogens on organic reactions are just beginning to be explored.[146] Metal-promoted reactions are in general more sensitive to steric factors than organic ones, thus there appears considerable scope for using mesophases and metallomesogens to promote stereoselectivity both in stoichiometric organometallic reactions and in metal catalyzed processes. However, great care will be needed in the design of properly controlled experiments and their careful execution to avoid spurious results.

Thus far one can speculate, but we suspect the best application has not yet been thought of. What a challenge for the future!

We thank all our many colleagues and co-workers who have contributed to metallomesogens and who made this review possible. We are especially grateful to Dr. N. A. Bailey, Dr. D. W. Bruce and Dr. D. A. Dunmur (Sheffield), Professor P. Espinet (Valladolid), Dr. D. Guillon (Strasbourg), Dr. J. C. Marchon, and Dr. P. Maldivi (Grenoble), and Professor J. L. Serrano (Zaragoza) for most fruitful collaborations. We also thank the SERC, the Royal Society, the EC Science Progamme (Grant ST2J-0387-C), CNRS, CEA, and BDH Chemicals plc for their strong support, and M Aubert for assistance with the drawings.

Catalytic Enantioselective Epoxidations of Simple Olefins

By *Carsten Bolm**

Asymmetric oxidation is of general importance for the synthesis of optically active organic compounds. With the enantioselective epoxidation of allyl alcohols, *Sharpless* and *Katzuki* introduced in 1980 an extremely efficient transition metal-catalyzed oxygen transfer, by means of which 2,3-epoxyalcohols can be synthesized in good yields and with very high enantiomeric excesses [Eq. (a), X = OH].[1] The titanium tartrate catalyst employed tolerates a high degree of structural variation in the prochiral substrate. By covalent bonding of the allyl alcohol to the chirally modified metal center, conformational freedom is restricted and generally enantioselectivities of over 90% are achieved.

(a)

Also other catalytic systems, such as the ruthenium-BINAP complex developed by *Noyori* et al. for the homogeneous enantioselective hydrogenation of ketones and olefins,[2] require directing groups which temporarily bind the substrate tightly to the metal center. This binding and any subsequent reaction are influenced by the interactions between substrate and optically active ligand, whereby the stereochemical course of the reaction is determined.

An especially interesting challenge in this connection was the development of catalysts for enantioselective oxidations of *unfunctionalized* olefins [Eq. (a), X = H, alkyl, etc.]. These alkenes cannot form conformationally restricting chelate complexes, and consequently differentiation of the enantiotropic sides of the substrate is rendered considerably difficult. The catalytic asymmetric dehydroxylation of unfunctionalized *trans*-alkenes with osmium tetroxide–alkaloid complexes first described by *Sharpless* et al.,[3] stimulated the development of enantioselective catalysts for the epoxidation of these substrates too, and numerous relevant studies have since been reported.

With the cationic (salen)manganese(III) complex **1**, *Jacobsen* et al. were able to epoxidize mono-, di, and trisubstituted olefins with good asymmetric induction (20–93% *ee*) (Fig. 1).[4] 1–8 mol-% of the complex catalyzes the transfer of oxygen from oxidants such as iodosylmesitylene or sodium hypochlorite to the prochiral substrate. The course of the enantioselection is interpreted in terms of a side-on approach of the substrate to the active oxomanganese(V) intermediate. To achieve higher enantioselectivities, sterically demanding *tert*-butyl groups have proven essential. Their interactions with the more hindered side of an unsymmetrical olefin determine the orientation of the substrate during its approach to the metal-oxo bond, and thus the enantiofacial selectivity of the oxygen transfer. In accord with this model, *cis*-disubstituted olefins are as a rule epoxidized with higher asymmetric induction than are comparable *trans*-alkenes (Fig. 1). Replacement of the *tert*-butyl groups by optically active substituents and addition of 2-methylimidazole can, in individual cases, lead to a slight increase in asymmetric induction.[5] These studies by *Katzuki* et al. also indicate possible radical intermediates, as were previously discussed in fundamental investigations by *Kochi* et al.[6]

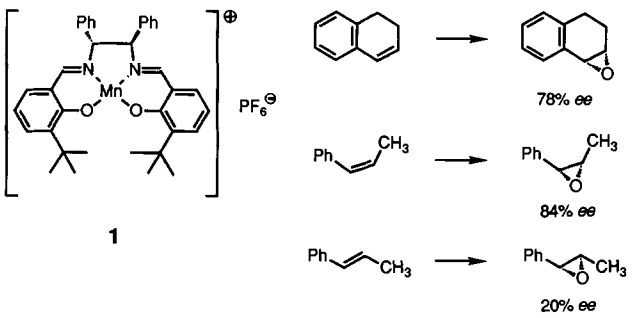

Fig. 1. Examples of enantioselective epoxidations of simple olefins with the (salen)manganese(III) complex **1** according to the method of *Jacobsen* et al. [4].

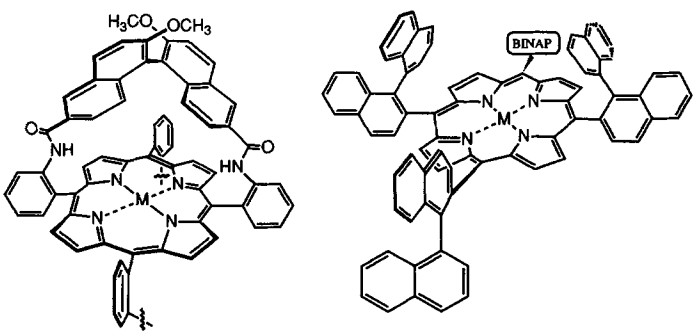
The development of chirally modified metalloporphyrins by the groups of *Groves, Mansuy*, and *Kodadek* provided a further transition metal-catalyzed entry to optically active epoxides.[7] Simple prochiral olefins such as β-methylstyrene can be epoxidized with enantiomeric excesses of up to 72%, both with bridged (basket handle) and with peripherally highly-substituted (picket) metalloporphyrins **2** and **3**, respectively. The chiral binaphthyl bridges in **2** generate a conformationally rigid, chiral environment at the metal center, which effectuates molecular recognition of the substrate. The inherent sensitivity of the porphyrins to oxidation can be reduced by skillful substitution of the *meso* phenyl groups, making higher turnover numbers in catalytic processes possible. Here again, hypochlorite or iodosylarenes are used as oxidizing agent.

The catalytic activity of the metalloporphyrins in oxidations is not limited to only epoxidations. *Groves* and *Viski* have also succeeded in carrying out the asymmetric hydroxylation of benzylic methylene groups and the enantioselec-



2, M = Mn, Fe **3**, M = Mn

Fig. 2. Metalloporphyrins for catalytic asymmetric epoxidation according to the methods of *Groves* et al. [7a] and *Kodadek* et al. [7d].

Institut für Organische Chemie der Universität
St.-Johanns-Ring 19, CH-4056 Basel (Switzerland)

tive sulfoxidation of prochiral alkyl sulfides with the metalloporphyrins **2**.[7a] With iron- and manganese-complexes they achieved enantiomeric excesses of up to 72%. Metalloporphyrins are thus not only important model compounds for oxygen transfer in cytochrome P-450, but they can also be used as effective catalysts for interesting asymmetric oxidations.

As long as ten years ago *Juliá* et al. described the efficient epoxidation of chalcones in the three-phase system toluene–water–polyamino acid.[8] The optically active epoxychalcones are obtained in good chemical and high optical yields (up to 96% *ee*) by oxidation with H_2O_2/NaOH at room temperature. Poly-α-amino acids can be synthesized via polymerization of the corresponding *N*-carboxyanhydrides with various chain lengths and different end groups. They are formed both in a stretched as well as in a helical conformation. To achieve higher enantioselectivities in the epoxidation of chalcones a polymer chain length of least ten amino acid units is necessary. Very good results were achieved with poly-L-leucine and poly-L-isoleucine, poly-L-valine on the other hand proved to be less efficient with respect to chemical yield and enantioselectivity.

Flisak et al. have recently described a further potential application of this reaction.[9] Using a commercially available poly-L-leucine they were able to epoxidize substituted chalcones with high enantioselection (up to 92% *ee*) by the Juliá method. The polymer can be recovered without loss of activity and used for further epoxidations. By regioselective Baeyer-Villiger oxidation of the epoxychalcones with *meta*-chloroperbenzoic acid (MCPBA) in boiling dichlormethane the synthetically valuable glycidic esters can be synthesized. The enantiomeric excess is increased by recrystallization, so the products are obtained almost enantiomerically pure (> 99% *ee*) [Eq. (b)]. This two-step oxidation sequence—enantioselective epoxidation with poly-L-leucine and regioselective Baeyer-Villiger oxidation—thus enables an efficient entry to important optically active intermediates for organic synthesis.

Asymmetric epoxidation with catalytic amounts of polyamino acids has thus far been restricted to only chalcones. Other electron-deficient olefins, such as nitroalkenes or cycloalk-2-enones, could be oxidized in this way only with slight asymmetric induction.[10] The development of new polymer-supported polyamino acids could fulfill far-reaching hopes in this area.[11]

Piezoelectric Liquid-Crystalline Elastomers

By *J. H. Wendorff**

In 1880 *Paul Jacques* and *Pierre Curie*[1] made the discovery that certain materials form electric charges on their surface if subjected to a mechanical stress. They called this effect *piezoelectricity*. This term denotes also the inverse effect: the induction of mechanical deformations due to the application of an electric field. Quarz is a typical example of a material displaying piezoelectricity and certain ceramics were later found to display huge piezoelectric effects.[2] They are used today in a large variety of applications: sensors, electromechanical or electroacoustic transducers, positioning elements (for instance in the scanning tunnel electron microscope) are some examples. Piezoelectric ceramics possess, however, disadvantages like brittleness (which makes handling and shaping difficult) and high dielectric constants and densities.

The report in 1969 of *Kawai*[3] that piezoelectric effects for the partially crystalline polymer poly(vinylidene fluoride) (PVDF) were orders of magnitude larger than usually observed for polymers and well within a range suitable for applications repesented important progress. This observation has stimulated much experimental and theoretical work on the nature of this effect and on the development of other polymers with similar or even higher piezoelectric responses.

Major advantages of piezoelectric polymers are, of course, the ease of manufacturing piezoelectric elements in any shape (including film elements as thin as 1 μm), the good mechanical properties of the polymers, their resistence to moisture and many organic solvents, and their low dielectric constant and density. PVDF and copolymers derived from it are currently used with great advantage in electroacoustic and electromechanical transducers because of their low impedance, their broad band modulation characteristics, and the low mass of active elements made form them.[2] Microphones, loudspeakers, positioning elements for robots, sensors used in medicine and biology, information storage—the number of applications of piezoelectric polymers is indeed very large today.

It could be much larger if we had piezoelectric polymers with a broad range of mechanical responses, dielectric properties, optical properties etc. *Kawai*'s discovery and the subsequent investigations, however, have not opened up promising routes to novel polymers with strong piezoelectric responses. The reason is simple: a fundamental requirement for the occurrence of piezoelectric properties is the absence of an inversion center. Even today when we can take advantage of computer-aided molecular modeling, it is almost impossible to design polymers so that their crystal structures have no inversion center.

It seems, however, that we are currently experiencing a major breakthrough in this area[4–8] as a result of the efforts of theoreticians and of experimentalists alike. The approach is based on a suitable combination of network properties and properties characteristic of certain liquid-crystalline phases.

As pointed out above, the absence of an inversion symmetry is essential for the occurrence of piezoelectricity. The cholesteric phase which displays locally a nematic structure (director $\vec{n}$) and a helical arrangement of this director in space (Fig. 1 a) does not have this symmetry. The same holds for the chiral smectic C* phase, where the molecules in the smectic layers (Fig. 1 b) are tilted in a regular fashion. Symmetry arguments suggest that such phases should display piezoelectric effects, but low molar mass liquid crystals displaying these phases are hardly suitable for technical applications.

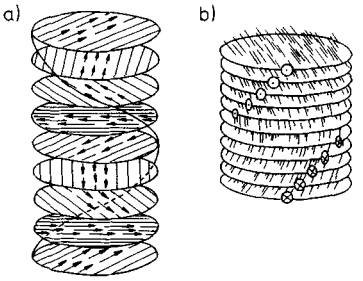

Fig. 1. Schematic representation of the structure of the cholesteric phase (a) and the chiral smectic C* phase (b).

A solution to this problem is on the horizon. The first step was made when *H. Finkelmann*[9] showed in 1981 that liquid-crystalline structures can be obtained in a lightly cross-linked polymeric network. A whole series of liquid-crystalline elastomers were synthesized and characterized by him and later by other groups,[8] among them cholesteric and chiral smectic C* elastomers. These polymers display mechanical properties similar to non-liquid-crystalline elastomers such as ductility of up to several 100%.

The second stop towards novel piezoelectric materials was made very recently when *H. Brand* et al.[4, 5] used a phenomenological approach—a Landau–Ginzburg type of expansion of the free energy of the elastomers for coupling to mechanical and electric fields—and came to the conclusion that such cholesteric and chiral smectic C* elastomers should display interesting electromechanical properties including special piezoelectric properties. Such properties result, according to this analysis, from the combination of network properties and the intrinsic properties of chiral liquid-crystalline phases. Predictions were that an electric polarization is caused by the deformation (compression) of the helix, as in the case of low molar mass liquid crystals. In addition, piezoelectric effects should arise from the coupling of the electric field and the network. Thus mechanical distortions cause an electric polarization and vice versa. Furthermore, the theoretical analysis suggests that various modes of distortion (shear, compression) give rise to piezoelectric effects.

The last months have seen the third step towards novel classes of piezoelectric materials. It was shown experimentally by *H. Finkelmann* et al.[6] and *S. U. Vallerian* et al.[7] that, qualitatively at least, these predictions are correct. Figure 2 shows the chemical structure of a typical cholesteric elastomer and Figure 2 b experimental proof of its piezoelectric properties.

Schlossgartenstrasse 6, W-6100 Darmstadt (FRG)

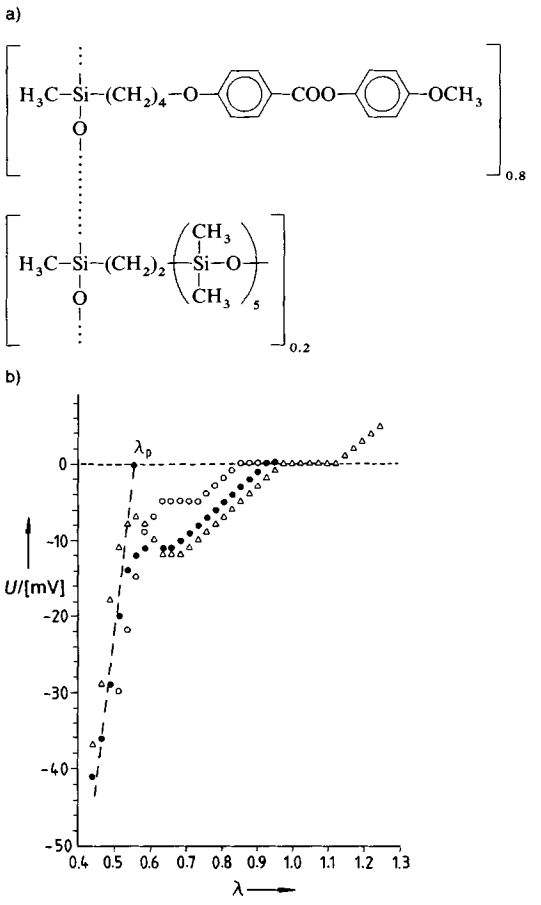

Fig. 2. a) Chemical structure of an elastomer displaying piezoelectric properties [6]. b) Dependence of the mechanically induced voltage U on the deformation (λ) for different reduced temperatures $T_{red} = T/T_i$ where T_i is the clearing temperature of the liquid-crystal elastomer. Δ: $T_{red} = 0.965$; ●: $T_{red} = 0.993$; ○: $T_{red} = 0.997$. The dashed line indicates extrapolation to a threshold deformation.

What are the advantages of this new class of piezoelectric polymers? First we know well-defined routes—drawn from the study of low molar mass and polymeric liquid crystals—to cholesteric or chiral smectic structures in elastomers. Second, we know from studies on non-liquid-crystalline networks how to modify the mechanical properties of the elastomers, varying for instance the cross-link density or the functionality of the cross-links. So we have most of the knowledge at hand to optimize the piezoelectric properties and other properties (mechanical, dielectric) relevant to piezoelectric applications and the manufacture of such materials.

The unique superposition of the piezoelectric responses of the intrinsic LC structure on one hand and the network on the other may even lead to surprising new modes of behavior and thus to new applications. Finally, based on the theoretical analysis,[5] we can expect these elastomers to display pyroelectric effects (charges induced on the surface as the temperature is changed), flexoelectric effects (electric response due to director field distortions), and electrostriction. Such effects may eventually be exploited in suitable applications.

After so much enthusiasm a word of caution should be sounded. Actual applications require, as pointed out above, a whole set of optimized properties: low impedance, broad band modulation characteristics, and optimized electromechanical coupling properties are just some of them. A minimum is known about these today. Many other properties come to mind, which have to be quantified, such as the actual strength of the coupling of the electric field to the network. A phenomenological treatment is, of course, not able to make predictions on the magnitude of effects. We do not know what will happen as we extend the elastomers up to large deformations, although this problem was briefly considered by *H. Brand*.[5] Now a major task, for which the theoretical predictions may serve as a guideline, is to investigate in detail the piezoelectric properties, but also other properties relevant to applications.

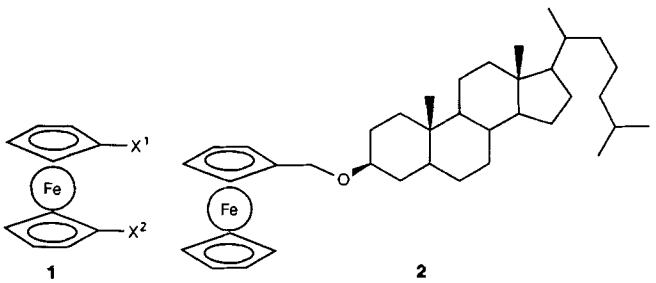
Sandwiches Bring a New Element to Molecular Recognition

By *Edwin C. Constable**

Contemporary chemistry is characterized by the number and variety of topics which cut across the traditional divides, both between organic, inorganic, physical, and theoretical chemistry and between chemistry and the biological sciences. Recently the term "molecular recognition" has been widely employed to describe the investigation of molecular systems which show specific and designed interactions with particular molecules or ions. This area of study is clearly at the interface of organic and biological chemistry. However, it is now apparent that the unique properties of metal ions may also be exploited. Recent examples have included the use of metal ions in the self-assembly of large molecular aggregates and novel topological arrays, and in the design of novel receptor systems. Transition metal complexes are also frequently characterized by their ability to undergo metal-centered redox processes to generate oxidized or reduced compounds with differing properties. In two recent papers, *Gokel* and his co-workers have described some unusual and imaginative applications of organometallic compounds to problems which are more commonly regarded as organic.[1, 2]

Ferrocene (**1**, $X^1 = X^2 = H$) is a simple and remarkably robust organometallic complex which may be formally considered in terms of two coplanar cyclopentadienyl rings lying above and below an iron center. *Gokel* et al. have considered the consequences of this unit in highly derivatized systems. In the first paper,[1] the consequences of the oxidation of the iron(II) center of a ferrocene are considered. A range of derivatives of **1** incorporating long-chain fatty acid or cholesterol residues were prepared by esterification or amidation reactions (**1**, $X^1 = X^2 = COCl \rightarrow$ **1**, $X^1 = X^2 = CO_2R$, CONHR, or $CONR_2$), or sequential Menschutkin and alcoholysis reactions (**1**, $X^1 = H$, $X^2 = CH_2NMe_2 \rightarrow$ **1**, $X^1 = H$, $X^2 = CH_2OR$). Although some of these compounds showed evidence for the formation of aggregates, the most interesting behavior was noted with the dihydrocholesteryl ester **2**. The neutral molecule **2** exhibited no aggregation phenomena in solution, but electron micrographs show that upon electrochemical or chemical oxidation to the cation, $\mathbf{2}^{\oplus}$, approximately spherical vesicles with membranes of ca. 45 Å thickness were formed and could be obtained in aqueous dispersion after ultrasonic treatment.



1 **2**

The most important observation that *Gokel* and *Echegoyen* have made is that the formation of the vesicles is genuinely redox-triggered: compound **2** does not aggregate in solution but upon oxidation the vesicles are formed; chemical reduction of these vesicles with dithionite results in their destruction. This use of a redox-active metal center as a molecular switch to control the formation of macromolecular assemblies is remarkable and suggests an entirely new methodology for the formation of membranes, micellar, and other supramolecular assemblies.

In the following paper,[2] entitled "A molecular receptor based on the ferrocene system: selective complexation using atomic ball bearings", *Gokel* et al. utilise some of the other properties of the ferrocene moiety in the design of diamine binders. The title refers to the fact that the two coplanar cyclopentadienyl rings of a ferrocene may rotate with respect to each other about the iron center as if the metal were a ball-bearing between two plane surfaces. Thus in the case of functionalized ferrocenes, a wide range of relative orientations of the substituents may be achieved. Since rotational barriers in substituted ferrocenes are low (similar to those in substituted ethanes), it is now possible to design a system which has all of the correct functionality for binding of a particular molecule, but which does not have this functionality in the correct spatial positions. The correct spatial arrangement is induced by the substrate, which organizes the functional groups of the receptor in an optimal manner by selective rotation of the cyclopentadienyl rings (Fig. 1). Only the correct substrate can selectively organize the receptor to the correct conformation, which provides an additional element of recognition.

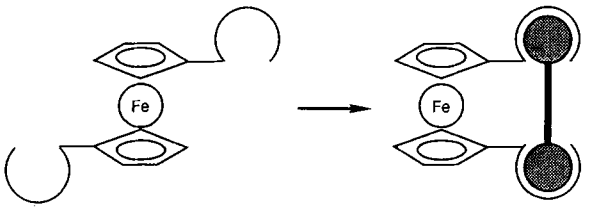


Fig. 1. The principle of binding of difunctional molecules to a ferrocene receptor. The active conformation of the receptor is induced by the presence of the substrate.

Gokel et al. have used the readily available substituted ferrocene **1**($X^1 = X^2 = CO_2H$) to prepare a series of bisferrocenes (**3a–d**) containing a potential bonding cavity designed for diamines. The primary receptor-substrate interaction is between the carboxylic acid residues and the amino groups, but a number of other features increase the specificity. The correct spatial arrangement of the carboxylic acids may be achieved by the "ball bearing" motion of the two cyclopentadienyl rings of an individual ferrocene unit (and also by the rotation of the two ferrocenyl units about the spacer group when appropriate). The use of aromatic spacer groups between the ferrocenes allows π-stacking interactions between the substrate and the receptor as an additional form of recognition.

Models suggested that the cavity size between the carboxylic acids in the correct conformation was 7–8 Å, and

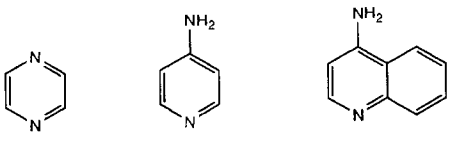
the binding of substrates such as **4a–e** was investigated. ^{1}H NMR chemical shift methods detected significant substrate-receptor binding interactions with compounds **4b** and **4c** ($K \approx 10^3\ M^{-1}$). These are the first members of a new non-macrocyclic receptor for organic substrates; future developments are likely to include the introduction of different functionality designed to bind other substrates.



The elegant fusion of organic and inorganic chemistry and the application to current problems presented in these two papers is most impressive. However, other workers have also recognised the potential of substituted ferrocenes as molecular switches or receptors.[3, 4, 5] In particular, the group of *Beer* has been especially interested in the design of molecular systems in which a ferrocene bears a metal binding substituent such as a crown ether. Coordination of an alkali metal ion to the crown ether results in steric and electronic changes to which the iron center is sensitive, and which may be monitored by electrochemical studies. In principle, this approach leads to the design of molecular switches or sensors in which a change in the redox potential of the ferrocene unit is triggered by alkali metal ion binding, a phenomenon of obvious biological relevance.

The concept of utilizing conformational changes upon substrate binding to optimize that binding are inherent in many descriptions of biological interactions and have been successfully applied to other chemical systems. Of particular note in this context is the work of *Rebek* who termed such phenomena "allosteric effects".[6] In a series of seminal papers, *Rebek* demonstrated that co-operative metal binding could be associated with conformational changes in 3,3′-di-substituted-2,2′-bipyridines.

The design of receptors for small organic molecules has been a recurrent theme in contemporary organic chemistry, and the work of *Lehn* and his group must be highlighted in this context.[7] Although the interactions of metal ions with amines have been known for several centuries, and played a pivotal role in the development of coordination chemistry, it is only relatively recently that the potential of inorganic systems for the selective, reversible binding of such species has been exploited. A very elegant example of this has been demonstrated recently by *Sanders* et al.[8] They have shown that cyclo-oligomers containing zinc porphyrins may be prepared in high yields by copper-mediated acetylenic coupling reactions. The relevance to the work of *Gokel* is that the reactions are performed in the presence of polyamines such as 4,4′-bipyridine or 2,4,6-tri(2-pyridyl)-1,3,5-triazine which assemble the precursors about them in the correct conformation by direct interactions between the heterocyclic nitrogen atoms and the zinc centers. Here we see the recognition extending one step further back; the substrate does not simply trigger a conformational change in the receptor, it also controls the synthesis of the correct receptor site. Such template reactions are well-known to inorganic chemists.

These papers illustrate the current trend of applying methodology and concepts from one discipline to another. In particular, they emphasize once again that the inorganic chemist, with an arsenal of 100 or so elements at his command, may be able to introduce novel and subtle elements of control into organic systems. These ideas are excellently summarized in *Seebach*'s recent review article entitled "Organic synthesis—where next".[9] The concepts of metal-directed reactivity are discussed in a recent book.[10]

A New Look at Electron Localization**

By *A. Savin,* A. D. Becke, J. Flad, R. Nesper, H. Preuss* and *H. G. von Schnering*

Ubiquitous chemical terms such as "the electron pair" and "the chemical bond" do not correspond unambiguously to directly measurable physical quantities. Because of their undeniable conceptual utility, however, clear and rigorous physical definitions are essential. The chemical bond is often described by localized molecular orbitals (see for example ref. [1]), but localized orbital sets are not unique. For example, two possibilities for bond localization of the π orbitals in benzene are shown in **1** and **2**, yet other, indeed infinitely many, mathematically equivalent schemes are also possible.[2] The localized molecular orbital description of chemical bonding is physically and mathematically arbitrary.

1 **2**

In this work it will be demonstrated, through a series of examples, that a new quantity, the Electron Localization Function (ELF),[3] is especially well suited to describe chemical bonds and electron pairs. ELF is based on measurable quantities and, moreover, the problem of nonuniqueness of localized molecular orbitals is not shared by ELF, at least in closed-shell systems.

In 1952 *Lennard-Jones* had already shown how, with the help of quantum mechanics, regions of space could be related to bonds and lone electron pairs.[4] He employed the two-particle density for electrons of parallel spin, a function of two electrons' coordinates (x, y, z and x', y', z') which gives the joint probability of finding one electron at position x, y, z and another electron of the same spin at position x', y', z'. The analysis showed that electrons of parallel spin restrict themselves to separate regions of space, and hence follows the notion of localized electron pairs. A well-known application of these concepts are the *Gillespie* and *Nyholm* rules.[5]

Becke and *Edgecombe* investigated another way of defining such regions of electron localization. They likewise made use of the two-electron density, exploiting its behavior at small interelectronic distances.[3] They showed that the probability of finding two electrons of the same spin close to one another is highly position dependent, leading to regions of both particularly high and particularly low pair probability. In the latter case, the electrons are "well localized". As a measure of this, *Becke* and *Edgecombe* introduced the Electron Localization Function (ELF), defined so as to have the convenient range of values $0 \leq \mathrm{ELF} \leq 1$. Regions in which the value of ELF is close to 1 correspond to well-localized electrons, and may be identified with atomic shells, chemical bonds and lone electron pairs. It is remarkable that the behavior of only the parallel-spin electrons so clearly discerns these details. The nature of electron pair correlation for opposite spins will not be considered here.

Technical details: Let us consider two electrons with parallel spins at positions x, y, z and x', y', z' (with separation r_{12}). The two-particle density is a function of both x, y, z and x', y', z'. Upon averaging over a sphere centered on x, y, z, one obtains a function of x, y, z and r_{12}, whose power series in r_{12} has the leading term $D(x,y,z)r_{12}^2$. The definition of ELF is then given by equation (a), where $D_h(x,y,z)$ is the value of D for a homogeneous electron gas with

$$\mathrm{ELF} = \frac{1}{1 + [D(x,y,z)/D_h(x,y,z)]^2} \qquad \text{(a)}$$

density $\varrho(x,y,z)$. In the Hartree–Fock approximation (closed shell) one obtains the explicit expression given in equation (b), where φ_i are the occupied orbitals

$$D/D_h = 0.3483\,\varrho^{-5/3}\left[\sum_i |\nabla\varphi_i|^2 - \frac{1}{8}|\nabla\varrho|^2/\varrho\right] \qquad \text{(b)}$$

and all quantities are expressed in atomic units. In this work, ELF has been calculated at the Hartree–Fock level [6], with pseudopotentials used for the tin compounds [7].

It is, in principle, possible to determine ELF from measured data. Knowledge of only the single-particle density matrix $\sum_i \varphi_i(\boldsymbol{r})\varphi_i(\boldsymbol{r}')$ is required at the Hartree–Fock level and methods to determine this from experimental data have been proposed long ago [8]. In many cases the experimental electron density was used to determine the density matrix. Knowledge of the density should be supplemented, however, by additional information from sources such as Compton spectroscopy [9, 10].

Here we present, using a newly developed computer graphics program,[11] the first extensive study of the utility of the Electron Localization Function. In the graphical representations of Figure 1, we see how well ELF reflects various intuitive concepts of atomic and molecular structure. The program calculates both the electron density and ELF for selected molecular planes, which generally contain atomic nuclei, and portrays them simultaneously. Electron density is represented by point density (i.e., electron clouds) as, for

example, in Frame 1 for the electron density of the NH_3 molecule, **3**. With white points on a black background, one

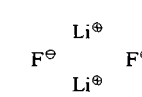
immediately recognizes the high-density maxima at the positions of the N nucleus and the H nucleus. Representations of this kind were introduced in 1931.[12]

In addition our points are assigned colors depending on the local value of ELF and inspired by geographical maps: the blue color of the sea corresponds to low ELF and the white of the mountains to high ELF, with green and brown in between. The color scale is given on the left in Frame 2. Thus our backgrounds remain black, and white points now indicate very highly localized electrons. This representation of ELF conveys considerable additional information. One now identifies in **3**, for instance (compare Frames 1 and 2), three regions of higher localization: one around the N nucleus, one containing the N and H atoms (lower right) and one on the free side of the N atom (top). These regions can be attributed to the core, the N–H bond and the lone pair.

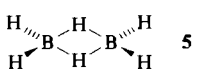
At this stage it should be pointed out that the Electron Localization Function, like the electron density, always possesses the full symmetry of the molecule, and therefore all symmetry-equivalent planes will give the same ELF. For NH_3 (**3**) all planes containing the C_3 axis and one of the N–H bonds will yield the same picture. Furthermore for linear molecules both the electron densities and ELF have axial symmetry. In the case of the Ne atom, ELF yields two spherical regions of higher localization which correspond to the core and valence shells (Frame 3). The same sharp separation between core and valence shells is also visible in molecules such as Li_2 (Frame 4).

In the C_2 molecule ($^1\Sigma_g^+$ state) the π-orbital bonding is discernible (Frame 5). In the N_2 molecule there exists within the valence shell a clear separation between the bonding region and the lone pair electrons, not as distinct, however, as the separation between core and valence regions (Frame 6). The F_2 molecule (Frame 7) shows a weak bond, whereas two Ne atoms at the same interatomic distance merely show a distortion of their valence shells (Frame 8).

Even with simple hydrides we find a large variety of bonding forms. The LiH molecule consists of a $Li^{\oplus}$ core (Frame 9, left) and a polarized $H^{\ominus}$ ion (right, white). In the BH molecule (Frame 10, B middle, H right) there exists along with the B–H bond an additional electron lone pair (left). In the HF molecule (Frame 11) the region of space to which one would assign the H–F bond is smaller and more difficult to discern from the region of the free electrons than in, for example, the BH molecule. We see already an indication of the tendency to form $H^{\oplus}F^{\ominus}$. In the LiF molecule we have essentially an ionic bond (Frame 12; compare with LiH,



4

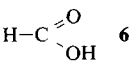


5

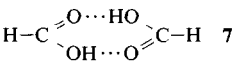
Frame 9), as implied by the nearly spherical structure of the ELF around each nucleus and the appearance of an intervening region with very low ELF values. This ionic character also appears, of course, in the dimer Li_2F_2 (**4**, Frame 13). In contrast, a polarized bond is found in the ClF molecule (Frame 14).

The more complicated case of three-center bonding appears in diborane (**5**, Frame 15). Here also, the agreement with classical concepts is very clearly illustrated by the electron density and ELF. In planar Li_4 and Li_6 clusters, calculated to be stable, the three-center bonds likewise appear.[6] In these cases, however, one might also expect bonds involving more than three centers. According to ELF (Frames 16 and 17), these clusters are held together almost exclusively by peripheral three-center bonds.

When H bridges two strongly electronegative partners the bonds show distinct ionic character, as indicated by the formic acid molecule **6** (Frame 18) and its dimer **7** (Frame 19). What happens, though, if the H atom lies symmetrically



6



7

between two equally electronegative atoms as in the FHF anion (Frame 20)? Here one notices a region of high ELF around the proton clearly separated from those of the neighboring atoms. A similar picture results if, in **7**, one imagines the transition state for the transfer of a proton from one O atom to another. In the change from an asymmetric to a symmetric H bridge the ionic nature of the bond is largely lost.

With the Electron Localization Function weaker effects, such as change in delocalization, can also be recognized. Let

Fig. 1. Electron density ρ as "cloud" and the color pattern of the Electron Localization Function, ELF (scale in Frame 2: small values of the ELF are represented as blue, large values as white; scale for remaining frames: blue, green, brown, white; background: black). Frame 1: ρ(**3**) as white cloud. The selected plane contains the N nucleus (middle), a H nucleus (bottom right) and the center point between two other H nuclei. Frame 2: ρ(**3**) and the ELF. The white regions correspond to the core, the lone electron pair and the N–H bond. Frame 3: Core and valence shells of the Ne atom. Frame 4: Core and bonding regions (white) in the Li_2 molecule. Frame 5: Core and π bond (white periphery) in the C2 molecule. Frame 6: Core, bond and lone electron pair (white) in the N_2 molecule. Frame 7: Core, cylindrical symmetric regions of the lone electron pair (white) and weak covalent bond (yellow-brown) in the F_2 molecule. Frame 8: Deformation of the electron density in the Ne_2 molecule (compare Frame 3). Frame 9: LiH molecule with $Li^{\oplus}$ core (left) and $H^{\ominus}$ ion (right). Frame 10: BH molecule with the lone electron pair, the B core and the B–H bond as white regions from left to right. Frame 11: HF molecule with the cylindrical symmetric regions of the lone electron pair, the F core and the F–H bond. Frame 12: LiF molecule with $Li^{\oplus}$ (left) and $F^{\ominus}$ (right). Model for an ion pair with separated region (small ELF values: blue). Frame 13: **4** with $Li^{\oplus}$ cations (top and bottom) and $F^{\ominus}$ anions (left and right). Frame 14: ClF molecule with Cl (left) and F (right); core and lone electron pair regions (large white regions); weak, polarized bond (brown-yellow region). Frame 15: **5** (plane of the B_2H_2 ring with the B atoms left and right) with core and two three-center bonds (large white regions around the H atoms). Frame 16: Planar Li_4 cluster with core and two three-center bonds. Frame 17: Planar Li_6 cluster with core and three peripheral three-center bonds; one notices that a central three-center bond is absent. Frame 18: **6** with cores, bonds and lone electron pairs (ketone oxygen at top right). Frame 19: **7** (compare Frame 18) shows the ionic character of the hydrogen bonds (blue regions between the monomers). Frame 20: $FHF^{\ominus}$ ion with a small area of high ELF values around the H nucleus. Frame 21: **8** (selected plane is 1 Bohr above the nuclear plane) with the C–H and C–C bonds (white regions). Frame 22: **9** (plane same as in Frame 21) shows a larger π region at the central C–C bond than **8**. Frame 23: ClF_3 molecule emphasizing the difference between the axial and equatorial Cl–F bonds. Frame 24: SnO molecule with Sn (left) and O (right) and the lone electron pair on the Sn (large white region). Frame 25: Sn_2O_2 molecule with the Sn atoms lying horizontally. Frame 26: **12** (plane through the Sn nuclei splits the H-Sn-H angle; the H nuclei are located top right and bottom left above and below the plane), see text for discussion. Frame 27: Sn_2H_2 molecule with hypothetical planar structure (Sn atoms sit right and left from the center point of the picture: all H atoms are located in a plane perpendicular to the represented plane. Frame 28: Cu_4Sn_4 molecule with heterocubane structure (Sn atoms top, Cu atoms bottom), for discussion see text.

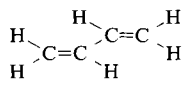
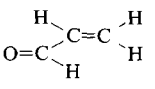
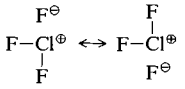
us compare the C–C bonds in butadiene (**8**, Frame 21), and acrolein (**9**, Frame 22). The illustrations present ELF values in a plane lying 1 Bohr above the plane of the nuclei and intersecting the π-bonding region, and show that the π component of the C–C bond is larger in **9** than it is in **8**.



8



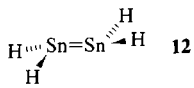
9



10 **11**

That ELF also represents three-center–four-electron bonds is shown by the example of ClF_3 (Frame 23). The two axial Cl–F bonds clearly have a weaker covalent character than the equatorial bond, corresponding well to the canonical forms **10** and **11**.[13]

The core electron densities vanish if one uses a pseudopotential method rather than performing all-electron calculations. We have done this in the case of Sn compounds, and therefore our representations of the Sn compounds exhibit no high electron densities around the nuclei but only the black background. The lone-pair electrons in Sn^{II} compounds are nicely illustrated by ELF. The spatial distribution of the lone pair in the SnO molecule (Frame 24) is clearly deformed and remarkably large. The Sn_2O_2 dimer (Frame 25) shows a similarly expanded spatial distribution of these electron pairs and is an impressive indication of its stereochemical activity. Unlike their carbon analogues, Sn_2R_4 molecules are not planar. The explanation involves the influence of the electron lone pairs.[14] For the bent Sn_2H_4 molecule **12**, ELF actually shows a strong deformation (Frame 26), and the influence of the lone pairs is especially clear in comparison with the hypothetical planar structure of Frame 27. The large white region is intermediate between the case of two isolated lone pairs (as in Frame 25) and the case of a pure double bond (as in Frame 27).



12

The heterocubane cluster Cu_4Sn_4 possesses an Sn_4 tetrahedron. Here one finds multicenter bonding with participation of the Cu atoms. The plane depicted in Frame 28 contains an edge of the Sn_4 tetrahedron (Frame 28 top, connecting the dark nuclear positions) and the middle of the opposite edge (Frame 28 bottom, middle of the yellow region). Two Cu atoms also lie in this plane (Frame 28 bottom, outer nuclear positions). Here again, the distribution of the Sn lone pairs is deformed.

In this first survey of the potential applications of the Electron Localization Function, ELF, we have demonstrated that notions such as atomic shells, chemical bonds, and lone electron pairs are readily manifested by a function that is based, in principle, on measurable physical quantities. Empirical findings, such as those expressed in the Gillespie–Nyholm rules, may be easily visualized thereby. Perhaps further investigations with the Electron Localization Function will prove beneficial in cases where classical concepts and chemical intuition fail.

Synthesis of a Biologically Active Taxol Analogue **

By *Siegfried Blechert** and *Andrea Kleine-Klausing*

The taxanes from the plant family Taxaceae form a group of very unusual tricyclic diterpenes.[1] An eight-membered ring with two geminal methyl groups, an annulated six-membered ring, and a C3-bridge results in a strained half-spherical ring system, that has many oxygen functionalities. One of the most interesting members is taxol **1**,[2] which at present is being intensively studied as a promising chemotherapy agent for several types of tumors.[3] Till now it has remained the only known naturally occurring compound that accelerates the polymerization of tubulin and blocks its depolymer-

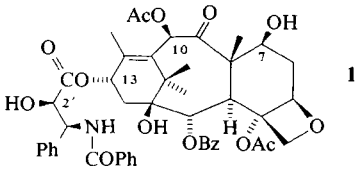
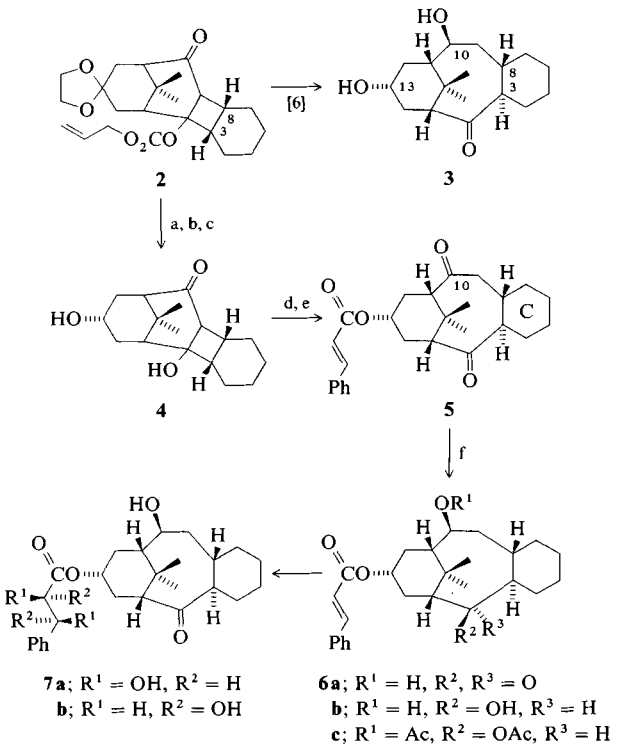
ization. Because of this novel mode of action, it has also become an important agent in cell research.



1

The limited accessibility of this natural compound (Taxaceae belong to the slowest-growing trees and the taxol content of the bark is very low), its insolubility, and its complex composition create an immense motivation to synthesize this class of substance. Till now, however, only very few groups have succeeded in preparing the functionalized taxane framework,[4] from which the analogues of **1** could be synthesized. We report herein on the first synthesis of a less highly functionalized taxol analogue that also restricts the depolymerization of tubulin.

Biological tests on taxol and its derivatives have shown the significance of the C-13 ester side chain and here in particular the C-2′ hydroxyl group.[5] We therefore planned the synthesis of a tricyclic C-13 hydroxylated taxane framework, that should have the spatial features of the natural product. The C-8 α-ring-formation required for the half-spherical construction of the tricycle was achieved through a stereoselective de Mayo reaction of cyclohexene with a suitable functionalized 1,3-diketone. The β-*exo*-attack directed by the ketal afforded photoadduct **2**. The Pd^0-catalyzed removal of the protecting group, retroaldol reaction, stereoselective reduction of the C-10 carbonyl group, base-catalyzed epimerization at C-3 and transformation of the ketal into the C-13 α-alcohol lead to the desired tricycle **3**.[6] The planned regioselective esterification at C-13 could not be achieved and the detour via a protected C-10 alcohol proved to be inefficient. A solution for the problem was found in the reaction sequence of Scheme 1.



7a; R^1 = OH, R^2 = H
b; R^1 = H, R^2 = OH

6a; R^1 = H, R^2, R^3 = O
b; R^1 = H, R^2 = OH, R^3 = H
c; R^1 = Ac, R^2 = OAc, R^3 = H

Scheme 1. a) Cat. $Pd(PPh_3)_4$, THF, morpholine (98%). b) THF, 2 N HCl(1:1). c) THF, lithium selectride, −70 °C (78%). d) *t*BuOH, KO*t*Bu, 70 °C, 2 h, (86%). e) Cinnamic acid, dicyclohexylcarbodiimide, 4-dimethylaminopyridine, toluene, 80 °C (70%). f) $NaBH_4$, citric acid, CH_3OH, 3 min (72%); **6b**: 30 min reaction time. **6c**: acetic anhydride, pyridine, 4-dimethylaminopyridine. g) OsO_4, *N*-methylmorpholine-*N*-oxide, pyridine, 1 h, (70%). For spectroscopic and physical data of compounds **6a**, **6c**, and **7**, see Table 1.

After liberating the aldol and deketalizing with aqueous acid, a diketone is obtained that can be reduced stereoselectively, still as crude product in THF, with lithium selectride to diol **4** at −70 °C at the sterically more accessible carbonyl group. The retroaldol reaction affords an eight-membered ring, whereby the complete isomerization to the thermodynamically favored *trans* orientation of ring **C** under the basic reaction conditions is achieved. The easy C-3 epimerization in this reaction step deserves special mention. Comparable retroaldol reactions with C-13 ketals in CD_3OD can be shown by H/D exchange to have an almost rigid conformation which is unfavorable for enolate formation, and no deprotonation at C-13 takes place. Only on reduction of the C-10 carbonyl group or through formation of the C-13 alcohol does the conformational flexibility of the eight-membered ring increase to allow the isomerization via enolate formation. The C-13 alcohol may be transformed without difficulty into the cinnamic acid ester **5**. The regio- and stereoselective reduction of the sterically more accessible C-10 ketone (over the C-2 ketone) is achieved with sodium borohydride/citric acid, whereby short reaction times lead exclusively to the desired α-alcohol **6a**. Over longer reaction times the diol **6b** is also formed, and its stereochemical assignment by NMR experiments at the diacetate stage (**6b**) is unambiguous. The chemical shift of all relevant protons could be assigned without doubt through $^1H,^1H$-correlated 2D NMR spectra. The nuclear Overhauser enhancement (NOE) difference spectra confirm the spatial proximity of H-3 and H-10, H-13 and C-15-methyl, H-2 and H-4, as well as H-2 and H-14. The coupling constants of H-2, H-3, H-10, and H-13 correspond to those calculated from the dihedral

Table 1. Selected data for **6a**, **6c** and **7**.

6a: ^1H NMR (400 MHz, $CDCl_3$): δ = 1.13 (s, CH_3), 1.23 (s, CH_3), 1.34 (m, 1H), 1.49 (m, 1H), 1.59 (m, 9-H, 2H), 1.71 (m, 5H), 1.86 (m, 11-H, 12-Hα, 2H), 1.98 (ddd, J = 16.5, J = 4.0, J = 2.0 Hz, 14-H, 1H), 2.32 (d, broad, J = 9.0 Hz, 1-H, 1H), 2.42 (ddd, J = 11.0, J = 11.0, J = 5.5 Hz, 9-H, 1H), 2.45 (dt, J = 16.5, J = 8.5 Hz, 14-H, 1H), 2.62 (ddd, J = 16.5, J = 10.0, J = 8.0 Hz, 12-Hβ, 1H), 3.16 (td, J = 11.0, J = 3.5 Hz, 3-H, 1H), 4.11 (ddd, J = 10.5, J = 4.0, J = 2.0 Hz, 10-H, 1H), 5.51 (m, 13-H, 1H), 6.45 (d, J = 16.0 Hz, 1H), 7.39 (m, 3H), 7.51 (m, 2H), 7.71 (d, J = 16.0 Hz, 1H); ^{13}C NMR (100 MHz, $CDCl_3$): δ = 25.4 (CH_2), 26.4 (CH_2), 27.1 (CH_2), 28.0 (CH_3), 30.1 (CH_2), 32.0 (CH_2), 34.8 (C), 35.4 (CH_3), 38.5 (CH), 40.3 (CH_2), 48.7 (CH), 49.1 (CH), 57.6 (CH), 66.9 (CH), 74.3 (CH), 118.2 (CH), 128.1 (CH), 129.0 (CH), 130.6 (CH), 134.2 (C), 145.3 (CH), 166.2 (C), 218.4 (C).

6c: M.p. = 150–152 °C; ^1H NMR (400 MHz, $CDCl_3$): δ = 1.06 (s, CH_3), 1.07–1.22 (m, 3H), 1.35 (m, H-9α, 1H), 1.40 (s, CH_3), 1.45–1.60 (m, 5H), 1.61–1.71 (m, H-12α, H-14α, H-8, H-11, 4H), 2.02 (m, H-1, 1H), 2.04 (s, $COCH_3$), 2.05 (s, $COCH_3$), 2.22 (t, broad, J = 9.6 Hz, H-3, 1H), 2.33 (dt, J = 16.0, J = 6.8 Hz, H-12β, 1H), 2.45 (ddd, J = 16.0, J = 9.6, J = 7.2 Hz, H-14β, 1H), 2.80 (broad, H-9β, 1H), 4.80 (d, J = 5.0 Hz, H-2, 1H), 5.30 (m, H-13, 1H), 5.43 (dd, broad, J = 9.6, J = 6.4 Hz, H-10, 1H), 6.44 (d, J = 16.0 Hz, 1H), 7.38 (m, 3H), 7.59 (m, 2H), 7.85 (d, J = 16.0 Hz, 1H). The stereochemical assignment is by NOE experiments.

7 (biologically active): ^1H NMR (400 MHz, $CDCl_3$): δ = 1.07 (s, CH_3), 1.12 (m, 1H), 1.18 (s, CH_3), 1.25–1.80 (m, 11H), 1.91 (d, broad, J = 16.0 Hz, H-14, 1H), 2.31 (d, J = 9.0 Hz, H-1, 1H), 2.36–2.47 (m, H-9, H-14, H-12β, 3H), 2.63 (broad, OH, 3H), 2.97 (td, J = 11.0, J = 4.0 Hz, H-3, 1H), 3.98 (ddd, J = 10.5, J = 4.0, J = 2.0 Hz, H-10, 1H), 4.38 (d, J = 3.6 Hz, 1H), 5.04 (d, J = 3.6 Hz, 1H), 5.51 (m, H-13, 1H), 7.35 (m, 5H); IR ($CHCl_3$): ν[cm^{-1}] = 3500 (broad, OH), 1725 (C=O), 1680 (C=O).

angles according to the Karplus equation. The isolated compound **6a** is, however, not able to be transformed into the diol under the same reaction conditions. This may be explained by a transannular reduction of the C-2 ketone by a C-10 alkoxy borohydride. The *cis* hydroxylation of **6a** with osmium tetroxide yields a 1:1 mixture of two easily separable diastereomers (**7**). The relative orientation of the stereocenters between the ester side chain and the tricycle cannot be determined; a crystal structure analysis has as yet not been possible. Both diastereomers **7** were subjected to an in vitro tubulin test.[7] The diastereomer which is less polar in an eluant system of dichloromethane/methanol on silica gel inhibits the depolymerization of tubulin and is thus the first synthesis product with a taxol-analogous action. This result confirms that less functionalized taxol derivatives also can be of interest. We are at present studying a further simplification of the structure and its influence on the activity.

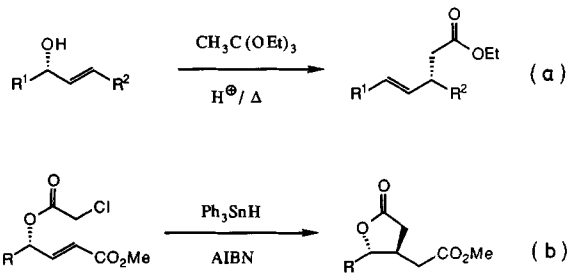
Intramolecular Diels–Alder Reactions: Diastereofacial Selectivity and Coupling with an Aliphatic Claisen Rearrangement**

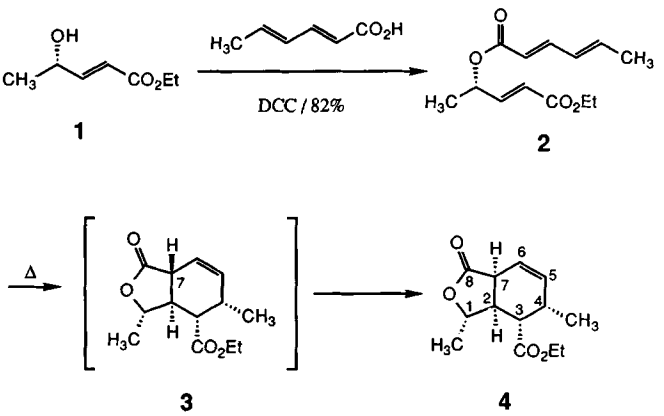
By *Johann Mulzer*, Harald Bock, Wolfgang Eck, Jürgen Buschmann*, and *Peter Luger*

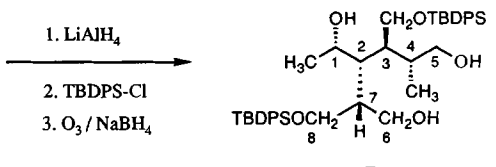
Intramolecular Diels–Alder reactions (IMDA reactions) are often studied because of their high regio- and stereoselectivity.[1] We were interested in two aspects of these reactions: 1) How can they be used for the rapid construction of acyclic chiral compounds? 2) Do they, like other pericyclic six-electron processes (Cope[2] or ene reactions[3]), allow coupling with the aliphatic Claisen rearrangement in a tandem reaction?

Allylic hydroxyl functions can be used in different ways for stereocontrolled C-C bond formation, as shown by the examples in equation (a) (1,3-chirality transfer[4]) and (b)



(1,2 induction through radical cyclization[5]). In this way a maximum of two (a) and three (b) stereocenters can be created; with the Diels–Alder reaction, however, up to four stereocenters per step are created. Thus we esterified the hydroxyester **1**, obtained in two steps from *O*-tetrahydropyranyl(THP)lactaldehyde, with sorbic acid to obtain triene **2**, which yields on heating (xylene, 160 °C, 3 days) the bicycle **4** (81 %) as well as two further diastereomers (5 and 9 % by HPLC analysis) (Scheme 1). According to an X-ray crystal





Scheme 1. DCC = Dicyclohexylcarbodiimide, TBDPS = *tert*-butyldiphenylsilyl.

structure analysis on **4**,[6] H-2 and H-7 are in *cis* orientation, in contrast to the (*E*,*E*) configuration in diene system **2**. Probably the primary adduct **3** epimerizes in situ at the CH-acidic 7-position.

The relative configuration at the four new chirality centers of **3** indicates that **2** reacts via conformation **6**, in which the methyl group shields one diastereoface of the dienophile. The Newman projection of **6** (**7**) shows that the attack on the dienophile conforms to the *Houk* model.[7]

7

The opening of **4** to further acyclic products can occur in several ways; for example, to **5**, which has a total of five distinguishable hydroxyl functions. The chiral information of **1** is thus transferred with high selectivity to the centers C-2, 3, 4, and 7 of the open chain compound **5** (numbering arbitrary).

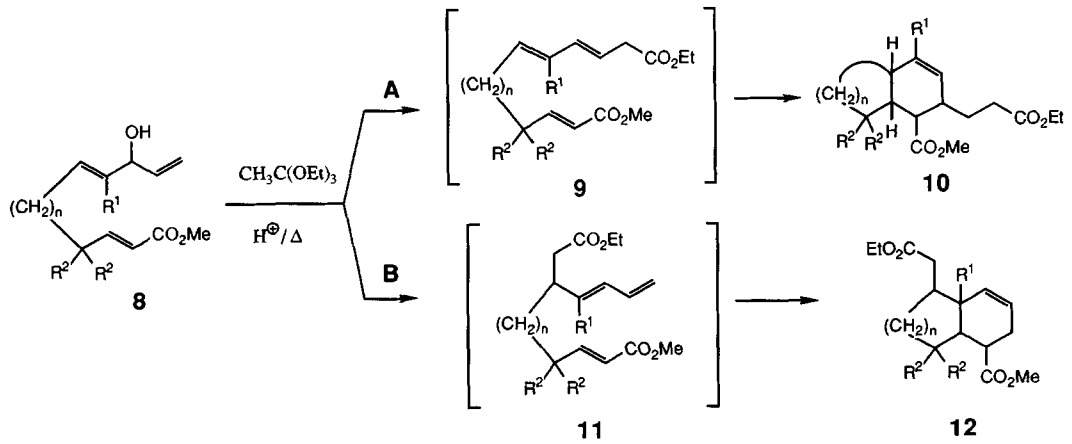
The coupling of two reactions is often considered a tandem reaction when they proceed one after the other without change in reaction conditions or buildup of intermediates.[8] In Scheme 2 we describe the first example of the coupling of an aliphatic Claisen rearrangement with an IMDA reaction.[9]

following conclusions: a) The relative amounts of products formed via route **A** or **B** is controlled by the degree of substitution of the internal double bond.[12] If it is trisubstituted (**8a**), route **A** dominates and chiefly the cyclization product

Table 1. Analysis of the tandem reactions of **8**; see also Scheme 2.

Compound	Diels–Alder reaction to **10** (route A)	**12** (route B)	expected	Product found (yield [%], ratio)
8a (n = 3)	favored: [6.6]-bicycle	unfavored: [7.6]-bicycle	**10, 11**	**10a/11a** (75, 10:1)
8b (n = 1)	unfavored: [4.6]-bicycle	favored: [5.6]-bicycle	**9, 12**	**9b/12b** (72, 1.3:1)

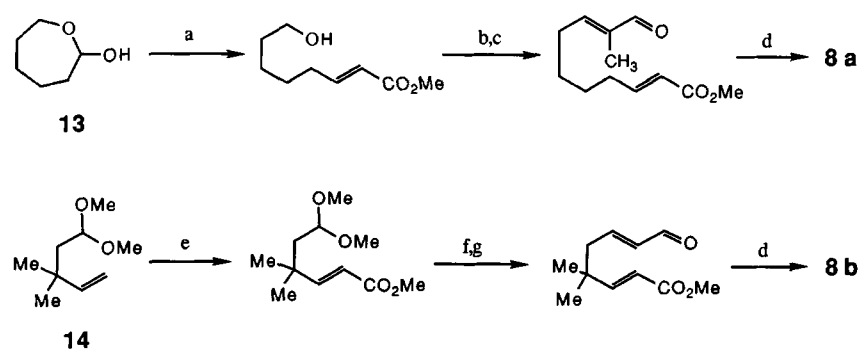
10a forms via intermediate **9a**. In the case of disubstitution (**8b**) on the other hand, the routes **A** and **B** are equally favored so that **9b** and **11b** form in approximately equal amounts. b) Diels–Alder reactions leading to rings of unfavorable size are avoided (**9a** → **10b** and **11a** → **12b**). Thus the reaction of **8b** leads to the formation of **9b** and **12b** in



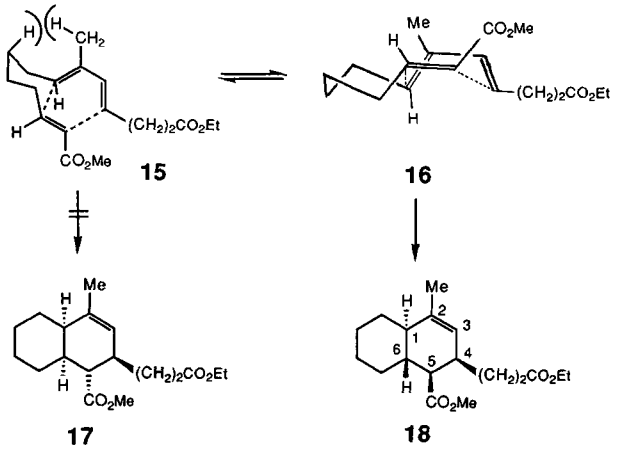
Scheme 2. **8a**–**12a**: n = 3, R^1 = Me, R^2 = H; **8b**–**12b**: n = 1, R^1 = H, R^2 = Me.

The trienols **8a** and **8b** are prepared from the known precursors **13**[10] and **14**[11] according to Scheme 3 and on heating with ethyl orthoacetate in diglyme (2 mol% propionic acid, 160 °C, 48 h) undergo a Claisen rearrangement (route **A** and **B**), followed by the spontaneous Diels-Alder reaction to **10** or **12**. The analysis of the reaction (Table 1) leads to the almost equal proportions, whereas **8a** yields **10a** as dominant product.

Stereochemically cyclization **9a** → **10a** differs from **11b** → **12b**. Compound **12b** is generated as a 43:35:14:4 mixture of the four diastereomers, whereas **10a** yields an isomer distribution of 91:9 (HPLC analysis). The relative configuration



Scheme 3. a) Ph_3PCHCO_2Me, $CHCl_3$, Δ (61%, *E*/*Z* = 10:1); b) Dimethylsulphoxide, CH_2Cl_2, $(CO)_2Cl_2$, −60 °C, (quant.); c) $Ph_3PC(CH_3)CHO$, $CHCl_3$, Δ (73%); d) $(CH_2{=}CH)MgCl$, Et_2O, −15 °C, (70–80%); e) $OsO_4/NaIO_4$ (80%); pyridine, H_2O; Ph_3PCHCO_2Me, $CHCl_3$, Δ (70%); f) SiO_2/CH_2Cl_2/*p*-TsOH (95%); g) $Ph_3PCHCHO$, $CHCl_3$, Δ (71%).



of the main diastereomer (**18**) of **10a** was determined by nuclear Overhauser enhancement (NOE) difference spectroscopy.[13] The cyclization **9a** → **10a** may be explained by considering the reactive intermediates **15** and **16**: intermediate **15** appears to be less favorable than **16** as a result of transannular H-methyl repulsion, and the cyclization product **17** is formed in only small amounts. Table 2 lists analytical data of the key compounds **4**, **12b** (major diastereomer) and **18**.

Table 2. Analytical data for the compounds **4**, **12b** (major diastereomer) and **18**. ^{1}H NMR: 270 MHz, $CDCl_3$, TMS as internal standard; ^{13}C NMR: 67.5 MHz, $CDCl_3$, TMS.

Enantioselective Protonation of a Simple Enol: Aminoalcohol-Catalyzed Ketonization of a Photochemically Produced 2-Methylinden-3-ol**

By *Françoise Henin,** *Jacques Muzart,** *Jean-Pierre Pete, Anastase M'boungou-M'passi*, and *Hermann Rau*

During the past few years, we have been concerned with asymmetric protonations of dienols produced by a Norrish type II photorearrangement of α,β-unsaturated carbonyl compounds.[1] The mechanistic model that we have proposed to rationalize the stereochemistry of the discrimination step involves principally the enol part of the dienol[2] and should apply equally well to enantioselective protonation of simple enols. As simpler enols could be generated from a Norrish type II photoelimination,[3] we examined the behavior of such prochiral enols under analogous conditions. Intensive research work has been devoted to the syn-

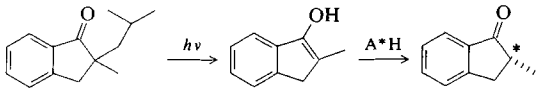
thesis and reactivity of stable enols[4] and to the asymmetric protonation of enolates,[5, 6] but to the best of our knowledge, the asymmetric protonation of a simple enol has never been reported.[7] We report here the results of such a study on 2-methylinden-3-ol **1** which is constrained to a single, rigid geometry and which was obtained photochemically from 2-methyl-2-isobutylindan-1-one **2**.



2 **1** **3**

Irradiations of deoxygenated acetonitrile solutions of **2** ($c = 3 \times 10^{-3}$ M) were first carried out in circular dichroism (CD) cells ($l = 1$ cm) with a nitrogen laser ($\lambda = 337$ nm) for 3–4 min. When an excess of (−)-ephedrine was added to the reaction mixture in the dark after irradiation, CD signals were observed at $\lambda > 300$ nm (Fig. 1, solid curve). These signals did not appear if a few drops of an aqueous NaOH solution were added before the ephedrine or when CH_2Cl_2 or MeOH was used as solvent in place of MeCN. Such CD signals could be attributed to chiral 2-methylindan-1-one **3**. Irradiations were also carried out with methylene chloride, dioxane, benzene, or acetonitrile solutions of **2** containing an excess of (−)-ephedrine. Similar signals appeared in the CD spectrum recorded after a few minutes of irradiation (Fig. 1, dotted curve). These CD signals disappeared in the presence

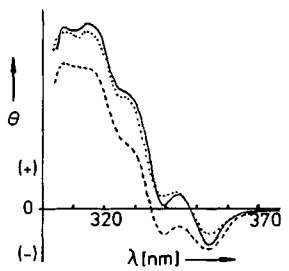


Fig. 1. CD spectra of irradiated mixtures of **2** and (−)-ephedrine (— and ···) and of pure **3** (---, in CH_2Cl_2). For details see text.

of an aqueous NaOH solution. These results suggest that **1** is formed and has a lifetime long enough to be protonated by (−)-ephedrine to form **3**. Similar CD signals were also observed when cinchonine was used instead of (−)-ephedrine. By contrast, such signals were not observed when (*S*)-α-methylbenzylamine, (*S*)-octan-2-ol or (−)-mandelic acid was the added chiral protonating species or when hexane was used as the solvent.

To support our interpretation, irradiation of a CD_3CN solution of **2** was carried out at 0 °C in an NMR tube. The 250 MHz ^1H NMR spectrum registered immediately after laser irradiation indicated a partial transformation of the starting material (40–50%) and showed the presence of singlet signals at $\delta = 1.96$, 3.16, and 6.38, which could be attributed respectively to the CH_3, CH_2, and OH groups of **1**. Addition of (−)-ephedrine induced the disappearance of these three signals with concomittent appearance of signals at $\delta = 1.24$(d), 2.7(m), 2.71(dd), and 3.41(dd), identical to the CH_3, CH, and CH_2 signals exhibited by the NMR spectrum of an authentic sample of **3**. From NMR integration, the yield was found to be essentially quantitative for this transformation. When this irradiated solution was transferred to a CD cell, we again observed the CD signals attributed to chiral **3**.

As the asymmetric formation of **3** had now been clearly established, we carried out semipreparative experiments. Chemical and optical yields are shown in Table 1 while the CD spectrum of purified **3** is shown in Figure 1, dashed curve. From these experiments, it appears that catalytic amounts of (−)-ephedrine are sufficient to induce an important enantioselectivity to the protonation of the enol. Furthermore, the best optical yields were reached with smaller amounts of added chiral species, and the major enantiomer of **3** isolated has the (*R*)-configuration,[8] as anticipated from the mechanistic scheme previously proposed for asymmetric protonation of dienols.[2]

Table 1. Asymmetric synthesis of 2-methylindan-1-one **3** from photolysis of **2**.

Solvent	(−)-ephedrine [equiv]	Conversion of **2** [%]	Yield of **3** [%] [a]	$[\alpha]_D^{22}$ (*c*, dioxane)	*ee* [%] config. [b]
CH_2Cl_2	0.68	90	42	−9 (0.19)	21 ± 3, (*R*)
CH_3CN	0.74	98	48	−12 (0.18)	28 ± 3, (*R*)
CH_3CN	0.10	98	59	−20 (0.26)	47 ± 3, (*R*)
CH_3CN	0.01	86	41	−19 (0.18)	45 ± 2, (*R*)

[a] Yield calculated on the amount of **2** introduced. [b] Determined on isolated **3** by comparison with literature data [8]; pure (*R*)-**3**: $[\alpha]_D^{22} = -42$ in dioxane.

Thus an enantioselective protonation of a simple enol was achieved.[9] Further developments of this photochemical approach towards chiral reactions are under way.

Experimental Procedure

Stirred deoxygenated solutions (15 mL) of **2** (10^{-2} M) and (−)-ephedrine (for concentrations see Table 1) in a round cell ($l = 5$ cm) were irradiated at 0 ± 3 °C with a nitrogen laser for 1.5 h. The irradiated mixture was then stirred overnight while the temperature of the cooling bath increased slowly to room temperature. After evaporation of solvent, **3** was isolated by preparative TLC (eluant EtOAc/petroleum ether, 5:95) followed by filtration on silica gel (same eluant). During the purification, precautions were taken to preclude enantiomer-differentiation of **3** [10].

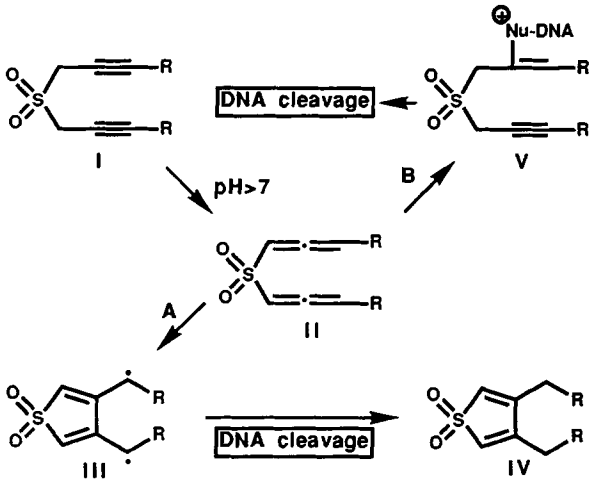


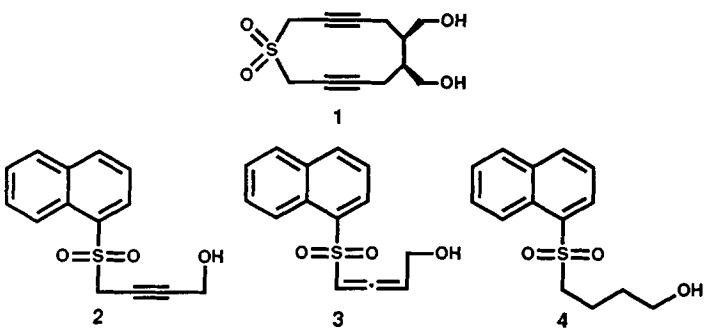
Scheme 1. Mechanistic rationale for propargylic sulfones.

Selectivity and Mechanism of Action of Novel DNA-Cleaving Sulfones**

By *K. C. Nicolaou,* S. Wendeborn, P. Maligres, K. Isshiki, N. Zein* and *G. Ellestad*

DNA is the target of several anticancer agents and antibiotics.[1] In recent years considerable effort has been directed towards the synthesis of DNA-cleaving molecules,[2] and site-specificity receives particular emphasis.[3] Recently we described[4] a simple class of propargylic sulfones that cleave DNA in a pH-dependent fashion. In this communication we report a) site-selective cleavage of double-stranded DNA by sulfone **1**, b) enhancement of the potency of these compounds by incorporating simple intercalators (compounds **2** and **3**), and c) studies elucidating the mechanism of action of this class of compounds.

Scheme 1 summarizes the two alternative modes of action of bis(propargylic) sulfones as originally proposed:[4] A Garratt–Braverman pathway[5, 6] proceeding via bis(allenes) **II** and diradicals **III** (path A), and an alkylation mechanism proceeding via intermediates **II** and **V** (path B). Compound **1** caused single- and double-strand breaks in covalently closed circular DNA. In order to probe mechanistic and reactivity questions, compounds **2**–**4**[7] were synthesized and tested.[8] Figure 1 shows the cleavage results with supercoiled ΦX174 DNA at pH 8.5 and 37 °C. Both compounds **2** (lane 3) and **3** (lane 4) exhibited much higher potencies (500–1000 times) than **1** (lane 2) as DNA-cleaving agents, whereas the saturated compound **4** was devoid of any activity (lane 5) as expected. Ethidium bromide, a known DNA intercalator,



inhibited the action of **2** (lane 8) and **3** (lane 9), but had no effect on the DNA-cleaving action of **1**. It was further observed that compound **4** also served as a weak inhibitor of the action of **2** and **3** on DNA (lanes 11 and 12 respectively), but again had no effect on the action of **1**. Neither catalase nor superoxide dismutase[9] showed any effect on the cleavage by these compounds, but the reaction was heavily dependent on the pH (best results pH 7.4–9.0). These results

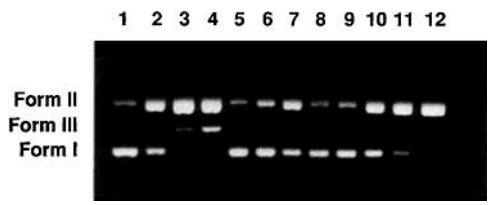


Fig. 1. ΦX174 form I DNA was incubated for 24 h at 37 °C with compounds **1**–**3** in buffer (50 mM Tris-Hcl, pH 8.5) and analyzed by electrophoresis (1% agarose gel, ethidium bromide stain). Lane 1: DNA control; lane 2: **1** [100 μM]; lane 3: **2** [5 μM]; lane 4: **3** [5 μM]; lane 5: **4** [10 mM]; lane 6: ethidium bromide [100 μM]; lane 7: **1** [100 μM] + ethidium bromide [100 μM]; lane 8: **2** [5 μM] + ethidium bromide [5 μM]; lane 9: **3** [5 μM] + ethidium bromide [5 μM]; lane 10: **1**[100 μM] + **4** [10 mM]; lane 11: **2** [5 μM] + **4** [10 mM]; lane 12: **3** [5 μM] + **4** [10 mM].

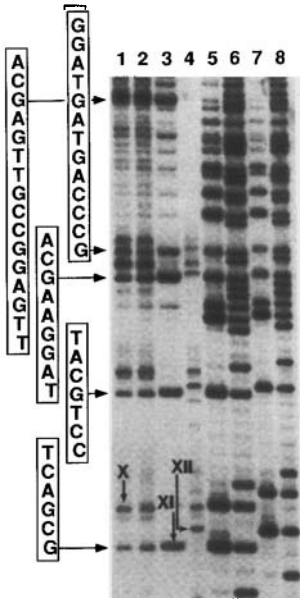

Fig. 2. High-resolution denaturing gel autoradiogram of cleavage of 5'-end ^{32}P-labeled Sal I/BamH I 275 bp restriction fragment of pBR 322 induced by sulfone **1** (bases 18–68 are shown). All incubations were carried out with 5 mM concentrations of **1** at 37 °C for 16 h. Lane 1: no further treatment; lane 2: 90 °C, 0.5 h; lane 3: piperidine (1 M), 90 °C, 0.5 h; lane 4: T4 polynucleotide kinase, 37 °C, 0.5 h; lanes 5 and 6: Maxam–Gilbert G and AG reactions respectively; lanes 7 and 8: Maxam–Gilbert G and AG reactions respectively, followed by T4 polynucleotide kinase, 37 °C, 0.5 h.

strongly suggested that a) the alkylation mechanism B rather than the radical mechanism A (Scheme 1) is the predominant (or exclusive) mode of action of compounds **1**–**3** and b) intercalation of the naphthalene nucleus of compounds **2** and **3** occurs prior to alkylation.[10]

To further examine and confirm the alkylation mechanism, 5'-end as well as 3'-end labeled restriction fragments from pBR 322 were reacted with compounds **1**–**3**. Figure 2 shows the cleavage results with compound **1** and 5'-end labeled DNA. Comparisons of the cleavage products (lane 3) with the chemically produced Maxam–Gilbert markers[11] (lanes 5–8) indicated preferential attack at guanine and, significantly, high selectivity for sequences 5-GCA, 5-GCG and 5-GCC (see horizontal arrows in Fig. 2). Several guanine residues present at various other sites remained unaffected or only slightly affected. Two products, **X** and **XI** (lanes 1–3), were observed on the gel autoradiogram. Whereas heating to 90 °C after incubation did not cause any significant changes (lane 2), piperidine treatment converted band **X** to band **XI** (lane 3). Band **XI** comigrates with the 3'-phosphorylated Maxam–Gilbert markers (lanes 5 and 6), and both had identical mobilities upon treatment with T_4 polynucleotide kinase[12] (**XII**, lane 4 and lanes 7 and 8). These observations are in accord with the mechanism of action depicted in Scheme 2.

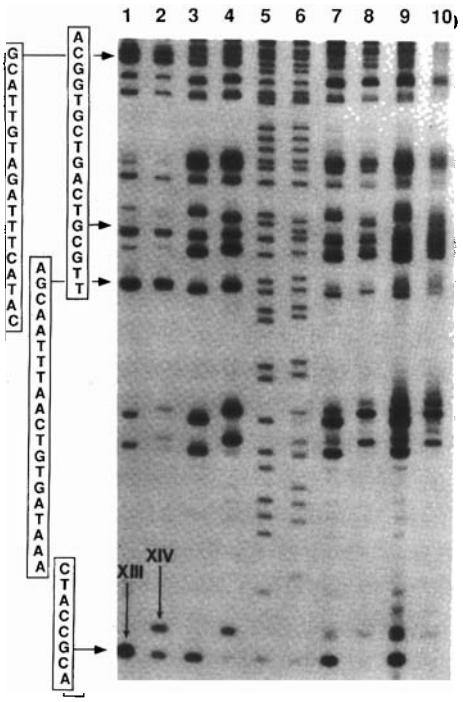

Fig. 3. High-resolution denaturing gel autoradiogram showing cleavage of 3'-end ^{32}P-labeled Cla I/BamH I 351 bp restriction fragment of pBR 322 induced by compounds **1**–**3** (bases 12–76 are shown). Lane 1: **1** [5 mM], 37 °C, 16 h; lane 2: **1** [5 mM]; 37 °C, 16 h, then calf intestine alkaline phosphatase (CIAP), 37 °C, 1 h; lane 3: Maxam–Gilbert G reaction; lane 4: Maxam–Gilbert G reaction followed by CIAP, 37 °C, 1 h; lane 5: Maxam–Gilbert AG reaction; lane 6: Maxam–Gilbert AG reaction followed by CIAP, 37 °C, 1 h; lane 7: **2** [100 μM], 37 °C, 16 h; lane 8: **2** [100 μM], 37 °C, 16 h, then CIAP, 37 °C, 1 h; lane 9: **3** [100 mM], 37 °C, 16 h; lane 10: **3** [10 μM], 37 °C, 16 h, then CIAP, 37 °C, 1 h.

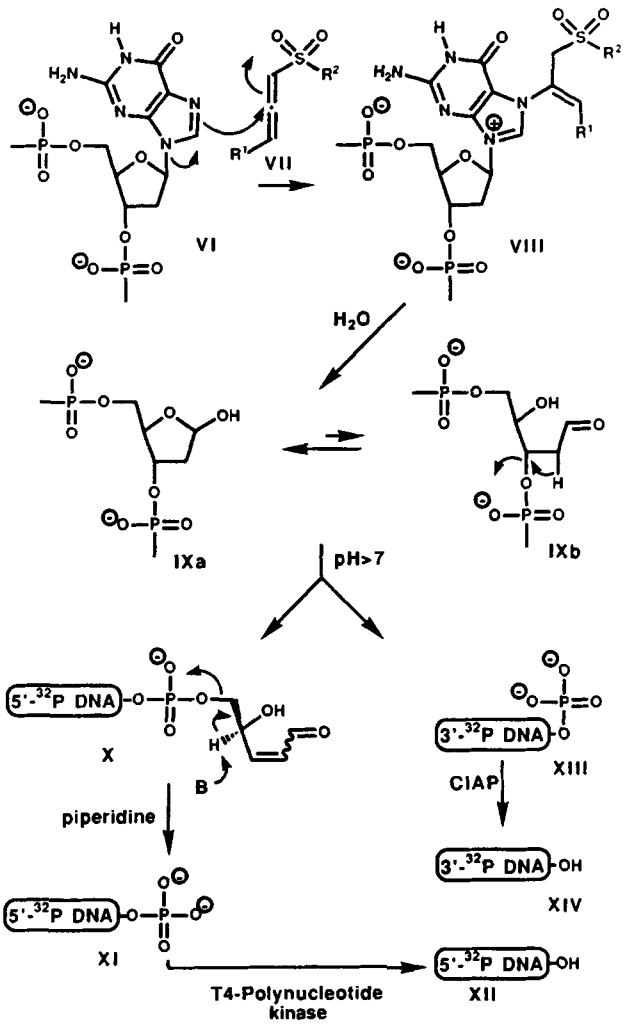

Scheme 2. Mechanism of action of 1–3 on DNA.

Similar experiments with 3'-end labeled DNA and compounds **1**–**3** (Fig. 3) provided further support for these intermediates and the overall alkylation mechanism presented in Scheme 2. Thus intermediates **XIII** and **XIV** were detected for compound **1** (Fig. 3, lanes 2 and 3, respectively). Com-

pounds **2** and **3** also exhibited identical cleavage profiles (Fig. 3, lanes 7 and 9), but different from that of **1** (Fig. 3, lane 1). The susceptibility of conjugated sulfones to nucleophilic attack is also in line with the proposed mechanism.[13]

The selectivity of compounds **1**–**3** in recognizing DNA regions may reflect not only their reactivity towards individual bases, but also local DNA shapes. This selectivity may be amplified synergistically by attaching these new DNA-cleaving moieties onto sequence-specific delivery systems.

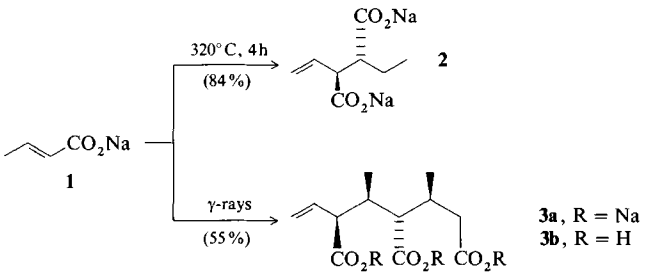
Stereospecific γ-Ray-Induced Trimerization of Crystalline Sodium *trans*-2-Butenoate **

By *Graciela C. Diaz de Delgado, Kraig A. Wheeler, Barry B. Snider*, and *Bruce M. Foxman**

Solid state reactions offer both an exceptional opportunity and a distinct challenge. In optimal cases, irradiation or thermolysis of crystals can lead to unusual stereospecific intermolecular reactions that cannot be accomplished in solution. The challenge lies in discovering new classes of materials capable of solid state reactivity, and in determining the principles which govern their behavior.[1]

For several years, we have been exploring the solid state reactivity of transition and nontransition metal salts of unsaturated carboxylic acids.[2] We were therefore fascinated by the unusual thermal reactivity reported[3] for sodium *trans*-2-butenoate (**1**). Heating **1** for four hours at 320 °C converts it stereospecifically, in high yield, to the dicarboxylate **2** by a unique ene reaction.[3] The unprecedented high thermal reactivity of crystalline **1** suggests the presence of short C=C···C=C interactions in its crystal structure.[4] We therefore anticipated interesting solid state chemistry during γ-irradiation of crystalline **1**.



Irradiation of crystalline **1** with ^{60}Co γ-rays (15–20 Mrad radiation dose) leads to a mixture containing 75–80% of *one of eight* possible diastereoisomers of the trisodium salt of 2,4-dimethyl-6-heptene-1,3,5-tricarboxylic acid (**3a**) in 70–80% conversion. GC analysis of the methyl esters of the crude reaction mixture showed the major products to be trimer **3a**, a head-to-tail dimer,[5] and two other trimers in a 12:2:1:1 ratio; the head-to-head dimer **2** was not formed upon γ-irradiation of sodium *trans*-2-butenoate. Dissolution of the irradiated solid in water followed by neutralization with hydrochloric acid precipitates triacid **3b** in 50–55% yield. The connectivity of **3b** was determined by analysis of the ^{1}H and ^{13}C NMR spectra of the crude triacid, which showed (along with GC analysis of the methyl esters) that the precipitated **3b** was greater than 90% pure. An X-ray structure determination[6] of **3b** recrystallized from 1:1 THF/H_2O confirmed the connectivity and allowed assignment of the four chiral centers (2*R**,3*R**,4*S**,5*R**; Fig. 1).

A number of unusual features characterize this process. The selective formation of a trimer is unprecedented. Solid state reactions of olefinic monomers usually result in either polymerization,[7–10] or dimerization as in the thermal reaction[3] of **1** and the classic ultraviolet irradiation of cinnamic acid derivatives.[4a] This work presents the first (to our

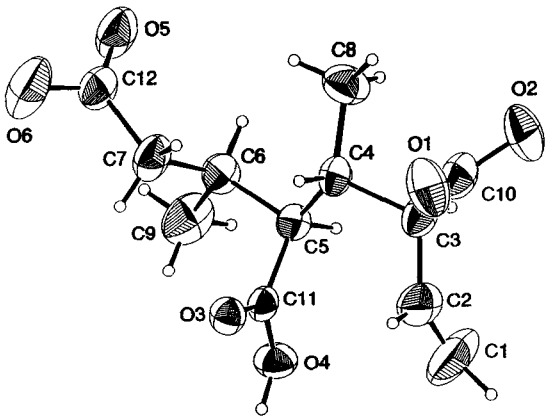

Fig. 1. Molecular structure of **3b**, showing 50% probability ellipsoids for atoms refined using anisotropic thermal parameters (H atoms have been reduced in size to improve clarity).

knowledge) efficient solid state synthesis of a small molecule using ionizing radiation.[11] The reaction is all the more remarkable since it is stereospecific, and the product cannot be prepared at all in solution[5, 12–14] by thermolysis, or by ultraviolet irradiation of crystalline **1**. Gamma ray irradiation of olefinic monomers, in either the solid state or in solution, produces polymers or oligomers with little, or at best incomplete stereochemical control.[7, 15] Stereoregular triads have been observed in the solid state polymerization of barium methacrylate[7a] and methacrylic acid,[7b] and thus the present reaction may be an excellent model for the early stages of oligomer formation in a solid state polymerization reaction.

X-ray powder patterns show that the present process minimally involves a crystal-to-polycrystal transformation, while the polymerization of related materials[7–10] produces amorphous products. Knowledge of the crystal structure of **1** would greatly aid our understanding of the course of the thermal[3] and radiation-induced solid state reactions. However, in spite of efforts by ourselves and others,[16] it has not been possible to grow crystals suitable for X-ray structure determination. We have recently obtained highly mosaic crystals of **1** from DMSO/H_2O solution (DMSO = dimethylsulfoxide). Interpretation of Weissenberg photographs of very thin, fragile crystals suggests the monoclinic crystal system, space group $P2_1$ or $P2_1/m$, with $a = 28.35$, $b = 5.28$, $c = 3.47$ Å; $\beta = 93.0°$. The unusually short c axis formally requires C=C···C=C distances ≤ 3.47 Å, and these must provide a pivotal influence on the reactivity of **1**.

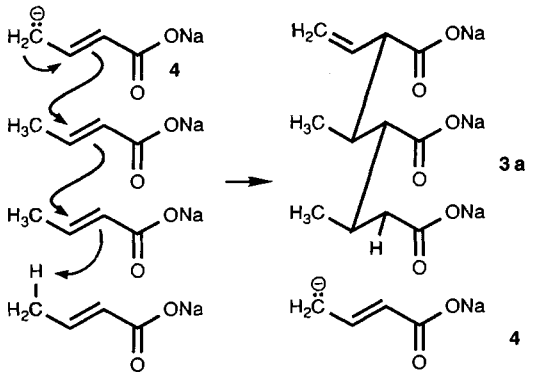

Fig. 2. Possible mechanism for the solid state formation of **3a**.

A possible mechanism consistent with the formation of the head-to-tail trimer is a γ-ray-induced anionic chain reaction (Fig. 2). Gamma-irradiation could result in the loss of an allylic proton to give anion **4**, which adds to the double bond of a neighboring molecule of **1**. A further addition step leads to the formation of a second carbon-carbon bond. The constraints of a reaction in a crystal and distortions caused by the formation of two carbon-carbon bonds could then favor abstraction of an allylic proton (rather than further C-C bond formation) to form **3a**; this would generate a second monomeric anion **4**, which would repeat the process. The reaction might, however, occur by a related free-radical mechanism with hydrogen atom (rather than proton) transfer, and radical addition to the double bonds. A full understanding of the mechanistic aspects of this reaction is precluded by the lack of a crystal structure analysis of **1** and the limited knowledge of interaction of γ-rays with organic molecules in crystals.[17]

In conclusion, a remarkable γ-ray-induced solid state reaction has been discovered that leads to *one of eight possible* diastereoisomers of a unique carboxylic acid.

Experimental Procedure

3b: **1** (3.24 g, 29.9 mmol) was irradiated (15.6 Mrad) in a Gammacell 220 Irradiation Chamber (Atomic Energy of Canada, Ltd.), equipped with a ^{60}Co source (nominal activity as of June 1990, 0.049 Mrad h^{-1}). The resulting colorless powder was dissolved in H_2O (20 mL) to give a homogeneous solution which was acidified with conc. HCl (3.5 mL). The colorless precipitate that formed was isolated by filtration and dried in vacuo (0.25 Torr) over anhydrous $CaSO_4$ to give **3b** (colorless powder, 1.40 g, 5.43 mmol, 55%). A small single crystal of **3b** was grown for X-ray crystal analysis by slow evaporation of a 1:1 THF/H_2O solution. Mp 203–205 °C; IR (KBr): $\tilde{\nu}$[cm^{-1}] = 2973 (C–H); 1721, 1706 (C=O); 990, 906 (C=C). ^1H NMR (300 MHz, [D_6]DMSO, 21 °C, TMS): δ = 12.2 (s, 3H; CO_2H), 5.85 (ddd, ^3J(H,H) = 16.5, 10.9, 8.6 Hz, 1H; CH), 5.11 (br d, ^3J(H,H) = 10.9, 1H; CH), 5.10 (dd, ^3J(H,H) = 16.5, 2.9, 1H; CH), 2.89 (dd, ^3J(H,H) = 8.6, 6.4, 1H; CH), 2.37–2.29 (m, 3H; CH), 2.10 (ddq, ^3J(H,H) ≈ 7.1, 7.1, 7.1, 1H; CH), 1.88 (dd, ^3J(H,H) = 15.3, 10.5, 1H; CH), 0.95 (d, ^3J(H,H) = 6.7, 3H; CH_3), 0.93 (d, ^3J(H,H) = 6.7, 3H; CH_3); irradiation at δ = 2.89 collapsed the peaks at 5.85 (dd, ^3J(H,H) = 16.5, 10.9, 1H; CH) and at 2.10 (dq, ^3J(H,H) ≈ 7.1, 7.1, 1H; CH); irradiation at 2.10 collapsed the peaks at 2.89 (d, ^3J(H,H) = 8.6, 1H; CH), 0.93 (s, 3H; CH_3) and 2.33 (sharper multiplet). ^{13}C NMR (300 MHz, [D_6]DMSO, 21 °C): δ = 174.8(C), 173.8(C), 173.4(C), 136.0(CH), 117.5 (CH_2), 53.9 (CH), 52.2 (CH), 36.6 (CH_2), 35.4 (CH), 28.3 (CH), 19.1 (CH_3), 13.3 (CH_3). Correct C,H analysis.

Methyl esters were prepared by diazomethane treatment of either a) an ethereal solution prepared by extraction of an acidified solution of the irradiated solid, or b) an ethereal solution of precipitated **3b**. Capillary GC analysis of the crude ester (poly(dimethylsiloxane), 30 m × 0.25 mm, 60→150 °C, 10° min^{-1}; 150→190 °C, 20° min^{-1}) indicated the presence of four components in a 2:1:12:1 ratio at 5.2, 11.9, 12.6, and 12.8 min. The methyl ester of the head-to-head dimer **2** (4.5 min) was not present. The peak at 5.2 min co-elutes with an authentic sample of the head-to-tail dimer. [5]

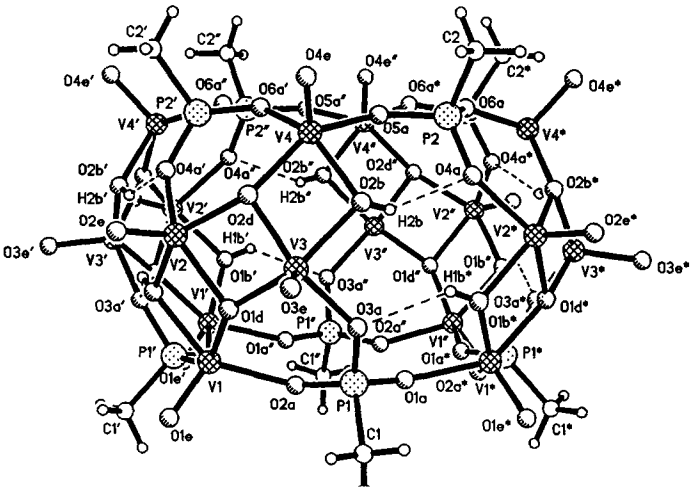
An Unusual Polyoxovanadium Organophosphonate Anion, $[H_6(VO_2)_{16}(CH_3PO_3)_8]^{8\ominus}$ **

By *Guohe Huan*,* *Allan J. Jacobson*, and *Victor W. Day*

Although the chemistry of polyoxovanadates is very diverse, a few structural motifs are commonly observed.[1] Vanadium atoms are usually square pyramidally coordinated by oxygen atoms. The VO_5 square pyramids are then condensed by sharing edges to form dimers as observed in $VOSO_4 \cdot 3H_2O$[2] or larger units, for example, the ring of eight edge-shared square pyramids $[V_8O_{24}]$ found in the anions $[V_8O_8(OCH_3)_{16}(C_2O_4)]^{2\ominus}$[3a] and $[V_{12}O_{32}]^{4\ominus}$.[3b] The basketlike shape of the $[V_{12}O_{32}]^{4\ominus}$ anion is completed by condensation with four additional VO_5 square pyramids through formation of μ_3-O connections. In the *closo* anion $[V_{15}O_{36}]^{5\ominus}$,[4] the shared oxygen atoms are either μ_2 or μ_3 connected, whereas in the $[V_{18}O_{42}(X)]^{n\ominus}$ (X = H_2O, VO_4, SO_4, Br, and I)[5–7] anions they are all of the μ_3 type. Other molecular units may also be used to complete the connectivity in polyoxovanadates, for example, the oxalate ion in $[V_8O_8(OCH_3)_{16}(C_2O_4)]^{2\ominus}$[2] and the $C_6H_5CO_2^{\ominus}$ group in the $[V_6O_6(\mu\text{-}O)_4(\mu\text{-}O_2CC_6H_5)]^{6\ominus}$[8] anion. Here we describe the synthesis and structure of **1**, a new heteropolyoxovanadate based on VO_5 square pyramids and R-PO_3 tetrahedra with μ_2 and μ_3 connections.

$$[N(CH_3)_4]_8[H_6(VO_2)_{16}(CH_3PO_3)_8] \cdot 11\,H_2O \qquad \mathbf{1}$$

X-ray structrual analysis[9] of **1** revealed the presence of discrete $Me_4N^{\oplus}$ ions and water of crystallization in the lattice, as well as $[H_6(VO_2)_{16}(CH_3PO_3)_8]^{8\ominus}$ anions (Figure 1) which each contain a single $Me_4N^{\oplus}$ cation at their center. The formulation of the anion is based on the results of the redox titration[10] which indicates that two of the total of sixteen vanadium atoms are V^V and fourteen are V^{IV}. The



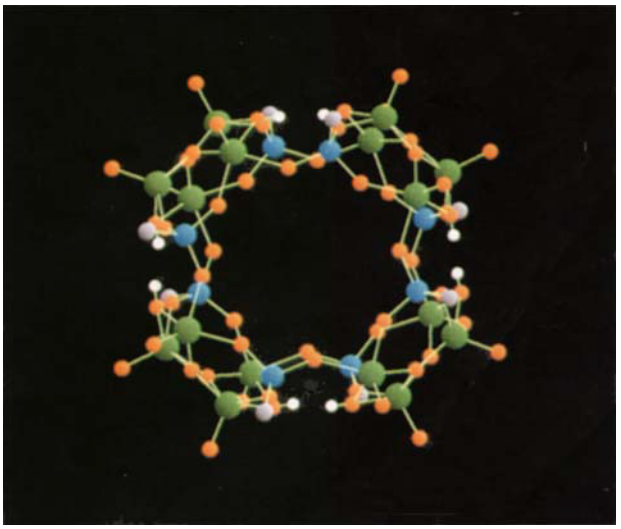


Figure 1. Perspective plots of anion **1** in the crystal structure. Top: View perpendicular to the crystallographic C_4-axis at 1/4,1/4, *z* in the unit cell; hydrogen bonds are indicated by dashed lines. Atoms labeled ′, ″, or * are related to atoms without one of those labels by the symmetry operations *y*, 1/2−x, *z*; 1/2−*x*, 1/2−*y*, *z*; and 1/2−*y*, *x*, *z*, respectively. Below: View down the C_4-axis; V, green, P blue, O red, C gray, H white. Bond distances [Å] and angles [°] of interest: V-O_{term} 1.580(4)–1.607(4), V-(μ_3-O) 1.925(4)–1.938(4), V-(μ_2-O(H)) 1.966(4)–1.990(4), V-(μ_2-O) 1.964(4)–1.979(4), V_{waist}-V_{waist} = 2.932(1), V_{waist}-V_{ring} 3.060(1)–3.066(1), O-(μ_2-O(H)) 2.76(1)–2.82(1); O_{term}-V-(μ_3-O) 107.8 (2)–112.6(2), O_{term}-V-(μ_2-O(H)) 105.9(2)–108.0(2), O_{term}-V-(μ_2-O) 106.5(2)–109.8(2), (μ_3-O)-V-(μ_3-O) 80.9(2)–81.3(2), (μ_3-O)-V-(μ_2-O(H)) 76.3(2)–77.1(2), (μ_3-O)-V-(μ_2-O) 88.3(2)–91.4(2), (μ_2-O)-V-(μ_2-O(H)) 87.3(2)–87.9(2), (μ_2-O)-V-(μ_2-O) 84.3(2)–85.2(2); V_{waist}-(μ_3-O)-V_{waist} 98.3(2)–98.5(2), V_{waist}-(μ_3-O)-V_{ring} 104.4(2)–105.2(2), V_{waist}-(μ_3-O)-V_{ring} 144.7(2)–146.1(2) ("Waist" designates atoms between the rims of the tire, "ring" the atoms in the outer rings).

anion possesses rigorous crystallographic C_4 symmetry and resembles a set of chains on a tire (recognized best when Fig. 1 (top) is turned through 90°). It consists of four condensed $(VO_2)_4$ tetramers, which span the "tread" and are covalently linked together along each "rim" by four PO_3C tetrahedra through corner-sharing oxygen atoms. The $H_{1.5}V_4O_8$ unit arises when distorted VO_5 square pyramids share an edge to form dimers which in turn share half of a long dimer edge to form step-shaped tetramers (see Fig. 2).

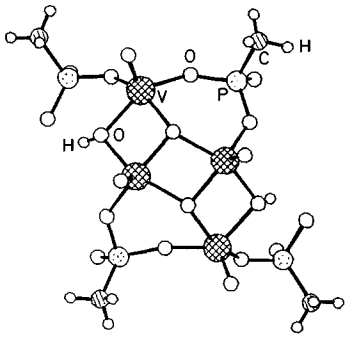

Figure 2. A projection of the tetramer and its covalently bonded $CH_3PO_3^{2\ominus}$ groups viewed as in Figure 1 top.

Each organophosphonate group shares two of its oxygens with one tetramer and its third oxygen with the adjacent tetramer. This results in the formation of sixteen-membered $(-O-V-O-P)_4$ rings (whose atoms are coplanar within 0.20 Å) along each "rim of the tire".

The six hydrogen atoms are disordered over eight sites in the anion and are covalently bonded to a $V-O_b-V$ oxygen atom. They form hydrogen bonds along the "tread" from the covalently bonded O_b oxygens in one tetramer to "non-rim" $P-O_a-V$ oxygen (O_{3a} or O_{4a}) atoms in an adjacent tetramer. A total of six such hydrogen bonds are used to stabilize each $[H_6(VO_2)_{16}(CH_3PO_3)_8]^{8\ominus}$ anion. The average oxygen-to-oxygen distance across the 16-membered rings at each "rim" is 6.68 Å and between the rings is 5.86 Å. If the oxygen ionic radius is assumed to be 1.40 Å, the free diameter of each 16-membered ring is estimated to be ~ 4 Å. The eight-membered silicon (aluminum) oxygen atom ring in zeolite A has similar dimensions. The free diameter across the "tire" midway between the two "rims" is much bigger (10.13 Å average oxygen-to-oxygen distance, free diameter ~7.5 Å). The $Me_4N^{\oplus}$ ion at the center of each "tire" is disordered about the crystallographic C_4 axis which contains the nitrogen and one methyl carbon atom.

1 is soluble in water and in a mixture of CH_3OH/CH_3CN. In the presence of oxygen, aqueous solutions gradually change color from dark to yellow indicating oxidation of V^{IV} to V^{V}. Cyclic voltammetry measurements under anerobic conditions in degassed water did not show reversible redox behavior. When exposed to air, the crystals of **1** slowly degrade by losing the water of crystallization.

The ethyl and phenyl analogues have also been prepared in similar hydrothermal syntheses from the corresponding phosphonic acids. The ethyl compound precipitates as deep blue prismatic crystals isostructural with **1** and contains the anion $[H_8(VO_2)_{16}(C_2H_5PO_3)_8]^{8\ominus}$. The phenyl analogue forms black hexagonal prismatic crystals with space group $C2/c$ but contains a structurally similar anion $[H_4(VO_2)_{16}(C_6H_5PO_3)_8]^{9\ominus}$. Preliminary results indicate that the solubility in water increases as the size of the organic group decreases and that the vanadium oxidation state can be controlled by varying reaction conditions.

Experimental Procedure

To 1.152 g (12 mmol) $CH_3PO_3H_2$ (Alfa), 0.300 g (2 mmol) V_2O_3 (Alfa), and 0.364 g (2 mmol) V_2O_5 (Alfa) in a Teflon lined autoclave was added ~ 2 mL of distilled water followed by 6.4 g Me_4NOH (25% in water, Aldrich). The autoclave was filled to 80% with distilled water and heated at 200 °C for 2 days. The autoclave was then cooled to room temperature. The black, prismatic crystals of the reaction product **1** (yield 0.60 g, ~ 42% based on vanadium) were suction-filtered, washed several times with distilled water, and air-dried. Satisfactory elemental analysis for $C_{40}H_{148}N_8V_{16}P_8O_{67}$. Main absorption bands in the IR spectrum (KBr pellet): $\tilde{\nu}[cm^{-1}]$ = 3399 (s), 3010 (m), 1625 (m), 1480 (s), 1410 (m), 1300 (s), 1110 (s), 1050 (s), 1000 (vs), 970 (vs), 935 (vs), 770 (m), 720 (s), 700 (s), 615 (s), 570 (s), 530 (s), 485 (s), 435 (m).

[9] **1**: Tetragonal, space group $P4/ncc$ (No. 130) with $a = 23.660(3)$, $c = 22.708(3)$ Å, $V = 12.711(3)$ Å^3, and $Z = 4$ ($\rho_{calcd} = 1.399$ g cm^{-3}; $\mu_a(Mo_{K\alpha}) = 1.25$ mm^{-1}), $R = 0.041$ for 3130 independent reflections having $2\theta < 48.3°$ and $I > 3\sigma(I)$; Nicolet P1 auto-diffractometer, graphite-monochromated $Mo_{K\alpha}$ radiation. The structure was solved at Crystalytics Company using "Direct Method" techniques with the Siemens Nicolet SHELXTL-Plus software package. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, W-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-54969, the names of the authors, and the journal citation.
[10] The vanadium oxidation states in **1** were determined by redox titration. Samples were dissolved in 1 M sulfuric acid. A known excess of cerium(IV) ammonium nitrate was added to the vanadium solutions to oxidize all the vanadium ions to the pentavalent state. The total vanadium content and the average vanadium oxidation state were determined by potentiometric titration using a standard solution of ferrous ammonium sulfate. Redox titrations of **1** gave an average vanadium oxidation state of 4.10 ± 0.02.

Parabolic Growth of a Self-Replicating Hexadeoxynucleotide Bearing a 3′-5′-Phosphoamidate Linkage **

By *Günter von Kiedrowski,* Britta Wlotzka, Jörg Helbing, Matthias Matzen*, and *Stephan Jordan*

The search for minimal models of self-replicating systems based on oligonucleotide constituents or related molecules is of considerable interest within the context of early biochemical evolution ("RNA-world").[1] In 1986 we showed that the

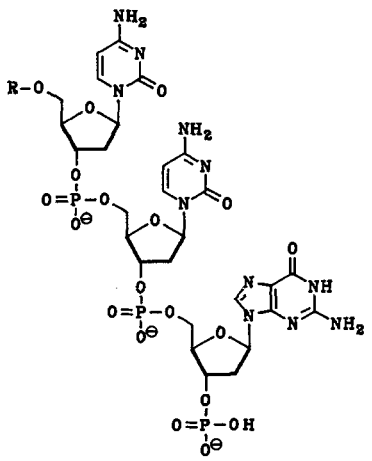
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. The results were presented at the symposium on "Molecular Biology and the Origin of Life" held in Berkeley, USA, July 15–21, 1990.

formation of the hexadeoxynucleotide template $\mathbf{T}^1$ from two trideoxynucleotides $\mathbf{A}^1$ and $\mathbf{B}^1$ in the presence of the carbodiimide EDC (EDC: $CH_3CH_2N{=}C{=}N(CH_2)_3N(CH_3)_2$) proceeds to a small but well-defined extent via an autocatalytic reaction channel. Here was evidence for self-replication in a nonenzymatic reaction system for the first time.[2] Initial rate kinetics resulted in a square-root law of template catalysis,[3] which has been corroborated for the condensation of $\mathbf{A}^2$ and $\mathbf{B}^2$,[4] as well as for the formation of a tetrameric template reported by *Zielinsky* and *Orgel*.[5] The same type of autocatalysis underlies the kinetic data of the self-replicating system recently described by *Rebek* et al.,[6] although this is not explicitely stated by the authors.

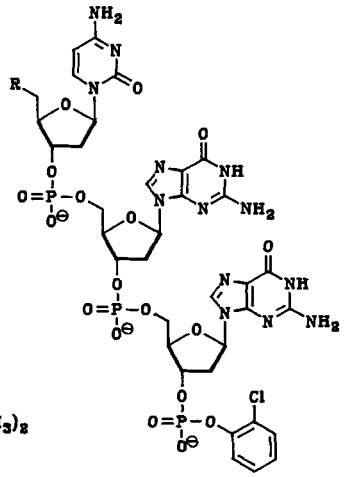
autocatalytic effect of the 3′5′-phosphoamidate template $\mathbf{T}^3$. The "sigmoidicity" (S-shape) of curve b is not a consequence of the preceeding activation, since it is less pronounced upon addition of template $\mathbf{T}^1$ (curves c–e). Furthermore, ^{31}P and ^1H NMR kinetic studies of the hydrolysis of EDC in the presence of various mononucleotides have revealed that the formation of EDC adducts is a quasireversible process[8] and that the maximum degree of activation (typically 5–10% at an EDC concentration of $c_{EDC} = 0.2$ M) is reached within a few minutes,[8] whereas the inflection of curve b occurs considerably later.

A computer program for the evaluation of self-replication experiments has been written to fit the complete set of exper-

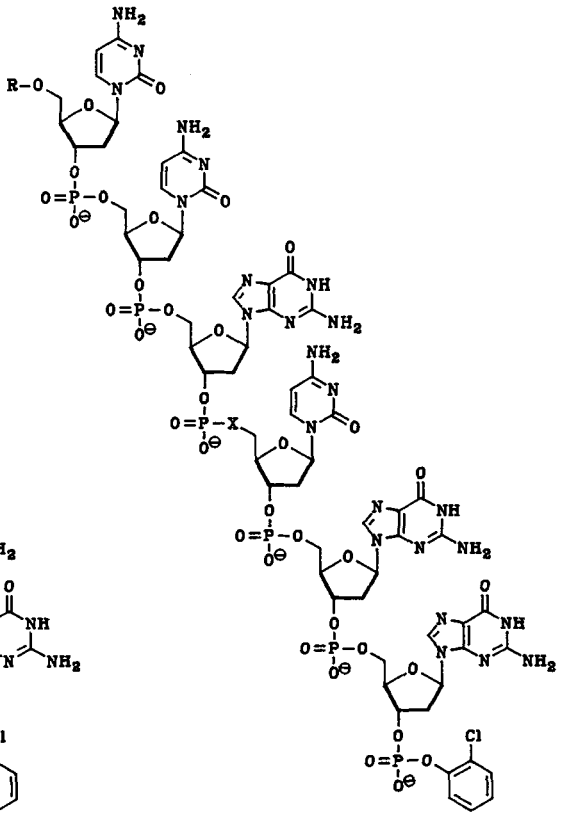


$\mathbf{A}^1$: R = CH_3
$\mathbf{A}^2$: R = CH_2SCH_3

EDC:
$CH_3CH_2{-}N{=}C{=}N{-}CH_2CH_2CH_2N(CH_3)_2$



$\mathbf{B}^1$: R = HO
$\mathbf{B}^2$: R = $HO_3PO^{\ominus}$
$\mathbf{B}^3$: R = H_2N



$\mathbf{T}^1$: R = CH_3, X = O
$\mathbf{T}^2$: R = CH_2SCH_3, X = $PO_4^{\ominus}$
$\mathbf{T}^3$: R = CH_2SCH_3, X = NH
$\mathbf{T}^4$: R = H, X = NH

We now report on the first recognition of sigmoidal (S-shaped) growth of template molecules in a remarkably efficient, nonenzymatic template-directed reaction. The synthesis of the oligonucleotides is described elsewhere.[7] In the presence of the carbodiimide EDC, the trideoxynucleotide 3′-phosphate $\mathbf{A}^2$ reacts with the 5′-aminotrimer $\mathbf{B}^3$ to give the self-complementary hexameric 3′-5′-phosphoamidate $\mathbf{T}^3$ as exclusive product. The reaction was performed on a nanomolar scale using the capillary technique as previously described.[2, 4] The time course for product formation was monitored by HPLC[4] (Fig. 1, curve b). The synthesis of $\mathbf{T}^3$ proceeds substantially faster in the presence of the phosphodiester template $\mathbf{T}^1$ (curves c–e), whose catalytic effect is comparable to that produced by the 3′-5′-phosphoamidate template $\mathbf{T}^4$ and therefore gives an indirect measure of the

imental time courses (b–e) to the integrated form of equation (a) by means of nonlinear regression. Equation (a) is derived from the original square-root law of template catalysis[2–4] with further consideration of the mass balance between $\mathbf{A}^2$, $\mathbf{B}^3$, and $\mathbf{T}^3$; c_A, c_B, and c_T are the initial concentrations of $\mathbf{A}^2$,

$$dc/dt = (c_A - c)(c_B - c)[k_a(c + c_T)^{1/2} + k_b] \exp(-k_c t) \quad (a)$$

$\mathbf{B}^3$, and $\mathbf{T}^1$, c is the concentration of the product $\mathbf{T}^3$, k_a and k_b apparent rate constants for the autocatalytic and the nonautocatalytic reaction channel, respectively, and k_c the apparent rate constant of the carbodiimide hydrolysis, which can be described as a pseudo-first-order process for low degrees of activation and low conversions of the phosphate constituent. The resulting rate constants are given in Table 1.

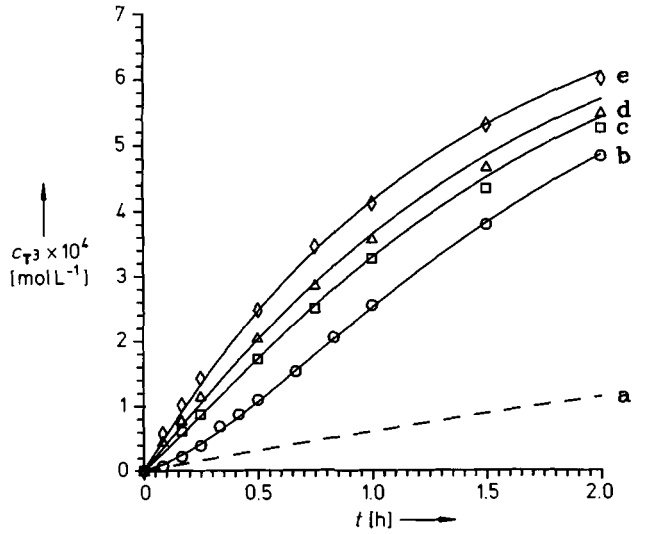


Fig. 1. Time course for the formation of the hexameric 3′-5′-phosphoamidate $\mathbf{T^3}$ in the absence (curve b) and in the presence of template $\mathbf{T^1}$ (curves c–e) as measured by HPLC. The data points shown are averages from the experimental time courses of $\mathbf{A^2}$, $\mathbf{B^3}$, $\mathbf{T^3}$. The set of theoretical curves b–e represents the solution of differential equation (a) for the parameters given in Table 1 and the experimental set of initial concentrations shown below. The yield of $\mathbf{T^3}$ is 50% after 2 h (curve b). Curve a represents the theoretical time course if no autocatalysis occurs. Initial concentrations and reaction conditions: $c_A = c_B =$ 1 mM, [EDC] = 0.2 M, [HEPES] = 0.1 M, pH = 7.5, T = 30 °C, c_{T^1} = 0(b), 0.08(c), 0.16(d), 0.32 mM (e), HEPES = 2-[4-(2-hydroxyethyl)-1-piperazino]-ethanesulfonic acid/sodium salt.

The exponential factor in equation (a) has been omitted for the system presented here, since the hydrolysis of EDC is negligible within the first two hours under the reaction conditions. As a consequence a three-parameter fit would produce a less reliable k_c. To show the general applicability of our method and for the sake of comparison, we have also evaluated by equation (a) the set of experimental time courses for the systems reported by *Orgel* et al.[5] and *Rebek* et al.[6] (exp $(-k_c t)$ omitted).[9]

Table 1. Apparent rate constants for the autocatalytic and the nonautocatalytic template production (k_a and k_b) and for the hydrolysis of the activated species (k_c). The experimental time courses of the systems reported by *Orgel* et al. and *Rebek* et al. have been taken from the literature.

System	k_a[M$^{-3/2}$ s^{-1}]	k_b[M^{-1} s^{-1}]	k_c[s^{-1}]
$\mathbf{A^2}$, $\mathbf{B^3}$, $\mathbf{T^3}$, $\mathbf{T^1}$	(7.43 ± 0.12) [a]	$(1.77 \pm 0.15) \times 10^{-2}$ [a]	
Orgel [5]	$(5.71 \pm 0.23) \times 10^{-2}$	$(1.66 \pm 0.19) \times 10^{-4}$	$(1.92 \pm 0.46) \times 10^{-6}$
Rebek [6]	$(9.87 \pm 0.17) \times 10^{-2}$	$(1.24 \pm 0.04) \times 10^{-3}$	

[a] The computation is conservative in the sense that k_b is slightly overestimated at the cost of k_a. This is because our method of calibration reflects a concentration dependant-recovery of single-component HPLC peaks, assuming that the recovery of the respective component is not influenced by other components. A multicomponent calibration method is in the development stages. However, the present method of calibration is more reliable than methods which assume direct proportionality between HPLC peak areas and concentrations.

An efficient self-replicating system should exhibit a high apparent rate constant k_a and a low constant k_b. The first criterion is especially important if the self-replicating template is formed via a condensation reaction in water, since template formation has to compete with hydrolysis of the activated species, i.e., the EDC adducts. If all three systems were measured under optimal conditions (especially with respect to the temperature), the above system is roughly 130 and 75 times more efficient than Orgel's and Rebek's system, respectively, in terms of k_a. A low k_b is necessary to achieve sigmoidal growth. Thus, the quotient k_a/k_b, which defines the factor by which the autocatalytic synthesis exceeds the noninstructed process at a template concentration of 1 M, must be large enough to observe sigmoidicity. With respect to the autocatalytic excess factor ε, as this quotient is termed hereafter, the above system ($\varepsilon = 420$) is comparable to Orgel's system ($\varepsilon = 340$) but exceeds Rebek's system ($\varepsilon = 80$). The type of growth observed in curve b is, however, an experimental novelty. We term it parabolic since the growth of an autocatalyst with a reaction order of 1/2 in the rate equation of its synthesis can be expressed as a second order polynomial of time for early reaction times.

The reasoning behind the mechanism proposed for the autocatalytic template production is the same as for the original system.[2] It is generalized in Figure 2 to account for

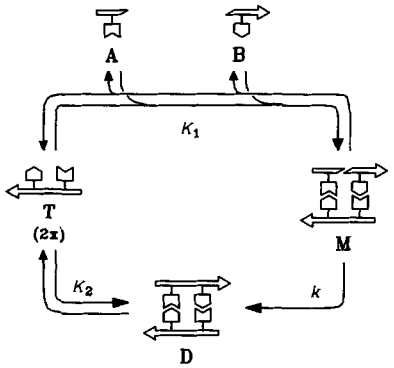

Fig. 2. General mechanism for a minimal self-replicating system. Constituent A represents the activated form of trimer A^2 here. Large arrowheads at the reaction arrows for the reversible reactions indicate the favored site of the equilibrium.

similarities between the systems known so far. The following should be noted:

1) The rate determining step is the irreversible formation of a 3′-5′-phosphoamidate linkage leading from the ternary complex **M** to the self-complementary duplex **D** which is expressed by: $d[\mathbf{D}]/dt = k[\mathbf{M}]$.
2) The system is in dynamic equilibrium with respect to all single- and double-stranded oligonucleotide constituents. With $K_1 = [\mathbf{M}]\,[\mathbf{A}]^{-1}\,[\mathbf{B}]^{-1}\,[\mathbf{T}]^{-1}$ and $K_2 = [\mathbf{D}]\,[\mathbf{T}]^{-2}$ it follows for the formation of duplex molecules that $d[\mathbf{D}]/dt = kK_1K_2^{-1/2}\,[\mathbf{A}]\,[\mathbf{B}]\,[\mathbf{D}]^{1/2}$.
3) Under parabolic growth conditions ($K_2 \gg K_1 \gg 1$), and for the special case of complete activation, the apparent rate constant k_a can be rationalized in terms of the elementary rate and equilibrium constants: $k_a = 2^{1/2}\,kK_1K_2^{-1/2}$.

According to *Eigen* and *Schuster*[10] parabolic growth should lead to Darwinian selection under conditions which allow self-replicating templates to compete for their constituents when the total concentration of templates is kept constant (i.e. in a chemostat). This statement has been refuted recently by *Szathmary* who proposes, with reference to experimental results,[2, 5] that parabolic growth invariably leads to coexistence of self-replicating templates,[11] (i.e., the most efficient template is not able to supersede its less efficient competitors completely). We agree with *Szathmary* on the point that this type of growth must have preceeded exponential growth in an RNA world, since it allows autocatalyt-

ic amplification while at the same time keeping a variety of "sequence modules", which seems necessary to assemble complex, functional molecules (i.e. ribozymes). Now that the proper chemistry is known, minimal models of coexistence and/or selection based on self-replicating oligonucleotide derivatives are visible on the horizon of bio-organic chemistry.

[3] The equation $dc_T/dt = a\ c_T^{1/2} + b$ (square-root law) describes the initial rate of template production as the sum of an autocatalytic ($a\ c_T^{1/2}$) and a nonautocatalytic rate contribution (b). From the linear plot of the initial rates vs. the square root of the initial template concentrations, the parameters a and b are obtained from the slope and the intercept. These parameters have been named K_a and K_b in [1b], k_a and k_b in [2] and α and β in [5]. They should not confused with the apparent rate constants k_a and k_b of equation (a) although they correspond to these quantities in the special case of complete phosphate activation as follow: $a = k_a c_A c_B$, $b = k_b c_A c_B$.

[9] Results from NMR titration studies [6] suggest that in the Rebek system the complex **M** is more stable than the corresponding duplex **D** (see Fig. 2): $K_2 = 630\ M^{-1}$, $K_1 = 3600\ M^{-2}$ (the latter quantity is not directly measurable and was estimated by the authors). [6] In this case the square-root model is no longer applicable and the Rebek system should more closely resemble an exponential replicator (reaction order of autocatalyst closer to 1 than to 1/2). If one substitutes the exponent 1/2 in equation (a) for 1, nonlinear regression yields a *substantially* poorer fit resulting in distances between the theoretical curves which do not correspond those found experimentally. The exponential model ($\exp(-k_c t)$ omitted) yields the regression coefficients $k_a = 2.02 \pm 0.08\ M^{-2}\ s^{-1}$ and $k_b = (2.22 \pm 0.07) \times 10^{-3}\ M^{-1}\ s^{-1}$; the sum of least squares of $S = 1.73 \times 19^{-8}\ M^2$ exceeds that of the square-root model by a factor of 6.6.

Characterization of Intermediate Steps in the Polymerizations with Ziegler Catalysts on MgH_2 by CP/MAS NMR Spectroscopy**

By *Reinhard Benn** and *Wolfram Hermann*

A significant number of the numerous investigations on heterogeneous catalysis[1] deal with the polymerization of α-olefins using third-generation Ziegler catalysts.[2] Although there are many proposals regarding the mechanism,[3] direct spectroscopic evidence of the intermediates has hitherto been found only in particular cases.[4, 5] With MgH_2 as support,[6] and zirconocene and ethylaluminum complexes as cocatalysts, we can now characterize components and intermediates fixed on the support by CP/MAS ^{13}C NMR spectroscopy (CP = Cross Polarization, MAS = Magic Angle Spinning)[7] during the polymerization of ethylene.

In toluene, dissolved $[Cp_2ZrMe_2]$ (**1**) evolves methane on reaction with MgH_2;[8] after evaporation of the solvent, the residue is characterized by CP/MAS ^{13}C NMR spectroscopy. Besides the signals assigned to **1** at $\delta = 111$ and 31, two new signals appear in the ^{13}C NMR spectrum at $\delta = 107$ and 17 (Fig. 1). Experiments with ^{13}C-labeled methyl groups in

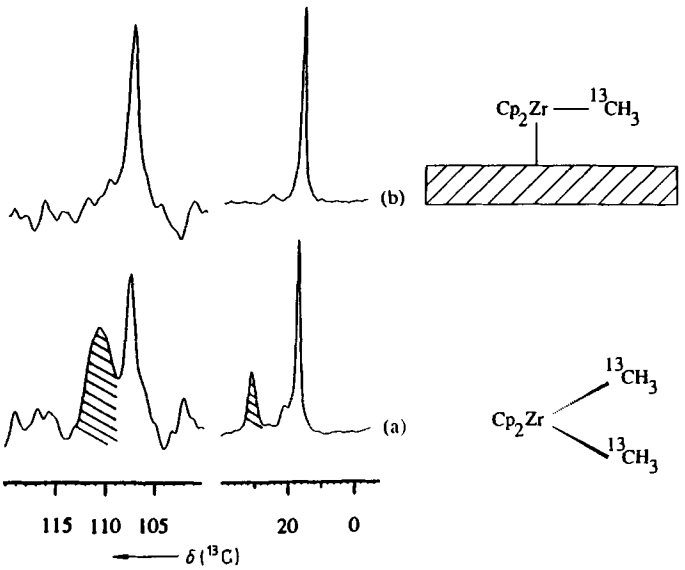

Fig. 1. CP/MAS ^{13}C NMR spectra (75.5 MHz) (a) after loading the support MgH_2 with $[Cp_2ZrMe_2]$ (**1**, hatched signals) and (b) after appearance of the complex $[Cp_2ZrMe]$ (**2**), chemically bound to the support, and removal of the starting material by washing with toluene. The methyl groups are labeled with ^{13}C (99%). ($T = 300$ K, rotation frequency (a) 3314 Hz and (b) 2968 Hz, contact time 1 ms, 90° (^1H) = 4.4 μs).

1 confirm that the new signals belong to one species. On the basis of the chemical shifts and experiments with interrupted proton decoupling,[9] these signals were assigned to Cp and methyl groups of a zirconocene complex. The ratio of intensities (samples with natural isotope abundance) of the signals 107:17 is 10:1. The support can be loaded to 5% capacity and washing with toluene can elute only **1** completely. From all these facts we conclude that the signals at $\delta = 107$ and 17 belong to a $[Cp_2ZrMe]$ species (**2**), which is chemically bound to the support through Zr. The NMR data of **2** resemble those of the complex $[\{Cp_2ZrMe\}_2O]$, whereas the signal for the methyl group of cationic $[Cp_2Zr(thf)Me]$ is found down-field at $\delta = 38.9$.[10, 11] The catalyst **2** requires a cocatalyst like $(Et_2AlCl)_2$ to polymerize ethylene, while the ionic complex mentioned above does not.

Addition of $(Et_2AlCl)_2$ to **2** changes the CP/MAS ^{13}C NMR spectrum as follows: the Cp signal is shifted to $\delta \approx 105$ and broadens ($W_{1/2} \approx 400$ Hz). Experiments with ^{13}C-labeled **2** show that the intensity of the signals for the methyl groups at the zirconium atom ($\delta = 17$) decreases and a broad signal appears at $\delta \approx -10$ ($W_{1/2} \approx 350$ Hz). This signal is attributed to a terminal methyl group bonded to aluminum.[12] In addition, two new signals appear at $\delta = 9.3$ and 10.3, whose intensities are not changed when the methyl-C

[**] We thank Prof. Dr. *Bogdanovic* for a gift of MgH_2 and Ms *P. Philipps* for the preparation of **1**.

atom of **1** is isotopically labeled. These signals must therefore arise from the cocatalyst components. Experiments with interrupted proton decoupling[9] show that they belong to methyl groups. The signal at 9.3 is not resolved; the smaller section of the area under the peak is assigned to the methyl carbon of a terminal ethyl group of $(Et_2AlCl)_2$, on the grounds of MAS experiments without cross-polarization (in these experiments more mobile groups have more intense signals)[13] (Fig. 2). The major portion of the area is assigned to the terminal ethyl group of an AlMeEt residue, which is bound through a μ-Cl and a μ-CH_2Me bridge to a $[Cp_2Zr]$ fragment attached to the support. The signal at 10.3 is assigned to the methyl groups of this bridging μ-CH_2Me group of the binuclear complex $[\{Cp_2Zr\}(\mu\text{-}Cl)(\mu\text{-}CH_2Me)\{AlMeEt\}]$, **3**. In control experiments without zirconium components, this signal is absent, and again no polymerization of ethylene takes place. Binuclear complexes with $[Cp_2Zr]$ and (AlR_2) units bridged via Cl and alkyl groups have been discussed previously as intermediates for polymerizations in the homogeneous phase.[14]

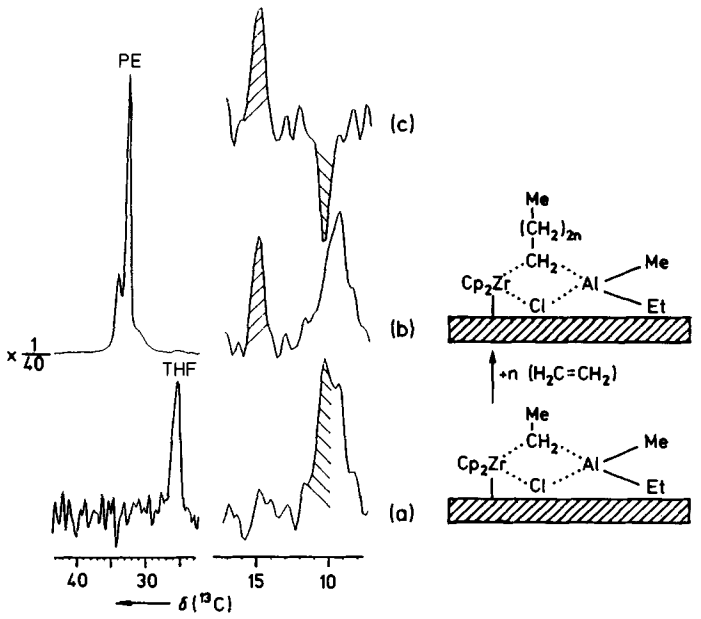

Fig. 2. CP/MAS ^{13}C NMR spectra (75.5 MHz, THF adsorbed on MgH_2 as reference) of $[Cp_2ZrMe]$ (**2**), attached to the support (a) after adding the cocatalyst $(Et_2AlCl)_2$ and (b) after adding ethylene. (c) The difference spectrum [(b)–(a)]. The signal of the methyl groups at $\delta = 10.3$ is shifted to 14.8. The intensity scale for the polyethylene peak in (b) is multiplied by a factor $^1/_{40}$.

Samples of **3** were subjected to dosed quantities of ethylene at 77 K and then slowly warmed to 300 K.[15] CP/MAS ^{13}C NMR spectra taken during the course of this reaction show that polyethylene is formed, and the signal at $\delta = 10.3$ decreases in favor of a new signal at 14.8. This new signal is assigned to the terminal methyl groups of linear polyethylene. Depending on the orthorhombic or monoclinic modifications of polyethylene,[16] the methylene signals appear at $\delta = 34.1$ and 32.7. The formation of polyethylene can be understood as the insertion of ethylene molecules into the zirconium-μ-CH_2Me bond.[17] The activity of the investigated systems at 310 K is ca. 50 kg polyethylene/(mol_{Zr} h bar) and is thus the same order of magnitude as related homogeneous systems.[18]

Experiments in which $[Cp_2ZrCl_2]$ (**1a**) is used as the zirconium complex, agree with this interpretation. Compound **1a** reacts with MgH_2 to give a species bound to the support, which gives a signal at $\delta = 103$ (probably $[Cp_2ZrCl]$). Addition of $(Et_2AlCl)_2$ produces no signal at $\delta = 10.3$ and the amount of polymerization of ethylene is negligible. If, on the other hand, $(Et_3Al)_2$ is used as cocatalyst, a Cp signal is observed, as with **3**, at $\delta = 105$ and a methyl signal at $\delta = 10.3$. This is again an active polymerization system.

Compound **3** also polymerizes propene, but only atactic oligomers are detected in the CP/MAS ^{13}C NMR spectrum. In the case of alkyl-substituted zirconium complexes a chirality center is generated directly at the zirconium atom.[19] Because the rotation barrier for Cp is significantly higher in the solid than in solution,[20] these systems could be interesting from the aspect of heterogeneous, stereospecific polymerization of α-olefins.[21]

Alkaline Earth Metal Complexes Containing Deprotonated Organic Acids and Water: Preparation, Structures and a New Synthetic Strategy**

By *Patrizia Mikulcik, Paul R. Raithby, Ronald Snaith,* and *Dominic S. Wright**

We reported recently the first lithiated organic compound containing water as a ligand, monomeric OxLi · TMEDA · H_2O (OxH = $\overline{C_6H_4O(C{=}S)\text{-}NH}$, TMEDA = *N,N,N',N'*-tetramethylethylenediamine).[1] This was prepared simply by adding H_2O to a solution of $(OxLi \cdot TMEDA)_n$ obtained by lithiating OxH in toluene containing TMEDA. The co-existence of H_2O within a lithiated organic ($R^{\ominus}Li^{\oplus}$, where $R^{\ominus}$ is an organic anion derived from an alkane or arene, an amine, an alcohol, etc) was startling. Usually the products of equation (a) dominate, i.e., such species are exceedingly moisture-sensitive.

In this case, however, the adduct of equation (b) is favored.

$$R^{\ominus}Li^{\oplus} + H_2O \rightleftarrows RH + LiOH \quad (a)$$
$$R^{\ominus}Li^{\oplus} + H_2O \rightleftarrows R^{\ominus}Li^{\oplus} \cdot H_2O \quad (b)$$

The reasons for this behaviour are: 1) the p*K*a of OxH is slightly less than that of H_2O and 2) after the H_2O displaces the S atom of the $(\overline{NCS})Li$ chelate in $(OxLi \cdot TMEDA)_n$ it is stabilized by intramolecular hydrogen bonding ($-S \cdots H_2O$). Related complexes containing hexamethylphosphoric acid triamide (HMPA) have since been prepared: $(OxLi \cdot HMPA \cdot H_2O)_2$ by addition of H_2O to $(OxLi \cdot HMPA)_n$, and $(OxLi \cdot HMPA)_2 \cdot H_2O$ by mixing the fully hydrated $(OxLi \cdot HMPA \cdot H_2O)_2$ and the anhydrous species.[2] Here we extend these findings to alkaline-earth metal complexes, revealing a new synthetic strategy, based on tested chemical procedures but with a key modification. The standard method of dissolving an organic acid, RH, is to treat it with aqueous alkali (equation (c); M = alkali metal). An ion-separated species (not a complex) results.

However, why not do the reaction using *solid* MOH (or $M(OH)_2$ etc.) in a *hydrocarbon* medium containing an additional Lewis base, L [Equation (d)]?

$$RH + MOH_{aq} \xrightarrow{H_2O} R^{\ominus} + M^{\oplus}{}_{aq} \quad (c)$$
$$RH + MOH_{(s)} + xL \xrightarrow{\text{hydrocarbon}} R^{\ominus}M^{\oplus} \cdot xL \cdot H_2O \quad (d)$$

This "assembles" H_2O in the stoichiometric amount required for ligation, the metal cation is not swamped, and a true complex (a contact-ion species) should result. The aqua complex produced thus could then be dehydrated, giving the anhydrous species. Here we illustrate two procedures: we describe the synthesis (using Ba metal) of $Ox_2Ba \cdot 3HMPA$, **1**, its crystal structure, and the addition of H_2O to **1** to give $Ox_2Ba \cdot 3H_2O$, **2**, as well as the *direct* synthesis [according to eq. (d)] of $Ox_2Ca \cdot 2HMPA \cdot 2H_2O$, **3**, by reaction of OxH with solid $Ca(OH)_2$ in toluene containing HMPA, its crystal structure, and its dehydration to give $Ox_2Ca \cdot 2HMPA$, **4**.

$[\overline{C_6H_4O(C{=}S)N}]_2Ba \cdot 3HMPA$ **1** $[\overline{C_6H_4O(C{=}S)N}]_2Ba \cdot 3H_2O$ **2**

$[\overline{C_6H_4O(C{=}S)N}]_2Ca \cdot 2HMPA \cdot 2H_2O$ **3** $[\overline{C_6H_4O(C{=}S)N}]_2Ca \cdot 2HMPA$ **4**

The anhydrous complex **1** was obtained in moderate yield by reacting Ba metal with OxH (molar ratio 1:1) in toluene containing HMPA (2 equiv). Treatment of a toluene solution of **1** with H_2O produces a white precipitate, which dissolves in excess of hot toluene. Cooling of the solution gives microcrystalline **2**. This route thus affords an aqua complex of Ox_2Ba, although the HMPA ligands of **1** are thereby displaced (TMEDA and HMPA remain coordinated in the OxLi complexes). Furthermore, the yield of **2** is poor; refrigeration of the mother liquor affords only the starting material **1**. The identities of **1** and **2** were confirmed by elemental analyses, by IR spectroscopy (ν(N-H) bands absent; ν(O-H) of H_2O present for **2** but not for **1**), and by ^1H NMR spectroscopy. X-ray crystallography (Fig. 1)[3] shows that the

[**] This work was supported by Gonville and Caius College, Cambridge (Fellowship for D. S. W.), the Associated Octel Co. Ltd. (R. S.), and the Deutscher Akademischer Austauschdienst (fellowship for P. M.). The reactions and products described are being patented by the Associated Octel Co. Ltd. (U.K.)

solid-state structure of **1** is monomeric and, as anticipated from structures of analogous lithium species, both $Ox^{\ominus}$ ligands chelate the $Ba^{2\oplus}$ center (mean Ba–N and Ba–S distances, 2.91(2) and 3.31(1) Å respectively). The $Ba^{2\oplus}$ cation is also ligated by three HMPA molecules (mean Ba–O distance 2.60(3) Å), making it seven-coordinate (low for a cation such as $Ba^{2\oplus}$[4]).

For the synthesis of **3**, solid $Ca(OH)_2$ (1 equiv) was stirred in a toluene solution of OxH and HMPA (2 and 4 equiv respectively) and soon dissolved. Further brief stirring causes precipitation of another solid which dissolves on heating. Cooling affords crystals of **3** in high yield. This aqua complex can be dehydrated easily by heating at 130 °C under vacuum. Crystallization of the resulting white powder from toluene solution gives the anhydrous complex **4**. The complexes **3** and **4** were identified as detailed for **1** and **2**. Complex **3** is monomeric in the solid state (Fig. 2).[5] The $Ca^{2\oplus}$

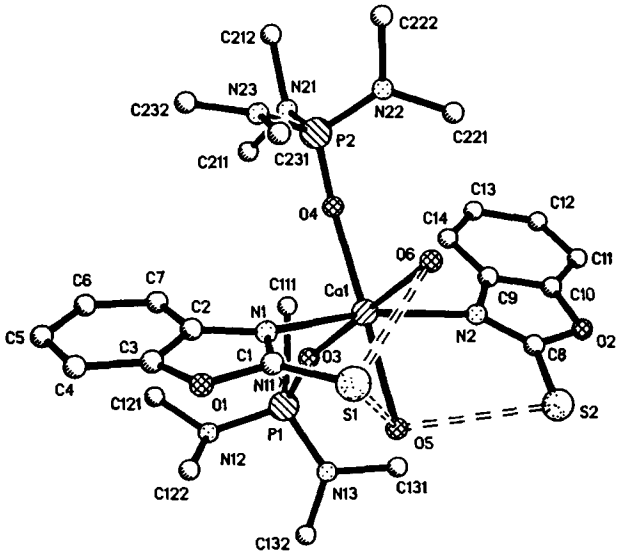

Fig. 2. Molecular structure of **3** [5].

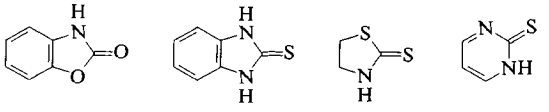
cation is complexed octahedrally: by two *cis* H_2O molecules (mean Ca–O distance 2.390(5) Å), by two *cis* HMPA ligands (mean Ca–O distance 2.267(4) Å), and by two *trans* *N*-attached $Ox^{\ominus}$ anions (mean Ca–N distance 2.545(6) Å). The S atoms of these anions are not attached to $Ca^{2\oplus}$, but hydrogen bond with H_2O molecules (intramolecular: S(1)···O(5), 3.20; S(2)···O(5), 3.14; S(1)···O(6), 3.25 Å; intermolecular: S(2)···O(6'), 3.30 Å].[6] On dehydration to give **4**, the $Ca^{2\oplus}$ center will probably remain six-coordinate; the $S^{\delta\ominus}$ centers, displaced in **3**, will simply re-engage the metal (cf. structure of **1**, Fig. 1).

These results herald some major synthetic advances. Firstly, organic acid precursors of type Y-R'-XH(R' is, for example, CH in a ring, $(CH_2)_n$ in a chain) with p*K*a close to that of H_2O and with two electronegative centers X and Y (N, O, or S) can be metalated at one center (X), while the other (Y) hydrogen bonds to H_2O ligands. For example, the lithiated derivatives[7] of **5**–**8** will all complex H_2O. Secondly, the



5 **6** **7** **8**

direct synthesis of aqua complexes by assembling H_2O ligands via solid metal hydroxides is very flexible: in the system nRH (organic acid) + xL (other ligand) + $M(OH)_{n(s)}$, R, L and/or x, and M (thus n) can be varied. LiOH also reacts with OxH and HMPA to give $(OxLi \cdot HMPA \cdot H_2O)_2$, and $Ba(OH)_2$ with OxH (2 equiv) and HMPA to give $Ox_2Ba \cdot 2HMPA \cdot 2H_2O$ (cf. **1** and **2**).[8] The use of metal oxides rather than hydroxides promises further variations: for example, solid CaO reacts with OxH (2 equiv) and HMPA to give $Ox_2Ca \cdot 2HMPA \cdot H_2O$ (cf. **3**).[8] Thirdly, other small complexants can be assembled by this direct method, e.g., Li_2S reacts with OxH (2 equiv) and HMPA to provide $(OxLi \cdot 2HMPA)_2 \cdot H_2S$.[8] Finally, all such assembled ligands (H_2O, H_2S; also NH_3) will be activated (as shown by ab initio MO calculations[2]), both by complexation and by hydrogen bonding to $Y^{\delta\ominus}$ centers of the anionic ligands. Thus, their metalation (by M' or M) will be enhanced, providing volatile homo- and heteronuclear metal hydroxides, oxides, sulphides, etc. For example, OxLi · TMEDA · H_2O,[1] provides OxLi · TMEDA · LiOH on treatment with *n*BuLi.[8]

Experimental Procedure

1: 2-Mercaptobenzoxazole (1.16 g, 7.7 mmol) and barium metal (1.06 g, 7.7 mmol) were taken in chilled toluene (10 mL) containing HMPA (2.76 g, 15.4 mmol). A reaction began at room temperature and continued, with gas evolution, for two days. The resulting orange-yellow precipitate was dissolved by heating, and the mixture filtered to remove excess metal. Cooling at 0 °C produced pale yellow cubic crystals of **1**. First batch yield 1.64 g (44%); m.p. 142–145 °C; correct C,H,N,P analysis; ^{1}H NMR (C_6D_6, 250 MHz, 25 °C): δ = 7.68 (m, 1H), 7.24 (m, 1H), 7.10 (m, 1H), 6.88 (m, 1H), 2.32 (d, J = 9.5 Hz, 27H of HMPA).

2: Complex **1** (4.87 g, 5.0 mmol) was dissolved in toluene (10 mL) and distilled water (0.18 mL, ca. 10 mmol) added. A white precipitate formed at once. Addition of more toluene (30 mL) and heating, caused the white solid to dissolve. Cooling of the resulting solution gave microcrystalline **2**. Yield 0.30 g (18%); m.p. (dec) 200 °C; correct C,H,N analysis; IR (Nujol mull): ν(O-H) of H_2O at 3315 (vs) cm^{-1}; ^{1}H NMR (C_6D_6SO, 250 MHz, 25 °C) δ = 7.08 (m, 2H), 6.94 (m, 1H), 6.83 (m, 1H), 3.37 (s, 3H of H_2O).

3: Solid calcium hydroxide (99%, anhydrous; 0.37 g, 5 mmol) was added to a solution of 2-mercaptobenzoxazole (1.51 g, 10 mmol) and HMPA (3.58 g, 20 mmol) in toluene (20 mL). After stirring for 5 min, most of the $Ca(OH)_2$ had dissolved. On further stirring (15 min), an off-white precipitate formed. This dissolved on heating, and overnight cooling of the solution then gave colorless crystals of **3**. Yield 3.31 g (90%); m.p. 104–106 °C; correct C,H,N,P, analysis; IR (Nujol mull): ν(O–H) of H_2O at 3388 (s), 3260 (w), 3150 (s) cm^{-1}; ^{1}H NMR (C_6D_6, 250 MHz, 25 °C) δ = 7.51 (m, 1H), 7.13 (m, 1H), 6.96 (m, 1H), 6.84 (m, 1H), 4.68 (s, 2H of H_2O), 2.21 (d, J = 9.6 Hz, 18H of HMPA).

4: Complex **3** (1.13 g, 1.54 mmol) was heated at 130 °C under reduced pressure (4 mbar) for 3 h. The initial semi-solid was thereby converted into a dry white powder, which was dissolved in hot toluene (10 mL). Cooling of the solution afforded colorless crystals of **4**. Yield 0.83 g (77%); m.p. 158–161 °C; correct C,H,N,P analysis; IR (Nujol mull): no ν(O–H) of H_2O, though brief exposure to air produces a spectrum identical to that of **3**; ^{1}H NMR (C_6D_6, 250 MHz, 25 °C) δ = 7.40 (m, 1H), 7.11 (m, 1H), 6.91 (m, 1H), 6.76 (m, 1H), 2.23 (d, J = 9.4 Hz, 18H of HMPA).

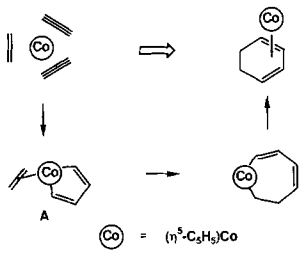
Reactions of Substituted Alkynes at a Conformationally Rigid (Olefin)cobalt Fragment**

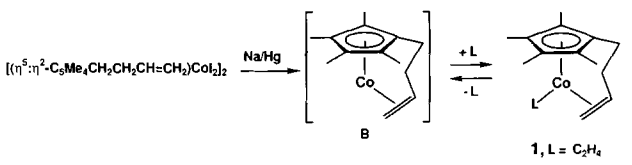
By *Jun Okuda,** *Karl Heinz Zimmermann,* and *Eberhardt Herdtweck*

Two alkynes can be coupled with an olefin in the coordination sphere of the 14-electron fragment (η^5-cyclopentadienyl)cobalt (CpCo) in a [2 + 2 + 2] cycloaddition to form cyclohexadiene derivatives.[1] In this way *Vollhardt* et al. have successfully applied the *intra*molecular cyclization of enediynes with $[CpCo(CO)_2]$ to construct steroid frameworks.[2] The *inter*molecular coupling of two alkynes with an olefin[3] promises to be useful synthetically, when the aim of suppressing the cobalt-induced di- and trimerization of the alkynes and of elucidating the stereochemical course of the reaction is achieved. In this process, metallacycle **A** (Scheme 1[1,4]) plays a key role as reactive intermediate. Molecular mechanical considerations led us to fix the olefin within the coordination sphere of the cobalt center using a 3-butenyl substituent on the cyclopentadienyl ligand. The reaction of alkynes at the resulting (η^2-alkene)cobalt fragment **B** yielded, depending on the alkyne substituents, cyclohexadiene complexes as well as for the first time an (η^2-alkene)(η^2-alkyne)cobalt and an (η^2-alkene)cobaltacyclopentadiene complex.



Scheme 1.

The coordinatively unsaturated 16-electron fragment **B** is formed in the reduction of the diiodide $[(\eta^5\text{-}C_5Me_4CH_2CH_2CH{=}CH_2)CoI_2]_2$ with sodium amalgam in THF and can be trapped with two-electron donor ligands L like PR_3 and CO.[5,6] The ethene complex **1** ($L = C_2H_4$) loses ethene in boiling hexane and is thus also suitable as a source of **B** (Scheme 2).[6b] If **B** is generated in the presence of bis(trimethylsilyl)acetylene, the alkyne complex **2** is obtained quantitatively under various reaction conditions and irrespective of the stoichiometry applied. Compound **2** forms red crystals, which melt at 27 °C (Scheme 3). Its chiral structure, which is also rigid in solution on the NMR time scale, is confirmed by spectroscopic data[7] and X-ray crystallographic analysis.[8] Each enantiomer in the racemate **2** bears an alkyne and an alkene ligand,[9] which lie parallel to each other, and together with the almost planar, η^5-coordinated Cp ligand determine the trigonal planar geometry around the cobalt(I) center (Fig. 1).



Scheme 2.

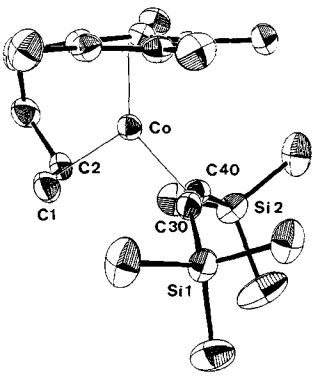


Fig. 1. Structure of an enantiomer of **2** in the crystal (ORTEP), 50% probability ellipsoids, without H atoms). Selected bond distances [Å] and bond angles [°]: C1-C2 1.409(3), Co-C1 2.023(2), Co-C2 2.036(2), C30-C40 1.249(3), Co-C30 2.010(2), Co-C40 2.007(2), Co-Cp (center of five-membered ring) 1.692, Si1-C30-C40 151.4(2), Si2-C40-C30 151.3(2), C1-C2-C3 122.5(3), C2-C3-C21 111.5(2).

On the other hand, 1,7-octadiyne reacts with **1** to give, in 90% yield, cobaltacyclopentadiene **3**, a red-brown oil that is shown by ^1H, ^{13}C NMR and IR spectroscopy to contain a five-membered metallacycle and the intact fragment **B** (Scheme 3).[7] Analogous to spectra of chelate complexes of type **1** ($L = CO, PR_3$), the signals of the two olefinic carbon atoms occur at $\delta = 48.56$ as triplet ($^1J = 153$ Hz) and at 68.49 as doublet ($^1J = 151$ Hz). In contrast to the cobaltacyclopentadienes thoroughly studied by *Yamazaki* et al.,[10] **3**

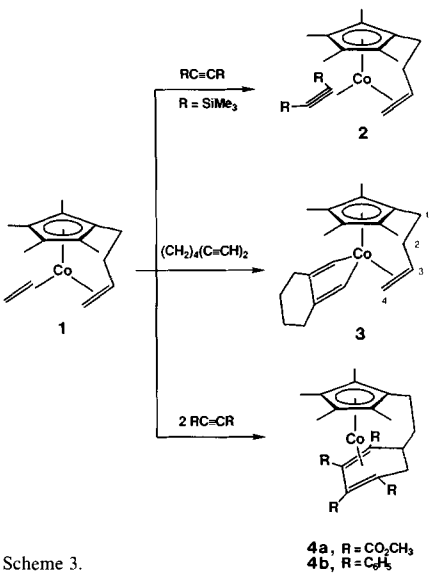
Herrmann* for his support. Part 4: J. Okuda, *Chem. Ber. 123* (1990) 1649.

is unusually inert and does not cyclize, even at higher temperatures (80 °C, 24 h), to the corresponding cyclohexadiene complex. To our knowledge, **3** is the first isolable cobaltacyclopentadiene complex with a π-coordinated ligand such as alkene or alkyne.[11]



Scheme 3.

The cobalt-centered [2 + 2 + 2] cycloaddition with **B** is observed with activated alkynes such as dimethyl acetylenedicarboxylate (DMAD) or tolane. Thus the reaction of **1** with DMAD leads quantitatively to the brown crystalline η^4-cyclohexadiene complex **4a** with a bridged ligand system. Spectroscopic data show unambiguously that the cyclization involves the C–C double bond of the 3-butenyl chain.[7] The proof lies in the ^{13}C NMR resonance signals of the original olefinic carbon atoms of the 3-butenyl chain, which occur in **4a** at $\delta = 35.32$ as doublet and 42.55 as triplet, each with $^1J_{CH} = 126$ Hz. An X-ray structure analysis on the analogous complex derived from tolane (**4b**) confirms the presence of a cyclohexadiene ring that is distorted as a result of the Cp–cyclohexadiene ethylene "handle".

The rigidity of the C–C double bond of the cobalt fragment **B** is apparently responsible for high activation barriers for the individual steps of the cycloaddition reaction, depending upon the nature of the alkyne substituents. Thus no catalytic alkyne trimerization is observed at the cobalt fragment **B**. Instead, **2**, **3**, and **4** are formed chemoselectively. Furthermore the fact that **3** is isolable, and in particular the unexpected inertness[12] of **3**, can be interpreted as another indication that the cobalt-induced cyclohexadiene formation

C

occurs via an (η^2-alkyne)cobaltacyclopentene complex **C** as reactive intermediate.

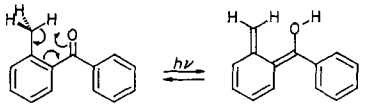
An Exception to the Bredt Rule in the Photoenolization of 4-Benzoyl[2.2]paracyclophane **

By *Henning Hopf*,* Thomas Laue*, and *Maximilian Zander**

Dedicated to Professor Siegfried Hünig on the occasion of his 70th birthday

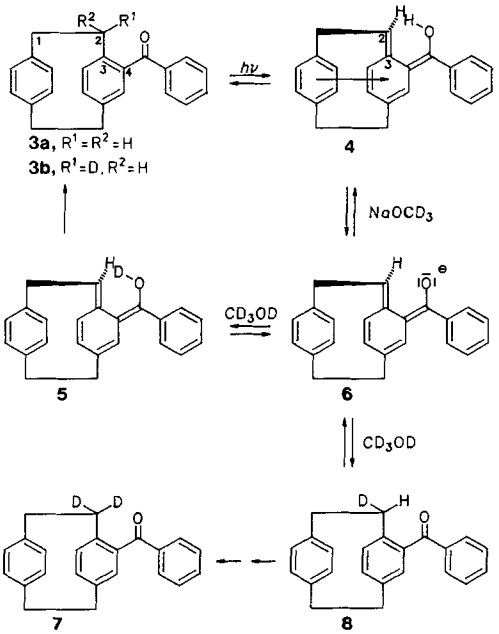
The photoenolization of *ortho*-alkylated benzophenones **1** to *ortho*-quinodimethane derivatives **2** has been known since the work of *Yang* et al. in the early sixties[1] and has been studied by several authors.[2, 3]



1 **2**

We posed the question whether this photoreaction can be applied to 4-benzoyl-[2.2]paracyclophane (**3a**),[4] which is easily prepared by Friedel-Crafts benzoylation of [2.2]paracyclophane. The resulting *ortho*-quinoid system **4** is a possible intermediate for the construction of [1.2]phanes by Diels–Alder addition. The [1.2]phanes form an unknown group of phanes with extremely short bridges. According to molecular models the C2-C3 double bond, which violates Bredt's rule, is extremely twisted. Nevertheless we could not exclude the formation of this bridgehead olefin during the irradiation of **3a** by a 1,5-migration of the *endo* hydrogen atom R^1 to the keto function, first because we had already observed that the ethano bridges in [2.2]paracyclophanes tolerate drastic deformations (for example, the formation of a triple bond[5]), and second because intramolecular charge-transfer stabilization in **4** by the benzene ring situated opposite was to be expected.

On irradiation of ethanolic solutions of **3a** at 88 K (with light of wavelength 320 nm or with the unfiltered light of a mercury lamp), we observed a pronounced yellow coloration, which was characterized in the low-temperature UV spectrum by a new broad band at 430 nm (half-height width: 5200 cm^{-1}). On slow warming of the irradiated, yellow solid reaction mixture, the color disappeared again and the absorption spectrum of the ketone **3a** was observed. The processes were completely reversible and could be repeated several times on the same solution. To test for the enol **4**, the photoenolization was repeated at $-30\,^{\circ}C$ in [D_4]methanol to which a catalytic amount of [D_3]sodium methanolate had been added. Already after a few seconds the photolysis mixture had assumed its characteristic yellow color, which again paled slowly on melting. An analytically pure sample of the ketone (84%) was recovered from the photolyzed solution by chromatography on silica gel. According to the mass spectrum, this ketone was 36% mono- and 8.5% dideuterated. The sites of deuteration were determined by 400-MHz ^1H NMR spectroscopy. The signals of the protons R^1 (multiplet shifted to lower field, $\delta = 3.33$) and R^2 (multiplet shifted to higher field, $\delta = 2.85$) lie apart from all other signals of the bridge protons (which appear between $\delta = 2.90$ and 3.28). The degree of deuteration was calculated from the reduced signal intensities: ca. 36% for the position R^1 and 24% for R^2. These results may be understood if two H/D exchange mechanisms are postulated, both of which begin with the loss of the hydroxyl proton of **4**. The resulting enolate **6** can then react further with the large excess of deuterated solvent to yield **5**, which equilibrates with the *endo*-deuterated ketone **3b** (stereospecific exchange of R^1 = H with deuterium). Alternatively, **6** can be deuterated at C2 by the solvent. For steric reasons this occurs from the side opposite to the substituents and yields the *exo*-monodeuterated product **8**. Through both exchange processes, which occur with approximately equal probability as the NMR data show, the 2-position is completely deuterated and the product is **7**. In the absence of light no H/D exchange in **3a** takes place even at $60\,^{\circ}C$ and in dimethylsulfoxide, a solvent known to favor this type of exchange.[3]



Bridged benzophenones like **3a** are not only of interest because of their reactivity, but may also be used as chiral sensitizers for photoreactions. We have therefore also characterized **3a** by luminescence spectroscopy. The intensity maximum of the broad phosphorescence band (ethanol, 77 K) lies at 19 880 cm^{-1}. Even when the (0,0) transition is taken into account, it should lie $< 22\,200$ cm^{-1} ((0,0) phosphorescence transition of benzophenone: 24 040 cm^{-1}). The average phosphorescence lifetime of **3a** is 128 ms (benzophenone: 5 ms). From this relatively long lifetime, we conclude that the lowest triplet level of **3a** is a $^3\pi,\pi^*$ state. The phosphorescence emission spectrum of **3a** corresponds to the UV absorption spectrum. Compound **3a** does not fluoresce. The most likely explanation is that the $^1n,\pi^*$ and $^3n,\pi^*$ levels, or just the $^3n,\pi^*$ level, lie between the lowest singlet π,π^* and the lowest triplet n,π^* state.[6] Characteristic of compounds with such term diagrams are high quantum yields when the lowest triplet state is occupied. It follows that the application

Triaurated Phosphonium Cations $[RP(AuPPh)_3]^{\oplus}$ and the Electron-deficient, Hypercoordinated Phosphonium Dication $[P(AuPPh_3)_5]^{2\oplus}$ **

By *Hubert Schmidbaur,* Gabriele Weidenhiller,* and *Oliver Steigelmann*

Complex compounds of monovalent gold tend to display *intra-* and *inter*molecular Au···Au interactions.[1] This is especially noticeable in the aggregation of gold atoms around heteroatoms to give novel centered gold clusters. Thus, not only could species of the type $[RC(AuL)_3]$,[2] $[RN(AuL)_3]^{\oplus}$,[3,4] and $[N(AuL)_4]^{\oplus}$[5] with classical four-coordination of carbon or oxygen (L = tertiary phosphane) be synthesized, but also the hypercoordinated cations $[RC(AuL)_4]^{\oplus}$,[6] $[C(AuL)_5]^{\oplus}$[7] and $[C(AuL)_6]^{2\oplus}$,[8] and $[N(AuL)_5]^{2\oplus}$,[9] but not $[N(AuL)_6]^{3\oplus}$.[10] The results allowed to correct literature inconsistencies[11], confirmed predictions based on MO considerations,[12] and could be placed on a sounder theoretical footing by new calculations taking into account relativistic effects.[13,14] Our studies were now also extended to *phosphorus*-centered gold clusters. After preliminary investigations on mono- and dinuclear gold complexes of tertiary,[11] secondary[15] and finally primary phosphanes,[16] the latter were now also triply aurated. Similarly as in the case of primary amines, this was achieved especially easily by reaction with tris(triphenyl phosphanegold(I))oxonium tetrafluoroborate **1**[17] at room temperature in tetrahydrofuran. The best results were obtained with arylphosphanes, but even there the yields were only moderate.

$$\underset{\mathbf{1}}{RPH_2} + [(Ph_3PAu)_3O]\,BF_4 \longrightarrow \underset{\mathbf{2}}{[RP(AuPPh_3)_3]\,BF_4} + H_2O$$

The complex **2a** (R = *o*-tolyl), obtained in 29% yield from *ortho*-tolylphosphane, crystallizes in the form of colorless needles (m.p. 183–186 °C, decomp) from a mixture of tetrahydrofuran, diethyl ether, and dichloromethane, and is readily identifiable by analytical data and NMR spectra.[18] In the case of the analogue **2b** (R = Ph) the yield and thermal stability are significantly lower. The very similar spectroscopic data, however, reveal a close structural relationship.

The ^{31}P-NMR spectra of **2a** at −70 °C show the expected doublet/quartet multiplicity of the signals (δ = 46.0(d), −19.0 (q, J_{PP} = 249 Hz)); at higher temperature, signal broadening with disappearance of coupling occurs. This is attributed to exchange processes in which presumably $LAu^{\oplus}$ and not L units are involved.

The X-ray structure analysis of **2a**[18] confirms the presence of organo(triaurio)phosphonium cations and tetrafluoroborate anions. The triclinic unit cell (space group $P\bar{1}$) contains two formular units, which are related to each other via a center of symmetry. The most important features are the small deviation of the Au-P-Au angle (average 106°) from ideal tetrahedral geometry and the associated long Au···Au contacts of ca. 3.7 Å (Fig. 1), i.e. the dimensions of the

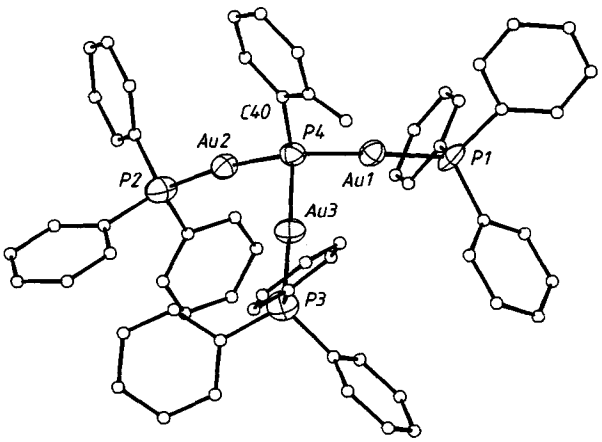

Fig. 1. Structure of the cation in **2a** in the crystal (ORTEP, thermal ellipsoids at the 50% probabiity level; C atoms with arbitrary radii, H atoms omitted; of the two possible positions of the methyl group of the disorded *o*-tolyl moiety only one is shown.)—Selected bond lengths [Å] and angles [°]: Au1-P1 2.315(8), Au2-P2 2.288(8), Au3-P3 2.280(9), Au1-P4 2.277(7), Au2-P4 2.317(8), Au3-P4 2.321(8); Au1-Au2 3.709, Au1-Au3 3.696, Au2-Au3 3.639; P1-Au1-P4 176.4(3), P2-Au2-P4 172.3(3), P3-Au3-P4 176.4(3); Au1-P4-Au2 107.7(3), Au1-P4-Au3 107.0(3), Au2-P4-Au3 103.3(3), Au1-P4-C40 114.7(7), Au1-P4-C40 113.7(9), Au3-P4-C40 109.6(9).

cations $[RP(AuL)_3]^{\oplus}$ differ significantly from those of the cations $[RN(AuL)_3]^{\oplus}$, where markedly smaller Au-N-Au angles (ca. 102°) and correspondingly short Au···Au contacts (ca. 3.1 Å) are found.[3,4] Apparently, the peripheral gold–gold distances are so large, due to the much larger radius of the phosphorus atom compared to that of nitrogen, that no noteworthy energy contributions to the stabilization of the cluster can result from direct metal–metal interactions. At least they do not suffice to induce a drastic distortion of the tetrahedral framework. The same also holds true in the case of diauriophosphonium salts.[19] Only an increase in the number of the polyhedral corners, e.g. from four to five, could lead to a convergence of the metal atoms.

All earlier attempts[20] to carry out tri- or tetraauration of PH_3 or its trimethylsilyl derivative $P(SiMe_3)_3$[21] failed at

[+] X-ray structure analysis.

[**] This work was supported by the Deutsche Forschungsgemeinschaft (Leibniz Program), the Fonds der Chemischen Industrie, Hoechst AG, Degussa AG, and Heraeus GmbH. The authors thank *J. Riede* and *H. Beruda* for assistance with the structure determination and Dr. *Kreissl* for the mass spectra.

first. With stoichiometric amounts of reaction partners decomposition always took place. The poor stability of triauriophosphanes $P(AuL)_3$ and tetraauriophosphonium cations $(P(AuL)_4^{\oplus}$ is remarkable and has a parallel in the non-existence of the tetraauriomethanes and triauricamines,[1] but not of the tetraaurioammonium salts.[5]

With sufficient supply of **1**, however, the $P(AuPPh_3)_4^{\oplus}$ cation can be stabilized by formation of the novel dication in **3** with a *five*-coordinate, electron-deficient central phosphorus atom.

$$\underset{\mathbf{1}}{[(Ph_3PAu)_3O]BF_4} \xrightarrow[-(Me_3Si)_2O]{P(SiMe_3)_3} \underset{\mathbf{3}}{[(Ph_3PAu)_5P](BF_4)_2}$$

3 can be precipitated from the yellow reaction mixture with diethyl ether and isolated from dichloromethane/pentane in the form of light-brown, air-stable crystals. The yields are below 10%, so that a commitment to a stoichiometry of an equation is not really justified. The by-product hexamethyldisiloxane is, however, unequivocally detectable in the reaction mixture by GC/MS analysis.

A first indication of the composition of **3** was provided by field desorption mass spectrometry: the (half) mass of the intact dication is observed at $m/z = 2327.4/2 = 1163.7$ (100%). Further high-intensity peaks at $m/z = 721.0$ (83%) and 262.1 (71%, from CH_2Cl_2) are assignable to $[(Ph_3P)_2Au]^{\oplus}$ and $[PPh_3]^{\oplus}$, respectively. Since no crystals suitable for an X-ray diffraction analysis could be obtained, low-temperature $^{31}P\{^1H\}$-NMR spectroscopy played the key role in the elucidation of the structure: at $-75\,^{\circ}C$, solutions of **3** in CD_2Cl_2 show a doublet ($\delta = 39.6$) and a sextet ($\delta = 122$, $^2J_{PP} = 186$ Hz) in the area ratio 5:1, thus demonstrating that a highly coordinated central phosphorus atom (recognizable by a marked upfield shift) is surrounded by five equivalent $AuPPh_3$ groups. The coupling constant is reduced significantly compared to that in **2a** ($^2J_{PP} = 249$ Hz), and thus is consistent with the diminished *s*-character of the orbitals of the central atom (sp^3 vs. sp^3d). On the basis of the structurally characterized C- and N-analogues a trigonal-bipyramidal structure, which apparently is fluctional in solution, is proposed for the dication (Fig. 2). The exchange processes are intramolecular, as recognizable by the persistence of the $^2J_{PP}$ coupling. The bonding situation can be described in terms of an MO scheme in which, under the point group D_{3h}, four strongly bonding states can be occupied by the available eight valence electrons to give a diamagnetic ground state.[7, 12] More recent relativistic calculations also indicate a dominance of these radial bonds if the radius of the central atom is larger.[13, 14] The bond order for each of the five central Au–P bonds is 4/5.

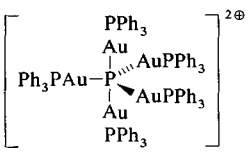

Fig. 2. Structure proposed for the dication in **3**.

Finally, it should be mentioned that electron-deficient, pentacoordinated phosphorus atoms have recently also been found in copper- and gold/platinum-clusters, so that this type of bonding is more common than was hitherto assumed.[22]

Experimental

2a: A suspension of **1** (0.90 g, 0.61 mmol) in tetrahydrofuran was treated dropwise with stirring with a solution of *o*-tolylphosphane (0.08 g, 0.61 mmol) in THF (10 mL). The color of the mixture changed to yellow and then to brown. After 20 min, the mixture was filtered and the residue recrystallized, first from CH_2Cl_2/Et_2O and then, for the isolation of single crystals, from CH_2Cl_2/THF/Et_2O. Yield 0.28 g (29%), m.p. 183–186 °C (decomp.), correct elemental analysis. ^1H NMR (CD_2Cl_2): $\delta = 2.91$ (s, 3H, CH_3), 7.11–7.25 and 8.23–8.30 (m, 4H, C_6H_4), 7.37–7.56 (m, 45H, C_6H_5); $^{31}P\{^1H\}$NMR (CD_2Cl_2, −70 °C): $\delta = 45.4$ (d, $^2J(PP) = 249$ Hz, PPh_3), −19.0 (q, PAu_3); at room temperature: $\delta = 46.0$ (br), −19.1 (br). − **2b** was prepared analogously. $^{31}P\{^1H\}$NMR (CD_2Cl_2, −70 °C): $\delta = 46.1$ (PPh_3), −4.6 (br, $^2J(PP) = 260$ Hz, PAu_3).

3: A suspension of **1** (1.10 g, 0.74 mmol) in THF (25 mL) was treated dropwise with stirring at −50 °C with a solution of $P(SiMe_3)_3$ (0.11 g, 0.57 mmol) in THF (20 mL). A yellow solution formed, from which a yellow precipitate of unknown composition was obtained 90 min after addition of 100 mL of Et_2O. Upon addition of a further 80 mL of Et_2O to the orange filtrate at −30 °C a light-brown precipitate was formed; this was recrystallized from CH_2Cl_2/pentane (1:1); yield 5–10%; air-stable, slow decomposition upon heating.

$[Cp_2^*La(thf)(\mu\text{-}\eta^1,\eta^3\text{-}C_4H_6)LaCp_2^*]$: Synthesis and Structure of a Butadiene-Lanthanoid Complex**

By *Annett Scholz, Astrid Smola, Joachim Scholz, Jörg Loebel, Herbert Schumann,* and *Karl-Heinz Thiele**

One reason for the increased interest in organolanthanoid compounds is that they frequently show high activity in the polymerization and hydrogenation of olefins.[1] The structural characterization of some olefin[2] and hydride complexes[3] of the lanthanoids and investigations related to the suitability of organolanthanoid compounds in the activation of C–H bonds[4] help to interpret important elementary steps of the complex reactions of homogeneously catalyzed olefin polymerization and olefin hydrogenation.[5] In this connection dienelanthanoid complexes are also of interest as model compounds; however, their synthesis was hitherto limited merely to the co-condensation of diene molecules and lanthanoid atoms in a metal-vapor reactor[6a] or to the reaction of lanthanoids with dienes in the presence of iodine or 1,2-diiodoethane.[6, bc] By using "magnesium(butadiene)"[7] as diene source we have now succeeded in preparing a dinuclear lanthanumbutadiene complex, whose X-ray structure analysis shows a novel type of bonding of a diene molecule to two metal atoms. To our knowledge this is the first structurally characterized butadienelanthanoid complex.

$[Cp_2^*La(\mu\text{-}Cl)_2K(dme)_2]$ **1**[8] (dme = 1,2-dimethoxyethane), dissolved in THF, reacts according to Equation (a) with "magnesiumbutadiene" in strict absence of air and moisture to give the dinuclear complex **2**, which, after recrystallization from pentane, precipitates as brilliant red crystals in ca. 10% yield.

$$2[Cp_2^*La(\mu\text{-}Cl)_2K(dme)_2] + [Mg(C_4H_6)(thf)_2] \xrightarrow[-MgCl_2,\ -2KCl]{} [Cp_2^*La(\mu\text{-}\eta^1,\eta^3\text{-}C_4H_6)LaCp_2^*(thf)] \quad (a)$$

$Cp^* = \eta^5\text{-}C_5Me_5$.

2 is readily soluble in the usual aromatic and aliphatic hydrocarbons and ethers, and, with a decomposition temperature of ca. 200 °C, is markedly stable towards heat. Upon exposure to air, butadiene is immediately liberated. Protolytically active agents lead to formation of 1-butene as well as *cis*- and *trans*-2-butene.

The observation of four signals in the ^{13}C-NMR spectrum[9] suggests an unsymmetrical charge distribution in the diene, i.e. a different participation in the bonding to the two La atoms is to be expected for each of the carbon atoms. A bond behavior as is characteristic, for example, for diene complexes of electron-deficient transition metals[10] may therefore be ruled out.

An X-ray structure analysis of **2** (Fig. 1)[11] confirmed this assumption. One La atom is located at the midpoint of each of the two different coordination polyhedra. The two metal centers are bridged by a *cis*-configurated butadiene unit: C42, C43 and C44 are η^3-coordinated to La1 with formation of an allyl system, while the terminal C41 is σ-bonded to the second Cp_2^*La unit. The bond parameters of the allyl system

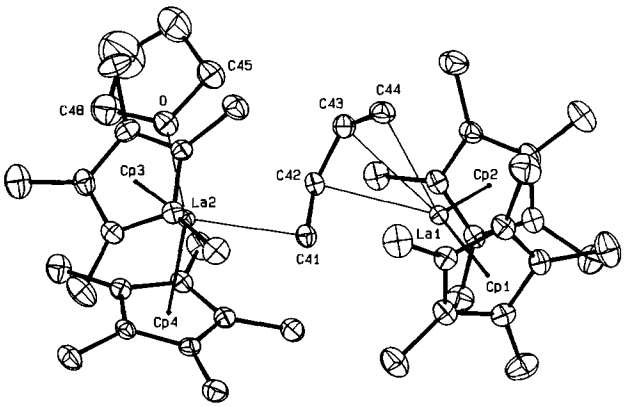

Fig. 1. Structure of **2** in the crystal: Selected bond lengths [pm] and angles [°]: La1-C41 289.4(4), La1-C42 273.4(4), La1-C43 275.9(4), La1-C44 268.8(4), La2-C41 263.3(4), La2-C42 284.2(4), La2-O 263.7(3), La1-Cp*1 258.6(1), La1-Cp*2 261.1(2), La2-Cp*3 255.7(2), La2-Cp*4 257.0(2), C41-C42 146.3(5), C42-C43 139.2(6), C43-C44 140.6(6); Cp*1-La1-Cp*2 129.56(5), Cp*3-La2-Cp*4 134.25(5), C41-C42-C43 126.2(4), C42-C43-C44 126.8(4), C41-C42-C43-C44 15.3(7), (Cp*1-La1-Cp*2)(Cp*3-La2-Cp*4) 88.00(4). Cp*1(C1-C5), Cp*2(C11-C15), Cp*3(C21-C25), and Cp*4(C31-C35) are the positions of the centroid of the carbon atoms given in the brackets.

C42–C43–C44, which formally require two coordination sites of La1, are comparable with those of other π-allyl complexes;[12] the La2–C41 distance is 263.3(4) pm and thus corresponds to a "normal" La–C σ-bond (e.g. Cp*La-$[CH(SiMe_3)_2]_2$: La–C 265.1(8) pm and 262.7(10) pm[13]). It seems remarkable that, despite this bond differentiation, the four C atoms deviate only slightly from the plane (torsional angle C41–C42–C43–C44: 15.3(7)°).

La2 is coordinatively saturated by a THF molecule. Nevertheless, the steric crowding of La1 by the allyl system is greater, as manifested in the small Cp*1-La1-Cp_2^* angle of 129.55(5)° (Cp*3-La2-Cp*4: 134.25(5)°) and large Cp*–La1 distances of 258.6(1) and 261.1(1) pm (La2–Cp*: 255.7(2) and 257.0(2) pm). Also worth mentioning is the sterically enforced staggering of the two Cp_2^*La units—the metallocene planes are oriented at almost 90° to each other (Cp*1, La1, Cp*2)(Cp*3, La2, Cp*4) = 88.00(4)°.

Surprisingly, the NMR spectra of **2** at room temperature do not reflect the different coordination of La1 and La2. The

methyl groups of all four Cp* ligands give rise to one sharp signal in the ^{1}H-NMR spectrum ([D]$_8$THF) at 25 °C.[9] However, it was possible to slow down the dynamic exchange process, which simulates the equivalence of the Cp* ligands, to such an extent that this signal splits into three singlets at $\delta = 1.95$, 1.91, and 1.85 at -80 °C.

The mode of coordination of the butadiene remains unaltered in solution and gives rise to a characteristic signal pattern for the allyl system C42–C43–C44 in the ^{1}H-NMR spectrum.[9]

For a $Cp^*_2La^{III}$ complex, the intense red color of **2** is unusual. Possibly, this points to a partial ionic character of the bonds, as is typical of organolanthanoid complexes.[14]

Experimental Procedure

$LaCl_3$ (2.83 g, 11.0 mmol) was added portionwise to a suspension of 6.10 (23.00 mmol) of [C_5Me_5K(dme)] in 150 mL of THF at room temperature. The reaction mixture was then stirred for 6 d, and, after cooling to -78 °C, treated with 1.28 g (5.0 mmol) of "butadienemagnesium". The resulting brilliant red reaction solution was warmed to room temperature and stirred for several hours before removing the solvent in a vacuum. The residue was extracted with 100 mL of pentane. Upon cooling the extract to -30 °C, 1.30 g (11%) of brilliant red crystals of **2** could be isolated. Corect C,H,La analysis, m.p. 215 °C (decomp.).

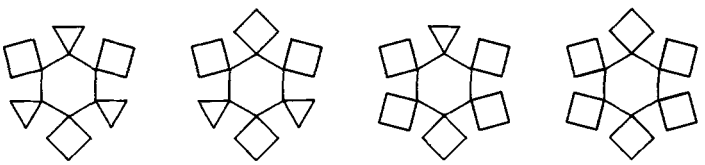
Hexaspiro[3.0.3.0.3.0.3.0.3.0.3.0]tetracosane ([6.4]Rotane)**

By *Lutz Fitjer,* Karl Justus, Peter Puder, Martin Dittmer, Carla Hassler,* and *Mathias Noltemeyer**

Fully substituted cyclohexanes are characterized by a frequent occurrence of anomalies in structure, conformation and dynamics.[1] Examples are the hexaspiranes **1**,[1a] **2**,[1c] and **3**[1e] in which a stepwise reduction of alternations, which are determined by different ring sizes, leads to a change from a chair/twist boat equilibrium in the case of **1** to a chair conformation in the case of **2** and **3** and to a precipitous rise in the inversion barriers (chair-chair) (**1**: $\Delta G^{\ddagger}_{298(c/c)} = 92.0$ kJmol^{-1},[1a] **2**: $\Delta G^{\ddagger}_{333(c/c)} = 112.1$ kJmol^{-1},[1e] **3**: $\Delta G^{\ddagger}_{423(c/c)} = 136.0$ kJmol^{-1}[1e]). It was therefore to be expected that the [6.4]rotane **4**, which is free from alternations, exists in a chair conformation and has the highest inversion barrier of all cyclohexanes known so far.[2]



1 **2** **3** **4**

In a model attempt to synthesize **4** the tetraspiroketone **5**[3] was converted, via a cyclopropylcarbene–cyclobutene rearrangement[4] as key step (**10** → **11**), into [5.4]rotane **12**. The spiroketone **5** was then homolyzed to **13**, which was subjected to the same reaction sequence as was used for the preparation of **12**.[5]

For the experimental realization **5** and **13** were methylenated (5 and 10 molar equivalents, 20 and 60 h respectively, at 130 °C) and the products **6** (liq)[6] and **14**[1e] (Scheme 1) converted by copper-catalyzed decomposition of methyl diazo-

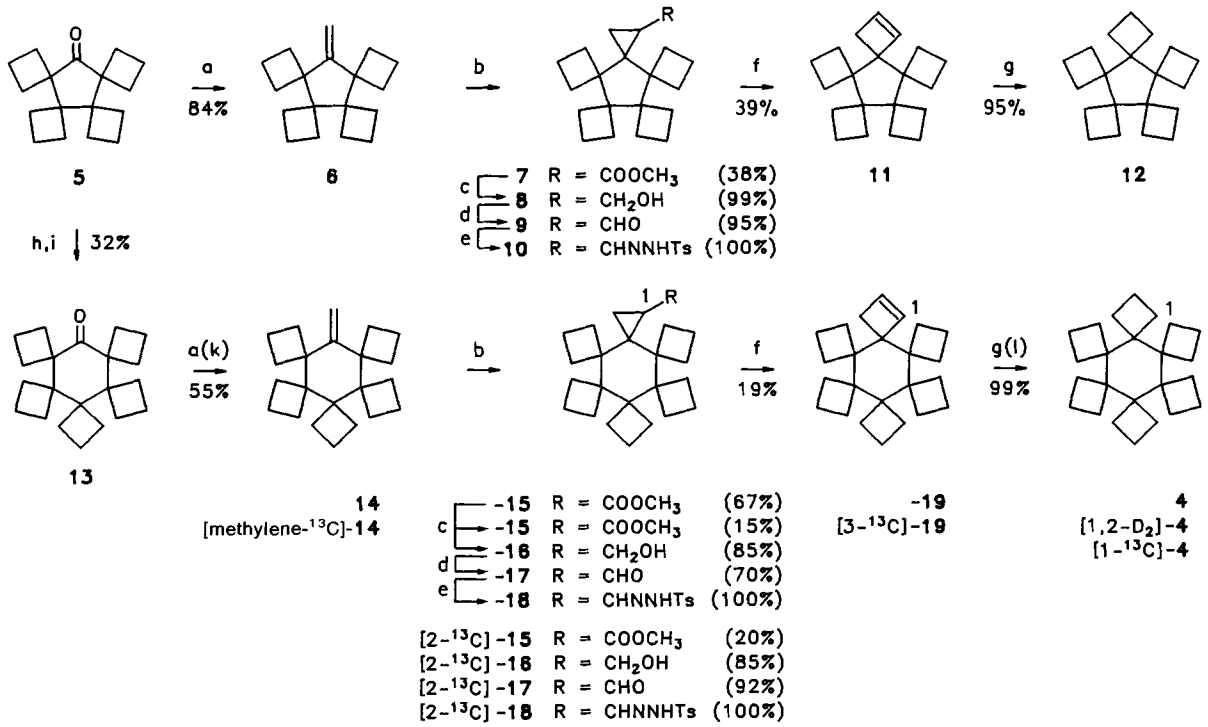
[**] Polyspiranes, Part 20. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. Part 19: L. Fitjer, A. Kanschik, M. Majewski, *NATO Adv. Study Inst. Ser. C 273* (1989) 431.



Scheme 1. (a) $Ph_3P{=}CH_2$, (b) $N_2CHCOOCH_3$/Cu, (c) $LiAlH_4$, (d) $(COCl)_2$/DMSO/NEt_3, (e) $TsNHNH_2$/NEt_3, (f) CH_3ONa, (g) H_2/Pd/C, (h) c-C_4H_6(Li)$SeCH_3$, (i) $AgBF_4/Al_2O3$, (k) $Ph_3P = [^{13}C]H_2$, (l) D_2/Pd/C. Formulas designated with primed numbers have C1 in the axial position referred to the central six-membered ring, in the case of those without a prime C1 is equatorial.

acetate (4 and 10 molar equivalents respectively at 110 °C) into the cyclopropanecarboxylates. This resulted in the formation of the pentaspirane **7** (m.p. 65 °C)[6] and the conformationally isomeric hexaspiranes **15** (m.p. 130–134 °C)[6, 7] and **15′** (m.p. 147–151 °C),[6, 7] of which, after chromatographic separation, only the excess conformer was used for further reaction. Reduction with lithium aluminum hydride afforded the alcohols **8** (m.p. 49 °C)[6] and **16** (m.p. 135–185 °C),[6] respectively, while oxidation with dimethyl sulfoxide/oxalyl chloride/triethylamine[8] furnished the aldehydes **9** (oil)[6] and **17** (oil),[6] respectively. Reaction with tosyl hydrazide in dichloromethane/triethylamine[9] and heating of the crude hydrazones **10** and **18** for a short time with sodium methoxide in diethylene glycol dimethyl ether (5 min at 135 °C) led to the cyclobutenes **11** (m.p. 105 °C)[6] and **19** (m.p. 175–188 °C),[6] respectively. Hydrogenation over palladium/carbon in pentane afforded the desired compounds [5,4]rotane **12** (m.p. 70–110 °C)[6] and [6.4]rotane **4** (m.p. 274 °C),[6] respectively; deuteration of **19** yielded [1,2-D_2]-**4**.[10]

The structures of the new rotanes follow from their ^{13}C-NMR spectra. **12** (δ = 16.78, 27.40, 55.30) shows three resonances for a planar species or a species rapidly inverting at room temperature (effective symmetry D_{5h}); in contrast, **4** shows four resonances for a fixed chair conformation (D_{3d} symmetry) at room temperature. **4** is present in the chair conformation, even in the crystal,[11] and has an inversion center. The cyclobutane rings show interesting anomalies: they are staggered almost ideally (dihedral angles 48.1–49.9°), are approximately planar (dihedral angles 0.6–2.5 °C), and are distorted in the shape of a kite with the smallest bond angle at the spirocenters (87.2–87.5°). Hereby, 1,3-diaxial interactions are apparently more effectively removed than by a more obvious flattening of the central ring ($\sum\omega = 306°$), for this would have led to stronger 1,2-diequatorial interactions.

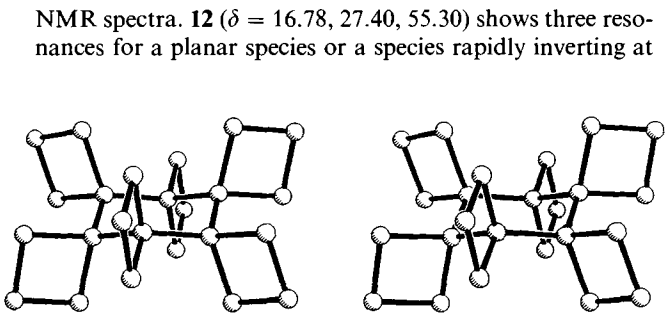


Fig. 1. Stereoscopic side-view of the structure of **4** (without hydrogen atoms) in the crystal. Bond lengths [pm] and angles [°]; cyclohexane ring: C–C 154.4–154.6, C-C-C 112.6–112.9; cyclobutane ring: C-C_{spiro} 157.0–157.6, C-$C_{peripher}$ 152.8–153.5, C-C_{spiro}-C 87.2–87.5, remaining C-C-C 90.2–91.3.

[6.4]Rotane **4** is very sparingly soluble. Attempts to determine its inversion barrier ^{2}H-NMR spectroscopically via a high-temperature equilibrium of [1,2-D_2]-**4** failed because of the large line widths and the poor solubility. To increase the sensitivity, stereospecifically ^{13}C-labeled material had to be prepared. To do this **13** was methylenated with ([^{13}C]methylene)triphenylphosphorane and subsequently converted as described for unlabeled **4** into [1-^{13}C]-**4′** (**13** → [methylene-^{13}C]-**14** → [2-^{13}C]-**15** → [2-^{13}C]-**16** → [2-^{13}C]-**17** → [2-^{13}C]-**18** → [3-^{13}C]-**19′** → [1-^{13}C]-**4′**).[12] For the determination of the barrier, [1-^{13}C]-**4′** was dissolved in 1,3-di-([D_3]methoxy)-benzene and the equilibration with [1-^{13}C]-**4** at + 214 ± 3 °C monitored by integration of the relevant ^{13}C-resonances.[13] This revealed a rate constant for the equilibriation at + 214 ± 3 °C of $k = (1.547 + 0.019) \times 10^{-4} s^{-1}$ and thus a free activation enthalpy for the chair/chair inversion of $\Delta G^{\neq}_{487(c/c)} = 156.8 \pm 1.1$ kJmol^{-4}. This is by far the highest inversion barrier reported so far for a cyclohexane.[2] Force field calculations are currently being carried out for an interpretation of this result.

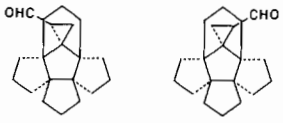
The IR, ^{1}H-NMR and mass spectrometric data are consistent with the given structures. ^{13}C-NMR data (so far as not mentioned in the text): **6** (126 MHz, $CDCl_3$): δ = 15.46, 15.92, 23.55, 31.56 (C_{sec}), 53.53, 53.60 (C_{quart}), 101.76 (C_{sec}), 171.60 (C_{quart}); **7** (50.3 MHz, $CDCl_3$): δ = 15.92, 15.94, 16.05, 16.53, 16.84 (C_{sec}), 23.61 (C_{tert}), 24.53, 24.96, 25.07, 25.16, 27.48, 28.57, 29.15, 29.42 (C_{sec}), 48.27, 51.62 (C_{quart}), 51.78 (C_{prim}), 53.87, 54.40, 55.39, 173.68 (C_{quart}); **8** (20 MHz, $CDCl_3$): δ = 14.01, 15.40, 15.64, 16.08, 16.47, 24.15, 24.32, 24.95, 25.29, 25.51, 27.95, 28.24, 29.22, 29.65, 41.73, 51.95, 53.12, 54.55, 55.58, 63.22; **9** (20 MHz, $CDCl_3$): δ = 14.87, 15.54, 15.76, 16.29, 18.84, 24.37, 24.63, 24.86, 24.97, 27.19, 28.66, 28.71, 32.07, (C_{sec}), 35.03 (C_{tert}), 51.33, 51.75, 53.67, 54.23, 54.99 (C_{quart}), 200.68 (C_{tert}); **11** (50.3 MHz, $DCDl_3$): δ = 16.36, 16.83, 26.62, 26.72, 27.57, 28.27, 36.40 (C_{sec}), 53.47, 54.74, 64.74 (C_{quart}), 136.30, 141.50 (C_{tert}); **15** (20 MHz, $CDCl_3$): δ = 11.90, 15.65, 16.25, 16.43, 16.51, 16.75, 18.80, 25.27, 25,34, 25.38, 25.88, 26.34, 26.56, 27.89, 28.61, (coincidence of two lines), 28.77, 34.06, 47.95, 49.16, 49.78, 50.72, 51.16, 51.90, 173.39; **15'** (20 MHz, $CDCl_3$): δ = 9.16, 16.18, 16.30, 16.49, 16.77, 16.80, 25.11, 25.33 (coincidence of two lines), 26.00, 26.15, 26.34, 27.20 (coincidence of two lines), 28.75 (coincidence of two lines), 31.27, 36.68, 49.41, 50.02, 50.23, 50.39, 50.59, 51.55, 174.14; **16** (20 MHz, $CDCl_3$): δ = 11.15, 15.29, 16.54 (coincidence of three lines), 16.83 (C_{sec}), 18.53 (C_{tert}), 25.22, 25.47, 25.62, 25.67, 26.50, 28.00, 28.27, 28.76, 28.92, 29.00, 29.62 (C_{sec}), 47.47, 49.17, 49.77, 50.61, 51.28, 61.37 (C_{quart}); **17** (20 MHz, $CDCl_3$): δ = 14.52, 15.41, 16.10, 16.43 (coincidence of two lines), 16.57, 25.09, 25.31 (coincidence of two lines), 26.01, 27.00, 27.87, 28.66, 29.01 (coincidence of two lines), 29.16 (C_{sec}), 29.52 (C_{tert}), 40.62, 48.13, 48.93, 50.29, 50.79, 51.20 (C_{quart}), 201.59 (C_{tert}); **19** (20 MHz, $CDCl_3$): δ = 16.10, 16.46, 16.57, 24.91, 25.16, 26.96, 27.15, 27.88, 28.03, 35.22, 47.99, 49.25, 49.69, 57.45, 135.39, 140.91; **21** (**22**, 20 MHz, $CDCl_3$): δ = 9.80, 18.86, 23.92, 25.23, 28.07, 31.31, 33.32, 33.92, 34.39, 35.55, 35.87, 37.36, 37.59, 37.99, 54.30, 58.01, 59.44, 63.75, 64.14, 200.85; **22** (**21**, 20 MHz, $CDCl_3$): δ = 18.74, 19.28, 25.57, 27.00, 27.87, 30.61 (C_{sec}), 30.95 (C_{tert}), 33.37, 33.92, 34.24, 34.41, 35.90, 37.40, 37.78 (C_{sec}), 51.00, 56.37, 58.86, 62.98, 65.09 (C_{quart}), 200.81 (C_{tert}); **23** (50.3 MHz, $CDCl_3$): δ = 9.07, 19.00 (C_{sec}), 21.54 (C_{prim}), 23.73, 25.40 (C_{sec}), 26.87 (C_{tert}), 28.22, 31.28, 33.26, 33.88, 33.93, 34.18, 36.02, 37.18, 38.07 (C_{sec}), 48.45, 57.61, 58.96, 63.51, 64.28 (C_{quart}), 127.98, 129.55 (C_{tert}), 135.22, 143.89 (C_{quart}), 154.10 (C_{tert}).

[7] We have already observed conformational isomers on several occasions in the case of comparable structures. The stereochemical assignment is tentative and assumes that methoxycarbonylcarbene is preferentially transferred equatorially. A direct domonstration in the form of a crystal structure analysis of **15'**, **15** or one of its secondary products (**16**, **17**) is still lacking [14].

[8] A. J. Mancuso, D. Swen, *Synthesis 1981*, 165. **9** and **17** were used as crude products and contained small amounts or triethylamine. Upon attempting a chromatographic purification on silica gel in dichloromethane **9** rearranged to a mixture of the aldehydes **21** (**22**) m.p. 202–212 °C, 55% [6] and **22** (**21**) m.p. 188–198 °C, 29% [6].



21(22) **22(21)**

[9] The successful conversion of cyclopropanecarboxaldehyde with tosyl hydrazide in aqueous methanol [K. B. Wiberg, J. M. Lavanish, *J. Am. Chem. Soc. 88* (1966) 5272] led in the case of **9** to a tosyl hydrazone **23** (m.p. 40–50 °C, 87%) derived from **21** or **22** [6].

[10] ^{2}H NMR (30.7 HMz, $CDCl_3$): δ = 1.70 (s, br, 1D), 2.52 (s, br, 1D).

[11] Crystal structure analysis of **4** ($C_{24}H_{36}$): space group $P\bar{1}$, a = 775.5(2), b = 807.0(2), c = 827.8(2) pm, α = 69.030(10), β = 74.14(3), γ = 76.130(10)°, V = 0.4595(2) nm^3, Z = 1, ρ_{calcd} = 1.173 g cm^{-3}, $\mu(Mo_{K\alpha})$ = 0.061 mm^{-1}. Of 1201 independently measured reflections 999 with $|F| > 3\sigma(F)$ were taken into account for the structure solution and refinement. The anisotropic refinement with inclusion of the hydrogen atoms converged with R = 0.036. Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information, W-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-54863, the names of the authors and the journal citation.

[12] The ^{1}H- and ^{13}C-NMR spectra of all ^{13}C-labeled compounds are consistent with the given structures. The degree of labeling is in each case 99% and follows from the degree of labeling of the ([^{13}C]methyl)triphenylphosphonium iodide (99%, ^{13}C) used for the methylenation of **14**.

[13] ^{13}C NMR (126 MHz, 1,3-di-([D_3]methoxy)benzene, 1,3-di-([D_3]methoxy)-benzene int.) [1-^{13}C]-**4'**: δ = 26.01; [1-^{13}C]-**4**: δ = 28.82. As reference we used the heptet of the methoxy groups of 1,3-di-([D_3]methoxy)benzene [$\delta_C(CDCl_3)$ = 54.05].

[14] *Note added in proof (February 18, 1991):* According to a crystal structure analysis of **15'** the stereochemical assignment is correct.

Synthesis and Structure of a *rac*-Tris(divinyldisiloxane)diplatinum(0) Complex and its Reaction with Maleic Anhydride**

By *Peter B. Hitchcock, Michael F. Lappert,** and *Nicholas J. W. Warhurst*

Speier's catalyst (hexachlorplatinic acid) is widely used in the commercially important hydrosilylation of unsaturated substrates such as alkenes.[1] A useful form of $H_2[PtCl_6].xH_2O$, Karstedt's solution, is obtained by treating it with a vinylsiloxane.[2] The catalytic hydrosilylation cycle was generally assumed to be initiated by a platinum(0) species. This was originally believed to have been formed by an $HSiX_3$-induced reduction of hexachloroplatinic acid.[1] Recently, however, it was shown that $H_2[PtCl_6].xH_2O$ and an excess of *sym*-tetramethyldivinyldisiloxane, $(H_2C{=}CHSiMe_2)_2O$, afforded a catalytically active solution, solution A, which, largely on the basis of its reaction with $PtBu_3$ to form the X-ray characterized com-

[**] We thank Johnson Matthey PLC for a loan of Pt, S: E. R. C. and Dow Corning PLC (Barry) for a C. A. S. E. award to *N. J. W. W.*, Dr. *P. Y. Lo* and Dr. *R. G. Taylor* for useful discussions, and Dr. *A. G. Avent* for NMR data.

plex $[Pt\{(\eta\text{-}H_2C=CHSiMe_2)_2O\}(PtBu_3)]$, was thought to be a platinum(0) complex.[3] Furthermore, solution A in C_6D_6 showed NMR features similar to those found for the product obtained from the reaction of $[Pt(cod)_2]$ with $(H_2C=CHSiMe_2)_2O$ (cod = cycloocta-1,5-diene) in toluene. It was concluded that solution A contained preponderantly compounds of the type **A**.

$[Pt\{\eta\text{-}H_2C=CHSiMe_2O(SiMe_2O)_x(SiMe_2CH=CH_2\eta)\}_y]$ **A**

$x = 0-14$ (usually = 0), $y = 2-4$ (usually 2)

We now report that reaction of $[Pt(cod)_2]$ with 3/2 tetramethyldivinyldisiloxane in diethyl ether affords colorless crystals of the complex *rac*-**1**, whose structure was established ultimately by X-ray crystallography (Fig. 1). Detailed multinuclear NMR spectroscopic studies of complex **1** showed that in [D$_8$]toluene it was converted into a mixture of isomers, probably principally the *rac*- and *meso*-form (vide infra) of **1**; thus, at ambient temperature there were two somewhat broad $^{195}Pt\{^1H\}$ signals separated by ca. 20 Hz centered at $\delta = -6151$ (rel. to $K_2[PtCl_6]$) of roughly similar intensity, and four $^{29}Si\{^1H\}$ signals at $\delta = 3.45$ and 2.63 (chelating ligand) and $\delta = 0.18$ and 0.17 (bridging ligand) (rel. to TMS).[4] (At lower temperatures, there is NMR evidence for the existence of fluxional processes.) Furthermore, this [D$_8$]toluene solution of **1** was essentially identical to that of solution A in C_6D_6; and similar products were obtained as with $[Pt(cod)_2]$ upon reaction of $(H_2C=CHSiMe_2)_2O$ with the platinum complexes **5**–**7** (Scheme 1) and most conveniently from **7**.

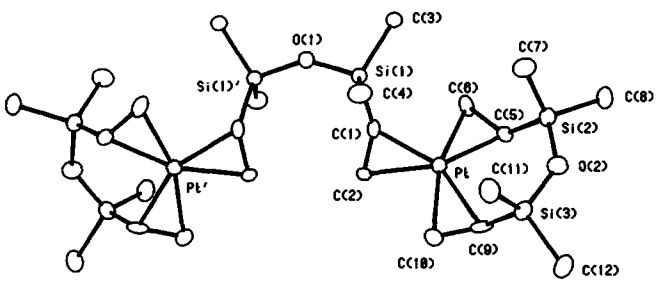

Fig. 1. Crystal structure of *rac*-**1**. Selected bond lengths [Å] and angles [°]: Pt-C(1) 2.19(2), Pt-C(2) 2.18(2), Pt-C(5) 2.19(2), Pt-C(6) 2.16(2), Pt-C(9) 2.21(2), Pt-C(10) 2.19(2), C(1)-C(2) 1.36(2), C(5)-C(6) 1.43(2), C(9)-C(10) 1.39(3), Si(1)-O(1) 1.645(7), Si(2)-O(2) 1.607(11), Si(3)-O(2) 1.631(13); C(1)-Pt-C(2) 36.4(6), C(5)-Pt-C(6) 38.3(6), C(9)-Pt-C(10) 37.0(7), Si(1)-O(1)-Si(1)' 146(1), Si(2)-O(2)-Si(3) 134.7(8).

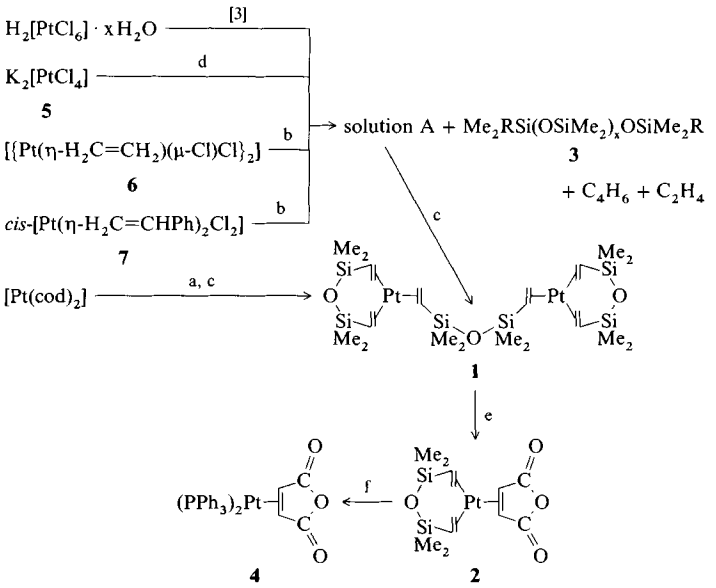
In the crystalline state complex **1** is relatively air-stable at ambient temperature, but in solution or as an oil it is somewhat thermally, photochemically, and aerobically sensitive, tending then to deposit platinum.

The siloxane by-products obtained by reaction of $(H_2C=CHSiMe_2)_2O$ with either $H_2[PtCl_6].xH_2O$[3] or **7** and subsequent aqueous washing were identical (GC/MS) and comprised the oligosiloxanes **3** (Scheme 1). Evidently a similar mechanism operates in the reduction of both a Pt^{IV}- and a Pt^{II}-chloride precursor to the Pt^0 complex **1**; this aspect is under further investigation, as are variable temperature NMR studies of **1** in [D$_8$]toluene.

The structure of *rac*-**1** (Fig. 1[5]) in the crystal revealed that the divinyldisiloxane ligand is present in both a bridging and chelating mode (cf. the cod ligand in $[Pt(cod)_2]$.[6] The term *rac* describes the relative configuration of the α-carbon atoms C(1) and C(1)′ of the bridging divinyldisiloxane ligand. **1** has a C_2 axis through the oxygen atom on the bridging divinyldisiloxane and the midpoint between the two platinum centers. The three vinyl groups are in a trigonal planar geometry about each Pt, with a deviation of less than 0.120(5) Å from the plane. Such an arrangement is similar to that observed for the tris(alkene)platinum(0) complexes $[Pt(\eta\text{-}H_2C=CH_2)_3]$[7] and $[Pt(\eta\text{-}C_7H_{10})_3]$ (C_7H_{10} = bicyclo-(2.2.1)heptene).[8] The mean C=C bond distances [1.39(3) Å] and Pt-C [2.19(2) Å] are unexceptional (cf.[7] $[Pt(\eta\text{-}H_2C=CH_2)_3]$ has C=C 1.402(7) Å and Pt–C 2.176(2) Å). The Si–O–Si angle of the chelating divinyldisiloxane [134.7(8)°] in complex **1** is smaller than that of the bridging ligand [146(1)°], and the chelating ligand is in a chair conformation around the platinum center.



Schema 1. Synthesis of *rac*-**1** and its conversion with maleic anhydride into complexes **2** and **4**, and routes to the catalytically active solution A. In the case of **3**: $x = 0-8$ (usually 0), mostly R = H_2C = CH, sometimes R = Et, seldom R = CH_2CH_2Cl[3]. Reagents and conditions: a) 3/2 $(H_2C=CHSiMe_2)_2O$, Et_2O, 25 °C, 2 h; b) 5 $(H_2C=CHSiMe_2)_2O$, toluene, 50 °C, 4 h; c) removal of excess $(H_2C=CHSiMe_2)_2O$, crystallization from EtOH/Et_2O at 30 °C; d) 5 (H_2C = $CHSiMe_2)_2O$ (560 mg), H_2O (1 mL), toluene (10 mL), 50 °C; e) maleic anhydride, toluene, 50 °C, 4 min; f) 2 PPh_3, tetrahydrofuran, 25 °C, 30 min.

If we assume that in solution the chelated disiloxane always has the "chair" conformation as in the crystal, then atoms C(5) and C(9) must have the opposite configuration, i.e. (*R*,*S*) or (*S*,*R*). If we further assume that there is free rotation about the Pt to C(1)–C(2) vinyl bond, which is rapid on the NMR time scale, then the two atoms C(5) and C(9) become equivalent and there is only one isomeric form of the coordinated chelating disiloxane. One is then left with the question of the configuration at C(1) and C(1)′, each of which can be either (*R*) or (*S*), giving rise to two possible isomers (*R*,*R*)/(*S*,S) (*rac*) or (*R*,*S*) (*meso*).

Reaction of complex 1 with maleic anhydride yielded **2**.[9] Treatment of complex **2** with PPh_3 led to displacement of the divinyldisiloxane, in preference to the maleic anhydride ligand, to form the known complex **4**[10] (Scheme 1).

Experimental Procedure

1: $[Pt(cod)_2]$ (400 mg, 0.97 mmol) was added slowly (50 mg portions) to a rapidly stirred solution of $(H_2C=CHSiMe_2)_2O$ (0.30 mL, 270 mg, 1.46 mmol) in diethyl ether (10 mL) at 25 °C. After ca. 2 h the volatile components were removed in vacuo to leave a colorless oil, which was dissolved in diethyl ether (5 mL) and transferred via a cannula onto a small Florisil column (1.5 × 2.5 cm) and washed with diethyl ether (2 × 10 mL). The solvent was removed from the eluant in vacuo to leave a pale white oil, from which the white solid **1** (380 mg, 0.40 mmol, 84 %) was obtained after ca. 50 h at 25 °C. Crystals suitable enough

for an X-ray structure analysis were obtained by dissolving the white solid in a mixture of ethanol/diethyl ether and cooling the solution to −30 °C for ca. 24 h.

[4] Complex **1** in [D$_8$]toluene (or + 10% toluene for ^{195}Pt-NMR spectrum) solution was characterized by $^{195}Pt\{^1H\}$, $^{29}Si\{^1H\}$, $^{13}C\{^1H\}$, ^1H, and 2D ^1H-^1H COSY NMR spectroscopy [this enabled a correlation to be made of the coupling between the adjacent protons on each of the vinyl groups; there are three distinct vinyl groups coordinated to each Pt center, $^2J(^1H$-$^{195}Pt)$ ca. 55 Hz] [11]. The $^{13}C\{^1H\}$-NMR data showed (DEPT) the presence of three methine (δ = 58.1, 56.4, 57.3) and three methylene (δ = 57.0, 57.2, 56.4) vinylic carbon atoms, each with coupling constants $^1J(^{13}C$-$^{195}Pt)$ of ca. 110 Hz. The assignment of the bridging/chelating vinylic protons was established by a sequence of decoupling and NOE experiments[11].

[5] Crystal data of **1**: $C_{24}H_{54}O_3Pt_2Si_6$, M = 949.4, monoclinic, space group $C2/c$, a = 29.810(5), b = 10.180(3), c = 12.527(2) Å, β = 107.64°, V = 3622.8 Å^3. Z = 4, ρ_{calcd} = 1.74 g cm^{-3}. The crystal data were collected on a CAD-4 diffractometer [$\mu(Mo_{K\alpha})$ = 80.1 cm^{-1}]. A total of 3330 unique reflections was measured for $2 < \theta < 25°$ and $+h + k \pm l$, and 1775 reflections with $|F^2| > 1.5\ \sigma(F^2)$ were used in the refinement where $\sigma(F^2) = \{\sigma^2(I) + 0.04(I)^2\}^{1/2}/L_p$. The structure was solved by routine heavy atom methods and refined by full matrix least squares. Hydrogen atoms were at fixed calculated positions with a common B_{iso} of 6.0 Å^2. The final residuals were R = 0.046, R' = 0.070. Further details of the crystal structure investigation are available on request from the Director of the Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW on quoting the full journal citation.

Bolaamphiphilic Polyols, a Novel Class of Amphotropic Liquid Crystals

By *Frank Hentrich, Carsten Tschierske,** and *Horst Zaschke*

Amphiphilic molecules can aggregate to supramolecular systems. An important form of this molecular self-organization is the formation of liquid crystalline phases.[1] Thus, amphiphilic *n*-alkane-1,2-diols **1**, with a chain length of n ≧ 5, exhibit monotropic mesophases which are stabilizable by addition of water.[2] These compounds are structurally related with liquid crystalline carbohydrate derivatives[3] and can be regarded as the simplest members of this large

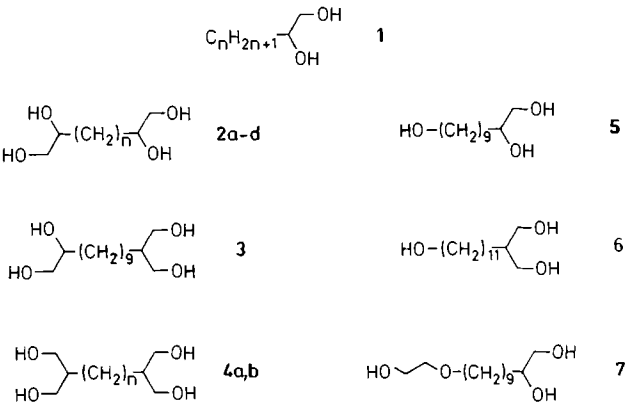

Scheme 1. n = 18 (**2a** [4]), 12 (**4b**), 9 (**2b**, **4a**), 5 (**2c**), 4 (**2d**).

class of amphiphilic mesogens. As recently reported, liquid crystalline phases are drastically stabilized by the coupling of two amphiphilic diols **1** (n = 9) via their hydrophobic molecular terminals to give the biamphiphilic (bolaamphiphilic) tetrol **2a**.[4]

We have now synthesized further bolaamphiphilic polyols with substantially shorter polymethylene chains and structurally different hydrophilic head groups,[5] in order to generalize this structural principle.[6] The liquid crystalline properties of the new substances **2**–**7** determined by polarization microscopic and differential scanning calorimetric (DSC) investigations are listed in Table 1. Surprisingly, even compound **2c**, with the very short pentamethylene spacer between ethane-1,2-diol groups, still has thermotropic liquid crystalline properties, although its hypothetical molecular halves (compound **1** with n = 2 and 3) do not display mesophases. Therefore, bolaamphiphilic polyols should not only be considered as simple, dimeric amphiphilic diols, but as an independent class of amphotropic mesogens.[13] The general validity of this structural concept is further supported by the variety of hydrophilic groups. Only in the case of compound **2d** and the symmetrical propane-1,3-diol derivatives were no mesophases detectable. The isotropic melts of compounds **4** are only very slightly supercoolable, and possible metastable mesophases are not recognizable. All other compounds show only a slight tendency to crystallize (often only after several days), so that their monotropic mesophases are easily observable. As a comparison of compounds **2a**–**2d** shows, the clearing points increase drastically with increasing length of the polymethylene chain. Compound **2b** and the bolaamphiphilic triol **5** are liquid crystalline above the melting point. The unsymmetrical tetrol **3** has the greatest mesophase diversity. On cooling the isotropic melts the appearance of a birefringence is observed under the polarizing microscope at 84 °C with a fan-like texture typical for lamellar α-phases, which can be oriented homeotropically very easily by shearing. This points to a layer structure, whereby the individual molecules in the layers do not exhibit long-range order. The hydroxy groups should, like those of amphiphilic diols, be coupled via a dynamic network of cooperative hydrogen bridges to give tile-shaped aggregates, which are both separated as well as bound by the conformationally mobile (molten) polymethylene chains (L_α phase). On further cooling to 75 °C the texture changes and the viscosity increases considerably. Probably the transition to a more highly ordered mesophase with rigid parallel polymethylene chains (L_β) occurs at this point.[7, 8] Both phase transformations have unusually high phase-transition enthalpies. At 43 °C, a further phase transition of small enthalpy takes

place, which, however, cannot be observed in more detail as a result of the onsetting crystallization.

The liquid crystalline phases of bolaamphiphilic polyols can be modified by addition of water, whereby the mesophases of compounds with long polymethylene spacers (e.g. **2a** and **6**) are stabilized and those with shorter polymethylene chains are destabilized (Table 1). The mesophase destabilization is more pronounced the greater the ratio between hydrophilic and hydrophobic structural units (hydrophilic–hydrophobic balance). This can be interpreted as resulting from the effect of two counteracting influences: the incorporation of water molecules in the region of the head groups leads to a strengthening of the hydrogen bonding between the hydrophilic groups and stabilizes the mesophases. The hydration of the head groups, however, also forces the polymethylene chains apart. The resulting free space between the molecules can, only in the case of sufficiently long polymethylene chains, be filled through their additional motions. As a result, one observes in the case of water-saturated samples, the appearance of the L_α phase, and, in the case of short-chain compounds, a destabilization or complete suppression of liquid crystalline phases. Figure 1 illustrates the stepwise transition from the amphiphilic diol to the bolaamphiphilic polyol. On introduction of increasingly polar terminal substituents into the hydrophobic moiety of the molecule of amphiphilic diols,[9] the distinct orientation of the molecules in the double layers is lost, since these polar groups can be incorporated into the network of the intermolecular hydrogen bridges in ever increasing amount with increasing ability to participate in hydrogen bonding. If these terminal substituents function only as proton acceptors, then they break the hydrogen bridge network and thereby destabilize the associates. However, if this terminal group is both proton acceptor as well as proton donor, then it can be incorporated concurrently in the hydrogen-bridge network of the head groups and additionally stabilize the mesophase.

Table 1. Phase transition temperatures [a] T [°C] of the bolaamphiphilic polyols 2–7 [b]. The values in brackets refer to the enthalpies ΔH kJmol^{-1} [c].

Cpd.	n [d]	Water-free samples	Water-saturated samples

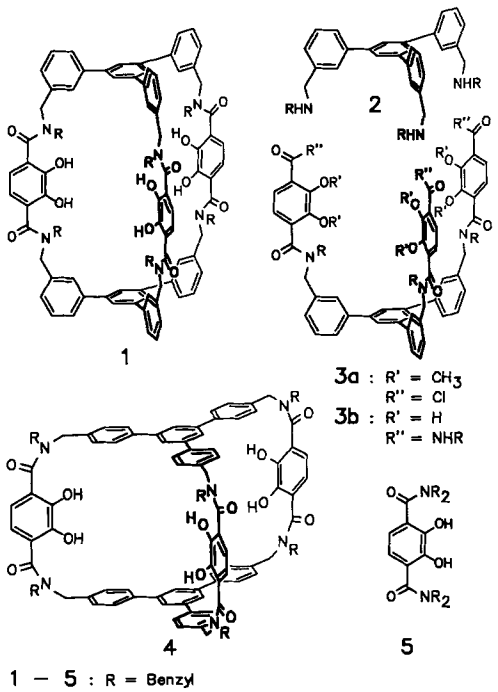
Molecular Recognition and Transport of Nucleobases — Superiority of Macrobicyclic Host Molecules**

By *Christian Seel* and *Fritz Vögtle**

Dedicated to Professor Heinz A. Staab on the occasion of his 65th birthday

A few years ago we reported on large cavity molecules, cage-like tris(catechol)[1] and tris(bipyridine) ligands,[2] which, through optimal preorganization of the binding centers, complex metal cations such as $Fe^{3\oplus}$[3] and $Ru^{2\oplus}$[4] extremely strongly. By means of a modular donor spacer strategy[5] we were able to obtain tris(bipyridine) host compounds with successively larger cavities which bind trihydrobenzenes selectively in organic solution.[6] Using the same strategy it was also possible to synthesize larger tris(catechol) hosts; due to their sparing solubility, however, so far all attempts to encapsulate organic molecules failed.[7] By increasing the lipophilicity with six *N*-benzyl groups we have now been able, with new cavity sizes, to selectively complex biological relevant guest compounds.

Reaction of the tricarboxylic acid chloride **3a** with the triamine **2** in chlorobenzene under dilution conditions[8] (cyclization yield 61%) and subsequent sixfold cleavage of the methoxy groups ($BBr_3 \cdot CH_2Cl_2$, 86% yield) yielded the macrobicyclic **1** in preparative amounts (2–3 g per run). **4** with all-*para*-substituted triphenylbenzene units was prepared analogously (yield 19% for the cyclization, 65% for the ether cleavage).[9]



In contrast to the above-mentioned tris(bipyridine) compounds (basic endoreceptors) the new macrobicycles, with their six phenolic hydroxy groups have pronounced proton-donor character (acidic endoreceptors); topologically complementary guest molecules with hydrogen bridge acceptor functionalities should therefore be readily bound. Whereas **4** dissolves in chloroform and dichloromethane only on addition of at least 10% methanol, **1** itself is sufficiently soluble to permit host–guest experiments even on addition of 25% *n*-hexane. This is remarkable when one considers that **1** is a hexahydroxy-hexaamide. Preliminary complexation experiments with strongly basic C_3-symmetrical compounds such as 1,3,5-tris(aminomethyl)benzene **6** led to saltlike solids of unknown composition. The non-benzylated macrocycles, with their symmetrical molecular frameworks, afforded well resolved and easily interpretable ^{1}H-NMR spectra with few signals, while the conformationally flexible benzyl groups on the amide nitrogen atoms of **1** and **4** led to strongly broadened, unclear multiplets. Consequently, the changes in the spectra observed in complexation experiments could not be interpreted precisely.[10]

When investigating the encapsulation of pyrimidine and purine bases and similar guest compounds[11] (less basic than **6**) we made use of the fact that they dissolve in acidic aqueous phases, whereas the lipophilic host **1**, however, just as sparingly so as the podand **3b** and the simple catechol derivative **5** used for comparison do not.[9] By extraction of the organic host-guest solutions with 1N hydrochloric acid, the complexation can be readily monitored UV spectroscopically. The sparing solubility of the guests in CH_2Cl_2 (mostly

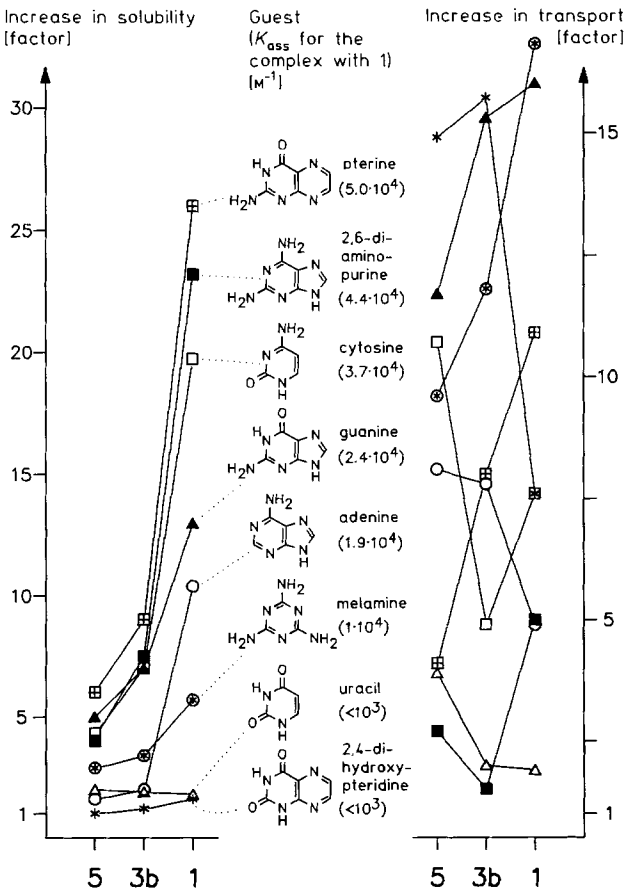


Fig. 1. Left: Enhancement factors of the solubility of the guests in CH_2Cl_2 at host concentrations of 5×10^{-4} M (in the case of **1** and **3b**) and 1.5×10^{-3} M (in the case of **5**). The data obtained were used for the calculation of the association constants of the complexes **1**. Right: Enhancement factors of the transport of the guests (solid) through CH_2Cl_2/*n*-hexane (3:1) in a 1N hydrochloric acid solution at host concentrations of 1×10^{-4} M (in the case of **1** and **3b**) and 3×10^{-4} M (in the case of **5**).

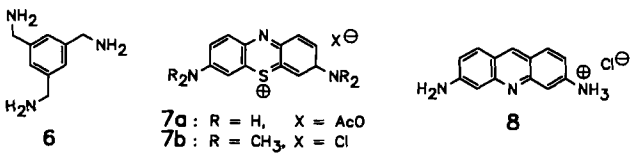
$< 10^{-5}$ M) is as a rule increased in the presence of the chatechol ligands but to very different extents.

Figure 1 (left) illustrates the superiority of the macrobicyclic host **1**, which in almost all cases affords by far the highest values.[12] The complexability of the podand **3b**, as anticipated, is nearer to that of **5** than that of **1**. This means that the number of binding centers alone is not crucial, but that the comparably rigid molecular structure has a decisive involvement (macrobicyclic effect). The linear dependence of the solubility of the guest compounds on the concentration of the host indicates a 1:1 stoichiometry in the case of complexes of **1**.[13] With other catechol compounds this is not so, therefore no complex constants can be quoted for these.

2,6-Diaminopurine is bound tighter than adenine. Apart from the stronger basicity the additional amino group seems to increase the degree of complementarity of host and guest. The association constants determined on the basis of the increase in solubility were $K_{ass} = 4.4 \times 10^{-4}$ and 1.9×10^{4} M^{-1}, respectively for the complexes of **1** with these two guests.[13] Also remarkable is the selectivity in the case of the cytosine/uracil and pterine/2,4-dihydroxypteridine pairs. They differ structurally only in that in each of the first (strongly bound) the amino group is replaced in the others by a hydroxy group. The correct harmonization of the pK_a and pK_b values respectively, of host and guest could be the decisive factor here for discrimination. The NH_2 groups are undoubtedly the better acceptors for the donor centers of the hosts.[14] In the case of the macrobicycle **1**, the strongly pronounced solution effects, the 1:1 stoichiometry, and the magnitude of the association constants justify the assumption that a guest molecule is encapsulated in the cavity and bound by multiple hydrogen bridges.

Particularly impressive are the extraction experiments with the phenothiazine dye thionine acetate **7a**, since they can be followed with the naked eye. A saturated dichloromethane solution is only weakly pink (λ_{max} = 581 nm), at a



concentration of **1** of 5×10^{-4} M, however, deep blue (λ_{max} = 614 nm, in methanol: λ_{max} = 599 nm; Table 1). The strong bathochromic shift of the absorption maximum likewise suggests an encapsulation of the ionic dyes **7a** and **8**. Their complexation is comparable with the solubilization of metal salts such as potassium permanganate by crown ethers in organic solvents.

Table 1. Some results of the complexation experiments with dye-guests (conditions as in Fig. 1).

Guest	Absorption maximum [nm] CH_2Cl_2	5[a]	1[b]	MeOH	HCL	K_{ass} [Guest · 1]
7a	581	589	614	599	601	61 000
8	442	442	456	456	450	17 000
	Increase in solubility by			Increase in transport by		
	5	**3b**	**1**	**5**	**3b**	**1**
7a	2.7	5.5	31.3	6.9	5.2	15.5
8	1.4	3.1	8.5	1.5	3.3	8.7

[a] 3×10^{-3} M solution of **5** in CH_2Cl_2, saturated with guest. [b] 1×10^{-3} M solution of **1** in CH_2Cl_2, saturated with guest.

The novel catechol compounds **1**, **3b** and **5** can also be used for the transport of the same guests through lipophilic phases. Owing to the low solubility of most purine and pyrimidine bases in water (pH 7) the well-proven liquid-liquid extraction (U-tube or coaxial tube) technique[5a, 13b, 15] could not be resorted to in this case. We therefore designed a simple apparatus, with which solid–liquid–liquid extractions can easily be carried out (Fig. 2). It consists of a dismountable glass tube; the guest is suspended as solid below an incorporated frit, which separates the organic phase (either pure solvent or a solution of one of the hosts). The frit prevents solid particles reaching the interface to the uppermost aqueous-acidic phase and thus to go into solution during the stirring. The host complexes the guest and transports it through the organic to the aqueous phase. The phase transfer of the complexed guest takes place there with dissociation of the supramolecular aggregates. Samples of the aqueous phase are taken at certain intervals of time and the change in guest concentration is monitored.

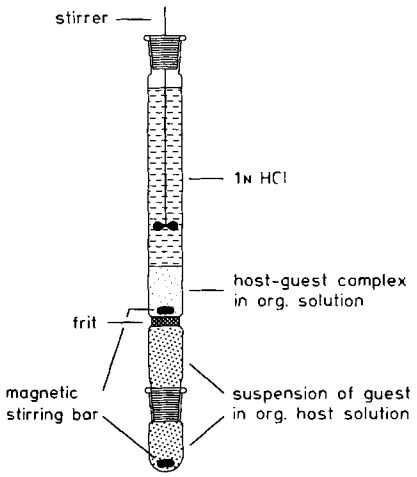


Fig. 2. Apparatus for the investigation of the transport of sparingly soluble guests through CH_2Cl_2/*n*-hexane (3:1) into an aqueous phase accelerated by the hosts.

Since relatively high transport rates can already be achieved in pure dichloromethane, we chose dichloromethane/*n*-hexane (3:1) as solvent. Even in this less polar solvent, purine and methylene blue **7b** are so readily soluble that the host has no noticeable influence on them.[16] In all other cases, significant, in part drastic, effects are recorded (Fig. 1, right). Thereby it must be remembered that, not only the thermodynamics and kinetics of the solution process play a role but also complexation and decomplexation; high complex stability and large increase in solubility do not necessarily mean therefore also rapid transport. Accordingly, the results also show no simple trend. For example, even the transport of such guests whose solubility is not substantially increased (e.g. 2,4-dihydroxypteridine) is accelerated by the hosts. This could be attributed to more rapid complexation/decomplexation. In some cases the macrocycle **1** affords, contrary to expectation,[17] the highest values; in this case the large increase in solubility seems to overcompensate the obvious slower decomplexation. The superior complexation of the cage host **1** justifies the higher synthetic effort compared to the acyclic compounds **3b** and **5**. The results of this work pose the question of whether the siderphores[18] containing catechol or hydroxamate units, which are important for the

transport of iron, play a role in the transport of purine and pyrimidine bases or nucleotides.

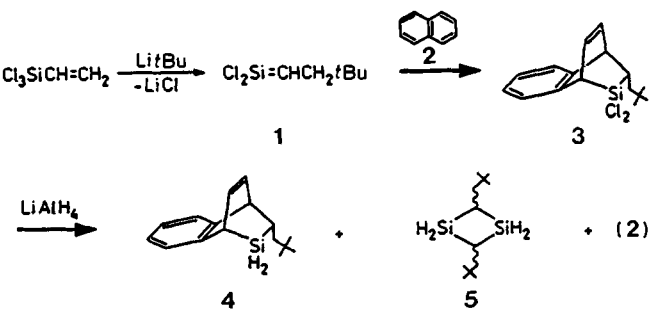
Novel Naphthalene- and Cyclohexa-1,3-diene–Silene Cycloadducts**

By *Norbert Auner,** *Claudia Seidenschwarz, Eberhardt Herdtweck,* and *Norbert Sewald*

Since the formulation of the Woodward-Hoffmann rules,[1] investigation of the mechanisms of cycloaddition reactions has constituted the central activity of numerous research groups.[2] This area of research has gained enormous impetus through the employment of more reactive heterodienophiles,[3] including recently Si=C-systems[4] and Si=Si-systems[4, 5]. Alongside the dimethylneopentylsilene $Me_2Si{=}CHCH_2tBu$ investigated by *Jones*[6] we now present a dichlorinated analog $Cl_2Si{=}CHCH_2tBu$ **1**, which exhibits a markedly different cycloaddition behavior; this can be attributed to the influence of the chlorine atoms on the position of the frontier orbitals and the magnitude of the orbital coefficients. The characteristic combination of higher dienophilicity and strongly dipolar Si=C character in the case of **1**[7] manifests itself in its different behavior towards naphthalene **2**, which has only slight diene qualities,[8] and cyclohexa-1,3-diene **6**, which finds frequent use as a [4 + 2]-trapping reagent for heterodienophiles.[9]

Reaction of $Cl_3SiCH{=}CH_2$ with an equimolar amount of Li*t*Bu and excess **2** at 0 °C leads (even in the dark) to formation of the thermally stable *endo* [4 + 2]-cycloadduct **3** in about 75% yield (GC integration of the product mixture), and can be isolated by sublimation at 10^{-2} mbar in ca. 40% yield. After recrystallization from *n*-pentane **3** precipitates in the form of colorless needles, which have been characterized analytically and NMR spectroscopically.[10]



Reduction of **3** with $LiAlH_4$ under mild conditions furnishes crystalline *endo*-**4**;[10] (*E*)/(*Z*)-isomeric 2,4-dineopentyl-1,3-disilacyclobutane **5**[11] and **2** are also formed. The colorless, slightly air-sensitive crystals of **4** are readily soluble in nonpolar solvents and were subjected to an X-ray structure analysis.[12] Thus, for the first time, it was possible to determine the structure of a [4 + 2]-cycloadduct of a silene with naphthalene. Characteristically, the molecule shows hardly any structural peculiarities compared to the [4 + 2]-cycloadduct of **1** and anthracene;[7] only the C3–C4 bond length (157.2(1) pm) is significantly longer than the mean value ($\bar{d}$ = 152.1 pm) of the other C–C single bonds. Due to the larger atomic radius of the Si atom the 2-silabicy-

[**] Silaheterocycles, Part 10. This work was supported by the Volkswagen-Stiftung, the Deutsche Forschungsgemeinschaft, and the Fonds der Chemischen Industrie.—Part 9: [11].

clo[2.2.2]octadiene parent compound is slightly distorted in comparison to the analogous carbon-compound.[13] The *endo* position of the neopentyl group to the ring skeleton in **4**[14] follows from the torsional angles C1-Si-C3-C13 [− 125.7(1)°] and C8-C4-C3-C13 [− 173.7(1)°].

Consistent with theoretical considerations,[15] the diene quality towards **1** increases in the series benzene → naphthalene → anthracene.[6, 14, 16] Formation of the thermodynamically unfavorable *endo*-product **3** suggests a concerted cycloaddition, especially since we could not trap any dipolar intermediates during the course of the reaction.

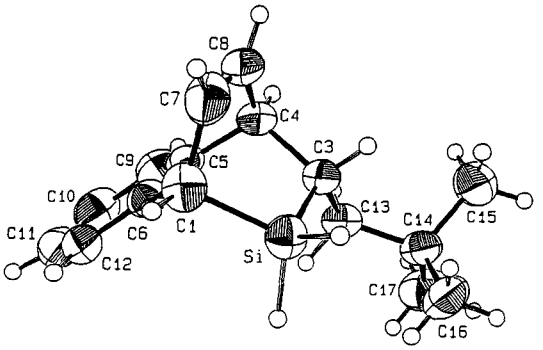

Fig. 1. Structure of **4** in the crystal (ORTEP at the 50% probability level, the hydrogens were given an arbitrary radius). Important bond lengths [pm] and angles [°]: Si–Cl 189.7(1), Si-C3 189.3(1), Si-H1 145.0(8), Si-H2 141.6(8), C3-C13 154.0(1), C13-C14 153.0(1), C3-C4 157.2(1), C4-C5 151.3(1), C5-C6 139.1(1), C1-C6 150.4(1), C1-C7 150.8(1), C7-C8 131.4(1), C4-C8 150.6(1); C1-Si-C3 100.29(4), Si-C3-C13 116.45(6), Si-C3-C4 105.87(6), Si-C1-C6 102.69(5), C6-C1-C7 109.84(8), C3-C4-C5 108.91(7), C3-C4-C8 107.70(8); C13-Si-C3-C1 − 125.7(1), C13-C3-C4-C8 − 173.7(1).

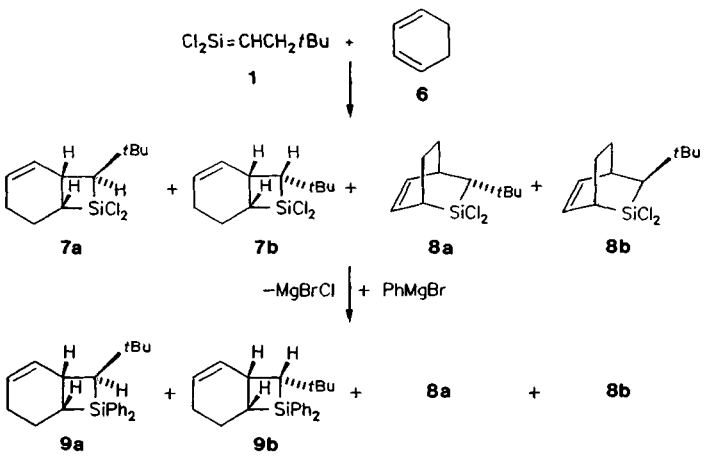
Even though **6** reacts mainly as a [4 + 2]-trapping reagent,[9] the [2 + 2]-addition is preferred in the cycloaddition of **1** with **6**. Thus, electrophilic attack of the silene at the diene leads mainly to regioselective formation of the stereoisomeric (*E*)/(*Z*)-silacyclobutane derivative **7**. Upon reaction of the product mixture (**7**/**8**) with phenyl-Grignard reagent only the Si atom in **7** is phenylated, probably on steric grounds. The cycloadducts **8** and **9** can therefore be separated from each other and be characterized by NMR spectroscopy (NMR data of **7** determined by difference spectrum).[10] **7** is obtained in 74% yield (isomeric ratio **7a**/**7b** 62/38) and **8** in 26% yield (**8a**/**8b** 63/37). Surprisingly, during storage (daylight, room temperature) the [2 + 2]-cycloadducts **7** transform completely within eight weeks into the thermodynamically more stable bicyclic 2-silaoctenes **8**, whose isomeric ratio remains unaltered; the silacyclobutanes **9**, on the other hand, are stable. Comparative studies on the [2 + 2]-cycloadducts **7** and **9** and on the reactivity of the diphenylneopentylsilene confirm that the unusual [2 + 2]-cycloaddition of **1** with **6** and the isomerization behavior of **7** are caused by the influence of the chlorine substituents. Dialkyl- and diaryl-substituted neopentylsilenes exhibit a markedly different cycloaddition behavior towards **6**.



Experimental procedure

3: A stirred mixture of 19 g (148 mmol) of **2** and 4.7 g (30 mmol) of H_2C=$CHSiCl_3$ in 600 mL of anhydrous benzene was treated slowly at 0 °C with 21.5 mL (30 mmol) of Li*t*Bu; this resulted in elimination of LiCl. After filtration and removal of the solvent by distillation, the oily solid residue was freed of excess **2** by sublimation (40 °C/10^{-2} mbar), whereby considerable amounts of **3** were lost. **3** was initially isolated as a highly viscous, colorless liquid (b.p. 65–70 °C/10^{-2} mbar); it subsequently crystallized in the receiver (m.p. 70 °C). Yield: 3.72 g, 12 mmol, 40%.

4: A suspension of $LiAlH_4$ (0.57 g, 15 mmol) in anhydrous Et_2O (40 mL) was treated dropwise at 0 °C with a solution of **3** (2.0 g, 6.5 mmol) in Et_2O (15 mL). After warming to room temperature the reaction mixture was filtered. Distillation of the solution yielded **4** and **5** at 50 °C/10^{-2} mbar, while **2** sublimed. After storage for 3 months at 20 °C, **4** crystallized (m.p. 60 °C) and was separated from **5**. Yields: **4**: 1.04 g (4.29 mmol), 66%; **5**: 0.25 g (1.1 mmol), 34%.

7: A mixture of 7.2 g (90 mmol) of **6** and 4.7 g (30 mmol) of H_2C=$CHSiCl_2$ in 500 mL of *n*-pentane was treated at −78 °C with 21.5 mL Li*t*Bu (30 mmol; 1.4 mmol/mL *n*-pentane). The stirred mixture was warmed to room temperature (LiCl precipitation at ca. − 5 °C), filtered, and the filtrate worked-up by distillation. **7** and **8** were isolated as colorless, viscous liquids (b.p. 60 °C/10^{-2} mbar). Yield 7.82 g, 29.8 mmol, 99.5%.

[12] P. Kiprof, E. Herdtweck, R. E. Schmidt, M. Birkhan, W. Massa: STRUX-III (Programmsystem zur Verarbeitung von Röntgendaten, Technische Universität München/Universität Marburg, 1989/1985). Compound **4** crystallizes from *n*-pentane as colorless rods, monoclinic space group $P2_1/c$. $a = 1502.9(1)$, $b = 860.4(1)$, $c = 1182.7(1)$ pm, $\beta = 106.80(2)°$, $V = 1464 \times 10^6$ pm^3, $C_{16}H_{22}Si$, $M = 242.4$, $Z = 4$, $F_{(000)} = 528$, $\varrho_{calcd} = 1.100$ g cm^{-3}; apparatus: Enraf-Nonius CAD-4, $Cu_{K\alpha}$ radiation ($\lambda = 154.184$ pm), graphite monochromator, $T = 21 \pm 1$ °C; range of measurement: $1.0° \leq \theta \leq 65.0$, $\theta/2\theta$ scan. 5604 measure reflections ($\pm h,k,l$, each at $\psi = 0°$ and 3°) were determined after LP correction and correction for a slight distortion (376 cancelled reflections and 278 with $I < 0$ were considered as unobserved). No absorption correction ($\mu = 12.0$ cm^{-1}). All 2425 independent reflections ($I > 0$) were refined with 243 parameters using full matrix least squares. $R = 0.043$, $R_w = 0.038$, GOF = 3.732 ($p = 0.00$) with $\omega = 1/\sigma^2(F_o)$. Solution of structure by direct methods and difference Fourier technique. Extinction effects ($\varepsilon = 0.1995 \times 10^{-5}$) were corrected. All hydrogen atom positions are successively taken from difference Fourier syntheses and refined with isotropic temperature factors. Anomalous dispersion is taken into account. After the last refinement cycle (shift/error < 0.00) the maximal/minimal residual electron density contributed + 0.19/− 0.29 e_o-/Å^3. Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, W-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-54651, the names of the authors, and the journal citation.

[13] To our knowledge no solid-state structure has been published for the parent compound bicyclo[2.2.2]octadiene. For a structural comparison see D. Döpp, C. Krüger, H. R. Memarian, Y.-H. Tercalicene and Quatercalicene

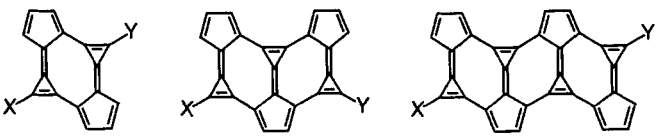
By *Toyonari Sugimoto,* Mitsuhiro Shibata, Akihiko Sakai, Hiroshi Ando, Yoshihisa Arai, Masashi Sakaguchi, Zen-ichi Yoshida,* Yasushi Kai,* Nobuko Kanehisa,* and *Nobutami Kasai**

In contrast to calicene,[1] which still remains a synthetic challenge, bicalicene **1a**, which is composed of two calicene units in a head-to-tail orientation, was already prepared by us a few years ago.[2] An X-ray structural analysis, ^{1}H- and ^{13}C-NMR spectra and theoretical calculations indicated that 2π (three-membered ring) and 6π (five-membered ring) electron conjugations, due to polarization of each calicene unit, significantly contribute to the electronic structure in the ground state.[3] This polarization could also be favored by the avoidance of an antiaromatic 16π electron conjugation in the periphery. In the next higher homologue, tercalicene **2a**, however, an aromatic 22 π electron conjugation could be present, whereas quatercalicene **3a** adopts a similar π electron conjugation mode to that of **1a** because of the presence of 28 π electrons in the periphery. We report here on the synthesis of **2a** and the 3, 10- and 3,17-bis(*tert*-butylthio) derivatives **2b** and **3b**, respectively, and discuss the possible electronic structures of **2a** and **3a** based on the molecular structure of **2b**, and the ^{1}H- and ^{13}C-NMR spectral data for **2a**, **2b** and **3b**.



1a: X=Y=H
1b: X=Y=S*t*Bu

2a: X=Y=H
2b: X=Y=S*t*Bu
2c: X=Y=Sn*n*Bu

3a: X=Y=H
3b: X=Y=S*t*Bu
3c: X=Y=Sn*n*Bu

2b and **3b** were synthesized from **1b** as shown in Scheme 1, and converted in a two-step process—distannylation and acid- or base-catalyzed hydrolysis—into **2a** and **3a**.

Thus, the 3,11-bis(*tert*-butylthio)derivative **1b**[2b] was allowed to react with lithium cyclopentadienide (20 equiv.) in THF at 0 °C to give the central intermediate **4** (yield 82%, Table 1). By successive reaction of **4** with lithium diisopropylamide (LDA) (2 equiv.) and 1,2-bis(*tert*-butylthio)-3,3-

dichlorocyclopropene[4] (1 equiv.) in THF at −78 °C, **2b** was obtained (11%). On the other hand, when **4** was treated successively with LDA (2 equiv.), the calicene derivative **5**[4] (1 equiv.) at −78 °C, and then with CH_3I (2 equiv.) at room temperature, the bis(bicalicene) **6** was formed (20%), which was converted into **3b** (48%) by refluxing in dry pyridine for 1 h. By reaction of **2b** and **3b** with tri-*n*-butyltin hydride (10 equiv.) and azobisisobutyronitrile (AIBN) (3 equiv.) in chlorobenzene,[5] the stannyl derivatives **2c** and **3c** were obtained (8 and 10%, respectively). Treatment of **2c** with an excess of acetic acid in methanol-benzene (1:1 v/v)[5] afforded **2a** (59%). Attempts to prepare **3a**, however, failed even though **3c** was allowed to react with acetic acid and sodium methoxide[8] under various conditions. Presumably, **3a** is extremely sensitive to both acids and bases.

An X-ray structure analysis of **2b**,[6, 7] showed that the crystal lattice contains two crystallographically independent molecules, which are characterized by the *syn* and *anti* positions of the two *tert*-butylthio substituents, (Fig. 1 shows *syn*-**2b**). Just as high planarity is observed in the skeletons of

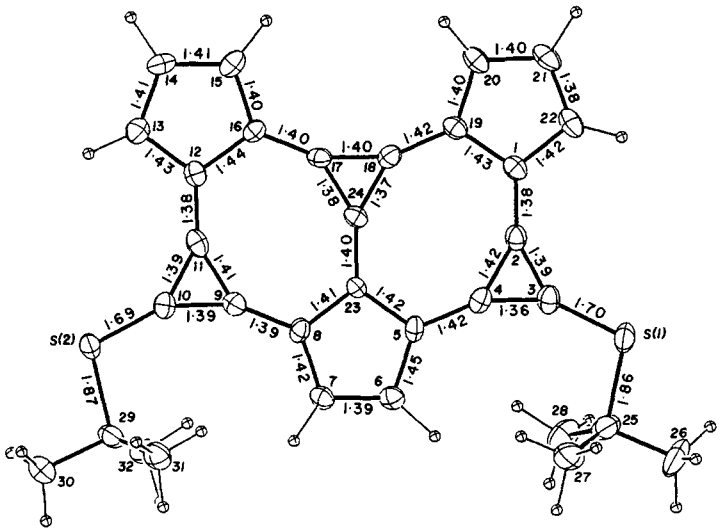

Fig. 1. Crystal structure of *syn*-**2b** with interatomic bond distances. Thermal ellipsoids for the non-hydrogen atoms are drawn at the 20% probability level while the hydrogen atoms are given by spheres with a temperature factor of 1.0 Å^2. The ESD values for bond distances are in the range of 0.009 and 0.019 Å.

1a and **1b**,[2, 3] the tercalicene skeleton in **2b** is also almost completely planar. With regard to the bond lengths, the following points are noteworthy: 1) the bridge bond of the inner calicene (C23–C24) is longer than those of the outer ones; 2) the C1–C19 and C12–C16 bonds are the longest in the five-membered rings of the outer calicenes; 3) the C2–C4 and C9–C11 bonds are equal to or longer than the other bonds in the three-membered rings of the outer calicenes; 4) the C6–C7 bond is the shortest in the five-membered ring of the inner calicene; and 5) the C17–C18 bond is longer than the other bonds in the three-membered ring of the inner calicene. The outer calicenes of **2b** have a very similar molecular structure as that of **1b**, while the inner calicene is markedly different.

The ^{1}H-NMR spectral data of **2a**, **2b** and **3b** are summarized (Table 1).[8] The chemical shifts (δ = 7.94, 7.06, 6.96, 6.39) of the protons of the outer calicene of **2a** resemble those (7.91, 7.11, 6.58) of **1a**. For the protons of the five-membered ring of the inner calicene the chemical shift (6.80) is intermediate between those of the down- and upfield shifted protons of the outer five-membered rings. The situation is similar upon comparing the chemical shifts of **1b**, **2b**, and **3b**. These results provide no significant evidence for diamagnetic and paramagnetic ring currents in the 22 π electron system **2a**[9] and in the 28 π electron system **3a**, just as there was no paramagnetic ring current induced in the peripheral 16 π electron system **1a**. The ^{13}C-NMR spectra of **2a** and **2b**[10] show the expected 13 signals. According to the chemical shifts of **1a** and **1b**,[11] there is no difference between **1** and the outer calicene **2**. The three carbons of the three-membered ring of the inner calicene have almost the same chemical shifts. In contrast, three carbons (C5, C8, and C23) are shifted upfield by 5–12 ppm compared with those of the remaining carbons. This result suggests preferential delocalization of a positive charge on the three-membered ring and preferential localization of a negative charge at the C5, C8 and C23 carbons of the five-membered ring.

Summarizing: as in **1a** the polarization of each calicene makes an important contribution to the electronic structures of **2a** and **3a**.[12] Furthermore, the degree of polarization is almost the same (ca. 50%) irrespective of the kind of calicene in **1a**, **2a** and **3a**, although the inner calicene in **2a** assumes a markedly different polarization structure from that of the outer one. The contribution of the mesomeric limiting structures shown in the formulas is also significant. Since the bridging bond of the inner calicene **2b** is longest a 16 π electron conjugation (as in **1a**) might describe **2b** better than a peripheral 22 π electron conjugation. This could also be val-

Table 1. Selected physical data of the compounds **2a**, **2b**, **2c**, **3b**, **3c**, **4**, and **6**[a].

2a: Dark brown crystals, m.p. 110–115 °C (dec.); IR: $\tilde{\nu}$[cm^{-1}] 2930, 1770, 1740, 1573, 1535, 1260, 1100, 1025, 800; UV: λ_{max} [nm] (log ε) = 251 (4.63), 290 (4.34), 345 (4.29), 382 (4.36), 435 (4.65), 522 (3.31), 574 (3.20), 662 (2.87), 730 (2.76); ^{1}H NMR: δ = 7.94 (s, 2H), 7.01 (dd, J = 3.5, 1.5 Hz, 2H), 6.96 (dd, J = 4.0, 1.5 Hz, 2H), 6.80 (s, 2H), 6.39 (dd, J = 4.0, 3.5 Hz, 2H); ^{13}C NMR: δ = 141.5, 131.9, 131.6, 126.0, 124.3, 120.4, 118.0, 114.5, 112.4, 109.3; FD-MS: m/z 298 ($M^{\oplus}$).

2b: Dark green crystals, m.p. 110–115 °C (dec); IR: $\tilde{\nu}$[cm^{-1}] 2970, 2940, 1565, 1535, 1265, 1100, 1020, 805; UV: λ_{max} [nm] (log ε) = 268 (4.57), 322 (4.42), 352 (4.36), 403 (4.42), 425 (4.47), 454 (4.68), 547 (3.30), 610 (3.47), ca. 760 (2.52); ^{1}H NMR: δ = 6.99 (dd, J = 3.4, 1.5 Hz, 2H), 6.90 (dd, J = 4.0, 1.5 Hz, 2H), 6.73 (s, 2H), 6.41 (dd, J = 4.0, 3.4 Hz, 2H), 1.72 (s, 18H); ^{13}C NMR: δ = 137.5, 134.8, 131.4, 131.3, 130.0, 129.5, 126.8, 124.4, 123.1, 119.0, 114.4, 111.2, 108.7, 48.4, 31.4; FD-MS: m/z 386 ($M^{\oplus}$).

2c: Dark brown semisolid; IR: $\tilde{\nu}$ [cm^{-1}] 2930, 1775, 1530, 1405, 1260, 1100; UV: λ_{max} [nm] (log ε) = 700 (2.94), 628 (3.06), 560 (3.38), 437 (4.72), 384 (4.49), 342 (4.48), 311 (4.43); ^{1}H NMR: δ = 7.10–6.96 (m, 4H), 6.83 (s, 2H), 6.50 (t, J = 3.6 Hz, 2H), 1.55–0.77 (m, 5H); FD-MS: m/z 878 ($M^{\oplus}$).

3b: Brown solid, m.p. 186–200 °C (dec); IR: $\tilde{\nu}$[cm^{-1}] 2900, 1795, 1510, 1450, 1385, 1365, 1265, 735; UV: λ_{max} [nm] (log ε) = 250 (4.58), 268 (4.55), 307 (4.40), 340 (sh, 4.43), 373 (4.46), 414 (4.36) 466 (4.44), 498 (4.78), 560 (sh, 3.88), 660 (3.67), 740 (sh, 3.18); ^{1}H NMR: δ = 6.97 (dd, J = 3.7, 1.2 Hz, 2H), 6.94 (dd, J = 3.7, 1.2 Hz, 2H), 6.81 (d, J = 4.0 Hz, 2H), 6.79 (d, J = 4.0 Hz, 2H), 6.46 (t, J = 3.7 Hz, 2H), 1.75 (s, 18H); MS: m/z 572 ($M^{\oplus}$).

3c: Dark brown semisolid; IR: $\tilde{\nu}$[cm^{-1}] 2958, 2925, 2852, 1770, 1716, 1552, 1516, 1468, 1402, 1365, 1329, 1261, 1088, 798, 742; ^{1}H NMR: δ = 7.15 (dd, J = 3.8, 1.5 Hz, 2H), 7.11 (dd, J = 3.8, 1.5 Hz, 2H), 6.97 (d, J = 4.1 Hz, 2H), 6.90 (d, J = 4.1 Hz, 2H), 6.61 (t, J = 3.8 Hz, 2H), 1.66–0.81 (m, 54H); FD-MS: m/z 976 ($M^{\oplus}$).

4: Reddish orange crystals, m.p. 197–199 °C; IR: $\tilde{\nu}$[cm^{-1}] 2900, 1820, 1557, 1340, 1068; UV: λ_{max} [nm] (log ε) = 252 (4.26), 338 (4.20), 403 (4.23), 520 (3.72); ^{1}H NMR: δ = 7.45 (m, 1H), 6.90 (d, 4H), 6.80 (m, 2H), 6.45 (t, 2H), 3.55 (br. s, 2H), 1.75 (s, 9H); MS: m/z 474 ($M^{\oplus}$).

5: Reddish purple crystals, m.p. 175-190 °C (dec); IR: $\tilde{\nu}$ = [cm^{-1}] 2940, 1805, 1545, 1340, 1255, 1090, 1065, 1020, 800; UV: λ_{max} [nm] (log ε) = 267 (4.49), 344 (4.46), 386 (4.31), 416 (sh, 4.20), 530 (4.05); ^{1}H NMR: δ = 7.05 (dd, 1H), 6.92 (m, 5H), 6.88 (d, 1H), 6.87 (d, 1H), 6.40 (t, 1H), 6.39 (t, 2H), 1.76 (s, 18H), 1.60 (s, 9H); MS: m/z 662 ($M^{\oplus}$).

[a] ^{1}H- and ^{13}C-NMR spectra at 400 and 100.6 MHz, respectively; solvent, $CDCl_3$. IR spectra: in KBr pellet. UV spectra: solvent, CH_2Cl_2.

id for the π electron conjugation mode of the covalent structure of **3a**.

[6] Single crystals of **2a** and **3b** have not been successfully prepared.
[7] Crystal data of **2b**: orthorhombic, space group *Pbca*, $a = 25.723(2)$, $b = 21.979(3)$, $c = 18.384(1)$ Å, $V = 10393.9(16)$ Å^3, $Z = 16$, $\rho_{calcd} = 1.213$ g cm^{-3}, $F(000) = 4000$, $\mu(Mo_{K\alpha}) = 19.4$ cm^{-1}. X-Ray diffraction data were measured on a Rigaku four-circle diffractometer using nickel-filtered $Cu_{K\alpha}$ radiation. A total of 6529 independent reflections were collected up to $2\theta = 110°$ by the $\theta - 2\theta$ scan technique. The intensity data were corrected for the usual Lorentz and polarization effects, but an absorption correction was not carried out. The structure was solved by direct methods (SHELXS-86) and refined by full-matrix least-squares using the 3477 observed reflections [$|F_o| > 3\sigma(F_o)$] to an R value of 0.084 and R_w value of 0.099 including non-hydrogen atoms with anisotropic thermal parameters and hydrogen atoms with isotropic ones, where $R = \Sigma(|F_o| - |F_c|)/\Sigma|F_o|$, $R_w = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{1/2}$, and the weighting scheme used was $w = [\sigma^2(F_o) + 0.003\,(F_o)^2]^{-1}$. The limited accuracy of the molecular structure may result from the rather weak diffraction intensity of the high angle reflections. Further details of the crystal structure investigation are available on request from the Director of the Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, GB-Cambridge, CB2 1EW (UK), on quoting the full journal citation.
[8] Measured in $CDCl_3$. **1a**: $\delta = 7.91$ (s, 2H), 7.11 (d, $J = 3.7$ Hz, 4H), 6.58 (t, $J = 3.7$ Hz, 2H); **1b**: $\delta = 6.87$ (d, $J = 3.8$ Hz, 4H), 6.40 (t, $J = 3.8$ Hz, 2H), 1.75 (s, 18H).
[9] For the outer protons of [22]annulene the signals appear at $\delta = 9.70$–8.50 (R. M. McQuilkin, B. W. Metcalf, F. Sondheimer, *Chem. Commun. 1971*, 338).
[10] Due to the poor solubility of **3b** a ^{13}C-NMR spectrum could not be measured.
[11] Measured in $CDCl_3$. **1a**: $\delta = 140.9$, 130.5, 124.7, 117.8, 110.2; **1b**: $\delta =$ 135.9, 128.2, 127.5, 123.0, 109.0, 48.0.
[12] This suggestion was supported by theoretical calculations (J. Aihara, *J. Am. Chem. Soc. 101* (1979) 5913; J. Aihara, T. Horikawa, *Bull. Chem. Soc. Jpn. 56* (1983) 1853). Of all the possible constituent rings, both inner and outer three- and five-membered rings have large resonance energies, while the values of peripheral 22- and 28-membered rings are negligibly small. The calculations also indicate that the percent resonance energies, representing a measure of stabilization of π electron systems, are still large (0.63 for **2a** and 0.57 for **3a**) in spite of being smaller than that of **1a** (0.87).

[{$Re_2Cl_4(dppm)_2$}$_2$(μ-TCNQ)], a Novel Charge Transfer Complex Derived from a Donor with a Metal-Metal Multiple Bond**

By *Stuart L. Bartley* and *Kim R. Dunbar**

The design of synthetic metals is a fertile area of research that continues to grow as new molecular-based materials are discovered. Many low-dimensional materials exhibit interesting optical and magnetic properties in addition to electrical conductivity.[1] The field of organic charge-transfer (CT) chemistry has been particularly well-investigated due to the discovery of highly conducting salts of tetrathiafulvalene (TTF) and tetramethyltetraselenafulvalene (TMTSF) with TCNQ.[2] Our interest focuses on the synthesis of new inorganic/organic charge-transfer solids comprised of multiply-bonded binuclear transition-metal complexes and organic donors or acceptors. There exists a wide variety of redox-active metal–metal bonded binuclear compounds whose properties may be easily tailored by subtle changes in the supporting ligand set.[3] To our knowledge, however, the reaction between the quadruply bonded [$Mo_2(C_{22}H_{22}N_4)_2$] (*Mo*≡*Mo*) and TCNE (tetracyanoethylene) represents the only example of the use of multiply-bonded systems in charge-transfer chemistry.[4] Herein we report the preparation, structure and properties of the novel paramagnetic donor-acceptor complex [{$Re_2Cl_4(dppm)_2$}$_2$ (μ-TCNQ)], **1** prepared from an electron-rich triply bonded metal complex.

The title compound was prepared by reaction of two equivalents of $Re_2Cl_4(dppm)_2$ ($E_{1/2(ox)} = +0.35$ volts vs Ag/AgCl) and one equivalent of TCNQ ($E_{1/2(red)} = +0.24$ V) under N_2 in THF or CH_2Cl_2. Black crystals of **1** were grown by slow diffusion of THF solutions of the starting materials at 0 °C. Bulk reactions carried out at room temperature proceeded through a kinetic intermediate before a stable product was obtained. Immediately upon mixing, the reaction solution turned an intense blue color which slowly converted to olive-green within 24 h.[5] An opaque green-brown solution formed within 48 h. Figure 1 shows the electronic spectrum of the reaction solution at various intervals in a 14 h period. The intense features in the near-infrared region of the spectrum are assigned to a metal→TCNQ charge-transfer band and a mixed-valence transition. The absorption in the high energy visible region ($\lambda_{max} = 420$ nm) is in accord with the $\pi \rightarrow \pi^*$ transition of a reduced TCNQ.[6]

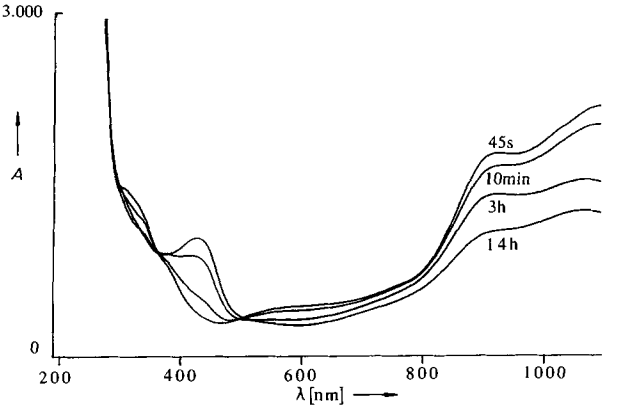

Fig. 1. Electronic spectrum of a 2:1 mixture of [$Re_2Cl_4(dppm)_2$] and TCNQ in CH_2Cl_2. A = absorption.

Infrared spectra were collected on dichloromethane solutions at various intervals starting with 1.5 min after mixing the reactants. The initial blue solution exhibits a sharp $\nu(C\equiv N)$ stretching vibration at 2195 cm^{-1} and an intense broad absorption at 2118 cm^{-1}. The position and number of $\nu(C\equiv N)$ bands indicates that the blue phase contains partially reduced TCNQ as well as TCNQ that is coordinated through at least one cyano group. The higher energy band is assigned to a free cyano moiety whereas the broad absorp-

Falvello* for help with the crystallographic refinement.

tion at 2118 cm^{-1} is attributed to a nitrile interaction. As points of reference, neutral TCNQ exhibits a single nitrile absorption located at 2221 cm^{-1} while the C≡N stretching vibration for $TCNQ^{\ominus}$ occurs at 2183 cm^{-1}.[7] During the next several hours of the reaction, the bands due to the blue species disappeared and two absorptions grew in which correspond to the final product. A Nujol mull sample of crystalline **1** shows a medium strong band at 2190 cm^{-1} and an intense band at 2109 cm^{-1}. Since the ν(C≡N) stretching frequency for the free CN group of **1** occurs at a value close to that found for fully reduced TCNQ (vide supra), we favor this assignment of the oxidation state for the *N*-bound TCNQ unit. The shifts of the metal-bound nitrile stretching vibrations to lower frequency relative to metal-free TCNQ are consistent with back-donation from the dirhenium molecules to *N*-bound TCNQ. These results suggest that an initial partial charge-transfer occurs to produce most likely a 1:1 kinetic product which undergoes further charge transfer and a structural change to form the 2:1 compound **1**. The olive-green "phase" is a physical mixture of the initial blue species and the final green-brown product.

The CT complex **1** exhibits a strong electronic transition centered at ca. 3000 cm^{-1} which extends well into the mid-infrared region. This feature is characteristic of CT phenomena and has been observed in many such complexes.[8] ESR spectra of **1** at − 160 °C (Fig. 2) indicate the presence of

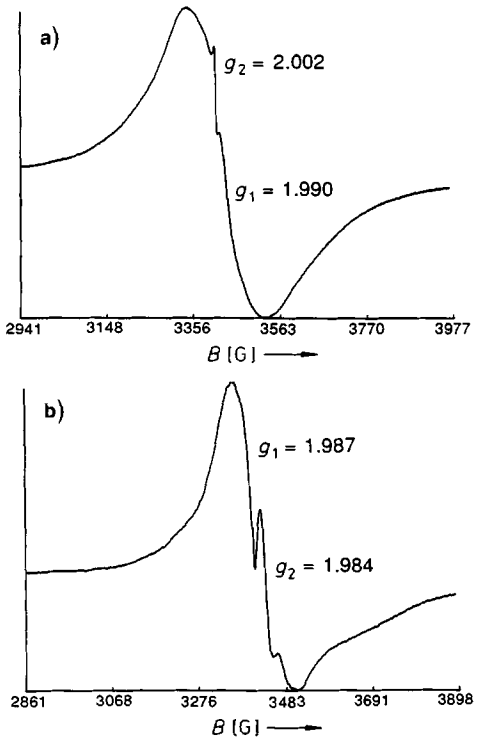

Fig. 2. ESR spectra of **1** at − 160 °C; (a) in the solid state and (b) in CH_2Cl_2 solution.

localized non-interacting spins on the Re_2 and TCNQ units. The solid sample exhibits a broad isotropic signal at $g_1 = 1.990$ and a sharp signal at $g_2 = 2.002$ whereas a CH_2Cl_2 solution shows the same features at $g_1 = 1.987$ and $g_2 = 1.984$.

A single crystal X-ray study of **1** confirmed its 2:1 formulation, and revealed the presence of a novel bridging bidentate mode for TCNQ.[9] The molecular structure of **1**, depicted in Figure 3, consists of two Re_2 units which are covalently linked through the *trans* cyanide groups of a bridging TCNQ molecule. The molecule is centrosymmetric, with the midpoint of the TCNQ moiety being situated on an inversion center. The coordination geometry of the two Re atoms within each dimer unit is different, with the nitrile-substituted metal center, Re(1), adopting an octahedral arrangement consisting of a terminal chloride, Cl(2), as well as an equatorial chloride, Cl(1), and a nitrogen ligand. Re(2) exhibits a trigonal bipyramidal structure similar to the parent complex $Re_2Cl_4(dppm)_2$. This structural type has been noted previously in a nitrile complex by *Walton* et al. who isolated the M_2L_9 cation complex $[Re_2Cl_3(dppm)_2(NCC_2H_5)_2](PF_6)$, in which a chloride ligand occupies an axial site.[10]

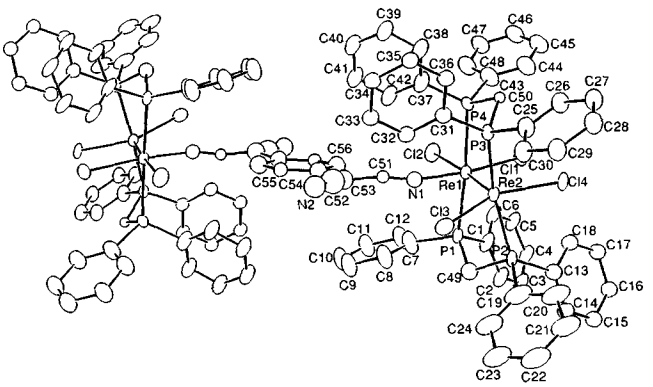

Fig. 3. ORTEP diagram of a molecule of $[Re_2Cl_4(dppm)_2]_2(\mu$-TCNQ) with 50% probability ellipsoids. Selected distances [Å] and angles [°]: Re1-Re2, 2.271(4); Re1-Cl1, 2.40(1); Re1-Cl2, 2.64(2); Re1-P1, 2.51(1); Re1-N1, 1.96(4); Re2-Cl3, 2.33(1); Re2-Cl4, 2.36(1); N1-C51, 1.11(6); N2-C52, 1.16(1); Re2-Re1-Cl1, 98.1(4); Re2-Re1-Cl2, 176.0(4); Re2-Re1-N1, 91(1); Cl1-Re1-N1, 169(1).

Distances and angles within the dirhenium unit are within the usual observed ranges for derivatives of $Re_2Cl_4(dppm)_2$.[11] A selection of important distances and angles in **1** is listed in the caption for Figure 3. Of special note is the Re–Re separation of 2.271(4) Å, which is longer than the distance of 2.234(3) Å found in the parent triply-bonded complex. In the absence of other considerations, one would predict a shorter metal–metal bond resulting from depopulation of an antibonding orbital upon oxidation (i.e. $\sigma^2\pi^4\delta^2\delta^{*2} \rightarrow \sigma^2\pi^4\delta^2\delta^{*1}$), but in the present system the application of an M_2L_8 bonding scheme is an oversimplification. The combined affect of structural changes and π-delocalization on the extent of Re–Re bonding must be taken into consideration. It is reasonable to argue, however, that a strong axial chloride interaction serves to weaken the σ-component of the metal–metal bond thus resulting in an overall lengthening of the Re–Re distance.

The structural characterization of a μ-TCNQ bonding mode is unprecedented to our knowledge. We found only two crystallographically determined examples of monodentate σ-bonded TCNQ or TCNE in the literature.[6] The existence of an η^4-TCNQ bonding mode was detected spectroscopically for TCNQ complexes of the unstable $[CpMn(CO)_2]$ fragment, but no solid-state structure was reported.[12] *Hünig* et al. have recently shown that *N,N'*-dicyanoquinonediimines (DCNQI's) interact with metal ions and organic donors through the nitrogen atoms of the CN groups.[13] Their results show great promise for the synthesis of highly conducting radical anion salts. As in the purely

organic systems, the conduction pathway is along the stacks of π-rings. An examination of the packing diagrams for the title compound revealed that our structure does not exhibit TCNQ–TCNQ interactions, since the separation of ca. 10 Å between the planar faces of TCNQ in adjacent molecules is far too large (Fig. 4).

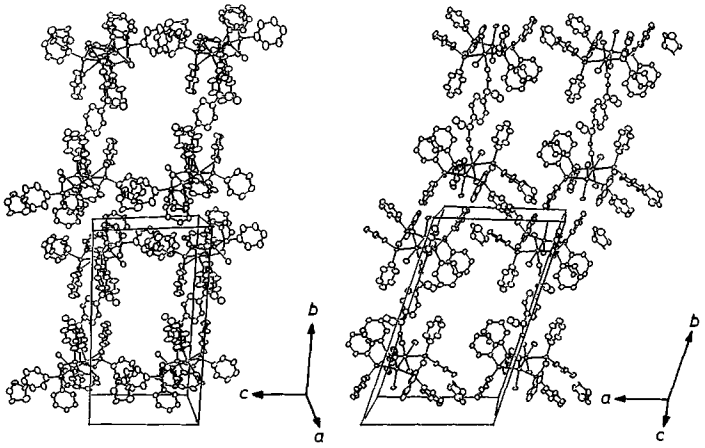

Fig. 4. Unit cell packing diagram of **1** viewed along the *c* and *a* axes.

According to preliminary magnetic measurements obtained between 2 and 300 K on a microcrystalline sample of **1**, the compound shows non-Curie-Weiss behavior with a constant increase in μ_{eff} up to ca. 5.0 B.M. at 300°K. This is surprising, as we would expect two unpaired spins based on the ESR spectra (vide supra); further studies to explain the magnetism are planned. Four-probe conductivity measurements performed on pressed pellets of both the initial blue product and the title compound, **1**, resulted in band gaps of 0.50 and 0.43 eV and room temperature conductivities of 3×10^{-7} and 1×10^{-5} S cm^{-1} respectively.

A final and interesting result in this work emerged from our studies of the reaction of $Re_2Cl_4(dppm)_2$ with TCNQ in the ratio 1:1. This ratio of donor:acceptor may lead to a polymeric phase with higher conductivity. Dichloromethane solutions of the 1:1 Re_2 complex/TCNQ reaction mixture produced a blue phase which turned black and deposited a highly reflective film upon evaporation. The physical properties of the film suggest that a polymerization reaction occurred to form an amorphous material. The electrical and magnetic properties of this film, as well as attempts to further elucidate the chemistry of various stoichiometries of $Re_2Cl_4(dppm)_2$ and TCNQ, are under further investigation.

Experimental Procedures

In a typical bulk reaction, 0.100 g of $Re_2Cl_4(dppm)_2$ (0.078 mmol) was stirred in 15 ml of THF together with 0.0080 g of TCNQ (0.039 mmol) at room temperature. The reaction solution immediately turned blue and within 4 h the color noticeably darkened in hue. The solution was stirred for 2 days, after which time the insoluble green-brown solid was collected, washed with THF, and dried in vacuo [yield 0.085 g, 77%]. A crystalline form of the product was obtained by slow diffusion of THF solutions of $Re_2Cl_4(dppm)_2$ and TCNQ. C,H,Cl analysis. The rod-like crystal contain two interstitial THF molecules which are easily removed by drying the crystals.

[9] Crystal data for **1** · 2THF at −100°C. $Re_4Cl_8P_8O_2N_4C_{120}H_{108}$, M_r = 2914.44, triclinic, space group $P\bar{1}$, a = 14.311(4), b = 23.25(7), c = 12.205(3) Å, α = 97.35(2), β = 103.75(2), γ = 72.73(2)°, V = 3761(2) Å^3, Z = 1, ϱ_{calcd} = 2.573 g cm^{-3}. Crystal dimensions 0.30 × 0.10 × 0.05 mm^3. The metal atoms were located by a Patterson Fourier synthesis. All remaining non-hydrogen atoms were obtained by the application of alternating least squares and difference Fourier syntheses. The crystal diffracted weakly, thus data were collected between 4 and 35° in 2θ. On the basis of the available data, the SHELEX program was used to refine phenyl groups as C_6H_5 rigid bodies with group anisotropic thermal parameters for the six carbon atoms and one parameter for the hydrogens. The P–C distances were fixed as were the distances in the TCNQ ring. The TCNQ atoms were refined isotropically. After this, the data-to-parameters ratio was 0.076. The structure converged with R and R_w values of 0.0715 and 0.0749 for 2073 observed reflections with $I > 3\sigma(I)$. Further details of the crystal structure investigation are available on request from the Director of the Cambridge Crystallographic Centre, University Chemical Laboratory, Lensfield Road, GB-Cambridge CB21EW(UK), on quoting the full journal citation.

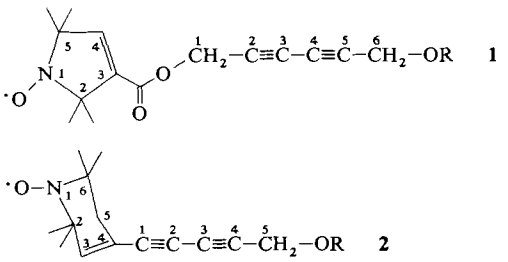
net, because prototype diacetylenes crystallize in a manner that enables topochemical polymerization.[1] Although several polymorphs have been identified, these diacetylenes did not crystallize with the -C≡C-C≡C-fragments parallel and close enough to each other to support the single crystal topochemical polymerization.[2] As part of our interest in molecular based ferromagnetic materials,[3] we have prepared 3-(6-hydroxyhexa-2,4-diynyloxycarbonyl)-2,2,5,5-tetramethyl-2,5-dihydropyrrolyl-1-oxide **1a** and 4-(5-hydroxypenta-1,3-diynyl)-2,2,6,6-tetramethyl-1,2,5,6-tetrahydropyridyl-1-oxide **2a** and their *p*-toluenesulphonates **1b** and **2b**, *p*-methoxybenzenesulphonates **1c** and **2c**, and *n*-butoxycarbonylmethylcarbamoyl derivatives **1d** and **2d**. In symmetrical diacetylenes with these substituents, as well as in the unsubstituted alcohols, topochemical polymerization readily occurs,[1] and it was hoped that the unsymmetrical derivatives of **1** and **2** would have the desired crystal packings. Unfortunately only the two alcohols crystallized. **1a–c** were obtained as pure oils; **2a–c** were unstable at room temperature resulting in poor analytical results.



1

2

a, R = H; **b**, R = OSO_2-*p*-$C_6H_4CH_3$; **c**, R = OSO_2-*p*-$C_6H_4OCH_3$; **d**, R = $CONHCH_2CO_2n$Bu

1a was synthesized by the condensation of 2,4-hexadiyne-1,6-diol with 3-carboxy-2,2,5,5-tetramethyl-2,5-dihydropyrrolyl-1-oxide[4a] and **2a** was prepared by the oxidative coupling of 4-ethynyl-2,2,6,6-tetramethyl-1,2,5,6-tetrahydropyridyl-1-oxide and propargyl alcohol.[4b] The derivatives were prepared by reacting **1a** and **2a** with the corresponding sulfonyl chlorides or with *n*-butyl isocyanatoacetate.

The structures of **1a**[5] and **2a**[6] were determined by X-ray diffraction. All bond distances are normal; the C≡C and CC-CC distances are 1.183 and 1.382 Å for **1a** and 1.191 and 1.396 Å for **2a**. In the solid **1a** packs as hydrogen bonded head-to-tail dimers with an NO ··· HO distance of 1.84(5) Å. These hydrogen bonds link the molecules into chains with aligned hexadiyne groups. However, the distance between the tails is relatively long and in the best case there are pairs where the distance is ca. 4.27 Å, so that topographical polymerization is not likely. The crystal structure of **2a** likewise shows strong head-to-tail hydrogen bonding [NO ··· O = 2.726(2) Å and NO ··· HO = 1.862(35) Å] which aligns the molecules in parallel sheets. The sheets are stacked with the tetrahydropyridyl rings shifted relative to adjacent sheets so that the center-to-center vector of the closest diacetylenic groups is 5.8 Å. The angle that each diacetylenic rod makes with this vector is 41.9°. *Baughman* and *Chance*[8] described as favorable conditions for topographical polymerization a vector length of between 4.4 and 5.4 Å and a diacetylenic rod–vector angle between 39 and 58°. Thus, even though the closest distance between end carbons of the two rods is only 3.90 Å, close enough for bond formation, the resulting displacements within the crystal packing would result in excessive lattice energy changes and preclude easy polymerization. In an attempt to induce topochemical polymerization,

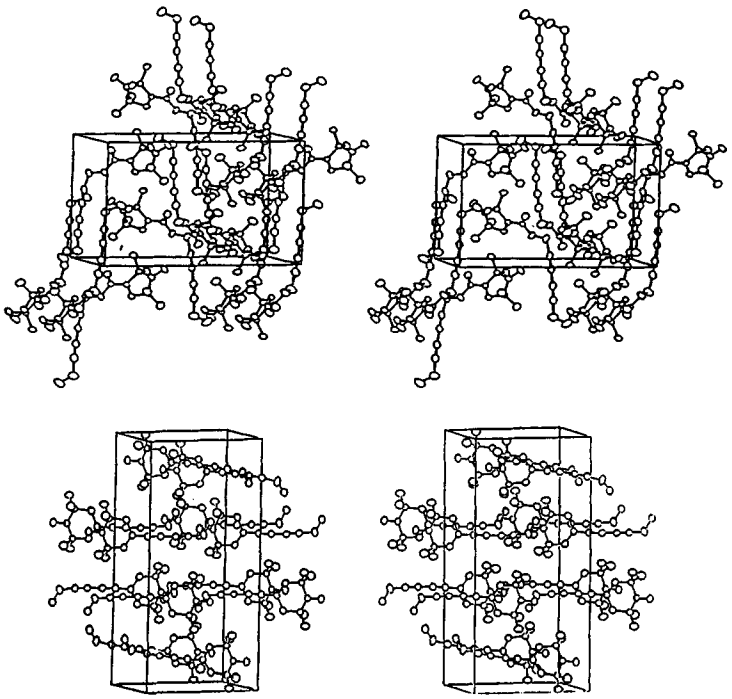


Fig.1. Top: stereoview of the unit cell of **1a**. Bottom: stereoview of the unit cell of **2a**.

both **1a** and **2a** were subjected to electron beam irradiation. As expected, no change in appearance or in the magnetic moment was noted for either compound.

The magnetic susceptibilities of **1a**, **1b**, **1c**, **1d**, and **2a** obey the Curie–Weiss expression, $\chi_M = C/(T-\theta)$, between 3 and 300 K with effective magnetic moments μ_{eff} ranging between 1.72 and 1.77 μ_B and θ between -0.26 and -5.77 K, consistent with one unpaired electron ($S = 1/2$) per molecule. **2b–d** slowly decomposed at room temperature resulting in poor elemental analyses and lower magnetic moments. The EPR spectra at 294 K of the solids **1a** and **2a** each consisted of a single line (at 2.011 with $\Delta H_{pp} = 15$ G and at 2.069 G with $\Delta H_{pp} = 32$ G, respectively). In deoxygenated toluene all compounds **1** and **2** exhibited the expected splitting to three lines centered at 2.011 G with $\Delta H = 14.5 \pm 1$ G.

Experimental Procedure

1: A solution of 3-carboxy-2,2,5,5-tetramethyl-2,5-dihydropyrrolyl-1-oxide and 2,4-hexadiyne-1,6-diol in THF was treated with dicyclohexylcarbodiimide in the presence of 4-dimethylaminopyridine as catalyst and stirred for ca. 15 h at 22 °C. The insoluble dicyclohexylurea was filtered off and the THF removed by distillation. The resulting mixture of the monoester **1a** and the corresponding diester was separated by chromatography on silica gel. Flash chromatography on silica (eluant petroleum ether/EtOAc, 3:2) gave pure **1a** (44%); hexane/EtOAc (4:1) was used for recrystallization.

2a: 4-Ethynyl-2,2,6,6-tetramethyl-1,2,5,6-tetrahydropyridyl-1-oxide and propargyl alcohol (1:4) was stirred in a methanol/pyridine solution (1:1) of cupric acetate for 3 hr at 22 °C. Dilution with water gave an insoluble coupling product from two moles of the tetrahydropyridyloxide. Extraction with ether, concentration, and removal of the pyridine by addition of 2 N NCl afforded crude product. Flash chromatography on silica gel (eluant, $CHCl_3$/EtOAc, 9:1) was used to separate more dimeric product and other impurities from **2a**. Recrystallization from hexane/EtOAc (4:1) gave pure **2a** (yield 35%).

The sulphonates of **1a** and **2a** were prepared by the slow addition of aqueous KOH to cold THF solutions of alcohol and sulphonyl chloride. The urethane

acetates of **1a** and **2a** were obtained by treatment with *n*-butyl isocyanatoacetate in THF for 24 hr at 0 °C with triethylamine catalyst. the reactions were worked up by diluting with water and extracting with ether. Purification was achieved by flash chromotography.

[4] a) **1a**: m.p. 105.5–106.5 °C. Correct elemental analysis (C,H,N); $MW_{calc.} = 276.31$; mass spectroscopy yielded a parent at *m/e* 276 ($M^{\oplus}$) and major peaks at 246 ($M^{\oplus} - CH_2O$) and 153. Thermal gravimetric analysis (TGA) and differential scanning calorimetry (DSC) (10° min^{-1}) showed no change until the 107 °C m.p., after which a mild exotherm preceded an endothermic weight loss of 8–9% over the range 160–190 °C. At 250–280 °C, more rapid decomposition started with a total weight loss of 50% by 350 °C. b) **2a**: mp 119.3–120.1 °C. **2a** is completely stable in the solid state, but darkens slowly and loses its free radical characteristics when dissolved in organic solvents. Correct elemental analysis (C,H,N); $MW_{calc.} = 232.30$; mass spectroscopy yielded a parent at *m/e* 232 ($M^{\oplus}$) and 202 ($M^{\oplus} - CH_2O$). TGA and DSC (10° min^{-1}) showed no change until the 117–121 °C mp, after which a sharp exotherm occurred. Small samples showed a slow weight loss of 3–5% up to 170 °C, where larger samples lost up to 60% of their weight already at 140 °C. This behavior reflects a weight loss owing to a sputtering of material out of the measuring cup.

BOOK REVIEWS

Book Reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the following address: Redaktion Angewandte Chemie, Postfach 101161, D-6940 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

Reviews in Computational Chemistry. Edited by *K. B. Lipkowitz* and *D. B. Boyd*. VCH Publishers, New York/VCH Verlagsgesellschaft, Weinheim 1990. xix, 419 pp., hardcover, DM 176.00.—ISBN 0-89573-754-X/3-527-27845-1

In the introduction to this book the editors try to arrive at a definition of "computational chemistry". According to the broadest of the definitions offered here, it includes all those areas of chemical research in which computers are used either to obtain results more quickly or to make the work possible at all. On this criterion there is nowadays scarcely a single area of chemical research that does not overlap with computational chemistry. The present volume is intended as the first of a series that will follow, by means of review articles, the development of every aspect of computational chemistry, including molecular modeling. It can be stated at the outset that the editors have succeeded here in presenting some excellent articles on topics of current interest in the field of computer applications in chemistry.

The first and last chapters in the book are both concerned with ab initio quantum chemistry. In the first of these, on "Basis Sets for Ab Initio Molecular Orbital Calculations and Intermolecular Interactions", *D. Feller* and *E. R. Davidson* describe basic principles and recent developments in this area; they include a section entitled "In-Depth Discussion", which well deserves this description. There is a useful table listing the polarization functions in common use, information which would be hard to find elsewhere.

In the second chapter *J. J. P. Stewart* discusses semiempirical methods. The rather bewildering array of methods originating from the *Dewar* school that have been developed in the last few years (MNDO, MNDOC, AM1, PM3, etc.) are described in chronological order. The theoretical fundamentals are only treated very briefly. The author justifies this by

referring to a recent review article on this topic by *W. Thiel*, commenting that to attempt to cover the same ground here would merely result in repetition—an admirable example of self-restraint! Although the account of the areas of application of the methods contains some slight inaccuracies—for example, it is wrongly stated on page 62 that for MINDO/3 no parameters for the P–O bond are available—these do not detract from the value of this fluently written article. The detailed survey, in the form of a table, of the average errors with the three main methods (MNDO, AM1 and PM3) for several classes of compounds is a very useful guide for the potential user.

In the third chapter ("Properties of Molecules by Direct Calculation") *C. E. Dykstra, J. D. Augspurger, B. Kirtman* and *D. J. Malik* address the question of which are the most suitable theoretical methods for directly calculating properties from the wave functions. They limit their discussion to the calculation of electrical, magnetic and optical properties, force constants and transition probabilities. The article is worth reading as an introduction and a concise account of the basic mathematics, but the discussion of the results, consisting of a mere nine pages, is too brief for such an extensive topic.

Four chapters are devoted to the subjects of molecular modeling and quantitative structure-activity relationships. This is appropriate and welcome in view of the rapid developments taking place in this area and the shortage of review articles. For this strongly applications-orientated area of computational chemistry it is also fitting that three of the four articles have been written by authors from industry. *D. B. Boyd* introduces this topic in Chapter 9 ("Aspects of Molecular Modeling"), where he discusses the usefulness of the different theoretical approaches from the viewpoint of the industrial chemist dealing with large molecules. The fact that molecular modeling is very far from being an "amateurish, watered-down, or incidental computational chemistry" (p. 321) is made clear by *E. L. Plummer* in Chapter 4 ("The Application of Quantitative Design Strategies in Pesticide Discovery"). This detailed article (49 pages) describes the application of theoretical aids, especially statistical methods, to synthetic and analytical strategies in the search for new pesticides compatible with present-day restrictions (ecological requirements). It has been known for some time that in order to realistically model the properties of large molecules one must take into account their dynamic behavior. The development of the three main approaches, namely Monte Carlo methods, molecular dynamics calculations, and the calculation of the free energy using perturbation theory, is sketched rather briefly (in 25 pages) by *T. P. Lybrand* in Chapter 8. The practical usefulness of computational chemistry is illustrated by *D. B. Boyd* in Chapter 9 by taking as examples four commercial compounds whose development depended crucially on computer-aided methods.

The importance to analytical chemistry of computers and of the multivariate analysis methods that are thereby possible is described in Chapter 5 ("Chemometrics and Multivariate Analysis in Analytical Chemistry", 43 pp.) by *P. C. Jurs*. This chapter too can be regarded as belonging to the area of molecular modeling in the wider sense, since the main emphasis is on applications concerning structure-activity relationships for biologically active substances.

The development of computer graphics, which allows one to quickly and conveniently display three-dimensional structures on the VDU screen, is of enormous significance for chemistry. The influence that this is having on the development of modern data banks, which allow one to rapidly test ideas about molecular structures using stored three-dimensional information, is described in Chapter 6 ("Searching Databases of Three-Dimensional Structures", 51 pp.) by *Y. C. Martin, M. G. Bures* and *P. Willet*. Whereas older data banks such as the Cambridge Structural Database are used essentially for storing data on atomic coordinates, the newer types of programs allow one to search for information about specific partial structures. References to available programs and information sources are included in this detailed report.

Advances in computer graphics have also contributed significantly to the development of concepts in which one is mainly interested in the molecular surface. In Chapter 7 ("Molecular Surfaces", 30 pp.) *P. G. Mezey* reviews theoretical models in which molecular properties are correlated with the shape of the surface. One such model is that developed by *M. L. Connolly* to describe the surface accessible to a solvent; this has contributed to a better understanding of solvent effects on proteins. It becomes clear from the article that this new concept would scarcely have been possible without the development of computer graphics.

The final chapter ("Perspectives on Ab Initio Calculations" by *E. R. Davidson*) is not concerned with the practical details of the development of ab initio methods but with the question of what can be learned, and has already been learned, by using ab initio programs. The author's personal views, supported by historical examples, are briefly set out under five headings; everyone will undoubtedly agree with the last of these headings, which asserts that "Computers do not Solve Problems, People do".

The book contains as an appendix a survey by *D. B. Boyd* of hardware and software relevant to molecular modeling (together with details of suppliers); this is prefaced by a useful and amusing checklist of points about which one needs to be clear *before* buying a computer or software.

The standard of production of the book is excellent, there are few printing errors, and the price seems reasonable in relation to the levels that are now typical. It can be recommended for everyone who wants to learn about the present state of development in computational chemistry, and is willing to look beyond the boundaries of his or her particular field of study. Specialists will need to decide for themselves whether the chapters of particular interest to them offer something new. Libraries of chemistry departments are strongly recommended to buy the book. The choice of topics is certainly subjective, but is sensible and relevant to current developments in computational chemistry. It is to be hoped that further volumes of the series will appear at intervals of, say, two years. The editors can be congratulated on this first volume.

Chemistry of Plant Protection. Vol. 4: Synthetic Pyrethroid Insecticides. By *K. Naumann*. Springer, Berlin 1990. xvi, 241 pp., hardcover, DM 224.00.—ISBN 3-540-51313-2

The series "Chemistry of Plant Protection" is the successor to the well-known handbook "Chemie der Pflanzenschutz- und Schädlingsbekämpfungsmittel" by *R. Wegler*. It is not only the language that has altered, there has also been a change in the editorial policy. Whereas the *Wegler* handbook follows a conventional division of subject matter, dealing in turn with herbicides, fungicides and insecticides, the volumes of this series will deal with individual topics of current importance. Thus Volume 1 is devoted to the inhibition of sterol biosynthesis, Volume 2 to the biological breakdown

of pesticides, the defoliation and dessication of green plants, and methods of influencing acetylcholine receptors, and Volume 3 to the detection of pyrethroid residues and the measurement of active substances of low molecular mass by immunoassay. With Volumes 4 and 5, which take pyrethroids as their common central theme, the editors now face the risk of breaking down the subject into too many individual topics. Volume 4 deals with the structures and biological activities of the most important pyrethroids, while Volume 5 (in preparation) will describe their synthesis and chemical properties.

Volume 4 begins with a brief historical account of the development of the synthetic pyrethroids based on the natural pyrethrins; the latter still play an important role in human hygiene (lice etc.), although they are unsuitable for plant protection uses because of their photolability. Many modern pyrethroids bear only a marginal resemblance to the natural pyrethrins; in some cases the only indispensable structural element that is retained is the geminal carbon branching, which acts as a lipophilic anchor. The author identifies the structural characteristics that need to be present in a "good" pyrethroid, and includes extensive tables describing the structure–activity relationships. It is interesting that the (1*R*) enantiomers are found to have the highest activities. With regard to the *cis*/*trans*-1,2-substitution of the cyclopropane ring or at the double bond the diastereomers show characteristic differences in their activities; which of the stereoisomers has the highest activity depends very markedly on the substitution pattern and the insect target group. However, the alcohol component of the cyclopropanecarboxylic acid ester also has a crucial effect; a phenoxyether has the effect of causing the molecule to adopt the important "horseshoe" conformation (pp. 76f).

About 80 pages are devoted to the biological effects of pyrethroids on insects and other forms of life. Nearly all insect species suffer physiological effects from pyrethroids. After absorption through the cuticulum (contact toxicity!) the substance produces the immediate "knock-down" effect, which may or may not be followed by death. In this respect it is possible to obtain some discrimination between harmful insects and those that are useful; useful insects such as bees can recover from the initial "knock-down", whereas harmful insects are killed. However, a serious drawback of nearly all pyrethroids is their high level of toxicity towards marine life (fishes, leeches etc.), which prevents their use in rice-fields. Pyrethroids are essentially harmless to warm-blooded species, although they cause unpleasant skin irritations in humans, which nevertheless quickly clear up. In insects, in contrast to warm-blooded species, pyrethroids rapidly penetrate into the nerve fibers, where they open up presynaptic sodium channels and thereby disrupt the entire nervous system. In warm-blooded species the pyrethroid molecules first undergo ester hydrolysis and hydroxylation which destroys the activity.

The final chapter discusses the market share enjoyed by pyrethroids (currently about 20%) and the areas of use. In addition there is a comprehensive list of the various derivatives, including not only the usual commercial products but also those still at the development or experimental stage, together with manufacturers and licensees.

On the whole this is an excellent book. No important aspect of the subject appears to have been overlooked; the factual information is supplemented by extensive numerical tables that have been carefully prepared. A possible criticism is that the environmental acceptability of the pyrethroids is only briefly discussed. For example, there is very little information (six lines on p. 124) about the biological degradation of the insecticides on cultivated land, and the avoidance of harm to useful insects is undoubtedly a serious problem. A minor detail that can be criticized is the frequent use of trivial names (deltamethrin, permethrin etc.) without giving the reader quick access to the structural formulas. It is only when one reaches page 192 that one finds, without an earlier reference to it, a table giving such information, and even here the compounds are not arranged alphabetically. However, these relatively minor criticisms scarcely detract from the favorable overall impression. The book is undoubtedly a must for everyone working in the area of pyrethroids, whether as a chemist, biologist, pharmacologist or toxicologist.

The Logic of Chemical Synthesis: Multistep Synthesis of Complex Carbogenic Molecules (Nobel Lecture)**

By Elias James Corey*

Carbogens, members of the family of carbon-containing compounds, can exist in an infinite variety of compositions, forms and sizes. The naturally occurring carbogens, or organic substances as they are known more traditionally, constitute the matter of all life on earth, and their science at the molecular level defines a fundamental language of that life. The chemical synthesis of these naturally occurring carbogens and many millions of unnatural carbogenic substances has been one of the major enterprises of science in this century. That fact is affirmed by the award of the Nobel Prize in Chemistry for 1990 for the "development of the theory and methodology of organic synthesis." Chemical synthesis is uniquely positioned at the heart of chemistry, the central science, and its impact on our lives and society is all pervasive. For instance, many of today's medicines are synthetic and many of tomorrow's will be conceived and produced by synthetic chemists. To the field of synthetic chemistry belongs an array of responsibilities which are crucial for the future of mankind, not only with regard to the health, material and economic needs of our society, but also for the attainment of an understanding of matter, chemical change and life at the highest level of which the human mind is capable.

The post World War II period encompassed remarkable achievement in chemical synthesis. In the first two decades of this period chemical syntheses were developed which could not have been anticipated in the earlier part of this century. For the first time, several very complex molecules were assembled by elaborately conceived multistep processes, for example vitamin A (*O. Isler*, 1949), cortisone (*R. B. Woodward, R. Robinson*, 1951), morphine (*M. Gates*, 1956), penicillin V (*J. C. Sheehan*, 1957), and chlorophyll (*R. B. Woodward*, 1960).[1] This striking leap forward, which was recognized by the award of the Nobel Prize in Chemistry to *R. B. Woodward* in 1965,[2] was followed by an equally dramatic scientific advance during the past three decades, in which chemical synthesis has been raised to a qualitatively higher level of sophistication. Today, in many laboratories around the world, chemists are synthesizing at an astonishing rate complex carbogenic structures which could not have been made effectively in the 1950's or early 1960's. This advance has been propelled by the availability of more powerful conceptual processes for the planning of chemical syntheses, the use of new chemical methods, in the form of reactions and reagents, and the advent of improved methods for analysis, separation and determination of structure. Many talented investigators all over the world have contributed to the latest surge of chemical synthesis. Their efforts constitute a collective undertaking of vast dimensions, even though made independently, and their ideas and discoveries interact synergistically to the benefit of all. I am happy to have been selected by the Nobel Committee for contributions to the science of chemical synthesis, but I am even more pleased that this important field of science has again received high recognition.

Genesis

In the fall of 1947, as an undergraduate at the Massachusetts Institute of Technology, I took a course in Advanced Synthetic Organic Chemistry, taught by the distinguished chemist *A. C. Cope*, in which the major reactions of synthesis were surveyed. It was explained that very few new synthetic methods remained to be found, since only five important

reactions had been discovered in the preceding fifty years; and we students were advised to learn how to devise chemical syntheses using the available portfolio of known constructions. We were given numerous molecular structures as synthetic problems. After doing a few of the problem sets, I had developed sufficient skill and experience to handle all of the remaining assignments with ease, much as I had learned to use the English language, to prove mathematical theorems, or to play chess. My new found competence in chemical problem solving seemed to result from an automatic "know how" rather than from the conscious application of well-defined procedures. Nonetheless, even though I had mastered the classical reactions, designing syntheses of molecules beyond the modest level of complexity of these instructional problems still eluded me. Molecules such as morphine, cholesterol, penicillin, or sucrose were so forbidding that they defined the frontiers of 1947; each seemed to be unique and to require a very high level of creativity and invention. Much of my research over the years has been devoted to probing those frontiers and advancing the level of synthetic science by an approach consisting of three integral components: the development of more general and powerful ways of thinking about synthetic problems, the invention of new general reactions and reagents for synthesis, and the design and execution of efficient multistep syntheses of complex molecules at the limits of contemporary synthetic science.

Retrosynthetic Analysis

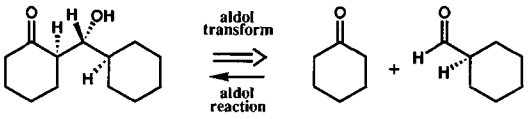
During the first half of this century most syntheses were developed by selecting an appropriate starting material, after a trial and error search for commercially available compounds having a structural resemblance to the target of synthesis. Suitable reactions were then sought for elaboration of the chosen starting material to the desired product. Synthetic planning in most instances was strongly dependent on an assumed starting point. In the fall of 1957 I came upon a simple idea which led to an entirely different way of designing a chemical synthesis. In this approach the target structure is subjected to a deconstruction process which corresponds to the reverse of a synthetic reaction, *so as to convert that target structure to simpler precursor structures, without any assumptions with regard to starting materials.* Each of the precursors so generated is then examined in the same way, and the process is repeated until simple or commercially available structures are arrived at. This "retrosynthetic" or "antithetic" procedure constitutes the basis of a general logic of synthetic planning which was developed and demonstrated in practice over the ensuing decade.[3, 4, 5] In an early example, retrosynthetic planning for the tricyclic sesquiterpene longifolene **1** (Scheme 1 at end of this section) produced several attractive pathways for synthesis, one of which was selected and validated by experimental execution.[6] The basic ideas of retrosynthetic analysis were used to design many other syntheses and to develop a computer program for generating possible synthetic routes to a complex target structure without any input of potential starting materials or intermediates for the synthesis.[4, 5] The principles of retrosynthetic analysis have been summarized most recently in the textbook, "The Logic of Chemical Synthesis"[7] which was written for advanced undergraduate and graduate students of chemistry. The retrosynthetic way of thinking about chemical synthesis also provided a logical and efficient way to teach synthetic planning to intermediate and advanced students, a good example of the intimate link between teaching and research in an academic setting. A brief synopsis of the retrosynthetic planning of syntheses will now be given.

Retrosynthetic[8] (or *antithetic*) analysis is a problem-solving technique for transforming the structure of a *synthetic target* (TGT) molecule to a sequence of progressively simpler structures along a pathway which ultimately leads to simple or commercially available starting materials for a chemical synthesis. The transformation of a molecule to a synthetic precursor is accomplished by the application of a *transform*, the exact reverse of a *synthetic reaction*, to a target structure. Each structure derived antithetically from a TGT then itself becomes a TGT for further analysis. Repetition of this process eventually produces a tree of intermediates having chemical structures as nodes and pathways from bottom to top corresponding to possible synthetic routes to the TGT. Such trees, called EXTGT trees since they grow out from the TGT, can be quite complex since a high degree of branching is possible at each node and since the vertical pathways can include many steps. This central fact implies the need for strategies which control or guide the generation of EXTGT trees so as to avoid explosive branching and the proliferation of useless pathways.

Each retrosynthetic step requires the presence of a target structure of a keying structural subunit or *retron* which allows the application of a particular transform. For example,

Elias J. Corey, born in 1928 in Methuen, 30 miles north of Boston, studied chemistry from 1945–1950 at the Massachusetts Institute of Technology, where he gained his doctorate for work on synthetic penicillins under the supervision of John C. Sheehan. At the early age of twenty-two he joined the University of Illinois at Urbana-Champaign as an Instructor in Chemistry under the distinguished chemists Roger Adams and Carl S. Marvel, and as a result of the success of his research, he was appointed in 1956, at age twenty-seven, as Professor of Chemistry. His areas of research at that time ranged from enantioselective syntheses to enzymology. In 1959 he received and accepted an offer of a Professorship at Harvard University which he still holds. His scientific successes, like the honors conferred him, are numerous and, culminated last year in the Nobel prize for chemistry.

the retron for the aldol transform consists of the subunit HO–C–C–C=O, and it is the presence of that subunit which permits transform function, e.g. as follows:



Transforms vary in terms of their power to simplify a target structure. The most powerful of simplifying transforms, which reduce molecular complexity in the retrosynthetic direction, occupy a special position in the hierarchy of all transforms. Their application, even when the appropriate retron is absent, may justify the use of a number of non-simplifying transforms to generate that retron. In general, simplifying transforms function to modify structural elements which contribute to molecular complexity: molecular size, cyclic connectivity (topology), stereocenter content, element and functional group content, chemical reactivity, structural instability, density of complicating elements.

Molecular complexity is important to strategy selection. For each type of molecular complexity there is a collection of general strategies for dealing with that complexity. For instance, in the case of a complex polycyclic structure, strategies for the simplification of the molecular network, i.e. topological strategies, must play an important part in transform selection. However, the most efficient mode of retrosynthetic analysis lies not in the separate application of individual strategies, but in the concurrent application of as many different independent strategies as possible.

The major types of strategies[7] which are of value in retrosynthetic analysis may be summarized briefly as follows.[8]

1. Transform-based strategies—long range search or look-ahead to apply a powerfully simplifying transform (or a tactical combination of simplifying transforms) to a TGT with certain appropriate keying features. The retron required for application of a powerful transform may not be present in a complex TGT and a number of antithetic steps (subgoals) may be needed to establish it.

2. Structure-goal strategies—directed at the structure of a potential intermediate or potential starting material. Such a goal greatly narrows a retrosynthetic search and allows the application of bidirectional search techniques.

3. Topological strategies—the identification of one or more individual bond disconnections or correlated bond-pair disconnections as strategic. Topological strategies may also lead to the recognition of a key substructure for disassembly or to the use of rearrangement transforms.

4. Stereochemical strategies—general strategies which clear, i.e. remove, stereocenters and stereorelationships under stereocontrol. Such stereocontrol can arise from transform-mechanism control or substrate-structure control. In the case of the former the retron for a particular transform contains critical stereochemical information (absolute or relative) on one or more stereocenters. Stereochemical strategies may also dictate the retention of certain stereocenter(s) during retrosynthetic processing or the joining of atoms in three-dimensional proximity. A major function of stereochemical strategies is the achievement of an experimentally valid clearance of stereocenters, including clearance of molecular chirality.

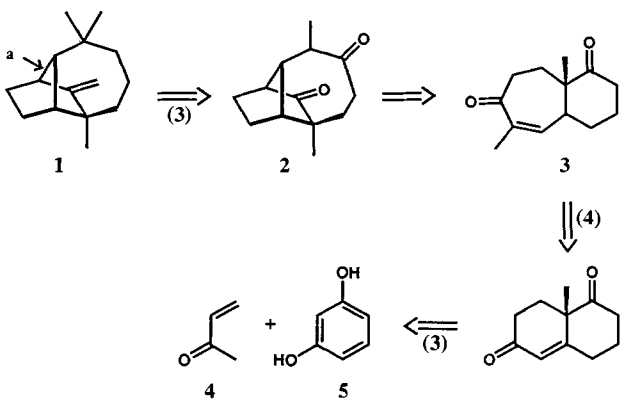
5. Functional group-based strategies. The retrosynthetic reduction of molecular complexity involving functional groups (FG's) takes various forms. Single FG's or pairs of FG's (and the interconnecting atom path) can key directly the disconnection of a TGT skeleton to form simpler molecules or signal the application of transforms which replace functional groups by hydrogen. Functional group interchange (FGI) is a commonly used tactic for generating the retrons of simplifying transforms from a TGT. FG's may key transforms which stereoselectively remove stereocenters, break topologically strategic bonds or join proximate atoms to form rings.

6. "Other" types of strategies. The recognition of substructural units within a TGT which represent major obstacles to synthesis often provides major strategic input. Certain other strategies result from the requirements of a particular problem, for example a requirement that several related target structures be synthesized from a common intermediate. A TGT which resists retrosynthetic simplification may require the invention of new chemical methodology. The recognition of obstacles to synthesis provides a stimulus for the discovery of such novel processes. The application of a chain of hypotheses to guide the search for an effective line of retrosynthetic analysis is important.

Other strategies deal with optimization of a synthetic design *after* a set of pathways has been generated antithetically, specifically for the ordering of synthetic steps, the use of protection or activation steps, or the determination of alternate paths.

Systematic and rigorous retrosynthetic analysis is the *broad principle* of synthetic problem solving under which the individual strategies take their place. Another overarching idea is the use *concurrently* of as many independent strategies as possible to guide the search for retrosynthetic pathways. *The greater the number of strategies which are used in parallel to develop a line of analysis, the easier the analysis and the simpler the emerging synthetic plan is likely to be.*[10]

An abbreviated form of the 1957 retrosynthetic plan for the synthesis of longifolene (**1**) is shown in Scheme 1. Changes in the retrosynthetic direction are indicated by a double arrow (⇒) to distinguish them from the synthetic direction of chemical reactions (→) and the number below indicates the number of transforms required for the retrosyn-



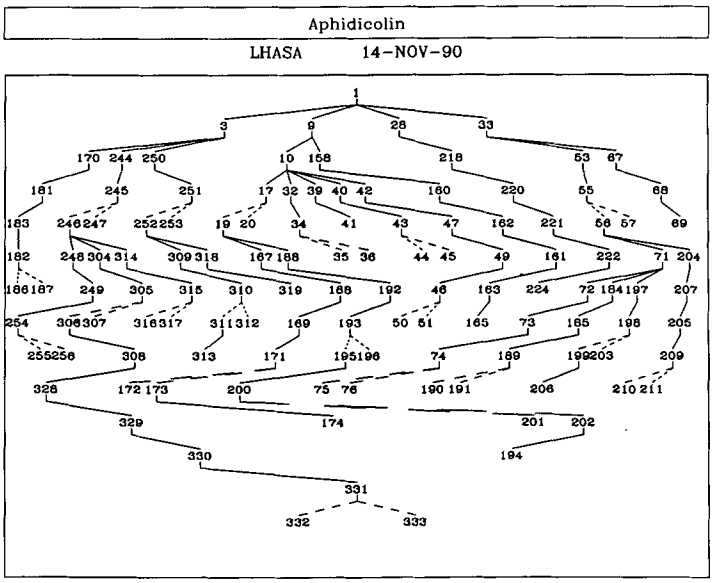
Scheme 1. Retrosynthetic analysis for longifolene **1** (1957) (see text).

thetic change if greater than one. The selection of transforms was initially guided by a topological strategy (disconnection of bond *a* in **1**). The Michael transform, which simplifies structure **2** to precursor **3**, can be found by general transform selection procedures.[5, 9] The starting materials for the synthesis which emerge from retrosynthetic analysis, **4** and **5**, have little resemblance to the target structure **1**.

A detailed explanation of this example of retrosynthetic analysis has been given.[6b, 10] During the past 20 years systematic retrosynthetic thinking has permeated all areas of carbogenic synthesis. It is no longer possible to teach the subject of carbogenic synthesis effectively without the extensive use of retrosynthetic concepts and thinking.

Computer-Assisted Retrosynthetic Analysis

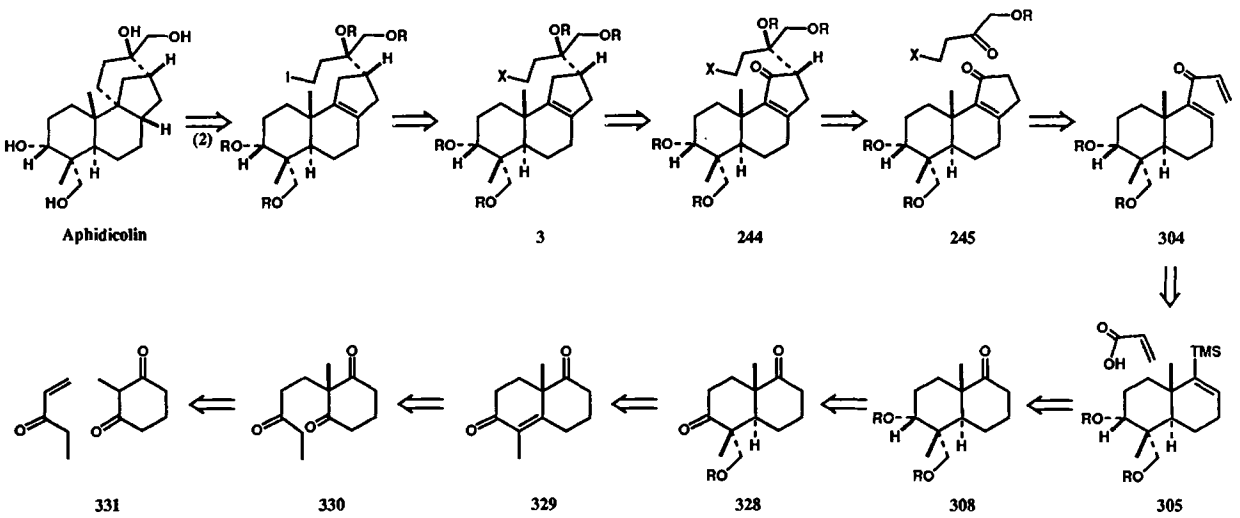
The use of computers to generate possible pathways for chemical synthesis, which was first demonstrated in the 1960's,[4, 5, 9, 11] was made possible by the development of the retrosynthetic methods outlined above and the required computer methodology. Graphical input of structures by hand drawing using an electrostatic tablet and stylus, in the natural manner of a chemist, and output to a video terminal[4, 12] provided an extraordinarily simple and effective interface between chemist and machine. Chemical structures were represented in the machine by means of atom and bond tables, and manipulated by appropriate instructions. Algorithms were devised for perception by machine of structural features, patterns, and subunits which are needed for synthetic analysis. Techniques were developed for storage and retrieval of information on chemical transforms (including retron recognition and keying) using a higher level "chemical English" language. The program (LHASA) was designed to be interactive, with any level of control or input desired by the user, and to emulate the problem-solving approaches of synthetic chemists. The chemical knowledge base, written so as to be intelligible to a practicing chemist, contains all the types of information required for generation and evaluation of retrosynthetic changes, for example, data on individual transforms and their mechanisms, scope, and limitations.



Scheme 2. A retrosynthetic analysis of aphidicolin carried out with the computer program LHASA.

The performance of the program is below that which should eventually be possible because of the immensity of the task and the modest size of our research effort. However, despite present limitations, including an incomplete knowledge base of about 2000 transforms, LHASA is capable of providing interesting suggestions of synthetic pathways for challenging targets. The present level of capability of LHASA can best be appreciated by its performance on specific problems. Shown in Scheme 2 is the EXTGT tree generated by LHASA for the antiviral agent aphidicolin, using just one particular line of analysis. The pathway in this tree from intermediates **332** and **333** to aphidicolin consists of the structures shown in Scheme 3.[13] The suggestion by LHASA of such non-obvious pathways is both stimulating and valuable to a chemist.

The field of computer assisted synthetic analysis is fascinating in its own right, and surely one of the most interesting problems in the area of machine intelligence. Because of the enormous memory and speed of modern machines and the



Scheme 3. A retrosynthetic path from Scheme 2 which leads from the structure **321** to aphidicolin.

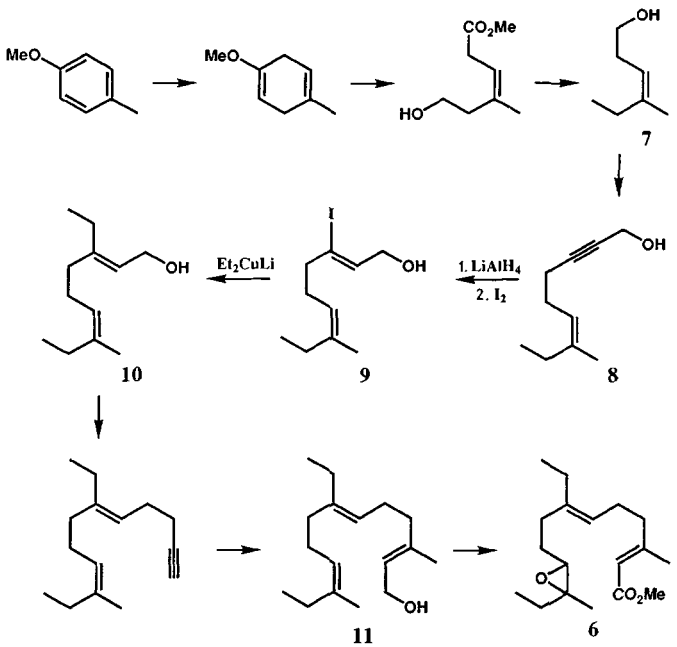
probability of continuing advances, it seems clear that computers can play an important role in synthetic design. However, before that potential can be realized many difficult computing problems must be solved. Multistep retrosynthetic look-ahead, even under strategic guidance, requires complex and powerful software. Vast amounts of information—structural, stereochemical, and chemical—must be generated and analyzed using all available chemical knowledge. A massive undertaking will be required.

New Synthetic Methodology and Multistep Synthesis of Complex Molecules

The invention of new reactions and reagents has revolutionized the field of carbogenic synthesis, literally placing an extraordinarily powerful new chemistry alongside the classical reactions of the pre-1950 period. Without this methodology, the achievements of modern chemical synthesis would not have been possible. Two early landmarks in this advance, the discovery of the Wittig synthesis of olefins and the hydroboration of olefins, were highlighted by the award of the Nobel Prize in Chemistry for 1979 to *G. Wittig* and *H. C. Brown*. More recent developments have provided many methods which are noteworthy for their great chemical selectivity and stereochemical control and for their suitability in the construction of complex molecules. Indeed, many new synthetic processes have been discovered as a result of a perceived need in connection with specific problems involving novel or complicated structures and a deliberate search for suitable methodology. The rational design of such methods depends on the use of mechanistic reaction theory, stereochemical principles, and a wide range of chemistry involving many elements and ephemeral reactive intermediates.

A key to the success of many of the multistep chemical syntheses which have been demonstrated in our laboratories over the years has been the invention of new methodology. Since more than fifty such methods have been developed in our laboratory, it is impossible to summarize this aspect of synthetic research in a brief article. However, a few examples may serve to illustrate the effectiveness of these new methods in providing access to rare and valuable carbogenic compounds and their impact on the whole field of chemical synthesis.

The discovery and identification of the insect juvenile hormone of *Cecropia* (**6**, now known as JH-I)[14] in 1967 generated immense interest because of the potential of such nontoxic compounds for insect control.[15] Chemical synthesis was essential because of the extreme paucity of material from natural sources. Despite the apparent simplicity of structure **6**, a stereospecific route for the synthesis was not obvious, because no general methods existed in 1967 for the stereocontrolled generation of the trisubstituted olefinic units which it contains. The first stereospecific synthesis of **6**[16] was possible using new methodology which was specifically devised for this application. An abbreviated version of the synthesis is shown in Scheme 4. The first olefinic intermediate (**7**) was synthesized from *p*-methoxytoluene in a way which guarantees the *Z*-configuration of the stereocenter. Reaction of **8** with $LiAlH_4$ (*trans* hydroalumination) followed by iodine (replacement of Al by I) produced **9** stereospecifically by a novel sequence.[16] The replacement of iodine in **9** by ethyl was effected by another new process, cross coupling of a vinylic iodide with an organocopper reagent, which provided **10** stereospecifically. A completely analogous series of reactions converted **10** to triene **11**, from which JH-I (**6**) was obtained by a novel selective oxidation sequence. Thus the synthesis outlined in Scheme 4 depended on no less than four new synthetic methods. Three of these methods have come into very general use. The coupling of carbon groups using organocopper chemistry is now a major method of chemical synthesis.[17] The related carbometalation of acetylenes, also developed in connection with the synthesis of **6**,[16b, 18] has been extended in many directions, and this approach has become commonplace for the stereospecific construction of trisubstituted double bonds, a frequently occurring type of structural unit in biologically active natural substances.

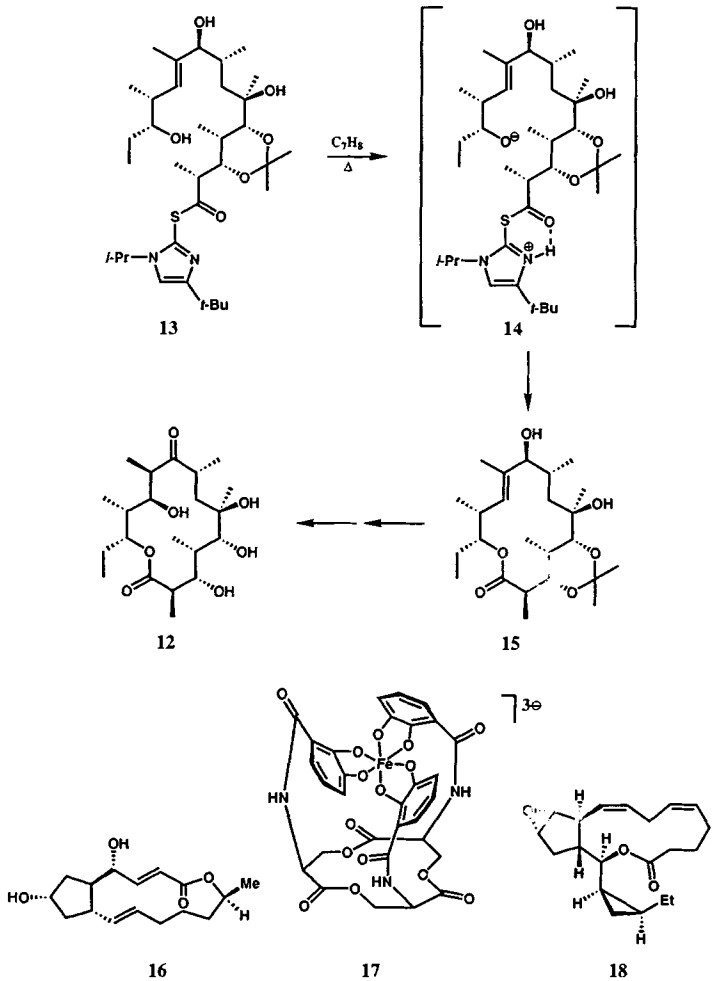


Scheme 4. Synthesis of the insect juvenile hormone JH-I **6**.

The ready availability of the insect juvenile hormone **6** permitted a wide range of biological studies and an understanding of the best ways of using such "third generation" agents for insect control. Inexpensive synthetic mimics of insect juvenile hormone are now produced commercially as environmentally safe insect control products.

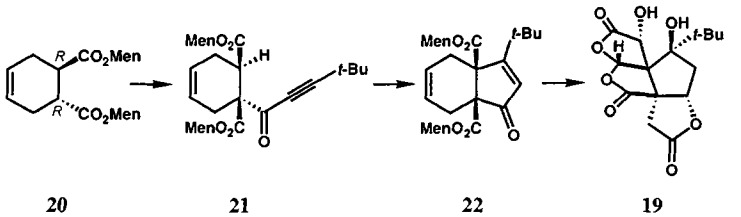
Numerous naturally occurring microbial substances, especially antibiotics, are members of the "macrolide" structural family and contain a lactone functional group as part of a many membered ring. The key to the successful synthesis of complex macrolides such as erythronolide B (**12**), the precursor of the erythromycin antibiotics, was the development of new methodology for macrolactone ring formation (Scheme 5). Our group developed a very mild, effective and general method for this synthetic operation, the double-activation method,[19] which subsequently has been widely used. Thio ester **13**, produced by total synthesis,[20] was converted into macrolactone **15** simply by heating in toluene solution.

Internal proton transfer in **13** generates the internal ion pair **14**, which is doubly activated for the internal carbonyl addition required for ring closure to **15**. Erythronolide B was obtained from **15** by a simple reaction sequence.[20] The double-activation method has been used effectively for the synthesis of a number of other remarkable natural macrocyclic lactones (Scheme 5) including brefeldin A (**16**), an inhibitor of protein transport and processing in mammalian cells,[21] the microbial iron transporter enterobactin (**17**),[22] and the marine eicosanoid, hybridalactone (**18**).[23]



Scheme 5. Synthesis of macrocyclic lactones.

Bilobalide (**19**) is a complex and unusual molecule produced by the ginkgo tree, *Ginkgo biloba*. An effective synthesis of **19** was made possible by the development of a remarkable reaction for the formation of five-membered rings (Scheme 6).[24] The readily available chiral diester **20** was converted by Claisen acylation to the acetylenic keto diester **21**. Treatment of **21** with base effected a novel ring closure to give the bicyclic ketone **22**, which was then transformed into bilobalide (**19**) by a multistep sequence. There are several variants of this cyclization methodology which demonstrate considerable scope.[25]



Scheme 6. Synthesis of bilobalide.

A wide range of reagents and reactants have played a role in the new methodology developed in our group: transition metals; metal-ion complexes; and silico, sulfo, boro, alumino, phospho, and stanno carbogens. The new general methods which have resulted include processes for ring formation, chain extension, oxidation, reduction, functional group transformation, activation, protection, and stereochemical control.

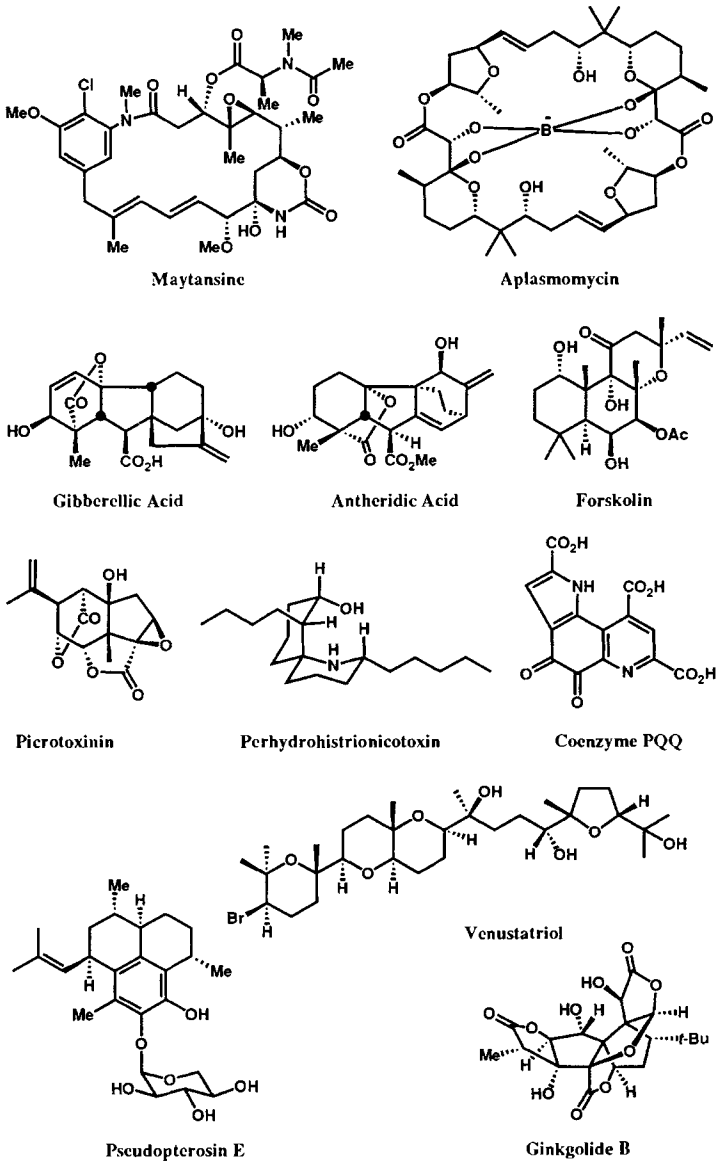
Multistep Synthesis—General

To a synthetic chemist, the complex molecules of nature are as beautiful as any of her other creations. The perception of that beauty depends on the understanding of chemical structures and their transformations, and, as with a treasured work of art, deepens as the subject is studied, perhaps even to a level approaching romance. It is no wonder that the synthetic chemist of today is filled with joy by the discovery of a new naturally occurring structure and the appearance of yet another challenge to synthesis. It makes no difference that the realization of a difficult synthesis entails long hours of study, thought and physical effort, since a complex chemical synthesis is an exciting adventure which leads to a beautiful creation. I believe that the case for molecular synthesis, as a high intellectual endeavor and as a scientific art form, can stand on these merits. The chemist who designs and completes an original and aesthetically pleasing multistep synthesis is like the composer, artist or poet who, with great individuality, fashions new forms of beauty from the interplay of mind and spirit.

It is fortunate that molecular synthesis also serves the utilitarian function of producing quantities of rare or novel substances which satisfy human needs, especially with regard to health, and the scientific function of stimulating research and education throughout the whole discipline of chemistry.

Our research group has been responsible for the creation of more than one hundred new multistep syntheses of interesting molecules, our sonatas and string quartets. The step-by-step construction of most of these targets of synthesis is outlined in the *"Logic of Chemical Synthesis"*[7] and is discussed in detail in the original research papers referred to therein. The structures of a small, and somewhat random, selection of these synthetic targets are shown in Scheme 7. A few comments will be given here on the syntheses of each of these to provide an overview of this aspect of our research.

Maytansine[26a] and aplasmomycin,[26b] each scarce and therapeutically interesting, were synthesized enantioselectively and with control of stereochemistry using novel methodology for assembling the molecular skeleton and for forming the macrocyclic unit. These syntheses and that of erythronolide B[19, 26c] provided early demonstrations that such complex, macrocyclic molecules can be made efficiently by multistep total synthesis.



Scheme 7: Structures of some complex natural products whose total syntheses have been arried out in our laboratories.

Gibberellic acid resisted total synthesis, despite studies in several leading laboratories, for more than two decades because of an unusually forbidding arrangement of structural subunits. The first successful synthesis, and subsequent improved versions,[26d] required a deep and complex retrosynthetic analysis[26e] and a number of new concepts and methods. An entirely different strategic approach was utilized for the first synthesis of the biosynthetically related plant regulator antheridic acid[26f] which confirmed the proposed gross structure and clarified the stereochemistry. The availability of synthetic antheridic acid is essential to the further study of this rare and potent plant hormone.

Forskolin, the first known activator of the enzyme adenylate cyclase, is a promising therapeutic agent which is available only in limited quantity from plant sources. An efficient multistep synthesis of forskolin, which is both enantio- and stereocontrolled, has been developed[26g] based on several new synthetic methods. The synthesis of picrotoxinin, known since 1811 and a potent inhibitor of the neurotransmitter γ-aminobutyric acid (GABA) would not have been possible without retrosynthetic analysis and new methodology.[26h] Perhydrohistrionicotoxin, a rare and highly bioactive alkaloid from poisonous frogs, is a useful tool in neuroscience which was easily produced by total synthesis.[26i]

Pseudopterosin E,[26j] a powerful antiinflammatory agent, and venustatriol,[26k] an antiviral agent, are biosynthesized by marine organisms in only trace amounts. Both are available in chiral form by efficient enantiocontrolled multistep syntheses.

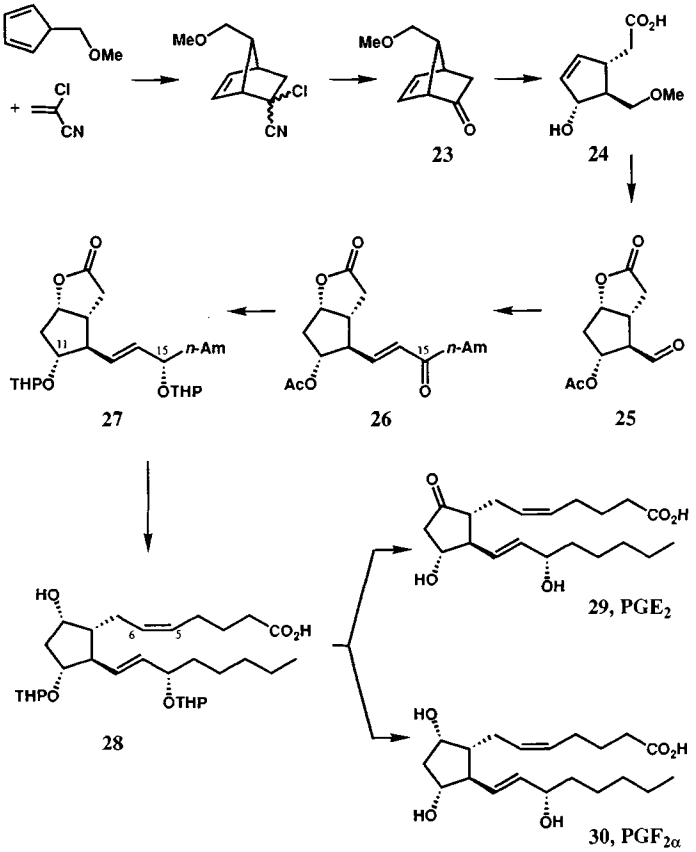
Last, but no means least, in this brief summary of our studies on the total synthesis of complex molecules, is the case of ginkgolide B, an unusual substance for several reasons. Ginkgolide B is biosynthesized in the roots of the unique and ancient ginkgo tree, *Ginkgo biloba*, by an extraordinarily complex biosynthetic process, for reasons that are unknown. It is an active ingredient in the medicinal extract of ginkgo which is now widely used in oriental and western medicine. The total synthesis of ginkgolide B posed a challenge for synthesis in the 1980's which was comparable to the most difficult problems of earlier eras, for example, steroids in the 1950's or vitamin B-12 and gibberellic acid in the 1970's. That challenge was met in just three years of research, thanks again to the power of modern retrosynthetic planning and to the invention of new tools for this particular synthesis.[26i, 27]

Multistep Synthesis Exemplified—The Prostaglandins

The prostaglandins, the first of the known eicosanoids, were detected as bioactive substances more than fifty years ago. However, it was not until the pioneering work of *K. Sune Bergström* and his group in Sweden in the 1950's and 1960's that the structures of the various members of the prostaglandin family were determined.[28] For that research *Bergström* and *Bengt Samuelsson* received (together with *John Vane*) the Nobel Prize in Medicine and Physiology for 1982, and deservedly so since, as has been written of the prostaglandins: "Their actions and the pharmacologic agents that influence their formation affect almost every aspect of medical practice."[29] The occurrence of only trace amounts of prostaglandins (PG's) in mammalian sources and the potent effect of these C_{20} carboxylic compounds on muscle and blood vessels indicated the need for an effective synthesis that would make available all of the PG's in ample amounts for the study of their physiologic effects and therapeutic uses. The problem of chemical synthesis was complicated by uncertainties regarding the stability and chemistry of PG's, and the existence of three different families (PG_1's, PG_2's and PG_3's) each consisting of several members. The first total synthesis of the principal PG's, demonstrated by 1967,[30, 31] made available the important members of the first family (PGA_1, PGE_1 and $PGF_{1\alpha}$) and allowed an evaluation of their chemical properties which facilitated the design of a general synthetic route to all of the prostaglandins. This general synthesis of prostaglandins provided access to all PG's from a single intermediate, commonly known as the Corey lactone aldehyde.[32, 33] In various forms this flexible synthesis has been used by laboratories all over the world to

prepare not only naturally occurring PG's but also countless structural analogs on any scale.[34]

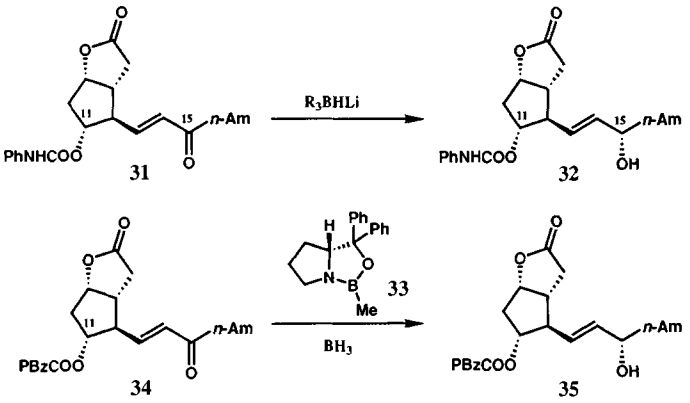
The original version of the 1969 general synthesis of PG's is summarized briefly in Scheme 8. The bicycloheptenone **23** was synthesized stereospecifically by a novel Cu^{II}-catalyzed Diels-Alder reaction followed by alkaline hydrolysis of the resulting adduct. Alkaline peroxide converted **23** into the hydroxy acid **24** which was readily resolved using (+)-ephedrine. Lactonization and functional group interchange operations transformed **24** into the Corey lactone aldehyde **25**, a versatile precursor of all of the PG's and analogs thereof. Enone **26**, produced stereospecifically from **25** by Horner-Emmons coupling, upon reduction with zinc borohydride generated the required (15*S*)-alcohol along with the (15*R*)-diastereomer which was separated and recycled via **26** to the (15*S*)-alcohol. Protection of the hydroxyl groups at C11 and C15 afforded the corresponding bistetrahydropyranyl (bis THP) ether, **27**. Reduction of the lactone function of **27** to lactol (R_2AlH) and Wittig coupling produced **28** stereospecifically. Acidic hydrolysis of **28** afforded $PGF_{2\alpha}$ (**30**), whereas oxidation of **28** followed by hydrolysis gave PGE_2 (**29**). Hydrogenation of the 5,6-double bond in **28** followed by these same final steps produced $PGF_{1\alpha}$ and PGE_1. A parallel series of transformations was used to convert **25** into $PGE_{3\alpha}$ and PGE_3.



Scheme 8. General synthesis of prostaglandin. Am = C_5H_{11}, THP = tetrahydropyranyl.

Although the 1969 bicycloheptenone route to PG's was highly effective for the synthesis on a large scale, it was not the ultimate. The Diels-Alder route to **23** produced racemic material which in turn necessitated the resolution of hydroxy acid **24**. Another problem was the lack of stereospecificity in the reduction of the C15 keto group of **26**. Both of these limitations were overcome by the invention of novel methodology which has simultaneously opened up large new areas of synthetic endeavor.

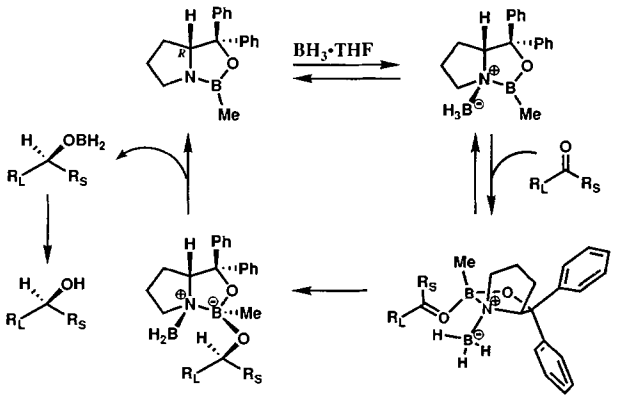
The problem of controlling the stereochemistry of reduction of the 15-keto group in **26** was solved in a number of different ways (Scheme 9). First, the use of a bulky trialkyl-



Scheme 9. Two routes of the highly heteroselective reduction of the C15 keto group in prostaglandin synthesis.

borohydride reagent with a suitably chosen "controller" group at the C11 oxygen, for example phenylcarbamoyl, resulted in reduction of C15 to give the required (15*S*) product with greater than 10:1 diastereoselectivity.[33, 35] Further, the small amount of (15*R*) by-product was easily separated for recycling. Second, using the chiral catalyst **33** (10 mole %) and borane (0.6 mole equivalent) in tetrahydrofuran as solvent at ambient temperature, the 15-ketone **34** was reduced to the (15*S*) alcohol **35** with 9:1 diastereoselectivity.[33, 36]

Oxazaborolidine **33** is a remarkable catalytic reagent. It controls the absolute stereochemistry of reduction of a large variety of ketones in addition to accelerating the rate of reduction by borane. The absolute stereochemistry of the reduction product of an achiral ketone R_SCOR_L, where R_S is smaller than R_L, is predictable.[37, 38] The observed catalysis and enantioselectivity are in accord with the mechanism outlined in Scheme 10. The catalyst **33** has been shown to complex with borane stereospecifically to give a species which is activated for binding to the ketonic substrate. Complexation at the sterically more available lone pair of the carbonyl oxygen and internal hydride transfer then leads to the observed enantiomeric secondary alcohol. In this mechanism the reagent **33** literally acts like a *molecular robot*: It first picks up and holds one of the reactants, BH_3, and becomes activated toward the other. It attaches to the ketone in a precise three-dimensional assembly that facilitates a transfer of hydrogen between the two reactants to form a *specific* enantiomer of the reduction product. The molecular robot finally discharges these products and repeats the reaction cycle. Such action by the small molecule **33** resembles catalysis by enzymes, which can also be regarded as molecular robots. Of course, **33** lacks the substrate-shape

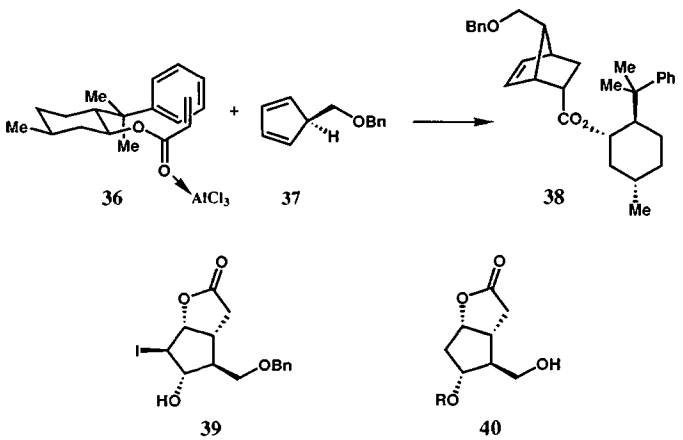


Scheme 10. Mechanism of the catalytic enantioselective reduction of ketones with the reagent 33/BH_3.

and size discrimination of enzymes because it is too small to possess a binding pocket or distal multicontact recognition sites.

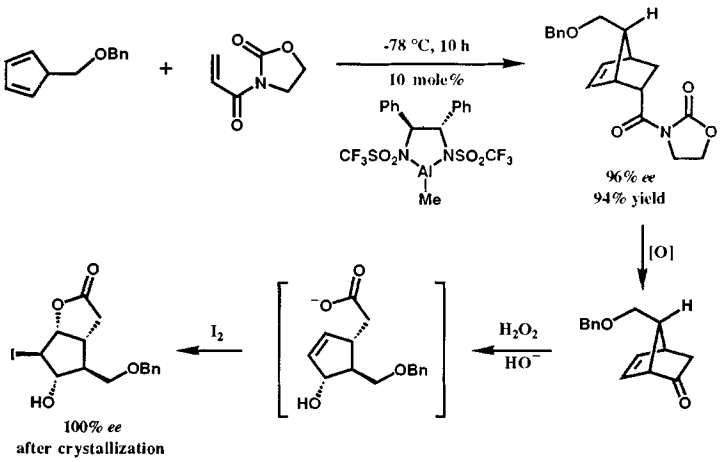
The action of the molecular robot **33** represents a new direction for chemical synthesis. In the past, most synthetic constructions have depended on pairwise collisions between reactants without the help of a robot-like assembler. It is likely that synthetic chemistry will produce many new molecular robots in the future as a part of its advance to greater heights.

Two solutions were developed for the enantioselective synthesis of bicycloheptenone **23** (Scheme 8), of the correct chirality for the production of natural prostaglandins. In the first of these, a stereocontrolled aluminum chloride-catalyzed Diels-Alder reaction between benzyloxymethylcyclopentadiene (**37**) (Scheme 11) and the acrylate ester of 8-phenylmenthol (**36**) was used with the result that the required adduct **38** was formed with very high (32:1) enantioselectivity.[39] Adduct **38** was converted via ketone **23** into iodolactone **39** which was obtained in enantiomerically pure form in high yield by a single recrystallization and converted into the standard PG intermediate **40**. In addition, 8-phenylmenthol was recovered efficiently. The enantioselective formation of **38** can be understood from the geometry shown for the complex **36** · $AlCl_3$ and the steric screening by phenyl of the *si* (rear) face of the acrylate α,β-double bond. The efficiency of the 8-phenylmenthol controller stimulated the development of other controllers (chiral auxiliaries) for use in enantioselective synthesis.[40]



Scheme 11. Enantioselective Diels-Alder reaction for the synthesis of the bicycloheptenone **23** (see Scheme 8).

More recently, this achievement has been surpassed by the development of a *molecular robot* which assembles the achiral components, as shown in Scheme 12, to give the required Diels-Alder adduct in 94% yield and almost 50:1 enantioselectivity.[38,41] Conversion to enantiomerically pure iodolactone **39** was accomplished using standard procedures.[42]

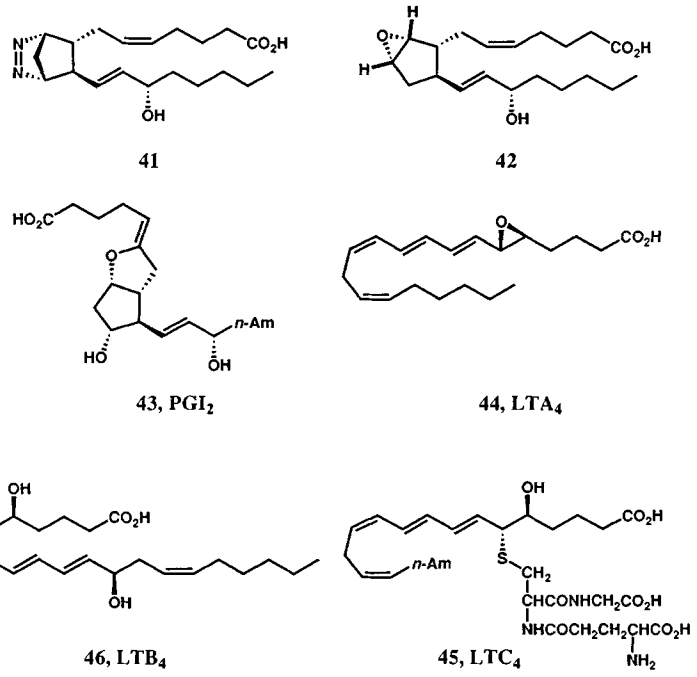


Scheme 12. Enantioselective, catalytic Diels-Alder reaction for the Synthesis of the bicycloheptenone **23**.

The general synthesis of prostaglandins by the 1969 pathway can now be carried out efficiently and with total stereochemical control, in a way that could not have been foreseen twenty years ago. Such progress augurs well for the future of chemical synthesis. It is not unlikely that today's chemical synthesis, magnificent as it may now appear, will prove to be rudimentary as compared to that of the next century.

The trail of research which originated with the synthesis of prostaglandins was followed for more than two decades, eventually including the synthesis of many other members of the eicosanoid (twenty-carbon) class of mammalian cell regulators. A few of the highlights of this program deserve mention. The biosynthesis of prostaglandins occurs by the oxidative conversion of the C_{20} unsaturated acid arachidonic acid to the bicyclic endoperoxide PGH_2, which serves as a precursor not only of PGE_2 and $PGF_{2\alpha}$, but also of PGI_2 and thromboxane A_2.[43] We were able to synthesize a stable, active azo analog (**41**) of the unstable PGH_2[44] (Scheme 13) and stable, active analogs (e.g. **42**) of the unstable thromboxane A_2[45] as well as PGI_2 itself (**43**).[46] In 1977 we suggested the structure of the unstable eicosanoid which is now known as leukotriene A_4 (LTA_4) (**44**) and, by early 1979, had synthesized that structure in advance of isolation from natural sources.[47] Collaborative research between our group and the Karolinska team headed by *Bengt Samuelsson* established that LTA_4 combines with glutathione to form the pri-

mary "slow reacting substance," now known as LTC_4 (**45**).[47] The detailed stereochemistry of the chemotactic leukotriene LTB_4 (**46**) was first established by synthesis.[47, 48] The chemical syntheses of these leukotrienes made these compounds available in quantity for the many hundreds of biological studies which ensued. Useful new compounds which are active as antagonists of $PGF_{2\alpha}$,[49] thromboxane A_2,[50] and LTB_4,[51] and as inhibitors of leukotriene biosynthesis[52] have also emerged from our synthetic program.



Scheme 13. Some unsaturated C_{20} compounds.

It is my hope that our studies in the eicosanoid field[34] will prove to be a harbinger of future programs in academic synthetic research, since there is an unparalleled opportunity for the application of chemical synthesis to biological and medical problems at a fundamental level.

Acknowledgement

It gives me great pleasure to express my indebtedness to many individuals who deserve credit for the accomplishments summarized herein: my teachers at the Lawrence High School and the Massachusetts Institute of Technology, my colleagues at the University of Illinois and Harvard University, my wonderful collaborators in research, and my very dear family. Research grants from the National Science Foundation, the National Institutes of Health, Pfizer Inc. and numerous other donors have provided the necessary financial support.

Chemical Characterization of Aerosols: On-Line and In Situ

By Reinhard Nießner*

Whereas aerosols were formerly considered to be important in meteorological processes but in little else, today they play a significant role not only in environmental protection but also in "new technologies" such as the formation of high performance ceramics, sinter metals, optical waveguides, and superconductors. Analytical procedures which are capable of a continuous qualitative and quantitative description of processes in which aerosols are formed are, however, still almost unknown. The present review will discuss initial developments (which will often appear exotic in nature) such as the use of the condensation properties of ultrafine particles or time-resolved laser-induced aerosol fluorescence spectroscopy. The progress of analytical chemistry in the last few years makes it clear that advances in miniaturization, data processing, and optronics will probably be capable of solving many problems which are presently regarded as unsolvable.

1. Introduction

1.1. Aerosols

Aerosols are colloidally disperse systems consisting of ultrafine or finely divided material (particle diameter between ca. 2 nm and a few μm) in a carrier gas. No distinction is made between liquids and solids in the suspension.

Aerosols play an important role in the atmosphere: they are responsible for atmospheric turbidity and thus for the limitation of visibility, they act as a source or sink for gaseous emissions (e.g. SO_x, NO_x, R_2S), and in addition they provide the condensation nuclei which are of prime importance in the life-giving water cycle. Aerosols are, however, also of increasing importance in technological processes. New technologies involve a large number of process stages in which substances are used or produced in a finely disperse form as aerosols: a) preparation of ultrapure, monodisperse and chemically homogeneous dusts as precursors for high-performance ceramics or for ceramic and metallic coatings,[1-7] b) solvent-free lacquer technologies (electrostatic coating),[8] c) production of optical waveguides,[9] d) microencapsulation of reactive substances,[10,11] e) manufacture of catalysts,[12,13] f) preparation of single crystals,[14,15] g) preparation of superconducting materials,[16,17] h) production of magnetically anisometric pigments,[18] and i) increasing the rate of slow reactions (e.g. aerosol fluorination of hydrocarbons[19,20]).

More exotic applications, which document the potential of aerosols in technical processes, are firstly their use in fusion experiments (neutron production during the formation of deuterated polyethylene aerosols from an exploding polyethylene fiber[21]), the development of "chemical lasers" (production of high concentrations of singlet oxygen for energy storage[22]), or the rapid and selective distribution of fertilizing and neutralizing mineral aerosols for the rehabilitation of woodland which has suffered damage from "acid" conditions.[23]

Aerosols also cause problems in everyday life. When certain types of emission are involved they are considered a toxicological risk for humans. The main subjects of discussion in this case are aerosols formed in combustion processes or at the workplace during production processes. Aerosol emissions result from incomplete combustion of polycyclic aromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs), dioxins, and dibenzofurans. Sources include automobiles, refuse incineration, domestic fuel, cigarette smoke, and coal-fired power stations. These substances are generally also found at the workplace since pyrolysis processes or direct contact with toxicologically relevant aerosols are often involved in work processes. A further important toxic class comprises the heavy metal aerosols formed in grinding, welding, and casting processes.

Particle size plays a particularly important role. Present knowledge lists aerosols with aerodynamic particle sizes below 3 μm diameter as particularly dangerous, because they represent the fraction which can penetrate the lung. However, conflicting reports exist on the metabolism of particles deposited in the lung and on synergistic effects (for example how irritant gases and solid aerosol particles act in combination to determine the risk potential), as demonstrated by the continuing discussion on the risk potential of diesel exhausts and tobacco smoke aerosols.

1.2. Problems of Measurement in Aerosol Characterization

The problem areas mentioned in Section 1.1 make it clear that a powerful measurement technique would be of great interest; the following properties of such a technique must be considered:

- *limits of detection*: Many substances, including PAHs and dioxins, are emitted in sub-ppb concentrations.
- *selectivity*: High selectivity is not necessarily required in control and regulation procedures, or when screening is to be carried out as a rapid initial measure. In particular for process technologies or in warning systems at the work place, the matrix composition of the environment is well-defined. A final analysis, however, requires the highest selectivity.

[*] Prof. Dr. R. Nießner
Institut für Wasserchemie der Technischen Universität
Marchioninistrasse 17, W-8000 München 70 (FRG)

- *on-line signal emission*: A continuous determination of the aerosol composition is required for devices which give a warning of toxic emissions or immission. Aerosol measurement techniques which form chemically sensitive elements in a measurement and regulation procedure can also dictate the time constant: thus the response time should be as short as possible so that signal generation is as close to continuous as possible.
- *in situ concentration determination*: The thermodynamic and kinetic stabilities of many substances are particularly low when they are present in the form of aerosols. Well-documented examples are ammonium salt aerosols and tri- and tetranuclear PAHs produced in combustion processes. If an enrichment step such as filtration collection on membrane filters is necessary prior to the actual analysis, a substantial amount of the substance will be transferred from the solid to the gas phase. As a consequence the analysis will give a reading which is much too low unless the sampling method takes account of both solid aerosol particles from the filter and gaseous components which pass through the filter. Other possibilities for falsification are provided by interactions between neighboring particles at the surface of the collection medium (filter, impactor) or by an irreversible reaction of the aerosol with the collector medium itself. It is also necessary to take into account reactions between the deposited material and reactive trace gases (e. g., HNO_3/NO_2 + pyrene → 1-nitropyrene). It is thus desirable to devise a technique for direct determination of the relevant substance in its state of suspension (i.e., in situ). The technique should subject the aerosol to as little disturbance as possible.

A complete characterization of an aerosol (see Fig. 1) can be divided into a chemical and a physical stage. The physical stage consists of the determination of particle concentration, particle size distribution, form and structure of single particles, electrical properties of the suspended particles, as well as of pressure, temperature, and relative humidity. That this area of aerosol characterization can in general be considered as already fully developed[24-26] is documented by the large number of commercially available devices.

The chemical part of a comprehensive aerosol characterization should take into account the composition of both the gas phase and the dispersed material, because they are dependent on each other. A simple example in the area of

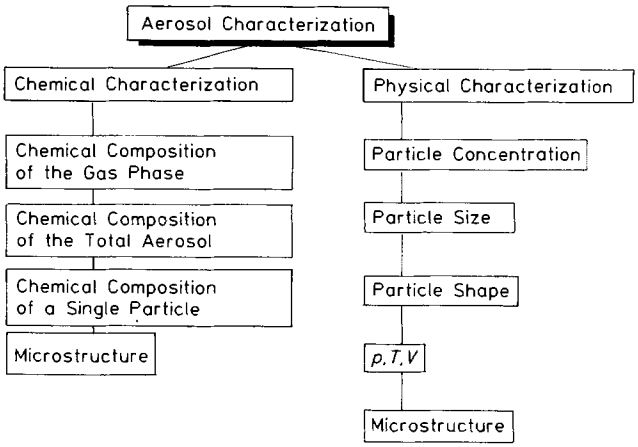

Fig. 1. Parameters of a complete aerosol characterization.

atmospheric aerosols is provided by the NH_4NO_3 aerosol [Eq. (a)].

$$NH_4NO_3(s) \underset{\text{cooling}}{\overset{\text{heating}}{\rightleftharpoons}} NH_3(g) + HNO_3(g) \qquad \text{(a)}$$

Even small variations in temperature cause as significant a change in the amount of solid NH_4NO_3 in the gas phase as a variation in the concentrations of the gases NH_3 and HNO_3. Similar effects have been observed in organic aerosol systems such as fluoranthene.

A further peculiarity of aerosol systems, namely the microstructure of aerosol particles, which is becoming increasingly important, makes their characterization more difficult.

The substance distribution across the total particle cross-section is not homogeneous (Fig. 2). A typical example of this behavior is the structure of fly ash particles: as a result of the stages in the cooling of a combustion gas (see Fig. 3), the toxicologically relevant substances become attached successively at the particle surface, either by adsorption or by condensation. In addition, because of the high particle concentration near the combustion center ($N > 10^{10}$ cm^{-3}), agglomerated submicron particles are found on the surface of the fly ash, which in turn can be microstructured. Another model for a microstructured particle, for example, a fog or cloud droplet, consists of an insoluble particle nucleus which as the result of a condensation process is covered by a liquid

Reinhard Nießner was born in Tuttlingen (FRG) in 1951 and started his studies in chemistry in Freiburg in 1972. He obtained his Diplom there in 1976 in analytical chemistry and his doctorate at Dortmund under Prof. D. Klockow in 1981, where he continued research for his habilitation till 1986. He was appointed full professor for Hydrogeology, Hydrochemistry and Environmental Analysis and head of the Institute for Aqueous Chemistry and Chemical Balneology at the Technische Universität München in 1989. Prof. Nießner was awarded the prize of the "Fachgruppe Analytische Chemie" in 1988 and the Heinrich-Emanuel-Merck Prize in 1990. His research interests lie in the classical analytical chemistry of water, the supervision of disposal sites, the chemical interaction of Xenobiotics with soil, the development of highly sensitive and selective immunoassays to detect harmful substances in the environment, analysis of aerosols, and in particular, the applications of laser spectroscopic techniques.

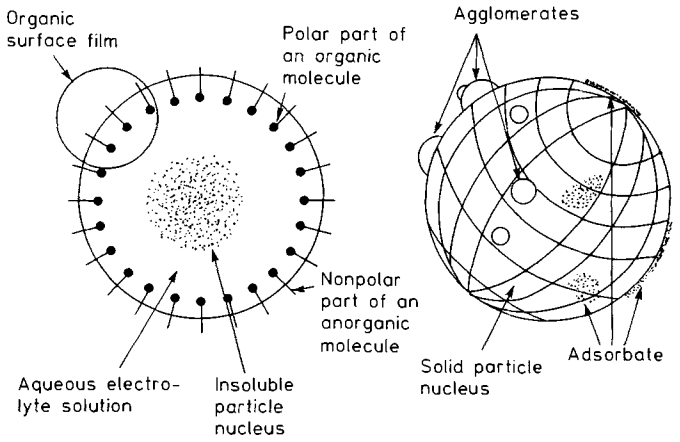

Fig. 2. Examples of microstructured aerosol particles.

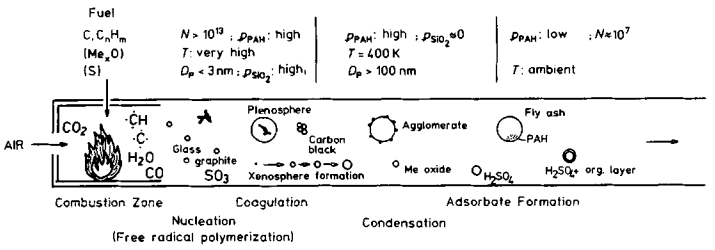

Fig. 3. A model of aerosol formation during cooling of combustion exhaust gases.

electrolyte layer. Because of the many subsequent evaporation and condensation processes occurring during the "lifetime" of these particles they can also be covered by a film of volatile organic substances such as terpenes, alkanes, alcohols, and carboxylic acids. This leads to an inverse micelle microstructure (see Fig. 2). Laboratory studies of artificially microstructured aerosols of this type have shown that such films can have a great influence on the phase transition of gaseous substances into the dissolved liquid phase (e.g., $NH_3(g)$ into $H^{\oplus}/H_2O$).[27, 28]

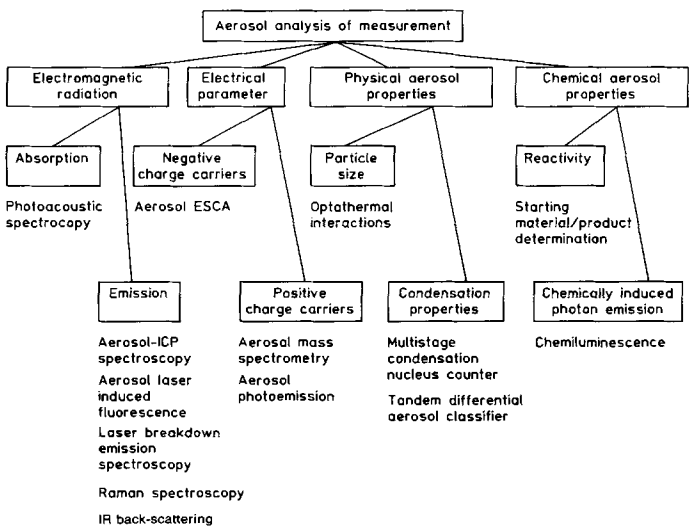

Fig. 4. In-situ and on-line aerosol determination procedures which are either already in use or potentially useful.

In the following discussion an attempt will be made to give a systematic overview of in situ and on-line aerosol characterization methods which either appear feasible or have already been realized. The special features and characteristics of these procedures will be discussed. A schematic summary is given in Figure 4.

2. Aerosol Characterization Based on Interactions with Electromagnetic Radiation

A large number of old and new techniques for on-line measurements based on the interaction of aerosols with electromagnetic radiation is now available. Well-known principles, such as emission, absorption, and scattering, covering the complete electromagnetic spectrum, can be used. Difficulties are, however, often encountered because of the small dimensions of the aerosol under study or because of the influence of the carrier gas, such as for example the production of unwanted new particles during photolysis. On the other hand, the observation of optical properties is the direct route to an in situ and on-line analysis.

2.1. Characterization on the Basis of the Light Extinction by Particles

The majority of procedures used in analytical chemistry are based on extinction measurements. For aerosols such a measurement is no longer trivial. Light incident on a particle can be either absorbed or scattered. Natural aerosols contain particles whose sizes lie between ca. 2 nm and 20 μm, while particle concentrations lie between less than 1 per cm^3 (e.g. in clean rooms) and greater than 10^9 per cm^3 (in combustion processes). Thus the extremely low effective interaction cross-section for the extinction measurement can readily be calculated. At present no simple procedure based on an extinction measurement is known which permits analysis at such low limits of detection. Improvements could perhaps be realized in applications involving synchrotron radiation and by the use of laser radiation within a laser resonator.

Luckily photoacoustic spectroscopy[29] is an indirect way of determining the absorption coefficient of an aerosol. The optoacoustic interaction is based on the conversion of vibration energy of excited vibration modes of molecular species into heat. This process causes the formation of a pressure wave in the surrounding gas. When the exciting energy source (typically a CW–IR laser) is modulated, the acoustic signal is subject to a similar modulation and can therefore be detected above the background noise by a sensitive microphone acting as a pressure sensor.

The absorbed photons thus cause a pressure increase as a result of the absorbing aerosol particles. If a resonant cell is used to create a standing wave, the acoustic signal is amplified, and the pressure p within the cell induced by irradiation with a sinusoidally modulated laser beam of frequency ω is described by Equations (b) and (c).[32]

Equations (b) and (c) represent the relation between the observed pressure in the resonant cell and the absorption coefficients β of the irradiated aerosol particles. The integral

$$p(\omega) = \sum A_j p_j \quad \text{(b)}$$

$$A_j = \frac{-i\omega(\gamma - 1)\beta(V_c)^{-1} \int p_j I dV}{\omega^2[1 - (\omega/\omega_j)^2 - i(\omega/\omega_j Q_j)]} \quad \text{(c)}$$

ω = frequency of the chopped laser source,
ω_j = frequency of the jth mode,
γ = ratio of the specific heats C_p/C_v at constant pressure and temperature,
β = absorption coefficient,
I = spatial variation of the light intensity,
Q_j = amplification factor of a mode j at resonance,
p_j = vibrational modes,
V_c = cell volume

$V_c^{-1} \int p_j I dV$ represents the coupling between the spatial profile of the irradiation intensity and the pressure waves p_j. The final result is that, within certain limits, the induced pressure p (the signal which is detected!) is a function of the applied irradiation intensity I.

Several groups are at present working on the development of photoacoustic aerosol sensors, in particular for the monitoring of diesel aerosols. Unsolved problems include the background signals caused by absorption of the incident light at cell walls or windows. The wide linear measurement range is a general advantage of this procedure. The application of photoacoustic spectroscopy to sulfate determination, initially demonstrated by *Röhl* et al.[31] for aerosol filter samples, is promising.

Adams et al.[32, 33] have recently published details of an aerosol spectrophotometer (Fig. 5). The photoacoustic cell

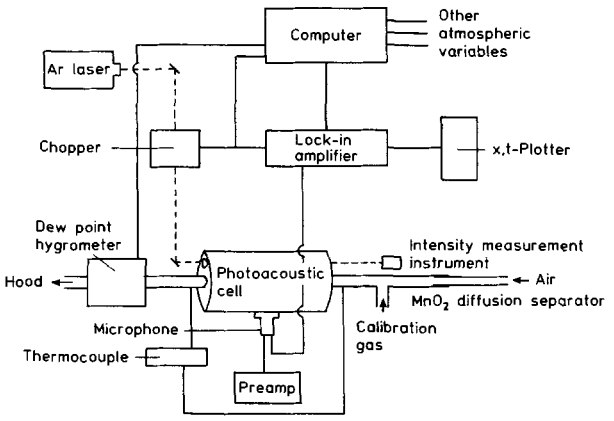

Fig. 5. Construction principle of a photoacoustic aerosol spectrometer. Preamp = preamplifier, Ar = argon.

consists of a brass cylinder which is constructed in the form of a resonant cell. The light source is an argon ion laser. The aerosol is drawn through the cell by a pump at the rate of 0.45 L min^{-1}. The aerosol is first passed through a MnO_2 diffusion separator to remove NO_2, which interferes in the measurement; the aerosol fraction is not reduced thereby. *Adams* et al. report a detection limit of 300 ng carbon per m^3.

A further improvement can be expected when cells are constructed within a laser resonator, in analogy with an application as a photoacoustic gas chromatographic detector as published by *Fung* and *Gaffney*.[34]

2.2. Analysis Based on Light Emission from the Particles

Another useful detection principle for quantitative or qualitative analysis of aerosols is photon emission from selectively stimulated molecules or particles. Relatively inexpensive techniques for the registration of single photons in the visible region already exist. There are thus a number of attractive possibilities for on-line and in situ detection of aerosols, such as laser-induced aerosol fluorescence (LIF), laser-induced breakdown spectrometry at aerosols (LIBS), laser-induced Raman spectroscopy at aerosols, IR backscattering at aerosols, and inductively coupled plasma (ICP) spectrometry.

2.2.1. *Analysis by Laser-Induced Fluorescence (LIF)*

Laser-induced fluorescence has been known for many years as an unwanted side effect of Raman spectroscopic studies in flame experiments.[35, 36] The first selective experiments designed to use these effects for the characterization of aerosols were reported by *Omenetto* and *Allegrini*,[37, 38] who generated pure polydisperse anthracene and fluoranthene aerosols.

Fluorescence occurs as a result of excitation of molecular or atomic systems by the absorption of one or more photons. Apart from fluorescence, other possibilities for a return to the ground state are available; their importance depends on structural considerations and on the nature of the excited state. Competing processes are quenching, internal relaxation (which leads to warming), and intersystem crossing (which leads to phosphorescence).

When fluorescence is compared as a detection principle with other optical principles, the high sensitivity and the possibility of achieving a high selectivity are immediately obvious. In contrast to photometry, where the sole available selectivity parameter is the absorption wavelength, two additional parameters can be used in fluorimetry: the fluorescence emission wavelength and the characteristic decay time for the fluorescence process. These three fluorimetric parameters should help either to identify and to quantify the various components in a mixture in the ideal case or at least to characterize of a group of similar substances.

A typical setup of an in situ and on line analysis of aerosols by time-resolved fluorimetry is shown in Figure 6.[39] It consists of three main components: the tuned laser system (207 nm–860 nm), the sensor unit (which is connected to the laser system by fiber optical cable), and the data accumulation and processing module.

The laser light (pulse length ca. 20 nsec, repetition rate up to 100 Hz) is transmitted via a fiber coupler to the optical wave-guide fiber and from thence to the sensor unit. Here the laser light is parallelized and subsequently crosses the aerosol flow. Within the light interaction volume the aerosol flow is conducted as a free-flowing current in a sheath air arrangement. The fluorescent light from the interaction volume is led perpendicular to both laser light and aerosol-flow axes through parallelization optics, an interference filter as a wavelength selector, and a second set of parallelization optics, and allowed to impede on the window of a fast-response photomultiplier.

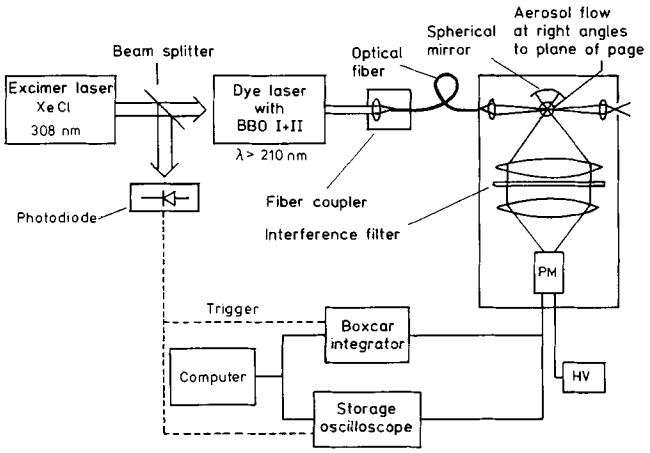

Fig. 6. Apparatus for the determination of polycyclic aromatic hydrocarbons on submicron aerosols by means of laser-induced time-resolved fluorescence. PM = photomultiplier, HV = high voltage, BBO = barium-β-borate crystal.

The data registration is performed by a 400 MHz storage oscilloscope. Triggering is accomplished by allowing a fraction of the exciting laser light to shine on a fast-response photodiode. The oscilloscope can now record a time-dependent study of the fluorescence process occurring after a laser discharge. The monitor image is processed by a CCD camera and transferred to the computer, where all subsequent processing is carried out.

The analytical possibilities are at present being studied on test aerosols. Initial results on monodisperse NaCl carrier aerosols with adsorbed polycyclic aromatic hydrocarbons (PAHs) gave decay times between 18 and 114 nsec. The absolute limit of detection lies in the femtogram range and is proportional to the amount of PAH adsorbed (Fig. 7).

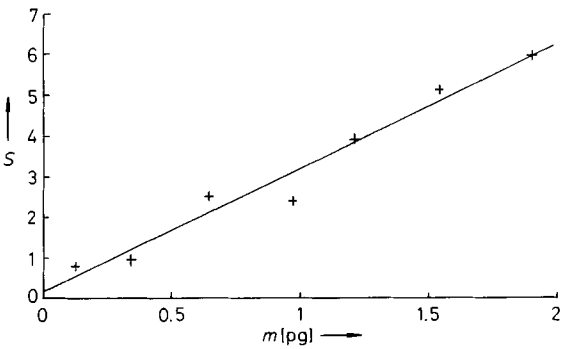

Fig. 7. Laser-induced fluorescence of a benzo[*a*]pyrene (BaP) coated aerosol. The fluorescence signal S (laser pulse energy normalized) is represented as a function of the amount of BaP [pg]. d_p = 80 nm (constant), T = 90–120 °C.

Fluorescence spectra of, for example, NaCl aerosols coated with benzo[a]pyrene or of particles consisting of pure BaP differ considerably from those of dissolved PAHs. Depending on the degree of surface coverage of the particles, a fraction of the fluorescence is red-shifted (see Fig. 8), due to the formation of PAH dimers on the particle surface at higher vapor pressures (i.e., higher PAH source temperatures).

Since the complete system (laser/photomultiplier/interference filter) can be connected via fiber optics, the procedure in principle enables remote sensing of toxic aerosols by fiber optics.

Work is presently in progress on deconvolution algorithms for the interpretation of superimposed fluorescence decay processes. One of the more severe problems in this type of measurement involves contributions from fluorescing substances in the air and from quench processes. On the other

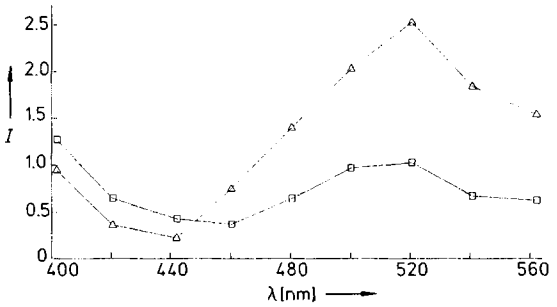

Fig. 8. Laser-induced aerosol fluorescence as a function of the observed fluorescence emission and the degree of coating (BaP on NaCl aerosol). Fluorescence intensity I [relative units], fluorescence wavelength λ [nm], □ at 95 °C, △ at 110 °C.

hand, the availability of further small lasers (e.g., the 337 nm N_2 laser or frequency-doubled semiconductor lasers) makes it possible to develop mobile measurement systems.

2.2.2. *Analysis by Laser-Induced Breakdown Spectroscopy (LIBS)*

The LIBS technique and its application to aerosols have been reviewed recently.[40–42] The procedure is based on a series of single processes: if a laser beam is focussed on solid material or on material particles, an aerosol cloud containing evaporated material is formed. If the laser pulse is of high energy (E > 100 mJ per pulse, pulse length ca. 10 nsec), the aerosol cloud forms a microplasma consisting of evaporated atoms, ions, electrons, and molecular fragments. All the molecules and particles within the plasma contribute to the light emission and can thus be determined both qualitatively and quantitatively. For example, detection limits of ca. 200 μg metal per m^3 were observed for aerosols containing cadmium, lead, and zinc.

2.2.3. *Analysis by ICP–Atomic Emission Spectroscopy*

The process of inductively coupled atomic emission has been applied to ceramic powder aerosols during studies involving materials science problems.[43] In ceramics technology, where the highest purity of trace elements is of prime importance, there would seem to be potential for further development. The generation of dry ceramic powder aerosols affords advantages over the previously used wet aerosols derived from slurries,[44] since a quench effect due to large amounts of water in the plasma can no longer occur.

Broekart et al.[45] have carried out a detailed study of the use of this technique in direct trace analysis of Al_2O_3 ceramic

powder aerosols. Problems exist in the case of larger particles (> 5 μm particle diameter), since when these are present the material is not completely evaporated.

2.2.4. *Analysis by Raman Spectroscopy*

Raman spectroscopy provides an extremely interesting tool for the characterization of suspended material. The phenomenon of Raman scatttering is caused by interaction between electromagnetic radiation and molecules or atoms in all aggregate states. Apart from the absorption or emission of photons, which is irrelevant in Raman spectroscopy, light scattering is observed within a very short time (ca. 10^{-14} sec). The energy of the incident photon can remain unchanged (Rayleigh scattering) or change (Raman scattering). The electric field of an electromagnetic wave induces a dipole moment proportional to the electric field strength. If vibrations are excited, the molecule's polarizability changes, and the prerequisite for observing a Raman spectrum is fulfilled. The identification of functional groups is possible, as in infrared spectroscopy.

The first Raman spectra of aerosol particles floating freely in an electrostatic suspension chamber were recorded by *Fung* and *Tang*,[46,47] who used an argon ion laser (488 nm) as the excitation source. The scattered light is focussed by a lens on the entrance slit of a double monochromator. Photon counting is carried out by means of a cooled photomultiplier and the necessary counting electronics. When this technique was applied to ammonium sulfate particles in the micrometer range, the resolution was excellent. However, no applications to freely flowing aerosols have so far been reported.

The use of resonance Raman spectroscopy in the ultraviolet range can be expected to bring a considerable amplification of the Raman intensity. *Asher*[48] applied this technique to deposited PAHs and achieved a remarkable selectivity and sensitivity.

2.2.5. *Analysis by IR Laser Back-scattering*

A laser beam which is allowed to pass through an aerosol cloud produces both absorption and scattering effects. This can be used as the basis for a remote investigation process for the physical and chemical description of an aerosol, the DISC process (differential scatter LIDAR system). *Wright* et al.[49] and *Mudd* et al.[50] were the first to study sulfuric acid and ammonium sulfate aerosols by this technique. DISC uses characteristic differences in the back-scattered IR radiation for quantification and differentiation purposes.

The LIDAR answer signal for a "laser shot" is given by Equation (d).[50] The qualitative information is obtained from β.

$$V(r) = \frac{KE_0\beta(r)\,T^2(r)}{r^2} \qquad \text{(d)}$$

$V(r)$ = direct back-scattered signal at a distance r
E_0 = transmitted laser pulse energy
$\beta(r)$ = back-scattering coefficient at a distance r
$T(r)$ = simple transmission of the mass of air from r to the detector
K = calibration constant.

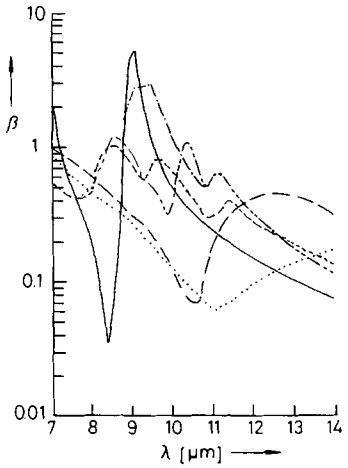

Fig. 9. Relative back-scattering of some environmental aerosols[50]. -·-· Basalt, ———— H_2SO_4 (95%), – – – H_2SO_4 (50%), — $(NH_4)_2SO_4$, ··· H_2O, and — — ice. β = relative volume back-scattering coefficient, λ = wavelength.

The relative back-scattering of various atmospheric aerosols as a function of the applied wavelength is shown in Figure 9. The limit of detection which can be achieved lies at best in the lower mg per m^3 range.

3. Aerosol Analysis by Measurement of Electrons, Ions, or Ionized Particles

Various techniques in analytical chemistry use electrons or ions as a measure of the amount of the species to be determined. These techniques include X-ray photoelectron spectroscopy (ESCA, UPS, XPS), photoemission, and mass spectrometry.

3.1. Analysis by Determination of the Kinetic Energy of the Electrons Released

The classical technique for the determination of the kinetic energy of emitted electrons is photoelectron spectroscopy or ESCA, which can in principle be used for all the elements of the periodic table (with the exception of hydrogen) in a quantitative manner. From the kinetic energy of the emitted photoelectrons and the energy of the exciting irradiation, the bonding energy E_b can be calculated. Detailed measurements of the bonding energy (chemical shift) provide information on the bonding states of the various elements.

It is a feature of ESCA that the observed photoelectrons arise mainly from the surface atom layers (the outer 5 nm or less, dependent on E_b, the material, and the exciting wavelength). ESCA can thus also be regarded as a very promising tool in the area of aerosol analysis.

One important drawback is that ESCA measurements on aerosol samples are normally carried out off-line.[51-53] The samples (e.g. from an aerosol-generating system) must be transferred as rapidly as possible from atmospheric pressure to the high-vacuum conditions of the spectrometer (up to 10^{-10} Torr) in order to avoid contamination by the pump oil or similar materials. On the other hand, many studies show that labile material such as organic substances and volatile

inorganic materials (e.g. ammonium salts) only survive for minutes or even seconds under these conditions.[54, 55] An on-line version of an ESCA spectrometer with a direct coupling between the aerosol and the high-vacuum compartment would thus be extremely useful.

Goldmann[56] was the first to develop such an instrument. As can be seen from the schematic diagram in Figure 10, expansion of the aerosol under vacuum forms an aerosol beam comparable with a molecular beam. This aerosol beam is irradiated by X-rays ($Al_{K\alpha}$ or $Mg_{K\alpha}$). Particle transfer through the two nozzles is particularly critical; transfer efficiencies have so far not been determined. The relatively complex pump system consists of Roots and turbomolecular pumps, which continuously pump off the incursing air.

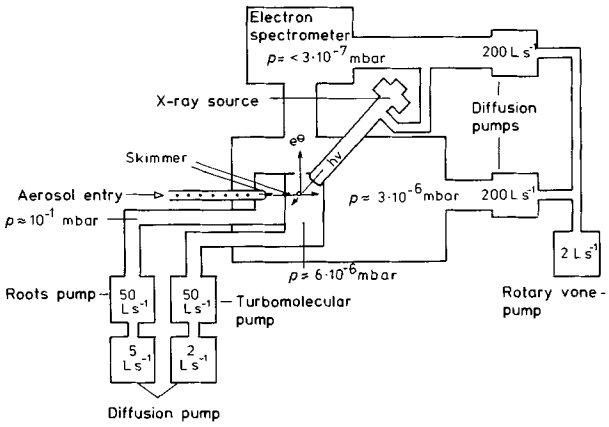

Fig. 10. Schematic diagram of an on-line aerosol ESCA apparatus as proposed by *Goldmann*[56].

The application of photoelectron spectroscopy as a quantitative analysis technique is limited in the case of aerosols by a marked dependence on particle size.[57] This is shown clearly in Figure 11 for a deposited sulfate aerosol. If the particles are perfectly spherical, the ESCA signal is expected to be proportional to the square of the particle radius. Since we are, however, generally interested in obtaining information on particle mass, the expected relationship is proportional to $1/r$. In Figure 11 the area of the S atom's 2p orbital, normalized with respect to carbon (the filter matrix) and the mass of sulfate, is plotted against particle size. The predicted $1/r$ dependence is reproduced very well.

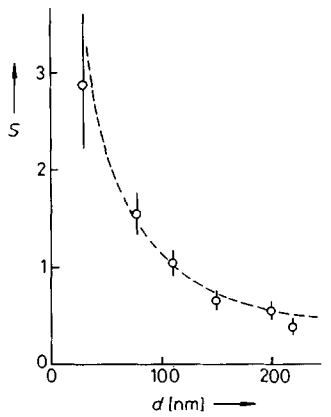

Fig. 11. ESCA signal S (in relative units) of the S atom's 2p orbital (normalized with respect to C 1s signal of the filter matrix and the mass of deposited sulfate) of monodispersed Na_2SO_4 aerosol as a function of the particle size (d = particle diameter). Dashed line: expected $1/r$ dependence.

Photoelectron spectroscopy can therefore only be used for mass determination of aerosols when an additional particle size determination is carried out; the surface-to-mass conversion assumes a homogeneous particle composition.

3.2. Analysis by Mass Spectrometry

The first analysis of airborne particles by mass spectrometry was reported by *Davis*.[58] His method involved focussing a particle beam from the surrounding air onto the ion source. Just as for the technique discussed in Section 3.1, the construction of an aerosol–vacuum interface is accompanied by substantial transmission losses. After a detailed study, *Stoffels*[59] suggested a solution in which the particle stream was passed through a capillary via a skimmer and a collimator and impacted directly onto a heated rhenium filament. This leads to surface ionization of the particles, giving charged fragments. A problem with this technique is the necessity for continuous pumping, which leads to the danger of contamination by back-diffusion of the pump oil.

The best solution at present is that proposed by *Sinha*.[60] Single particles are allowed to enter the ion source of a Mattauch–Herzog mass spectrometer in a sequential manner, where they are completely vaporized and ionized. The mass fragments are separated in space along a focusing plane of the magnetic sector. The electro-optical ion detector, which allows the simultaneous detection of all ions across the focusing plane, makes this apparatus unique. The ions impact on the active surfaces of a two-dimensional electron multiplier array. The electrons from the array are in turn accelerated and strike the end of the fiber optics, which is coated with a luminous material. The procedure generates "light pulse images" for the corresponding ion masses. The intensity of the bright spots is proportional to the total number of ions of a particular mass. The position and intensity of the ion images are registered by a CCD array. The detection limit of this mass spectrometer, determined using a dibromodiphenyl aerosol (particle size 1.8 μm), is ca. 10^{-13} g, and the simple relative standard deviation is 10–19%.

These results indicate areas of potential development for the mass spectrometric technique.

3.3. Characterization by Aerosol Photoemission

The principle of aerosol photoemission (APE) is the detection of positively charged aerosol particles.[61–63] In contrast to photoelectron spectroscopy, where the actual signal represents the kinetic energy of the emitted photoelectrons, APE makes use of the positive particles (their determination at atmospheric pressure by an aerosol electrometer is relatively easy) as a measure of the photoemitting material at the surface of the particles [Eq. (e)].

Nießner et al.[64] were able to show that $N^{\oplus}$ is directly proportional to the total photoelectrically active surface

$$dN^{\oplus}/dt = f\left\{\frac{\pi}{2} d^2 F,\ Y(h\nu),\ \Phi_{UV},\ N\right\} \quad \text{(e)}$$

$N^{\oplus}$ = number of positively charged particles
N = total number of all photoemitting particles
F = degree of surface coverage by photoemitting material
t = time
d^2 = irradiated particle cross-section
$Y(h\nu)$ = photoelectrical quantum yield at a photon energy $h\nu$ (dependent on the material and the light wavelength used)
Φ_{UV} = photon flux

area, which in turn comprises the surface areas of the various particles and the frequency of their occurrence in a polydisperse aerosol [Eq. (f)].

$$N^{\oplus} \sim S_{total}\left\{\frac{\pi}{2} d_i^2,\ N_i\right\} \quad \text{(f)}$$

S_{total} = total photoelectrically active surface of all particles
d_i = particle diameter of the component i
N_i = number of the particles of diameter d_i

The various components of a mixture of different photoelectrically active substances can be individually determined when their characteristic quantum yields are known from prior calibration experiments.[64] In analogy to photoelectron spectroscopy the height of the signal is proportional to the surface area; a mass determination thus shows a $1/r$ relationship between the signal's height and the aerosol mass. Photoemitting materials which can be studied include metal dust, some heavy metal oxide aerosols, and polycyclic aromatic hydrocarbons. The technique is at present applied in the control of diesel exhaust gases,[65] the control of waste incineration,[66] cigarette smoke analysis,[67, 68] and workplace monitoring.[64]

Figure 12 shows, as an example, the aerosol photoemission signals at an irradiation wavelength of 185 nm as a function of the PAH concentration in the smoke generated by six different brands of cigarette. There is a good linear correlation between the photoemission signal and the PAH concentrations in the aerosol as determined by HPLC analysis. It could be concluded that the PAH profile in the cigarette smoke varies only in the concentration but not in the relative ratios of the PAHs. The detection limit of the photoemission technique is in general in the lower ng m^{-3} range.[69, 70] The reproducibility of this technique is determined solely by the electronics and the stability of the UV lamp.

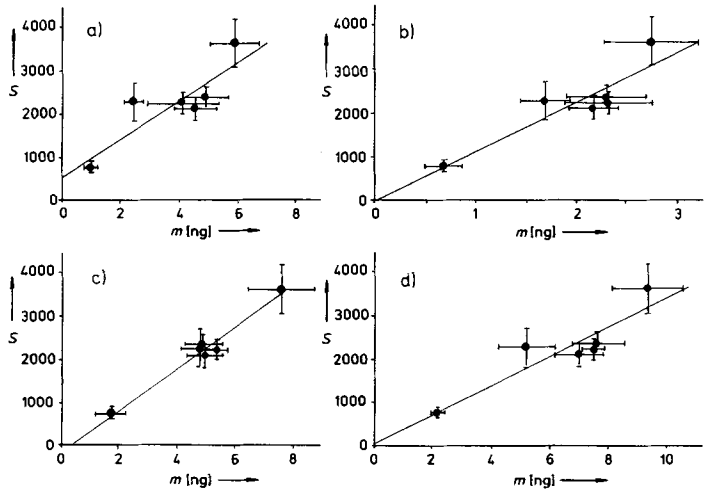

Fig. 12. Correlation between the photoelectric signal S and the content determined by wet chemical methods (m per cigarette) of a) benzo[*a*]pyrene, b) dibenzo[*a*,*h*]anthracene, c) benzo[*b*]fluorene, and d) benzo[*b*]fluoranthene. Each point represents the average of 5 analyses (with simple standard deviations) of one of 6 types of cigarettes.

4. Aerosol Analysis by Measurement of Physical Properties

4.1. Analysis by Observation of Hygroscopic Properties

Several techniques for aerosol characterization depend on the observation of the particle size after treatment with moisture or heat.

A good example is provided by the sulfuric acid aerosol detector proposed by *Liu* et al.[71] The process has also been described as an aerosol mobility chromatograph, since it depends on a continuous selection of particles which have different mobilities in an electric field. H_2SO_4 particles are mixed with air of a well-defined relative humidity, and as a result they swell. In combination with a differential electrostatic classifier (DMA) it is possible to perform extremely precise measurements of the particle diameter.

The construction of such an instrument is shown schematically in Figure 13. The aerosol to be analyzed is first passed

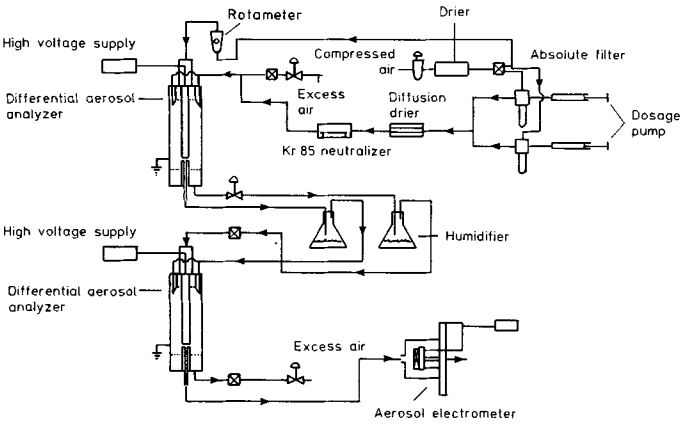

Fig. 13. Block diagram of the continuously operating aerosol mobility chromatograph [71].

through a krypton-85 neutralizer in which the particles are electrically charged according to a Boltzmann distribution. The charged particles are then allowed to pass into the first DMA. Particles of a certain polarity and electrical mobility are continually removed, humidified to a defined extent and fed into a second identically constructed and operated DMA. If water absorption and subsequent swelling has caused the particle diameter to increase and thus changed the electrical mobility, the "swollen" aerosol fraction will be able to pass through the apparatus (as a band pass) at a different collector voltage. The new particle diameter can be determined exactly from the voltage difference (see Fig. 14). At 53% relative humidity sulfuric acid particles swell, while

chloride, sulfate etc. remain unchanged. Aerosol electrometers or condensation nucleus counters are used as the on-line particle detector. The detection limit of this technique is ca. 10 ng H_2SO_4 per m^3 with an aerosol electrometer as detector and ca. 1 ng H_2SO_4 per m^3 with a condensation nucleus counter.

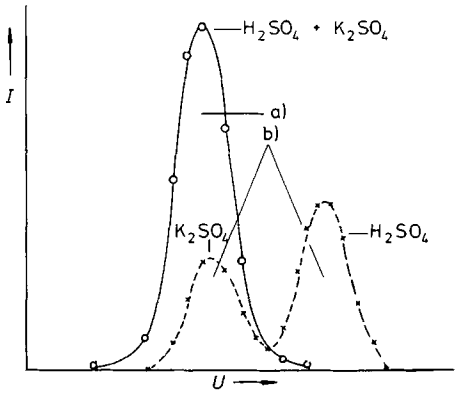

Fig. 14. Current/voltage curve for aerosol mobility chromatography of humidified and dry H_2SO_4/K_2SO_4 mixtures[71]. I = electrometer current, in relative units; u = voltage at central electrode, in relative units; a) without humidification: relative humidity 8.4%; b) with humidification: relative humidity 53%.

The same principle has been applied by *Charlson* et al.[72] who used a nephelometer to detect particle size changes. The resolution is, however, much lower than with a DMA, so that the detection limit lies in the µg range.

4.2. Characterization by Observation of the Particle Size after IR Absorption

An optothermal procedure in which submicron particles are irradiated by modulated CO_2 laser light has been combined with the observation of the particle size-dependent Mie scattering.[73-78] Under certain conditions when modulated IR radiation is used, the observed light scattering amplitude is proportional to the IR photon absorption. It is thus possible to record optothermally induced absorption spectra when a tunable IR laser is used.

The principle of the method is shown in Figure 15. A chopped IR source irradiates the aerosol particles. When light is absorbed, the particle radius of liquid aerosols varies according to the rhythm of the modulation. Photons from a second laser (in the visible range) are subjected to continuous elastic scattering at the aerosol particles. The resulting Mie scattering thus contains a component dependent on the modulation frequency and one dependent on the absorption cross-section of the particles. The first applications involved flowing ammonium sulfate aerosols (IR absorption band at 1110 cm^{-1}).

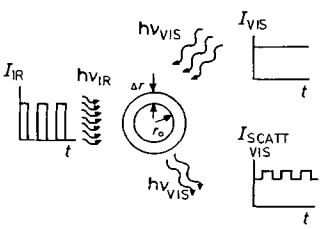

Fig. 15. The principle of optothermal absorption spectroscopy (after *Campillo* et al. [73]). For further details, see text.

4.3. Characterization Based on the Condensation Properties of Monodisperse Particles

The ability of ultrafine particles to act as condensation nuclei can be used for the characterization of the surface properties of such particles.[28, 79] Monodisperse particles with differing surface compositions can thus be characterized by observing the point at which water condensation occurs. The particles for study are selected by an electrostatic classifier. Droplet growth is then registered by a multistage condensation nucleus counter (Fig. 16). Hydrophobic organic layers deposited on hygroscopic nuclei can be studied especially well.

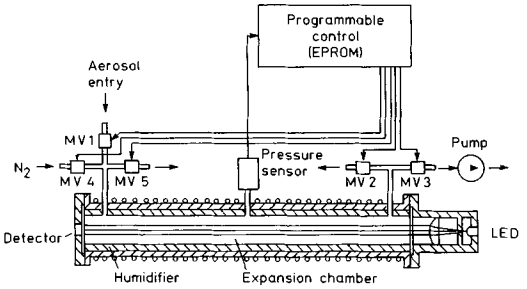

Fig. 16. Block diagram of a multistage condensation nucleus counter for the detection of the condensation properties of a monodisperse aerosol[79]. MV = magnetic valve; LED = light emitting diode.

Exemplary results, which were obtained by applying various degrees of water vapor supersaturation to monodisperse aerosols (Fig. 17), clearly show the effect of a small number

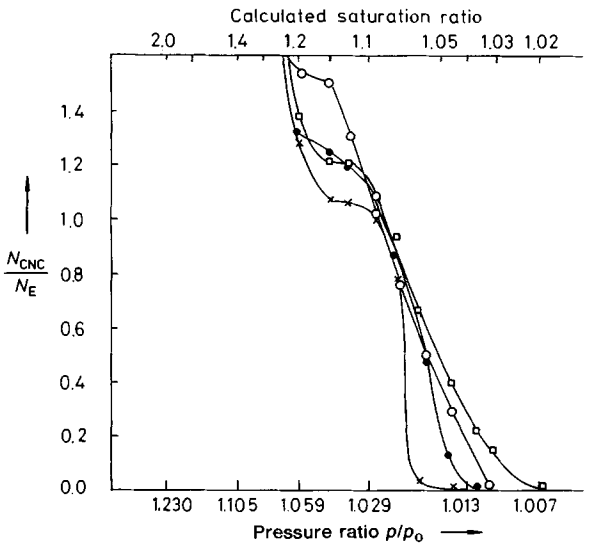

Fig. 17. Condensation spectra of monodisperse H_2SO_4 aerosol at constant total diameter as a function of water supersaturation. $d_p = 20$ nm; $p_o = 760$ Torr; □ H_2SO_4, $r = 10$ nm; organic coating ($r_{H_2SO_4} = 5$ nm, $\Delta r = 5$ nm): ○ 1-(hydroxymethyl)adamantine; ● n-hexadecane, × n-hexadecanol. N_{CNC}/N_E = droplet formation parameter.

of monolayers of a hydrophobic material on sulfuric acid droplets in a condensation process. The molecular structure of the coating material apparently causes an incomplete shielding of the nucleus in some cases. Thus a particle which is coated with *n*-hexadecanol is apparently wetted only with difficulty, while an H_2SO_4 droplet coated with 1-hydroxyadamantane can be activated even at low degrees of supersaturation.

5. Aerosol Characterization Based on Chemical Properties

The natural way for a chemist to carry out an aerosol determination is by chemical identification. Many such detection reactions are now available. Suitable identification reactions must be well-defined and reproducible, and must lead to a readily observable and easily quantifiable "signal".

5.1. Characterization by Means of a Selective Stoichiometric Reaction and Observation of the Products

A good example of an in situ and on-line process is the determination of aerosol sulfuric acid by a diffusion separator technique using radioactively labeled $Na^{36}Cl$.[80] A tube coated with $Na^{36}Cl$ is heated to 140 °C; though it is used as a sampler for H_2SO_4 aerosols, it also acts as an analyzer. The $H^{36}Cl$, which is formed in the stoichiometric reaction [Eq. (g)] can readily be bound on a filter impregnated with alkali or in an absorber solution and quantified by means of radiometric techniques.

$$H_2SO_4 + Na^{36}Cl \longrightarrow NaHSO_4 + H^{36}Cl\uparrow \qquad (g)$$

Figure 18 shows an automatic system for a quasicontinuous determination of sulfuric acid and ammonium sulfate in an atmospheric aerosol.[81] The air is first freed from gaseous inorganic and organic sulfur compounds (without any particle loss) by passing it through K_2CO_3 and activated charcoal diffusion tubes. The aerosol to be analyzed then passes through a Cu/CuO diffusion tube system heated to 120 °C or 220 °C. At 120 °C only the sulfuric acid is vaporized, while

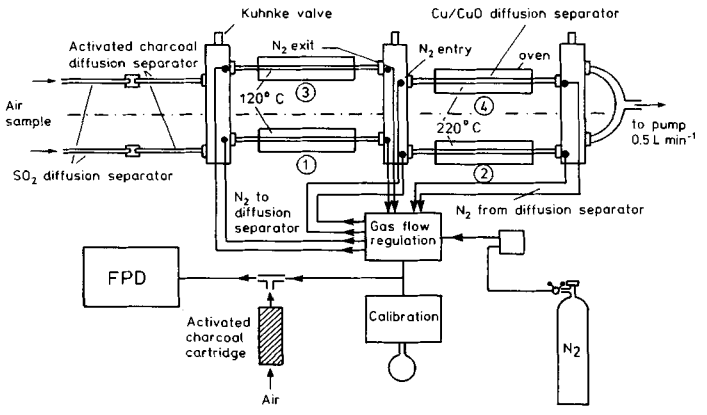

Fig. 18. Block diagram of a microprocessor-controlled H_2SO_4/ammonium sulfate aerosol analyzer. FPD = flame photometric detector.

the ammonium sulfate is decomposed at 220 °C. The fragments (molecular H_2SO_4) diffuse to the sink at the wall of the tube, where they are irreversibly sorbed. Thermostable aerosols pass through the various diffusion tubes without loss. After a predetermined sampling time the system is purged with ultrapure gas regulated by computer-controlled magnetic valves. Each sample tube is separately subjected to a short heating pulse, during which the sorbed acid is desorbed and converted at the Cu/CuO surface to SO_2, and each reproducible SO_2 pulse is registered on-line by a flame photometric detector. During SO_2 detection, sampling continues in a second system driven in parallel. The detection limit is ca. 0.1 μg H_2SO_4 per m^3 with a sampling time of ca. 5 min.

A similar apparatus has been developed for the determination of nitric acid and ammonium nitrate aerosols.[82] In this case thermolysis gives NO, which is detected via a chemiluminescence reaction with ozone.

5.2. Characterization by Chemiluminescence

Stauff and *Stark* et al.[83–86] were the first to make use of chemiluminescence in aerosols during combustion processes to characterize aerosols. A particularly promising improvement of this technique involves the use of CCD arrays for the simultaneous observation of luminescence across a wide wavelength range.

6. Summary and Future Prospects

This review makes it clear that a large number of classical optical techniques can be applied to aerosol systems. The procedures presented include not only typical surface-sensitive techniques such as ESCA and photoemission, but also mass-proportional methods such as LIF, LIBS, and aerosol mass spectrometry.

In the near future it will be of prime importance to have available chemometric evaluation methods coupled with broad-band detection techniques. A great deal of effort will also have to go into the miniaturization of the methods presently available. In this respect integrated optical circuits in combination with frequency-doubled laser diodes as UV source and CCD arrays as receiver optics have a great future. Aerosols in the form of selectively prepared substances with a high specific surface area, a particle size distribution which is as narrow as possible, and whose formation is continuously controlled will surely take up a permanent place in further technologies in the future.

The author wishes to thank all those who were responsible for stimulating, encouraging, and sustaining his interest in the analytical chemistry of finely dispersed systems.

The Isoinversion Principle— a General Model of Chemical Selectivity

By Helmut Buschmann, Hans-Dieter Scharf,* Norbert Hoffmann, and Peter Esser

Dedicated to Vladimir Prelog and to the memory of Horst Pracejus

A large number of successful methods for chirality transfer, using either stoichiometric or catalytic chiral auxiliaries, are in use today. However, there is a lack of practical and dynamic selectivity models, i.e. models which take into account the entire reaction sequence, and which allow simple and reliable assessment, optimization and prediction of selectivity in asymmetric syntheses. The models that are available are either too strongly biased to the steric requirement of the particular molecules reacting, but do not go beyond classical considerations of static facial differentiation, or they take a demanding, theoretical approach, which because of its inherent limitations and the great theoretical effort required has not yet found its way into the practical world of the synthetic chemist. The "Isoinversion Principle", developed on the basis of Eyring's theory, closes this gap. With its aid, the synthetic chemist can determine the characteristic isoinversion temperature T_i for the reaction type of interest from a few temperature-dependent measurements of selectivity parameters. T_i then affords information on interesting questions such as optimization etc. The advantage of this method is that it is useful not only for stereoselectivity, but for any kind of process where selectivity in general (regio-, chemo-, etc) is generated at two or more stages of a reaction sequence, regardless of whether these reactions involve the ground state or a diabatic photoprocess. The present review will demonstrate that this generation of selectivity at two or more stages of a reaction sequence occurs more commonly than is generally thought.

1. Introduction

Since the discovery of the phenomenon of molecular chirality last century,[1-3] chemists have been more and more interested in devising methods and conditions which would enable them not merely to resolve racemates in the classical manner, but to direct chemical reactions asymmetrically.[4, 5] The chemist's aim is to produce only one of the two enantiomers of a compound, either selectively or specifically.

The last twenty years have seen a storm of developments in this field,[6-8, 46] spurred on by the aims of exploiting the increasing knowledge of enzyme reactions, of understanding and imitating their mechanisms, and by the discovery that enantiomers can have different physiological effects.[46b]

Today, good empirical knowledge, and the model-like ideas of ground-state chirality transfer that arise from it, are part of the everyday experience of the synthetic chemist.[6-8] Based on the classical work of *Cram* et al.[6-9] and *Prelog* et al.,[6-8, 10-15] *Helmchen* and *Schmierer*[16] have recently proposed a qualitative working model in their "concave-convex model" (Fig. 1). This model is based on the conformational effects of reactant molecules, and is now used all over the world as an aid in assessing asymmetric syntheses. It has led to numerous successes in the preparation of enantiomerically pure synthons for natural and synthetic products.[17, 18]

In so-called stoichiometric asymmetric synthesis, this has led to the successful application of a series of "concave" secondary alcohols as chiral auxiliaries. A selection of the most commonly used members of this group, with no guarantee of completeness, is shown in Figure 1.

The predictions of this model are quite general, and are limited to the reactant molecule. To achieve high diastereomeric excesses they require firstly chiral auxiliaries as bulky as possible, and secondly reaction temperatures as low

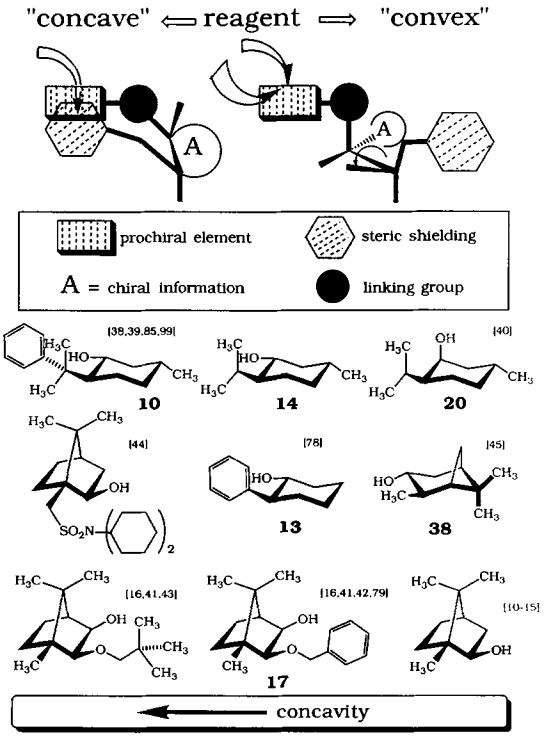

Fig. 1. Schematic diagram of concave and convex reagents, after *Helmchen* and *Schmierer* [16]. The figure shows a selection of the most important concave, secondary alcohols which have found use as chiral auxiliaries in stoichiometric asymmetric synthesis.

Prof.-Pirlet-Strasse 1, W-5100 Aachen (FRG)

as possible, in order to freeze the concave conformation (usually the more energy-rich) and achieve complete facial differentiation.

Attempts to construct quantitative models for stereodifferentiation have so far proved less productive for the practical chemist. Possible solutions in this direction have been provided by *Izumi* et al.[8, 9] and *Salem*[8, 264a, 268] and by approaches on the basis of free reaction enthalpy by *Ugi* and *Ruch*,[8, 20–24] and *Fukui*.[25]

Reports of successful diastereoselectivity in photochemical reactions appeared only after a long delay.[26–33] They extended the spectrum of synthetic possibilities in many ways. Detailed studies of the temperature dependence of the Paternò-Büchi reaction,[34–36] especially, led to the discovery of the Isoinversion Principle.[37] The Principle of Isoinversion includes the Helmchen-Schmierer model as a boundary case. It is a dynamic model, which takes into account *all* the reaction components in the planning and optimization of selective steps. It judges both the usefulness of auxiliaries or catalysts and the suitability of substrates, and, in addition, can be used to test mechanisms. It can be applied wherever selectivity is generated on two or more reaction levels. This article will show that this is clearly the case for a wide variety of selective reactions.

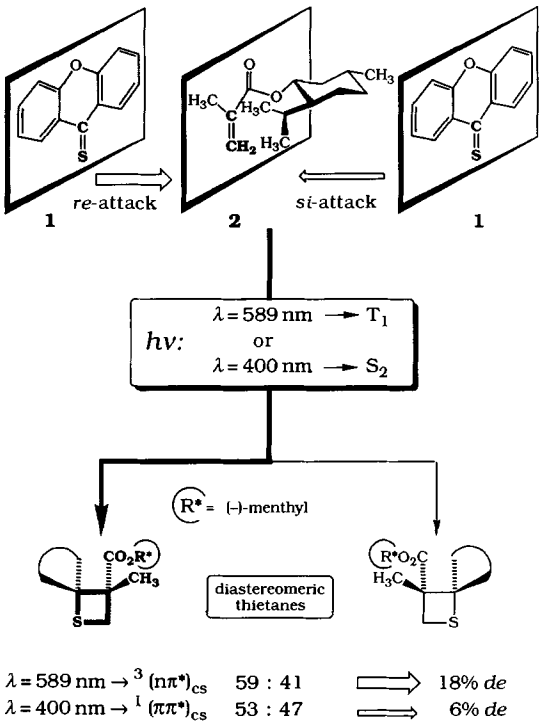

Fig. 2. Photochemically-induced, diastereoselective thietane formation, after *Gotthard* and *Lenz* [32b].

2. Asymmetric Induction in the Paternò-Büchi Reaction

Asymmetric induction in [2 + 2]-cycloadditions has been reported several times in the literature.[31, 47] The first example of a photochemical, diastereoselective hetero-[2 + 2]-cycloaddition appeared in 1979, in an article by *Gotthardt* and *Lenz*,[32b] who prepared thietanes by this method. The authors made use of the known fact that for their starting molecule, xanthione **1**, either the singlet or the triplet state can be specifically excited, in a wavelength-dependent manner. The chiral information is present here in the form of a menthyl residue in the methacrylate ester **2**, which functions as the olefinic partner (Fig. 2).

Although the *de* values achieved were low on an absolute basis, the most remarkable outcome of the experiment was that the singlet and triplet reactions afforded different diasteromeric excesses, with the triplet value higher than that for the singlet. If anything, the opposite result was expected, since the triplet pathway passes through a conformationally less rigid biradical intermediate.

In the same year, the authors also reported an "unusually high asymmetric induction" in the analogous photochemical

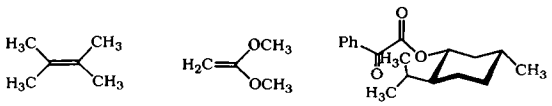
Hans-Dieter Scharf, born 1930 in Leipzig, studied chemistry from 1949 to 1950 at the University of Leipzig and from 1954 to 1960 at the University of Bonn. After receiving his doctorate in 1960 for work on the Ipatiev reaction under the supervision of F. Korte he joined the staff of the Shell-Grundlagenforschungs GmbH in Birlinghoven near Bonn, where he carried out fundamental research, first as research chemist, later as section leader. From 1966 to 1968 he completed his habilitation at the University of Bonn on the theme "Photochemical [2 + 2] Cycloadditions", and shortly thereafter he accepted an appointment as Wissenschaftlicher Rat and as Professor of Organic Chemistry at the Technische Hochschule Aachen. After rejecting several calls from other places, in 1972 he was appointed Full Professor and Director of the Institute for Organic Chemistry. His areas of research include photochemistry, chiral induction in photochemical and ground-state reactions, applicaton of solar photons in photochemistry and energy storage, the synthesis of bicyclic acetal pheromones of pests and of deoxy sugars and their employment in the partial synthesis of antibiotics.

Helmut Buschmann, born 1960 in Kaldenkirchen, studied chemistry from 1980 to 1987 at the Technische Hochschule Aachen, where he is now finishing his doctorate.

Peter Esser, born 1963 in Jülich, completed his graduate studies in chemistry in 1989 at the Technische Hochschule Aachen, where he is now working for his doctorate.

Norbert Hoffmann, born 1960 in Kesfeld, studied chemistry at the Technische Hochschule Aachen from 1979 to 1986, and is now also finishing his doctorate.

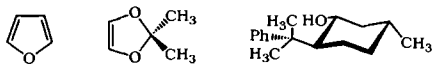
oxetane formation. They treated menthyl phenylglyoxylate **35** with tetramethylethylene **3** or ketene acetal **4**, and obtained diastereomeric excesses of 37% and 53% respectively.[32b]



3 **4** **35**

In 1982, *Jarosz* and *Zamojski*[48,49] reported a further example of diastereoselectivity in oxetane formation in the sense of the Paternò-Büchi reaction, on treatment of glyoxylic acid derivatives esterified to chiral alcohols with furan **5**.[30] However, the diastereomeric excesses obtained lay only in the region 2–7%.[30]

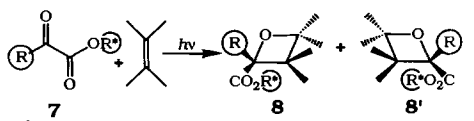
We were able to show, in 1983, that on reaction of optically active phenylglyoxylates with electron-rich cyclic olefins such as 2,2-dimethyldioxol **6** or furan **5**, using 8-phenylmenthol as a chiral auxiliary, complete induction in photochemical oxetane formation can be achieved.[50,51] Since then, a series of successful examples of photochemical [2 + 2]-cycloadditions have been described, with average to very good diastereomeric excesses obtained by chiral induction.[52–55,282]



5 **6** **10**

2.1. Studies on the Mechanism of Stereoselectivity

Systematic studies on the mechanism of stereoselectivity in the diastereoselective Paternò-Büchi reaction showed the *de* value of the oxetane product mixture to be a sensitive mechanistic probe, which responds even to minor structural changes in the reactants and to the slightest perturbations of experimental conditions.[34–37,56–58] The addition of $^3(n\pi)^*$-excited chiral α-keto esters of type **7** to electron-rich olefins, as shown in Equation (1), leads to the diastereomeric oxetanes **8** and **8'** in high yield.[48–50]



7 **8** **8'**

Ⓡ* = chirale auxiliary

(1)

This reaction was discovered in 1909 by *Paternò* and *Chieffi*,[59] and was later studied in detail by *Büchi*,[60] *Caldwell* et al.,[61] *Turro* et al.[62,63] and *Wagner*,[64] and more recently by *Peters* and *Freilich*.[65,66] Its mechanism is one of the best known for photoreactions, and it is also of great preparative importance.[67–69] The scheme given in Figure 3 was proposed by *Peters* et al.[66] and contains a resumé of the

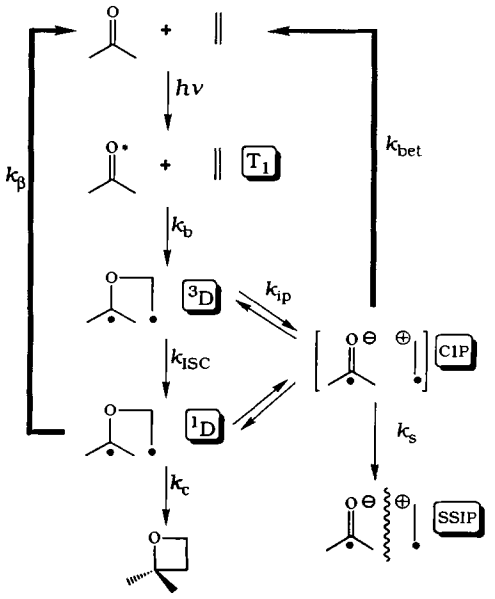


Fig. 3. Mechanism of photochemically-induced oxetane formation, from *Freilich* and *Peters* [66]. After photoexcitation of the ketone to the first excited singlet state, there follows a rapid intersystem crossing step into the lowest energy triplet state (T_1). The excited ketone attacks the olefin with its electrophilic oxygen atom, forming the 1,4-biradical triplet (^3D) (k_b). The possibility of a charge-transfer complex with subsequent exciplex formation is disregarded. Before ring closure to the oxetane (k_c), or retrocleavage to the ground state ketone and olefin with loss of the excitation energy (k_β) can occur, the 1,4-biradical species (^3D) must be converted into a singlet state (^1D) by intersystem crossing (k_{ISC}). Starting from the triplet biradical, however, an initial heterolytic cleavage (k_{ip}) to a contact ion pair (CIP) can also take place, before the triplet biradical is formed. Alternatively, the contact ion pair may be transformed (k_s) by the solvent into a solvent separated ion pair (SSIP), or may decompose to the ground state ketone and olefin by a second, reverse charge transfer (k_{bet}).

mechanism for photochemical oxetane formation widely accepted today. The individual weighting of each postulated intermediate is largely determined by the electronic and steric nature of the substrates concerned.

In the literature, the formation of an exciplex from the olefin and the T_1-excited carbonyl compound is often postulated.[67] Indirect evidence for the existence of an exciplex does exist,[62–67] but to date there is no direct proof of its existence.[70,100] After dissipation of a large part of the excitation energy, a 1,4-biradical intermediate is formed,[86] which has been detected by trapping reactions[71] and transient analysis.[65,66] This 1,4-biradical intermediate now has two possible paths for further reaction: either bond formation occurs to give the oxetane, or the 1,4-biradical undergoes bond cleavage to re-form the starting material (retrocleavage). In the model reaction (1) studied, high chemical yields are obtained, and side-products are not observed. Stereoselectivity in this reaction is determined by the chiral auxiliary Ⓡ*,[34,56,57,72–74] the nature of the olefinic reaction partner,[50,72,74] the nature of the Ⓡ substituent of the α-keto ester,[36,50] and the reaction conditions (temperature,[34–37,54,56] solvent, metal ions[75]).

When cyclic, electron-rich olefins of type **9** react with chiral α-ketoesters as in (1), the diastereomeric, bicyclic oxe-

9

tanes **31** and **31'** are generally formed *endo*-selectively relative to the Ⓡ substituent of the α-keto ester[51, 74] (Fig. 4).

The period of illumination and the rate of conversion have no effect on the diastereomeric product ratio. Light-induced secondary products, isomerizations or photolytic cleavage of the products are not observed under the reaction conditions given.[74] The concentration of the carbonyl and olefin components could be varied widely without any change in the *de* value, under otherwise identical conditions.[74] The effect of the spin multiplicity of the excited carbonyl component could not be studied with reaction (1), since oxetane formation in this case proceeds entirely from the carbonyl triplet state, passing through 1,4-biradical intermediates.[62]

2.1.1. The Influence of the Auxiliary

Table 1 shows some examples of the influence of the chiral auxiliary on diastereoselectivity. Chiral phenylglyoxylates **7** were transformed with **6** as olefinic partner at room temperature, and the diastereomeric excess obtained for the various chiral auxiliaries was measured by ^{13}C-NMR spectroscopy.[76]

Table 1. The influence of the chiral auxiliary on the *de* value in the photochemical formation of oxetanes from **7** and **6**. The *de* values were determined from the ^{13}C-NMR spectra [76].

When **10** was used, complete induction was observed.[51] With the methyl derivative **11** the extent of induction is reduced only slightly.[74] Electronic interactions between the phenyl ring and the ester carbonyl function (π–π interaction[77]), which have been suggested to be important for certain ground state reactions, are hence unimportant in the course of the diastereoselective reaction. Removal of the methyl group in the 1-position in **11** gives **12**, without decreasing the induction potential of the reaction.[74] With *trans*-2-phenylcyclohexanol **13** (a strictly concave substitute for **10** which has been used successfully in a number of ground state reactions[78]), a diastereomeric excess of only 56% was obtained, comparable with the induction potential of menthol **14**.[74] If the sterically shielding group is enlarged by introducing a second phenyl ring, as in *trans*-2-(*p*-biphenyl)cyclohexanol **15**, the *de* value even falls significantly to 42%. This value, on the other hand, can be achieved even with simple *trans*-2-methylcyclohexanol **16**, from which one expects no facial selectivity in the sense of the static "concave/convex model" (Fig. 1).

Auxiliaries of the bornane type, like *exo*-2-benzyloxy-*exo*-3-bornanol **17**,[16, 41, 42, 79] an auxiliary usually regarded as highly concave, have proved highly effective inducers in many ground state reactions. In the Paternò-Büchi reaction, however, they yielded diastereomeric excesses which can only be placed in the lower third of the *de* value scale.

Configurational isomers of the menthol type (Systems 1, 5, 7, 8 in Table 1) reveal the considerable influence of the configuration of the methyl group in the 1-position on stereoselectivity.

In isomenthol **18** (No. 7), the methyl group is in the axial position and the inductive potential is decidedly reduced, although according to the simple shielding model this methyl group ought not to have any influence on facial differentiation.[74] The methyl group in the equatorial position, however, shows no significant effect on stereoselectivity, as a comparison of the *de* values for menthol **14** (No. 1) and *trans*-2-isopropylcyclohexanol **19**, or for 8-methylmenthol **11** and *trans*-2-*tert*-butylcyclohexanol **12** shows. Auxiliaries of the neomenthol type **20** (No. 5) also give reduced stereoselectivity in comparison with alcohols with the substitution pattern of menthol **14**, but the effect is not as great as for the axial methyl group in the 1-position. In addition, with neomenthyl type **20** auxiliaries the opposite chiral information to the corresponding menthol derivative is induced, so that the easily accessible (+)-8-phenylneomenthol[80] **21** has been discussed in the literature as a substitute for the less available (+)-8-phenylmenthol *ent*-**10**.[85]

From these few examples it can be seen that the predictive power of the static concave/convex model (Fig. 1), which only accounts for steric effects, is most uncertain in the cases shown, and explains the observed effects either poorly or not at all.

2.1.2. The Influence of the Olefinic Component

Table 2 shows the *de* values obtained for reaction of the phenylglyoxylates of menthol **35** or 8-phenylmenthol **22** with a variety of olefins.

Extremely high diastereomeric excesses are observed for the ester **22** in all cases. Use of menthol **14** as chiral auxiliary, however, gave a considerable spread of *de* values, depending on the structure of the olefin used under otherwise identical conditions.[98]

Table 2. The influence of the olefinic component on the *de* value in the photochemical formation of oxetanes from the phenylglyoxylates **22** and **35**. The chiral auxiliaries used were **14** and **10**. The major oxetane obtained is printed in bold face.

The influence of the R substituent in the 2-position of the dioxols on selectivity is remarkable, for instance. This cannot be explained by purely steric effects. The dimethyl derivative **6** always yields the highest diastereomeric excesses, regardless of the auxiliary used. Dioxols with R = H (**23**) or R = Ph (**24**) bring about a moderate fall in the *de* value, while in the case of the menthol auxiliary **14** the 2,2-diisopropyl-1,3-dioxol **25** gives rise to a drastic decrease. With cyclic olefins, photooxetane formation generally proceeds in a strictly *endo*-phenyl-selective manner. Only when the imidazole derivative[284] **26** was used could a small amount of the corresponding *exo*-product **27** be detected.[81]

Ketene acetal **4** is a noncyclic, C_{2v}-symmetric olefin with the C_2 axis lying parallel to the double bond. When the 1,4-biradical intermediate (**28** and **28'**) is formed, no new chiral center is created (Fig. 4). Here, diastereoselective oxetane formation leads to an additional regioisomerism,[82, 94] which is eliminated when symmetrical, tetrasubstituted olefins such as tetraethoxyethylene **29** or tetramethylethylene **3** are used.

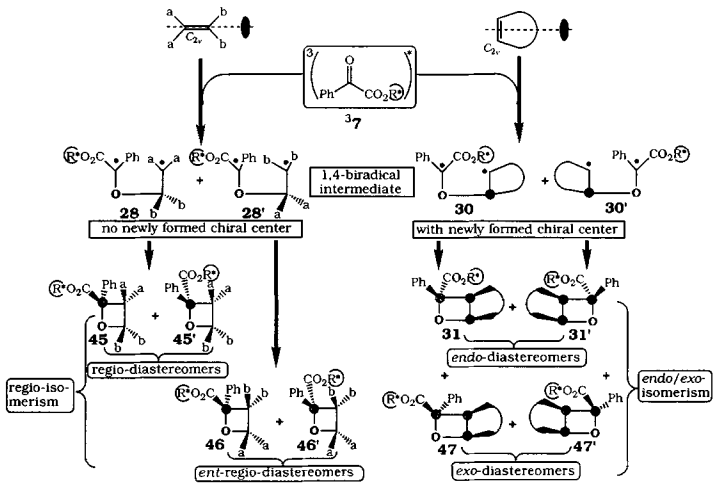

Fig. 4. The formation of diastereomeric, regioisomeric and *exo*/*endo* isomeric oxetanes by reaction of chiral phenylglyoxylates **7** with C_2-symmetric olefins that possess a C_2-axis parallel or perpendicular to the double bond. (• denotes a newly formed chiral center).

Cyclic C_{2v}-symmetric olefins with the double bond perpendicular to the C_2 axis already form a new chiral center in the 1,4-biradical intermediate (**30** and **30'** in Fig. 4). This chiral center then determines all the other chiral centers, due to the *endo*-phenyl selectivity of the oxetane formation reaction (1). One exception—already mentioned—is olefin **26**, which also leads to oxetanes with an *exo*-directed phenyl group (**27** and **27'**).

Figure 4 shows schematically the possibilities for *endo*/*exo*, regio-, and diastereomeric products[82] in Reaction (1), when symmetrically-substituted olefins with a C_2 axis parallel or perpendicular to the double bond are used.

Furan **5** is a cyclic olefin with a C_2 axis external to the double bond. In the biradical intermediate a new chiral center is also generated, but cycloaddition to phenylglyoxylates of hindered alcohols leads regioselectively to the diastereomeric bicyclic oxetanes **31** and **31'**.[48–50, 69]

2-Methylfuran **32** is a cyclic olefin without a C_2-symmetry element, and yields regiomeric oxetanes. In the structural analogue 1-methylcyclopentadiene **33**, only one regiomeric pair of diastereomers with structure **34** is observed.[50]

2.1.3. The Influence of the Glyoxylic Acid Residue (R)

In order to investigate the influence of the residue (R) on diastereoselectivity we treated variously substituted α-keto esters of **14** and **10** with **5**. Table 3 shows that the diastereoselectivity is directed considerably by the substituent (R).[36]

Table 3. The influence of the (R) substituent in the α-keto ester component on the *de* value in the photochemical formation of oxetane according to Equation (1). The menthyl and phenylmenthyl phenylglyoxylates were treated with furan **5** at 20 °C or − 23 °C. The major oxetane obtained is printed in bold face.

[a] With 2,2-diisopropyl-1,3-dioxol **25** as olefin, however, oxetanes were obtained in 95% yield [73].

The diastereomeric excesses that could be obtained varied from 7% to 60% in the case of menthol **14**, and between 12% and complete induction for 8-phenylmenthol **10**.

The Paternò-Büchi reaction is a diabatic photoreaction, i.e., after excitation of the carbonyl component to form the 1,4-biradical intermediate, a large part of the absorbed photon energy has to be dissipated. The substituent (R) exerts a decisive influence here on the extent of energy dissipation. Along with the phenyl (No. 8) and 2-thienyl groups (No. 7) the *tert*-butyl group (No. 4) proved especially effective in this sense; in all these cases, complete induction was observed with **10**, while reactions of glyoxylates ((R) = H, No. 1) afforded only low levels of induction.[36, 50]

To obtain information on how far the action of substituent (R) in the selectivity process can be traced to electronic and/or steric effects, we treated various *para*-substituted phenylglyoxylates with furan **5** in the Paternò-Büchi reaction, and correlated the *de* values obtained with the σ_p-values of the substituents in the Hammett Equation (2).[83]

$$\lg(k/k_0) = \sigma\rho \qquad (2)$$

From the linear dependence observed ($\rho = -0.176 \pm 0.051$, correlation coefficient = 0.99, $T = -23$ °C),[84] it can be concluded that the influence of substituent (R) is clearly mainly of an electronic nature,[83b] and that a uniform mechanism exists. No correlation was found to the values for direct conjugation, σ^+ and σ^-, which indicates that purely ionic intermediates are probably not important, although a certain dependence of the *de* value on the polarity of the solvent can be seen.[75] Hence, the initial assumptions, according to which substituent (R) plays a purely steric role in diasteroselectivity,[50] are not confirmed. The *de* values obtained for alkyl-substituted α-keto acid derivatives (Table 3, No. 2–6) also display a dependence on the ionization potential of these residues. This can be seen as a further indication of the importance of electronic effects in stereoselectivity by (R). This argues that the selectivity process in the Paternó-Büchi reaction takes place close to the ground state.

2.1.4. The Influence of Reaction Temperature

The influence of reaction temperature on the selectivity of photochemical processes has, until now, been studied for only a few cases.[54, 87] We made the first observations of temperature-dependent diastereoselectivity in the reaction of menthyl phenylglyoxylates **35** with tetramethylethylene **3** and ketene acetal **4** (Table 2), i.e., with C_{2v}-symmetric olefins having a C_2 axis parallel to the double bond.[34] Following the modified Eyring approach[88] of Equation (3a), a linear dependence of the ln(P) value on the reciprocal temperature was found. P is defined by Equation (3b), where k and k' are the overall rate constants for the formation of diastereomeric or regioisomeric oxetanes according to Equation (1) and I and I' are the intensities of the selected signals in the ^{13}C-spectrum of the diastereomeric or regioisomeric product mixture.[76]

$$\ln(P) = -\frac{\Delta\Delta H^{\ddagger}}{R}\frac{1}{T} + \frac{\Delta\Delta S^{\ddagger}}{R} \qquad (3a)$$

$$P = \frac{k(\text{excess oxetane})}{k'(\text{oxetane deficit})} = \frac{I(\text{excess oxetane})}{I'(\text{oxetane deficit})} \qquad (3b)$$

Figure 5 shows the temperature dependence of diastereoselectivity in the form of an Eyring diagram.[36]

Even in these early studies it was found[50] that the reaction temperature does not exert a uniform influence on the diastereoselectivity of photooxetane formation (1). As the temperature falls, an increase in the *de* value is not the only effect observed. In contrast to current opinion the diastereomeric excess may also fall or remain constant.

In addition, an isoselectivity relationship was observed, as has been reported by *Pracejus*[91] and later by *Giese* et al.,[92] who studied temperature-dependent selectivity in carbene and simple radical reactions. These reports are based on the observations of isokinetic phenomena,[269] described in the fifties and sixties by *Exner*[89] and *Leffler*.[90]

In further studies of temperature dependence in the diastereoselectivity of photooxetane formation, we treated C_{2v}-symmetric, cyclic olefins of type **9** with a series of chiral,

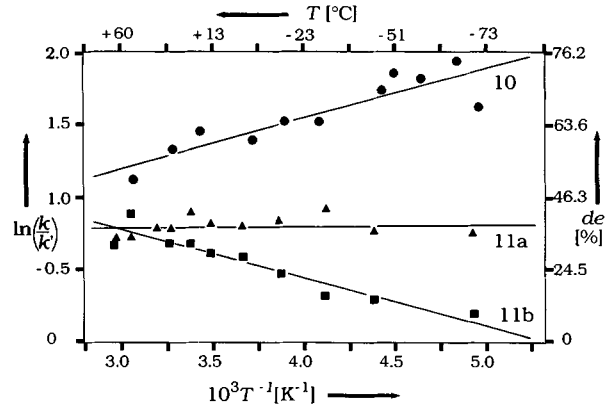

Fig. 5. Temperature-dependence of diasteroselectivity in the reaction of menthyl phenylglyoxylate with tetramethylethylene **3** and ketene acetal **4** (Systems 10, 11a, 11b in Table 2).

unsubstituted and *p*-phenyl-substituted glyoxylates. Table 4 presents a summary of all reactions studied so far.

As chiral information bearers we used a number of substituted cyclohexanols, since these afford average diastereomeric excesses (*de* values in the region 20–70%). In this region the activation parameters $\Delta\Delta H^{\neq}$ and $\Delta\Delta S^{\neq}$ are particularly easy to determine experimentally.

In reactions with the cyclic olefins **6**, **23**, **25** and **36**, toluene was used as solvent. In the case of furan **5**, the olefin itself acts as a solvent, because of the greatly decreased reactivity of the furan to photochemical oxetane formation. The temperature region studied reached from + 50 to − 90 °C. In our case,[37] the period of illumination was 6 h for **6**, **23**, **25**, and 15 h for **5** and **36**.

Surprisingly, for all the systems in Table 4 that were studied, we found two linear regions in the Eyring-diagram, with a characteristic inversion point. Some typical results of temperature measurements on the systems in Table 4 are given in Figures 6 and 7, in the form of Eyring diagrams. Figure 6 shows diagrams for oxetane formation from *trans*-2-phenylcyclohexyl phenylglyoxylate **40** with the olefins **5**, **6**, **23**, **25** and **36** (Table 4, Nos. 1–5), while for the Eyring diagram of Figure 7 the phenylglyoxylates of **39** (**41**), **37** (**42**), **14** (**35**), **18** (**44**) and **12** (**43**) were treated with the unsubstituted dioxol **23** (Table 4, Nos. 6, 11, 16, 21, 26).

Table 4. Overview of the systems in which the influence of temperature on the *de* values have already been investigated. the phenylglyoxylates of **13**, **37**, **39** and **12** were used in racemic form. Control experiments with the enantiomerically pure phenylglyoxylates gave the same product distribution of diastereomeric oxetanes [264, 265].

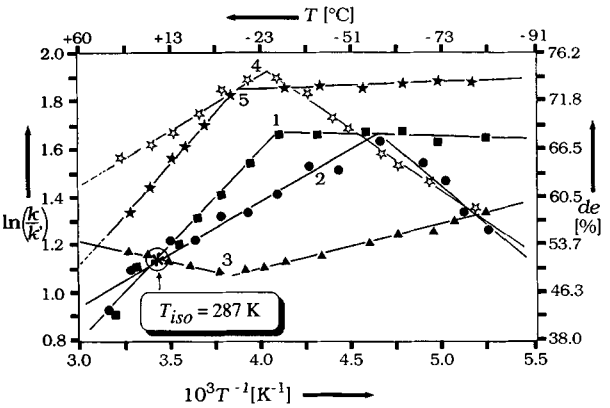

Fig. 6. Temperature-dependence of stereoselectivity in the reaction of *trans*-2-phenylcyclohexyl phenylglyoxylate **40** with olefins **5**, **6**, **23**, **25**, and **36**, presented as an Eyring diagram (Systems 1–5 in Table 4). Systems 1–3 yield an isoselective point in the high-temperature region ($T > T_{inv}$), with isoselective temperature T_{iso} = 287 K.

We describe the temperature at the isoinversion point as the inversion temperature T_{inv} of the system,[*] because at this temperature it is clear that a change occurs in the dominance of enthalpy and entropy in the partial selectivity steps. The inversion temperature found varies between − 61 °C and − 8 °C. In contrast to general opinion—the lower the reaction temperature, the higher the stereoselectivity—this result teaches us that the opposite relation can also be true. Even if an increase in selectivity is found on decreasing the temperature, this relationship need only hold for a particular temperature region. For the systems studied in Table 4, two temperature regions can be identified, with different linear

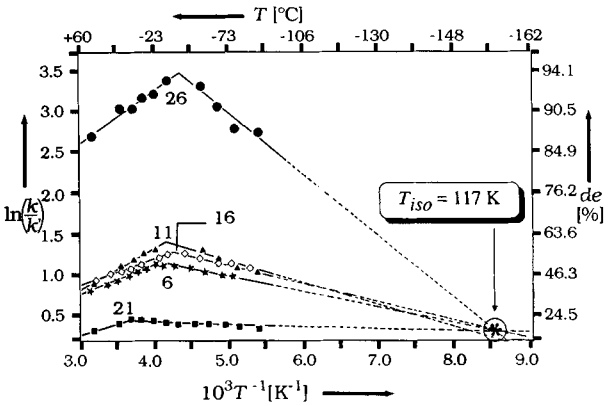

Fig. 7. Temperature-dependence of diastereoselection in the reaction of 1,3-dioxol **23** with chiral phenylglyoxylates, presented as an Eyring diagram (Systems 6, 11, 16, 21 and 26 in Table 4). Other than in Figure 6 an isoselective point occurs in the low-temperature region ($T < T_{inv}$) with T_{iso} = 117 K.

[*] We define a system as an ensemble of reactants, which react in a certain ratio of concentration under well-defined reaction conditions (e.g. solvent, catalytic additives). Temperature and/or pressure are the variable parameters of the system.

temperature dependence of the diastereoselectivity. In the case of Systems 1, 2, 4 and 5 of Table 4, the *de* value first increases as the temperature falls to the inversion point, and then decreases. With 2,2-diisopropyl-1,3-dioxol **25** (System No. 3) the inverse course is observed in the high- and low-temperature regions. This is a result of the Price-Hammett principle,[93] which states that as the degrees of freedom of the substituents at the 2-position of the dioxol increase, the influence of entropy in the high-temperature region will overcompensate for the enthalpy effect in comparison to dioxols **6** and **23**, under otherwise identical conditions. The corresponding line in the high-temperature region of the Eyring diagram constitutes an isoselectivity relationship with the corresponding lines for dioxols **6** and **23**.[92]

2.2. The Isoinversion Principle for the Paternò-Büchi Reaction

Because of the appearance of inversion temperatures T_{inv}, i.e. of two linear regions in the Eyring-diagram, two sets of activation parameters ($\Delta\Delta H_1^{\ddagger}$, $\Delta\Delta S_1^{\ddagger}$ ($T > T_{inv}$) and $\Delta\Delta H_2^{\ddagger}$, $\Delta\Delta S_2^{\ddagger}$ ($T < T_{inv}$) are available which correspond to enthalpy and entropy in each of the partial selectivity steps. By simple subtraction of the activation parameters for the high- and low-temperature regions ($T > T_{inv}$ and $T < T_{inv}$), one obtains the new parameters $\delta\Delta\Delta H^{\ddagger}$ and $\delta\Delta\Delta S^{\ddagger}$ [Eqs. (4) and (5)]. These represent the change in dominance of enthalpy and entropy in the partial selectivity steps within one system.

$$\delta\Delta\Delta H^{\ddagger} = \Delta\Delta H_2^{\ddagger} - \Delta\Delta H_1^{\ddagger} \quad (4)$$

$$\delta\Delta\Delta S^{\ddagger} = \Delta\Delta S_2^{\ddagger} - \Delta\Delta S_1^{\ddagger} \quad (5)$$

If these new parameters $\delta\Delta\Delta H^{\ddagger}$ and $\delta\Delta\Delta S^{\ddagger}$ for all the systems in Table 4 are plotted on an enthalpy/entropy diagram, a strictly linear correlation (correlation coefficient > 0.99, passing through the origin) is observed for all systems studied for this reaction.

Clearly there exists a common relationship for the change in dominance of the activation parameters in the partial selectivity steps, for all the systems studied. This relationship is independent of the actual *de* values measured, and hence also of the factors that influence the *de* value (e.g. the chiral auxiliary, the partner olefin, the Ⓡ residue of the α-keto acid fragment, the solvent and the concentration).

We have called this linear correlation in the $\delta\Delta\Delta H^{\ddagger}/\delta\Delta\Delta S^{\ddagger}$ diagram the *Isoinversion Relationship*.[37]

The gradient of the line in the isoinversion diagram has the dimensions of a temperature, which is defined as the Isoinversion Temperature T_i [Eq. (6)].[37] (For the case of the diastereoselective Paternò-Büchi reaction, it has the value 231 K.)

$$T_i = \frac{\partial(\delta\Delta\Delta H^{\ddagger})}{\partial(\delta\Delta\Delta S^{\ddagger})}. \quad (6)$$

This temperature is a characteristic constant for the selectivity of the reaction studied. The practical significance of this T_i is that at this temperature the optimal value of a selectivity parameter (here, for instance, the *de* value) is to be expected. If, for example, one plots the *de* values obtained for the systems in Table 4 at the inversion temperature T_{inv} against the inversion temperatures T_{inv}, one obtains the diagram shown in Figure 9.

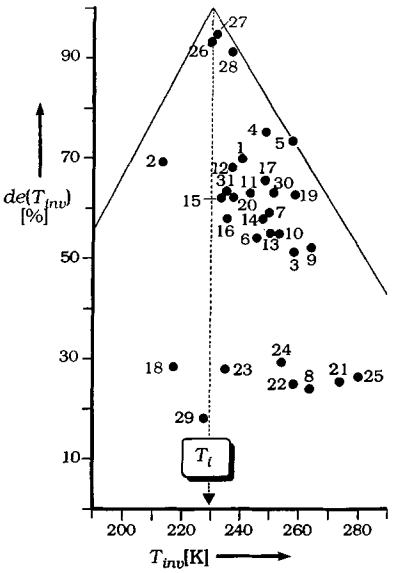

Fig. 9. $de(T_{inv})/T_{inv}$ diagram for the systems from Table 4.

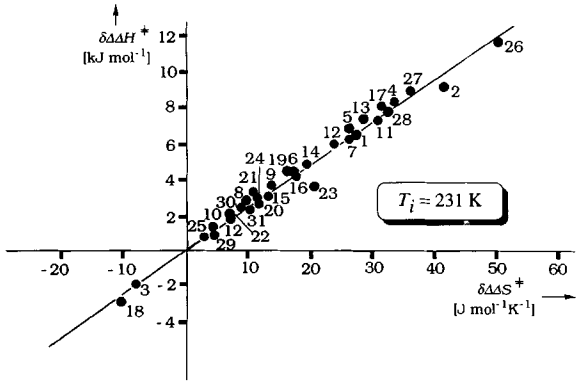

Fig. 8. $\delta\Delta\Delta H^{\ddagger}/\delta\Delta\Delta S^{\ddagger}$ diagram (isoinversion relationship) for diastereoselective photooxetane formation from chiral *p*-substituted and unsubstituted phenylglyoxylates with cyclic olefins of type **9** (correlation coefficient > 0.99). The numbers correspond to those in Table 4.

In systems which produce high diastereoselectivity, the inversion temperature T_{inv} lies close to the isoinversion temperature T_i (Systems 26–28 from Table 4) while for systems with lesser selectivity a broad spread of inversion temperatures is found. If, then, one takes any one example of the reaction under study, measures the *de* value at temperature T_i, and finds a low selectivity, one may be sure that no notable improvement can be achieved by varying the temperature. A "bad" system will remain a "bad" system, and this cannot be changed by even the most bulky substituents (Price-Hammett principle). In addition, from the charge and size of the $\delta\Delta\Delta H^{\ddagger}$ and $\delta\Delta\Delta S^{\ddagger}$ parameters, some insight can be obtained into what structural variations in the system could lead to an increase in selectivity.

2.2.1. *Mechanistic Conditions for the Occurrence of Inversion Points*

The question of why certain systems display inversion points in selectivity in the Eyring-diagram while others do not, can be answered by explaining the mechanism of stereoselectivity in the Paternò-Büchi reaction. If one extends the mechanistic knowledge of achiral, photochemical oxetane formation (Fig. 2) to the reaction of chiral α-keto esters with cyclic, electron-rich olefins of type **9**, then the mechanism of diastereoselectivity in oxetane formation can be understood by the simplified, kinetic model of Figure 10.

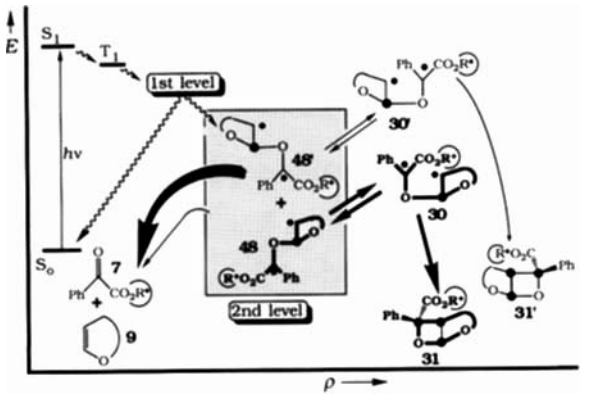

Fig. 10. A simplified kinetic model for the diastereoselective Paternò-Büchi reaction with cyclic olefins of type **9**. The *trans*-1,4-biradical intermediates **48** and **48'** are very probably formed first, and must then be converted into the *cis*-configurations **30** and **30'** for ring closure to occur. The intermediate formed preferentially, **48**, gives rise to the major oxetane **31**, while the minor 1,4-biradical intermediate **48'** undergoes preferential retrocleavage.

According to this model, the selectivity of the reaction occurs at two different levels. After photochemical excitation of the keto carbonyl group, and subsequent dissipation processes, the biradical intermediates **48** and **48'** are formed. In the case of cyclic olefins of type **9**, these two intermediates are diastereomeric, since a chiral center is formed with the first bond (first level of selectivity). The formation of this chiral center in the biradical intermediate determines all further, newly generated chiral centers in the oxetane, providing oxetane formation proceeds *endo*-phenyl selectively. For the biradical intermediates (one of them is generated preferentially), however, two reaction pathways are possible (second level of selectivity). They may undergo ring closure to give oxetanes, or they may decompose to the starting materials, losing all their excitation energy (retrocleavage). The system will then be excited once more, and may pass through the reaction cycle again. After the intermediate has formed, a further increase in diastereoselectivity is only possible by retrocleavage, whereby one diastereomeric intermediate is preferentially cleaved to the starting materials and the other preferentially transformed into oxetane. Retrocleavage therefore gives a second level of selectivity. The entire system may be described as a photon-driven selectivity amplifier, which continues to function until a significant proportion of the starting material has accumulated as the major diastereomer. This requires that apart from bond formation and retrocleavage, no side reactions take place. Further indications that retrocleavage functions as a selectivity step also

Table 5. Selected quantum yields for diastereoselective photochemical formation of oxetane according to Equation (1).

	Olefin	Quantum yield ϕ		de[%] (T=20 °C, C_6H_6)	Ref.
C_6H_5	**10**	**3**	0.22	for the formation of the major oxetane diastereomer	90	[34]
C_6H_5	**10**	**3**	0.06	for the formation of the minor oxetane diastereomer	90	[34]
C_6H_5	**10**	**3**	0.34	for the substrate consumption	90	[34]
C_6H_5-CH=CH	**10**	**25**	0.78	for the substrate consumption	28	[73]

derive from measured quantum yields, a few of which are summarized in Table 5.

It turns out that there is a corresponding difference in the quantum yields for consumption of starting material and those for product formation, in the absence of any side reactions. Systems that generate high diastereoselectivity yield smaller quantum yields than those with lower selectivity. The fact that on irradiation in the absence of the olefinic component α-keto esters rapidly decompose by photofragmentation[50] is a further indication for retrocleavage. In the presence of the olefin, the biradical intermediate is formed very rapidly (first level), but oxetane formation is very slow, because of retrocleavage (second level). The existence of inversion temperatures T_{inv} suggests that the selectivity levels described are weighted differently according to temperature. In the high temperature region ($T > T_{inv}$) we observe enthalpy-determined selectivity[37] in the vast majority of systems. According to *Skell* et al.[95] and *Giese*,[92a] this behavior is found for transition states close to the starting materials in the fragmentation of energy-rich compounds (the 1,4-biradical intermediate must be seen as the starting material here). Hence, retrocleavage, the second level of selectivity, is dominant in the high-temperature region for enthalpy reasons. In contrast, in the low-temperature region ($T < T_{inv}$), we find entropy-determined selectivity, with the formation of the biradical intermediate from as an energy-rich precursor.[37] This is a bond formation step (approach of the olefin to the prochiral triplet carbonyl) with a transition state like the starting material; here, the triplet carbonyl may be regarded as the starting compound.

By a kinetic description of the selectivity process we have also shown[37] that for the first selectivity step, where the diastereomeric 1,4-biradical intermediates are formed, the nature of the auxiliary has a dominant influence on the selectivity process. In the second step, the nature of the olefin gains importance.

The good correlation for the isoinversion line shows that the activation entropy difference for the selectivity steps gains in importance as a determinant energy parameter at the same rate as the activation enthalpy loses it, and vice versa (compensation[96] of enthalpy and entropy on the $\delta\Delta\Delta H^{\neq}$ and $\delta\Delta\Delta S^{\neq}$ levels). If substrates are used where no new chiral center is formed in the biradical intermediate, then the production of diastereoselectivity is the result of only one selectivity level, so that inversion points (T_{inv}) are not expected in the Eyring diagram.

Indeed, the reactions of menthyl phenylglyoxylate **35** with tetramethylethylene **3** and ketene acetal **4** show only one linear region with respect to temperature.[34] In the case of ketene acetal **4**, two regioisomeric intermediates **28** and **28'** are formed, which yield two regioisomeric pairs of two diastereomeric oxetanes, **45** and **45'**, and **46** and **46'** (Fig. 4). The temperature-dependence of the regioisoselectivity R[97] then gives an inversion point in the Eyring diagram (Fig. 11),

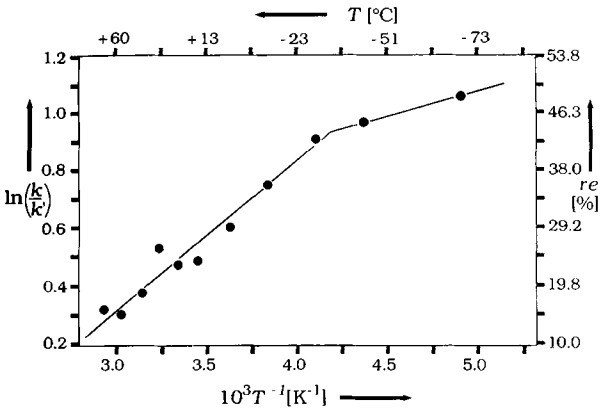

Fig. 11. Eyring diagram for the temperature dependence of the regioselectivity R in the reaction of **35** with **4** (Systems 11a and 11b in Table 2). This reaction leads to two regioisomeric pairs of two diastereomeric oxetanes **45** and **45'** or **46** and **46'** respectively. The *re* value (regioisomeric excess) is defined analogously to the *de* value.

since selectivity (in this case regioselectivity) plays a role in the formation of the intermediate. R is here defined in terms of Equation (7) with n as amount of oxetanes in the product mixture and k, k' ($k > k'$) as overall rate constants of the reactions leading to oxetanes of type **45**/**45'** and **46**/**46'** respectively.

$$R = \frac{n(45) + n(45')}{n(46) + n(46')} = \frac{k}{k'} \tag{7}$$

The parameters $\delta\Delta\Delta H^{\neq}$ and $\delta\Delta\Delta S^{\neq}$ for the regioselectivity give a pair of values which obey the isoinversion relationship in Figure 8 exactly. Here again, we see the general importance of the isoinversion temperature T_i for all types of selectivity processes, regardless of the nature of the selectivity, as long as they are generated on different levels. Accordingly, the temperature dependence of the ratio of *endo* isomers **31**, **31'** to *exo* isomers **47**, **47'** (see Fig. 4) in the Paternò-Büchi reaction should also follow the isoinversion relationship. Indeed, this has been confirmed by the latest experimental results.[81]

The assignment of the activation parameters $\Delta\Delta H^{\neq}_{1,2}$ and $\Delta\Delta S^{\neq}_{1,2}$ to the selectivity levels is supported by the nature of the isoselectivities found.[92] In the high-temperature region ($T > T_{inv}$), there exist several isoselective points with respect to variation of the olefin with constant auxiliary, whereas in the low-temperature region ($T < T_{inv}$) the isoselective points observed are for variation of the auxiliary with the same olefin.

All of the isoselective points for the high- and low-temperature regions are shown in Figure 12 as an Eyring diagram.

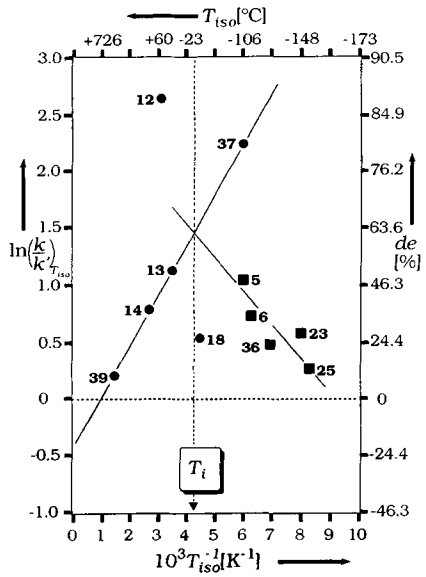

Fig. 12. The isoselective points for all of the Systems 1–28 in Table 4, for the high- and the low-temperature regions ($T > T_{inv}$ and $T < T_{inv}$, respectively) in an Eyring diagram. For the high-temperature region the isoselective points shown are those obtained by variation of the dioxols **6**, **23** and **25** (see Table 2) with a constant phenylglyoxylate of **12**–**14**, **18**, **37** and **39** (see Table 1), for the low-temperature region, those obtained by variation of the same phenylglyoxylates with a constant olefin **5** (furan), **6**, **23**, **25**, and **36**. The T_{iso} values were determined in each case from a $\Delta\Delta H_i^{\neq}/\Delta\Delta S_i^{\neq}$ diagram (i = 1, 2) accroding to *Giese* et al. [92].

The position of the isoselective points in the high-temperature region represents a measure of the induction potential of an auxiliary independent of the partner olefin. The closer the isoselective temperature T_{iso} comes to the isoinversion temperature T_i, and the higher the *de* value which can theoretically be obtained at T_{iso}, then the higher the selectivity that can be expected from the auxiliary. The position of isoselective points in the low-temperature region can be seen as a measure of the importance of the olefin in the selectivity process, independent of the auxiliary. Here, too, the closer T_{iso} lies to T_i, and the higher the *de* values obtainable at T_{iso}, then the greater the effect of the olefinic component on selectivity.

2.2.2. *A General Kinetic Scheme for all Types of Selectivity Process*

These results were first obtained from a study of the diastereoselective Paternò-Büchi reaction (see Section 2.2), but they can be couched in a universal kinetic scheme, as shown in Figure 13.

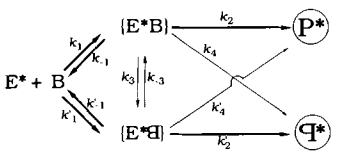

Fig. 13. Generalized kinetic scheme for the isoinversion relationship for any desired selectivity process. As stated by the isoinversion principle, the selectivity is generated at two distinct levels: 1) formation of isomeric intermediates, and 2) the possibility of retrocleavage of the intermediates, or their mutual interconvertibility. The overall rate constants k_1 and k'_1 are decisive for the first selectivity level, while the rate constant ratios k_2/k_{-1} and k'_2/k'_{-1} (or alternatively k_2/k_3 and k'_2/k'_3) represent the second level of selectivity.

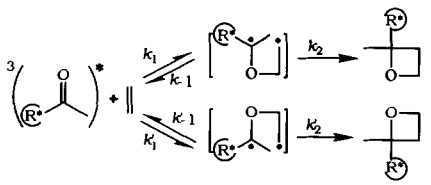
Starting material B, containing a prochiral element, reacts with a chiral substrate or chiral catalyst E* to afford the two diastereomeric intermediates [E*B] and [E*Ɓ]. These can be formed in different proportions and are in equilibrium with each other. Formation of this diastereomeric intermediate represents the first level of the selectivity process. The intermediates can either react further, yielding the diastereomeric products P* and Ƥ*, where one of the two products is generally greatly favored, or retrocleavage of the intermediate to the starting materials may occur. These can then be fed back into the reaction cycle.

As an alternative to retrocleavage, the conversion of one diastereomeric intermediate into the other is conceivable. Hence, the second selectivity level is made up of the possibility of retrocleavage and that of interconvertibility of the intermediates.

Whenever selectivity is generated on two or more different levels, in any kind of selectivity process, inversion points are expected in the Eyring diagram for temperature-dependent measurement of a selectivity parameter. We understand the kinetic model in Figure 13 as a general principle, with which Nature produces most cases of selectivity. Each particular case of selectivity can hence be reduced to the temperature-dependent interaction of all relevant rate constants, which themselves are determined by the temperature-dependent dominance of activation entropy or enthalpy. This makes it possible for Nature to optimize the selectivity of a system either by choice of temperature or by structural changes to the system for a prescribed temperature. In the sense of the isoinversion principle, enzymes are species structurally adapted for $T_i = 37\,^{\circ}C$, for optimal stereoselectivity in biochemical reactions. The importance of each of the rate constants shown in Figure 13 for selectivity depends in any given case on the reaction concerned. For the diastereoselective Paternò-Büchi reaction, in the sense of Equation (1), the isoinversion principle from Figure 13 may, for example, be reduced to the reaction step shown in Scheme 1.



Scheme 1. Reduction of the kinetic scheme of Figure 13 for the case of the diastereomeric Paternò-Büchi reaction.

The rate constants shown have achieved the quality of overall rate constants, implicitly containing all the partial steps that are not relevant to the selectivity process. In this case the 1,4-biradical intermediates are not interconvertible. By formation of a new element of chirality in the intermediate the entire stereoselectivity of the oxetane is fixed, so that once an intermediate is formed it can give rise to *only one* diastereomeric product, provided no retrocleavage takes place.

For the weighting of the rate constants k_1 and k_1' on the one hand, and k_2/k_{-1} or k_2'/k_{-1}' on the other, two boundary cases can be discussed in the simplified kinetic inversion model of Scheme 1:

1. The intermediate formed preferentially can also react preferentially to give the product (Fig. 14).

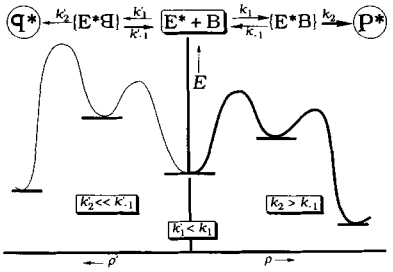


Fig. 14. Schematic diagram for the simplified isoinversion relationship of Scheme 1. The intermediate formed in excess {E*B} also gives rise to the major diastereomer P*.

2. The minor intermediate may be responsible for the major diastereomeric product, because of greater reactivity (Fig. 15).

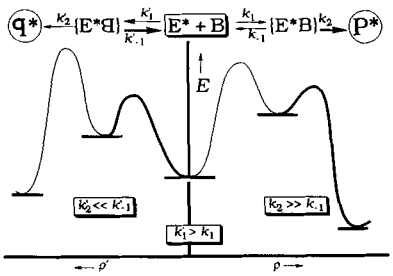

Fig. 15. Schematic diagram for the simplified isoinversion relationship of Scheme 1. Because of its greater reactivity, the minor intermediate {E*B} is responsible for the major diastereomer P*.

While the latter behavior has been considered for generation of chirality in catalytic, homogeneous processes, in the diastereoselective Paternò-Büchi reaction the former is relevant, i.e., the major diastereomer arises from the preferentially formed intermediate, while the minor intermediate undergoes preferential retrocleavage. Therefore, no inversion of the stereochemistry of the major oxetane by temperature effects is observed, as might be expected for an otherwise weighted selectivity mechanism.

In the following, it will be shown that from knowledge of a particular reaction—the diastereoselective Paternò-Büchi reaction—it is possible to develop a universal selectivity model, which is also applicable to selectivity processes in ground state reactions as shown below. The temperature dependence proves to be the most important instrument for understanding the selectivity process here.

In their monograph on asymmetric synthesis, *Morrison* and *Mosher* confine themselves to the remark: "Obviously, temperature-dependence measurements of asymmetric synthetic reactions should be made whenever possible."[101]

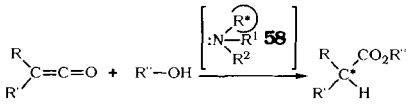
With this in mind, we have worked through the literature on stereoselective reactions from recent years, initially seeking temperature-dependent measurements of optical yield.

We found a series of examples of widely varying reaction types, all of which fitted readily into the kinetic scheme of Figure 13. For each reaction type it was possible to draw an isoinversion line from the literature data, regardless of whether the reactions were stoichiometric or catalytic, and of whether they were photochemically induced or in the ground state. Finally, we could show that the isoinversion principle is applicable not only to asymmetric reactions, but can be extended to any selectivity process, as long as the temperature dependence of a selectivity parameter has been conscientiously determined. Even pressure-dependent selective processes may be characterized with the aid of the isoinversion principle.

3. Asymmetric Ester Synthesis

3.1. Enantioselective Amine-Catalyzed Additions of Alcohols to Ketenes in Homogeneous Phases

In the early sixties, *Pracejus*[91] carried out extensive studies of the addition of achiral alcohols to unsymmetrical, disubstituted ketenes, catalyzed by chiral tertiary amines [Eq. (8)].[102-104]



(8)

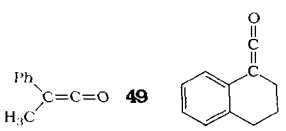
Remarkably, the author even at that time performed an extended test of the temperature dependence of stereoselectivity at the start of his systematic studies.

The ester synthesis (8) proved especially suitable for a study of temperature dependence, as it proceeds at a sufficiently high rate in a homogeneous phase throughout the temperature range +75 °C to below −100 °C. Addition of the amines causes a sharp acceleration in rate. In addition, the reaction is irreversible in the selectivity determining step, so that the basic catalyst causes no racemization of the product ester. In the temperature range studied, no side reactions were observed.

The *ee* values obtained in reaction (8) could be influenced by the following parameters;[91, 103, 104] the ketene component, the alcohol component, the structure of the catalyst, the reaction conditions (concentration of the reactants, solvent, temperature).

3.1.1. The Influence of Ketene and Alcohol Components and of Catalyst Structure

The ketene components used were methylphenylketene **49** and 1-carbonyltetrahydronaphthalene **50**.[105] Methanol and ethanol served as the alcohol component. Numerous



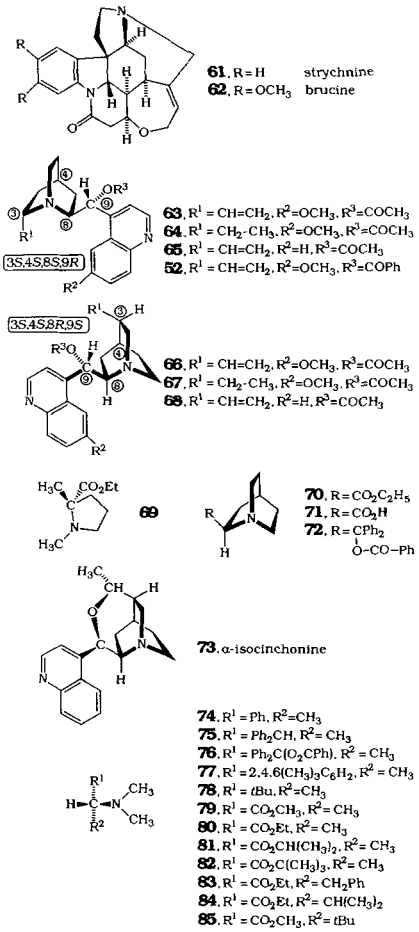


Fig. 16. Overview of the tertiary, chiral amines of general structure **58** that were used by *Pracejus* et al. [91, 102, 103] as catalysts in asymmetric ester synthesis (8).

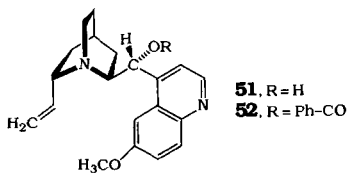
derivatives of strychnine and quinine bases were studied as catalysts, as well as a series of chiral tertiary amines with an acyclic C–N bond. Figure 16 gives an overview of the structural diversity of the chiral catalysts **61**–**85** used by *Pracejus*.

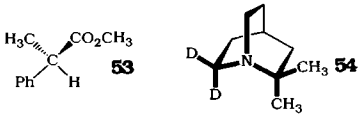
Cinchona alkaloids have been studied in catalytic asymmetric synthesis since the discovery of their catalytic action in asymmetric cyanohydrin synthesis, by *Bredig* and *Fiske* in 1912,[106] to the present day.[107] Thus, for example, quinine **51** has been used as a chiral catalyst in Michael reactions,[110] epoxidations,[111] thiol additions,[112] and even in [2 + 2]-cycloadditions.[113] The catalytic effect of **51** in autoinduction processes is especially remarkable.[115]

The *ee* values obtainable in the asymmetric ester synthesis (8) described proved to be a sensitive probe of structural variations in the substrate and particularly of the structure of the chiral catalyst.



As well as displaying remarkable enantiomeric excesses (e.g. methylphenylketene **49** reacts with methanol in the pres-

ence of benzoylquinine **52** at $-110\,^{\circ}C$ according to Equation (8) to give methyl (*R*)-(−)-α-phenylpropionate **53** in an enantiomeric excess of 76%), even the minor steric differences between CMe_2 and CD_2, which generate the chirality of nitrogen base **54**, can be observed in an asymmetric reaction.[114]



3.1.2. *The Influence of Temperature*

Table 6 lists the systems for which the temperature dependence of stereoselectivity has been studied. We have transferred the published results of temperature-dependence measurements to an Eyring diagram. In doing so it becomes clear that the temperature dependencies of all the systems listed in Table 6 are characterized by two linear regions, and the appearance of an inversion point. In several cases, indeed, an inversion of stereoselectivity could only be achieved by variation of the temperature.

Table 6. An overview of the systems whose stereoselectivity in the reaction (8) has been measured with respect to temperature [91, 102, 103]. Ketene (0.1 mol) was treated with alcohol (0.11 mol) under standard conditions, using 10^{-3} mol of the catalyst. Deviations from these standard conditions are indicated. Toluene served as solvent; at temperatures below 173 K a 1:1 mixture of toluene and pentane was used. Enantiomeric excesses were determined from the optical rotation, by setting the optical yield equal to the *ee* value.

A selection of typical results from the diverse data published is presented in Figure 17.

On the basis of the temperature dependence of stereoselectivity, *Pracejus* developed his "model for the preferred conformations of transition states".[116] This mechanism, which has been confirmed by kinetic studies,[108] is depicted in Figure 18.

The rate-determining step is the nucleophilic attack of an intermediate catalyst–alcohol associate **55** on the ketene. The next step is seen as a rapid proton transfer within the

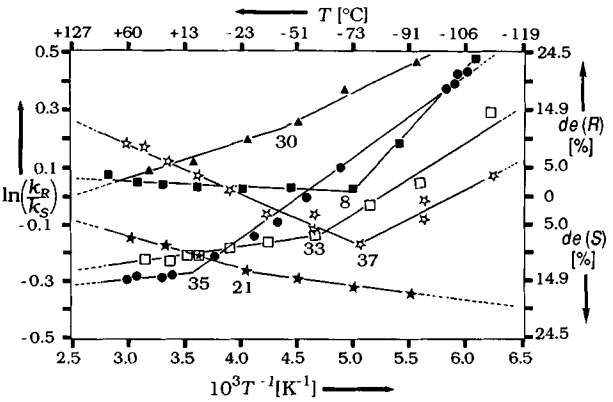

Fig. 17. Representation of the temperature-dependent *ee*-values in asymmetric ester synthesis (8), in the form of an Eyring diagram. Systems 8, 21, 30, 35 and 37 in Table 6 are shown as examples.

ammonium ester–enolate ion pair **56** thus formed. The chiral information is transferred in this step.[271] Early work by *Prelog* and *Wilhelm* has shown that the chiral nitrogen catalysts transfer chiral information to the substrate not as the free bases but in their protonated form.[109]

In the transition state for the "specificity-determining proton transfer", *Pracejus*[116] assumes a linear $^{\delta\oplus}N\cdots H\cdots C^{\delta\ominus}$ conformation, oriented perpendicular to the bond framework of the anionic partner. If one imagines the $^{\delta\oplus}N\cdots H\cdots C^{\delta\ominus}$ grouping as a pseudo-bond of the ethane type, then the conformation may be drawn as a Newman projection (**57a** and **57b** in Fig. 18; in **57b** the anionic C-atom of **57a** conceals the proton and the N atom behind it).

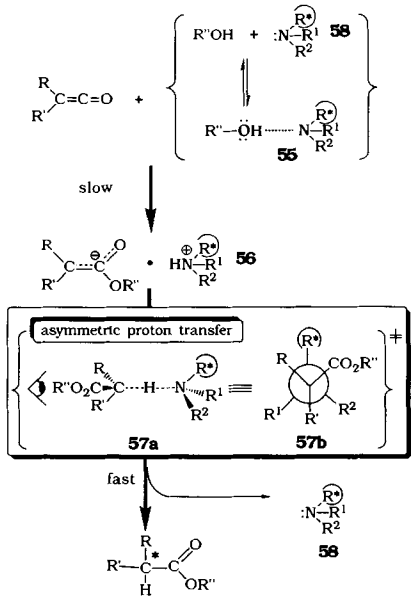

Fig. 18. Mechanism of nucleophilic addition of achiral alcohols to unsymmetrically substituted ketenes, catalyzed by chiral, tertiary amines **58** [Eq. (8)] [108].

The extent of chiral induction in the selectivity-determining step with ionic pair **56** ($N^{\oplus} \rightarrow C^{\ominus}$ proton transfer) is determined by a series of competing transition states, which show varying degrees of steric hindrance and are in equilibrium with each other. For catalysts of the general type **58**, the

situation is explained in Figure 19. (Here, Ⓛ, Ⓜ, and Ⓢ symbolize large, medium and small residues on the asymmetric C-atom in **58**, in the Cram sense.)

The protonated bases **58** are depicted by the authors in three staggered conformations **59a–c**, which are interconvertible by rotation around the C–N bond. Of the conformations shown, **59a** is regarded as the most stable, and **59c** as the least hindered for proton transfer. On addition of the ester enolate, each of these conformations leads to two diastereomeric transition states, for each of which three new, staggered conformations may be drawn. Of all the possible transition states, Figure 19 shows only those presumed lowest in energy, formulas **60a–c**.

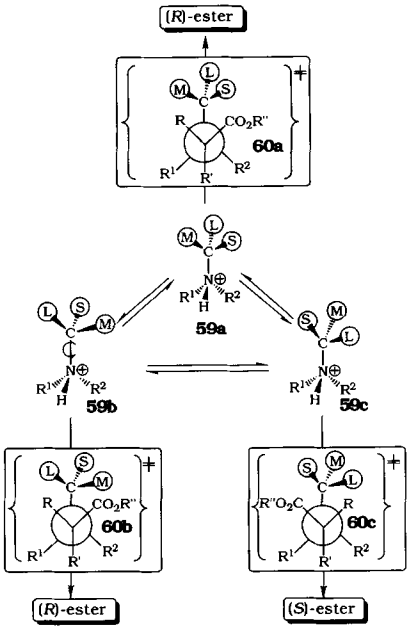

Fig. 19. Conformations **59a–c** of the ion pair formed as an intermediate are in equilibrium with each other. In the asymmetric reaction step they pass through diastereomeric reaction channels. Here, only the lowest energy tansition states **60a–c** are depicted. In our opinion, the data available do not allow us to order the conformations clearly with respect to enthalpy or entropy content.

The temperature dependence of the stereoselectivity of this reaction is currently understood as the interplay of these competing, mutually interconvertible conformations of the species and transition states involved in the selectivity-determining step. *Pracejus* et al. describe the situation thus:[103] "The causes are not to be sought in a temperature-determined alteration of reaction mechanism, but in the antagonism of enthalpy and entropy effects on the stability of the diastereomeric transition states."

3.1.3. *The Isoinversion Relationship for Asymmetric Ester Synthesis*

If one analyzes the published data in the sense of the isoinversion relationship, i.e., if the activation enthalpy and entropy differences for the high- and low-temperature regions of the relevant Eyring diagram are converted into the $\delta\Delta\Delta H^{\neq}$ and $\delta\Delta\Delta S^{\neq}$ values, one obtains the isoinversion relationship shown in Figure 20, with isoinversion temperature $T_i = 210$ K. The correlation coefficient for the isoinversion line is > 0.99.

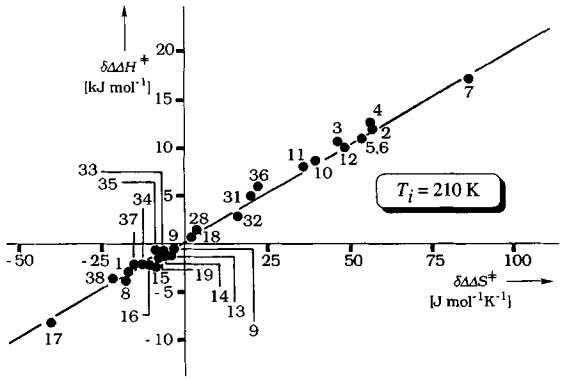

Fig. 20. The isoinversion line for homogeneous-phase, asymmetric ester synthesis (8), catalyzed by chiral bases (the numbers correspond to those in Table 6). The $\delta\Delta\Delta H^{\neq}$ and $\delta\Delta\Delta S^{\neq}$ values were determined from Equations (4) and (5), respectively. In order to calculate the fundamental $\Delta\Delta H^{\neq}_{i,2}$ and $\Delta\Delta S^{\neq}_{i,2}$ values, the (*R*)-ester was assumed to be uniformly the major enantiomer, even though in a few cases the (*S*)-enantiomer was present in excess. The corresponding $\delta\Delta\Delta H^{\neq}$ and $\delta\Delta\Delta S^{\neq}$ values do not differ from each other in magnitude in these cases, but carry the opposite sign. The $\delta\Delta\Delta H^{\neq}$ and $\delta\Delta\Delta S^{\neq}$ values for Systems 20–27 and 29, 30 (Table 6) all lie in the range -0.4 to -1.5 kJ mol^{-1}, or -1.4 to -4.1 J mol^{-1} K^{-1} respectively, and are not plotted because of the density of data points in this region.

The mechanistic evidence (Figs. 18, 19) can now be readily represented by the simple kinetic scheme of Figure 13: In the nucleophilic addition of a chiral particle to a prochiral substrate, chiral intermediates are generated, which may exist in several different diastereomeric conformations in equilibrium with one another.

This is an alternative selectivity level to retrocleavage. For a given temperature region, one conformation will develop preferentially, determined by enthalpy or entropy. This conformation will then be channeled—influenced again by enthalpy or entropy differences—through diastereomeric reaction pathways to give differing amounts of enantiomeric products. The temperature dependence of stereoselectivity gives insight into the interplay of enthalpy and entropy.

At this point it should be emphasized that as early as 1960 *Pracejus* recognized the great importance of the temperature dependence of asymmetric reactions for efficient practical application.[116] However, the consequences of this were not sufficiently appreciated by his colleagues: "Vergleicht man die wenigen bisher vorliegenden Beobachtungen über die Temperaturabhängigkeit der Stereospezifität asymmetrischer Synthesen miteinander, so gewinnt man den überraschenden Eindruck, daß in der Regel Aktivierungsenthalpie und Aktivierungsentropie-Differenzen einander entgegenwirken und daß es von der Reaktionstemperatur abhängt, welcher von beiden Faktoren überwiegt und das Vorzeichen der Spezifität bestimmt. Es bleibt abzuwarten, ob sich diese "Regel" für eine größere Zahl von Reaktionstypen bewährt; im positiven Falle hätte das wichtige Konsequenzen für die Interpretation des sterischen Verlaufs asymmetrischer Synthesen. Das heute allgemein übliche Verfahren, aus dem Vorzeichen der Stereospezifität bei einer willkürlich gewählten Reaktionstemperatur Schlüsse auf Konformation und Konfiguration der Reaktanten zu ziehen, würde damit in Frage gestellt oder in seiner Anwendbarkeit eingeengt werden. Eine Klärung

der Situation durch möglichst ausgedehnte Untersuchungen über die Zusammenhänge zwischen Reaktionstemperatur und Stereospezifität bei asymmetrischen Synthesen erscheint deshalb dringend geboten". – Quod erat demonstrandum.[*]

3.2. Addition of Alcohols to Ketenes Catalyzed by Polymer-Fixed Chiral Amines

The area studied intensively by *Pracejus*, amine-catalyzed addition of methanol to methylphenylketene **49**, has been interestingly extended by the work of *Yamashita* et al.[117–120] In their investigations they report on temperature-dependent stereoselectivity in the formation of **53**, using chiral amine catalysts bound to a polymeric matrix.[121–127]

Once again, it proved that for the vast majority of systems studied, two linear regions were found in the Eyring diagram, with an inversion point, though systems are also described for which a linear dependence of stereoselectivity in the chosen temperature region was observed.

In the light of the isoinversion relationship, the polymer-fixed chiral amine catalysts also show a zero-point line in the isoinversion diagram. The isoinversion temperature T_i determined from the gradient is identical to that found in the systems studied by *Pracejus* (T_i = 210 K).[91, 102–105]

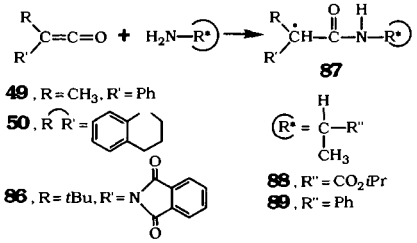
3.3. Diastereoselective Addition of Alcohols to Ketenes

Anders, Ruch and *Ugi*[23a] have studied a diastereoselective variant of ester synthesis (8). They treated phenytrifluoromethylketene with racemic secondary alcohols in a non-catalyzed reaction. The stereoselective acylation of the alcohols served as an experimental test of the stereochemical structural model developed by the authors.[20–24] The temperature dependence of the diastereoselectivity was measured for two selected examples, and here, too, inversion points were observed in the Eyring diagram. Analysis in the sense of the isoinversion principle yields T_i = 259 K, a different value from the isoinversion temperature found for the catalytic variant of asymmetric ester synthesis. This is an indication that the mechanism of stereoselectivity is different for catalytic enantioselective and uncatalyzed diastereoselective ester syntheses.[294] *Jähme* and *Rüchardt*[274, 293] have also studied the addition of chiral secondary alcohols to methylphenylketene, but using achiral catalysts (such as pyridine and 1,4-diazabicyclo[2.2.2]octane). The authors report not only a rate acceleration, but also a "drastic increase in the stereoselectivity by addition of achiral bases". Analysis of the data for the diastereoselective addition of chiral alcohols to ketenes catalyzed by achiral amines leads to an isoinversion line with gradient T_i = 289 K.[292, 293]

[*] "If one compares the few available observations of temperature dependence in the stereospecificity of asymmetric syntheses, one has the surprising impression that differences in enthalpy and entropy in general work against each other, so that the reaction temperature determines which of the two factors dominates and decides the sign of the specificity. It remains to be seen whether this "rule" will hold for a larger number of reaction types; if so, this has important consequences for the interpretation of the steric course of asymmetric syntheses. The usual procedure today is to draw conclusions regarding configuration and conformation from the sign of the specificity at an arbitrarily chosen temperature, but this would then be questionable, or limited in applicability. Clarification of the situation by extensive studies on the connection between reaction temperature and stereospecificity in asymmetric synthesis seems, therefore, to be urgently required."

4. Asymmetric Amine Addition to Ketenes

As well as his detailed work on catalytic asymmetric ester synthesis, *Pracejus* also studied the nucleophilic addition of chiral primary amines **88** and **89** to the C=C double bond of unsymmetrical disubstituted ketenes **49**, **50** and **86**, yielding two diastereomeric amides **87** [Eq. (9)].[116, 128, 129]



(9)

The stereoselective step of this stoichiometric, asymmetric synthesis consists of a proton transfer from the NH_2 group to the α-C-atom of the ketene component.[271] The chiral information is induced by the asymmetric C atom of the amine. If (*S*)-**89** is used in the reaction, then the newly formed chiral center in the major diastereomer will also display (*S*)-configuration, in almost every case. The diastereomeric amide with (*R*,*S*)-configuration is therefore the minor product (Fig. 23). The selectivity of this reaction is under purely kinetic control, since the diastereomeric amides formed under the reaction conditions given are configurationally stable and can therefore not be in thermodynamic equilibrium with each other.

Here too, the *de* values obtainable are determined not merely by the structures of the ketene and the chiral amine employed, but are also significantly temperature dependent. In addition, the solvent plays an important role. This reaction proceeds in quantitative yield throughout the temperature range studied, and no side product formation is observed.

4.1. The Influence of Temperature and Solvent

Table 7 gives an overview of the systems for which the temperature and solvent dependence of the diastereoselectivity have been studied.

If the data in Table 7 are evaluated in the form of Eyring diagrams, then in all but a few examples one finds two linear regions in the temperature-dependence curve, with an inversion point.

For the reaction of the ketene **50** with (*S*)-α-phenylethylamine **89** in chloroform, an inversion point is not observed within the temperature range studied (System 20, Table 7). Starting with methylphenylketene **49** in tetrahydrofuran, temperature-*in*dependent diastereoselectivity was found, within experimental error (System 7, Table 7).

Figure 21 shows the temperature-dependent stereoselectivity in a few typical systems from Table 7, in the form of an Eyring diagram.

Table 7. Overview of the ketenes and chiral amines whose temperature-dependent diastereoselectivity in Reaction (9) has been measured in various solvents.

4.2. The Isoinversion Relationship for Asymmetric Amide Synthesis

From the gradient of the zero-point curve in the $\delta\Delta\Delta H^{\neq}/\delta\Delta\Delta S^{\neq}$ diagram (Fig. 22; correlation coefficient > 0.99), the isoinversion temperature $T_i = 276$ K may be determined. The systems with only one linear region lie at the zero point of the $\delta\Delta\Delta H/\delta\Delta\Delta S$ diagram.

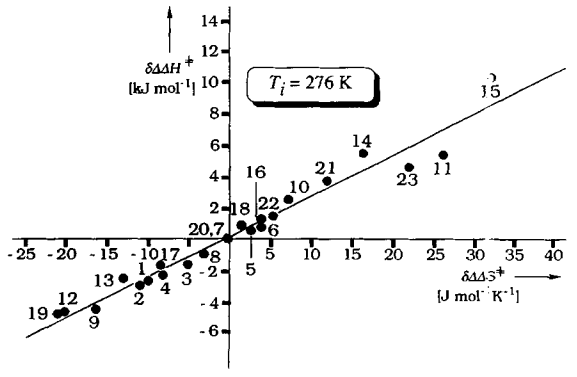

Fig. 22. Isoinversion line (correlation coefficient > 0.99) for stoichiometric asymmetric amide synthesis by Equation (9) ($T_i = 276$ K).

Because of the high overall rate of the reaction (in 0.1 M solution the conversion is quantitative in less than twenty seconds, even at temperatures below −100 °C), thorough mechanistic studies have not yet been undertaken. The authors propose a two-step mechanism (Fig. 23), analogous to catalytic, asymmetric ester synthesis.

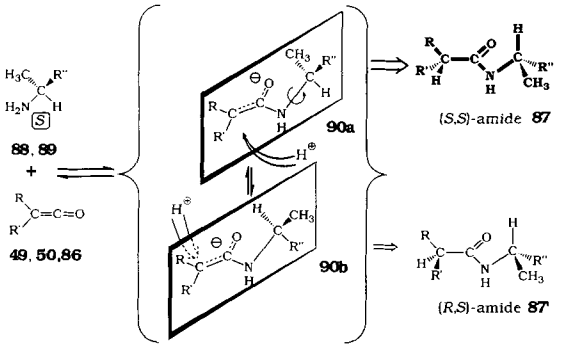

Fig. 23. Probable mechanism for stoichiometric, asymmetric amide synthesis according to Equation (9), with conformationally diastereomeric intermediates **90a, b** having an ammonium enolate structure.

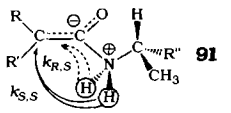
In the initial step, an adduct with an ammonium enolate structure is formed. In the stereoselective step, a proton migration occurs from the N atom to the α-C-atom of the ketene unit. An ionic pair, which can exist in the conformations **90a** and **90b**, is favored as an intermediate. However, the resonance-stabilized anion **91** is also a plausible intermediate.[130]



91

In both cases, however, the extent of stereoselectivity depends on the relative conformational arrangement of the amine moiety to the ketene part of the molecule.

At different temperatures, different conformations may be preferentially adopted, determined once more by enthalpy and entropy factors. Each conformation then opens into two competing diastereomeric reaction channels for proton transfer, whose cross-section is again temperature dependent, due to enthalpy and entropy effects.

Starting with this working hypothesis, *Pracejus* et al.[128, 129] describes intermediate **90a** as the preferred conformation for the low-temperature region ($T < T_{inv}$). This region depends on the solvent, but as a rule is determined by negative activation entropy differences and negative activation enthalpy differences ($\Delta\Delta H_2^{\neq}$, $\Delta\Delta S_2^{\neq} < 0$) for diastereomer formation. The influence of the activation parameters on conformer **90a** explains why the (*S,S*)-amide **87** is preferentially formed as the temperature falls.

For the high-temperature region ($T > T_{inv}$), conformation **90b** is assumed to be favored (compared to **90a**, the chiral group is rotated through 120°, so that the CH_3 group and the

hydrogen are staggered relative to the carbonyl group). In general, the influence of the activation parameters on **90b** show more negative activation entropy and activation enthalpy differences ($\Delta\Delta H_1^{\neq}$, $\Delta\Delta S_1^{\neq} \ll 0$), so that in some cases the diastereomeric (*R,S*)-amide **87′** can be formed in excess even at temperatures above 100 °C. According to *Pracejus*,[116, 128] of two sterically different, competing reactions, the more sterically hindered will normally be disfavored on energetic grounds (higher $\Delta H^{\neq}$), but favored on entropic ones (higher $\Delta S^{\neq}$).

At this point, it should be pointed out that the experimentally measurable differences in activation enthalpy and entropy of two competing reactions are generally complex values. They reflect not only the enthalpy and entropy differences of two diastereomeric transition states, but also the temperature dependence of the ratio of various conformational isomers in the starting material and products. The ratio of conformation-dependent diastereomeric intermediates also proves to be relevant, as does the temperature dependence of solvation equilibria (for reactions in solution). However, the fact that all the systems belong to the isoinversion line shows that despite the complexity of the activation parameter differences $\Delta\Delta H_{1,2}^{\neq}$ and $\Delta\Delta S_{1,2}^{\neq}$, their influence on the complex reaction may be represented simply. Here, too, one can state that: The enthalpic influence is repressed to the same extent as the gain in entropy influence, in a given temperature region.

The extreme solvent dependence of the reaction, and especially the characteristics of the temperature dependence of stereoselectivity, make it likely that polar intermediates play a part in the reaction mechanism. A concerted mechanism has also been discussed in the literature,[130] and is depicted schematically in Figure 24. It cannot, however, explain the

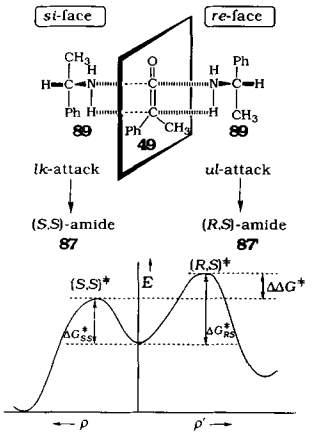


Fig. 24. Hypothetical concerted mechanism for stoichiometric asymmetric amide synthesis according to Equation (9) [130].

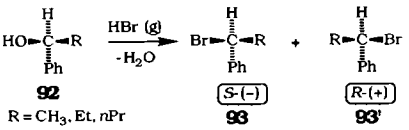
competing influence of enthalpy and entropy in the sense of the isoinversion relationship. In a concerted mechanism, the extent of stereoselectivity would depend solely on the difference in free activation enthalpy $\Delta G^{\neq}$ for *re*-directed versus *si*-directed attack. Inversion points in the Eyring diagram ought not to occur. The proposed concerted mechanism is therefore unlikely.

Ugi et al.[23] as well as *Ruch* et al. and *Youn*[273] have also studied the temperature dependence of diastereoselectivity in asymmetric amide synthesis (9). They treated phenyltrifluoromethylketene with phenylethylamine **89** and chiral α-ferrocenylalkylamines in a variety of solvents and also observed inversion points in the Eyring diagram. Independent analysis of this data also leads to an isoinversion relationship, with $T_i = 276$ K, a temperature identical with that for the systems studied by *Pracejus*.

5. Nucelophilic Substitution Reactions

In *Levene's* mechanistic study[131] of nucleophilic substitutions, inversion points were also observed in the temperature-dependent enantioselectivity of Reaction (10).[304] Chiral, secondary alcohols of type **92** were treated with gaseous HBr without a solvent, to afford bromides **93** and **93′**. The enantiomeric excess obtained, which also measures the ratio of retention to inversion, was determined by optical rotation. This is possible because below 0 °C the products do not racemize, and even above this temperature they do so only slowly.



(10)

The reaction was carried out heterogeneously with gaseous HBr. In a homogeneous system, using a solvent, one observes complete S_N2-inversion in the temperature range − 80 °C to + 20 °C.

For the first two homologues of alcohol **92**, with R = Me and Et, the optical rotation of the product mixture falls with increasing temperature from maximum levorotation (retention) to 0° (at − 36 °C), and reaches a maximum dextrorotation (inversion) at − 30 °C. If the temperature is increased further, the rotation once again falls.

The temperature dependence of enantioselectivity is similar for compound **92**, with R = *n*Pr. Here, though, the measured rotations are all negative, so that only a minimum in the levorotation is observed (at − 20 °C).

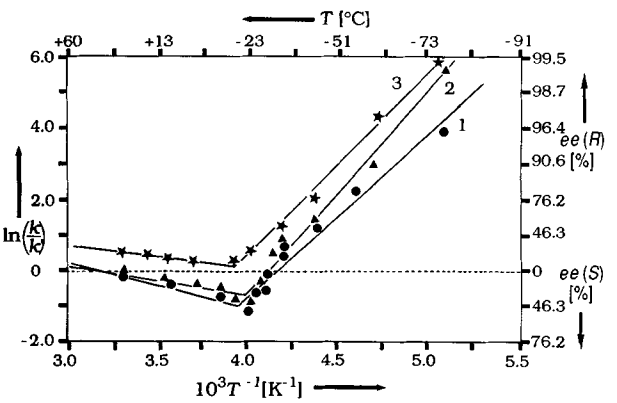


Fig. 25. Eyring diagram for the systems studied for Equation (10) (numbering as in Table 8).

All the systems in Equation (10) reveal two linear regions in the Eyring diagram, with the corresponding inversion points (Fig. 25). The activation entropy and enthalpy differences ($\Delta\Delta H^{\ddagger}_{1,2}$ and $\Delta\Delta S^{\ddagger}_{1,2}$) determined from the Eyring diagram, and the inversion temperatures T_{inv} are presented in Table 8. The gradient of the isoinversion curve obtained in Figure 26 yields an isoinversion temperature of $T_i = 250$ K.

Table 8. Activation energy differences $\Delta\Delta H^{\ddagger}_{1,2}$ and $\Delta\Delta S^{\ddagger}_{1,2}$ for the high- and low-temperature regions in reaction (10), with the inversion temperatures T_{inv}. Parameters $\delta\Delta\Delta H^{\ddagger}$ and $\delta\Delta\Delta S^{\ddagger}$ were determined from the above using Equations (4) and (5).

No.	R in **92**	$\Delta\Delta H_1^{\ddagger}$ / $\Delta\Delta H_2^{\ddagger}$ [kJ mol^{-1}]	$\delta\Delta\Delta H^{\ddagger}$ [kJ mol^{-1}]	$\Delta\Delta S_1^{\ddagger}$ / $\Delta\Delta S_2^{\ddagger}$ [J mol^{-1} K^{-1}]	$\delta\Delta\Delta S^{\ddagger}$ [J mol^{-1} K^{-1}]	T_{inv} [K](°C)
1	CH_3	+ 11.1 − 38.0	− 49.1	+ 36.6 − 161.4	− 198.0	248 (− 25)
2	Et	+ 7.2 − 47.4	− 54.5	+ 22.7 − 200.2	− 222.9	245 (− 28)
3	*n*Pr	+ 5.4 − 42.6	− 48.1	+ 21.5 − 172.3	− 193.9	248 (− 25)

The literature distinguishes between three idealized mechanisms of nucleophilic substitution: the S_N1, S_N2 and S_Ni mechanisms. The transition between the S_N1 and S_N2 mechanisms is a smooth one, depending on many marginal factors and leading to varying levels of inversion or retention. In addition, there is the rarer S_Ni mechanism, which leads to retention.

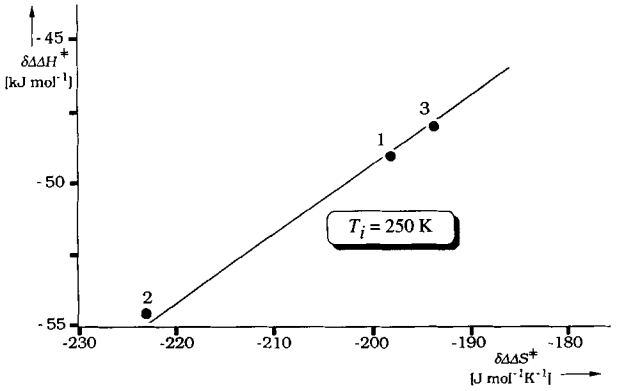

Fig. 26. Isoinversion diagram for nucleophilic substitution (10), with T_i = 250 K (correlation coefficient > 0.99).

In the case studied, it is this S_Ni mechanism that is observed in the low-temperature region. As well as the observed rate acceleration, this mechanism also allows isolation of the primary adduct **94** of alcohol E* and HBr (Fig. 27). At higher temperatures, however, this intermediate decomposes readily, so that the S_N2 or S_N1 mechanisms gain in importance, and inversion or a reduced level of retention is observed. The temperature-dependent interplay between the competing reaction channels of the S_N1, S_N2 and S_Ni mechanisms is illustrated schematically in Figure 27.

In the low-temperature region a high activation enthalpy and entropy is notable, which is responsible for formation of

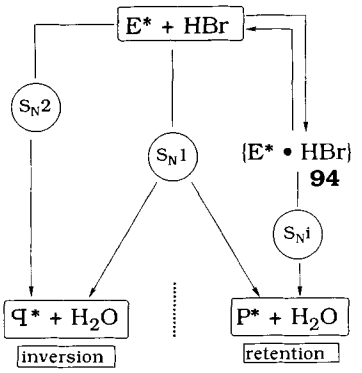

Fig. 27. Schematic diagram of the competing reaction channels of S_N1, S_N2 or S_Ni mechanisms, which lead to different ratios of retention and inversion according to weighting. The level of enantioselectivity is determined by which of the possible reaction channels dominates; the cross-section of this dominance is determined by the temperature-dependent interplay of activation enthalpy and activation entropy differences.

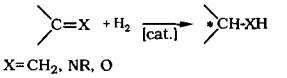
adduct **94**. In the high-temperature case both activation parameters are low, but a clear dependence on the structure of the alcohol **92** used may be seen. Obviously, for larger residues, the proportion of S_N2 reaction is reduced by steric hindrance, so that the extent of enantioselectivity in the high temperature region is reduced by the change from S_N2 to S_N1. This also explains the low levels of inversion for compound **92** with R = *n*Pr, where only levorotatory products are found.

6. Hydrogenations Catalyzed by Transition Metals

6.1. General

The catalytic hydrogenation of carbon–carbon or heteroatom–carbon multiple bonds to give one or more chiral centers is an intensively studied field of organic chemistry [Eq. (11)].[132–139, 144] Such hydrogenations can not only be



(11)

subdivided according to the phase of the catalyst (homogeneous[140–143] or heterogeneous catalysis[19, 132–135, 275]), but also according to the nature of chirality generation, as shown schematically in Figure 28 for C=C double bond hydrogenation, which is also useful.

On the one hand, the chiral information my be contained in the substrate itself, by suitable substitution of the prochiral unit. The use of an achiral catalyst then produces diastereomers (case B). In this case the chiral information is required in stoichiometric amounts. On the other hand, it is possible to convert double bonds into chiral centers with the help of chiral catalysts; the chiral information for generation of enantiomers then needs to be present in only substoichiometric amounts (case A). In this way, large amounts of an optically active compound can be synthesized, even though only a comparatively small amount of a chiral transition

metal catalyst is used. Because of this multiplication of chiral information, enantioselective catalysis has aroused interest in chemistry from beyond the traditional subject boundaries (chiral amplification).

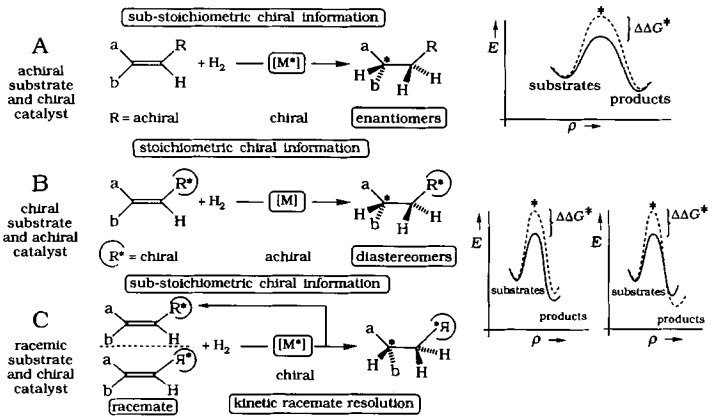


Fig. 28. Classification of catalytic C=C double bond hydrogenation according to the nature of chirality generation.

A further field for homogeneous hydrogenation in stereoselective synthesis lies in the kinetic resolution of racemates.[143, 145–146] For racemic starting materials, enantioselectivity in the course of hydrogenation leads to racemate resolution. In these experiments, the optical purity of the product decreases with time, while that of the starting material improves at the same rate (case C).

6.2. Enantioselective Catalytic Hydrogenation in the Homogeneous Phase

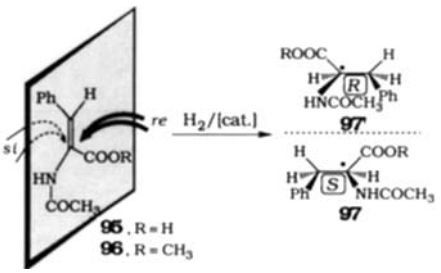
With respect to activity, selectivity, and mild reaction conditions, the present generation of homogeneous catalysts is quite comparable to enzymatic processes. In addition, hydrogenation in the homogeneous phase with substrates possessing several reactive groups can be carried out with a regioselectivity ("site specificity") which cannot generally be obtained with heterogeneous catalysts.

Although high optical inductions have also been achieved for particular substrates using monodentate, optically active phosphanes,[151] it was the transition to chelate-forming phosphanes that brought decisive improvements in optical yield.[152]

The great synthetic potential of homogeneous hydrogenation has been known since the sixties. *Noyori*[147] reported the first example of homogeneous enantioselective catalysis in organic chemistry with a transition metal system in 1966. In 1968, *Horner* et al.[148] and *Knowles* et al.[149] discovered independently of each other that prochiral olefins can be enantioselectively hydrogenated using rhodium complexes of the Wilkinson-catalyst type[150] with optically active phosphane ligands. The extraordinarily mild reaction conditions (room temperature, hydrogen at atmospheric pressure) and the possibility to hydrogenate dehydroamino acids and their esters to derivatives of amino acids with high enantioselectivity aroused great interest in homogeneous hydrogenation around the world. "The development of stereoselective homogeneous phase catalysis hydrogenation methods is one of the glorious chapters of synthetic organic chemistry."[132]

Systematic studies culminated a few years ago in the development of an industrial process for the synthesis of L-Dopa, a drug active against Parkinson's disease.[153, 154] In the following period, hundreds of optically active phosphanes and countless prochiral substrates were tested, not only in enantioselective hydrogenation, but also in transition metal catalyzed enantioselective hydrosilylation, hydroformylation, and similar reactions.[155–159]

In mechanistic studies of enantioselective homogeneous phase hydrogenation, these rhodium–chelate phosphane systems take the leading role, and dehydroamino acids (such as (*Z*)-α-acetaminoacrylic acid, itaconic acid, (*Z*)-α-*N*-acetylamino- and (*Z*)-α-*N*-benzoylaminocinnamic acid, and their esters) are by far the best investigated substrates for this reaction. These compounds have therefore established themselves as standard substrates for testing new ligand systems.[139, 160–166, 173] Scheme 2 shows a typical hydrogenation, that of (*Z*)-α-*N*-acetylaminocinnamic acid **95** and its methyl ester **96** leading to the phenylpropanoic acid derivates **97**/**97'**.



Scheme 2. Catalytic hydrogenation of **95** and **96**. Typical reaction conditions: 1 g of substrate in 20 mL of methanol, 1.1 bar H_2, 25 °C, 10 h, catalyst: substrate ≈ 1:200. **97** (R = H): $[\alpha]_D^{16} = +46.0$ ($c = 1.0$, EtOH); **97** (R = Me): $[\alpha]_D^{25} = +101$ ($c = 1.0$, $CHCl_3$).

6.2.1. *Mechanistic Considerations for Homogeneous, Rhodium-Catalyzed Hydrogenation*

Halpern's mechanistic studies on homogeneous hydrogenation show that for the achiral case the catalytic cycle may be divided into four fundamental steps. These are shown in simplified form in Figure 29 for the [Rh(diphos)]$^{\oplus}$-catalyzed hydrogenation of **96**.[167–171] The catalytic cycle has been confirmed by kinetic measurements and spectroscopic characterization of the intermediates observed for this example.

The catalyst precursor is the ionic diene adduct **98**. As hydrogen is taken up, the diene is saturated and substituted by solvent molecules, producing the solvated complex **99**. This represents the real starting point of the catalytic cycle. The first step is now the rapid establishment of an equilibrium to give the catalyst-substrate complex **100**, where the substrate is coordinated to the central atom through the double bond and the amide group. The second step, which is

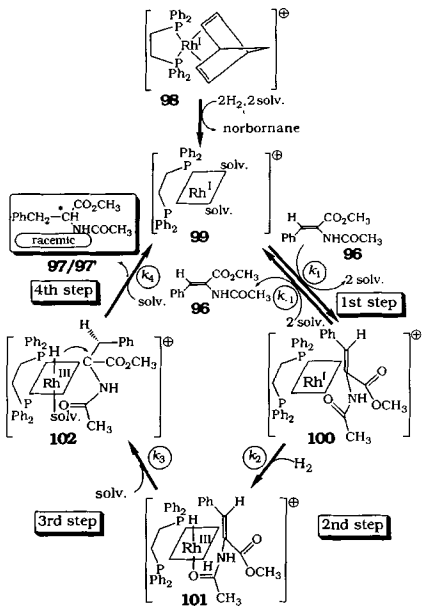


Fig. 29. The four basic steps in the catalytic cycle according to *Halpern* et al. [167–171], using as an example the [Rh(diphos)]$^{\oplus}$-catalyzed hydrogenation of **96**. The diagram shows the cycle for the production of only one enantiomer. Since an achiral catalyst is being used, the mirror-image catalytic cycle is equally justified, so that a racemate **97**/**97'** is produced. (solv. = solvent).

rate-determining at room temperature, consists of the irreversible oxidative addition of hydrogen to the central atom, forming the octahedral complex **101**. The irreversible transfer of a hydrogen atom to one of the sp^2-hybridized C-atoms leads to an alkylrhodium intermediate, which is converted into the octahedral σ-alkyl complex **102** by taking up a solvent molecule. Irreversible reductive elimination and release of the amino acid derivative then regenerates the active catalyst species for a repeat of the catalytic cycle. Kinetic measurements have shown that at temperatures below $-40\,^{\circ}C$, this final step is rate-determining, because of the high activation enthalpy. The kinetic parameters of the system studied are summarized from the literature[167] in Table 9.

Table 9. Rate constants and activation parameters for the [Rh(diphos)]$^{\oplus}$-catalyzed hydrogenation of **96** at 25 °C [167].

Step	k at 25 °C	$\Delta H^{\neq}$ [kJ mol^{-1}]	$\Delta S^{\neq}$ [J mol^{-1} K^{-1}]
1	$k_1 = 1.4 \times 10^4$ mol^{-1} s^{-1}	–	–
	$k_{-1} = 5.2 \times 10^{-4}$ s^{-1}	77	8.3
2	$k_2 = 1.0 \times 10^2$ mol^{-1} s^{-1}	26	−115.8
3	$k_3 > 1$ s^{-1}	–	–
4	$k_4 = 23$ s^{-1}	71	25

Depending on the type of catalyst, the substrate and the reaction conditions, however, the order of the individual steps has been disputed.[132, 135a, 163, 174–176] Thus, the reaction sequence depicted in Figure 30 (complexation of the substrate prior to oxidative addition) has been called the "unsaturated route" or "olefinic route"[167–171] (Path B in Fig. 30), whereas a mechanism in which the two steps are reversed is described as the "hydride route"[174–176] (Path A, Fig. 30).

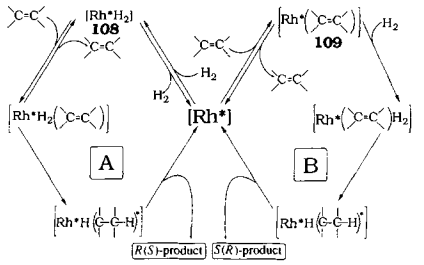

Fig. 30. According to catalyst type, substrate, and reaction conditions, homogeneous double bond hydrogenation is divided into the "unsaturated" or "olefin route" (Path B) and the "hydride route" (Path A). In reaction cycle B, the hydrogen is oxidatively added before complexation of the substrate as **109**, in cycle A the H_2-complex **108** is formed first ([Rh*] = chiral phosphanerhodium chelate complex).

For the enantioselective variant of the homogeneous hydrogenation of prochiral substrates, using rhodium catalysts containing chiral phosphane chelate ligands, the mechanistic scheme in Figure 29 must be altered such that each of the intermediates is present in two diastereomeric forms. Selectivity is derived here from two competing, diastereomeric reaction cycles. According to the mechanism presented in Figure 31, the stereochemistry of the product is fixed by the primary complexation of the substrate to the chiral catalyst. The extent of enantioselectivity in the overall reaction, however, is determined by the first irreversible step in the catalytic cycle, the oxidative addition of hydrogen.

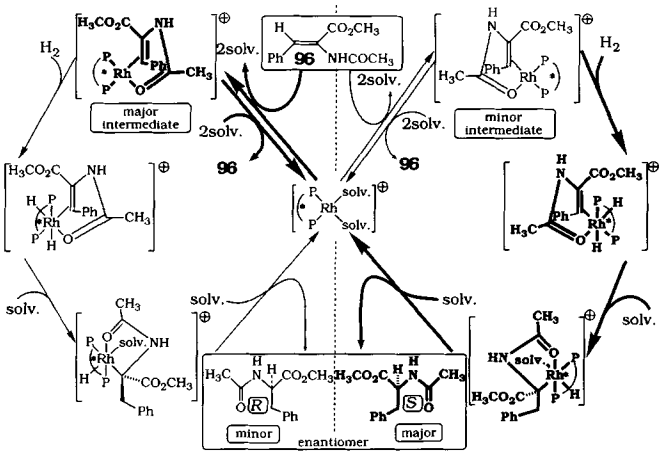

Fig. 31. Enantioselective variant of the "olefin route". The diagram shows the two diastereomeric catalytic cycles obtained when rhodium catalysts are used that contain chiral phosphane chelate ligands (P*P) (solv. = solvent).

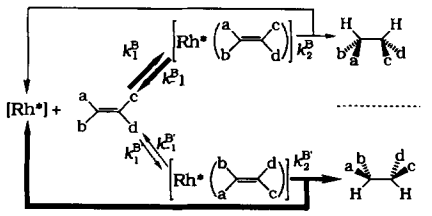
Starting from the mechanism depicted in Figure 31, two borderline cases may be discussed. It is conceivable that the major enantiomer may be produced from a preferentially formed catalyst-substrate complex; alternatively, it may arise from the minor diastereomeric intermediate if the latter possesses far greater reactivity towards hydrogen than the major intermediate produced. The formation of the major enantiomer from the minor intermediate is probable, according to the mechanistic studies of *Halpern*. If these statements are transferred from the mechanistic diagrams of Figures 30 and 31 to the kinetic scheme of an isoinversion relationship (Fig. 13), then the asymmetric catalytic process may be represented in the simplified form shown in Scheme 3.[167, 170–172]



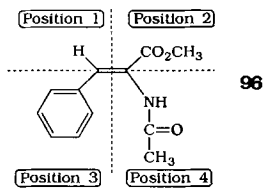
Scheme 3. Kinetic scheme of the catalytic asymmetric hydrogenation modeled on Figure 13.

Here, k_1^B and $k_1^{B'}$ represent the overall rate constants for formation of the diastereomeric catalyst-substrate adducts, while k_2^B and $k_2^{B'}$ are the sum of the rate constants for all the steps involved in formation of the hydrogenation products from the intermediates. The weighting of rate constants postulated by *Halpern* and indicated in Scheme 3 is represented schematically in Figure 15.

The enantiomeric excess that can be attained in the hydrogenation of prochiral olefins with chiral transition metal catalysts in homogeneous phase is influenced by the following parameters: the substrate (substitution pattern of the prochiral double bond), the catalyst complex (charge of the catalyst, central atom, nature of the ligands, e.g. monodentate/chelate ligands, nature of ligand chirality, nature of the coordinated phosphorous atom (phosphane, aminophosphane, phosphite etc.)) and the reaction conditions (solvent, temperature, H_2-pressure, added amine).

6.2.2. The Influence of Substrate Structure

Although the phosphanerhodium-catalyzed hydrogenation is one of the most elegant methods for synthesizing chiral compounds in high optical yields, the variety of possible substrates that can be used is very small.[132] Nonetheless, the correlation between substrate structure **96** and attainable enantiomeric excesses is a well studied area (Scheme 4).[160]



96

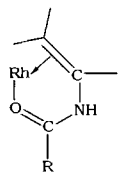
Scheme 4. Identification of substituent positions for analysis of the influence of the substrate structure on the enantiomeric excess in catalytic asymmetric hydrogenation.

Systematic studies have shown that the phenyl group in *position 3* of **96** can be replaced by all types of alkyl and aryl groups, and even by hydrogen.

The hydrogen atom in *position 1*, geminal to the phenyl group, cannot by substituted by any other functional group. Although (*E*)- and (*Z*)-isomeric substrates in a few cases yield the same product configuration, in many cases the (*Z*)-configurated substrate is hydrogenated faster and more selectively.[160, 177]

The functional group in the *2-position* must have electron-withdrawing character.[178] Carboxyl, carboxylate, carbonyl and cyano groups geminal to the amide group are all equally suitable for the generation of high enantiomeric excesses, though the free carboxyl group has been used most often in the past. For a variety of carboxylic esters, the *ee* value is not significantly affected by the steric requirements of the alcohol moiety.[179, 180] In a few cases, use of chiral alcohols has led to the observation of double induction.

The substituent situated in the *4-position* is the most important for achieving high enantiomeric excesses. Substituents such as NHCOR, OCOR or CH_2COOR possess a carbonyl group in the β-position to the double bond (β-carbonyl substituent). During complexation of the double bond and carbonyl functional groups to the rhodium, a chelate complex with structure **103**[160, 181] is then formed.



103

N-Acetyl- and *N*-benzoylenamines are usually preferred as substrates.[132]

6.2.3. The Influence of the Central Atom

In the area of homogeneously catalyzed double bond hydrogenation, rhodium complexes take a position ahead of all other transition metals with respect to activity and selectivity.[132] Chiral phosphaneruthenium complexes[182] are inferior to their rhodium analogues for hydrogenation reactions, and only a few examples of enantioselective double bond hydrogenation by cobalt[183] and titanium[184] complexes have been described. Cationic and neutral rhodium complexes, using the same phosphane ligands, yield different enantioselectivities, although no general correlation between the charge of the complex and attainable *ee* values has yet been observed.[132, 166]

6.2.4. The Influence of Ligand Structure

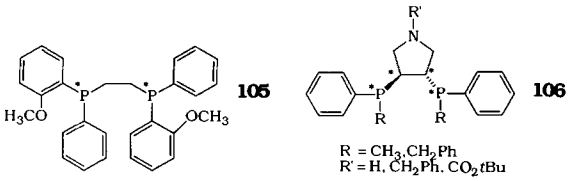
The carrier of the chiral information that is transferred to the substrate is the catalyst ligand system in the phosphane-rhodium complex.[155, 160] Model development has not been able to keep pace with the extensive experimental studies, so that asymmetric catalysis today still relies largely on empirical results.[132, 135, 156, 160] Nevertheless, a few guidelines can be recognized which optically active phosphorus-containing ligands must fulfill if high optical yields are to be attained in an asymmetric hydrogenation. Some of the factors that favor high enantioselectivities are, according to *Kagan*[267] and *Brunner*:[155] a) the use of bidentate ligands, b) the possibility of forming a conformationally rigid chelate ring, and c) aryl substitution on the phosphorus atoms of the chelate ligands.

From this point of view, factor (a) has an especially strong effect. Phosphorus chelate ligands are far more effective with respect to selectivity than monophosphanes.[139, 152] In com-

plexes with monodentate phosphanes, each rotamer relative to the metal–phosphorus bond is a separate catalyst species with an individual *R*/*S* selectivity. In complexes with chelate ligands, however, free rotation about the metal–phosphorus bond is abolished due to ring formation.

Most chiral 1,2-diphosphinoethanes carry their stereocenters in the carbon skeleton,[139] most effectively in the two-carbon chain connecting the phosphorus atoms.[132] In comparison, very few bisphosphanes are known with phosphorus atoms as stereocenters. One example of a ligand with chiral phosphorus atoms is the phosphane dipamp **105**.[163]

Examples of 1,2-diphosphinoethanes containing phosphorus and carbon stereocenters are even rarer in the literature. The bis(alkylphenylphosphino)pyrrolidines of type **106**, described by *Nagel* and *Rieger* et al.,[185, 186] are examples of these.



The vast majority of bisphosphanes form five- or seven-membered chelate rings with the rhodium.[132] Although efficient catalysts have now been found in both groups, the five-membered ring chelates still provide the greater number of highly selective catalyst systems.[139] Only very few chiral phosphane ligands have been described that build six-membered chelates.[142] Eight-membered and larger ring systems seem to be too flexible for effective chirality transfer.[132]

The five- and seven-membered rhodium chelate complexes that are mostly used are conformationally chiral[132, 173a] (Fig. 32) because of their non-planar conformation. The introduction of chiral ligands leads to a strongly favored preferred conformation. For a staggered five-membered-ring rhodium chelate complex, a λ-conformation (**106a**) or δ-conformation (**106b**)[187] is adopted, i.e. one of two conformations which behave like mirror images. Analogously, seven-membered chelate rings in the chair form take up a λ-conformation (**107a**) or δ-conformation (**107b**).[173a]

According to *Pavlov* et al.,[176, 185] a strict correlation must exist between catalyst conformation and the product configuration of the major enantiomer, since the chiral information is transferred to the substrate by the conformation of the chelate ring in the catalyst. In line with this argument, five-membered chelate ring complexes with λ-conformation (**106a**) and seven-membered chelates with chair-λ-conformation (**107a**) give an (*S*)-configuration in product **97**, starting from (*Z*)-*N*-acetylenamides **95**. In contrast, chelate rings with δ-conformation (**106b**) and chair-δ-conformation (**107b**) lead to the (*R*)-configurated products. Figure 32 illustrates schematically the stereochemical relationship between catalyst conformation and product configuration for bis(diphenylphosphane)rhodium complexes with a C_2-axis.[188]

In chelate complexes with chiral phosphorus atoms the configuration at the phosphorus atom merely influences the

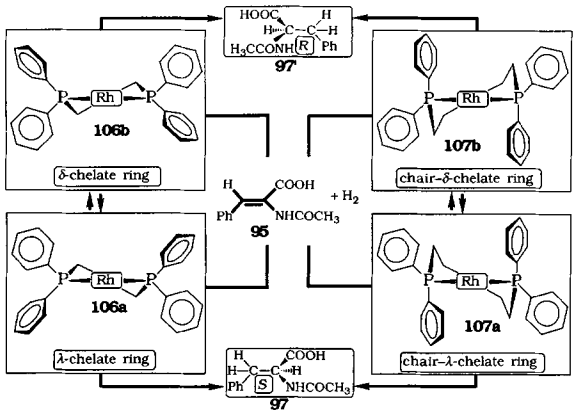


Fig. 32. Correlation between the conformation of chiral bisphosphanerhodium complexes and the product configuration of the major enantiomer in homogeneous double-bond hydrogenation.

extent of enantioselectivity, and the induced configuration in the major diastereomer remains the same.[185] The aryl substituents on the phosphorus atoms function as the actual agents of chirality transfer in asymmetric double bond hydrogenation. As a consequence of the staggered nature of the chelate ring, the phenyl groups may find themselves in either equatorial or axial position (see Fig. 32). Since the geminal phenyl rings lie almost next to one another, these two configurations are distinguished as "face exposed" or "edge exposed". The arrangement of the two phenyl groups on the phosphorus atom is therefore decided by a chirality which is determined by the shape of the chelate rings. The chiral information is then transferred from the centers of asymmetry in the chelate ring through the phosphorus phenyl groups to the catalytically active coordination sites on the metal.

According to *Brunner*,[155, 189] this chirality transfer from the ligand system must be associated with an "information smoothing" or even with a total loss of information.

From this hypothesis a concept was developed, whereby the inducing chiral center should be located directly at the site where the chirality transfer takes place. This idea of a direct interaction between the inducing chiral center and the coordination sites on the metal atom was then successfully realized for several systems, using molybdenum complexes.

The working model developed for catalytic asymmetric reactions, that of a catalyst-conformation directed product configuration,[176] displays a close relationship to the static shielding model for stoichiometric asymmetric synthesis described by *Schmierer* and *Helmchen*.[16]

On the basis of the extensive data collected, it is now possible to predict in some cases empirically which substrates and rhodium-ligand systems will lead to high enantiomeric excesses. At present, however, we cannot design an optimal catalyst system for a given substrate, or vice versa.[132, 160] Further, the selectivity of a catalyst depends largely on the reaction conditions chosen, which have to be experimentally determined for every catalyst–substrate combination.

6.2.5. *The Influence of the Solvent*

For many systems, considerable solvent effects are observed, since the mechanistic hypotheses described involve

solvent molecules in the catalytic cycle.[132, 162] (Hence, alcohols, especially methanol, and also benzene, benzene/alcohol mixtures, THF and water/alcohol mixtures have been used as solvents.) A direct correlation between a solvent property (e.g. dielectric constant) and attainable enantiomeric excess has been reported for only very few examples of homogeneous C=C double bond hydrogenation, so that solvent effects on a particular catalyst-substrate system may still be said to be unpredictable.

However, according to *Pavlov* et al., solvents with high dielectric constants inhibit the hydride route (Fig. 30, pathway A) significantly more than the reaction pathway B in Figure 30, with a consequent loss of selectivity.[176]

6.2.6. *The Influence of an Added Base*

The enantioselectivity of a particular catalyst for a given substrate is also influenced by the addition of a base (triethylamine is the most commonly used).[132, 138, 174, 175, 190, 191] In general, a reduction in selectivity is seen, which in some cases is quite considerable and can even lead to a stereoinversion of the major enantiomer.[175] The effect of added base is particularly catalyst-dependent, but also varies with substrate, and is not always clearly explicable. If unsaturated carboxylic acids are used as substrates, addition of a base will generate the anion, with the result that the equilibrium constant for catalyst-substrate complex formation will increase.[132]

According to *Ojima* et al.,[175] the olefin route may be favored over the hydride route in this manner, if one assumes that each of the two competing reaction pathways in Figure 30 leads preferentially to the opposite enantiomer. In addition, systems with added base show a different temperature and pressure dependence of the enantioselectivity.[175]

6.2.7. *The Influence of Temperature*

Data concerning the temperature dependence of attainable enantiomeric excesses at constant hydrogen pressure are only available for a few systems.[132, 160, 172, 289–291] However, it is known that the enantioselectivity of asymmetric hydrogenation is especially sensitive to temperature effects.

In several cases, an increase in enantiomeric excess is observed as the temperature falls.[161, 176, 192–194] However, catalyst-substrate systems have also been described which show the reverse behavior for optical yield, i.e., increasing temperature results in a rise in *ee* value.[174, 175] *Ojima* et al. report an improvement in optical yield from 0% to 60% on raising the temperature from 0 °C to 100 °C.[175]

One problematic aspect of temperature-dependent measurements is that reduced temperature generally leads to a severe loss of catalyst activity.[132] A loss of selectivity with a fall in temperature is explained by *Halpern*'s mechanistic theory on the origin of enantioselectivity in catalytic hydrogenation processes (Fig. 29) as follows.[170–172] High enantiomeric excesses are brought about in part by a rapid interconversion of the initial, reversibly formed catalyst-substrate complexes, compared with the reaction of these intermediates with hydrogen. In the ideal case, the starting material can, in this manner, be entirely converted into the major product enantiomer. Since the dissociation of the catalyst-substrate adduct has a larger activation enthalpy than H_2-addition (cf. $\Delta H^{\neq}$ to k_{-1} and k_2 in Table 9), at lower temperatures the interconversion process of the diastereomeric primary adducts will be "frozen", with the result that the major intermediate formed will have a higher probability of also reacting with hydrogen, leading to increased production of the minor hydrogenation product.

Ojima et al.,[175] on the other hand, explain an increase in enantioselectivity with increasing temperature as a favoring of the olefin route relative to the hydride pathway, since increasing temperature should inhibit the formation of the hydrido species [Rh*H_2] **108** (Fig. 30).[174]

The opposite temperature behavior, which has been observed by *Selke* and *Pracejus*,[194] for example, cannot be explained by the mechanistic interpretations of *Ojima* et al.[175] and *Halpern* et al.[170, 172]

Hydrogenation of amino acid precursors using carbohydrate phosphinites as chiral ligands showed a linear depen-

6.2.8. The Isoinversion Relationship for Homogeneous, Rhodium-Catalyzed Hydrogenation

Studies of temperature effects on catalytic hydrogenation have been carried out by several authors.[193, 289–291] The subject was investigated systematically by *Sinou* et al.[174] Table 10 lists the systems investigated. Here, too, plotting of the literature data (Fig. 33) gave two linear regions with an inversion point in the Eyring diagram for every system.

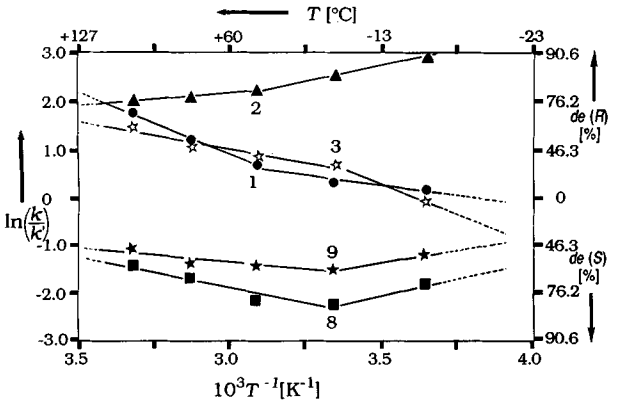

Fig. 33. Eyring diagram for the temperature-dependent *ee* values for Systems 1–3, 8 and 9 (Table 10), measured at constant pressure. The enantomeric excess was set equal to the optical yield. Ethanol was employed as solvent; at T = 100 °C, *n*-butanol served as solvent. The *ee* values were measured after complete conversion.

Analysis of the activation parameters in the sense of the isoinversion relationship yielded an isoinversion line with gradient T_i = 322 K (Fig. 34). This means that for a given pressure, optimal selectivity can be expected at this temperature for the homogeneous rhodium-catalyzed hydrogenation of prochiral substrates of type **96**.

Further, the existence of inversion points in temperature-dependent selectivity measurements teaches us that the temperature-dependent interplay of the overall rate constants in Scheme 3 determines the extent of enantioselectivity, under

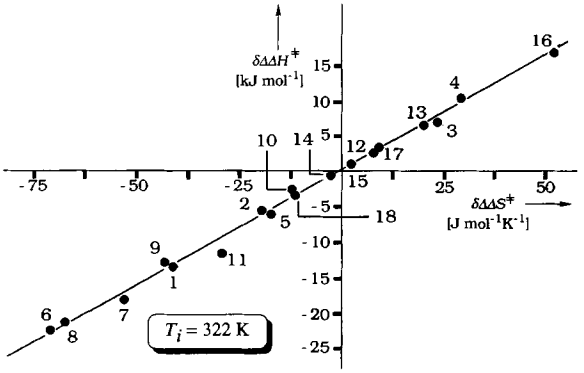

Fig. 34. $\delta\Delta\Delta H^{\neq}/\delta\Delta\Delta S^{\neq}$ diagram for the [Rh(cod)(P*P)]⊕-catalyzed hydrogenations in the homogeneous phase at constant hydrogen pressure (T_i = 322 K, correlation coefficient > 0.99).

given reaction conditions. The available data also reveal that the mechanistic statements regarding temperature-dependent selectivity by *Halpern* et al.[167–172] on the one hand, and *Ojima* et al.,[175] *Sinou* et al.[174] and *Pavlov* et al.[176] on the other may be valid for many systems in a particular temperature region, but they cannot explain simply a changed or inverse temperature dependence in another temperature range. Temperature does not have an isolated effect in one catalytic step, but in the dynamic model of the isoinversion relationship according to Scheme 3 it can lead to a reweighting of the enthalpy/entropy dominance in selectivity-determining partial steps.

6.2.9. The Influence of Hydrogen Pressure

Depending on substrate and catalyst structure, the hydrogen pressure may also have a significant influence on stereoselectivity at a given reaction temperature, since H_2-addition constitutes an important step in the catalytic cycle.[132, 196, 197] A series of systems are known where increasing hydrogen pressure leads to a loss of selectivity,[160, 174, 175, 185, 195] in some extreme cases even to an inversion of the configuration of the major enantiomer.[175] However, a few examples are also known where the stereoselectivity shows a reversed[176, 197] pressure dependence, or no dependence at all in the range measured.[176, 194] According to *Halpern* et al.,[160, 170, 172] the reduction in selectivity with increased pressure can be explained by an increased rate of hydrogen addition, with a simultaneous, relative decrease in the interconversion process between the two diastereomeric catalyst-substrate complexes. The stereochemistry is hence primarily determined by the initial step, and retrocleavage loses importance as a second selectivity level. For this mechanistic theory, the selectivity process requires low hydrogen pressures and high temperatures for high enantiomeric excesses. Since the activity of the catalyst increases considerably as the H_2-pressure rises, the loss of selectivity must be compensated for by an increase in reaction temperature.

Ojima et al.[175] and *Sinou* et al.[173] trace the loss of selectivity at higher hydrogen pressure to a contraselective favoring of the hydride route, with preferential formation of the [Rh*H_2] species **108** rather than the primary catalyst-substrate adduct **109** (see Fig. 30). However, neither selectivity mechanism can explain a changed or reversed pressure dependence of selectivity in the range studied.

6.2.10. The Pressure Analogue of the Isoinversion Relationship in Homogeneous, Rhodium-Catalyzed Hydrogenation

If *Ojima* and *Sinou*'s experimental data on pressure-dependent selectivity are plotted on a $\ln(k/k')/p$ diagram, then for a single system, two linear regions with an inversion point can again be recognized. The results from a selection of the systems listed in Table 11, where enantioselectivity has been measured with respect to temperature, are presented in Figure 35, in the form of a $\ln(k,k')/p$ diagram.

For pressure-dependent *ee*-value determinations, the gradient of a linear $\ln(k/k')/p$ correlation at a constant temperature gives, according to Equation (12), the activation vol-

Table 11. Overview of the systems studied by *Ojima* et al. [175], *Sinou* et al. [174] as well as *Nagel* and *Rieger* [185] to determine the enantioselectivity at constant temperature as a function of the hydrogen pressure.

ume difference $\Delta\Delta V^{\neq}$.[198–200] k, k' are the overall rate constants leading to the major and minor enantiomers respectively, in rhodium-catalyzed asymmetric hydrogenation.

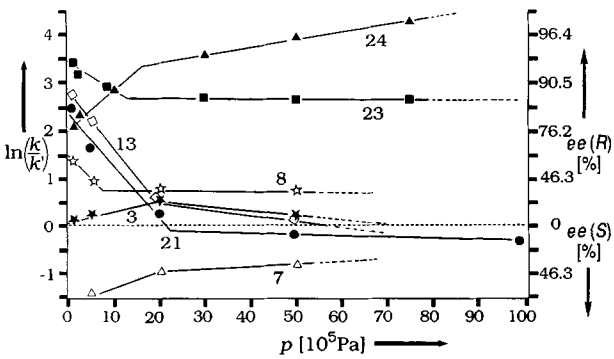

Fig. 35. $\ln(k/k')/p$ diagram for pressure-dependent *ee*-value measurements at constant temperature. A few selected systems are shown (Systems 3, 7, 8, 13, 21, 23, 24 in Table 11). An inversion pressure p_{inv} is assigned to the inversion point.

As for an Eyring diagram, in systems with two linear regions an inversion pressure p_{inv} may be assigned to the inversion point. This divides the pressure range into a high-pressure region ($p > p_{inv}$) and a low-pressure region ($p < p_{inv}$).

$$\Delta\Delta V^{\neq} = -RT\left(\frac{\partial \ln\left(\frac{k}{k'}\right)}{\partial p}\right)_T \tag{12}$$

The intercept on the ordinate at $p = 0$ in a $\ln(k/k')/p$ diagram corresponds to an activation entropy difference $\Delta\Delta S^{\neq}$ [Eq. (13)], analogously to the Eyring approach for stereoselective reactions. This demonstrates the formal equivalence of activation volume and activation enthalpy differences, and hence the formal equivalence of the parameters p and T^{-1}.

$$\lim_{p \to 0}\left(\ln\left(\frac{k}{k'}\right)\right) = \frac{\Delta\Delta S^{\neq}}{R} \tag{13}$$

The isoinversion principle derived from temperature-dependent selectivity measurements at constant pressure can also be applied for pressure-dependent selectivity measurements at constant temperature, by using Equation (14), which relates the activation volumes for the high- ($\Delta\Delta V_2^{\neq}$) and low-pressure ($\Delta\Delta V_1^{\neq}$) regions to each other.

$$\delta\Delta\Delta V^{\neq} = \Delta\Delta V_2^{\neq} - \Delta\Delta V_1^{\neq} \tag{14}$$

If one now plots the parameters $\delta\Delta\Delta V^{\neq}$ and $\delta\Delta\Delta S^{\neq}$ in a volume/entropy diagram, then here, too, the vast majority of systems[266] in Table 11 display a linear relationship. $\delta\Delta\Delta S^{\neq}$ can be calculated analogously to Equation 5 from the entropy values for the low- and high-pressure regions. The regression curve passes directly through the coordinate origin (Fig. 36).

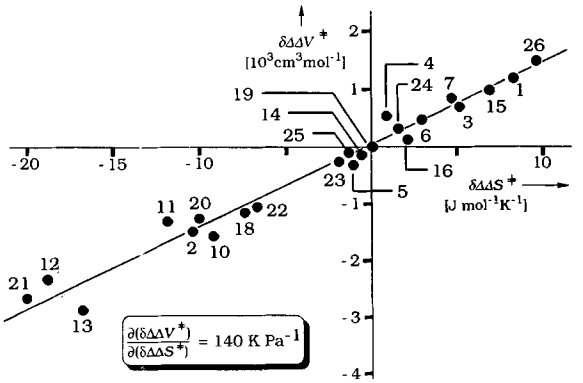

Fig. 36. $\delta\Delta\Delta V^{\neq}/\delta\Delta\Delta S^{\neq}$ diagram (correlation coefficient = 0.98) for the systems in Table 11. Systems 8, 9 and 17 have been disregarded in this diagram, as their deviations in the $\delta\Delta\Delta V^{\neq}/\delta\Delta\Delta S^{\neq}$ value were too high [266].

Figure 36 shows that a common relationship exists for the dominance change in the activation parameters $\Delta\Delta V_{1,2}^{\neq}$ and $\Delta\Delta S_{1,2}^{\neq}$ in the partial selectivity steps of homogeneous rhodium-catalyzed double bond hydrogenation. This relationship is independent of the *ee* value actually obtainable, and therefore also of the factors affecting the reaction-specific *ee* val-

ue, e.g. catalyst, substrate, added amine, temperature, and pressure.

The gradient of the line in Figure 36 is 140 K Pa^{-1}. The pressure analogue isoinversion diagram in Figure 36 yields an optimal pressure p_i for a given reaction temperature T in the selectivity process studied. (Eq. 15).

$$p_i = T\left(\frac{\partial(\delta\Delta\Delta V^{\neq})}{\partial(\delta\Delta\Delta S^{\neq})}\right)^{-1} \tag{15}$$

A comparison between the isoinversion relationship for temperature inversion (Fig. 34) and the isoinversion relationship for pressure inversion (Fig. 36) shows that here, too, p and T^{-1} are corresponding quantities, since the $\delta\Delta\Delta V^{\neq}/\delta\Delta\Delta S^{\neq}$ diagram (Fig. 36) incorporates the corresponding $\delta\Delta\Delta H^{\neq}/\delta\Delta\Delta S^{\neq}$ diagram, on the basis of Equation (16).

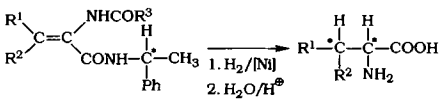
$$\delta\Delta\Delta H^{\neq} = \delta\Delta\Delta V^{\neq} \times p \tag{16}$$

From this it is clear that a pair of values exists (p_i/T_i), for which optimal selectivity will be observed for a given system [Eq. (17)].

$$p_i(T_i = 322\ \text{K}) = 2.3 \times 10^5\ \text{Pa} \tag{17}$$

6.3. Diastereoselective Heterogeneous Hydrogenation of the C=C Double Bond

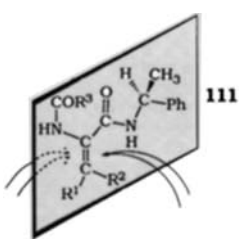
Sheehan and *Chandler* have studied numerous examples of heterogeneous-phase asymmetric hydrogenation of the C=C double bond in chiral α,β-unsaturated amides of type **110**.[202] After removal of the chiral auxiliary, they obtained enantiomeric excesses between 6% and 39% [Eq. (18)]. Further works are described in Refs. [203–208].



(18)

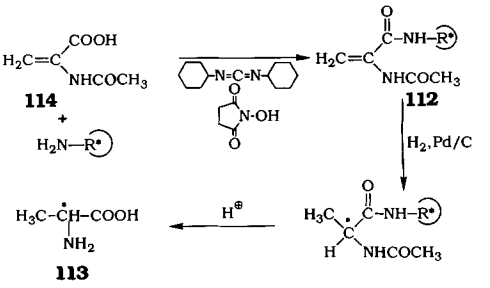
110 **a**, $R^1 = R^2 = R^3 = CH_3$ valine 39% *ee*
b, $R^1 = R^2 = CH_3$, R^3 = Ph valine 18% *ee*
c, R^1 = H, $R^2 = R^3$ = Ph phenylalanine 6% *ee*

To explain the steric course of the reaction, a model **111** was developed corresponding to the Prelog rule.[111] In this model, the carbonyl and the alkene units are arranged *trans* to each other , and the carbonyl group is fixed between the H atom and the methyl group of the chiral center in staggered conformation so that attack can occur from the sterically less hindered face.



111

Harada and *Takasaki* have studied the temperature-dependence of the palladium-catalyzed hydrogenation of chiral *N*-acetyldidehydroalaninamides **112** in various solvents [Eq. (19)].[209]



(19)

The enantiomeric excesses obtained for the product alanine **113** lie in the range 0 to 24%, while the chemical yield reaches 78–98%. The chiral *N*-acetyldidehydroalaninamides **112** were synthesized by the reaction of *N*-acetyldidehydroalanine **114** with the corresponding chiral amine and dicyclohexylcarbodiimide in the presence of *N*-hydroxysuccinimide.

Table 12 gives an overview of the systems studied and the solvents used.

Table 12. Overview of the systems whose stereoselectivity according to equation (19) has been studied with respect to temperature. The numbers assigned to the chiral amine components H_2N-(R•), with which **114** was allowed to react, and the solvents used, are as in Figure 38.

H_2N—(R•) \ Solvent	MeOH	EtOH	iPrOH	AcOEt
89	1	2	3	4
115	5	6	7	8
116	9	10	11	12

6.3.1. The Influence of Temperature and the Isoinversion Relationship for Diastereoselective, Heterogeneous C=C Double-Bond Hydrogenation

If one analyzes the published data on temperature-dependent stereoselectivity, one finds two linear regions and an inversion point here, too. Figure 37 shows the temperature dependence of several typical systems from Table 12.

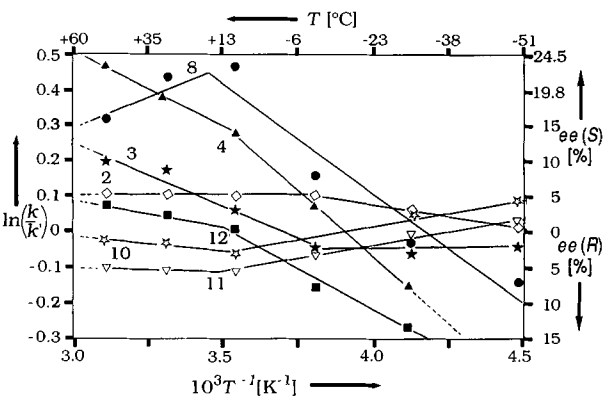


Fig. 37. Temperature-dependent course of stereoselectivity for a few typical systems (Systems 2–4, 8, 10, 11 and 12) from Table 12, in the form of an Eyring diagram.

Significantly better selectivities can be attained in catalytic hydrogenation when ethyl acetate is used as solvent, rather than alcohols. Further, it turns out that by varying the temperature a stereoinversion of the chiral C-atom in alanine may be achieved.

Analysis of the temperature-dependent selectivity in the sense of the isoinversion relationship gives a zero-point curve in the $\delta\Delta\Delta H^{\neq}/\delta\Delta\Delta S^{\neq}$ diagram, with $T_i = 293$ K (Fig. 38).

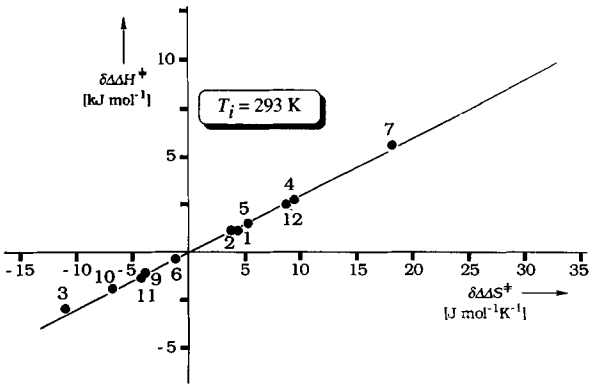

Fig. 38. The isoinversion line (correlation coefficient > 0.99) for heterogeneous, palladium-catalyzed hydrogenation of the C=C double bond in chiral amides of the type **110**, according to Equation (19) (Table 12).

The authors do not present a mechanistic model which could explain the temperature course of stereoselectivity. However, in the light of the isoinversion relationship, the following conclusions may be drawn: In the Eyring diagram, all the systems reveal generally small activation enthalpy differences and large activation entropy differences in both the high- and low-temperature regions. Throughout the temperature range studied, the stereoselectivity is largely determined by entropy effects, due to the complex equilibria responsible for formation of the diastereomeric, activated catalyst-substrate complexes. The relatively weak interactions which are responsible for adsorption of the substrate molecule onto the catalyst surface act to strengthen the unfavorable entropy term, so that overall the stereoselectivity attainable is only moderate. The molecular cause is presumably an equal weighting of the diastereomeric catalyst-substrate complexes with regard to formation and further reaction.

Ikeda and *Yamagishi* et al.[288] studied the diastereoselective hydrogenation of the C=C double bond in dehydrodipeptides[287] with achiral rhodium catalysts in homogeneous phase. The analysis of the data yields the isoinversion temperature $T_i = 308$ K.

6.4. Hydrogenolytic Asymmetric Transaminations (Heterogeneous Hydrogenation of the C=N Double Bond)

Numerous non-enzymatic, asymmetric syntheses of α-amino acids from the corresponding α-keto acid precursors have been reported in the literature.[210-222] A common feature of these reactions is the catalytic asymmetric reduction of a C=N double bond within a chiral starting compound.[223, 224]

Starting with a carbonyl compound (usually an α-keto acid) and an optically active amine, a chiral Schiff-base (**117**) is generated. This can then be converted into an optically active α-amino acid by catalytic reduction and subsequent hydrogenolytic cleavage of the C–N bond. The entire sequence is described as hydrogenolytic asymmetric transamination (Fig. 39),[225, 226] in analogy to biochemical processes.[232]

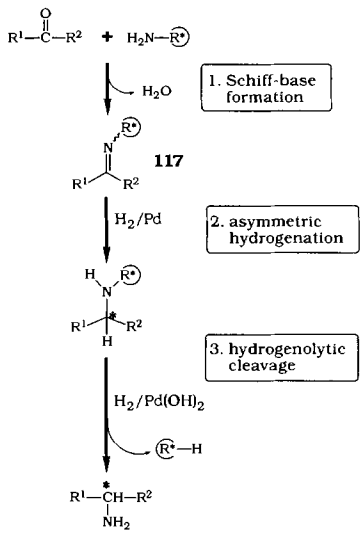

Fig. 39. Schematic diagram of hydrogenolytic asymmetric transamination. An optically active Schiff base **117** is generated from a keto component R–CO–R′ and a chiral amine H_2N-Ⓡ*. This is then hydrogenated in the stereoselective step, with heterogeneous palladium catalysis. Subsequent hydrogenolytic cleavage to remove the chiral auxiliary Ⓡ*–H yields an optically active amino acid derivative.

A fundamental disadvantage of this chemical chirality transfer from a chiral amine to a keto-compound is the loss of the original chirality carrier by cleavage of the C–N bond in the final step. Building on work by *Hiskey* and *Northrop*,[214, 219] who obtained amino acids from α-substituted benzylamines in optical purities of 12–81% and chemical yields of 20–80%, *Harada* et al.[210, 211, 215–217, 220–222, 227–231] carried out a very intensive study of the asymmetric transamination reaction. They showed that the attainable enantiomeric excesses in the product α-amino acids are dependent on the following parameters, if one starts from α-keto acids or α-keto esters and primary, α-substituted benzylamines or amino acid esters: the chiral amine component H_2N-R*,[223, 224] the nature of the α-keto acid derivative[223, 224] R^1-(C=O)-R^2 (R^1 = Me, R^2 = COOH or COOR′), the solvent,[221, 223, 224, 227–230] and the reaction temperature.[210, 211, 223, 224]

6.4.1 *The Influence of Amine and α-Keto Acid Structure*

The optical yields using α-phenylethylamine **89** are consistently higher than for the corresponding α-phenyl-*n*-propylamine **115** (cf., e.g., Nos. 4 and 8 in Fig. 37). The highest enantiomeric excess obtained so far has been with α-(1-naphthyl)ethylamine **116**. If the (*S*)-configuration amine is used in the reaction, the (*S*)-amino acid is usually obtained.

The *ee* values reached are very sensitive to the nature of the R^1 group in the keto component. However, no general-

ized correlation can be established between the size of the R^1 group and the *ee* value. With **89**, the following rankings were found for the R^1 residues: $CH_3 > CH_2COOH > C_2H_5 > Ph > CH_2Ph > CH_2CH_2COOH$. (" > " = higher *ee* values obtained under otherwise identical conditions). These rankings can be considerably changed, however, by altering the amine component.

The use of α-keto esters rather than the free acids has no significant effect on the enantiomeric purity of the amino acid synthesized (R^2 = COOH or COOR'), even if esters of chiral alcohols such as menthol **14** are employed (double induction). The (*E*)/(*Z*) ratio of the Schiff base **117** formed from the α-keto acid and the chiral amine ought to have no effect on the stereoselectivity.

6.4.2. *The Influence of Solvent and Temperature*

Hydrogenolytic transamination (Fig. 39) is very sensitive to solvent effects. If polar solvents (e.g. methanol, water) are used, lower enantiomeric excesses are generally found (30–50% *ee*) than for less polar solvents such as benzene, dioxane, ethyl acetate or tetrahydrofuran (60–80% *ee*). In many examples, a nearly linear relationship can be seen between the optical purity of the product amino acid and the dielectric constants of the solvent employed, under otherwise identical reaction conditions.

Asymmetric, palladium-catalyzed hydrogenation of the C=N double bond also shows a significant temperature effect.[210, 211, 228–230] Stereoinversion of the asymmetric reaction can be achieved merely by changing the temperature.

A series of systems exist which reveal only one linear region in the Eyring diagram for the temperature range studied.[211, 230] Others are also known, however, whose temperature-dependent stereoselectivity yields two linear regions with an inversion point.[210, 211, 228, 229, 285, 286] One example of a system whose temperature-dependent stereoselectivity is characterized by two linear regions is the hydrogenation of Schiff bases of type **117**, which can be synthesized from pyruvic acid or pyruvic acid esters and various chiral amines.[210, 211, 228, 229, 285]

Table 13 gives an overview of the systems studied. In Figure 40, some characteristic systems of temperature-dependent enantiomeric excess measurements are presented, both as an *ee* value/temperature diagram (top) and as the corresponding Eyring diagram (bottom).[210, 211]

Table 13. Overview of several systems whose stereoselectivity in the palladium-catalyzed hydrogenation of Schiff bases of type **117** has been studied with respect to temperature..

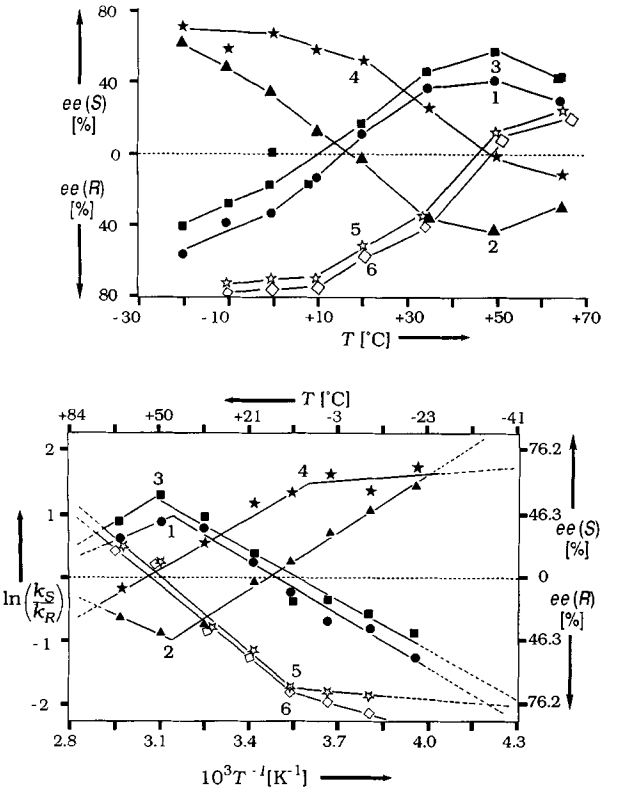

Fig. 40. Top: *ee* value/temperature diagram for the Systems 1–6 listed in Table 13. Bottom: Corresponding Eyring diagram for the Systems 1–6 listed in Table 13. To determine the enantiomeric excesses given, the alanine obtained after hydrogenolysis was converted into the corresponding dinitrophenyl derivative [210].

The results show very nicely that if chiral information carriers of opposite configuration are used (e.g. Systems 1 and 2, Table 13), an almost identical temperature dependence is observed, but with opposite sign. This is expected for enantiomers of equal optical purity.

With many systems, the influence of temperature can be used to achieve an inversion of stereochemistry at the newly formed chiral center. If one transforms the activation parameters $\Delta\Delta H^{\ddagger}_{1,2}$ and $\Delta\Delta S^{\ddagger}_{1,2}$ from the Eyring diagram into $\delta\Delta\Delta H^{\ddagger}$ and $\delta\Delta\Delta S^{\ddagger}$ values in the sense of the isoinversion relationship, then one also obtains an isoinversion diagram with a zero-point curve (T_i = 303 K, Fig. 41), independent of the solvent and the nature of the substituents R^1, R^2 and Ⓡ* in **117**.

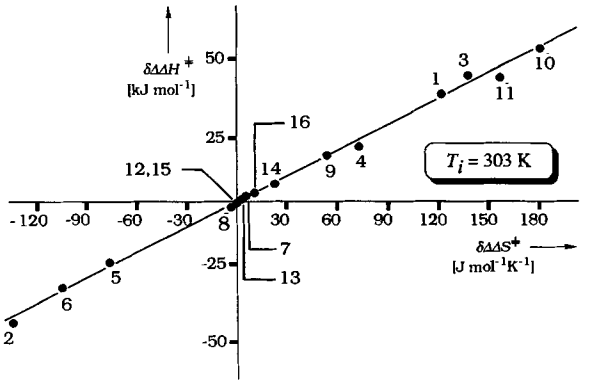

Fig. 41. The isoinversion line (correlation coefficient > 0.99) for hydrogenolytic transamination as in Figure 39 (T_i = 303 K); numbering of systems as in Table 13.

6.4.3. *Mechanistic Considerations on Hydrogenolytic Transamination in the Light of the Isoinversion Relationship*

The temperature and solvent dependence of stereoselectivity in palladium-catalyzed, hydrogenolytic, asymmetric transamination is explained by *Harada* as due to the appearance of intermediates **118**, which are in equilibrium with non-chelated particles **119** (Fig. 42),[210, 211, 215–217, 220, 221, 227–231] if Schiff bases of the type **117** ($R^1 = CH_3$, $R^2 = CO_2Et$) are used.

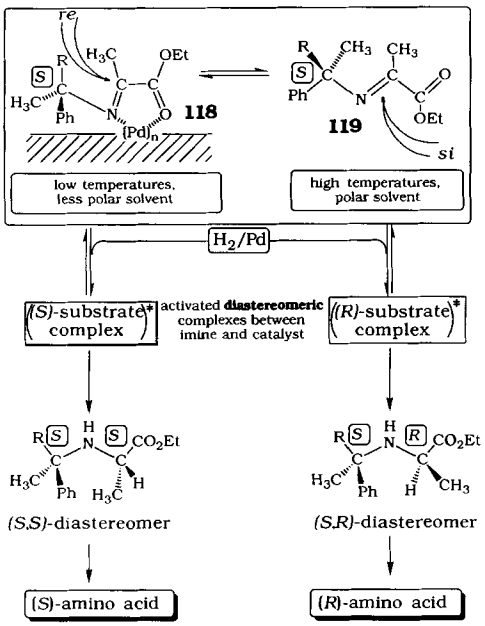

Fig. 42. Schematic diagram of the "chelation model" developed by *Harada* et al. showing the Schiff base **117** with $R^1 = CH_3$, $R^2 = CO_2Et$ as example.

In this theory, the imine **117** is fixed to the catalyst surface by formation of a five-membered chelate complex **118** before hydrogenation takes place. In the stereoselective hydrogenation step, an activated complex forms between this five-membered cyclic intermediate and the catalyst, such that the metal attacks the chelated species from the sterically less hindered face. In the example in Figure 42, attack takes place from the *re*-face of the fixed intermediate, so that one finally obtains the (*S*)-amino acid in excess. If the reaction temperature is increased, then the population of chelated intermediate **118** falls, because of the weak interaction between substrate and catalyst, and the proportion of the unfixed species **119** rises. In the stereoselective step the non-chelated intermediate **119** is also attacked from the sterically less hindered face, so that in the example given, an *si*-face attack takes place, and an (*R*)-amino acid is preferentially generated.

With the help of the equilibrium between chelated and unfixed intermediates, the influence of the solvent on stereoselectivity can also be explained.[221] In less polar solvents the formation of the five-membered chelate complex **118** is favored, partly because the electrostatic interaction between substrate and catalyst is more pronounced than in polar solvents, and partly because the substrate is less strongly solvated, increasing the tendency to form the chelate complex **118**. In polar solvents the reverse is true; the interaction between catalyst and substrate is weaker, and the formation of a chelate complex is hindered by stronger solvation of the substrate. According to the working hypothesis,[210, 211] the extent of stereoselectivity is determined by equilibrium between the chelated species and unfixed species, which takes place before the actual hydrogenation.

The chelation model developed by *Harada* et al.,[210, 211] which is generally applied to Schiff bases of the type **117**, does not, however, take into account the complex events in this heterogeneous reaction that are responsible for forming diastereomeric, activated complexes of substrate and catalyst. Complex equilibria between substrate and catalyst lead to two diastereomeric reaction channels, both for a chelated intermediate and for an unfixed species. The cross-section of these channels depends both on the temperature and on the solvent used. The preliminary equilibrium and the equilibria in the stereoselective step together determine the temperature course of stereoselectivity. If it were solely the equilibrium between chelated species and unfixed species that were responsible for the temperature dependence of stereoselectivity under otherwise identical conditions, then the Eyring diagram would contain merely one linear region, and large $\Delta\Delta H^{\ddagger}$ and even larger $\Delta\Delta S^{\ddagger}$ values would be expected. The influence of entropy is considerably larger in a chelation equilibrium than in a comparable conformation equilibrium. Indeed in each of the systems studied, a temperature interval was observed which was characterized by very large activation entropy differences. In this region, an equilibrium between fixed and unfixed particles may indeed be largely responsible for the temperature course of stereoselectivity. At the inversion temperature T_{inv}, i.e., at the changeover for entropy and enthalpy in the weighting of the selectivity process, the later equilibria between substrate and catalyst determine the temperature course. Here too, the fact that all systems belong to the isoinversion relationship teaches us that at particular temperature intervals the influence of enthalpy and entropy on a complex reaction course can be weighted differently. The observed temperature dependence of stereoselectivity cannot be explained by a change of mechanism, but by the temperature-dependent interplay of enthalpy and entropy in the selectivity-determining partial step concerned.

6.5. Catalytic Hydrogenation of the C=O Double Bond

In the case of the hydrogenation of methyl acetoacetate with modified Raney-nickel catalysts (modifying reagents: tartaric acid, amino acids) in heterogeneous phase the temperature dependence of enentioselectivity yields an isoinversion line with gradient $T_i = 321$ K.[272] Within experimental error, this value is identical to the T_i-value for homogeneous-phase rhodium-catalyzed hydrogenation.

The enantioselective hydrogenation of α-keto esters with chiral modified platinum catalysts in the heterogeneous phase yields the isoinversion temperature $T_i = 313$ K,[301] a slightly lower value. However, the use of homogeneous rhodium catalysts with constant type of substrate leads to $T_i = 229$ K.[302] In the palladium-catalyzed, heterogeneous hydrogenation of chiral α-keto amides $T_i = 291$ K is found. This is an example of a diastereoselective hydrogenation of the C=O double bond.[230, 303]

7. Further Examples of the General Applicability of the Isoinversion Principle in Chemistry

The isoinversion principle is not only applicable to stereoselective reactions. The following, randomly chosen examples show that this principle can apply whenever a selectivity process with competing reaction channels can be reduced to a simple scheme (Fig. 13), in which the starting materials are in equilibrium with reactive intermediates that can react in different ways. The partial steps differ in their activation enthalpy and entropy and therefore dominate in different temperature ranges, leading to an isoinversion relationship.

7.1. Temperature Dependence of Polymer Phosphorescence

Guillet et al.[233] have studied the temperature dependence of the phosphorescence intensity of polymer films. The inversion points that appear in the corresponding Eyring diagram result from transitions in the mobility of segments or side chains.[233] A knowledge of such transitions is interesting for an assessment of the material characteristics of polymers. During polymer film production, carbonyl groups arise by oxidation. These, like those already present, display an absorption maximum at 310 nm and a phosphorescence maximum at 460 nm.

One of the groups of polymers studied by *Guillet* et al.[233] is: polystyrene, carbonyl-containing copolymers of styrene and polystyrene-containing benzophenone (Table 14). The inversion points lie in a temperature range between 175 and 183 K (Fig. 43) and are therefore identical with the respective transition temperatures T_γ for the mobility of the phenyl moiety (rotation about the C–C single bond).

Table 14. Thermodynamic data for the transition in phenyl group mobility of polystyrene (PS(1), PS(2)), and copolymers of styrene and benzophenone-containing polystyrene.

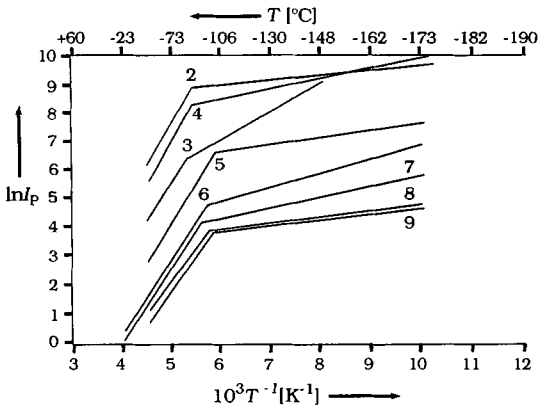

Fig. 43. Temperature-dependent phosphorescence intensities I_p measured for various polymers in Table 14, as an Eyring diagram (Systems 2–9). (The data points are too numerous to be shown individually.)

7.1.1. *The Causes of Temperature Dependence for Phosphorescence*

The simplified *Jablonski* scheme (Fig. 44) shows that the phosphorescence quantum yield ϕ_P is given by Equation (20).

$$\phi_P = \phi_{isc}\left(\frac{k_P}{k_P + k_Q}\right) \tag{20}$$

ϕ_{isc} is the quantum yield for intersystem crossing, k_P the phosphorescence rate, i.e., rate of $T_1 \rightarrow S_0$ transition, k_Q the total rate of all quenching processes.

Phosphorescence is quenched predominantly by oxygen diffusing into the system.[234] Although intersystem crossing (ϕ_{isc}) and phosphorescence (k_P) show a slight temperature dependence (entropy-determined), the temperature behavior of the quenching process (k_Q) is controlled by the temperature dependence of diffusion (enthalpy-determined). Because the weighting of the competing processes with respect to enthalpy and entropy differs, one of the two processes dominates in each of the temperature regions (Fig. 44).

If one considers the polymer film/oxygen system on a molecular scale, one finds that at temperature T_γ the phenyl

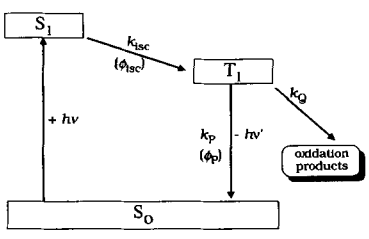

Fig. 44. Simplified Jablonski scheme for phosphorescence quenching. The equilibrium in the sense of the isoinversion principle is in this case a photostationary equilibrium. The irreversible reaction of excited species is here the formation of oxidation products by the quenching process.

rings of the styrene units become mobile. The tangled polymer then expands, and oxygen can diffuse in more rapidly. Since this system obeys the isoinversion principle (T_i = 188 K, Fig. 45), the transitions at T_y are all of the same type.

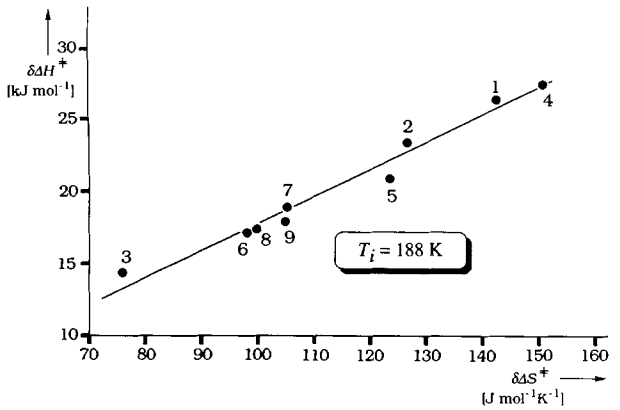

Fig. 45. Isoinversion diagram for the temperature-dependent phosphorescence of polystyrene-containing copolymers (Table 14). In this case the diagram is a $\delta\Delta H^*/\delta\Delta S^*$-diagram ($T_i$ = 188 K, correlation coefficient > 0.99).

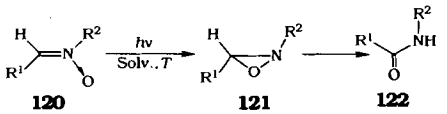
The transition from one process to the other (phosphorescence and its quenching by oxygen) is associated with a distinct phase transition. Therefore T_{inv} is nearly equal for all systems. For simple mathematical reasons, in such a case $T_i \approx T_{inv}$. Because of the substraction of the activation parameters ($\delta\Delta H^{\neq}$, $\delta\Delta S^{\neq}$) during derivation of T_i the differences in the y ordinates vanish. In contrast to the examples mentioned so far in which the competing reactions produce different amounts of the two stereoisomeric products (two-dimensional process), in this case the two competing reactions determine only one variable quantity (ϕ_P). Therefore this process can be described as one-dimensional.

7.2. Photoisomerization of Nitrones to Oxaziridines

On irradiation, nitrones **120** isomerize to oxaziridines **121** [Eq. (21)],[243, 244] as was first observed by *Kalmet* and *Kaplan*.[235]

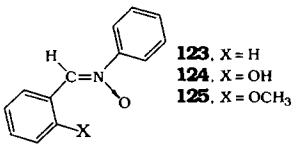
Oxaziridines **121** are generally unstable, and rearrange to the amides **122**. The reaction proceeds from an excited singlet state[236] of **120**, and the quantum yields are solvent and temperature dependent.[237, 238]



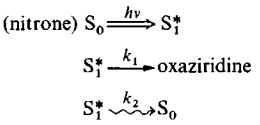
(21)

Thus, in benzene, for example, oxaziridines are formed, which in the dark re-isomerize to nitrones; in ethanol, amides are mainly observed.[239, 240]

Nitrones have been described, however, which yield exclusively oxaziridines, and where no side reactions have been observed. Examples of these are compounds **123**–**125**, which have been used by *Harada*, *Mori* and *Tanaka*[241] to study the temperature and solvent dependence of the quantum yields for the isomerization reaction.



The compounds absorb in the range λ = 370–315 nm, and the only reaction steps observable are summarized in Scheme 5.



Scheme 5. Reaction steps of the isomerization **120** → **122**.

The quantum yield for photoisomerization of **123**–**125** in ethanol and cyclohexane at λ = 313 and 265 nm is presented in Table 15.

The quantum yield for **123** is lower in ethanol than in cyclohexane. This effect is interpreted as the result of intermolecular hydrogen bonding between ethanol and **123**, which accelerates the deactivation step k_2. On the other hand, it is interesting that the solvent effect for **124** is exactly the opposite. The quantum yield for **124** is higher in ethanol than in cyclohexane.

Table 15. Quantum yield ϕ for the photoisomerization of **123**–**125** in ethanol and cyclohexane after excitation at λ = 313 nm and 365 nm.

	123		**124**		**125**	
Solvent	λ_{max}	ϕ	λ_{max}	ϕ	λ_{max}	ϕ
ethanol	315	0.36	353	0.14	345	0.26
cyclohexane	320	0.52	370	0.04	341	0.27

This is explained by intramolecular H-bonding of **124** in cyclohexane, which quenches the excited singlet state of **124** most efficiently. The higher quantum yield in ethanol is then the result of conversion of the intra- to an intermolecular H-bond by the protic solvent, giving at least an average value of ϕ = 0.14.

Table 16 shows the quantum yield for the isomerization of compounds **123**–**125**, with respect to temperature.

Table 16. Quantum yield ϕ for the photoisomerization of **123**–**125** with respect to temperature.

Nitrone	Solvent	T[°C]	ϕ
123	ethanol	15	0.36
123	ethanol	- 90	0.36
124	ethanol	25	0.14
124	ethanol	- 100	0.25
124	pyridine	25	0.08
124	pyridine	- 35	0.10
124	diethyl ether	25	0.06
124	diethyl ether	- 60	0.07
125	ethanol	15	0.26
125	ethanol	- 90	0.26

From this, one can see that the quantum yields for **123** and **125** are clearly independent of temperature. Surprisingly, however, the value for **124**, in a variety of solvents, is higher at low temperature than at room temperature.

The Eyring diagram for the photoisomerization of **124** in various solvents shows significant inversion points at $-18\,^{\circ}C$ in ethanol, at $-4\,^{\circ}C$ in pyridine, and at $2\,^{\circ}C$ in diethyl ether (Fig. 46).

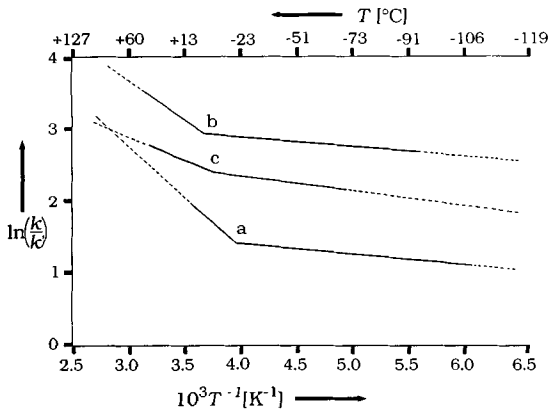


Fig. 46. Eyring diagram for the photoisomerization of **124** in the solvents a) ethanol, b) diethyl ether, and c) pyridine (Table 16). Here, the term $(1-\varphi)/\varphi$ is equivalent to the ratio $k/k' = k_1/k_2$ (Scheme 5). Hence, $\varphi = k_1/(k_1 + k_2)$. (The data points are too numerous to be shown individually.)

The authors concede that: "The sharp break in these curves is obviously indicative of a different mechanism" and "At present, it is impossible to tell what each line of different temperature dependence corresponds to individually..."

Since we suspected that the reason for the above situation was an isoinversion relationship, we analyzed the Eyring diagram published by the authors[241] in the sense of the isoinversion principle (Fig. 46).

7.2.1. The Isoinversion Relationship in the Photoisomerization of Nitrones

From the data in Figure 46 and the isoinversion line shown in Figure 47, $T_i = 260$ K may be calculated on the basis of the isoinversion principle.

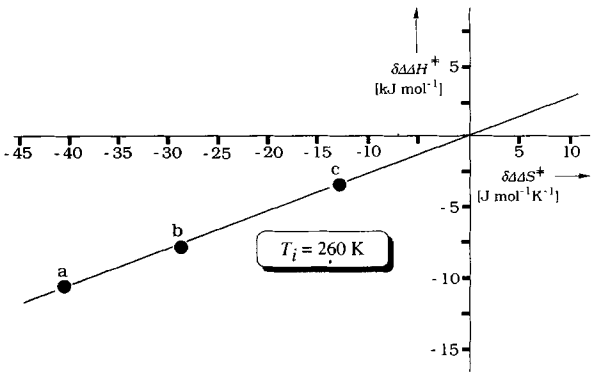

Fig. 47. Isoinversion line for the photoisomerization of **124** in a) ethanol, b) diethyl ether, and c) pyridine. ($T_i = 260$ K, correlation coefficient > 0.99).

Since neither of the nitrones **123** and **125** display temperature-dependent quantum yields in the photoisomerization to oxaziridines **121**, the authors[241] had already suspected that the change from an intra- to an intermolecular H-bond played a part in the "change of mechanism"—as they put it.

Indeed, in excited states, rapid deactivating processes via vibrational modes appear when an intermolecular H-bond is present in the molecule [242] (so-called "loose bolt effect"). However, from the applicability of the isoinversion principle to the photoisomerization of **124** it is obvious that this is

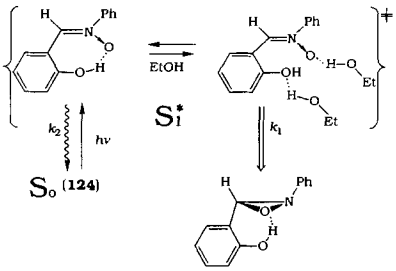

Fig. 48. Simplified reaction scheme for the photoisomerization of nitrones to oxaziridines. This represents the simplest kinetic model for an isoinversion relationship: $S_0 \underset{k_2}{\overset{h\nu}{\rightleftarrows}} S_1^* \xrightarrow{k_1}$ product.

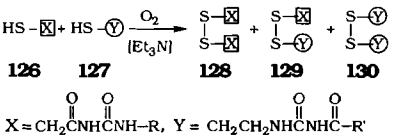
again not a temperature-dependent change of mechanism in general, but a change in the weighting of the enthalpy and entropy terms of the same reaction. It is therefore not unexpected that the H-bonds in the excited state play a role in the mechanisms (Fig. 48).

7.3. The Oxidation of Thiols

The concurrent oxidation of two thiols of type **126** and **127** with molecular oxygen in binary solvent mixtures, catalyzed by triethylamine [Eq. (22)], has been intensively studied by



(22)

Endo et al.[248] as a model of "molecular recognition"[250] (Table 17).

Table 17. Overview of the thiols **126** and **127** used in Reaction (22).

HS-⊠ **126**	HS-Ⓨ **127**
X = CH₂CNHCNH-Ⓡ	Y = CH₂CH₂NHCNHC-Ⓡ
Ⓡ	Ⓡ
a R = *p*-$(H_3C)_2N$-C_6H_4	**a** R' = C_6H_5
b R = *n*Bu	**b** R' = *p*-$CH_3C_6H_4$
c *n*-C_5H_{11}	**c** R' = *p*-$C_2H_5C_6H_4$
	d R' = $(CH_2)_2CH(CH_3)_2$
	e R' = *n*-C_5H_{11}
	f R' = *n*Bu
	g R' = *cyclo*-C_6H_{11}
	h R' = $CH_2CH_2CH_2CH(CH_3)_2$

The starting thiols **126** and **127** consist of three structural units: the SH-group (reactive unit), the CONHCONH-group (formation of intermolecular hydrogen bonds) and an alkyl or aryl moiety, which is responsible for "molecular recognition".

For their investigations, the authors used 1:1 mixtures of thiols **126** and **127**, giving rise to the unsymmetrical disulfide (**129**) and the symmetrical disulfides (**128** and **130**). The selectivity of the reaction is described by the parameter P, which is defined for reaction (22) by Equation (23), where

$$P = \frac{n_u}{2n_s} = \frac{k_u}{2k_s} \tag{23}$$

n_u, n_s are the amounts of the unsymmetrical or symmetrical oxidation products **129**, or **128** and **130**, respectively, and k_u, k_s are the overall rate constants leading to the unsymmetrical and symmetrical oxidation products respectively.

The dependence of the selectivity on temperature was investigated for 13 systems (Table 18).[246, 247, 249] For Systems 5, 7 and 9 in Table 18, the reaction system was a heterogeneous water/ethanol binary mixture; in all other cases a homogeneous phase was employed.

Table 18. Overview of the systems whose selectivity in the Reaction (22) has been studied with respect to temperature.

No.	HS-[X] **126**	HS-(Y) **127**	Solvent
1	**a**	**a**	acetonitrile/water = 80/20
2	**a**	**b**	acetonitrile/water = 80/20
3	**a**	**c**	acetonitrile/water = 80/20
4	**a**	**d**	acetonitrile/water = 80/20
5	**a**	**e**	water/ethanol = 75/25
6	**a**	**e**	dioxane/ethanol = 75/25
7	**a**	**d**	water/ethanol = 75/25
8	**a**	**d**	dioxane/ethanol = 75/25
9	**b**	**f**	water/ethanol = 75/25
10	**b**	**f**	dioxane/ethanol = 75/25
11	**c**	**a**	acetonitrile/water = 58/42
12	**c**	**g**	acetonitrile/water = 58/42
13	**c**	**h**	acetonitrile/water = 58/42

If the results for these systems are transferred to an Eyring diagram (Fig. 49), then Systems 1–6, 8 and 11–13 yield two linear regions with an inversion point. For Systems 7, 9 and 10, the measurements were too few to permit interpretation. From the activation parameters determined for Systems 1–6, 8 and 11–13, an isoinversion line may be drawn, in the sense of the isoinversion principle (Fig. 50), with T_i = 314 K.

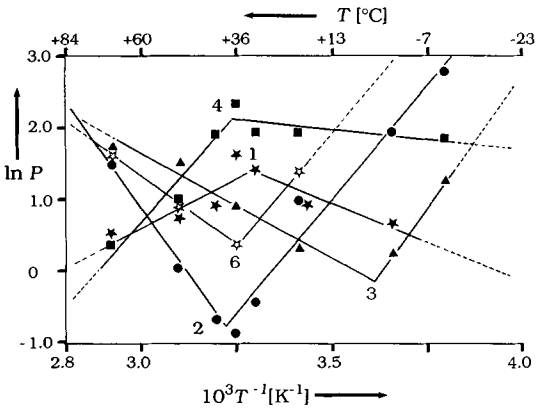


Fig. 49. Eyring diagram for the oxidation of thiols **126** and **127** according to Equation (22) (Systems 1–4 and 6 in Table 18). The selectivity parameter P is defined by Equation (23).

From a purely kinetic point of view, the symmetrical disulfides of type **128** would be expected clearly to dominate, since thiols **126** react most rapidly. However, preferential formation of the unsymmetrical disulfides of type **129** is observed, depending on the temperature and above all on structural variations in the thiol. Only for Systems 2, 9, 11 and 12 in Table 18 does one find minima with preferred formation of the symmetrical disulfides **128**. The thiols exist in the reaction medium as dimeric (**131a–c**) and tetrameric (**132a–e**) aggregates (Fig. 51).[247] Oxidation occurs at these aggregates, as is also demonstrated by the very negative activation entropies[246] of -214 to -189 JK^{-1}mol^{-1}. Since the thiol aggregates exist in a temperature- and substitution-dependent equilibrium, the selectivity is directed by these two parameters.

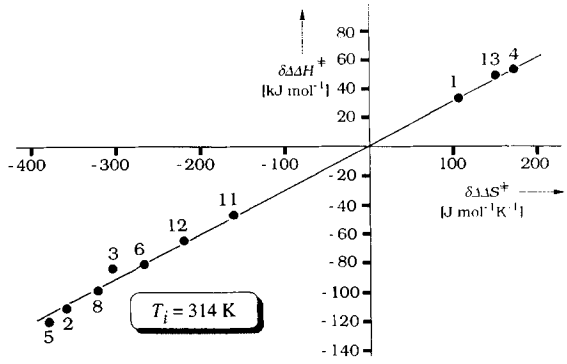

Fig. 50. Isoinversion line (T_i = 314 K correlation coefficient = 0.99) for the oxidation of the thiol pair **126**/**127** according to Equation (22) (for numbering see Table 18).

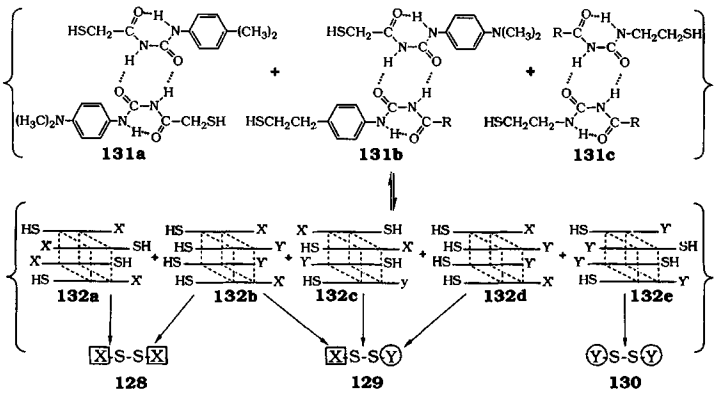

Fig. 51. Kinetic scheme for the oxidation of thiols of type **126** and **127**.

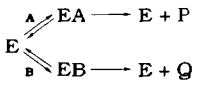
The temperature series presented shows that this example of "molecular recognition"[246] obeys the isoinversion principle. Intensive work on temperature-dependent selectivity in the oxidation of thiols **126** and **127** is expected to lead to important contributions to the understanding of "molecular recognition".

7.4. The Isoinversion Principle in Enzymatic Reactions

Enzyme reactions are classic examples of highly selective asymmetric reactions directed by optically active catalysts,[225, 270] where minimal amounts of "chiral information" are used to produce large quantities of optically active products. An enzyme molecule turns over its substrate 100 000 times per minute, and in a sense multiplies the information stored in it as optical activity by his factor.[251] However, both the activity and the stereoselectivity of this highly enantioselective, biological variant of "chiral amplification"[252] falls away rapidly with substrate variation.

On the basis of Michaelis-Menten kinetics (preliminary equilibrium between enzyme and substrate on the one hand and a substrate-enzyme complex on the other), isoinversion relationships ought to be observable here, too.[253] A suitable kinetic scheme for two competing products P and Q (e.g. stereoisomers) was proposed by *Wong* (Scheme 6).[254]



Scheme 6. Kinetic scheme for enzyme reactions, according to *Wong* [254]. E = enzyme; A, B = substrate; P, Q = products.

Inversion points T_{inv} are often observed in the Eyring diagram for enzyme activity.[255] However, except for compensation phenomena for denaturation of enzymes[263] insufficient data on any one system have appeared in the literature for a reliable isoinversion or compensation relationship to be constructed.

Application of the isoinversion relationship to enzymatic reactions will certainly lead to a better understanding of the selectivity process in these cases as well.

8. Outlook

As has been demonstrated, with the help of the isoinversion principle it is possible to interpret, assess and optimize selectivity phenomena in various areas of chemistry from a single point of view. To do so, the selectivity parameter in question must be measured with respect to the temperature and/or the pressure of the reaction.

The application of this principle to selectivity-producing reactions includes all those processes where the selectivity is generated at two or more levels. This is evident from the appearance of temperature inversion points T_{inv} in the relevant Eyring diagram. A lack of such inversion points may occur for the following reasons:

1. Selectivity is decided at only one level (e.g. Helmchen-Schmierer model; concerted reactions).
2. The inversion point corresponding to T_{inv} could lie outside the thermally tolerable measurement region for the reaction.
3. The enthalpy/entropy weighting could coincidentally be identical for the different selectivity levels.

It is now possible to create a flow chart for the application of the isoinversion principle to optimization of a selectivity parameter depending on the reaction temperature (Fig. 52). Similar considerations also hold for pressure-dependent selectivity processes (see Sections 6.2.9 and 6.2.10)

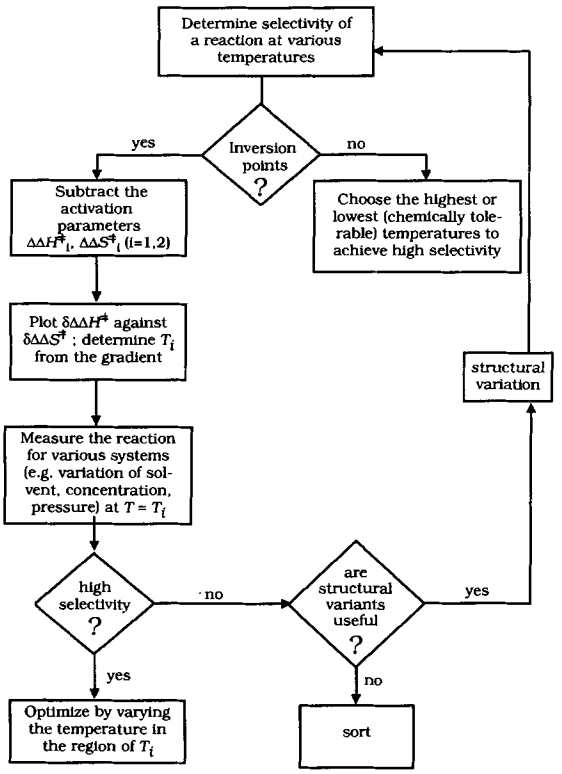


Fig. 52. Flow chart for the application of the isoinversion principle to optimization of a selectivity parameter, depending on the reaction temperature.

In addition to the reactions selected for this article, there are certainly numerous other phenomena[144b, 245, 281, 297, 298] which could be arranged and interpreted using the isoinversion principle, e.g. asymmetrically-directed hydrosilylation reactions,[155, 195, 259] or the problem of selectivity in hydroformylation reactions[256, 257] (branched/unbranched products, enantioselectivity).[258] Other examples that could be mentioned are asymmetric cyclopropanation reactions,[276] Diels-Alder reactions,[16, 295] the osmium-catalyzed asymmetric dihydroxylation[283] and asymmetric oxidation of sulfides to sulfoxides,[277] nucleophilic addition to the C=O double bond including the asymmetric reduction of ketones by metal hydride reagents,[278] stereoselective acylation of chiral amines by azlactones[279] as well as the four component condensation according to *Ugi*,[296] enantiomer separation on chiral GC-phases,[260] and various enantioselective photochemical reactions,[262, 280] especially the enantioselective protonation of photodienols catalyzed by chiral β-amino alcohols, which has been investigated by *Pete*.[261]

There are further examples of the application of the isoinversion principle other than stereoselective processes—for instance in the oxidative decomposition of methane to C_2-hydrocarbons catalyzed by metal oxides in heterogeneous phase[299] or the product-selective Lewis-acid cata-

lyzed polymerization of aromatic disulfides to poly(aryl sulfides).[300]

Herr Dr. H. Koch (Deutsche Shell GmbH) carried out the initial, pioneering studies on the asymmetric control of the Paternò-Büchi reaction and its temperature-dependence. We thank Herrn Dipl. Chem. M W. Plath, for his help in preparing Section 5. We are grateful to Herrn Dr. J. Runsink for important discussions on the interpretation of the mechanism of the Paternò-Büchi reaction and for carrying out extensive NMR analyses. Our thanks are due to the Fonds der Chemischen Industrie for supporting us with equipment and to Herrn Prof. Dr. K. H. Büchel and Herrn Dr. W. Draber of Bayer AG, Herrn Dr. R. Hopp of Haarmann and Reimer, and Herrn Prof. Dr. H. Offermanns of Degussa AG for generous donations of chemicals. We also thank Dr. W. Küsters of BASF AG for supporting our work with equipment. Finally, our special thanks go to Frau I. Voss for the preparation of the manuscript, and for her patience with us while doing so.

[76] The diastereoselectivity of photochemical oxetane formation according to Equation (1) is characterized by the *de* value of the major oxetane and

$$de\,[\%] = \frac{c - c'}{c + c'} 100 = \frac{\sum_{i=1}^{n} (I_i - I_i')/(I_i + I_i')}{n} 100 \qquad (24)$$

determined from the ^{13}C-NMR spectrum according to (24), where c is the concentration of the major diastereomer, and c' the concentration of the minor diastereomer in the product mixture. Depending on the system, between 14 and 16 pairs of signals can be drawn on for determination of the *de* value. The *de* values given in Table 1 are averages of several independent measurements. By using this technique, the influence of nuclear Overhauser and spin relaxation effects can be kept to a minimum.

[84] It should be noted here that in this correlation the rate constant quotients obtained from the diastereomeric excesses have been related to those of the unsubstituted system. This affects the ϱ value found, in that the σ values (defined as quotients of the equilibrium constants for the substituted or unsubstituted systems) are taken from references where they had been determined by direct quotient formation from the rate constants for substituted or unsubstituted systems.

[97] The presence of an inversion point in temperature-dependent regioselectivity was not recognized by us in the original publication. [34] A new analysis of the original experimental data in the light of the isoinversion relationship, however, indicated the existence of an inversion point in the Eyring diagram.
[98] At this point, the usefulness in mechanistic studies of auxiliaries that yield diastereomeric excesses in the low to middle range should be noted. Middle range *de* values are especially sensitive to small variations in reactant structure and/or minor changes in reaction conditions [36, 37].

[187] The δ/λ conformation of the RhPCCP five-membered ring is defined as in the corresponding structural element MNCCN in numerous ethylenediamine complexes; cf. The Commission on the Nomenclature of Inorganic Chemistry of the International Union of Pure and Applied Chemistry, *Inorg. Chem. 9* (1970) 1.
[188] According to *Brown* et al., in seven-membered chelate rings the product configuration is determined by the chair or twist-boat conformation of the catalyst complex. Starting from (*Z*)-enamides, the chair conformation yields (*S*)-amino acids, whereas the twist-boat form leads to the (*R*)-enantiomer [173a].

[232] Transamination plays a role in the biosynthesis and biodegradation of protein molecules. Aminotransferases make possible an amination/deamination exchange between keto acids (especially pyruvate) and glutamate, without the appearance of free ammonia. The coenzyme in amino-transferases is pyridoxal phosphate (Vitamin B_5).

[265] According to *H. Wynberg*, the use of racemic auxiliaries for determining *de* values is only permissible to a first approximation. Because of the presence of chiral reagents, the medium itself becomes chiral, giving a chiral solvent effect. In a racemic system, the interactions of the enantiomers with each other (*R–R*, *R–S* and *S–S* interactions) can lead to differing asymmetric induction: H. Wynberg, B. Feringa, *Tetrahedron 32* (1976) 2831.
[266] The analysis of the data for pressure-dependent selectivity measurements must be treated with caution in some cases, since the experimental details for the measurements were not given in the literature. The appearance of the inversion points described could hence also be due to non-uniform experimental conditions. We thank *R. Selke* for this observation.

[304] The results from *Savéant* reveal relevant points about the mechanism of the interaction of alkyl bromides with aromatic anion radicals and with low oxidation state iron porphyrins. The observation of inversion points in the Arrhenius diagram is explained in terms of single electron transfer and subsequent S_N2-like substitution: D. Lexa, J.-M. Savéant, K.-B. Su, D.-L. Wang, *J. Am. Chem. Soc. 110* (1988) 7617.

Chemical Sensors and Biosensors—Principles and Applications

By Karl Cammann,* Udo Lemke, Anja Rohen, Jürgen Sander, Hildegard Wilken and Babette Winter

Chemical and environmental engineering and biotechnology are among the fields now being transformed by continually increasing levels of automation. Whereas the objective in other sectors of industry is simply to increase efficiency, here considerations of system theory or safety demand a high level of automation. Either the processes are too complex and require multifunctional control with feedback, or an analysis of the safety requirements shows the necessity for a certain degree of redundancy in the safety measures, and for elimination of human error as a risk factor. With regard to quality control, cost-benefit analyses lead to striking conclusions which again indicate the need for highly automated, and above all reliable, systems to eliminate rejects. The crux of any automated system is the measurement and control technology; of central importance is the rapid, reliable, and in some cases continuous, measurement and interpretation of key processes or control variables. For this purpose a wide variety of recording instruments and sensors are used to give as accurate a picture as possible of the state of the system. It is obvious from this that the performance of the control system is critically dependent on the sensors. Errors in the measured quantities can become amplified in the control variables or, in dynamic systems, can lead to undesirable operating conditions. Moreover, as a consequence of great advances in microelectronics, "intelligent sensors" which can calibrate and control themselves will be one of the key technologies of the nineties. Unless fast and immediate information on the true current status of a system is available, microprocessors as control devices react blindly and unpredictably to errors in input information. New discoveries in the fields of electronic, electrochemical, and optical transducers are now being applied in heterogeneous catalysis and surface physics, and in biochemistry (enzymology and immunology); in these fields new chemical sensor principles are being tested, which could revolutionize instrumental methods of molecular analysis in particular, owing to their very favorable cost-performance relationship. This article aims to give an up-to-date overview of the current state of the art in these developments, with emphasis on their importance for analysis and their significance in relation to the chemist's interest in mechanisms for identifying substances.

1. Introduction[**]

1.1. Definitions

Following a definition which has been proposed under the relevant IUPAC Commission,[1] analytical chemical sensors are miniaturized transducers that selectively and reversibly respond to chemical compounds or ions and yield electrical signals which depend on the concentration. Interpreting this strictly, one only has a true sensor if concentration changes in both directions can be detected. These conditions are not in general satisfied by devices such as indicator tubes and test strips. Moreover, these cannot provide a continuous signal proportional to concentration, and according to another IUPAC discussion paper[2] they are better described as dosimeters. Similarly there is a consensus of opinion in the relevant IUPAC committees that a large analytical instrument (e.g. a mass spectrometer) used with an external probe or a flow injection system (FIA) cannot be regarded as a sensor, although in the case of integrated optics the dividing line between such devices and true sensors is blurred.

According to these nomenclature proposals biosensors can be regarded as a sub-group of chemical sensors in cases where biological recognition mechanisms or principles are used as a means of recognizing substances or molecules. Some types of "biomolecules" isolated from living systems, such as enzymes, antibodies, or receptors, are able to recognize chemical compounds with high specificity and can be adapted to generate signals. Biosensors are vastly superior to chemical sensors as regards selectivity. They would be the ideal sensors if their lifetime were not severely limited by stability problems.

1.2. History

When around the turn of the century it was discovered purely by accident, in the course of physiological studies on the properties of thin membranes, that certain types of glass were sensitive to pH,[3] the significance of this effect for the development of sensors with applications in analytical chemistry could not be foreseen. Subsequently by using suitably

[**] The following abbreviations are used: Chem FET = chemical field-effect transistor; ENFET = enzymatically modified, ion-selective field-effect transistor; FET = field-effect transistor; FIA = flow injection analysis; ISE = ion-selective electrode; ISFET = ion-selective field effect transistor; PZ = piezoelectric crystal; SAW = surface acoustic wave.

designed pH electrodes made with glass membranes, it became possible for the first time to determine the hydrogen ion concentrations in aqueous solutions with high selectivity and remarkable precision,[4] a facility which proved extremely useful in guiding the development of early acid-base theories. However, it was not until 1935, when the first commercial electrometer amplifiers for measurements on high-resistance voltage sources became available (with the founding of Beckman Instruments by Prof. *A. O. Beckman*), that this brought about a major changeover from the optical pH indicator methods used previously to the much better potentiometric method, whose theoretical basis had been laid as early as 1889 by *Nernst*, in the equation named after him. The technique of electrometric pH measurements[5–7] subsequently became the most frequently used method in instrumental analysis, due to a large extent to further advances in measurement technology. A further breakthrough in chemical sensor technology came with the development in 1966 of ion-selective electrodes (ISEs) for calcium, fluoride, silver, and sulfide ions,[8, 9] and in 1967 for potassium ions;[10, 11] using these electrodes one could determine the relevant ions in a procedure analogous to a pH measurement. The knowledge gained during research in the field of ISEs led in the years that followed to the development of further electrodes for a number of different ions,[12, 13] so that nowadays a dozen cations and anions can be determined by direct potentiometric measurements (see Table 1).[14–16]

The technology of chemosensors was not confined to ion-selective potentiometry and other electrochemical methods of detection such as polarography, voltammetry, or amperometry, which gained considerably in importance as a result of the development of the gas-membrane-covered O_2 electrode by *Clark*.[17] Detection systems based on semiconductors, e.g. SnO_2, which can detect oxidizable gases, were first conceived in the 1970s.[18] Mass-sensitive systems incorporating piezoelectric crystals (PZ or quartz oscillator systems) and surface acoustic wave (SAW) devices were first reported in the mid-sixties as sensitive detectors for hydrocarbons in gas chromatography.[19] The first studies in the field of miniaturized fiber-optic sensors (optodes or optrodes) were published in 1975.[20, 21]

Enzyme electrodes were first described in 1962;[22] these depended for their selectivity on the enzymic breakdown of glucose, which could be arranged as an amperometric electrode, enabling glucose to be determined in physiological investigations. The term "biosensor" to describe enzyme-modified ion-selective electrodes first appeared in the analytical literature in 1977.[23] Biosensors are nowadays available commercially for many highly relevant substrates such as glucose, lactate, urea, penicillin, etc.

Table 1. Summary of the different types of electrodes, classified as conventional types and newer types.

Type of electrode	Species measured
Conventional electrodes	
glass membrane	$H^{\oplus}$ $Na^{\oplus}$, $Ag^{\oplus}$, $Li^{\oplus}$, $Cs^{\oplus}$, $Rb^{\oplus}$, $NH_4^{\oplus}$, $K^{\oplus}$, $Tl^{\oplus}$
liquid membrane	$Cu^{2\oplus}$, $Cl^{\ominus}$, $Mg^{2\oplus}$, $Ca^{2\oplus}$, $NO_3^{\ominus}$, $ClO_4^{\ominus}$, $UO_2^{2\oplus}$, $BF_4^{\ominus}$,
ion-exchange	organic cations and anions, some drugs
neutral carrier	$K^{\oplus}$, $Li^{\oplus}$, $H^{\oplus}$, $Ca^{2\oplus}$, $Mg^{2\oplus}$, $Na^{\oplus}$, $NH_4^{\oplus}$, $Sr^{2\oplus}$, $Ba^{2\oplus}$, $Cd^{2\oplus}$
crystal membrane	
single crystal	$F^{\ominus}$
polycrystalline	$S^{2\ominus}$, $Ag^{\oplus}$, $Hg^{2\oplus}$, $Cl^{\ominus}$, $Br^{\ominus}$
mixed crystal	$Cl^{\ominus}$, $Br^{\ominus}$, $I^{\ominus}$, $CN^{\ominus}$, $SCN^{\ominus}$, $Cd^{2\oplus}$, $Pb^{2\oplus}$, $Cu^{2\oplus}$
gas sensor based on ISE	CO_2, NH_3, H_2S, SO_2, HCN, HCl, HF, NO_x
Newer electrodes	
ISFET (ion-selective field-effect transistor)	H_2, H_2S, $H^{\oplus}$, $Li^{\oplus}$, $Na^{\oplus}$, $K^{\oplus}$, $NH_4^{\oplus}$, $Ca^{2\oplus}$, $Cl^{\ominus}$, $F^{\ominus}$
coated wire	$H^{\oplus}$, $Li^{\ominus}$, $Na^{\oplus}$, $K^{\oplus}$, $NH_4^{\oplus}$, $Ca^{2\oplus}$, $Fe^{3\oplus}$, $Cl^{\ominus}$, $Br^{\ominus}$, $I^{\ominus}$, $SCN^{\ominus}$, $SO_4^{2\ominus}$, $NO_3^{\ominus}$, $ClO_4^{\ominus}$, organic ions, amino acids, drugs
polymer matrix	$Cu^{2\oplus}$, $Mg^{2\oplus}$, $Ca^{2\oplus}$, $Cs^{\oplus}$, $Li^{\oplus}$, $Na^{\oplus}$, $K^{\oplus}$, $NH_4^{\oplus}$, $Co^{2\oplus}$, $NO_3^{\ominus}$, $S^{2\ominus}$
microelectrodes	$H^{\oplus}$, $K^{\oplus}$, $Na^{\oplus}$, $Li^{\oplus}$, $Ca^{2\oplus}$, $Mg^{2\oplus}$
film electrodes	$H^{\oplus}$, $K^{\oplus}$, $Na^{\oplus}$, $Li^{\oplus}$, $Cl^{\ominus}$

1.3. General Design Features of Chemo- and Biosensors

The essential principle of a chemo- or biosensor is described in terms of three basic components (Fig. 1). The most important component is the receptor (the recognition system), where in general an energetic interaction specific to the substance in question (the analyte) enables it to be recognized. The development of new recognition principles, or the improvement of known processes for this purpose, is a task for the chemist or physical chemist. Compared with this challenge the next stage is less difficult; the function of this second component of any chemo- or biosensor is to "relay" the substance-specific signal, in other words to transform an energy quantity into an electrical signal proportional to it.

Karl Cammann, born in 1939 in Düsseldorf, studied Chemistry at the Technical University of Munich after obtaining a degree in chemical engineering and working in industry (Beckman Instruments) for several years. His scientific advisor for the Diplom thesis was H. Gerischer; his Ph.D. advisor was G. Ertl (University of Munich). After postdoctoral positions with G. A. Rechnitz (State University of New York at Buffalo) and S. Mazur (University of Chicago) he accepted an assistant professorship for Analytical Chemistry at the University of Ulm. In 1986 he became an Associate Professor of Analytical Chemistry at the Technical University of Munich and shortly thereafter (1987) Full Professor of Analytical Chemistry at the Westfälische Wilhelms University of Münster (chair of Prof. F. Umland). His research interests lie in the field of selective chemical detectors and monitors. In 1987 he received two awards for the development of a new plasma-emission-spectroscopic GC-detector (Océ van der Grinten Pollution Control Award; Technology Transfer Award of the German Ministry for Education and Science).

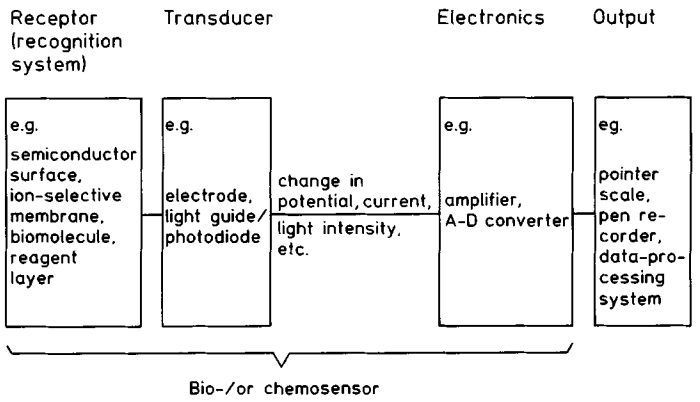

Fig. 1. Schematic arrangement of a chemo- or biosensor system.

This task is usually performed by one of a wide choice of familiar physical transducers. Often a third component, consisting of a further electronic unit (a preamplifier, impedance converter, multiplexer, analogue-to-digital converter, etc.) is placed directly after the transducer, to suppress as far as possible external influences caused by interfering electric or magnetic fields, or to feed the separate signals from several recognition systems simultaneously to the data processing unit through a single electrical connection.

Chemo- and biosensors can be classified according to the type of sensor element used for molecular recognition, or according to the type of transducer. If the emphasis is on analytical selectivity, the most important component is the recognition system. If on the other hand the limit of detectability or the signal-to-noise ratio is crucial, the critical component may be the physical or electronic transducer (see Table 2).

Table 2. Classification of chemo- and biosensors according to the type of transducer.

Type of transducer	Measuring principle or property measured
electrochemical	potentiometry
	amperometry
	voltammetry
	field effect (chemFET, ISFET)
electrical	surface conductivity (MOS)
	electrolyte conductivity
optical	fluorescence
	absorption
	reflection
	luminescence
	refractive index (surface plasmon resonance, SPR)
	light scattering
	evanescent wave
magnetic	paramagnetism
mass-sensitive	resonance frequency of a piezoelectric crystal (PZ)
	surface acoustic wave (SAW)
thermal	heat of reaction
	heat of adsorption

All chemo- and biosensors can be used directly for analyzing gases and liquids (the latter also includes suspensions or pastes) for specific ions or molecules, in concentrations varying from the ppb range to the percent range. As the sample preparation required for chemo- or biosensors of adequate selectivity is minimal, and the sensors are available at low cost, high rates of growth are forecast by all the market studies that have been carried out. For sensors that are less selective, it is still possible in many cases to design a comparatively inexpensive measuring instrument, by incorporating automatic sample preparation based on a chemical reaction which is selective, or on separation techniques. Flow injection analysis is especially valuable in this respect.[24]

2. Chemosensors

2.1. Electrochemical Sensors

2.1.1. Ion-Selective Electrodes

Till a few years ago ion-selective electrodes (including the glass pH electrode) were the most important class of chemosensors in economic terms, since at that time the "lambda-probe" for controlling three-way catalytic converters for automobiles was not yet produced in today's numbers because of the absence of legal requirements. In ion-selective potentiometry the data are processed using an extension of the Nernst equation derived empirically by *Nicolsky*.[25] This extended equation (a) relates the activity of the ion species to be determined and the measured voltage when an ISE half-cell is connected to a common reference electrode, taking into account the effects of all interfering components.

$$U = U^0 + \frac{RT}{z_M F} \ln \left[a_M + \sum_I K_{M-I}\, a_I^{z_M/z_I} \right] \qquad \text{(a)}$$

U = potential of the cell
U^0 = standard potential of the cell
R = universal gas constant
T = absolute temperature
F = Faraday constant
a_M = activity of the ion being measured
z_M = charge of the ion being measured (with appropriate sign)
K_{M-I} = selectivity coefficient (measured ion vs. interfering ion)
a_I = activity of the interfering ion
z_I = charge of the interfering ion (with appropriate sign)

The selectivity is described by the selectivity coefficient K_{M-I}, which unfortunately is not a constant, since it depends on the method used for the determination and on the concentrations of all the interfering species and the ion to be measured. For good ISEs it is of the order of 10^{-4}, which means that a 10^4-fold excess of the interfering ion would change the reading by a factor of 2 (i.e. an error of 100%). A new theoretical model of the mechanism for the selectivity in the potential generated at the phase boundary between the ion-selective membrane and the measured medium has been developed in the last few years.[26–30] This is based on the studies of *Koryta*[31] and others on electrochemical phenomena at the interface between two immiscible electrolytes, and also on results from studies on corrosion involving competing electrode reactions.

The basic principle of ion-*selective* potentiometry is the observation of an ion-*selective change* in the potential at the phase boundary. This in turn depends on the ion-selective change (or shift) of charge (or charge distribution) at this boundary, i.e., a significant transfer between the phases occurs only for the ion species in question. This requires that

certain energetic and geometrical variables be optimally matched.

If an uncharged ion-selective membrane electrode which satisfies the electrical neutrality condition is immersed in an electrolyte solution, a transfer of charge carriers occurs between the phases. The direction of this (membrane → solution or the reverse) is determined by the gradient of the chemical potential. When only one species of ion can selectively cross the boundary (this selectivity results, for example, from specific complex formation in liquid or PVC membranes, or from the dimensions of lattice sites in polycrystalline or semicrystalline materials), this selective transfer of charge carriers leads to a redistribution and an accumulation of charge at the phase boundary. This generates an electric field, thus counteracting the ion transfer which was at first energetically favored, so that eventually, under the combined influence of the electrostatic repulsion between similarly charged particles and the attractive forces due to the oppositely charged carriers left behind, the transfer of charge carriers ceases and the reverse reaction is favored. In the equilibrium state the microscopic ion currents passing in both directions through the phase boundary are equal, and the ion-selective potential difference that is thereby established is constant and can be measured. Externally the condition is one of zero current (a requirement for potentiometric measurement).

In terms of electrochemical kinetics the transport of charge carriers (measured ions) across the phase boundary between the electrode or ion-selective membrane and the solution corresponds to a directed electric current $\vec{i}$ or $\overleftarrow{i}$ (depending on whether the direction is from membrane to solution or the reverse). In the equilibrium state $\vec{i} = \overleftarrow{i} = i_0$. The current density j_0 ($= i_0/A$, A = area) is called the exchange current density (see Fig. 2). The two opposing current densities $\vec{j}$ and $\overleftarrow{j}$ maintain the ion-selective charge distribution at the phase boundary at a constant value. Furthermore, these microscopic ion-currents actually make it possible to measure the charge distribution at this interface, since in practice one cannot avoid drawing a current of 10^{-10} to 10^{-14} A in the measuring circuit, depending on the amplifier used, which corresponds to a net flow of 10^9 to 10^5 elementary charges per second. The ion-selective electrical potential generated at the phase boundary of such an ion sensor by selective charge separation is, of course, dependent on the concentration of the ionic species which can cross the boundary. The relationship between ion concentration and interfacial potential was derived theoretically by *Nernst* as long ago as 1889, in the brilliant work leading to the equation named after him. From the ion-exchange current density j_0, which can be determined experimentally, the recent theory predicts the selectivity of a potentiometric sensor. The potential in each case is determined by the ionic species that has the greatest exchange current density.

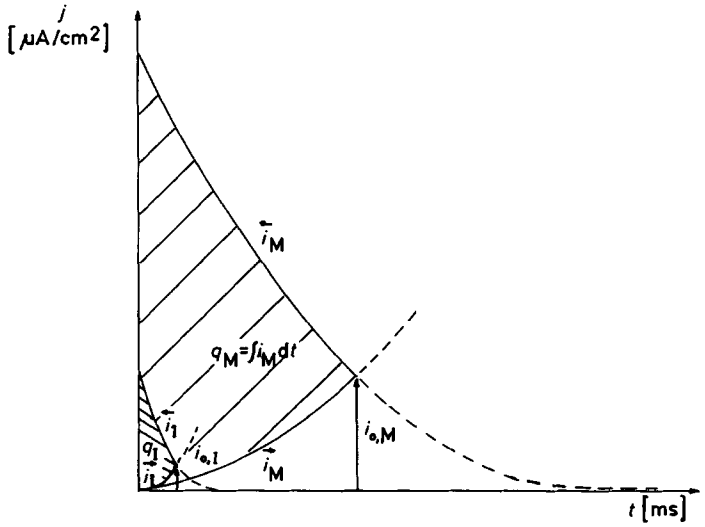

Fig. 2. Schematic representation of the forward and reverse currents $\vec{i}$ and $\overleftarrow{i}$ passing through the phase boundary; the selectivity is given by the ratio of the (equilibrium) charges q_M and q_1 for the measured and interfering ions respectively (see text).

Other reactions may take place at the phase boundary in parallel with the process described (because real solutions usually contain interfering ions in addition to those being measured). The thermodynamic equilibrium potentials for the individual electrode reactions (in this case, the parallel processes in which the measured and interfering ions cross the phase boundary between two ionic conductors), as in the case of corroding metal electrodes, may not be fully achieved. This results in deviations from the theoretical Nernst behavior. In order to achieve a high ion-exchange current density and thereby obtain the desired selectivity, appropriate changes can be made in the thermodynamic and kinetic variables. For example, introducing into the membrane an ionophore for a particular ion species causes an increase in the exchange current density, and therefore in the selectivity for that ion. The selectivity obtained in this way is probably due to a long-range ion–dipole interaction between this particular ion species in the solution and the ionophore in the membrane surface. It is conceivable that, specifically for the potential-determining ion species, an overlap of the energy barriers involved (desolvation and decomplexation activation-energy profiles) occurs, which results in the lowering of the effective activation energy for ion transfer over the entire phase boundary. This activation energy can also be expressed in electrochemical terms as an ion-transfer resistance. This in turn is inversely proportional to the exchange current density, and can be obtained, for instance, from impedance spectra.[32, 33]

The selectivity of all types of ion-selective membranes, the rapid establishment of the potential, even for thick membranes, and the abnormally large graph slopes in the U vs. $\log a$ diagram that are occasionally found (steeper than predicted by the Nernst factor preceding the logarithm of the activity of the measured ion, see Eq. (a)), can all be satisfactorily explained by this novel theoretical approach which also considers kinetic parameters. Numerous fundamental studies have been carried out in our research group since 1975 to determine the conditions that must be fulfilled for a particular ion to be potential-determining (and therefore able to be measured selectively). For every type of electrode the critical factor was the ratio of the exchange current density for the measured ion to that for the relevant interfering ion. In every case this ratio was equal to the potentiometrically measured selectivity coefficient in the extended form of the Nernst equation [Eq. (a)].

A comparison of good ion-selective electrodes reveals several common features. Firstly, they have a rather high poten-

tial-determining exchange current density for the measured ion at the phase boundary between the ion-selective membrane and the solution. Secondly, for solid membranes, there is a preferential ionic conductivity in regions near the surface (e.g., Ag_2S is a good conductor for $Ag^{\oplus}$ ions, and LaF_3 doped with $Eu^{2\oplus}$ is a good conductor for $F^{\ominus}$ ions). In PVC membranes with selective ionic charge carriers the preferred method is to use only ion–dipole interactions, as is evident from a glance at the list of so-called electroactive compounds that are available.[34] Apparently the course of the activation energy threshold for the transfer of ions from the membrane phase to the solution, together with the course of activation energy for the desolvation process, determines the intersection point (i.e., the effective energy of activation for the phase transition of the relevant ion).

The existence of a purely kinetic effect in favor of the ion being measured is a necessary, but not a sufficient, condition for a selective Nernst sensor which performs well and above all is stable over long periods. In addition there must be a certain degree of nonpolarizability. This quantity, as electrochemists use it, is, in simple terms, a measure of the ability of an electrochemical half-cell to maintain a constant potential regardless of the instantaneous current density at the interface. Good ion-selective electrodes, like good reference electrodes, have a relatively steep characteristic curve in the current vs. voltage diagram (C–V curve) for the ion being measured. Viewed from this standpoint, the interfering ions have characteristic C–V curves that are less steep than that for the ion being measured. If these ions are present in a solution together with the measured ions, according to our present state of knowledge a mixed potential is established, as is the case for corroding metal electrodes. This is determined predominantly by the equilibrium potential for that electrode reaction (transfer of ions between phases) which has the steepest C–V characteristic. To obtain a favorable C–V characteristic over as large a range of overpotential as possible, it is also necessary to take concentration polarization effects into account. Here higher concentrations of the measured ions in the membrane phase turn out to be beneficial; their diffusion from there into the solution, which has an unfavorable effect on the limits of detection, is hindered by complexation and by the charges of appropriately chosen counterions. This also has the advantage of increasing the buffer capacity for the chemical potential of the measured ions in the membrane phase. A detailed treatment of these aspects has been published.[35]

Ion-selective electrodes can be used as electrochemical half-cells in combination with suitable constant-potential reference electrodes for the quantitative determination of a wide range of substances (see Table 1). They can be classified according to the type of membrane, viz., glass, solid, liquid, or PVC membrane electrodes.[36, 37] Glass and solid membrane electrodes are robust and have a typical lifetime of several years, much longer than liquid or PVC membrane electrodes, which only remain effective for about six months, depending on the application, unless one is prepared to accept large sacrifices in sensitivity and selectivity. However, for the latter types of electrodes some manufacturers have introduced a modular design which allows the easy and rapid renewal of sensitive electrode elements. The most important types of ionophores required to make one's own selective PVC membranes are available commercially,[38] and are supplied complete with instructions; these were developed mainly by *Simon*'s research group in Zürich.

2.1.2 Ion-Selective Field Effect Transistors (ISFETs)

It was believed for a long time that in ion-selective field effect transistors, first described by *Bergveld*[39, 40] in 1970, we at last had a new generation of sensors which met all the requirements of miniaturizability, compatibility with microelectronics, and the capability for being mass-produced, with attendant cost savings. The now familiar production techniques of microelectronics seemed to offer prospects for developing chemosensors in the form of disposable mass-produced articles. Since then the initial euphoria has given way to a more realistic assessment, since these sensors still pose difficulties with regard to long-term stability and integration with miniaturized reference electrodes. Nevertheless, it is of interest to examine this class of sensors in a little more detail in the following discussion, since they bring together the disciplines of chemistry, electronics, and thin film technology, and they provide the basis for biochips.

An ISFET can be generally regarded as a very miniaturized version of an ion-selective half-cell with an in-built impedance converter. It can be used to determine the activity of not only individual ion species, for which ion-selective macro-electrodes are also available, but also—in the form of an enzyme-coated ISFET (biochip)—a wide variety of substrates. The transistors that are used can in most cases be made as very small devices, allowing the accommodation of several sensitive surfaces for detecting different ions or substrates on a single chip with an area of only a few mm^2. The entire electronic control circuit, including temperature compensation, can also be fitted on the same chip.

The basic building block of all ISFETs is a field effect transistor (FET), in which the metallic gate of a conventional transistor is replaced by an insulating layer, above which is an ion-selective layer. The value at any instant of the gating potential, which controls the current between the source and the drain, is determined by the activity of the ion species being measured, through the presence of the ion-selective surface film. Figure 3 shows the basic construction of an ISFET in a form which has certain advantages. Often, however, instead of measuring the variation of the source-to-drain current as a function of the activity of the measured ion

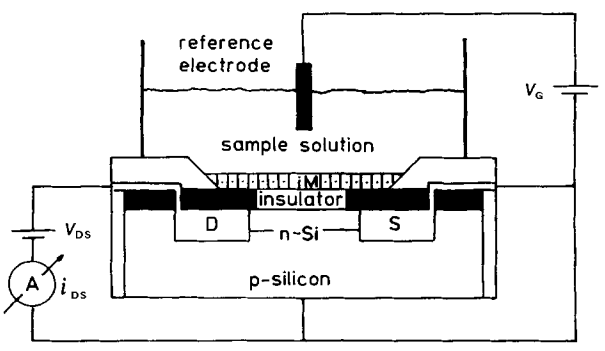

Fig. 3. Operating principle of an ISFET; the applied gate potential V_G controls the current i_{DS} flowing from source S to drain D.

species, one measures the control voltage that must be applied via a reference electrode to hold this current at a constant value; this makes it possible to maintain an optimal working point, chosen to reduce temperature effects.

In an ISFET the ion-selective PVC membrane, which is applied to the gate surface mainly by spin-coating, forms the sensor element, which recognizes specific substances. By using known electroactive compounds, all types of ion-selective PVC membrane electrodes can also be incorporated into ISFETs. However, problems with the adhesion of the plastic membrane to the gate surface result in contact difficulties, since the membrane which gives the selectivity becomes detached, usually after a few weeks. In a pH-ISFET[41-44] protons produce a field, whose intensity depends on the $H^{\oplus}$ concentration, at a thin film of SiO_2, Si_3N_4, Al_2O_3 or Ta_2O_5. A serious disadvantage of these materials is that in many cases they still have some sensitivity to light and redox systems. Also, the diffusion of impurities into the lower layers of the semiconductor, which are known to be sensitive to this, usually results in a slow drift of the measuring signal, of the order of a few mV per day.

The disadvantages mentioned, together with the fundamental problem of leakage-path formation in the insulation of the remaining transistor surfaces, which again causes drift in the readings before the device finally ceases to function, has so far prevented ISFETs from achieving a larger commercial success. However, recent developments in the area of electrolytic glazing offer some hope of improvements.[45] In the development of ISFETs work is already in progress on multisensor arrays[46, 47] in which several different ion-selective sensor elements controlling separate gates are integrated on a single chip. Here, however, one is approaching the limits of miniaturization technology. The spin-coating technique cannot lay down closely spaced regions of different selectivity less than 1 mm^2 in area. Experiments in which a common plasticized PVC membrane is laid down to cover all the gates before local regions above individual gate surfaces are doped with different electroactive compounds have also encountered problems, because diffusion of ionic carriers within the membrane smears out the ion selectivities.

It is also necessary to integrate into the ISFET a miniaturized reference electrode with long-term stability, in order to exploit fully the advantages of the device as a miniaturized chemosensor. If the dimensions of the salt-bridge elements are too small, resulting in only short-term resistance of the integrated reference electrode to invasion by potential-falsifying substances, it will only be possible to make disposable sensors. Here, however, it is important to investigate the possibility of using a conventional thick-film design for the electrodes, which might also be cheaper.

In this connection an interesting alternative to ISFETs are film electrodes produced using planar technology.[48] These too offer the advantages of miniaturized sensors which can be economically mass-produced. One commercially available system[49, 50] is based on the principle of zero-point potentiometry. In this one-shot disposable sensor, the measuring and reference systems are identical, and as the pair are made under identical conditions from the same materials the potential difference with the relevant membranes in contact with the same solution is zero. If one now deposits on one of the sensor surfaces a reference solution of known concentration, and on the other the solution to be tested (see Fig. 4), according to the Nernst equation the observed potential difference gives a direct measure of the concentration difference between the two solutions for the relevant measured ion species (concentration meter design). The errors that are pos

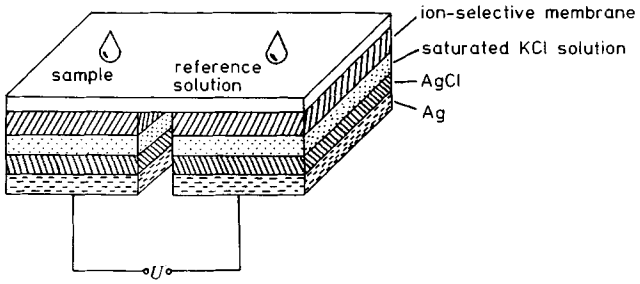

Fig. 4. Construction of a film sensor (Kodak), which works on the zero point potentiometry principle.

sible in difference methods of this sort (where no transport of samples is involved) are very small, as the problems with conventional reference electrodes (variations in potential due to diffusion), ageing effects, and electrode poisoning effects are avoided. However, continuous measurements are not possible with this device.

2.1.3. *Ion-Conducting Solid Electrolyte Sensors*

The lambda-probe, which has become familiar because of the three-way catalytic converter, is currently the most widely used of all electrochemical sensors. It enables the measurement of the residual oxygen content in the exhaust from internal combustion engines, making use of the selective ionic conductivity of the $O^{2\ominus}$ ion in yttrium-doped ZrO_2 at temperatures above 400 °C. A potentiometer device for measuring O_2 concentrations can be designed as a concentration cell, which allows the gaseous oxygen to be in equilibrium with the lattice oxygen in the solid electrolyte [reaction (1)].

$$O_2(g) + 4e^- \rightleftharpoons 2O^{2\ominus} \quad (1)$$

If there is a higher oxygen concentration on one side of the ZrO_2 membrane than on the other (i.e. on one side an oxygen partial pressure $p_{O_2}^{ref}$, for example, of the outside atmosphere or of a reference gas, and on the other side a partial pressure $p_{O_2}^{sample}$, for example, of the exhaust gas or other medium being analyzed), according to the Nernst equation a potential difference proportional to the logarithm of the ratio of the two oxygen pressures is set up [Eq. (b)].

$$U = \frac{RT}{4F} \ln \frac{p_{O_2}^{ref.}}{p_{O_2}^{sample}} \quad (b)$$

The selectivity of this sensor results from the fact that in ZrO_2 there is a selective conductivity for $O^{2\ominus}$ ions (similar to that for $F^{\ominus}$ ions in single crystals of LaF_3), which also determines the surface reaction. Figure 5 shows schematically the construction of a lambda-probe working on the potentio-

metric principle.[51, 52] With regard to the other analytical properties of the device, the same arguments as for ion-selective membrane electrodes apply here. The range of concentrations that can be measured is enormous (> 10 decades), provided that the current in the measuring circuit is considerably less than the exchange current for the redox reaction (a) at the platinum contact electrodes. The precision in this case also is limited to 0.1 mV, and at constant temperature this gives a relative precision of about 2% in the measured concentration. This accuracy is sufficient for the typical use in a three-way catalyst for automobiles; due to the logarithmic dependence of the signal according to the Nernst equation an immense potential difference results.

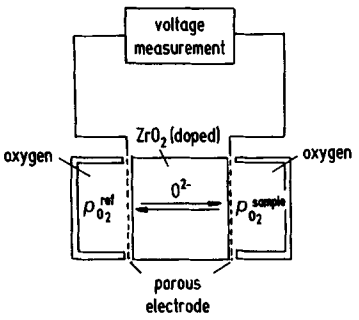

Fig. 5. Schematic representation of a lambda-probe, operated as a potentiometric sensor.

LaF_3, which has an appreciable ionic conductivity even at room temperature, has been found to be a suitable solid electrolyte for the determination of O_2 at room temperature.[53] In this material a change in potential is produced by $OH^{\ominus}$ and $HO_2^{\ominus}$ ions formed as intermediates, and this allows an indirect measurement of the O_2 concentration.[54]

High temperature solid electrolytes with $O^{2\ominus}$ conductivity can also be used at a constant oxygen concentration for detecting oxidizable substances, by making use of a second reaction that takes place at the electrodes. An example where this occurs is in the catalytic oxidation of NH_3 and the determination of chromium in molten steel,[55] by reaction (2).

$$3O^{2\ominus}(SIC) + 2Cr(metal) \longrightarrow Cr_2O_3(2nd\ phase) + 6e^-(metal) \quad (2)$$

(SIC = solid ionic conductor)

Here the $O^{2\ominus}$ ions moving in the solid electrolyte oxidize the chromium with the release of electrons, which can be measured as a change in potential. It has also been shown that silicon can be determined by a similar method when $ZrSiO_4$ is the solid ionic conductor.[56] A very compact sensor suitable for applications at these high temperatures (above 1600 °C) has recently been developed; this can be used for up to 10 h in molten steel.[57] Special sensors have also been developed for determining oxygen in liquid sodium, which is used in fast breeder reactors.[58, 59] In addition to withstanding high temperatures and mechanical loading, these sensors must also be resistant to radiation and corrosion by sodium.

Solid electrolyte sensors that have been developed for determining substances other than oxygen include especially those for SO_2/SO_3 and CO_2.[60] These consist for example, of $Li_2SO_4 + Ag_2SO_4$[57, 61–64] and have a working temperature of about 400 °C. The sensitivity of such sensors is in the range of 3 to 10^4 ppm of SO_3, and they are currently being tested for use in monitoring exhaust gases. The measurement of Cl_2 is also possible with surface-modified solid electrolytes, e.g. the ionic conductor $LiAlCl_4$ with its surface covered by a thin film of LiCl or $AlCl_3$. The cell voltage is determined by the partial pressure of chlorine, and obeys the Nernst equation.[65, 66]

2.1.4. *Amperometric Sensors*

To avoid the requirements for temperature constancy in the lambda-probe, and obtain a linear instead of a logarithmic relationship between signal and concentration with higher accuracy, which is essential in engines working with $\lambda > 1.0$, the sensor can alternatively be designed as a limiting current probe.[67, 68] This configuration, which can also be operated at temperatures below 400 °C, differs from the potentiometric form of a lambda-probe in that a current flows through the O_2 concentration cell as a result of an externally applied voltage ("pumping voltage"), thereby transporting oxygen from one side of the ZrO_2 membrane to the other (an "oxygen pump"). In front of the cathode there is a diffusion barrier (e.g. a porous ceramic layer), which the oxygen must traverse before being reduced and transported through the ZrO_2 to the anode (Fig. 6). If the applied voltage is chosen

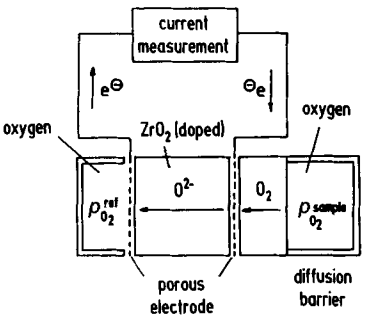

Fig. 6. Schematic representation of a lambda-probe operated as a limiting current sensor.

so that each oxygen molecule that arrives is immediately reduced at the cathode, a voltage-independent limiting current region is obtained, as in polarography. The current then flowing is directly proportional to the O_2 concentration to be measured, and the temperature coefficient is no longer given by the Nernst factor, but is determined by the properties of the diffusion barrier.[69]

The amperometric measuring principle has largely been used to advantage in industrial chemosensors for gases. The classic example of this is the Clark oxygen sensor.[17] The oxygen whose concentration is to be measured diffuses through a gas-permeable membrane 10 to 50 μm thick, which is made of polytetrafluoroethylene (Teflon) or a fluorinated ethylene–propylene copolymer (FEP) with a very high permeability to oxygen. Behind this membrane is an electrolyte solution containing chloride ions, in which are immersed a platinum or gold cathode as the working electrode

and an anode of Ag/AgCl as the constant potential counter-electrode (cf. Fig. 14). The reduction of the oxygen takes place at a working electrode potential of approximately -0.8 V relative to the Ag/AgCl electrode. The rate-limiting step is the diffusion of the oxygen through the gas-permeable membrane, and the rate of this depends on the gradient of the O_2 partial pressure across the membrane. The current is therefore determined primarily by the O_2 partial pressure. As the membrane is impermeable to liquids and electrolytes, the sensor can also be used to determine dissolved oxygen in liquids; in this case the dependence on the partial pressure must be noted. The sensor gives the same reading for air and for a liquid that is saturated with air! To obtain a reading which indicates the dissolved oxygen in $mg\,L^{-1}$ it is necessary to calibrate the sensor.

A disadvantage of most O_2 sensors based on this principle is that oxygen is consumed. When they are used in stationary liquids there may not be a sufficient flow of oxygen to the electrode (resulting in an oxygen-deficient layer in the liquid whose growth follows a $\sqrt{t}$ law), which gives readings that are too low. The solution being measured must therefore be stirred, but this leads to some extent to a dependence of the observed signal on the convection flow. The effects of this disadvantage (especially in biomedical applications) can be minimized by reducing the area of the working electrode, which in turn causes difficulties because the current then becomes very small. Efforts are now in progress to overcome this problem by using an array of ultramicroelectrodes (Fig. 7). The use individual electrodes as small as 1 μm in diameter, has led to such low reaction rates that the Brownian motion of the molecules together with the radial diffusion sphere ensures a sufficient oxygen supply. However, sensor technologies of this sort can only be put into effect with the most modern microelectronics manufacturing processes. Amperometric oxygen electrodes are widely used as transducers for many types of biosensors (see Table 7).

Many gas sensors for SO_2, CO and NO function on a similar principle. The measurement is based on the electrochemical oxidation of the relevant gas in the space separated off by the gas-permeable membrane.

The selectivity of amperometric sensors can be tailored to suit particular needs. Up to now the main technological use for amperometric chemosensors has been for measurements on gases, even though amperometry is also suitable for analyzing liquids, because of their limited selectivity. In the most commonly used aqueous electrolytic media, the usable voltage range extends over about 2 V. All substances that can be altered electrochemically, i.e. those that can be oxidized or reduced, which number many tens of thousands, are converted at voltages within this range. In the ideal case one can expect to distinguish ten substances at best in a voltammetric diagram by virtue of their different half-wave potentials.[70] The separation capacity achieved by the proper choice of a working electrode potential within the limiting current region for the substance to be determined is in general inadequate for the analysis of unknown liquids. However, if a gas-permeable membrane is interposed, the interfering substances are limited to gases that can permeate the membrane equally well, and also undergo electrochemical reactions under these conditions. In the case of the Clark O_2 sensor, for example, these are chlorine and some haloforms (CHX_3). These interferences can be even further reduced by a careful choice of the membrane material and the electrolyte. Occasionally a difference in electrochemical reversibility coupled with pulse techniques is also exploited to increase selectivity. The limit of detectability for amperometric gas sensors is determined by the noise level of the background current. Nevertheless, chemosensors for environmental applications (measurement of NO_x, SO_2 etc.) can be employed in the low ppm region without special signal-processing techniques.

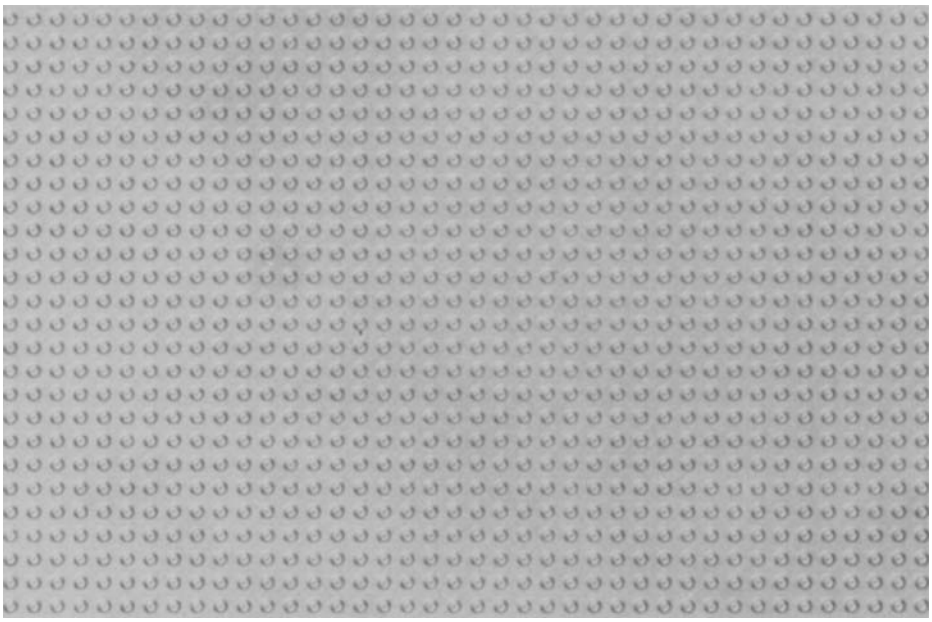

Fig. 7. Microelectrode array for amperometric determination of oxygen; the diameters of the platinum and silver electrodes are 1.5 μm and 20 μm respectively. [With permission of the Institut für Medizintechnik (IMT), Münster, FRG].

2.1.5. *Galvanic Sensors*

Amperometric measurements are also possible without an external current source, if a galvanic circuit is formed. The

best known example is the so-called internal electrolysis, in which $Cu^{2\oplus}$ ions are reductively deposited on a platinum wire mesh when this is connected to a zinc rod immersed in a zinc sulfate solution which is separated by a diaphragm from the solution containing the copper ions. Here again the driving force for the current which arises when zinc dissolves and copper ions are deposited on the platinum surface is the difference between the chemical potentials, or the energy difference between the two redox reactions in the electrochemical series. If in this example one connects a galvanometer externally between the zinc electrode and the platinum mesh, the current vs. time diagram obtained during the electrolysis has an exponential shape. The quantitative deposition of the $Cu^{2\oplus}$ ions on the platinum mesh is complete when the current has fallen to about 0.1% of its initial value. In this case, instead of using the gravimetric method, the amount of copper deposited can be calculated by Faraday's law from the total charge that has flowed (the integral of the current vs. time curve) as long as interference from side-reactions is absent. This coulometric procedure is one of the most precise absolute determination methods available, and requires no calibration. Coulometry is still an elegant method with exciting new possibilities for the development of intelligent sensors, and regrettably is too little used.

Over 25 years ago a coulometric measurement cell for SO_2 was proposed.[71] Subsequent advances in miniature electrochemical cells based on thin-film and thick-film technologies allow the easy application of such a cell as a chemosensor (Fig. 8). If the reaction is quantitative, a current of the order

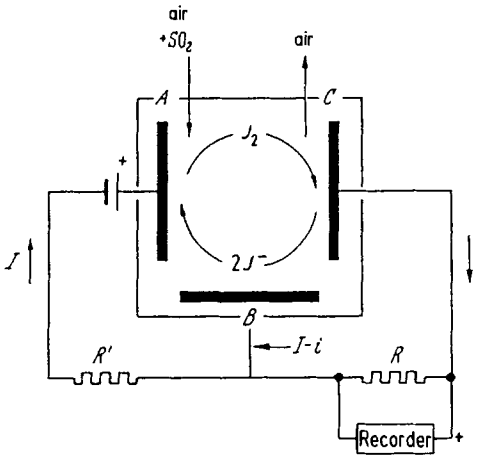

Fig. 8. "Fuel cell" detector for SO_2; a generation current flowing between electrodes A and B liberates free iodine, which then undergoes spontaneous reduction at electrode C, causing a current between electrodes B and C. In the absence of SO_2, this current is exactly equal to the generation current, and is registered by the recorder. The SO_2 whose concentration is to be measured reduces the reading by an amount given by the stoichiometry. (The symbol J is used here for iodine to avoid confusion with *I*, the symbol for current.)

of 1 μA, which is easily measurable, corresponds to an analyte reaction rate of only 10^{-10} mol s^{-1}! Here the selectivity is achieved by a preceding chemical reaction or membrane separation stage, either of which can nowadays easily be realized by means of a suitable layered structure. An "analytical fuel cell" of this kind has recently also appeared on the market in the form of an alcohol meter (for analysis of breath samples). As well as using the catalytic activity of noble metal electrodes, it is also possible, of course, to use enzymes to give increased selectivity. The H_2O_2, which is then often produced in quantities proportional to the amount of analyte, can also be easily determined coulometrically.

A galvanic measuring cell for the determination of oxygen in solutions has been well-known since the mid-1960s.[72] In contrast to the Clark sensor, the Mackereth oxygen sensor uses lead instead of silver as the anode material, and silver instead of platinum as the cathode material. This has the important advantage that a calibration in a blank solution (such as a saturated sulfide solution) is no longer necessary, since the electrodes produce no current in the absence of oxygen. For the internal electrolyte either sodium hydroxide or potassium hydrogen carbonate can be used.

2.2. Semiconductor Gas Sensors

Sensors based on semiconductors are often used in gas alarm devices. The underlying principle here depends on a transfer of electrons between a semiconductor surface and adsorbed gas molecules. This charge transfer results in an increase or decrease in the number of free charge carriers at the semiconductor surface, causing a change in conductivity which can be measured and is proportional to the number of reacting gas molecules present. Oxidizable gases such as hydrogen, hydrogen sulfide, carbon monoxide, and alkanes of low molecular mass reduce the surface conductivity of certain n-type semiconductors (SnO_2, ZnO etc.), which are used at temperatures between 100 and 600 °C. Reducible gases such as chlorine, oxygen, or ozone have an analogous effect on p-type semiconductors (NiO, CuO etc.). The mechanism of the electron transfer is still under intensive study and one possible model shown in Figure 9. When a gas molecule of

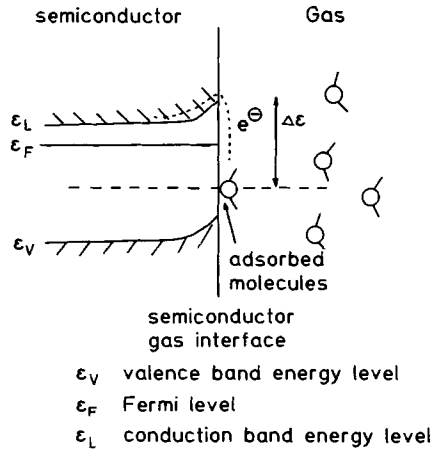

Fig. 9. Simplified mechanism of electron transfer at the semiconductor–gas interface.

the analyte approaches the surface of the semiconductor it first undergoes a weak physisorption. In the following step it can be either desorbed or chemisorbed with the transfer of an electron. The latter process causes a distortion of the valence

and conduction bands, and alters the electronic work function. Depending on the composition and the structure of the surface and on the interactions between the molecules and the surface, certain types of molecules can act preferentially. The selectivity of simple sensors of this kind, which can be easily and cheaply produced with thick film techniques (see Fig. 10), can be altered within certain limits using existing knowledge of heterogeneous catalysis. To obtain improved

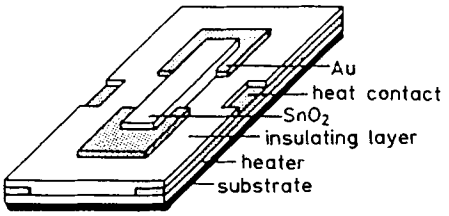

Fig. 10. Construction of a gas sensor of the SnO_2 thick-film type.

sensitivities and selectivities for particular applications, however, mechanistic studies of the kind used in heterogeneous catalysis research, requiring sophisticated and expensive equipment, are necessary, rather than the time-consuming trial-and-error methods of nonspecialists. Often the semiconductor surface is modified by introducing metals such as palladium, silver, or platinum, whose purpose is to weaken the O_2 double bond. The selectivity can be further increased to a certain extent by choosing the best operating temperature (Fig. 11). Nevertheless, the selectivities of these types of

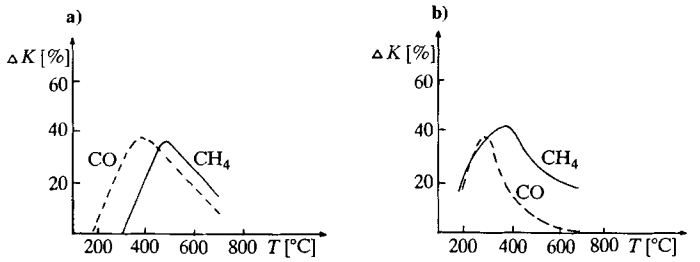

Fig. 11. Effects of temperature and of the presence of platinum on the selectivity of an SnO_2 gas sensor. a) Pure SnO_2 sensor, b) SnO_2 sensor with 1% platinum.

sensors based on semiconductors are often insufficient.[73] The surface composition, density of charge carriers, Fermi energy level, number of reactive centers at the surface, and even the extent of distortion of the bands, can be affected by the presence of other species (interfering molecules such as water, catalyst poisons etc.). This can cause changes in selectivity. These effects must be taken into account during calibration. A change in the selectivity, sensitivity (signal per unit concentration in the analyte) or zero point of the calibration line between carrying out the calibration and the analysis is inadmissable.

As it is a simple matter to modify the sensitivity, experiments are now in progress to use a sensor array in which each miniaturized individual sensor has a different sensitivity profile. Samples which contain interfering substances cause each individual sensor to give a different signal. By carrying out calibration measurements with different concentrations of the various interfering components, it should be possible, by a pattern recognition analysis, to use a special algorithm for the calculation of the true sample content. A simultaneous analysis on a mixture using such a sensor array should in principle enable the determination of every substance which has an effect on the signal, if more sensors than components to be analyzed are used. This has in fact been achieved for simple and well-defined mixtures.[74] Nevertheless, the analytical chemist with experience of industrial practice will harbour doubts about the feasibility of this method for real samples whose composition is generally unknown and continually changing. Taking the simplest form of an analytical function (c) is it possible to keep the parameters a and e constant between the calibration and the measurement? How can the algorithm take into account situations where interfering substances poison the sensors to differentor cause different drift phenomena? What are the consequences of "matrix effects" which cause the sensitivity e to vary from sample to sample?

$$s = a + ec \qquad (c)$$

s = analytical signal
a = intercept on the axis (blank value)
e = slope of the calibration function (sensitivity)
c = concentration of the analyte

Table 3 gives a summary of the most important materials currently used to make selective sensor elements for electrochemical sensors.

Table 3. Materials for selective chemosensor elements.

Sensor materials	Examples	Species detected	Refs.
glasses	Li_2O-BaO-SiO_2	$H^{\oplus}$	[5,6]
	Na_2O-Al_2O_3-SiO_2	$Na^{\oplus}$	[7]
synthetic polymers	PVC, silicone and PMMA membranes[a] with plasticizers and suitable carriers	e.g. $K^{\oplus}$, $Na^{\oplus}$, $Ca^{2\oplus}$, $Mg^{2\oplus}$, $NH_4^{\oplus}$, $NO_3^{\ominus}$	[14–16, 34,36–38]
	PTFE membranes for gas sensors	NH_3, CO_2, SO_2	[37]
solid	LaF_3	$F^{\ominus}$	[37]
		O_2	[53,54]
	ZrO_2 (lambda probe)	O_2	[51,52]
		Cr	[55]
	TiO_2, Nb_2O_5	O_2	
	$ZrSiO_4$	Si	[56]
	$Na_2SO_4 + Ag_2SO_4$	SO_2/SO_3	[57,60–64]
	Nasicon[b]	Na	[65]
		$Na^{\oplus}$	[66]
semi-conductors	Si, GaAs, SiC, SnO_2, ZnO, CuO	Oxidizing or reducing gases	[73,109–111]
metal oxide or nitride films	Al_2O_3, Si_3N_4, SiO_2, TiO_2 as insulators, electronic conductors and electroactive materials	$H^{\oplus}$, H_2, O_2	[73,109–111]

[a] Polylmethylmethacrylate. [b] $Na_{1+x}Zr_2Si_xP_{3-x}O_{12}$.

2.3. Fiber-Optic Sensors (Optodes)

Chemical information can also be translated into measurable signals through the interaction of electromagnetic radiation with the analyte. Spectroscopic analysis, spectrophoto-

metry, fluorimetry, and luminescence measurements are well-established and proven techniques. Their adaptation for performing in situ analyses with miniaturized probes that can be employed in the same way as chemosensors has come about through the application of modern light-guide technology. For use in conjunction with fiber optics a new class of sensors was developed, known as optodes (also as optrodes).[75-78] These optical sensors make use of changes in fluorescence, absorption, chemiluminescence, light scattering, polarization, Raman scattering, refractive index, or reflection, which at present are still detected by conventional optical or spectroscopic instruments. The light input is fed into the sample by a light-guide. The return path for the fluorescence emission or reflected light from the sample to the detector can be through the same light-guide or through a second branch (in a Y-branched light-guide). Figure 12 shows as an example the layout of a fiber-optic analytical system as commonly used for fluorescence measurements. The AC signal produced by a chopper is amplified frequency- and phase-selectively by a lock-in amplifier. This procedure makes it possible to measure delayed fluorescence as well (by the phase shift). Fluorescence and luminescence measurements give high sensitivity compared with other optical measurement methods and are therefore preferable for trace analysis.

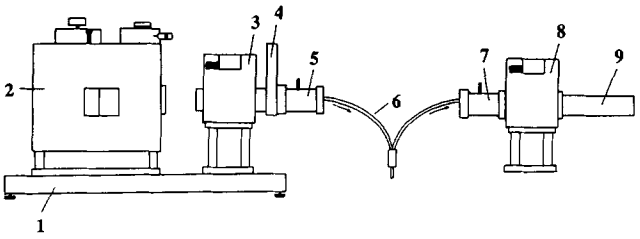

Fig. 12. Fiber-optic system for analysis by fluorescence measurements; the excitation unit (2) contains the light source (xenon or halogen lamp or laser) producing a beam which is passed through a monochromator (3), a chopper (4), and an optical coupler (5) into the light guide (6). The fluorescence radiation passes through a second light guide branch, coupler (7), and monochromator (8) to the detector (9), which consists of a photodiode or photomultiplier. (1) is the base plate.

Chemiluminescence measurements have an additional advantage, as they do not require an external light source. However, because chemiluminescence is a comparatively rare phenomenon, the method is mainly limited to systems such as H_2O_2/luminol.

The great advantage of fiber-optic sensors is that the measurements do not require a reference system, apart from comparison of the light intensities in the beam before and after it passes through the sample compartment (i.e. measuring I_0/I), or the use of a dual beam arrangement to compensate for fluctuations in the intensity of the light source. With the electrochemical sensors described earlier a second electrode giving a constant potential is always needed. Optodes can easily be miniaturized, as light-guides of suitably small diameter (e.g. 0.1 mm) are commercially available, although increasing miniaturization makes good coupling of the input radiation more difficult. Optodes can also be used in complex media such as blood. They are less susceptible to disturbance by electromagnetic fields and temperature changes than are potentiometric electrodes and semiconductor sensors. On the other hand, problems can arise from scattered and background light falling on optodes. In many cases these sensors can only be used within a small range of concentrations, like the spectroscopic analytical cuvette techniques on which they are usually based, and their selectivity is similar to that of those techniques. The detection limit also leaves room for future improvements, as it is restricted at present by the thinness of the optical films generally used for the measurements (see Table 4).

Despite all this, fiber-optic sensors are expected to emerge from their present status as research devices and find a place in industrial use in future; the flow-through cuvettes will probably be abandoned first. The types most studied are pH-optodes. The technique is based on the immobilization of an indicator dye at the end of the light-guide, which allows pH values to be determined by measuring fluorescence or absorption. Indicators that have been used include 8-hydroxypyrene-1,3,6-trisulfonate (HPTS) as well as conventional dyes such as eosin or phenyl orange.[79]

Such pH-optodes also form the basis for a range of gas sensors. For example, CO_2 and NH_3 optodes contain a pH optode immersed in a suitable internal solution behind a gas-permeable membrane, as in the analogous potentiometric sensors. The acidity or basicity of the above gases alters the pH of the internal solution by an amount related to the gas concentration to be measured. Such sensors are of particular interest for in vivo applications (blood, body fluids, etc.), since unlike electrochemical sensors they do not have electrical connections to voltage-carrying components.

The fields of application are similar for O_2 optodes, which work on the principle of direct fluorescence quenching. The mathematical basis of this type of sensor is given by the Stern–Volmer equation.[80] The fluorescence of an indicator such as decacyclene or perylene, which is immobilized on the tip of the light-guide, is partially quenched by oxygen. This effect can be used, after calibration, for the determination of O_2.

Some new developments are based on applying knowledge of the selectivity mechanism of ion-selective electrodes to fiber-optic systems. For example, valinomycin as a selective $K^{\oplus}$ carrier can be immobilized in a suitable matrix, together with a pH-sensitive indicator in its protonated form, so as to produce a membrane which can be attached to the tip of a light-guide. If this sensor is immersed in a solution containing $K^{\oplus}$ ions, these ions will preferentially enter the membrane phase, with the formation of a potassium–valinomycin complex. To maintain electrical neutrality $H^{\oplus}$ ions (as the most readily mobile ion species) move out of the membrane phase, causing a change in the absorption or fluorescence of the pH indicator in the membrane, which can easily be measured.[81]

In conclusion it should be noted that at present there are only a few manufacturers of optodes, and it will certainly take several more years before such fiber-optic analytical systems become as widely used as electrochemical sensors.

2.4. Mass-Sensitive Transducers

Chemosensors based on mass-sensitive transducers have been less thoroughly investigated, and their use has so far been restricted to special applications. The measuring prin-

ciple depends on the shift Δf in the characteristic frequency of a quartz oscillator due to a mass change Δm, which occurs when a layer of foreign material is deposited on its surface. The oscillation frequency is usually in the 9 to 14 MHz range, and the selectivity is obtained by coating the surface with an appropriate adsorbent. By using phthalocyanine, for example, planar-conjugated molecules and higher alcohols can be determined; in this case mass changes as small as 10^{-9} g can be detected.[82, 83] When working in vacuum the relationship between Δf and Δm is linear for small values of Δm and is given by the Sauerbrey equation [Eq. (d)].[84]

$$\frac{\Delta f}{f_0} = -\frac{\Delta m}{m} \qquad \text{(d)}$$

f_0 = resonance frequency in the unloaded condition
m = mass of the quartz crystal in the unloaded condition

The suitability of quartz oscillators for gas analysis has been demonstrated beyond doubt. Difficulties arise, however, in the search for selective ab- or adsorbents for particular analytes, and in compensation for the effects of moisture and other interfering deposits. Also it must be noted that the surface adsorption or film absorption are not usually reversible. Transducers of this type are potentially important for biosensors for gas phase use. At present, however, their high cost inhibits the development of practicable one-shot disposable sensors.

When quartz oscillator detectors are used directly in liquids[85, 86] without a drying stage before the mass-change measurement, the damping of the oscillations must also be taken into account [Eq. (e)].

$$\Delta f = f_0^{3/2} \left(\frac{\eta \rho}{\pi \mu_Q \rho_Q} \right)^{1/2} \qquad \text{(e)}$$

η = viscosity of the liquid
ρ = density of the liquid
μ_Q = shear modulus of the quartz
ρ_Q = density of the quartz

The latest studies,[87] which are based on an exact coulometric calibration, show that a 0.4 μm thick layer of the surrounding liquid moves with the quartz crystal surface during its oscillation. This makes exacting demands on the constancy of all the effects that shift the frequency. The layer of liquid that moves with the surface reduces the mass resolution (i.e. the ability to measure very small mass changes). It should also be mentioned here that a similar device is marketed for determining the densities of liquids; density changes of the order of a few parts per million can be detected.

Surface acoustic wave (SAW) detectors are devices in which acoustic waves are produced at the surface of a suitable material, by setting up appropriate resonance conditions between two surfaces. The resonance frequency is typically a few hundred MHz, and according to the Sauerbrey equation (d) this should result in greater sensitivity. However, this cannot be fully exploited, as it is only possible to measure the change in mass within a very thin layer between the two specially shaped electrodes. The selectivity is governed by the same considerations as above.

2.5. Applications of Chemosensors

The use of chemosensors in technology has grown enormously during the past decade. R & D in the field of chemosensors is being energetically pursued worldwide, but especially in Japan. The range of uses of conventional chemosensors extends from chemical process control technology through applications in clinical chemistry to municipal services. A field of special importance for chemosensors is environmental protection, where increased public awareness and ever stricter legislation make it increasingly necessary to set up on-line monitoring systems for environmentally significant gases such as NO, SO_2, NH_3, CO, or CO_2.[88–93]

The wide variety of chemosensors that have so far been developed means that in many cases the most suitable one for a particular application can be chosen from a number of alternative constructions. As an example Table 4 lists the various methods of measurement available for determining a single substance, in this case oxygen.

Table 4. Comparison of methods available for the determination of a single substance. Oxygen is used as example.

Sensor type	Principle	Measurement medium	Range
amperometry (*Clark*'s method)	amperometric arrangement with gas membrane	liquid or gas	0.1 ppm to 100 vol. %
potentiometry (principle of lambda-probe)	O_2 concentration cell with solid ionic conductor at elevated temperature	gas	1–100 vol. %
optical	e.g. quenching of fluorescence of an immobilized dye	oxygen dissolved in liquids	0.01 ppm–sat. solution
paramagnetic	deflection of a magnetic balance due to the paramagnetism of the O_2	gas	0.1–100 vol. %

The largest market for chemosensors at present is the automobile industry, which even in 1987 required over ten million oxygen sensors (lambda-probes) throughout the world for controlling the operating conditions of the three-way catalytic converter.

A similarly large market exists for semiconductor sensors based on SnO_2 for detecting oxidizable gases such as CO, NO_x and CH_4, which are used mainly in monitoring instruments (alarm devices) in underground garages, tunnels, and coal mines, and for measuring emissions in industry. Here the poor selectivity is not a serious disadvantage; on the contrary it gives extra safety. Conventional electrochemical sensors too are widely used in measurement and control technology, especially glass pH electrodes, of which about a million are produced every year throughout the world.[94]

The largest areas of use for conventional potentiometric sensors are in medicine and environmental technology. In clinical chemistry, for example, ion-selective sensors have many uses for measurements in biological media.[95–99]

They have been used successfully for some years to measure concentrations of individual ion species such as $Na^{\oplus}$, $K^{\oplus}$, $Ca^{2\oplus}$, and $Mg^{2\oplus}$ in blood. Unlike other methods of analysis such as atomic absorption spectroscopy (AAS), which always measure the total concentration of the ion species (both free and bound ions), ion-selective sensors allow a direct measurement of the activity of the free ion, which is the effective concentration and the only component that is relevant for medical diagnostic purposes.[100] Fluoride in urine and blood can be determined by, for example, a LaF_3 single crystal electrode, which gives an extremely high selectivity for $F^{\ominus}$. A knowledge of the fluoride concentration is important in the chemotherapeutic treatment of osteoporosis and kidney disease, and in the determination of the $F^{\ominus}$ content of the blood after the use of narcotics.[97]

The detection of traces of cyanide in blood is necessary during treatment of hypertonia with sodium pentacyanonitrosylferrate(II) (sodium nitroprusside), and this too can be carried out with an ion-selective electrode.

Iodide- and bromide-selective sensors are of interest in clinical toxicology, in connection with radioimmunological investigations into the functioning of the thyroid gland (using the iodine-131 isotope) and the administration of the bromine-containing sleeping drugs, ureides. Use of the latter often causes toxic effects due to metabolic dehalogenation and a dangerous build-up of $Br^{\ominus}$ ions.

In treating manic-depressive patients a control of the lithium content is of particular importance; this can be determined using ion-selective membrane electrodes which consist of PVC and a lithium ionophore such as ETH 1810 (*N*,*N*-dicyclohexyl-*N'*,*N'*-diisobutyl-*cis*-cyclohexane-1,2-dicarboxamide).

The non-invasive measurement of the transcutaneous blood CO_2 partial pressure is a technique that can be used to advantage in operations, in amputational surgery and in sport related medical practice. Here the sensor works on a principle analogous to that of other potentiometric gas sensors such as NH_3 or SO_2 detectors. It is essentially a pH probe consisting of a glass electrode and an Ag/AgCl reference electrode. The gas diffuses through a semipermeable membrane into an intermediate electrolyte, whose pH changes according to the gas partial pressure and is measured by the pH electrode. Figure 13 shows a sketch of the sensor.

The sensors that have been described are still used mainly for in vitro measurements, but the main research objective is to develop catheter needle electrodes for in vivo measurements. Figure 14 shows an example of an amperometric catheter electrode for measuring O_2 partial pressures.[101]

ISFETs have proved successful mainly in medical technology. Up to now pH-ISFETs have become commercially available and are used for determining acidity in blood and serum (whose normal pH value is 7.41) and other body fluids. Another technological application is in the photographic industry; here ISFETs are used in process control, to maintain important parameters such as the concentrations of $H^{\oplus}$ and $Ag^{\oplus}$ ions at constant levels.[102]

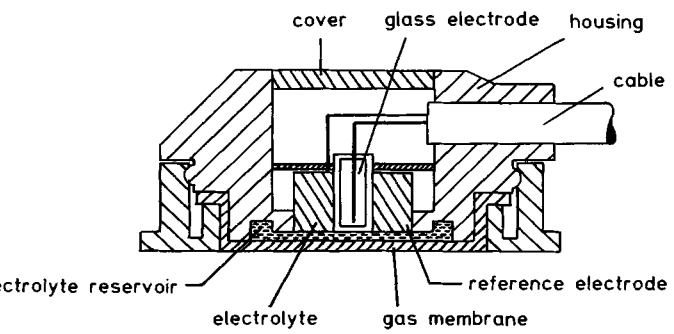

Fig. 13. Gas sensor for measuring CO_2 partial pressures in medical applications[95]; the sensor allows transcutaneous measurement of CO_2.

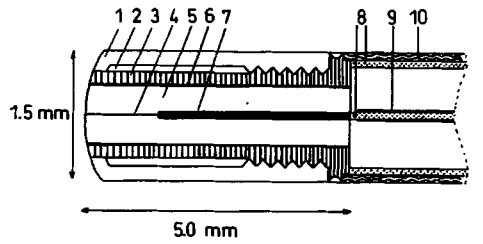

Fig. 14. Amperometric catheter sensor for measuring O_2 partial pressures [101]; (1) Teflon (PTFE) membrane and cap, (2) electrolyte space, (3) Ag/AgCl anode, (4) Pt cathode, (5) glass, (6) Araldite (epoxy resin), (7) platinum wire, (8) copper screening, (9) insulation, (10) cover tube.

The Ektachem film electrodes mentioned earlier (cf. Fig. 4) can be used as one-shot disposable sensors in medical applications. The Kodak Ektachem DT 60 is a commercially available system[49, 50, 103] and can be used for the determination of $K^{\oplus}$, $Na^{\oplus}$, $Cl^{\ominus}$ and other substances. Figure 15 shows a film sensor of this type for potassium.

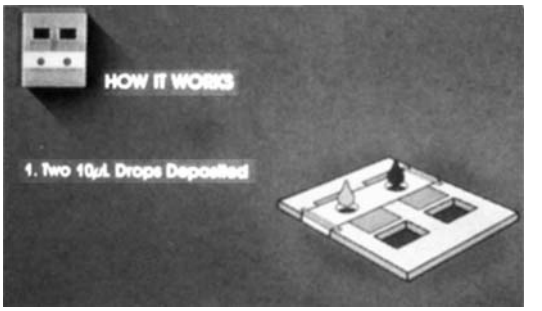

Fig. 15. Kodak DT 60 Ektachem system for the determination of potassium.

Potentiometric sensors can be used for environmental protection both in laboratory investigations and on-line applications. One task that they can perform is the continuous monitoring of $NO_3^{\ominus}$ and $NH_4^{\oplus}$ concentrations in groundwater and drinking water. This gives early warning of excessive concentrations in the water, allowing the necessary corrective measures to be applied quickly. Figure 16 is an example of a recorder trace obtained with a sensor used to monitor nitrate in drinking water. The trace shows immediately if the maximum legally permitted nitrate concentration of 50 mg L^{-1} (50 ppm) is exceeded. Here the technique of flow injection analysis (FIA) can be used, since the selectivity of the sensor makes a preliminary chromatographic separation unnecessary.[104]

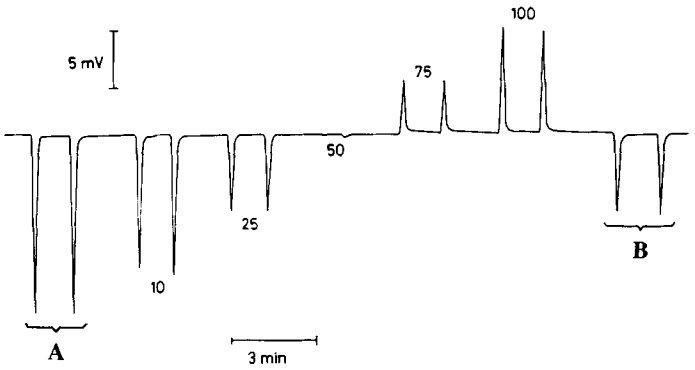

Fig. 16. Recorder trace obtained during the FIA monitoring of $NO_3^{\ominus}$ in drinking water; carrier electrolyte: 50 ppm $NO_3^{\ominus}$ in 0.01 M $NaH_2PO_4 \cdot H_2O$; flow rate: 3.0 mL min^{-1}; sample quantity: 0.3 mL in 0.01 M $NaH_2PO_4 \cdot H_2O$. The numbers represent the concentration of nitrate in mg L^{-1}; A: doubly distilled water; B: drinking water.

In process engineering, ion-selective sensors for $Ca^{2\oplus}$, $Na^{\oplus}$, $NH_4^{\oplus}$, or $Cl^{\ominus}$ can monitor the purity of boiler feed water in steam turbines;[105] with a glass electrode for $Na^{\oplus}$, ppb concentrations are detectable. Monitoring these concentrations is critically important in relation to boiler scale formation and turbine corrosion.

Table 5 lists important characteristics of the various types of sensors described here, such as the range of measurement, useful life and detection limits. ISEs that do not incorporate PVC membranes can also be used to a limited extent in nonaqueous media. For example, it is well known in the oil industry that impurities in crude oil feedstocks can adversely affect the refining process, and it is therefore essential to carry out continuous analyses.[106]

Table 6 gives a summary of some commercially available sensors.[107]

Table 6. Summary of commercially available sensors.

Supplier detector	Species detected	Range	Applications
AEG NO_x monitor	NO_x	0–600 ppm	vehicle exhausts, flue gases
MSI (Dräger) gas analyzing computer	O_2	0–20.9%	flue gases
	CO	0–1500 ppm	
	SO_2	0–1500 ppm	
	NO	0–1000 ppm	
	NO_2	0–200 ppm	
Unitronic (Figaro) gas monitor	CH_4	500–10,000 ppm	gas alarms (camping)
	C_3H_8	500–10,000 ppm	
	C_4H_{10}	500–10,000 ppm	
	CO	50–1000 ppm	gas alarms (garages, tunnels)
	NH_3	30–300 ppm	
	H_2S	5–100 ppm	gas alarms
	H_2O	0–100 ppm	humidity
Transducer Research, Inc. gas monitor	NO_2	10 ppb–50 ppm	gas alarms
	H_2S	0–1000 ppm	
	CO	0–1000 ppm	
Bran & Lübbe Ionometer	$Na^{\oplus}$	0–20 ppb	quality control monitoring liquids (maximum permitted concentrations)
	$Cl^{\ominus}$	0–100 ppb	
	$NH_3/NH_4^{\oplus}$	0–10 ppm	
	$F^{\ominus}$	0–10 ppm	
	$S^{2\ominus}$	0–30 ppm	

2.6. Development Trends

One should not overlook the fact that the majority of development work on sensors proceeds by methods that are still more or less empirical. Recently the most up-to-date research techniques, e.g., electrochemical impedance spectroscopy,[108] tracer methods, and surface analytical techniques[109–111] such as secondary ion mass spectrometry (SIMS), Auger electron spectroscopy (AES), or X-ray photoelectron spectroscopy (XPS, also known as ESCA), have been applied to optimize performance parameters such as selectivity, stability, dynamic behavior, reproducibility and sensitivity. These methods will at the same time provide a deeper insight into the mechanisms of functioning of the selective sensor elements.

A changing trend can now be seen in the technology of chemosensors, away from the hitherto conventional sensor design principle based on electrode-like structures, towards miniaturization with recognition systems and signal processing integrated in a single device.[112, 113] These developments can benefit from the existing technology of microelectronics. Besides savings in materials, this technology can also lead to considerable cost reductions through mass production, and may sometimes even result in sensors with improved proper-

Table 5. Characteristics of selected sensors.

Sensor	Species	Range	Detection limit	Sample form	Useful Life
ISFET	$H^{\oplus}$	pH 2–12	10^{-13} mol L^{-1}	liquid or paste	several weeks
ChemFET	$Na^{\oplus}$	$1-10^{-5}$ mol L^{-1}	$10^{-5.5}$ mol L^{-1}	liquid or paste	several weeks
ISE	$H^{\oplus}$	pH 0–14	10^{-14} mol L^{-1}	liquid or paste	years
	$Na^{\oplus}$	10^{-1}–10^{-5} mol L^{-1}	$10^{-5.5}$ mol L^{-1}	liquid or paste	years
	$F^{\ominus}$	10^{0}–10^{-6} mol L^{-1}	3×10^{-7} mol L^{-1}	liquid or paste	years
	$K^{\oplus}$	10^{-1}–$10^{-5.5}$ mol L^{-1}	10^{-6} mol L^{-1}	liquid or paste	months
	$NO_3^{\ominus}$	10^{0}–10^{-5} mol L^{-1}	5×10^{-6} mol L^{-1}	liquid or paste	months
film	$Na^{\oplus}$	10^{-5}–10^{-1} mol L^{-1}	10^{-5} mol L^{-1}	liquid or paste	disposable
electrode	$K^{\oplus}$	10^{-5}–10^{-1} mol L^{-1}	10^{-5} mol L^{-1}	liquid	sensor
Clark sensor	O_2	1–200 ppm	1 ppm	O_2 in solution	years
lambda-probe	O_2	1–100 vol. %	0.5 vol. %	gas	years
gas alarm	CO	1–100 vol. %	1 vol. %	gas	years
	H_2	1–100 vol. %	1 vol. %	gas	years
	Alkane	1–100 vol. %	1 vol. %	gas	years
fiber-optic (fluorescence)	$K^{\oplus}$	10^{-3}–10^{-1} mol L^{-1}	5×10^{-4} mol L^{-1}	liquid or paste	weeks
	O_2	10^{-3}–10^{0} mol L^{-1}	10^{-3} mol L^{-1}	O_2 in solution	months

ties. Physical sensors for a wide variety of variables are produced by these methods and are already well-known, while chemical sensors made in this way are just appearing on the market.

Thick-film technology offers an alternative way of integrating sensor recognition systems and subsequent signal processing on a single chip, and is within the financial budgets of medium-sized industrial concerns. A potentiometric hydrogen sensor based on thick-film technology and developed by the Battelle Institute is shown in Figure 17. The

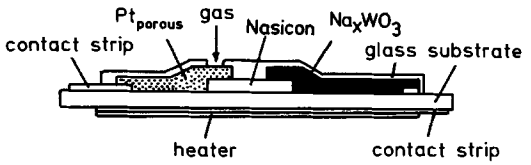

Fig. 17. Hydrogen sensor produced by thick-film technology[113] (see Text).

sensitive material is Nasicon ($Na_{1+x}Zr_2Si_xP_{3-x}O_{12}$), a solid ionic conductor which responds to hydrogen at elevated temperatures, but is a good $Na^{\oplus}$ sensor at room temperature and in solutions. This sensor based on Nasicon is at present one of only a few commercially available sensors made by thick-film technology.

3. Biosensors

A biosensor combines in a single sensor element the sensitivity of a chemosensor with the selectivity of a biological recognition mechanism. The great promise offered by such a combination has been the subject of increasing research efforts in the last few years, as is evident from the rapid growth in the number of publications in this area and the appearance of the first monographs on the topic.[114, 115] A number of different biosensors with biological or biochemical recognition systems coupled to various types of chemosensors have been demonstrated. Although to date biosensors have commercial importance only in medical technology, their use in future in other fields such as environmental monitoring and process engineering is likely. For this reason some relevant developments are described below.

Biosensors functioning on enzymic principles belong to the oldest generation of sensors in this category; they employ selective chemical reactions catalyzed by selected enzymes. The most effective method is to immobilize the relevant enzymes in or on the sensor element, which allows the device to be used repeatedly. Unfortunately the stability of enzymes immobilized in this way is at present rather limited, and consequently the lifetime at room temperature under working conditions varies between only a few days and several months, depending on the enzyme used and the immobilizing technique. However, if it is refrigerated and freeze-dried, an immobilized enzyme retains its activity almost indefinitely.

Another class of biosensors are immunosensors. These operate on a different principle, namely the selective association between antigens and antibodies. This specific biocomplex formation can be exploited in a number of ways as a means of analysis for one of the two partners. The methods that are of importance for the development of these sensors differ from those involved in radio immuno-assay (RIA), and are based either on enzymic immuno-assay (EIA) in combination with various detection methods (photometry, amperometry, or surface plasmon resonance), or on direct potentiometry.

Some of the systems under development function without isolation of biomolecules. In other words, these are enzymic biosensors in which biological materials such as intact cell cultures, tissue sections or microorganisms are used directly without purification; for immunosensors one uses intact receptors, receptor structures or reconstituted units.

As the development of biosensors follows on that of transducers or chemosensors, biosensors are not yet at such an advanced stage, and only a few types are commercially available at present. Nevertheless, some important advances have been achieved in each class of biosensors.

3.1. Monoenzyme Sensors

Monoenzyme sensors were the first biosensors to be developed, and are the best known. Here an enzyme is coupled to an optical or electrochemical chemosensor, which selectively detects one of the reaction partners of the substrate, or a reaction product. As early as the 1960s with the first enzyme electrodes, immobilization of the enzyme was a development goal. Although the immobilization technique is crucial to the behavior of the biosensor, it will not be considered in detail here. The situation is basically similar to that in bioreactors, where the aim is to achieve a high surface activity combined with a high durability; accordingly, the immobilization techniques used in biosensors are similar to those for bioreactors.[116–120] However, it must be said that many of the techniques are still far from giving reproducible results. Many preparative procedures evolved by trial and error, and if a breakthrough could be achieved in immobilization without loss of activity, many of the present disadvantages of biosensors would be overcome.

The modification of the coenzyme nicotinamide adenine dinucleotide ($NAD^{\oplus}$) can also be regarded as a type of immobilization.[121, 122] If the effective molecular mass of $NAD^{\oplus}$ is increased by reaction with polyethylene glycol (PEG) to give PEG-$NAD^{\oplus}$, the coenzyme can be immobilized behind a dialysis membrane, so that it can be used repeatedly after a recycling procedure.

Chemically preactivated membrane filters for simple and rapid immobilization of enzymes have recently become commercially available (Immunodyne, Gelman Sciences). The simplification of the procedure brought about by them could lead to a breakthrough in extending the storage life of biosensors. If a filter membrane freshly coated with the enzyme could be fitted to the sensor shortly before making a measurement, the cost of the biomaterial would be worthwhile in view of the great advantages of a rapid but selective measurement.

3.1.1. Electrochemical Biosensors

In the past the development of monoenzyme biosensors with different transducers was mainly limited to electro-

chemical sensors. This situation has now changed to some extent through the development of new optodes and of the technique of surface plasmon resonance. Biosensors with electrochemical transducers are still essentially restricted, owing to the nature of the products from enzymic reactions, to two methods of measurement, namely amperometry and potentiometry.

Amperometric Biosensors: The majority of biosensors used in research are of the amperometric type. Table 7 gives a short summary, which is by no means exhaustive, of the many different types of biosensors using conventional amperometry.

Table 7. Amperometric biosensors.

Substrate	Enzyme	Product(s) detected	Range	Refs.
alcohol, malate, formiate	dehydrogenase	NADH	10–150 mmol L^{-1} ; (5–100) × 10^{-6} mol L^{-1}	[121, 124]
choline	choline oxydase	H_2O_2	500 mmol L^{-1} [a]	[125]
ethanol	alcohol oxidase	H_2O_2	10 mg L^{-1} [a]	[114]
formaldehyde	formaldehyde dehydrogenase	NADH	10^{-6} mol L^{-1} [a]	[126]
glucose	glucose oxidase	H_2O_2	0–7 g L^{-1}	[127–135]
glutamine	glutaminase, glutamate oxidase	H_2O_2	0–25 mmol L^{-1}	[136]
glycerol	glycerol dehydrogenase	NADH, O_2		[137]
hypoxanthine	xanthine oxidase	H_2O_2	4–180 × 10^{-6} mol L^{-1}	[138, 139]
lactate	lactate oxidase	H_2O_2	1–40 mmol L^{-1}	[114]
oligosaccharides	glycoamylase, glucose oxidase	H_2O_2	0.1–2.5 mmol L^{-1}	[140]
phenol	polyphenol oxidase	quinone	–	[125]
inorganic phosphorus	nucleoside phosphorylase	O_2	–	[141]

[a] Only the upper limit is known.

In amperometric transducers, reaction partners or products of the enzymic reaction are directly reduced or oxidized at the working electrode, and the resulting current is measured. From this, on the basis of the stoichiometry, the quantity of the substrate that has reacted can be determined. As is evident from Table 7, the most commonly used transducers are based on the oxygen/hydrogen peroxide electrodes described in Section 2.1.4, since many enzymic reactions (e.g. those of the oxygenases) involve the consumption or production of oxygen. This consumption of O_2 or production of H_2O_2 is measured by an O_2 electrode.

In this area of development considerable time has been invested in the glucose sensor, which is based on reaction (3)

$$\beta\text{-D-glucose} + O_2 + H_2O \xrightarrow{GOD} \text{gluconic acid} + H_2O_2 \quad (3)$$

catalyzed by the enzyme glucose oxidase (GOD). In this selective reaction three concentration changes can be and have been used to determine the amount of material reacted:

1) the reduction in concentration of the cosubstrate (reduction in O_2),

2) the increase in H_2O_2 concentration, or

3) the concentration of the $H^{\oplus}$ ions generated by the dissociation of the gluconic acid.

Greater progress has been made in the area of in-vitro glucose measurements than in any other, which is not surprising in view of the large amount of research effort on this topic (about half of all the papers on biosensors are concerned with glucose measurements). Despite this, however, an implantable glucose sensor, which would be desirable in medical technology, is still not within sight. Implants need to have a lifetime of several years, because if it is shorter the added trauma for the patient as a result of more frequent operations is unacceptable. Up to now the lifetime of the enzyme GOD in synthetic glucose solutions has been at best about 100 days.[123] Among the problems which hinder applications are those arising from the nature of the cosubstrate (the quantity of O_2 available for reaction (3) limit the measurement range), from product inhibition, from the possibility of the enzyme being attacked by proteases, and from diffusion difficulties caused by encapsulation of the implant.

Other types of amperometric biosensors are those based on the detection of a coenzyme. Well over 100 enzymic reactions are known in which nicotinamide adenine dinucleotide ($NAD^{\oplus}$) functions as a coenzyme. The direct electrochemical reduction of $NAD^{\oplus}$ or oxidation of the reduced form NADH have both been successfully demonstrated,[142, 143] but owing to the very large overvoltage that must be applied (+ 0.7 to + 1.0 V vs. Ag/AgCl), the determination of both species is instead carried out with electron carriers (mediators), which work on the principle shown in Figure 18.[144–147] A similar situation exists for the coenzyme $NADP^{\oplus}$.

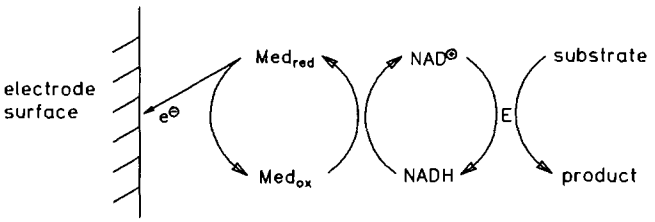

Fig. 18. Mediator-modified amperometric enzyme electrode.

The compounds used as mediators are reversible redox systems with high exchange current densities, often redox dyes such as methylene blue or thionine, or sometimes modified ferrocenes or hexacyanoferrates. The advantages of such a mediator are well-known: it reacts with the coenzyme $NAD^{\oplus}$ in a homogeneous solution without significant inhibition by kinetic factors, the mediator itself is electrochemically reversible, and it reacts at the electrode at a significantly lower potential than $NAD^{\oplus}$. Because of the lower working potential fewer interfering effects from other electrolyzable substances in the sample are expected.

Ferrocenes have also been used to effect the direct transfer of electrons between the enzyme and the electrode. A modified ferrocene serves as mediator between immobilized glucose oxidase and a graphite electrode.[148] This glucose sensor, developed at the Cranfield Institute of Technology (UK), is unaffected by O_2, as the ferrocene replaces oxygen as the cosubstrate. The sensor can therefore also be used in anaerobic media (e.g. in fermenters). In general the immobi-

Table 8. Potentiometric biosensors.

Substrate	Enzyme	Product(s)	Transducer	Range	Refs.
aspartam	L-aspartase	NH_3	NH_3 gas electrode	0.1–0.6 mmol L^{-1}	[149]
fats	lipase	fatty acids	pH electrode	5–50 10^{-6} mol/L^{-1}	[150, 151]
glucose	glucose oxidase	gluconic acid	pH electrode (pH ISFET)	0.12–2 g L^{-1}	[152]
urea	urease	$NH_4^{\oplus}$, CO_2	$NH_4^{\oplus}$ electrode pH electrode CO_2 gas sensor	0.01–10 mmol L^{-1}	[153–155]
nitrite	nitrite reductase	$NH_4^{\oplus}$	$NH_4^{\oplus}$ sensor	10^{-3} mol L^{-1}	[156, 157]
penicillin	penicillinase	$H^{\oplus}$	pH electrode	0.2–70 mmol L^{-1}	[158]
sulfate	sulfate reductase	$HS^{\ominus}$	Ag_2S ISE		[159]
antigen or antibody	partner of couple	antigen-antibody couple	$K^{\oplus}$ ISE	0–100 ppm	[187]

lization of mediators presents difficulties. An immobilization effective enough to prevent loss of the mediator from the transducer with time is usually accompanied by severe deactivation of that mediator.

Potentiometric Biosensors: Biosensors with potentiometric transducers can be used in any situation where protons are either generated or removed in the course of the enzymic reaction. Most types are based on a pH electrode, as can be seen from Table 8, which gives a short summary of potentiometric biosensors.

A pH measurement is an alternative way of following the glucose conversion reaction (eq. (3)) already described under amperometric biosensors. In this case the change in pH caused by the formation of gluconic acid is measured. Fats may be determined by measuring the change in pH caused by the formation of fatty acids, as listed in Table 8. Though still at the development stage,[151] this method seems to offer great promise, especially in view of the numerous potential applications in food technology. Recently stable lipases which even allow the determination of fats in organic solutions have been isolated.

The performance of all biosensors that work by means of a pH measurement is greatly affected by the buffer capacity of the sample solution. A lipophilic layer or membrane between the reaction zone and the buffer system decreases this dependence. Whereas with amperometric sensors, which consume some of the substance being determined during the course of the measurement, deposits of proteins formed on their surface attenuate the signal, with potentiometric sensors only the response time and not the magnitude of the signal is affected, since here the measurement does not consume the substance. This can be a crucial factor in the case of implants.

The conversion of aspartam by the enzyme L-aspartase is of interest in connection with the production and use of artificial sweeteners. The NH_3 generated in the reaction can be determined by the well-known NH_3 gas electrode. This type of electrode has also been used successfully for some time to determine urea in urine by means of the enzyme urease. The enzymic hydrolysis of urea [reaction (4)], like the oxidation of glucose, allows the use of various chemosensors as transducer.

$$CO(NH_2)_2 + 2\,H_2O \xrightarrow{\text{urease}} 2\,NH_4^{\oplus} + CO_3^{2\ominus} \quad (4)$$

In aqueous solution the reaction products give the pH-dependent equilibria (5) and (6), which provide further spe-

$$NH_4^{\oplus} + OH^{\ominus} \rightleftharpoons NH_3 + H_2O \quad (5)$$

$$CO_3^{2\ominus} + H^{\oplus} \rightleftharpoons HCO_3^{\ominus} \underset{-H^{\oplus}}{\overset{H^{\oplus}}{\rightleftharpoons}} CO_2 + H_2O \quad (6)$$

cies for which transducers are available. Potentiometric ISEs are available for two of the reaction products, the ammonium and carbonate ions. Furthermore, the gases NH_3 and CO_2 which may be produced depending on the pH in the reaction zone can be detected by means of the appropriate gas electrodes mentioned above.[160] A urea sensor as described here can be made in the form of a simple triple-membrane configuration as shown in Figure 19.

Conductometry is another electrochemical transducer principle which can be applied to biosensors, since the progress of an enzymic reaction can also be measured by the change in the resistivity of the solution. However, as well as lacking selectivity, this method suffers from the fundamental difficulty that only the total resistivity can be measured and the change in resistivity is caused not only by the reaction, but also by the introduction of an ion-containing medium. A difference method has been proposed by *Watson*.[161] Con-

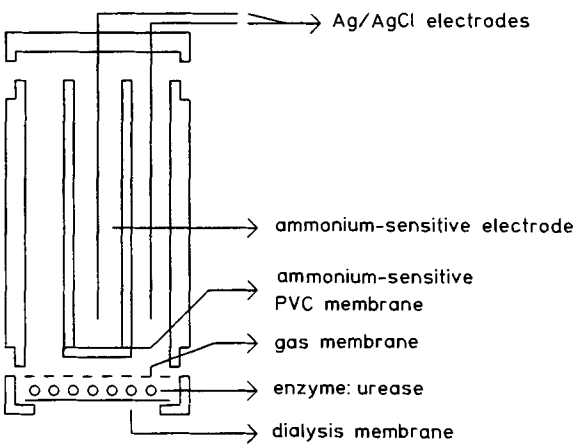

Fig. 19. Triple-membrane structure of, for example, a urea sensor.

ductometric biosensors for urea and for D-amino acids are described by *Rechnitz* et al.[162]

3.1.2. Biochips

The new microelectronic transducers are becoming increasingly important, as they make it possible to produce one-shot disposable biosensors. This offers a possible solution to the ever-present problems of poor storage properties and short lifetimes of biosensors. Even the problem of sterilization could be solved by sterile sensor elements which are introduced immediately before the measurement.

Special mention must be made here of ion-selective field effect transistors (ISFETs), whose small size, particularly, warrants their application as transducers in biosensors, as this factor is of great importance for catheter sensors in medical technology. Enzyme-modified ISFETs, known as ENFETs, consist in many cases of pH-sensitive ISFETs with an enzyme immobilized on their surface; this catalyzes the reaction of a substrate which generates or removes protons.

Examples of the use of ENFETs are the determination of glucose,[152, 163] urea, and penicillins,[158, 165] in which the appropriate enzymes were immobilized on the pH-sensitive surface of the ISFET with glutaraldehyde and bovine serum albumin, or in membranes. To compensate for errors caused by temperature fluctuations or by pH changes from effects other than the enzymic reaction, a differential measurement can be performed with two pH-ISFETs, one coated with the enzyme and one bare, as described in the first German patent for a biochip.[164]

Table 9. Enzymic sensors based on FETs. pH FETS serve as transducers.

Substrate	Enzyme	Product(s)	Range [10^{-3} M]	Refs.
glucose	GOD	gluconic acid	0–20	[163]
urea	urease	CO_2, $2NH_3$	0–6	[165]
penicillin G	penicillin G amidase	phenylacetic acid	1.5–50	[165]
penicillin	penicillinase	penicillic acid	0.2–20	[158]
triolein	lipase	fatty acids	0.6–3	[166]

The determination of triglycerides has also been performed by a differential measurement, with lipase immobilized in a polyvinylpyrrolidone membrane on the pH-sensitive surface of a pH-ISFET.[166] Table 9 gives a summary of the ENFETs that have been reported.

3.1.3. Optical Transducers

In addition to the well-proven electrochemical transducers, optical sensors have recently been exploited to an increasing extent for substrate recognition by enzymic reactions, since fiber-optic spectrophotometers and fluorimeters are now commercially available. The way in which these optical biosensors function will be described here with the help of a few examples.

Wolfbeis and *Trettnak*[167] have developed a biosensor for glucose determination using the reaction described in Eq. (3); this sensor contains as its transducer an oxygen optode which has already been described in Section 2.3. The glucose oxidase was bound to a nylon membrane by activated carboxyl groups (Immunodyne) and the membrane was attached to the surface of the optode.

Another approach of *Wolfbeis* et al.[168] is based on the intrinsic fluorescence of the enzyme concerned. Enzymes with FAD (flavine adenine dinucleotide) as prosthetic group change their fluorescence properties during the reaction with the substrate, because flavoproteins have different properties in their oxidized and reduced states. This change can be measured with optical fibers that have the enzyme held at their ends by a dialysis membrane. Experiments have been carried out on this system with glucose oxidase, lactate monooxygenase and cholesterol oxidase as enzymes.

An optical biosensor has been developed for controlling the biotechnological manufacture of penicillin. This sensor monitors the change in pH caused by the enzymic conversion of penicillin to penicillic acid; the measurement can be performed either electrochemically or optically.[169] For the latter the enzyme penicillinase was immobilized in a polymer together with a pH-indicator, as described in Section 2.3 for pH-optodes. Urea can be determined by an analogous method.[170]

These examples of optical sensors, which are summarized in Table 10, clearly illustrate that, like electrochemical biosensors, nearly all optical sensors depend on just a few basic principles, such as

1) the measurement of oxygen concentration by the fluorescence quenching of a dye (transducer: O_2 optodes),

2) pH-measurements (transducers: pH optodes), and

3) the determination of NADH fluorescence using a bifurcated light-guide.

Combining these measurement principles with different enzymes results in biosensors similar to those based on electrochemical transducers. There are no great differences in performance between them. Figure 20 shows the basic design features of an optical biosensor.

Table 10. Enzymic sensors based on optodes[a].

Substrate	Enzyme	Product	Transducer	Range [10^{-3} mol L^{-1}]	Refs.
ethanol	ADH/LDH	NADH	fiber-optic	0–1	[174]
glucose	GOD	D-gluconolactone	O_2 optode	0.1–20	[167]
urea	urease	ammonia	NH_3 optode	0.3–3	[170]
lactate	LMO	pyruvate	fiber-optic	0.5–1	[168]
penicillin	penicillinase	penicillic acid	pH optode	0.25–10	[169]

[a] Abbreviations: ADH = alcohol dehydrogenase; LDH = lactate dehydrogenase; GOD = glucose oxidase; LMO = lactate monooxygenase.

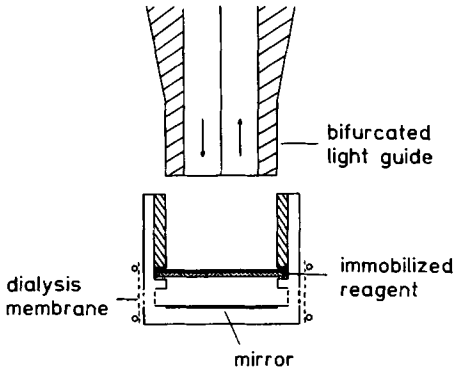

Fig. 20. Schematic arrangement of an optical biosensor.

3.1.4. Mass-Sensitive Transducers

A class of biosensors that have hitherto not been widely used are those based on piezoelectric crystals or surface acoustic wave (SAW) devices.[171] These provide a simple means of detecting changes in mass through the alteration in the resonance frequency of a crystal. If such a transducer is covered with a selectively adsorbing surface or absorbing film, the concentration of the ab- or adsorbed substance can be determined from the change in resonance frequency. Using a 9 MHz piezoelectric quartz crystal, for example, it is theoretically possible to measure mass changes as small as 10^{-9} g. *Guilbault* et al. describe sensors based on piezoelectric crystals coated with enzymes. The selectivity is provided by the formation of an enzyme-substrate complex, and the sensitivity is given by the stoichiometric mass increase given by the equation of the reaction. With immobilized formaldehyde dehydrogenase,[172] atmospheric formaldehyde concentrations in the range from 1 to 100 ppm can be detected, with choline esterase,[173] pesticides in the ppb range. Measurements in liquid media cause greater problems and are controversial. To maintain the theoretical sensitivity described in Equation (d), piezoelectric sensors should be subjected to a reproducible drying step in air before use.

3.2. Multienzyme Sensors

The repeated use of expensive coenzymes is possible if they are regenerated by a second enzyme.

The recycling method described by *Schepers* et al.[174] could be applied to many analytes. The fluorescence of the reduced coenzyme nicotinamide adenine dinucleotide (NADH) is measured in a flow-through cell using a fiber-optic device. The molecular mass of the $NAD^{\oplus}$ is increased by binding it onto polyethyleneglycol in order to trap it within the cell, together with an enzyme such as alcohol dehydrogenase, behind a dialysis membrane. When a second enzyme, e.g. lactate dehydrogenase, is also included behind this membrane, it becomes possible to regenerate the NADH by adding pyruvate. However, the need to add this reagent means that the device is no longer a sensor in the narrow sense, because a sensor should work without addition of reagents. Several enzymes, or even a whole enzyme series, could be necessary in cases where a single enzymic reaction step does not yield a substance which can be detected by a transducer.[114, 115]

3.3. Biosensors Based on Tissue Sections or Cell Cultures

Not only isolated enzymes but also entire groups of intact cells can be used as the basis for biosensors. Compared with the isolated enzymes, these often have the advantage of being active for longer periods, as the enzymes are kept in their natural environment. In this case an additional immobilization step for the coenzymes or cofactors is not necessary. However, such cell groups are often less selective, as they contain mixtures of enzymes.

Arnold and *Rechnitz*[175] published a table listing biosensors based on tissues and related materials. NH_3 or O_2 chemosensors are often used as transducers.

The principle of these devices will be explained by taking as an example a biosensor for hydrogen peroxide. As bovine liver contains relatively high concentrations of the enzyme catalase, a section of fresh tissue only 0.1 mm thick is immobilized with nylon mesh on the surface of a membrane-covered O_2 electrode. The hydrogen peroxide whose concentration is to be determined undergoes enzymic decomposition to oxygen and water, and the oxygen thus produced is measured amperometrically. This sensor is less sensitive to fluctuations in temperature and pH, and has a longer lifetime than a biosensor containing an isolated enzyme.[176] Another device of this kind which is frequently cited is the "bananatrode" which has been described by *Rechnitz* et al.[177] Here a thin slice of banana in front of an O_2 sensor is used as a detector for dopamine, which undergoes oxidation by the enzyme polyphenol oxidase present in bananas. The consumption of oxygen is then measured.

3.4. Microbial Biosensors

The majority of biosensors based on immobilized microorganisms function with amperometric oxygen sensors as transducers.[178] Biosensors for the determination of phosphate, nitrate, nitrite, sulfite, methane, and phenol have recently been described, but none has yet achieved a commercial breakthrough.

The determination of phosphate was performed with a sensor based on the microorganism *Chlorella vulgaris* in immobilized form. An O_2 optrode was used to measure the increase in the photocurrent on introducing phosphate. The photocurrent was found to be a function of the phosphate concentration in the range from 8 to 70 mmol L^{-1}.[179] *Karube*, *Kitagawa* et al.[180] have developed a microbiological sensor for alcohol using a pH ISFET as a transducer. For this the acetic acid bacterium *Gluconobacter suboxydans* was immobilized on the ISFET behind a gas-permeable membrane. Ethanol which diffuses in through the membrane is converted to acetic acid by the bacteria. This biosensor can be used for the determination of ethanol in the range from 3 to 70 mmol L^{-1}.

3.5. Immunosensors

Antibodies (Ab) and antigens (Ag) (or haptenes) bind specifically and strongly to each other. Techniques for following such reactions in order to determine one of the reac-

tion partners have up to now relied mainly on labeling one of the immunoreactands. This is the principle used in immunoassays, which are now indispensable in biochemical analysis. Immune reactions are subject to the limitations imposed by the law of mass action. In the equilibrium reaction between the free antigen (Ag) and the antibody (Ab) to form the antigen–antibody complex, the equilibrium ratio between the concentrations of the complex and of the free reaction partners is determined by the affinity constant K [Eq. (f)].

$$K = [AgAb]/[Ag][Ab] \quad (f)$$

In immunoassays quantitative determinations can be carried out by means of competitive binding tests or sandwich tests. In competitive tests labeled antigens are used. If radioactive labeling is used, the procedure is called a radioimmunoassay (RIA). If instead, an enzyme is covalently bound to the antigen (horseradish peroxidase or alkaline phosphatase are often used), the procedure is called enzyme immunoassay (EIA). The labeled antigen and the antigen to be assayed compete for the binding of the immobilized antibody, and the concentration of the antigen can be determined by comparison with a reaction of a known concentration of the pure antigen. Sandwich tests are carried out with labeled antibodies. When radioactive labeling is used the measurement is described as an immunoradiometric assay (IRMA), whereas if the antibody is attached to an enzyme it is called an enzyme-linked immunosorption assay (ELISA). The antigen which is to be determined binds to an antibody which is immobilized on a support, and is quantitatively determined by means of a second labeled antibody.

Both systems have important disadvantages. Purified antibodies and antigens are required. The calibration curves are only linear over a small concentration range. With radioactive labeling there are problems of waste management. Although an immunoassay is simple to perform, it involves a succession of stages, and often a separation step, requiring several hours of work.

In the last few years several immunosensors have been developed in which the immunological reaction is measured directly. These sensors use electrochemical, optical, or piezoelectric transducers or capacitance bridges. It should eventually be possible to perform the most important types of immunochemical analysis with disposable sensors.[181]

Enzyme immunoelectrodes comprise the transducer (electrode), the immune reaction system, and an enzyme indicator and are based on the usual EIA principles, except that the product of the enzyme-catalyzed reaction (often H_2O_2) is detected electrochemically and not by photometry.[182, 183]

Ion-selective membrane electrodes have also been used for the determination of antibodies. The method is described by *Rechnitz* et al.,[184] in which the corresponding antigen is covalently bound to an ionophore of the benzo-crown-ether group and immobilized in a PVC membrane to give an electrode sensitive to alkali metal ions. The change in the potential of the electrode which occurs on adding the appropriate antibody is caused by the alteration of the properties of the ionophore when the antibody binds to the antigen–ionophore complex. Another type of immunosensor is based on the antigen-induced change in the potential of a chemically modified semiconductor surface (TiO_2), the mechanism of which is still not understood.[185] Based on early fundamental studies on potentiometric immunosensors during the period 1978–89, the interdisciplinary research center for chemo- and biosensors at the Westfaelische Wilhelms University (FRG) has just elucidated the general mechanism of immunologically-induced changes in electrode potential.[186, 187] There are in principle many different antibodies for a particular antigen or haptene, so that a large variety of organic molecules can be selectively determined. If the remaining problems of standardization and storage life can be solved, this analytical technique should revolutionize at least molecular analysis, since a potentiometric immunoassay is fast, sensitive, and extremely economic.

Immunosensors based on mass-sensitive transducers (piezoelectric crystals and SAW devices) exploit the mass increase which results from the immune reaction.[188] Here again measurements in liquids present problems.

Immune reactions at surfaces also alter certain optical properties, on which optical sensors are based. One optical effect that can be used to determine antigens with immobilized antibodies is the change the resonance angle in surface plasmon resonance (SPR) spectroscopy[189] when immunocomplexation forms a film on a silicon or metal oxide base layer. Others are the change in light scattering from a coated glass surface when an immunocomplex is formed,[190] and changes in the reflection and absorption of a light beam (evanescent wave technique).[191]

A strict definition classifies immunosensors not as true sensors, but as dosimeters, because the immune reactions are not reversible. Under suitable conditions (e.g. by altering the pH) it is possible to break down the biocomplex to recover the antibody and the antigen, allowing a quasi-continuous measurement sequence.[186, 187]

A continuously operating type of immunosensor based on competitive reactions has been developed; here the analyte and a heterobifunctional complex compete for binding sites on an immobilized antibody.[192]

Nonspecific binding is a difficulty which limits the sensitivity of immunosensors in many applications. This problem has been investigated in detail by *Cullen* and *Lowe*.[193]

3.6. Biosensors Based on Receptors

A very promising approach is the development of biosensors in which individual receptors or receptor structures from living organisms are immobilized on transducers.[194] The advantages of receptors over enzymes, for example, lie in very high sensitivities and short response times. It is known, for example, that some marine species can recognize substances at concentrations as low as 10^{-13} mol L^{-1}. However, the problems of isolating receptor molecules and of their instability when immobilized are still so great, that this idea must be regarded at present as an interesting approach with potential for future developments.

A sensor for the determination of glucose which is based on a receptor protein has been developed by *Schultz* and *Meadows*.[195] This makes use of the competition between glucose and a glucose analogue, a dextran labeled with fluorescein isothiocyanate (FITC-dextran), for binding sites on

the glucose receptor protein concanavalin A labeled with rhodamine (Rh-Con A). FITC-dextran and Rh-Con A are sealed in a length of dialysis tube at the end of a bifurcated light guide with a diameter of 100 μm (Fig. 21). Light of a suitable wavelength excites FITC, which fluoresces. If the FITC is connected via the dextran to the Rh-Con A, the energy absorbed by the FITC is transmitted to the rhodamine, which then also fluoresces. If glucose diffuses

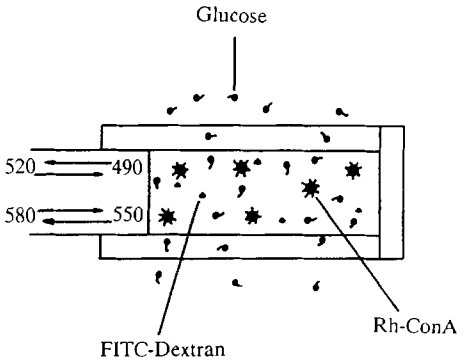

Fig. 21. Glucose sensor based on the use of a receptor[195]. The numbers represent the wavelengths (in nm) of the irradiating light (left) and fluorescent light (right).

through the dialysis membrane into the measuring cell, the dextran is partly displaced from its binding sites by the glucose and the measured FITC fluorescence increases, because less energy is transferred from FITC to rhodamine. From increase in fluorescence intensity the glucose concentration can be determined.

3.7. Applications of Biosensors

An important technological application of biosensors is the control of fermentation processes. Here it is desirable to measure continuously as far as possible, to ensure optimization of the fermentation process and to minimize the consumption of expensive nutrients. It is particularly important to monitor glucose, ethanol, lactate, cephalosphorins and penicillins.

Another area in which biosensors are used, is food technology and food testing. Of interest is the glucose content of wine and fruit drinks,[196] lactate production during milk processing,[197] and the freshness of fish, which is measured with a hypoxanthin sensor.[198]

An area of growing importance is monitoring the quality of water and effluents. Most of the sensors developed so far are based on the combination of microorganisms and transducers. Some sensors serve to determine individual constituents of water, such as phosphate, nitrite, and nitrate,[178] while others measure composite parameters through their inhibiting effects on microorganisms or enzymes. However, the latter are more like simple early warning systems (screening) than true sensors, as an alarm indication needs to be followed by a more precise analysis. Moreover, these systems work irreversibly. Such warning systems are used in particular to monitor pesticide contents or concentrations of heavy metal ions and the inhibition of the microorganisms is measured by the reduction in CO_2 production.[199] To obtain a quantity which can be related to the biological oxygen demand (BOD), changes in the respiratory rate of *Trichosporon cutaneum* are measured with an oxygen electrode.[200] A sensor of this type is already in routine operation in Japan.

A final example of a field in which biosensors are finding application is medical technology. The most frequently performed analyses are of glucose and lactate, and it is therefore in this area that the most intensive research is being undertaken. The desirability of in-vivo measurements, for example, to control an insulin pump, is giving impetus to the development of miniaturized biosensors. Here of utmost importance is the requirement that the reagents are biocompatible and physiologically harmless.

Already a few biosensors, based on electrochemical or optical transducers or on piezoelectric crystal measurements in the gas phase, are commercially available.

Analytical instruments have been developed to avoid some problems of biosensors. Here pretreatment of the samples can prolong the life of the sensor.

The early commercially available analytical instruments for medical technology are usually based on an oxygen or hydrogen peroxide electrode as a transducer, with an oxidase as the biochemical component. They permit analyses on whole blood for glucose content in the range from 0 to 30 mmol L^{-1} or lactate content from 0 to 15 mmol L^{-1}. A BOD-measuring instrument based on the BOD sensor described earlier is now also available.

A list of commercially available analytical instruments based on biosensors can be found in the article by *Owen*.[201]

4. Outlook

This article aimed to give a concise overview of the present state of development of chemical sensors that are already or might become important for chemical, medical, and environmental applications. However it does not claim to be exhaustive. In the field of biosensors alone there are, according to recent CAS on-line searches, over 3000 publications and over 300 patents, although there are at present barely a dozen types of commercially available sensors, of which more than a half are for glucose. One of the main reasons for this striking imbalance with regard to marketing success may be found in the low degree of interdisciplinary cooperation among scientists. Many of the publications go no further than demonstrating a reproducible effect observed for a single chemical substance. Often there is no investigation into the effects of interfering substances, nor an answer to the central analytical question: how accurately and reliably does the sensor measure the substance for which one is analyzing? Reports which only give information on reproducibility, measured on pure synthetic samples containing no interfering constituents, should be avoided in view of the present wealth of knowledge about sources of systematic errors. To an analytical chemist a report on the development of a new analytical method which tells one nothing about matrix effects, and therefore about its absolute accuracy (defined as coincidence with the true content in the sample) is like a report on a synthetic method for a new compound which was identified by elemental analysis alone (i.e. without

confirmation by universally recognized and indeed prescribed methods of modern structural analysis).

In the field of chemosensor development, as in that of ultra-trace analysis, there is a growing tendency to play down the importance of interfering effects. The disproportionately large amount of research effort devoted to the microelectronic aspects of modern transducers is pointless if not accompanied by a deeper understanding of the mechanisms by which substances are specifically recognized. The fundamental mechanisms of the molecular interactions taking place in these devices cannot be planned and optimized on purely engineering considerations; they depend on natural laws that one can use but cannot alter!

In summary it may be concluded that the development of sensors will advances further simply because there is a strong demand for it. The more research effort concentrated on the central problem of a selective molecular recognition, the quicker such advances will be achieved. Our present knowledge of mechanisms indicates that it is necessary to involve chemists from a wide variety of disciplines: theoretical, inorganic, organic, biochemical, analytical, and physico-chemical. The development of new sensors can only progress by an interdisciplinary approach, which must also include the collaboration of biologists, physicists, and medical scientists.

At this stage improvement in the transducer properties has a lower priority than improvement in the selectivity of chemosensors and the lifetime of biosensors. The transducers now available have adequate stability and sensitivity, and their full exploitation is prevented only by the laws of physical-chemistry or by shortcomings in the properties of the sensor elements.

The basic ideas of the novel approach to the theory of ion-selective electrodes described here were developed in 1975 by K. Cammann in his Ph.D. thesis. He would like to thank his academic teachers, Prof. Dr. G. Ertl and Prof. Dr. H. Gerischer, for many discussions and helpful suggestions. During a Humboldt-Fellowship, for which the Alexander von Humboldt Foundation is sincerely thanked, Prof. Dr. S. L. Xie could verify this far-reaching theory completely by means of the most modern experimental equipment. The basic research in this field during recent years was generously funded by the Deutsche Forschungsgemeinschaft (DFG) and the Fonds der Chemischen Industrie, which we have much appreciated. Grateful acknowledgement is also given to the Bundesministerium für Forschung und Technologie (BMFT) for its generous financial help to research in the field of biosensors at Münster. Last but not least, we owe a debt of gratitude to the State of Nordrhein–Westfalen, which is establishing a research institute for chemical sensors and biosensors (attached to the University of Münster) in cooperation with the Fraunhofer-Management-Gesellschaft (FhM). The aim of this interdisciplinary institute is to support applied research on all aspects of chemical sensing, including the development of complete measurement systems and monitoring equipment.

Optical Detection of Single Molecules in a Solid: A New Frontier in Optical Spectroscopy?

By *Dietrich Haarer** and *Lothar Kador**

On examining the emission spectrum of atomic hydrogen *Balmer* discovered a sequence of narrow spectral lines which didn't fit into the picture of classical physics. This observation triggered the birth of quantum mechanics. A comparable success story in molecular spectroscopy has not occurred since or, if there is such a story, the development stages have been smaller and less spectacular. This can be explained on the following grounds.

Firstly, larger molecules have a much larger variety of excited electronic states and, hence, the Hamiltonian cannot be solved without major approximations. Secondly, the molecular energy states in the condensed phase are, other than in diluted gases, not sharply defined but smeared out over a large energy interval due to intermolecular interactions. This phenomenon which smears out the well defined molecular states to broad, structureless bands is called inhomogeneous broadening.[1, 2] It is much more pronounced in amorphous materials than in ordered crystals. In spectroscopic experiments, it obscures the 'intrinsic' molecular information as is shown schematically in Figure 1. Recording

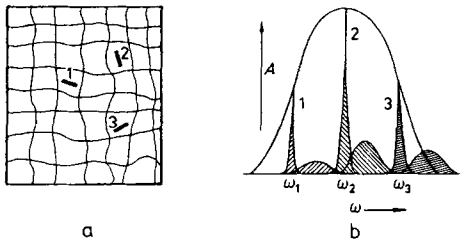

Fig. 1. Schematic representation of an ensemble of dye molecules in a disordered solid (a) and the corresponding distribution of their absorption frequencies (b)[11]. Although all the absorption lines belong to the same electronic transition of a set of identical molecules, their exact positions are affected by a variation of the dye–matrix interactions in the different local environments. In a straightforward optical experiment, the envelope of the full ensemble of lines yields the observed inhomogeneously broadened spectrum. A = absorption.

homogeneous, molecular absorption lines, i.e. absorption lines of single dopant molecules, has therefore until recently been an unfulfilled dream in the world of molecular spectroscopy.

In the past, scientists had to live with the above-mentioned 'nuisance' of inhomogeneous broadening and, hence, the success of straightforward optical spectroscopy in the solid state was rather limited. Following the advent of the laser with its unique capabilities of generating light of extremely narrow bandwidth or ultrashort pulses, a number of methods were devised as approaches to overcome this problem. They operate either in the time domain like two-pulse[3] and accumulated photon echo[4] or in the frequency domain like fluorescence line narrowing[5] and persistent spectral hole burning.[6, 7]

The experiments of the first group probe more or less all the absorbing centers in the inhomogeneous distribution and eliminate the differences of their absorption frequencies by sophisticated sequences of short light pulses, forcing the centers to emit coherent pulses of fluorescence radiation whose characteristics are solely determined by the homogeneous line shape. These methods are based on the similar technique of generating spin echoes in magnetic resonance.[8] They measure the homogeneous absorption linewidth on the time scales of picoseconds (two-pulse photon echo) and microseconds (accumulated photon echo) and are thus able to reveal fast time dependences which may occur in disordered matrices due to structural relaxation processes.[9, 10] On the other hand, it is difficult to decide with these methods if the limiting 'natural' linewidth, the homogeneous width, is really the same for all the molecules in the sample or if there is some distribution. In the latter case, the measurements yield an average value.

The second group of the above-mentioned experimental techniques selects and probes only a small subset of the absorbing centers whose transition frequencies are identical to within roughly one homogeneous linewidth. The common feature of these methods is that the sample is illuminated with laser light of very small bandwidth so that only those dye molecules are promoted to the excited state whose absorption lines are in resonance with the laser. Since the excitation frequency can be varied throughout the inhomogeneous distribution, it is possible to investigate correlations between optical properties of the dopant molecules and their exact transition frequencies. With the technique of persistent spectral hole burning[11, 12] it was shown, for instance, that in some dye–matrix systems the matrix-induced electric dipole moments of the absorbers,[13, 14] the pressure shifts of their transition frequencies,[15] and partly even the homogeneous linewidths[14, 16] vary with the position in the inhomogeneous band, i.e. with the solvent shift and, thus, the transition frequency. These results indicate that imperfections and disorder in a solid do not only influence the absorption frequencies but also a number of other properties of the dopant molecules. Therefore, the question arises as to whether at least a subset of absorbers with identical transition frequency is characterized by a number of coinciding physical parameters.

In order to address this point, several spectroscopic experiments of ultra-high sensitivity have been carried out during the past three years, which were aimed at detecting and probing very few or, ideally, only one single absorber in a solid at low temperatures. In vacuum, the spectroscopy of single metal ions trapped in Paul cages has meanwhile become a well-established technique[17] since the fluorescence signals of these particles can be detected very sensitively without any background light present. In condensed matter, the situation

is distinctly more difficult. Due to diffraction effects, the probing light cannot be focussed to a volume much smaller than 1 μm^3 which still contains roughly 10^{10} matrix molecules. The latter give rise to Rayleigh and/or Raman scattering and, in fluorescence experiments, tend to obscure the desired signal of the dopant, the 'needle in the haystack'. Thus, the first ultra-sensitive measurement of this type[18] had a detection limit of five $Sm^{2\oplus}$ ions in a CaF_2 crystal. The excitation of the ions was hereby performed using a fixed-frequency laser. The first spectra of single molecules were recorded in an absorption experiment with a double-modulation technique.[19] The sample was a molecular host crystal of *p*-terphenyl doped with pentacene. Single absorption lines of dopant molecules were selected by tuning the laser frequency to positions way out in the wings of the inhomogeneous absorption band. The same system was subsequently investigated by a different group of researchers using an improved fluorescence technique.[20] They observed that some of their single-molecule signals disappeared and reappeared in the course of a few seconds and they explained this effect as being due to single-molecule hole burning. However, the latest investigation of pentacene in *p*-terphenyl[21] revealed a far more fascinating origin of the unstable signals. *Ambrose* and *Moerner* found that there are two classes of absorbing pentacene molecules in the crystal: Class I has stable absorption frequencies, whereas the transition lines of the Class II molecules jump spontaneously between two or more frequency positions.

Figure 2 shows a sequence of 22 fluorescence excitation spectra which were recorded successively in a spectral region around 592–593 nm. These data clearly indicate the presence of three Class I molecules whose fluorescence signals appear as stable ridges, and one absorber of Class II. The absorption frequency of the latter varies from one scan to the next. In fact, the corresponding absorption line can change its position several times in a 2-minute laser scan and, as a consequence, it gives rise to one or more broad fluorescence signals in some spectra and seems to be totally absent in others. No influence of the intensity of the probing light on the frequency jumps was detected.

This is the first report[21] of spectral diffusion of single molecules and, most interestingly, the effect was observed on a crystal rather than an amorphous sample. It shows that new and unexpected physical phenomena can be found in ultra-sensitive optical experiments which probe single, separate absorbing centers. In conventional site-selective techniques such as persistent spectral hole burning, these effects are not immediately visible since the optical experiment averages over many molecules.

So far, most of the extremely sensitive spectroscopic experiments which were capable of detecting signals from individual centers were performed on the molecular crystal *p*-terphenyl doped with pentacene. In several respects this system is ideally suited, because it is characterized by a large optical absorption cross section, narrow homogeneous lines, and an extremely low quantum yield for photochemical reactions. Similar conditions may be found in a number of other organic mixed crystals containing strongly absorbing dye molecules. It will be an experimental challenge, however, to apply such a technique to inorganic or amorphous systems, since the oscillator strengths of inorganic ions are usually smaller by several orders of magnitude and ions or molecules in glasses tend to exhibit far higher hole-burning quantum yields. On the other hand, the study of spectral-diffusion and hole-burning processes on a single-molecular level in a glass would certainly contribute to our present understanding of the amorphous state in general. Another interesting direction in which the experiments could be extended would be the investigation of single homogeneous lines close to the center of their absorption band rather than far out in the wings. For this purpose, samples of much lower dopant concentrations would have to be used. These measurements should reveal details about the dye–matrix interaction for molecules sitting in almost unperturbed equilibrium positions. However, the chemical purity of the samples will be of utmost importance in these investigations. The results obtained thus far on the pentacene/*p*-terphenyl system are very encouraging and can be considered as a step towards molecular spectroscopy as described by 'Molecular Hamiltonians'.

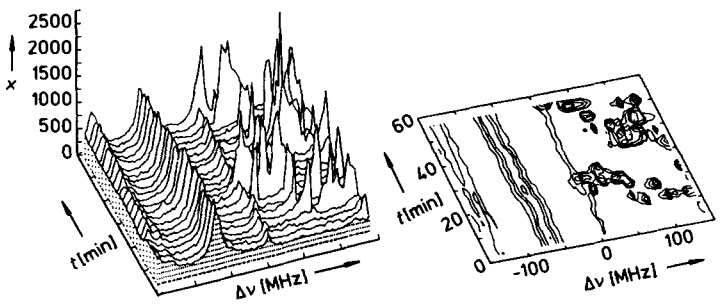

Fig. 2. Time dependence of the fluorescence excitation signals of single pentacene molecules in a *p*-terphenyl crystal[21]. Left: three-dimensional representation of 22 individual spectra which were recorded successively; x = number of photons per s; right: contour plot of the signal intensities as a function of excitation frequency and time. The recording time was 2 minutes for each spectrum.

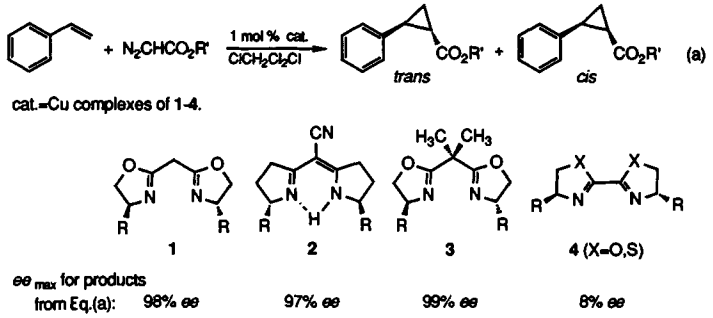
Bis(4,5-dihydrooxazolyl) Derivatives in Asymmetric Catalysis

By *Carsten Bolm**

The successful use of metal complexes for enantioselective catalysis is largely dependent on the structure and electronic properties of chiral ligands. These ligands should form an ideal, asymmetric environment at the catalytically active metal center, thereby allowing molecular recognition of the substrate and subsequent stereoselective reaction. To achieve efficient catalysis with high turnover numbers, the spatial requirements of the ligand must be minimized to avoid steric hindrance of the reaction partner. Especially the development and investigation of tailor-made, chiral mono- and bidentate phosphanes has led to a greater understanding of the prerequisites for chirality transfer.[1]

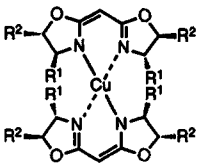
Nitrogen-containing chelating ligands are acquiring increasing importance in this respect. Their synthesis is often advantageous since the starting materials can be obtained in optically pure form from the "chiral pool". Thus, separation of enantiomers, as in the synthesis of optically active phosphanes, is no longer necessary. Because of their structural diversity and the wide-ranging possibilities for chemical modification and de novo synthesis, amino acids have become important nitrogen-containing building blocks for enantiomerically pure ligands.

In a paper that attracted much attention, *Masamune* et al. reported at the end of 1990 on the catalytic enantioselective cyclopropanation of alkenes [Eq. (a)] with copper complexes of C_2-symmetric bis(4,5-dihydrooxazolyl)methanes (**1**).[2] This article was shortly followed by further reports from other groups on syntheses, complexation properties, and asymmetric catalyses involving structurally very similar ligand systems.[3-8]



As early as 1986, *Pfaltz* et al. reported the synthesis of C_2-symmetric semicorrins (**2**) derived from pyroglutamic acids.[9a] The use of metal semicorrinato complexes allowed efficient control of the enantioselective cyclopropanation of olefins with diazo compounds (M = Cu; ee_{max} 97%) [Eq. (a)] as well as the asymmetric reduction of α,β-unsaturated carboxylic esters and amides with sodium borohydride (M = Co; up to 99% *ee*).[9]

The ligands used by *Masamune* et al., **1**, may be obtained directly from diethyl malonate and the corresponding β-amino alcohols in a reaction catalyzed by dichloromethylstannane.[2] Enantiopure β-amino alcohols are synthesized by racemization-free reduction of the corresponding amino acids. Deprotonation of **1** with *n*BuLi followed by addition of $CuCl_2$ gives the copper(II) complexes **5**, which can be purified by chromatography. The crystal structure of **5d** was determined by *Lehn* et al. in order to investigate the possibility of forming optically active, double-stranded helical complexes.[3] For the asymmetric catalytic cyclopropanation of olefins, **5** is activated by addition of phenylhydrazine.[2] The cyclopropanation of styrene with ethyl diazoacetate [Eq. (a), R' = Et] in the presence of **5a–5c** as catalysts occurs with good yields and high enantioselection. Two diastereomeric products are formed in a *trans*:*cis* ratio of about 2.5:1. The enantiomeric excess of the two enantiomers is strongly dependent on the substituents R on the ligand. The best results are obtained when the ligand bears bulky substituents such as *tert*-butyl (complex **5a**: *trans*, 90% *ee*; *cis*, 77% *ee*).[2]



5a: R^1 = *t*Bu, R^2 = H
5b: R^1 = *i*Pr, R^2 = H
5c: R^1 = Ph, R^2 = H
5d: R^1 = CH_2OSi*t*BuMe$_2$, R^2 = Ph

The stereoselectivity is also influenced by the structure of the diazoacetate. Use of the chiral cyclopropanation reagent (−)-menthyl diazoacetate improves the diastereomeric ratio and increases the enantiomeric excess [*trans* (98% *ee*):*cis* (96% *ee*) = 86:14].

Evans et al. reported that copper complexes of **3** increase the enantioselectivity still further.[4] The geminal dimethyl groups prevent enolization of the ligand, which therefore reacts in *neutral* form with copper(I) triflate to give a catalytically active complex. In this case, the cyclopropanation of mono- and 1,1-disubstituted olefins with *achiral* diazoesters affords very high optical yields (up to 99% *ee* for styrene) and excellent *trans*/*cis* ratios (up to 94:6 for styrene). The reaction can be carried out at room temperature and 0.1 to 1 mol % of the complex is sufficient for efficient catalysis. The bis(dihydrooxazolyl)propanes **3**, which should form a six-membered ring chelate with copper ions, are more effective ligands than the tetrahydro-2,2'-bioxazoles **4**, for which only a five-membered ring chelate is expected.

For the enantioselective hydrosilylation of acetophenone [Eq. (b)], *Brunner* and *Obermann* reported the use of rhodium complexes with dihydrooxazolylpyridines (**6**) as nitrogen-containing chelating ligands in 1989.[10a,b] An enantiomeric excess of 83% was achieved with a complex prepared in situ from dihydrooxazolylpyridine (**6**, R = *t*Bu) and [{Rh(cod)Cl}$_2$]. The enantioselectivity is strongly dependent on the ligand/metal ratio, as well as on steric effects due to the reducing silane and to the substituents on the dihydroox-

St. Johanns-Ring 19, CH-4056 Basel (Switzerland)

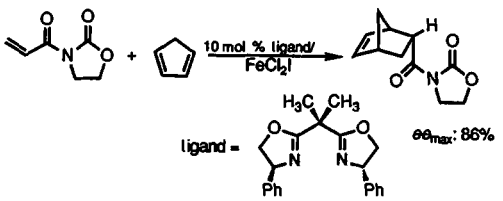
azole.[10a–c] Small structural changes have significant effects. Furthermore, dihydrooxazolylpyridine complexes of copper were found to catalyze the monophenylation of diols with triphenylbismuth diacetate. Optical yields of up to 50% *ee* were thereby achieved.[10d]

Nishiyama et al. introduced the concept of C_2 symmetry to this field with the synthesis of bis(4,5-dihydrooxazolyl)pyridines (**7**).[11] They react with rhodium trichloride to form 1:1 complexes, one of which, [**7** · $RhCl_3$] (R = *i*Pr), has been structurally characterized. After addition of Lewis acids, especially silver salts, these rhodium complexes containing **7** become efficient catalysts for the asymmetric hydrosilylation of ketones [Eq. (b)]. Use of 1 mol % of the rhodium complex followed by acidic workup affords optically active alcohols in good yields with enantiomeric excesses of up to 94%.

The tetrahydro-2,2′-bioxazoles **4** (X = O) were tested by *Helmchen* et al. as ligands in the rhodium-catalyzed asymmetric hydrosilylation of acetophenone [Eq. (b)].[6] The 1:1 complexes [**4** · {Rh(cod)PF_6}] and [Rh(cod) · **4**] (X = O, R = *i*Pr) show only low enantioselectivities. As found for the dihydrooxazolylpyridines of *Brunner* et al., the enantiomeric excess can be increased (up to 84% *ee* for **4**: Rh^I = 10:1 with X = O, R = Bn) by increasing the ligand/Rh^I ratio. Tetrahydro-2,2′-bithiazoles (**4**, X = S) also effect chirality transfer, but they are less effective (ee_{max} = 50% for **4** with X = S, R = Bn).

Bolm et al. synthesized structurally related 1,2-bis(4′,5′-dihydrooxazolyl)benzenes (**8**), which also act as ligands.[5] After addition of zinc or palladium chloride, they form 1:1 complexes, which were investigated in solution by NMR spectroscopy. The X-ray crystal structure analyses of a palladium and a zinc complex show that the metal salts are complexed through the nitrogen atoms of the ligand. The first attempts to carry out a catalytic reaction indicated that the complexes are not stable enough. Therefore, the addition of stabilizing ligands (such as phosphanes) is necessary.[5b]

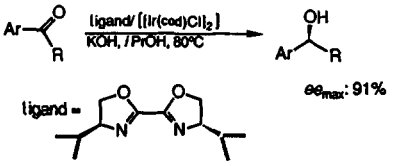
The iron(III) complex of the bis(dihydrooxazolyl) propane **3** (R = Ph) catalyzes the Diels–Alder reaction of cyclopentadiene with the bidentate dienophile 3-acryloyl-1,3-oxazolidin-2-one [Eq. (c)].[7] *Corey* et al. reported that treatment of **3**



(c)

with $FeCl_2$ and iodine resulted in formation of an active complex, presumably [**3** · $FeCl_2I$], which catalyzes the formation of the *endo* cycloaddition product with high selectivity. The use of 10 mol % of the complex at −50 °C in dichloromethane/2-nitropropane results in an enantiomeric excess of 86% (*endo*:*exo* = 99:1). The catalytically active species is presumably [**3** · FeX_2]$^{\oplus}$ (X = Cl,I).

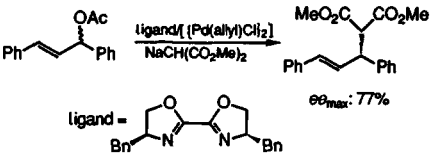
It is of little surprise that, after their investigations of C_2-symmetric semicorrin ligands,[9] the group of *Pfaltz* also employed bis(dihydrooxazolyl)alkanes as chiral ligands for enantioselective catalysis.[8] The results obtained for the asymmetric cyclopropanation of olefins with copper complexes of bis(dihydrooxazolyl)methanes (**1**) are in agreement with the results described by *Masamune* et al.[2] Two further metal-catalyzed reactions were investigated. The hydrogenation of aryl alkyl ketones [Eq. (d)] with an iridium complex



(d)

formed in situ from [{Ir(cod)Cl}$_2$] and tetrahydro-2,2′-bioxazole **4** (X = O, R = *i*Pr) gives optically active alcohols with enantiomeric excesses of between 47 and 91%. The corresponding complexes containing the anionic ligands **1** and **2** as well as the neutral compounds **3** (R = *i*Pr) and **4** (X = O, R = *t*Bu) do not exhibit catalytic activity.[8]

The nucleophilic allylic substitution of 1,3-diphenylprop-2-enyl acetate with sodium dimethyl malonate is catalyzed by 2 mol % of a palladium complex of tetrahydro-2,2′-bioxazole **4** (X = O, R = Bn) [Eq. (e)]. The product is obtained



(e)

in good yield with an enantiomeric excess of 77%. Again, complexes containing bulky ligands such as **4** with *t*Bu show no activity under these conditions.[8]

The ready accessibility and the high structural variability of bis(dihydrooxazolyl) derivatives and tetrahydro-2,2′-bioxazoles make them attractive, very promising new ligand systems, which may be of importance for other metal-catalyzed processes as well. The successful use of chiral dihydrooxazoles in diastereoselective reactions by *Meyers* et al.[12] as well as the investigations of *Pfaltz* et al. and *Brunner* et al. on enantioselective catalysis with semicorrins[9] and dihydrooxazolylpyridines[10] have provided the groundwork for the development of these new classes of ligands.

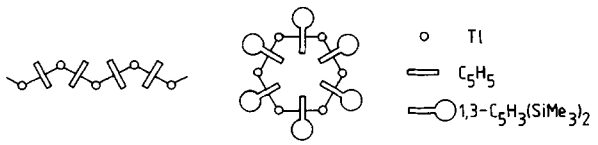
Monovalency of the Third Main-Group Elements: News from EX-Type Compounds

By *Peter Paetzold**

To start with divalent derivatives of the fourth main group elements, we can easily classify the structural diversity by taking the fluorides EF_2 as examples. The molecules, CF_2, SrF_2, GeF_2, SnF_2, and PbF_2, are stable in the gas phase at elevated temperatures. Higher molecular aggregates E_nF_{2n} may be held together either mainly by covalent E–E or mainly by polar E–F interactions. The C–C double bond of the volatile C_2F_4, metastable at room temperature with respect to disproportionation into C and CF_4 as well as to polymerization, represents an example of E–E interactions. On the other hand, in crystalline Sn_4F_8 an eight-membered ring Sn_4F_4 includes four bridging F atoms, while another four F atoms are terminally bonded to the Sn atoms and interact weakly with neighboring molecules. The solid compounds of the type EF_2 can also be differentiated according to covalent E–E interactions, as in poly(tetrafluoroethylene), and polar E–F interactions, as in ionic PbF_2.

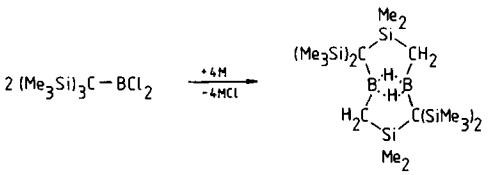
Such a structural system turns up again, more or less, in the third main group with compounds of the type EX of elements E in the oxidation state + I. Solids with mostly ionic E–X interactions are found among the halides of the heavier elements in this group, InHal and TlHal, which crystallize in a CsCl, distorted NaCl, or α-TlI structure. On looking closer at InCl, for example, deviations from the ideal NaCl structure are detected that make some In–In interactions possible. Similarly, Tl–Tl interactions may be found in α-TlI. Solids with substantially covalent E–X interactions are represented by the organometallics $In(C_5H_5)$ and $Tl(C_5H_5)$, whose structure is characterized by zigzag chains of type **1** with cyclopentadienyl groups pentahapto bonded to each of two E atoms. A more complex example for a solid of type EX is provided by $Ga[GaCl_4]$ with long, predominantly ionogenic bonds between $Ga^{\oplus}$ and $GaCl_4^{\ominus}$ (318 pm) besides short, predominantly covalent bonds between Ga^{III} and Cl in the $GaCl_4$ tetrahedra (218 pm).



1 **2**

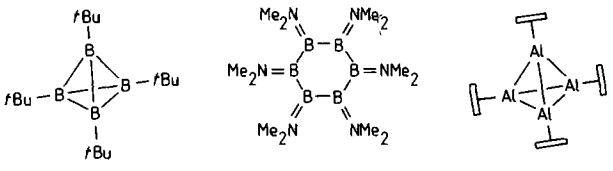
Molecules of the type E_nX_n containing E–X–E bridges are well known for thallium. An ideal example is represented by the cubane-type structure of $Tl_4(OR)_4$ in which each Tl is coordinated to three O atoms and vice versa (symmetry group T_d). The above-mentioned zigzag chains of $Tl(C_5H_5)$ with *trans* orientation within a Tl_4 chain fragment must give way to a *cis* orientation and hence to a ring structure when one side of the cyclopentadienyl moiety exhibits a high steric demand, as in $[Tl_6\{1,3\text{-}C_5H_3(SiMe_3)_2\}_6]$, which was found to be a six-membered ring compound of type **2**.[1] The molecule AlF in an argon matrix behaves in a way typical for the combination of a metal and a nonmetal: it dimerizes to give a four-membered ring with F bridges and not a molecule FAl=AlF with E–E bonds.[2]

Among dimeric molecules E_2X_2 with EE bonds, a linear chain of the type X–B=B–X is predicted in the case of boron, which would result in the occupation of symmetrically equivalent orthogonal π orbitals and thus a triplet ground state. For the heavier elements, a E=E double bond which is made up from two π bonds is also feasible, leading to a singlet ground state. The cyclopentadienides $(R_5C_5)EE(C_5R_5)$ (E = In, Tl; R = $PhCH_2$) have a well-known structure with a *trans* orientation of the η^5-ligands across the E–E axis (symmetry group C_i).[3] Since the In–In and Tl–Tl distance of 363 pm in each case is considerably longer than in the metals themselves (334 and 340 pm, respectively), the dimeric arrangement with weak E–E interactions may be caused mainly by steric factors. The reduction of $RBCl_2$ (R = $(Me_3Si)_3C$) by Na/K alloy gives a product, according to Equation (a), which makes an intermediate of the type RB=BR reasonable.[4]



(a)

Molecules of the type E_nX_n (n > 2) are well-established in boron chemistry. Closed Δ-faced polyhedra, such as the tetrahedron, Δ-dodecahedron, and tricapped trigonal prism, were shown to represent the structures of B_4Cl_4, B_8Cl_8, and B_9Cl_9, respectively.[5] Since the number of polyhedral edges is larger than the number of electron pairs available for the cluster skeleton, these molecules belong to the class of nonclassical, electron-deficient compounds, which cannot be represented by structural formulas in which lines connecting neighboring atoms mean classical bonds set up by two electrons. Moreover, these molecules show electron-"hyperdeficiency", violating Wade's rules for the counting of cluster electrons, which stipulate n + 1 skeletal electron pairs for a closed polyhedron with n vertices. Only n pairs are available for B_nCl_n. The stability of these closed polyhedral boranes, in spite of their hyperdeficiency, had been ascribed to electronic effects exhibited by the chloro ligands. Recently, however, the tetrahedral structure of the molecule B_4tBu_4 (**3**) has been proven, which turned out to be unexpectedly stable



3 **4** **5**, = C_5Me_5

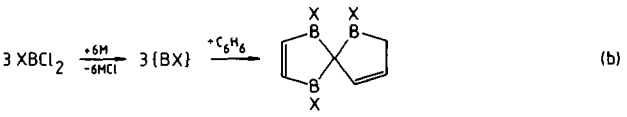
[*] Prof. Dr. P. Paetzold
Institut für Anorganische Chemie der Technischen Hochschule
Templergraben 55, W-5100 Aachen (FRG)

though lacking skeletal electrons as well as electron-rich ligands.[6] The amino groups of $B_6(NMe_2)_6$ (**4**) apparently determine the structure by their electron-donating effect: instead of an electron-deficient cluster structure, a six-membered ring of B atoms is present with six exocyclic B=N double bonds, for which the octet rule and a classical structural formula are valid.[7] The anionic closed polyhedral species $B_nH_n^{2\ominus}$ also obey Wade's rules, but need not be considered in this context, as the oxidation state of boron is lower than +1.

Little is known about molecules E_nX_n containing E–E bonds in the case of the heavier elements in the group. All the more fascinating, therefore, is the tetrahedral structure of the molecule $[Al_4(C_5Me_5)_4]$ (**5**) with C_5Me_5 groups that are bonded in a pentahapto manner to Al.[8] The average Al–Al bond length of 277 pm is shorter than in the metal (286 pm). In the related compound $[In_6(C_5Me_5)_6]$, an In_6 octahedron is distorted into a trigonal antiprism in which the C_5Me_5 groups, again pentahapto-bonded to In, are arranged in a propellerlike manner around a C_3 axis of the antiprism (symmetry group S_6).[9] The In–In bond lengths of 394–396 pm are so distinctly longer than in the metal (334 pm) that, different from the related aluminum species, only weak In–In interactions can be present. Mention should be made of the icosahedral anion $[Al_{12}iBu_{12}]^{2\ominus}$ as an example for the blossoming cluster chemistry of aluminum, even though this element is not entirely monovalent in this case.[10]

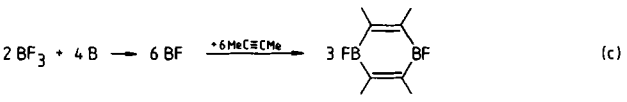
The monomeric molecules EX, finally, might be called "borylenes", "aluminylenes", "gallylenes", etc., or better—following IUPAC recommendations—boranediyls, alanediyls, gallanediyls, etc. The halides, EF, ECl, EBr, and EI, the spectroscopic properties of which have been thoroughly studied, are stable in the gas phase at elevated temperatures, with respect to disproportionation into E and $EHal_3$ (E = B, Al, Ga) or to crystallization as EHal (E = In, Tl). Gas phase structural analysis of the cyclopentadienides $In(C_5H_5)$, $In(C_5Me_5)$, and $Tl(C_5H_5)$ reveal that the ligands are again bound in a pentahapto fashion to E (symmetry group C_{5v}).

Experiments to trap boranediyls or alanediyls EX start from the postulated generation of such short-lived molecules in solution (e.g. on dehalogenation of $XEHal_2$ by alkali metals) or from the high-temperature generation in the gas phase of stable EX, which are then quenched and allowed to react at low temperature. The reduction of $(iPr_2N)BCl_2$ with Na/K alloy in aromatic hydrocarbons yields a variety of unexpected products; in benzene, for example, a triboraspiro[4.4]nonane is formed [Equation (b)].[11] The occurrence



(b)

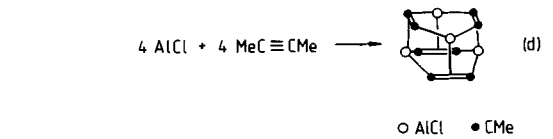
of such products may be rationalized by the formation of the reactive boranediyl BX (X = $NiPr_2$) that cleaves the arene. The molecule BF, formed by passing BF_3 over boron at



(c)

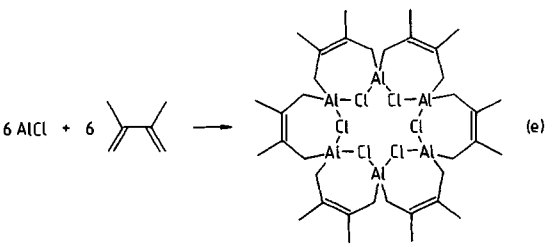
2000° C, may be reacted at low temperature with B_2F_4, CO, PF_3, or alkynes. Its reaction with 2-butyne, for instance, yields the corresponding diboracyclohexadiene, according to Equation (c).[12]

The molecule AlCl, easily formed from HCl and Al at nearly 1000° C, can be kept metastable at low temperature in a mixture of toluene and diethyl ether. This observation turned out to be fruitful for the chemistry of AlCl, though there is no structural evidence on the interactions between AlCl and the solvent molecules.[13] Similar to BF, AlCl in toluene–diethyl ether solution reacts with 2-butyne to give a dimetallacyclohexadiene, but in this case two six-membered rings are positioned above each other in such a way that the Al atoms of each form dihapto bonds to the double bonds of the other [Equation (d)].[14] The addition of 2,3-dimethylbutadiene to AlCl [Equation (e)] gives a product which has an S_6 axis. Six Al atoms at the vertices of a hexagon are connected by six Cl bridges lying alternately above and below the hexagon.[15] Finally the substitution of a Cl atom of AlCl



(d)

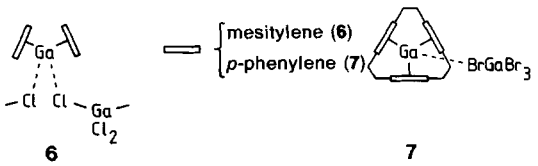
○ AlCl ● CMe



(e)

in solution seems to be a broadly applicable reaction. The treatment with $Mg(C_5Me_5)_2$, for example, yields the above-mentioned tetraaluminatetrahedrane, $Al_4(C_5Me_5)_4$, a molecule with a fascinating structure.

Monovalent gallium can be stabilized by hexahapto bonding to one, two, or even three aromatic six-membered rings. There are additional interactions of Ga^I with one or more halogen atoms of neighboring units of $Ga^{III}Cl_4$ or $Ga^{III}Br_4$. The bond lengths Ga^I-Hal are a good 100 pm longer than Ga^{III}-Hal. Chainlike associations may arise by linking Ga^I with two units of $GaCl_4$, as in the case of bis(η^6-mesitylene)-gallium(I)-tetrachlorogallate(III) (**6**),[16] but molecular associations are also known, such as for the [2.2.2]paracyclophane complex **7** in which the three lines from the central Ga atom to the centers of the *p*-phenylene rings are almost coplanar.



6 **7**

The boranediyls, alanediyls, and gallanediyls are no match for the carbenes, silanediyls, and germanediyls, in quantity

of available information. In terms of the structural diversity and the unorthodox reactivity, however, they outstrip the more conventional diyls of the fourth main group.

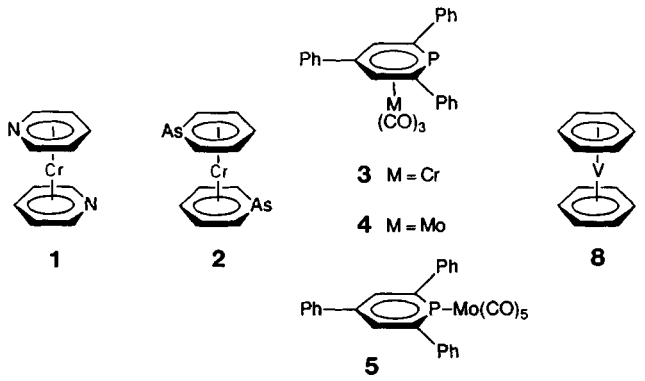
Bis(η^6-phosphabenzene)vanadium: Synthesis, Structure, Redox Properties, and Conformational Flexibility**

By *Christoph Elschenbroich,* Mathias Nowotny, Bernhard Metz, Werner Massa, Jens Graulich, Karl Biehler,* and *Wolfgang Sauer*

Dedicated to Professor Kurt Dehnicke on the occasion of his 60th birthday

The unsubstituted heteroarenes analogous to pyridine namely phospha-, arsa-, stiba-, and bismabenzenes,[2] a class of compounds that has been developed by *Ashe III*, offer the coordination chemist a rich field of activity. The heterocycles C_5H_5E (E = element of group 15) are ambidentate, since, in principle, they can bind to metals via the lone σ-electron pair at E (η^1) and/or via the π-electron sextet (η^6). In the case of the pyridine ligand σ-coordination clearly predominates, since bis(η^6-pyridine)chromium **1** can be obtained only if complexation is effected via an intermediate in which the N atom is sterically blocked by neighboring trimethylsilyl groups.[1] In the synthesis of bis(η^6-arsabenzene)chromium

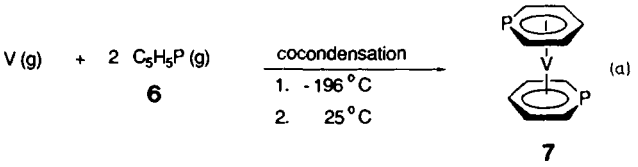


1 **2** **8**

5

2 this shielding is unnecessary.[3] η^6-Coordination of phosphabenzene—albeit only in ring-substituted form—is exemplified by a few ternary complexes[4] (first example: tricarbonyl(2,4,6-triphenyl-η^6-phosphabenzene)chromium **3**[4a]). The readiness of phosphabenzene to undergo η^6-coordination manifests itself, inter alia, in that on heating the η^1-complex **5** rearranges almost quantitatively to the η^6-complex **4**.[4b] We therefore engaged in the synthesis of binary phosphabenzene-transition-metal complexes and report here on the first representative of this series.[5] In order to study a possible conformational preference unaffected by steric effects we have chosen unsubstituted phosphabenzene **6** as ligand.[6]

Metal atom–ligand cocondensation affords bis(η^6-phosphabenzene)vanadium **7** in the form of reddish-brown, sublimable crystals, whose air-sensitivity is noticeably reduced compared to that of the free ligand **6** [Eq. (a)]. The robust



ness of the metal–ligand bond in **7** is reflected in the thermal stability (m.p. 210 °C) and the appearance of the molecular ion $7^{\oplus}$ in the mass spectrum as base peak. Anaerobically prepared solutions of **7** in aromatic solvents are storable without decomposition for several hours when exposed to air, whereas both bis(η^6-benzene)vanadium **8** as well as free phosphabenzene are oxidized instantaneously. This observation is consistent with the cyclovoltammetrically determined redox potentials (Fig. 1, Table 1), which feature the anodic shifts $\Delta E_{1/2}$ ($7^{\ominus}/7$, $8^{\ominus}/8$) = + 0.72 V and $\Delta E_{1/2}$ ($7/7^{\oplus}$, $8/8^{\oplus}$) = + 0.53 V.[8] That the shifts for reduction and oxidation of the pair **7**, **8**, in contrast to those of the pair **7**, **6** are very similar follows from the electronic structure of the bis(arene)vanadium complex ($\ldots e_2^4 a_{1g}^1$), according to which both reduction and oxidation of **7** as well as **8** involve the same redox orbital a_{1g}.

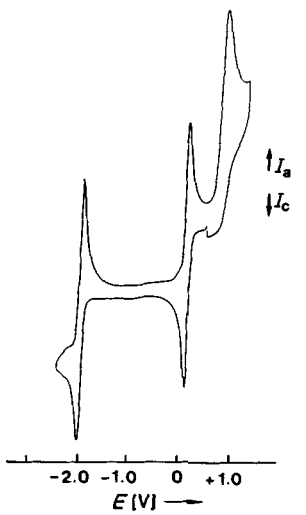


Fig. 1. Cyclic voltammogram of **7** in DME/$(n\text{-Bu})_4NClO_4$ (0.1 M), glassy carbon electrode, $T = -48$ °C, $v = 50$ mVs^{-1}.

[a] In DME/(n-Bu)$_4$NClO$_4$ (0.1 M) at glassy carbon vs. saturated calomel electrode, $v = 50\,mVs^{-1}$, data for **8** from [8]; [b] $E_{1/2} = (E_{pa} + E_{pc})/2$, $\Delta E_p = E_{pa} - E_{pc}$; [c] $= I_{pc}/I_{pc}$; [d] irreversible oxidation of a secondary product of the partially reversible reduction (ECE mechanism); [e] irreversible oxidation; [f] chemically only partially reversible reduction; [g] reversible at $-48 < T < +25\,^{\circ}C$; [h] reversible at $T = -48\,^{\circ}C$, irreversible at $T = 25\,^{\circ}C$; [i] expected value: $\Delta E_p = 2.2\,RT/nF = 42$ mV; [j] quasireversible.

The phosphorus heteroatom has a much stronger influence on the electron affinity of the free arene than in the complex-bound arene. This manifests itself in the redox potentials [$E_{1/2}$ ($C_6H_6^{\ominus}/C_6H_6$) = −3.42,[9] $E_{1/2}$ ($C_5H_5P^{\ominus}/C_5H_5P$) = −2.27; $\Delta E_{1/2}$ = +1.15 V] and in the electron-transmission spectra (ETS), which indicate that in the gas phase anion states for phospha-, arsa- and stibabenzene are binding.[10] Replacement of CH by E (E = P,As,Sb,Bi) modifies the electronic structure through the change in electronegativity and the reduction in the resonance integral β_{CE} as a result of increasing bond length. Figure 2 depicts the changes in the π-orbital energies for the benzene/phosphabenzene pair, whereby step ① outlines the removal of the

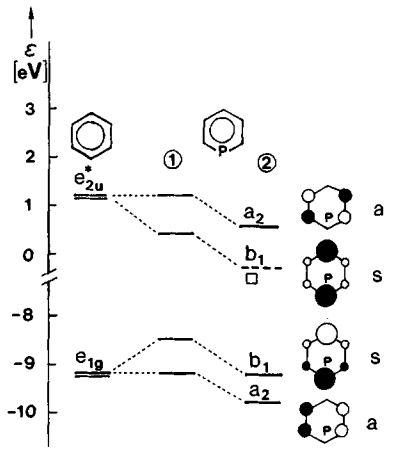

Fig. 2. Correlation diagram of the frontier orbitals for benzene and phosphabenzene, modified as described in [10]. ① Removal of the degeneracy as a result of the variation in the resonance integrals, $\beta_{CC} > \beta_{CP}$. ② Decrease in energy caused by increasing effective π-orbital electronegativity $\chi^{\pi}_C < \chi^{\pi}_P$ [11]. The positions on the energy scale are taken from PE [18] and ETS [20] measurements. □ Position inaccessible by ETS, since anionic state is binding.

degeneracies of e_{1g} and e^*_{2u} and step ② indicates the decrease in the energies of the π-MO caused by the inductive perturbation of the p_z orbital on the phosphorus atom.[11] With regard to the coordination properties, this means that phosphabenzene (relative to benzene) is a ligand with comparable π-donor but higher π-acceptor strength. Thus the central vanadium atom in **7** should carry a more positive partial charge than in **8**, and the anodic shifts $\Delta E_{1/2}$ ($7^{\ominus}/7$, $8^{\ominus}/8$) and $\Delta E_{1/2}$ ($7/7^{\oplus}$, $8/8^{\oplus}$) are plausible.[12]

Under this premise the EPR data are, at first sight surprising: the hyperfine coupling constants $a(^{51}V)$, $A_z(^{51}V)$ and $A_{x,y}(^{51}V)$ in **7** are larger and the couplings $a(^1H)$ are smaller than the corresponding values a, $A_{\parallel}$ and $A_{\perp}$ in **8**, even though **7** bears ligands with stronger acceptor properties (Fig. 3. and Table 2). This, however, is only an apparent contradiction, since the SOMO in **7** and **8** is almost void of ligand contributions. Rather, the increased $\delta^{\oplus}$ charge on the central metal atom in **7** leads to a contraction of the V($3d_{z^2}$) orbital, a weaker overlap V($3d_{z^2}$)-ligand (a_{1g}, σ), more effective spin polarization $(3d_{z^2})^1/(ns)^2$ of inner shells,[13] and thus to an increased Fermi contact interaction with the vanadium nucleus. The EPR spectrum of **7** in a glassy solution features an orthorhombic g-tensor (Fig. 3). The resolution of g_x and g_y (z axis = sandwich axis) shows that the frequency of ring rotation at 120 K in the rigid phase must be smaller than $5 \times 10^7\,s^{-1}$ (i.e. $\Delta g_{x,y}$ in frequency units). Thus, the EPR signal could be caused either by superposition of the spectra

Table 2. EPR spectroscopic data of **7**.

	T[K]⟨g⟩	g_x[a]	g_y	g_z[b]	a[c]	(^{51}V) A_x[a]	A_y	A_z[b]	a[c]	(^{1}H) $A_{x,y}$	A_z[b]

[a] x,y assignment uncertain; [b] calculated according to $g_z = 3g - (g_x + g_y)$ or $A_z = 3a - (A_x + A_y)$; [c] cf. **8**: $a(^{51}V) = 6.35$ mT; $A_{\perp}(^{51}V) = 9.2$ mT; $A_{\parallel}(^{51}V) = 0.65$ mT; $a(^1H) = 0.40$ mT; [d] in liquid and rigid DME respectively, coupling constants in mT; [e] in [2.2]paracyclophane as mixed crystal powder, coupling constants in mT.

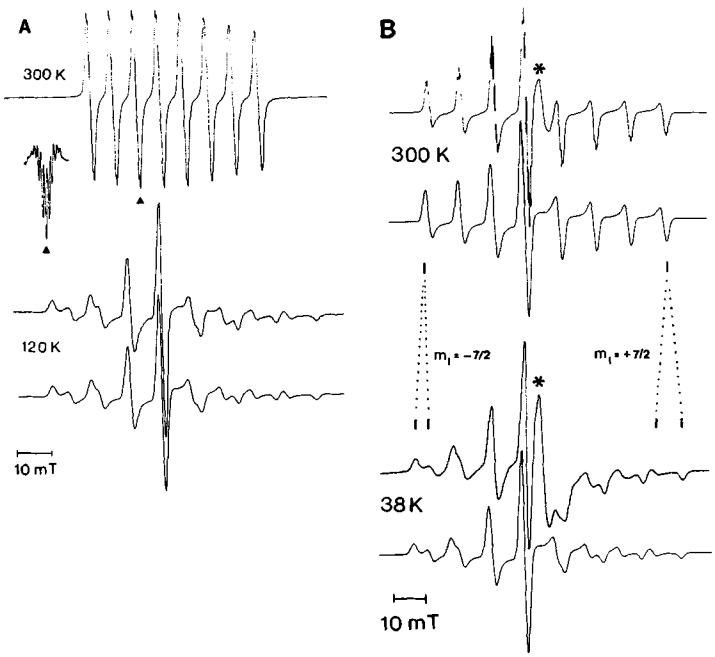

Fig. 3. EPR spectra of **7**, X-band, at various temperatures; lower traces are simulated [17]. Left **A**: In DME, liquid or rigid solution; right **B**: as mixed crystal powder (≈ 1 % **7** in [2.2]paracyclophane **9**). * Exchange narrowed signal of microcrystallites of pure **7**.

of two different rotameric forms of **7** each with an axial g tensor, or by the presence of a single rotamer **7** with a non-axial g tensor.[14] In both cases the excitation of ring rotation should lead to removal of the inequivalencies in the x,y planes. As a matrix which permits variation of temperature over a wide range we have chosen [2.2]paracyclophane **9**, which is structurally related to **7**.[15] Indeed, EPR powder spectra of mixed crystals (ca. 1% **7** in **9**) at 120 K furnish orthorhombic and at 293 K tetragonal g- and ^{51}V-hyperfine tensors (Fig. 3). Coalescence (A_x, A_y) $\rightarrow A_\perp$(^{51}V) for the low field components ($m_I = -7/2$) occurs at $T_c \approx 170$ K and for the high field components ($m_I = +7/2$) at $T_c \approx 220$ K. Hence, the rotational barrier in the heteroarene complex **7** is comparable with that in the homoarene complex **8**[15] and is largely determined by packing forces. This conclusion is further supported by the fact that a complete suppression of the ring rotation is effected at substantially lower temperature in the mixed crystal than in glassy solution (Fig. 3). Since the molecular dimensions of the host **9**[16] exceed those of the guest **7**, the latter should experience relatively slight matrix-induced hindrance to internal rotation.

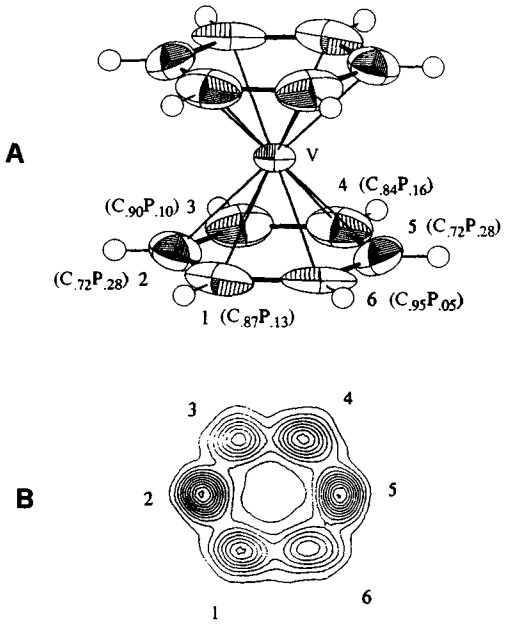

Fig. 4. **A**: ORTEP plot of a molecule of **7** in the crystal with data of the C:P occupation. Thermal ellipsoids at the 50% probability level. Important bond lengths [pm] and angles [°] (because of disorder the probable errors have to be set higher than derived from the standard deviations): (C,P)1-(C,P)2 158.3(5), (C,P)1-C6 158.1(6), (C,P)2-C3 154.5(5), C3-(C,P)4 159.1(6), (C,P)4-(C,P)5 154.7(5), (C,P)5-C6 147.8(5), mean: 155.4 pm; ring angles at (C,P)1 121.7(3), (C,P)2 112.8(3), C3 124.9(3), (C,P)4 119.4(3), (C,P)5 117.6(3), C6 123.6(3), V-(C,P)1 225.1(4), V-(C,P)2 231.7(3), V-C3 222.9(4), V-(C,P)4 227.1(3), V-(C,P)5 232.0(3), V-C6 225.5(4) pm, mean V-(C,P) 227.4 pm. **B**: Observed electron densities (F_0 Fourier section) in the "best" ring plane of **7**. Intervals of the contour lines 0.5, beginning at 0.5 e/ Å^3.

In order to clarify whether a certain conformation is preferred in the single crystal of **7** we have carried out an X-ray structure analysis.[18] It led to a very similar unit cell and the same space group type $P2_1/n$ as in the chromium complexes bis(η^6-pyridine)chromium **1**[1] and bis(η^6-arsabenzene)-chromium **2**[3] studied previously. As anticipated, **7**, like **1** and **2**, shows disorder of the heteroatom in the ring (Fig. 4). However, the three disorder models differ significantly.[19] Interestingly, the only common structural interpretation, which includes the compounds **1**, **2** and **7**, is that of an orientational disorder of the antiperiplanar conformation.[19]

[5] Bis(2,4,6-*tert*-butyl-η^6-phosphabenzene)chromium was first prepared in 1984 and was characterized by ^{1}H-NMR and ^{31}P-NMR spectroscopy as well as by cyclic voltammetry: E. Bilger, *Dissertation*, Marburg 1984; C. Elschenbroich, E. Bilger, unpublished results.
[6] Experimental procedure: The wall of a cocondensation reactor equipped with an electron beam heated metal-vapor source was cooled to -196 °C and coated with 40 mL of methylcyclohexane. Vanadium (0.66 g, 12.9 mmol) and phosphabenzene **7b** (2.3 g, 23.9 mmol) were then condensed onto the wall at 5×10^{-6} mbar and an electron-beam power of 490 W within 2 h. After equalization of pressure (N_2) and warming to 25 °C the dark-brown cocondensate was filtered through a G4 frit and the filtrate evaporated to dryness. For removal of colloidal metal the residue was extracted with methylcyclohexane, the extract evaporated to dryness, and the residue taken up in 5 mL of toluene. After adding a layer of hexane (5 mL), 26 mg (0.11 mmol, ca. 1%) of **7** crystallized at + 4 °C in the form of dark-brown rhombs (m.p. 201 °C). UV/VIS (methylcyclohexane): λ_{max}[nm](ε): 311 (7150), 333 (8300), 447 (975), 675 (75); MS (EI, 70 eV): m/z 234 ($M^{\oplus}$, 100%), 147 ($M^{\oplus}$-C_5H_5P, 90.5), 51 ($V^{\oplus}$, 91.3).

[11] In such considerations, effective π-orbital electronegativities χ_E^π are to be used instead of the Pauling electronegativity values. The χ_E^π values for P, As, Sb are higher than for C; compare J. Waluk, H.-P. Klein, A. J. Ashe III, J. Michl, *Organometallics 8* (1989) 2804.
[12] According to EPR spectroscopic measurements the redox orbital a_{1g} in the case of **7** and **8** has almost exclusively metal $3d_{z^2}$ character. The anodic shifts $\Delta E_{1/2}$ for unsymmetrical sandwich complexes (C_5H_5) $(C_7H_7)M$ relative to the symmetrical forms $(C_6H_6)_2M$ are explained in an analogous way [8].

[18] Crystal structure determination of **7**: A blackish-brown crystal (ca. $0.2 \times 0.2 \times 0.1$ mm), after orienting film exposures, was measured on a CAD4 diffractometer, Enraf-Nonius, $Mo_{K\alpha}$ radiation, graphite monochromator at -80 °C. The monoclinic unit cell ($a = 651.2(1)$, $b = 782.2(1)$, $c = 977.6(2)$ pm, $\beta = 97.13(1)°$ was determined on the basis of 25 reflections with $\theta > 12°$. The space group is $P2_1/n$, $Z = 2$. The structure was solved with Patterson and difference Fourier syntheses and, owing to different electron densities at the six ring atom positions, described and refined using a disorder model (the ring positions display varying P/C occupation). The relative occupation ratios were calculated from the maxima of a Fourier synthesis, the P fraction for the lowest maximum was

varied iteratively in the refinement until an equivalent isotropic displacement factor comparable with that at the other positions resulted. For each ring position in the disorder model so obtained the C:P ratio was fixed, an anisotropic displacement factor refined together with the atomic positions, and—corresponding to the C fraction—an H atom was introduced "riding" at a calculated position with a common isotropic displacement factor ($U = 0.09$ Å^2). The refinement converged well and led (considering the positional disorder) to reasonable displacement factors. Using the weights $w = 1/\sigma^2(F_0)$ and after introduction of an extinction correction the residuals $R = 0.054$, $wR = 0.037$ resulted for 920 observed reflections with $F_0 > 4\sigma$. Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, W-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-55147, the names of the authors, and the journal citation.

[19] Whereas the N atom in **1** occupies the 1,3 positions (50/50 ratio) and in **2** As occupies the 1,4 positions, the electron density distribution in the ring of **7** (Fig. 4) shows that the P atom, like in the As-analogue of chromium, is preferentially located at the 1,4-positions, but that differing and smaller fractions of P are located on all other ring positions. Because of superposition of several orientations of a distorted six-membered ring, varying bond lengths from 148 to 159 pm are encountered, whereby the mean value (155.4 pm) lies well above the mean of the bond lengths in free phosphabenzene (150.7 pm) [2]. This is plausible since, because of its higher number of electrons the P atom "prevails" more strongly during the superposition of C and P atoms than corresponds to its percentage. The deviations of a "best plane" through the six ring atom positions of **7** are less than 0.3 pm and thus indicate planarity. The V atom is located 166(1) pm above the ring plane, its distance from the ring atoms is on the average 227.4 pm. The second ring is generated through the symmetry center in the V atom, i.e. is parallel to the other ring and is in the eclipsed orientation. Since pairwise oppositely disposed positions in the ring are occupied to about the same extent by P, the disorder model is compatible both with the assumption—with varying contribution—of differently oriented molecules with antiperiplanar and with synperiplanar conformation. The exclusive presence of a synclinal conformation is ruled out by the different extent of occupation of the "*meta*" positions; an admixture cannot by ruled out, however.

Cp'_2TiS_5O and Cp'_2TiOS_5—Isomeric Titanocene Complexes with Two Novel S-O Chelate Ligands ($Cp' = \eta^5$-$CH_3C_5H_4$)**

By *Ralf Steudel,* Andreas Prenzel,* and *Joachim Pickardt*

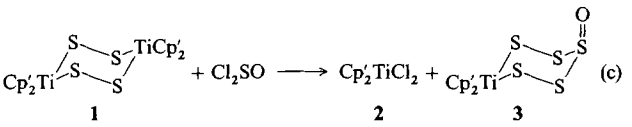
S_8O and other cyclic sulfur oxides can be prepared by oxidation of sulfur rings with trifluoroperoxoacetic acid [Eq. (a)].[1] They contain the group –S–S(O)–S–, which can also be incorporated into organic compounds by condensation of thiols or thiolates with thionyl chloride, whereby sulfane oxides are formed [Eq. (b)].[2]

$$cyclo\text{-}S_n + CF_3CO_3H \longrightarrow S_nO + CF_3CO_2H \quad (a)$$
$$n = 6\text{–}10$$

$$2\,RSH + Cl_2SO \longrightarrow R\text{-}S\text{-}S(O)\text{-}S\text{-}R + 2\,HCl \quad (b)$$
$$R = Aryl$$

Unfortunately these reactions are not suitable for the preparation of inorganic or organic heterocyles with the group –S–S(O)–S– according to Equation (a) or of chain-like sulfane oxides with essentially more than three sulfur atoms according to Equation (b). We report here on the first synthesis of a polysulfide oxide complex of titanocene, which should enable the -S_5O- group to be incorporated into chain-like or ringlike compounds, i.e. analogously to the use of Cp_2TiS_5 ($Cp = \eta^5$-C_5H_5) for the synthesis of ring- and chain-like polysulfur compounds.[3]

The dinuclear titanocene complex $Cp_4Ti_2S_4$ **1**[4] reacts spontaneously with thionyl chloride in the ratio 1:1 at 0 °C in CS_2 to give the titanocene dichloride **2** and the pentasulfide oxide complex **3**, which is sparingly soluble in CS_2 and precipitates in the form of red crystals (m.p. 105 °C, decomp.)[5] [Eq. (c)].



1 **2** **3**

Solid **3**, in contrast to the decomposable *cyclo*-sulfur oxides S_nO, is stable at 20 °C in air. The IR spectrum of **3** (KBr pellet) shows the SO stretching vibration as a very strong band at 1094 cm^{-1}, an unequivocal indication of the –S–S(O)–S– group, as ν(SO) for S_8O appears at almost exactly the same wave number.[6] Since the SSO deformation vibration of **3** (380 cm^{-1}) also appears at exactly the same wave number as in S_8O, it can be assumed that the O atom in **3**, as in S_8O, is in the axial position, which is stabilized by the anomeric effect.

The EI mass spectrum of **3** (sample temperature 140 °C) does not show a peak for the molecular ion $M^{\oplus}$, but peaks for the characteristic fragments $[M - S_2O]^{\oplus}$ and $[M - S_3O]^{\oplus}$; the base peak is $S_2^{\oplus}$. The elimination of S_2O and S_3O is also typical for *cyclo*-sulfur oxides S_nO.[1] The ^{1}H-NMR spectrum of **3** in $CDCl_3$ (400 MHz) shows two singlets at $\delta = 2.012$ and 2.466 for the methyl groups and four triplets at 5.863, 5.911, 6.277 and 6.398 for the aromatic ring protons. Thus, with respect to the number of lines, this spectrum corresponds exactly to the ^{1}H-NMR spectrum of Cp'_2TiS_5,[7] i.e. the TiS_5O ring in **3** must have a mirror plane. As to be expected from the synthesis, **3** is present as $Cp'_2Ti(\mu\text{-}S_2)_2S{=}O$ and not as $Cp'_2Ti(\mu\text{-}S)(\mu\text{-}S_3)S{=}O$, since the ring protons of the unsymmetrical compound would have to give eight quartet signals.

3 is readily soluble in $CHCl_3$, CH_2Cl_2 and THF, but the solutions decompose within 45 min at 20 °C, whereby **3** is converted via ring expansion into the isomeric complex **4** [Eq. (d)].

$$Cp'_2TiS_5O \xrightarrow{CH_2Cl_2} Cp'_2TiOS_5 \quad (d)$$
3 **4**

This reaction can be monitored by means of reversed phase HPLC,[8] since **4** has a significantly greater retention time than the obviously more polar **3**; further reaction products are not formed (eluent: CH_3OH; stationary phase: octadecylsilane). The UV absorption spectra of **3**, **4**, and—for comparison—of Cp'_2TiS_5 **5** were measured immediately after the chromatographic separation.[8] Whereas the spectra of **3** and **5** are, as expected, very similar, that of **4** shows a marked shift of the absorption at ca. 300 nm (Table 1).

4 crystallizes from CH_2Cl_2/hexane in the form of dark-brown, rhomboidal, monoclinic, air-stable crystals,[9] which

Table 1. Absorption spectra of **3**–**5** in methanol (range: 220–600 nm, relative extinctions in brackets).

Cp'_2TiS_5O **3**	Cp'_2TiOS_5 **4**	Cp'_2TiS_5 **5**
240 (100)	240 (100)	240 (100)
310 (33; shoulder)	328 (38)	310 (41)
484 (4)	482 (3)	486 (8)

were characterized X-ray crystallographically.[10] The novel chelate ligand OS_5 in **4** is bound to the metal via the O atom and one S atom, whereby a seven-membered ring with C_1 symmetry is formed (Fig. 1.). In this ring the torsion angles vary between 22.5° (Ti–O–S–S) and 88.0° (S1–S2–S3–S4), the motif (signs of the torsion angles) is + + − + − + −. Other than in the case of *cyclo*-heptasulfur[11] there is no torsion angle close to 0°.

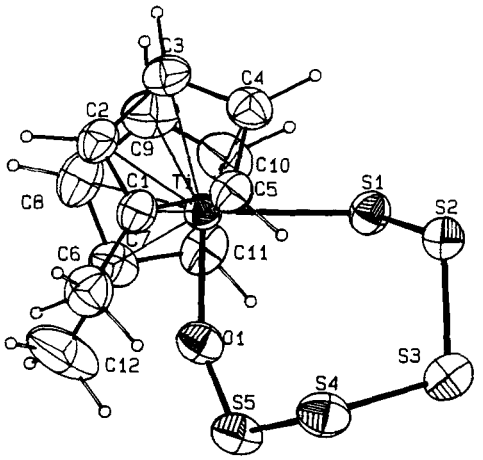

Fig. 1. Structure of **4** in the crystal. Selected bond lengths [pm], angles and torsion angles [°]: Ti-O1 194.6, Ti-S1 246.7, S1-S2 204.5, S2-S3 204.4, S3-S4 208.1, S4-S5 199.9, S5-O1 152.9; O1-Ti-S1 92.3, Ti-S1-S2 111.8, S1-S2-S3 106.5, S2-S3-S4 105.7, S3-S4-S5 106.2, S4-S5-O1 110.9, S5-O1-Ti 154.8; O1-Ti-S1-S2 −70.8, Ti-S1-S2-S3 84.9, S1-S2-S3-S4 − 81.0, S2-S3-S4-S5 88.0, S3-S4-S5-O1 −79.5, S4-S5-O1-Ti 22.5, S5-O1-Ti-S1 39.8.

The seven covalent bonds in the ring are of different bond order: the Ti–S bond (246.7 pm) is somewhat longer than in Cp_2TiS_5 (243 pm);[12] the Ti–O bond (194.6 pm) is substantially longer than in $(Cp_2ClTi)_2O$ (184 pm) or analogous Cp_2Ti alkoxy compounds.[13]

The S–O bond (152.9 pm) lies between S–O single bonds (e.g. 163–165 pm in $(CH_3O)_2S$ and $(CH_3O)_2S_2$[14]) and S=O double bonds (e.g. 143 pm in SO_2). The S–S bond lengths (199.9–208.1 pm) fluctuate about the value of the single bond (205 pm),[15] whereby, as usual,[11,15] the longest bond (S3–S4) is adjacent to the shortest bond (S4–S5).

The ^{1}H-NMR spectrum of **4** in CD_2Cl_2 at 20 °C shows a single sharp singlet at $\delta = 2.14$ for the two methyl groups, which can only be explained in terms of a rapid inversion (pseudorotation) of the $TiOS_5$ ring on the NMR time scale. At − 10 °C, this singlet is strongly broadened, and at − 40 °C two sharp singlets are observed at $\delta = 2.0$ and 2.1 as well as eight quartets in the range $\delta = 5.4$–7.5 for the aromatic ring protons.[9] At this temperature the metallacycle is conformationally rigid. The appearance of eight quartets is characteristic for unsymmetrical titanocene complexes with two $CH_3C_5H_4$ ligands (e.g. $Cp'_2TiSe_3S_2$[16] and $Cp_2'(\mu\text{-}S)(\mu\text{-}S_3)CH_2$[17]). In the IR spectrum of **4** the SO stretching vibration is observed at 868 cm^{-1} (KBr pellet).

At present one can only speculate on the mechanism of the isomerization **3** → **4**: during a transition of the presumably chair-shaped TiS_5 ring of **3** into the boat conformation, Ti–O contacts can occur, which lead to rupture of a Ti–S bond and the rearrangement of some S–S bonds, whereby the oxophilicity of the titanium atom is apparently the driving force. Preliminary experiments show that **3** reacts similarly to Cp_2TiS_5 with S–Cl compounds, affording access to compounds containing –S-S–S(O)–S–S groups which could not be prepared hitherto. These reactions proceed more rapidly than the isomerization.

Proof of Strong S–H···S Bridges in $[Ru(SH_2)(PPh_3)('S_4')]\cdot THF$, the First H_2S Complex Characterized by X-Ray Crystallography **

By *Dieter Sellmann,* Peter Lechner, Falk Knoch,* and *Matthias Moll*

The interaction of H_2S, $HS^{\ominus}$ and $S^{2\ominus}$ with transition metals is a primary step in the formation of ores and in the construction of the $[M_xS_y]$ clusters in enzymes like ferredoxines or nitrogenases. Here, as in the metal-enzyme catalyzed $SO_4^{2\ominus}/H_2S$ transformation in the biological sulfur cycle, H_2S complexes are assumed to be intermediates. Because of their extreme reactivity,[1, 2a] such complexes could be detected,[2b, f, g] or isolated,[2a–e] only in exceptional cases in the past, but never be studied by X-ray crystallography. In this respect they differ from the numerous well-characterized H_2O complexes.

$$[Ru(PPh_3)('S_4')] \xrightarrow[5\ min]{H_2S/-70\,^{\circ}C} [Ru(SH_2)(PPh_3)('S_4')]\ \mathbf{1} \qquad (a)$$

We have now succeeded in obtaining the H_2S complex $[Ru(SH_2)(PPh_3)('S_4')]$ **1** from $[Ru(PPh_3)('S_4')]$[3] (eq. (a)), which could be characterized by X-ray crystallography (Fig. 1a).[4] Compound **1** precipitates as **1**·THF on recrystallization from H_2S-saturated THF as yellow-orange crystals and can be ionized in a mass spectrometer without decomposition. In contrast to the highly labile solvent-free **1**, **1**·THF is stable at 25 °C and loses H_2S slowly in vacuum only. Both compounds are rapidly oxidized by O_2 to turquoise-colored $[(\mu\text{-}S_2)\{Ru(PPh_3)('S_4')\}_2]$[5] (Eq. (b)).

$$2\,[Ru(SH_2)(PPh_3)('S_4')]\ \mathbf{1} \xrightarrow[-2H_2O]{O_2} [(\mu\text{-}S_2)\{Ru(PPh_3)('S_4')\}_2] \qquad (b)$$

In the unit cell of **1**·THF, two enantiomers are each associated via two S–H···S bridges to a cyclic dimer containing an inversion center. In addition each H_2S ligand is bound to a THF molecule via one S–H···O bridge (Fig. 1, bottom). The position of the H_2S hydrogen atoms were localized by difference Fourier synthesis.

The Ru atoms are each surrounded by five sulfur and one phosphorus atom in a pseudo-octahedral geometry. The angles in the coordination polyhedron are all close to 90 or 180° and do not exhibit anomalies. The Ru–S distances (236.1(5)–239.7(5) pm) and the Ru–P distance (232.4(5) pm) are typical for these complexes. Only the Ru1–S3 distance in *trans* position to the H_2S ligand is clearly shorter (229.3(5) pm); comparison with other $[Ru(L)(PPh_3)('S_4')]$ complexes[6] suggests a stronger Ru → S (thioether) π acceptor bond.

The S–H···S bridges in **1**·THF are of particular interest (Fig. 1, bottom). For the first time the existence of these bridges in H_2S complexes could be proved by X-ray crystallography. They are very strong in comparison with the usually weak S–H···S bridges (e.g., in H_2S: $\Delta H_f^{298} = 7\ kJ\ mol^{-1}$[7]).

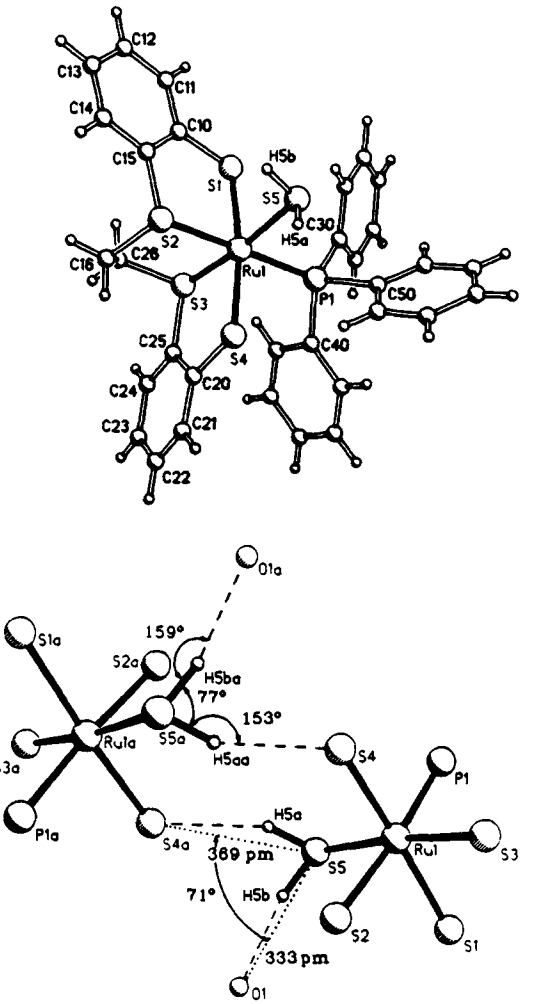

Fig. 1. Top: Structure of **1**·THF in the crystal (THF omitted); bottom: S–H···S and S–H···O hydrogen bridges in **1**·THF.

The strongest S–H···S bridges known as yet ($\Delta H_f^{298} \approx 12\ kJ\ mol^{-1}$[8]) were found in dithiophosphinic acids, which have S···S distances of 375 to 384 pm, ν(SH) between 2340 and 2400 cm^{-1} (KBr) and S–H···S angles in the range 159 to 173°.[9] In comparison, the calculated S–H···S limiting

[**] $('S_4')^{2\ominus}$ = 2,2'-(ethylenedithio)bis(thiophenolate). Transition Metal Complexes with Sulfur-Containing Ligands, Part 64. This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and Degussa AG, Hanau (gift of $RuCl_3\cdot xH_2O$). Part 63: D. Sellmann, M. Geck, F. Knoch, M. Moll, *Inorg. Chim. Acta*, in press.

distance is ca. 439 pm,[9a] and the ν(SH) in gaseous H_2S occur at 2615 and 2628 cm^{-1}.[10] The angle formed by the S–H···S bridge in **1**·THF is 153°, the sum of the distances S5–H5a and H5a–S4a is 378 pm and the distance S5–S4a 369 pm. In particular this extremely short distance indicates that the S–H···S bridges in **1**·THF must be exceptionally strong; this is corroborated by the ν(SH···S) at 2290 cm^{-1} (KBr) that is the lowest frequency observed for S–H···S bridges as yet. In H_2S complexes without hydrogen bridges, the ν(SH) appear at significantly higher wavenumbers (2590 to 2510 cm^{-1}). Compound **1**·THF shows in contrast to **1** a ν(S–H···O) at 2410 cm^{-1}, which together with the short S···O distance of 333 pm indicates that the S–H···O bridges are also strong.[11]

^{1}H NMR spectroscopic evidence for SH protons in **1**·THF can only be obtained by using solutions of freshly prepared **1** in H_2S-containing mixtures of CD_2Cl_2/[D_8]THF (1:2). Besides the signal of free H_2S ($\delta = 1.00$), a signal for the protons of the H_2S ligand at $\delta = 1.96$ is observed. When the sample is oxidized by air, the signal for the H_2S ligand decreases and splits, until it finally can no longer be detected. In the ^{1}H NMR spectrum of the corresponding D_2S complex [$Ru(SD_2)(PPh_3)('S_4')$] it does not appear.[12]

1·THF thus shows that H_2S in complexes with a sulfur-dominated coordination sphere is stabilized by strong hydrogen bonds. Their strength results on one hand from the high charge density in the [RuS] framework, through which the thiolate donors become good H acceptors, and on the other from the large polarity of the S–H bond in coordinated H_2S. The short S···S distance and the low frequency of ν(S–H···S) confirm that S–H···S bridges can be significantly more stable than hitherto suspected. This result is of considerable interest, because S–H···X bridges (X = N, O, S) in ferredoxines and most other metal-sulfur enzymes, influence redox potentials and equilibrium configurations, and thereby reactivities.[13]

Experimental Procedure

All procedures were conducted in an H_2S atmosphere under strict O_2 and H_2O exclusion. 10 mL of H_2S was condensed onto 830 mg (1.24 mmol) of [$Ru(PPh_3)('S_4')$] at −196 °C in a Schlenk tube. Slow warming of the mixture to −70 °C gave a red suspension, which rapidly turned into a clear yellow solution. Concentration to 1 mL at −60 °C caused precipitation of yellow **1**. Careful dissolution in 30 mL of cold (−50 °C) THF and slow addition of 30 mL pentane (−10 °C) with stirring yielded finely crystalline **1**·THF, which was separated, washed with pentane/THF (10:1) and dried in a stream of H_2S gas. Correct elemental analysis. 745 mg (77%) yield. ^{1}H NMR of **1** (270 MHz, CD_2Cl_2/[D_8]THF (1:2), TMS): δ = 7.67–6.40 (23 H, m, C_6H_4, PPh_3), 2.85–2.35 (4H, m, C_2H_4), 1.96 (2H, s, SH); ^{31}P{^{1}H} NMR of **1** and **1**·THF (109 MHz, CD_2Cl_2/[D_8]THF (1:2), H_3PO_4): δ = 42.2; FD-MS: *m/z* 706 ([$Ru(SD_2)(PPh_3)('S_4')$]: *m/z* 708). Single crystals were obtained from a saturated solution of freshly synthesized **1** in THF at 0 °C by layering with the same volume of pentane.

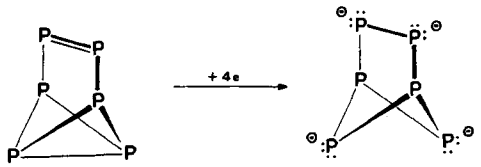
Bicyclic P_6 as Complex Ligand**

By *Otto J. Scherer,* Bernd Werner, Gert Heckmann,* and *Gotthelf Wolmershäuser*

Dedicated to Professor Marianne Baudler on the occasion of her 70th birthday

If one considers the opening of one edge and one bond of the double bond of the as yet unknown hexaphosphabenzvalene **A**[1] by a four-electron reduction, the formally bicyclic $P_6^{4\ominus}$ anion **B** is formed. The cothermolysis of the butadiene



A **B**

complex **1** and P_4 leads in about 30% yield to the binuclear thorium complex **2** with a new structure variant of the P_6 ligand.[2]

$$[Cp''_2Th(\eta^4\text{-}C_4H_6)] \xrightarrow[\text{ca. 100 °C, ca. 20 h}]{P_4,\ \text{toluene}} [Cp''_2Th(\mu, \eta^3, \eta^3\text{-}P_6)ThCp''_2]$$

1 **2**

$Cp'' = \eta^5$-1,3-tBu$_2$C$_5$H$_3$

The reaction of **1** with P_4 in the presence of $MgCl_2$ affords the binuclear complex **3** in about 80% yield. In this complex

Erwin-Schrödinger-Strasse, W-6750 Kaiserslautern (FRG)
[+] X-ray crystallography

[**] This work was supported by the Fonds der Chemischen Industrie.

the oxidation state of IV, which is almost the only occurring state for thorium, is possible if the unsubstituted phosphorus ligand is described as *cyclo*-$P_3^{3\ominus}$, a formulation isoelectronic with *cyclo*-S_3.[3]

$$2\,\mathbf{1} \xrightarrow[\text{toluene, ca. 100 °C, ca. 20 h}]{P_4,\ 1/2\,MgCl_2(OEt_2)} \underset{\mathbf{3}}{[Cp''_2Th(\mu,\eta^3\text{-}P_3)Th(Cl)Cp''_2]}$$

The extremely air-sensitive crystals of the amber-colored **2** or yellow-orange **3** are very soluble in dichloromethane, soluble in toluene, but only slightly soluble in hexane.

The ^{31}P NMR spectrum[4] reveals an AA'MM'Q_2 system for **2**; for **3** a broad singlet is observed at 293 K, which splits into an A_2B system at 193 K (see Fig. 2). The rotation barrier of the *cyclo*-P_3 unit is ca. 44 kJ mol^{-1}.[4]

The X-ray structure[5] shows that **2** is a cage compound, in which the Th_2P_6 framework consists of a P_6 bicycle (similar to **B**) with the thorium atoms capping the five-membered rings (Fig. 1). As in the structurally related tricyclic

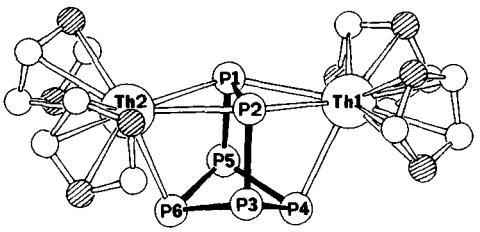

Fig. 1. Structure of **2** in the crystal. Selected bond lengths [Å] and angles [°]: Th1-P1 2.878(7), Th1-P2 2.921(7), Th1-P4 2.840(7), Th2-P1 2.919(7), Th2-P2 2.899(7), Th2-P6 2.847(7), Th1-Cp'' (center) 2.55/2.58, Th2-Cp'' (center) 2.57/2.57, P1-P2 2.183(10), P2-P3 2.271(9), P1-P5 2.281(10), P3-P4 2.235(10), P3-P6 2.227(11), P5-P4 2.228(10), P5-P6 2.212(10), P3···P5 3.01, P4···P6 2.97; P1-Th1-P2 44.2(2), P2-Th1-P4 73.6(2), P1-Th1-P4 74.9(2), P1-Th2-P2 44.1(2), P2-Th2-P6 74.8(2), P1-Th2-P6 73.0(2), Th1-P1-Th2 134.1(2), Th1-P2-Th2 133.0(3), Th1-P1-P2 68.9(3), Th2-P1-P2 67.5(3), Th1-P2-P1 66.9(3), Th2-P2-P1 68.5(39), Th1-P1-P5 85.6(3), Th2-P1-P5 88.9(3), Th1-P2-P3 88.8(3), Th2-P2-P3 85.2(3), Th1-P4-P3 91.5(3), Th1-P4-P5 87.5(3), Th2-P6-P3 87.3(3), Th2-P6-P5 92.2(3), P1-P2-P3 100.0(4), P2-P1-P5 100.9(4), P2-P3-P4 100.0(4), P2-P3-P6 101.7(4), P1-P5-P4 101.0(4), P1-P5-P6 99.4(4), P4-P3-P6 83.5(4), P4-P5-P6 84.0(4), P3-P4-P5 84.8(4), P3-P6-P5 85.4(4). ⊘ = C*t*Bu.

polyphosphane $P_6(C_5Me_5)_2$ (**4**),[6, 7b] the P_1-P_2 bond of 2.18 Å is the shortest. (In **4** an η^1-C_5Me_5 substituent is bonded to each of these atoms.) The P2–P3 distance of 2.27 and P1–P5 distance 2.28 Å are distinctly longer than the corresponding 2.19 Å in **4**.[6, 7b] The average of 2.225 Å for the remaining four P–P bond lengths (P3 to P6) differs only minimally from the $\bar{d}$(P–P) = 2.21 Å of the P_4 molecule. The P_6R_4 compounds **5a** (R = *t*Bu)[7a] and **5b** (R = C_5Me_5),[7b] which have been characterized by X-ray crystallography, and which have a five-membered ring with an annelated three-membered ring as P_6 framework,[7c] give values for $\bar{d}$(P–P) of 2.195 Å for **5a** and 2.221 Å for **5b**.[7b] The Th–P bond lengths in **2** (2.84 to 2.92 Å, Fig. 1) lie in the range for thorium phosphido complexes.[8] Although the atoms Th1 P1 P2 Th2 (dihedral angle = 165.1°) lie almost in a plane, the dihedral angle between the planes defined by P3 P5 P4 and P3 P5 P6 is 129.9°.

The X-ray structure[5] of **3** (Fig. 2) shows that the distance from Th1 to the center of the P_3 ring is 2.57 Å, ca. 0.1 Å shorter than the corresponding distance to Th2 of 2.68 Å. Accordingly the Th1–P1 distance of 2.81 Å is the shortest and the Th2–P1 distance of 2.99 Å the longest Th–P distance in the molecule. The average P–P distance of 2.185 Å in the almost equilateral P-triangle (2 × 2.192, 1 × 2.171 Å) is slightly longer than the calculated 2.174 Å for *cyclo*-$P_3^{\ominus}$[3c] and comparable with those for the [(triphos)M(μ,η^3-P_3)M(triphos)]$^{n\oplus}$ class of substances where, for example, M = Co, n = 2, and triphos = $CH_3C(CH_2PPh_2)_3$.[9] The coordination environment of Th1 (sum of the angles Th1Cp''Cp''*cyclo*-P_3(center) = 356°) differs only minimally from the exactly trigonal-planar environment of the Th atom in [Th{η-$C_5H_3(SiMe_3)_2$}$_3$],[10] while Th2 occupies a distorted tetrahedral site formed by the four ligands Cl, Cp'', Cp'', *cyclo*-P_3(center). The Cl ··· P1 and Cl ··· P2 distances of 3.76 and 3.66 Å respectively are nonbonding.

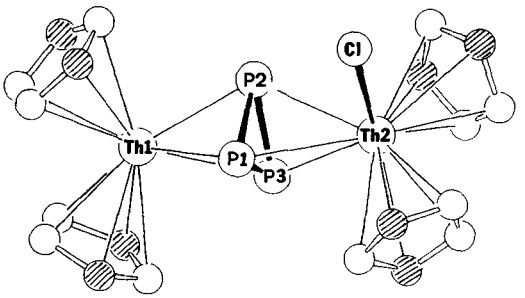

Fig. 2. Structure of **3** in the crystal. Selected bond lengths [Å] and angles [°]: Th1-P1 2.809(6), Th1-P2 2.898(7), Th1-P3 2.892(6), Th2-P1 2.994(7), Th2-P2 2.974(8), Th2-P3 2.910(6), Th2-Cl 2.675(5), Th1-Cp'' (center) 2.54/2.54, Th2-Cp'' (center) 2.59/2.605, P1-P2 2.171(9), P2-P3 2.192(9), P1-P3 2.192(8), P1-Th1-P2 44.7(2), P2-Th1-P3 44.5(2), P1-Th1-P3 45.2(2), P1-Th2-P2 42.7(2), P2-Th2-P3 43.7(2), P1-Th2-P3 43.6(2), P1-Th2-Cl 82.9(2), P2-Th2-Cl 80.5(2), P3-Th2-Cl 120.1(2). ⊘ = C*t*Bu.

Experimental Procedure

2 [3]: 2.00 g (3.12 mmol) of **1** [11], dissolved in 10 mL toluene, and 0.77 g (6.24 mmol) P_4 [and 0.16 g (0.94 mmol) $MgCl_2(OEt_2)$] were stirred in a sealed Schlenk tube at 100 °C for 20 h (tested for completion with ^1H NMR). The orange-red solution slowly darkened. After removal of the solvent in vacuum and subsequent sublimation of P_4 (0.01 Torr, 60 °C, 1 h), the solid, red-brown residue was washed (only for **2**) several times with 5 mL portions of cold hexane. **2** precipitated as a yellow powder (purity > 90 %, determined by ^1H NMR spectroscopy). The solid was taken up in toluene and filtered through filter flakes [for **3**, a small amount of a red-brown solid precipitated, which was insoluble in the common organic solvents] and crystallized at −18 °C. Yield: 0.66 g (31 %) [1.64 g (81 %)] amber-colored [yellow-orange] crystals [amongst them intergrowing needles].

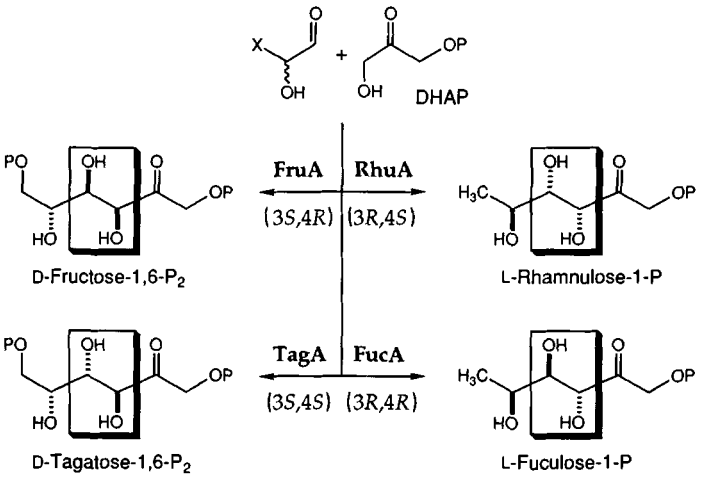
Diastereoselective Enzymatic Aldol Additions: L-Rhamnulose and L-Fuculose 1-Phosphate Aldolases from *E. coli***

By *Wolf-Dieter Fessner*, Gudrun Sinerius, Achim Schneider, Matthias Dreyer, Georg E. Schulz, Josefa Badía,* and *Juan Aguilar*

Aldolases hold great promise as catalysts for organic synthesis, since enzyme-catalyzed C-C bond formations proceed with a high degree of enantio- and diastereoselectivity, which is rarely rivaled by classical synthetic methodology.[1] Particularly, four complementary aldolases are known in carbohydrate metabolism (Scheme 1) which catalyze the asymmetric addition of dihydroxyacetone phosphate (DHAP) to L-lactaldehyde or D-glyceraldehyde 3-phosphate to generate a unique product each, namely only one of the four possible diastereomeric configurations. D-Fructose 1,6-bisphosphate aldolase (FruA) has been shown to accept a broad range of aldehydes as substrate.[2] The development of the full potential value of DHAP aldolases into a general and efficient methodology for asymmetric synthesis will largely depend on the availability of the whole tetrad of enzymes. This would allow the creation of all four possible diastereomers at will in a building block fashion by simply selecting a suitable aldehyde and the correct enzymic catalyst. Here we report the subcloning, overexpression, isolation, and application in synthesis of two bacterial DHAP aldolases, the L-rhamnulose (RhuA; EC 4.1.2.19) and L-fuculose 1-phosphate aldolases (FucA; EC 4.1.2.17) of *E. coli*, which likewise accept a useful range of structurally diverse aldehydes, but provide products which are stereochemically distinct from those generated by FruA.



Scheme 1. Product stereochemistries generated by the four complementary DHAP aldolases (P = orthophosphate ester). FruA = D-fructose 1,6-bisphosphate aldolase, X = CH_2OP; RhuA = L-rhamnulose 1-phosphate aldolase, X = CH_3; TagA = D-tagatose 1,6-bisphosphate aldolase, X = CH_2OP; FucA = L-fuculose 1-phosphate aldolase, X = CH_3.

Cells of *E. coli* K-12 are able to grow on L-rhamnose or L-fucose as the sole sources of carbon and energy by two parallel, inducible pathways, each of which capitalizes on the aldol cleavage of the C_6 sugar by the action of RhuA or FucA. To generate the large amounts of the enzymes required for preparative utilization, separate overexpression systems were constructed. For RhuA, a *Bam*HI–*Hin*dIII genome fragment of 3.3 kilobase, which contained the complete structural *rhaD* gene encoding for the aldolase, was subcloned into the pUC18 vector.[3] A *rec*A derivative of *E. coli* strain ECL40 was transformed with the recombinant plasmid from which the enzyme was constitutively overexpressed relative to wild-type cells by a factor of ca. 15 (0.4 U mg^{-1} in crude cell extracts with a total of 400 U from 1 L of culture[4]) when grown in 1% CAA medium supplemented with ampicillin (100 μg mL^{-1}).[5] The structural gene for FucA was subcloned by introducing *Eco*RI–*Pst*I restriction sites according to standard PCR protocols from plasmid pfuc41a[6] into a pUC18-derived expression vector,[7] where it came under control of the *tac* promoter. Cells of *E. coli* strain HB101 transformed with this recombinant plasmid overexpressed FucA protein by a factor of 20 relative to wild-type cells (5 U mg^{-1} in crude cell extracts with a total of 900 U from 1 L of culture[4]) upon induction with 0.5 mM isopropyl-β-D-thiogalactopyranoside (IPTG).[8]

[**] Enzymes in Organic Synthesis, part 1. This research was supported by the Deutsche Forschungsgemeinschaft (Grant Fe 244/2-1), the Wissenschaftliche Gesellschaft Freiburg, and the Fonds der Chemischen Industrie and the Comisión Asesora de Investigación Científica y Técnica (Grant PB 85-0084). We gratefully acknowledge the generous gift of bacterial strains and plasmid DNA harboring the *fuc* genes by Prof. Dr. *E. C. C. Lin* and Dr. *Y.-M. Chen* of Harvard Medical School, Boston, and a preprint of ref. [8] obtained from Dr. *A. Ozaki*.

The enzymes were purified to homogeneity (one band upon SDS polyacrylamide gel electrophoresis or upon isoelectric focusing; no FruA activity detectable) in $\geq 60\%$ (for RhuA) or $\geq 40\%$ (for FucA) overall yields by similar three-step preparations consisting of ion exchange, hydrophobic interaction, and gel-permeation chromatography. Both catalytically active aldolases appear to be homotetramers with a subunit molecular weight of 30 kDa (RhuA)[3] and 25 kDa (FucA).[6] In a pure state, both enzymes readily form crystals (RhuA: rods or rectangular platelets form $\geq 10\%$ $(NH_4)_2SO_4$ solution; FucA: square platelets from 22% $(NH_4)_2SO_4$ solution at pH 7.8) that are suitable for X-ray analyses.

The stereoselectivity and substrate tolerance of purified enzymes were determined in two series of preparative syntheses, each employing a range of representative achiral and homochiral aldehydes **1**–**13** as substrate analogues (Table 1). All reaction rates, as determined by separate enzymic assays, were found to be sufficiently fast to allow an efficient and economical conversion of DHAP.[9] Reactions were carried out on 1–20 mmol scales at which nonoptimized isolated yields typically amounted to 70–90%. Diastereomeric composition was analyzed by high-field ^{1}H-NMR spectroscopy of crude reaction products. In addition, products were purified by ion-exchange chromatography[10] and were identified either by comparison with authentic samples, which were available from another study,[11] or by comparison with enantiomeric material obtained from respective FruA-catalyzed reactions.

All single or major diastereomers obtained from RhuA reactions were indistinguishable from analogous material generated by FruA, except for the opposite optical rotation. This confirms that RhuA generates vicinal diol units having the absolute (3*R*,4*S*)-*trans* configuration ("L-*threo*") as opposed to the (3*S*,4*R*)-*trans* stereochemistry ("D-*threo*") formed by FruA. In contrast, all the single diastereomers obtained from FucA-catalyzed reactions with achiral or homochiral hydroxaldehydes **1**–**5** were disparate to those produced upon FruA or RhuA catalysis. This corroborates that FucA generates vicinal diol units having a *cis* instead of a *trans* relationship among the hydroxyl substituents around the C3–C4 bond. Product identity, and thereby the common absolute (3*R*,4*R*) configuration ("D-*erythro*"), was unambiguously established by comparison with authentic samples.[11]

Within the limits of detection by high-field ^{1}H and ^{13}C NMR ($\leq 3\%$), enzymes RhuA and FucA both formed only single diastereomers from hydroxyaldehydes **1**–**5**, which suggests that the typifying magnitude of diastereoselectivity in the formation of L-rhamnulose or L-fuculose 1-phosphate (**16** and **17** respectively) is usually well conserved with related polar substrate analogues. Thus, these entries provide a straightforward, highly stereocontrolled access to phosphates of less common or nonnatural sugars like L-xylulose (**14**), D-sorbose (**18**), L-fructose (**20**), D-ribulose (**15**), D-psicose (**19**), L-tagatose (**21**), or corresponding 5-deoxy derivatives (**22**, **23**). The phosphorylated compounds are of interest in studies of carbohydrate metabolism[12] and are additionally a stable source for the free sugars.[2]

In experiments employing RhuA with a series of nonpolar aliphatic aldehydes **7**–**10**, however, in addition to the expected deoxysugars **25**, **27**, **29**, and **31**, the formation of varying amounts of a second stereoisomer was detected by the distinctive signals of 3-/4-H in high-field proton NMR spectra (Fig. 1). The wrong diastereomers, formed in larger amounts the smaller the substituent size (maximum of ca. 30% for acetaldehyde), were determined to be of opposite stereochemistry at C-4 (e.g. **26**) by their identity with corresponding FucA-derived materials and hence must have emerged due to imperfect guidance of the aldehyde approach. Apparently, the active site is so constructed that a more stringent binding occurs for hydrogen-bonding than for non-hydrogen-bonding substituents within the aldehyde part. Although highly selective with acetaldehyde **7** (95:5 ratio), FucA proved less selective with the sterically more demanding isobutyraldehyde **10** (70:30). These results accentuate the difficulty of demonstrating applicability of enzymic catalysts for synthesis by only assaying for substrate conversion[8]

Table 1. RhuA/FucA-catalyzed enzymic syntheses of ketose 1-phosphates[a]

Aldehyde	Formula	Product Configuration *trans*	*cis*	Enzyme	Diastereomer Ratio *trans* : *cis*	Yield [%] [b]	Relative Rate [%] [c]
1, glycolaldehyde		**14**	**15**	RhuA	≥ 97 : 3	82	43

[a] For conditions, see *Experimental*. P = orthophosphate ester. Denotation of absolute configurations at C-4: *trans* |||, *cis* –. [b] Determined as crystalline bis(cyclohexylammonium) salts; values in parentheses refer to noncrystallizing bis(triethylammonium) salts of diastereomers[10]. [c] Rate for L-lactaldehyde is set at 100%. Initial rates were determined by assaying for remaining DHAP in aliquots which were taken in 1 min intervals from reaction mixtures containing 5 mM DHAP, 50 mM aldehyde and an appropriate quantity of purified aldolase.

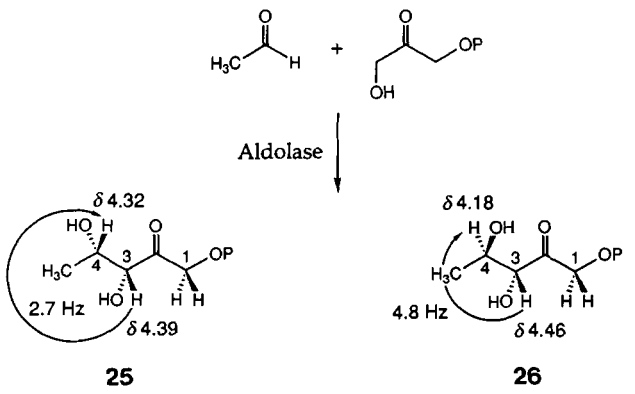

Fig. 1. Exemplary ^{1}H NMR data (400 MHz, D_2O, pH 7.0) for diastereomeric aldol adducts **25** (*trans*) and **26** (*cis*).

without analyzing the product composition thoroughly for every case as well.

The breadth of substrate tolerance is exemplified by additional FucA-catalyzed reactions of DHAP with some representative aldehydes **11**–**13** as substrate analogues that incorporate a number of functional groups typical for those useful in synthesis. The level of diastereoselectivity was found to be generally better than 97%. While we have been unable so far to rigorously assign the absolute configurations of products **34**, **36**, and **38** due to limitations in unambiguous comparison samples, it may safely be assumed from mechanistic considerations[13] that the absolute configuration at C-3 will be conserved throughout with any DHAP aldolase. For similar reasons, a rather narrow restriction for DHAP analogues has to be expected.

Both purified microbial aldolases display excellent stability in the presence of low levels of $Zn^{2\oplus}$ ions ($\leq$ 1 mM), with estimated half-lives at room temperature of several weeks and negligible inactivation during storage at 4°C for months. In addition, the enzymes tolerate remarkable proportions of organic cosolvents, e.g., 30–50% of ethanol, DMF, or DMSO (Fig. 2).

In summary, this data demonstrates that both RhuA and FucA accept a significant variety of aldehydes as substrate analogues for the efficient, highly enantio- and diastereocontrolled de-novo synthesis of carbohydrates, related polyhydroxy compounds, and phosphorylated derivatives. Although diastereoselectivity may be biased for certain substrate classes and may require careful choice of substitution patterns, the accessibility and broad applicability make these aldolases valuable enzymic catalysts for organic synthesis.

In general, the methodology of enzymic aldol addition benefits from the high level of catalytic asymmetric induction for two stereocenters at the same time, the mild reaction conditions, and the fact that no protection of functional groups is required. Nevertheless, practical limitations still remain in the control of the fourth, as yet inaccessible (3*S*,4*S*)-*cis*("L-*erythro*") aldol diastereochemistry and the inherent restriction to ketose-type products.[14] Efforts are now being directed at making the TagA as well as supplementary ketose → aldose isomerases available by recombinant DNA techniques.

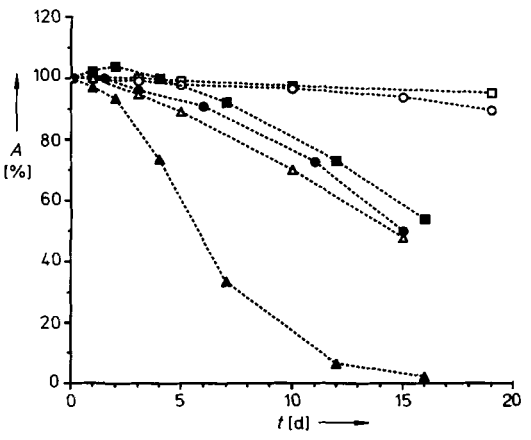

Fig. 2. Stabilities of the aldolases in phosphate buffer (50 mM; 0.5 mM $ZnCl_2$; pH 7.2; ca. 1 U mL^{-1}) at 25°C, determined by assays according to [4]. Examples are a) □ RhuA; b) ○ RhuA, 30% EtOH; c) △ RhuA, 50% DMSO; d) ■ FucA; e) ● FucA, 30% DMSO; f) ▲ FucA, 30% DMF.

Experimental

An aqueous solution of D-glyceraldehyde **3** (25 mmol in 300 mL) was combined with a solution of DHAP[9] (20 mmol in 200 mL) freshly adjusted to pH 6.8. The mixture was incubated with RhuA (100 U) at room temperature for 24 h with monitoring of conversion by thin-layer chromatography (2-propanol/sat. ammonia/water 6:4:2) and enzymic assay for DHAP. The product was isolated by passage through an ion-exchange column (Dowex AG1-X8, $HCO_3^{\ominus}$; 100 mL) and consecutive elution with 200 mM triethylammonium bicarbonate solution. After ion exchange with Dowex AG50W-X8 ($H^{\oplus}$) and neutralization with cyclohexylamine, the product was crystallized from aqueous ethanol (90%) to afford colorless crystals of α-D-sorbopyranose 1-phosphate bis(cyclohexylammonium) salt (**18**); yield: 7.71 g (84%); m.p. 158°C (dec); $[\alpha]_D^{20} = +8.0$ (H_2O, c = 1); ^{1}H NMR (400.1 MHz, D_2O, TSPNa, pH 7.0) δ = 3.56 (d, 3-H), 3.62–3.76 (m, 4-, 5-, 6-H), 3.78 (dd, 1-H_A), 3.87 (dd, 1-H_B); ^{13}C NMR (100.6 MHz, D_2O, CH_3CN, pH 7.0) δ = 62.2 (C-6), 66.5 (C-1, J(C-P) = 3.7 Hz), 70.0 (C-5), 71.2 (C-4), 74.0 (C-3), 98.1 (C-2, J(C-P) = 7.3 Hz).

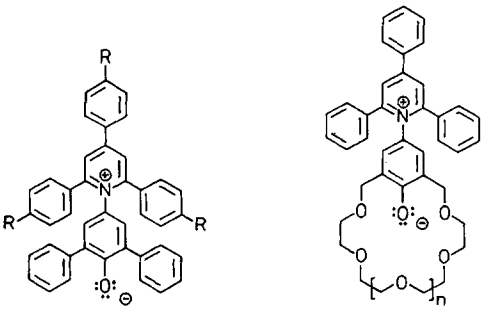
Chromoionophoric Pyridinium-*N*-phenolate Betaine Dyes**

By *Christian Reichardt** and *Siamak Asharin-Fard*

The pyridinium-*N*-phenolate betaine dye **1** is solvatochromic, thermochromic, piezochromic, and halochromic, i.e. the longest wavelength absorption band in the UV-vis solution spectrum is dependent on the polarity of the solvent, the temperature of the solution, the external pressure, and the nature and concentration of an added electrolyte.[1] The exceptionally large negative solvatochromism of **1** was used to define an empirical parameter for solvent polarity, the $E_T(30)$ values.[1, 2] The application of the betaine dye **2**, which is more soluble in water, recently enabled the empirical determination of the polarity of aqueous electrolyte solutions.[3] Both betaine dyes show a *true general* (*nonspecific*) *halochromism*.[3, 4]

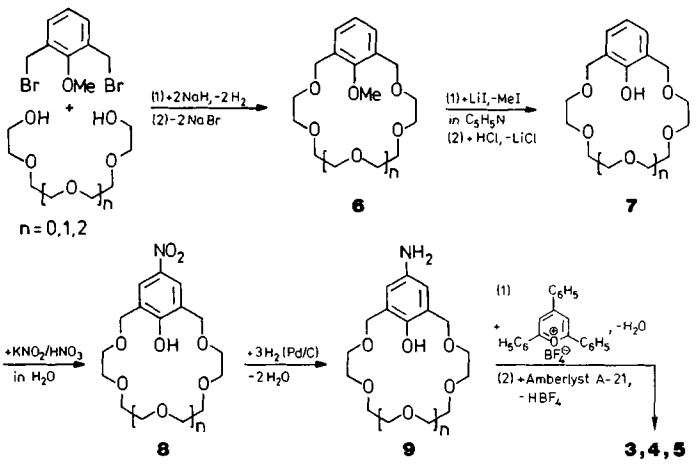
The extreme sensitivity of the long-wavelength absorption band in the UV-vis spectrum of **1** to a slight change in surrounding medium suggests that the introduction of crown ether substituents in the phenolate moiety of **1** would create a chromoionophoric,[5] cation-selective betaine dye displaying true halochromism.[4] A study of the UV-vis spectroscopic properties of such halochromic betaine dyes in aqueous and nonaqueous media would be interesting. We describe here the synthesis and cation-selective true halochromism of the betaine dyes **3**–**5**, which have several advantages over the chromoionophoric dyes known to date.[6]

In our improved synthesis,[7] a solution of 2,6-bis(bromomethyl)anisol and tri-, tetra-, or pentaethylene glycol and sodium hydride in THF is transformed into the crown ether substituted anisols **6** (yields 38–50%) and demethylated with lithium iodide in boiling pyridine to give **7** (yields 60–86%). The careful nitration of **7** with potassium nitrite in dilute nitric acid at room temperature to the 4-nitrophenols **8** (yields 73–86%), followed by catalytic reduction with hydrogen in methanol to the extremely oxidation-sensitive 4-aminophenols **9** (yields 93–99%) and treatment immediately thereafter with 2,4,6-triphenylpyrylium tetrafluoroborate in dichloromethane/AcOH affords (4-hydroxyphenyl)pyridinium salts (yields 80–84%), which are deprotonated practically quantitatively to the betaine dyes **3**–**5** by a basic ion-exchange resin (Amberlyst A-21) suspended in dichloromethane. The other common deprotonation with sodium methanolate in methanol does not yield salt-free betaines **3**–**5**, because of their excellent cation-complexing properties!



1 (R = H)
2 (R = SO_2CH_3)

3 (n=0): [15] crown-4-betaine
4 (n=1): [18] crown-5-betaine
5 (n=2): [21] crown-6-betaine



Like **1** and **2**, the dyes **3**–**5** show a pronounced negative solvatochromism. Thus changing from chloroform ($\lambda_{max} = 668$ nm) to water ($\lambda_{max} = 433$ nm), the long wavelength UV-vis absorption band of the [18]crown-5-betaine **4** undergoes a hypsochromic shift of 235 nm(!). The corresponding molar transition energies E_T[8] of the betaines **3**–**5** correlate linearly with the $E_T(30)$ values of the standard betaine **1**.

The pronounced cation-selective negative halochromism[4] of the new chromoionophoric[5] betaine dyes **3**–**5** can be demonstrated by a test-tube experiment: treatment of a ca. 10^{-3} M solution of **4** in acetonitrile with 10^{-2} M potassium iodide causes a distinct color change from violet ($\lambda_{max} = 583$ nm) to dark red ($\lambda_{max} = 529$ nm; $\Delta\lambda = -54$ nm). The long-wavelength UV-vis band of the betaines **1**–**5** is caused by an intramolecular charge-transfer(CT) transition, through which charge is transported from the phenolate to

the pyridinium moiety.[1, 2] This band disappears on protonation of the phenolate-*O* atom. The crown-ether-mediated complexation of the phenolate moiety of **3**–**5** by suitable cations introduces a hypsochromic shift of the CT band, because the $O^{\ominus}/M^{\oplus}$ interaction increases the ionization energy of the electron donor moiety, while the electron affinity of the electron acceptor moiety is unaffected.

Systematic variation of the cation ($Na^{\oplus}$, $K^{\oplus}$, $Rb^{\oplus}$, $Cs^{\oplus}$, and $nBu_4N^{\oplus}$ as iodides) and anion ($F^{\ominus}$, $Cl^{\ominus}$, and $I^{\ominus}$, as potassium salts) in the solvents methanol, acetonitrile, and propylene carbonate (ca. 10^{-3} M betaine + 10^{-2} M salt) shows that the halochromism of **3**–**5** is selective for cations but hardly dependent on the anion. With tetra-*n*-butylammonium iodide in methanol or acetonitrile, a significantly smaller, but for these three compounds practically equally large, hypsochromic band shift is obtained for all **3**–**5** because of a nonspecific general salt effect (general halochromism[3]).

It follows from the dependence of the λ_{max} shifts of **3**–**5** in methanol on the size of the alkali metal ion of the iodide salt added (Fig. 1) that [15]crown-4-betaine **3** complexes preferably with $Na^{\oplus}$, [18]crown-5-betaine **4** with $K^{\oplus}$, and [21]crown-6-betaine **5** with $Cs^{\oplus}$. Treatment of the $Na^{\oplus}$-

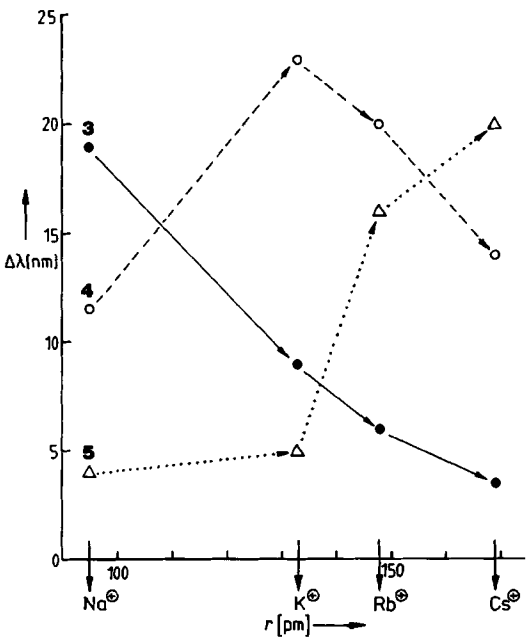

Fig. 1. Halochromism of **3**–**5** in methanol at 25 °C as a function of the Pauling cation radius *r* of the alkali metal iodides NaI, KI, RbI, and CsI (betaine concentration ca. 10^{-3} M; salt concentration 10^{-2} M). $\Delta\lambda = \lambda_{max}$(free of salt) – λ_{max}(with salt).

selective **3** in methanol with a mixture of Na, K, Rb, and Cs iodide, causes a hypsochromic λ_{max} shift as if NaI alone were added. On addition of lithium and alkaline earth metal salts to solutions of **3**–**5** in methanol or acetonitrile, the long-wavelength halochromic CT absorption band disappears, which corresponds to a more intense cation complexation by the phenolate moiety similar to the effect of protonation (formation of contact ion pairs).

Conclusion: The crown-ether-substituted betaine dyes **3**–**5** show, in contrast to several other chromoionophores,[6] a cation-selective negative halochromism,[4] which is manifested as a hypsochromic shift of the long-wavelength CT absorption band of the pyridinium-*N*-phenolate chromophore on addition of salt. As this absorption band lies in the visible spectral region, the cation-induced color changes can be followed easily by eye, which suggests an application of these new chromoionophores as cation indicators.

Experimental Procedure

The spectra were recorded on Hitachi U-3410 (UV/vis), Bruker AC-300 (^1H and ^{13}C NMR), and Varian MAT 711 (MS-FD) spectrometers. All compounds gave correct elemental analyses and were completely characterized by spectroscopy.

3: 1.00 g (3.1 mmol) of **8** (n = 0)[7] in 40 mL anhydrous methanol is reduced with hydrogen at normal pressure (H_2 consumption ca. 230 mL) after addition of 40 mg palladium on activated carbon (0.1 g per g carbon). Removal of the catalyst by filtration and the solvent by distillation under inert gas (N_2) affords 0.90 g (99%) of the aminophenol **9** (n = 0) as bright yellow crystals, which darken immediately on oxidation in air and therefore must be treated further without delay: To a suspension of 0.81 g (2.00 mol) of 2,4,6-triphenylpyrylium tetrafluoroborate [9] in 5 mL dried, N_2-saturated dichloromethane is added, while stirring under N_2, 0.90 g (3.10 mmol) of **9** (n = 0). After 1.5 h stirring at room temperature, 0.10 mL glacial acetic acid is added. The mixture is stirred for 4 h, whereupon 300 mL diethylether is added dropwise, the bright yellow precipitate filtered off, dried over P_4O_{10}, and precipitated from a solution in 5 mL acetone by addition of 15 mL diethylether. 1.10 g of "protonated" **3** (82%, **3**·HBF4) as bright yellow, finely crystalline powder (m.p. 207–209 °C) was obtained, whose composition according to elemental analysis still included 0.5 equiv water. MS(FD): *m/z* 574 [$M^{\oplus}$ – BF_4, 100%]. UV/vis(acetonitrile): λ_{max}[nm](ε)=306(32580). A solution of 0.50 g (0.75 mmol) **3**·HBF_4 in 10 mL dried dichloromethane was treated with 2.00 g Amberlyst A-21 (Serva) and stirred for 3.5 h at room temperature. The dark blue solution was filtered, the solvent distilled off, and the residue dried at 35 °C/0.01 Torr over P_4O_{10} in a drying pistol. Black-red, very hygroscopic crystals of **3** (0.41 g, 97%) were obtained (m.p. 135–139 °C), whose composition according to elemental analysis still includes 1 mol dichloromethane. UV/vis(acetonitrile): λ_{max}[nm](ε) = 581(330), 305(29920).

The betaine dyes **4** and **5** were prepared analogously.

[3] C. Reichardt, G. Schäfer, P. Milart, *Collect. Czech. Chem. Commun. 55* (1990) 97.

[4] Following a proposal of *A. von Baeyer* and *V. Villiger* (*Ber. Dtsch. Chem. Ges. 35* (1902) 1189), halochromism means the color change of a dissolved compound on addition of acid or base during which a chemical reaction transforms a colorless compound into a colored one. In contrast to this trivial halochromism, the true halochromism of dyes like **1** and **2** refers to a color change on addition of an electrolyte to the dye solution not accompanied by a chemical change. We have suggested the term "negative (positive) true halochromism" for a hypsochromic (bathochromic) shift of the UV/vis absorption band of a dissolved substance on increasing electrolyte concentration, when this shift is *not* caused by a chemical change of the chromophore: C. Reichardt, E. Harbusch-Görnert, G. Schäfer, *Liebigs Ann. Chem. 1988*, 839; see also [3].

[5] Chromoionophores are dye molecules which contain chromophoric and ionophoric units. Such an ionophore can complex ions with concomittant color change: a) J. P. Dix, F. Vögtle, *Chem. Ber. 114* (1981) 638 (cf. footnote 2); b) A. Villiger, W. E. Morf, W. Simon, *Helv. Chim. Acta 66* (1983) 1078. Ionophores are neutral macrocyclic molecules (or parts of molecules) which form complexes with ions, and as carriers transport them through biological membranes: B. C. Pressman: "Alkali Metal Chelators – the Ionophors" (*Inorg. Biochem. Vol. 1* (1973) 203). This term was chosen somewhat unfortunately, because previously ionophores referred to ionic compounds which—in contrast to ionogenes—consist of ions in the crystal, in the melt, and in solution: R. Fuoss, *J. Chem. Educ. 32* (1955) 527.

Stoichiometric Mono *N*-Functionalization of Tetraazamacrocycles via Phosphoryl-Protected Intermediates**

By *Ayoub Filali, Jean-Jacques Yaouanc,* and *Henri Handel**

Owing to the cost of polyazacrowns, a stoichiometric and direct method to introduce mono *N*-functionalization is needed.[1] During the past ten years, some phosphorous P^{III}- and P^{V}-containing tetraazamacrocycles have been reported,[2] but they have surprisingly not yet found any synthetic application. Our previous studies on selective mono *N*-alkylation of tetraazamacrocycles[3] prompted us to consider the P^{V}-phosphorylated macrocycles as potential precursors of monofunctionalized tetraazamacrocycles, since they could be seen as cyclic analogues of hexamethylphosphoric triamide containing, besides three inert nitrogen atoms, a free nitrogen atom available for further reaction.

We now report the reaction of these phosphorylated macrocycles with some electrophiles RX giving rise to mono *N*-functionalized ligands after removal of the phosphoryl protection, as depicted in Scheme 1.

The polyaminophosphoranes **1** were obtained according to a previously described reaction by transaminating hexamethylphosphoric triamide with the appropriate tetraazacycloalkane. As noted by *Atkins* and *Richman*[2a] these compounds exist as P^{III}/P^{V} tautomers. After oxidation with CCl_4, the resulting phosphonium salts **2** were hydrolyzed with sodium hydroxide to yield quantitatively the oxides **3**. The action of a suitable electrophile gave finally, after hydrolysis of the intermediate **4**, the desired mono *N*-substituted macrocycles **5**.

In general, the reaction of alcohols with the phosphonium salts **2** leads to a stable, distillable pentacoordinated alkoxyphosphorane **6**;[2b] nevertheless, in the special case of activated alcohols like benzyl, allyl, or propargyl alkohols we observed that **6** isomerized to the *N*-alkylated intermediates **4**. Using this principle we alkylated a series of tetraazamacrocycles (Table 1). When applied to less symmetrical azamacrocycles (for instance isocyclam "3322"), this method led to a mixture of regioisomers which are not easily separable by usual techniques. It is thus better suited to symmetrical macrocycles.

This easy-to-run process constitutes a powerful and stoichiometric method of preparing the mono *N*-functionalized tetraazamacrocycles.

Table 1. Mono *N*-functionalization of tetraazamacrocycles.

Experimental Procedure

General Procedure

The tetraazamacrocycle **1** (1.0 mmol) in dry toluene (30 mL) was refluxed under nitrogen with hexamethylphosphoric triamide (1.0 mmol) until dimethylamine evolution ceased. After cooling to 0–5 °C, excess CCl_4 was added upon which a white solid separated. The solvent was removed under reduced pressure and the remaining crude phosphonium salt **2** treated with 2 N sodium hydroxide (5 mL). The aqueous phase was extracted with $CHCl_3$ (2 × 50 mL); the combined organic phases were dried and finally concentrated to dryness in vacuo giving the crude phosphorylated tetraazamacrocycle **3** pure enough for the next reaction.[4]

To a solution of **3** (1.0 mmol) in dry DMF (20 mL) was added an excess of dry Na_2CO_3 and the mixture heated to 100 °C. The alkylating agent (1.0 mmol) was

introduced by syringe and the temperature maintained at 100 °C for 2 hours. After cooling to room temperature, the solvent was removed in vacuo. The resulting residue was taken up in 3 N HCl (10 mL) and refluxed for 10 hours. The pH was then carefully adjusted to 12 with NaOH pellets. After extraction with $CHCl_3$ (2 × 50 mL), drying of the combined organic phases, and evaporation of the solvent, the pure mono *N*-alkylated tetraazamacrocycle was obtained, generally as an oily residue.

Modified Procedure: direct alkylation of the phosphonium salt **2**

The suspension of **2** in toluene was treated with the required alcohol (1.0 mmol) (Scheme 1), the solvent was removed and replaced by dry DMF (20 mL), an excess of Na_2CO_3 was added, and the mixture was heated at 100 °C for 2 hours. The subsequent work-up was as described above. All the mono *N*-alkylated tetramines gave satisfactory IR, MS, and ^1H NMR data.

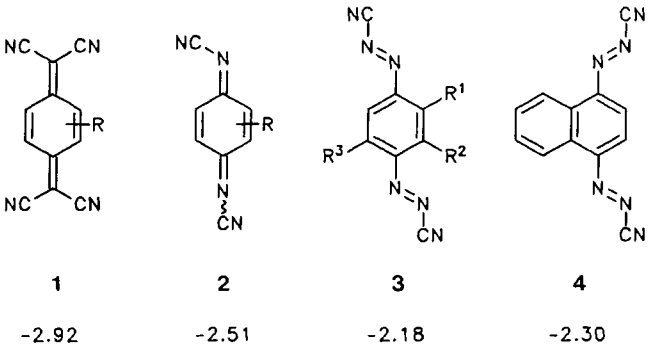
Benzene Bis(diazocyanides)—the First Acceptors of the Inverse Wurster Type for Conductive Organic Materials**

By *Hartmut Almen, Thomas Bauer, Siegfried Hünig,* Vladimir Kupčik, Uwe Langohr, Tobias Metzenthin, Klaus Meyer, Harald Rieder, Jost Ulrich von Schütz, Ekkehart Tillmanns,* and *Hans Christoph Wolf*

Tetracyanoquinodimethane(TCNQ)[1] and *N,N'*-dicyanoquinonediimine(DCNQI)[2] and derivatives thereof (**1** and **2** respectively) have proved to be the most important organic electron acceptors for charge-transfer(CT) complexes or radical anion salts with electrical conductivity. Both types of compound form two-stage reversible redox systems and thus belong to the Wurster type, in which the defined acceptor end groups are connected to the six membered π ring system in such a way that the oxidized stage has quinone character.[3] We wondered whether the as yet unused two-stage redox systems of inverse Wurster type, that is, with aromatic oxidized stage[3] (see Scheme 2), is also suitable as acceptor for conductive organic materials.

The benzene-1,4-bis(diazocyanides) **3** (dicyanazobenzene [DCNAB]) appeared to be promising candidates, since the



Scheme 1. Organic electron acceptors and their LUMO energies calculated with MNDO-AM1 for the parent compounds.

LUMO energy as calculated by MNDO-AM1[4] (Scheme 1) of the almost planar structure lies in a similarly favorable range to the tried and tested compounds **1** and **2**.[5] It was, however, doubtful whether the orbital symmetry of **3**, which is vastly different from that of the quinones, would allow the stacking in the crystal essential for conduction.

We now use the first examples, which also include naphthalene-1,4-bis(diazocyanide) **4**, to show that these compounds, besides having spectroscopically detectable radical anions[6], not only form fully reversible two stage redox systems of the inverse Wurster type,[3] but are also potent acceptors in conductive CT complexes and radical anion salts.[7]

Table 1 shows that the redox potentials of **3** and **4** lie in the same region as those of TCNQ, **1**(R = H) and DCNQI, **2** (R = H). The semiquinone formation constants of lg K_{SEM} =

Table 1. Redox potentials E_1 and E_2 determined by cyclic voltammetry (Pt electrode vs. Ag/AgCl/CH_3CN, electrolyte nBu$_4$NBF$_4$) and semiquinone formation constants lg K_{SEM} of **1**–**4** (see also Scheme 2.)

	R^1	R^2	R^3	E_1 [V]	E_2 [V]	lg K_{SEM}
3a	Me	H	Me	− 0.15	+ 0.20	5.92
3b	H	H	H	− 0.15	+ 0.22	6.10
3c	Cl	H	Cl	+ 0.07	+ 0.47	6.82
4				− 0.01	+ 0.32	6.49
1 (R = H) [5]				− 0.28	+ 0.39	11.42
2 (R = H) [5]				− 0.25	+ 0.39	10.75

5.92–6.82 are still very large, although a factor of ca. 10^4 smaller than in TCNQ and DCNQI. That is predictable, because the Coulomb repulsion in the longer systems of **3** and **4** (they contain two more atoms) has less effect on the gain of electrons.[8] Surprisingly, a higher acceptor capacity (LUMO = 2.30 eV) is calculated for **4** than for **3b**, which is also reflected in a higher reducibility (E_2 = + 0.32 V). The opposite is true for the transition from DCNQI to the corresponding naphthalene derivate.[5]

Furthermore, the MNDO-AM1 calculations show that during the reduction (OX → SEM → RED) **3b** indeed assumes progressively a quinoid structure. Thus the exocyclic C_{aryl}–N single bond becomes shorter on gain of electrons (144 (OX) via 138 (SEM) to 133 pm (RED)); the bond between C2 and C3 also shortens (139 (OX), 137 (SEM), 135 pm (RED)). The corresponding experimentally determined bond lengths in DCNQI are 130 (C–N) and 134 pm (C=C).[9]

On combining solutions of **3** or **4** with solutions of tetrathiofulvalenes(TTF) or tetramethyltetraselenafulvalenes-

(TMTSF), black CT complexes crystallize, the majority of which have a high powder conductivity (Table 2), so that they compare well with the CT complexes of TCNQ[10] and DCNQI.[11]

Table 2. Powder conductivities σ of CT complexes with **3** or **4** as acceptor.

Acceptor	Donor [a]	m:n [b]	σ [S cm^{-1}]
3a	TTF	1:1	120 [c]
3b	TTF	1:1	3×10^{-1}
3b	TMTTF	1:1	3×10^{-3} [c]
3c	DBTTF	1:2	2×10^{-5}
3c	TTF	1:1	2×10^{-4}
3c	TMTTF	1:2	1×10^{-2}
3c	TMTSF	1:2	4×10^{-2}
4	TTF	1:1	1
4	TMTTF	1:1	1

[a] TMTTF = tetramethyltetrathiafulvalene, DBTTF = dibenzotetrathiafulvalene. [b] Ratio Acceptor: Donor derived from elemental analysis. [c] Single crystal conductivities.

Thus segregated donor and acceptor stacks can also be assumed for the new CT complexes.[12] This characteristic arrangement for conductive CT complexes was confirmed by a crystal structure analysis of the **3a**/TTF complex (for which

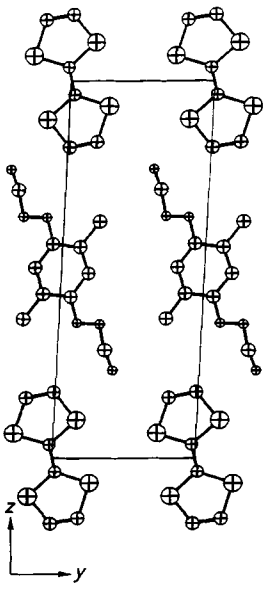

Fig. 1. Structure of **3a**/TTF in the crystal; projection along [100]; space group $P\bar{1}$, $a = 3.76$, $b = 6.54$, $c = 18.12$ Å, $\alpha = 87.0$, $\beta = 85.8$, $\gamma = 87.7°$.

$\sigma = 120$ S cm^{-1}).[13] A preliminary picture could be obtained by synchrotron–X-ray radiation. Figure 1 shows the projection onto the yz plane. Although the poor quality of the crystals, and therefore of the crystal data, has not yet enabled the determination of the atomic coordinates in the x direction with satisfactory accuracy, the small lattice constant of 3.76 Å allows only one molecular unit per unit cell, so that the separate arrangement of donor and acceptor stacks is assured.

The temperature dependence of the conductivity of this compound (Fig. 2, top) corresponds with that of a metal-like semiconductor with a small band gap of $\Delta E \approx 40$ meV. This value results from the charge carrier concentration C, which could be followed in the electron spin resonance experiments (Fig. 2, bottom) down to very low temperatures. The small

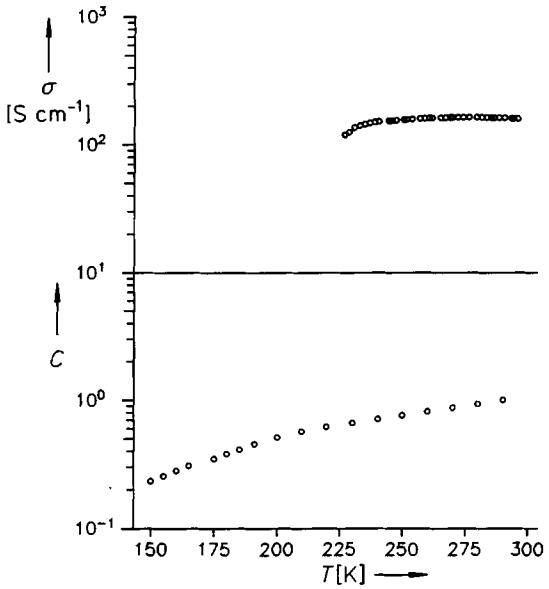

Fig. 2. Top: Temperature dependence of the single crystal conductivity of **3a**/TTF. All crystals break at $T < 215$ K. Bottom: Normed spin carrier concentration $C = \chi T/300\chi_{300K}$ as function of the temperature.

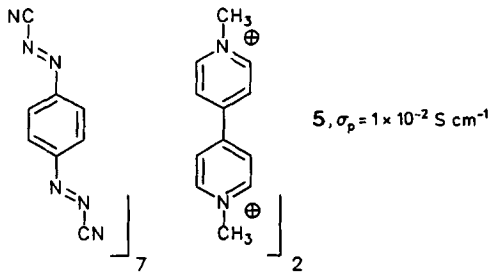
ESR signal width of 2 Gauss at 300 K is a strong indication that the **3a** stack is the dominant factor in conductivity, because when the charge carriers in such complexes come into contact with sulfur atoms of the TTF stack, the signal widths are usually at least 6–100 Gauss.[14]



Example **5** shows that conductive radical ion salts can also be formed from the new acceptor types. This proves that acceptors of the inverse Wurster type can assume the role of those of normal Wurster type used till now.[15] These results have prompted us to synthesize further derivatives of **3** and to test them in conducting materials.

Experimental Procedure

Reaction of **3a** with TTF: 21 mg (100 μmol) **3a** in a mixture of 0.5 mL dry dichloromethane and 0.5 mL acetonitrile is treated at room temperature with a solution of 30 mg (147 μmol) TTF in 1 mL acetonitrile. Immediately a dark precipitate forms. After 45 min at 0 °C, filtration and drying over silica gel yields 36 mg (86%) green-golden needles. M.p. 146 °C (dec.). IR(KBr): $\nu = 2100\ cm^{-1}$. UV/vis (CH_3CN): $\lambda_{max}(\lg \varepsilon)$ = 226(sh, 3.989), 321(4.256), 360(4.416), 572 nm(2.739).

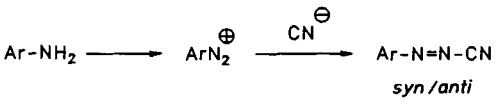
A New Route to Aromatic Diazocyanides**

By *Siegfried Hünig** and *Tobias Metzenthin*

Benzene-1,4-bis(diazocyanide) and naphthalene-1,4-bis(diazocyanide) belong, as the previous communication shows,[1] not only to the reversible two-stage redox systems, but also to the first acceptors of the inverse Wurster type for conductive organic materials.[2] We therefore required a flexible synthesis route for this class of compounds.

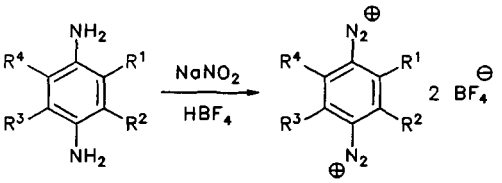
The problem appeared to be very simple to solve along the lines of the classical synthesis of arene diazocyanides **1** according to *Hantzsch* et al.[3] (Eq. (a)). Many compounds have been prepared in this way, especially for the study of *syn/anti* isomerism.[4]



(a)

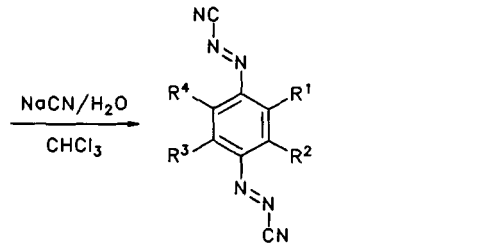
1

The arene bis(diazocyanides) **4** could indeed be synthesized from some *p*-phenylenediamines **2** via the bis(diazonium) salts **3**[5] (Eq. (b)). It was, however, necessary to isolate the labile and occasionally explosive salts **3** and to extract the diazocyanides **4**, which form in the reaction with cyanide, continuously into chloroform in order to suppress a further addition of cyanide at the nitrile group.[4a,d] Even under these conditions the yields are only 10–50%. A more serious disadvantage is that some bis(diazonium) salts (e.g. **3d**, $R^1 = R^3 = Me$; $R^2 = R^4 = H$) can be isolated only in impure state or sometimes not at all.



2 **3**

(b)



4

a, R^1-R^4 = H; **b**, $R^2 = R^4 = H$, $R^1 = R^3 = Cl$; **c**, $R^1R^2 = (CH)_4$, $R^3 = R^4 = H$

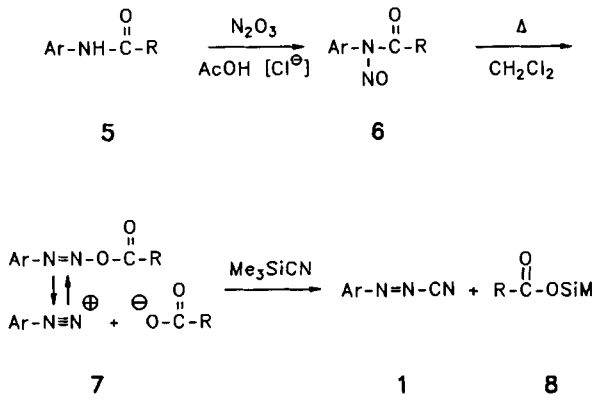
Therefore we searched for a synthesis of **4** in which the isolation of the bis(diazonium) salts was unnecessary and the diazocyanide function could be formed without further reaction with excess cyanide. We describe now a general route to the diazocyanides **1**, which can also be applied in the case of the difunctional derivatives **4**[6] without these difficulties.

This route requires first the nitrosation of *N*-aryl amides **5** to the *N*-nitroso derivatives **6** by known methods,[7] whose rearrangement to the *O*-aryldiazo esters **7** was studied thoroughly, in particular by *Huisgen* et al.[8] The thermal rearrangement in the presence of trimethylsilylcyanide in an organic solvent affords the desired diazocyanides **1**, in good yields after their easy separation from the trimethyl esters **8** (e.g., for 4-chlorobenzenediazocyanide,[4a] 60% after sublimation; see Scheme 1).

The conversion **7** → **1** is apparently very rapid, because the competing intramolecular reaction of the methyl group in an *o*-substituted arene, which leads smoothly to indazoles, is not observed. (The same is true for **10** → **4**.)

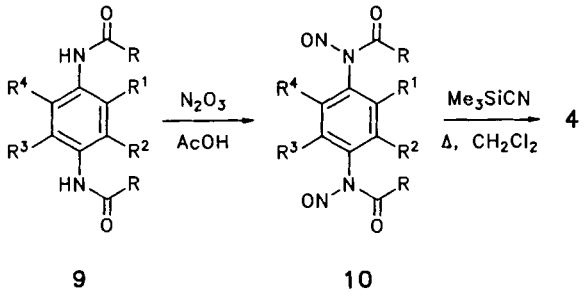
[*] Prof. Dr. S. Hünig, Dipl.-Chem. T. Metzenthin
Institut für Organische Chemie der Universität
Am Hubland, W-8700 Würzburg (FRG)

[**] This work was supported by the Volkswagen-Stiftung and the Fonds der Chemischen Industrie.



Scheme 1. Ar = C_6H_5; *p*-ClC_6H_4, R = CH_3.

The extension of steps **5** → **7** to the bifunctional derivatives failed at first because of the low solubility of the bis(acylamines) **9**. Whereas the solubilities when R = Me, Et, *n*Pr, *i*Bu, and *t*Bu hardly differ, the bis(acylamines) **9** with R = CH_2OMe were very soluble and could be nitrosated in the usual way in 70–95% yield (Scheme 2). The methoxyacetyl residue gave the added advantage that the dinitroso derivatives **10** then could easily be handled at room temperature and rearranged only in boiling dichloromethane. The high temperatures involved cause the bis(diazocyanides) **4** to precipitate exclusively as *trans* isomers.



Scheme 2. Synthesis of bis(diazocyanides) **4**. Optimal R: CH_2OMe. Yields: 62% **4c**, 68% **4d**.

The proposed route for the introduction of the diazocyanide function into arenes is thus a clear improvement over the classical method, at least for the difunctional derivatives **4**. At the same time it represents a new trapping reaction for the *O*-diazoesters formed by rearrangement.

Experimental Procedure

4d: Into a heated flask is placed a solution of 1.50 g(4.43 mmol) **10d** [7,10] in 80 mL dried dichloromethane and 20 mL trimethylsilylcyanide (Aldrich). The mixture is heated in a fume hood for 4 h at 50 °C, whereupon the solvent and trimethylsilyl cyanide is distilled off at 1 torr. The residue is dried for 0.5 h at 0.1 Torr, taken up in dichloromethane, and quickly filtered over silica gel (0.032–0.063 mm). The eluant is evaporated to dryness and the product dried under vacuum (oil pump). Yield: 635 mg deep red crystals of **4d**, m.p. 171 °C(dec.). – IR(KBr): $\tilde{\nu}$ [cm^{-1}] = 3090(CH), 3030(CH), 2180 (C≡N), 1475, 1380, 1360, 1300, 1150, 910. UV(CH_3CN): λ_{max} [nm] (lgε) = 208 (4.23), 227 (sh, 3.88), 361 (4.44). ^1H NMR (200 MHz, $CDCl_3$): δ = 2.72 (s, 6H, CH_3), 7.58 (s, 2H, H_{aryl}). ^{13}C NMR(50.3 MHz, $CDCl_3$): δ = 17.39 (q, CH_3), 115.20 (s, CN), 117.26 (d, C-3,6), 141.31 (s, C-2,5), 155.23 (s, C-1,4).

The Tetrameric Aluminum(I) Compound $[\{Al(\eta^5\text{-}C_5Me_5)\}_4]$**

By *Carsten Dohmeier, Christian Robl, Matthias Tacke,* and *Hansgeorg Schnöckel**

Gaseous, low-valent aluminum compounds have been known for a long time. *Klemm* et al. reported in 1948 already[1] the formation of gaseous AlCl during the reaction of Cl_2 with Al at 1000 °C. The first structural investigations on compounds with low-valent aluminum and Al–Al bonds are fairly recent. *Nesper* et al [2] prepared solid Al_7Te_{10} and *Uhl* the first molecular compound with an Al–Al bond: R_2Al–AlR_2(R = $CH(SiMe_3)_2$) **1**.[3]

For some time we have been studying the high temperature molecule AlCl,[4] its stabilization, and applications in preparative chemistry. The application of cryochemical methods enabled the preparation of unusual compounds of the trivalent aluminum from AlCl and unsaturated organic molecules.[5] Recently we prepared and identified a solution of AlCl which is metastable at −78 °C in the mixed solvent toluene/diethylether.[6] The first compound of monovalent aluminum stable at room temperature could be synthesized by treatment of this solution with $[Mg(C_5Me_5)_2]$ (eq. (a)).

$$\underset{\mathbf{2}}{4(AlCl \cdot x\,Et_2O)} + \underset{\mathbf{3}}{2[Mg(C_5Me_5)_2]} \xrightarrow{\text{toluene/}Et_2O} \underset{\mathbf{4}}{[\{Al(C_5Me_5)\}_4]} + 2(MgCl_2 \cdot 2Et_2O) + (4x-4)\,Et_2O \qquad \text{(a)}$$

The constitution of the (η^5-pentamethylcyclopentadienyl)-aluminum(I) **4** was confirmed by X-ray crystallography (Fig. 1).[7] The four aluminum atoms form a regular tetrahedron. Each pentamethylcyclopentadienyl ring is η^5-coordinated to an aluminum atom, whereby the planes of the C_5Me_5 rings are, in good approximation, parallel to the opposite base of the tetrahedron. The average Al–C distance is

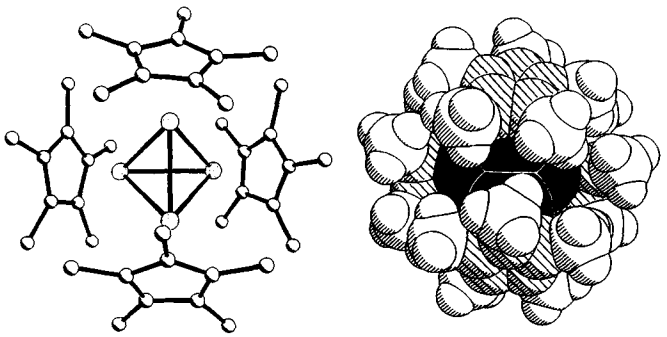

Fig. 1. Left: Structure of **4** in the crystal (hydrogen atoms omitted.) Selected distances [pm] and angles [°] (standard deviations in parentheses): ($d_{max}/d_{min}/\bar{d}$) Al-Al (277.3 (4)/276.7 (5)/276.9), Al-C_{Ring} (229.2 (13)/237.8 (11)/233.4), Al-Cp_{center} (203.2/199.7/201.5), Al-Al-Al (60.1 (1)/59.9 (1)/60.0). Right: Space-filling model of 4; Al atoms are black, C atoms hatched, and methyl-C and hydrogen atoms white.

233.4 pm and is thereby comparable with that in **3** (234.8 pm).[8]

The average Al–Al distance of 276.9 pm lies between that of **1** (266.0 pm) and of metallic aluminum (286 pm). This intermetallic distance distinguishes the aluminum compound from other oligomeric and polymeric M^I–η^5-C_5Me_5 compounds (M = In, Tl). In the octahedral cluster [In(η^5-C_5Me_5)]$_6$,[9] the In–In distances are 394.2 and 396.3 pm and therefore significantly longer than in In metal (394, 336 pm). Shorter metal atom distances are found in "dimeric" [In{η^5-$C_5(CH_2Ph)_5$}] (363.1 pm).[10] In the structurally analogous thallium compound, [Tl{η^5-$C_5(CH_2Ph)_5$}],[11] the distance between thallium atoms is 363.2 pm, in metallic thallium 336 and 343 pm. [Tl(η^5-C_5Me_5)][12] forms a polymeric chain of alternating thallium atoms and C_5Me_5 rings. In this compound the distance between chains is so large (641 pm) that a Tl–Tl interaction can be excluded. Thus, the interactions between the aluminum atoms in **4** are significantly larger than in the known cyclopentadienyl compounds of monovalent indium or thallium.

In the FT Raman spectrum of solid **4**, a broad band is observed at 377 cm^{-1},[14] which we assign to the breathing vibration (A_1) of the Al_4 tetrahedron. The Al–Al frequency of **1** lies at 373 cm^{-1}.[3] In spite of the weak bonding in the Al_4 species relative to the Al–Al bond in **1**, the frequencies agree. This can be explained by different vibration equations.[15]

The ^{27}Al NMR spectrum (70.4 MHz, external standard $[Al(H_2O)_6]^{3\oplus}$) of a solution of **4** in benzene exhibits a sharp signal at $\delta = -80.8$ ($\omega_{1/2} = 170$ Hz). This is to our knowledge the highest known chemical shift for an aluminum nucleus. The structure and reactions of **4** in solution are at present under investigation.

The compound [{Al(η^5-C_5Me_5)}$_4$] **4** presented here is the first molecular aluminum(I) compound stable under normal conditions, whose structure could be determined by diffraction methods and the third example (after In and Tl) of a $M^I(C_5Me_5)$ compound of the third main group elements. After the successful synthesis of **4** one expects that the missing members [B(C_5Me_5)] and [Ga(C_5Me_5)] can be prepared along similar lines.

Experimental Procedure

To a solution of 3.3 mmol **2** in 13 mL toluene at −78 °C is added dropwise a solution of 1.5 mmol **3** in 10 mL toluene. 214 mg(44%) yellow octahedral crystals of **4** are isolated from the resulting deep red solution at −25 °C. The product is air- and moisture-sensitive.

Difference Electron Densities in a Spiropentene**

By *Hermann Irngartinger,** and *Stefan Gries*

Dedicated to Professor Heinz A. Staab on the occasion of his 65th birthday

Spiropentene ranks among the most strained organic molecules known. The calculated strain energy lies between 82.1 and 92.3 kcal mol^{-1}.[1, 2] To prove that the bonds are bent,

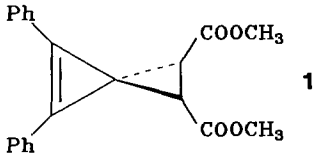
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

we determined the difference electron density of the crystalline spiropentene derivative, dimethyl 4,5-diphenyl-4-spiropentene-(*E*)-1,2-dicarboxylate **1**, by low temperature X-ray diffraction measurements (105 K) according to the X-X method.[3]



The spiropentene **1** was synthesized by carbenoid-addition techniques.[5] As in spiropentanes,[6] the central bonds in spiropentene **1** are shorter than the peripheral C–C single bonds (Fig. 1). Because of the large strain and the conjugation with both phenyl rings, the C–C double bond in 1 (C4–C5: 1.311 Å) is longer than in cyclopropene (from microwave spectroscopy: 1.296 Å[7]). The conditions for conjugation with both phenyl rings are favorable, because the dihedral angles are only 6.0° and 11.3°.

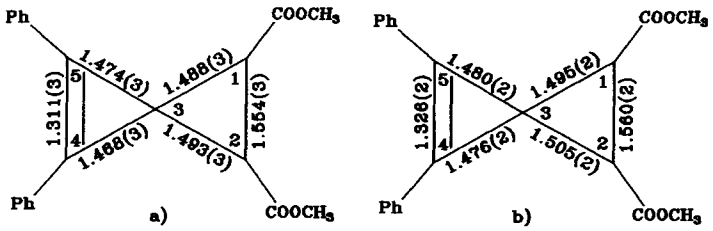


Fig. 1. Bond lengths (Å) of the spiropentene **1**: a) at room temperature (293 K), b) at 105 K.

The peripheral bond C1–C2 in **1** is longer than in spiropentane.[6] As in the cyclopropane derivatives[8] this bond is lengthened by the electron-withdrawing properties of the ester groups (Fig. 1). The two ester groups deviate by only 0.3° and 5.3° from a bisecting orientation, which allows an optimal interaction between the orbitals of the substituents and the Walsh orbitals of the three-membered ring. The electronic effects on the central bonds C1–C3 and C2–C3 weaken each other, since these bonds are in geminal and distal positions, respectively. Therefore, on comparison with spiropentane[6] no significant differences in these bond lengths can be observed. The interatomic distances at low temperature are longer than at room temperature, because the shortening effects due to libration and to the influence of the bonding electrons are minimal (Fig. 1).

All the single bonds of the spiropentene **1** are strongly bent, which is easily recognized in the shifts of the electron density maxima relative to the bond axes (Fig. 2). The bending of the bonds in spiropentanes is of the same order of magnitude.[6] Significantly more pronounced bending in the saturated three-membered ring of **1** relative to the less strained cyclopropane[9] and its derivatives[9, 10] could not be observed within experimental error.

The C4–C5 bond has a very high degree of bending compared with other strained double bonds. The density maximum is shifted significantly from the bond axis (0.18 Å, angle between bond axis and the line connecting the atom and the electron density maximum: 15°). The bending is more pronounced than in the double bonds of the four-membered ring system of cyclobutadiene (0.08 Å and 8° respectively[11]). In benzocyclopropenes the bending is greater as a result of the reduced bond order.[12] Strong deformations of the bonds in spiropentane and spiropentene are also predicted by quantum mechanical calculations.[2, 13]

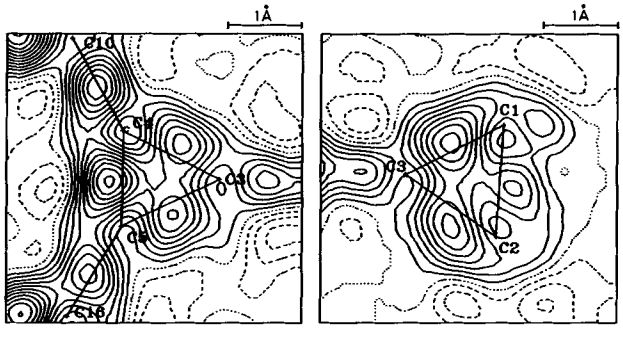

Fig. 2. Difference electron density map of the planes containing the cyclopropene (C3, C4, C5) and cyclopropane (C1, C2, C3) rings of spiropentene **1**. Contour interval 0.05 e/Å^{-3}. Standard deviation of the difference density outside the atomic positions 0.03–0.04 e/Å^{-3}. Zero density line dotted, negative electron densities dashed.

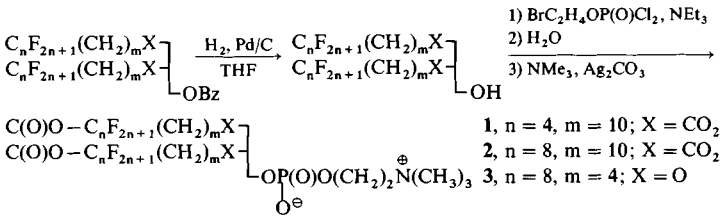
Highly Stable Liposomes Derived from Perfluoroalkylated Glycerophosphocholines**

By *Catherine Santaella, Pierre Vierling,* and *Jean G. Riess**

Dedicated to Professor Rolf Appel on the occasion of his 70th birthday

Vesicles formed from phospholipids (liposomes) provide chemical models for the study of biological membrane functions[1] as well as challenging drug carrier and delivery systems.[2] Vesicles made from pure phospholipids, however, have low stability. The development of more stable membranes usually requires multicomponent systems and elaborate formulations resulting in increased complexity.[3] Natural soybean or egg-yolk phospholipid (EYP) mixtures are also routinely used as surfactants in injectable preparations such as fat emulsions for parenteral nutrition,[4] emulsions of fluorocarbons to be used as artificial oxygen carriers and contrast agents,[5] and drug delivery systems.[6] However, these phospholipids have limitations owing to their biological origin (complex, not exactly reproducible mixtures) and to their chemical nature (hydrolizable and oxidizable). Moreover, they leave little leeway for varying the properties of vesicles and emulsions, and further additives such as cholesterol are generally needed to achieve practical shelf lives.

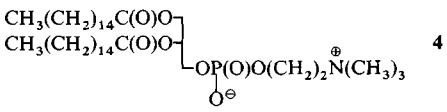
Future progress will aim at obviating these limitations and therefore at developing new lines of biocompatible membrane- and vesicle-forming amphiphiles, which may also be used as surfactants or co-surfactants for injectable fluorocarbon emulsions. Accordingly, we have synthesized analogues of phosphatidylcholines, the main components of natural EYPs[7] (Scheme 1), in which the natural fatty acid tails are



Scheme 1. Synthetic pathway for the preparation of F-alkyl GPCs **1**–**3**.

replaced by saturated chains (to avoid oxidation) terminated by perfluoroalkylated chains, and linked to the glycerophosphocholine polar head through an ester (**1** and **2**) or an ether junction (to avoid hydrolysis) (**3**). The perfluoroalkylated tails were expected to increase the hydrophobicity of the membrane lipids, which usually leads to improved stability of the vesicle shell,[8] and their fluorophilicity, which should facilitate and stabilize the dispersion of fluorocarbons in water.

We report here that the *pure* perfluoroalkylated glycerophosphocholine (F-alkyl GPC) esters **1**, **2** and ether **3** do effectively form highly stable liposomes without any secondary additive, and that these vesicles can be heat-sterilized under the standard norms of the Food and Drug Administration. Their shelf-life is considerably higher (months vs. days) than that of the vesicles formed by their hydrocarbon analogue 1,2-dipalmitoyl 3-*rac*-glycerophosphocholine (DPPC, **4**). Some preliminary data on their biocompatibility and on their ability to emulsify fluorocarbons are also given.



4

Like their hydrocarbon analogue **4**, the F-alkyl GPCs **1** to **3** are insoluble but dispersible in water, on application of standard procedures such as sonication. Concentrations as high as, or even higher than 200 g L^{-1} of F-alkyl GPC could be attained. Electron microscopy of these dispersions after freeze fracture (exemplified for **1** in Fig. 1a) shows that they consist of vesicles. These vesicles[9] have average sizes (60–200 nm, by light scattering spectroscopy (LSS) after brief sonication) in the range of those formed by natural or synthetic phospholipids in similar conditions.[10]

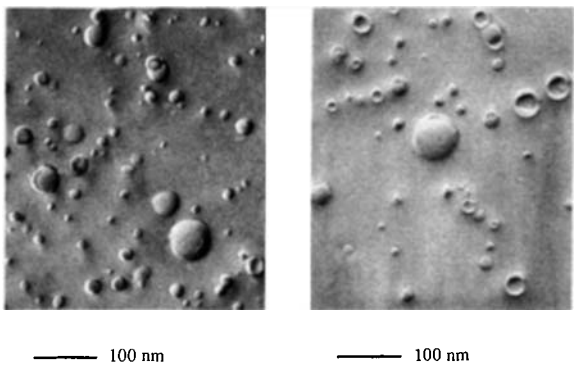


Fig. 1. Unilamellar and multilamellar vesicles made from F-alkyl GPC **1**. Left: before sterilization; right: after sterilization (121 °C, 15 min, 10^5 Pa)

Two issues are of major importance in the technology of liposomes and injectable emulsions for medical purposes: their resistance to sterilization and their in vitro storage stability.[11] Electron microscopy after freeze fracture (Fig. 1) showed that the vesicles formed by the F-alkylated amphiphiles **1** were morphologically not affected by thermal sterilization (121 °C, 15 min, 10^5 Nm^{-2} 10^5 Pa. LSS measurements also established that no significant modification of the average particle sizes had occurred (Table 1). By contrast, when a dispersion of **4** was prepared under the same conditions, a new population of much larger-sized vesicles (1150 nm diameter) appeared and became predominant upon sterilization.

Most remarkable is the fact that the F-alkyl GPC dispersions can be stored at room temperature for several months without sedimentation or any other visible change. LSS measurements showed that only a limited particle size increase had occurred after five or ten months for sterilized dispersions of F-alkyl GPC esters **2** and **1** respectively (Table 1). Likewise, dispersions of the F-alkyl GPC ether **3** have been stored (without sterilization) for 1.5 years without sedimentation or other visible changes. However, particle size measurements show that two populations of liposomes had

[**] We acknowledge the generous support of the Centre National de la Recherche Scientifique (CNRS) and the Agence de Transferts de Technologies Avancées (ATTA) throughout this research.

formed (53 nm and 207 nm). The absence of large particles ($> 1\ \mu m$), especially with **1**, indicates that the fusion of vesicles during storage is very slow. The behavior of **1**, **2** and **3** thus contrasts strongly with that of DPPC (**4**) whose liposomal dispersions, whether sterilized or not, can only be stored for a few days. When prepared by sonication or French press extrusion the latter were shown to retain their original sizes and integrity for 48 h at most.[12] When treated in the same way as the F-alkyl GPC, heat-sterilized dispersions of DPPC vesicles (3% w/w) displayed already after two days an increase in turbidity and a fluffy aspect which indicated the formation of larger particles and precluded valid LSS particle size measurements; an irreversible sedimentation was observed after six days at room temperature.

Table 1. Particle sizes D after preparation (left), sterilization (center), and ageing (right) at 25 °C of dispersions of F-alkyl GPC (**1**, **2**, **3**) and DPPC (**4**)[a].

Compound	D [nm] [a]	Amount [%]	D [nm] [a]	Amount [%]	D [nm] [a]	Amount [%]	Age days

	260 (70)	57	140 (20)	14	precipitate		
			1150 (230)	60			

[a] Standard deviations [nm] in parentheses. [b] Sterilized dispersion of 3% (w/w) of **1**, **2**, or **4** in either water, NaCl (0.9%) or Hepes buffer (10^{-2} M). No difference in size or size distribution was observed whatever the aqueous phase. [c] Nonsterilized dispersion of **3** at 6% (w/w) concentration in NaCl (0.9%).

The remarkably long shelf life of the F-alkyl GPC vesicles indicates that their membrane is highly stable. Apparently the partial replacement of hydrocarbon chains by fluorinated ones resulted in sufficient increase of the hydrophobic interactions[8] to counterbalance any destabilizing effect[13] arising from lower intermolecular interactions and an increase of steric repulsions between the fluorinated chains.

With the new F-alkyl GPCs as emulsifier, stable emulsions of 50% (w/v) of perfluorodecalin, a fluorocarbon rather difficult to emulsify, can be readily prepared using sonication.[14] Compound **2** was compared to EYP and to hydrogenated EYP (Lecinol®, which, because it is saturated, is structurally closer to **2** than EYP). Both EYP and Lecinol are mixtures of amphiphiles and are therefore known to be considerably more efficacious emulsifiers than any single phospholipid. It is therefore noteworthy that **2** when used alone was significantly more effective than Lecinol (which failed in the emulsification of perfluorodecalin), and was nearly as efficient as the natural EYP mixture. Thus, for example, 50/50 (w/v) emulsions of perfluorodecalin were prepared with 32.5 mM of surfactant. The emulsions prepared from EYP in a phosphate buffer had an average particle size of 0.24 μm (76% < 0.40 μm, no particle larger than 1.1 μm) after preparation, 0.23 μm (79% < 0.40 μm, 3% > 1.1 μm) after sterilization, and 0.31 μm (67% < 0.40 μm, 3.5% > 1.1 μm) after one month at 25 °C; in comparison, when **2** was used as the surfactant the average particle sizes were 0.24 μm (85% < 0.40 μm, 0% > 0.95 μm) after preparation, 0.32 μm (73% < 0.40 μm, 0% > 1.1 μm) after sterilization, and 0.36 μm (58% < 0.40 μm, 0% > 1.1 μm) after ageing at 25 °C. Further improvement in stability of such emulsions is expected when mixtures of F-alkyl phospholipids, or mixtures of F-alkyl GPCs with other surfactants, are used.

As the F-alkyl GPCs are destined for in vivo applications, preliminary biological tests, including effect on cell cultures, hemolytic activity, and acute toxicity in mice, were undertaken.[15] Compounds **1** to **3**, in the form of dispersions, did not perturb the growth or viability of lymphoblastoid Namalva cell cultures. It is particularly remarkable that no hemolytic effect on a suspension of human red blood cells was detected, even at high concentrations (for example 60 g L^{-1} of **2**), while saturated hydrocarbon phosphatidylcholines of similarly low chain lengths (eight to twelve carbon atoms) are definitely hemolytic,[16] (for example a 1 g L^{-1} dispersion of 1,2-dilauryl-3-*rac*-glycerophosphocholine). Preliminary in vivo tests indicate that the intravenous LD_{50} in mice are higher than 2500 mg kg^{-1} body weight (no death among ten animals after one month observation). Although these synthetic phospholipids are racemic, the non-natural D-isomer apparently does not lead to any acute toxicity, at least not in these initial screening tests.

[9] Dispersions of phospholipids were prepared by hydrating the powdered or thin-layered lipid with water, NaCl (0.9%) or Hepes buffer (10^{-2} M) for ten minutes above the phase transition temperature of the lipid, shaken for 1 min to produce a coarse dispersion, which was then sonicated briefly (2 to 5 min, Branson B30 sonifier, titanum probe 15 mm, dial 5, pulse 50). Sterilization was achieved by autoclaving the samples (5 ml) for 15 min at 121 °C under 10^5 Pa. Particle sizes and size distributions were determined by light scattering on a Coulter N4SD Sub-Micron Particle Analyser.

Direct Observation of Streptavidin Specifically Adsorbed on Biotin-Functionalized Self-Assembled Monolayers with the Scanning Tunneling Microscope**

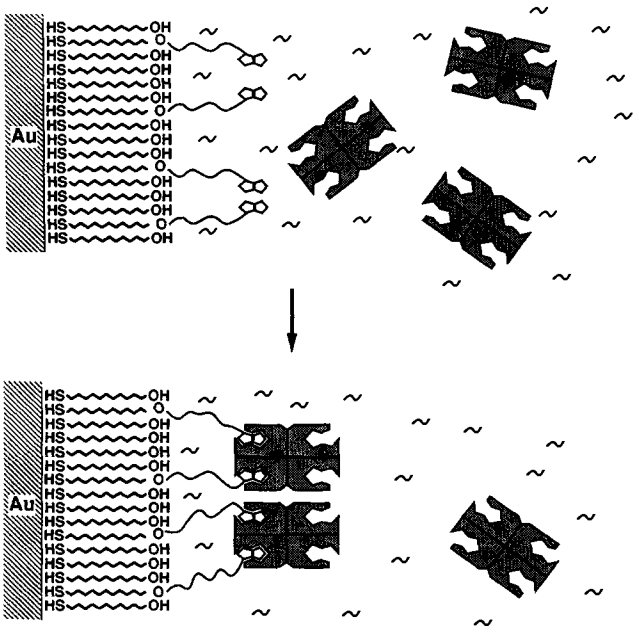
By *Lukas Häussling, Bruno Michel,* Helmut Ringsdorf,** and *Heinrich Rohrer*

Molecular recognition, i.e. the specific and selective interaction between host and guest molecules, is of critical importance not only in biology, but also in materials science for the molecular architecture of organized materials.[1]

Scanning tunneling microscopy (STM) and related methods[2] facilitate direct investigation of adsorbed molecules.[3-6] A broad spectrum of organic molecules can be bound by functionalized chemisorbed monolayers to conducting surfaces for subsequent study with the STM.

Binding of biotin (vitamin H) by the bacterial protein streptavidin is a model case of molecular recognition for the following reasons: 1) The binding constant ($K_a = 10^{15}$ L mol^{-1}) is extremely high and very specific. 2) Biotin can easily be functionalized and its binding properties are only slightly influenced by this process.[7] 3) Streptavidin has four binding sites for biotin situated on two opposite sides of the tetrameric protein. It can thus be used to link two different functions in the new molecular complex.

Since two-dimensional crystallization of fluorescence-marked streptavidin was recently achieved[8] on biotinylated lipid monolayers, we became interested in the analogous experiment on so-called "self-assembled monolayers" (see Scheme 1). *Nuzzo* and *Allara*[9a] as well as *Sagiv*[9b] showed that such films adsorbed from isotropic solutions onto solid supports are indeed monolayers with nearly perfect two dimensional organization. It was shown for the chemisorption of thiols and disulfides onto gold surfaces[10] that these self-assembled monolayers are well suited to functionalize metallic surfaces on a larger scale.



Scheme 1. Surface recognition on a mixed monolayer of **1** and **3** by streptavidin.

In order to perform the recognition reaction between biotin and streptavidin on functionalized gold surfaces, we synthesized the thiols **1** and **3**, and disulfide **2**.[11] 11-Mercaptoundecanol **1** was chemisorbed from a solution onto gold (111),[13] and the contact angle measured (Table 1). Figure 1 shows the STM picture of a chemisorbed monolayer of **1** on gold (111): a smooth surface with randomly distributed depressions[14] (bare gold shows none of these depressions).

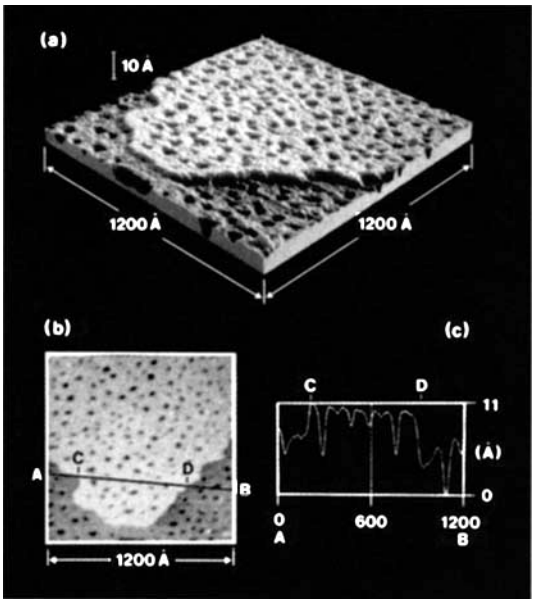


Fig. 1. Monolayer of **1** chemisorbed from a 2.1×10^{-4} M solution in ethanol on gold (111); imaging conditions: tungsten tip, 200 mV and 100 pA. a) Three-dimensional image with simulated illumination. b) Top view of a) in gray-scale scheme with a vertical dimension of 24 Å from black to white. c) Cross-section along line AB with an additional monolayer of gold from C to D.

The smooth parts cover approximately 95% of the surface (by STM analysis). The new organic surface exhibits the same terraced structure (e.g., step height and sharpness) as the uncovered gold films. The depressions have lateral dimensions of up to 35 Å and a maximum depth of 11 Å (cf. Fig. 1 b and c). We conclude that the gold substrate is covered by a densely packed monolayer of **1** except for the depressions. These are either empty or contain loosely packed molecules which yield laterally to the scanning tip. We note further that the observed 95% coverage also corresponds to the ratio of the area requirement of perpendicular paraffin chains to that of a $\sqrt{3} \times \sqrt{3}$ superlattice[15] of sulphur atoms on gold (111), i.e., densely packed sulfur atoms on the gold surface and a consequent loose packing of a certain percentage of the hydrocarbon chains.

Following the same procedure, the bisbiotin disulfide **2** was adsorbed (see Table 1). The biotin-functionalized gold surface was then dipped into the protein solution[16]; still no proteins were detectable with the STM, even after an incubation period of 12 hours.

Weber et al.[17] showed that the reason for the high binding constant of biotin to streptavidin is that the biotin molecule is completely engulfed by the protein. Therefore, streptavidin cannot bind tightly to a monolayer of **2** chemisorbed

[**] We thank Mrs. *G. Bender* for her enthusiastic help with the syntheses, and Mr. *H.-G. Batz* (Boehringer, Mannheim) for a gift of streptavidin

on gold, because of steric hindrance and limited mobility of the densely packed biotin molecules. This steric hindrance can be overcome by "diluting" the biotin functionalities on the gold surface by means of coadsorption of an unfunctionalized thiol or disulfide. The mobility can be increased by the introduction of a long hydrophilic spacer as with mercaptobiotin **3** (Scheme 1).

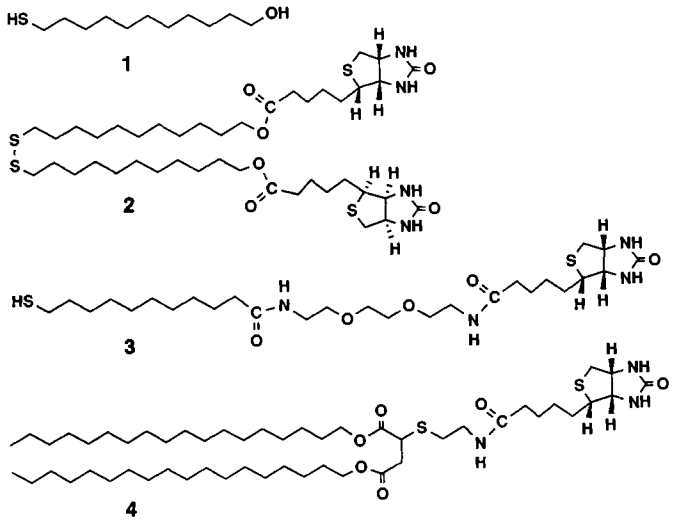

Table 1. Contact angles of water with chemisorbed thiols on gold(111) surfaces [12].

Compound	Adsorption time [h]	θ_{adv} [°] [a]	θ_{re} [°] [a]
1	14	42	7
2	5	66	25
3	18	52	20
1/3 2:1	21	60	18
1/3 50:1	24	35	8
Gold (111)	–	70–80	38–50

[a] adv = advancing, re = receding

Compound **3** was chemisorbed from pure solution and mixtures with mercaptoundecanol **1** on gold (111) surfaces. The monolayer of pure **3** is wetted sufficiently by water (Table 1); a periodicity of 10 Å in one direction and 20 Å in the perpendicular direction is visible in the STM (not shown). Figure **2** shows a mixed monolayer obtained by coadsorption from a solution of **1** and **3** (2:1). This monolayer exhibits marked depressions with lateral dimensions of 120 Å and a depth of approximately 3 Å. We associate this with a difference in length of the two components, the depth of the depressions indicating that the protruding spacer with the biotin lies flat on the densely packed alkane layer. Occasionally, we observe a periodicity of 7.5×10 Å which is in agreement with the length and width of the protruding hydrophilic part of **3**. This, however, requires a much larger ratio of **1/3** in the adsorbed monolayer than in the original solution (i.e. **3** adsorbs slower than **1**).

A mixed monolayer chemisorbed from a solution of **1** and **3** in the ratio 50:1 was incubated with a buffered protein solution[16] for 72 h at room temperature, subsequently removed and rinsed thoroughly with diluted buffer. The individual proteins are visible in the STM image (Fig. 3), especially in the profile along AB (Fig. 3b). The width of 45 Å is in accordance with values in the literature ($42 \times 42 \times 56$ Å)[17] (lattice constant 80 Å).[18] We observed regions free of

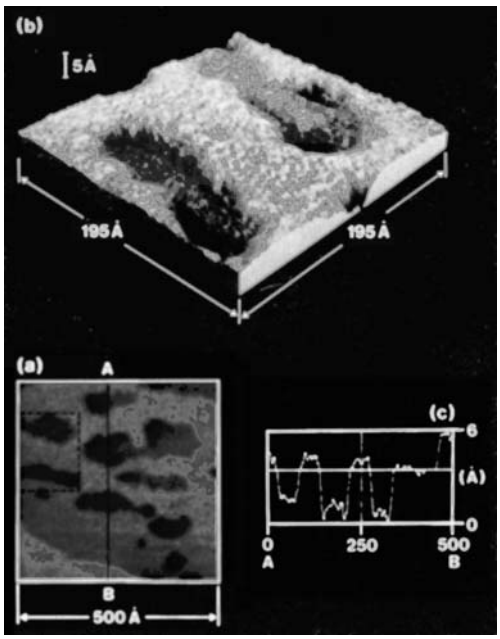

Fig. 2. Chemisorbed monolayer of **3** and **1** (1:2) on gold (111); imaging conditions as in Figure 1. a) Top view in gray-scale scheme with a vertical dimension of 54 Å from black to white. b) Three-dimensional image of the zone marked in a) with simulated illumination. c) Cross-section along line AB; B has an additional monolayer of gold.

protein as well as areas covered with several layers; true monolayer coverage was rarely found. The mobilities of both the chemisorbed biotin and proteins docked to it are apparently rather small, causing lateral and vertical disorder of the proteins.

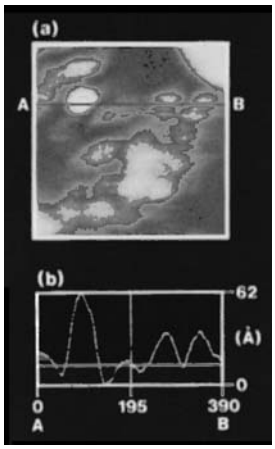

Fig. 3. Streptavidin docked onto a chemisorbed monolayer consisting of **3** and **1** (1:50); imaging conditions as in Figure 1. a) Top view in gray-scale scheme with a vertical dimension of 140 Å from black to white. b) Cross-section along line AB.

To demonstrate the effect of steric hindrance, lateral and especially vertical mobility in the underlying self-assembled monolayers, we spread the bisbiotin disulfide **2** on buffer solution[16] in a Langmuir trough. Figure 4 shows the pressure area diagram of this compound. We incubated these monolayers with streptavidin at two surface pressures for 30–60 minutes at room temperature. The film of oriented bisbiotinylated disulfide **2** and bound streptavidin was then

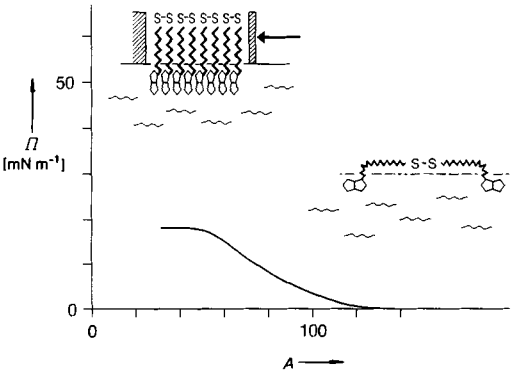

Fig. 4. Pressure area diagram of **2** at 20 °C on water. A = area in Å per molecule, Π = surface pressure.

transferred to the gold support by the Langmuir-Schäfer technique. Figure 5a shows the STM picture of the layer obtained after incubating a monolayer of **2** for 30 minutes with streptavidin at 1 mN m^{-1} in the liquid analogous phase. It shows terraces of about 3 Å in height caused by steps in the gold substrate, and in the background a large protein aggregate several hundred angstroms high (Fig. 5b).

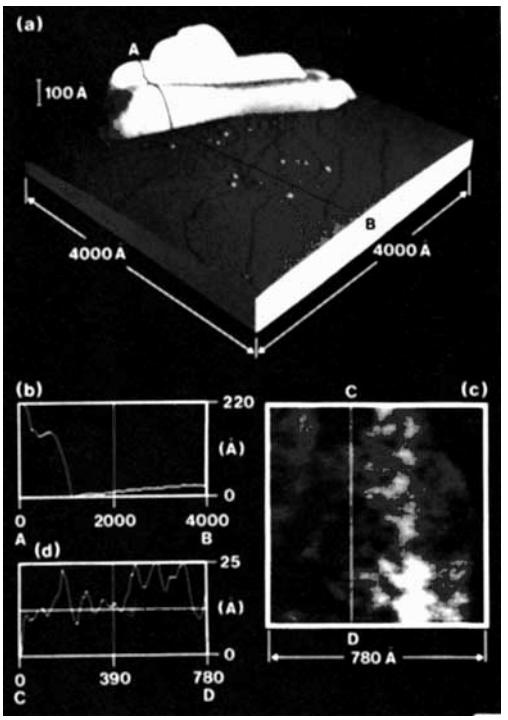

Fig. 5. Compound **2** spread over NaCl/Tris-HCl (each 10 mM), pH 7, incubated with streptavidin and transferred to gold (111); imaging conditions: gold tip, 200 mV and 100 pA. a) Three-dimensional image of an area with a streptavidin aggregate grown in the liquid analogous phase at 1 mN m^{-1}, with simulated illumination. b) Cross-section along line AB; the steps in the right-hand side of the image correspond to monoatomic gold steps. c) Top view with streptavidin docked on a monolayer of **2** in the gas analogous phase with a vertical dimension of 50 Å from black to white. d) Cross-section along line CD.

This needle-shaped type of aggregation has not been observed previously,[8, 18] but the protein concentration used in this experiment was much higher than before. Figure 5c shows the STM image of a monolayer composed of **2** and streptavidin, which was kept at 0 mN m^{-1} (gas analogous phase) during an incubation time of one hour. Here, however, small patches of proteins show tetragonal symmetry, similar to the two-dimensional structures found with biotinylated lipid monolayers at the air–water interface.[8, 18]

To compare the epifluorescence microscopy experiments of *Blankenburg* et al.[8, 18] with the recognition reaction at self-assembled monolayers on solid surfaces, we spread the biotin lipid **4** on a buffer solution[16] and compressed it to 4 mN m^{-1} (solid analogue packing). Compound **4** forms solid analogue packed monolayers and thus can be more easily imaged by scanning tunneling microscopy. In addition it could be shown by parallel monolayer experiments, that this biotin lipid leads to many small protein domains at the gas water interface, which are also more suitable for STM experiments.

The subphase below this monolayer was then exchanged by a solution of streptavidin (1 μM) in the same buffer. After an hour at room temperature, this film was transferred to a gold (111) surface by the Langmuir-Schäfer technique and investigated with STM. Figure 6a shows the typical structure of the streptavidin aggregates, which have a two fold symmetry, stretched shape and characteristic grooves in the short sides. Most aggregates are 100–120 Å thick, corresponding to two layers of streptavidin; only few of the protein aggregates are true monolayers, as demonstrated by the trace of the line AB in Figure 6b corresponding to two double layered protein aggregates on the left and a single layer protein aggregate on the right. Figure 6c displays a close-up of the groove of such a protein aggregate. The cross-section CD in Figure 6d displays top left three protein

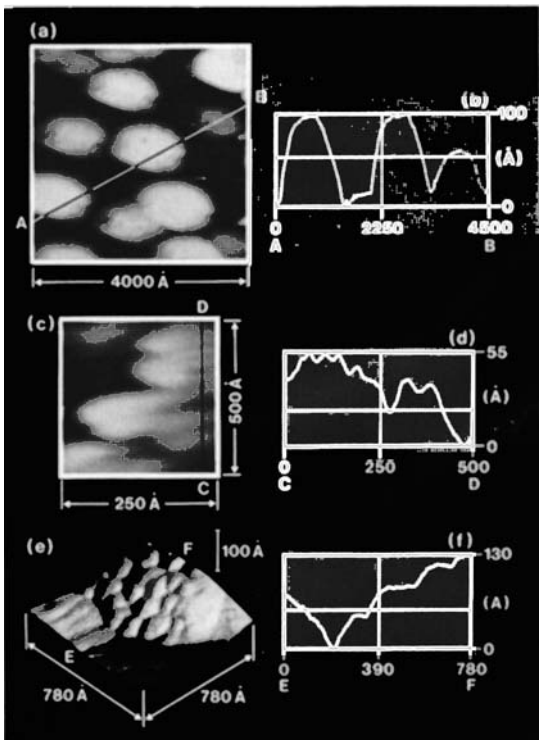

Fig. 6. Biotin lipid **4** spread over NaCl/Tris-HCl solution (each 10 mM), pH 7, exchanged with a subphase of streptavidin and transferred to gold (111); imaging conditions as in Figure 1. a) Top view of streptavidin aggregates in gray scale scheme, the vertical dimension is 100 Å from black to white. b) Cross-section along line AB. c) Close up of a top view of a groove area of one of the aggregates in a), shown in grayscale scheme; the vertical dimension in 55 Å from black to white. d) Cross section along line CD. e) Three dimensional image with simulated illumination of the edge of a multilayered protein aggregate. f) Cross-section along line EF.

molecules next to each other with lateral dimensions of about 40 Å. On the right are two protein molecules with a spacing in between, this time corresponding to the 80 Å lattice constant found in monolayer experiments.[18] The overall irregularity in the packing points to the fact that the protein aggregates are not perfectly ordered. In Figures 6e and the cross-section 6f, part of a 400–500 Å thick aggregate of streptavidin is shown. This thickness corresponds to about 8 layers of streptavidin, four of which are visible in the image (Fig. 6f). Such multilayered streptavidin aggregates at lipid monolayers have not been observed previously. This may be due to the unusually high concentration of streptavidin used in the incubation solution.

Chemisorbed self-assembled monolayers, e.g. of mercaptoundecanol **1**, possess sufficient adhesion to the substrate to allow the tunneling tip to scan over them without significant displacement of the molecules. This is in contrast to monolayers of fatty acids or lipids, whose mobility on solids is too high to resist repulsive or attractive tip interaction. We confirmed the surface coverage postulated from contact angle measurements,[9, 10] even though the microstructure of the layer is quite heterogeneous. Unlike Langmuir monolayers on water, however, chemisorbed monolayers on solids exhibit only limited lateral and no vertical mobility.[19] Only after three days incubation could we detect proteins docked directly to the functionalized solid, whereas the same process on a monolayer formed in a Langmuir trough took less than one hour.

Nevertheless, upon imaging with the STM, the insufficient adhesion of such transferred Langmuir-Blodgett monolayers poses a problem. Good adhesion can be obtained by compounds of type **2**, which can be spread on a liquid surface and whose transferred monolayers are chemically bound by the solid support. However, the fact that imaging of protein aggregates on solid surfaces is possible at all is very promising for investigations of functionalized solid surfaces.

[11] Compound **4** has been described in [8]. Compounds **1**–**3** were synthesized as follows: **1**: 11-bromoundecanol (Merck) was converted with sodium thiosulfate into the corresponding Bunte salt. The crystalline product was filtered off, recrystallized from ethanol, subjected to acid hydrolysis, and recrystallized from *n*-hexane to yield **1** (95%). **2**: The Bunte salt of 11-bromoundecanol was converted into the symmetric disulfide following the description by *Milligan* and *Swan* [22] (98% yield). The disulfide was isolated and esterified with a small surplus of a-biotin, following the method of *Steglich* et al. [23]. The reaction mixture was separated chromatographically to produce pure **2** with a yield of 13%. **3**: The activated ester of 11-bromoundecanoic acid was treated with a surplus of 1,8-diamino-3,6-dioxaoctane (German Texaco) and unchanged amine was removed. The intermediate product was treated with biotin-active ester and the product was isolated. The bromide was converted into the corresponding Bunte Salt and subjected to acid hydrolysis. Flash chromatography ($CHCl_3/CH_3OH$ 1:1) yielded **3** (3% yield pure according to NMR spectrum).
[12] To characterize the gold-coated substrates quickly and easily, the contact angle of a drop of water was measured at the three-phase line between air, water, and solid. Liquid was pumped into the drops with a micrometer-driven glass syringe. We measured the constantly advancing or receding contact angles. The contact angles were measured with the contact angle microscope GI (Krüss Inc., Hamburg, FRG).
[13] As substrate for chemisorption and the STM measurements, epitaxially grown gold on freshly cleaved mica was used. The mica was cleaved in air and rinsed immediately with millipore water. 2500 Å of gold was evaporated onto it at a pressure of $< 10^{-7}$ mbar. The gold was evaporated at a rate of 5 Å/s onto the mica, which was heated to 300 °C before and during the evaporation [21]. The surface shows (111) crystal faces which are atomically flat over regions of > 1000 Å.
[14] The STM investigations were performed under normal conditions in air with a Bioscope STM [20]. The images shown were recorded at a tunneling current (I_t) of 100 pA and a tunneling voltage (V_t tip to sample) of + 200 mV. Using both electrochemically etched gold and also tungsten tips, we obtained essentially the same results.

The High-Yield Synthesis and Characterization of the First Porphyrin–Cyclam Dinucleating Ligand and Its Iron(III)/Copper(II) Complex **

By *Véronique Bulach, Dominique Mandon** and *Raymond Weiss**

Access to homo- or heterobimetallic porphyrin complexes by simple and high-yield pathways is of special interest, not only in the field of synthetic analogues of active sites in biological processes, but in many other different areas where metalloporphyrins are involved, such as catalysis, redox processes, mixed-valence chemistry, or even selective cleavage of DNA.[1–4]

Among the variety of polymetallic enzymes, one of the most remarkable is cytochrome c oxidase,[5] in which one iron(cyt_a) and one copper (Cu_A) interact with the cyt_{a3}–Cu_B heme-iron–copper pair to catalyze the reduction of dioxygen to water in protic media ($O_2 + 4H^{\oplus} + 4e^{\ominus} \rightarrow 2H_2O$, $E_o = +1.23$ V vs NHE).

So far the structure of this enzyme has not been unambiguously established. Whereas cyt_a and Cu_A seem to act as electron carriers, the cyt_{a3}–Cu_B pair is probably responsible for the complexation, reduction, and cleavage of the dioxygen molecule. In the oxidized state, this pair displays magnetic and ESR properties consistent with a ground spin state of $S = 2$, arising from a strong antiparallel coupling ($-J > 200\ cm^{-1}$) between the high-spin ferric iron and the cupric system, and suggesting the involvement of an endogenous or exogenous bridging ligand. The most recent EXAFS studies indicate that the Cu–Fe distance in cyt_{a3}–Cu_B is close to 3 Å.[6]

Access to heterobimetallic species is generally achieved either by self-assembling[7] methods, which requires work with reactive precursors, or by design of a chelating ligand covalently attached to a porphyrin;[8] nevertheless, only a few examples of such a chelating ligand are known, and efficient selective metalation has to be carried out.

To fulfill the requirements of thermal stability in the solid state as well as in solution and the relative proximity of the two metal centers combined with flexibility of the system, we have developed a modeling strategy involving the coupling of the 1,4,8,11-tetraazacyclotetradecane (cyclam)—a macrocycle which forms very stable complexes with transition metals and is easily functionalized[9]—with the *meso*-mono(*o*-aminophenyl)triphenylporphyrin[10] (*o*-$MAPTPH_2$) by a lateral arm, which allows a free rotation of the two macrocycles relative to each other and therefore introduces important flexibility. We report in this paper the high-yield synthesis and characterization of the first porphyrin–cyclam dinucleating ligand (Fig. 1), as well as a synthetic pathway leading to the corresponding heterobimetallic complexes of this ligand.

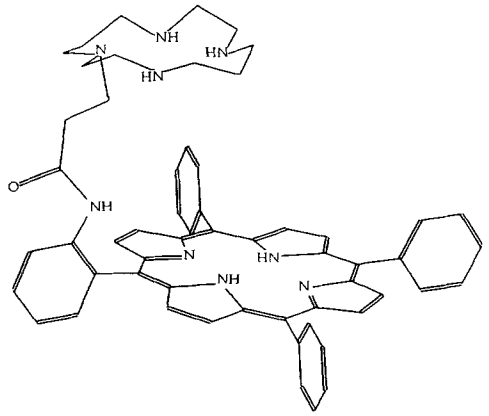

Figure 1. Structure of the porphyrin-cyclam ligand, 3.

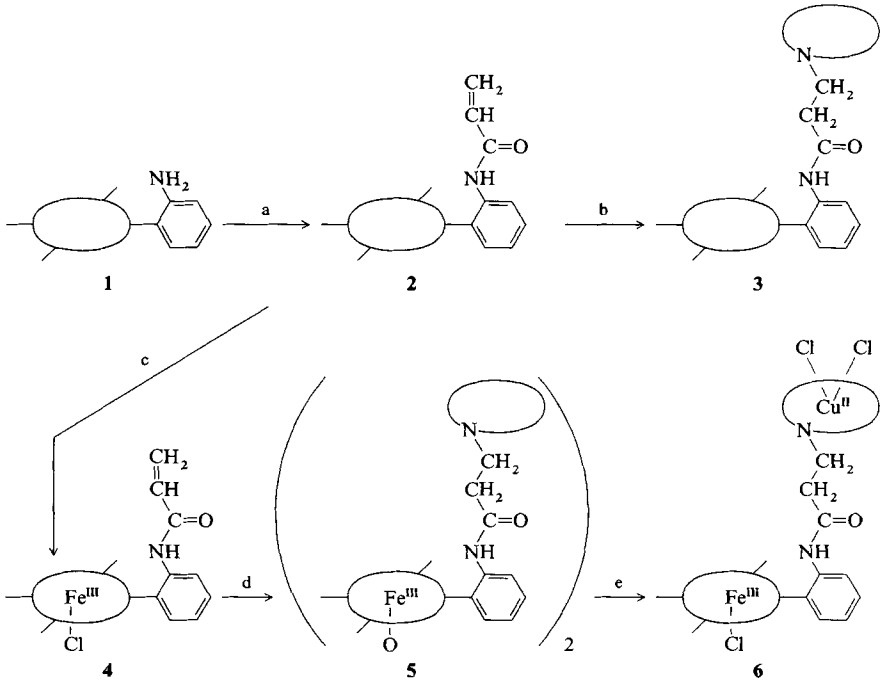
Treatment at 0 °C of a dichloromethane solution of *o*-$MAPTPH_2$ **1** with one equivalent of acryloyl chloride affords, after extraction, chromatography, and crystallization (CH_2Cl_2/hexane), the new prophyrin **2**, monofunctionalized by an activated olefin, in 70% yield. This functional group reacts with secondary amines under mild conditions:[11] indeed, the complete reaction of **2** with an excess of cyclam is achieved within three days simply by stirring the two reagents in CH_2Cl_2 at room temperature (Scheme 1). After extraction and chromatographic procedures (dextran-type stationary phase), the porphyrin **3** with appended cyclam[12] can be crystallized from CH_2Cl_2/*n*-hexane, with a 67% yield. ^1H and ^{13}C NMR spectroscopy confirms the structure of this bisheteromacrocycle (Fig. 2a): the 12 nonequivalent methylene groups appear in the ^1H NMR spectrum at $0.1 \leq \delta \leq 1.8$, upfield from the corresponding signals in tetrasubstituted free macrocyle[13] ($1.7 \leq \delta \leq 2.8$), indicating an important interaction of the cyclam with the porphyrin core. Variable temperature experiments have been carried out between 293 and 215 K. Below 243 K the pyrrole signals



Scheme 1. a) $ClCOCH{=}CH_2$, 0 °C, 1 h, CH_2Cl_2; b) cyclam, excess, RT, 3 days, CH_2Cl_2; c) $FeCl_2$, 3 days, RT, THF; d) cyclam, excess, RT, 1 day, CH_2Cl_2; e) $CuCl_2 \cdot 2H_2O$, reflux, 2 days, THF/H_2O 50/50; then HCl. Large ellipses represent porphyrin; ellipses containing N, the cyclam moiety.

are split into two components (Fig. 2b), as previously reported for some more rigid, functionalized porphyrins.[14] Moreover, the upfield shift of the methylene protons, although significant, is less marked at low temperature. These observations suggest that free rotation of the cyclam relative to the porphyrin is reduced at low temperature.

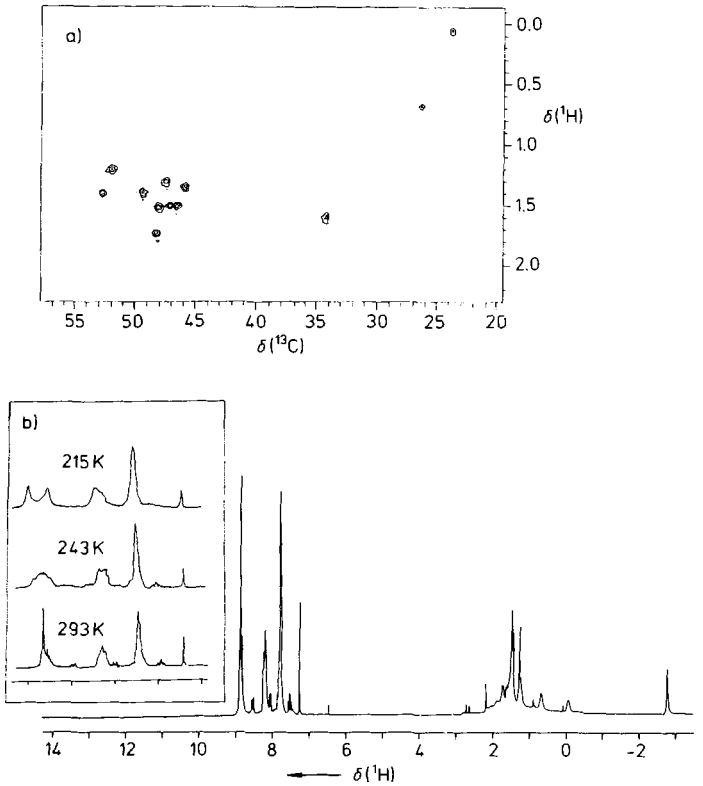


Figure 2. a) 2D NMR spectrum ($^1H/^{13}C$ correlation) for **3** ($CDCl_3$, RT), showing the 12 nonequivalent methylene groups. b) ^1H NMR ($CDCl_3$, RT) spectrum of **3**, and temperature dependence of the region from $\delta = 6$ to 10.

Access to binuclear systems is now anticipated, by metalation of the two coordination sites in **3**. Nevertheless, if *hetero*bimetallic systems have to be synthesized, statistic metalation of both macrocycles might occur, even if 1 equivalent of metal is used initially, leading to tedious separation procedures. To avoid this problem we have investigated the reactivity of the cyclam ligand with the appended olefin of the metalated porphyrin **4**:[15] indeed, this reaction in CH_2Cl_2 is achieved within 24 hours, faster than with **2** under the same conditions. After workup, the microcrystalline material **5** is obtained from dichloromethane/*n*-hexane in 60% yield. Spectroscopic investigations of this material (UV/VIS(CH_2Cl_2): λ_{max} [nm] = 410 (Soret band), 570, 615; ESR (CH_2Cl_2, 4.2 K): nonactive; ^1H NMR (CD_2Cl_2, 25 °C, TMS): $\delta_{pyrrole} = 13.8$) indicate that **5** is a μ-oxoiron(III)-porphyrin dimer. Treatment of **5** with hydrochloric acid and recrystallization yielded the corresponding high-spin chloroferriporphyrin **5'** as an hygroscopic, microcrystalline solid, in which the cyclam is in its fully protonated form (UV/VIS(CH_2Cl_2): λ_{max} [nm] = 418 (Soret band), 505, 575, 660; ESR (CH_2Cl_2, 4.2 K): $g_\perp = 6$, $g_\parallel = 2$; ^1H NMR (CD_2Cl_2, 25 °C, TMS): $\delta_{pyrrole} = +80.0$).

The cyclam ligand in **5** can be easily metalated by refluxing with an excess of cupric chloride in a 50/50 THF/water mixture for 48 hours. After extraction, chromatography on a dextran-type stationary phase, and treatment with hydrochloric acid, a stable microcrystalline solid can be isolated in a 65% yield. Mass spectroscopy measurements (FAB$^\oplus$, nitrobenzyl alcohol (NBA)) indicate that it is chloroiron(III) porphyrin–dichlorocopper(II) cyclam complex **6** (characteristic fragments: m/z = 1105.02 (**6**$^\oplus$), 1072.0 (**6**$-Cl^\ominus$), 1035.1 (**6**$-2\,Cl^\ominus$), and 1000.1 (**6**$-3\,Cl^\ominus$). ^1H NMR ($CDCl_3$, 25 °C, TMS) as well as optical spectroscopy display typical ferric high-spin features ($\delta_{pyrrole} = +80.0$ and λ_{max} [nm] = 420 (soret band), 505, 575, 660 nm). The X band ESR spectrum of **6**, run at 10 K in frozen THF solution, displays a signal at $g = 6.0$ together with a signal close to $g = 2$. This spectrum can be simulated (see Fig. 3) as a superimposition of two independent subspectra corresponding to an axial high-spin iron(III) complex ($g_\perp = 6$ and $g_\parallel = 2$, line width = 45 G), and a slightly rhombic copper(II) derivative ($g_z = 2.25$, $g_y = 2.05$, $g_x = 2.04$, line width = 150 G), in a 1:1 Fe(III)/Cu(II) ratio. The lack of magnetic interaction between the two paramagnetic centers in **6** is presumbably due to their separation in space and to the absence of any bridging ligand between the two metals[16] in this molecule.

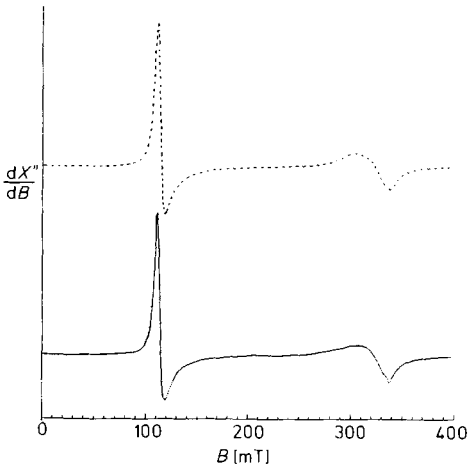

Figure 3. Simulated (dashed line) spectrum of a high-spin Fe^{III}porphyrin/Cu^{II} complex (1:1) and experimental (solid line) spectrum of **3** (10.0 K, THF).

In conclusion, the very mild conditions involved in the addition of secondary amines to activated olefins allow the preparation of the first linked-cyclam porphyrin ligand, and provide an easy access to a heterobimetallic iron(III)–copper(II) derivative. Reactions with bridging ligands, as well as extension of this strategy to other metals, is presently under investigation. Compound **3** is a lipophylic porphyrin linked by a flexible arm to a hydrophilic macrocycle. Appropriate selection of the olefin substituent should lead to species displaying different flexibility features; also, choice of aryl groups on the porphyrin,[17] as well as substitution of the cyclam moiety, would allow variation in the hydrophilicity of the system.

Experimental

2: ^1H NMR (200 MHz, $CDCl_3$, TMS): $\delta = 8.9$ (m, 8H; β pyrrole), 8.3 (m, 6H; *o*-phenyl), 7.9 (d, 1H; *o*-phenyl subst.), 7.8 (m, 9H; *m,p*-phenyl) 7.1 (m, 2H; *p*-phenyl subst.; *m'*-phenyl subst), 7.6 (t, 1H; *m*-phenyl subst.), 6.8 (s, 1H; NHC=O), 5.7 (m, 1H; $CH{=}CH_2$), 4.9 (m, 2H; $CH{=}CH_2$), -2.77 (NH pyrrole); IR (Nujol) $\tilde{\nu}$, [cm^{-1}] = 1692 (C=O); MS (FAB$^\oplus$, tetraglyme): m/z 684.5 (**2**$^\oplus$); correct elemental analyses (C, H, N).

3: ^{1}H NMR (200 MHz, $CDCl_3$, TMS): δ = 8.9 (m, 8H; β pyrrole), 8.5 (d, 1H; *o*-phenyl), 8.2 (m, 6H; *o*-phenyl), 8.0 (d, 1H; *m'*-phenyl), 7.8 (m, 10H; *p,m*-phenyl; *p'*-phenyl), 7.5 (t, 1H; *m*-phenyl), − 2.8 (NH pyrrole), 1.9–0.0 (6 m, 28H; CH_2, $3H_2O$, N*H*C=O, cyclam and lateral arm); ^{13}C NMR (50.33 MHz, $CDCl_3$, TMS): δ = 170.8 (C=O), 140.7 (α-pyrrole), 142.1, 141.9, 139.0 (C *meso*), 135.0 (*o*-phenyl subst.), 134.6 (*o*-phenyl), 132.2, 131.9, 131.4, 130.7, 129.2 (β-pyrrole), 129.4 (*p*-phenyl subst.), 127.9 (*p*-phenyl), 126.8 (*m*-phenyl), 122.9 (*m*-phenyl subst.), 122.2 (*m'*-phenyl subst.), 120.9, 120.5 (*ipso*-phenyl), 52.7, 51.3, 49.1, 48.2, 47.8, 47.4, 47.2, 47.0, 46.1, 34.3, 27.3, 23.5 (12 CH_2, cyclam and lateral arm); IR (Nujol) $\tilde{\nu}$, [cm^{-1}] = 1680(C=O); MS (FAB$^{\oplus}$, NBA): *m/z* 884.4 (**3**$^{\oplus}$); correct elemental analyses (C, H, N).

4: ^{1}H NMR (200 MHz, $CDCl_3$, TMS): δ = 86, 81, 78 (broad, 8H; β-pyrrole), 16.1 (6H; *m*-phenyl), 13.3 (1H; *m*-phenyl subst.), 12.8 (6H; *o*-phenyl), 12.2 (1H; *o*-phenyl subst.), 8.1 (3H, *p*-phenyl), 7.8 (1H; *p*-phenyl subst.); IR (Nujol) $\tilde{\nu}$[cm^{-1}] = 1689 (C=O); correct elemental analyses (C, H, N).

5: ^{1}H NMR (200 MHz, $CDCl_3$, TMS): δ = 13.8 (broad, 8H; β-pyrrole), 8.4, 7.7 (broad, phenyl); ESR (4.2 K, CH_2Cl_2): diamagnetic, ca. 1% high-spin contamination. MS (FAB$^{\oplus}$, NBA): *m/z* 1892.5 (**5**$^{\oplus}$).

5': ^{1}H NMR (200 MHz, $CDCl_3$, TMS): δ = 80 (broad, 8H; β-pyrrole), 13.3 (broad, *m*-phenyl), 12.8 (broad, *o*-phenyl), 7.8 (broad, *p*-phenyl); ESR (4.2 K, CH_2Cl_2): $g_{\perp}$ = 6, $g_{\parallel}$ = 2; IR (Nujol) $\tilde{\nu}$[cm^{-1}] = 1670 (C=O); MS (FAB$^{\oplus}$, NBA): *m/z* 973.6 (**5'**$^{\oplus}$−4HCl). correct elemental analyses (C, H, N).

6: ^{1}H NMR (200 MHz, $CDCl_3$, TMS): δ = 80 (broad, 8H; β-pyrrole), 13.5, 12.1, 7.1 (broad, phenyl); ESR 10 K, THF) $g_{\perp}$ = 6, ferric; $g_{\parallel}$ = 2, ferric, cupric cyclam; IR (Nujol) $\tilde{\nu}$[cm^{-1}] = 1680 (C=O); MS (FAB$^{\oplus}$, NBA): *m/z* 1105.2 (**6**$^{\oplus}$), 1072.0 (**6**−Cl$^{\ominus}$), 1035.1 (**6** − 2Cl$^{\ominus}$), 1000.1 (**6**-3 Cl$^{\ominus}$). Correct elemental analyses (C, H, N).

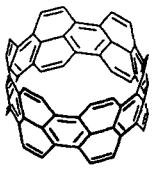
[16] It is not clear whether the chlorine atom ligated to the iron is on the same side as the substituent, or not; on the other hand, the chlorocupric moiety may have a *cis* configuration at the opposite side of the porphyrin. For copper dichloride/cyclam complexes, see: B. Bosnisch, *Inorg. Chem. 4* (1965) 1102–1107.

[17] For example, tetrapyridinyl porphyrin salts are well-known as water-soluble compounds: P. Hambright, E. B. Fleischer, *Inorg. Chem. 9* (1970) 1757–1761.

Strategy for the Synthesis of Tube-Shaped Molecules**

By *Fritz Vögtle,* Axel Schröder* and *Detlef Karbach*

Molecules whose structures[1] and functions[2] closely resemble and imitate those of well-known macroscopic objects have repeatedly motivated new developments in synthetic chemistry.[3] Some eight years ago we commented on tube-shaped molecules of type **I**, whose synthesis still presents a challenge to the preparative chemist.[4] The molecular ribbons,[5] belts or collars[6] which have in the meantime become well known provide some progress but all contain merely "classic" 1,2-coupled double bonds or *ortho*-condensed benzene rings.



I

The aim of our studies was to develop a generally applicable entry to longer tube-shaped molecules. Thus far no synthetic concept has been reported concerning molecular tubes, which are of interest not only for the encapsulation of guest compounds but also as channels for the transport of ions and neutral molecules. Prerequisite for subsequent host/guest matching is a variable repetitive synthetic strategy with several reproducible steps as we have used in connection with the first cascade-like synthesis.[7]

The difficulties in the synthesis were encountered in particular in the development of isolable yet reactive tetrafunction-

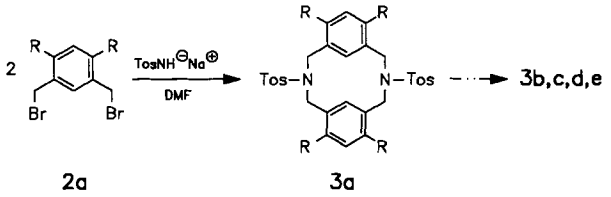
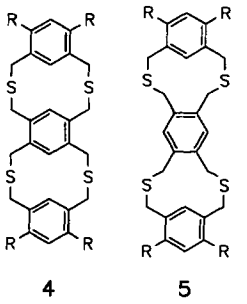
alized cyclization components. Key building blocks for the synthesis of the desired tube-shaped compounds **1** are tetrasubstituted monocycles such as the [3.3]phanes **3**, which are obtainable by "cyclizing elongation" of fourfold functionalized benzene building blocks of type **2**.



2a **3a**

	2a/3a	3b	3c	3d	3e
R	CO_2Et	CH_2OAc	CH_2OH	CH_2Br	CH_2SH

Although the synthesis of the building blocks **4a–c** and **5a–c** (with sulfide bridges) was possible, the key compounds **4d, e** and **5d, e** could not be prepared because of the sparing solubility of **4c** and **5c** and their low stability towards acidic reagents (e.g. HBr/glacial acetic acid, PBr_3, $SOBr_2$).[8]

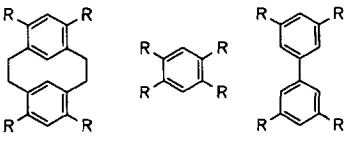


4 **5**

	R
a	CO_2Et
b	CH_2OAc
c	CH_2OH
d	CH_2Br
e	CH_2SH

Isolation of the cyclization components **3d** and **3c** was possible only after exchange of the sulfide sulfur atoms in the bridges by *N*-Tos (Tos = *p*-$SO_2C_6H_4CH_3$).

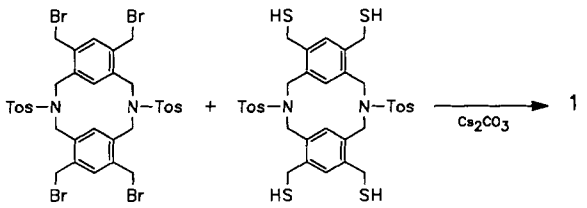
Although cyclization of **3d** with the easily accessible, fourfold functionalized building block **6b** of the metacyclophane type used in the first experiments did not lead to the desired compound because of side reactions, we were able to detect macrocyclizations of **3d** with 1,2,4,5-tetrakis(mercaptomethyl)benzene **7b** and 3,3′,5,5′-tetrakis(mercaptomethyl)-biphenyl **8b** mass spectroscopically.



6a,b **7a,b** **8a,b**

a: R = CH_2Br, b: R = CH_2SH

In the following we discuss what we consider the most important cyclization in this context, **3d** + **3e** → **1**. It was carried out as a two-component reaction according to the dilution principle[9] (by simultaneous dropwise addition of the components **3d** and **3e** to a suspension of Cs_2CO_3 in benzene/ethanol).



3d **3e**

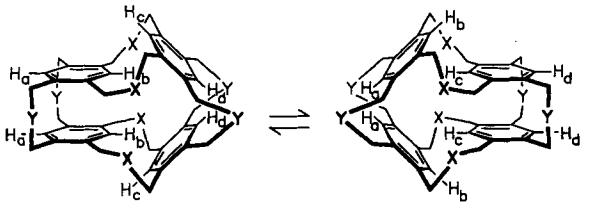
In principle, in macrocyclizations of this type two isomers can be formed: tube-shaped molecules such as **1a** and less formally tube-shaped isomers such as **1b** with a "crossed" arrangement of the [3.3]phane building blocks. Isolation of one of the isomers of **1** was remarkable easy after flash chromatography of the crude product on silica gel (eluent $CHCl_3$/ethyl acetate 2/1, v/v) and crystallization from dichloromethane/*n*-hexane (colorless crystals, m.p. 280 °C (decomp.), yield 3.4%). Whereas the isomer isolated in this way was obtained in pure form in 50 mg amounts, a second isomer could not be found even upon careful work-up by means of HPLC (inter alia Nucleosil-CN phase 5 μm; eluent CH_2Cl_2/CH_3CN 1/1, v/v).

Due to the poor quality of the otherwise well-formed crystals[10] it was not possible to differentiate by an X-ray structure analysis which isomer had been formed. The formation of one of the two isomers **1a/1b** could, however, be confirmed ^{1}H-NMR spectroscopically and by FAB mass spectrometry [m/z = 1325.3 ($M^{\oplus}$ + H)]; the assignment of the isolated isomers as **1a** or **1b** was at first difficult because of the similarity of the two structures. 90-MHz ^{1}H-NMR spectra of the isolated isomer at room temperature show broadened signals, which are sharper and in each case doubled in the 200-MHz and 400-MHz spectra. Thus, at 20 °C, the 400-MHz spectrum shows four AB systems (CD_2Cl_2: δ = 5.05(br) and 3.15(br), 5.0(d), and 4.6(d), 4.3(d) and 3.2(d), 3.85(d) and 3.65(d); assignment by double resonance experiments) for the protons of the methylene bridges and four signals (δ = 8.75(s, $H_{b,c}$) 6.7(s, $H_{a,d}$), 6.65(s, $H_{a,d}$), and 6.35(s, $H_{b,c}$) for the protons of the benzene rings.

Noteworthy is the signal for the protons of the benzene rings at δ = 8.75, whose extreme downfield position prompted us to assign the structure **1a** to the compound isolated, since only the hydrogen atoms H_b and H_c of this isomer should show such a shift. On the basis of a comparison with known cyclophanes[11] and taking into consideration the influence of the magnetic anisotropism of the neighboring benzene ring[12] all other hydrogen atoms of **1a** and **1b** should absorb at higher field.[13]

This assignment is also consistent with observations made in other cyclophane syntheses, which show that cyclizations can be accomplished when the functional groups of the precursors (here **3d** and **3e**) fit together spatially (principle of rigid groups).[14] This is to be expected all the more if the two reactants are oriented parallel to each other, i.e. formation of the crossed isomer **1b** is not favored. We therefore assume that the cyclic compound isolated is **1a**.

Remarkably, the ^{1}H-NMR spectrum of the compound is temperature dependent. At 160 °C only two AB systems are observed for the protons of the methylene bridges (90 MHz, $C_2D_2Cl_4$; δ = 4.8 (d, CH_2-N) and 4.2 (d, CH_2–N) and 3.9 (d, CH_2-S) and 3.5 (d, CH_2–S) and only two signals for the protons of the benzene rings (δ = 7.5 (s, $H_{b,c}$) and 6.7 (s, $H_{a,d}$). It follows, therefore, that **1a** is present in the less symmetric conformation **A** at room temperature and slowly transforms (on the NMR time scale) into the conformer **B**.



A X, Y = S, N-tos B

1a

The barrier for this process is ca. 65–70 kJ mol^{-1} (with $T_c = 70\,^{\circ}C$ and $\Delta\nu = 215$ Hz for H_b and H_c).

1a, "a short molecular tube" is comparatively easily accessible since the starting compounds are readily synthesized. Its cavity is large enough to accomodate a benzene molecule. By suitable choice of other tetrafunctionalized building blocks it should be possible in analogous way (if necessary with subsequent extrusion of the bridge heteroatoms) to prepare further tube-shaped "endoreceptors" (longer, expanded ring hydrocarbons, Möbius strips), the cavities of which are enclosed as by cell walls.

Se_4N_2, a Novel Selenium Nitride

By *Kurt Dehnicke,* Fritjof Schmock, Klaus F. Köhler,* and *Gernot Frenking*

The only binary nitride of selenium reported thus far is the highly explosive tetraselenium tetranitride **1**,[1] whose crystal structure analysis[2] revealed strong intermolecular Se···N contacts between the cage molecules, thus making its insolubility in all solvents understandable. This property, and its explosivity, limit its application as a preparative reagent severly compared to that of the well-investigated tetrasulfur tetranitride **2**.[3] Therefore only very few preparative applications of **1** have been reported.[4–7]

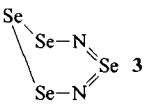
Se_4N_4 S_4N_4 Se_4N_2 S_4N_2
1 **2** **3** **4**

In the search for less sensitive selenium nitrides we found an entry to the previously unknown tetraselenium dinitride **3** in the reaction of diselenium dichloride with trimethylsilylazide in dichloromethane [Eq. (a)].

$$2Se_2Cl_2 + 4Me_3SiN_3 \longrightarrow \underset{\mathbf{3}}{Se_4N_2} + 5N_2 + 4Me_3SiCl \qquad (a)$$

It is formed almost quantitatively as a black, finely crystalline powder, whose thermal and mechanical stability is greater by far than that of **1**. It can be handled with ease at room temperature, but on heating to 80 °C it decomposes explosively; it also explodes when struck with a hammer. These properties are comparable with those of **2**.[2] In contrast to the hydrolysis-insensitive **1**,[1] **3** slowly decomposes with disproportionation on exposure to moisture, forming red Se_8 and ammonium hydrogen selenite.

The IR spectrum of **3** shows a sequence of bands corresponding to that shown by the crystallographically characterized tetrasulfur dinitride **4**,[8, 9] so that we assume an analogous molecular structure with C_s symmetry for **3**.



3

According to the irreducible representations, this model requires twelve IR-active fundamental vibrations, of which seven belong to the symmetry type A′ and five to the symmetry type A″. Of these six are stretching vibrations (3A′, 3A″) and six are deformation vibrations.[10] With the assumption of coincidental degeneration of the deformation vibration at 281 cm^{-1}, which is supported by the ab initio calculation, this expectation is fulfilled (Table 1). Consistent with the different bond orders Se=N and Se–N two pairs of stretching vibrations appear at 828 and 792 cm^{-1} and at 584 and 571/554 cm^{-1}, of which the A″ band splits by Fermi reso-

nance with the deformation vibration at 281 cm^{-1} into a doublet. This finding correlates very well with the IR spectrum of **1**, in which the Se–N bond order is 1.5 and the two highest frequency stretching vibrations lie at 800 and 788 cm^{-1}.[11] The two resulting bands at 352 and 325 cm^{-1} in the IR spectrum of **3** can then be freely assigned to the two Se–Se stretching vibrations.

This interpretation is confirmed by an ab initio[13] calculation carried out with the 3-21G* all-electron basis set[12] (Table 1). With exception of the two highest-frequency vibrations the agreement with the experimental data is satisfactory. The deviations are due both to the harmonic approximation, with which the calculations are additionally restricted to the approximations of the Schrödinger equation, as well as to the neglection of strong intermolecular interactions, as are also reflected in the low solubility of **3**.

The results of the optimization of the geometry of **3**, which were carried out both with the 3-21G* program as well as with an effective core potential,[12] lead to a chair-shaped structure with C_s symmetry (Fig. 1) which closely resembles

that of the valence isomer **4**.[9, 14] The folding of the SeN_2 unit is very slight, $\tau = 176°$ (**4**: 177°[14]). The dihedral angle τ_1 in the case of **3** (121.9° and 123.1°, respectively) is calculated as being somewhat smaller than for **4** (124.2° and 125.0°, respectively[14]). The calculations also give two short Se–N bonds ($\approx$ 168 pm) and two long Se–N distances ($\approx$ 182 pm) corresponding to double and single bonds.[1]

Experimental procedure

A solution of diselenium dichloride (1.64 g) in anhydrous dichloromethane (20 mL) was cooled to −30 °C and treated dropwise with occasional shaking with a solution of trimethylsilylazide (1.70 g) in dichloromethane (10 mL). The mixture was allowed to warm slowly to room temperature and the black, fine precipitate filtered off under dry nitrogen, washed with dichloromethane, and dried in vacuo. Yield 1.14 g (92%).

Warning: Explodes on heating to 80 °C and on subjection to mechanical stress.

Conformational Preference of 2-Triphenylphosphonio-1,3-Dithianes: Competition Between Steric and Anomeric Effects

By *Marian Mikołajczyk,* Piotr Graczyk, Michal W. Wieczorek* and *Grzegorz Bujacz*

Dedicated to Professor Rolf Appel on the occasion of his 70th birthday

There has been considerable interest in the conformation of 1,3-diheteroanes containing phosphoryl and related groups at the anomeric carbon atom, as well as in understanding the origin of the anomeric effect operating in these systems.[1, 2] Perhaps the most interesting recent observation is that the phosphoryl group favors the axial conformation in 2-phosphoryl 1,3-dithianes **1**, but strongly prefers the equatorial position in 1,3-dioxanes[3, 4] and 1,3-oxathianes **2**.[4, 5] The magnitude of the anomeric effect in **2**, estimated recently by *Juaristi*,[6] was found to be quite substantial and close to 3 kcal mol^{-1}.

Because the anomeric effect is very often rationalized in terms of electrostatic effects (dipole-dipole interactions),[7] we investigated the conformations of 1,3-dithianes containing the triphenylphosphonium group at C2 where the phosphorus atom formally bears a positive charge. Conforma-

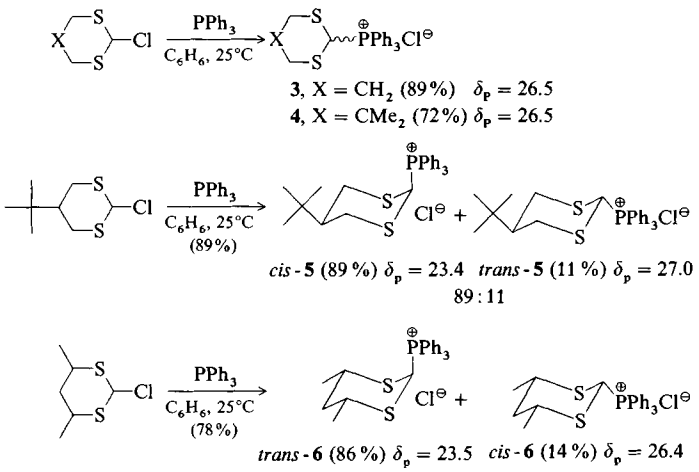
tional studies of this type of compounds are also interesting in view of the reverse anomeric effect observed for the ammonium-substituted six-membered heterocycles.[8] With this in mind we prepared the conformationally labile 2-triphenylphosphonio-1,3-dithianes **3** and **4** and two diastereomeric pairs of 2-triphenylphosphonio-1,3-dithianes, **5** and **6**, from the corresponding 2-chloro-1,3-dithianes and triphenylphosphane (Scheme 1).



Scheme 1.

The major diastereomer was isolated in a pure state from the mixture of two diastereomeric dithianes, *cis*- and *trans*-**5**, by careful crystallization from DMF/ether.[9] Its *cis* geometry was established by X-ray analysis,[10] (Fig. 1) which also revealed that this isomer exists in a chair conformation in which the triphenylphosphonium group at C1 is in an axial and the *tert*-butyl group at C3 in an equatorial position (numbers refer to Fig. 1). The phenyl ring lying over the

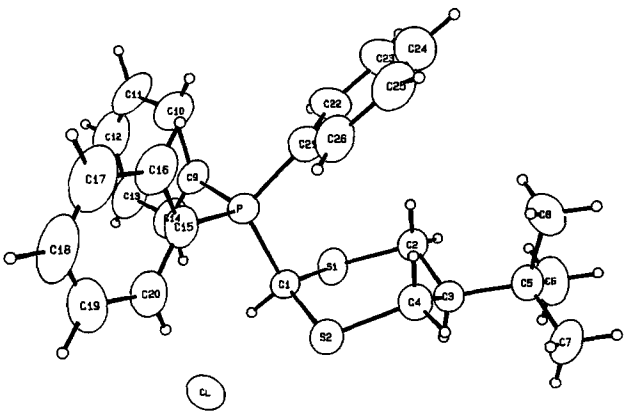


Figure 1. A three-dimensional view of the structure of *cis*-**5** in the crystal. Important bond lengths [Å] and bond angles [°]: S(1)–C(1) 1.798(4) S(2)–C(1) 1.807(4), C(1)–P 1.817(4); S(1)–C(1)–S(2) 115.9(2), S(1)–C(1)–P 111.4(2), S(2)–C(1)–P 114.0(3)

dithiane ring is almost parallel to the plane formed by the S1, S2, C2 and C4 atoms. The distances between this phenyl ring and two axial hydrogens at C2 and C4 are 2.642 and 2.576 Å, respectively.

When a concentrated DMF solution of a mixture of *cis*-**5** and *trans*-**5** (89:11) was heated for a few minutes, the diastereomeric ratio was changed in favor of *trans*-**5** indicating that the *trans* isomer is thermodynamically more stable. By crystallization of this mixture containing ca. 60% of *trans*-**5** from DMF/ether we were able to obtain *trans*-**5** of 95% diastereomeric purity. Similarly, in the synthesis of **6** the less thermodynamically stable isomer was the predominant product (*trans*:*cis* 86:14).

The ^{1}H-NMR spectrum (300.13 MHz, CD_2Cl_2) of *cis*-**5** revealed that the *t*Bu signal ($\delta = 0.59$) is slightly shielded due to the anisotropic effect of the phenyl ring located over the heterocyclic 1,3-dithiane ring. Even more pronounced shielding ($\Delta\delta \approx 1$) is observed for the axial hydrogens at C4 and C6 in *cis*-**5** and *trans*-**6**. While in the 1,3-dithianes without PPh_3 substituents these proton signals occur at $\delta = 2.63$ (5-*tert*-butyl-1,3-dithiane) and 2.83 (*cis*-4,6-dimethyl-1,3-dithiane), in *cis*-**5** and *trans*-**6** the relevant chemical shifts are $\delta = 1.64$ and 1.79, respectively. The two-proton, deceptively simple doublet at $\delta = 2.4$ ($J = 10.9$ Hz) in *cis*-**5** may be tentatively assigned to the equatorial methylene protons. Since the chemical shifts of the methine proton at C5 and axial methylene protons are almost the same ($\delta = 1.64$), the first-order approximation cannot be applied, and the coupling constant values cannot be simply extracted from the spectrum. In contrast, the proton spectrum of *trans*-**5** showed well-separated signals for all protons. Thus, the *tert*-butyl signal occurred at $\delta = 0.92$, and the equatorial and axial methylene protons at $\delta \approx 2.9$ and 3.8, respectively. The equatorial position of the *tert*-butyl group was confirmed by the *trans*- and *gauche*-coupling constants of $^3J_{H-H} = 11.3$ and 2.2 Hz, respectively, between the methine and methylene protons. Based on the splitting pattern, the signals at $\delta = 2.87$ were assigned to the equatorial protons and the downfield resonance at $\delta = 3.81$ to the axial ones. Similarly, the axial protons at C4 and C6 in *cis*-**6** are shifted to lower field ($\delta \approx 4.08$).[11] The equatorial position of the triphenylphosphonium group in *cis*-**6** was also supported by the long-range coupling constant ($^5J_{H-P} = 4.1$ Hz) between the equatorial proton at C5 and phosphorus.

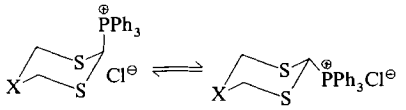
The ^{13}C-NMR spectrum (75.47 MHz, CD_2Cl_2) of *cis*-**5** and *trans*-**6** showed no coupling between phosphorus and C4 or C6. Such coupling is expected for the synclinal (*gauche*) arrangement of the C-S-C-P fragment. In both cases the γ-effect is negative (-4.48 for *cis*-**5** and -3.55 for *trans*-**6**), as was found earlier for the axially substituted 2-phosphoryl-1,3-dithianes.[12] The ^{13}C-NMR spectra of the more stable diastereomers *trans*-**5** and *cis*-**6** revealed long-range coupling constants of $^3J_{C-P} = 7.5$ and $^3J_{C-P} = 7.4$ Hz, respectively, in agreement with the antiperiplanar arrangement of the C4,6–S and C2–P bonds. As would be expected by analogy with the equatorially substituted 2-phosphoryl-1,3-dithianes,[12] the values for the γ-effect are positive (1.09 and 1.14 for *trans*-**5** and *cis*-**6**, respectively).

Both ^{1}H and ^{13}C-NMR spectra of the conformationally mobile dithianes **3** and **4** strongly suggest that the conformation in which the PPh_3 group is in the equatorial position predominates in solution. Thus, in the ^{1}H-NMR spectrum of **4** the methylene protons appear at $\delta = 2.3$ and 3.6. Because the coupling constant with phosphorus ($^4J_{H-P} = 4.9$ Hz) is observed in the upfield part of the spectrum, this signal was assigned to the equatorial protons. In the ^{13}C-NMR spectra of **3** and **4**, the methylene carbons C4 (C6) are coupled with

 © VCH Verlagsgesellschaft mbH, W-6940 Weinheim, 1991 0570-0833/91/0505-0579 $ 3.50+.25/0

phosphorus ($^3J_{C-P}$ = 6.2 and 5.7 Hz, respectively) indicating an antiperiplanar conformation of the C-S-C-P fragment and hence the prevailing equatorial position of the triphenylphosphonium group in solution. The γ-effect values (+ 0.135 and − 0.26 for **3** and **4**, respectively) are also in accord with this interpretation.

Chemical equilibration (CD_2Cl_2, Et_3N, 293 K, ^{31}P-NMR assay) of the conformationally fixed diastereomeric dithianes **5** and **6**, initiated from both sides, allowed us to estimate the following equilibrium constants and ΔG° values: $K = 1.74$, $\Delta G^\circ_{293} = -0.32$ kcal mol^{-1} for **5** and $K = 6.10$, $\Delta G^\circ_{293} = -1.05$ kcal mol^{-1} for **6**. The K and ΔG° values for conformational equilibria of the labile derivatives **3** and **4** were calculated using the Eliel equation[13] with the assumption that the value of the γ-effect on ^{13}C-NMR chemical shifts in these systems is the weighted average value of those for the model diastereomeric dithianes **5** or **6**. In this way the following values were obtained: $K = 4.84$, $\Delta G^\circ_{293} = -0.92$ kcal mol^{-1} for **3**, $K = 3.14$, $\Delta G^\circ_{293} = -0.66$ kcal mol^{-1} for **4** using *cis*- and *trans*-**5** as models; $K = 3.65$, $\Delta G^\circ_{293} = -0.75$ kcal mol^{-1} for **3** and $K = 2.35$, $\Delta G^\circ_{293} = -0.50$ kcal mol^{-1} for **4** using *trans*- and *cis*-**6** as models. Moreover, the ^{31}P-NMR spectrum of **4** at 190 K showed two singlets at $\delta = 22.0$ and 26.2 which can be assigned to the axial and equatorial conformers of **4**, respectively. Since their intensity ratio was 1:2.5, the equilibrium constant $K_{190} = 2.5$.[14] This value corresponds to $\Delta G^\circ_{190} = -0.35$ kcal mol^{-1} and is close to the calculated value.



ax-**3** X = CH_2 eq-**3**
ax-**4** X = CMe_2 eq-**4**

The data presented above indicate a surprisingly small equatorial preference for the bulky triphenylphosphonium group in the 1,3-dithiane ring.[15] Most probably, in this case a considerable anomeric effect that partially compensates for 1,3-diaxial repulsive interactions is also operating.[16]

The diversity of the K (and ΔG°) values determined experimentally or calculated for the 2-triphenylphosphonio-1,3-dithianes **3**–**6** is most probably due to the solvent effect on conformational equilibria of the variously substituted 1,3-dithiane rings, which should also differ, although to a small extent, in some structural parameters. The solvent effect may play an important role, especially in the systems investigated when steric and anomeric effects act in opposite directions. Therefore even a small disturbance of this balance by the solvent-solute interactions may substantially affect K and ΔG° values.[17]

With regard to the origin of the anomeric effect in the system described above, three mechanisms can be taken into account. The first, commonly accepted one may involve $n_S \rightarrow \sigma^*_{C-P}$ conjugation.[8] The second, proposed recently by *Juaristi*,[2] is based on a through-space 3p–3d electron donation from sulfur to phosphorus in the axial conformation. Finally, in our opinion, the equatorial position of the triphenylphosphonium group may be destabilized by repulsive interactions between lone electron pairs on the endocyclic sulfur atoms and π-electrons of the phenyl ring. Further experiments to test this hypothesis are in progress.

[14] The K_{190} value should be somewhat larger than K_{293}: therefore **6** would be the better reference system.
[15] X-ray structure analysis of **4** showed that the PPh_3 group is located in an axial position in the solid state.
[16] Although the magnitude of the anomeric effect in 2-triphenylphosphonio-1,3-dithianes cannot be calculated, because of the absence of the A-value for the corresponding cyclohexane, it is possible to estimate its value by assuming that the triphenylphosphonium group is larger than the diphenylthiophosphinoyl one. The A-value for the latter was found by *Juaristi* et al. [2] to be 3.61 kcal mol^{-1}. Therefore, an anomeric effect in **5** and **6** should be at least 2.5 kcal mol^{-1}. The synthesis of the desired triphenylphosphoniocyclohexanes is currently under way in this laboratory.
[17] Similar diversity of K and ΔG° values (up to 0.25 kcal mol^{-1}) was observed by *Tschierske* et al. (see ref. [18]).

Carbonyl(pentaphosphacyclopentadienyl)–Transition Metal Complexes (M = Cr, Mo, W, Mn) through Directed Syntheses with *cyclo*-$P_5^\ominus$ **

By *Marianne Baudler** and *Thomas Etzbach*

Dedicated to Professor Rolf Appel on the occasion of his 70th birthday

A few years ago we reported on the formation of the pentaphosphacyclopentadienide ion, *cyclo*-$P_5^\ominus$ (**1**), upon the nucleophilic fission of white phosphorus, and on the preparation of

[*] Prof. Dr. M. Baudler, Dipl.-Chem. T. Etzbach

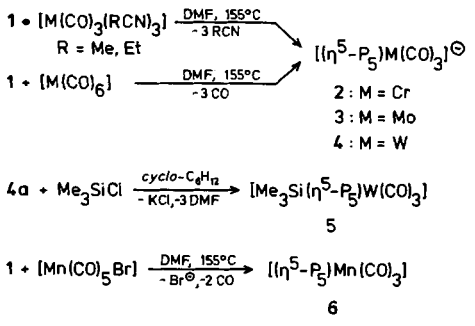
Greinstrasse 6, W-5000 Köln 41 (FRG)

[**] Contributions to the Chemistry of Phosphorus, Part 216. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. Part 215: M. Baudler, T. Etzbach, *Chem. Ber.*, in press.

pure LiP_5/THF and NaP_5/[18]crown-6/THF solutions.[1-4] Recently, we have also obtained surprisingly stable KP_5/DMF solutions through degradation of red phosphorus with potassium dihydrogenphosphide in dimethylformamide (DMF).[5]

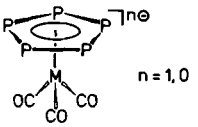
1

Because of its electronic structure (resonance-stabilized 6π electron system), **1** can be bound in transition metal complexes as an (η^5-P_5) ligand. The first examples, described recently by *Scherer*,[6] are the sandwich and triple decker complexes [(η^5-P_5)M(η^5-C_5Me_4R)] (M = Fe, Ru; R = Me, Et) and [(η^5-C_5Me_5Cr)$_2$(μ,η^5-P_5)], respectively, which were prepared from white phosphorus by cothermolysis with suitable starting complexes. In the case of the mixed sandwich complex [(η^5-P_5)Fe(η^5-C_5Me_5)], we also realized the directed synthesis from LiP_5, LiC_5Me_5, and $FeCl_2$.[3] All the *cyclo*-P_5 complexes known to date have an additional (η^5-$C_5R^1_4R^2$) ligand (R^1 = R^2 = Me, H; R^1 = Me(H), R^2 = Et(Me)) at the metal center. Attempts to prepare metallocene analogues with two P_5 ligands led, without exception, to high molecular weight solids which appeared amorphous under X-ray examination. Their formation can presumably be attributed to the additional coordination capability of the λ^3-phosphorus via the lone pair.[7] We have now achieved the directed synthesis of the first mixed carbonyl(pentaphosphacyclopentadienyl)-metal complexes through thermal ligand exchange reactions, using **1** as a synthetic reagent (Scheme 1).



Scheme 1. Thermal ligand-exchange reactions with **1**. Compounds **4a**: [K(dmf)$_3$] [(η^5-P_5)W(CO)$_3$]; **4b**: Li[(η^5-P_5)W(CO)$_3$].

During the reaction of **1** with tris(nitrile)tricarbonyl complexes of chromium, molybdenum or tungsten, the corresponding tricarbonyl(pentaphosphacyclopentadienyl)metalate ions **2**–**4** form on exchange of the three nitrile ligands. Their formation occurs via intermediates which were not further characterized, but could be detected by ^{31}P NMR spectroscopy in the early stages of the reaction, especially at room temperature. The use of the complex in which R = Et and of the KP_5/DMF solution[5] is particularly favorable because of their stability. With prolonged reaction times (24 h), the substitution of three carbonyl ligands of the corresponding hexacarbonyl-metal complexes can also be achieved by **1** using KP_5/DMF solution. At the same time small amounts of by-products, very probably multinuclear P_5 complexes, are formed in addition to **2**–**4**. Compound **4** was isolated in the form of the salts **4a** (dark brown, honeylike) and **4b** (brown powder). Compound **4b** is significantly more sensitive to oxidation than **4a**. The solutions of **2** and **3** in DMF or THF are also brown. In suspension **4a** reacts smoothly with chloro(trimethyl)silane to yield the silyl derivative **5** (colorless, volatile oil). The reaction of KP_5/DMF solution with bromo(pentacarbonyl)manganese(I) affords tricarbonyl(pentaphosphacyclopentadienyl)manganese (pentaphosphacymantrene) (**6**), a volatile, pale yellow solid which was separated from saltlike by-products by extraction with THF. In the mass spectrum of **6**, the signals of the characteristic fragment ions $Mn(CO)_nP_5^{\oplus}$ (n = 2–0), formed by loss of CO, occur besides the signal for the $M^{\oplus}$ ion (m/z = 294).



Scheme 2. Complexes with C_{3v} symmetry; M = W, Mo, Cr, Mn.

Proof of the constitution of **2**–**6** is provided by the spectroscopic data. In the ^{31}P-NMR spectrum of each, a singlet appears (**2**: δ = 163.4; **3**: δ = 141.6; **4**: δ = 105.2, $^1J(^{31}P,^{183}W)$ = 11.9 Hz; **6**: δ = 126.7), which lies in the same region as the signals of the pentaphosphametallocenes.[6] In the case of the metalate ions **2**–**4**, the position of the signal is practically independent of the counterion ([K(dmf)$_3$]$^{\oplus}$, Li$^{\oplus}$); in the case of the silyl compound **5** (δ = −23.4), the electropositive substituent causes an additional shielding. The strongly negative coordination shift[8] in **2**–**6** compared to free **1** (δ = +470[1,5]) is a general feature of π-phosphaarene complexes.[9] The ^{13}C-NMR signal of the CO ligands of **4** (δ = 218.7, $^1J(^{13}C,^{183}W)$ = 3.5 Hz, ^2J(C,P) = 1.7 Hz) lies in the normal range; the small ^{13}C,^{183}W coupling constant is remarkable. The ^{1}H-NMR signal of the Me_3Si group of **5** (δ = −0.55) has a very similar chemical shift as in the corresponding cyclopentadienyl complex.[10]

In the IR spectrum of **4** and **6**, the two intense CO bands that are typical for [M(CO)$_3$] fragments with undisturbed C_{3v} symmetry appear. Their position is significantly shifted with respect to that of the corresponding cyclopentadienyl complex:[11,12] for **4** to larger, and for **6** to smaller wave numbers. Obviously, **1** and $C_5H_5^{\ominus}$ have a markedly different donor/acceptor behavior.

All spectroscopic findings confirm a structure for **2**–**6** analogous to the corresponding cyclopentadienyl complexes. It is to be expected that numerous other *cyclo*-P_5 complexes may be prepared through directed synthesis reactions with **1**.

Experimental Procedure

4a: 30 mL (1.13 mmol) of a 3.8×10^{-2} M KP_5 solution in DMF [5] was added dropwise under inert gas with vigorous stirring within 5 min to [W(CO)$_3$(EtCN)$_3$] [13] (4.0 g, 9.24 mmol, excess). Thereafter the mixture was heated to boiling for 30 min. The dark brown solution was cooled to room temperature and monitored by ^{31}P NMR spectroscopy, which confirmed a quantitative reaction of KP_5. Removal of DMF and excess starting complex at 50 °C in vacuo (oil pump) gave 0.71 g of **4a** (92%, based on KP_5). IR (in DMF, selected data): $\tilde{\nu}$[cm^{-1}] = 1988 vs (CO, A_1), 1886 vs (CO, E); correct elemental analysis.

4b: [W(CO)$_3$(EtCN)$_3$] (0.35 g, 0.82 mmol, excess) in THF (10 mL) was added dropwise with vigorous stirring within 15 min to 125 mL (0.088 mmol) of a 7×10^{-4} M LiP_5 solution in THF [1], whereupon a brown precipitate separated. After stirring for a further 30 min, the colorless solution was siphoned off, the solid washed with THF (3×10 mL) and dried in vacuo (oil pump); yield 36 mg **4b** (96%, based on LiP_5). Correct elemental analysis.

5: A suspension of **4a** (2.0 g, 2.94 mmol) in cyclohexane (5 mL) was stirred with chloro(trimethyl)silane (1.3 g, 11.93 mmol) for 24 h at room temperature. Sep-

aration of the colorless reaction solution from unchanged **4a** and removal of the solvent under vacuum afforded 0.70 g **5** (48%, based on **4a**).
6: 10 mL (0.38 mmol) of a 3.8×10^{-2} M KP_5 solution in DMF [5] was added dropwise under inert gas with vigorous stirring within 5 min to $[Mn(CO)_5Br]$ (0.85 g, 3.09 mmol, excess). After 24 h stirring at the boiling point, the solvent of the red-brown solution was removed in vacuo at room temperature. The residue was stirred with THF (5 mL) for 12 h and the solvent removed completely from the colorless extract; yield 27 mg **6** (23%, based on KP_5). IR (in THF, selected data): $\tilde{\nu}$[cm^{-1}] 1960 s (CO, A_1), 1778 s (CO, E).

A 1,2-Phenylene-Bridged Porphyrin Dimer—Synthesis, Properties, and Molecular Structure**

By *Atsuhiro Osuka,* Satoshi Nakajima, Toshi Nagata, Kazuhiro Maruyama,** and *Koshiro Toriumi*

The X-ray structure analyses of photosynthetic reaction centers (RCs) of bacteria have stimulated extensive studies of model compounds.[1] These included coupled diporphyrins, the study of which should clarify the role of the special pair (SP) acting as primary electron donor in the reaction center. Two important criteria for a synthetic analogue of SP are 1) an energetically lower S_1-state and 2) a lower one-electron oxidation potential.[2] One of the central issues is under discussion is: how porphyrin-porphyrin interactions influence the electronic properties of the dimer. Herein, we describe the synthesis, X-ray crystallography, and physical properties of the novel 1,2-phenylene-bridged porphyrin dimer **1**-Zn_2,[3] which meets the criteria mentioned above.[4] The synthetic route is illustrated in Scheme 1. Formyl-substituted porphyrin **5**, which was obtained from the cross-condensation of *p*-tolualdehyde **2**, dipyrrylmethane **3**, and mono-protected phthalaldehyde **4**, was again cyclized with **2** and **3** to give the dimer **1** in 48% yield.

Small red crystals of **1**-Zn_2 were grown by slow evaporation of a dichloromethane/hexane solution. Figure 1 shows the molecular structure of **1**-Zn_2.[5, 6] The most remarkable

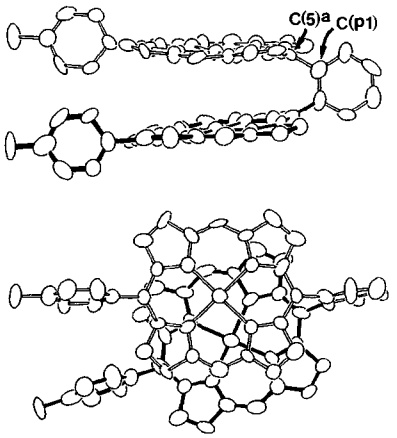

Fig. 1. Molecular structure of **1**-Zn_2. Above: side view; below: top view. Peripheral alkyl groups are omitted for clarity.

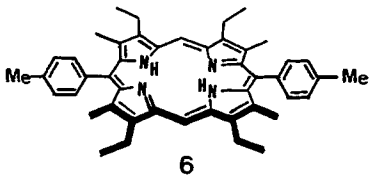
[a] In CH_2Cl_2 [b] Energy of the lowest singlet excited state. [c] Oxidation potentials (vs. ferrocene/ferrocenium) measured by cyclic voltammetry at a Pt electrode in CH_2Cl_2 containing 0.1 M n-Bu_4NClO_4 at 20°C. [d] Peak potentials.

structural feature is that, though the two porphyrin rings are bridged by the 1,2-phenylene moiety, they tend to closely overlap each other and assume an almost parallel conformation (dihedral angle 6.6°). This overlapping conformation appears to increase the van der Waals interaction of the two porphyrin rings. The average interplanar separation between the two rings is 3.43 Å, which is similar to the reported value of 3.45 Å in biphenylene-bridged Cu_2-diporphyrin,[6b] and 3.52 Å in Cu_2-"hexyldiporphyrin-7".[6c] The interplanar separations between the neighboring molecules (3.61 Å and 4.92 Å) are larger than the intramolecular separation. This fact indicates that the parallel conformation is induced by the attractive intramolecular interactions between the two porphyrin rings. A large strain is generated at the C5a-Cp1 bond by this "enforced" parallel structure, but is dispersed widely over the whole porphyrin ring. The second interesting feature is the rotation of the two porphyrin rings about the phenylene bridge (by 22.7°) rather than an exact "stacked" conformation. This offset geometry may be the result of electrostatic interactions between the two porphyrin rings.[7] The ^{1}H-NMR data provide information about the structure of **1** and **1**-Zn_2 in solution. The large upfield shifts of the NH and *meso* protons in the dimers indicate that a parallel conformation is present even in solution. However, the ^{1}H-NMR spectra of **1** and **1**-Zn_2 contain only half the number of signals predicted by the crystal structure of **1**-Zn_2, indicating that a very rapid switching between the two conformations must take place.

The absorption and fluorescence properties of **1** and **1**-Zn_2 are listed in Table 1, together with the data for the monomers **6** and **6**-Zn for comparison. Strong excitonic interactions are observed for the diporphyrins **1** and **1**-Zn_2, i.e. blue-shifted Soret bands, red-shifted Q-bands, and broad red-shifted fluorescence.[8] **1** and **1**-Zn_2 exhibit relatively large Stokes shifts, (760 and 1060 cm^{-1}, respectively), suggesting nuclear geometric changes in their excited states. The characteristic vibrational mode of Zn-porphyrin is no longer observed in the relatively broad fluorescence band of **1**-Zn_2, which is reminiscent of the emission from an excimer of condensed aromatics. The relative fluorescence quantum yields of **1** and **1**-Zn_2 are 0.25- and 0.087-fold those of the corresponding monomers. On the basis of the absorption and fluorescence spectra, the energy levels of the S_1-states of **1** and **1**-Zn_2 were estimated to be lower by ca. 700 and 1500 cm^{-1} respectively than the corresponding monomer. The reduced fluorescence quantum yield indicates the presence of additional nonrediative decaying channels in the S_1-state of **1**-Zn_2. However, the shape and intensity of the fluorescence of **1**-Zn_2 were not significantly altered by the solvent polarity (from C_6H_6 to CH_3CN). This suggests that excimer interactions are more important than charge transfer interactions in the S_1 state of **1**-Zn_2.

Cyclic voltammetry of **1**-Zn_2 in CH_2Cl_2 solution, using (n-Bu_4N)ClO_4 as supporting electrolyte, reveals four reversible oxidation waves (Table 1). It is reasonable to assign the wave at 0.01 V to the one-electron oxidation of the neutral Zn-porphyrin ($E^+_{1/2}$(ZnP–ZnP$^{\oplus}$/ZnP–ZnP)). Therefore, it is concluded that **1**-Zn_2 undergoes reversible one-electron oxidation 160 mV more easily than **6**-Zn.



6

In conclusion, the strong interactions in **1**-Zn_2 result in a decrease both in the energy of the S_1-state and in the one-electron oxidation potential, which make it a promising candidate for the electron donor in an artificial photosynthetic reaction center involving oligomeric porphyrins.

Experimental Procedure

1: The formyl-substituted porphyrin **5** (249 mg, 0.37 mmol) and *p*-tolualdehyde **4** (175 mg, 1.455 mmol) were dissolved in CH_3CN (20 mL) containing trichloroacetic acid (131 mg, 0.8 mmol). Then, the dipyrrylmethane **3** (422 mg, 1.83 mmol) in CH_3CN (3 mL) was added, and the mixture was stirred for 19 h (in the dark, under nitrogen). *p*-Chloranil (662 mg, 2.69 mmol) in THF (30 mL) was added, and stirring was continued for 3 h. After work-up in the usual way, the porphyrin products were separated by flash column chromatography, giving **1**. Yield 48% based on the amount of **5** used (215 mg): ^{1}H NMR (400 MHz, $CDCl_3$, 25°C, TMS): δ = −6.31 (broad, NH, 2H), −5.77 (br, NH, 2H), 1.32 (t, 12H), 1.53 (t, 12H), 3.3–3.6 (m, 16H), 2.35 (s, Me, 12H), 2.81 (s, Ar–Me, 6H), 2.91 (s, Me, 12H), 7.28 (dd, J = 2 and 7.8 Hz, 2H), 7.36 (d, J = 7 Hz, 2H), 7.76 (d, J = 7 Hz, 2H), 8.17 (dd, J = 3.8 and 5.8 Hz, 2H), 8.26 (dd, J = 7.3 and 2 Hz, 2H), 8.39 (s, *meso*-H, 4H), and 9.00 (dd, J = 3.4 and 5.4 Hz, 2H) ppm. FAB MS: m/z 1211 ($M^{\oplus}$ + 1).

1-Zn_2: ^{1}H NMR (400 MHz, $CDCl_3$, 25°C, TMS): δ = 1.28 (t, Et, 12H), 1.53 (t, Et, 12H), 2.30 (s, Me, 12H), 2.79 (s, Ar–Me, 6H), 2.90 (s, Me, 12H), 3.4–3.6 (m, Et, 16H), 7.10 (dd, J = 2 and 7.5 Hz, 2H), 7.29 (dd, J = 2 and 7.5 Hz, 2H), 7.77 (dd, J = 2 and 7.5 Hz, 2H), 8.11 (t, J = 7 Hz, 2H), 8.33 (s, *meso*-H, 4H), 8.35 (dd, J = 2 and 7.5 Hz, 2H), 8.93 (dd, J = 3.8 and 6 Hz, 2H) ppm. FAB MS: m/z 1341 ($M^{\oplus}$ + 1).

[8] Recently several monomeric non-planar porphyrins were reported to exhibit similar red-shifted Q-bands and reduced oxidation potentials; a) K. M. Barkigia, L. Chantranupong, K. M. Smith, J. Fajer, *J. Am. Chem. Soc. 110* (1988) 7566; b) C. J. Medforth, M. D. Berber, K. M. Smith, J. A. Shellnutt, *Tetrahedron Lett., 31* (1990) 3719. However, the porphyrin ring in **1**-Zn_2 is rather flat, indicating that its unusual properties are not due to the porphyrin ring distortion but mainly due to the strong interactions between the two porphyrin rings.

A Complex with Three-Coordinate Tungsten Atom: [(silox)$_2$W=N*t*Bu](silox = *t*Bu$_3$SiO)**

By *Daniel F. Eppley, Peter T. Wolczanski,** and *Gregory D. Van Duyne*

The application of sterically demanding ligands often permits the isolation of low-coordinate transition metal complexes. Recently, the utilization of bulky imido and siloxido ligands led to the synthesis of [Ta(silox)$_3$] (silox = *t*Bu$_3$SiO)[1] and [Os{=N-2,6-*i*Pr$_2$C$_6$H$_3$)}$_3$],[2] both rare examples of three-coordinate, third row compounds. Herein we describe the preparation and structure of [(silox)$_2$W=N*t*Bu] **3**. To our knowledge, this imido complex is the first example of a three-coordinate tungsten species.[3]

Thermolysis of [(*t*BuNH)$_2$W(=N*t*Bu)$_2$][4] and 2.0 equiv of (silox)H[5] in benzene afforded *t*BuNH$_2$ and colorless [(silox)$_2$W(=N*t*Bu)$_2$] **1** in 81% yield upon crystallization from hexane [Eq. (a)]. Treatment of **1** with 3.0 equiv of HCl in C_6H_6 eliminated [*t*BuNH$_3$]Cl and provided light-yellow [(silox)$_2$Cl$_2$W=N*t*Bu] **2** in 88% yield after crystallization from hexane [Eq. (b)]. Reduction of **2** with Mg dust in diethyl ether generated a dark green solution. Removal of the Et_2O, followed by filtration and crystallization from hexanes, produced three-coordinate [(silox)$_2$W=N*t*Bu] **3** as emerald-green crystals in 91% yield [Eq. (c)]. The bis(silox-imido) complex **3** is stable as a solid, but unstable in benzene or hydrocarbon solutions. Cryoscopic molecular weight measurements of **3** were precluded by its slow decomposition ($t_{1/2} \approx 1$ h), but ^{1}H-NMR and IR spectra (ν(W=N) = 1295 cm^{-1}) were indicative of a diamagnetic, monomeric imido complex.[6]

$$[(t\text{BuNH})_2\text{W}(=\text{N}t\text{Bu})_2] + 2\,\text{H(silox)} \xrightarrow[-\,2\,t\text{BuNH}_2]{C_6H_6,\ >3\text{d},\ 90\,^\circ\text{C}} \underset{\mathbf{1}}{[(\text{silox})_2\text{W}(=\text{N}t\text{Bu})_2]} \quad \text{(a)}$$

$$\underset{\mathbf{1}}{[(\text{silox})_2\text{W}(=\text{N}t\text{Bu})_2]} + 3\,\text{HCl} \xrightarrow[-\,[t\text{BuNH}_3]\text{Cl}]{C_6H_6,\ 3.5\text{d},\ 110\,^\circ\text{C}} \underset{\mathbf{2}}{[(\text{silox})_2\text{Cl}_2\text{W}=\text{N}t\text{Bu}]} \quad \text{(b)}$$

$$\underset{\mathbf{2}}{[(\text{silox})_2\text{Cl}_2\text{W}=\text{N}t\text{Bu}]} \xrightarrow[-\,\text{MgCl}_2]{\text{Mg},\ \text{Et}_2\text{O},\ 25^\circ,\ 7\text{h}} \underset{\mathbf{3}}{[(\text{silox})_2\text{W}=\text{N}t\text{Bu}]} \quad \text{(c)}$$

The structure of **3** was confirmed via single crystal X-ray diffraction studies (monoclinic, $P2_1/c$, $R = 0.078$, $R_w = 0.092$), although the bond distances and angles reflect some imprecision due to the disorder of all peripheral *t*Bu groups.[7] Similar disorder problems have been observed in other complexes with the silox-ligand.[1, 8] As Figure 1 shows, the (SiO)$_2$W=NC framework of **3** is nearly trigonal planar, with a slight distortion toward a T-shape. Relatively short W–O (1.826(16), 1.814(15) Å) and W=N (1.658(17) Å) bonds are observed,[6] consistent with a low-coordinate, electrophilic metal center. The steric requirements of the silox ligands[9] render the O1–W–O2 angle (127.4(6)°) greater than the O1–W–N (115.7(8)°) and the O(2)–W–N (116.8(8)°) angles. The W–O1–Si1 (177.8(8)°), W–O2–Si2 (169.7(10)°) and W=N–C (175.3(16)°) angles manifest minimal deviations from linearity; thus, electronic effects that maximize O(pπ) → W(sπ) and N(pπ) → W(dπ) bonding may play consequential roles.[10] Provided the linearity of the W–O–Si and W=N–C linkages can be attributed to the maximum π-donation of oxygen and nitrogen filled p-orbitals, the valence shell of tungsten contains 20e. As in the related d^2 complexes, [Os{=N(2,6-*i*PrC$_6$H$_3$)}$_3$] and [Ta(silox)$_3$], 2e reside in a non-bonding π-type ligand-based orbital, thus the complex possesses at most 18e.[2] Due to the lower symmetry (C_{2v}), this orbital has greater oxygen than nitrogen character.

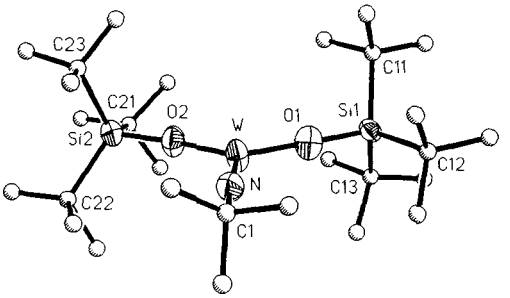

Fig. 1. Structure of **3** in the crystal. The inner coordinate sphere is depicted with 40% vibration ellipsoids, while the best model of the disordered peripheral *t*Bu groups is illustrated by isotropic spheres.

Simple σ-donors, such as THF, do not bind to **3** because of a significant 4e repulsion between a σ-donor orbital and

the d_{z^2} orbital of the metal,[1] yet π-accepting ligands readily form adducts. Exposure of **3** to either ethylene or 2-butyne[11] generated the orange and colorless four-coordinate

$$[(silox)_2W{=}NtBu] + L \xrightarrow{\text{hexane, } 25^\circ,\ 1.5\,h} [(silox)_2LW = NtBu] \qquad (d)$$

4, L = C_2H_4; **5**, L = Me_2C_2

$[(silox)_2LW{=}NtBu]$ derivatives **4** and **5** respectively [Eq. (d)]. ^{1}H- and ^{13}C-{^{1}H}-NMR spectra indicate that the ethylene is bound with its carbons parallel to the two oxygens, and variable temperature ^{1}H-NMR studies indicate that the barrier to rotation is 15.3 kcal mol^{-1} (T_{coal} = 69 °C). This is the orientation expected from comparisons with analogous $[(RO)_2(R'N)W{=}CHR'']$ complexes,[12] hence the 2-butyne is presumed to coordinate in similar fashion. Further reactivity studies of **3** and related derivatives are currently underway.

Experimental Procedure

All operations were performed using glovebox (N_2) or high vacuum line (Ar) techniques. Ethereal and hydrocarbon solvents were dried over Na/benzophenone and twice distilled. Satisfactory C and H analysis were obtained for all isolated species.

1: 50 mL of benzene was distilled into a glass bomb reactor containing $[(tBuNH)_2W(=NtBu)_2]$ (8.53 g, 18.1 mmol) and (silox)H (7.85 g, 36.3 mmol) at −78 °C. The mixture was heated and stirred for 3 d at 90 °C, then checked by ^{1}H NMR. Additional (silox)H (≈ 2 g) and further heating (≈ 1 d) was occasionally required. The benzene was removed, hexane added, and the solution filtered and cooled to −78 °C. Yield of colorless microcrystalline **1**: 11.04 g (81%). ^{1}H NMR (C_6D_6): δ = 1.26 (s, 54H, silox), 1.42 (s, 18H, *t*Bu); ^{13}C{^{1}H}-NMR: δ = 23.94 (SiC), 30.21 ($SiC(CH_3)_3$), 33.79 ($NC(CH_3)_3$), 66.50 (NC). IR (nujol): ν(W = N) = 1215, 1245 cm^{-1}.

2: 30 mL of benzene was distilled into a glass bomb reactor containing 6.87 g (9.08 mmol of **1**). HCl gas (27.24 mmol) was then passed at −196 °C into the bomb reactor, which was heated and stirred for 3.5 d at 110 °C. The benzene and residual HCl were removed, 50 mL of hexane added, and the solution filtered and cooled (−78 °C) to yield 5.47 g (88%) of pale yellow, crystalline **2**. ^{1}H NMR (C_6D_6): δ = 1.28 (s, 9H, *t*Bu), 1.34 (s, 54H, silox); ^{13}C{^{1}H}-NMR: δ = 24.82 (SiC), 30.28 ($NC(CH_3)_3$), 30.48 ($SiC(CH_3)_3$), 75.23 (NC). IR (nujol): ν(W = N) = 1280 cm^{-1}.

3: 25 mL of diethyl ether was distilled into a flask containing **2** (3.10 g, 4.10 mmol) and Mg dust (440 mg, 19.1 mmol) at −78 °C. The solution was stirred at 25 °C for 7 h and the ether removed to yield a crusty green solid. Hexane (25 mL) was added and the solution filtered and cooled to −78 °C to give 2.57 g (91%) of emerald-green **3**. ^{1}H NMR (C_6D_{12}): δ = 1.15 (s, 54H, silox), 1.74 (s, 9H, *t*Bu). IR (nujol): ν(W=N) = 1295 cm^{-1}.

4: 10 mL of hexane was distilled into a glass bomb containing 448 mg (0.653 mmol) of **3**. Ethylene (0.656 mmol) was then added at −196 °C. The solution was stirred for 1 h at 25 °C and cooled to −78 °C, yielding 208 mg (45%) of orange, microcrystalline **4**. ^{1}H NMR (C_6D_{12}): δ = 1.14 (s, 54H, silox), 1.32 (s, 18H, *t*Bu), 1.64 (br m, 2H, *H*HC=C*H*H), 2.83 (br m, 2H, H*H*C=CH*H*); ^{13}C{^{1}H}-NMR (C_6D_6): δ = 23.36 (SiC), 30.31 ($SiC(CH_3)_3$), 31.09 ($NC(CH_3)_3$), 52.51 (C_2H_4). IR (nujol): ν(W=N) = 1295 cm^{-1}.

5: 8 mL of hexane was distilled into a glass bomb containing 598 mg, (0.872 mmol) of **3**. Ca. 3 mL of 2-butyne (60 mmol) was then added at −78 °C. The resulting brown solution was stirred for 1.5 h at 25 °C, filtered and cooled to 0 °C, yielding 215 mg (33%) of colorless **5**. ^{1}H NMR (C_6D_6): δ = 1.17 (s, 18H, *t*Bu), 1.29 (s, 54H, silox), 2.59 (t, *J*(WH) = 5 Hz, 6H, Me_2); ^{13}C{^{1}H}-NMR: δ = 20.83 (Me_2), 23.77 (SiC), 30.50 ($SiC(CH_3)_3$), 32.99 ($NC(CH_3)_3$), 68.34 (NC), 199.73 (C≡C). IR (nujol): ν(W=N) = 1281 cm^{-1}.

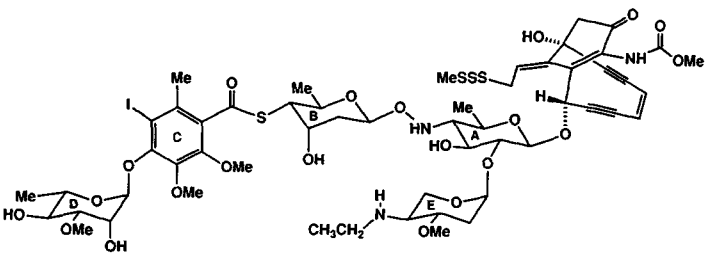
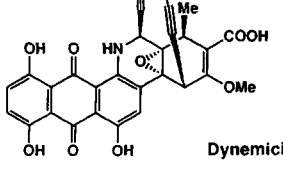
Synthetic Strategy for the Coupling of the Calicheamicin Oligosaccharide with Aglycons: Synthesis of Dynemicin A–Calicheamicin Hybrid Structures**

By *K. C. Nicolaou,* E. P. Schreiner* and *W. Stahl*

Studies in the area of enediyne antibiotics[1-3] recently reported from these laboratories include the total synthesis[4] of the oligosaccharide fragment of calicheamicin γ_1^I and the construction[5] of a number of dynemicin A models. Crucial to a successful total synthesis of calicheamicin γ_1^I is the stereoselective coupling of the oligosaccharide and agly-



Calicheamicin γ_1^I



Dynemicin A

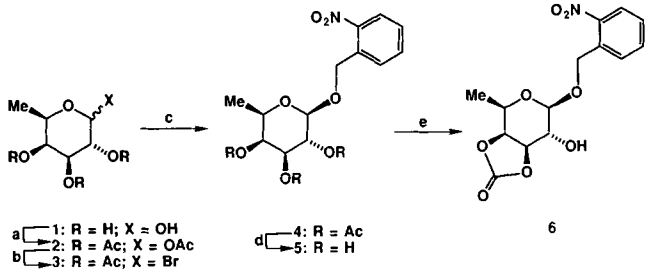
con fragments under mild conditions that will ensure the survival of sensitive functionalities. In this communication we report a) a synthetic strategy that addresses the stereoselective connection of the calicheamicin γ_1^I oligosaccharide and aglycon fragments, and b) the construction of novel calicheamicin γ_1^I–dynemicin A hybrid structures.

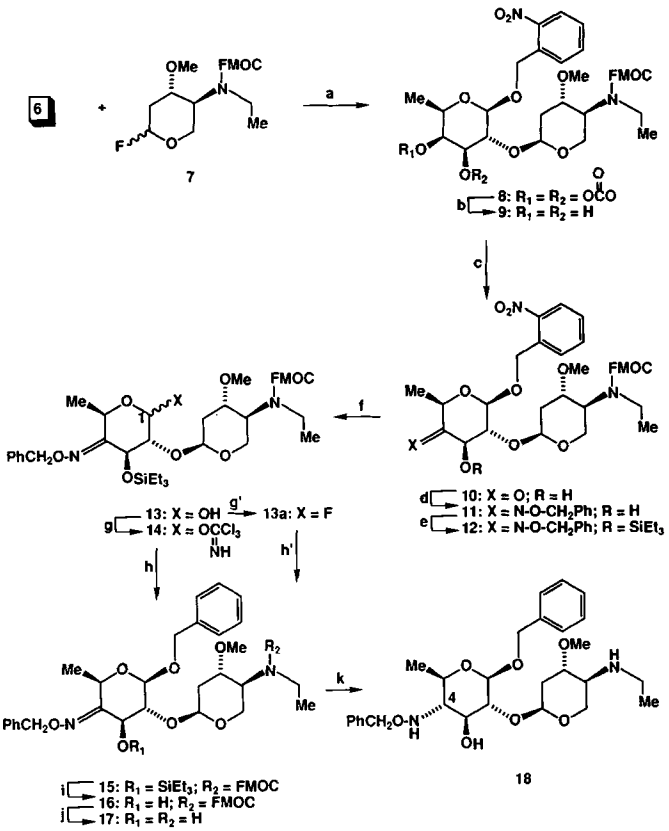
To test a possible scenario for the stereoselective coupling of the calicheamicin γ_1^I oligosaccharide and aglycon fragments, model **18** (Scheme 2) was chosen for synthesis. The key intermediate **6** was synthesized from D-fucose as outlined in Scheme 1. Thus, D-fucose (**1**) was acetylated to form te-



Scheme 1: Synthesis of intermediate **6**; reagents and conditions: a) 6.0 eq Ac_2O, 8.0 eq NEt_3, 4-dimethylaminopyridine (DMAP) cat., CH_2Cl_2, 0–25 °C, 2 h, 98%; b) HBr (30%) in HOAc, 0 °C, 0.5 h; c) 1.3 eq HOBn-NO_2, 1.3 eq $AgCO_3$, 3 Å molecular sieves, CH_2Cl_2, 25 °C, 16 h, 65% from **2**; d) NaOMe cat., MeOH, 25 °C, 3 h, 95%; e) 2.5 eq CDI, MeCN, reflux, 2 h, 90%.

traacetate **2**, which was converted into the anomeric bromide **3**. Glycosylation with *o*-nitrobenzyl alcohol afforded compound **4** (63% overall yield). Deacetylation of **4** led to **5**, which reacted selectively with carbonyl diimidazole (CDI) to afford the requisite ring A intermediate **6** in 86% overall yield.

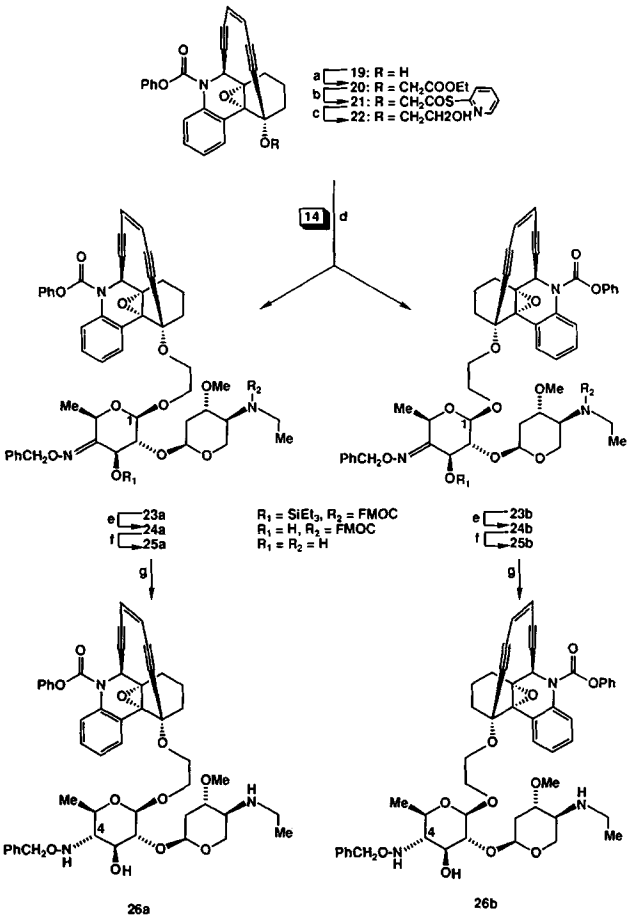
Intermediate **6** was then coupled[6] to glycosyl fluoride **7**[7] (Scheme 2) with $AgClO_4$–$SnCl_2$ catalyst, leading stereoselectively to disaccharide **8** as the major anomer (80% yield, ca. 5:1 ratio of anomers). Chromatographic purification of **8** followed by removal of the carbonate protecting group ($NaH/HOCH_2CH_2OH$, 90%) and treatment with $n$$Bu_2SnO$-$Br_2$[8] led to hydroxyketone **10** (65% yield plus 17% **9**) via intermediate **9**. Oxime formation with *o*-benzylhydroxylamine under acid conditions led to **11** (90%, single geometrical isomer of unassigned stereochemistry), which was silylated under standard conditions to furnish compound **12** (90%). Photolytic cleavage[9] of the *o*-nitrobenzyl group from **12** (THF/H_2O, 15 min) produced lactol **13** in 95% yield. Treatment of **13** with NaH–$Cl_3CC{\equiv}N$ in CH_2Cl_2[10] for 2 h at 25 °C resulted in the formation of the α-trichloroacetimidate **14** in 98% yield. Reaction of benzyl alcohol (2.0 equiv) with trichloroacetimidate **14** under Schmidt conditions[10] [$BF_3 \cdot Et_2O$, CH_2Cl_2, $-60 \rightarrow -30$ °C] resulted in stereoselective formation of the β-glycoside **15** (79% yield) together with its anomer (16%, separated by chromatography; ^{1}H NMR, 500 MHz, C_6D_6: **15**: $J_{1/2} = 6.5$ Hz, *epi*-**15**: $J_{1,2} = 2.4$ Hz). On the other hand, treatment of lactol **13** with diethylaminesulfurtrifluoride (DAST) led to the glycosyl fluoride **13a** in 90% yield (ca. 1:1 anomeric mixture). Reaction of **13a** with benzyl alcohol in the presence of silver silicate[11]/$SnCl_2$ resulted in the formation of the β-glycoside **15** and its anomer in 85% (ca. 1:1 anomeric mixture). Generation of intermediate **17** via **16** proceeded smoothly under standard deprotection conditions. Finally, exposure of **17** to Ph_2SiH_2 in the presence of $Ti(OiPr)_4$ resulted in the formation of the target **18**[12] as the only detectable product (92% yield). Interestingly, reduction of **17** with $NaCNBH_3/H^{\oplus}$ led predominantly to the 4-epimer of **18** (90% yield). The stereochemical assignments of **18** and *epi*-**18** at C-4 were based on ^{1}H NMR coupling constants (^{1}H NMR, 500 MHz, C_6D_6, **18**: $J_{3,4} = 9.5$, $J_{4,5} = 9.5$ Hz; *epi*-**18**: $J_{3,4} = 1.9$, $J_{4,5} = 1.5$ Hz).



Scheme 2: Synthesis of benzyl glycoside model **18**; reagents and conditions. a) 1.2 eq of **7**, 2.5 eq $AgClO_4$, 2.5 eq $SnCl_2$, THF, −90 to −10 °C, 6 h, 80%, (α:β ca 5:1); b) NaH cat., $HOCH_2CH_2OH$/THF (1:10), 0 °C, 0.5 h, 90%; c) 1.05 eq $n$$Bu_2SnO$, MeOH, reflux, 1 h, then 1.0 eq Br_2, 1.0 eq $n$$Bu_3SnOMe$, CH_2Cl_2, 25 °C, 2 h, 65% + 17% starting material **9**; d) 1.1 eq $BnONH_2$, pyridinium-*p*-toluenesulfonate (PPTS) cat., benzene, 25 °C, 0.5 h, 90%; e) 1.0 eq Et_3SiOTf, 1.2 eq 2,6-lutidine, CH_2Cl_2, 0 °C, 0.5 h, 98%; f) *hv*, THF/H_2O (9:1), 0 °C, 15 min, 95%; g) NaH cat., CCl_3CN/CH_2Cl_2 (1:12), 25 °C, 2 h, 98%; g') 3.0 eq DAST, THF, −78 to 0 °C, 1 h, 90%; h) 2.0 eq BnOH, 1.0 eq $BF_3 \cdot OEt_2$, CH_2Cl_2, −60 to −30 °C, 95%, (α:β ca 1:5); h') 1.2 eq BnOH, 1.2 eq silver silicate, $SnCl_2$ cat., CH_2Cl_2, 25 °C, 3 h, 85%; i) excess HF · py, CH_2Cl_2/THF (7:1), 0 °C, 20 min, 98%; j) Et_2NH/THF (1:1), 25 °C, 2 h, 98%; k) excess $Ti(OiPr)_4$, excess Ph_2SiH_2, CH_2Cl_2, 25 °C, 1 h, 92%. FMOC = fluoroenylmethoxy-carbonyl.

As an application of this strategy, the calicheamicin-dynemicin A hybrid structures **26a** and **26b** (Scheme 3) were targeted starting with the recently reported model system **19**.[5] Thus, coupling of **19** with ethyl bromoacetate under basic conditions led to derivative **20** (60% yield), which was converted to primary alcohol **22** (80% overall yield) by: 1) ester hydrolysis, 2) 2-pyridyl thiolester formation, and 3) reduction. Coupling of **22** (1.2 equiv) with trichloroacetimidate **14** under the influence of $BF_3 \cdot Et_2O$ as described above led to the formation of two major products (70%, ca. 1:1 ratio) and two minor products (14%, ca. 1:1 ratio) which were separated by chromatography. The major isomers were proven to be the diastereomeric β-glycosides **23a** ($R_f = 0.12$, silica, 20% ethyl acetate in petroleum ether) and **23b** ($R_f = 0.10$, silica, 20% ethyl acetate in petroleum ether) [^{1}H

NMR, 500 MHz, C_6D_6: **23a**: $J_{1,2} = 6.5$ Hz; **23b**: $J_{1,2} = 6.5$ Hz], and the minor isomers the anomers of **23a** and **23b** at C-1 [^{1}H NMR, 500 MHz, C_6D_6: *epi*-**23a**, $J_{1,2} = 2.4$ Hz; *epi*-**23b**, $J_{1,2} = 2.4$ Hz]. Sequential deprotection of **23a** and **23b** as described above for **15** led to oximes **25a** and **25b** via intermediates **24a** and **24b** respectively. Finally, reduction of **25a** and **25b** under the $Ph_2SiH_2/Ti(OiPr)_4$ conditions led exclusively to the targeted compounds **26a**[12] and **26b**[12] respectively (90% yield). The C-4 configuration of **26a** and **26b** was again based on the coupling constants $J_{4,3} = 9.5$ and $J_{4,5} = 9.5$ Hz for the newly installed H-4. Structures **23a**–**26a** and **23b**–**26b** are interchangeable, since the absolute stereochemistry of the aglycons has not been determined.



Scheme 3: Synthesis of calicheamicin-dynemicin A models **26a** and **26b**; reagents and conditions: a) 3.0 eq $BrCH_2CO_2Et$, 2.0 eq $CsCO_3$, 1.0 eq 18-crown-6, MeCN, 50 °C, 5 h, 60%; b) 2.0 eq LiOH, THF/H_2O (1:1), 0.5 h; then 1.1 eq $(pyS)_2$, 1.1 eq PPh_3, CH_2Cl_2, 25 °C, 0.5 h, 92%; c) 5.0 eq $NaBH_4$, CH_2Cl_2/*i*PrOH (1:1), 25 °C, 20 min, 92%; d) 0.83 eq **14**, $BF_3 \cdot OEt_2$ cat., CH_2Cl_2, −60 to −40 °C, 1 h, 84%, (α:β ca 5:1), e) excess HF · py, CH_2Cl_2/THF (7:1), 0 °C, 20 min, 98%; f) Et_2NH/THF (1:1), 25 °C, 2 h, 98%; g) excess $Ti(OiPr)_4$, excess Ph_2SiH_2, CH_2Cl_2, 25 °C, 1 h, 90%.

These successful coupling reactions demonstrate a) the facile resolution of racemic aglycons such as **22** using enantiomerically pure carbohydrate chains, and b) the survival of the highly sensitive functionalities present in the enediyne antibiotics under the reaction conditions. Furthermore, the C-4 nitrogen functionality of the calicheamicin skeleton may be stereoselectively installed in these systems under mild conditions. Finally, the synthesized model systems are novel and potentially biologically active enediyne compounds. It is hoped that the described chemistry will be valuable in the total synthesis of calicheamicin γ_1^I and in the construction of further hybrid molecules within the enediyne class.

Formation of a Cluster Sheath around a Central Cluster by a "Self-Organization Process": the Mixed Valence Polyoxovanadate $[V_{34}O_{82}]^{10\ominus}$ **

By *Achim Müller,* Ralf Rohlfing, Joachim Döring,* and *Michael Penk*

Studies on the properties of mixed valence species are of importance in catalysis research, geochemistry, and above all biochemistry, but also in general for material sciences.[1, 2]

The title compound, a high-nuclearity mixed valence binary cluster anion which is of interest topologically, magnetochemically, and by pre-formation of a solid state structure, could be prepared as the potassium salt **1** by reduc-

$K_{10}[V^{IV}_{16}V^{V}_{18}O_{82}] \cdot 20H_2O$ **1**

tion of an aqueous potassium vanadate solution, and could be characterized by elemental analysis (including manganometric titration of the V^{IV} content and thermogravimetric determination of the water of crystallization), IR spectroscopic and magnetic measurements, as well as single-crystal X-ray structure analysis.[3]

1 crystallizes in the triclinic space group $P\bar{1}$. Its cluster anion $[V_{34}O_{82}]^{10\ominus}$ displays approximate D_{2d} symmetry (Fig. 1a) and consists of an ellipsoid-shaped $V_{30}O_{74}$ sheath, which is formed by linking 30 tetragonal VO_5 pyramids, and a central $\{V_4O_4\}O_4$ cube. This means that assemblage of the VO_5 pyramids results in a shell which fits the distorted, central V_4O_4 cube (and its four terminal O atoms, Fig. 1b). The two identical halves of the $V_{30}O_{74}$ shell are, as demanded by the

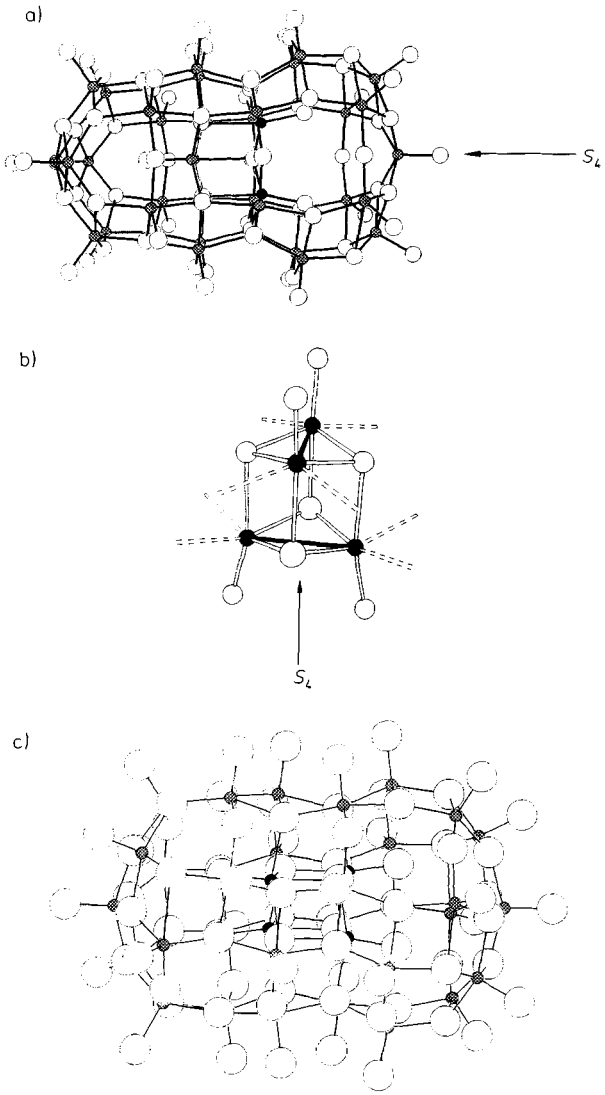

Fig. 1a) Structure of the $[V_{34}O_{82}]^{10\ominus}$ anion in the crystal of **1** (view perpendicular to the virtual S_4 axis); b) structure of the central $\{V^{IV}_4O_4\}O_4$ unit of **1** (V^{IV}-μ_3-O 192–196 and 220–222 pm) with two (in bold print) V–V bonds (265 pm) and (indicated) V–O bonds to the shell (205–210 pm; with approximate D_{2d} symmetry corresponding to the rotation of the two cluster halves with respect to each other; c) demonstration of the (approximative) layers of the oxygen atoms of **1** (for clarification of the transition to the solid-state structure; view perpendicular to the virtual S_4 axis, but rotated by 45° compared to (a). V = grey, V^{IV} = black, O = white.

geometry of the central cube, rotated by 90° with respect to each other (Fig. 1a).

Topologically the anion can be described in a simplified way as follows: each of the $V_{15}O_{37}$ halves contains 20 of the 24 O atoms of the O_{24} rhombicuboctahedron, a basic unit for many aspects of polyoxometalate chemistry (twelve square {110} faces and six {100} faces as well as eight {111} triangles), which form the μ_2-O atoms, e.g., in an α-Keggin ion.[4] Nine of the twelve occupied {110} faces and two of the unoccupied {100} faces in the Keggin ion are capped by a V=O group. In addition a novel form of capping occurs: above two {110} faces of the Keggin ion, each of which is flanked by two {111} triangles, the V=O group is replaced by an O=V–O–V=O group.

Also remarkable is that the anion, with exception of two $\{V_3O_7\}$ units at the poles, can be regarded as a distorted section of the NaCl lattice (which is also present in the VO_x defect structure, cf. Ref. [6]). The oxygen atoms form ap-

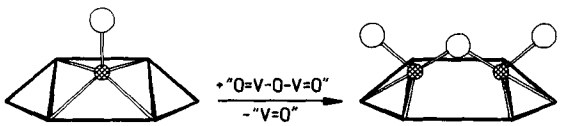
Postfach 8640, W-4800 Bielefeld 1 (FRG)

[**] We thank Prof. Dr. *K. Wieghardt*, Prof. Dr. *W. Haase*, and Prof. Dr. *E. Pedersen* for carrying out the magnetic measurements, and Dr. *H. Bögge* for help with the X-ray structure analysis.

proximately a cubic close packing arrangement whose octahedral holes are occupied by the V centers but, as expected, in each case clearly displaced towards the terminal O atoms (transition to the solid-state structure; Fig. 1c).

In the formally neutral, central $\{V_4O_4\}O_4$ unit there are, according to the calculated bond valence sums,[5] four localized V^{IV} centers, which in accord with an "exact electron count" form two covalent V–V bonds of 265 pm in length (Fig. 1b). Also novel are the four terminal V=O bonds (162–166 pm) of the enclosed cube, which stabilize a "cluster in a cluster" (regarding the tendency of formation see below).



α-Keggin ion

In contrast, the V–V distances in the shell (Table 1) lie in the range of values reported for most known reduced polyvanadates.[4] The bond valence sums for the atoms of the shell indicate a "delocalization" of the remaining twelve V^{IV} centers (the manganometric titration affords 16 V^{IV} centers per formula unit),[5] whereby, as in almost all other reduced V–O clusters,[4] an antiferromagnetic coupling exists (Table 1).

Due to the two very short V–V distances (quasi-diamagnetism) the spin-spin coupling in the central cube should be comparable with that in the monoclinic VO_2[6] and more pronounced than in the $[V_{19}O_{41}(OH)_9]^{8\ominus}$ cluster in **2**[8,9] containing exactly six very strongly antiferromagnetically coupled V^{IV}–V^{IV} pairs ("weak chemical bonding"[7]; number of V^{IV}–V^{IV} pairs n/2(!), n = number of 3d electrons), whereby **2** contains a further seven localized V^{V} centers.[10]

A relatively large number of comparable V–V distances leads, as in many known V–O clusters, e.g. the $[V_{18}O_{42}(SO)_4]^{8\ominus}$ anion in **3**,[11] to weaker antiferromagnetic coupling, i.e. with decreasing temperature to a smaller lowering of the μ_{eff} value (here: n/2 < number of the almost equivalent V–V contacts). This applies to an equal extent for the shell of **1**, but also for the total magnetism of the compound (because of the quasi-diamagnetism of the central unit). The anions in **1**, **2**, and **3** are molecular electronic models for the monoclinic and tetragonal VO_2 phase;[6] for the tetragonal phase, however, only in a limited sense because of the conduction electrons and the resulting virtually *T*-independent Landau diamagnetism and Pauli paramagnetism—both albeit with relatively small contribution. The relevant distances and μ_{eff} data for all the species discussed are listed in Table 1.

The breadth of variation from weak exchange interactions (in the case of **3** and the majority of known V–O species[4]), through very strong exchange interactions (in the case of **2**) to relatively strongly covalent bonds (in the case of **1** and monoclinic VO_2) is unique in clusters with exclusively "classical" ligands such as $O^{2\ominus}$. The magnetic properties correlate unequivocally with the bond data and with the presence of V^{IV}–V^{IV} pairs (as "spin traps").

Generally, very different high nuclearity V–O clusters can be generated by assemblage of a cluster shell formed from tetragonal VO_5 pyramids around a central unit (template),[17] which is added before the reaction or, as here, formed during the course of the synthesis. In the present case the ellipsoid-shaped structure as well as the distorted NaCl-type V–O lattice is determined by the formally neutral $\{V_4^{IV}O_4\}O_4$ center (with the stoichiometry of amphoteric VO_2!). The latter is probably formed from the reaction solution with attachment to the shell, and then as "pseudo template," non-existent in isolated form, influences the structure of the cluster with regard to its size and shape in a self-organization process,[16] whereby the cluster shell halves are rotated by 90° with respect to each other (Fig. 1a, b). At the same time the symmetry of the central unit is correspondingly lowered from T_d to approximate D_{2d}.

Table 1. Relationships between V–V distances and magnetic properties of V–O species.

V–O Species	V–V Distances [pm]	μ_{eff} [μ_B] (in brackets per V^{IV} center) [f]
$K_{10}[V_{34}O_{82}] \cdot 20H_2O$ **1**	265 (two V^{IV}-V^{IV} pairs in the cube) [a] 292–315 (V^{IV}/V^{V} shell) [b]	4.8 (1.2) at 290 K 3.8 (1.0) at 80 K [c] (weak *T* dependence)
$(NH_4)_8[V_{19}O_{41}(OH)_9] \cdot 11H_2O$ [8] **2**	290–300 (six V^{IV}-V^{IV}-pairs) [a] 330–360 (V^{IV}-V^{IV}, V^{IV}-V^{V})	3.1 (0.9) at 290 K 1.1 (0.3) at 80 K [c] (strong *T* dependence)
$(NH_4)_8[V_{18}O_{42}(SO_4)] \cdot 25H_2O$ [11] **3**	291 [b] (no localized V^{IV}-V^{IV} pairs) [d]	4.0 (1.2) at 290 K 2.8 (0.8) at 80 K [c] (weak *T* dependence)
VO_2 (monoclinic, 298 K) [14]	262 (V^{IV}-V^{IV}-pairs) [a] 317 (between the pairs)	0.4 at 293 K [6, 15]
Δ		Δ (strong *T*-dependence at the phase transition)
VO_2 (tetragonal, 351 K) [14]	285 (no pairs)	1.4 [e] at 353 K [6, 15]

[a] Numbers of pairs = n/2 with n = number of 3d electrons and practically covalent bonds in **1** and monoclinic VO_2. [b] As well as longer distances. [c] This work. [d] 12 V^{IV} centers not localized; in the corresponding $Na_6[V_{18}O_{42}H_9(VO_4)] \cdot 21H_2O$ [11] (as in the tetragonal VO_2) *only* localized V^{IV} centers are present in the shell (number of electrons n = number of V centers). [e] The relatively small proportion of Pauli spin paramagnetism is proportional to the density of states of the conduction electrons at the Fermi edge, whereby the *T*-dependence of χ above the phase transition also proves the presence of strong exchange interactions [6]. [f] Correction for diamagnetic, but not TIP portions.

The $VO^{n\oplus}$ unit resembles $Fe^{n\oplus}$ centers in its chemical behavior (cf. the biochemically relevant incorporation of $VO^{2\oplus}$ into the biological Fe-transport and storage proteins transferrin and ferritin, respectively[12] and the existence of aggregated Fe–O clusters in the ferritin with ca. 4000 Fe centers). It would therefore also be of interest to synthesize high-nuclearity mixed V/Fe–O clusters. In this connection it should be emphasized that a knowledge of the mechanistic aspects of the mode of action of transferrin and ferritin is also of fundamental importance from the medicinal point of view[13] (for instance in the case of rheumatic arthritis).

Experimental

KVO_3 (3.45 g, 25.0 mmol) was dissolved in H_2O (50 mL) at 90 °C in a 100-mL Erlenmeyer flask covered with a watch glass. The clear solution was then treated with 182 μL of hydrazinium hydroxide (100%, 3.75 mmol) and kept at 90 °C. After 1 h, the pH of the now deep-black solution was adjusted to 3.8 by addition of glacial acetic acid. After a further 2 h the solution was filtered hot, the filtrate kept at 90 °C for 3 h and finally cooled to room temperature. After storage for 1 d the precipitated black, needle-shaped crystals were filtered off, washed with a little 50% aqueous 2-propanol, and dried in air. Yield: ca. 1 g (53% of the theoretical referred to V). IR data (solid/KBr pellet):

$\tilde{\nu}$[cm^{-1}] = 990 (vs, sheath), 890 (s, cube) (ν(V=O_{term})); 745 (s), 615 (vs) (ν_{as}(V–O–V)).

Döring, *ibid. 102* (1990) 927 and *29* (1990) 926, and references cited therein; c) A. Müller, J. Döring, H. Bögge, *J. Chem. Soc. Chem. Commun. 1991*, 273.

[5] The bond valence sums for the V atoms were calculated using the expression $\sum_i n_i = \sum_i (d(V\text{-}O_i)/178)^{-5.15}$ (cf. I. D. Brown, K. K. Wu, *Acta Crystallogr. Sect. B 32* (1976) 1957) (V_4O_4 cube: 4.1).

[6] In monoclinic VO_2 (low-temperature modification with distorted rutile structure) the V–V distances along the c-axis are not, as in TiO_2, of equal length but alternately short and long (covalent V^{IV}–V^{IV} bond formation) and, as a result, very small and almost T-independent μ_{eff} values are found; compare known values for polyacetylene. On heating above 67.5 °C the V^{IV}–V^{IV} pairs "break apart" with consequences for the structure (transition into the tetragonal rutile structure of VO_2 with antiferromagnetic behavior), the magnetism (jump for χ and μ_{eff}; Table 1), the conductivity (transition from semiconductor into a metallic conductor), and other physical properties. Also fascinating is the "mechanical breakage" of the V–V bonds in very small particles, which manifests itself in monoclinic VO_2 in an increase of the susceptibility. V–O phases, including the defect systems VO_x (x = 0.8–1.3) are of exceptional interest from the physical point of view (cf. D. L. Kepert: *The Early Transition Metals*, Academic Press, London 1972, p. 192; J. B. Goodenough: *Les Oxydes Des Métaux De Transition*, Gauthiers-Villards, Paris 1973, p. 143, 297; A. Wold in L. V. [9] In this case the magnetism can be described with the help of the Hamiltonian $H = -2\sum_i J_{i,i+1} \cdot \hat{S}_i \cdot \hat{S}_{i+1}$. The coupling constant J is a measure of the strength of the exchange interaction (cf. F. E. Mabbs, D. J. Machin: *Magnetism and Transition Metal Complexes*, Chapman and Hall, London 1973, p. 177).

[10] The structurally enforced formation of V^{IV}–V^{IV} pairs (but without strong covalent bonding) as in **2** generally effects a significantly stronger temperature dependence of the μ_{eff} values, so that at low, but nevertheless for the magnetochemist still relatively high temperatures, almost exclusively the S = 0 (singlet) state is populated (Table 1; accordingly relatively large difference in energy between the triplet and singlet state (pair consideration), which corresponds to a high Néel temperature (T_N (**2**) > 300 K) and a large J value).

Synthesis of Prothymosin α (ProTα)—a Protein Consisting of 109 Amino Acid Residues**

By *Kleomenis Barlos**, *Dimitrios Gatos*, and *Wolfram Schäfer*

The synthesis of proteins using either the solid phase technique or the fragment condensation technique in solution is still a difficult task, even when extremely pure amino acid derivatives and efficient coupling and deblocking procedures are used. Indeed only a few protein syntheses such as for ribonuclease,[1] interleukin 3,[2] ubiquitin,[3] and angiogenin[4] have been described. Biotechnological procedures seem to be more effective,[5] but this technique can only be used for proteins with biologically codable structural information. Nevertheless, large peptides and proteins are becoming increasingly important, especially in the areas of immunology and cancer therapie.[6a] The development of a generally applicable strategy for protein synthesis which allows to check the synthesis at each step and which yields very pure proteins is therefore of considerable interest.[6b]

Such a synthesis could be accomplished, as postulated earlier,[7] by sequential coupling of totally blocked peptide fragments to a resin. In order to check the progress of the synthesis after each peptide coupling, the new peptide fragment may be split off from the resin for analysis and purification if necessary. Peptide fragments whose side chains are blocked by easily removable *tert*-butyl- and triphenylmethyl (trityl) type groups should be prepared quickly and with the highest possible yield and purity. At present this seems to be only possible by using the solid phase technique with specially prepared resins.

After testing a series of acid labile resins of the diphenylmethyl- and triphenylmethyl-type[8, 9] the 2-chlorotriphenylmethyl (trityl) resin **2**[8] turned out to be especially suitable. The most important properties of this resin are: a) the quick, high yield coupling of the C-terminal amino acid to the resin. The reaction of Fmoc amino acids with **2** is accomplished in dichloromethane and diisopropyl(ethyl)amine (DIEA) within 25 min at room temperature. Because the esterification does not need electrophilic activation of the amino acid, the reaction proceeds without racemization. b) The large volume of the chlorotrityl group prevents completely the forma-

[**] This study was sponsored by the Greek Ministry for Industry Energy and Research (*K. B.*) and the Bundesministerium für Forschung und Technologie (PTb 038824) (*W. S.*). We thank Dr. *C. N. Baxevanis* and Dr. *M. Papamihail* (Department of Immunology, Anitcancer Institute, Athen), for testing the biological activity of the synthetic ProTα.

tion of diketopiperazines during the dipeptide step in the SPPS procedure. This is still an unsolved problem especially in the synthesis of peptides with C-terminal glycine and proline; these amino acids are used preferentially for fragment couplings because of their optical stability. c) The stability of the ester bond between the C-terminal amino acid and the resin during peptide extension. This was confirmed by the synthesis of several peptides which were always isolated in high yield. d) The splitting of the peptides from the 2-chlorotrityl resin is done under very mild conditions, for example with acetic acid/trifluoroethanol/dichloromethane (1:1:8) (splitting solution) for a few minutes, and without loss of any of the side chain blocking group.

As a first example of a protein synthesis with resin **2** we prepared human prothymosin α (ProTα[10]), which is shown in Figure 1 in protected and resin-bound form. ProTα is 109 amino acid residues long. It is widely distributed in human cells,[11-13] protects against infection from *Candida albicans*[11,14] and systemic lupus erythematosus,[15] induces the enhanced secretion of interleukin[16] and MIF (migrating inhibition factor),[11] activates monocytes and T-lymphocytes, is a strong immunomodulator,[17] and seems to be necessary for cell division.[18] To establish its therapeutic potential ProTα should be available in larger amounts.

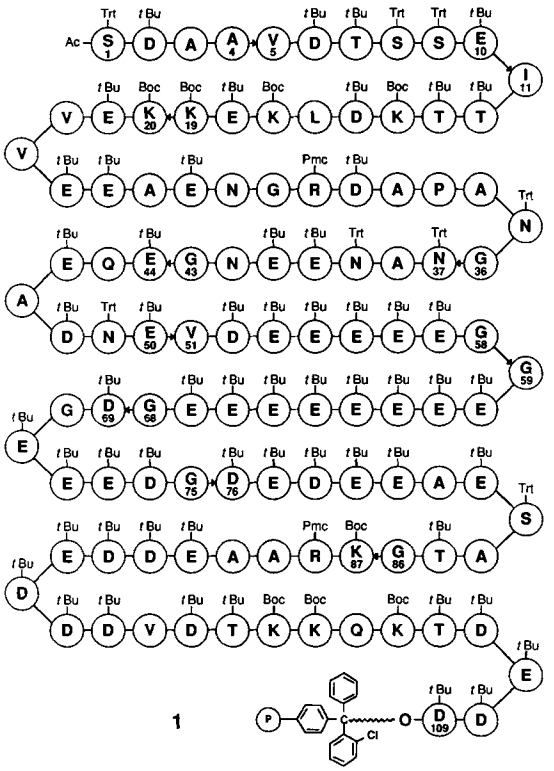

Fig. 1. Sequence of prothymosin α (ProTα), including side chain blocking group, bound to the 2-chlorotrityl resin; arrows indicate the coupling positions for the fragment condensation. Ac = acetyl, Trt = trityl, Boc = *tert*-butoxycarbonyl, Pmc = 2,2,5,7,8-pentamethylchroman-6-sulfonyl.

The synthesis of ProTα was carried out follows: reaction of Fmoc-Asp(*t*Bu)OH (0.1 mmol) with **2** (1 g, 1.6 mmol Cl) and DIEA (2 mmol) in dichloromethane yielded resin **3** with a substitution density of 0.09 mmol amino acid per gram (Fig. 2, top). According to our experience such a low substitution density is most important for good coupling yields during the synthesis of large peptides (for example of **4**) and

Fig. 2. Synthesis of peptide fragments for the synthesis of ProTα.

also to achieve optimal reaction conditions during the fragment condensation reactions. Starting with **3** we synthesized the ProTα (76–109) fragment **4**. After preactivation with 1-hydroxybenzotriazole (1-HOBt) and dicyclohexylcarbodiimide (DCC) a threefold molar excess of Fmoc amino acids were used. Removal of the Fmoc protective groups was carried out by incubation in 20% piperidine in DMF. The completness of the coupling was proved by the Kaiser test. The totally blocked peptide fragments **5**–**13** were prepared in an analogous manner. The resins had substitution densities of 0.4–0.6 mmol amino acid per gram of resin. The blocked peptides were recovered in yields greater than 90% after 60 min incubation in the splitting solution as described above. Purity was checked by HPTLC and RP-HPLC. We found a purity of > 98% for fragments **5**, **6**, **7** and **9**, > 96% for **8** and **10** and > 90% for **11** and **12**. Despite the high purity, the peptides were further purified by column chromatography (silica gel 60, 240–400 mesh, Merck; eluant: mixtures of chloroform, methanol and acetic acid). In order to remove completely traces of adsorbed acetic acid, the peptides were dissolved in trifluoroethanol, precipitated with water and dried. Because of their low solubility fragments **13a** and **13b** could not be analyzed by HPLC. The structure of the blocked peptides were confirmed by FAB-MS, Xe,

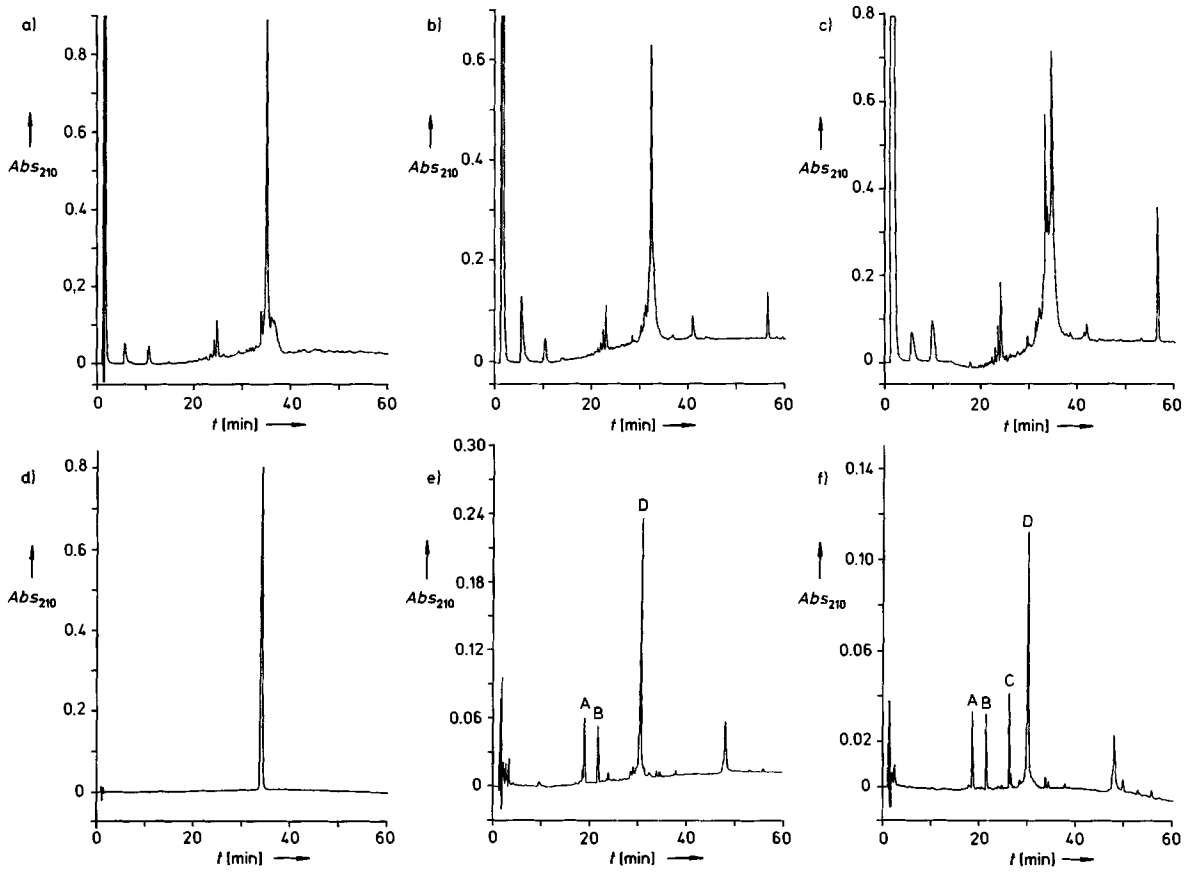

Fig. 3. HPLC: a) raw material of the deblocked ProTα (11–109), b) same for de-acetyl-ProTα, c) same after acetylation of the mixture of ProTα (11–109) and ProTα (1–109); d) ProTα after HPLC purification; e) tryptic digest of ProTα (11–109); f) same of ProTα. Conditions: Nucleosil C-8 (4.6 × 25 mm); flow 1 ml/min, 5 min isocrat., then from 100% A to 100% B in 60 min. A: 0.1% TFA in water, B: 0.1% TFA in acetonitrile for 3a–c; A 0.06% TFA in water, B 0.054% TFA in acetonitrile for 3d–f; detection at 210 nm. Components eluting after 40 min in 3b, c are partially blocked peptides, those which are eluted in e and f after 48 min are components of the trypsin preparation.

9 kV, ca. 50 μA or LSIMS, $Cs^{\oplus}$, 20 kV, 4 μA, matrix *m*-nitrobenzyl alcohol (NBA) or NBA/glacial acetic acid. The actual molecular weights of the peptide fragments were as expected.

The synthesis of blocked ProTα was established by sequential condensation of the fragments **5**–**13** with fragment **4** immobilized on the resin via the ester bond. A fivefold excess of blocked fragment/1-HOBt/DCC (1:1.5:1) in dimethyl sulfoxide was used. The coupling reactions were followed by HPTLC and Kaiser test; the reactions were complete after 6–18 h. After each coupling reaction a small aliquot of peptide ester resin was withdrawn, the peptide split from the resin and the protective groups removed from the side chains by treatment with trifluoroacetic acid/water (95:5). HPLC analyses of the recovered material confirmed the high yield of the coupling reactions until ProTα (11–109) (Fig. 3). Fragment **13a**, because of its low solubility in dimethyl sulfoxide could only be coupled to the immobilized ProTα (11–109) with 55% yield (Fig. 3b). Replacing the *tert*-butyl groups of serine against trityl groups improved the solubility of **13b** in dimethyl sulfoxide, but the coupling yield was not improved because the benzotriazolyl ester of **13b** precipitated during the reaction.

The resin-bound product mixture from the last fragment condensation, which was primarily de-acetyl-ProTα and unchanged ProTα (11–109), was acetylated with a 10-fold excess of acetic anhydride/DIEA in dimethyl formamide (Fig. 3c). After removal of the side-chain protective groups, the overall ProTα was isolated by HPLC in 11% yield from the product mixture (Fig. 3d). The identities of ProTα and the other peptides ProTα (87–109), (59–109), (11–109) which were obtained in > 55% yield were verified through amino acid analyses. ProTα and ProTα (11–109) were digested with trypsin and the expected peptide products were obtained (Fig. 3e, f); the main fragments (89–109), (21–30) and acetyl-(1-14) were isolated by HPLC and identified by FABMS. Because of its high acidity, fragment (31–87) and ProTα itself could not be analyzed by FABMS.

The biological activity of synthetic prothymosin α was tested with the auto-MLR-reaction (autologous multiple lymphocyte reaction)[16] using T-lymphocytes from healthy human donors. The immune response was enhanced by a factor of 1.7; using the same test system an enhancement factor of 1.5 was observed with prothymosin α from rat thymus.

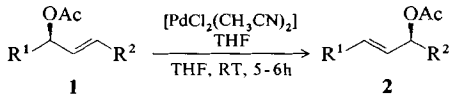
Palladium(II)-Induced Conversion of α-Acetoxyalkynes into α,β-Unsaturated α-Acetoxyketones; a Novel Access to α-Diketones.

By *Rainer Mahrwald* and *Hans Schick**

Allyl acetates of type **1** rearrange in tetrahydrofuran at room temperature (RT) in the presence of bis(acetonitrile)palladium(II) chloride $[PdCl_2(CH_3CN)_2]$ in an equilibrium reaction to form the isomeric allyl acetates of type **2**.[1] This [3,3]-sigmatropic rearrangement, which takes place



1 **2**

with chirality transfer, has been used, for instance, for the construction of the (1*E*,3*S*)-3-hydroxyoct-1-enyl side chain of prostaglandins.[2-6] While investigating this reaction we observed by chance that a propargyl acetate (α-acetoxyalkyne) of type **3** is converted into an α-acetoxyenone of type **4**. Since the behavior of α-acetoxyalkynes of type **3** has not yet been studied systematically under these conditions,[7-9] we looked into the problem.

On treatment with an equimolar amount of bis(acetonitrile)palladium(II) chloride in aqueous tetrahydrofuran at 20 °C, the α-acetoxyalkynes **3a–d** are converted within three hours into the α-acetoxyenones **4a–d**. The yield of pure product is 45–75%. The reaction is accompanied by the precipitation of metallic palladium and the formation of hydrochloric acid. The structures of **4a–d** are deduced from the ^{13}C- and ^1H-NMR spectra, mass spectra, and the elemental analyses.

Although the reaction was performed under argon, the compounds **4a–d** contain one more oxygen atom than the starting compounds **3a–d**. The conditions for the transfor-

	R^1	R^2	R^3
a	H	n-C_4H_9	n-C_6H_{13}
b	H	Ph	n-C_6H_{13}
c	H	Ph	Ph
d	$-(CH_2)_4-$		n-C_6H_{13}

mation of **3a** into **4a** were studied more closely to discover the origin of this oxygen atom. On strict exclusion of air and water in dried THF, no trace of the α-acetoxyenone **4a** is observed even after many days. A thin-layer chromatographic study of the reaction solution reveals that **3a** ($R_f = 0.66$)[10] is completely converted into a substance with higher polarity ($R_f = 0.26$), which is not the α-acetoxyenone **4a** ($R_f = 0.43$), and which does not change even after two days in the solution. There is also no change if the argon is replaced by rigorously dried oxygen and the solution stirred vigorously for a further 24 h. The formation of **4a** is only observed when an equimolar amount of water is added. As the formation of **4a** on addition of water does not depend on whether the reaction is performed under an argon or oxygen atmosphere, the oxygen atom must, in the case of an argon atmosphere at least, stem from water.

A reaction of **3a** with only 0.15 to 0.20 equivalents of $[PdCl_2(CH_3CN)_2]$, in dried tetrahydrofuran at 20 °C and with strict exclusion of air and moisture, affords quantitatively after 24 h a mixture (1:1) of **4a** and **5a**. The surprising formation of the α-acetoxyketone **5a** is explained most easily by a hydrogen addition to the α-acetoxyenone **4a**. The tendency to add hydrogen decreases from **4a** through **4b** to **4c**. Although the palladium(II)-induced transformation of **3b** into **4b** in the presence of catalytic amounts of $[PdCl_2(CH_3CN)_2]$ affords **4b** and **5b** in the ratio 7:3, compound **3c** under the same conditions yields exclusively **4c**. The formation of the hydrogenation products **5a** and **5b** is suppressed in the presence of an equimolar amount of cyclohexene.

The catalytic cycle sketched in Scheme 1 reflects our preliminary understanding of the palladium(II)-induced transformation of the α-acetoxyalkynes **3** into the α-acetoxyenones **4**. The regeneration of $PdCl_2$ from HPdCl and HCl is only possible if hydrogen is formed in this reaction. Although this could not be detected analytically, the α-acetoxyketones **5a** and **5b** and the suppression of their formation in the presence of cyclohexene may be considered as indications that hydrogen is formed.

The proposal for the mechanism must be confirmed by further studies. Recently other authors[11] reported that during the palladium(II)-induced transformation of α-acetoxyalkynes into α-acetoxyenones oxygen can purposely be

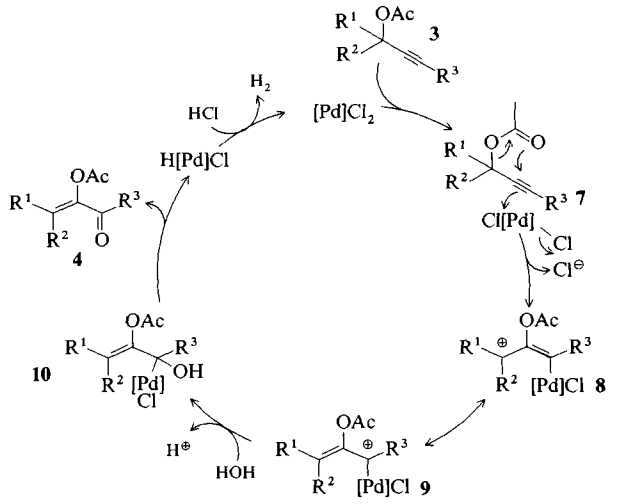

Scheme 1. [Pd] = $Pd(CH_3CN)_2$

added as oxidizing agent. This does not conflict with our results obtained in the absence of oxygen, but may represent an alternative pathway.[12]

The α-acetoxyenones **4** obtained by palladium(II)-induced conversion of the α-acetoxyalkynes **3** were used in further synthesis steps. For instance, **4a–d** can be readily converted into the α-diketones **6a–d** through hydrolysis with a basic ion-exchanger as expected.

Experimental Procedure

4a: 1.0 g (4.2 mmol) of 5-acetoxytridec-6-yne **3a** was dissolved in 20 mL of dried THF and treated with 1.1 g (4.2 mmol) of $[PdCl_2(CH_3CN)_2]$[13]. The bright yellow suspension was stirred under inert gas for about 1 h at 20 °C till the palladium complex dissolved. The solution was then dark brown to black. After the addition of 76 μL (4.2 mmol) of water the mixture was stirred for a further 3–4 h at 20 °C. At this stage **3a** could no longer be detected by thin-layer chromatography. 10 mL of saturated aqueous $NaHCO_3$ solution was added, and after extraction with diethyl ether and drying with Na_2SO_4, the solvent was removed in vacuum. The residue was purified by flash chromatography[14] on silica gel. Yield: 780 mg (72.5%) of **4a** as colorless oil. TLC (silica gel, hexane/acetone 95:5): $R_f = 0.43$; ^1H NMR ($CDCl_3$, 80 MHz): $\delta = 0.82$ and 0.86 (2 m, 6H; 1-H, 13-H), 2.20 (s, 3H; CH_3CO), 6.30 (t, $J = 10$ Hz, 1H, 5-H); ^{13}C NMR (75 MHz, [D_8]THF): $\delta = 13.93$, 14.18, 22.99, 23.20, 24.57, 25.10, 25.64, 26.26, 29.52, 32.42, 37.33, 131.14, 147.20, 168.34, 193.27. MS (EI, 70 eV): m/z 212 (100), 142 (50), 113 (35), 99 (40).

6d: 252 mg (1 mmol) of **4d** was dissolved in 20 mL of methanol and stirred with 10 g of the basic ion-exchange resin SBW for 1 h at 20 °C. The ion-exchange resin was removed by filtration, the solvent evaporated under reduced pressure, and the product purified by flash chromatography[14] on silica gel with hexane/acetone (95:5) as eluant. Yield: 134 mg (64%) colorless oil. TLC (silica gel, hexane/acetone 97:3, developed three times): $R_f = 0.71$. ^1H NMR (20 MHz, $CDCl_3$): $\delta = 14.00$, 22.53, 26.63, 29.07, 31.58, 36.21, 44.02, 46.52, 49.52, 109.87, 119.38, 167.92, 200.70. MS (EI, 70 eV): m/z 209 ($M^{\oplus}-1$, 10%), 194 (4), 113 (25), 94 (40), 55 (100).

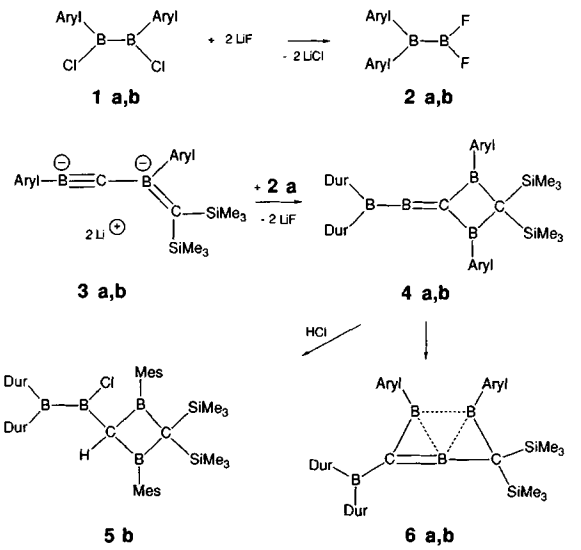
A Cyclic Methyleneborane with Trapezoidal Geometry**

By *Andrea Höfner, Bernd Ziegler, Ralf Hunold, Peter Willershausen, Werner Massa,* and *Armin Berndt**

Dedicated to Professor Kurt Dehnicke on the occasion of his 60th birthday

On attempting to transform the 1,2-dichloroboranes(4) **1a, b**[1] into the corresponding 1,2-difluoro compounds with lithium fluoride according to the method of *Kaufmann* et al.[2] we obtained the 1,1-difluoroboranes(4) **2a, b**.[3] Reaction of **2a** with the dilithium compounds **3a, b**[1,4] led to the orange-red compounds **4a, b** (Scheme 1), the first methyleneboranes bearing an acceptor substituent on the dicoordinat-



Scheme 1. **a**: Aryl = Dur (2,3,5,6-tetramethylphenyl); **b**: Aryl = Mes (2,4,6-trimethylphenyl).

Table 1. Some physical data of compounds **2a**, **4b**, **5b** and **6a** [a]. Standard for ^{1}H- and ^{13}C NMR spectra TMS, for ^{11}B-NMR spectra $BF_3 \cdot OEt_2$.

2a: colorless crystals, m.p. = 75 °C, yield: 92%. – ^{1}H NMR (100 MHz, $CDCl_3$, 25 °C): δ = 2.21 (s, 24 H, CH_3), 7.02 (s, 2 H, *p*-H); ^{13}C NMR (25 MHz, $CDCl_3$, 25 °C): δ = 19.2, 19.7 (each 4 C, CH_3), 133.9, 134.4, 136.1 (C_{sp^2}), 145.1 (br., 2 C, *i*-C); ^{11}B NMR (96 MHz, $CDCl_3$, 25 °C): δ = 29, 82 ($\nu_{1/2}$ each $\approx$ 700 Hz).

4b: orange-red crystals, m.p. = 150 °C (dec.), yield: NMR-spectroscopically ca. 95%. – ^{1}H NMR (300 MHz, C_6D_6, 25 °C): δ = 0.29 (s, 18 H, $Si(CH_3)_3$), 1.91, 2.06 (each s, each 12 H, *o*- and *m*-CH_3), 2.16 (s, 6 H, *p*-CH_3), 2.39 (s, 12 H, *o*-CH_3(Mes)), 6.68 (s, 4 H, *m*-H), 6.79 (s, 2 H, *p*-H); ^{13}C NMR (100 MHz, CD_2Cl_2, – 40 °C): δ = 4.5 (q, 6 C, $Si(CH_3)_3$), 19.7, 20.0 (each q, each 4 C, *o*- and *m*-CH_3), 21.1 (q, 2 C, *p*-CH_3), 24.8 (q, 4 C, *o*-CH_3), 62.5 (s, 1 C, CSi_2), 128.0 (d, 4 C, *m*-C, (Mes)), 132.1 (br. s, 1 C, CB_3), 134.0, 136.4 (each s, each 4 C, *o*- and *m*-C), 134.1 (d, 2 C, *p*-C (Dur)), 136.9 (s, 2 C, *p*-C (Mes)), 138.7 (s, 4 C, *o*-C (Mes)), 140.5, 144.3 (each s, each 2 C, *i*-C); ^{11}B NMR (96 MHz, toluene, 90 °C): δ = 62, 76 ($\nu_{1/2} \approx$ 590, 1260 Hz).

5b: pale yellow crystals, m.p. = 160 °C (dec.), yield: NMR-spectroscopically ca. 95%. – ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 0.07, 0.25 (each s, each 9 H, $Si(CH_3)_3$), 1.82, 2.11 (each s, each 12 H, *o*- and *m*-CH_3), 2.20 (br. s, 12 H, *o*-CH_3), 2.31 (s, 6 H, *p*-CH_3), 3.71 (s, 1 H, CHB_3), 6.74 (s, 4 H, *m*-H), 6.89 (s, 2 H, *p*-H); ^{13}C NMR (75 MHz, $CDCl_3$, 25 °C): δ = 4.5, 5.8 (each q, each 3 C, $Si(CH_3)_3$), 19.8, 20.2 (each q, each 4 C, *o*- and *m*-CH_3), 20.9 (q, 2 C, *p*-CH_3), 24.8 (br. q, 4 C, *o*-CH_3), 72.3 (s, 1 C, CSi_2), 79.5 (d, 1 C, CB_3, $^1J(^{13}C, ^1H)$ = 101.4 Hz), 127.7 (d, 4 C, *m*-C), 132.7 (d, 2 C, *p*-C), 133.4, 135.3, 137.2 (each s, each 4 C, *o*- and *m*-C), 136.8 (s, 2 C, *p*-C), 139.3, 146.7 (each br. s, each 2 C, *i*-C); ^{11}B NMR (96 MHz, toluene, 80 °C): δ = 75, 85 ($\nu_{1/2} \approx$ 1100, 1700 Hz).

6a: colorless crystals, m.p. > 230 °C, yield: NMR-spectroscopically ca. 70%. – ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 0.03 (s, 18 H, $Si(CH_3)_3$), 1.57, 1.92, 1.96, 2.00 (each s, each 6 H, *o*- and *m*-CH_3), 2.17 (s, 24 H, *o*- or *m*-CH_3), 6.68, 6.82 (each s, each 1 H, *p*-H), 6.90 (s, 2 H, *p*-H); ^{13}C NMR (100 MHz, $CDCl_3$, 25 °C): δ = 2.4 (q, 6 C, $Si(CH_3)_3$), 19.7, 20.0 (each q, each 2 C, CH_3), 19.8, 22.3 (each br. q, each 2 C, CH_3), 20.2 (q, 4 C, CH_3), 23.0 (br. q, 4 C, CH_3), 31.9 (br. s, 1 C, CSi_2), 130.4, 132.9 (each d, each 1 C, *p*-C), 131.3 (d, 2 C, *p*-C), 131.9, 133.1, 136.37, 136.43 (each s, each 2 C, *o*- resp. *m*-C), 133.0, 134.9 (each s, each 4 C, *o*- resp. *m*-C), 138.9; 150.5 (each br. s, each 1 C, *i*-C), 140.1 (br. s, 1 C, CB_3), 145.6 (s, 2 C, *i*-C); ^{11}B NMR (96 MHz, toluene, 25 °C): δ = 23, 33, 71 ($\nu_{1/2} \approx$ 1445, 1700, 2975 Hz).

[a] **2b** has NMR data similar to those of **2a**; **4a** and **6b** were identified on the basis of their NMR data similarly to **4b** and **6a** in a mixture with by-products.

ed boron atom—as shown by the NMR data (Table 1) and the crystal structure of the HCl-adduct **5b**.[5]

Whereas the methyleneboranes corresponding to **4a**, **b**,[6] which bear the substituents mesityl or duryl (2,3,5,6-tetramethylphenyl) on the dicoordinated boron atom instead of the boryl residue, are stable at room temperature, **4a**, **b** transform in solution within days (**4a**) or weeks (**4b**) into a mixture of compounds which contain as major components **6a** and **6b**, respectively, the first cyclic methyleneboranes. **6a** crystallizes from hexane in the form of colorless platelets. Figure 1 shows the structure of **6a** in the crystal.[7]

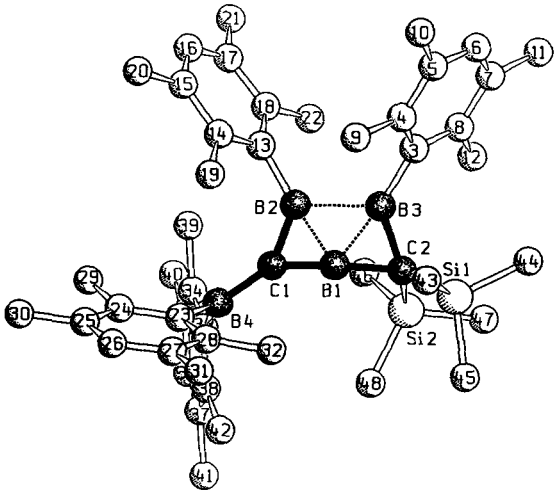

Fig. 1. SCHAKAL drawing of the structure of **6a** in the crystal. Projection on the B1,B2,B3 plane. Important bond lengths [pm] and angles [°]: B1-C1 142.5(5), C1-B2 149.5(5), B2-B3 193.3(6), B3-C2 155.8(5), C2-B1 154.5(5), B1-B2 166.2(6), B1-B3 170.4(6), C1-B4 152.0(5), B2-C13 157.6(5), B3-C3 158.1(5), C2-Si1 188.2(3), C2-Si2 191.1(3); C1-B1-C2 170.9(4), B1-C1-B2 69.3(3), B1-C2-B3 66.6(2), B1-C2-Si1 123.8(2), B1-C2-Si2 101.9(2); B2-C1-B1-B3 – 0.5(4), B1-C1-B2-B3 0.3(3), C1-B2-B1-B3 179.6(3), B3-C2-B1-B2 10.9(3), B1-C2-B3-B2 – 8.0(3), B2-B3-B1-C2 170.6(3), B2-C1-B4-C23 – 85.2(6), B2-C1-B4-C33 96.4(6).

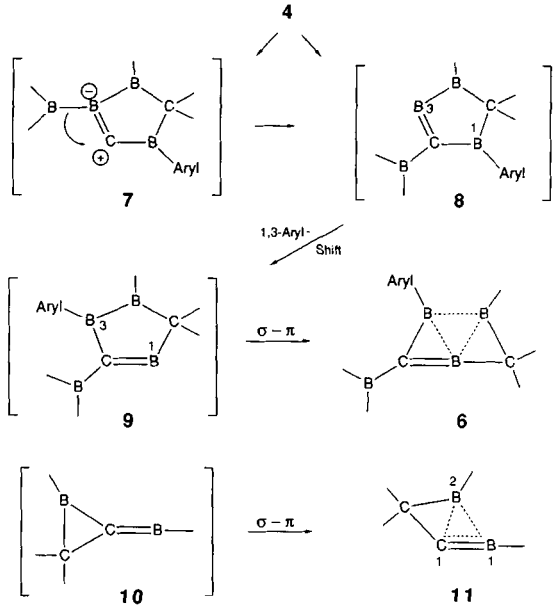
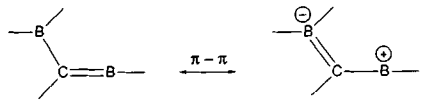
The four-membered ring compound **4a** with two exocyclic boron atoms bound together is converted into the five-membered ring compound **6a** with only one exocyclic boron atom. It has an unusual shape for a five-membered ring, namely trapezoidal: B1,C1,B2 and B3 lie in a plane, which is inclined at an angle of only 9° to the plane through B1,C2,B3. The didurylboryl group, which is bound to the dicoordinated boron atom in **4a**, is attached to the carbon atom of the B=C double bond in **6a**. The carbon atom with the two trimethylsilyl groups, which in **4a** has two duryl-substituted boron atoms as neighbors, has only one such boron atom as neighbor in **6a**, the other is the almost linearly (171°) coordinated B of the B=C double bond.

The transformation **4** → **6** can readily be explained in terms of the intermediates **7** through **9** or **8** and **9**. The very high deficiency of electrons at the dicoordinated boron atom in **4** is compensated for by a shift of the σ electrons of a C_{sp^2}–B_{ring} bond to this center, i.e. rearrangement to **7**, the very high deficiency of electrons at the dicoordinated C atom of the diborylcarbene **7** by a shift of the σ electrons of the exocyclic B–B bond to the carbene C-atom, i.e. by rearrangement to **8**. Probably both rearrangements take place synchronously (dyotropically[8]), without formation of **7** as an intermediate.

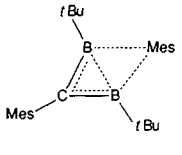


Subsequent 1,3-migration of an aryl group in **8** from the tri- to the di-coordinated boron atom—a reaction characteristic for C-borylmethylene boranes[9]—leads to **9**, which already has the same skeletal framework as **6**. The distortion of **9** to the trapezoidal arrangement of **6** with an almost linearly coordinated boron atom of the B=C double bond is the consequence of strong σ-π interaction between the dicoordinated boron atom as π-electron deficient center and the σ electrons of the oppositely disposed B–B bond. The three-center, two-electron bond formed thereby (B1, B2, B3) with

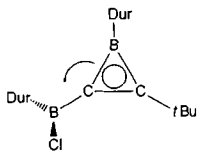
a long (193.3 pm) B2–B3 distance belongs to the simplest with three boron atoms.[10] A similarly strong distortion of the molecular geometry by σ-π interaction as in **9** → **6** is also found in **10** → **11**.[11] In **6** the B=C double bond (142.5 pm) is longer than in H_2C=B–H (138 pm[12]). This is the result of the π–π delocalization characteristic for[6, 9] *C*-boryl-methyleneboranes,[13] which also explains the short C1–B2 distance of 149.5 pm. A similar bond situation as for the framework atoms B1,C1,B2 of **6a** is also found in **12**.[14]



Since the planes through B1,C1,B2 and C23,B4,C33 in **6a** form an angle of 85°, π–π delocalization to the exocyclic boryl substituents is ruled out. The nevertheless remarkably short C1–B4 distance of 152 pm can be explained—like the short exocyclic B–C distance (150 pm) in *C*-borylborirene 13[15]—in terms of C–B hyperconjugation between the strained C1–B2 and C1–B1 σ bonds and the p-orbital at the exocyclic boron atom. Finally, the small B1–C2–Si2 angle of



12



13

102° (B1–C2–Si1 124°) together with the long C2–Si2 distance of 191 pm (C2–Si1 188 pm) indicate C–Si hyperconjugation of this σ bond with the p-orbital of B1, which is positively charged by the above discussed π-π interaction.

In the structure of **6** strong and very strong variants of σ-π interactions participate in hyperconjugation and bridging. In addition, variants of their extreme form participate in the rearrangement which leads to formation of **6**.

A Stable Os^0 16-Electron Complex: Synthesis and Structure of $[OsCl(NO)(PiPr_3)_2]$**

By *Helmut Werner,* Annette Michenfelder,* and *Michael Schulz*

Dedicated to Professor Siegfried Hünig on the occasion of his 70th birthday

d^8-Metal complexes with 16-electron configuration, e.g. the Wilkinson catalyst $[RhCl(PPh_3)_3]$, or the active intermediate $[HCo(CO)_3]$ in the oxo synthesis, play a decisive role in various homogeneous catalytic processes.[1] Whereas numerous compounds of the d^8-systems Rh^I, Ir^I, Ni^{II}, Pd^{II}, Pt^{II} and Au^{III} having the composition $[ML_4]$ (L = monodentate ligand) have already been reported it has so far not been possible to prove the existence of a corresponding osmium(0) complex that is stable under normal conditions. We report here on the synthesis and reactivity of $[OsCl(NO)(PiPr_3)_2]$ **1** as the first structurally characterized $[OsL_4]$ complex.[3]

The 18-electron compound $[OsCl(NO)(PPh_3)_3]$, which was first synthesized by *Roper* et al., and used, inter alia, for the preparation of carbene, sulfur dioxide, and disulfur oxide complexes,[5, 6] reacts with excess triisopropylphosphane at room temperature with complete removal of the PPh_3 ligands to give **1** in almost quantitative yield.[7] The ^{1}H-NMR data (*one* doublet of virtual triplets for the $PCHCH_3$ protons) point to a square-planar configuration with *trans* $PiPr_3$ ligands. This is confirmed by the X-ray structure analysis of **1**[8] [angles [°]: P–Os–N 89.8(2), P–Os–Cl 90.53(5), N–Os–Cl 178.7(3), Os–N–O 179.5(6). As already indicated from space group and unit cell content, the Os atom lies on the crystallographic center of symmetry, resulting in a 1:1 disorder of

[*] Prof. Dr. H. Werner, Dipl.-Chem. A. Michenfelder, Dipl.-Chem. M. Schulz
Institut für Anorganische Chemie der Universität

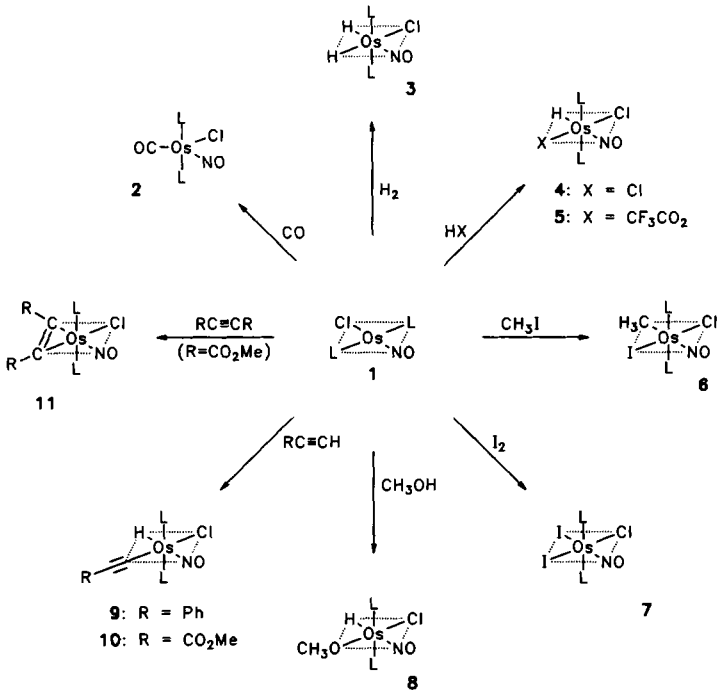
[**] This work was supported by the Deutsche Forschungsgemeinschaft (SFB 347), the Fonds der Chemischen Industrie, and Degussa AG.

the Cl and NO ligands. Due to the disorder, the Os–Cl, Os–N and N–O distances are subject to a relatively high uncertainty, which is not revealed in the standard deviations. Disorders of this type are apparently characteristic for square-planar complexes of the composition *trans*-[MCl(L)($P\mathit{i}Pr_3$)$_2$], as shown by the structural analyses of [RhCl(O_2)($P\mathit{i}Pr_3$)$_2$],[9] [RhCl(N_2)($P\mathit{i}Pr_3$)$_2$],[9, 10] [IrCl(CO)($P\mathit{i}Pr_3$)$_2$],[11] and [IrCl(SO)($P\mathit{i}Pr_3$)$_2$].[12]

In contrast to the isoelectronic compound *trans*-[IrCl(CO)($P\mathit{i}Pr_3$)$_2$],[13] complex **1** reacts not only with Lewis acids but also with Lewis bases. The reactions carried out so far, which splendidly document the electronic and coordinatively unsaturated character of the osmium complex, are shown in Scheme 1. The transition from the 16-electron con-



Scheme 1. Reactions of **1**; L = $P\mathit{i}Pr_3$.

figuration in **1** to the 18-electron configuration in **2**–**11** is accompanied by a characteristic color change from dark-green (**1**) to yellow (**2**–**8**) or red (**9**–**11**). The ^{1}H-NMR spectra of **5**, **6** and **8**–**11** each show two signals for the diastereotopic PCHCH_3 protons of the triisopropylphosphane ligands, thus confirming the proposed structure with four different bonding partners in the basal plane of the octahedron. The reaction of **1** with methanol leading to **8**[7] in almost quantitative yield is remarkable, since alkoxo(hydrido)osmium(II) complexes are, to our knowledge, unknown. A rearrangement of **9** and **10** to the isomeric vinylidene compounds [OsCl(NO)(=C=CHR)($P\mathit{i}Pr_3$)$_2$] cannot be achieved thermally (up to ca. 60 °C); the structurally related iridium complexes [IrHCl(C≡CR)(CO)($P\mathit{i}Pr_3$)$_2$] are similarly inert.[13b]

Experimental

1: To a suspension of 847 mg (0.81 mmol) of [OsCl(NO)(PPh_3)$_3$] in 15 mL of toluene was added 0.4 mL (2.0 mmol) of $P\mathit{i}Pr_3$ and the mixture stirred for 10 min at 25 °C. The solution was concentrated to ca. 3 mL in vacuo and treated with 5 mL of hexane. A dark-green, microcrystalline solid was formed; yield 384 mg (82%).—**2**: By passage of CO gas (ca. 1 min) into a solution of **1** in toluene; yellow solid; m.p. 101 °C (decomp.); yield 85%.—**3**: By passage of H_2 (ca. 2 min) into a solution of **1** in toluene; bright yellow solid; m.p. 102 °C; yield 92%.—**4**: A solution of 91 mg (0.16 mmol) of **1** in 7 mL of toluene was treated dropwise with an ethereal solution of HCl until a color change from green to yellow occurred. After removal of the solvent and repeated washing of the residue with cold ether, there remained a yellow solid; m.p. 126 °C (decomp.); yield 87 mg (89%).—**5**: A solution of 89 mg (0.15 mmol) of **1** in 7 mL of toluene was treated with 12 µL (0.16 mmol) of CF_3CO_2H. The solvent was removed in vacuo, the residue extracted with ether, the extract evaporated to dryness, and the resulting yellow residue washed with hexane; m.p. 82 °C (decomp.); yield 81 mg (78%).—**6**: From **1** and CH_3I in toluene; after extraction with hexane and removal of the solvent an orange-yellow solid was obtained; m.p. 125 °C (decomp.); yield 76%.—**7**: From **1** and I_2 in toluene; yellow solid; m.p. 186 °C (decomp.); yield 97%.—**8**: A suspension of 127 mg (0.22 mmol) of **1** in 15 mL of methanol was heated at 60 °C for 3 h. After cooling, the solution was concentrated to ca. 5 mL and cooled to − 40 °C; yellow crystals; m.p. 110 °C (decomp.); yield 121 mg (90%).—**9**: From **1** and PhC_2H in toluene; reaction time 4 h at 25 °C; bright red solid; m.p. 162 °C (decomp.); yield 94%.—**10**: From **1** and methyl propiolate in toluene; duration of reaction 3 h at 25 °C. After evaporation of the solvent, extraction with ether, and removal of the solvent a red solid was obtained; m.p. 131 °C (decomp.); yield 74%.—**11**: From **1** and $C_2(CO_2Me)_2$ in toluene; red solid; m.p. 51 °C; yield 75%.

Hexanuclear Ferric Complex with a Novel $S = 5$ Ground State**

By *Daniel F. Harvey,* Cheryl A. Christmas, James K. McCusker, Paula M. Hagen, Raj K. Chadha,* and *David N. Hendrickson**

Oxo-bridged iron complexes have been found to exist in a variety of metalloproteins.[1] Studies of the oligomerization of lower nuclearity oxo Fe^{III} units have resulted in the preparation of higher nuclearity oxo-iron complexes.[2] In all of these high-spin Fe^{III} complexes, oxo, hydroxo or alkoxo bridges have been found to support *only* antiferromagnetic pairwise interactions between Fe^{III} ions. In this communication we report that the chelating ligand 1,1-bis(*N*-methylimidazol-2-yl)ethanol **1** reacts with the acetato-oxo Fe^{III}_3-complex **2** to give the hexanuclear Fe^{III} complex **3**. Complex **3** has been found to have novel magnetic properties. Even though all six iron ions are high-spin Fe^{III} ions, complex **3** has an $S = 5$ ground state.

Addition of 3.1 equivalents of **1** to a stirred acetonitrile solution of 1 equivalent of $[Fe_3O(OAc)_6(py)_3]ClO_4$ **2** gave a dark brown solution. After 20 minutes the solution was concentrated in vacuo and a brown oil was obtained. Addition of CH_2Cl_2 to the brown oil gave a brown solution, which was kept in an open flask at room temperature. Upon slow evaporation of solvent, red block-like crystals of $\mathbf{3} \cdot 8CH_2Cl_2$ suitable for characterization by X-ray crystallography were obtained.[3] Further drying gave $\mathbf{3} \cdot CH_2Cl_2$ in 40% yield[4] which was used for the magnetization studies. The X-ray crystal structure of **3** is shown in Figure 1. Com-

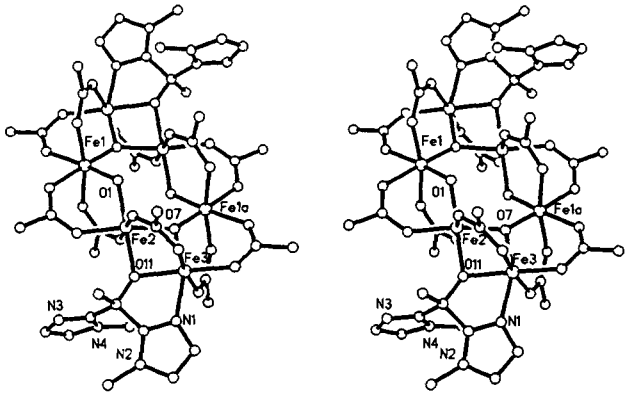

Fig. 1. Stereoview of **3**. H atoms and solvent molecules (CH_2Cl_2) have been omitted for clarity. Selected bond lengths [Å] and angles [°]: Fe1a-O7, 1.873(4); Fe2-O7, 1.963(3); Fe3-O7, 1.908(5); Fe3-N1, 2.111(6); Fe1-O1, 1.977(4); Fe2-O1, 1.948(4); Fe2-O11, 2.014(5); Fe3-O11, 2.021(3). Fe1a-O7-Fe2, 137.9(3); Fe2-O7-Fe3, 100.2(2); Fe1a-O7-Fe3, 119.7(2); Fe1-O1-Fe2, 123.5(2); Fe3-O11-Fe2, 94.8(2); 07-Fe3-N1, 157.7(1).

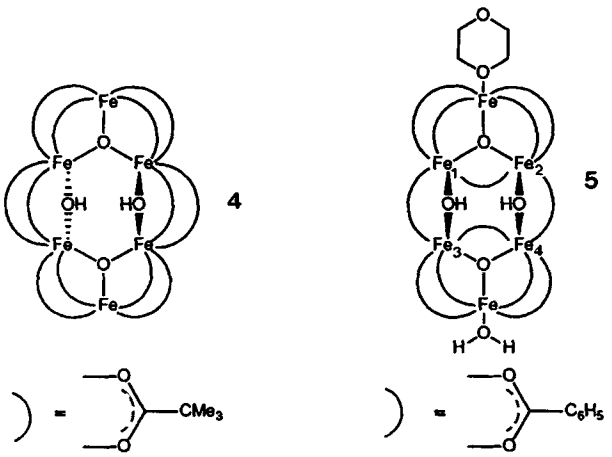
plex **3** possesses a center of inversion and has three unique Fe^{III} centers. Iron atoms Fe1 and Fe2 both have only oxygen ligation whereas Fe3 has both oxygen and nitrogen ligation. Fe1 is bound to one μ_3-oxo, one μ_2-hydroxo, and four acetato oxygen atoms. Fe2 has the same coordination as Fe1 except one of the acetate oxygen atoms is replaced by a μ_2-O-bound, deprotonated ligand **1**. Fe3 (like Fe2) has only three μ_2-acetato oxygen atoms in its coordination sphere. The remaining coordination sites of Fe3 are filled by one of the imidazole rings of the ligand **1** and its μ_2-alkoxide function. The second imidazole ring of **1** is not bound to any of the iron centers. This structure may be viewed as two Fe^{III}_3 μ_3-oxo scalene triangles bridged by four μ_2-acetato and two μ_2-hydroxo ligands. The four central ions (Fe1, Fe2, Fe1a, and Fe2a) are planar with one μ_2-hydroxo bridging above the plane and the other below the plane.

Two similar Fe_6 complexes have recently been reported. The structure of **3** is quite similar to that of $[Fe_6O_2(OH)_2(O_2CCMe_3)_{12}]$ **4**[2f] but is fundamentally different than $[Fe_6O_2(OH)_2(O_2CPh)_{12}(1,4\text{-dioxane})(OH_2)]$ **5**.[2g, h] In **4**, the two peripheral irons are five-coordinate and all of the carboxylate ligands are pivalates. Complex **5** contains bridging carboxylates between the edges of the trinuclear subunits that face one another. In **5**, both of the bridging hydroxides are on the same side of the iron plane, whereas in **3** and **4** the bridging hydroxides are on opposite faces.

The unusual magnetic properties of complex **3** are summarized in Figure 2. At 10.0 kG the magnetic moment (μ_{eff}) per molecule gradually increases from 9.21 μ_B at 346.1 K to a maximum of 10.89 μ_B at 20.00 K, where it plateaus before it decreases to a value of 10.44 μ_B at 6.00 K. The increase in μ_{eff} as the temperature is decreased is unprecedented for com-



plexes comprised of only high-spin Fe^{III} ions. Zero-field Mössbauer spectra at 300 and 200 K can be fit with parameters consistent with high-spin Fe^{III} ions.[5]

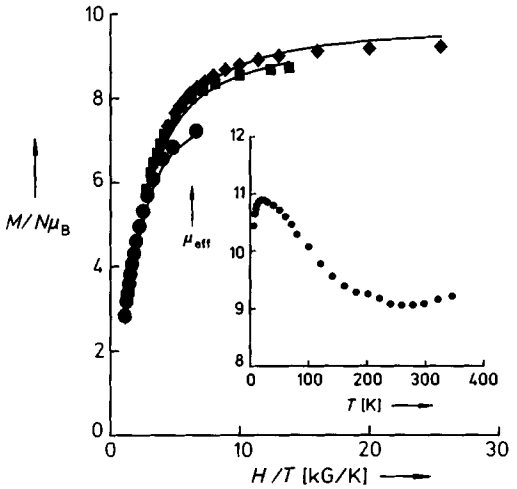


Fig. 2. Plot of the reduced magnetization ($M/N\mu_B$) of a polycrystalline sample of complex $3 \cdot CH_2Cl_2$ versus H/T, whereby the values for H are ●, 10.0; ■, 25.0; and ◆, 40.0 kG. The solid lines result from a fit of all data to a spin Hamiltonian for an $S = 5$ state. The inset shows a plot of effective magnetic moment μ per molecule [μ_B] versus temperature for complex **2** in an applied field of 10.0 kG.

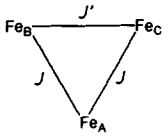
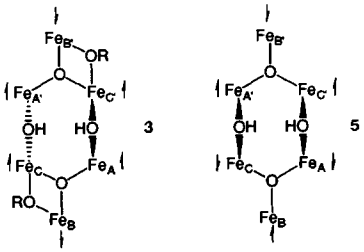
The spin of the ground state of a Fe_6^{III} complex could range from $S = 0$ to $S = 15$. However, from the literature[2] it would be expected that pairwise antiferromagnetic interactions in a Fe_6^{III} complex would give an $S = 0$ ground state. In fact, complex **5** has been reported[2g,h] to have an $S = 0$ ground state. The plot of μ_{eff} versus temperature in Figure 2 is strongly suggestive of a complex with an $S = 5$ ground state, which would be expected to give a spin-only value of 10.95 μ_B/molecule for a Fe_6^{III} complex. Substantiation of this unusual ground state was obtained by field-dependent magnetization measurements. It should be mentioned that due to the topology of complex **3** it is *not* possible to use the Kambe operator replacement technique[6] to derive an eigenvalue energy level expression for complex **3**. Thus, to fit the 10.0 kG susceptibility data and to extract exchange parameters for pairwise $Fe^{III} \cdots Fe^{III}$ interactions in complex **3** would require on each iteration diagonalization of a 46 656 × 46 656 matrix.

However, the isofield magnetization data (1.51–9.04 K at 10.0 kG; 1.81–9.00 K at 25.0 kG; 1.57–9.04 K at 40.0 kG) shown in Figure 2 definitively establish that the ground state of complex **3** has $S = 5$. At the highest field employed, the reduced magnetization, $M/N\mu_B$ (N is Avagadros number and μ_B is the Bohr magneton) is saturating at $\approx 9.2\,\mu_B$. The solid lines show how well the data can be fit by assuming a theoretical model with an $S = 5$ ground state experiencing axial zero-field interactions ($D\hat{S}_z^2$). The three isofield data sets are simultaneously fit [diagonalization of two $(2S + 1) \times (2S + 1)$ matrices on each iteration] with parameters $g = 1.94$ and $D = 0.22\ cm^{-1}$ for $S = 5$. Fits with $S = 4$ and 6 spin Hamiltonian matrices give unreasonable g values of 2.39 and 1.63, respectively. It is thus clear that complex **3** has a $S = 5$ ground state.

The unusual $S = 5$ ground state for complex **3** can be rationalized as a manifestation of spin frustration. By "spin frustration" we refer to an effect whereby the interplay of various exchange pathways results in spin vector alignments which deviate from those anticipated based upon the intrinsic nature of the pairwise exchange interactions. It is well documented[7] that triangular trinuclear complexes can exhibit spin frustration. For example, consider the exchange interactions in an isosceles Fe_3^{III} triangle: When both J and J'



are negative and $J/J' > 2$, the ground state has $S = 5/2$. The dominance of the two J-type interactions leads to a frustration in the $Fe_B \cdots Fe_C$ interaction and a net parallel alignment of the spin vectors on Fe_B and Fe_C despite the fact that the interaction between these two ions is antiferromagnetic. Spin frustration in higher nuclearity complexes is *not* as well documented.[8] The $S = 5$ ground state for the Fe_6^{III} complex **3** and $S = 0$ ground state for the analogous complex **5** can be rationalized by differing degrees of spin frustration. One possibility is shown in the schematic drawings (Scheme 1). In



Scheme 1. Description of the groundstate of **3** ($S = 5$) and **5** ($S = 0$). The arrows indicating spin vectors merely reflect orientations, not absolute magnitudes.

both complexes the interaction propagated by the hydroxo bridges is assumed to be the weakest pairwise exchange interaction. In complex **3**, the presence of the μ_2-OR group breaks the symmetry of the pairwise interactions within the iron triangle. If any one of these interactions is sufficiently strong, frustration of the weak antiferromagnetic μ-$OH^{\ominus}$ pathway may occur, resulting in a net spin alignment of the spin vectors on these ions and an $S = 5$ ground state. On the other hand, perhaps any one interaction is not so dominating in complex **5**, then all three Fe^{III} ions (A, B and C) in each

triangle are comparably involved in a mutual spin polarization which would tend to give an $S = 0$ ground state.

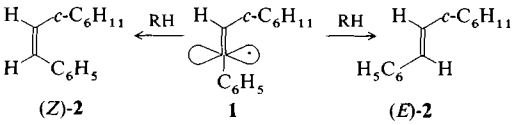
Isoselective Relationship for the Stereoselectivity of the Transfer of Hydrogen Atoms to Cyclic Alkyl Radicals**

By *Bernd Giese*,* *Hassan Farshchi, Jörg Hartmanns, and Jürgen O. Metzger**

With the increasing use of radical reactions in organic synthesis a more detailed understanding of the reactivities and selectivities is of decisive importance.[1] Especially important is an exact knowledge of the stereoselectivity of hydrogen transfer and the possibility of controlling it, since this reaction is frequently the decisive product-forming step in radical reactions.[2]

Using the π-alkenyl radical **1** as example we have shown that the stereoselectivity of hydrogen transfer to give (*Z*)-**2** and (*E*)-**2** can be steered by both variation of the H donor RH as well as by the temperature, and that it obeys the

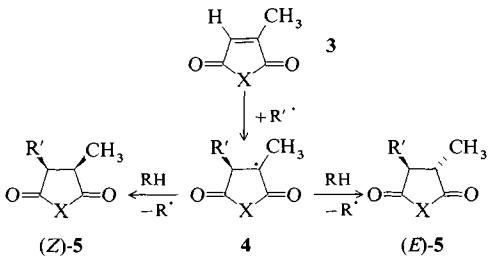


(*Z*)-**2** **1** (*E*)-**2**

isoselective relationship (a) with an isoselective temperature T_{iso} of 60–80 °C.[3] At this isoselective temperature, variation of the H donor has no influence on the selectivity.[4a]

$$T_{iso} = \frac{\delta(\Delta H_E^{\ddagger} - \Delta H_Z^{\ddagger})}{\delta(\Delta S_E^{\ddagger} - \Delta S_Z^{\ddagger})} \qquad \text{(a)}$$

Such isoselective realtionships are of practical importance, but also enable us to assess the selectivity of a series of reactions over a large temperature range and possibly to anticipate reversal of selectivity as a function of the temperature.[4] In addition, the occurrence of an isoselective relationship points to a common reaction mechanism. Hitherto a series of reactions in which isoselectivity occur, were experimentally measured with variation of only one reaction partner.[4a] We have now for the first time, by H trapping with the radical **4**, measured a series of reactions, which upon variation of both reaction partners—radical **4** and H donor RH—leads to a single isoselective relationship (Scheme 1).



Scheme 1. X = O, PhN; RH = Bu_3SnH, PhMe, PhEt, c-C_6H_{12}; R′:Me (**a**), n-C_6H_{13} (**b**), $PhCH_2$ (**c**), c-C_6H_{11} (**d**), PhCH(Me) (**e**).

The radicals **4** were obtained by addition of a radical R′· to methylmaleic anhydride or *N*-phenyl(methyl)maleimide **3**. Transfer of H from H donors RH to the planar π-alkyl radical **4** leads to formation of (*Z*)-**5** and (*E*)-**5**, whose ratio was determined in the temperature range 0–400 °C. The stereoselectivity of the H transfer is significantly greater with the alkyl radical **4** than with the alkenyl radical **1** as acceptor. It is strongly influenced by the β-substituent R′, by the H donor and by the temperature, but is largely independent of whether **3** is employed as the *N*-phenylimide or the anhydride (Table 1).

Since the approach of the H donor RH upon **4** from the *anti*-side with respect to R′ is less hindered than from the *syn*-side, the activation enthalpy for the formation of (*Z*)-**5** is 3.5–10.9 kmol^{-1} lower than for the formation of (*E*)-**5**.

Thereby, the energy difference $\Delta H^{\neq}((E)\text{-}5) - \Delta H^{\neq}((Z)\text{-}5)$ with the same H donor tributyltin hydride increases with increasing size of the β-substituent R′ from 5-6 (methyl, *n*-hexyl,benzyl) to 8.2 kJ mol^{-1} (cyclohexyl), and accordingly the stereoselectivity increases. Since also the differences in the activation entropies increase in the same direction from 9 (methyl, *n*-hexyl) through 11.3 (benzyl) to 14.3 J mol^{-1} K^{-1} (cyclohexyl), the compensation of the activation enthalpies and activation entropies leads to an isoselective temperature[4a] of 750 K with $[(Z)\text{-}5]/[(E)\text{-}5] = 0.72 + 0.07$ (Fig. 1). At this temperature, which lies outside the measurement range, the radicals **4a**–**4d** (X = PhN) react with the H donor tributyltin hydride (Experiments 1–4) with the same stereoselectivity.

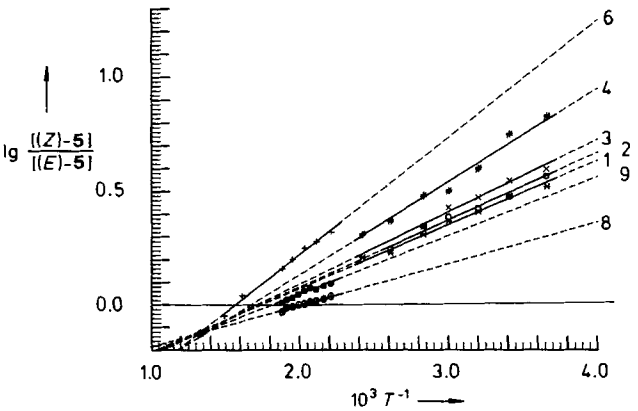

Fig. 1. Temperature dependence of the stereoselectivity of the H transfer to the alkyl radicals **4** by Bu_3SnH, *c*-C_6H_{12}, PhMe and PhEt. The numbers on the Arrhenius curves correspond to the experiment numbers in Table 1. The unbroken portions of the curves demarcate the ranges of measurement (cf. Table 1).

The H transfer from toluene to **4c** (X = PhN), from ethylbenzene to **4e** (X = PhN), and from cyclohexane to **4d** (X = O) (Experiments 8, 9, and 6) obey the same isoselective relationship as the H transfer from tributyltin hydride to the radical **4** (Fig. 1). This is a remarkable result, since it shows that the reactions of five sterically differently shielded radicals **4** with four differently reactive H donors RH[5] obey a common isoselective relationship. It can therefore be concluded that the stereoselectivity of the H transfer is determined by the steric interaction between H donor and β-substituent in radical **4**. The finding that **4c** (X = PhN) reacts more selectively with the H donor tributyltin hydride (Experiment 3) than with the much less reactive toluene, is surprising, since the difference in the steric shielding by R′ should have all the more stronger effect on the activation energies the less reactive the H donor is.[3a] Our result—a further deviation from the reactivity–selectivity principle[6]—shows that the steric effect of tributyltin hydride on **4c** (X = PhN) is greater than that of toluene in the transition state of the H transfer, so that the above effect is overcompensated. In contrast, in the case of the radical **4d** (Experimental pairs 4 and 7 as well as 5 and 6), the expected behavior is observed even when the differences are smaller than in the case of the alkenyl radical **1**.[3]

The temperature dependence of the stereoselectivity with incorporation of the isoselective point is shown in Figure 1. The selectivity $\lg\{[(Z)\text{-}5]/[(E)\text{-}5]\}$ decreases as expected with increasing temperature, and between 475 K (Experiment 8) and 638 K (Experiment 6) is equal to zero. Above these temperatures the selectivity increases again, and entropically favored preferentially (*E*)-**5** is formed. This reversal of selectivity lies within the range of measurement in the case of Experiments 6–9, and could therefore be measured directly.

Our investigations on the alkyl radicals **4** show that the stereoselectivity of radical hydrogen transfer reactions can be controlled by variation of the β-substituent, the H donor, and the reaction temperature. These results are important for the planning of syntheses in which the subsequent H transfer takes place at a prochiral center.

Helical Semiquinones: Proof of Chirality by ENDOR Spectroscopy**

By *Manfred Mäurer, Klaus Scheffler, Hartmut B. Stegmann,** and *Albrecht Mannschreck*

4,5-Disubstituted phenanthrenequinones **II** are helical and therefore, in contrast to the unsubstituted species **I**, chiral. The twist is mainly caused by the repulsion between the substituents in 4,5 positions. The nonbonding oxygen-oxygen interaction adds a smaller contribution.[1] For the methyl substituted compounds the free activation enthalpy of racemization lies between 94 and 131 kJ mol^{-1}, that is, the enantiomers can be separated at room temperature by liquid chromatography (LC).[1] The corresponding semiquinones are also expected to have a twisted ground state and a relatively high enantiomerization barrier. EPR and ENDOR studies of thallium complexes of these semiquinones show smaller values of the thallium coupling constants for the nonplanar species than for the planar ones.[2] An estimate of the height of the enantiomerization barrier was not possible by this method.

The helical form of these semiquinones has now been proved by ENDOR spectroscopic studies of the diastereomeric radicals, which were prepared by reduction of the corresponding quinones with prochiral auxiliaries. The 2,2'-biphenyldiyl(*p*-tolyl)tin chloride **B** provides a suitable probe.[3] For comparison, triphenyltin chloride **A** was also used. **A** and **B** react with quinones, whereby in each case an aryl substituent is lost and semiquinone chelates of trigonal-bipyramidal, pentacoordinate tin are formed, in which the bidentate ligand takes up axial-equatorial positions because of the ring strain.[3] Thus the chlorine atom in chelates with **B** must occupy an equatorial position, and tin is therefore a chiral center. When **A** is used, the chlorine atom, as an electronegative substituent, is bound axially, and the organometallic component is achiral. Studies of the corresponding benzoquinone complexes have shown[3] that the permutation isomerization at room temperature is slow on the EPR time scale.

Since the behavior of these paramagnetic complexes is determined by the central atom, a similar situation is anticipated with the phenanthrenesemiquinones. In order to distinguish between the spectral properties of the diastereomers and "nonchiral" effects, planar as well as helical phenanthrene quinones[4] were treated with **A** and **B** (in **7** the positions 3 and 4 as well as 5 and 6 are linked by dioxymethylene bridges).

	$R^{1/8}$	$R^{2/7}$	$R^{3/6}$	$R^{4/5}$
1	H	H	H	H
2	H	H	CH_3	H
3	H	H	H	CH_3
4	H	H	CH_3	CH_3
5	H	CH_3	H	CH_3
6	H	CH_3	CH_3	CH_3
7	H	H	$-O-CH_2-O-$	

The EPR spectra are only partly resolved, and the large number of coupling nuclei prevents a complete interpretation (Fig. 1). In all cases they are symmetric and the g factors

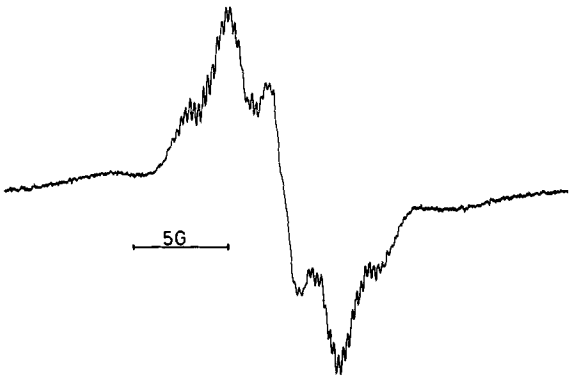

Fig. 1. EPR spectrum of **5B** in toluene at room temperature.

vary only slightly (e.g. $g_{1A} = 2.00339$ and $g_{1B} = 2.00341$). The ^1H coupling constants were obtained from ENDOR spectra at various temperatures (Table 1).

The assignment of the coupling constants in phenanthrene semiquinones is known[2, 5] and can be applied to the tin chelates. This was confirmed by the determination of their relative signs. This means large values of the coupling constants for the positions 1, 3, 6, and 8, but small ones for the positions 2, 4, 5, and 7. However, the equivalence of the positions 1/8, 2/7, 3/6, and 4/5 is lifted in the tin complexes, because the semiquinones are axial-equatorially bound. Thus for each of the radicals **1A–6A** with achiral tin components four small ($|a| < 1$ G) and four large ($|a| > 1$ G) couplings are expected. The complexes **1B** and **2B** must behave completely analogously, as in these cases the phenanthrene moiety is achiral. The ENDOR spectra of these compounds do not, however, show the theoretical number of lines in all cases because of coincidental degeneracy; nevertheless there are always enough lines to exclude rapid permutation isomerization.

The spectra of the radicals **3B–5B** at 213 K show up to seven large couplings (Table 1 and Fig. 2, top spectrum), so that the diastereomeric complexes, which arise from a combination of helical semiquinones with chiral organometallic

[a] All compounds were studied in toluene. The experimental error in proton couplings is ca. 0.02 G, and the difference between two couplings of a diastereomeric pair 0.01 G. In some spectra an additional small coupling of 0.03 to 0.05 G is observed, which is assigned to the aryl protons at tin. [b] **6B** gave no reproducible ENDOR spectra. [c] The couplings up to 1.2 G were assigned to positions 2 and 7 and to the methylene protons, the couplings > 1.2 G to positions 1 and 8.

components, can be recognized by their different proton couplings. Theoretically, in the case of the diastereomeric pairs of enantiomers *M,R/P,S* and *P,R/M,S* four splittings with $|a| > 1$ G are expected, for each species, leading to a total of eight large couplings. They could, however, not be resolved completely. Nevertheless, in all examples the number of experimentally observed splittings is higher than four.

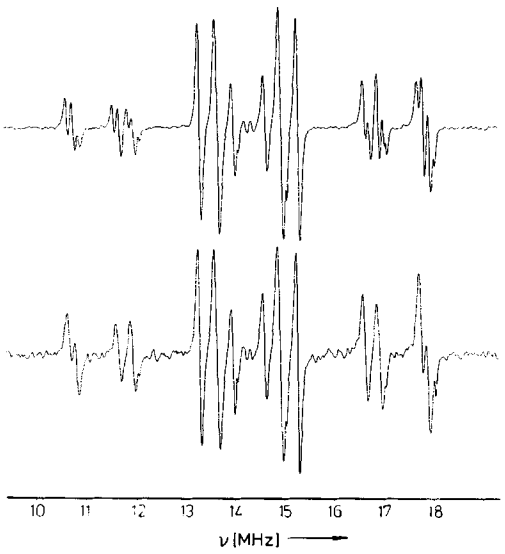

Fig. 2. ENDOR spectra of **5B** in toluene at 213 K (top) and 253 K (bottom).

The coupling constants of the diastereomers differ by ca. 100 mG, which is about 5% of the total. Such small differences can not be found for couplings with $|a| < 1$ G because of the line widths (Fig. 2, top spectrum). At 233 K only a maximum of four incompletely resolved peaks were observed in the range where large couplings are to be found. At 253 K nothing suggests the presence of diastereomers of **3B–5B** any more (Fig. 2, bottom spectrum). As the line widths are largely independent of temperature, the conclusion is that already at 253 K a rapid interconversion between the diastereomers takes place. The free activation enthalpy is estimated from the coalescence temperature of ca. 240 K to be approximately 33 kJ mol^{-1}.

Since the permutation isomerization at tin could be excluded, a rapid conformational interchange at the phenanthrene moiety must be assumed. Thus the barrier for the enantiomerization of the semiquinones must have been substantially lowered on going from the phenanthrene quinone to the semiquinone chelate. The change in the double-bond character between C4a and C4b, less twisting of the ligand by chelate formation, the decrease of the O–O distance and the concomitant stretching of the C4a–C4b bond are perhaps reasons for the lower barrier.

In the radical **7A** only two large proton couplings are observed, which must be assigned to the hydrogen atoms in positions 1 and 8. The diastereomeric effects should therefore be particularly easy to detect when comparing **7A** with **7B**. With ^{1}H NMR spectroscopy and LC, however, no proof for the helicity of 7 could be found.[1b] This is in good agreement with the EPR studies on the thallium complexes.[2b] Correspondingly, the barrier for enantiomerization of the semiquinone chelate is now so low that no evidence for diastereomers can be found, even at 213 °C.

Till now different EPR couplings of diastereomeric radicals were rationalized mainly on the grounds of different hyperconjugation angles of corresponding β protons.[6, 7] As compounds **3B–5B** have either α protons or freely rotatable methyl groups to serve as probes, this explanation cannot hold for the helical phenanthrene quinones. Therefore the differences must be caused by the spin polarization and/or the spin density distribution. Since the diastereomers **4B** differ in both their α and their β couplings, it is more likely that the stereomers have different distribution functions for the free electron. A possible reason for this is the different orientation of the Cl atom in relation to the π electron system of the phenanthrene moiety and the resulting difference in orbital interaction.

Experimental Procedure

The samples were prepared by mixing approximately equivalent amounts of quinone and organotin chloride in toluene in an EPR tube and flushing with nitrogen for several minutes. In some cases the sample was also irradiated with light from a mercury vapor lamp. The EPR spectra were recorded on a Varian E 12 EPR spectrometer, ENDOR and TRIPLE spectra on a Varian E line EPR spectrometer fitted with a Bruker ENDOR ER 810 unit and Bruker ER 140 data system (typical instrument parameters: microwave output 5 mW, RF output 7 dB, 500 W, modulation 30 kHz, 20 scans).

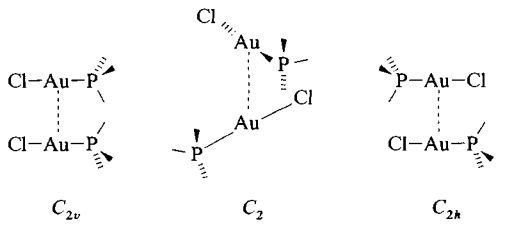
Ab initio Calculations on the $(ClAuPH_3)_2$ Dimer with Relativistic Pseudopotential: Is the "Aurophilic Attraction" a Correlation Effect?

By *Pekka Pyykkö** and *Yongfang Zhao*

Schmidbaur et al. and *Jansen*[1,2] have recently found empirical evidence for an $Au^I \cdots Au^I$ "aurophilic" attraction of about -30 kJ/mol (-0.011 a.u.), leading to secondary metal–metal bond lengths of about 300–340 pm. A 5d6s6p hybridization,[3] analogous to the 3d4s4p one discussed for $Cu \cdots Cu$,[3a] was proposed as a possible mechanism. No earlier ab initio calculations are known to us.

We therefore carried out calculations with GAUSSIAN 90 on a $(ClAuPH_3)_2$ dimer in parallel (C_{2v}), perpendicular (C_2) and antiparallel (C_{2h}) configuration (Scheme 1). The 5d6s6p double-zeta, 11 valence-electron "LANL1DZ" quasirelativistic pseudopotential of *Hay* and *Wadt*[4] is used in Gaussian 90 at HF, MP2 and MP3 levels. For Au_2 this potential gives a calculated R_e of 267.1, 264.9 and 265.9 pm at the Hartree-Fock (HF), MP2 and MP3 level, respectively, compared to the experimental value of 247.2 pm.[5]



Scheme 1. Calculated configuration of $(ClAuPH_3)_2$.

The C_{2v} and C_{2h} HF curves in Figure 1a are dominated by electrostatic dipole–dipole interactions, dependent on the orientation chosen. In the crossed, C_2 case, a weak attraction of about -0.02 Hartree is found. The Au–Au overlap populations are small and negative for all three geometries (-0.026 for C_2 symmetry at $R = 350$ pm). Thus, the experimental attraction is not reproduced at the HF level. Note the existence of the attraction for both planar and rotated, symmetrical $(LAuL)_2$ systems,[2] where no dipole–dipole interactions occur. The first non-vanishing electrostatic term is the quadrupole–quadrupole one.

The MP2 and MP3 curves in Figure 1b closely agree, suggesting convergence of the Møller-Plesset perturbation series. Correlation effects are attractive for all three geometries and lead to comparable attractive wells for the C_2 and C_{2h} geometries. The parallel, C_{2v} curve still remains repulsive. The C_2 (MP2) well depth of -0.019 Hartree at 300 pm, is comparable with *Schmidbaur*'s surmised interaction. In the antiparallel case, the depth of the (MP2) minimum is -0.026 Hartree at 370 pm.

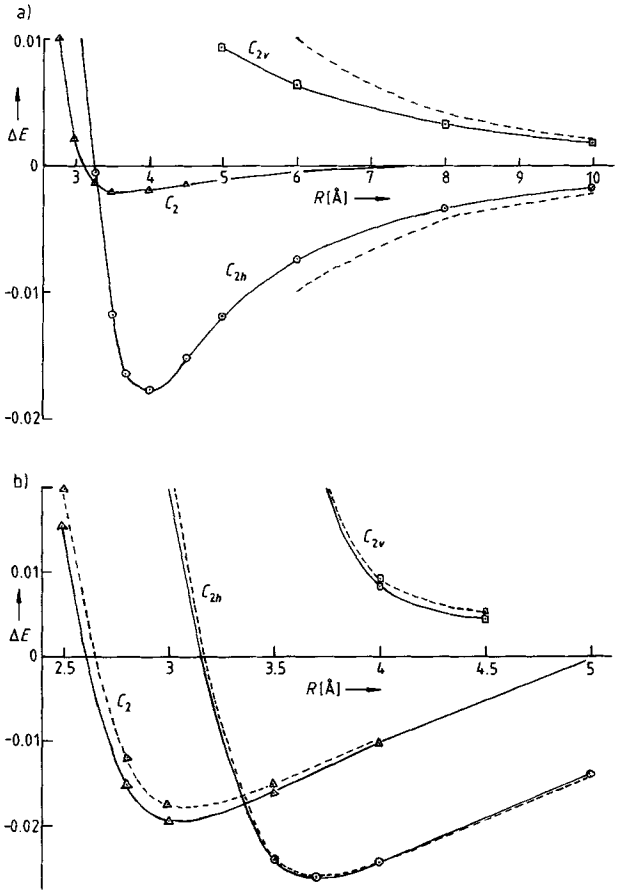


Fig. 1. Calculated interaction energies ΔE [Hartree] for the dimer $ClAuPH_3$ in parallel (C_{2v}), perpendicular (C_2) and antiparallel (C_{2h}) configurations. The two Cl-Au-P-"H" planes of the C_2 case are parallel (see Scheme 1). R = Au–Au. a) — HF calculation; - - - classical dipole-dipole interaction corresponding to the HF dipole moment μ (of the monomer $\pm \mu^2/R^3$). b) — MP2; - - - MP3.

Experimentally the Au–A distance is 344.0(1) pm in the antiparallel dimer of **1**,[6] 336 pm in **2** with almost perpendicular P–Au–Cl unit,[7a] 300 pm in **3**, in which the phosphino groups are covalently bound,[1] and on average 313 pm in **4**.[7b] The two compounds **3** and **4** with parallel P–Au–Cl units give an impression of dipole repulsion and Au–Au attraction.

We have only tried to analyze the nature of the correlation effects by omitting the Au 6p functions from the base in a single case, the C_{2h} geometry for $R = 370$ pm. This diminished the ΔE_{corr} in Table 1 from -0.0097 to -0.0033 Hartree suggesting a 5d-6p correlation.

If Au is replaced by Ag, the C_2 MP2 well depth diminishes from -0.0194 Hartree at R = 300 pm to -0.0115 Hartree

4

at $R' = 320$ pm. As the difference between gold and silver is mainly attributed to relativistic effects,[8] they seem to be important, as originally presumed.[1]

Table 1. The interaction energies ΔE and correlation contributions ΔE_{corr}[Hartree] for two monomers in the C_{2h} configuration with $R = 370$ pm, calculated with and without Au 6p functions in the basis set.

	ΔE(HF)	ΔE(MP2)	ΔE_{corr}
With 6p	− 0.165	− 0.0261	− 0.0097
Without 6p	− 0.0199	− 0.0232	− 0.0033

We conclude that the expected attraction is indeed there, but caused by correlation effects and strengthened by relativitic effects, rather than caused by hydridization. A similar conclusion on considerable correlation shortening of the Cu ··· Cu distance was found by *Kölmel* and *Ahlrichs*.[7] An extended Hückel hybridization picture[3] only holds in the allegorical sense that EHT include correlation effects. The eventual role of these correlation effects in the $(XAu_n)^{m\oplus}$ clusters, which were already calculated at the HF level,[10] remains to be studied. So do the systematic trends of the Au–Au distances and the detailed analysis of the correlation.

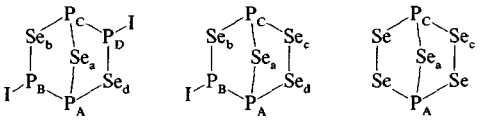
A Novel Phosphorus Chalcogenide: P_2Se_5 **

By *Roger Blachnik,* Hans-Peter Baldus, Peter Lönnecke,* and *Bruce W. Tattershall**

Dedicated to Professor Marianne Baudler on the occasion of her 70th birthday

P_4E_3[1, 2] and its derivatives α-$P_4E_3X_2$ **1** and β-$P_4E_3X_2$ (E = S, Se; X = halogen, pseudohalogen or similar groups)[3–6] contain four phosphorus atoms in an approximately tetrahedral arrangement. Replacement of one PI group of $P_4Se_3I_2$ by Se affords the structurally similar P_3Se_4I **2**,[7] while replacement of both PI groups by Se affords P_2Se_5 **3**, described here. The bicyclic species **3** contains only two three-coordinate phosphorus atoms, in bridgehead positions.



1 **2** **3**

The selenide **3** was observed as a decomposition product of the monoiodide **2** in CS_2 solutions. By annealing a P_2Se_5 glass above the glass temperature and prolonged extraction with CS_2, we have now been able to prepare **3** in pure form. **3** crystallizes as black needles and can be recrystallized from CS_2.[8]

For determination of the structure the ^{31}P- and ^{77}Se-NMR spectra of **3** were analyzed and the coupling constants compared with those of the known compounds **1** and **2**. Three kinds of isotopomers of **3** were observed in the ^{31}P-NMR spectrum: the ^{31}P-resonance signal of the ^{77}Se-free isotopomers **3** at $\delta = 104.95$ is flanked by two ^{77}Se satellite spectra (Fig. 1), which are due to a differing occupation of Se positions in P_2Se_5 by ^{77}Se. The isotopomers **3c**, which contain ^{77}Se nuclei in the diselenide bridges (Se_c), give rise to ABX spin systems; the isotopomers **3a**, with ^{77}Se in the monoselenide bridges (Se_a), give rise to A_2X spin systems. The measured ratio of integrals of the satellite spectra (**3c**:**3a** = 4.02:1) correlates well with the expected ratio of

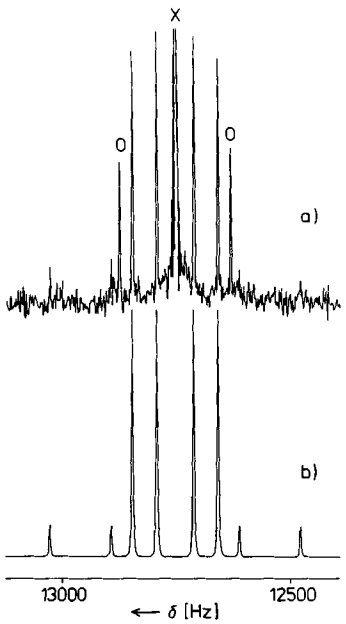

Fig. 1. ^{31}P-NMR spectrum of P_2Se_5 at 121.5 MHz. a) Observed spectrum (X: isotopomers **3** without ^{77}Se. O: isotopomers **3a**). b) Calculated spectrum of isotopomers **3c**.

4:1. The four intense signals of the AB part in the ^{31}P-NMR spectrum, and the three intense signals of the X part in the ^{77}Se-NMR spectrum (Fig. 2), are easily recognizable for the isotopomers **3c**, as is the ^{31}P doublet of the A_2X spin system of isotopomers **3a**. To find all of the less intense signals, long measuring times (^{31}P, 16 h; ^{77}Se 64 h), saturated solutions, and 10-mm NMR tubes had to be used. The spectra of **3a** and **3c** were fitted by computer[9] to yield the NMR parameters.[8]

The coupling constants $^2J(P_AP_C)$ increase monotonically (87.2 for **1**, 121.0 for **2**, and 181.0 Hz for **3c**), as the replacement of P_D and/or P_B by the larger selenium atoms widens the bond angle at Se_a. The ^1J(PSe) couplings to Se_a show a similar trend: -279.6 ($^1J(P_ASe_a)$ in the α-$P_4Se_3I_2$ isotopomers **1a**), -267.6 (mean value of $^1J(P_ASe_a)$ and $^1J(P_CSe_a)$ in the P_3Se_4I isotopomers **2a**) and -243.5 Hz ($^1J(P_ASe_a)$ in the P_2Se_5 isotopomers **3a**). Similar, albeit less extreme, changes are observed when sulfur is replaced by selenium, or phosphorus replaced by arsenic, in P_4S_3 compounds.[10] The $^1J(P_CSe_c)$ coupling in the isotopomers **3c** (-283.6 Hz) is very similar to that in the P_3Se_4I isotopomers **2c** (-286.1 Hz). In solutions of **2** at room temperature an intramolecular exchange takes place which can be suppressed only at low temperatures.[7] The solubility of **2** in CS_2 is then, however, so sparing that the parameter $^2J(P_ASe_c)$ is not determinable. The corresponding values of $^2J(P_ASe_c)$ for P_3Se_4Cl and P_3Se_4Br are 17.0 and 16.5 Hz respectively, which are comparable with the corresponding coupling in isotopomers **3c** (14.7 Hz). The secondary isotope shifts for **3** correlate well with those of α-$P_4Se_3I_2$ [$^1\Delta P_A(Se_a) = 0.0062$, $^1\Delta P_C(Se_b) = 0.0047$ and $^2\Delta P_A(Se_b) = 0.0024$ ppm].

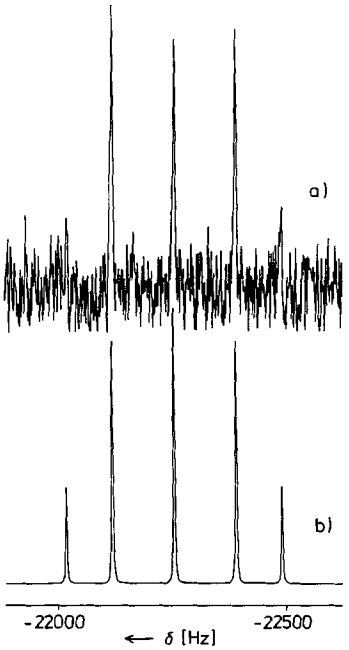

Fig. 2. ^{77}Se-NMR spectrum of isotopomers **3c** at 57.3 MHz. a) Observed and b) calculated spectrum.

Berzelius[11] presumed the existence of P_2Se_5, and there has been no lack of attempts[12] to prepare the compound by direct synthesis from the elements. In all the cases so far it was formed as an amorphous insoluble solid, whose structure was first investigated only recently. *Monteil* and *Vincent*[13] concluded that, in analogy to P_4S_{10}, a P_2Se_5 glass of P_4Se_{10} moieties should be formed. To support this hypothesis an IR absorption band at 500 cm^{-1} was assigned to a P=Se double bond. This band becomes more intense through the action of water vapor on crystalline P_2Se_5 and on glasses which were prepared according to *Monteil* and *Vincent* from P_4Se_3 and Se, and it should probably be assigned to a decomposition product. ^{77}Se-isotopomers of P_4Se_{10} would give NMR spectra with the spin systems AB_3X (exocyclic ^{77}Se) and A_2B_2X (endocyclic ^{77}Se), with which the ^{31}P- and ^{77}Se-NMR signals observed for our soluble product are not reconcilable. Moreover, ions with a higher m/z ratio than the molecular ion $P_2Se_5^{\oplus}$ were not observed in mass spectra of P_2Se_5 solutions. The first detailed investigation of the structure of P-Se glasses was carried out by *Price* et al.[14] According to their observations a P_2Se_5 glass consists predominantly of P_4Se_5 moieties, which are coupled to each other via selenium atoms or chains. They could unequivocally rule out P_4Se_{10} moieties. We presume that in the polymeric matrix of such glasses, isolated P_2Se_5 molecules or very similar, less cross-linked moieties are present which can be removed from the matrix by extraction with CS_2.

The phosphorus selenide **3** (P and Se in the stoichiometric ratio 2:5) does not have a P_4X_{10} structure. It exhibits a different type of structure from other phosphorus-chalcogen systems. An increase in chalcogen content in the phosphorus-selenium system does not lead to a larger coordination number of the phosphorus due to exocyclic selenium atoms, but instead the threefold coordination of the phosphorus remains unchanged, and the increased selenium content appears in the form of two diselenium bridges.

Experimental

Red phosphorus (0.762 g; 24.6 mmol; Knapsack) and selenium (4.858 g; 61.5 mmol; Retorte) were sealed in an evacuated quartz ampoule. A homogeneous melt was obtained by heating for ten days at 400 °C. The ampoule was quenched in ice-water, the product pulverized, resealed, and annealed for four months above the glass temperature of 100 °C. The subsequent CS_2-extraction was accomplished by several days stirring of the pulverized product with 200 mL CS_2 at room temperature. Filtration of the straw colored solution and cooling to -50 °C afforded the first crystal fraction. The supernatant liquid was reunited with the crude product and the extraction repeated five times. All

operations were carried out under inert gas. Yield: 0.32 g P_2Se_5 **3** (5.62% of the roretical).

Blocking of Acidic Centers upon Hydrothermal Dealumination of ZSM-5 Zeolites

By *Manfred Richter**

Treatment of the ZSM-5 zeolites with water vapor at high temperatures removes aluminum from lattice positions and thus reduces the concentration of acidic Brønsted centers.

The question whether the extra-lattice aluminum species (Al_{ex}) block acidic centers of the lattice during the dealumination is controversial. *Vogt* et al.,[1] e.g., reported an increase in the concentration of acidic centers after dealumination with HCl in the case of the zeolite ZSM-5. Apparently, the acid treatment leads to the extraction of Al_{ex} and thus to exposure of lattice Brønstedt centers. *Mavrodinova* et al. report analogous findings in the case of the zeolite US-Y: on the basis of the NH_3 thermodesorption, after extraction of Al_{ex} both an increase of the total concentration of acidic centers as well as a modification of the distribution of acidity is observed. The authors concluded that Al_{ex} species partially neutralize lattice Brønsted centers. In the case of the ZSM-5 zeolites T3 and HS 30 (Chemie AG, Bitterfeld), which were synthesized without organic templates, IR spectroscopic investigations and NH_3-thermodesorption[3, 4] show that neither a further dealumination occurs nor does the number of acidic centers increase upon extraction of hydrothermally dealuminated samples with 1 M HNO_3. However, the isomerization of *m*-xylene on samples treated this way leads to higher conversions and to a modified isomeric ratio (smaller amount of *p*-xylene), i.e. to a diminished shape selectivity.[5, 6] This is explained in terms of a partial extraction of Al_{ex} and the associated exposure of blocked centers on the inner and outer surfaces of the zeolite.[6] Since the reaction of *m*-xylene on ZSM-5 zeolites is disguised by internal mass transport effects,[5] which vary according to the concentration of Al_{ex}, it cannot be decided on the basis of activity and selectivity data whether the blocking of acidic centers by Al_{ex} or the exposure of such centers is responsible for the effects observed during the extraction.

The present communication demonstrates for the ZSM-5 zeolites discussed in Refs. [3–6], by checking their catalytic activity, that the extraction of Al_{ex} does not expose acidic centers, and therefore the prior hydrothermal dealumination has not blocked acidic centers. The isomerization of *m*-xylene and the conversion of ethylbenzene served as test reactions. Due to the smaller kinetic diameter of the ethylbenzene the latter reaction is not disguised by internal mass transport effects.

Starting from the NH_4-form of the template-free synthesized ZSM-5 zeolite HS 30, samples with various degrees of dealumination by hydrothermal treatment were prepared and the catalytic activity of the dealuminated samples and of the untreated zeolite were determined, both without as well as after extraction with 2 M HNO_3 (385 K, 2 h). Further details of the experimental determination of the Si/Al(lattice) ratio, of the acidity characterization, and of the measurements of the catalytic activity are given in the References [4–6, 8]. The samples investigated here are listed in Table 1.

Table 1. Zeolite samples investigated[a]

Sample	1	2	3	4
Treatment	2 h, 775 K	hydrothermal treatment at 775 K		
	shallow bed	1 h[b]	3 h	6 h
Si/Al (lattice)	20.0	31.0	51.5	75.4
Al_{ex} (total)[c]	0.088	0.359	0.562	0.660
Al_{ex} (extr.)[d]	0.021	0.025	0.11	0.153

[a] Starting material was the ZSM-5 zeolite H530 in the NH_4-form, Si/Al (lattice) = 20. [b] Additional calcination 2 h at 775 K under shallow bed conditions (ca. 2 cm layer height). [c] Concentration of Al_{ex} after dealumination, data in mmol Al g^{-1}, total Al content 0.871 mmol g^{-1}. [d] Amount of the soluble Al_{ex} in mmol g^{-1} after extraction with 2 M HNO_3 (385 K, 2 h).

The isomerization of *m*-xylene on the zeolite samples shows (Fig. 1a) that at Si/Al (lattice) ratios > 30 the conversions decrease, the extraction of about 20% of Al_{ex} (cf. Table 1) however increase the conversions by maximally 20%. Since a loss of activity on continuing dealumination is unavoidable (the concentration of acidic centers is reduced by the transformation of Al of the zeolite lattice into Al_{ex}), the influence of an additional blocking of acidic centers by Al_{ex} cannot be estimated. The higher activity of the extracted samples would be reconcilable with the concept that the extraction of Al_{ex} exposes acidic centers. The lower shape selectivity after the extraction (lower *p*-/*o*-xylene ratio (Fig. 2) would come about by the exposure of blocked centers on the outer zeolite surface, which is not shape-selective. This interpretation is not tenable however if one takes into consideration the results of the ethylbenzene conversion under the same conditions (Fig. 1b). In the case of the ethylbenzene conversion an extraction of acid-soluble Al_{ex} species has no recognizable influence on the activity of the samples, i.e. acidic centers are apparently not exposed by the extraction.

[*] Dr. M. Richter
Institut für Physikalische Chemie, Bereich Katalyse
Rudower Chaussee 5, O-1199 Berlin-Adlershof (FRG)

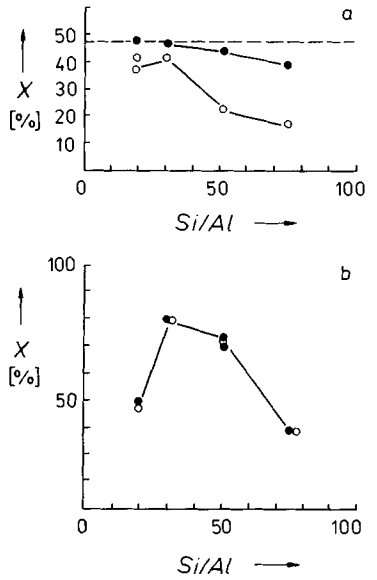

Fig. 1. Dependence of the conversion X of *m*-xylene (a) and ethylbenzene (b) on the Si/Al (lattice) ratio of the ZSM-5 zeolites. o samples dealuminated, not extracted, • samples dealuminated, extracted. Reaction conditions: normal pressure flow reactor, carrier gas N_2 (10 L h^{-1}, 1 vol % C_8), 1 g zeolite (without binder), reaction temperature 623 K. – – – thermodynamic equilibrium conversion of the *m*-xylene at 623 K [12].

A blocking of these centers by the Al_{ex} species formed in the hydrothermal dealumination can therefore be ruled out (under the plausible assumption that both test reactions take place, in principle, at the same acidic centers). The activity maximum, which is observed for all samples in dependence on the Si/Al ratio, could, as in the case of *n*-hexane conversion on the H form of ZSM-5,[9, 10] be attributed to a special

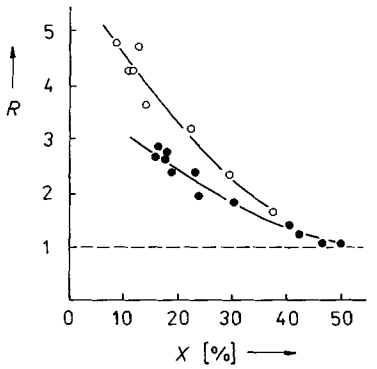

Fig. 2. Ratio R of the *p*-/*o*-xylene formation as a function of the *m*-xylene conversion for Sample 4. o sample dealuminated, not extracted, • sample dealuminated, extracted. Reaction temperature 573 K. Conversion was changed by variation of residence time. – – – thermodynamic equilibrium value at 573 K [12].

interaction of the substrate with Brønsted centers and Al_{ex} species. Since the dependence of the activity on the Si/Al (lattice) ratio of the zeolite does not change, even after extraction of the soluble Al_{ex} species, it is conceivable, as in the case of the substrate *n*-hexane, that insoluble Al_{ex} species are decisive for the modified interaction of the substrate with the active centers. Hence, the following conclusions can be drawn:

1. The modification of activity/selectivity in the isomerization of *m*-xylene is only apparently determined by a blocking or exposure of acidic centers on the internal/external surfaces of the ZSM-5 zeolites.

2. The results of the ethylbenzene conversion confirm the IR spectroscopic[3, 4] and the NH_3-desorption data:[4] an extraction of Al_{ex} neither exposes acidic centers nor leads to the formation of new acidic sites.

3. The modification of activity/selectivity in the isomerization of *m*-xylene is obviously a result of the mass transport influenced by Al_{ex}. This not only concerns the diffusion of the isomers but also the movement of *m*-xylene in the pore system. The reaction takes place in the range of internal diffusion as is suggested by the activation energy for the *m*-xylene conversion.[5] Since *p*-/*o*-xylene values above the thermodynamic equilibrium ratio (Fig. 2) are also observed on the extracted catalysts, the mass transport barriers are still not completely removed with the removal of the acid-soluble Al_{ex} species.

[7] Starting from the NH_4-form of the zeolite, the hydrothermal treatment is accomplished by passage of water vapor (ca. 1.5 mol h^{-1}) at 775 K for the times quoted in Table 1. In the case of shorter hydrothermal treatment an additional calcination was necessary for complete conversion of the NH_4-form into the H-form. The H-form of the non-dealuminated sample was prepared by thermal decomposition of the NH_4-form.

Publishers should send brochures or (better) books to the following address: Redaktion Angewandte Chemie, Postfach 101161, W-6940 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

International Encyclopedia of Composites. Volumes 1 and 2. (Six-volume work). Edited by *S. M. Lee*. VCH Publishers, New York/VCH Verlagsgesellschaft, Weinheim 1990. Vol. 1: xvi, 563 pp., hardcover, £ 170.00 (subscription price: £ 156.00).—ISBN 0-89573-731-0/3-527-27947-4. Vol. 2: xii, 524 pp., hardcover, £ 170.00 (subscription price: £ 156.00).—ISBN 0-89573-732-9/3-527-27948-2 (set: 0-89573-290-5/3-527-26852-9)

The field of composites is one of the main research topics of modern materials science. Major advances have been made in the last decade, resulting in a great diversification of this area of research into many different directions. The factors that have led to this are firstly the considerable advances that have occurred in the production of reinforcing fibers with extraordinary mechanical properties, and secondly the development of new matrix materials and special techniques for producing composites reinforced with fibers, platelets and particles. Fundamental studies on the relationships between the properties of the separate components and those of the composite have provided an important stimulus for composites research. In many fields of application the superiority of composites over conventional materials is so great that one can with justification speak of the beginning of a composites era.

The rapid developments in the area of composites have led to a rapid growth in the number of publications concerned with a wide variety of scientific disciplines. The fact that these publications are so widely scattered makes it difficult to monitor the literature effectively and to coordinate the different disciplines and directions of research. Modern composites technology is the result of many diverse contributions from inorganic, organic and macromolecular chemistry, from research on ceramics and metals, and from mechanical engineering and textile technology. This encyclopedia of composites aims to provide scientists interested in this area with a broad and detailed survey of the current state of research and development. It contains contributions from more than 300 experts engaged in a wide variety of research activities, thus ensuring a comprehensive coverage of the many different aspects of research and development.

The topics treated in these first two volumes range from "Acetal Resins and Composites" to "Joining Polymeric Composites: Adhesives". The majority of the 77 contributions are from industrial research laboratories. Consequently the main emphasis is on results of applied research and on practical aspects of the manufacture of composites and their applications in structural components. When one reflects that large numbers of scientists in Europe and Japan are working in the area of composites, it is surprising that about 90% of the articles in this encyclopedia are from the USA, and there is not a single one from Japan. From this standpoint the name "International Encyclopedia" is not entirely accurate. It is also noticeable that even with most of the experts being drawn from the USA it has not always been possible, at least in some of the areas, to engage the services of those with the highest international reputations.

Despite this restricted selection of authors, most of the contributions have a high information content. The work offers a comprehensive overview for the newcomer to the field of composites, while specialists in particular aspects can use it to broaden their knowledge to include areas outside their immediate experience. The bibliographies attached to the individual articles are extensive in some cases, and enable readers to pursue their own special lines of interest within the topics covered. The encyclopedia can be especially recommended for materials research centers that are mainly concerned with applications-orientated work and engineering aspects.

der Universität Marburg (FRG)

General Chemistry. International Student Edition. By *P. W. Atkins*. Scientific American Inc., 1989 (Suppliers: W. H. Freeman, Oxford). 989 pp., paperback, £ 16.95.—ISBN 0-7167-2053-1

If you should happen to come across this textbook in a bookshop or at a book fair, stop and take a look inside it. It will prove worthwhile! As one who appreciates aesthetic presentation you will admire the exemplary typography and the overall arrangement, and as a scientist used to presenting information visually you will take pleasure in the hundreds of impressive color illustrations, ranging from molecular models that convey a three-dimensional picture, through sectional diagrams of industrial plants, to vivid representations of reaction sequences. The many brilliant photographs would justify a book in themselves; they range from the Crab nebula, the planet Earth and the hole in its ozone layer, and the launching of the space shuttle Atlantis, via a picture of a student holding a plastic cube to show the molar volume of an ideal gas, the coloration of a flame by alkali metal atoms, and indicator solutions on both sides of the transition point, through to a Tiffany glass window, the Stanford linear accelerator and electromicrographs of a silicon surface and of the retina of the eye. In short, leafing through this book will reveal an introduction to chemistry for first-year science students which is exemplary in its quality of production and in the care that has been devoted to presenting information in visual form.

The contents are arranged under five main topics: "Matter and Reactions", "Atoms, Molecules and Ions", "Rates and Equilibrium", "The Elements" and "Organic Chemistry". The book as a whole consists of sections headed "Contents in Brief", "Table of Contents", including "Worked Examples", "Preface" with a note "To the Student", then the above-listed sections grouped under "General Chemistry", followed by "Appendix I: Mathematical Information",

"Appendix II: Experimental Data", "Glossary", "Answers to Odd-Numbered Numerical Exercises", and a detailed "Index" with over 3600 entries. Each of the 24 individual sections has a separate title page, its own introduction, a summary at the end and numerous exercise problems.

As a representative example we may take the topic "Atoms, Molecules and Ions" and consider the treatment in detail. This section consists of three chapters headed "Atomic Structure and the Periodic Table", "The Chemical Bond" and "The Shapes of Molecules". The starting point is the structure of the hydrogen atom, whose emission spectrum is described in the context of the total electromagnetic spectrum, and also in relation to the definition of the photoelectric effect and the ionization threshold. After introducing the de Broglie equation and the Heisenberg uncertainty principle, quantum numbers and the related orbital functions are described. A discussion of atoms with many electrons, their effective nuclear charges and their electron configurations leads to the Periodic System of the elements, quoting selected experimental data on atomic and ionic radii, ionization energies and electron affinities to illustrate the points. The distinction between metals and non-metals, classified into s-, p- and d-block elements, is discussed in terms of their characteristic "periodic" properties and reactions. The formation of ion pairs and ionic lattices is then discussed, illustrated by thermodynamic data and with the help of Born-Haber cycles in some cases, together with "variable valence" effects. Covalent bonds are introduced via the octet rule and are described in terms of Lewis structures; these concepts are related to real situations with the help of space-filling molecular models. The topic of bond enthalpies and lengths leads into a detailed discussion of charge distributions (illustrated in some cases by dipole moments). The third chapter—"The Shapes of Molecules"—begins with arguments based on the repulsion between electron pairs. Regrettably, the author has decided against introducing simple point-group symmetries, and instead devotes an unnecessary amount of space to the fictional description in terms of hybridization. The molecular orbital considerations that follow could with advantage have taken symmetry-adapted bonding orbitals as a starting point rather than partially hybridized atomic orbitals. On the other hand one welcomes the correct discussion of diatomic molecules (with $2p_\pi < 2p_\sigma$) and the description of electron delocalization in terms of molecular orbitals, especially for electron-deficient compounds. Altogether the three chapters contain 278 (!) exercise problems. Despite the comments above regarding alternative ways of presenting concepts, the section viewed as a whole is a lucid and unified introduction to the various aspects of the chemical bond, supported by experimental data, and can therefore be recommended for first-year students. It also provides an excellent foundation for the sections that follow dealing with liquids, solids and solutions.

The sections on "General Chemistry", which include those on chemical kinetics, equilibria, acids and bases and electrochemistry, are clearly presented, mainly experimentally orientated, well illustrated, and mostly excellent from a teaching standpoint. In the opinion of this reviewer, and also of other chemists (see, for example, *Chemistry in Britain 1990,* 357), it is in these that the main strength of the textbook lies. Other textbooks competing for acceptance by students will find them difficult to match.

It is less easy to evaluate the later and rather meager chapters of the book, on "The Elements" (divided into those of the s-, p- and d-blocks with a mere 28, 64 and 32 pages respectively), and on nuclear chemistry and organic chemistry, both of which are likewise disproportionately short, with 32 and only 80 (!) pages respectively. The treatment of organic chemistry is certainly too brief, its length being more appropriate to schools than to first-year undergraduate classes. Without going into further detail, however, one can be more positive about the inorganic part. The clarity of the text and the exemplary visual presentation extend throughout the description of the typical compounds of the various elements, and although the examples are few in number they are chosen with a high degree of topicality. Nevertheless, for the next edition of the book, which must certainly already be at the planning stage, it would be desirable to considerably enlarge the coverage of this field. In this way university teachers, who will probably be very pleased with the general chapters, could be relieved of the necessity to recommend in addition a second textbook orientated more towards chemical substances.

To sum up, if you happen to come across this excellent textbook for first-year science students, allow yourself time to have a closer look at it...

Spectroscopy of Matrix Isolated Species. (Series: Advances in Spectroscopy, Vol. 17). By *M. J. Almond* and *A. J. Downs*. Edited by *R. J. H. Clark* and *R. E. Hester*. Wiley, Chichester 1989. xiv, 511 pp., hardcover, £ 111.00.—ISBN 0-471-92170-X

The development of almost every new technique follows a characteristic pattern: the pioneering phase is followed by a period of rapid expansion during which many different laboratories test the limits of the method, then comes a much quieter phase of consolidation. The founding fathers of the technique then go into retirement, their sons are now firmly established, but for the grandsons the technique has become a routine procedure.

This sequence of events applies to matrix isolation spectroscopy. The matrix technique has now become a standard part of the textbooks, and specialists from all over the world have had their seventh successive conference. The doyen of the technique, *Georg Pimentel*, whose pioneering experiments over the last 35 years have had such a great influence and attracted so much interest, died prematurely in the early part of 1989.

This book is the seventeenth in the series "Advances in Spectroscopy". It differs from the normal pattern in being devoted to a single topic, matrix spectroscopy, which is treated by two British authors, *Matthew J. Almond* and *Anthony J. Downs*, in a main text of 185 pages together with many figures. Two-thirds of the book's 511 pages consist of a tabulation of the species investigated between 1977 and 1986, together with a bibliography of 60 pages containing 2250 literature references.

As is so often the case, this is the right book at the wrong time. If it had been published in 1987, or even early in 1988, the impressive and diligent compilation of the bibliography alone would have allowed one to overlook the weak points. However, it has appeared in 1989. In the previous year *David W. Ball* and his collaborators at Rice University in Houston published their excellent "Bibliography of Matrix Isolation Spectroscopy: 1954–1985" (Rice University Press), which is also available as a DBase file on floppy disk. Two years earlier *Martin Moskovits* covered the subject of atoms and small clusters in the book "Metal Clusters" (Wiley-Inter-

science), and the same author in collaboration with *Lester Andrews* published the book "Chemistry and Physics of Matrix-Isolated Species" (North-Holland).

In comparison with these works the weaknesses of the present book cannot be ignored; to the well-informed reader it seems more like a patchwork rug than the product of a single hand. However, even a patchwork rug has its charm.

The introductory chapter (14 pp.) describes the history of matrix isolation; seven of the pages are devoted to a list of all the main books and review articles on the subject, with their titles and the topics covered. Here a disadvantage of the computerized literature searching system becomes apparent: although many obscure papers are cited, some important ones are missing—for example, there is no reference to the book "Cryochemistry" by *Gleb. B. Sergeev* and *Vladimir A. Batyuk* (Mir Publishers, Moscow, 1978), which is the Soviet matrix spectroscopists' "bible". As in many review articles written in the Western world, the coverage of publications originating from the Eastern block is incomplete.

The experimental techniques of matrix isolation spectroscopy have changed little since the publication of the classic works by *Moskovits* and *Ozin* and by *Hallam*. Therefore the second chapter treats the problems of and recent results from the relevant spectroscopic techniques in a condensed form. A three-page table again lists the most important publications. Together with a series of large-format figures the chapter comes to a total of 23 pages.

Chapter 3 (17 pp.) deals with problems of energy transfer in matrices and includes several full-page figures. As a comparison the same topic in the book by *Andrews* and *Moskovits* takes up 33 closely printed pages. The following chapter treats matrix photochemistry in rather more detail; here the authors must be given credit for describing, though briefly and at third hand, the techniques of photolysis in liquid inert gases and flash photolysis with infrared detection that were developed in the early 1980s.

Chapter 5 discusses hydrogen-bonded species and isomerization processes within the matrix, and Chapter 6 deals with ionic and high-energy molecules. The next chapter, on atoms and small clusters, went to press at a time when the subject had already been covered in a book and several review articles. This is probably why the authors decided to confine their discussion to resonance Raman studies of dimers and trimers and to the iron cocondensation experiments of *Margrave*'s group in Houston. Regrettably there is no mention of the studies on bimetallic clusters that were carried out during the period covered by the report.

The subject of Chapter 8, astrochemistry and atmospheric processes, is one on which only a few groups are working. For this reason it is all the more pleasing to find it discussed here, as a striking illustration of the interdisciplinary application possibilities of the matrix technique.

The rest of the book is almost entirely occupied by four tables which list for each species the method of preparation, the spectroscopic detection method, the main results and the literature references. However, the order of presentation seems a little unsystematic. Thus the reader is left to decide whether to search for a desired molecule among the inorganic species (Table 7, 93 pp.), the organometallic species (Table 8, 41 pp.), or the organic species (Table 9, 95 pp.), or possibly even among the molecular complexes (Table 10, 18 pp.). In cases of doubt it is worth trying a permutation (AgCr appears under CrAg, for example), or better still to look in the more clearly arranged matrix bibliography of *Ball* et al. The literature citations, of which there are nearly 2250, numbered in the sequence of the atoms and molecules under discussion, would undoubtedly be more useful and easier to check if a different method of indexing were used, e.g. by first-named author. It remains a mystery why 63 of the references are listed separately in the middle of the book.

Summary: The book is useful subject to certain limitations, but is not very suitable for beginners in matrix isolation spectroscopy. Nevertheless, as part of the "Advances in Spectroscopy" series it has a place in scientific libraries. For the specialist its strength lies in the critical summaries of research results.

Werner E. Klotzbücher [NB 1109 IE]
Max-Planck-Institut für Strahlenchemie,
Mülheim (FRG)

Houben-Weyl. Methoden der Organischen Chemie. Band E 19a, Parts 1 and 2. C-Radikale. Edited by *M. Regitz* and *B. Giese*. Thieme, Stuttgart 1989. Part 1: pp. 1–716; Part 2: pp. 717–1567, hardcover DM 1960.00 (subscription price: DM 1764.00).—ISBN 3-13-218904-9

Supplementary Volume 19 of "Houben-Weyl" is devoted to "low-valency carbon compounds", i.e. carbon radicals, cations and anions together with carbenes. The preparative chemistry of a class of compounds that in most cases cannot be isolated or even observed—can this really be a true "Houben-Weyl"?

As the opening to this new series on methods for the preparation and conversion of reactive intermediates, Volume 19a, Parts 1 and 2, deals with carbon radicals. This is an indication that the editors of Houben-Weyl attach a particularly high importance to these species, which is not surprising in view of the rapid developments that have occurred in free radical chemistry during the last decade, and the considerable stimulus that this has given to organic synthesis and will continue to do in the future. To anticipate the verdict: since the well-proven Houben-Weyl principle of placing applications to preparative chemistry in the foreground, while keeping the treatment of individual compounds in the background, has been consistently applied, the question posed above can be answered with an unequivocal "yes".

The contents of the volume on carbon radicals are divided into three parts. First there is a brief introduction, in textbook style, to the principles and special features of free radical chemistry (*B. Giese*). This is followed by a section on methods for generating free carbon radicals (*J. O. Metzger*). The last section, which is the most important and the most voluminous, describes the conversion of radicals into products belonging to a wide variety of compound classes (C-X: *J. O. Metzger*; C-C: *A. Ghosez, B. Giese, W. Mehl, H. Zipse*).

This book is therefore unusual in the context of the series, not only because it treats species that are characteristically short-lived, but also because it includes a general discussion of the special properties of these compounds and the factors controlling their reactivities and selectivities, in a separate section orientated towards the non-specialist. The introduction outlines general principles for the successful use of free radical reactions in synthesis, briefly referring to elementary methods for generating and detecting free radicals, and listing some values of activation parameters, ESR coupling constants for typical radicals, and half-lives of commonly used initiators; concepts explained include orbital interactions and even "radical clock" reactions.

After a detailed account of C-X homolytic reactions useful for preparing radicals, the long main section details the wide range of applications of free radical reactions in organic synthesis for a great variety of conversions. The very detailed

breakdown into subsections, with sometimes as many as eight levels of subheadings, means that after a little practice one can unerringly find the possible ways of synthesizing a compound of the type R-Y from R-X by breaking bonds and forming new ones. By varying X and Y virtually the entire range of the periodic system is systematically covered; however, the main emphasis is on inter- and intramolecular carbon-carbon linkages. This treatment is clearly orientated towards the needs of the synthetic chemist, whose main interest is in the selective interconversion of functional groups or in the build-up of carbon skeletons. Admittedly the mainly educt-orientated structure of the text is a disadvantage in the latter case, since a product-orientated search can easily lead to confusion owing to the large number of potential precursors. A similarly undesirable effect results from the breakdown into the volume parts, which seems rather arbitrary and causes an unnecessary fragmentation of the treatment of C-C bond formation.

All the subsections are illustrated by clear formula schemes, following the usual high standard of Houben-Weyl. The high utility value is further enhanced by the many tables and experimental protocols; the many individual results that are here cited and evaluated would otherwise only be accessible at the cost of much tedious searching through the original papers. The coverage is unusually up-to-date for such a bulky work; many very recent developments are included, and the literature references extend up to the end of 1988 (and this does not merely apply to the authors' own publications!). The homogeneous presentation of the material, despite the considerable size of the work, is explained by the limited number of authors.

The volumes contain few printing errors (Hun*d*sdiecker? p. 143) and the figures are rich in detail, even though not completely free of errors (e.g. the nonsensical Scheme 2 on page 42). Without wishing to be too petty, the critical comments that follow are offered more with the aim of showing that the reviewer has been conscientious. As an innovation aimed at greater visual clarity, free radical reactive centers have been emphasized in structural formulas by using bold type (**C**·). One has to get used to this device, which can be rather confusing at times, since on the one hand the incoming or departing radical carriers (heteroradicals; R·) are not labeled, and on the other hand the use of bold type for the carbon radical carriers themselves is often not consistently applied (sometimes within single formula schemes, sometimes through entire passages). A similar criticism applies to the use of bold type to emphasize compound names in the text. The statement on page 22 that ab initio calculations on small molecules are nowadays sufficiently reliable to provide an indication of the stabilities of free radicals ("... so vertrauenswürdig, daß ihre Ergebnisse für die Kenntnis von Radikal-Stabilitäten brauchbar sind") is too sloppy and misleading. It would have been desirable to be more specific here, especially since modern computational methods at a sufficiently high level of sophistication have now become more than a mere alternative to experimental measurements for quantitatively determining the molecular properties of transient species and those that are highly reactive and difficult to handle. It is annoying to find that the discussion of the Cope reaction (p. 135), although relevant to the topic, adopts a dubious one-sided position in favor of a diradical mechanism. Also, on the same page, the (singlet) diradical structure for the *Berson* 1,4-diradicals (3,4-dimethylfuran-3′,4′-diyl and 3,4-dimethylthiophen-3′,4′-diyl) is uncritically perpetuated, without referring to the dipolar canonical structures which are at least equally plausible.

As a valuable addition to the chemical literature, this volume it deserves a wide readership. However, the fact that it is in German, in common with the rest of the series, may be a disadvantage, even though the very systematic manner of presentation and the generous provision of formula schemes enable non-German readers to make some limited use of it. Can a publishing house still afford to continue the anachronism whereby, through publishing a work exclusively in German, it reaches only an elite and severely restricted readership? This applies especially when, as in this case, it treats a highly topical subject for which there is (as yet) no equivalent in English.

One can thus sum up by saying that with this volume yet another extremely useful "true Houben-Weyl" has been added to the series; it is of the usual high quality as regards content and production, which of course has its (very high) price. Despite the latter, it should find a place in every good chemical library.

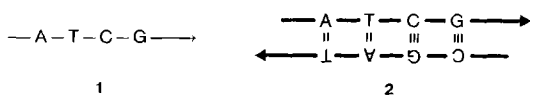
Chemically Modified Oligonucleotides as Probes and Inhibitors

By Uwe Englisch* and Dieter H. Gauss*

Oligonucleotides bind specifically to single-stranded nucleic acids to form a double helix if there is a complementary antiparallel nucleotide sequence. In addition, certain oligonucleotides bind specifically to a variety of proteins. Therefore, biological processes involving these nucleic acids or proteins can be modulated (normally inhibited) by addition of the respective oligonucleotides. The effects of these oligonucleotides and the fields of potential application can be broadened by the introduction of chemically modified nucleotides. For instance, replacing oligonucleotide phosphate groups by methylphosphonates results in the loss of one negative charge per nucleotide and the oligonucleotide becomes more lipophilic. An oligonucleotide carrying a reactive group can modify its binding partner. An oligonucleotide covalently linked to a dye can be localized in a biological specimen. Oligonucleotides attached to an enzyme can be detected in very small amounts since the enzyme can catalyze the formation of large amounts of the substance assayed (e.g., a fluorescent product). An important biochemical application is the detection and localization of a messenger RNA or its gene. Medical applications include the detection of bacterial or viral sequences. There is also great interest in inhibiting the translation of messenger RNA and the transcription and replication of DNA. So-called antisense oligonucleotides are currently being used for the inhibition of protein biosynthesis and of reverse transcription of retroviruses.

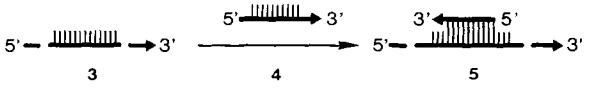
1. Design, Synthesis, and Testing of Modified Oligonucleotides as Therapeutic Agents: Psoralen-modified Oligonucleotides

Double-stranded nucleic acid is generally considered to be in an arrested state in a living cell. In contrast, single-stranded RNA and DNA usually undergo active processing; for example, DNA is replicated and transcribed and RNA, as messenger RNA, is used as template for protein biosynthesis. Oligonucleotides of complementary and antiparallel sequence can bind to these single-stranded tracts (e.g., **1**),



1 **2**

establishing new double-helical tracts (**2**) via Watson–Crick base-pairing (**3** + **4** → **5**).



This binding obviously can find two different applications. Labeled oligonucleotide allows detection of the complementary sequence in solution. In addition, the complementary sequence can be localized in an extract, a cell, or a tissue. Thus, oligonucleotides can be used for identification of specific sequences. Oligonucleotides can also be used for inhibition. In this case the function of a single-stranded sequence is decreased or totally suppressed as the single-stranded region is converted into an inactive double strand. This principle of regulation occurs in nature, where the regulatory agent is usually called antisense RNA (for reviews

see Refs. [1–6]); correspondingly, synthetic products that mimic this sort of regulation are called antisense oligonucleotides.

However, the use of synthetic, unmodified oligonucleotides in living cells to mimic antisense RNA faces the following obstacles:

1. Oligonucleotides, which carry one negative charge per phosphate group, do not easily pass through the mainly lipophilic cell membrane.
2. In cells many nucleases rapidly degrade oligonucleotides.
3. The stability of a duplex formed from an RNA or DNA tract and an oligonucleotide of medium chain length is not very high; thus, the half-life is often considerably lower than desired.

1.1. Modified Oligonucleotides

Whereas unmodified oligonucleotides have not proven very successful in modulating biochemical processes in living cells (for reviews see Refs. [7–9]), chemically modified oligonucleotides should be able to surmount the above-mentioned obstacles.

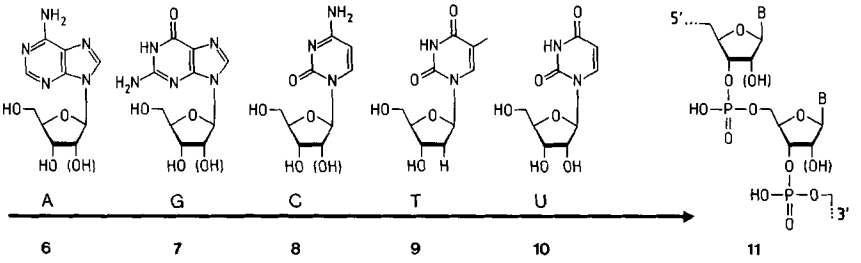
1. Increasing the hydrophobicity of an oligonucleotide should improve its uptake since membranes largely consist of lipids and lipophilic proteins. On the other hand, high lipophilicity could destroy the antisense activity owing to tight binding of the oligonucleotide in the cell membrane or any other lipophilic cell compartment. Moreover, an oligonucleotide must be sufficiently water soluble both outside and inside the cell.
2. Since nucleases cleave the sugar-phosphate backbone of an oligonucleotide, suitable modifications of these moieties could increase the stability toward nucleases. For example, cleavage of the internucleotide link could be prevented by modification of the ribose or phosphate moiety. Alternatively, access of nucleases to the internucleotide link could be sterically hindered by a bulky group. However, since the nucleobases can also strongly influence the structure of a nucleic acid, even nucleobase modifications can decrease cleavage by nucleases.
3. Upon hybridization of two complementary sequences (for reviews see Refs. [10, 11]), the formation of each hydrogen bond and the stacking of each nucleobase releases a small amount of energy. The total energy determines the stability of the double helix. The stability varies only slightly for formation of a "ribo" or "deoxy" duplex (homo duplex) or a hetero duplex. (Therefore, most of the experiments mentioned can be done with ribo- and deoxyoligonucleotides. In general, deoxyoligonucleotides are easier to prepare and handle). Stable duplexes are not formed with short oligonucleotides, and long oligonucleotides have the tendency to bind unspecifically. With oligonucleotides of appropriate length, oligonucleotide binding may depend on only one additional or missing nucleotide or on only one mispair. In these cases physical parameters such as temperature and ionic strength play an important role. Under physiological conditions double-helical stretches longer than about 15 base pairs are quite stable; under extraordinary conditions double-helical regions containing only five base pairs are sometimes stable. Hybridization can be modulated by chemically modifying the oligonucleotide; for example, changes in the nucleobases can improve pairing or stacking, and intercalating substituents can be tethered to the oligonucleotide. Ultimately, the use of an appropriately substituted oligonucleotide may result in covalent linkage between the two strands of a duplex. It is essential, however, that the additional energy (for example, that released on intercalation) not be so high that the sequence-dependent hybridization becomes negligible.

Uwe Englisch, born in 1954 in Oldenburg, studied biochemistry at the University of Michigan, USA, and chemistry at the Universität Göttingen. He received his doctorate in 1983 under F. Cramer. Since 1984 he has been employed at the Max-Planck-Institut für experimentelle Medizin, where he has been a group leader since 1987. His fields of interest are the molecular biology and biochemistry of transfer RNA as well as the synthesis and application of modified oligonucleotides in molecular biology.

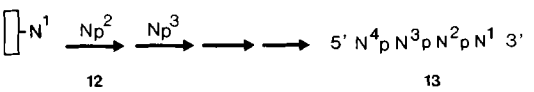
Dieter Gauss, born in 1933 in Stuttgart, studied chemistry and medicine at the Universität Tübingen and received his doctorate in biochemistry in 1967 under G. Weitzel. Since then he has worked in the chemistry department (director: Prof. Dr. F. Cramer) at the Max-Planck-Institut für experimentelle Medizin. His regular duties include library and information technologies.

1.2. Synthesis

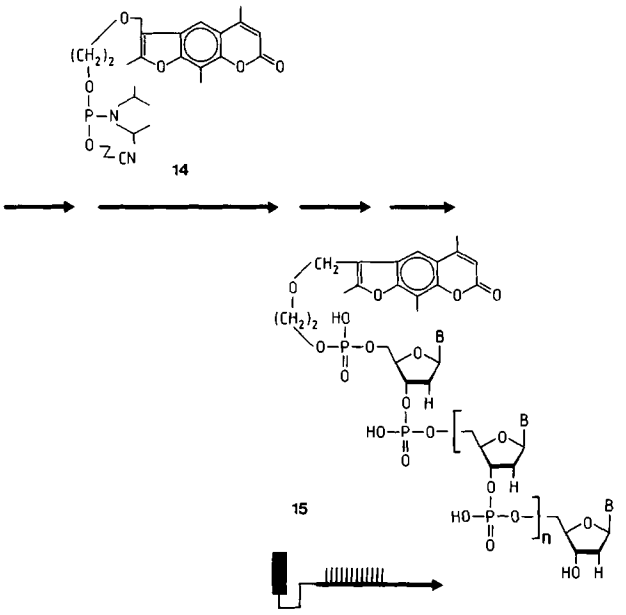
Oligonucleotides (**11**) can be synthesized (using several protocols) by commercially available automated synthesizers starting with suitably phosphorylated, protected, and activated nucleosides (**6**–**10**) (for reviews see Refs. [8, 12–17]).



The syntheses of modified oligonucleotides do not require major changes in the normal automated elongation steps. One of the usual nucleotide building blocks can be replaced in any given synthesis cycle by a modified nucleotide derivative. This derivative can bear the desired modification or may be an intermediate which is converted into the final product later on. In the simplest case only the last step of an oligonucleotide synthesis requires a modified substance, as exemplified by one of the syntheses of psoralen-modified oligonucleotides.[18] Typically, the oligonucleotide is elongated according to the phosphoramidite method on a solid support in the 3'-to-5' direction (**12** → **13**). Compound **14**, a



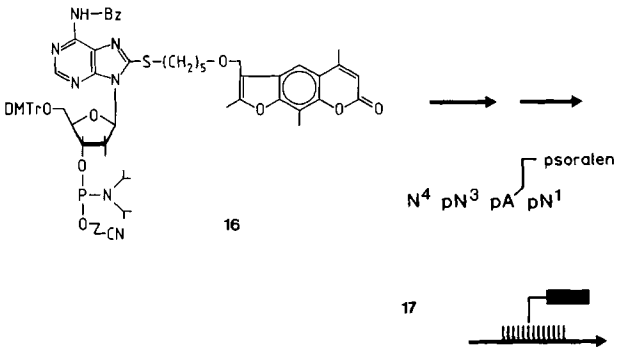
derivative of 4,5',8-trimethylpsoralen, is used instead of a nucleotide derivative in the last step. Cleavage of the product from the solid support and cleavage of the protecting groups yields the psoralen-modified oligonucleotide **15**.[*]



[*] All psoralen-modified compounds discussed here contain the psoralen derivative shown in **14**–**16**.

Another preparation of psoralen-modified oligonucleotides (**17**) uses the adenosine derivative **16** in a phosphoramidite solid-support synthesis.[19]

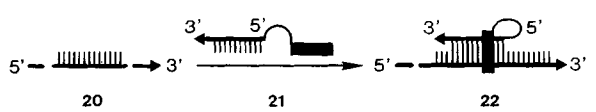
Thus, any adenosine in a sequence can be replaced by the psoralen-modified adenosine. Additional protocols describing covalent psoralen–oligonucleotide couplings[20–22] use other building blocks and synthetic schemes, although essentially the same as those described above.



1.3. Psoralen and Psoralen-modified Oligonucleotides

Psoralen is found in plant extracts that have been used for 3000 years to treat skin and tumor diseases (for reviews see Refs. [23–25]). Psoralen intercalates between two base pairs of DNA as shown by **18**, thereby inhibiting transcription and replication of DNA. Upon irradiation of this adduct with UV light (300–400 nm) psoralen can form covalent linkages to neighboring thymidines (see **19**) through both the furan and pyran moiety; thus, the inhibitory effect is long-lasting.

Psoralen-modified oligonucleotides (**21**) are expected to be considerably better drugs than psoralen (which obviously binds to DNA unspecifically), since hybridization of the oligonucleotide to the complementary sequence (**20**) places the psoralen at a specific position in the DNA (see **22**). This DNA tract should then be inactivated. A potential application would be the inactivation of a DNA tract known to be transcribed in tumor cells but not in nontransformed cells.



In vitro experiments have shown that this strategy is reasonable. After hybridization, a psoralen-modified oligonucleotide and its complementary oligonucleotide (see **23**) were

23

covalently linked by irradiation. As expected, the covalently linked oligonucleotides remain together under denaturing chromatographic conditions.[18, 19] The inhibition of transcription and translation by psoralen-modified oligonucleotides has also been described.[20, 21, 26, 27]

Especially important is the length of the linker between the substituent (e.g., psoralen) and the oligonucleotide. If no linker is there, the substituent has limited flexibility for interaction, whereas a so-called spacer enhances the ability of the substituent to interact with the complementary oligonucleotide. Without a spacer some interactions or reactions are impossible; a well-designed spacer—regularly three to twenty atoms in length—enables a substituent to contact exclusively the desired site. Usually, however, the substituent comes in contact with more than one nucleotide. The subsequent reactions, which involve a characteristic stretch of nucleotides, are classified as having high or low regioselectivity, as symbolized by large or small arrows pointing to specific sites in the complementary oligonucleotide.

Psoralen-modified oligonucleotides exhibit greater hydrophobicity and are expected to be more resistant to nuclease digestion owing to the bulky psoralen residue. Both these properties are increased further in another family of psoralen-modified oligonucleotides where the charged phosphate groups are replaced by uncharged methylphosphonate groups.[20, 21] After hybridization, the length of the spacer governs the possible site of intercalation. In compound **15**, the spacer is eight atoms long; thus, the choice of an intercalation site is limited. The sequence of this oligonucleotide is specifically designed so that, after hybridization (see **23**), the psoralen intercalates between thymine residues where the cross-linking photoreaction can occur (see **23** and **18/19**). The coupling of the two thymine residues to the psoralen can be reversed by UV irradiation (< 300 nm). In addition, if the linker between the psoralen and the oligonucleotide contains a disulfide bridge, this bridge can easily be cleaved by a standard reduction procedure.[22]

1.4. Modified Oligonucleotides as Substrate Analogues

A third way of applying modified oligonucleotides is to use them as substrate analogues for nucleases, polymerases, and other enzymes or to use them to bind proteins. For these studies the oligonucleotides need not be in a single-stranded form but can be used as duplexes. Thus, possible applications include investigations of reaction mechanisms (e.g., those of restriction endonucleases), labeling (e.g., upon sequencing), and modulations of regulatory cycles.

1.5. Literature

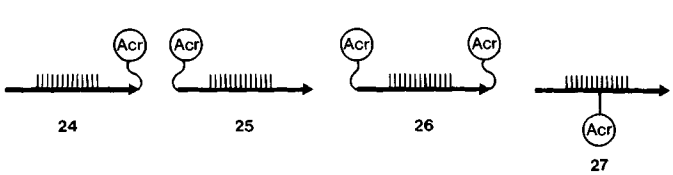
Oligonucleotides—with or without chemical modification—are the subject of more than 3000 publications. Thus, unmodified and modified oligonucleotides have been reviewed critically several times. For instance, their chemistry,[7, 9] their role in enzymatic replication,[28] their inhibition of gene expression in extracts as well as in cell cultures,[9, 29–35] and their application as antineoplastic drugs has been reviewed.[36–38] Also, their use to identify nucleic acids and proteins[39] and their application in medical diagnosis have been discussed critically.[40] In this article we report on those fields with publications in recent years (up to the middle of 1990). Even with this restriction only selected citations can be given. The reader may refer to other publications, in particular several comprehensive reviews.[7, 9, 30–35, 37–40]

2. Inhibition of the Function of RNA and DNA by Modified Oligonucleotides

Psoralen-modified oligonucleotides, which were used as examples in the introduction, are a subgroup of oligonucleotides designed for inhibiting the function of RNA or DNA. Numerous other subgroups of potentially inhibitory oligonucleotides exist. In this article the following five examples are dealt with: (1) acridine oligonucleotides, which belong to the group of oligonucleotides bearing intercalators (for a review see Ref. [41]), (2) modified oligonucleotides able to establish a covalent linkage to the complementary strand (or to a protein), (3) modified oligonucleotides equipped to cleave the complementary strand, (4) oligonucleotides carrying tumor-inhibiting platinum complexes, and (5) oligonucleotides potentially inhibiting virus proliferation.

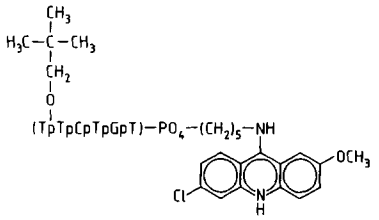
2.1. Acridine-modified Oligonucleotides

Acridine oligonucleotides (for reviews see Refs. [42, 43]) are comparable to psoralen oligonucleotides in that the acridine moiety is also able to intercalate. Since acridine is similar in size and chemical properties to psoralen, the amount of energy released upon intercalation of acridine is also similar to that of psoralen. In contrast, reversible photoreaction occurs only with psoralen. The acridine moiety (normally derived from 9-amino-6-chloro-2-methoxyacridine, see **28**) can be linked to several different sites of an oligonucleotide, following one of the standard coupling procedures; possible sites are the 3'-phosphate (**24**),[44] the 5'-phosphate (**25**),[45, 46] both phosphates (**26**),[45] and an internal phosphate (**27**).[45, 47] In each case the reactive group of



acridine is the amino moiety. The binding of these oligonucleotides to nucleic acids and the intercalation of the acridine residue are well documented by NMR[48, 49] using short nucleic acid fragments. A typical example is compound **28**,[48]

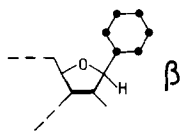
which is modified by a neopentyl residue to render the oligonucleotide more lipophilic and to inhibit nuclease attack by steric hindrance.[48] Besides compound **28** there are



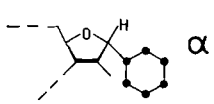
28

further acridine oligonucleotides with a second modification, such as phosphorothioate groups[46, 50] or 3′-phosphate triesters carrying an additional positive charge[51] or a photoreactive group.[52] These acridine oligonucleotides exhibit biological activity in several assays (e.g., the inhibition of translation of β-globin mRNA[46, 53] or trypanosomal mRNA[54]). Furthermore, the proliferation of certain viruses, such as influenza virus[55] and simian-40 virus,[52] and of bacteriophages[56] is inhibited. Acridine oligonucleotides not only bind to nucleic acid single strands to form duplexes but can also bind to double-stranded DNA yielding triple helices[52, 57] (see Section 5). In these cases, the acridine is also known to intercalate between the nucleobases.

The stability of acridine oligonucleotides towards digestion by cell nucleases dramatically increases when the oligonucleotide is synthesized from the α anomers of nucleosides (**30** instead of **29**).[58–61] Because of the increased stability toward nucleases, the inhibitory potency of these substances also increases.[62]



29



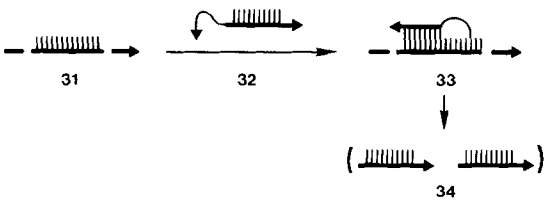
30

In normal nucleic acid duplexes, with both strands consisting of β anomers, the strands are base-paired in an antiparallel direction. In duplexes where one strand consists of α anomers and the other strand contains β anomers, the strands are base-paired in the parallel direction.[58, 61] These duplexes can be quite stable, in particular the one formed between an α-deoxyoligonucleotide and β-RNA; however, the stability is also sequence-dependent.[63] The disadvantage of α-oligonucleotides (and of methylphosphonate oligonucleotides as well) is that they do not activate RNase H[62] (see Section 2.4). Thus, the inhibitory effect rests solely on duplex formation and there is no enzymatic hydrolysis of the complementary RNA strand.

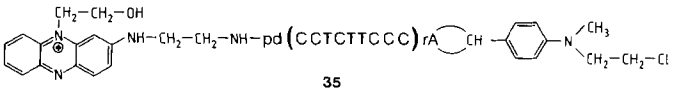
Oligonucleotides containing α anomers of nucleosides have not only been described for acridine oligonucleotides (for a review see Ref. [64]).[65–68] Antisense α-oligonucleotides, without a second modification, are reported to inhibit the reverse transcription of human immunodeficiency virus,[65, 66] the synthesis of β-globin,[67] and the cleavage of RNA by RNase H.[65, 68] In another group of substances, similar to acridine α-oligonucleotides, oligonucleotides of α anomers are coupled with a second functional agent, such as proflavin,[69] or are modified with a *p*-azidophenacyl group.[61, 70] Both of these oligonucleotides can undergo photochemical cross-linking reactions (see Section 2.2).

2.2. Covalent Linkage of Modified Oligonucleotides with the Complementary Strand

Another possibility to increase the inhibitory effect of hybridization of an oligonucleotide to an RNA or DNA single strand is to modify the oligonucleotide (**32**) so that, after hybridization, a covalent linkage to the complementary strand is formed (**31** + **32** → **33**). Thus, the resulting duplex has a long life (for reviews see Refs. [71, 72]).



A typical oligonucleotide is **35**;[73] the alkylating functional group is tethered to the oligonucleotide via the 2′- and 3′-hydroxyl groups of the 3′-terminal ribose. The 5′-phenazinium group is incorporated to improve the binding after hybridization but prior to covalent linking (compare Section 2.1). Oligonucleotides of this sort can inactivate the function of single-stranded DNA,[74, 75] of double-stranded DNA,[76] and of phages or viruses.[73] Most frequently, alkylation of a guanine nucleobase of the target nucleic acid occurs, followed by strand breakage (**33** → **34**).[73, 75] Instead of a phenazinium moiety, a cholesterol moiety can be tethered to such oligonucleotides;[77] the uptake into cells is thereby considerably improved, whereas hybridization and binding do not change dramatically.



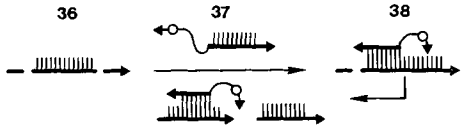
35

There are many other functional groups that allow analogous linking reactions (e.g., the *p*-azidophenacyl group,[61, 70] the proflavin residue,[69] the azidoproflavin residue,[78] a 5-azido-substituted uridine residue,[79, 80] a 5-methyl-N^4,N^4-ethanocytidine residue,[81] and a naphthoquinone derivative[82]). The first four groups and the last group require irradiation for cross-linking to occur, similar to the psoralen oligonucleotides (see Section 1.3). Finally, a nucleic acid strand and a (modified) oligonucleotide can become covalently linked by a third compound, such as a platinum complex.[83] A modified oligonucleotide may also be covalently linked to a protein.[79, 84–86] This cross-linking is reversible if the modified oligonucleotide is linked via a disulfide bridge to a cysteine of the protein.[86]

If they can be developed up to the stage of drugs, these reagents are expected to exhibit the most intensive and long-lasting inhibition, for example towards viruses.

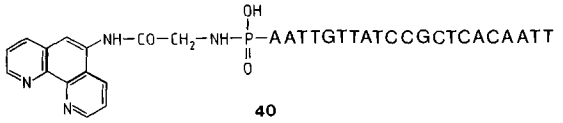
2.3. Cleavage of the Complementary Strand by a Modified Oligonucleotide

Another possibility to prolong the inhibitory effect due to hybridization of an oligonucleotide to a nucleic acid strand rests on triggering a strand break in the complementary strand (**36**). This can be effected by activating a nuclease within the cell (see Section 2.4)—the duplex that forms then has to fulfill certain structural requirements—or it can be effected by the oligonucleotide itself. In the simplest case a cleaving enzyme is linked to an oligonucleotide (**37**),[87, 88] for example a ribonuclease to a deoxyoligonucleotide; following hybridization (see **38**), the enzyme cleaves the complementary RNA strand (see **39**). There is another group of reagents effecting the cleavage of the complementary strand by a complexed metal ion linked to the oligonucleotide through a spacer.



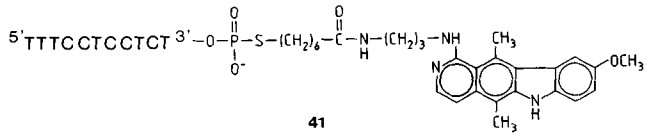
39

Oligonucleotides bearing iron porphyrin complexes[89, 90] or iron EDTA complexes[91–93] can cleave single-stranded DNA[89–94] or RNA (porphyrin;[94] EDTA[95]). Additionally, double-stranded DNA can be cleaved by an iron EDTA complex via triple-strand formation.[96–98] Furthermore, a copper phenanthroline complex has been attached as reactive moiety to an oligonucleotide to cleave single-stranded DNA[99, 100] and RNA[101] and double-stranded DNA,[102] a typical example being compound **40**.[101]



40

These metal-catalyzed cleavage reactions do not cleave in *one* step to *one* well-defined product. Rather, secondary reactions and side reactions are observed. Therefore, a therapeutic application in living cells does not seem possible. Strand cleavages of the complementary strand also can originate from completely different reactions, namely, those following photochemical reactions and/or various alkylation reactions.[7, 61, 69, 70, 78, 103, 104] Ellipticin oligonucleotides (**41**)



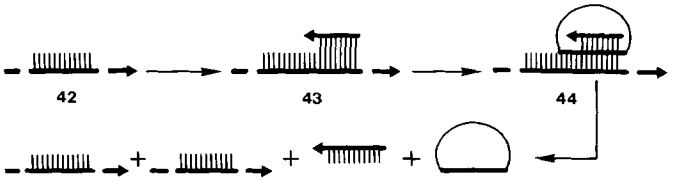
41

are reported to cleave both strands of a double-stranded DNA, a triple strand being the reactive intermediate.[104]

An important application of this type of cleavage reaction would be the preparation of artificial specific endonucleases capable of cutting single strands of RNA or DNA at specific internucleotide bonds. Natural restriction endonucleases need double-stranded DNA as substrate and the enzyme needed for cleavage at a specific site is often not available. Specific RNA cleaving enzymes are generally not available. Since gene technology requires the cleavage of nucleic acids with high selectivity, such artificial scissors need considerable improvement to be applicable.

2.4. Cleavage of the Complementary Strand by RNase H Triggered by a Modified Oligonucleotide

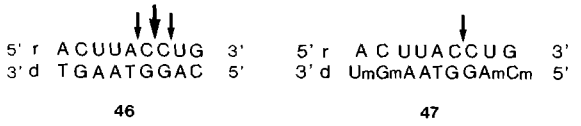
Scission of only one strand in a duplex occurs in biological processes such as repair events, in which a stretch of one strand is excised and the gap is refilled, or initiation of replication, after which the primer, a ribooligonucleotide, is digested separately. In each case the structure of the duplex, which deviates from that of a normal duplex, triggers an enzyme. Therefore, hybridization of an oligonucleotide to a single strand (or to a double strand with a single-strand tract) might mimic such a structure. For instance, a naturally occurring enzyme might be triggered to cleave a phosphodiester bond at a certain nucleotide, which would depend on the sequence of the oligonucleotide used. An example is RNase H, which cleaves RNA after hybridization of the RNA single strand (**42**) with a deoxyoligonucleotide (**42** → **43** → **44** → **45**).



45

This sort of cleavage can be effected with unmodified deoxyoligonucleotides[105–108] and with some modified oligonucleotides (e.g., phosphorothioate oligonucleotides). However, methylphosphonate oligonucleotides and phosphoramidate oligonucleotides (or oligonucleotides containing longer tracts of these groupings) do not stimulate cleavage by RNase H.[107, 108] Another series of modified oligonucleotides able to trigger RNase H cleavage are constructed in a nonuniform manner in order to direct the cleavage of the complementary strand to one specific internucleotide bond. Such oligonucleotides have a ribo part and a deoxy part, linked in some cases by a pyrophosphate group instead of a phosphate group[109] or they contain a longer 2′-O-methylated ribo part followed by a short deoxy sequence.[110] Furthermore, a deoxy sequence containing two to four nucleotides can be inserted into a ribooligonucleotide[111] or either a methylphosphonate oligonucleotide[112] or a phosphorothioate deoxy stretch can be placed in a methylphosphonate oligonucleotide.[108] These oligonucleo-

tides for the most part cleave one specific internucleotide bond. This is particularly evident in **46** and **47**. When 2′-*O*-methylribonucleotides (**47**) instead of deoxynucleotides (**46**) flank the central deoxyoligonucleotide stretch,[113] cleavage occurs at only one internucleotide bond.

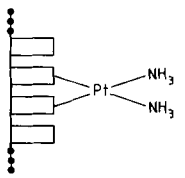


46 **47**

These enzymatic cleavage reactions at any desired internucleotide bond appear particularly promising for application in molecular biology and gene technology (see Section 2.3). Finally, it should be mentioned that most of the anti-messenger oligonucleotides do not only inhibit by hybridization but also by activating RNase H.

2.5. Antineoplastic Platinum Compounds

Cisplatin, *cis*-$[Pt(NH_3)_2Cl_2]$ (for a review see Ref. [114]) and some other platinum compounds[115] are used as antineoplastic drugs, although their detailed mechanism is still unknown. These platinum compounds form DNA adducts (without intercalation), binding especially to two neighboring guanosine residues of one strand, thereby bending the DNA.[116–120] In a model experiment an oligonucleotide containing two neighboring guanosine residues was allowed to react with cisplatin to give an oligonucleotide containing the stretch *cis*-$[Pt(NH_3)_2dGpG]$ (see **48**) and then cloned into DNA. The function of the platinum-carrying single strand was largely suppressed,[121] thus indicating that such inhibition could be the mechanism of the antineoplastic platinum compound.

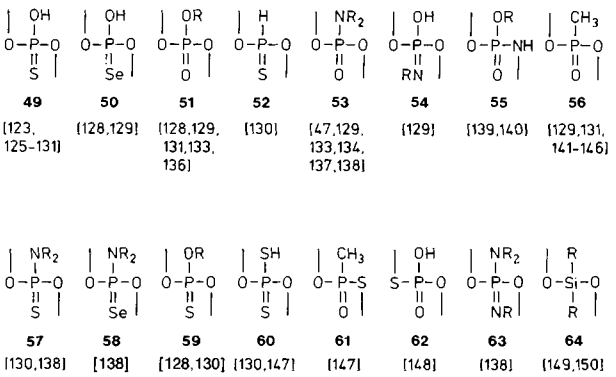


48

There are other examples of nucleic acids being bent by agents or chemical modifications such as the formation of thymine dimers (see Section 4.2) in DNA. Unmodified DNA, too, can be bent, in particular when it contains A·T stretches, the A_n sequences of which lie on one side of the helix (see Sections 4 and 5). The bending plays an important role for DNA structure and function (not discussed here).

2.6. Modified Oligonucleotides as Potential Inhibitors of Virus Proliferation

The inhibition of gene expression by modified oligonucleotides has been mentioned above and also has been reviewed elsewhere in terms of substances[122, 123] or effects[35, 43, 124] (e.g., inhibition of oncogene expression[36]). In this article the structure and function of some antiviral oligonucleotides will be discussed. Since phosphate-modified oligonucleotides are of particular interest, a compilation of some important and/or recently published classes of phosphate-modified oligonucleotides is given (**49**–**64**). These compounds range from substances with only one atom exchanged (e.g., phosphorothioates) to those in which the whole sugar-phosphate backbone is replaced by another backbone (not discussed here).



49	**50**	**51**	**52**	**53**	**54**	**55**	**56**
[123, 125–131]	[128,129]	[128,129, 131,133, 136]	[130]	[47,129, 133,134, 137,138]	[129]	[139,140]	[129,131, 141–146]

57	**58**	**59**	**60**	**61**	**62**	**63**	**64**
[130,138]	[138]	[128,130]	[130,147]	[147]	[148]	[138]	[149,150]

The oldest, and perhaps most important, class of phosphate-modified oligonucleotides comprises phosphorothioate oligonucleotides (**49**) (for reviews see Refs. [123, 125–127]).[128–131] Like natural nucleic acids, these substances have one negative charge per nucleotide unit. In contrast, methylphosphonates (**56**) have lost this charge and therefore pass more easily through cell membranes. The properties of oligonucleotides are still more fine-tuned in some oligonucleotides, such as those with CHF_2 instead of CH_3 groups.[132] In some cases the modification changes the whole character of the oligonucleotide; examples include triesters (**51**) in which the substituent is lipophilic[133] or, for amidates (**53**), carries a positive charge ($R = -X-NR_3^{\oplus}$)[133, 134] or can bear a group suitable for intercalation.[47] Exchange of an oxygen atom belonging to the backbone can be carried out either 5′ or 3′ to the phosphorus atom (**55**, **61**, **62**). The Si-containing substances (**64**) are one simple example of the large family of non-phosphorus-containing compounds (not reviewed here).

Replacing one of the nonbridging oxygen atoms of phosphorus with CH_3 or SH, for example, creates a new stereogenic center. With n modified centers one obtains 2^n isomers. These isomers are distinguished by enzymes. On hybridization, these isomers bind differently to the target sequence (a substituent may protrude into the major or minor groove of the resulting duplex) and hence the stability of the duplexes and their biological activity differ. For these reasons stereoselective syntheses of modified oligonucleotides (for reviews see Refs. [7, 39, 135]) have been developed and the biological activities of the isomers have been tested separately (not reviewed here).

A considerable number of modified oligonucleotides have been tested as inhibitors of the proliferation of HIV (human immunodeficiency virus) or of other viruses and phages. They were first tested in an in vitro assay to determine whether the formation of viruses or phages or subparticles

thereof was diminished or whether the expression of a single viral protein was inhibited. Inhibitory effects were found for the following oligonucleotides: acridine oligonucleotides towards T4 phages,[56] polylysine oligonucleotides towards vesicular stomatitis virus (VSV),[151,158] methylphosphonate oligonucleotides towards VSV, simian-40 virus (SV 40), and herpes viruses,[144,152] and phosphorothioate oligonucleotides towards herpes viruses.[153] Analogous effects against HIV were found using phosphorothioate oligonucleotides[154,155] and oligonucleotides containing α anomers[65,66] (see Section 2.1). The phosphorothioate oligonucleotides have proven to be less toxic and more inhibitory than the corresponding seleno oligonucleotides.[156] An inhibitory effect against HIV[66,154,155] and herpes viruses[153] was also detected using S-dC-28, a phosphorothioate-containing deoxyoligocytidylic acid (and some further related modified homooligonucleotides[137]). This is surprising since there is no complementary sequence in the virus for these oligonucleotides. In these cases the reverse transcriptase or viral polymerase seems to be the target for the oligonucleotide. Inhibitory transcription initiation complexes, not formed according to the antisense principle, are probably involved here. Nonetheless, this is very interesting since reverse transcriptase does not exist in normal eukaryotic cells and is therefore a suitable target enzyme for drugs.

The second step towards drug development is to assay potential antisense oligonucleotides in cell cultures. Two viral systems, HIV and VSV, have been rigorously tested. In addition, the inhibition of influenza viruses by acridine oligonucleotides,[55] of herpes viruses and SV 40 viruses by methylphosphonate oligonucleotides[144,157] and acridine oligonucleotides,[52] and of coliphages by alkylating oligonucleotides[73] has been investigated. Methylphosphonate oligonucleotides,[144,152] polylysine oligonucleotides,[151,158–160] and lipid-substituted oligonucleotides[161] have proven effective against VSV. Towards HIV, in cell culture, an inhibition was found for deoxyoligonucleotides with phosphoramidate,[137,162] phosphorothioate,[137,162–165] or methylphosphonate groups.[162] Similar results were found for oligonucleotides carrying polylysine moieties[166] and for ribooligonucleotides with phosphorothioate or 2′-*O*-methyl groups.[167] In these cases the oligonucleotides are complementary to viral sequences and it is well established that the inhibition is the result of antisense effects. Oligonucleotides (with or without phosphorothioates) carrying a cholesterol moiety exhibit considerable anti-HIV activity. However, this activity is not due to the antisense principle.[168] Comparison of unmodified and phosphorothioate-modified oligonucleotides that contained antisense sequences and random sequences clearly showed that antisense phosphorothioate oligonucleotides are the most powerful agents[165] in accordance with earlier studies.[73,157,167]

Although antiviral effects have been demonstrated unambiguously, their origin is still largely unclear—at least two mechanisms, one following the antisense principle and another based on the initiation of transcription are involved. Perhaps still more mechanisms will emerge. To date, modified oligonucleotides have not been used clinically; however, clinical trials have been started. Once found, an inhibitory system will probably be adapted for use against additional viruses. Formula **65** shows part of a methylphosphonate oligonucleotide.[144] Suitable combinations of phosphate (p) and methylphosphonate (p) groups, as shown by the oligonucleotides **66**, should allow the oligonucleotide properties (e.g., hydrophobicity and charge distribution) to be modulated in order to obtain antiviral drugs.

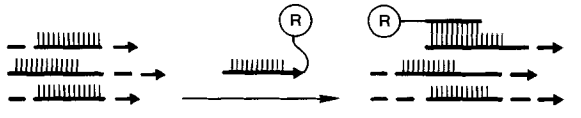
66

A promising modification to improve uptake into cells is the linkage of polylysine moieties to potentially virus-inhibiting oligonucleotides;[151,158–161,166] for example, $lysine_{100}$ was attached to an oligonucleotide containing 15 nucleotides.[159] These oligonucleotides exhibit good inhibitory activity in cells infected with VSV[151,158–161] or HIV.[166] In some cases, however, they were found to be toxic. Oligonucleotides coupled with peptides of nonuniform sequence have also been prepared[169,170] but their antiviral application has not yet been fully investigated.

Derivatives of 2′-5′ oligoadenylates are a separate class of antiviral substances which will not be discussed further here. They do not act according to the antisense principle (for reviews see Refs. [171,172]).[158,173,174]

3. Identification and Localization of RNA or DNA Sequences with Modified Oligonucleotides

The presence of a certain RNA or DNA sequence can be determined by hybridizing a complementary oligonucleotide to it. The oligonucleotide—after separation from unbound oligonucleotide—is recognized via a label. Unmodified oligonucleotides (for reviews see Refs. [39,175–179]) are radioactively labeled and modified oligonucleotides, in the simple cases, are substituted with a colored, chemiluminescent, or fluorescent marker (**67** + **68** → **69**). Suitable sub-

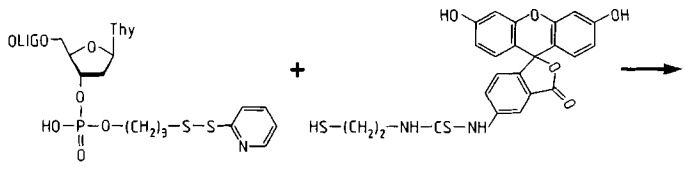


67 **68** **69**

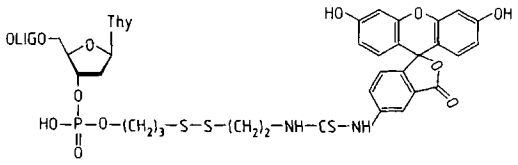
stituents used for this purpose are fluorescein,[180–187] isoluminol,[180] rhodamine compounds,[180,188] a ruthenium bathophenanthroline complex,[189] and a pyrene derivative.[182] The linkage of the dye (e.g., **71**) to the oligonucleotide can be accomplished in many ways, for example via the 3′-phosphate (**70** + **71** → **72**).[183] After detection of a given

RNA or DNA sequence, it can be immediately isolated by known procedures.[39, 179]

Another approach is to attach antigenic groupings to the oligonucleotide. After hybridization of the oligonucleotide to the target sequence, binding of the antibody to the oligonucleotide, and suitable staining, the target sequence



70 71

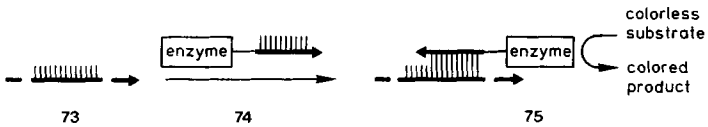


72

can be visualized by electron microscopy. This protocol was used, for instance, to pinpoint some ribosomal areas via the antigenic determinants 2,4-dinitrophenyl and isopentenyladenosyl.[190, 191]

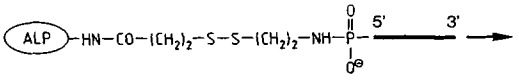
3.1. Enzyme-linked Oligonucleotide Probes

Enzyme-linked oligonucleotide probes can be used for the recognition of an RNA or DNA sequence with high precision, comparable to that of radioactively labeled compounds. The enzyme is designed to multiply a signal, such as the production (or disappearance) of a colored or fluorescent product (**73** + **74** → **75**). The enzyme can be linked to the

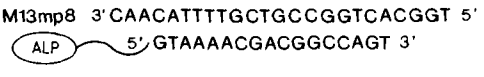


73 74 75

oligonucleotide directly or, alternatively, the enzyme can be linked to any agent which immediately or in situ binds to the enzyme. In the first case an enzyme and an oligonucleotide might be linked through a bifunctional reagent[192–197] or by UV irradiation;[198] normally, a spacer of about 30 atoms in length is used. Compound **76**[196] is an appropriate example, where the oligonucleotide was constructed to hybridize to a sequence of phage M13mp8 (see **77**).



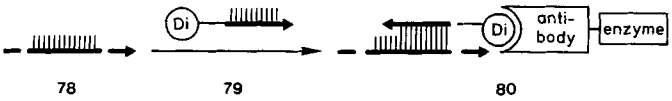
76



77

In this case alkaline phosphatase (ALP) is linked to an oligonucleotide (**76**). After hybridization, the ALP-catalyzed degradation of *p*-nitrophenyl phosphate to *p*-nitrophenol allows colorimetric detection of the phage sequence.[194–196] Alternatively, alkaline phosphatase can initiate the formation of a dye of 5-bromo-4-chloroindolyl phosphate (BCIP) and nitroblue tetrazolium (NBT),[193, 196] also assayed colorimetrically. This enzyme can also cleave 4-methylumbelliferone phosphate, which releases a fluorescent product.[193, 194, 196] When peroxidase is used as oligonucleotide-linked enzyme, dye formation from the reaction of *o*-phenylenediamine and hydrogen peroxide is assayed.[180]

The enzyme need not be linked directly to the oligonucleotide. Instead, the oligonucleotide can be coupled to any agent which in situ binds the enzyme. The antibody variation of this system requires that the oligonucleotide carry an antigenic substituent such as digoxigenin,[199, 200] 5-bromo-2′-deoxyuridine,[201] fluorescein,[181] or DNA protein A.[198] An antibody linked to the enzyme then binds to the antigenic group and the enzyme generates a signal (**78** + **79** → **80**).

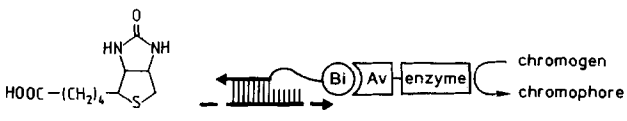


78 79 80

Among these assay systems, the most widely used is the system biotin–(strept)avidin (see Section 3.2).

3.2. The System Oligonucleotide–Biotin–Avidin–XXX

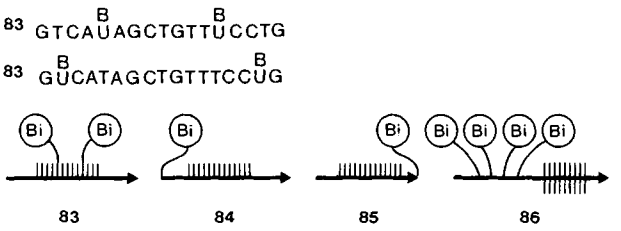
Biotin-linked oligonucleotides in solutions, extracts, or tissue specimens form very tight and specific aggregates of the biotin group (**81**) and the protein avidin or streptavidin. Avidin can be easily coupled to further agents suitable for recognition, such as alkaline phosphatase or peroxidase (see **82**). In either case a chromogen is converted into a chromophore or vice versa (see Section 3.1).



81 82

The linking of biotin (Bi) to an oligonucleotide—normally through a spacer of about 10 atoms—can be accomplished chemically or enzymatically. In a simple protocol biotin and the oligonucleotide are linked unspecifically through a bifunctional reagent[202] or photochemically.[203] Most of the coupling procedures published, however, form specific linkages so that the number of biotin residues per oligonucleotide is known. In most cases a nucleotide derivative already substituted with all or part of the spacer is used in conjunction with an automated oligonucleotide synthesis. The oligonucleotide is biotinylated after the synthesis is complete. Suitable nucleotide derivatives are 8-substituted adenosine,[204] 5-substituted 2′-deoxyuridine,[182, 205] the

so-called biotin-11-dUMP (examples **83**,[205] B or Bi = biotinyl), and cytidine substituted at the exocyclic amino group.[182, 206, 207] Furthermore, biotinylation can use a terminal phosphate group[184, 208, 209] or a terminal hydroxyl group[192] (examples **84**, **85**) for attachment. Finally, biotinylation of oligonucleotides (synthesized or isolated) also can be successfully accomplished by adding a biotin-carrying nucleotide to an oligonucleotide using an appropriate polymerase[210, 211] or the enzyme terminal nucleotidyltransferase.[181, 212]



Oligonucleotide **86** is composed of a deoxy stretch of four biotinylated cytidine phosphates and a ribo stretch of 2′-*O*-methylribonucleotides (see **122** in Section 5). This modified oligonucleotide combines good recognition with good stability towards nucleases.[207] Oligonucleotides with this typical structure have been used successfully for recognition and inhibition even in complex biological processes, such as the splicing process on the spliceosome.[213, 214]

The synthesis of many biotinylated oligonucleotides has encouraged their use in nucleic acid recognition assays. The sensitivity of this system is always very good when one of the detection systems mentioned above or immunofluorescence assays are used.[215]

The detection assays described in Sections 3, 3.1, and 3.2 are not restricted to applications in molecular biology (for a review see Ref. [216]), where they have been used to detect genes or gene fragments,[215, 217, 218] find enterotoxin genes[181, 219] or sequences originating from enterotoxic *E. coli*,[195] localize RNA,[220] and prove the presence of viruses.[181, 221] They have also become more and more important in biology, where they have been used for classification in phylogeny and for detection of microorganisms,[188] and in medicine as well (for a review see Ref. [40]), where they have found application in the diagnosis of viral infections by detection of viral sequences in specimens (for a review see Ref. [222]), the detection of other infections,[222] of genetic diseases,[40, 222] and of neoplastic diseases,[40] and the identification of persons.[40] Under optimal assay conditions these assays are sensitive enough to detect one nucleobase exchange in a target sequence.[192]

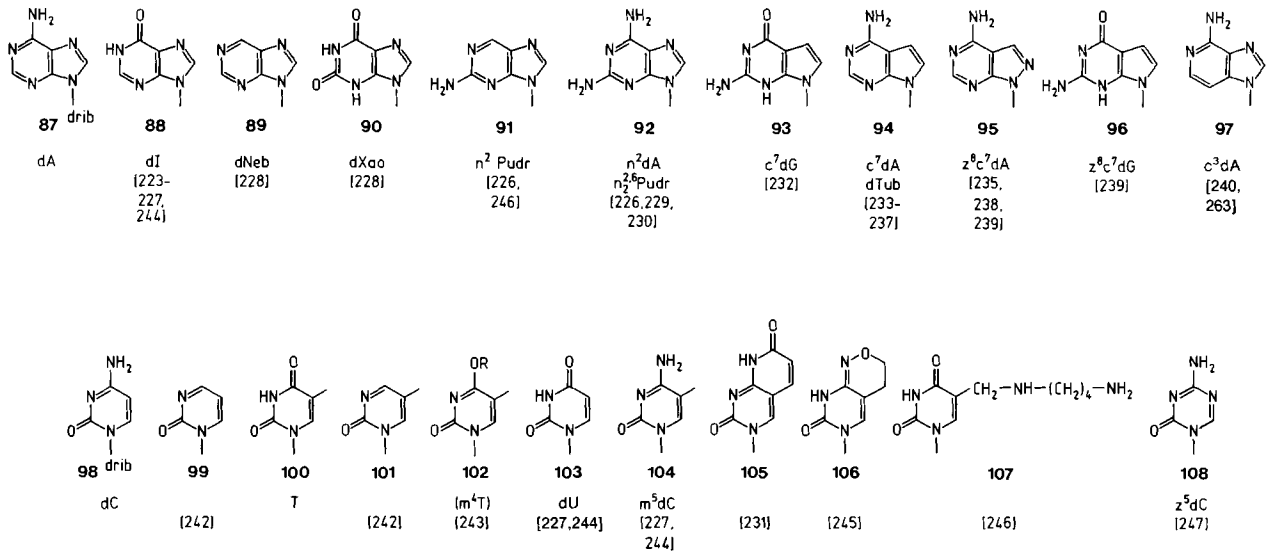
4. Modified Oligonucleotides as Substrates for Nucleases and Polymerases

A third way of applying modified oligonucleotides is to use them as substrate analogues of nucleases, polymerases, and other enzymes and for interaction with nonenzyme proteins. The examples described here show how modified oligonucleotides contribute to the elucidation of the mechanisms of restriction endonucleases and to the manipulation of these enzymes. Also discussed is work on mutation processes initiated by apurinic DNA stretches or thymine dimers in DNA as well as sequencing techniques using fluorescence indicators.

One of the easiest modifications of an oligonucleotide that is a substrate for a given nuclease is to change the ribose-phosphate backbone (see Sections 2.1 and 2.6). Indeed, the mechanisms of numerous nucleases were (and still are) investigated with backbone-modified oligonucleotides,[7] most often phosphorothioate analogues.[124–126] However, the role of the nucleobases is not restricted to defining the sequence. The recognition of a nucleic acid by an enzyme, whether a nuclease or a polymerase, is additionally determined by the helix diameter, the length of the repeating unit, the tilt and twist of the nucleobase, and further parameters, all of which are dependent on the nature of the nucleobases. Therefore, some of the nucleobases introduced into oligonucleotides in recent years will first be discussed before turning to the restriction endonucleases.

Inosine can be inserted opposite all four regular nucleobases without disrupting the double helix. Therefore, oligonucleotides containing 2′-deoxyinosine (dI, **88**)[223–227] are suitable as polyvalent probes. Oligonucleotides containing 2′-deoxynebularine (dNeb, **89**)[228] or 2′-deoxyxanthosine (dXao, **90**)[228] can act similarly. Double helices containing these nucleobases are generally less stable than those with normal nucleobases. In contrast, the helix stability is increased by inserting 2-amino-2′-deoxyadenosine (n^2dA, **92**)[226, 229, 230] as well as by introducing **105**, a fluorescent pyridopyrimidine which is able to pair with guanine and adenine.[231] In another series of oligonucleotides, the aromatic nuclei of the nucleobases are modified; examples include 7-deaza-2′-deoxyguanosine (c^7dG, **93**),[232] 7-deaza-2′-deoxyadenosine (c^7dA, **94**; also called 2′-deoxytubercidine),[233–237] 7-deaza-8-aza-2′-deoxyadenosine (z^8c^7dA, **95**),[235, 238, 239] 7-deaza-8-aza-2′-deoxyguanosine (z^8c^7dG, **96**),[239] and 3-deaza-2′-deoxyadenosine (c^3dA, **97**).[240] Some of these oligonucleotides have additional modifications, namely, N^6-methylation (as in **94** and **95**)[241] and glycosidic linkages to N-8 instead of N-9.[238, 241] The latter compounds, in particular, are specifically designed tools for DNA structure and function studies (e.g., DNA bending and recognition by proteins).

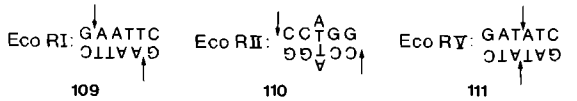
Pyrimidine nucleoside analogues of 2′-deoxycytidine (**98**) and thymidine (**100**) each lacking the functional group *para* to the glycosidic linkage (**99** and **101**, respectively)[242] were synthesized in order to quantify the contribution of these functional groups to duplex stability. Additional modified pyrimidine nucleosides incorporated into oligonucleotides are O^4-methyl- or O^4-ethylthymidine (m^4T or et^4T, **102**),[243] 2′-deoxyuridine (dU, **103**),[227] 5-methylcytidine (m^5dC, **104**),[227, 244] the pyridopyrimidine nucleoside mentioned already (**105**[231]) and a similar compound which is able to pair with several nucleobases (**106**[245]), 5-putrescinylthymidine (**107**) as well as some other 5-substituted thymidines,[246] which occur in bacteriophages and inhibit nuclease digestion, and an oligonucleotide with 5-azacytidine (z^5dC, **108**) (or 5,6-dihydro-5-azacytidine[247]); thus, the pyrimidine field, too, presents compounds modified in the aromatic nucleus of the nucleobases.



Furthermore, there are a series of double-helical nucleic acid analogues[28, 248, 249] based on artificial base pairs (not described here). Recent work has provided nucleobase analogues sufficiently voluminous to replace a complete base pair;[249] the fitting of these voluminous nucleobase analogues into DNA may be related to the intercalation of polycyclic aromatic compounds.

4.1. Recognition Sequences and Cleavage Sites of Restriction Endonucleases

Restriction endonucleases—about 600 enzymes have been characterized—differ from simple nucleases in that they cleave double-stranded DNA only at those internucleotide linkages coded for by their respective recognition sequences (**109**–**111**).



The mechanism of cleavage by restriction endonucleases as well as the structure of the recognition sequence can be studied with modified oligonucleotides as substrate analogues. Phosphate-modified oligonucleotides (containing pyrophosphate, triester, or phosphorothioate moieties),[148, 250–252] sugar-modified oligonucleotides (containing ribose or xylose moieties),[250, 251, 253] and nucleobase-modified oligonucleotides have been used. The latter include pyrimidine nucleobases with or without 5-methyl groups[250, 254–258] or with further substitutions (e.g., thio, bromo, alkyl, fluoro, or cyano groups),[250, 251, 253, 254, 257, 259–261] methylated purine nucleobases,[258, 260, 262, 263] and purine moieties with modified functional groups[230, 260, 263–265] or modified aromatic nuclei.[235, 236, 238, 240, 241, 262, 263, 265] The compilations of the oligonucleotides **112** and **113** display one oligonucleotide in which two thymidines are replaced by uridines or uridine derivatives (**112**)[259] and three adenosine-containing oligonucleotides in which adenosines are replaced by 7-deazaadenosines (**113**).[236]

113

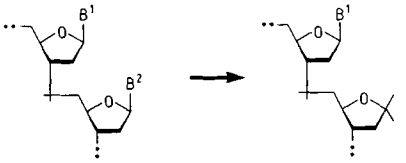
A number of functional groups have been identified as essential recognition elements for identification and cleavage of deoxy duplexes by restriction endonucleases (e.g., the exocyclic amino groups of adenine and cytosine, the N-7 of adenine, and the methyl group of thymine are essential contact points for the enzyme Eco RV[265] and another known series of functional groups are essential for the enzyme Eco RI[260]). Despite a detailed search for essential functional groups that, when modified, prevent an oligonucleotide from being cleaved, the general result of modifications of

functional groups in deoxyoligonucleotide duplexes is to change the substrate properties of these duplexes. Therefore, a more valid statement is that recognition and cleavage subtly depend on the whole three-dimensional structure of the recognition sequence. Many times, after a modification and subsequent incubation with a restriction endonuclease, cleavage of a deoxyoligonucleotide duplex is not completely suppressed but only slowed down or limited to one strand. The site-directed mutagenesis procedure of *Eckstein* et al.[126, 127] is based on the inability of a restriction endonuclease to hydrolyze a phosphorothioate-containing strand of a double-helical DNA substrate.

4.2. Polymerases and Oligonucleotides Containing Apurinic/Abasic Stretches or Thymine Dimers

The numerous interactions of polymerases, ligases, etc., with RNA or DNA can be mimicked with (modified) oligonucleotides. Thus, experiments to discover mechanistic details can be designed and biological regulation circuits can be influenced by using modified oligonucleotides. In this article, oligonucleotides with abasic stretches and oligonucleotides containing thymine dimers will be discussed, owing to their importance in mutation events.

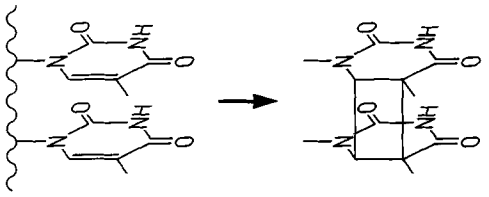
Apurinic or abasic nucleotides or stretches of nucleotides (**115**) play an important role in biology since breakage of the glycosidic linkage can occur under in vivo conditions. These sites of abasic RNA or DNA must therefore be digested or repaired in order to avoid mutations (for a review see Ref. [266]). Abasic[267–270] and apurinic[271–274] oligonucleotides can be used as model substrates for nucleases and polymerases.



114 115

Abasic oligonucleotides lack one or several nucleobases. One way of preparing these oligonucleotides is to cleave nucleobases from the complete oligonucleotide.[268, 271] The other approach is oligonucleotide syntheses in which one or several steps use sugar-phosphate building blocks without nucleobases.[267, 270, 273, 274] The structure of a series of these oligonucleotides has been thoroughly investigated by NMR, CD, and IR;[267, 273, 274] these substances have a gap in the nucleobase sequence and, accordingly, their structures deviate from those of normal oligonucleotides. Preparatively, the abasic sites within an oligonucleotide can be used for triggering chain cleavage (by alkaline agents[272]) or for introducing reporter moieties (via amino groups of the reporter compounds[274–276]). In biological test systems containing abasic oligonucleotides and nucleases or polymerases, unusual reaction intermediates are produced or the enzymes are completely inhibited.

Thymine dimers (**117**) are the most important reaction product formed upon irradiation of DNA. In this reaction, two thymines belonging to the same strand and nucleobase stack are linked by formation of a cyclobutane moiety (**116** → **117**). The standard DNA functions are thereby inhibited. In vivo a DNA stretch modified in this way will be subject to repair. A number of oligonucleotides containing thymine dimers have been prepared, either by irradiation of unmodified oligonucleotides[277–279] or by synthesis of oligonucleotides incorporating preformed thymine dimers.[280, 281] These oligonucleotides have been used for

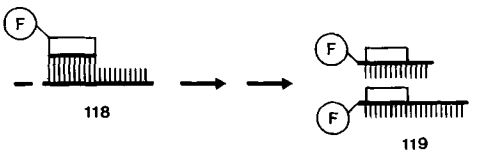


116 117

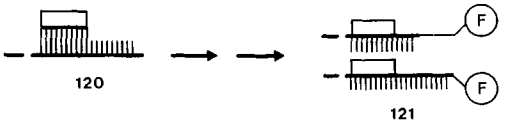
structural analyses[282–285] in order to elucidate the structure of DNA containing thymine dimers[286] (thymine dimers bend DNA; compare Section 2.5) or for studying DNA repair[277, 287] and mutagenesis[279] (in cases of incomplete or lacking repair).

4.3. Sequencing with Fluorescent Dyes Instead of Radioactive Isotopes

Sequencing techniques are under development with several different goals (for a review see Ref. [288]). First, there is a need for machine-readable sequencing gels[289–291] and for sequencing systems suitable for rare and artificial nucleotides.[292] Second, methods to obtain nucleotide sequences from very small amounts of material (mass spectrometry systems) are a target of research. Third, nonradioactive sequencing systems based on fluorescence spectroscopy are under development. The fluorescent label (e.g., rhodamine or fluorescein) can be linked to the primer.[189, 291, 293–297] After chromatographic separation of all oligonucleotides, the label is linked to the 5′ terminus of every oligonucleotide (**118** → **119**). Alternatively, the fluorescent dye can be coupled to that nucleotide terminating the chain, in which case all oligonucleotides are 3′-labeled[290, 298, 299] (**120** → **121**).



118 119



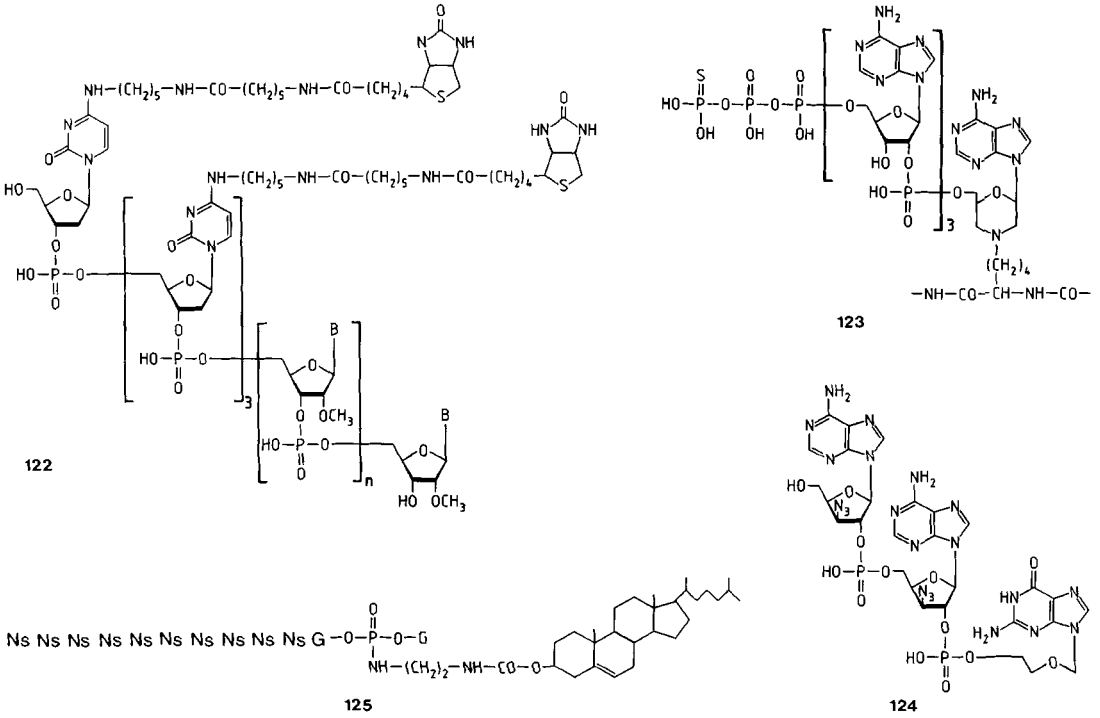
120 121

5. Summary and Outlook

A number of applications of modified oligonucleotides have been described in this article; many other applications have not been mentioned, such as those in the field of artificial enzymes or ribozymes. Other oligonucleotides of great interest include cyclic,[300-302] branched,[303-306] magnetic,[307] catalytic,[308, 309] and bent oligonucleotides[226, 227, 233, 234, 244, 286] (compare Sections 2.5 and 4), oligonucleotides carrying spin labels,[310] oligonucleotides suitable for immobilization of nucleic acids,[311, 312] oligonucleotides capable of binding heavy metals for X-ray analyses[295, 313] or for electron microscopy,[314] and antigenic or antigenic-response-modulating[315] oligonucleotides.

Modified oligonucleotides have been developed so far as substrate analogues, for identification, and as antisense oligonucleotides. A few applications as substrate analogues have been discussed above. The use of modified oligonucleotides to identify and localize nucleic acids has become a routine procedure. However, so far no modified oligonucleotide has been used as therapeutic agent. This would be particularly desirable since sequence-specific access to a given RNA or DNA stretch can be accomplished only with an antisense oligonucleotide or a protein (repressor, antibody, restriction endonuclease). To date such proteins cannot be designed or synthesized. In contrast, oligonucleotides can be synthesized and the mechanism of the inhibitory action of oligonucleotides via base-pairing is well understood. Three practical problems, already mentioned above, block application of a modified oligonucleotide as therapeutic agent: poor uptake into cells, digestion by cell nucleases, and short lifetime of the duplex formed. Nuclease-resistant oligonucleotides can be constructed. The lifetime of the duplex can be increased in several ways. For example, a covalent linkage can be formed between the two strands of a duplex. In addition, the methods to induce a strand scission in the complementary strand are well worked out. The problem that still needs attention is insufficient uptake of oligonucleotides into cells. (An alternative would be to transcribe an appropriate oligonucleotide from an artificial gene in the cell, but this approach is not possible at present.)

There is little knowledge regarding the mechanism of uptake.[131] Perhaps charged oligonucleotides, whether modified or not, are taken up by an active transport mechanism.[316, 317] Uncharged oligonucleotides, if considerably more lipophilic, also might be transported by passive mechanisms. The concentrations of oligonucleotides required in the cell culture medium for an effective inhibition of virus proliferation in virus-infected cells range from 0.5 to 30 μM for phosphorothioate oligonucleotides. In comparison, methylphosphonate oligonucleotides need 50–200 μM concentrations (see Section 2.6), perhaps owing to their lower water solubility or the lack of activation of RNase H. The concentration of the oligonucleotide inside the cell is considered to be roughly 10% of that outside the cell;[318] the uptake occurs in the range of minutes to hours. In addition, oligonucleotides can enter the nucleus[77] since oligonucleotides directed to bind to splice regions show inhibitory effects.[144, 157, 162, 213] In general, however, knowledge regarding distribution of oligonucleotides within the cell compartments is rather sketchy.[319] These data for in vivo systems largely agree with the in vitro finding that to yield an inhibition of 80–90% the molar relation of oligonucleotide to target sequence must range from 1000:1 to 5:1.[27] The uptake problem urgently needs more attention. For artificial therapeutic agents additional oligomer delivery systems are being considered, such as the inclusion of oligonucleotides in liposomes. Such particles, via an antigen–antibody reaction,



might even be selectively transported to one target tissue.[320] An oligonucleotide can also be linked to a protein (for example, interleukin[321]) and then internalized through the receptor specific for the protein. Some further artificial uptake systems are under development.[38]

In theory, the concentration of oligonucleotide needed for inhibition at the level of transcription would be considerably smaller than at the level of translation, since the concentration of the target nucleic acid is by far lower at the transcription level. On the translation level inhibition by an oligonucleotide generally means the formation of a duplex of a single-stranded messenger RNA and an oligonucleotide. In contrast, transcription principally starts from double-stranded DNA. The formation of a triple-helix structure as an inhibitory entity is documented for polypurine and polypyrimidine stretches of DNA (which occur in control regions of eukaryotic genes; for an example see Ref. [322]) and for oligothymidylates or similar oligonucleotides.[57, 76, 96, 97, 102] In contrast, triple-helix formation with variable sequences has not been established[323] and no successful inhibition via such a triple helix has been reported (for a review see Ref. [324]).

Another prerequisite for selecting a drug out of the many prepared oligonucleotides is to test each oligonucleotide in many biological systems. So far, however, each oligonucleotide synthesized has usually been tested in only one biological system. Obviously, an oligonucleotide will exhibit different properties in different biological test systems (e.g., normal and neoplastic tissues or normal and infected cells). Establishing and compiling such data might reveal some general rules. The rules—in the sense of rational drug design—might then describe how to increase at least the uptake, nuclease resistance, and duplex stability of a modified oligonucleotide without increasing properties, such as toxicity (for reviews see Refs. [7, 31–34, 37, 40, 325]).

Modified oligonucleotides will continue to be a field of exciting research with the ultimate goal of clinical application. Probably, those oligonucleotides that are able to escape all the "traps" in the cells must deviate considerably from unmodified oligonucleotides; that is, they must be modified in several ways. Typical examples may be a biotin-carrying oligonucleotide (**122**),[207] a 5′-γ-phosphorothioate(2′-5′)A_4-poly(Lys) construct (**123**),[174] a trinucleotide analogue (**124**)[326] with three modifications (designed to release the antiviral compound acyclovir monophosphate within the cell[327]), and a cholesterol-phosphorothioate oligonucleotide (**125**).[168]

The authors would like to imagine an oligonucleotide that is hydrophobic in the uptake step, then changes its properties through contact with RNase, for example, so that, in a highly reactive state, it forms a covalent dead-end complex. Certainly, organic chemistry should be able to synthesize such an oligonucleotide.

The authors thank Ute Rust for typing this manuscript and Dr. W. Freist and Dr. H. Rosemeyer for critically reading it.

Molecular Structures from Density Functional Calculations with Simulated Annealing

By Robert O. Jones*

The geometrical structure of any aggregate of atoms is one of its basic properties and, in principle, straightforward to predict. One chooses a structure, determines the total energy E of the system of electrons and ions, and repeats the calculation for all possible geometries. The ground state structure is that with the lowest energy. A quantum mechanical calculation of the exact wave function Ψ would lead to the total energy, but this is practicable only in very small molecules. Furthermore, the number of local minima in the energy surface increases dramatically with increasing molecular size. While traditional ab initio methods have had many impressive successes, these difficulties have meant that they have focused on systems with relatively few local minima, or have used experiment or experience to limit the range of geometries studied. On the other hand, calculations for much larger molecules and extended systems are often forced to use simplifying assumptions about the interatomic forces that limit their predictive capability. The approach described here avoids both of these extremes: Total energies of predictive value are calculated *without* using semi-empirical force laws, and the problem of multiple minima in the energy surface is addressed. The density functional formalism, with a local density approximation for the exchange-correlation energy, allows one to calculate the total energy for a given geometry in an efficient, if approximate, manner. Calculations for heavier elements are not significantly more difficult than for those in the first row and provide an ideal way to study bonding trends. When coupled with finite-temperature molecular dynamics, this formalism can avoid many of the energetically unfavorable minima in the energy surface. We show here that the method leads to surprising and exciting results.

1. Introduction

A knowledge of the exact wave function Ψ of an interacting system of electrons and ions would allow one to determine many quantities of interest, including the total energy E (Eq. 1), where $\mathscr{H}$ is the Hamiltonian of the system. Calcu-

$$E = \langle \Psi | \mathscr{H} | \Psi \rangle / \langle \Psi | \Psi \rangle \tag{1}$$

lations of this type can be carried out for systems with very few electrons, the most familiar example being the hydrogen atom. However, approximations for Ψ are generally unavoidable, and are usually based on the variational principle of *Rayleigh* and *Ritz*: If $|\Phi\rangle$ is an approximate wave function, then Equation 2 is valid, where E_{GS} is the exact energy of the ground state.

$$\langle \Phi | \mathscr{H} | \Phi \rangle / \langle \Phi | \Phi \rangle \geq E_{GS} \tag{2}$$

The simplest form of a many-particle wave function is that of *Hartree* (1928), who represented Φ as a product of single-electron functions (Eq. 3), where each ϕ_i satisfies a

$$|\Phi\rangle = \phi(\boldsymbol{r}_1)\,\phi_2(\boldsymbol{r}_2) \ldots \phi_n(\boldsymbol{r}_n) \tag{3}$$

Schrödinger equation whose potential term is given by the mean field of all other electrons (Eq. 4). V_{ext} is the external

$$(-\tfrac{1}{2}\nabla^2 + V_{ext} + \varphi)\phi_i(\boldsymbol{r}_i) = \varepsilon_i \phi_i(\boldsymbol{r}_i) \tag{4}$$

field of the nuclei, and the Coulomb potential φ is determined by solving Poisson's equation (we use atomic units, i.e., the unit of charge is the electron charge e, of distance the Bohr radius a_0, and of mass the electron mass m). Replacing the product by a single (Slater) determinant—the Hartree–Fock (HF) approximation—leads to an additional "exchange" potential, without changing the single-particle picture. Although this has been the basic method of atomic and molecular physics for many years, a single determinant does not generally lead to a satisfactory value of the total energy. While a linear combination of determinants ("configuration interaction", CI) should lead in principle to an exact wave function and energy, the numerical effort required increases explosively with increasing electron number.

These arguments apply to a *one* geometry, that is, for a particular set of internal coordinates of a system. If we have N atoms in an aggregate ($N > 2$), the total number of internal coordinates is $3N - 6$, since the internal energy of the aggregate is independent of any translational or rotational motion. With so many independent interatomic degrees of freedom, the scale of the problem is clear: 1) Finding the energy minimum by calculating the exact energy for all possible geometries is impracticable, since it would require a vast number of calculations in a system where *one* is difficult! 2) The ability to locate the closest minimum to a particular geometry would simplify the calculations greatly, particularly if the number of possible isomers is small. In general, however, it is difficult to predict the most stable structure, since the number of local minima in the energy surface can be very large indeed.

The enumeration of topologically different isomers consistent with a given chemical formula is one of the oldest problems in theoretical chemistry. In 1874, only a decade after the

[*] Dr R. O. Jones
Institut für Festkörperforschung
Forschungszentrum Jülich, W-5170 Jülich (FRG)

chemical bond was first denoted by a line joining the nuclei, *Cayley*[1] showed that the number of isomers could grow rapidly with increasing N, and much work in the intervening period has confirmed this. *Hoare* and *McInnes*,[2] for example, located all the minima in small aggregates with simple, pairwise interatomic interactions, and found a rapid, perhaps exponential, increase in their number with increasing N. In fact, for aggregates of identical atoms interacting with a pairwise potential, *Wille* and *Vennik*[3] have shown that there is no known algorithm for determining the ground state energy and structure that grows with time as a power of N. Such problems are classified as "NP—hard"[4] and are termed intractable. It is indeed sobering when mathematicians derive such a result. Moreover, the parameters in force laws such as those used by *Hoare* and *McInnes* are usually derived from experiment, and one cannot be sure that the results are not affected by the choice of parameters.

This discussion shows that there are two distinct problems to be solved, and the difficulties are multiplicative in nature. The approach we now describe addresses both aspects. First, the density functional formalism provides a numerically efficient scheme for calculating the ground state energy of the interacting system of ions and electrons without attempting to calculate the wave function Ψ. Second, we use the strategy of simulated annealing (SA) to determine low-lying energy minima. We show that, even in small molecules, there are energetically favorable structures that had not been found on the basis of experiment or intuition. In Section 2 we outline the density functional (DF) formalism and discuss the form of the exchange–correlation energy E_{xc} and local density approximations to it. The results of local spin density (LSD) calculations given in Section 3 illustrate the level of accuracy to be expected, and we show in Section 4 how DF calculations can be combined with molecular dynamics. We present some applications in Section 5 and our concluding remarks in Section 6.

2. Density Functional Formalism

2.1. Formal Basis

The basic theorems of the density functional formalism were derived by *Hohenberg* and *Kohn*.[5] They showed that:

1) Ground state (GS) properties of a system of electrons and ions in an external field V_{ext} can be determined from a knowledge of the electron density $n(\boldsymbol{r})$ *alone*. The total energy E is such a functional of the density, that is, $E = E(n)$.

2) $E(n)$ satisfies the variational principle $E(n) \geq E_{GS}$, and the density for which the equality holds is the ground state density n_{GS}.

A simple and general proof of these assertions has been given by *Levy*.[6]

The step to a practical scheme for energy calculations resulted from the observation by *Kohn* and *Sham*[7] that the minimization of $E(n)$ can be simplified if we write E as in

$$E(n) = T_0(n) + \int d\boldsymbol{r}\, n(\boldsymbol{r})\,(V_{ext}(\boldsymbol{r}) + \tfrac{1}{2}\varphi(\boldsymbol{r})) + E_{xc}(n) \qquad (5)$$

Equation 5. Here T_0 is the kinetic energy that a system with density n would have in the absence of electron–electron interactions, $\varphi(\boldsymbol{r})$ is the Coulomb potential, and the remainder E_{xc} is our definition of the exchange–correlation energy. The variational principle now yields Equation 6, where μ is the Lagrange multiplier associated with the requirement of constant particle number.

$$\frac{\delta E(n)}{\delta n(\boldsymbol{r})} = \frac{\delta T_0}{\delta n(\boldsymbol{r})} + V_{ext}(\boldsymbol{r}) + \varphi(\boldsymbol{r}) + \frac{\delta E_{xc}(n)}{\delta n(\boldsymbol{r})} = \mu \qquad (6)$$

Equation 6 applies to the interacting system of electrons and ions. The solution of the corresponding equation for a system of noninteracting particles, Equation 7, can be found

$$\frac{\delta E(n)}{\delta n(\boldsymbol{r})} = \frac{\delta T_0}{\delta n(\boldsymbol{r})} + V(\boldsymbol{r}) = \mu \qquad (7)$$

by solving the Schrödinger equation, Equation 8a. The density is given by Equation 8b, where the sum runs over orbitals i with occupation numbers f_i. The problems (6) and (7)

$$(-\tfrac{1}{2}\nabla^2 + V(\boldsymbol{r}))\,\psi_i(\boldsymbol{r}) = \varepsilon_i \psi_i(\boldsymbol{r}) \qquad (8a)$$

$$n(\boldsymbol{r}) = \sum_i f_i |\psi_i(\boldsymbol{r})|^2 \qquad (8b)$$

are mathematically identical, provided that $V(\boldsymbol{r})$ is defined according to Equation 9. This condition can be satisfied in practice by a "self-consistency" cycle: From a starting value of n we compute $V(\boldsymbol{r})$ and the n' that results, and continue this procedure until $n = n'$.

$$V(\boldsymbol{r}) = V_{ext} + \Phi(\boldsymbol{r}) + \frac{\delta E_{xc}(n)}{\delta n(\boldsymbol{r})} \qquad (9)$$

Robert O. Jones was born in 1941 in Kojonup, Western Australia. He graduated in 1963 from the University of Western Australia, Perth, and obtained his Ph.D. in 1967 from the University of Cambridge, England, under V. Heine. From 1967 to 1970 he worked as Research Associate, Laboratory of Atomic and Solid State Physics, Cornell University, Ithaca, NY, USA and since 1970 as Scientist at the Forschungszentrum Jülich (KFA). In 1975 he was NORDITA Professor at the Chalmers Technical University, Göteborg, Sweden and has been Fellow of the Australian Institute of Physics since 1978.

The problem of determining the total energy of a system of electrons and ions has therefore been reduced to the solution of a single-particle equation of Hartree form (cf. Eq. 4), leading to the energy and electron density of the lowest state and all quantities derivable from them. This method can be extended to the lowest energy state of a given symmetry by restricting the variation to densities compatible with the corresponding symmetry quantum numbers.[8] In the form of Equations 8 and 9, density functional theory is an *orbital* theory and it shares the main advantage of the Hartree–Fock method, namely the interpretation of the results in a single-particle picture. In contrast to the HF potential, however, the effective potential $V(\boldsymbol{r})$ has a *local* dependence on the density.

This situation may seem to be almost too good to be true. Before celebrating, however, we should note the following:

1) The total energy E of the most stable state of a given symmetry is found by solving equations describing a fictitious system of noninteracting "electrons", and the eigenvalues ε_i and eigenfunctions ψ_i in Equation 8 can *not* be viewed as excitation energies and wave functions of the interacting system. The use of such fictitious systems leads to additional complications, since it is not always possible to draw an unambiguous connection between the states of the interacting and noninteracting systems. In the latter, the f_i will be compatible with a single determinant—or at most a small number of determinants—of the same symmetry.[9]

2) While in the energy expression (5) T_0, the electron–ion and electron–electron interaction energies can readily be evaluated, E_{xc} is *defined* only as the difference between the sum of these terms and the exact energy. It is a small but far from negligible part of the total energy of atoms and molecules. Moreover, if there is no simple expression for E_{xc}, how do we determine in practice its functional derivative in Equation 6? Approximations to E_{xc} therefore play an essential part in applications of DF theory, and we now study its form in more detail.

2.2. Exchange–Correlation Energy

The connection between the noninteracting and interacting systems—both of density $n(\boldsymbol{r})$—can be drawn simply by considering an electron–electron interaction $\lambda\phi$ and increasing λ slowly from 0 to 1. One can use this construction to derive an exact expression (10) for E_{xc},[8] in which n_{xc} is defined as in Equation 11. The pair-correlation function $g(\boldsymbol{r}, \boldsymbol{r}', \lambda)$ describes the fact that an electron at point $\boldsymbol{r}$ reduces the probability of finding one at $\boldsymbol{r}'$, so that E_{xc} can be viewed as the interaction between $n(\boldsymbol{r})$ and the exchange–correlation hole $n_{xc}(\boldsymbol{r})$. This picture is, of course, very similar to that of the exchange hole introduced by *Slater* for electrons of parallel spin.[10]

$$E_{xc} = \frac{1}{2}\int d\boldsymbol{r}\, n(\boldsymbol{r}) \int d\boldsymbol{r}' \frac{1}{|\boldsymbol{r}-\boldsymbol{r}'|} n_{xc}(\boldsymbol{r}, \boldsymbol{r}'-\boldsymbol{r}) \tag{10}$$

$$n_{xc}(\boldsymbol{r}, \boldsymbol{r}'-\boldsymbol{r}) \equiv n(\boldsymbol{r}') \int_0^1 d\lambda (g(\boldsymbol{r}, \boldsymbol{r}', \lambda) - 1) \tag{11}$$

The isotropic nature of the Coulomb interaction suggests the variable substitution $\boldsymbol{R} \equiv \boldsymbol{r}' - \boldsymbol{r}$ in (10), leading to Equation 12.[8] E_{xc} depends only on the spherical average of

$$E_{xc} = \frac{1}{2}\int d\boldsymbol{r}\, n(\boldsymbol{r}) \int_0^\infty d\boldsymbol{R}\, R^2 \frac{1}{R}\int d\Omega\, n_{xc}(\boldsymbol{r}, \boldsymbol{R}) \tag{12}$$

$n_{xc}(\boldsymbol{r}, \boldsymbol{R})$, so that approximations for it can give an accurate value even if the description of the nonspherical parts of n_{xc} is very poor. Furthermore, a sum rule following from the definition of the pair-correlation function requires that the exchange–correlation hole contain one electron, that is, for all $\boldsymbol{r}$, Equation 13 is valid. If we consider $-n_{xc}(\boldsymbol{r}, \boldsymbol{r}'-\boldsymbol{r})$ as

$$\int d\boldsymbol{r}'\, n_{xc}(\boldsymbol{r}, \boldsymbol{r}'-\boldsymbol{r}) = -1 \tag{13}$$

a normalized weight factor and define locally the radius of the exchange–correlation hole (Eq. 14), Equation 15 follows.

$$\left\langle \frac{1}{\boldsymbol{R}} \right\rangle_{\boldsymbol{r}} = -\int d\boldsymbol{r}\, \frac{n_{xc}(\boldsymbol{r}, \boldsymbol{R})}{|\boldsymbol{R}|} \tag{14}$$

$$E_{xc} = -\frac{1}{2}\int d\boldsymbol{r}\, n(\boldsymbol{r}) \left\langle \frac{1}{\boldsymbol{R}} \right\rangle_{\boldsymbol{r}} \tag{15}$$

Provided the sum rule (13) is satisfied, E_{xc} depends only weakly on the details of n_{xc} and is determined by the first moment of a function whose second moment is known exactly.

The experience of the last twenty years shows that the exact exchange–correlation energy functional $E_{xc}(n(\boldsymbol{r}))$ must be extremely complicated. The calculation of correlation functions (see Eq. 11, for example) generally requires the knowledge of the exact wave function. Nevertheless, the above argument shows that simple, useful approximations to E_{xc} may exist. The practical necessity of approximating E_{xc} is an essential difference between the density functional and configuration interaction approaches. While the latter seeks an exact numerical solution of the Schrödinger equation and precise values of related quantities, even the best solution of the DF equations can only reflect the accuracy of the approximation used for E_{xc}. Furthermore, while the CI approach can be improved systematically by increasing the number of determinants and basis functions, a corresponding scheme for improving the accuracy of LD calculations is presently not known.

2.3. Local Density Approximations for E_{xc}

Local density calculations have a long history in condensed matter physics, where a special role has been played by the approximate exchange potential introduced by *Slater*.[10] It is sometimes overlooked that *Slater*'s derivation was based on the concept of the exchange-hole discussed above, and not on the particular form of the exchange energy density obtained for a homogeneous electron gas. The approximation for E_{xc} in most widespread use today is the local spin density (LSD) approximation (16). Here $\varepsilon_{xc}(n_\uparrow, n_\downarrow)$ is

$$E_{xc}^{LSD} = \int d\boldsymbol{r}\, n(\boldsymbol{r})\, \varepsilon_{xc}(n_\uparrow(\boldsymbol{r}), n_\downarrow(\boldsymbol{r})) \tag{16}$$

the exchange and correlation energy per particle of a homogeneous, spin-polarized electron gas with spin-up and spin-

down densities $n_\uparrow$ and $n_\downarrow$, respectively. This approximation is free of adjustable parameters—ε_{xc} is taken from the best available calculations for the uniform electron gas—and its use can be justified in systems with small departures from homogeneity. Density distributions are far from homogeneous in atoms, molecules, and most solids, and the usefulness of the approximation relies on arguments such as those in Section 2.2. The approximation satisfies the sum rule (13); more details are given in the review article by *Jones* and *Gunnarsson*.[11]

3. DF Calculations with Local Density Approximations

Density functional calculations with the LSD approximation are common in extended systems, and the results show some general features. Equilibrium geometries are given reliably in most materials, and energy variations in the neighborhood of local minima are described well, so that vibration (phonon) frequencies are generally in reasonable agreement with experiment. In this section, we select examples from the applications to molecular systems[11] to indicate the level of accuracy to be expected in such systems. They illustrate two strengths of the method: the ability to study molecules containing elements from the whole periodic table, and the advantages of an interpretation based on a single-particle picture. They also demonstrate the tendency of LD calculations to overestimate strengths of bonds involving sp orbitals.

3.1. First-row Diatomic Molecules

Diatomic molecules of first-row atoms Li–F have served as a testing ground for numerous methods of electronic structure calculation. In Table 1 we compare measured potential well depths[12] in first-row dimers (homonuclear diatomic molecules) with values calculated using Hartree–Fock,[13] and local spin density approximations for E_{xc} and E_x (exchange only).[7, 14, 15] The HF approximation leads to substantial underestimates of the binding energies, particularly for singlet ground states. The LSD values overestimate the stability of these molecules, particularly beyond carbon in this row, although the deviations from experiment are small for H_2 and Li_2. In cases where it leads to an energy minimum, the HF approximation usually leads to a small underestimate of the equilibrium interatomic separations. The values for r_e calculated using the LSD approximations are generally in good agreement with experiment. An overestimate of 1–2% is common.[15, 16] Ground state vibration frequencies are correspondingly low. The dipole moment of CO and its variation with internuclear separation are given significantly better by the LSD approximation than by HF calculations.[17]

Table 1. Experimental and calculated well depths [eV] for the experimental ground states of the first-row dimers.

Molecule	Expt [a]	LSD [b]	XO [b, c]	HF [d]
H_2	4.75	4.91	3.59	3.64
Li_2	1.07	1.01	0.21	0.17
Be_2	0.10	0.50	0.43	[e]

3.2. Alkaline Earth Dimers Be_2, Mg_2, Ca_2 ...

While the LSD and HF approximations generally lead to similar bond lengths in first-row molecules, Be_2 is quite different. The lowest-lying state in the alkaline earth dimers ($^1\Sigma_g^+[1\sigma_g(\uparrow\downarrow)\,1\sigma_u(\uparrow\downarrow)]$) has equal occupancies of bonding and antibonding orbitals, and Hartree–Fock calculations[18] lead to repulsive curves. Bonds in these molecules have often been referred to as Van der Waals bonds, in the expectation that the bond strength increases monotonically $Be_2 \rightarrow Mg_2 \rightarrow Ca_2$ ... with increasing atomic polarizabilities. The earliest CI calculations supported this picture, since they predicted for Be_2 a very weak bond with an equilibrium separation near $9a_0$.[19]

The local density approximation gives qualitatively different results and a different picture of bonding in this homologous series.[20] The energy curves show minima in all cases, and the equilibrium separations in Mg_2 and Ca_2 agree well with measured values. The bond length in Be_2 (4.86 a_0) was found to be much shorter than in CI calculations. Most striking, however, is the variation in bond energies shown in Figure 1. The bond in Be_2 is *stronger* than in Mg_2, and the variation with atomic number parallels the irregular behavior observed in the bulk cohesive energies (Fig. 1, experiment: ref. [21]; LD calculations: ref. [22]). The bond energies in the molecules and solids are overestimated by the LD approximation in those cases where experimental values are

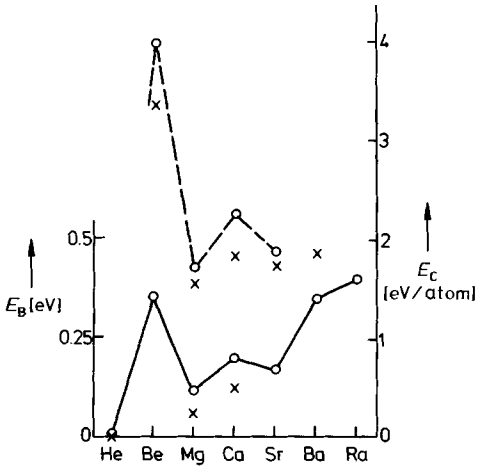

Fig. 1. Bond energies E_B calculated for the $^1\Sigma_g^+$ state of alkaline earth dimers (full curve, left scale, Ref. [20]) and cohesive energies of bulk materials (broken curve, right scale, ref. [22]). Experimental values Refs. [12] and [21]) are given as crosses.

known. The error is significant in Be_2, as we show in Table 2, where we include the results of more recent LD and CI calculations[23, 24] and gas-phase experimental results.[25] The DF and experimental equilibrium separations are in very good agreement, and the extensive CI calculations reproduce both the well depth and equilibrium separation satisfactorily.

Table 2. Experimental and calculated spectroscopic constants of Be_2 ($^1\Sigma_g^+$).

	r_e [a_0]	ω_e [cm^{-1}]	D_e [eV]
Experiment [25]	4.658	223.4	ca. 0.11

LD-LCAO[15]	4.63	362	0.50

[a] Estimated. [b] R. O. Jones, unpublished results (1982).

To discuss the bonding in this homologous series, it is useful to consider the valence orbitals (Fig. 2) of the atoms. With the exception of He_2, there is a substantial overlap between the electron densities on the two atoms, particularly in Be_2. Furthermore, the radial extent of the orbitals does not increase smoothly with core size, but shows a "secondary periodicity". For example, the valence s orbital in Mg is not

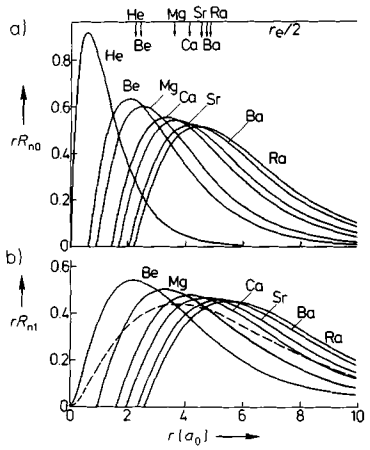

Fig. 2. Radial valence orbital functions for helium and alkaline earth atoms: a) s functions for the ^1S (ns^2) states, b) p functions for the ^3P (ns^1np^1) state. The dashed curve is the 2p function of He (1s2p). The arrows denote half of the calculated equilibrium separation ($r_e/2$) in each dimer [20].

much more extended than that in Be. The 2p functions in the Mg core have no repulsive (orthogonalization) effect on the 3s function and are sufficiently extended that the additional core charge is incompletely screened. A similar orbital compression is evident in Sr and Ra, where 3d and 4f functions enter the core for the first time. The unoccupied p orbitals are generally more extended than the s valence functions, but Figure 2 shows that Be is an exception. The similar extent of the 2s and 2p orbitals suggests that sp mixing will be favored. This picture is in accord with the pseudopotential theory of cohesion in the bulk: a stronger sp hybridization (and larger band gap) in Be than in Mg, and increasing sd hybridization with increasing atomic number. It is encouraging that the trends predicted by the DF calculations, particularly the relative strength of the bond in Be_2, were confirmed by both exhaustive CI calculations and by experiment.

3.3. Diatomic Molecules of the Fourth Main Group: C_2, Si_2, Ge_2

The absence of core p states, the strong attractive potential experienced by the 2p states, and their relatively compact nature apply to all first-row atoms. As a consequence, their bonding properties differ qualitatively from those of atoms in the remainder of the periodic table. The experimental ground state in C_2, for example, is $^1\Sigma_g^+$, and the excitation energy ($T_e = 0.09$ eV) to the $^3\Pi_u(2\sigma_g\pi_u^3)$ is very small.[12] The remarkable ease of the $\sigma_g \rightarrow \pi_u$ transfer is not found in the heavier dimers of this group; these have $^3\Sigma_g^-(2\sigma_g^2 1\pi_u^2)$ ground states, excitation energies of 1.0 to 1.5 eV to the $^1\Sigma_g^+$ state ($1\pi_u^4$), and substantially weaker π bonds.[26]

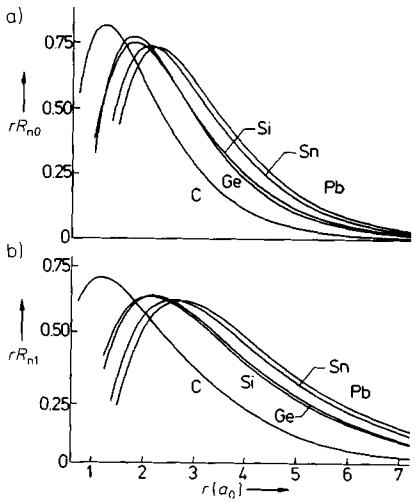

Fig. 3. Radial valence orbital functions for atoms of the fourth main group: a) s functions, b) p functions.

The radial functions of the valence orbitals of these elements (Fig. 3) show a similar behavior to that discussed above. The valence functions of Si and Ge are remarkably

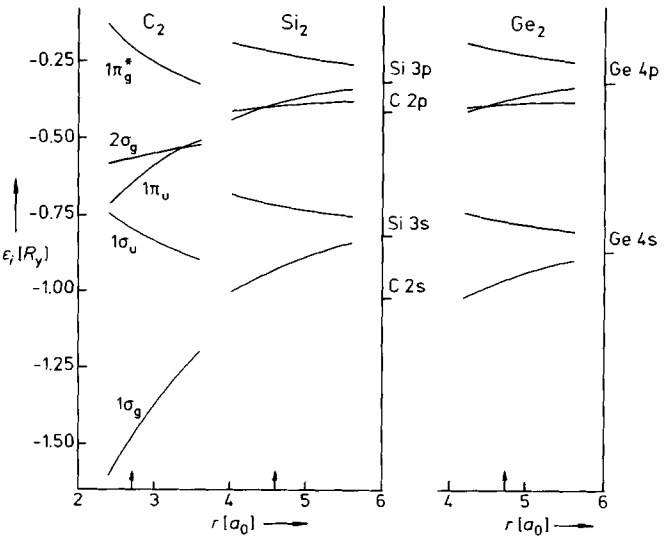

Fig. 4. Dependence of the self-consistent eigenvalues for $^3\Sigma_g^-$ state of C_2, Si_2, and Ge_2 on the interatomic distance r. The valence eigenvalues for the isolated atoms are given and the arrows on the r axis denote half of the calculated equilibrium separation ($r_e/2$) in each case.

similar, since the relatively diffuse 3d core density in Ge screens the additional nuclear charge imperfectly. This is reflected in very similar bulk properties, such as ground state geometries, and in the eigenvalues of Si_2 and Ge_2 shown in Figure 4. The C_2 eigenvalues reflect the compact valence p function and show why the multiplet structure is so different. The $^1\Sigma_g^+$ state obtained by placing four electrons in the π_u orbital has a very similar energy to the $^3\Sigma_g^-$ state obtained by transferring two electrons to the $2\sigma_g$ orbital. The eigenvalues in Figure 4 suggest that occupancy of the latter orbital will be favored in the heavier dimers, resulting in weaker π bonds. The consequences for the formation of simple saturated molecules have been discussed by *Harris* and *Jones*.[26]

3.4. Triatomic Molecules of the Sixth Main Group: O_3, SO_2

As a further example, we study the energy hypersurfaces of O_3 and SO_2,[27] which have ground states with $^1A_1(C_{2v})$ symmetry and similar bond angles (116.8° and 119.4°, respectively). Although the absorption spectrum of ozone has been studied in detail, particularly for ultraviolet radiation, little experimental information is available on the excited state energy surfaces, and theoretical studies have been essential. Attention has been focused in the past on the presence of two minima in the $^1A_1$ energy hypersurfaces and the energy difference between them. The HF approximation gives a qualitatively incorrect ordering of the low-lying states of O_3, since there are two configurations with substantial contributions to the ground state wave function.

In Figure 5 we show the energy hypersurfaces for low-lying states of ozone. DF calculations reproduce the ground

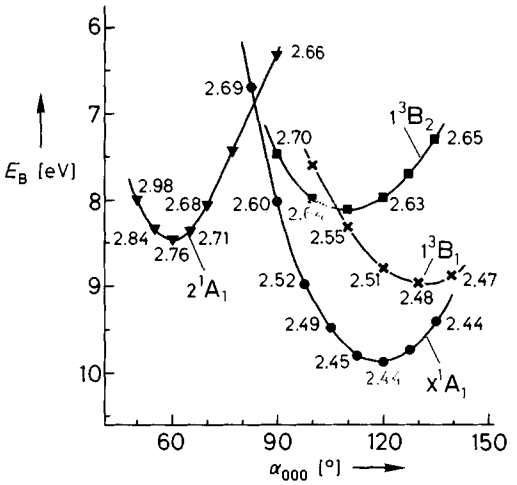

Fig. 5. Energy surfaces for low-lying states of O_3. α = bond angle. The values on the curves give the bond lengths [a_0] that optimize the energy for each angle α.

state geometry well, and the excitation energy between the two $^1A_1$ minima (1.4 eV) is in reasonable agreement with the most recent CI calculations, which give results between 1.0 eV and 1.4 eV.[27] In both O_3 and SO_2, the bond lengths increase in the order $x^1A_1 \rightarrow 1^3B_1 \rightarrow 1^3B_2 \rightarrow 2^1A_1$, and the bond angles in the order $2^1A_1 \rightarrow 1^3B_2 \rightarrow x^1A_1 \rightarrow 1^3B_1$. However, there are qualitative differences between the energy ordering of the states. In particular, the excitation from the ground state to the low-lying triplet states requires substantially more energy for SO_2 than for O_3, and the energy separation between the two $^1A_1$ states (4.1 eV) is almost three times as large for SO_2.

These differences can be related to the larger radius of the sulfur atom and the higher energy of the p orbital.[27] The ground state (x^1A_1) has the valence configuration $1a_2^2 3b_2^2 4a_1^2 2b_1^0$, and the 2^1A_1 state corresponds to the excitation ($3b_2^2 \rightarrow 2b_1^2$). While the $1a_2$ and $3b_2$ orbitals have significant contributions only from the outer (oxygen) atoms, the higher-lying $4a_1$ and $2b_1$ orbitals have a strong contribution from the central atom (O in O_3, S in SO_2). The eigenvalue spread in SO_2 is therefore much larger, so that the large excitation energy $x^1A_1 \rightarrow 2^1A_1$ in SO_2 reflects simply the double excitation to the high-lying $2b_1$ orbital.

The above molecules are only a small sample of those that have been studied with the DF method. Nevertheless, they illustrate some general features of the results. As in extended systems, equilibrium geometries and vibration frequencies are described satisfactorily, even in molecules—such as Be_2 and O_3—where the Hartree–Fock method gives qualitatively incorrect results. While energy variations near equilibrium geometries are given satisfactorily, this is not true of all regions of configuration space. The errors in the dissociation energies of first-row diatomic molecules and the ozone family (up to ca. 2 eV), for example, are unacceptably large and have contributed to the motivation behind the search for improved approximations.[11] The single-particle picture and the relative ease of performing calculations for elements with large atomic numbers is very useful in understanding the differences between first-row and heavier elements. A discussion on similar lines was presented subsequently by *Kutzelnigg*.[28]

4. The Molecular Dynamics/Density Functional Approach

While we cannot expect to be able to determine the exact ground state if the energy hypersurface has many local minima, it is essential to develop methods for avoiding energetically unfavorable local minima. *Kirkpatrick* et al.[29] noted that this can be achieved by allowing the system to evolve at finite temperature and implemented this "simulated annealing" strategy using a Monte Carlo sampling. Molecular dynamics (MD) provides an alternative, and *Car* and *Parrinello*[30] showed that it could be combined with the density functional (DF) scheme for calculating total energies. The use of the LSD approximation for the exchange–correlation energy avoids the parameterization of the interatomic forces common in MD schemes,[31] and should give a reliable description of energy variations for large regions of configuration space.

To perform geometry optimization using DF calculations, we face two minimization problems: The total energy must be minimized for each geometry by varying the density (the solution of Eq. 7), and the geometry with the lowest energy must be found. This is done conveniently by viewing E as a

function of two interdependent sets of degrees of freedom, $\{\psi_i\}$ and $\{\boldsymbol{R}_I\}$, and using standard MD techniques (Eq. 17, where Z_I are the ionic charges).[30]

$$E(\{\psi_i\}, \{\boldsymbol{R}_I\}) = \sum_i \left\langle \psi_i(\boldsymbol{r}) \left| -\frac{\nabla^2}{2} \right| \psi_i(\boldsymbol{r}) \right\rangle + \int d\boldsymbol{r} n(\boldsymbol{r}) \left(V_{ext}(\boldsymbol{r}, \{\boldsymbol{R}_I\}) + \tfrac{1}{2}\varphi(\boldsymbol{r})\right) + E_{xc}(n(\boldsymbol{r})) + \frac{1}{2} \sum_{I \neq J} \frac{Z_I Z_J}{|\boldsymbol{R}_I - \boldsymbol{R}_J|} \quad (17)$$

The energy minimization required for structure determination can be performed using standard MD techniques,[30] since the evolution of the system of electrons and ions is reproduced exactly by the evolution of a dynamic system defined by the Lagrangian (18) and the equation of motion 19a and 19b. M_I and $\boldsymbol{R}_I$ denote the ionic masses and

$$\mathscr{L} = \sum_i \mu_i \int_\Omega d\boldsymbol{r} |\dot{\psi}_i^* \psi_i| + \sum_I \tfrac{1}{2} M_I \dot{\boldsymbol{R}}_I^2 - E(\{\psi_i\}, \{\boldsymbol{R}_I\}) + \sum_{ij} \Lambda_{ij} \left(\int_\Omega d\boldsymbol{r} \psi_i \psi_j^* - \delta_{ij}\right) \quad (18)$$

$$\mu_i \ddot{\psi}_i(\boldsymbol{r}, t) = -\frac{\delta E}{\delta \psi^*(\boldsymbol{r}, t)} + \sum_k \Lambda_{ik} \psi_k(\boldsymbol{r}, t) \quad (19a)$$

$$M_I \ddot{\boldsymbol{R}}_I = -\nabla_{\boldsymbol{R}_I} E \quad (19b)$$

coordinates, μ_i are fictitious "masses" associated with the electronic degrees of freedom, dots denote time derivatives, and the Lagrangian multipliers Λ_{ij} are introduced to satisfy the orthonormality constraints on the $\psi_i(\boldsymbol{r}, t)$. From these orbitals and the resultant density $n(\boldsymbol{r}, t) = \sum_i |\psi_i(\boldsymbol{r}, t)|^2$ we use Equation 17 to evaluate the total energy E, which acts as the classical potential energy in the Lagrangian function 18. The artificial Newton's dynamics for the electronic degrees of freedom, together with the assumption $\mu_i \ll M_I$, prevent transfer of energy from the classical to the quantum degrees of freedom, even for long simulations.

5. Applications of the MD/DF Scheme to Molecules

MD/DF calculations have been performed for several families of molecules containing main-group elements, using a large unit cell with periodic boundary conditions to guarantee a weak interaction between the molecules. We give some examples here to show the value of the approach in several contexts.[32] The scattering properties of the individual atoms are described by nonlocal pseudopotentials, and the eigenfunctions ψ_i are expanded in a plane wave basis. We set the velocities $\dot{\psi}_i$ and $\dot{\boldsymbol{R}}$ equal to zero for an arbitrary starting geometry, and use an efficient self-consistent iterative diagonalization technique to determine those ψ_i that minimize E. With the electrons initially in their ground state, the dynamics (Eq. 19a and b) generate Born–Oppenheimer (BO) trajectories without the need for additional diagonalization/self-consistency cycles for the electrons. In the present applications, the minimum of the potential energy surfaces can be found by alternating MD calculations at finite temperature with steepest descents (or conjugate gradient) determinations of the nearest local minimum. Further details are given in the original papers.

5.1. Sulfur Clusters S_n

The elements of the sixth main group provide some of the best characterized of small atomic clusters. These elements are unique in that many allotropes comprise regular arrays of well-separated ring molecules, and X-ray structure analyses have been performed for S_n, $n = 6$–$8, 10$–$13, 18, 20$, and Se_n, $n = 6, 8$. S_9 has been found as microcrystals, and S_{18} exists in two distinct forms. Several mixed crystals of the form Se_nS_m and a range of sulfur oxides and ions are also known. The preparation and structure of these clusters has been reviewed by *Steudel*.[33]

The theoretical results for sulfur clusters S_2 to S_{13}[34] show that it is possible to determine low-lying energy minima even if the starting geometries are far from correct: linear chains in S_3 to S_6 and nearly planar rings in S_7 to S_{13}. The final structures agreed well with experiment in all cases where X-ray data were available. For example, the D_{3d} symmetry in S_{12} (Fig. 6b) is reproduced very closely, and the structural parameters (bond length $d = 3.97 a_0$, bond angle $\alpha = 106°$, dihedral angle $\gamma = 88°$) are in good agreement with measured values ($3.88 a_0$, $\alpha = 106.2°$, $\gamma = 87.2°$). The discrepancy in bond length is reduced by using a more accurate pseudopotential, as shown by calculations for the D_{4d} form of S_8, where the structure ($d = 3.900 a_0$, $\alpha = 108.5°$, $\gamma = 98.1°$) is very close to the experimental result ($d = 3.893 \pm 0.006 a_0$, $\alpha = 108.0 \pm 0.7°$, $\gamma = 98.3 \pm 2.1°$).[35]

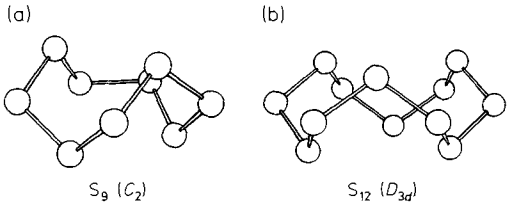

Fig. 6. Structures of a) S_9 and b) S_{12}.

Cases where the most stable isomers are not yet known are of particular interest. There is no experimental information on S_4 and S_5, for example, and S_9 has only been prepared as crystallites that are too small for X-ray diffraction analysis. The most stable S_4 isomer in our calculations was an unusual rectangular structure made up of two weakly interacting dimers. This minimum of the energy surfaces is very shallow and it is easy to distort the molecule. The detailed ab initio calculations of *Raghavachari* et al.[36] support our assignment of the ground state. This is also true in S_9, where we found a ground state isomer with C_2 symmetry (Fig. 6a) as well as several local minima with C_s symmetry with energies > 0.2 eV higher. The calculated ground state structure is consistent with measured Raman spectra, which indicate narrow ranges of bond lengths and bond angles, and dihedral angles in the range 70–130°.

5.2. Structural Change in S_7O

A surprising example of structural optimization is provided by the S_7O molecule.[37] In the course of the simulation

shown in Figure 7—1200 time steps at $T = 2000\,K$—the molecule changed from one with a stable local minimum and a ring structure similar to that in S_8 (Fig. 7a) to a structure with different topology: an oxygen atom outside the S_7 structure (Fig. 7i). The structure found on reducing the temperature slowly to $T = 0\,K$ (Fig. 7j) agrees well with the experimental ground state.[37] The entire structural change

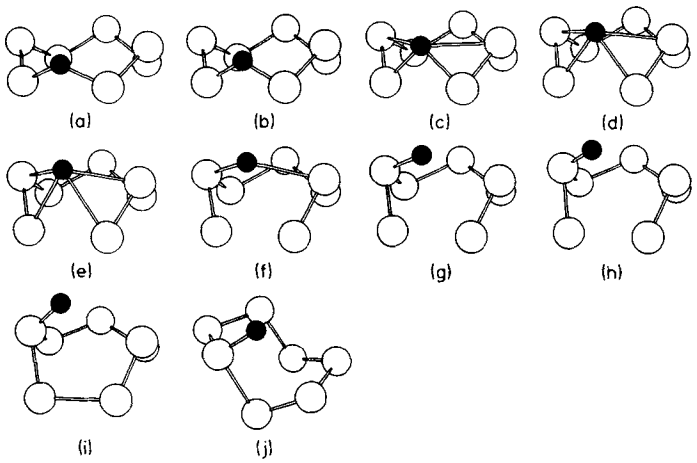

Fig. 7. Evolution of S_7O from ring (a) to ground state structure (j). The time difference between successive frames is 1.1×10^{-14} s.

(including cooling) took only about 8000 time steps ($< 10^{-12}$ s), although the energy barrier between ring and ground state structures is ca. 5 eV and the energy difference only about 0.2 eV. This shows just how efficient molecular dynamics can be in generating geometrical configurations.

5.3. Isomers of Se_2S_6, Se_6S_2

Sulfur and selenium have much in common, and binary systems have been studied extensively in the vapor phase[38, 39] and as liquids and as solid solutions.[40–42] The different species tend to crystallize together, leading to structures with sulfur and selenium atoms distributed over the atomic sites.[43] The possible complexity is evident in the eight-membered rings S_nSe_{8-n}, where thirty different crown-shaped isomers can occur. Apart from the intrinsic interest in molecules of the form Se_mS_n, an understanding of their structures could provide insight into the structures of related liquid and amorphous materials, including Se itself.

The interconversion of various Se_nS_m isomers and ring–chain equilibration processes involves reactions of the type in (20). This reaction is endothermic in the liquid.[44] For

$$\text{–S–S–} + \text{–Se–Se–} \longrightarrow 2\ \text{–Se–S–} \qquad (20)$$

diatomic S–Se molecules in the gas phase,[45] the measured enthalpy change is $+7.9 \pm 6.7\,kJ\,mol^{-1}$ and the sum of the dissociation energies on the left side of (20) is greater than the sum on the right. Theoretical predictions of the relative stability of different isomers are difficult to make,[46] and it is natural to ask whether DF calculations can describe reliably the small energy differences involved.

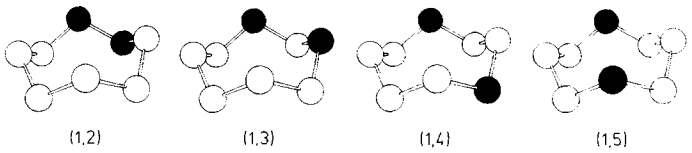

Fig. 8. Possible cyclic structures for Se_2S_6 and Se_6S_2. The numbers in parentheses indicate the positions of the two atoms of the minority element.

Calculations have been carried out on seven- and eight-membered rings of the type Se_mS_n,[47] starting with the ground state structures of S_7 (C_s) or S_8 (D_{4d}). The eight-membered rings are characterized by small deviations from the crown-shaped (D_{4d}) structures, and the possible cyclic structures in Se_2S_6 and Se_6S_2 are shown in Figure 8. The results for these molecules show several remarkable features, illustrated by the structural parameters for Se_2S_6 given in Table 3. In all eight structures, the bond lengths (d_{S-S}, d_{S-Se}, d_{Se-Se}) are the same to within 0.02 a_o (3.93 a_o, 4.21 a_o, 4.44 a_o), and d_{S-S} and d_{Se-Se} are the same as found previously for the ring structures of S_8 and Se_8. The (1,2) isomers are the most stable in both Se_2S_6 and Se_6S_2, and the energies of the other three structures are ca. 0.08 eV higher and degenerate to within $\pm$ 3 meV in each case. We now show that these findings can be understood in terms of a very simple model.

Table 3. Molecular parameters $d[a_o]$, α and γ[°] for all isomers of Se_2S_6 (see Fig. 8). Bond lengths between atoms i and j are denoted by d_{ij}, bond angles at atom i by α_i and dihedral angles at bond ij by γ_{ij}.

	Isomer [symmetry]			
	(1,2) [C_2]	(1,3) [C_s]	(1,4) [C_2]	(1,5) [C_{2v}]
d_{12}	4.42	4.20	4.20	4.21
d_{23}	4.21	4.20	3.92	3.93
d_{34}	3.92	4.20	4.21	3.93
d_{45}	3.93	3.93	4.21	4.21
d_{56}	3.95	3.93	3.93	4.21
d_{67}	3.93	3.93	3.92	3.92
d_{78}	3.92	3.93	3.93	3.93
d_{81}	4.21	4.20	4.21	4.21
α_1	105.9	106.1	106.7	106.7
α_2	105.8	108.1	108.2	108.9
α_3	108.1	106.2	108.2	108.6
α_4	108.8	108.4	106.7	108.4
α_5	109.1	108.7	108.5	106.5
α_6	109.2	109.2	108.7	109.2
α_7	108.8	108.7	108.8	108.7
α_8	108.2	108.5	108.6	108.5
γ_{12}	96.8	98.0	98.3	99.1
γ_{23}	97.2	96.6	97.8	96.6
γ_{34}	97.6	96.1	96.3	98.2
γ_{45}	100.6	100.4	99.1	100.5
γ_{56}	102.9	102.1	101.1	99.0
γ_{67}	100.5	100.4	98.9	96.5
γ_{78}	97.5	99.0	99.1	97.7
γ_{81}	97.3	97.6	99.1	100.4

The transferability of the bond lengths and the known connection between bond length and bond strength[26] suggest that we can associate with each bond type a contribution to the binding energy, E_{S-S}, E_{S-Se}, and E_{Se-Se}. This leads to (21) for the (1,2) structure in Se_2S_6 and to (22) for all remain-

$$E_{12} = E_{Se-Se} + 2E_{S-Se} + 5E_{S-S} \qquad (21)$$

$$E_{13} = E_{14} = E_{15} = 4E_{S-Se} + 4E_{S-S} \qquad (22)$$

ing structures. This argument predicts that the energies of the last three structures will be equal, and will differ from the energy of the (1,2) structure by ΔE (23).

$$\Delta E = E_{Se-Se} + E_{S-S} - 2E_{S-Se} \quad (23)$$

If we apply the same argument to the Se_6S_2 structures, Equations 21–23 still apply when S and Se are interchanged. This explains why the energy orderings in Se_2S_6 and Se_6S_2 are the same, and why the most stable (1,2) isomers are separated from three structures with almost identical energies. The separation in the present calculations (ca. 0.08 eV, 7.4 kJ mol^{-1}) is consistent with the endothermic reaction (20) and in reasonable agreement with the measured heats of reaction in the gas and liquid phases.

In spite of its simplicity, this model—based on a very careful geometry optimization—gives results that agree with trends found in recent measurements, particularly the relative abundance of structures in which the minority atoms are adjacent. The symmetry between the energy ordering of the isomers of Se-rich and S-rich molecules is perturbed, of course, by differences between the elements such as the atomic radius, but the essential features should be unchanged. The trend to segregation of minority components could also occur in the disordered liquid and amorphous states. Segregation in this model is a consequence of the sign of ΔE in Equation 23, and other systems with a small value of ΔE or with one of opposite sign would behave differently.

5.4. Phosphorus Clusters P_n

The structural variety shown by phosphorus exceeds that of all elements other than sulfur and perhaps boron, and there have been many studies of its crystalline and amorphous forms.[48, 49] A problem of continuing interest in gas-phase clusters has been the detection of only P_2, P_3, P_4, and (possibly) P_8 in the vapor phase at high temperatures.[50] There have been numerous speculations about the apparent absence of heavier clusters,[51] and several calculations indicate that the cubic form of P_8 is less stable than two P_4 tetrahedra.[52, 53] Recently, *Martin*[54] was able to detect by mass spectroscopy P_n molecules up to $n = 24$ in a low-temperature beam. In spite of this, almost nothing is known about the structure of clusters with $n > 4$.

MD/DF calculations have been performed on phosphorus clusters up to P_{10},[55] and calculated and experimental geometries and vibration frequencies agree well in those cases (P_2, P_4) where the latter are known. In the larger clusters there were several unexpected findings: 1) Although the tetrahedral structure is energetically favored in P_4, there is a large "basin of attraction" for a D_{2d} "roof" structure, that is, this structure is the closest minimum for a large region of configuration space. 2) The roof structure is a prominent feature in the low-lying isomers in P_5 to P_8. The most stable isomers found in P_5, P_6, and P_7 have a P_4-roof with an additional one, two, and three atoms, respectively.

The two forms of P_8 shown in Figure 9 are energetically more stable than the cubic structure. The structure in Figure 9a shows again the preference for the "roof" structure (two such units are bonded together), and the isomer shown in Figure 9b was the most stable we found. It can most easily be understood as a (distorted) cube with one bond rotated through 90° and is ca. 40 kcal mol^{-1} more stable than the cubic form. This "wedge" or "cradle" structure is found as a structural unit in violet (monoclinic, Hittorf) phosphorus.[56]

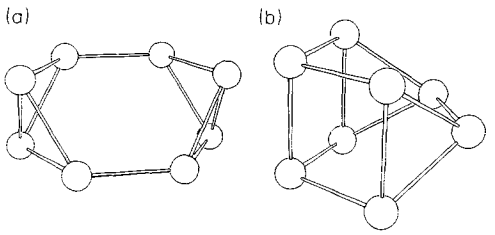

Fig. 9. Two isomers of P_8.

There is a pronounced analogy between the structures of the P_8 isomers and those of the corresponding isoelectronic hydrocarbons C_8H_8. The cubic form of the latter (cubane) has been prepared by *Eaton* and *Cole*,[57] and can be converted catalytically to the wedge-shaped form cuneane.[58] The third possible isomer of C_8H_8 (analogous to Fig. 9a) was estimated to have a strain energy intermediate between the other two, in agreement with the energy ordering we found in the P_8 isomers.[55]

The results for the P_n clusters show two particularly interesting features: 1) The presence of a large basin of attraction for the energetically unfavorable roof structure in P_4. This shows that the most favorable structures are not necessarily surrounded by the most extensive minima in the energy surfaces. 2) The existence of two isomers of P_8 that are more stable than the cubic form. Although attention had been focused for many years exclusively on the last, our finite-temperature simulation led almost immediately to more stable forms. The lowest energy for P_8 lies ca. 0.5 eV below the energy of two P_4 tetrahedra in the LD calculations. It would be interesting to see the energy difference found using ab initio methods.

5.5. Aluminum Clusters Al_n

The calculations for the sulfur and phosphorus clusters reproduce known structures satisfactorily. This is also true for small aluminum clusters, where spectroscopic data are available for Al_2, and ab initio calculations have been performed for a limited range of geometries up to Al_6.[59] If we can reproduce known structures of small clusters with our methods, we may have confidence in our predictions for larger clusters of these elements. Aluminum is a prototype "simple metal" of the condensed matter theorist, which is characterized by a weak electron–ion interaction and a valence electron charge distribution that is nearly uniform. It is natural then that calculations of the electronic structure of Al clusters have often used a "spherical jellium" model,[60] where both the electron density and the positive-ion distribution are assumed to be uniform inside a sphere of appropriate size. The focus in such calculations has been on particularly stable electronic configurations with "magic numbers" of electrons.

MD/DF calculations up to $n = 10$ give structures for $n = 2-4$ in good agreement with other calculations, and a satisfactory description of variations in ionization energies. There were, however, some unexpected results for larger clusters,[61] including the existence of a class of energetically favorable structures that can by no means be viewed as spherical. Figure 10 shows three such structures for Al_8. They can be viewed as distorted planar arrays of approximately equilateral triangles, connected so that adjacent triangles are either nearly coplanar (dihedral angle near zero) or have dihedral angles ca. 35°–55°. These features are also apparent in bulk aluminum (the face-centered-cubic structure comprises equilateral triangles with dihedral angles zero or 54.7°) and in the α form of the neighboring boron-group element gallium, as shown in Figure 10d. There are, of course, many possible structures of this type in molecules of finite extent. It is surprising, nevertheless, that DF calculations show that they are of comparable stability to the more compact "metallic" structures of Al_8. The structure shown in Figure 10c was, in fact, the most stable found in this molecule.

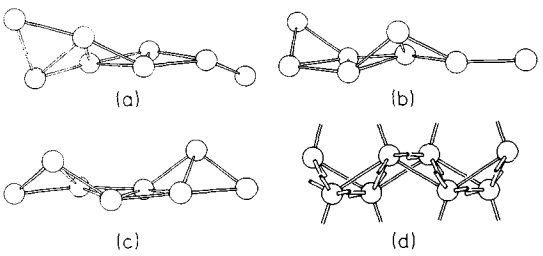

Fig. 10. a)–c) Three isomers of Al_8. d) Crystal structure of α-Ga.

We have noted above how useful the DF approach has been in finding trends in families of molecules, and in relating them to single-particle properties such as the valence orbital. This is also true in the elements of the third main group. We find that the bonds in gallium clusters are generally shorter than the corresponding bonds in aluminum clusters, and that this can again be correlated with the range of the valence orbitals.[61]

6. Concluding remarks

Theory should be able to contribute much to the determination of molecular structures. The calculation of the energy surfaces and the location of low-lying minima should lead to the most stable isomers, but there are severe problems: The determination of the energy E from the exact wave function is impracticable in all but the smallest molecules, and there are usually many local minima in the energy surface.

The approach described here addresses both aspects. The density functional formalism, with the local spin density approximation for the exchange–correlation energy, enables us to carry out energy calculations in an efficient manner, and the use of finite temperature molecular dynamics prevents the molecule becoming trapped in unfavorable energy minima. The results have been encouraging. The structures of small clusters of sulfur are described well and, in the case of S_7O, we can simulate structural changes involving a high energy barrier. The final structure (an O atom outside an S_7-ring) is in good agreement with the structure determined by X-ray diffraction. The heterocyclic ring molecules Se_mS_n are characterized by structures with very small energy differences and energy barriers that are small on a thermal scale. The calculations led in this case to a simple model of the energy differences in mixed Se–S ring structures and predictions for molecules for which calculations have not yet been performed. In the case of phosphorus clusters, we predict structures with plausible trends and with an interesting analogy to isoelectronic hydrocarbons $(CH)_n$. In Al_n clusters we have found a class of energetically favorable structures that was quite unexpected. There have been so many surprises, in fact, that one can only assume that many calculations using other methods have overlooked important minima in molecular energy surfaces. The number of minima and the fact that many can have comparable stability show how difficult it is to determine structures on the basis of "chemical intuition" alone. There is little doubt that other methods of calculating electronic structures would benefit from the implementation of simulated annealing.

The successes of this approach should not lead us to overlook its limitations. Even the most careful calculation reflects the approximations used, and the LSD approximation is an essential part of most of the calculations performed so far. Overestimates in the binding energy are evident in all the molecules discussed above, and there are indications that an inadequate description of exchange energy differences is an important factor.[111] Improved approximations would be useful, if implemented in a systematic way, but attempts in this direction have had mixed success. Moreover, there are many local minima in the energy surfaces even for clusters containing less than 10 atoms. The implementation of molecular dynamics techniques does not change this, and no method can guarantee finding the global energy minimum, or even all of the most important minima. The development of alternative optimization schemes and of simplified energy functionals[62] will be important in the future.

Density functional calculations are common in condensed matter physics and it is not surprising that workers from this field have played the major role in theoretical developments and in molecular applications. In fact, density functional methods have been slow to find favor amongst chemists. The coupling to molecular dynamics has opened up perspectives not currently available to some of the traditional methods of theoretical chemistry, and—perhaps in conjunction with these methods—the prospects of applications to many problems of chemical interest are very good.

I have benefited greatly from collaboration over the years with O. Gunnarsson, J. Harris, and D. Hohl, and from discussions with many colleagues. Special thanks are due to the developers of the MD/DF method, R. Car and M. Parrinello, and to G. Eilenberger for critical remarks on the manuscript.

Spectroscopy of Fluid Phases—The Study of Chemical Reactions and Equilibria up to High Pressures

By Michael Buback*

The properties of fluid phases can be altered considerably by the external conditions. Phase equilibria and chemical equilibria can be greatly affected, and it is possible to carry out chemical reactions by exploiting the special properties of compressed fluid phases. The use of high pressure in chemical reactions is of considerable diagnostic and preparative value. Applied research is directed towards elucidating the details of existing technical high pressure processes and to the development of novel fluid phase reactions where the application of high pressure is able to induce selectivity. In order to pursue these lines of research, and to study structure and dynamics throughout the entire range from gaseous to liquidlike states, it is important to have spectroscopic methods for characterizing systems at high pressures and temperatures. This article is concerned with quantitative absorption spectroscopy in the infrared to the ultraviolet spectral region at pressures up to about 7 kbar and temperatures up to 900 K.

1. Introduction

The application of pressure to gaseous substances causes a significant reduction in the intermolecular distances. At pressures greater than 1000 bar all substances exist in dense states. In the kbar pressure range one probes intermolecular effects, and at very high pressures significant intramolecular effects occur, such as changes in the structures of the molecules or the formation of ionic or metallic states.[1,2]

For the chemist the study of fluid phases at pressures up to several kbar is of particular interest, especially with regard to possible preparative applications. The pressure–temperature diagram shown in Figure 1 indicates in a qualitative way[1] the behavior of a substance in the fluid, i.e. nonsolid, region. The density of packing of the circles is proportional to the density of the substance. In the bottom left part of the diagram the vapor-pressure curve, which extends to the critical point, divides the (condensed) liquid phase from the gaseous phase. At very high pressures the fluid region is bounded by the melting-pressure curve (not shown in the figure). In the literature[3] the region where temperature and pressure are both supercritical ($T > T_c, p > p_c$) is sometimes treated as a special region, that of the "supercritical fluid".

Figure 1 indicates that high-pressure experiments at supercritical temperatures offer special advantages: one can alter the density of a substance continuously from a gaseous to a liquidlike state, and if suitable physical measurement techniques are available, one can investigate the structure and dynamics over a wide range in the fluid state. It is important for practical applications that in supercritical fluid phases, properties such as the viscosity, dielectric constant, and heat-transfer coefficients vary considerably. This behavior has been studied in particular detail for supercritical water.[2,4–6]

When the pressure and temperature can be varied over a wide range, it is possible to produce large changes in the positions of the phase boundaries, and therefore also in solubilities. The chemist would like to influence chemical equilibria and reactions by applying high pressure. Kinetic experiments focus on the study of reaction mechanisms[7] including fast elementary processes, as well as on the use of high pressures for the development of new reaction routes or new products. In reactions that involve complex kinetic mechanisms, a difference between the pressure dependence of individual reaction steps can sometimes be exploited to achieve a pressure-induced selectivity.[8]

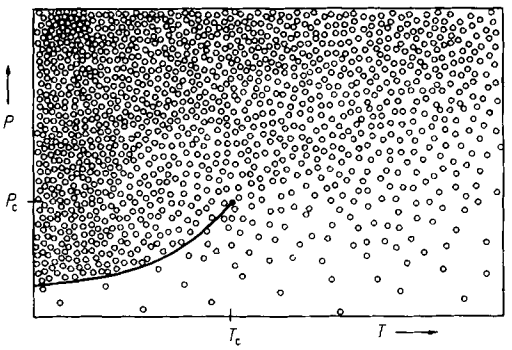

Fig. 1. Pressure-temperature diagram representing the density of a simple substance; p_c: critical pressure, T_c: critical temperature.

For measuring the effects of pressure, it is very useful to be able to perform quantitative analyses under high-pressure conditions. Particularly suitable methods for this are infrared and near infrared (near-IR) spectroscopy, but spectroscopy in the visible and ultraviolet regions also has some important applications. This article is concerned with measurements on fluid phases under conditions of both high pressure and temperature.

Section 2 describes sample cells that can be used for measurements at wavelengths throughout the range from IR to UV, with pressures up to 7000 bar and temperatures up to 900 K in some cases. Section 3 describes the changes in the vibrational spectra of pure substances over a wide range of densities. Section 4 contains examples of the use of quantitative absorption spectroscopy to study equilibria in fluid phases. In Section 5 the capabilities of quantitative absorption vibrational spectroscopy as a means of investigating pressure-induced reactivity and selectivity in chemical reactions are illustrated by examples. Section 6 shows how quan-

Tammannstrasse 6, W-3400 Göttingen (FRG)

titative vibrational spectroscopy can be used very effectively for a direct study of industrial processes carried out at high pressures, taking free-radical polymerizations as an example.

2. Experimental Arrangements for Absorption Spectroscopy at High Pressures and Temperatures

Cells for fluid phase spectroscopy require windows that can withstand high pressures and can be used over as wide a spectral range as possible. It is necessary to be able to observe at least one characteristic absorption band for each relevant species in the system. For components whose concentration undergoes large changes during the course of the high-pressure reaction the ability to record several bands with widely different molar absorption coefficients is desirable.

The books by *Isaacs*[9] and by *Sherman* and *Stadtmuller*[10] contain detailed descriptions of high-pressure optical cells, including not only hydrostatic pressure cells but also other designs for measurements on solids, e.g. diamond-anvil cells. Only a few of these cell types are suitable for quantitative spectroscopic measurements in the fluid phase under conditions of simultaneous high pressure and high temperature. Cells with these capabilities that can be used up to 7 kbar and 900 K have been developed chiefly by *Franck*'s group at the University of Karlsruhe.[11] A basic design for such a high-pressure optical cell is described here.

The sealing of the optical window is based on the Poulter principle,[12] which is a modification of *Bridgman*'s unsupported area principle. The arrangement is shown in Figure 2. The window (2) rests on the optically flat polished surface (3) of a hollow steel ram (4) with a cylindrical bore. The high pressure side is denoted by P and the atmospheric pressure side by A. The pressure on the seating face (3) exceeds that at P by the factor $(d_1^2/d_1^2 - d_2^2)$, the ratio of the total surface area to the supported surface area, with the result that the arrangement is self-sealing at this interface. A sealing ring of poly(tetrafluoroethylene) (PTFE) film or gold foil inserted between the window and the steel seating compensates for any irregularities at the two surfaces. The high-pressure window is held under compression by a cap (1), to ensure effective sealing even at low pressures. The choice of the material for the cap is determined essentially by the working temperature. Stainless steel is suitable to 650 K. At higher temperatures it is important that the thermal expansion coefficient of

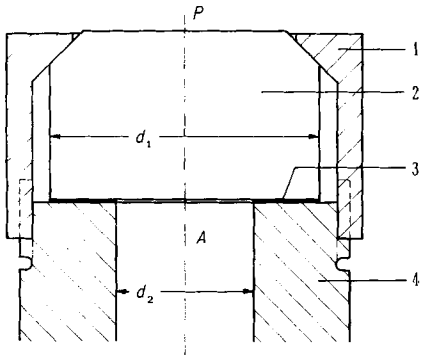

Fig. 2. Sealing arrangement of the high-pressure optical window; 1: cap, 2: window, 3: polished front surface of the ram with sealing ring in position, 4: steel ram; P: high-pressure side, A: atmospheric pressure, d_1: window diameter, d_2: diameter of free area available for passage of beam.

the material of the cap should be well matched to that of the window; for example, niobium is a suitable cap material for use with a sapphire window. This ensures that the compressional stress in the window remains sufficient up to high temperatures, giving good sealing even at low pressures.

Figure 3 shows a sample cell designed for pressures up to 3500 bar and temperatures up to 550 K. The two high-pressure optical windows (1) are supported on stainless steel rams (5) in accordance with the Poulter principle. Each ram is pressed against the body of the cell by a flange (3), which is secured by several bolts (2). The optical path length is determined by the distance between the inner surfaces of the high-pressure windows. Holes are drilled perpendicular to the axis of the cylindrical cell for introducing the sample and allowing one or more sheathed thermocouples (6) to be in-

Michael Buback was born in 1945 in Nobitz near Altenburg (Thüringen) and from 1963 studied chemistry at the University (Technische Hochschule) of Karlsruhe, gaining his doctorate in 1972 under Professor Ernst Ulrich Franck. Following his habilitation in 1978 he was awarded a Heisenberg fellowship by the Deutsche Forschungsgemeinschaft. In 1981 he took up the position of Professor of Applied Physical Chemistry at the University of Göttingen. He was awarded the Carl Duisberg Memorial Prize by the Gesellschaft Deutscher Chemiker, and in 1989 received the Dechema Prize from the Max Buchner Research Foundation. His special fields of interest are the kinetics and selectivity of reactions in fluid phases up to high pressures and temperatures, the study of free-radical polymerizations, especially using excimer laser initiation, and the development of absorption spectroscopy techniques for quantitative investigations of fluid systems under extreme conditions.

serted. The cell is heated from the outside by a resistive heating element (4) which may be mounted in a brass support.

For measurements requiring good optical transparency in the range from about 2000 cm^{-1} to 50 000 cm^{-1} at pressures up to 10 kbar, sapphire is unrivalled as a high-pressure, high-temperature window material, especially since it is also very resistant to chemical attack. In the wavenumber range below 2000 cm^{-1} windows made of polycrystalline silicon (down to 1450 cm^{-1}) or CaF_2 single crystals[13] (down to 1000 cm^{-1}) can be used. The maximum working pressures with these materials are 3 kbar and 2 kbar respectively. For still lower wavenumbers extending into the far infrared region one can use windows made of diamond (type IIa), or in some cases of quartz or silicon. Further information on high-pressure window materials can be found in the paper by *Ferraro* and *Basile*[14] and in relevant books.[10, 11]

High-pressure, high-temperature optical cells, based on the principles sketched in Figures 2 and 3, have also been developed for several special applications.[11, 15] These allow higher pressures to be reached by reducing the internal diameter of the cell[11, 16] or enable the separation of the sample under investigation from the pressurizing medium by a stainless steel bellows inside the optical cell.[11, 17, 18] Particular problems arise when attempting quantitative IR spectroscopic measurements on pure substances at very high pressures. Here path lengths need to be as short as several μm, and these distances are comparable with the changes in path length caused by altering the pressure and temperature in sample cells of the type shown in Figure 3. Considerable difficulties also arise in joining together the parts of such optical cells for working with path lengths shorter than 0.1 mm. These difficulties can be overcome by using cells in which the path length can be adjusted from outside while the cell is under pressure.[19] In this case two spectra are recorded under the same measurement conditions but with different path lengths; one of these serves as the sample spectrum and the other as a reference spectrum. The difference between the path lengths can be accurately determined.

The walls of the vessel, which are of stainless steel and can contain large amounts of nickel, cobalt, molybdenum, or other catalytically active constituents (e.g., German Standard No. 2.4668), can substantially influence the course of chemical reactions. This problem can be avoided by a procedure introduced by *le Noble*, in which the system under investigation is contained in an inner cell of quartz with a movable piston which is ground to give a close fit.[20] A recently introduced alternative method uses a PTFE container into which the reaction mixture is sealed by welding. The PTFE inner cell has a wall thickness of about 0.1 mm and the analyzing light beam readily passes through it. It is fitted into the high-pressure cell in such a way that it is in direct contact with the inner faces of the two high-pressure windows.[16, 21]

3. Absorption Spectra of Pure Substances in Fluid States

Experimental arrangements of the types described in Section 2 can be used to measure absorption spectra in the far infrared (far-IR) to the UV range. The far-IR spectra of condensed phases arise mainly from hindered rotations and intermolecular librational motions. *Bohn* and *Franck*[22] have demonstrated the continuous transition that occurs between these two types of motions in monochlorodifluoromethane on passing from the gaseous to the liquidlike state at a constant supercritical temperature. However, the far-IR spectrum is not very useful for determining the composition of fluid systems. The UV spectrum too is generally of little use for quantitative analysis, since the absorption bands of electronic transitions are broad and not very specific, so that qualitative and quantitative analyses are only advantageous in systems where the components are few in number and very different. A totally different situation prevails in the region of the fundamental, overtone, and combination frequencies of molecular vibrations: here, in the IR and near infrared (near-IR), one finds a wealth of characteristic absorption bands. The proven suitability of this spectral region for qualitative and quantitative analysis of gases, liquids, and solids under normal conditions should apply equally to studies on fluid phases up to high pressures and temperatures. Some IR and near-IR spectra of polar and nonpolar pure compounds in fluid phases are described below.

Figure 4 shows a plot of the molar absorption coefficient ε for the O–D stretching vibration in HDO at 673 K (above T_c = 647 K) for densities ranging from 0.01 to 0.90 g cm^{-3}, taken from the results of *Franck* and *Roth*[23], which extended up to 773 K and 4 kbar. Here $\varepsilon = A/cl$, in which A is the

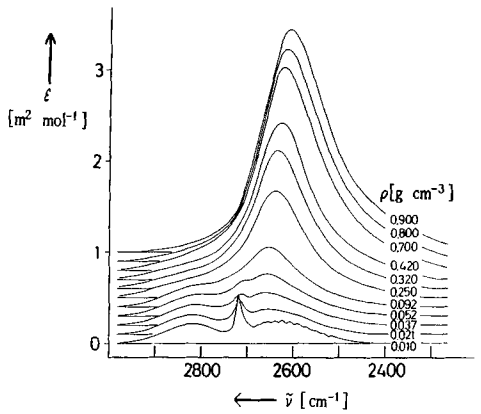

Fig. 4. Molar absorption coefficient ε for the O–D stretching vibration in HDO at 673 K and various densities ϱ.

logarithmic absorbance (decade scale), c is the concentration or density, and l is the path length. The bands are shifted slightly relative to each other along the baseline. At the lowest density the pressure-broadened spectrum observed is the envelope of the P, Q, and R branches. At higher pressures the spectrum changes to a strong broad band without shoulders.

Figure 5 shows how the vibrational spectrum of pure hydrogen chloride at 373 K (above T_c = 324 K) varies with the density.[24] At the lowest density (0.0065 g cm^{-3}) one observes the familiar spectrum with the P and R branches. With increasing density the rotational structure is lost, and at the highest density one again finds a single band, which is essentially symmetrical.

Figures 4 and 5 confirm that, as a result of dynamic and static effects, the infrared spectrum changes appreciably with

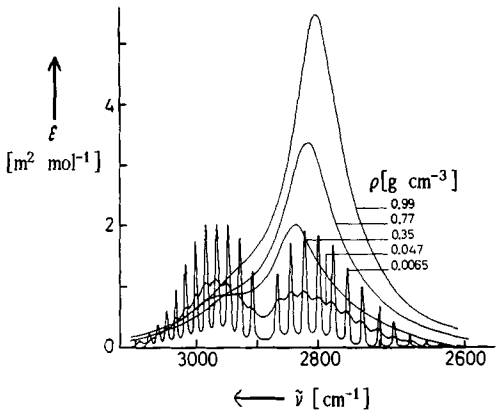

Fig. 5. Molar absorption coefficient ε for pure hydrogen chloride at 373 K and various densities ϱ.

the pressure or density. For these two polar compounds the vibrational intensity $B = \int \varepsilon(\tilde{\nu})\,d\tilde{\nu}$ increases markedly with increasing density, and the absorption maximum is shifted in the direction of smaller wavenumbers. In Figure 6 the shift of the band maximum to longer wavelengths for the O–D stretching mode of HDO and the H–Cl mode is plotted as a function of the "reduced" density ϱ/ϱ_c, where ϱ_c is the critical density for each substance; here the shifts are expressed as $\Delta\tilde{\nu} = \tilde{\nu}_{gas} - \tilde{\nu}_{max}$, i.e. the shift relative to the position in the gas phase. For both compounds $\Delta\tilde{\nu}$ is strongly dependent on the density at a given constant temperature. For a constant density, in the case of HCl, $\Delta\tilde{\nu}$ shows only a slight temperature-dependence, whereas in HDO the band maximum of the O–D stretching mode shifts considerably with temperature. However, above 673 K the stretching mode in HDO behaves in a similar way to the HCl stretching vibration, showing only a small effect on the band position when the temperature is increased further to 773 K. The behavior shown in Figure 6 for HCl can be regarded as typical for a normal dipolar liquid, whereas a strong temperature-dependence of $\Delta\tilde{\nu}$ at constant density, as observed for water up to about 573 K (Fig. 6), is regarded as an indication of significant hydrogen-bonding effects.[24] According to this criterion the behavior of water at supercritical temperatures, even in a highly condensed phase, resembles that of a normal dipolar liquid.

When the vibrational intensity B changes with the density and—as in the case of water—with the temperature, the absorbance $A(\tilde{\nu}) = \varepsilon(\tilde{\nu})cl$, as obtained directly from experimental absorption spectra, does not allow concentrations to be determined reliably, even if the path length l is accurately known. However, as we shall see below, polar fluids have overtone and combination bands for which the vibrational intensities show little or no dependence on density and temperature.

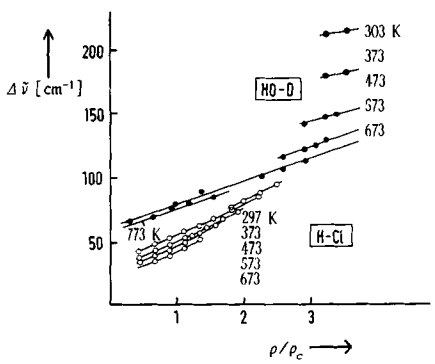

Fig. 6. The shift $\Delta\tilde{\nu} = \tilde{\nu}_{gas} - \tilde{\nu}_{max}$ of the band maximum (in wavenumber units) for the H–Cl vibration (lower curves) and the O–D vibration in HDO (upper curves) as a function of the reduced density ϱ/ϱ_c at various temperatures.

Figure 7 shows the vibrational intensity $B(0 \rightarrow 2)$ of the first overtone $(0 \rightarrow 2)$ absorption of pure CO over a wide range of densities at temperatures from 293 to 500 K.[25] The dependence of $B(0 \rightarrow 2)$ on density is quite different from the behavior of the absorption bands of strongly polar fluids (Figs. 4 and 5); it changes by only a few percent, and is independent of the temperature, at least between 293 and 500 K. Thus one has favorable conditions for the quantitative spectroscopic determination of CO over a wide range of fluid states. The same also applies for the fundamental mode IR absorption $(0 \rightarrow 1)$[26] at 2150 cm^{-1}, and with slight restrictions, also for the second overtone $(0 \rightarrow 3)$[25], which gives an absorption at about 6350 cm^{-1}.

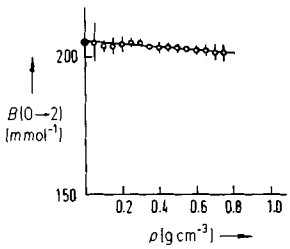

Fig. 7. Dependence of the vibrational intensity $B(0 \rightarrow 2)$ on density for the first overtone absorption in pure CO at temperatures between 293 and 500 K; ●: value from Ref. [27].

Further evidence that intermolecular interactions only weakly influence the vibrational spectrum of CO is provided by the band shapes in the condensed phase, which can be well described using the parameters of the gas phase spectrum. For this, a model developed by *Bouanich* et al. can be used,[27, 28] in which the band contour, expressed as the reduced molar absorption coefficient $\varepsilon_n(\tilde{\nu}) = \varepsilon(\tilde{\nu})/B(0 \rightarrow n)$, is calculated as a summation over the individual rotational–vibrational lines of the gas phase spectrum. These lines are assumed to have a modified Lorentzian shape with a half-width proportional to the density. The model contains only one adjustable parameter, which has the effect of varying the band shape of the individual lines between a Lorentzian and a nearly Gaussian function.

The spectra calculated using this model (data points in Fig. 8) are in very good agreement with the experimentally observed spectra (solid curves in the figure) for the fundamental mode and the first and second overtones at moderately high densities (0.1 $g\,cm^{-3}$) throughout the temperature range investigated (up to 500 K).[25] The first overtone region depicted in Figure 8 shows that at higher densities (up to 0.3 $g\,cm^{-3}$) the experimental curves for the P-branch are still very well described by the model, while the agreement for the R-branch is just barely satisfactory. In liquidlike states (densities around 0.6 $g\,cm^{-3}$) discrepancies of as much as 10% in the P-branch and 20% in the R-branch are found.[25] Since a density of 0.3 $g\,cm^{-3}$ at 500 K corre-

sponds to a pressure of about 600 bar, the conclusion from Figure 8 is that this model which, apart from one adjustable parameter, is based solely on the spectroscopic data from the gas phase spectrum, is applicable over quite a broad range of pressures and temperatures.

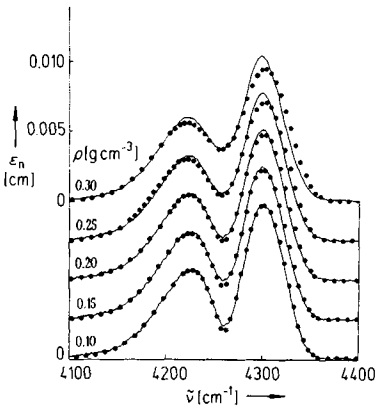

Fig. 8. Comparison of observed line shapes (——) with those calculated from Ref. [27] (●) for the first overtone absorption of pure CO at 500 K and various densities ϱ.

Similar studies of the density-dependent band shapes have been carried out for pure CO_2 in the region from 3200 to 7400 cm^{-1}.[29, 30] In this case the overlapping of several vibrational bands, and particularly a vibrational coupling by Fermi resonance must be taken into account. For some of the CO_2 modes, such as the $3\nu_3$ overtone, the wavenumber position of the band maximum does not continue to move downwards at very high densities, and at the highest attainable densities a shift in the opposite direction starts to occur. Effects of this kind are known from studies by *Drickamer* et al.,[31, 32] and are attributed to the influence of repulsive interactions.

The IR spectra of the fundamental stretching modes in water (Fig. 4) and hydrogen chloride (Fig. 5), and also in ammonia,[33] are not very suitable for quantitative analytical purposes, as the vibrational intensities vary considerably with changes in densities from the gaseous phase to liquidlike states. In contrast, carbon monoxide,[25, 26] carbon dioxide,[29, 30] ethylene,[34–36] and *n*-heptane[37] have several bands in the IR and near-IR whose intensities remain constant or change by only a few percent when the density or temperature is altered over a broad range in the fluid state. In the near-IR, even polar substances have combination and overtone bands whose vibrational intensities show little or no variation with density and temperature. This behavior has been observed for the O–H stretching modes in water by *Luck*[38] and in alcohols by *Luck* and *Ditter*.[39] Figure 9 shows a series of absorption spectra for pure NH_3 at 523 K at densities from 0.025 to 0.525 g cm^{-3}.[40] The band with a maximum at 4400 cm^{-1} is assigned to the combination frequency $\nu_2 + \nu_3$ and that at 5000 cm^{-1} to $\nu_3 + \nu_4$.[40, 41] When the absorption spectra of Figure 9 are integrated and normalized to a standard path length and concentration, the resulting vibrational intensity B is found to be independent of the density within the limits of accuracy of the measurements. In contrast, the values of B measured in the region of the N–H fundamental stretching modes (ca. 3200 cm^{-1}) alter by about 300% on going from the gas phase to a liquidlike phase. Thus the near-IR region, which has the additional advantage of greater path lengths, is very well suited for quantitative measurements on fluids. For nonpolar compounds and those that are only weakly polar the combined use of the IR and near-IR spectra brings considerable analytical advantages, as illustrated below for the example of the ethylene–polyethylene system.

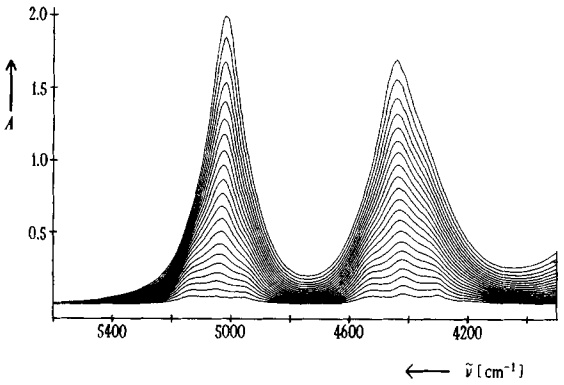

Fig. 9. Original traces obtained in measurements of the near-IR absorbance A of pure ammonia at 523 K and various densities ϱ, increasing from 0.025 g cm^{-3} (lowest curve) in steps of 0.025 g cm^{-3} to 0.525 g cm^{-3}.

Figure 10 shows selected IR and near-IR bands in the range 2000 to 12 000 cm^{-1} for dense fluid ethylene (E) under high pressure and for polyethylene (PE). In order of increasing wavenumber the four absorption regions shown are assigned to the fundamental C–H stretching mode and the first, second, and third overtones. However, this is only a rough classification, since the near-IR absorption is largely determined by combination modes.[34, 35] In ethylene, for example, all the odd-numbered overtones are forbidden on symmetry grounds.

For quantitative analysis on compressed fluid phases by IR and/or near-IR spectroscopy, it is highly advantageous that the molar absorption coefficient ε varies by several orders of magnitude in an extended wavenumber range such as the one shown in Figure 10 (which can be recorded in less than one second on a Fourier transform spectrometer). The relationship $A(\tilde{\nu}) = \varepsilon(\tilde{\nu})cl$ leads directly to two types of applications: 1) Measurement of the entire spectrum allows the

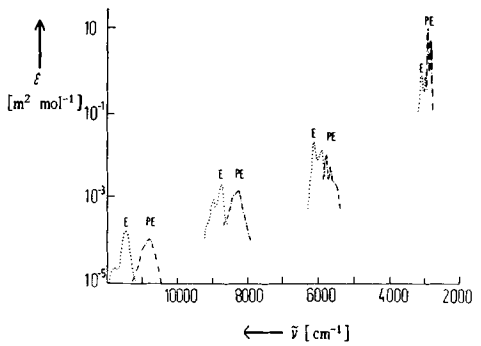

Fig. 10. Molar absorption coefficient ε for selected bands of compressed fluid ethylene (E) and of polyethylene (PE) between 2000 and 12 000 cm^{-1}.

detection of low concentrations with high spectroscopic sensitivity (high ε) from data for the fundamental mode region, while components present in relatively high concentrations can be measured in the less sensitive near-IR region. Thus use of a large spectral region greatly increases the range of concentrations that can be measured in a single experiment, and the entire course of a reaction can be followed up to a high percentage conversion. This is especially useful in high-pressure experiments. For example, in the early stages of a high-pressure polymerization the monomer, which is at first the only component or in overwhelming excess, is measured by a higher overtone, while the polymer, initially present only in trace amounts, is detected by the fundamental mode; during the middle stage the monomer and polymer are monitored by their first or second overtones; then as the reaction nears complete conversion, the polymeric product is measured by a higher overtone and the monomer, now present only in a low concentration, by the fundamental mode. Analytical possibilities of this kind exist for nearly all substances, provided that the absorption bands of the starting material and the product are sufficiently separated, because the absorption intensities always decrease rapidly the higher the overtones. 2) The large differences in the absorption intensities enable the selection of regions of the spectrum to measure concentrations in fluid systems with widely different optical path lengths, and therefore in reactors of different dimensions. For ethylene at a density of about 0.5 g cm^{-3}, which is typical in high-pressure polymerization reactions, the optical path lengths l needed to give an absorbance value $A = 1$ at the band maximum in each case are as follows: for the fundamental mode at 3000 cm^{-1}, $l = 0.05$ mm; for the first overtone at 6000 cm^{-1}, $l = 1.1$ mm; for the second overtone at 9000 cm^{-1}, $l = 12.5$ mm; for the third overtone at 11 500 cm^{-1}, $l = 140$ mm.

4. Fluid Phase Equilibria

The ability to determine the nature and concentration of species of interest in fluid phases directly by spectroscopic measurements can be used in many ways. Some examples of applications to the study of fluid phase equilibria are described below.

A knowledge of the positions of phase boundaries in fluid mixtures is of considerable scientific and technological importance. The two standard methods for determining phase behavior are the synthetic and the analytical method, based on repeated sampling.[42] A procedure based on near-IR measurements was first used by *Nees*[17,43] in studies on the ethylene–polyethylene system at pressures up to 3000 bar and temperatures up to 573 K. *Schneider* et al.[44] determined the solubilities of adamantane, octacosane, and squalane in fluid CO_2 by near-IR spectroscopy at pressures up to 1000 bar. The solubility of anthracene in a number of fluid phases at pressures up to 3000 bar and temperatures up to 550 K was studied by *Rößling* and *Franck*[45] by quantitative UV spectroscopy. The same method was also successful in the determination of the solubility of caffeine in fluid CO_2.[46]

Quantitative spectroscopy in the visible and UV range can be used to investigate complex equilibria in aqueous solutions up to high pressures and temperatures.[47–49] Figure 11 shows measurements by *Lüdemann* and *Franck*[48] of the molar absorption coefficient ε for 0.005 M cobalt(II) bromide in an aqueous solution (4 M) of NaBr at 6 kbar and temperatures from 298 to 773 K. At temperatures up to 473 K the cobalt is present mainly in the form of the pink octahedral hexaquacobalt complex (band maximum at 500 nm). At higher temperatures the solutions are blue. The band at 700 nm is assigned to the tetrahedral tribromomonoaquacobalt complex.

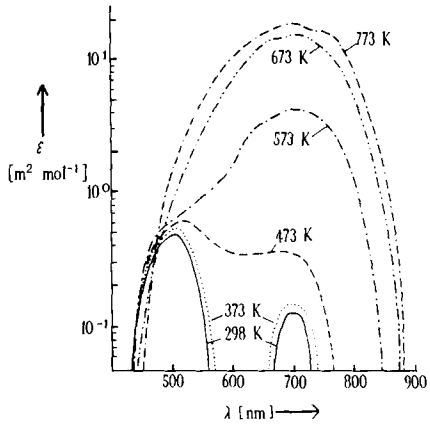

Fig. 11. Molar absorption coefficient ε for 0.005 M $CoBr_2$ in an aqueous solution of NaBr (4 M) at 6 kbar and temperatures from 298 to 773 K.

Studies on aqueous solutions of cobalt(II) halides diluted without further addition of sodium halide show that here too the dominant form up to 573 K is the pink octahedral hexaquacobalt complex.[47] At higher temperatures and moderately high pressures (about 1000 bar) the dominant species is the blue tetrahedral dichlorodiaqua complex with an absorption maximum at 680 nm. On increasing the pressure, e.g. to 6 kbar, it is found that at 773 K the pink-to-blue color change can be reversed. A review of the formation of metal complexes in aqueous solutions can be found in the publication by *Seward*.[49]

Quantitative IR spectroscopy has been used to study the effects of pressure and temperature on the equilibria between monomers and cyclic dimers in dilute solutions of carboxylic

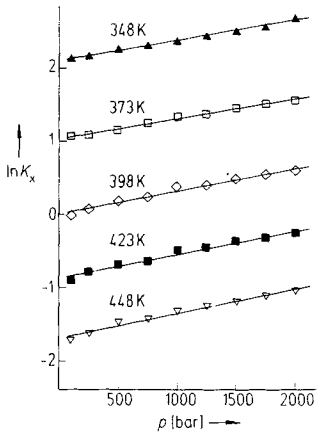

Fig. 12. Dependence of the equilibrium constant K_x on pressure for the dimerization of pivalic acid as a solution in *n*-heptane (1.0×10^{-2} M) at various temperatures.

acids.[50-52] Characteristic absorption bands for the two species without significant overlapping occur in the regions of the C=O and O-H stretching fundamentals. The intensities of the vibrational bands for the monomer and dimer in the C=O region are found to be independent of pressure and temperature, and can therefore be used to measure concentrations and hence determine equilibrium constants. Results obtained by this method for pivalic acid dissolved in heptane at temperatures from 348 to 448 K and pressures up to 2000 bar are shown in Figure 12; here the equilibrium constant is defined as $K_x = x_D/x_M^2$, where x_D and x_M are the mole fractions of the dimer and monomer respectively.[50]

Figure 13 shows the intensities of the O-H stretching modes for pivalic acid (monomer and dimer) referred to 1 mole of the monomer. The values for the monomer

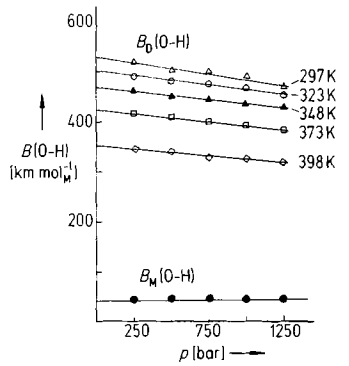

Fig. 13. Vibrational intensities B_M(O-H) and B_D(O-H) for the monomer and the cyclic dimer respectively of pivalic acid (5.0×10^{-2} M in CCl_4) as a function of the pressure p at various temperatures.

(B_M(O-H)) are independent of pressure and temperature within the limits of accuracy. On the other hand the values for the dimer (B_D(O-H)), which are greater by an order of magnitude, decrease with increasing temperature and—to a lesser extent—with increasing pressure.[50] This observation suggests that the nature of the dimer present in the equilibrium mixture changes with temperature and pressure. Figure 13 also provides a further example of the high sensitivity of the fundamental intramolecular O-H stretching mode as an indicator of intermolecular interactions (cf. Fig. 4).

From the pressure dependence of the equilibrium constant K the dimerization volume change $\Delta V = -(\delta(RT\ln K)/\delta p)_T$

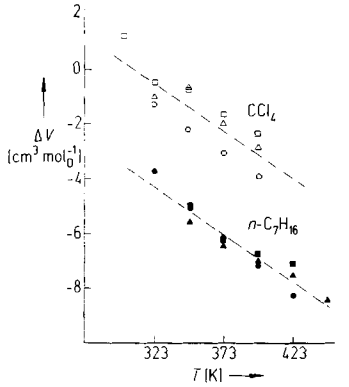

Fig. 14. Temperature dependence of the dimerization volume change ΔV for acetic acid (○), benzoic acid (□) and pivalic acid (△) in CCl_4 (open symbols) and in n-heptane (filled symbols).

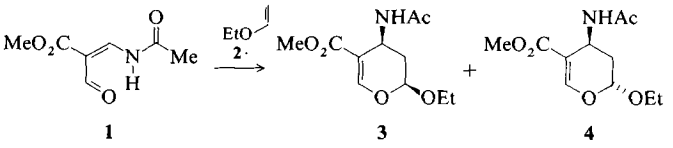
can be determined. In Figure 14 ΔV is plotted as a function of the temperature for several carboxylic acids. The equilibrium constant represents $K_c = c_D/c_M^2 = K_x/c$ (where c = total concentration of carboxylic acid). In both solvents (CCl_4 and n-heptane) ΔV increases with decreasing temperature. A CCl_4 solution of benzoic acid yields a positive value for ΔV at room temperature, indicating that increasing pressure favors a dissociation of the cyclic dimer into monomer molecules. In order to explain the temperature dependence of ΔV it is assumed that at lower temperatures the dimers have a more stable planar structure with a greater volume, whereas at higher temperatures dimers with less perfect structures and a lesser degree of planarity are present. The latter species occupy a smaller volume, and consequently at higher temperatures increasing pressure always favors dimer formation.

5. Chemical Conversions in Fluid Phases

The review article by *Asano* and *le Noble*[7a] and the more recent review by these authors together with *van Eldik*[7b] provide a very good account of the many different types of investigations of chemical reactions at high pressures. The extensive field of high-pressure organic syntheses has also been covered in two review articles by *Matsumoto* et al.[53, 54] Preparative aspects of chemical reactions at high pressures are treated in the articles by *Jurczak*[55] and *Klärner*.[8] However, up to now there have been only a few cases where reaction kinetics have been studied directly by quantitative high-pressure absorption spectroscopy, although this method enables one to make very detailed observations and to recognize and study even quite complex reaction sequences.

The use of quantitative spectroscopic methods to study high-pressure reactions will first be illustrated by some examples of hetero-Diels–Alder reactions. The reactions of enamine carbaldehydes and enamino ketones with various vinyl ethers have been studied.[16, 21, 56-58] Figure 15 shows absorbance difference spectra in the region of the N-H



1 3 4

stretching modes recorded during the reaction of **1** and **2** at 333 K and 1500 bar in CH_2Cl_2 solution, yielding the diastereomeric products **3** and **4**. The traces were obtained by subtracting the first spectrum, recorded after establishing the experimental conditions, from each of the spectra recorded thereafter; this eliminates the absorptions of the solvent and of groups that do not change absorption during the reaction. With this difference procedure the products give positive absorbances and the diene starting compound gives negative absorbances. In some solvents it is possible to observe separate N-H stretching bands for the two diastereomeric products.[16, 21]

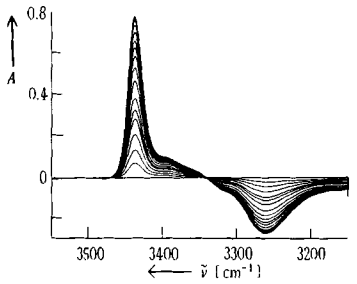


Fig. 15. Infrared difference spectra (see text) in the region of the N–H stretch during the reaction of **1** and **2** in CH_2Cl_2 at 333 K and 1500 bar.

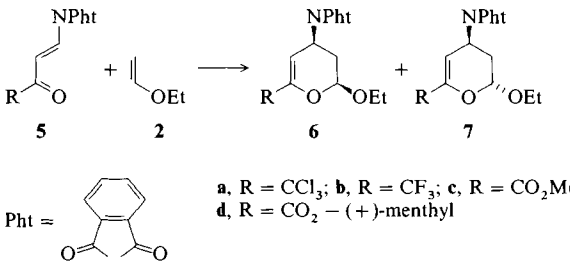
Quantitative spectroscopy in the region of the carbonyl stretching modes has been used to investigate the Diels–Alder reactions of **2** with enamino ketones of the general structure **5**, yielding the diastereomeric dihydropyrans **6a–d** and



a, R = CCl_3; **b**, R = CF_3; **c**, R = CO_2Me; **d**, R = CO_2 – (+)-menthyl

7a–d.[21, 57] The formation of the *cis* adducts **6** is thought to occur via an *endo* intermediate and that of the *trans* adducts **7** via an *exo* intermediate. In the presence of an excess of ethyl vinyl ether (**2**) over the diene, the spectroscopically measured concentration data have been used to determine rate coefficients k by a modified *Kezdy–Swinbourne* procedure.[16, 21, 59] Figure 16 shows the pressure dependence of k

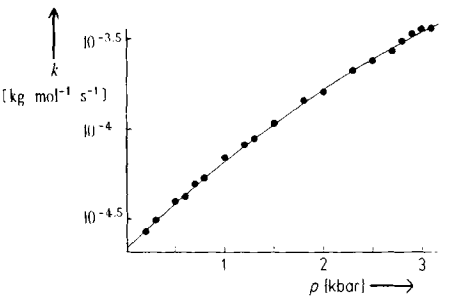


Fig. 16. Dependence of the rate coefficient k on pressure for the cycloaddition reaction of **5b** and **2** in CH_2Cl_2 at 318 K.

for the cycloaddition reaction of **5b** and **2** in CH_2Cl_2 at 318 K. Figure 17 shows the temperature dependence of k for the cycloaddition of **5a** and **2** in CH_2Cl_2 at 1000 bar.

In all these experiments the reaction solution was contained in a sealed, thin-walled PTFE cell, as described in Section 2, to avoid catalytic effects from the stainless steel walls of the autoclave. In each case the kinetic measurements were followed by HPLC measurements on the reaction mixture when the conversion was nearly or fully completed, to determine the ratio of the concentrations of the two diastereomers **6** and **7**. From the pressure and temperature dependence of this ratio one can directly obtain the quantities $\Delta\Delta V^{\neq}$ and $\Delta\Delta H^{\neq}$ which are the differences between the activation volumes and activation enthalpies for the reaction channels leading to the two diastereomers.[16, 56–58] For the reaction of **5a** with **2** the difference between the activation volumes is especially large, $\Delta\Delta V^{\neq} = 5.9 \pm 0.5\ cm^3\ mol^{-1}$.

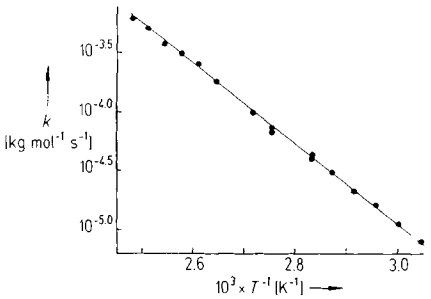

Fig. 17. Dependence of the rate coefficient k on temperature for the cycloaddition reaction of **5a** and **2** in CH_2Cl_2 at 1000 bar.

In Figure 18 the percentage yield of the *cis* diastereomer **6a** from the reaction of **5a** with **2** is plotted as a function of pressure for a range of temperatures. The solid curves were obtained from the experimentally measured selectivity data (filled circles), partly by extrapolation. With increasing pressure and decreasing temperature the reaction becomes increasingly selective in favor of the *cis* diastereomer. Thus at

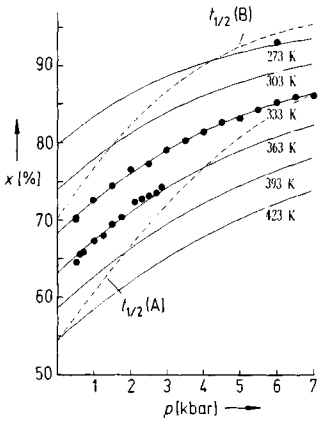

Fig. 18. Percentage yield x of the *cis* diastereomer **6a** in the cycloaddition reaction of **5a** and **2** in CH_2Cl_2 as a function of pressure at various temperatures. The broken lines correspond to reaction half-lives of $t_{1/2}(A) = 15$ minutes and $t_{1/2}(B) = 6$ days for the chosen concentrations. These times encompass the range of "reasonable" values in reactions with on-line spectroscopic detection.

273.5 K and 6 kbar one obtains **6a** and **7a** in the ratio 13.6 to 1.0, compared with a ratio of 1.67 to 1.00 at atmospheric pressure and 363 K. The dashed curves contain information obtained from kinetic measurements as a function of time. The lower of these two curves (labeled $t_{1/2}(A)$) intersects the solid curves at the pressure and temperature values corresponding to a half-life of 15 minutes at the concentrations present in the experiment. The upper curve ($t_{1/2}(B)$) corresponds to the intersection points for a half-life of 6 days.

From the rate coefficients k one can calculate similar dashed curves for any given reaction conditions. Figure 18 indicates that at atmospheric pressure and 273 K, an 80% yield of **6a** should be obtainable. The corresponding half-life is about 1.5 years. The data in this figure show that high pressure provides two advantages: firstly, at a given temperature a higher pressure gives increased selectivity; secondly, raising the pressure significantly increases the rate of the cycloaddition reaction, so that satisfactory reaction rates are achieved at lower temperatures. Thus the advantage of increased selectivity at lower temperature can also be exploited. By further increasing the pressure and reducing the temperature it should be possible to achieve high selectivities.

A further example of the use of quantitative absorption spectroscopy in fluid phases is seen in Figure 19, which shows infrared absorption spectra measured in the carbonyl stretching region during the decomposition of *tert*-butylperoxypivalate dissolved in *n*-heptane at 353 K and 2000 bar.[60] The peroxide band at 1775 cm^{-1} decays, and the absorption at 2340 cm^{-1} due to CO_2 that is formed increases. The growing absorption at 1725 cm^{-1} is assigned to acetone. From measurements in the O–H stretching region between 3500 and 3700 cm^{-1} the formation of *tert*-butanol and (in smaller amounts) pivalic acid during the decomposition can also be detected.[60] Such measurements provide access to the kinetics of the decomposition, and to direct observation of several reaction pathways and their dependence on the pressure and temperature. The spectroscopic method can also be used to measure the efficiencies of initiators in free-radical polymerizations.[61] Experiments of the kind shown in Figure 19 have already been carried out for di-*tert*-butyl peroxide,[62] dioctanoyl peroxide,[61] dibenzoyl peroxide,[61] and *tert*-butylperoxybenzoate.[63]

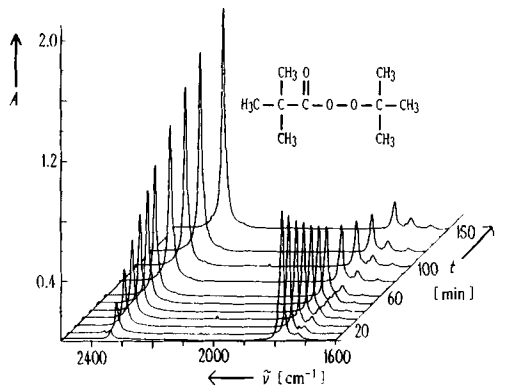

Fig. 19. Infrared absorption spectra recorded during the thermal decomposition of *tert*-butylperoxypivalate in *n*-heptane at 353 K and 2000 bar.

6. Free-Radical Polymerizations at High Pressures

The high pressure polymerization of ethylene and various copolymerization reactions of ethylene with polar comonomers are of special technical importance. The scientific interest in these reactions is directed mainly towards determining individual rate coefficients over a wide range of pressure, temperature, and degree of conversion, and as a function of the radical chain length. For such investigations the ability to make direct spectroscopic observations during polymerization is of great value.

Figure 20 shows a series of spectra measured in the region of the second overtone of the C–H stretching vibration during the homopolymerization of ethylene at 463 K and an initial pressure of 2630 bar.[64] The progress of the reaction can be measured both by the reduction in the ethylene absorbance at 8730 and 8960 cm^{-1} and by the growth of the polyethylene absorbance at 8260 cm^{-1}. The spectra in Figure 20 cover a range extending to about 80% conversion. In the case of ethylene–acrylic ester copolymerizations, the concentration of the acrylate comonomer can be measured from its C=C stretching band (the corresponding vibration in ethylene is inactive); in butyl acrylate, for example, this occurs at 1630 cm^{-1}.[65] The extended IR and near-IR region also contains other bands that are suitable for quantitative analysis. The high-pressure spectroscopic method has also been used in studies of the copolymerization of ethylene with carbon monoxide[66] and with acrylonitrile,[67] and of the homopolymerization of styrene[68] and of methylmethacrylate.[69]

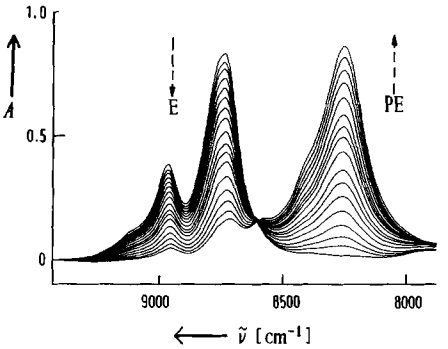

Fig. 20. Near-IR absorbance spectra recorded during the free-radical polymerization of ethylene at 463 K and 2630 bar (E: ethylene, PE: polyethylene).

The use of excimer lasers for initiating free-radical polymerizations, in conjunction with IR or near-IR spectroscopy for detection, has proved to be a very effective method for determining kinetic parameters under a wide range of conditions. Two procedures have been used. The first (Method 1) involves time-resolved measurements, in the microsecond to millisecond range, of the growth of macromolecules initiated by a single pulse of about 20 ns duration from an excimer laser.[70, 71] In the second procedure (Method 2) the progress of the polymerization is measured at intervals, after applying sequences of excimer laser pulses varying the number of pulses and the pulse repetition frequency.[64, 72] In this case each pulse train is followed by a measurement of the IR and near-IR spectrum over a broad range of wavenumbers using a Fourier transform spectrometer. In experiments based on Method 1 the measurements are made at a fixed wavelength. Figure 21 shows a signal recorded in this way for an ethylene polymerization at 463 K and 2550 bar. At t = 0 a KrF laser pulse of 248 nm wavelength was applied to the reaction mixture already containing 9.5% polyethylene. The resulting conversion to polyethylene, measured by the near-IR ab-

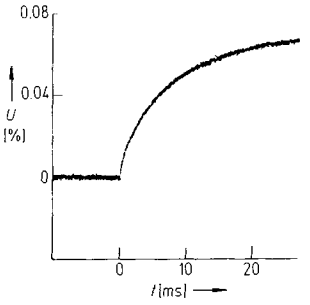

Fig. 21. Time resolved near-IR measurement (at $8258 \pm 5\,cm^{-1}$) of the monomer conversion U induced by a single pulse from a KrF excimer laser (248 nm) in an ethylene polymerization at 463 K and 2550 bar (degree of conversion already existing before this particular pulse experiment starts: 9.5%).

sorption at $8258 \pm 5\,cm^{-1}$ (cf. Fig. 20) with a time resolution of 10 μs, is less than 0.1%. The recorded signal was processed by fitting the curve to Equation (a), which describes the amount of polymerization induced by the laser pulse.[70] Here $c_M(t=0)$ and $c_M(t)$ are the monomer concen-

$$\frac{c_M(t)}{c_M(t=0)} = (2k_t c_R(t=0)t + 1)^{-0.5k_p/k_t} \quad \text{(a)}$$

trations at the instant when the pulse is applied and at a time t later, k_p and k_t are the rate coefficients for the propagation and termination reactions respectively, and $c_R(t=0)$ is the initial instantaneous concentration of growth-initiating primary free radicals produced by the laser pulse, which is related to the primary quantum yield φ_i by Equation (b), where

$$c_R(t=0) = 2\,\varphi_i n_{abs} V^{-1} \quad \text{(b)}$$

n_{abs} is the number of absorbed quanta and V is the volume of the sample.

The pulse experiment has certain important advantages. The kinetic parameters k_p/k_t and $k_t\varphi_i$ obtained directly by fitting the data to Equation (a) are very well resolved as functions of the degree of conversion, since the polymerization induced by each pulse is very small. As the formation of all the radicals, and thus the initiation of growth, occurs simultaneously, the radicals present at a given time t after the pulse have a very narrow size distribution, provided that transfer reactions are insignificant. This enables one to obtain information about kinetic parameters for radicals of different chain lengths.[70, 73] Method 2 also yields values of k_p/k_t and $k_t\varphi_i$, but does not give comparable resolution as a function of the degree of conversion; moreover, the pulse repetition frequencies that can currently be attained are insufficient to enable one to study the dependence of the rate coefficients on chain length.

In Figure 22 the primary kinetic parameters $k_t\varphi_i$ and k_p/k_t obtained from excimer laser experiments[70, 74] are plotted as functions of the conversion U for the high-pressure free-radical polymerization of ethylene at 503 K and 2550 bar. It can be seen that $k_t\varphi_i$ decreases with the degree of conversion, at first quite rapidly, then at a slower rate, and again rapidly at high degrees of conversion, with an overall reduction of about three orders of magnitude to 80% conversion ($U = (c_M^0 - c_M)/c_M^0 = 0.8$, where c_M^0 refers to zero conversion). In the case of k_p/k_t we find an increase with the degree of conversion, at first rapid then slower. The change (increase) in k_p/k_t to 80% conversion is much smaller than the change (decrease) in $k_t\varphi_i$. Before discussing the data in Figure 22 it is useful to examine the behavior of the quantity

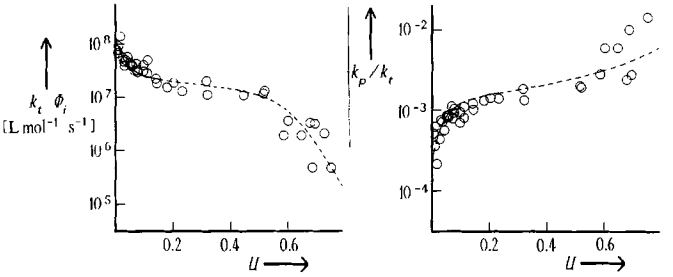

Fig. 22. Kinetic parameters for the free-radical polymerization of ethylene at 503 K and 2550 bar plotted as functions of the degree of conversion. Left: the product $k_t\varphi_i$ of the termination rate coefficient k_t and the primary quantum yield φ_i; right: the quotient k_p/k_t (k_p = propagation rate coefficient).

$k_p\varphi_i$ obtained by multiplying together the values of $k_t\varphi_i$ and k_p/k_t from experiments performed by Method 1. This product is plotted in Figure 23 for the polymerization of ethylene at 503 K and 2550 bar. Over a considerable range extending to about 50% conversion, $k_p\varphi_i$ is found to remain constant within the range of experimental error. At higher degrees of conversion the value falls steeply. It is unlikely that in the range from 0% to 50% conversion, over which the viscosity of the medium increases by about five orders of magnitude, k_p and φ_i change in such a way that their product remains constant, and the results shown in Figure 23 must therefore mean that k_p and φ_i both remain constant under the chosen conditions of pressure and temperature. It follows from this that where independent information is available on either k_p or φ_i within this range of conversion, one can determine all three quantities, k_p, k_t, and φ_i.

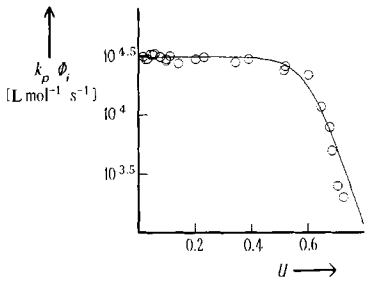

Fig. 23. The product $k_p\varphi_i$ for the free-radical polymerization of ethylene at 503 K and 2550 bar as a function of the degree of conversion.

Measurements show that φ_i [see Eq. (b)] has a value close to 1.[72] It is assumed that this value continues to apply beyond 50% conversion, and $k_p\varphi_i$ in Figure 23 can therefore be regarded as identical to k_p. One should be able to describe this k_p curve using the equation given in the literature for a diffusion-controlled propagation rate coefficient [Eq. (c)].[75, 76] Here $k_{p,0}$ is the (chemical) propagation rate

$$k_p = \frac{1}{k_{p,0}} + \frac{1}{k_{p,D}} \quad \text{(c)}$$

coefficient without any influence from diffusion control and $k_{p,D}$ describes the diffusion-controlled contribution. It is assumed that $k_{p,D}$ is inversely proportional to the viscosity of the solution [Eq. (d)]. The quantity $\eta_r = \eta/\eta_0$ is the relative

$$k_{p,D} = k^0_{p,D}/\eta_r \tag{d}$$

viscosity for the conditions of the experiment, expressed relative to the viscosity η_0 of the pure monomer under the same conditions. Equation (d) is based on the questionable assumption that bulk viscosity is a relevant transport parameter for the elementary processes under consideration (see also Eq. (h) below). An essential reason for introducing η_r is that a few high-pressure, high-temperature viscosities are available from the literature, whereas monomer, polymer, and especially free-radical diffusion coefficients are not yet known. From Equations (c) and (d) we obtain Equation (e).[77] This simple kinetic relationship, together with the

$$k_p = (k^{-1}_{p,0} + \eta_r/k^0_{p,D})^{-1} \tag{e}$$

data given by *Ehrlich* and *Woodbrey*[78] for the viscosity of the ethylene–polyethylene system, leads to the solid line in Figure 23. The relative viscosities were calculated using Equation (f), which is approximately valid for the particular

$$\log \eta_r = 5.39\,U + 3.70\,U^{0.5} \tag{f}$$

reaction conditions. It is important to note that the viscosity depends on both the degree of conversion *and* the properties of the polymer that is formed (described, for example, by its intrinsic viscosity). Thus viscosities should be taken from experiments under identical or at least similar polymerization conditions.

The rate coefficient k_t for the chain-termination reaction is several orders of magnitude greater than k_p, and the termination reaction is usually already diffusion-controlled in the initial stages of the polymerization. The termination process may be regarded as a multistage reaction consisting of three steps: translational diffusion (TD) of two radicals, segmental diffusion (SD) bringing the radical centers into direct contact, and lastly the chemical reaction (CR). The kinetics should be represented by Equation (g).[79] The rate coefficient for the translational diffusion step is assumed to be inversely proportional to the viscosity of the medium [Eq. (h)].

$$\frac{1}{k_{t,D}} = \frac{1}{k_{TD}} + \frac{1}{k_{SD}} + \frac{1}{k_{CR}} \tag{g}$$

$$k_{TD} = k^\circ_{TD}/\eta_r \tag{h}$$

It turns out that Equation (g) is not adequate to describe the entire range of conversion. At high degrees of conversion and high viscosities, where the center-of-mass motions of the radicals are largely suppressed, the values calculated for k_{TD}, and therefore for $k_{t,D}$, are too low. Under these conditions termination occurs mainly through a "reaction diffusion" mechanism, as was first shown by *Schulz*.[80] Radical chain ends come into contact with each other through propagational growth reactions within the monomer matrix in which they are embedded.[76, 77, 80, 81] The rate coefficient for this process is proportional to k_p and to the monomer concentration c_M, i.e. to $(1 - U)$, where, as before, $U = (c^\circ_M - c_M)/c^\circ_M$; it is given by Equation (i) where C_{RD} is the reaction diffusion constant.

$$k_{t,RD} = C_{RD} k_p (1 - U) \tag{i}$$

Termination occurs by the parallel mechanisms of diffusion-controlled termination ($k_{t,D}$) and reaction diffusion ($k_{t,RD}$) [Equation (j)].

$$k_t = k_{t,D} + k_{t,RD} \tag{j}$$

By inserting into Equation (j) the expressions (e) and (g)–(i), and assuming that $k_{CR} \gg k_{TD}, k_{SD}$, we obtain the overall termination rate coefficient k_t [Eq. (k)].

$$k_t = \frac{1}{k^{-1}_{SD} + \eta_r/k^0_{TD}} + \frac{C_{RD}\cdot(1-U)}{k^{-1}_{p,0} + \eta_r/k^0_{p,D}} \tag{k}$$

Various simplifying approximations[77] can be applied to this equation depending on the system. For example, in the ethylene high-pressure polymerization reaction k_{SD} is usually, much greater than k_{TD}, so that the term k^{-1}_{SD} in Equation (k) can be neglected. The resulting simplified equation yields the broken curve in Figure 22 (left) and gives a very reasonable fit to the experimental points for $k_t\varphi_i$.

The transition between regions in which k_t and k_p show little change and rapid change with the degree of conversion indicates a change in the mechanism controlling the kinetics. In ethylene, for example, k_t (Fig. 22, left) is, at low degrees of conversion, initially controlled by translational diffusion, and later by reaction diffusion, and at high degrees of conversion the diffusion control of k_p has a significant effect on the termination reaction (see Equation (i), in which C_{RD} is assumed to be independent of the degree of conversion).

The kinetic relationships arrived at on the basis of spectroscopic studies of the dependence of k_t and k_p on degree of conversion [e.g. Eq. (k)] can also be applied to the free-radical polymerization of other monomers. This is illustrated in Figure 24, which shows results for butyl acrylate (BA) and methyl methacrylate (MMA). The data for BA are from our excimer laser experiments at 383 K,[82] while the results for MMA are a combination of literature data for 273 K[83] and

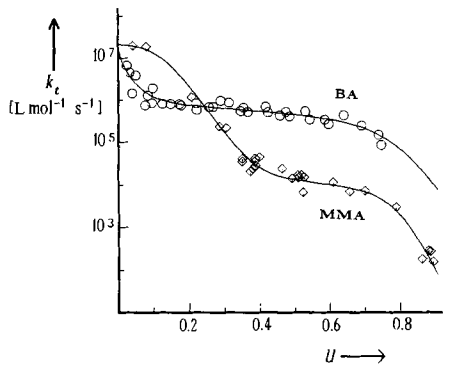

Fig. 24. The termination rate coefficient k_t as a function of the degree of conversion for the free-radical polymerization reactions of butyl acrylate (BA) at 383 K [82] and methyl methacrylate (MMA) at 273 K [83] and 323 K [84].

323 K.[84] The dependence of k_t on degree of conversion for BA is closely related to that for ethylene. For MMA, however, there are substantial differences, because at low conversion k_t is limited by segmental diffusion. The subsequent rapid decrease in k_t indicates that here the limiting mechanism is translational diffusion. This is followed by regions in which reaction diffusion, and finally at very high conversion, diffusion-controlled propagation, are the dominant mechanisms. The steep fall of k_t in the region of 20 to 40% conversion, closely related to the *Norrish–Trommsdorff* effect, can be understood in terms of the model represented by Equation (k) as being due to the much slower termination by reaction diffusion here compared with BA and ethylene (k_p and C_{RD} in Eq. (i) are considerably smaller for MMA[77]). Because of this the translational diffusion, which decreases with increasing viscosity, controls the overall termination reaction up to a higher degree of conversion. The solid lines in Figure 24 show that Equation (k) accounts very well for the experimental data for both monomers over this wide range of the degree of conversion, in which the viscosity increases by many orders of magnitude [see Eq. (f)].

The parameters in the kinetic model described by Equation (k) are mainly concerned with the initial stage of the polymerization (near-zero conversion) and have a physical meaning ($k_{p,0}$, $k^0_{p,D}$, k^0_{TD}, k_{SD}). The description of the dependence on degree of conversion is reduced to (at least) one measurement to determine C_{RD} and an independent measurement or estimation of the reduced viscosity during the polymerization.[77] The representation of free-radical rate coefficients in an extended conversion range by Eq. (k) is quite remarkable. The model should certainly be further extended and refined. It should always be kept in mind that the kinetics at a given conversion, temperature, and pressure depend on the history of the particular system, because the rate coefficients can change with U, T, and p, which in turn affects polymer properties and thus transport processes.

The technique of using an excimer laser to induce the reaction is not only of great importance for basic studies of high-pressure free-radical polymerizations, but also offers some interesting prospects for technological applications. These concern possibilities such as polymerization of pure monomers without the use of additives (initiators or chain transfer agents), and effective external control of the progress of a polymerization and to some extent also of the properties of the polymer produced. Studies that are already well advanced for ethylene homopolymerization could be extended to include high-pressure copolymerizations involving ethylene. Systems that have already been investigated in some detail are ethylene–carbon monoxide,[66] ethylene–acrylonitrile,[67] and ethylene–butyl acrylate.[65]

7. Summary and Outlook

Techniques are now available for measuring absorption spectra in the range from the IR to the UV on fluid systems at pressures up to 7000 bar and temperatures up to 900 K. At only moderately high temperatures, this pressure range can be extended still higher, and conversely, moderate pressures allow higher temperatures to be reached. For example, in studies of fluid metals at pressures up to 2500 bar, it has been possible to record spectra at temperatures up to 2000 K.[85]

These methods enable one to study equilibria and reactions throughout the whole field of organic, inorganic, and macromolecular chemistry. Some reactions of inorganic complex species in liquid solutions have already been systematically studied by high-pressure spectroscopy,[86] and it is expected that the range of the measurements can be extended to include fluid states at higher temperatures. Also spectroscopic studies in biochemistry[87] and geochemistry[15,49] will become increasingly important. Whereas high-pressure high-temperature absorption spectroscopy has up to now been used mainly for qualitative and quantitative analysis of fluid systems, the technique will in future be used increasingly for fundamental studies of ultra-fast elementary chemical processes; here systematic investigations of the pressure- und temperature-dependence of different representative reactions should provide a method for thoroughly testing theoretical reaction models. This is illustrated by the work of *Troe*, *Schroeder*, and collaborators,[88,89] who have used pump-and-probe absorption spectroscopy with picosecond and subpicosecond time resolution to follow fast reactions, especially isomerizations, directly. An example of such measurements is an investigation of the isomerization of diphenylbutadiene in ethane at 298 bar and 354 K; the lower curve of Figure 25 shows the transient absorption of the S_1 state of diphenylbutadiene at 616 nm after excitation by a picosecond pulse at 308 nm (at $t = 0$).[88] The kinetics of the reaction can be determined directly from the exponential decay curve corresponding to the population of the S_1 state.

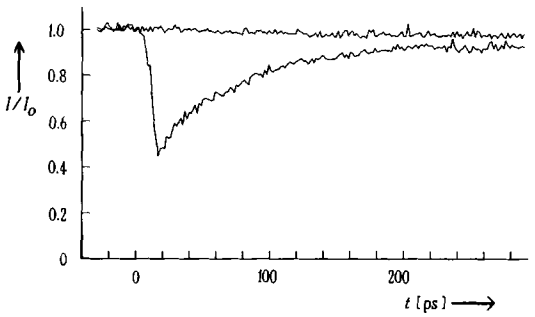

Fig. 25. Transient absorption of the S_1 state of diphenylbutadiene at 616 nm following excitation by a picosecond laser pulse at 308 nm; reaction in ethane at $p = 298$ bar and $T = 354$ K (upper curve was recorded without laser pulse excitation).

Isomerization kinetics of the kind shown in Figure 25 have also been measured for *trans*-stilbene in a wide variety of liquid and supercritical solvents at pressures up to 7000 bar and temperatures up to 425 K.[89] An important result of these studies is that by combining standard equations of the theory of unimolecular reactions with the hydrodynamic Kramers model one obtains a satisfactory description of the experiments under nearly all conditions, provided that the effects of the multidimensionality of the barrier region of the potential energy hypersurface on the dynamics are taken into account. High-pressure high-temperature spectroscopy, especially when used in combination with pulsed laser experiments, will make important contributions to investigations

of other elementary reactions in future. The method is of great importance for studying the kinetics and selectivity of chemical processes over a wide range of fluid states. Interest in potential technological applications is centered on the search for new reaction routes and new products; the ability to study existing fluid phase processes under reaction conditions is already proving to be very important from a practical standpoint.

The studies carried out in the author's own laboratory and described in this article were generously supported by the Deutsche Forschungsgemeinschaft (SFB 93: "Photochemie mit Lasern") and by the Fonds der Chemischen Industrie. The author thanks Dr. J. Schroeder for additions to the manuscript, and Dr. H.-P. Vögele for his support in completing this work.

The Chemistry of Rose Pigments

By Conrad Hans Eugster* and Edith Märki-Fischer

In this article we present a survey of the pigments found in the flowers and fruits of old and modern varieties of roses. The yellow colors are produced by carotenoids, the reds by anthocyanins, and the modern oranges by a mixture of the two. The great structural diversity of the carotenoids contrasts with a surprisingly small number of anthocyanins. For the carotenoids found in roses, a clear correspondence exists between the structure and the breeding partners used; the old yellow roses, which arose from crosses with Chinese varieties, mainly contain carotenoids from early stages in the biosynthesis, while in the modern yellow roses, which are descended from Central Asian *foetida* types, hydroxylations, epoxidations, and epoxide transformations readily occur. A recently elucidated carotenoid degradation sequence follows the scheme $C_{40} \rightarrow C_{13} + C_{27} \rightarrow C_{13} + C_{14}$. The C_{13} compounds are odoriferous substances that contribute to the scent of roses. In the physiological pH region, copigmentation with flavonol glycosides is crucial for stabilization of the anthocyanin chromophores. Many roses, including the "apothecary's rose", which was once used medicinally, contain large amounts of strongly astringent ellagitannins, monosaccharide esters of gallic acid.

1. Introduction

The word "rose" is laden with meaning and evokes different images for everyone. These range from the fragrance of roses to the fine-sounding name of rosebushes in our own or a neighbor's garden, or in rosariums throughout the world; they include cut roses as gifts or for decorating the table on festive occasions, but also the symbolism of roses,[1] their role in history, architecture, heraldry, painting, and literature, especially valuable, old illuminated works.[2] Possibly they also encompass rose societies and their journals, as well as the breeding, propagation, trade, and uses of roses in horticulture.[3]

All garden roses are descended from wild roses (botanical roses consist of species and their natural hybrids). Selection, mutation, and hybridization have gradually led to a large number of garden roses (varieties are genetically identical plants which are propagated vegetatively). In *Jaeger*'s *Rosenlexikon*,[4] some 15000 varieties are described, while *Modern Roses*[5] includes some 14000 old and new registered varieties.[6] Specialists estimate the total number of garden rose varieties bred to date at 50000.[3b] Even though many varieties, especially the more modern ones, disappear again after a few decades, the rose is still the only garden plant where the results of so many hybridizations have been retained. The development of some varieties reaches back into the late Middle Ages.[7] This unique situation has never yet been used for a comparative scientific study.

Garden roses and wild roses possess three structurally distinct groups of pigments: chlorophylls, flavonoids (including anthocyanins), and carotenoids. Yellow colors were unknown in old European garden roses; the flowers of the classical provins, alba, damask, cabbage, and moss roses were always white, pink, or red, in all their variations. The advent of yellow in garden roses, from about 1820 on, was greeted with great enthusiasm, as can be seen in old books on roses. Today, we find the illustrations and descriptions in those books correspondingly exaggerated. The development of yellow colors up to the present day will be explored in detail in Section 7.7.

2. Carotenoids in Roses

2.1. General Considerations

The assumption that the yellow pigmentation of rose petals is due to flavonol glycosides has persisted up to the present day.[8] It is only since 1963 that qualitative tests (solubility in ether, blue staining with $SbCl_3$, etc.) have led to the proposal that carotenoids are present.[9] With one exception,[9b] identification was never attempted. In fact, all rose flowers, including yellow ones, contain quite a lot of flavonoids. However, only when they are present in high concentrations, together with carotenoids, do they contribute to visible absorption, giving rise to a bronze color.[10] This has been proven experimentally for 'William Allen Richardson' (*Ducher*, 1878) and 'Whisky Mac' (*Tantau*, 1967),[11, 12] whose flowers are brownish yellow.

Carotenoids are widely distributed in the anthers of roses. Their function is still a mystery. Moreover, some carotenoids in the anthers have not yet been found in the petals (see Section 2.2).

Our studies on about 40 different yellow or yellowish rose varieties and species have led to the identification of about 75 carotenoids[13] (Fig. 1). The individual structures will be described in more detail in the following sections.

2.2 Analysis and Identification

In 1977, our first analysis of the carotenoids from the yellow rose *R. foetida*, using classical adsorption chromatography, led to the identification of seven carotenoids.[13a] Seven years later, a further study of material from the same

Fig. 1. Carotenoids isolated from roses and their bands in the visible (λ_{max} in nm). Formula numbers with letters indicate all-*Z* compounds; those without letters are *E* isomers. The position of the *E* double bond is given by a wavy line from the preceding single bond; that is, a wavy line from C(14) to C(15) indicates the presence of a (15*Z*,15'*Z*) double bond. Note that not only mono-*Z*-carotenoids can occur, but that di-*Z* compounds, etc., are also found.

plant, using more refined techniques, allowed us to identify nearly 40 components.[13d] This was primarily due to the introduction of new HPLC methods, which, together with high-field NMR and other spectroscopic techniques permit us to analyze even very minor components. Comparison with standard compounds, which we have synthesized parallel to the isolation studies, was also helpful. It quickly became obvious that, in submilligram amounts, the isolates

Fig. 1. Continued.

always contained contaminants that made the interpretation of the spectra very difficult. The most urgent question concerned the steric configurations of the 5,6- and 5,8-epoxides, large amounts of which are present in the more modern rose varieties.[14] The commonly used constitutional terms "aurochrome", "luteoxanthin", and "auroxanthin" concealed numerous stereoisomers which had not yet been identified. Thus, "auroxanthin" contains three pairs of constitutionally identical chiral centers. An all-*E* configuration would lead to a total of twenty possible diastereoisomers (sixteen enan-

tiomeric pairs and four *meso* forms). If there is just a single, noncentral *Z* double bond, the numbers of isomers rises to thirty-two enantiomeric pairs! Even if biogenetic arguments are used to justify 3*S*,5*S*,3′*S*,5′*S* chirality, numerous isomers remain to be identified. Noteworthy in this connection is the surprising presence of 3′-epilutein (**15**) in the anthers of *R. gallica officinalis* and other roses.[131] If the usual precautions are taken (material as fresh as possible, degassed solvents, avoidance of direct light, rapid work, inert atmosphere (whenever possible), then the isolation of carotenoids from flowers presents no great difficulties. The lability of the 5,6-epoxides towards acids must be noted. We always add sufficient quantities of finely powdered $CaCO_3$ to the material to be extracted. Before chromatography, phytosterols are precipitated from acetone solution by cooling. Preliminary purification of the saponified carotenoids is usually carried out on silica (Merck, 40–63 μ) using hexane/ether or hexane/acetone mixtures containing 0.05% Et(*i*Pr)$_2$N (beware of possible acetone condensation with aldehydes!). For small amounts we also use silica plates (e.g., Merck 60, F254, 0.25 or 0.5 mm). When major components are present, these must be removed by crystallization (check by HPLC!).

The subsequent HPLC separations were performed as follows: hydrocarbons on Spherisorb ODS-5μ with acetonitrile/THF mixtures or on Spherisorb NH_2-5μ with hexane/Et(*i*Pr)$_2$N; fractions with monohydroxy, dihydroxy, hydroxyepoxy, neoxanthin, and latoxanthin polarity were each purified separately on Spherisorb S-5 CN with hexane containing 0.1% Et(*i*Pr)$_2$N and a gradient of various dichloromethane/methanol mixtures.[13, 15]

For conclusive identification of rare carotenoids or those only present in trace amounts it is necessary to record UV/VIS, NMR, mass, and CD spectra and to carry out cochromatography with authentic samples. A library of spectra is extremely useful here; compilations of UV/VIS,[16] NMR,[17] CD,[18] and mass spectra[17a, 19] are available.

3. White Roses

The petals of white roses reflect a large proportion of the incident light. They are therefore more or less free of compounds that absorb light of wavelength 400–700 nm. Nonetheless, the petals are not transparent. This is due to the many air-filled spaces between the cells, the so-called intracellular spaces. When the air is displaced, for example, by dipping a petal into acetone, the luster und reflection are rapidly diminished. On the other hand, the petals contain significant amounts of UV-absorbing substances, above all large amounts of flavonol glycosides. Up till now, these have only been studied in a very few varieties; thus, 'Niphetos' (*Bougère*, 1843) contains a great deal of quercetin, some isoquercetin, rutin, spireoside, and other, unknown flavonoids (see Section 8.5.2).

Table 1. Carotenoids in white roses.

Roses	Content	*N* [b]	HC [c]	OH [d]	Amount [%] epoxides	AC [e]
R. pimpinellifolia	5.8	29	56 (**1**,**2**)	22 (**14**)	17	5
'Sombreuil' (*Robert*, 1850)	3.8	32	80 (**1**,**2**)	6.8	9.9	1.4
'Virgo' (*Mallerin*, 1947)	8.6	15	94 (**1**,**2**)	2.2	0.7	2.9

[a] Milligrams of carotenoids per 100 g of dried petals. [b] *N* = number of identified carotenoids. [c] HC = hydrocarbons; main carotenoids in parentheses. [d] Xynthophylls. [e] AC = apocarotinols.

More is known about the carotenoids[12] (Table 1). All the white roses we have studied contain significant amounts of carotenoids; examples include *R. pimpinellifolia*, 'Niphestos', 'Mme Plantier' (*Plantier*, 1835), 'Alberic Barbier' (*Barbier*, 1900), 'Yvonne Barbier' (*Turbat*, 1910), 'Nevada' (*Dot*, 1927), 'Virgo' (*Mallerin*, 1947). 'Iceberg' = 'Schneewittchen' (*Kordes*, 1958), although colorless hydrocarbons predominate. The few colored carotenoids also found presumably come from the base of the petals. Even epoxides are present. The apocarotenols, which comprise primarily esterified rosafluene (**40**), are remarkable.[13h] Rosafluene, like phytofluene (**2**), has a fluorescence emission maximum in the blue-green (λ_{ex} = 359 nm, $\lambda_{em} \approx$ 525 nm). If the apocarotenols are present in sufficient amounts and their fluorescence is not quenched, these compounds act as natural brighteners. Rosafluene is a catabolite of any carotenoid from ζ-carotene onwards (see Section 7.6). For the determination of the degree of whiteness in roses, see Ref. [13i]. Beautiful examples of white roses are shown in Figure 2.

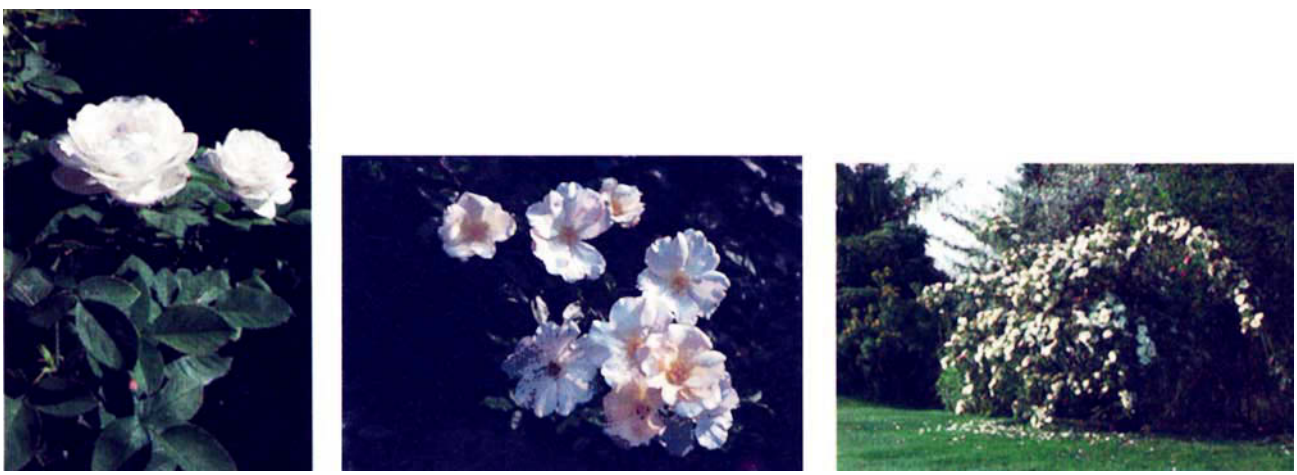

Fig. 2. Left: 'Merveille de Lyon' (1:5.5 scale; bush rose, *Pernet Père*, 1882), in which pigment synthesis is practically fully blocked. Middle: 'Schneeschirm' (1:5; small shrub, *Tantau*, 1946). Right: 'Nevada' (shrub, *Pedro Dot*, 1927). Temperature-dependent, partial pigment synthesis occurs in both 'Schneeschirm' and 'Nevada'.

4. Green Roses

Roses with green petals are very rare. The best-known example is *R. chinensis viridiflora* (Fig. 3), which is said to have arisen by mutation in South Carolina in 1833.[20] Its pale green, often lightly russet flowers doubtless contain chlorophylls, but no detailed studies have been performed.

Fig. 3. *Rosa chinensis viridiflora* (1:5 scale).

Various modern, white roses occasionally reveal a definite green tinge, such as 'Green Ice' (*Moore*, 1971), 'Greensleeves' (*Harkness*, 1980), and 'White Success' (*Jelly*, 1985). These, too, presumably contain chlorophylls.

5. The Structure of Rose Carotenoids

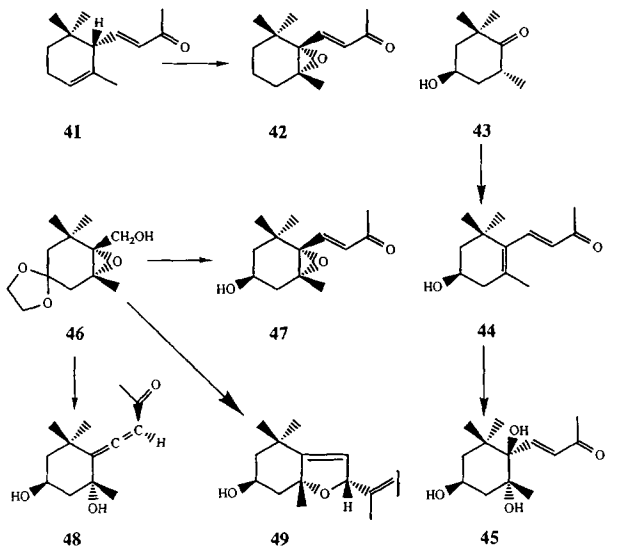
Most of the carotenoids listed in Figure 1 also occur in other yellow, carotenoid-containing flowers, but in no other case has such a detailed analysis been made. The large number of epoxides, the many *Z*/*E* isomers, and the multitude of apocarotenoids are novel and should be stressed. The absolute configurations of chiral carotenoids given in the formulas have in some cases been determined parallel to the studies on roses; for example, the structure of the C(5),C(6) diols in latoxanthin (**28**), latochrome (**29**), karpoxanthin (**31**),[13d, 21] neoflor,[22] and other carotenoids with triol end groups.[23] This also applies to the 5,6-epoxy[14, 24] and 5,8-epoxy end groups.[14, 24c, 25]

The most fundamental of these studies was the determination of the absolute configuration of C(6) in the ε end group,[26] of OH-C(3) in the zeaxanthin end group,[24a] and of OH-C(3′) in lutein (**14**)[27a] and 3′-epilutein (**15**)[27b] as well as the allene configuration in neoxanthin (**25**) and its relatives.[28] These are all distinguished by characteristic spectral and chiroptical data and can now be easily recognized in isolates. Positional isomerism in *Z*/*E*-isomeric carotenoids can readily be determined by NMR methods.[17] Often, this can also be inferred from the so-called *cis* peak.[29]

6. The Synthesis of Standard Carotenoids for Comparison Purposes

As mentioned in Section 2.2, minor rose carotenoids have been synthesized for comparison in order to confirm their structures. The syntheses leading to optically active end groups will be described briefly here; more detailed information on the construction of the polyene chains can be found in Ref. [30].

Optically active carotenoids with an ε end group, such as β,ε-carotene (**9**), were prepared from the enantiomers of α-ionone (**41** and *ent*-**41**, Scheme 1). These were always obtained by racemate resolution of the diastereomeric menthylhydrazones according to Ref. [31] modified as in Ref. [32a]. Straightforward transformations of **41** led to **42**, which was hydrolyzed to give the corresponding glycol.[32b] For the synthesis of oxygenated carotenoids, such as zeaxanthin (**13**), (4*R*,6*R*)-4-hydroxy-2,2,6-trimethylcyclohexanone (**43**) has become important[33] and is now produced industrially. For example, **43** can be converted into 3-hydroxy-β-ionone (**44**),[34] which is otherwise difficult to synthesize. The synthesis of the triol end group **45** is described in Ref. [23]. The violaxanthin end group **47** was obtained from **46**, which, in



Scheme 1.

turn, was prepared by enantioselective epoxidation of a β-cyclogeraniol derivative,[35] using the Katsuki–Sharpless procedure.[36] Compound **46** also proved to be a suitable starting material for the synthesis of allenic end groups such as **48**[37] and of the auroxanthin end group **49**.[38] The way was thus open for synthesis of neoxanthin (**25**), one of the most abundant carotenoids found in green plants. These results show that the study of rose pigments has led to results whose importance extends far beyond the boundaries of this field.

7. Biogenesis of Carotenoids in Rose Flowers

If we attempt to summarize the results presented in Sections 2, 3, and 5, one solution is to classify them in a bio-

genetic sequence. This biogenesis has been worked out for plants other than roses,[39] but ought also to be valid for roses, at least in outline. The most important steps, besides the catabolic reactions discovered in roses, are shown in Scheme 2, though Z/E isomerism has been largely ignored. In recent years, however, it has become clear, thanks to improved methods of separation, that these isomers are not artifacts of workup. Phytoene (**1**) is genuinely a 15*Z* compound. In roses, we have found a mixture of (15*Z*)-**1** and (15*E*)-**1**. With the exception of those at C(1) and C(1′), all the

1. Acetyl-CoA → C_{40} → **1** (phytoene)
2. Dehydrogenations: **1** → **2** → **3** → **4** → **5**

   6.4. Degradation reactions

Scheme 2. The most important steps in carotenoid biosynthesis and transformation.

other trisubstituted double bonds have *E* configuration. Nonetheless, most of the Z/E-isomeric carotenoids that have been investigated in this respect show isomerism at one or more of the trisubstituted double bonds, possibly due to a new isomerization for each step of carotenoid biosynthesis. However, the isomerization described by *Pattenden* et al.[40] is also possible. This occurs during the dehydrogenation step, so that the double bond moving into conjugation can assume *Z* configuration. However, this theory leads to a cascade of different biosynthetic pathways, each with Z/E-isomeric intermediates.

7.1. Biogenetic Step 2

Carotenoids **1**–**5** are found in most rose flowers in variable, but also characteristic amounts. In white roses, the dominant compounds are phytofluene and occasionally ζ-carotene, as mentioned in Section 3. Hence, the biosynthesis is strongly inhibited at the level of the desaturating enzymes. The products of carotene catabolism found in white roses, rosafluene (**40**) and geranylacetone (**60**, see Table 2) demonstrate that even ζ-carotene is degraded.

The colored hydrocarbons neurosporene (**4**) and lycopene (**5**) only occur in minute amounts in roses. This not only indicates a gap in the possible palette of colors in these flowers, but also shows that **4** and **5** are very rapidly consumed in the following step. Therefore, cyclases are active in non-white roses. They are clearly much more active than in the rosehips of many species, where lycopene (**5**) can be the major pigment (see Section 11).

7.2. Biogenetic Step 3

Lycopene (**5**) is a proven substrate for the cyclases, though neurosporene (**4**) may also be used.[39] Here, the pathways branch, leading to carotenoids with a β end group and those with an ε end group, clearly recognizable in **6** and **8**, respectively. Our interpretation of this phenomenon is that it is due to the differing configurations at C(5); (5*E*)-lycopene leads to **6**, whereas the 5*Z* isomer gives rise to **8**.[41] Various incorporation experiments in other organisms have shown[42] that the terminal methyl groups in **5** retain their identity during the proton-catalyzed ring closure, which therefore proceeds stereoselectively. The same is true for **8**, though with a different folding of (5*Z*)-**5**. This ring closure generates a chiral center at C(6), which possesses *R* chirality in all higher plants studied to date.[43]

7.3. Biogenetic Step 4

As in all higher plants, hydroxylation occurs in roses only on cyclic end groups, at C(3) or C(3′). To date, exclusively 3*R* chirality has been found at the β end groups, while at ε rings the reverse configuration appears (owing to the sequence rules this is also 3*R*). So far, the only exception is 3′-epilutein (**15**),[13] which, however, always occurs together with lutein (**14**) and is produced by a redox process with an oxo compound as intermediate.[27b] There are as yet no indications that hydroxylations of carotenoids can take place at a later biogenetic stage. Rubixanthin (**10**) is found primarily in rosehips.

7.4. Biogenetic Step 5

The 5,6-epoxides antheraxanthin (**16**) and violaxanthin (**19**) are found in large amounts in roses; the other 5,6-epoxides **25**, **28**, and **37** are products of subsequent reactions. Epoxidation thus occurs preferentially at hydroxylated β end groups. We have not yet been able to identify epoxides of hydrocarbons such as β,β-carotene.[44] The epoxide oxygen atom is derived from O_2 and is presumably introduced via the so-called violaxanthin cycle [Eq. (a)].[45]

$$\text{zeaxanthin (13)} \underset{h\nu}{\overset{\text{dark}}{\rightleftharpoons}} \text{antheraxanthin (16)} \underset{h\nu}{\overset{\text{dark}}{\rightleftharpoons}} \text{violaxanthin (19)} \quad \text{(a)}$$

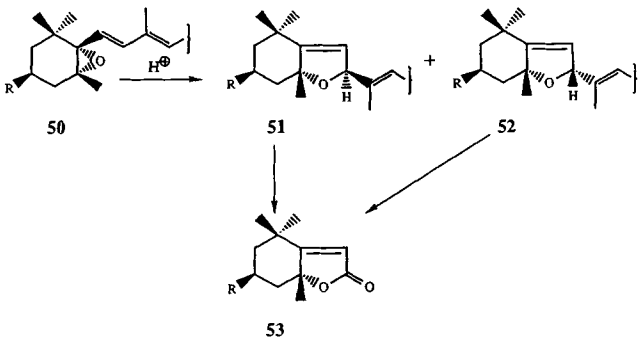
Since some yellow roses have total epoxide levels of > 80%, the violaxanthin cycle appears to be disrupted. The 5,6-epoxides always have 5*R*,6*S* chirality; introduction of the oxygen atom therefore takes place from the opposite face to the hydroxyl group.

Although hydroxylation at C(3) does not alter the light absorption of the polyene system, the epoxidation shifts it significantly to shorter wavelengths, that is from the orange

region of the visible into the yellow. At the same time, epoxidation makes the molecule labile, especially towards acids.

7.5. Biogenetic Step 6

The acid-catalyzed transition from the 5,6- to the 5,8-epoxides is an important epoxide rearrangement (Scheme 3). It can take place even in the intact plant, for example, during chromoplast senescence, but occurs very readily on insufficiently careful workup (cf. Section 2.2). The configuration at C(5) is retained during the rearrangement, except for compounds like **47**, where hydrolysis occurs with inversion at C(6).[32b, 46] A new chiral center is formed at C(8); hence, all acid-catalyzed, nonenzymatic epoxide rearrangements afford a mixture of diastereomers. C(8) is especially easily oxidized in the furanoid epoxides **51** and **52**. Peroxidation and rearrangement leads to lactones of type **53**, which contribute, for example, to the aroma of tea.



Scheme 3. R=H, OH, OAc.

The rearrangement of the 5,6- to the 5,8-epoxides also leads to a shortening of the chromophoric system. The first step, from **19** to **20**/**21**, shifts the absorption maximum 20 nm to shorter wavelengths, while the second step, leading to the auroxanthins **22**–**24**, yields a further 25-nm shift. This affords a pure, somewhat greenish yellow of high saturation. For pure yellow colors, without any trace of red. the epoxide rearrangement is of great importance.

Recently, the hydrolysis of carotenoid-5,6-epoxides in flowers and fruits has also been discovered. The 5,6-diols produced are highly polar compounds. This is one reason for their late discovery; latoxanthin (**28**) and latochrome (**29**) in 1983,[13b, 13d] karpoxanthin (**31**) in 1985[13b, 21, 47a] (for others see Refs. [47b, c]). The 5,6-diols are presumably substrates of further catabolic reactions.

The transformation of violaxanthin (**19**) into allenes **25**–**27** is a very strange one and as yet mechanistically unexplained. Any theories proposed must take into account the uniform *S*-axial chirality observed in the allene bond to date.

7.6. Carotenoid Catabolism in Roses

Our findings show that, besides citrus fruits,[48] rose flowers are also a relatively rich source of degraded carotenoids. In total, we have isolated fifteen apocarotenoids, including stereoisomers, and characterized their structures. These compounds include β-citraurin (**32**), usually a trace component in the flowers of various roses. We were able to isolate quite large amounts from the Chinese shrub rose *R. hugonis* and from the bush roses 'Piccadilly' (*S. McGredy*, 1960) and 'Alexander' (*Harkness*, 1972).[12] The 10′-apolycopene derivatives **33** and **34** were first found by us in the famous old climber 'Maréchal Niel', whose large, gloriously scented flowers are primrose yellow owing to the presence of **33**, as long as the plants flower in a greenhouse. In the open air (i.e., in direct sunlight), the blooms are yellow with a tinge of green, owing to the replacement of **33** by **34**.[13f] Both compounds are especially prevalent in old noisette hybrids and in tea roses such as 'Safrano' (*Beauregard*, 1839), but even modern roses such as 'Alexander' and 'Elina' (= 'Peaudouce', *P. Dickson*, 1985) contain significant quantities.

10′-Apo-β-caroten-10′-ol (**35**) and 10′-apozeaxanthin-10′-ol (**36**) have been found in several old and modern garden roses.[12, 13e, 13g] Compound **35** is novel, as are **33** and **34**, but **36** is already known under the name galloxanthin and has previously been isolated from the retina of birds. Apparently, birds and roses possess similar carotenoid-cleaving enzymes.

The epoxides sinensiaxanthin (**37**) and the sinensiachromes **38** and **39** are widespread in fruits, where they give rise to the yellow color of the flesh in apple varieties such as "Golden Delicious", for example. The structures, synthesis, and purification of the multiple stereoisomers present have, however, only been studied in connection with roses.[13g, 38] Sinensiaxanthins and sinensiachromes are found in many white, yellow, or orange roses, usually together with the stereoisomeric violaxanthins and auroxanthins, from whose cleavage they arise.

The colorless, highly fluorescent C_{14} compound rosafluene (**40**), mentioned briefly in Section 3, is most remarkable. Rosafluene occurs as an ester and possesses extremely similar characteristics to phytofluene (**2**). It is very unstable, especially as the free alcohol. We have found it in numerous old and modern roses, with relatively high amounts in 'Piccadilly', 'Alexander', and 'Penelope' (*Pemberton*, 1924).

With the exception of **34** and **40**, the apocarotenoids found are all C_{27} alcohols. They are definitely carotenoid metabolites and arise by cleavage at C(9) and/or C(9′). The apocarotenoids from roses are not aldehydes but the corresponding alcohols, just as is the case with Car(15,15′) dioxygenase. This enzyme cleaves β,β-carotene (**7**) to retinal, a C_{20} compound which is stored after reduction as the alcohol (retinol, Vitamin A_1). Presumably aldehydes also occur, but because of the very small amounts present, they have not yet been identified.[12]

An analysis of the products shows that the postulated Car(9,10:9′,10′) dioxygenase is not specific for end groups. It cleaves excentrically according to Equation (b). The widespread occurrence of rosafluene (**40**) indicates that the enzyme can also cleave the C_{27} compounds a second time.

$$C_{40} \rightarrow C_{13} + C_{27} \longrightarrow C_{13} + C_{14} \qquad \text{(b)}$$

Recently, we have begun to identify the postulated C_{13} compounds in Equation (b).[50] Our results (Table 2) con-

Table 2. C_{13} compounds in the "headspace" of rose flowers [a].

vincingly show the other side of the carotenoid catabolism under discussion. The detection of acyclic C_{13} ketones and alcohols is also important. If the latter were stored in the form of glycosides, they would not be detectable by gas chromatography.[51]

In summary, the degradation starts with ζ-carotene (**3**) and includes all the end groups in Figure 1 found in roses to date[52] (Table 3).

Table 3. Products of the Car(9,10:9',10') dioxygenase reactions.

Substrate	C_{13} found	C_{27} found	C_{14} possible
ζ-Carotene **3**	**60/61**	?	+

Violaxanthin **19**	?	**37**	+
Auroxanthin **22–24**	?	**38/39**	+
Neoxanthin **25**	?	presumed	+

The results presented in Tables 2 and 3 complete the picture of our pigment analyses of carotenoid-containing roses. Originally, carotenoids may have served in the plant's showpiece as a means of communication with potential pollinators. Then followed the degradation of carotenoids to aroma compounds and to other substances with many different physiological qualities, whose significance is still unclear to us. If one also remembers the fundamental role of carotenoids in photosynthesis, then it is clear that all in all they are the most multifaceted of all natural product groups.

7.7. Carotenoids and the Genealogy of Garden Roses

Old European garden roses, that is, those before 1830, had flowers that were white or red (in many shades). The only exceptions were a few botanical roses which had been introduced to Europe centuries earlier: *R. hemisphaerica* with its full, sulfur-yellow flowers, *R. foetida* (also called *R. lutea* by later authors, the so-called Austrian briar), with a simple, bright yellow flower, and *R. foetida bicolor* (Austrian copper), also with a simple flower, but in two colors, yellow outside and red within. They all originated in central Asia and possibly represent cultivated forms of the original species. *R. hemisphaerica* is often to be seen in old floral still-life paintings. Remarkably, no hybrids between these roses and the old European garden roses are known, although they have been grown in gardens for centuries. The same is true of the yellowish-flowering varieties of *R. pimpinellifolia*. Only after 1800, when several cultivated forms of Chinese roses, including the yellow 'Park's Yellow Tea-scented China'[53] were introduced, did crossings lead to a gradual expansion of the color scale (Fig. 4). 'Park's Yellow' was of crucial importance for the yellow shades. Unfortunately, it has died out[54] and is not available for analysis. On looking through old rose lists one notices that yellow flowers were commoner in noisette roses than in tea roses. These were usually pink on a yellow base or vice versa. Noisette roses arose from crosses with *R. moschata*, which had an as yet unknown effect on the flower color. Famous yellow roses were 'Elise Sauvage' (*Millez*, 1818, tea rose, pale yellow with an orange center[55]), 'Jaune Desprez' (*Desprez*, 1830, noisette, yellow and pink), 'Solfaterre' (*Boyau*, 1843, noisette, sulfur yellow), and the varieties listed in Table 4.

One can see that breeders have always aimed for a purer and more saturated yellow, a development which culminated in 'Maréchal Niel'. Nonetheless, the yellow color in most of these roses was unstable and faded a great deal during flowering. One exception was *R. x harisonii* (*x* indicates a hybrid), which only flowers once. The red roses developed much more rapidly than the yellow varieties and gave rise to the new rose classes of portland, bourbon, and hybrid perpetuals. Among the roughly 4000 hybrid perpetual varieties, there was not a single yellow rose! Even the tea hybrids, which developed slowly from ca. 1850—one of the most important classes today—displayed only very few good yellow varieties before 1900. The emergence of varieties with an intense, highly saturated yellow did not begin till 1900, with the breeding of 'Soleil d'Or' (*Jean Pernet-Ducher*, Lyon), a hybrid of *R. foetida persiana* (Fig. 5) and a red hybrid perpetual. Predecessors such as 'Gottfried Keller' (*Hermann*

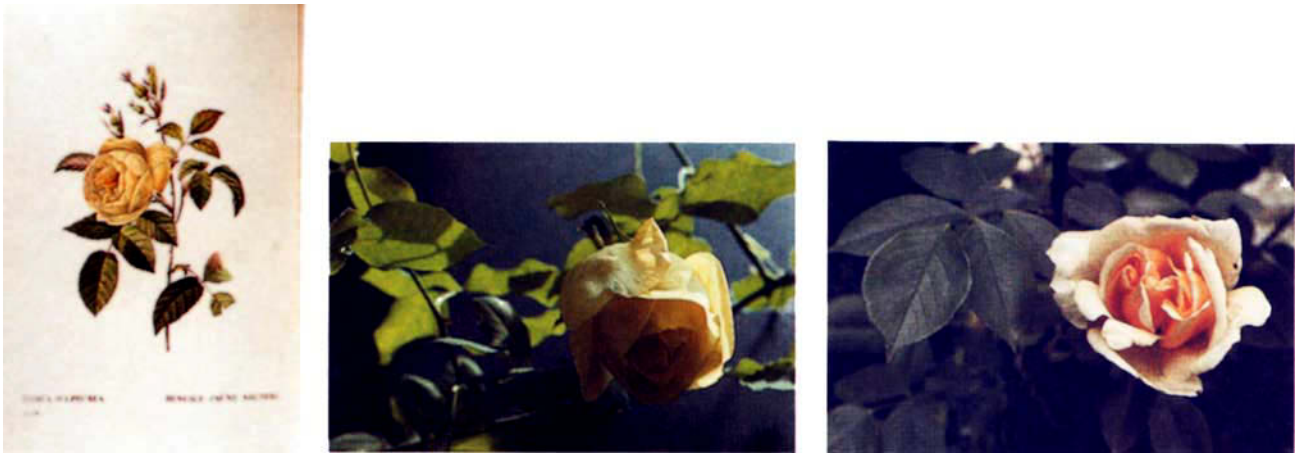

Fig. 4. Old yellow garden roses with carotenoid biogenesis steps 1–3 and pronounced degradation reactions. Left: 'Park's Yellow' (1:3.5, died out; photo taken from P. J. Redouté: Les Roses, 3rd ed. 1828; a specimen from the *Jardin botanique de la Ville* de Genève; parent of the old yellow garden roses). Müller, 1894) had practically no effect on the development of modern yellow varieties.

We have analyzed forty old and modern varieties of yellow garden rose and several important species.[12] In Table 4, some results of this study are presented. The data allow the following conclusions to be drawn:

1. Old, yellow, garden roses that have the Chinese cultivars and above all 'Park's Yellow' and *R. moschata* in their pedigree display an incomplete carotenoid biosynthetic pathway; hydrocarbons at step 2 are accumulated, though usually without neurosporene (**4**) and lycopene (**5**). As a rule, there is a pronounced inhibition of the

[b] *N* = number of carotenoids identified; *Z*/*E* isomers counted separately. A quantitative analysis was carried out for each of the rose varieties listed. [c] Carotenoid content in mg per 100 g dry weight. [d] HC = hydrocarbon s; based on carotenoids = 100%. [e] Mono- and dihydroxylated carotenoids. [f] C_{40} epoxides. [g] AC = apocarotenoids. [h] *Z*/*E*-isomeric carotenoids of the same type counted together. MC = main carotenoids. [i] *R. foetida persiana* and *R. ecae* show practically identical results. [k] Results of low accuracy. [l] Our results are completely different from those in [9b].

Fig. 5. Representatives of *foetida* wild roses that were most important for the breeding of modern, yellow roses. Left: *R. foetida bicolor* (1:2.2), known in Europe since the Middle Ages. Middle: *R. foetida* (1:3), originated in middle Asia, first described by *Conrad Gessner* in 1561 and *Matthias Lobelius* in 1581. Right: *R. foetida persiana* (1:3), introduced from middle Asia in 1837. Characteristic of all is the high content of carotenoids, especially those arising at biogenetic step 6, and a weak catabolism. Thus, these carotenoids are very stable toward light. The main anthocyanin in *R. foetida bicolor* is peonin.

desaturating enzymes, and catabolic reactions are prominent.

2. One exception is *R. odorata x pseudindica*, which has the ability to carry out cyclization (step 3). Unfortunately, it was never used for breeding.
3. Garden roses with pure, stable and strongly saturated yellows emerged only by crossing in of roses of the *foetida* group (Fig. 6), especially *R. foetida persiana*. They contain a complete carotenoid biogenetic sequence; step 5 is pronounced. Degradation reactions are minimal.
4. Carotenoid analysis shows that *R. x harisonii* is descended from *R. pimpinellifolia* and *R. foetida*.
5. Modern, light yellow rose varieties such as 'Mme Meilland' (*Meilland*, 1945) or 'Elina' combine a complete carotenoid biogenetic pathway with enhanced Car(9,10:9′,10′) dioxygenase activity.

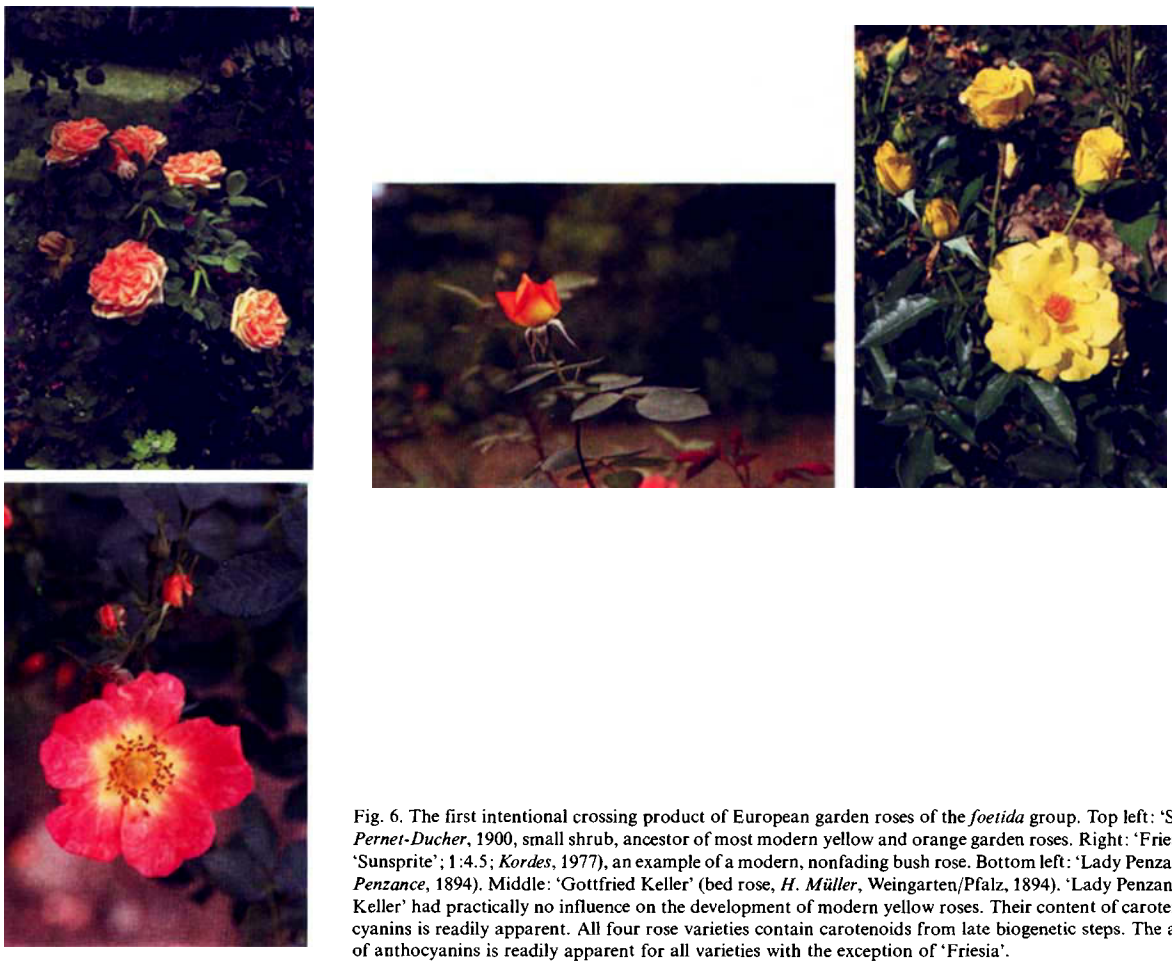

Fig. 6. The first intentional crossing product of European garden roses of the *foetida* group. Top left: 'Soleil d'Or' (1:6.5; *Pernet-Ducher*, 1900, small shrub, ancestor of most modern yellow and orange garden roses. Right: 'Friesia' (= 'Korresia', 'Sunsprite'; 1:4.5; *Kordes*, 1977), an example of a modern, nonfading bush rose. Bottom left: 'Lady Penzance' (1:2.5; shrub, *Penzance*, 1894). Middle: 'Gottfried Keller' (bed rose, *H. Müller*, Weingarten/Pfalz, 1894). 'Lady Penzance' and 'Gottfried Keller' had practically no influence on the development of modern yellow roses. Their content of carotenoids and anthrocyanins is readily apparent. All four rose varieties contain carotenoids from late biogenetic steps. The additional content of anthocyanins is readily apparent for all varieties with the exception of 'Friesia'.

8. Anthocyanins in Roses

8.1. General Considerations

Anthocyanins are more important than carotenoids for the colors of roses, because their light absorption extends over a greater part of the spectrum. At short wavelengths, the orange almost coincides with that of the carotenoids, while at long wavelengths the color extends to a pale mauve. The properties of anthocyanins could hardly be more different from those of the carotenoids; they are hydrophilic and are generally dissolved in the cell sap. Analytical studies on rose anthocyanins began as early as 1915 with the classical work of *Willstätter* and *Nolan* on the isolation of cyanin (**66**) from dried "flores rosae gallicae rubrae".[56] In 1934, pelargonin (**62**) was isolated for the first time from the new, orange scarlet variety 'Gloria Mundi' (*de Ruiter*, 1929);[57] this was followed in 1961 by peonin (**71**) from *R. rugosa* and its hybrids[58] as well as the 3-glucosides **63** and **68**.[9a] For systematic analytical studies of hundreds of hybrids and species, see Refs. [9a, 59]. Our own HPLC studies of roughly 160 varieties and botanical roses have led to the identification of five to six further anthocyanins and anthocyanidins.[60] The structures of the anthocyanins so far identified in rose petals are shown in Figure 7.

Table 5. Spectrophotometric determination of anthocyanins.

Rose variety	Flower color	Anthocyanin	Content [a]
'Mister Lincoln' (*Swim & Weeks*, 1964)	dark red	**66** (little **67**, **68**)	0.6
'Papa Meilland' (*Meilland*, 1963)	dar red	**66**	0.3
R. rugosa rubra	violet-pink	**71** (little **72**, **73**)	0.25
'Veilchenblau' (*Schmidt*, 1909)	lilac with white	**66**	0.1

anthocyanins on acid treatment, are not present in significant amounts, since there is no visible deepening of the color during extraction of pink roses. The noncorrelation between flower color and the light absorption of the flavylium cations (Fig. 12) responsible will be discussed in Section 8.5.

8.2. Pelargonin in Roses

Pelargonin (**62**; see Fig. 8) did not appear in roses in color-determining concentrations until 1929. In other garden plants, such as pelargoniums and geraniums, it had been known for years. However, analysis shows that pelargonin is hardly ever formed on its own, but is accompanied in almost all scarlet roses by cyanin (**66**). 'Gloria Mundi' is one of the very few roses that contains almost pure pelargonin (Fig. 8). Since then, the unexpected appearance of **62** in roses has been traced by many authors (cf. Ref. [62]) to a mutation. Now, however, analyses show[9a, f] that even very old varieties contain significant amounts of **62**; examples are *R. centifolia muscosa* (moss rose, appeared before 1750), 'Königin von Dänemark' (*Booth*, 1816, alba hybrid?), 'Général Jaqueminot' (*Roussel*, 1853, hybrid perpetual), 'Crimson Rambler' (Japan, pre 1890, multiflora hybrid), and 'Soleil

Not yet identified in rose petals.	

Fig. 7. Anthocyanins identified in rose flowers. The flavylium cations stable at low pH are shown.

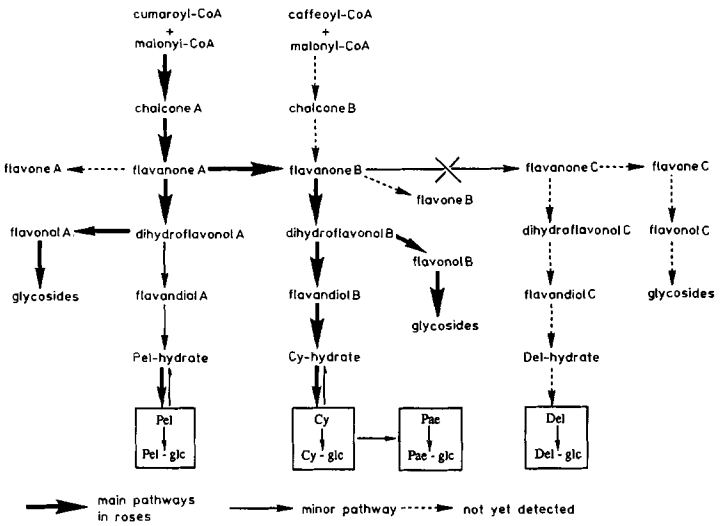
Only glucose is used for glycosidation, and the 3,5-diglucosides are the dominant pigments. All the others are minor components and play only an occasional color-determining role in pink flowers. Whether other glycosides occur in the nonidentified trace components is not yet known. They may be important for breeding. The absence of delphinidin derivatives (e.g., **75**) is most important, since the hope of a blue rose vanishes with them.

A qualitative relationship exists between the intensity and saturation of petal coloration and the anthocyanin content (Table 5; see also the older analyses in Ref. [61]).

Less colored precursors of anthocyanins such as chalcones (**79**) and hydrates (**78**) (see Scheme 5), which can re-form

Fig. 8. 'Gloria Mundi' (1:2.5; *de Ruiter*, 1929); the first garden rose in which mainly pelargonin is responsible for the color.

d'Or'. In contrast to the views of Refs. [9a, d], we also found pelargonin in botanical roses, such as *R. pendulina*, *R. willmottiae*, *R. rugosa*, *R. pomifera*, and *R. gallica versicolor*. These are species that originate in quite different parts of the world and are members of different botanical sections of the subgenus *Eurosa*. This can be explained by referring to the general biosynthetic scheme for flavonoids, modified according to Ref. [63] (Scheme 4 and Fig. 9). It shows that there



Scheme 4. Flavonoid biogenesis, modified from [63]: ⟶, major pathways in roses; ⟶, minor pathways; - - ⟶, not yet detected in roses. The abbreviations refer to Figure 7. PeL = compounds of the type **62**–**65**, Cy = **66**–**70**, Pae = **71**–**74**, Del = **75**, glc = D-glucose.

is no immediate connection between pelargonin, cyanidin, and delphinidin, but that they represent different branches from a series of precursors. Pelargonidin only occurs if the reduction of dihydroflavonol A to flavandiol A is *not* inhibited, while the hydroxylation of flavanone A to flavanone B is blocked. How the formation of flavonol A is correlated to pelargonidin is not yet known.

With pelargonin one also always finds some of the 3-glucoside (callistephin, **63**; see Fig. 7). The 5-glucoside **64** is very rare; it occurs, for instance, in 'Super Star' (*Tantau*, 1960). We assume that pelargonidin also arose spontaneously in other breeding strains not related to 'Gloria Mundi' and its relatives, such as 'Independence' (= 'Kordes Sondermeldung', *Kordes*, 1951).

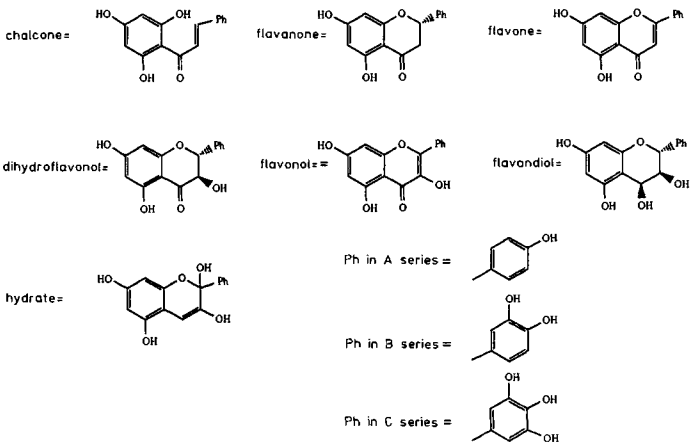


Fig. 9. Key to Scheme 4.

8.3. Cyanin in Roses

Cyanin (**66**) is the most important pigment in red roses. Often it is accompanied by smaller quantities of chrysanthemin (**68**). We have only found a few varieties where the ratio **68**:**66** is greater than 1, for example, in the old bourbon rose 'Souvenir de la Malmaison' (*Béluze*, 1843) and in the climbers 'François Juranville' (*Barbier*, 1906) and 'Dorothy Perkins' (*Jackson* and *Perkins*, 1901). As the cherry red flowers of the latter variety show, high levels of chrysanthemin can yield surprising red shades. We found the 5-glucoside **69** quite often, but always in low amounts. Cyanidin (**70**) and the 3,7-diglucoside (**67**) are rare. The well-known paradox that cyanin is present in both red and purple flowers is also true for roses; the mauve-colored 'Blue Moon' (= 'Mainzer Fastnacht', *Tantau* 1964) and 'Veilchenblau' (Fig. 10) both contain almost pure cyanin. For a possible explanation, see Section 8.5. A direct synthesis of cyanidin from caffeoyl-CoA in roses cannot be excluded, as it has not been studied (see Scheme 4).

8.4. Peonin in Roses

The earlier assumption that peonin (**71**) is typical for *R. rugosa* and *rugosa* hybrids must today be modified. More recent studies[9a, 60, 64] show a broad distribution in the sections Cinnamoneae, namely, *R. arkansana*, *R. acicularis*, and *R. x dulcissima* (all from North America), and *R. moyesii*, *R. multibracteata*, and *R. sweginzowii macrocarpa* (all from China), the Caninae (*R. canina*, *R. glauca*, and *R. pomifera*; all European), and the Pimpinellifoliae (*R. foetida bicolor*!). The mysterious 'Crimson Rambler' and 'Königin von Dänemark' also contain unexpectedly high levels of peonin, which throws new light on their unknown pedigrees.

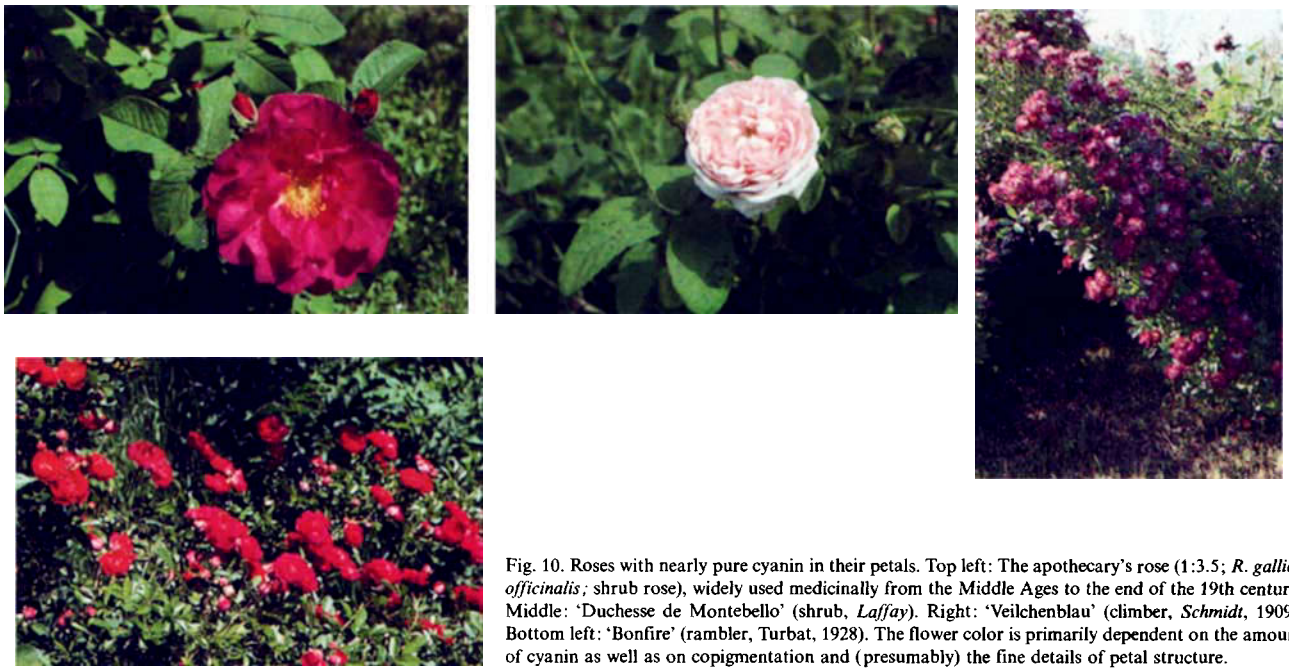

Fig. 10. Roses with nearly pure cyanin in their petals. Top left: The apothecary's rose (1:3.5; *R. gallica officinalis;* shrub rose), widely used medicinally from the Middle Ages to the end of the 19th century. Middle: 'Duchesse de Montebello' (shrub, *Laffay*). Right: 'Veilchenblau' (climber, *Schmidt*, 1909). Bottom left: 'Bonfire' (rambler, Turbat, 1928). The flower color is primarily dependent on the amount of cyanin as well as on copigmentation and (presumably) the fine details of petal structure.

Pure peonin is not found even in *R. rugosa rubra*; it is accompanied by much cyanin. The richest source of almost pure peonin is the old shrub rose 'Hansa' (*Schaum* and *Van Tol*, 1905; Fig. 11). Its mauve-red flowers show what can be achieved by high levels of pure peonin! Rarely have we found the 3- or 5-glycosides **72** (oxycoccicyanin) and **73**, or free peonidin (**74**).

8.5. The Stabilization of the Anthocyanin Chromophore in Roses

8.5.1. General Considerations

The sap of the anthocyanin-containing epidermis cells of the cerise-red 'Better Times' has a pH of 3.7–4.2, as deter-

Fig. 11. Peonin-dominated flower colors. Left: 'Frau Dagmar Hartopp' (1:2.5; small shrub, *Hastrup*, ca. 1914). Right: 'Hansa' (1:3; shrub rose, *Schaum* and *van Tol*, 1905).

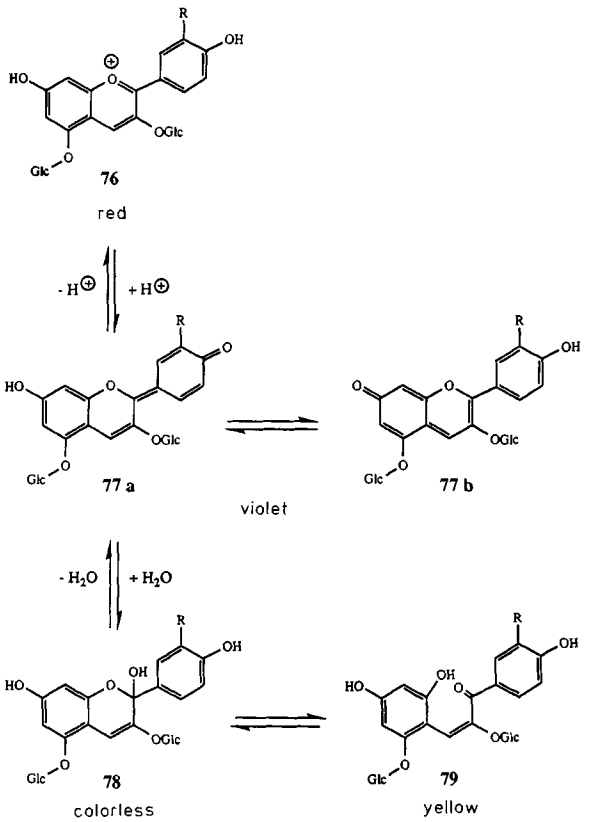
The Austrian copper (*R. foetida bicolor*) contains surprising amounts of peonin, as already mentioned.[9a, 60] If its progeny contain anthocyanins—which is not always the case—they always include peonin. An example is 'Lady Penzance' (*Penzance*, 1894), a shrub rose bearing coppery red flowers with a yellow center (see Fig. 6). However, a connection between *rugosa* type and the peonin content of the flowers need not exist. Thus, analysis of the flowers of 'Conrad Ferdinand Meyer' (*H. Müller*, 1899) shows them to be free of peonin.

Peonin is probably derived from cyanin.[63] Whether the methylation occurs at the level of the cyanidin or only at its glucosides is unknown. A direct route starting from activated ferulic acid (3-*O*-methylcaffeoyl CoA) is also possible.

mined by spectrometric microtechniques.[61c] Within three days, this rises to 4.4–4.5, and the petals take on a slightly bluish tinge. In this pH range, pure flavylium ions are mostly transformed into the colorless hydrates **78** or the yellow chalcones **79** (Scheme 5), since the intermediate quinone methides **77** are so electrophilic that they do not survive in aqueous solution.[65] Hence, the question of stabilization arises for all anthocyanin pigments in plant organs, and a great many studies have been devoted to the subject, especially recently.[66] The interpretations given are selectively true for certain plants and to various extents: complex formation between anthocyanins and flavonoids with metal ions,[66a, 66b] intramolecular stacking,[66a, 66b] association (copigmentation) with the related chalcone,[67] stacking by

self-association,[66c] copigmentation with flavonols and related compounds.[66] Which of these are true for roses?

Metal complexes with anthocyanins and flavonoids have not yet been detected. These would be most likely for lilac or mauve varieties. In any case, studies of 'Veilchenblau' showed that the isolable, intense blue-violet fractions are very unstable and do not correspond[60] to the types described by *Goto* et al.[66] Intramolecular stacking appears when the glycosyl residues on the anthocyanidin (disaccharides!) are esterified to cinnamic acids. This shields the pyrylium ring from nucleophilic attack at C(2) and hence protects the anthocyanin chromophore. In roses, neither disaccharide glycosides nor esters of phenylpropanoid acids have been found, so that this form of stabilization must be disregarded. Copigmentation with the related chalcone,



Scheme 5. R=H, OH, OCH_3.

which is in equilibrium with the anthocyanin, leads in vitro, in a 1:1 ratio, to significant stabilization, with bathochromic and hyperchromic effects.[67] This stabilization mechanism was suggested only recently and cannot be excluded for roses. However, it would lead to a great increase in the extinction on acidification, due to a shift of the equilibria towards the flavylium cation (Scheme 5), and this has not yet been observed.

Stacking by self-association has been demonstrated in in vitro experiments by deviation from the Lambert–Beer relationship and by strong exciton couplings in the circular dichroism spectrum. $Al^{3\oplus}$ salts may also play a role here.[68] This phenomenon could be important in roses with high anthocyanin content, but proof is lacking.

8.5.2. Copigmentation in Roses

From our current knowledge, copigmentation is the most important process for stabilization of rose anthocyanin chromophores. It consists of a loose association between a flavylium cation or quinone methide and a flavonol or related compound and is only observed in aqueous medium. To date, no such loose complexes have been isolated. This association has several consequences: shifting of the anthocyanin equilibria in Scheme 5 towards **76** and/or **77**; stabilization of the light absorption in the visible even in the physiological pH range; a shift in the visible maximum towards longer wavelengths; an increase in the extinction compared to a solution without copigment (see Fig. 12). Copigmentation effects are proportional to the concentration of the copigment. Initial studies of the copigments in 'Better Times' revealed a series of flavonol glycosides,[61c] including kaempferol-3-*O*-β-D-glucoside, a xyloside, quercitrin (**84**), and a quercitrin glucoside, arabinoside, and glucuronoside.

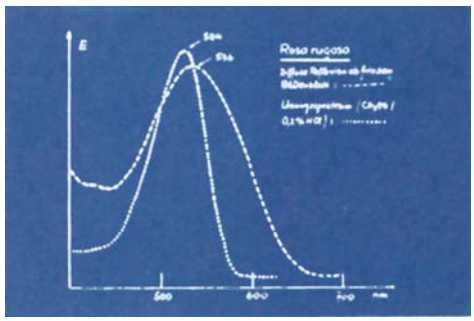


Fig. 12. Copigmentation effect for peonin: Absorptions of the pigment from *Rosa rugosa* in solution (···, in CH_3OH/0.2% HCl) and of its diffuse reflectance from fresh petals (----).

Recent studies on 'Veilchenblau' and 'Papa Meilland' have confirmed the wealth of flavonol glucosides present.[13k, 60a] Compounds **80**–**84** were identified in both these varieties (Fig. 13). They also occur in numerous white, yellow, and red roses in quite different proportions and mixed with other, not yet identified flavonoids. Spireoside (**82**) displays an especially strong copigmentation effect. At pH 4.7 and in a cyanin/spireoside ratio of 1:1, λ_{max} is shifted by 18 nm to longer wavelenghts; at a 1:2 ratio the shift is as great as 27 nm.[69] More detailed studies of roses with respect to their flavonol glycosides and other, as yet unknown copigments will be most worthwhile.

9. Tannins in Rose Petals

As many rose lovers know, chewing a rose petal produces an astringent effect in the mouth. The assumption that tannins occur in roses is an old one. Tannins have even been considered as possible stabilizers of the anthocyanin chromophore.[70] A more detailed study has now revealed that rose flowers contain a great many *ellagitannins*.[13k] These are esters of gallic acid (3,4,5-trihydroxybenzoic acid) and its oxidation products with monosaccharides.[71] Compounds

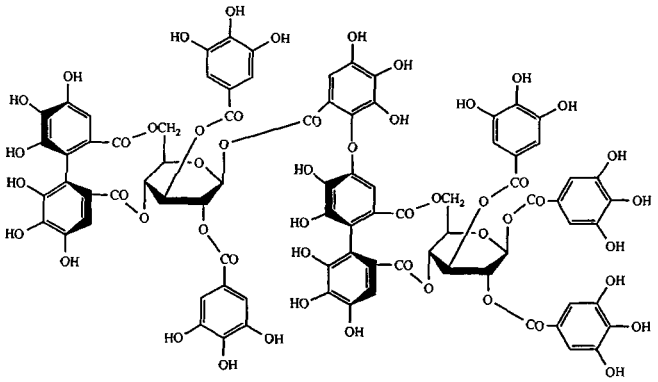
88 (rugosin A)



89 (rugosin D)

Fig. 14. Ellagitannins identified in rose petals.

85–89 were identified in 'Papa Meilland' and compound **86** in 'Veilchenblau' (Fig. 14). Ellagitannins are widespread and occur in high concentrations in all rose varieties. Many still await identification.

The presence of ellagitannins offers the first rational explanation for the long-standing medicinal use of dried rose petals. The apothecary's rose (*R. gallica officinalis*), in particular, has been used to treat diarrhoea, bleeding, and all kinds of inflammations.[72]

Compounds **85–89** display very little copigment effect. Though anthocyanins do not bleach in their presence, they lose their distinct maxima in the visible.

The trihydroxylated benzene ring of gallic acid is most remarkable! If this hydroxylation were to take place on anthocyanins to yield, for example, **75**, then the path to blue roses would lie open. It follows, therefore, the gallic acid and the flavonoids are synthesized by different routes.

10. Orange Roses

In recent decades, the breeding of orange roses has been strongly promoted. These modern varieties give particularly bright colors when planted in large beds; their shades lie somewhere in the overlap region between yellow and red. The almost uniform coloration is remarkable in these roses and is quite different from that of the yellow-red, two-tone roses. In the latter, carotenoids and anthocyanins show quite clear local differences in concentration. A good example is the Austrian copper (*R. foetida bicolor*), which has carotenoids on the outside and anthocyanins on the inside of the petals. In modern orange garden roses, this differentiation is absent. Pigment analysis shows that the saturation of the yellow cannot be explained by the presence of high levels of pelargonin (**62**): the new orange roses contain easily detectable quantities of carotenoids and high levels of anthocyanins (Table 6, Fig. 15). Even though the carotenoids are concentrated in the base of the petal, they are easily detectable in the blade by reflection spectroscopy; in vivo, 'Alexander' shows a reflection maximum at 425/445 nm, typical of carotenoids. Two further examples demonstrate how strongly carotenoids influence the color: flowers of the old rose 'Daily Mail Rose' (= 'Mme Edouard Herriot', *Pernet-*

Fig. 15. Modern orange-red roses in which the brightness of the pigments is increased by the presence of carotenoids. The most important anthocyanin is pelargonin. Left: 'Ville de Zürich' (1:3.8; bush rose, *Gaujard*, 1967). Right: 'Orangeade' (1:3.7; bush rose, *McGredy*, 1959).

Ducher, 1913) show almost uniform areas of a strong, coppery orange, and the same is true for the bright orange rose 'Louis de Funè' (*Meilland*, 1984). To our surprise, the anthocyanin content of both of these comprises practically pure cyanin, and the coppery orange is due to a mixture with carotenoids.

Table 6. Anthocyanins and carotenoids in orange-red roses.

Variety	Anthocyanins	Carot. [a]	*N* [b]	MC [c]
'Sarabande' (*Meilland*, 1957)	**62** + **63** (ca. 1:1)	1.5	16	**7**, **10**, **14**
'Super Star' (*Tantau*, 1960)	**62** + **66** (ca. 3:2)	1.6	21	**7**, **13**, **22–24**
'Orange Bunny' (*Meilland*, 1980)	**62** + **66** (ca. 2:1)	1.0	17	**7**, **10**, **14**

[a] Carotenoids: mg per 100 g dry weight. [b] *N* = number of carotenoids identified. [c] M_C = main carotenoids.

The physiological conditions that allow such an intimate mixture of pigments with such different solubility characteristics, and yet give a uniform coloration, are unknown.

A development is therefore in progress which, according to measurement of color and analytic findings, has not yet reached a conclusion. This is shown by a comparison between modern orange varieties of garden roses and the nasturtium (*Tropaeloum majus*), an old garden plant. Its flowers also contain the usual carotenoids and anthocyanins.[73] Nevertheless, its orange attains a higher saturation of the yellow than has yet been found in any comparable variety (Table 7).

Table 7. Measurement of color (CIELAB).

Flowers	L* [a]	+ a* [b]	+ b* [c]
'Super Star'	51–55	56–58	48–55
'Orange Bunny'	54	58	53–55
'Alexander'	56	54	51
Nasturtium (orange)	52–53	55–57	80–83

L*, measure of lightness; a*, measure of color saturation on the red-green axis; b*, measure of color saturation on the yellow-blue axis.

11. Pigments of Rosehips

Rosehips come in many different colors, shapes, and sizes. The flesh is colored a lively yellow, orange, pink, red, brown, or deep black by carotenoids and anthocyanins. Chemical studies on these pigments began in 1913, many years before carotenoid structures were known.[74] It is striking that they only concerned the hips of botanical roses; perhaps, especially in more recent times, this has been due to an interest in their possible content of provitamin A_1.[75] The published results are difficult to evaluate, because of often inadequate purification and identification procedures. Table 8 contains some relevant, recent results.[12, 76] The dominance of lycopene (**5**) and β,β-carotene (**7**) can be seen, also occasionally of rubixanthin (**10**) and lutein (**14**). In contrast to rose flowers, epoxides are almost completely absent; in *R. pomifera* only 3–4% of the total content consisted of epoxides, including the stereoisomeric mutatoxanthins (**17**, **18**), which are only found in traces in flowers if at all.

Table 8. Carotenoid content of rosehips.

Rose	Content [a]	*N* [b]	Main carotenoids [c]	Ref.
R. canina	1.2–2.5	14	**5**, **7**, **10**	[76a]
	133 [d]	11	**5**, **7**, **10**	[76b]

'Golden Wings' (*Shepherd*, 1956)	6.1	15	**7**, **14**	[12]
'Sarabande' (*Meilland*, 1957)	5.4	16	**7**	[12]

[a] mg carotenoids per 100 g fresh weight. [b] *N* = number of carotenoids identified. [c] HC = main carotenoids. [d] mg in dried rosehip flesh. [e] Analyzed by HPLC.

The anthocyanins in rose hips have hardly been studied at all. The conspicuously black hips of *R. pimpinellifolia* contain almost pure chrysanthemin (**68**), according to *Demi-*

na[77] and demonstrate in extremis how important it is to identify the copigments that are presumably responsible for the black color.

12. The Dream of a Blue Rose

Many breeders and even more rose fanciers have dreamed of a blue rose—to the disapproval of more traditional rose lovers. However, violet-red roses have existed for a long time; for example, 'Tuscany' (gallica hybrid, pre-1600), 'Cardinal de Richelieu' (*Laffay*, 1840), and several others from the hybrid perpetuals, such as 'Reine des Violettes' (*Millet-Malet*, 1860). The roses tending most to violet are, however, 'Veilchenblau', a climbing rose with large inflorescences full of small, simple, lilac-colored individual flowers, and 'General Stefanik' (*J. Böhm*, 1931), a dwarf hybrid perpetual. In the former, 'Crimson Rambler' may have given rise to the violet color, in the latter *R. rugosa*. The hybrid polyantha 'Baby Faurax' (*Lille*, 1924) appeared later, as did the pale lilac tea hybrid 'Blue Moon' and many others. No breakthrough has been achieved to date.

The anthocyanins detected so far leave little hope for breeding a blue rose by conventional methods. With peonidin (**74**) as a basis, a rose with sky-blue flowers like those of *Ipomoea coerulea* (morning glory) would be possible if the requirement for intramolecular pigmentation (stacking with disaccharides and caffeic acid esters[78]) were fulfilled. With cyanidin (**70**), one can fall back on a comparison with cornflowers. Here, too, suitable glycosidation, acylation, and complex formation with cations would be required (see Section 8.5.1).

In Section 9 it was mentioned that rose petals are full of gallic acid esters. Could this hydroxylation activity be redirected to ring B of cyanidin? Otherwise, only the gene-technological path remains, with introduction of suitable genes from *Petunia*, for example. A far-fetched idea? One must not forget that a successful breeder could expect to receive several millions in licence fees for a good blue rose.[79]

13. Epilog

Our studies of rose pigments bring some more light into the long history of rose breeding. Roses are still full of unsolved puzzles, however. We would like to prompt young researchers to take them on with further scientific methods. Roses are also of great economic importance.[80] Moreover, our investigations have revealed gaps in the color range of current varieties. In yellow roses, the degree of the saturation of the color of the *foetida* group has still not been reached; an improvement in the lycopene, β,β-carotene, or rubixanthin content could produce quite new shades (compare tomatoes, corollas of narcissus with about 1.5% β,β-carotene, and rosehips); an increase in the content of chrysanthemin (**68**) would afford purer und more powerful red shades.

The analysis of rose carotenoids has furnished more insight into the genealogy of garden roses than bare the anthocyanins, where the small number of structures is a disadvantage. The identification of trace components, especially flavonol glycosides and other copigments, could help. Above all, the copigments must be studied more intensively. To date, breeders have always oriented themselves by the anthocyanin colors expressed and have ignored (or have been unable to consider) the copigments that are required for stabilization of the color and which are also passed on genetically. Scientifically, a study of carotenoid-degrading enzymes is also long overdue; roses constitute a readily available starting material, and well-developed procedures for analyzing the cleavage products are known.

We thank the Swiss National Science Foundation for financial support of our studies. The Ministry of Education (Canton Zürich) made possible the installation of a rose garden close to the Institute. Our thanks also go to the members of our research group for expert collaboration. We thank the rosarians K. Hauenstein (Rafz), K. Herter (Nussbaumen), R. Huber (Dottikon), Hauser (Vaumarcus), D. Woessner (Neuhausen), P. Täckelburg, and H. Vonholdt (Sangerhausen rosarium) for their help in procuring the roses. We are grateful to J. Klitscher (D-Klein Offenseth-Sparrieshoop) for statistical data.

[80] A large rose company in Germany makes roughly 100 000 crosses annually, which give to some 250 000 seedlings. Of these, three to five come onto the market as new varieties, after the required testing. In addition, old and new varieties are propagated; in Germany this amounts to about 30 million rose plants every year. The world production is unknown, but is presumably over 150 million. The number of cut roses produced from rose plantations is also enormous; the area of cultivation worldwide is > 3000 hectares.

Metalla-enes and Metalla-ynes—from Small Molecules to Infinite Polymers

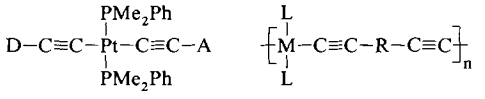
By *Malcolm H. Chisholm**

Conjugated organic π-systems in rings, chains, and polymers have long been of interest in terms of their structure and bonding. The delocalized π-systems endow these materials with enhanced electrical conductivities and nonlinear optical responses.[1] Multiple bonding between metal atoms[2] and between metal atoms and carbon, nitrogen, or oxygen atoms[3] form the basis for innumerable possibilities for molecular design of metalloorganic analogues. In the small molecules $[\{(CO)_5Re\}_2C_2]$,[4] $[\{(tBu_3Si)_3Ta\}_2C_2]$,[5] and $[\{(tBuO)_3W_2\}_2C_2]$[5,6] we find a central linear M-C-C-M moiety with distances and electronic structure consistent with the valence bond descriptions shown in **1**, **2**, and **3** below.

$M-C\equiv C-M$ $M=C=C=M$ $M\equiv C-C\equiv M$

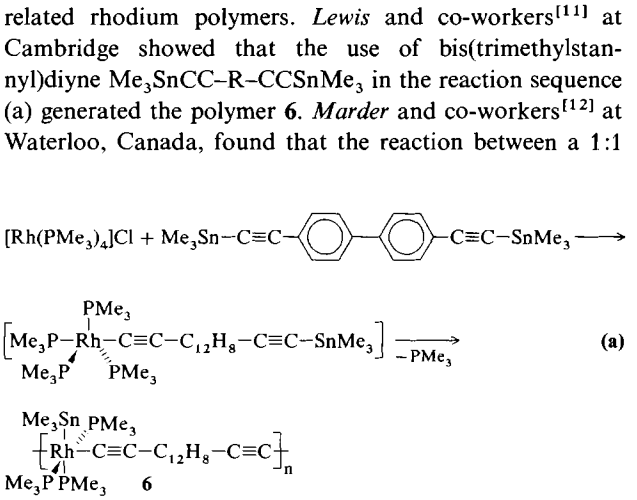
1 **2** **3**

The *trans*-bis(acetylide) complexes of platinum depicted by **4**, where D and A represent π-donor and π-acceptor groups, respectively, have been synthesized and shown to exhibit second-order nonlinear optical behavior.[7] Polymeric species of the type shown in **5** were first reported by *Takahashi* and co-workers[8] and have been shown to have nonlinear optical (large $\chi^{(3)}$)[9] and liquid-crystalline properties.[10]



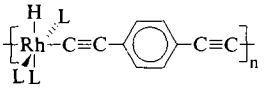
4 **5**

Two recent independent reports described the synthesis of related rhodium polymers. *Lewis* and co-workers[11] at Cambridge showed that the use of bis(trimethylstannyl)diyne $Me_3SnCC-R-CCSnMe_3$ in the reaction sequence (a) generated the polymer **6**. *Marder* and co-workers[12] at Waterloo, Canada, found that the reaction between a 1:1 mixture of $Rh(PMe_3)_4Me$ and $HC\equiv C-C_6H_4-C\equiv CH$ yielded **7** with the elimination of methane.



(a)

6



7, L = P*n*Bu$_3$

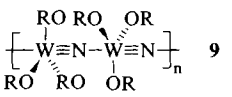
The solubilities of the two rhodium alkynyl polymers **6** and **7** were very similar as were the values of $\nu_{C\equiv C}$ (2080 cm^{-1}). The crystal structure of the bridged rhodium compound shown in **8** provides a structural model for a segment of one of these rigid-rod or stiff-chain polymers.[13]

$[(Me_3P)_4Rh-C\equiv C-C_6H_4-C\equiv C-Rh(PMe_3)_4]$ **8**

The Cambridge group reported that the use of $Me_3SnCC-R-CCSnMe_3$, $R=p\text{-}C_6H_4-C'_6H_4\text{-}p$, in Equation (b) led to polymers with average molecular weights of *ca.* 100000, somewhat higher than that reported in the original preparation by the Japanese workers.[8]

$$trans\text{-}(PBu_3)_2MCl_2 + Me_3Sn-C\equiv C-R-C\equiv C-SnMe_3 \longrightarrow 1/n\ \{M\equiv C-C-R-C\equiv C\}_n + 2\ Me_3SnCl \quad (b)$$

The nitrides $(tBuO)_3M\equiv N$, where M = Mo or W, crystallize in noncentrosymmetric space groups ($P6_3cm$, $P6_3$) and contain infinite chains of alternating short (ca. 1.7 Å) and long (2.7 Å) M–N bonds corresponding formally to triple and single (or dative) bonds as shown in **9**.[14]



9

Hopkins and co-workers[15] recently reported that time-resolved spectroscopic analysis of the light emitted by powdered samples of $[(tBuO)_3M\equiv N)]_\infty$ showed nonlinear optical activity (a second harmonic generation, SHG). The relative yield of the SHG was only ca. 30% of that of urea. These efficiencies are surprisingly modest since these compounds should in principle possess large molecular hyperpolarizabilities (β), as predicted from the $\beta \propto L^3$ dependence of this property on the conjugated chain length (L).

Crystals of these nitride polymers were also found to be highly emissive at low temperature (77 K) and have extremely long excited-state lifetimes. That for molybdenum ($\tau = 750$ µs) was amongst the longest known of any transition-metal-containing complex (indicative that emission is a

spin-forbidden process). The vibronic structure allowed a simple estimate of the M≡N–M distortion (ca. 0.2 Å) for the excited states. This is consistent with an earlier band calculation on the hypothetical infinite linear polymer $[W(OH)_3N]_\infty$ that placed the valence and conduction bands are correspondent with the W≡N σ/π (occupied) and W–N π^* (empty) orbitals of the monomer $W(OH)_3N$.[16]

These recent findings serve to highlight some of the interests that surround a growing class of materials containing metal ions in conjugated systems: metalla-enes and metallaynes.

Stable Carbenes—Illusion or Reality?

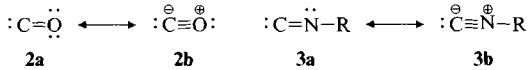
By *Manfred Regitz**

Carbenes (**1**) are divalent carbon compounds with two nonbonding electrons on one carbon atom. The electron spins can be either antiparallel (singlet, **1a**) or parallel (triplet, **1b**). Carbenes are regarded as short-lived and highly reactive and they play a prominent role in the broad field of reactive intermediates. They are especially fascinating because chemists used to thinking in terms of the tetravalency of carbon are confronted with a radical change in perspective and with a bewildering array of reactions.

1 **1a** **1b**

Retrospect: Attempts to obtain the parent compound, methylene, by dehydration of methanol date from the first half of the last century, when the compound was thought to be stable.[1] Although such efforts seem daring today, it should be recalled that the tetravalency of carbon was not an established fact at that time. There were many subsequent attempts, all in vain, to find "bottle-able carbenes". Milestones on the route leading to recognition of the true character of carbenes as reactive intermediates included the work of *H. Staudinger* (decomposition of diazo compounds and ketenes, 1911–1916), *H. Meerwein* (C–H insertion of carbenes, 1942), *J. Hine* (α elimination of haloforms, 1950), and *W. von E. Doering* (addition of dihalocarbenes to olefins, 1956), who also coined the name. These developments led to an explosive growth in our knowledge of carbenes, a subject treated in several important monographs.[2] Even a standard handbook of organic synthesis has had to include carbenes in its palette of synthetically useful species.[3]

Stabilization of Carbenes: The electron deficiency due to the sextet on the carbene carbon can be partly relieved by donor substituents. Thus, carbon monoxide (**2**) and isocyanides (**3**), formulated as neutral species, can also be included in the definition of carbenes given above. In these cases, however, the heteroatom compensates for the electron deficiency on the divalent carbon. Of course, it would be erroneous to speak here of stable carbenes, even though



2a **2b** **3a** **3b**

carbene behavior, such as [2 + 1] and [4 + 1] cycloadditions, is observed. The so-called nucleophilic carbenes such as 1,3-diphenylimidazolidin-2-ylidene (**5**) and 1-methyl-1,3-benzthiazolin-2-ylidene (**8**) are more relevant to the question

[*] Prof. Dr. M. Regitz

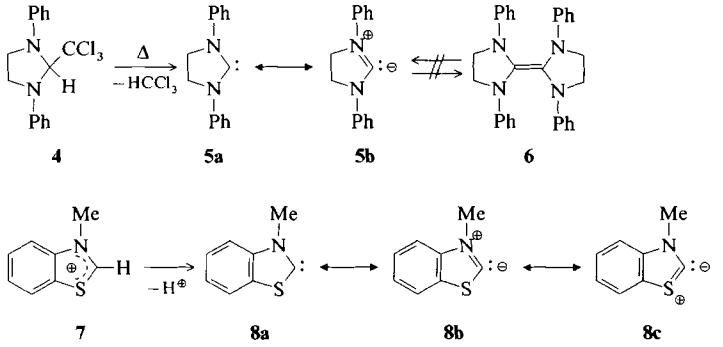
at hand. The former can be generated by thermal α elimination from **4**,[4] for example; the latter can be generated by deprotonation of cation **7**.[5] Both species have been trapped by numerous electrophiles.[3]

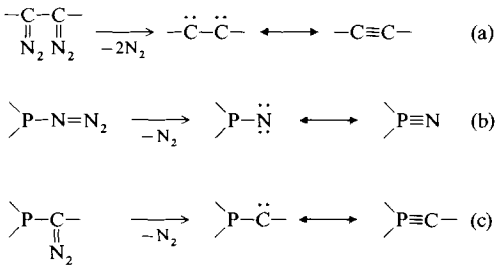


4 **5a** **5b** **6**

7 **8a** **8b** **8c**

The assumption that the "Wanzlick olefin" **6**, despite many indications to the contrary from its reactive behavior, exists in equilibrium with carbene **5** at about 150 °C is not supported by crossing experiments.[6] Similarly, the product obtained on deprotonation of **7** proved to be the dimer of carbene **8** rather than **8** itself.[5] Despite stabilization by donor substituents (**5a** ↔ **5b** and **8a** ↔ **8b** ↔ **8c**), both species still behaved as reactive intermediates. Nonetheless, the possibilities discussed here for thermodynamic stabilization of carbenes, together with steric shielding of the reaction center, play a crucial role in answering the question posed in the title. Recently, the groups of *G. Bertrand* in Toulouse and *A. J. Arduengo* in Wilmington, Delaware, published exciting results that have revived the discussion.

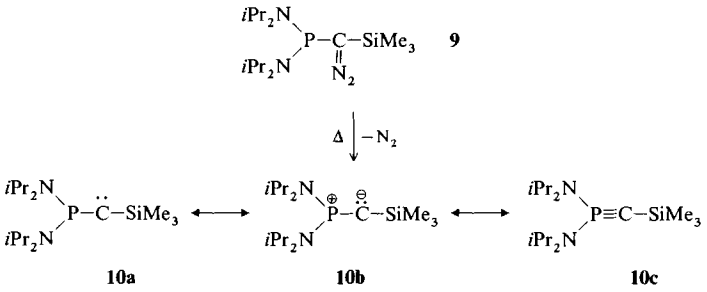
Bertrand's Carbene: The starting point in this development was the observation made by *T. Curtius* over 100 years ago that α-bis(diazo) compounds spontaneously lose N_2 to give acetylenes [Eq. (a)]. Combination of this fact with the



knowledge that low-coordinate phosphorus can engage in double- and triple-bond formation[7] leads logically to the question whether the species formed on loss of N_2 from azidophosphanes are best characterized as nitrenes or as phosphanitriles [Eq. (b)]. The experiments—1,2 additions, [3 + 2] cycloadditions, cyclooligomerizations[8]—support unequivocally an intermediate with multiple-bond character. The formulation of a corresponding carbene intermediate was obvious [Eq. (c)]. It required, however, the synthesis of phosphinodiazo compounds.

The model diazo compound **9** was synthesized from lithiated diazotrimethylsilylmethane and chlorobis(diisopropylamino)phosphane.[9, 10] Thermolysis of **9** at 160 °C afforded a spectroscopically and analytically well-characterized, distillable red oil in 80% yield.[10] The title of the published results, "Synthesis of a Stable λ^3-Phosphinocarbene-λ^5-phosphaacetylene", points to both the carbene *and* acetylene character.

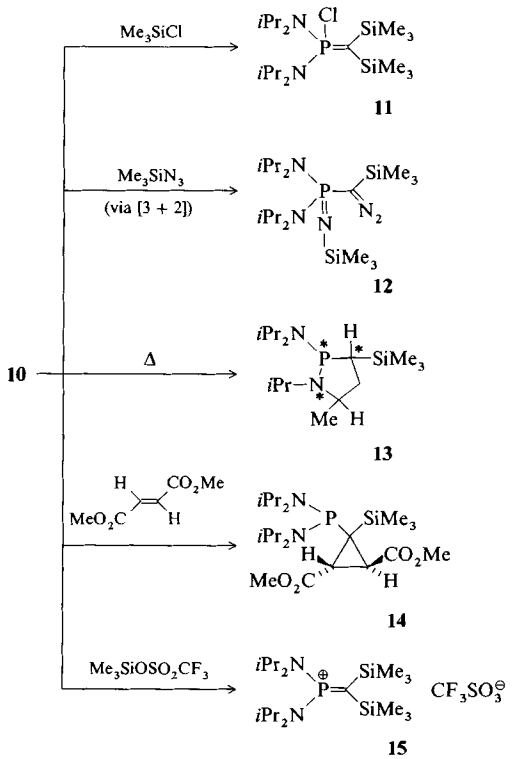
The initial studies of its reactivity showed that **10** can undergo 1,2 addition of chlorotrimethylsilane, for example, **10** → **11**, although an alternative mechanism involving insertion of **10** into the Si–Cl bond followed by C → P Cl shift must also be considered.[10] On the other hand, the result of [3 + 2] addition of trimethylsilyl azide to **10** is unequivocal. The initially formed cycloadduct has been detected by NMR spectroscopy before it undergoes ring opening to give the diazo compound **12**.[10] Reactivity typical of carbenes has also been observed for **10**. Thus, it undergoes intramolecular



9

10a **10b** **10c**

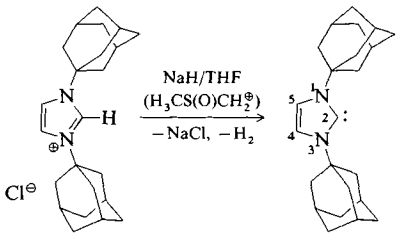
C–H insertion, albeit at 300°, to form the tetrahydro-1,2-diazophosphole **13**;[10] thermodynamic stabilization (**10a** ↔ **10b** ↔ **10c**) carries a price! Finally, the stereospecific [2 + 1] cycloaddition of **10** to electron-poor olefins such as dimethyl fumarate (**10** → **14**) demonstrates its character as a nucleo-



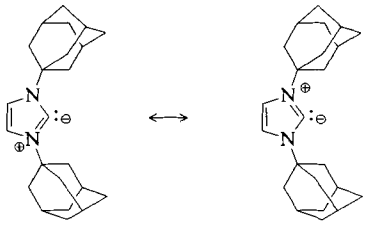
11 **12** **13** **14** **15**

philic carbene.[11,12] This character also accounts for its silylation to give the methylenephosphonium fluoromethanesulfonate **15**.[13] A preliminary conclusion, based only on the reactivity of **10**, is that the nonbonding electrons on phosphorus are involved in stabilizing **10**, as shown by formula **10b**. The silyl group also acts to stabilize the negatively charged center. Moreover, steric shielding presumably plays a role as well. If it is possible to synthesize a crystalline member of this class, the crystal structure analysis will reveal still more about its character.

Arduengo's Carbene: "A Stable Crystalline Carbene" is the title of a communication that appeared at the beginning of the year and reported on compound **17**, which melts only at 240–241 °C. It was obtained as colorless crystals on deprotonating bis(adamantyl)imidazolium chloride (**16**) with sodium hydride in the presence of catalytic amounts of dimethyl sulfoxide anion.[14,15]



16 **17**



17a **17b**

Analytical and spectroscopic data support unambiguously the structure of **17**. In the ^{13}C NMR spectrum, for example, the carbene carbon gives rise to a very low-field signal ($\delta = 211.43$); the molecular mass was determined by electron impact fragmentation. The crystal structure analysis revealed several salient features that indicate the nature of the carbene. The bond angle at the carbene center (102.2°) is appreciably smaller than the corresponding angle in imidazolium salts of type **16** (108.5–109.7°), in very good agreement with the values calculated for π-donor-substituted singlet carbenes. The N1–C2 and N3–C2 bonds (1.367 and 1.373 Å) are significantly longer than those of imidazolium salts (1,32 Å). This also holds for the N1–C5 and N3–C4 distances, although the effect here is less pronounced. These findings indicate that the π delocalization in **17** is smaller than in **16**. In agreement with this conclusion, the signals of the olefinic hydrogens of **16** ($\delta = 7.92$) are shifted to higher field on going to **17** ($\delta = 6.91$).

The donor character of the N–C=C–N structural unit (**17a** ↔ **17b**) on the one hand and the σ-electronegativity effect of the two heteroatoms on the other are the factors responsible for the thermodynamic stabilization of **17**. However, the importance of the resonance structures **17a** and **17b** appears to be very limited, since the calculated charge on C2 is only − 0.08 e. Furthermore, the kinetic stabilization due to the two adamantyl moieties plays an important role. They make it possible to isolate this almost true carbene. Work in *Arduengo*'s laboratory should soon answer the question whether this stabilization affects the typical carbene reactivity expected of such a species.

Thermodynamic and kinetic stabilization have once again proved to be concepts useful for the isolation of "bottleable" reactive intermediates. The title question is thereby answered. Clearly, however, the electronic relationships and reactivity will be somewhat changed in such species.

Novel Polymeric Materials from Monodisperse Copolypeptides by Biotechnological Methods**

By *Helmut Ritter**

The multiplicity of chemical methods that has been described and employed for the synthesis of peptides impressively demonstrates that an ideal synthetic method is apparently still lacking. Emil Fischer already recognized this need at an earlier date, and neatly summed up the situation at that time with the poignant remark "der Ochs kann's besser" ("the ox can do it better"). Meanwhile, however, there has been a change of approach with increasing application of biotechnological methods, and success has not only been reported in the pharmaceutical and agricultural sectors, but quite topically a first breakthrough is also recognizable in the directed preparation of novel and interesting protein materials with predetermined structures.[1]

The effort to realize the kinetically and thermodynamically controlled synthesis of peptides, not only by more improved chemical methods but also biocatalytically using free or supported enzymes has long surpassed the stage of an experimental exercise, and, e.g. in the case of racemization-free preparation of the sweetener aspartame (Asp–Phe) with thermolysin, has found industrial use.[2] As an extension to the widely developed synthesis of peptides on polymer supports[3] we are currently also concerned with the employment of pure enzymes, e.g. α-chymotrypsin, for the coupling of peptides to side chains in comblike structured polymers.[4]

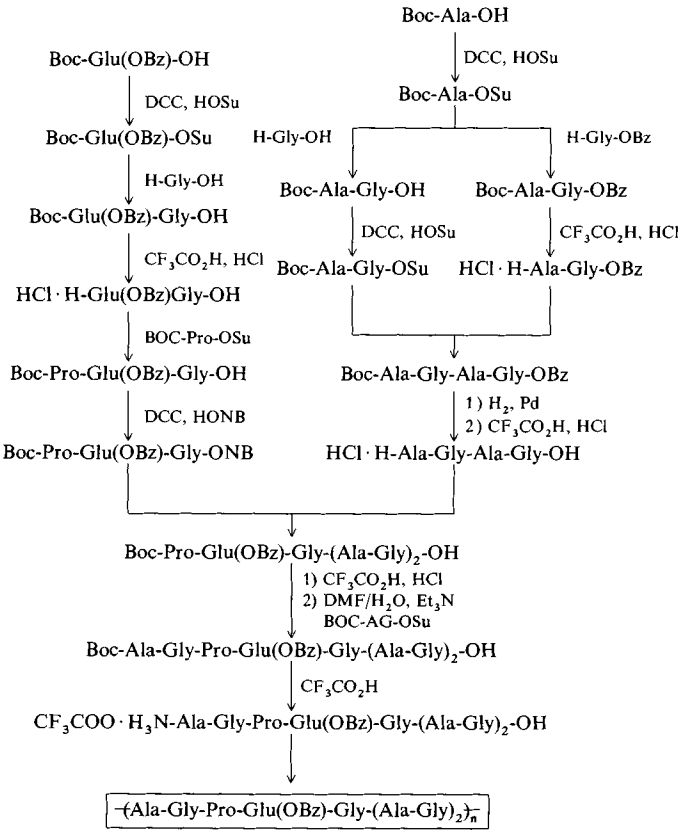
The use of the enzyme apparatus of whole cells has recently led to the synthesis of chiral polyesters with the side chains containing phenyl groups and fluorine atoms. The molecular weights of such polyesters generated by *Pseudomonas oleovorans* reached $\bar{M}_w$ values of up to 350000.[5]

The procedure recently elaborated by *Tirell* et al. for the directed synthesis of proteins with predetermined molecular weights and repetitive sequences by gene manipulation provides a completely new entry to materials similar to naturally occurring proteins (e.g. silk or elastin) and having interesting properties such as elasticity in fibers or the adhesiveness of excretory products of certain types of mussels. Whereas biotechnologically produced enzymes or hormones exhaust the full spectrum of the twenty common amino acids, the new biomaterials consist of only few repeating amino acids. This means, however, that the respective DNAs and mRNAs must to a large extent also be built up in a repeating fashion. Since this simple regular structural assemblage presents problems, e.g. stiffening of the mRNA by secondary hydrogen bonds, whereby translation is made difficult, the genetic code was alternatingly varied. For example, the coding of glycine was alternatingly carried out by GCT and GGC, that of alanine by GCC and GCT. In order to keep the errors in the gene synthesis as small as possible DNA sequences were first prepared by conventional chemical methods with two repeat units, e.g. of a nonapeptide, and these subsequently cloned by insertion in a plasmid which was introduced into *Escherichia coli* as host cell and reproduced. The DNA segments amplified in this way were coupled to a series of multimers by self ligation and recloned with *E. coli* in nutrient containing antibiotics. Individual colonies were separately further reproduced and the respective molecular weight of the protein produced therefrom ascertained by gel electrophoresis. Staggered monodisperse proteins with predetermined molecular weights can be produced in large amounts (ca. 40 mgL^{-1}) from the separate cultures. A copolypeptide with exactly 14 repeat units of the undecapeptide sequence **1** was very effectively prepared by the above-mentioned simple, general method.[1]

$$-(AlaGly)_4ProGluGly- \quad \mathbf{1}$$

The novel "polycondensate" has a glass temperature of 182°C and decomposes above ca. 250°C. Homogeneous films can be readily cast from formic acid solution. The respective oligonucleotide **2** containing 82 base pairs was synthesized on a support using the phosphoramidite method.

For comparison the chemical synthesis of a protein with repeating nonapeptide units was also carried out in a rather tedious way according to Scheme 1.[6] The total yield after



Scheme 1. Conventional peptide chemical method for the synthesis of a protein with repeating nonapeptide sequences. DCC = dicyclohexylcarbodiimide, HOSu = *N*-hydroxysuccinimide, HONB = *N*-hydroxy-5-norbornene-2,3-dicarboximide.

Gausstrasse 20, W-5600 Wuppertal (FRG)

[**] I thank Professor Dr. *W. Reineke*, Wuppertal, for valuable information.

18 steps was only 11% in the conventional method. The presence of a polydisperse mixture having only a relatively small molecular weight of ca. 10000 was established by gel chromatography.

According to recent findings,[1] the entry to proteins with repeating amino acid sequences by biotechnological methods seems to be very promising. The great efforts made to prepare materials with such relatively simple structures is justified in particular by the fact that applications in medicine are now already recognizable. Thus, e.g., block cocondensates containing repeating amino acid sequences which are analogues of silk, and sequences which are capable of binding strongly to cell surfaces, may be useful for the "adhesion" of individual cells to give large aggregates such as is required, e.g., in cases of severe burning. The coupling of hard and soft segments of appropriate repeating structural amino acid sequences is considered as the reason for the high elasticity of spider's silk.

The materials now accessible biotechnologically should show similar properties in blocklike coupling and be of particular interest in the form of films for covering wounds or coatings for implants.[7] The route outlined by *Tirrell* et al. for the synthesis of proteins which contain few repetitive amino acid sequences and have a predetermined molecular weight has proven better than classical methods as regards outlay and results. Hence, polymer chemists and protein chemists now have new materials on hand that should be further convertible by chemical and enzymatic processes, e.g. into block and graft cocondensates. Finally, there remains the question as to what extent the structural variants of the monodisperse proteins can be further enlarged, e.g. by fluorinated amino acids in the nutrient.

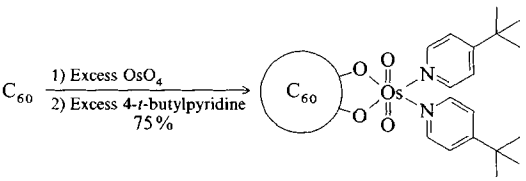
C_{60}: From Soot to Superconductors

By *François Diederich** and *Robert L. Whetten*

In 1990, a team of astronomers led by *Krätschmer* and *Huffman*[1] reported that the new allotrope of carbon C_{60} (buckminsterfullerene, so named after Buckminster Fuller, an architect renowned for his geodesic domes)[2] can be produced in macroscopic quantities through resistive heating of graphite under inert atmosphere. In an *Angewandte Chemie* Highlight article in January 1991, *Fraser Stoddart* summarized the early results in the vigorous worldwide research efforts that were triggered by this surprising development.[3] Only half a year later, a series of exciting new findings require that yet another Highlight article be written (closing date May 20, 1991).

X-ray Crystal Structure Analysis of Osmylated C_{60}

Although the icosahedral-cage structure of C_{60} was strongly suggested by ^{13}C NMR[3], IR[3-6], Raman[6], and photoelectron spectroscopy,[7] as well as by scanning tunneling microscopy (STM) imaging,[8-10] the ultimate confirmation and detailed parameters of the soccerball-shaped framework had to await X-ray crystallography. However, rapid isotropic rotational motion of the orderly packed spherical molecules in the crystal to temperatures down to 100 K[11,12] have so far prevented a successful high resolution X-ray crystal structure analysis. To break the symmetry of C_{60} and prevent its rapid spinning in the crystal, *Hawkins* et al. prepared by osmylation [Eq. (a)] a remarkable 1:1



(a)

C_{60}–osmium tetraoxide adduct.[13,14] The crystal structure of this adduct was subsequently solved by the Berkeley group and clearly confirms the soccerball structure of C_{60}, composed of 20 six-membered rings fused to 12 five-membered rings (Fig. 1).[14] All tricoordinate carbon atoms of C_{60} are pyramidalized and lie at an average distance of 3.512(3) Å from the center of the sphere. The unfunctionalized five- and six-membered rings are all planar within ± 0.05 Å. The two bond lengths in these rings are 1.388(9) Å for the fusion between two six-membered rings and 1.432(5) Å for the fusion between a six- and a five-membered ring. Values of 1.40 (± 0.015) Å and 1.45 (± 0.015) Å were determined for the two bond lengths in C_{60} by solid-state ^{13}C NMR.[15]

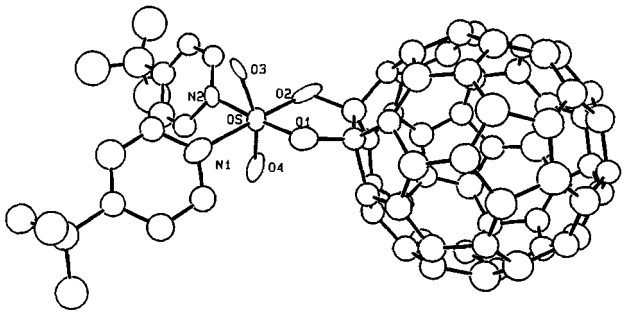

Fig. 1. Structure of the C_{60}–osmium tetraoxide–di(*p-tert*-butylpyridine) adduct in the crystal [16].

Reactivity of C_{60}

The chemistry of C_{60} promises to develop rapidly in the coming months. Initial reactivity studies with this fully delocalized closed-shell molecule[17] might have been of limited success since they probably relied too much on analogy to the chemistry of polycyclic aromatic hydrocarbons. However, C_{60} differs in many aspects from these planar molecules and shows "ambiguous"[18] aromatic character. The C_{60} structural framework is highly stable. Ion-beam collision experiments, in which $C_{60}^{\oplus}$ or $C_{60}^{\ominus}$ collide with silicon or graphite surfaces at speeds up to 50 000 km per hour ($\hat{=}$ 250 eV impact energy) show high inelasticity of the ions, but no evidence for impact-induced fragmentation.[19] This behavior differs from those of any other molecule or similar-sized cluster ions that have been tested, including benzene and naphthalene ions, which show fragmentation under these drastic conditions. The electronic properties predicted by *Elser* and *Haddon*[20] were confirmed. C_{60} possesses a vanishingly small π-electron ring-current magnetic susceptibility χ, far below that of graphite or benzene, resulting from accidental cancellation of the diamagnetic and paramagnetic contributions to χ.[18, 21] Electrochemical studies showed that C_{60} is a very strong oxidizing agent, comparable to methyl viologen and flavin chromophores, and its first reduction potential ($E^{\circ} = -180$ mV in THF against Ag/AgCl) is at least 1 V more positive than those of most polycyclic aromatic hydrocarbons.[3, 4, 22] This electron-deficient character of C_{60} determines much of the chemistry that is currently being pursued. C_{60} does not react with electrophiles or as a diene in Diels–Alder and other cycloadditions. Rather, it is easily reduced and reacts readily with nucleophilic agents.[23, 24] In an exploratory investigation, *Olah* et al. obtained deep red-brown solutions of diamagnetic polyanions of C_{60} upon reaction with lithium in THF.[23] Subsequent alkylation with methyl iodide led to polymethylated C_{60}; according to mass spectrometric analysis, one or more (all the way up to 24) methyl groups were covalently added to the sphere. *Wudl* et al. observed multiple additions of amine nucleophiles to C_{60} and were able to prepare polyaminated derivatives that are soluble in water.[24] In sharp contrast to rigid aromatic polycycles, C_{60}, upon excitation, exhibits no significant fluorescence or phosphorescence despite a richly structured optical spectrum in the red and violet regions;[25–27] luminescence observed for neat C_{60} films is probably due to solid-state interactions between spheres.[28] Besides being a strong oxidizing agent, C_{60} is a potent sensitizer of singlet oxygen and, therefore, should be handled with caution.[25]

Superconductivity of Alkali-Metal-Doped C_{60}
