Recent reports from AT&T Bell Laboratories on the conductivity and superconductivity of C_{60} are breakthrough results with potentially significant technological implications.[29, 30] Today, doped C_{60} is the molecular superconductor with by far the highest onset temperature of superconductivity T_c. It is not difficult to predict in view of extremely rapid developments that the following information might well be outdated when this article is published.

Earlier, the *Wudl* group used C_{60}'s high electron affinity to prepare a crystalline semiconducting (10^{-5}–10^{-7} Scm^{-1}) $Ph_4P^{\oplus}/C_{60}^{\ominus}$ salt by bulk electrolysis.[31] *Haddon* et al. found that C_{60} films doped with alkali-metal vapor become organic metals that exhibit conductivities at ambient temperature comparable to those of *n*-type doped polyacetylene (100 Scm^{-1} for Rb/C_{60} and 500 Scm^{-1} for K/C_{60}).[29] Doping is presumed to occur in the tetrahedral interstices between C_{60} molecules. Soon after, a report from the same laboratory appeared on the superconductivity of potassium-doped C_{60}, both in forms of thin films and polycrystalline powders.[30] The powder samples showed a well-defined, yet small (circa 1%), diamagnetic shielding (Meissner effect) with an onset temperature T_c of 18 K. The C_{60} group at the University of California in Los Angeles (UCLA) subsequently characterized the composition of the stable superconductive phase as K_3C_{60}, and $T_c = 19.3$ K.[32] Controlled sample preparation raised the Meissner effect to above 40% of the perfect diamagnetic shielding, which is a high value for a powder sample. This should probably be regarded as a stoichiometric compound ($K_3^{\oplus}C_{60}^{3\ominus}$) rather than a doped molecular solid. The UCLA group also found that Rb_xC_{60} shows an even higher onset temperature for superconductivity ($T_c = 30$ K); diamagnetic shielding was 7% at the time of manuscript preparation.[32] An onset temperature of $T_c = 28$ K for a Rb-doped C_{60} sample was measured by the Bell Lab group.[33] Theoretical models for the superconductivity of doped fullerenes are already appearing.[34]

The Fullerene and Heterofullerene Family

Buckminsterfullerene (C_{60}) and C_{70}, whose ellipsoidal-cage structure with D_{5h}-symmetry is now firmly supported by a variety of spectroscopic methods,[3, 4–6, 22, 35] are both major, but not the only products that can be isolated from

 © VCH Verlagsgesellschaft mbH, W-6940 Weinheim, 1991 0570-0833/91/0606-0679 $ 3.50+.25/0

the toluene-soluble fraction of the fluffy soot produced by resistive heating of graphite. By repeated chromatography on alumina, *Diederich* et al.[36] obtained small quantities of C_{76}, C_{84}, C_{90}, and C_{94}, which, like C_{60} and C_{70}, are members of the same family of hollow-cage all-carbon molecules called the fullerenes.[37] In addition, they also showed that the toluene-insoluble fraction of the soot contains a variety of larger fullerenes in the range between C_{100} and C_{212} that dissolve in boiling 1,2,4-trichlorobenzene.[36, 38] The structures of the higher fullerenes above C_{70} have yet to be determined. The UCLA group also isolated $C_{70}O$, a stable oxide of D_{5h}-C_{70} with the oxygen atom covalently attached to the convex external surface of the ellipsoid.[36] Apparently, this oxide forms from trace oxygen impurities in the helium gas used as the inert atmosphere during the resistive heating process. A recent study by *Smalley* et al. suggests the existence of heterofullerenes, and it should not take long before such compounds are actually isolated.[39] Supersonic beams produced by laser vaporization of a graphite pellet containing boron nitride powder were found to contain heterofullerenes, e.g. $C_{58}B_2$ and $C_{59}B$, in which presumably one or more atoms of the soccerball are replaced by a boron atom. The doped carbon balls are Lewis acidic and readily chemisorb one ammonia molecule per boron atom.

It is obvious from this short account that research on C_{60} and the other fullerenes is about to revolutionize chemistry within a rather short period of time. Since these new materials are readily prepared[3, 22, 40] as well as commercially available,[41] the exploration of their tremendous basic research and technological perspectives is now limited only by the imagination of the individual investigators.[42]

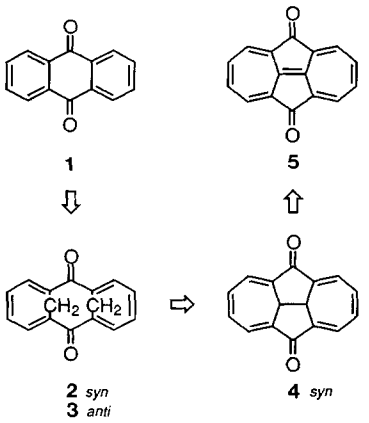
[14]Annulenequinones with Anthraquinone Periphery: "Isopyrenequinone" **

By *Emanuel Vogel,* Lutz Schmalstieg, Peter Henk, Oswald Wilmes, Johann Lex, Rolf Gleiter,** and *Michael Langer*

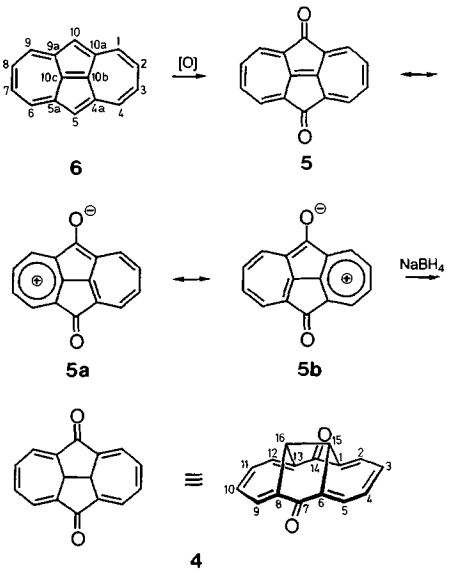
Anthraquinone **1**, the weakly quinonoid, very stable oxidation product of anthracene is the parent compound of many industrially important carbonyl dyes and pigments.[1] The significance of **1** in dye chemistry aroused our interest in the [14]annulenequinones *syn*- and *anti*-bishomoanthraquinone **2** and **3**, respectively, *syn*-1,6:8,13-ethanediylidene[14]annulene-7,14-dione **4**, and "isopyrenequinone" (azuleno[2,1,8-*ija*]azulene-5,10-dione) **5** (Scheme 1), which are structurally closely related to **1** through the anthraquinone periphery, yet, in part, differ considerably from it with regard to the π-electron system.



Scheme 1. Conceptual interrelationship of **1** and [14]annulenequinones **2**–**5**.

After having been able to synthesize **2** and **3**, and to demonstrate in the case of **2** that its redox behavior is comparable with that of **1**,[2] we can now also report the successful preparation of **5**, the availability of which concomitantly opens an entry to **4**.

A chance to obtain **5** was provided by the oxidation of isopyrene (azuleno[2,1,8-*ija*]azulene) **6**, modeled on the anthracene–anthraquinone conversion.[1] This nonbenzenoid (and non-alternating) aromatic hydrocarbon can be described as a resonance hybrid in which, according to spectroscopic and structural data, the resonance structure **6** has special weight.[3] Isopyrene may therefore be considered, to a first approximation, as a bridged [14]annulene with a central C=C unit as a perturbation. As already demonstrated, the highest occupied orbital (HOMO) of **6** shows significant orbital coefficients only at C-5, C-10, C-10b, and C-10c, so that electrophiles should attack the hydrocarbon preferentially at these positions.



Consistent with predictions based on the HOMO orbital coefficients, the relatively reactive **6** can be converted with a series of oxidizing agents into the desired isopyrenequinone **5** (5-/10-attack) and/or into 1,6:8,13-ethanediylidene[14]annulene derivatives (oxidative addition at the C-10b–C-10c bond),[4] whereby it depends on the oxidizing agent and conditions whether only one or both reaction routes are followed. According to observations made so far, **5** is best

Table 1. Selected physical data of **4** and **5**.

[**] This work was supported by the Minister für Wissenschaft und Forschung des Landes Nordrhein-Westfalen (FRG).

accessible when *m*-chloroperbenzoic acid (MCPBA) is used as oxidizing agent[5] and the reaction is carried out as follows: a solution of isopyrene **6** (100 mg, 0.5 mmol) in ether (50 mL) is treated with a solution of eight equivalents of MCPBA in 20 mL of ether at 0° C in the presence of sodium hydrogen carbonate as buffer (840 mg).[6] The reaction mixture is stirred for 90 min at this temperature and then transferred to a silica gel column[7] and the oxidation products chromatographed with dichloromethane/ethyl acetate (1:1) as eluent. Two fractions are obtained, first a brown one and then an intensely blue one,[8] the latter of which contains the desired isopyrenequinone **5**. After threefold crystallization from dichloromethane/ether (1:2), compound **5** precipitates in the form of black-violet needles with a copperlike luster [no decomposition up to 300 °C, yield 20%].

Isopyrenequinone **5** was characterized by NMR, IR, UV/VIS and mass spectra (Table 1), X-ray structure analysis, and cyclic voltammetry. The ^{1}H-NMR spectrum, which shows only the signals of two equivalent AA'BB' systems at $\delta = 8.12$ (H-1,4,6,9) and 7.60 (H-2,3,7,8) with $^3J_{1,2} = 10.8$, $^3J_{2,3} = 9.4$, $^4J_{1,3} = 0.5$ and $^5J_{1,4} = 1.2$ Hz, is indeed consistent with the assumed D_{2h} symmetry of the compound, but the chemical shifts and the vicinal coupling constants are not reconcilable with a heptafulvenoid molecule as formulated in **5**. If the bonding situation in the isopyrenequinone were comparable with that in a heptafulvalene[9] then the ^{1}H-NMR signals would have to appear at noticeably higher field, despite the presence of the carbonyl groups, whereas for the vicinal coupling constants one should expect—judging from the situation in heptafulvalene reference compounds[10]—a strong alternation in the sense of $^3J_{2,3} > {}^3J_{1,2}$. As a matter of fact, however, it is observed in the case of **5** that $^3J_{1,2}$ is even somewhat greater than $^3J_{2,3}$. The measured ^{1}H-NMR parameters become understandable if isopyrenequinone is regarded as a resonance hybrid in which the polar tropylium resonance structures **5a** and **5b** make a relatively high contribution.

The description of **5** as a resonance hybrid with contributing tropylium resonance structures **5a** and **5b**, as suggested by the ^{1}H-NMR spectrum, finds support in the outcome of the X-ray structure analysis[11] (Fig. 1). In the crystal, the molecule is almost planar (maximum deviation from the mean plane: 0.027 Å) and has, within the limit of error, D_{2h} symmetry. Convincing arguments in favor of **5a**/**5b** as resonance structures are provided mainly by the following observations: 1) the C–C bond lengths in the perimeter segments C-10a, C-1 to C-4, C-4a and C-5a, C-6 to C-9, C-9a lie approximately within the range of lengths found in aromatic C–C bonds. Their alternation, which is the inverse of that which was established for the corresponding bond lengths in **2** and **4**, could be largely due to strain effects; 2) the central C–C bond (1.441 Å) has approximately the character of an sp^2–sp^2 single bond, as required for a partial bond equalization in the seven-membered ring moieties. Since the length of the central C–C bond in **6** is only 1.354 Å,[3c] the latter finding is particularly informative.

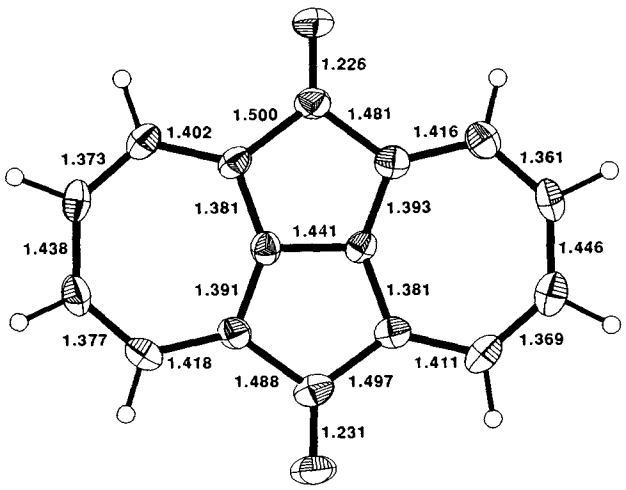

Fig. 1. Structure of **5** in the crystal. Bond lengths [Å]; standard deviation ca. 0.006 Å. Vibration ellipsoids drawn at the 40% probability level.

The troponoid nature of **5** implicated by the tropylium resonance structures manifests itself chemically in that the compound is relatively strongly basic and, analogously to tropone,[12] forms a stable monohydroperchlorate upon reaction with perchloric acid in dichloromethane. This salt, which is isolable in crystalline form [reddish-violet needles (from dichloromethane); no decomposition up to 300 °C], apparently undergoes a rapid proton exchange in solution, since its ^{1}H-NMR spectrum has the same form as that of **5** (two equivalent AA'BB' systems), but all signals are shifted downfield by $\Delta\delta \approx 0.5$. The UV/VIS spectrum of **5** in 96% sulfuric acid resembles that of the hydrocarbon **6** in the same solvent, for which a monoprotonation in the 5-/10-position is confirmed NMR spectroscopically under these conditions.[13]

5 is readily reduced to 5,10-diacetoxy-azuleno[2,1,8-*ija*]-azulene [brownish-black needles (dichloromethane/hexane); slow decomposition above 180 °C; yield 50%] upon reaction with zinc/acetic anhydride in pyridine.

Cyclovoltammetric measurements carried out on **5** showed that the dicarbonyl compound, as is typical for quinones, can be reduced in two reversible one-electron transitions via the semiquinone radical anion to the dianion. Information about the corresponding reduction potentials, including those of *p*-benzoquinone, **1**, **2**, and **4**, is given in Table 2.

Table 2. Comparison of experimentally determined reduction potentials of *p*-benzoquinone, **1**, **2**, **4**, and **5** [a].

[a] Measuring conditions: dimethylformamide (DMF) as solvent, in the case of **5** dichloromethane, with 0.1 M nBu$_4$NPF$_6$ under argon. Glassy carbon working electrode, Ag/AgCl reference electrode (**5**: calomel electrode) and Pt as counter electrode. Scan rate 15 mVs^{-1}. Oxidation potential for ferrocene $E_{1/2}$ = 0.705 V in DMF, 0.455 V under the conditions as for **5**.

In the case of **4** and **5** the first reduction potential is significantly less negative than in the case of **1** and **2**. Also, the dianion is formed more readily in the case of **4** and **5** than in the case of the reference compounds. It can be concluded from Table 2 that the E_1 values of the quinones correlate with the energies of the LUMOS calculated by the MINDO/3 method. That the difference between E_1 and E_2 observed in the case of **2**–**5** is smaller than in the case of **1** could, in the first instance, be due to a reduced coulomb interaction of the electrons in the LUMO (cf. J_{LUMO} in Table 2).[14] This can be explained in terms of an increased π/σ interaction in the case

of **2** and **4**,[2] and in terms of an increased conjugative interaction between the hydrocarbon framework and the CO groups (**5a**/**5b**) in the case of **5**.

Among the chemical reactions of **5**, that which deserves special attention, aside from the protonation and reductive acetylation already mentioned, is its reduction with sodium borohydride in methanol/dichloromethane. The reaction product formed thereby—formally with saturation of the central C=C bond—is the 10b,10c-dihydro compound, the no longer planar *syn*-1,6:8,13-ethanediylidene[14]annulene-7,14-dione **4** [red rhombs (from acetone/hexane); slow decomposition above 165 °C; yield 20%]; when dissolved in concentrated sulfuric acid, **4** is re-oxidized by atmospheric oxygen to **5**. If one assumes a relatively high contribution of the tropylium resonance structures to **5**, then the initial step of the observed hydrogenation might be interpreted as a nucleophilic addition of a hydride ion at C-10b (or C-10c).[15] Proof of the structure of **4** is based not only on the spectra (Table 1) and their analogy to those of **2**, but also on an independent synthesis of this new [14]annulenequinone, which, together with the structure and electrochemical investigations on **4**, will be reported upon in a separate communication.[16]

[16] The marked difference in the redox behavior of **2** and **4**—as a result of a strongly planarized perimeter in the case of **4**—should already be pointed out here.

σ-Homoacenaphthylene and π-Homoacenaphthene **

By *Roland Arnz, José Walkimar de M. Carneiro, Wolfgang Klug, Hans Schmickler, Emanuel Vogel,* Rolf Breuckmann,* and *Frank-Gerrit Klärner**

Dedicated to Professor Wolfgang R. Roth on the occasion of his 60th birthday

More than 25 years ago, in the course of our studies concerning the cycloheptatriene-norcaradiene structural problem, we discovered the 10π-electron Hückel system 1,6-methano[10]annulene **1**.[1] Since then almost the entire armory of physical instrumentation available to the organic chemist has been mobilized[2] to gain closer insight into the subtle bonding situation in this hydrocarbon, which can be regarded as an aromatic homologue of benzene. Spectroscopic and structural findings reinforce the assumption, based on model considerations, that homoconjugation across the carbon atoms 1 and 6 contributes significantly to the electronic stability of the molecule.[2e] Consequently, there is a certain justification for **1** being alternatively termed "π-homonaphthalene".[3]

1 **2**

According to ab initio calculations,[4] as regards free energy **1** is favored over its olefinic "bisnorcaradiene" valence tautomer **2** by only 4.5 kcal mol^{-1} [4a]—a value which closely corresponds to that for the tautomerism cycloheptatriene ⇄ norcaradiene.[5] The hereby aroused expectation

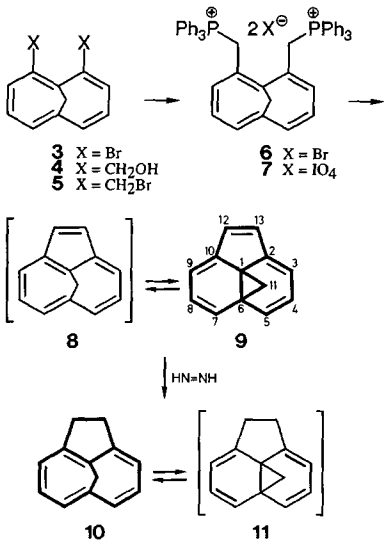
that the postulated arene-olefin equilibrium $\mathbf{1} \rightleftarrows \mathbf{2}$[6] responds to acceptor substituents on the methylene carbon atom[7] in the same way as the cycloheptatriene–norcaradiene equilibrium could be impressively demonstrated a few years ago: 1,6-methano[10]annulene-11,11-dicarbonitrile[8] exists, analogously to cycloheptatriene-7,7-dicarbonitrile,[9] exclusively as norcaradiene valence tautomer (>99%).

With the intention of exploring the limits of existence of 1,6-methano[10]annulenes, in the present study we examined what influence a *peri*-CH_2–CH_2 or *peri*-CH=CH bridge has on the equilibrium $\mathbf{1} \rightleftarrows \mathbf{2}$. Force field calculations (MM2 ERW)[10] revealed that a *peri*-CH_2–CH_2 bridge has virtually no effect on the enthalpy difference between 1,6-methano[10]annulene and norcaradiene valence tautomer, while a *peri*-CH=CH bridge alters this energy difference by no less than 10 kcal mol^{-1} in the sense of a stabilization of the norcaradiene valence tautomer. Unlike a *peri*-CH_2–CH_2 bridge, a *peri*-CH=CH bridge should therefore shift the equilibrium far on the side of the norcaradiene form.

Consistent with these calculations we now established that 2,10-etheno-1,6-methano[10]annulene **8** mainly exists as the norcaradiene valence tautomer **9**—here referred to as "σ-homoacenaphthylene"; 2,10-ethano-1,6-methano[10]annulene **10**, on the other hand, is present practically only as such ("π-homoacenaphthene"), with total exclusion of **11**.

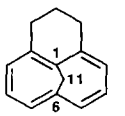


8 9 10 11

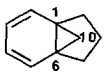
Scheme 1. **3** → **4**: *n*BuLi/hexane, ether, −40°C → −10°C, then CH_2O, 1 h reflux, 70%; **4** → **5**: PBr_3/benzene, 0°C, then 65°C, 1 h, 75%; **5** → **6**: PPh_3, dimethylformamide (DMF), 3 h, 100°C, 95%; **6** → **7**: $NaIO_4$, H_2O, 10°C, 80%; **7** → **8**/**9**: $NaNH_2/NH_3$, −40°C, then 3 h NH_3 reflux, 41%. Important physical data of **4**–**7**, **9** and **10** are collected in Table 2.

Of the conceivable entries to **8**/**9**, the periodate oxidation of the resonance-stabilized diylide derived from the diphosphonium salt **6**, which is modeled after the Bestmann acenaphthylene synthesis,[11] seemed most promising, since the reaction conditions largely allow for the presumed thermal instability of the product (tendency to undergo the norcaradiene "walk"-rearrangement). Starting from the readily available 2,10-dibromo-1,6-methano[10]annulene **3**,[12] the diphosphonium bromide **6** can be obtained in a conventional way via the 2,10-bis(hydroxymethyl)-1,6-methano[10]annulene **4** and the corresponding dibromide **5** as isolated intermediates. When **6**, dissolved in hot water, was added to a cold saturated aqueous solution of sodium periodate the diperiodate **7** immediately separated as a yellow microcrystalline compound. In order to bring about intramolecular C=C bond formation leading to **8**/**9**, the diperiodate **7** was treated with sodamide in liquid ammonia under the conditions as described for similar cases.[11] After addition of pentane to the reaction mixture, the product was worked up in the usual way at 0°C and finally distilled in a high vacuum (4×10^{-5} torr, bath temperature 0°C, trap cooled to −78°C). **8**/**9** separated as an orange-yellow crystalline solid (m.p. ≈ 5°C, yield 41%).

The position of the equilibrium between **8** and **9** as well as between **10** and **11** (see later) follows from NMR spectroscopic comparisons, in which, aside from **1**, the compounds 2,10-propano-1,6-methano[10]annulene **12**[13] and tricyclo[4.3.1.0^{1,6}]deca-2,4-diene **13**[14] serve as reference compounds for the [10]annulene- and norcaradiene-valence tautomers.



12



13

The exclusive presence of **9** was already indicated by the ^{1}H-NMR spectrum, since the signals of the vinylic protons H-3 to H-5 and H-7 to H-9 appear at relatively high field [$\Delta\delta$ = 1.2 (mean value), with respect to **12**] and the vicinal coupling constants $^3J_{3,4}$ and $^3J_{4,5}$ correlate perfectly with the corresponding couplings in cyclohexa-1,3-dienes. The presence of **9** is even more convincingly demonstrated by the ^{13}C-NMR spectrum (Fig. 1), which, from experience, responds particularly sensitively to a σ/π bond change in valence tautomers. It is found that **9** not only compares very well with **13** regarding the position of the C1 and C6 signals, but also shows a ^{13}C-^{1}H coupling constant for C11 which is typical for cyclopropane C-atoms (160–170 Hz) (Table 1).

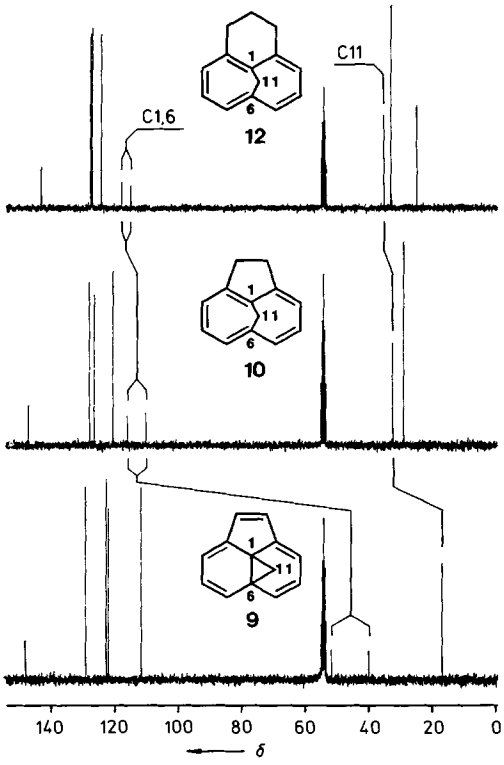


Fig. 1. ^{13}C-NMR spectra of **12**, **10**, and **9** (75.5 MHz, CD_2Cl_2).

Table 1. Selected ^{13}C-NMR data of **12**, **10**, **9** (75.5 MHz, CD_2Cl_2) and **13** [14] (22.6 MHz, CCl_4, $CDCl_3$); couplings in Hz.

	12	**10**	**9**	**13**
δ(C1) [a]	117.17	115.41	51.14	37.70
δ(C6) [a]	114.32	109.53	39.58	
δ(C11)	34.50	31.85	16.71	15.40 [b]
^1J(C11, H)	141.5	146.2	167.3	161.0 [b]

[a] Assignment not certain. [b] For C10.

Upon reaction with diimine, generated from the potassium salt of the azodicarboxylic acid with acetic acid in dichloromethane, σ-homoacenaphthylene **9** is selectively hydrogenated to the 12,13-dihydro compound, which, after chromatography on silica gel is obtained in the form of yellow crystals [m.p. 38°C (from methanol); yield 30%]. Interestingly, the product proved to be almost exclusively π-homoacenaphthene **10**, which means that the hydrogenation of **9** entails saturation of the *peri* double bond with a complete reversal of the bisnorcaradiene–1,6-methano[10]annulene equilibrium. The drastic shift of the equilibrium is evident from characteristic changes in the ^{1}H-NMR spectrum, particularly in the downfield shift of the signals of H-3,4,5,7,8,9 by $\Delta\delta = 0.88$ (mean value) and the approximate equalization of $^3J_{3,4}$ and $^3J_{4,5}$, but manifests itself most impressively in the ^{13}C-NMR spectra of the two compounds (Table 1). As can be seen from Figure 1, the signals of C1,6 and C11 are shifted downfield so much in the transition from **9** to **10**, that they now almost coincide with the corresponding signals of **12**, which can be regarded as the optimal [10]annulene reference compound for **10**.

The difference between **9** and **10** regarding type of structure[15] is also reflected in the chemical behavior of the two compounds, particularly in their tendency to undergo the norcaradiene walk rearrangement upon thermolysis.[16] The walk rearrangement of **9**, initiated by the homolytic cleavage of the cyclopropane bond C6–C11,[17] already takes place at 120°C [$\Delta G^{\neq}$ (determined ^{1}H-NMR spectroscopically) = 33.0 kcal mol^{-1} in benzene], whereas the corresponding isomerization of **10** requires temperatures around 250°C [$E_A = 41.7 \pm 0.5$ kcal mol^{-1}, lg$A = 14.3 \pm 0.2$ (gas phase)]. An increase in the activation barrier of the rearrangement in the case of **10** is consistent with expectation, since here the migration of the CH_2 bridge is preceded by the endothermal formation of the bisnorcaradiene **11**.[18]

[10] W. R. Roth, O. Adamczak, F. Bauer, H.-W. Lennartz, unpublished (we thank Professor *Roth* for permission to use the program). Also according to AM1 calculations the bisnorcaradiene **9** is more stable than the valence tautomeric [10]annulene **8** (with C_s symmetry), whereas a higher stability is determined for **10** than for **11**. For details of the method see M. J. S. Dewar, E. G. Zoebisch, E. F. Healy, J. J. P. Stewart, *J. Am. Chem. Soc. 107* (1985) 3902.

[11] H. J. Bestmann, R. Armsen, H. Wagner, *Chem. Ber. 102* (1969) 2259.

[12] E. Vogel, W. A. Böll, M. Biskup, *Tetrahedron Lett. 1966*, 1569.

[13] **12** (Table 2) was obtained by reduction of 2,10-(1'-oxo-propano)-1,6-methano[10]annulene [K. Nakasuji, M. Katada, I. Murata, *Tetrahedron Lett. 1978*, 2515; R. Neidlein, H. Zeiner, *Chem. Ber. 115* (1982) 3353] with $LiAlH_4/AlCl_3$, J. Pinger, *Diplomarbeit*, Universität Köln 1983.

[14] E. Vogel, W. Wiedemann, H. D. Roth, J. Eimer, H. Günther, *Liebigs Ann. Chem. 759* (1972) 1; H. Schmickler, *Dissertation*, Universität Köln 1974.

[15] According to the X-ray structure analysis, **10** is also present as [10]annulene valence tautomer in the crystal. Moreover, the analysis shows quite clearly that the deformation of the annulene ring and reduction in the C1–C6 distance deduced from models of **10** are consistent with the geom-

etry of the molecule (C1–C6: 2.121 Å compared to 2.235 Å in **1**). Apart from that, in the case of **10** one finds an asymmetry in the lengths of the C–C bonds caused by the *peri*-bridge, both in the CH_2 bridge (shortening of C1–C11 to 1.45 Å and lengthening of C6–C11 to 1.51 Å referred to the C1–C11/C6–C11 bond lengths of 1.485 Å in **1**) as well as in the annulene ring; slight deviations from the expected C_s symmetry of the molecule could be due to packing effects (according to studies in collaboration with *J. Lex*). Details of the crystal structure investigation are available on request from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, W-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-55354, the names of the authors, and the journal citation.

[17] For a detailed discussion of the walk-rearrangement of **9** and **10** see: R. Arnz, *Dissertation*, Universität Köln 1989.

[18] Apart from the mentioned enthalpy effect, the still unknown influence of the *peri*-double bond on the dissociation energy of the C6–C11 bond in **9** has to be taken into account for the difference in reactivity of **9** and **10**. Other than in **9**, the walk-rearrangement initiated by cleavage of the C1–C11 bond also takes place in the case of **10** [$E_A = 43.5 \pm 1.9$ kcal mol^{-1}; $\lg A = 14.4 \pm 0.8$ (gas phase)].

Synthesis and Characterization of P-containing ZSM-5 Zeolites

By *Wladimir Reschetilowski,* Brit Meier, Michael Hunger, Baldur Unger,* and *Klaus-Peter Wendlandt*

Zeolites of the Pentasil type can be modified in various ways by incorporation of different elements in the aluminosilicate lattice, both under the conditions of hydrothermal synthesis as well as by post-treatment or impregnation.[1] Often very little is known of the bond order of these elements in the zeolite.

The aim of the present study was to prepare a series of P-containing zeolites with ZSM-5 structure (P-ZSM-5) by direct synthesis and to characterize them NMR spectroscopically as well as by adsorptive and catalytic measurements.

Silicon-rich P-ZSM-5 zeolites with variable P content were synthesized in laboratory autoclaves under the conditions used for the synthesis of ZSM-5[2] by hydrothermal crystallization of a reaction mixture of water glass, aluminum sulfate and phosphoric acid with the addition of *n*-propylamine. The reaction temperature was 170 °C and the duration of crystallization 55 h. The product was thoroughly washed with distilled water, dried, and tempered at 500 °C over the course of 6 h. The freshly calcined product was converted into the H-form by ion-exchange with a 0.5 N NH_4NO_3 solution at 80 °C for 3 h. The ion-exchange was followed by thermal deammonization at 500 °C over the course of 4 h.

The composition of the modified P-ZSM-5 zeolite was determined by electron probe microanalysis and with the help of ^{27}Al-MAS-NMR spectroscopy (MAS = magic angle spinning). The measurement of the isopiestic H_2O adsorption capacity of the sample tempered at 500 °C was performed at 20 °C. The catalytic properties of the P-ZSM-5 zeolites in the H-form were investigated in the acid-catalyzed cracking reaction of *n*-hexane in an integral flow reactor at normal pressure and at a reaction temperature of 300 °C. Taking a first-order rate law as basis, reaction rate constants could be determined which were used to establish the catalytic activity and the tendency of zeolite samples employed to deactivate according to the equation $1/k = 1/k_0 + B\tau$[3] (k and k_0 = reaction rate constants at time τ and $\tau = 0$; τ = time on stream; B = deactivation parameter).

The P contents, Si/Al ratios, results of adsorption and ^{1}H-MAS-NMR investigations and the catalytic measurements are summarized in Table 1.

Table 1. P-ZSM-5 zeolites investigated in the H-form and results of the adsorption, ^{1}H-MAS-NMR and catalytic measurements.

Sample No.	P per unit cell	Si/Al	A_{H_2O} [cm^3 g^{-1}]	SiOH/POH [10^{19} g^{-1}]	Si–OH–Al [10^{19} g^{-1}]	k_0[a]	B[b]
1	0	15	0.19	10	50	1.71	0.005
2	0.14	30	0.18	8.5	38	0.51	0.032
3	0.4	31	0.16	11	41	0.36	0.043
4	0.5	30	0.16	13	37	0.28	0.089
5	0.8	30	0.14	10	38	0.12	0.355

[a] k_0 = rate constant at time $\tau = 0$ in mol MPa^{-1} g^{-1} h^{-1}. [b] B = deactivation factor in MPa g mol^{-1}.

The ^{31}P-MAS-NMR signal of the P-ZSM-5 samples synthesized is shifted to lower range compared to the ^{31}P-NMR signal of H_3PO_4 and lies at $\delta = -2.5$. Together with the significantly reduced H_2O adsorption capacity in the samples with the highest P content this can be regarded as a further indication that the phosphate groups in the synthesized products are linked to the aluminosilicate framework preferentially in the form of dihydrogen phosphate groups. Hence, the geminal P–OH groups protruding into the channeling of the framework fill a part of the pore volume which would otherwise be available for an unhindered H_2O adsorption.

^{1}H-MAS-NMR measurements show that the phosphorus-free reference sample (Sample 1) contains bridging OH groups ($\delta = 4.2 \pm 0.1$) in a concentration of 50×10^{19} g^{-1} (Table 1). The concentration of the SiOH/POH groups ($\delta = 2.0 \pm 0.2$), whose differentiation is not possible, is 10×10^{19} g^{-1} and hardly changes on transition to P-containing ZSM-5 zeolites (Samples 2 to 5); the concentration of bridging OH groups clearly increases thereby to 40×10^{19} g^{-1} independently of the P content.

It seems plausible that the bridging OH groups determine the catalytic activity in proton-catalyzed reactions since the reference sample, which has the largest concentration of Si–OH–Al groups, shows the highest catalytic activity in the cracking of *n*-hexane (Table 1). It seems surprising at first sight that the P-ZSM-5 samples exhibit differing catalytic activity despite the almost equal concentration of acidic OH groups: an increase in the P content in P-ZSM-5 zeolites with unchanged Si/Al ratio in the zeolite framework leads to a reduction of the catalytic activity and a poorer activity-time behavior. Apparently the acid-strength distribution of the acidic OH groups is shifted more and more in favor of weakly acidic Brønsted acid centers with increasing P content, and results in a reduced catalytic activity. This explanation is consistent with the observation of *Lercher* et al.[4] that the concentration of strongly acidic Brønsted acid centers decreases and that of the weakly acidic centers increases when the number of the dihydrogen phosphate groups in the zeo-

lite surface is increased. This then also explains the increased tendency to deactivation observed on the P-ZSM-5 zeolite samples investigated. Both a rapid "fatiguing" of the catalytically active centers as a result of coking as well as blocking of the pores following deposition of coke can be regarded as the cause of the rapid deactivation at high P contents in the zeolite.

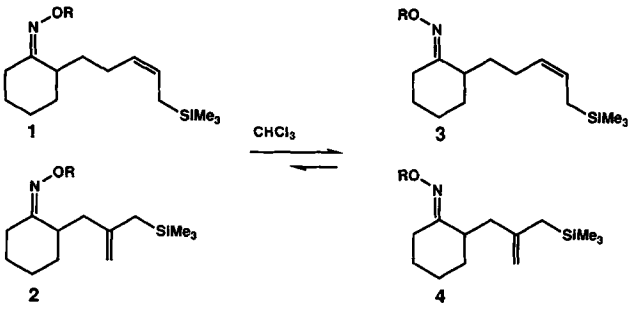
Synthesis of Heterocycles by Tandem Reactions: Beckmann Rearrangements/Allylsilane Cyclizations**

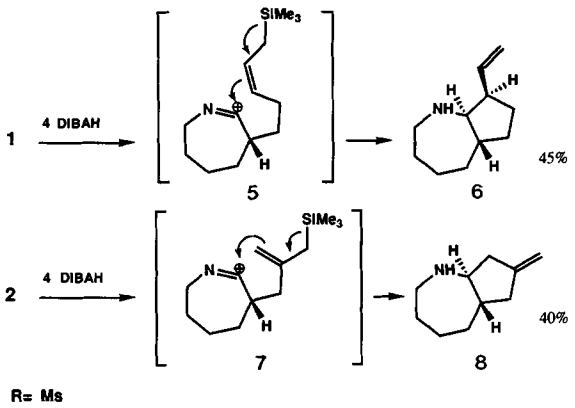
By *Dieter Schinzer** and *Yunxin Bo*

Diastereoselective cyclization reactions leading to five- to eight-membered rings by intramolecular Sakurai reactions have proven to be a very useful preparative strategy.[1] Herein, we now describe for the first time the use of this method for the synthesis of heterocycles by tandem reactions of functionalized oximes. The starting compounds necessary for this purpose, such as **1** and **2** (R = H), are readily accessible by alkylation of simple oximes.[2] By stirring in chloroform (acid actalysis) they can also be converted into the (*E*)-configurated isomers **3** and **4**, respectively ((*Z*) : (*E*) ratio ca. 2.5 : 1). Reaction with mesyl chloride affords the corresponding methanesulfonates **1**–**4** (R = Ms).



When the compounds **1** and **2** (R = Ms) are allowed to react with four equivalents of DIBAH[3] (diisobutylaluminum hydride) in methylene chloride at low temperature (−78 °C to 0 °C), the heterocycles **6** and **8**, derivatives of azepane, are obtained in a tandem reaction.

In this reaction sequence DIBAH apparently reacts initially as a mild Lewis acid and induces a stereoselective Beckmann rearrangement[4] to give the ring-expanded intermediates **5** and **7**, which are trapped in situ and regioselectively by the electron-rich allylsilane. In the last reaction step the imines are reduced stereoselectively to the secondary amines **6** and **8**, respectively. We are thus in a position to prepare precursors for the syntheses of azepine alkaloid systems stereoselectively in a one-pot reaction.[5]



The analogous reaction of the (*E*)-configurated oximes **3** and **4** leads, when R = Ms, to their decomposition; in contrast, with R = H we surprisingly isolated **10** and **12**, heterocycles of the perhydroquinoline type, and not the expected 1,3-annelated products. Apparently the allylsilane-cyclization is now more rapid than the Beckmann rearrangement—in contrast to **1** and **2**, where, for steric and stereoelectronic reasons, a Beckmann rearrangement takes place first—so that the oxime nitrogen atom is now incorporated directly into the ring being formed. This is to our knowledge the first case in which an allylsilane reacts with a positively charged nitrogen atom.

Here too, a polarization of the NO bond by DIBAH most likely takes place first. In the cyclization step the Beckmann rearrangement cannot compete with the allylsilane cyclization; it is therefore suppressed and the cyclization to the six-membered ring ensues via the intermediates **9** and **11**. Subsequently, these are reduced in situ to give the heterocycles **10** and **12**, respectively.[5–7]

Hagenring 30, W-3300 Braunschweig (FRG)

[**] This work was supported by the Volkswagen-Stiftung and the Fonds der Chemischen Industrie.

The stereoselective reaction sequences presented here enable the synthesis of numerous heterocyclic ring systems. Depending upon the oxime system used, the reaction sequences lead with ring expansion to products of the azepane type or by direct cyclization to products of the perhydroquinoline type, whereby the functionalization of the heterocycle formed is determined by the allylsilane-substituent. Considering the number of steps involved in a one-pot reaction the yields of 40–50% obtained are very good. An analogous reaction could be carried out with cyclopentanone, however we have not yet been able to establish the relative configurations of the products.

[5] All the new products were characterized by standard methods. The configurations were determined NMR spectroscopically by 600-MHz COSY experiments, C/H correlations, and NOE effects. Due to the flexibility of the seven-membered ring the *trans*-coupling of the seven-membered rings in **6** and **8** could not be established with certainty. This was possible, however, from model considerations. The relative configuration of the ethenyl group could be determined by NOE effects. We thank Dr. *V. Wray*, Gesellschaft für biotechnologische Forschung (GBF), Braunschweig-Stöckheim, for the NMR measurements.
[6] The configuration of the ethenyl group in **7** could not be determined; however, only one diastereomer is formed. The *trans* configuration of the six-membered ring follows unequivocally from the coupling constants.
[7] The reaction described does not implicate any mechanism, but merely contributes to an elucidation of the product formation.

Oxidative Cleavage of Triethylenetetramine (trien) to Yield Diethylenetriamine (dien): Structure of the Mn^{II}/Mn^{III} Heptanuclear Complex $[Mn_7(trien)_2(dien)_2O_4(OAc)_8](PF_6)_4 \cdot 2H_2O$ **

By *Rajumati Bhula* and *David C. Weatherburn**

Polynuclear manganese complexes where the metal is in oxidation states III, IV, V have interesting spectroscopic and magnetic properties. Such complexes can serve as useful models for manganese-containing biomolecules.[1–4] We are investigating manganese complexes of linear polyamine ligands and have described complexes of manganese(III) with diethylenetriamine (dien)[5] and Mn^{III}, and mixed-valent Mn^{III}/Mn^{IV} complexes with 1,5,8,12-tetraazadodecane (3,2,3-tet).[6] Extension of these studies to reactions with the ligand triethylenetetramine (trien) resulted in the isolation of a species which indicates that under certain experimental conditions oxidation of the polyamine ligands can occur.

Reaction of trien with manganese(III) acetate and sodium acetate in methanol solution, followed by the addition of NH_4PF_6, results in the precipitation of red needles of a novel septanuclear manganese salt (**1**). The same compound can be prepared from manganese(II) acetate with essentially the

$[Mn_7(trien)_2(dien)_2O_4(OAc)_8](PF_6)_4 \cdot 2H_2O$ **1**

same procedure. Figure 1 shows the arrangement of the manganese atoms in the cation.[7] Mn1 lies on an inversion

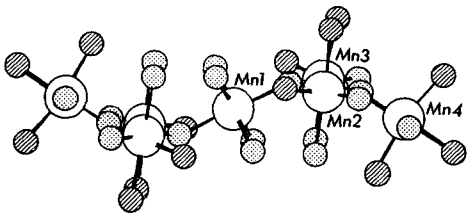

Fig. 1. Arrangement of the manganese atoms and the atoms coordinated to manganese in the cation of **1**. ◎ = N, ○ = O.

center. The overall shape of the cation is best described as two $[Mn_4(\mu_3\text{-}O)_2]$ units, the familiar 'butterfly' moiety,[6, 8–10] which share a manganese atom, Mn1, at the wing-tip. Figure 2 shows the asymmetric unit of the cation. Charge requirements indicate that probably six Mn^{III} ions and one Mn^{II} ion are present in the complex cation. The bond distances to Mn1 suggest that this is the Mn^{II} center and that the complex is valence trapped. Bond distances between the μ_3-oxo and μ_2-acetato oxygens and Mn2, Mn3, and Mn4 are comparable to those observed for Mn^{III} centers in similar complexes.[5, 6, 8–16]

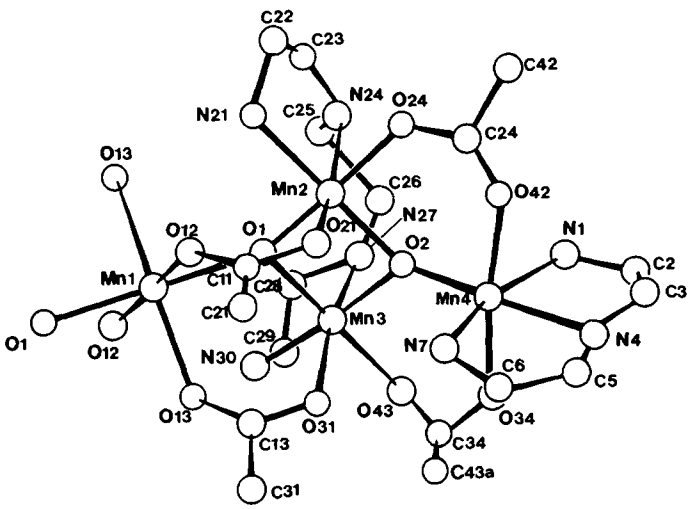

Fig. 2. Structure of the asymmetric unit of the cation of **1** showing the numbering system used.

The Mn2–N and Mn3–N bond distances are notable in that there are short bonds to the primary amines and long bonds to the secondary amines. The magnitude of the distortion is much greater than is usually observed for Mn^{III} centers so that steric constraints imposed on the trien ligand as it bridges the two metal ions rather than Jahn–Teller distortion are probably responsible. The Mn–O_{oxo} bond is *trans* to the short Mn–N bond. A similar lack of a structural *trans*

influence of the Mn–O_{oxo} bond has been noted previously.[15] The Mn4–N bond distances are in accord with normal Jahn–Teller distorted Mn^{III} centers.[6, 15]

The ESR spectrum of **1** has been measured in a frozen DMF solution. A six-line spectrum centered at $g = 1.97$, $A = 100$ G, was observed together with a small broad feature at $g = 3.9$. This spectrum is consistent with other reported spectra for mixed-valence Mn^{II}/Mn^{III} complexes.[16]

Mn4	N4	2.069(15)	Mn4	N7	2.147(15)

An unexpected feature of the isolated complex (**1**) is the presence of the dien ligand. The trien used in the preparation was carefully purified by a standard procedure[17] and no detectable quantity of dien (gas chromatography and mass spectra) was present in the starting material. In contrast, the mother liquor from which **1** was isolated contained significant quantities of both dien and trien ligands. We suggest that under the 'acidic' conditions provided by NH_4PF_6, the trien is oxidized to an imine intermediate, which is then hydrolyzed to give dien. A ^{13}C NMR spectrum of a CH_2Cl_2 extract of the mother liquor showed resonances assigned to both trien and dien. Other peaks present were an extra resonance in the C–N region ($\delta = 49.5$) and a carbonyl resonance ($\delta = 173.2$). These resonances suggest that the $C_2H_4NH_2$ residue cleaved from the trien has formed glycine. The ultimate oxidant is oxygen from the air as no dien can be detected in solutions which have been reacted in the absence of air. Mixed-valent Mn^{III}/Mn^{IV} complexes can be isolated from more basic solutions containing a similar tetraamine[6] so that high-valent manganese complexes are probably responsible for the oxidation reaction. Whether the oxidation proceeds before or after complexation to manganese has not been established; both Mn^{II} and Mn^{III} ions are labile so that uncoordinated dien present in the mother liquor cannot be taken as evidence for a pathway involving oxidation of the uncoordinated ligand. Oxidative dehydrogenation of coordinated ligands has been observed previously for complexes of Co^{II}, Ni^{II}, and Fe^{II},[18] and coordinated dioxygen has been implicated as the oxidant. In this context it is interesting that the center of Photosystem-II preparations which evolves oxygen is capable of oxidizing both primary and secondary amines,[19] and recent evidence suggests that the $S_2 \rightarrow S_3$ transition occurring in Photosystem-II corresponds to the oxidation of histidine.[20]

Experimental Section

$Mn(OAc)_3$ (0.5 g, 0.002 mmol) and NaOAc (0.3 g, 0.0036 mmol) were dissolved in methanol (25 mL) and the solution heated to 60 °C. Trien (0.3 g, 0.002 mmol) was added and the solution became a deep green color. Addition of solid NH_4PF_6 (0.5 g, 0.003 mmol), followed by further heating to dissolve the solid, gave a light orange solution. Upon cooling in air the solution developed a deep red color and red needles crystallized out overnight. If the reaction is carried out in the absence of air, it does not proceed beyond the light orange solution stage. Correct elemental analysis (C, H, N, P, F, Mn) for $C_{36}H_{90}N_{14}O_{22}P_4F_{24}Mn_7$. Crystals suitable for the structural analysis were isolated from the reaction mixture.

[7] Crystal data of **1**: $M_r = 2035.7$, monoclinic, space group $P2_1/n$, $a = 10.263(4)$, $b = 18.922(6)$, $c = 20.007(8)$ Å, $\beta = 92.39(3)°$, $V = 3882(3)$ Å^3, $Z = 2$, $\lambda(Mo_{K\alpha}) = 0.71069$ Å, crystal dimensions $0.76 \times 0.36 \times 0.14$ mm, $F(000)$ 1930, $\mu = 16.02$ cm^{-1}. 5578 reflections were collected (− 120 °C, ω scans in the $4° \leq 2\theta \leq 45°$ range) 4647 were unique, 2825 with $I \geq 3\sigma(I)$ were used in the refinement. Cell parameters were obtained from 25 accurately centered reflections in the $12.4° \leq 2\theta \leq 29°$ range. Three intensities were monitored every 100 reflections; no significant variation. Lorentz polarization, and empirical absorption corrections (ω scans) were applied (T_{max} 0.775, T_{min} 0.731). Structure solved with SHELXS using heavy atom methods and subsequent difference Fourier maps using SHELX-76. Neutral atom scattering factors, full-matrix least-squares refinement with 393 parameters and a fixed weight of 0.0006 gave $R = 0.0927$ ($R_w = 0.0889$). The Mn and P atoms, and the O and N atoms bound to Mn were refined anisotropically, all other atoms (including hydrogens at calculated positions) were refined isotropically. Both $PF_6^{\ominus}$ anions in the asymmetric unit exhibited disorder. In the final cycles of the refinement these $PF_6^{\ominus}$ groups were treated as rigid groups with four of the six fluorine atoms bound to *P*1 refined with partial occupancies over two sites (occupancy 0.64, 0.36) while all fluorines around *P*2 were refined as two sets (occupancy 0.57, 0.43). There is also evidence for some disorder in the positions of one of the methyl carbons, C43, and in one of the chelate rings of the dien molecule. Max. shift/esd = 0.3 for *P*1, max. peak in final difference map = 0.88 e Å^{-3}, 1.67 Å from *P*2. Further details of the crystal structure determination are available from the Director of the Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, GB-Cambridge CB2 1 EW (UK) upon quoting the full journal citation.

Dichloro(pentamethylcyclopentadienyl)ruthenium—Novel Dichotomy in a Molecular Structure**

By *Ulrich Kölle,* Janusz Kossakowski, Norbert Klaff, Lars Wesemann, Ulli Englert,* and *Gerhard E. Heberich*

The title complex $[\{Cp^*RuCl_2\}_2]$, **1** ($Cp^* = \eta^5$-C_5Me_5),[1,2] is a much-used reagent in the preparation of Cp*Ru sandwich and, in particular, half-sandwich complexes.[3–7] Although the solubility of the complex in halogenated hydrocarbons and the molar mass in chloroform (as determined by osmometric methods[6b]) speaks against the existence of a polymer, the compound is always seen as such.[8] We report on the structure of **1**[9] and analogous complexes $[\{Cp'RuCl_2\}_2]$ ($Cp' = \eta^5$-C_5Me_4Et) **2**[10] and the bromine derivative $[\{Cp^*RuBr_2\}_2]$ **3**.[6b]

In the preparation from $RuCl_{3(aq)}$ and Cp*H in methanol[1] or ethanol,[2] **1** precipitates as a red-brown, microcrystalline powder, which for some time thwarted attempts at crystallization. Crystals suitable for X-ray crystallography were finally obtained by diffusion of ether into a concentrated dichloromethane solution of **1**, after purification of an ether/dichloromethane solution by chromatography on silylated silica gel.[12] For compounds **2** and **3** the chromatographic procedure is unnecessary.

The structure determination[13–15] showed that all three compounds were dimers, as anticipated. A pecularity of the crystals of **1** was the equal distribution of forms **1a** and **1b** (Fig. 1), which have distinctly different Ru–Cl distances and

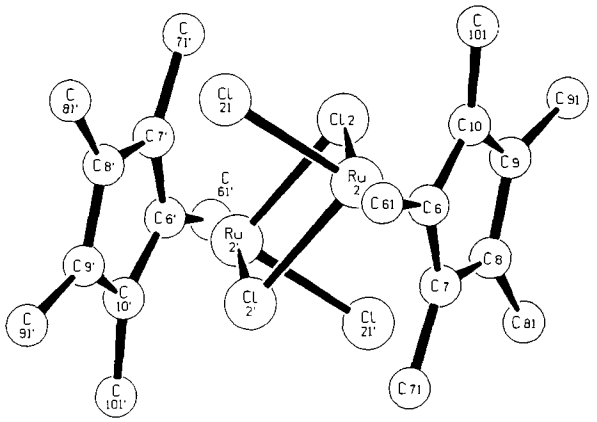

Fig. 1. Schakal picture of the structure of the isomer **1b** in the crystal.

Ru-Cl-Ru angles, and Ru–Ru distances of 2.93 and 3.75 Å (Fig. 2), and are located at positions 000 and $0\frac{11}{22}$ (**1a**) and $\frac{111}{222}$ and $\frac{1}{2}00$ (**1b**) of the monoclinic unit cell. The bonding parameters of **1a** and **1b** differ enough to justify the term "deformational isomerism". The molecular geometries of the compounds **2** and **3**, where crystals consist of only one form, correspond to isomer **1a** (Table 1).

The different Ru–Ru distances in the isomers suggest a strong exchange interaction between the unpaired spins of the d^5 low-spin Ru centers[16] in **1a**, but not in **1b**, where the metal–metal distance is similar to the nonbonding Rh–Rh distance in the analogous Rh complex $[\{Cp^*RhCl_2\}_2]$ **4**

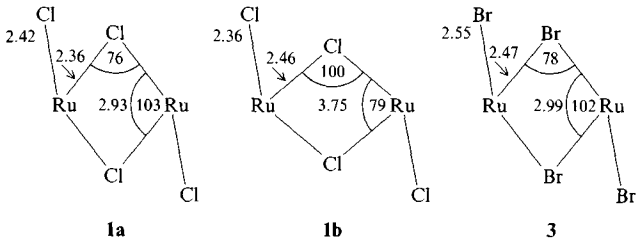

Fig. 2. Ru–halogen bond lengths [Å] and angles [°] of **1a**, **1b**, and for comparison **3b**.

(3.712 Å[17]). This isomer should thus be paramagnetic. This interpretation is supported by solid-state CP/MAS NMR spectroscopy on **1**.[18] The ^1H and ^{13}C NMR spectra each show two resonance signals ($\delta = 2$ and 18, and $\delta = 13$ and 246, respectively), which can be attributed to the deformational isomers. The low-field signals show the temperature proportionality characteristic of NMR signals of paramagnetic compounds. In contrast to the IR spectrum of **4**, in the case of **1** (CsI pellet) the bands assigned to the M–Cl vibrational modes at 292/309 and 260/275 cm^{-1} are split. This correlates with the different distances between the Ru atoms and the terminal chloro ligands in **1a** and **1b** (Table 1).

Table 1. Distances [Å] and bond angles [°] in **1**–**3**[a].

	1a	**1b**	**2**	**3**
Ru-Ru	2.930(1)	3.752(1)	2.9256(3)	3.098(2)
Ru-X_T	2.418(2)	2.365(2)	2.3619(6)	2.543(2)
Ru-X_B	2.366(1)	2.445(1)	2.4147(6)	2.479(2)
R-C_{Cp}[b]	2.191	2.173	2.191	2.178 2.194
Ru-X_B-Ru[b]	76.50(4)	100.24(5)	76.53(2)	76.25
X_B-Ru-X'_B[b]	103.50(4)	79.76(5)	103.47(2)	102.76
X_T-Ru-X_B[b]	89.99(6)	91.50(6)	89.56(2)	90.30

[a] X_T = terminal halogen, X_B = bridging halogen, C_{Cp} = C atom of the C_5 ligand. [b] Average values.

Finally the existence of a diamagnetic and a paramagnetic isomer explains the temperature dependence of the ^1H NMR signals of **1** and **2**, and to a lesser extent of **3**, in solution (Fig. 3). In dichloromethane a resonance signal which shifts reversibly with temperature in the range 109–350 K between $\delta = 1.6$ and 8,[19] accompanied by corresponding changes in line width (2.7 Hz at 190 K, 41 Hz at 350 K), is observed. Susceptibility measurements on solid samples of **1**[16] revealed an almost constant effective magnetic moment in the relevant temperature range (2.24 μ_B at 295 K, 2.22 μ_B at 95 K). Thus the temperature dependence of the chemical shift can only be caused by a dissociation into paramagnetic monomers or a temperature-dependent equilibrium between the deformational isomers **1a**/**1b**. Since we could not detect a concentration dependence of the chemical shift as predicted for a dissociation into monomers,[20] the second explanation apparently takes precedence, at least in the temperature range up to room temperature; **1b** is the less energetic form.[21] This means that the isomers also exist in solution. The same argument holds for **2**. In this case the four ^1H NMR signals in CD_2Cl_2 show an analogous temperature dependence, although only one form is present in the crystal. Apparently the often more favorable packing of the tetramethylethyl ligand prevents two isomers from crystallizing. Similar behavior is inferred for **3** above room temperature

(Fig. 3). The NMR spectrum of the bromine compound suggests that it is diamagnetic; a paramagnetic form would be substantially more energetic.

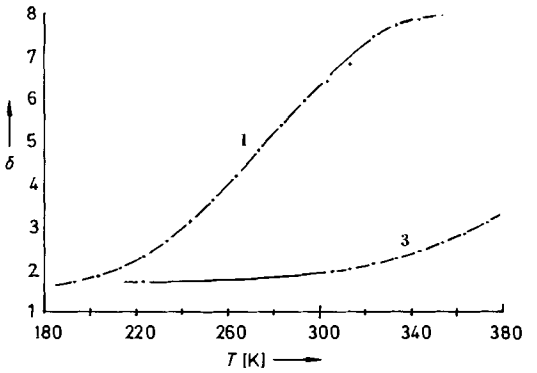

Fig. 3. Temperature dependence of the ^{1}H NMR chemical shift of **1** and **3**. Solvent CD_2Cl_2; standard: CH_2Cl_2, external ($\delta = 5.32$)

The deformational isomerism observed in crystals of **1** can be understood as a transition from magnetically interacting to noninteracting edge-sharing octahedra. The metal–metal distances in a large number of dimeric complexes[22] cluster around 2.8 Å where interaction is present (d^1–d^5) and around 3.7 Å where it is not. The d^5-d^5 low spin configuration in **1** is expected to lead to a rather weak interaction between the metal centers. As a result both molecular geometries, namely that dominated by the weak Ru–Ru bond and that by the repulsion between the Cl ligands, can coexist.

Synthesis and Structure of the Novel Ga_3P_3 Ring Compound $[(2,4,6\text{-}Ph_3C_6H_2)GaP(cyclo\text{-}C_6H_{11})]_3$**

By *Håkon Hope, Doris C. Pestana,* and *Philip P. Power**

Multiple bonding between elements of the main groups 3 and 5 and related species has been one recent focus of research in this laboratory.[1–9] Part of this work has involved the synthesis of various types of novel six-membered, quasi aromatic rings such as $(RBPR')_3$,[2,4] $(RAlNR')_3$,[5] $(GeNR)_3$,[6] $(RZnER')_3$ (E = S,[7,9] Se,[8] and R,R′ = large alkyl or aryl substituent). All of these rings have displayed structural properties (for example, planarity and shortened, equivalent ring bonds) that are suggestive of some aromatic character. The experimental results have also been supported by calculations that indicate varying degrees of stabilization owing to π-electron delocalization.[10] A feature of these compounds is that, with the exception of the zinc–sulfur and

Davis, California 95616 (USA)

[**] This work was supported by the National Science Foundation.

the zinc–selenium species, the rings invariably involve an element from the first row such as B or N. Rings composed exclusively of heavier main-group elements, where all the ring members are three coordinate, so that the possibility of extensive delocalization is preserved, are currently unknown.[11] In this paper the synthesis and structure of the first example of such a ring, involving only three-coordinate heavier main-group elements, is reported.

$[TriphGaP(C_6H_{11})]_3$ **1**, triph = $2,4,6\text{-}Ph_3C_6H_2$

The title compound (**1**) was synthesized in moderate yield by treatment of $triphGaCl_2$ with $Li_2P(cyclo\text{-}C_6H_{11})$ in an Et_2O/toluene solution. The ^1H and ^{13}C NMR spectra of **1** indicate that equal amounts of triph and C_6H_{11} are present. In addition, the ^{31}P NMR spectrum displays a single resonance at $\delta = -61$. The structure[12] of **1** was determined by X-ray crystallography (Fig. 1). The core involves a non-

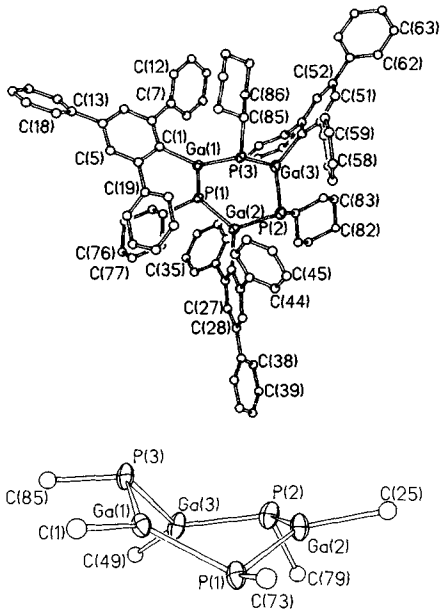

Figure 1. Schematic drawing of **1** (top) and the Ga_3P_3 core (bottom); H atoms are omitted for clarity. Bond distances (Å) and angles (°): Ga(1)–P(1) 2.286(4), Ga(1)–P(2) 2.283(4), Ga(2)–P(1) 2.279(4), Ga(2)–P(2) 2.338(5), Ga(3)–P(2) 2.291(3), Ga(3)–P(3) 2.302(3), Ga(1)–C(1) 2.004(9), Ga(2)–C(25) 1.992(11), Ga(3)–C(49) 2.019(13), P(1)–C(73) 1.863(14), P(2)–C(79) 1.892(12), P(3)–C(85) 1.880(15); Ga(1)-P(1)-C(73) 108.5(3), Ga(1)-P(1)-Ga(2) 108.3(2), Ga(2)-P(1)-C(73) 114.3(4), Ga(2)-P(2)-C(79) 104.2(4), Ga(2)-P(2)-Ga(3) 103.9(2), Ga(3)-P(2)-C(79) 107.6(5), Ga(1)-P(3)-C(85) 110.8(4), Ga(1)-P(3)-Ga(3) 104.3(1), Ga(3)-P(3)-C(85) 114.3(4), P(1)-Ga(1)-P(3) 118.6(1), P(1)-Ga(2)-P(2) 120.6(2), P(2)-Ga(3)-P(3) 114.7(2).

planar ring comprising three Ga and three P atoms. All the ring members are three-coordinate. The Ga–P bond lengths average ca. 2.3 Å. Although the Ga centers have almost planar coordination, the geometry at the P atoms is pyramidal and the sum of the angles at the P centers varies from 315.7° to 331.1°. Moreover, this sum may be correlated with the relevant Ga–P bond lengths. Thus the shortest Ga–P distances are associated with the flattest phosphorus center at P(1). The P–C, Ga–C, and C–C distances are unremarkable. The angle between each GaP_2C plane and the plane of the corresponding phenyl substituents is 82° for Ga(1), 64.3° for Ga(2), and 65.7° for Ga(3).

The structure of **1** is interesting for several reasons. It is the first well-characterized compound that has a ring consisting exclusively of three-coordinate, heavier main-group elements. In addition, the Ga–P bond length, 2.3 Å, is the shortest that has been observed to date.[13] It is significantly shorter than the Ga–P distance (2.338(1) Å) seen in the Ga_2P_2-ring species **2**.[11] Presumably, the longer distance in

$[\{2,6\text{-}(CH_2NMe_2)_2C_6H_3\}GaPSiPh_3]_2$ **2**

2 is due to the four-coordinate nature of the Ga center. The most significant structural feature of **1** concerns the nonplanarity of the Ga_3P_3 array and the P centers. The puckering indicates that delocalization in the Ga_3P_3 ring is not extensive. This view is supported by the upfield chemical shift($\delta = -61$) observed in the ^{31}P NMR spectrum. Had the amount of the delocalization of the P lone pairs onto Ga been large, a downfield chemical shift of $\delta \approx +50$ similar to those observed in the $(RBPR')_3$ rings[2,4] would have been expected. Thus the structural and spectroscopic data for **1** point to a sharp contrast in bonding with respect to the closely related planar B_3P_3 rings,[2,4] which were calculated to have greater delocalization than borazine.[10] It may be concluded that the energy gained by forming Ga–P π bonds is insufficient to overcome the high inversion barrier at phosphorus. Competition between these two factors exerts a considerable influence on B–P multiple bonding.[4] In this Ga–P system, at least, the inversion barrier appears to be dominant. Suitable variations of the substituents or replacement of Ga by the more electropositive Al will probably result in a planar array.

The stoichiometry and structure of **1** has proved that an earlier prediction, arising from the synthesis of the cluster **3**[14]

$[Ga_4(trip)_3\{P(1\text{-}ad)\}_4P(H)(1\text{-}ad)]$ **3**, trip = $2,4,6\text{-}i\text{-}Pr_3C_6H_2$, 1-ad = 1-adamantyl

of the existence of species such as $(RPGaR')_3$ is correct. Efforts to synthesize further examples of these and related species are under way.

Experimental Procedure

Under anaerobic and anhydrous conditions, a hexane solution of *n*BuLi (6.25 mL, 1.6 M) was added dropwise to an Et_2O solution of $H_2P(C_6H_{11})$ (0.61 mL, 5 mmol) with cooling in an ice bath. The yellow suspension was then stirred for a further 2 h. This was added by a double-tipped needle to a toluene/Et_2O (20 mL) solution of $triphGaCl_2$ derived from $GaCl_3$ (0.88 g, 5 mmol) and $triphLi(Et_2O)_2$ (2.3 g, 5 mmol)[15]. The addition produced a yellow solution which was filtered after 12 h stirring. The volume was reduced to ca. 15 mL and filtered again. Cooling to −20 °C afforded the product **1** as almost colorless, pale yellow crystals. Yield: 1.1 g, 45%; heating produces apparent desolvation at ca. 155 °C and decomposition above 200 °C.

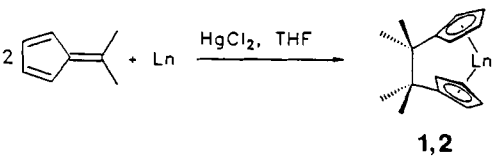
One-Step Synthesis of Organolanthanide(II) Complexes from the Metal**

By *Anja Recknagel* and *Frank T. Edelmann**

The organometallic chemistry of the divalent lanthanides has developed into a fascinating research area in the past ten years.[1] The decamethylmetallocene derivatives of samarium, europium, and ytterbium play a central role in this area. A prominent example is the unusually reactive THF adduct of decamethylsamarocene, $[Cp^*_2Sm(thf)_2]$.[2] This compound, first prepared by *Evans* et al., reacts with a number of substrates to yield organosamarium(III) complexes.[1c] The range of novel reactions of $[Cp^*_2Sm(thf)_2]$ stretches from the reductive CO trimerization[3] through the dimerization of phosphaalkynes[4] to the formation of the first complex of an f-block element containing an N_2 ligand.[5]

Cyclopentadienyl complexes of the divalent lanthanides are usually obtained in two-step syntheses.[1] The reaction of lanthanide(II) iodide with alkali cyclopentadienide has often proved its worth in the preparation of complexes such as $[Cp^*_2Sm(thf)_2]$, $[Cp^*_2Yb(Et_2O)]$ and $[\{(Me_3Si)_2C_5H_3\}_2Sm(thf)]$.[6] A further method is the reduction of bis(cyclopentadienyl)lanthanide(III) halides with alkali metals.[1] We report here on a new, direct synthesis of organolanthanide(II) complexes from the metal, in which the organic ligand is formed in situ.

On treatment of a suspension of activated samarium or ytterbium powder in THF with two equivalents of 6,6-dimethylfulvene, the solution becomes intensely red (Yb) or violet (Sm) after an induction period of ca. 2–4 h. After further stirring for 24 h at room temperature, the metal has almost completely dissolved. The organolanthanide(II) complexes **1** (Ln = Sm, 46%) and **2** (Ln = Yb, 75% yield) can be isolated from the filtered reaction solutions. Apparently the difunctional C_2-bridged bis(cyclopentadienyl) ligand $[Me_4C_2(C_5H_4)_2]^{2\ominus}$ is formed by reduction and subsequent dimerization of 6,6-dimethylfulvene during the reaction (Scheme 1). The compounds **1** (deep violet crystals) and **2**

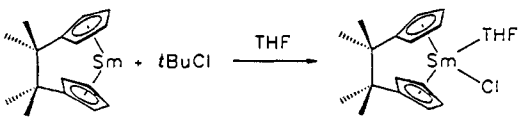


1,2

Scheme 1. **1**: Ln = Sm, **2**: Ln = Yb.

(dark red crystals) are very air-sensitive and soluble in THF, but sparingly soluble in hexane. The EI mass spectra of the complexes exhibit a peak with high intensity for the molecular ion of the unsolvated species $[\{Me_4C_2(C_5H_4)_2\}Ln]$. The chemical analyses and ^1H NMR spectra also show that the complexes **1** and **2** contain no coordinated THF. A comparable reaction is known for the alkaline earth metals: a reaction of magnesium and 6,6-dimethylfulvene in THF/CCl_4 yields the bis-Grignard reagent $[Me_4C_2(C_5H_4MgCl)_2]\cdot 4\,THF$, which in contrast to **1** and **2** is insoluble in THF.[7] It is still not clear whether the heavier alkaline earth metals also react with fulvenes in a similar manner.

The new organolanthanide(II) complexes **1** and **4** should be as reactive as their Cp* analogues. Compound **1**, for example, is converted extremely easily with *tert*-butylchloride into the organosamarium(III) complex **3**. This yellow,



1 **3**

thermally very stable compound was characterized by spectroscopy and elemental analysis. The EI mass spectrum shows the molecular ion peak at $m/z = 471$, whose isotope pattern coincides with that calculated for $C_{20}H_{28}ClOSm$. The easy access to the lanthanide(II) complexes **1** and **2** makes them attractive starting materials for organometallic synthesis. Only a small step is needed from compounds of type **3** to potentially catalytically active organolanthanide(III) complexes.

Experimental Procedure

Because of the extreme air-sensitivity of the compounds described here, all reactions were performed under purified nitrogen in dry, oxygen-free solvents. **1**: To a suspension of Sm powder (2.00 g, 13.3 mmol) in THF (20 mL) was added $HgCl_2$ (ca. 100 mg), and the mixture was stirred for 2 h at 20 °C. Dropwise addition of 6,6-dimethylfulvene[8] (1.41 g, 13.3 mmol) in THF (100 mL) and further stirring at room temperature for 24 h yielded a deep violet solution, which was filtered through a thin Celite layer. The filtrate was concentrated to 50 mL, and crystallization at −25 °C afforded deep violet crystals (2.21 g, 46%). M.p. 158 °C; correct elemental analysis (C,H); IR (Nujol): $\tilde{\nu}$[cm^{-1}] = 1261 m, 1040 s, 896 m, 765 s; EI-MS: *m/z* 364 ($M^{\oplus}$, 24%), 259 ($[Me_2C(C_5H_4)]Sm^{\oplus}$, 18), 91 ($MeC(C_5H_4)^{\oplus}$, 100); ^1H NMR (80 MHz, [D$_8$]THF): δ = 15.5–15.0 (m, 8H, C_5H_4), 6.6 (s, br, $\nu_{1/2}$ = 30 Hz, 12H, Me). **2**: Analogously, a deep red crystalline solid (3.34 g, 46%) is obtained from Yb powder (2.00 g, 11.6 mmol) and 6,6-dimethylfulvene (1.22 g, 11.6 mmol). M.p. 142 °C; correct elemental analysis (C,H); IR (Nujol) $\tilde{\nu}$[cm^{-1}] = 1261 m, 1034 s, 880 m, 802 m, 728 vs; EI-MS: *m/z* 386 ($M^{\oplus}$, 87%), 279 $[Me_2C(C_5H_4)]Yb^{\oplus}$, 72), 91 ($MeC(C_5H_4)^{\oplus}$, 100); ^1H NMR (80 MHz, [D$_8$]THF): δ = 5.90–

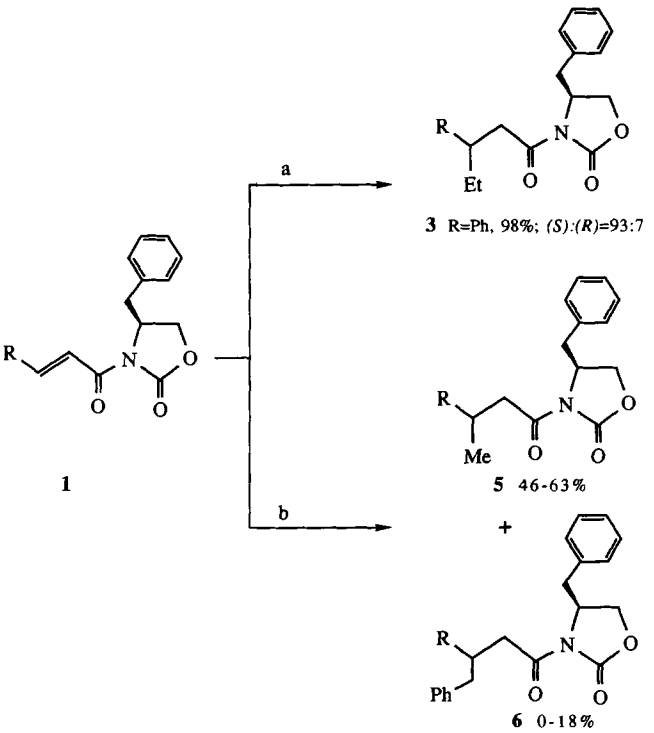
β-Alkyl and β-Alkyl-α-Hydroxy Carboxylic Acid Derivatives from Radical or Ionic 1,4 Addition of Dialkylaluminum Chlorides to α,β-Unsaturated *N*-Acyl Urethanes**

By *Karola Rück* and *Horst Kunz**

Dedicated to Professor Leopold Horner

Chiral β-branching carboxylic acids are interesting building blocks for syntheses of natural products. The same is true of β-alkyl α-hydroxy carboxylic acid derivatives, which have, in comparison with the products of aldol reactions on enolates, the opposite α- and β-substituent pattern. Recently we reported a new access to chiral β-alkyl carboxylic acids by 1,4 addition of dialkylaluminum halides to α,β-unsaturated *N*-acyl urethanes.[1] A particular feature of this reaction is the smooth transfer of the alkyl group to the acceptor by diethylaluminum chloride but not by dimethylaluminum chloride under the same conditions. Dimethylaluminum chloride will catalyze the 1,4 addition of higher alkyl homologues. In contrast to our results,[1] *Evans* et al.[2a] observed that during Diels–Alder reactions, 1,4 additions of organoaluminum compounds do occur, but as side reactions and not only with Et_2AlCl but also with Me_2AlCl.

We therefore studied more closely the new reaction of the chiral oxazolidinones used by *Evans* on α,β-unsaturated acyl derivatives (**1**). Compounds **1** react with Et_2AlCl (**2**) under 1,4 addition, as do the oxazinone derivatives of xylofuranose[1] (Scheme 1). Treatment with 4 equivalents of **2** in a toluene/*n*-hexane solution with exclusion of oxygen at −78 °C yields the ethyl-substituted derivative **3** in high yield and with a high diastereomeric ratio in favor of the *S* configurated product (93:7). Under the same conditions Me_2AlCl (**4**) did not react, despite raised temperatures (−20 °C). In the presence of air, however, a slow reaction was observed. A useful preparative reaction is the 1,4 addition of **4** to acceptors (**1**) on photochemical induction (λ_{max} = 254 nm), which yields branched β-(methyl acyl) oxazolidinones.



Scheme 1. a) Et_2AlCl (**2**, 4 equiv, 1 M) in *n*-hexane/toluene at −78 °C under argon. b) Me_2AlCl (**4**, 4 equiv) in *n*-hexane/toluene, 5 h irradiation. Total reaction time 30–48 h.

This indicates that the methyl transfer takes place by a radical mechanism, and indeed, can be completely inhibited by 5 mol % galvinoxyl.[3] The formation of **6** on addition of benzyl radicals also confirms the radical nature of the process. Radical reactions of the strong Lewis acid **4** with polar compounds such as **1** were till now unknown.[4] The stereoselectivity of the radical methyl transfer lies between 4:1 and 12:1 (Table 1). The separation of the diastereomeric ethyl compounds **3**,[5] as well as for the aromatic compounds **5b**

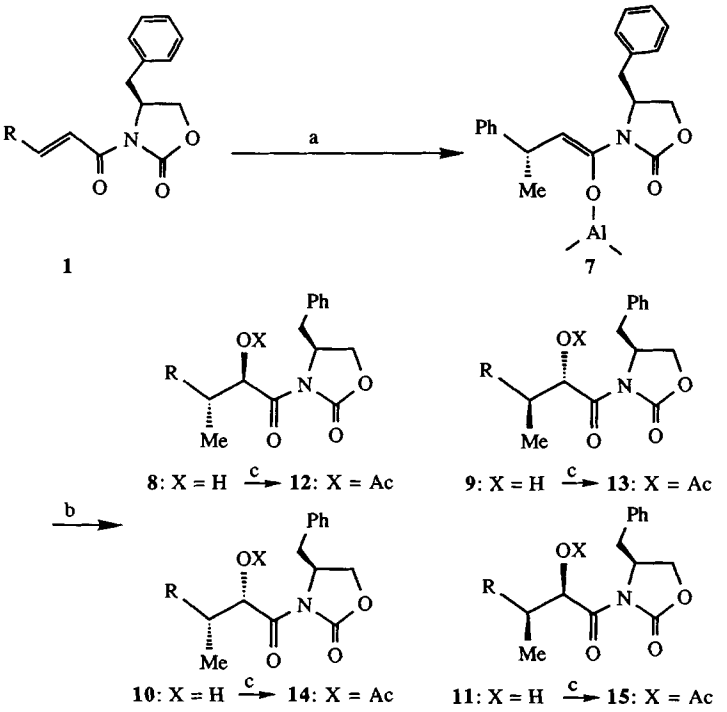
($R = C_6H_5$) and **5c** ($R = p\text{-}C_6H_4Cl$), can be achieved by flash chromatography.[6] Hydrolysis of the diastereomeric mixture of **5b** yields predominantly (*S*)-3-phenylbutyric acid.[7]

We have extended the radical transfer of a methyl group from Me_2AlCl to a cascadelike double functionalization of the α,β-unsaturated carboxylic acid derivatives (**1**) to yield β-methyl α-hydroxy carboxylic acid derivatives. Interestingly, the aluminum enolate intermediates **7**, which are formed stereoselectively in the radical process, react more smoothly with triplet oxygen than with polar oxidizing agents to form the target compounds **8**–**11**. Till now the alkali enolates could not be satisfactorily oxidized to α-hydroxy carbonyl compounds with oxygen,[8] a reaction which could also be achieved stereoselectively[9–11] with *N*-sulfonyl oxaziridine[12] and a MoO_5/pyridine/hexamethylphosphoric triamide complex.[13]



Scheme 2. a) Me_2AlCl (**4**, 4 equiv) in *n*-hexane/toluene is irradiated for 5 h and allowed to react for 24 h thereafter without irradiation at −40 °C. b) Oxidation: passage of oxygen for 1 h; thereafter allowed to react for 48–72 h. c) Acylation with Ac_2O, DMAP.

To perform the reaction sequence the compounds **1** (see Table 2) were irradiated in the presence of **4** (4 equiv, 1 M in *n*-hexane) in toluene at −40 °C with a mercury immersion lamp ($\lambda_{max} = 254$ nm) for 5 h (Scheme 2). The mixture was allowed to react without irradiation for 24–48 h, after which dry air was passed through the solution for 1 h at the same temperature. The reaction was quenched after a total of 72–96 h by hydrolysis with NH_4Cl solution and the diastereoisomers of (β-methyl α-hydroxy acyl) oxazolidine (**8**–**11**), were isolated after flash chromatography with petroleum ether/ethyl acetate in yields of 50–92%. The *syn*/*anti* product ratio was determined by ^1H NMR spectroscopy directly from the crude product.[14] After acetylation of the crude product with Ac_2O/DMAP (4-dimethylaminopyridine)[15] at 0 °C in dichloromethane, the ratio of the diastereomeric *O*-acylated hydroxy carboxylic acid derivatives **12**–**15** were

Table 2. Synthesis of (β-methyl α-hydroxy acyl) oxazolidinones **8**–**11**.

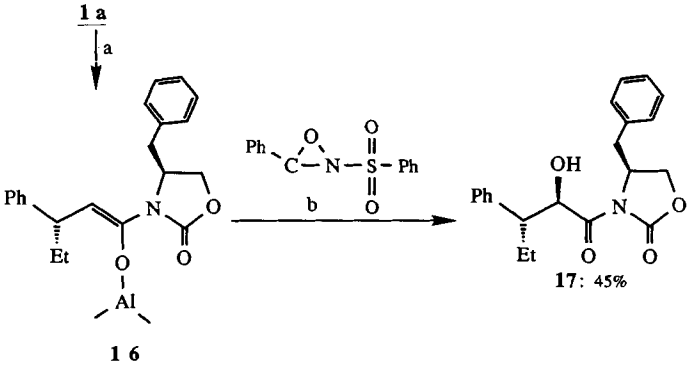
[a] *T* = Reaction temperature [°C], *t* = reaction time [h]; [b] yield [%] after flash chromatography in petroleum ether/ethyl acetate mixtures, [c] diastereomeric ratio determined by HPLC on RP columns in MeOH/H_2O or by ^1H NMR spectroscopy (400 MHz, $CDCl_3$) of the *O*-acylated Derivatives **12**–**15**; [d] see [22].

determined by analytical HPLC (Table 2). The results agreed with the ratios obtained by ^1H NMR spectroscopy.[16] The diastereomers **8**–**11** were separated by flash chromatography. In each case the *anti* configuration was assigned to the major diastereomer **8a**–**d** and **12a**–**d**, since their ^1H NMR spectra showed the larger coupling constant $J_{\alpha/\beta}$ for the signals of the acyl side chain.[17] This was also true for the diastereomers **9a**–**d** and **13a**–**d**. The structure assignment was confirmed, since the absolute configurations of the diasteromers **9d** and **13d**, and their place in the *anti* series, could be proved by comparison of the ^1H NMR spectrum with that of an authentic sample isolated from L-isoleucine.[18]

The decisive step in the stereoselection of this reaction sequence is the initial 1,4 addition of the methyl group. The chiral center formed by this 1,5 induction in the β-position of the enolate **7** controls the following enolate oxidation. Thus for the aryl-substituted enolates **7b**, **c**, the (β*S*/4*S*) diastereomers form the matched pair in the intramolecular double stereodifferentiation. They react with oxygen with high stereoselectivity ($R:S \approx 93:7$) preferentially to the β*R*,α*R* diastereomers **8b**, **c**.[19] The β*R*,4*S* enolates represent the mismatched pair for the subsequent α-oxidation. Their oxidation shows low stereoselectivity ($R:S \approx 1:4$[20]). Stereoselectivity amongst the aliphatic examples **7a**, **d** of the 1,4-methyl addition, and in particular the inducing influence of the newly formed chirality center, is substantially smaller.[20]

Although the reaction mechanism needs further clarification, no long-lived hydroperoxides are formed during the oxidation process. Such alkylaluminum peroxides would undergo a rapid intra- or intermolecular reaction to alkoxyaluminum compounds.[21] This explains why in our reaction sequence the free hydroxy carboxylic acid derivatives **8**–**11** are isolable directly after hydrolysis. Furthermore, the example of **1e** (R = Me) makes it clear that the actual oxida-



Scheme 3. a) Et_2AlCl (**2**, 4 equiv) in *n*-hexane/toluene at −78 °C, 9 h reaction time. b) Reaction temperature of −78 to +5 °C, 15 h reaction time. **17**: *anti*/*syn* ratio > 95:5, (β*R*):(β*S*) ≈ 9:1.

tion of the aluminum enolate is hardly influenced by the oxazolidinone auxillary in **7**. In this case the *R*-hydroxy carboxylic acid derivative is formed in only slight excess.[22]

The described double functionalization of the unsaturated acyl oxalidinones **1** gains a significant extension in that the ionic transfer of higher homologue alkyl groups from alkylaluminum halides to these acceptors[1] can be followed by an oxidation. These ionic processes afford enolates such as **16** (Scheme 3), whose subsequent oxidation with atmospheric oxygen, in contrast to that of **7**, is unsatisfactory. It is significant that with *N*-sulfonyl oxaziridine, which reacts ionically,[12] **16** reacts with high *anti*-selectivity to form the diastereoisomer **17** of the β-ethyl α-hydroxy carboxylic acid in 85% yield.

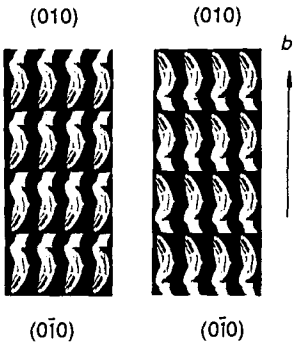
Direct Assignment of Absolute Configuration of Chiral Alkyl Gluconamides by Wettability Measurements

By *Jinn-Lung Wang, Meir Lahav,* Leslie Leiserowitz**

Dedicated to Professor Vladimir Prelog on the occasion of his 85th birthday

For a century, from the milestone experiment of *Pasteur*[1] in 1848 on the manual separation of the two enantiomorphs of $NaNH_4$ tartrate tetrahydrate, till 1951, when *Bijvoet*[2] directly assigned the absolute configuration of crystals by anomalous X-ray scattering only relative stereochemistry was considered. In the absence of anomalous X-ray scattering, one cannot differentiate by conventional X-ray diffraction, in accordance with Friedel's law, between a chiral crystal structure and its mirror image.[3] Recently, several independent methods for assignment of absolute molecular configuration were proposed, including the use of tailor-made molecular additives for inducing controlled morphological changes in crystals,[4] crystal etching,[5] and reduction of symmetry in crystals,[6] as well as gas/solid reactions[7] and ferroelectric measurements in liquid crystals.[8]



Scheme 1. The principle used to determine the absolute configuration of chiral molecules.

These methods involve the principle of fixing the orientation of the constituent chiral molecules vis-à-vis the polar axis, or axes, of the crystal and subsequently determining the absolute configuration of the chiral molecules. This principle is depicted schematically in Scheme 1. The fingers of the hands are exposed at the (010) face for the right-handed "molecules" and, by symmetry, at the (0$\bar{1}$0) face for the left-handed "molecules". Thus, by determining at which face

of the crystal specimen the fingers or wrists are exposed, one may assign the handedness of the constituent molecules.

In the course of studies on induced freezing of supercooled water via structured surfaces, we investigated crystals of the class of chiral resolved alkyl gluconamides $H(CH_2)_nNHCO(CHOH)_4CH_2OH$ ($n = 7-10$). We noticed that the molecular packing arrangements, crystal morphology, and cleavage properties of the entire class permit a direct determination of the absolute configuration of the molecules by simple wettability measurements at opposite hemihedral faces of the crystals.

Saenger et al. recently reported the crystal structures of chiral resolved alkyl gluconamides.[9] Compounds with an odd number of carbon atoms in the hydrocarbon chain crystallize in space group $P1$ with one molecule per unit cell (Fig. 1 a); compounds with an even number of carbon atoms appear in space group $P2_1$ with two molecules per unit cell (Fig. 1 b).

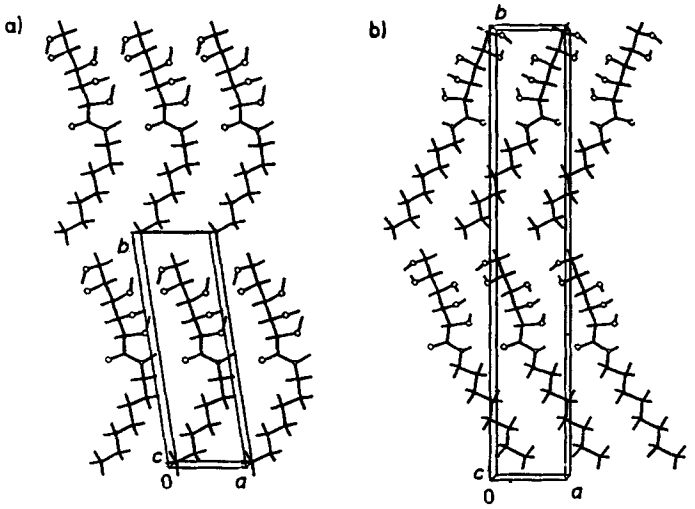

Fig. 1. Head-to-tail packing arrangements of alkyl gluconamides in the crystal. a) *N*-*n*-heptyl-D-gluconamide, space group $P1$. b) *N*-*n*-octyl-D-gluconamide, space group $P2_1$.

For both the n odd and even series, the molecules form layers by translation symmetry only. Within each layer the molecules are interlinked by hydrogen bonds at the gluconamide moiety and by methylene–methylene contacts at the alkyl side. The layers are similar in structure for the whole class of compounds (Fig. 1) and are stacked head-to-tail in a polar arrangement either by translation for n odd or by twofold screw symmetry for n even. The crystals form {010} plates whose faces are parallel to the molecular layers. Thus, the ω-CH_3 group at the hydrophobic end of the molecule emerges at one {010} face of the crystal plate and the terminal CH_2OH moiety at the opposite face, with the hydroxyl oxygen oriented such that its lone pair protrudes from the crystal surface. For sugars of D configuration the $(0\bar{1}0)$ face of the crystal plate is hydrophobic and the opposite (010) face is hydrophilic. The reverse situation holds for molecules of L configuration. Thus, the assignment of the hydrophobic–hydrophilic character of the plate faces by simple wettability measurements would fix the sense of polarity of the crystal and subsequently the absolute configuration of the sugar molecules.

The contact angle between a liquid drop and a flat solid surface reflects the difference between cohesion forces of the liquid and the adhesion forces to the solid surface. Systematic studies of contact angle measurements on a variety of surfaces, including those of crystals, monolayers, and polymers, have demonstrated that the contact angle depends primarily on the groups constituting the exposed surface, with some modulation by the presence of polar groups embedded below the surface.[10-12] These studies have led to a correlation between contact angle and the hydrophobic or hydrophilic nature of the surface. Therefore, a pronounced difference was expected for the contact angles for the two opposite (010) and $(0\bar{1}0)$ hemihedral faces of the alkyl gluconamide crystals.

The advancing contact angle α for this class of crystals was measured with three different solvents: water, glycerol, and ethylene glycol. Advantage was taken of the intrinsic property of these crystals to cleave along the {010} face and so provide clean, fresh surfaces. The results are given in Figure 2. The contact angles can be classified into two distinct groups; the angles range in value from 75 to 87° at the $(0\bar{1}0)$ face and from 44 to 56° at the opposite (010) face. The average difference in contact angle at the two opposite faces for the three solvents and the four compounds is 32°.

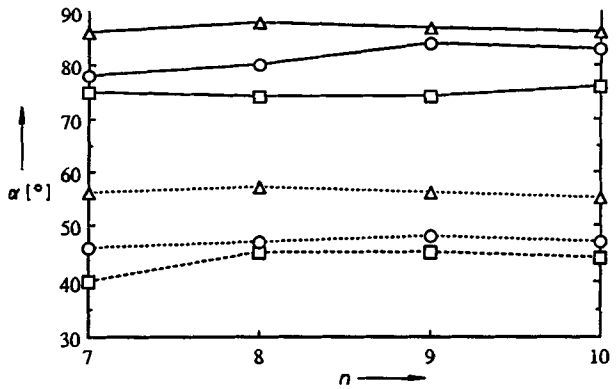

Fig. 2. Advancing contact angles α of the {010} faces of *N*-alkyl-D-gluconamide crystals ($n = 7-10$). △=glycerol, ○=water, □=glycol, —— = contact angles at the $(0\bar{1}0)$ face, – – – = contact angle at the (010) face.

These results may be compared with contact angle measurements on model surfaces of known hydrophilic and hydrophobic character.[13] As a hydrophilic surface, we made use of 1,9-nonanediol, which crystallizes as thick plates in which the molecules are arranged in layers. The two dominant faces of the platelike crystals expose hydroxyl groups. The contact angle for the water was 44°, comparable to the average contact angle of 46° for the (010) face of the alkyl gluconamides. As a model for the hydrophobic face, we prepared Langmuir–Blodgett films of an alkyl gluconamide (n=18) which forms a Z-type multilayer[14] and whose exposed faces were thus hydrophobic. The average value for each of the three solvents glycerol, ethylene glycol, and water were 95, 82, and 79°, respectively, comparable to the average contact angle on the $(0\bar{1}0)$ face of the alkyl-gluconamide crystals.

All these results are completely consistent with the assignment that the $(0\bar{1}0)$ face of the alkyl gluconamides is hydrophobic and the (010) face hydrophilic. This assignment fixes the absolute configuration of the chiral gluconamide molecules to be the D configuration as expected.

Thus, there are now available a variety of chemical methods, including simple wettability measurements, for the direct assignment of absolute configuration of chiral molecules

in crystals. The importance therein lies not only in the fact that we may directly correlate macroscopic chemical behavior with molecular chirality, but also in the educational value of the method, particularly for students of organic chemistry who find the usual method of anomalous X-ray scattering too esoteric.

Tetraethynylethene **

By *Yves Rubin, Carolyn B. Knobler,* and *François Diederich* *

Dedicated to Professor Heinz A. Staab on the occasion of his 65th birthday

Despite the enormous importance of acetylene and ethylene in chemistry, the tetraalkynylethene system has received little attention so far.[1] Our research on molecular and polymeric carbon allotropes has led us to isolate tetraethynylethene (**4a**), the ultimate and hitherto elusive member of this class.[2–4] We believe that the preparation of **4a**, the only known isomer of molecular formula $C_{10}H_4$, is important for several reasons: (1) Compound **4a** and its substituted derivatives are interesting examples of cross-conjugated π systems.[1] (2) Tetraethynylethene (**4a**) is a direct precursor of new carbon networks.[5, 6] (3) Double Bergman cyclization[7] of **4a** could provide a convenient route to poly(*peri*-naphthalenes), which have been predicted to pos-

sess a low-lying band gap.[8] (4) Finally, derivatives of **4a** could show the potent anticancer activity observed for strained *cis*-enediynes.[9]

A general synthetic route to **4a** and its derivatives **4b** and **4c** required the preparation of the differentially protected tetraalkynylethenes **3a**–**3c** (Table 1). Accordingly, 1,5-bis(trimethylsilyl)-1,4-pentadiyn-3-one (**1**)[10] was converted into the dibromomethylene derivative **2a** with CBr_4/PPh_3.[11] The $[Pd(PPh_3)_4]$-catalyzed alkynylation of **2a** was successfully carried out with trimethylsilylacetylene, triisopropylsilylacetylene, and phenylacetylene in the presence of CuI and *n*-butylamine in benzene (25 °C) to give **3a**,[1b] **3b**, and **3c**, respectively.[12] Removal of the trimethylsilyl groups in **2a** and **3a**–**3c** with catalytic amounts of K_2CO_3 in methanol smoothly afforded the free alkynes **2b** and **4a**–**4c** in essentially quantitative yields. The lower isolated yields for **2b** and **4a** reported in Table 1 are due to material loss occurring upon drying these highly volatile compounds.

Tetraethynylethene (**4a**) is fairly soluble in pentane and crystallizes out of this solvent at −10 °C as white plates. At 25 °C, **4a** becomes rapidly brown even in the absence of oxygen and polymerizes to a black solid with metallic luster; the same process happens slowly in solution to give a brown precipitate. Similarly, the triisopropylsilyl derivative **4b** decomposes at 25 °C in the neat state, although more slowly than **4a**. A dramatic instability is observed for **4c**: the neat oil polymerizes to a black hard mass in a matter of a few seconds. Therefore, all manipulations with this compound were made in solution.

The gated decoupled ^{13}C NMR spectrum of **4a** in [D_6]acetone shows only three absorptions with the expected CH coupling constants for the alkyne carbons. The remarkably simple FT-IR spectrum of **4a** in CCl_4 shows a characteristic strong C–H stretching band at 3307 cm^{-1}, together with a weak C≡C stretching band at 2102 cm^{-1} (Fig. 1). The

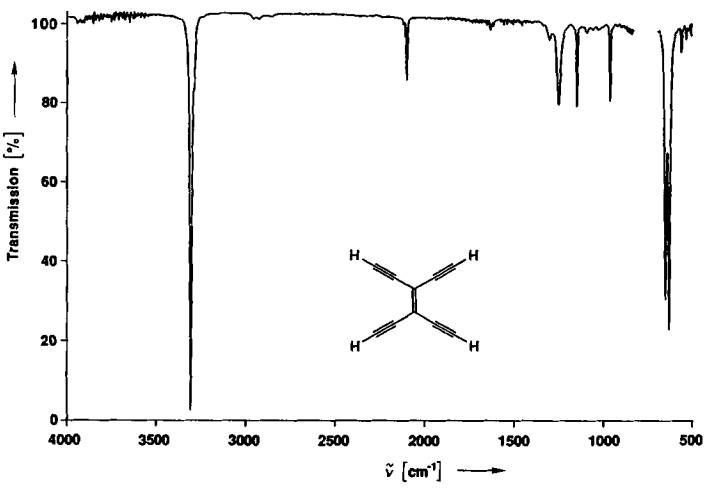

Fig. 1. FT-IR spectrum of **4a** in dilute CCl_4 solution.

strong absorptions at 653 and 632 cm^{-1} are due to the coupled C–H bending modes in **4a**. The UV spectrum of **4a** in MeOH is very similar to the one of its $SiMe_3$-substituted derivative **3a**,[1b] although the absorption bands for **4a** are shifted 20–35 nm to higher energy and are somewhat broader (Fig. 2).

An X-ray structure analysis was performed with the stable derivative **3a** (Fig. 3).[13, 14] The molecule is nearly planar: the maximum deviation from the least-squares plane through

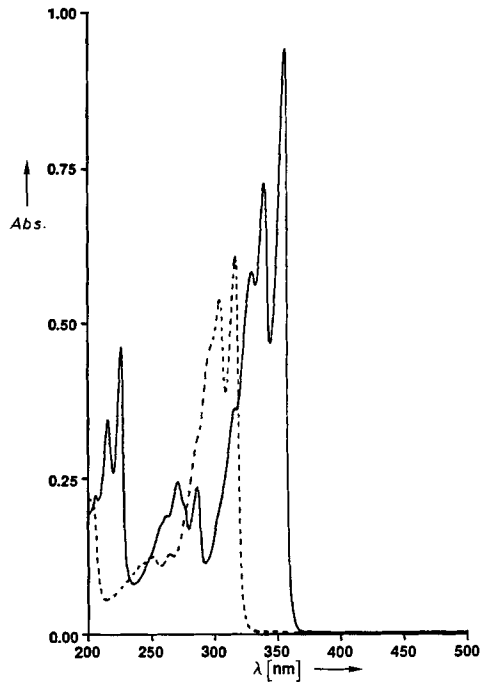

Fig. 2. Electronic absorption spectra of **3a** (——) and **4a** (---) in MeOH, $T = 25$ °C, $d = 1$ cm, $[\mathbf{3a}] = [\mathbf{4a}] = 2.33 \times 10^{-5}$ M.

the tetralkynylethene framework including the four silicon atoms is 0.032(9) Å. The tetralkynylethene framework itself is planar within 0.007(8) Å. The molecule is slightly distort-

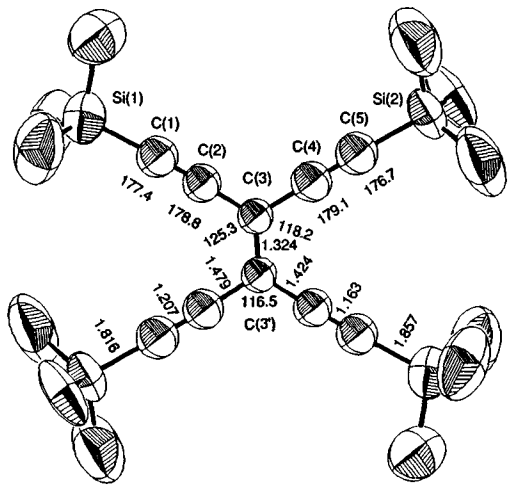

Fig. 3. X-ray crystal structure of **3a**.

ed: the C3′–C3–C2 angle is 125.3(7)°, a value similar to those calculated for other unstrained *cis*-enediynes,[15] while the C3′–C3–C4 angle is unusually small, with a value of 118.2(7) Å. This distortion presumably results from crystal packing effects in the solid.[4] The bond lengths in **3a** are within the normal range for C=C and C≡C bonds.

Experimental Procedure

4a: A solution of tetrakis[(trimethylsilyl)ethynyl]ethene (**3a**) (1.25 g, 3.0 mmol) in 50 mL of methanol was stirred with solid K_2CO_3 (200 mg) for 15 min at 25 °C. The mixture was poured into pentane/water with stirring, and the organic phase was washed with more water and dried with $MgSO_4$ and silica gel. Evaporation at ≤25 °C gave 325 mg (87%) of **4a** as volatile white platelets,

which became brown within 2 min. Solutions of **4a** in Et_2O were conveniently stored for more than two months at $-5\,^{\circ}C$.

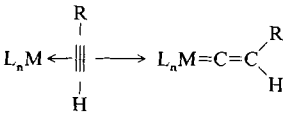
Mononuclear Silylvinylidene Rhodium Complexes from Silylalkynes: The $SiMe_3$ Migration as an Alternative to the [1,2]-H Shift**

By *Dirk Schneider* and *Helmut Werner**

Dedicated to Professor Rolf Appel on the occasion of his 70th birthday

The rearrangement of 1-alkynes to vinylidenes in the coordination sphere of a transition metal has been intensively investigated in recent years.[1, 2] The general reaction, as shown in Equation (a), is often inhibited for kinetic reasons, in particular if both the starting material (**1**) and the product (**2**) are 18-electron species.[3] However, if ML_n is $[RhCl(PiPr_3)_2]$ or $[IrCl(PiPr_3)_2]$, a smooth transformation takes place;[4, 5] in this case, the isolation of intermediates of composition $[MH(C{\equiv}CR)Cl(PiPr_3)_2]$ supports the assumption[1a] that the rearrangement occurs stepwise.

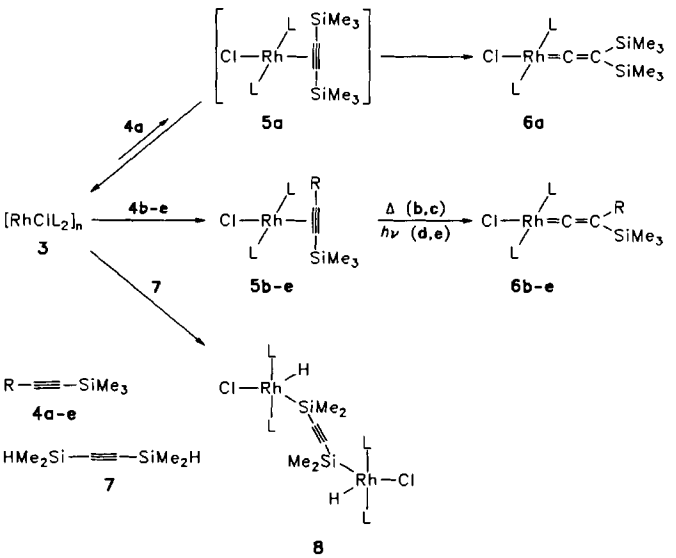


(a)

1 **2**

Almost nothing is known about the conversion of a disubstituted alkyne, $RC{\equiv}CR'$, into the isomeric vinylidene, $:C{=}CRR'$, in the vicinity of one metal center.[1, 6] We report here that with silylalkynes, $RC{\equiv}CSiMe_3$, such a reaction takes place in the coordination sphere of rhodium and that, independent of the substituent R, the [1,2]-$SiMe_3$ migration proceeds analogously to the [1,2]-H shift.

Complex **3**[7] does not react with an equimolar amount of bis(trimethylsilyl)acetylene (**4a**). If, however, a larger excess of **4a** is added to a pentane solution of **3** at $-20\,^{\circ}C$, a quick color change from violet to orange-red is observed. After a few minutes, the solution turns violet again. Upon workup and recrystallization at low temperatures dark violet crystals of **6a** are isolated; the spectroscopic data of **6a** (Table 1) confirm the structure shown in Scheme 1. The most typical



Scheme 1. L = $PiPr_3$; **4**: **a**, R = $SiMe_3$; **b**, R = Me; **c**, R = Ph; **d**, R = CO_2Et; **e**, R = CO_2SiMe_3.

features of the spectra, the position of the ^{13}C NMR signal of the α-carbon atom of the vinylidene ligand[1] and the appearance of a sharp triplet in the ^{29}Si NMR spectrum, support the equivalence of the $SiMe_3$ groups. If, after the addition of the alkyne, the reaction solution is worked up immediately at $-78\,^{\circ}C$, an orange solid (**5a**) can be isolated; its IR spectrum [$\nu(C{\equiv}C) = 1832\,cm^{-1}$] indicates the presence of a coordinated alkyne. Compound **5a** is extremely labile and, even in the solid state, rearranges to give the isomer **6a**.

The reaction of **3** with **4b–e** leads, in some cases almost quantitatively, to the silylalkyne rhodium complexes **5b–e** (Scheme 1), which, in contrast to **5a**, are stable at room temperature. Upon warming in pentane or hexane, only **5b, c**, but not **5d, e**, react to give the isomers **6**. On the other hand, the conversion of **5d,e** into the corresponding silylvinylidene complexes **6** proceeds photochemically; the yields are 55–60%. Attempts to observe a stepwise reaction sequence involving an acetylide(silyl)metal compound as intermediate failed. The reason for the different behavior of **5b,c** on one hand and of **5d,e** on the other is not yet clear; the positions of the charge-transfer (CT) and $\pi-\pi^*$ bands in the UV spectra of **5c** and **5d** are almost the same.

The properties of the violet, moderately air-stable solids **6b–e** are similar to those of **6a** and the previously described complexes *trans*-[RhCl(=C=CHR) (P*i*Pr$_3$)$_2$] (R = H, Me, *t*Bu, Ph, CO$_2$Me).[4] However, a characteristic difference is the presence of two sets of signals for the protons and the carbon atoms of the phosphane-CH$_3$ groups in the ^{1}H and ^{13}C NMR spectra of **6b–e** even at room temperature, indicating a hindered rotation of the vinylidene ligand around the Rh–C bond. We assume that the reason for this is steric hindrance between the two substituents on the β-carbon atom of the vinylidene and the bulky P*i*Pr$_3$ ligands. For the known complexes *trans*-[RhCl(= C=CHR) (P*i*Pr$_3$)$_2$] a comparable restriction of the rotation at 25 °C cannot be detected.[4]

The C–Si bond in **6a–e** can easily be cleaved by proton sources. After chromatography of benzene or hexane solutions of the silylvinylidene complexes on Al_2O_3 (activity grade III), not the original compounds but the desilylated complexes *trans*-[RhCl(= C=CHR) (P*i*Pr$_3$)$_2$][4] are eluted. If alumina deactivated with D_2O is used, the deuterated derivatives *trans*-[RhCl(= C=CDR) (P*i*Pr$_3$)$_2$] are obtained.

Surprisingly, the behavior of the SiMe$_2$H-substituted alkyne **7** toward **3** is completely different from that of the SiMe$_3$ analogue **4a**. It reacts with **3** under the same conditions as used for the synthesis of **6a** (in pentane) to form the binuclear compound **8**.[8] The oxidative addition of the Si–H bond to the metal center is obviously preferred over π coordination. Mononuclear rhodium complexes of composition [RhH(SiX$_3$) (Y) (PPh$_3$)$_2$] (Y = Cl, Br, I; X = Cl, OEt, Me, Et, Ph) are known[9] but, for X = alkyl, are unstable in solution.

Using silylalkynes as starting materials for the preparation of vinylidene complexes is probably not restricted to rhodium.[10] Recently, *Vahrenkamp* and co-workers showed that treatment of [Ru$_3$(CO)$_{11}$] with **4b** gave the alkyne-bridged cluster [RuCo$_2$(CO)$_9$(μ_3-MeC≡CSiMe$_3$)] accompanied by the rearranged complex [RuCo$_2$(CO)$_9$(μ_3-C=C(Me)SiMe$_3$].[11] No vinylidene complex is obtained from [RuCo$_2$(CO)$_{11}$] and **4a**; instead, a cluster fragmentation takes place. In contrast, at rhodium as metal center, the course of the reaction is clear for all the silylalkynes used so far. The ease of the [1,2]-SiMe$_3$ shift is particularly noteworthy because such a process only occurs under extreme thermal conditions for free alkynes.[12]

Experimental Procedure

6a: A solution of **3** (287 mg, 0.63 mmol) in pentane (25 mL) was treated at − 20 °C with **4a** (1 mL). A spontaneous color change from violet to orange-red occurred and in a few minutes, the solution became violet again. The solvent was removed in vacuo and the oily residue was dissolved in hexane (3 mL). On cooling the solution to − 78 °C, dark violet crystals were obtained: yield 242 mg (61%); m.p. 72 °C (dec.). **5b–e**: A solution of **3** (397 mg, 0.87 mmol) in pentane (30 mL) was treated at 0 °C with an equimolar amount of **4b–e** and then stirred for 30 min at room temperature. Workup as described for **6a**; orange-yellow crystals: **5b**, yield 53%; m.p. 86 °C (dec.); **5c**, yield 57%; m.p. 86 °C (dec.); **5d**, yield 84%; m.p. 69 °C (dec.); **5e**, yield 89%; m.p. 74 °C (dec.). **6b**: A solution of **5b** (171 mg, 0.30 mmol) in pentane (20 mL) was stirred for 6 h at 35 °C. After concentration of the solution to about 3 mL and cooling to − 78 °C, dark violet crystals were isolated: yield 53%; m.p. 83 °C (dec.). **6c**: Prepared analogously to **6b**, but **5c** was stirred for 25 h at 60 °C in hexane: yield 67%; m.p. 97 °C (dec.). **6d**: A solution of **5d** (189 mg, 0.30 mmol) in benzene (20 mL) was irradiated for about 5 h at room temperature; the color changed from orange to red-violet. Workup as described for **6a**: yield 54%; m.p. 116 °C (dec.). **6e**: As described for **6d**: yield 59%; m.p. 107 °C (dec.). **8**: A solution of **3** (397 mg, 0.87 mmol) in pentane (30 mL) was treated at 0 °C with an equimolar amount of **7**. The bright yellow solid that precipitated was washed with pentane and dried in vacuo: yield 415 mg (90%); m.p. 102 °C (dec.). Satisfactory elemental analyses were obtained for all compounds.

Furfural as a Marker of DNA Cleavage by Hydroxylation at the 5′ Carbon of Deoxyribose**

By *Geneviève Pratviel, Marguerite Pitié, Jean Bernadou,** and *Bernard Meunier**

Besides naturally occurring nucleases which cleave DNA by phosphodiester bond hydrolysis, there is a growing interest in synthetic compounds that show DNA-cleaving activity.[1] The common feature of these systems is an oxidative attack on the sugars of the DNA backbone. DNA degradation is initiated by the abstraction of an H atom from a C–H bond of a deoxyribose, as also observed in DNA cleavage by radiolysis.[2, 3] The C–H bond cleaved depends on the DNA cleaver used. C4′–H is the major target of iron-bleomycin,[4] whereas the bis(*o*-phenanthroline)copper attacks at C1′–H.[1, 5] A hydrogen atom is abstracted from C5′–H′ (or H″) by neocarzinostatin and drugs related to calicheamicin.[6, 7] In the case of neocarzinostatin, two other minor routes of DNA sugar attack have also been described: at C1′ with cytosine release[8, 9] and at C4′ with thymine release.[10] A minor pathway at C1′ was also proposed in the bleomycin degradation of the hybrid poly(dA)·poly(rU).[11]

The artificial nuclease we used is a cationic manganese porphyrin, *meso*-tetrakis (*N*-methylpyridinium-4-yl)porphyrinatomanganese(III) pentaacetate (Mn-TMPyP), that has been shown to interact with DNA in the minor groove.[12] In the presence of a water-soluble oxygen-atom donor, such as $KHSO_5$, potassium monopersulfate, or magnesium monoperphthalate (MMPP), a high-valent manganese oxo porphyrin complex (reminiscent of the activated form of cytochrome P-450 capable of activating the C–H bond of saturated compounds) is generated in the close vicinity of DNA. Subsequent DNA cleavage is observed for nanomolar concentrations of the metalloporphyrin.[13] Previous analysis of the reaction products on a simplified model of DNA, polyadenylic acid or poly(dA), led us to propose the sugar C1′–H bond as the main target of this artificial nuclease.[14]

We wish to report here that, depending on the type of DNA substrate, the Mn-TMPyP/$KHSO_5$ system can hydroxylate deoxyriboses at the C1′ and/or C5′ carbon. The C1′ route has been confirmed through the release of 5-methylene-2-furanone (5-MF) as the product of deoxyribose oxidation.[5, 14] Evidence for the C5′ route is provided by the release of another oxidized sugar residue, furfural (FUR). To our knowledge, this is the first identification of furfural as a marker of hydroxylation at the 5′ carbon of deoxyribose in oxidative DNA cleavage. The quantitative comparison of the FUR/5-MF ratio is indicative of the relative reactivities of the activated Mn-TMPyP complex towards C5′ and C1′.

A typical experiment consisted of preincubation of DNA substrate (700 μM nucleotides) with Mn-TMPyP (35 μM) in 50 μL of pH 8 phosphate buffer (34 mM) and NaCl (100 mM) for 15 minutes. The reactions were initiated by the addition of $KHSO_5$ (2 mM). After 3 minutes at room temperature, the reactions were stopped by addition of pH 8 Hepes buffer (100 mM).[13b] Concentrations in brackets are final concentrations. The products released were analyzed by HPLC, either after 3 minutes at 20 °C or after a heating step at 90 °C for 15 minutes. Examples of HPLC chromatograms are shown in Figure 1 and the results are summarized in Table 1. The free bases are released at ambient temperature. No guanine is observed because of its high oxidizability under the experimental conditions. After heating, two other products were detected and have been identified as 5-MF[5, 14] and FUR by HPLC (Fig. 1) and by GC/MS.[15] The appearance of FUR correlates with an enhanced release of the corresponding bases during heating. Some of the variations in the results are

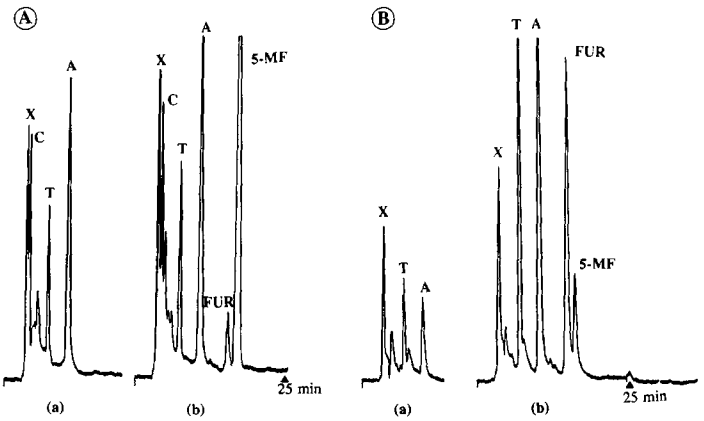

Fig. 1. Chromatograms of products released during the reaction of Mn-TMPyP/$KHSO_5$ with CT DNA, Ⓐ, and poly(dA)·poly(dT), Ⓑ, after 3 min at 20 °C (a) and 15 min at 90 °C (b). Nucleosil C_{18} 5 μ column eluted with 0.1 M triethylammonium acetate, pH 6.5, 5% acetonitrile, 0.5 mL min^{-1}; UV detection at λ = 254 nm (X: porphyrin degradation product).

[a] For reaction conditions see text. [b] All values (μM) represent the mean standard deviation from three measurements. Free G, owing to its high oxidizability, was not found in these experiments. [c] % = 100 × [FUR]/[5-MF] + [FUR]. [d] Poly(dG) was not tested owing to its special polymerization process in solution.

due to degradation of the bases through partial or, for guanine, complete oxidation by Mn-TMPyP/$KHSO_5$; also, FUR and 5-MF are slightly unstable. The quantitative results for the products listed in Table 1 should be supplemented by further kinetic studies. However, preliminary kinetic data indicate that our conclusions are largely valid. The last column of Table 1 reflects the ratio of attack at C5′ versus C1′. C1′ is still the main hydroxylation site for calf thymus DNA (CT DNA) and G-C polymers (the percent attack at C5′ is 12, 6, and 7% for CT DNA, poly(dG)·poly(dC), and poly[d(G-C)·d(G-C)][*]). Highly selective attack at C5′ is observed for A-T polymers (the percent attack at C5′ is 64 and 83% for poly[d(A-T)·d(A-T)] and poly(dA)·poly(dT), which suggests that the mechanism of DNA cleavage is highly sequence-dependent.

The molecular mechanism proposed to account for these product distributions is presented in Scheme 1. Hydroxylation of the C1′ carbon induces spontaneous release of the corresponding free base. Two subsequent βeliminations lead to 5-MF and leave two DNA strands terminated by phosphate groups. The first βelimination creates a 5′-phosphate end. This reaction probably takes place at ambient temperature because the addition of $NaBH_4$ before heating prevents the 5-MF release ($NaBH_4$ was allowed to react for 30 minutes and then was completely destroyed by acetone before increasing the temperature). $NaBH_4$ should not react with intermediate **I** but rather with **II** (Scheme 1).[16] On the other hand, hydroxylation of the C5′ carbon gives a C5′ aldehyde at one strand terminus and a 3′-phosphate at the other at ambient temperature. Upon heating, two βeliminations result in the formation of FUR, free base, and a 5′-phosphate terminus.

Both routes give rise to the same phosphate termini but not in the same order, and the sugar degradation products are different. In both cases a DNA single-strand break is created at ambient temperature.

DNA models suggest that the distance between H1′ on one strand and either H1′ or H5′ (or H5″) of deoxyribose (shifted by two or three base pairs in the direction of the 3′ end) on the opposing strand are very close. Thus, it is not so surprising that small changes in the interaction of the cleaving reagent with the DNA minor groove direct the reactivity from one target to the other.

Our results show that furfural is a convenient marker of the C5′ hydroxylation of DNA deoxyribose, just as 5-MF was previously shown to be a marker of the C1′ hydroxylation.[5, 14, 17] These two targets (C1′ on one strand and C5′ on the other strand) are often involved in bifunctional DNA-cleaving agents. When one active part of the molecule points inside the minor groove at C1′ of one DNA strand, the second active part is close to C5′, which is at the entrance of the minor groove on the other strand. The biradical intermediate of neocarzinostatin is an example. For manganese porphyrin complexes a similar explanation applies if the orientation of the axial ligand is colinear with the C1′–C5′ axis and the possible formation of the active manganese-oxo species at one of the two axial positions in *trans* configuration is also considered. Such subtle changes in the geometry of the interactions between cleaving reagent and DNA should give rise to dramatic changes in the selectivity of C–H bond activation of the deoxyribose units within the minor groove of DNA.

[*] d(G-C) represents an alternating copolymer consisting of guanine and cytosine deoxynucleotides; poly[d(G-C)·d(G-C)] is the hybrid formed from two such copolymers.

[15] A 50-μL sample was prepared as described in the text with poly(dA) · poly(dT) as DNA substrate. After the heating step, it was extracted with 300 μL of diethyl ether and the solvent was concentrated before injection in the GC/MS apparatus. GC/MS analyses were carried out with a Hewlett Packard 5890 gas chromatograph interfaced to a Hewlett Packard 5970 mass spectrometer. Gas-chromtography was carried out on a silica capillary column (12.5 m × 0.20 mm inner diameter) coated with cross-linked methylsilicone. Isothermal separation was performed at 80 °C, with the injector and interface maintained at 210 °C. Mass spectra were taken at 70 eV. In the heated sample a product with a GC retention time identical to an authentic sample of FUR gave a mass spectrum with a molecular peak (96) and fragmentations corresponding to FUR.

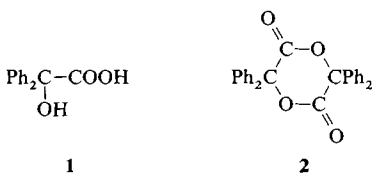
[17] The hydroxylation of the sugar C1′–H bond has also been described for γ-irradiation of DNA [2, 3]. However, without the thermal step(s) (formation of 5-MF from intermediate **I** of Scheme 1) but after acid hydrolysis of DNA, deoxyribonolactone, not 5-MF, is the observed sugar oxidation product.

The Structure of "Organic Permanganate"

By *Maree L. Burgess, Donald C. Craig,* and *Michael J. Gallagher**

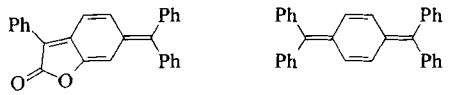
Over 120 years ago *Jena* reported[1] that the distillation of benzilic acid (**1**) gave a red-brown (actually "rotbraunes, empyreumatisch riechendes") oil. Other workers[2, 3] subsequently confirmed the formation of a deeply colored product in addition to carbon dioxide, diphenylacetic acid, and benzophenone. In 1911 *Staudinger*[4] showed that the dilactone **2** was formed on gentle heating and this decomposed at higher temperatures to give carbon dioxide, diphenylketene, and benzophenone as well as a deep red resin presumed to arise by polymerization of diphenyl ketene.



1 **2**

Eventually, in 1928, *Langenbeck* and *Langenbeck*[5] obtained from the pyrolysis mixture permanganate-colored crystals which they considered to be a dimer of diphenylketene on the basis of microanalysis and molecular weight data. As *Staudinger* had already obtained a colorless dimer of the ketene, the *Langenbecks* proposed that their dimer was in fact tetraphenylcyclobutanedione. There is, however, no obvious reason why this should be colored and almost immediately *Wittig* and *Lupin*[6] suggested an open-chain diradical variant. *Müller*[7] subsequently showed that the crystals were not paramagnetic, casting doubt on this interpretation, which was already considered unlikely as the compound is quite stable in air. Further studies[8, 9] over a number of years and using a variety of physical techniques failed to resolve the nature of this intriguing chromophore. We now report its structure.

Repetition of the *Langenbecks*' preparation, or *LeFevre*'s modification, afforded deep black-red crystals which possessed a pronounced purple cast by reflected light. The mass spectral molecular weight ($M = 374$)[10] immediately excluded all previous structures based on a dimer of diphenylketene ($M = 386$). ^1H and ^{13}C NMR spectra[10] were not particularly informative, though the latter showed only a single carbonyl absorption which was in the ester/lactone range ($\delta = 169.4$), suggesting that the chromophore was not quinonoid. A single-crystal X-ray analysis[11] has shown the structure to be the *p*-quinodimethane derivative **3** related to *Thiele*'s orange-yellow hydrocarbon **4**,[12] whose crystal structure has been recently determined.[13]



3 **4**

The structures of **3** and **4** are very similar, with distinct bond alternation and twisting of the Ph_2C group by ca. 15°, though of course **3** lacks the symmetry of **4**. The major difference is that **3**, excluding the phenyl groups, is significantly less planar than **4**. All atoms in the core of the molecule are displaced in the same direction (above the plane of the diagram) from the almost perfect plane through C1-C2-C4-C5-O1, the largest deviations being ca. 0.17 Å for C7 and C9.

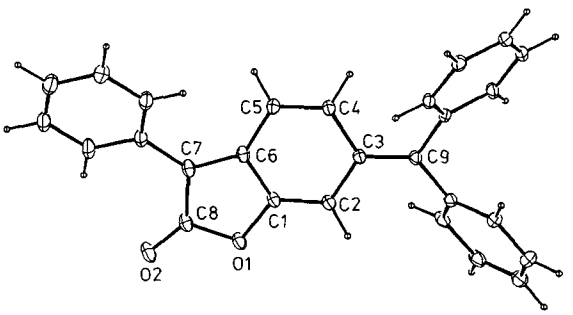


Fig. 1. Molecular structure of **3** (ORTEP). Selected bond lengths [Å] and angles [°]: C1-C2 1.346(3), C4-C5 1.353(3), C2-C3 1.448(3), C5-C6 1.422(3), C6-C7 1.387(3), C1-C6-C7 107.7(2), C2-C3-C9 122.1(2).

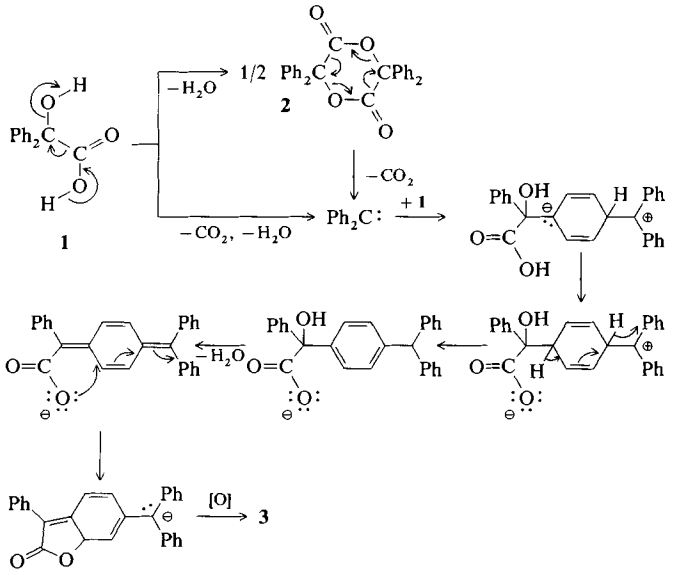
School of Chemistry, University of New South Wales
P.O. Box 1, Kensington, 2033 NSW (Australia)

[**] We thank the School of Chemistry for the award of a summer scholarship to *M. L. B.*

The bathochromic shift in the UV spectrum of **3** (λ_{max} = 463 nm in dioxane[9]) compared with **4** (λ_{max} = 426 nm in dioxane[14]) presumably reflects the extended conjugation resulting from formation of the furanone ring and the lower twist angle (ca. 27°) of the phenyl group on C7 compared with those for **4** (mean value ca. 43°).

A possible route to this compound is via the attack of diphenylcarbene on benzilic acid (Scheme 1).



Scheme 1. Possible mechanism for the formation of **3**

Cyclization and oxidation to form the furanone ring system could occur either before or after formation of the chromophore and the carbene may be envisaged as arising from **1** or **2** by pyrolysis.

Experimental Procedure

A mixture of benzilic acid (5 g) and anhydrous sodium carbonate (0.1 g) was heated rapidly and briefly (ca. 2 min) with a Bunsen flame. After cooling, the virtually black residue was dissolved in chloroform and washed with aqueous sodium bicarbonate and water. The dried extract was concentrated and chromatographed over silica gel (200 g) and eluted with chloroform. The second band off the column comprised a mixture of **3** and the dilactone **2**. A pure sample of **3** was obtained by recrystallization from a mixture of chloroform and ethanol (m.p. 168–172°; lit. [5, 9], 168°/169°). The yield was low, closer to that reported by *Le Fevre* (ca. 3%) [9] than by the *Langenbecks* (ca. 10%).

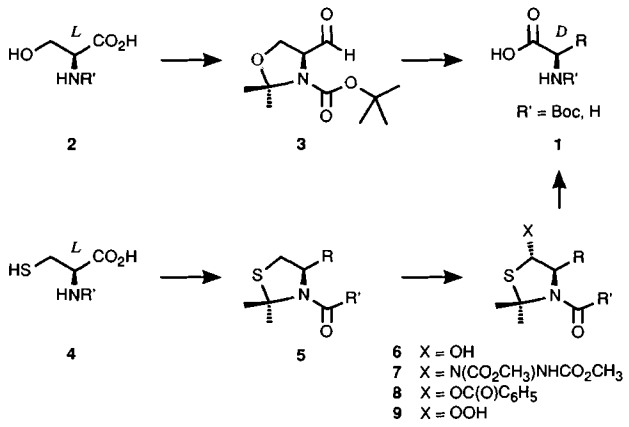
Synthesis of β,γ-Unsaturated D-α-Amino Acids from L-Cysteine**

By *Rudolf O. Duthaler**

Despite numerous new methods for the synthesis of α-amino acids in enantiomerically pure form,[1] there are only a few stereoselective routes to the sensitive β,γ-unsaturated amino acids,[2] which are of interest as enzyme inhibitors[3] or conformationally constrained receptor antagonists.[4] The L enantiomers are obtained conveniently by enzymatic resolution of racemates (e.g., Ref. [2f]). The D enantiomers **1** (for R see Table 1), on the other hand, can be synthesized from L-serine (**2**, R′ = H) (e.g., Ref. [2g, h, j, 4a]). A favored intermediate for this strategy is the astonishingly stable 4-formyloxazolidinone **3** introduced by *Garner* et al.[5] (Scheme 1). However, the oxidation of the hydroxymethyl group to the carboxylic acid is a pivotal disadvantage of this sequence, especially in the case of unsaturated compounds, because Pt/O_2[6] and Cr^{VI} reagents,[2h, 4a] the only means for this



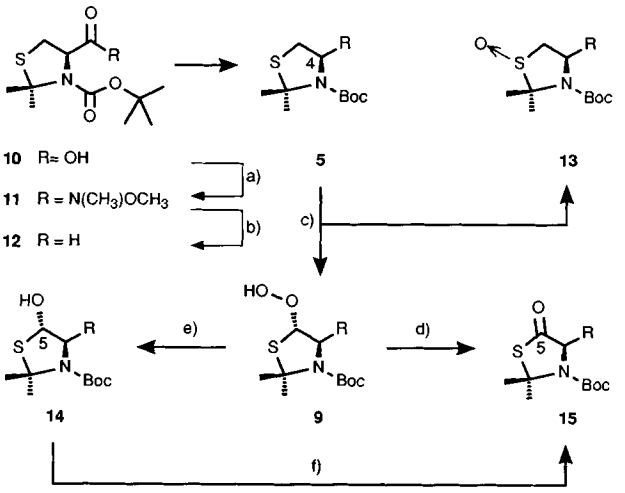
Scheme 1. Transformation of L-serine and L-cysteine to D-amino acids (for R see Table 1).

[*] Dr. R.O. Duthaler
Central Research Laboratories, Ciba-Geigy AG
Post Office Box, CH-4002 Basel (Switzerland)

[**] This work was presented at the autumn meeting of the Swiss Chemical Society and the Association of Swiss Chemists, October 19, 1990, in Bern; cf. *Abstracts of Communications and Posters*, p. 30.

transformation, are unacceptable, at least in industrial production, for economical and ecological reasons (low yields, price, toxicity, risks).[7] The *N*-acylthiazolidines **5**, derived from L-cysteine (**4**), offer an attractive alternative, since they can be oxidized by a variety of methods to stable hemithioacetals (**6**) or precursors thereof (**7**, **8**, and **9**).[8] We have now demonstrated that the elegant $^1O_2$ oxidation introduced by *Ando* et al.[8d-f] is compatible with substrates bearing *tert*-butyloxycarbonyl (Boc) protecting groups as well as with unsaturated substrates. Further, the hydroperoxides **9** can be transformed readily into 5-thiazolidinones, which, upon hydrolysis, afford β,γ-unsaturated D-amino acids of high enantiomeric purity (Scheme 1).

N-Boc-2,2-dimethylthiazolidine-4-carboxylate (**10**)[8a, 9] is transformed via amide **11** into the aldehyde **12**, an intermediate for the thiazolidines **5d**–**k**[10] (Scheme 2, Table 1).



Scheme 2. Synthesis and singlet O_2 oxidation of *N*-Boc-thiazolidines. a) *N*-Methoxy-*N*-methylamine/dicyclohexylcarbodiimide/EtOAc, room temperature (RT) (74%); b) $LiAlH_4/Et_2O$, 0°C (95%); c) *meso*-tetraphenylporphyrin (1–2 ppt)/O_2/*hv* (125 W, halogen)/THF, −78°C; d) Ac_2O/Et_3N/THF, −78°C; e) Ph_3P/THF, −78°C to RT, f) DMSO/oxalyl chloride/$EtNiPr_2$/CH_2Cl_2, −78°C to RT.

Table 1. Transformation of thiazolidines **5** to **14** and **15**[a].

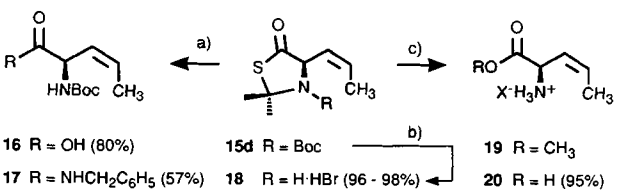
[a] Structures and reaction conditions are given in Scheme 2. [b] The yields are not optimized, with the exception of **11**, **5d**, and **5j**. [c] The polar sulfoxides **13** (mixtures of epimers) have usually not been isolated, since the separation from $(Ph)_3PO$ is difficult. [d] The overall yield of **15** from **5** (or **11**) via **14** is given in parentheses. [e] $[\alpha]_D = -145°$ ($c = 0.58$, $CHCl_3$), the optical purity is most probably ≥ 95%, since this β-dicarbonyl compound is racemized less readily than the corresponding 5-thiazolidinone from **15d** (cf. [21]), which is isolated with ≥ 95% *ee*. [f] Racemic, $[\alpha]_D = 0$. [g] $[\alpha]_D = -18°$ ($c = 0.3$ $CHCl_3$), presumably of low optical purity. [h] Reaction in toluene. [i] Reaction in $tBuOCH_3$. [j] Reaction in CH_2Cl_2. [k] The alcohol function was protected temporarily as its trimethylsilyl ether.

$^1O_2$ oxidation leads then to the hydroperoxides **9**; the only side products of these otherwise clean reactions are the sulfoxides **13** corresponding to the "normal" course of sulfide oxidation.[12] After reduction of **9** with triphenylphosphane, the hemiacetals **14** can be isolated in satisfactory yields by chromatography. Crucial for the feasibility of this method as opposed to other $^1O_2$ processes,[13] are its mildness and the high substrate concentrations (12% wt/vol.) tolerated. This allows application to reactive substrates (**5i**) or compounds otherwise sensitive to $^1O_2$ oxidation (**5e**–**g**). As demonstrated by the examples **5j**,**k**, complex side chains can be constructed in analogy to the serine method.[2g, h, j, 4a] Bulky substituents at N(3) and C(4) appear to increase the rate of oxidation and favor the formation of **9** and therefore **14** (cf. Table 1, **11**, **5a**–**c**).[14] The effect of solvent, normally THF, has been investigated for **5d**. Whereas more hydroperoxide **9** is formed in *tert*-$BuOCH_3$ at the expense of **13**, the sulfoxides **13** are the sole products in CH_2Cl_2.

The 5-hydroxythiazolidines **14** are amenable to oxidation by the method of *Swern* et al.[15] with the exception of the product obtained from **5a**. Preferable, however, would be a direct transformation of the hydroperoxides **9** to the 5-thiazolidinones **15**. While such formal eliminations of water are known for various secondary alkyl hydroperoxides,[16] no such transformation of an α-thioalkylhydroperoxide has been reported yet. After many unsuccessful experiments[17] it was found surprisingly that, for all cases studied so far, a clean transformation of the hydroperoxides **9** to **15** can be effected by Ac_2O/Et_3N at −78°C. The yields are significantly better than those of the two-step procedure via **14** (Scheme 2, Table 1). Unwanted acetylations of alcohols like **5h** can be avoided by temporary protection as silyl ethers.

The final transformation to D-amino acids has been optimized for the thiol lactone **15d** (Scheme 3). Treatment with LiOH gives the *N*-Boc-protected acid **16** with 78% *ee*;[18] the amide **17**[19] is obtained with dimethylaluminum amide.[20] Since the thiol lactone **15d** is slowly racemized by Et_3N at temperatures above −30°C,[21] partial racemization upon cleavage with nucleophiles can be expected. Acid-catalyzed hydrolysis is therefore preferable. Treatment with Me_3SiBr/phenol to afford **18**, in analogy to Ref. [22], is the best method for the removal of the Boc protection. In Me_3SiBr/CH_3OH, **18** is then slowly transformed (one week) into methyl ester **19** (≥ 99% *ee*).[11, 23] Water in turn effects the hydrolysis of **18** to **20** (86% *ee*) in nine days without acid catalyst. The 5-thiazolidinone **18**, however, is cleaved more efficiently (one to two days) in 1 N HCl, affording the product **20** with higher optical purity (94–96% *ee*).[24] Compared to enzymatic methods (e.g., Ref. [2f]), this type of transfor-



Scheme 3. Transformation of 5-thiazolidinones to D-amino acids. a) LiOH/H_2O-THF (→ **16**, 78% *ee*); $(CH_3)_2AlNHCH_2C_6H_5$/toluene (→ **17**); b) $(CH_3)_3SiBr$ (2 equiv.)/phenol (6 equiv.)/CH_2Cl_2; c) $CH_3OH/(CH_3)_3SiBr$ or $(CH_3)_3SiCl$ (→ **19**, ≥ 99% *ee*); 1 N HCl (→ **20**, 95% *ee*).

mation gives D-amino acids of similar quality but with fewer structural restrictions. This new route offers advantages over the synthetic methods so far available,[1, 2] especially when sensitive compounds are involved. In addition to D enantiomers, racemization of either aldehyde **12**[10] or 5-thiazolidinones **15**[21] allows the preparation of racemic amino acids. Thanks to improved methods for the preparation of D-cysteine,[25] L enantiomers can be obtained with little more effort.

[7] As described recently (W. D. Lubell, T. F. Jamison, H. Rapoport, *J. Org. Chem. 55* (1990) 3511–3522), such an oxidation of a compound with a triple bond is effected by transformation to an unstable α-amino aldehyde with *N*-chlorosuccinimide/Me_2S, followed by $NaClO_2$ oxidation. It is questionable, however, whether this procedure is applicable to olefinic substrates..

Facile N–H Cleavage of Ammonia**

By *Robert Koelliker* and *David Milstein**

Ammonia is one of the most abundant and useful industrial chemicals[1] and its direct, catalytic functionalization with organic substrates, such as olefins, is of much current interest.[2] Most of the chemistry of ammonia is dominated by its nucleophilicity. Our strategy is to develop new modes of reactivity based on oxidative addition of ammonia to a metal center yielding, in the first step, amido hydride complexes. Such an N–H activation approach has already led to catalytic stereoselective addition of aniline to norbornene.[3]

Examples of oxidative addition of ammonia to a metal center in solution are rare.[4] We now report that, upon coordination of ammonia to a low-valent metal olefin complex, the metal center may become electron-rich enough, even in the absence of other strong σ donors, to induce N–H cleavage of a subsequent incoming ammonia molecule. This oxidative addition process takes place under exceedingly mild conditions and leads to complexes of interest in their own right.

When a slurry of the Ir^I complex **1** in THF is treated with excess ammonia at 25 °C, a homogeneous red solution containing mainly the adduct **2** is immediately formed.[5] After two minutes at 25 °C (or 18 hours at −50 °C) a yellow precipitate starts to form. Isolation of the precipitate after two hours under an NH_3 pressure of 35000 Pa reveals that it consists of the Ir^{III} complexes **3b** and **4b** in the ratio of 1:3 (combined yield 32% based on **1**[6]). Complex **5** can be iso-

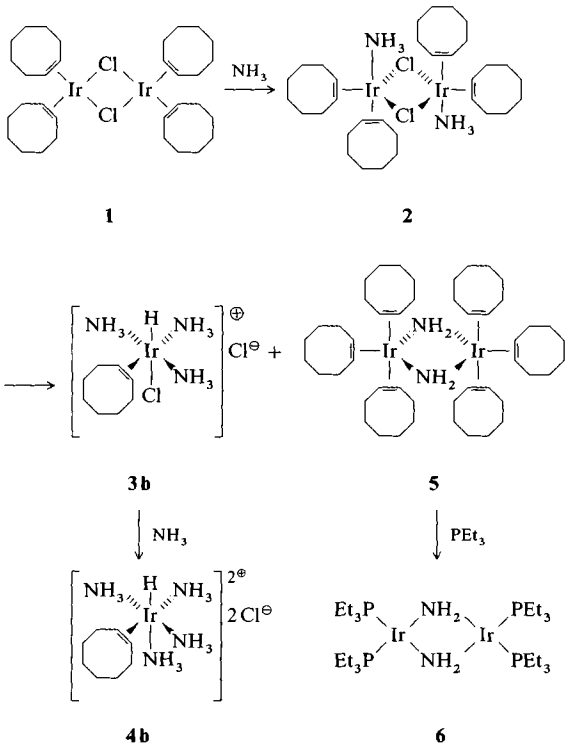
lated from the red mother liquor in 32% yield.[6] When ND_3 is used, the corresponding Ir-D complexes are formed (as detected by IR and ^{2}H NMR), thus excluding participation of C–H activation processes. Anion exchange of complexes **3** and **4** with $NaPF_6$ leads to the more soluble complexes **3a** and **4a**, which were identified by ^{1}H and ^{13}C NMR, as well



as by ^{2}H and ^{15}N NMR of the labeled complexes obtained from the reaction with NH_3 and $^{15}NH_3$, respectively. ^{15}N NMR of a representative product mixture of **3a** and **4a** is shown in Figure 1. The ammine ligand *trans* to the hydride in **4a** appears as a doublet of quartets as a result of coupling with both the N–H protons and the hydride ligand.

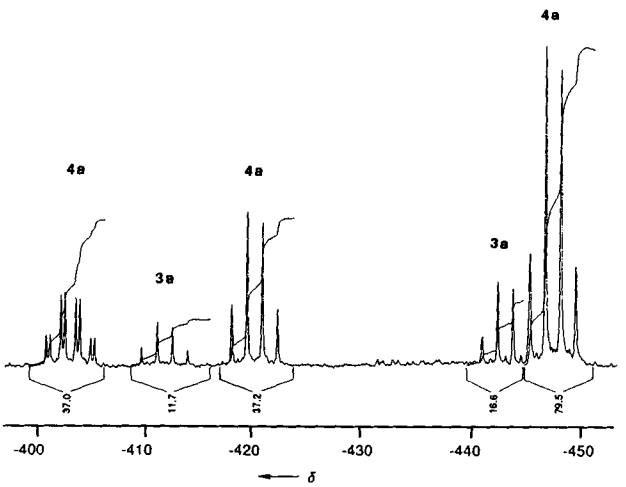


Fig. 1. ^{1}H-coupled ^{15}N NMR spectra of a mixture of **3a** and **4a** in THF.

Complexes **3** and **4** are the first reported ammine olefin hydride complexes. The fairly unusual *cis* arrangement of olefin and hydride ligands is probably thermodynamically favored in this electron-rich system over that of the corresponding alkyl complex because of stabilization provided by back-donation to the olefin, the only π acceptor present.

Reaction of the monocationic complex **3a** with ammonia leads to the dicationic **4a**, indicating that **3b** is probably an intermediate in the formation of **4b**. The unexpected displacement of the chloride rather than the olefin ligand and the retention of the *cis* arrangement of olefin and hydride ligands, even in the presence of added ammonia, are again a reflection of considerable back-donation to the olefin, promoted by the strong σ-donor character of the ammine ligand and its inability to participate in π back-bonding.

In the coupled ^{15}N NMR spectrum at $-50°$, the air-sensitive Ir^I complex **5** exhibits only one triplet at $\delta = -372.8$ ($J = 68.6$ Hz), indicating one type of bridging NH_2 ligand. The $^{13}C\{^1H\}$ NMR spectrum shows one broad signal for the olefinic carbons even at $-30°C$, compatible with fluxional behavior. Complex **5** is the first reported amido olefin complex. Its saturated nature in solution, which is uncommon for a d^8 complex, and its surprising substitutional stability towards excess ammonia may both reflect the high electron density on this Ir^I amide complex. In contrast, facile substitution of the cyclooctene ligand occurs by the soft PEt_3, leading to complex **6**, which is also obtained by deprotonation of **7** with lithium diisopropylamide.[7] The difference in substitutional activity of ammonia and PEt_3 is likely to be influenced by π back-bonding to the phosphane.

Table 1. Selected physical data for compounds **2**, **3a**, **4a**, **5**, and **6** [a].

2: IR (Nujol): $\tilde{\nu}$[cm^{-1}] = 3296(s), 3230(s), 3172(s) (ν(NH), ν(NH)/ν(ND) = 1.34). ^{1}H NMR: $\delta = 2.02$ (br, NH_3), $^{13}C\{^1H\}$ NMR: $\delta = 69.9$ (br), 55.5 (br), 30.9 (br, 2C), 29.8, 28.6, 26.9, 26.5. ^{15}N NMR: $\delta = -377.3$ (q, $J = 70.1$ Hz).
3a: ^{1}H NMR ([D$_8$]THF): $\delta = -19.66$ (s, 1H), 2.96 (s, br, 6H; $^{15}NH_3$:d, $J = 70.4$ Hz), 4.18 (s, br, 3H; $^{15}NH_3$:d, $J = 71.0$ Hz). ^{2}H NMR: $\delta = -19.39$ (s). $^{13}C\{^1H\}$ NMR ([D$_8$]THF): $\delta = 63.6$, 31.6, 27.3, 26.9. ^{15}N NMR: $\delta = -411.8$ (q, 1N, J(NH) = 71.2 Hz), -442.8 (q, 2N, J(NH) = 70.3 Hz).
4a: IR (neat) $\tilde{\nu}$[cm^{-1}] = 3367(s), 3305(s) (ν(N–H), ν(NH)/ν(ND) = 1.34); 2928(s), 2859(s) (ν(C–H); 2209(m) (ν(Ir–H), ν(IrH)/ν(IrD) = 1.38); 1633(m) (δ(N–H)). ^{1}H NMR ([D$_8$]THF): $\delta = -18.05$ (s, 1H; $^{15}NH_3$: d, $J = 19.1$ Hz), 3.04 (s, br, 6H; $^{15}NH_3$:d, $J = 70.3$ Hz), 3.63 (s, br, 3H; $^{15}NH_3$:d, $J = 68.5$ Hz), 4.35 (s, br, 3H; $^{15}NH_3$:d, $J = 70.6$ Hz). ^{2}H NMR: $\delta = -17.74$(s). $^{13}C\{^1H\}$ NMR ([D$_8$]THF): $\delta = 63.7$, 31.3, 26.9, 26.7. ^{15}N NMR: $\delta = -403.2$ (dq, 1N, J(NH) = 68.6 Hz, J(NIrH) = 18.9 Hz), -420.0 (q, 1N, J(NH) = 70.8 Hz), -447.2 (q, 2N, J(NH) = 70.1 Hz).
5: IR (Nujol): $\tilde{\nu}$[cm^{-1}] = 3393w, 3270w, 3252w (ν(N–H); ν(NH)/ν(ND) = 1.34 and 1.36. ^{15}N NMR: ($-50°C$): $\delta = -372.8$ (t, J(NH) = 68.6 Hz). $^{13}C\{^1H\}$ NMR: $\delta = 60.5$(br), 31.1, 30.2, 27.0. ^{1}H NMR: $\delta = 1.03$ (s, br, 2H, mit $^{15}NH_3$: d, $J = 67.9$ Hz), 1.2–2.4 (m, 42H).
6: ^{15}N NMR: $\delta = -415.2$ (tt, J(NH) = 68.3 Hz, J(PN) = 32 Hz. $^{31}P\{^1H\}$ NMR (THF): $\delta = +3.5$ (s; ^{15}N:d, $J = 31.0$ Hz).

[a] The standard for ^{1}H (270 MHz), ^{13}C (125.76 MHz), and ^{2}H NMR (41.45 MHz) spectra was ext. TMS; for ^{15}N NMR (50.70 MHz) spectra, ext., neat CH_3NO_2; for ^{31}P NMR (109.29 MHz) spectra, ext. 85% H_3PO_4, internal capillary in the corresponding solvent. ^{2}D NMR and ^{15}N NMR were recorded from complexes obtained from reactions with ND_3 and $^{15}NH_3$, respectively [10]. Unless otherwise stated, ^{1}H and ^{13}C NMR spectra were recorded for C_6D_6 solutions, ^{2}H NMR spectra for THF solutions, and ^{15}N NMR spectra for THF/[D$_8$]THF solutions.

$[\{Ir(PEt_3)_2(\mu\text{-}NH_2)(NH_3)(H)\}_2]Cl_2$ **7**

Although ammine complexes of late transition metals are quite common,[8] especially in high oxidation states, they have not been reported to undergo N–H activation in the absence of other σ-donor ligands. Indeed, starting with a low-oxidation-state precursor containing loosely bound ligands, we observed novel reactivity which is strongly influenced by the σ-donor properties of ammonia. This leads to

uncommon complexes with unique features. The overall reactivity pattern observed here is substantially different from that of electron-rich Ir^I phosphane complexes with ammonia,[4c] perhaps because of the better ability of phosphanes to stabilize the soft Ir^I metal center and the steric constraints imposed by these ligands. Indeed, the reaction described here, which occurs even at $-50\,^{\circ}C$, is to our knowledge the fastest reported ammonia oxidative addition to a transition-metal center in solution.[9]

We are currently studying the mechanism and scope of this unusual N–H cleavage process and the chain of events leading to the final products. The advantages of using ammonia as both a substrate and ligand for potential catalysis is also being explored.

[5] We also observe a small amount of the monomeric, square-planar complex *cis*-$[(C_8H_{14})_2Ir(NH_3)Cl]$, which exhibits sharp vinylic ^{13}C NMR signals, as opposed to the broad ^{13}C NMR signals of **2**. The broadness is probably a result of fluxional behavior expected in a trigonal-bipyramidal complex. Free cyclooctene is not observed (^1H NMR), thus excluding dissociative equilibria.

[6] The maximum theoretical yield is 50%.

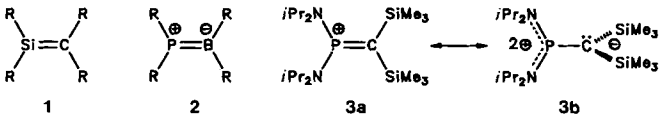
[9] A mechanism based on deprotonation of an ammine ligand by ammonia is highly unlikely since (1) deprotonation of Ir^{III}-NH_3 would be preferred over that of Ir^I-NH_3 and formation of at least some Ir^{III}-NH_2 would be expected, but none is observed, (2) the Ir^{III}-NH_3 complexes **3** and **4** do not undergo deprotonation even in the presence of a large excess of ammonia, (3) reaction of **4a** with $KN(SiMe_3)_2$ leads to deprotonation of Ir-H (and not of Ir-NH_3), and (4) equivalent amounts of Ir^{III} and Ir^I complexes are formed, regardless of the ammonia concentration employed.

[10] Complexes **4a**, **5**, and **6** were obtained as pure solids. Complex **2** was isolated together with minor amounts of its monomer. Complex **3a** was obtained in a mixture with **4a**. The structures of **3a** and **4a** were further confirmed by substitution reactions with PEt_3.

Methylene Phosphonium Ions**

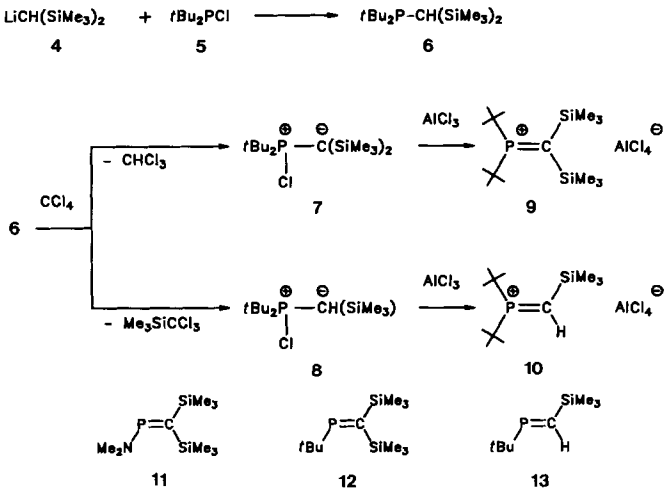
By *Hansjörg Grützmacher** and *Hans Pritzkow*

Stable silaethenes **1**[1] and phosphinoboranes **2**[2] are well-known. In contrast, the methylenephosphonium ion **3**, which is isostructural with these compounds, could only recently be completely characterized.[3] Although for steric reasons the halves of the molecule are twisted through 60° relative to one another, the P–C distance of 1.62 Å is very short, which can be attributed to strong electrostatic interactions.[4] Variation of the substituents at the P or C atom, or both, should change the character of the P–C bond. Thus the synthesis of P-alkylated methylene phosphonium ions, which we now report, is interesting.



1 **2** **3a** **3b**

The reaction of lithiobis(trimethylsilyl)methane **4**[5] with di-*tert*-butylchlorophosphane **5** in THF afforded quantitatively phosphane **6**.[6] Oxidation of this compound with CCl_4[7] in hexane led to loss of $CHCl_3$ and the concomitant formation of the chloro-substituted phosphorus ylide **7**, whereas the reaction at $-78\,^{\circ}C$ in CH_2Cl_2 yielded ylide **8** exclusively, with loss of Me_3SiCCl_3. The abstraction of chloride from $(iPr_2N)_2ClP^{\oplus}$–$C^{\ominus}(SiMe_3)_2$ by aluminum trichloride to form **3** was not successful,[9] but the corresponding reactions with **7** and **8** yielded the desired methylene phosphonium ions **9** and **10**, respectively.[10]



4 **5** **6** **7** **8** **9** **10** **11** **12** **13**

Rapid workup of the reaction mixtures at temperatures below $-30\,^{\circ}C$ allowed the isolation of **9** and **10** as colorless, crystalline solids. They may be stored in the solid state at $-30\,^{\circ}C$, but decompose in dichloromethane solution.

The NMR spectra of **9** and **10** differ greatly from those of **3** (Table 1). The resonance signal of both the phosphorus

Table 1. Selected NMR data of **3**, **9**, **10**, **11**, **12**, and **13** [a].

Cmpd.	$\delta(^{31}P)$	$\delta(^{13}C)$	$^1J(CP)$ [Hz]	Ref.

atom and the carbon atom of the double bond are strongly shifted to lower field relative to **3**. Comparison with **11**,[11] **12**,[12] and **13**[13] shows that the chemical shifts of the sp^2 carbon atoms in **9** and **10** lie among the typical values for phosphaalkenes. Predictably, the ^{31}P NMR signals of **9** and **10** are strongly shifted to higher field with respect to the corresponding signals in **12** and **13**, as a result of the increase in the coordination number of the phosphorus atom. On the grounds of these NMR data, **9** and **10** may be considered analogues of olefins, while in **3** interaction with the lone pairs of the amino groups compensates for the electron deficiency at the phosphorus atom. The "double bond" between the phosphorus and carbon atoms in **3** has a pronounced ylide character.

Because of the facile decomposition of **9** and **10** in solution, only crystals of **10** have been obtained, though in poor quality, by rapid crystallization from *n*-hexane/CH_2Cl_2. The X-ray structure analysis[14] could give only qualitative information about the molecular geometry, but indicates that the phosphorus atom is in an almost planar environment (sum of the bond angles: 359°C) and the halves of the molecule are twisted 11° relative to one another. The length of the P–C double bond is 1.69(4) Å, which lies in the range typical of phosphaalkenes. The cations and anions are separated in the crystal (shortest P–Cl distance: 3.9 Å).

Remarkably, in both the ^1H and ^{13}C NMR solution spectra of **10**, even at temperatures as low as −90 °C, the signals of the *tert*-butyl groups are equivalent, from which we conclude that the rotational barrier for the P–C multiple bond is unusually low compared with phosphaalkenes.

The reactivities of **3**, **9**, and **10** also differ widely. Whereas only nucleophilic attack on the phosphorus atom is available to **3**,[3] **9** and **10** react rapidly with 2,3-dimethylbutadiene at room temperature, in spite of steric hindrance of the P–C bond. (The reaction of **10** is exothermic!) The product from **9** in this reaction is predominantly **14**, formed by an ene reaction, while the sterically less hindered **10** undergoes exclusively a [2+4] cycloaddition to yield **15**.[15] The ene reaction is, to our knowledge, not yet described for phosphaalkenes, but is often observed in the chemistry of the silaethenes **1** and underlines their close relationship to **9** and **10**.[16]

[10] Preparative details: **7**: Compound **6** (3.04 g, 10 mmol) was dissolved in dry, degassed *n*-hexane (20 mL), and CCl_4 (4.62 g, 30 mmol) was added at −78°C. The reaction vessel was then warmed to room temperature and stirred for 3 h. Thereafter all volatile components were removed under vacuum, CH_3CN (10 mL) was added to the bright yellow, oily residue, and the mixture was solidified at −30 °C. Further purification of **7** can be achieved by sublimation at 100°C/10^{-1} Torr. M.p. 127°C; $^{31}P\{^1H\}$ NMR (C_6D_6): $\delta = 105.9$; ^{13}C NMR (C_6D_6): $\delta = 8.5$ (d, $^3J(PC) = 3.7$ Hz, $^1J(SiC) = 52.9$ Hz, $SiCH_3$), 27.65 (d, $^1J(PC) = 130.1$ Hz, $P^{\oplus}$-$C^{\ominus}$), 28.68 (d, $^2J(PC) = 3.5$ Hz, CCH_3), 44.3 (d, $^1J(PC) = 39.3$ Hz, CMe_3); ^1H NMR (C_6D_6): $\delta = 0.46$ (s, 18H, $SiCH_3$), 1.12 (d, $^3J(PH) = 16.4$ Hz, 18H, CCH_3); ^{29}Si NMR ($CDCl_3$, $T = 230$ K): $\delta = -2.43$ (d, $^2J(PSi) = 1.8$ Hz), −11.33 (d, $^2J(PSi) = 23.3$ Hz). MS (EI, 70 eV): *m/z* 338 ($M^{\oplus}$, 5%), 323 ($M^{\oplus}-CH_3$, 7.5), 267 (5), 226 (7), 211 (9), 147 (11), 120 (13), 73 (Me_3Si, 46), 57 (Me_3C, 100). **9**: Compound **7** (1 g, 3 mmol) was dissolved in CH_2Cl_2 (10 mL) and added dropwise by syringe to a suspension of freshly sublimed $AlCl_3$ (0.45 g, 3.4 mmol) at −78 °C. The resulting pale yellow solution was stirred for 10 min and then rapidly separated from unreacted $AlCl_3$ by filtration without warming. The solvent was thereafter removed in vacuum at −30–−10 °C. The crystalline residue was washed with *n*-hexane and dried in vacuum; yield 80–90%. ^{13}C NMR (CD_2Cl_2): $\delta = 5.1$ (d, $^3J(PC) = 6$ Hz, $^1J(SiC) = 54.5$ Hz, $SiCH_3$), 31.4 (s, CCH_3), 54.6 (d, $^1J(PC) = 8.7$ Hz, CMe_3), 178.8 (d, $^1J(PC) = 8.6$ Hz, P = C); ^1H NMR (CD_2Cl_2): $\delta = 0.48$ (s, 18H, $SiCH_3$) 1.75 (d, $^3J(PH) = 18.5$ Hz, 18H, CCH_3); ^{27}Al NMR (CD_2Cl_2): $\delta = 103.6$. **10**: Analogous to **9**, from **8** (1 g, 3.7 mmol) and $AlCl_3$ (0.56 g, 4.2 mmol). ^{13}C NMR (CD_2Cl_2): $\delta = 1.2$ (d, $^3J(PC) = 6.3$ Hz, $SiCH_3$), 30.3 (d, $^2J(PC) = 1.4$ Hz, CCH_3), 47.5 (d, $^1J(PC) = 10.6$ Hz, CMe_3), 149.6 (d, $^1J(PC) = 45.2$ Hz, P = C); ^1H NMR (CD_2Cl_2): $\delta = 0.11$ (d, $^4J(PH) = 1$ Hz, 9H, $SiCH_3$), 1.43 (d, $^3J(PH) = 18.8$ Hz, 18H, CCH_3), 7.75 (d, $^2J(PH) = 36.7$ Hz, 1H, CH); ^{27}Al NMR (CD_2Cl_2): $\delta = 103.6$. The chloride abstraction from **7** or **8** failed with $GaCl_3$ or $SbCl_5$.

[16] With silaethenes the [2+4] cycloaddition product is often observed in a mixture with products of the ene reaction; see, for example, N. Wiberg, M. Link, G. Fischer, *Chem. Ber. 122* (1989) 409

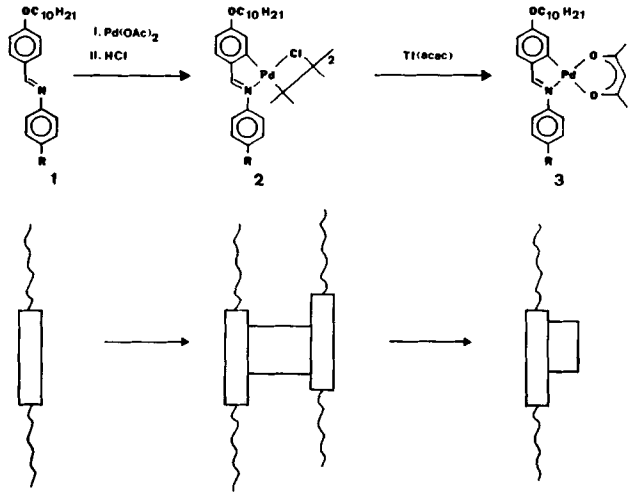
Effects of Perturbed Symmetry: Low-Melting Stable Mesogens Based on *ortho*-Palladated Imines**

By *María Jesús Baena, Pablo Espinet,* María Blanca Ros,* and *José Luis Serrano**

Among the rapidly growing family of metallomesogens (liquid crystals containing coordinated metals),[1] a minority are organometallic compounds. Cyclometalated palladium complexes derived from azobenzenes,[2] azomethines,[3] azines,[4] or related ligands[5] are a distinct subclass mostly constituted by halogen-bridged dimers, which can be further elaborated. Thus, replacement of the halide by carboxylate has provided mesogens based on a novel open-book molecular shape.[4] Such mesogens offer a novel approach to introducing ferroelectric properties as well as [6] the possibility of tuning the mesogenic properties by varying the bridging carboxylate.[7]

A drawback of these cyclopalladated systems is their high melting and clearing temperatures (usually > 130 and $> 200°$ C, respectively), which cause thermal decomposition of the products during prolonged studies. In the azomethine and azine systems, moreover, there is a clear predominance of smectic mesophases, and nematic mesophases are a rarity.

Both properties suggest that excellent packing of the molecules in these systems leads to high lattice energies and ordered mesophases. Consequently, perturbing the highly symmetric molecular shape might lead to lower melting points and less ordered mesophases. We describe here a successful application of this idea. A different approach to this idea of producing asymmetry in the long molecular axis of a rodlike molecule[8] has yielded low-melting mesogens, but their properties cannot be compared with the corresponding symmetrical molecules.



Scheme 1. Syntheses and sketch of molecular shapes of **1**–**3**. **a**, R = H; **b**, R = OC_2H_5; **c**, R = O-*n*-C_6H_{13}; **d**, R = O-*n*-$C_{10}H_{21}$.

Azomethines **1** were *ortho*-palladated to give the binuclear complexes **2** and these were treated with Tl(acac) (acac = acetylacetonate) to give the mononuclear species **3** (Scheme 1). All the compounds gave elemental analyses, ^{1}H NMR spectra, and IR spectra in full agreement with the proposed structures. The chemical transformations result in changes in molecular shape from the rodlike (or I-shaped) molecules **1** to the H-shaped (or ladderlike) binuclear complexes **2** and finally to the P-shaped (or "humpbacked") mononuclear compounds **3**.

The thermotropic behavior of **1**, **2**, and **3** was studied by optical microscopy and differential scanning calorimetry (DSC). Their thermal data are summarized in Table 1. The

[a] C, crystal; N, nematic; S_A, smectic A; S_C, smectic C; S_F, smectic F; I, isotropic liquid. [b] Monotropic transition. [c] Combined enthalpies. [d] Optical microscopy data.

nematic phase (N) of complexes **3** was assigned on the basis of their optical textures. The photomicrograph of the nematic phase of **3c** at 121°C (Fig. 1) shows the characteristic[9] two- and four-brush isogyres at the termination of disclination lines. Smectic A (S_A) and C (S_C) phases are observed showing optical mielinic, focalconic, and schlieren textures similar to those of classical rodlike organic compounds but more viscous.

The free ligands **1** are typical calamitic compounds, like other previously described azomethines,[3, 10] and all except **1a** are mesogenic. Except **3a**, all the palladium complexes are also liquid crystals (Fig. 2). The binuclear complexes **2** show the behavior typical of this type of molecule: they exhibit high melting ($> 130°$ C) and clearing ($> 180°$ C) temperatures and decomposition generally occurs at the clearing point.

A dramatic change in properties is observed in the corresponding mononuclear complexes **3**, which give rise to

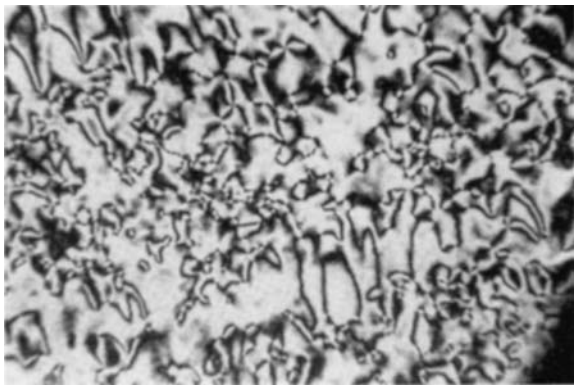

Fig. 1. Photomicrograph of **3c** in its nematic phase at 121°C viewed between crossed polars.

mesophases at temperatures below 90°C, about 50°C lower than the parent binuclear compounds **2**. The clearing temperatures are lowered to about 125°C with the consequence that the compounds can be taken from the crystalline to the isotropic state repeatedly without decomposition. This is important with respect to their eventual processability.

A second noticeable property of the mononuclear complexes **3** is the consistent occurrence of nematic (N) mesophases, which is unusual in the *ortho*-palladated binuclear species **2** we have previously described.[3] (The accessibility of a nematic phase facilitates ordered arrangements in liquid-crystal-based devices.) Broadly speaking, a decrease of order in the mesophase is observed such that S_C behavior in **2** leads to S_A behavior in **3**, and S_A behavior in **2** leads to N behavior in **3**. Thus, the only previously reported[5] acac mononuclear complex containing an *ortho*-palladated phenyl-substituted pyrimidine ligand was monotropic (S_A), whereas its parent binuclear complex displayed an enantiotropic (S_A) mesophase.

Moving from I-shaped "one-dimensional" molecules **1** to highly symmetrical H-shaped "two-demensional" structures **2** greatly increases the range of mesogenic behavior, but at the expense of high transition temperatures and a scarcity of nematic phases. The new P-shaped "two-dimensional" symmetry-perturbed mononuclear species **3** are an excellent compromise, since they show mesophase ranges broader than the free ligands, melting temperatures even lower than the free ligands, and a less complex mesogenic behavior. The complete family of I-, H-, and P-shaped mesogens, which can be extended to many related complexes, offers a very promising horizon in the tailoring of mesogenic materials.

phenylglycine and the corresponding 4-OH derivative, D-serine, and D-thienylglycine are incorporated into the side chains of important β-lactam antibiotics;[1] D-valine is one of the starting materials used to prepare the pyrethroid fluvalinate.[2] Rapid progress in the development of active peptides, in particular, requires the ready availability of a large number of structurally diverse D-amino acids.[3] Candidates include the D enantiomers of protein amino acids, of other naturally occurring amino acids, and of amino acids not present in nature.

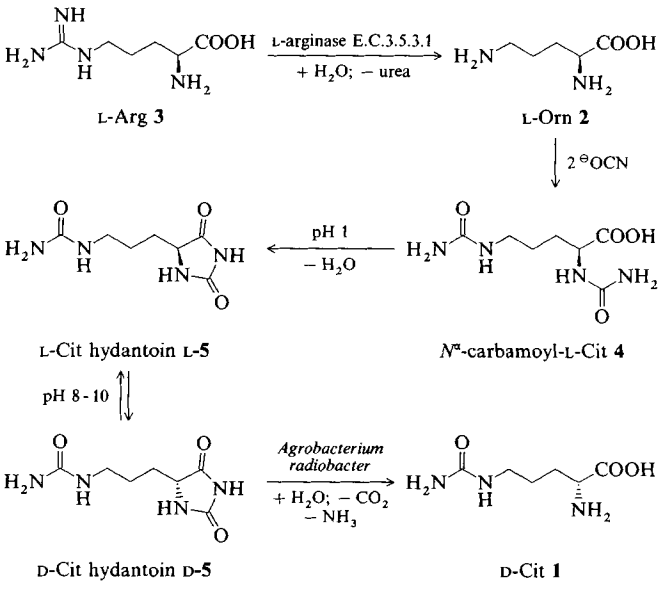
Recently, therapeutic concepts based on influencing the formation of releasing hormones have been developed. A prominent example is the decapeptide LH-RH (luteinizing hormone releasing hormone or gonadorelin), a member of the liberin family that is formed in the hypothalmus. LH-RH induces release of gonadotropins, that is, the sex hormones follitropin (FSH) and lutropin (LH).

Potent LH-RH agonists and antagonists have potential use in treating sex-hormone-dependent diseases such as breast and prostate cancer as well as endometriosis.[4] In particular, recently developed LH-RH antagonists are capable of blocking the LH-RH receptors and reducing the release of LH and FSH immediately after the start of therapy. The first-generation drugs were unsuitable for therapy because they strongly induced the release of histamines and thus caused allergic reactions. Variation of the peptide sequence, especially the incorporation of nonproteinogenic D-amino acids at various positions, resulted in a marked reduction in the side effects. The most important LH-RH agonists and antagonists are summarized in Table 1.

The synthesis of the releasing hormone antagonist SB075, which is at the stage of clinical development, requires D-citrulline (D-Cit, **1**), an ω-ureido D-amino acid not found in nature.[5] Preparation of D-Cit by asymmetric synthesis poses problems; classical enantiomer separation necessitates a good route to racemic citrulline, which can only be obtained with difficulty from L-Cit or other precursors owing to the considerable formation of side products. We therefore sought to prepare D-Cit via the simplest possible route starting from an inexpensive, chiral amino acid.

Racemic amino acid hydantoins can often be converted practically quantitatively into D-amino acids by a system consisting of D-hydantoinase and carbamoylase.[6] The function of hydantoinases in vivo is to degrade nucleobases. These enzymes have therefore been classified as dihydropyrimidine amidohydrolases (E. C. 3.5.2.2). The hydantoinase/carbamoylase systems have only been used up to now in the large-scale production of D-phenylglycine and D-*p*-hydroxyphenylglycine, which may be employed in turn to prepare other aromatic as well as simple aliphatic D-amino acids. Nothing has been reported on the substrate specificity with respect to the side chain of amino-functionalized hydantoins.[7]

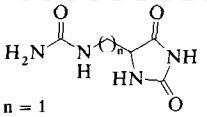
We also used this strategy for the synthesis of D-Cit. D-Cit may formally be derived form L-ornithine (**2**), which has the same number of C atoms and is accessible by enzymatic cleavage of the inexpensive protein amino acid L-arginine (**3**) (Scheme 1). Reaction of **2** with two equivalents of cyanate yields the α,ω-bisureido compound **4**, which can also be obtained from L-Cit and one equivalent of cyanate. Under acid conditions, **4** is converted into the 5-(3-ureidopropyl) hydantoin (citrulline hydantoin, **5**). Surprisingly, our hydantoinase/carbamoylase system, obtained from the strain *Agrobacterium radiobacter*, accepts this substrate[8] and affords D-citrulline in good chemical and optical yields.

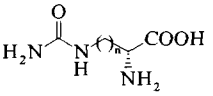


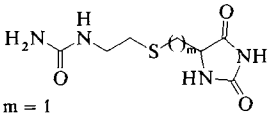
Scheme 1.

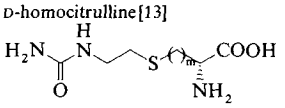
Hydantoins that are sufficiently acidic undergo chemical racemization under the alkaline reaction conditions. In the presence of racemases, the reaction can also be catalyzed enzymatically. Thus, D-amino acids may be obtained from L-hydantoins. In principle, this reaction offers a method of configuration reversal.

Table 2. Preparation of ω-ureido D-amino acids.

Hydantoin	D-amino acid	Yield [%] [a]	Content of D [b]
			




n = 1	D-albizziin [10]	69	>99
n = 2	D-4-ureido-2-amino-butyric acid [11]	73	98–99.8
n = 3	D-citrulline [12]	79	96–99.8
n = 4	D-homocitrulline [13]	70	60
			




m = 1	D-ω-ureido-AEC [c]	71	98–99.8
m = 2	D-ω-carbamoylthialysine [14]	78	98–99.8

[a] Yield of isolated product [%]. [b] Amount of D enantiomer [%], determined by comparison with literature data or by chromatography with the racemic compounds for comparison [10–14]; the ranges refer to different runs. [c] AEC = *S*-aminoethylcysteine.

Furthermore, we desired to determine the spectrum of substrates accepted by this biocatalyst. Readily obtainable racemic or L-α,ω-diamino carboxylic acids were converted into hydantoins analogous to **5**[9] and subjected to biotransformation (Table 2).

This approach provides a series of interesting ω-ureido δ-amino acids that are chemically synthesized only with difficulty and are not obtainable at all through fermentation. These examples show the advantages of combining chemical and enzymatic steps in the preparation of enantiomerically pure amino acids unknown in nature.

Experimental Procedure

Summary of the synthesis of D-citrulline (**1**, $C_6H_{13}N_3O_3$, M = 175.19) [15]: A solution of **5** (4 g, 22.8 mmol), prepared according to [9], in water (55 mL) was adjusted to pH 8.4 by addition of concentrated aqueous sodium hydroxide. The solution was then degassed by agitating in a mechanical shaker at 40 °C for 10 min, treated with the bacterial culture (*Agrobacterium radiobacter*, 0.5 g) under N_2, degassed once again, and then sparged with N_2. The vessel was shaken for 24 h at 40 °C under N_2 at 6 bar and then for 24 h at 40 °C under normal pressure before cooling it and adjusting the pH of the solution to pH 9. The solid portion of the culture was separated by centrifugation and the remaining liquid was treated with charcoal to clear the solution. Yield in solution 95%. Isolation was accomplished by filtering the solution through a strongly acidic ion exchanger (Merck, IR 120) and eluting the product with 5% aqueous NH_3. The solution thereby obtained was evaporated and the residue was dissolved in a small amount of water. Addition of ethanol precipitated the product. 3.4 g (85%), m.p. 215–218 °C (dec.), $[\alpha]_D^{20}$: +22 (c = 2 in 1 N HCl) ^{1}H NMR (250 MHz, D_2O): δ = 3.73 (m, 1H, Hα), 3.1 (m, 2H, Hγ); 1.4–2.0 (2 × m, each 2H, Hβ + Hγ).

2,3,6,7-Tetramethoxythianthrene Dication: An "Aromatic" π System "Gives Up the Ghost"**

By *Hans Bock*,* *Andreas Rauschenbach*, *Klaus Ruppert*, and *Zdenek Havlas*

Dedicated to Edgar Heilbronner on the occasion of his 70th birthday

Well over half a century ago, *E. Hückel* proposed the (4n + 2)-electron rule for cyclic π systems. Since then, this simple and fascinating concept[1] has stimulated the syntheses of a great variety of novel molecules and molecular ions, which in lab jargon are frequently termed aromatic (Greek: aromatikos = herbal smelling) and which, according to numerous experimental data as well as quantum-chemical results, are distinguished by an energetically favorable electron distribution.[2] Deviations from the optimum number of electrons, therefore, should inflict severe perturbations and, as is known for redox reactions of other organic compounds, result in surprising structural changes.[3]

For a model compound, we have selected 2,3,6,7-tetramethoxythianthrene (TMT, Scheme 1),[4a, b] which, unlike the related hydrocarbon anthracene with 14 π electrons, is not

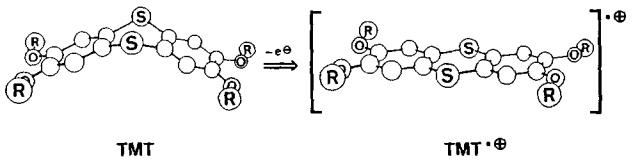
[**] Structures of Sterically Overcrowded or Charge-Perturbed Molecules, Part 6. This research was supported by the Land Hessen, by the Fonds der Chemischen Industrie, and by the Alexander von Humboldt-Stiftung (*Z.H.*) Parts 5: H. Bock, I. Göbel, Z. Havlas, H. Oberhammer, S. Liedle, *Angew. Chem. 103* (1991) 193; *Angew. Chem. Int. Ed. Engl. 30* (1991) 187.



TMT $\qquad$ TMT$^{\cdot\oplus}$

Scheme 1. Structures of TMT and its radical cation.

planar. Since sulfur substitution increases the number of π electrons by 2, TMT shows the same "butterfly"-like folding of its skeleton as the parent compound $C_{12}H_8S_2$.[4c]

Its one-electron oxidation by $NO^{\oplus}SbCl_6^{\ominus}$ or I_2 yields a blue radical cation, $TMT^{\cdot\oplus}$, the tricyclic skeleton of which is flattened[4d] even though the "ideal" 14-π-electron configuration is still exceeded by 1. Cyclic voltammetric measurements[4e] under aprotic conditions and at enhanced recording speed[4f] reveal, in addition to the first half-wave potential at + 0.88 V, a second reversible oxidation at + 1.27 V (Fig. 1).

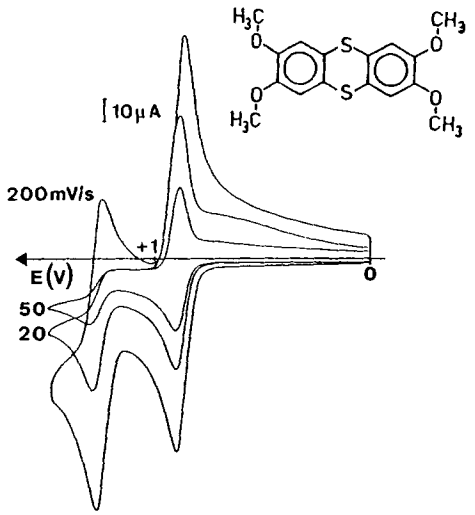


Fig 1. Cyclic voltammograms of TMT in Al_2O_3-dried H_2CCl_2 under argon at 293 K (electrolyte 0.1 M $Bu_4N^{\oplus}ClO_4^{\ominus}$, glassy carbon electrode vs. SCE, recording speed 20 to 200 mV s^{-1}, each ΔE 60 mV).

What structural changes will result on the removal of a second electron to produce the dication $TMT^{2\oplus}$?[4f, g]

Reaction of TMT with $SbCl_5$ in H_2CCl_2 under argon and under aprotic conditions ($c_{H^{\oplus}} < 1$ ppm) yields a green solution, from which, after several days at 5 °C, rhombuses with a metallic luster crystallize. The crystals are black, but dark red when viewed against light. Their low-temperature structure determination[6] provides an unexpected result (Fig. 2).

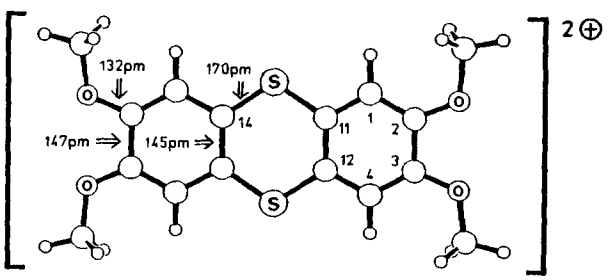

Fig. 2. Molecular structure of $TMT^{2\oplus}$ [6]. Important distances [pm ± 0.8] and angles [° ± 0.3] (average values): C2-C3 147.2, C11-C12 145.3, C1-C2 138.7, C1-C11 140.1, C11-S 169.5 C2-O 131.5, C11-S-C14 109.9, S-C11-C1 115.1, C11-C1-C2 120.4, C1-C2-O 126.8, C2-O-C_{Me} 118.7.

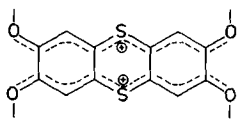
The dication $TMT^{2\oplus}$, which has 14 π electrons in the three annelated six-membered rings does not exhibit the "aromatic" character expected. Instead, the π molecular skeleton is extended by the methoxy oxygens to include altogether 18 centers; the O–C and C–S bonds are shortened to 132 and 170 pm and the ring C–C bonds shown in Figure 2 are elongated to 147 and 145 pm. Comparison with the corresponding C–X bond distances of both TMT[4b] and $TMT^{\cdot\oplus}$ suggests that the structure of $TMT^{2\oplus}$ consists of two fourfold C–C-connected and positively charged chains, H_3CO-CCC-$S^{\oplus}$-CCC-OCH_3 (Scheme 2; Table 1).

Table 1. Bond lengths [pm] in TMT, $TMT^{\cdot\oplus}$, and $TMT^{2\oplus}$. Numbering shown in Figure 1.

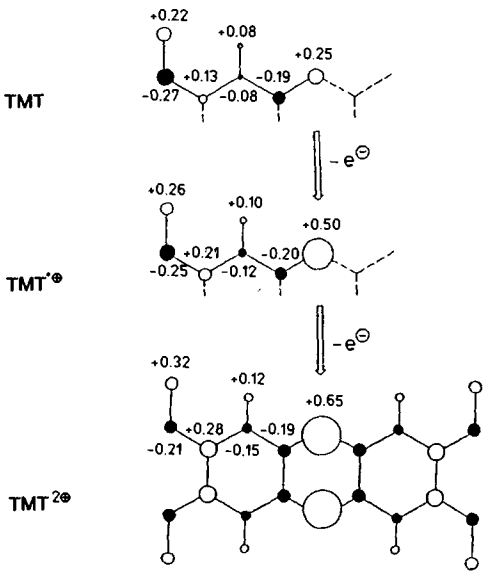
	C2-C3	C11-C12	C1-C2	C1-C11	C11-S	C2-O
TMT	141.0	138.3	138.0	139.7	177.6	136.9
$TMT^{\cdot\oplus}$	143.0	139.5	136.2	140.0	172.3	134.9
$TMT^{2\oplus}$	147.2	145.3	138.7	140.1	169.5	131.5



Scheme 2. Structural proposal for $TMT^{2\oplus}$ based on comparison of the bond lengths of TMT, $TMT^{\cdot\oplus}$, and $TMT^{2\oplus}$ (Table 1).

This assumption is supported by geometry-optimized MNDO calculations,[7] which reproduce satisfactorily both the structure (e.g., C2-C3 = 148 pm) and the color ($\tilde{\nu}_m^{exp.} = 14100\ cm^{-1}$, $\tilde{\nu}_m^{calcd} = 13700\ cm^{-1}$) of the dication $TMT^{2\oplus}$. Furthermore, the charge distributions calculated for the species TMT, $TMT^{\cdot\oplus}$, and $TMT^{2\oplus}$ (Scheme 3) demonstrate a localization of the positive charges predominantly at the electron-rich sulfur centers and, to a lesser extent, around the methoxy oxygens, which possess the highest effective nuclear charge within the system.

In addition, the electron densities, which decrease significantly especially at the outer ring centers, provide a plausible explanation for the elongation of the C2–C3 and C11–C12 distances by 7 pm each (see Table 1).



Scheme 3. Calculated charge distribution in TMT, $TMT^{\cdot\oplus}$, and $TMT^{2\oplus}$.

The structural (Table 1) and quantum-chemical (Scheme 3) observations for $TMT^{2\oplus}$ can be discussed in terms of the well-known "cyanine concept". On the basis of UV/VIS data and HMO calculations,[8] the formation of chainlike π subsystems was first proposed 25 years ago for π systems with subunits which contain an even number of π electrons distributed over an odd number of π centers[3a, b, 9]. In the meantime, such distortions have been confirmed many times over by structure determinations. From this point of view, the dications of suitably donor-substituted ethene derivatives[3a, 9a] and the dianions of suitably acceptor-substituted[3b] ethene derivatives formally consist of two cyanine-like three-center subsystems, $(R_2N)_2C^{\oplus}$ and $(H_5C_6)_2C^{\ominus}$, each with 4 π electrons, which are connected by C–C single bonds and twisted by 76°[3a, 9a] and 56°, respectively.[3b] The surprising structures of the 1,2,4,5-tetrakis(dimethylamino)benzene dication[9a] and the dipotassium salt of 2,5-dihydroxy-*p*-benzoquinone[9b] are also rationalized by the existence of two cyanine subunits, $R_2N^{\delta\oplus}$-CCC-$^{\delta\oplus}NR_2$ and $^{\delta\ominus}$O-CCC-$O^{\delta\ominus}$, respectively, containing five centers and six electrons, which are connected by C–C single bonds of 153 and 154 pm length, respectively. Despite the three annelated six-membered rings in $TMT^{2\oplus}$ and although two more π electrons would have to be removed to generate two complete cyanine subsystems, the formation of two positively charged chains connected by elongated C–C bonds, H_3CO-CCC-$S^{\oplus}$-CCC-OCH_3, wins over an increased cyclic π delocalization.

Altogether, the cyanine concept[8] constitutes a general and powerful structure perturbation principle.[10] With quite some excitement one may look forward to the skeletal distortions predicted by this old rule of thumb in other organic salts[11] prepared by appropriate redox reactions.

[5] a) The oxidizing agent is presumably the chloromethyl carbocation formed by the reaction $SbCl_5 + H_2CCl_2 \rightarrow SbCl_6^{\ominus} + H_2CCl^{\oplus}$; oxidation potential $E_{1/2}^{ox} \approx +1.6$ V (H. Bock, U. Lechner-Knoblauch, *J. Organomet. Chem. 294* (1985) 295); b) Preparation: $SbCl_5$ (1.2 g, 4 mmol) in 50 mL of H_2CCl_2 was added at room temperature and under Ar to a solution of TMT (670 mg, 2 mmol) in 50 mL of H_2CCl_2 dried by treatment with Al_2O_3, which had been heated to high temperature. The solution instantly turned green. The amorphous precipitate was filtered off under Ar. Its H_2CCl_2 solution, saturated at 40 °C, was kept for 1 day at 20 °C and then cooled to 5 °C. After 1 week, black rhombuses crystallized; on viewing in front of a cool-light lamp, the crystals shine dark red.

[6] Crystal structure analysis: $TMT^{2\oplus}$ (661.88 g mol^{-1}), $a = 963.4(5)$, $b = 2502.3(12)$, $c = 1350.2(7)$ pm, $\beta = 97.6(3)°$; $V = 3226.4 \times 10^6$ pm^3 (200 K), $P2_1/n$, $Z = 4$, $\mu(Mo_{K\alpha}) = 27.48$ cm^{-1}, Siemens AED II with graphite monochromator, $3° < 2\theta < 50°$, 5094 registered reflections, of which 3478 are independent with $I > 1.5\,\sigma(I)$; $R = 0.0524$, $R_w = 0.0530$ ($\omega = 1.6648/\sigma^2(F) + 0.002594\,F^2$). All C, O, S, Cl, and Sb atoms refined anisotropically, all H atoms of thianthrene refined with fixed temperature factor (0.5), all methyl protons refined with common temperature factor within a "rigid-body" model. Average values for additional bond distances [pm ± 0.8] and angles [° ± 0.3]: O-C(H_3) 146.6 S-C 11-C12 125.2, C1-C11-C12 119.9, C3-C2-O 113.4, Sb-Cl 237.3, Sb-Cl 234.8, Cl-Sb-Cl 179, Cl···H 280. The $TMT^{2\oplus}$ dications are stacked layerlike in the lattice; their average separation is 450 pm. Additional details of the crystal structure investigation can be obtained from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, W-7514 Eggenstein-Leopoldshafen 2 (FRG), by quoting the depository number CSD-55289, the names of the authors, and the literature citation.

[7] Extensive MNDO and especially PM3 calculations yield inter alia the following results: The structure optimizations based on at least C_{2v} symmetry and planar dimethoxybenzene units predict for the neutral compound TMT an interplanar angle γ of about 150° between the two molecular halves; this value significantly exceeds the experimental value of 131°[4b]. Altogether, however, a rather shallow double minimum potential with a barrier of only approximately 5 kJ mol^{-1} results for the flattening to $\gamma = 180°$ and, therefore, the planar structure of the radical cation [4b] can be readily explained by crystal effects only. For the radical cation $TMT^{\cdot\oplus}$ and the dication $TMT^{2\oplus}$ planar tetraoxothianthrene skeletons were calculated. The respective PM3 enthalpies of formation ΔH_f[kJ mol^{-1}] are −311 for TMT, +406 for $TMT^{\cdot\oplus}$, and +1501 for $TMT^{2\oplus}$. Therefore, adiabatic ionization energies $IE_1^a(TMT \rightarrow TMT^{\cdot\oplus}) \approx 7.4$ eV and $IE_2^a(TMT^{\cdot\oplus} \rightarrow TMT^{2\oplus}) \approx 11.4$ eV result. The first vertical ionization energy of tetramethoxythianthrene is predicted according to Koopmans' theorem to be $IE_1^v \approx -\varepsilon_1^{PM3} = 8.0$ eV. In addition, PM3/CI calculations based on altogether 100 configurations yield the following energies for the long-wavelength excitations within the visible spectral region state assignments in brackets: $\tilde{\nu}_{m,1} \approx 13\,700$ cm^{-1} ($\pi \rightarrow \pi^*$, $b_{1g} \times b_{3u} = B_{2u}$), $\tilde{\nu}_{m,2} = 15\,900$ cm^{-1} ($\pi \rightarrow \pi^*$, $b_{3u} \times b_{3u} = Ag$), $\tilde{\nu}_{m,3} = 16\,300$ cm^{-1} ($\pi \rightarrow \pi^*$, $b_{2g} \times b_{3u} = B_{1u}$).

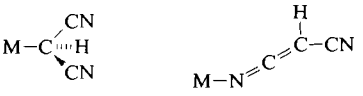
which may be represented by the resonance structures **A**. Transition-metal complexes with the dicyanomethanide ion have been reported;[1] they usually contain a dicyanomethyl–metal linkage as in **B**. In some rhodium and iridium complexes the monocyanoketenimine structure **C** has been assigned on the basis of IR data.[1a] Some ruthenium complexes containing either monodentate malononitrile or bridging substituted malononitrile have also been described.[2]

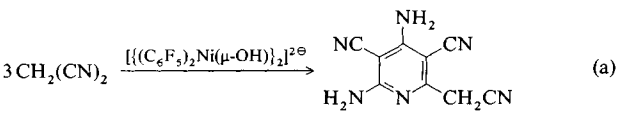
A



B **C**

Recently, the synthesis of a number of new hydroxo-bridged binuclear complexes of nickel, palladium, and platinum has been reported.[3] These complexes have potential utility in organic and organometallic synthesis.[4]

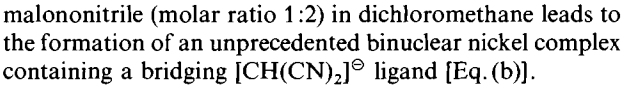
In the course of our research into the chemistry of $[\{R_2M(\mu\text{-}OH)\}_2]^{2\ominus}$-type complexes (M=Ni, Pd, Pt), we have found that the nickel complex ($R=C_6F_5$)[5] can be used as an efficient catalyst for the cyclotrimerization of malononitrile [Eq. (a)]. The isolated product[6] was identified as the so-called Trimer I of malononitrile.[7]



(a)

The high basicity of the OH bridges in the hydroxo-nickel complex (its ^{1}H NMR spectrum shows the OH resonance at $\delta = -5.74$) should facilitate the formation of $[CH(CN)_2]^{\ominus}$; the carbanion can then react further to produce an anionic dimer, and the reaction of this with a third malononitrile molecule (and abstraction of one proton) produces the trimer.[8]

The reaction of the hydroxo-bridged nickel complex with malononitrile (molar ratio 1:2) in dichloromethane leads to the formation of an unprecedented binuclear nickel complex containing a bridging $[CH(CN)_2]^{\ominus}$ ligand [Eq. (b)].



(b)

1

The conductance of **1** in acetone solution corresponds to that of a 2:1 electrolyte[9] and the ^{19}F NMR spectrum indicates that the two C_6F_5 groups are equivalent. The IR spectrum of **1** shows two bands in the $\nu(C\equiv N)$ region at lower energy than in free malononitrile (at 2270 cm^{-1})[10] (see *Experimental Procedure*).

An X-ray crystal structure determination of **1**[11] revealed the anion structure shown in Figure 1. The Ni atoms are coordinated in a distorted square-planar arrangement, the deviations from the plane towards a tetrahedral disposition being $\pm$ 0.01 Å. The average Ni–C_6F_5 bond length of 1.89(1) Å is in good agreement with those reported for other binuclear nickel complexes containing the C_6F_5 group.[12]

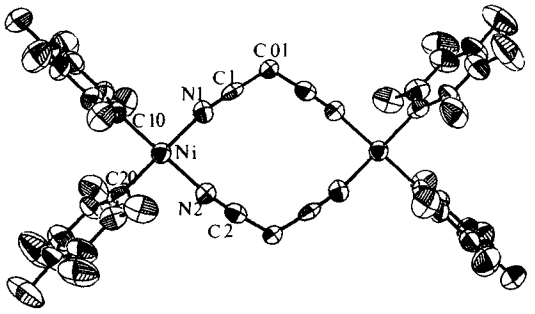


Fig. 1. Centrosymmetric anion structure of **1** (ORTEP). Selected bond lengths [Å] and angles [°]: Ni-C10 1.88(1), Ni-C20 1.90(1), Ni-N1 1.87(1), Ni-N2 1.89(1), Ni-C1 1.14(1), N2-C2 1.15(2), C1-C01 1.39(2), C2'-C01 1.36(2); N1-Ni-C10 92.7(4), C10-Ni-C20 88.4(4), C20-Ni-N2 92.0(4), N2-Ni-N1 87.0(4), Ni-N1-C1 170.3(7), Ni-N2-C2 170.5(8), N1-C1-C01 175(1), C1-C01-C2' 118.9(9). The atoms labeled with a prime sign are generated by reflection of the corresponding atoms through a crystallographic inversion center.

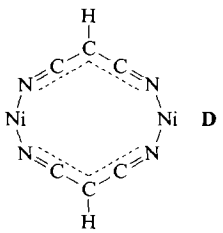
The C1–C01–C2' angle (118.9(9)°) and the C–C distances in the bridge indicate that the C01 atom is sp^2 hybridized. Taking into further account the C–N distances, the best description of the coordinated $[CH(CN)_2]^{\ominus}$ ion should assign an electron pair to a bonding molecular orbital extending over the whole NCCCN skeleton. The value of 170.4(8)° for the Ni–N–C angle is consistent with the above description. Thus, the twelve-membered ring Ni(μ-NC-CHCN)$_2$Ni may be represented as depicted in **D**.



D

Experimental Procedure

Malononitrile (0.010 g, 0.153 mmol) was added to a solution of $(NBu_4)_2$-$[\{(C_6F_5)_2Ni(\mu\text{-}OH)\}_2]$ (0.1 g, 0.077 mmol) in CH_2Cl_2 (5 mL) and the mixture was stirred at room temperature for 30 min, whereupon a yellow solid precipitated. The isolated compound was identified as **1** (84% yield). Correct C,H,N elemental analysis. M.p. 209 °C (dec.) Λ_e [S cm^2 mol^{-1}] = 164 × 10^{-4} M acetone solution. IR (Nujol): $\tilde{\nu}$(CN) = 2215(s), 2160(br,s); $\nu(C_6F_5)$ = 1630(m), 1495(vs), 1055(vs), 950(vs), 780(s) cm^{-1}. UV/VIS(acetone): λ_{max}[nm](ε) = 421 (1390). ^{1}H NMR (200 MHz, [D$_6$]-acetone TMS): δ = 1.66 (s, 2H, CH), and additional peaks from $[NBu_4]^{\oplus}$ at δ = 3.47, 1.86, 1.45, 0.97. ^{19}F NMR (80 MHz, $CFCl_3$): δ = – 116.1 (dd, 8F, $J(o\text{-}m)$ = 29.3 Hz, $J(o\text{-}o)$ = 4.8 Hz, *o*-F), – 165.3 (t, 4F, $J(m\text{-}p)$ = 19.3 Hz, *p*-F), – 167.2 (m, 8F, *m*-F).

BOOK REVIEWS

Book Reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the following address: Redaktion Angewandte Chemie, Postfach 101161, D-6940 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

The Chemistry of Sulphenic Acids and their Derivatives. Edited by *S. Patai*. Wiley, Chichester 1990. xvi, 819 pp., hardcover, £ 190.00.—ISBN 0-471-92373-9

This volume of the *Patai* series sets out to provide a comprehensive account of the current state of knowledge concerning the chemistry of sulfenic acids and their derivatives. It can be said at the outset that this aim has, by and large, been fulfilled.

As the negative aspects of the book are in the minority, these will be mentioned first. Local patriotism in the choice of literature references can be justified in a publication intended for a local readership, even though it is of little value; however, an internationally orientated work should not concentrate almost exclusively on citations originating from the United Kingdom and the USA, as one finds in Chapters 1, 2 and 9. Nor should about 50% of the references be to the author's own publications, as is the case in Chapters 13 and 15. While on the subject of literature citations, it is remarkable that the name *H. Böhme* (Marburg) is only once cited (in Chapter 10), even though he could hardly be regarded as a minor contributor in the field of sulfenic acid derivatives! The only possible excuse for this is that many of the chapters contain references to earlier review articles. A further criticism is that there are few references to recent publications; for example, of the 70 references in Chapter 18 only eight are to publications after 1980.

In a monograph on sulfenic acids and their derivatives one can criticize the omission of the chemistry of sulfenyl carboxylates (mixed anhydrides of sulfenic and carboxylic acids); the only mentions of these are in the well-balanced contribution by *Horspool* (Chapter 11, pp. 539–540) in connection with their photochemistry, and in Table 15 (Chapter 10, p. 449) without further details. It seems strange that *D. R. Hogg* (Chapter 9) has not mentioned this class of compounds, which he has himself previously studied (see Ref. [7] in K. Schank et al., *J. Org. Chem. 48* (1983) 4580). It would also have been desirable to mention here the mixed anhydrides of sulfenic and sulfonic acids (K. Schank, F. Werner, *Phosphorus Sulfur 8* (1980) 335). Another puzzling question is that of the meaning of Table 1 (Chapter 1, p. 12) which lists bond lengths; this reviewer was unable, on the basis of the element symbols given, to relate these data to the formulas above and the compound classes to the left of them. Also the tables on pages 550–563 are only likely to be understood by readers familiar with the subject.

There are some excellent contributions that deserve a special mention, namely those by *A. R. Bassindale* and *I. Iley* (Chapter 4), *M. Mikolajczyk* et al. (Chapters 5 and 6), *S. Braverman* (Chapter 8), *G. Capozzi, G. Modena* and *L. Pasquato* (Chapter 10), *W. M. Horspool* (Chapter 11), *M. Zielinski* and *M. Kanska* (Chapter 14), *H. C. J. Ottenheijm* et al. (Chapter 16) and *P. K. Claus* (Chapter 17); these chapters are in themselves enough to make the book worth buying. Another good feature is the unusually small number of printing errors (examples of these few are Equation 17 on page 97,

where four methyl groups have unexpectedly become five, and formula **117** on page 455, which has a pentavalent carbon).

Lastly we come to the price. Books can be classified as cheap (rarely found), expensive (very common) or good value for the price. The reviewer places this one in the third category. It should be in every chemical library, and can be recommended to all chemists and biochemists other than those who associate sulfur compounds only with awful smells and keep well away from them.

The Chemistry of Sulphinic Acids, Esters and their Derivatives. Edited by *S. Patai*. Wiley, Chichester 1990. xvi, 728 pp., hardcover, £ 165.00.—ISBN 0-471-91918-7

In this further volume of the *Patai* series the aim was to give a comprehensive treatment, in 23 chapters, of sulfinic acids and their derivatives. It can be said at the outset that the conception of this volume is not nearly so successful as that of the volume on sulfenic acids. What should one expect of a work whose objective is that stated in the above title? 1) An attractive external presentation, an up-to-date and consistent nomenclature, and as few errors as possible in the typography and figures. 2) Contributions with a high level of scientific competence, with references to earlier review articles. The literature coverage should concentrate mainly on the period since the cutoff point of the previous review collection, bearing in mind, however, that in bringing out the most important features of a topic one must also refer (in an up-to-date context) to older publications. With regard to these two criteria, the *Patai* volume reviewed here has failed badly in some parts.

Although the external presentation is very attractive, the frequent switching between "sulphinyl" and "sulfinyl" is annoying. In the volume on sulfenic acids only one chapter was allowed to use the "f" spelling, but here this applies to seven of the chapters, with the additional complication that for Chapters 7 and 8 the contents list on the cover uses "ph" whereas the chapters themselves use "f".

With regard to errors in the text and figures, the following can be noted, without claiming the list to be complete: p. 89, what about stoichiometry in the equation given here?; p. 93, Section 11: elemental sulfur converts a sulfinate to a thiosulfonate, not to a thiosulfinate ArS(= O)SH; p. 133: in Figure 1 the assignment for H^4, which is cited at the top of page 135, is not shown; p. 193: electron distribution in Scheme 17?; p. 204: Equation (42) has kindly been credited to our group, but does not originate from here; p. 235, line 2: 1-damantyl; p. 376: in formula **117** a CH_2 group is missing; p. 433, Scheme 1: according to Equation (9) the reaction arrows go in the wrong direction (left side of the equation); p. 455: the "sulfonyl nitrites" referred to in Equation (4) contain neither a sulfonyl group nor a nitrite function; p. 462: in Equation (29) two negative charges appear from neutral molecules in the intermediate complex, then disappear again in the end products; p. 496, Scheme 6: hexavalent carbon; p. 498, Scheme 1: pentavalent nitrogen, Reference [25]: *Heesing* instead of *Hessing*; p. 534: the "dominant resonance structure" **18** seems questionable; p. 538, Equation (16): in the text the reaction is described as a photooxidation, whereas in the equation for the reaction the reaction conditions are given as H_2O_2/HOAc/60 °C; p. 542 discussing Ref. [87]: the oxidations are carried out using oxaziridines, not azyridines; p. 548, Figure 3: in ten formulas the positions of the ^{13}C NMR signals are not shown beside the correct carbon atoms; p. 552: Equation (47) indicates a baffling stoichiometry involving ethane; p. 597: diazomethane is given as CH_3N_2; p. 597, Scheme 4: the decomposition of sulfinyl peroxide must produce *tert*-butoxy, not *tert*-butyl radicals, especially in view of the fact that *tert*-butyl alcohol then appears as a reaction product; p. 611, Equation (27): $BF_2^{\ominus}$; Equation (28): the positive charge is missing from the ylid sulfur atom; Equation (32): according to the text the action of elemental sulfur gives sulfinamides, but the origin of the amide function is not explained; p. 612: formula **19** leads to an oxygen atom with an electron deficit; p. 615, Scheme 2, the second and third lines of the formula are barely understandable; p. 617, top line: "chain carrier ArN·" should probably read ArNH; p. 618, Equation (46): amyl nitrite is shown as the corresponding nitro compound; p. 619, Equation (48): here a phenyl group has become a phosphane; Equation (49): the nitrogen atom is missing from the educt, but then appears in the intermediate and end-product; p. 620, Equation (53): *m*-chloroperbenzoic acid is abbreviated as CPA; in Equation (55) a hydrogen transfer is shown (by the curved arrow) as taking place onto the group R^2 instead of onto the triple bond; p. 659, formula **14**: the OH group in the *ortho* position is missing. Of the entire volume Chapter 20 in particular is really annoying.

Also many of the chapters are less up-to-date than one would wish. For example, only seven of the 23 chapters include a reference to Volume E11 of Houben-Weyl, which was published in 1985 and contains the most recent comprehensive review to date of this class of compounds. In many of the chapters the proportion of literature references that relate to publications later than 1980 is about 10%; for certain chapters that may be justified, but for many it is not. This reviewer has some experience in the field of sulfinic acid chemistry, and has to disagree with many of the statements in the book. For example, it is claimed on page 3 that an *inter*molecular substitution of a sulfinate at the saturated carbon atom (p. 3) is not possible either for sulfones or for sulfinyloxy compounds. This is certainly true under normal circumstances, but is not an absolute rule (e.g. sulfones: D. T. Gibson, *J. Chem. Soc. 1937*, 1509; B. G. Boldyrev et al., *Zh. Org. Khim. 11* (1975) 455; sulfinyloxy compounds: K. Schank, *Houben-Weyl Bd. E11* (1985), p. 1148; pp. 1260, 1278 for sulfones). *Intra*molecular substitution of a sulfinate from a sulfone is cited (Ref. [14]) as occurring only under fairly brutal conditions; however, this must be compared with the synthesis of *trans*-chrysanthemum acid methyl ester (see L.-F. Tietze, Th. Eicher: *Reaktionen und Synthesen im organisch-chemischen Praktikum*, Thieme, Stuttgart 1981, p. 433), which was achieved in 72 h in DMF at room temperature. On page 318 mesomerism is confused with tautomerism, but it suffers this fate again and again, as it is often explained in terms of resonance. Nevertheless it always causes pain anew to a former student of *B. Eistert*, the author of the book "Tautomerie und Mesomerie". On page 456 the pioneering work of *Barnard* is mentioned (Ref. [11]), but without the important information that 1 mol of methylbenzenesulfenate requires only 0.7 mol of ozone to become quantitatively oxidized to methylbenzenesulfinate; $^3O_2$ is not capable of effecting the oxidation under these reaction conditions. On page 579 the reader is introduced to only two basically different methods for synthesizing sulfinyl chlorides: a) replacement of OH (or ONa) by Cl, and b) the chlorinating oxidation of sulfanes or disulfanes. One can excuse the fact that the citation given here ([Ref. 20]) only refers to *Herrmann*'s rediscovery of the method that we described using disulfide and sulfuryl chloride (W. Müller, K. Schank, *Chem. Ber. 111* (1978) 2870), since *Herrmann* also did not cite our work. However, the omission of the method for synthesizing sulfinyl chlorides by reacting thionyl chlo-

ride with suitable C-nucleophiles is unforgivable; this method has been applied by several research groups (e.g. trichloroethane sulfinyl chloride from 1,1-dichloroethene: B. M. Gladshtein et al., *Zh. Obshch. Khim. 41* (1971) 2580; CH-acid-ketones: J. Voss et al., *Angew. Chem. 92* (1980) 559; *Angew. Chem. Int. Ed. Engl. 19* (1980) 563; *Phosphorus Sulfur 10* (1981) 213; *Liebigs Ann. Chem. 1983*, 1116; K. Oda, *Synthesis 1981*, 661 (review!); M. Ohoka et al., *J. Org. Chem. 40* (1975) 3540; J. S. Pizey, K. Symeonides, *Phosphorus Sulfur 1* (1976) 41; *8* (1980) 1, and many others). It is also regrettable that the state of knowledge regarding the α-ketosulfones (p. 652) has apparently remained unchanged since 1949 (Ref. [68]). We first succeeded in synthesizing this class of compounds in 1977, and the fourth publication on the subject appeared in 1983 (K. Schank, H. Frisch, B. Zwanenburg, *J. Org. Chem. 48* (1983) 4580) not counting a correcting short communication (A. Senning, K. Schank, *Acta. Chem. Scand. Ser. B 32* (1978) 780. Unfortunately the book then goes on to mention in this connection the isolation of the mixed anhydride from benzoic acid and benzenesulfinic acid (Ref. [70]), which was subsequently corrected by us in the second publication on α-ketosulfones (K. Schank, F. Werner, *Liebigs. Ann. Chem. 1979*, 1977). Similarly the information concerning α-hydroxysulfones comes to an end in 1955, with no mention of our more recent publication on α-hydroxy-β-oxosulfones (*Chem. Ber. 99* (1966) 48; *103* (1970) 3087). However, this contribution includes an excellent discussion of the ambivalence of the sulfinate anions and its consequences.

Moreover, this volume of the *Patai* series contains some quite excellent contributions (those by *A. Nudelman, A. R. Bassindale* and *J. N. Iley*, by *U. Zoller, D. C. Dittmer* and *M. D. Hoey*, by *H. Fujihara* and *N. Furukawa*, by *S. Braverman, J. Drabowicz, P. Kielbasinski* and *M. Mikolajczyk*, and by *S. Oae, J. Shorter, T. Okuyama, A. Kalir* and *H. H. Kalir*). The only contribution that seems unsatisfactory is Chapter 20 in which, characteristically, the discussion of the *N*-sulfinylamines on page 605 does not once mention the name of *G. Kresze*, who pioneered this area. For readers who can live with the shortcomings mentioned above, the significant number of excellent articles in this volume, together with the aim of completing the series, are sufficient reasons to recommend it.

Kurt Schank [NB 1121/1125]
Institut für Organische Chemie
der Universität Saarbrücken (FRG)

New Solid Acids and Bases. By *K. Tanabe, M. Misono, Y. Ono* and *H. Hattori*. Elsevier, Amsterdam 1989. x, 365 pp., hardcover, HFl 375.00. – ISBN 0-444-98800-9

This well-organized monograph describes the present state of research in the field of solid acids and bases, and includes over 1300 literature references, most of them comparatively recent (up to 1988). The authors have taken great care to present the information concisely and accurately. Although the text is not easy reading because of its high information density, it is relieved by the many diagrams, tables and graphics. Since a large proportion of the carefully selected citations originate from Japan, one cannot escape the impression that Japanese research is at the forefront in this field.

After giving a definition of acid and base strengths on surfaces in Chapter 1, the whole question of "analysis" is treated in Chapter 2. The state of the art in determining acid and base strengths and their concentrations on solid surfaces is described. The importance of bifunctional surface sites and their determination is discussed in detail.

Chapter 3 is concerned with the surface acidities and basicities of metal oxides, mixed oxides, aluminas, zeolites, heteropolyacids, ion-exchange resins, metal sulfides, sulfates and phosphates, superacids and superbases. The metal oxides are treated in the order of the periodic table. Here the authors deal in great detail with the acidic and basic properties of the surfaces as influenced by the composition, pretreatment and mode of formation of the surfaces; in this connection they also discuss the catalytic properties and reactions of individual metal oxides. The importance of making a clear distinction between Brønsted and Lewis acidity, which seldom occur together, is emphasized. *Tanabe*'s theoretical model for mixed metal oxides is described; this allows one to predict the Lewis and Brønsted acidities of binary oxides. Special attention is given to mixed metal oxides based on SiO_2, Al_2O_3 and TiO_2. In the case of the aluminas the many different types of catalytic reactions in sheet silicates and other clays are discussed; the special properties of these sheet silicates as catalysts are clearly and concisely described. The discussion of zeolites is confined to a detailed consideration of the acidic properties as influenced by the Si/Al ratio, by pretreatment, and by metal exchange at the surface of the zeolite and in the skeletal structure. The newer aluminum phosphate zeolites are also briefly described. The section on heteropolyacids is mainly concerned with $H_3PW_{12}O_{40}$ and its metalated derivatives. Attention is here drawn to the differences between bulk and surface catalytic properties, and the relationship between catalytic activity and acidity.

Chapter 4 discusses the catalytic activity and selectivity of a wide variety of heterogeneously catalyzed reactions that are affected by the surface acidities and basicities of the catalysts used. The types of reactions considered are isomerizations, alkylations, acylations, the hydration of alkenes, methanol conversion, dehydrogenations, dehydrohalogenations, polymerizations, ester exchange, hydrolysis, catalytic cracking, hydrocracking and reforming, hydrogenations, oxidations, aldol condensations, NO reduction, and reactions of methanol and amines. It is impressive to learn how many homogeneous reactions have been successfully transformed into heterogeneous reactions of technological importance. This chapter gives a very concise, clear and informative summary of the knowledge about the catalysis of these reactions and the most effective catalysts. Much emphasis is placed on understanding the mechanisms of the reactions and their dependence on the surface acidities and basicities of the catalysts. With such a wide variety of reactions it is, of course, not possible to claim complete coverage; for example, in discussing the hydration of alkenes only that of ethylene is considered, and no reference is made to the problems of activity and selectivity that arise in the hydration of higher olefins.

The chapter on deactivation and regeneration of metal oxide catalysts is mainly confined to a discussion of the process of carbonation and the subsequent regeneration of the catalyst. The final chapter describes some advanced technological applications of solid acids and bases, such as gas sensors, sorbents and pressure-sensitive printing or copying papers.

This book, which deals with aspects of the chemistry of solids and surfaces, is a treasure of information, not only for everyone concerned with heterogeneous catalysis but also for all whose work is related to the chemistry of metal oxides. However, the text is difficult to read, since definite and in-

definite articles and prepositions are often missing or incorrectly used. Nevertheless, this book should be in the library of every scientist working in heterogeneous catalysis or related fields.

Analytical NMR. Edited by *L. D. Field* and *S. Sternhell*. Wiley, Chichester 1989. viii, 250 pp., hardcover, £ 32.95.–ISBN 0-471-91714-1

Following the rapid developments that have occurred in NMR spectroscopy there is now a flood of monographs of widely different kinds. Just as one thinks that every corner of the potential readership must already have been covered, yet another publisher strikes out in a supposedly new direction. This book, containing a selection of review articles, is aimed at the (industrial) analytical chemist who is looking for up-to-date information on special applications. It seems to me that there is a real need here, as the NMR user frequently has problems in choosing between the many different experimental approaches.

Unfortunately in this case the disadvantages of a heterogeneous selection of articles are all too apparent. An illustration of this is the recommendation on page 44 that one should use 90° pulses for quantitative measurements, followed by the next author's recommendation (on page 73) to use pulses of 40° or less. Also there are annoying instances of repetition, for example in the discussion of quantitative NMR spectroscopy of solids on pages 52–56 and again on pages 95–98, and in the concept of cross-polarization which is explained by three different authors in a total of seven pages (fortunately they all agree).

The first article is an introduction entitled "Fundamental Aspects of NMR Spectroscopy". Such attempts to cover the fundamentals of NMR in just a few pages are apt to bring a tolerant smile. This article by *L. D. Field* (34 pp.) is, as expected, no better than previous attempts, and is unnecessary for an understanding of the articles that follow.

The second article by *J. R. Mooney* (22 pp.) is concerned with quantitative ^{13}C NMR spectroscopy. The emphasis is on experimental aspects; however, for the reader who starts off enthusiastically, it would have been useful and sobering to give some data on molar concentrations. The discussion of the mathematical treatment of the data, e.g. integration and corrections of baseline and of phase, is very superficial. Some important methods such as integration with interpolation, or the use of algorithms for the quantitative treatment of partially overlapping signals, are not mentioned.

However, tucked into the middle of the book are three articles which might lead one to consider buying it. The article "Analysis of Fossil Fuels" by *C. E. Snape* (48 pp.) gives an authoritative and comprehensive survey of the methods that should be used by the self-critical NMR spectroscopist, with the emphasis on analysis of solids and high-boiling fractions. This is followed by an article on "NMR of Zeolites, Silicates and Solid Catalysts" by *A. D. H. Clague* and *N. C. M. Alma* (41 pp.). Although the last of these topics is treated rather too briefly, the article offers the reader an excellent overview of the ^{29}Si and ^{27}Al NMR spectroscopy of zeolites and silicates, together with a wealth of references to original papers (240 citations) as a basis for studying these topics in more depth. The sixth chapter on "Biological Applications of NMR" by *P. W. Kuchel* (62 pp.) describes techniques for in vitro measurements on cell suspensions, organs and body fluids. This rapidly growing field of research could have a great future in view of the increasing restrictions on animal experiments. The emphasis in this review is on the experimental possibilities rather than on the biological interpretation of the results. This limitation is to be welcomed, as it enables the author to give an expert and complete review of the aspects related to analysis; some minor inaccuracies (e.g. on p. 160, where the correct expression is $160\Delta\nu_{1/2}$) can be excused.

The book ends with an article by *M. Spraul* and *R.-D. Reinhard* (25 pp.) on automation in the NMR laboratory. Unfortunately this is unlikely to help an experimentalist in his work. There are hardly any literature references for further reading (actually six altogether), although there is a section dealing with computerized interpretation of spectra. In view of the various data banks that are commercially available and the methods based on them (not a single mention here of the work of *W. Bremser*!), and the numerous algorithms for computerized analysis of two-dimensional NMR spectra that have come from groups such as those of *Ernst, Bodenhausen, Kalbitzer* and *Levy*, it is regrettable that so many opportunities have been missed here.

In summary: for practical work in the NMR laboratory some introductions that are more useful than this one already exist, and for obtaining a basic understanding of the experiments there are better books. The specialist already has access to comparable reviews in the usual journals. One can only hope that the needs of analysts will be met by other books that can be unreservedly recommended.

Nomenclature of Inorganic Chemistry: Recommendations 1990. *International Union of Pure and Applied Chemistry*. Edited by *G. J. Leigh*. Blackwell Scientific Publications, Oxford 1990. xxiv, 289 pp., paperback, $ 27.50.–ISBN 0-632-02494-1. Hardcover version is no longer available.

Nomenclature has been an integral part of modern chemistry since its inception. The publication of Guyton de Morveau, Lavoisier, Berthollet, and de Fourcroy's *Méthode de nomenclature chimique* (1787) preceded by two years the publication of Lavoisier's *Traité élémentaire de chimie* (1789), which is universally regarded as marking the birth of modern chemistry. In 1913 the Council of the International Association of Chemical Societies appointed a commission on inorganic and organic nomenclature, and in 1921 its successor organization, the International Union of Pure and Applied Chemistry (IUPAC), appointed commissions on inorganic, organic, and biological chemistry.

The first report of the IUPAC's Commission on the Nomenclature of Inorganic Chemistry (CNIC) ("1940 Rules") was published in the leading journals of different countries. These rules, revised and rewritten, were published as a small book, *Nomenclature of Inorganic Chemistry 1957*, Butterworths, London 1959, ix, 93 pp., known as the "1957 Rules" or the "Red Book" from the color of its cover. A second revision, *Nomenclature of Inorganic Chemistry: Definitive Rules 1970*, Pergamon, Oxford 1971, xi, 110 pp., was supplemented by a 36-page IUPAC booklet, *How to Name an Inorganic Substance*, and by articles in various publications.

Since the appearance of the 1970 Rules, many new compounds have been prepared, some of which are difficult to name because they contain new types of bonding or structures. Trivial and local systems sprouted, especially for coordination and boron compounds, emphasizing the need for a systematic, widely comprehensible nomenclature. Consequently, in 1978 the IUPAC CNIC decided to replace the 1970 Red Book. The result is "not a revision... but a completely new version presented in a new way which it is hoped will be much more useful to the general reader." Because many of the new fields of chemistry are highly specialized and need complex names, the new edition will appear in several parts.

Part I, under review here, required 15 years to produce and is almost three times as long as its predecessor. It is concerned with the basic principles of nomenclature for the fundamental areas of inorganic chemistry. The principal authors, thirteen eminent chemists from the United States, the United Kingdom, France, the Netherlands and Hungary, hope that "its general principles will not be undermined, and that it should retain its currency for many years." Part II will deal with more specialized areas such as quasi-single strand inorganic polymers, organometallic and labeled compounds, and polyoxoanions; some of its contents have already been published in *Pure and Applied Chemistry*. Scheduled for publication in the near future, it will probably require more frequent revision because of its more specialized nature. Subsequent volumes are also planned.

The user-friendly 1990 edition contains more than 250 illustrations and is presented in an instructional format with numerous examples, rather than as a series of numbered rules as in previous editions. After two entirely new, concise chapters on the history and usages of inorganic nomenclature, the remaining nine chapters of Part I deal with elements, atoms, groups of atoms, formulas, names based on stoichiometry, solids, neutral molecular compounds, ions, substituent groups, radicals, salts, oxoacids and derived anions, coordination compounds, and boron hydrides (the "very thorough and useful" last two named sections are the longest in the book). Each chapter was written by nominated individuals, assisted by working parties, and was repeatedly reviewed and edited by about 15 CNIC members. British spelling is used consistently.

Because of the conflicting use of A and B notation for groups of elements in the periodic table, the unpopular 1-18 designation is presented as the preferred one, but the related controversy and other systems are discussed in an appendix, which concludes that "any ultimate recommendation... must be responsive to the broadest possible constituency." Another recommendation likely to be disputed or ignored by chemists is the use of "lanthanoid" and "actinoid," although "owing to wide current use, 'lanthanide' and 'actinide' are still allowed" even though "the ending -ide normally indicates a negative ion." Similarly, the system recommended for naming elements of atomic numbers greater than 103 not yet discovered or named by their discoverers, resulting in such awkward names as ununquadrium (element 114), will probably not find favor with most chemists, who are likely to continue referring to these species by atomic numbers. Other recommended changes include the avoidance of the term "radical" in anything other than the context of free radicals, the replacement of the terms "Stock number" and "Ewens-Bassett number" by the more readily comprehensible terms "oxidation number" and "charge number", the use of oxide names for anhydrides of fully dehydrated inorganic acids, and the use of configuration indexes for *fac* and *mer* isomers "for precise nomenclature purposes."

As expected for such a thoroughly reviewed and edited volume, the errors are few and minor, e.g., Gebieten for Gebiete, Jorisson for Jorissen, Damens for Damiens, and entitled for titled. A useful companion volume dealing with further types of species and providing additional examples has recently been published (Block, B. P.; Powell, W. H.; Fernelius, W. C. *Inorganic Chemical Nomenclature: Principles and Practice*, American Chemical Society, Washington, DC, 1990). CNIC Chairmen Joseph Chatt, Yves Jeannin and Daryle H. Busch and their dedicated band of collaborators, including editor G. J. Leigh, deserve our profound thanks for melding "established and traditional practices and systems of nomenclature" into a reference book that should be definitive for many years to come. I am pleased to recommend it highly not only to specialists concerned with problems of nomenclature but to all members of the international chemical community, who should find it invaluable in choosing correct and consistent names for inorganic and metalloorganic compounds dealt with in their research publications.

The Crystal Chemistry of Copper Oxometalates

By Hanskarl Müller-Buschbaum*

Dedicated to Professor Hans Georg von Schnering on the occasion of his 60th birthday

Up to three or four years ago oxocuprates were a class of chemical compounds no more remarkable than countless others. Then, as a result of the euphoria surrounding the high-temperature oxide superconductors and the discovery that copper plays an essential role in these materials, there was a world-wide awakening of interest in copper-containing oxide compounds. The number of scientists engaged in the synthesis and structure determination of copper oxometalates has grown from just a few to very many. As superconductivity is inseparably connected with the structure of the solid state, there has been a spontaneous awakening of interest in the role of copper in the crystal chemistry of solid materials, leading to new research projects on this aspect of oxocuprates. Most of the work published so far on the interesting chemistry of this group of compounds has related to individual compounds. New aids in describing complex solid state structures are now available through the development of methods that give three-dimensional displays of crystal structures using computer graphics terminals, as this review illustrates for the example of the oxocuprates.

1. Introduction

Since the discovery of the high-temperature oxide superconductors,[1, 2] oxocuprates have been at the focus of interest. As by-products of superconductivity research many new oxocuprates have been discovered, and there has been an intensification of research in the whole area of the crystal chemistry and coordination chemistry of copper in different oxidation states. In view of the large amount of published work on new copper-containing oxide compounds and phases, and the no less remarkable number of new investigations of oxocuprates that have long been known, a review of the crystal chemistry of copper oxometalates is now appropriate. The first review article on the crystal chemistry of copper appeared thirty years ago.[3] Nearly two decades later a series of oxocuprates with planar oxygen coordination were described in a report on planar coordinated ions in oxometalates.[4] At about the same time a review article appeared discussing the plasticity of Cu^{2+} coordination spheres in complex compounds.[5] However, up to now there have been no reviews of the crystal chemistry of oxocuprate(I) compounds or of mixed-valence oxocuprates, nor has there been a comprehensive account of the newly reported copper oxometalates and the valence-specific anomalous properties of copper in these substances. The present article surveys this latest chapter in the crystal chemistry of oxometalates, grouped in order of the valence of the copper atom; within each group the various compounds are described according to principles that emerge with respect to the coordination of oxygen to the copper atom. All the oxide superconductors are intentionally excluded, as their structures have already been reviewed in a recent article.[6] Also excluded are those phases that belong to one of the known high-temperature superconductors, even though they do not themselves exhibit superconducting properties.

In order for the crystal chemistry of copper to be more clearly understood, the structures of some selected compounds have been displayed using a graphic workstation and

are reproduced here in color. Such images produced by a scanning graphics VDU represent the latest technology for displaying the structures of three-dimensional solids. For reasons of cost it has been necessary to reduce the number of images of copper oxometalate structures with octahedral or tetrahedral coordination to a minimum. However, this is an acceptable limitation since, as will appear later, most of these compounds do not belong to the oxocuprates group. The clarity of the color images also makes it possible to limit the descriptions of the structures to the basic essentials.

2. The Crystal Chemistry of Oxocuprate(I) Compounds

2.1. Isolated O–Cu–O Dumbbell Structures

2.1.1. O–Cu–O Dumbbells in Irregular Formations

The crystal chemistry of copper-containing oxometalates is determined not only by the proportions of the different elements appearing in the empirical formula, but also by the specific properties of the ions present in the compound. A good example of this is Rb_3CuO_2,[7] whose structure is representative of a particular type found in oxocuprate(I) compounds. In the crystal structure of Rb_3CuO_2 the O–Cu–O dumbbell coordination usually found for Cu^+ ions is partly obscured by an excess of Rb^+ ions which alters the structure, so that only isolated O–Cu–O dumbbells occur. In Figure 1 the violet-colored bonds represent the coordination of the Cu^+ ions (yellow spheres) by the O^{2-} ions (blue spheres).[*] These dumbbell formations are shown extending beyond the region of the polyhedra around the rubidium atoms, so as to show the presence of isolated O–Cu–O units in the crystal structure. Although in this article on oxocuprates the main focus of attention is the coordination of copper, one cannot ignore the no less interesting crystal chemistry of the large alkali metal ions in these metal-rich compounds. From the published studies on Rb_3CuO_2 it is seen, when considering the primary structure, that each of the three alkali metal ion sites has a tetrahedral oxygen environment. Such a low coordination number is unusual for ions of large volume, and is a direct consequence of the extreme shortage of anionic coordination partners. The secondary structure shows that Rb(1) (red polyhedra) forms a two-dimensional arrangement of polyhedra. The polyhedra around Rb(2) (green spheres) and Rb(3) (orange polyhedra) are each joined together by one side to form a network. As Figure 1 shows, the Cu^+ ions are enclosed within this loose coordination of the alkali metal ions, which gives them a nearly linear dumbbell environment.

The crystal structure of $Cu_5Ta_{11}O_{30}$ shown in Figure 2[8] is of a completely different type; however, it also contains isolated O–Cu–O units. Ta^{5+} has the octahedral oxygen coordination that is typical of oxometalates. The octahedra occupied by the non-equivalent tantalum ions are distinguished by different colors (Ta(1): red, Ta(2): yellow, Ta(3): green). In the region of the octahedra shown in yellow one can recognize a perovskite-type structure. It is also interesting that each of the inner regions of the perovskite blocks contains no Cu^+. The rather irregularly arranged O–Cu–O dumbbells are mainly in positions linking the green and red TaO_6 octahedra.

2.1.2. O–Cu–O Dumbbells in Planar Configurations

An interesting feature of the alkali metal oxocuprate(I) compounds is the change in crystal chemistry from Rb_3CuO_2 to K_3CuO_2.[9] Whereas rubidium and potassium behave similarly in many areas of chemistry, this is not the case for the oxocuprates, and this leads to different structural types. Figure 3 shows the structure of K_3CuO_2. Here the potassium ions occupy four non-equivalent sites, three of which again have a tetrahedral oxygen environment, as shown by the orange, green and white polyhedra, corresponding to K(1) to K(3) respectively. To provide a better insight into the crystal structure, K(4) is here shown in spherical form (red spheres). Also, to make it clear that the coordination of the large K^+ ions does not completely enclose them in a shell of O^{2-} ions, the radii chosen for three of the potassium sites were approximately 80% of that of the K^+ ion. Even with an alkali metal ion of this size, Figure 3 clearly shows that it is not fully coordinated. The lattice formed by the K/O polyhedra contains within it nearly linear O–Cu–O dumbbells, and these lie in parallel planes in the crystal structure.

[*] Apart from a few exceptions, which are clearly pointed out, copper ions are shown as yellow spheres, regardless of oxidation state, and oxygen ions by blue spheres. All Cu–O bonds are shown in violet. For other elements and polyhedra the colors are explained in each case.

Hanskarl Müller-Buschbaum was born in 1931 in Wallendorf in the Thüringer Wald. He studied chemistry and physics at the University of Greifswald, finally gaining his doctorate in 1960 under the supervision of H. Witzmann for research on UV-excited borate luminophores. He then joined the research staff at Siemens in Munich, where he carried out research work on hard superconductors. In 1962 he continued his academic career at the University of Münster with Wilhelm Klemm and in 1965 he joined Rudolf Hoppe at the University of Giessen where he gained his habilitation in 1966 for work on the generation of high temperatures with the low-pressure/high-frequency plasma burner and its application in high-temperature solid-state reactions. In 1969 he accepted the offer of a professorial chair for inorganic chemistry at the University of Kiel. His main research interests focus on solid-state chemical reactions at high temperatures using high frequency plasma discharges and the synthesis of metastable materials with the CO_2 laser technique.

2.1.3. O–Cu–O Dumbbells Forming Links Between Layers

A particularly interesting alkali metal oxocuprate(I) compound is KNa_2CuO_2,[10] which has exactly linear O–Cu–O dumbbells. Figure 4 shows that the alkali metal and oxygen ions are arranged in layers, which are linked by Cu^+ ions to form the three-dimensional structure. This compound, which has a marked deficiency of non-metallic ions, again shows the unusual coordination of Na^+ and K^+. If one limits the radii of these ions to the center of electron density radii as determined crystallographically, it can be seen that Na^+ has tetrahedral coordination to four O^{2-} ions (red polyhedra and spheres), and K^+ has tetragonal pyramidal coordination to five O^{2-} ions (green polyhedra and spheres). One can also see from Figure 4 how these polyhedra are arranged and linked together. However, if the radii assumed for the alkali metal ions are increased to 80% of the ionic radii found in the tables, one obtains a better understanding of the unusual coordination of these large ions. This applies especially to the remarkably asymmetrical environment of the K^+ ions. The K^+ ion lies outside the basal plane of the square pyramid, but despite this its distance from the apex of the pyramid is appreciably less than that from the four O^{2-} coordination partners in the basal plane of the pyramid. All of the O^{2-} ions lying on the opposite side of the tetragonal pyramids are very far distant. If one assumes the radius of the Cu^+ ion to be increased from 0.3 Å to values between 0.6 and 1.0 Å, the KNa_2CuO_2 structure is found to contain layers of potassium and copper resembling those of a metal. This can be regarded as a filled variant of the $XeFe_2$ structure.[10]

Other examples in which O–Cu–O dumbbell units act as links between layers are $CuMnO_2$,[11] compounds with delafossite-type structures, $CuAlO_2$,[12–15] and the halogenooxocuprates Ba_2CuO_2Cl,[16] Sr_2CuO_2Cl,[17] Sr_2CuO_2Br,[18] and Ba_2CuO_2Br.[19] Figure 5 shows the structure of the mineral krednerite, $CuMnO_2$, and Figure 6 that of the delafossites. The $CuMnO_2$ structure consists of layers of MnO_6 octahedra (green) joined together by Cu^+ ions. This results in the Cu^+ ion adopting a linear dumbbell coordination to O^{2-} ions. The delafossite structure has more closely packed adjacent layers of MO_6 octahedra (red octahedra in Fig. 6). Both these classes of compounds show a well-defined layer structure, including planes that contain only Cu^+ ions.

In the halogenooxocuprates, M_2CuO_2X (M = alkaline-earth metal, X = halogen), the region containing the layers of octahedra is expanded compared to that in the delafossite structure, having in this case a double layer of edge-sharing MO_6 octahedra. In addition to the dumbbell-type coordination of Cu^+, which is important for the crystal chemistry of oxocuprate(I) compounds, these compounds are also interesting with regard to the arrangement of the Cl^- ions in the double layers of octahedra and the geometry of the MO_3Cl_3 octahedra. Figure 7 shows the structure of Sr_2CuO_2Cl. Here the Cl^- ions (orange spheres) are shown as having a radius of half the actual ionic radius (0.9 Å). It can be seen that they are always in the middle plane of the double layers of octahedra. The Cu^+ ions are thus screened from Cl^-, which is necessary for energetic reasons. If the Cl^- ions were at the outer faces of the layers of octahedra and were at the same time coordination partners of Cu^+, the coulomb part of the lattice energy compared to the lattice energy of the copper would be greatly reduced. A closer examination of the SrO_3Cl_3 octahedra shows that one of the triangular faces is formed by three Cl^- ions, whereas the opposite face is formed by three O^{2-} ions. For reasons of symmetry the centers of the Cl^- or O^{2-} ions in each triangular face are all separated by the same distance. This means that the distances between the oxygen ions are the same as the X–X separations, and are therefore much greater than normal, especially in compounds for which $X = Br^-$. The equality of the O_3 and Cl_3 triangular faces in the SrO_3Cl_3 octahedra, which is required by symmetry, makes it apparent why a corresponding iodine compound can no longer form a structure of the Ba_2CuO_2Cl type.[16] The compound Ba_2CuO_2I also exists, but the classification adopted here, according to the types of O–Cu–O dumbbells in the crystal structure, means that it must be dealt with in the next section. To conclude the discussion of the present group of compounds, it should be noted that the Sr^{2+} or Ba^{2+} ions occupy off-center positions within the MO_3X_3 octahedra which are shown in a filled representation in Figure 7, being shifted in the direction of the oversized O^{2-} triangular faces.

2.1.4. O–Cu–O Dumbbells as Tunnel Units

Within the last few years, a number of compounds have been reported as having structures in which O–Cu–O dumbbells are held within a closed network of polyhedra. Compounds of the general formula $CuLnW_2O_8$, in which Ln is a lanthanoid metal or yttrium, have been especially thoroughly studied. An earlier publication[20] reported that $CuLnW_2O_8$ crystallizes in two structural types. For Ln = La to Dy the α-$LiPrW_2O_8$ type is formed,[21] whereas for the smaller lanthanoid ions (Ln = Ho to Lu) and yttrium the β-$LiYbW_2O_8$ type is formed.[22] It should be noted that according to the latest convention for describing compounds of the general formula $M^ILnW_2O_8$, the low-temperature form of $CuNdW_2O_8$ must be described as α-$CuNdW_2O_8$. The authors expressed the view that no polymorphism occurred, but this later proved to be incorrect. Neither structure (α-$LiPrW_2O_8$ or β-$LiYbW_2O_8$) is identical to the structure of $CuNdW_2O_8$ which is shown in Figure 8. This recent discovery indicates that a third type of structure exists, and appears to be a consequence of the conditions of preparation.[23] The publication[23] reports a structure determination carried out on single crystals of $CuNdW_2O_8$. In Figure 8 one can clearly recognize the double octahedra of WO_6 (green polyhedra) joined at their edges; these are linked through Nd^{3+} ions (red spheres) to form a three-dimensional framework. The coordination polyhedra around the Nd^{3+} ions, which are here shown unfilled, can be regarded as trigonal prisms. Here again the radius of the Nd^{3+} ion has been reduced slightly from that given in tables[24] to a value of 0.9 Å in order to give a better insight into the crystal structure. The tunnels which are left in the $[NdW_2O_8]^-$ part of the lattice contain Cu^+ ions spaced at equal intervals. These have a coordination number of two due to the nearest oxygen neighbors. In this case, however, the O–Cu–O dumbbells are markedly non-linear, with an angle of 167°. The existence of this structural type has been further confirmed by an independen

study[25] on single crystals of β-$CuYW_2O_8$, which also showed that small Ln^{3+} ions can form structures of this type.

Another oxocuprate(I) compound with Cu^+ ions in a tunnel structure is $Sr_9Zn_4Cu_2O_{14}$.[26] This forms a unique structural type whose main feature is an Sr/O lattice. In Figure 9 the SrO_6 octahedra, which are appreciably deformed, are shown in red, together with trigonal prisms capped at one end. In the direction of the long a-axis the sequence of the layers is prism—octahedron—octahedron—prism. In Figure 9 the triples formed by Sr_3O_{12} octahedra joined by their faces, which can be recognized in the middle of the unit cell and at $x = 0$ (left and right edges) are an interesting feature. The zinc polyhedra, shown here in green, partly fill the Sr/O lattice. Owing to the fact that Figure 9 shows only the polyhedra within the region of one unit cell, it is not apparent here that the ZnO_4 tetrahedra are joined to form Zn_2O_7 units whose bond angle Zn—O—Zn differs markedly from 180°. Further details can be found in the literature.[26] The role of the Cu^+ ion in the crystal chemistry is here that of a tunnel unit. The tunnels in the $[Sr_9Zn_4O_{14}]^{2-}$ framework are so severely distorted that for Cu^+ there are only two O^{2-} ions that can act as coordination partners across the shortest dimension of the tunnel.

The last example of Cu^+ as a tunnel unit that will be described here is Ba_2CuO_2I.[19] From the standpoint of its empirical formula this halogenooxocuprate(I) compound belongs to the M_2CuO_2X group (X = halogen) described in Section 2.1.3. There it was explained that opposite triangular faces of the octahedra contain O^{2-} and X^- ions, with the result that, owing to symmetry requirements, the O—O distances are abnormally large. On going from $X = Br^-$ to $X = I^-$ it is found that a completely new type of structure is formed, as shown in Figure 10. Each of the four barium sites (green, red and yellow polyhedra) is surrounded by O^{2-} and I^- ions (orange spheres) in a severely distorted octahedral structure. The three-dimensional linking of these octahedra gives a lattice structure containing small rectangular tunnels and large hexagonal tunnels. The Ba(1) site is not involved in the formation of the hexagonal tunnel, and similarly Ba(2) does not form part of the small rectangular tunnel. It can be seen from Figure 10 that Cu(1), which is in the rectangular tunnel, has a nearly linear dumbbell type coordination, with an O—Cu—O bond angle of 178°. The larger hexagonal tunnel contains two $Cu^+(2)$ ions; despite the fact that in this case the dumbbells are considerably bent (165.6°), the distance between the ions (1.80 Å) is shorter than that for Cu(1).

2.2. O—Cu—O Dumbbells in Linked Formations

2.2.1. *Linking of O—Cu—O Dumbbells to Form Rings*

The compound KAgO, which has been known for a long time,[27] has a crystal chemistry which is also shared by some oxocuprate(I) compounds, including KCuO,[28] NaCuO, RbCuO,[29, 30] and LiCuO.[31, 32] The KAgO type structure adopted by these compounds is a remarkable one, which will be described with the help of two figures. First let us consider the coordination of the alkali metal ions (red spheres with a radius of 0.5 Å). Owing to the limited availability of oxygen ions relative to the cations, the alkali metal ions Li^+ to Rb^+ have only a fourfold coordination to O^{2-} in this type of structure. The resulting polyhedron can be regarded as being formed from an octahedron by removing two *cis* oxygen ions from the base plane. The abnormally large molar volume is explained by the existence of relatively large channels along the [001] direction. Cu^+ ions are built into this alkali metal-oxygen lattice, which again results in a dumbbell type O—Cu—O coordination. A novel, and so far unique, feature of this class of compounds is the formation of closed Cu_4O_4 four-membered rings. In Figure 12, the bonds between the alkali metal and oxygen ions have been omitted so as to show more clearly the closed polyhedra made up of dumbbells (violet bond lines). A more recent study[31] has shown that the Cu_4O_4 rings are exactly planar.

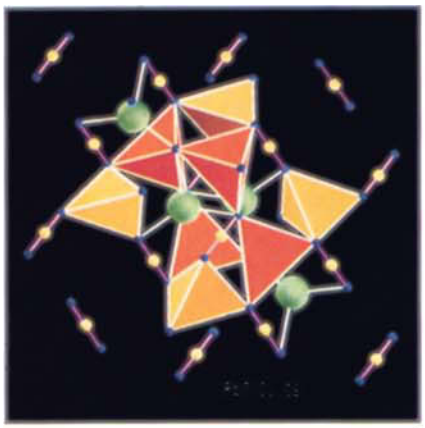
2.2.2. *Linking of O—Cu—O Dumbbells to Form Chains*

The compounds MCuO (M = Li to Rb) described above have a structure into which the larger Cs^+ ion does not fit. CsCuO represents a new structural type within the alkali metal oxocuprate(I) class.[28, 33] In this type of crystal structure the O—Cu—O units are linked to form zig-zag chains. In Figure 13, the coordination around the Cs^+ ions is shown by closed polyhedra (red), linked by dumbbells formed by the coordination of O^{2-} to Cu^+. Here again, as in compounds described in Section 2.1.3, there is a layer-like structure. Layers of fourfold coordinated Cs^+ ions are joined together through Cu^+ ions. The CsCuO structure shows some similarities to the KAgO type insofar as here also the polyhedron around the Cs^+ ion can be regarded as a portion of an octahedron. Here again, two of the *cis* sites of the octahedron are not occupied by O^{2-} ions. Features of interest are the O—Cu—O angle of 178°, departing slightly from the ideal value of 180°, and the fact that, as can be seen from Figure 13, all the O—Cu—O dumbbells that are linked together to form infinite one-dimensional chains are bent in the same direction.

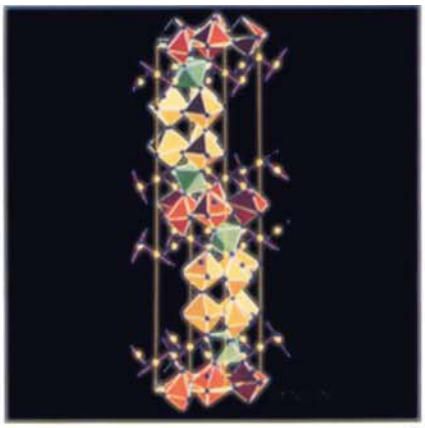
Infinite one-dimensional zig-zag chains have also been found for oxocuprate(I) compounds of alkaline-earth metals, namely for $SrCu_2O_2$[34] and $BaCu_2O_2$.[35] The basis of these strutures is shown in Figures 14 and 15. It can be seen that the SrO_6 or BaO_6 octahedra are joined at their edges in a space-filling structure, with the Sr^{2+} or Ba^{2+} ions shown as red spheres in Figure 14 and as red polyhedra in Figure 15. The lattice of the octahedra contains spaces along two directions for infinite one-dimensional O—Cu—O chains which extend throughout the structure in the same way as in CsCuO.

2.2.3. *Linking of O—Cu—O Dumbbells to Form Layers*

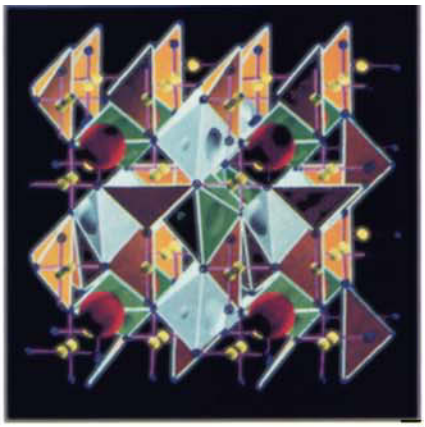
In $K_3Cu_5O_4$, $Rb_3Cu_5O_4$, $Cs_3Cu_5O_4$ and $Rb_2KCu_5O_4$ the O—Cu—O dumbbells are linked together in a much more complicated fashion,[31, 36, 37] as shown in Figure 16. We start by considering the coordination spheres of the alkali metal ions, with Rb^+ as an example. In Figure 16 the three metal sites occupied by rubidium are shown by red polyhedra and by red spheres whose radius is 80% of the tabulated ionic radius.[24] The fourfold coordination of Rb^+ which is



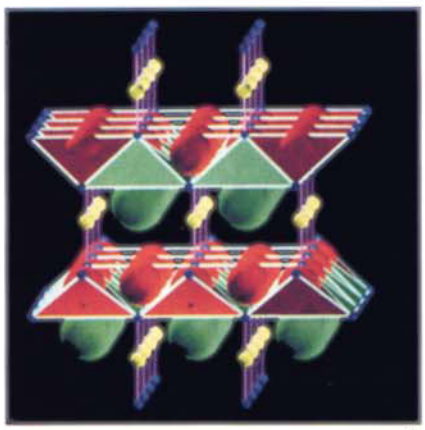
1



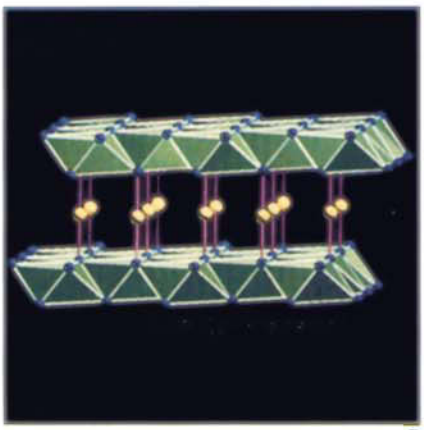
2



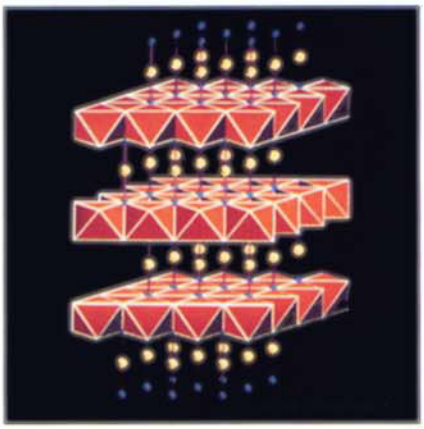
3



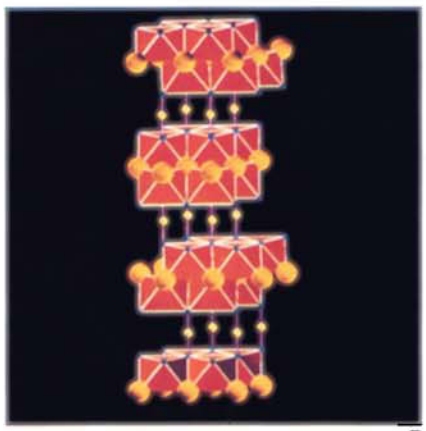
4



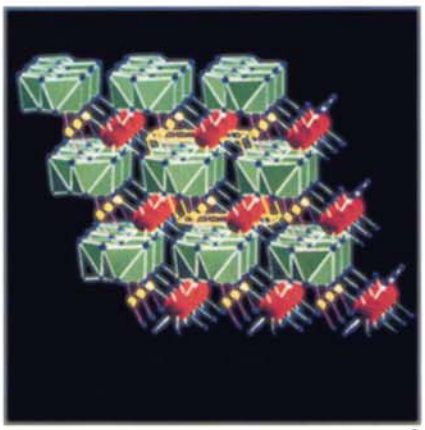
5



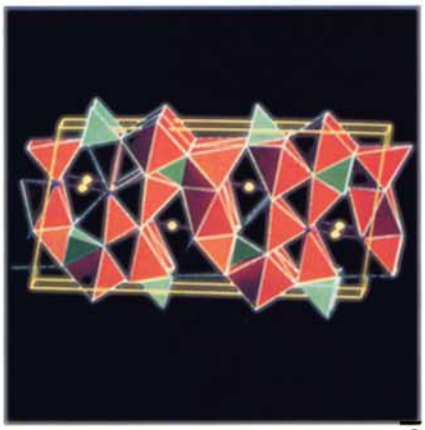
6



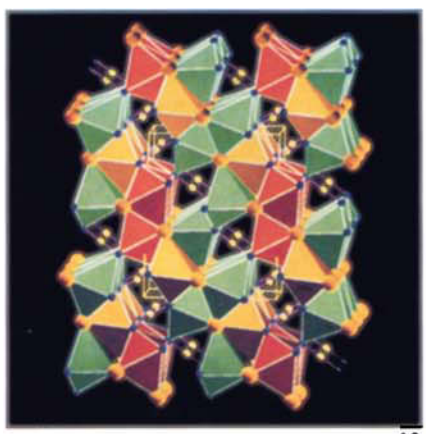
7



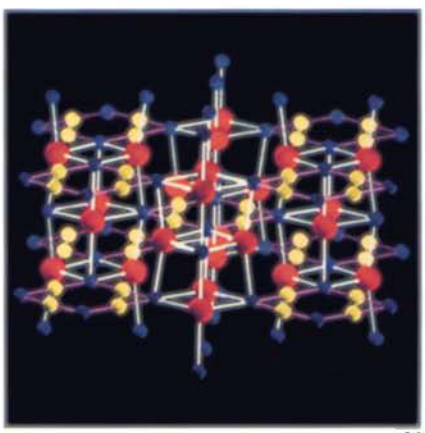
8



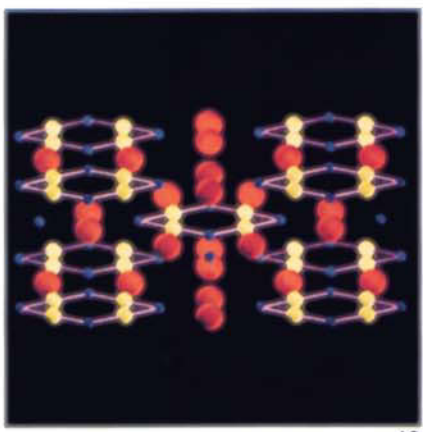
9



10



11



12

evident from the figure can again be deduced from the valence angles of an octahedron. Two of the *cis* sites of each octahedron are not occupied by O^{2-} ions. The resulting distortion of the portion of the octahedron gives a shape which is almost a tetrahedron. The asymmetric and open coordination of all the Rb sites, which is comparable with the situation in KNa_2CuO_2, can be clearly seen. The alkali metal ions together with a proportion of the O^{2-} ions form a layer structure which is again linked by O–Cu–O dumbbells. Helical chains with the structure –O–Cu–O–Cu– extend along the [010] direction, and are linked along the direction of the *a*-axis by other Cu^+ ions to form an open Cu/O network, $^2_\infty[Cu_5O_4]$. Evidently this class of compounds represents a step towards a three-dimensional network of O–Cu–O units, but so far no further examples of this have been found in oxocuprate(I) compounds.

2.3. Departures from the Dumbbell Type O–Cu–O Coordination

In Section 2.1.4 compounds with the β-$CuLnW_2O_8$ structure were described. It was also mentioned there that an older publication[38] had indicated, on the basis of the lattice constants of compounds with the general formula $CuLnW_2O_8$, that these were isotypes of the α-$KNdW_2O_8$ structure. The papers already cited[20, 21] also indicate the existence of triclinic compounds with the α-$LiPrW_2O_8$ structure in which Li^+ is replaced by Cu^+. Recently, single crystals of $CuLaW_2O_8$ and $CuSmW_2O_8$ were synthesized for the first time,[39] and these revealed that the structure and the coordination behavior of Cu^+ towards O^{2-} involves further subtleties. The crystal structure of $CuLnW_2O_8$ (Ln = La or Sm), as shown in Figure 17, contains blocks of four WO_6 octahedra (green) which are joined together by their edges. The $[W_4O_{16}]^{8-}$ groups are held together in a three-dimensional structure by the lanthanoid ions (red spheres) and Cu^+ ions. Up to now it has appeared that the crystal chemistry of oxocuprate(I) compounds always involves dumbbell units of a more or less linear type. However, the compound $CuLaW_2O_8$ shows a departure from this structural feature. On the basis of the Cu–O interionic distances (1.89 Å; 1.95 Å; 2.36 Å; 2.70 Å), it must be assumed that here Cu^+ has a [2 + 1] coordination. This can be clearly seen at the lower edge of Figure 17, despite the foreshortening in the perspective view. Thus the dominance in the oxocuprate(I) compounds described so far of the dumbbell type O–Cu–O coordination is broken in the case of $CuLaW_2O_8$, and the range of types must be extended to include a rare planar trigonal coordination. In $CuSmW_2O_8$ the Cu–O distances give a stronger indication of a deformed octahedron, which is ultimately derived from the coordination around Li^+ in α-$LiPrW_2O_8$.

The structure of Cu_2WO_4, which was finally clarified recently,[40, 41] fits well into this picture of the transition from a Cu^+ environment of the dumbbell type to others with higher coordination numbers. The structure is shown in Figure 18. The non-equivalent tungsten sites (W(1): red, W(2): green, W(3): orange, W(4): white) have octahedral coordination to O^{2-}. It can be seen from Figure 18 that the crystal lattice contains isolated blocks of four octahedra, each formed by the joining together of two pairs. However, the most interesting aspect in the context of the oxocuprate(I) compounds is the coordination of the Cu^+ ions. The Cu–O distances indicate the presence of copper ions with a dumbbell-type coordination, shown here by the violet colored bonds to O^{2-}. However, there are also sites that can be described by a [2 + 1] coordination, and others with threefold coordination. In Figure 18, the [2 + 1]-coordinated groups have also been shown as O–Cu–O dumbbells for simplicity. The departure from linearity is apparent even in the color graphics images. The Cu^+ sites that have unambiguous threefold coordination to O^{2-} are shown with a yellow background to emphasize the near-planarity of the CuO_3 polygons. The Cu^+ ion is in fact slightly shifted out of the plane of the three oxygen ions.

For compounds in which Cu^+ ions are present in a tetrahedral oxygen environment, the departure from the dumbbell formation is beyond dispute. An example of this type is $Cu_6Mo_5O_{18}$,[42, 43] whose crystal structure is shown in Figure 19. The polyhedra shown in green are those around Mo^{6+}, while those around Cu^+ are distinguished by yellow. The details of the linking between the polyhedra can be found in the original papers. If the empirical formula is changed somewhat to $Cu_4Mo_5O_{17}$, we obtain a compound[44, 45] in which the majority of the Cu^+ sites have a tetrahedral coordination. In this copper oxomolybdate one of the sites, Cu(2), already has octahedral coordination to O^{2-}, and a consideration of the overall picture for all the cuprates reported up to now shows an almost continuous transition from C. N. = 2 to C. N. = 6 (C. N. = coordination number). The study of $CuNb_3O_8$[46] cited here as additional evidence also contains tetrahedrally coordinated Cu^+. The oxomolybdates mentioned above and the oxoniobate $CuNb_3O_8$ should not be regarded as oxocuprate(I) compounds. This point will be considered further in the summary (Section 7). In these compounds Cu^+ acts as a cation in the anionic partial lattice formed by $[Mo_5O_{18}]^{6-}$, $[Mo_5O_{17}]^{4-}$ or $[Nb_3O_8]^-$, and thus the specific crystal chemical behavior typified by the dumbbell type O–Cu–O coordination is here replaced by a different behavior like that of the cations in salt-like compounds.

3. The Crystal Chemistry of Mixed-Valence Oxocuprates(I)/(II)

Mixed-valence oxocuprates formed by the Cu^+ and Cu^{2+} oxidation states were of no real importance until the discovery of the lead superconductor $Pb_2Sr_{2.24}Nd_{0.76}Cu_2O_{8+x}$,[47] and were ignored in research on oxocuprates. The compound Cu_2TiO_4[48] was known, and the mineral paramelaconite, Cu_4O_3, had been known for many years,[49] and was studied in greater detail in the 1940s.[50] It was not until 38 years later that the complicated structure of this compound, whose constitution is expressed in terms of the different copper valence states as $Cu^I_2Cu^{II}_2O_3$, was finally determined.[51] The remarkably complicated crystal structure of Cu_4O_3 will be shown here, even though this involves an appreciable sacrifice in relation to other compounds because of the necessary limit on the number of colored illustrations. Figures 20 and 21 show the coordination in the partial lat-

24

tices formed by the Cu^{2+} and Cu^{+} ions. It can be seen from Figure 20 that the Cu^{2+} ions have a square planar coordination to O^{2-}. Infinite one-dimensional chains of CuO_4 squares joined by their edges run in the vertical and horizontal directions, and are linked at each crossing point by a common oxygen ion partner to form a loose three-dimensional lattice. In Figure 21 this three-dimensional network is reduced to only the Cu^{2+}–O^{2-} bonds, which are shown in violet. The figure also shows the positions of the Cu^{+} ions (green) and their dumbbell-type coordination (yellow bonds). It can be seen that the open-structured $[Cu^{II}_2O_3]^{2-}$ part of the lattice is filled by one-dimensional zig-zag chains of $O-Cu^{I}-O$ dumbbell units. The essential feature of this binary oxide structure is the crystallochemical separation of two oxidation states, apparently without the valency fluctuations that often occur with other transition metals. Figure 22 shows the positions of all the ions in the complex structure of this oxide (Cu_4O_3), which has so far not been possible to produce synthetically.

In the course of experiments aimed at preparing thallium-containing superconductors the compound $TlCu_2O_2$ was discovered.[52] This is in fact $Tl^{I}Cu^{I}Cu^{II}O_2$, containing the Tl^{+} ion which has interesting crystallographic properties. In $TlCu_2O_2$ the Tl^{+} ion shows the expected lone pair effect.[53] Figure 23 shows the structure and the coordination of all the metal ions involved. In the form of presentation chosen here it can be clearly seen that undulating chains made up of planar Cu/O polyhedra (joined by their edges) run in the horizontal direction. The square polygons are shown with a yellow border. This is the coordination sphere of Cu^{2+}. These isolated $^{1}_{\infty}[CuO_2]$ chains are joined transversely (i.e. in the vertical direction) by Cu^{+} ions in a dumbbell-type coordination. Finally, the spacing in the third dimension is fixed by the Tl^{+} ions (shown here with a radius of 1.0 Å). Figure 23 gives the impression that the Tl^{+} ions are held in a tunnel structure. This is not the case, however; instead these ions are active partners in the formation of the three-dimensional network. It can be seen that the Tl^{+} ions lie close to the planar CuO_4 chains, thereby leaving sufficient space for the s^2 electron pairs. It should also be noted that Figure 23 shows only the Tl^{+} ions within one unit cell, whereas the Cu/O coordination is shown well beyond the limits of the cell.

During the preparation of this article, but after the figures had already been completed, I became aware of a report[54] describing two new mixed-valence oxocuprates of lithium, $LiCu_2O_2$ (A) and $LiCu_3O_3$ (B). The structures of both these compounds show close similarities to $TlCu_2O_2$. The Cu^{+} ions have a dumbbell-type coordination, and both (A) and (B) have $O-Cu-O$ units arranged in a square network. The Cu^{2+} ion has a planar coordination to four O^{2-} ions, and in compound (B) one of the copper ions, Cu(2), is in the plane of the oxygen ions while the other one, Cu(3), is outside the plane. A fifth O^{2-} neighbor, which should also be included on the basis of its distance (2.41 Å), extends the coordination of Cu(2) to form a tetragonal pyramid. This polyhedron will appear repeatedly in Section 5 on the oxocuprate(II) compounds. The essential difference between (A) and (B) is in the occupancy of the sites by lithium and copper. In (A) the Li^{+} and Cu^{+}/Cu^{2+} ions occupy clearly defined sites, whereas in (B) the Cu(2) and Cu(3) copper ion sites are partially occupied by randomly distributed Li^{+} ions. Finally, it may be mentioned that a mixed-valence Cu^{2+}/Cu^{3+} compound with the formula $Li_2Cu_2O_4$ has long been known to exist,[55] although its structure is not known.

4. The Crystal Chemistry of Oxocuprate(III) Compounds

It would appear logical to treat the oxocuprates in order of increasing oxidation states, but instead this section will describe the few known examples of oxocuprate(III) compounds. The justification for this is that Cu^{3+} (a d^8 ion) is the only one which, due to its electron configuration, consistently follows a square planar coordination to oxygen. It is therefore easier to first consider the CuO_4 units that are invariably planar in the solid state, before moving on to the less consistent crystal chemistry of the oxocuprate(II) compounds.

4.1. Isolated Double Square Structures Formed from Planar Units

The only known example of an oxocuprate with isolated Cu_2O_6 double squares is $Na_6Cu_2O_6$.[56] In Figure 24 the coordination around Na(1), Na(2), Na(5) and Na(6) is indicated by filled red and yellow polyhedra. As it was not yet possible at the time of writing to use transparent colors on the graphic workstation, Na(3) and Na(4) were shown as spheres (green, radius 0.2 Å) to give a clearer impression of the crystal structure. The polyhedra around Na^{+} can be described as distorted tetrahedra in the cases of Na(2) and Na(6), octahedra for Na(1), Na(3) and Na(4), and a trigonal prism for Na(5). An important feature of the crystal chemistry of oxocuprate(III) compounds is the isolated Cu_2O_6 unit that is held within the Na/O lattice. This is exactly the configuration found in electron-deficient compounds such as $AuCl_3$, which is commonly used as a teaching example to illustrate how the electron deficiency is rectified by dimerization to Au_2Cl_6. It should be noted that the deviations from planarity in $Na_6Cu_2O_6$ are only slight, and in Figure 24 the Cu/O coordination spheres have been continued beyond the region of the Na/O polyhedra for greater clarity.

4.2. Isolated Chains of Planar Units

Up to now oxocuperate(III) compounds with $^{1}_{\infty}[CuO_2]$ chains have only been observed for alkali metal cuprates. $NaCuO_2$[55] and $KCuO_2$[57] were prepared as long ago as the 1950s, but their structures were not determined until more than a decade later. As an example, the structure of $NaCuO_2$[58] will first be described. In Figure 25 the NaO_6 octahedra are shown as red octahedra, which are joined by their edges to form two-dimensional layers as in the delafossites. Cu^{3+} ions are located between the layers in such a way that they are in a square planar environment of O^{2-} ions. The linking of planar units by their edges leads to one-dimensional chains (Fig. 25). It can be seen that the $^{1}_{\infty}[CuO_2]$ chains are rigidly coupled to the NaO_6 octahedra, which

means that the Cu–Cu distance of 2.75 Å is equal to the Na–Na distance within the layers of octahedra. This coupling between chains and octahedra evidently explains why $KCuO_2$, $RbCuO_2$ and $CsCuO_2$ cannot form this structure.

In $KCuO_2$[59] the requirement for equal Cu–Cu and K–K distances is avoided by the formation of the crystal structure shown in Figure 26. Here K^+ has a trigonal prismatic coordination to O^{2-} as shown by the red polyhedra. However, the essential feature of the linking of the KO_6 prisms is a sequence in which prisms containing K^+ ions alternate with empty prisms. If the Cu–O distances were the same as in $NaCuO_2$, the same chain structure would result, but in $KCuO_2$, $RbCuO_2$, and $CsCuO_2$ the distances between the alkali metal ions are considerably greater due to the presence of the empty trigonal prisms. A recent neutron diffraction study[60] on $NaCuO_2$ and $KCuO_2$ indicated the same crystal chemistry. These authors also cite results on $NaCoO_2$[61] for comparison; its structure is of the α-$NaFeO_2$ type, which is understandable if one assumes that the planar CuO_4 polygon (4×1.85 Å) is extended by adding two very distant O^{2-} neighbors to form an octahedron.

Na_3CuO_3[62] is another cation-rich oxocuprate. However, the recent finding[56] that it has a monoclinic β form has reopened the discussion regarding its crystal chemistry. Another possibility to be considered[56] is a mixed-valence cuprate(II)/(III) with the formula $Na_{12}Cu^{II}_2Cu^{III}_2O_{11}$.

The last compound to be mentioned in this section is $TlSr_2CuO_6$.[63] Here the Cu–O distances (4×1.88 Å; 2×2.49 Å) indicate a stretched octahedron. However, this seems unlikely for copper in the oxidation state Cu^{3+}. Confirmation of this structure would prove that Cu^{3+} can show deviations from strict planarity and from its valence-specific crystal chemistry.

5. The Crystal Chemistry of Oxocuprate(II) Compounds

This section, which has deliberately been delayed until now, describes the many different coordination forms of Cu^{2+}. The discussion will be structured by taking as a common thread the coordination polyhedra around the copper ion. For reasons of space and cost the numerous examples of compounds with Cu^{2+} ions in closed polyhedra will be reduced to a basic minimum.

5.1. Isolated Planar Units

One of the earliest oxocuprate(II) compounds with isolated square planar units to be investigated was Bi_2CuO_4.[64, 65] Figure 27 shows that CuO_4 square units with their planes parallel to the *a*/*a* plane of the tetragonal unit cell are stacked up along the [001] direction. Here again the borders of the CuO_4 squares are shown in yellow. As in the columnar structures of the planar coordinated ions Ni^{2+}, Pt^{2+} and Pd^{2+}, successive CuO_4 squares are rotated by 45° relative to each other about the stacking axis. The Bi^{3+} ions, shown in red, link the isolated planar CuO_4 units to form the three-dimensional crystal lattice. Figure 28 shows the coordination of the Bi^{3+} ions. Owing to the presence of the s^2 electron lone pair, the coordination sphere of the bismuth ion is open on one side; each of the electron lone pairs extends to the middle of a tunnel formed by four stacks of CuO_4 polygons.

Another group of compounds with isolated square planar units are those of the general formula $BaCuLn_2O_5$ (Ln = La to Nd).[66–68] Their structure consists of a lattice of trigonal prisms formed by O^{2-} ions around Ln^{3+} (capped at two of the rectangular faces) and a cubic coordination around the Ba^{2+} ion. The complete crystal structure is shown in Figures 29 and 30. In Figure 29, the BaO_{8+2} polyhedra are shown in open form, with the Ba^{2+} ions represented by red spheres whose radius is about 80% of the tabulated value[24] for this ion. Figure 30 shows the Ba/O polyhedra (red) in a closed representation, whereas the trigonal prisms around the Ln^{3+} ions (green spheres) have been left open. Both figures show that the yellow-bordered CuO_4 squares are isolated from one another in the crystal lattice. It will be shown later (in Section 6.1) that in other compounds with the formula $BaCuLn_2O_5$, as one progresses from Ln = Sm towards the heavier lanthanoid elements a new structure without planar coordinated Cu^{2+} ions appears.

A third example with isolated planar units is $CuTa_2O_6$;[69, 70] its structure is shown in Figure 31. So that the arrangement of the planar units formed by O^{2-} ions around Cu^{2+} can be clearly seen, the Cu/O partial lattice has been extended well beyond the limits of one unit cell. Despite the distortion introduced by the perspective view, it can be seen that the CuO_4 squares are arranged with their planes perpendicular to the directions of the three cartesian axes. Considering these in conjunction with the TaO_6 octahedra, which are shown in red and form a distorted perovskite-type partial structure, the structure in Figure 31 can be understood as one in which each CuO_4 square links the corners of two octahedra in the severely deformed octahedral lattice. The distortion from the ideal perovskite structure results in the presence of large and small holes in the structure. The large holes are usually unoccupied, and the fact that an ion is missing from the perovskite structure is indicated in the empirical formula $Cu\square Ta_2O_6$, where $\square$ represents a hole.

The last compound with isolated CuO_4 squares that will be described is $CaCu_3Ge_4O_{12}$,[71] which shows a puzzling structural resemblance to $CuTa_2O_6$. The similarity between the crystal chemistries of the two compounds can be understood from considerations based on their molecular formulas. If we double the formula $Cu\square Ta_2O_6$, which indicates the unoccupied large holes ($\square$) in the perovskite lattice, we obtain $Cu_2\square_2Ta_4O_{12}$. If four Ta^{5+} ions are replaced by four Ge^{4+} ions, the deficit of four positive charges must be compensated for. This is achieved by introducing one Ca^{2+} ion and one Cu^{2+} ion. The chemical constitution, with the holes in the perovskite lattice now filled, is given by $Cu_2(Ca,Cu)Ge_4O_{12}$. If we now look at Figure 32, we see that it depicts the above situation. $CaCu_3Ge_4O_{12}$ contains all the crystal chemical structural units of $CuTa_2O_6$, and in addition the holes in the perovskite lattice are now filled. The tilting of the GeO_6 octahedra (shown in green in Fig. 32) causes deformation holes at the center and corners of the unit cell, which are occupied by the Ca^{2+} ions shown in red. The holes of the second type in the empirical formula $Cu_2\square_2Ta_4O_{12}$ are occupied by Cu^{2+} ions in such a way that

the corners of the octahedra which are tilted towards each other form the corners of the planar CuO_4 groups.

5.2. Single Chains Formed by Isolated Planar Units

The first, and up to now the only, known oxocuprate(II) of an alkali metal is Li_2CuO_2. It was first mentioned in 1943, and was later reported as a light brown powder.[55, 73] Almost ten years after the first suggested structure had been put forward, single crystals were obtained,[74] allowing a full X-ray structure determination. It turned out that the earlier suggested structure, based on powder diffraction data, was in principle correct, and the structure of the compound is shown in Figure 33. The LiO_4 tetrahedra, shown in red, are arranged in layers which are joined together by isolated chains of CuO_4. The planar polygons around the Cu^{2+} ions are joined by their edges, as in $NaCuO_2$ and $KCuO_2$ (Figs. 25, 26). The most recent study of Li_2CuO_2 by neutron diffraction[75, 76] is concerned with the magnetic structure. Below 10 K an antiferromagnetic structure is observed, which means that the Cu^{2+} magnetic dipoles have an antiparallel orientation along the 0,0,0 and $1/2,1/2,1/2$ directions perpendicular to the *c*-axis.

This topic is concluded by noting that isolated chains of edge-linked CuO_4 squares have also been observed in phases with the constitution $M_{14}Cu_{24}O_{38-x}$;[179] this has been discussed in more detail in a previous article.[6]

Investigations of two oxocuprate(II) compounds of alkaline-earth metals, namely Ca_2CuO_3[77] and Sr_2CuO_3,[78] led to the first observations of isolated chains of corner-linked CuO_4 squares. In the course of attempts to prepare bismuth-type superconductors, single crystals of Ca_2CuO_3 were obtained by accident, and were used in a later reinvestigation of the crystal structure of this compound.[79] Figure 34 shows the characteristic arrangement in this type of structure. Trigonal prisms (shown in red) are formed by the coordination of O^{2-} ions around Ca^{2+} or Sr^{2+}. One of the rectangular faces of each prism is capped by a seventh O^{2-} ion. Four MO_6 prisms are joined by their long edges of rectangular faces to form a square tunnel, which is occupied by Cu^{2+} ions positioned at the points corresponding to the triangular faces of the prisms. The seventh coordination partner of the alkaline-earth ion forms transverse links to adjacent double chains of prisms running parallel to the first. In Figure 34 the CuO_4 squares are again shown with yellow borders for clarity.

Compounds with the general formula $Ln_2Cu_2O_5$ show a structure which goes beyond the isolated straight chains of CuO_4 squares of the kind described above, in that two types of linkage patterns (by corners and by edges) are combined. This structural type was first observed for $In_2Cu_2O_5$.[80; 81] Subsequently it was confirmed by single crystal studies on the compounds with Ln = Ho to Lu,[82] Sc[83] and Y[84], and the coordination of the copper ion was determined more precisely. Figure 35 shows how the LnO_6 octahedra (yellow) are linked together to form a lattice. Rods formed by edge-linked octahedra are joined by their corners to form a framework with wide tunnels whose cross-section is an elongated hexagon. The tunnel diameter is large enough to accomodate two Cu^{2+} ions which, with their nearest oxygen neighbors, form an edge-linked Cu_2O_6 pair of squares. These pairs of squares, which resemble those in $Na_6Cu_2O_6$ (Fig. 24), are joined by two diagonally opposite corners to form one-dimensional ribbons (see Fig. 35). Here again the CuO_4 squares are shown with a yellow border. However, the view of the $^1_\infty[Cu_2O_5]$ chains chosen here does not make it clear that the individual CuO_4 polygons are twisted. This not only makes them markedly non-planar, but also alters the coordination polyhedra of the Cu^{2+} ions, a point that will be discussed later in Section 5.7.

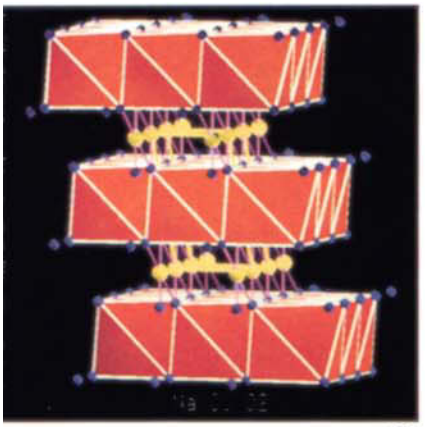
5.3. Double Chains of Planar Units

In the double chains of the $SrCuO_2$ structure[85] the degree of cross-linking between the square planar CuO_4 polygons is greater than in the compounds discussed up to now, as Figure 36 illustrates. In a direct comparison with Figure 34, it is seen that the linking between the polyhedra around the Sr^{2+} ions (singly capped trigonal prisms shown in red) is very similar. However, in Figure 36 there is a gap at one of the longitudinal edges, bridged by a double Cu/O chain (shown by the yellow borders around the CuO_4 squares). The isolated planar double chains can be regarded as consisting of Cu_2O_4 units joined at two of their edges. However, there are a number of other structural relationships between Sr_2CuO_3 and $SrCuO_2$, which have been discussed in detail in a previous article.[6]

Attempts in our laboratory to prepare the compound $CaCuO_2$, which should be an isotype of $SrCuO_2$, have invariably failed. Reports of the preparation of $CaCuO_2$ at 850 °C[86] appear to have later been refuted.[87] Again in the course of research on superconductors, while investigating systems containing the oxides of copper and alkaline-earth metals, a phase $Ca_{0.86}Sr_{0.14}CuO_2$ with a unique crystal structure was discovered.[88] Independently of this, other investigators[87] discovered the phase $Ca_{0.91}Sr_{0.09}CuO_2$, containing very little strontium, which comes closest in its constitution to the pure compound $CaCuO_2$. The surprising results reported by these two groups remind us yet again of the remarkable inventiveness of nature. To understand the structure of $Ca_{0.91}Sr_{0.09}CuO_2$ we must imagine a perovskite $CaM^{IV}O_3$ in which the tetravalent ion M is replaced by Cu^{2+}. This automatically involves the loss of one oxygen ion per formula unit. If we remove an oxygen ion from one, and only one edge of the cubic perovskite structure, this means that the Cu^{2+} ion occupying the former M^{4+} site is in a planar environment. This leads to planar networks of CuO_4 squares, as described in the next section.

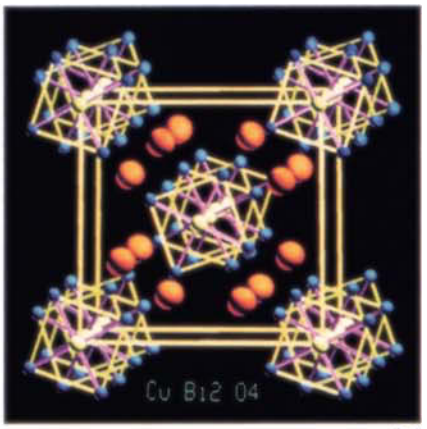
5.4. Networks of Planar Units

As was shown at the end of the previous section, $Ca_{1-x}Sr_xCuO_2$ ($x \simeq 0.09-0.14$) crystallizes in a distorted perovskite structure forming networks of the type $^2_\infty[CuO_2]$ arranged in parallel planes. One of the oxocuprate(II) compounds with a network structure (square planar CuO_4 polygons joined at all corners) that has been known for quite a long time is Nd_2CuO_2.[89] It was at first assumed that the oxometalates with the general formula Ln_2CuO_4 (Ln = La to Gd) belonged to the K_2NiF_4 structural

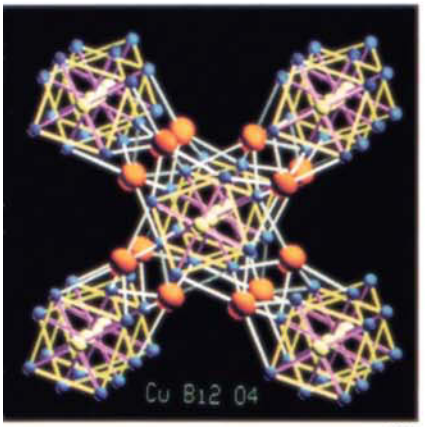


25

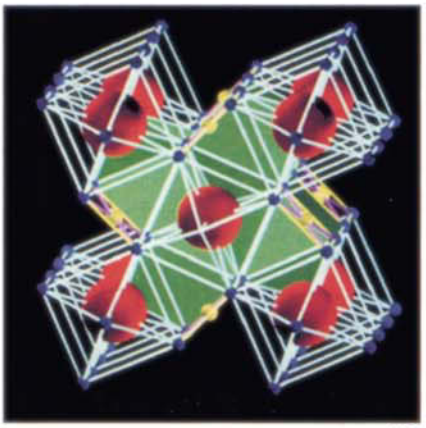
26



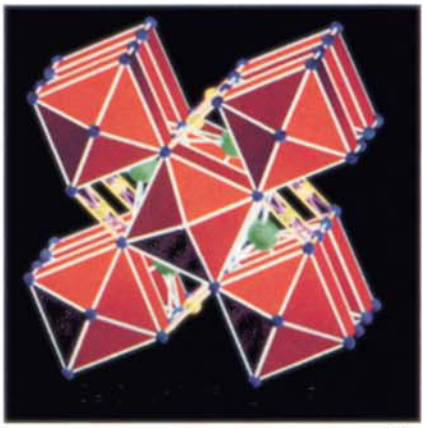
27



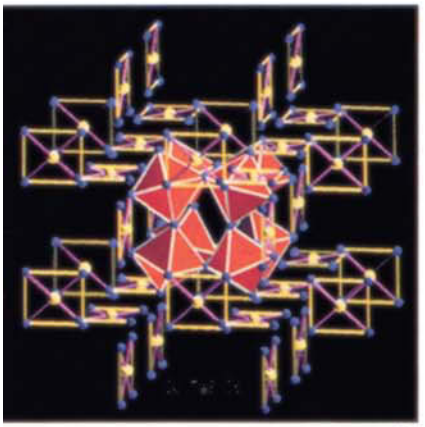
28



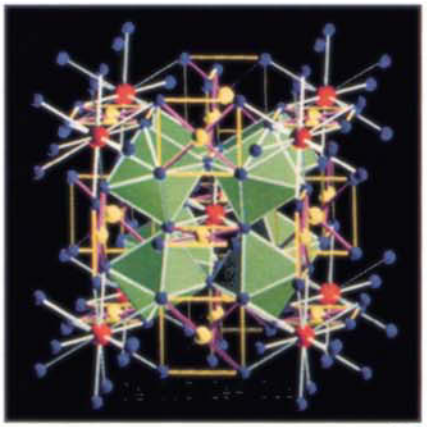
29



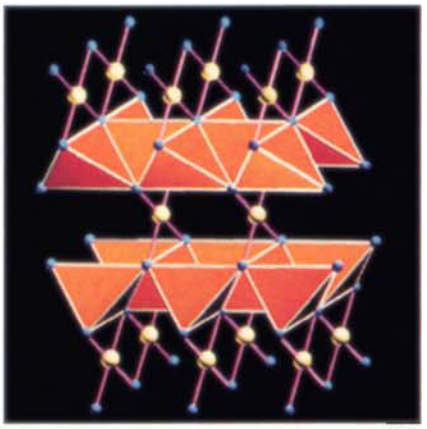
30



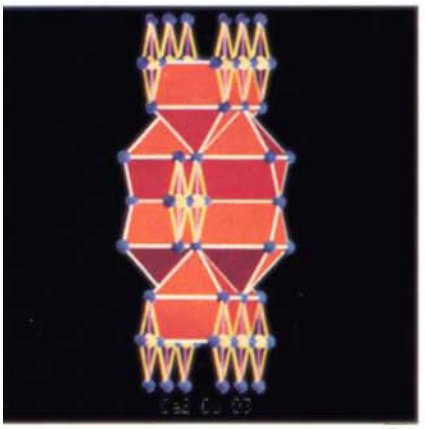
31



32

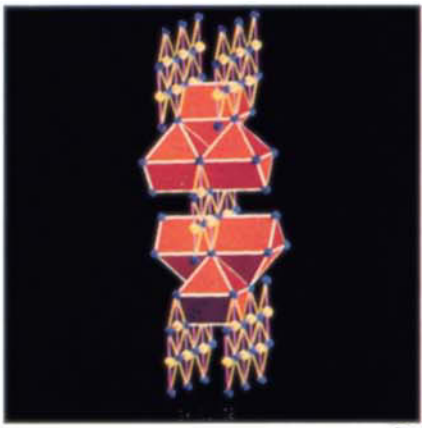


33



34

35



36

type,[90-92] and thus crystallized with octahedrally coordinated Cu^{2+}. In fact, however, the structure that is now accepted for this group of compounds is that shown in Figures 37 and 38, which is only distantly related to the K_2NiF_4 structure. A notable characteristic of this structure is the infinite two-dimensional Cu/O network, which can be seen especially clearly at the center of Figure 37. The CuO_4 squares are shown with a yellow border. It can be seen that alternate sites within the square grid of oxygen ions are unoccupied. The Nd^{3+} ions (red spheres) are positioned centrally above these unoccupied squares. The change from the K_2NiF_4 type structure to the Nd_2CuO_4 type also involves an alteration to the coordination polyhedra of the large ions (Nd^{3+} in this case). Whereas in the K_2NiF_4 structure these can be described as singly capped square antiprisms, they are practically cubic in the Nd_2CuO_4 structure. It can be seen from Figure 38 that the planar Cu/O networks are linked together by double cubes joined by their faces. The Nd^{3+} ions are shifted away from the centers of the cubes, which increases the Nd–Nd distance. It is also evident from Figure 38 that in the direction of the long axis, above and below each planar CuO_4 polyhedron, there is an empty cube formed by eight O^{2-} ions. More recent studies on the transition between the La_2CuO_4 structure with non-planar copper coordination and the Nd_2CuO_4 type have shown that for the range of ionic radii from that of Ce^{3+} up to Gd^{3+} the crystal structure shown in Figures 37 and 38 with planar coordinated copper is formed.[93,94] It is also interesting that in $Nd_2(Cu,Ni)O_4$ the Cu^{2+} and Ni^{2+} ions again have octahedral coordination,[95] despite the fact that Ni^{2+}, with a d^8 configuration, would be expected to show planar coordination. However, as it was found that compounds with the formula $Nd_{2-x}Ce_xCuO_4$ also have superconducting properties,[96] the crystal structures of numerous phases with the constitution $Nd_{2-x}M_xCuO_4$ were studied in detail, in the course of which another structure (described in the literature as the T″ or T* phase) was discovered.[97] These studies led to the interesting conclusion that the T″ or T* phase contains structural units that are a modified version of those in the crystal structures of La_2CuO_4 and Nd_2CuO_4. The octahedral or planar copper coordination is partially transformed into a square pyramidal type. The T* phase has been investigated by neutron diffraction,[98,99] and results on this have been summarized and discussed together with the already known compounds La_2CuO_4 (T phase) and Nd_2CuO_4 (T′ phase).[100]

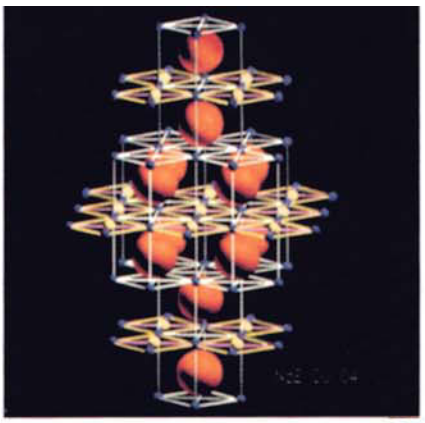
Networks formed by planar units are common, but they do not always have a planar structure. A good example of an undulating network made up of planar CuO_4 polygons is seen in the compounds $CaCu_2O_3$,[101] $MgCu_2O_3$[102] and the recently newly prepared $CoCu_2O_3$.[103] In the case of $CaCu_2O_3$, the electrical conductivity and magnetic properties have also been measured recently.[104] Figure 39 shows its structure, with CaO_6 octahedra (red) held between undulating Cu/O networks. It can be seen in the upper part of this figure that each of the unoccupied O_4 squares in the Cu/O network is bridged by a face of an octahedron. When Ca^{2+} is replaced by smaller ions (Mg^{2+}, Co^{2+}), the distortion of the Cu/O network becomes more severe.[103] Surprisingly, it has not been possible to prepare mixed crystals of $CaCu_2O_3$ and $MgCu_2O_3$. These would be important as a means of studying how the coordination sphere of the Cu^{2+} ion changes with the nature of the M^{2+} ion. The interatomic distances of the pure compounds show that the two O^{2-} neighbors of the Cu^{2+} ions, which are quite large distances in $CaCu_2O_3$, move closer in $MgCu_2O_3$ when Ca^{2+} is replaced by Mg^{2+}. On the evidence of the Cu–O distances in $MgCu_2O_3$ and $CoCu_2O_3$ it must be concluded that here the Cu^{2+} ions have an octahedral [4 + 2] coordination. Surprisingly, it has recently been found that mixed crystals with the constitution $Ca_{1-x}Co_xCu_2O_3$[103] can be formed, from which it emerges that the deformation of the Cu/O network does not change in a linear manner with the radius of the M^{2+} ion. From this it appears that for compounds of the type $Ca_{1-x}M_xCu_2O_3$ a planar copper–oxygen lattice, which is of interest with regard to superconductors, is only to be expected as one moves to larger ions ($M = Sr^{2+}$, Ba^{2+}). Unfortunately, however, replacing Ca^{2+} by these ions is difficult owing to the tendency for preferential formation of the compounds $SrCuO_2$, Sr_2CuO_3 and $BaCuO_2$.

The phase $Bi_{0.31}Ca_{5.64}Sr_{4.05}Cu_{17}O_{29}$,[105] which will here be referred to for brevity as $M_{10}Cu_{17}O_{29}$, is a classic example of a continuous transition in the manner of formation of the Cu^{2+} coordination polyhedra. In Figure 40, the complicated structure of this phase has been reduced to show only the Cu/O coordination. To give a clearer impression the planar units are shown with a yellow border. The structure of $M_{10}Cu_{17}O_{29}$ contains planar networks of square-coordinated Cu^{2+} ions, like those described earlier in this section, and isolated chains as described in Section 5.2. However, the most interesting aspect is the twisting of some of the CuO_4 squares which occurs at regular intervals along the chains. This twisting results in a gradual transition form planar to tetrahedral coordination.

5.5. Planar Units Extended to Form Polyhedra

The description of the crystal chemistry of copper in its twofold oxidation state has up to this point been confined to situations where the Cu^{2+} ion has a planar coordination to O^{2-}. However, this is not the only type of copper coordination occurring in oxocuprate(II) compounds, as is shown by the following examples.

In the course of experiments aimed at preparing Sr_2CuO_2 from $SrCO_3$ and CuO, the compound $Sr_2CuO_2(CO_3)$ was obtained.[106] The features of particular interest in its crystal chemistry are shown in Figure 41. First, one again notices the square network of O^{2-} ions, with Cu^{2+} ions occupying alternate squares. Also, here again the Sr^{2+} ions, shown in red, are positioned above the unoccupied squares. In addition one sees, in the middle of Figure 41, a grouping of O^{2-} ions around a carbon atom (green), which forms the CO_3^{2-} group lying between the layers. This at first sight very unusual coordination of carbon can only be understood by assuming that the CO_3^{2-} groups are randomly orientated in space. Here the spheres representing the O^{2-} ions in the CO_3 groups are drawn significantly smaller than normal, so as to indicate that these oxygen sites are under-occupied in a random way. Furthermore, it can be seen that the oxygen ion at one of the sites in the middle is shown somewhat larger, to indicate that this site has a higher occupancy than the other



37

eight. It is this site that forms the extension of the planar CuO_4 polygon to give a stretched octahedron. It must therefore be assumed that in microregions octahedral CuO_6 polyhedra can occur in addition to the usual planar CuO_4 polygons.

Cu^{2+} also exhibits a crystal chemistry similar to that described above in the halogenooxocuprate(II) compounds. For example we consider here $Ba_2Cu_3O_4X_2$ with $X = Cl^-$ and Br^-,[107,108] and $Sr_2Cu_3O_4X_2$ with $X = Cl^-$ and Br^-.[109,110] Figure 42 shows the structure of $Ba_2Cu_3O_4Cl_2$, with planar Cu/O networks, as already described in many previous examples. Here each Ba^{2+} ion (red) is held in a position above an unoccupied square of four O^{2-} ions. The halogen ions, shown as orange spheres whose radius is 80% of the actual ionic radius, form bridges between the Cu/O networks, with the result that the Cu^{2+} ion gains two X^- ions as extra neighbors, giving rise to a stretched CuO_4X_2 octahedron. However, it can be seen, with the help of the green lines shown between Cu^{2+} and X^-, that only alternate CuO_4 squares are extended by X^- to form octahedra.

If the molecular formula of the above barium compound is modified in the direction of more Ba^{2+} and less Cu^{2+}, we obtain $Ba_3Cu_2O_4Cl_2$,[111] which belongs to a new class of compounds in which copper shows an unusual crystal chemistry. Figures 43 and 44 give an insight into the crystal structure of this compound. In the first figure one can see zig-zag chains of square planar CuO_4 polygons together with five-fold coordinated copper in square CuO_4Cl pyramids. The latter polyhedra, shown in yellow, each have a Cu^{2+} ion within. A Cl^- ion at a further site (orange sphere) forms the only coordination partner of the Ba^{2+} ion (red sphere). Figure 44 shows how the space is filled by the large Ba^{2+} and Cl^- ions. Here the Ba^{2+} ions (red) and the Cl^- ions (orange) are shown with 80% radii. The Cl(2) site, which is the only one belonging to the Ba^{2+} ion, has been omitted from Figure 44. It is interesting that the already relatively short Cu–Cu distance observed in a linear chain of edge-linked squares ($\simeq 2.69$ Å) is here further shortened to 2.45 Å by the zig-zag creasing (in accordance with the representation in Figures 34 and 44). The Cu–Cu distances would be even shorter if it were not for the displacement of the Cu^{2+} ions towards the interiors of the tetragonal CuO_4Cl pyramids. Partial oxidation of the copper in $Ba_3Cu_2O_4Cl_2$ might be expected to result in one-dimensional metallic conductivity along the direction of the alternating sequence of polyhedra (square—tetragonal pyramid—square...). The structure of $Ba_3Cu_2O_4Cl_2$ shows that in the crystal chemistry of oxocuprate(II) compounds, planar CuO_4 polyhedra can be extended by halogen ions to form square pyramids.

As our final example of a transition from a planar Cu^{2+} environment to three-dimensional polyhedra we consider $KCuTa_3O_9$.[112] As Figure 45 shows, the $[Ta_3O_9]^{3-}$ framework can be regarded as a tetragonal bronze structure. Here it must be mentioned, by way of explanation, that the tetragonal bronzes, such as $Pb_5Nb_{10}O_{30}$,[113,114] $Ba_6CoNb_9O_{30}$[115] and $Ba_6Ti_2Nb_8O_{30}$,[116] have an octahedral structure with tunnels of triangular, rectangular and pentagonal shape, which are small, medium-sized and large respectively. The large Pb^{2+} and Ba^{2+} ions are present only within the two larger types of tunnels (square- and pentagonal-shaped). The Nb^{5+} ion can be partly replaced by smaller ions, as the above examples show. The electrical neutrality is then maintained by the occupation of the tunnels. In the case of $Ba_4CoTa_{10}O_{30}$[117] it has been shown that this bronze structure belongs to the $Na_2Nb_{12}O_3F_2$ type.[118,119] This means that the pattern of the linking in the octahedral lattice is slightly altered,[117] which results in a distortion of the rectangular tunnels, enabling these also to accept small ions such as Co^{2+}. This alteration in the linkage pattern of the MO_6 octahedra in the bronze structure also occurs in $KCuTa_3O_9$.[112] The structure of this compound is shown in Figure 45. The TaO_6 octahedra are shown in yellow, and the large K^+ ions in the large pentagonal tunnels are shown as red spheres. However, a more interesting point is that the distorted rectangular tunnels are occupied by Cu^{2+} ions. It can be seen that the two crystallographic sites of copper, Cu(1) (orange border) and Cu(2) (yellow border), are both shown with only a square planar environment. The way in which the planar units are arranged perpendicular to each other in the rectangular tunnel sites can be seen most clearly at the top edge of Figure 45. However, the representation chosen here does not quite give a true impression of the coordination of the copper ions, as the Cu(1) environment (orange-colored squares) is extended by two O^{2-} neighbors at a distance of 2.4 Å to form a [4 + 2] coordination (a distorted trigonal prism). Also the ion at Cu(2) "sees" more distant oxygen neighbors; the distance of 2.7 Å is exceptionally large, and these are therefore not regarded as bonding O^{2-} ions.

5.6. Planar Units Linked to Form Giant Polyhedra

It has been shown so far that CuO_4 polygons can join together in chains, ribbons and planes. These examples show only small departures from two-dimensionality, in the form of undulating networks and zig-zag chains. This is not the case, however, for $Ba_3Cu_3In_4O_{12}$,[120] which has the unusual crystal structure shown in Figure 46. It consists of a lattice of InO_6 octahedra (green) linked by their corners forming a structure of square tunnels. Some of the tunnels are occupied by Ba^{2+} ions, shown here in red, whereas others contain Cu^{2+} ions, which are coordinated with the neighboring oxygen ions of the tunnel walls to form a skeleton consisting of CuO_4 squares. The viewing angle in the figure reveals a succession of planar CuO_4 squares spaced at equal intervals with their planes perpendicular to the viewing direction. These are joined together by other CuO_4 squares orientated with their planes along the direction of the tunnel axis. These latter CuO_4 squares are arranged in opposing pairs, and with increasing distance from the observer the orientations of their planes alternate through 90°. This results in a giant polyhedron which is infinite along one dimension, and consists entirely of CuO_4 squares (Fig. 46).

A second example of an oxocuprate with giant polyhedra, although closed ones in this case, is $Ba_9Cu_7O_{15}Cl_2$.[121] In this halogenooxocuprate(II) compound Cu^{2+} behaves in an unusual way. It can be seen from Figure 47 that the hexagonal rings are formed by six planar CuO_4 units (with yellow borders) linked together, with copper in the Cu(1) sites, and these in turn are joined together through Cu(2) (large yellow spheres). Here Cu(2) has the unusual coordination number

C.N. = 12. In the crystal lattice, therefore, Cu(2) lies at the center of a hexagonal prism formed by O^{2-} ions. These chains of polyhedra formed by infinite linking along one dimension are further linked together in the third dimension through Ba^{2+} ions (Fig. 48, red polyhedra). Here Ba^{2+} has a [6 + 2] coordination (six O^{2-} and two Cl^- ions) in the form of a hexagonal bipyramid. The peaks of the pyramids are formed by the Cl^- ions (orange-colored). This coordination of Ba^{2+} can be understood if one regards it as arising from a spherical close packing arrangement (regular cuboctahedron), in which three O^{2-} ions on each side of the sixfold planar coordination are replaced by one Cl^- ion.

Probably the most complicated crystal structure found is that of an oxocuprate which appeared to have the very simple empirical formula "$BaCuO_2$".[122] This very easily prepared compound was later reinvestigated, and it was found that the true constitution is $Ba_{44}Cu_{45}O_{90}$.[123-125] The cubic unit cell contains two such formula units, and thus has a total of 358 atoms. Of these, Figure 49 shows only the 88 Ba^{2+} ions and the 180 O^{2-} ions. The reader may like to try to envisage how the additional 90 Cu^{2+} ions can be fitted into this abundance of atomic sites and bonds in such a way that each Cu^{2+} ion has the correct coordination. Nature has solved this problem in a masterly fashion. The incorporation of the Cu^{2+} ions and the resulting coordination can be thought of as occurring in a stepwise manner. In Figure 50, tetragonal pyramids (yellow) formed by O^{2-} ions around Cu^{2+} are shown along the edges of the unit cell and on the normals to the large faces. The crystallographic sites Cu(4) and O(6) are not all fully occupied. This means that where the adjacent square base faces of the tetragonal pyramids are packed too closely together in Figure 50, therefore only alternate ones are in fact present. The same also applies to the corresponding Cu^{2+} ions of these pyramidal fragments. Another publication on "$BaCuO_2$" proposes, on the basis of Fourier synthesis calculations, that further randomly unoccupied O^{2-} and Cu^{2+} sites exist.[126] However, for some of the Fourier peaks this calculation gives Cu–O distances that are hardly credible (1.75 Å, 1.71 Å, 1.25 Å and 1.22 Å), unless sites that are too close together are assumed to be alternately unoccupied. To summarize, the hypothesis that Cu(4) is coordinated by randomly occupied sites is ambiguous and can only be understood in a vague way according to plausibility considerations. Figure 50 also shows that on the diagonals of the unit cell there are large gaps in the partial lattice. As can be seen from Figure 51, these are occupied by ring-shaped Cu_6O_{12} units. Thus we find here the same structural principles as in $Ba_9Cu_7O_{15}Cl_2$ (Fig. 47). However, in contrast to the compound described earlier, the six-membered rings are internally twisted in this case, and as a result the CuO_4 polygons are no longer exactly planar. Also in "$BaCuO_2$" the corners and the center of the cubic unit cell are occupied by another giant polyhedron of a special kind. This is shown in Figure 52 in open form (with yellow borders to the CuO_4 squares), and in Figure 53 with the planar CuO_4 units filled in yellow. Three mutually orthogonal rings, each made up of eight CuO_4 squares, are fused together to form a roughly spherical giant polyhedron with a diameter of about 6.5 A. Figure 53 clearly shows that those Cu^{2+} ions that are shown in Figure 50 with tetragonal pyramidal coordination are pushed out of the plane of the square towards the inside of the square pyramid. Thus, of the eighteen Cu^{2+} ions in the giant polyhedron, six are not in a planar oxygen environment. The discovery that the formula "$BaCuO_2$" must be corrected corresponds to an empty giant polyhedron. From each unit cell volume, which would otherwise have the constitution 90 $BaCuO_2 = Ba_{90}Cu_{90}O_{180}$, two Ba^{2+} ions are missing (from the center and a corner of the unit cell), so that the formula corresponding to this volume is $2 \times Ba_{44}Cu_{45}O_{90}$. Figure 54 illustrates how this comes about. Here one is looking into the interior of the large polyhedron and sees a portion of its inner surface. The spherical cavity, with a diameter of more than 6 Å, has 18 Cu^{2+} ions and 24 O^{2-} ions distributed over its surface, with the result that a charged particle in the interior of this giant polyhedron is surrounded by a roughly spherical shell with alternating positive and negative surface charges, and the coulomb attraction and coulomb repulsion forces are approximately balanced.

5.7. The Transition from Planar to Three-Dimensional Coordination

It was mentioned in Section 5.2, in connection with the example of $HoCu_2O_5$ (Fig. 35), that Cu^{2+} ions can certainly also have a distorted square coordination. This was also the case for parts of the $M_{10}Cu_{17}O_{29}$ crystal structure (Fig. 40). For oxocuprate(II) compounds of the $Ln_2Cu_2O_5$ series, it has been found[127] that the distortion of the CuO_4 squares is a function of the size of the Ln^{3+} ion. For large ions one obtains the [4 + 1] coordination of Cu^{2+} that is shown in Figure 55. At the ends of the Cu/O double chains that run parallel to each other it can be seen that one corner of the CuO_4 square is bent away. As a result, each Cu^{2+} ion acquires a fifth O^{2-} neighbor, forming a polyhedron in the form of a severely distorted tetragonal pyramid.

Transitions from planar units to polyhedra can be seen more clearly in the novel phases $La_{8-x}Sr_xCu_8O_{20-x/2}$.[128-131] The situation is illustrated by Figure 56, where the lanthanoid ions are shown in green. The coordination polygons of copper are shown in yellow, as in previous examples where copper ions were shown as spheres. It is immediately apparent that the Cu^{2+} ions are present in three different types of coordination: first, in isolated chains of square planar units; second, in an octahedral coordination; and third, in a tetragonal pyramid, with the positions interchanging cyclically between 0.25, 0.75 and 0.0. It should be noted that the Cu^{2+} ion shown in orange is in the base plane of the square pyramid.

The crystal structure of $La_{8-x}Sr_xCu_8O_{20-x/2}$ (Fig. 56) is related to that of $La_4BaCu_5O_{13+x}$,[132] as is evident from Figure 57. In this compound the chains of planar CuO_4 polyhedra are absent. To facilitate comparison with Figure 56, the lanthanoid ions in $La_4BaCu_5O_{13+x}$ (Fig. 57) are again shown in green, while the Ba^{2+} ion is shown as a red sphere. In this phase also the Cu^{2+} ions that are shown in orange do not lie inside the CuO_5 pyramids (yellow) but in their base planes. These structural features are not exceptional cases, as they are also found in other crystal structures, for example that of $Ba_3Y_2PtCu_2O_{10}$ (Fig. 58).[133] In Figure 58, the Ba^{2+} ions are shown in red, both as spheres and in a cubic coordi-

nation. The PtO_6 octahedra are orange-colored, and the tetragonal pyramids around the Cu^{2+} ions are shown in yellow, while the Y^{3+} ions are shown as green spheres. It can be clearly seen that in this compound also the copper ions do not lie inside the tetragonal pyramids formed by the oxygen ions. The same is found for the halogenooxocuprate $Ca_3Cu_2O_4Cl_2$ whose structure has recently been published.[134] Its structure is derived from the $Sr_3Ti_2O_7$ type;[125] other isotypes of $Ca_3Cu_2O_4Cl_2$ are the phases $Ln_{2-x}A_{1+x}Cu_2O_{6-x/2}$[136,137] and $Ba_3In_2O_6$[138] and related compounds.[139,140] The removal of one oxygen ion from the $Sr_3Ti_2O_7$ type results in compounds with the general formula $M_3A_2X_6$, whose structure is shown in Figure 59 for the case of $Ca_3Cu_2O_4Cl_2$. The double layer of octahedra in the $Sr_3Ti_2O_7$ type structure is replaced here by a double layer of tetragonal CuO_4Cl pyramids (yellow polyhedra), each with a Cl^- ion (orange-colored sphere) at its apex. The Ca^{2+} ions are shown in red. Those Cu^{2+} ions that are here shown in green can be clearly seen projecting out of the faces of the pyramids.

A particularly good example of the transition from planar to three-dimensional coordination is seen in the severely distorted CuO_4 squares in $CaCuV_2O_7$.[141] The complete structure of this compound is shown in Figure 60. The polyhedra around the vanadium ions are shown in green and those around Ca(2) in orange, while the Ca(1) ions are shown as red spheres in open polyhedra. However, from the standpoint of the coordination of the Cu^{2+} ions, the main point of interest here concerns the severely twisted CuO_4 squares, which are shown in yellow. The twisting is, however, not so severe as to produce a regular tetrahedron; instead the CuO_4 coordination in $CaCuV_2O_7$ can be regarded as comparable with the twisted squares in $M_{10}Cu_{17}O_{29}$ (Fig. 40).

6. Cu^{2+} Ions in Closed Polyhedra

6.1. Tetrahedra, Square Pyramids, and Small Distorted Polyhedra

We have already encountered in the previous section some crystal structures (those of $La_{8-x}Sr_xCu_8O_{20-x/2}$ and $La_4BaCu_5O_{13+x}$, Figs. 56 and 57) in which a proportion of the Cu^{2+} ions have an octahedral coordination to O^{2-}. The following examples show that Cu^{2+} ions in oxometalates can also occur exclusively in closed polyhedra. Figure 61 shows that $Cu_2V_2O_7$ has perfectly formed CuO_4 tetrahedra (yellow) and VO_4 tetrahedra (red).[142] Tetrahedrally coordinated Cu^{2+} ions are also found in, for example, α-$CuVO_3$,[143] $Cu_xV_4O_{11}$[144] and the β-alumina (Ba,Sr)-$CuAl_{10}O_{17}$.[145]

Figure 62 shows the essential features of the structure of a group of compounds with the general formula $BaCuLn_2O_5$.[68,84,146,147] This group of copper-containing oxometalates constitutes a further structural type with the same empirical formula as those in Section 5.1, but having Cu^{2+} in a square pyramidal instead of a planar coordination. The green polyhedra are trigonal prisms formed by O^{2-} ions around Ln^{3+} ions, while the red polyhedra show the oxygen environment of the Ba^{2+} ions, and the yellow square pyramids with a noticeably stretched apex have Cu^{2+} ions within them.

Identical Cu^{2+} coordination polyhedra are found for $SrCuV_2O_7$,[148] whose structure is shown in Figures 63 and 64. The Sr^{2+} ions and the polyhedra around Sr^{2+} are shown in red, while those around V^{5+} are green and around Cu^{2+} are yellow. It is clearly seen that the V_2O_7 double tetrahedra, which are not linked in a straight line, are joined to form a network with the yellow CuO_5 polyhedra. Further details of the coordination spheres can be found in the original publication.[148] In $SrCuV_2O_7$ the Cu^{2+} ions are again unambiguously found to occupy the interior of a tetragonal pyramid formed by their coordination to oxygen. Other examples of structures in which Cu^{2+} ions have a square pyramidal coordination are those of α-$Cu_2V_2O_7$[149] and β-$Cu_2V_2O_7$.[142,150]

When we move on to the barium copper oxovanadate $BaCu_2V_2O_8$,[151] which contains a higher proportion of copper, we obtain a new insight into the crystal chemistry of the Cu^{2+} ion. The Cu–O distances found for this compound (4×1.94 to 1.98 Å; 1×2.31 Å; 1×2.65 Å) indicate that here we have a transition from a tetragonal pyramid to an octahedron. Figure 65 shows the complete structure of $BaCu_2V_2O_8$. The polyhedra around Ba(1) are shown in red, while the Ba(2) sites are shown by orange-colored spheres and the tetrahedra around the V^{5+} ions are shown in green. In constructing the polyhedra around the Cu^{2+} ions (yellow), the value assumed for the Cu–O distance was 2.31 Å. However, the sixth O^{2-} neighbor, whose distance is 43% greater than those for the base of the octahedron (1.94 to 1.98 Å), is not shown. If one were to ignore the sixth O^{2-} neighbor, this would, of course, result in the Cu^{2+} ion lying in the plane of the tetragonal pyramid, and this indicates that the more distant coordination partner (2.65 Å) cannot be totally ignored. Examples of structures with a combination of tetragonal pyramids and octahedra are those of $Cu_3Mo_2O_9$,[152] $Cu_{4-x}Mo_3O_{12}$ ($x = 0.15$)[153] and $CuMoO_4$.[154]

6.2. Cu^{2+} Ions with Octahedral Coordination

The best known example of the group of oxometalates with copper in a stretched octahedral coordination, following the discovery of the superconductor $La_{2-x}Sr_xCuO_4$, is the lanthanum oxocuprate La_2CuO_4.[93,155] Of all the compounds with the general formula Ln_2CuO_4 (Ln = lanthanoid), La_2CuO_4 is the only one with octahedrally coordinated Cu^{2+}; this is surprising, and remains unexplained. In all the other compounds (Ln = Pr to Gd), Cu^{2+} has a planar oxygen environment (see Section 5.4). Despite its orthorhombic symmetry and the slight tilting of the base faces of the CuO_6 octahedra relative to each other, the structure of La_2CuO_4 is of the same type as K_2NiF_4. Figure 66 shows the crystal structure of La_2CuO_4. A noticeable feature is the position of the La^{3+} ions, shown as red spheres, which are quite close to the large faces of the square antiprisms formed by the O^{2-} ions. It is less obvious from the figure that the CuO_6 octahedra (yellow) are considerably elongated in the direction of the long c-axis. The oxygen partners orientated along the [001] axis, i.e. at the upper and lower vertices, are

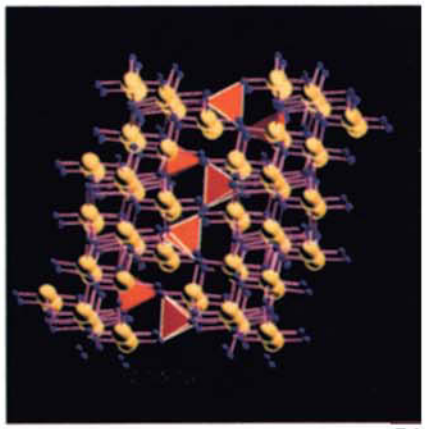
71



72

about 30% further away from the Cu^{2+} ion than are those in the basal plane of the octahedron.

The compound $La_2Li_{0.5}Cu_{0.5}O_4$, whose structure has recently been published,[156] is closely related to La_2CuO_4. It can be seen from Figure 67 that the layers of octahedra, resembling those of La_2CuO_4, are here made up of orderly arrays of octahedra occupied by Cu^{2+} (yellow) and Li^+ (orange). As before, the lanthanum ions are shown in red, and their arrangement corresponds to that in La_2CuO_4.

The halogenooxocuprates with the constitution $M_2CuO_2X_2$ are also variants of the K_2NiF_4 type structure, as shown by the results for the cases where $M = Sr^{2+}$, $X = Cl^-$[157] or Br^-,[158] and $M = Ca$, $X = Cl^-$ or Br^-.[159] The relationship of their crystal chemistry to that of La_2CuO_4 can be seen from Figure 68. Comparing this with Figure 66, it is evident that here the apexes of the octahedra orientated along the [001] direction are occupied by halogen ions (orange-colored spheres). The noticeably greater Cu–X distances lead to an enlargement of the square antiprism coordination around the Sr^{2+} or Ca^{2+} ions (red spheres), with the result that these cations are now within the MO_4X_5 polyhedra (M = Ca, Sr; X = Cl, Br).

Recently there has been increased activity in the measuring of the physical properties of halogenooxocuprates. As an example we may take the compound $Sr_2CuO_2Cl_2$, whose electrical conductivity, band gaps and magnetic properties have been investigated.[160]

Ba_2CuWO_6 also has considerably stretched octahedra (shown in yellow Fig. 69).[161] However, a more interesting feature in this compound is the [6 + 2] coordination of O^{2-} ions around Ba^{2+}, shown here by red polyhedra. It is shown here in filled surface form, together with the elongated CuO_6 octahedra (yellow) and the WO_6 octahedra (green). This structure should be compared with that in Figure 48, where we saw that in $Ba_9Cu_7O_{15}Cl_2$, the Ba^{2+} ion is surrounded by six O^{2-} ions and two Cl^- ions forming a hexagonal bipyramid. It was noted that there one had a spherical close packing arrangement in which three O^{2-} ions were replaced by a Cl^- ion, which is understandable in view of the size of the Cl^- ion. In the compound Ba_2CuWO_6 that is under discussion here, the Cl^- ions of Figure 48 have been formally replaced by O^{2-} ions in a one-for-one exchange, which means that the space occupied by three O^{2-} ions in the regular cuboctahedron of the spherical close packing shrinks to the volume of a single O^{2-} ion. This results in a BaO_{6+2} bipyramid.

To finish these examples of octahedrally coordinated Cu^{2+} ions we consider Figures 70, 71 and 72. Figure 70 shows the crystal structure of $CuUO_4$[162, 163] and Figure 71 that of $CuVO_3$.[164, 165] Both structures contain isolated CuO_6 octahedra, shown in yellow. Figure 72 shows the structure of $V_2Cu_5O_{10}$,[166] consisting of a tightly knit lattice made up of CuO_6 octahedra and trigonal bipyramids, within which lie isolated VO_4 tetrahedra. The "ball and stick" representation chosen here gives a better indication of the dense network formed by the Cu/O polyhedra in $V_2Cu_5O_{10}$. Other compounds with octahedrally coordinated Cu^{2+} ions are $CuSb_2O_6$,[167, 168] $CuGeO_3$,[169, 170] $LiVCuO_4$,[171, 172] CuV_2O_6,[173] $Cu_xV_2O_5$,[174] $Cu_3V_2O_6$[175] and $Ba_4CaCu_3O_{8.61}$.[176]

Finally, it must be mentioned that Cu^{2+} can also have a trigonal bipyramidal coordination,[166, 167] and in the phase $Cu_{0.64}V_2O_6$ it lies within a doubly capped trigonal prism of O^{2-} ions.[178] The very large Cu–O distances found in $Cu_{0.64}V_2O_5$ (2.45 Å, 2.55 Å and 2.65 Å) lead one to suspect that there is a valence exchange with the vanadium ions and that the large CuO_{6+2} prisms are occupied by Cu^+ as the cation.

7. Summary

The crystal chemistry of copper in oxometalates, as presented through the examples that have been discussed in Sections 2 to 6, conveys an impression of the many different types of coordination adopted by copper in solids, depending on its oxidation state and on its role in the crystal structure. Of the oxidation states of copper, the Cu^{3+} ion is the only one that at present appears to behave consistently, apart from an isolated exception. The oxocuprate(III) compounds discussed here all have Cu^{3+} in a square planar environment of oxygen ions, the observed planar coordination conforming to what is expected for the d^8 electron configuration. Unfortunately, the number of oxocuprate(III) compounds that have been studied thoroughly is very small, and consequently the question of possible departures from planarity cannot yet be answered with certainty.

Although a sweeping generalization cannot be made, the Cu^+ oxidation state is typically found to result in an O–Cu–O coordination with a more or less well-defined dumbbell shape. This structure is found for all compounds with alkali metals, and for all compounds containing bulky and strongly basic ions such as Ca^{2+}, Sr^{2+}, Ba^{2+}, Nd^{3+} or La^{3+}. Thus, when large cations are present, the Cu^+ ions and the associated oxygen ions take on the role of a kind of anionic partial lattice whose main crystal chemical characteristic is the dumbbell-shaped O–Cu–O coordination. Compounds of this type are referred to as oxocuprate(I) compounds. One can also include in this class compounds in which the anionic role of the copper is not so obvious in their constitution, for example as in $CuAlO_2$ (Fig. 6), $Sr_9Zn_4Cu_2O_{14}$ (Fig. 9) and β-$CuNdW_2O_8$ (Fig. 8). In addition to these oxocuprate(I) compounds there are other examples, such as α-$LaCuW_2O_8$ (Fig. 17) and Cu_2WO_4 (Fig. 18), that contain structures other than the dumbbell-shaped coordination (e.g. those containing planar CuO_3 groups), through to the more radically different types with tetrahedral coordination ($Cu_6Mo_5O_{18}$, Fig. 19) and octahedral coordination ($Cu_4Mo_5O_{17}$). In the latter two compounds Cu^+ has the role of a cation in a situation comparable with salt-type compounds of non-metals, and it thus loses the dumbbell-shaped coordination typical of oxocuprate(I) compounds.

The crystal chemistry of oxocuprate(II) compounds is by far the most interesting, as it encompasses a wide variety of types of coordination ranging from isolated planar CuO_4 units to closed polyhedra. The results from studies during the last ten years, especially those that have given rise to research programs on superconductors, lead one to seriously question whether the planar Cu^{2+} coordination that has in

the past been regarded as characteristic of oxocuprate(II) compounds is truly typical for this oxidation state. Unfortunately the situation on this point is confused owing to the existence of a pronounced Jahn–Teller effect for the Cu^{2+} ion with its d^9 configuration. Where Cu^{2+} is in a truly planar environment of O^{2-} ions this is, after all, just a limiting case of a severely stretched octahedron. Some examples of compounds in which the planarity of the polygons formed by O^{2-} ions around Cu^{2+} is only apparent are $CaCu_3Ge_4O_{12}$ (Fig. 32), $CaCu_2O_3$ (Fig. 39) and $KCuTa_3O_9$ (Fig. 45), since there is a degree of arbitrariness in ignoring the coordination to distant O^{2-} neighbors in these oxocuprate(II) compounds; in most cases these have the effect of extending the planar polygons to form stretched octahedra. On the other hand there are other examples, such as $La_{8-x}Sr_xCu_8O_{20-x/2}$ (Fig. 56), $La_4BaCu_5O_{13+x}$ (Fig. 57), $Ba_3Y_2PtCu_2O_{10}$ (Fig. 58) and $Ca_3Cu_2O_4Cl_2$ (Fig. 59), and also many oxide superconductors that are not covered in this article, whose structures indicate quite different preferences with regard to the arrangement of coordination partners. In the examples mentioned, Cu^{2+} is regarded as having a square pyramidal coordination, but this does not take into account the fact that the Cu^{2+} ion "ignores" the fifth (more distant) coordination partner, insofar as it lies exactly in the base plane of the square pyramid. Is the apex of the square pyramid really a normal coordination site, despite its relatively close proximity to the Cu^{2+} ion? There is less ambiguity regarding the other compounds, directly comparable with the above, in which the apex of the tetragonal pyramid is formed by a halogen ion (examples: $Ca_3Cu_2O_4Cl_2$, Fig. 59, and $Ba_3Cu_2O_4Cl_2$, Figs. 43 and 44); this ion must be regarded as a normal coordination partner in view of its size in relation to the Cu–Cl distance.

It has also been shown here that for the oxometalates of divalent copper one can recognize transitions from a planar to a closed (three-dimensional) coordination, for example in $Ho_2Cu_2O_5$ (Fig. 55) and $CaCuV_2O_7$ (Fig. 60). Copper in the divalent oxidation state can also exhibit well-formed coordination polyhedra of the tetragonal pyramidal, bipyramidal, tetrahedral and octahedral types. Thus it can be concluded that the Cu^{2+} ion, like the Cu^+ ion, adapts its crystal chemical role according to the nature of the cations present in the compound concerned.

From the above we can arrive at the following statement concerning the crystal chemical role of divalent copper in oxo compounds: if the Cu^{2+} ions together with oxygen form an anionic partial lattice, then they assume a planar coordination. This also applies to compounds with extremely stretched octahedra that cannot be accounted for by a Jahn–Teller distortion. The neighboring ions that extend the polyhedra to form an apparently octahedral [4 + 2] coordination make a negligible contribution as coordination partners, and under these circumstances it seems justifiable to regard the coordination as being reduced to planar polygons. Coordination in the form of square pyramids with Cu^{2+} in their basal planes can also be regarded as evidence that the copper forms part of an anionic partial lattice. In either of these cases one has an oxocuprate(II) compound. If, on the other hand, Cu^{2+} acts as a cation, as in the numerous oxovanadates (or in salts of non-metals), one finds closed polyhedra such as tetrahedra, octahedra, bipyramids or trigonal prisms. Compounds of this kind should be described as copper oxometalates.

The crystal chemical function of Cu^{2+} in compounds with square pyramids or moderately stretched octahedra, such as $BaCuLn_2O_6$ (Fig. 62), La_2CuO_4 (Fig. 66) or $M_2CuO_2X_2$ (Fig. 68), remains unclear. In La_2CuO_4 chemical considerations indicate that the strongly basic La^{3+} ion is the cation, so that the Cu^{2+} ion is compelled to become a constituent of the anionic partial lattice. However, this view is contradicted by the fact that one cannot ignore the two distant O^{2-} neighbors which extend the planar coordination to form a stretched octahedron. A good example of how the crystal chemical role of Cu^{2+} is adapted according to the basicity of the ions involved is provided by structures of the $CaCu_2O_3$ type. The Cu^{2+} ion is only rather weakly basic compared with Ca^{2+}, which means that for practical purposes it has an anionic role in the crystal structure and is planar coordinated. In the analogous compounds $MgCu_2O_3$ and $CoCu_2O_3$, Cu^{2+} is similar in basicity to Mg^{2+} or Co^{2+}. Consequently two further O^{2-} ions are drawn into the coordination, thereby unambiguously extending it to form a stretched octahedron (cf. Section 5.4). This shows that for the divalent oxidation state of copper also the transition from oxocuprate to copper oxometalate is gradual rather than abrupt.

The ability of Cu^{2+} to form giant polyhedra within the three-dimensional crystal lattice is a unique phenomenon in copper–oxygen chemistry. The beauty of the shapes of these and the elegant simplicity that frequently emerges in the way they are formed from planar units comes as a reward for the often very laborious work of structure determination.

In conclusion one is left with the impression that, despite the fact that many oxo compounds of copper have been studied in great detail in the intervening years, the crystal chemistry of these compounds certainly does not present a simpler and clearer picture today than it did thirty years ago, when the first review article on the subject appeared.[3]

I thank the Fonds der Chemischen Industrie and the Bundesministerium für Forschung und Technologie for providing funds to purchase a computer graphics workstation. My colleagues Dr. Bluhm and Herr Voss wrote the computer programs for the scanning method used to display the crystal structures in color. Herr Gressling helped in the preparation of a series of ORTEP files used in preparing the 3D graphics. I thank them all for their help.

Chemical Reactions in the Manufacture of Waveguides for Long Distance Optical Data Transmission

By Michael Binnewies,* Marion Jerzembeck, and Andreas Kornick

Dedicated to Professor Hans Georg von Schnering on the occasion of his 60th birthday

One of the modern high technologies which has advanced enormously in the last few years is glass fiber technology. This is used in the manufacture of glass fibers for lighting purposes and for the optical transfer of analog and digital data with a high transfer density. The technical demands made on the glass fibers required for data transfer, the optical waveguides, are extremely high and are already fulfilled to a large extent by industry. At present about four million kilometers of fiber, worth ca. 800 million DM are produced worldwide (10% in the Federal Republic of Germany). Numerous chemical processes take place during the manufacture of optical waveguides. However, in contrast both to the high and constantly growing demands on the quality and to the increasing production volume of such fibers, little is in fact known about the reactions involved. The present article will attempt to develop a picture of the multifarious reactions occurring in the course of this technical process on the basis of literature data and our own studies.

1. Introduction

The transmission of analog, and in particular digital signals at a high spatial and temporal information density has been of rapidly growing importance in the past few years. Classical metallic conductors are subject to physical limits as far as the maximum information density which can be transmitted is concerned. Much higher information densities should in principle be achievable when optical communication media are used. The prerequisites for an effective transfer of information with the aid of light are:

1. Powerful transmitters.
2. Materials which are capable of fast modulation of the light waves.
3. Transfer media which permit the transmission of the modulated light waves across long distances with as low a degree of attenuation as possible.
4. Sensitive and fast light detectors.

Scientific progress in solid-state chemistry and physics during the last 20 years has played a decisive role in the development, manufacture and in particular in the *understanding* of the materials referred to under 1, 2 and 4. However, the transfer medium, the optical waveguide, has been brought to an exemplary state of technical perfection in a manner which is basically empirical (though by no means less effective!); the term "empirical" refers not to the well-known *physical* basis of this technology but to the extremely complex *chemical* reactions occurring during the manufacturing processes. It is however by no means unknown in history for technologies to undergo purely empirical development. The best-known example is the history of metallurgy, in the beginnings of which our ancestors were able to obtain metals from oxide minerals and coal without knowing anything of the chemistry involved (to say nothing of the Boudouard equilibrium!). The heretical postulate which could be put forward at this juncture is: *research is not necessary*. In the case of many technically manufactured materials the scientist is justifiably still interested even today in the material itself, while the processes by which it is formed are of only minor interest. The relationships between the properties and the genesis of a material are often studied only empirically in the absence of parallel studies which can lead to an understanding of the chemical mechanisms involved in their formation.

1.1. The Physical Principle of the Optical Waveguide

The purpose of the present article is not to present the physical background of light propagation in optical waveguides in detail but to investigate the chemical processes involved in their manufacture. However, a brief look at the physical principle[1] appears imperative in order that we can understand why "chemistry" is in fact necessary here at all.

When a ray of light passing through a medium of refractive index n_1 is incident on a medium of lower refractive index n_2 ($n_1 > n_2$) at an angle of incidence below a certain limiting value it will undergo total reflection, i.e. it cannot leave the medium. Thus if it is possible to produce a transparent rod consisting of a core of refractive index n_1 and a coating of refractive index n_2, light entering the core of the rod at one end will exit at the other end without being able to leave the rod sideways at any stage; this will be the case even when the rod is bent. Such a rod can be easily prepared by fusing a glass tube (n_2) on to a glass rod (n_1) and readily be drawn out to give a thin filament without any appreciable change in the refractive index profile, so that the optical properties remain unchanged. A so-called step-index fiber in which the refractive index changes in a stepwise manner over the fiber cross-section (Fig. 1a) does however have one principle disadvantage which makes a high transmission density impossible; this is the dispersion (for details see Ref. [2]). One of the important points here is that light pulses which enter an optical waveguide can have differing transit times: a pulse which enters exactly parallel to the fiber axis will in an ideal case be able to exit the fiber without undergoing

reflection (assuming the fiber to be linear). However, a pulse which is subject to repeated reflection will traverse a longer path and will thus exit the fiber with a certain small time delay. This leads to a broadening of the output signal with respect to the input signal and thus a priori to a lower transmission density. These differences in the transit time can be considerably reduced if the refractive index does not vary in a stepwise manner across the fiber diameter but decreases from the fiber center to its boundary according to a certain predetermined parabolic function (Fig. 1 b). In this case the

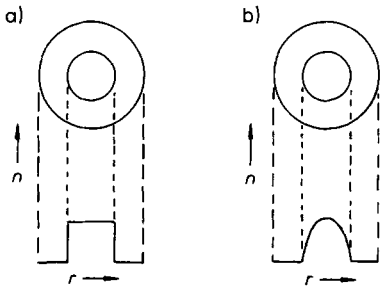

Fig. 1. Schematic representation of the variation of the refractive index across the fiber diameter in step index fibers (a) and gradient fibers (b).

light pulse which passes through the center of the fiber without undergoing reflection is slowed down by the higher refractive index (i.e. by the reduced light velocity) so that differences in transit time can be eliminated to a large extent. Such a fiber, known as a gradient fiber, can of course not be obtained simply by fusing a rod and a tube together.

2. The Internal Coating Process for the Manufacture of Gradient Fibers

Initial attempts to obtain gradient fibers involved the application of glass-forming powder layers of continually increasing refractive index to the inner surface of a quartz tube; the powder layers were subsequently fused to the quartz tube, and the blank thus prepared was then allowed to melt under controlled conditions to give a rod which could be pulled out to give a fiber. However, this process could not be developed to a stage suitable for commercial manufacture.

The much more successful processes used today involve the deposition from the gas phase of glass-forming oxides of higher refractive index.

The starting material is a tube made of high-purity quartz (external diameter ca. 3 cm, length ca. 2 m). A stream of oxygen containing $SiCl_4$ vapor is passed through the rotating tube. Dopant materials such as $GeCl_4$, BCl_3 and $P(O)Cl_3$ are added to this gas stream at concentrations which can be metered and varied exactly according to a predetermined program.[3] When the necessary energy of activation is applied, the reaction of the oxygen with the volatile halides or oxide halides of the elements silicon, germanium, boron and phosphorus leads to the formation of the oxides of these elements; these are deposited as solids on the inner surface of the quartz tube and fuse with it at high temperatures. Figure 2 shows the nature of the industrial process. The gas

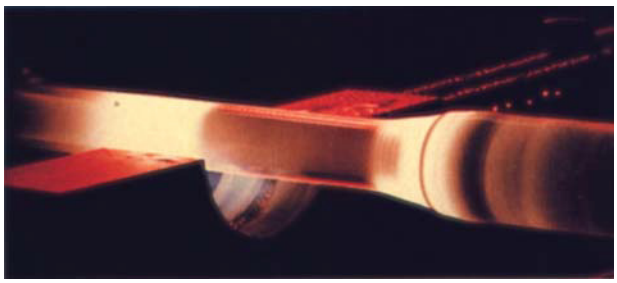

Fig. 2. Manufacture of the blanks for optical waveguides. The photograph shows a rotating glass tube through which the reaction mixture is passed. The tube is heated by oxyhydrogen burners which are slowly moved parallel to the axis of rotation of the tube during the process, which lasts several hours; an even deposition is thus achieved along the whole length of the tube.

mixture enters the quartz tube from the left and is heated by a battery of oxyhydrogen burners. The deposition of the solids occurs within and immediately subsequent to the zone of heating.

Variation of the concentrations of the added dopant substances permits the predetermination and continual variation of the refractive index of the deposited layers. Such a CVD (*C*hemical *V*apor *D*eposition) process makes it possible to obtain the required refractive index profile. When this goal has been achieved, the tube is fused at high temperatures to give a rod, from which a fiber can be drawn which has the originally constructed refractive index profile. Such a blank affords ca. 50 km of optical waveguide material.

Michael Binnewies, who was born in 1947 in Hagen/Westfalen (FRG), studied chemistry at the University of Münster, where he gained his Diploma and thereafter his doctorate in 1973 under the supervision of Harald Schäfer. He then spent a few years doing research into the development of mass spectrometric measuring techniques for the investigation of chemical transport reactions. His current research interests focus on high-temperature reactions, plasma chemistry, and halogen compounds of semi- and non-metals. After continuing his researches at the Max-Planck-Institut für Festkörperforschung, Stuttgart (1979), he returned to Münster, where he habilitated in 1985. In 1988 he accepted the offer of a professorial chair at the University of Freiburg.

Figure 3 shows a raster electron microscope picture of the end face of such a fiber. The deposited layers can be seen clearly within the higher-refracting core of the fiber. The activation of the required chemical reaction can be carried

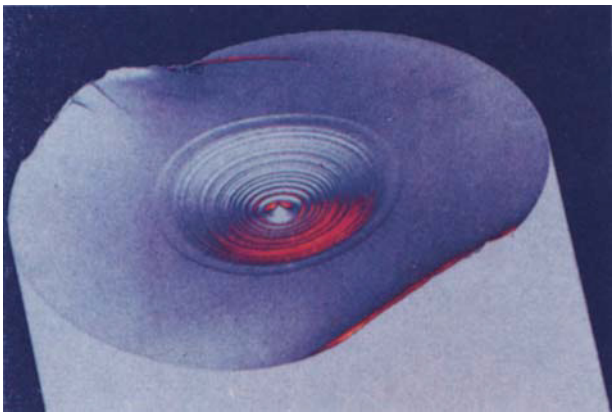

Fig. 3. Raster electron microscope picture of the end face of an optical waveguide. The external diameter of the fiber is ca. 120 μm.

out either thermally ($T > 1300$ K) or by means of the application of a non-isothermal plasma.

3. Chemical Reactions

The chemical reactions occurring in the course of the process described seem at a first glance to be simple [Eq. (a)–(d)]. All these reactions are exothermic, the equilibrium constants are larger than unity even at higher temperatures (except for (b)), ΔG^0 is negative (except for (b) above 1200 K). Some numerical values are collected in Table 1. The reactions (a)–(d), like all reactions involved in CVD processes,

$$SiCl_4 + O_2 \rightleftharpoons SiO_2 + 2Cl_2 \quad (a)$$

$$GeCl_4 + O_2 \rightleftharpoons GeO_2 + 2Cl_2 \quad (b)$$

$$2BCl_3 + 1.5O_2 \rightleftharpoons B_2O_3 + 3Cl_2 \quad (c)$$

$$4POCl_3 + 3O_2 \rightleftharpoons P_4O_{10} + 6Cl_2 \quad (d)$$

describe processes in which solids separate from a gaseous phase; thus molecular precursors undergo conversion into infinite three-dimensional lattices (the fact that the oxides are deposited as a glass rather than in a crystalline form is of no importance for the following discussion). Such processes cannot in fact be so simple as the equations (a)–(d) would lead one to expect. A number of very basic questions must be addressed when we consider how a solid is formed starting from a gas phase (or from a solution or melt): are detectable intermediates formed and what are their nature? What are the thermodynamic properties of the system? How does nucleation occur starting from such a gas phase? When can one already speak of the existence of a solid and when must one still speak of a molecule? Questions of this and similar types are presently being addressed and discussed by many groups working with "simpler" systems such as metal vapors (cluster formation in molecular beams).

In the following discussion we shall deal with the above reactions of the non-metal halides and oxide halides of silicon, germanium, and phosphorus, and attempt to find answers to some of the above questions.

Table 1. Selected thermodynamic data of the reactions (a)–(d).

Reaction	ΔH^0_{298} [kJ mol^{-1}]	ΔS^0_{298} [J K^{-1} mol^{-1}]	K_{1000}	K_{1500}	ΔG_{1200} [kJ mol^{-1}]
(a)	−242.7 [4]	−40.1 [4]	3.8×10^{10}	2.3×10^{6}	−194.6
(b)	−79.9 [4, 5]	−67.8 [4, 5]	4.3	0.17	1.5
(c)	−456.9 [4, 5]	−165.1 [4, 5]	1.7×10^{15}	1.9×10^{7}	−258.8
(d)	−770.7 [4]	−349.9 [4]	9.6×10^{21}	1.45	−350.8

3.1. The Reactions of $SiCl_4$ and $GeCl_4$ with O_2

The first studies of these apparently simple reactions were carried out long before their future technical importance could be imagined. In 1868 *Friedel* and *Ladenburg* reported the formation of Si_2OCl_6 during the reaction of $SiCl_4$ with O_2 in a porcelain tube heated by burning coke.[6] *Troost* and *Hautefeuille* obtained mixtures of higher molecular weight chlorosiloxanes in a similar manner a few years later.[7, 8] A series of further studies of the reaction followed in which the original results were confirmed and supplemented.[9, 10] A large number of related chlorosiloxanes have been described[11–13] and in part structurally characterized[11] in recent years. The common feature of all these reports is that the compounds described were prepared in the reaction between $SiCl_4$ and O_2 at high temperatures (around 1300 K) or in a gas discharge (plasma), i.e. in the same reaction and under similar conditions as those which are so important for the technology of the manufacture of optical waveguides. The chlorosiloxanes presently known are collected in Table 2. Thus, reaction (a) apparently does not by any means occur as formulated above via the formation and separation of solid SiO_2, but in a much more complex manner. How can we understand the formation of such a large number of compounds? Let us start by considering their structures. The plethora of siloxanes listed in Table 2 can be divided into four groups:

Table 2. Chlorosiloxanes observed in the plasmachemically and thermally activated reactions of $SiCl_4$ with O_2.

Formula	Plasma-chemical	Thermal	Formula	Plasma-chemical	Thermal
Si_2OCl_6	[12, 13]	[6], [9–13]	$Si_4O_5Cl_6$	[12, 13]	
$Si_3O_2Cl_8$	[12, 13]	[10–13]	$Si_5O_6Cl_8$	[12, 13]	[7, 8]
$Si_4O_3Cl_{10}$	[12, 13]	[10–13]	$Si_6O_8Cl_8$		[11, 13]
$Si_5O_4Cl_{12}$	[12, 13]	[10, 12]	$Si_6O_7Cl_{10}$	[13]	[11, 13]
$Si_6O_5Cl_{14}$	[12, 13]	[10]	$Si_7O_8Cl_{12}$		[13]
$Si_7O_6Cl_{16}$	[12]	[10]	$Si_7O_9Cl_{10}$		[13]
$Si_3O_3Cl_6$	[12, 13]	[11–13]	$Si_8O_{11}Cl_{10}$		[12]
$Si_4O_4Cl_8$	[12, 13]	[9–13]	Si_3OCl_8	[12]	
$Si_5O_5Cl_{10}$	[12, 13]	[11, 12]	Si_4OCl_{10}	[12]	
$Si_6O_6Cl_{12}$	[12, 13]	[12]	$Si_4O_2Cl_{10}$	[12]	
$Si_7O_7Cl_{14}$	[12]		$Si_5O_3Cl_{12}$	[12]	

Group 1: $Si_nO_{n-m}Cl_{2n+2}$ (n = 3–5, m = 2, 3)
Group 2: $Si_nO_{n-1}Cl_{2n+2}$ (n = 2–7)
Group 3: $Si_nO_nCl_{2n}$ (n = 3–7)
Group 4: $Si_nO_{n+m}Cl_{2n-2m}$ (n = 4–8, m = 1–3)

The siloxanes thus classified differ in their oxygen content, which increases on going from Group 1 to Group 4. This has consequences for the structure of the compounds:

Group 1. The composition indicates that Si–Si bonds must be present.[13] These siloxanes have only been observed in plasma-activated reactions, and they are of no importance for the following discussion.

Group 2. The compounds in this large group are built up from chains in which the Si atoms are bridged by oxygen atoms.[11, 14, 15]

Group 3. In most cases these molecules have closed monocyclic structures, although monocyclic arrangements with an exocyclic $SiCl_3$ group bonded via an oxygen bridge are known.[11] The molecular structure of $Si_4O_4Cl_8$ was determined by X-ray crystallography[16] (Fig. 4).

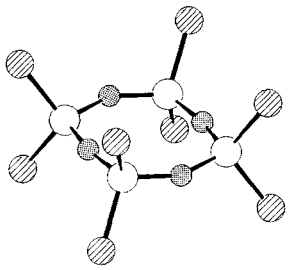

Fig. 4. Molecular structure of $Si_4O_4Cl_8$. Open circles are Si atoms, dotted are O atoms, and shaded are Cl atoms.

Group 4. Chlorosiloxanes which contain more oxygen than silicon atoms must be oligocyclic in nature. Bicyclic structures result for m = 1, tricyclic for m = 2,[11] etc. The limiting case in this series (n = m) is SiO_2. An initial relationship between the chlorosiloxanes and solid SiO_2 thus becomes clear.

An answer to the question as to the stability of the chlorosiloxanes is given by mass spectrometric studies of the reaction of $SiCl_4$ with O_2[12] and the thermolysis of Si_2OCl_6.[13] These have shown that the proportion of the siloxanes in the various groups changes greatly as a function of the reaction temperature (Fig. 5): the amount of chain-like siloxanes decreases very rapidly with increasing temperature, while the concentrations of the monocyclic and in particular of the oligocyclic siloxanes increase. Thus, an increase in the temperature accelerates reactions in which relatively oxygen-poor open chain siloxanes such as Si_2OCl_6 are converted into oxygen-richer compounds. This is shown by the representative reactions described by Equations (e) to (g).

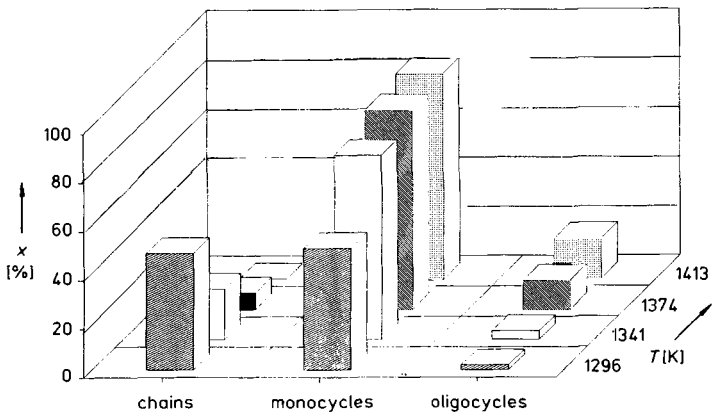

Fig. 5. Temperature dependence of the distribution of the chlorosiloxanes observed during the pyrolysis of Si_2OCl_6.

$$4\,Si_2OCl_6 \rightleftharpoons Si_4O_4Cl_8 + 4\,SiCl_4 \quad (e)$$

$$8\,Si_2OCl_6 \rightleftharpoons Si_6O_8Cl_8 + 10\,SiCl_4 \quad (f)$$

$$11\,Si_2OCl_6 \rightleftharpoons Si_8O_{11}Cl_{10} + 14\,SiCl_4 \quad (g)$$

The limiting case of such reactions is the decomposition of a siloxane to give the binary compounds $SiCl_4$ and SiO_2 [Eq. (h)]:

$$2\,Si_2OCl_6 \rightleftharpoons SiO_2 + 3\,SiCl_4 \quad (h)$$

What is the enthalpy and entropy balance of these reactions? Since the total number of Si–O and Si–Cl bonds remains unchanged, the reaction enthalpies are expected to be close to zero,[12, 13] as the bonding situation in the starting materials and products is very similar (see Section 3.2). However, increasing oxygen content and decreasing chlorine content in a siloxane corresponds to increasing stabilization. This can be demonstrated on the basis of the bond energies of the Si–O and Si–Cl bonds: Si–O bond 464.8 kJ/bond (in SiO_2, data from Ref. [4]), Si–Cl bond 399.5 kJ/bond (in $SiCl_4$, data from Ref. [4]). The reactions (e)–(h) thus involve the formation of a product with a lower enthalpy content (oxygen-richer siloxane and SiO_2 respectively) and a product with higher enthalpy content ($SiCl_4$), so that the energy balance will be around 0 kJ.

However, all four reactions involve an increase in the number of moles present, so that there is a gain in entropy. This entropy effect favors the formation of the oxygen-richer reaction products, and in particular that of the oxygen-richest compound SiO_2. It can thus be concluded that all the chlorosiloxanes must be metastable with respect to decomposition to give SiO_2 and $SiCl_4$. However, the formation of detectable amounts of SiO_2 is only observed above ca. 1500 K.[12] The origin of this reaction inhibition presumably lies in the fact that the formation of the SiO_2 structure must be a kinetically extremely complex process which requires a high energy of activation.

The increasing degree of formation of oxygen-rich siloxanes with increasing temperature signifies in several respects that these compounds are continually becoming more "SiO_2-like":

1. More and more Si–O bonds are formed.
2. The molecular structures become increasingly more complex (one-dimensional Si–O skeletons in the chain-like, two-dimensional in the monocyclic, and three-dimensional in the oligocyclic siloxanes).
3. The enthalpy content steadily approaches that of SiO_2.

Let us return to the technology of the optical waveguide manufacture (thermal activation of the reaction) and attempt to develop a picture of the reaction scheme on the basis of the above discussion: the gas mixture $SiCl_4/O_2$ (+ dopant materials) enters the glass tube at room temperature and is heated steadily as it approaches the heating zone. The formation of halosiloxanes, mainly Si_2OCl_6, starts at

around 1300 K. However, this cannot be the first step in the long reaction sequence which leads to solid SiO_2, as it would require a thermolecular reaction step in which two molecules of $SiCl_4$ and one molecule of oxygen combine with elimination of Cl_2. The primary formation of a reactive molecule appears much more likely, the most probable candidate being $Si(O)Cl_2$. Nothing is presently known with respect to the existence of this molecule in the gas phase; however, it has been detected in a helium-cooled argon matrix,[17] so that its intermediate formation in the gas phase also appears likely. The formation of cyclic siloxanes $Si_nO_nCl_{2n}$ in higher concentrations thus points to the formation of $Si(O)Cl_2$, since the former are oligomers of this reactive molecule and could be formed from it via oligomerization reactions. The formation of open-chain siloxanes such as Si_2OCl_6 from a reaction between $Si(O)Cl_2$ and excess $SiCl_4$ is also plausible. The formation of the oligocyclic siloxanes is most probably due to the entropically favored decomposition (see above) of the monocyclic compounds into oxygen-richer oligocycles and oxygen-poorer chain compounds or $SiCl_4$ (see above); other reaction pathways are of course possible. There are in principle two types of reaction which could in the final analysis be responsible for the deposition of SiO_2: either the decomposition of oligocyclic chlorosiloxanes which are presumably oxygen-rich and already contain several Si–O bonds to give the binary components SiO_2 and $SiCl_4$ (or oxygen-poorer siloxanes) or an exothermic reaction between chlorosiloxanes and oxygen via reactive intermediates which eventually leads to the formation of SiO_2 and Cl_2.

Figure 6 shows one of many possible routes from molecular $SiCl_4$ to solid SiO_2; this includes a number of the compounds listed in Table 2. Without any doubt the higher molecular weight siloxanes such as $Si_8O_{11}Cl_{10}$ are of particular interest in this connection; one of its many possible isomers is shown in Figure 6. A small detail of the SiO_2 structure, two SiO_4 tetrahedra joined via a common apex, is already preformed. The formation of solid SiO_2 from such molecules appears plausible and should be kinetically readily achievable. The formation of solid SiO_2 from $Si_8O_{11}Cl_{10}$ requires the formation of oxygen-poorer siloxanes (or $SiCl_4$) which can then re-enter the reaction cycle. The chlorosiloxanes formed in a stepwise manner can thus be regarded as intermediates in a chemical reaction between simple molecules ($SiCl_4$ and O_2) which eventually lead to the formation of a three-dimensional solid structure (including glasses). The formation of the Si–O bonds occurs in a stepwise manner: one or two Si–O bonds per Si atom in the chain molecules, two Si–O bonds in the monocycles and two, three (for the bridgehead Si atoms) or even four Si–O bonds ($Si_8O_{11}Cl_{10}$) in the oligocyclic siloxanes.

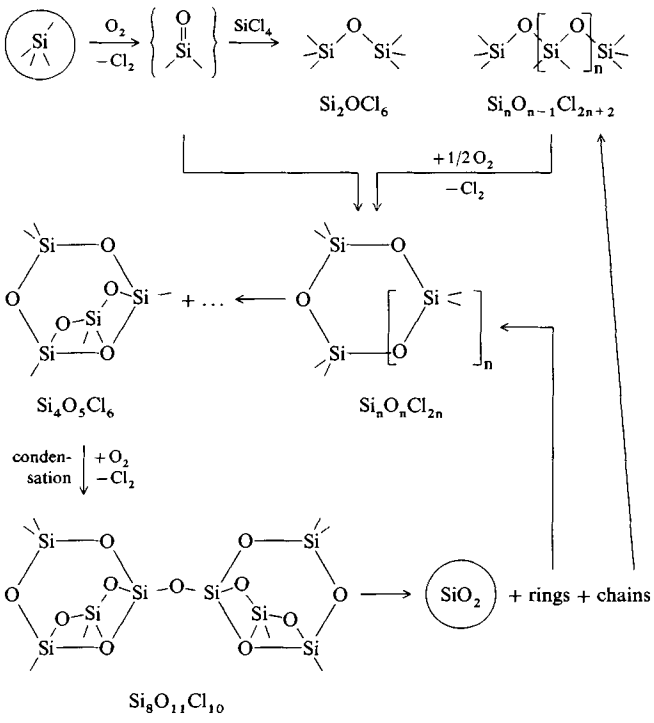

Fig. 6. Reaction scheme for a possible course of the reaction between $SiCl_4$ and O_2 to yield SiO_2.

Thus the system Si/Cl/O offers fascinating possibilities for studying the stepwise transition from molecular compounds to solids and thus for increasing our understanding of reactions of this type in which solids are deposited from the gas phase. The formation of this large variety of chlorosiloxanes (which are thermodynamically unstable with respect to SiO_2 and $SiCl_4$) is certainly not fortuitous; their stepwise formation is possibly a necessary prerequisite for the construction of an SiO_2 structure.

In contrast to the reaction pathways suggested here, other intermediates and mechanisms have been discussed in the literature. Thus in connection with optical waveguide technology *McAfee, Laudise* and *Hozack* have published a detailed paper dealing with the thermodynamics of gaseous species in the system Si/Ge/O/Cl; their discussion mainly involves the existence of lower (oxidation state + 2) halides and oxides of Si and Ge (i.e. molecules of very low molecular weight) in the temperature range 1400–4000 K.[18] However, the evidence presented above shows clearly that the deposition of SiO_2 is almost complete at temperatures of ca. 1500 K, so that a discussion of the composition of the gas phase at temperatures far above 1500 K does not appear particularly useful. In addition, thermodynamically unstable compounds such as the siloxanes discussed above are naturally not amenable to thermodynamic calculations.

In contrast to the reaction between silicon tetrachloride and oxygen, which has been studied in great detail, the literature contains very little information on the analogous reaction of germanium tetrachloride. Ge_2OCl_6 has been described as a reaction product.[19, 20] Our own studies of this reaction under the conditions of low-pressure gas discharge have also demonstrated the formation of the additional chlorogermoxanes $Ge_3O_2Cl_8$, $Ge_4O_3Cl_{10}$, $Ge_3O_3Cl_6$, $Ge_4O_4Cl_8$, $Ge_5O_5Cl_{10}$ and $Ge_4O_5Cl_6$.[21] This indicates that the system Ge/O/Cl is very similar to the system Si/O/Cl described above.

3.2. The Reaction of BCl_3 with O_2

Studies of the equilibrium between liquid B_2O_3 and BCl_3 vapor at temperatures above 500 K have demonstrated the existence of the cyclic chloroboroxines $B_3O_3Cl_3$ and $B_4O_4Cl_4$ as well as of BOCl, which is formed at measurable

concentrations at higher temperatures (> 1200 K).[22-24] The thermodynamic data determined indicate that at temperatures above 1000 K these compounds should be formed in a direct reaction between BCl_3 and O_2, i.e. during reactions of $SiCl_4/GeCl_4/BCl_3/P(O)Cl_3/O_2$-mixtures occurring during the manufacture of glass fibers. In contrast to the behavior of the siloxanes, the decomposition of (for example) $B_3O_3Cl_3$ into the binary compounds B_2O_3 (liquid) and BCl_3 (gas) is not expected. In agreement with this hypothesis the formation of $B_3O_3Cl_3$ has been detected spectroscopically in the course of the reaction of BCl_3 with O_2.[25] Studies of this reaction under plasmachemical conditions show that apart from the cyclic boroxines the linear molecules B_2OCl_4 and $B_3O_2Cl_5$ are also formed.[26] Oligocyclic analogues of the siloxanes are unknown in the system B/O/Cl. If the decomposition of the chloroboroxines cannot lead to the formation of B_2O_3, the deposition of which certainly occurs, the formation of the boroxide must occur via another reaction pathway. This can only involve the reaction of the initially formed boroxines with oxygen, which is present in excess. The thermodynamic data[4] for such reactions do indeed lead us to expect that the deposition of B_2O_3 will occur. Thus the reaction of $B_3O_3Cl_3$ with O_2 as shown in Equation (i) is strongly exothermic ($\Delta H^0_{298} = -551.7\ kJ\,mol^{-1}$,[4] though it is accompanied by an entropy loss ($\Delta S^0_{298} = -295.5\ J\,K^{-1}\,mol^{-1}$).[4]

$$2\ B_3O_3Cl_3\ (gaseous) + 1.5\ O_2 \rightleftharpoons 2\ B_2O_3\ (liquid) + 3\ Cl_2 \qquad (i)$$

These values lead to equilibrium constants much greater than unity even at high reaction temperatures.

Why is the thermal behavior of the gaseous chlorosiloxanes and chloroboroxines predicted on the basis of thermodynamics so different? To answer this question we shall take as an example the monocyclic compounds $Si_3O_3Cl_6$ and $B_3O_3Cl_3$ and their decomposition according to Equations (j) and (k) to give the binary compounds ($T > 1500$ K).

$$Si_3O_3Cl_6\ (gaseous) \rightleftharpoons 1.5\ SiO_2\ (solid) + 1.5\ SiCl_4\ (gaseous) \qquad (j)$$

$$B_3O_3Cl_3\ (gaseous) \rightleftharpoons B_2O_3\ (solid) + BCl_3\ (gaseous) \qquad (k)$$

Both reactions are expected to have low reaction enthalpies, since (with similar bonding conditions in starting materials and products) the number of element–oxygen and element–chlorine bonds remains unchanged (ΔH^0_{298} is unknown, $\Delta H^0_{298} = -42.9\ kJ\,mol^{-1}$[4]). The reason must thus lie in the entropy balance. Reaction (j) is expected to have a reaction entropy considerably larger than zero (see above), while for reaction (k), in which the number of moles is constant, there should be no great entropy change (experimental value: $\Delta S^0_{298} = -56.3\ J\,K^{-1}\,mol^{-1}$[4]). Thus, the different thermal behavior depends on the stoichiometry of the decomposition reactions of $B_3O_3Cl_3$ and $Si_3O_3Cl_6$ and the resulting difference in the entropy balance.

Attempts to obtain $B_3O_3Cl_3$ in the condensed phase have been unsuccessful; the main reason for this is also the change in the entropy balance of the decomposition reaction of hypothetical $B_3O_3Cl_3$ (solid, liquid) in favor of the decomposition products.

Since the thermodynamic data of several of the chloroboroxines formed in the system B/O/Cl are known, it is possible to discuss the relation between their stabilities and those of the starting material BCl_3 and the reaction product B_2O_3 [in the sense of Equation (c)]. The standard enthalpies of formation[4, 25, 26] of the compounds of interest here are plotted in Figure 7 against the quotients of the number of moles of B and O (as a measure of the composition of the compound). It is clear that the relationship between composition and energy content is almost linear. This shows that the bonding energies of the B–Cl bond in BCl_3 and of the B–O bond in B_2O_3 are almost the same as the corresponding bonding energies in the chloroboroxines. The replacement of

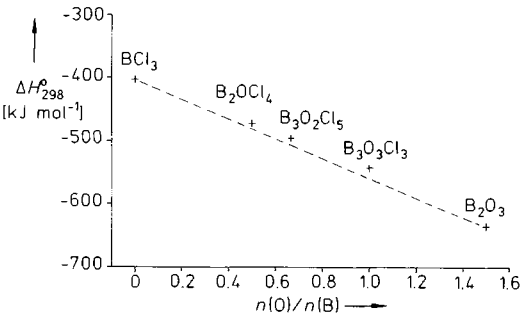

Fig. 7. Graphical representation of the enthalpy content of BCl_3, B_2O_3, B_2OCl_4, $B_3O_2Cl_5$ and $B_3O_3Cl_3$.

each B–Cl bond by a B–O bond corresponds to a stepwise approach to the thermodynamically stable final product B_2O_3 without any marked change in the bonding situation. Thus, from the thermodynamic point of view we can consider the formation of the chloroboroxines as initial steps towards the formation of B_2O_3. In this system the formation of a highly reactive molecule, here O=B–Cl, must also be considered as a possible first step; the oligomerization of this intermediate can lead to the formation of the cyclic boroxines,[24] while its reaction with excess BCl_3 makes possible the formation of B_2OCl_4 and longer chain analogues. Structural relationships between the molecular chloroboroxines and B_2O_3 are also evident, for example the tendency for the formation of chains and rings containing alternating O and B atoms which is also a feature of the structure of solid B_2O_3.

3.3. The Reaction between $POCl_3$ and O_2

Our own investigations into the plasma-activated reaction of PCl_3 with O_2[27] have demonstrated the formation of a

Table 3. Phosphorus oxychlorides observed in plasmachemically and thermally activated reactions.

Formula	Plasma-chemical	Thermal	Formula	Plasma-chemical	Thermal
$P_2O_3Cl_4$	[28]	[28–57]	$P_5O_6Cl_7$	[28]	[28, 36, 39]
$P_3O_6Cl_3$	[28]	[28, 36, 39, 40, 44, 46–48]	$P_6O_{13}Cl_4$	[28]	
			$P_6O_{12}Cl_6$	[28]	[28]
$P_3O_5Cl_5$	[28]	[28, 38, 39]	$P_6O_{11}Cl_8$	[28]	[28, 36]
$P_4O_9Cl_2$	[28]	[28]	$P_7O_{16}Cl_3$	[28]	
$P_4O_8Cl_4$	[28]	[28, 39]	$P_7O_{15}Cl_5$	[28]	[39]
$P_4O_7Cl_6$	[28]	[28, 36, 39]	$P_7O_{14}Cl_7$	[28]	
$P_5O_{11}Cl_3$	[28]	[39]	$P_8O_{17}Cl_6$	[28]	[39]
$P_5O_{10}Cl_5$	[28]	[28]			

large variety of phosphorus oxide chlorides.[28] The compounds detected in this reaction can also be obtained in the condensed phase from the reaction between P_4O_{10} and $POCl_3$ as well as from other reactions. They have been characterized by various spectroscopic (NMR, IR, Raman) and chromatographic techniques and in some cases structurally characterized. All the molecular oxide chlorides of phosphorus presently known which contain more than one P atom in the oxidation state + 5 are collected in Table 3. In analogy to the chlorosiloxanes these can be divided into several homologous series:

Group 1: $P_nO_{2n-1}Cl_{n+2}$ (n = 2–7)
Group 2: $P_nO_{2n}Cl_n$ (n = 3–7)
Group 3: $P_nO_{2n+1}Cl_{n-2}$ (n = 4–8)

In contrast to the situation in the siloxane series, the composition of the compounds does not permit us to draw unequivocal conclusions as to the structure of the compounds. Thus the members of Group 1 could be chain molecules, but there are also other possibilities: thus $P_4O_7Cl_6$ could also be an oligocyclic compound derived from P_4O_{10} by replacement of three terminal oxygen atoms by six chlorine atoms. Here we must refer to the experimental studies cited in Table 3. In analogy to the structural chemistry of the metaphosphates (the compounds discussed here correspond formally to the chlorides of the corresponding metaphosphates) we can expect the compounds in Group 2 to be monocyclic. However, oligocyclic compounds are also possible, at least in some cases. Thus while $P_4O_8Cl_4$ could be an eight-membered ring, a structure derived from P_4O_{10} by replacement of two terminal oxygen atoms by four chlorine atoms would also be in agreement with the structural chemistry of the phosphates. Group 3 must contain only oligocyclic compounds if we exclude structures in which a phosphorus atom is doubly bonded to two oxygen atoms. The literature contains no information regarding the thermodynamic stability of any of the compounds listed in Table 3. The most likely decomposition reaction involves the formation of P_4O_{10} and $POCl_3$, here demonstrated for the case of $P_5O_{10}Cl_5$ [Equation (l)]:

$$3\,P_5O_{10}Cl_5 \rightleftharpoons 2.5\,P_4O_{10} + 5\,POCl_3 \qquad (l)$$

Decomposition to give the binary components P_4O_{10} and PCl_5 (or PCl_3 and Cl_2) is not expected because of the extreme thermodynamic stability of $POCl_3$. The reaction enthalpy for the process described by (l) is unknown and cannot readily be estimated. The reaction entropy should however be clearly positive, so that we can assume that the decomposition products are thermodynamically favored. The compounds listed in Table 3 should thus be metastable. This is supported by reports[28, 44] in which the thermal instability of these oxide chlorides of phosphorus is described.

As in the system Si/O/Cl, metastable compounds are thus formed which can be regarded as intermediates in the reaction between $POCl_3$ and O_2 (the final product of this reaction in the manufacture of optical waveguides is certainly not molecular P_4O_{10} but compounds in which silicon atoms in SiO_2 are replaced by phosphorus, the excess positive charge being compensated by the incorporation of boron atoms at other positions in the lattice). The initial step in the long series of reactions leading to the deposition of the solid may well be the formation of PO_2Cl, which has been detected and characterized both in the gas phase by mass spectrometry[58] and by means of matrix spectroscopy[59] and photoelectron spectroscopy.[60] The formation of oligomers of this molecule ($P_nO_{2n}Cl_n$, n = 3–7) can be regarded as evidence for its primary formation.

3.4. Comments on the Incorporation of the Dopant Materials into the SiO_2 Matrix

In Sections 3.1–3.4 we have dealt separately with the chemical processes involved in the reactions between oxygen and the chlorides or oxide chlorides of silicon, germanium, boron and phosphorus. However, in the course of the technological application of these reactions in the manufacture of optical waveguides they will not occur in a spatially or temporally separated manner but simultaneously. The question thus arises as to the manner in which the dopants are incorporated into the SiO_2 glass occurs during the deposition of the solids are from the extremely complex gas phases present. Two basically different processes must be considered:

1. The oxides of the above elements are deposited in separate domains; the homogeneous distribution of the dopant substances occurs via diffusion processes.
2. The molecular "precursors" of the solids described above already contain the dopants in the form of "alien atoms".

It is of course not known whether these two possibilities are of any practical importance. However, since this is a question of scientific interest, we have carried out a series of experiments in which the plasma-activated reactions of oxygen with the mixtures $SiCl_4/GeCl_4$ and $SiCl_4/BCl_3$ were studied by mass spectrometry in order to clarify the situation regarding the possibility of the incorporation of "alien atoms" into the oxide halides of silicon. Since these gas phases naturally have enormously complex compositions, the analysis of the mass spectra obtained is difficult. It was however possible to identify the molecules $BSiOCl_5$, $BSi_2O_2Cl_7$, $SiGeOCl_6$, $Si_2GeO_2Cl_8$, $SiGe_2O_2Cl_8$ and $Si_2GeO_3Cl_6$ unequivocally.[21] This makes it clear that the incorporation of the alien atoms can in principle occur in the precursors of the solids. It can be assumed that both the above-mentioned possibilities for dopant incorporation will play a part in practice.

4. Summary and Future Prospects

The available information summarized above on the apparently very simple chemical reactions of elementary oxygen with the chlorides of silicon, germanium, boron and phosphorus which occur in the course of the manufacture of optical waveguides show clearly that the deposition of the solid oxides is preceded by the formation of a large number of oxide halides which can in several respects be regarded as precursor molecules of the oxides:

1. Their chemical compositions lie between those of the chlorides and the oxides, and are (in the case of the system $SiCl_4/O_2$ studied) strongly temperature-dependent in the

sense that the compounds become steadily oxygen-richer as the reaction proceeds (i.e. as the temperature increases).

2. The structural principles found in the oxides are already preformed in the oxide chloride molecules.
3. The thermodynamic stability of the oxide chlorides lies between those of the chlorides and the oxides.
4. Many of the oxide halides are formed even though they are thermodynamically unstable with respect to decomposition into the chloride and oxide. This can be explained on the basis that their intermediate formation is a necessary prerequisite for the construction of the solid oxide.
5. The primary formation of reactive, coordinatively unsaturated molecules ($SiOCl_2$, $GeOCl_2$, BOCl, PO_2Cl) is probable in all the cases discussed.

On the basis of the still very limited information presently available on the structures of the complex oxide chlorides it is possible to develop mechanisms which describe the transition from molecules to solids. These, although unconfirmed, appear reasonable in view of the establishment of the identities (and in many cases of the structures and stabilities) of the intermediately formed oxide chlorides. However, the enormously complex nature of the reactions involved makes it unlikely that it will become possible to obtain unequivocal evidence for the mechanisms discussed.

All the reactions described here lead to the deposition of oxides which are typical precursors of glasses. It should be noted that the information presently available indicates that the formation of polynuclear molecular oxide halides is limited to exactly these elements. This may be due to the fact that the latter have been the subject of particularly detailed studies, but it may also indicate that the prerequisites for the formation of such compounds are similar to those occurring during the formation of glasses (low coordination numbers, apical linking of the polyhedra).

The structural relationships between molecular compounds and "related" solids is by no means limited to the class of compounds described here. Thus for example we find details of the corresponding solid structures in many molecular cluster compounds.[61] A further impressive example is provided by the pyrolytic formation from $Si(CH_3)_4$ of a variety of carbosilanes, in which details of the lattice of the silicon carbide generated at high temperature are already preformed.[62]

Detectable unstable intermediates in which the final product of the reaction is already recognizable are also formed in other completely different reactions. Thus, *Goubeau* and *Keller* have demonstrated that the careful hydrolysis of BCl_3 leads to the formation of $B_3O_3Cl_3$,[63] i.e. exactly the same compound which is formed during the reaction between BCl_3 and O_2 in the gas phase at high temperatures. The formation of the siloxanes Si_2OCl_6, $Si_3O_2Cl_8$, $Si_4O_3Cl_{10}$, $Si_6O_2Cl_{14}$ and $Si_8O_3Cl_{18}$ was observed under analogous conditions during the hydrolysis of $SiCl_4$ and Si_2Cl_6 respectively.[64–66] It is thus clear that reactions can occur in a very similar manner even when they are carried out under such extremely different conditions. From this point of view it appears desirable to study the processes occurring during the hydrolysis of halides under the conditions described here as regards precursors (intermediates).

Numerous technical processes based on high-temperature reactions or on hydrolyses are carried out (successfully!) even though nothing is known about the course of the reactions involved. Monographs on industrial chemistry thus offer a rich source of impulses for scientific studies on the manner in which such reactions take place.

We thank the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie for their support of our investigations. We also thank Kabelmetall Elektro, Stuttgart, for making available the photographs showing industrial processes and Dr. M. Wittmann of this company for valuable discussions and suggestions.

On the Quasicrystalline State

By Sten Andersson,* Sven Lidin, Michael Jacob, and Osamu Terasaki

Dedicated to Professor Hans Georg von Schnering on the occasion of his 60th birthday

Zur Zeit ist zwar noch nicht ganz sicher, ob das durch unsere Brille Gesehene auch wirklich auf Dauer tragfähig sein wird, aber selbst wenn nur das Schöne in den Strukturen fester Stoffe bleiben sollte, es hätte sich allemal gelohnt.[**]

When we started to write the introduction to this article, we sought to describe *von Schnering*'s enormous contributions to solid-state science. Pages later we suddenly realized the introduction had become too long. As there was no way to shorten it, we gave up.

1. Introduction

In a little book by *Kowalewski*[3] published in 1921 there are some remarkable things we want to discuss. *Kowalewski* described the "Keplerschen Körper", a Kepler "Dreißigflach" that we now refer to as a rhombic triacontahedron or just triacontahedron. This polyhedron is built from what *Kowalewski* called Kepler rhombs, which have the property that the ratio of their diagonals is the golden mean, $\tau (= (\sqrt{5} + 1)/2)$. *Kepler* was interested in this polyhedron because it consists of two Platonic solids, the small diagonals forming the edges of a dodecahedron and the larger diagonals the edges of an icosahedron. Thirty such Kepler rhombs make up the triacontahedron, and *Kowalewski* showed how this solid can be built from two different building blocks (Bausteine), which he called "Flachblöcke" and "Steilblöcke" and we now call oblate and prolate rhombohedra. *Kowalewski* showed how ten of each kind make up the triacontahedron, and he was sure *Kepler* already knew this. Using a coloring scheme, *Kowalewski* derived our matching rules for filling space with such solids, in his case the triacontahedron. *Kowalewski* was not sure whether *Kepler* knew these rules.[4]

Kowalewski also found that, in a six-dimensional cube, 32 of the 64 corners constitute the six-dimensional *Urbild* of the triacontahedron. The other 32 corners also form an *Urform*, a *Komplement* of the first, which, in three dimensions, is a triacontahedron. He also showed that the 20 *Blöcke* (oblates and prolates) that make up the triacontahedron show up in the six-dimensional *Urbild* as equally sized three-dimensional cubes.

Kowalewski further described the rhombic dodecahedron as a compound of four oblates (Flachblöcke). Each such oblate is built of six rhombs, the diagonals having the ratio $1 : \sqrt{2}$ (Fig. 1). This fundamental Kowalewski oblate is the smallest unit that describes the body-centered cubic (bcc) structure and also is space-filling. Following Kowalewski, 14 of the 16 corners of a four-dimensional cube form the *Urbild* of the rhombic dodecahedron.

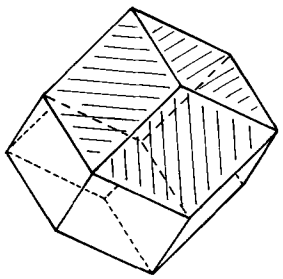

Fig. 1. The rhombic dodecahedron with one of the four Kowalewski "Flachblöcke" (oblates) that make up the solid.

2. Model for Quasicrystal Structures

Our first model was constructed from high-resolution electron microscopic (HREM) images of an AlCuFe alloy.[5, 6] It was clear it could be scaled down metrically by τ to four different structures. A recurrent theme in these structures is the principle of interpenetration. Polyhedra with icosahedral symmetry cannot fill space, but, if the polyhedra are allowed to interpenetrate, such packing can be achieved. The principle of interpenetration also explains the general features of

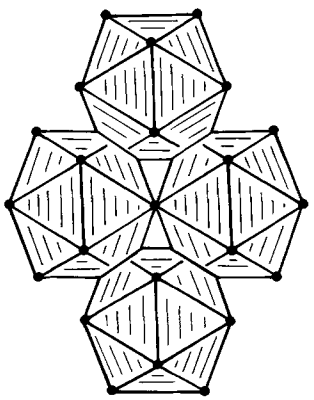

Fig. 2. Four icosahedra forming a Kepler rhomb.

[**] It is not yet certain whether our way of seeing things will hold up in the long run. However, even if only the beauty in the structures of solids should remain, it will have been worth the effort [1, 2].

HREM images of quasicrystalline materials. These images invariably seem to be composed of intersecting polygons.

We can show the principle of interpenetration with our simplest structure ($n = 1$). Four icosahedra are organized so that their centers form a Kepler rhomb (Fig. 2). If the icosahedral edge length is set to unity, the short and long diagonals are τ and τ and $\tau + 1$, respectively. This arrangement forces the icosahedra to interpenetrate along the fivefold axis (Fig. 3), so that the rhomb edge (quasi cell constant) becomes $(\tau\sqrt{\tau^2 + 1})/2$.

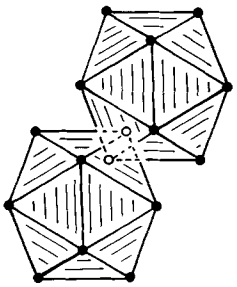

Fig. 3. The icosahedral interpenetration necessary to make the Kepler rhomb in Figure 2.

We have here the first fundamental building unit. We continue to fill space, with the important restriction that translation is forbidden, by adding icosahedra. A new type of interpenetration is created along the threefold axes of the icosahedron (Fig. 4). Having done this with a great number of icosahedra, we realize that prolates and oblates are created and they also appear to be joined together according to the matching rules. During the interpenetration most of the icosahedral corners are lost, but fivefold symmetry is imposed on the structure produced by the starting building block, the icosahedron.

In terms of prolates and oblates this is the same structure as reported before by *Elswijk* et al.[7] who also pointed out that the prolate structure is very close to a Laves phase structure. To this we want to add that two prolates joined via a mirror plane give a 36-atom unit of the hexagonal $MgZn_2$ structure, and also that the oblate contains an eight-atom bcc unit arranged as the Kowalewski oblate described in Figure 1. There is no need to use a special oblate structure—such units are always generated by the prolate arrangements. Another way to say this is that all the atoms of bcc units are created by prolates or $MgZn_2$ units or simply by the interpenetration principle.

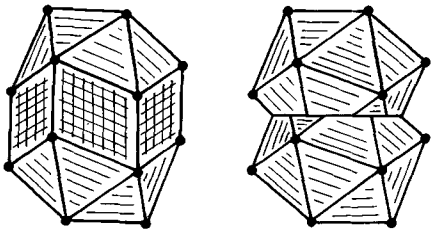

Fig. 4. Interpenetration along the icosahedral threefold axes.

The various steps in building a quasicrystal structure are shown with icosahedra in Figure 5. This algorithm, constructed[8] for deriving quasicrystal structures according to the interpenetration principle, will work equally well for the simulation of quasicrystal growth. This is of course general and applies also for members with $n = 2$–4. The expansion τ on $n = 1$ gives the structure shown in Figure 6 for the Kepler rhomb, which is the building unit for $n = 2$. The sequence along the fivefold axes is now as follows: interpenetration of icosahedra + interpenetration of pentagonal prisms and icosahedra. Along the twofold axes a part of the WAl_{12} structure is easily traced.

Complete icosahedral interpenetration on each corner of a central icosahedron gives the pentagonal dodecahedron, with edge lengths of unity. Complete pentagonal prism interpenetration on each corner of a central icosahedron gives the icosidocecahedron, with edge lengths of unity for $n = 1$ and 2. When further members are formed, the interpenetration around a central atom is interrupted along the twofold axis, that is, where parts of the Cr_3Si and WAl_{12} structures appear.

In the next member, $n = 3$, such icosidodecahedra are joined via icosahedra (Fig. 7); parts of the WAl_{12} structure form the threefold axis and the α-AlFeSi structure forms the twofold axis. We have earlier described the structures for $n = 4$.[5, 6] The structural and metric relationships for $n =$ 1–4 are given in Table 1.

Sten Andersson was born in 1931 on the island of Öland in Sweden. He studied at the University of Stockholm, where he received his Ph.D. in 1963. During his studies, he worked with the late A. D. Wadsley for one year (1960) in Melbourne. He was employed at the Research Institute of National Defense from 1962 to 1970 and was docent in Lund until 1983, when he became Professor of Inorganic Chemistry. He has published about 140 papers and one book, Inorganic Crystal Chemistry with B.G. Hyde. He has received an honorary doctorate from the University of Toulouse and was awarded the Humboldt research price in 1990. His present interest is the application of differential geometry and curvature to solid structures.

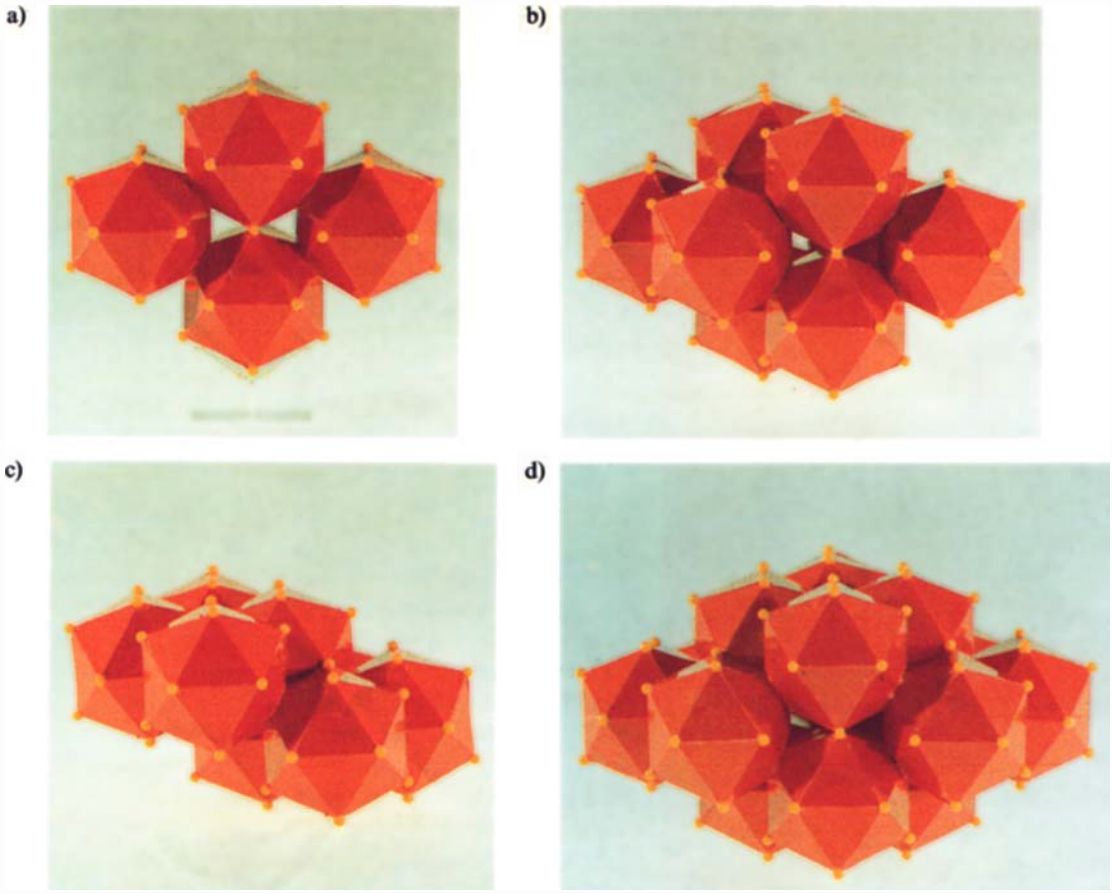

Fig. 5. *Icosahedra put together according to the interpenetration and nontranslational principle. Various well-known solids are formed directly:* a) a Kepler rhomb; b) two Kepler rhombs forming a prolate; c) two Kepler rhombs forming an oblate; d) two prolates and two oblates.

3. Relationships between the Model and the Structure of α-AlFeSi

The structures for $n = 3$ and 4 show strong similarities to the structure of the ternary alloy α-AlFeSi. In our description for $n = 4$,[5] we used the small rhombicosidodecahedron combined with the icosidodecahedron to build the structure. Later on we found that these two polyhedra also make up the α-AlFeSi structure, which we want to describe in more detail here.

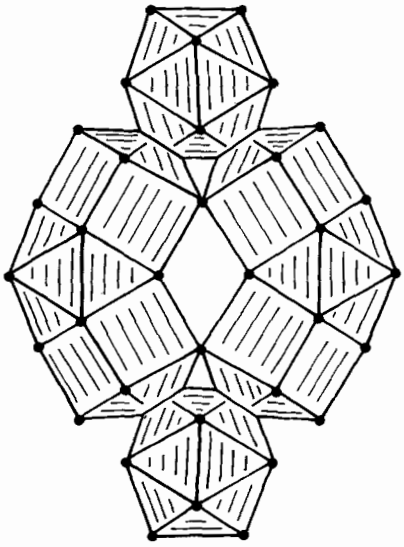

Fig. 6. Kepler rhomb for $n = 2$.

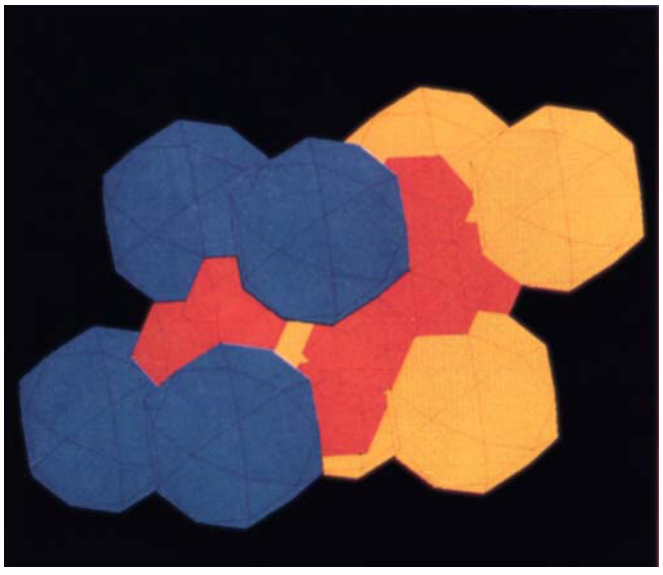

Fig. 7. Prolate for $n = 3$.

Table 1. Structural and metric relationships for $n = 1-4$.

n	Threefold quasi cell constant	Structure	Twofold quasi cell constant	Structure	Fivefold quasi cell constant
1	$\frac{\sqrt{3}}{2}$	bcc	τ	Cr_3Si	$\frac{\tau\sqrt{\tau^2+1}}{2}$
2	$\frac{\tau\sqrt{3}}{2}$	Cr_3Si	τ^2	WAl_{12}	$\frac{\tau^2\sqrt{\tau^2+1}}{2}$
3	$\frac{\tau^2\sqrt{3}}{2}$	WAl_{12}	τ^3	α-(AlFeSi)	$\frac{\tau^3\sqrt{\tau^2+1}}{2}$
4	$\frac{\tau^3\sqrt{3}}{2}$	α-AlFeSi	τ^4	–	$\frac{\tau^4\sqrt{\tau^2+1}}{2}$

In his structure determination of α-AlFeSi, *Cooper*[9] reports that in the cubic unit cell ($a = 12.56$ Å, space group $Im3$) certain sites are only partly occupied. He concludes that this is only an average structure, and that if space group $Pm3$ is used, with two different unit cells for a crystal, a chemically better model is obtained.

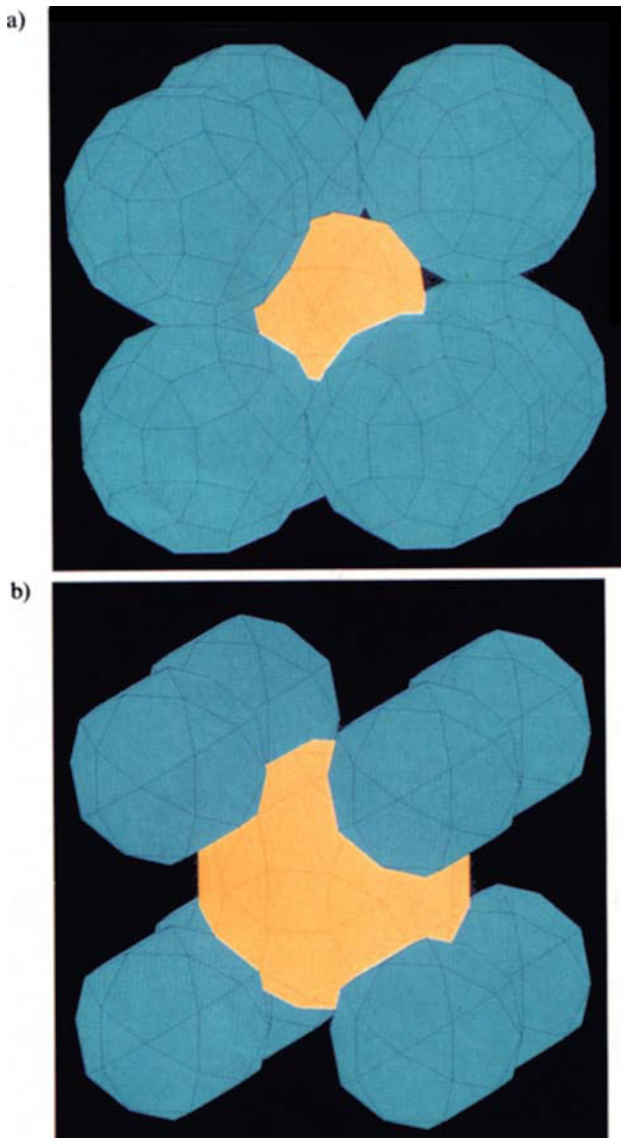

Fig. 8. The Cooper structures I (a) and II (b).

The Cooper structure is very accurately described with the small rhombicosidodecahedron sharing squares along the twofold axes and sharing triangles with an icosidodecahedron along the space diagonal. His two-unit-cell structures are then just related by a translation 1/2 1/2 1/2 (Fig. 8); his sets of coordinates for cell I and cell II were used in the calculation. The small rhombicosidodecahedron is built as follows: A central icosahedron is capped by pentagonal prisms to give the icosidodecahedron, which, in turn, is capped with pentagonal antiprisms to give the small rhombicosidodecahedron (Fig. 9).

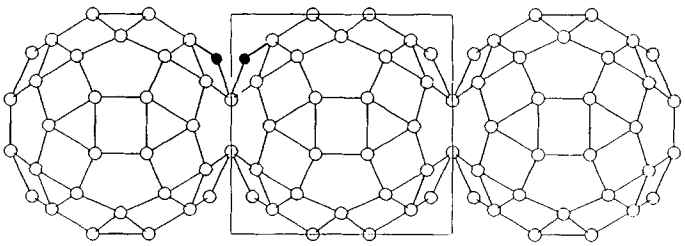

Fig. 9. The small rhombicosidodecahedron built of Al atoms in α-AlFeSi. The solid circles are undistorted polyhedral positions for Al(9).

Calculated and observed coordinates are given in Table 2. The major discrepancy is with atom Al(9). This atom has a distance to itself, via a mirror plane of 2.44 Å, and this is shortened for steric reasons. The square-face sharing of the small rhombicosidodecahedra forces neighboring atoms

Table 2. Comparison of observed [9] and calculated coordinates for α-AlFeSi.

Atom [a]	Observed x	y	z	Calculated x	y	z
Al(3)	0.165	0.101	0	$\frac{\tau^{-2}\sqrt{3}}{4} = 0.165$	$\frac{\tau^{-3}\sqrt{3}}{4} = 0.102$	0
Al(1)	0.378	0	0	$\tau^{-2} = 0.382$	0	0
Al(5)	0.115	0.187	0.300	$\frac{\tau^{-3}}{2} = 0.118$	$\frac{\tau^{-2}}{2} = 0.191$	$\frac{\tau^{-1}}{2} = 0.309$
Al(9)	0.327	0.403	0	$\frac{\tau^{-1}}{2} = 0.309$	$\frac{\tau^2+1}{2\tau^3} = 0.427$	0
Al(11)	0.128	0.117	0.5	$\frac{\tau^{-3}}{2} = 0.118$	$\frac{\tau^{-3}}{2} = 0.118$	0

[a] Al(2), Al(4), and Al(6) are obtained by translation $\frac{1}{2}\frac{1}{2}\frac{1}{2}$ from Al(1), Al(3), and Al(5), respectively. The Al(3) atoms are the corner atoms of the icosahedron centered in the icosidodecahedron. Al(1) and Al(5) are the corner atoms of the icosidodecahedron centered in the small rhombicosidodecahedron, but also "free". Al(9) and Al(11) are the corner atoms of the small rhombicosidodecahedron.

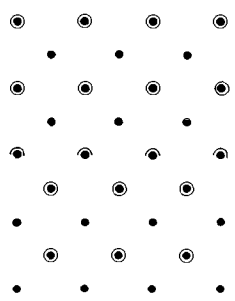

Fig. 10. Transition between two primitive structures—the average structure is body-centered. Small circles represent the icosidodecahedron, large the small rhombicosidodecahedron in *Cooper*'s structure.

from two polyhedra to come very close—after all, it is a large polyhedron—and the atoms are repelled from the polyhedral position. The standard deviation for this particular atom, $\sigma = 0.020$ Å, is also unique, since all other σ are less than 0.004 Å.

Alloy structures are often reported with certain sites partially occupied. *Cooper*'s solution to this problem using two unit cells is very elegant. We show in Figure 10 how domain regions could occur in a crystal.

Complex Transition Metal Hydrides

By Welf Bronger*

Dedicated to Professor Hans Georg von Schnering on the occasion of his 60th birthday

Compounds having structural units formed by transition metals and hydrogen have only become known fairly recently. Only the synthesis and structural characterization of ternary metal hydrides $A_xM_yH_z$, in which A is an alkali or alkaline-earth metal and M is a transition metal, led to the discovery of anionic complex groups of the form $[MH_z]$. Although there are obvious structural similarities to the corresponding halides and oxides, the dynamic properties of the hydride ligand are somewhat unusual and are responsible for numerous phase transformations. Transitions throughout the range from saltlike to metallic behavior make us expect interesting physical properties and applications.

1. Introduction

Our knowledge concerning metal-hydrogen compounds is relatively meager. This is largely because the preparation of such compounds, which in many cases are unstable, is more laborious and complicated than for other compounds of metals with nonmetals, as also is the determination of their structures and properties. This explains the fact that already for the binary hydrides of many metals only incomplete or vague information is available regarding their existence and properties. So far as main-group metals are concerned this situation applies, for example, to the hydrides of gallium and indium, and to the corresponding compounds of the metallic elements in later groups of the Periodic System. A similar picture emerges for the transition metals. Here too there remain many unresolved questions, such as whether or not manganese hydrides exist that are compounds of unique structural types, what phases exist in the chromium–hydrogen system, and many more. However, even on the basis of the incomplete knowledge available one can already classify binary metal hydrides into three groups: saltlike hydrides, covalent hydrides and metallic hydrides. Typical representatives of the first group are the hydrides of the alkali metals and alkaline-earth metals. The second group includes the hydrides of the remaining main-group metals or semimetals, and the third group includes the transition metal hydrides. However, the boundaries between these three groups are not sharply defined; this is not surprising since already for the elements there is a gradual transition from metallic to nonmetallic behavior.

If we extend this method of classification from the binary to the ternary metal hydrides, we can expect to find that of the various possible combinations of binary components one will result in a further group of hydrides, in which one of the metals (A) belongs to the type that forms saltlike hydrides whereas the other (M) belongs to those that form metallic hydrides. Compounds of this group have the general formula $A_xM_yH_z$. These hydrides can have a range of properties varying from metallic to saltlike, depending mainly on the position of the metal A in the scale of electronegativities. Thus we can expect that hydrides in which the component A is a heavy alkali metal or alkaline-earth metal will have more saltlike properties, whereas those containing lithium or magnesium, for example, will have more metallic properties. One can also predict that these hydrides will have crystal structures containing complex $[H_yH_z]$ groups that are stabilized by accepting the valence electrons from the x atoms of element A to form $[M_yH_z]^{nx-}$ anions, where n = 1 for alkali metal compounds and n = 2 for compounds of alkaline-earth metals.

This article describes complex hydrides with the composition $A_xM_yH_z$ and attempts, on the basis of the knowledge so far established, to summarize the conclusions that emerge, both expected and unexpected, so as to build up an initial picture. This picture should then be looked at in a wider context, since research on metal hydride complexes in the field of molecular chemistry has recently experienced a notable increase in acitivity and has led to interesting discoveries. Furthermore, knowledge now being gained is likely to unite previously disparate points of view, since molecular chemistry and solid-state chemistry both stem from the same roots.[1]

2. Methods of Synthesis and Structure Determination

Methods for synthesizing ternary hydrides $A_xM_yH_z$ that have been investigated include both molecular reactions in solvents and solid-state reactions in gaseous atmospheres.

Reaction of metal-alkyl compounds with metal hydrides in suitable solvents is reported to give ternary hydrides; for example, it is claimed that $Zn(sec\text{-}C_4H_9)_2$ reacts with KH to give K_2ZnH_4,[2] and $LiCu(CH_3)_2$ reacts with $LiAlH_4$ to give $LiCuH_2$.[2] However, these findings have not been verified beyond any possible doubt; the structures of the compounds are not known, and thus no firm answer can be given to the question of whether or not solvent molecules are inserted to exercise a stabilizing role. In another reaction, which is reminiscent of alchemy, a perrhenate or a pertechnetate is allowed to react with elemental potassium in an aqueous solution of ethylenediamine, and after a work-up procedure one obtains the respective ternary hydrides K_2ReH_9[3] or K_2TcH_9.[4]

[*] Prof. Dr. W. Bronger
Institut für Anorganische Chemie der Technischen Hochschule
Professor-Pirlet-Str. 1, W-5100 Aachen (FRG)

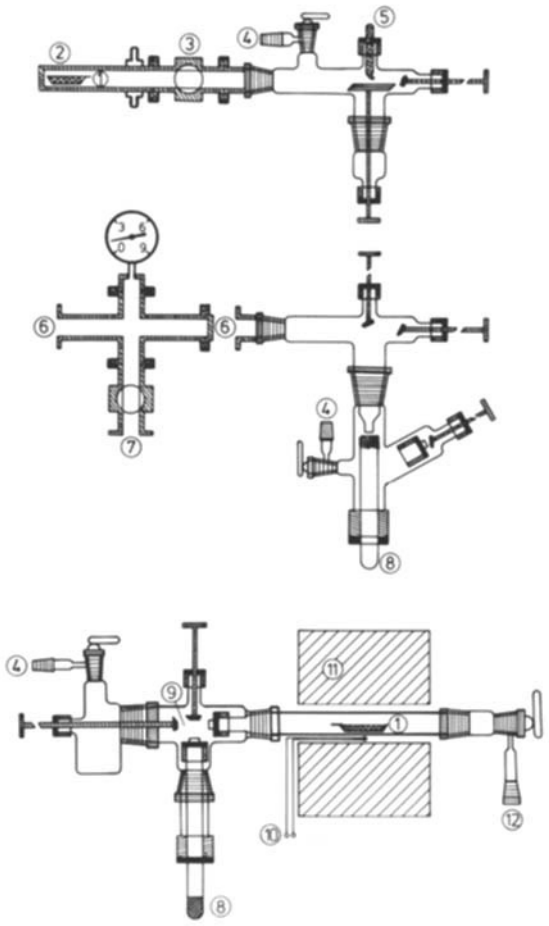

Fig. 1. Experimental arrangements for synthesizing binary and ternary metal hydrides. The upper two diagrams show types of apparatus for preparing binary alkali metal hydrides, while the bottom diagram illustrates the preparation of ternary hydrides: ① Reaction boats. ② Steel autoclave with cooling jacket. ③ Ball valve with flange connections. ④ Connection for vacuum/argon/hydrogen. ⑤ Ampoule containing alkali metal. ⑥ Connection for steel autoclave; ⑦ connection for vacuum/hydrogen. ⑧ Receiver tube for product. ⑨ Transfer chamber. ⑩ Thermocouple. ⑪ Reaction oven. ⑫ Connection for manometer.

In the solid-state reactions referred to, one either starts out from an intermetallic compound into which the hydrogen is directly inserted using suitable pressures and temperatures, or alternatively reacts a hydride of an alkali metal or alkaline-earth metal with a transition metal in an atmosphere of hydrogen or inert gas. These methods have been found useful especially during the last few years for synthesizing various ternary hydrides containing transition metals of subgroup eight. Examples are the hydrides Mg_2NiH_4,[5] obtained by reacting Mg_2Ni with hydrogen, and Na_2PtH_4,[6] obtained by reacting NaH with Pt in an atmosphere of hydrogen.

One of the reasons why there is as yet so little firmly established knowledge concerning complex metal hydrides is that many of them are extremely sensitive to air and moisture. However, the difficulties that otherwise occur in the synthesis and subsequent handling of these hydrides can be avoided by consistently working with closed apparatus systems. Figure 1 shows experimental arrangements that allow all the operations to be performed from outside the system using suitable manipulators.

In determining the crystal structures of metal hydrides one comes up against the problem that the positions of hydrogen atoms in an array of metal atoms can usually only be measured approximately, if indeed at all, by X-ray diffraction methods. The normal procedure based on measurements on single crystals is rarely successful here, especially in view of the fact that growing single crystals of hydrides is difficult. Consequently, the determination of the structure is usually approached by combining X-ray and neutron diffraction experiments on powdered samples; here the use of high resolution techniques is now becoming increasingly important.

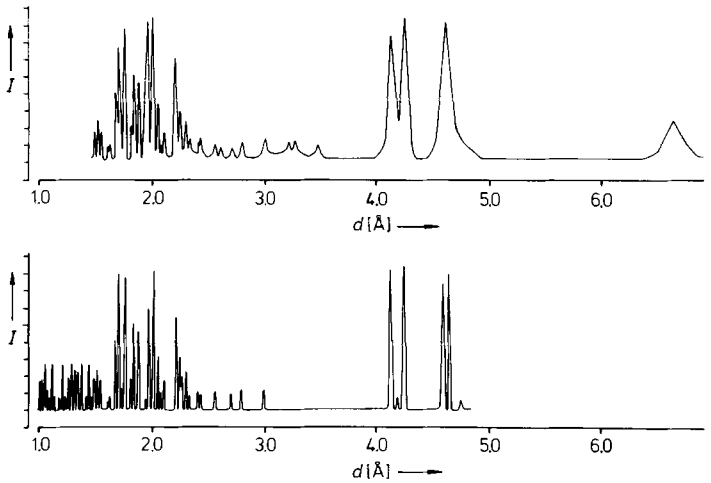

Fig. 2. Comparison of neutron diffraction patterns of Na_3RhD_6 measured using the TAS I and HRPD facilities (upper and lower traces respectively) at 295 K. The measurement times were 24 hours with TAS I and 12 hours with HRPD (the backgrounds were smoothed to produce the traces). The figure shows that some reflections which coincide in the TAS I trace are resolved when using the HRPD system. On the other hand, the neutron diffraction experiment using TAS I gives extra information at large *d*-values. For *d*-values greater than 3 Å the severe reduction in neutron flux with the HRPD system results in a progressive deterioration of the signal-to-noise ratio for a comparable measurement time, and consequently weak reflections cannot be detected in this region. *I* = intensity.

Welf Bronger, born in 1932 in Hamburg, studied chemistry at the universities of Innsbruck and Münster and gained his doctorate in 1961 under Wilhelm Klemm. After a short period working in industry for Degussa, he returned to the Universität Münster as an assistant, where he received his "Habilitation" in 1966. In 1969 he took up the chair of Inorganic and Analytical Chemistry at the Technische Hochschule, Aachen. His main research interests are concerned with intermetallic phases, metal chalcogenides and metal hydrides, with special emphasis on structural studies and magnetochemistry.

This is illustrated by Figure 2, in which two neutron diffraction patterns of Na_3RhD_6 are compared.[7] The upper one was recorded using a three-axis spectrometer (TAS I) with the cold neutron source of the DR3 reactor at the Risø National Laboratory (Denmark), whereas the lower one was recorded using a high-resolution time-of-flight spectrometer (HRPD) with the spallation source at the Rutherford Laboratory (Great Britain). In both these neutron diffraction experiments the deuterium compound was used because the scattering by ^1H atoms is not sufficiently coherent.

3. What Ternary Transition Metal Hydrides of Alkali Metals and Alkaline-Earth Metals are Known, and What are their Structures?

The structures of binary transition metal hydrides of the metallic type can be described as close-packed arrays of metal atoms containing interstitial hydrogen atoms. Isolated transition metal–hydrogen groups are only expected in compounds where they occur as anions stabilized in a matrix of cations. Thus, as has already been mentioned, ternary transition metal hydrides that satisfy the latter conditions will be obtained particularly for combinations with alkali or alkaline-earth metals.

Hydrides of this type will be described below; to begin with, compounds of alkaline-earth and alkali metals will be treated separately.

3.1. Ternary Hydrides of Transition Metals with Alkaline-Earth Metals

Our knowledge of complex hydrides of the type $A_xM_yH_z$, in which A is an alkaline-earth metal, is limited to those where M belongs to sub-group eight. Table 1 lists the compounds whose composition and crystal structure can be regarded as known with certainty.

[a] Here, and in Tables 2 and 3, each field and symbolizes the region of a transition metal. Each box contains a family of hydrides of a specific transition metal. No entries indicate missing members.

The only iron compound so far known is Mg_2FeH_6, which is dark green and crystallizes with the K_2PtCl_6-type structure.[8] Its structure was determined by neutron diffraction measurements on Mg_2FeD_6. The arrangement of the atoms is shown in Figure 3. The magnesium and iron atoms occupy positions equal to those in fluorite, and the iron atoms are octahedrally coordinated by the hydrogen atoms. Mg_2CoH_5[9] and Mg_2NiH_4[5] both have high-temperature forms whose structures are analogous to that of the iron compound. In accordance with the different compositions

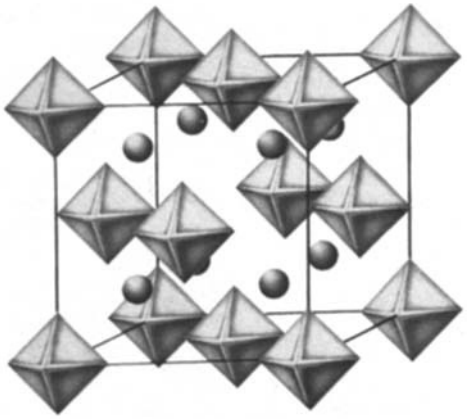

Fig. 3. Structure of Mg_2FeD_6 (K_2PtCl_6 type), showing the positions of the $[FeD_6]$ octahedra and the magnesium ions.

the hydrogen sites have occupancy factors of 5/6 for the cobalt hydride and 4/6 for the nickel hydride. It appears that in these cases there are dynamic processes occurring in the sphere of the hydrogen ligands, as it is found that these motions are frozen out at low temperatures; the cobalt and nickel atoms then adopt a tetragonal-pyramidal or a tetrahedral coordination by hydrogen respectively. Figure 4 shows selected regions of each of these structures.

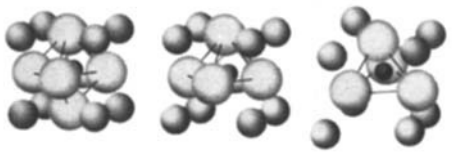

Fig. 4. Selected regions of the structures of Mg_2FeD_6 (left), Mg_2CoD_5 (middle) and Mg_2NiD_4 (right). The small dark spheres are the sites of the transition metal atoms, the medium-sized spheres those of the magnesium atoms, and the large pale spheres those of the hydrogen atoms.

An essentially analogous situation is found for hydrides of the 4d and 5d transition metals of sub-group eight. The ternary ruthenium hydrides[10–12] and Mg_2OsH_6[13] all crystallize with the K_2PtCl_2-type structure. The same is also true of the high-temperature forms of the rhodium and iridium hydrides A_2RhH_5 and A_2IrH_5 so far investigated, although here again the population parameters of the hydrogen positions are altered according to the composition.[11] Up to now exact structural data for a low-temperature form are only available for Sr_2IrH_5.[14] These indicate that the iridium atom has a hydrogen coordination that can be described as a tetragonal bipyramid, in which the four equatorial hydrogen sites are fully occupied. From the composition Sr_2IrH_5 one expects that the top and bottom apexes of the bipyramid should each have an occupancy of 0.5. The

value found experimentally was 0.7 (± 0.04), which may indicate a phase broadening.

$CaPdH_2$ crystallizes with an atomic arrangement similar to perovskite, as shown in Figure 5.[15] The occupancy factor for the hydrogen atom sites is 2/3. To investigate whether additional ordering occurs at low temperatures, neutron diffraction measurements were carried out at 10 K. The neutron diffraction pattern obtained was identical to that at room temperature. It seems possible that in this case, instead of a dynamic disordering of the hydrogen ligands, there is a statistical distribution of linear $[PdH_2]^{2-}$ units, which are distributed over the three directions in space without forming a superstructure. In the case of the corresponding sodium compound Na_2PdH_2 it has been possible to obtain direct evidence for such $[PdH_2]^{2-}$ groups (see Section 3.2).[16]

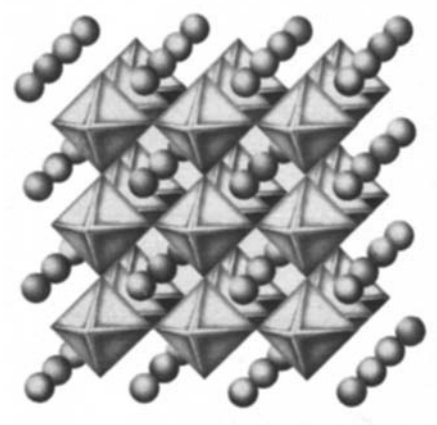

Fig. 5. The perovskite-like atomic arrangement of $CaPdD_2$. The hydrogen atoms occupy the vertices of the octahedra to the extent of 2/3 on average; the rest of the symbols correspond to those in Figure 3.

The results from measurements of electrical and magnetic properties that have so far been published show that ternary hydrides of transition metals with alkaline-earth metals do not have metallic properties. The observed electrical conductivities are at best in the semiconductor range, as is the case for the rhodium compounds, for example. These observations are supported by band structure calculations. Thus, for the series Mg_2FeH_6, Mg_2CoH_5 and Mg_2NiH_4, the calculated values for the energy gap between the valence and conduction bands are 1.8, 1.92 and 1.36 eV respectively. Magnetic susceptibility measurements show a very weak paramagnetism or diamagnetism.[17]

The compositions and structures of the above ternary hydrides suggest that the compounds should be described as complexes: in the $[MH_z]^{2x-}$ units—all of which are systems of 18 valence electrons except for the $[PdH_2]^{2-}$ anion—the hydrogen ligands form coordination polyhedra corresponding to the expected d-electron configurations of the transition metal atoms M. For Mg_2FeH_6 the magnetic susceptibility measurements and the Mössbauer spectrum indicate an iron(II) complex with a low-spin configuration.[17] In Mg_2CoH_5 it appears that the cobalt atoms have a spin-paired d^8 configuration; the tetragonal-pyramidal coordination shows four shorter Co–H distances and one somewhat longer distance to the apex of the pyramid (cf. Fig. 3).[9] In Mg_2NiH_4 the fourfold coordination leads, as expected, to a tetrahedral arrangement of ligands for Ni^0. The linear $[PdH_2]^{2-}$ group also fits into this picture, as it corresponds to the ligand arrangement in complexes of the isoelectronic Ag^+ ion.

To summarize, hydrides of the composition A_xMH_z (where A is an alkaline-earth metal) appear, on the basis of those known up to now, to have structures characterized by the presence of complex anions of the form $[MH_z]^{2x-}$. Here the M atoms evidently have oxidation numbers that are smaller than those in the corresponding halides, which appear to be their nearest structural relations. The treatment of the ternary hydrides of the alkali metals in the next section will still deepen our understanding.

3.2. Ternary Hydrides of Transition Metals with Alkali Metals

Table 2 lists all the complex hydrides of the type $A_xM_yH_z$ (where A is an alkali metal) whose structures are known with certainty. Among the ternary platinum hydrides the only one containing lithium known up to now is the phase $LiPtH_{0.66}$.[18] Its structure consists of an ordered hexagonal close-packed array of metal atoms, in which hydrogen atoms can reversibly enter or leave half of the tetrahedral sites up to an occupancy of 0.33. In the case of sodium the first complex platinum hydride was discovered, a colorless com-

pound with the composition Na_2PtH_4.[6] Investigations of its structure revealed that it is of a hitherto unknown tetragonal type, which is shown in Figure 6. The characteristic structural units here are planar $[PtH_4]^{2-}$ groups. The structure is closely related to the K_2PtCl_4 type (see Fig. 7). Above 573 K it forms a second modification, in which the arrangement of the atoms corresponds to the K_2PtCl_6 type structure with the chlorine sites statistically occupied by hydrogen ligands with an occupancy factor of 2/3. Figure 8 shows how the crystal structures of the two modifications of Na_2PtH_4 are related.

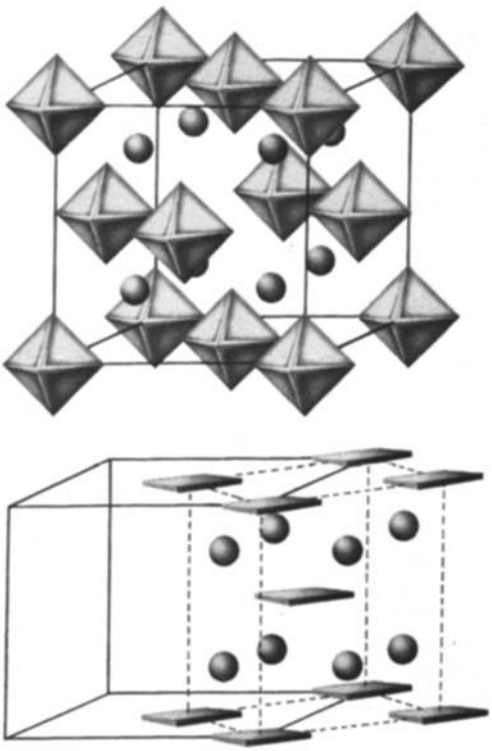

Fig. 8. The phase transformation in Na_2PtD_4. Lower diagram: low-temperature form; upper diagram: high-temperature form, in which hydrogen atoms occupy the vertices of the octahedra to the extent of 2/3 on average.

In the K/Pt/H system there again exists a colorless hydride with the composition K_2PtH_4.[19, 20] At room temperature its structure is already of the K_2PtCl_6 type. Neutron diffraction measurements on the deuterated compound K_2PtD_4 led to a complete structure determination, and showed that the deuterium sites have an occupancy factor of 2/3. Here again the statistical occupancy appears to involve a dynamic process (which will be discussed in more detail in Section 4), as is indicated by the appearance of a low-temperature form, in which the four hydrogen ligands attached to the platinum atom with its d^8 configuration result in the expected planar coordination (Fig. 9). Rb_2PtH_4 and Cs_2PtH_4 also each have two crystalline modifications, which are isotypes of the corresponding K_2PtH_4 structures.[20]

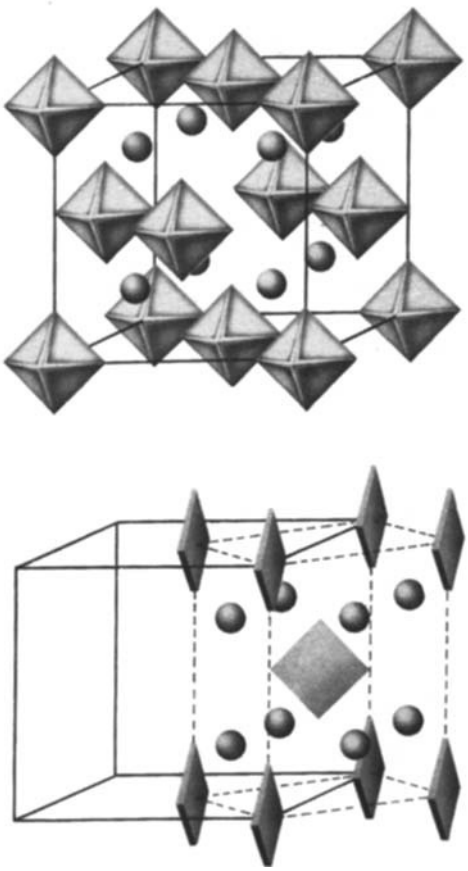

Fig. 9. Low-temperature and high-temperature modifications of K_2PtD_4. The arrangement of the diagrams and the symbols correspond to those in Figure 8.

In the preparation of K_2PtH_4, Rb_2PtH_4 and Cs_2PtH_4 it was found necessary to use an excess of the corresponding alkali metal hydride in each case. Closer investigation revealed that this is because hydrides containing a higher proportion of the alkali metal are formed initially, and these are then converted into the A_2PtH_4 compounds at higher temperatures. These novel hydrides have the formula A_3PtH_5,[21] with the atomic arrangement shown in Figure 10. This tetragonal structure contains two differently bonded types of hydrogen atoms. It is found that the first

type form the characteristic $[PtH_4]^{2-}$ units, whereas the second type are octahedrally coordinated by six alkali metal atoms, as in the binary alkali metal hydrides. The structural relationship of the complex hydrides to the corresponding halides, which has already been mentioned several times previously, is also found here, since the ternary fluorides A_3PdF_5, in which A is Rb or Cs, crystallize in the same structure type.[22] However, as is also commonly found in

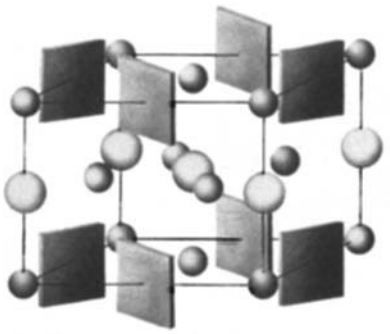

Fig. 10. Atomic arrangement of A_3PtD_5 with A ≙ K, Rb, Cs. The symbols correspond to those in the previous figures.

other cases, the hydrides differ from the halides in having a high degree of mobility in the coordination sphere of the transition metal atom. For example, studies of the structures of Rb_3PtH_5 and Cs_3PtH_5 and the corresponding deuterides as a function of temperature showed that at higher temperatures the structure changes from tetragonal to cubic, before the hydrides A_3PtH_5 decompose to A_2PtH_4 and AH (see Fig. 11). To describe this phase transition Figure 12 shows the arrangement of the atoms in the tetragonal (low temperature) form, projected along the *c*-axis. The alignment of the planar $[PtH_4]^{2-}$ groups results in different distances between the platinum and alkali metal atoms, the shorter distances being those perpendicular to the planar coordination of the ligands, while the longer distances are parallel to this plane. In the cubic (high-temperature) form all these distances are equal. Evidently motions occur within the $[PtH_4]^{2-}$ groups, such that the averaged structure corresponds again to an octahedral coordination of the hydrogen atoms around the platinum atoms with an occupancy factor of 2/3 (see Fig. 12).

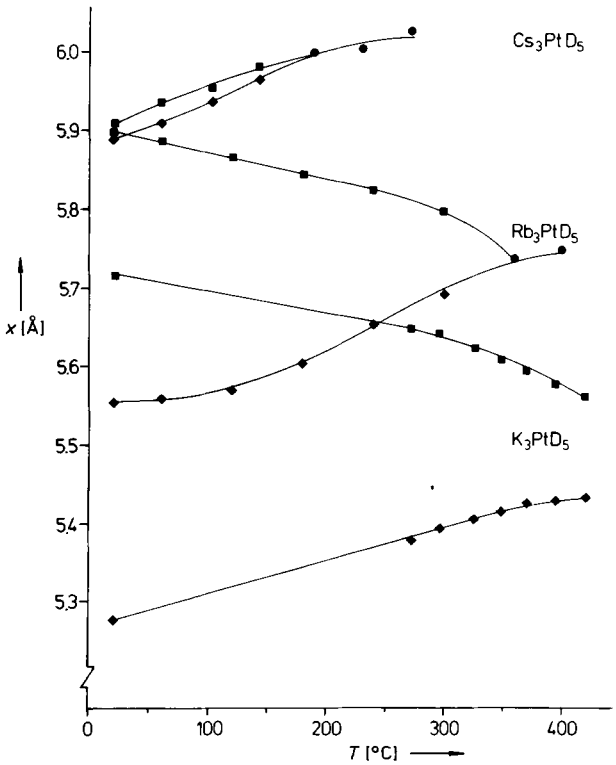

Fig. 11. Temperature dependence of the lattice constants in A_3PtD_5 (A ≙ K, Rb, Cs) from X-ray investigations. For the tetragonal (low-temperature) modification ♦ denotes values of $a/\sqrt{2}$ and ■ denotes values of *c*; for the cubic (high-temperature) modification ● denotes values of *a*. The transition temperatures *T* for the corresponding hydrogen compounds are the same within the limits of accuracy of the experiments.

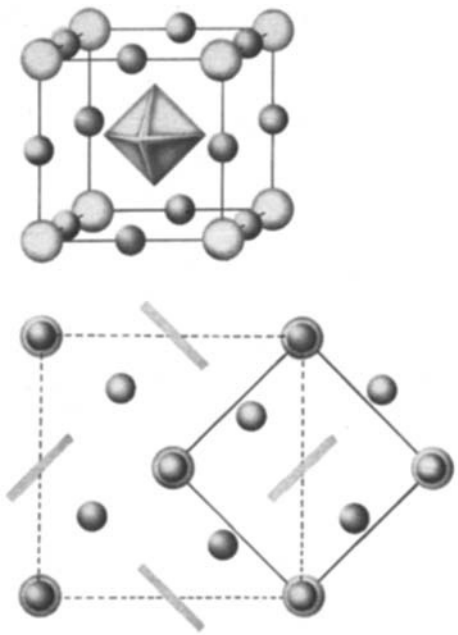

Fig. 12. The phase transformation in A_3PtD_5 (A ≙ Rb, Cs). Lower diagram: structure of the low-temperature modification shown as a projection along the *c*-axis (the $[PtD_4]$ groups are shown in an edge-on representation). Upper diagram: structure of the high-temperature phases; the D sites in the Pt/D octahedron are 2/3 occupied.

With regard to the palladium compounds, the hydride Na_2PdH_2 has already been mentioned earlier.[16] Its crystal structure is shown in Figure 13. The complex anions in this case are linear $[PdH_2]^{2-}$ groups. Assuming that the palladium atoms have an oxidation number of zero, the arrangement of the ligands here corresponds to that in analogous Ag^I complexes. Although there is no known halide whose crystal structure is an isotype of this, there is an oxide, Na_2HgO_2, in which the central atom has the same d^{10} configuration.[23] In the case of the Li/Pd/H system the isostructural compound Li_2PdH_2 has been reported.[24] Hydride phases with lower proportions of lithium also exist; as in the case of the platinum phases referred to earlier, their structures can be regarded as consisting of an ordered array of metal atoms in which the hydrogen atoms, enter octahedral sites in this case.[25]

Coming now to the K/Pd/H system, a yellow compound with the composition K_3PdH_3 has been synthesized.[26] Its

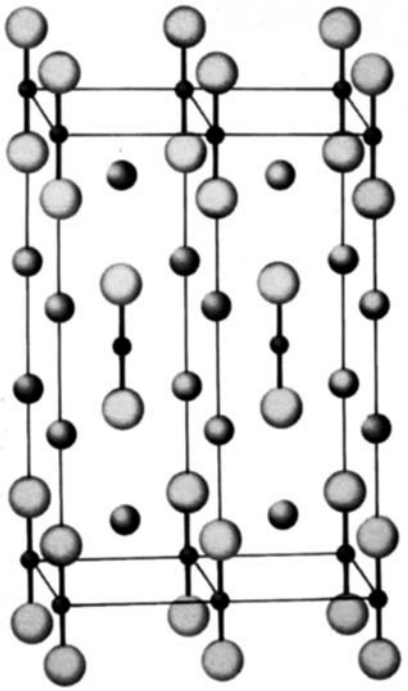

Fig. 13. Crystal structure of Na_2PdD_2; two tetragonal unit cells are shown. The symbols correspond to those in Figure 6.

structure is related to that of K_3PtH_5. Here again it is found that there are two differently bonded types of hydrogen atoms, firstly those in $[PdH_2]^{2-}$ groups that are characteristic of Pd^0, and secondly those that are octahedrally coordinated by potassium atoms, as in the potassium hydride. Owing to the space occupied by the linear groups the potassium octahedra are tilted relative to each other (see Fig. 14). A

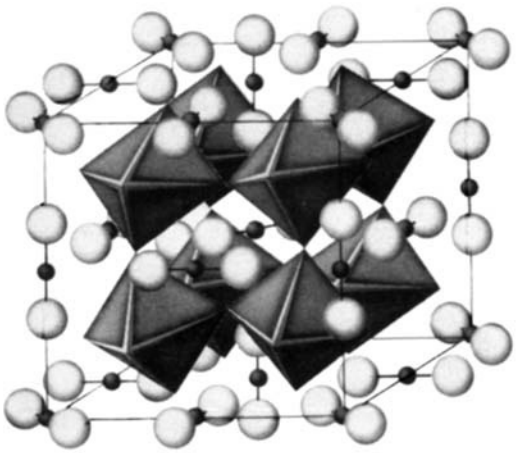

Fig. 14. Atomic arrangement of the tetragonal (low-temperature) modification of K_3PdD_3, showing the vertex-shared potassium octahedra, which have hydride ions at their centers, and the linear $[PdD_2]^{2-}$ groups.

phase transition is observed at 500 K, and this again appears to result from the dynamic behavior of the hydrogen atoms in the complex groups, so that the average arrangement of the ligands around the palladium atoms is of cubic symmetry. The tilting of the potassium octahedra thus disappears (see Fig. 15). This gives a cubic unit cell whose volume is one-eighth of that of the tetragonal cell in the low-temperature form. The arrangement of the potassium and palladium atoms corresponds to the Cu_3Au type structure, and is identical to that in the high-temperature modification of K_3PtH_5 (cf. Fig. 12).

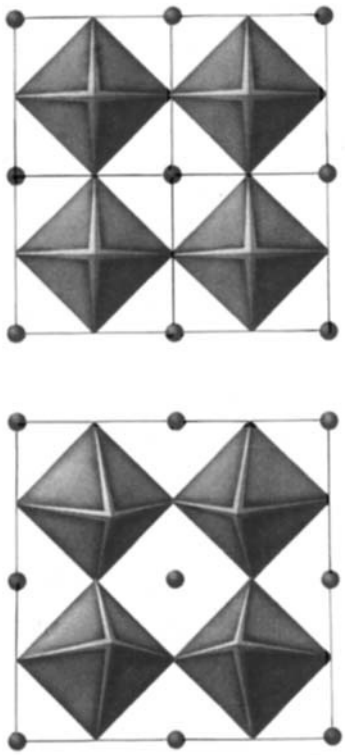

Fig. 15. Arrangement of the potassium octahedra and of the palladium atoms in the tetragonal, low-temperature modification of K_3PdD_3 (lower diagram) and in its cubic, high-temperature modification (upper diagram).

Up to now the only ternary alkali metal hydrides of the remaining platinum sub-group metals, whose structures are certainly known, are Li_3IrH_6, Na_3IrH_6 and Na_3RhH_6.[7] These are colorless compounds that crystallize in a rhombic structure. Here once more the structure-determining units are complex $[MH_z]^{x-}$ groups, in these cases almost regular octahedra consisting of $[IrH_6]^{3-}$ or $[RhH_6]^{3-}$ units (see Fig. 16).

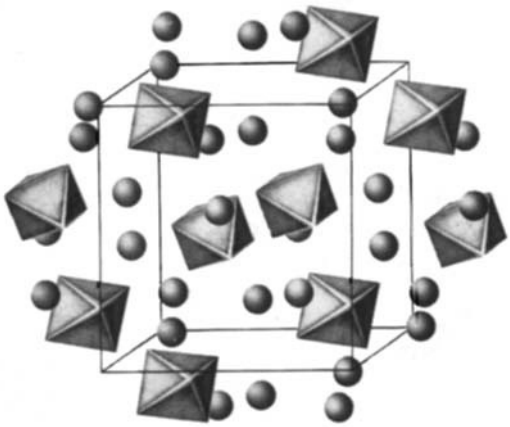

Fig. 16. Crystal structure of Na_3RhD_6, showing the $[RhD_6]$ octahedra and the positions of the sodium ions.

The ternary hydrides K_2ReH_9 and K_2TcH_9,[3,4] which, as mentioned earlier, were synthesized via molecular reactions in solvents, contain complex $[MH_9]^{2-}$ anions. The coordination polyhedron is a tricapped trigonal prism. A detailed structure determination has been carried out for K_2ReH_9, and shows that the Re–H distances are all equal within the threefold standard deviation. Figure 17 shows a selected region of the hexagonal atomic arrangement.

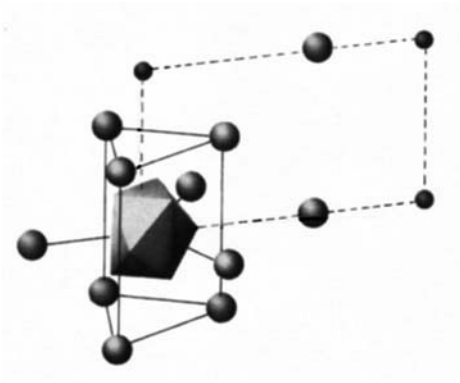

Fig. 17. A portion of the crystal structure of K_2ReH_9, showing the $[ReH_9]$ polyhedron, the positions of the adjacent potassium ions, and one *ac* plane of the hexagonal unit cell (dashed line).

Summarizing the results obtained up to now concerning the existence and structures of ternary transition metal hydrides with alkali metals, the picture already described for the compounds of the alkaline-earth metals in the previous section can now be extended to include these compounds. Here again, a characteristic feature of the structures is the presence of complex $[MH_z]^{x-}$ groups.

The heavy alkali metals are usually found to give colorless compounds, and transformations to phases with metallic properties are thus ruled out from the outset. Their structures show marked resemblances to those of the corresponding halides and chalcogenides. However, as in the ternary hydrides of the alkaline-earth metals, the higher oxidation states of the transition metals are not reached. Thus, the platinum compounds predominantly have planar $[PtH_4]^{2-}$ anions with platinum in the + 2 oxidation state. For palladium mainly Pd^0 complexes are known up to now; corresponding planar $[PdH_4]^{2-}$ or linear $[PtH_2]^{2-}$ units could so far only be stabilized as mixed crystals in the system Na/Pd/Pt/H.[20] The highest oxidation state found for rhodium and iridium is + 3. In this context the high oxidation state of + 7 in the hydrides K_2ReH_9 and K_2TcH_9 is surprising and difficult to understand. Some of the ternary hydrides containing lithium and sodium have interesting properties. For example, Na_2PdH_2 has a metallic gray appearance and shows semiconducting properties. The conductivity increases as the temperature is raised, and at 273 K was measured as $7.3 \times 10^{-2}\,cm^{-1}\Omega^{-1}$. In the Li/Pt/H and Li/Pd/H systems one already begins to find properties characteristic of metallic hydrides: there is considerable phase broadening, and dependent on the pressure or temperature the hydrogen undergoes a reversible uptake–release process, without a significant change in the arrangement of the metal atoms.

4. Hydrogen—an Anomalous Ligand?

The ternary hydrides $A_xM_yH_z$, in which A is an alkali metal or alkaline-earth metal and M is a transition metal, can be described as complex hydrides. Their crystal structures contain anionic $[MH_z]$ units. They have obvious similarities to the corresponding halides and oxides, but there are also some noticeable differences which clearly show that hydrogen is a special kind of ligand. Thus, one is struck by the fact that in all the crystal structures that have so far been determined—though these are admittedly few in number—isolated $[MH_z]$ complexes have always been found. Polynuclear complexes or framework structures, which are very common in ternary halides or chalcogenides, are not found here. It is even more surprising that the change in properties from those of isolated complexes to those of intermetallic phases is a direct transition, without any intermediate stages in which chain or layer structures are successively built up. This transition is illustrated by the following observations. The hydrides of the heavy alkali metals have essentially salt-like character, whereas Na_2PdH_2 is already a semiconductor, and the adjacent element, magnesium, forms a hydride, Mg_2NiH_4, in which the hydrogen can undergo a reversible uptake–release process as in typical metallic hydrides; finally, the Li/Pt/H and Li/Pd/H systems give compounds that show phase broadening and already have obvious metallic properties. These characteristic changes in the nature of the bonding could lead to interesting results especially concerning the magnetic and electrical properties, of which there have been few measurements up to now. One aspect worth mentioning here is that a number of binary and ternary hydrides of transition metals have been found to show superconductivity; for example, in the Pd/D system a maximum T_c value of 11 K has been reported.[27]

Another special feature of hydride ligands is their dynamic behavior. Thus the motional processes occurring in the sphere of the hydrogen ligands are responsible for the phase transitions that are observed in nearly all these systems. No corresponding behavior has ever been observed for the halides and chalcogenides with isotypic or closely related structures. In those complex hydrides that resemble metallic hydrides, such as Mg_2NiH_4, it is also found that at higher temperatures the hydrogen is released in a reversible process. Mg_2NiH_4 has potential applications as a hydrogen storage medium, especially as the hydrogen/metal mass ratio is more advantageous than for other transition metal hydrides. This compound has already been used by Daimler Benz for hydrogen-driven automobiles.[28]

An initial insight into the dynamic behavior of the hydrogen ligand is provided by NMR studies. Measurements have been made on K_2ReH_9 and K_2TcH_9 in solvents. A single line was found, which is explained by the fact that the hydrogen ligands are all equivalent as a result of rapid exchange.[3] In the case of K_2PtD_4, which undergoes a reversible crystallographic phase transition at 195 K (see Fig. 9), temperature-dependent ^{2}H-NMR measurements were performed on a powdered sample (see Fig. 18).[29] Below 180 K the width of the spectrum remains nearly constant, with a spin-lattice relaxation time T_1 of the order of minutes, indicating rigid lattice behavior. Between 180 and 210 K the shape of the spectrum changes radically. The experimental observations

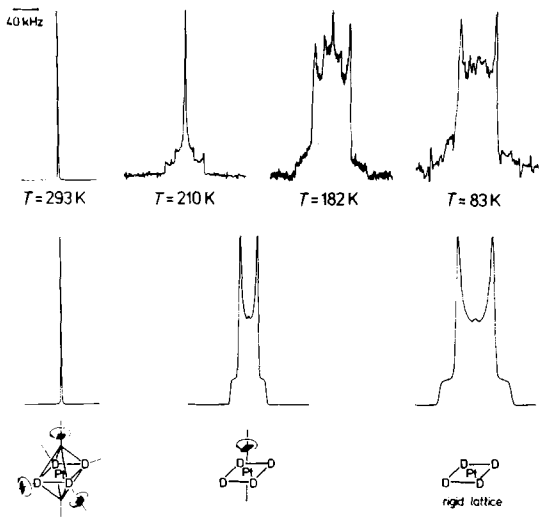

Fig. 18. ^{2}H-NMR spectra of K_2PtD_4 at different temperatures. Top: observed spectra. Bottom: calculated spectra for the dynamic processes described in the text.

are consistent with a model in which the square $[PtD_4]$ groups undergo rotational jumps in the plane of the square. Above the phase transition temperature the octahedral coordination of the platinum atoms results from rapid rotational jumps of the four deuterium atoms of each square planar unit around the fourfold axes. At 292 K, T_1 is 40 ms.

The different bonding situations in the hydrides cannot easily be explained in terms of the average metal–deuterium distances (Table 3). On the other hand, the volume increments give an indication of how wide a variation there is in the volume of the hydride ligands, especially when compared with the corresponding values for halides with analogous structures. In Figure 19 the volume increments for hydrogen in the complex hydrides $A_xM_yH_z$ are compared with the increments for fluorine and chlorine in the corresponding halide complexes $A_xM_yX_z$, in which X ≙ F or Cl. The plots give average volume increments as a function of the oxidation state of the transition metal M. The change in the volume increments for the fluoride and chloride ions are already known,[30] whereas this is the first time it has been possible to give values for the hydride ion. One is struck by the high "polarizability" of the hydride ion, which is indicated by the decrease of the volume increment with increasing oxidation number of the bonding partner. The volume contraction corresponds closely to that for the chloride ion, although the actual values are much closer to those for the fluoride ion, which shows scarcely and "polarizability". If we compare the alkali metal compounds with those of the alkaline-earth metals, the effect is seen even more clearly: in the latter compounds the increments for the fluoride ion show a slight increase with oxidation number, whereas for the chloride ion they are probably constant, and for the hydride ion there is again a marked contraction. This is greatest for the compounds in which one begins to observe a transition to metallic properties, and it is therefore not surprising that there are already appreciable deviations from the expected values in the cases of Na_2PdH_2 and $CaPdH_2$.

[a] See footnote in Table 1. [b] In these cases the metal–deuterium distances were determined by extrapolation. [c] A ≙ Na, K, Rb, Cs. [d] A ≙ K, Rb, Cs.

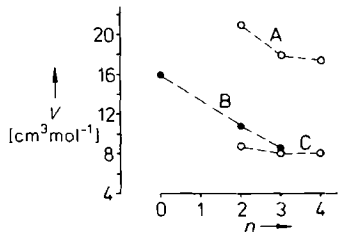

Fig. 19. Volume increments of X^- ions in compounds having the composition A_xMX_z, with X ≙ Cl (curve A), X ≙ H (curve B) and X ≙ F (curve C). In A_xMX_z, in all cases A represents K, Rb or Cs, and M is a transition metal of group eight.

Hydrogen—an anomalous ligand? Perhaps one should replace the question mark here by an exclamation mark!

5. Concluding Remarks

It has now become possible, through the use of specialized preparative techniques and by combining X-ray and neutron diffraction measurements over a wide range of temperatures, to begin to obtain a deeper insight into the relationships between structure and properties of complex transition metal hydrides. Only a few compounds have been studied in detail up to now, and those that are known at present nearly all belong to sub-group eight of the Periodic System. Thus there remains a great deal to be done. Indications regarding the existence of further hydrides which have not yet been properly characterized can be found in the literature. The study of this new group of compounds offers attractive prospects, since the position that they occupy between salts and metals is likely to result in interesting physical properties and applications.

I express sincere thanks to my present and former co-workers who have contributed to the investigations cited in this review. I expecially thank Dr. G. Auffermann and Dr. P. Müller. Thanks are also due to the Bundesministerium für Forschung und Technologie, the Deutsche Forschungsgemeinschaft, and the Fonds der Chemischen Industrie for financial support.

Transition-Metal Thiolates: From Molecular Fragments of Sulfidic Solids to Models for Active Centers in Biomolecules

By Bernt Krebs* and Gerald Henkel*

Dedicated to Professor Hans Georg von Schnering on the occasion of his 60th birthday

Thiolates are presently a subject of great interest in the chemistry of complexes involving transition-metal elements and soft ligands. The manifold electronic and steric capabilities offered by the monodentate ligands $RS^{\ominus}$ and the bidentate chelate ligands $^{\ominus}SRS^{\ominus}$ have been used to stabilize a broad spectrum of mononuclear, oligomeric, and polymeric complexes with new and remarkable structures and properties. Impetus has especially been provided by the synthesis of polynuclear cagelike homo- and heteroleptic metal–sulfur frameworks, which can often be regarded as "molecular fragments" of the structures of inorganic sulfides. Thiolates and mixed sulfide-thiolates of the late open- and closed-shell 3d metals (Fe, Co, Ni, Cu, Zn) and some of their homologues (Au, Cd, Hg), as well as of Mo, are of particular importance as model complexes for biologically important metal centers coordinated by sulfur. They have played an important role in increasing our understanding of the structure, bonding, and function of the reactive centers in ferredoxins, rubredoxins, nitrogenases, blue copper proteins, metallothioneins, and antiarthritic drugs.

1. Introduction

Transition-metal thiolates are an enormously rich class of compounds. As typical soft ligands (as defined by *Pearson*), the electron-rich thiolate groups $RS^{\ominus}$ and their multifunctional homologues have a great affinity for a large number of metals. They have been used as ligands since the very beginnings of coordination chemistry and were of importance for the development of this area of inorganic chemistry. Because of their chemical properties and their low solubilities, they have also found practical applications in, for example, analytical chemistry. However, many of the products synthesized have not been characterized precisely because of the lack of suitable physical techniques.

The thiolate ligands $RS^{\ominus}$ and $^{\ominus}SRS^{\ominus}$ are capable of extreme variations in their coordination and bonding to metals. While the monofunctional ligands can bond in a monodentate, μ_2-bridging or μ_3-bridging manner, the coordination possibilities offered by the difunctional thiolate anions are even greater. For various reasons the mono- and polynuclear complexes with a complete thiolate and/or sulfide coordination sphere are of special importance at present and are the subject of intensive studies. The polynuclear species in particular have multifarious and fascinating structural properties; in many cases they can be regarded as "molecular fragments" of the polymeric structures of solid sulfides.

Metal coordination centers with complete or partial sulfur coordination play an important part in the chemistry of life processes. Examples are provided by electron transferases such as the redox metalloproteins of iron (e.g., ferredoxins), oxidoreductases such as the nitrogenases (nitrogen-fixing enzymes), hydrolases such as the various zinc enzymes, nickel-containing hydrogenases, blue copper proteins such as plastocyanin, azurin, and ceruloplasmin, heterometalloenzymes such as cytochrome *c* oxidase, the group of nucleic acid binding proteins important in gene transcription, and the "metal-regulating" MerR proteins (mercury reductases), and, finally, the large group of metallothioneins, which are thought to have both a storage and transport function for metals and a detoxifying protective function against heavy metals. Thiolates are extremely useful as model ligands to simulate the bonding of the ligands present in biological systems (generally the thiolate function of cysteine) to active metals. Gold thiolates are of importance as drugs, particularly in arthritis therapy, and their use is likely to increase.

A new and interesting development is the use of volatile molecular thiolates as starting materials for the chemical vapor deposition (CVD) of metallic or sulfidic surface layers. In addition, the theoretical and practical interest in special 3d elements has been a major stimulus for the study of the chemistry of the polynuclear sulfur complexes of all the other transition metals; the spectacular development of this area promises to continue for some time.

Since the chemistry of metal–sulfur complexes is of such wide scope, this article will of necessity concentrate only on certain aspects of the very important class of homoleptic and heteroleptic polynuclear transition-metal complexes with thiolate or mixed sulfide-thiolate ligands. We shall limit our discussion to the chemistry of the important metals, Fe, Co, Ni, Cu, Ag, Au, Zn, Cd, and Hg. Complexes with 1,1-dithiolates and 1,2-dithiolenes, with other abiotic dithio ligands, or with pure sulfide and polysulfide coordination spheres, organometallic complexes with metal–carbon bonds and with π-acceptor ligands, complexes in which the metals have only a partial sulfur environment, and complexes with oxo ligands will not be included; here we refer the reader to detailed review articles.[1–14]

2. Iron Thiolate Complexes

2.1. The Homonuclear Centers of the "Simple" Iron–Sulfur Proteins

Iron is used by all known forms of life. The "simple" biomolecules with iron–sulfur centers include the rubredoxins, the ferredoxins, and the high-potential iron proteins (HIPIPs).[15] These molecules are known as iron–sulfur proteins. More complex metalloenzymes are also known; these contain additional prosthetic groups involving nickel (e.g., some hydrogenases and CO dehydrogenases)[16] and molybdenum or vanadium (e.g., nitrogenases).[17]

The mononuclear centers of the rubredoxins, the binuclear centers of the 2Fe-2S ferredoxins, and the tetranuclear centers of both the 8Fe-8S ferredoxins and the high-potential iron proteins (Fig. 1) were identified and completely characterized by about 1980.[18, 19]

Iron–sulfur proteins are characterized by distorted FeS_4 tetrahedra, which are linked in the polynuclear ferredoxin-like centers by common edges. The resulting short metal–metal distances allow for direct electronic interactions. The bridging ligands are always "naked" sulfide ions, and the terminally bonded sulfur atoms are provided by cysteine residues in the polypeptide chains.

The trinuclear iron–sulfur centers in ferredoxins from *Azotobacter vinelandii* (*Av* FdI) and *Desulfovibrio gigas* (*Dg* FdII)[20–22] were identified spectroscopically in 1980. Shortly thereafter, the structure of *Av* FdI was determined by protein crystallography.[23, 24] According to this study, the active center was discussed in terms of three vertex-linked FeX_4 tetrahedra, the distance between the iron atoms being about 4.1 Å. However, this structure did not agree with the results of resonance Raman studies of *Av* FdI in the native

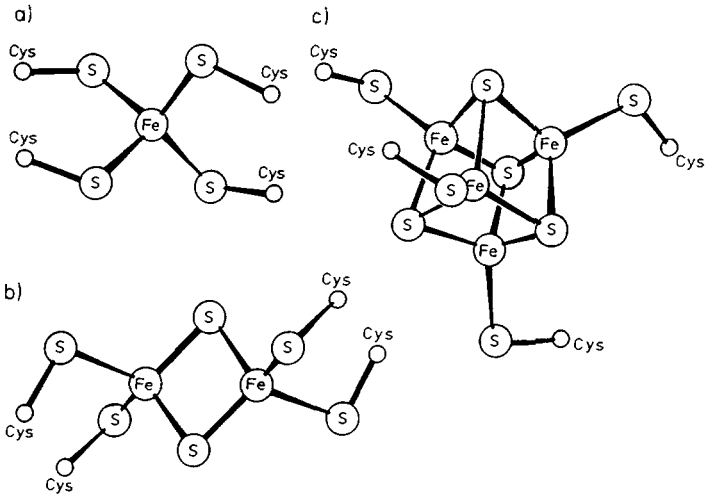

Fig. 1. Classical types of Fe–S centers in simple iron–sulfur proteins with cysteine ligands. a) 1Fe center in rubredoxins. b) 2Fe-2S center in chloroplast ferredoxins. c) 4Fe-4S center in bacterial and HIPIP ferredoxins.

state and of other proteins with 3Fe centers.[25] According to the resonance Raman studies and in agreement with EXAFS results on *Dg* FdII[26] and beef heart aconitase,[27] the iron atoms form an equilateral triangle with an edge length of about 2.7 Å.

Reinvestigations of the crystal structure of *Av* FdI[28–30] corrected the original results as far as the linking of the FeS_4 tetrahedra is concerned. The structure of the biological 3Fe centers corresponds to a model with an Fe_3S_7 framework, which we developed on the basis of the structural characteristics of the topologically related $[Fe_3S(SCH_2C_6H_2Me_2CH_2S)_3]^{2\ominus}$ (Fig. 2).[31, 32] According to protein structure analyses, trinuclear protein centers such

Gerald Henkel, born in 1948 in Burow (Mecklenburg), studied chemistry at the University of Kiel (1968–1973) and obtained his doctorate with B. Krebs at the University of Bielefeld in 1976. After work as a teaching and research assistant in Bielefeld (until 1977) and in Münster, he completed his habilitation (Münster, 1984) with work on coordination compounds of electron-rich transition metals with sulfur-containing ligands. Since 1988 he has been Professor of Inorganic Chemistry at the University of Duisburg, where he is Head of the Section Inorganic Chemistry/Solid State Chemistry. The main areas of his research are in the fields of structural and solid-state chemistry, of synthetic coordination chemistry (complexes with sulfur, selenium and tellurium ligands), and of bioinorganic chemistry.

Bernt Krebs, born in 1938 in Gotha (Thüringen), studied chemistry at the University of Göttingen, where he completed his doctorate with G. Gattow in 1965. From 1965 to 1966 he worked as a research assistant with W. C. Hamilton and D. F. Koenig at Brookhaven National Laboratory, Upton, N.Y. After returning to Göttingen, he completed his habilitation in 1969 in O. Glemser's laboratory with the synthesis and structure of Mo, Tc, and Re oxo compounds. In 1971 he took over an associate professorship at the University of Kiel, and in 1974 he became the first Professor of Inorganic Chemistry at the newly established University of Bielefeld. Since 1977 he has been Professor of Inorganic Chemistry at the University of Münster. His research interests include the synthesis and structural chemistry of polynuclear inorganic sulfur, selenium, and tellurium compounds, of polynuclear transition-metal oxo compounds, and of biologically relevant transition-metal complexes with sulfur ligands, as well as diffraction and other structural methods (EXAFS) in inorganic and bioinorganic chemistry.

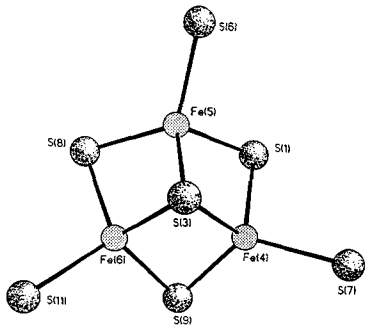

Fig. 2. Synthetic model of the 3Fe-4S center of 3Fe proteins [31].

as those in *Av* FdI are also present in *Dg* FdII[33] and in the (inactive) form of aconitase.[34-36]

In spite of the successful investigations in the area of "classical" protein centers, work closely associated with the name of *R. H. Holm*,[18, 19, 37] it has not yet been possible to synthesize any "good" models for the centers of the 3Fe ferredoxins. From the chemical point of view the 3Fe fragments of the complexes $[Fe_6S_9(SR)_2]^{4\ominus}$ (see Section 2.2.4) represent the best approximation presently available with respect to the oxidation state of the iron atoms and the chemical definition of the $[Fe_6S_{11}]$ framework.[38-42, 31]

2.2. Model Complexes

The class of homo- and heteroleptic iron thiolates comprises mono-, bi-, and tetranuclear species; the coordination number is generally 4 in all cases. Higher coordination numbers are apparently only achieved when the (mean) oxidation state of iron does not fall below + 3 and when, at the same time, the steric effects of the ligands would otherwise lead to too great a distortion of the FeS_4 tetrahedra. In the mixed sulfide-thiolate complexes, however, the coordination number is always 4; neighboring FeS_4 tetrahedra have common edges when the number of iron atoms is smaller than six. In other cases both vertex- and edge-linked FeS_4 tetrahedra occur simultaneously.

With respect to the manner in which the FeS_4 tetrahedra are linked, the binuclear sulfide-thiolate complexes are closely related to the binuclear iron thiolates. As in the 2Fe-2S ferredoxins themselves, their Fe_2S_6 frameworks form fragments of the infinite $[MS_2]_\infty$ chain of *trans*-edge-linked tetrahedra with the SiS_2 structure, as found in naturally occurring minerals such as erdite ($NaFeS_2 \cdot 2H_2O$)[43] or in synthetic inorganic solids such as the alkali-metal thioferrates(III).[43] The principle of linking FeS_4 tetrahedra via common vertices is also observed in the tetranuclear iron thiolates; in this case, however, no combination with edge-linking, as found in sulfide-thiolates, is observed.

2.2.1. *Binuclear Complexes*

The (formal) replacement of the cysteine residues in the 2Fe-2S ferredoxins by alkanethiolate ligands leads to binuclear mixed sulfide-thiolate complexes. The first compound of this class to be obtained was $[Fe_2S_2(SCH_2C_6H_4CH_2S)_2]^{2\ominus}$ (Fig. 3a).[45, 46] Since the iron atoms are trivalent, it was also the first model for (oxidized) 2Fe-2S ferredoxins.

Other binuclear iron sulfide-thiolates have since been described; these include complex ions with monofunctional thiolate ligands[39, 46] and analogous compounds with central Fe_2Se_2 centers[47, 48] or derivatives with terminally bonded halide ions.[49-52] An elegant route to binuclear iron sulfide-thiolate complexes involves the reduction of S_8 by ligands of the complex anion $[Fe(SR)_4]^{2\ominus}$, which are replaced in the course of the reaction by the sulfide ions formed.[53] Preparative and spectroscopic details can be found in review articles and the literature cited therein.[18, 19, 37, 54]

Purely inorganic derivatives of the binuclear sulfide-thiolate complexes with complete chalcogen ligand spheres have also been prepared: these include $[Fe_2S_2(S_5)_2]^{2\ominus}$[51, 55] and the interesting selenium analogue $[Fe_2Se_2(Se_5)_2]^{2\ominus}$[56] (Fig. 3b).

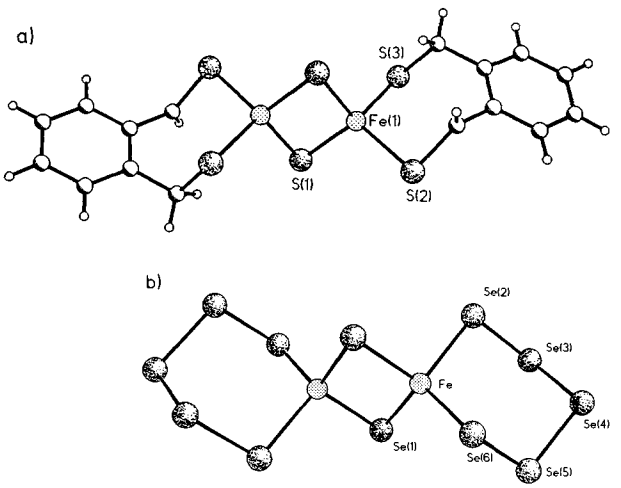

Fig. 3. Structural comparison of the anions $[Fe_2S_2(SCH_2C_6H_4CH_2S)_2]^{2\ominus}$ (a) [46] and $[Fe_2Se_2(Se_5)_2]^{2\ominus}$ (b) [56].

Homo- and heteroleptic iron thiolates form a further group of binuclear complexes with a complete sulfide ligand sphere. With the exception of the 1,2-dithiolate complexes, these compounds are characterized by a bi-tetrahedral Fe_2S_6 framework. In contrast to the sulfide-thiolates, these compounds contain thiolate bridges, which introduce only half as many negative charges into the complex as do the corresponding sulfide ions, so that in principle they favor lower oxidation states of iron. In these complexes the iron does indeed prefer the oxidation state + 2, and it has not so far been possible to isolate oxidized examples with tetrahedral metal coordination.

Binuclear thiolates of iron(III) can in principle be stabilized by the bonding of additional thiolate ligands, with a corresponding increase in the coordination number. However, the known examples are limited to complexes with bifunctional 1,2-dithiolate ligands such as $[Fe_2(SC_6H_3MeS)_4]^{2\ominus}$[57] (Fig. 4). The square-pyramidal coordination, which is unusual for iron thiolates, is due to the short S···S distances in the ligands; these do not permit a sufficiently undistorted tetrahedral sulfur coordination.[57-61]

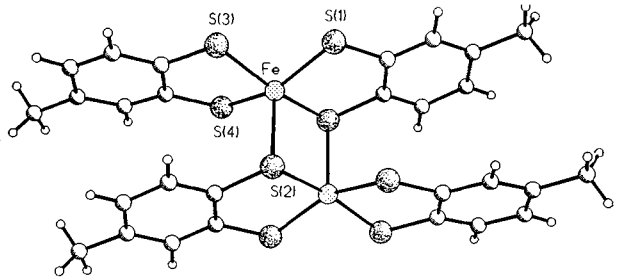

Fig. 4. Structure of $[Fe_2(S_2C_6H_3Me)_4]^{2\ominus}$ [57].

$[Fe_2(SCH_2C_6H_4CH_2S)_3]^{2\ominus}$, the first binuclear thiolate complex with tetrahedral FeS_4 centers to be isolated, was obtained as an unexpected product in the course of attempts to synthesize mononuclear compounds.[62, 63] Because of the bifunctionality of the ligands, the isomeric forms **IIa–c** shown in Figure 5 are theoretically possible. In addition to the frameworks with tetrahedral stereochemistry, Figure 5 also shows the corresponding frameworks for square-planar metal coordination (**Ia**, **Ib**). Isomer **IIa** was identified in

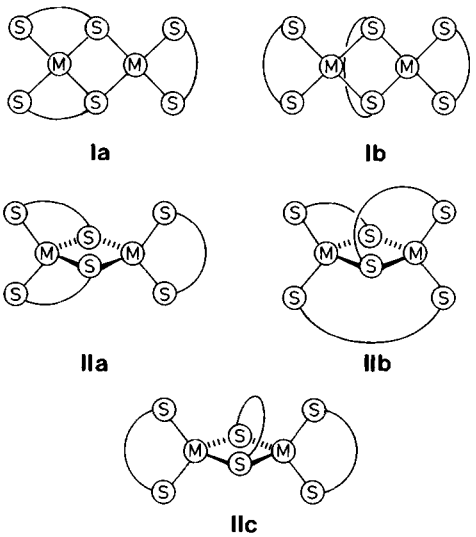

Fig. 5. Possible structural isomers of binuclear four-coordinated metal(II) dithiolates, $[M_2(SRS)_3]^{2\ominus}$. **Ia,b**: square planar. **IIa–c**: tetrahedral metal coordination [107].

$[Et_4N]_2[Fe_2(SCH_2C_6H_4CH_2S)_3]\cdot 2MeCN$; the alkyl groups are oriented *anti*, the Fe–Fe distance being 3.034 Å.[65, 66] The centrosymmetrical anion $[Fe_2(SEt)_6]^{2\ominus}$ has a similar configuration in the tetraethylammonium salt.[65] The synthesis of isomer **IIb** of the complex anion $[Fe_2(SCH_2C_6H_4CH_2S)_3]^{2\ominus}$ (Fig. 6, top) was also possible when other counterions were chosen.[66] In this case the coordination of one of the ligands is unusual: instead of acting as a chelating ligand, it occupies two terminal positions in the complex. Since the S–S distance in this ligand is only 4.25 Å, the complex is folded and the Fe–Fe distance is decreased to 2.88 Å. The unconventional bonding of the ligand also leads to the unusual *syn-exo* arrangement of the alkyl residues. Analogous complexes of cadmium,[67] cobalt,[68] and manganese[69] have also been described.

$[Fe_2(SCH_2C_6H_4CH_2S)_2(SPh)_2]^{2\ominus}$ (Fig. 6, bottom) is a heteroleptic iron thiolate with a centrosymmetric structure and terminal thiophenolate ligands.[66] The Fe–Fe distances in the planar $Fe_2(SR)_2$ units (*anti* configuration) are 2.98 Å; the complex is closely related to a derivative in which the thiophenolate ligands are replaced by dithiocarbamate groups.[57] The introduction of the bifunctional dithio ligands leads to an increase in the coordination number of iron and a lengthening of the Fe–Fe distance (3.16 Å). Heteroleptic complexes of this type are also formed by manganese.[69]

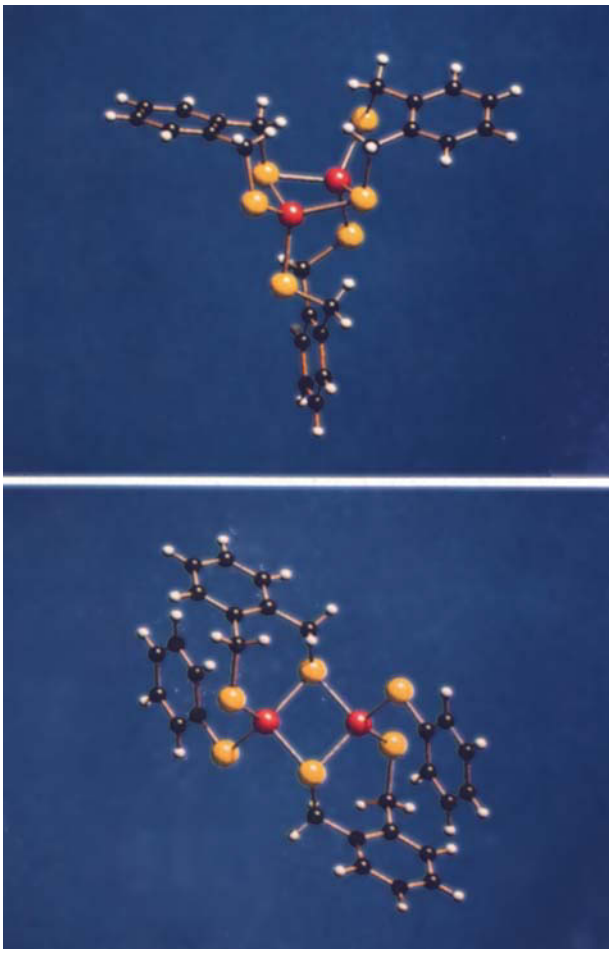

Fig. 6. Structures of the homologous anions $[Fe_2(SCH_2C_6H_4CH_2S)_3]^{2\ominus}$ (top) [66] and $[Fe_2(SCH_2C_6H_4CH_2S)_2(SPh)_2]^{2\ominus}$ (bottom) [66].

The magnetic behavior of the binuclear iron complexes is dominated by antiparallel spin couplings, which are due either to superexchange mechanisms with participation of orbitals from bridging sulfur atoms or to direct metal–metal interactions.

2.2.2. *Trinuclear Complexes*

Trinuclear thiolate complexes have not yet been described, although mixed iron sulfide-thiolate species are known, either as Fe^{III} complexes whose linear Fe_3S_8 frameworks correspond to fragments of the SiS_2 chain structure or as Fe^{II} complexes whose Fe_3S_7 frameworks have a defect cubane structure.

The first trinuclear iron sulfide-thiolate compound to be reported, $[Fe_3S(SCH_2C_6H_2Me_2CH_2S)_3]^{2\ominus}$ (Fig. 7, top), was initially obtained as an unexpected product of the reaction between 4,5-dimethyl-1,2-bis(methylthio)benzene, $FeCl_3$, *p*-thiocresol, and NaOMe in MeOH.[32] The synthesis proceeds in better yields when the reagents are mixed in stoichiometric ratios. When NaHS is used as the sulfide component and $(SCH_2C_6H_2R_2CH_2S)^{2\ominus}$ (R = Me or H) as the thiolate component, complexes of the general composition $[M_3S(SCH_2C_6H_2R_2CH_2S)_3]^{2\ominus}$ are formed; these are stable when M = Fe,[66] Co,[70] or Ni.[71] Similar reaction systems were studied in which the sulfide component was Li_2S, and analogous complexes with M = Fe and Co were isolated.[41] When NaHS is replaced by the corresponding selenium compound, the mixed selenide-thiolate complex $[Fe_3Se(SCH_2C_6H_4CH_2S)_3]^{2\ominus}$ is formed.[66]

According to the most recent protein structure analyses, the Fe_3S_7 framework of $[Fe_3S(SCH_2C_6H_2Me_2CH_2S)_3]^{2\ominus}$ described above (Fig. 2) is topologically closely related to the 3Fe-4S centers of ferredoxins and aconitase.[28–30, 33–36] Apart from the sulfide bridge, the complex also has three thiolate bridges; these probably stabilize the unusually low oxidation state, since Fe^{II} has so far not been observed in any other sulfide-thiolate complex. The thiolate character of the μ-S atoms and the low oxidation state of the iron are also responsible for the fact that chemical similarities to the 3Fe-4S protein centers are only small. The corresponding proteins contain only sulfide bridges; these stabilize a mixed-valent metal state with a mean oxidation state of + 2.67.[22] The search for model complexes for the biological 3Fe centers also led to the synthesis of the trinuclear complex $[Fe_3S_4(SEt)_4]^{3\ominus}$. The complex anion is formed in the reaction of $[Et_4N]_2[Fe(SEt)_4]$ with S_8; subsequent reaction with thiophenol leads to the formation of the analogous thiophenolate-substituted complex (Fig. 7, bottom).[39, 64] The Fe_3S_8 framework represents a trinuclear fragment of the SiS_2 structure and is thus an extension of the corresponding frameworks of binuclear compounds with edge-linked FeS_4 tetrahedra. Its magnetic behavior obeys the Curie–Weiss law with antiferromagnetically coupled iron atoms. The $S = 5/2$ ground state is commensurable with high-spin $Fe^{3\oplus}$ ions.[72]

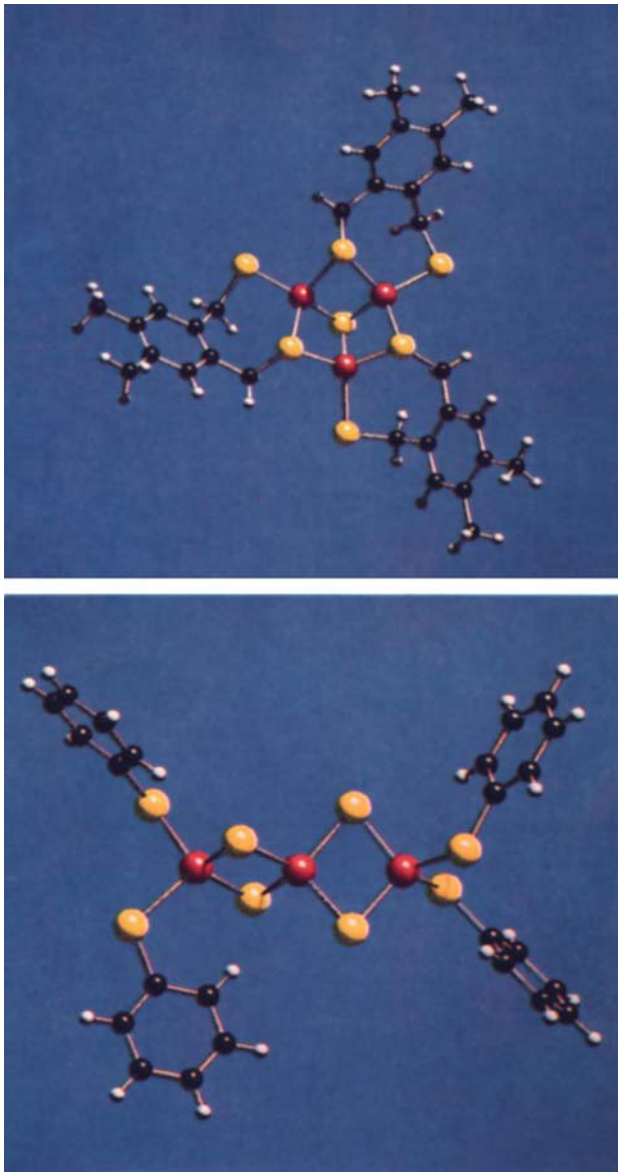

Fig. 7. Structures of the cyclic trinuclear $[Fe_3S(SCH_2C_6H_2Me_2CH_2S)_3]^{2\ominus}$ (top) [32] and the linear trinuclear $[Fe_3S_4(SPh)_4]^{3\ominus}$ (bottom) [64].

2.2.3. *Tetranuclear Complexes*

The synthesis of the first tetranuclear sulfide-thiolate complexes of iron has made electronic, chemical, and structural models for the active sites of 4Fe-4S proteins accessible. The preparation of $[Fe_4S_4(SCH_2Ph)_4]^{2\ominus}$ from $FeCl_3$, NaOMe, NaSH, and $PhCH_2SH$ in methanol was reported in 1972.[73, 74] Since that time, a large number of derivatives of the general composition $[Fe_4S_4(SR)_4]^{z\ominus}$ with $z = 1$, 2, and 3 have been prepared and studied; the extensive literature has been surveyed in several review articles.[18, 19, 37, 54]

A particularly important feature of these highly condensed compounds is the possibility of replacing sulfur by its homologues selenium and tellurium without any change in the mode of coordination. The structurally characterized derivatives in the series of mixed chalcogenide-chalcogenolate complexes $[Fe_4X_4(YR)_4]^{z\ominus}$ include the following anions:

X = S: $[Fe_4S_4(SePh)_4]^{2\ominus}$, $[Fe_4S_4(TePh)_4]^{2\ominus}$[75, 76]

X = Se: $[Fe_4Se_4(SPh)_4]^{2\ominus}$,[77] $[Fe_4Se_4(SPh)_4]^{3\ominus}$,[84] $[Fe_4Se_4(SePh)_4]^{2\ominus}$, $[Fe_4Se_4(SePh)_4]^{3\ominus}$, $[Fe_4Se_4(TePh)_4]^{3\ominus}$[75, 76]

X = Te: $[Fe_4Te_4(SPh)_4]^{3\ominus}$,[75, 76, 78, 79] $[Fe_4Te_4(SPh)_4]^{2\ominus}$, $[Fe_4Te_4(SePh)_4]^{3\ominus}$,[75, 76] $[Fe_4Te_4(TePh)_4]^{3\ominus}$[75, 76, 78, 80]

Compounds with a cubane-like Fe_4S_4 framework are as yet unknown in the chemistry of solid sulfides. Direct relationships between the structural principles of the tetranuclear chalcogenide-chalcogenolate complexes and crystalline nonmolecular solids do however exist in the system iron–tellurium; here the phase $Cs_7Fe_4Te_8$ is known to consist of defined $[Fe_4Te_8]^{7\ominus}$ units and $Cs^{\oplus}$ ions;[81] these units are closely related to the Fe_4Te_8 framework of the anion $[Fe_4Te_4(TePh)_4]^{3\ominus}$ (Fig. 8).

The central iron–sulfur framework of the tetranuclear sulfide-thiolate complexes consists of two interpenetrating tetrahedra, one formed by iron atoms, the other by sulfur

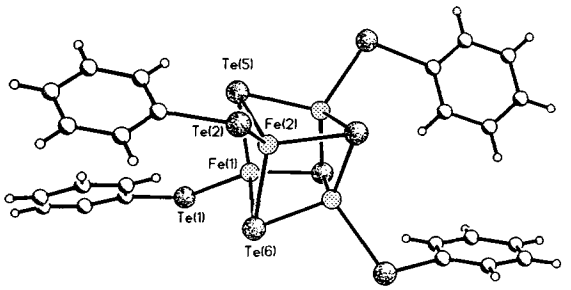

Fig. 8. The anion $[Fe_4Te_4(TePh)_4]^{3\ominus}$ in crystalline $[Et_4N]_3[Fe_4Te_4(TePh)_4] \cdot 2MeCN$ [80].

atoms. In the methanethiolate complex anion,[82] a typical example, the Fe–Fe distances are 2.7–2.8 Å, the S–S distances 3.7–3.8 Å (Fig. 9). The volumes of the tetrahedra in the redox system $[Fe_4S_4(SPh)_4]^{2\ominus}/[Fe_4S_4(SPh)_4]^{3\ominus}$ have been calculated as 2.41 and 2.40 Å^3 (Fe), respectively, and 5.54 and 5.75 Å^3 (S), respectively.[83, 84] The uptake of an additional electron thus leads to a significant increase in the volume of the (inner) S_4 tetrahedron, while the volume of the Fe_4 tetrahedron remains practically unchanged. Because of the short Fe···Fe distances, the magnetic behavior of the complexes is determined by antiparallel spin couplings, as in the bi- and trinuclear cases.

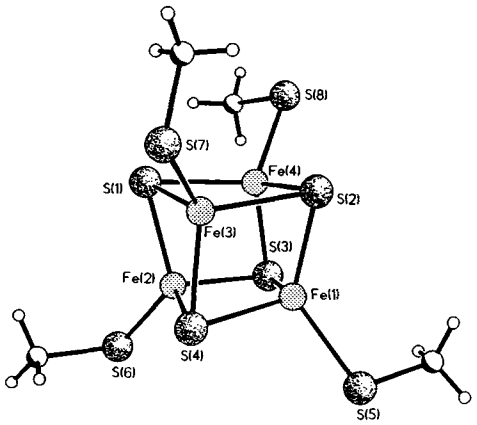

Fig. 9. Structure of $[Fe_4S_4(SMe)_4]^{2\ominus}$ [82] determined from neutron diffraction data.

Fe_4S_4 cubane frameworks in crystalline complexes deviate to a greater or lesser degree from an ideal T_d symmetry; this distortion and its possible origins have already been discussed in the literature.[85] It appears that the electronic ground state ($S = 0$) of the dianionic species $[Fe_4S_4(SR)_4]^{2\ominus}$ favors the tetragonal distortion of the Fe_4S_4 cubane unit. In the case of the more strongly reduced trianionic species $[Fe_4S_4(SR)_4]^{3\ominus}$ there is no uniform picture of distortion.[84–86]

A further group of tetranuclear complexes with complete sulfur ligand spheres is formed by the homoleptic thiolates $[Fe_4(SEt)_{10}]^{2\ominus}$[65] and $[Fe_4(SPh)_{10}]^{2\ominus}$ (Fig. 10),[87, 88] which, like the binuclear complexes, contain tetrahedrally coordinated Fe^{II}. In contrast to all other known complexes, the FeS_4 tetrahedra are linked here only via vertices. The metal–sulfur framework corresponds to a fragment of the zinc blende structure and contains an adamantane-like Fe_4S_6 cage with four terminally bonded thiolate sulfur atoms.

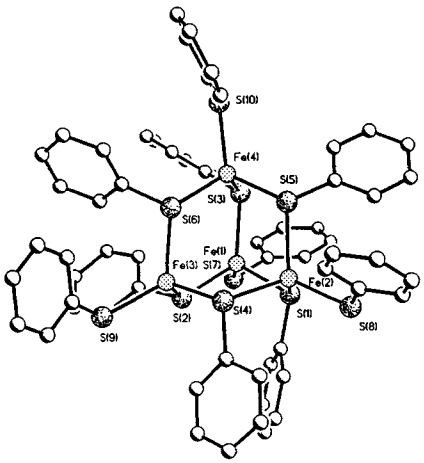

Fig. 10. Structure of the adamantane-like sulfide-thiolate anion $[Fe_4(SPh)_{10}]^{2\ominus}$ [88].

2.2.4. *Complexes Containing More than Four Iron Atoms*

Strenuous efforts have been made to prepare suitable models for the iron–sulfur centers of the 3Fe-4S proteins and the mixed iron–molybdenum–sulfur centers of the nitrogenases. In addition to the synthesis and characterization of trinuclear sulfide-thiolate complexes (see Section 2.2.2), a further milestone was the synthesis of hexanuclear sulfide-rich thiolates, which have played an important role in increasing our understanding of 3Fe-4S centers and the nitrogenases. The preparation of $[Fe_6S_9(SCH_2Ph)_2]^{4\ominus}$ (Fig. 11) was achieved via the reaction of $FeCl_3$ with $NaSCH_2Ph$ and Na_2S_2 in methanol.[31, 42, 89] The Fe_6S_{11} framework of this

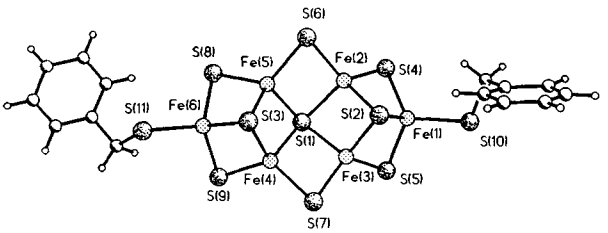

Fig. 11. The anion $[Fe_6S_9(SCH_2Ph)_2]^{4\ominus}$ in crystalline $[Et_4N]_4[Fe_6S_9(SCH_2Ph)_2] \cdot H_2O$ [42].

compound consists of six FeS_4 tetrahedra which are linked via common edges and vertices in such a way that all the iron atoms lie in a plane. The differing Fe–S distances, as well as the Mössbauer spectra, indicate that the four iron atoms in the center of the complex anion have an oxidation state of + 2.5, whereas the two terminal metal centers are Fe^{III}.

The sulfur atoms take up one of four different coordination states: in additon to a symmetrical μ_4-sulfide bridge there are two symmetrical μ_3-sulfide bridges, six μ_2-sulfide bridges, and two terminally bonded thiolate S atoms.

Comparably built complexes with ethanethiolate and *tert*-butanethiolate ligands were synthesized in a different man-

ner.[38, 39, 90] An interesting tetradecanuclear example is found in crystals of $[Et_4N]_6[\{Fe_6S_9(SMe)_2\}_2Na_2]$[31] (Fig. 12). It consists of two hexanuclear units which are linked via sodium. The sulfide ions in the subunits can be exchanged for selenide ions; in this way it was possible to obtain the hexanuclear selenide-thiolate complex $[Fe_6Se_9(SMe)_2]^{4\ominus}$,[40, 91] which was also structurally characterized.

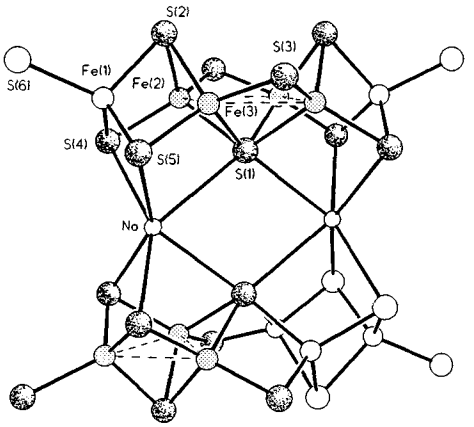

Fig. 12. $[(Fe_6S_{11})_2Na_2]$ framework of the $[\{(Fe_6S_9)(SMe)_2\}_2Na_2]^{6\ominus}$ structural unit in crystalline $[Et_4N]_6[\{(Fe_6S_9)(SMe)_2\}_2Na_2]$. The upper part shows an Fe_4S_9 unit as a part of a model for the M-Fe-S cluster (M = Mo, V) of nitrogenase, the lower part an Fe_3S_7 unit as a model for the 3Fe-4S centers of the 3Fe proteins [31].

Two important fragments of the metal–sulfur framework of the heteronuclear complex anion $[\{Fe_6S_9(SMe)_2\}_2Na_2]^{6\ominus}$ are emphasized in Figure 12: the Fe_4S_9 framework with the central square Fe_4 unit in the upper part of the molecule and the Fe_3S_7 framework of the trinuclear subunits at the lower left. Neighboring FeS_4 tetrahedra in the Fe_4S_9 unit are linked not only by common edges but also via common vertices. This interesting condensation principle, which is new in iron sulfide-thiolate chemistry, leads to the formation of square pyramids whose bases are occupied by iron atoms and whose vertices by sulfur atoms. In the parent compound, the structure of which is based on the Fe_4S_9 fragment, the bases of six of these (μ_4-S-Fe_4) pyramids are linked to form a cubic arrangement of iron atoms. In this model each of the eight iron atoms is surrounded by three sulfide ligands and bonded terminally to a thiolate group in such a way that a tetrahedral FeS_4 coordination is achieved.

On the basis of these considerations we developed a new structural hypothesis for the Fe–M–S centers of the molybdenum- (M = Mo) and vanadium-dependent (M = V) nitrogenases and the Mo–Fe and V–Fe cofactors isolated from them;[31, 42] a comparable suggestion based on the structural principles of a cobalt compound has also been made.[37, 92] The model (Fig. 13) contains a central cube formed by seven iron atoms and a heterometal. In the case of the vanadium-dependent enzymes this site is occupied by vanadium, in the biogenetically younger form by molybdenum. The heterometal cage is surrounded by an octahedron of sulfur atoms, which are located above the centers of the faces of the cube and therefore act as μ_4 bridges. The terminal ligands bonded to the iron atoms in the enzyme are thiolate residues

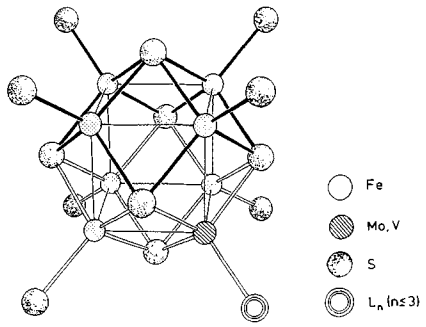

Fig. 13. $[Fe_7MS_{13}L_n]$ framework of the $[Fe_7MS_6(SR)_7L_n]^{z\ominus}$ cluster (M = Mo, V; n = 1, 2 or 3), which has been suggested as a model for the M–Fe–S center of nitrogenase. The atoms connected by bold lines correspond to the Fe_4S_9 unit in $[\{Fe_6S_9(SMe)_2\}_2Na_2]^{6\ominus}$ (compare Fig. 12 above) [31].

from cysteine groups. Molybdenum can most probably bond up to three exogenous ligands and thus has the necessary flexibility to coordinate both the N_2 molecule to be reduced and its activation products.

The Fe_3S_7 units of the hexanuclear complexes (Fig. 12) have a defect cubane structure, as in the trinuclear sulfide-thiolate complexes of Fe^{II}. Chemically they are closely related to the centers of the 3Fe-4S proteins, since all four μ-S atoms of this unit are simple sulfide ions and the iron atoms (mean oxidation state + 2.67) exist in corresponding states. It has not so far been possible to prevent the condensation of these units to form hexanuclear complexes.

An interesting extension of the condensation of these units was recently discovered in the complex salt $[n\mathrm{Pr}_4N]_6Na_4[Fe_{18}S_{30}] \cdot 14\,MeCN$,[93, 94] which contains only bridging sulfide ligands. The remarkable toroidal anion of this compound contains two Fe_6S_{11} units, the construction of which is similar to the metal-sulfur framework of the hexanuclear sulfide thiolate complexes; these Fe_6S_{11} units are linked via condensation with two three-membered chains of edge-linked FeS_4 tetrahedra in a cyclic manner.

3. Cobalt Thiolate Complexes

As in the case of iron, the coordination chemistry of cobalt with mono- and bifunctional thiolate ligands is dominated by the tendency to form tetrahedral MS_4 units, also in the presence of sulfide. However, in contrast to iron, cobalt avoids the formation of higher oxidation states than + 2 in its thiolate and sulfide-thiolate complexes. This probably prevents the formation of tetranuclear sulfide-thiolate complexes of cobalt with cubane-like M_4S_4 frameworks, although the latter are particularly stable in the case of iron.

The first cobalt complex with a mixed sulfide-thiolate ligand sphere was obtained in 1982 from the reaction of $CoCl_2$ with Li_2S and LiSPh in methanol solution in the presence of excess LiOMe.[92, 95] In the octanuclear anion $[Co_8S_6(SPh)_8]^{4\ominus}$ (Fig. 14) the cobalt atoms occupy the corners of a cube the lengths of whose sides lie between 2.63 and 2.68 Å; six sulfur atoms are arranged above the centers of the faces in the form of an octahedron. A second, much larger outer cube, whose faces are almost parallel to the faces of the inner Co cube, is formed by the eight S atoms of the thiophenolate ligands. The complex can be reduced to the

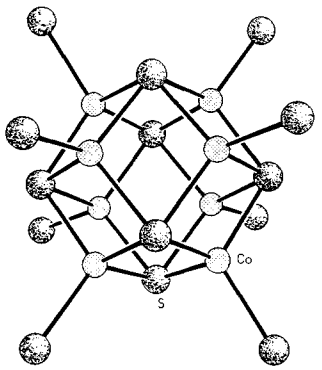

Fig. 14. Structure of the sulfide-thiolate anion $[Co_8S_6(SPh)_8]^{4\ominus}$. The phenyl groups have been omitted for the sake of clarity [92].

mixed-valent anion $[Co_8S_6(SPh)_8]^{5\ominus}$, with a slightly larger central Co_8S_6 cage.[92]

The cobalt compound $[Co_3S(SCH_2C_6H_4CH_2S)_3]^{2\ominus}$[41, 70] is an example of a trinuclear anion $[M_3S(SR)_6]^{2\ominus}$ with divalent metal atoms. Here, the bridging sulfide can be replaced not only by selenide but also by telluride when the homologous chalcogenides are used in the synthesis instead of NaHS. In this manner the novel complex anions $[Co_3Se(SCH_2C_6H_4CH_2S)_3]^{2\ominus}$ and $[Co_3Te(SCH_2C_6H_4CH_2S)_3]^{2\ominus}$ (Fig. 15) were obtained; these were the first mixed selenide-thiolate and telluride-thiolate complexes of cobalt[96] to be described. In addition, the bifunctional thiolate ligands can be replaced by the corresponding selenolates. Two members of the series of mixed cobalt chalcogenide-selenolate complexes are already known: $[Co_3S(SeCH_2C_6H_4CH_2Se)_3]^{2\ominus}$ and $[Co_3Se(SeCH_2C_6H_4CH_2Se)_3]^{2\ominus}$.[96]

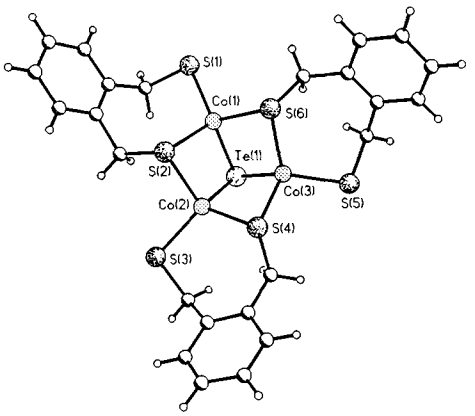

Fig. 15. The telluride-thiolate anion $[Co_3Te(SCH_2C_6H_4CH_2S)_3]^{2\ominus}$ [96].

Apart from these sulfide-thiolate complexes of cobalt and their Se- and Te-substituted derivatives, several multinuclear homoleptic cobalt thiolate complexes with complete sulfur ligand spheres have been prepared: $[Co_4(SPh)_{10}]^{2\ominus}$,[88, 97, 98] *syn*- and *anti*-$[Co_2(SEt)_6]^{2\ominus}$,[65] and *syn-exo*-$[Co_2(SCH_2C_6H_4CH_2S)_3]^{2\ominus}$ (isomer **IIb**, cf. Fig. 5).[68] With the exception of *syn*-$[Co_2(SEt)_6]^{2\ominus}$, they correspond to the analogous iron compounds. The general preparative and structural aspects of the iron thiolate complexes can thus in principle be transferred to the cobalt reaction system.

4. Nickel Thiolate Complexes

There has been extreme interest in nickel complexes with thiolate ligands ever since the discovery of nickel–sulfur interactions in hydrogenases from *Methanobacterium thermoautotrophicum*[99] and *Desulfovibrio gigas*[100] as well as in the CO dehydrogenase from *Clostridium thermoaceticum*.[101]

Both nickel complexes with ligands of the saturated thiolate type and with mixed sulfide-thiolate coordination generally contain divalent metal centers. In contrast to iron and cobalt, the divalent d^8 nickel in these compounds is characterized by square-planar MS_4 units which have a particularly strong tendency in both protic and aprotic solvents to form condensed species sharing common edges.[102] Heterocyclic Ni_2S_2 rings are thus formed; these are generally not completely planar, but are folded to a greater or lesser degreee along their S ··· S diagonals. Three structures are in principle possible for the Ni–S framework of the open-chain oligonuclear nickel thiolates with μ-S bridges:

1. fragments of the infinite one-dimensional zigzag-shaped $[NiS_2]_\infty$ chain (all-*trans* condensation of the NiS_4 units, Fig. 16a);
2. fragments of cyclic systems (Fig. 16b) such as the hexanuclear $[NiS_2]_6$ unit (all-*cis* condensation of the NiS_4 units);
3. fragments combining both types of condensation.

Examples of all three possibilities are in fact known. All open-chain nickel thiolates except for $[Ni_2(SEt)_6]^{2\ominus}$ and $[Ni_3(SEt)_8]^{2\ominus}$[103] are stabilized by bifunctional thiolate ligands.

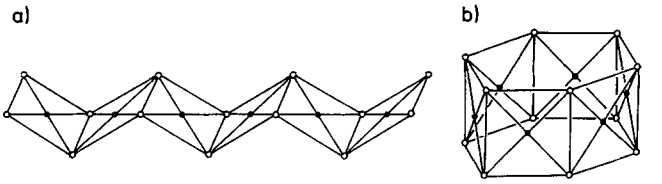

Fig. 16. Stereochemical possibilities for the arrangement of square-planar NiS_4 units: a) folded one-dimensional chain, *trans* condensation; b) cyclic arrangement, *cis* condensation [107].

The structural types found in the known metal(II) thiolates of coordination number 4 with bifunctional ligands are shown schematically in Figure 17. Several tetrahedrally coordinated species (structure types a, b, and d) are already known for iron and cobalt (see Sections 2 and 3), while the group with square-planar coordination (structure types c, e, f, and i) is limited to the nickel complexes (types g and h with tetrahedral sulfur coordination are found only for mercury).

Type c is found in $[Ni_2(SCH_2CH_2S)_3]^{2\ominus}$[104, 105] and also in $[Ni_2(SEt)_6]^{2\ominus}$,[103] which has monofunctional ligands. In contrast to the situation in all other known oligonuclear complexes, the central Ni_2S_2 unit in the latter complex is planar.

The extension of the metal–sulfur framework to include three coordination centers leads to structures of either type e or f, which are realized in $[Ni_3(SCH_2CH_2S)_4]^{2\ominus}$[106, 107] (type e, Fig. 18, top) and $[Ni_3(SCH_2C_6H_4CH_2S)_4]^{2\ominus}$[68, 107] (type f, Fig. 18, bottom). The trinuclear complexes differ in

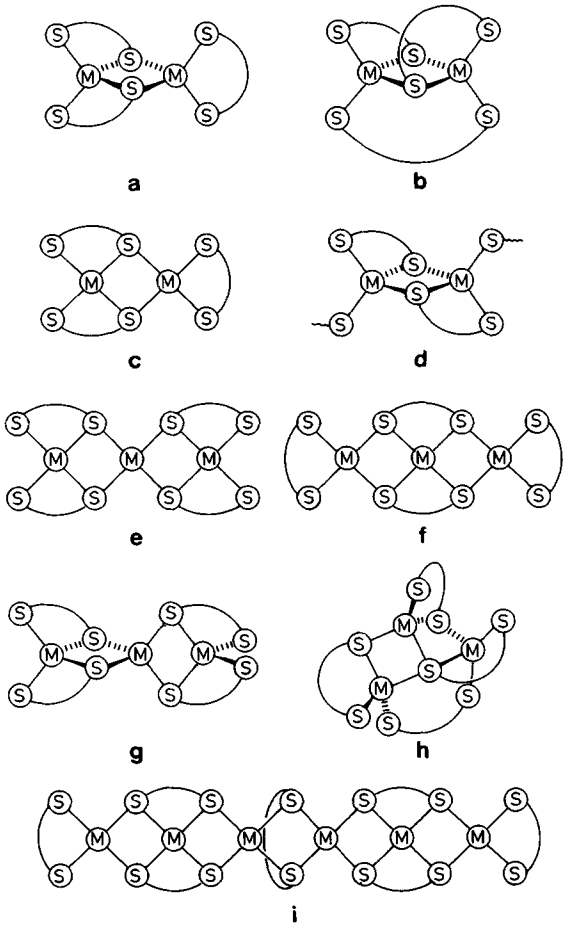

Fig. 17. Experimentally determined structures of tetracoordinated polynuclear metal(II) dithiolates. a) Fe, Zn; b) Mn, Fe, Co, Cd; c) Ni; d) Hg; e) Ni; f) Ni; g) Hg; h) Hg; i) Ni (see also [107]).

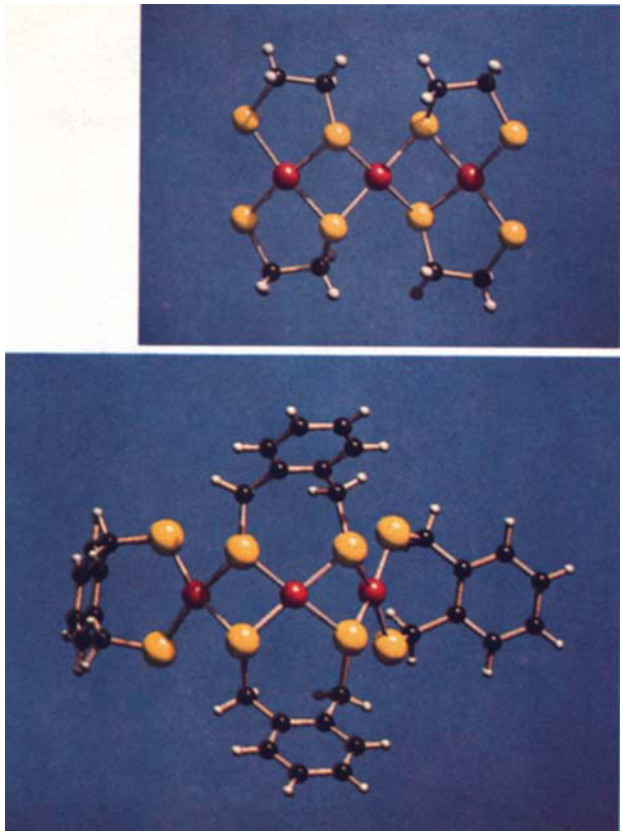

Fig. 18. Top: Structure of $[Ni_3(SCH_2CH_2S)_4]^{2\ominus}$ in crystalline $[Ph_4P]_2[Ni_3(SCH_2CH_2S)_4]$ (*trans* configuration). Bottom: Structure of the anion $[Ni_3(SCH_2C_6H_4CH_2S)_4]^{2\ominus}$ in crystals of $[Et_4N]_2[Ni_3(SCH_2C_6H_4CH_2S)_4] \cdot 2\,MeOH$ (*cis* configuration) [107].

the arrangement of the ligands and in the type of condensation (cf. Fig. 16): whereas *trans* linking is observed in the ethanedithiolate complex (Fig. 18a), *cis* linking is found in the *o*-xylene-α,α'-dithiolate complex (Fig. 18, bottom). Both types of linkage are observed in the hexanuclear complex anion $[Ni_6(SCH_2CH_2CH_2S)_7]^{2\ominus}$,[107] the unusual structure of which is shown in Figure 19 (structure type i). In the compound two trinuclear subunits with *cis* configuration are linked via a *trans* condensation step.

It is clear that hexanuclear nickel thiolates with all-*cis* condensed NiS_4 units can no longer form open-chain systems because the ends of the chain approach one another too closely. As a result, an additional condensation step occurs, which involves the two ends of the chain; this leads to the formation of cyclic complexes with a prismatic nickel–sulfur framework. Examples are provided by the hexanuclear species $[Ni_6(SR)_{12}]$ with R = Et[108–110] and R = C_2H_4OH[111] as well as $[Ni_6(SC_3H_6NHMe_2)_{12}]^{12\oplus}$.[112] The smallest stable cyclic complexes contain four nickel centers and thus have the general structure $[Ni_4(SR)_8]$. Compounds of this class exist with R = 4-(*N*-methylpiperidyl),[113] R = cyclohexyl (Fig. 20a),[114] and R = isopropyl;[115] the octanuclear $[Ni_8(SCH_2C(O)OEt)_{16}]$ is also known.[116] It is interesting that most cyclic thiolates have an even number of nickel centers. There are only two known cyclic compounds in which this number is odd, the novel pentanuclear complex $[Ni_5(SEt)_{10}]$ (Fig. 20b)[114] and the similarly constructed $[Ni_5(SCH_2SiMe_3)_{10}]$.[117]

The electrochemical behavior of the nickel thiolate complexes is of great interest because of the biological function of nickel in the hydrogenases and CO dehydrogenases. Whereas the open-chain nickel thiolates cannot be oxidized without their destruction, the cyclic neutral complexes are capable of electrochemical oxidation within the potential range of about 500–700 mV.[118] Chemical oxidation can be achieved by the use of elemental bromine or iodine in dichloromethane. For example, $[Ni_4(SC_3H_7)_8]$ can be oxi-

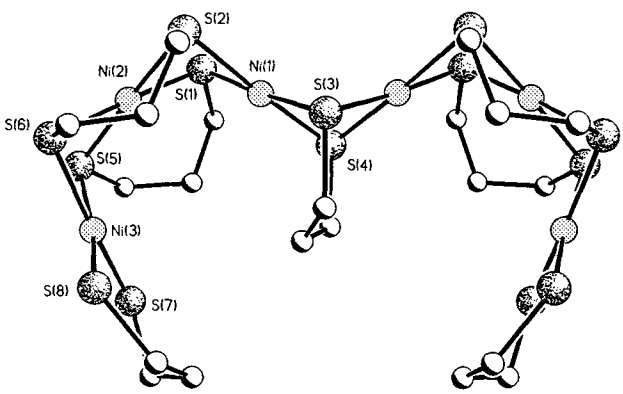

Fig. 19. The hexanuclear anion $[Ni_6(SCH_2CH_2CH_2S)_7]^{2\ominus}$ (mixed *cis*/*trans* configuration) [107].

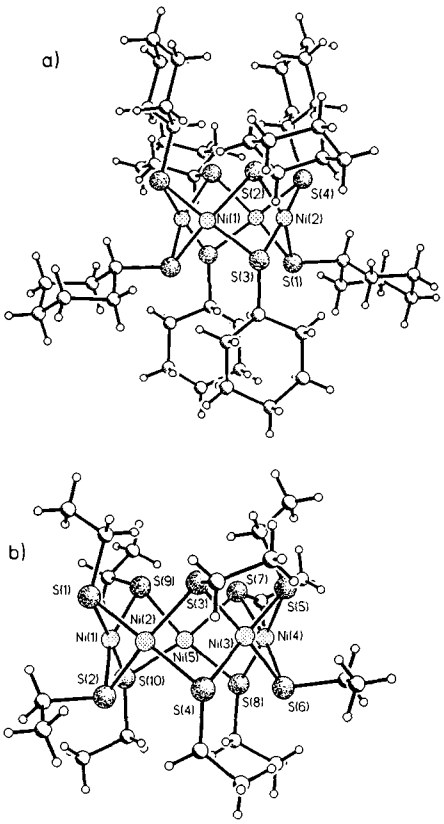

Fig. 20. Cyclic nickel thiolates with even and odd numbers of nickel centers. a) $[Ni_4(SC_6H_{11})_8]$; b) $[Ni_5(SEt)_{10}]$ [114].

dized by bromine to give black crystals of the novel complex $[Ni_4(SC_3H_7)_8Br]$, while oxidation with iodine leads to black $[Ni_4(SC_3H_7)_8I]$.[118] The crystals of $[Ni_4(SC_3H_7)_8Br]$ contain tetranuclear molecular complexes with one trivalent nickel atom each (Fig. 21). The nickel(II) centers have the

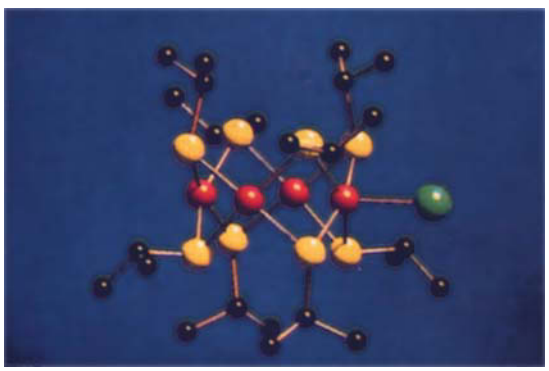

Fig. 21. Structure of the mixed-valent complex $[Ni_4(SC_3H_7)_8Br]$ [118].

usual sulfur environment with a mean Ni–S distance of 2.22 Å and the oxidized nickel atom binds a bromine in an axial position at a distance of 2.53 Å; the equatorial bonds to the S atoms are somewhat longer (mean value 2.26 Å). The molecules are arranged in the crystal along these axes in the form of infinite chains in such a way that the bromide ion is only 3.02 Å away from a (divalent) nickel atom of a neighboring molecule. The halogen atom in the iodo compound is bonded symmetrically between the Ni atoms within the chains; the Ni–I distances (2.82 and 2.88 Å) indicate almost complete bond-length equalization.

The condensation of square-planar NiS_4 units to give trinuclear systems is not limited to parallel edges of the central NiS_4 unit but can also take place at right angles. This type of sulfur linking leads to a sulfur atom which must be bonded to all three nickel atoms simultaneously. Trinuclear compounds of nickel with μ_3-S bridges are indeed known; however, these bridges are not formed by thiolate S atoms but only by sulfidic S atoms. An example with bifunctional thiolate ligands is $[Ni_3S(SCH_2C_6H_4CH_2S)_3]^{2\ominus}$.[71] Whereas the analogous Fe and Co compounds of the general type $[M_3S(SR)_6]^{2\ominus}$ exist in a defect cubane structure, the square-planar coordination observed here leads to a completely different structure. The seven sulfur atoms of the Ni_3S_7 unit occupy seven corners of a distorted cube, while the nickel atoms lie at the centers of three neighboring faces. In contrast to the situation for Fe^{II} and Co^{II}, trinuclear sulfide-thiolate complexes of nickel with monofunctional thiolate ligands have been obtained: $[Ni_3S(SMe)_6]^{2\ominus}$ (Fig. 22)[119] and $[Ni_3S(SPh)_6]^{2\ominus}$[120] are two further remarkable mixed sulfide-thiolate complexes of nickel.

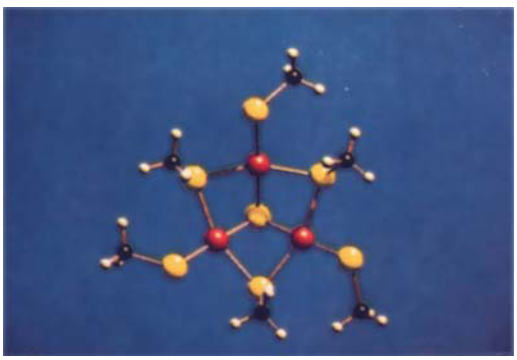

Fig. 22. Structure of the anion $[Ni_3S(SMe)_6]^{2\ominus}$ [119].

In addition to these "classical" sulfide-thiolate complexes, nickel also forms compounds which contain not only thiolate but also disulfide ions. The tetranuclear complex anion $[Ni_4(S_2)(SCH_2CH_2S)_4]^{2\ominus}$ (Fig. 23) can be obtained from the reaction of $NiCl_2$ with $NaSCH_2CH_2SNa$ and Na_2S_2 in MeOH.[106, 121] Complexes containing polysulfide and thio-

Fig. 23. Structure of the disulfide-thiolate anion $[Ni_4(S_2)(SCH_2CH_2S)_4]^{2\ominus}$ [121].

late ligands in the same molecule are unusual, since thiolates normally act as reducing agents towards S_8 and polysulfides, themselves being oxidized to organic disulfides. Apart from $[Ni_4(S_2)(SCH_2CH_2S)_4]^{2\ominus}$, only two further structurally characterized mixed polysulfide-thiolate complexes are known, namely, the trinuclear molybdenum compound $[Mo_3S(S_2)_3(SCH_2CH_2S)_3]^{2\ominus}$[69, 122] and the mononuclear vanadium complex $[V(S_2)S_2(SPh)]^{2\ominus}$.[123]

The first nickel thiolates in which the oxidation state of the metal is lower than two have recently been described. Reaction of $NiCl_2$ with *t*BuSNa in MeOH results in the formation of the octanuclear complex anion $[Ni_8S(SC_4H_9)_9]^{\ominus}$ (Fig. 24).[115] The reduction processes occurring in the

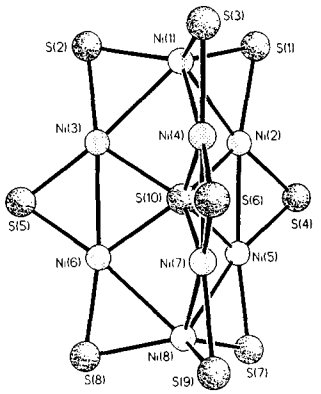

Fig. 24. The Ni_8S_{10} framework of the cluster anion $[Ni_8S(StBu)_9]^{\ominus}$ [115].

course of the reaction are not yet completely understood. In this novel mixed-valent sufide-thiolate complex six nickel atoms form a trigonal prism, the triangular faces of which are capped by two further nickel atoms; the mean oxidation state of the nickel is +1.25. The $[Ni_8S_{10}]$ unit has the first direct Ni–Ni bonds in a nickel thiolate complex, both between the capping nickel atoms and their metal neighbors and, within the prism, between atoms on opposing triangular faces. The presence of bonding interactions is shown by the short Ni ··· Ni distances of 2.47 and 2.44 Å; the Ni–Ni bonds are flanked by thiolate bridges. At the center of the Ni_6 prism there is a sulfide S atom which is bonded to all six nickel atoms at a (mean) distance of 2.18 Å. The trigonal-planar sulfur environment of the nickel atoms is just as unusual as their oxidation state.

5. Thiolate Complexes of the Metals of the Copper and Zinc Groups

The interest in the chemistry and the structural properties of the thiolates and sulfide-thiolates of the six metals in groups 11 and 12 has been stimulated by the great importance of completely or partially sulfur-coordinated biologically active copper, zinc, cadmium, and mercury centers; examples are provided by the blue copper proteins (plastocyanin, azurin, stellacyanin, ceruloplasmin, laccase), other important redox enzymes such as cytochrome *c* oxidase, and, in particular, the different types of metallothioneins (MT).[124–127] The latter are low-molecular-weight proteins (ca. 6 kD) characterized by a high cysteine content and a high metal:cysteine ratio, which ranges from 1:3 for the zinc and cadmium MTs to a value approaching 1:1 in the postulated $[Cu_6S_7]$, $[Cu_6S_9]$, and $[Cu_8S_{12}]$ units in copper MT (e.g., the copper MT from *Neurospora crassa*[125, 128]). The fascinating thiolates of the copper and zinc group are at present the subject of intensive investigation, and the synthesis of a series of remarkable new polynuclear complexes of Cu, Zn, Cd, and Hg has also stimulated the somewhat neglected chemistry of silver and gold. In addition, the chemistry of the gold thiolates is of interest because of the well-known antiarthritic properties of some members of this class of compounds (see, for example, Ref. [129]).

5.1. Copper Thiolates

Copper is normally monovalent in its thiolate complexes, and the coordination is generally trigonal planar, although a number of linearly coordinated examples are known. In the oligonuclear complexes, which are normally prepared from Cu^{I} or Cu^{II} salts and thiolates under various reaction conditions in solvents such as methanol, the ligands are normally bridging.

Copper forms characteristic tetranuclear complexes of the type $[Cu_4(SR)_6]^{2\ominus}$ with simple saturated or aromatic thiolates; these have a cagelike *tetrahedro*-Cu_4-*octahedro*-(μ-S) structure[130–136] (Fig. 25). As is

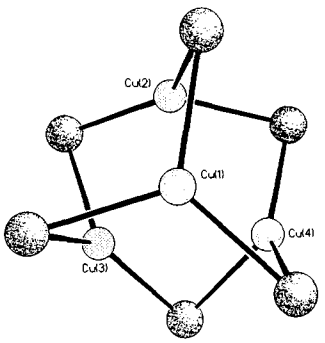

Fig. 25. The M_4S_6 framework of the complexes $[Cu_4(SR)_6]^{2\ominus}$.

shown by $[Cu_4(SMe)_6]^{2\ominus}$,[131] $[Cu_4(SEt)_6]^{2\ominus}$,[137] $[Cu_4(SPh)_6]^{2\ominus}$,[130–132] $[Cu_4(SCH_2CH_2S)_3]^{2\ominus}$,[133] and $[Cu_4(SCH_2C_6H_4CH_2S)_3]^{2\ominus}$,[134–136] the examples prepared so far, this structure is stabilized by both monofunctional and bifunctional thiolates. The compound $[Cu_3(SCH_2CH_2S)_3]^{3\ominus}$[60] in which the metal:ligand ratio is 1:1, contains a nonplanar $[Cu_3(\mu\text{-}S)_3]$ ring with trigonally coordinated copper. Under different reaction conditions the reaction with thiophenolate gives pentanuclear $[Cu_5(SPh)_7]^{2\ominus}$, the structure of which is derived from $[Cu_4(SPh)_6]^{2\ominus}$ by replacement of an $SPh^{\ominus}$ ligand by a linear PhS-Cu-SPh building block.[138, 139] When sterically demanding ligands such as $StBu^{\ominus}$ are used, steric hindrance leads to a ligand-poorer complex, the pentanuclear anion $[Cu_5(StBu)_6]^{\ominus}$, in which two copper centers are trigonally planar and three linearly coordinated. As for other thiolates of the d^{10} metals, there

are indications of weak bonding interactions between the metal atoms.

The heteroleptic complex $[Cu_7(SCH_2CH_2S)_4(SEt)]^{2\ominus}$ (Fig. 26) with mono- and bifunctional thiolate moieties contains a Cu_7 framework which consists of two vertex-linked Cu_4 tetrahedra.[134, 136, 143] If the central metal atom is removed, the remaining Cu_6S_9 framework, which has a trigonal-prismatic arrangement of the metal atoms, may serve as a model for the proposed metal–sulfur centers in copper metallothioneins.[125, 128] A compound of similar

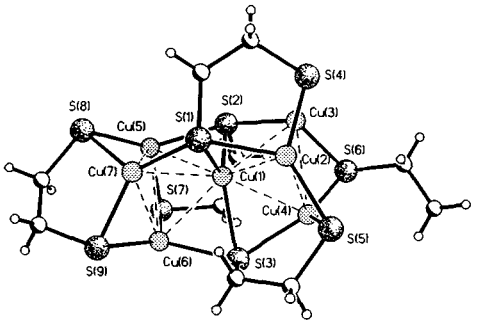

Fig. 26. Structure of the heteroleptic thiolate $[Cu_7(SCH_2CH_2S)_4(SEt)]^{2\ominus}$ [134, 136, 143].

composition with monodentate ligands, $[Cu_7(SEt)_8]^{\ominus}$, has a polymeric chain structure in which cagelike $[Cu_7(SEt)_{10}]$ structural units with trigonal-planar coordination of the Cu atoms are linked via four S atoms to give one-dimensional infinite polymers.[137, 144] A similar reaction system in which thioxanthate is present as a coligand affords the octanuclear $[Cu_8(SC_5H_{11})_4(S_2CSC_5H_{11})_4]$, in which the Cu_8S_{12} framework represents a new type of cage; Cu is coordinated in a trigonal-planar fashion and the cage consists of eight Cu_3S_3 rings in a boat form and two Cu_4S_4 rings.[145]

Two recently reported 1:1 complexes are worthy of particular attention, since they represent oligomers of the long-sought "simple" compound CuSR. The first of these is the octanuclear complex $[Cu_8\{SC_6H_2(iPr)_3\}_8]$ with a twisted 16-membered ring consisting of alternating linearly coordinated Cu and μ_2-bridged SR ligands;[146] the second is $[Cu_{12}\{SC_6H_4(o\text{-}SiMe_3)\}_{12}]$, in which the sterically demanding ligands cause the formation of a remarkable paddle-wheel-like $Cu_{12}S_{12}$ molecular skeleton[147, 148] (Fig. 27). Six

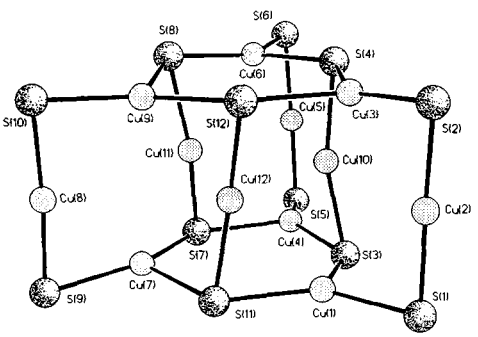

Fig. 27. $Cu_{12}S_{12}$ molecular framework of $[Cu_{12}\{SC_6H_4(o\text{-}SiMe_3)\}_{12}]$ [147, 148]. Only the thiolate S atoms of the 2-(trimethylsilyl)thiophenolate ligands are shown.

of the Cu^I atoms in the $[2_3](1,3,5)$-cyclophane-like structure are almost trigonal planar, the other six are linearly coordinated. The two parallel, "stacked" Cu_3S_3 rings are twisted with respect to one another by about 10°. The considerable contraction of the triangle Cu(10)-Cu(11)-Cu(12) in the direction of the center of the molecule (S–Cu–S angle 163.3°) possibly indicates the presence of weak attractive interactions between the metals.

There has also been great interest in the search for possible structural models for the copper centers in cytochrome *c* oxidase. The paramagnetic mixed-valent cluster complex $Cu^I_2Cu^{II}_3[\{SCH_2CH(CO_2CH_3)NHCH_2\text{-}\}_2]_3[ClO_4]_2 \cdot H_2O$ (Fig. 28)[149] can be regarded as a close approximation to the

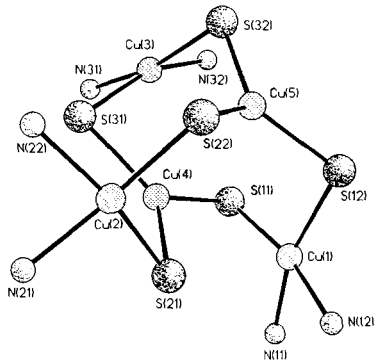

Fig. 28. $Cu^I_2Cu^{II}_3[\{SCH_2CH(CO_2CH_3)NHCH_2\text{-}\}_2]_3[ClO_4]_2 \cdot H_2O$: $Cu_5N_6S_6$ framework of the mixed-valent $[Cu^I_2Cu^{II}_3\{\{SCH_2CH(CO_2CH_3)NHCH_2\text{-}\}_2\}_3]^{2\oplus}$ cluster [149].

steric and electronic situation provided by the *cis*-$[CuN_2(his)S_2(cys)]$ ligand arrangement in Cu_A. There is a weak antiferromagnetic exchange coupling ($J = -0.26\ cm^{-1}$) between the three slightly distorted square-planar *cis*-$Cu^{II}N_2S_2$ units; the two Cu^IS_3 polygons are almost trigonal planar.

5.2. Silver and Gold Thiolates

The chemistry of the silver thiolates, their methods of preparation, and their stereochemistry (which tends

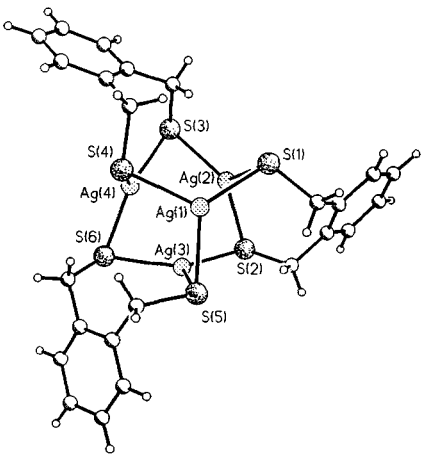

Fig. 29. Structure of the anion $[Ag_4(SCH_2C_6H_4CH_2S)_3]^{2\ominus}$ in crystals of $[Ph_4P]_2[Ag_4(SCH_2C_6H_4CH_2S)_3]$ [150].

Fig. 30. Structures of the polynuclear anions $[Au_2Cu_4(SCH_2CH_2S)_4]^{2\ominus}$ (left) and $[Ag_9(SCH_2CH_2S)_6]^{3\ominus}$ (right) [133].

towards the formation of cage structures) are all remarkably similar to those of copper. A series of polynuclear metal–sulfur frameworks has been reported in the recent literature. These range from the Ag_4S_6 cages in $[Ag_4(SCH_2C_6H_4CH_2S)_3]^{2\ominus}$[150] (Fig. 29) and in $[Ag_4\{SC_6H_3(Me)S\}_3]^{2\ominus}$[151, 152] to the pentanuclear Ag_5S_6 and Ag_5S_7 units in the (similarly anionic) complexes $[Ag_5(StBu)_6]^{\ominus}$ and $[Ag_5(SPh)_7]^{2\ominus}$[142, 139, 153] and to a large number of oligomeric or polymeric neutral $[AgSR]_n$ complexes. Their preparation is generally subject to steric control by the size and charge distribution of the ligands; important, and stereochemically extremely variable, structure elements are the (to a varying extent) undulating Ag_3S_3 and Ag_4S_4 metallacycles, which exhibit linear S–Ag–S coordination and can be associated via secondary Ag ··· S bonds. Examples are provided by the trinuclear $[Ag_3\{SC(SiPhMe_2)_3\}_3]$,[154] the tetranuclear $[Ag_4\{SC(SiMe_3)_3\}_4]$[154] and $[Ag_4\{SSi(OtBu)_3\}_4]$,[155] and the octanuclear complexes of the composition $[Ag_8\{SC_6H_4(o\text{-}SiMe_3)\}_8]$[148] and $[Ag_8\{SCH(SiMe_3)_2\}_8]$[154] with two ligand-bridged eight-membered Ag_4S_4 metallacycles.

Ligand-dependent oligomerization equilibria are observed in solution for 1:1 thiolates $[AgSR]$.[159] From these solutions it is possible to isolate ring oligomers and chain polymers with linear S–Ag–S coordination (and additional very weak secondary bonding interactions). The cyclohexyl derivative forms a 24-membered molecular metallacycle, $[Ag_{12}(SC_6H_{11})_{12}]$,[156, 157] while the 3-methylpentane derivative crystallizes as a chain polymer, $[AgSCMeEt_2]_n$.[160]

A series of remarkable mixed-metal complexes of the composition $[Au_{6-n}M_n(SCH_2CH_2S)_4]^{2\ominus}$ (with M = Ag, n = 4; M = Cu, n = 3,4), and $[Au_{9-n}Cu_n(SCH_2CH_2S)_6]^{3\ominus}$[133, 134, 136, 143, 150] (Fig. 30) are derived from the equally new anionic homoleptic cage complex $[Ag_9(SCH_2CH_2S)_6]^{3\ominus}$[133] or the postulated $[M_6(SPh)_8]^{2\ominus}$ (M = Cu, Ag).[158]

A stabilization of the polynuclear electroneutral silver thiolates $[AgSR]_n$ is apparently possible when additional phosphane ligands are present. Examples of a new heteroleptic polynuclear species of this type are provided by the octa- and tetradecanuclear tertiary alkanethiolates $[(AgSCMeEt_2)_8(PPh_3)_2]$ and $[(AgStBu)_{14}(PPh_3)_4]$.[161]

The chemistry of gold thiolate complexes is completely different from that of the homologous copper and silver complexes in that Au^I is only found in a linear two-coordinate form, which is observed in the above-mentioned mixed-metal complexes. In addition, gold is able to form stable thiolates of d^8 Au^{III}. Only complexes of low nuclearity have so far been obtained when aliphatic thiolates are used. Gold(III) forms a mononuclear anion, $[Au(SCH_2CH_2S)_2]^{\ominus}$, with square-planar coordination.[151, 152] The remarkable selenide-thiolate $[Au_2Se_2(SCH_2CH_2S)_2]^{2\ominus}$ (Fig. 31),[151, 152]

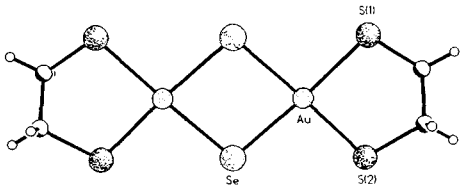

Fig. 31. Structures of $[Au_2Se_2(SCH_2CH_2S)_2]^{2\ominus}$ [151, 152].

the first member of a new class of heteroleptic mixed-ligand chalcogenide thiolates, was obtained from the system NaHSe/Se/$BH_4^{\ominus}$/$[Ph_4P][AuCl_3Br]$/ethane-1,2-dithiolate.

The anionic thiolatoaurates(I) $[Au_2(SCH_2CH_2CH_2S)_2]^{2\ominus}$ and $[Au_2(SCH_2C_6H_4CH_2S)_2]^{2\ominus}$[151, 152] (Fig. 32) are formed in the reaction between $[AuCl_4]^{\ominus}$ and propane-1,2-dithiolate or *o*-xylene-α,α′-dithiolate; the thiolates act as re-

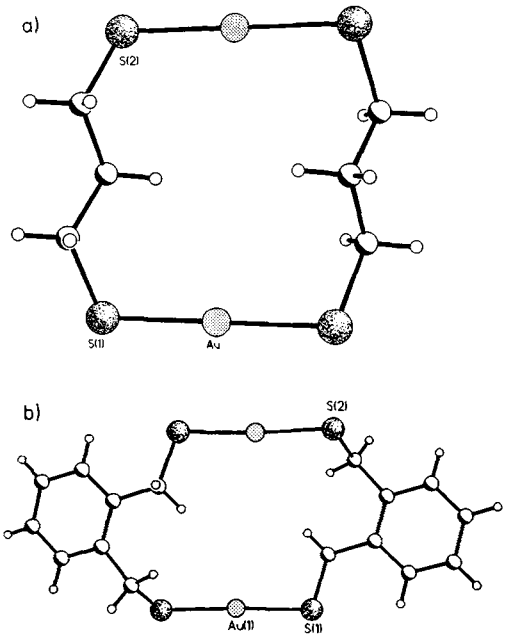

Fig. 32. Structures of $[Au_2(SCH_2CH_2CH_2S)_2]^{2\ominus}$ (a) and $[Au_2(SCH_2C_6H_4CH_2S)_2]^{2\ominus}$ (b) [151, 152].

ducing agents so that Au^I is formed. The complex anions contain interesting 12- and 14-membered metallacycles with linearly coordinated gold.

5.3. Zinc, Cadmium, Mercury

A chemistry with completely different reactive properties and individual structural principles is exhibited by the thiolates of the closed-shell d^{10} elements of group 12. Their reactive behavior is determined in a characteristic manner by their tendency to form polynuclear aggregates of tetrahedral building blocks; the interest in this class of compounds has been stimulated not only by their general chemistry but also by the necessity for the development of model systems for important classes of metal-centered bioactive molecules.

5.3.1. On the Bioinorganic Chemistry of Zn, Cd, and Hg

A large number of metalloenzymes of zinc are known; apart from the dominant coordination by imidazole and aquo ligands, partial or complete coordination by cysteine or methionine sulfur atoms is also important. Examples are provided by liver alcohol dehydrogenase (coordination at the catalytic center, $[ZnONS_2]$; "structural" zinc, $[ZnS_4]$), aspartate transcarbamylase ($[ZnS_4]$), β-lactamase ($[ZnN_3S]$), and 5-aminolevulinate dehydratase ($[ZnNS_3]$). As already mentioned, all three metals are found in metallothioneins; here again a predominantly tetrahedral coordination of the metals by sulfur must be assumed.[162-164] The metallothioneins of Zn, Cd, and Hg so far studied contain seven metal atoms, which, according to X-ray structural studies on Cd/Zn-thioneins, occur in two separate domains in the form of a trinuclear NH_2-terminal M_3S_9 and a tetranuclear COOH-terminal M_4S_{11} unit, each M (M = Zn, Cd) being bonded to four cysteine residues[124, 126, 162-164] (Fig. 33). At higher mercury concentrations the formation of Hg-richer metallothioneins (up to Hg_{18}) with lower coordination numbers and with higher degrees of condensation has been postulated.[165]

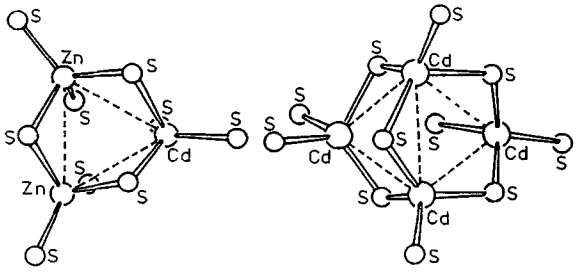

Fig. 33. The β and α domains of Zn/Cd metallothionein-2 from rat liver; in Cd metallothionein, the trinuclear center is closer to the amino terminal of the protein chain and the tetranuclear center is closer to the carboxyl terminal [163, 164].

The coordination of zinc (and other metals) by cysteine sulfur (and/or histidine nitrogen) atoms is also the most important structural principle of the nucleic acid binding proteins, which have only been recognized and intensively studied in the last few years. These transcription factors, in which zinc is an essential element, bond specifically to certain DNA sequences and thus modulate gene expression. The metal centers stabilize conserved partial sequences by complexation; these are folded to give the so-called "zinc fingers" (see, for example, Refs. [166-168]).

A further important role is played by HgS_x centers in the remarkable MerR proteins (mercury reductases). They provide the first example of "metal-regulating" proteins and may function as "genetic switches";[169] for example, bacteria can become resistant to the toxic effects of mercury. This is due to resistance genes, which cause the formation of MerR proteins and whose activation is controlled via these proteins as a function of the Hg concentration. The Hg-controlled self-regulating MerR proteins bond to heavy metals and are thus involved in signal transfer, so that they can, for example, act as sensitive biosensors for mercury in nanomolar and for cadmium in micromolar concentrations. The mercury in the protein is probably trigonally coordinated in a MerR dimer by three cysteine sulfur ligands[170, 171] (see also Ref. [199]).

Thiolates have long been used as selective drugs in the treatment of mercury (or As, Au, Sb, and Co) poisoning; they act by competing with the cysteine ligands of enzymes for coordination of these metals.[172] The commonly used reagents 2,3-dimercapto-1-propanol (BAL = British Anti-Lewisite) and penicillamine are being increasingly replaced by the water-soluble drugs sodium 2,3-dimercaptopropane-1-sulfonate and dimercaptosuccinic acid, which are administered orally.[173] Little is known about the structures of the insoluble polymeric mercury compounds.

5.3.2. Zinc and Cadmium Thiolates

The preparative methods for the synthesis of thiolates and sulfide thiolates of Zn, Cd, and Hg with a complete sulfur coordination sphere are similar to those used for the copper group; they typically involve the reaction between thiolate anions (or corresponding thiolate-sulfide mixtures) and the dihalides in solvents such as methanol, with subsequent precipitation as salts of large quaternary onium cations such as $[Ph_4P]^{\oplus}$, $[Ph_4As]^{\oplus}$, $[Ph_3PNPPh_3]^{\oplus}$, and $[nBu_4P]^{\oplus}$.

Mononuclear tetrahedral zinc and cadmium thiolates of the types $[Zn(SPh)_4]^{2\ominus}$, $[Cd(SPh)_4]^{2\ominus}$,[174] and $[Cd\{SC_6H_4(o\text{-}SiMe_3)\}_4]^{2\ominus}$[148] are stable and have been structurally characterized; species with trigonal-planar coordination of the metal are hardly known and can only be stabilized by sterically demanding ligands. The first examples, $[Zn(S\text{-}2,3,5,6\text{-}Me_4C_6H)_3]^{\ominus}$[175] and $[Cd(S\text{-}2,4,6\text{-}iPr_3C_6H_2)_3]^{\ominus}$,[176] have been described only recently. It has been suggested that this seldom encountered type of MS_3 coordination (M = Zn, Cd) may play a role in biologically important metal-cysteine systems.[168, 175]

Binuclear complexes of the type $[M_2(SR)_6]^{2\ominus}$ with R = Et or Me are known for all Zn, Cd, and Hg.[103, 177, 178] They contain an M_2S_6 unit formed by two edge-linked tetrahedra, which is also found in analogous Fe^{II} and Mn^{II} complexes and in other zinc and cadmium complexes containing aromatic and bidentate ligands; examples are $[M_2(SPh)_6]^{2\ominus}$[179] and $[M_2(SCH_2C_6H_4CH_2S)_3]^{2\ominus}$ with M = Zn, Cd.[177, 180]

A very characteristic structural feature of the polynuclear zinc and cadmium thiolates and sulfide-thiolates is their ten-

dency to form adamantane-like cage systems via parallel vertex-linked condensation of MS_4 tetrahedra; extension of these systems in three dimensions gives polymeric products.[10] The analogy to the zinc blende structure is clear: zinc blende is the final product of the condensation when all thiolate ligands are replaced by sulfide.

Examples of the first step in this condensation process involving parallel tetrahedra are the adamantane-like thiophenolate complexes $[M_4(SPh)_{10}]^{2\ominus}$ with M = Zn, Cd.[181-183] This adamantane framework is also found in the preparatively interesting heteroligand complexes $[M(EPh)_6X_4]$ (M = Zn, Cd; E = S, Se; X = Cl, Br, I), which can be prepared by direct halogenation (for example, using $PhICl_2$) of the anions $[M_4(EPh)_{10}]^{2\ominus}$.[184]

The next step is represented by the synthesis of decanuclear "macrotetrahedral" frameworks containing ten parallel tetrahedra; these contain 16 thiolate ligands, while the μ_3-bridging sulfur functions exist in the sulfide form. Examples are $[Zn_{10}S_4(SPh)_{16}]^{4\ominus}$,[185] $[Zn_{10}S_4(SCH_2C_6H_4CH_2S)_8]^{4\ominus}$[180] (Fig. 34), and $[Cd_{10}S_4(SPh)_{16}]^{4\ominus}$.[185] This framework, which resembles the zinc

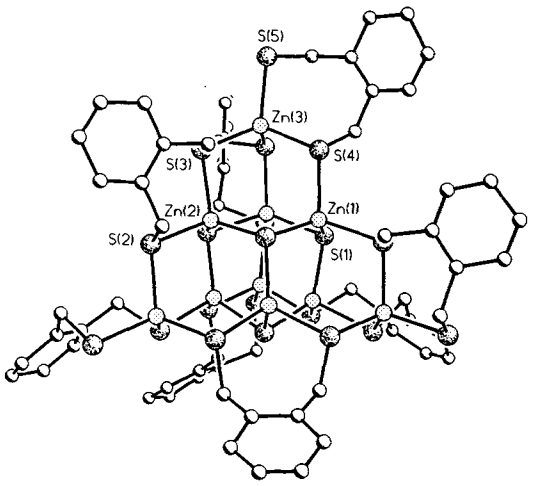

Fig. 34. Molecular structure of the polyanion $[Zn_{10}S_4(SCH_2C_6H_4CH_2S)_8]^{4\ominus}$ in crystals of $[nBu_4N]_4[Zn_{10}S_4(SCH_2C_6H_4CH_2S)_8] \cdot 8\,MeOH$ [180].

blende structure, is present in a modified form in the cation $[Cd_{10}(SCH_2CH_2OH)_{16}]^{4\oplus}$, in which the coordination of four of the Cd atoms is increased by the OH ligand functions to $[CdS_4O]$ (4x) or $[CdS_3O_3]$ (4x).[186, 187] An even higher degree of condensation in a molecular species has been achieved in the complex $[Cd_{17}S_4(SPh)_{28}]^{2\ominus}$[188] (Fig. 35). The Cd–S framework (T_d symmetry) contains a $Cd_{13}S_{28}$ core (zinc blende type) consisting of corner-sharing parallel CdS_4 tetrahedra; a central $Cd(\mu_4\text{-}S)_4$ tetrahedron is surrounded by a Cd_{12} cuboctahedron. Four of the eight triangular faces of the Cd_{12} cuboctahedron are capped by four additional outer $Cd(\mu\text{-}S)_3S$ tetrahedra in a wurtzite-like manner.

In the α-cristobalite-like structure of $[Cd(SPh)_2]_n$ the adamantane-like $[Cd_4(SPh)_{10}]$ units are three-dimensionally linked in the sense of polymeric $[(\mu\text{-}SPh)_6Cd_4(\mu\text{-}SPh)_{4/2}]$; the compound has a melting point of 340°C but dissolves readily with solvolysis in solvents such as DMF.[189, 190] The structure of the polymeric $[Cd(SC_6H_4pMe)_2]_n$, which is also composed of vertex-linked adamantane units, has interesting

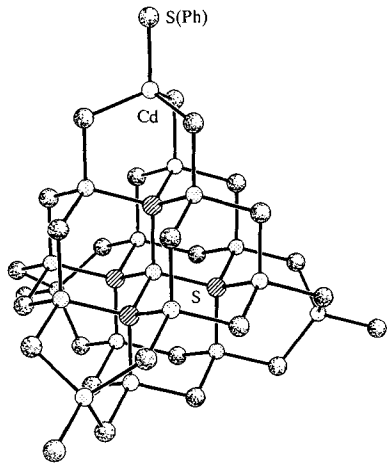

Fig. 35. Structure of $[Cd_{17}S_4(SPh)_{28}]^{2\ominus}$ [188].

analogies to the zeolite-like microporous aluminosilicate frameworks.[190] Furthermore, a polymer with the composition $[Cd_7(C_6H_4oMe)_{14}(DMF)_2]_n$ does not contain adamantane building blocks but consists of three-dimensionally cross-linked, spirocyclically linked Cd_3S_3 rings as well as macrocycles such as $[Cd_{24}S_{24}]$.[191]

The close chemical relationship between the d^{10} elements Zn^{II} and Cd^{II} and their isoelectronic neighbors in the periodic table, Ga^{III}, In^{III}, and Sn^{IV}, is shown clearly by the remarkable analogies between their oligomeric thiolate-sulfide species. Gallium, indium, and tin also form macrotetrahedral decameric thiolate-sulfide anions with $M_{10}S_{20}$ frameworks identical to those in $[M_{10}S_4(SPh)_{16}]^{4\ominus}$ (M = Zn, Cd). The anions $[M_{10}S_{16}(SPh)_4]^{6\ominus}$ (M = Ga, In) (Fig. 36),[192] as well as $[Sn_{10}O_4S_{20}]^{8\ominus}$,[193] have been prepared in solution. Even boron(III) compounds with analogous decameric $B_{10}S_{20}$ building blocks can be obtained via solid-state reactions: in

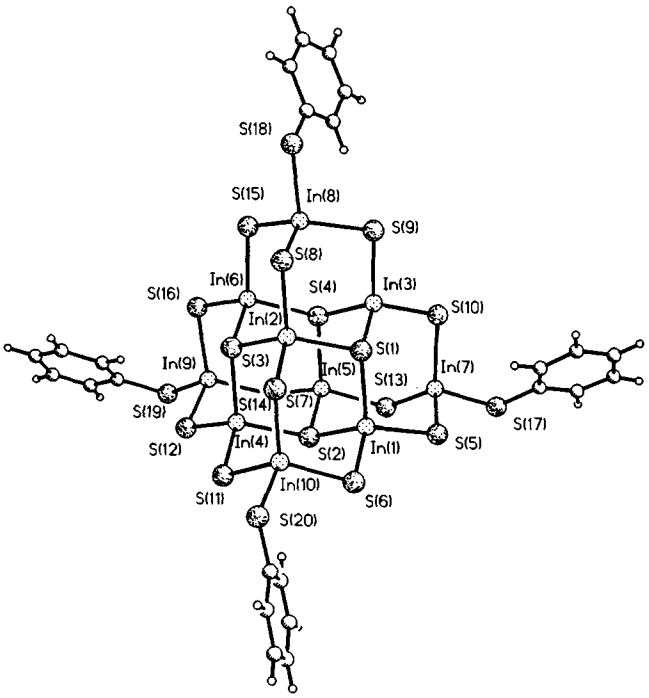

Fig. 36. Structure of $[In_{10}S_{16}(SPh)_4]^{6\ominus}$ in crystals of $[Et_4N]_6[In_{10}S_{16}(SPh)_4] \cdot MeOH$ [192].

$Ag_6[B_{10}S_{18}]$,[194,195] $Li_{6+2x}[B_{10}S_{18}]S_x$, $Li_5[B_7S_{13}]$, and $Na_6[B_{10}S_{18}]$,[196] these are linked in three dimensions via the four vertices of their macrotetrahedra.

The varying thiolate/sulfide ratios within the homologous series of decanuclear anions are in general caused by charge effects; an increase in the valency (formal charge) of the metals must lead to an increase in the amount of sulfide. Similar homologies exist for the tetranuclear adamantane-like species (see, for example, Ref. [195]).

A new series of topologically interesting molecular Cd chalcogenolates of the compositions $[Cd_8E(E'Ph)_{16}]^{2\ominus}$ with E, E' = S, Se, Te (including the complex $[Cd_8S(SPh)_{16}]^{2\ominus}$) form polycyclic cage systems of approximate *T* symmetry which can be described as *centro*-S-*tetrahedro*-Cd_4^i-*icosahedro*-(μ-SPh)$_{12}$-*tetrahedro*-Cd_4^0-*tetrahedro*-$(SPh)_4$ with tetrahedrally coordinated cadmium.[197] A similar icosahedral sulfur framework is found in the octanuclear thiolate halides $[Cd_8X(SCH_2CH_2OH)_{12}X_3]$ with X = Cl, Br, I; however, the tetrahedrally (5 x $[CdS_3X]$) or fivefold (3 x $[CdS_3O_2]$) coordinated cadmium atoms in these complexes form a compressed hexahedron.[198]

5.3.3. *Mercury Thiolates*

The flexible coordination properties of mercury make possible the formation of more or less distorted polyhedra $[HgS_n]$ (n = 2–4), depending on the electronic and steric requirements of the ligands. This has led to the synthesis of structurally very different mononuclear, oligomeric, and polymeric Hg^{II} thiolates (see also Ref. [199]). The mononuclear species include the following:

1. linear molecules $[Hg(SR)_2]$ which are associated to some extent in the solid state:

$[Hg(SEt)_2]$,[200] $[Hg(S\text{-}2,4,6\text{-}i\text{Pr}_3C_6H_2)_2]$,[176] $[Hg\{SC_6H_4(o\text{-}SiMe_3)\}_2]$,[201] $[Hg\{SCH_2CH(NH_3)COO\}\{SCH_2CH(NH_3)COOH\}]Cl \cdot 1/2H_2O$;[202]

2. anionic, trigonally coordinated complexes $[Hg(SR)_3]^{\ominus}$ with model character for important biomolecules:[170]

$[Hg(SPh)_3]^{\ominus}$,[203,204] $[Hg(S\text{-}2,4,6\text{-}i\text{Pr}_3C_6H_2)_3]^{\ominus}$,[176] $[Hg(S\text{t}Bu)_3]^{\ominus}$;[170]

3. species with tetrahedral coordination of the metal:

$[Hg(SPh)_4]^{2\ominus}$,[204] $[Hg(SC_6H_4Cl)_4]^{2\ominus}$,[205] $[Hg(SC_6F_5)_4]^{2\ominus}$,[206] $[Hg(C_6Cl_5)_4]^{2\ominus}$.[207]

Two types of binuclear Hg thiolates are known. Apart from $[Hg_2(SMe)_6]^{2\ominus}$,[178] which corresponds to the homologous Zn and Cd compounds, a neutral complex, $[Hg(2\text{-}SC_6H_4)_2SiMe_2]_2$, has also been obtained;[201] in this complex the linearly coordinated Hg atoms and the bridging bidentate ligands form a 16-membered heteronuclear [-Hg-S-C-C-Si-C-C-S]$_2$ ring. Other remarkable examples of oligomeric Hg^{II} thiolates are provided by the binuclear $[Hg_2(SPh)_4(PPh_3)_2]^{2\ominus}$[177] and the trinuclear anions $[Hg_3(SCH_2CH_2S)_4]^{2\ominus}$ and $[Hg_3(SCH_2C_6H_4CH_2S)_3]^{2\ominus}$[208,209] (Fig. 37). The structures of the anions, which are governed by the steric demands of the ligands, are completely different: ethane-1,2-dithiolate makes possible a linear Hg_3 arrangement (Fig. 37, left) with the coordination numbers 4 (tetrahedral, 1x) and 2 (quasi-linear, 2x), while the different "bite" of *o*-xylene-α,α'-dithiolate leads to a triangular arrangement of the metal atoms, resulting in HgS_4 tetrahedra with terminal (5x), μ_2-bridging (2x), and μ_3-bridging (1x) thiolate functions (Fig. 37, right).

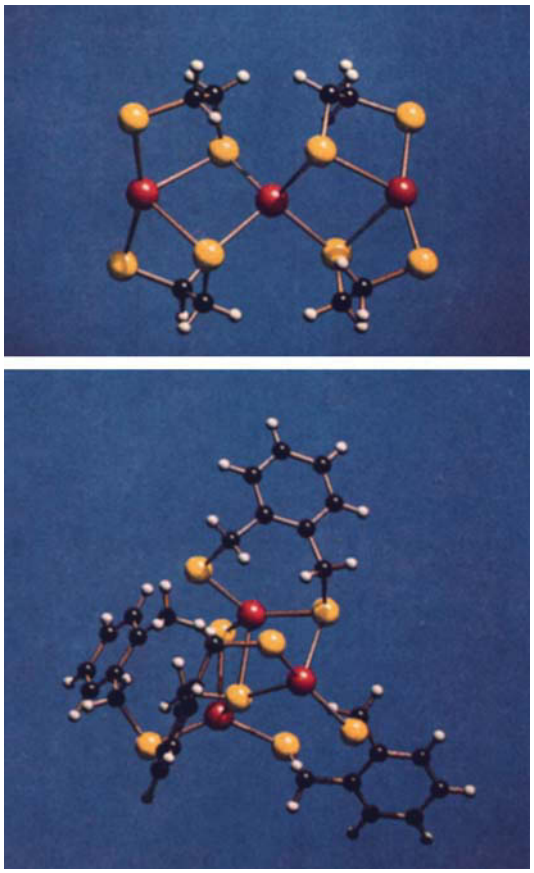

Fig. 37. Left: Structure of $[Hg_3(SCH_2CH_2S)_4]^{2\ominus}$ [208], Right: Structure of $[Hg_3(SCH_2C_6H_4CH_2S)_4]^{2\ominus}$ [209].

The novel pentanuclear anion $[Hg_5(SCH_2CH_2S)_4(SEt)_4]^{2\ominus}$[134,136] (Fig. 38) is the first mixed-ligand compound in the series of oligomeric Hg^{II} thiolates. The tetrahedrally coordinated central Hg in this anion is linked to the remaining Hg atoms via one of the thiolate sulfurs of the

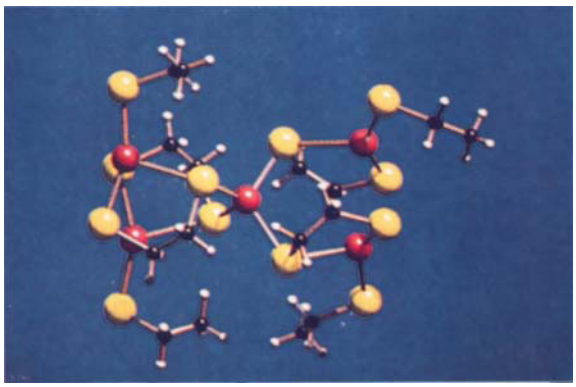

Fig. 38. Structure of $[Hg_5(SCH_2CH_2S)_4(SEt)_4]^{2\ominus}$ [134, 136].

four ethanedithiolate ligands, while the second thiolate sulfur and one $[SEt]^{\ominus}$ ligand complete the environment of the four outer Hg atoms to form a HgS_3 triangle which is considerably distorted from a trigonal symmetry.

The Hg thiolates show a pronounced tendency to undergo ligand-directed association with the formation of high-polymer aggregates by means of primary and/or secondary Hg–S bonds. As the series of polymeric phases so far characterized makes clear, a structurally rich area of new inorganic polymeric materials is in the process of development here; these may possibly be of importance as models for Hg-rich metallothioneins. $[Hg(StBu)_2]_n$[210] has a structure consisting of chains of edge-linked HgS_4 tetrahedra; this is analogous to the SiS_2 type of structure.

The three complexes $[\{Hg_2(SCH_2CH_2S)_3\}^{2\ominus}]_n$,[208] $[\{Hg_2(SCH_2CH_2CH_2S)_3\}^{2\ominus}]_n$,[134, 136] and $[\{Hg_2(SCH_2CH_2CH_2CH_2S)_3\}^{2\ominus}]_n$[211, 212] form a homologous series in which the surprisingly great influence of the ligands (and the cations and solvate molecules) on both structure and properties becomes clear. Tris(ethanedithiolato)dimercurate(2 −) (Fig. 39) exists in the form of infinite one-dimensional polymeric chains with centrosymmetric Hg_2S_6 subunits. The subunits, which consist of two edge-linked HgS_4 tetrahedra, contain two ethanedithiolate ligands and each subunit is linked to its neighbors through two $-CH_2-CH_2-$ chains.

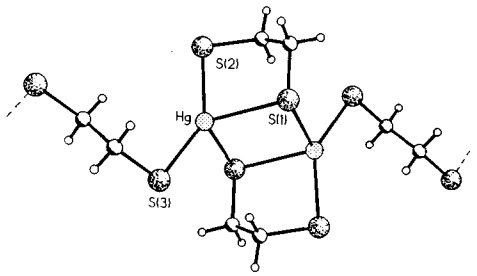

Fig. 39. Fragment of the polymeric chain structure of $[\{Hg_2(SCH_2CH_2S)_3\}^{2\ominus}]_n$ in crystals of $[Ph_4P]_2[Hg_2(SCH_2CH_2S)_3]$ [208].

In contrast, the propanedithiolato complex (Fig. 40) has a honeycomb-like two-dimensional polymeric structure with trigonal-planar coordination of the Hg atoms; the characteristic structural elements are unusually large undulating 36-membered $[Hg\text{-}S\text{-}CH_2\text{-}CH_2\text{-}CHg_2\text{-}S\text{-}]_6$ metallacycles. There are two isomeric butanedithiolate anions with completely different polymeric structures. Crystalline $[Ph_4P]_2[Hg_2\{SCH_2CH_2CH_2CH_2S\}_3] \cdot 3\,MeOH$ (Fig. 41a) forms a two-dimensional polymer with trigonal-planar coordination of the Hg atoms. The layer framework of the polyanions consists of condensed undulating 42-membered $[\text{-}Hg\text{-}S\text{-}CH_2\text{-}CH_2\text{-}CH_2\text{-}CH_2\text{-}S\text{-}]_6$ supermacrocycles. Crystalline $[Et_4N]_2[Hg_2\{SCH_2CH_2CH_2CH_2S\}_3] \cdot 2\,MeOH$ (Fig. 41b), however, contains Hg_2S_6 building blocks formed from two edge-linked HgS_4 tetrahedra, which are in turn linked with four neighboring units via butanedithiolate bridges to form a two-dimensional layer polymer. The layers contain fused four-membered [-Hg-S-Hg-S-] rings, 14-membered $[Hg\text{-}S\text{-}CH_2\text{-}CH_2\text{-}CH_2\text{-}CH_2\text{-}S\text{-}]_2$ rings and 28-membered $[Hg\text{-}S\text{-}CH_2\text{-}CH_2\text{-}CH_2\text{-}CH_2\text{-}S\text{-}]_4$ rings.[211, 212]

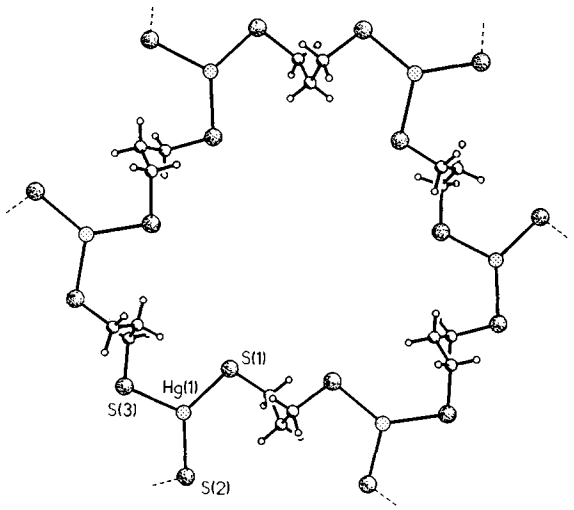

Fig. 40. Section of the polymeric layer structure of the anion $[\{Hg_2(SCH_2CH_2CH_2S)_3\}^{2\ominus}]_n$ in crystals of $[Ph_4P]_2[Hg_2(SCH_2CH_2CH_2S)_3] \cdot 2\,MeOH$ [134, 136].

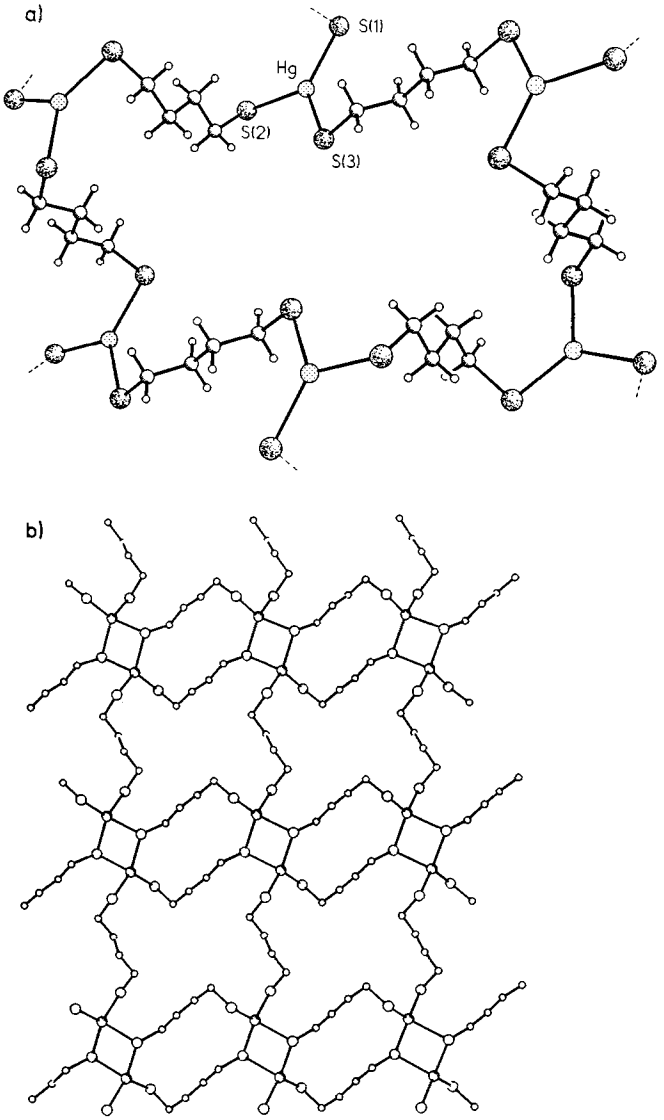

Fig. 41. Sections of the polymeric layer structures of the anion $[\{Hg_2(SCH_2CH_2CH_2CH_2S)_3\}^{2\ominus}]_n$ in crystals of $[Ph_4P]_2[Hg_2(SCH_2CH_2CH_2CH_2S)_3] \cdot 3\,MeOH$ (a) and in crystals of $[Et_4N]_2[Hg_2(SCH_2CH_2CH_2CH_2S)_3] \cdot 2\,MeOH$ [211, 212] (b).

6. Taking Stock and Looking Ahead: New Chances, Problems, and Applications

As the examples of metal thiolate chemistry discussed here make clear, this still expanding area of complex chemistry extends far into solid-state chemistry and materials science on the one hand and biology on the other. On the preparative side more emphasis needs to be placed on the synthesis of new thiolates of the early and late transition metals, which are not "fashionable" because of their lacking "biochemical relevance". In addition, the synthesis of cage and cluster systems of even higher nuclearity—with π acceptors as coligands, for example—must be pursued.

The solubility of the thiolate complexes in suitable polar protic and aprotic solvents, coupled with their thermal instability, suggests their potential use as precursor materials for the thermolytic preparation of chalcogenide and metal surface layers. This application will be particularly interesting for the metal-rich polynuclear cages and the thermally even more labile selenolate and tellurolate complexes; the generation of semiconductor layers is also conceivable.

The extremely important redox properties of the metal–sulfur systems, which could be treated only very briefly in this article, must also be systematically studied and preparatively applied for systems other than the classical metals (iron and copper) of redox enzymes. The remarkable stability of the cluster complexes $[Ni_8S(StBu)_9]^{\ominus}$[115] (Fig. 24) and $[Ni_4(SC_3H_7)_8X]$[118] (Fig. 21) leads us to expect that other transition metals will also provide a broad area of new and exciting thiolate complexes with metals in unusual oxidation states as well as new mixed-valence complexes. In the case of nickel, the much too neglected area of the hydrogenases is still awaiting the characterization of the active metal centers.

The redox properties of proteins with sulfur-coordinated metal centers promise to pave the way for the development of new specific sensors; the biosensor based on the Hg MerR proteins mentioned above provides a first example. It appears quite possible that similar sensor systems (possibly with reduced specificity, but increased stability) will be prepared with thiolate model systems; this could lead to a renaissance in the interest in thiolates, which have long been used in a conventional manner in chemical analysis.

Finally, it is also worthwhile for inorganic chemists to continue to work intensively on the development of thiolates which are of therapeutic (e.g., Au) and diagnostic use (e.g., ^{99m}Tc).

We thank all our present and past co-workers who were involved in the work cited here for their enthusiastic and zealous efforts. Thanks are due to B. Budde, Dipl.-Chem. S. Teipel, and Dipl.-Chem. D. Volkmer for their assistance. The Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie and the Bundesminister für Forschung und Technologie have all provided us with generous financial support.

Bonding Patterns in Intermetallic Compounds

By Reinhard Nesper*

Dedicated to Professor Hans Georg von Schnering on the occasion of his 60th birthday

Intermetallic phases have long been among the black sheep in the family of chemical compounds. Their chemical bonding has eluded description by the valence rules, which otherwise are extremely effective. As a result, understanding of the structure–bonding relationships in these phases to date has remained nebulous, even though they form the largest group of inorganic compounds. Their broad industrial applicability and richly varied structural chemistry call for new approaches for explaining their structures, electronic structures, and physical properties. A combination of new experimental and theoretical investigations has revealed interesting local aspects of chemical bonding in metals and thereby pointed to a route from the valence compounds, through the cluster and electron-deficient compounds, to the intermetallic phases.

*Die Zahl der bis jetzt bekannten einfachen wägbaren Stoffe beträgt 48; hiervon sind 38 metallischer Natur; die 10 übrigen erscheinen ohne metallisches Ansehen, theils gasförmig, theils in fester Gestalt. Sie sind die wichtigsten, welche durch die Mannigfaltigkeit ihrer Verbindungen die Einförmigkeit der Metalle aufheben.**

Leopold Gmelin 1817[1]

1. Introduction

Examination of modern chemical textbooks leads to the conclusion that *Gmelin*'s opinion, written 170 years ago as the introduction to his "Handbuch", is still valid today. Even at that time, the metallic elements possessed the greatest potential for chemical combination, since they formed by far the largest group. Nevertheless, we know much less about structure and chemical bonding in alloys and intermetallic compounds than in other classes of chemical compounds.

From the very beginning, the properties of metals and intermetallic compounds have been of use to man, so that these materials were always associated with cultures and civilizations. They occupied key positions as currency, tools, construction materials, and medical prostheses even in the earliest advanced civilizations. Mirrors made of δ-CuSn were apparently among the earliest metallic utensils.[2] The knowledge of better alloys often decided the outcome of wars and the weal and woe of nations in antiquity and the Middle Ages. Man has always known how to determine the properties of metals, to optimize them, and to exploit them—even without detailed knowledge of structures and chemical bonding. A listing of only the most important uses would exceed the scope of this article. Important research areas for traditional and future applications include refractory high-strength superalloys, magnetic compounds, superconductors, metallic glasses, and amorphous metals. Composite materials—combinations of intermetallic phases and nonconducting materials—are also expected to have a bright future in technology.

1.1. Intermetallic Compounds

In the last 20 years, a large number of inorganic compounds have been synthesized and their study has given much information about structure–property relationships. In particular the Zintl phases, which chemically are located between the insulators and the intermetallic phases, are worthy of mention here.[3, 4] The investigation of compounds with unusual electronic structures has broadened our knowledge and changed our viewpoint,[5–7] so that we can now confront intermetallic phases with new ideas and concepts.

The apparently uniform elements and their compounds have turned out to be enfants terribles in terms of chemical bonding. A major contribution to our better understanding of the complicated electronic structures of intermetallic phases has come from advanced theoretical methods, especially quantum mechanics.[10–12] The chemical bonding in these structures is complex, but, to an increasing extent, it is becoming quantitatively determinable and therefore clearer.[7–13] Today, it is impossible to give a comprehensive review of the great variety of intermetallic compounds within a single article. Therefore, the discussion here will focus on new and unusual attempts to understand intermetallic phases. That which is not understood can often be made more understandable through the use of analogies. Figure 1 gives an overview of the correlation between classes of chemical compounds, electron counts, and structural elements. Among the earliest systems to be understood electronically were the saltlike compounds, in which cationic and anionic components attain a complete octet or an 18-electron shell. Sulfates, phosphates, and derivatives of many other oxo acids showed that chemical units with varying strength of binding can exist side by side in a structure.

[*] The number of simple, weighable substances known to date is 48, 38 of which are of metallic nature; the remaining 10 seem to be without metallic appearance; some are gaseous, some solid. They are the most important, since they overcome the uniformity of the metals through the diversity of their compounds.

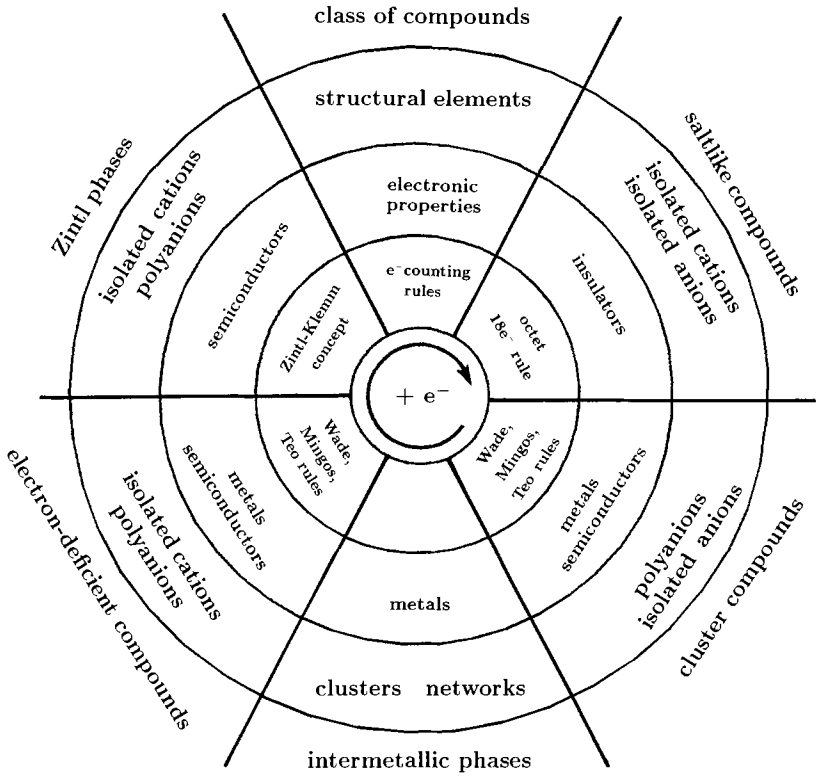

Fig. 1. Relations between classes of chemical compounds through the comparison of structural elements, electronic properties, and electron-counting rules. Note the exchange of anion and cation structures between the electron-deficient compounds and the cluster compounds.

The Zintl phases, with their various anion frameworks, now form a large family of compounds whose electronic structures mostly conform to the 8 − N rule.[5, 14, 15] Fundamentally speaking, they do not differ from the insulators. It is therefore not surprising that many insulator compounds have Zintl counterparts with similar chemical structures but different elements.

Borderline cases of Zintl phases, that is, those exhibiting "locally delocalized electrons" and not conforming to either the 8 − N rule or the Zintl–Klemm concept, mark the transition to the intermetallic phases. This transition can be investigated by systematic chemical combination. In the last twenty years, a large number of new intermetallic phases that, chemically speaking, must be located in the neighborhood of the Zintl phases have been synthesized in this way; however, we are only just beginning to understand the chemical bonding in their structures. The increasing knowledge of the bonding in intermetallic phases is leading to chemical structures whose overall chemical features make clear once again the unity of chemical materials.

If we leave the insulators and semiconductors in Figure 1, we can travel in two directions: to the electron-deficient compounds or to the cluster compounds. The former usually contain polyanions, and the latter, polycations. Both types of oligo- or polymeric building blocks belong to the so-called electron-deficient species. Often, however, they do not suffer from electron deficiency, but instead possess precisely adapted structures with well-defined electron counts. These so-called magic numbers of skeletal electrons are, as shown by *K. Wade*, *D. M. P. Mingos*, *B. K. Teo*, and many others, strongly dependent on the type of arrangement and less strongly on whether polycations or polyanions are present.[5] In many intermetallic compounds both cases occur, mostly well hidden in the jungle of high coordination numbers. Although their discovery will require the "right pair of spectacles",[*] theory and practice are correcting the optics to an increasing extent. *A. Simon* recently published a detailed re-

[*] *H. G. von Schnering* referred to this important instrument some time ago [4].

Reinhard Nesper, born in 1949 in Elze/Hannover, studied chemistry at the University of Münster and received his doctorate from the Max-Planck-Institut für Festkörperforschung in Stuttgart and the Universität Münster. From 1978 to 1990 he was a research fellow at the Max-Planck-Institut and, during this time, was also a guest researcher in Prof. R. Hoffmann's group at Cornell University (1984). He completed his Habilitation at the Universität Stuttgart in 1989, and in 1990 this was followed by his accepting a chair in inorganic chemistry at the ETH in Zürich. His research interests include solid-state chemistry, structure determination and electronic structures of solid materials, structure–property relationships, and general structural systematics.

view in this journal on clusters of valence-electron-poor metals.[33]

On going from the electron-deficient compounds to the cluster compounds, only the signs of the charges on the condensed units formally changes; the electronic structure of the cluster arrangement remains practically unchanged. Isoelectronic polyanionic and polycationic units often have the same structure.

The definition of the intermetallic compounds as a uniform family is not easy. A clear definition is almost impossible, in particular owing to the fluid transition to the semiconductors, the kaleidoscopic variety of chemical bonding, and the extremely diverse structural chemistry. *Pearson's Handbook of Crystallographic Data for Intermetallic Phases* by *P. Villars* and *L. D. Calvert*[17] contains crystallographic data for thousands of structures.[*] The simplest definition would be that intermetallic phases are (1) compounds between metals and (2) metallic conductors.

W. B. Pearson has distinguished five groups of intermetallic phases:[19]

1. Compounds with dense packing. These generally have molar volumes that are considerably smaller than the sum of the atomic volumes, and the interatomic distances are shorter than those calculated from *L. Pauling*'s formula for bond order n ($\triangleq$ valence/coordination number) in intermetallic phases with $d_n = d_1 - 0.6 \lg n$ (d_1 is the single-bond length).[20]
2. Compounds in which the band-structure energy accounts for a large part of the total energy (see Section 5.5). These include, among others, the Hume–Rothery phases (the so-called α, β, and γ phases), which occur only for certain valence-electron concentrations.[**][21–24]
3. Compounds with framework structures. In these compounds, all atoms form a common framework in which the distances to the nearest neighbors obey the Pauling formula (see above). They supposedly do not follow the valence and valence-electron-concentration rules.
4. Compounds with hybrid framework structures such as $BaAl_4$. These contain partial structures made up of one or more types of atom, which depend in certain ways on the number of valence electrons (see also Section 5.4).
5. *Pearson* named valence compounds, that is, compounds that follow the valence rules, as the fifth group. However, these are better classified as Zintl phases.

Numerous geometrical classifications have been given for groups of intermetallic compounds;[24–26] still, they do not clearly distinguish such compounds from other classes of compounds, such as Zintl phases.

1.2. Structure Maps

The first attempts to determine the range of existence of various structures were made in the 1920s for the structures of ionic crystals and were based on the ratios of the radii of rigid spheres.[20, 29–32] But even the separation of simple AB compounds in this way was not particularly successful. In the late 1970s chemical criteria were increasingly used to generate such structure maps. These criteria included the radii r_s and r_p for s and p orbitals,[36] which can be obtained from pseudopotential calculations, for example.[37] Radii for hybrid orbitals were developed for main-group and transition elements and used to discriminate between the structures.[38–40] In addition, *D. G. Pettifor* has empirically developed a new electronegativity scale which can be used to cleanly separate over 500 AB compounds (Fig. 2).[45] However, an atomic interpretation of his values remains to be found. On a much larger scale, *P. Villars* et al. have attempted to produce coordinates for the prediction of stable binary and ternary intermetallic compounds.[46, 47] Other recent attempts to derive chemical coordinates for the generation of structure maps can be found in a concise summary by *J. Hafner*.[12]

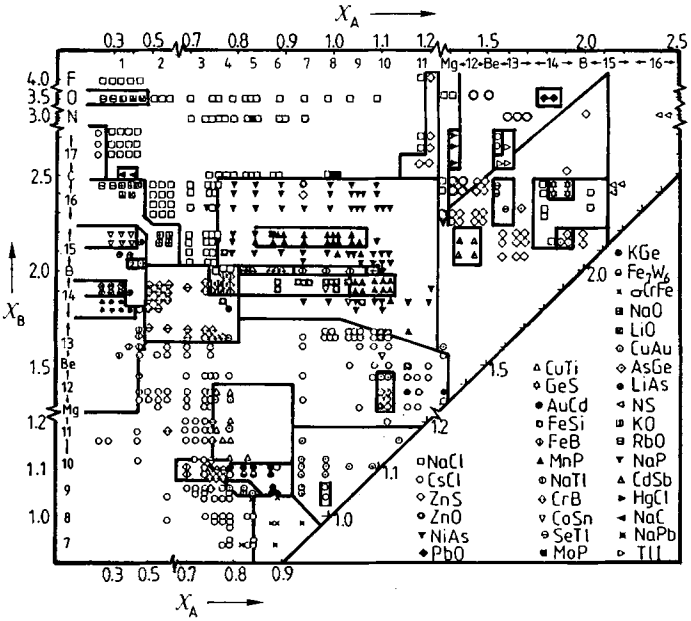

Fig. 2. Structural field after [45] with division of 574 AB compounds by means of a specially adjusted electronegativity.

2. Unusual Elemental Structures

2.1. α-Gallium: An Alternative to Boron Structures

Why does elemental gallium crystallize with a relatively complicated structure,[48] whereas aluminum has a simple face-centered cubic (fcc) structure? In fact, gallium does not evade the simple close packing very well. According to the latest ab initio SCF calculations of *M. Parrinello* et al., gallium has a choice between several structures that differ energetically by only a few $kJ\,mol^{-1}$.[49] The melting and boiling points of α-gallium (303 and 2510 K) differ considerably. The relatively high boiling temperature shows that the chemical bonds in gallium are by no means weak. Apparently, the melting point is so low because, above 303 K, gallium cannot

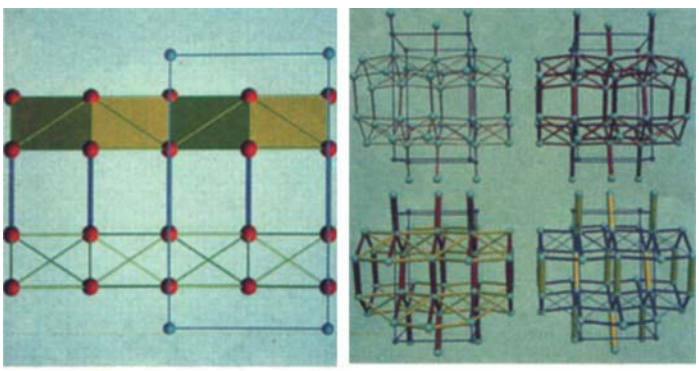
[*] About 21 000 publications from 1973 to 1982 (in part, up to 1984) were assessed. The *Binary Alloy Phase Systems* [18] comprise about 1800 binary phase diagrams.

[**] Valence-electron concentration (VEC) usually denotes the average number of valence electrons per atom.

decisively "choose" a particular crystal structure. Thus, continuous phase transformations are initiated, the result of which can only be a liquid phase.[51] Chemical real-time depictions of such processes are known from *J. O. Bovin*'s fantastic electron microscopic studies of small metal crystallites.[50]

The orthorhombic crystal structure of α-gallium shows two things (Fig. 3a):

1. A simple compromise is not the best solution. According to pseudopotential studies by *V. Heine* et al.,[11] it is energetically more favorable for gallium to form only five shorter contacts of differing length rather than twelve longer contacts of the same length: d(fcc Ga) = 3.03 Å (12×), d(α-Ga) = 2.48, 2.69 (2×), 2.79 Å (2×) for V(fcc Ga) = V(α-Ga). The difference in the distances allows a compromise between volume optimization and distance optimization (cf. Section 5.5). It is likely that many such competing effects are one reason for the difficulties we have in understanding intermetallic phases.
2. There are alternatives to boron structures. Figure 3b clearly reveals Ga_2 pairs with pronounced covalent bonding; this is why *M. Parrinello* et al. described α-Ga as a "molecular metal". However, the remaining partial structure is by no means a "typical metallic tangle" of long contacts. Instead, it turns out to be a two-dimensional polymer composed of semi-icosahedra. The optimum electron count for gallium, calculated by using the extended Hückel method due to *Hoffmann* et al.[8-10] is in fact three electrons per atom.[51] Thus, there is no electron deficiency; the structure is optimally adapted to a relatively low electron count. In this structure, with its semi-icosahedra oriented alternately upwards and downwards, the short Ga–Ga bonds are the terminal two-electron two-center bonds of the polyhedron fragments. It is indeed an alternative to boron structures, and it is certainly possible that a modification of boron with an α-Ga structure would have semiconducting properties.



a b

Fig. 3. Structure (a) and probing of the chemical bonding (b) of α-Ga; (b) shows the change in the strength of chemical bonding (COOP) as the number of electrons increases from 1 to 2.5, 3.25 and 3.5 electrons per gallium (increasing, red; unchanged, yellow; decreasing blue) (top left, 1 electron per Ga; top right, 2.5 electrons per Ga; bottom left, 3.25 electrons per Ga; bottom right, 3.5 electrons per Ga).

Investigations of the variation of the chemical bonding with the number of electrons per atom show that, up to a value of three electrons per atom, the relative bond strength increases to approximately the same extent for all atoms. The relative strengths correspond more or less to the reciprocal distances (cf. Fig. 3b). The largest overlap population is attained at three electrons per Ga.[*] Above this value, the overlap population decreases, at first only for the bonds in the semi-icosahedra. However, up to about 3.25 electrons per Ga, the bonds in a graphitelike partial structure (Fig. 3b, bottom left), which contains the shortest Ga–Ga bonds, become increasingly strong. Hence, the graphite structure is implicitly contained in that of α-gallium and appropriate electron transfer to gallium could result in the corresponding changes in the distances!

If elemental aluminum is offered nucleation centers, a fantastic structural chemistry unfolds which barely resembles the dreary monotony of the elemental structure. Examples, from the many compounds of this type, include β-Mg_2Al_3, WAl_{12}, VAl_{10}, α-V_7Al_{45}, $LiMgAl_2$, Fe_3Al_{13}, Ni_4Mn_{60}, and, of course, the new quasicrystalline compounds such as $MnAl_6$.[60] From a chemical viewpoint, one would attribute to gallium a clear tendency to form few, but directed, bonds. But the same could be true of aluminum. However, this is not the case, because, as was mentioned earlier, aluminum has an fcc structure. The pseudopotential theory gives us interesting information here (see Section 5.5).

2.2. Manganese

Manganese does not adopt the simple arrangements of its neighboring elements either, namely, body-centered cubic (bcc: Cr, Fe) and hexagonal close-packed (hcp: Tc, Re). Manganese can apparently better do justice to its chemical bonding in a somewhat complex structure.[61] Manganese and aluminum are the crucial components in the quasicrystalline compounds known up to now. Both have a pronounced tendency to form directed chemical bonds (cf. Section 2.1). Manganese occurs in two complicated modifications: α-Mn with 58 atoms per unit cell and β-Mn with 20 atoms per unit cell and a chiral structure (space group $P4_132$).[48] In α-Mn, which is stable under normal conditions, four crystallographically distinct positions in the unit cell are occupied, the coordination polyhedra of which have 12, 13, and 16 neighbors. The large differences in the bond lengths and the differing magnetic moments[52] indicate that these positions have different crystallochemical functions. Conspicuous are the very short distances (between 2.24 and 2×2.38 Å) between Mn atoms joined to a fragment of a Friauf polyhedron, a truncated tetrahedron (T) (Fig. 4). It can be shown not only with the help of the cluster "spectacles" mentioned earlier,[4] but also by experimental and theoretical investigations, that these units are the centers of stability of the structure.

Decompositions of the α-Mn structure such as $Mg_{17}Al_{12}$ and $Li_xMg_{17-x}Al_{12}$, with partly ordered atomic distributions, have been found experimentally.[53-55] In both compounds, aluminum occupies exclusively one of the four crystallographically distinct Mn positions and forms isolated

[*] *R. Hoffmann*'s method of crystal orbital overlap populations (COOP) [8] allows the variation of the relative bond strength to be studied as a function of the number of valence electrons. This is also referred to as different degrees of filling in a rigid band model.

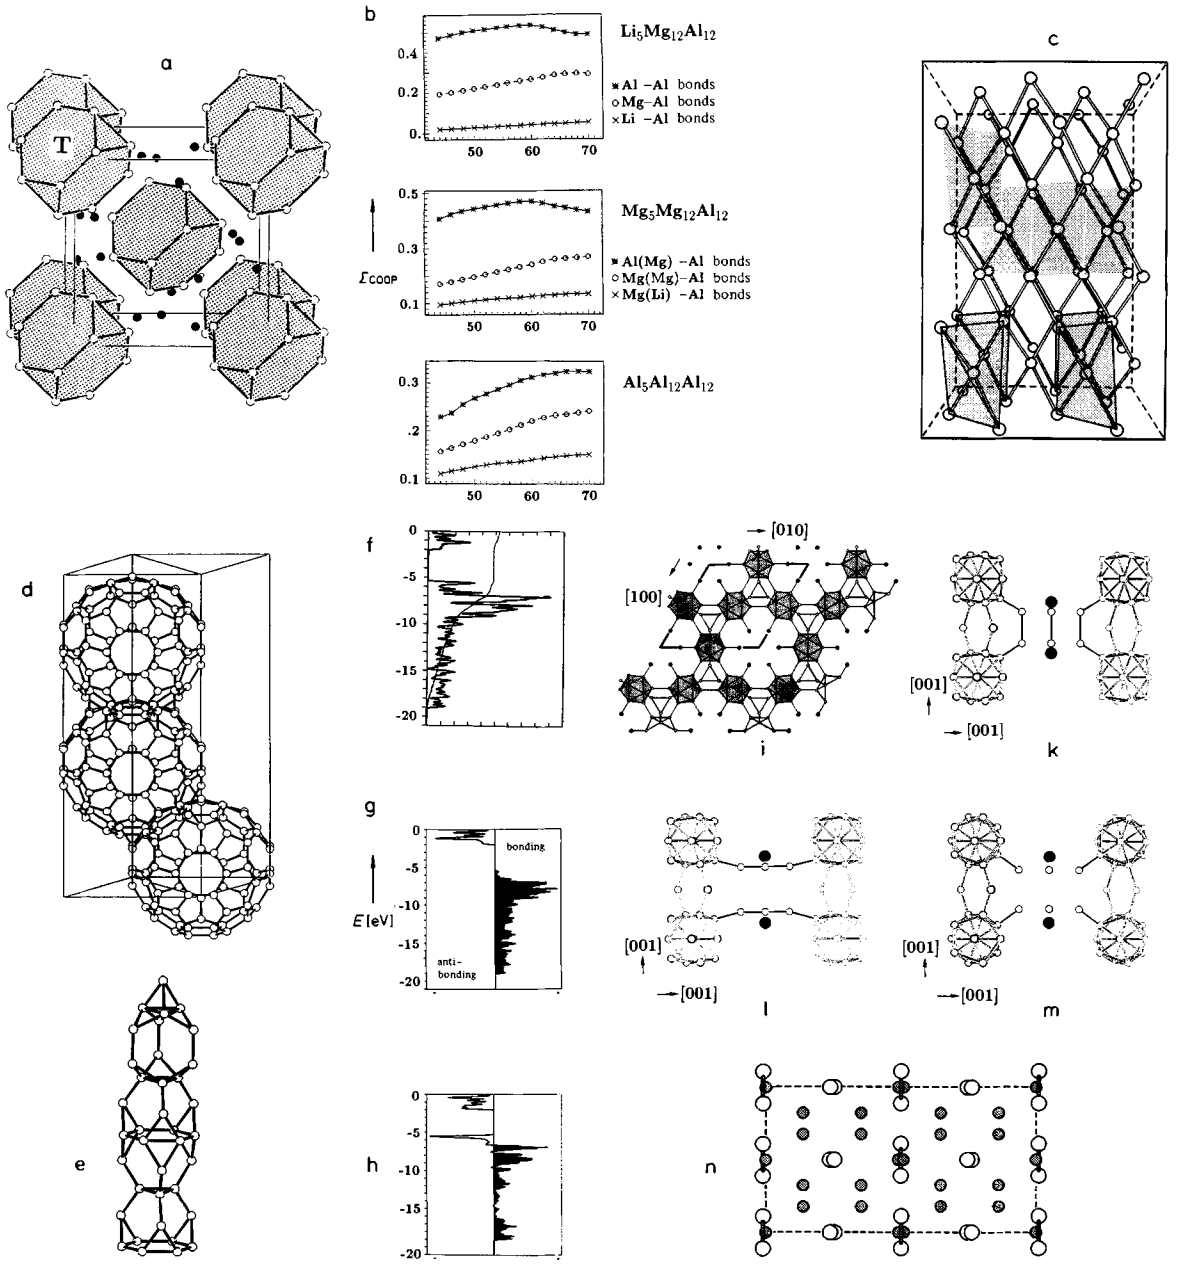


Fig. 4. Unusual elemental structures and intermetallic phases. a) Structure of the intermetallic phase $Li_5Mg_{12}Al_{12}$ as a model for α-Mn; the centers of the truncated tetrahedra (T) are occupied by Li; the coordinating atoms are Mg (solid circles) and Li (not visible). b) COOP sums for the model compounds $Li_5Mg_{12}Al_{12}$, $Mg_{17}Al_{12}$, and elemental Al in the α-Mn structure (electron counts apply to the primitive unit cell; high values of $\sum$ COOP correspond to strong bonding components. c) Structure of γ-Pu, with distorted tetrahedral coordination. d), e) Partial depiction of the Al framework in $LiMgAl_2$. f) Electronic density of states for the three-dimensional Al partial structure; weighted density of states (COOP) from (f), relative to the Al atoms with four (g) and with five and six neighbors (h). The highest bond strength (maximum overlap population) occurs at 4 electrons per Al for the former and at only about 3.5 electrons per Al for the latter. The more highly coordinated Al atoms apparently take part in "electron-saving" multicenter bonds. i) Structure of $Na_xMg_{5-x}Ga_6$ with three-dimensional Ga framework of icosahedra and truncated tetrahedra. k)–m) Part of the three-dimensional Ga framework in $Na_xMg_{5-x}Ga_6$ with different connections of the terminal Ga atoms (solid circles, Na and Mg atoms). The one- (m), two- (k), and three-bond (l) situations result in different electron requirements for the terminal Ga atoms. n) Structure of Mg_5Ga_3 with Ga–Ga double bonds.

Al_{12} clusters. In $Li_xMg_{17-x}Al_{12}$ a further position is reserved for Mg atoms. Two sites of higher symmetry exhibit mixed Li/Mg occupation. This natural partitioning of the structure can be understood by means of quantum-mechanical extended Hückel (EH) calculations (COOP[8, 9]), whereby the existence of compounds with main-group elements greatly simplifies the theoretical treatment because d orbitals need not be taken into account. For $Li_5Mg_{12}Al_{12}$, $Mg_{17}Al_{12}$ ($\triangleq Mg_5Mg_{12}Al_{12}$), and elemental aluminum with an α-Mn structure ($= Al_5Al_{12}Al_{12}$), one obtains, with increasing uncertainty, the following result (Fig. 4b):[55] The optimum electron count of 60 electrons for the truncated tetrahedron can be understood in terms of the 8 – N rule or the Zintl–Klemm concept. The Al atoms form three bonds, thus corresponding to pseudophosphorus atoms, and can be formally regarded as five-electron species, $(3b)Al^{2\ominus}$. The positions in $Li_5Mg_{12}Al_{12}$ occupied by Mg clearly participate in the 12 electron pairs (one per Al atom) which are directed outwards and which are not essentially involved in the bonding of the Al_{12} group. If it is assumed that there are 36 skeletal elec-

trons (18 topological bonds) in the Al_{12} unit, then this implies that the Friauf polyhedron strives to attain the electron count required for classical two-center two-electron bonds. At least for main-group elements such as gallium and aluminum, the truncated tetrahedron follows the Zintl–Klemm concept. α-Manganese, with its 58 instead of 60 electrons per truncated tetrahedron, also comes close to this description. However, significant electron transfer or charge disproportionation between the individual positions must occur (see above).

Many intermetallic phases, and particularly those with complex structures, contain Friauf polyhedra, whose stable framework is formed by truncated tetrahedra. Here, the simple valence-structure description might provide new insights until the theoretical methods become capable of treating structures with 200 or more atoms in the unit cell. However, it is not always easy to find the structural unit that is relevant to the chemical bonding in the structures of intermetallic phases. This requires knowledge of the particularly stable clusters. In this respect, the synthesis of polynary replacement structures will surely be of great help (see Section 3.3).

In the β-Mn structure, there are only two crystallographically distinct positions, but these behave towards each other analogously to those in α-Mn. The numerically superior Mn type (12 Mn) has 12 neighbors which are much more remote (d(Mn-Mn) ≈ 2.57 Å) than those of the other type (6 Mn), which once again exhibit three short distances of 2.36 Å and nine longer ones. This suggests that the majority components are cationic in nature and the minority components anionic.

2.3. Does Manganese Have Four Hands?

Interesting similarities between the structures of α-Mn, β-Mn, and γ-Pu as well as the two modifications of white phosphorus and P_4S_3 have been described by *H. G. von Schnering*[56] and *A. Simon*.[57]

White phosphorus, P_4, crystallizes at room temperature as a "stuffed" variant of α-Mn[56] in which each Mn atom is replaced by a P_4 molecule. As a 20-electron system, P_4 has four lone pairs, one on each P atom, which extend the vertices of the tetrahedron. These lone pairs avoid each other. The closest approaches of the P_4 groups should therefore occur in such a way that an optimum arrangement of tetrahedral faces and tetrahedral vertices is possible. If there is a correlation between the two structures in terms of chemical bonding, then the Mn atoms should also form directed bonds with tetrahedral character. Do the Mn atoms in α-Mn have sp^3-like bonds; that is, do they have "tetrahedrally oriented hands" that contribute to the formation of the α-Mn structure? This idea is not necessarily as eccentric as it might seem, given what was said in Section 2.2, but it must also explain why other structural solutions such as the diamond structure or, more so, the double diamond structure, namely, the body-centered cubic arrangement as in α-Fe, do not play a role. Apparently, the tetrahedron interacts more strongly in some directions and less strongly in others, completely in accordance with the geometry of the truncated tetrahedra Mn_{12} and $(P_4)_{12}$.

There is also a molecular analogue of the β-Mn structure. P_4S_3 crystallizes with a structure in which the centers of the molecules form the β-Mn arrangement.[58, 59] P_4S_3 molecules can undergo particularly dense packing with three neighboring molecules at specific positions, namely, in the direction of the fivefold surfaces. This requires that the other 12 neighbors be more remote.

Like almost all actinides, plutonium does not crystallize in a dense sphere packing; instead, it forms a distinctly distorted structure. This is attributed, among other things, to interactions between the f orbitals, which are more extended than those of the lanthanides. γ-Pu is the stable modification above 508 K.[48] The coordination number is ten, with four short distances of 3.026 Å and six longer distances of 3.16 to 3.29 Å. The four short distances correspond to the four possibilities of approaching a P_4 molecule in the direction of the faces. The structure can also be understood as a strongly distorted variation of the diamond structure. Figure 4c shows the unit cell, a larger section of the structure, and a polyhedra representation for the four nearest neighbors. Thus, the attractive interactions in γ-Pu and the closest approaches in P_4 are in the direction of the edges of these distorted tetrahedra. Interestingly, *W. B. Pearson* has categorized the elemental structures α-Pu, γ-Pu, α-Np, and α-U as unclassified structures.[24]

Even at room temperature, the molecular units P_4 and P_4S_3 tend to undergo librational and rotational movement. These excited states can best express themselves in different structures, such as those that are known for P_4. *Pauling* based his bonding theory for (transition) metals on the existence of different resonance structures. A large number of such valence states contribute to the average chemical bonding, to varying extents for each metal (cf. Section 5.3). It is certainly an unusual but interesting question whether there might be connections between these valence states and the librational movements in structurally related arrangements of molecules.

3. At the Zintl Border

The Zintl border between semiconducting and metallic elements, in its original form as given by *Zintl*, passed between groups 13 and 14 of the periodic table. Both as elements and in their compounds, boron, aluminum, indium, and thallium exhibit an extremely unconventional structural chemistry, whose complexity indicates the effect of directed chemical bonds. In addition, these elements often do not conform to the classical chemical bonding concepts. In its compounds, aluminum suddenly throws off the unprepossessing mask of its face-centered cubic (fcc) structure. Even before the discovery of quasicrystalline $MnAl_6$,[60] Al was known for the exceedingly complex structures of its intermetallic phases. Near the Zintl border, a particularly interesting entry into the structural chemistry of intermetallic compounds is possible. It is certainly no coincidence that in the last ten years so many preparative and theoretical investigations have been performed in precisely this region of the periodic table.

3.1. γ-Brass as a Borderline Case

The compounds $Li_{21}X_5$ (X = Si, Ge, Sn, Pb, Tl) crystallize in the γ-brass structure. It has been proved (up to now for

X = Si, Ge, Sn[64-66]) that earlier reports of the composition $Li_{22}X_5$ are erroneous. The central structural elements are $M_{20}X_6$ and $M_{22}X_4$ units, which geometrically are a combination of two tetrahedra, an octahedron, and a cuboctahedron and are thus a distorted section of a body-centered cubic parent structure.[64] *E. Parthé* et al. have described several such combinations of nested polyhedra as the fundamental building blocks of intermetallic phases.[69]

In spite of their high lithium contents, the silicides, germanides, and stannides are brittle materials with a silver metallic luster. As shown by the analysis of the formal charges $(Li_{21})^{20\oplus}$ $(Si^{4\ominus})_5$, they do not entirely conform to the Zintl–Klemm concept. Quantum-mechanical investigations have shown that, in the double formula unit, two electrons belong to an energetically low-lying, essentially Li-centered orbital.[70] This so-called cage orbital is symmetrically distributed over all 12 Li atoms of the outer cuboctahedron. Cage orbitals have also been found in other Li silicides and germanides with unusual electron counts.[7] All other valence electrons are in states which, as is typical of valence compounds (insulators and Zintl phases), can be assigned to the electronegative atoms. Thus, compounds such as $Li_{21}X_5$ behave like a cross between valence compounds and intermetallic phases. As γ-brass variants, they belong to the Hume–Rothery phases, while their properties (brittleness, semiconductivity) classify them as Zintl phases. Their electronic structure is similar to those of cluster compounds, which can be metallic or semiconducting. Most of the valence electrons are centered on the anions (X), but a small number remain on the cations and are available for cation–cation bonding.

The electronic structure of $Li_{21}Si_5$ shows a further feature: not only the atoms Li and Si, but also the larger structural elements $Li_{20}Si_6$ and $Li_{22}Si_4$, exchange electrons among themselves. This leads to donor–acceptor interactions between the groups $[Li_{20}Si_6]^{\delta\ominus}$ and $[Li_{22}Si_4]^{\delta\oplus}$ (cf. Section 2.2). The phases $M_{21}X_5$ can be used to demonstrate exemplarily the symbiotic relationship between classical valencies and metallic electronic states. Upon traveling further into the realm of intermetallic phases, the balance between the two changes: delocalization increases while charge separation decreases. Nevertheless, both types of chemical bonding are retained (cf. KNa_2, Section 3.4).

3.2. Aluminides and Gallides

Binary and ternary compounds of aluminum and gallium exhibit a particularly rich structural chemistry, in which nearly all features of chemical bonding that are known from boron compounds find a worthy counterpart. It is not only the aluminides of the transition metals that captivate us with their complex arrangements; even the long-known Mg-Al compounds have structures, of which until now only the simplest could be understood. Recently, *W. Uhl* et al. synthesized and characterized an isolated Al_{12} icosahedron surrounded by a sphere of ligand molecules.[67]

Experimental chemistry is particularly well suited for gaining insights into the chemical bonding in intermetallic phases. Since intermetallic phases allow far greater phase widths than semiconductors and insulators, the isomorphic replacement of components with the same or different valence makes possible an experimental probing of the chemical bonding. The partitioning of a structure AB_x by several components to give $(A,A')(B,B')_x$ has already been exemplified for α-Mn (Section 2.2). However, the question remains as to how the chemical bonding in the series of compounds $Li_xMg_{17-x}Al_{12}$ changes as x is varied. Increasing x means oxidation or removal of electrons. According to structural studies, this leaves the Al–Al distances in the truncated tetrahedron unchanged, but alters the distances to and between the coordinating Mg atoms. These changes can be understood in terms of the COOP formalism.[16, 55] The Mg-centered orbitals contain essentially surplus electrons (> 60) that are not required for the Al_{12} unit ($Li_5Mg_{12}Al_{12}$, 65 electrons per formula unit; $Mg_{17}Al_{12}$, 70 electrons per formula unit). Therefore, removal of electrons affects primarily these orbitals.

In the ternary system Li-Mg-Al a new ternary phase occurs near the composition $LiMgAl_2$.[55, 68] Although the numerous binary border phases of the system have metallic properties, they are not all able to accommodate well enough the variation of the valence electrons in ternary descendants of their structures. $LiMgAl_2$ has a novel, complex structure (see Fig. 9a, b).[55] The formation of complex structures is an indication of how close such phases are to the valence compounds. It seems reasonable to assume that most of the electrons are involved in local chemical bonding and that only a few mobile conduction electrons are present.

Quantum-mechanical treatment of the entire $LiMgAl_2$ structure is not yet feasible, although this is possible for the pure Al framework (Fig. 4d, e), which has "only" 46 atoms in its primitive rhombohedral cell. Its electronic density of states exhibits a band gap at 3.9 electrons per aluminum atom. Analysis of the COOP curves shows that the majority of the Al atoms, namely, those with four Al neighbors, attain their maximum relative valence at four electrons per atom.[*] The few Al atoms that are four- or fivefold coordinated by aluminum attain this maximum already at about 3.5 electrons per atom (see Fig. 4f–h). They are involved in multicenter bonding at condensation positions of the polyhedra. Unfortunately, a study of this type, which does not take the other atoms into account, suffices only for a highly qualitative understanding of the Al framework and is less relevant to the complete structure. Nevertheless, the isolated Al_{76} polyhedron could also be of interest for the chemistry of carbon—C_{76} as superball?

In the ternary system Na-Mg-Ga, a situation occurs similar to that observed in Li-Mg-Al. Here, the Na gallides $Na_{22}Ga_{39}$[74] and Na_7Ga_{13}[75], in particular, stand out owing to the complexity of their crystal structures. Apart from $NaGa_4$,[78, 79] the compounds Mg_2Ga_5,[80, 81] $MgGa_2$,[82] and MgGa[83] occur on the gallium-rich side of the ternary system. *J. Burdett* and *E. Canadell* have investigated the skeletal electron counts of a whole series of structurally complex gallides, especially those with large Ga polyhedra.[84] They found that the local chemical bonding in the polyhedral frameworks and their interconnections agreed well with the observed total electron count. The results are listed in Table 2. In principle, an extended Zintl–Klemm concept is

[*] This number refers to the COOP overlap populations.

used here, in which, in addition to the 8 − N rule, there are also other counting rules for special polyhedra.[85] After the electrons of the cations have been formally transferred to the anionic (gallium) partial structure, the geometry, electron counts, and electronic structures can be related to one another in a straightforward manner.

$Na_xMg_{5-x}Ga_9$[55,86] is a new ternary phase with its own structural type (see Fig. 4i). Ga_{12} icosahedra are condensed with truncated tetrahedra (see Section 2.2). A few terminal Ga atoms exhibit a site disorder with minor displacements (Fig. 4k–m). These are correlated with a disorder of the Na and Mg atoms in the immediate vicinity. Each of the three observed split positions of these terminal Ga atoms apparently belongs to a specific bonding state and to a corresponding electron requirement. Applying the Zintl–Klemm concept gives $(1b)Ga^{4\ominus}$, $(2b)Ga^{3\ominus}$, and $(3b)Ga^{2\ominus}$. Apparently, the compound can react locally to changes in the total electron count, without the basic framework of the Ga_{12} polyhedra being influenced.

A similar case has been reported by *Burdett* et al.[84] For the redox pair $Na_{21}Ga_{39}$ ($\triangleq Na_7Ga_{13}$)/$Na_{22}Ga_{39}$, the significant structural difference is the change in only one Ga–Ga bond from 2.43 to 2.54 Å. According to MO calculations by *Burdett* et al., the shorter distance corresponds to a double bond and supposedly represents the first of its type. The compound Ca_5Ga_3 apparently contains another case of a Ga–Ga multiple bond (see Fig. 4n). In terms of the Zintl–Klemm concept, Ca_5Ga_3 is formulated as $(Ca^{2\oplus})_5[(0b)Ga^{5\ominus}][Ga_2]^{5\ominus}$ with equal numbers of isolated Ga atoms and Ga_2 pairs per formula unit.[*] The bond length of 2.49 Å is not much longer than that in Na_7Ga_{13},[75] although both are considerably longer than would be expected for an uncharged Ga–Ga double bond. It is known, however, that the effective charge on the anion can lead to lengthening of the bonding even in the solid compound.[4,85–87] We ourselves have observed such local changes in bond length as a function of the valence electron count in the semiconducting phases $Li_{3-x}B_{14}$,[72,73] whereby the oxidized variants with $x \geq 0$ remain transparent, red semiconductors. Thus, in systems with phase widths, optimal electron counts can be attained by means of local geometrical changes.

There is still little known about how many of the disordered intermetallic phases in fact possess locally well-defined stable clusters whose variants are a result of differing local valence electron concentrations. The concepts of chemical twinning presented by *S. Andersson*[162] and by *E. Parthé* et al.[163–165] show that, for certain compositions, no optimal uniform structural solution exists in the sense that a local stoichiometry is maintained everywhere. Instead, it is often observed, also for intermetallic phases, that sections of stable structures with totally different compositions are bound together (chemically twinned). The result is a third composition, but one that only occurs globally and not locally (see Section 6.2).

3.3. Variants of the Th_6Mn_{23} Type

The Th_6Mn_{23} structure, with 116 atoms in the unit cell, is relatively complex (Figs. 5a, 9c[89]) and is built up from a large number of intermetallic phases M_6N_{23}.[*][41] The smaller, majority components are usually the electronegative atoms N. They form a partial structure, whose basic cluster is a so-called tetrahedral star—an arrangement of a central tetrahedron and four facially linked tetrahedra. All edges of the central tetrahedron are bridged by further N atoms (Fig. 5b), which are linked with the neighboring units to

[*] The atoms without homopolar bonds (0b) are given octet configurations (i.e., $(0b)Ga^{5\ominus}$). The remaining valence electrons are formally assigned to the Ga_2 pairs.

[*] Here, M and N are symbols for metal atoms [24]. N does not designate nitrogen.

Table 1. Structures, structure elements, and valence electron numbers for some aluminides and gallides.

Compound	Structure type	q [a]	Structure elements [b]	Z [c]	N_e [d]	$N_{e'}$ [d]	Ref.

form a three-dimensional cubic primitive array. The large M atoms form noncentered M_6 octahedra, which in turn make up a face-centered cubic partial structure. (In this respect, the M_6N_{23} structure is geometrically related to the fluorite type.) Finally, one type of N atom remains in an environment composed exclusively of M atoms if only the first coordination sphere is considered. Even without knowledge of the wide-ranging coordination chemistry of tetranuclear metal clusters, one would assume a versatile chemical behavior for the tetrahedral star. The complete unit $N_4[N_4]N_{6/2} \triangleq N_{11}$ combines virtually all possible coordinations of a tetrahedron. All edges and faces are coordinated in a μ_3 or μ_2 fashion by the larger M atoms, and the vertices are triply coordinated by M atoms. A glance at the literature confirms what was already suspected.[17] The structure provides a geometrical solution for widely differing structures such as Sr_6Li_{26}, with 35 electrons per formula unit, and $(Co_{16}Si_7)Ta_6$, with up to 90.[*] A valence compound, the Zintl phase $Mg_6(Cu_{16}Si_7) \triangleq (Mg^{2\oplus})_6(Cu^{\oplus})_{16}(Si^{4\ominus})_7$, is also found among the approximately 160 variants of this structure type. The ternary system Li-Ca-Al contains variants $Ca_6Li_xAl_{23-x}$ which exhibit characteristic partition patterns of the N partial structures (Fig. 5c–f; N = Li, Al). The (partially ordered) occupation of certain positions by Li gives rise to Al_{11-n} fragments. Since these generally do not

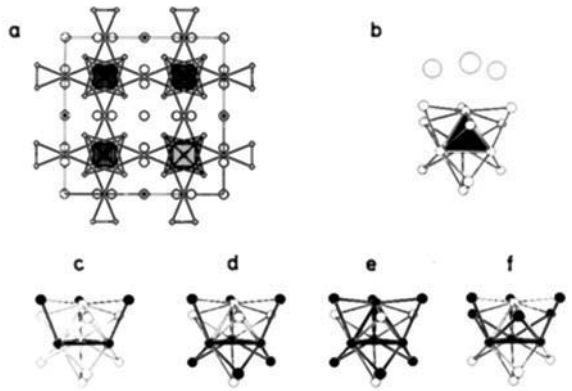

Fig. 5. The Th_6Mn_{23} type: a) Unit cell in the [001] direction (central Mn tetrahedra shaded; tetrahedral star, bottom right); b) Tetrahedral star with coordination of the edges of the central tetrahedron (black) by Mn atoms and the vertices by the large Th atoms (shown for one vertex). c)–f) Some possibilities of generating clusters as fragments of the tetrahedral star in the Th_6Mn_{23} type for $Ca_6Li_xAl_{23-x}$ variants. The solid circles are supposedly occupied by Al and the open circles by Li. According to COOP calculations, the following numbers of electrons per Al atom are assigned to these clusters for optimum bonding: 4.5 (c), 4.2 (d), 3.6 (e), and 3.2 (f) (*hypho*-icosahedron).

form isolated oligomeric units, but instead remain associated with other N atoms, their electron requirements can once again only be determined by means of band structure calculations (COOP). Indeed, initial investigations apparently show that a large number of differing fragments with specific electron requirements can readily be accommodated structurally.[71]

[*] Four valence electrons are taken into account for Si, five for Ta, and two for Co. Simple rules of how many of the d electrons contribute to the chemical bonding and how many remain essentially inert on the transition element could not be given up to now. Approaches to this problem, however, have been proposed by *Pauling* [20].

3.4. Laves Phases as Examples

Laves phases MN_2 belong to the typical intermetallic phases. The three classical types of Laves phases, with $MgCu_2$ (Fig. 6a, second top left, and Fig. 9a), $MgNi_2$ (Fig. 6a, third top left), or $MgZn_2$ structures (Fig. 6e, first top left), occur for different valence electron concentrations. *Laves* has himself stressed the importance of geometrical factors (highest possible symmetry, highest space filling, and highest number of neighbors), but only under the condition that no other factors are influential.[90] *Laves*'and *Parthé*'s corresponding model, based on rigid spheres, has already been criticized by *Pearson* as being inadequate.[24] Some intermetallic phases, even though they have a radius ratio r_M/r_N or 1.225, crystallize in other structures, like $ThAl_2$, which prefers the AlB_2 type. A general geometrical formulation, which relates the radii, coordination numbers, and the Vegard rule with one another, has been published recently by *A. Simon*.[91] Directed chemical bonding, however, gives rise to deviations from this concept. Thus, it would appear that a purely geometrical interpretation of the structural relationships in Laves phases leaves more questions open than it can satisfactorily answer.[24]

Pearson gives two alternative descriptions of Laves phases: (1) the large M atoms form 3^6 nets and the small N atoms form 3636 nets[*] (Kagomé nets) perpendicular to C_3 and C_6 axes, respectively (in hexagonal and rhombohedral structures, perpendicular to the [001] direction; in the cubic structure, perpendicular to the [*hhh*] directions with $h = \pm 1$). (2) The M and N atoms form 35^3 and 3535 nets (in the cubic structure, perpendicular to [*hh*0] directions with $h = \pm 1$). Regarded in this way, the Laves phases are related to Frank Kasper structures with predominantly icosahedral coordination.

As with the tetrahedral structures (e.g., the SiC variants[14]), a large number of polytypes can be generated by varying the stacking sequences in the Kagomé nets. Indeed, a whole series of these polytypes are now known (see Fig. 6 for examples) in addition to the simple types of Laves phases.

The study of these structures shows that Laves phases, as typical representatives of intermetallic phases, can also respond extremely sensitively to changes in composition and valence electron counts. In contrast to the polytypes for structures with tetrahedral structural units, the hexagonal sequence of the Kagomé nets results in a connection pattern of the N partial structure different from a cubic stacking. In the first case, vertex-sharing trigonal bipyramids N_5 are formed, in the second case vertex-sharing tetrahedra N_4. Even *Wade*'s electron-counting rules give different optimum numbers of valence electrons for the trigonal bipyramid and the tetrahedron. Having the formulas $N_5^{2\ominus}$ and $N_4^{4\ominus}$, the two are isoelectronic, but the electron requirement per N atom is greater for the tetrahedron.

This trend has also been found for the condensed polyhedra in the crystal structures of the ternary Laves phases $CaLi_xAl_{2-x}$.[96] In the ternary system Li-Ca-Al, $CaLi_2$ and $CaAl_2$ occur as border phases with hexagonal $MgZn_2$ and cubic $MgCu_2$ structures, respectively. The ternary mixed

[*] The Schäfli symbols denote the types and the numbers (small indices) of polygons around a net point: $3^6 \triangleq$ six triangles, $n^m \triangleq$ m n-gons.

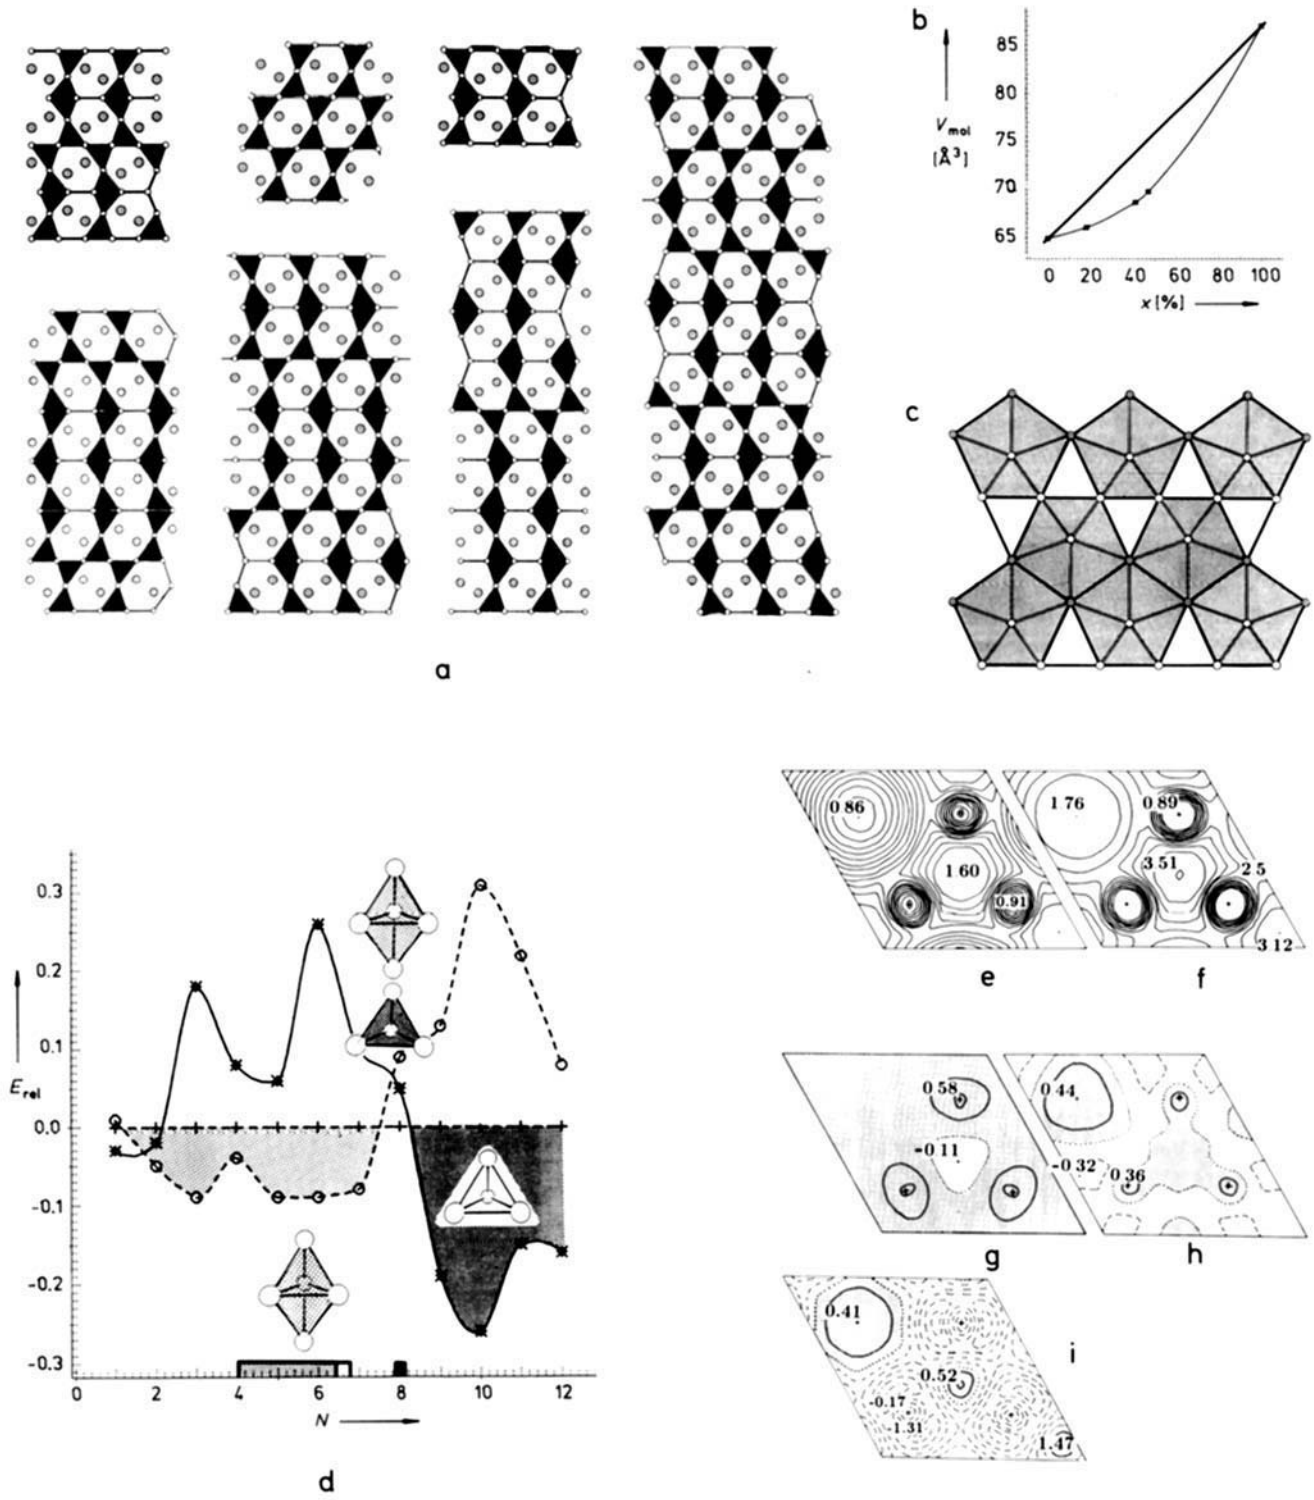

Fig. 6. Laves phases MN_2: a) Some stacking variants, with the polyhedra of the majority component N drawn in black. The hexagonal sequences are characterized by the linking of trigonal bipyramids N_5 (vertex-sharing bitriangular faces), and the cubic sequences by linking of tetrahedra N_4 (vertex-sharing triangular faces). b) Experimentally determined molar volumes for the ternary phases $CaLi_x Al_{2-x}$ as a function of composition. The deviation from the Vegard rule can clearly be seen. c) Nets of pentagons and triangles in the cubic Laves phase. d) Comparison of the relative energy values of the $MgCu_2$ (*), $MgZn_2$ (o), and MgN_2 (+) structures as a function of the valence electron count N from extended Hückel band-structure calculations [96]. The structures observed for the phases $CaLi_xAl_{2-x}$ are shown as blocks on the abscissa. e)–i) Calculated electron densities and electron density differences for the hexagonal Laves phase KNa_2 (e), $MgZn_2$ (f), $CaLi_2$ (g), $CaMg_2$ (h), and cubic $CaAl_2$ (i). Cross-sections through the basal plane of the trigonal bipyramid (for (i), through the center of the tetrahedron). The numbers are selected maxima and minima (reproduced from [12]).

phases $CaLi_xAl_{2-x}$ are found between them, but not over the entire range. With increasing Al content, they crystallize initially in the $MgZn_2$ type, then in the $MgNi_2$ structure with 50% hexagonal and 50% cubic stacking sequences, and finally in the $MgCu_2$ type. In this series, the number of valence electrons per formula unit increases from four to eight. In disagreement with the Vegard rule,[91] the changes in molar volume deviate significantly from a linear behavior (Fig. 6b). Comparative extended Hückel investigations are in good agreement with these observations. Figure 6 shows the cal-

culated relative stability ratios and the observed structures as a function of the number of valence electrons. For Laves phases that are composed of main-group elements, the determining factor for the choice of structure would appear to lie in the chemical bonding, which can adapt itself to different numbers of valence electrons through structural changes.[96]

Y. Komura et al. have found that with increasing valence electron concentration his ternary Laves phases containing copper, silver, and zinc exhibit first cubic, then hexagonal, and finally cubic structures again.[92-95] Thus, it is not clear whether this different sequence of structures is attributable to the influence of the d orbitals, or whether the cubic structure type is favored once again for valence electron concentrations less than four electrons per formula unit. The optimal valence electron concentrations for Laves phases with d metals have been calculated by *R. Haydock* and *R. L. Johannes* using a recursion method. The values obtained for the three classical Laves phases are listed in Table 2.

Table 2. Laves phases: comparison of structure types and preferred valence electron concentrations for main-group and transition-metal representatives [97].

Structure type	Valence electron concentration		
	Transition metal [a]		Main-group element
$MgCu_2$	≤ 3.4	≤ 7.7	≤ 6.4
$MgZn_2$	≤ 4.9		≤ 6.6
$MgNi_2$	6.5–6.9	≥ 7.7	≤ 8.0

[a] The values on the left are the optimal valence electron counts calculated for $CaAl_2$.

The local chemical bonding of the transition-metal compounds remains to be interpreted. In any case, the electron-poor alkali-metal compounds KNa_2, $CsNa_2$, and CsK_2 have hexagonal structures.

According to investigations by *J. Hafner*, the valence electron densities of binary intermetallic phases characteristically differ from those of the corresponding pure metals. Even in compounds such as KNa_2 (Fig. 6e) and CsK_2 he has found a density distribution with pronounced maxima that is considerably less homogeneous than those of the elemental structures. Thus, in $CaLi_2$ (Fig. 6g), maxima are observed at the Li positions, while in $CaMg_2$ (Fig. 6h) there is, in addition, electron density in the center of the Mg_5 polyhedron. Both compounds have the $MgZn_2$ structure (Fig. 6f). In the Al_4 tetrahedra of cubic $CaAl_2$ (Fig. 6i), the density reaches a particularly high value. Since the Al atoms do not lie in the same cross section as the centers of the tetrahedra shown in Figure 6i, the electron density around the Al atoms cannot be seen here. These interstitial maxima are entirely restricted to the interior of the N_4 tetrahedra ($MgCu_2$ type) or the N_5 trigonal bipyramids; polyhedra that involve M atoms are not affected.[12]

Such density redistributions are not only observed in Laves phases. Related alkali-metal compounds such as Cs_6K_7 exhibit similar effects. The M_6N_7 phases crystallize in a structure that contains two-dimensional sections of the cubic Laves phase, in which layers of vertex-sharing K_4 tetrahedra alternate with layers composed solely of Cs atoms. In the latter the electron density is uniform, whereas density maxima have been calculated for the centers of the K_4 polyhedra.[12]

The series of Laves phases demonstrates how the chemical bonding emerges stepwise from the original uniform electron density, starting from the pure alkali-metal compound, through calcium magneside,[*] to $CaAl_2$ with apparently quite strong chemical bonding (m.p. 1352 K). The wide variation in the Laves phases studied by *Komura* et al. also fits the concept of a stereoselective bonding.

4. How Are Structures Built Up?

Why do the compounds Cu_5Zn_8 and Cu_9Al_4 exist, since they have no similarity in chemical composition but are isomorphous, and have atomic arrangements of a ridiculous complexity?

W. Hume-Rothery 1926[21]

This question, posed by *W. Hume-Rothery* in 1926[21] and repeated by *F. Laves* in 1967,[90] has not yet been answered in a chemically satisfactory manner. On the contrary, in spite of the rapid development of theoretical methods for the description of the electronic structures of chemical compounds, the even faster advances in the determination of structures[98,99] have revealed new structures whose complexity is orders of magnitude greater than those of the older structures, which themselves have yet to be understood. Nowadays, quasicrystalline intermetallic phases are providing us with structures that are so large that even proteins and polymers are dwarfed in comparison. Each quasicrystal is effectively a giant molecule.

However, this example is not really necessary to demonstrate that intermetallic compounds, like classical valence compounds, are able to form extensive, complex structural patterns despite the forces of dense packing, which always favor the simplest geometrical solution.[11] *S. Samson*'s magnificent structure determinations on Mg_2Al_3, $NaCd_2$, and Cu_4Cd_3,[100-102] solved laboriously as early as 25 years ago, have been almost forgotten today owing to their great complexity. The compound Mg_2Al_3 serves us in many materials, even without our understanding its innermost chemical structure.

4.1. Polyhedra and Nets

The geometrical description of intermetallic phases is generally carried out in terms of the coordination polyhedra or of the arrangements of planar nets. These have been used, with different weightings, for the classification of the structures of these compounds in the monographs by *K. Schubert*,[23] *W. B. Pearson*,[24] *P. I. Kripyakewitsch*,[103] and *S. Andersson* and *B. G. Hyde*.[26] Some of the more commonly occurring polyhedra are depicted in Figure 7. Owing to the general trend towards dense packing, the larger poly-

[*] One automatically hesitates at this designation—a Mg polyanion is still too unusual. It is, however, fully consistent with the findings.

hedra are always centered. Hexagonal prisms (e.g., in VAl_{10}), square antiprisms (e.g., in VAl_{10}), and tetrahedra (e.g., in the Laves phases) can, like the pyramids, also occur without central atoms. Coordination with more than 12 neighbors arises especially if the atomic dimensions are markedly different. In the Frank–Kasper structures, to which the Laves phases are also assigned, coordination numbers of 12, 14, 15, and 16 are found. The Frank–Kasper polyhedra usually interpenetrate one another. They therefore give a confusing representation of the total structure, but can often be reduced to subunits that are relevant to the chemical structure. One such unit is the Friauf polyhedron, made up of 16 atoms, which can be divided into 12 + 4 and, in this form, is relevant to the chemical bonding (cf. Section 2.2).

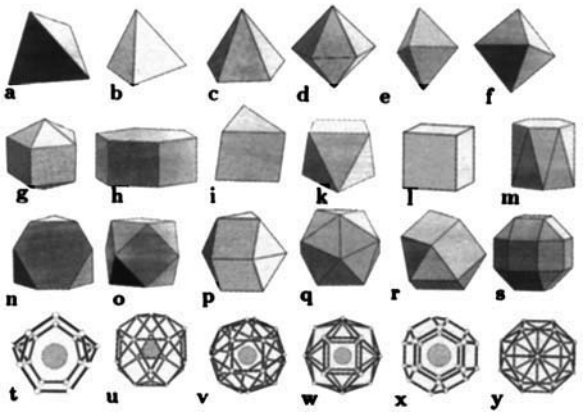

Fig. 7. Typical polyhedra in intermetallic phases (CN = coordination number): a) Tetrahedron (CN = 4); b) square pyramid (CN = 5); c) pentagonal pyramid (CN = 6); d) hexagonal bipyramid (CN = 8); e) trigonal bipyramid (CN = 5); f) octahedron (CN = 6); g) doubly capped pentagonal prisms (CN = 12); h) hexagonal prism (CN = 12), i) trigonal prism (CN = 6); k) Archimedian antiprism (square antiprism) (CN = 8); l) cube (CN = 8); m) hexagonal antiprism (CN = 12); n) truncated tetrahedron (core of the Friauf polyhedron, CN = 12); o) cuboctahedron (cubic dense packing, fcc, CN = 12); p) hexagonal counterpart of the cuboctahedron (anticuboctahedron, CN = 12); q) icosahedron (CN = 12); r) Edshammar polyhedron (CN = 11); s) coordination polyhedron (CP) around an Sr_6 octahedron in Sr_6Mg_{23} (CN = 44; 20 of the 32 faces are centered by Mg); t) B_{18} CP around Th in ThB_4 (CN = 18); u) Hg_{20} CP around Ba in $BaHg_{11}$ (CN = 20); v) Zn_{24} CP around Na in $NaZn_{13}$ (CN = 24); w) Mg_{20} CP around Ce in Ce_5Mg_{41} (CN = 20); x) B_{24} CP around U in UB_{12} (CN = 24); y) Cd_{22} CP around Ba in $BaCd_{11}$ (CN = 22). In t)–y), the central atom in the polyhedron is shown.

Even larger polyhedra that are centered by only one atom occur in, for example, Ce_5Mg_{41} as $CeMg_{18}$,[*] in $BaHg_{11}$ as $BaHg_{20}$, in $BaCd_{11}$ as $BaCd_{22}$, in $NaZn_{13}$ as $NaZn_{24}$, and in UB_{12} as UB_{24}.[24] In UB_{12}, boron forms a partial structure of uncentered cuboctahedra, from which in turn the B_{24} polyhedra are built up. A complete Sr_6 octahedron is surrounded by 44 Mg atoms in Sr_6Mg_{23}. Not all polyhedral descriptions are useful in terms of chemical bonding. Some polyhedra can be dissected or are only part of another stable unit. The condensation of clusters to give oligomeric and polymeric units and the increasing radial cluster size build bridges to the intermetallic phases. Studies of this topic are appearing in increasing numbers, indicating the importance attached to these links between "molecules" and the solid state.

[*] Eighteen Mg atoms surround one Ce atom.

The description of intermetallic phases by means of mostly planar nets of interconnected triangles, rectangles, pentagons, and hexagons has been reported in detail by *Pearson*,[24] by *O'Keeffe* and *Hyde*,[28] and in part by *Kripyakewitsch*.[103] All these authors concentrate on the geometrical relationships. Under the aspect of chemical bonding, these net descriptions must surely be revised; for instance, they contain widely differing interactions. An example is the description of the cubic Laves phase $MgCu_2$, in which nets of triangles and pentagons (Schläfli symbols: $3^5 + 3^5 3^5$,[24] see Fig. 6c) lie parallel to the ($hh0$) planes ($n = \pm 1$). The fact that both Mg and Cu atoms are involved in these nets is, however, somewhat misleading in terms of the chemical bonding, since the stronger interactions are those between the Cu atoms (see Section 3.4). Especially in the last five years, systematic theoretical investigations of the electron requirements of polyhedra and nets in intermetallic phases have been carried out (see Section 5.4 for further details).

4.2. Fractals and Quasicrystals

The reproduction of optimal building principles under differing boundary conditions is apparently one of the fundamental strategies of nature. In the real world, however, geometrical patterns can only be repeated with similarity and not with exact sameness because distances (d), surfaces ($\sim d^2$), and volumes ($\sim d^3$) are not simultaneously linearly scalable. Optimal patterns can, however, be repeated in similar form with a different scaling. This process is termed self-similarity, and it was *B. Mandelbrot* who first recognized it as the concept of fractal geometry and described it mathematically.[104] Not only have fractals opened up the comprehension of complex growth processes, they also present the possibility of establishing transitions between dimensions. For the mathematician a line is one-dimensional. Its chemical counterpart, a linear chain of atoms, however, is only a quasi-one-dimensional construction of three-dimensional objects (the atoms). Although a sufficiently long linear molecule may exhibit pronounced one-dimensional properties, it nevertheless has a two-dimensional surface (the van der Waals surface, for example) and a three dimensional distribution of electron density. The reactivity of a molecule is certainly a function of these and other properties and could depend on, among other things, a fractal dimension of $2 < n < 3$ between the surface and the volume based on its outer electrons.

The chemist must always single out those aspects that are fundamental to his purpose and use them to develop a strategy that fits his needs, especially when a complete theory is not available. I am sure that the use of fractal relationships has subconsciously long been a part of what is known as a "feel" for chemistry and chemical systems. It is therefore pleasing to see that Brownian motion is now known to have a fractal dimension $n > 1$.[105] Thus, a particle in motion presents, on time-average, something between a line and a surface for various interactions (e.g., chemical reactions), even if it possesses no extension of its own.

Fractal principles have been recognized for numerous growth processes. Apparently, only crystals, with their precisely defined order, are able to evade fractal behavior. Al-

though this may be true for the ideal crystal of a given structure, the number of favorable arrangements with a small translation period in three-dimensional space is not particularly large. The examination of suitable structures of varying complexity reveals indications of fractal building principles. That is, a favorable geometrical arrangement serves as a model for structures comprising individual atoms, clusters, molecules, or aggregates of clusters and molecules and will repeatedly reappear in a similar form but with different scalings.

As mentioned above, a single "orderly" crystal (just?) evades the fractal building principle. In contrast, quasicrystals embody precisely this principle in the form of the golden mean[60-62] as growth factor $[(\sqrt{5}+1)/2]$, which allows the formation of ordered structures, even without fulfillment of the translation symmetry. Models for quasicrystals such as $MnAl_4$ will now be briefly examined. There is much literature on this topic, including a contribution in this issue.[*] In quasicrystals, a complex structural pattern with wide-reaching order is maintained. All quasicrystals known up to now belong to the intermetallic phases. Therefore, long-range directed forces can also be highly effective in these compounds. However, the precise atomic positions have still to be determined and this is also an indication of the fractal character of these structures, since self-similarity does not reproduce precisely.

Figure 8f shows the growth of the cell edge of pseudo unit cells (Penrose cells, see below) according to the golden mean. In Figure 8d, radial growth according to the golden mean is shown for a tenfold point distribution. With increasing distance from the center, voids of ever-increasing size are inevitably formed, which, of course, in a real structure must be filled. As a simple approximation for the filling of the voids, one can begin the same construction at points lying further from the center. The diffraction pattern of such a distribution of only 550 points (Fig. 8e) is already remarkably similar to that obtained for fivefold projection directions in quasicrystals. Thus, the size of the voids increases with increasing distance from the center, but their shapes hardly differ from one another (Fig. 8d). Therefore, voids of various sizes must be filled with objects of similar geometry but with different numbers of atoms. This self-similarity—the similarity of differently sized parts of an object—is synonomous with the fractal concept.

Pauling has attempted to explain the structure of quasicrystalline $MnAl_4$ in terms of twinning of the translationally symmetrical structure of $Mg_{32}(Zn,Al)_{49}$ (see Fig. 9f).[106] Although controversial, his model comes quite close to the observations, even if it does not give us the best description of quasicrystals.[107] In any case, the relationship between large clusters in known translationally symmetrical structures and those in quasicrystals has become apparent through *Pauling*'s description.

Structures other than that of $Mg_{32}(Zn,Al)_{49}$ could possibly also be used to design models for the arrangements in quasicrystals. For instance, there is an interesting relationship between cubic dense packing and the pseudo unit cells of quasicrystals. *A. L. Mackay* defines these as three-dimensional representations of the two-dimensional Penrose patterns, which are composed of two different types of rhombohedra.[109] Today, it seems clear that quasicrystals possess something similar to a unit cell, namely, the two different pseudo cells (see Fig. 8f), both of which are rhombohedra but with differing angles.[111] Their space-filling arrangements are known as Penrose patterns.[108,109] The larger pseudo cell has a rhombohedral angle of $\alpha = 63.43°$, which is quite close to that of the primitive unit cell of the face-centered cubic lattice ($\alpha = 60°$) (Fig. 8b).[110] (The corresponding rhombohedron for the body-centered cubic lattice (Fig. 8a) has $\alpha = 70.46°$.) If an fcc structure is distorted to a rhombohedral angle of 63.43° and then subjected to a tripling operation, as shown in Figure 8c, the second pseudo cell is automatically generated in the remaining holes. Face-

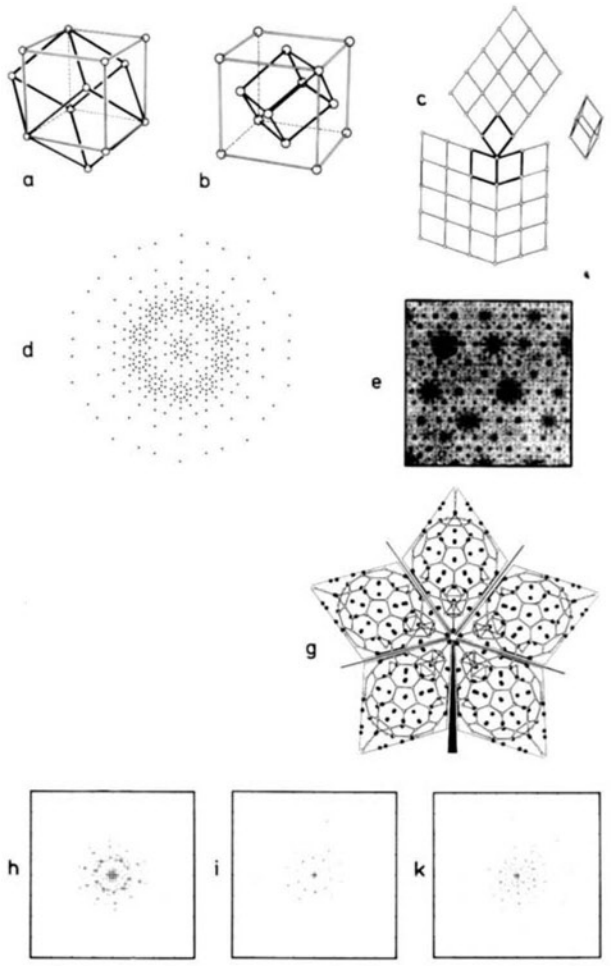

Fig. 8. Relationship between quasicrystalline arrangements and fcc structures: a), b) Primitive rhombohedral unit cells (solid lines) for the bcc and fcc lattice (rhombohedral angle $\alpha_{rh}^{bcc} = 70.46°$, $\alpha_{rh}^{fcc} = 60°$). c) Formal twinning of blocks of primitive fcc cells to give the nucleus of a Penrose pattern (central three unit cells). d) C_{10}-symmetrical model structure with the golden mean $[(\sqrt{5}+1)/2]$ as radial growth factor and the corresponding diffraction pattern. e) Diffraction pattern of (d). f) Section of a Penrose pattern with two types of "unit cells". The bold lines indicate Penrose cells with radial growth according to the golden mean. g) Smaller section of the Penrose pattern (f) with filling (decoration) of the unit cells by the $LiMgAl_2$ structure. The angular discrepancy between the primitive fcc cell and the large Penrose cell is emphasized. h)–k) Diffraction pattern of decorated Penrose cells such as (g) composed of 5, 20, and 55 cells [(h) inner, shaded part of (f); (i) inner, shaded and next lighter ring in (f); (k) all shaded cells in (f)]. Although the structural model was not optimized, increasingly quasicrystalline features are apparent in the diffraction patterns.

[*] S. Andersson, S. Lidin, M. Jacob, O. Terasaki, *Angew. Chem. 103* (1991) 771; *Angew. Chem. Int. Ed. Engl. 30* (1991) 754.

centered cubic structures can therefore be regarded as closely related to the arrangements of quasicrystals.

There is now little doubt that the quasicrystalline structures are built up according to Penrose patterns. However, as was mentioned earlier, very little is known about the so-called decoration (i.e., the structural content) of the pseudo cells. Should we, therefore, following in *Pauling*'s footsteps, search for decorations of the pseudo cells other than $Mg_{32}(Zn,Al)_{49}$? If so, then known aluminides and Mn compounds should be considered; for example, either those that exhibit an fcc arrangement or those which are related to it. Manganese and aluminum are the crucial components in the quasicrystals known up to now (Table 3). Both have a marked tendency to form directed chemical bonds (see Sections 2.1 and 2.2).

Table 3. Composition of some quasicrystalline compounds (minority components normalized to unity). One of the few quaternary quasicrystalline compounds known at present is $(Mn_{0.72}Fe_{0.28})Al_{85}Si_{14}$ [117].

"$LiMgAl_2$" is a new aluminide that has a complex rhombohedral structure and an almost fcc metric ($\alpha_{rh} = 59.7°$).[55] Its structure is composed of Al_{76} polyhedra, centered by $(Li,Mg)_{40}$ units (Fig. 9a), which are themselves filled by $(Li,Mg)_{7-9}Al_3$ polyhedra. The Al_{76} polyhedra form an fcc-like arrangement, which is, however, not cubic because the polyhedra exhibit only $3m$ symmetry (Fig. 9b). The polyhedra have 40 faces comprising 12 pentagons and 28 hexagons.[*] The pentagons are approximately oriented with the vertices of an icosahedron. However, fivefold symmetry applies only in the immediate environment of these rings. A symmetry center is also absent (icosahedral symmetry $5\bar{3}m$; symmetry of Al_{76}, approximately $\bar{4}3m$ and in reality $3m$). A projection of the rhombohedral unit cell along one of its axes clearly reveals elements of fivefold symmetry in the structure.

The formation of a fivefold twinning in this projection according to the Penrose pattern is now quite straightforward (cf. Fig. 8f). The result is a two-dimensional quasicrystalline structure. Such structures are already known and are termed pentagonal or decagonal phases.[113] Accordingly, a twinning to give an icosahedral quasicrystal must be performed in all six planes perpendicular to the six fivefold axes.[**]

[*] Such polyhedra are not usually found in the relevant literature, because, with their triply condensed hexagons, they should exhibit planar areas. The hexagons in this case are, however, neither regular nor planar.

[**] It can be shown that such structures possess translational symmetry in six-dimensional space.

In Figure 8h–k the calculated diffraction patterns in the direction of the fivefold axis for differently sized sections of the Penrose pattern (Fig. 8f) are shown. The sections contain 5(h), 20(i), and 55(k) unit cells of $LiMgAl_2$. The rapidly increasing resolution in the diffraction patterns can be seen clearly. This example is not intended to show that $LiMgAl_2$ could also form a quasicrystalline arrangement with exactly this observed structure, but is intended to demonstrate the close relationship between classical fcc arrangements and quasicrystalline structures.

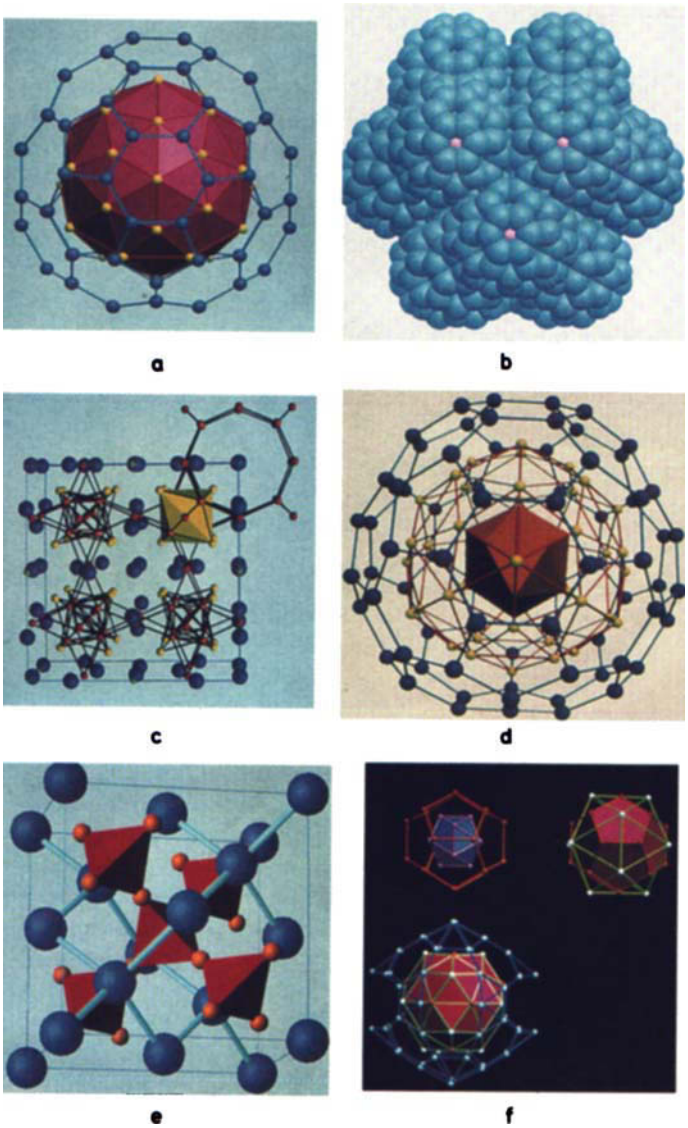

Fig. 9. Structures of intermetallic phases. $LiMgAl_2$: a) Al_{76} polyhedra (blue) with dual inner polyhedra (Li, $Mg)_{40}$ (red); b) space-filling model of 13 Al_{76} polyhedra (central + 12 outer polyhedra); c) structure of Th_6Mn_{23} with tetrahedral star (yellow) and Th atoms (blue); d) cation framework in $Bi_{22}Sr_{36}Al_{48}O_{141}$ [182] (Al, blue; Sr, yellow; Bi, central polyhedron; cf. Fig. 9a) (see Section 6.3); e) structure of the cubic Laves phase $MgCu_2$ (Mg, blue; Cu_4 tetrahedron, red); f) partial structure from $Mg_{32}(Zn,Al)_{49}$ [195], proposed by *Pauling* as model for crystallization centers in quasicrystals.

Who knows how many "poor crystals" that were discarded during their structural determination in fact exhibit quasicrystalline features. It will be interesting to see just how large the ever-growing number of such compounds will become in the future. Seek and ye shall find.

4.3. Structures, Holes, and Fractals

The atomic and molecular view of chemical species in particular has been enormously successful: just consider the formalism of the frontier orbitals in fragments, molecules, and clusters,[129] reaction mechanisms involving functional groups in organic chemistry,[130] or the study of active sites in enzymes. Today there are many incremental classifications in chemistry which allow important conclusions to be drawn without the need to analyze the total arrangement in each case.

Each granular description automatically has the consequence that there is something else between the grains or centers which is less stable: the holes or voids. Each structure possesses a priori holes, otherwise it would not be a structured object. At the same time this means that each structure can be filled to give a new variant, for example, by filling the holes according to their size.

The term homotypic is used for structural relationships in which the strict geometrical correspondence of isotypism is not fulfilled.[*] *K. Schubert*, in his book,[23] gives several examples of homostructural relationships, including replacement and inclusion structures. The description of replacement structures is based on dense packing (fcc, hcc). Either two or three neighboring atoms are replaced by a larger atom, giving rise to double or triple replacement structures. *Schubert* describes the $MgCu_2$ structure as a double-replacement variant of the fcc arrangement. If Mg is replaced appropriately by two smaller atoms, the fcc structure is obtained. Accordingly, $CaZn_5$ can be understood as a triple-replacement structure of a hexagonal-dense-packed arrangement.[23] Even in the very beginnings of structural chemistry, such connections were recognized and also found for intermetallic phases.

An example of such a real sequence of filled-up structures beginning with the diamond type is M_8(C, cF8) → M_8N_8 (NaTl, cF16) → M_8N_{16} ($MgCu_2$, cF24) → $M_{16}N_{16}$ (PtCu, cF32) → $M_8N_{16}O_{32}$ ($MgAl_2O_4$, cF56) → $M_{16}N_{160}$ (VAl_{10}, cF176) (see Fig. 16b).[63, 128] Possible correlations between stuffed intermetallic phases and ionic compounds are discussed in Section 6.3. In principle, the stuffing of the holes can be continued indefinitely because the filled-up structure itself has new holes.

Another series starts, for example, with the Cu structure, which has an fcc arrangement of Cu atoms (see Fig. 10d). Filling the tetrahedral holes generates the fluorite structure CaF_2. The replacement of the cations by $[PtCl_6]^{2\ominus}$ ions and of the anions by $K^{\oplus}$ ions leads to the K_2PtCl_6 structure, in which the octahedral holes of the original cubic dense packing are still unoccupied. Finally in Na_3AlF_6, they are occupied ($NaNa_2AlF_6$[25]). Such structural correlations appear to be quite natural, and they are known in various forms, although we are still a long way from having a comprehensive classification in this respect.

There are considerable problems in locating the holes in structures. Whereas this is simple for highly symmetrical structures, the search for the holes in complex structures can often only be performed by means of laborious model building. However, there is a well-known method that can be used for this purpose and which provides the required mathematical formalism. It is the partitioning of space into polyhedral regions, known as Voronoi polyhedra or Dirichlet domains (Fig. 10a–c).[133] Starting with a reference atom, one sets up

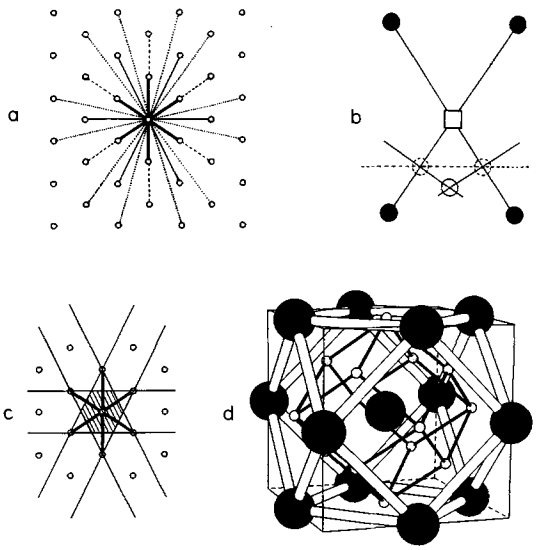

Fig. 10. Localization of holes in structures by construction of Voronoi polyhedra: a) Model structure with different coordination spheres (bold, thin, dashed, and dotted lines) around a central atom; b) construction of polyhedron faces perpendicular to the atomic bond lines; c) two-dimensional counterpart of the Voronoi polyhedron (the shaded region represents the interior of the polyhedron; its vertices define the first coordination by holes); d) fcc arrangement (large black circles) and corresponding holes (small circles; tetrahedral holes, shaded; octahedral holes, open). The corresponding Voronoi polyhedron is a rhombododecahedron (thin black lines).

planes on all interatomic vectors. These planes form a convex polyhedron around the starting point, whereby the faces of the polyhedron become smaller with increasing distance between the neighboring atoms. Thus, a distance range ≤ 6–7 Å is usually sufficient to obtain all the faces belonging to a polyhedron in a chemical structure. The more remote neighbors of the starting point generate planes which do not intersect with its (first) polyhedron. *F. L. Carter* proposed this method as a tool to determine effective coordination numbers.[134] The method always gives a limited number of neighbors in the first coordination sphere, whose contribution to the coordination number can be evaluated by means of the corresponding face of the polyhedron. Each of these contributions can be converted to a solid angle, which can be regarded as a measure of "how much room a neighbor is entitled to in the total panorama around an atom".

This purely geometrical viewpoint must be combined with physical quantities such as interaction functions if it is to be relevant to other than geometrical questions. Whether this method is superior to other attempts to calculate effective coordination numbers has up to now only been investigated to a limited extent. (A shelllike construction of structures, starting from one or more centers, has also not been treated in depth. This model has come under discussion again with the discovery of the quasicrystals; see Section 4.2.) *D. M. P.*

[*] Compounds are isostructural if they crystallize in the same structure type (e.g., $CaAl_2$ and $MgCu_2$). If the structure type contains positions with free parameters, then the (often controversial) question arises as to how large the differences in the free parameters may be. These cases are better referred to as isopointal structures [24], meaning the occupation of the same Wyckhoff positions in a space group.

Mingos has extended the analysis of solid-angle regions to the ligand distribution in multinuclear transition-metal clusters.[6] The construction of Voronoi polyhedra allows all coordination spheres around an atom to be successively determined. This will give us much information about dual relationships in structures.[*]

It must be emphasized that determination of holes is already contained in the rules for the construction of Voronoi polyhedra.[135] Owing to the dual relationship between Voronoi polyhedra and coordination polyhedra (see Fig. 10), the vertices of the Voronoi polyhedron are always the holes in a structure. Different compounds can even be taken into account in one structural type, since all distances are given by predetermined radii.[**]

The calculation of the holes for an fcc arrangement, for instance, can be performed as a "thought experiment". The coordination polyhedron is a cuboctahedron made up of the 12 nearest neighbors. The dual Voronoi polyhedron is a rhombododecahedron, whose vertices lie near to the centers of the faces of the coordination polyhedron, that is, exactly in all octahedral and tetrahedral holes.

There is no doubt that the positions of the inserted atoms in a stuffed structure need not be coincident with those of the biggest voids. Actually, covalent bonding avoids close-packed structures (cf. Section 5.5); the diamond structure is one example. The oxygen atoms in the β-cristobalite structure do not occupy the largest holes but those which have only twofold Si coordination. However, these smaller voids are part of the construction of Voronoi polyhedra as well. They fall near to the face centers of the polyhedra. It might be that the distribution of electrons in semiconducting or in intermetallic compounds, can be identified with the face centers or the vertices, respectively, of the corresponding Voronoi polyhedra (and of the anions in more covalent or more ionic salts; cf. Section 6.3).

The detection of holes and the analysis of their structural meaning is certainly an important contribution to the development of a comprehensive general structural chemistry.

4.4. Localized Electron Spaces?

In arrangements of atoms, are the positions that are unoccupied by atoms and relatively remote from all atoms really empty? Certainly not in all cases! Conspicuous empty spaces are found, for example, in structures with lone pairs. Here, it has long been known that the lone pairs are displaced into common structural regions, although there are no attractive interactions between them. Internal cavities and surfaces are formed like surfactant interfacial surfaces in liquids. Do intermetallic compounds also contain spatially discrete regions of weak and strong interactions? One is reluctant to carry out a classification of electrons and local spatial regions in intermetallic phases, because it is known that the valence electrons are hardly influenced by the positively charged atom cores, and because the latter are strongly shielded. Furthermore, the valence orbitals of metal atoms are very diffuse and extensive.

But these limitations should not be allowed to discourage us. The following questions must be posed: (1) Are the valence electrons sufficiently strongly influenced by the atom cores? Answer: probably, since for chemical bonding, these belong to the forbidden zone. Hence, chemical bonding between the cores must take place outside the so-called hard-core radii R_0, that is, in the interstitial region. (2) Do the electrons have a shortage of space? Yes, because they must avoid electron–electron repulsions as best they can. Although the location of optimal electron residences, for instance, by the so-called electron localization function (ELF), is still in its infancy,[137] the first results look promising. The ELF gives an interpretation of the electron density which allows the preferred locations of the electrons to be determined and displayed graphically. For instance, the space required for a lone pair can be seen clearly. Interesting results have already been obtained for selected molecules.[138]

5. Theory of Chemical Bonding in Intermetallic Phases

The literature on the theory of chemical bonding in intermetallic phases is very extensive. There are numerous interesting new contributions on methods and applications, for example, within the framework of the method of linear combination of muffin-tin orbitals, described by *O. K. Andersen* et al.[184] and by *N. E. Christensen*.[185, 186] In this article, therefore, emphasis is given to only a few of those works that deal in depth with the local picture of the chemical bonding in intermetallic phases.

5.1 *Pearson*'s Neighborhood Diagrams

W. P. Pearson has defined geometrical strain parameters which can be used to investigate series of compounds MN_x that crystallize in the same structural type.[24] The three different interactions M-M, M-N, and N-N are analyzed in terms of the observed distances d_M, d_N, and d_{MN} and the predicted values $D_M = 2r_M$, $D_N = 2r_N$, and $D_{MN} = 1/2(D_M + D_N)$. The strain parameter $(D_M - d_M)/D_N$ is plotted versus the ratio of the atomic diameters $D_M/D_N = r_M/r_N$ (= radius ratio). Figure 11 shows the values for a large number of cubic Laves phases with the $MgCu_2$ structure. The straight lines represent the corresponding expected values with $D_M - d_M = 0$, $D_N - d_N = 0$, and $D_{MN} - d_{MN} = 0$. *Pearson* differentiates three borderline cases:

1. The coordination-defined situation, in which the observed values lie close to an intersection. In this case, the expected values are obtained for the different coordinations (M-M, M-N, N-N).

[*] Two geometrical bodies exhibit a dual relationship if replacing the edges of one of them by faces generates the other. *Euler*'s formula for the number of edges (E), vertices (V), and faces (F) gives the relationship $E_{1,2} + 2 = V_1 + F_1 = F_2 + V_2$ with $E_1 = E_2$, $V_1 = F_2$, and $F_1 = V_2$. Dual polyhedron pairs are, for example, cube ($E_0 = 12$, $V_0 = 8$, $F_0 = 6$)/octahedron ($E_0 = 12$, $V_0 = 6$, $F_0 = 8$), and pentagonal dodecahedron ($E_{pd} = 30$, $V_{pd} = 20$, $F_{pd} = 12$)/icosahedron ($E_i = 30$, $V_i = 12$, $F_i = 20$).

[**] The best partition method has been developed by *F. Fischer* and *E. Koch* [136]. It is based on the so-called potential plane construction and always volume-filling if sufficient neighbors are included in the construction (see above [136]).

2. The "true" geometrically determined situation, in which the values lie between at least two straight lines over a wide range of D_M/D_N (cf. Fig. 11).

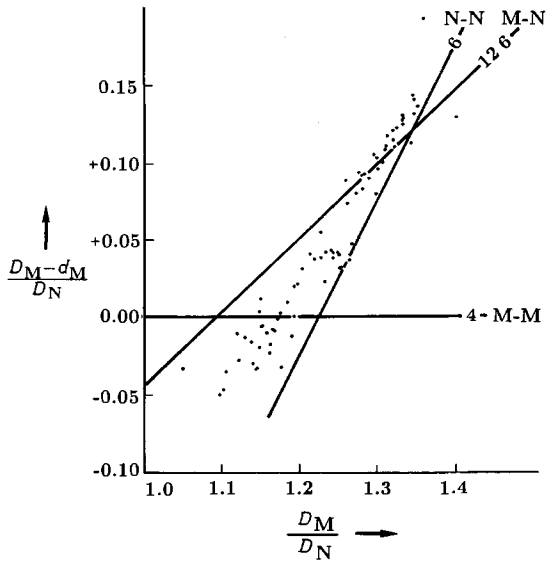

Fig. 11. Nearest-neighbor diagram [24] for the $MgZn_2$ structure type. The straight lines define the strain-free arrangements for M–M, M–N, and N–N interactions (normalized with respect to the M–M interactions). The most favorable number of neighbors is also given on the line.

3. Situations determined by chemical bonding, whereby the values run alongside a straight line that defines the dominant interaction. *Pearson* has shown in numerous examples that plots of this type can be used to identify the interaction that is most important for the chemical structure. More recent work on this topic has been published by *A. Simon*[91] and *W. B. Pearson*.[139]

This method is, however, unable to provide a deeper understanding of the accompanying chemical bonding. A combination with the basic pseudopotential theory of *Heine*, *Weaire*, and *Hafner*, which contains only the radial (distance) interaction, appears to be quite attractive (see Section 5.5).

5.2. *Schubert*'s Correlation Model

In the older literature, there are only a few references to the possibility that electrons in intermetallic phases can form correlation structures.[21, 187, 188] In a series of publications, *K. Schubert* has investigated a model in which the mutual evasion of electrons leads to correlation structures.[23, 140, 141] Instead of static structures, these are supposedly dynamic structures, which—and this is the most important point of the model—must be commensurable with the metric of the unit cell in at least two directions. According to his model, structures of intermetallic phases are only stable on this condition. *Schubert* starts from the assumption that the electrons are essentially free and concludes that their correlation structures must therefore be simple dense packings. Furthermore, he makes a distinction between valence and core electron correlations. In simple terms, this means that each structure of an intermetallic phase has two commensurate lattices, in the positions of which the respective valence or core electrons must be accommodated. The d electrons of the outer d shell of transition metals are usually counted as core electrons. Although *Schubert* has presented correlation structures for numerous compounds,[142–144] his model has met with little acceptance.

A legitimate reason for doubting the model is certainly the assumption of quasi-free electrons. In particular, the complex intermetallic phases exhibit a pronounced cluster-forming tendency and wide-range ordering, which indicates that electrons with varying strengths of binding are present.

However, it remains an open question whether the averaging of such effects will allow general trends to be determined by using the correlation lattices. The application of the ELF (see Section 4.4[138]) to intermetallic phases represents a further step towards an understanding of chemical bonding and, possibly, of the correlation structures of valence electrons in these compounds as well.

5.3. *Pauling*'s Theory of Asynchronous Resonance

Pauling has developed a modified valence bond theory to explain chemical bonding in metals, whereby resonance structures are postulated for the chemical bonds in insulators and semiconductors.[20, 146, 147] Since the coordination number in a metal is usually much larger than the number of available electron pairs, each possible bonding situation is assigned a resonance structure. *Pauling* regards this as a type of asynchronous resonance, in which, in contrast to insulators and semiconductors, resonance structures with charged atoms also occur (Scheme 1).[147]

Scheme 1. Description of chemical bonding in metals by asynchronous resonance.

Two conditions must be fulfilled: unpaired electrons must be present and charge differences greater than ± 1 are not taken into account. *Pauling* has developed a statistical method for determining the number of resonance structures with covalent bonds per atom, v. According to this method, there are approximately as many synchronous as asynchronous resonance structures, and it is these additional valence structures which are responsible for the stabilization of metallic compounds. Specifically, the number of resonance structures depends on the valence v and the number of coordination or bonding partners L of the atoms involved. In addition, a distinction must be made between atoms in which the ratio of valence electrons N_e to valence orbitals N_0 is less than 1 (hypoelectronic) and those with a ratio greater than 1 (hyperelectronic) [Eqs. (1) and (2)].

$$v_{hypo} = \frac{v^{\frac{v}{2}}(L-v)^{\frac{L-v}{2}}L!}{L^{\frac{L}{2}}v!(L-v)!}\left(\frac{L-v}{L-v+1}+1+\frac{v}{v+1}\right) \quad (1)$$

$$v_{hyper} = \frac{\sqrt{2}L!v^{\frac{v-1}{2}}(L-v)^{\frac{L-v+1}{2}}}{L^{\frac{L}{2}}(v-\frac{1}{2})!\,(L-v+\frac{1}{2})!}\left(1+\frac{v(L-v+\frac{1}{2})}{(v+\frac{1}{2})(L-v)}\right) \quad (2)$$

The number of metal orbitals per atom, ω, that is, those orbitals subject to asynchronous resonance, is given by Equations (3) and (4), where $-z \leq v \leq +z$ defines a valence range, and e is defined in Equation (5).

$$\omega_{hypo} = \frac{4Lv - 4v^2 + 3L + 2}{6Lv - 6v^2 + 4L + 2} \tag{3}$$

$$\omega_{hyper} = \tfrac{1}{2}([e - \{e(e-1)\}^{\frac{1}{2}}] + 1) \tag{4}$$

$$e = \frac{(z+1)(L-z-1)}{L-2z-1} \tag{5}$$

A systematic study of the v and L values shows that the largest resonance stabilization in metals is possible when $v = L/2$, that is, when the number of resonance structures is half the number of bonding partners (Fig. 12). This result

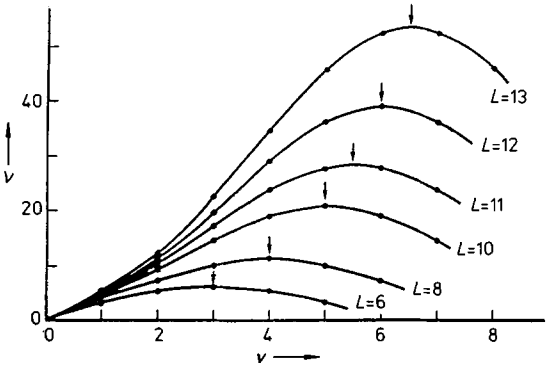

Fig. 12. Number of resonance structures, v, as a function of the number of ligands L and the valence v for intermetallic phases [145].

implies a statement, which *Pauling*, on account of his electron pair concept, has not formulated in his way: metals tend to form half-bonds.[*]

With transition metals such as tungsten, a valence is obtained which is indeed somewhat higher than six.[**] This is the highest valence expected for metals.[147] Using the theory of asynchronous resonance, *Pauling* et al. have determined a new set of single-bond radii.[147] At the same time, *Pauling* has improved his well-known relationship between distance d_n, single-bond length d_1, and bond order n by including the number of resonance structures [Eq. (6)].

$$d_n = d_1 - 0.700 \lg \{n[1 + 0.064(v-1)]\} \tag{6}$$

Two criticisms of the *Pauling* theory are encountered particularly often. First, an assumption about the valences must be made.[111] Second, a linear relationship is assumed to exist between the number of resonance structures and the energy.

[*] *Heine* and *Samson* [149], as well as *Bieber* and *Gautier* [150] have made the following interesting statement: Alloys of transition metals have ordered structures when the d bands are half-occupied. For almost empty or nearly filled d bands, cluster formation dominates. These conclusions are clearly related to the classical chemical rules of cluster formation for boranes as well as to the formation of nets for four-electron species.

[**] The number of neighbors in the W structure is 8 + 6 with distances of $\sqrt{3}/2$ a or a (a = lattice constant).

In a recently published article on the application of *Pauling*'s ideas to the improvement of proposed structures in structure–stability comparisons as well as the prediction of nonstoichiometry and the existence of intermetallic phases, *F. L. Carter* writes: "...we have found as a user (and not the originator) that the advantages of *Pauling*'s metallic radii scheme render it far superior to any other proposed approach... notwithstanding its limitations."[148] However, to this approval must be added the reservation that promising quantum-mechanical concepts are now available for problems such as the local chemical bonding in intermetallic phases (see Sections 5.4 and 5.5).

5.4. Extended Hückel Investigations

Since the early 1980s, *R. Hoffmann* has extended his work on molecules and coordination compounds to the study of the chemical bonding in typical solid-state structures and intermetallic phases. To this end, *M. H. Whangbo*, *R. Hoffmann*, and *T. Hughbanks* extended the EH method with formalisms which make it possible to compare fragments with a total structure and to investigate the local chemical bonding (COOP method[8]) in the solid state. In a series of studies, *R. H. Hoffmann* et al. and *J. Burdett* et al. obtained critical insights into the chemical bonding in intermetallic phases.[9,43] The method of moments developed by *J. Burdett* and *S. Lee* elegantly takes into consideration the differing neighborhood interactions.[41–44] It also gives promising and chemically comprehensible analyses in the study of nets of partial structures (see Fig. 13c), particularly those that have become known from the work of *W. B. Pearson*, *A. F. Wells*, *E. Hellner*, *M. O'Keeffe*, and *B. G. Hyde*.[24, 25, 27, 28]

One of the most commonly occurring structures of intermetallic phases is that of $BaAl_4$[169] or $ThCr_2Si_2$[170] as a ternary representative. More than 400 compounds crystallize in this structure type. Clearly, this arrangement must be capable of adapting to widely differing valence electron concentrations as the Th_6Mn_{23} structure does. In this connection, a series of interesting physical properties have been observed, including valence fluctuations, superconductivity with heavy fermions, and unusual magnetic properties.[171] As can be seen in Figure 13a, the AB_2X_2 type belongs to the framework structures in the Pearson classification (see Section 1.1). B_2X_2 layers are coordinated on both sides by the large A atoms. The B atoms form a square net, whose squares are coordinated by X atoms in such a way that the resulting square pyramids are alternately directed upwards and downwards. However, the crucial structural elements are the X–X contacts between the layers, which, through changes in the X–X distance, can adapt to changes in the valence electron concentration (Fig. 13b).[167, 168]

In a series of alkaline-earth transition-metal phosphides, reported by *A. Mewis*, P–P distances between 2.25 and 3.43 Å are found. Here, the entire range from a normal P–P single bond (2.20 Å) to a completely unbound state is found in a series of seven compounds AB_2P_2 (A = Ca, Sr; B = Fe, Co, Ni, Cu). The extended Hückel investigation clearly confirms that once again a bonding mechanism in accordance with the Zintl–Klemm concept is responsible for the adap-

tation. Depending on the filling of the electronic states, only bonding or bonding and antibonding P–P crystal orbitals are populated.[167] An understanding of the effect of the transition element B requires knowledge of some band-structure terminology. Electron-poor B atoms to the left of the periodic table populate the antibonding P–P states to a greater extent than the electron-richer atoms such as Ni and Cu. In the latter, the d states and the σ^* states fall into the same energy range owing to the higher effective nuclear charge. In other words, although Mn and Fe have fewer electrons than Ni and Cu, they transfer more electrons to the P atoms and are therefore more strongly oxidized.

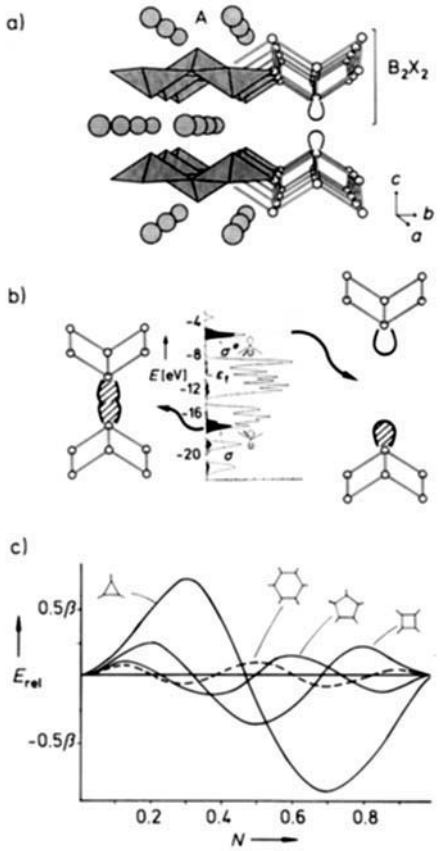

Fig. 13. Extended Hückel investigations [167]: a) $BaAl_4$ and $ThCr_2Si_2$ structure type: section of the crystal structure of $ThCr_2Si_2$. The B_2X_2 partial structure is shown on the left as a polyhedral depiction (square pyramid) and on the right as a framework. The X–X bond is shown by the hybrid orbitals (right-hand side, between the layers). b) X–X interactions as a function of the filling of the orbitals with electrons. Left: Short distance, bonding interaction, only the σ state is populated. Center: Density of states with contribution of σ and σ^* states [168]. Right: Large distance, nonbonding interaction, σ and σ^* states are populated (see text). c) Comparison of the relative energies for nets of triangles, squares, pentagons, and hexagons as a function of the number of electrons, calculated by the method of moments (reproducted from [13]).

W. Tremel and *R. Hoffmann* have elegantly studied the electronic structure of 4^4 networks in crystalline solids, which form either ideal or distorted arrangements, depending on the difference in electronegativity between the atoms and the number of valence electrons.[183] Some further studies of planar and puckered nets have been published by *Burdett* et al.[43] The quantum-mechanical study of polyhedra and nets has apparently turned out to be the fundamental starting point for the analysis of chemical bonding in intermetallic phases. These two merge in the borderline case in which the polyhedra become infinitely large (cf. footnote in Section 5.3).

5.5. Pseudopotential Theory

A remarkable theory of chemical bonding in metals was published about 20 years ago by *V. Heine*, *M. Cohen*, and *D. Weaire*.[111] In three detailed articles, they investigated pseudopotentials, their generation, and their application to metals as well as the relationships between pseudopotential theory and the formation of structures in metals and intermetallic phases. They split up the total energy of a crystal structure into several terms [Eq. (7)], of which only U_E and U_{BS}, the Coulomb or band-structure energy, are dependent on the structure (see also Section 6.1). U_0 is a function of the

$$U = U_0 + U_E + U_{BS} \tag{7}$$

atoms involved and contains no structure-specific information. The starting point for the work of *Heine* et al. is the statement that "the electronic band structure $E(\boldsymbol{k})$ for very many solids is recognizably a greater or smaller distortion from that of free electrons."[111] Of course, this does not imply that essentially free electrons are present in the compounds they have successfully studied. The perturbation of the free-electron gas may describe the real electron structure just as well or badly as a complementary theory based on the delocalization of a strongly localized electron structure (Fig. 14a).

First, a few definitions should be given. Figure 14b shows schematically the dependence of the energy $E(\boldsymbol{k})$ on the wave vector $\boldsymbol{k}$[*] for the free-electron gas (dotted line) and the perturbation by the periodic potential in a crystal structure (solid line). The function $E = f(\boldsymbol{k})$ is termed an electronic band. The parabolic relationship $E(\boldsymbol{k}) = 1/2k^2$ applies for the free-electron gas.

Between the energetically lowest unoccupied (LUMO in a molecule) and the highest occupied electronic state (HOMO in a molecule) is the Fermi level or Fermi energy E_F. In reciprocal $\boldsymbol{k}$ space, the corresponding value k_F is the radius of a sphere, the so-called Fermi sphere. However, this applies only for the free-electron gas. All real crystal structures have many bands, which can also cross one another if they have different symmetry. In metallic conductors the Fermi level is not a defined energy; it always intersects bands (see Fig. 14c, E_F^M); that is, the highest occupied and lowest unoccupied electronic states follow one another without an energy gap.

The intersection of the Fermi energy and an electronic band gives in one dimension a point, in two dimensions a line, and in three-dimensional $\boldsymbol{k}$ space a surface of intersection, which is termed the Fermi surface. This is the surface of the so-called Fermi body, which, in the case of a free-electron gas, includes the occupied electronic states. As mentioned previously, the Fermi surface is only spherical for a free-electron gas (see Fig. 14d). Each metal has its typical Fermi surface, which, depending on the structure and atomic proper-

[*] $\boldsymbol{k}$ represents vectors in reciprocal space and can also correspond to reciprocal lattice vectors in a crystal structure.

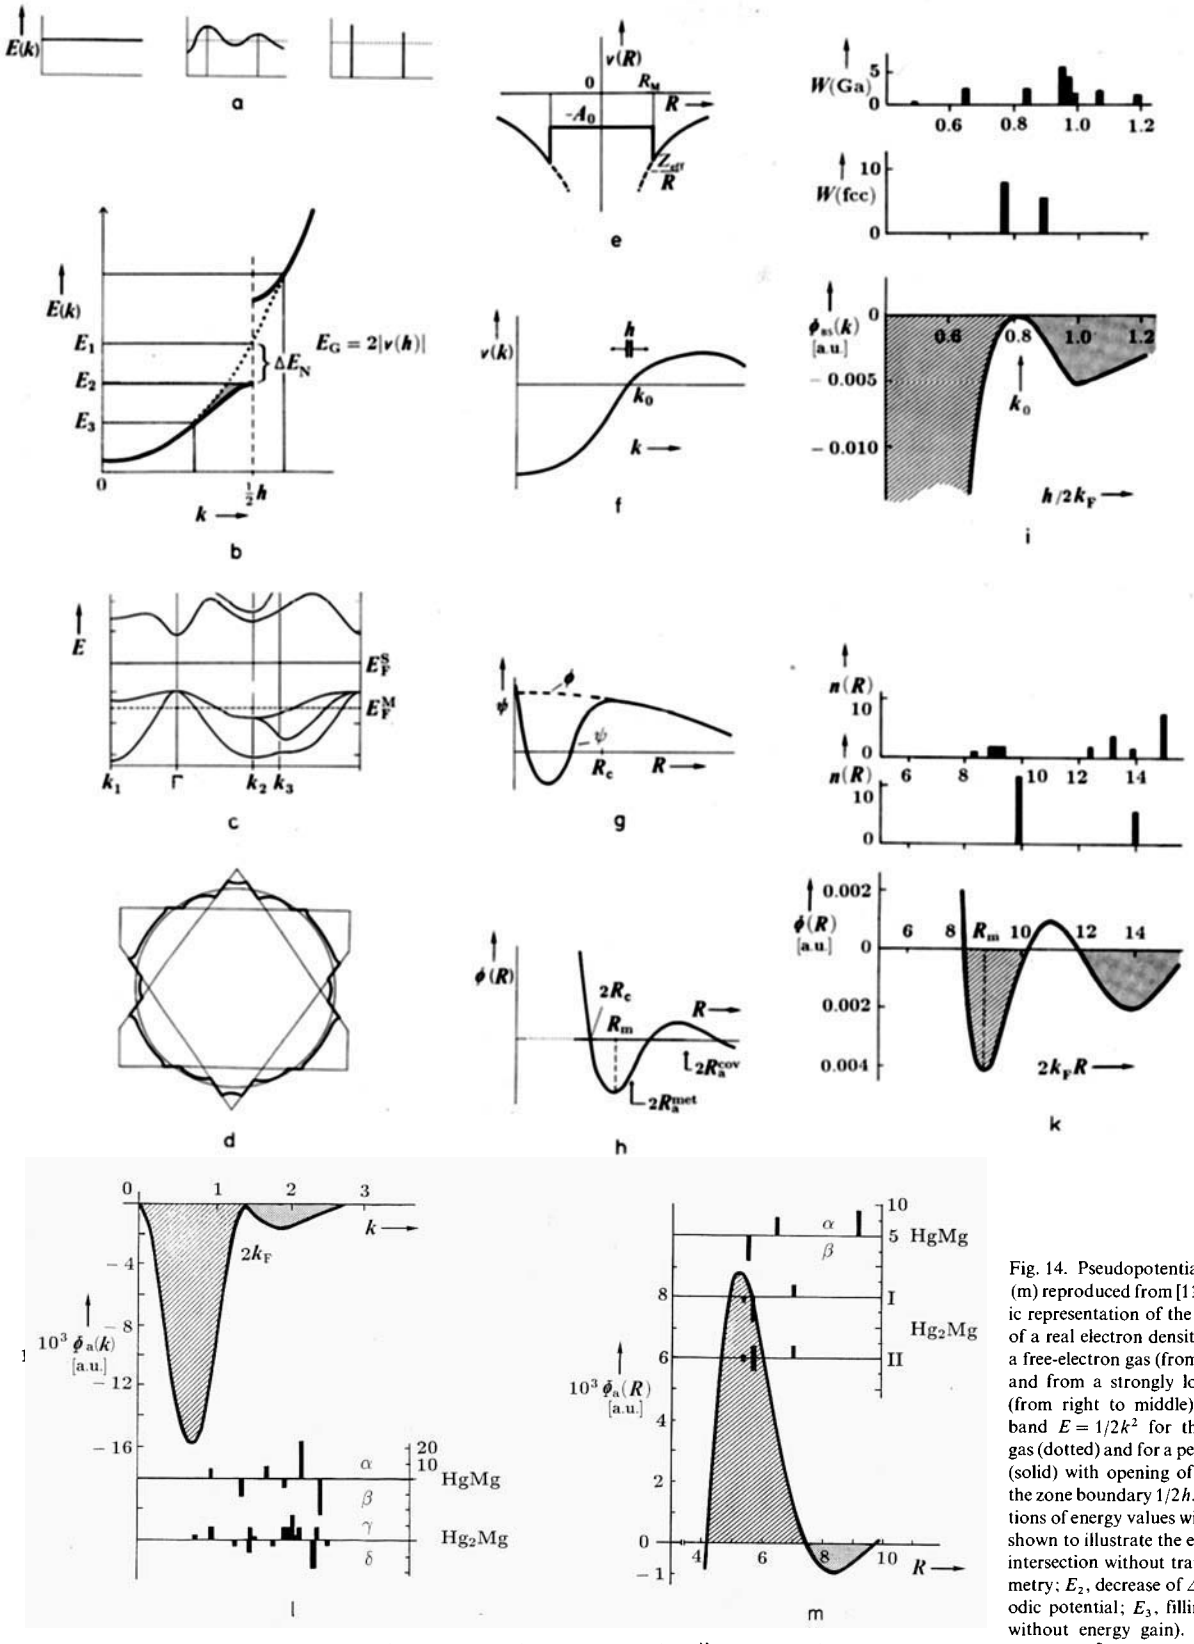

Fig. 14. Pseudopotential theory ((b)–(m) reproduced from [11]): a) Schematic representation of the approximation of a real electron density starting from a free-electron gas (from left to middle) and from a strongly localized picture (from right to middle). b) Electronic band $E = 1/2k^2$ for the free-electron gas (dotted) and for a periodic potential (solid) with opening of a band gap at the zone boundary $1/2h$. Three intersections of energy values with the band are shown to illustrate the energy gain (E_1, intersection without translational symmetry; E_2, decrease of ΔE_N by the periodic potential; E_3, filling of the band without energy gain). c) Part of the band structure of a metal (aluminum); the horizontal lines mark the Fermi energies E_F^M for a metal (dotted) and for a semiconductor "E_F^S" (solid). d) Intersection of the Fermi sphere (dotted) with a plane of $\boldsymbol{k}$ space. In the periodic potential, deformations of the Fermi surface arise at the zone boundaries (thin lines) with formation of band gaps. As an example, the experimentally determined [110] projection of the Fermi surface of lead is shown. e) Schematic depiction of an atomic pseudopotential v. Outside a limiting radius (model radius $\boldsymbol{R}_m$), the pseudopotential follows the Coulomb law $v(R) \sim Z_{eff}/R$. f) Fourier transformed pseudopotential $v(\boldsymbol{k})$. The position $v(\mathbf{k}_0) = 0$, which is as far as possible avoided by the important structure factors $\boldsymbol{h}$ of an energetically favorable structure, is marked. g) Schematic radial course of an orbital and a pseudo orbital (dotted). h) Schematic course of a pair correlation function $\Phi(\boldsymbol{R})$ and comparison of the relative positions of the atomic radii $\mathbf{R}_a$ to the hard-core radius $\mathbf{R}_c$ for electronegative elements with covalent semiconductor structures and for metals. Comparison of the pair correlation function $\Phi(\boldsymbol{k})$ (i) and $\Phi(\boldsymbol{R})$ (k) for gallium with the distribution of the structure factors, $\omega(h)$ and the histogram of distances, $n(\boldsymbol{R})$ for the α-Ga structure (top) and for the fcc arrangement (bottom). l) Comparison of the pair correlation function $\Phi_a(\boldsymbol{k})$ for Hg-Mg compounds and the structure factors for the observed structures of MgHg (CsCl type, α) and $MgHg_2$ ($MoSi_2$ type, γ) as well as for the structures given by a statistical distribution (MgHg, body-centered cubic, β; $MgHg_2$, body-centered tetragonal, δ). $\Phi_a(\boldsymbol{k})$ favors the ordered structures α, γ. m) Comparison of $\Phi_a(\boldsymbol{R})$ with the distance distribution for MgHg and $MgHg_2$ (α, Mg–Mg and Hg–Hg distances plotted downwards; β, Mg–Hg distances plotted downwards: I, distances around Mg; II, distances around Hg). Note the distance accumulation at the maximum of $\Phi_a(\boldsymbol{R})$.

ties, can adopt widely differing forms. Since the Fermi surfaces contain the least favorable, that is, the energetically highest lying, electronic states, a decrease in the surface always leads to an energy gain. The inclusion of a periodic potential, as is present in crystals, corresponds to the formation of zone boundaries in $\boldsymbol{k}$ space. For the electronic bands, the band gaps arising at these zone boundaries result in precisely such a decrease in the Fermi surface (Fig. 14d). It is therefore not surprising that periodic Fermi surfaces, like those of gold, resemble periodic minimal surfaces (see Section 6.1).

In insulators and semiconductors (Zintl phases), the Fermi level always lies in an energy gap which extends through the entire $\boldsymbol{k}$ space continuously but with varying width (Fig. 14c, E_F^S). The smallest gap between the highest occupied and the lowest unoccupied electronic state is the band gap E_G (Fig. 14b). This is called a direct band gap for a transition at the same $\boldsymbol{k}$ point and an indirect band gap for a transition between two different $\boldsymbol{k}$ points (Fig. 14c). Accordingly, there are also direct and indirect electronic transitions. The Fermi level lies in the middle of the band gap and therefore does not cross any bands, which means that insulators and semiconductors have no Fermi surface. The bands in these classes of substances are of course also subject to a stabilization by the periodic structure, which can be seen in the cross-sectional surface of constant energy $E(\boldsymbol{k}) < E_F$. As a rule, however, these cross-sectional surfaces become increasingly small as $E(\boldsymbol{k})$ approaches the highest energy of the highest occupied band, $E_m(\boldsymbol{k})$. Thus, in insulators and semiconductors, too, a minimization of the surface $E(\boldsymbol{k})$ occurs for the energetically unfavorable states with high energy, analogous to that discussed for metals. Indeed, the tendency to minimize the Fermi surfaces always corresponds to a tendency for the formation of valence compounds.[111]

Various approximations play an important role in the concept of *Heine* et al. First, the influence of the atomic-core regions is described by a pseudopotential $v(\boldsymbol{R})$ in real space (Fig. 14e) or $v(\boldsymbol{k})$ in reciprocal space (Fig. 14f). The effect of the pseudopotential approximation is shown in Figure 14g. In the valence region, the corresponding pseudoorbitals ϕ correspond to the valence orbitals ψ and can be chosen such that no nodes occur in the core region. For this, only the valence region need to be taken into account in the quantum-mechanical treatment. A further advantage is that the pseudopotential of an atom can be used for different valence states. The only structure-dependent quantities in Equation (7) are the Coulomb energy U_E and the so-called band-structure energy U_{BS}. The latter is largely determined by the lowering of the bands at the Brillouin zone planes. U_E is part of the electrostatic energy for pointlike cations in a uniform electron gas, most of which is also structure-independent, as shown by *F. Bertaut*[175,176] (see Section 6.1). U_E is only the structure-dependent correction term of the Coulomb energy.

Heine and *Weaire* emphasize in their studies that the Coulomb repulsion (or that of the charged atom cores) favors highly symmetrical structures. However, this means that only U_{BS} and related quantities are responsible for the formation of complex structures. In the following, some simple relationships will be developed on this basis. Figure 14b shows schematically the energy gain obtained for various Fermi energies when the bands split at the zone boundaries. The value of U_{BS} is proportional to the square of the band gap ($U_{BS} \sim -|v(\boldsymbol{h})|^2$) arising at the zone boundary $1/2h$. The lowering of the energy is large whenever $\mathbf{k}_F$ approaches a zone boundary as closely as possible and $v(\boldsymbol{h})$ adopts a high value.[*] Figures 14e and 14f show the radial pseudopotentials as a function of the real and reciprocal coordinates $\boldsymbol{R}$ and $\boldsymbol{k}$. The two representations $v(\boldsymbol{R})$ and $v(\boldsymbol{k})$ can be interconverted by Fourier transformation and are completely equivalent.

Of particular importance is the point $\mathbf{k}_0$ at which the pseudopotential has its root. If U_{BS} governs the formation of the structure, then, in the reciprocal representation, structure factors with high weight avoid the position $\mathbf{k}_0$. The lattice vectors $\boldsymbol{h}$ close to the origin are important here, because $v(\boldsymbol{k})$ decreases quite rapidly with increasing $\boldsymbol{k}$. A similar dependence occurs in the *Bertaut* "ansatz" of the Coulomb energy (see Section 6.1).

For the correlation of energetic and structural quantities, another function, the so-called band-structure characteristic Φ_{BS}, is more appropriate than the pure pseudopotentials. Φ_{BS} is a function of the product of two pseudopotentials and has the character of a pair potential. Since Φ_{BS} is also structure-independent, the only remaining structure-dependent terms in U_{BS} are the geometrical structure factors $S(\boldsymbol{h})$ in Equation (8).[**]

$$U_{BS} = \sum_h n_h |S(\boldsymbol{h})|^2 |v(\boldsymbol{h})|^2 \gamma(\boldsymbol{h}) = \sum_h W(\boldsymbol{h}) \Phi_{BS}(\boldsymbol{h}) \tag{8}$$

$W(\boldsymbol{h}) = n_h |S(\boldsymbol{h})|^2$ is termed the structural weight.[111] Exclusively this quantity contains the structural information and it corresponds to the sum of the squares of symmetry-equivalent normalized structure factors (n = multiplicity of $S(\boldsymbol{h})$). For $\Phi_{BS}(\boldsymbol{k})$, too, the following applies: structure factors $S(\boldsymbol{h})$ with large weight $W(\boldsymbol{h})$ should avoid the first root $\mathbf{k}_0$ and should lie in the region of the minima of $\Phi_{BS}(\boldsymbol{k})$.

$\Phi(\boldsymbol{R})$ is a corresponding pair potential in real space (Fig. 14h) and is made up of a Coulomb term and the Fourier transform of $\Phi_{BS}(\boldsymbol{k})$ [Eq. (9)]. This function is directly

$$\Phi(\boldsymbol{R}) = \frac{q^2}{|\boldsymbol{R}|} + \frac{2\Omega}{(2\pi)^3} \int \Phi_{BS}(\boldsymbol{k}) \exp(i\boldsymbol{k}\boldsymbol{r})\, d^3k \tag{9}$$

relevant to the distances between two atoms. The distances should avoid the maxima, especially the first maximum, of the pair correlation function. However, $\Phi(\boldsymbol{R})$ is not a complete interatomic potential; it is a reorganization potential for constant volume. The radial course of $\Phi_{BS}(\boldsymbol{k})$ and $\Phi(\boldsymbol{R})$ is shown in the lower part of Figures 14i and 14k. For aluminum, the fcc arrangement best fulfills these conditions. The set of cubic structure factors $S(\boldsymbol{h})$ with $|\boldsymbol{h}| < 2\mathbf{k}_F$ can make significant contributions to U_{BS}.

[*] In some cases, this can occur through formation of superstructures; that is, through small changes in the translation lattice, corresponding zone boundaries can optimally approach the Fermi surface. In other cases, two very different structure types with different Fermi surfaces may compete with one another, whereby, depending on the number of valence electrons, one of them is favored energetically. This idea is the basis of the Hume-Rothery rules [177-179].

[**] $\varepsilon(\boldsymbol{k})$ is a shielding function, the dielectric function of the free-electron gas. $\chi(\boldsymbol{h})$ is termed the polarization operator or perturbation characteristic [11, 12]. These two quantities introduce correlation and exchange interactions for the nonuniform electron gas. $\gamma(\boldsymbol{h}) = \chi(\boldsymbol{h})\varepsilon(\boldsymbol{k})$ is structure-independent in this approximation.

Heine and *Weaire* showed that gallium, in contrast to aluminum, cannot crystallize well with an fcc structure, because the cubic structure factors F (111) lie to close to $\mathbf{k}_0$ with $\Phi_{BS}(\mathbf{k}_0) = 0$. The observed structure (α-gallium) has a significantly better $W(\boldsymbol{h})$ distribution. Accordingly, distances with large weight (higher abundance, $n(\boldsymbol{R})$) in the distance spectrum of the α-gallium structure can far better avoid the maximum of $\Phi(\boldsymbol{R})$ than those of the fcc arrangement with the same volume (Fig. 14k).

According to *Heine*, distortion of structures arises as a result of the difficulty of simultaneously achieving volume and distance optimization in a highly symmetrical structure. The volume requirement in intermetallic phases is usually not structure-dependent, but is instead a function of the atomic electron density.[11] A corresponding observation, made more than 60 years ago, was the basis for a compilation of volume increments by *W. Biltz* and *W. Klemm*.[151] Typical examples of simple distorted structures are those of Zn, Cd, and Hg, with their unusual c/a ratios of 1.8562, 1.8856, and 1.936, as well as the structures of Ga and In.

Figure 14h shows the relationship between the more open structures in covalent semiconductor arrangements and the dense packings of the intermetallic phases through the curve $\Phi(\boldsymbol{R})$. Elements with high effective nuclear charges have a hard-core radius R_0 that is small compared with the atomic radius R_A. Given the volume requirement $4/3\,\pi R_a$, only a few neighbors can have the particularly favorable distance R_m (diamond structure: $R_m/R_a \approx 0.70$). For intermetallic phases R_m/R_a is about 0.9.[11]

After a few modifications, *Heine*'s approach can also be used to investigate the stability of alloys and intermetallic phases. In a compound $A_{1-c}B_c$, the different interactions A-A, A-B, and B-B must be taken into account. After splitting up the pseudopotential in the crystal, $V(\boldsymbol{k})$, one obtains an expression for the potential that contains two terms [Eq. (10)]. The first term is the sum of the structure factors

$$V(\boldsymbol{k}) = S_{AB}(\boldsymbol{k})\,\bar{v}(\boldsymbol{k}) + [c\,S_A(\boldsymbol{k}) - (1-c)\,S_B(\boldsymbol{k})]\,v_{diff} \qquad (10)$$

with

$$S_{AB}(\boldsymbol{k}) = S_A(\boldsymbol{k}) + S_B(\boldsymbol{k})$$
$$\bar{v}(\boldsymbol{k}) = c\,v_B(\boldsymbol{k}) + (1-c)\,v_A(\boldsymbol{k})$$
$$v_{diff}(\boldsymbol{k}) = v_A(\boldsymbol{k}) - v_B(\boldsymbol{k})$$

for the atoms, namely, S_A and S_B, multiplied by an average atomic pseudopotential $\bar{v}$. The second term is a weighted correction which involves the difference potential v_{diff}. For the band structure energy per ion one then obtains Equation (11). The first term contributes to the reciprocal lattice

$$\begin{aligned} U_{BS} &= \sum_{\boldsymbol{h}} |S_{AB}(\boldsymbol{h})|^2 \bar{v}(\boldsymbol{h})^2\,\gamma(\boldsymbol{h}) + \sum_{\boldsymbol{k}} [c\,S_A(\boldsymbol{k}) - (1-c)\,S_B(\boldsymbol{k})] \\ &\quad [c\,S_A^*(\boldsymbol{k}) - (1-c)\,S_B^*(\boldsymbol{k})]\,v_{diff}(\boldsymbol{k})^2\,\gamma(\boldsymbol{h}) \\ &= \sum_{\boldsymbol{h}} |S_{AB}(\boldsymbol{h})|^2\,\Phi_{BS}\,v(\boldsymbol{h}) + \sum_{\boldsymbol{k}} [c\,S_A(\boldsymbol{k}) \\ &\quad - (1-c) S_B(\boldsymbol{k})]\,\Phi_{BS}^{diff}(\boldsymbol{k}) \end{aligned} \qquad (11)$$

vectors, which correspond to the Bragg points, while at these points the second term is zero. For $\boldsymbol{k} \neq \boldsymbol{h}$ only the second term, which takes into account the degree of ordering in the structure, is present. The splitting into two terms corresponds to the concept of coherent and incoherent scattering in diffraction experiments. For ordered structures, the structure factors $S_{AB}(\boldsymbol{h})$ belong to a subcell—which must be chosen appropriately—in the true unit cell. The remaining Bragg points form the group $S_{AB}(\boldsymbol{k})$ of the superstructure cell. Once again, the first strong structure factors have considerable influence on U_{BS} and therefore on the formation of the structure. Large values of $S_{AB}(\boldsymbol{h})$ should coincide with the minima of $\Phi_{BS}(\boldsymbol{k})$, and those of type $S_A(\boldsymbol{k})$ and $S_B(\boldsymbol{k})$ with the minima of $\Phi_{BS}^{diff}(\boldsymbol{k})$. The second term in Equation (11) is also known as the reorganization term or as the energy of alloy formation. The expression for the structure-dependent component of the total energy in real space, obtained by Fourier transformation of U_{BS} and adding the Coulomb energies of the atom cores U_E, contains corresponding summations over all pair interactions A-A, A-B, and B-B for a phase $A_{1-c}B_c$. Equations (12), (13) and (14) are the general form of this pseudopotential theory for alloys and intermetallic phases. The first term in Equation (13) and (14) is in each case the corresponding Coulomb component.

$$\begin{aligned} U_E + U_{BS} &= \frac{N}{2} \sum_{i \neq j} \Phi_M(\boldsymbol{R}_{ij}) + c^2 \sum_{i \neq j}^{AA} \Phi_a(\boldsymbol{R}_{ij}) \\ &\quad + (1-c)^2 \sum_{i \neq j}^{BB} \Phi_a(\boldsymbol{R}_{ij}) \\ &\quad - 2c(1-c) \sum_{i \neq j}^{AB} \Phi_a(\boldsymbol{R}_{ij}) \end{aligned} \qquad (12)$$

$$\Phi_M = \frac{(q_A + q_B)^2}{4|\boldsymbol{R}|} + \frac{2\Omega}{(2\pi)^3} \int \Phi_{BS}(\boldsymbol{k}) \exp(i\,\boldsymbol{k}\boldsymbol{r})\,d^3k \qquad (13)$$

$$\Phi_a = \frac{(q_A - q_B)^2}{4|\boldsymbol{R}|} + \frac{2\Omega}{(2\pi)^3} \int \Phi_{BS}^{diff}(\boldsymbol{k}) \exp(i\,\boldsymbol{k}\boldsymbol{r})\,d^3k \qquad (14)$$

Figure 14l shows the course of Φ_a and the correlation for the Hg-Mg pair with the structure factors $S(\boldsymbol{k})$ of the compounds HgMg (CsCl structure) and Hg_2Mg ($MoSi_2$ structure).[11] The structure factors of the ordered structures (plotted upwards) are closer to the minimum of $\Phi(\boldsymbol{k})$ than those of the disordered arrangements (plotted downwards). Accordingly, for the ordered structures, the distances between different types of atoms, $\Phi_a(\boldsymbol{R})$, lie at large values of the function, and those between like atoms at the smallest values (Fig. 14m). The result is that the structural part of the total energy is decreased.[11]

Heine's and *Weaire*'s theory has been derived from first principles and presented in an extended form in a recently published monograph by *Hafner*, which describes the consequences of extending the theory to perturbations of higher than second order as well as the treatment of compounds with transition metals.[12]

The pseudopotential theory of metals and intermetallic phases can be of great use to the chemist, because it elegantly simplifies the complex interplay of difficultly definable pair interactions—especially in intermetallic compounds—and restricts them in the basic form to radial interactions. In contrast to *Pauling*'s relationship between distance and bond order,[20] $\Phi(\boldsymbol{R})$ is not a monotonously ascending or descending function. It is precisely the radial sequence of minima and maxima of $\Phi(\boldsymbol{R})$ which is of crucial importance for the formation of the structure.

The energetical gradation resulting from perturbation theory treatment leads to a total energy composed of the increments U_0, U_E, and U_{BS}, which is in accordance with the chemist's conception. This is also true of U_{BS} and the pair interaction Φ_{BS}, which, by taking into account the partial structure factors, can be related to the partial structures. Because the localized pseudopotentials and the band-structure character are not dependent on the direction, the preceding analysis can also be applied to metallic melts and amorphous metals. According to *Hafner*, the metals Zn, Cd, Hg, In, and Tl exhibit asymmetric coordination even in the molten state. *Nagel* and *Tauc* postulate that the average interatomic distance is so large that the maxima of the distance spectrum coincide with the minima of the pair potential function $\Phi(\boldsymbol{R})$.[152] Although there are no bands, Brillouin zones, or well-defined reciprocal lattice vectors for such a system, this hypothesis has provided remarkably good results.[12] This indicates that smaller, noncrystalline units can also be approximately described in this way and confirms the idea that the band-structure description contains a large amount of information on local bonding.

5.6. The Density of Alloys

The rules, which are a priori incompatible, are often used to derive densities and related quantities. The Vegard rule assumes a linear dependence of the unit-cell dimensions and interatomic distances upon the atomic radii r_A and r_B.[154] The so-called Zen law postulates the additivity of the volumes.[155] However, a comprehensive review of volume additivity, treated in terms of ionic and intermetallic phases, was published much earlier by *Biltz* and *Klemm*.[151] According to *Hafner*, these rules "are perhaps the only laws in physics for which it is much harder to find a system to agree with, than to disagree with".[12] Owing to their different dimensions, $\sum r_i$ and $\sum v_i$ ($\sim\sum r_i^3$) cannot simultaneously show a linear dependence. However, both quantities are optimized as well as possible in each structure, and it therefore seems only natural that complications arise which lead to the formation of distorted, complex or open, voluminous structures.

Hafner gives a quadratic relation for the change in density in an intermetallic compound whose components A and B have the same valence [Eq. (15)]. The values R_s are the radii of one-electron spheres $4/3\pi R_s^3 = V(e)$, which thus represent the electron density.[*]

$$\begin{aligned} \bar{R}_S^2 &= c_a^2 \bar{R}_{S_A} + c_B^2 \bar{R}_{S_B} \\ \bar{R}_S &= -1 + 1.229\, R_S \\ \bar{R}_{S_{A/B}} &= -1 + 1.229\, R_{S_{A/B}} \end{aligned} \tag{15}$$

Deviations $\Delta R < 0.1\%$ occur for the alkali-metal alloys K/Rb, K/Cs, and Rb/Cs and for Ca/Sr phases.[12] Interestingly, the optimized quantity is apparently a surface ($\bar{R}_s^2$). Whether this surface is related to geometrical surfaces such as periodic nodal surfaces (see Section 6.1) has not yet been investigated.

[*] Variational methods performed as a function of the electron density are termed density functional methods. They are used in various forms for calculating the electronic structures of chemical compounds.

6. Structural Principles and Similarity Relationships

6.1. Inner Surfaces

We are just beginning to learn about the principles according to which gaps or chemically weak interactions are arranged in crystal structures, or rather how they are arranged by the stronger interactions. The surfaces of all stable solid or liquid materials strive for the formation of a minimal surface. The energetical situation on the surface is always less favorable than that in the interior of a solid or liquid substance. But in the interior, too, the distribution of the interactions is structured rather than uniform. In the interior of each structure there are forces of differing strength, and it is a logical consequence that the weaker interactions are grouped around the stronger interactions in an ensemble of the smallest possible size. This tendency leads to the formation of inner surfaces, which in the crystal apparently strive for the form of a symmetry-adapted minimal surface.[174]

It was recently recognized that the symmetry-adapted minimal surfaces in crystals can be replaced by periodic nodal suraces (PNS). The PNS can easily be derived by Fourier transformation of the shortest symmetry-consistent structure factors.[*] In many cases the general root distributions in space groups with translational symmetry form curved periodic surfaces in three-dimensional space. Upon inclusion of physical quantities, the density amplitudes (potential distribution or electron densities) are rescaled, but the PNS's are essentially retained. The general equation for the generation of the PNS is (16), where $\boldsymbol{R}$ and $\boldsymbol{h}$ are the vectors in real and reciprocal space, α_h is the phase angle, and $S(\boldsymbol{h}) = 1/N \sum_j \exp(i\boldsymbol{R}_j\boldsymbol{h})$ is the so-called geometrical structure factor, calculated by summation over all atom positions of each unit cell. In *Bertaut*'s equation for the Coulomb

$$0 = \rho(\boldsymbol{R}) = \sum_{\boldsymbol{h}} S(\boldsymbol{h}) \cos(\boldsymbol{R}\boldsymbol{h} - \alpha_h) \tag{16}$$

potential, $S(\boldsymbol{h})$ is replaced by a corresponding expression $F(\boldsymbol{h})$, which is summed over the charges q_j ($F(\boldsymbol{h}) = 1/N \sum_j q_j \exp(i\boldsymbol{R}_j\boldsymbol{h})$).[175, 176] Owing to spreading of the charges over a large region, only a few of the coefficients near the origin $F(\boldsymbol{h})$ have a significant weight. The corresponding nodal surfaces $\rho(\boldsymbol{R}) = 0$ are identical to those of Equation (16). The Coulomb components of the lattice energy after *Bertaut* is made up of two terms [Eq. (17)]. The second

$$U_{Coul} = \frac{1}{2\Omega} \sum_{\boldsymbol{h}} S(\boldsymbol{h})^2 \frac{|\Phi(\boldsymbol{h})|^2}{|\boldsymbol{h}|^2} - \frac{3}{5R} \sum_i q_i^2 \tag{17}$$

term is a constant for each compound and is structure-independent (cf. pseudopotential theory, Section 5.5). It contains only a normalized sum of the squares of the charges. The first term contains the required structural information,

[*] The six reciprocal points $hkl = \pm 100$, 0 ± 10, and 00 ± 1 with $|F_{hkl}| = 1$ and phase angle $\alpha_{hkl} = 0$, for example, belong to the symmetry group $Pm3m$. Their Fourier transform gives a density space with artificial density amplitudes. However, the roots are determined by the symmetry!

which, according to *Bertaut*, is already contained with high accuracy in a few structure factors $F(\boldsymbol{h})$.[176]

As we have already shown, a few structure factors very close to the origin afford periodic nodal surfaces which have a fundamental influence on the structure of the total ensemble.[173, 174] Up to now it was unclear which of the structure factors further removed from the origin of reciprocal space still make an appreciable contribution to the formation of the structure. This relationship can be explained in terms of the pseudopotential theory. In the framework of the pseudopotential theory (Section 5.5), those structure factors that contribute significantly to the Coulomb component of the total energy lie close to the origin in a strongly negative region of the pair interaction Φ_{BS} (Fig. 14i). These can, however, also simultaneously contain contributions from the heteroatomic pair interaction Φ_a. These are precisely the structure factors that *Bertaut* uses to calculate the Coulomb component of the lattice energy and which we have used in the derivation of the structure-determining PNS. Other structure factors with significant influence on the total energy lie to both sides of the root of Φ_{BS}. In principle, both these and the former are suitable for the generation of the PNS, the general geometrical organizer of the structures. The PNS should be independent of fine adjustment of the potential functions because they determine the general geometrical pattern, whereas the latter depend on individual atomic properties.

A publication by *V. N. Novikow* is of particular interest in connection with our concept of structure formation by means of the PNS.[153] He describes melting as a transition from a Euclidean space to a curved space, whereby the two states, crystal and liquid, are treated as crystalline forms in appropriately chosen space groups. The curvature of the corresponding space is the ordering parameter for the transition crystal → liquid. While the formation of structures for crystals can be generalized in terms of the curved two-dimensional PNS, there are apparently related three- and higher-dimensional descriptions for noncrystalline states. This concept is also of interest in connection with the six-dimensional description of the structures of quasicrystals.

6.2. Chemical Twinning

For Laves phases (Section 3.4), the formation of stacking variants, some of which have considerable translation periods, has already been referred to. They form a link to a family of structures in which simpler basic motifs are combined to give a more complex arrangement. *S. Andersson* has named such arrangements chemical twinning.[162] *E. Parthé* et al. have also studied numerous cases of this type, which they calls intergrowth structures.[163–166] Typical examples are shown in Figure 15. The structure of $CeNiSi_2$, for instance, consists of an alternating stacking of two-dimensional sections of the $BaAl_4$ structure—or rather the $ThCr_2Si_2$ type—and the AlB_2 structure (Fig. 15b).[163] Although the composition $Ce(NiSi_2)$ is not formed locally and would apparently be less stable, the composition AB_3 finds an optimal energetical solution in the stacking of AB_4 ($\triangleq CeNi_2Si_2$) and AB_2 ($\triangleq CeSi_2$) layers.[*] Actually, this type of structure formation is simply a logical extension of structures with isolated heteroatomic clusters to one and two dimensions. The relevance to Zintl phases, in which one-, two-, and three-dimensional polyanions form their own partial structures, is clearly evident. The two layers $CeSi_2$ and $CeNi_2Si_2$ will most likely exhibit an acceptor–donor behavior with correspond-

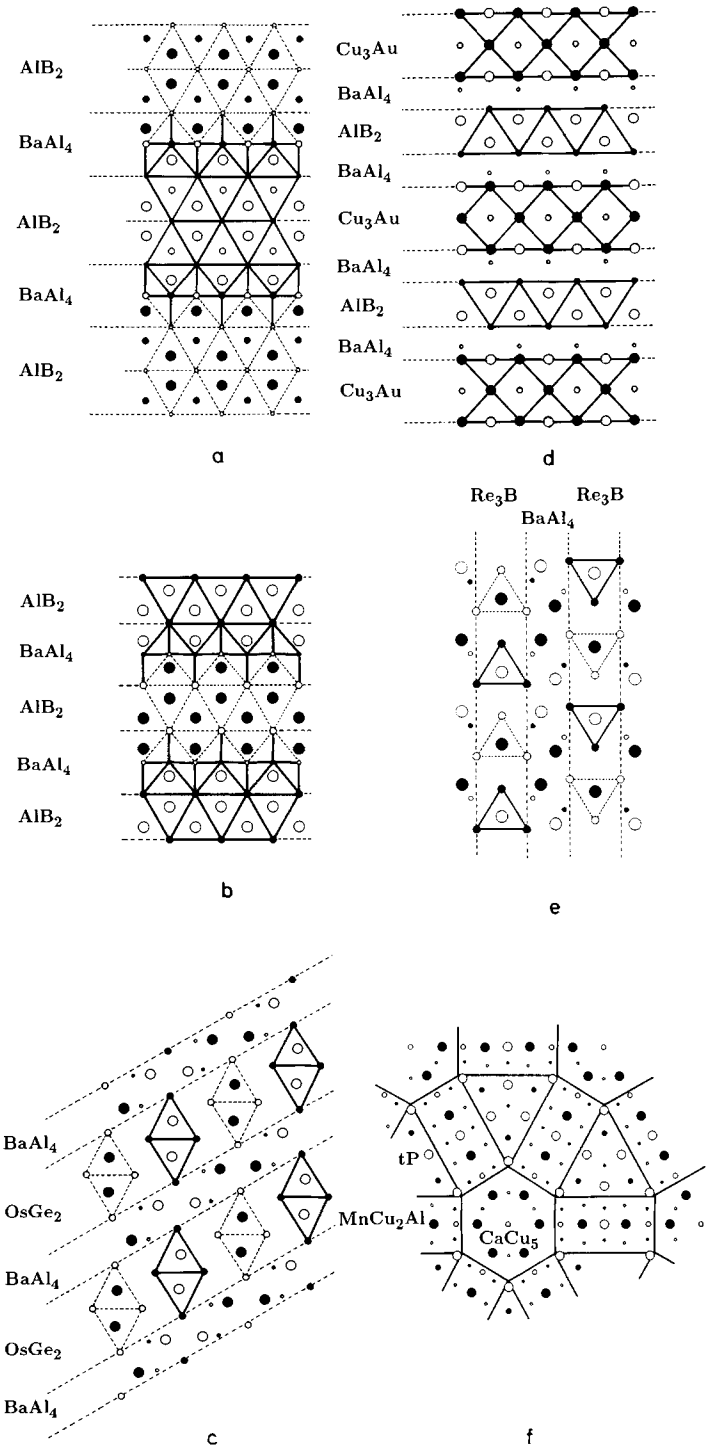

Fig. 15. Examples of chemical twinning [163, 164]. Compounds and structure types of the blocks making up the structure: a) $Ca_3Rh_4Ge_4$ and b) $CeNiSi_2$, respectively, consisting of $BaAl_4$ and AlB_2 blocks; c) $ScCoSi_2$, consisting of $BaAl_4$ and $OsGe_2$ blocks; d) $Ca_3Co_2Sn_7$ consisting of $BaAl_4$ and Cu_3Au blocks; e) $Sc_3Co_2Si_3$ consisting of $BaAl_4$ and Re_3B blocks; f) $Y_{13}Pd_{40}Sn_{31}$ cyclically consisting of $CaCu_5$, $MnCu_2Al$ (Heusler phase [199]), and primitive tetragonal (tP) blocks.

[*] The A_6B_7 variant Cs_6K_7 of the Laves phase $MgCu_2$ also belongs to this family of structures (see Section 6.3).

ing charge transfer. *R. Hoffmann* et al. have recently described similar cases of pure variants of the $ThCr_2Si$ type.[167, 168]

Further examples are shown in Figure 15. In a remarkable manner whole blocks of simple structures are used as building elements for complex arrangements. The connection with inner surfaces as boundary surfaces between the individual structural blocks also becomes clear.

Can we go any further at this point? Do structures not arising from translationally symmetrical layer formation and multiple twinning in accordance with a given point symmetry exist? The answer is yes. Why should interpenetration structures not exist, in which one-, two-, or three-dimensional partial structures interpenetrate without intersecting one another, roughly like the strands of a rope or the links of a chain, with intermediate curved boundary surfaces. These boundary surfaces are once again the periodic nodal surfaces described in Section 6.1.

At this point, a new challenge for the theoretical methods arises: If clusters, chains, and frameworks are relatively stable units, then they must have unfavorable electronic surface states. These should essentially be the energetically unfavorable orbitals, corresponding to the HOMOs and LUMOs in molecules. Will it now be possible to describe theoretically the building of complex structures with two approximations? One of these must determine the chemical bonding in the actual interior of the partial structures, while the other must consider the chemical bonding at the surfaces by means of appropriate frontier orbitals (i.e., according to *Hoffmann*[129]). Such an incremental approach would have great advantage over any total calculation of the band structure, first because it could greatly reduce the amount of calculation needed, and second because the general building principles of structures would be taken into account. Preliminary approaches of this kind have been used in recent theoretical treatments of structures.

6.3. Are Intermetallic Phases Electrides?

A few years ago *von Schnering* himself used the term electride for a metal in connection with quantum-mechanical calculations on a high-pressure modification of cesium, namely, Cs IV.[156, 173] The reason for this was that in Cs IV the 6s electrons are "compressed" into free d states. These d states have their highest probability at the centers of trigonal prisms in a sixfold coordination of the neighboring Cs cores. In a structure-chemical sense the electrons behave like anions.[*]

In this sense the existing knowledge of structural chemistry could perhaps be useful in locating favored electron spaces. Could anion distributions in ionic structures give, for instance, indications of the electron density in structurally related intermetallic phases? Only to a limited extent, of course; since anions cannot be orthogonal to one another, they cannot avoid mutual repulsion in this way. However, they are affected by repulsions similar to those between electrons. They may also be subject to a directional dependence if particular bond angles are favored by the covalent component of the bonding. Ligand or crystal field theory provides the bridging link that describes the interaction between anionic ligands and the electrons remaining on the central atom. It also gives very clear explanations for the distribution of the valence electrons in multinuclear clusters such as those in $MoCl_2$[158] and Nb_3Cl_7[159]. In $MoCl_2$ ($\triangleq Mo_6Cl_8Cl_4$), the Mo_6 octahedron is coordinated by eight $Cl^{\ominus}$ ions, which occupy μ_3 positions over the faces, leaving the 12 edges (= 24 skeletal electrons) as the only remaining available electron spaces. In contrast, the Nb_6 octahedron in Nb_3Cl_7 ($\triangleq [Nb_6Cl_{12}]Cl_2$) is surrounded by $Cl^{\ominus}$ ions over the 12 edges, leaving space for at most eight electron pairs over the faces of the octahedron (= 16 skeletal electrons).[160] Can insulators and semiconductors therefore serve as models for possible electron distributions in structurally related intermetallic phases?

"Oxides as stuffed alloys"—the concept of the structures of oxides as stuffed intermetallic compounds is discussed in an article by *M. O'Keeffe* and *B. G. Hyde* in which the authors present a number of structural relationships between the two classes of compounds.[161] The basis of this relationship is the fact that the pure cation distribution in oxides is often isotypic with the complex structure of an intermetallic phase. Can we invert this concept: "intermetallic phases as electrides"? It is hardly surprising when electronegative ligands occupy precisely those positions in a structure which are also the preferred locations of electrons. In other words, could the electrons find good residence regions at those points in the structure where the favored anion positions are found?

Agreement of the number of oxygen atoms in oxides AB_xO_y with the number of valence electrons in the corresponding intermetallic phases AB_x is not surprising because the cations must provide one electron pair per $O^{2\ominus}$ ion. The structural correlations are nevertheless striking, since there is no reason to form the same or similar AB_x pattern in both cases, unless the distributions of the negative particles ($O^{2\ominus}$ in AB_xO_y and $(e)_2$ in AB_x structures) are similar.

It has long been known for instance, that Si atoms in α-Si (diamond structure) and those in β-cristobalite exhibit isotypic structures and partial structures. Inserting an oxygen atom in the middle of each Si–Si bond of α-Si gives, with a corresponding increase in volume, the cristobalite structure (d(Si-Si, α-Si) = 236 pm, d(Si-O-Si, β-cristobalite) = 340 pm). A similar relationship exists between the structure of Cu and that of cuprite Cu_2O, a doubly interpenetrating β-cristobalite structure.[25]

There is of course a series of elements with different electron counts and, therefore, differing electron distributions, but *O'Keeffe* and *Hyde* have also given a number of different examples for stuffing the Cu structure, namely, Cu_2O, MgO, Cu_3O_4, Y_2O_3, and ThO_2. It is not difficult to find metals with the Cu structure and a number of anions corresponding to the number of electrons.

Another example is the cubic Laves phase $MgCu_2$. In its variant $CaAl_2$, eight valence electrons per formula unit are present. The corresponding oxide $MgAl_2O_4$ has the spinel structure, in which the Mg and Al atoms, as partial structure, form the structure of the Laves phase. The oxygen atoms form an fcc arrangement in spinel. This might not be a bad correlation structure for the electrons in $CaAl_2$ according to

[*] This conjecture had been formulated before the result of the quantum-mechanical treatment was known.

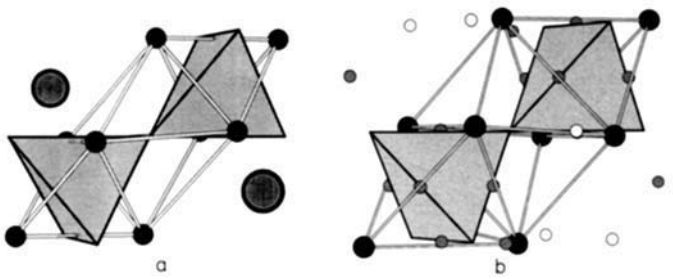

Fig. 16. Comparison of the spinel and VAl_{10} structures: a) An octahedral hole (open framework) and two tetrahedral holes (shaded) in spinel ($MgAl_2O_4$; O atoms, solid circles). In the cubic Laves phase $MgCu_2$, the Mg atoms occupy tetrahedral and the Cu atoms octahedral holes (vertices of the shaded tetrahedra). b) Similar section of the VAl_{10} structure (small circles: Al atoms, open and hatched circles indicate different crystallographic positions; V atoms center the octahedra (open sticks) ≅ vertices of the shaded Al tetrahedra). The solid circles correspond to the O positions in (a) and are not occupied by atoms in VAl_{10}.

Table 4. Comparison of the structures of intermetallic compounds and oxides as well as of valence electron pairs and oxide anions. The numbers of valence electrons given can vary because the number of sterically active pairs is not known before hand.

Structure type	Intermetallic phase/metal	Filling variant	Electron pairs per formula unit	Anions formula unit
Cu	Cu	Cu_2O	0.5	0.5
	Cu	MgO	0.5	1
	$CaAl_2$	Cu_3O_4	4.0	4
	Al_2	Y_2O_3	3.0	3
	Pb	ThO_2, CaF_2	2.0	2
Cu_3Au	Cu_3Au	$TlPd_3O_4$	2.0–4.5	4
CuPt	CuPt	$NaFeO_2$	1.5–2.0	2
$MoPt_2$	$MoPt_2$	Li_2CuO_2	2.0	2
WAl_5	WAl_5	Li_5ReO_6	7.5–10.5	6
$TiAl_3$	$TiAl_3$	Na_3PaF_8	6.5	8
Mg	Mg	ZnO	1.0	1
	Sc_2	La_2O_3	3.0	3
	Re	YF_3	3.5	3
Sm	Sm_3	Th_3N_4	4.5	4
$BaPb_3$	$BaPb_3$	Ca_3SiO_5	4.0–7.0	5
Ni_3Sn	Ni_3Sn	Li_3PO_4	4.0–5.0	4
W	W	χ-La_2O_3	3.0	3
β-Hg	β-Hg	TiO_2	1.0	2
NaTl	NaTl	$KFeO_2$	2.0	2
CuZn	$(CuZn)_2$	$Ca_2Fe_2O_5$	3.0–4.0	5
$MoSi_2$	$MoSi_2$	Sr_2TiO_4	2.0	2
Fe_3Al	Fe_3Al	BaW_2O_6	4.5–6.0	6
UCo	UCo	$K_2Pb_2O_3$	3.0	3
Cu_2MnAl	Cu_2MnAl	K_2NaAlF_6	3.5–5.0	6
$MgCu_2$	$CaAl_2$	Mg_2AlO_4	4.0	4
CrB	CrB	β-Ga_2O_3	3.0	3
FeB	FeB	$BaSO_4$	3.0	4
Mn_5Si_3		$Ca_5P_3O_{12}OH$	11	13
NiAs	NiAs	$BaNiO_3$	3.0–3.5	3
MnP	MnP	$CuSO_4$	3.0–4.0	4
A_2B_5	Mg_5Ga_2	$Na_5Zr_2F_{13}$	8.0	13
Th_3P_4	Th_3P_4	$Bu_4Si_3O_{12}$	12.0–16.0	12
W_2CoB_2	W_2CoB_2	$Mg_3(BO_3)_2$	6.0	6
U_3Si_2	U_3Si_2	$CaZnSi_2O_7$	8.0	7
$PbCl_2$	Ni_2Si	Ca_2SiO_4	4.0	4
FeS_2	FeS_2	ZrP_2O_7	7.0	7
SiP_2	SiP_2	SiP_2O_7	7.0	7
$CuAl_2$	$CaAl_2$	$Ca_2CO_3F_2$	3.5–4.0	5
Cr_3Si	Cr_3Si	$NaPt_3O_4$	4.0–5.0	4
Re_3B	Re_3B	Fe_3BO_6	3.0–5.0	6
$PtPb_4$	$PtPb_4$	$BaMn_4O_8$	5.0–9.0	8
Th_3Pd_5	Th_3Pd_5	$K_3V_5O_{14}$	8.0–11.0	14
diamond	Si, Ge, Sn	SiO_2 (cristobalite)	2.0	2
γ-Ge	γ-Ge	SiO_2 (keatite)	2.0	2
AlP	AlP	$AlPO_4$	4.0	4
LiAlSi	LiAlSi	$NaAlSiO_4$	4.0	4
LiGaGe	LiGaGe	$KAlSiO_4$	4.0	4
CrB_4	CrB_4	$CaAl_4Si_2O_8$	7.0–7.5	8

Schubert. However, this would require that the electrons be present as pairs. In the local picture there are four bonding skeletal electron pairs per Al_4 tetrahedron which can be combined to hybrids with bonding interactions over the four faces. The $O^{2\ominus}$ ions in the spinel structure are found precisely at these positions and thus form an electrostatically favorable (distorted) hetercubane Al_4O_4 (Fig. 16a). This coincidence may also be purely accidental; in all stuffing variants of the $MgCu_2$ structures, however, the positions of the $O^{2\ominus}$ ions or of the bonding electrons of the Al_4 tetrahedron are not occupied by the additional atoms. These regions are apparently reserved for the skeletal electrons.

The structure of the cubic Laves phase $MgCu_2$ can also be understood as a bonding model for Zintl phases of the NaTl type. In the middle of each bond of the diamondlike partial structure of Tl atoms, $MgCu_2$ has a Cu atom. The Mg atoms are located at the Na positions of NaTl.

In Figures 9a and 9d, two remarkably similar patterns are depicted. The former is the Al_{76} unit with dual inner $(Li,Mg)_{40}$ polyhedra in $LiMgAl_2$, in whose interior an icosahedron and an Edshammar polyhedron exhibit disordered interpenetration.[16, 55] This description could also (approximately) apply for Figure 9d. This is a new ternary oxide, $Bi_{22}Sr_{36}Al_{48}O_{141}$[182] (only the cation positions are shown!). One can find many correlations of this type (cf. Table 4), even though these were collected according to other criteria,[161] and on closer examination even more will be found. However, the stage of qualitative correlation will only be overcome through quantitative experimental and theoretical investigations.

7. Summary and Future Prospects

The family of intermetallic phases is an exciting class of chemical compounds with a wealth of geometric forms and chemical bonding. New concepts and methods make tangible their electronic structures even in the chemist's language.

The chemist is used to "seeing the chemical bonding". A pure ensemble of points representing the atomic positions, as given by the structure determination, will inevitably result in his drawing in lines. But which lines are superior to other connections? Which are important?[*] Through the spectacles of individual authors (e.g., von Schnering's cluster spectacles[4]) many different aggregations have been revealed in one and the same structure. In some cases, arrangements and correlations are found which had already been surmised in the early days of structural chemistry.[**] Recently, the theoretical methods have, with good approaches and results, made inroads into the problems of phase stabilities and phase diagrams of intermetallic phases. With the pseudopotential theory and COOP[8] we have the means to analyze locally even slight differences in chemical bonding and thereby calculate the strength of our auxiliary lines in the structural picture. The pseudopotential theory makes it possible to weight the relative importance of the interatomic interac-

[*] "Nothing but the bonds are shown here, and no longer the atoms!" (*H. G. von Schnering* in a lecture on the occasion of the 50th anniversary of *E. Zintl*'s death).

[**] "As an older person, it is easy for me to admit that there are even older persons who also have had good ideas" (*H. G. von Schnering*).

tions by means of the pair correlation function $\Phi(R)$. $\Phi(R)$ is ideally suited to calculating nearest neighbor diagrams and determining the dominant correlations. A more precise analysis of these diagrams would seem to be of interest from the viewpoint of structural chemistry.

However, it seems to me that too little attention has been paid to the local, or at least semilocal, aspect of the chemical bonding. At a time of an enthusiastic "clustering" of chemistry, accompanied by the continual discovery of magic numbers of electrons and in which the universal character of chemical bonding principles is expanding to cover all classes of chemical substances, *Dalton* appears once again to have won territory from the regime of *Berthollet*. The experimental chemist is, in any case, like the first pioneer in a new land. His results provide new impulses for changes in and improvement of the theory. It is to be hoped that the experimental chemists and the theoreticians find ever more common ground—at least the omens for this are good. It is certain that in the field of intermetallic phases, deeper knowledge can only be attained through the interaction of both of them.

I wish to thank my co-workers for their help and advice, and for energetically making up for miscellaneous research opportunities that were unavailable during the move to Zürich. Special thanks is owed to my family for their patience and support.

[107] Just like a powder sample, a multiply twinned crystal generates not more and not fewer Bragg reflections than the corresponding single crystal. For quasicrystals one observes a large and increasing number of sharp reflections with increasing resolution. This can only be result of a nontranslational symmetry in three dimensions. However, all these reflections can be indexed on the basis of a six-dimensional reciprocal lattice with six integral numbers. It is not clear yet whether an icosahedral chemical twinning of twelve or more very small crystallites could yield an adequate description of quasicrystalline structures. Translational symmetry, however, would then be lost again.

[128] The Pearson symbolism for the classification of crystal structures uses the three quantities (l, M, n) l denotes the crystal system (c = cubic; h = hexagonal, trigonal; t = tetragonal; o = orthorhombic; m = monoclinic; a = anorthic), M stands for the Bravais type (P = primitive; I = body-centered; F = face-centered; R = rhombohedral; A, B, C = singly face-centered), and *n* is the number of atoms per unit cell.

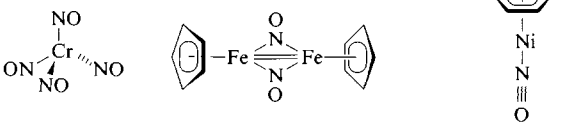
Between Stars and Metals: Phosphorus Monoxide, PO

By *Wolfgang A. Herrmann**

Sodium nitroprusside,[1a] red or black Roussin salt[1b]—this is how the beginning student encounters nitrogen monoxide as complex ligand in his basic labcourse training, whilst his more advanced fellow student has to know about "π-acid ligands" in organometallic complexes such as **1**–**3**.[2, 3]



1 **2** **3**

The old "*Emeléus and Andersen*" (first published in 1940) already enthused about the great future of nitrosyl-complex compounds.[4] And, indeed, this area of chemistry has impressively developed parallel to the metal carbonyl research initiated by *Hieber* and his school in Munich.[5] Common features establish the isovalent relationship between carbon monoxide and the nitrosyl cation ("nitrosonium" ion), as manifested in stable salts such as [NO] [BF_4]:

1) CO and (to an even greater extent) $NO^{\oplus}$ act as π-acceptor ligands *par excellence* towards low-valent metals. The NO valence vibration frequencies decrease more markedly (300–500 cm^{-1}) than those of CO (100–300 cm^{-1}) upon complexation with metals.

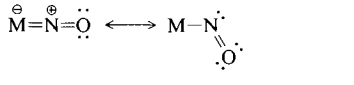
2) CO and $NO^{\oplus}$ are normally two-electron ligands with linear M–C–O and M–N–O atomic sequences of similar dimensions. Accordingly, isoelectronic series of complexes exist, e.g. in the case of tetrahedrally configurated complexes of the type $[M(CO)_n(NO)_{4-n}]$ (n = 0–4) (Table 1), within

Table 1. Melting points [°C] and NO vibration frequencies [cm^{-1}] of an isovalent electronic series of CO/NO-metal complexes.

	$[Cr(NO)_4]$	$[Mn(CO)(NO)_3]$	$[Fe(CO)_2(NO)_2]$	$[Co(CO)_3NO]$	$[Ni(CO)_4]$
M.p.	39	27	18	−1	−19
ν(NO)	1721	1823, 1734	1810, 1766	1806	–

which there is a regular gradation of properties. The "nitrosyl shift rule" formulated by *Seel* in the early years of this chemistry (1942) groups together complexes of this type[3a] and enables a certain degree of reaction designing. μ_2- (cf. **2**) and μ_3-coordination are known for the nitrosyl ligand, but occur more rarily than in the case of carbon monoxide. (Neutral NO is a three-electron ligand.)

3) In contrast to carbon monoxide, there are also complexes with bent M–N–O arrangement (one-electron ligand), namely in the sense of the isomeric equilibrium **A** (linear) ↔ **B** (bent).



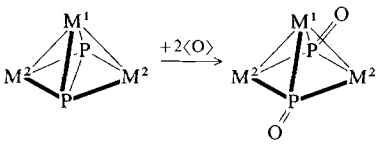
A; d^n-M^z/$[NO]^{\oplus}$ **B**; d^{n-2}-M^{z+2}/$[NO]^{\ominus}$

An example for arrangement **B** is the square-pyramidally structured cation $[\{P(C_6H_5)_3\}_2Ir(CO)Cl(NO)]^{\oplus}$.[6] Arrangement **B** occurs when the π* acceptor orbital of the $NO^{\oplus}$ ligand is energetically lowered to such an extent relative to the metal d-orbitals that a d-electron pair can be transferred to the ligand and become stereochemically active. **A** and **B** are not reliably distinguishable by IR spectroscopy.

4) NO ligands are far less readily displaced from metals than carbon monoxide. Most NO reactions are accompanied by redox processes, which complicate this chemistry considerably.

Applications of nitrosyl complexes are first met with only recently in catalysis, e.g. in olefin metathesis with the system $[Mo(NO)_2Cl_2\{P(C_6H_5)_3\}_2]/[(C_2H_5)AlCl_2]$, though the importance of the respective class of substances here lags far behind that of the metal carbonyls. Of academic interest are the novel thionitrosyl (NS) complexes, which are best prepared from trithiazyl trichloride (*cyclo*-$N_3S_3Cl_3$) or thionitrosyl salts [NS] [Y].[7]

This brief survey of the nitrosyl-metal complexes should highlight possible perspectives which are conceivable in the case of the likewise recently initiated class of *phosphorus monoxide* complexes: *Otto J. Scherer* at al. report a first metal complex of the PO molecule, hitherto only detected (spectroscopically) "between the stars" i.e. in interstellar space (see communication on p. 852). Oxidation of the square pyramidal $[WNi_2P_2]$complex **4** to give the (structurally analogous) $[WNi_2(P{=}O)_2]$ derivative **5** of the *nido* type is elegantly achieved in 60% yield by means of bis(trimethylsilyl)-



4 $M^1 = W(CO)_4$ **5**
$M^2 = (\eta^5\text{-}C_5H_5)Ni$

peroxide.[8] The P–P bond is cleaved, and both PO groups assume bridge positions (μ_3-coordination). The P–O distances (146–148 pm) are very long. However, they do not deviate from those calculated and experimentally found for *free* PO. The IR data are surprising: ν(PO) = 1218 cm^{-1} (free) and 1260 cm^{-1} in the complex **5**. For CO and NO, as well as the homologous ligands CS and NS, respectively,

[*] Prof. Dr. W. A. Herrmann
Anorganisch-chemisches Institut der Technischen Universität München
Lichtenbergstrasse 4, W-8046 Garching (FRG)

the differences are greater, especially in the bridged form: $\nu(NO^{\oplus}) = 2376\ cm^{-1}$; $\nu(NO) = 2250\ cm^{-1}$ (free), ca. $1350\ cm^{-1}$ in μ_3-coordination.

A comparison with the higher homologues of carbon monoxide—thio-, seleno-, and tellurocarbonyl[9]—reveals that the significance of the IR data decreases in the quoted sequence. Nevertheless, in the case of bridge coordination, the differences between the free ligands, as far as data are available, and their metal-fixed form remain the same (Table 2). One must, of course, be particularly careful when

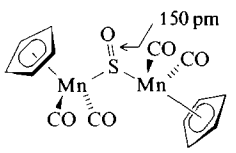
Table 2. Characteristic vibration frequencies [cm^{-1}] and bond lengths [pm] of metal complexes of higher chalcogen derivatives of carbon monoxide [a].

	M–CO	M–CS	M–CSe	M–CTe
ν(CX)	2000–1800	1450–1150	1130–1060	ca. 1050
d(CX)	113–118	143–178	ca. 160	190–195
d(MC)	170–190	ca. 188	ca. 191	ca. 180

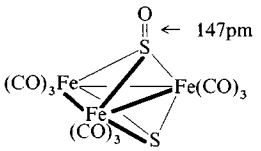
[a] X = chalcogen atom. Data for neutral metal complexes (η^1-coordination), the values of the lowest series apply for M = Os.

interpreting the IR data when vibrational couplings can be expected due to more complex structures. However, the bonding of all these diatomic ligands is weakened upon metal complexation. The readiness of the ligands to undergo additional intermolecular metal complexation increases with increasing basicity (O < S < Se < Te). The *trans* influence increases in the series CO < CS < CSe < CTe.[9c] CS and NS are better σ-donors and stronger π-acceptors than their oxygen analogues, and they adapt far better than the latter to the conditions of the complex fragment.

And what about PO's neighbors? Whereas SiO and $BO^{\ominus}$—both carbonyl analogues?—have thus far defied all attempts at their metal complexation, SO complexes are very well known.[10] Bridge-bonding sulfur monoxide is encountered in the complexes **6** (from thiirane 1-oxide) and **7** (from



6



7

the μ_3-disulfido complex with H_2O_2), in which SO acts as four-electron ligand. The Lewis basicity of P_x- and S_x-ligand ensembles attached to the metal facilitates their comparatively easy oxidation, whereas nitrido- and carbido-complexes are mostly inert in this respect, even though the N and C atoms, respectively, are not shielded. As shown by IR and X-ray diffraction data, the SO ligand has a weaker bond in the complexed state than in the free state, irrespective of its type of coordination: $\nu(SO) = 1137\ cm^{-1}$ (free), 1050–$1130\ cm^{-1}$ (complexed).[10] A frontier orbital situation similar to that in CO is found for SO, only that the two additional electrons occupy the antibonding 3π-orbital and enforce bending of the atomic sequence MSO towards themselves (η^1-coordination, e.g. $[IrCl(SO)\{P(i\text{-}C_3H_7)_3\}_2]$). Ready cleavage ($\rightarrow$ SO) and oxidation ($\rightarrow L_xM\text{-}SO_2$) appear typical for terminally bound sulfur monoxide, which indeed disproportionates extremely rapidly according to Equation (a).

$$3SO \longrightarrow S_2O + SO_2 \qquad (a)$$

If one considers *Scherer*'s PO complex **5** in the context of the nearest relatives (NO, NS, SO) a wide variety of structures can be expected. Despite little prospects of a terminally metal-bound phosphorus monoxide, an interesting synthetic chemistry is expected to develop by way of PO functionalization reactions. If M^1 in **5** is replaced by a less reactive group (isolobal principle!), then, for example, the reduction P=O → P or olefinations P=O → P=CH_2 (with Tebbe reagent?) would be conceivable. Also cluster couplings via P–P bonds (with low-valent titanium or samarium reagents) and "metathesis" reactions in the sense P=O → P=S can be envisaged.

Activation of Methane

By Helmut Schwarz *

The selective functionalization of alkanes[1] has been called "the search for the chemist's Holy Grail" by *Barton*[2] and the most important of all C–H bond activation reactions is the metal-mediated activation of methane. On the one hand, this is due to the great economic interest in the direct transformation of methane to more "valuable" products such as methanol[3] or its oligomerization to higher hydrocarbons (Fischer–Tropsch synthesis[4]). On the other hand, this transformation poses a scientific challenge that has been met piecemeal at best. In recent years, many research groups have attempted to elucidate at least the principal aspects of methane activation and there have been many reports of success.[5] The work discussed here involves reaction of naked transition-metal ions $M^{\oplus}$ or coordinatively unsaturated metal fragments $ML^{\oplus}$ in the gas phase in molecular-beam-type experiments.

Earlier attempts to carry out oxidative additions of CH_4, as shown in Equation (a), failed for the simple reason that the insertion is endothermic for most metal ions $M^{\oplus}$ (M = Sc, Y, lanthanides, U, Ti, V, Nb, Cr, Fe, Co, Rh, Ni, Zn). Only electronically or translationally excited species

$$CH_4 + M^{\oplus} \longrightarrow [H\text{-}M\text{-}CH_3]^{\oplus} \longrightarrow \text{product} \qquad (a)$$

brought about insertion. Moreover, dehydrogenation [Eq. (b)], which proceeds readily for higher alkanes with many $M^{\oplus}$,[6] causes problems in the case of methane, since the reaction is only exothermic for metals with $D^0(M^{\oplus}\text{-}CH_2) \geqq 111$ kcal mol^{-1}. Transition-metal ions $M^{\oplus}$ of the first and second period do not fulfill the prerequisite.[7]

$$CH_4 + M^{\oplus} \longrightarrow [M{=}CH_2]^{\oplus} + H_2 \qquad (b)$$

Dehydrogenation does take place for metal ions of the third row, as shown by experiments with $Ta^{\oplus}$[8] and $Os^{\oplus}$.[9] In a recent paper,[10] *Irikura* and *Beauchamp* not only reported the reaction of all 5d elements from $Hf^{\oplus}$ to $Au^{\oplus}$ with CH_4,[11] but also showed that, for some metals, slow ligand condensation reactions, in which several CH_2 units are linked [Eq. (c)], follow the rapid dehydrogenation. For example, $W^{\oplus}$ reacts with CH_4 to give ions as large as $WC_8H_{16}^{\oplus}$ (Fig. 1 shows the first condensation steps). The exothermicity of the dehydrogenative CH_2 coupling [Eq. (c)] implies

$$M^{\oplus} + n\,CH_4 \longrightarrow [MC_nH_{2n}]^{\oplus} + n\,H_2 \qquad (c)$$

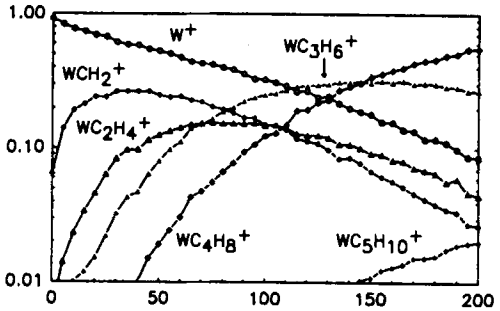

Fig. 1. Reaction of labeled $^{186}W^{\oplus}$ with methane (3.5×10^{-6} Torr). The relative intensity I is plotted against the reaction time t.

unusually strong bonding of the C_nH_{2n} fragment to the metal ion. Thermochemical considerations reveal that, for n = 4, for example, each of the two metal–carbon bonds in the resulting metallacyclopentane has a bond energy of at least 69 kcal mol^{-1}.

Beauchamp's observation may be of fundamental importance for the understanding of elementary processes in C_1 chemistry, since this is the first time that the coupling of CH_2 units, which is so characteristic of Fischer–Tropsch synthesis, does *not* have to take place at several metal centers.

It should be mentioned that doubly charged transition-metal cations $M^{2\oplus}$ (M = Nb, Ta, Zr) are also capable of inducing dehydrogenation and Fischer–Tropsch-like coupling of CH_4 [Eq. (d)],[12] in addition to hydride- and charge-transfer reactions. Owing to competition with hydride and electron transfer [Eqs. (e) and (f)], however, this variant is only of interest in special cases.

$$M^{2\oplus} + CH_4 \longrightarrow [MCH_2]^{2\oplus} \longrightarrow [MC_nH_{2n}]^{2\oplus}, [MC_nH_{2n-2}]^{2\oplus} \qquad (d)$$
(Nb, Ta, $n \leq 6$; Zr, $n \leq 5$)

$$M^{2\oplus} + CH_4 \longrightarrow MH^{\oplus} + CH_3^{\oplus} \qquad (e)$$

$$M^{2\oplus} + CH_4 \longrightarrow M^{\oplus} + CH_4^{\oplus\cdot} \qquad (f)$$

Of particular interest is the direct oxidation of methane to methanol by oxometal fragments [Eq. (g)], which is very important for the mechanism of the σ-metathesis reaction described by Equation (h) and, in the area of enzyme-mediated processes, for the mechanism of methane monooxygenase.[1] The investigation of these processes with isolated metal ions can justifiably be regarded as providing models for the complicated processes of heterogeneous or enzymatic catalysis. If entropic effects are ignored to a first approximation, since

$$[M{=}O]^{\oplus} + CH_4 \longrightarrow M^{\oplus} + CH_3OH \qquad (g)$$
$$(\Delta H_r^{\circ} = D(M^{\oplus}\text{-}O) = -90.0 \text{ kcal mol}^{-1})$$

$$[M{=}O]^{\oplus} + CH_4 \longrightarrow [M{=}CH_2]^{\oplus} + H_2O \qquad (h)$$
$$(\Delta H_r^{\circ} = D(M^{\oplus}\text{-}O) - D(M^{\oplus}\text{-}CH_2) = -6.6 \text{ kcal mol}^{-1})$$

[*] Prof. Dr. H. Schwarz
Institut für Organische Chemie der Technischen Universität
Strasse des 17. Juni 135, W-1000 Berlin 12 (FRG)

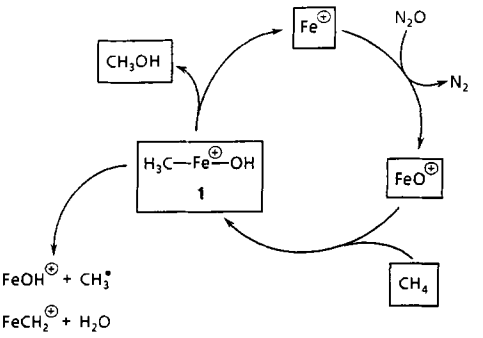
they are presumably small for gas-phase reactions, then the reactions described by Equations (g) and (h) will only proceed if they are exothermic.

Straightforward thermochemical considerations lead to the values given below the equations; for example, both processes are favored for those metals whose $D(M^{\oplus}\text{-}O)$ value is relatively small.

Whereas initial attempts to carry out reactions analogous to Equations (g) and (h) failed, the groups of *Beauchamp*[9] and *Schwarz*[14] have recently shown that both $OsO^{\oplus}$ and $FeO^{\oplus}$ [Eq. (i)] are able to activate CH_4. The most recent investigations[15] have provided further evidence on the intermediates involved along the $[Fe,C,H_4,O]^{\oplus}$ hypersurface, for example, $CH_4 \cdot FeO^{\oplus}$, $FeOH^{\oplus} \cdot CH_3$, $CH_3Fe(H)O^{\oplus}$, and $H_2C{=}Fe(H)OH^{\oplus}$.

$$FeO^{\oplus} + CH_4 \xrightarrow{\begin{array}{l}(57\%)\\(2\%)\\(41\%)\end{array}} \begin{array}{l}[FeOH]^{\oplus} + CH_3^{\bullet}\\ [FeCH_2]^{\oplus} + H_2O\\ Fe^{\oplus} + CH_3OH\end{array} \quad (i)$$

Although $Fe^{\oplus}$ was used in equimolar amounts in the experiments described so far [Eq. (i)], the possibility of a *catalytic* activation of CH_4 with $FeO^{\oplus}$ remains, since the $Fe^{\oplus}$ generated in the course of reductive elimination of CH_3OH can be reoxidized with N_2O, for example, and can thereby reenter the cycle (Scheme 1).[16]



Scheme 1.

Presumably, the metal centers in enzyme-catalyzed and in enzyme-free processes of alkane oxidation are high-valent ionic iron oxides in systems containing iron.[1, 2, 13, 17] The exact oxidation state of iron and the precise composition of the active centers are still matters of speculation. Recently, gas-phase experiments in which the stoichiometry and oxidation states were perfectly controlled showed[18] that the Fe^{IV} oxide $[O{=}Fe{-}OH]^{\oplus}$ is also capable of oxidizing CH_4 [Eq. (j)].

Noteworthy is the finding that $[O{=}Fe{-}OH]^{\oplus}$, a 12-electron complex, yields no products of radical nature, in contrast to $FeO^{\oplus}$ (an 11-electron complex). This result is presumably of importance for understanding the mechanism of enzyme-mediated oxygenations.

$$[O{=}Fe{-}OH]^{\oplus} + CH_4 \xrightarrow{\begin{array}{l}(25\%)\\(10\%)\\(65\%)\end{array}} \begin{array}{l}[FeOCH_3]^{\oplus} + H_2O\\ [HFeOH_2]^{\oplus} + CH_2O\\ [FeOH]^{\oplus} + CH_3OH\end{array} \quad (j)$$

Irikura and *Beauchamp*[19] recently reported on their attempts to generate porphyrin complexes, $[MP]^{\oplus}$, in the gas phase and to use these—after oxidation to the corresponding oxo complexes—as enzyme-like models for the C–H oxygenation mediated, for example, by cytochrome P-450. Although both the preparation of $[MP]^{\oplus}$ and its oxidation to $[Fe(P)OH]^{\oplus}$ were accomplished, $[Fe(P)O]^{\oplus}$ has not yet been synthesized, but perhaps this is only a matter of time.

Light-Directed Parallel Synthesis of Up to 250000 Different Oligopeptides and Oligonucleotides**

By *Günter von Kiederowski**

The development of enzyme inhibitors based on oligopeptides makes it imperative to prepare a daunting number of oligopeptides with different sequences and to test their binding properties in order to find an optimally binding ligand. Even if we restrict ourselves to the twenty naturally occurring amino acids, $20^2 = 400$ dipeptides, $20^3 = 8000$ tripeptides, and in general 20^N oligopeptides of length N are possible. A systematic testing of all sequence alternatives with conventional techniques is already out of the question with tetrapeptides (160000 compounds). Molecular modeling and quantitative structure–activity relationships rule out many sequence alternatives based on a known guide sequence, but for a "rational drug design"[1] in the true sense, a three-dimensional structure of the receptor must be known. The prerequisite for "irrational drug design"[2] (i.e., the filtering out of binding sequencer from the pool of statistical sequences) is the ability to isolate the best ligand in pure form and in high enough quantities for a structure determination—or it must be possible to raise the concentration to the required level. This last criterion restricts irrational drug design largely to biopolymers that can be cloned (e.g., antibodies) or replicated in vitro (nucleic acids). Such attempts to select and amplify biomolecules possessing the desired binding properties have already been honored in a Highlight in this journal.[3]

Recently *Fodor* et al. described a chemical method for irrational drug design.[4] A combination of three processes—solid-phase synthesis, photolithography, and affinity labeling—makes it possible to lay down next to each other up to 250000 different oligopeptides or oligonucleotides per square centimeter on a glass slide and to test their binding to a given receptor molecule. The principle of photolithographic solid-phase synthesis is shown in Figure 1 for the example of the parallel construction of two dipeptides from two amino acids.

The glass surface is first treated with 3-(aminopropyl)triethoxysilane and then the free amino groups, now bound the the glass surface by a C_3 spacer, are protected with a nitroveratryloxycarbonyl (NVOC) group (Step **I**), which can be photochemically removed. On illumination (Step **II**) only those NVOC groups that are not covered by an opaque mask are removed. The irradiated amino groups on the surface (field **A**) are now acylated with the first amino acid, which is protected by NVOC and is activated as its 1-hydroxybenzotriazol (HOBt) ester (Step **III**). Field A is now masked, and field B exposed to light and thereafter acylated with the second amino acid, thus completing the first phase of the synthesis (Step **IV**). Further analogous irradiation and coupling steps construct the dipeptides in the second phase (Step **V**).

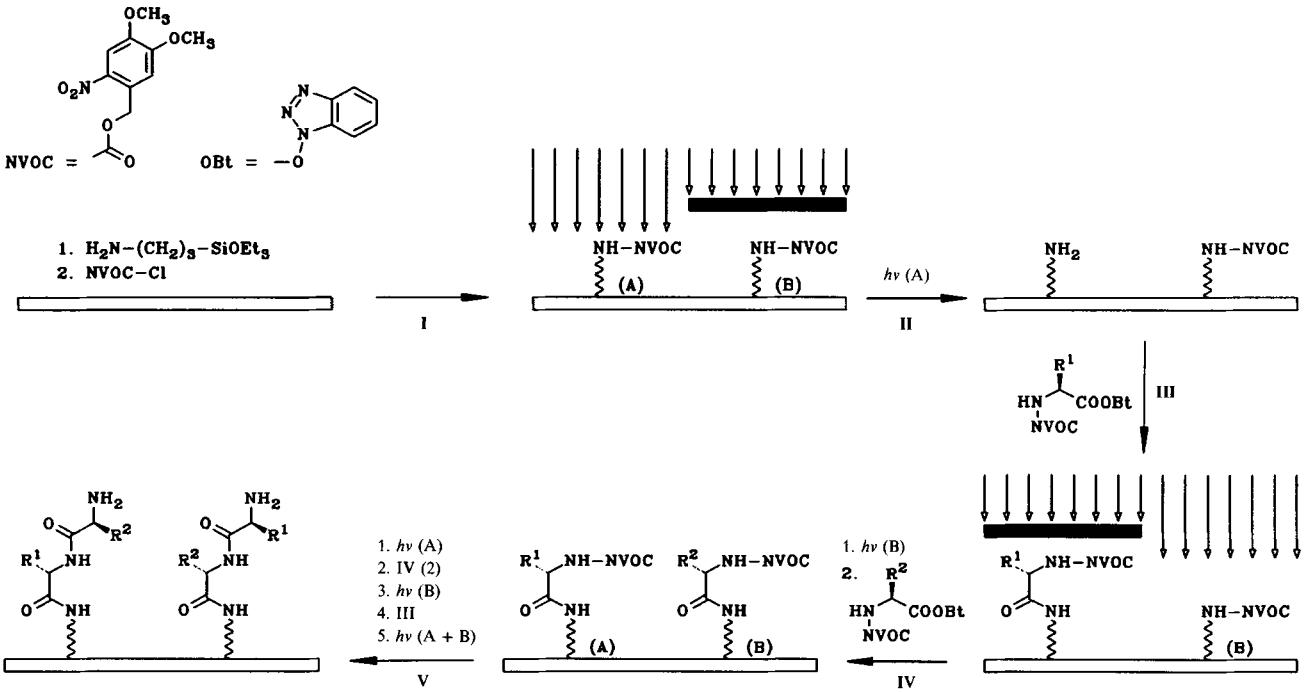

Fig. 1. Light-directed parallel synthesis of two dipetides from two amino acids in two irradiation fields.

In practice strips of the surface are exposed in each photolysis and coupling round of the synthesis. The strips irradiated in the next round lie perpendicular to those of the preced-

[*] Dr. G. von Kiedrowski
Institut für Organische Chemie der Universität
Tammannstrasse 2, W-3400 Göttingen (FRG)

ing round. This corresponds to oligopeptide construction in the rows and columns of a square matrix and enables a considerably shorter synthesis than were possible with successive illumination of each field. The shortest synthesis is achieved with the binary masking technique, in which the direction of the strip is changed in every cycle and its width is reduced to half every second cycle, while the number of strips in the mask is doubled. In this way, with n synthesis cycles 2^n different oligomers can be constructed, whose lengths are described by a binomial distribution (combinatorial synthesis). Ten synthesis cycles, for example, yield 1024 (minus 1) different peptides with "1 of length 0", and successively 10, 45, 120, 210, 252, 210, 120, 45, and 1 with lengths 1–10. Each peptide sequence is situated at one field of the (32 × 32) matrix.

The last irradiation step removes the *N*-terminal NVOC groups of all peptides; other deprotecting steps may be necessary to free the functional groups in side chains. For the affinity test the glass slide is simply held in a solution of the fluorescence-labeled receptor, rinsed, and scanned under the fluoresence microscope. The affinity of a peptide for a given receptor is determined from the fluorescence intensity of the corresponding field in the array. The authors demonstrated the whole process on a combinatorial synthesis of 1024 peptides, whose binding to the antibody 3E7 was to be tested. The 15 peptides with clearly recognizable affinity all begin with the sequence 5′-H_2N-Tyr-Gly. This result agrees with those by *Cwirla* et al., who claim an *N*-terminal tyrosine residue as the key determinant in the binding to 3E7.[5]

As light source, the authors used a mercury arc lamp, that required an exposure of 20 min at $\lambda = 365$ nm and 12 mW cm^{-2}. Shorter exposure times should be possible with an argon laser. To prevent excitation at aromatic side chains and, in particular, a photochemical decomposition of tryptophan, shorter wavelengths are not recommended. The total yield per synthesis cycle (irradiation and coupling) lies between 85 and 95%, so that for oligopeptides with more than ten amino acids the process only makes sense in exceptional cases. With mask technology a resolution of $> 20\ \mu m^2$ per synthesis field can be achieved; thus with $50\ \mu m^2$ elements, 250000 syntheses can be addressed on a glass cover slide for microscopy. The authors show that their process is not only restricted to oligopeptides, but can also be applied to light-directed oligonucleotide syntheses, in which case 5′-NVOC-protected nucleoside-3′-cyanoethylphosphoamidites are suitable monomeric building blocks.

Three critical questions must, however, be answered experimentally before a general application to affinity studies is recommended:

1. Does the carrier-bound oligopeptide have the same conformation as in solution?
2. Which spacer can be used as alternative to a C_3-chain, so that a large proportion of biological receptors can bind unhindered?
3. Can the yields of the synthesis cycles be improved, for instance, by the use of other protecting groups?

We wait in suspense for a report in the near future that the authors can suggest a solution to these problems. If this is the case it is foreseeable that light-driven parallel synthesizer machines, similar to the present peptide and DNA synthesis machines with soon revolutionize many university and pharmaceutical research laboratories. The site of the Affymax Research Institute of the authors in "Silicon Valley" will, of course, not hinder the the development of the first prototype of the commercial machines.

[1] H. Frühbeis, R. Klein, H. Wallmeier, *Angew. Chem. 99* (1987) 413; *Angew. Chem. Int. Ed. Engl. 26* (1987) 403.

[2] The term "irrational drug design" was recently proposed by *S. Brenner* at a symposium on natural and artificial selection processes (Max-Planck-Institut für Biophysikalische Chemie, Göttingen, 17th–19th April 1991). In contrast to "rational drug design", in which more or less detailed knowledge about the receptor, the ligands, and their interaction is available and does influence the development of better ligands, "irrational drug design" embodies attempts in the face of a void of knowledge in which a large repertoire of ligands are tested blindly.

In_7Cl_9—A New "Old" Compound in the System In-Cl**

By *Horst Philipp Beck** and *Doris Wilhelm*

Dedicated to Professor Hans Georg von Schnering on the occasion of his 60th birthday

The compounds In^ICl,[1,2] In_2Cl_3 ($In^I_3In^{III}Cl_6$),[3] In_5Cl_9 ($In^I_3In^{III}_2Cl_9$),[4] and $InCl_3$[5,6] have been unambiguously characterized in the system In-Cl. The phase diagram of the quasi-binary system InCl-$InCl_3$ has been investigated repeatedly by thermoanalytical methods.[7-10] The results indicated that, besides the above-mentioned compounds, a compound of composition In_3Cl_4 ($InCl_{1.33}$) or In_4Cl_5 ($InCl_{1.25}$) exists. However, this phase has still not been unambiguously characterized chemically or structurally. During our investigations of the system InCl-$SnCl_2$,[11] we discovered a new binary mixed-valent phase of the In-Cl system, since, surprisingly, the redox reaction between $In^{\oplus}$ and $Sn^{2\oplus}$ led to the formation of In^{III} according to the reaction equation $In^{\oplus} + Sn^{2\oplus} \rightarrow In^{3\oplus} + Sn^0$. This phase of composition In_7Cl_9 ($InCl_{1.29}$) can also be prepared directly from stoichiometric amounts of InCl and $InCl_3$ by sintering (14 d, 220–250 °C) or by sublimation from $InCl/In_2Cl_3$ mixtures. We believe that this phase is in fact the insufficiently characterized phase mentioned above.

The structure of In_7Cl_9 ($In^I_6In^{III}Cl_9$),[12] like that of the low-temperature phase of InCl, can be derived from the NaCl type. In both cases, relatively small displacements of the cations from their ideal positions result in aggregates of cations with ns^2 configuration: triangles and tetrahedra for InCl (with In^I–In^I distances of 3.61 to 3.68 Å) and only triangles for In_7Cl_9 ($d(In^I\text{-}In^I) = 3.87$ Å). In InCl, In^I_3 triangles are linked through bridging In^I cations to form a complex three-dimensional network with isolated In^I_4 tetrahedra in its cavities (Fig. 1, left). The transition from the InCl structure to that of In_7Cl_9 occurs formally by replacement of the bridging In^I cation by a $Cl^{\ominus}$ anion and of one corner of the tetrahedron by the higher-valent In^{III} cation. This change results in disruption of the network into individual triangles and, after displacement of the In^{III} corners of the tetrahedra, only the base triangles remain (Fig. 1, right).

This aspect of the structural relationship is particularly emphasized in the left and right side of Figure 1, which shows a comparable section of the cation partial lattice of the two compounds. For the sake of clarity, only the cations are shown in the picture of the α-InCl structure and, besides the cations, only the $Cl^{\ominus}$ ions (large circles) that replace In ions in the picture of In_7Cl_9. To clarify further the relationship to the tetrahedra in InCl, narrow lines are drawn from the In^{III} cations of In_7Cl_9 to the In^I triangles despite the relatively large separations. Replacement of the In^I cation by a halogen anion leads to a rotation of the surrounding In^I_3 aggregates in In_7Cl_9. As a result, the $Cl^{\ominus}$ ion is drawn closer to one of its cations (from about 3.6 to 3.2 Å) owing to Coulomb interaction. All In^I_3 triangles are now symmetrically equivalent.

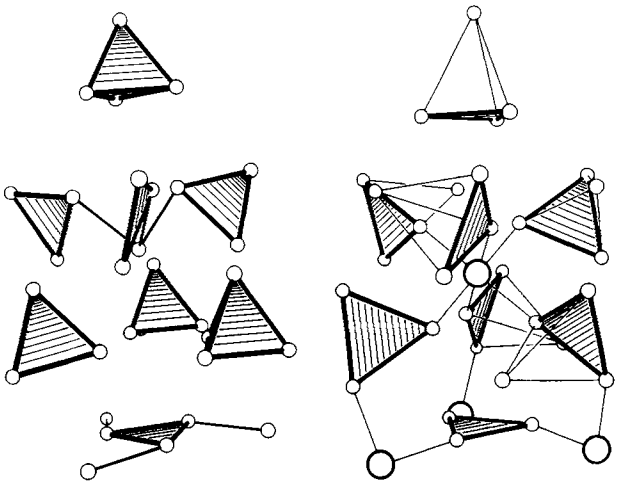

Fig. 1. Left: Cation structure in α-InCl. Right: Partial structure of In_7Cl_9 (see text). Small circles, In^I and In^{III}; large circles, $Cl^{\ominus}$. The separations are inversely proportional to the thickness of the lines drawn.

The In–In distances in InCl are about 10% longer than those in In metal. In In_7Cl_9 they are markedly longer, so that an interaction involving electron-pair bonding may be ruled out with certainty. In our view, the special aggregation to In_3 triangles best satisfies the steric requirements of a lone pair on indium (cf. Ref. [13]). Figure 2 shows the distorted anion coordination. The anion polyhedra, one of which is highlighted in bold lines, are open in the direction of neighboring cations. The repulsion between the ns^2 centers and the anions (noble-gas configuration) is thereby minimized (see also Refs. [14, 15]), in that lone pairs with strong excentricity[16]

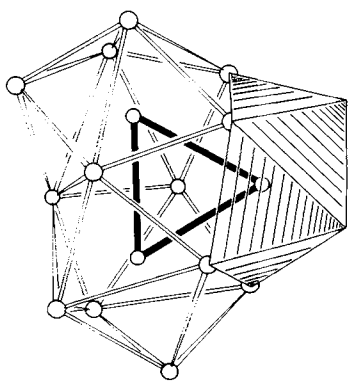

Fig. 2. Coordination of anions around an In_3 group. The In atoms are joined by bold dashed lines. One of the anion polyhedra is highlighted by bold lines.

are oriented toward the same region. The lowering of the ionicity by the smaller electronegativity of the ns^2-configurated cations[17] and the "mutual shielding" of the positive charge centers by the s^2 electrons[13] contribute to the stabilization of these unusual structures.

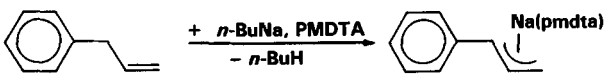
Phenylsodium Compounds with η^3-Allyl or η^6-Phenyl Coordination**

By *Siegfried Corbelin, Jürgen Kopf, Nis Peter Lorenzen*, and *Erwin Weiss**

Dedicated to Professor Hans Georg von Schnering on the occasion of his 60th birthday

After a phase of intensive structural investigation of organolithium compounds, interest is turning increasingly toward organosodium compounds.[2] The latter are accessible by metalation of hydrocarbons[3] with *n*-butylsodium, although the applicability of this method of synthesis is limited.[1]

Reaction of allylbenzene with *n*-butylsodium gave bright yellow 1-phenylallylsodium, which, on addition of the chelator PMDTA (pentamethyldiethylenetriamine) or directly in



1

a one-pot reaction, afforded the solvate [Na(1-PhC_3H_4-(pmdta)] (**1**). The X-ray structure analysis of **1** shows a contact ion pair with η^3 coordination of the allyl system (Fig. 1).

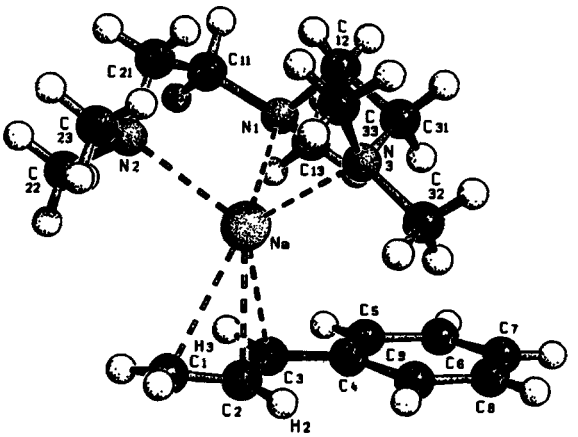


Fig. 1. Molecular structure of **1** [5]. Important distances [pm] and angles [°]: Na-C1 279.1(9), Na-C2 257.7(7), Na-C3 267.6(3), Na-N1 243.1(5), Na-N2 242.8(5), Na-N3 245.6(5), C1-C2 130.9(14), C2-C3 146.9(9), C3-C4 141.8(6), C4-C5 142.0(9), C5-C6 139.6(10), C6-C7 137.5(10), C7-C8 137.8(13), C8-C9 137.4(11), C9-C4 141.2(9); C1-C2-C3 127.2(8), C5-C4-C9 115.8(6), C4-C5-C6 121.4(6), C5-C6-C7 120.4(7), C6-C7-C8 119.2(7), C7-C8-C9 121.4(7), C8-C9-C4 121.5(7).

Only a few allyllithium compounds have been investigated so far by X-ray methods, although allyl anions are of special interest as simple resonance-stabilized systems. Examples include [Li(η^2-C_3H_5)(pmdta)],[8] [Li(η^3-1,3-$Ph_2C_3H_3$)-(Et_2O)]$_n$,[9a] and [Li{η^3-1,3-$(SiMe_3)_2C_3H_3$}(tmeda)].[9b] For allyllithium, ab initio calculations correctly predicted the deformations in the allyl anion caused by the metal[10] and, moreover, favored a Li site on the mirror plane of the allyl anion. Only for [Li(η^2-C_3H_5)(pmdta)] did the X-ray structure analysis reveal a strongly asymmetric site with η^2 coordination, due largely to the bulky PMDTA ligand.

NMR investigations and MO calculations indicate that allylsodium should also be symmetric (C_s).[11] In agreement with these findings, the allyl system in **1** is η^3-coordinated as in other metalated allyl systems. However, the middle C atom, C2, exhibits the shortest Na–C contact (258 pm). The distances to the outer C atoms, C1 and C3 (279 and 268 pm, respectively), differ, although this is expected owing to the different substitution of the terminal C atoms. The C–C distances within the allyl system differ by an unexpectedly large amount (131 and 147 pm). On the other hand, the increase in the angle of the allyl group (127°) and the decrease in the angle (116°) at the *ipso*-C atom of the phenyl group, C4, appear normal; the latter, for example, is observed for [NaPh(pmdta)]$_2$ as well.[12]

We obtained 1-phenylcyclohexenylsodium, a further carbanion with a phenyl-substituted allyl system, in the same

2

way by metalation of 1-phenylcyclohexene and isolated it as the PMDTA solvate **2**.

Because of the close analogy to **1**, we also expected an η^3 coordination of the allyl moiety here. Surprisingly, however, the X-ray structure analysis (Fig. 2) showed an η^6 coordination of the phenyl moiety, whereby the Na ion is sandwiched between the chelating ligand and the carbanion.

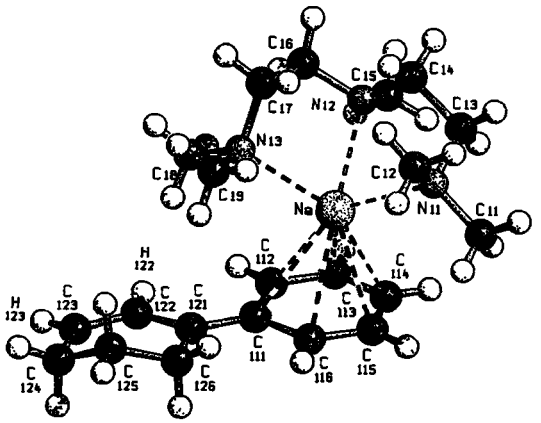

Fig. 2. Molecular structure of **2** [13]. Important distances [pm] and angles [°]: Na-C111 295.8(2), Na-C112 294.5(2), Na-C113 286.6(3), Na-C114 275.2(3), Na-C115 270.1(2), Na-C116 277.4(2), Na-N11 254.0(2), Na-N12 244.3(2), Na-N13 244.5(2), C111-C112 144.0(3), C112-C113 138.1(3), C113-C114 139.5(3), C114-C115 138.9(4), C115-C116 138.5(3), C111-C116 143.7(3), C111-C121 141.1(3), C121-C122 143.1(3), C122-C123 135.9(4), C123-C124 148.2(4), C124-C125 151.4(4), C125-C126 151.2(4), C126-C121 149.2(3); C112-C111-C116 113.4(2), C111-C112-C113 123.0(2), C112-C113-C114 121.4(2), C113-C114-C115 117.7(2), C114-C115-C116 121.8(2), C115-C116-C111 122.7(3), C121-C122-C123 124.3(2).

What is the reason for the different coordination of the two anions? The $[Na(pmdta)]^{\oplus}$ ion has a nearly hemispherical shape; that is, the metal ion is shielded on one side. In **2**, a close approach of $[Na(pmdta)]^{\oplus}$ to the allyl system is prevented by steric interaction between the H atoms of the methyl groups of PMDTA and the neighboring CH_2 groups (C124–126). The negative charge of the planar, conjugated carbanion is also delocalized over the phenyl moiety, however. For steric and electrostatic reasons, therefore, the solvated cation prefers to shift along this negatively charged hypersurface to the phenyl group, where it is optimally coordinated.

The six Na–C distances are not identical (270 pm (C115) to 296 pm (C112)); thus, the η^6 coordination is not symmetrical. According to all previous experience,[14, 16] the metal–C interactions in organosodium compounds are more flexible than in their lithium analogues. The deformation of the coordination geometry in **2** can therefore be explained in terms of packing effects in the lattice. In any case, the Na ion interacts with only one carbanion; all other Na–C distances to symmetry-related carbanions are larger than 460 pm and therefore meaningless.

The angles in the phenyl group are not identical; they are significantly smaller than 120° at the opposite-lying C atoms C111 and C114. The C–C distances in the phenyl group correlate with the corresponding Na–C distances: short C–C distances are associated with short Na–C distances. In the allyl system, the C–C distances are significantly shorter than those between the sp^3-hybridized C atoms C124 to C126 (151 pm).

Important in this context is tetraphenylallylsodium–diethyl ether, recently characterized by X-ray analysis.[15] In this case, too, the Na ion cannot approach the allyl system for steric reasons and is therefore sandwiched between two phenyl rings. An additional ether molecule coordinated to the Na ion closes the cage formed by the phenyl groups.

Experimental Procedures

1: a) 1-Phenylallylsodium: *n*-Butylsodium [3,4] (1.8 g, 23 mmol) was suspended in a mixture consisting of 70 mL of benzene and 30 mL of *n*-hexane and the stirred solution was treated dropwise with allylbenzene (3 mL, 23 mmol). The reaction mixture was stirred for 3 h and the precipitated, finely crystalline 1-phenylallylsodium was then collected by filtration, washed with a mixture of 50 mL of hexane and 20 mL of benzene, and dried under reduced pressure. The product was obtained as a deep yellow, pyrophoric crystalline powder (needles), which is sparingly soluble in hexane and benzene; under inert gas, it is stable from some time in the dark. Yield 2.84 g (90%) (contains some *n*-butylsodium). b) 1-Phenylallylsodium (0.6 g, 4.3 mmol) was suspended in a mixture of 10 mL of hexane and 2 mL of benzene and then largely dissolved by addition of PMDTA (10 mL, 5 mmol) with stirring. The solution was cooled to 10 °C, filtered, and allowed to stand at 7 °C; after a long period of time, intense yellow, very pyrophoric needles of **1** formed. Yield 0.5 g (38%); soluble in hexane, readily soluble in benzene. Correct analyses for Na, C, H, N. Compound **1** was also obtained directly from *n*-butylsodium, allylbenzene, and PMDTA in 28% yield, in analogy to the synthesis of **2**.

2: *n*-Butylsodium (2.6 g, 32 mmol) was suspended in 50 mL of hexane and dissolved by addition of PMDTA (6.3 mL, 30 mmol, dried over CaH_2). A solution of 1-phenylcyclohexene (5 g, 32 mmol) in 100 mL of benzene was then added in a single portion to the yellow, turbid solution. The solution immediately turned red and violet **2** (8.7 g) precipitated. Compound **2** was collected by filtration and dried under oil-pump vacuum. When the filtrate was allowed to stand at 7 °C, an additional 0.9 g of **2** was obtained, including single crystals suitable for X-ray structure analysis. Air-sensitive, but not pyrophoric. Total yield 9.6 g (90%, based on *n*-BuNa); correct analyses for Na, C, H, N.

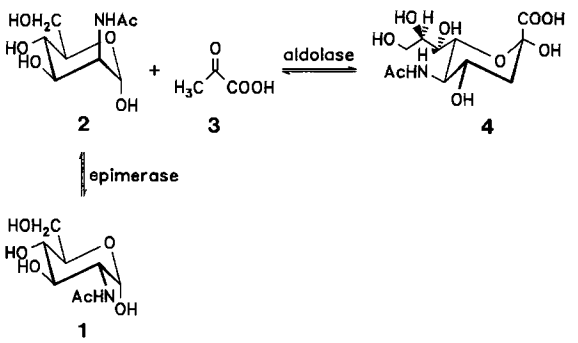
Enzymatic Two-Step Synthesis of *N*-Acetylneuraminic Acid in the Enzyme Membrane Reactor

By *Udo Kragl, Daniel Gygax, Oreste Ghisalba,* and *Christian Wandrey**

N-Acetylneuraminic acid (Neu5Ac, **4**) is the best-known member of a special class of amino sugars, the sialic acids. These compounds are incorporated at the terminal positions of glycoproteins and glycolipids, which play an important role in biological recognition processes.[1, 2] Derivatives of Neu5Ac have found use as inhibitors of sialidases.[3] Neu5Ac activated with cytidine 5'-monophosphate has been used in the in vitro synthesis of sialyloligosaccharides.[4] Since this class of substances has attracted increasing interest owing to its biological function, increasing amounts of Neu5Ac are required. The compound is isolated from natural sources at present. Its accessibility is therefore limited and its price relatively high.

In recent years several enzymatic syntheses of Neu5Ac (**4**) starting from *N*-acetylmannosamine (ManNAc, **2**) and pyruvic acid (**3**), have been described with *N*-acetylneuraminic acid aldolase (E.C. 4.1.3.3) as catalyst.[5] A seven- to tenfold excess of **3** was usually used in order to attain high yields. Compound **2** was prepared chemically by base-catalyzed epimerization of *N*-acetylglucosamine (GlcNAc, **1**).[6] The reaction product contains the two epimers in a ratio of about 1:1. Compound **1** is not a substrate for the aldolase.[5]



Here we describe a procedure in which the epimerization is accomplished enzymatically with *N*-acetylglucosamine 2-epimerase (E.C. 5.1.3.8).[7] Coupling this reaction with the enzyme reaction mentioned above allows **2** to be converted directly into **4** without isolation. The synthesis of Neu5Ac (**4**) can be achieved in a particularly economic way by using the two enzymes in dissolved form in the enzyme membrane reactor (EMR).

The use of purified enzymes in the EMR is an established procedure.[8] The principle behind the EMR is shown schematically in Figure 1. The substrates are pumped into the reactor through a sterile filter at a constant rate corresponding to a constant residence time. The enzymes, in homogeneous solution, are retained in the reactor by an ultrafiltration membrane that is permeable only to the substrates and products. The setup is sterilized before use, so that the addition of antibacterial agents, which would have to be separated from the products, is unnecessary.

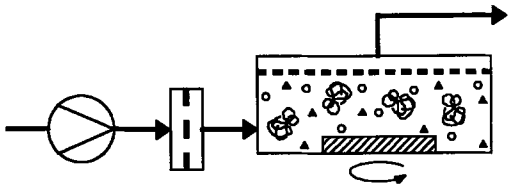


Fig. 1. Principle of the enzyme membrane reactor with pump and sterile filter.

Batch experiments and kinetic investigations were carried out to determine the conditions for continuous use of the two enzymes. Both enzymes can be used in a pH range of 7.0 to 8.0 without loss of activity or stability. Since the EMR operates as a continuously stirred tank reactor with constant discharge, the pH in the reactor can be held constant at 7.5 by controlling the pH of the substrate solution. Buffers are completely unnecessary, so that the workup is simplified. Based on the equilibrium position of the reaction of **2** and **3** to give **4**, the temperature was set at 25 °C ($K_{25} = 28.7$ L mol^{-1}).[9] Lower temperatures shift the equilibrium to the product side; K was found to be 83.1 L mol^{-1} at 10 °C. However, the activity of the aldolase at this temperature is only 20% of that at 25 °C, so that high conversion can only be achieved by increasing the residence time. The enzyme concentration cannot be raised arbitrarily to compensate for the lower activity, since, at high concentrations, only part of the protein is in the active conformation.

The epimerase requires ATP and $Mg^{2\oplus}$ for activation, so that these substances must be added to the substrate solution.[7] The aldolase is inhibited only very weakly by **1** (19% loss of activity when 200 mM **1** is used in the synthesis) and not at all by $MgCl_2$ and ATP. Since the epimerase is inhibited by **3**, a multiple excess of **3** cannot be employed. On the other hand, high concentrations of **1** lead to higher intermediate concentrations of **2**, which shift the equilibrium position of the second reaction toward Neu5Ac. This is also advantageous in view of the chromatographic isolation of the product with anion exchangers, since **3** and **4** exhibit similar pK_a values in the region around 2.2. Compounds **1** and **2** are not bound and can easily be recovered. The concentration–time curve for the continuous synthesis of **4** is shown in Figure 2. After an initial phase, all compounds attain a constant concentration.

In this way, 15 g of Neu5Ac was synthesized and isolated with a space–time yield of 109 $g L^{-1} d^{-1}$ (based on the reactor volume). A decrease in the conversion, which would have indicated deactivation of the enzyme, was not observed. Moreover, by-products, which would have indicated lowered enzyme selectivity, were not found. In the reaction, 28% of **1** was converted and 35% of **3**; 64% of **2**, formed as an intermediate, was converted. When an epimeric mixture

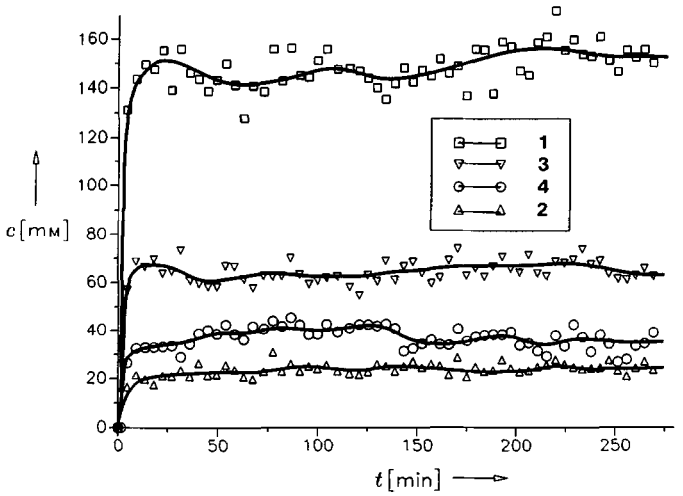

Fig. 2. Concentration–time curve for the continuous synthesis of *N*-acetylneuraminic acid (**4**) in the enzyme membrane reactor. Starting concentrations: 200 mM **1**, 100 mM **3**, 5 mM ATP, 5 mM $MgCl_2 \cdot 6H_2O$; pH 7.5; 25°C; 11.9 $mg mL^{-1}$ epimerase; 4.0 $mg mL^{-1}$ aldolase; residence time 171 min.

of **1** and **2** was used, conversions of between 80 and 90% in 4–5 days were reported, whereby **4** was isolated in yields of up to 67%.[5] In order to achieve the higher conversion, an eightfold excess of **3** was employed. The ratio of excess **3** to the product formed, **4**, has a large effect on the isolation of product, however. This value is about 1.9 in our work, whereas it was about 8 in earlier studies.[5] The smaller this value, the easier it is to isolate the products by chromatography. At the same time, the required volume of exchanger is reduced, resulting in savings in both time and cost.

The procedure described here, which can be scaled up, allows Neu5Ac (**4**) to be prepared in large amounts directly from inexpensive GlcNAc (**1**).

Experimental Procedure

The EMR (volume 14.3 mL) was sterilized with 0.1 percent peracetic acid. The ultrafiltration membrane (YM-5, Amicon, Witten) was pretreated with 1 $mg mL^{-1}$ of bovine serum albumin. After addition of 11.9 $mg mL^{-1}$ of epimerase (0.1 $U mg^{-1}$) and 4.0 $mg mL^{-1}$ of aldolase (8.5 $U mg^{-1}$) (both enzymes from Toyobo, Osaka, Japan), the substrate solution (1400 mL, 200 mM **1**, 100 mM **3**, 5 mM ATP, 5 mM $MgCl_2 \cdot 6H_2O$, ph 7.5, no buffer) was pumped through the reactor with a residence time of 171 min. The pH was controlled by taking samples from the reactor outlet, and the amounts of the various components were determined by HPLC. HPLC conditions: BioRad Aminex HPX-87H column, 6 mM sulfuric acid eluent, 0.9 $mL min^{-1}$ flow rate at 65°C; photometric detection at 205 nm. Isolation of the product was carried out in analogy to the described procedure by anion-exchange chromatography on Dowex 1X2, 200–400 mesh, formate form, using gradient elution with formic acid (0 to 0.5 M) [2]. The neuraminic acid fractions were lyophilized. Yield 15 g (35%). The 200-MHz ^1H NMR spectrum in D_2O is in agreement with the literature data [5, 10]; purity according to HPLC > 99%; $[\alpha]_{25\,°C}^{D} = -28.8°$ ($c = 1$ in H_2O), identical with commercially available **4**; correct elemental analysis.

Do Partial Charges Alone Govern the Relative Stability of the Isomeric Heptaheteronortricyclane Anions $[P_{7-x}As_x]^{3\ominus}$?**

By *Armin Burkhardt, Wolfgang Hönle,** and *Ulrich Wedig*

Dedicated to Professor Hans Georg von Schnering on the occasion of his 60th birthday

Mixed crystals with the composition $Rb_3[P_{7-x}As_x]$ ($O \leq x \leq 7$) can be synthesized from stoichiometric amounts of the elements at 900 K. The dark red mixed crystals with $x \approx 3$ dissolve completely in ethylenediamine. The ^{31}P NMR spectrum shows that, as in the polyphosphides M_3P_7 (M = Li–Cs), trianions with heteronortricyclane structure (cf. Fig. 1) are present and show valence tautomerism at room temperature. According to the intensities of the ^{31} P NMR signals, a particular P/As ratio is not favored in the cluster.[1]

Böhm and *Gleiter*[2] employed MINDO/3 calculations to investigate the valence tautomerism of $P_7^{3\ominus}$. They analyzed the charge distribution in the trianion and the structure of the transition state and calculated an activation energy of 59.12 $kJ mol^{-1}$ for the tautomerism. This value is in good agreement with the results of the variable-temperature ^{31}P NMR investigations of *Baudler* et al.[3, 4]

Gimarc and *Joseph* applied the concept of "topological charge stabilization" to mixed nortricyclane clusters.[5] They thereby interpreted the experimental findings of *Blachnik* and *Wickel*, who showed that mainly PA_3S_3 was present in a mixture of P_4S_3 and As_4S_3 in a 1 : 3 molar ratio.[6] According to their concept, particularly stable structures are formed when, in a homoatomic isoelectronic reference system, the positions of greatest charge density are occupied by those heteroatoms with the largest electronegativity. They determined the charge density at each position by population analysis starting from an extended Hückel wave function for

[**] This work was supported by the Bundesministerium für Forschung und Technologie and by the Hoechst AG.

$P_7^{3\ominus}$. In later work, *Gimarc* and *Ott* used the same approach to make, for example, predictions about the relative stability of clusters with the composition $[P_{7-x}As_x]^{3\ominus}$.[7]

Prompted by discrepancies between predictions made in this way and our NMR investigations,[1] we carried out restricted Hartree–Fock calculations[8] on clusters with the composition $[P_{7-x}As_x]^{3\ominus}$ ($x = 0,1,2,3,7$). To ensure reliable ab initio treatment of the valence shell on the one hand and to limit the required calculations on the other, we used pseudopotentials adjusted to ionization and excitation energies.[9] A double zeta basis set with polarization functions (DZP), which was optimized for these pseudopotentials, was used.[10] Expansion of the basis set to include diffuse s and p functions (DZPD)—as usually carried out for anions—led to no significant changes in the structural parameters (Table 1). Moreover, because of the structural interrelationship of the clusters discussed, the valence electron correlation was not expected to affect significantly the properties observed. All cluster structures, as well as the transition state postulated in Ref. [2], were optimized in the highest point group symmetry possible.

Table 1. Comparison of the independent structure parameters ($C_{3v} - 3m$) of $P_7^{3\ominus}$ and Li_3P_7, obtained in HF calculations using different basis sets, with the experimental values for Li_3P_7, (energies in Hartrees, distances in $a_0 = 5.29 \times 10^{-11}$ m, angles in °). For the structure of $P_7^{3\ominus}$ see Figure 1, *top left*.

	Isolated $P_7^{3\ominus}$			Li_3P_7
	DZP	DZPD	exp. [13]	DZP [10]
E_{val}	−44.664092	−44.695588	–	−67.466587
ε_{homo}	+0.196383	+0.169834	–	−0.283442
r_{bb} [a]	4.25	4.24	4.26	4.19
r_{be} [a]	4.09	4.09	4.05	4.16
r_{ae} [a]	4.18	4.18	4.17	4.15
ω_{eae} [a]	102.6	102.4	101.7	101.0

[a] r_{bb}, distance between the basal atoms; r_{ae}, distance between the equatorial and the apical atoms; r_{be}, distance between the equatorial and basal atoms; ω_{eae}, equatorial-apical-equatorial angle.

Ab initio calculations on isolated anionic systems are problematic, because orbitals with positive orbital energies can be occupied. This indicates that such systems are not stable in the context of the Hartree–Fock approximation. These orbital energies can be reduced to zero by including continuum functions.[11] Work of *Pyykkö* et al. shows, however, that the structures of anionic systems optimized at the Hartree–Fock level are in good agreement with the experimental structures.[12] This is ascribed to the use of a restricted basis set, which is optimized for binding states, and to stabilization of these systems by counterions in the solid state or in solution.

We, too, have found that our calculations for the free ion $P_7^{3\ominus}$ and for Li_3P_7 are in good agreement with the experimental structure data (Table 1).[13] The deviations for Li_3P_7 are due to the omission of the solvent molecules and to the small Li–P distances. Nonetheless, the agreement is good enough to justify the use of the method and to obviate the calculation of the normal frequencies.

The structures and partial charges of $P_7^{3\ominus}$, the postulated transition state (TS) involved in valence tautomerism, and the most stable isomers of $[P_5As_2]^{3\ominus}$ and $[P_4As_3]^{3\ominus}$ are shown in Figure 1. To name these isomers, we use the number of the apical, equatorial, and basal As atoms (cf. Fig. 1). If this approach does not result in an unambiguous classification, a descriptor Z is added when an equatorial and a basal As atom are neighboring, and a descriptor E when this is not the case.

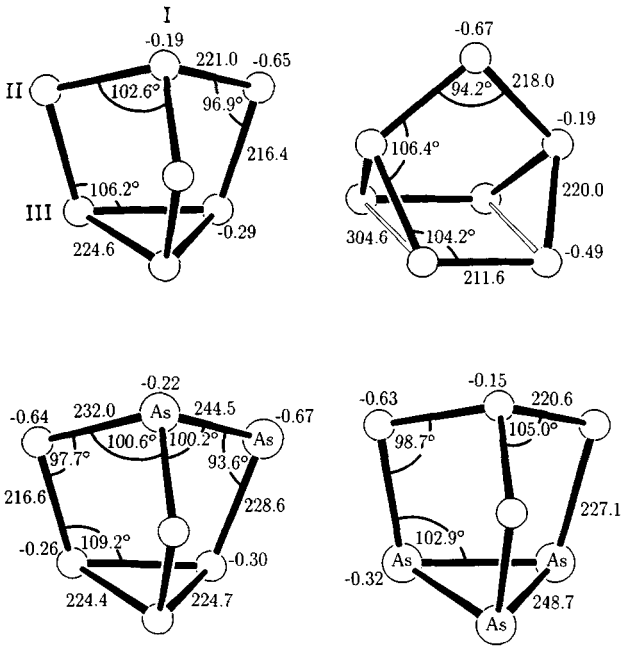

Fig. 1. Optimized structures of selected heteronortricyclane anions. The Mulliken partial charges, as well as important bond lengths [pm] and bond angles, are given. The arsenic atoms are specially labeled. Top left: $P_7^{3\ominus}$, ground state ($C_{3v} - 3m$). Top right: transition state (TS) ($C_{2v} - 2m$). Bottom left: $[P_5As_2]^{3\ominus}$, isomer 110 ($C_s - m$). Bottom right: $[P_4As_3]^{3-}$, isomer 003 ($C_{3v} - 3m$). *I* = apical, *II* = equatorial, *III* = basal position.

The partial charges for $P_7^{3\ominus}$ and its postulated transition state are more balanced than those determined by *Böhm* and *Gleiter*[2] and the interatomic distances are slightly larger. We found an activation energy of 65.6 kJ mol^{-1} for the valence tautomerism of this ion, a value also in good agreement with Ref. [2]. For $As_7^{3\ominus}$—in which valence tautomerism has not yet been experimentally observed—we calculated an activation energy of 63.5 kJ mol^{-1}. Replacement of a P atom by an As atom in the mixed clusters led to an increase in the corresponding bond lengths by 12–24 pm and to considerable deformation of the cluster. The Mulliken partial charges

Table 2. Valence energies in Hartrees for selected heteronortricyclanes $[P_{7-x}As_x]^{3\ominus}$ obtained by Hartree–Fock calculations. Energies are given in kJ mol^{-1} of the energetically favored isomer in each case. See text for the nomenclature of the isomers.

on the As atoms are only slightly larger than those on the corresponding P atoms, in agreement with recent electronegativity values.[14]

A glance at Table 2 shows that the difference in energy between the individual isomers is less than 7.4 kJ mol^{-1}, which corresponds to only about 10% of the activation energy of valence tautomerism. Thus, the valence tautomerism is not expected to favor specific isomers and a classification of the isomers as stable, metastable, and unstable is inappropriate. In view of the method used, the small differences between the isomers do not allow far-reaching conclusions to be drawn.

These results contradict the predictions of *Gimarc* and *Ott*,[7] who assumed in their work that the relative energy differences were considerably larger than the rotational barrier found. It is therefore unsatisfactory to consider relative cluster stability only in terms of its dependence on partial charges, since this ignores a number of important factors such as bond energy, polarizability, and, above all, framework strain, which is undoubtedly present in the clusters examined. Here we use $[P_4As_3]^{3\ominus}$ to discuss the effect of substitution by arsenic on framework strain.

The bond angle of 60° necessary for formation of the basal three-membered ring—without consideration of the bent bonds present—requires less angle deformation energy for an element with larger atomic radius. Furthermore, the bonds in the ring are thereby considerably lengthened, resulting in less angle deformation at the equatorial and apical atoms. This explains not only the stability of PAs_3S_3[6] but also a series of experimental findings which show that phosphorus can readily be replaced by arsenic if the strain in the pure phosphorus framework is thereby reduced. Examples are arsenic-substituted Hittorf phosphorus with the composition $P_{20}As$, helical structures of the type $M(P_{1-x}As_x)_7$ with M = Li,Na and $x \leq 0.50$, and $P_2As_2S_7$. In the first case, exclusively one position is occupied by 0.5 As[15] and, in the second case, the substitution is governed by the decreasing strain on going from the periphery to the axis of the helix.[16] In the third case, a long P–P bond in P_4S_7 is substituted in such a way that the framework strain decreases.[7]

$Li_{10}P_4N_{10}$—A Lithium Phosphorus(v) Nitride Containing the New Complex Anion $P_4N_{10}^{10\ominus}$**

By *Wolfgang Schnick** and *Ute Berger*

Dedicated to Professor Hans Georg von Schnering on the occasion of his 60th birthday

Phosphorus(v) nitrides, like the nitrides of other light main-group elements (boron, aluminum, silicon), are potential starting compounds for the development of new ceramic materials with special properties.[1] However, a systematic entry to the class of compounds comprising binary phosphorus(v) nitrides and their ternary compounds with electropositive elements has been hindered in the past, because the methods used to prepare these compounds did not lead to defined, pure or monocrystalline products. Recently, we employed a new method to prepare defined and finely crystalline P_3N_5.[2] We obtained pure Li_7PN_4, as well as $LiPN_2$, by reaction of the binary nitrides P_3N_5 and Li_3N. Exact structural characterization of these ternary nitrides led to the first detailed knowledge of the structure of phosphorus(v) nitrides in the solid state.[3, 4] "Isolated" $PN_4^{7\ominus}$ ions were found in Li_7PN_4, whereas, in $LiPN_2$, which has a P–N partial structure analogous to β-cristobalite, PN_4 tetrahedra are vertex-linked on all sides to produce the highest conceivable degree of interconnection. Both compounds show a noticeable cation mobility in the solid state and are therefore novel lithium ion conductors.[5]

We have now discovered $Li_{10}P_4N_{10}$, a new lithium phosphorus(v) nitride whose composition lies between those of Li_7PN_4 and $LiPN_2$ and which therefore represents the first example of a phosphorus(v) nitride with an intermediate degree of condensation of PN_4 tetrahedra. $Li_{10}P_4N_{10}$ can be prepared by solid-state reaction of the binary nitrides Li_3N and P_3N_5 [Eq. (a)] as well as by reaction of $LiPN_2$ with Li_3N [Eq. (b)] or of Li_7PN_4 with P_3N_5 [Eq. (c)]. The title compound is obtained as a colorless powder and as transparent octahedral single crystals.[6]

$$10\,Li_3N + 4\,P_3N_5 \xrightarrow[W\ crucible,\ N_2]{720\,^\circ C,\ 5d} 3\,Li_{10}P_4N_{10} \quad (a)$$

$$2\,Li_3N + 4\,LiPN_2 \xrightarrow[W\ crucible,\ N_2]{700\,^\circ C,\ 5d} Li_{10}P_4N_{10} \quad (b)$$

$$10\,Li_7PN_4 + 6\,P_3N_5 \xrightarrow[W\ crucible,\ N_2]{630\,^\circ C,\ 10d} 7\,Li_{10}P_4N_{10} \quad (c)$$

Single-crystal X-ray structure analysis[7] revealed that $Li_{10}P_4N_{10}$ has an ionic structure and contains the new complex anion $P_4N_{10}^{10\ominus}$, which is isoelectronic to molecular phosphorus(V) oxide, P_4O_{10} (Fig. 1). The anion shows ideal T_d symmetry in the solid. As expected, the IR spectrum of $Li_{10}P_4N_{10}$ displays six vibrational bands for the complex anion between 540 und 1070 cm^{-1}.[8] The P–N bonds to the terminal nitrogen atoms of the $P_4N_{10}^{10\ominus}$ ion are significantly shorter than those to the bridging N atoms (P-N2 158.1(3), P-N1 167.6(3) pm). This is presumably due to a greater degree of polar-bond character in the bonds between phosphorus and terminal nitrogen.

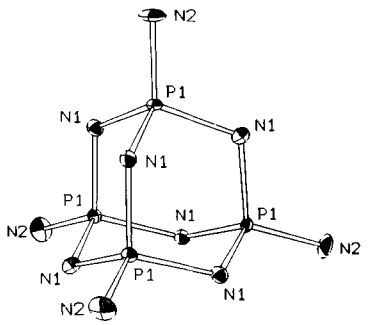

Fig. 1. Structure of the $P_4N_{10}^{10\ominus}$ ion in the solid state (ellipsoids drawn at 50% probability). Selected distances [pm] and angles [°] (standard deviations in parentheses): P-N2 158.1(3), P-N1 167.6(3); N1-P-N2 112.7(1), N1-P-N1 105.9(1), P-N1-P 116.0(2).

Surprisingly, the packing of the $P_4N_{10}^{10\ominus}$ ions in the solid corresponds to that of molecular As_4O_6 in the cubic high-temperature phase arsenolite, despite the differing compositions.[9, 10] Thus, the $P_4N_{10}^{10\ominus}$ ions in the solid are arranged in a zinc blende fashion, resulting in an appreciably more favorable packing of the complex anions compared with, for example, molecular phosphorus(V) oxide, P_4O_{10} (distorted body-centered arrangement).[11] It is this ionic structure formed by lithium cations and $P_4N_{10}^{10\ominus}$ anions which renders possible the space-saving packing, which cannot be achieved for the topologically comparable and isoelectronic, but uncharged, P_4O_{10}.

The arsenolite-like packing of the $P_4O_{10}^{10\ominus}$ ions in the solid forces the $Li^{\oplus}$ ions in $Li_{10}P_4N_{10}$ to occupy markedly different positions. In addition to trigonal-planar coordination of $Li^{\oplus}$ ions, tetrahedral and even near-octahedral coordination by nitrogen are found. Finally, one-tenth of the $Li^{\oplus}$ ions in $Li_{10}P_4N_{10}$ are distributed with disorder over positions with a multiplicity higher than the actual number of atoms. The Li–N contact distances (193–220 pm) correspond roughly to the sum of the ionic radii[12, 13] and they increase, as expected, with the coordination number of the cations.

The close packing of the complex anions realized here is apparently caused by the tendency toward coordinative saturation of the $Li^{\oplus}$ ions. Owing to the topology of the complex $P_4N_{10}^{10\ominus}$ ions, however, it is not possible to coordinate the relatively large number of $Li^{\oplus}$ ions ($Li^{\oplus}$: $P_4N_{10}^{10\ominus}$ = 10:1) in the same way. For this reason the $Li^{\oplus}$ ions are distributed over positions that, from the viewpoint of crystal chemistry, are surrounded by nitrogen in an unusual number of different ways. Analogously to Li_7PN_4 and $LiPN_2$, we expect $Li_{10}P_4N_{10}$ to exhibit a significant lithium ion conductivity.

$Sr_2Li[Fe_2N_3]$ and $Ba_2Li[Fe_2N_3]$: Nitridoferrate(II) Isotypes with $^1_\infty[(FeN_{3/2})_2^{5\ominus}]$ Anions**

By *Peter Höhn, Sabine Haag, Wolfgang Milius,* and *Rüdiger Kniep**

Dedicated to Professor Hans Georg von Schnering on the occasion of his 60th birthday

$Li_4[FeN_2]$, the only nitridoferrate(II) known so far, contains $[FeN_2]^{4\ominus}$ units isostructural to CO_2.[1] Trigonal-planar $[FeN_3]^{6\ominus}$ anions, isostructural to $[CO_3]^{2\ominus}$, have been found in the nitridoferrates(III) $Ba_3[FeN_3]$[2] and $(Ca_3N)_2[FeN_3]$.[3] We have now succeeded in synthesizing $Sr_2Li[Fe_2N_3]$ and $Ba_2Li[Fe_2N_3]$,[4] nitridoferrate(II) isotypes containing the polymeric anions $^1_\infty[(FeN_{3/2})_2^{5\ominus}]$ (Fig. 1), whose structure is closely related to that of the formally isoelectronic B_2S_3[5] (Fig. 2). Fe^{II} is coordinated in a distorted trigonal-planar fashion. The Fe^{II}–N bonds in the crystal structures of $Sr_2Li[Fe_2N_3]$ (187.2(3), 190.0(3), and 193.1(4) pm) and $Ba_2Li[Fe_2N_3]$ (186.6(8), 190.9(7), and 191.7(3) pm) are longer than Fe^{III}–N bonds in the trigonal-planar anions $[FeN_3]^{6\ominus}$ ($Ba_3[FeN_3]$, 173(1) pm;[2] $(Ca_3N)_2[FeN_3]$, 177(2) pm[3]), but they are in very good agreement with the lengths of the Fe^{II}–N bonds (186(1) pm) in the linear anions

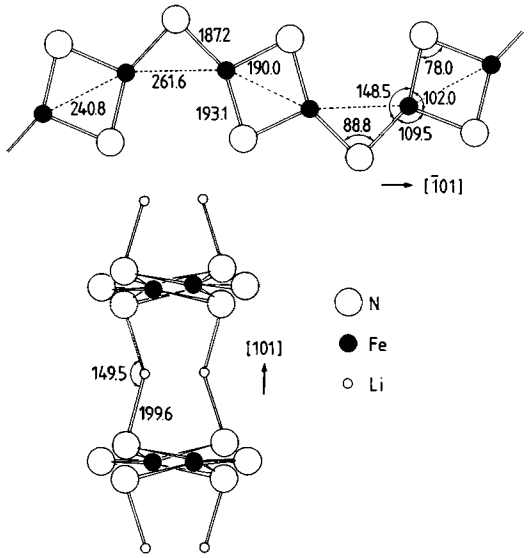

Fig. 1. $Sr_2Li[Fe_2N_3]$: Section of the anion chain $^1_\infty[(FeN_{3/2})_2^{5\ominus}]$ (top) and linking to give the layers $^2_\infty\{Li_{2/2}[(FeN_{3/2})_2]^{4\ominus}\}$ (bottom). Bond lengths in pm, bond angles in °; maximum standard deviations for distances (7), for angles (9), referred in each case to the last digit given.

$[FeN_2]^{4\ominus}$ of $Li_4[FeN_2]$.[1] The polymeric anions $[(FeN_{3/2})_2^{5\ominus}]$ are formed by linking of FeN_3 groups through two common nitrogen atoms, thereby giving planar Fe_2N_4 groups with central Fe_2N_2 four-membered rings and short transannular $Fe^{II}\cdots Fe^{II}$ contacts (240.8(2) pm (243.5(2) pm)).[6] Linking of the Fe_2N_4 groups through common exocyclic nitrogen atoms results in the $^1_\infty[(FeN_{3/2})_2^{5\ominus}]$ chains. Figure 2 shows the close relationship of the $^1_\infty[(FeN_{3/2})_2^{5\ominus}]$ anion partial structure to the formally isoelectronic B_2S_3[5] (24-electron systems: two electrons are counted for each Fe^{II} and the d^6 system is ignored).

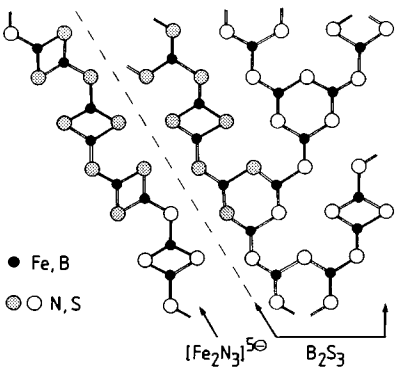

Fig. 2. Comparison of the B_2S_3 layer structure[5] with the formally isoelectronic chain anion $[Fe_2N_3]^{5\ominus}$. Identical linking patterns are indicated by dashed lines.

The discussion of further structural details will be restricted to the strontium compound: The $^1_\infty[(FeN_{3/2})_2^{5\ominus}]$ chains are joined through Li–N bonds along [101] to form layers, $^2_\infty\{Li_{2/2}[(FeN_{3/2})_2]^{4\ominus}\}$ (Fig. 1., bottom), in which the Li–N bond lengths are 199.6(7) pm and the N–Li–N bond angles 149.5(9)°. For comparison, the Li–N bonds in the crystal structure of Li_3N[7] are 193.8(1) pm (twofold coordinated Li) and 210.6(1) pm (threefold coordinated Li). The strontium ions lie between the $^2_\infty\{Li_{2/2}[(FeN_{3/2})_2]^{4\ominus}\}$ layers and are coordinated in a distorted trigonal-bipyramidal fashion by nitrogen. The Sr–N distances (257.8(5) to 277.6(1) pm) are in the range of the sums of the effective ionic radii (260 to 275 pm[8]).

Experimental Procedure

For the synthesis of $Sr_2Li[Fe_2N_3]$ ($Ba_2Li[Fe_2N_3]$), Li_3FeN_2[9], Sr_2N[10], and Fe (Li_3N[7], Ba_3N_2[11], and Fe) were used in a molar ratio of 1 : 3 : 5 (4 : 2 : 1). The powders were mixed and pressed into pellets under inert atmosphere, heated (100 °C h^{-1}) in iron crucibles to 750 °C, and kept at this temperature for 36 h under a stream of nitrogen (1 atm, about 5 L h^{-1}). Cooling was carried out at a rate of 20 °C per hour (10 °C per hour). The shiny black reaction products, thin layers of which appear red when viewed against the light, contained small amounts of unreacted iron besides the quaternary compounds. Single crystals (tetragonal prisms) suitable for structure analyses were isolated under paraffin and placed in sealed Lindemann capillaries.

drogen is coordinated to a metal center in an η^2 fashion.[1] Subsequently, further compounds of this kind were characterized as stable solids,[2] in argon matrixes,[3] and in liquid xenon.[4] As in the case of the tungsten complex, however, the stability of these complexes was increased by additional ligands. Simpler hydrogen complexes, which could serve as model compounds for this class of substances, are still unknown.[5] Here we report the preparation of [Cu(η^2-H_2)Cl], a copper complex that represents the first compound of this kind accessible to both experimental and theoretical investigation.

Cocondensation of copper(I) chloride[6] and elemental hydrogen[7] in an argon matrix results in the immediate appearance of new IR absorption bands,[8, 9] which must be assigned to a CuCl complex with hydrogen coordinated in a side-on fashion (see Table 1 and Ref. [10]). These absorption

Table 1. Absorption frequencies [a] of matrix-isolated [Cu(η^2-H_2)Cl] and of the corresponding mono- and dideuterated complexes.

Assignment	[Cu(η^2-H_2)Cl]	[Cu(η^2-$^1H^2H$)Cl]	[Cu(η^2-$^2H_2$)Cl]
ν(CuCl)	410.7	$\approx$409	407.8
$\nu(CuH)_{as}$	934.8	765.6	696.6
$\nu(CuH)_s$	1538.9	1353.7	1077.0
ν(HH)	3222.0 [b]	2900.4	2394.6

[a] All frequencies in cm^{-1}. [b] Besides these bands, an absorption band at 3425.95 cm^{-1} was observed in all spectra obtained in experiments with CuCl and $^1H_2$. The assignment of this band is still questionable [14].

bands were not observed in control experiments involving either CuCl and argon or a mixture of hydrogen and argon. The positions of the bands of the metal–hydrogen stretching vibrations of [Cu(η^2-H_2)Cl] are in good agreement with those found by *Kubas* et al. for solid [$W(CO)_3$-$(PCy_3)_2(H_2)$].[11] However, those authors appear to have mistakenly reversed the assignments of the antisymmetric and symmetric absorption bands.[11]

Ab initio calculations[15] on free CuCl and H_2 as well as on [Cu(η^2-H_2)Cl] with C_{2v} symmetry and on the corresponding complex with hydrogen coordinated in an end-on fashion ($C_{\infty v}$ symmetry) gave geometries and IR absorption frequencies[16] for the free species in good agreement with those already reported.[20]

The calculated H–H distance in [Cu(η^2-H_2)Cl] is 80.7 pm (MP2) or 79.4 pm (CPF) and therefore lengthened by 6.9 pm

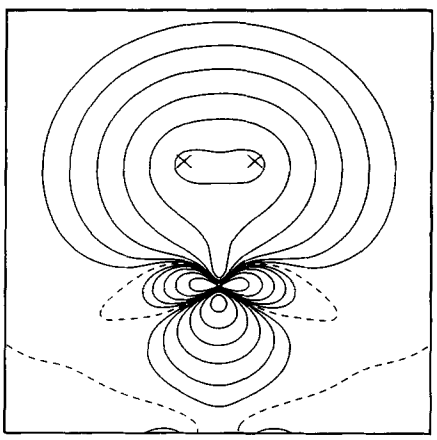

Fig. 1. Contour diagram of the 10_{a_1} MO of [Cu(η^2-H_2)Cl]. Values of the wave function: 0.0 (nodal plane, dashed line), $\pm$ 0.02, $\pm$ 0.04, $\pm$ 0.08, $\pm$ 0.16, $\pm$ 0.32, $\pm$ 0.64.

or 4.9 pm, respectively, compared with that in H_2.[16] The Cu–H distance in [Cu(η^2-H_2)Cl] is 157.2 pm (MP2) or 161.1 pm (CPF) and thus significantly longer than that in CuH (146.2 pm).[20] By contrast, the Cu–Cl distance in [Cu(η^2-H_2)Cl] is 204.7 pm (MP2) or 207.5 pm (CPF), values hardly different from the value for free CuCl.[16]

A cross-section through the electron density of the H–H–Cu bond in the molecular plane is shown in Figure 1. According to a population analysis[21] of the SCF wave function, the MO shown forms a strong three-center bond (shared electron number (SEN) = 1.1). This three-center bond is largely responsible for both the bonding H–H interaction and the bonding Cu–H interactions. Other MOs do not make significant contributions to the H–H or Cu–H bonds. A comparison of the experimentally determined and calculated positions of the IR bands, together with their scaled intensities, is shown in Figure 2. The harmonic fre-

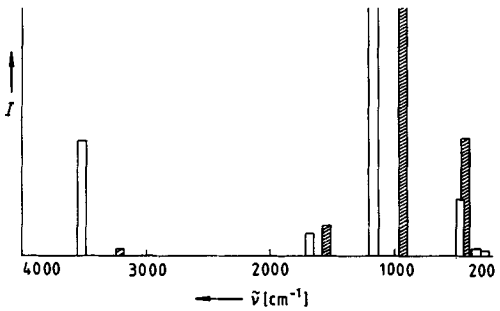

Fig. 2. Schematic drawing of the experimentally determined (hatched) and calculated (MP2) IR spectrum (frequencies and intensities *I*, the latter normalized to that of the most intense band) for [Cu(η^2-H_2)Cl].

quencies calculated for [Cu(η^2-H_2)Cl] on the MP2 level (Table 2) deviate from the experimental values by the amounts expected when anharmonicity of the vibrations is not taken into consideration. On the other hand, the IR frequencies obtained by ab initio calculation and their isotopic shifts are in good agreement with the corresponding results of normal coordinate analysis; both procedures assume a harmonic approximation.

Table 2. Frequencies [a] calculated for [Cu(η^2-H_2)Cl] and for the corresponding mono- and dideuterated complexes on the MP2 level.

Assignment	[Cu(η^2-$^1H_2$)Cl]	[Cu(η^2-$^1H^2H$)Cl]	[Cu(η^2-$^2H_2$)Cl]
"rocking"	285.6	239.6	213.2
"out of plane"	308.3	272.1	230.2
ν(CuCl)	445.7	443.7	441.9
$\nu(CuH)_{as}$	1170.1	936.9	842.0
$\nu(CuH)_s$	1681.9	1496.2	1191.5
ν(HH)	3517.0	3055.1	2488.5

[a] All frequencies in cm^{-1}.

The harmonic frequencies were also calculated for the complex with H_2 coordinated in an end-on fashion. The two negative eigenvalues in the force constant matrix of this molecule show that the calculated geometry does not correspond to a local minimum on the potential hypersurface.

Energy optimization did not give a potential minimum for a copper complex with a bent H_2 ligand (C_s symmetry); these calculations converged to the geometry of [Cu(η^2-H_2)Cl].

The energies of formation for the side-on and end-on complexes were also determined by ab initio calculations

(Scheme 1).[17] The calculated values show that both complexes are stable toward decomposition to the starting compounds. The end-on complex is appreciably less stable than

$$CuCl + H_2 \rightarrow [Cu(\eta^2\text{-}H_2)Cl] + 93\,kJ\,mol^{-1}(84\,kJ\,mol^{-1})$$

$$CuCl + H_2 \rightarrow [Cu(\eta^1\text{-}H_2)Cl] + 19\,kJ\,mol^{-1}(23\,kJ\,mol^{-1})$$

Scheme 1.

$[Cu(\eta^2\text{-}H_2)Cl]$. The bond energies of $[Cu(\eta^2\text{-}H_2)Cl]$ correspond in magnitude to those for the first coordination of a CO ligand to a nickel center.[22]

The surprisingly large energies of formation and the strong CuH_2 three-center bond in $[Cu(\eta^2\text{-}H_2)Cl]$ indicate that attempts to stabilize complexes of composition $[(CuCl)_n(H_2)_m]$ and related compounds at low temperatures should be promising. Also of interest would be an investigation of the properties of monomeric copper(I) chloride with respect to catalytic hydrogenation.

[5] Cocondensation of metal atoms and hydrogen in noble gas matrixes resulted in cleavage of the H_2 bond and formation of hydride bonds to the metal center: G. A. Ozin, C. Gracie, *J. Phys. Chem. 88* (1984) 643–645; G. A. Ozin, J. G. McCaffrey, *ibid. 88* (1984) 645–648.
[6] Monomeric copper(I) chloride was synthesized by reaction of copper turnings with elemental chlorine at about 1300 K in a Knudsen cell.
[7] The usual conditions of matrix isolation allow condensation of hydrogen and its isotopes in concentrations of up to 10% in argon matrixes: G. R. Smith, J. A. Warren, W. A. Guillory, *J. Chem. Phys. 65* (1976) 1591–1593; J. A. Warren, G. R. Smith, W. A. Guillory, *ibid. 72* (1980) 4901–4908.
[8] We have already described the cryostats and the vaporization conditions: R. Ahlrichs, R. Becherer, M. Binnewies, H. Borrmann, M. Lakenbrink, S. Schunck, H. Schnöckel, *J. Am. Chem. Soc. 108* (1986) 7905. The IR investigations were carried out with an FT IR instrument (Bruker IFS66v). Above 500 cm^{-1} the spectra were recorded with a resolution of one wave number; below 500 cm^{-1}, the resolution was two wave numbers.
[9] If, instead of $^1H_2$, deuterium or mixtures of $^1H_2$, $^2H_2$, and $^1H^2H$ were used, the bands were shifted (Table 1). These isotope shifts confirm the presence of a single H_2 ligand in the species investigated.
[10] In addition to the frequencies in Table 1, bands in the region of the CuCl stretching vibration were also observed. We assign these to CuCl stretching modes (νCuCl) of the following isotopomers of $[Cu(\eta^2\text{-}H_2)Cl]$: $(^1H_2)^{65}Cu^{35}Cl$, 408.84 cm^{-1}; $(^1H_2)^{63}Cu^{37}Cl$, 404.02 cm^{-1}; $(^1H_2)^{65}Cu^{37}Cl$, 401.12 cm^{-1} and $(^2H_2)^{65}Cu^{35}Cl$, $\approx$ 406 cm^{-1}; $(^2H_2)^{63}Cu^{37}Cl$, 401.12 cm^{-1}; $(^2H_2)^{65}Cu^{37}Cl$, 398.23 cm^{-1}. The relative intensities of these bands in the spectra correspond to those of unperturbed CuCl with its four natural isotopomers: $^{63}Cu^{35}Cl$, 420.41 cm^{-1}; $^{65}Cu^{35}Cl$, 418.00 cm^{-1}; $^{63}Cu^{37}Cl$, 413.66 cm^{-1}; $^{65}Cu^{37}Cl$, 411.25 cm^{-1}. T. P. Martin, H. Schaber, *J. Chem. Phys. 73* (1980) 3541–3546. These findings, together with the observed $^1H/^2H$ shifts for the symmetric and antisymmetric CuH stretching vibration [9] confirm the composition of the investigated species as consisting of an H_2 ligand and a CuCl unit.
[11] For $[Cu(\eta^2\text{-}H_2)Cl]$, force constant calculations were carried out for the five A_1 and B_1 vibrational modes [12]. Owing to the large anharmonicity of the vibrational modes involving hydrogen [13], the harmonic frequencies and their corresponding isotopic shifts are not comparable with the experimental data. These model calculations (normal coordinate analysis and ab initio calculations for $[Cu(\eta^2\text{-}H_2)Cl]$) show that, due to the small bond angle at the metal atom (α = 29.7° (MP2), 28.5° (CPF)), a strong coupling for the metal–hydrogen bonds and, in addition, a high CuH/CuH interaction force constant are expected for the coordination of an H_2 ligand to a metal center. This also means, however, that the antisymmetric CuH stretching vibration will lie at lower wave numbers than the antisymmetric. This assignment is generalizable, since the comparable band positions and isotopic shifts of the MH vibrational modes in $[Cu(\eta^2\text{-}H_2)Cl]$ and the hydrogen complexes so far known indicates similar vibrational motions.
[12] For the model calculations on the force field of $[Cu(\eta^2\text{-}H_2)Cl]$ (A_1 and B_1 symmetry), the following force constants were estimated: f(CuCl) = 230, f(CuH) = 100, f(HH) = 300, f(ClCuH) = 10, f(CuH/CuH) = 45, f(CuH/HH) = 5, f(CuCl/CuH) = 10 Nm^{-1}.
[13] H. J. Becher, *Fortschr. Chem. Forsch. 10* (1968) 156–205.
[14] We assume that the band at 3425.95 cm^{-1} is assignable to a combination mode ($2 \cdot \nu(CuH)_{as} + \nu(CuH)_s$) shifted by Fermi resonance. The intensity of this absorption band would then be due almost solely to the HH stretching vibration. In experiments with $^1H_2$, $^1H^2H$ and $^2H_2$, additional but only poorly resolved, absorptions were observed at higher wave numbers (4122.14, 3731.13, and 2965.44 cm^{-1}). They do not correspond to the previously observed vibrations of matrix-isolated hydrogen. Moreover, they only appear when CuCl is also present in the matrix. We therefore assign these bands to a weak interaction of molecular hydrogen with monomeric copper(I) chloride. This assignment is supported by the small deviation of the measured HH absorption frequencies compared with those in hydrogen, as well as the corresponding relation in the $^2H_2$ complexes.
[15] Both CI calculations with the CPF method [18] (only geometry optimization) and MP2 calculations with the program package CADPAC [19] (geometry optimization and harmonic frequencies) were carried out. Basis sets for the CI calculations: copper-relativistic pseudopotential (Ne core) 8s7p6d2f/[6,5,3,2]; chlorine 12s9p2d1f/[7,5,2,1]; hydrogen 6s2p1d/[4,2,1]. Basis sets for the MP2 calculations: copper 14s11p6d3f/[8,6,4,2]; chlorine 12s9p2d/[7,5,2]; hydrogen 5s1p/[3,1].
[16] The following results were obtained for the free molecules CuCl and H_2 (MP2/CPF/Exp. [20]): d(CuCl) = 205.8/207.7/205.1 pm; ω(CuCl) = 420.3/412.5/415.3 cm^{-1}; d(HH) = 73.8/74.5/74.1 pm; ω(HH) = 4545.3/4351.5/4401.2 cm^{-1}.
[17] The energies calculated on the MP2 level are given. The corresponding values for the CPF method are given in parentheses.

[**] Compounds of Germanium and Tin, Part 6. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. Part 5: M. Weidenbruch, K. Schäfers, K. Peters, H. G. von Schnering, *J. Organomet. Chem. 381* (1990) 173.

been established unambiguously. Thus, *Lappert*'s distannene **3**,[9] the only structurally characterized compound of this kind, is better regarded as a double donor–acceptor adduct of the two stannylenes (stannanediyls) **4**. This description is

$R_2E{=}ER_2$ — **1**, E = Si; **2**, E = Ge — R = alkyl, aryl

$R_2SnSnR_2 \rightleftharpoons 2\,R_2Sn$: — **3** — **4** — R = $(Me_3Si)_2CH$

consistent with the tin–tin bond length, which is only slightly shorter than that of a tin–tin single bond,[9, 10] the results of quantum-mechanical calculations,[10] the solid-state ^{119}Sn NMR data,[11] and, finally, the reversible decomposition to two stannylenes **4** in solution.[12]

On the other hand, the distannene **7**, synthesized by *Masamune* and *Sita*,[13] probably does have a tin–tin multiple bond according to spectroscopic evidence. Compound **7** is accessible by photolysis or thermolysis of the cyclotristannane **6**, with which it is in thermal equilibrium over a broad temperature range. A more detailed characterization of **7** has been hindered so far by the laborious synthesis of **6**, which is obtained in only 12% overall yield starting from tin tetrabromide.[13]

$$6\,\mathrm{ArylMgBr} + 3\,SnCl_2 \longrightarrow \underset{\mathbf{6}}{\overset{\mathrm{Aryl_2Sn}}{\overset{\mathrm{Sn}}{\overset{\mathrm{Aryl_2Sn{-}SnAryl_2}}{}}}} \rightleftharpoons 3/2\,Aryl_2Sn{=}SnAryl_2$$

5 — **7**

Aryl = 2,4,6-iPr$_3$C$_6$H$_2$

We have now found that treatment of tin(II) chloride with the aryl Grignard **5** provides a high-yield and extremely simple synthetic route to **6** and therefore **7**. This synthesis makes it possible to study the chemical behavior of **7**. Thus, **7** undergoes smooth [2 + 1] cycloaddition with tellurium to give the telluradistannirane **8**, the first compound with an Sn_2X framework.[14] Crystals of **8** are stable to light and to temperatures below their melting point. The X-ray structure analysis of **8**[15] (Fig. 1) reveals a nearly equilateral triangle consisting of one tellurium atom and two tin atoms. The tin–tin and tin–tellurium bonds are somewhat longer than those usually found. Especially interesting is the environment of the tin atoms; it is formed by the two *ipso*-carbon atoms of the aryl groups and the other tin atoms as nearest neighbors. The sums of the bond angles at Sn1 and Sn2, 355° and 357°, respectively, indicate a nearly planar bonding geometry, in remarkable agreement with that found for the silicon and germanium atoms in recently prepared telluradisiliranes[16] and telluradigermiranes,[17] respectively. These comparable structures indicate that the bonding is similar in all three three-membered ring compounds. Further treatment of **8** with tellurium, as well as reaction of **7** with tellurium in excess, leads exclusively to the 1,3-ditelluradistannetane **9**, whose constitution was established mainly by ^{119}Sn and ^{125}Te NMR spectroscopy. It remains an open question whether this known ring system[18] is formed here by insertion of tellurium into the tin–tin bond, which is shielded by substituents, or whether insertion of tellurium into the comparatively easily accessible tin–tellurium bond first leads to formation of a 1,2-ditelluradistannetane, which then rearranges to the constitutional isomer **9**.

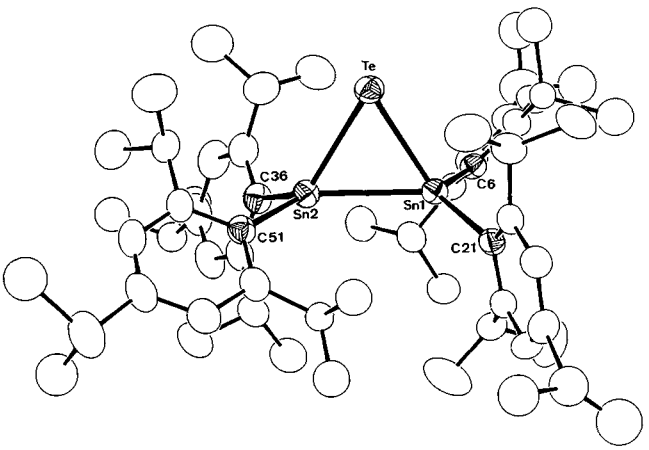

Fig. 1. Molecular structure of **8** (ORTEP, thermal ellipsoids at 30% probability, hydrogen atoms omitted). Selected bond lengths [pm] and angles [°]: Sn1-Sn2 282.7(1), Sn1-Te 280.0(1), Sn2-Te 277.9(1), Sn1-C6 217.7(7), Sn1-C21 219.1(6), Sn2-C36 217.0(6), Sn2-C51 215.9(8); Sn1-Te-Sn2 60.9(1), Te-Sn2-Sn1 59.9(1), Sn2-Sn1-Te 59.2(1); torsion angle (average of the angles between the opposite planes defined by C21-Sn1-Sn2/C51-Sn2-Sn1 and by C6-Sn1-Sn2/C36-Sn2-Sn1) 13.5°.

The lighter chalcogens sulfur and selenium react analogously with **7** to give the corresponding three- and four-membered ring compounds. However, these products are always formed simultaneously, their relative amounts depending on the ratio of the starting materials, and their separation is difficult. We will report later on their isolation.

Experimental Procedure

8: Compound **6** (2.00 g, 1.27 mmol) was allowed to react with tellurium (0.25 g, 1.96 mmol) in refluxing toluene (40 mL) until the red color of **7** had vanished (about 2 h). After separation of unreacted tellurium and removal of toluene by distillation under vacuum, the residue was crystallized twice from *n*-pentane to give 1.60 g (71%) of **8** as yellow-orange cubes (m.p. 175°C, turns dark red above 163°C). ^1H NMR (300 MHz, C_6D_6): δ = 1.27 (m, 72H), 2.83 (sept, 4H), 3.96 (very broad, 8H), 7.15 (s, 8H, $^4J(^{119}Sn\text{-}^1H)$ = 21.7 Hz). ^{13}C NMR (75.44 MHz, C_6D_6): δ = 14.21; 22.66, 24.10, 24.39, 24.66, 25.96, 34.46; 40.05 (broad), 122.95, 150.47, 155.29 (broad). ^{119}Sn NMR (93.23 MHz, C_6D_6, versus Me_4Sn): δ = −594, $^1J(^{119}Sn\text{-}^{117}Sn)$ = 3382 Hz. ^{125}Te NMR (78.87 MHz, C_6D_6, versus Me_2Te): δ = −903, $^1J(^{125}Te\text{-}^{119}Sn/^{117}Sn)$ = 844/806 Hz. UV/VIS: λ_{max} [nm] (ε) = 378 (3060). Correct C,H,Te analysis.

9: a) Similarly, **6** (2.00 g, 1.27 mmol) and tellurium (0.50 g, 3.92 mmol) were allowed to react in 40 mL of refluxing toluene for 15 h. Corresponding workup afforded 1.80 g (73%) of **9** as orange needles (m.p. 229–231°C). ^1H NMR (300 MHz, C_6D_6): δ = 1.33 (d, 24H, ^3J = 6.9 Hz), 1.40 (d, 48H, ^3J = 7.0 Hz), 2.89 (sept, 4H), 4.16 (sept, 8H), 7.15 (s, 8H, $^4J(^{119}Sn\text{-}^1H)$ = 25.2 Hz). ^{13}C NMR (75.44 MHz, C_6D_6): δ = 24.10, 25.35, 34.49, 37.31, 122.41, 134.67, 150.56, 154.45. ^{119}Sn NMR (93.23 MHz, C_6D_6, versus Me_4Sn): δ = −752, $^2J(^{119}Sn\text{-}^{117}Sn)$ = 417 Hz. ^{125}Te NMR: (78.87 MHz, C_6D_6, versus Me_2Te): δ = 171, $^1J(^{125}Te\text{-}^{119}Sn/^{117}Sn)$ = 1975/1894 Hz. UV/VIS: λ_{max} [nm] (ε) = 460 (320). Correct C,H,Te analysis. b) Likewise, reaction of **8** (0.50 g, 0.42 mmol) and tellurium (70 mg, 0.55 mmol) for 15 h in refluxing toluene) gave **9** in quantitative yield (NMR).

On the Electrochemical Oxidation of $Cs^{\oplus}$ and Other Alkali-Metal Ions in Liquid Sulfur Dioxide and Acetonitrile **

By *Christophe Jehoulet* and *Allen J. Bard**

A recent paper suggested that $Cs^{\oplus}$ (as the $OTeF_5^{\ominus}$ salt) could be oxidized electrochemically at a Pt electrode in acetonitrile solutions containing $Et_4N^{\oplus}PF_6^{\ominus}$ at ca. + 3 V vs. SCE (near the background oxidation limit of MeCN).[1] The addition of cryptand decreased the potential for the observed oxidation to 2.7 V vs. SCE. Similar oxidation waves were not seen with $K^{\oplus}$, $Rb^{\oplus}$, and $nBu_4N^{\oplus}$ salts of $OTeF_5^{\ominus}$. However, the oxidation of $Cs^{\oplus}$ at such a relatively low potential appears to be at variance with our studies of electrochemical oxidations in liquid SO_2, which has been shown to have a background oxidation limit of > +5 V vs. SCE, considerably beyond that of MeCN.[2-4] Indeed, in a recent paper[4] it was shown that a $CsAsF_6$ supporting electrolyte in liquid SO_2 allowed studies to + 5 V without apparent oxidation of the $Cs^{\oplus}$. We report here cyclic voltammetric studies of $Cs^{\oplus}$ and other alkali-metal ions in liquid SO_2 which suggest that oxidation of these ions may be possible, but only at considerably more positive potentials than those suggested from the MeCN studies.[1] These studies were carried out with an ultramicroelectrode[5] (UME) (10- or 25-μm diameter) to minimize effects of solution resistance and allow studies of the salts to be carried out in the absence of supporting electrolyte.[3,4] The possibility of hydration of these salts and its influence on the electrochemical response was also examined. Finally, we reexamined the behavior of these compounds in MeCN.

Experiments in SO_2 with $CsAsF_6$ as a supporting electrolyte in the study of other compounds have been reported.[4] However, we have not been able to reproduce some aspects of this earlier work. For example, we found the maximum solubility of $CsAsF_6$ at −70 °C to be about 4 mM and oxidation of $Cs^{\oplus}$ to occur at less positive potentials. Figure 1 A shows a cyclic voltammogram (CV) of a 4 mM solution at a 10-μm UME in SO_2 without added supporting electrolyte. Figure 1 A was obtained for a saturated solution; the solubility of $CsAsF_6$ and the other alkali salts in liquid SO_2 was very low (≈4 mM for $CsAsF_6$ and even lower for the other alkali-metal salts). The CV recorded with an UME (10- or 25-μm diameter) did not show a reverse cathodic wave, even for higher scan rates (up to 20 Vs^{-1}), suggesting low stability of the oxidation product. The half-wave potential $E_{1/2}$, was 4.75 V vs. SCE for $CsAsF_6$. The other alkali salts, $KAsF_6$ or $RbAsF_6$, were also studied in the absence of supporting electrolyte and displayed similar electrochemical behavior ($E_{1/2}$ values of 4.64 and 4.66 V vs. SCE for $K^{\oplus}$ and $Rb^{\oplus}$, respectively). However, SO_2 is a resistive solvent and in order to get more quantitative information, it was necessary

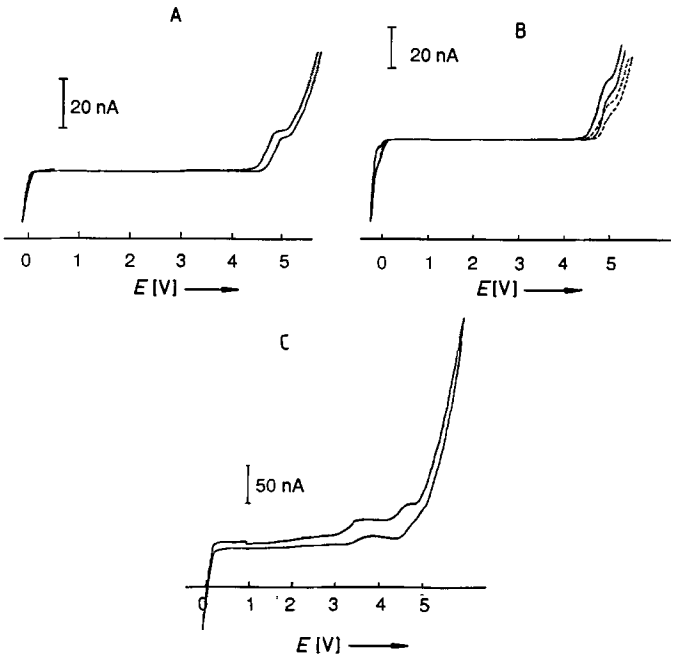

Fig. 1. Cyclic voltammogram of solutions of $Cs^{\oplus}$ at 203 K in liquid SO_2. Scan rate, 1 Vs^{-1}; working electrode, platinum disk, 10-μm diameter (A and B), 50-μm diameter (C). A) Saturated solution of $CsAsF_6$ (≈4 mM) without supporting electrolyte. B) $CsAsF_6$ (3.5 mM) with nBu_4NAsF_6 (5.2 mM). Solid curve: compound in presence of supporting electrolyte. Dashed curve: supporting electrolyte alone. C) Saturated solution of $CsClO_4$ without supporting electrolyte.

[**] Electrochemistry in Liquid SO_2, Part 10. This work was supported by the National Science Foundation (CHE8901450). Part 9: [4]

to compensate for the effect of ohmic drop and migration. Therefore, experiments were performed with nBu$_4$NAsF$_6$ as a supporting electrolyte. We found this electrolyte to be oxidized at slightly more positive potentials than $Cs^{\oplus}$ ($E_{1/2} = 4.9 \pm 0.1$ V vs. SCE). Electrolytes with shorter alkyl chains[4] oxidize at more positive potentials, but their lower solubilities and rates of dissolution made them less convenient than nBu$_4$NAsF$_6$. A CV for the oxidation of $Cs^{\oplus}$ is shown in Figure 1B. The oxidation wave did not display a reverse wave and occurred at about the same potential as that for the oxidation of nBu$_4$N$^{\oplus}$, as expected from the $E_{1/2}$ values of the alkali salts found in the preliminary experiments. The other alkali salts displayed the same electrochemical behavior.

The $E_{1/2}$ values for the oxidation of various alkali cations are given in Table 1. These correspond to those found for the experiments without supporting electrolyte. The $E_{1/2}$ found for $Cs^{\oplus}$ is much more positive than the one reported previously.[1] The experiments were also conducted as a function of salt concentration. The limiting current (i_l) varied with concentration (Fig. 2), in the absence and presence of supporting electrolyte. The linear variation observed shows that the oxidation wave is effectively due to the oxidation of the added salt. Unfortunately, we could not determine the number of electrons, n, involved in the electrode reaction by coulometry. However, a rough estimate of the diffusion coefficient, D, was made assuming a one- or a two-electron charge-transfer reaction and using the expression of the steady-state current for a micro-disk.[5] The values obtained at $-70\,^{\circ}C$ are given in Table 1. Those values can be used together with the Stokes–Einstein equation to estimate the diameter of the solvated ion. The values obtained in the case of a one-electron transfer seem more compatible with the value of the crystalline radius, even in the case of solvation by molecules of solvent.

Table 1. Electrochemical parameters of alkali salts.

Salt	$E_{1/2}$ [V] vs SCE	D [10^{-5} cm^{2}s^{-1}]		d [Å] [a]		r [Å] [9]
		$n = 1$	$n = 2$	$n = 1$	$n = 2$	
$CsAsF_6$	4.73 ± 0.07	1.68	0.84	5.9	11	1.65
$RbAsF_6$	4.67 ± 0.07	2.10	1.05	4.75	9.5	1.49
$KAsF_6$	4.64 ± 0.1	2.38	1.19	4.1	8	1.33
$NaPF_6$	4.8	–	–	–	–	–

[a] Calculated from the Stokes–Einstein relationship.

Several other experiments were undertaken to demonstrate that the oxidation was due to the alkali-metal ion rather than the anion ($AsF_6^{\ominus}$) or adventitious water. For example, alkali-metal salts are easily hydrated and this can affect their electrochemical behavior. Therefore, alkali salts were dried in a vacuum oven at 150 °C for 48 h and stored in a dry box under a helium atmosphere. To determine the amount of water in the compounds and its possible effect on the voltammograms, the salts were titrated by the Karl Fischer method. The reagent (Fluka) was standardized with sodium tartrate dihydrate salt as described by *Neuss* et al.[6] Titrations were performed with both visual and amperometric end-point detection. To prevent any contamination of the reagents, titrations were conducted[7] in the dry box under a helium atmosphere. All reagents were opened and used only in the dry box. This should exclude all contamination by external moisture.

After the standardization of the reagent, the salts were added in MeOH solution. There was no change in the color of the solution or in the amperometric current, even after stirring for more than 30 min. Thus, the water in the salt was less than 0.05%. This implies that, in each experiment, the concentration of water in the cell from the compound was less than 10 μM. This low concentration is not compatible with the waves seen in the voltammograms. Moreover, when water was intentionally added to the solutions to observe its effect on the electrochemical behavior, it catalyzed the limiting oxidation process and produced sharp peaks totally different from the waves attributed to the alkali metals; the same behavior was observed with imperfectly dried compound. Sometimes the compounds also displayed a small wave at about 3.8 V vs. SCE, which can be assigned to the moisture from the salt. This wave was also observed when a small amount of water was added to the solution. These observations suggest that the alkali-metal wave in the voltammograms cannot be attributed to free water or that bound to ions.

Finally, to demonstrate that the wave was not due to $AsF_6^{\ominus}$ oxidation, $CsClO_4$ was examined in SO_2 in the absence of supporting electrolyte. The voltammogram (Fig. 1C) displayed two oxidation waves. The first one is assigned to the oxidation of the perchlorate anion, as observed in previous studies.[2, 8] The other $E_{1/2}$ was the same as that observed with $CsAsF_6$ solutions.

This study suggests that the alkali-metal cations might be oxidized, but only at high potentials in SO_2. This oxidation cannot be observed in MeCN. The electrochemical behavior of $CsAsF_6$ in MeCN was studied in our laboratory and Fig-

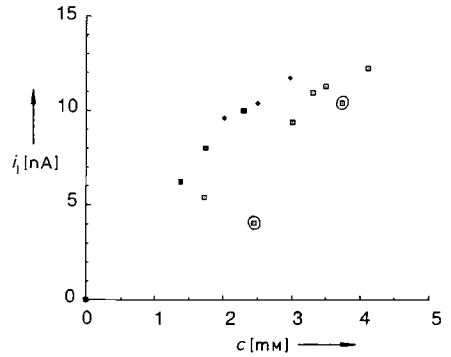

Fig. 2. Steady-state current as a function of concentration for various salts. ◆ = $RbAsF_6$; ■ = $KAsF_6$; ⊡ = $CsAsF_6$. Circled values were recorded without supporting electrolyte; these currents are lower because of electrorepulsion (migration) effects on the cation at these very positive potentials. The current was determined after subtraction of the nBu$_4$N$^{\oplus}$ background. The reduction of the solvent was chosen as a reference potential. This procedure does not allow the use of a large amount of supporting electrolyte (1–10 mM) and therefore requires measurement with UMEs. (Working electrode: platinum disk, 10-μm diameter).

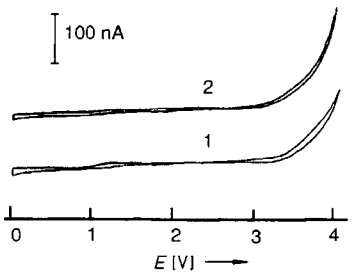

Fig. 3. Cyclic voltammograms of $CsAsF_6$ in acetonitrile at 298 K. 1) nBu$_4$NPF$_6$ (0.1 M) and [2.2.2]cryptand (5.9 mM) in acetonitrile. 2) In the presence of $CsAsF_6$ (6 mM). Acetonitrile was dried on Woelm neutral activated alumina before use. Scan rate, 0.2 Vs^{-1}; working electrode, platinum disk, 25 μm diameter.

ure 3 shows that the voltammogram does not display any oxidation wave before background, even in the presence of cryptand, introduced to stabilize the oxidized form of the alkali cation.

The oxidation of $Cs^{\oplus}$ and the other alkali-metal ions in SO_2 is not unambiguous. It is surprising that $Cs^{\oplus}$, $Na^{\oplus}$, and $K^{\oplus}$ are oxidized at the same potential, given their very different ionization potentials in the gas phase. However, salts from different origins show the same behavior, suggesting that a common impurity is unlikely. Water, the most likely candidate impurity, does not show this CV behavior, and the effect of added electrolyte suggests the oxidation wave can be attributed to a positive species.

Experimental Procedure

The measurements, the purification of SO_2, and the preparation of the supporting electrolyte, nBu$_4$NAsF$_6$ and the alkali salts (CsAsF$_6$, RbAsF$_6$, KAsF$_6$) followed the procedure described previously[3, 4]. NaPF$_6$ (Aldrich) was used after recrystallization from Me$_2$SO/CH$_2$Cl$_2$ and drying in a vacuum oven under the same conditions as above.

Experiments in MeCN were performed in a dry box (Vacuum Atmospheres) under a helium atmosphere using high-purity MeCN with a low concentration of water (0.003%) (Burdick & Jackson). Kryptofix (Aldrich) and Woelm neutral activated alumina (ICN Biomedicals) were used as received. The supporting electrolyte, nBu$_4$NPF$_6$, was thrice recrystallized from EtOH/THF (1:1), then dried in a vacuum oven and stored in the dry box.

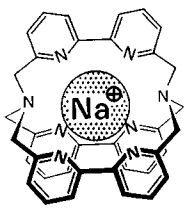
Cryptatium: A Species of Expanded Atom/Radical Ion Pair Type from Electroreductive Crystallization of the Macrobicyclic Sodium Tris(Bipyridine) Cryptate**

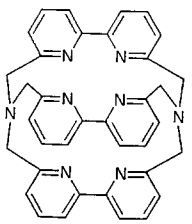
By *Luis Echegoyen, André DeCian, Jean Fischer,* and *Jean-Marie Lehn**

The inclusion of a metal cation into a macropolycyclic ligand results in the formation of a very large, charge-diffuse cryptate cation.[1, 2] The spherically shaped cryptates of alkali-metal cations[1] are expected to have very low surface charge density and to interact very weakly with anions or solvent molecules. They represent an extrapolation of the $Cs^{\oplus}$ cation (1.65 Å radius) to very large size (about 5 Å radius) and might formally be considered as "super-heavy" alkali-metal cations.[2] If the anion associated with such a cation is an electron, the resulting species could be considered as a very large alkali-metal atom of extremely low ionization potential (which in the isolated state would have analogies with a Rydberg atom) or as a salt containing an electron as anion, an electride,[3, 4] such as that derived from the $K^{\oplus}$ cryptate of the ligand [2.2.2], $\{[K^{\oplus} \subset$cryptand 2.2.2$], e^{\ominus}\}$. Between the two extremes, the atom and the electride, one may envisage (as suggested earlier by Lehn[5]) a species in which the electron would be located on acceptor sites incorporated into the ligand shell surrounding the metal cation bound in the molecular cavity of a spheroidal cryptate, thus yielding a self-contained neutral entity. Such a unit represents a way of expanding the atom by stabilizing the electron on a ligand orbital rather than on a metal-centered one. It may be described either as a radical contact ion pair, containing a more or less delocalized electron, or, more intriguingly, as a sort of molecular "expanded atom".[6, 7]

We now report the generation and some physical and structural properties of such a species formed by electroreductive crystallization of the sodium cryptate $[Na^{\oplus} \subset \mathbf{1}]$ of the macrobicyclic tris(bipyridine) ligand **1** [tris(bpy)].[8]



$[Na^{\oplus} \subset \mathbf{1}]$



1

Electrochemical reduction of a solution of $[Na^{\oplus} \subset \mathbf{1}]\,Br^{\ominus}$ in dimethylformamide (DMF) gave three clearly resolved, quasi-reversible reductions at $E_{1/2} = -2.40$, -2.51, and -2.68 V versus $Fc^{\oplus}/Fc$ (Fc = ferrocene), with anodic and cathodic peak potentials $E_p^a = -2.36$, -2.44, -2.61 and $E_p^a = -2.44$, -2.57, -2.73 V vs $Fc^{\oplus}/Fc$.[9] They correspond respectively to the monoreduced (neutral), direduced (monoanionic), and trireduced (dianionic) derivatives of the starting cryptate. The species formed may be considered to result from the successive reduction of the three bipyridyl groups of the tris(bpy) cryptand. Multiple electron reduction has been reported for other bpy complexes such as $[Ru(bpy)_3]^{2\oplus}$.[10]

Cyclic voltammetry in acetonitrile gave the same results as in DMF, but coulometric reduction at -2.50 V led to the deposition of a deep blue solid from the beginning of the experiment. No color developed in the bulk of the stirred solution during the electrolysis; only a faint and transitory purplish color was seen in the vicinity of the working Pt coil electrode, while the deeply colored solid accumulated on its surface. This solid did not have the usual "fluffy" appearance of most electrodeposited materials; it appeared fairly crystalline from the beginning. As soon as the Ar atmosphere was removed, the solid faded to a colorless-yellowish precipitate. Based on these results, a controlled-current electrocrystallization was attempted, using high-vacuum condi-

tions.[11] It led to the formation on the cathode, of good deep blue-violet, air-sensitive crystals of pyramidal shape (Fig. 1), which were subjected to X-ray crystallographic analysis.[12]

Fig. 1. Crystals formed on a Pt wire cathode by electroreduction of the sodium cryptate $[Na^{\oplus} \subset \mathbf{1}]Br^{\ominus}$.

Two views of the crystal structure determined are shown in Figure 2 together with the packing. The species is a cryptate complex in which the sodium cation is contained in the cavity of the tris(bpy) macrobicyclic ligand, as in the case of the sodium bromide cryptate of the related tris(phenanthroline) [tris(phen)] macrobicycle.[13]

Comparison of the structural data of the latter complex[13] with the present one is especially instructive. Whereas bromide ions are located in the crystal lattice of $[Na^{\oplus} \subset$ tris(phen)$]Br^{\ominus}$, no anions are found in the present structure, in which the molecules of complex are tightly packed (Fig. 2) together with one acetonitrile molecule of crystallization for each complex. The shortest $Na^{\oplus} \cdots Na^{\oplus}$ distance is 8.21 Å. In addition, this close packing leaves no "empty" space that could contain electrons as in the case of the electrides.[3,4] Consequently, the present species is electroneutral, and the electron must be located on the tris(bpy) ligand.

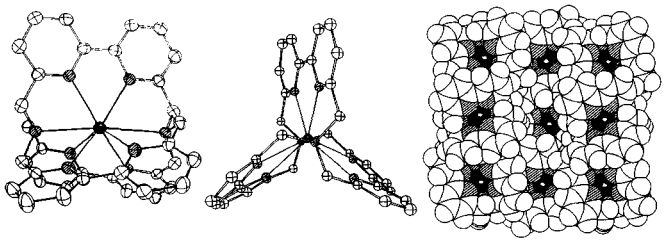

Fig. 2. Crystal structure of the sodio-cryptatium species $\{[Na^{\oplus} \subset \mathbf{1}]e^{\ominus}\} \cdot CH_3CN$ formed by electroreduction. Left: ORTEP side-view into the cavity showing the coordination of $Na^{\oplus}$ to the eight N sites; the bpy′ unit is at the top; center: ORTEP view along the bridgehead axis N, $Na^{\oplus}$, N; right: space filling presentation of the crystal packing showing the absence of any significant void.

The tris(phen) $Na^{\oplus}$ complex showed an approximate $\mathbf{C}_3$ symmetry axis. In contrast, the $[Na^{\oplus} \subset \mathbf{1}]$ cryptate cation presents a $\mathbf{C}_2$ axis, through the $Na^{\oplus}$ cation and the middle of the 2,2′-connecting bond of the uppermost bpy in Figure 2 (left) (designated by bpy′).

The $Na^{\oplus} \cdots$ N distances to the bridgehead nitrogens are 2.780 Å, very close to those in the tris(phen) complex (2.79 Å).[13] The $Na^{\oplus} \cdots$ N distances to the heterocyclic nitrogens display striking features: they are much shorter for the bpy′ nitrogens (2.589 Å) than for the other two, identical bipyridines (2.82–283 Å), whereas in the tris(phen)-$Na^{\oplus}$ complex they fall between these two values (2.70 Å).[13] Thus in the present complex, the $Na^{\oplus}$ cation is pulled towards the unique bpy′ group, suggesting that the unpaired electron is located on this bpy′ unit. Further support comes from the C2–C2′ distances; this distance is appreciably shorter for bpy′ (1.418 Å) than for the other two bpy groups (1.482 Å). In addition, whereas bpy′ is almost flat, the two other bpy units are not (dihedral angles of 0.7(5)° and 15.9(4)° between the two pyridine groups respectively). These features are consistent with the generation of the anion radical $bpy^{\bullet\ominus}$, where the additional electron is introduced into the lowest unoccupied molecular orbital of bpy which is bonding between the two pyridine rings.[14] The bpy′ groups do not overlap in the crystal.

The anion radical $bpy^{\bullet\ominus}$, obtained by electrochemical reduction, forms paramagnetic ion pairs whose ESR features have been described.[15]. The neutral species $[M(bpy)_3]^{\circ}$ (with M = Ru, Fe, or Os) have been generated via coulometric reduction of the dicationic parent complexes.[16] On the other hand, the electrochemical reduction of macrocyclic complexes incorporating an electron acceptor site has been studied in solution.[17]

Additional information comes from spectroscopie data. Allowing some of the crystals to decompose in air afforded a yellowish material. FAB mass spectrometry showed the peak corresponding to $[\mathbf{1}, Na^{\oplus}]$ at 597 *m/z*; the spectrum was identical to that of an authentic sample of the starting material, $[Na^{\oplus} \subset \mathbf{1}]Br^{\ominus}$. The 200-MHz ^1H NMR spectrum of this air-decomposed material was also the same as that of the starting complex.

All the above data agree with the formulation of the species obtained by electrocrystallization of $[Na^{\oplus} \subset \mathbf{1}]Br^{\ominus}$ as a neutral entity, which one may consider to be an expanded alkali-metal atom or a radical contact ion pair $\{[Na^{\oplus} \subset \mathbf{1}]e^{\ominus}\}$, and term *sodio-cryptatium*, the first member of the cryptatium family. The crystal structure indicates that, in the solid, the electron is localized on one of the bpy units, $[Na^{\oplus} \subset (bpy^{\ominus})(bpy)_2]^{\bullet}$.[18] Such a species is also of interest by its analogy with the monoreduced and the excited states, respectively $[Ru^{II}(bpy^{\ominus})(bpy)_2]^{\oplus}$ and $[Ru^{III}(bpy^{\ominus})(bpy)_2]^{2\oplus *}$, of the very intensively studied $[Ru(bpy)_3]^{2\oplus}$ complex,[19] providing structural data for the $(bpy^{\ominus})$ unit in these states. The sequence: metal atom, cryptatium, electride,[3,4] may be depicted as shown in Figure 3, representing for instance the cases: Na, $\{[Na^{\oplus} \subset \mathbf{1}]e^{\ominus}\}$, $\{[K^{\oplus} \subset$ cryptand-2.2.2$]e^{\ominus}\}$, where the electron is progressively "removed" from the atom.

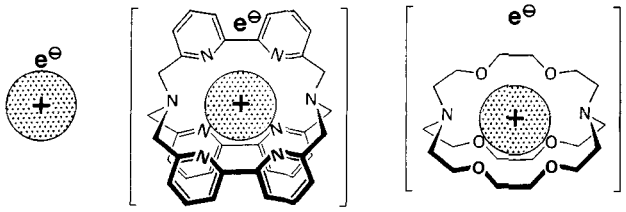

Fig. 3. Schematic representation of the series: (from the left to right) alkali-metal atom, cryptatium (expanded atom or radical contact ion pair $\{[Na^{\oplus} \subset \mathbf{1}]e^{\ominus}\}$), electride (Rydberg atom or electron salt) $\{[K^{\oplus} \subset$ cryptand-2.2.2$]e^{\ominus}\}$.

Numerous extensions of these results may be envisaged. The ESR spectra of the substance in the solid state and in

solution should provide information about electron delocalization within a given bpy unit and over the three bpy groups of the ligand, a feature of special significance for an expanded atom description.[20] Conductivity and magnetic properties are also of much interest. Furthermore, it might be possible to extend the list of such molecular "elements" from sodio-cryptatium to doubly reduced calcio-cryptatium and to triply reduced lanthano-cryptatium, for instance.

[11] The electrocrystallization cell was made by our own glassblower and consisted of an H-type arrangement with a glass frit (porosity no. 5) separating the two compartments. The compartments were coupled to the high vacuum independently, in order to be able to distill the solvent through the vacuum line directly into them, without going through the glass frit. In this fashion, it was possible to save complex by placing typically, 7 mg in only one of the compartments along with enough supporting electrolyte (Bu_4NPF_6) for a 0.1 M solution, while using only electrolyte in the other compartment. The typical vacuum obtained was ca. 10^{-5}–10^{-6} mm. The current was controlled with a current source made in the institute. In this two-electrode configuration, both electrodes were Pt wires, 0.7 mm in diameter and ca. 3 cm long. The optimal current was 10 μA and a typical run was complete in 15 hours. After this period deep blue-violet crystals of pyramidal shape had formed on the cathode (Fig. 1); they were of optimal size and qualitity for X-ray analysis. For removal from the cell, the vacuum was broken with purified Ar, and the electrode removed and placed in a Schlenck tube. After selection under the microsope of several crystals for X-ray analysis, the electrode was taken out of the Schlenck tube under a strong nitrogen flow, the highly air-sensititve crystals were removed from the Pt surface, and one was quickly selected and mounted for X-ray analysis all under a constant cold nitrogen stream.
[12] a) Crystal data: $C_{38}H_{33}N_9Na$, $M_r = 638.74$, tetragonal, space group $I4_1$, $a = 14.685(4)$, $c = 14.731(4)$ Å, $V = 3176.7$ Å^3, $\varrho_{calcd} = 1.335$ gcm^{-1}, $Z = 4$, $\mu(Cu_{K\alpha}) = 7.392$ cm^{-1} (graphite monochromator). A total of 1021 reflections were collected using a Philips PW1100/16 automatic diffractometer. Quantitative data were obtained at -100 °C using a locally built gas flow device. The resulting data set was analyzed using an Enraf-Nonius SDP/VAX package [12b]. Three standard reflections measured every hour during the data collection period showed no significant trend. The raw step-scan data were converted to intensities using the Lehmann–Larsen method [12c] and corrected for Lorentz, polarization, and absorption factors. The structure was then solved with SIR [12d] and refined to $R = 0.036$ using 897 reflections with $I > 3\sigma^*(I)$. b) B. A. Frenz: *The Enraf-Nonius CAD4-SDP* in H. Schenk, R. Olthof-Hazekamp, H. Isolated and Condensed Ta_2Ni_2 Clusters in the Layered Tellurides $Ta_2Ni_2Te_4$ and $Ta_2Ni_3Te_5$**

By *Wolfgang Tremel**

Dedicated to Professor Hans Georg von Schnering on the occasion of his 60th birthday

Chalcogenides of the early transition metals have been intensively investigated in recent years owing to their physical properties (e.g., anisotropic optical and electrical properties, superconductivity, charge density waves).[1] However, nearly all preparative investigations have been limited to sulfides and selenides.[2] Until very recently, tellurides were ignored,[3] even though their chemical uniqueness is already indicated by a comparison of simple binary compounds with analogous formulas: $NbSe_3$[4]—one of the best-studied inorganic compounds—has no counterpart among the tellurides; $HfTe_5$[5] and $TaTe_4$,[6] in turn, have no counterpart among the sulfides and selenides. Although the trichalcogenides MQ_3 (M = Ti, Zr, Hf; Q = S, Se, Te) are similar in terms of formula and structure for the sulfides, selenides, and tellurides,[7] the compounds exhibit significant differences in their properties.[8]

The starting point of our work was an investigation of the electronic structures of the layer compounds MTe_2 (M = Hf, Ta, W, Re).[9] The crystal structures of these compounds are derived from the CdI_2 structure. The $HfTe_2$ structure (d^0 system) corresponds to the CdI_2 aristotype.[10, 11] $TaTe_2$

(d^1),[12] WTe_2 (d^2),[13] and $ReSe_2$ (d^3),[14] on the other hand, represent structural variants whose metal partial structures are distorted in a way characteristic of the respective band occupation. Analysis of the band structure in this series of compounds showed that the changes in structure are induced electronically.[9] An interesting partial result of this investigation was the finding that, in $TaTe_2$ the Ta–Ta bonding orbitals are not completely occupied; therefore, modification of the structure should be possible by, for example, inclusion of cations.

Surprisingly, the reaction of Ta, Te, and Ni did not lead to inclusion of Ni in the interlayer regions, but instead to the novel layer compounds $Ta_2Ni_2Te_4$[15–17] and $Ta_2Ni_3Te_5$,[18,19] which contain isolated and condensed Ta_2Ni_2 cluster units, respectively. In both compounds, the layers are held together by van der Waals interactions only ($d_{Te-Te} \geq 3.846(2)$ Å).

The structure of $Ta_2Ni_2Te_4$ can be described starting from a hexagonal close packing of Te atoms; one-half of the octahedral holes in this packing are occupied by Ta atoms and one-quarter of the tetrahedral holes are occupied by Ni atoms. As illustrated in Figure 1, this description reveals the structural relationship to the NiAs and CdI_2 structure. Figure 1a shows a projection of the NiAs structure along *c*. Removal of every second layer of metal atoms in planes parallel to *bc* (open circles) results in formation of a (fictitious) $TaTe_2$ layer structure. The distortion of the $TaTe_2$ partial structure by movement of the Ta atoms in the directions shown by the arrows and the partial occupation of the tetrahedral holes (marked by black points in Fig. 1a) leads to the structure of $Ta_2Ni_2Te_4$. Pairwise shift of the Ta atoms away from the centers of the octahedral holes of one layer results in a coordination of the Ta atoms by 4+2 Te atoms (d_{Ta-Te}: 2.789 and 3.235 Å).

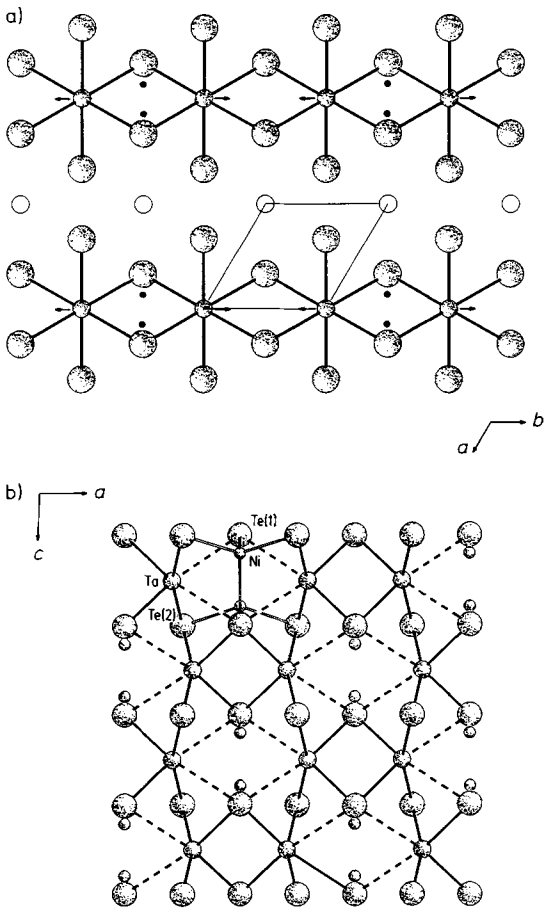

Fig. 1. a) Derivation of the $Ta_2Ni_2Te_4$ structure from the NiAs structure; parallel projection along [001] (large circles, Te; medium-sized circles, Ta). For explanation see text. b) Parallel projection of the $Ta_2Ni_2Te_4$ structure on a layer along [010] (large circles, Te; medium-sized circles, Ta; small circles, Ni). The different Ta-Te distances are symbolized by differing lines joining the atoms (solid line, $d_{Ta-Te} = 2.789$ Å; dashed line $d_{Ta-Te} = 3.235$ Å).

Noteworthy are the following points: (1) The known CdI_2 structure type is derived from the NiAs structure by removal of every second layer of metal atoms in planes parallel to *ab*. The two structures thus differ only in the arrangement of the metal layers. This gives rise to the question why only the CdI_2 structure type is observed. (2) In the (fictitious) $TaTe_2$ structure, tetrahedral holes exist between the layers and within the layers, but only the latter are occupied. Presumably, therefore, this "alternative" structural variant is stabilized by inclusion of Ni atoms within the layers.[20] The occupation of the octahedral and tetrahedral holes within a layer results in rhombuslike Ta_2Ni_2 clusters[21] ($d_{Ni-Ni} = 2.503(6)$, $d_{Ta-Ni} = 2.646(2)$ Å), which are linked through longer Ta–Ni and Ta–Ta contacts ($d_{Ni-Ta} = 2.873(3)$, $d_{Ta-Ta} = 3.196(1)$, 3.236(2) Å) to form a two-dimensional network (Fig. 2).

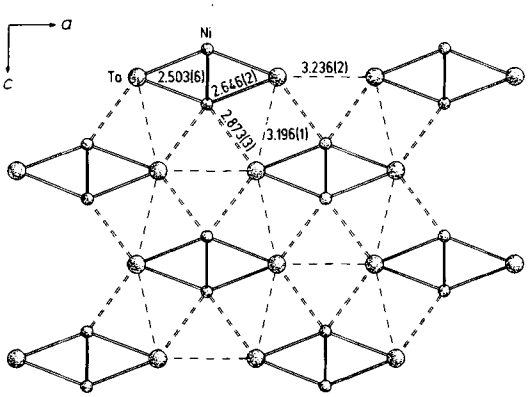

Fig. 2. $Ta_2Ni_2Te_4$, parallel projection of the metal lattice along [010] (large circles, Ta; small circles, Ni).

The Ni–Ni distance in the Ni_2Ta_2 clusters is nearly identical with the Ni–Ni distance in Ni metal ($d_{Ni-Ni} = 2.492$ Å);[22] an assessment of the Ni–Ta distance of 2.646 Å is possible by comparison with the metal-rich sulfidic phase $Ta_9Ni_2S_6$[23] ($d_{Ta-Ni} = 2.495$ Å).

The second compound obtained upon reaction of $TaTe_2$ with nickel, $Ta_2Ni_3Te_5$, like $Ta_2Ni_2Te_4$, has a layer structure. Figure 3 shows projections of the structure along *b* (Fig. 3a) and *a* (Fig. 3b). Each unit cell contains two $Ta_2Ni_3Te_5$ layers, which are stacked along *a*, and each layer has two chemically distinguishable Ni positions. Ni atoms of type A display short distances to two other Ni(A) atoms and Ni atoms of type B exhibit no Ni–Ni contacts.

A possible structural description is based on the hierarchy of interatomic distances. All Ni atoms are coordinated in a (distorted) tetrahedral fashion by Te ($\bar{d}_{Ni(A)-Te} = 2.562$ Å (3×), 2.744 Å (1×); $\bar{d}_{Ni(B)-Te} = 2.553$ Å (4×)), and the Ta atoms are surrounded in a square-pyramidal fashion by five Te atoms ($d_{Ta-Te} = 2.757$ Å (1×), 2.785 Å (2×), 2.869 Å (2×)). Furthermore, each metal atom displays other metal–metal contacts. The Ni(A) atoms have two further Ni(A) neighbors ($d_{Ni-Ni} = 2.502$ Å) and three Ta neighbors ($\bar{d}_{Ta-Ni} = 2.648$ Å (1×), 2.717 Å (2×)) and the Ta atoms possess five Ni neighbors ($\bar{d}_{Ta-Ni(A)} = 2.648$ Å (1×), 2.717 Å

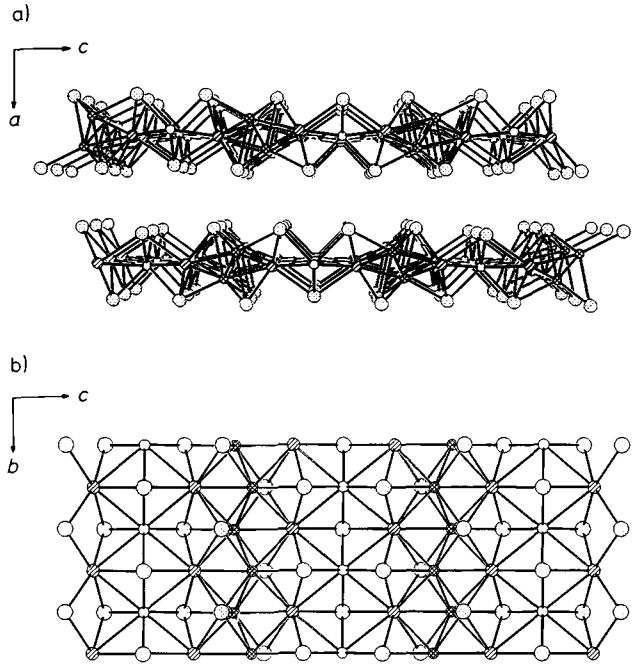

Fig. 3. $Ta_2Ni_3Te_5$: a) Perspective view of a section of the layer structure along [010]. b) Parallel projection of a layer along [100] (dotted circles, Te; hatched circles, Ta; cross-hatched circles, Ni(A); open circles, Ni(B)).

(2×); $\bar{d}_{Ta-Ni(B)} = 2.922$ Å (2×)); Ni atoms of type B have only four neighboring Ta atoms ($\bar{d}_{Ta-Ni(B)} = 2.922$ Å).

A structural description in terms of polyhedra starts from a chain of $NiTe_4$ tetrahedra. Ni(A) atoms are part of a chain of edge-linked $NiTe_4$ tetrahedra and Ni(B) atoms part of a chain of vertex-linked tetrahedra. Finally, the pyramidal $TaTe_5$ building blocks are linked through five common edges with five neighboring $NiTe_4$ tetrahedra.

More instructive for understanding the structure and for elucidating the structural relationship of $Ta_2Ni_2Te_4$ and $Ta_2Ni_3Te_5$ is to consider the partial "naked-metal" structure of one layer (Fig. 4). The $Ta_2Ni_3Te_5$ structure also contains

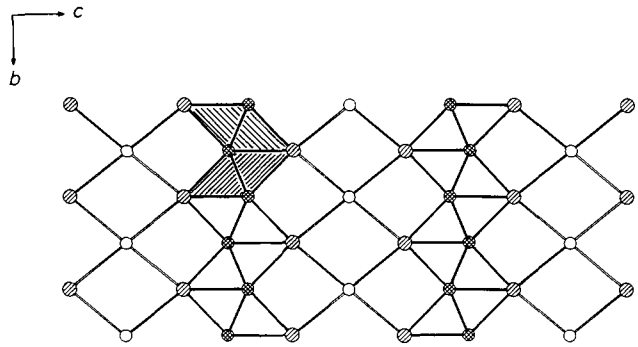

Fig. 4. $Ta_2Ni_3Te_5$: Projection of the metal lattice along [100] (hatched circles, Ta; cross-hatched circles, Ni(A); open circles, Ni(B)). Two of the rhombus-shaped Na_2Ni_2 clusters are highlighted by shading.

rhombuslike Ta_2Ni_2 clusters, but, in this case, they are linked through common Ta–Ni edges to give $^1_\infty[Ta_2Ni_2]$ chains; that is, cluster condensation through *trans* edges results in one-dimensional infinite chains. These chains are joined through the Ni(B) atoms to form a two-dimensional metal layer.

This structural description has mnemonic advantages. In principle, the occurrence of clusters in compounds of electron-deficient 4d and 5d metals is not surprising[24]—remarkable, however, is the occurrence of condensed clusters in typical layer compounds. Some of the few known examples are ZrCl,[25] $TbClH_{1-x}$,[26] and $Gd_2Cl_2C_2$,[27] where octahedral metal clusters are condensed to form two-dimensional layers. Also remarkable is the occurrence of layer compounds for nonmetal/metal ratios of 1/1. Here, too, the low-valent zirconium halides (e.g., ZrCl) are a prime example. Presumably, therefore, the "isoelectronic correlation" Zr-Cl and Ta-Te is not a mere coincidence.

Metallic properties are expected for both compounds, $Ta_2Ni_2Te_4$ and $Ta_2Ni_3Te_5$,[28] as shown by an attempt to assign formal oxidation numbers on the basis of electronegativity considerations (e.g., $(Ta^{2\oplus})_2(Ni^{2\oplus})_2(Te^{2\ominus})_4$ or $(Ta^{3\oplus})_2(Ni^{1\oplus})_2(Te^{2\ominus})_4$ for the former and $(Ta^{2\oplus})_2(Ni^{2\oplus})_3(Te^{2\ominus})_5$ for the latter). Band-structure calculations of the LCAO type (EH approximation)[29] confirm that this approach is basically correct. The calculated density of states for $Ta_2Ni_2Te_4$ with the contributions of Ta and Ni (Fig. 5a) shows the metallic character of the compound. The calculated Ta–Ta, Ta–Ni, and Ni–Ni overlap populations (COOP diagram, Fig. 5b) indicate the relative strength of the respective metal–metal interactions. The numerical values of 0.040, 0.155, and 0.156/0.078 ($d_{Ta-Ni} = 2.646(2)/2.873(3)$ Å) for the Ni–Ni, Ta–Ta, and Ta–Ni overlap populations reveal the importance of Ta–Ta and Ta–Ni interactions in comparison to Ni–Ni interactions.

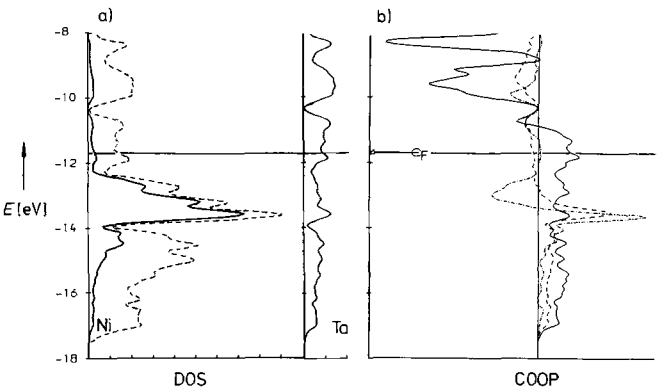

Fig. 5. a) Density of states (DOS) for $Na_2Ni_4Te_4$. Left: Total density (dashed line) and Ni partial density. Right: Ta partial density. b) COOP diagram (left, antibonding; right, bonding): solid line, Ta-Ta; dashed line, Ta-Ni (average); dashed and dotted line, Ni-Ni. The Fermi level is marked by a horizontal line.

The high formation tendency of the title compounds and the preferred formation of clusters instead of inclusion of the 3d metal in the interlayer region may be ascribed to the large affinity between electron-deficient and electron-rich metals (according to the generalized Lewis acid-base concept of *Brewer* et al.[30]). This fact is also documented by the synthesis of other related compounds such as M_2FeTe_4 (M = Nb, Ta), $M_2M'_2Te_4$ (M' = Fe, Co; M = Nb, Ta), TaM'_2Te_2 (M' = Co, Ni) $Ta_4M'Te_4$ (M' = Fe, Co),[31], and $TaFe_{1+x}Te_3$ ($x \approx 0.07$).[32]

[15] In order to synthesize $Ta_2Ni_2Te_4$, the corresponding stoichiometric amounts of the elements, together with I_2 as mineralizer, were heated in a sealed quartz glass tube for 14 d at 1000 °C. The product (EDAX (energy dispersive X-ray spectroscopy): Ta, Ni, Te) consists of platelets with a metallic luster and is a single phase according to the Guinier diagram.

[16] Space group *Pmna* (No. 53), $Z = 2$ (based on $Ta_2Ni_2Te_4$), $a = 7.897(1)$, $b = 7.228(1)$, $c = 6.230(1)$ Å (Siemens R3), $Mo_{K\alpha}$ ($\mu = 51.60\ mm^{-1}$); crystal size, $0.04 \times 0.035 \times 0.035\ mm^3$; ω-2θ scan, $2\theta_{max} = 75$ °C, 1734 reflections $(h, k, +l)$, empirical absorption correction, 807 symmetry-independent reflections, $R(F_0)/R_w = 0.0646/0.0693$. b) Further details in the crystal structure investigations are available on request from Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, W-7514 Eggenstein-Leopoldshafen 2 (FRG), by quoting the depository number CSD-55272, the names of the authors, and the journal citation.

[17] An independent structure determination of $Ta_2Ni_2Te_4$ was recently reported: J. L. Huang, B. G. Huang. *Acta Crystallogr. Sect. A 46 (Suppl.)* (1990) C-287.

[18] $Ta_2Ni_3Te_5$ was synthesized from the corresponding stoichiometric amounts of the elements at 900 °C in a sealed quartz glass tube (10 d) with addition of $TeCl_4$ as mineralizer. The product (EDAX: Ta, Ni, Te) consists of needles with metallic luster which are up to 1 cm long. The Pd analogue $Ta_2Pd_3Te_5$ was synthesized under analogous conditions ($T = 850$ °C). Lattice constants $a = 13.989(3)$, $b = 3.713(1)$, $c = 18.630(4)$ Å, space group *Pnma* (Nr. 62), $Z = 4$.

[19] Space group *Pnma* (No. 62), $Z = 4$, $a = 13.897(4)$, $b = 3.695(1)$, $c = 17.729(6)$ Å (Siemens R3), $Mo_{K\alpha}$ (μ) $= 45.49\ mm^{-1}$); crystal size, $0.006 \times 0.03 \times 0.15\ mm^3$; ω-2θ scan, $2\theta_{max} = 80°$, 3321 reflections (h, k, l), empirical absorption correction, 3158 symmetry-independent reflections, 2353 with $I > 2\sigma(I)$, $R(F_0)/R_w = 0.043/0.044$ [16b].

[20] The preferential occurrence of the CdI_2 structure type can be understood on the basis of LCAO band-structure calculations (extended Hückel (EH) approximation) and on the basis of symmetry arguments. The incorporation of nickel (and, in general, of elements of the iron group) in the tetrahedral holes of a layer of the $TaTe_2$ structure leads to their electronic stabilization due to interaction of unoccupied t_{2g} levels of tantalum with the corresponding occupied levels of nickel: W. Tremel, unpublished results.

[21] The formulation $Ta_2Ni_2Te_4$ (instead of $TaNiTe_2$) was chosen in order to give the cluster formal recognition as well.

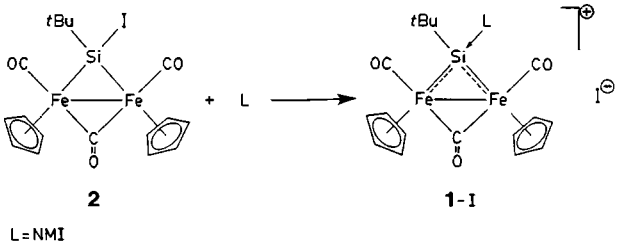
$[Cp_2Fe_2(CO)_3(\mu\text{-Si}t\text{Bu} \cdot \text{NMI})]I$: The First Silanetriyldiiron Complex**

By *Yasuro Kawano*, *Hiromi Tobita*, and *Hiroshi Ogino**

The chemistry of mononuclear[1] and dinuclear[2] carbyne complexes is well established. However, there are no reports on the analogous silanetriyl complexes. Here we wish to report the synthesis and crystal structure of the first donor-stabilized cationic silanetriyl diiron complex, **1** (NMI = *N*-methylimidazole), which was isolated as **1**-I.

$[Cp_2Fe_2(CO)_3(\mu\text{-Si}t\text{Bu} \cdot \text{NMI})]^{\oplus}$

The synthesis of **1**-I was achieved by exchanging an iodide on the silanediyl bridge of the μ-silanediyl complex **2**[3] with a strong Lewis base, NMI.



2 **1**-I

L = NMI

The unprecedented silanetriyl-bridged structure of **1**-I was determined unequivocally by an X-ray crystal structure analysis (Fig. 1).[4] Coordination of the lone pair on the nitrogen atom of NMI to the Si atom in the *tert*-butylsilanetriyl ligand causes pyramidalization of the silicon atom (the angle between the Fe_2Si plane and Si–C8 is 143.2°). The two Cp rings, which are mutually *cis*, and the *tert*-butyl group are located on the same side of the Fe_2SiC bicyclic ring. The distance between the Si and I atoms (5.388(2) Å) is substantially longer than the sum of the effective van der Waals radii of Si and I (4.08 Å).[5] This clearly indicates that there is no chemical bond between Si and I. The plane of the five-membered ring of NMI is parallel to the Fe–Fe bond and the NMI ligand is disordered between the two possible orientations related by a crystallographic mirror plane. The Fe–Si

[**] This work was supported by the Nissan Science Foundation and by the Ministry of Education, Science and Culture (Grant-in-Aid for International Scientific Research Program). NMI = *N*-methylimidazole.

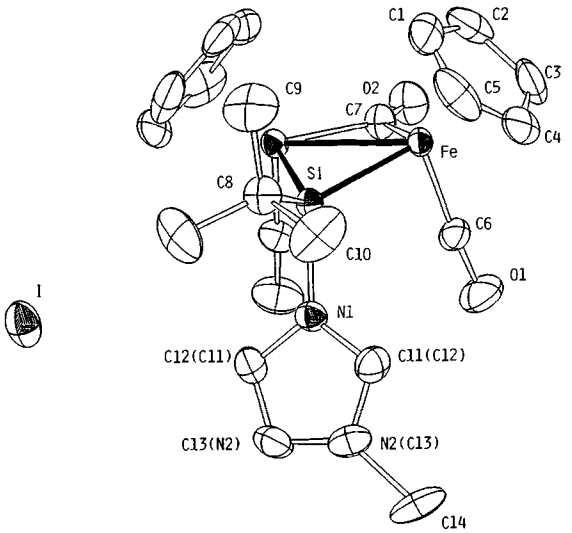

Fig. 1. Crystal structure of **1**-I (ORTEP, thermal ellipsoids at the 30% probability level, H atoms omitted). Selected interatomic dictances [Å] and angles [°]: Si···I 5.388(2), Si–Fe 2.262(2), Si–N1 1.885(7), Si–C8 1.910(9), Fe–Fe' 2.626(2), Fe–C6 1.745(6), Fe–C7 1.913(8), C6–O1 1.137(8), C7–O2 1.185(12); Fe–Si–Fe' 70.96(7), C8–Si–N1 96.2(4); $SiFe_2$ plane and Si–C8 vector 143.2, $SiFe_2$ plane and Si–N1 vector 120.7.

bond length (2.262(2) Å) is shorter than the known values for neutral silanediyl-bridged diiron complexes, **3**

$[Cp_2Fe_2(CO)_3(\mu\text{-SiH}t\text{Bu})]$ **3**

(2.270(1) and 2.272(1) Å)[6] and $[Cp_2Fe_2(CO)_3\{\mu\text{-SiMe(SiMe}_3)\}]$ (2.294(1) and 2.301(1) Å).[7, 8] Also, the Si–N bond length is 1.885(7) Å, which is significantly longer than the usual value for Si–N covalent bonds (ca. 1.75 Å).

When NMI was added to a CD_3CN solution of **2**, two new singlets, assignable to the Cp and *tert*-butyl groups of **1** appeared at lower field than the corresponding signals of **2**. Even when the bromo derivative of **2**, $[Cp_2Fe_2(CO)_3(\mu\text{-SiBr}t\text{Bu})]$, was used instead of **2**, the formation of **1** could be confirmed by ^{1}H NMR spectroscopy. The ^{29}Si NMR signal of **1** in CD_3CN appears at remarkably low field ($\delta = 251.5$), which is consistent with the existence of a "silanetriyl" ligand.

The FAB mass spectrum of **1**-I in a sulfolane matrix clearly shows the peak of the cation **1** at $m/z = 493$. Interestingly, the spectrum also shows a peak assignable to the base-free silanetriyl complex $[Cp_2Fe_2(CO)_3(\mu\text{-Si}t\text{Bu})]^{\oplus}$ at $m/z = 411$.

In the IR spectrum of **1**-I, ν_{CO} bands of carbonyl ligands appear at 1980, 1932, and 1766 cm^{-1}, which are higher in wavenumber than those of **3** by about 30 cm^{-1} on average. This is attributable to the decrease in back-donation from Fe atoms to carbonyl ligands caused by back-donation from Fe atoms to the electron-deficient Si atom in **1**.

Cation **1** is readily reduced by $NaBH_4$ to give **3** in fair yield, whereas **2** does not react with $NaBH_4$ under the same experimental conditions. This result also demonstrates the electron deficiency of the Si atom in **1**. The activation of a silicon-containing group by a Lewis base promises to be of synthetic importance.[12]

Experimental Procedure

N-Methylimidazole (14 μL, 0.18 mmol) was added to a stirred solution of **2** (88 mg, 0.16 mmol) in 1 mL of CH_3CN. The mixture was allowed to stand at 40 °C for 30 min, then gradually cooled to room temperature. Et_2O (2 mL) was added and the reaction mixture was cooled to − 48 °C. After 2 h, the supernatant fluid was removed by syringe. The red crystals thus obtained, **1**-I · CH_3CN, were washed with Et_2O (2.5 mL) three times and dried under vacuum. Yield 65 mg (0.10 mmol, 66%). Correct elemental analysis. ^{1}H NMR (200 MHz, CD_3CN): $\delta = 1.40$ (s, 9H; *t*Bu), 3.83 (s, 3H; NCH_3), 5.10 (s, 10H; Cp), 7.29, 7.46, 8.82 (m, 3 × 1H; $CH_3C_3H_3N_2$). ^{13}C NMR (75.5 MHz, CD_3CN): $\delta = 29.1$ (NCH_3), 29.9 ($C(CH_3)_3$), 36.3 ($C(CH_3)_3$), 86.4 (Cp), 123.3, 128.6, 141.4 ($CH_3C_3H_3N_2$), 213.6 (*CO*). The μ-CO signal was not observed because of the low solubility of **1**-I in CD_3CN. IR (KBr): $\tilde{\nu}$[cm^{-1}] = 1980, 1932, 1766 (ν CO). FAB-MS (sulfolane matrix): *m/z* 493 ($M^{\oplus}$, 38%), 411 ([*M* − NMI]$^{\oplus}$, 53), 203 ([CpFeNMI]$^{\oplus}$, 100), 83 ([NMI + H]$^{\oplus}$, 74).

Photocatalysis of the Homogeneous Water-Gas Shift Reaction under Ambient Conditions by Cationic Iridium(III) Complexes**

By *Raymond Ziessel**

The reaction of CO with H_2O to form CO_2 and H_2 [Eq. (a), $\Delta H^{\circ}_{298} = -41$ kJ mol^{-1}] is an important industrial reaction, the so-called water-gas shift reaction (WGSR). It is

$$CO(g) + H_2O(g) \rightleftharpoons CO_2(g) + H_2(g) \qquad (a)$$

a practical method for the production of H_2 and for the elimination of CO, which contaminates industrial gases in-

volved in catalytic processes (e.g., Haber–Bosch synthesis of NH_3).[1] Conventional heterogeneous catalysts,[2] based on chromium-activated iron oxide or cobalt-molybdenum oxides are only active at high temperatures and pressures ($T > 400\,°C$, $p > 200$ atm CO). Homogeneous catalysts based on metal carbonyls, $M(CO)_6$,[3] work under milder conditions (180 °C, 35 atm) in alkaline or acidic medium. Recently, Ir^{I}[4] and Ru^{II}[5-6] complexes have been shown to efficiently catalyze the *thermal WGSR* at 100 °C/1 atm and at 20–80 °C/1–35 atm, respectively. Examples of the *photoassisted WGSR* have been reported using heterogeneous TiO_2[7] or ZnS.[8] A true homogeneous *photochemical WGSR* has not as yet been found, despite many attempts using bipyridine complexes of Ru^{II}.[9]

The thermodynamics of the WGSR make it important to find catalytic systems that are active at low temperatures. The negative entropic term, $S^{\circ}_{298} = -42\,J\,K^{-1}$, of reaction (a) disfavor it as the temperature is increased, in spite of its exergonic character at room temperature ($\Delta G^{\circ}_{298} = -28\,kJ\,mol^{-1}$). In addition, efficient room-temperature catalysts would allow large energy savings, since liquid water could be used instead of steam. We describe here our results and mechanistic analysis of the first highly efficient light-assisted WGSR, which takes place under extremely mild conditions (room temperature, ambient pressure, neutral pH, visible light) and is catalyzed by novel Ir^{III} pentamethylcyclopentadienyl (Cp*) complexes containing novel 4,4′-substituted bipyridine ligands (L).

The complexes of type $[Cp^*Ir(L)Cl]^{\oplus}Cl^{\ominus}$ (**2**, Scheme 1) were prepared, almost quantitatively, by reaction of a dimethylformamide solution of $[\{Cp^*IrCl(\mu\text{-}Cl)\}_2]$[10] with

[a] Chemical shifts of the Cp* ligand. [b] *m*-Nitrobenzyl alcohol as matrix. All species display a molecular ion peak with the expected isotopic distribution (ca. 35% ^{191}Ir and 65% ^{193}Ir) and a peak corresponding to the loss of the coordinated chloride (**1a**, **2a–e**), triflate (**1b**), or hydroxide (**1d**).

two equivalents of the 4,4′-substituted, ligand (substituents: R = COOH,[11] COO*i*Pr,[12] Br,[13] NO_2,[14] NMe_2[13,15]). The complexes were recrystallized by slow diffusion of diethyl ether into an acetonitrile solution of the crude material. Compound **1b** was quantitatively synthesized by allowing **1a** to react with two equivalents of silver trifluoromethanesulfonate in acetonitrile. Their compositions have been established by ^1H and ^{13}C NMR spectroscopy, positive fast atom bombardment (FAB^+) mass spectroscopy (Table 1), and elemental analysis. When complexes **1a–d** and **2a–c**, **e** were irradiated with visible light in the presence of CO (1 atm) and H_2O at 25 °C, CO_2 and H_2 were detected by gas chromatography (Table 2). All complexes showed a marked

[a] Irradiation for 2 h with white light ($\lambda > 400$ nm). [b] Adjusted using a 0.01 M phosphate buffer. [c] Calculated by dividing the number of moles of H_2 by the number of moles of the starting complexes. [d] Dark reaction with a 15-h contact time. [e] Bleaching of the solution after a few minutes of irradiation.

pH effect on catalytic activity (Fig. 1, left) which proved that both CO oxidation (favored in basic media) and H_2 formation (accelerated in acid media) are two kinetically important reactions. Figure 1, right, shows that the rate of H_2 formation increases with increasing catalyst concentration. In the concentration range of 0.045–0.20 mM of catalyst **2a**, the reaction showed a first-order rate dependence on catalyst concentration, with a calculated rate constant of $0.34\,h^{-1}$.

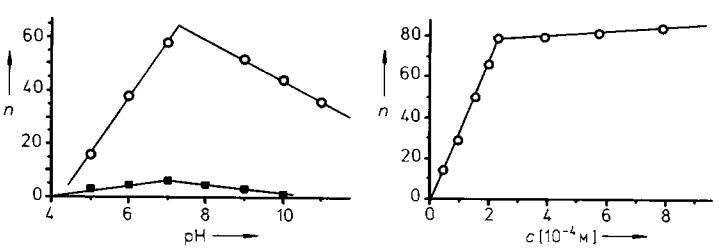

Fig. 1. Left: Effect of pH on the turnover number *n* of the photochemical WGSR (2.3×10^{-4} M **2a** (o) and **1a** (■), 1 atm CO, 15 °C, irradiation time 2 h). Right: Effect of catalyst concentration (**2a**) on *n* (15 °C, 1 atm CO, pH 7.0, irradiation time 2 h).

A remarkable increase in catalytic activity was observed when the nonsubstituted ligand **1a** was substituted with electron-withdrawing groups such as COOH (**2a**) or COO*i*Pr (**2b**). However, a dramatic decrease in activity was observed when an electron-donating substituent such as NMe_2 (**2e**) was used. This suggests that the substitution pattern in the 4,4′-position of the bipyridine strongly affects the rate-limiting step of this process, via an electronic effect. The absence of catalytic activity of the NO_2-substituted complex (**2d**) is due to a light-assisted hydrolysis of the NO_2 group, followed by loss of the ligand, as shown by the disappearance of the metal–ligand charge-transfer absorption band in the UV/VIS absorption spectra. It is also of interest to note that the thermal displacement of $Cl^{\ominus}$ by CO appears not to limit the efficiency of the process. The use of a more labile ligand ($CF_3SO_3^{\ominus}$ in complex **1b**) had no effect on the rate of reaction (Table 2).

The effect of temperature on the rate of H_2 formation was studied between 15 and 45 °C with two different complexes (**1a** and **2a**), as shown in the plot of ln *r* versus $1/T$ in Figure 2. Activation energies, E_a, of 29.6 kJ mol^{-1} and

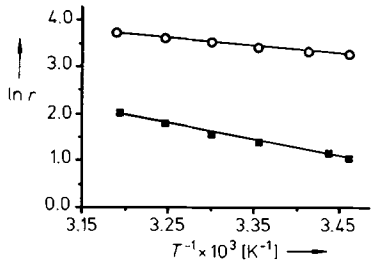

Fig. 2. Effect of temperature on the rate *r* [M min^{-1}] of the photochemical WGSR (2.3×10^{-4} M **2a** (o) and **1a** (■), 1 atm CO, Ph 7.0, irradiation time 1 h).

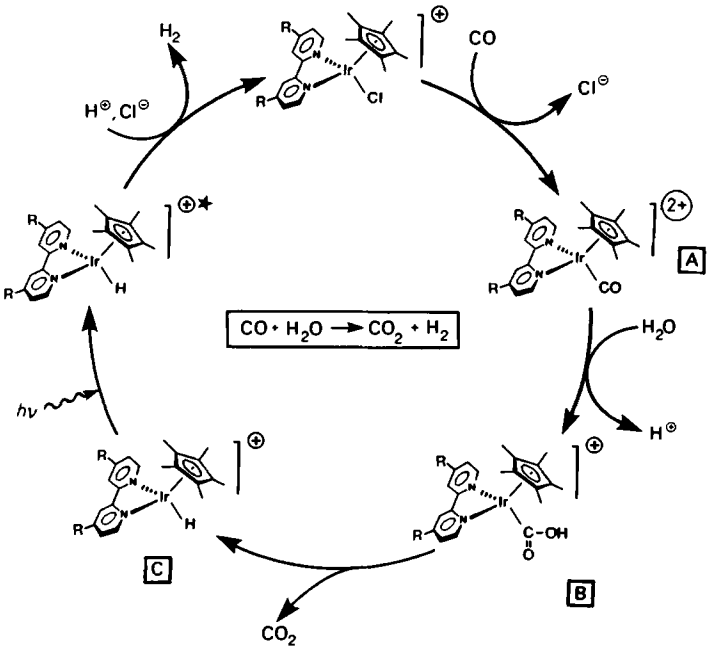
14.6 kJ mol^{-1} were found for complexes **1a** and **2a**, respectively. Assuming that the photochemical step has a very low activation energy,[16] these values indicate, by comparison with similar values obtained in thermal WGS processes described in the literature,[17] that decarboxylation of intermediate **B** (Scheme 2) is the rate-limiting step. Other studies on systems with higher activation energies (96–100 kJ mole^{-1}) show that the rate-limiting step is no longer decarboxylation but the reductive elimination of H_2.[4, 18] The presence of an electron-withdrawing group on the bpy-chelate halves the E_a and thus favors the decarboxylation of the intermediate. This is in good agreement with the observation that classical organic acids are much easier to decarboxylate when an electron-withdrawing group is present in the molecule.[19, 20]

From the above observations, along with further ^1H and ^{13}C NMR experiments carried out in sealed NMR tubes with labeled ^{13}CO, a proposed mechanism for the overall WGSR catalyzed by $[Cp^*Ir(L)Cl]^{\oplus}$ is shown in Scheme 2. It involves the formation of a highly reactive Ir^{III}-CO complex (intermediate **A** in Scheme 2) by CO displacement of $Cl^{\ominus}$. These species could not be isolated but have been characterized by ^{13}C NMR ($\delta = 178.2$ for precursor **1a** and 163.1 for precursor **2a** with CD_3CN as internal standard), FT-IR ($\nu_{CO} = 2069$ cm^{-1} for precursor **1a** and 2095 cm^{-1} for precursor **2a** in D_2O), and UV/VIS absorption spectroscopy (broad bands centered at 402 nm for precursor **1a** and 410 nm for precursor **2a**). Nucleophilic attack of water at this carbonyl gives the hydroxycarbonyl intermediate **B**, whose formation might also strongly be favored by the pres-



Scheme 2. Proposed reaction mechanism for the homogeneous catalysis of the photochemical WGSR by Ir^{III} complexes.

ence of an electron-withdrawing group on the bpy ligand. Preparation of related carboxylato-bpy Ir^{III} derivatives[21] and exchange reactions of water oxygen with cationic carbonyl oxygen[22] have previously been described. Decarboxylation of intermediate **B** (the rate-limiting step) gives a hydrido-Ir^{III} species[23, 24] (intermediate **C**), which, under photolysis and protonation, liberates H_2 and the starting complex. The photochemical nature of this last step was established as follows: (1) no H_2 was produced in the dark; (2) when complexes **1a**, **2a**, **b** were kept in the dark under CO (1 atm) in a sealed NMR tube, the ^1H NMR spectrum of the solution shows peaks at $\delta = -11.4$, -11.8, and -12.09, respectively, for hydride intermediates **C** in Scheme 2. These signals disappear after short photolysis; (3) dissolution of $[Cp^*Ir(bpy)(H)]^{\oplus}$,[23, 24] under vacuum in the dark, in phosphate buffer at pH = 7.0 results in no H_2 formation. Upon irradiation, however, stoichiometric amounts of H_2 are generated. All these observations corroborate the fact that the formation of H_2 is a fast reaction under irradiation.

The possibility that intermediate **B** could be formed by insertion of CO into Ir^{III}-OH was ruled out by the absence of thermal or photochemical reactivity of complex **1d** with carbon monoxide.

Experimental Procedure

The water-gas shift reaction was carried out in a 30-mL thermostated Schlenk flask containing 10 mL of 0.01 M phosphate buffer (pH 2 to 13) and 0.45×10^{-4} to 7.9×10^{-4} M **1a–d** and **2a–e**. Thermal equilibrium (in the range of 5–60 °C) was ensured by a water/ethyleneglycol circulation in a double-walled Schlenk flask. The flask and contents were degassed by three freeze–pump–thaw cycles and the internal pressure was adjusted to 1 atm with CO (99.94% purity). Irradiation was conducted with a 250-W halogen lamp (slide projector) focused on the solution. Gaseous samples were analyzed by gas chromatography. The sealed NMR tubes (5 or 10 mm) were prepared as previously described,[25] under a 90.5% ^{13}C-enriched CO atmosphere. The 200-MHz (^1H NMR) and 50-MHz (^{13}C NMR) spectra of the solution were recorded in aqueous phosphate buffer using 20% CD_3CN as internal standard. A homonuclear presaturation program (solvent suppression) was used to record the ^1H NMR spectrum.

Dinuclear Cyanoalkylidene Complexes of Iron**

By *Vincenzo G. Albano, Silvia Bordoni, Dario Braga, Luigi Busetto,* Antonio Palazzi,* and *Valerio Zanotti*

Compounds containing a cyanoalkylidene, C(CN)X, as bridging ligand are not very common, in spite of the vast literature on μ-alkylidene bimetallic complexes.[1] In fact, prior to our synthesis of $[Fe_2Cp_2(CO)_2(\mu\text{-}CO)\{\mu\text{-}C(CN)SMe\}]$,[2] only two such complexes had been reported. Both contained the μ-$C(CN)_2$ group.[3] Very recently, we succeeded in preparing the complex sulfonium salt **1** via *S*-

$[Fe_2Cp_2(CO)_2(\mu\text{-}CO)\{\mu\text{-}C(CN)SMe_2\}]SO_3CF_3$ **1**

methylation of the μ-(methylthio)cyano complex.[4] The chemistry of the cation in **1** has now revealed a surprising versatility. The concomitant presence of the electron-withdrawing CN and the nucleofugal Me_2S substituents at the bridging carbon atom confers on **1** the properties of both cationic μ-alkylidyne[5] and terminal dichloroalkylidene[6]

Reaction of **1** with $NaBH_4$, nBu_4NCN, LiMe/CuCN, NaAc, or NaSMe results in elimination of Me_2S to form complexes of type **2**. These reactions clearly demonstrate the pseudo-cyanoalkylidyne nature of the sulfonium salt. This behavior is even more evident in the reactions with alcohols, which spontaneously produce high yields of a variety of alkylidene complexes **3**, including those containing functionalized or sterically demanding alkoxy groups. Although the configuration of **1** is *cis* according to X-ray analysis,[7] the μ-cyanoalkylidenes **2** and **3** exist as a mixture of *cis* and *trans* isomers, which could not be separated by column chromatography or fractional crystallization (Table 1). We assume that the *cis-syn* form with the smaller CN substituent of the alkylidene moiety on the Cp side is the main isomer. In complex **2** (X=H), however, the small difference in steric hindrance of the substituents on the alkylidene unit favors a comparable distribution of the three isomers in CD_2Cl_2 as solvent (*cis-syn*:*cis-anti*:*trans* $\approx$ 3.3:1.6:1). These isomer ratios were estimated from NMR data by analogy with recent findings on the related $[Fe_2Cp_2(CO)_2(\mu\text{-}CO)\{\mu\text{-}C(H)SR\}]$[8] complexes in which the lowest-field ^1H NMR methylidene proton signal was attributed to the isomer bearing H on the Cp side (*cis-anti*).

Reactions with a variety of primary amines cause degradation of the metal-bound μ-$C(CN)SMe_2$ fragment; only the bridging atom is retained in the resulting isocyanide complexes **8**. These reactions, similar to those already reported for mononuclear dichloro-[6] and dithiocarbene[9] complexes, have been now successfully extended to the preparation

[a] 200-MHz ^{1}H and ^{13}C{^{1}H} NMR spectra recorded in CD_2Cl_2 at 25 °C with TMS as standard, unless stated otherwise. [b] Due to **8** (R=Ph); see text.

of a variety of dinuclear species, including those containing functionalized μ-isocyanide ligands. The isolation of **4** and **5** from the reaction of **1** with tertiary and secondary amines suggests that formation of **8** proceeds via ammonium (type **4**) and aminoalkylidene complexes (type **7**), which subsequently lose HCN. In the reaction with the weakly basic aniline, the supposed intermediate has been isolated and structurally characterized by an X-ray diffraction study (Fig. 1). This intermediate shows the same *cis-syn* arrangement of the substituents as **1**. The retained *syn* arrangement observed for **7** and suggested for the major isomer in **3**–**5**, **10**, and **11** may be due to an attack of the nucleophile from the less hindered CO face of the μ-cyanoalkylidyne intermediate formed from **1** after loss of Me_2S. Complex **7**,[10] which is slowly transformed into the μ-phenylisocyanide complex in solution, represents the first structurally characterized dinuclear μ-aminoalkylidene complex in which no stabilization due to additional coordination to one of the metals through the amino N atom or the functionalized end of the amino group is present.[11] It may therefore be assumed that the electron-withdrawing CN group stabilizes the dimetallacyclopropane ring even when a π-donating N atom is present on the μ-C atom. The crystal structure of *cis*-**7** (R = Ph) (Fig. 1) indicates that the lone pair on the aniline nitrogen atom is not parallel to the π orbital on the carbene atom (C4) nor to the π orbitals of the phenyl ring. The torsion angles C5-C4-N2-C6 (42°) and C4-N2-C6-C7 (17°) indicate a better interaction with the phenyl ring, as confirmed by the bond distances N2-C4 (1.429(3) Å) and N2-C6 (1.397(3) Å). The reactions of **1** with the bulky diisopropylamine or with ethylenediamine, which, respectively, afford the terminal aminocarbene complexes **6** and **9**, indicate that steric as well as electronic effects play a role in the position of the alkylidene group. Either sterically demanding or π-donating N-substituents at the bridging carbon may ultimately cause the alkylidene ligand to shift from the expected bridging to the terminally coordinated position.

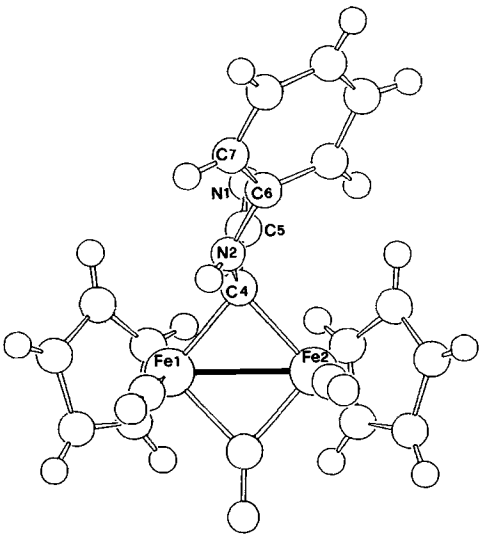

Fig. 1. Molecular structure of *cis*-**7** (R = Ph). The molecule adopts an asymmetric conformation but is present as a racemic mixture in the crystal. Space group $P2_1/c$, a = 9.711(2), b = 11.910(2), c = 16.426(1) Å, β = 89.91(1)°, Z = 4, V = 1899.8 Å^3, $2\theta \leq 56°$, 3664 measured reflections, 3607 observed ($I > 2\sigma(I)$), 317 refined parameters, anisotropic temperature factors for non-hydrogen atoms, R = 0.029. Selected bond lengths [Å] and angles [°]: Fe1-Fe2 2.533(1), C4-Fe1 2.004(2), C4-Fe2 2.028(2), C4-C5 1.450(3), C5-N1 1.155(3), C4-N2 1.429(3), N2-C6 1.397(3); C5-C4-N2 108.7(2), C4-N2-C6 127.9(2).

The strong electrophilic properties of the μ-C atom in **1** are also evident from its reaction with the nitrogen end of the metalate $[W(CO)_5CN]^{\ominus}$, which yields complex **10**. In **10**, the unusual (cyano)isocyanoalkylidene group, C(CN)NC, is bonded to three metal centers. Complex **10** is isomeric to **11**, which has been obtained by reaction of the dicyanoalkylidene complex **2** (X=CN) with [W(CO)$_5$(thf)]. Whereas the isomer **11** reacts with pyridine (Py) to form quantitatively **1** and [M(CO)$_5$Py], the isocyano form **10** does not react with pyridine or CO up to 100 atm. This observation is in line with the predicted ability of the isocyano function to stabilize carbenes,[12] which has recently been confirmed through the preparation of the somehow related terminal alkylidene complex $[(CO)_5CrC(NCCl_2)(NCMnCp(CO)_2]$.[13]

Experimental Procedure

2 (X=H): Complex **1** (370 mg, 0.64 mmol) was dissolved in MeCN (10 mL) and the resulting solution was treated with $NaBH_4$ (35 mg, 0.93 mmol); the color of the solution turned immediately from red brown to red and the solvent was removed under vacuum. The residue was dissolved in dichloromethane and filtered on an alumina column (5 × 3 cm). The red solution was evaporated to dryness under vacuum and the residue crystallized from CH_2Cl_2 layered with *n*-pentane at − 20 °C to yield 168 mg (72%) of **2** (X=H).

3 (R=CH_2-CH=CH_2): In a typical experiment, **1** (300 mg, 0.52 mmol) was dissolved in MeCN (15 mL) and an excess of $HOCH_2$-CH=CH_2 (4 mL) was added after stirring. The resulting solution was filtered on an alumina column (10 × 3 cm; eluent, CH_2Cl_2). The collected solution was evaporated to dryness and the residue recrystallized from CH_2Cl_2 layered with *n*-pentane at − 20 °C to afford 162 mg (74%) of **3** (m.p. 124–126 °C, dec.).

5 (R=Me): Gaseous dimethylamine was bubbled into an MeCN solution (10 mL) of **1** (91 mg, 0.16 mmol); the color of the solution turned immediately bright-red and the mixture was dried under vacuum. The residue, worked up as described for **2**, was crystallized from CH_2Cl_2 layered with *n*-pentane to yield 45 mg (69%) of **3**.

6: Complex **1** (108 mg, 0.19 mmol) in MeCN (10 mL) was treated with $NHiPr_2$ (40 mg, 0.4 mmol). The reaction mixture immediately turned from red-brown to violet and the solvent was evaporated to dryness. After dissolving the residue in CH_2Cl_2, the solution was chromatographed on an alumina column (15 × 3 cm) by using CH_2Cl_2/petroleum ether (1/2, v/v) as eluent. After eluting the first fraction containing $[Fe_2(Cp)_2(CO)_4]$, the second fraction was collected and the solvent evaporated to dryness. Crystallization from CH_2Cl_2 layered with *n*-hexane at − 20 °C afforded 56 mg (64%) of **6**.

7 (R=Ph): Complex **1** (160 mg, 0.28 mmol) was dissolved in MeCN (10 mL) and treated with aniline (0.54 mmol). After 10 min the mixture was worked up as described for **5**, yielding 40 mg (32%) of **7**. When the same reaction was carried out with a fivefold excess of aniline,, complex **8** (R=Ph) was obtained in 60% yield. This latter complex was also obtained (90%) by stirring a CH_2Cl_2 solution of **7** for 24 h.

11: Complex **2** (X=CN) (100 mg, 0.26 mmol) was dissolved in THF (10 mL) and treated with $[W(CO)_5(thf)]$, which was obtained from photolysis of $[W(CO)_6]$ (275 mg, 0.78 mmol) in THF (20 mL). The reaction mixture was stirred overnight and dried under vacuum. The residue, dissolved in CH_2Cl_2 (≈3 mL) was chromatographed on an alumina column (15 × 3 cm). Elution with CH_2Cl_2/petroleum ether (1/1, v/v) gave four fractions containing: (1) $[W(CO)_6]$, (2) a small amount of the complex bearing the fragment μ-[C{CN-$W(CO)_5$}$_2$] (15 mg), (3) **11**, and (4) the starting complex **2**. The third fraction was concentrated (3 mL) and layered with *n*-pentane. On cooling to − 20 °C, 130 mg (70% yield) of **11** was obtained.

Optically Active "Stereocomplexes" of Isotactic Poly(methyl methacrylates) with Main-Chain Chirality **

By *Günter Wulff** and *Joachim Petzoldt*

Dedicated to Professor Leonhard Birkofer on the occasion of his 80th birthday

The possible occurrence of optical activity in linear vinyl- and vinylidene polymers due to the configuration or conformation of the main chain has long been discussed.[1] Isotactic chains such as **1** pose an interesting problem in this respect. In principle, such chains can be chiral if the end groups differ. However, this difference is negligible for long chains, so that such chains should behave as *meso* forms. Depending on their molar mass, they should thus exhibit only very small optical activity or practically none. They can therefore be called "cryptochiral".[2]

Anionic polymerization of trityl methacrylate in the presence of chiral catalysts, first introduced by *Okamoto* et al.,[3] gives isotactic polymers that exhibit high optical activity and are present as stable, one-handed (atropisomeric) helices. After replacement of the trityl group by the very much smaller methyl group, the polymer adopts a random-coil conformation and the optical activity almost vanishes (residual rotation $[\alpha]^{20}_{546} < 1.2°$).[3] However, investigations of the oligomers obtained in this polymerization reaction show that the stereogenic centers in the main chain are formed with high asymmetric induction and with uniform absolute configuration.[4] These kinds of compounds thus offer the first models for the investigation of enantiomerically pure, cryptochiral isotactic chains.

We have now varied the chain ends R^1 and R^2 in such enantiomerically pure or enriched isotactic poly(methyl methacrylates) (PMMA) in order to study their effect on the optical activity. In addition, we have attempted to investigate not only the effect of configuration but also that of conformation on the optical activity. Isotactic PMMA can undergo a transition to helical conformations; for identical chain ends (*meso* form), the (+) and (−) helices should be formed with equal probability. However, if helix formation from one chain end is favored owing to differing chain ends, then diastereomeric (+) and (−) helices should be formed from an enantiomerically pure chain and one screw sense of the helix should be preferred.

[a] In the table and in the text, polymers **2** and **3** with R = methyl are indicated by the letter **a**, those with R = trityl by the letter **b**. Polymer **2b** was prepared by anionic polymerization of trityl methacrylate with diphenylmethyllithium/(+)- or (−)-2,3-dimethoxy-1,4-bis(dimethylamino)butane ((+)- or (−)-DDB) in toluene at −78 °C. The block copolymers **3** [7] were obtained by anionic polymerization of styrene with *n*-butyllithium/(+)- or (−)-DDB in toluene at −20 °C followed by further polymerization at −78 °C after addition of trityl methacrylate[7]. In the case of **3** (No. 1), the reaction was initiated with *n*-butyllithium/tetramethylethylenediamine. [b] The molar masses refer to the poly(trityl methycrylate) (PTMA), the poly(methyl methacrylate) (PMMA), and the polystyrene moieties. The values were determined for the methyl esters by NMR investigation and gel permeation chromatography (versus polystyrene as standard). [c] The values given are the specific optical rotations based on the weight percent of PTMA or PMMA. **2b** and **3b** in THF, $c = 0.4-0.6$; **2a** in benzene, $c = 0.33$; **3a** in benzene, $c = 0.15$. The limits of error refer to the accuracy of the polarimeter. [d] The stereocomplexes were prepared with syndiotactic PMMA ($M_n = 35000$) according to [6]. Weight ratio of syndiotactic PMMA to **2a** or to **3a** 4:1. Total concentration in benzene 2 wt %.

Poly(methyl methacrylates) (PMMA) (see Table 1) with diphenylmethyl and hydrogen (**2a**) as well as with atactic polystyrene and hydrogen (block copolymer **3a**) as end groups were prepared from the corresponding optically active poly(trityl methacrylates) (PTMA). In both cases, the tritylated polymers **2b** and **3b** exhibited strong optical rotations ($[\alpha]_{546}^{20}$ 389–453°), whereas the methyl esters **2a** and **3a** showed only residual rotations of 0.4–1.9°. These rotations are in part near the limits of detection and are due to the configuration of the chains. By appropriate choice of the catalyst (+)- and (−)-2,3-dimethoxy-1,4-bis(dimethylamino)butane ((+)- and (−)-DDB), polymers **2** and **3** with either positive or negative rotation could be obtained.

In order to transform the chains into helices to an appreciable extent, "stereocomplexes" with achiral syndiotactic PMMA chains were prepared. In such stereocomplexes, the isotactic PMMA chain is present as a tightly folded inner helix in a 9/1 double helix with syndiotactic PMMA.[5] The complex formation in benzene or toluene could be detected by NMR spectroscopy[6] (about 40% of isotactic PMMA complexed) and showed the expected temperature dependence. The optical activity due to complex formation gradually disappears as the temperature is raised to about 70 °C, leaving only the residual rotation due to the configuration.

Table 1 shows the optical rotations obtained by complex formation. For polymers **2a** (R = methyl), the absolute values are a factor of 2.3 to 4.5 larger than for the uncomplexed polymers, whereas they are enhanced up to tenfold for the block copolymer **3a**. Noteworthy is the fact that, for the same absolute configuration in the chains of **2a** and **3a** (R = methyl) as well as for the same sign of optical rotation of **2b** and **3b** and of the uncomplexed polymers **2a** and **3a**, the sign of the rotation reverses only for the homopolymers **2a** on complexation. This means that the complexed polymers **2a** and **3a** must exist as helices of opposite screw sense; for example, helix formation might begin at the diphenyl end in **2a** and at the H end in **3a**.

The investigations show, therefore, that even a large difference in the chain ends of isotactic polymers is not sufficient to cause significant optical activity due to the configuration of the main chain. However, the chirality inherently present in the polymer structure (cryptochirality) can be revealed by complexing the polymer with a chiral superstructure. Unfortunately, the method described here does not allow the preparation of polymers with appreciably higher molar masses, which would allow more detailed study of the dependence of the optical activity on molar mass.

cyclo-As_8 as Complex Ligand**

By *Otto J. Scherer,* Rainer Winter, Gert Heckmann,* and *Gotthelf Wolmershäuser*

Dedicated to Professor Hans Georg von Schnering on the occasion of his 60th birthday

In the complex chemistry of substituent-free E_n units (E = P, As, Sb, Bi), the following arsenic species have been stabilized by coordination: *cyclo*-As_3, *cyclo*-As_4, *cyclo*-$As_5^{\ominus}$, and *cyclo*-As_6.[1] The largest rings found for the polyarsenides are the $As_7^{\ominus}$ unit, a norbornadiene analogue, and the crown-shaped *cyclo*-$As_8^{8\ominus}$ unit in the ionic compounds $[As_7\{Cr(CO)_3\}]^{3\ominus}$ (**1**)[2] and $^1_\infty[Rb\{NbAs_8\}]^{2\ominus}$ (**2**), respectively.[3] In analogy to cyclooctatetraene (**A**), structure **B** can formally be postulated for a *cyclo*-As_8 unit.

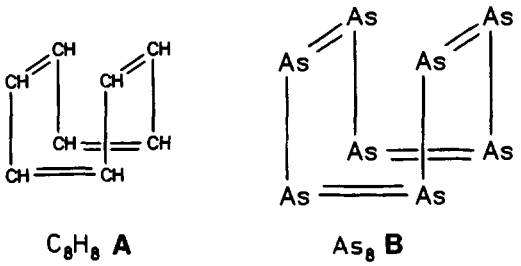
[+] X-ray structure analyses

[**] This work was supported by the Fonds der Chemischen Industrie (doctoral fellowship for *R. W.*).

Reaction of the tetracarbonylniobium compound **3** with yellow arsenic (As_4) in excess results in formation of the binuclear niobium complex **5** in about 17% yield together



C_8H_8 **A** As_8 **B**

with small amounts of the trinuclear complex **4**,[4] whose structure has not yet been established. Complex **5** reacts with $[Cr(CO)_5(thf)]$ to give **6**.

$$[Cp''Nb(CO)_4] \xrightarrow[170\,^\circ C,\ 2\ h]{As_4,\ decalin} [(Cp''Nb)_3As_6] + [(Cp''Nb)_2(\mu,\eta^{4:4}\text{-}As_8)]$$
3 **4** **5**

$$\mathbf{5} \xrightarrow[THF,\ 20\,^\circ C,\ 1.5\ h]{[Cr(CO)_5(thf)]} [(Cp''Nb)_2\{As_8Cr(CO)_5\}]$$
6

$Cp'' = \eta^5\text{-}1,3\text{-}t\mathrm{Bu}_2C_5H_3$

Complex **4** forms a brown, microcrystalline powder, **5** mahogany-colored crystalline needles with metallic luster, and **6** red crystals, which are sparingly soluble in petroleum ether, moderately soluble in benzene, and readily soluble in dichloromethane; **4** exhibits the best solubility.

The ^1H NMR spectrum[4] of **4** reveals only one kind of Cp″ ligand even at low temperatures. For **5** and **6**, the signal pattern expected on the basis of symmetry[4] is observed.

X-ray crystal structure analyses[5] show that, for both **5** and **6**, the arsenic analogue **B** of cyclooctatetraene forms a puckered, strongly distorted eight-membered ring (Figs. 1 and 2, respectively). To our knowledge, such a coordination geometry has not yet been observed for cyclooctatetraene complexes.[6] Possibly, the two ten-valence-electron fragments Cp″Nb are largely responsible for this *cyclo*-As_8 distortion. Together with the two sets of four arsenic atoms As1, As2′, As4, As3 and As1′, As2, As4′, As3′ in **5** (Fig. 1) as well as As3, As5, As7, As8 and As1, As2, As4, As6 in **6** (Fig. 2), they define two distorted tetragonal pyramids. The corresponding bond lengths and angles in the Nb_2As_8 framework, which consists of annelated three-, four-, and five-membered rings, differ only slightly in **5** and **6**. The average

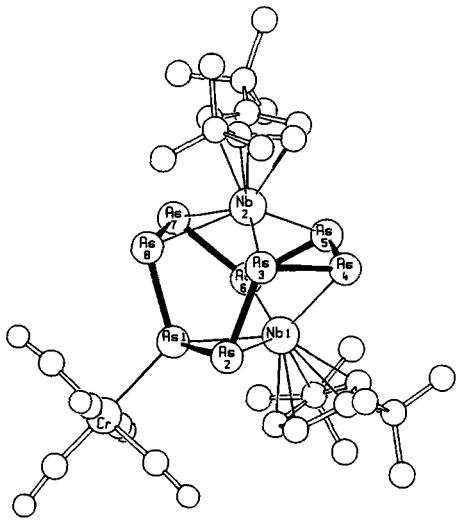

Fig. 2. Molecular structure of **6**. Selected bond lengths [Å] and angles [°]: Nb2-As5 2.573(6), Nb2-As3 2.533(5), Nb2-As7 2.637(6), Nb2-As8 2.735(6), Nb1-As4 2.576(6), Nb1-As6 2.539(5), Nb1-As2 2.669(5), Nb1-As1 2.714(5), As5-As4 2.546(6), As4-As3 2.393(6), As3-As2 2.380(6), As2-As1 2.361(6), As1-As8 2.432(6), As8-As7 2.360(7), As7-As6 2.390(6), As6-As5 2.380(6), As1-Cr 2.508(8), Nb1-$Cp''_{(center)}$ 2.09, Nb2-$Cp''_{(center)}$ 2.08; As5-As4-As3 106.1(2), As4-As3-As2 107.1(2), As3-As2-As1 94.6(2), As2-As1-As8 102.6(2), As1-As8-As7 98.0(2), As8-As7-As6 99.1(2), As7-As6-As5 108.0(2), As6-As5-As4 106.6(2), $Cp''_{(center)}$Nb1-Nb2 162.4, $Cp''_{(center)}$Nb2-Nb1 156.3.

values of the very different As–As and Nb–As distances are 2.415 and 2.629 Å, respectively, for **5** and 2.405 and 2.622 Å, respectively, for **6**; these bond lengths are 2.405 Å for **1**[2] and 2.434 as well as 2.619 Å for **2**[3] and are also comparable to $\bar{d}$(As-As) in complexes with $(RAs)_n$ ligands.[7] The average value of the As–As–As angle is 102.8° in **5** and **6**. Noteworthy are the following transannular distances, some of them very short: Nb···As1′ = 3.022(2) and Nb···As2 = 2.861(2) Å in **5**; Nb1···As3 = 2.882(5), Nb1···As5 = 2.999(5), Nb2···As4 = 3.010(5), and Nb2···As6 = 2.854(5) Å in **6**. The Nb···Nb distance in **5** (3.326(2) Å) and **6** (3.311(5) Å) lies at the limits of bonding interactions.[8]

Experimental Procedure

4, **5**: Complex **3**[9] (765 mg, 2.00 mmol), dissolved in 10 mL of decalin, and 150 mL of a freshly prepared decalin solution of As_4 (ca. 862 mg = 2.9 mmol) were stirred at about 170 °C and the reaction was monitored by IR (after ca. 2 h, CO bands were no longer observed). After removal of the solvent under oil-pump vacuum (ca. 50 °C bath temperature), the black-brown, oily residue was treated with 3 mL of CH_2Cl_2 and about 2.5 g of Al_2O_3 (basic, 3% H_2O) and the mixture was then dried under oil-pump vacuum until it was free-flowing. Unreacted, red **3** (20 mg, 2.6%) was eluted with petroleum ether (column: 30 × 2.5 cm, Al_2O_3). Complex **4** (106 mg, 4.3% based on reacted **3**) was eluted with petroleum ether–toluene (20:1). Recrystallization from toluene–hexane (1:2) afforded 88 mg (3.6%) of brown, microcrystalline **4**. Complex **5** was eluted as a mahogany-colored fraction with petroleum ether–toluene (10:1). Concentration of the solution to about 5 mL followed by two-day crystallization gave 196 mg (8.8% based on reacted **3**) of **5**. An additional 177 mg (8.0%) could be isolated from the mother liquor. Suitable single crystals were obtained

by dissolving **5** in diethyl ether, adding petroleum ether, gently concentrating the solution until the onset of crystallization, and allowing the solution to stand for two days at room temperature. Complex **5** forms mahogany-colored crystalline needles.

6: A solution of [Cr(CO)$_5$(thf)], prepared photochemically from freshly sublimed [Cr(CO)$_6$] (11.7 mg, 0.053 mmol), in 50 mL of THF was added to **5** (61 mg, 0.053 mmol). The reaction mixture was stirred for about 1.5 h at room temperature (IR monitoring showed no further increase in the newly appeared CO bands) and then worked up as described for **5**. Unreacted **5** (8 mg, 13.1%) was eluted as a mahogany-colored fraction with petroleum ether–diethyl ether (15:1), followed by a red-brown fraction of **6**. The fraction of **6** was concentrated to about 10 mL and allowed to stand at room temperature. Ruby-red, cube-shaped crystals of **6** (48 mg, 71% based on reacted **5**) formed within 20 h. An additional 3 mg of product was isolated from the mother liquor (total yield 51 mg (76%)).

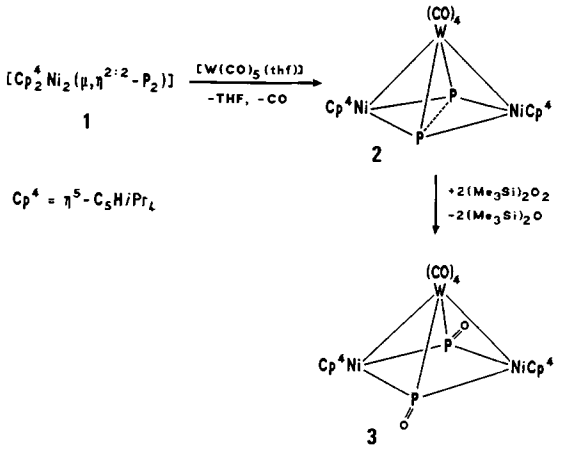
Phosphorus Monoxide (PO) as Complex Ligand**

By *Otto J. Scherer*, Jürgen Braun, Peter Walther, Gert Heckmann,* and *Gotthelf Wolmershäuser*

In contrast to the ubiquitous nitrogen monoxide (NO), whose ligand properties also have been investigated in detail,[1] only a few spectroscopic data[3] have thus far been reported for the phosphorus analogue PO, probably the most abundant phosphorus-containing molecule occurring in interstellar clouds.[2]

Reaction of diphospha-dinickela-tetrahedrane with [W(CO)$_5$(thf)] leads to formation of the Ni_2WP_2-complex **2**, which can be oxidized with bis(trimethylsilyl) peroxide to give **3**, the first complex with a PO ligand. **1**, **2** and **3** form,



respectively, black, dark green, and black crystals, which are briefly stable in air, readily to moderately soluble in pentane, and very readily to readily soluble in benzene and dichloromethane. Solutions of **2** are extremely sensitive to traces of oxygen. Table 1 lists the most important X-ray structure data[4] and IR ($\tilde{\nu}$(CO), $\tilde{\nu}$(PO)) and ^{31}P-NMR[5] spectroscopic data of the complexes **1**–**3**.

Table 1. Selected bond lenghts [Å] and angles [°] as well as $\tilde{\nu}$(CO), $\tilde{\nu}$(PO) [cm^{-1}] and ^{31}P-NMR data of the complexes **1**–**3**.

[+] X-ray structure analyses.

[**] This work was supported by the Fonds der Chemischen Industrie.

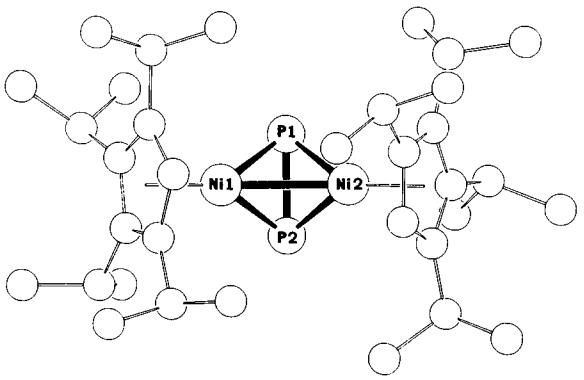

Fig. 1. Structure of **1** in the crystal [4a].

(Fig. 1) to the tetragonal-pyramidally structured complexes **2** (Fig. 2) and **3** (Fig. 3) with rhomboidal Ni_2P_2 pyramid base, from 2.185 Å in the case of **1** through 2.17 Å (**2**) to 2.14 Å in the case of **3**.

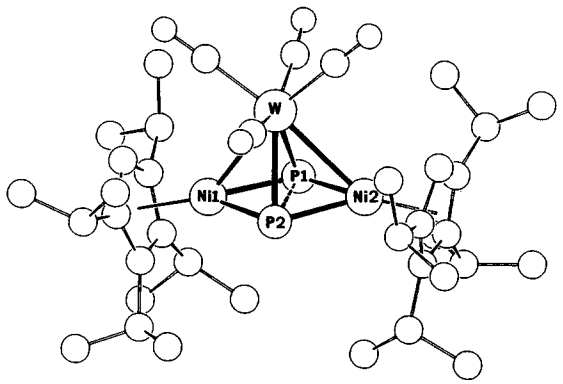

Fig. 2. Structure of **2** in the crystal [4b].

The P–P distance in **1** (2.053(5) Å) lies in the expected range,[6] whereas an extremely short P–P distance [7] of 2.304(4) Å is found in the Ni_2P_2 pyramid base in the case of **2**. Indeed, the P–P bond here is even shorter than in the

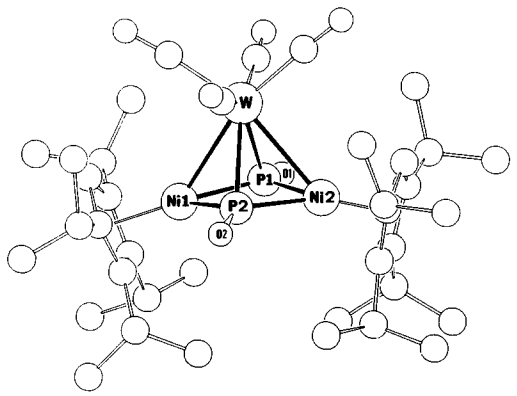

Fig. 3. Structure of **3** in the crystal [4c].

molecules $(RB)_2P_2$ (2.349(2) Å[8a]) and $[(R_2Si)_2P_2\{W(CO)_5\}_2]$ (2.342(2) Å[8b]) with E_2P_2-butterfly framework.

The complexes **1**–**3** are further illustrative examples for the isolobal principle.[9] If one imagines that two P atoms in white phosphorus (P_4) are each replaced by an isolobal Cp^4Ni fragment, then one finds an average length of 2.23 Å for the six bonds in **1** (in the case of P_4 2.21 Å); a similarly good agreement is found in the case of **2** ($\bar{d}$(Ni–P) = 2.17 Å) and $[Cp^*(CO)_2Nb(\eta^4\text{-}P_4)]$ ($\bar{d}$(P–P) = 2.16 Å[10]).

The most remarkable structural moiety in **3** are the μ_3-PO ligands, whose P–O bond lengths of 1.46 and 1.48 Å agree completely with the calculated (1.46 Å[3a]) and experimental values (1.48 Å[3b]) for the PO molecule. $\tilde{\nu}$(PO), with a value of 1260 cm^{-1} in the case of **3** compared to 1218 cm^{-1} in the uncomplexed PO[3c] and 1240 cm^{-1} for the terminal P=O group of the P_4O,[3c] is slightly shifted to higher wave numbers.

Whereas a very slight out-of-plane folding of ca. 3° about the P–P axis and towards the W atom is observed for the rhomboidal Ni_2P_2 structural moiety in **2**, in the case of **3** one finds a folding of ca. 10° in the opposite direction (Table 1). In **2** and **3** the four CO ligands are arranged almost ecliptically to the Ni_2P_2 pyramid base.

According to the Wade-Mingos electron-counting rules[11] **1** has six and **2** and **3** have seven skeletal electron pairs, and thus a *nido* framework structure. Extended Hückel MO calculations on the star-shaped $[\{(OC)_5W\}_3As_2]$[12] with three 16-valence electron (VE) $W(CO)_5$-fragments show that in this case :As≡As: functions as 6e donor ($4\times\pi$, $2\times\sigma$). If one extends this bond description to **2**, the 14VE-$W(CO)_4$ fragment and two 15VE-Cp^4Ni fragments would be formally bound to one :P≡P: unit; to achieve 18VE per metal atom, the linking of two Ni–W bonds would then be required for the formation of the tetragonal pyramid in **2**.

Experimental

2: A solution of **1** (87 mg, 0.135 mmol) [13] in ca. 5 mL of freshly distilled THF was treated with a solution of $[W(CO)_5(thf)]$, prepared by irradiation (30 min; 150 W mercury high-pressure lamp) of 71 mg (0.202 mmol) of $W(CO)_6$ in 70 mL of freshly distilled THF, and the mixture stirred at room temperature. After ca. 10–15 min the initially deep-brown solution turned brilliant neon green (weak evolution of CO!). After 20 min the solvent was removed in a high vacuum and the residue scraped from the walls of the glass vessel and transferred to a silica gel/petroleum ether column (30 × 2 cm). The remainder of the residue was removed from the vessel with a little petroleum ether and also transferred to the column. Upon elution with petroleum ether/toluene (20:1) a brilliant green fraction was obtained, from which, after removal of the solvent, we recovered 114 mg (90% referred to **1**) of **2** (dark green powder). Subsequent recrystallization from a little hot heptane (80 °C) by slow cooling to room temperature afforded **2** in the form of glittering green needle-like crystals.

3: A solution of $(Me_3Si)_2O_2$ (34 μL, 0.152 mmol) in diethyl ether (10 mL) was added dropwise within 10 min to a solution of **2** (36 mg 0.038 mmol) in diethyl ether (15 mL). The mixture was then stirred for 20 h at room temperature, whereupon a gradual change in color from brilliant green through dark green to red was observed. After removal of solvent in an oil-pump vacuum the residue remaining was transferred with a little petroleum ether to a column (30 × 1.5 cm) packed with silica gel (activity grade II). Upon chromatographic separation, elution with petroleum ether/ether (7:1) initially afforded traces (< 1 mg) of a pale green fraction (monooxidized **2**), then **3** as a dark-red fraction. After removal of solvent from the latter in an oil-pump vacuum there remained 22 mg (60% based on reacted **2**) of **3**, which formed blackish, block-shaped crystals upon recrystallization from a little hexane.

Triple Inclusion by a Calixarene: the Crystal Structure of the Europium(III) Complex of Bis(homooxa)-*p-tert*-butylcalix[4]arene **

By *Zouhair Asfari, Jack M. Harrowfield,* Mark I. Ogden, Jacques Vicens,* and *Allan H. White*

The inclusion chemistry of the calixarenes[1] is remarkably varied. Both neutral and cationic guests are numerous.[1-3] A particular form of cation inclusion is the direct coordination of a metal ion, and in seeking to characterize the coordination chemistry of the calixarenes with lanthanide and actinide elements,[4-9] we have also been interested in establishing the influence of metal-ion binding on other forms of inclusion. As has been noted by others,[10] the dissymmetric conformation adopted by *p-tert*-butylcalix[8]arene in several of its metal-ion complexes even raises the prospect of selective inclusion of chiral species.

The crystal structure of the europium(III) complex of *p-tert*-butylcalix[4]arene (**L1**)[7] shows a form of "double inclusion" in which the metal ion is bound by phenoxide coordination and a molecule of dimethylformamide (DMF) solvent is included within the ligand "cup" possibly as a result of Van der Waals interactions between the solvent methyl groups and the ligand *t*Bu substituents. The polar carbonyl moiety of DMF is directed out of the cup and away from the metal. In contrast, the two included DMF molecules of $[Eu_2$(*p-tert*-butylcalix[8]arene−6 H)$(dmf)_5]$[4,6] are bound to the metal atom through carbonyl O atoms. As a result, these DMF molecules are oriented in such a way that the carbonyl moieties are directed *into* the calixarene cavity. A similar orientation of dimethylsulfoxide (DMSO) is seen in its inclusion complex with "free" **L1**,[7] however, suggesting that factors other than binding to a coordinated metal ion can favor insertion of a polar moiety deep within the calixarene.

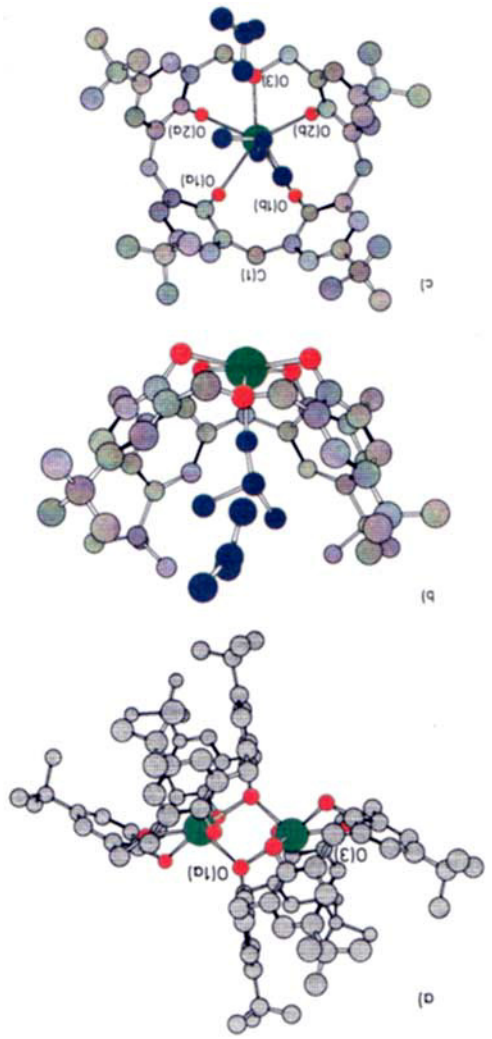

Figure 1. a) A view of the centrosymmetric dimer, normal to the Eu_2O_2 plane, obtained using the atomic coordinates and the molecular modeling program "Chem 3D+" from Cambridge Scientific Computing. The coordinated DMSO and the included acetone molecule are omitted for clarity. Eu(green), O(red). b) A single Eu/L2 aggregate, showing the disposition of the major components of the coordinated DMSO and acetone molecules (blue). Eu–O (DMSO) 2.28(1) Å; Eu–O1a 2.46(1), Eu–O1b 2.47(1), Eu–O2a 2.28(1), Eu–O2b 2.23(1), Eu–O3 2.67(1) and Eu($\bar{x},\bar{y},\bar{z}$)-O1a 2.29 Å. Eu and O3 lie 0.26 and 1.51 Å out of the O1a-O1b-O2a-O2b plane ($\chi^2 = 6$), respectively. c) As b), projected normal to the O1a-O1b-O2a-O2b plane; DMSO and the disordered *t*Bu group without H atoms. The inversion related O1a···Eu line lies beneath the Eu···O1a line; i.e., it is unsymmetrically disposed relative to the median C1···Eu···O(3) line vertical to the page with consequent loss of perfect *m* symmetry in respect to such parameters as phenyl/O_4 dihedral angles (Table 1).

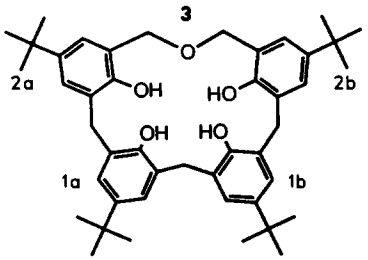
In this regard, it is notable that the position of the methyl group of these included solvent molecules is similar, relative to the calix rim, in all these complexes.

The crystal structure of the present europium(III) complex of bis(homooxa)-*p*-*tert*-butylcalix[4]arene (**L2**)[11] shows the presence of a binuclear species (Fig. 1) similar to that found with **L1**. There are, however, several significant differences. Most obvious is the fact that, seemingly as a result of the increase in the size of the ligand and a strong coordinative interaction with the ether-oxygen donor atom (Scheme 1), the metal ion is drawn further into the ligand cup of **L2**, thereby leaving no room for any unincluded solvent binding as found with the Eu complex with **L1**. Seven-coordination



Scheme 1. The structure of the fully protonated ligand, bis(homooxa)-*p*-*tert*-butylcalix[4]arene, **L2**. Component numbering as applied in the complex ion structure (and used in the text) is indicated.

of the metal ion is retained by *O*-coordination of a DMSO molecule which also has its methyl groups positioned close to the *t*Bu rim of the calixarene and which therefore can be considered coordinatively included. Nonetheless, this does not, in this system at least, mean that further inclusion is impossible, and perhaps the most interesting feature of this structure determination is the inclusion of a second neutral molecule, the solvent acetone,[12] selectively included from an acetone/acetonitrile mixture.

One of the principal reasons for the investigation of calixarenes has been their potential as "enzyme mimics",[1] and certainly this structure demonstrates that it is entirely reasonable to regard the calixarenes as molecules wherein a substrate, possibly activated by metal ion coordination, may be held in a weakly solvating environment in close proximity to a reactant species.

Chiefly in respect of the pitch of the 2a/2b phenyl rings (Table 1), the ligand conformation in the europium complex of **L2** defines a considerably steeper cup than is found in either the fully protonated ligand or the uranyl-ion complex.[9] The remoteness of the ether-oxygen donor O3 from the uranium atom implies that **L2** is essentially quadridentate in the latter, and hence the rather different conformation observed in the europium complex may be due to the distortions resulting from the strong interaction of all five donor atoms with the metal ion. The fact that **L2** is fully deprotonated in the uranyl-ion complex but only triply deprotonated in the europium species must also give rise to some differences; the locations of the phenoxide protons in the Eu complex are somewhat uncertain, and Eu–O(na,b) distances are remarkably symmetrical, although O1a has a very close interaction with Eu($\bar{x}$,$\bar{y}$,$\bar{z}$). Of particular relevance, however, may be the close contact between O1b of one ligand and O2a of its inversion image, with the possible implication of a hydrogen bond. Whatever the cause of conformational differences, the simply included molecules, (a triethylammonium cation for the uranyl-ion complex, acetone for the europium-ion complex, and dimethylformamide in the free

[a] Eu···Eu, O···O of the central Eu_2O_2 plane are 3.9067(7), 2.661(6) Å in Eu/L1; in Eu/L2, 3.772(2) and 2.88(1) Å. In Eu/L1, the O1a-O1b-O2a-O2b array is puckered (χ^2 = 2978; δO: 0.19, −0.25, −0.24, 0.23, δEu 1.01 Å), whereas in Eu/L2 it is planar (χ^2 = 6.1; δO < 0.02 Å; δEu, O3: 0.26, 1.51 Å). O1a, O1b, O2a, and O2b correspond to O1–O4 of ref. [8]).

ligand) occupy a similar position above the CH_2OCH_2 chain in all.

We have not as yet fully characterized complexes with all the rare earths, but the yttrium(III) complex with **L2**, for example, appears, on the basis of microanalytical results and its solution ^{1}H NMR spectrum (Fig. 2; Table 2), to adopt the

Table 2. Resonances in the 300-MHz ^{1}H NMR spectrum of $[Y_2(L-3H)_2(dmso)_2]\cdot 2$ acetone [a].

δ = 0.29, 0.32 (s, CH_3 of DMSO), 1.24, 1.25, 1.30, 1.31 (s, $C(CH_3)_3$), 1.54 (s, acetone), 3.36, 3.40, 5.45, 5.49, 3.62, 3.66, 5.90, 5.94, 3.64, 3.68 [c], 6.40, 6.44 (d, pairs, $ArCH_2Ar$ [b]), 3.68 [c], 3.71, 5.12, 5.15, 3.78, 3.81, 5.41, 5.44 (d, pairs, $ArCH_2O$ [b]), 6.76–7.45 (d, 8 pairs, aromat. H), 15.08 (s, phenol. OH).

[a] The weak signals at δ = 1.15, ca. 4.0, 6.61, and 7.21 vary in intensity depending upon the age of the sample and appear to be due to small amounts of free ligand, possibly produced by dissociation or hydrolysis due to adventitious water. [b] Assignments based on decoupling experiments. [c] Overlapping peaks.

same binuclear structure in solution as found for europium in the solid state. Thus, all five methylene groups are nonequivalent, as are the four *t*Bu groups and the eight aromatic protons.[13, 14] For the mononuclear uranyl-ion complex,[9] the solution ^{1}H NMR spectrum demonstrates retention of the effective plane of symmetry through the ligand seen in the solid state. As noted previously, however, the europium and yttrium complexes do retain one phenolic proton which could reduce the symmetry of any mononuclear solution species. A special feature of the yttrium spectrum is the upfield shift of the DMSO methyl group resonances, consistent with coordinative inclusion of the DMSO molecule where the methyl groups are placed in close proximity to the calixarene phenyl rings. The nonequivalence of the two methyl groups suggests that any rotation of the DMSO mol-

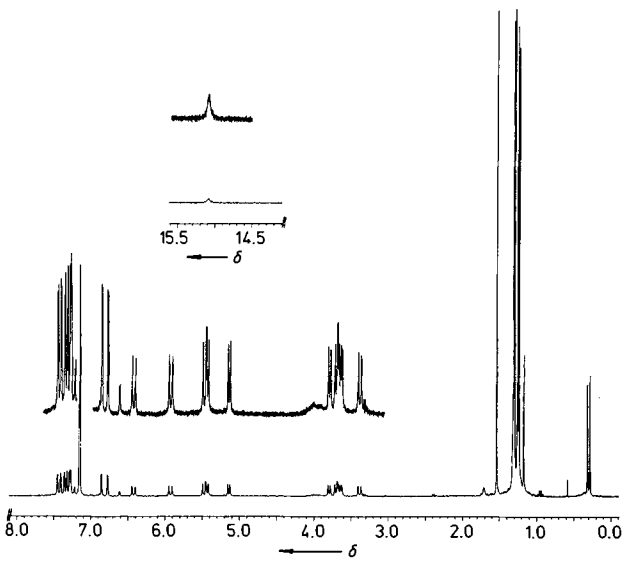

Figure 2. The 300-MHz ^{1}H NMR spectrum of $[Y_2(L2-3H)_2(dmso)_2]\cdot 2$ acetone in C_6D_6 at 298 K.

ecule in the ligand cavity is slow on the time scale of the NMR experiment. The resonance due to the acetone molecule does not exhibit any significant change from the chemical shift expected for acetone in benzene, suggesting that this molecule is easily displaced from the ligand cavity, at least in benzene solution.

Experimental

Synthesis of $[Eu_2(L2-3H)_2(dmso)_2]\cdot 2$ acetone: L2·acetone [9] (0.25 g, 0.34 mmol) was dissolved in acetone (10 mL), and triethylamine (0.5 mL) was added giving a clear, colorless solution. A solution of $[Eu(dmso)_7](ClO_4)_3$ (0.38 g, 0.38 mmol) in CH_3CN (10 mL) was then added at room temperature forming a clear orange solution. $[Eu_2(L2-3H)_2(dmso)_2]\cdot 2$ acetone was deposited overnight as orange plates, and was collected by filtration (0.17 g, 52%). Correct elemental analysis.

Synthesis of $[Y_2(L2-3H)_2(dmso)_2]\cdot 2$ acetone: The procedure was essentially as described for the europium derivative, substituting $[Y(dmso)_7](ClO_4)_3$ for $[Eu(dmso)_7](ClO_4)_3$. The compound was deposited as colorless plates (0.17 g, 55%). Correct elemental analysis.

Enraf-Nonius (CAD-4 diffractometer, monochromatic $Mo_{K\alpha}$ radiation, $\lambda = 0.71069$ Å, $\mu_{Mo} = 12.2$ cm^{-1}; specimen: $0.35\times 0.20\times 0.10$ mm (capillary) (twinned; data measured on the major reciprocal lattice component), $A^*_{min,max}$ (Gaussian correction), 1.10, 1.27. $2\theta_{max} = 45°$, 6461 independent reflections, 3267 with $I > 3\sigma(I)$ (nonoverlapping). Full matrix least-squares refinement, anisotropic thermal parameter refinement confined to Eu, O, nondisordered *t*Bu groups, and major DMSO component; $R = 0.076$, $R_w = 0.072$, $n_v = 385$. Within the ligand one *t*Bu group was disordered over two sites, populations 0.56(4), 1 − 0.56(4). The DMSO is disordered with single envelopes for O, C, and two for S, populations: 0.77(2), 1 − 0.77(2). Thermal motion is high at the molecular periphery and on the acetone solvent. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, W-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-55149, the names of the authors, and the journal citation.
[12] Simple inclusion of acetone has been observed with various calixarenes, see ref. [2] and A. W. Coleman, S. G. Bott, S. D. Morley, C. M. Means, K. D. Robinson, H. Zhang, J. L. Atwood, *Angew. Chem. 100* (1988) 1412; *Angew. Chem. Int. Ed. Engl. 27* (1988) 1361.
[13] The complex appears to be considerably more rigid in solution than the ligand itself; uncomplexed **L2** in chloroform shows a coalescence temperature of −2 °C for the CH_2OCH_2 resonances and −8 °C for the $ArCH_2Ar$ resonances; see C. D. Gutsche, L. J. Bauer, *J. Am. Chem. Soc. 107* (1985) 6052.
[14] The ^{1}H NMR spectrum of the europium(III) complex, which will be one of the subjects of a later publication concerned more generally with the spectroscopy of lanthanide complexes of the calixarenes, is more complicated to interpret because of the shifting and appreciable broadening effects of europium. It is, however, possible to identify eight aromatic proton resonances at $\delta = 19.25$, 17.41, 12.99, 5.16, 4.03, 3.57, 2.95, and −3.35, confirming that at least the symmetry of the complex in solution is the same as that in the solid.

A Novel Oligomer of Condensed Metal Atom Clusters in $[Y_{16}Ru_4I_{20}]$**

By *Martin W. Payne*, *Masahiro Ebihara*, and *John D. Corbett**

Dedicated to Professor Hans Georg von Schnering on the occasion of his 60th birthday

Heterometal atoms (Z) bound within M_6X_{12}-type metal halide clusters are relatively recent discoveries. The first examples involved 3d elements in the phases $[Zr_6(Z)I_{12}]$, $[Zr_6(Z)I_{12}]I_2$,[1] and $[Zr_6(Z)Cl_{12}]Cl_3$.[2, 3] Transition metals encapsulated in the rare-earth-metal (R) iodide clusters $[R_6(Z)I_{10}]$ and $R[R_6(Z)I_{12}]$ were subsequently established among R = Y, Pr, Gd for a much larger range of Z, namely Mn–Cu, Ru–Pd, and Re–Au.[4, 5] Newer products from the condensation of such clusters through shared metal edges (and halogens) into infinite chains, first discovered with centered nonmetals in compounds like $[Sc_7(C_2)Cl_{10}]$[6] and $[Y_4(C)I_5]$,[7] have recently been found in the form of single chains for $[La_4(Ru)I_5]$ and $[Pr_4(Z)I_5]$, Z = Co, Ru, Os,[8] and double chains for $[Pr_6(Ru_2)I_6]$, $[Y_6(Ir_2)I_6]$, etc.[9] To date all structures have exhibited either isolated clusters or those condensed into infinite chains or sheets, regardless of the interstitial type. (A few cluster dimers like $[Gd_{10}C_4Cl_{18}]$[10] are exceptions.) We report here a remarkable oligomeric example of condensed halide clusters, in this

case with the same composition as single chain compounds of other R elements, such as $[La_4(Ru)I_5]$.

The metal portion of the remarkable $[Y_{16}(Ru_4)I_{20}]$ consists of a 16-membered Friauf polyhedron of yttrium centered by a tetrahedron of Ru.[11] As shown in Figure 1 A, this polyhedron can be generated by truncation of every apex of a larger tetrahedron (open circles, included for clarity) followed by capping the approximately hexagonal faces of the resulting unit Y_{12} with a Y_4 tetrahedron (outlined by open connections). In this case, Y1 and Y3 define the truncated unit and Y2 caps the faces (Fig. 1 B). Finally, the Y_{16} unit encapsulates four Ru atoms that form an ideal tetrahedron within experimental error ($d = 3.572(3)$ Å) and are, in fact, the inner image of the starting, outer tetrahedron. The $[Y_{16}Ru_4]$ polycluster has $\bar{4}2m(D_{2d})$ symmetry and is completely separated from other similar clusters by iodine bridges (see below). Polyhedra like that found here with yttrium are well-known in Laves phases where they are condensed with other polyhedra and are usually centered by a single atom.[13] On the other hand, the untruncated polyhedron in Figure 1 A, but without interstitials, has recently been found as $[Os_{20}CO_{40}]^{2-}$.[14]

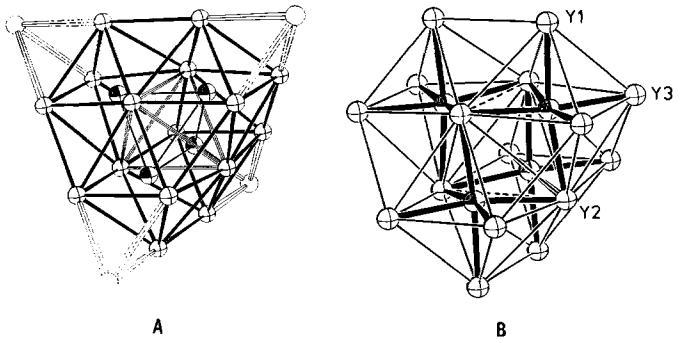

Fig. 1. The $Y_{16}Ru_4$ cluster in $[Y_{16}Ru_4I_{20}]$ ($\bar{4}2m(D_{2d})$ symmetry, major axis vertical). A) The generation of a Y_{16} cluster by consecutive truncation of larger tetrahedron (open spheres), introduction of tetrahedron of Y2 atoms on hexagonal faces (open outline), and encapsulation of Ru_4 tetrahedron (shaded spheres). B) The same cluster as generated by pairwise condensation of four centered Y_6Ru clusters (with shared edges in the dimers dashed) and the numbering of the yttrium atoms.

It is easy to see (without special glasses[15]) that the new cluster can also be viewed as the condensation product of four $[Y_6(Ru)I_{12}]$-type octahedral clusters—as emphasized in Figure 1 B—in a two-by-two manner starting with pairs of clusters joined by shared Y2–Y2 edges (dashed lines); the same process forms the infinite chain structures. The Ru atoms in the oligomer are somewhat displaced toward each other; *trans* angles in the Y_6Ru octahedra are 168.5° (×2) and 169.6(1)°; however, the Ru–Ru separations still correspond to negligible bonding (Pauling bond order ca. 0.02). The geometry of the $Y_{16}Ru_4$ metal core is analogous to that found in the cubanelike $[Cl_{16}Te_4]$,[16] except that the displacements are in the opposite sense, reflecting the very different types of interactions between Y–Y and Cl···Cl. Distortions in $[Y_{16}(Ru_4)I_{20}]$ appear to be largely the result of the rather diverse surroundings for the three types of yttrium atoms, through their proximity to other metals and iodine as follows: Y1 (top and bottom atoms, Fig. 1) is surrounded by 5 Y, 1 Ru, and 4 + 1(exo) I atoms; Y2 (capping hexagonal faces) by 6 Y, 3 Ru, and 3 I; Y3 (unshared waist atoms) by 5 Y, 1 Ru, and 4 + 1 I. The Y–Y and Y–Ru distances are in the ranges of 3.581(2) Å to 3.920(3) Å and 2.684(3) to 2.837(3) Å, respectively. Long, shared Y2–Y2 edges not counted in the foregoing are 4.284(2) Å in the dimers (dashed) and 4.337(3) Å (×2) between pairs of condensed octahedra with a vertical component to the distance.

Four unique iodine functionalities serve to cap triangular faces or bridge edges on the yttrium polyhedron as well as to interconnect each cluster to eight others in a three-dimensional network. One example of each type is illustrated in Figure 2. Four pseudotetrahedral connections arise from I2 and I4 bridging between clusters, as shown for the pair centered at $\frac{3}{4}, \frac{1}{4}, \frac{1}{4}$ and $\frac{1}{4}, \frac{3}{4}, \frac{3}{4}$; the $I4^{i-i}$ arrangement is reminiscent of that in $[Y_6(Ru)I_{10}]$.[4] A second group of four clusters lie along $\pm \boldsymbol{a}$ and $\pm \boldsymbol{b}$ from each cluster. These are interlinked

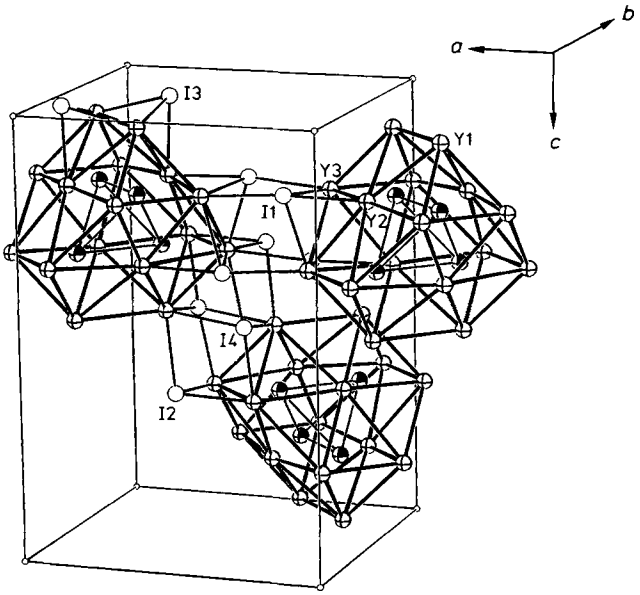

Fig. 2. The two modes of intercluster bonding through shared iodine atoms (open spheres); see text.

by I1 atoms that cap Y3–Y3–Y2 faces and are also exo to Y3 atoms in an adjoining cluster and vice versa. One such connection is shown at the top center of Figure 2. Finally, I3 atoms, two of which are shown at the top left, cap Y1–Y2–Y1 faces and are not involved in intercluster bridging. The structure can also be described in terms of cubic-close-packed I and Ru layers that lie parallel to $(2\bar{2}3)$, the yttrium ordering in octahedral holes clustered about the ruthenium sites.

Extended Hückel calculations indicate that the $[Y_{16}(Ru_4)I_{20}]$ cluster with its 60 cluster-based electrons has a closed shell configuration and a calculated band gap of ca. 0.3 eV.[17] The splitting of T_d orbital symmetries on descent to D_{2d} is small, so the labels of the former can be used for simplification. The Y(d)–I(5p) bonding and iodine nonbonding 5p levels lie in a group below −10.8 eV, while a narrow band of ten MOs between −8.5 and −9.0 eV are principally Y–Ru bonding, the lowest four being s- and t_{2g}-like on Ru. A group of three MOs ($t_2 + a_1 + e$ (HOMO)) above this between −7.9 and −7.5 eV are basically only Y–Y bonding. The energy disposition of these three classes of bond types is quite similar to that calculated for the chain compound $[Pr_4(Ru)I_5]$,[8] basically reflecting intrinsic characteristics of centered $[R_6(Ru)I_{12}]$ clusters. The six lowest antibonding MOs, with a t_1 LUMO, lie between −7.2 and −6.6 eV and are all Y–Ru-"t_{2g}" in character except

for the next to the lowest (a_1), which resembles the a_{2u} of many $[M_6(Z)X_{12}]$ clusters.[1] Bonding within the cluster appears to be dominated by Y–Ru interactions; overlap populations are from 1.7 to 2.8 times those for the majority of the Y–Y bonds. The long Y2–Y2 separations discounted earlier are only about half as large. More striking are the low populations for Y3–Y3 between dimers (3.920 Å) and the Y1–Y1 separation at the top and bottom of the clusters (3.870 Å). These values are only 25–30% of those of the principal Y–Y interactions.

The discovery of this surprising macrocluster of centered octahedral clusters is a forecast of still more novel chemistry and structures. Further considerations of the structure and bonding suggest that smaller rare-earth elements may be more favorable for such aggregates.

Experimental Procedure

The high purity of the reagents, the synthetic and sublimation techniques for YI_3, and the reaction procedures utilizing welded Nb tubing have been described [5, 6]. Reactions with Y:Ru:I ratios between 4:1:5 and 1:1:1 at temperatures from 800 °C to 975 °C and reaction times of three to four weeks were explored in a search for condensed cluster systems. The main products were only $[Y_{16}(Ru_4)I_{20}]$ and the double chain $[Y_6(Ru_2)I_6]$ [9]; no clear boundary exists between the two. Ratios for Y:I of less than 4:5 gave only the known $[Y_7(Ru)I_{12}]$ and $[Y_6(Ru)I_{10}]$ [4, 5], and for Y:Ru:I of 1:<1:1, $[Y_6(Ru_2)I_6]$. The black $[Y_{16}(Ru_4)I_{20}]$ grew as small cubes and octahedra that were fused together on faces and edges. Reactions run at higher temperatures (950–975 °C) favored the formation of $[Y_6(Ru_2)I_6]$, while those at lower temperatures gave 90–100% yields of $[Y_{16}(Ru_4)I_{20}]$. Analogous reactions with Pr and Gd yielded only the infinite chain polymorph $[Pr_4(Ru)I_5]$ [8] and other phase types noted above. Extended Hückel calculations were performed on an isolated cluster with the experimental distances and the composition $[(Y_{16}(Ru_4)I_{20})I_{16}]^{16-}$, the extra iodine atoms representing those with intercluster bridging functions. Charge-self-consistent valence energies derived for $[Y_6(Ru)I_{10}]$ [4] were utilized.

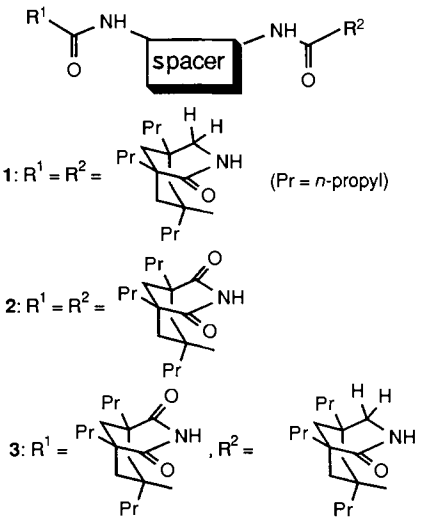
[17] The compound exhibits a small temperature-independent paramagnetism of ca. 4.9×10^{-4} emu mol^{-1} $[Y_4RuI_5]$ between 310 and ca. 60 K, with a presumed Curie tail. The former may represent an intrinsic van Vleck (field-induced) behavior.

Enantioselective Complexation of Flexible and Rigid Substrates through Molecular Recognition**

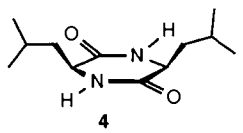
By *Michael Famulok, Kyu-Sung Jeong, Ghislain Deslongchamps,* and *Julius Rebek, Jr.**

The interaction of chiral drugs with their target receptors involves highly enantioselective recognition mechanisms. In order to get a better understanding of such processes, a current thrust in molecular recognition research concerns the synthesis of abiotic low molecular weight receptors capable of enantioselective complexation of neutral substrates.[1] A well-known example of this is found in nature in the form of the antibiotic, vancomycin. This macrocycle disrupts the synthesis of bacterial cell walls by its highly enantioselective binding to the carboxy terminal sequence D-alanyl–D-alanine of the peptidoglycan precursors.[2]

Recently we introduced a synthetic receptor molecule **1a** whose two enantiomers bind the cyclic dipeptide diketo-



a: spacer = 2,6-naphthyl
b: spacer = 2,7-naphthyl
c: spacer = *p*-phenylenediamine



4

piperazine **4** with considerable enantioselectivity, corresponding to a difference in relative binding affinities of more than 2.5 kcal mol^{-1}.[3]

The hydantoins (**5–8**) and hydroorotic acid methyl ester (**9**) are complexed by the (+)- and (−)-enantiomers of the dilactam **1b**. For the complexation of dipeptides we investigated the achiral diimides **2** and the chiral imide lactam **3c**. The enantiomers of **3c** and **1b** were seperated on a chiral Pirkle column.[4] The absolute stereochemistry of the receptor enantiomers (+)-**1b**, (−)-**1b**, (+)-**3c**, and (−)-**3c** was not determined. Association constants were measured by ^1H NMR titrations.[5] The results of the binding studies are shown in Table 1.

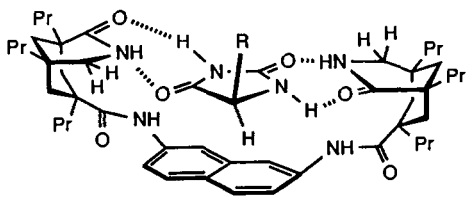
Table 1. Association constants [M^{-1}] and $\Delta\Delta G$ values [$\Delta\Delta G$ = ΔG (−)-enantiomer − ΔG (+)-enantiomer] of the chiral receptor **1b** with substrates **5–9** and **14** [a], the achiral receptors **2b** with **14**, **2c** with **12** and **14** [a], and the chiral receptor **3c** with **10–15**.

Substrate	Association constants K_a[M^{-1}] of (−)-**1b**	(+)-**1b**	**2b**	**2c**	(−)-**3c**	(+)-**3c**	$\Delta\Delta G$ [kcal mol^{-1}]
5	4800	1720					−0.6
6 [b]	1050	390					−0.6
7	7080	705					−1.4
8	7070	650					−1.4
9	380	*2110*					*1.0*
10					1672	1003	−0.3
11					4736	2340	−0.4
12				9000	4250	2320	−0.4
13					62	134	0.5
14	186 [a]		900	5900	2920 [a]		
15					320	405	0.2

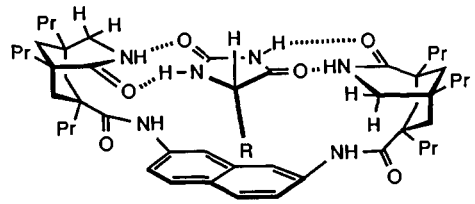
[a] With the achiral **14** racemic chiral receptors **1b** and **3c** were used. [b] The low K_a's are due to the fact that the $CDCl_3$ solution contained 10% [D_8]THF.

The phenylalanine- and leucine-derived hydantoins **5** and **6** bind to **1b** with differences in the relative binding affinities of -0.6 kcal mol^{-1} in favor of (−)-**1b**. Branching at the β-carbon of the substrate, as found in the valine- and isoleucine-derived hydantoins **7** and **8**, greatly increases the enantiomeric differentiation ($\Delta\Delta G = -1.4$ kcal mol^{-1}). The L-hydroorotic acid methyl ester (**9**) binds with lower binding constants than the hydantoins (see Table 1). With $\Delta\Delta G = 1.0$ kcal mol^{-1}, the relative binding affinities of **1b** to **9** are in the order of values observed for enantioselective recognition of other neutral substrates.[1]

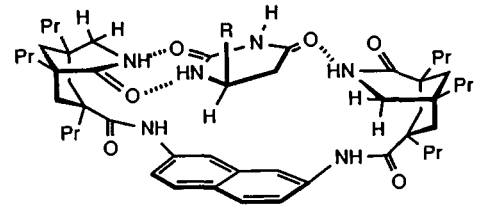
These results are in accordance with the proposed binding mode shown in Scheme 1. In **16α**, up to four hydrogen bonds can form between substrates **5–8** and receptor **1b**. Molecular modeling studies of complex **16β** show that the β-CH_2 group of the substrates **5** and **6** allows the γ-branched side chain to rotate out of unfavorable steric interactions to the receptor. Such a rotation is impossible with the $-CH(CH_3)_2$ and the



16α



16β



17

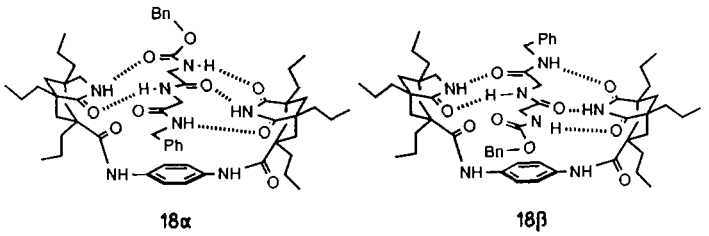
Scheme 1. Proposed binding modes for the enantiomers of **1b** to the hydantoins **5–8** (**16**) and the hydroorotic acid methyl ester **9** (**17**).

$-CH(CH_3)CH_2CH_3$ group of substrates **7** and **8** respectively. The six-membered ring of the hydroorotic acid methyl ester (**9**) is too large for optimal fit into the cleft. Therefore three hydrogen bonds can at best be formed with **1b**, which accounts for the lower binding constants. The direction of the $\Delta\Delta G$ values for **9** changes with respect to the $\Delta\Delta G$ values for the hydantoins **5–8**. The proposed structures of complexes **16** and **17** give an excellent rationale for this difference. The enantioselectivity of these receptors for L-hydantoins and for the L-hydroorotic acid methyl ester (**9**) are among the highest observed with neutral substrates.

Enantioselectivity in the binding of the chiral, non-C_2-symmetric **3c**[6] to the flexible dipeptide substrates **10–13** is detectable ($\Delta\Delta G = -0.3$ to 0.5 kcal mol^{-1}), but much lower than that with the rigid **7–9**. A chiral, C_2-symmetric macrocycle recently presented by *Still* et al.[7] shows considerable enantioselective binding to acetyl-L-alanine derivatives, including the dipeptides $CH_3C(O)$-L-ala-L-ala-OBn/$CH_3C(O)$-D-ala-D-ala-OBn ($\Delta\Delta G \approx 1.1$ kcal mol^{-1}).

The achiral diimide **2c** binds to the nonchiral dipeptide **14** with a binding constant of 5900 M^{-1}. The corresponding *rac*-**3c** complexes **14** with half the K_a ($K_a = 2920$ M^{-1}, see Table 1). These results are in accordance with the two binding modes **18α, β**, shown in Scheme 2.

In the diimide receptor **2c**, the peptide has four possibilities of fitting into the cleft, whereas in **3c**, only two binding



18α 18β

Scheme 2. Proposed binding modes for the complexation of N-CBz-gly-gly-NHBn (**14**) by **3c**.

permutations are possible (Scheme 2). This results in a statistical factor of 2 in the observed relative affinities of **2c** and **3c** for dipeptide **14**. We observe the same trend with the chiral peptide **12**, which binds to the achiral diimide **2c** with $K_a = 9000\ M^{-1}$ and to (−)-**3c** with $K_a = 4250\ M^{-1}$ (see Table 1).[8]

The five hydrogen bonds depicted in **18α, β** do not necessarily have to correspond to a binding constant higher than that observed in **16**. Rigid, cyclic molecules show binding constants ranging from ca. $7000\ M^{-1}$ (**7**, **8**) to more than $70000\ M^{-1}$ (**4**),[2a, b] although only four hydrogen bonds are present in the complexes. In the binding mode proposed by *Still* et al. for dipeptide complexes,[6] three hydrogen bonds are present. The binding constants observed in $CDCl_3$, however, are in the order of 10 to $100\ M^{-1}$. Whether the lower binding constants in these linear (presumably very flexible) molecules with respect to rigid substrates are due to less optimal fit into the cleft or to changes in the peptide tertiary structure upon complexation ("induced fit"; perhaps involving intramolecular H-bonds), remains to be investigated. We are currently studying the binding mode of **18** and the tertiary structure of the uncomplexed peptides by NMR spectroscopy.

The binding of linear dipeptides by **3c** is sensitive to steric effects. The (−)-enantiomer of **3c** binds N-CBz-L-leu-gly-NHBn (**11**) and N-CBz-L-ile-gly-NHBn (**12**) much better than N-CBz-L-ile-L-ile-NHBn (**13**) (K_a: **11** $4736\ M^{-1}$, **12** $4250\ M^{-1}$, **13** $62\ M^{-1}$, see Table 1). With the bulky side chain at the carboxy terminal end (**10**, $K_a = 1672\ M^{-1}$) the K_a is nearly thirty times higher than with **13**. Small side chains in both amino acid residues, as in N-CBz-L-ala-L-ala-NHBn (**15**) gave comparatively low binding constants (K_a: **15** $320\ M^{-1}$). These results suggest that **3c** displays selectivity towards the glycine-containing dipeptides.

The dilactam **1b** expands the spectrum of receptors for the enantioselective complexation of neutral substrates. The structural features provided by these compounds are very convenient for the rational design of enantioselective receptors for rigid cyclic guest molecules. The enantioselectivity of the asymmetric chiral imide lactams **3c** in binding studies with flexible dipeptides, is comparatively low, even though relatively high binding constants were obtained. We are currently developing clefts which contain chiral spacers for enantioselective dipeptide recognition.

[5] The association constants were determined in $CDCl_3$ from the ^1H NMR titration data by nonlinear least-squares fit of the saturation curves; errors are estimated as ± 10%. The observed ^1H NMR signals were due to the lactam-NH in **1b**, the imide NH in **2**, and the aromatic protons in **3c**. Titrations were carried out at 295 K (± 1 K). In the peptide complexation studies with **2**, clearly the strongest binding constants were obtained in combination with the *p*-phenylenediamine spacer **c**. Therefore, **3c** was the only imide lactam receptor that was synthesized for this study. We also synthesized the (racemic) dilactam receptor **1c**, but this compound was insoluble in $CDCl_3$.

[6] The synthesis of **3c** will be described in the forthcoming full paper.

[7] R. Liu, P. E. J. Sanderson, W. C. Still, *J. Org. Chem. 55* (1990) 5189.

[8] Compound **14** binds to the diimide **2b** with a 5-fold higher K_a than to the related dilactam **1b** (see Table 1). That indicates that all three binding points of at least one imide function in the receptors are required for strong binding to the aminobenzyl-protected dipeptides. N-CBz-gly-gly-methyl ester, a dipeptide that lacks the additional amide group provided by the aminobenzyl-protecting group in **14**, binds to the diimides **2b** and **2c** with 10 to 15 times lower K_a's than does **14**. These results give further support for the binding mode **19**, in which the carboxy terminal NH-group in **14** forms a hydrogen bond to the imide moiety in receptor **3c**

Synthesis and Structure of an N_2Sb_2 Ring with Different Types of Coordination for Antimony Atoms**

By *Herbert W. Roesky,* Kay Hübner, Mathias Noltemeyer,* and *Michael Schäfer*

Dedicated to Professor Hans Georg von Schnering on the occasion of his 60th birthday

$Me_3Si–N=PPh_3$ reacted with $TeCl_4$ to yield a four-membered Te_2N_2 ring and not, as we expected, a chloro-bridged heterocycle.[1] Thus the question arose how $SbCl_3$, the corresponding compound of the neighboring element antimony, would react on treatment with a $Me_3SiN=S$ system. The reaction of *N,N'*-bis(trimethylsilyl)dimethylsulfodiimide (**1**)[2] with $SbCl_3$ in trichloromethane in the mole ratio 1:1 led to the Sb_2N_2 system (**2**).

Compound **2** is a colorless, air-stable solid, and good quality crystals can be obtained on crystallization from MeCN. The molecular structure of **2** (Fig. 1, top) was surprising. As in the above-mentioned reaction with tellurium, a four-membered nitrogen–metal ring had formed, whose chemically equivalent antimony atoms Sb1 and Sb2 were differently coordinated. Both antimony atoms are, to a first approximation, in a pseudo-trigonal-bipyramidal environment. In the case of Sb1, N1 and N2 occupy equatorial positions (Sb1–N1 209.6(2), Sb1–N2 212.7(2) pm), while Cl1 and Cl2 are axially bound (Sb1–Cl1 261.8(1), Sb1–Cl2 259.0(1) pm). At Sb2, N2 and Cl3 are in equatorial (Sb2–N2 206.4(2), Sb2–Cl3 239.3(1) pm) and N1 and Cl4 in axial positions (Sb2–N1 223.3(2), Sb2–Cl4 258.0(1) pm). The different Sb–N and Sb–Cl bond lengths are thus adequately accounted for.

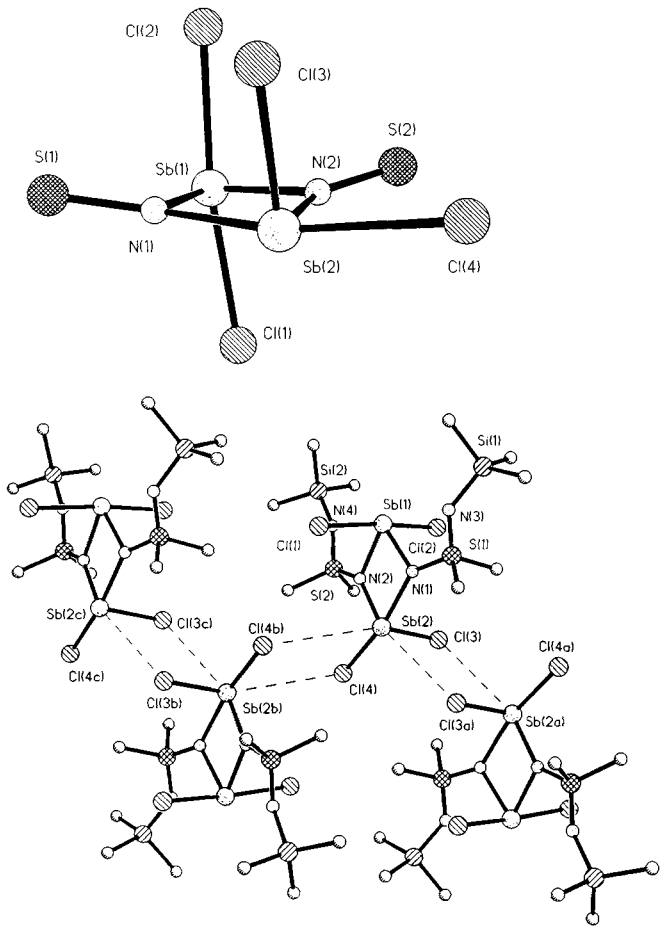

Fig. 1. Top: Structure of the Sb_2N_2 rings of **2**, surrounded by their immediate neighbors; bottom: arrangement of four molecules of **2** in the crystal structure. Selected bond lengths [pm] and angles [°]: Sb1-Cl1 261.8(1), Sb1-Cl2 259.0(1), Sb1-N1 209.6(2), Sb1-N2 212.7(2), Sb2-Cl3 239.3(1), Sb2-Cl4 258.0(1), Sb2-N1 223.3(2), Sb2-N2 206.4(2), S1-N1 155.7(3), S1-N3 149.5(3), S2-N2 157.1(3), S2-N4 149.1(3); Sb1-N1-Sb2 105.1(1), Sb1-N2-Sb2 110.2(1), N1-Sb1-N2 72.9(1), N1-Sb2-N2 71.3(1), Cl1-Sb1-N1 91.4(1), Cl3-Sb2-Cl4 87.0(1), Cl2-Sb1-N1 90.1(1), N2-Sb2-Cl3 98.0(1).

In the crystal **2** associates to form chains (Fig. 1, bottom). The Cl–Sb distances within the chain are 375 pm (Sb2···Cl3a, Cl3···Sb2a) and 411 pm (Sb2···Cl4b···Sb2b). If one includes neighboring atoms arising from the association in the consideration of the geometry, Sb2 has distorted octahedral environment. Furthermore, we assume that mainly the *cis* $Me_3SiNSMe_2$ residues determine the coordination sphere of the antimony atoms. The four-membered ring is not planar, but folded (ca. 10° along the Sb1–Sb2 axis). The deviations from the best plane are approximately 50 pm.[3] The mean Sb–N distance (213.0 pm) is comparable to that in known four-membered Sb_2N_2 rings.[4–6]

The ^1H NMR spectrum at room temperature shows two singlets at $\delta = 3.6$ ($S–Me_2$) and $\delta = 0.5$ (Si–Me). The peak with the highest m/z ratio in the mass spectrum (341) corresponds to the fragment ion $[M/2 - Me]^+$. The ^{121}Sb Mössbauer spectrum also conforms to these findings (Fig. 2).[7] From the least-squares fit two antimony positions

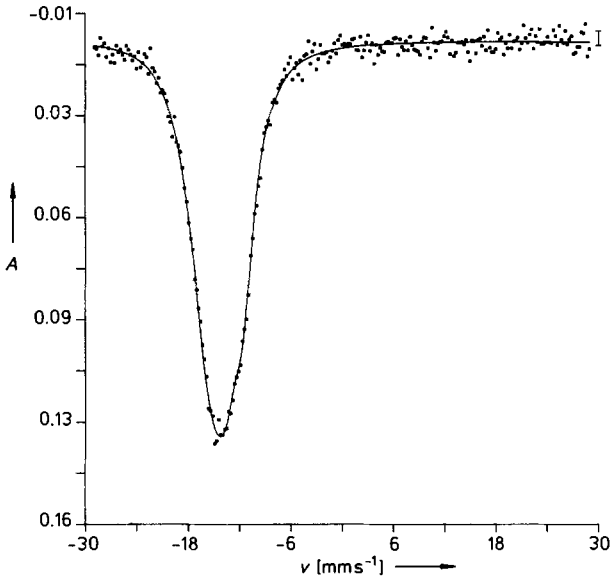

Fig. 2. ^{121}Sb Mössbauer spectrum of **2**. A = resonance absorption, v = relative velocity.

are observed with typical isomer shifts for Sb^{III} compounds of $-13.5(1)$ (Sb1) and $-14.9\ mm\,s^{-1}$ (Sb2). The 24 overlapping lines of the spectrum make it difficult to determine the quadrupole splitting with certainty. The best fit gave values for ΔE^Q of 21.0(1.0) (Sb1) and $-13.4(1.5)\ mm\,s^{-1}$ (Sb2). The negative quadrupole splitting at Sb2 (trigonal-bipyramidal mononuclear compounds of Sb^{III} generally show positive quadrupole splittings[9]) is probably due to the almost perendicular arrangement of the lone pairs on the Sb atoms. If it is assumed that the gradient of the electrical field is determined only by the position of the lone pairs,[10] this arrangement leads to a ratio of 2:−1 for the quadrupole splittings, according to the point charge model[11] for ideal trigonal-bypramidal Sb atoms. When one considers the approximations involved (influence of the other ligands on the electric field, deviations from ideal trigonal-bipyramidal structure, errors in fit due to the two superimposed Sb sites), the agreement between model and experiment is surprisingly good.

In conclusion, we could show that **2** is the first four-membered ring system which in the solid state has two chemically equivalent elements in different environments in the ring.

Experimental Procedure

2: A solution of **1** (1.2 g, 4.9 mmol) in $CHCl_3$ (40 mL) was added dropwise to a solution of $SbCl_3$ (1.1 g, 4.9 mmol) in $CHCl_3$ (100 mL) within 1 h at room temperature. With the addition of the first drops, the initially clear solution became cloudy. Thereafter the reaction was stirred at room temperature for a further 12 h, and the white, flocculent solid which formed was separated by

filtration. The filtrate was allowed to stand at room temperature for a day, whereupon more solid precipitated and was removed by filtration, before the filtrate was evaporated to dryness. The solid, yellow, granular residue was dissolved in MeCN and the solution allowed to stand for 12 h. Single crystals of **2** suitable for an X-ray structure analysis were obtained. Yield: 0.3 g, m.p. 165°C (dec.). IR: $\tilde{\nu}$ [cm^{-1}] = 1260 vs, 1094 vs, 975 vs, 842 vs, 758 vs, 636 vs, 535 s, 415 m, 313 s. Correct elemental analysis (Cl, N).

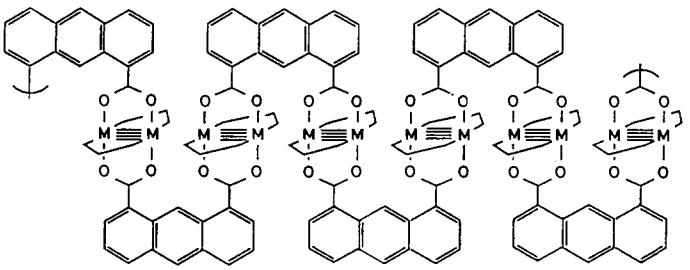
Mo–Mo Quadruple Bonds Bridged by 1,8-Naphthyridinyl-2,7-Dioxide: an Insight into the Nature of a Parallel-Linked Stiff-Chain Polymer: $+M^nM\sim\sim\sim M^nM+_x$**

By *Roger H. Cayton, Malcolm H. Chisholm,* John C. Huffman*, and *Emil B. Lobkovsky*

Dedicated to Professor Hans Georg von Schnering on the occasion of his 60th birthday

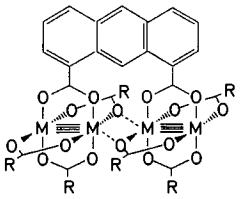
The reactions between 1,8-anthracene dicarboxylic acid and $[Mo_2(O_2CR)_4]$ compounds lead to materials that we formulate as stiff-chain polymers[1] as depicted by **1** below. These materials tend to be insoluble in THF once the degree of polymerization x approaches 10. We are exploring the use



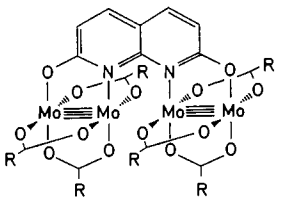
1

of long chain carboxylates (soaps) as attendant ligands with the hope of obtaining more soluble polymers.

The dimer $[\{Mo_2(O_2CtBu)_3\}_2(\mu\text{-}C_{16}H_8O_4)]$, **2**, has been prepared and studied in some detail[2] but regrettably no single crystals have been obtained that were suitable for X-ray analysis.

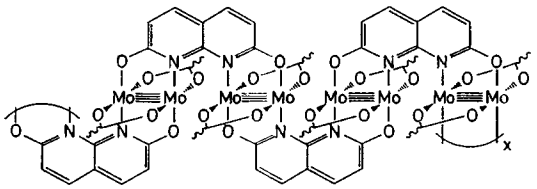


2, R = *t*Bu, M = Mo



3, R = *t*Bu

We have, however, been able to prepare a dimer bridged by 1,8-naphthyridinyl-2,7-dioxide (**3**) which in turn provides a model for a tetranuclear subunit of a naphthyridinyl dioxide-bridged polymer, **4**.



4

The synthesis of the dimer **3** is outlined by the reaction shown in equations a to c.[3]

$$[Mo_2(O_2CtBu)_4] + Me_3O^{\oplus}BF_4^{\ominus} \xrightarrow[CH_2Cl_2/CH_3CN]{22\,^\circ C} [Mo_2(O_2CtBu)_2(CH_3CN)_6](BF_4)_2 \quad (a)$$

5 → **6**

$$\mathbf{6} + \mathbf{5} \underset{CH_3CN}{\rightleftharpoons} 2\,[Mo_2(O_2CtBu)_3(CH_3CN)_2]BF_4 \quad (b)$$

7

$$\mathbf{7} + Na_2O_2N_2C_8H_4 \xrightarrow[THF/MeOH]{0\,^\circ C} [\{Mo_2(O_2CtBu)_3\}_2(\mu\text{-}O_2N_2C_8H_4)] \quad (c)$$

3

Orange crystals of **3** were obtained from THF, and the molecular structure determined by X-ray crystallography[4] is shown in Figure 1. The metal–metal distances alternate along the Mo_4 chain (short, 2.12 Å; long, 3.17 Å; short, 2.09 Å) consistent with the view of two localized Mo–Mo quadruple bonds brought together by the 1,8-naphthyridinyl-2,7-dioxide bridge. There is a twisting of the dimer

[**] We thank the National Science Foundation for support and for a postdoctoral fellowship (R. H. C.). n represents the number of the bonds between the metal centers.

(Mo–Mo–Mo angle 149°) brought about by the desire of each Mo atom to coordinate to an oxygen atom along the Mo–Mo axis. The twisting allows a μ-carboxylate ligand of one Mo_2 unit to bind to a Mo atom of its neighboring Mo_2 unit as indeed occurs in the solid-state and liquid-crystalline phases of the $[Mo_2(O_2CR)_4]$ compounds.[5] This interaction is relatively weak as judged by the long Mo···O distances of 2.81 and 2.84 Å.

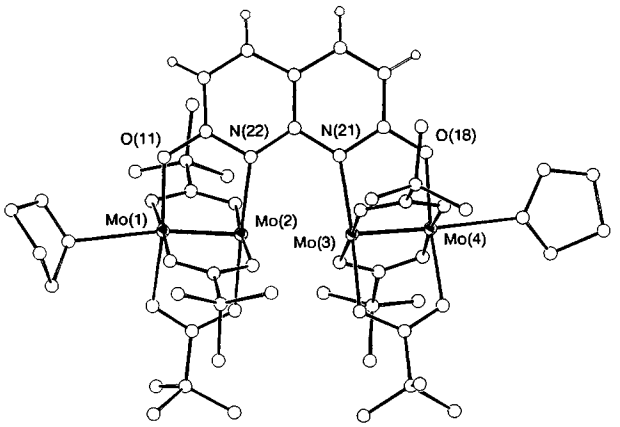

Fig. 1. A ball-and-stick drawing of the 2,7-naphthyridinyl dioxide-bridged tetranuclear complex **3**·2THF. Selected bond distances [Å]: Mo1–Mo2 = 2.0960(3), Mo2–Mo3 = 3.171(1), Mo3–Mo4 = 2.0963(4), Mo1–O(THF) = 2.5596(4), Mo4–O(THF) = 2.4943(4), Mo1–O11 = 2.0626(4), Mo4–O18 = 2.0662(4), Mo2–N22 = 2.1871(4), Mo3–N21 = 2.1682(5), Mo–O(pivalate) = 2.11(1).

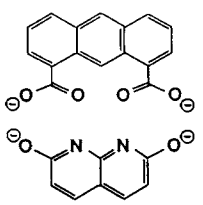
In solution the temperature-dependent NMR behavior of **2** and **3** is very similar. At room temperature there are, in addition to the signals of the anthracene and naphthyridinyl dioxide ligands, only two types of *t*Bu resonances (2:1 ratio) indicating a time-averaged structure of C_{2v} symmetry. At low temperatures (**2**, −80 °C, $[D_8]$THF; **3**, −50 °C, CD_3OD/CD_2Cl_2) the signal of intensity 2 splits into two signals to give a 1:1:1 pattern as expected for a molecule displaying only C_2 symmetry due to the axial $(Mo_2\cdots O)_2$ interactions noted above. Evidently these weak $(Mo_2\cdots O)_2$ bonds are easily broken ($\Delta G^{\neq}$ = ca. 9–10 kcal mol^{-1}) leading to the time-averaged structure with a mirror plane and presumably a linear (or at least nearly linear) Mo_4 chain. It should be noted that in the C_{2v} structure the rigid nature of the spanning ligands constrains the "inner" Mo atoms to be separated by only 2.4–2.7 Å.

The 1,8-anthracene dicarboxylate and 1,8-naphthyridinyl-2,7-dioxide ligands are stereochemically correspondent as shown in Scheme 1, and we believe the Mo_4 chains in **2** and **3** must be very similar. However, the extent of electronic coupling in these molecules is remarkably different.

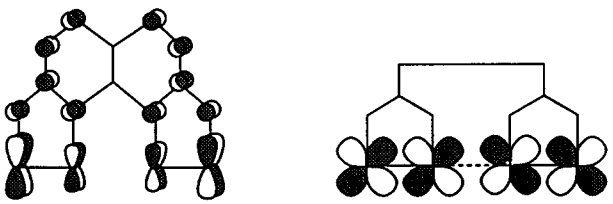
Compound **3** exhibits two successive oxidation waves (representing the removal of electrons from the Mo–Mo δ orbitals) in THF separated by 373 mV, whereas the analogous oxidations of **2** are estimated to be separated by only ca. 100 mV. The exact $\Delta E_{1/2}$ value of **2** cannot be determined due to competitive oxidation of the electrons from the anthracene ligand; however the analogous tungsten complex displays a $\Delta E_{1/2}$ of only 156 mV. (The tungsten compounds are invariably more strongly coupled than their molybdenum analogues.[2]) The coupling in **3** is similar to that of the Creutz–Taube ion (**8**, $\Delta E_{1/2}$ = 390 mV):[6]



Scheme 1. Stereochemical equivalence of the ligands anthracene dicarboxylate and naphthyridinyl dioxide.

$[(H_3N)_5Ru(\mu\text{-pyrazine})Ru(NH_3)_5]^{n+}$ **8**, n = 4–6

Because of the vastly different degrees of electronic communication between the Mo_2 centers in **2** and **3** we suggest that the coupling in **3** occurs through the naphthyridine bridge. This is supported by Fenske–Hall MO calculations[7] that reveal strong interactions between the Mo–Mo δ and the naphthyridine π orbitals as shown in Scheme 2, **A**. By contrast two Mo–Mo quadruple bonds separated by 2.4 Å in a parallel alignment show little orbital mixing for their in- and out-of-phase combinations.



Scheme 2. **A** = HOMO of **3** from Fenske–Hall MO calculations; Mo–Mo δ orbitals form 60%. **B** = HOMO of a Ru_2 dimer, whose structure is analogous to that of **3**.

The situation could be very different for parallel-linked Ru_2 dimers where the HOMO would contain both M–M π* and M···M π interactions as shown schematically in Scheme 2 B. Therefore by the appropriate choice of either metal or ligand bridge we believe that stiff chain polymers of the type schematically represented by **1** or **4** will show insulating, semi-conducting, or metallic properties.

Experimental Procedure

All syntheses were carried out under an inert atmosphere (N_2) and using dry and degassed solvents.

Compound **6** was prepared in a manner directly analogous to that reported in Ref. [3a] for $Mo_2(O_2CCH_3)_2(CH_3CN)_6(BF_4)_2$.

Compound **7** was prepared by combining **5** (0.524 g, 0.88 mmol) and **6** (0.716 g, 0.88 mmol) in CH_3CN and heating to 70 °C for 24 hours. Removal of the volatiles under vacuum afforded a peach-colored powder which, after repeated washings with toluene, was 89 mol % pure (^{1}H NMR). The tetranuclear complex, **3**, was prepared by adding a 0 °C methanol solution of $Na_2O_2N_2C_8H_4$ (0.138 g, 0.67 mmol) (see Ref. [3b]) to a 0 °C THF solution of **7** (0.800 g, 1.28 mmol) and warming to room temperature. The volatiles were removed under vacuum and the residue extracted with THF. The extracts were filtered through celite, concentrated, then cooled to −20 °C to yield orange crystals (0.520 g, 70%). Satisfactory elemental analyses were obtained for all compounds.

The polymer shown in **4** could be prepared by the treatment of a THF solution of $[Mo_2(O_2C\text{-}n\text{-}C_{11}H_{23})_2(CH_3CN)_6](BF_4)_2$ (0.485 g, 0.48 mmol) with a methanol solution of $Na_2O_2N_2C_8H_4$ (0.099 g, 0.48 mmol), removal of the volatiles under vacuum, and extraction of the residue with toluene. Elemental analysis of the polymer indicates the average general formula, $Na[Mo_2(O_2C\text{-}n\text{-}C_{11}H_{23})_2(O_2N_2C_8H_4)]_{20}(CH_3CN)_2(BF_4)$.

New Intermediate Phases of the Composition $La_{2n+2}Cu_{n+4}O_{4n+7}$ in the La–Cu–O System: the Crystal Structure and Thermal Stability of $La_2Cu_2O_5$ **

By *Rolf Norrestam,* Mats Nygren,* and *Jan-Olov Bovin*

Dedicated to Professor Hans Georg von Schnering on the occasion of his 60th birthday

In the lanthanum oxide–copper(II) oxide system, La_2CuO_4 has been considered to be the only existing intermediate phase.[1, 2] La_2CuO_4 is of particular interest, as compounds such as $La_{2-x}M_xCuO_4$, M = Sr and Ba, which have the La_2CuO_4 structure type are superconducting[3] with transition temperatures exceeding 30 K. We now describe a new phase obtained when growing single crystals of La_2CuO_4 according to the preparation scheme suggested by *Chen* et al.[4] for the growth of crystals of the composition $(La,Sr)_2CuO_4$ from CuO flux. The X-ray powder photographs of the obtained specimen showed extra intense lines of an unknown phase. Needle-shaped crystals were selected from the specimen and examined by single crystal X-ray diffraction techniques.[5] These proved to be $La_2Cu_2O_5$ and all the extra lines in the powder photograph belong to this phase.

Powder samples of $La_2Cu_2O_5$ and $La_8Cu_7O_{19}$ were obtained by heat treatment of carefully mixed La_2O_3 (dried) and CuO mixtures pressed into tablets. The tablets were placed in Pt crucibles, heat-treated in air or in oxygen at various temperatures between 1050 and 1125 °C for 15–20 hours, and then quenched by allowing them to cool outside the furnace. Almost monophasic samples were obtained in the temperature range 1075–1100 °C. A slight excess of CuO seems to favor the formation of $La_2Cu_2O_5$. Outside this temperature range La_2CuO_4 is the dominant phase. Partial replacement of La^{3+} in $La_2Cu_2O_5$ by divalent ions, such as Mg^{2+}, Ca^{2+}, Sr^{2+}, and Ba^{2+} or tetravalent ions such as Ce^{4+} and Th^{4+} has been attempted. Crystals large enough for electrical measurements were grown in a flux of CuO. All the powder specimens prepared have been characterized by means of their X-ray powder patterns, obtained in a Guinier-Hägg focusing camera.

From single crystal X-ray diffraction data,[5] the probable space groups (as deduced from systematic absences in the reflection data) are *Cn* or *C2/n*. The choice of the centrosymmetric space group *C2/n* is supported by the observed distributions of normalized structure factors[6] and by the outcome of the structural refinements. The structure was solved by heavy atom techniques. Refining the occupancies of the oxygen atomic positions did not reveal any substantial deviation from 100%. The atomic coordinates and thermal parameters are listed in Table 1 and selected interatomic distances in Table 2.

Table 1. Fractional atomic coordinates ($\times 10^4$) and thermal parameters ($\times 10^4$ Å^2) for the structure of $La_2Cu_2O_5$.

A sketch of the $La_2Cu_2O_5$ structure is given in Figure 1. A characteristic pattern is the occurrence of slabs of La_2CuO_4, which are the width of two octahedra, each centered around Cu1[7, 8] (Fig. 1). The walls separating the La_2CuO_4 slabs consist of the oxygen coordination polyhedra formed around the Cu2 and Cu3 atoms. These polyhedra are connected to the La_2CuO_4 slabs by corner-sharing. The irregular coordination geometries around Cu2 and Cu3 show some slight resemblance to those found in the $M'_2Cu_2O_5$ phases, where M′ are smaller trivalent rare-earth ions.[9]

The polyhedron of O atoms within 2.96 Å from Cu2 in the $La_2Cu_2O_5$ structure can be considered as a flattened tetrahedron with Cu–O bond distances ranging from 1.91 to

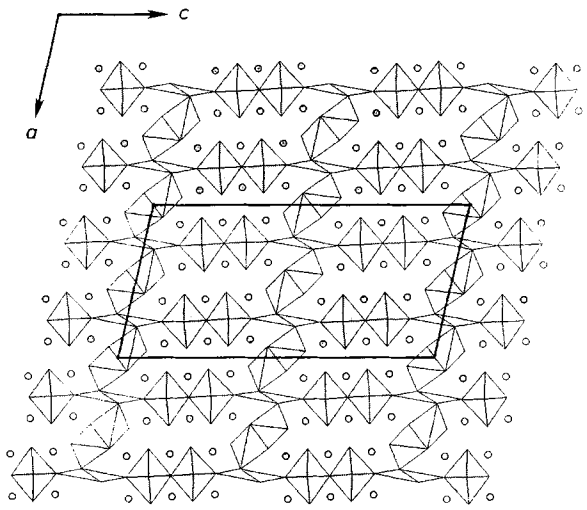

Fig. 1. Polyhedral representation of the structure of $La_2Cu_2O_5$, projected along [0 1 0]. For clarity, only the coordination polyhedra around the Cu atoms are shown: the positions of La atoms are indicated by circles.

2.10 Å. Two such tetrahedra share an edge. These entities are linked to infinite bands of edge-sharing polyhedra around the Cu3 atoms extending in the *b* direction (Fig. 2). The coordination geometry around Cu3 may be considered as an elongated octahedron, where bond lengths of the four approximately equatorial Cu–O bonds range from 1.91 to 2.02 Å and the two axial ones are about 2.6 Å. The average bond distances for the Cu and La atoms agree with expected bond distances.[10]

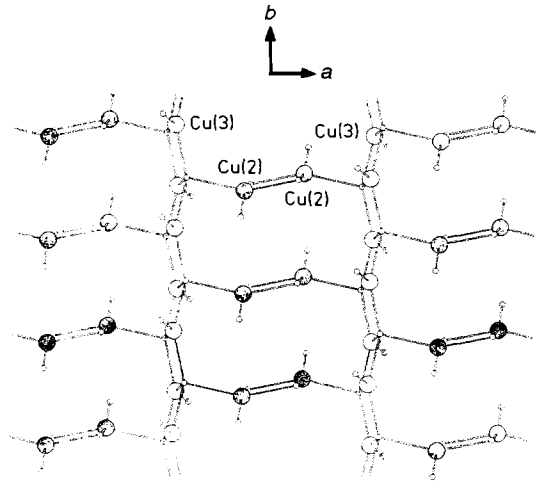

Fig. 2. Ball-and-stick representation, viewed perpendicular to (0 0 1), of the atomic arrangement in the walls separating the La_2CuO_4 slabs in the $La_2Cu_2O_5$ structure.

The structural features within the La_2CuO_4 slabs agree with those found for La_2CuO_4 itself[7, 8] (Table 2), namely, elongated octahedra around Cu1 and nine-coordinated La^{3+} ions (i.e., all atoms within 3.2 Å). Thus, it seems reasonable to expect that phases related to $La_2Cu_2O_5$, but with other widths of the La_2CuO_4 slabs, might exist. Such predicted phases would have the general compositions $La_{2n+2}Cu_{n+4}O_{4n+7}$ ($La_4Cu_5O_{11}$, $La_6Cu_6O_{15}$ ($=La_2Cu_2O_5$), $La_8Cu_7O_{19}$, $La_{10}Cu_8O_{23}$, ..., La_2CuO_4, where $n = 1-\infty$ is the number of edge-sharing CuO_6 octahedra between La_2CuO_4 slabs). The phase compositions can alternatively be written $mLa_2CuO_4 \cdot 3\,CuO$ ($m = 2,3,\ldots$), emphasizing the occurrence of La_2CuO_4 building blocks. The unit cell parameters would ideally only show an increment in the *c* axis of 7.5 Å for each additional La_2CuO_4 unit.

High resolution transmission electron microscopy (HREM) on $La_2Cu_2O_5$ and $La_8Cu_7O_{19}$ crystals show that some crystals are rich in structural defects.[11] The first three members of the series can sometimes exist together in the same crystal, but there are also crystals of $La_2Cu_2O_5$ fairly free from defects. The HREM images (Fig. 3a) agree with the structure of the n = 2 member as determined by X-ray diffraction methods. From HREM pictures of crystals of $La_8Cu_7O_{19}$ (Fig. 3b), the predicted structure of the n = 3 member was verified.

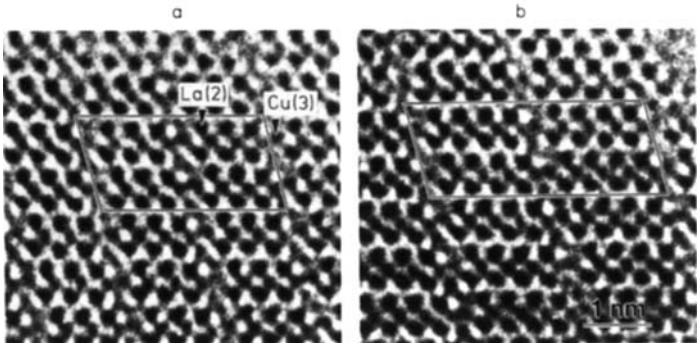

Fig. 3. HREM (JEM-4000EX) images of thin crystal fragments of a) $La_2Cu_2O_5$ and b) $La_8Cu_7O_{19}$, imaged with the electron beam down [0 1 0]. The metal positions are imaged as black spots and the La2 and Cu3 positions are marked with arrows.

HREM studies show that the structures of the members in the present homologous series are different from those of the series $La_{n+1}Cu_nO_{3n+1}$ (n = 1,2,...), stable below ca. 900 °C, observed by *Davies* and *Tilley*.[12] For this series no samples with n > 1 as a major constituent has been prepared. While the present series can be written $mLa_2CuO_4 \cdot 3\,CuO$, the *Davies* and *Tilley* series can be written $mLaCuO_3 \cdot La_2CuO_4$, emphasizing the different types of building blocks forming the structures. The latter series thus contains both Cu^{2+} and Cu^{3+}, while the former contains only Cu^{2+}.

The unit cell parameters of $La_2Cu_2O_5$ ($a = 13.877(2)$, $b = 3.750(1)$, $c = 27.571(3)$ Å and $\beta = 102.87(1)°$, calculated from 46 uniquely indexed powder pattern line positions) agree well with those obtained for the selected single crystal. Annealing of samples of the nominal composition $La_8Cu_7O_{19}$, at 1075 °C, yielded samples containing $La_8Cu_7O_{19}$ as the major phase. The expected powder pattern for $La_8Cu_7O_{19}$ was calculated,[13] using geometrically predicted atomic coordinates. The cell parameters for $La_8Cu_7O_{19}$ ($a = 13.833(3)$, $b = 3.761(1)$, $c = 35.128(8)$ Å and $\beta = 103.59(3)°$) refined from the powder photographs agree well with those predicted.

The electrical properties of $La_2Cu_2O_5$ have been investigated using four-probe conductivity measurements on single crystals of sizes up to 1 mm in length[14] and on powder pellets containing $La_2Cu_2O_5$ as major phase. These studies showed that $La_2Cu_2O_5$ exhibited insulating properties. The narrow temperature range of stability (1075–1100 °C) seems to prevent the preparation of $La_2Cu_2O_5$ samples where part of the La^{3+} ions have been replaced by M^{2+} or M^{4+} ions. Thus, all samples were found to contain La_2CuO_4, $La_{2-x}M_xCuO_4$ and CuO, but no $La_2Cu_2O_5$. In an attempt to

incorporate excess oxygen into the structure, powder pellets with $La_2Cu_2O_5$ as major phase were annealed at an oxygen pressure of 150 atm at 800, 400, and 200 °C during 24 h, 48 h, and 1 week, respectively. The oxygen content of the samples was determined by thermogravimetric methods and shown to be the same before and after the annealing ($La_2Cu_2O_{5\pm0.01}$). The electrical measurements revealed them still to be insulators. $La_2Cu_2O_5$ samples annealed at 900 °C in nitrogen atmosphere decomposed into La_2CuO_4 and CuO.

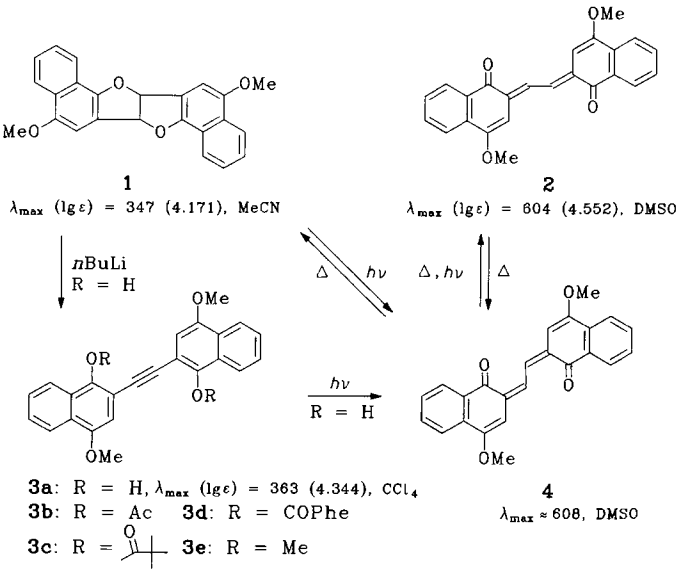
2,2′-(Ethynediyl)bis(4-alkoxy-1-naphthols) and Dinaphthofuro[3,2-*b*]furans—Substances with Unusual Photoreactivity and Photochromic Behavior

By *Andreas Johann Schmidt*, *Hartmut Laatsch** and *Mathias Noltemeyer*

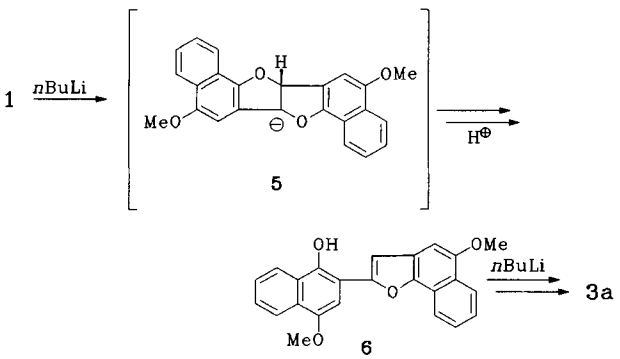
Colorless dialkoxydinaphthofuro[3,2-*b*]furans of type **1**[1a] become momentarily blue and then violet in UV light ($\lambda_{max} = 604$ nm, dimethyl sulfoxide (DMSO)), whereby a dimeric *trans*-quinonemethide[1b] of type 2 is formed as sole end product. A short-lived intermediate, which we interpret as the *cis*-configurated **4**, is detectable by UV spectroscopy ($\lambda_{max} = 608$ nm) during the reaction; **4** can thermally recyclize to the starting compound **1**, most likely in an antarafacial [$4_s + 4_a$] cycloaddition. Furofurans and bismethides thus form a novel photochromic system, which is remarkable because of the unusual mechanism, the intensity of the color change, and the large difference in the absorption maxima of starting material and product.[2]



Scheme 1. Photochromic transformation of the furofuran **1**.

Unfavorable, however, is the rapid isomerization of the initially formed (*Z*,*Z*)-methide **4** into the (*E*,*E*)-form **2**, whose cyclization to **1** requires activation energies around 100 kJ mol^{-1}. We therefore decided to investigate the influence of bridgehead substituents on the stability of **4** and the photochromic behavior of **1**.

Lithiation of **1** and subsequent reaction with alkyl halides, however, did not lead to bridgehead-substituted furofuran, but to the alkyne **3a**. Apparently the anion **5** is not stable, even at low temperatures, as trapping experiments with deuterium oxide always revealed the presence of only unchanged starting compound **1** besides **3**. Presumably the ring-opening proceeds in two steps, since the furylnaphthalene **6** postulated as intermediate also reacts in the form of its anion with *n*-butyllithium to give the alkyne **3a**. Similarly, 3-bromobenzofuran reacts with *n*-butyllithium to give *o*-hydroxyphenylacetylene.[3]



Scheme 2. Anionic rearrangement of **1** to **3a**.

[*] Prof. Dr. H. Laatsch, A. J. Schmidt

Dr. M. Noltemeyer
Institut für Anorganische Chemie der Universität Göttingen (FRG)

In contrast, reactions with acid chlorides at room temperature led to the *O*-acylated alkyne derivatives **3b**–**3d** in yields of between 75 and 90%. The naphthol **3a** could easily be liberated from these by hydrolysis with methanolic sodium hydroxide; **3a** reacts with dimethyl sulfate via phase transfer catalysis to give the tetramethyl ether **3e** in high yields; upon treatment with trifluoroacetic acid or also on heating in boiling 1,2-dichlorobenzene, **3a** cyclizes to **6** in high yields.

The naphthol **3a** and its derivatives **3b**, **3c** and **3e** fluoresce remarkably strongly (Φ_f(**3a**) = 0.223). An X-ray structure analysis of **3b** revealed that the planes of the two naphthalene units are rotated through ca. 40° with respect to each other in the crystal, whereby the acetate moieties assume a synperiplanar arrangement referred to the triple bond;[4] bond lengths and angles lie in the expected range.

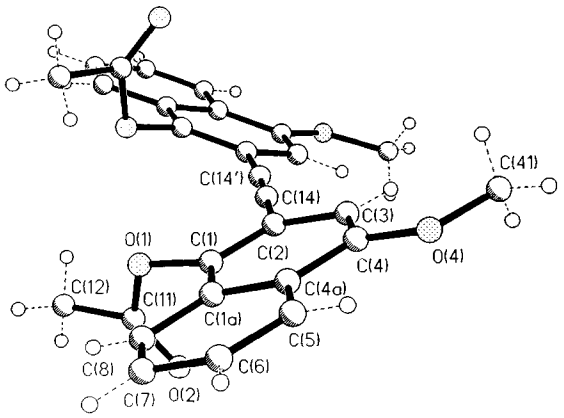

Fig. 1. Structure of **3b** in the crystal [4].

Of the numerous known diarylalkynes only the di-(2-hydroxyphenyl)acetylene[5] is hydroxylated in the *o*,*o*'-position to the triple bond; no unusual properties have been reported. Quite unexpected, therefore, was the extreme photolability of **3a**, which rearranges in less than 20 ns into the dimeric (*Z*/*Z*)-methide **4** under UV light, even at 120 K.[6] Also as solid or molecular dispersion in a polymer matrix, the dimethyl ether **3a** is momentarily tinted blue in light (long wavelength UV or photoflash). No parallel for this photoreaction has thus far been observed in the acetylene series.

Acetylene is present in the first excited state in a configuration corresponding to the *trans*-butene.[7] If **3a** is appropriately bent in the electronically excited state, the unusual photoreaction of the alkyne **3a** is best explained in terms of a double [1,5]-sigmatropic hydrogen shift to give the (*Z*/*Z*)-configurated, dimeric quinomethide **4**. Indeed, preliminary measurements show that **4** is formed from **3a**; apparently side reactions and secondary reactions are concealed by the rearrangement.

The anionic ring opening of **1** promises wide application for the synthesis of hydroxylated aryl- and diarylalkynes. And conversely, an alternative synthesis of the latter opens up the possibility of a photochemical access to novel, substituted furofurans and also the opportunity to investigate their photochemical behavior.

Experimental

2,2'-(Ethynediyl)bis(4-methoxy-1-naphthol) **3a**: a) a suspension of furofuran (1.0 g, 2.7 mmol) in anhydrous THF (50 mL) was treated with 6.7 mL (10.8 mmol) of *n*BuLi (1.6 M in hexane) at room temperature under N_2. After 6 hours' stirring 10 mL of MeOH were pipetted into the green fluorescing solution, and stirring continued for 10 minutes. The reaction mixture was then filtered with CH_2Cl_2 through silica gel (10 × 3 cm) and the residue obtained on evaporating the filtrate recrystallized from toluene/petroleum ether. **3a** (672 mg; 67%) was obtained in the form of colorless needles which decomposed on melting at 174°C and exhibited a blue fluorescence in solution. b) An analogous reaction of 640 mg (1.73 mmol) of **6** in 30 mL of anhydrous THF with 2.16 mL (3.46 mmol) of *n*BuLi (1.6 M in hexane) yielded 493 mg (76%) of **3a**. c) A suspension of **3b** (160 mg, 35.2 mmol) in MeOH (30 mL) and 10 mL of 2 N NaOH was heated under reflux in an atmosphere of N_2 for 10 min. The reaction mixture was neutralized with acetic acid and extracted with CH_2Cl_2. The organic phase, after evaporation and drying over magnesium sulfate, gave a polymeric material at the start, and then two major zones on column chromatography (CH_2Cl_2) through silica gel. Fraction 1 contained 18 mg (11%) of educt (R_f = 0.9, CH_2Cl_2), fraction 2 88 mg (76% based on conversion) of **3a** (R_f = 0.75, CH_2Cl_2).—UV (CCl_4): λ_{max} (lg ε) = 264 (4.811), 287 (4.549), 363 nm (4.344); ^{1}H NMR (200 MHz, $CDCl_3$): δ = 8.27 (m, 4H), 7.62 (m, 4H), 6.80 (s, 2H; 3-, 3'-H), 6.18 (s, 2H; 1-, 1'-OH), 4.02 (s, 6H; 4-, 4'-OMe); ^{13}C NMR ($CDCl_3$, 50.3 MHz, 50°C): δ = 149.4 (C-4,4'), 148.6 (C-1,1'), 127.3 (C-8a,8a'), 127.1 (C-6,6'), 126.7 (C-7,7'), 124.5 (C-4a,4a'), 122.3 (C-5,5'), 122.2 (C-8,8'), 104.5 (C-3,3'), 101.3 (C-2,2'), 91.5 (C-alkyne), 55.9 (CH_3).

2,2'-(Ethyndiyl)bis(1-acetoxy-4-methoxynaphthalene) **3b**: A suspension of **1** (1.0 g, 2.7 mmol) in anhydrous THF (50 mL) was treated with 6.7 mL (10.8 mmol) of *n*BuLi (1.6 M in hexane) under N_2. After 12 h stirring 0.77 mL (10.8 mmol) of acetyl chloride was pipetted into the mixture and stirring continued for 12 h. The mixture was transferred to a silica gel column (10 × 3 cm), eluted with CH_2Cl_2 and the pale yellow residue obtained on evaporation of the eluate purified by crystallization from toluene/petroleum ether. 1.09 g (89%) of **3b** was obtained as colorless monoclinic needles, which melted with decomposition at 224°C and fluoresced intense blue in solution.—^{1}H NMR (200 MHz, $CDCl_3$): δ = 8.32 (m, 2H), 7.86 (m, 2H), 7.60 (m, 4H; 6-, 6'-H, 7-, 7'-H), 6.96 (s, 2H; 3-, 3'-H), 4.02 (s, 6H; 4-, 4'-OMe), 2.52 (s, 6H; Ac-H).

3c [8] and **3d** [9] were formed analogously by trapping reactions of the anion with pivaloyl and benzoyl chloride, respectively; **3e** [10] was obtained by reaction of **3a** with dimethyl sulfate.

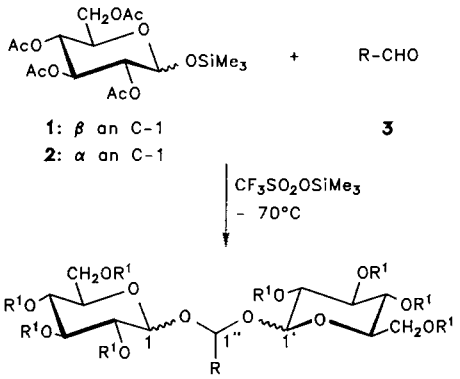
Stereoselective Synthesis of Acetal-β,β-diglucosides, a Novel Class of Glycosides and Chiral Acetals**

By *Lutz F. Tietze** and *Matthias Beller*

Dedicated to Professor Horst Prinzbach

Owing to their chemical properties and physiological functions, glycosides are of outstanding importance in chemistry and biology.[1] For the chemical industry they are of interest as potential raw material for the synthesis of novel products.[2] A possibility of gaining access to novel useful sugar derivatives involves the development of previously unknown glycoside structures. We describe here the synthesis of acetal diglycosides, a novel class of substances.

The carbohydrate derivatives occurring in Nature are predominantly *O*-glycosides in which a sugar is linked with an alcohol at an anomeric center. In addition there are also compounds, such as, e.g. secologanin, the parent compound of the secoiridoid glycosides and precursor of many alkaloids which are characterized by linkage of a cyclic hemiacetal with the anomeric center of a sugar.[3] Thus far unknown, however, are glycosides **4**–**7**, in which two sugars are



4: R^1 = Ac, β an C-1 und C-1'

5: R^1 = Ac, α an C-1, β an C-1'

6: R^1 = Ac, α an C-1 und C-1'

7: R^1 = H, β an C-1 und C-1'

bound via an aldehyde. Such substances are of interest because of their unusual trisacetal structure, their synthetic potential as chiral acetals,[4] and because of their potentially special material properties, e.g. as emulsifiers.

The synthesis of acetal-diglycosides,[5] e.g. of the acetyl-protected acetyl-β,β-diglucosides **4a**–**f** can be accomplished very easily by reaction of trimethylsilyl-2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranoside **1** with aldehydes **3a**–**f** in the presence of trimethylsilyl trifluoromethanesulfonate (trimethylsilyl triflate) as catalyst (Table 1).[6] Subsequent removal of the protecting groups (e.g. from **4a**) by solvolysis with potassium carbonate in methanol affords the deprotected compounds (e.g. **7a** in 83% yield). The products **4a**–**f** are

Table 1. Synthesis of acetal-β,β-diglucosides **4**.

Educts	Products	1:3 [mmol]	Yield [%]
1 + **3a**	**4a**	1:0.6	83
1 + **3b**	**4b**	1:2	80
1 + **3c**	**4c**	1:2	70
1 + **3d**	**4d**	1:1	18
		1:2	22
		1:3	26
1 + **3e**	**4e**	1:0.6	38

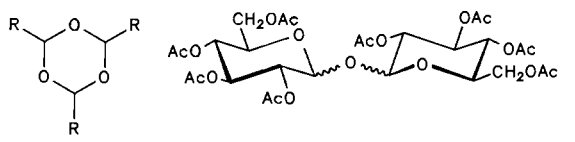
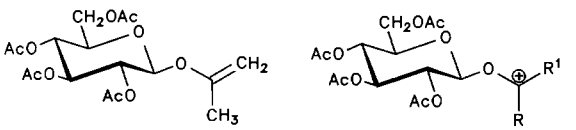
		1:9	54

formed stereoselectively at −78 °C with retention at the anomeric center of the trimethylsilyl-β-D-glucopyranoside **1** employed. At higher temperatures however, the reaction leads to a mixture of acetal-β,β- **4**, -α,β- **5** and -α,α-diglucosides **6**, which are very difficult to separate chromatographically. The yield of acetal-β,β-diglucosides **4** largely depends, as expected, on the reactivity of the aldehyde **3** employed. Simple aldehydes such as **3a** or **3b**, which are not deactivated by steric and electronic effects afford the acetyl-protected acetal-β,β-diglucosides **4a** and **4b** respectively in very good yields already on using a slight excess of the aldehyde. The yield of **4** decreases with increasing steric bulkiness of the aldehydes (**3b** < **3e** < **3d**); however, this effect can be partially compensated by using an excess of the aldehyde (Table 1). The poor yields in the reaction of benzaldehyde **3f** with **1** are presumably due to the low carbonyl activity of **3f**. In analogy to the synthesis of **4**, the acetal-α,α-diglucoside **6a** could be obtained in 26% yield by in situ anomerization[7] of **1** to **2** (0 °C, 10 mol-% trimethylsilyl triflate) and subsequent reaction with two equivalents of hexanal **3a** at −70 °C in the presence of trimethylsilyl triflate. The acid stability of **4a**–**4f** is greater than that of corresponding acetals of aliphatic alcohols.



8 **9**



10 **11**

The aldehyde trimers **8** and the trehaloses **9** are formed as by-products in the synthesis of **4**–**6**. The chromatographic separation of the trehaloses **9** from the acetal-diglycosides **4** and **6** was difficult in some cases (**4b**,**e**), but could be achieved by repeated column chromatography.

Attempts to prepare acetal-diglucosides by reaction of **1** and **2** with ketones under the same conditions have thus far failed. With acetone, the vinyl-β-glucoside **10** is formed in 16% yield as well as **9**. We attribute this to the fact that the carbocation **11** postulated by us as intermediate is not reactive enough towards **1** and **2** because of steric interactions when $R^1 \neq H$. This explanation is consistent with the strong

[**] Glycoside Syntheses, Part 19. This work was supported by the Fonds der Chemischen Industrie.—Part 18: L. F. Tietze, C. Schröter, S. Gabius, U. Brinck, A. Goerlach, H.-J. Gabius, *Bioconjug. Chem.*, in press.

dependence of the yields on steric requirements in the reaction of **1** with the aldehydes **3**.

The ^{1}H- and ^{13}C-NMR spectra of the acetal-diglucosides **4**–**7** are complex, since the two pyranose rings are magnetically non-equivalent. Surprising is the relatively large difference in the chemical shifts for C-1 and C-1′ in **4** and **7** ($\Delta\delta \leq 3.83$). Comparable differences are also observed for the signals of 1-H and 1′-H ($\Delta\delta \leq 0.59$). The presence of two β-glucosidic bonds in **4** and **7** follows from the doublet at $\delta = 4.6-5.1$ with $J = 7.5-8$ Hz for 1-H and 1′-H. In the ^{1}H-NMR spectrum of the acetal-α,α-diglucoside **6** 1-H and 1′-H give rise to signals at $\delta = 5.41-5.52$ with $J = 3.5$ Hz. The signal of 1″-H appears in the spectra of **4**–**7** as a triplet at $\delta = 4.64-5.05$ with $J = 5.5-7.5$ Hz.

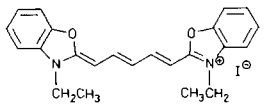
Circular Dichroism of a Chiral Cyanine Dye Dimer Trapped in γ-Cyclodextrin**

By *Volker Buss**

Aggregation of cyanine dyes in polar solvents or on solid matrices is a phenomenon of considerable theoretical and practical interest. The characteristic spectral changes accompanying dye aggregation[1] are easily understood at least on a qualitative level. Thus, the appearance in the UV of a new high-intensity band blueshifted relative to the monomer is generally assumed to indicate the formation of a sandwich-type dimer (or oligomer) aggregate. Recently, it was shown that β- and γ-cyclodextrin greatly enhance dimerization of certain cyanine dyes presumably by stabilization of the sandwich inside the cyclodextrin cavity.[2] We have now observed what appears to be the first example of a chiral cyanine dye dimer trapped within the channel of two γ-cyclodextrin molecules.



1

The temperature-dependent UV spectra of 3,3′-diethyloxadicarbocyanine iodide (DODC iodide, **1**) in a moderately concentrated (10^{-2} M) aqueous solution of γ-cyclodextrin, with 15% ethylene glycol added to allow cooling below 0 °C, are shown in Figure 1, left. The spectra change little with temperature because, under these conditions, most of the dye molecules are present already as dimers. This behavior is in contrast to what is observed in the circular dichroism (CD) spectra obtained under identical conditions (Fig. 1, right): the positive band at 534 nm, which must be attributed to dimer absorption, is gradually replaced by another band with negative amplitude, while the weak positive band at 589 nm increases in amplitude. There is a negative band at 635 nm (also manifest as a broad baseline absorption in the UV) whose origin we are not able to explain fully at the moment.

The changes brought about in the CD spectra by cooling the sample can be enhanced considerably by increasing the cyclodextrin concentration. Figure 2 shows the UV and CD spectra of DODC in a 50/50 (v/v) mixture of ethylene glycol and water in the presence of 0.125 M γ-cyclodextrin. The monomer absorption is markedly higher at room temperature owing to the high diol content. However, lowering the temperature increases the dimer concentration, and from about −50 °C on an equilibrium is reached comparable to the one in Figure 1, left.[3]

In the corresponding CD spectra the positive dimer absorption at 534 nm is observed only in passing while the spectra at lower temperature are dominated by the features which started to develop in Figure 1, namely, two strong

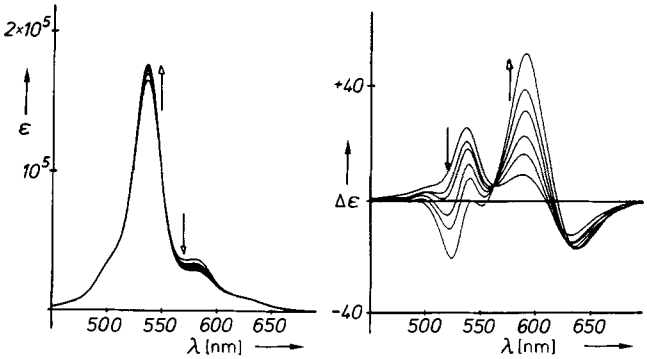


Fig. 1. Temperature-dependent UV (left) and CD spectra (right) of a solution of **1** (8.8×10^{-4} M) and γ-cyclodextrin (0.01 M) in 15% (v/v) ethylene glycol/water. Curves correspond to measurements at +10, 0, −5, −10, −15, and −20 °C. Arrows indicate direction of spectral changes as the temperature is lowered.

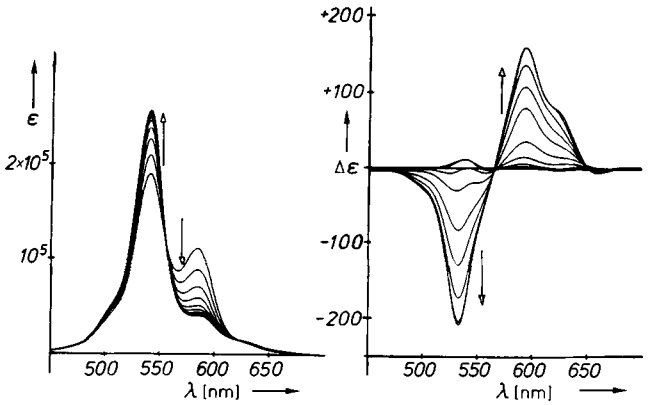

Fig. 2. Temperature-dependent UV (left) and CD spectra (right) of a solution of **1** (6×10^{-4} M) and γ-cyclodextrin (0.125 M) in 50% (v/v) ethylene glycol/water. Curves correspond to measurements at +25, +5, −10, −25, −40, −50, −60, −70, and −80 °C. UV maxima are at 539 and 583 nm, CD maxima at 533 and 594 nm.

oppositely signed, almost symmetrical bands with maxima at 533 and 594 nm and rotatory strengths, at −80 °C, of, respectively, -33.6×10^{-39} and $+31.5\times10^{-39}$ cgs units. Sufficient concentrations of both dye and cyclodextrin are necessary for the formation of what looks very much like an exciton coupling effect. In solutions with either a low γ-cyclodextrin concentration (e.g., 10^{-3} M in the presence of 6×10^{-4} M DODC) or dye concentration (10^{-5} M with 10^{-2} M γ-cyclodextrin) couplet formation is almost negligible even at −80 °C.

Since neither temperature changes nor changes in the dye or cyclodextrin concentration affect the position of the dimer band in the UV at 539 nm, we are dealing with basically the same dimer geometry throughout the experiment. On the other hand, the strong absorptions observed in the CD spectra indicate a chiral distortion of the dimer brought about by the interaction with γ-cyclodextrin. A structural model that explains all the observed phenomena and is in line with what is known about cyclodextrin host–guest complexes is depicted schematically in Figure 3. According to this model γ-cyclodextrin and DODC form a 2:2 inclusion complex with the dye dimer being trapped inside the channel formed by two cyclodextrin molecules. Chiral interaction between host and guest results in a twist of the dye monomers against each other, whose magnitude cannot be ascertained without much more work (according to the UV data it is rather small) but whose absolute sense is that shown in Figure 3.

X-ray analyses of several α-cyclodextrin complexes have revealed the existence of hydrogen-bridged dimers with the relative orientation of the cyclodextrin monomers being dependent on the guest molecules: head-to-tail dimers are found in the complex formed with methyl orange,[4] while, in complexes with metal iodides[5] or, recently, in a mixed-sandwich iron complex,[6] the cyclodextrin monomers are bridged head-to-head.

The difference between these two types of dimers is fundamental: following the oligosaccharide chain (e.g., in the 1 → 4 direction of the glycosidic bonds) the sense of rotation with respect to the symmetry axis is inverted when passing through the channel of the head-to-head dimer, a consequence of the dihedral symmetry of the host (D_8 in the case of γ-cyclodextrin). In the head-to-tail dimer, on the other hand, (C_8 symmetry), it stays the same. It follows that a guest molecule inside a cyclodextrin dimer of the first kind will experience opposite chiral forces, such as twists in opposite directions, in the two halves of the host. It is reasonable to assume, therefore, that the DODC dimer **1** observed through its chiroptic properties is of the twisted geometry shown in Figure 3 and that the reason for this is the head-to-head dimerization of the two cyclodextrin monomers.

Correlation between the absolute chirality of the DODC dimer in Figure 3 and the shape of the CD couplet is straightforward. A preliminary calculation on the basis of an extended dipole model[7] and using a distance between the planes of the dye molecules of 400 pm gave an exciton splitting of 2500 cm^{-1}. This value should be compared to the energy difference of 1900 cm^{-1} between the two excited states leading to CD bands at 533 and 594 nm.[8] For twist angles of 3 and 5° the calculated rotatory strengths for the two exciton states are ±11 and $\pm20\times10^{-39}$ cgs units, respectively. These values are an indication that the proposed model is able to account for the observed spectral properties. More elaborate calculations are in progress.

[7] The transition moment was approximated by two opposite charges, of 0.21 *e* each, located at a distance of 1000 pm in the long axis of the dye monomer.
[8] Actually, the two states will be closer in energy because the oppositely signed CD bands tend to shift the maxima apart.

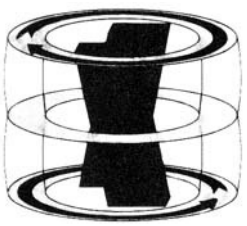

Fig. 3. Schematic drawing of the host–guest complex formed between two γ-cyclodextrin molecules and **1**. It shows the twisted dye aggregate inside the channel formed by the two γ-cyclodextrin monomers. The arrows indicate the torque exerted on the dye dimer by the two cyclodextrin monomers. They are opposite, leading to the observed chirality of the dye aggregate, if the two host monomers are joined head-to-head.

Tricarbonyl-η^6-(3,4-dimethylenecyclobutene)chromium(0), a Second Isomer of [(Benzene)Cr(CO)$_3$]

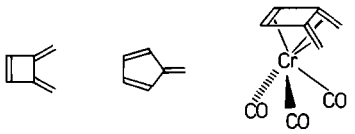
By *Doris Rau* and *Ulrich Behrens**

Dedicated to Professor Erwin Weiss on the occasion of his 65th birthday

Dimethylenecyclobutene **1**, like fulvene **2**, is a monocyclic isomer of benzene with three conjugated double bonds. **1**

[*] Prof. Dr. U. Behrens, Dipl.-Chem. D. Rau
Institut für Anorganische und Angewandte Chemie der Universität
Martin-Luther-King-Platz 6, W-2000 Hamburg 13 (FRG)

and **2**, which have found considerable theoretical interest in the past,[1-3] are, according to MO calculations, polar compounds.[4]



1 **2** **3**

By reaction of **1** with $[Cr(CH_3CN)_3(CO)_3]$ in pentane we have now been able to obtain the first transition metal complex of **1**, namely complex **3**, in which, as confirmed by an X-ray structure analysis (Fig. 1),[6] all six C atoms of the ligand are coordinated.[5] As in [(fulvene)$Cr(CO)_3$],[7] the two exocyclic C–C bonds are bent strongly (32°) from the ring plane, thus enabling a good interaction of the exocyclic π bonds with the chromium atom. The $Cr(CO)_3$ group is so

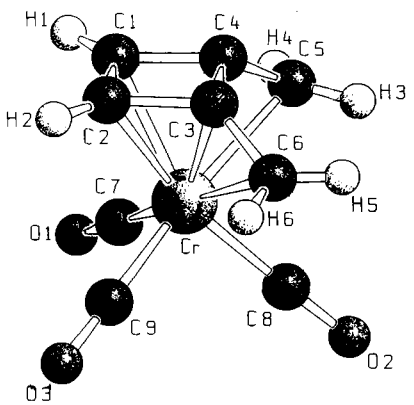


Fig. 1. Structure of **3** in the crystal. Clearly recognizable is the bending of the two exocyclic bonds (32°). Important bond lengths [Å] and angles [°]: Cr–Cl 2.186(2), Cr–C2 2.188(2), Cr–C3 2.041(2), Cr–C4 2.036(2), Cr–C5 2.318(2), Cr–C6 2.323(3), Cr–C7 1.848(2), Cr–C8 1.871(2), Cr–C9 1.864(2), C1–C2 1.394(4), C1–C4 1.459(3), C2–C3 1.469(3), C3–C4 1.490(3), C4–C5 1.372(3), C3–C6 1.371(3); C7–Cr–C8 91.7(1), C7–Cr–C9 88.1(1), C8–Cr–C9 (92.3(1), C2–C1–C4 91.9(2), C1–C2–C3 91.9(2), C2–C3–C4 87.8(2), C3–C4–C1 88.5(2), C2–C3–C6 129.7(2), C1–C4–C5 129.7(2), C4–C3–C6 125.3(2), C3–C4–C5 125.1(2); angle between the planes C1/2/3/4 and C3/4/5/6 40.6(1).

arranged that a CO ligand lies in the projection between the two exocyclic C–C bonds. A rotation of the $Cr(CO)_3$ group through 180°—this conformation is realized in [(fulvene)$Cr(CO)_3$][7]—would lead to superposition of two CO ligands and the two exocyclic C–C bonds. The C–C distances in the ligand are only slightly influenced by the coordination of the $Cr(CO)_3$ group (compare: dimethylenecyclobutene[3]). The three double bonds are found to be only about 3 pm longer, the three single bonds about 1 pm shorter. Thus, the interaction between chromium atom and ligand is apparently not very strong. The $Cr(CO)_3$ group has C_s symmetry. Two OC–Cr–CO angles are 92°, the other 88°.

That the dimethylenecyclobutene ligand is in fact not bound tightly is demonstrated by the reaction of **3** with trimethylphosphane, which results in cleavage of **1** and formation of $[Cr(CO)_3(PMe_3)_3]$. The [(fulvene)$Cr(CO)_3$] complex reacts differently, namely with addition of the phosphane to the exocyclic C atom.[7]

Experimental

All operations were carried out under nitrogen. A suspension of tris(acetonitrile)tricarbonylchromium (1.35 g, 5.2 mmol) in pentane (30 mL) was treated with ca. 1 g (13 mmol) of dimethylenecyclobutene [8] and the resulting mixture boiled under reflux for 4 h. After removal of the solvent in a vacuum, the residue was taken up in 20 mL of pentane and filtered. On cooling to 0 °C the complex **3** crystallized in the form of orange colored platelets. Yield 400 mg (36%). Spectroscopic data: IR (KBr): $\tilde{\nu}$[cm^{-1}] = 1994, 1950, 1883 (CO); ^{1}H NMR (400 MHz, C_6D_6, TMS): δ = 4.58 (s, 2H; CH), 2.58, 1.96 (d, ^2J = 2.3 Hz, each 2H; CH_2); MS (70 eV): *m/z* 214 ($M^{\oplus}$, 14%), 186 ($M^{\oplus}$ − CO, 10), 158 ($M^{\oplus}$ − 2CO, 12), 130 ($M^{\oplus}$ − 3CO, 40), 52 ($Cr^{\oplus}$, 100).

A Tetrathiotrimethylenemethane Derivative**

By *Martin R. Bryce,* Malcolm A. Coffin, Michael B. Hursthouse* and *Mohammed Mazid*

A major contemporary challenge facing the organic chemist is the synthesis of high-spin or ferromagnetic systems. Many theoretical models have been proposed for obtaining ferromagnetically interacting spins in organic solids,[1-7] and in this context the study of trimethylenemethane (TMM) derivatives is of considerable interest.[8-14] TMM is a triplet diradical which is relatively stable, considering it is a "Y-antiaromatic", 4π-electron structure.[15] It is known that the thermal stability of TMM is enhanced by its incorporation into a five-membered ring (i.e. a 2-alkylidene-1,3-cyclopentadiyl derivative)[9, 16] and theoretical calcula-

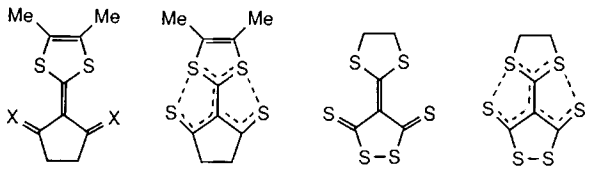
tions show that alkylthio- and dialkylamino-substituents stabilize triplet TMM relative to both singlet TMM and singlet methylenecyclopropane.[11]

In this communication we describe the synthesis, X-ray structure and reactions of the novel heterocycle **2** in which the TMM framework is both incorporated into a five-membered ring and is tetrathio-substituted. **2** is, in some ways,



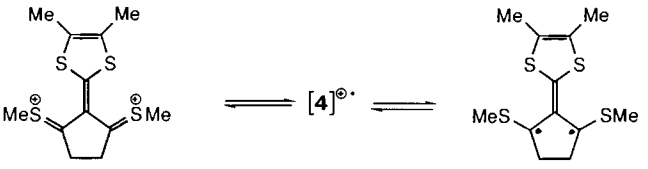
1, X=O
2, X=S

2' **3** **3'**

structurally related to compound **3**, which has recently been synthesized using a completely different methodology by *Wudl* and co-workers.[12] However, there are striking differences in the reactivity of **2** and **3**.

The reaction of 4,5-dimethyl-2-methylthio-1,3-dithiolium iodide[17] and the anion of 1,3-cyclopentanedione, under conditions described previously for analogous reactions,[18] yielded the diketone **1** (48% yield, m.p. 216–218 °C), which on thionation with phosphorus pentasulfide (anhydrous benzene, 50 °C, 2 h) afforded the title compound **2** as orange crystals (58% yield, m.p. > 340 °C; λ_{max} (CH_2Cl_2) = 262, 370, 464 nm; δ_H ($CDCl_3$) = 3.31 (s, 4H) and 2.49 (s, 6H); δ_C ($CDCl_3$) = 205.0, 171.7, 143.2, 131.4, 47.8 and 13.3).

values; (iii) the S···S distances (S1–S3 and S2–S4) are considerably shorter (by ca. 0.7 Å) than the sum of the van der Waals radii of two S atoms; (iv) the C7–C9 bond length of 1.328 Å is normal for a C=C double bond, which implies that the two π electrons of this bond are not involved to any extent in the delocalized system in **2'**. Molecule **2** is essentially planar but with a small amount of puckering at the ethylene bridge of the dithione ring. A packing diagram reveals that molecule **2** forms overlapping dimers in the solid state within which there are two relatively short intermolecular non-bonding S···S contacts (viz. S3–S4' = 3.912 Å and S1–S4' = 3.960 Å) (Fig. 1, right).



4 **5**

Wudl et al. observed that compound **3** did not react with methyl iodide, either neat at room temperature or in refluxing acetone.[12] In marked contrast to this, both thioxo sulfur atoms of compound **2** are readily methylated by methyl iodide in dichloromethane at 20 °C to yield the air-stable dication salt **4** (black powder, 90% yield, m.p. 119–125 °C (decomp.); λ_{max} (CH_2Cl_2) = 295 and 461 nm). This observation is entirely consistent with the X-ray data which imply that compound **2** is less aromatic than compound **3**.

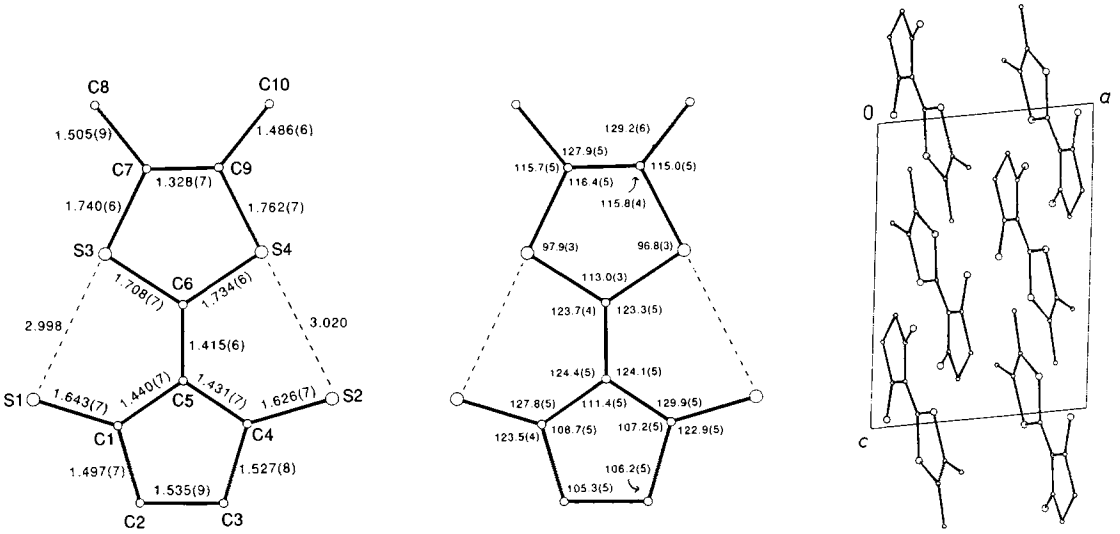


Fig. 1. Structure of **2** in the crystal with bond lengths (left) and angles (middle). Typical bond lengths are: C=S 1.55 Å [21], C–S 1.82 Å [21], S···S (van-der-Waals distance) 3.7 Å [21, 22]. Right: Unit cell of **2** viewed along the *b* axis.

The X-ray crystal structure[19] of **2** (Fig. 1) establishes that the molecule is best represented as a hybrid of dithione structure **2** and the heteroaromatic 10π-electron 1,2-dithiolo-1,2-dithiole structure **2'**. *Wudl*'s compound **3** exhibits more pronounced 10π-electron delocalization (**3'**).[12] Intramolecular bond distances and angles for **2** are shown in Figure 1. Notable features are as follows: (i) while there is considerable shortening of both the C1–C5 and C4–C5 bonds, they are significantly longer than the C5–C6 bond; (ii) the C=S bond lengths are longer (by ca. 0.07 Å) than the accepted literature

Cyclic voltammetry of dication **4** revealed two reversible one electron reductions at $E_1^{1/2} = +0.34$ and $E_2^{1/2} = +0.61$ V vs Ag/AgCl.[20] These data clearly point to the formation in solution of the tetrathiotrimethylenemethane diradical **5**, for which delocalized structures comprising a 1,3-dithiolyl radical can be drawn. Attempts to detect diradical **5** by ESR spectroscopy have, to date, been unsuccessful. The strong ESR signal obtained in dichloromethane solution from reduction of dication **4** is assigned to the radical cation $4^{\bullet\oplus}$. The spectra at 293 K and 153 K are

featureless and the g value of 2.0059 is consistent with spins partially localized at the sulfur atoms.

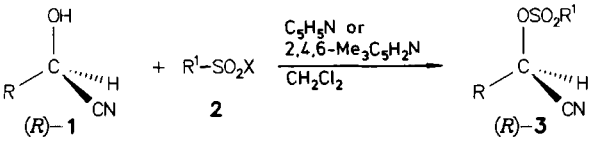
Synthesis and Stereoselective Reactions of (*R*)-α-Sulfonyloxynitriles**

By *Franz Effenberger** and *Uwe Stelzer*

Dedicated to Professor Hans Georg von Schnering on the occasion of his 60th birthday

(*R*)- and (*S*)-cyanohydrins are accessible via the enzyme-catalyzed addition of hydrocyanic acid to aldehydes.[1] They are useful, inter alia, for the production of enantiomerically pure α-hydroxycarboxylic acids[1c, 2] and β-aminoalcohols.[1a, 2] We report here on an important extension of the synthetic potential of optically active cyanohydrins by conversion of the hydroxy group into a good leaving group. Of particular interest are reactions of the cyanohydrin derivatives in which the nitrogen of the cyano group remains in the molecule, since compounds of this type are not directly accessible via α-amino- or α-hydroxycarboxylic acids.

Whereas stereoselective nucleophilic substitution in the α-position of carboxylic acids and carboxylates presents few difficulties,[3] very little is known about a corresponding reaction of α-substituted nitriles.[4] Starting from optically active nitriles with a leaving group in the α-position, only α-halonitriles have so far been prepared,[4] but these readily racemize in the presence of halide ions liberated in substitution reactions.[4a] Optically active α-sulfonyloxynitriles, which should be considerably more stable configurationally on account of the less nucleophilic sulfonate leaving groups,[3] have so far not been described. By reaction of the optically active cyanohydrins (*R*)-**1** as starting compounds with the sulfonyl halides and anhydrides **2**, we have now been able to synthesize aliphatic and aromatic (*R*)-α-sulfonyloxynitriles (*R*)-**3** free of racemization and in good yields.



X = Hal, OSO_2R^1

R	R^1

Aryl	CH_3, CF_3

With aliphatic cyanohydrins the tosylates and methane- and trifluoromethanesulfonates were synthesized in pure form. In the case of aromatic cyanohydrins, however, the preparation of mesylates is possible, but trifluoromethanesulfonates could only be synthesized and allowed to react in situ. These findings are consistent with data given in the literature on racemic cyanohydrin sulfonates, according to which the aliphatic compounds can be distilled without decomposition, whereas, e.g., the tosylate of mandelic nitrile already decomposes at room temperature.[5]

So far, it has not been possible to develop a suitable method for the direct determination of the optical purity of the compounds (*R*)-**3**. No information about the enantiomeric excesses can be gleaned from the experimentally determined rotation values, which lie between + 20° and + 60°, because of a lack of data for comparison. That the sulfonylations of (*R*)-**1** leading to (*R*)-**3** proceed without racemization could be demonstrated by the reactions of the α-sulfonyloxynitriles (*R*)-**3** with nucleophiles outlined in Scheme 1. According to Scheme 1, the cyanohydrin derivatives (*S*)-**4**, α-(phthaloylamino)nitriles (*S*)-**5**, α-azidonitriles (*S*)-**6**, and aziridines (*S*)-**7** are readily accessible in optically active form from the compounds (*R*)-**3**.

The reactions (b) and (c) have so far only been carried out with the aliphatic α-sulfonyloxynitriles (*R*)-**3**, the reactions (a) and (d) with both aliphatic as well as aromatic α-sulfonyloxynitriles (*R*)-**3**. Already at room temperature the reaction of (*R*)-**3a** with potassium acetate leads in very good yields to the cyanohydrin acetate (*S*)-**4a**, the enantiomeric purity of which was estimated by comparative investigations[6] to be 96.1% *ee*. Since the (*R*)-**1a** employed had an enantiomeric

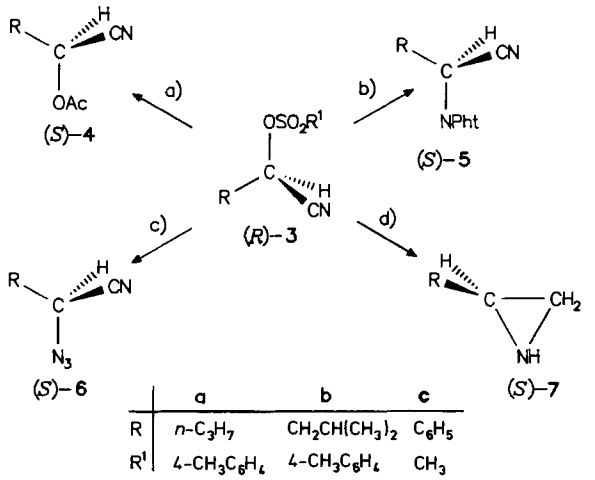
[**] Enzyme-Catalyzed Reactions, Part 11. This work was supported by the Bundesministerium für Forschung und Technologie and by the Fonds der Chemischen Industrie.—Part 10: F. Effenberger, M. Hopf, T. Ziegler, J. Hudelmayer, *Chem. Ber.*, in press.



Scheme 1. a) (*R*)-**3a** + 1.5 mol CH_3CO_2K in dimethylformamide (DMF), 79 h, 20 °C; 84% (*S*)-**4a** (*ee* = 96%). b) (*R*)-**3a** + 1.5 mol potassium phthalimide in DMF, 6 d, 20 °C; 70% (*S*)-**5a** (*ee* = 93%). Pht = phthaloyl. c) (*R*)-**3b** + 1.5 mol KN_3 in DMF, 3 d, 20 °C; 78% (*S*)-**6b** ($[\alpha]_D^{20} = -36.1°$ (*c* = 0.77, CH_2Cl_2)). d) A solution of (*R*)-**3b** in Et_2O was added dropwise to a solution of $LiAlH_4$ in Et_2O at −80 °C; after warming to room temperature within 2 h the mixture was neutralized at −70 °C with K_2HPO_4/KH_2PO_4 buffer (pH 7); 64% (*S*)-**7b** ($[\alpha]_D^{20} = -16.8°$ (*c* = 5.39, EtOH)). (*R*)-**3c** was allowed to react under the same conditions; 56% (*S*)-**7c** ($[\alpha]_D^{20} = +31.7°$ (*c* = 2.59, $CHCl_3$)).

purity of 96.3% *ee*, it must be concluded that the conversion of (*R*)-**1a** into (*R*)-**3a** proceeds almost free of racemization and the nucleophilic substitution of (*R*)-**3a** leading to (*S*)-**4a** solely involves an S_N2-mechanism. Since aliphatic (*S*)-cyanohydrins, in contrast to the (*R*)-cyanohydrins, are not accessible via the enzyme-catalyzed addition of hydrocyanic acid to aldehydes,[1c] this route provides a valuable extension to the synthesis of aliphatic (*S*)-cyanohydrins.

The reactions with potassium phthalimide leading to *N*-phthaloyl-protected α-aminonitriles (*S*)-**5**[7] and with potassium azide leading to the α-azidonitriles (*S*)-**6** also take place at room temperature. α-Azidonitriles have thus far not yet been described in the literature, neither as (*R*)- nor as (*S*)-enantiomers. That the substitutions of (*R*)-**3b** to give (*S*)-**6b** also proceed stereoselectively, was confirmed by hydrogenation of (*S*)-**6b** in the known (2*S*)-1,2-diamino-4-methylpentane.[8] The enantiomeric excess in (*S*)-**5a** was determined with NMR-shift reagents to be 93% *ee*.

Aziridines[9] are of equally great importance as intermediates in synthesis as oxiranes. The ready accessibility of the compounds (*R*)-**3** opened up the possibility of preparing optically active aziridines (*S*)-**7** in a simple way by the method of *Ohta* et al.,[4b] via hydrogenation of the cyano group with $LiAlH_4$, followed by intramolecular substitution. The optical purity of the compounds (*S*)-**7b** and (*S*)-**7c** obtained were determined by comparison of their rotation values with data quoted in the literature,[10] though in the hydrogenation of (*R*)-**3c** there arises the problem that difficultly separable 2-phenylethylamine is formed as by-product.

α-Sulfonyloxynitriles (*R*)-**3** show a pronounced dependence on structure in nucleophilic substitutions: the aliphatic compounds react with potassium acetate and other nucleophiles exclusively with inversion of configuration, the aromatic compounds, on the other hand, generally with racemization. Partial Walden inversion is found also upon reaction of the aromatic compounds with cesium acetate but only when trifluoromethanesulfonates are employed. A favoring of the S_N2-reaction is also observed in the case of the aromatic compounds by way of an intramolecular reaction with formation of a three-membered ring, as follows from the reaction of (*R*)-**3c**, which gives (*S*)-**7c** in good optical yields. An explanation for this reaction behavior of the α-sulfonyloxynitriles of aromatic cyanohydrins could possibly be the additional stabilization of the benzyl cations by the nitrile group in the α-position.[11]

Ligand-Stabilized Bimetallic Colloids Identified by HRTEM and EDX**

By *Günter Schmid*,* *Andreas Lehnert*, *Jan-Olle Malm*, and *Jan-Olov Bovin*

Dedicated to Professor Hans-Georg von Schnering on the occasion of his 60th birthday

Bimetallic clusters and colloids are of special interest for two reasons. Firstly, they may serve as models for studying the formation of different alloys. Secondly, it is possible to save precious metal, like Pt, by optimizing the synthetic conditions so that only very thin surface layers occur.

Miner et al.[1] described the synthesis of gold–platinum and palladium–platinum alloys as monodisperse sols by

[**] *G. S.* and *A. L.* are grateful to the Fonds der Chemischen Industrie for financial support. *J.-O. B* and *J.-O. M.* thank the Swedish Natural Science Research Council and the Swedish National Energy Administration. HRTEM = high-resolution transmission electron microscopy; EDX = energy disperse X-ray microanalysis.

simultaneous reduction of corresponding salt mixtures in various molar ratios. They asserted that formation of gold–platinum alloys occurs at any atomic ratio, even if the two metals show a broad miscibility gap between 2 and 85 wt.-% Au.[2] The homogeneous character of the various Au/Pt alloys was suggested to be proven by means of optical spectra, sedimentation measurements, and electron microscopy investigations. The particle sizes used in the relevant investigations varied between 3–6 nm. The variations in the d_{111}-spacing could not be determined accurately enough by transmission electron microscopy (TEM) to confirm the homogeneity of the particles being as claimed in the paper by *Miner* et al.

This paper describes the synthesis of ligand-stabilized bimetallic colloids and will identify the shell structure of such particles by high-resolution transmission electron microscopy (HRTEM) and energy dispersive X-ray (EDX) microanalysis.

Gold colloids with a diameter of 18 nm[3, 4] can be covered by platinum or palladium shells, if an aqueous solution of the colloids is added to a solution of H_2PtCl_6 or H_2PdCl_4 and H_3NOHCl. The original red color of the gold colloid then changes to brown-black. Addition of *p*-$H_2NC_6H_4SO_3Na$ stabilizes the generated particles in the same manner as P(*m*-$C_6H_4SO_3Na)_3$ the gold colloids,[3] so they can be isolated in the solid state. This kind of stabilization differs characteristically from former methods in the literature when colloids were more or less embedded into various polymers. The ligands used here behave like in complexes and clusters and impart the colloids "molecular" character. The colloid shows a metallic luster. The HRTEM studies of the gold–platinum and gold–palladium particles show that there are considerable differences between their structures even if the size is uniform (ca. 35 nm) in both cases.

In the case of the Au/Pt particles we observe uniform heterogeneous agglomerates, which have an average gold content of around 15 atomic%. These agglomerates are built up by a gold core surrounded by platinum crystals of about 5 nm. They are connected together in a rather "open" way, as can be seen in Figure 1 (left). The EDX microanalysis shows clearly that the outer layer of small crystals consists of platinum (cf. Fig. 1, right). This is demonstrated by comparing the spectrum obtained by focusing the electron beam (diameter 30 nm) over the whole particle (lower left circle in Fig. 1, left), which affords information about both Au and Pt, with the one recorded when the beam only covers the outer 5 nm of the particle (the circle to the right in Fig. 1, left). The latter spectrum includes only signals from Pt, as presented in the Au and $Pt_{L\alpha}$ spectra compared in Figure 1 (right). The beam broadening (0.8 nm at 200 kV and 10 nm crystal thickness) is negligible in small particles of this thickness.

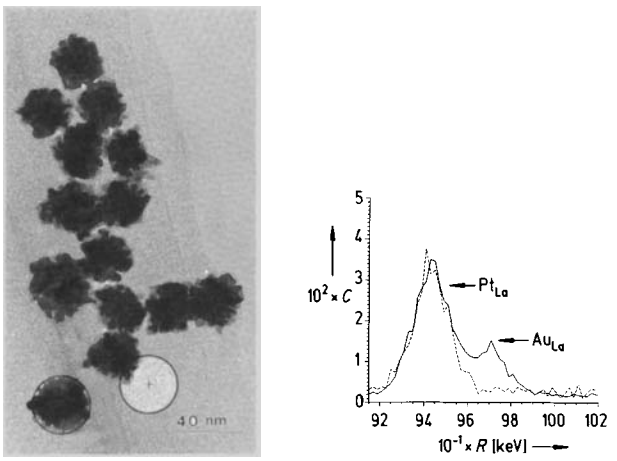

Fig. 1. Left: HRTEM image of gold/platinum particles supported on an amorphous carbon film. The selected EDX spectra (right) are recorded with the electron beam positioned as the circles indicate in the picture on the left. The counting time of the EDX spectrum recorded with the beam touching the edge of the particle is ten times longer than in the case of the centered beam. – – – edge of particle, — center of particle. C = count rate, R = measuring range, L_α signifies the electron transition from the M shell into the L shell.

The HRTEM images of the Au/Pt particles indicate that the growth of the outer Pt layer is preceded by a pregrowth of 5 nm small crystals of Pt. These small crystals are then added to the surface of the 18 nm large Au particles.

Laser-optical diffractograms of images of the 35 nm large particles show that the crystals constituting the whole particle can in principle be oriented in two different ways with respect to each other (Fig. 2, left). The particle marked **A** has almost all the small crystals oriented in the same crystallographic direction, as shown by the optical diffractogram of **A**.

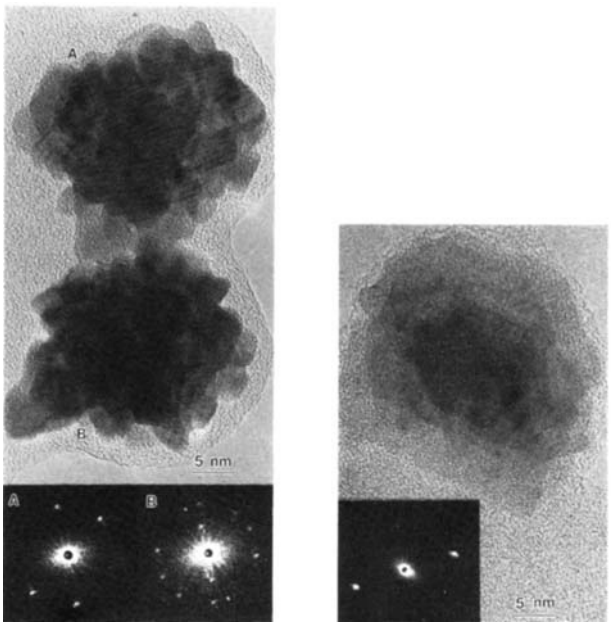

Fig. 2. Left: Two different types of Au/Pt particles imaged with HRTEM at 400 kV. The optical diffractogram of the whole particle **A** is shown below on the left and the corresponding one of **B** below on the right. Right: a structurally well-ordered Au/Pd particle imaged with HRTEM at 400 kV. The optical diffractogram of the whole particle is inserted.

On the other hand, the optical diffractogram of **B** shows a random orientation for the small Pt crystals making up the outer layer of the particle. The reason for the two kinds of intergranular structures is not fully understood but it may well depend on the structure of the 18-nm Au core. Earlier investigations[5] of the structure of gold colloids show that the structure can either be single crystal without defects or a multiply twinned structure. A single crystal structure of the core may well give rise to the particle type **A** if the Pt crystals add on epitaxial to the Au core, while the multiply twinned structure gives several possibilities to different orientations of the added-on Pt crystals.

In contrast to the gold platinum alloy, gold and palladium form a continuous series of solid solutions.[2] If an aqueous solution of H_2PdCl_4 is reduced by hydoxylamine in the presence of 18-nm gold colloids, followed by a complexation

with p-$H_2NC_6H_4SO_3Na$, gold/palladium colloids can be isolated as a silver grey, metallic looking precipitate. Such colloids are soluble in water giving a brown color.

HRTEM investigations of these colloids show different intergranular structural images than the Au/Pt combinations. Two different types of particles can be distinguished. In Figure 2, right, one particle with the whole structure ordered is shown, as indicated by the optical diffractogram inserted. A comparison of this particle with the Au/Pd particle **A** in Figure 2, left, shows that the Au/Pd particle has a smoother surface—most likely resulting in a smaller surface area. The dark nucleus of the Au/Pd particle can be interpreted as the gold core, which is surrounded by the lighter shell of well-ordered palladium atoms. This will turn up more clearly for the lighter Pd shell compared to Pt.

The second type of structure for the Au/Pd case is similar to the type **B** of Au/Pt in Figure 2 in such a way that the particle also gives an optical diffractogram of "polycrystalline" type (Fig. 3, left). The intergranular structure has also in this case a smoother surface compared to the Au/Pt case. The HRTEM image of the approximately spherical specimen also shows a darker core.

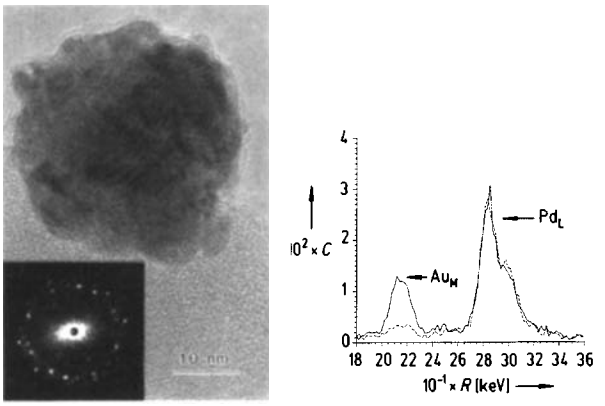

Fig. 3. Left: HRTEM image of a "polycrystalline" Au/Pd particle recorded at 400 kV and with the corresponding optical diffractogram inserted. Right: A comparison of EDX spectra recorded from a Au/Pd particle, with the electron beam positioned as the circles indicate in Figure 1. The counting time of the EDX spectrum recorded with the beam touching the edge of the particle is ten times longer than the centered case. --- particle edge, — particle center. C = count rate, R = measuring range, L and M signify electron transitions into the L and M shells, respectively, from higher states, not distinguishable if α or β.

The EDX spectrum of such a single particle shows a composition of about 17 atomic% of gold and 83 atomic% of palladium. Analyses of peripheral parts of the particle (cf. in Fig. 1) give a spectrum of almost pure palladium (cf. Fig. 3). The composition of the colloids varies only a little. The colloid shown in Figure 3 has a diameter of about 36 nm. As the nucleate gold colloids have an average diameter of 18.5 nm, the Au:Pd ratio is calculated to be between 1:5 and 1:6. This is in good agreement with analytical results, giving an average atomic ratio of about 1:5 for Au/Pd particles.

During the observation, using a beam current intensity of 20–40 Acm^{-2}, the particles were stable apart from some surface rearrangements, which can always be seen on metallic surfaces. The X-ray microanalyses were performed with a little less intense electron beam ($\sim 5\ Acm^{-2}$). In no case could any structural changes in the particles be observed.

The sequence of the metals can also be reversed in this kind of particles. For example, 15-nm palladium colloids can be prepared by treatment of $PdCl_2$ in hydrochloric acid solution with trisodium citrate. Tetrachloroauric acid is added to the colloidal solution and is then reduced by hydroxylamine to generate the outer shell of gold. The stabilization of such Pd/Au colloids by P(m-$C_6H_4SO_3Na)_3$ yields isolable colloids. Their color is like that of pure ligand-stabilized gold colloids.

From these investigations it can be assumed that bimetallic colloids can easily be prepared and stabilized. HRTEM and EDX have proven to be useful methods for establishing the structure of the layered colloids.

Experimental

Gold–platinum colloids: 1600 mL of completely demineralized water was heated to boiling in a 2 L beaker. 16 mL of a 1 per cent solution of $HAuCl_4$ (5.00 g Au/L) and 80 mL of a 1 per cent solution of trisodium citrate was added gradually with vigorous stirring. The solution was then kept boiling for another hour. Approximately 1500 mL of a ruby red gold sol containing particles of 18–19 nm in diameter, was obtained, as observed in many electron microscopic investigations. This gold colloid solution was stirred into a mixture of 116 mL of a 1 per cent solution of H_2PtCl_6 (5.00 g Pt/L) and 100 mL of 1 per cent solution of H_3NOHCl in 8 L of water and was then heated to 60 °C. In the course of 3 h the red color of the gold sol changed to the dark brown color of platinum colloids. To stabilize the particles, 50 mg of $H_2NC_6H_4SO_3Na$ was added to the solution. Concentration in a water-jet pump vacuum followed until coagulation began (decolorizing of the solution). The precipitate was separated by centrifugation (5000 revolutions per minute) and dried under vacuum.

Gold–palladium colloids: The gold sol, prepared by the procedure above, was diluted to 8 L in a 10 L beaker. In the course of 8 h 83 mL of a 0.037 molar solution of H_2PdCl_4 (6.6 g $PdCl_2$ and 7.5 mL of a 1 n HCl in 1 L of H_2O) and 100 mL of a 1 per cent solution of H_3NOHCl were simultaneously added dropwise. After 48 hours' stirring at room temperature 2 g of p-$H_2NC_6H_4SO_3Na$ was added, and an isolation procedure carried out as described above. The product consisted of silver-grey gold–palladium colloids, completely soluble in water.

Microanalysis and microscopy: The colloid was dispersed in methanol and transferred onto a holey carbon support film. The sample was then loaded into the microscope while still wet with methanol, and the high vacuum inside the microscope column was used to evaporate the solvent. The ligands stabilizing the colloids can be removed when the electron beam irradiates the area of observation. High resolution electron microscopy was performed with a JEM-4000EX, which was operated at an accelerating voltage of 400 kV and able to achieve a structural resolution of 0.16 nm. The energy dispersive X-ray (EDX) microanalysis was performed with a Link AN 10000 system coupled to a JEM-2000FX STEM-microscope with a beam focusing ability of 30 nm. The EDX spectra were evaluated with a software for thin foil analysis, Link RTS 2/FLS.

The Structure of $IF_8^{\ominus}$**

By *Ali-Reza Mahjoub* and *Konrad Seppelt**

Dedicated to Professor Hans Georg von Schnering on the occasion of his 60th birthday

The only main group element heptafluoride reported so far, IF_7, forms an adduct with NOF which has been formulated as $NO^{\oplus}IF_8^{\ominus}$.[1] However, vibrational spectroscopic studies permitted no unequivocal conclusions to be drawn

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

regarding the structure of the adduct. Coordination numbers greater than six are of interest since usually several structures are conceivable, and we are not always able to predict the correct one with our current model concepts. Thus, a pentagonal bipyramidal structure has been established for IF_7, but *nothing exact is known* about deviations from the ideal geometry (pseudorotation).[2] For the coordination number eight, generally two structures are discussed, the Archimedean square antiprism and the dodecahedron. The elucidation of the structure of salts with the anion $IF_8^{\ominus}$ is thus of fundamental importance, as this ion contains eight equal ligands, and non-bonding electron pairs or a d-orbital participation (as in the case of subgroup elements) do not need to be taken into consideration.

Other than previously described,[1] reaction of NOF and IF_7 takes place in the ratio 3:1 [Eq. (a)].

$$3\,NOF + IF_7 \longrightarrow \underset{\mathbf{1}}{[NO(NOF)_2]IF_8} \qquad (a)$$

Compound **1** can be recovered in the form of large colorless crystals by sublimation at $-20\,^{\circ}C$. However, the crystals still have a measurable vapor pressure at $-100\,^{\circ}C$, so that the X-ray diffraction had to be carried out at the lowest temperature achievable with our equipment ($-163\,^{\circ}C$).

The cation and anion moieties are significantly separated from each other. The shortest distances between the iodine atom and oxygen atoms are 380, 384, 394 and 398 pm. The cation moiety is a polymer of $NO^{\oplus}$ and NOF, in which the fluorine atoms are bridging (Fig. 1). Noteworthy is that the

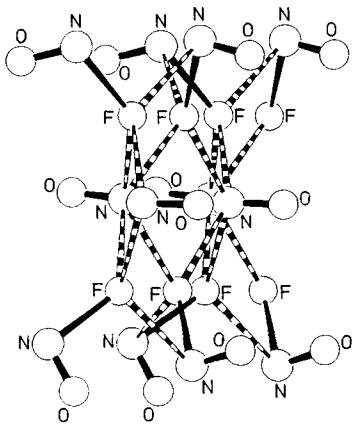

Fig. 1. Section of the cation moiety of **1**, Schakal plot. The structure consists of a layer of square-pyramidally surrounded nitrogen atoms (N–O 105.2–106.4(8), N···F 228.0–241.1 pm) and a double layer of pyramidal NX_3 units (N–O 102.3–17.5(8), N–F 184.2–203.0(8), N···F 241.0–260.5(8) pm).

nitrogen atoms bearing formal charges have a square-pyramidal geometry with apical oxygen atoms and four basal fluorine atoms.

Interestingly, the two crystallographically independent $IF_8^{\ominus}$ ions have square antiprismatic geometries (Fig. 2a), whose bond lengths and angles differ only very slightly. Apparently a regular antiprism is formed, i.e. all distances and all respective angles are of almost equal size. A regular antiprism is described by one distance and by only one angle, the latter determining the elongation or the flatness of the antiprism. The important angle here is the F–I–F angle between two neighboring fluorine atoms within one hemisphere; it is 73.3° (average of 16 values, Fig. 2b). This angle leads to an angle of 78.1° (average of 16 values) between neighboring fluorine atoms of different hemispheres. The similarity of the two angles indicates that the square $IF_8^{\ominus}$ antiprism is neither mentionably elongated nor flattened along the S_8 axis.

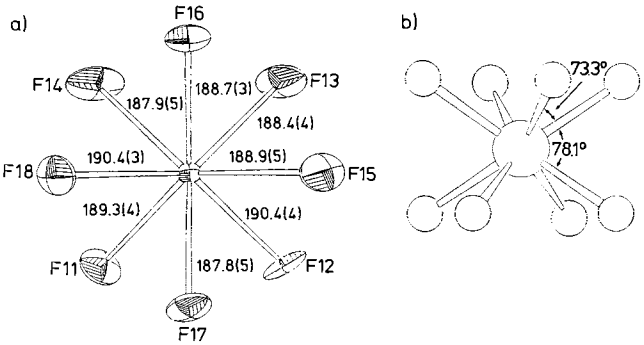

Fig. 2. a) The anion $IF_8^{\ominus}$(I) in **1**, ORTEP plot, vibration ellipsoids at the 50% probability level. The crystallographically different anion (II) is almost identical. b) Side view of the $IF_8^{\ominus}$ ion (I), Schakal plot. The angle F–I–F between neighboring fluorine atoms within a hemisphere (73.1, 73.5, 73.7, 74.7, 73.0, 73.1, 73.3, 72.0(2)°) are only slightly smaller than those between neighboring fluorine atoms between two hemispheres (77.0, 78.6, 78.2, 77.8, 76.2, 76.3, 78.5, 77.5(2–3)°).

$IF_8^{\ominus}$ also has square-antiprismatic geometry in the compound $[(CH_3)_4N]IF_8$ **2**. However, owing to a fourfold disorder or twinning, which involves only the anion, the bond lengths and angles in this structure determination must be regarded as very inaccurate (Fig. 3).

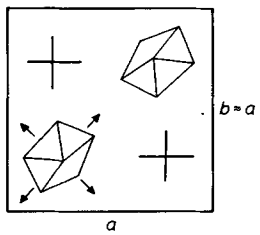

Fig. 3. Structure of **2** in the crystal, projection on (001) of the pseudotetragonal cell, $a \approx b$. The square antiprism is inclined to [001]. As indicated by the four arrows, the anion has four possible orientations, which arise from the four fold disorder or—more likely—from the twinning. The crosses denote cations.

In the compound $(NO^{\oplus})_2XeF_8^{2\ominus}$,[3] the anion $XeF_8^{2\ominus}$, which has an additional non-bonding electron pair, likewise has a square-antiprismatic geometry. The angles, as shown in Figure 2b, are extraordinarily similar to those in $IF_8^{\ominus}$ (73.1–75.8° within the hemispheres, 76.2–77.7° between the hemispheres). Only the lengths of the bonds to the four fluorine atoms in one hemisphere are somewhat longer. Nevertheless, no apparent space for accomodation of the nonbonding pair of electrons is made available by this small deviation from the ideal structure. Rather, the deviations are attributed to different contacts to the cations. It can be assumed that the small $NO^{\oplus}$ ion interacts electrostatically much more strongly than the larger cations in **1** and **2**.

The pair of ions $IF_8^{\ominus}/XeF_8^{2\ominus}$ provide the second example demonstrating that a structural principle remains unchanged on introducing a non-bonding electron pair, but that merely all the bond lengths are enlarged. The first example is the pair $BrF_6^{\oplus}/BrF_6^{\ominus}$.[4] The likely explanation for the failure of the electron-pair repulsion model[5] is that the bromine atom with six fluorine atoms and the iodine or xenon atom with eight fluorine atoms as ligands are sterically already so crowded that the non-bonding electron pair must reside in a centrosymmetric orbital, which, however, leads to a bond lengthening.

Experimental

1: In a metal vacuum apparatus NOF and IF_7 were condensed in the molar ratio 3:1 into a Teflon FEP tube, which was then sealed. Upon storage at $-20\,^{\circ}C$, colorless crystals separated out. A suitable crystal ($0.6 \times 0.6 \times 0.2\,mm^3$) was transferred with a special apparatus [6] to a CAD4 diffractometer ($Mo_{K\alpha}$, $-163\,^{\circ}C$, ω-θ scan). $a = 618.92(7)$, $b = 1039.43(17)$, $c = 2842.14(15)$ pm, $P2_12_12_1$ (No. 19). 4475 measured reflections in the range $2^{\circ} < \theta < 35^{\circ}$, $+h$, $+k$, $+l$, 4445 unique reflections, 4070 reflections with $I \geq 3\sigma(I)$, $\mu = 19.5\,cm^{-1}$, full matrix. SHELXTL plus, all atoms anisotropic, $R = 0.038$, $R_w = 0.032$.

2: Anhydrous $(CH_3)_4N^{\oplus}F^{\ominus}$ [7] was suspended in CH_3CN in a Teflon FEP tube; a slight excess of IF_7 was then condensed into the suspension. The fluoride dissolved with formation of a complex, which upon cooling crystallized out in the form of needle shaped crystals. Diffraction photographs showed that all reflections are slightly split. $a = 866.9(3)$, $b = 866.9(2)$, $c = 683.6(3)$ pm, $\alpha = \beta = \gamma = 90^{\circ}$ ($-153\,^{\circ}C$). 927 measured reflections in the range $2^{\circ} < \theta < 30^{\circ}$, $\pm h$, $+k$, $+l$, 460 unique reflections, 431 reflections with $I \geq 3\sigma(I)$, $\mu = 31.8\,cm^{-1}$, full matrix. Calculation with SHELXTL plus in space group $P4/nmm$ (No. 129); C, N and I anisotropic, H in isotropically fixed calculated positions, F fourfold disordered, isotropic: $R = 0.049$, $R_w = 0.043$. Calculation with the program SFLS [8] in the space group $Pmmn$ (No. 59) according to the twinning law (010)(−100)(001) gave $R = 0.051$, $R_w = 0.045$ for C, N, I anisotropic, F isotropic, twofold disordered, without H. For a non-disordered anion the space group $P2_1mn$ (No. 31) would suffice. Refinement in this space group however generates four positions again for each fluorine atom.

Further details of the crystal structure determinations are available on request from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, W-7514 Eggenstein-Leopoldshafen (FRG), on quoting the depository number CSD-55274, the names of the authors, and the journal citation.

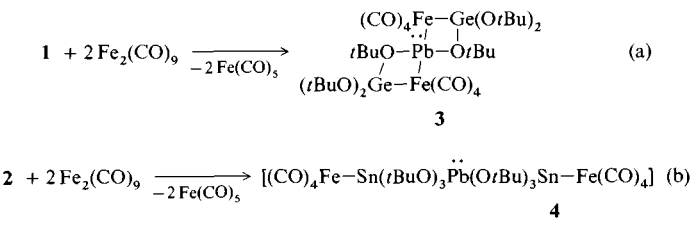
Different Reaction Behavior of Lead Bis(tri-*tert*-butoxygermanate) and Lead Bis(tri-*tert*-butoxystannate) towards Nonacarbonyldiiron**

By *Michael Veith** and *Johannes Hans*

Dedicated to Professor Hans Georg von Schnering on the occasion of his 60th birthday

In the course of our comparative studies on molecular compounds of elements of the fourth main group in their lower oxidation state II (cf. Refs. [1–3]) we have now carried out reactions of the homologues lead bis(tri-*tert*-butoxygermanate) **1** and the corresponding stannate **2** with nonacarbonyldiiron in order to investigate the stereochemical activity of the lone pair of electrons on the metallic element. Whereas **1** at room temperature contains a linear arrangement of the metallic elements (Ge, Pb and Ge are connected to each other via *tert*-butoxy groups, whereby the lead atom forms the center of the $\bar{3}(S_6)$ symmetric arrangement and thus possesses no stereochemically effective electron pair), the Sn ··· Pb ··· Sn array in **2** is bent.[3] We had expected that it would be possible to influence the coordination sphere of the central lead atom by coupling $Fe(CO)_4$ units to the Lewis basic germanium and tin atoms in **1** and **2**, respectively, and by the concomitant withdrawal of electron density. As can be seen in Equations (a) and (b) the products **3** and **4** are



$[M(OtBu)_3Pb(OtBu)_3M]$ **1**, M = Ge; **2**, M = Sn

$$\mathbf{1} + 2\,Fe_2(CO)_9 \xrightarrow[-2\,Fe(CO)_5]{} \underset{\mathbf{3}}{(CO)_4Fe{-}Ge(OtBu)_2 \cdots Pb(OtBu)_2 \cdots Ge{-}Fe(CO)_4} \quad (a)$$

$$\mathbf{2} + 2\,Fe_2(CO)_9 \xrightarrow[-2\,Fe(CO)_5]{} \underset{\mathbf{4}}{[(CO)_4Fe{-}Sn(tBuO)_3Pb(OtBu)_3Sn{-}Fe(CO)_4]} \quad (b)$$

formed, which are similar in their composition, behave similarly spectroscopically, and differ noticeably only in their color.[4]

Single-crystal X-ray structure analyses of **3** and **4** (Fig. 1 and 2) show that **3** has a pseudocrystallographic twofold axis, **4** a crystallographic twofold axis, in each case passing through the lead atom. In **4** the metal atoms are, as expected, coupled one-dimensionally, whereas **3** is spirocyclic, with the lead atom as spirocenter of two four-membered PbFeGeO rings. In the slightly folded, trapezoidal oxametallacycles the lead atom (smallest angle), as expected, takes over the main burden of the ring strain. Whereas all five metal atoms in **3** are coupled via σ bonds, in **4** only the tin atoms are bound directly to the iron atom.

Due to replacement of four *tert*-butoxy groups by two $Fe(CO)_4$ moieties the environment of the lead atom in **3** is completely different from that in the starting compound **1**.

[**] Chemistry of Alkoxystannates, Part 7. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industry.—Part 6: M. Veith, K. Kunze, *Angew. Chem. 103* (1991) 92; *Angew. Chem. Int. Ed. Engl. 30* (1991) 95.

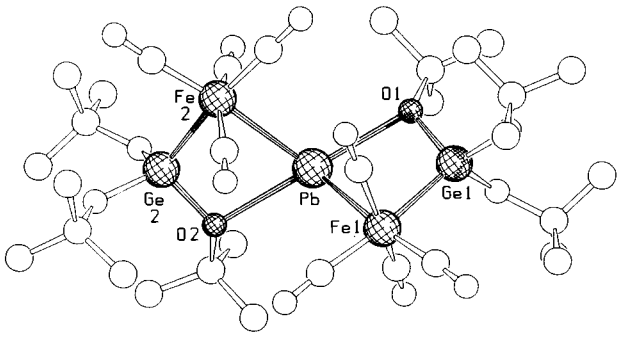

Fig. 1. Molecular structure of **3** [4, 5]. The unmarked spheres are carbon atoms or oxygen atoms. Hydrogen atoms have been omitted. Important bond lengths [Å] and angles [°] (see also text): Ge1–Fe1 2.395(3), Ge2–Fe2 2.396(3), Ge1–O1 1.80(1), Ge1–O5 1.75(1), Ge1–O6 1.782(8), Ge2–O3 1.78(1), Ge2–O4 1.789(9); Fe1–Pb–Fe2 112.9(1), O1–Pb–Fe2 108.5(2), O2–Pb–Fe1 109.1(2), Pb–Fe1–Ge1 80.0(1), Pb–Fe2–Ge2 80.4(1), O1–Ge1–Fe1 102.9(3), O2–Ge2–Fe2 103.0(3), Ge1–O1–Pb 100.5(4), Ge2–O2–Pb 100.6(4).

The lead atom is ψ-trigonal-pyramidally coordinated with two long[3] Pb–O bonds (2.64(1) Å), which run axially (O1–Pb–O2 = 177.7(2)°) and two likewise long Fe–Pb distances (Pb–Fe1 = 2.939(2), Pb–Fe2 = 2.934(2) Å) in the equatorial plane, which is inclined to the O1–Pb–O2 axis (O1–Pb–Fe = 72.5(2)°, O2–Pb–Fe2 = 72.6(2)°). It can be concluded from the observed geometry and the long distances that the central lead atom is, furthermore, divalent, but in contrast to

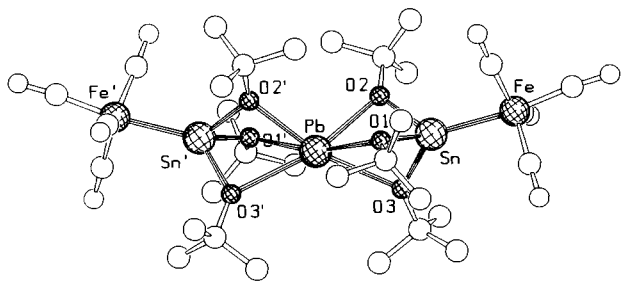

Fig. 2. Molecular structure of **4** [4, 5] (see also caption to Fig. 1). Selected bond lengths [Å] and angles [°]: Pb–O1 2.566(7), Pb–O2 2.482(7), Pb–O3 2.730(7), Fe–Sn 2.476(1), Sn–O1 2.027(6), Sn–O2 2.031(6), Sn–O3 1.992(7), Sn···Pb 3.327(1); C(axial)–Fe–Sn 171.6(5), Fe···Sn···Pb 172.6(1), mean values: O–Pb–O 63.2(1), 113.5 (6.0), 164.6(8), O–Sn–O 84.9(2.0), O–Sn–Fe 128.6(2.0).

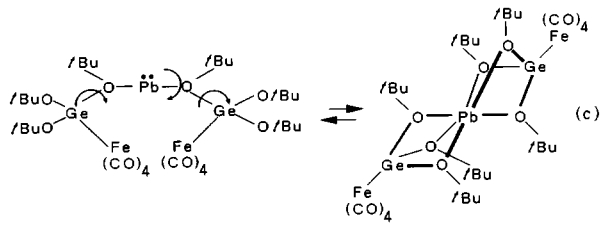
that in **1** has a stereochemically effective electron pair (for related and similar coordination spheres of Si^{II}, Ge^{II} and Sn^{II} with ligands such as $C(PMe_2)_3^{\ominus}$ cf. Ref. [6]). The unusually long Pb–Fe contacts in **3** are unmistakable when compared with the Pb–Fe distances in $[Pb\{Fe(CO)_4\}_4]$ (2.62(1) Å)[7] or in the dianion $[Pb\{Fe(CO)_4\}_2Fe_2(CO)_8]^{2\ominus}$ (2.62(1)–2.83(1) Å).[8] The bonds from the distorted tetrahedrally coordinated germanium atoms can be regarded as simple σ bonds (in $[Ge\{Fe(CO)_4\}_4]$: Ge–Fe = 2.41(2) Å[9] and in the $[GeFe_4(CO)_{14}]^{2\ominus}$ dianion 2.38(2) Å[7]), the bonds to the two-coordinate oxygen atoms being expectedly shorter than those to the three-coordinate atoms.[3] Accordingly, on the basis of the structure and simple bonding models, **3** can be formally described in terms of a $Pb^{2\oplus}$ ion and two $[Ge(OtBu)_3Fe(CO)_4]^{\ominus}$ ions which coordinate the lead atom chelate-like via an oxygen atom and a "nucleophilic" iron atom. This description is naturally to be regarded as only *one* of many possibilities, since other resonance structures can be arrived at with other electron assignments. Also worth mentioning is that **3** can be converted, at least purely formally (but reasonably from a structural point of view), into a structure **5** which is analogous to **4**, by rotation about the Ge–O axes of the four-membered rings **3** remaining after opening of the Fe–Pb bonds [Eq. (c)].



3 **5**

How far such a rearrangement in the reverse direction plays a role in the formation of **3** is still unclear. Remarkably, however, only one ^{1}H-NMR signal is observed for the *tert*-butyl groups of **3** in solution,[4] which at least indicates intramolecular mobility (also the CO vibration frequencies of **3** hardly differ from those of **4**).

The most important difference between **2**[3] and **4** is the enhanced distortion of the coordination sphere of the lead atom; thus, for example, the Sn···Pb···Sn angle decreases from 173.5° to 165.0(0)°, and the angle of intersection of the O_3-planes of the tris(*tert*-butoxy) moieties increases from 10.8° to 24.3°. The overall striking feature is that the whole molecule is *curved*, with the curvature extending to the axial carbonyl groups (concerning curved structures in chemistry see Ref. [10]).

It follows from these results that a withdrawal of electron density at the germanium or tin atom in compounds such as **1** and **2** not only has a local effect, but affects the whole molecule, and the stereochemical activity of the lone electron pair at the central lead atom is manifested more strongly. In analogy to the definition presented in Ref. [3], the ligands at the lead atom (tri(*tert*-butoxy)germanate and -stannate) appear to become inflexible in the transition from **1** and **2** to **3** and **4**, respectively. However, as the different structures of **3** and **4** show, the withdrawal of electron density can be so strong that rearrangements occur. Referred to the metal atoms, we have here the "transition" from a structure with bonding oxygen atoms between the metals (**4**) to a metal cluster (**3**).

Experimental

A solution of 0.7 mmol of **1** [3] or **2** [3] in 25 mL of toluene was added dropwise to a suspension of 0.51 g (1.40 mmol) of nonacarbonyldiiron in 15 mL of toluene. After 2 h and 12 h stirring, respectively, the reaction is complete; the solution of **1** turned ruby red, that of **2** yellow. After filtration and removal of solvent in a vacuum there remained a solid residue, which was recrystallized from 5 mL of cyclohexane (**3**) or toluene (**4**); yields: **3**, 0.72 g (84%); **4**, 0.79 g (95%) [4].

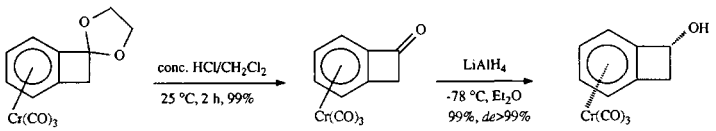
Ring Opening of a Cyclobutabenzene Complex under Very Mild Conditions**

By *Hans G. Wey* and *Holger Butenschön**

Dedicated to Professor Paul Binger on the occasion of his 60th birthday

Cyclopentadienyl and arene complexes with annelated four-membered ring moieties are of special interest because of their ring-opening reactions leading to non-planar di-*exo*-methylene compounds and successive stereoselective cycloadditions with dienophiles. So far only two such reaction sequences are known: an η^5-(bicyclo[3.2.0]hepta-1,3-dienyl)-cobalt(I) complex reacts at 200 °C in 13 h with several dienophiles to give the corresponding [4 + 2] cycloadducts.[1] Reaction of η^6-(1-ethoxycyclobutabenzene)tricarbonylchromium(0) with the unusual dienophile *trans*-bis(trimethylsilyl)ethene at 160° leads in 6 h to formation of the corresponding tetralin complex.[2] We report here on the



1 **2** **3**

preparation of the tricarbonylchromium(0) complexes **2** and **3** of the 1-oxo and the 1-hydroxycyclobutabenzenes, respectively, as well as on the ready ring-opening of the alkoxide **5** obtainable from **3** and the trapping of the intermediate with conventional dienophiles.

[**] *H. G. W.* thanks the Max-Planck-Gesellschaft for a doctoral fellowship and *H. B.* thanks the Verband der Chemischen Industrie for a Liebig fellowship. We thank Herr *M. Brands* for help with the purification of **6** and Prof. Dr. *G. Wilke* for supporting interest.

The reaction of 1-oxocyclobutabenzene with [Cr(CO)$_6$] affords **2** in only 4% yield. In contrast, **2** is readily accessible in 99% yield as an orange-red powder (m.p. 70.9 °C) by hydrolysis of **1**[3] in a two-phase mixture of dichloromethane and concentrated hydrochloric acid. The identity of **2**, with its three sp^2-C centers in the four-membered ring one of the most strained arene complexes known to date, follows unequivocally from the spectroscopic data (IR, ^{13}C NMR; ^{1}H NMR see Table 1), the mass spectrum, and the correct elemental analysis. Like **2**, the tricarbonylchromium(0) complex **3** of the 1-hydroxycyclobutabenzene is also not obtainable by direct reaction of the ligand with [Cr(CO)$_6$] or [Cr(CO)$_3$(NH$_3$)$_3$].[3b] Therefore **2** was reduced with lithium aluminum hydride to **3**. The withdrawal of electrons by the tricarbonylchromium(0) moiety leads to a noticeable increase in reactivity of the keto group: whereas 1-oxocyclobutabenzene is reduced to the extent of 83% in 30 min in boiling diethyl ether,[4] the reduction of the corresponding tricarbonylchromium(0) complex **2** proceeds immediately at −78 °C, as can be seen by the immediate color change from orange-red to pale yellow upon dropwise addition of **2** to the reducing agent. The yield of **3** of 99%—under considerably milder conditions and shorter reaction time—is also significantly higher than that in the reduction of the tricarbonylchromium(0) complexes of indan-1-one (36 °C, 8 h, 84%) and tetralin-1-one (36 °C, 8 h, 72%).[5] Moreover, the reduction of **2** to **3** proceeds diastereoselectively to the *endo*-1-hydroxy compound: the ^{1}H- and ^{13}C-NMR spectra show only the signals of one diastereomer. Also only one diastereomer is detectable by analytical HPLC (de > 99%). That **3** is, in analogy to the products of the reductions of the higher homologues,[5] in fact the *endo*-1-hydroxy compound could be demonstrated by an NOE experiment. A CO ligand in **3** was replaced by a PPh_3 ligand by irradiation in the presence of PPh_3; this led to formation of **4** in 49% yield.

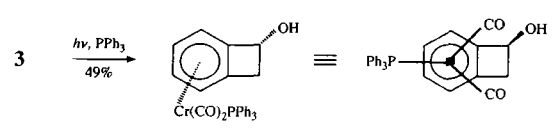
Table 1. ^{1}H-NMR data of **2**–**4** and **6**.

2: (200 MHz, [D$_8$]THF): δ = 3.81 (d, 1 H, *exo*-2-H or *endo*-2-H, ^2J(*exo*-2, *endo*-2) = −16.4 Hz), 4.02 (d, 1 H, *exo*-2-H or *endo*-2-H), 5.27 (dd, 1 H, 4-H, ^3J(4,5) = 6.2 Hz, ^3J(4,3) = 6.4 Hz), 5.82 (dd, 1 H, 5-H, ^3J(5,6) = 6.2 Hz), 5.89 (d, 1 H, 6-H), 6.02 (d, 1 H, 3-H)

3: (200 MHz, [D$_8$]THF): δ = 2.87 (dd, 1 H, *endo*-2-H, ^2J(*endo*-2, *exo*-2) = −13.9 Hz, ^3J(*endo*-2, *exo*-1) = 2.2 Hz), 3.35 (dd, 1 H, *exo*-2-H, ^3J(*exo*-2, *exo*-1) = 5.2 Hz), 4.72 (br, 1 H, OH), 5.04 (ddd, 1 H, 4-H, ^3J(3,4) = 6.2 Hz, ^3J(4,5) = 5.9 Hz, ^4J(4,6) = 1.3 Hz), 5.06 (dd, 1 H, 1-H) 5.39 (ddd, 1 H, 5-H, ^3J(5,6) = 6.2 Hz, ^4J(3,5) = 0.7 Hz), 5.45 (dd, 1 H, 6-H, ^5J(1,6) = 0.9 Hz), 5.68 (dd, 1 H, 3-H)

4: (200 MHz, [D$_8$]THF): δ = 3.04 (dd, 1 H, *endo*-2-H, ^2J(*exo*-2, *endo*-2) = −13.5 Hz, ^3J(*endo*-2, *exo*-1) = 2.3 Hz), 3.34 (dd, 1 H, *exo*-2-H, ^3J(*exo*-2, *exo*-1) = 5.4 Hz), 3.56 (d, 1 H, OH, ^3J(OH, *exo*-1) = 9.4 Hz), 3.87 (m, 1 H, 5-H, ^3J(5,6) = 6.5 Hz, ^3J(4,5) = 5.9 Hz, J(3,P) = 6.0 Hz), 4.33 (ddd, 1 H, 4-H, ^3J(3,4) = 6.1 Hz, J(4,P) = 3.4 Hz), 4.76 (d, 1 H, 3-H), 5.05 (m, 1 H, *exo*-1-H), 5.25 (d, 1 H, 6-H), 7.3 (m, 9 H, 8-H, 9-H), 7.52 (m, 6 H, 7-H)

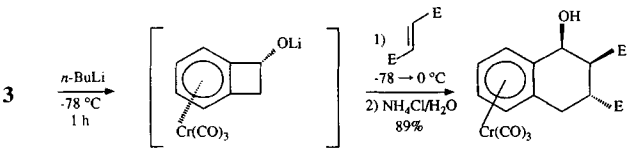
6: (400 MHz, [D$_8$]THF): δ = 2.73 (dd, 1 H, 4-H, ^2J(4α, 4β) = −17.0 Hz, ^3J(4β,3) = 11.9 Hz), 3.04 (dd, 1 H, 4-H, ^3J(4α,3) = 6.3 Hz), 3.12 (dd, 1 H, 2-H, ^3J(3,2) = 12.0 Hz, ^3J(2,1) = 3.4 Hz), 3.24 (ddd, 1 H, 3-H), 3.65 (s, 3 H, 12-H), 3.68 (s, 3 H, 11-H), 4.79 (dd, 1 H, ^3J(1,OH) = 3.4 Hz), 5.16 (d,OH), 5.36 (dd, 1 H, 6-H or 7-H), 5.43 (d, 1 H, 8-H or 5-H), 5.58 (dd, 1 H, 7-H or 6-H), 5.63 (d, 1 H, 5-H or 8-H)



4 ■ = Cr

Instead of a NOE between the *ortho* protons of the PPh_3 ligand and the protons of the four-membered ring, however, a NOE at the protons of the benzene ring in the bicyclic ligand was observed. Apparently that conformation is preferred in which the PPh_3 ligand is oppositely disposed to the four-membered ring. The reason for this could be the *endo*-1-hydroxy group, as the conformation found for **4** was not preferred in the case of the *exo*-1-trimethylsilyl compound.[3]

The DSC (differential scanning calorimetry) analysis of **3** shows a reaction above 101 °C, from which we presume, in analogy to other results, that it involves a thermal opening of the four-membered ring to give an *ortho*-quinodimethane complex. Attempts to trap such a complex as a [4 + 2] cycloadduct with dimethyl fumarate, however, afforded only decomposition products. On the basis of the results reported by *Choy* et al.[6] we considered it possible that the four-membered ring of the alkoxide **5** opens at lower temperatures than that of the alcohol **3**. Therefore, **3** was allowed to react with 1.1 equivalents of *n*-butyllithium at −78 °C in THF, whereupon an immediate color change from bright yellow to brown-red occurred. After 1 h the clear solution was treated with 1.1 equivalents of dimethyl fumarate. After hydrolysis at 0 °C a slightly contaminated cycloadduct **6** was obtained in a total yield of 89% and was characterized on the basis of the spectroscopic data (IR, ^{13}C NMR; ^1H NMR see Table 1) and the mass spectrum.[7] In analogy to the findings of *Kündig* et al.[2] we assume that the hydroxy group in **6** is *exo*. The complex **6** is likewise obtained as the main product when the reaction is carried out with dimethyl maleate as dienophile. Whether this follows as a result of an isomerization of the dienophile at the transition metal[11] or a radical reaction is currently under investigation. No statement can yet be made regarding the structure of the intermediary *ortho*-quinodimethane complex; a complex with an η^6-coordinated ligand[2, 8] is as equally conceivable as one with an η^4-coordinated *ortho*-quinodimethane ligand as a result of an $\eta^6 \rightarrow \eta^4$ ring slippage reaction.[9]



We have shown that the ketone complex **2** and the alcohol complex **3**, which are not obtainable by a direct route, can be prepared in very high yields almost diastereoselectively. Compared to the two hitherto known ring-opening reactions of cyclopentadienyl and arene complexes containing four-membered annelated rings, the reaction starting from **3** offers considerable advantages. The lower reaction temperature of more than 160 °C, markedly shorter reaction time, and higher yield, as well as accessibility of various educts[10] from the 1-oxocyclobutabenzene complex **2** and the use of commercially available dienophiles make the reaction not only mechanistically but also preparatively interesting. The resolution of chiral **2** should enable the formation of enantiomerically pure *ortho*-quinodimethane complexes, which are of importance for the enantioselective synthesis of polycyclic natural products.[11, 12]

[7] By repeated dissolution in THF and subsequent trapping by addition of pentane a sample was obtained which gave a satisfactory elemental analysis. The ^1H NMR spectrum of the crude product showed signals of very low intensity which indicated a diastereomer of **6**. The relative configuration in the ligand of **6** follows from the ^1H-NMR data. The question as to which side of the ligand the $Cr(CO)_3$ unit is coordinated is presently under investigation.

Spontaneous Self Assembly of an Octanuclear Iron-Nickel Cluster by Reaction of $[Fe_6S_6I_6]^{2\ominus}$ with $[NiI_4]^{2\ominus}$ **

By *Wolfgang Saak* and *Siegfried Pohl**

Dedicated to Hans Georg von Schnering on the occasion of his 60th birthday

Numerous metalloproteins contain clusters of transition metals in their active sites. In many cases, however, not even the structure of these centers is known. Thus, the structures proposed for the active site of the FeMo cofactor of nitrogenase are based only on spectroscopic and analytical data,[1] according to which the central unit is formed from an $[M_8S_6]$ cluster. Remarkably, with $[Fe_8S_6I_8]^{3\ominus}$[2] so far only one cluster corresponding at least structurally with this model, for example in the "Fe-only" nitrogenase,[3] has been synthesized. In contrast, electron-richer clusters of this type, i.e. with cobalt and nickel, have not only been prepared synthetically,[4, 5] but are also found in minerals such as the pentlandites,[6] bartonite,[7] or djerfisherite[8] (see also Ref. [9]). This would suggest that $[Fe_8S_6]$ clusters can be stabilized by incorporation of nickel. Calculations of the electronic structures of clusters in pentlandites point in the same direction.[10]

By reaction of Fe–S clusters with nickel complexes we have found a novel route to Fe–Ni clusters and have been able to isolate such a cluster with cubic arrangement of the metals (regarding an $[Fe_3NiS_4]$ cluster, see Ref. [11]), which is of interest in connection with cluster transformations in the active site of nitrogenase.

Reaction of $[Fe_4S_4I_4]^{2\ominus}$ with iodine and $[NiI_4]^{2\ominus}$ leads to formation of a $[Fe_3Ni_5S_6I_8]^{4\ominus}$ cluster anion which can be isolated as the ammonium salt in ca. 70% yield.

[*] Prof. Dr. S. Pohl, Dipl. Chem. W. Saak
Fachbereich Chemie der Universität
Postfach 2503, W-2900 Oldenburg (FRG)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

Initially, $[Fe_6S_6I_6]^{2\ominus}$ is formed quantitatively according to Equation (a) by oxidation of the tetranuclear cluster (see also

$$2[Fe_4S_4I_4]^{2\ominus} + 3I_2 \longrightarrow [Fe_6S_6I_6]^{2\ominus} + 2[FeI_4]^{\ominus} + 2S \qquad (a)$$

Ref. [12]). In the second step the hexanuclear iron cluster reacts according to Equation (b) with tetraiodoniccolate(II) to give $[Fe_3Ni_5S_6I_8]^{4\ominus}$, which can be isolated as the salt $(PhCH_2NEt_3)_4[Fe_3Ni_5S_6I_8]$ **1** in the form of black crystals.

$$[Fe_6S_6I_6]^{2\ominus} \xrightarrow{[NiI_4]^{2\ominus}} [Fe_3Ni_5S_6I_8]^{4\ominus} \qquad (b)$$

Upon evaporation of the solution an $[Fe_2S_2I_4]^{2\ominus}$ anion with the same cation can be crystallized in pure form. Whereas $[Fe_2S_2I_4]^{2\ominus}$ and $[FeI_4]^{\ominus}$, which is also formed, contain only iron(III), the M_8 cluster is made up exclusively of divalent metal ions and contains almost the total nickel employed. This mode of reaction suggests a great tendency for formation of an electron-rich cluster.

1 was characterized by an X-ray structure analysis.[13] The cluster anion (Fig. 1) with approximate O_h symmetry has crystallographic C_{4h} symmetry. The eight cubically arranged metal atoms together with the circumscribing S_6 octahedron form a rhombododecahedron. A differentiation between iron and nickel is already impossible because of the symmetry of the cluster. The metal–metal distances (mean value: 268.1 pm) are significantly shorter than the corresponding values in $[Fe_8S_6I_8]^{3\ominus}$ (mean value: 272.3[2] and 274.0 pm[14]), but are comparable with those in $[Co_8S_6(SPh)_8]^{4\ominus}$ [4] and $[Ni_8S_6Cl_2(PPh_3)_6]$.[5]

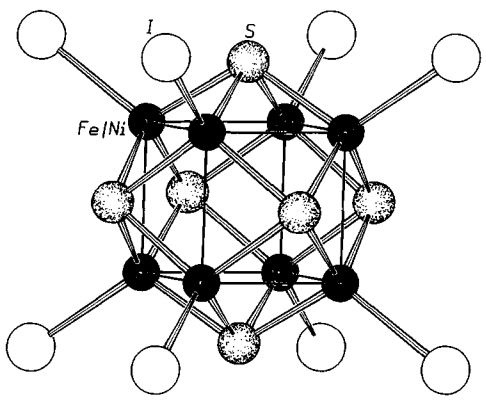

Fig. 1. Cluster anion of **1** in the crystal (C_{4h} symmetry). Important bond lengths [pm] and angles [°] (M ≙ Fe/Ni): M–M 267.7(2) and 268.5(3), M–I 254.6(1), M–S 223.8(3); M–S–M 106.3(1) and 73.6(1); M–S–I 112.2(1) and 112.9(1).

Differences and similarities, respectively, are also found in the number of skeletal electrons. For $[M_8S_6]$ clusters with π-donors *Burdett* and *Miller*[10] determined an optimal electron number of 110, a value which is reached exactly by $[Fe_3Ni_5S_6I_8]^{4\ominus}$ and almost by $[Co_8S_6(SPh)_8]^{4\ominus}$ with 108 electrons. Corresponding clusters with π-acceptor ligands, e.g. $[Ni_8(PPh)_6(CO)_8]$[15] or $[Ni_8(PPh)_6(CO)_4(PPh_3)_4]$[16] contain 120 skeletal electrons (see also Ref. [17]).

In contrast $[Fe_8S_6I_8]^{3\ominus}$ contains only 99 skeletal electrons. This unusually low number perhaps explains the high reactivity of this cluster anion (see Ref. [2]). A comparable $[Fe_8S_6]$ cluster fragment in the nitrogenase should, however, also show a high reactivity rather than high stability. Particularly effective are redox reactions by cluster transformations, since a larger number of electrons can be "reacted" in this way.

$$[Fe_8S_6]^{4\oplus} \rightleftharpoons [Fe_6S_6]^{4\oplus} + 2Fe^{3\oplus} + 6e \qquad (c)$$

Thus, in analogy to the reversal of the formation of $[Fe_3Ni_5S_6I_8]^{4\ominus}$ according to Equation (c), six electrons, as are required for the N_2 reduction, could be "set free" by a cluster transformation. The apparently essential homocitrate[18] could favor this transformation by complexing the iron(III) ions formed. An N_2 reduction in such a dinuclear complex is not inconsistent with the previously synthesized model complexes (see, in particular, Ref. [19] and, concerning bridged clusters, Ref. [20]).

Experimental

All operations were carried out under N_2 in anhydrous N_2-saturated solvents. BTEA: benzyltriethylammonium BTBA: benzyltri-*n*-butyl-ammonium.
1: A solution of $(BTEA)_2[Fe_4S_4I_4]$ (0.933 g, 0.75 mmol), $(BTBA)_2[Fe_4S_4I_4]$ (0.353 mg, 0.25 mmol) and I_2 (0.381 g, 1.5 mmol) in CH_2Cl_2 (150 mL) was heated for 15 min under its own pressure at ca. 50 °C. After cooling and addition of a solution of 1.119 g (1 mmol) of $(BTBA)_2[NiI_4]$ in 60 mL of CH_2Cl_2 this process was repeated. Crystallization commenced after 3–4 h and was complete after ca. 12 h. A small amount of finely powdered precipitate was removed by washing on a coarse frit. 0.35 g (72%) of **1** was obtained (satisfactory analyses of all elements). The use of different cations is necessary for the crystallization of pure **1**.

$Ag_{25}Bi_3O_{18}$, a Potentially Valence-Unstable Bi^{III}/Bi^{V} Compound **

By *Manfred Bortz* and *Martin Jansen**

Dedicated to Professor Hans Georg von Schnering on the occasion of his 60th birthday

As demonstrated for example by $BaBiO_3$[1] and its variants generated by incorporation of potassium[2] or lead,[3] mixed valence Bi^{III}/Bi^{V} oxides are suitable candidates for semiconductor/metal transitions or even for phase transformations in the superconducting state.[4] There are plausible concepts, according to which a conceivable mechanism for the formation of Cooper pairs in the sense of the Bardeen-Cooper-Schrieffer (BCS) theory is seen in the periodic localization of two electrons to the non-bonding pair at Bi^{III} and their delocalization (transition to Bi^{V}), and the accompanying atomic shifts corresponding to a normal vibration.[5] This concept together with the meanwhile largely confirmed knowledge that monovalent silver in silver-rich oxides also tends to form cluster-like partial structures corresponding to the arrangement in silver metal with an unoccupied s-band,[6] would lead one to expect interesting electronic effects. In the case of silver-rich bismuth(III/V) oxides, the aforementioned semiconductor/metal transitions might result.

With $Ag_{25}Bi_3O_{18}$ we present one of the first compounds with these structural properties, which at the same time is the most rich in silver of the hitherto known ternary silver(I) oxides. One difficulty encountered in its synthesis from the binary components Ag_2O and "Bi_2O_5" or from Ag_2O and $AgBiO_3$ was in choosing the correct reaction temperature and oxygen pressure; too high a temperature (too low an O_2 pressure) led to silver(III) bismuthates; conversely, bismuth in the oxidation state + V was preferred. Crystal growth required the addition of water as mineralizer.[7] The new silver bismuthate was first obtained in the form of single crystals admixed with other phases. After determination of the composition of the single crystals by energy dispersive microanalysis[10] and X-ray structure analysis[11] it was possible to prepare single-phase powders on a gram scale.

$Ag_{25}Bi_3O_{18}$ forms shiny black crystals and is not air-sensitive. Thermal decomposition[13] takes place between 410 and 480 °C, leading to metallic silver and Bi_2O_3.

According to the X-ray structure analysis (Fig. 1) the compound undoubtedly contains both trivalent (Bi 1) and pentavalent (Bi 2) bismuth. Bi 1 has characteristic trigonal-pyramidal coordination with three proximal (3 × 221 pm) and three more distant (3 × 251 pm) oxygen neighbors, while Bi 2 is surrounded by an almost regular octahedral array of six oxygen atoms at a distance of 213 pm; thus, in each case, the assigned valence is consistent with that in other comparable bismuth oxides as regards the distances and the type of coordination polyhedron. The crystallographically independent silver atoms Ag 1 to Ag 5 are each twofold coordinated by oxygen atoms, whereby the angles at silver lie between 167 and 180°. Measurement of the electrical conductivity by the four-point method[14] showed a temperature dependence typical for semiconductors at relatively high specific resistances ($\rho = 7.9\ \Omega$cm, $T = 273$ K). This is to be expected, since, according to the results of the structural analysis, the valence electrons are localized.

According to the structural geometry a simple process is now conceivable by which the Bi^{III} is converted into Bi^{V} and at the same time the electron pair delocalized: by shifting the oxygen atoms into the coordination sphere of Bi 1 by less than 40 pm the unsymmetrical 3 + 3 coordination (characteristic for Bi^{III}) can convert into a regular octahedral coordination (Bi^{V}). Of the various possible ways of experimentally determining this process we first selected measurement of the reflection in the infrared spectral region under pressure.[15] Indeed above 1.9 GPa at 300 K a Drude-like optical behavior with a sharp plasma reflection edge at 0.5 eV is observed. With increasing pressure this reflection edge shifts to higher energies, thus indicating a steady increase in the density of free charge carriers. This process is reversible, i.e., the metallic behavior cannot be kept metastable under normal pressure. All further exploratory investigations of this interesting semiconductor/metal transition must therefore be carried out under permanent pressure.

Endohedral Cluster Compounds: Inclusion of Helium within $C_{60}^{\bullet\oplus}$ and $C_{70}^{\bullet\oplus}$ through Collision Experiments **

By *Thomas Weiske, Diethard K. Böhme, Jan Hrušák, Wolfgang Krätschmer*, and *Helmut Schwarz**

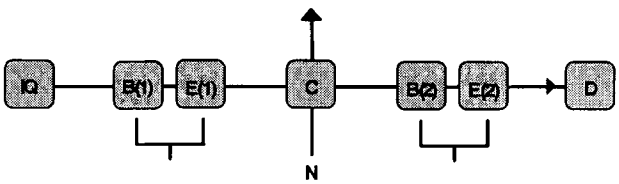
Dedicated to Dr. Curt Brunnée

Of all the C_x carbon clusters,[1] the fullerene C_{60} (the "third allotropic form of carbon"[2]) is currently of greatest interest, largely because it can be produced in macroscopic quantities with the convenient method developed by *Krätschmer, Huffman*, et al.[3] Not long thereafter sufficient experimental evidence had been reported[1–3] to verify the visionary suggestion[4, 5] that C_{60} was the celebrated icosahedron of the I_h-point group.

What are the physico-chemical properties of C_{60}? Early results suggest, for example, that doped C_{60} can be regarded as a three-dimensional organic superconductor,[6] that it can be hydrogenated by the Birch-reduction to produce $C_{60}H_{36}$,[7] and that up to 24 methyl groups can be added to the polyanions of C_{60} as has just been reported.[8] Is an "endohedral chemistry", i.e. a chemistry which proceeds inside the cage of C_{60} or its radical cation, $C_{60}^{\bullet\oplus}$ also possible? While theory has postulated a variety of endohedral cluster compounds for C_{60} with interesting properties,[9] experimental findings for the production of C_xM-clusters ($x \geq 60$; M = La, Cu, Ba, Sr) from the laser-induced vaporization of a mixture of salt and graphite have been interpreted more diversely: *Smalley* et al.[10] indicate that their experimental results point to the production of a spherically-constructed C_x cluster with a metal atom inside it; on the other hand, *Kaldor* et al.[11] are of the opinion that $C_{60}La$, for example, is an empty C_{60} cluster which has "custody" of the metal on its outside surface.

Here we report results of a molecular-beam experiment in which mass-selected ions of $C_{60}^{\bullet\oplus}$ and $C_{70}^{\bullet\oplus}$ produced by electron-impact ionization at 70 eV collide with a stationary neutral gas N; products are observed which are dependent on the nature of the collision gas and which leave no doubt about the incorporation of N.[12]

Earlier experiments have already shown[13] that highly accelerated $C_{60}^{\bullet\oplus}$ and $C_{70}^{\bullet\oplus}$ ions lose C_2 unimolecularly and even-numbered C_n units ($n = 2, 4, 6$ etc.) upon collisional activation (CA);[14] however, nothing has been reported about the incorporation of N. Perhaps this is a consequence of the limited performance parameters of the mass spectrometers which have been employed, which do not allow certain experiments to be performed. The four-sector machine used by us (Scheme 1) records measurements which demonstrate



Scheme 1. Sketch of the tandem mass spectrometers used in this study: IQ = ion source, B = magnetic sector, C = collision chamber, E = electric sector, D = ion detector, N = neutral gas. For a complete description of the machine see Ref. [15].

the incorporation of N according to the collision-induced reaction [Eq. (a)].

$$C_x^{\bullet\oplus}\ (8\ keV) + N \longrightarrow [C_{x-n} + N]^{\bullet\oplus} + C_n \qquad (a)$$

$x = 60, 70$ $n = 2, 4, 6, \ldots$

For this purpose $C_x^{\bullet\oplus}$ ions ($x = 60$ or 70) were accelerated up to 8 keV, were mass-selected in the B(1)E(1) sector (resolution $m/\Delta m = 1500$), and then were allowed to react with various gases N in the collision cell C with ca. 75% reduction of the primary ion beam. The products of this high-energy

reaction were detected and identified with a combined momentum and energy analysis ("linked scan": B(2)/E(2) = constant[16]). With H_2, D_2, Ar, and SF_6, the experiments show exclusive production of fragments in which C_n (n = 2, 4, 6, 8) or, less likely,[13b] multiple units of C_2 have been splitt off. A typical example is shown in Figure 1 for N = D_2. The same processes were observed for the other gases, but the relative intensities are somewhat different because of differences in "center-of-mass" energy, E_{cm}.[17]

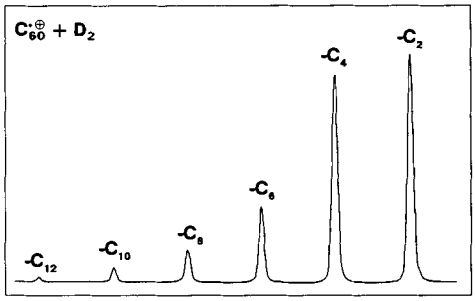

Fig. 1. CA mass spectrum for $C_{60}^{\bullet\oplus}/D_2$; E_{cm} = 44.2 eV.

A fundamentally different result is obtained when helium is used as a collision gas (Fig. 2). New signals appear at *higher* masses at all signals, corresponding to the loss of C_n; the mass difference Δm is equal to 4 when ^{4}He is used (Fig. 2, top) and 3 when ^{3}He is used (Fig. 2, bottom). The differences

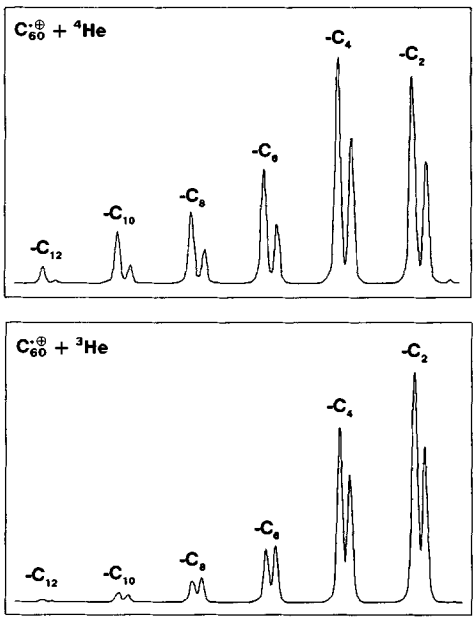

Fig. 2. CA mass spectra for $C_{60}^{\bullet\oplus}$ with ^{4}He(E_{cm} = 44.2 eV) (top) and ^{3}He(E_{cm} = 33.2 eV) (bottom).

which appear with D_2 and He cannot be accounted for by energy since E_{cm} is identical for these two gases; other factors (presumably size and shape of N) must be responsible. Totally analogous results are obtained with $C_{70}^{\bullet\oplus}$: while helium is incorporated (appearance of $[C_{70-n}He]^{\bullet\oplus}$), the other collision partners only lead to collision-induced elimination (loss of C_n). The observation that the $C_{60}^{\bullet\oplus}$/He fragment arises from $C_{70}^{\bullet\oplus}$/He (Fig. 4) is particularly noteworthy. If *Smalley*'s argument[5d] that loss of C_2 units is accompanied by a "repair" of the cluster-cage applies, this $C_{60}^{\bullet\oplus}$/He is the fullerene-noble gas complex which has been sought for a long time.[18]

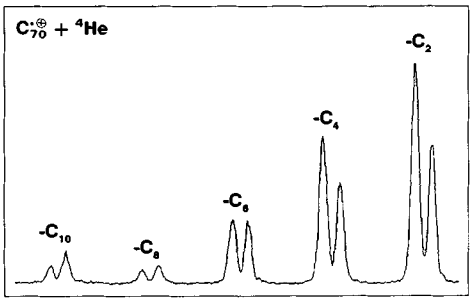

Fig. 3. CA mass spectrum for $C_{70}^{\bullet\oplus}$ with ^{4}He (E_{cm} = 37.9 eV).

The location of the helium atom in the $[C_{x-n}He]^{\bullet\oplus}$ clusters of course cannot be determined with the experiments described here, but there are indirect indications that we are almost certainly dealing with intra-cavity bonding rather than with cluster ions in which helium is fixed to the outer wall. The process $C_{60}^{\bullet\oplus} \rightarrow C_{58}^{\bullet\oplus} + C_2$ requires at least 4–5 eV according to *Lifshitz* et al.[13e] and *Smalley* et al.,[19] while the binding energy of He to $C_6H_6^{\bullet\oplus}$, for example, is less than 0.2 eV accoding to ab initio MO calculations.[20] If the helium was not incorporated by the cage during the collision process, it would have had to leave the complex on energetic and kinetic grounds before a C_2 unit splits off. Accordingly an increase in mass, Δm = 3 and 4, would not have appeared. Furthermore mass-selected $[C_xHe]^{\bullet\oplus}$ ions lose not He, but C_2 unimolecularly.

How much energy is required to bring a helium atom inside the $C_x^{\bullet\oplus}$ cages (x = 60, 70)? We have obtained an upper limit of less than 10 eV in model calculations in which He is forced through a C_6H_6 or $C_6H_6^{\bullet\oplus}$ plane.[20] This energy barrier,[21] whose accuracy should not be overemphasized, is clearly smaller than the kinetic energy of greater than 30 eV which is available to the collision complexes $C_x^{\bullet\oplus}$/He (x = 60, 70). Consequently, the inclusion of a helium atom into the cluster is energetically possible. *There is no doubt that a He atom is incorporated into the $C_x^{\bullet\oplus}$ (x = 60, 70) cluster in the course of the collision.*

The experiments and thoughts presented here provide a first item in the cornucopia of endohedral bonded (ionized) C_x fullerenes.[2, 9, 22]

[17] The "center of mass"-energy (E_{cm}) determines the maximum energy which can be transferred in a collision of a projectile A with a stationary particle N. The following relationship holds: $E_{cm} = E_A[m_N/(m_N + m_A)]$, where E_A = kinetic energy of A (corresponding to 8000 eV in the experiments described here) and m_i the masses of A and N.
[18] Direct production of $C_{60}^{\oplus\bullet}$/He or $C_{70}^{\oplus\bullet}$/He according to Equation (a) in a high-energy collision experiment is fundamentally impossible on kinematic grounds. However, we are planning experiments with "slow" $C_x^{\oplus\bullet}$ ions. Furthermore, we intend to expose the $C_x^{\oplus\bullet}$/He species to a neutralization–reionization (NRMS) experiment. The experiment (which has not yet been performed because of insufficient intensities) will answer the question about the existence of neutral C_xHe clusters.
[19] S. C. O'Brien, J. R. Heath, R. F. Curl, R. E. Smalley, *J. Chem. Phys. 88* (1988) 220.
[20] The ab initio MO calculations were performed at the MP2/6-31G**// MP2/3-21G* level of theory. We expect that calculations with larger basis sets will lead to *smaller* values for the binding energy of $C_6H_6^{\oplus\bullet}$/He as well as for the energy required to pass He through a C_6H_6 or $C_6H_6^{\oplus\bullet}$ plane.
[21] For MNDO calculations of the barrier for the *endo* → *exo* migration of $Li^{\oplus}$ in C_x clusters see: D. Bakowies, W. Thiel, *J. Am. Chem. Soc. 113* (1991) 3704.
[22] Note added in proof (12 June 1991): First experiments with $C_{60}^{\oplus\bullet}$ and Ne (E_{CM} = 216 eV) show that this noble gas can also be incorporated into the cavity (appearance of $[C_{60-n}Ne]^{\oplus\bullet}$, $n = 2 - 10$), but the "yield" is a factor 10 smaller than in the case of He.

BOOK REVIEWS

Book Reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the following address: Redaktion Angewandte Chemie, Postfach 101161, D-6940 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

Comprehensive Medicinal Chemistry. The Rational Design, Mechanistic Study and Therapeutic Application of Chemical Compounds. Six volumes. Edited by *C. Hansch, P. G. Sammes* and *J. B. Taylor*. Pergamon, Oxford 1990. Hardcover \$ 1995.00. (Individual volume: \$ 350.00 each).—ISBN 0-08-032530-0 (complete work)

Volume 1: General Principles. Volume Editor: *P. D. Kennewell*. xv, 811 pp.—ISBN 0-08-037057-8

The first section of this volume is very heterogeneous in content; it sets out to describe the development of medicinal chemistry by giving a chronology of drug introductions and tracing the history of the pharmaceutical industry. It shows how the different initial conditions and environments existing in German-speaking countries, in Great Britain and in the USA have led to the industry developing in different ways. The important role of legislation and of public regulatory agencies such as the FDA in imposing quality standards is emphasized, and it is shown how this led to a strengthening of the German and North American pharmaceutical companies even before the First World War.

The account of drug introductions is not in chronological order, nor is it complete. Admittedly it would not be possible to cover this subject exhaustively within the space allowed, but it is surprising that some important milestones such as the introduction of antihyperlipidemic aryloxycarboxylic acids ("Fibrates"), HMG-CoA-reductase inhibitors ("Lovastatin") and calcium antagonists of the dihydropyridine type are not included. On the other hand the space devoted to compounds such as LSD, tetrahydrocannabinol and chloramin-T is disproportionately large in relation to their importance. Antibacterial agents and their development are discussed in detail, but only penicillins and cephaalosporins are covered. Neither quinolones nor carbapenemes are mentioned. The important contribution of the azoles in antifungal therapy is also ignored. This not entirely successful historical introduction ends with brief accounts of Egyptian, Greek and Arabic medicine, plus two separate chapters on traditional Chinese and Indian medicine.

The second section on "Targets of Biological Active Molecules" follows a logical sequence, starting with the essentials of anatomy and physiology and proceeding via cell architecture to the identification of specific macromolecular targets. Principles of general pharmacology, such as the receptor theory, are derived in the course of the discussion.

Although the introduction to anatomy and physiology is pleasingly concise, this means that the non-biologists for whom this chapter is mainly intended will find that their needs are not fully satisfied here; it would have been useful to include references to suitable books covering these topics.

It is difficult to understand why a topic so important to pharmacology as the smooth muscular system is given such little emphasis, hidden away under the headings "Musculoskeletal System" and "The Neuromuscular Junction". The otherwise good introduction to renal physiology lacks a clear and full explanation of the renin–angiotensin–aldosterone system. The physiology of the central nervous system is treated systematically from an anatomical standpoint. The same also applies to the discussion of endocrine glands and of hormones, although here some new findings such as those concerning ANP, EDRF and endothelin are not mentioned. As the treatment is so concise, one expects that it should be clear and unambiguous, and should not conflict at any point with the textbooks (as, for example, in the cases of the Hagen-Poiseuille equation or of renal autoregulation). The chapter provides good basic information in the simplified account of the complex relationships in the immune system. However, only a relatively small amount of space is devoted to the AIDS problem. Basic concepts of general pharmacology and their quantitative aspects are explained with the help of examples. The contents of the articles entitled "The Concept of Bioselectivity" and "Bioselectivity" could have been presented more concisely by either combining them or relating them more effectively.

The third section, "Bioactive Materials", begins with an excellent discussion of structure–activity relationships, their importance for classifying active substances, and the problems that this entails. The two following chapters illustrate, for the benefit of outsiders, the complex nature of the search for new structural types with pharmaceutical activity. However, the expert too will undoubtedly discover here stimulating viewpoints for example the discussion of the advantages and disadvantages of different types of organizational structures for finding and evaluating new active agents in an interdisciplinary way. Two chapters deal with natural products, but these are devoted exclusively to hormones. In some parts the discussion becomes lost in experimental details that are of little interest to the outsider. On the other hand the chapter on analytical methods is clearly presented. Unfortunately, however, the great advances made possible by the use of molecular biological techniques in this field are only touched on briefly. This is followed by a rewarding chapter in which the many problems that nowadays confront a chemist engaged in process development are described. Even readers unfamiliar with this field will gain a clear impression of the factors that often force one to adopt a synthetic strategy far removed from the laboratory method.

The field of gene molecular biology, gene structure and cloning techniques is only covered in a very patchy fashion, as is evident from the fact that there are only 40 literature references altogether. It would have been better to save this space by referring the reader to appropriate textbooks, and to devote it instead to gene expression and manipulation, which is only treated very briefly in the following chapter. Although many topics are touched on, the information content remains rather meager. The final chapter ("Genetic Engineering: Commercial Applications") deals with the therapeutic applications of recombinant proteins and fits very well into the subject area of this series. However, it does not make any reference to antibodies produced by genetic engineering.

The last section, "Socio-Economic Factors of Drug Development", is again very heterogeneous. The topics covered are regulatory authorities, the organization and funding of pharmaceutical research, health care systems, clinical pharmacology, animal experiments, and patenting. Nearly all the material on the first four subjects named above relates to the situations in Great Britain and the USA. For an international standard source it would have been desirable to also discuss the situation in the European Community, which will become an increasingly important factor in the future, and also to describe, at least briefly, the special features of the Japanese licensing mechanisms for pharmaceuticals. Apart from these reservations most of the chapters provide good concise reviews of their subjects. There are special sections devoted to the now highly interesting topics of "Good Clinical Practice" (GCP), "Good Manufacturing Practice" (GMP) and "Postmarketing Surveillance" (PMS).

To summarize, in aiming to present a comprehensive account of this broad area the authors have in general given basic information, but the chapters vary greatly in their provision of references to literature covering the topics in greater depth. One would have liked to find more cross-references to more detailed discussions to be found in other chapters or in other volumes of this series, and this would undoubtedly have added greatly to the usefulness of the volume.

Axel Unterbeck, Thomas Weihrauch

Volume 2: Enzymes and other Molecular Targets. Volume Editor: *P. G. Sammes*. xvii, 887 pp.—ISBN 0-08-037058-6

Volume 2 deals with enzymic processes, and also describes agents that interfere with the synthesis of the bacterial cell wall or produce changes in nucleic acids. It begins with a general introduction describing the structures, nomenclature and classification of enzymes, the mechanisms of catalysis and inhibition, and the development of resistance and tolerance towards antimicrobial agents. This is followed by descriptions of particular enzymes and enzyme systems of importance. It is, of course, not possible within this relatively limited space (a little over 500 pages) to give an exhaustive survey of this complex field. The criteria used in making the selection have clearly been based mainly on pathophysiological importance and on the ability to influence systems by pharmacological means. In the following commentary several chapters will be picked out as examples.

The article on protease inhibitors (*D. H. Rich*, University of Wisconsin) is confined to inhibitors of low molecular mass, with the main emphasis on renin and ACE inhibitors. Unfortunately there is not much discussion of the relationship to biology and medicine. Good features are the inclusion of X-ray structural data and the discussion of "molecular mechanics" calculations. The chapter on enzyme cascades, coagulation, fibrinolysis and hemostasis agents (*M. P. Taylor*, Warner Lambert Company) gives a very good overall description of the processes of hemostasis, fibrinolysis and coagulation. Less satisfactory, however, are the formula schemes and diagrams, which could have been set out more clearly, and are too small relative to the typeset formulas. Whereas the account of fibrinolysis therapy includes references to the latest developments in molecular biology (e.g. the use of rTPA), the discussion of blood coagulation does not give enough information about developments of this kind (e.g. the treatment of hemophilia using rFVIII as an alternative to plasma concentrates). In general molecular biological aspects are underrepresented; for example, the cloning of blood factors and the techniques that have grown from it are not adequately covered. In contrast the chapters on the arachidonic acid cascades (*G. A. Higgs, E. A. Higgs* and *B. Moncada*, Wellcome Research Laboratories), on phosphodiesterase inhibitors (*R. E. Weishaar* and *J. A Bristol*, Warner Lambert Company), on phospholipase-A_2

(*H. van den Bosch*, Utrecht), and especially that on protein kinases (*K. J. Murray* and *B. A. Warrington*, Smith, Kline and French) contain comprehensive information, presented concisely with clear tables and diagrams. In the last-named chapter especially, a wealth of information on all the known protein kinase inhibitors, including structure–activity relationships and a discussion of the biological effects, is clearly and concisely presented. This chapter is of equal interest to the chemist and the biologist. However, it would have been useful, especially from the standpoint of up-to-dateness, to include here a discussion of the protein phosphatases and their inhibitors; this would undoubtedly have contributed to giving a more complete picture of cellular regulatory mechanisms.

The clearly set out and succinct chapter on agents that affect nucleic acids provides the reader with a soundly-based insight into the various molecular mechanisms involved. Suggestions are put forward for setting up selective therapeutic strategies to counteract tumor cells and pathogens. The chapters that follow discuss other aspects of antimicrobial agents: the development of resistance and tolerance to antibiotics, substances that intervene in metabolic processes, and agents that affect cell walls. The discussions of these include details on a wealth of chemical structures and pharmacological effects. However, this inevitably means that some aspects are treated too briefly and without sufficient attention to the latest state of knowledge. The disjointed treatment is especially noticeable in the fact that there are two chapters on β-lactams by different groups of authors.

There is no doubt that Volume 2 of this work again illustrates the general rule that length and up-to-dateness are inversely related, despite the fact that quite a number of the chapters contain references to recent literature (1986 to 1988). This, and the non-uniformity in the treatment due to the large number of authors, are penalties that the reader must incur along with the benefits of comprehensive books of this kind. Nevertheless, the book is of considerable value because of the wealth of information that it contains. The biologist working in the pharmaceuticals area who needs to find ways of controlling cellular or molecular processes will find here many pointers to active compounds that are already known. Looked at from this standpoint, as a reference source, the book is undoubtedly a valuable addition to the literature.

Rüdiger W. Braun, Axel Dalhoff,
Detlef Schmidt

Volume 3: Membranes and Receptors. Volume Editor: *J. C. Emmett*. xvii, 1280 pp.—ISBN 0-08-037059-4

The third volume of the handbook deals with the pharmacology of the cell membrane and of membrane receptors. The arrangement of the contents according to types of mechanisms is sensible and makes it easy to find the subject areas one is seeking; unfortunately, though, sufficient cross-references are not provided to enable one to gather information on processes that fall into several mechanistic categories (as in the case of the "receptor operated ion channel", for example). Also one searches in vain for membrane processes of such central importance as active and passive ion transport. These are in fact treated in Volume 2 with its vague title "Enzymes and other Molecular Targets".

The explanatory sections on methods and mechanisms that introduce the volume as a whole and some individual chapters are very useful, especially for readers new to the field. For example, the introductory section on the structure and function of cell membranes gives a comprehensive and very clearly set out overview of the current state of knowledge in this area. As well as indicating some general principles of membrane biochemistry with the help of examples, the techniques used to study these systems are introduced in an easily understandable way. These topics include the quantitative analysis of ligand–receptor interactions and a brief review of methods for isolating and purifying membrane receptors and investigating their molecular biology.

The chapter on transduction of signals and "second messenger" analogues unfortunately fails to live up to its promise to introduce the reader to the mechanisms of signal transduction. It seems that the adenylate cyclase, guanylate cyclase and phospholipase C systems are only mentioned here as a vehicle for including a few literature citations. The discussion that follows deals only with "second messenger" analogues, and here reference is continually made to "inositol 1,4,5-triphosphate" instead of the correct name inositol 1,4,5-trisphosphate.

The authors of the chapters on neurotransmitters and their receptors have succeeded in providing an excellent and informative review of this field, which has now become very complex. A pleasing feature here is the use of a standard structure for each of the chapters. Starting with a description of neuroanatomy and of the neurotransmitter pathways in the brain and/or its periphery, the authors proceed to discuss the biosynthesis and metabolism of each type of neurotransmitter. This is followed by the mode of action of the neurotransmitters and the ways in which they are influenced by agonists and antagonists.

The traditional classification of receptors according to their response to synthetic transmitter analogues is nowadays being replaced increasingly by one based on molecular biological criteria. It has not been possible to cover this aspect adequately here, in view of the rapid developments that have occurred in the last few years.

Most of the authors conclude their discussion of the receptors concerned by describing the potential or already practised therapeutic applications of agents with specific activity towards the neurotransmitter–receptor system. This means that each chapter is a very useful and informative reference source, not only for chemists, biochemists and pharmacologists but also for medical scientists, providing a clear description of the sequence from the chemical synthesis of a receptor-specific substance to a practical therapeutic agent.

The treatment of peptide receptors is very clear and informative, and the division of this complex subject into ten chapters is appropriate. These describe the characterization of the receptors, their biosynthesis and metabolism, the ways in which they are affected by the endogeneous peptides and by peptide and non-peptide ligands, and, where appropriate, the therapeutic applications of these substances. Structure–activity relationships are treated at considerable length.

In the chapter on angiotensin receptors one would have liked to be given a rather more balanced treatment by the inclusion of important research results from other groups. Moreover, the non-peptide angiotensin-II antagonists are underrepresented, being only mentioned in a single sentence. One also searches in vain for a description of endothelin receptors.

In the treatment of ionic channels the pharmacology of the sodium and calcium channels in particular is covered very well and in great detail. However, the discussion of the potassium channels fails to come up to standard because of recent developments that are not included. Chloride channels are not treated at all.

The lymphokins and cytokins of the immune system are treated separately. Although this makes for a clear division of topics, it means that the complex interaction between these mediators is not sufficiently brought out. Some of the sub-chapters, such as the account of the physiological and clinical importance of interleukins, are very informative. On the other hand the importance of the role of TNF is understated; in the account of analytical techniques there is not enough discussion of the advantages and disadvantages of the various methods, and some of the literature references are not mentioned in the text. The bibliographies are in many cases more than five years out of date, and thereby fail to live up to expectations in this respect, especially in the discussion of pharamacological agents that affect the immune system.

The final chapter of this volume is devoted to the molecular structure, regulation and ligand chemistry of the most important intracellular receptor systems, namely vitamin D, thyroid hormone and steroid hormone. The treatment is for the most part of an impressively high standard. An exception to this is the physiology and pathophysiology of the steroid receptors, which unfortunately has been subdivided and placed in different parts of the chapter in a confusing way. The literature references here are up-to-date and comprehensive, making it easy for the reader to refer to the original papers when special questions arise.

To summarize, this volume is a substantial collection of good review articles dealing with specific topics, but cannot be regarded as a self-contained textbook or comprehensive work of reference.

Martin Bechem, Arno Friedl, Siegbert Hebisch, Gabriele Hecker, Henning Sommermeyer, Hans-Peter Stasch

Volume 4: Quantitative Drug Design. Volume Editor: *C. A. Ramsden*. xvi, 766 pp.—ISBN 0-08-037060-8

Volume 4 of this work contains 24 articles by well-known authors. The main emphasis is on the "classical" methods of investigating structure–activity relationships and on molecular modeling methods.

Methods for quantifying the physicochemical properties of chemical structures and their interactions are treated in detail. The discussion is concentrated mainly on computer-aided theoretical methods, ranging from molecular fragment approaches to predicting lipophilic behavior (*A. J. Leo*), through to molecular dynamics methods for calculating relative free energies of ligand–receptor complexes (*J. A. McCammon*).

The quantitative description of biological data and the transport of substances to the target site are each covered in only one chapter, these being by *Y. C. Martin* et al. and *J. C. Dearden* respectively.

Several further articles are devoted to the models and mathematical techniques used in correlating structure with activity; for example, the *Hansch* approach and the *Free–Wilson* method are described in detail with many examples by *T. Fujita* and *H. Kubinyi* respectively. Other articles are concerned with the design of testing programs and methods of pattern recognition. This group of articles is completed by an account of some further methods, including the application of substructure analysis for predicting toxicity and choosing suitable test compounds for screening tests (*P. N. Craig*), followed by a description of the distance-geometry method (*A. K. Ghose* and *G. M. Crippen*).

The use of models and molecular graphics techniques in drug design is described in three articles by *R. Langridge* and *T. E. Klein*, by *G. R. Marshall* and *C. B. Naylor*, and by *J. M. Blaney* and *C. Hansch*. The relationship between these and the quantitative methods is also discussed.

The editors do not appear to have set out to present a balanced and comprehensive account of all the models and methods that are in use in this field. In some cases the authors of the contributions seek to justify the omissions, as, for example, in the case of the unduly brief treatment of connectivity indices. In other topics, such as the treatment of QSAR parameters for peptides or the study of structure-pharmacokinetic relationships, the omissions are less easy to understand.

The unavoidable instances of overlapping between the contributions have mainly been kept to a reasonable minimum. However, this is not always the case in the introductory articles; for example, the information on chemical data banks could have been shortened, as these were already listed in Volume 1.

The layout of the volume is excellent. However, the long period required to prepare it has meant that only developments up to about 1988 are included. For this reason some topics of current importance, such as 3D data banks, computer methods for designing ligands to match known receptor structures, and methods of quantifying chemical similarity, are unfortunately not included.

Despite the high price and the fact that some good monographs on this field already exist, especially in the QSAR area, the eminence of the contributing authors ensures that the book is of a high standard and will be successful.

Eike Möller, Martin Blunck

Volume 5: Biopharmaceutics. Volume Editor: *J. B. Taylor*. xvii, 756 pp.—ISBN 0-08-037061-6

Volume 5 is concerned with "Biopharmaceutics" and embraces a wide range of topics, from "Principles of Pharmacokinetics and Metabolism" through "Analytical Methodology" to matters of pharmacy and formulation in "Chemistry and Pharmacy in Drug Development".

The first part deals with the fundamentals of pharmacokinetics, beginning with general chapters on absorption, distribution and metabolism. These chapters provide the scientist involved in pharmaceuticals development with a good overview of the basic principles underlying pharmacokinetics. Especially useful is the concisely written chapter by *T. N. Tozer*, which forms an excellent introduction for the beginner. The emphasis that is placed on the physiological basis of pharmacokinetic processes in these introductory chapters, for example that on absorption (*Dennis*), is commendable. However, it would have been desirable to include here a more detailed treatment of bioavailability and bioequivalence, which has become a highly interesting theme in recent years. The chapter on "Distribution and Clearance Concepts" by *Gaillot* et al. contains an excellent summary of current knowledge concerning the physiological basis and importance of distribution processes, but clearance concepts deserved to be treated at considerably greater length.

The section on "Sites of Drug Metabolism, Prodrugs and Bioactivation" contains a well organized discussion of aims and approaches in the design of prodrugs. The comprehensive bibliography and the tables listing details of review articles are useful for readers from other disciplines. The very large field of bioactivation of chemicals to form reactive intermediates, and the toxicological problems that this causes, is only treated in the form of a concise summary, which is understandable.

These general review articles are followed by discussions of some special areas, some of which are very up-to-date.

These short reviews also serve to provide the specialist with a quick overview. Readers interested in following these up in greater depth are helped by the mainly well selected bibliographies, which extend up to about 1988.

In the very informative chapter by *Juchau* on "Species Differences in Drug Metabolism" the benefits and problems arising in the use of various animal species as models for predicting effects on humans are discussed. In drawing attention to the effects of extrahepatic biotransformation and to differences in the isoenzyme patterns of different species, and discussing enzyme systems that have received little study, the authors make it clear that present knowledge still leaves many gaps. Equally informative and interesting are the chapters on "Developmental Drug Metabolism" (*Juchau*) and "Stereoselectivity..." (*Lennard* et al.). There are further specialized chapters on highly topical matters, such as that on "Chronokinetics" (*Reinberg* et al.). The remarkable variations observed in pharmacokinetic processes according to the time of day are described with many examples, and the relative importance of endogenic factors (biorhythms) and exogenic factors (e.g. food intake) is examined. To complete the picture, some of the methodology used to investigate these problems is described. It is pointed out that the regular, and therefore predictable, cyclic changes that are observed in chronokinetics studies are of practical importance in the development of programmed delivery devices, and the possible therapeutic implications are also discussed.

The chapter by *Paalzow* on "Pharmacodynamics" discusses concentration–activity relationships by considering numerous examples. The detailed description of the mathematical models used is sufficient to enable the reader to become thoroughly involved in the theories of this area of research; the comprehensive and up-to-date bibliography offers further new ideas in this field.

The second part, entitled "Analytical Methodology", suffers to a noticeable extent from the problems caused by the complexity of this subject. The growth that has occurred in analytical chemistry in recent years is such that there is a danger of parts of this chapter being reduced to a mere collection of technical terms. For example, under the title "Isolation and Identification of Metabolites" the book covers, in only 18 pages, not only enzymic but also chromatographic and spectroscopic methods. Such a sketchy summary can at best only be of interest to beginners. The introduction to biological analytical techniques by *Chamberlain* is excellent from a learning standpoint. However, one would have preferred this chapter to be more up-to-date; for example, the use of monoclonal antibodies only receives a brief mention. *Boobis* et al. review techniques for in vitro investigations of the metabolization of foreign substances, including a detailed evaluation of alternative experimental procedures. This chapter also includes a very comprehensive bibliography. *Vaughan* describes the mathematical aspects of pharmacokinetics from a strongly theoretically-orientated standpoint. In view of the intended readership it would have been desirable here to relate the discussion more closely to the physiological background and the application of the theoretical model to practical situations.

The final part, entitled "Chemistry and Pharmacy in Drug Development", covers a variety of topics, ranging from the properties of pharmaceutical substances, and their consequences for the formulation of products by conventional methods, also taking physiological factors into account, to new approaches such as drug targeting.

The first article, by *Curry* and *Thakker*, is entitled "Physicochemical Principles", and is mainly concerned with the crystallinity and particle size distribution of pharmaceutical compounds and their consequences for the method of formulation. Here it would have been useful to include a more detailed description of other important variables and techniques for adjusting them at the pre-formulating stage. In the chapter on "Formulation" *Florence* and *Halbert* emphasize the importance of in vitro tests on drug release for arriving at the best formulation. This is followed in logical sequence by a description of in vitro and in vivo correlation methods, including a useful table listing many published studies on this theme.

In their contribution on "Routes of Administration and Dosage Regimens" *Johnson* and *Lewis* provide the newcomer to the subject of formulation with a comparative review of the advantages and disadvantages of various alternative routes of administration in pharmaceutical therapy. Newer therapeutic routes such as the nasal administration of peptides, buccal administration, and transdermal absorption are described. The second part of this article, which deals with devising dosage regimens, seems out of place in the part of the book concerned with pharmacy, especially as it has already been treated in the first part, "Principles of Pharmacokinetics and Metabolism".

The article on "Delivery System Technology" discusses various methods of retarding drug release and ways of achieving improved absorption with peroral formulations. Transdermal therapeutic systems are also discussed as a modern formulation principle, together with the requirements that must be satisfied by the substances to be administered because of the structure of the skin; here the principles are related to practical situations by describing a number of commercial products.

In the noteworthy review of "Drug Targeting" by *Crommelin* and *Storm* the authors provide a comprehensive overview of the current situation in this very active field of research, including much information that is useful not only for newcomers but for those already working in this area. A commendable feature is the comprehensive and up-to-date bibliography.

This volume must be evaluated in relation to the ambitious claim that the collection of articles represents "a milestone ... in terms of coverage, clarity, and a sustained high level of presentation". In view of the wide range of topics covered, it is understandable that it has not been possible to treat all of these with equal thoroughness, although there has clearly been an effort to achieve complete coverage. Taken as a whole this collection, despite some weaknesses, offers a good overall survey of the current state of knowledge in biopharmaceutics, and it provides easy access to more advanced reading. It can therefore be recommended for all scientists interested in the development of pharmaceuticals.

Hans-Peter Krause, Hans-Jürgen Ahr, Michael Boberg, Jürgen Günther

Volume 6: Cumulative Subject Index and Drug Compendium. Volume Editor: *C. J. Drayton.* xv, 991 pp.—ISBN 0-08-037062-4

This is a useful book.

The first 236 pages consist of a detailed subject index to Volumes 1–5. This is followed by a "Drug Compendium" of over 700 pages, compiled by *P. N. Craig* in a remarkably laborious achievement. This lists over 5500 compounds (established and potential pharmaceuticals, pharmacological agents, etc.) with their generic names and their structural formulas produced by the ChemBase program. The principal sources that have been drawn on are *USAN* and the *USP Dictionary of Drug Names*, while additional data have come

from the *Merck Index (10th edition), The National Formulary, Annual Reports in Medical Chemistry, The American Drug Index,* and *Martindale: The Extra Pharmacopoeia.* Besides structure and generic name (from *USAN* or *INN*) further entries are given: the CAS Registry Number, the molecular mass, molecular formula, partition coefficients and indications of the physiological effects and therapeutic uses.

It is evident that identifying the first manufacturer has been problematic, and has led to numerous incorrect statements. In the author's favor it must be admitted that outsiders can easily lose their way in the jungle of licensing, cross-licensing, subsidiary companies, franchises, etc., but more care should have been taken in this area. It is evident that other authors should be warned against using the book as their primary source with regard to first manufacturers—it could lead to regrettable mistakes.

The entry *classification* is also not very clearly presented. Insufficient attention has been given to consistently listing not only the activities but also the mechanisms. It would have been worthwhile to go into this matter thoroughly, since the mechanism of action is particularly important to the medicinal chemist involved in drug design; this is especially the case when making a search in the 3(D)-Database (Molecular Design Ltd.), which is identical in content.

Despite the above teething troubles, which one hopes will be overcome in the next edition, the verdict still remains: this is a useful book.

Adolf Butenandt. Biochemiker, Hormonforscher, Wissenschaftspolitiker. By *P. Karlson.* Wissenschaftliche Verlagsgesellschaft, Stuttgart 1990. 336 pp., hardcover DM 78.00. – ISBN 3-8047-0830-7

It is risky enough to write the biography of an eminent scientist and individual during his lifetime, and even more so when it comes from one of his closest students. Is it not essential to stand at some distance to write a biography? Can a student and close friend such as *Peter Karlson* write a biography of his "boss" and teacher, without falling into the traps of either excessive praise or resentment? This book proves that such doubts are unfounded.

Karlson spent 24 years close to *Butenandt*, years that witnessed many changes in *Butenandt*'s many-sided life, including the beginnings of research into viruses, insect biochemistry, and hormones and the introduction of the gene-product hypothesis. It was in the latter studies that *Karlson* was most closely involved. However, the lively and absorbing account is not confined to these years; the author has carried out scholarly study into *Butenandt*'s childhood and youth, his hometown, and his student days, and he has continued this into *Butenandt*'s later years with devoted interest. His factual and impressive account of the life of this great researcher contains not only a wealth of scientific history and factual information, but also much personal detail and historical background.

I first came to know *Adolf Butenandt* personally during my work in the Max-Planck-Gesellschaft from 1962 onwards, although of course I was already familiar with his work before this. For me an important criterion in assessing any one of the older generation is how he behaved during the Hitler regime, and therefore I will quote from *Karlson*'s book the passage describing how *Butenandt* was forced to turn down the Nobel Prize: "Butenandt was summoned to the Reichskultursministerium. At the door stood a towering SS man, who remained there silently on guard duty. On the desk lay a very harshly worded letter of refusal. Menzel said: 'This draft has been on the Führer's desk and he has approved it, and therefore none of its text can be altered.' Butenandt read the letter, found it unacceptable, and said that he was unable to sign it immediately. He was given three days to think it over. Menzel dismissed him with the words: 'But please consider carefully what consequences it will have for you and your family if you fail to obey an order of the Führer in wartime!' Adolf Butenandt went home with this moral dilemma and discussed it with his wife. After much thought they decided together that Butenandt would not sign this letter, but would instead send a courteous and factual letter to Stockholm. Shortly afterwards Alfred Kühn and Fritz von Wettstein arrived. They too were aware of the text of the letter that Butenandt was supposed to sign. They both urged him not to put up any foolish resistance in view of the menacing political situation. Kühn's exact words were 'I shall not leave your house until you promise us that you will not do anything foolish. You would achieve nothing by refusing to sign, and you would risk bringing ruin on your family and your academic institute. That would be stupid.' These conversations, especially those with his friends Kühn and Wettstein, finally persuaded Butenandt to sign the letter... it still remains a painful recollection for Butenandt that he yielded to the President's [the President of the Kaiser-Wilhelm-Gesellschaft] request and to his friends' entreaties. He said this was the only time that he had ever signed anything that was untrue!" Can any scientist of the younger generation fully appreciate what was going on at that time in the country and in the minds of many of its people? It is good to find such matters treated so openly in this biography.

Reviewing this comprehensive and, at the same time, highly readable account of the life's work of *Adolf Butenandt* has again evoked my admiration of the remarkable versatility of this researcher. After earning a Nobel Prize for the discovery and structure determination of sex hormones, he went on to achieve at least two or three further scientific successes of comparable importance, in his research on viruses, in the isolation and structure determination of insect hormones, and finally in his research on gene products which was stimulated by his association with *Kühn*. However, it is unfortunate from the standpoint of scientific history that the scientific community has apparently forgotten that *Butenandt* proposed the "one gene one enzyme" theory as early as 1940, at least five years before *George Beadle*.

I experienced firsthand *Butenandt*'s activities in the organizational aspects of science, especially his work as president of the Max-Planck-Gesellschaft. *Karlson* describes this period of *Butenandt*'s life from a thorough knowledge of the facts, telling how for twelve years *Butenandt* guided the fortunes of the Max-Planck-Gesellschaft in a way that was both well-informed and personally honest—one can even say in a noble and dignified way.

This discussion has now become not only a favorable book review but also a eulogy of *Butenandt* himself—I hope he will forgive me.

The book can be recommended to everyone with an interest in scientific history, from the student to the emeritus professor. Their scientific knowledge will benefit from reading it, and it will extend their knowledge of scientific history and of the turbulent period covered by *Butenandt*'s life from

1903 onwards. Thus, *Peter Karlson*'s biography of *Adolf Butenandt* is an important book from many points of view.

Friedrich Cramer [NB1135IE]
Max-Planck-Institut für experimentelle Medizin
Göttingen (FRG)

Countercurrent Chromatography. By *W. D. Conway*. VCH Verlagsgesellschaft, Weinheim 1990. 475 pp., hardcover DM 138.00. – ISBN 3-527-26527-9

Liquid-liquid distribution, the partition of a mixture of substances between two incompletely miscible liquid phases, is an effective method for separating mixtures of involatile soluble compounds. It became important as Craig distribution and partition chromatography, and nowadays it is still the basis of many technical separation processes. Regrettably it has now been almost entirely replaced in the laboratory by modern chromatographic methods. Even today it still has potential uses in the laboratory by virtue of its excellent capabilities, especially for isolating and purifying involatile compounds on a preparative scale. Particular advantages are the ability to simply and accurately calculate the efficiency of separation, and the ease with which the method can be scaled up.

Therefore the appearance of this comprehensive review of recent developments in the field of liquid-liquid chromatography is very welcome. The main chapters of the book describe the development of countercurrent chromatography, methods for producing the flow of the phases and the centrifugal forces, liquid partition and mixing of the phases, chromatography theory, solvent systems and applications. A comprehensive and well arranged bibliography follows the main text.

The book describes the techniques and equipment for achieving chromatographic separation, usually in a helical column made of glass or plastic, without the need for a solid porous membrane between the two liquid phases. Relative motion between the phases is obtained using either gravitational or centrifugal forces. The centrifugal forces are produced by rotating the separating apparatus in various ways. The fact that so many different arrangements are described illustrates that the development of the technique is still far from finished, and it will probably be some time yet before there is a routine system that is versatile enough for general use. The systems described here are capable of separating up to 1 g of a mixture with a separation efficiency of 350 to 1000 theoretical plates. The time required to achieve separation is of the order of hours.

Although countercurrent chromatography will undoubtedly always remain a specialized technique, it is nevertheless desirable that it should become widely used. In view of the continually growing importance of methods for isolating and purifying compounds, one needs to have access to as wide a variety of efficient separation techniques as possible. The book reviewed here is a comprehensive introduction to this subject, and can be recommended.

Corrigendum

The communication entitled "Parabolic Growth of a Self-Replicating Hexadeoxynucleotide Bearing a 3′–5′-Phosphonamidate Linkage" by *G. von Kiedrowski, B. Wlotzka, J. Helbing, M. Matzen*, and *S. Jordan* (*Angew. Chem. 103* (1991) 456; *Angew. Chem. Int. Ed. Engl. 30* (1991) 423) contained an error. The values of k_a and k_b calculated for *Rebek*'s system (T. Tjivikua, P. Ballister, J. Rebek, Jr., *J. Am. Chem. Soc. 112* (1990) 1249–1250) are wrong. The following values are correct: $k_a = (4.26 \pm 0.09) \times 10^{-2}\ \mathrm{M}^{-3/2}\ \mathrm{s}^{-1}$, $k_b = (1.94 \pm 0.04) \times 10^{-3}\ \mathrm{M}^{-1}\ \mathrm{s}^{-1}$. These values are in agreement within the limits of error with those caluclated by *Rebek* on the basis of Equation (a) given in our communication (J. Rebek, private communication). The value for ε is therefore not 80—as given in the text—but 22. For the exponential model (note [9] in our communication), the regression coefficients are $k_a = (5.20 \pm 0.24) \times 10^{-1}\ \mathrm{M}^{-2}\ \mathrm{s}^{-1}$ and $k_b = (2.56 \pm 0.07) \times 10^{-3}\ \mathrm{M}^{-1}\ \mathrm{s}^{-1}$; the sum of least squares exceeds that of the square-root model by a factor of 4.6. The other information in this communication is not affected.

The Isocyanide–Cyanide Rearrangement; Mechanism and Preparative Applications**

By Christoph Rüchardt,* Michael Meier, Klaus Haaf, Joachim Pakusch, Erwin K. A. Wolber and Barbara Müller

Dedicated to Professor Horst Prinzbach on the occasion of his 60th birthday

Until recently the isocyanide–cyanide rearrangement was of interest almost solely as an example of a unimolecular gas-phase reaction, and kinetic studies had been carried out in only a few simple cases. Kinetic measurements in solution were made possible only by the discovery and suppression of a parallel free-radical chain process which leads to the same products. The rate of the isomerization is almost independent of the structure of the starting material and of the substituents present. An exception is provided by extreme steric hindrance in three dimensions which, as in tris-α-substituted triptycyl isocyanides, leads to a considerable increase in the activation energy. The results can be interpreted in terms of a purely sigmatropic mechanism, as predicted by ab initio calculations. The preparative application of this rearrangement reaction requires the suppression of side reactions and can best be carried out by flash pyrolysis; yields are then almost quantitative. Allyl isocyanides react without allyl isomerization, optically active isocyanides with complete retention of configuration. New, economically interesting syntheses for the known nonsteroidal anti-inflammatory drugs ibuprofen and (*S*)-naproxene are described. The application of the useful synthetic building blocks, the optically active β-acyloxy cyanides, which are formed from optically active α-amino acids, will be demonstrated.

1. Introduction

Organic isocyanides **1** were known as early as the middle of the last century,[1] mainly because their characteristic and obnoxious smell demonstrated their formation in the course of unsuccessful attempts to form cyanides **2** from alkyl halides and silver cyanide. However, their exact structure[1] could only be determined when modern spectroscopic methods were introduced. Hückel, MNDO, and finally ab initio MO calculations[2] led to a clarification of the bonding situation. Results obtained for methyl isocyanide are given in

While the chemistry of the isocyanides has received fresh impetus since the introduction of practicable synthetic meth-

3

ods such as the dehydration of formamides as described by *Ugi* et al.,[4] the history of the isocyanide–cyanide rearrangement goes back to the last century;[5] preparative applications of the reaction were, however, almost unknown at that time.[7] *Weith*[8] showed in 1873 that the evil-smelling phenyl isocyanide **4** formed in the reaction of aniline with $CHCl_3$ and KOH was transformed by heating into the much less odorous phenyl cyanide **5**.

4 **5**

At an early stage this reaction was grouped together with the known 1,2-rearrangements such as the Wagner–Meerwein, Beckmann, Curtius, or Criegee rearrangements;[9, 10] it has more recently been compared to the Lewis–Zollinger isotopomerization of the aromatic diazonium ions (isoelectronic to the isocyanides) which occurs during hydrolysis to phenols[5] [Eq. (a)] and the corresponding thermal rearrangement of acetylenic anions[5] [Eq. (b)].

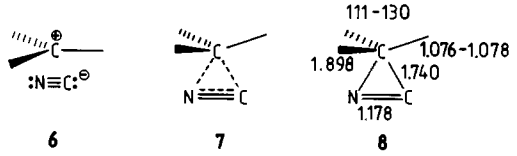
(b)

2. Reaction Mechanism and Transition State

Formulations of the transition state for the isocyanide–cyanide rearrangement were considered at an early stage, particularly for comparison with the known 1,2-sextet rearrangements; they can be discussed in terms of the two alternative extreme formulations **6** and **7** (Fig. 2).



6 **7** **8**

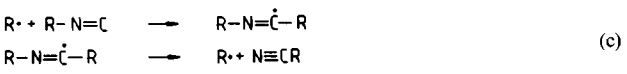
Fig. 2. Suggested structures for the transition state in the rearrangement of methyl isocyanide to acetonitrile. **6**: π-complex with hypovalent, carbenium-like, migrating C atom; **7**: sigmatropic transition state with hypervalent five-bonded (carbonium-like) migrating C atom; **8**: results of ab initio calculations [11]. Bond lengths in Å and angles in degrees.

Detailed studies carried out by the group of *B. S. Rabinowitch* in the 1960's[5] used the thermal rearrangement of methyl isocyanide, and later ethyl isocyanide, to check the RRKM theory[6] of the chemical kinetics of unimolecular gas-phase reactions. The rearrangement is ideal for this purpose; it is a quantitative, uncatalyzed, and homogeneous first-order gas-phase reaction. Kinetic measurements were carried out across a wide range of pressure and temperature, and the typical decrease of the reaction rate and the corresponding increase of the activation energy with increasing pressure were verified by the RRKM theory. It was necessary to assume a three-membered transition state **7** with defined geometric parameters. The agreement between experiment and theory was confirmed by the measurement of kinetic isotope effects,[5] kinetic shock tube experiments[5] and studies of thermal explosions.[12] Without recourse to the assumptions of the kinetic gas theory, *H. F. Schaeffer III* et al. calculated the transition state for the methyl isocyanide rearrangement using ab initio methods and the gradient technique for geometry optimization.[11] The calculated transition state is compatible with the findings of *Rabinovitch* et al., although the bond lengths and angles differ considerably.

The structural parameters for methyl isocyanide and methyl cyanide (see Fig. 1) and for the transition state **8** for the rearrangement predicted by ab initio calculations[2, 11] are striking in that the migrating methyl group maintains its H–C–H bond angle of 109° throughout the reaction, while the N–C triple bond is elongated by only 1% in the transition state. The activation energy calculated by *Schaeffer III* et al. (E_a = 40.9 kcal mol^{-1})[11] agrees relatively well with the experimental value of 38.4 kcal mol^{-1}.[13] The calculations[11] also predict that there will be no charge separation in the transition state, which thus corresponds much more closely to **7** than to **6**.

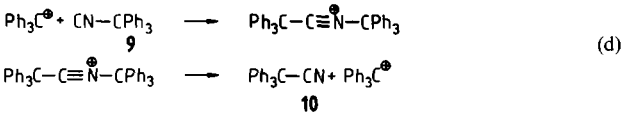
Christoph Rüchardt was born in Munich in 1929. He studied chemistry at the Ludwig-Maximilian University in Munich and the University of Georgia in Athens, gaining the degrees of M.Sc. (1952), Dipl.-Chem. (1954), and Dr. rer. nat. (1956), the latter under the supervision of R. Huisgen. From 1957–1959 he worked as a postdoctoral fellow at Harvard University with P. D. Bartlett and at the California Institute of Technology with J. D. Roberts. After his habilitation in Munich (1963) he accepted a chair of organic chemistry at the University of Münster in 1968. In 1972 he moved to the University of Freiburg, where he has been Rector since 1987. Rüchardt is a member of the Heidelberger Akademie der Wissenschaften. His main research interests involve reaction mechanisms, free radical chemistry, questions involving bond dissociation, and stereochemistry.

Attempts to verify these predictions by a kinetic determination of the dependence of the reactivity on the structure of the isocyanide were initially subject to difficulties.[14] The results obtained when the reaction was carried out *in solution* in glass ampules were often not reproducible and were dependent on the concentration, the solvent, and the degree of care taken in degassing the solution. The activation entropy was strongly negative, the reaction order higher than unity, and additional reaction products were formed in a side reaction. Under these conditions the sigmatropic reaction was accompanied by a free radical chain process leading to the same reaction products;[5, 15] this process is probably initiated by autoxidation steps, as indicated by the fact that extremely careful degassing can eliminate the unwanted side effects [Eq. (c)]. The two chain steps, free radical addition to the isocyanide and subsequent β scission, led to the formation of the cyanide.



(c)

The free radical reaction was also eliminated by the addition of 1,1-diphenylethene or 3-pyridyl cyanide as inhibitors.[15, 16] Under these conditions at 200–220 °C the rearrangement generally occurs almost quantitatively, so kinetic measurements in solution are possible. A side reaction which occurs in certain cases was observed during the isomerization of triphenyl isocyanide **9** to triphenylacetonitrile **10** [Eq. (d)].[17] This cationic chain reaction[18] can also lead to an extreme acceleration of the reaction, particularly when catalyzed by Lewis acids. The addition of ethanol as a cation trap thus leads to the stabilization of these isocyanides.[18]



(d)

The isomerization of cumyl isocyanide and the highly sterically congested aliphatic *tert*-alkyl isocyanides is apparently also perturbed by this cationic side reaction. In contrast β elimination appears to occur only very seldom, since the yields of cyanide are generally almost quantitative.[7, 10]

The first kinetic studies were carried out by *Casanova* et al.,[19] in diglyme as solvent but without the addition of a radical inhibitor; as for the Curtius rearrangement,[10] almost no difference in reactivity between methyl, ethyl, isopropyl, and *tert*-butyl isocyanide was observed (see Table 1). However, the reaction rate increases greatly within this series for both the Beckmann and Criegee rearrangements, since in these reactions there is a charge separation in the transition state (as in **6**).[10] The slight fall in reactivity exhibited by secondary and tertiary alkyl isocyanides could be due to a steric effect which inhibits the formation of the three-membered transition state (**7**).

Table 1. Relative reactivities of various isocyanides R–NC in diglyme at 200 °C [19].

R	Me	Et	*i*Pr	*t*Bu	C_6H_5	*p*-ClC_6H_4	*p*-$CH_3C_6H_4$
k_{rel}	5.6	7.8	2.6	≡ 1.0	20.6	18.2	23.8

The absence of charge separation in the transition state was also demonstrated by the absence of a polar substituent effect on the isomerization of aryl isocyanides (Table 1).

The ready isomerization of cyclobutyl isocyanide (without any formation of cyclopropylcarbinyl or homoallyl cyanide) has been considered a further argument against the transition state **6**.[19] This is, however, by no means conclusive, since the cyclobutyl residue also remains unchanged during the 1,2-shift of the Beckmann and Criegee rearrangements. The observation of *partial* retention of the stereochemistry of optically active 2-butyl isocyanide during the isomerization to the cyanide[19] is also a poor mechanistic criterion for

Table 2. Free activation energies $\Delta G^{\neq}$(250 °C) [kcal mol^{-1}] and reaction rates $10^4\,k_1$ [s^{-1}] at 210 °C of the isocyanide-cyanide rearrangement in hexadecane, dodecane or mesitylene [10]; % yield denotes the preparative results of flash pyrolysis experiments [7].

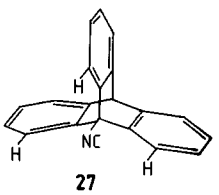
[a] In solution under kinetic conditions. [b] Triptycene derivatives are named as in Chemical Abstracts.

the structure of the transition state, since the migration occurs with *complete* retention during the Beckmann and Criegee rearrangements. Possibly the conditions used by *Casanova*[19] did not completely suppress the free radical chain reaction leading to racemization [Eq. (c)].

A more recent, wide-ranging kinetic study[10, 20, 21] of the electronic and steric effects on the reactivity of aliphatic and aromatic isocyanides presents reliable experimental criteria for the definition of the structure of the transition state of the isocyanide-cyanide rearrangement (Table 2). The separation of $\Delta G^{\neq}$ into $\Delta H^{\neq}$ and $\Delta S^{\neq}$ is not taken into account in Table 2 (see refs. [10, 20, 21]), since in all cases $\Delta S^{\neq}$ lies close to zero ($0 \pm 3\,J\,K^{-1}\,mol^{-1}$).

As expected, α branching slows the reaction rate though only by a factor of 16 (see entries **11**–**13**). The small effect of the β branching, particularly in **15**, indicates that in the transition state the presence of two bulky α substituents does not lead to additional steric interactions because one is situated in front of and the other behind the plane of the ring (see Fig. 2). It was unfortunately not possible to measure the kinetics of isomerization of $(t\mathrm{BuCH_2})_2\mathrm{C(CH_3)NC}$ (**56**), because product analysis showed that under these conditions β elimination and/or ionic chain decomposition has a disturbing effect.[22] The small influence of branching on the reaction rate supports transition state **7** rather than **6**, since in the latter the bond angles at the migrating C-atom should increase, thus leading to back-strain effects (i.e., an increase in rate due to release of steric compression at the back side of the reaction center by an increase in the bond angles). The behavior of the cyclic isocyanides **21** and **22** agree with this hypothesis.

A particularly significant argument against charge separation in the transition state is provided by the lack of influence of α-aryl and α-carbomethoxy groups on the reactivity (cf. **9**, **18**–**20**). The small increase in reactivity of the triphenylmethyl isocyanide **9** compared with *tert*-octyl isocyanide **13** (less than a factor of 4) and the lack of a substituent effect (**18**, **19**) can only be interpreted in terms of the hypervalent transition state **7** with a pentacoordinate carbon atom which is incapable of further conjugation.

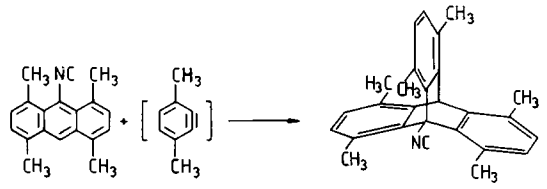


27

The lack of change of the H–C–H angle at the migrating C atom becomes clear from the reactivity of the bridgehead isocyanides **23**–**27**. Apart from 9-triptycyl isocyanide (**27**), these rearrange at rates which do not differ significantly from that of the open-chain *tert*-octyl isocyanide **13**; virtually no other reactions are known which do not exhibit a bridgehead effect.

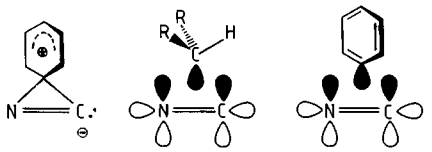
The unusual behavior of **27**, which reacts 200 times more slowly than the other bridgehead isocyanides, but only 600 times more slowly than triphenylmethyl isocyanide **9**, cannot be due to an electronic aryl effect. Instead an explanation was sought in the steric congestion in three dimensions caused by the hydrogen atoms in β positions to the NC group. This hypothesis was confirmed by the investigation of the rearrangement of the hexamethyl derivative, **28**.

The hexamethyltriptycyl isocyanide (**28**) was prepared, though only in poor yield, from 1,4,5,8-tetramethyl-9-anthryl isocyanide (**34**). On heating to 250–300 °C this isocyanide, which is strongly sterically hindered in *three* dimensions, isomerizes quantitatively to the corresponding cyanide.[23] The activation energy required to form the transition state is 4.5 kcal mol^{-1} higher than for **27**.[23b] The temperature at which the half-life is 1 h, differs by almost 60 °C for the two isocyanides (303 and 361 °C), which emphasizes that the three-membered ring of the transition state can no longer avoid strong steric repulsions due to the β-methyl groups. Thermochemical calculations show that the C–NC bond dissociation energy for aliphatic isocyanides is about 100 kcal mol^{-1},[20, 23b] so that even in the case of **28**, the most stable of all known isocyanides, an alternative dissociation–recombination reaction mechanism is out of the question.



34 **28**

It is amazing that aromatic isocyanides are only slightly more reactive than their aliphatic counterparts (cf. **29** and **11**), that polar substituent effects are small (see Tables 1 and 2), and that the introduction of bulky groups into *ortho* positions of phenyl isocyanide (**4**) or in positions 1 and 8 of 9-anthryl isocyanide (**33**) lowers the reactivity only minimally (cf. **30**–**32** and **34**). The phenonium-like transition state (**35**) postulated for most electron sextet rearrangements requires charge separation and can therefore be excluded. Thus, both the aliphatic and the aromatic rearrangements pass through a hypervalent three-center transition state (**36** or **37**). One of the resulting advantages is the avoidance of charge separation.



35 **36** **37**

In the aliphatic case (**36**) a gauche arrangement of the two groups R leads to minimal steric interactions with the NC group; in the aromatic case (**37**) the preferred conformation involves an orthogonal arrangement of the three-membered ring and the aromatic ring. Otherwise *ortho* substituents would give rise to a more pronounced decrease in reactivity due to steric effects, as is shown by hexamethyltriptycyl isocyanide **28**. The effect of two *ortho tert*-butyl groups in **32** is, in contrast, surprisingly small. The greater reactivity of the aromatic isocyanides compared with that of the aliphatic

compounds, in spite of the loss of conjugation energy in the transition state, is probably explained by the smaller steric interactions in the transition state of the aromatic isocyanide. A further advantage of the sigmatropic reaction pathway via **37** is that the aromatic π system remains almost unperturbed.

Aliphatic and aromatic isocyanides also differ only very little in their heats of isomerization. More recent experimental results[24] for mesityl isocyanide (**30**, $\Delta H_{isom} = -19.8\ kcal\,mol^{-1}$), 1-adamantyl isocyanide (**23**, $-19.3\ kcal\,mol^{-1}$), and 1-norbornyl isocyanide (**25**, $-21.7\ kcal\,mol^{-1}$) are in agreement with older values for methyl isocyanide ($-23.7\ kcal\,mol^{-1}$) and ethyl isocyanide ($-21.5\ kcal\,mol^{-1}$); the latter were obtained from controlled thermal explosion experiments.[25] The conjugation energy of the cyanide and isocyanide groups with the aromatic ring is apparently very similar.

The isocyanide–cyanide rearrangement of aliphatic and aromatic isocyanides is thus characterized by an amazingly small dependence of the reactivity on the structure of the substrate. Almost all the compounds in Table 2 react in virtually quantitative yields at between 210 °C and 250 °C with $\tau_{1/2} = 1$ h under the special conditions of the kinetic measurements in solution (addition of inhibitor, degassed solution). This is, however, apparently not the case for isocyanide groups attached to heteroatoms, such as trimethylsilyl isocyanide **38**; this compound is reported to be in equilibrium with the cyanide **39** at room temperature.[26]

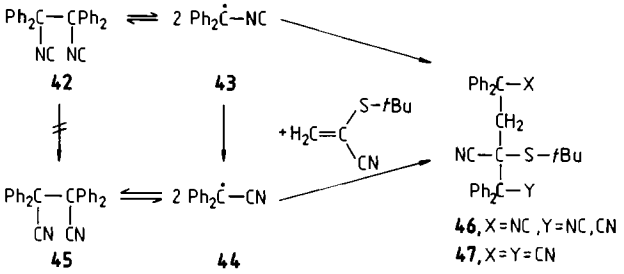
$$(CH_3)_3Si{-}NC \rightleftharpoons (CH_3)_3Si{-}CN$$
38 **39**

Isocyanide groups attached to carbanionic or free radical C atoms also appear to isomerize more rapidly. The isomerization energies of the isocyanomethyl anion and the α-isocyanomethyl radical were estimated from thermochemical data (-25.5 and $-14.3\ kcal\,mol^{-1}$ respectively).[20, 27] α-Lithiated isocyanides are important organometallic intermediates which can be handled at room temperature.[1, 28] However, the phosphorus ylide anion **40**, which has a structural element similar to an α-metalated isocyanide, isomerizes to **41** at 70 °C.[29]

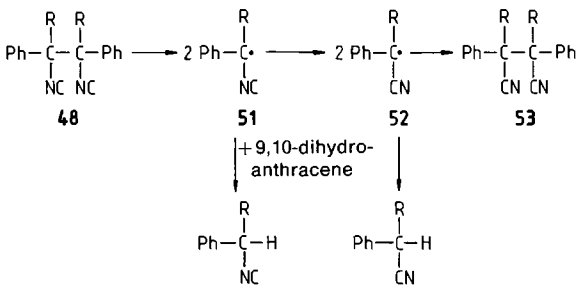
$$(C_6H_5)_3\overset{\oplus}{P}{-}\overset{\ominus}{C}H{-}NC \longrightarrow (C_6H_5)_3\overset{\oplus}{P}{-}\overset{\ominus}{C}H{-}CN$$
40 **41**

The isomerization of α-isocyanoalkyl radicals was studied recently in a kinetic competition system.[20] Evidence for their isomerization had previously been observed by *U. Schöllkopf* and co-workers,[30] who were, however, not able to provide a reliable mechanistic interpretation.

Heating the diisocyanide **42** to 60 °C led to the formation of 38% 1,2-dicyanotetraphenylethane as well as four uncharacterized by-products (thin-layer chromatography). Since the isocyanide–cyanide rearrangement normally occurs at or above 200 °C, independent of the structure of the starting material, these results indicate an isomerization pathway involving primary homolysis of the C–C bond in **42** to give α-isocyanodiphenylmethyl radicals **43**, which isomerize at 60 °C to α-cyanodiphenylmethyl radicals **44**. The latter are known to be in equilibrium with **45** under the reaction conditions.[31] Since isocyano groups stabilize alkyl radicals less well than cyano groups (resonance energy $H_r = 2.5 \pm 0.7$ and $4.1 \pm 0.5\ kcal\,mol^{-1}$),[20] the isomerization should occur in the direction **43** → **44**. When **42** was heated in an ESR spectrometer, the primary spectrum observed was that attributable to **43**, which was then completely transformed into one corresponding to **44**.



The thermolysis of **42** in the presence of a 25-fold excess of α-(*tert*-butylmercapto)acrylonitrile led to the formation of the adducts **46** and **47** in 97% yield. In the presence of 9,10-dihydroanthracene as an H donor the 1,2-diisocyanides **48a–c** similarly yielded the nonisomerized and isomerized products **49** and **50** derived from the radicals **51** and **52**; in the absence of the H donor **53** is formed. Although the system for $R = CH_3$ (**48a**) could unfortunately not be analyzed quantitatively since **49a** also rearranged slowly to **50a** under the reaction conditions, it has the advantage of being least affected by side reactions. The differing yield ratios of **50**:**49**

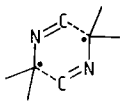


a, R = CH_3 (196 °C)	23%	50%
b, R = C_2H_5 (171 °C)	26%	35%
c, R = iC_4H_9 (138 °C)	3%	14%

can be understood in part when the longer lifetime of the radicals **51** at lower temperatures (where trapping is slower) is taken into account: the ratio **52**:**51** increases while the side reactions of **51** which decrease its yield also become more important. Independent experiments reveal that the radicals **52** are less prone to side reactions. On the other hand, these trapping experiments demonstrate that free radicals **51** can isomerize at relatively low temperatures during their short lifetime in this system. The rate of the isomerization is thus considerably higher than that of saturated isocyanides.

More difficult to understand is the observation that the synthesis of the isocyanides **48** via oxidation of the lithiated

isocyanides **49** at −70 °C by 2,3-dibromo-2,3-dimethylbutane gives the corresponding cyanide **53** as well as the required isocyanide **49**. The dimerization possibly occurs within the organometallic aggregates and involves complex mechanisms which open new avenues for isomerization, for example, through formal recombination of radicals and "carbanions" to give dimeric radical anions.[32] *Kehne*[30] has, however, suggested that the radical dimerization of **51** could also be accompanied by rearrangement (Scheme 1).

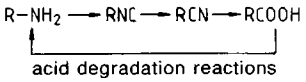


Scheme 1. Possible explanation for the formation of **53** in the synthesis of **48** from **49**.

This could explain why the synthesis of the isocyanides **48** only yielded 1,2-dicyanoethanes **53**, but no mixed dimers.

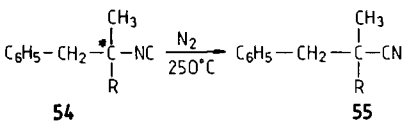
3. Preparative Application

Why did (until very recently) the isocyanide–cyanide rearrangement fail to find a place in the synthetic chemist's arsenal of preparative methods?[7] The reaction offers an additional method for chain extension and is in principle the reverse of the well-known degradation reactions of the Curtius, Hoffmann, and Lossen types (Scheme 2).



Scheme 2. Isocyanide–cyanide rearrangement as reverse of common degradation reactions.

One reason is no doubt the formerly difficult preparation of isocyanides;[4] a second lies in the high reaction temperatures (>200 °C). These require the use of high-boiling solvents, which often lead to separation problems during workup. In addition, *Yamada* et al. have shown[33] that under these conditions the formation of cyanides from optically active amines is accompanied by extensive loss of the optical activity. This is not due solely to a base-catalyzed racemiza-

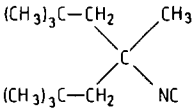


54 **55**

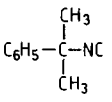
	% retention in diphenylether	% retention no solvent
a, R = $COOC_2H_5$	9	0
b, R = C_2H_5	90	47

tion of the cyanides, since *tert*-isocyanides such as **54** also react to give partially racemized **55**. Thus the rearrangement of the isocyanides **54a** and **54b** gave **55a** and **55b** in over 75% yield, but with considerably lower optical activity.[33]

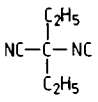
The key to understanding and overcoming this preparative disadvantage was provided by our observation that the optical yields were always higher when working in solution than in the absence of solvent. This led to the suggestion that the free radical chain reaction (c) competes under these conditions with the stereospecific rearrangement and that the racemization occurs at the free radical stage. Because of its higher reaction order, the chain reaction dominates to a greater degree at higher concentrations than in more dilute systems. This hypothesis agreed with the results of stereospecific isocyanide rearrangements at very high temperatures (270–310 °C).[34] Either these reactions took place in the gas phase, or an increase of the reaction temperature accelerated the first-order reaction more than it did the radical chain process. Our hopes of overcoming these disadvantages for the application of the isocyanide rearrangement in synthesis by recourse to flash pyrolysis were indeed realized, as shown by the yields documented in Table 2:[7] in all cases they are ca. 90% or higher. The unwanted chain reaction is suppressed by working in the gas phase at 10^{-2} torr, while at the high reaction temperatures (520–550 °C) the unimolecular rearrangement is favored over potential side reactions such as β elimination because its activation entropy is very close to zero. Since all isocyanides react at comparable rates the standard conditions described above apply to a wide range of substrates. The required equipment is readily available[7, 35] and can be dimensioned to convert 20 g isocyanide to the cyanide in ca. 30 min[36] with ease. Extremely sterically hindered compounds also react very readily, as is demonstrated by the simple synthesis of 2,4,6-tri(*tert*-butyl)phenyl cyanide.[21] Yields of the cyanide are high even in those cases which were shown to be accompanied by large amounts of by-products under the conditions used in the kinetic studies, for example, isocyanides **56** (93% cyanide),[22] **57** (77%), and **58** (85%).[20]



56



57



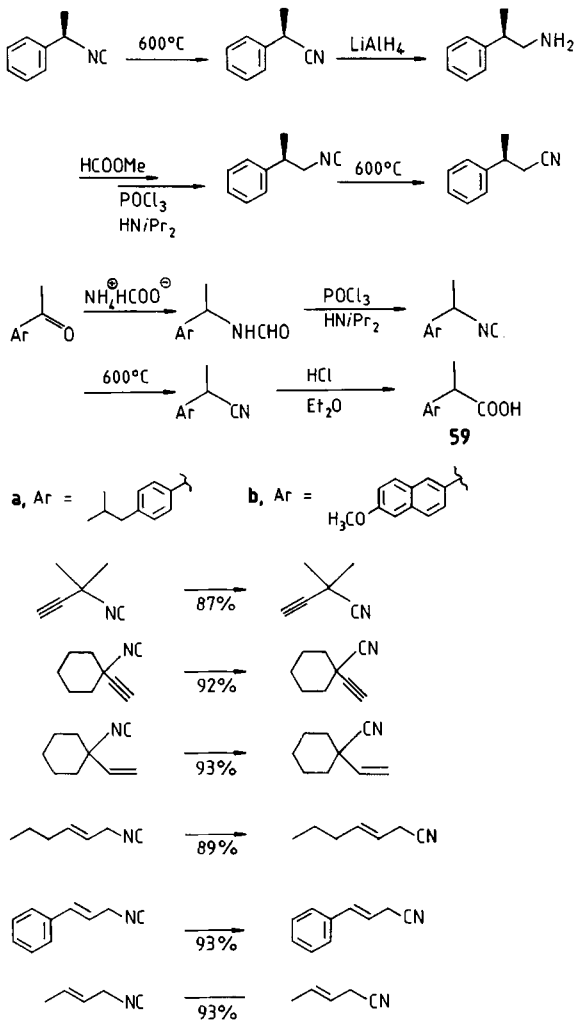
58

However, the isomerization of 2-phenylcyclopropyl isocyanide[7] and of 1-homocubyl isocyanide[7] was accompanied by ring opening reactions. Some examples of preparative applications for chain extension are shown in Scheme 3.[37]

A new simple approach to α-alkylphenylacetic acids, which are important as antipyretics and insecticides of the pyrethroid type,[38] is particularly attractive. Examples are the high-yield syntheses of ibuprofen **59a** and naproxene **59b**.[39]

For less volatile isocyanides, flash pyrolysis can be replaced by short contact flow thermolysis, although the yields are lower.[7, 35]

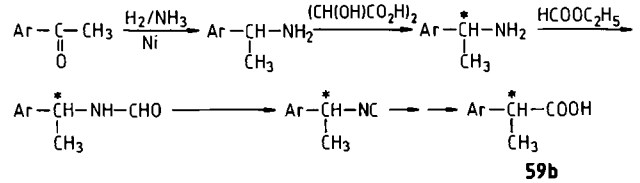
Under these novel reaction conditions the isocyanide–cyanide rearrangement has two additional important synthetic advantages: allyl and propargyl isocyanides react without allyl isomerization (see examples in Scheme 3); this



Scheme 3. Examples for the use of the isocyanide–cyanide rearrangement for chain extension.

is an advantage offered by only few reactions, in particular sextet rearrangements.

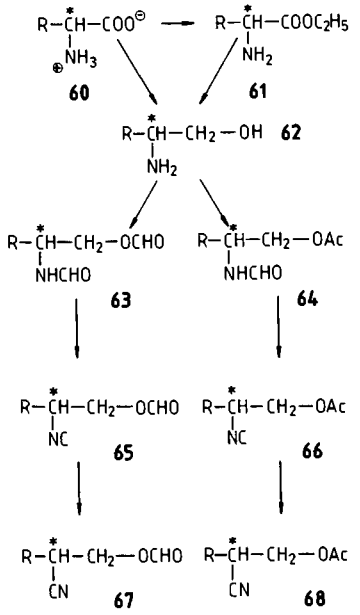
The second advantage is the ability to convert optically active amines into cyanides, and thus to carboxylic acids, without racemization. Amines can in general be readily separated into their enantiomers by classical racemate separation methods, while the "wrong" enantiomer can probably be racemized under the conditions of a Leuckart–Wallach reaction. Interesting applications are thus possible, independent of the modern methods for the synthesis of enantiomerically pure amines. An example of potential industrial importance is the preparation of the important nonstereoidal anti-inflammatory drug naproxene (**59b**) in the form of the pure (*S*)-enantiomer (Scheme 4);[39] a technical stereo-



Scheme 4. Synthesis of (*S*)-naproxene (**59b**) by using the isocyanide–cyanide rearrangement.

specific synthesis for the latter has been described only very recently.[38]

Finally the next step was to develop new synthetic building blocks and new syntheses starting from naturally available optically active amines, in particular from α-amino acids (**60**). Since isocyanides derived from esters of α-amino acids cannot be handled without racemization because of the high acidity of the α-hydrogen atoms,[7, 36] we prepared optically active β-amino alcohols (**62**) by reduction of the amino acids



or their esters (**61**); these were either diformylated in one step to give **63** or successively formylated and acetylated to give **64**.[36, 40] These compounds can be converted by standard

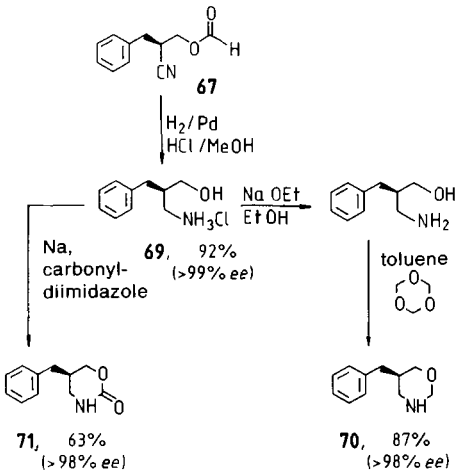
Table 3. Preparation of β-acyloxy cyanides **67** and **68** from optically active α-amino acids **60** by flash pyrolysis of the β-acyloxy isocyanides **65** and **66** [36].

Amino acid	Reaction steps	β-Acyloxy-cyanide	Yield for rearrangement [%]	Total yield [%]
(*S*)-phenylalanine	4		83	54
(*S*)-leucine	6		90	61
 (*S*)-alanine	6		91	50
 (*S*)-tyrosine	7		93	47
 (*S*)-lysine	5		83	55
 (*S*)-aspartic acid	8		93	52

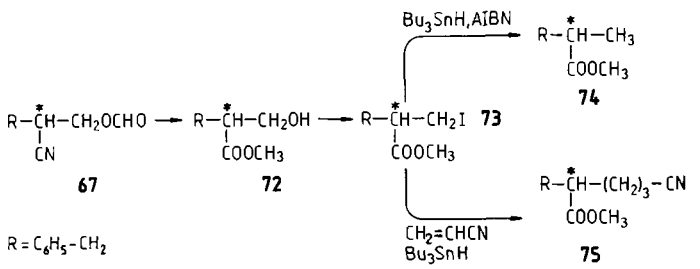
methods into the isocyanides **65** and **66**, flash pyrolysis of which gives the cyanides **67** and **68** in 70–93% yield; ester pyrolysis was observed as a side reaction. The yields obtained for various types of amino acid are shown in Table 3. The techniques used for the protection of the functional groups and the reaction conditions optimized for each particular amino acid[43] will not be discussed here. The overall yields of the optically pure β-acyloxy cyanides **67** and **68** of 47–61% indicate the considerable potential of this synthetic sequence.

The use of **67** (R = benzyl) will be given here as an example of the application of these new synthetic building blocks in further chemical transformations.

1. Reduction of **67** with H_2/Pd and subsequent hydrolysis to give the aminoalcohol **69** (92%) can be followed by cyclization either with formaldehyde to give (*R*)-5-benzyl-1,3-oxazinane **70** (87%) or with carbonyl diimidazole (di-1-imidazolyl ketone) to give (*R*)-5-benzyl-1,3-oxazinan-2-one **71** (63%); both products are optically pure.

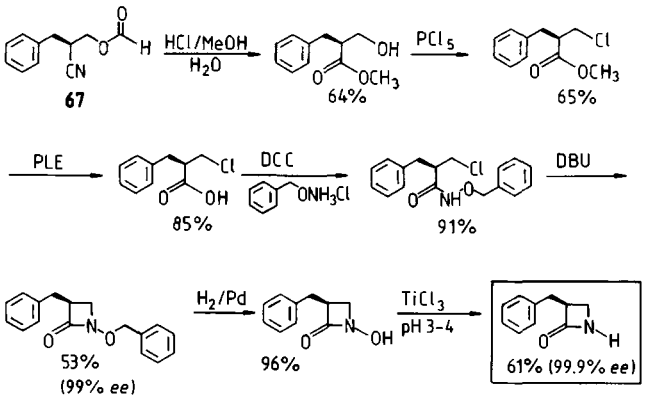


2. Cyanide **67** can be converted by a Pinner reaction into the β-hydroxymethyl ester **72**,[40] which in turn was treated with I_2/PPh_3/imidazole to give the β-iodomethyl ester **73**.[36] Iodine can be removed by the tributyltin hydride reduction,[41] giving the optically active α-methyl-β-phenylpropionate **74**. The iodide **73** can also undergo reductive addition



to acrylonitrile in the presence of tributyltin hydride according to *Giese*'s procedure,[42] affording an enantiomerically pure product **75**.[36]

3. Finally, we were also able to transform the acyloxycyanide **67** (from phenylalanine) through a well-developed synthetic sequence[40] into the optically pure 3-benzyl β-lactam. Corresponding β-lactams were also prepared from alanine and leucine.[36]

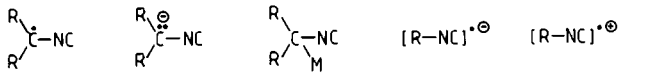


Scheme 5. Synthesis of β-lactams starting, in effect, from phenylalanine. PLE = pig liver esterase, DCC = dicyclohexyl carbodiimide, DBU = 1,8-diazabicyclo[5.4.0]undec-7-ene.

4. Summary and Future Prospects

The development of the methodology for the preparative application of the isocyanide–cyanide rearrangement provides a process for chain extension of amines and ketones (subsequent to Wallach-Leuckart reduction) to give cyanides and carboxylic acids; this process takes place in the opposite direction to the well-known Curtius and Hofmann degradation reactions. The wide variety of applications demonstrated here for selected examples leads us to expect that this rearrangement will soon be included in the chemist's standard repertoire of synthetic reactions.

Studies of the rearrangement for isocyanides in exceptional valence states, such as radicals, anions, α-metalated isocyanides or radical ions are still at a preliminary stage (Scheme 6).



Scheme 6. Isocyanides in exceptional valence states. M = metal.

Substantial reactivity differences are expected in this series. The isomerization of isocyanide functions bonded to atoms other than carbon has also hardly been studied as yet. The investigation of such reactions is not only of theoretical interest, but could also lead to the discovery of milder reaction conditions for the isomerization, for example, under the influence of one-electron redox catalysts.[44]

We thank Dr. Günter Range, Dr. Ingrid Mergelsberg, and Dipl.-Chem. Constantin von Kessel for important preliminary investigations, Dr. M. Schmittel for useful discussions, and the Fonds der Chemischen Industrie and the Deutsche Forschungsgemeinschaft for their support of our own work in this area of chemistry.

Strained-Ring and Double-Bond Systems Consisting of the Group 14 Elements Si, Ge, and Sn**

By Takeshi Tsumuraya, Scott A. Batcheller, and Satoru Masamune*

Dedicated to Professor Dr. Emanuel Vogel

The organometallic chemistry of the Group 14 elements E = Si, Ge, Sn in the 1980's is highlighted by the successful construction and thorough characterization of three systems previously thought to be too reactive to exist: 1) three-membered ring compounds including cyclotrisilane, cyclotrigermane, and cyclotristannane, 2) molecules containing E–E double bonds including disilene, digermene, and distannene, and 3) strained polycycles containing a skeleton of Group 14 elements, such as bicyclo[1.1.0]tetrasilane, hexagermaprismane, and octasilacubane. The majority of these numerous compounds now available are fully substituted with bulky ligands to suppress the reactivity intrinsic to the systems. These compounds permit examinations of 1) the variation of physical and chemical properties of a system with these elements and also with the ligands and 2) how two systems are interrelated thermally and photochemically with the intermediacy of the divalent (carbene-like) species. Theoretical calculations on virtually all of the parent compounds discussed in this review are evaluated alongside the experimental results. Some polycycles may constitute a stepping-stone on the way to compounds with a triple bond.

1. Introduction

Over the past decade significant and exciting progress has been made in the organometallic chemistry of Group 14 elements (E = Si, Ge, Sn). Species once thought to exist only as reactive intermediates such as divalent (carbene-like) species have been thoroughly characterized,[1] and molecules containing double bonds to Group 14 atoms (including $R_2E{=}ER_2$) have yielded to synthesis.[2] Furthermore, numerous compounds with these elements embedded in small and highly strained rings are now available.[3] Perhaps most importantly, these accomplishments have greatly enhanced our understanding of the bonding in these systems.

Our research in Group 14 chemistry was initiated in 1980 as an extension of the prior work on strained carbocyclic skeletons such as cyclobutadiene.[4] The accumulated results obtained in our and other laboratories since then clearly demonstrate that 1) the chemistry of the three-membered rings $(R_2E)_3$ is intimately related to that of the corresponding double-bond systems ($R_2E{=}ER_2$) and carbene analogues (R_2E), 2) the physical and chemical properties of these systems with Si, Ge, and Sn vary systematically with the elements in a manner consistent with theory, and 3) strained polycyclic molecules can be constructed with these elements and exhibit unique properties often unexpected from their carbogenic analogues. This review outlines the framework of this Si, Ge, and Sn chemistry, minimizing overlap in content with recent review articles on 1) E–E double-bond systems as reactive intermediates,[1d, 2d, e, 5] 2) compounds containing Si and Ge doubly bonded to other elements,[2d–f] and 3) theoretical aspects of disilenes and small ring organosilicon compounds.[6]

2. The Chemistry Known Prior to 1980

2.1. Cyclopolysilanes and Disilenes

The first attempted preparation of a disilene ($R_2Si{=}SiR_2$) was made by *Kipping* in 1911.[7] Treatment of dichloroethylphenylsilane (**1a**) with sodium metal in the manner of a Wurtz coupling reaction provided a compound which was thought to be 1,2-diethyl-1,2-diphenyldisilene (**2a**). In 1921 *Kipping* and *Sands* recorded a similar reaction of dichlorodiphenylsilane (**1b**), only to report that the product expected to be tetraphenyldisilene (**2b**) was actually a cyclopolysilane derivative according to quantitative analyses of iodine absorption.[8] The reaction product from **1b** and sodium was eventually shown to be a mixture of $(Ph_2Si)_n$ with n = 4–6

by *Gilman* et al. in the 1960's.[9] This result was consistent with *Burkhard*'s 1949 report that described the isolation of dodecamethylcyclohexasilane (**3**), the first identified peralkylcyclopolysilane, on treatment of dichlorodimethylsilane with sodium metal.[10] Such results raised serious doubt as to whether stable disilenes could exist.

Later *Kumada* and *Ishikawa* discovered that photolysis of **3** with a low-pressure mercury lamp afforded two of the lower homologues, cyclopentasilane **4** and cyclotetrasilane **5**, with the successive extrusions of dimethylsilylene **6** (Scheme 1).[11] However, hexamethylcyclotrisilane **7**, expected from the ring contraction of **5**, was not observed in this photolysis. Instead, the cyclotetrasilane underwent homolytic scission of the Si–Si bond to give a diradical which abstracted hydrogen atoms from the solvent to produce linear tetrasilane **8**.

A large number of cyclopolysilanes $(R^1R^2Si)_n$ with R^1,R^2 = alkyl or aryl and $n \geq 4$ have subsequently been constructed by the reaction of the corresponding dichlorosilanes (or, less frequently, α,ω-dihalopolysilanes) with alkali or alkaline-earth metals.[12] The ring size of the cyclopolysilanes obtained varies with the type of substituent. For instance, the reductive coupling of dichlorodimethylsilane provides mainly $(Me_2Si)_6$ as the thermodynamically controlled product,[13] while the analogous reactions of diisopropyl- or *tert*-butylmethyldichlorosilanes afford cyclotetrasilanes.[12a,d]

Thus, by 1980 numerous derivatives of the type $(R_2Si)_n$ with R = alkyl, aryl, halogen[14] and $n \geq 4$, and several parent compounds $(H_2Si)_n$ with $n \geq 5$ had been synthesized and characterized.[15] Cyclopolysilanes show characteristic properties which are consistent with the interpretation that 1) the energy of the Si–Si σ bond is high (as compared with C–C σ bonds) and 2) contiguous Si–Si bonds (as in Si–Si–Si) experience electron delocalization.[12e–h] This latter effect is manifested in the electronic and photoelectron (PE) spectra of compounds such as $(Me_2Si)n$ with n = 4, 5, and 6 and in ESR spectra of the anion- and cation-radicals derived from $(Me_2Si)_n$ with n = 5 and 6.[12e–h, 16]

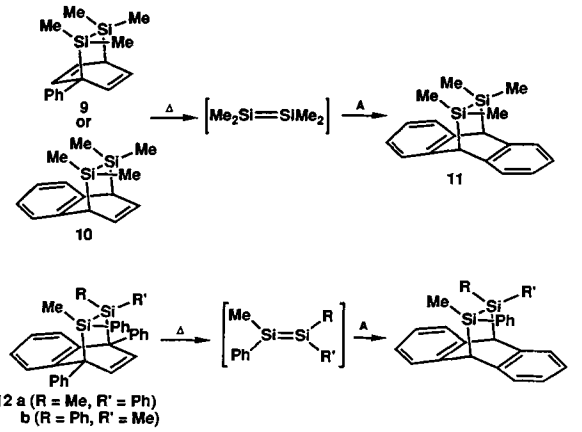
In 1969, *Peddle* et al. provided evidence for the existence of tetramethyldisilene as a transient species in the thermolysis of the compounds **9** and **10** with anthracene, isolating the Diels–Alder adduct **11**.[17] This pioneering work rekindled the investigation of disilenes, and several publications quickly appeared which supported the existence of disilenes as reactive intermediates.[18, 19] In 1979 *Sakurai* et al. reported that thermolysis of disilene precursors **12a** and **b** with anthracene provided adducts which retained the original configurations of **12a** and **b** to 95%.[19] This indicated that rotation about the Si–Si double bond was slow compared to

Satoru Masamune was born in Fukuoka, Japan in 1928. As one of the first Fulbright exchange students he pursued, and completed in 1957, Ph.D. work at the University of California, Berkeley. After temporary research appointments at the University of Wisconsin and Mellon Institute he joined, in 1964, the Faculty of the University of Alberta, Canada and stayed there until he moved in 1978 to his present location, Massachusetts Institute of Technology. He now holds the chair of the Arthur C. Cope Professorship His major honors include election to Fellow of the Royal Society of Canada (1975) and Fellow of the American Academy of Arts and Sciences (1987), The American Chemical Society Awards for Creative Work in Synthetic Chemistry (1978), the A. C. Cope Scholar Award from the American Chemical Society (1987), and selection as Centenary Lecturer of the Chemical Society, London (1980). His research interests lie in the synthesis and characterization of π-electron systems and natural products synthesis. His major accomplishments in the first area concern cyclobutadiene, [10]annulenes, the $(CH)_5^+$ pyramidal cation, and the subject discussed in this Article. Masamune's work in natural product chemistry included syntheses of diterpenes, indole alkaloids, and macrolide chemistry. The latter has led to the development of a powerful strategy in asymmetric syntheses which directed him into the field of abiotic and biotic catalysts.

Takeshi Tsumuraya was born in Ibaraki, Japan in 1962, and studied group 14 organometallic chemistry at University of Tsukuba where he completed his doctoral work in 1990 under the direction of Professor W. Ando. Since 1990 he has been a postdoctoral associate in the Chemistry Department at Massachusetts Institute of Technology and investigating germanium chemistry and then catalytic antibodies with Professor S. Masamune.

Scott A. Batcheller, born on November 1, 1961 in Cincinnati, Ohio, completed his undergraduate work at the University of Miami (Florida) in 1983 and his Ph.D. under Prof. S. Masamune at Massachusetts Institute of Technology in 1989. His thesis work primarily concerned studies on the three-membered and double-bond systems consisting of silicon and germanium. In 1989, he held a brief post-doctoral position with Cambridge Isotope Laboratories, where he synthesized organic compounds labeled with stable isotopes. Batcheller now works as a Product Development Chemist for EM Science in Cincinnati, an associate of E. Merck, Darmstadt.

the rate of cycloaddition (Scheme 2), thus demonstrating the typical π character of that bond.

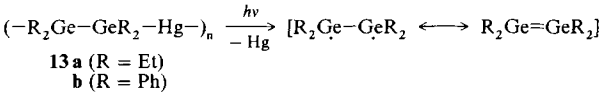


Scheme 2. A = anthracene

2.2. Cyclopolygermanes and Digermenes

In 1930 *Kraus* and *Brown* first investigated the reaction of dichlorodiphenylgermane with sodium in xylene,[20] but the main product, octaphenylcyclotetragermane, was not identified until *Neumann* and *Kühlein*'s reinvestigation, carried out in 1963.[21] Many cyclopolygermanes $(R_2Ge)_n$ with $n \geq 4$ were subsequently synthesized.[22]

Evidence seemingly consistent with the intermediacy of a digermene was presented in 1973 by *Satgé* et al. and *Mazerolles* et al.[23] Photochemical decomposition of digermylmercury compounds **13a,b** could possibly have provided digermenes or equivalent species, which were trapped by 2,3-butadione or dienes (Scheme 3). In 1976 *Lappert* et al.



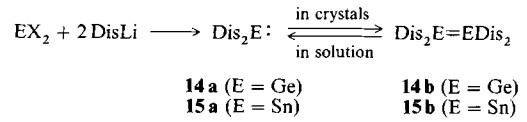
Scheme 3.

reported the preparation of bis[bis(trimethylsilyl)methyl]germanium(II) (**14a**), a stable dialkylgermylene, which dimerizes to digermene **14b** in crystalline form as confirmed in 1984 by X-ray crystal analysis (Scheme 4).[24]

2.3. Cyclopolystannanes and Distannenes

In 1852 *Löwig* prepared what was initially considered to be a divalent organotin compound by treatment of ethyl iodide with a sodium–tin alloy.[25] This product (so-called "diethyl tin") and "diphenyl tin" have since been obtained by a variety of methods. Later, *Neumann* et al. established that these compounds were mixtures of polymers which contained both straight and branched chains, including $(Et_2Sn)_5$ and $(Ph_2Sn)_n$ with $n = 5$ and 6.[26] By 1980 several cyclopolystannanes $(R_2Sn)_n$ with $n \geq 4$ had been characterized.[27]

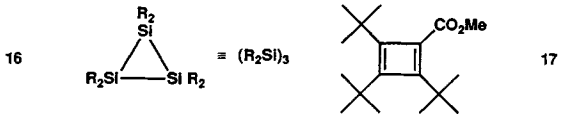
In 1973 *Lappert* et al. isolated a dialkyltin(II) compound, bis[bis(trimethylsilyl)methyl]tin(II) (**15a**) and showed by X-ray analysis that this compound exists as a dimer, distannene **15b**, in crystalline form.[24a, b, d, e, 28] Compound **15b** was the first verified example of an E–E double-bond system for the heavier elements of Group 14. However, interest in this compound was tempered because it dissociates to the monomer in solution or in the gas phase (Scheme 4). It is therefore regarded as a formal dimer of stannylene, not an authentic doubly bonded species. These compounds will be discussed in Section 5.



Scheme 4. X = Cl or $N(TMS)_2$

3. An Approach to the Construction of Reactive Systems

Prior to 1980, cyclotrisilanes such as **16** were thought to be synthetically inaccessible due to the reactivity intrinsic to this strained system. During the course of our investigation of cyclobutadienes during the 1970's we encountered a similar situation. The synthesis and characterization of cyclobutadiene derivatives were eventually achieved by attaching bulky substituents to the ring, as shown in **17**, in order to block dimerization and suppress attack by external reagents.[4, 29]



The adoption of this simple concept in Group 14 chemistry, coupled with fortuitous discovery of the photochemical conversion of **16** into the corresponding disilenes, laid the foundation for the many subsequent discoveries presented in this review.

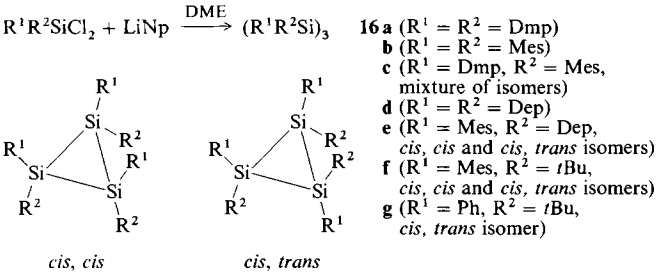
4. Cyclotrisilanes, Cyclotrigermanes, and Cyclotristannanes

4.1. Synthesis

4.1.1. Cyclotrisilanes

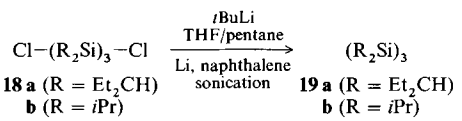
The employment of 2,6-dimethylphenyl groups as substituents on silicon and judicious selection of reaction conditions led to the first isolation of a cyclotrisilane derivative in our laboratories in the fall of 1981.[30] Thus, the reduction of dichlorobis(2,6-dimethylphenyl)silane with lithium naphthalenide (LiNp) provides hexakis(2,6-dimethylphenyl)cyclotrisilane (**16a**) in 10% yield. This compound displays long

Si–Si bond distances, a general inertness to moisture and oxygen, and temperature-dependent ^{1}H NMR spectra, all giving testimony to the high degree of steric congestion around the cyclotrisilane framework in **16a**. (Compare with the cyclotetrasilanes $(R_2Si)_4$ which react readily with oxygen if the substituents are small, e.g., R = CH_3[11].) Various other hexaaryl- and trialkyltriaryl-substituted cyclotrisilanes (**16b–g**) have since been synthesized in a similar manner (Scheme 5).[31]



Scheme 5.

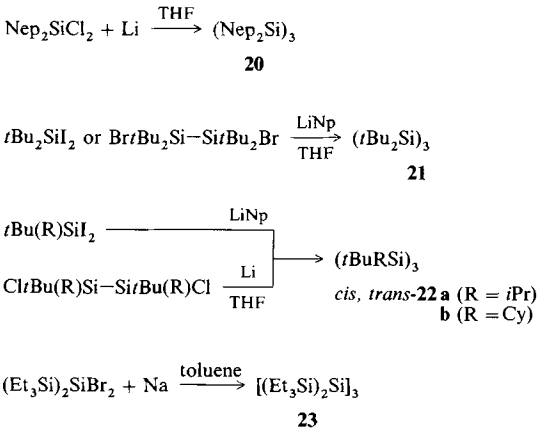
The aryl substitution of **16a** was expected to cause significant perturbation of the electronic structure intrinsic to the cyclotrisilane system. In order to eliminate this complication, the synthesis of peralkyl derivatives was undertaken. Thus, the reductive cyclization of 1,3-dichlorohexaalkyl trisilanes **18a,b** was found to proceed effectively to provide **19a,b** in 80–90% yield using a particular combination of reductants and solvents, different from that used for the synthesis of **16a** (Scheme 6).[32] In 1983 *Nagai* et al.



Scheme 6.

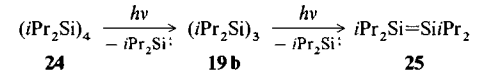
independently succeeded in the synthesis of **20**, through the reaction of dichlorodineopentylsilane with lithium (Scheme 7).[33] *Weidenbruch* et al. achieved the synthesis of the much sought hexa-*tert*-butylcyclotrisilane **21** in 1984 from the treatment of di-*tert*-butyldiiodosilane or 1,2-dibromotetra-*tert*-butyldisilane with lithium naphthalenide.[34] Interestingly, this reaction proceeds very efficiently despite the extreme steric congestion of the substituents, evidenced by extraordinarily long Si–Si and Si–C bond lengths in **21** (X-ray analysis). Replacement of one *tert*-butyl group on each silicon atom by less encumbering isopropyl or cyclohexyl groups leads to the formation of either cyclotrisilanes **22a,b** or cyclotetrasilanes depending on the reaction conditions employed.[35] A persilyl cyclotrisilane **23** has also been recently prepared by the reduction of 2,2-dibromohexaethyltrisilane with sodium.[36]

Irradiation of octaisopropylcyclotetrasilane (**24**) also reportedly provided hexaisopropylcyclotrisilane (**19b**),



Scheme 7.

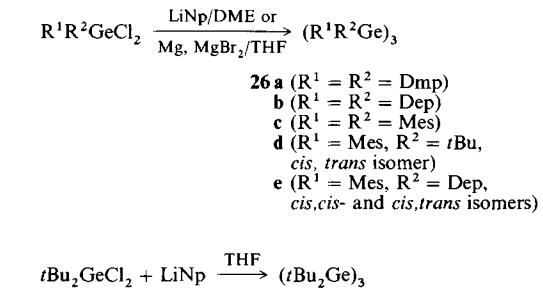
which was characterized only by UV spectroscopy (λ_{max} = 310 nm).[37] Prolonged photolysis of **24** apparently afforded disilene **25** (Scheme 8).



Scheme 8.

4.1.2. Cyclotrigermanes

In 1982 we isolated the first cyclotrigermane, hexakis(2,6-dimethylphenyl)cyclotrigermane **26a** in 17% yield, using much the same synthetic methodology developed for cyclotrisilane **16a**.[38] Similarly, cyclotrigermanes $(R^1R^2Ge)_3$ with $R^1 = R^2$ = 2,6-diethylphenyl (**26b**); R^1 = *tert*-butyl, R^2 = mesityl (*cis,trans*-**26d**); R^1 = mesityl, R^2 = 2,6-diethylphenyl (*cis,cis*- and *cis,trans*-**26e**) have also yielded to synthesis (Scheme 9).[31c,39] *Ando* and *Tsumuraya*[40] have since

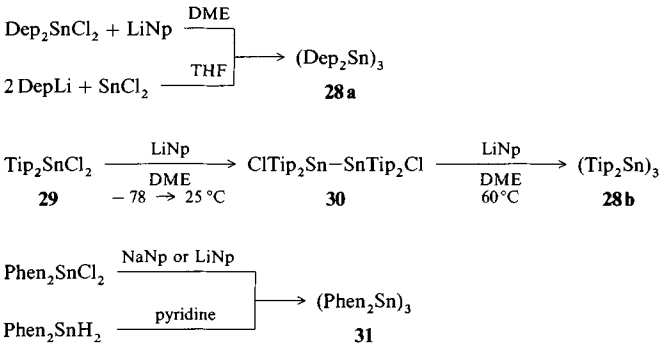


Scheme 9.

improved the synthesis of cyclotrigermanes of the type $(R^1R^2Ge)_3$ (**26a**, **26b**, and **26d**, as well as **26c**, $R_1 = R_2$ = mesityl), using Mg as a reductant. In 1988 *Weidenbruch* et al. succeeded in isolating hexa-*tert*-butylcyclotrigermane **27**, the only peralkylcyclotrigermane reported to date, by the reduction of di-*tert*-butyldichlorogermane with lithium naphthalenide.[41]

4.1.3. Cyclotristannanes

In 1983, the first cyclotristannane derivative **28a** yielded to synthesis through the same general strategy successful for the first cyclotrisilane and cyclotrigermane (Scheme 10).[42] This product can also be prepared by the reaction of 2,6-diethylphenyllithium with tin dichloride.[43] However, an interesting observation was made in the synthesis of hexakis(2,4,6-triisopropylphenyl)cyclotristannane (**28b**).[44] As shown in Scheme 10, the reaction of dichlorobis(2,4,6-triisopropylphenyl)stannane (**29**) with lithium naphthalenide provided distannane **30**, which upon further treatment with the same reductant at 60 °C (in the absence of the dichloride **29**) led to the formation of **28b**. The mechanism of this latter reaction apparently involves an equilibration between **28b** and the corresponding distannene, and is discussed in Section 5.1.3.



Scheme 10.

In 1984 *Neumann* and *Fu* reported the preparation of hexa-9-phenanthrylcyclotristannane (**31**) from either $Phen_2SnCl_2$ or $Phen_2SnH_2$.[45a] The so-called "di-(9-phenanthryl)tin" products prepared much earlier from 9-phenanthrylmagnesium bromide and tin dichloride[45b] were found to contain **31** also.[45c]

4.2. Molecular Structures

4.2.1. Theoretical Studies

Since the successful synthesis of cyclotrisilane **16a**, a number of theoretical calculations on the parent compound $(H_2Si)_3$ have appeared.[6,46] The predicted Si–Si bond distance of 2.33–2.34 Å is slightly shorter than that of cyclotetrasilane $(H_2Si)_4$ (2.37–2.38 Å) or disilane ($H_3Si-SiH_3$, 2.35 Å).[6,46,47] The calculated strain energy (SE) of $(H_2Si)_3$ is 36–41 kcal mol^{-1}, significantly larger than the 16–17 kcal mol^{-1} strain energy of $(H_2Si)_4$. This result contrasts with the observation that the analogous three- and four-membered rings are almost equally strained (ca. 27 kcal mol^{-1}) in the carbon series.[48] Similar results have been obtained for the cyclotrigermane and -stannane. The expected Ge–Ge bond distance of 2.448 Å in $(H_2Ge)_3$ is shorter than that expected in $(H_2Ge)_4$ (2.462 Å); the SE of $(H_2Ge)_3$ is calculated to be 44.6 kcal mol^{-1}, which is considerably larger than that of $(H_2Ge)_4$ (13.5 kcal mol^{-1}).[49] The Sn–Sn bond distance in $(H_2Sn)_3$ is predicted to be 2.80 Å, while that in $(H_2Sn)_4$ is estimated at 2.81 Å.[46a]

4.2.2. Observed Structures

To date the X-ray crystal structures of six cyclotrisilanes (**16a**, *cis,trans*-**16f**, *cis,cis*-**16f**, **20**, **21**, and *cis,trans*-**22b**), four cyclotrigermanes (**26a**, **26b**, *cis,cis*-**26e**, **27**), and a cyclotristannane (**28a**) have been determined. Selected data pertinent to the structures are summarized in Table 1, including bond lengths computed for the three parent compounds.

All of the crystal structures of these ring compounds show equilateral or nearly equilateral triangular Si, Ge, and Sn skeletons with E–E bonds longer than predicted for the parent compounds (see 4.2.1). The observed large bond lengths are likely due to steric congestion caused by a high degree of substitution.

Table 1. Selected structural parameters of the three-membered ring compounds $(R^1R^2E)_3$.

4.3. Physical Properties

4.3.1. Electronic Absorption Spectra

The absorption maxima of peralkylcyclotrisilanes are located above 300 nm (Table 2). By comparison, the maxima of similar linear trisilanes, for example **18a,b** and their dihydrides, and even the long linear peralkylpolysilanes, $Me(Me_2Si)_nMe$ (n = 10–24), which exhibit more red-shifted absorptions than their shorter analogues, are all under 300 nm.[12e–h, 51] The absorbances of **19b** and **20** exhibit bathochromic shifts from those of cyclotetrasilanes with the same substituents.[12a, 52] This tendency is consistent with the finding that the absorption maxima move to longer wavelengths with a decrease of the ring size (nine- to four-membered) in other series of cyclopolysilanes.[3d, 12e–h]

Table 2. Electronic absorptions of cyclotrisilanes $(R^1R^2Si)_3$.

Cpd.	R^1	R^2	λ_{max} [nm] (log ε)	Ref.

23	Et_3Si	Et_3Si	335 (3.1)	[36]

The bathochromic shift observed for peralkylcyclotrisilanes is in all likelihood caused by the weaker σ bond of the strained ring and the delocalization over the σ orbitals. In addition, the steric repulsion created by the bulky substituents results in long, weak Si–Si bonds. As the bulk of the substituents increases, the absorption maxima of the cyclotrisilanes shift to red in the order of **19b** < **19a** < **21**.

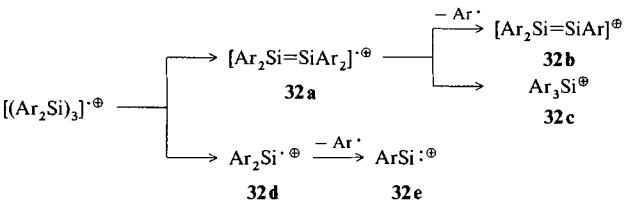
[a] The absorptions tail off into the visible region.

The arylated cyclotrisilanes also show absorptions beyond 330 nm (Table 2). Similarly, cyclotrigermanes and cyclotristannanes have intense absorptions above 300 nm (Table 3).

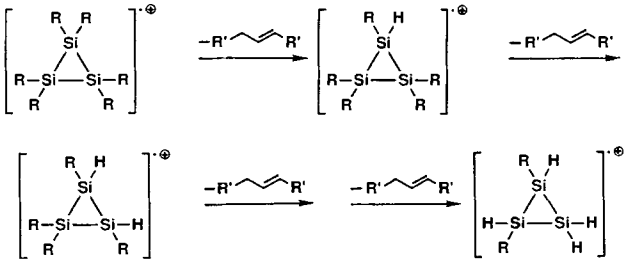
4.3.2. Mass Spectra

The electron impact mass fragmentation patterns of peralkyl and peraryl cyclotrisilanes are characteristic and distinct.[31d] The molecular ion peaks ($M^{\oplus}$) of peraryl cyclotrisilanes are either very weak or absent; predominating is the tetraaryl disilene cation-radical **32a** produced by extrusion of a diarylsilylene from $M^{\oplus}$.[30] Other characteristic fragments are the 1,1,2-triaryldisilenyl cation **32b**, the triarylsilyl cation **32c**, the diarylsilylene cation-radical **32d**, and the monoarylsilylenyl cation **32e** (Scheme 11). By contrast, the $M^{\oplus}$ peaks of peralkylcyclotrisilanes are typically strong.[32] The dominant mode of fragmentation in this case



Scheme 11. Fragmentation of perarylcyclotrisilanes in the mass spectrometer.

appears to be the loss of a substituent as the corresponding alkene; the three-membered ring apparently remains intact upon electron impact (Scheme 12). The mass spectra of the trialkyltriarylcyclotrisilanes show both of the fragmentation patterns mentioned above.[31b]



Scheme 12. Fragmentation of peralkylcyclotrisilanes **19a** and **19b** in the mass spectrometer. **19a**: R = Et_2CH, R′ = CH_3; **19b**: R = *i*Pr, R′ = H.

Cyclotrigermanes and -stannanes exhibit similar tendencies in their electron impact mass spectra.[38, 42]

4.3.3. NMR Spectroscopy

Most of the known aryl-substituted three-membered ring compounds show temperature-dependent ^1H NMR signals, indicating hindered rotation of the aromatic rings around the axis of the $M–C_{Ar}$ bond.[30, 38, 42]

As shown in Table 4, ^{29}Si nuclei in cyclotrisilanes are relatively shielded. Chemical shift values fall between $\delta = -30$ and -80 for alkyl-[33a] and aryl-substituted[53] cyclotrisilanes and $\delta = -174.38$ for persilylated cyclotrisilane **23**.[36] The $^1J_{^{29}Si-^{29}Si}$ coupling constant in cyclotrisilanes can be as small as 24.1 Hz,[54] compared to typical ^1J values of 55–70 Hz in unstrained Si–Si bonds.[54, 55] These observations

Table 4. ^{29}Si chemical shifts of cyclotrisilanes $(R^1R^2Si)_3$.

Cpd.	R^1	R^2	$\delta(^{29}Si)$	Ref.
16d	Dep	Dep	−50.8	[53]
cis,cis-**16e**	Mes	Dep	−52.69	[31c]
20	Nep	Nep	−81.68	[53]
cis,trans-**16g**	Ph	*t*Bu	−33.42, −37.33	[54]
23	Et_3Si	Et_3Si	−174.38	[36]

are consistent with the view that the magnitude of ^1J is correlated to the amount of s character of the silicon ring orbitals. This will be discussed further in Sections 5.3.2 and 9.1.

^{119}Sn NMR chemical shift values for cyclotristannanes **28a** and **28b**, $\delta = -416.5$ and -378.9, respectively, are also indicative of shielded tin nuclei.[42, 44] The spectra of both **28a** and **28b** exhibit ^{117}Sn–^{119}Sn satellites ca. 7–8% as intense as the parent signal (Fig. 1), which is consistent only

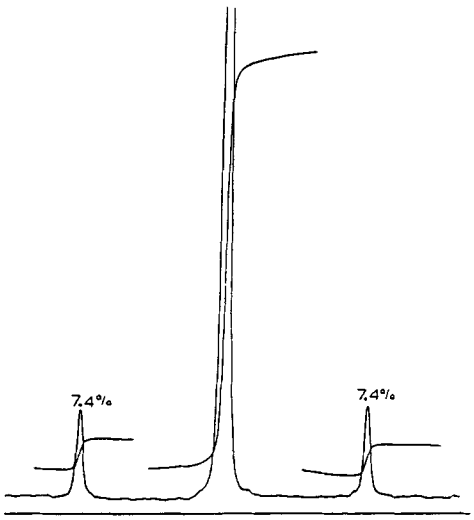


Fig. 1. The ^{1}H-decoupled ^{119}Sn NMR spectrum (100.74 MHz) of cyclotristannane **28b** in [D_{14}]methylcyclohexane.

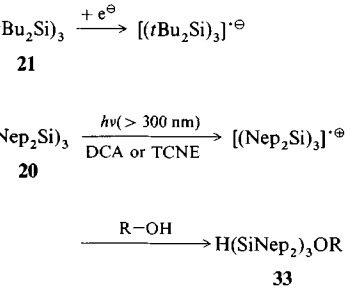
with formulations as cyclotristannanes (see Section 9.2 for an elaboration of the technique).[44]

4.3.4. Electrochemical Properties

Peralkylcyclotrisilanes **20** and **21** have been shown by cyclic voltammetry to possess unusually low oxidation potentials (0.44 V (vs. SCE) in CH_3CN and 0.84 V (vs. SCE) in DME compared to 0.94–1.48 V vs. SCE in CH_3CN for cyclopolysilanes $(R_2Si)_n$ with $n \geq 4$[3c, 57]). Cyclotrigermanes **26b** and **26c** also show relatively low oxidation potentials of 0.80 V (vs. SCE) and 0.72 V (vs. SCE), respectively.[58]

Similar to other cyclopolysilanes, cyclotrisilane **21** is easily converted into the anion-radical, which can be detected by ESR spectroscopy (<200 K).[3c] *Nagai* et al. showed that electron-transfer reagents promoted ring-opening of **20**, producing a linear product (**33**) upon trapping with ethanol (Scheme 13).[59]

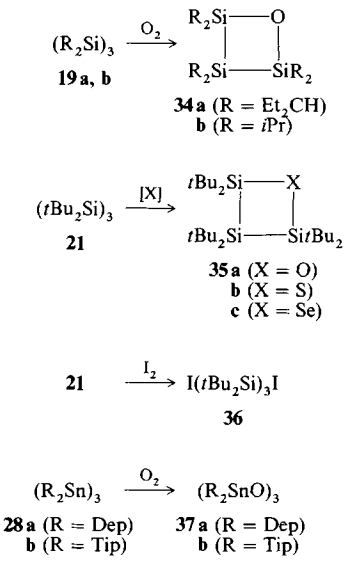


Scheme 13. DCA = 9,10-dicyanoanthracene, TCNE = tetracyanoethylene.

4.4. Chemical Properties

4.4.1. Oxygenation and Related Reactions

Although most of the cyclotrisilanes and cyclotrigermanes are inert to atmospheric oxygen, the relatively less hindered cyclotrisilane **19a** is slowly converted into the corresponding oxa compound **34a** on standing in air for several days at room temperature (Scheme 14).[32] Compound **19b** is instantly converted into monoxa and dioxa derivatives (Si_3O and Si_3O_2) under similar conditions.

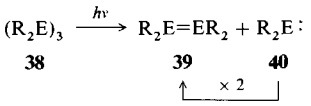


Scheme 14. [X] = O_2, DMSO, *m*-CPBA, S_8, and Se.

Compound **21** is inert to atmospheric oxygen in the crystalline form, but in solution it reacts with oxygen, DMSO, or *m*CPBA to yield the oxa compound **35a**.[60] Sulfur and selenium also react with **21** to provide the corresponding four-membered heterocycles. Treatment of **21** with iodine leads to the efficient formation of the 1,3-diiodotrisilane **36**, which has unusually long Si–Si bonds of 2.581 and 2.644 Å;[61] the longest Si–Si bond length reported thus far is ca. 2.70 Å found in hexa-*tert*-butyldisilane.[62] Cyclotristannanes **28a** and **28b** are air-stable in crystalline form, but in solution are converted by air into the corresponding cyclotristannoxanes **37a** and **37b**, respectively.[42, 44]

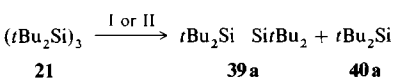
4.4.2. Cleavage of Three-Membered Rings into Double-Bond and Divalent Species

Of the many reactions **38** undergo, photoinduced cleavage of these three-membered rings is undoubtedly the most exciting, giving rise to the double-bond systems **39** and the corresponding carbene-like species **40**, which dimerize to **39** in solution (Scheme 15).[3a] In the case of cyclotrigermanes and



Scheme 15. E = Si, Ge, Sn.

cyclotristannanes, thermal conversion to $R_2E{=}ER_2$ has also been observed.[31c, 44, 63] Decomposition of cyclotrisilane catalyzed by a palladium complex also gives disilene and silylene.[64] *Weidenbruch* et al. reported many reactions of di-*tert*-butylsilylene (**40a**) and tetra-*tert*-butyldisilene (**39a**), both of which were generated by the photolysis or the palladium-catalyzed decomposition of **21** (Scheme 16; see also Section 5.6.1).[3c, 64–67] The conversion (and interconver-



Scheme 16. I: *hν*; II: $[Pd(PPh_3)_2Cl_2]$, Δ.

sion) of **38** into **39** has turned out to be a reaction of central importance, and this chemistry is elaborated in the following section.

5. Disilenes, Digermenes, and Distannenes

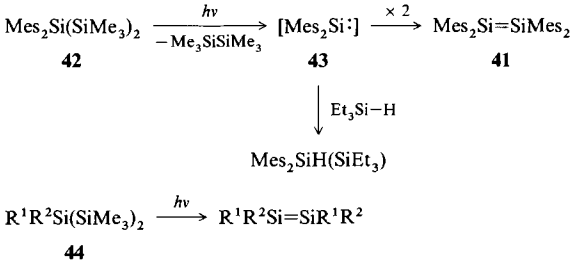
Three recent review articles on disilene chemistry are now available.[2a, d, e] As noted in the introduction, this section attempts to minimize overlap and summarizes the significant accomplishments with different emphasis.

5.1. Synthesis

Syntheses of stable disilenes, digermenes, and distannenes for the most part have involved the same reactions, the most common being 1) dimerization of carbene analogues, 2) photochemical transformation of the strained rings (**38**), and 3) reductive coupling reactions that presumably involve a β elimination. For the purpose of cohesiveness, the following discussion of these syntheses will be grouped according to synthetic method.

5.1.1. Dimerization of Silylenes, Germylenes, and Stannylenes

In 1981 *West*, *Fink*, and *Michl* succeeded in isolating the first disilene derivative, tetramesityldisilene (**41**), by photolysis of linear trisilane **42** and consequent dimerization of the divalent intermediate, dimesitylsilylene (**43**) (Scheme 17).[68] The blue silylene **43** has itself been observed (λ_{max} at 577 nm) by photolysis of the trisilane in a 3-methylpentane glass at −196 °C and can be trapped with reagents such as

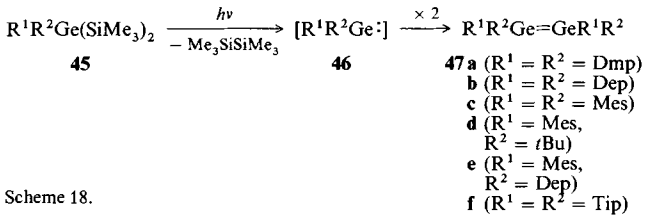


Scheme 17. At least one of R^1 or R^2 is an aryl group.

triethylsilane upon annealing the glass. In the absence of a trapping reagent **43** dimerizes to form disilene **41** upon annealing. The photolysis of linear trisilanes represented by **44** has since become a general method for the preparation of stable disilenes.[2a, 69]

In 1973 and 1976 (before the disilene synthesis described above) *Lappert* et al. reported the syntheses of dialkylstannylene **15a** and dialkylgermylene **14a**, respectively, by the reactions of $(Me_3Si)_2CHLi$ with divalent tin and germanium compounds (Scheme 4).[24, 28] Both compounds **15a** and **14a** form the corresponding centrosymmetric dimers (**15b** and **14b**) in crystalline form with the E atoms well within bonding distance (see Section 5.2.2).[24a–c, e] However, both **15b** and **14b** easily dissociate extensively, if not entirely, to their monomers **15a** and **14a** in solution, as demonstrated by their solution reactivity (see Sections 5.6.2.1 and 5.6.3).[1g, 24c]

The method used by *West* for the synthesis of stable disilene derivatives is also applicable to some digermenes.[70–72] Irradiation of the bis(trimethylsilyl) germanes **45** with a low-pressure mercury lamp yielded the corresponding germylene derivatives (**46**) which dimerized to digermenes **47a–f** as shown in Scheme 18.

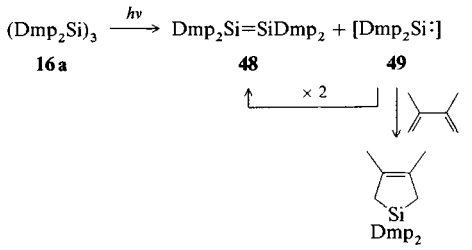


Scheme 18.

5.1.2. Photochemical Cleavage of Cyclotrisilanes, Cyclotrigermanes, and Cyclotristannanes

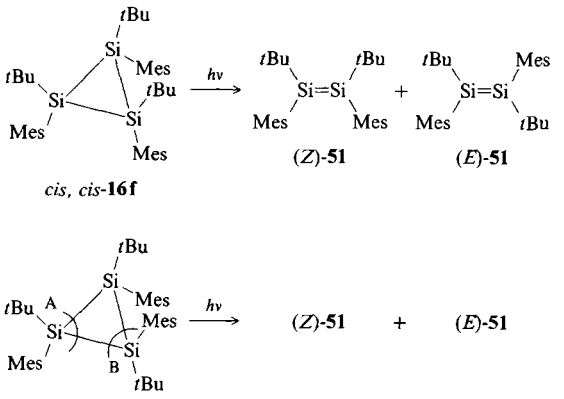
In 1981, our synthesis of the first cyclotrisilane derivative **16a** led us to discover that its photolysis produces the corresponding disilene, tetrakis (2,6-dimethylphenyl)disilene (**48**),

almost quantitatively as shown in Scheme 19.*[30] The cyclotrisilane **16a** (1 equiv) initially provides on photolysis disilene **48** (1 equiv) and silylene **49** (1 equiv), the latter species providing additional disilene **48** (0.5 equiv) by dimerization. The formation of silylene **49** in the photolysis of **16a** is confirmed by trapping with 2,3-dimethyl-1,3-butadiene, yielding the cycloadduct **50**.[73] The photolysis of cyclotrisilanes has been adapted for the synthesis of a variety of stable and marginally stable disilenes.[31-34,36]



Scheme 19.

In 1984 we reported that different ratios of isomeric disilenes (*Z*)-**51** and (*E*)-**51** were obtained from separate photolyses of the 1,2,3-tri-*tert*-butyl-1,2,3-trimesitylcyclotrisilanes (*cis,cis*-**16f** and *cis,trans*-**16f**).[31b] This suggests that cyclotrisilanes undergo photofragmentation with retention of configuration at silicon in the disilene fragment. Furthermore, in the case of *cis,trans*-**16f**, it has been demonstrated that one of the two possible modes of cleavage of the three-membered ring (mode A, Scheme 20) is favored over the other (mode B) by a factor of 4.** Preference of mode A over mode B may reflect the fact that the Si–Si bond between the two *cis*-oriented mesityl groups (2.441 Å) in *cis,trans*-**16f** is



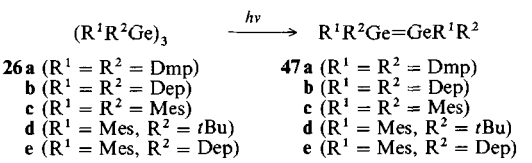
Scheme 20. Top: (*Z*)-**51**:(*E*)-**51** = 7.1:1; bottom: (*Z*)-**51**:(*E*)-**51** = 0.38:1

[*] When the synthesis of disilene **48** was accomplished, the disilene system was unknown (the submission date of the communication describing **48** was December 7, 1981 [30]). We, as newcomer to this field, were not aware that *West*'s communication [68] on the synthesis of tetramesityldisilene (**41**) was in press at that time.

[**] The observed *Z* to *E* ratio of 7.1:1 for *cis,cis*-**16f** agrees well with the calculated ratio of 6.9:1, which is calculated on the basis of the kinetic product *Z* to *E* distribution ratio of 1.6:1 observed for silylene dimerization. For *cis,trans*-**16f**, if mode A is favored over mode B by a factor of 4 the ratio can be calculated to be 0.39:1, which also agrees very well with the observed ratio of 0.38:1. The *Z* to *E* ratio calculated for random cleavage is 0.75:1; for mode A only it is 0.26:1.

longer (and weaker) than the other two Si–Si bonds (2.395 Å and 2.413 Å).[50]

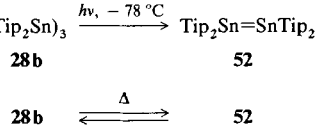
In 1982 solution spectra were first recorded for a digermene derivative, tetrakis(2,6-dimethylphenyl)digermene (**47a**), formed upon photolysis of cyclotrigermane **26a**.[38] Digermene **47a** could not be isolated due to the slow conversion of **26a** into **47a** and eventual photodecomposition of **47a**. It is now clear that **26a** and **47a** constitute a photoequilibrated mixture and the cyclotrigermane/digermene ratio is subtly affected by the structure of substituents. In contrast to **26a**, hexakis(2,6-diethylphenyl)cyclotrigermane **26b** undergoes exceptionally clean photolytic conversion into digermene **47b** in > 90% yield.[39] Thus, **47b** was the first isolated digermene that retains its structural integrity in solution (Scheme 21), as substantiated by both its physical properties and solution reaction products (see below).[39,58,74,75] Other cyclotrigermanes similarly provide the corresponding digermenes, but only the photolysis of **26b** is clean enough to permit facile isolation of a digermene of 100% purity. This contrasts with the highly efficient photochemical conversions of arylated cyclotrisilanes into disilenes (see above).[3a]



Scheme 21.

Irradiation of 1,2,3-trimesityl-1,2,3-tris(2,6-diethylphenyl)-cyclotrigermanes (*cis,cis*- and *cis,trans*-**26e**) provides a mixture of isomeric digermenes (*Z*)- and (*E*)-**47e**, the ratio of which is dependent upon which cyclotrigermane is used.[31c] The stereochemical courses of the photolyses appear to be much the same as those observed for the analogous disilenes described above.

This photolyis strategy was successfully extended to the synthesis of tin analogues in 1985 (Scheme 22).[44] Although conversion of **28a** into the corresponding distannene was not effected, irradiation of **28b** at −78 °C provided a 100% yield of distannene **52**, whose structure has been established by ^{119}Sn NMR spectroscopy (see Section 9.2). Thermal reversion of **52** to **28b** is sufficiently slow at −78 °C to permit the isolation and characterization of **52** (see the following section).



Scheme 22.

As noted above, the yield of the photoconversion of three-membered ring compounds **38** (1.0 equiv) to tetraaryl double-bond systems **39** (1.5 equiv, Scheme 15) is highly dependent on the nature of E and its ligand.[3a] The steric demand for the high-yield photoconversion (**38** → **39**) in-

creases in the order of E = Si < Ge < Sn: the tetrakis(2,6-dimethylphenyl), tetrakis(2,6-diethylphenyl), and tetrakis(2,6-diisopropylphenyl) substituents on E are needed for the series Si, Ge, and Sn, respectively.

5.1.3. *Thermal Cleavage of the Three-Membered Rings*

No example of thermal conversion of a cyclotrisilane into a disilene is known, but such reactions have been identified for cyclotrigermanes and -stannanes.[31c, 44, 63] For example, cyclotrigermanes **26b, c** and **e** have all been found to produce low concentrations of digermenes in solution at or above 80 °C.[31c, 63] Thermolysis of **26c** in the presence of various trapping reagents generates products resulting from the reaction of both the digermene and/or the germylene in high yield.[63] Equilibrium constants have been recently established between the cyclotrigermanes and digermenes at these temperatures.[76]

Cyclotristannane **28b** and distannene **52** are cleanly interconvertible.[44] This interconversion proceeds very slowly at low temperature (−78 °C), but rapidly at higher temperatures (90 °C). The equilibrium favors **28b** (> 99.9%) at or below 0 °C, but a substantial amount of **52** exists at 90 °C (Scheme 22).

5.1.4. *Reductive Coupling and Elimination Reactions*

The syntheses of disilenes and digermenes by reductive coupling exactly complement their syntheses by ring photolysis. In this way, double-bond systems possessing larger substituents than can be tolerated upon the corresponding three-membered ring systems are generally constructed.[77] In 1987 we synthesized tetrakis[bis(trimethylsilyl)methyl]disilene **53** by the reductive coupling of diiodosilane derivative **54** with lithium naphthalenide in THF (Scheme 23), representing the first isolation of a stable tetraalkyldisilene.[78] *Nagai* et al. found independently that either the reductive coupling of dichlorobis(2,4,6-triisopropylphenyl)silane or the reductive elimination of the corresponding 1,2-dichlorodisilane **55** using lithium naphthalenide provided stable disilene **56**.[79] Similarly, isomeric disilenes (*Z*)- and (*E*)-**57** have been prepared by us in good yield.[80]

$$\underset{\mathbf{54}}{Dis_2SiI_2} + LiNp \xrightarrow{THF} \underset{\mathbf{53}}{Dis_2Si{=}SiDis_2}$$

$$Tip_2SiCl_2 \text{ oder } ClTip_2Si{-}SiTip_2Cl \xrightarrow[DME]{LiNp} \underset{\mathbf{56}}{Tip_2Si{=}SiTip_2}$$
$$\mathbf{55}$$

$$Dip(Mes)SiCl_2 + LiNp \xrightarrow{DME} \underset{\mathbf{57}}{Dip(Mes)Si{=}SiDip(Mes)}$$

Scheme 23.

Treatment of the 2,6-diisopropylphenyl-substituted dichlorogermane derivatives **58** and **59** with lithium naphthalenide directly produces the corresponding digermenes (Scheme 24).[80, 81] The synthesis of **61** is significant as it represents the first and only digermene of type $R^1R^2Ge{=}GeR^1R^2$ ($R^1 \neq R^2$) to be isolated, which has permitted the measurement of the activation energy required for $Z \rightleftharpoons E$ isomerization in a digermene (see Section 5.4).[80]

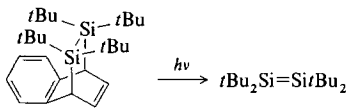
$$\underset{\mathbf{58}}{Dip_2GeCl_2} + LiNp \xrightarrow{DME} \underset{\mathbf{60}}{Dip_2Ge{=}GeDip_2}$$

$$\underset{\mathbf{59}}{Dip(Mes)GeCl_2} + LiNp \xrightarrow{DME} \underset{\mathbf{61}}{Dip(Mes)Ge{=}GeDip(Mes)}$$

Scheme 24.

5.1.5. *Photochemical Retro Diels–Alder Reaction*

Sterically crowded tetra-*tert*-butyldisilene **39a** is obtained by low-temperature photolysis of 2,3-benzo-7,7,8,8-tetra-*tert*-butyl-7,8-disilabicyclo[2.2.2]octa-2,5-diene (**62**), which is prepared by the reaction of di-*tert*-butyldichlorosilane with lithium naphthalenide (Scheme 25).[82] Disilene **39a** is rather unstable thermally. It has a half-life of only several hours at room temperature and has been purified to an extent of approximately 40%.



62 **39a**

Scheme 25.

5.2. Molecular Structures

5.2.1. *Theoretical Studies*

An extensive theoretical investigation of the ground-state geometry of parent disilene $H_2Si{=}SiH_2$ (**63**) has been carried out in recent years.[83] As shown in Table 5, calculations at various levels lead to different results with regard to the ground-state conformation of **63**, especially the fold (or bent) angle α. This marked basis-set dependence may reflect a flat potential surface for varying α in disilene **63**. The most sophisticated calculation provides a very large fold angle of 36°.[83n]

In contrast to disilene, the calculated geometries of parent digermene, $H_2Ge{=}GeH_2$ (**64**), and distannene, $H_2Sn{=}SnH_2$ (**65**), have been found to be nearly independent of the basis set or the method of calculation (Table 6). Theoretical studies on **64** using various basis sets predict a *trans*-bent geometry with a relatively short Ge=Ge bond length of 2.27–

2.33 Å and a significant fold angle of 34–40°. Likewise, parent distannene **65** is calculated to have a Sn=Sn bond of ca. 2.7 Å and a wider fold angle of 41–49°.

In summary, both the calculated stability of the *trans*-bent form relative to the planar form* and the predicted fold angle α in $H_2E=EH_2$ increase with the atomic number of E (E=Si, Ge, Sn). In the *trans*-bent conformation for Ge and Sn, stabilization of the homo $\pi(b_u)$ orbital which is mixed with the E–E σ^* orbital predominates over destabilization of E–E $\sigma(a_g)$ bonding.[24e] The degree of orbital mixing and hence the degree of bending, α, depends on the energy difference between the $\pi(b_u)$ orbital and the E–E σ^* orbital; this energy difference decreases with increasing atomic number of E.

[a] For definition of α, see Table 5.

5.2.2. *Observed Structures*

To date five disilene derivatives, three digermene derivatives, and a distannene derivative have been subjected to crystallographic analysis; pertinent data are summarized in Table 7.

[*] This correlates with the increasing energy difference between the singlet and triplet states of EH_2. Although the ground state of CH_2 is a triplet of $^3B_1$ symmetry [85], EH_2 where E=Si [86], Ge [86c, 87], and Sn [86c, 87, 88] have singlet ground states of $^1A_1$ symmetry; the energy gap (ΔE_{ST}) between the $^1A_1$ and $^3B_1$ states increases in the order Si < Ge < Sn. A simple rule has been proposed that links the occurrence of a *trans*-bent distortion to a function of ΔE_{ST} of carbene and its analogues and the double-bond energy $E_{\sigma+\pi}$ [89].

Disilenes have the following structural characteristics: 1) shortened Si=Si bond distances of 2.14–2.16 Å relative to known, unstrained Si–Si single bonds (ca. 2.35 Å) and 2) generally planar disilene moieties (fold angles ca. 0°) with a small or no twist angle. Only disilene **41** exhibits sizable fold angles of 10° and 13°.[90b] The small differences found between **41** and other disilenes may reflect a shallow potential energy surface for the out-of-plane *trans* bending.

All three digermenes apparently have *trans*-bent double bonds and fold angles increase with steric congestion. The Ge=Ge bond lengths also increase as the pyramidalization at Ge becomes more pronounced. The relatively large ligands in (*Z*)-**61**[80] and **14b**[24e] compared with those in **47b**[39] apparently force the Ge=Ge bonds in the former compounds to elongate to where mixing of the homo $\pi(b_u)$ orbital and the Ge–Ge σ^* orbital becomes important. As a result (*Z*)-**61** and **14b** favor markedly *trans*-bent conformations. Although the crystal structure of (*Z*)-**61** is very similar to that of *Lappert*'s digermene **14b**, the latter exists as a dimer only in crystalline form and dissociates to the corresponding germylene **14a** in solution,[24c] whereas (*Z*)-**61** retains its structural integrity.[80] Therefore, the observed small bond dissociation energy of **14b** is apparently not directly related to its conformation.

Table 7. Selected structural parameters of double-bond systems ($R^1R^2E=ER^1R^2$).

Cpd.	E	R^1	R^2	Comments	d(E=E) [Å]	Fold angle α [°]	Twist angle [°]	Ref.
41	Si	Mes	Mes	[a]	2.16 (0.92) [c]	18	12	[90b]
41	Si	Mes	Mes		2.14 (0.91)	10, 13	3	[90b]

14b	Ge	Dis	Dis		2.35 (0.96)	32	0	[24e]
15b	Sn	Dis	Dis		2.77 (1.00)	41	0	[24e]

[a] The crystal contains toluene. [b] The crystal contains THF. [c] The value in parentheses is the ratio of double bond length to a single bond length of 2.35 (Si), 2.46 (Ge), or 2.78 Å (Sn).

In distannene **15b**,[24e] the Sn=Sn bond has a fold angle of 41° and its length is comparable to that of an average Sn–Sn single bond, therefore representing a further enhancement of the effects discussed above. Table 7 shows that the fold angles increase in the order Si, Ge, Sn and that the shortening of the E–E double bonds compared to E–E single bonds decreases in this sequence.[3a]

5.3. Physical Properties

5.3.1. *Electronic Absorptions*

All stable double-bond systems color yellow to red. The electronic absorption maxima lie between 390 and 500 nm (Table 8). The longest-wavelength absorptions have been attributed to electron transitions between the modified π and π* orbitals as described in the previous section. These ab-

[a] These compounds dissociate to the corresponding carbene analogues in solution.

sorbances are considerably red-shifted from those of ethenes.

While tetraalkyldisilenes (except tetra-*tert*-butyl derivative **39a**) have absorption maxima at about 400 nm, the absorptions of tetraaryldisilenes are red-shifted by 20–30 nm, perhaps due to a weak conjugation effect. Dialkyldiaryldisilenes and tetraalkyldisilenes have essentially equal absorption maxima even though only the former carry aryl groups, possibly because these aryl rings are oriented in such a manner as to prohibit conjugation.[69a,d] The unexpectedly high λ_{max} (433 nm) of disilene **39a** is possibly caused by significant twisting of the Si=Si bond due to steric repulsion.[82]

The absorptions of digermenes are slightly blue-shifted compared to those of disilenes, while those of distannenes are largely red-shifted. The wavelengths of the lowest energy absorptions of digermenes are not significantly affected by their conformations.

The extinction coefficients (ε) of *Lappert*'s distannene **15b** are dependent on concentration and temperature; the value of ε for the absorption at 332 nm increases upon dilution while that for the 495 nm absorption decreases.[56,78] This suggests that two different species give rise to these absorptions. Based on the proximity of the two lowest energy absorptions observed for compounds **15b** and **52** and also on the results of low-temperature ^{119}Sn NMR spectroscopy (see the following section), the absorption at 495 nm can probably be assigned to the dimeric form. These spectroscopic data can, however, be interpreted differently.

5.3.2. NMR Spectroscopy

Similar to the deshielding observed in the ^{13}C chemical shifts of doubly bonded carbons compared to those of saturated hydrocarbons, the ^{29}Si nuclei of disilenes are strongly deshielded. Chemical shifts range from $\delta = 49$ to 95 (vs. TMS).[2a,68,69,79a] The solid state ^{29}Si NMR spectrum of tetramesityldisilene (**41**) has been reported to exhibit anisotropy comparable to that in the solid state ^{13}C NMR spectrum of ethene, indicating that the electronic structures of the Si=Si and C=C bonds are similar.[91] The ^{29}Si NMR coupling constants, $^1J_{Si=Si}$, observed for disilenes of 155–158 Hz represent an almost twofold increase over the $^1J_{Si-Si}$ values typically seen in unstrained Si–Si single bonds.[92] (Ab initio calculations on the parent disilene predicted a slightly higher $^1J_{Si=Si}$ value of 183.6 Hz.[93]) This indicates a greater s character for the orbitals involved in disilene bonding, which is consistent with sp^2 hybridization of Si atoms in disilenes.

The ^{119}Sn signal of distannene **52** also appears in a strongly deshielded region ($\delta = 427.3$ vs. Me_4Sn) and is accompanied by two tin–tin coupling satellites ($^1J_{^{119}Sn-^{117}Sn} = 2930$ Hz; relative peak intensities, 3.8% of the parent peak) which are expected only for a structure possessing two directly bonded tin atoms (see section 9.2).[44] The $^{119}Sn\{^1H\}$ NMR spectrum of *Lappert*'s distannene **15b** taken at −90.7 °C features two signals at $\delta = 735$ and 750, each with its own pair of $^{119}Sn-^{117}Sn$ coupling satellites ($^1J_{^{119}Sn-^{117}Sn} = 3317$ Hz for $\delta = 735$ and $^1J_{^{119}Sn-^{117}Sn} = 1784$ Hz for $\delta = 750$; intensities, ca. 3.5% of the main resonance).[56,78,94] These results suggest that **15b** exists, at least partially, in a dimeric form in solution at low temperatures. A large magnitude of anisotropy has also been observed in the ^{119}Sn cross polarization/magic angle spinning NMR (CPMAS) spectrum of **15b**.[94]

5.3.3. IR and Raman Spectroscopy

The Si=Si stretching vibrations of disilenes **41** and (*Z*)-**51** have been observed by Raman spectroscopy at 529 and 525 cm^{-1}, respectively.[2a,68] These frequencies are about 30% higher than those of Si–Si stretching vibrations, reflecting the (at least partial) double-bond character of disilenes.

Tetramethyldigermene has been isolated in an argon and a nitrogen matrix at 5 K, and its IR and Raman spectra have been recorded.[95] The observed frequencies are in good agreement with the calculated values for the *trans*-bent (C_{2h}) digermene with d(Ge=Ge) = 2.30 Å and a fold angle α of 37°. The ν_{Ge-Ge} Raman band of 404 cm^{-1} is definitely higher than that of $Me_3Ge-GeMe_3$, indicating some double-bond character in this digermene.

5.3.4. Electrochemical Properties

The electrochemical behavior of tetraaryldisilenes and dialkyldiaryldisilenes has been investigated by cyclic voltammetry, and all compounds apparently undergo irreversible oxidation and reduction.[96] The oxidation potentials are very similar for both types of disilenes (0.38–0.54 V vs. SCE), while the reduction potentials for the tetraaryldisilenes (−2.03– −2.20 V vs. SCE) are much lower than those for the arylalkyldisilenes (−2.66 and −2.64 V vs. SCE).

This may be due to a lowering of the LUMO energy by interaction of disilene "π^*" and aromatic π^* orbitals in tetraaryldisilenes; such an interaction is apparently minimized in diaryldialkyldisilenes as deduced from X-ray analysis.[69a, d]

5.4. Energy of the E=E π Bond in Si, Ge, and Sn Double-Bond Systems

The synthesis of an *E* or *Z* stereoisomer of type $R^1R^2E{=}ER^1R^2$ ($R^1 \neq R^2$) provides a means of measuring the activation energy required for thermal $E \rightleftharpoons Z$ isomerization which is normally equated to the so-called π-bond energy of the E=E bond. To date, several such disilene derivatives and a digermene derivative have been isolated, and the rates for their $E \rightleftharpoons Z$ thermal interconversions have been measured in standard fashion.[31b, c, 69c, d, 80] These compounds containing E–E double bonds exhibit first-order isomerization kinetics, and the kinetic parameters pertinent to these first-order processes are summarized in Table 9. The more stable isomers of all known disilenes of type $R^1R^2Si{=}SiR^1R^2$ have an *E* configuration. By contrast, the *Z* isomer of digermene **61** has been found to be more stable than the corresponding *E* isomer.[80]

The mechanism of these isomerizations exclusively involves rotation about the E=E bond, instead of a thermal dissociation–recombination. Thus, the presence of 2,3-dimethylbutadiene, an efficient silylene and germylene trapping agent, did not affect the rates of isomerization or produce trapping products even after prolonged exposure at temperatures where the isomerization is completed within a few hours. Interestingly, digermene **47e** has been found to show non-first-order kinetics in the $E \rightleftharpoons Z$ isomerization, suggesting the existence of a mechanism other than simple rotation about the Ge=Ge bond for less hindered digermenes.[31c]

The enthalpies of activation for the disilene $E \rightleftharpoons Z$ isomerizations fall between 25 and 28 kcal mol^{-1} (except for disilene **51**).* The π-bond energy for PhMeSi=SiPhMe (**66**) is estimated at greater than 26 ± 5 kcal mol^{-1} from a thermochemical analysis of $E \rightleftharpoons Z$ isomerization of **66**,[98] which has been generated as an intermediate by *Sakurai* et al.[19] (see Section 2.1). This is in good agreement with the $E \rightleftharpoons Z$ thermal isomerization kinetics data described above (Table 9). The enthalpy of activation for the Ge=Ge bond isomerization is somewhat lower than that of the disilene isomerization. Most recent calculations arrive at an estimate of about 25 kcal mol^{-1} for the double bonds of both parent disilene and digermene.[83o, 99] Considering the sizable ligands employed in the derivatives used in the experiment, theory and experiment are in reasonable agreement.

The dissociation energy of the Sn=Sn bond is apparently very small, and experimental attempts to measure the kinetic parameters for $E \rightleftharpoons Z$ isomerization of a distannene have not yet appeared.

Table 9. Kinetic parameters for $E \rightleftharpoons Z$ isomerizations for $R^1R^2E{=}ER^1R^2$.

5.5. Dissociation Energy

Ab initio molecular orbital calculations on the parent $H_2E{=}EH_2$ systems predict E=E dissociation energies near 52–58 kcal mol^{-1} for E = Si,[83h, o] 30–45 kcal mol^{-1} for E = Ge,[24e, 83o, 84a] and 22–28 kcal mol^{-1} for E = Sn.[24e, 84d] These energies contrast with the high stability of C–C double bonds and are much lower than the E–E single bond dissociation energies.[24e, 100] Recently, several experiments which support the above computed data have appeared.

Although disilenes are stable to 170 °C for a prolonged period of time, digermene **47b** and distannene **52** undergo facile thermal transformation (Scheme 26).[31c, 44] Thus, digermene **47b**, which is stable at or below room temperature, is slowly converted into cyclotrigermane **26b** above 80 °C. Similar conversion of distannene **52** into cyclotristannane **28b** has been observed at even lower temperatures. The distannene **52** is kinetically stable at −78 °C, but is cleanly converted into **28b** at 0 °C (Scheme 22), as noted earlier.

$$\underset{\textbf{47b, 52}}{R_2E{=}ER_2} \rightleftharpoons 2\,R_2E{:}$$

$$R_2E{:} + R_2E{=}ER_2 \rightleftharpoons \underset{\textbf{26b, 28b}}{(R_2E)_3}$$

Scheme 26. **47b**, **26b**: E = Ge, R = Dep; **52**, **28b**: E = Sn, R = Tip.

The simplest mechanism for the direct conversion of a double-bond system into the corresponding three-membered ring involves the initial rate-determining, first-order dissociation of $R_2E{=}ER_2$ into two R_2E species, each of which then reacts with a second molecule of $R_2E{=}ER_2$ to form the cyclotrimer. Preliminary kinetic investigation of this reaction suggests that an upper limit to the dissociation energy of **47b** is about 30 kcal mol^{-1}.[76] The enthalpy of dissociation

[*] Table 9 shows that we [31b] and West et al. [69c] reported two sets of kinetic parameters which show a nonnegligible discrepancy for the isomerization of disilene **51**. While we used the Eyring equation to obtain $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ from two rate constants measured at temperatures that are sufficiently different (>20 °C), the other group measured rates at several different temperatures and analyzed the data using an Arrhenius plot. The solvents used were also different: [D_{14}]methylcyclohexane (*Masamune*) and [D_6]benzene (*West*). It was stated that our data "may be less accurate since it (our data) is based on rate measurement at only two temperatures" [2a]. This statement is unacceptable. The errors in securing the kinetic parameters are minimized by the use of a large difference ΔT between the extreme temperatures *T* and *T'*, but not by addition of rate constants measured at temperatures between *T* and *T'* [97]. Moreover, our data are reproducible [39b]. We only offer the explanation that this discrepancy may be due to a solvent effect.

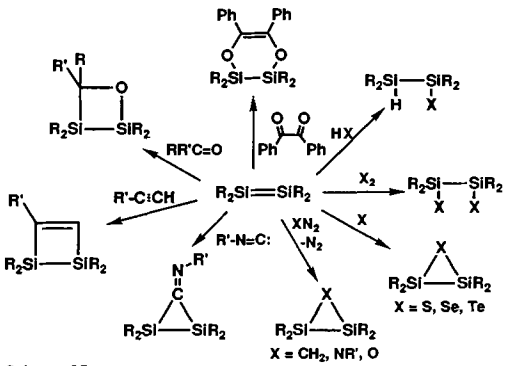
of the Sn=Sn bond is definitely lower than that of digermene dissociation (estimated near 20 kcal mol^{-1}), although we have not obtained accurate kinetic parameters.

The low dissociation energies associated with *Lappert*'s digermene **14b** and distannene **15b** appear to be due largely to the unique stabilization of the monomers by the $CH(SiMe_3)_2$ group (β effect). The enthalpy for the dissociation of **15b** to **15a** has been reported as 12.8 kcal mol^{-1}.[94] Unlike its Ge and Sn counterparts **14b** and **15b**, disilene **53** does not dissociate in solution to a detectable extent.[78] This obviously reflects the expected high thermodynamic stability of the Si–Si double bond relative to those for the Ge–Ge and Sn–Sn double bonds.

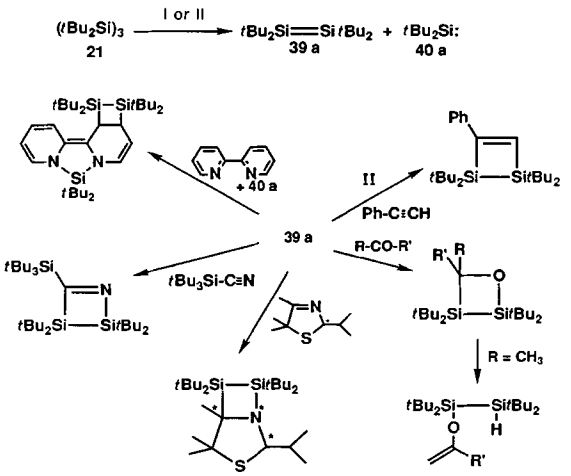
5.6. Chemical Properties

5.6.1. Disilenes

The reactions of aryl-substituted disilenes, as summarized in *West*'s 1987 review,[2a] are diagrammed in Scheme 27.[68, 73, 101, 102] More recently, *Weidenbruch* has investigated the reactions of tetra-*tert*-butyldisilene (**39a**) (Scheme 28).[3c, 64, 65c, 66, 103, 104] These schemes show that disilenes undergo addition of protic acids (HX), halogens (X_2), and chalcogens, as well as complexation with transition metals, cycloadditions, and oxidation (see the next section).

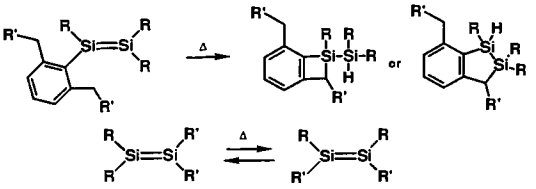


Scheme 27.



Scheme 28. I: *hv*; II: $[Pd(PPh_3)_2Cl_2]$, Δ.

In addition to these bimolecular reactions, disilenes undergo several isomerization reactions in the absence of external reagents, as exemplified by $E \rightleftharpoons Z$ isomerization (see Section 5.4),[31b, 69c, d] thermal rearrangement,[103a] and 1,2-migration of aryl substituents (Scheme 29).[105] Many new ring

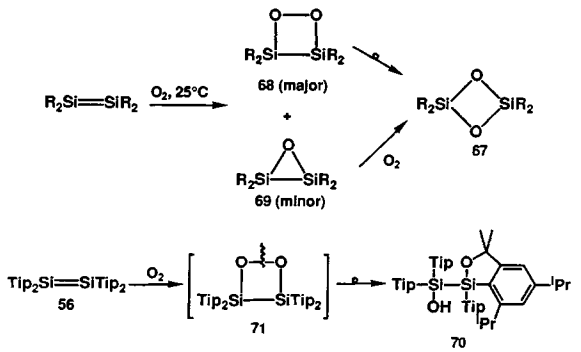


Scheme 29.

systems have been constructed from disilenes.[2a, 3c, 66, 102b] The following reactions deserve further discussion.

5.6.1.1. Oxidation

Disilenes are highly reactive toward oxygen. Many solid disilenes react with atmospheric oxygen to provide 1,3-cyclodisiloxanes **67** with retention of configuration (Scheme 30).[92, 101b, c, f, 102] When disilenes are oxidized in solution two products form: 1,2-dioxadisiletanes **68** and oxadisiliranes **69**.[101c, 102] The former (**68**) slowly rearranges

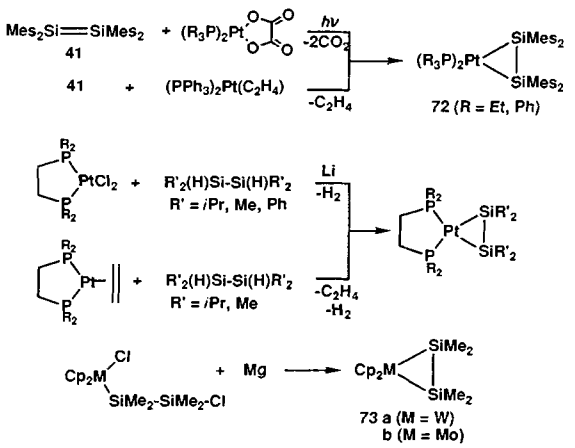


Scheme 30.

to cyclodisiloxane **67**, and the latter (**69**) undergoes further oxidation also to **67**. The oxidation of tetrakis(2,4,6-triisopropylphenyl)disilene (**56**) has been found to provide a novel rearrangement product **70**, very likely through 1,2-dioxadisiletane **71**.[79b]

5.6.1.2. Formation of η^2-Disilene Complexes

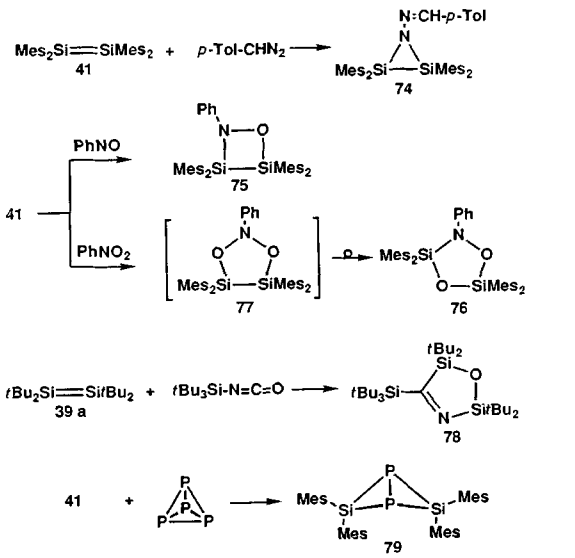
Very recently, η^2-disilene complexes **72** have been synthesized by the reaction of tetramesityldisilene (**41**) with platinum complexes (Scheme 31).[106a] Several stable η^2-disilene complexes have also been isolated by different routes.[106, 107] Furthermore, less sterically encumbered disilenes (such as tetramethyldisilene) can be stabilized as η^2-disilene–metal complexes. The significantly short Si–Si bond of **73a** (2.260 Å) reflects the partial double-bond character of its Si–Si bond.[107]



Scheme 31.

5.6.1.3. *Additional Bimolecular Reactions*

Although disilene **48** reacts smoothly with diazomethane to yield a disilirane,[73] the reaction of tetramesityldisilene (**41**) with *p*-tolyldiazomethane has been found to provide azadisiliridine **74** (Scheme 32).[108] Disilene **41** also reacts with nitrosobenzene and nitrobenzene to provide 1,2-oxazadisiletidine **75** and 1,3,2-dioxazadisilolidine **76**, respectively.[109]

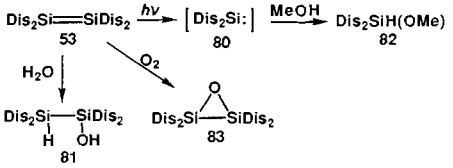


Scheme 32.

The latter compound may be produced by an interesting rearrangement of the initially formed [3+2]-cycloaddition product **77**. A similar type of rearrangement has been observed in the addition of isocyanate to tetra-*tert*-butyldisilene (**39a**), providing a similar five-membered heterocyclic product **78**.[102] Disilene **41** also reacts with white phosphorus to give the bicyclic compound **79** in good yield.[110]

5.6.1.4. *Chemical Properties of Tetrakis[bis(trimethylsilyl)-methyl]disilene (53)*

The chemistry of disilene **53** is worthy of special attention because its Ge and Sn counterparts **14b** and **15b** both predominantly dissociate to the corresponding monomers in solution as already noted above. Disilene **53** shows no indication of dissociation into the corresponding bis(disyl)silylene (**80**) in solution; its chemical properties are fully consistent with the disilene formulation.[78] It reacts with water to provide the corresponding hydrate **81**. Rather unexpectedly, **53** is inert to methanol even in a refluxing THF solution over 24 h. However, photolysis rapidly cleaves **53** into



Scheme 33.

silylene **80**, which subsequently reacts with methanol to afford the methoxysilane **82**. Bubbling O_2 through a solution of **53** provides the oxadisilirane **83** as the major product (Scheme 33).

5.6.2. *Digermenes*

The known digermenes are divided into two separate groups: 1) the readily dissociating digermene **14b** of *Lappert* and 2) tetraaryldigermenes that retain their structural integrity in solution. The reactions of the former are probably more accurately regarded as reactions of germylenes, and those of the latter are much the same as the corresponding disilenes.

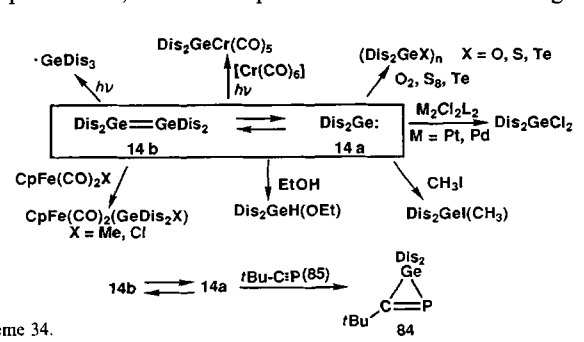
5.6.2.1. *Lappert's Digermene (14b)*

The monomer **14a** derived from **14b** 1) behaves as a Lewis base, 2) undergoes oxidative addition to form a tetravalent germanium compound, and 3) yields a germyl radical (Scheme 34).[24c] The products derived from these processes are generally monogermanium compounds. Recently, a novel three-membered heterocycle **84** has been prepared by the addition of **14a/14b** to phosphaalkyne **85**.[111]

5.6.2.2. *Tetraaryldigermenes*

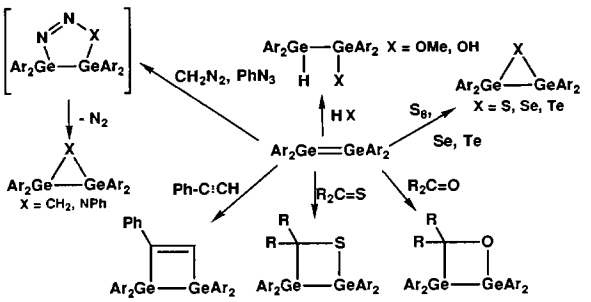
1,2-Additions and Cycloadditions

Tetraaryldigermenes readily react with protic species to provide 1,2-addition products and also undergo



Scheme 34.

smooth cycloadditions with a variety of reagents to provide new three- or four-membered ring systems (Scheme 35).[38–40a, 58, 70, 74, 75, 81, 112] Reactions of digermenes with sulfur, selenium, and tellurium provide three-membered rings consisting of two germanium atoms and the chalcogen atom. Digermenes apparently undergo [2+3]-cy-

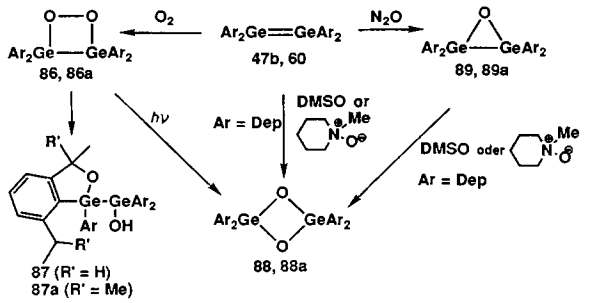


Scheme 35.

cloadditions with diazomethane or phenyl azide, in each case generating three-membered ring products following loss of N_2. Digermenes also react with phenylacetylene as well as carbonyl and thiocarbonyl compounds to provide the formal [2+2]-cycloadducts in good yield.

Oxidation

Tetrakis(2,6-diethylphenyl)digermene (**47b**) and tetrakis(2,6-diisopropylphenyl)digermene (**60**) undergo oxidation in a manner generally analogous to, but subtly different from, that observed for the disilene series (Scheme 36).[74b]



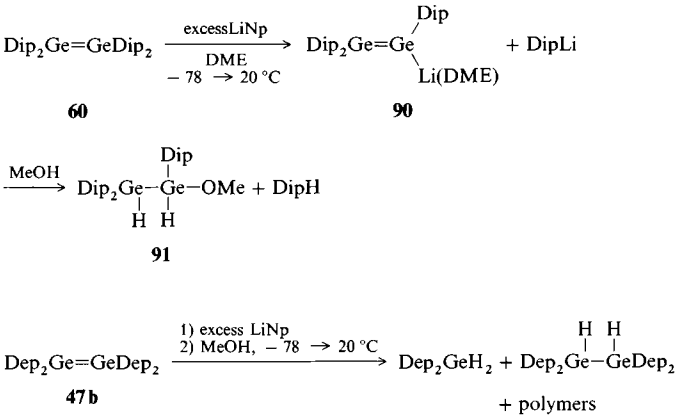
Scheme 36. **86**–**89**, Ar = Dep. **86a**–**89a**, Ar = Dip.

Thus, exposure of digermene **47b** in toluene to O_2 provides 1,2-dioxadigermetane derivative **86** quantitatively, which upon heating at 90 °C rearranges to **87**. The 1,2-dioxadigermetane **86** is photochemically converted into cyclodigermoxane **88**. This thermal and photochemical behavior of **86** contrasts with that of silicon analogue **68**, which undergoes thermal rearrangement to provide **67**.[101c, 102] However, the thermal rearrangement of **86** to **87** is analogous to the oxygenation behavior of disilene **56**.[79b] Digermene **60** behaves similarly and provides **86a**, **87a**, and **88a**.

Cyclodigermoxane **88** has also been obtained directly and quantitatively from **47b** upon treatment with excess DMSO or *N*-methylmorpholine-*N*-oxide. Treatment of digermenes **47b** and **60** with nitrous oxide produces oxadigermiranes **89** and **89a**, respectively, via [2+3]-cycloadditions followed by loss of N_2. Conversion of **89** into **88** with DMSO or *N*-methylmorpholine-*N*-oxide proceeds very rapidly compared to the conversion of digermene **47b** into **88** by the same reagent; therefore, **89** appears to be a likely intermediate in this latter conversion.

Reductive Cleavage

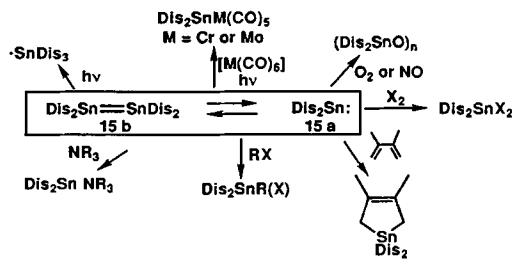
Rather unexpectedly, treatment of digermene **60** with an excess of lithium naphthalenide leads to Ge–C_{Ar} bond cleavage to provide the isolable digermenyllithium **90** (germanium analogue of a vinyllithium), a species hitherto unknown in Si, Ge, and Sn double-bond chemistry (Scheme 37).[81] Compound **90** is an extremely air-sensitive, red crystalline compound which reacts readily with methanol to give digermane **91**. In contrast, the reduction of digermene **47b** with lithium naphthalenide under the same conditions provides products which are converted upon protonation into diarylgermane, tetraaryldigermane, and unidentified polymers. 1,3-Diethylbenzene was not obtained; therefore, cleavage of a Ge–C_{Ar} bond apparently does not occur in this case.



Scheme 37.

5.6.3. Distannenes

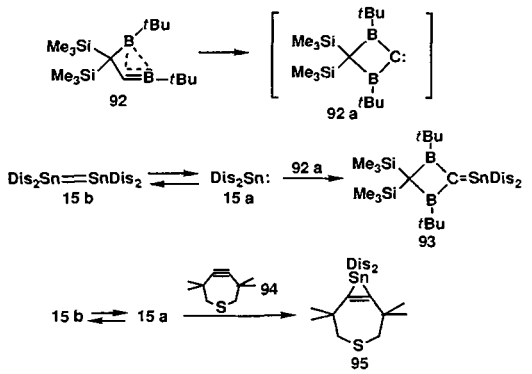
In a manner similar to *Lappert*'s digermene **14b**, **15b** behaves as the corresponding monomer **15a** as summarized in Scheme 38.[1g] Several other reactions have been recorded



Scheme 38. X = Halogen

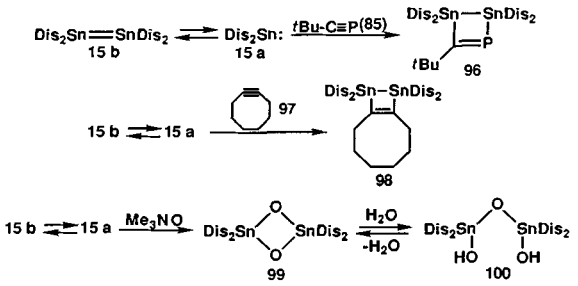
recently. Addition of distannene **15b**/**15a** to boranediylborirane **92**, which behaves as carbene **92a** in the presence of suitable reagents, leads to the formation of the stable stannaethene **93** (Scheme 39).[113a] Distannene **15b**/**15a** also re-

acts smoothly with cyclic acetylene **94** to afford pale yellow crystalline stannacyclopropene derivative **95**.[113b] Although **95** is stable in crystalline form or in solution below $-25\,^{\circ}C$, it readily reverts to **15a/15b** and acetylene **94** in solution at room temperature. This behavior is reminiscent of the thermal equilibrium between a cyclotristannane and a distannene.[44]



Scheme 39.

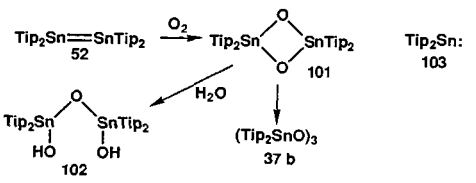
The above reactions provide products containing only one tin atom per molecule. However, more recent investigations show that some reactions provide products in which the Sn–Sn moiety may have been preserved. Phosphaalkyne **85** reacts with distannene **15b/15a** to afford a derivative of the 1,2,3-phosphadistannetene **96** (Scheme 40).[114] Direct reaction of distannene **15b** with **85** has been proposed for the formation of **96**, although successive additions of stannylene **15a** to **85** cannot be ruled out (see below). In contrast to the reaction with the alkyne **94**, **15b/15a** reacts only slowly with cyclooctyne **97** to provide the stable 1,2-distannetene **98** quantitatively.[115] Successive insertion of stannylene **15a**



Scheme 40.

into the alkyne has been proposed for this reaction. Very recently, *Lappert* et al. reported the synthesis of the first cyclodistannoxane derivative **99** obtained by the oxidation of distannene **15b/15a** using Me_3NO.[116] Compound **99** easily hydrolyzes to yield **100**, which is converted back to **99** by dehydration. The structures of both **99** and **100** have been established by X-ray analysis.

In contrast with **15b**, tetraaryldistannene **52** retains its double bond at $-78\,^{\circ}C$, as noted above. Thus, bubbling dioxygen through a solution of **52** at $-78\,^{\circ}C$ leads to the quantitative formation of cyclodistannoxane **101**, which is thermally unstable and eventually forms cyclotristannoxane **37b** (>90% conversion within 24 h at room temperature).[117] Compound **101** is easily hydrolyzed to **102** (Scheme 41). Whether the observed products arise from oxidation of the distannene **52** or reactive intermediate stannylene **103** has not been determined.



Scheme 41.

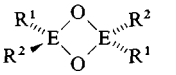
6. Small-Ring Compounds Derived from Disilenes, Digermenes, and Distannenes

The reaction products of the unsaturated compounds produced several new small-ring systems, some of which merit further elaboration.

6.1. Cyclodisiloxanes, Cyclodigermoxanes, and Cyclodistannoxanes

The structures of four cyclodisiloxanes (**67a–d**), one cyclodigermoxane (**88**), and one cyclodistannoxane (**99**) have been established by X-ray crystal analysis, and selected structural parameters are summarized in Table 10. These four-membered rings have abnormally small E–O–E bond angles, ranging from 86° to 98°. Even more surprising are the presumably nonbonded E···E distances across the ring, ranging from 2.31 to 2.45 Å for E = Si, 2.617 Å for E = Ge, and 2.94 Å for E = Sn. These values represent 98–106% of the corresponding E–E single bond distances (Si–Si: 2.35 Å, Ge–Ge: 2.46 Å, Sn–Sn: 2.78 Å).

Table 10. Selected structural parameters for the cyclodisiloxanes, cyclodigermoxanes, and cyclodistannoxanes, **II**.

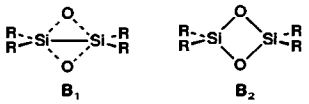


Cpd.	E	R^1	R^2	<E-O-E [°]	d(E···E) [Å] [a]	Ref.
67a	Si	Mes	Mes	86.2	2.306 (0.98)	[101f]
67b	Si	Mes	*t*Bu	91.1	2.396 (1.02)	[101f]
67c	Si	Mes	*N*-TMS_2	89.7, 89.4	2.349 (1.00)	[101f]
67d	Si	*t*Bu	*t*Bu	95.8	2.453 (1.04)	[102b]
88	Ge	Dep	Dep	92.1	2.617 (1.06)	[74b]
99	Sn	Dis	Dis	97.5	2.94 (1.06)	[116]

[a] The value in parentheses is the ratio of d(E···E)/d(E–E).

These characteristic features have raised questions concerning bonding in cyclodisiloxanes.[101b,f,102] Different models suggest that either 1) there is a σ bond between the silicon atoms, making the Si–O bonds necessarily electron-deficient (structure $\mathbf{B}_1$) or 2) there is a localized σ-bond

framework in which oxygen–oxygen repulsion dominates the structure, thus forcing the two silicon atoms together (structure $\mathbf{B}_2$). Several theoretical investigations support structure $\mathbf{B}_2$ for the parent cyclodisiloxane $(H_2SiO)_2$.[118a–e]



$\mathbf{B}_1$ $\mathbf{B}_2$

The small $^1J_{^{29}Si-^{29}Si}$ coupling constants of ca. 4.0 Hz observed for cyclodisiloxanes are consistent with this theoretical result,[92, 118f] since in structure B_1 $^1J_{^{29}Si-^{29}Si}$ should be within the range of 55–70 Hz obtained for directly bonded Si–Si bonds. Apparently 1) the shortening of the Si···Si distance in disiloxanes is due mainly to the short Si–O bond (1.66 Å) compared to other bond lengths and 2) the "effective" van der Waals radius of the Si atom along the direction toward the other Si atom is smaller than that normally established for this atom.[119] Structural homology for the ring system is further discussed in Section 9.3.

6.2. Disiliranes and Digermiranes

To date, the crystal structures of four disiliranes **104a–e**[120] and six digermiranes **105a–f** have been determined (see Table 11 for selected parameters). A surprising feature

Table 11. Selected structural parameters for the three-membered rings of type **III**.

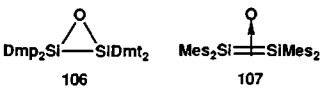
[a] ΣE = <R-E-E′ + <R′-E-E′ + <R′-E-R

of these systems except for telluradigermirane **105d** are the relatively short E–E distances, which are not characteristic of other known three-membered ring compounds of $(R_2E)_3$ type: cyclotrisilanes and cyclotrigermanes have longer-than-normal bond lengths, as shown in Section 4.2.2. (Note that the replacement of R_2E in $(R_2E)_3$ rings with X relieves the steric congestion in the $(R_2E)_3$ rings.) Table 11 shows that, as the electronegativity of X increases, the Si–Si bonds are shortened and the deviation of the C_2Si–Si unit (where C represents the *ipso* C atom of the aryl substituent) from coplanarity becomes less pronounced. Similar tendencies have been observed for the analogous germanium compounds, although to a lesser extent.

In the most extreme case, oxadisilirane **104c**, the Si–Si bond distance is actually closer to those for Si–Si double



106 **107**

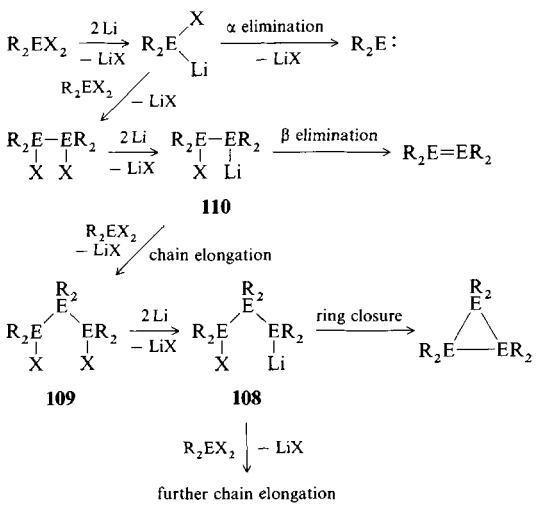
bonds (2.13–2.16 Å) than Si–Si single bonds (ca. 2.35 Å). Furthermore, the C_2Si–Si framework is planar.[101i] *West* has proposed a bonding model in which a significant amount of the double-bond character of the disilene is retained in **104c**. The large $^1J_{^{29}Si-^{29}Si}$ coupling constant of 99 Hz measured for **106**, which is intermediate between that of disilenes (155 Hz) and disilanes (55–70 Hz), indicates that the oxadisilirane **104c** may be described as a π complex **107**.[101i, 121] (The $^1J_{^{29}Si-^{29}Si}$ of cyclotrisilane is small—24 Hz; see Section 4.3.3.)

7. Comments on Reductive Coupling of Dihalosilanes and Their Germanium and Tin Analogues

In summarizing the construction of ring systems and double-bond systems by reductive coupling of various dihalosilanes, -germanes and -stannanes, one notes that there exist distinct parallels in the silicon and germanium series. Upon treatment with lithium naphthalenide, bis(2,6-dimethylphenyl)- and bis(2,6-diethylphenyl)dichlorosilane and the corresponding dichlorogermanes provide three-membered ring compounds,[30, 31a, 38, 39] whereas the unsaturated compounds $(R_2E{=}ER_2)$ are obtained as the major products from dichlorobis(2,4,6-triisopropylphenyl)silane and dichlorobis(2,6-diisopropylphenyl)germane under similar conditions.[79a, 81] In the tin series, reductive coupling of both dichlorobis(2,6-diethylphenyl)- and dichlorobis(2,4,6-triisopropylphenyl)stannanes leads to the corresponding cyclotristannanes, respectively.[42, 44] That these results are apparently inconsistent with those of the Si and Ge series is only superficial; reductive coupling of dichlorobis(2,4,6-triisopropylphenyl)stannane proceeds via the initial formation of the corresponding distannene, which is rapidly converted into cyclotristannane under the reaction conditions.[44]

These cyclotrimerizations may be proceeding through routes such as those outlined in Scheme 42. This mechanism involves the stepwise building of the polysilane, -germane or -stannane backbone until the steric congestion of the substituents "forces" the ends of the chain so close together that the chain is likely to cyclize (known as the Thorpe-Ingold effect). With 2,6-dimethylphenyl or 2,6-diethylphenyl groups on dichlorosilanes or dichlorogermanes, the cyclization occurs when the chain reaches the trimeric stage **108**. Indeed, for E = Si and Ge the compounds **109** undergo reductive cyclization with lithium naphthalenide in good yields, rather than further chain elongation, even in the presence of excess starting material R_2EX_2.[3a] When the substituents on E become even larger, the intermediate **110** may be too congested to permit chain elongation and prefers to undergo β elimination to form a double bond. This apparently occurs in the silicon and germanium series and even in the tin series (see above) when the substituents are 2,6-di- or 2,4,6-triisopropylphenyl groups. The involvement of a β elimination is supported by the alternative synthesis of disilene **56** by the reductive treatment of the 1,2-dichlorodisilane **55**.[79b] Con-

ceivably, the attempted reductive coupling of R_2EX_2 where the substituents R are sufficiently large to prohibit the first coupling could result in the generation of a stable carbene analogue (R_2E:).[122]



Scheme 42. Reductive coupling of dihalosilane, -germane, and stannane.

Cyclotrisilanes, -germanes, and -stannanes could possibly result from the addition of a carbene analogue (R_2E:) to an E–E double-bond system in a manner similar to the reaction between carbenes and olefins. This process has been postulated in situations where a rapid equilibration between three-membered rings and double bonds is feasible.[31c, 44, 76] The formation of cyclotristannane **28b** from dichlorodistannane **30**,[44] and **28a** from tin dichloride and the aryllithium[43] constitute examples. In contrast, the above equilibration for Ge is attainable only at high temperatures and is not possible for Si, and therefore the R_2E: addition reaction is unlikely to be involved in the reductive coupling of dihalogermanes and -silanes. However, definite proof to endorse this interpretation is yet to be secured.

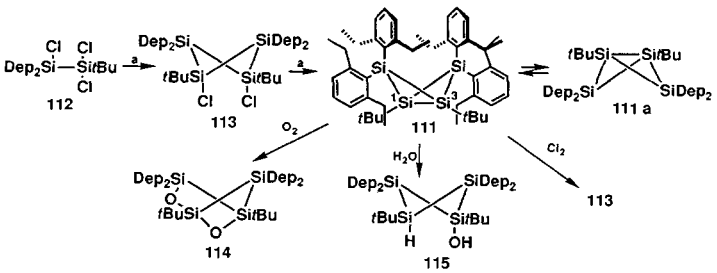
8. Strained Polycyclic Systems

Our work with the three-membered rings of Si, Ge, and Sn, was extended to strained polycyclic systems. The successful construction of a bicyclo[1.1.0]tetrasilane derivative in 1985 stimulated the work in this field.[123] Numerous stable polycyclic compounds of theoretical interest have recently been prepared by either stepwise or "one-shot" synthetic schemes.

8.1. Bicyclic Compounds

8.1.1. Bicyclo[1.1.0]tetrasilanes

Scheme 43 outlines the synthesis of 1,3-di-*tert*-butyl-2, 2, 4, 4-tetrakis(2, 6-diethylphenyl)bicyclo[1.1.0]tetrasilane (**111**).[123, 124] Treatment of the trichlorodisilane **112** with lithium naphthalenide gives rise to the cyclotetrasilane **113**, which after purification is subjected to a second reductive



Scheme 43. a: 2 equiv LiNp

cyclization with the same reductant at 0 °C to provide **111** quantitatively. Compound **111** is extremely reactive and its exposure to air, water (atmospheric moisture), and chlorine immediately converts **111** into **114**, **115**, and **113**, respectively. A notable feature of the bicyclic ring is its facile inversion (**111** ⇌ **111a**). Thus, while three distinct ethyl signals appear in the ^{1}H NMR spectrum taken at −30 °C or below, these signals are replaced by a single quartet–triplet pair at 115 °C, indicating that all the aryl groups have attained equivalence on the NMR time scale. The barrier to this inversion is estimated to be ca. 15 kcal mol^{-1}.

The crystal structure (Fig. 2) of **111** shows the crucial Si1–Si3 bond to be relatively (and unexpectedly) short (2.373(3) Å).[123b] This bond is believed to be highly bent and rich in p character.

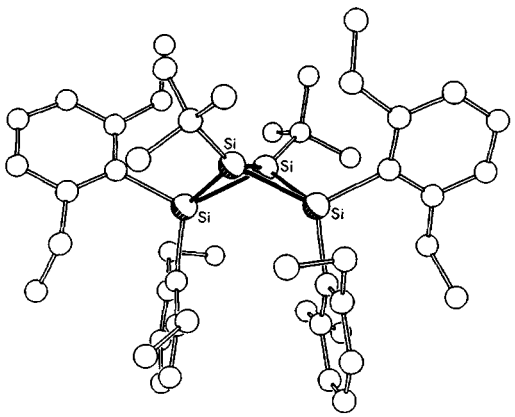


Fig. 2. Structure of the bicyclo[1.1.0]tetrasilane **111** in the crystal.

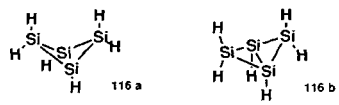
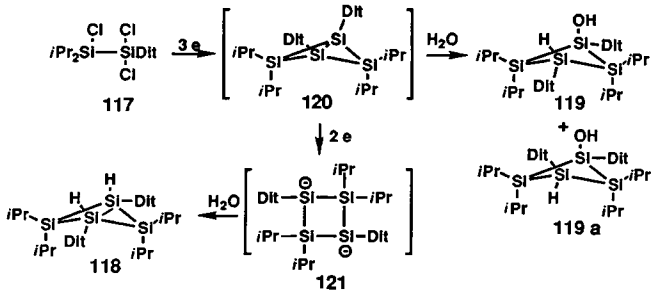
Several ab initio calculations on the parent compound **116** show two distinctly different energy minima, namely **116a** (central Si1–Si3 distance of ca. 2.3–2.4 Å) and **116b** (the corresponding bond length is 2.7–2.8 Å).[46g, 125] The former is 17 kcal mol^{-1} less stable than the latter (MC–SCF level). Other geometrical differences between these two minima are the dihedral angles between the three-membered rings (ca. 120° for **116a** vs. 140° for **116b**) and the Si–Si–H angles at the bridgehead positions (ca. 140° for **116a** vs. 90° for **116b**). That the observed short central Si1–Si3 bond in **111** corresponds to that of the less stable **116a** rather than



116b is possibly due to the steric requirements of the bulky bridgehead substituents.

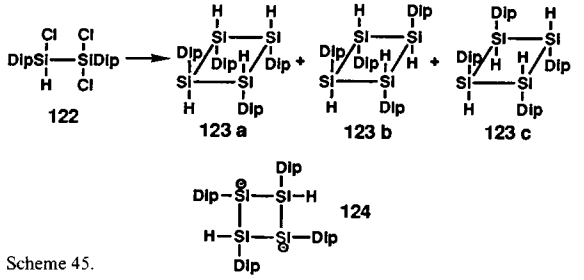
The reactivity of the Si1–Si3 bond in a bicyclo[1.1.0]tetrasilane is further enhanced by placing aryl groups on the bridgehead positions. Reductive cyclization of trichlorodisilane **117** under similar conditions to those applied to **112** leads to products which result from the reductive cleavage of the Si1–Si3 bond of the bicyclic system.[126] Thus, treatment of **117** with 5 equiv of lithium naphthalenide provides, after hydrolysis, **118** as the sole isolable product (Scheme 44). The use of 3.5 equiv of reductant leads to a 4:1



Scheme 44.

mixture of **119** and **119a** after hydrolysis. By analogy to the hydrolysis of **111**, the precursor of **119** is in all likelihood **120**. The Si1–Si3 bond in **120** appears to be further reduced to yield **121** with the excess reductant, a reaction not observed for **111** even at room temperature.

Reductive coupling of trichlorodisilane **122** with excess reductant appears to proceed in a manner similar to that described for **117**.[126] Thus, reaction of **122** with 5 equiv of lithium powder at −78 °C provides a mixture of three cyclotetrasilane derivatives **123a, b**, and **c** (Scheme 45). All

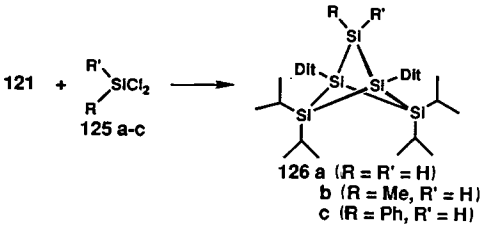


Scheme 45.

of these products apparently form from the corresponding dianion **124** and represent the first cyclotetrasilane derivatives of the $(RHSi)_4$ type.

8.1.2. Bicyclo[1.1.1]pentasilanes

The dianion **121**, which is formed as shown in Scheme 44, reacts with excess dichlorosilanes **125a–c** to provide **126a–c** (Scheme 46).[119] The crystal structure of **126a** dicloses the following interesting structural features. As expected, the three cyclotetrasilane rings are highly puckered with an average dihedral angle of 60°, which contrasts with the 0–37°

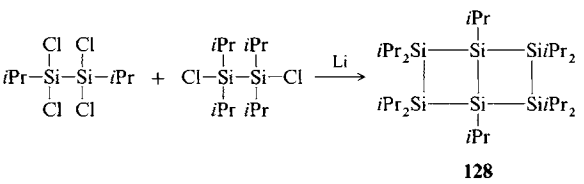


Scheme 46.

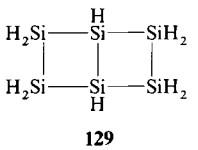
angle normally found in monocyclic systems.[3b, d] The Si-Si-Si angles in **126a** are very close to the C-C-C angles found in bicyclo[1.1.1]pentanes **127**,[127] showing a high degree of structural homology between the carbon and silicon systems, a feature also seen in other similar Group 14 ring systems (see Section 9.3).

8.1.3. Bicyclo[2.2.0]hexasilanes and Tin Analogues

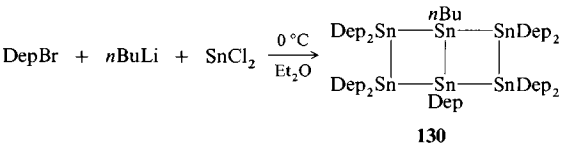
In 1987 *Nagai* et al. isolated in 3% yield the first bicyclo[2.2.0]hexasilane derivative **128** from the reaction products obtained from the cocondensation of 1,1,2,2-tetrachlorodiisopropyldisilane and 1,2-dichlorotetraisopropyldisilane with lithium (Scheme 47).[128a] The X-ray analysis of **128** discloses a *cis*-fused structure with a central Si–Si bond distance of 2.394 Å, which is comparable to those for the peripheral Si–Si bonds (2.385–2.426 Å).[128b] This structure is consistent with the computed structure of the parent compound **129**.[125d]



128



129



130

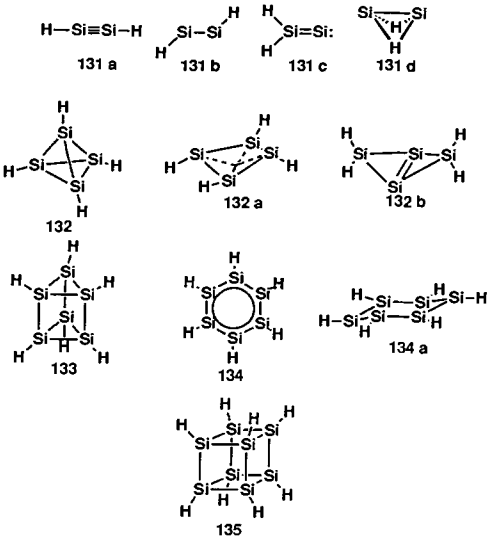
In 1989, *Sita* and *Bickerstaff* isolated in 1.5% yield bicyclo[2.2.0]hexastannane derivative **130**, from the reaction product of 2,6-diethylphenyllithium with tin dichloride in ether at 0 °C.[43] The selection of reaction conditions is critical, as a similar reaction in a different solvent (THF) at 0 °C provides the corresponding cyclotristannane **28a**. The crystal structure of **130** shows tin–tin bond lengths of 2.82–2.93 Å, which fall in the range commonly found for cyclopolystannanes possessing bulky ligands. The mechanism of formation of **130** is not obvious.

In contrast to the high reactivity of bicyclo[1.1.0]tetrasilanes toward a variety of reagents, bicyclo[2.2.0]hexasilane

(**128**) and -stannane (**130**) are air-stable. This may reflect the fact that Si, Ge, and Sn four-membered rings become significantly less strained. The computed strain energy (SE) of parent bicyclo[2.2.0]hexasilane **129** (ca. 30 kcal mol^{-1}) is much lower than that of parent bicyclo[1.1.0]tetrasilane **116** (ca. 65 kcal mol^{-1}).[46g, j, 125d]

8.2. Polycyclic $(RE)_{2n}$ Systems with E=Si, Ge, and Sn

The successful construction of the strained rings discussed above naturally aroused intense interest in the tetrahedrane, prismane, and cubane systems consisting of Group 14 elements. Not only are the physical properties of these new systems interesting in their own right, but they are also potential precursors to the corresponding triple-bond systems (RE≡ER). Calculations on singlet disilyne tend to agree that the relative stabilities increase in the order of linear disilyne (**131a**, $D_{\infty h}$), *trans*-bent disilyne (**131b**, C_{2h}), silasilene (**131c**, C_{2v}), and bridged disilyne (**131d**, C_{2v}).[6, 129] Recently, the



possible generation and trapping of dimethyldisilyne has been claimed.[130]

8.2.1. Theoretical Aspects

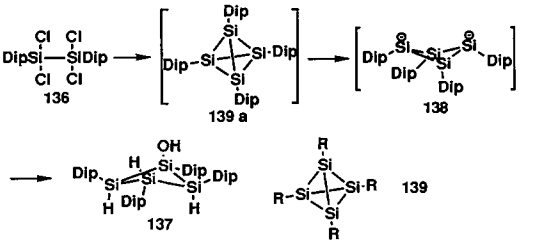
For the $(SiH)_4$ energy surface *Schaefer* and *Clabo* predict the isomer (**132**) of T_d symmetry to be, at least, a kinetically stable species which is connected by a large barrier to other $(SiH)_4$ isomers.[131] The local minimum of **132** is also identified by *Sax* and *Kalcher*.[132] In contrast to these results *Nagase* and *Nakano* contend that **132** is unlikely to be a minimum on the potential energy surface and isomerizes without a barrier.[133] Relative stabilities increase in the order of tetrasilatetrahedrane **132**, cyclotetrasilabutadiene **132a**, and bicyclo[1.1.0]tetrasilabut-1(3)-ene **132b**.[134]

For the $(SiH)_6$ species *Nagase* and *Sax* have found that hexasilaprismane (**133**) is the most stable of the Si_6H_6 isomers,[135a, b] consistent with the reluctance of silicon to form double bonds. Hexasilabenzene, unstable relative to **133**, was initially predicted by *Nagase*, *Sax*, and *Schaefer* to have a planar D_{6h} symmetry (**134**),[135] which was later replaced by *Nagase* and *Sax* with a chairlike puckered structure of D_{3d} symmetry (**134a**).[136] This dependence of the results on the method of computation may reflect a flat potential energy surface on which **134** and **134a** are located.

An interesting comparison of **132**, **133**, and **135** (octasilacubane) has been carried out by *Nagase* et al.[46e] The calculated Si–Si bond lengths increase in the order **132** (2.314 Å), **133** (2.359, 2.375 Å), and **135** (2.396 Å). Therefore, the Si–Si bond lengths in the three-membered rings are shorter than the typical bond length, while those in the four-membered rings are longer (see Section 4.2.1 for the structures of $(H_2Si)_3$ and $(H_2Si)_4$). Moreover, the SE decreases in the order of **132** (140.9 kcal mol^{-1}), **133** (113.8), and **135** (93.5). The octasilacubane **135** contains markedly less strain than the carbocyclic analogue, cubane (SE = 154.7 kcal mol^{-1}).[48] This result generally holds for silicon four-membered rings relative to cyclobutanes, which is probably due to an increasing tendency to keep the $(ns)^2(np)^2$ valence electron configuration in compounds with the heavier atoms. As a result, 90° bond angles with a low strain are made favorable.[137] Similarly, the germanium, tin, and lead counterparts are calculated to show low strain energies compared to that of cubane.[137]

8.2.2. Preparation and Structures of $(RE)_{2n}$

The successful construction of bicyclo[1.1.0]tetrasilane from 1,1,2-trichlorodisilane ($RCl_2Si-SiClR'_2$) suggests that 1,1,2,2-tetrachlorodisilanes ($RCl_2Si-SiCl_2R$) could serve, with the judicious selection of R, as precursors of hitherto unknown polycyclic systems including those represented by the molecular formula $(RSi)_{2n}$. Thus, reductive coupling of the tetrachlorodisilane **136** leads to the formation of several products from which **137** is isolated as a minor product after hydrolytic workup (Scheme 48).[3a] Compound **137** proba-

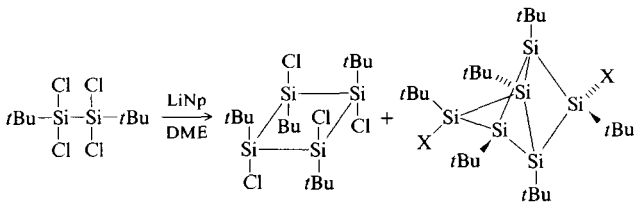


Scheme 48.

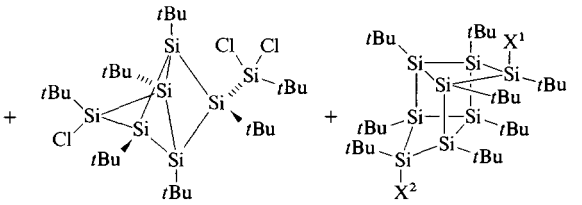
bly arises from intermediate **138**, which may have formed by the reductive cleavage of one of the Si–Si bonds of tetrasilatetrahedrane **139a**. From this result and the results outlined in Schemes 44 and 45 it becomes clear that a tetrasilatetrahedrane derivative **139** or other $(RSi)_{2n}$ derivatives would have to be "loaded" with bulky alkyl (rather than aryl) substituents in order to be synthesized.

The reductive oligomerization of 1,2-di-*tert*-butyl-1,1,2,2-tetrachlorodisilane (**140**) proceeds in a unique and somewhat unexpected manner to provide tricyclo[2.2.0.0^{2,5}]hexasilanes **141** and **142**, and tetracyclo[3.3.0.0^{2,7}.0^{3,6}]octasilane **143** as

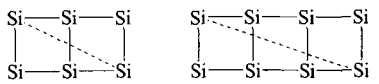
outlined in Scheme 49.[138] The reaction course is sensitive to the reductant/**140** molar ratio. Typically, use of 2.5 equiv of lithium naphthalenide in the reduction followed by fractional recrystallization gives rise to compounds **144** (8–20% yield), **141a** (4%), **142** (6%), and **143a** (6%). In contrast, an



140 **144** **141a** (X = Cl)
b (X = CH_3)



142 **143a** ($X^1 = X^2 = Cl$)
b ($X^1 = CH_3$, $X^2 = Cl$)
c ($X^1 = X^2 = CH_3$)



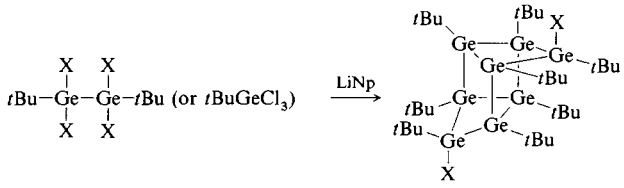
141 **143**

Scheme 49.

increase in the amount of reductant to 5 equiv leads to the formation of **141b**, **143b**, and **143c**. All spectral data including 2D-INEPT-INADEQUATE $^{29}Si-^{29}Si$ coupling data (INEPT = *I*nsensitive *N*uclei *E*nhanced by *P*olarization *T*ransfer, INADEQUATE = *I*ncredible *N*atural *A*bundance *D*ouble *Qua*ntum *T*ransfer *E*xperiment; see Section 9.1) are fully consistent with the structures shown in Scheme 49, and the molecular structures of **142** and **143a** have been established by X-ray analysis. The anion derived from **141a** appears to react with DME and **140** to provide **141b** and **142**, respectively, and **143b**, **143c** are derived from the anion or dianion formed by the reduction of **143a**. Since the structures of the products have been established, the likely pathways leading to these interesting products can be suggested. The dotted lines in the two skeletons **141** and **143** indicate the modes of intramolecular ring closure that are involved in the formation of these tri- and tetracyclic systems. No traces of octasilacubane and hexasilaprismane derivatives were found among the reduction products of **140**.

Syntheses analogous to that of **143a** have been reported recently. Thus, *Weidenbruch* et al. and *Sakurai* et al. have described the synthesis of [3.3.0.$0^{2,7}$.$0^{3,6}$]octagermane derivatives **145a** and **b** by the reduction of tetrahalodigermanes **146a** and **b** (Scheme 50).[139]

In addition to many precursors of type $RX_2Si-SiX_2R$ (R = Tsi, X=Br; R = Dis, X=Cl; R = Et_3Si, X=Cl; R = 1-Ad, X=Cl[53]) used for the construction of the $(RE)_{2n}$ system, a number of REX_3 compounds have been subjected to reductive coupling, often failing to generate in-



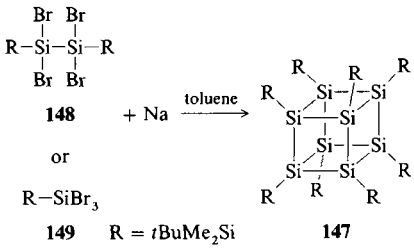
146a (X = Br)
b (X = Cl)

145a (X = Br)
b (X = Cl)

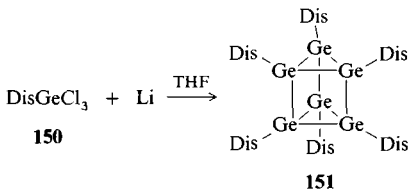
Scheme 50.

teresting ring systems such as tetrahedranes, prismanes, and cubanes.[140] The exceptions are two "one-shot" syntheses of a cubane and a prismane which are detailed below.

In 1988 *Nagai* et al. reported the successful synthesis of the first octasilacubane, **147**, obtained by condensation of 2,2,3,3-tetrabromo-1,4-di-*tert*-butyl-1,1,4,4-tetramethyltetrasilane (**148**) or 1,1,1-tribromo-2-*tert*-butyl-2,2-dimethyldisilane (**149**) with sodium (Scheme 51).[141] Octasilacubane **147** is an air-sensitive yellow compound. The structural assignment is based on its simple ^1H, ^{13}C, and ^{29}Si NMR spectra, consistent with the highly symmetrical structure. The crystal structure of **147** has not been reported.



148 + Na → **147**
or
$R-SiBr_3$
149 R = $tBuMe_2Si$



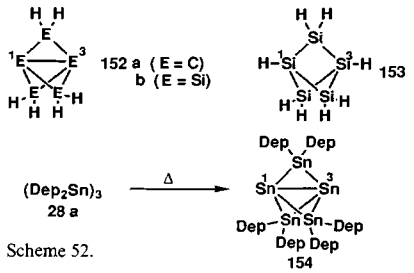
150 → **151**

Scheme 51.

Sakurai et al. have found that reductive coupling of bis(trimethylsilyl)methyltrichlorogermane (**150**) by lithium provides hexagermaprismane **151** as a yellow crystalline compound.[142] This compound is unexpectedly stable toward atmospheric oxygen and moisture. The prismane structure has been established by X-ray analysis. Notably, the Ge–Ge bond lengths in the triangles (2.578–2.584 Å) are longer than those in the rectangles (2.516–2.526 Å). This relationship lies in marked contrast with theoretical results (2.502 Å for the triangles and 2.507 Å for the rectangles of the parent hexagermaprismane which is free from steric congestion of the substituents).[137]

8.3. [1.1.1]Propellane System

[1.1.1]Propellane **152a** is an intriguing species that has received considerable experimental[143] and theoretical interest,[144] which focuses on the nature of the interbridgehead C–C bond. Recently, several theoretical investigations on the parent compound of the silicon analogue of **152a**, **152b**, have been reported.[46j, 125c, 145] The computed Si–Si



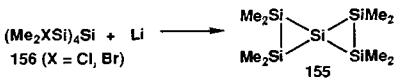
Scheme 52.

bond length of the central bridgehead bond Si1–Si3 is considerably stretched to ca. 2.72 Å, while the peripheral Si–Si bond length of 2.35 Å is normal. This central bond length of 2.72 Å is rather close to the nonbonding Si1 ··· Si3 distance of bicyclo[1.1.1]pentasilane **153** (2.92 Å, see Section 8.1.2).[146] These structural features show that the molecule possesses significant singlet diradical character. The calculated strain energy of **152b** is 62–70 kcal mol^{-1},[46j, 145] which is relatively low, particularly in comparison with the strain energy of **152a** (98 kcal mol^{-1}).[48]

In 1989 *Sita* and *Bickerstaff* succeeded in the isolation of a pentastanna[1.1.1]propellane derivative **154** in 13% yield by the thermolysis of cyclotristannane **28a** in xylene at 200 °C (Scheme 52).[147] Compound **154** is an air-sensitive, dark blue-violet crystalline compound and shows temperature-dependent ^{1}H NMR spectra. The propellane structure of **154** is verified by X-ray crystallography. The length of the pivotal Sn1–Sn3 bond is 3.367 Å, which falls well outside the normal range of Sn–Sn bonds (2.93–3.05 Å). This feature and the ^{119}Sn NMR spectrum are consistent with a significant singlet diradical character for the structure of **154**.

8.4. Spiropentasilane

In 1984 *Boudjouk* reported the synthesis of spiropentasilane **155** by the reductive ring closure of tetrakis(dimethylhalosilyl)silanes **156** with lithium (Scheme 53) in good



Scheme 53.

yield.[148] The assignment of the structure to **155** is based on the ^{1}H NMR spectrum and the products obtained from several chemical reactions. The stability of **155** is surprising, since this strained ring is "protected" only by the small methyl groups (see Section 4.1.1).

9. Instrumental and Interpretational Techniques Specially Adapted to This Research

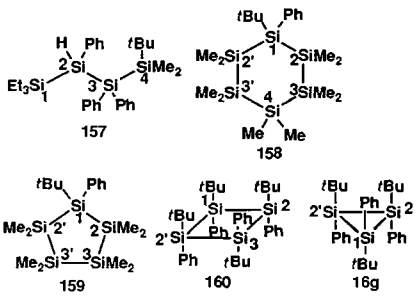
9.1. 2D INEPT-INADEQUATE ^{29}Si NMR Spectroscopy for Determination of ^{29}Si–^{29}Si Long-Range Couplings in Strained Cyclic Polysilanes

^{13}C 2D-INADEQUATE spectroscopy has seen widespread use in the convenient disclosure of connectivity of carbon atoms in complex organic molecules.[149] This technique is extremely powerful when the size of ^{13}C–^{13}C one bond coupling (^1J) is much larger than that of long-range coupling (^nJ, n ≥ 2), which is usually the case in acyclic and unstrained systems.[150] Use of the INEPT-INADEQUATE technique specifically modified for ^{29}Si nuclei to obtain ^{29}Si–^{29}Si couplings can similarly reveal the connectivity of complex polysilane frameworks.[54]

Table 12. ^{29}Si–^{29}Si coupling constants in several acyclic or monocyclic polysilanes.

Cpd.	δ [a]	^1J [Hz]	^nJ (n ≥ 2) [Hz]
157	−1.55 (1) [b]	68.4 (3–4)	4.9 (2–4)
	−3.92 (4)	65.4 (1–2)	2.9 (1–3)
	−37.54 (3)	57.6 (2–3)	2.9 (1–4)
	−63.78 (2)		
158	−22.90 (1)	62.1 (3–4 or 3′–4)	9.4 (2–4 or 2′–4)
	−40.33 (3 and 3′)	57.4 (1–2 or 1–2′)	8.2 (1–3 or 1–3′)
	−42.21 (2 and 2′)	[c] (2–3, 2′–3′)	
	−42.59 (4)		
159	−18.50 (1)	57.6 (1–2 or 1–2′)	9.8 (1–3 or 1–3′)
	−41.73 (2 and 2′)	[c] (2–3, 2′–3′)	9.8 (2–3′, 3–2′)
	−43.22 (3 and 3′)		
160	9.11 (1 or 3)	46.9 (1–2 or 1–2′)	27.3 (1–3)
	1.40 (3 or 1)	46.9 (2–3 or 2′–3)	
	−8.02 (2 and 2′)		
16g	−33.42 (2 and 2′)	24.1 (1–2 or 1–2′)	
	−37.33 (1)		

[a] ^{29}Si chemical shifts and coupling constants of **157**–**160** and **16g** in C_6D_6 (25 °C) at 53.7 MHz; standard Me_4Si. [b] The numbers in parentheses refer to the silicon atom numbering scheme shown in the structures of **157**–**160** and **16g**. [c] The chemical shifts of these ^{29}Si nuclei were too close to permit accurate measurement of the coupling constant between them.



Information on the size of ^{29}Si–^{29}Si coupling constants has been extended.[55] Table 12 and 13 list ^1J and ^nJ of **157**–**160**, **16g**, **143a,b**, and **142**. Acyclic compounds, represented by **157**, show ^1J values in the range 55–70 Hz, while the ^2J and ^3J values are an order of magnitude smaller (2.5–5.0 Hz). In the (relatively) strain-free six- and five-membered ring compounds **158** and **159**, the ^1J values are slightly decreased, but a sizable increase in ^2J values is observed. In the strained systems **160** and **16g**, ^1J values are still approximately twice as large as ^2J values in **160**, but the observed ^1J for **16g** is only 24.1 Hz. This increase in the magnitude of ^1J with an increase in ring size is consistent with the view that the magnitude of ^1J reflects the amount of s character of the Si ring orbitals.

The 2D-NMR spectrum of polycyclic compound **143b** reveals the presence of fifteen ^{29}Si–^{29}Si couplings of approximately 20 to 40 Hz as shown in Figure 3. Since this system has eleven Si–Si bonds, four of the fifteen couplings

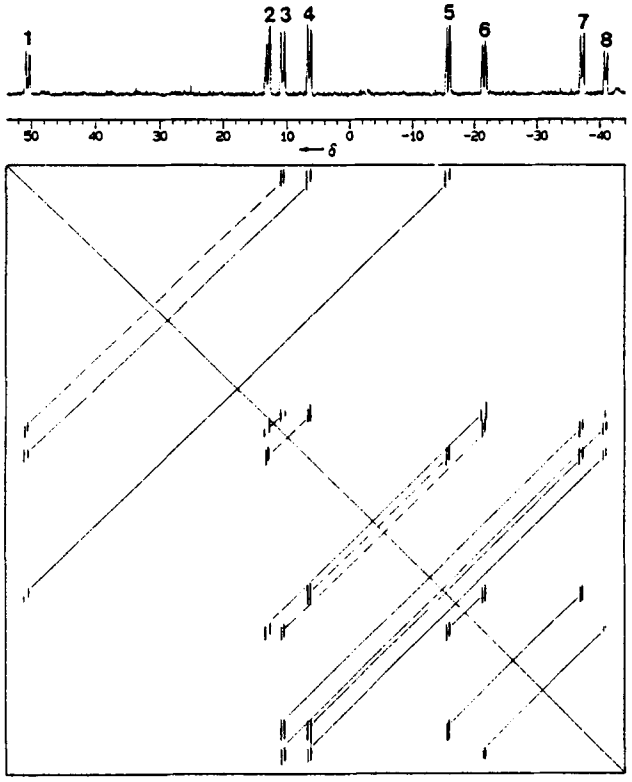


Fig. 3. 53.7 MHz $^{29}Si-^{29}Si$ 2D-INEPT-INADEQUATE spectrum of the tetracycle **143b** in C_6D_6 and projection of the 2D spectrum onto the F_2 axis (top). Signals connected by solid lines correspond to one-bond interactions (^1J); those connected by dotted lines denote long-range couplings (^nJ).

must be long-range (^nJ, $n \geq 2$). Through somewhat lengthy but logical arguments, ^{29}Si signals 1–8 are assigned to the Si nuclei of compound **143b** in the manner shown in Table 13. With the completion of the spectral assignment of **143b**, that of **143a** follows. In **143a** there are three pairs of observable,

Table 13. $^{29}Si-^{29}Si$ coupling constants for the polycyclic polysilanes **143a**, **b** and **142**.

Cpd. [a]	^1J [Hz]		^nJ ($n \geq 2$) [Hz]

	41.0 (2–3)	33.4 (1–4)	23.1 (4–5)
	30.8 (4–7)	28.9 (3–8)	22.5 (3–6)
	28.3 (3–7)	25.7 (4–8)	19.9 (2–4)
	25.7 (5–6)	18.0 (5–7)	
	17.3 (6–8)		
 **143a**	41.0 (1–3, 1′–3′)		23.5 (1–2′, 1′–2)
	35.1 (1–2, 1′–2′)		23.5 (2–3, 2′–3′)
	29.3 (2–4, 2′–4, 2′–4′)		5.8 (1–4, 1′–4′)
	17.5 (3–4, 3′–4′)		
 **142**	43.0 (2–3)	36.1 (1–4)	13.7 (1–3)
	34.1 (2–6)	32.2 (2–7)	16.6 (3–4)
	29.3 (1–5)	27.4 (5–7)	
	24.5 (4–6)	23.4 (4–7)	
	[b] (5–6)		

[a] The silicon nuclei of each molecule are numbered according to the order of their chemical shifts as shown in Figure 3. [b] The chemical shifts of these ^{29}Si nuclei were too close to permit accurate measurement of the coupling constant between them.

significant long-range couplings of which one is rather small (5.8 Hz). Compound **142** also exhibits two sizable long-range couplings, and the most appropriate chemical shift assignments of **142** are given in Table 13.

West and *Hengge* independently reported 2D ^{29}Si NMR spectroscopy of five- and six-membered rings, showing that this is an efficient method for the structure determination of silicon frameworks.[151] In these systems ^1J couplings can be easily distinguished from long-range ones ^nJ ($n \geq 2$). However, in strained systems such as **143** and **142**, ^1J and ^nJ couplings cannot be distinguished merely through the inspection of their magnitudes.

A considerable amount of information has been accumulated pertaining to long-range $^{13}C-^{13}C$ couplings in both unstrained and strained systems. In comparison with the data in Tables 12 and 13, long-range $^{13}C-^{13}C$ and $^{29}Si-^{29}Si$ interactions show more or less similar trends, although the latter are more pronounced in strained systems. The ^4J value in **142** is particularly noteworthy.

9.2. Determination of *n* for Cyclopolystannanes $(R_2Sn)_n$ by ^{119}Sn NMR Spectroscopy

Due to the natural abundance of ^{117}Sn (7.67%, $I = 1/2$), cyclopolystannanes ($[R_2Sn]_n$, $n \geq 1$) theoretically produce a unique set of $^{119}Sn-^{117}Sn$ coupling satellites with the upper limit of ^mJ and the intensities of the satellites governed by n as shown in Table 14.[56]

Table 14. Calculated intensities of the satellite signals arising from $^mJ(^{119}Sn-^{117}Sn)$ coupling in the ^{119}Sn NMR spectra of cyclopolystannanes $(R_2Sn)_n$. The intensities of the satellites are relative to the main resonance.

n	Intensities [%] ^1J	^2J	^3J
1	0	0	0
2	4.1	0	0
3	8.2	0	0
4	8.2	4.1	0
5	8.2	8.2	0
6	8.2	8.2	4.1
7	8.2	8.2	8.2

For comparison of these calculated intensities Table 15 lists experimental values for various cyclopolystannanes. Of primary interest is the ^{119}Sn NMR spectrum of the cyclotristannane **28a** whose structure has been determined by X-ray analysis.[42] The main resonance should be accompanied by

Table 15. Observed ^{119}Sn chemical shifts, $^mJ(^{119}Sn-^{117}Sn)$ coupling constants, and intensities of satellites relative to the main resonance in the ^{119}Sn NMR spectra of cyclopolystannanes $(R_2Sn)_n$.

Cpd.	n	δ	^mJ [Hz]	Intensities [%]
28a	3	−416.5	$^1J = 2285$	8.2

only two satellites with relative intensities of 8.2% of the main resonance. The actual spectrum fits this prediction; the satellite intensities are measured at 8.2% of the parent peak.[44] The ^{119}Sn NMR spectrum of cyclotetrastannane **161**, whose structure has also been confirmed by X-ray analysis,[152] also generates two sets of coupling constants that are in close agreement with the predictions.[44] However, **161** unexpectedly exhibits a ^{2}J coupling constant larger than that of the ^{1}J coupling.[153] Finally, the ^{119}Sn NMR spectrum of hexamethyldistannane **162** shows the expected satellite intensities (3.7% of the main resonance).[44, 56]

The general applicability of the above technique permitted the structures of cyclotristannane **28b** and distannene **52** to be easily determined without recourse to X-ray crystal analysis.[44] ^{119}Sn NMR splitting patterns should henceforth serve as a powerful tool for the structural determination of other cyclopolystannanes.

Caution must be taken in interpreting spectral data, however. For example, accurately determining whether a cyclopolystannane is five- or six-membered relies on the ability to unequivocally determine the presence of a ^{3}J value, and experimentally, this is not always easy to do, especially when ^{3}J may be smaller than the experimental linewidth of the main resonance. For some polycyclic structures, ^{3}J is near zero due to the 90° dihedral angles in certain structures. The power of the technique still remains, however, in its ability to determine the symmetry of a polystannane and relative intensities can be used to distinguish between the $(R_2Sn)_n$ and $(RSn)_n$ series.

9.3. Comments on Structural Homology

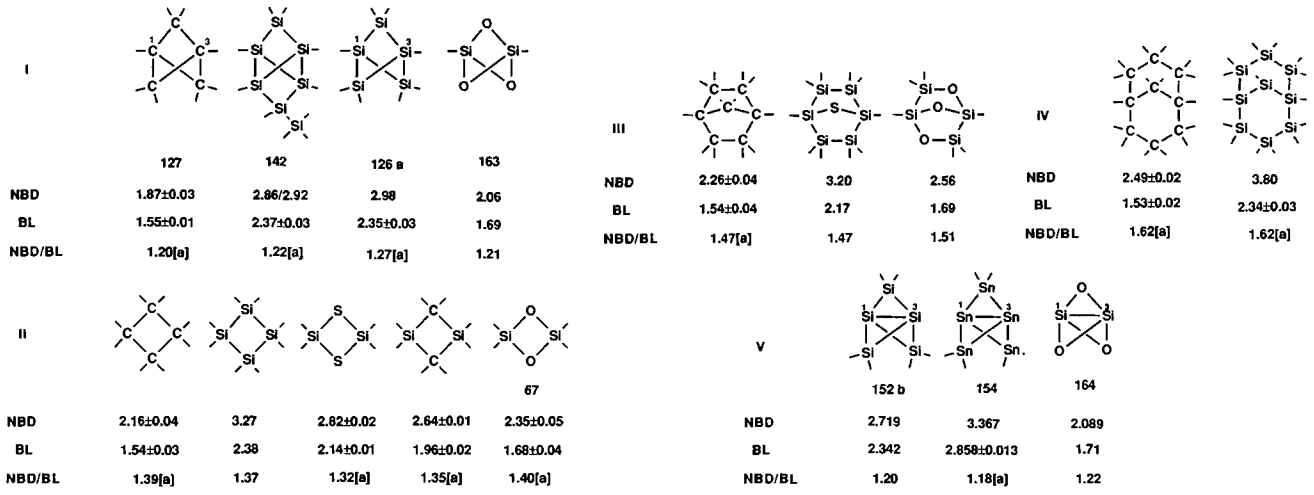
Comparison of the two molecular structures **126a** and **127** in Scheme 54 reveals a high degree of structural homology.[119] Thus, in **126a** the ratio of the nonbonding Si1 ··· Si3 distance (NBD) to the averaged length of the Si–Si bonds (BL) is 1.27, a ratio close to that observed for carbocycle **127**. Two other examples having the same framework are **142** and the unknown trioxo analogue **163** whose geometry was computed recently. Both **142** and **163** exhibit NBD/BL ratios of ca. 1.21.

The validity of this approximate homology rule is not confined to the compounds of the above series I but also applies to those of four other series. Thus, a nearly constant NBL/BL ratio was obtained for each series II (cyclobutane system), III (bicyclo[2.2.1]heptane system), IV (bicyclo-[3.3.1]nonane system), and even V ([1.1.1]propellane system where the E1 and E3 are uniquely bonded).

The oxygen-bridged compounds **163** in series I, **67** in series II, and **164** in series V are of particular interest. The finding that the Si ··· Si distance in compound **67** falls within the normal Si–Si BL has aroused much discussion on the nature of the bonding between those Si atoms (Section 6.1).[101b, f, 102, 118] Compound **163** is calculated to have an Si ··· Si NBD of 2.06 Å, a distance well below the normal Si–Si bond distance;[146, 154] similarly **164** has a very short bridgehead Si–Si bond distance of 2.089 Å.[145b] The remarkable consistency observed for each of series I, II, and V implies that the shortening of the Si ··· Si distance of **163**, **67**, and **164** is due mainly to the short Si–O (ca. 1.66 Å) bond distance compared to others in these ring systems. The approximate homology rule appears to provide an instant, good estimate on the NBD of unknown and known compounds.

10. Final Remarks

Approximately 10 years have passed since the synthesis of the first cyclotrisilane derivative and subsequent generation of the corresponding disilene. The silicon project has been extended to include Ge and Sn and also to the synthesis of strained polycyclic systems. Its pursuit has been extremely rewarding, and the synthesis of each new compound has been accompanied by excitement. At this moment several immediate synthetic targets are obvious: 1) a pentasila-[1.1.1]propellane derivative (from the bicyclo[1.1.1]pentasilane derivative), 2) a tetrasilatetrahedrane, and 3) a disilyne, the challenge increasing in this order. Additionally,



Scheme 54. The NBD/BL ratio in bi- and monocycles; NBD and BL are given in [Å]. The analogous carbacyclic and tin systems are also shown for comparison. [a] NBD/BL from averaged distances.

the project will not be complete without the generation and spectral characterization of the parent cyclotrisilane, -germane, and -stannane as well as disilene, -germene, and -stannene, following the approach of our previous work on cyclobutadiene.

In addition to the above relatively short range prospects, two fundamental problems of Group 14 element chemistry concern 1) the meager understanding of the reaction mechanisms involving organometallic compounds (even for the oxygenation of Si–Si to Si–O–Si with O_2) and 2) the almost complete lack of synthetic methodology for E–E bond formation except for the Kipping reaction. This is in sharp contrast with the enriched knowledge of carbon chemistry, and it is not obvious how to explore these unknown fields. Here exists a real challenge; the discovery of a new E–E bond-forming reaction will herald a new generation of this chemistry and may also be needed for the synthesis of a triple bond between these elements.

Addendum (May 6, 1991)

After submission of the original manuscript several articles pertinent to this review have appeared; also, those who read our manuscript have kindly called to our attention references which we had overlooked. These additional references[155–166] are tabulated below with reference numbers, titles, and the locations where they should be inserted.

We wish to thank with great pleasure the many collaborators who are listed in the references. They have contributed experimentally as well as conceptually to the development of the Group 14 metal chemistry summarized in this review. We would like to acknowledge the careful examination and criticisms of the manuscript kindly offered by Orin Tempkin of our laboratories as well as many of the experts in this field including Michael Lappert, Wilhelm Neumann, Jacques Satgé, Larry Sita, and Manfred Weidenbruch. Many of the improvements are a direct result of their efforts but errors remain ours. The work quoted in the review has been supported by grants from the National Science Foundation (USA) as well as from the Kao Corporation (Japan).

The Biochemical Reactions of Organometallics with Enzymes and Proteins

By Alexander D. Ryabov*

Most specialists doing organometallic chemistry have little understanding of what modern biochemistry is. On the other hand, most biochemists believe that organometallic chemistry stands much apart from the problems they study. But the real distance, if any, between these magnificent pyramids of modern science is progressively decreasing. Their interaction has given birth to a new branch of science, organometallic biochemistry, the general aspects of which are discussed here.

1. Introduction

This article will not deal with the chemistry of vitamin B_{12}, a natural organometallic molecule with a cobalt–carbon bond,[1] which has long served as a firm, but the only, bridge between organometallic chemistry and biochemistry, two very active areas of modern science. Instead, the article will focus on a newborn branch of science, organometallic biochemistry. This area no longer centers around the chemistry of vitamin B_{12} itself and its numerous models,[2–7] but has spread out to encompass many organometallic compounds which can undergo various biochemical transformations in the presence of enzymes or microorganisms. At present, biocatalysts are not sufficiently "educated" to carry out the direct synthesis of organometallics from metals, ions, or complexes and organic structures, but they are able to modify organometallics and, in some cases, to cleave selectively a carbon–metal bond. Moreover, organometallics have been "taught" to be substrates of biocatalysts and, therefore, to undergo enzyme-catalyzed transformations. The biochemical reactions of organometallic reagents, mostly in the presence of enzymes and microorganisms, will be discussed here in three sections. Section 2 shows the use of biocatalysts in selective conversions of organometallics. Section 3 describes systems in which redox-active organometallics behave as substrates in reactions catalyzed by oxidases and peroxidases. Section 5 deals with enzymes that destroy environmentally damaging organometallic species, organomercurials in particular, in the biosphere. These enzymes are in fact unique, since they catalyze the cleavage of the "heart" of organometallic molecules, the metal–carbon bond.

2. Selective Conversions of Organometallics by Biocatalysts

2.1. General Remarks

The impressive achievements in the use of enzymes[8–13] and microorganisms[14] in organic synthesis, a general understanding that they can function both in binary mixtures of organic solvents and water and in pure organic solvents,[15–19] and the demonstration that the specific catalytic activity of enzymes entrapped in reversed micelles is preserved or even increased without any loss in stability[20] were compelling reasons for the use of biocatalysts in organometallic synthesis as well. In fact, many organic syntheses realized in the presence of biocatalysts proved that enzymes display much broader substrate specificity than once assumed.[11] Therefore, it was reasonable to expect that organometallics would also be accepted as substrates by enzymes. On the other hand, since organometallics are usually water-insoluble, their reactions with enzymes have to be carried out in nonaqueous media. This is indeed a challenging problem for both chemists and biochemists. Moreover, the catalytic activity and specificity of an enzyme can be tuned by properly varying its environment, for example, in the inner cavity of reversed micelles[21] and, probably, by changing the composition of the organic medium. Therefore, there are ways to adjust the enzyme specificity with respect to a particular organometallic substrate.

2.2. From Carbon to Silicon and Germanium

Organometallic biosynthesis has not yet reached the state where detailed critical analysis is possible. But there are two basic approaches. The first is aimed at metallocene compounds, in particular ferrocene derivatives. We will see later that, at present, ferrocene derivatives are undoubtedly the most "biological" materials in the ocean of organometallic compounds. The second approach, which is being developed by the group of *Tacke*, may seem trivial at a first glance, but, in fact, it is a very balanced, well-reasoned, and fruitful concept. The idea is simple: since enzymes carry out enantiomeric synthesis of many, not necessarily natural, organic compounds, why should not these enzymes convert a compound with one or several silicons replacing carbons. Indeed, some enzymes of microorganisms do! Further, if silicon, why not germanium? Again, such enzymes have been found! The virtue of this "simple" approach cannot be overestimated, since optically active organosilicon compounds are already used as so-called siladrugs.[22–24] The corresponding germanium species may appear even more advantageous, since even now they are considered as possible alternatives to platinum complexes in cancer chemotherapy.[22, 25, 26]

The first report by *Tacke* et al.[27] dealt with the microbiological enantioselective reduction of trimethylsilylalkyl acetoacetates **1b, d** to the corresponding (+)-3(*S*)-hydroxybutanoates **2** in the presence of *Kloeckera corticis* (ATCC 20109) [Eq. (a)]. The enantiomeric purity was found to be

[*] Prof. A. D. Ryabov

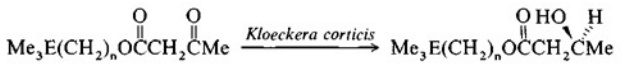
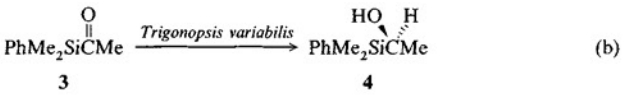
Stremyanny per. 28, 113054 Moscow (USSR)



80% for **2a**, **b**, **d** and 65% for **2c**. Remarkably, replacement of carbon by silicon increases the enantiomeric purity of the products formed.

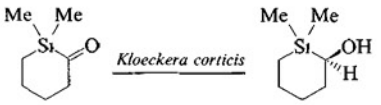
Trigonopsis variabilis (DSM 70714) appeared to be the best yeast among one hundred tested for the enantioselective reduction of acetyldimethylphenylsilane (**3**) to (*R*)-(1-hydroxyethyl)dimethylphenylsilane (**4**) [Eq. (b)]. *Trigonopsis*



3 4

variabilis showed the best results concerning the reaction rate, the isolation of **4**, and its purity with respect to the formation of biogenic by-products.[28] When resting cells were used under optimal conditions (37 °C, pH 6–8, 0.25 g L^{-1} of **3**), product **4** was isolated in 70% yield with an enantiomeric purity of 86%. Preliminary studies have shown that acetyldimethylphenylgermane is also accepted as a substrate by *Trigonopsis variabilis* to give the reduction product as the *R* enantiomer. Interestingly, the activity of the yeast decreases on going from the silicon compound **3** to the germanium compound to the carbon compound (21:12:1). Unexpectedly, the activity of the carbon analogue of **3** was substantially lower than that of the silicon and germanium derivatives. The enantioselective microbial reductions of RR′R″SiC(O)Me (R = Me, R′ = Ph, R″ = Me_3C, Me_3Si) to the corresponding alcohols can be performed in the presence of *Trigonopsis variabilis*.[29]

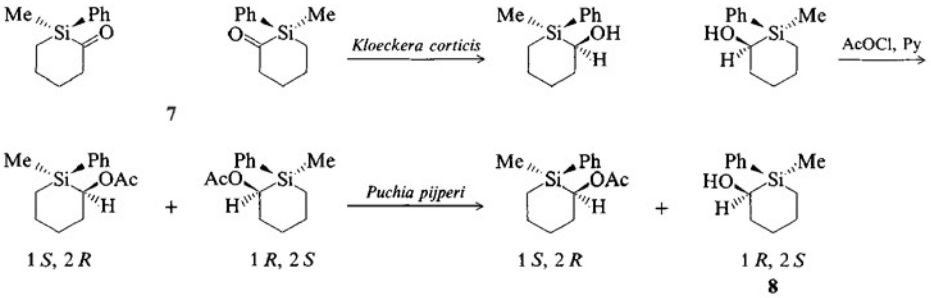
Silacyclohexanones also undergo enantioselective reduction. In particular, growing cells of the yeast *Kloeckera corticis* reduce 1,1-dimethyl-1-silacyclohexan-2-one (**5**) to afford the corresponding enantiomeric alcohol **6** in 60% yield (92% *ee*) [Eq. (c)]. Recrystallization from *n*-hexane increases the optical purity up to 99% *ee*.[30] A similar route to opti-



5 6

cally active (1*R*,2*S*)-1-methyl-1-phenyl-1-silacyclohexan-2-ol, starting from racemic 1-methyl-1-phenyl-1-silacyclohexan-2-one (**7**), was reported.[31] The diastereomerically pure product could be obtained by two biotransformation steps and one chemical step (Scheme 1).Diastereoselective reduction of **7** by *Kloeckera corticis* gave a 1:1 mixture of (1*S*,2*R*)- and (1*R*,2*S*)-1-methyl-1-phenyl-1-silacyclohexan-2-ol in 97% yield with a diastereomeric excess of about 90%. The quantitative esterification of the mixture with acetyl chloride in pyridine afforded again a 1:1 mixture of the corresponding acetates. This mixture was then converted into optically active alcohol **8** with *R* configuration at silicon and *S* configuration at carbon by a highly enantioselective hydrolysis with *Puchia pijperi* (ATCC 20127). After separation from the unreacted 1*S*,2*R* acetate by chromatography on silica gel, the desired product was isolated in a very pure form (*ee* > 96%).

The examples discussed above convincingly show clear perspectives of this field of organometallic biochemistry. One may expect that organometallic molecules with tetrahedral metal centers will also be involved in such biotransformations. Undoubtedly, these studies will be stimulated by the tremendous need for new drugs.

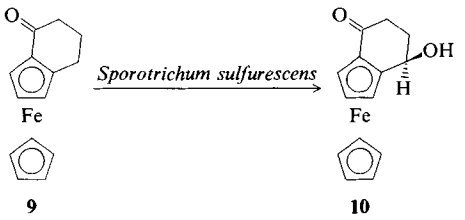


Scheme 1. Two biotransformations and one chemical step afford diastereomerically pure **8**.

Professor Alexander D. Ryabov was born in Moscow in 1953 and educated at Moscow State University. He graduated in 1976, obtained a Ph.D. degree in 1979 and a Doctor of Science degree in 1987. Since 1989 he has been Professor of Chemistry at the Division for Chemistry, G. V. Plekhanov Institute of National Economy. His present interests are aimed at enzymes and organometallics.

2.3. Ferrocene and Cymantrene Derivatization

The history of biotransformations of ferrocene probably started in 1971 when *Johnson* and *Murray* reported on microbial hydroxylation of 1,2-(α-oxotetramethylene)ferrocene (**9**) in the presence of the mold *Sporotrichum sulfurescens* (ATCC 7169) to afford hydroxyketone **10**.[32] The best results were obtained at low substrate levels. Compound **10** was the optically active, *exo* product, thus suggesting the enzymatic nature of the oxidation [Eq. (d)].



9 **10** (d)

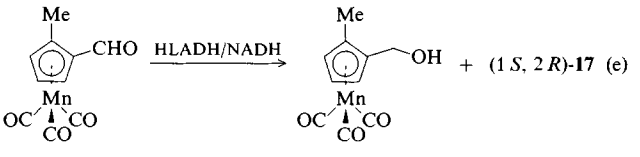
A detailed investigation of the asymmetric reduction of carbonyl ferrocene derivatives has been launched by *Ratajczak* and *Misterkiewicz*,[33] who reported that formylferrocene, ferrocenyl trifluoromethyl ketone (**11**), and [3]ferrocenophan-1-one (**12**) are effectively reduced by baker's yeast in the presence of D-glucose, (Table 1, entries 1, 2, 5). Formylferrocene, in particular, is quantitatively reduced at 33 °C in a matter of 20–40 min to hydroxymethylferrocene. Prochiral molecules **11** and **12** are transformed into (−)-1-ferrocenyl-2,2,2-trifluoroethanol and (−)-[3]ferrocenophan-1-ol in 50 and 10% yield, respectively. Acetyl-, propionyl-, isobutyryl-, benzoyl-, and 1,1′-diacetylferrocene, as well as **9**, did not undergo the reduction by baker's yeast. The product of reduction of **11** initially has an optical rotation of − 6.4,[33] which was finally increased to − 27.7, the yield being 90.5%.[34] Use of other microorganisms extends the substrate specificity of the reduction. In particular, although acetylferrocene (Table 1, entry 3) is resistant to baker's yeast, other microorganisms, such as *Candida tropicalis* (IFO 199), *Pichia quercuum* (IFO 949), and *Saccharomyces cerevisiae* (IFO 305), reduce this compound to the corresponding *S* alcohol.[35] The yield is low, but the reduction gives a high enantiomeric excess (96% *ee*). Additional examples of microbiological or enzymatic redox transformations aimed at the -CO-⇌-CH(OH)- couple are summarized in Table 1. Entries 6 and 7 need special comment. 1,2-Bis(hydroxymethyl)ferrocene (**13**) was oxidized with horse liver alcohol dehydrogenase (HLADH) at 30 °C, pH 8.3, in the presence of $NAD^{\oplus}$ and glutamate dehydrogenase for cofactor recycling.[36] The product isolated has the same properties, except for the sign of optical rotation, as the material obtained by the HLADH-catalyzed reduction of 1,2-diformylferrocene (**14**) in the presence of NADH and ethanol at 5 °C and pH 7.5. The fact that HLADH oxidizes *meso*-diol **13** to the 1*R*,2*S* semialdehyde and reduces *meso*-dialdehyde **14** to the 1*S*,2*R* antipode indicates that the enantiotopic discrimination of HLADH for the *meso* compounds is the same for both oxidation and reduction reactions. Such a phenomenon had not been previously observed,[36] although

Table 1. Redox transformations of ferrocene derivatives (Fc-R).

Entry	Starting material	Product	Microorganism or enzyme	Yield [%] (*ee* [%])	Ref.
1	Fc-CHO	Fc-CH_2OH	baker's yeast	100	[33]
2	Fc-$COCF_3$ **11**		baker's yeast	50 90.5	[33] [34]
3	Fc-$COCH_3$		*Candida tropicalis* *Saccharomyces cerevisiae*	7 (96)	[35]
4	Fc-COD	 *S*	baker's yeast	90.8	[38]
5	 **12**	 (−)	baker's yeast	10	[33]
6	 **13**	 (1*R*, 2*S*)	HLADH, $NAD^{\oplus}$	81 (86)	[36]
7	 **14**	 (1*S*, 2*R*)	HLADH, NADH	80(94)	[36]
8	 **15**		HLADH, $NAD^{\oplus}$, FMN	44(100)	[37]

a large number of HLADH-catalyzed asymmetric syntheses involving *meso* diols or diketones had been carried out. The organometallic nature of substrates **13** and **14** thus reveals some features of HLADH catalysis which are hidden in the case of purely carbon substrates.

Entry 8 presents an example of kinetic resolution of racemic alcohols. Notably, the corresponding ruthenocene and osmocene derivatives behave in a similar way.[37]



17 (1*R*, 2*S*)-**18** + (1*S*, 2*R*)-**17** (e)

Alcohol dehydrogenase was also used for kinetic resolution of chiral aldehydes in the cymantrene series. Enantioselective reduction of (±)-tricarbonyl(η^5-1-formyl-2-methylcyclopentadienyl)manganese (**17**) with HLADH and NADH at 4 °C and pH 7 afforded (1*R*,2*S*)-**18** in 35% yield together with unreacted (1*S*,2*R*)-**17** (31%) [Eq. (e)]. Remarkably, (1*R*,2*S*)-**17** can be easily obtained from (1*R*,2*S*)-**18** by oxidation with manganese dioxide.[37]

Lipases are another class of enzymes that readily accept the ferrocene functionality. In particular, reaction of 1-hydroxyethylferrocene (**15**) with vinyl propionate in toluene in the presence of porcine pancreas lipase yielded (*R*)-**16** [Eq. (f)]. The reaction is irreversible since the acylating agent affords a volatile product, acetaldehyde.[39] The enantiomeric purity of the (*S*)-**15** and (*R*)-**16** thus obtained is 84%. Similar transformations have also been carried out using lipase from *Pseudomonas fluorescens* in *tert*-butyl alcohol as solvent with $MeCOOCH{=}CH_2$ as an acylating agent.[40]

$$\mathbf{15} + EtCOOCH{=}CH_2 \xrightarrow{PPL} \textit{S}\text{-}\mathbf{15} + Fc(H)(OCOEt) + H_3CCHO \qquad (f)$$

R-**16**

2.4. Other Examples

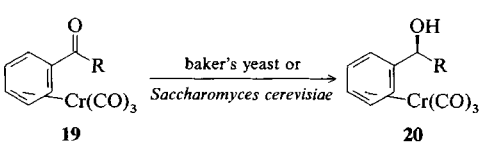
Therisod[41] has recently reported on lipase-catalyzed transesterification in benzene or cyclohexane via *O*-stannyl ethers [Eq. (g)]. Lipases from porcine pancreas (PPL), *Chromobacterium viscosum*, and *Candida cylindracea* were tested. Only lipase from the latter source was indifferent to organometallic substrates. The highest rate of PPL-catalyzed reaction was achieved for reaction of ethyl butanoate with $Me(CH_2)_5OSnBu_3$. Interestingly, stannyl ethers were found to be much more active than the corresponding alcohols.

$$R^2{-}C(=O){-}O{-}Et + R^1OSnR_3 \rightleftharpoons R^2{-}C(=O){-}O{-}R^1 + EtOSnR_3 \qquad (g)$$

R = Me, *n*-Bu; R^1 = *n*-C_6H_{13}, cyclohexyl; R^2CO = acetyl, *n*-butyryl, capryloyl, lauryl

Organic chemists widely use the chromium tricarbonyl moiety, a powerful electron-releasing group, which, on complexation, strongly affects the reactivity of arenes.[42] An intriguing question is how such complexation affects the enzymatic reactivity of arenes. Additionally, such a complexation with asymmetrically 1,2-disubstituted arenes gives rise to a pair of enantiomers, which might be kinetically resolved by enzymes or microorganisms.

In the presence of D-glucose, (η^6-acetophenone)tricarbonylchromium (**19a**) can be converted into (*S*)-(η^6-1-phenylethanol)tricarbonylchromium (**20a**) by baker's yeast[43] and by *Saccharomyces cerevisiae*[35] in 96% (99% *ee*) and 94% (74% *ee*) yield, respectively [Eq. (h)]. Remarkably, baker's yeast reduces uncomplexed acetophenone under the same conditions to (*S*)-1-phenylethanol in only 69% yield, with an optical purity of only 92%.[43] With the more bulky propionate complex **19b**, the reduction was very slow; after two weeks, only a 20% yield of **20b** was obtained. In



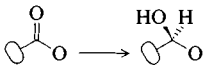
(h)

19 **20**

19a, R = Me; **19b**, R = Et

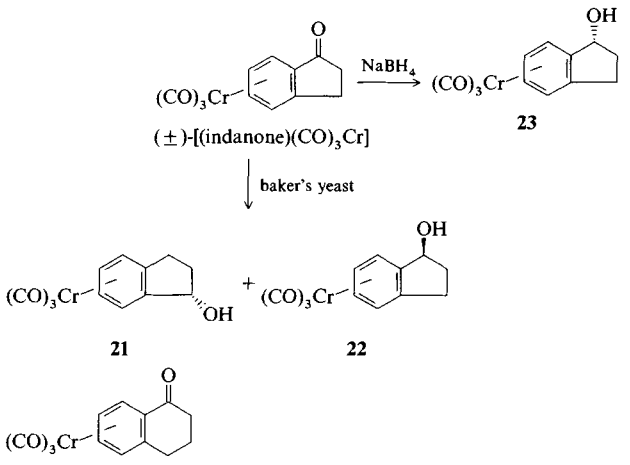
contrast, free propiophenone is 50% reduced in six days. In both cases, the enantiomeric excess of *S* alcohol was 87%. The analogue of **19a** in which one CO ligand is replaced by PPh_3 is not reduced either. Thus, the steric bulk in this part of the molecule also affects drastically the reaction course. The effect of bulky groups has two possible explanations. First, the size of the organometallic substrate may be too large for the enzyme active site. Second, a change in the steric bulk may cause a change in the permeability of cell walls to organometallic substrates; that is, the hydrophobicity of the organometallic substrate is changed. It is difficult to assess which contribution is larger until studies with individual enzymes are carried out.

In general, the reduction follows the so-called Prelog rule illustrated by Equation (i).[43] As would be expected, more complex substrates give several products. For example, reduction of (±)-(η^6-indanone)tricarbonylchromium by baker's yeast affords the (−)-(*S*)-*endo* alcohol **21** and the (−)-(*S*)-*exo* alcohol **22** in 47% (55% *ee*) and 5% (71% *ee*) yield,



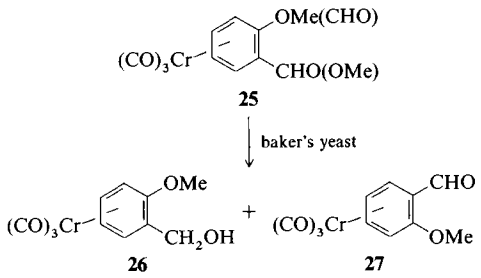
(i)

respectively, together with unreacted material, which was chemically reduced by $NaBH_4$ to the (+)-(*R*)-*endo* alcohol **23** (48%, 25% *ee*)[44] (Scheme 2). Similarly, the tetralone complex **24** is reduced without the formation of the *exo* product. A 52% yield of the 1*S* *endo* alcohol (92% *ee*) was achieved in a buffered solution at pH 7. Use of unbuffered media decreases the optical purity of the product to 83% *ee*.



Scheme 2. Reduction of (±)-[(η^6-indanone)$(CO)_3$Cr] with baker's yeast.

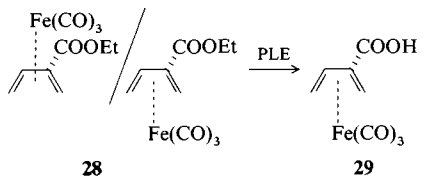
Several examples of enantioselective microbiological kinetic resolution of chiral organometallics are shown below. Enantioselective reduction of (±)-(η^6-1-formyl-2-methoxybenzene)tricarbonylchromium (**25**) by baker's yeast at 22 °C in water, in the presence of D-glucose, afforded (+)-(*R*)-(η^6-1-hydroxymethyl-2-methoxybenzene)tricarbonylchromium (**26**) with 66% *ee* and optically active, unchanged (+)-(1*S*)-(η^6-1-formyl-2-methoxybenzene)tricarbonylchromium (**27**) with 81% *ee*[45] (Scheme 3). Even better resolution of **25** was



Scheme 3. Kinetic resolution of a racemate by enantioselective reduction with baker's yeast.

achieved in the presence of HLADH and NADH.[37] The optical purity of the compound was as high as 100%.

Another enzyme successfully used for resolution of a racemic organometallic compound is pig liver esterase (PLE)[46] (Scheme 4). The PLE-catalyzed reaction of the



Scheme 4. Resolution of enantiomers with pig liver esterase (PLE).

racemic 2-ethoxycarbonyl-substituted butadieneiron complex **28** in aqueous methanol (pH 7, room temperature, 30 h) affords acid **29** in 40% yield. The unhydrolyzed ester was recovered and hydrolyzed (LiOH) to give the antipode of **29** in 38% yield. Both the enzymatic hydrolysis product (**29**) and the acid obtained from the unhydrolyzed ester were found to be of 85% *ee*. The optical purity of both the acids was raised to > 98% *ee* by one recrystallization.

2.5. Organometallics in NADH/NAD$^{\oplus}$ Recycling

The conversion of NAD$^{\oplus}$ to NADH requires a transfer of two electrons and one proton, and, obviously, it is not easy to carry out such a process concertedly. A stepwise transfer should be avoided since it may lead to the enzymatically inactive NAD$^{\oplus}$ dimer.[47] Indeed, the NADH recycling in dehydrogenase reactions is still a barrier that prevents a decrease in the cost of dehydrogenase-promoted asymmetric syntheses.[48] The recognition that a two-electron, one-proton transfer is the same as a hydride transfer may be the key to a solution of this problem. The hydride is transferred in one step, and, undoubtedly, the best hydride carriers are transition-metal complexes.[49] Such a transfer was first realized by *Steckhan* and co-workers.[50] On the basis of results reported earlier by *Kölle* and *Grätzel*,[51] they demonstrated that the complex [Cp*(bpy)ClRh]Cl can be electrochemically[50] or chemically reduced by formate[52, 53] to give, presumably, the hydride complex [Cp*(bpy)HRh]$^{\oplus}$, which, in turn, can reduce NAD$^{\oplus}$ to NADH. As a result, the electrochemically driven enzymatic reduction of pyruvate to D-lactate catalyzed by D-lactate dehydrogenase became possible at a rate of five turnovers per hour.[50] The yield of D-lactate was 67% with an enantiomeric excess of 93.5%.

This approach is obviously promising in view of the vast possibilities of transition-metal complexes as oxidants or reductants of the corresponding forms of nicotinamide cofactors. The species involved need not necessarily be organometallic in nature. A detailed discussion of this area is beyond the scope of this review, but a few examples can be mentioned. In particular, a tris(2,2'-bipyridyl) complex of rhodium(III) was reported to carry out the electrochemical regeneration of NADH from NAD$^{\oplus}$.[54] Photochemical reduction of NAD(P)$^{\oplus}$ to NAD(P)H was also described.[55, 56] The reverse reaction, that is, regeneration of NAD$^{\oplus}$ and NAD(P)$^{\oplus}$, occurs in the presence of $[FeL_3]^{2\oplus}$[57] and $[RuL_3]^{2\oplus}$[58] complexes, where L is a 2,2'-bipyridine- or 1,10-phenanthroline-type ligand.

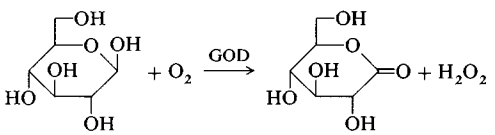
3. The Reactions of Oxidases and Peroxidases in the Presence of Organometallics

This is undoubtedly the most advanced area of organometallic biochemistry and was relaunched in 1984 by *Cass* et al.,[59] who reported on the extremely advantageous mediator abilities of ferrocene derivatives in glucose-oxidase-catalyzed oxidation of β-D-glucose. Of course, many other examples of redox processes involving proteins and coordination compounds or organometallic species had been known and reviewed,[60–62] but none is as appropriate to the present discussion as the above-mentioned results. The work of *Cass* et al. has stimulated both rapid production of novel amperometric biosensors and intensive research in this field (see Section 3.1).

3.1. Ferrocenes as Substrates of Oxidases

Enzymes using flavin adenine dinucleotide as cofactor can catalyze oxidation of various molecules by O_2 to yield hydrogen peroxide together with the corresponding oxidation product [Eq. (j)]. An example is the oxidation of β-D-glucose catalyzed by glucose oxidase (GOD)[59] [Eq. (k)]. Remarkably, ferricenium ions have also been found to be substrates of glucose oxidase (GOD);[59] the organometallic ions replace O_2.

$$\text{Red-H}_2 + \text{O}_2 \longrightarrow \text{Ox} + \text{H}_2\text{O}_2 \qquad \text{(j)}$$



(k)

Cyclic voltammetry is the best technique for monitoring this catalysis. It is nicely seen in Figure 1 that practically the limiting currents are achieved in the system ferrocene–D-glucose–GOD, while the absence of either of the latter two components restores the trace typical of ferrocene alone. The electrocatalysis in the presence of the organometallic media-

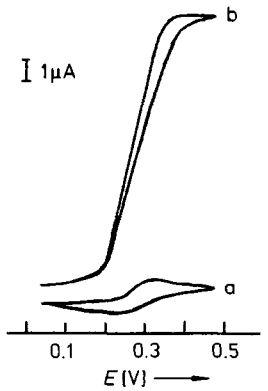


Fig. 1. a) The dc cyclic voltammogram of hydroxycarbonylferrocene (0.05 mM) at pH 7 and 25°C, in the presence of D-glucose (50 nM) at a scan rate of 1 mVs^{-1}. b) As for (a), but with addition of GOD (10.9 μM) [59].

tor can be accounted for in terms of Equations (l)–(n),[59] where E(ox) and E(red) are oxidized and reduced forms of

$$E(ox) + \beta\text{-D-glucose} \longrightarrow E(red) + \text{D-gluconolactone} \quad (l)$$

$$E(red) + 2\,Fc^{\oplus} \longrightarrow E(ox) + 2\,Fc + 2\,H^{\oplus} \quad (m)$$

$$2\,Fc - 2e^{-} \longrightarrow 2\,Fc^{\oplus} \quad (n)$$

GOD, respectively, and Fc is a ferrocene derivative. Other oxidases that function in a similar way, ferrocenes

(R^1–Fc–R^2), and the corresponding rate constants for the oxidation of reduced enzymes evaluated from the electrochemical data are shown in Table 2. Two similar enzymes tried, oxalate oxidase and choline oxidase, did not couple with ferrocenes.[63] The rather large values of the second-order rate constants in Table 2 show that oxidases readily accept ferrocenes, which therefore appear to be true substrates of the enzymes. Octacyanomolybdate(IV) and octacyanotungstate(IV) are also accepted by lactate and sarcosine oxidase in the same way.[64] The rate constants for the oxidation of the reduced enzymes by $W(CN)_8^{3\ominus}$ or $Mo(CN)_8^{3\ominus}$ are almost as high as those for ferricenium ions [$(3-4)\times 10^4\ M^{-1}s^{-1}$]. Glucose oxidase and D-amino acid oxidase react with a poly(vinylpyridine) complex of $[OsL_2Cl]^{\oplus/2\oplus}$ (L = 2,2′-bipyridyl) similarly.[65,66]

The principle of enzymatic enhancement of the electrochemical response of organometallic mediators described above has already been realized in many amperometric biosensors, including that for the monitoring of D-glucose[59] and carbon monoxide.[68] This promising approach to designing biosensors[69–71] has stimulated further studies in the field of organometallic biochemistry. Although organometallic mediators are indeed very effective, bioelectrocatalytic systems without mediators are thought to be more advantageous.[72–77] Therefore, an attempt was undertaken to make the oxidase–ferrocene systems pseudo-mediatorless by covalent attachment of ferrocenes to the enzyme.[78–80] When GOD was modified by $Fc(CH_2)_nCOOH$ (n = 0, 1, and 3) using water-soluble carbodiimides, it appeared to be electrocatalytically active without added ferrocenes. It is tempting to conclude that there is direct electrical communication between chemically modified GOD and electrodes, but a subsequent report[81] that ferrocene-modified bovine serum albumin is also a mediator of the electron transport between the active site of GOD and an electrode indicated that ferrocene-modified GOD may function intermolecularly. In any case, oxidoreductases modified by organometallic species are a challenging object for research.[82] In this respect, one purely organometallic approach to ferrocene-modified enzymes should be mentioned.[83] It is based on the high activity of organomercurials toward free cysteine residues of proteins.[84] Reaction of chloroferrocenylmercury, for example, with cytochrome c from baker's yeast results in attachment of the ferrocenylmercury group to the Cys-102 residue [Eq. (o)]. The product obtained is electrochemically active with a wave at 450 mV versus the normal hydrogen electrode (NHE). Apparently, this approach can be successfully applied to oxidoreductases, if the catalytically important SH groups remain intact.

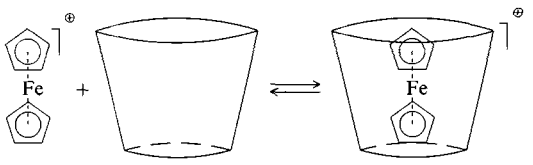
$$\text{CYT(Cys 102)-SH} + \text{ClHgFc} \longrightarrow \text{CYT(Cys 102)-SHgFc} + H^{\oplus} + Cl^{\ominus} \quad (o)$$

Interestingly, while flavoproteins couple with oxidized ferrocenes, peroxidase catalyzes the oxidation of ferrocenes by hydrogen peroxide.[85] Unmodified ferrocene, together with $FcCH_2OH$, FcCHMeOH, $FcCMe_2OH$, $FcCH_2COOH$, $FcB(OH)_2$, and $FcCH_2N^+Me_3I^{\ominus}$, were involved. This observation has led to the development of an amperometric biosensor for hydrogen peroxide where ferrocenes shuttle between an electrode and the active site of peroxidase[86] and of cytochrome c peroxidase.[87]

3.2. Ferrocenes in Immunoassay

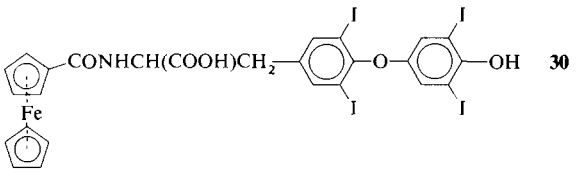
Ferrocenes as hydrophobic molecules are perfect guests for cyclodextrins in aqueous media.[88,89] It has been recently reported[90] that ferricenium ions also form inclusion com-

plexes with cyclodextrins [Eq. (p)]. The complexed species are no longer substrates of glucose oxidase and do not give rise to catalytic currents in the system ferrocene–D-glucose–GOD. Thus, the incorporation of ferrocenes into the host cavities or their shielding by the fragments of large molecules may dramatically affect the mediator abilities of ferrocenes.

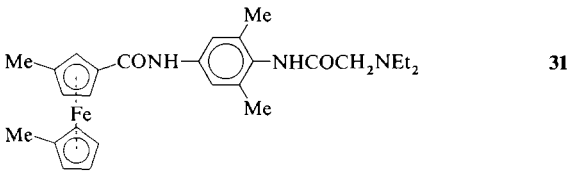


(p)

This effect is evidently disadvantageous in the case of simple ferrocene-based sensors, since host molecules will interfere with the oxidase response. But it is very advantageous if immunoanalysis is concerned. Consider a molecule in which a hapten is covalently bound to ferrocene. If this conjugate does not lose its affinity for the corresponding antibodies, the antigen–antibody interaction can result in the shielding of the organometallic moiety and, hence, the conjugate may become bioelectrocatalytically inactive. If free antigen is now added to the system, it will replace the conjugate, since the affinity of the free antigen is at least as high as that of the conjugate. The conjugate liberated will now be accepted by an oxidase and the resulting increase in current will be a function of the concentration of the free antigen. This approach has been realized in analyses for thyroxine[91, 92] and lidocaine.[93] The corresponding conjugates **30** and **31** were prepared. A closely related procedure for quantification of human chorionic gonadotrophin was also described.[94, 95] The coupling of ferrocene conjugates with oxidases is a



30



31

breakthrough in the metalloimmunoassay concept put forward by *Cais* et al.[96, 97] in the late 1970s. Many ferrocene, cobaltocene, and cymantrene derivatives of estriol, morphine, barbiturates, amphetamine, and cocaine were then prepared, but the necessity of using atomic absorption spectrometry as analytical routine precluded the general acceptance of this approach.

It should be emphasized that even simple binding of ferrocene conjugates to the corresponding antibodies decreases the electrochemical response of a ferrocene label. This was first shown for ferrocenecarboxylic acid conjugated with morphine.[98] The effect is low, however, and does not meet the requirements of current immunoassays.[99] The use of the oxidase enhancement improves the situation considerably, making it appropriate for analyses.

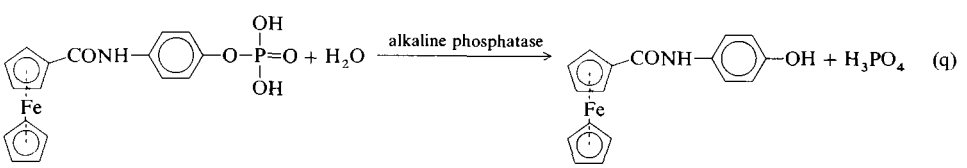
The ability to change the redox potentials of functionalized ferrocenes by varying their side chains offers a way to use various proteases in bioelectroanalysis. For example, compound **32** was prepared for assaying alkaline phosphatase and estriol.[100] The key point here is that the substrate of alkaline phosphatase, compound **32**, has a quasi-reversible peak at 390 mV. Product **33** has two irreversible peaks, corresponding to oxidation of the phenol and ferrocene moieties, at 590 and 180 mV, respectively, versus the saturated calomel electrode (SCE). Remarkably, the oxidation of the product of enzymatically driven reaction (q) occurs at a potential 210 mV lower than that of the starting substrate. The product thus can be detected in an excess of the substrate, thereby allowing the assay of alkaline phosphatase. In fact, the enzyme was monitored at a level of 1.2×10^{-12} M. The procedure was also found suitable for the enzyme-linked immunoassay using alkaline phosphatase as a marker enzyme. Three criteria have been put forward[100] for achieving further enzyme amplification:

1. The product must have a lower oxidation potential than the substrate.
2. The difference in oxidation potential must be of the order of 100–200 mV.
3. The product in its oxidized form must be accepted by an enzyme of the glucose-oxidizing type.

4. Receptors That Bind Organometallic Species

Of course, there are no receptors yet that are specific for organometallics. However, attachment of organometallics to biomolecules need not eliminate their ability to be accepted by receptors. This strategy has been worked out in a very elegant procedure for assaying hormone receptors by FT-IR spectroscopy.[101] Its general principles have already been reviewed twice by the authors[102, 103] and, therefore, only a brief outline will be given here for the sake of demonstrating what unexpected and hence exciting results organometallic biochemistry can provide.

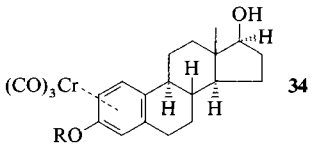
Most proteins have an IR "window" around 2000 cm^{-1}. Metal carbonyls, on the contrary, have a strong absorption in this region. Further, $[Cr(CO)_3]$, $[Cr(CO)_2CS]$, or related



(q)

32 ($E_{1/2}$ = 390 mV) **33** ($E_{1/2}$ = 180 mV)

fragments can be attached to a variety of biologically relevant molecules[104-106] including estradiol derivatives.[101] The organochromium-labeled steroids **34** are stable in aqueous methanol, and their relative binding affinities to estrogen receptor vary in the range 0.4–28%, the highest value being achieved when R = $HO(CH_2)_3$. The latter com-



34

pound has been prepared in a tritiated form with a high specific activity. It binds reversibly to the estradiol receptor in lamb uterine cytosol with a dissociation constant (K_D = 0.85 nM) and a number of binding sites close to the values observed for estradiol itself. The level of nonspecific binding is low, and the hormone is not bound significantly to other nontarget tissues. The tricarbonylchromium-labeled molecules are good markers for detection of hormone receptors by FT-IR at 1880 and 1957 cm^{-1} in the case of **34**. This and other related examples[107] show how advantageous organometallic derivatization of biomolecules can be. Not only novel drugs[108] but also convenient markers may be prepared in this way.

5. Organometallic Lyases

One of the environmental hazards brought about by civilization is pollution by heavy metals. Particularly dangerous is organomercury poisoning. The total oceanic reservoir of mercury is estimated at 200 million tons. The reservoir of the volatile forms (Hg^0 and MeHgX) in the atmosphere is about 4 million tons with an annual flux between these reservoirs of roughly 15000 tons.[109] Mercuric salts are biomethylated with methyl coenzyme B_{12} to give methyl mercuric salts and this organomercurial is a potent human neurotoxin. To survive, nature has had to develop a mechanism for resisting the invasion of organometallics.[110] Bacteria chose a two-step two-enzyme detoxification strategy for recycling organomercurials back to nontoxic, volatile, elemental Hg^0.[111-115] The first enzyme, organomercury lyase,[116,117] catalyzes a protonolytic cleavage of a carbon–mercury bond [Eq. (r)]. The second, mercuric ion reductase,[118-124] reduces Hg^{II} to Hg^0 in an NADPH-dependent process [Eq. (s)].

$$H_3C{-}HgX + H_2O \longrightarrow CH_4 + Hg(OH)X \quad (r)$$

$$Hg(OH)X + NADPH \longrightarrow Hg^0 + NADP^{\oplus} + H_2O + X^{\ominus} \quad (s)$$

To this end, nature has created an enzyme whose natural substrate is an organometallic molecule and which attacks at the carbon–metal bond.

5.1. Organomercury Lyase: Structure and General Properties

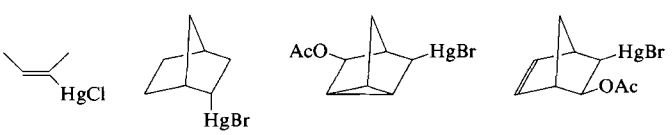
Organomercury lyase is a simple monomeric polypeptide with a molecular weight of 22400 Da.[116] Qualitative neutron activation analysis indicated the absence of metal ions in the pure enzyme. It should be pointed out, however, that the absence of Pb, Mg, Ca, Mo, Ir, and Sn cannot be unequivocally established by this method. The amino acid composition and the amino-terminal sequence of the enzyme have also been reported. Remarkably, there are four cysteine residues. The Lineweaver–Burk plot for organomercury lyase activity with MeHgCl shows a strong substrate inhibition above 1 mM for reasons as yet undetermined. The same effect is also observed for *t*BuHgCl but not for other mercurials. The rate of enzymatic protonolysis is dependent on both the structure and the concentration of the buffer thiol. Indeed, the rate for cysteine (5 mM) is eight times the rate for 2-mercaptoethanol (5 mM), and no protonolysis occurs with 2-aminoethanethiol. In the case of cysteine, no protonolysis of EtHgCl takes place at concentrations less than 2 mM. At concentrations greater than 2 mM, the rate increases with increasing cysteine concentration and finally levels off above 15 mM.

The enzyme catalyzes the protonolysis of a wide range of organomercurials of type RHgX but does not accept those of type RHgR (Table 3). This is rather curious in view of the fact that the former are much more labile to acidic cleavage.[125]

Table 3. Substrate specificity and kinetic parameters of organomercurials in the lyase-catalyzed reaction [116].

Substrate	V_{max} [nmol $mg^{-1} min^{-1}$]	K_m [mM]	Turnover [min^{-1}]
MeHgCl	31	0.5	0.7
*n*BuHgCl	880	0.9	20
*s*BuHgCl	110	0.8	2.5
*t*BuHgCl	40	0.8	2.5
PhHgCl	670	0.9	15.0
(crotyl)HgCl	2600	1.3	58
$H_2C{=}CHHgCl$	530	1.0	12
(*cis*-2-butenyl)HgCl	10700	3.3	240
MeHgMe	0		0

Another remarkable feature of the enzyme is the pH profiles for V_{max} and $V_{max}K_m^{-1}$ determined with EtHgCl. The rate increases up to pH 10.2, where denaturation of the enzyme occurs, the apparent pK_a being 9.0. Again, there is a dramatic discrepancy with the protonolytic cleavage of organomercurials, where the rate is first-order in the acid.[125] Much work has been done on elucidating the detailed mechanism of the enzymatic C–Hg bond cleavage.[117] The discrimination between S_N1, radical, S_E1, and S_E2 pathways in favor of the latter has been made on the basis of mechanistic study of the reactivity patterns of organomercurials **35**–**38**.

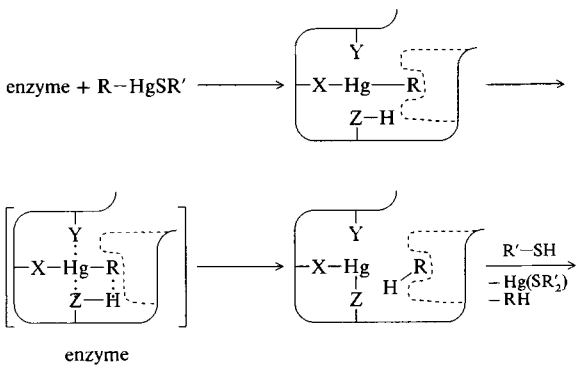


35 **36** **37** **38**

The conversion of **35** and **36** demonstrates the retention of stereochemical configuration. The former affords exclusively *cis*-2-butene, while the latter transforms into the *endo* deuterio product. The enzymatic protonolysis of **37** and **38**, which are very diagnostic for probing radical steps,[126] occurs without skeletal rearrangements and radical intermediates, thus ruling out a radical pathway.

The substrate specificity of the lyase has been also studied.[117] Various organomercurials of the type RHgCl are converted, including alkyl, alkenyl, allyl, and phenyl derivatives (Table 3). Among these, compound **35** and MeHgCl turned to be the most and the least reactive, respectively. The significant solvent deuterium isotope effect at pH 7.4 of $V_{max}(H_2O)/V_{max}(D_2O)$ is equal to 2.1 and 4.9 for turnover of **35** and EtHgCl, respectively, suggesting a kinetically important proton delivery. Finally, the stoichiometric formation of 2-butene and Hg^{II} from **35** and of methane and Hg^{II} from MeHgCl eliminates the possibility of an S_N1 solvolytic mechanism.

Concerning the fate of organomercurials in the active site of the lyase, the following suggestions, depicted in Scheme 5,

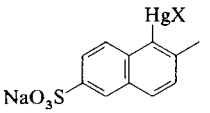


Scheme 5. Proposal for the interaction of organomercurials with the active site of the lyase.

have been put forward.[117] The substrates undergo initial binding to the enzyme via coordination to group X to give an enzyme–substrate complex (saturation kinetics are observed for all substrates). Coordination of another nucleophilic moiety, Y, to the organomercurial would then activate the C–Hg bond toward protonolysis. This conclusion was made in view of the well-documented nucleophilic assistance of the electrophilic cleavage of carbon–metal bonds.[125, 127] The carbon–mercury bond rupture would then occur via the indicated S_E2 transition state, although the present state of knowledge does not allow a discrimination between three- and four-centered pathways. It is believed, however, that the latter pathway is more likely. Finally, exchange of Hg^{II} with thiols in the solvent leads to free enzyme ready for another catalytic cycle. Without excess thiols in the buffer for removing Hg^{II} from the enzyme active site, the enzyme accumulates as an inhibited enzyme–Hg^{II} complex.

Organostannanes were the next organometallics subjected to catalysis by organomercury lyase.[128] Of the compounds tested, tetravinyltin is turned over with the highest specific activity, yielding ethene as the organic product. Similarly, triethylvinyltin undergoes turnover by the lyase to yield ethene and ethane in a 97:3 ratio, at 1/60 the rate of tetravinyltin turnover. Finally, Me_4Sn and Me_3SnF yield small amounts of methane prior to eventual loss of enzyme activity. The loss is consistent with the observed inhibition by Me_2SnBr_2. Interestingly, silicon and germanium counterparts of stannanes accepted by the lyase do not undergo the enzymatic cleavage, nor do Et_4Sn, Bu_4Sn, Et_3SnOAc, and $BuSnCl_3$. Hence, the enzymatic activity may be very specific to the nature of the metal center.

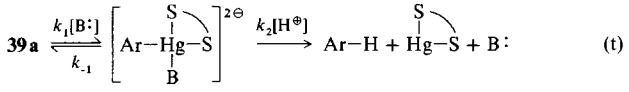
Organomercury lyase attracted the attention of many workers involved in various fields, and a model system was soon provided by chemists.[129] It threw light on both the assistance by thiol ligation and the nature of nucleophilic catalysis. Compound **39** was prepared and its protonolysis rates were measured under various conditions. At pH 6.6



39a, X = S(SH)CH2SO3Na

39b, X = Cl

with 0.3 M phosphate buffer, k_{obsd} is $10^{-7}\ s^{-1}$. In the presence of 100 equivalents of 2,3-dimercaptopropanesulfonate, k_{obsd} is $10^{-4}\ s^{-1}$. Most (90%) of this rate acceleration is observed on adding only two equivalents of dithiol. Ligation of **39** is therefore completed and the substrate is **39a**. The reaction is catalyzed by buffer since $k_{obsd} = (k + k_{BT}[B]_t)$, where $[B]_t$ is the total buffer concentration. In formate, acetate, or phosphate buffers the plots of $\lg k_{BT}$ versus pH are bell-shaped, the maximal rates being observed at pH values of about 4, 5, and 6, respectively. The bell-shaped profile of the reaction points to the importance of both the buffer acid and the buffer base and this finds explanation in a sequential two-step mechanism with a pH-dependent change in the rate-determining step [Eq. (t)]. This study suggests that ligation



(t)

by two thiols is necessary not only for removing Hg^{II} from the active site of the lyase but for creation of the actual substrate as well.

6. Summary and Outlook

Organometallic biochemistry will undoubtedly develop extensively in the near future. There is a great variety of objects for research, especially in the field of organometallic biosynthesis and biosensoring. Both university and industrial chemists and biochemists will be involved. Environmental and health problems associated with increasing use of organometallics in industry and medicine will probably stimulate further studies in this field.

I thank Dr. Vadim V. Mozhaev for critical reading of the manuscript and stimulating criticism.

Lise Meitner and Fission: Fallout from the Discovery

By Ruth Lewin Sime*

Much has been written about *Lise Meitner*, but she remains on the periphery. Of her pioneering work in nuclear physics, little is said; she is remembered primarily for nuclear fission, a discovery in which she did not share. Especially in Germany the staging seldom varies: *Otto Hahn* in the spotlight, *Fritz Straßmann* in his shadow, *Lise Meitner* in the wings, dimly outlined in reflected light. Her role is open to speculation. One writer sees her work "crowned by the Nobel Prize for Otto Hahn";[1] another, once director of an institute that bears her name, portrays her as the physicist who obstructed the discovery from the start.[2] Often she is cast as *Hahn*'s *Mitarbeiterin*;[3] sometimes she is completely invisible, as in one of the world's great science museums, which for 30 years displayed[4] the fission apparatus–equipment assembled by *Lise Meitner* on a table in *her* laboratory in *her* physics section of the Kaiser-Wilhelm-Institut für Chemie—without ever mentioning her name.[**] The principals themselves do not agree. In his memoirs, *Hahn* has remarkably little to say of his closest colleague and friend. Only over a glass of wine, we are told, "konnte ihm die Äusserung entschlüpfen: 'Ich weiss nicht; ich fürchte, Lischen hätte mir die Uranspaltung verboten.'"[5] ("he might let slip: 'I don't know; I'm afraid Lischen would have forbidden me to discover fission.'") *Straßmann* insists: "Lise Meitner war die geistig Führende in unserem Team gewesen"![6] ("Lise Meitner was the intellectual leader of our team"!) From *Lise Meitner* herself we have no autobiography. Available, however, is the large collection of letters and documents she has left behind, and these make it possible for us to learn much more.

1. Introduction

The historian *Fritz Stern* has written of this century's most famous scientist, "Einstein and Germany: they illuminate each other."[7] The same can be said of *Lise Meitner*, only more so—because she was more attached to Germany, because she stayed longer and never cut her ties to it, because her best years of work and the bitter consequences of her exile could not be separated from the science, culture, and politics of her German experience.

She came to Berlin from her native Vienna in 1907. Women were still excluded from Prussian universities, yet she found a place of work and a chance to prove herself. Before long Germany was her professional home, the sanctuary that rescued her, as she believed, from a wasted life in Austria.[8] In time the milestones of her career became markers for the inclusion of women into German science; she flourished in Germany's brilliant physics community and became one the great nuclear physicists of her day.

After 1933 her very success in Germany made her cling to what she had and stay too long, and when she was driven out, finally, exile shattered her career and clouded her scientific reputation. In December 1938, five months after *Meitner* fled Berlin, *Hahn* and *Straßmann* identified barium as a product of the neutron irradiation of uranium. This was, as *Meitner* herself put it, "wirklich ein Meisterstück radioaktiver Chemie"[9] ("truly a masterpiece of radiochemistry"); it was also an intrinsic part and the direct result of a team investigation which *Meitner* brought to Berlin, led for four years, and to which she made crucial contributions until the end. There can be no doubt that had *Meitner* been anything other than a "non-Aryan" in exile, she would have fully shared in the discovery.[10] Instead, she—and physics—were eventually blamed for the failure to make the discovery sooner.

In this article I intend to show that *Lise Meitner*'s exclusion arose not from science but from the racial policies and political aberrations of National Socialist Germany, and to show further that her exclusion was unjustly perpetuated—indeed, deliberately reinforced—long after the Third Reich was over. This article is not a comprehensive review of the fission discovery: it is, instead, an alternative perspective, a focus upon *Lise Meitner* and her work. By documenting her leadership of the uranium investigation in Berlin, I wish to emphasize the importance of physics and its essential interplay with chemistry; by showing that *Meitner* remained a de facto member of the Berlin team until the discovery and beyond, I intend to make clear that political, not scientific, considerations kept her from being acknowledged. Finally, I wish to examine the aftermath of the discovery, during which *Meitner*'s exclusion was codified, physics blamed, and history distorted. For this I shall turn primarily to *Otto Hahn*, who claimed the discovery for chemistry alone, and whose singular prominence in postwar Germany ensured that his version would dominate. Fifty years have passed: there is a need for balance. With this article I seek to reintegrate *Meitner* with the discovery, physics with chemistry, science into its historical and political context.

Sacramento, CA 95822 (USA)

[**] On 4 July 1991 the Deutsches Museum placed a bust of Lise Meitner in the *Ehrensaal*, where busts, reliefs, and portraits of 38 renowned scientists, discoverers, and inventers are displayed, including Nikolaus Copernicus, Johannes Gutenberg, Carl Benz, Conrad Röntgen, Max Planck, Albert Einstein, and Otto Hahn.

2. The Beginnings of the Uranium Project

Although the discovery of fission is certainly an important chapter in the history of chemistry,[11] it was driven by fundamental questions of nuclear physics. The physicist who originated the investigation was *Enrico Fermi*; the physicist who brought it to Berlin and framed it at every step was *Lise Meitner*. Some years later, in 1944, she described the beginnings to *Max von Laue*. She was in Stockholm by then, unhappy with her working conditions; *von Laue* had suggested that her dissatisfaction was due to the absence of *Otto Hahn*:

> ... so ist Ihre strikte Erklärung, es fehle mir die Zusammenarbeit mit Otto, so irrig, dass ich, verzeihen Sie, lieber Freund, etwas lächeln musste. Otto und ich haben von 1920–1935 auf ganz getrennten Gebieten gearbeitet, er hat sich sogar nach eigenem Geständnis gar nicht für meine physikalischen Probleme interessiert und wir sind dabei sehr gute Freunde geblieben. Dass wir dann nach so langer Zeit wieder gemeinsam gearbeitet haben, lag daran, dass mich die Fermi'schen Untersuchungen brennend interessiert haben und es mir zugleich klar war, dass man mit Physik allein auf diesem Gebiet nicht weiter kommen konnte. Es musste ein so ausgezeichneter Chemiker wie Otto mithelfen, wenn es Erfolg haben sollte. Ich habe mehrere Wochen gebraucht, bis ich Otto dafür interessiert hatte, er wird es Ihnen gern bestätigen, dass es sich so verhält.[12][*]

2.1. Neutron Irradiations

The investigations which so interested *Lise Meitner* began in Rome in March 1934[13, 14] when Fermi and his co-workers sought to induce nuclear reactions and create new radioactive isotopes by irradiating elements with neutrons. Proceeding systematically through the periodic table, they succeeded first with fluorine and then aluminum;[15] two weeks later they reached lanthanum and reported nearly 20 more.[16, 17] The Italian scientists sent their results to *Ricerca Scientifica*, and mailed preprints a few days later to 40 or so of the most prominent and active nuclear physicists worldwide.[18, 19] *Lise Meitner* was thus among the first to learn of the work in Rome; by May she had verified[20] their neutron irradiations of Al, Si, P, Cu, and Zn, observing the first three in a cloud chamber and measuring the half-lives of the activities formed.

2.1.1. Lise Meitner's Background[21–26]

Expert in radioactivity and familar with neutron reactions, *Meitner* was in a perfect position to pursue these experiments. Her work in radioactivity went back to 1906 in Vienna; from 1907 in Berlin she and *Otto Hahn* identified several new radioisotopes, developed techniques of radioactive recoil, pioneered in magnetic beta spectra, and in 1918 discovered protactinium ($Z = 91$).[27] By then they were in the Kaiser-Wilhelm-Institut für Chemie in Berlin-Dahlem, each heading their own section. About 1920, when radioactivity no longer seemed to promise fundamental new insights,[28] *Meitner* turned to the infant field of nuclear physics, while *Hahn* stayed with the refinement and development of radiochemical techniques.

Always close to theory, *Meitner* explored nearly every aspect of experimental nuclear physics: the sequence of radioactive decay, the continuous beta spectrum, nuclear scattering experiments, high-energy gamma radiation. She was quick to use and adapt new instruments, among them the Wilson cloud chamber for nuclear reactions and Geiger-Müller counters for studies of gamma absorption. After the discovery of the neutron and positron in 1932, she used the cloud chamber to determine neutron mass, and she was the first to observe electron–positron pair formation. *Otto Hahn* would later remember this as a period when her work, far more than his, brought international recognition to their institute.[29] In addition to her own students and assistants, *Meitner* frequently welcomed foreign visitors to the institute. One of them was *Franco Rasetti*, an associate of *Fermi*, who spent most of the year 1932 in Dahlem learning the nuclear techniques—radioactivity, neutron sources, cloud chamber—needed for the new experimental program in Rome.[30]

[*] Your assertion that what is missing for me is the collaboration with Otto is so much in error that—forgive me, dear friend—I had to smile a little. Otto and I worked from 1920 to 1935 in completely separate fields; he in fact admitted that he was not at all interested in my physics problems and still we remained good friends. That we worked together once again after such a long time was due to the fact that Fermi's investigations were of consuming interest to me, and it was at once clear to me that one could make no progress in this field with physics alone. The help of an outstanding chemist such as Otto was needed to get results. It took me several weeks to get Otto interested; he will gladly verify for you that it went that way.

Ruth Lewin Sime was born in New York City in 1939, graduated from Barnard College in 1960, and obtained her doctorate in chemistry from Harvard University under William Lipscomb in 1964 for X-ray diffraction studies of molecular structures. Since then she has been engaged primarily in teaching chemistry; she is involved with programs designed to increase the representation of women and minority students in math-based sciences. Her interest in Lise Meitner began some 15 years ago when she taught a women's studies course on "Women in Science" and discovered, to her surprise, that little scholarly attention had been paid to Meitner's life and work. She is currently completing a scientific and personal biography of Lise Meitner.

Fig. 1. *Lise Meitner*, ca. 1937 (Source: Archives of Churchill College, Cambridge, England)

2.2. Elements beyond Uranium: "Ich fand diese Versuche so faszinierend..." ("I found these experiments so fascinating...")

As *Fermi* and his group worked their way through the periodic table, some generalizations became evident: (n, α) and (n, p) reactions were observed only for lighter elements; heavy elements favored neutron capture (n, γ); the new artificial radioactivities in every case decayed by beta emission to the next higher element. Thus, when the neutron irradiation of uranium yielded several new beta emitters, Fermi suggested "the spontaneous hypothesis that the active substance of U might have atomic number 93."[31] This appeared in *Ricerca Scientifica* in May; in *Nature* in June, *Fermi* cautiously proposed the possible formation of elements 94 and 95, although he considered it "premature to form any definite hypothesis on the chain of disintegrations involved."[32, 33] It was at this point that *Lise Meitner* spoke to *Otto Hahn*:

> Ich fand diese Versuche so faszinierend, daß ich sofort nach deren Erscheinen im Nuovo Cimento und in der Nature[34] Otto Hahn überredete, unsere... direkte Zusammenarbeit wieder aufzunehmen, um uns diesen Problemen zu widmen.[9][*]

It took several weeks, *Meitner* remembered, to get *Otto* interested.

2.2.1. Otto Hahn

Hahn remembered it differently. In his memoirs there is no mention of *Meitner*'s initiative; instead *Hahn* always traced the impetus for the Berlin investigation to *Aristide von Grosse*, a former student who had embroiled *Hahn* in an unpleasant public dispute over the discovery and properties of protactinium:[35]

> Nach dem Erscheinen dieser Arbeiten durch Fermi etc. kam eine Arbeit von v. Grosse und Agruss, nach der es durchaus nicht sicher sei, daß die Fermischen Körper El. 93 oder ähnliches seien, sondern es sei durchaus mit dem El. 91: Ekatantal [Protactinium] zu rechnen. Nach diesen Arbeiten beschlossen L. Meitner und ich, die Fermischen Arbeiten zu wiederholen und die Grossesche Annahme zu prüfen.[*]

Hahn wrote this in 1945[36] and used almost the same words in 1946, 1950, 1959, 1962, and 1968,[37-41] among others. But the note by *von Grosse* and *Agruss* did not appear in *Physical Review*[42] until 1 August 1934, and it would not have arrived in Germany before the end of August, many weeks after *Lise Meitner* first approached *Otto Hahn*.[43] *Hahn*'s repeated failure to credit *Meitner* for initiating their collaboration cannot be attributed entirely to memory lapse, because a published record exists: in their first joint uranium publication[44] *Hahn* and *Meitner* clearly state: "Wir haben im Laufe einiger anderer Versuche—here they cite two earlier neutron studies[20, 46] done by *Meitner* on her own—"jetzt eine eingehende Untersuchung dieser Uranprozesse in Angriff genommen..." ("In the course of several other experiments we have now undertaken a thorough investigation of these uranium processes...")

2.3. Formation of the Berlin Team

In August 1934 the institute was closed for vacation; in September *Meitner* and *Hahn* traveled to Leningrad for the centenary of *Mendeleev*'s birth. Although *Fermi*'s experiments were very much on *Meitner*'s mind,[46] they could not begin work in earnest until their return.

In a comparison of neutron sources, *Meitner* found[45] that fast neutrons are required for the (n, α) and (n, p) reactions typical of light elements, while slower neutrons are more readily captured by heavy elements. This mirrored the discovery[47] by *Fermi* and his group a few weeks later that neutrons slowed by hydrogenous materials enhance the efficacy of neutron-capture reactions.

For their first joint work[44] *Meitner* and *Hahn* verified four beta activities found in Rome. Two had half-lives of 10 s and 40 s, too short for chemical identification, but two others, with half-lives of 13 min and 90 min, could be distinguished chemically from every element from Hg to U. Assisted by *Fritz Straßmann*, a young analytical chemist in the institute, *Hahn* and *Meitner* developed an improved procedure for coprecipitating these with platinum and rhenium sulfides, took special pains to prove that none of the activities were isotopes of protactinium, and concluded, as *Fermi*

[*] I found these experiments so fascinating that, as soon as they appeared in Nuovo Cimento and Nature, I talked to Otto Hahn about resuming our direct collaboration once again... in order to resolve these problems.

[*] After the appearance of the articles by Fermi, etc. came an article by v. Grosse and Agruss, according to which it was not at all certain that the Fermi activities were element 93 or so, but that it most likely was element 91: Ekatantal [Protactinium]. After these articles L. Meitner and I resolved to repeat the Fermi experiments and test Grosse's assumptions.

had, that the 13-min and 90-min activities might well be elements 93 and 94.

Meitner and *Hahn* soon realized that the 13-min and 90-min activities were themselves mixtures[48] and in mid-1935 asked *Straßmann* to join them full-time. Their team was bound by political affinity as well: *Meitner*, "non-Aryan"; *Hahn*, anti-Nazi; *Straßmann*, the exceptionally principled younger man whose aversion to National Socialism and refusal to join the NS-associated *Verein Deutscher Chemiker* isolated him within the institute and made him unemployable outside.[49]

3. "Wege und Irrwege"—Roads and Mistaken Roads

Later, *Lise Meitner* would describe the road to the discovery of fission as "astonishingly long and in part a mistaken road" ("erstaunlich lang und zum Teil ein Irrweg".[9] *Fermi*, *Meitner*, indeed all who worked on the uranium investigation were misled by two false premises, one from physics—that only small changes would occur in nuclear processes—and the other from chemistry—that elements beyond uranium would be higher homologues of the third-row transition elements Re, Os, Ir, Pt, etc. When neutron irradiation of uranium yielded new beta activities which coprecipitated with platinum and rhenium sulfides, the two assumptions unluckily dovetailed—and even after the discovery of fission proved the first one wrong, scientists still did not suspect that the second was wrong as well.[50]

However mistaken, these false premises do not entirely account for the failure to explore alternatives. *Ida Noddack*'s suggestion[51] of a major nuclear breakup was never seriously considered;[52] *Noddack* herself did not pursue it; *Max Delbrück*, *Meitner*'s *Haustheoretiker* for a time, remembered with chagrin how he helped in the "Holzweg der zahllosen 'Transuran'-Isomere" (the "bog of countless 'transurane' isomers") instead of finding a way out.[53]

There was something dazzling about elements beyond uranium.[54] That, coupled with the great difficulty of identifying weak new activities in the presence of the strong natural radioactivity of uranium, led the Berlin team to investigate only the platinum sulfide precipitate, which, they presumed, contained the "transuranes". For the most part they ignored the filtrate, assuming it contained nothing more than uranium and its natural decay products. This was a mistake, *Meitner* remembered:

> Unsere Fällungen bei Bestrahlung mit schnellen Neutronen wurden immer so ausgeführt, daß U, Pa und Th im Filtrat bleiben mußten, wodurch wir meinten eine gewisse Stütze für die Transurannatur der gefällten Elemente zu gewinnen. Darum haben wir – und das war unser Irrtum – zunächst niemals, auch nicht bei den Versuchen mit verlangsamten Neutronen, die Filtrate unserer Fällungen untersucht.[91][*]

[*] During irradiation with fast neutrons our precipitations were always conducted so as to keep U, Pa and Th in the filtrate, from which we drew a certain support for the transurane nature of the precipitated elements. Thus we—and this was our mistake—for a time never examined the filtrate, not even in the experiments with slowed neutrons.

The oversight was remarkable, because the Berlin group did discover that an important activity, a 23-min U, was produced only when slowed neutrons were used.[55]

> Also ich glaube wirklich unser Unglück war, dass wir die Filtrate nicht untersuchten. Wir konnten sich nicht untersuchen, weil wir das Uran drin gehabt haben, nicht wahr, da konnten wir nichts sehen. Wir hatten zu schwache Bestrahlungsquellen... [D]ie Chemiker wollten absolut nicht, ich habe sie geplagt, sie sollen es machen wie ich dort war, weil ich so unruhig war. Gerade weil ich zu wenig von Chemie verstehe, war ich natürlich immer unruhig über das was nicht gemacht worden ist, aber dann haben es ja Hahn und Strassmann so wunderbar gemacht, also zu der Zeit hat es wirklich keine Chemiker gegeben, die das hätten machen können.[56][*]

Later *Hahn* and his associates would claim the discovery for chemistry alone, blaming the "Irrwege" solely upon physics and its assumption of small nuclear changes. This was not done in a spirit of scientific objectivity—it ignored the mistakes of chemistry and the guidance of physics. Physics did not predict fission, to be sure, but it detected errors chemistry could not; without physics, chemists would not have begun the investigation; without physics they would have had no reason to sustain it.

3.1. Chemistry: Certainty

The scientific literature of the period[57] makes clear that the investigation was fed by chemical data but interpreted by nuclear physics. The dual roles are particularly evident in parallel reports by *Hahn*, the senior author for chemistry, and by *Meitner* for physics. In 1936 and 1937, the Berlin chemists listed three U activities and two parallel "transurane" sequences including two EkaRe (the presumed element 93), two EkaOs (94), one EkaIr (95), and one EkaPt (96), all beta emitters. Of the uranium activities, just one, 23-min U, was chemically certain; the 10-s and 40-s activities, too short-lived for chemical identification, were attributed to U because genetic sequences obtained from radioactivity data indicated they preceded the two EkaRe. Altogether, the fit between the chemistry expected for transuranium elements and the genetic sequences seemed too good not to be true. In 1936: "[D]ie Zuordnung des 2.2-Min- und des 16-Min-Körpers zum Eka-Rhenium ist frei von Willkür; sowohl die genetischen Beziehungen als auch die chemischen Eigenschaften lassen wohl keinen Zweifel über ihre Zugehörigkeit zum Element 93."[58] ("The assignment of the 2.2-min and 16-min activities of EkaRe is unquestionable; not only the genetic relationships but also the chemical properties really leave no doubt they belong to element 93.") And for EkaOs, EkaIr, and EkaPt, "sind wir nach ihrem allge-

[*] I really think our misfortune was that we didn't search the filtrate. We couldn't search it because uranium was in it, we couldn't see anything. Our neutron sources were too weak... The chemists absolutely didn't want to, I begged them to do it while I was there because I was so disturbed by it. Because I understood too little chemistry I was naturally always worried about what wasn't done, but then Hahn and Straßmann did such a wonderful job; surely at the time no other chemists could have done it.

meinen chemischen Verhalten sicher bezüglich ihrer Gruppen-Zugehörigkeit" ("we are certain from their general chemical properties to which group they belong").[58] In 1937: "Vor allem steht ihre chemische Verschiedenheit von allen bisher bekannten Elementen ausserhalb jeder Diskussion."[59] ("Above all, their chemical distinction from all previously known elements needs no further discussion.")

3.2. Physics: Doubt

As the chemists grew more confident with each new link in the chain of transuranes, the physical interpretation was buckling under a profusion of data. It was *Meitner*'s task to integrate chemistry, radiochemistry, and her own physical experiments into nuclear reactions that made sense. Her recognition that this could not be done sustained the investigation.

To account for three uranium activities, *Meitner* first proposed[60] three different neutron–uranium reactions, but after an exhaustive series of physical experiments she concluded that all three reaction mechanisms appeared the same. She correctly identified the 23-min U as U-239,[61] formed by a typical resonance capture of fairly slow neutrons by U-238. But the 10-s and 40-s U, which headed the two parallel series of "transuranes", also appeared to be U-239: both series varied identically with neutron energy, were produced by fast neutrons and enhanced by thermal neutrons. Together the results were incomprehensible: the triple isomerism of U-239 was problematic, *inherited* triple isomerism persisting for several generations virtually impossible. In 1937 she concluded: "Dieses Ergebnis ist mit den Kernvorstellungen sehr schwer in Übereinstimmung zu bringen."[55] ("This result is very difficult to reconcile with current ideas of nuclear structure.") And in 1938, after thorium showed similar multiple isomerism: "Dieser Erklärungsversuch stößt auf erhebliche Schwierigkeiten..."[62] ("This attempt at an explanation runs into considerable difficulty...") In addition, *Meitner* was always particularly disturbed by the long chain of beta decays EkaRe, EkaOs, EkaIr, EkaPt, and beyond: capture of just one neutron by U-238 should not have produced instability so great that five or more beta decays were required to relieve it:

> [I]ch war immer unglücklich darüber weil ich nicht verstehen konnte, 'wie kann eigentlich die Kernladung steigen bei derselben Masse?' Das war immer, was ich [C. F. von] Weizsäcker gefragt habe: Wie ist das möglich? Also ich war nie glücklich über unsere Versuche vor der fission.[63][*]

In Paris, meanwhile, *Irène Curie* and *Paul Savitch* had examined the entire uranium mixture without chemical separation and reported a strong new 3.5-h beta emitter with unexplained chemical properties.[64] In Berlin they ascribed it to contamination and named it "Curiosum".[65]

[*] I was always unhappy about it because I couldn't understand 'How can the nuclear charge increase [so much] with the same mass?' That's what I always asked Weizsäcker: How can that be? You see, I was never satisfied with our experiments before fission.

4. Escape from Germany

In 1938 came the *Anschluß* and then whispers: "Die Jüdin gefährdet das Institut".[66] ("The Jewess endangers the Institute.") *Hahn* grew nervous, mindful that Prof. *Kurt Heß*, a "fanatic Nazi" ("fanatischer Nationalsozialist")[67] who worked in the *Gastabteilung* (guest section) upstairs in the Kaiser-Wilhelm-Institut für Chemie, was eager for his position. Her dismissal imminent, *Meitner* learned that technical and academic people would be forbidden to leave Germany; she fled secretly on 13 July 1938. Dutch friends, physicists *Dirk Coster* and *Adriaan Fokker*, got her into Holland; *Niels Bohr* and Swedish friends arranged a place for her in *Manne Siegbahn*'s Nobel Institute for Experimental Physics in Stockholm.[68]

4.1. "Radium" Isomers

Meitner and *Hahn* had worked under the same roof for 31 years; their separation was a shock to them both. Intellectually, however, she was not immediately cut off from Berlin. *Meitner* and *Hahn* wrote to each other[69, 70] constantly; she was still very much a member of the team.

On 23 October *Meitner* was inquiring[71] about the Curie–Savitch 3.5-h substance just as a new report[72] by the Paris scientists reached Berlin. Suspecting that the 3.5-h substance might contain radium, *Straßmann* proposed his own cleaner method of separation.[73] "Vielleicht hat sogar ein Ra-Isotop was dabei zu tun" ("Perhaps a Ra isotope has something to do with it"), *Hahn* wrote *Meitner* on 25 October,[74] and a week later;

> Wir sind jetzt *fast* überzeugt, daß es sich um einige – 2 oder 3 – Radiumisotope handelt, die sich in Ac etc. umwandeln... Es wäre uns natürlich sehr lieb, Du würdest Dir den Fall einmal überlegen, wie eine α-Strahlenumwandlung [U(n, α) → Th → Ra] mit wahrscheinlich auch langsamen Neutronen zu Stande kommen kann, und dabei gleich auch wieder mehrere Isomere...[75][*] (text highlighted in the original is here printed in italics)

Meitner responded instantly:

> Ich will mir brennend gern überlegen, wie Ra od[er] Ac Isotope entstehen können, wenn Du mir nur tatsächlicher schreiben wolltest... Warum glaubt Ihr daß mehrere Körper da sind, habt Ihre mehrere Halbwertszeiten? Warum glaubt Ihr daß es verstärkbar ist? Habt Ihr mit langsamen Neutronen erheblich mehr bekommen? Und wie stark ist denn die Aktivität... verglichen mit dem 16 Min K[örper (Eka-Re)]?... Bitte sei lieb und beantworte alle Fragen. Auch wenn es noch nicht so definitiv ist...[76][**]

[*] We are now *almost* convinced that we are dealing with several—2 or 3—radium isotopes which decay to actinium, etc... Naturally, we would like it very much if you could think about the situation, how an α-transformation [U(n,α) → Th → Ra] can come about, probably also with slow neutrons, and at the same time produce several isomers...

[**] I am extremely eager to think over how Ra or Ac isotopes could be produced, if you would only write more factual details. Why do you think it is several substances, do you have several half-lives? Why do you think it can be enhanced? Did you get considerably more with slow neutrons? How strong is the activity... compared to the 16-min [EkaRe]?... Please be nice and answer all these questions. Even if it's not yet so definite...

The reaction conditions, *Otto Hahn* replied,[77] were essentially the same as for the transuranes. In *Naturwissenschaften* he and *Straßmann* listed three Ra and three Ac isomers and emphasized, "Hier liegt also wohl zum ersten Male der Fall einer *α-Strahlenabspaltung mit verlangsamten Neutronen vor*"[78] ("Here surely for the first time is a case of *α-particles being split off by slow neutrons.*")

4.2. Meeting in Copenhagen

A week later *Lise Meitner* and *Otto Hahn* met in Copenhagen, both invited to *Bohr*'s Institute for Theoretical Physics. There, face-to-face, *Meitner* could make clear to *Hahn* that something was terribly wrong with the new Ra-Ac isomers: an (n, α) reaction induced by slow neutrons was truly impossible.

Their meeting took place three days after the *Kristallnacht*; it was a secret outside Copenhagen. And years later in his memoirs, *Hahn* never mentioned it, although he did recall *Bohr* being "skeptical" and "quite unhappy"[79, 80] ("ziemlich unglücklich") about the radium isomers, and he even remembered talking to *Meitner*'s nephew *Otto Robert Frisch*.[65] But we know from the guest book in *Bohr*'s institute that *Lise Meitner* was there from November 10 to 17,[81] and we know from *Hahn*'s own pocket calendar[82, 83] that she met his train at 6:48 on the morning of November 13, that they had breakfast together and talked for hours, that the next day, after breakfast with *Niels* and *Margrethe Bohr*, *Lise Meitner* and her nephew took *Hahn* to the station and saw him off on the 11:13 train to Berlin. There is also no doubt that *Lise Meitner* forcefully urged *Otto Hahn* to examine the radium isomers more thoroughly than before: this was the message *Hahn* brought back to Berlin. *Straßmann* remembered clearly:

> Jedenfalls hat sie (laut einer Äußerung von O. Hahn) dringend darum gebeten, diese Experimente noch einmal sehr sorgfältig und intensiv zu überprüfen... Zum Glück hatte L. Meitners Ansicht und Urteil bei uns in Berlin ein so großes Gewicht, daß die erforderlichen Kontrollversuche sofort unternommen wurden.[84][*]

4.3. *Barium: "Eine Art Arbeit zu Dreien"*

A few days later *Hahn* and *Straßmann* began the fractional crystallization experiments which led directly to the discovery of barium.[85, 86] From their own statements, we know they still regarded *Meitner* as a member of their team. *Straßmann* wrote later:

> Was bedeutet es, daß Lise Meitner nicht *direkt* teilhatte an der 'Entdeckung'?? Ihrem Impulse ist der Beginn des gemeinsamen Weges mit Hahn, ab 1934, zuzuschreiben – *4 Jahre danach gehörte sie zu unserem Team* –, anschließend war sie von Schweden aus gedanklich mit uns verbunden... Hahn hatte gründliche radiochemische, nur übliche analytische Kenntnisse—bei mir war es umgekehrt, und die Analytik gab den Ausschlag! Aber es ist meine Überzeugung: Lise Meitner war die geistig Führende in unserem Team gewesen, und darum gehörte sie zu uns – auch wenn sie bei der "Entdeckung der Kernspaltung" nicht gegenwärtig war.[6][*]

At the time *Hahn* felt the same. He informed *Meitner* about barium on December 19, without speaking to any of the institute physicists:[87] "Ich habe mit Straßmann verabredet, dass wir vorerst nur Dir dies sagen wollen." ("Strassmann and I have agreed that for now we shall tell only you.") The barium finding was a "schreckliche[r] Schluß" ("frightful conclusion"); he pleaded for interpretation:

> Vielleicht kannst du irgend eine phantastische Erklärung vorschlagen... Falls Du irgendetwas vorschlagen könntest, das Du publizieren könntest, dann wäre es doch noch eine Art Arbeit zu Dreien![88][**]

Anxious to publish quickly, *Hahn* did not wait for *Meitner*'s reply before submitting the article to *Naturwissenschaften* on 22 December. He[89] mentioned the barium results only at the end, after pages of radium data, and then "with hesitation" ("zögernd"). His report expresses the chemistry-physics duality that had characterized the entire investigation. From the chemistry he drew confidence—"Als Chemiker müßten wir... statt Ra, Ac, Th die Symbole Ba, La, Ce einsetzen"[***]—and from physics, doubt: "Als der Physik in gewisser Weise nahestehende 'Kernchemiker' können wir uns zu diesem, allen bisherigen Erfahrungen der Kernphysik widersprechenden, Sprung noch nicht entschließen..."[90][***] To *Lise Meitner* he wrote:[88] "Wir wissen dabei selbst, dass es eigentlich nicht in Ba zerplatzen *kann*!... Also überleg Dir noch, ob sich nicht irgendeine Möglichkeit ausdenken liesse; so etwa Ba-Isotope mit viel höheren A.G. [Atomgewicht] als 137?"[****] *Hahn* had not yet realized that uranium had split in two.[91]

Lise Meitner received *Hahn*'s letter on December 21, her first news of the barium finding. She answered by return mail:

> Mir scheint vorläufig die Annahme eines so weitgehenden Zerplatzens sehr schwierig, aber wir haben in der

[*] In any case (according to what O. Hahn said) she urgently requested that these experiments be very carefully and intensively scrutinized one more time... Fortunately, L. Meitner's opinion and judgement carried such weight with us in Berlin that we immediately undertook the necessary control experiments.

[*] What did it matter that Lise Meitner did not *directly* participate in the "discovery"?? Her impulse was the beginning of the work with Hahn from 1934, *4 years later she belonged to our team*; in addition she was in close contact with us from Sweden... Hahn was thoroughly versed in radiochemistry, only the usual analytical knowledge—with me it was the reverse, and analytical chemistry achieved the result! But I am convinced, L. Meitner was the intellectual leader of our team, therefore she was one of us, even if she was not actually present for the "discovery of fission".

[**] If there is anything you could propose which you could publish, then after all it would still in a way be work by the three of us!

[***] As chemists we should substitute the symbols Ba, La, Ce for Ra, Ac, Th... As "nuclear chemists" fairly close to physics we can not yet resolve to take this step which goes against all previous experience in nuclear physics.

[****] We ourselves know that it cannot really break apart to Ba!... You should reconsider whether there isn't some other possibility; for example, Ba isotopes with much higher atomic weights than 137?

Kernphysik so viele Überraschungen erlebt, dass man auf nichts ohne weiteres sagen kann: es ist unmöglich.[92][*]

Hahn must have been surprised and relieved. In November *Meitner* had vehemently objected to the radium isomers; now she was puzzled but not opposed, intuitively ready to consider the barium result an expansion rather than a contradiction of previous experience in nuclear physics.

Years later, *Hahn* was known to say that had *Lise Meitner* remained in Berlin, she might have talked him out of the discovery, might have "forbidden" him to make it.[93] Clearly, *Meitner*'s letter of 21 December says just the opposite—and at the time *Hahn* must have found it most reassuring, because only after he received it on 23 December did he add to the *Naturwissenschaften* galley proofs a paragraph suggesting that the uranium nucleus has split in two.[94] This strengthened the article, showing that *Hahn* and *Straßmann* had not just identified barium, but understood that fission had taken place. Meanwhile, during their holiday together between Christmas and New Year's Day, *Meitner* and her nephew *Otto Robert Frisch* did propose and prepared to publish the first theoretical interpretation of the fission process.[95]

Meitner's contributions to the discovery thus formed a continuum from the first work in Berlin to the discovery of barium and beyond. At the end only her physical presence was missing. *Meitner* and *Hahn*'s own experience shows that physical presence is not required at all times for every member of a team: in 1917 and 1918 when *Hahn* was in the army, *Meitner* did nearly all the work, and both, without question, were credited with the discovery of protactinium.[27, 96] In 1938 *Lise Meitner* was excluded only because the same racial policies that had driven her from Germany made it impossible for her to be part of the barium publication, made it uncomfortable, as we shall see, for *Hahn* to even admit his ongoing collaboration with a "non-Aryan" in exile.

4.4. Transmutation: "Wir haben die Physik absolut nicht berührt..."

Meitner knew nothing could be done;[97] congratulating *Hahn* and *Straßmann* for their "beautiful finding" ("wunderschönes Ergebnis") she could not help but add; "I stand here with very empty hands." ("wenn ich jetzt auch mit sehr leeren Händen dastehe."[98]) It was worse, for while her name was missing from the discovery of barium, it was still firmly associated with the false "transuranes", which *Meitner* now understood to be fission fragments, not elements beyond uranium at all.

The timing was bad: *Meitner* was struggling to make a new start in Stockholm. She feared for her reputation, worried that people might say: "[D]ie Drei haben also Unsinn gemacht, und jetzt nach dem Weggang des einen haben die zwei andern das in Ordnung gebracht."[99] ("The three must have done nonsense, and now that one is gone the other two made it right.") She hoped[100] *Hahn* would say in his next paper that the discovery of barium was based upon techniques and results they had developed together. She could not imagine that *Hahn* himself would soon suppress and deny not only her ongoing collaboration, but the value of nearly everything she had done before.

On 16 January 1939 *Meitner* and *Frisch* sent their theoretical explanation of the fission process to *Nature*.[101] They described the nucleus as a classical liquid drop, its surface tension diminishing under increasing charge, dividing in two, converting mass into 200-MeV energy, forming neutron-heavy fission fragments whose long chain of beta decays finally made sense. It was a good piece of work, *Meitner* knew. Although it could not compensate for being excluded from the discovery itself, it tied her to it, permitted her to be the first to lay inherited isomerism and the "transuranes" to rest, and allowed her to salvage one earlier result: the 23-minute U-239 was still valid and the precursor of the first true element 93.

Meanwhile in Berlin the barium report appeared in *Naturwissenschaften* on 6 January 1939—and physicists in the institute were most upset that they had not been told before. *Hahn* was vulnerable, surrounded by Party members of all degrees of enthusiasm and opportunism, worried about the ambitious and dangerous Prof. *Heß* in the *Gastabteilung* upstairs.[102] When he wrote the next Hahn–Straßmann paper[103] at the end of January, *Hahn* gave only the briefest mention to *Meitner*'s earlier contributions and barely acknowledged the theoretical interpretation of *Meitner* and *Frisch*.[104]

Meitner reacted with despair. To her brother she wrote:

> Hahn hat jetzt in Fortsetzung unserer letzten gemeinsamen Arbeiten ganz wunderbare Dinge gefunden... Und so sehr mich diese Resultate wissenschaftlich und persönlich für Hahn freuen – so denken hier jetzt manche Menschen, dass ich überhaupt nichts gemacht habe.[105][*]

In Stockholm, she wrote to *Hahn*, she had a room in *Siegbahn*'s institute but no equipment, no help, no rights; she had ideas for experiments but could not do them, and she did not get along with *Manne Siegbahn*:

> Jetzt wird Siegbahn allmählich glauben – besonders nach Euern so schönen Ergebnissen, dass ich überhaupt nichts gemacht habe und Du auch die ganze Physik in Dahlem gemacht hast. Ich verliere allmählich allen Mut. Verzeih diesen unfrohen Brief. Ich weiss manchmal nicht mehr, was ich mit meinen Leben anfangen soll. Wahrscheinlich geht es vielen, die weggegangen sind, so wie mir, aber darum ist es doch sehr schwer.[106][**]

[*] To me at the moment the assumption of such a large-scale breakup appears very difficult, but we have experienced so many surprises in nuclear physics that one can not unconditionally say: it is impossible.

[*] Hahn has just published absolutely wonderful things based on our work together... And much as this makes me happy for Hahn, personally and scientifically, many people here must think I contributed nothing to it.

[**] Now Siegbahn will gradually believe, especially after your beautiful results, that I never did anything and you also did all the physics in Dahlem. I am gradually losing all my courage. Forgive this unhappy letter. Sometimes I don't know what to do with my life. Most probably there are many who emigrated who feel as I do, but still it is very hard.

Hahn responded with a list of physicists and their complaints:

> Ich fürchte, es wird mir auch etwas übel genommen, daß wir strikte nichts über unsere Versuche erzählten... [Ich] möchte den Herren [Physikern im Institut] aber doch nicht beichten, daß Du der Einzige warst, der sofort alles erfahren hat... Wie Du glauben kannst, Siegbahn denkt, Straßmann und ich machten auch die Physik, verstehe ich nicht. Wir haben bei der ganzen Arbeiterei die Physik absolut nicht berührt, sondern immer und immer wieder nur chemische Trennungen gemacht. Wir kennen doch unsere Grenzen und wissen natürlich auch, daß in diesem besonderen Falle es zweckmäßig war, nur Chemie zu machen... [D]ie Arbeit über das Uran [ist mir] ein vom Himmel gesandtes Geschenk. Ich fürchte nämlich manchmal, daß Dr. K.[107] dem Herrn... allmählich Teile des Instituts geben will...[108][*]

In this letter *Hahn* reveals the fear that drove him, in just two months, to transmute "eine Art Arbeit zu Dreien" into a work that "absolutely did not touch upon physics". By redefining the discovery to be just those chemical separations he and *Straßmann* had done in December, he divorced fission from physics—and himself from *Lise Meitner*.

5. Priorities

Hahn never retreated from this view. Throughout the spring of 1939 he was in a state of constant anxiety, fearful of losing priority for his "heaven-sent gift". As physicists worldwide rushed into print, they occasionally failed to cite *Hahn* and *Straßmann* fully. *Hahn* was defensive and irritable: he quarrelled with *Meitner*, with *Bohr*, with English colleagues; when *Lise Meitner* suggested he might have been more generous to *Curie* and *Savitch* he was annoyed;[109] when *Ida Noddack* chastised him for failing to mention her 1934 paper, he refused to answer.[110] As a non-Nazi he was feeling isolated in Germany; as a German, estranged from scientists abroad. Even as a chemist he felt left out. Having convinced himself the discovery owed nothing to physics, he was irritated to see the development of fission so throughly dominated by physicists, the more so because he had trouble understanding what they were doing. He never developed a close relationship with physicists in his institute; it was *Lise Meitner* who patiently explained things to him.[111] Finally, by the summer of 1939, his institute seemed secure, his position safe: "Die 'Uranspaltung' hat da die ganze Situation gerettet."[66] ("Fission saved the entire situation.")

[*] I fear it is held against me that we said nothing to anyone about our findings... I do not want to confess to these gentlemen that you were the only one who learned of everything immediately... I don't understand how you can believe that Siegbahn thinks Straßmann and I also did physics. In all our work we absolutely did not touch upon physics, but instead we did chemical separations over and over again. We know our limits and also know of course that in this case it was useful to do only chemistry... [For me] the uranium work [fission] is a heaven-sent gift. Namely, I was fearful sometimes that... Dr. K. wants gradually to turn over parts of the institute to Herr...

6. The Bomb

During the war *Lise Meitner* and *Otto Hahn* corresponded cautiously, avoiding politics, the war, fission. In Sweden *Meitner* felt forever homeless,[112] unwelcome in *Siegbahn*'s institute, isolated from nuclear physics. To her distress she saw herself become a nonperson in Germany, her work either ignored entirely[113] or cited using an "Auswahlprinzip bei Zitieren"[114] ("selection principle for citation")—that is, with her name omitted. She tried not to dwell on her troubles; much as she wished for the defeat of Germany, she agonized over the war casualties on both sides.[115] In 1943 she was asked to join the British scientists bound for Los Alamos. It would have meant escape from Sweden, interesting physics, valued colleagues. But she could not do it: "I will not work on a bomb!"[116] She knew very little of the corresponding German effort, only that it existed, that *Werner Heisenberg* was in charge and *Hahn* involved—enough to be anxious whenever reports came in of powerful new German weapons.[117]

When the war in Europe ended without an atomic bomb, she was greatly relieved; the news of Hiroshima came as an enormous shock.[118] For weeks the press swarmed around her, made up interviews when she refused to talk to them, got the facts wrong when she did.

Otto Hahn meanwhile was interned in Farm Hall, a country estate near Cambridge, England. He, too, was shocked by the bomb, then upset that the scientist of the day was not he, but *Lise Meitner*. In his memoirs, he noted: "Zum Teil unwahre Angaben über die Entdeckung; besonders am Anfang spielt Lise Meitner dabei eine große Rolle, ich selbst werde nicht genannt."[119] ("Partly untrue articles about the discovery; especially in the beginning Lise Meitner played a large role. I myself was not mentioned.") On 8 August 1945, two days after President *Truman*'s announcement of the first bomb, *Hahn* prepared a press release:

> So lange Prof. Meitner in Deutschland war, war von einer Spaltung des Urans keinerlei Rede. Sie wurde für unmöglich gehalten. Auf Grund von ausführlichen, chem. Untersuchungen über die bei der Bestrahlung des Urans mit Neutronen auftretenden chemischen Elemente wurden Ende des Jahres 1938 Hahn und Strassmann zu der Annahme gezwungen, dass bei diesen Vorgängen das Uran in zwei Teile zerplatzt, von denen ein Teil, das chem. Element Barium, sicher nachgewiesen wurde... Mit ihrem Neffen, Dr. O. R. Frisch gab [Prof. Meitner] eine Erklärung für diese von Hahn und Strassmann experimentell gefundene, bisher für unmöglich gehaltene "Atomspaltung".[120][*]

This was the summer of 1945; it could have been a new beginning, a time to set the record straight, to recall *Meitner*'s part in the Berlin team and the discovery of fission.

[*] ... As long as Prof. Meitner was in Germany, there was no discussion of the fission of uranium. It was considered impossible. Based on extensive chemical investigations of the chemical elements resulting from neutron irradiation, Hahn and Strassmann were forced to assume at the end of 1938 that uranium splits into two parts... of which one part, the element barium, was identified with certainty... With her nephew, Dr. O. R. Frisch, [Prof. Meitner] explained these experimental findings of Hahn and Strassmann, the 'atom-splitting' which until then had been considered impossible...

Instead, *Hahn* was taking care to create the impression that *Meitner* had done nothing for fission except "consider it impossible" and prevent it from being discoverd earlier.

7. Suppressing the Past

Hahn was calling upon fission to serve again—not himself this time, but his defeated country. He had already been awarded the 1944 Chemistry Nobel Prize—in secret, but he knew. He would use his personal prestige and the importance of the discovery to call attention to Germany's misery, to rebuild German science. To do this, he felt it necessary to make the discovery his, and his alone. He saw no purpose in looking back to the injustices of the Nazi period; he felt no personal necessity to make amends. With the Third Reich gone, the old nationalism resurged. *Hahn* was concerned for Germany—and only Germany.

Meitner had sensed this attitude even before the end of the war. In March 1945 she wrote to a Swedish friend:

> Die Briefe der deutschen Freunde klingen sehr gedrückt und doch glaube ich nicht, dass sie ganz erfasst haben, welchem Schicksal sie Deutschland durch ihre Passivität ausgeliefert haben. Und noch weniger scheinen sie sich bewusst, dass sie ein Stück Mitverantwortung haben für die schrecklichen Verbrechen, die Deutschland begangen hat. Dieser Gedanke macht mich richtig unglücklich. Wie soll die Welt Vertrauen zu einem neuen Deutschland haben, wenn seine besten und geistig höchst stehenden Vertreter nicht diese Einsicht haben und nicht den brennenden Wunsch haben, gut zu machen, was gut zu machen ist. Sie müssten das nicht nur stark fühlen, sondern sich zur gegebenen Zeit offen dazu bekennen. Aber ich fürchte, davon sind sie noch sehr weit entfernt. Darum glaube ich auch nicht an einen Widerstand "en masse" von innen heraus.[121][*]

Otto Hahn was released from Farm Hall in January 1946 and returned to a Germany that was hungry, cold, utterly destitute. His letters to *Lise Meitner* were a litany of hardships. *Meitner* sympathized, she sent packages—more than she could afford—but she could not stand *Hahn*'s nationalistic self-absorption. When *Otto Hahn* complained about food shortages, demeaning travel restrictions, and requisitioned apartments, *Lise Meitner* responded sharply that Germany had inflicted suffering and death upon millions;[122] when he wrote," [O]b das Verhalten der Besatzungsmächte heute so sehr großzügiger ist als das der Deutschen in Teilen der besetzten Länder, möchte ich fast bezweifeln"[123] ("I almost doubt that the behavior of the current occupation forces is so much nobler than that of the Germans in the occupied countries"), *Meitner* was aghast and reminded him of the millions murdered by Germans in occupied Poland.[124] They fought continuously until December 1946, when *Otto Hahn* and his wife *Edith* came to Stockholm for his Nobel Prize. *Meitner* expected their visit to be an "Eiertanz"[125]—like walking on eggs—but she was determined to be friendly.

Hahn came to Stockholm not only to claim his Prize, but to plead for Germany.[126] *Lise Meitner* was prepared for that, but she did not fully realize until then that she no longer had a place in *Hahn*'s life, or even his memory. In his many press interviews, he never spoke of their work together; not once did he even mention her name. In his Nobel lecture[37] he could not omit her entirely, but he gave no sense of their teamwork and emphasized instead that the discovery had been made in opposition to the experience of nuclear physics.

After the *Hahns* left, *Lise Meitner* tried to sort things out in letters to friends:

> Dass [Hahn] mit keinen Wort mich in seinen Inverviews erwähnt hat, geschweige von unserer mehr als 30jährigen Zusammenarbeit etwas gesagt hat, fand ich etwas schmerzhaft. Was ihn dazu veranlasst haben mag, ist komplizierter Natur. Er ist überzeugt, dass den Deutschen Unrecht geschieht und das umso mehr als er die Vergangenheit einfach verdrängt. Daher war sein einziger Gedanke hier für Deutschland zu sprechen. Ich bin ein Teil der zu verdrängenden Vergangenheit und das umso mehr als ich bevor er hierher kam... versuchte, ihn darauf aufmerksam zu machen, dass die anständigen Deutschen Deutschland nur helfen können, wenn sie die Geschehnisse objectiv sehen...[127][*]

> In seinem... Interview, sagte er... er sei glücklich, dass sich Deutschland nicht mit der Schuld der Konstruktion einer Atombombe und dem sinnlosen Töten von so vielen tausend Menschen belastet hätte. Ich versuchte ihm klar zu machen, dass er das wohl hätte sagen dürfen, wenn er dazu gefügt hätte, er sei darum darüber froh, weil die Deutschen ja so viel Schreckliches getan hätten. Aber darauf ging er wieder nicht ein... [E]r verdrängt die Vergangenheit mit aller Macht, obwohl er die Nazi wirklich immer gehasst und verachtet hat. Aber da sein zweites Hauptmotiv ist, Deutschland wieder zu internationalem Ansehen zu bringen und er weder ein starker Charakter, noch ein sehr nachdenklicher Mensch ist, leugnet er einfach das Geschehene oder bagatellisiert es...[128][**]

[*] The letters from German friends sound very depressed, yet I don't think they comprehend just what fate has befallen Germany through their passivity. And they understand even less that they bear some responsibility for the horrible crimes Germany has committed. These thoughts make me terribly unhappy. How shall the world trust a new Germany when its best and intellectually most prominent people do not have the insight to understand this and do not have a burning desire to make whatever amends are possible? They must not only feel this strongly, but at the proper time state it openly. But I fear they are still far from it. For this reason I do not believe that for the most part they had a strong inner resistance.

[*] I found it quite painful in his interviews Otto didn't say one word about me, let alone our 30 years of work together. His motivation is somewhat complicated. He is convinced that Germans are being treated unjustly, the more so in that he simply suppresses the past. Therefore his only thought here was to speak for Germany. I am part of that suppressed past, the more so since before he came... I tried to tell him that decent Germans can help Germany only by seeing things objectively...

[**] In one interview he said... he was glad that Germany was not burdened with the guilt of constructing an atomic bomb and causing the needless deaths of so many thousands. I tried to tell him that he certainly might say that, but only if he also said that Germany had done so many terrible things. But he did not respond to that... He suppresses the past with all his might, even though he always truly hated and despised the Nazis. One of his motives is to gain international respect for Germany once again, and since he does not have a very strong character, nor is he a very thoughtful person, he deceives himself about the facts, or belittles their importance.

In 1947 *Fritz Straßmann* asked *Lise Meitner* to come to Mainz as head of physics and director of the newly relocated Kaiser-Wilhelm-Institut (soon-to-be Max-Planck-Institut) für Chemie.[129] She considered the offer, but only because she valued *Straßmann*; then she refused.[130] To a Swedish friend she wrote:

> [D]ie Deutschen [haben] noch immer nicht begriffen, was geschehen ist und alle Greuel, die nicht ihnen persönlich widerfahren sind, völlig vergessen. Ich glaube, ich würde in dieser Atmosphäre nicht atmen können.[131][*]

Ten years after fleeing Germany, *Meitner* finally understood she could not return.

8. Postscript: "die *Mitarbeiterin*"[3]

Meitner did not continue her battles with *Hahn*. A nostalgic warmth gradually returned to their friendship, and she often visited Germany for lectures and conferences. Underneath, nothing was resolved. *Hahn* became postwar Germany's major scientific hero: Nobel laureate, president of the Max-Planck-Gesellschaft, prototype of the "decent German", lionized at every turn. *Meitner*, in every sense the outsider, was witnessing the disappearance of her scientific past. In 1953 she wrote to *Hahn*:

> Jetzt möchte ich etwas Persönliches schreiben, das mich bedrückt und das ich Dich bitte in Erinnerung an unsere mehr als 40-jährige Freundschaft und mit dem Wunsch, mich zu verstehen, zu lesen. In dem Bericht der Max-Planck-Gesellschaft wird der Vortrag, den ich in Berlin gehalten habe (ein rein physikalischer Vortrag) angeführt und ich werde genannt als "langjährige Mitarbeiterin unseres Präsidenten." Gleichzeitig habe ich in der Naturwissenschaftlichen Rundschau einen Artikel von Heisenberg gelesen über die Beziehungen zwischen Physik und Chemie in den letzten 75 Jahren, wo die einzige Erwähnung von mir... lautet: "Die langjährige Mitarbeiterin Hahns, Frl. Meitner."[132] Ich bin im Jahr 1917 vom Verwaltungsrat des K.W. für Chemie offiziell mit der Einrichtung der Physikalischen Abteilung betraut worden und habe sie 21 Jahre geleitet. Versuche Dich einmal in meine Lage hineinzudenken! Was würdest Du dazu sagen, wenn Du nur charakterisiert würdest als der langjährige Mitarbeiter von mir? Soll mir nach den letzten 15 Jahren, die ich keinem guten Freund durchlebt zu haben wünsche, auch noch meine wissenschaftliche Vergangenheit genommen werden? Ist das fair? Und warum geschieht-es?[133][**]

It is unlikely that *Hahn* understood; certainly he never spoke out on *Meitner*'s behalf. On the contrary, in his autobiographies[40, 41] his treatment of *Lise Meitner* the person was utterly perfunctory—except for a few coarse anecdotes[134] she appears more a ghost than a real human being. His protrayal of *Lise Meitner* the scientist gives little sense of their early collaboration or her independent work, no mention of her initiative in 1934, her leadership of the Berlin team, their crucial meeting in Copenhagen, her encouragement later. Apparently written without consulting scientific literature, correspondence, or his own personal diaries, *Hahn*'s autobiographies reveal a memory so faulty, superficial, selective, and self-serving that his character and motives must be called into question. It may be that *Hahn*'s self-deception and absence of feeling, which served as a survival tactic under a terror regime, congealed so irreversibly in the post-war period that it became impossible for him to examine the past. *Lise Meitner*, in her Viennese way, simply said: "Man kann wahrscheinlich nicht ein so charmanter Mensch sein und daneben sehr tief sein."[135] ("Probably one can not be such a charming person and also very deep.")

Meitner's public reaction was muted; she had no desire to battle the phenomenon of *Otto Hahn*.[136] Indeed, *Hahn*'s unparallelled celebrity status spawned an enormous quantitiy of derivative biographical material. A chorus of former associates, none close, echoed his contention that fission had nothing to do with physics or *Meitner*. Fission, they insisted, was discovered by the chemists in spite of the physicist.[137] In Germany only *Fritz Straßmann* and *Max von Laue* cared to recognize the obvious: if *Lise Meitner* had not been forced to emigrate, "sie wäre sonst zweifellos in der einen oder anderen Form an der Entdeckung der Uranspaltung mitbeteiligt..."[6, 138] ("she would undoubtedly, in one form or other, have participated in the discovery of fission.")

Had *Lise Meitner* been in Germany in December 1938, the discovery would have been hailed as the brilliant work of an interdisciplinary team. Instead, the politics of race demanded her exclusion. Rather than recognizing this as an injustice, *Hahn* and his followers invented spurious scientific explanations for it: they blamed the victim. Arrogantly, with misplaced national pride, they denied the injustice, created new injustice, perpetuated it—and implicated themselves.

9. Future

Primo Levi has written, "[T]he entire history of the [Third] Reich can be re-read as a war against memory, an Orwellian falsification of memory, falsification of reality, negation of reality."[139] *Lise Meitner*'s experience shows how memory and reality came to be falsified, even by those who were nominally anti-Nazi, even by scientists who were trained to pursue the truth. But for *Meitner*, at least, it appears that a

[*] The Germans have still not grasped what has happened and have completely forgotten all atrocities that did not personally happen to them. I think I could not breathe in such an atmosphere.

[**] Now I want to write something personal, which bothers me, and which I ask you to read with our more than 40-year friendship in mind and with the desire to understand me. In the report of the Max-Planck-Gesellschaft there is reference to a lecture I gave in Berlin (a purely physics lecture), and I am named as the long-time *Mitarbeiterin* of our President. At the same time I read an article by Heisenberg in Naturwissenschaftliche Rundschau about the relationship between physics and chemistry in the last 75 years, where the only mention of me... is: "Hahn's long-time *Mitarbeiterin*, Frl. Meitner." In 1917 I was given official responsibility by the board of the K.W. für Chemie to set up the Physics Section, and I led it for 21 years. Try to put yourself in my place. What would you say, if you were only characterized as the "long-time *Mitarbeiter*" of mine? After the last 15 years, which I wouldn't wish on any friend, shall my scientific past also be taken from me? Is that fair? And why is it happening?

genuine rehabilitation is underway: a new generation has begun to illuminate *Lise Meitner*'s scientific past, her life, and the world in which she lived.[140]

I am grateful to Irmgard Straßmann and the late Professor Fritz Straßmann for valuable discussions, to Ulla Frisch and the late Professor Otto Frisch for access to the Meitner Collection in Churchill College, to the late Marie-Luise Rehder for untold help, and to Dr. Marion Kazemi and the Archiv zur Geschichte der Max-Planck-Gesellschaft for access to the archives. I wish to thank Joan Bromberg, Stanley Goldberg, and Pieter Van Assche for critically reading this article. Support by the (U.S.) National Science Foundation and the National Endowment for the Humanities is gratefully acknowledged.

[84] Ref. [6], p. 18; [22], p. 208.
[85] Ref. [22], pp. 247ff.
[86] In 1945 (Ref. [29], p. 58) *Hahn* does not give a reason for the fractionation experiment: "Aus irgendwelchen Gründen wollten wir unsere Ra-Isotope etwas anreichern" ("For some reason or other we wanted to enrich our Ra-isotopes somewhat"); later, in Ref. [41a], pp. 255–256, Ref. [38], p. 20, Ref. [80], etc., he says only that fractionations were needed to detect the weak radiation of a long-lived Ra isomer, a reason *G. Hermann* in Ref. [11a,b] regards as "rather trivial". More likely, *Hahn* and *Straßmann* were responding to *Meitner*'s request they look for thorium, since if $Ra \rightarrow Ac \rightarrow Th$ were true, the resulting Th-231 would be identical or isomeric to the known UY. See *Meitner* to *Hahn*, 26 November and 5 December 1938, abridged in Ref. [22], pp. 250–251.
[87] Ref. [22], pp. 104–105.
[88] *Hahn* to *Meitner*, 19 December 1938; facsimile in Ref. [70], pp. 166–167.
[89] The *Hahn/Straßmann* articles were written by *Hahn* alone. See [6], p. 19, [22], p. 209.
[90] O. Hahn, F. Straßmann, *Naturwissenschaften 27* (1939) 11.
[91] W. Gerlach: *Ein Forscherleben unserer Zeit*, Oldenbourg, München 1969, p. 53.
[92] *Meitner* to *Hahn*, 21 December 1938; facsimile in Ref. [70], p. 171.
[93] According to *E. Bagge*, *Hahn* said in 1945: "Wenn Frl. Meitner im Dezember 1938 noch im Institut gewesen wäre, hätte sie uns das Barium ausgeredet." ("If Frl. Meitner had still been in the institute in December 1938, she would have talked us out of barium.") [Private communication, *R. Fleischmann* to *P. Van Assche*, 1982]; also see *Heisenberg* in [5]. Although such second- and third-hand reports require evaluation of the sources, they are consistent with *Hahn*'s later refusal to include *Meitner* in the discovery.

[126] *Hahn*, [41a], pp. 208–210; [41b], pp. 201–203.
[127] *Meitner* to *Eva von Bahr-Bergius*, 24 December 1946.
[128] *Meitner* to *James Franck*, 16 January 1947 (incorrectly dated 1946).
[129] *Straßmann* to *Meitner*, 11 November 1947.
[130] *Meitner* to *Straßmann*, 21 December 1947, and *Meitner to Hahn*, 6 June 1948.
[131] *Meitner* to *Eva von Bahr-Bergius*, 10 January 1948.
[132] Space does not here permit a discussion of the effect of gender inequity upon *Meitner*, but it is unlikely that a male scientist of *Meitner*'s status would be remembered as anyone's *Mitarbeiter*. That *Heisenberg*, who knew *Meitner* very well when she was still in Germany, would refer to her as *Hahn*'s *Mitarbeiterin* and ignore her work probably indicates chauvinism of more than one variety.
[133] *Meitner* to *Hahn*, 22 June 1953.
[134] *Hahn*, [40a], p. 86, pp. 147–148.
[135] *Meitner* to *Lola Allers*, 29 December 1946.
[136] In a very mild response to *Hahn*'s 1962 scientific biography, *Meitner* in 1963 ("Wege und Irrwege zur Kernenergie" [9]) described for the first time her own initiative and noted mistakes in both physics and chemistry; much the same in a 1963 taped interview: Ref. [56].
[137] So stated by *Zimen* in [2]. For "proof" *Zimen* suggests that physicist *Manne Siegbahn* knew *Meitner* personally and would have nominated her for a Nobel Prize had her work deserved it. The suggestion is disingenuous and mean: *Zimen*, who lived in Sweden at the time, surely knows that it was precisely the poor relationship between *Meitner* and *Siegbahn* that *prevented* her from being considered for a Prize. *K. Starke* (*J. Chem. Educ. 56* (1979) 771) is less strident but also ties the discovery to *Meitner*'s absence (which he attributes to her loss of Austrian citizenship!).
[138] In the U.S.A. this was understood; according to *Glenn Seaborg* (personal communication, 1988), *Meitner* was included with *Hahn* and *Straßmann* in the 1966 Enrico Fermi Prize for this reason.

[140] An abbreviated list of recent German contributions: The work of *Fritz Krafft* (Refs. [22, 23, 96]) has had significant influence; *Charlotte Kerners*'s book [24] received the (West) German prize for *Jugendliteratur* in 1987; the comments of *Renate Feyl* [1] have struck a resonant chord, so also the work by *H. Königsdorfer*: *Respektloser Umgang*, Luchterhand, Darmstadt 1986; *Lemmerich*'s 1988–1989 "Ausstellung zur Geschichte der Kernspaltung" [70] included *Meitner* equitably; ceremonies in 1988 and 1989 for the Lise-Meitner-Gymnasium in Böblingen included contributions by *Peter Brix* (Heidelberg) (P. Brix, *MPG-Spiegel* 1/90, p. 29), *Paul Kienle* (GSI Darmstadt) und *Evelies Mayer* (TH Darmstadt).

Toward the Understanding of Immunosuppression

By *Horst Kessler,* Dale F. Mierke, David Donald,* and *Mark Furber*

Slowly the fog is lifting: the elucidation of the three-dimensional molecular structure of the immunosuppressive compounds cyclosporin A (CsA) **1**,[1,2] FK506 **2**,[3] and rapamycin **3**, as well as biochemical observations are illuminating the mechanisms of immunosuppression.[4] A cascade of events take place (Fig. 1): the antigen is presented to the T-cell receptor (TCR) on the surface of the T-lymphocyte with the major histocompatability protein (MHC) and induces a signal which is transmitted through the cytoplasm to the nucleus by an unknown mechanism leading to the production of interleukin-2 (IL-2). CsA and FK506 inhibit this process. Rapamycin, on the other hand, acts later on in the cascade inhibiting the differentiation and proliferation of T-cells normally stimulated via IL-2.

Cell surface	Cytoplasm	Nucleus	Inhibitor
Antigen + MHC molecule reacts with T-cell receptor	Signal →	Production of interleukin-2	FK506 Cyclosporin A
Interleukin-2 and receptor	Signal →	Proliferation and differentiation of T-cells	Rapamycin

Fig. 1. The cascade of events leading to differentiation and proliferation of T-lymphocytes.

The medical relevance of immunosuppression is large: many illnesses are caused by unwanted reactions of the immunosystem. The success of transplantation surgery is to a large extent based on the "miracle" drug cyclosporin.[5] With the use of cyclosporin we can now transverse the fine line between graft rejection and infection of the patient due to a necessary suppression of the immune system.

Cyclosporin is a water-insoluble, lipophilic undecapeptide, whose spatial structure is well known in solid state and solution.[6] Recently a peptidomacrolide, FK506,[7] approximately 100-fold more active, was isolated and is currently undergoing clinical testing. The structure of FK506 is also well known.[7,8]

A first breakthrough in the understanding of the biology of immunosuppression came from the discovery of the cytosolic binding proteins cyclophilin (for cyclosporin) and FK506 binding protein (FKBP).[9] These proteins are ubiquitous rotamases (i.e. enzymes that catalyze the already fast *cis-trans* isomerism of peptide bonds).[10] Whether this property is directly connected with immunosuppressive activity is not yet clear. However, while bound to the protein the immunosuppressive is transported from the cell wall to the nucleus through the cytosol of the T-lymphocyte.[4] The structure of the cyclosporin–cyclophilin complex in solution was studied independently by the groups of *K. Wüthrich* at the ETH Zürich, Switzerland[2] and *S. Fesik* from Abbott laboratories, USA.[1] The results, which are in press, have been shrouded in secrecy. Until now it is only known that the *cis* peptide bond between MeLeu^9 and MeLeu^{10} of free cyclosporin is changed to *trans* when it is bound.[1] Is this an effect of the rotamase?

Recently a preliminary publication of the structure of the FK506–FKBP complex by the group of *M. Karplus* and *S. Schreiber* from Harvard appeared.[3] For this complex a characteristic high-field shift of all proton signals of the piperidine ring of FK506 was observed and explained as an

effect of the close proximity of the indole ring of the only tryptophan residue in FKBP. An NOE (*N*uclear *O*verhauser *E*nhancement) from substrate to receptor is direct proof of this assumption. The basis for all of the described studies is the use of isotope-labeled substrates and/or receptors. Labeling with ^{13}C, ^{15}N, and ^{2}H allow a filtering of the interesting information and an unambiguous identification and localization of the interacting species.

Which rotamer of the amide bond of FK506 corresponds to the bioactive form (while bound)?[11] In the crystal there is a *cis* orientation,[7] which also dominates (2:1) in $CDCl_3$ solution.[8] However, the structurally related rapamycin is *trans* in the crystal.[12] The knowledge of the conformation in the bound state is important for the design of therapeutically interesting analogues. In our opinion, the above-mentioned article[3] yields clear hints for a *trans* conformation in the FK506–FKBP complex: a comparison of the proton chemical shifts of the piperidine ring in the complex[3] and of both rotamers in solution[8] exhibits a high-field shift in the complex for all protons. There is only one exception: the equatorial proton at C2 is essentially not shifted if a *cis* peptide bond is assumed (Fig. 2). This makes no sense. If a

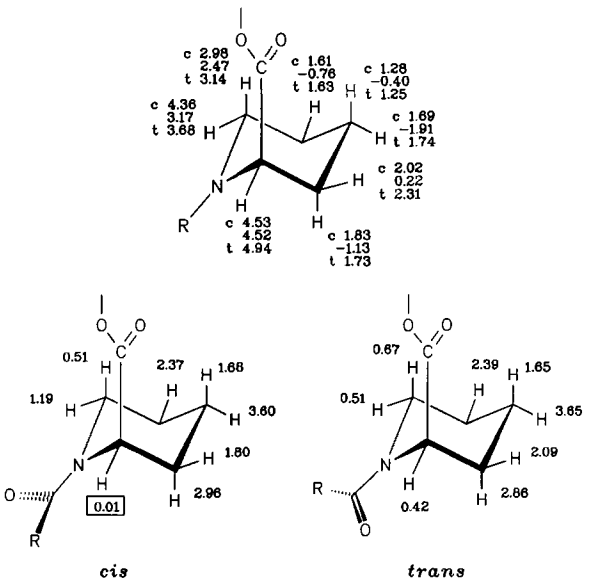

Fig. 2. Top: Comparison of the ^1H NMR chemical shifts of the piperidine ring of FK506 in the complex (number in the middle) with both rotamers of the amide bond of the free molecules in $CDCl_3$ (c = *cis*, t = *trans*). Bottom: the induced negative shift values caused by complexation are shown for both rotamers (see text).

trans rotamer is assumed, a reasonable high-field shift for all signals is observed. Also, the direct coupling of the carbonyl carbons 8 and 9 (see structural formula **2**) in the complex (61 Hz)[11] corresponds to that of the *trans* FK506 in solution (61 Hz) and not the *cis* rotamer (64 Hz).[13]

We look forward with great interest to the refined structures of the immunosuppressants and their receptors. In any case it is already clear that in spite of the very similar binding region of FK506 and rapamycin, which indicate a similar structure in the complex, the pure compounds exhibit different conformations of this region in the crystal. Hence, the structure at least one of the immunosuppressants differs in the crystal and in the complex. Cyclosporin also changes the backbone conformation from solution or crystal to the bound molecules.

Schreiber et al. have proposed that FK506 is an analogue of the transition state.[11] The carbonyl group $C^9{=}O$ is perpendicular to the amide plane ($O{=}C^8{-}N$) and therefore corresponds to a 90° twisted amide bond. Similar to statine, an inhibitor and the transition-state analogue of the aspartic proteases,[14] where the number of atoms in the chain does not exactly correspond to the peptide chain, the additional carbonyl group $C^8{=}O$ of FK506 does not disturb the inhibiting function. An acyl residue with a carbonyl group in the plane of the piperidine ring of FK506 is necessary to ensure the axial position of the ester group at C2. Hence, FK506 exhibits a delicate balance of a spatial structure, which certainly creates headaches for pharmaceutical chemists.[15]

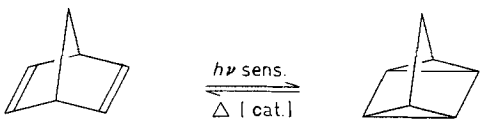
Energetic and Constitutional Hysteresis in Bistable Molecules

By *Ulrich Kölle**

Bistable or multistable systems, so-called flip-flops, which remain in a state Z_1 until they are converted by a trigger signal into a second state Z_2, are the key building blocks of all digital electronic devices. *Taube* and *Sano*[1] have recently realized such a system at the molecular level in an elegant way in the form of a dinuclear Ru-sulfide/Ru-sulfoxide complex.

In principle, any isomeric pair whose isomers are separated by a sufficiently high activation energy barrier constitutes such a bistable chemical system. However, the interconversion of the isomers can involve complicated chemical operations, including even chemical degradation and synthesis with the breaking and making of bonds; such conversions can no longer be considered as being equivalent to electrical triggering.

Molecules which photochemically isomerize and undergo thermal reconversion approach more closely the ideal of a triggerable multistable molecular system; like the norbornadiene/quadricyclene system [Eq. (a)], which, together with similar compounds, has been studied intensively as a converter of light energy into storable thermal energy.[2] A conversion catalyst, for example a suitable transition metal complex, can be used as trigger for the thermal reconversion.



(a)

Systems in which the conversion in both directions is triggered photochemically by light of suitable wavelengths already show a high degree of reversibility. In a series of Fe^{II} complexes[3] with relatively weak ligands which have been investigated by *Gütlich* et al., the thermal conversion barrier between a ^1A- and a ^5T-term is large enough in both directions to prevent a spontaneous conversion, at least at temperatures < 60 K. The reason for this is the considerably larger ionic radius of a high-spin Fe^{II} ion compared to the low-spin form. On the other hand, high-spin and low-spin forms can be intentionally interconverted by selective light excitation [Eq. (b)].

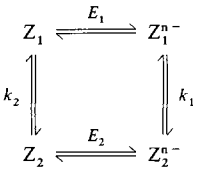
$$^1A_{1g}\,[Fe(mtz)_6]^{2+} \underset{h\nu\,(700\ nm)}{\overset{h\nu\,(350-650\ nm)}{\rightleftharpoons}} {}^5T_{2g}\,[Fe(mtz)_6]^{2+} \qquad \text{(b)}$$

mtz = 1-methyl-1*H*-tetrazole

At present, most examples of triggerable isomerizations involve transition metal complexes in which the triggering is brought about by an electrochemical oxidation or reduction at the electrode. In some cases the process is not only completely reversible, but also selectively and specifically triggerable by applying a suitable potential.

[*] Prof. Dr. U. Kölle
Institut für Anorganische Chemie der Technischen Hochschule
Templergraben 55, W-5100 Aachen (FRG)

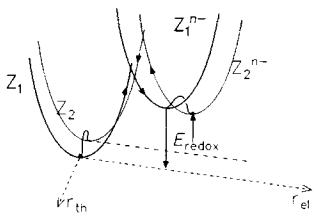
For a bistable system in the above sense, however, not only the comparatively trivial recharging is necessary but also a concomitant chemical reaction, often an isomerization. Such a system (Scheme 1) is characterized by (at



Scheme 1.

least) two redox potentials E_1 and E_2 and, in each case, two chemical reactions with the rate constants k_1 and k_2. The redox pairs $Z_{1(2)}/Z_{1(2)}^{n-}$ are in principle reversibly interconvertible; however, if the subsequent chemical reaction is sufficiently rapid, the electron transfer appears irreversible. Since Z_1 and Z_2^{n-} differ in chemical constitution, E_1 and E_2 can differ. In electroanalytical terminology this is designated an ECEC system. In the cyclic voltammogram such a system is characterized by a more or less strong displacement of the reduction peak compared to the oxidation speak.

These systems are bistable in the above sense when the chemical reaction can be separated from the electron transfer; i.e. the energy minima Z_1^{n-} and Z_2, which are reached after the electron transfer, must be separated by a small activation barrier from the stable configuration Z_2^{n-} or Z_1 for each charge state (see Scheme 2). In organotransition-



Scheme 2. r_{el} = electrochemical reaction coordinate, r_{th} = thermal reaction coordinate.

metal complexes which obey the 18-electron rule, the constitution often changes upon varying the charge of the complex. As long as this process is reproducible and reversible a chemical bistable system can exist.

Many compounds in which reversible bond rearrangements take place during a charge transfer have long been known, and redox isomerizations have recently been reviewed in detail.[4] However, the possibility of isomerization does not appear to suffice for separate redox potentials in reduction and oxidation; rather, examples are known in which the redox transition takes place reversibly electrochemically despite drastic changes in the molecular structure.[5]

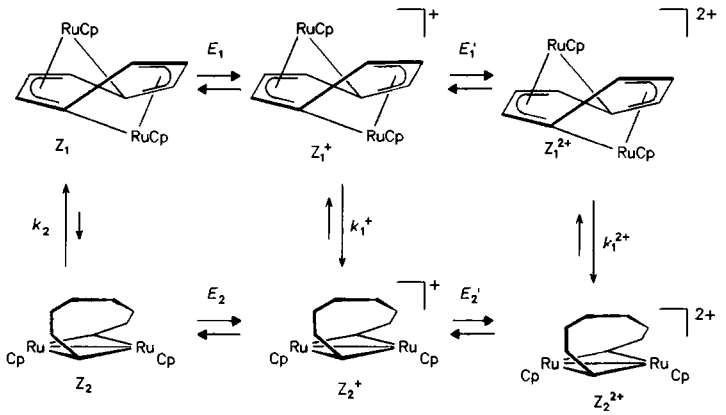
Examples of compounds in which the reduction potential and oxidation potential differ greatly, and in which reversible bond breaking and bond formation take place dur-

 © VCH Verlagsgesellschaft mbH, W-6940 Weinheim, 1991 0570-0833/91/0808-0956 $ 3.50+.25/0

ing the course of the charge transfer are dinuclear carbonyl derivatives with metal–metal bonding ([{Mn(CO)$_5$}$_2$], [{Co(CO)$_4$}$_2$], [{CpFe(CO)$_2$}$_2$] etc.[6]), for which reductive cleavage and oxidative coupling of the metal–metal bond are characteristic reactions. Closed cycles in the ECEC scheme are realized in particular when the metal centers are linked by suitable substituents (e.g. fulvalenes).[7] In sandwich complexes, the formation and breakage of peripheral C–C bonds, concomitantly in some cases with isomerization of the π-cyclic ring ligands during the charge transfer, is a frequently observed reaction.[8] But also purely intramolecular redox isomerizations with closed cycles have in the meantime been well documented. Examples are the *cis-trans-* and *fac-mer*-isomerizations of octahedral carbonyls [ML$_4$(CO)$_2$] and [ML$_2$L$'_2$(CO)$_2$], respectively, of the chromium and manganese groups, the cleavage of a metal–metal bond in dinuclear, anionically bridged transition metal complexes during a two-electron reduction, and the opening of clusters by the uptake of electrons.

In some sandwich complexes which can change their oxidation states in two-electron steps, a change in the hapticity and thus an isomerization occurs in accord with the equivalence of one double bond to two complex electrons in the valence electron count,[9] for example by bending of an η^6-arene to give an η^4-cyclohexatriene ligand. So-called pseudo-triple-decker complexes alter the conformation of the cyclic π-bridge ligand during the charge transfer.[4]

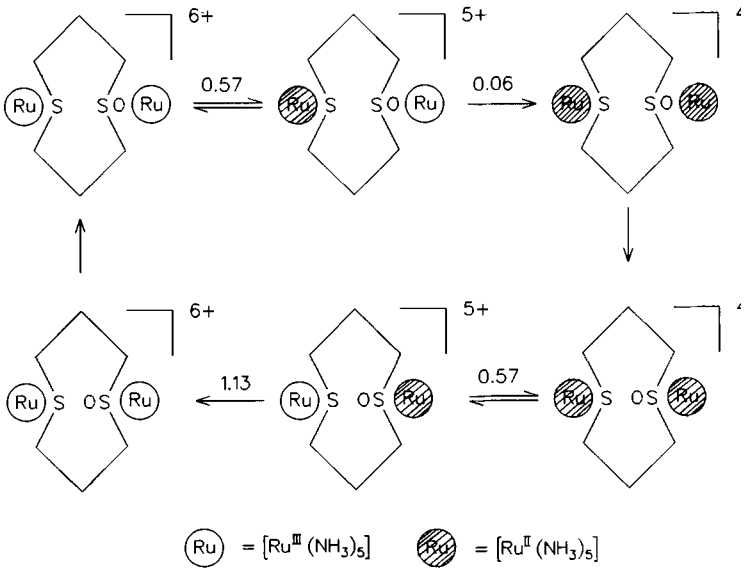
The reversible rearrangement of bonds in the redox isomerization of the diruthenium complex [(CpRu)$_2$(cot)] (Scheme 3) is *one* of the examples that has been studied in detail.[10] Two [CpRu] units are linked via a cyclooctatetraene unit to give a neutral molecule in which two C-atoms are pentacoordinated. Upon oxidation to the dication a C–C bond is opened and a so-called flyover complex is formed. A detailed insight into the reaction mechanism is



Scheme 3.

provided in this case by cyclic voltammetry. Firstly, the system is characterized by a chemically irreversible two-electron oxidation and reduction with potentials of 0.02 and − 0.26 V (glassy carbon electrode), due to the fact that $E_2' < E_1$ and $E_2 \approx E_2'$. Below room temperature the isomerization $Z_1^+ \rightarrow Z_2^+$ is slow. The oxidation of Z_1 gradually becomes a reversible one-electron oxidation and a second oxidation step can be observed at 0.4 V ($Z_1^{+/2+}$). This clearly shows that the isomerization takes place at the stage of the monocation at room temperature (indeed the generation of Z_1^{2+} at low temperature leads to another product). A similar sequence is found for the reduction of the stable and likewise structurally characterized dication Z_2^{2+}, with the exception, that here, reduction to the flyover neutral complex must take place first in order to trigger the isomerization to Z_1.

Finally, in the area of classical complex chemistry, redox isomerization can be expected wherever an ambident ligand changes its coordination site with changing oxidation state of the central metal. The few well-known examples are all from the coordination chemistry of Ru, since both Ru^{II} as well as Ru^{III} are coordinated exclusively octahedrally, and in addition, both oxidation states are inert to substitution.



Scheme 4.

In sulfoxide complexes the transition Ru^{II} → Ru^{III} can lead to a bond isomerization from Ru–SO to Ru–OS. This fact is exploited by *Taube* et al.[11] The authors have incorporated an S-function and an SO-function into a macrocycle and complexed both groups to a [Ru(NH$_3$)$_5$]-unit (Scheme 4). Starting from a complex in which both Ru atoms have the oxidation state + II, firstly the Ru–S group and subsequently, at a more positive potential, the Ru–SO function is oxidized. The isomerization to the Ru–OS isomer takes place during the second oxidation step. The Ru$^{3+/2+}$ potential of the Ru–OS group now lies at a more negative value than that of the Ru–S function, so that Ru^{III}–S is reduced prior to Ru^{III}–OS during the back-reduction. Thus, by selective redox triggering both the Ru–OS as well as the Ru–SO isomer can be generated, depending upon whether one starts from the completely oxidized or reduced complex with Ru–S as Ru^{II} or Ru^{III} center. As the authors remark, similar cases can be expected in coordination chemistry in the case of ambident ligands capable of bond isomerization (NO_2^-, NCS^-, CN^-, R_2SO).

A broad spectrum of applications are conceivable for molecules which can be triggered selectively between different states: from micro- and macroscopic display systems to

molecular information storage devices. The results obtained by *Taube* et al. disclose, in particular, a strategy for the planned search for novel systems with molecular hysteresis, which could satisfactorily meet practical requirements.

Dyes for Visual Distinction between Enantiomers: Crown Ethers as Optical Sensors for Chiral Compounds**

By *Fritz Vögtle** and *Peter Knops*

The discovery of crown ethers by *Pedersen* and the study of their complexation properties heralded the blossoming of the supramolecular chemistry which deals with host–guest interactions.[1] Crown ethers enable not only the selective complexation of cations and neutral organic molecules; with chiral crown ethers as host compounds, the (enantio)selective complexation of optically active guests can be achieved.[2]

By combining a crown ether with chromophoric units a "chromoionophore" is created. With these crown-dyes the selective cation complexation is made visible by a color change in the same molecule.[3] Figure 1 gives an idea of the significant effects which can be achieved with a crown ether coupled to a quinonimine.

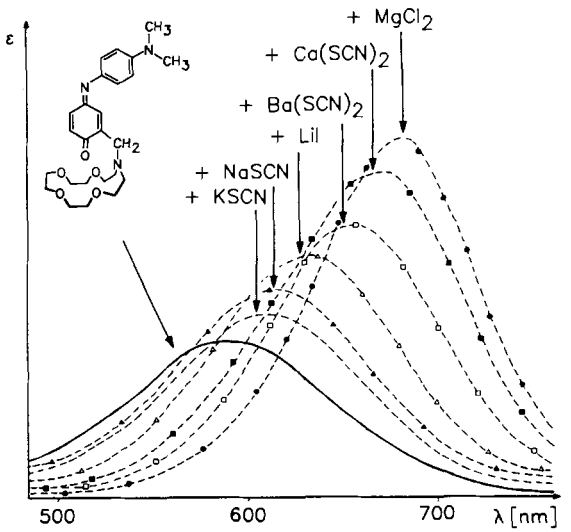

Fig. 1. Selective ion detection by a chromoionophore of the neutral quinonimine type as a result of cation-selective absorption of light.

Now the fascinating challenge of making the enantioselective complexation of chiral guests visible through a color change was recognized, i.e. of being able to see the enantiomeric differentiation of chiral guests by an optically active host molecule in order to draw conclusions about the absolute configuration of the guest molecule. Figure 2 illustrates the concept: through complexation of the chiral guest **1** with the enantiomerically pure chromoionophore **2**, different shifts for the absorption maximum are induced for the resulting complexes depending on the absolute configuration of the guest **1**. In the ideal case, these can be observed with the naked eye.

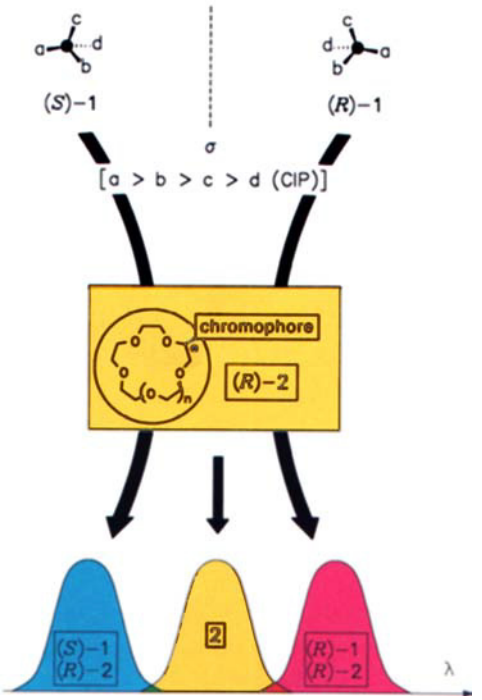

Fig. 2. Mode of action of chiral chromoionophores (schematic) for the visual recognition and differentiation of enantiomeric guest compounds.

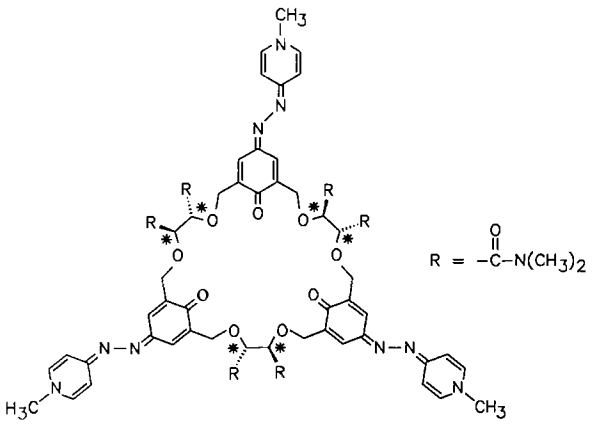
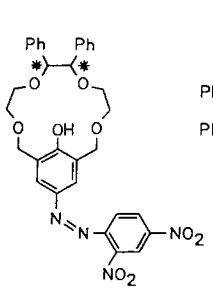
However, the first attempts to make the structural difference between the enantiomers of optically active ammonium ions visible through color effects with the chiral crown-dye **3** based on tartaric acid ("chiroselective halochromism") failed:[4, 5] neither ^{1}H NMR nor CD and UV/VIS spectra of solutions of **3** showed the anticipated changes on addition of chiral guests, and also extraction experiments were without success.



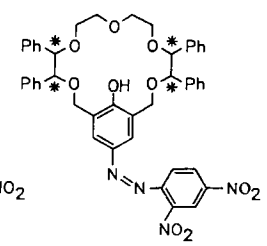
3

The color-giving azamerocyanin unit proved to be the problem in these studies, since it was protonated on addition of the ammonium ions $RNH_3^{\oplus}$, and furthermore, the ionophore periphery of **3** seemed too flexible, and lacked other coordination sites, to provide sufficiently strong interactions with the guest molecules. Consideration of models also revealed that the D_3 symmetry of the potential host was unfavorable for enantioselective complexation.

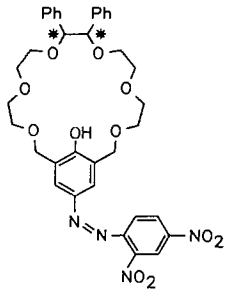
The breakthrough in distinguishing primary, secondary, and tertiary amines from one another, and in differentiating between the enantiomers of chiral amines by UV/VIS spectroscopy was finally achieved in 1985 by *Misumi* et al.:[6, 7] the chiral hosts **4**–**6** could be prepared through a combination of the long-known *acid* (phenolic) crown ethers with 2,4-dinitroazobenzene units as color-giving component. Addition of amines to ethanolic solutions of **4**–**6** afforded violet solutions of the ammonium phenolates, and distinct shifts of the absorption maxima in the UV/VIS spectra (up to 11 nm) were observed between complexes with the enantiomeric forms of the guest. (See also the review by *Misumi*.[7]) The visual differentiation between the enantiomers of a guest with host molecules **4**–**6** is, however, not possible because the difference in wavelength of the absorption maxima of the diastereomeric complexes is too slight.



4

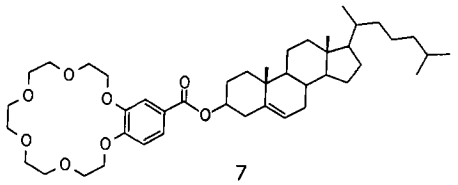


5



6

Recently *Shinkai* et al.[8] were able to intensify the effects for the chiral recognition of optically active ammonium ions by chiral crown ethers. They utilized the property that the wavelength of reflection for incident light in cholesteric liquid crystals depends on the pitch of the helical structures in the liquid crystalline phase: introduction of complexes of steroid crown ether **7** with chiral ammonium compounds



7

into a cholesteric liquid-crystal matrix gave visible color changes. The difference in wavelength of reflection between the diastereomeric complexes was up to 65 nm and thus capable of observation with the naked eye.[8] The conventional chromophoric group is no longer required, as here the whole system of crown-ether complex and liquid crystal functions as (supramolecular) chromophore.

The visual chiral recognition of not only optically active ammonium salts, but also alkali-metal salts of chiral compounds is possible. Alkali-metal salts of (*R*)- and (*S*)-mandelic acid similarly form complexes with steroid crown ether **7**; introduction of these complexes into a cholesteric liquid-crystal matrix changes the pitch of the helical structure depending on the chirality of the anion used, and (*R*) and (*S*) isomers can be distinguished by the observed color of the liquid crystal.[9] The complexation recognition process is thereby transferred through the chiral crown-ether to the overall structure of the liquid crystal and, in general, an only slight color difference in the diastereomeric host–guest complexes is significantly intensified and can be detected by the naked eye.

The liquid-crystal system used by *Shinkai* et al. can therefore be considered the first direct (visual) optical sensor for chirality. Particularly important for the optical differentiation of enantiomers in these studies appears to be the extension of the chromoionophore concept: the self-aggregation and -organization of liquid crystals is exploited to intensify the slight color effect markedly—a lesson in the logical application of knowledge from supramolecular chemistry.

Thus by using chiral host compounds it is possible today to distinguish the enantiomers of an optically active compound alone on the grounds of the color of their complexes. The progress in this area of chiral chromoionophores has, however, by no means reached an end; most recent reports describe halochromic and "chirosolvatochromic" betaine dyes,[11] and research on chiral large-cavity compounds[12] with color-giving units are under way.

Polyacetylene in Polyacrylonitrile Matrix: Novel Soluble Matrix Polyacetylenes by Ylide-Nickel Catalysis**

By *K. Alexander Ostoja Starzewski** and *Günter M. Bayer*

Dedicated to Professor Karl Heinz Büchel

The bis(ylide)nickel catalysts **1**, which we described in 1985,[1] are characterized by one rearranged and one structurally intact ylide ligand. They exhibit high activity and offer good possibilities for control of selectivity (molecular mass, degree of branching) in ethene polymerization.[1-4] Their likewise remarkable suitability for the synthesis of polyacetylene,[5] especially in highly polar solvents, prompted us to carry out polymerization experiments in polyacrylonitrile/dimethylformamide (PAN/DMF) solutions. A better stability, for example, is expected for polyacetylene in a highly polar polymer matrix, since the matrix should serve as a barrier to oxygen. However, such a material has not yet been prepared, perhaps because of the sensitivity of the Ziegler–Natta catalysts often used.[6] Our strongly polar bis(ylide)nickel catalysts have now proved to be doubly interesting in this respect.

$[NiPh(Ph_2PCHCPhO)(Me_3PCH_2)]$ **1a**

When acetylene is admitted to a solution of catalyst **1a** in PAN/DMF at 60 °C, an exothermic reaction occurs and the solution almost immediately turns black-violet; the catalyst is active and polymerizes acetylene. However, no polyacetylene can be filtered out and even highly dilute solutions, that is, low-viscosity solutions, show no evidence of sediment formation, even after standing for long periods. The polyacetylene is soluble and can be precipitated with, for example, toluene as a black polymer—referred to as PANPAC in the following discussion. The FT-IR spectrum of the solid shows, besides the polyacrylonitrile bands, the characteristic absorptions of a polyacetylene with a high *trans/cis* ratio ($\geq 80:20$). In order to determine the polyacetylene content of PANPAC, a calibration curve was obtained by grinding PAN with differing amounts of insoluble PAC. To characterize such reaction products spectroscopically, we used the quantitative UV/VIS spectrum of the homogeneous reaction solution in addition to the FT-IR spectrum of the solid. The UV/VIS spectrum shows a broad absorption band (halfwidth: 300–400 nm) with a maximum near 545 nm, corresponding to an average conjugation length of about 20 double bonds.[7] By correlation of IR and UV data, we calculated a mean specific extinction coefficient of 108 $L g^{-1} cm^{-1}$ (1.24×10^5 cm^{-1} based on pure polyacetylene with a density of 1.15 $g cm^{-3}$[8]) for the absorption maximum of the solubilized polyacetylene in the visible region. This value is in good agreement with the literature values for "classical" cross-linked, insoluble polyacetylene (1×10^5 to 4×10^5 cm^{-1}[9]). Thus, measurement of the UV extinction allows determination of the respective PAC content of the solution and, for known PAN concentration, that of PANPAC.

The solubility properties and spectroscopic features of the novel matrix polyacetylenes indicate that they are graft copolymers in which polyacetylene branches are attached to a polyacrylonitrile backbone.[10] The examples in Tables 1 and 2 show the scope of variation for the composition of such polymers as well as the corresponding reaction conditions. Particularly noteworthy are the easy attainment of high PAC contents and the solubilization present in all cases.

Table 1. Acetylene content x_{PAC} in PANPAC and UV/VIS absorption maximum λ_{max} of soluble PANPAC for different concentrations of catalyst, c_{cat} [a].

$c_{cat.}$ [mmol per g PAN]	λ_{max} [nm]	x_{PAC} [mol %] UV	IR
0.2	540	28	28
0.3	545	42	46
0.4	550	53	55
0.5	545	60	59
0.6	545	68	67

[a] After 15 min of acetylene polymerization in 1% PAN/DMF solution at 60 °C with **1a**.

Table 2. Acetylene content x_{PAC} in PANPAC and UV/VIS absorption maximum λ_{max} of soluble PANPAC for different polymerization times t [a].

t [min]	λ_{max} [nm]	x_{PAC} [mol %] UV	IR
5	510	18	18
15	550	53	55
30	535	63	62
60	540	70	69

[a] Acetylene polymerization with 0.4 mmol of **1a** per gram of polyacrylonitrile in 1% PAN/DMF solution at 60 °C.

Decisive for the efficiency *and* selectivity is again the presence of the structurally intact ylide ligand.[1] If this ligand is replaced by triphenylphosphane, for example, as in **2**, only a small amount of acetylene reacts. The reaction solution is yellow and the UV/VIS spectrum shows no absorption maximum between 400 and 800 nm. Use of the active bis(ylide)nickel catalysts, on the other hand, allows the absorption maximum for visible light to be shifted to shorter or

[**] Electronic Structure and Reactivity of Ylide Systems, Part 17. Part 16: [5].

[NiPh(Ph_2PCHCMeO)(Me_3PCH_2)] **1b**

[NiPh(Ph_2PCHCPhO)(iPr_3PCHPh)] **1c**

[NiPh(Ph_2PCHCPhO)(Ph_3P)] **2**

longer wavelengths by variation of the ligand, in accordance with different average degrees of polyene conjugation. When **1b** is used, for example, the absorption maximum is around 450 nm and the product contains about 85% *trans* double bonds. With the more active catalyst **1c**, the PANPAC is deep blue with an absorption maximum near 670 nm and more than 90% *trans* double bonds (Fig. 1). With respect to

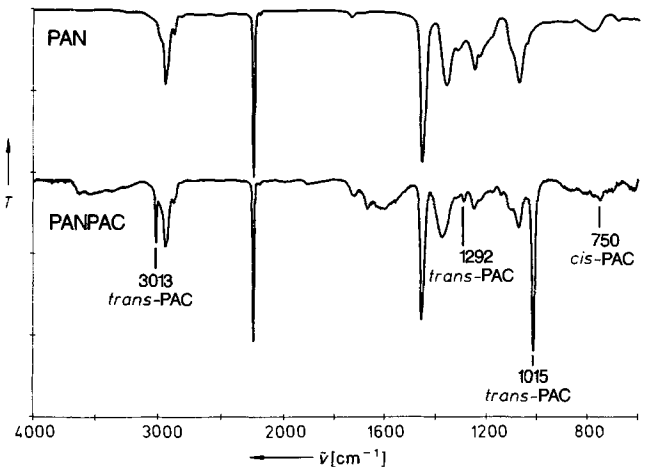

Fig. 1. FT-IR spectrum of PANPAC with 32 mol% acetylene; the polyacetylene segments have about 95% *trans* configuration [11] (bottom). For comparison: polyacrylonitrile (top). T = transmittance.

their conjugation length, the *trans* polyacetylene segments are no longer distinguishable from classical *trans*-PAC by UV spectroscopy. For comparison, the absorption maximum of classical cross-linked and correspondingly high-molecular-mass *trans*-PAC lies at 645–670 nm, whereas the corresponding isomer with mainly *cis* configuration absorbs most strongly at about 540 nm.[9]

The ability to control the percentage content of polyacetylene in PANPAC by varying the amount of catalyst and the polymerization time allows novel, soluble, and processable PAC-containing polymers to be prepared directly. The key prerequisites are thereby fulfilled to develop polyacetylene into an "advanced material".[12]

Thiadistannirane, 1,2-Dithiadistannetane, and Selenadistannirane: Small Rings with Tin–Tin Bonds**

By *Annemarie Schäfer, Manfred Weidenbruch,* Wolfgang Saak, Siegfried Pohl*, and *Heinrich Marsmann*

Dedicated to Professor Peter Sartori on the occasion of his 60th birthday

A number of molecules with multiple bonds between heavy main-group elements have been isolated in recent years and have proven to be excellent building blocks for otherwise hardly accessible compounds. For example, disilenes, $R_2Si{=}SiR_2$, and digermenes, $R_2Ge{=}GeR_2$, react smoothly with heavy chalcogens to give three-membered ring systems, namely, the thia-,[1] selena-, and telluradisiliranes[2] and the thia-,[3] selena-,[3,4] and telluradigermiranes.[5]

Surprisingly, no additions to tin–tin double bonds have been reported, even though the formally reverse reaction was observed in 1985 by *Masamune* and *Sita*.[6] On heating hexakis(2,4,6-triisopropylphenyl)cyclotristannane (**1**), they obtained distannene **2**, which is stable in solution. However, **1** was only accessible in low yield via a multistep synthesis.[6] Recently, we showed that treatment of tin(II) chloride with 2,4,6-triisopropylphenylmagnesium bromide gives **1** in a single step and in high yield. Moreover, reaction of **2** with tellurium afforded a telluradistannirane, the first three-membered ring with a Sn_2X framework.[7]

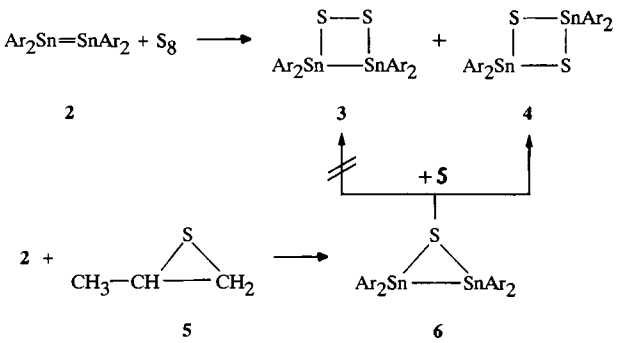
[**] Compounds of Germanium and Tin, Part 8. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. Part 7: M. Weidenbruch, J. Schlaefke, K. Peters, H. G. von Schnering, *J. Organomet. Chem.*, in press.

The reaction of **2** with sulfur proceeds differently, since the reaction is complete—as revealed by disappearance of the deep red color of **2**—only when the ratio of starting materials is one to two (Scheme 1). Two products are isolated. Their elemental analyses and mass spectra indicate the presence of isomeric dithiadistannetanes. The colorless isomer was identified as the known 1,3-dithiadistannetane **4**,[8] the yellow isomer as the 1,2-dithiadistannetane **3**. The constitution of **3** is supported, for example, by the ^{119}Sn NMR spectrum, which shows a $^1J(^{119}Sn,^{117}Sn)$ coupling of 4667 Hz, typical for molecules with a tin–tin bond.



Scheme 1. Ar = 2,4,6-iPr$_3$C$_6$H$_2$.

The X-ray structure analysis of **3**[9] (Fig. 1) confirms this proposal and also shows several unexpected features. The Sn_2S_2 four-membered ring is folded with an interplanar an-

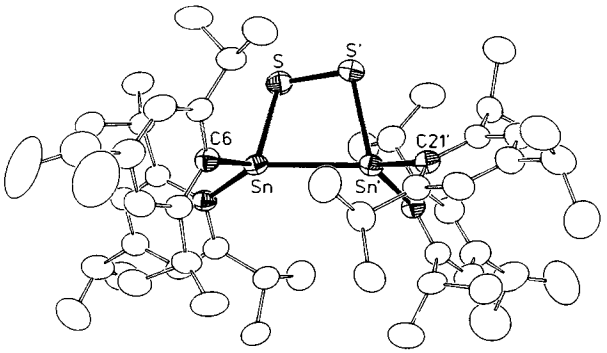


Fig. 1. Molecular structure of **3** (ORTEP, thermal ellipsoids at 30% probability, hydrogen atoms omitted). Symmetry-equivalent atoms are indicated by primes. Selected bond lengths [pm] and angles [°]: Sn–Sn' 288.9(1), Sn–S 248.0(1), S–S' 209.1(3), Sn–C6 218.9(4), Sn–C21 217.9(4); Sn–S–S' 95.8(1), S–Sn–Sn' 78.2(1); torsion angle (average of the angles between the opposite-lying planes C6–Sn–Sn'/C21'–Sn'–Sn and C6'–Sn'–Sn/C21–Sn–Sn') 0.7.

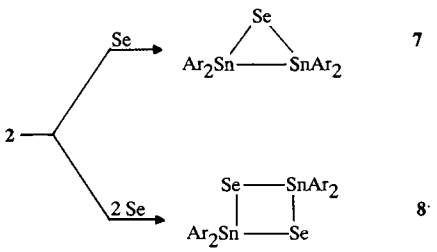
gle of 22° between the Sn–Sn'–S and Sn–Sn'–S' planes. The molecule possesses crystallographic C_2 symmetry, the C_2 axis passing through the midpoints of the S–S and Sn–Sn bonds. Especially interesting is the coordination sphere of the tin atoms; the two C atoms of the aryl groups together with the other tin atom form a nearly planar ligand environment (the sum of angles at each tin atom is 354°). A similar phenomenon was observed for oxa-,[10] thia-,[1] and selenadisiliranes,[2] for example, and was discussed, in connection with the short Si–Si distances, as evidence for π complexes between the disilene and the chalcogen atoms. A similar model of bonding is ruled out for **3**, however, since all bonds within the ring are lengthened relative to those usually found.

The ready formation of **3** is surprising, because the analogous ring systems with heavy elements of the 4th main group were previously unknown. In organic chemistry, too, 1,2-dithietanes were long regarded as only reactive intermediates, until, a few years ago, the first four-membered ring of this kind was isolated as part of a polycyclic system.[11]

The thiadistannirane **6**, which is not accessible by treatment of **2** with sulfur, is smoothly obtained by reaction of **2** with methylthiirane **5** (see Scheme 1). The constitution of **6** was established from the elemental analysis, the mass spectrum, and the ^{119}Sn NMR spectrum, in which the $^1J(^{119}Sn,^{117}Sn)$ coupling of 5745 Hz indicates, as in the case of **3**, the presence of a tin–tin bond. Moreover, further reaction of **5** with **6** results in insertion of sulfur into the tin–tin bond to give exclusively **4**.

The latter reaction, together with other findings, makes plausible the following proposal for the formation of **3** and **4**. Addition of an S_2 fragment to **2** results in direct formation of **3**; any **6** formed during the heterogeneous reaction reacts spontaneously with sulfur to give **4**. The possibility that **4** might be formed from **3** by a sequence of cycloreversion and cycloaddition reactions could not be verified experimentally, since **3** remained unchanged after heating for several days. Likewise, the assumption that stannylenes (stannanediyls), initially formed by fragmentation of **2**, might react with sulfur to afford rings **3** and **4** via stannathiones, Ar_2SnS, can probably be excluded. In this case, in analogy to the reaction of **5** with **6**, only the thermodynamically favored ring **4** should form.

The reactivity of selenium lies between that of sulfur and tellurium, as is evident in its reaction with **2** (Scheme 2). Even for a less than stoichiometric amount of selenium, only a mixture of the selenadistannirane **7** and the 1,3-diselenadis-



Scheme 2. Ar = 2,4,6-iPr$_3$C$_6$H$_2$.

tannetane **8** is formed. The constitution of both rings was established by elemental analyses and spectroscopic data. Characteristic of **7** is again the ^{119}Sn NMR spectrum, which shows a $^1J(^{119}Sn,^{117}Sn)$ coupling of 4873 Hz and thus supports the presence of the tin–tin bond in **7**.

Experimental Procedure

3 and **4**: Sulfur (0.15 g, 4.70 mmol) was added to **1** (2.00 g, 1.27 mmol) in 50 mL of toluene at 90 °C and the mixture was kept at this temperature for 0.5 h, its color turning from red to yellow. Toluene was replaced by n-pentane and unreacted sulfur was filtered off. HPLC of this solution showed that quantitative conversion had occurred to give a mixture of **3** (55%) and **4** (45%). Fractional crystallization from n-pentane gave initially 0.75 g (35%) of **3** as yellow crystals, m.p. 232–234 °C, ^{1}H NMR (300 MHz, C_6D_6): δ = 1.16 (m, 72H), 2.71 (sept, 4H), 3.52 (very broad, 8H), 7.06 (s, $^4J(^{119}Sn,^1H)$ = 20 Hz, 8H). ^{13}C NMR (75.44 MHz, C_6D_6): δ = 14.23, 22.67, 24.06, 25.44, 34.53, 38.70, 122.78, 150.76, 154.43. ^{119}Sn NMR (93.23 MHz, C_6D_6, versus Me_4Sn): δ =

121.5 $^1J(^{119}Sn,^{117}Sn)$ = 4666 Hz). MS (CI, isobutane): *m/z* 1115 ($M^{\oplus}$ + 1, 23%). UV/VIS: λ_{max} [nm] (ε) = 391 (756).

Subsequently, 0.40 g (19%) of colorless **4** was obtained from a small amount of *n*-pentane: m.p. 234–236 °C, ^{1}H NMR: δ = 1.14 (d, 24H), 1.22 (d, ^3J(H,H) = 7 Hz, 48H), 2.69 (sept, ^3J(H,H) = 7 Hz, 4H), 3.92 (m, broad, 8H), 7.06 (s, $^4J(^{119}Sn,^1H)$ = 28.3 Hz, 8H). ^{13}C NMR: δ = 24.02, 25.17, 34.55, 37.05, 122.57, 142.56, 150.96, 155.06. ^{119}Sn NMR: δ = −46.9 ($^2J(^{119}Sn,^{117}Sn)$ = 174 Hz).

6: Addition of **5** (0.14 g, 1.90 mmol) in 7 mL of toluene to **1** (2.00 g, 1.27 mmol) in 50 mL of toluene at 90 °C resulted in a spontaneous color change from red to yellow. Toluene was replaced by *n*-pentane and the sparingly soluble products were removed by filtration. Crystallization from about 5 mL of *n*-pentane gave 1.2 g (58%) of **6** as bright yellow crystals, m.p. 169–172 °C. ^{1}H NMR (300 MHz, C_6D_6): δ = 1.22 (m, 72H), 2.72 (sept, 4H), 3.77 (very broad, 4H), 3.90 (very broad, 4H), 7.06 (s, $^4J(^{119}Sn,^1H)$ = 24.4 Hz, 8H). ^{13}C NMR (75.44 MHz, C_6D_6): δ = 24.08, 24.57, 25.18, 25.64, 34.55, 37.04, 39.13 (broad), 122.35, 150.62, 155.08 (broad), 155.30 (broad). ^{119}Sn NMR (93.23 MHz, C_6D_6, versus Me_4Sn): δ = −309 ($^1J(^{119}Sn,^{117}Sn)$ = 5745 Hz). UV/VIS: λ_{max} [nm] (ε) = 340 (12320).

Further treatment of **6** with **5** under the same conditions gave exclusively **4** and no **3** (HPLC, NMR analysis).

7: Compound **1** (2.00 g, 1.27 mmol) and selenium (0.20 g, 2.53 mmol) were heated in 50 mL of toluene for about 1 h at 90 °C until the deep red color of **2** had vanished. Toluene was replaced by *n*-pentane and unreacted selenium was filtered off. Fractional crystallization from *n*-pentane resulted initially in a mixture of **7** and **8**, followed by precipitation of 0.50 g (23%) of **7** as light yellow crystals, m.p. 158–162 °C. ^{1}H NMR (300 MHz, C_6D_6): δ = 1.17 (m, 72H), 2.72 (sept, 4H), 3.69 (very broad, 8H), 7.06 (s, $^4J(^{119}Sn,^1H)$ = 21.9 Hz, 8H). ^{13}C NMR (75.44 MHz, C_6D_6): δ = 24.09, 24.58, 25.19, 25.77, 34.53, 39.83 (broad), 122.33, 150.56, 155.34. ^{119}Sn NMR (93.23 MHz, C_6D_6, versus Me_4Sn): δ = −393, ($^1J(^{119}Sn,^{117}Sn)$ = 4873 Hz). ^{77}Se NMR (47.67 MHz, C_6D_6, versus Me_2Se) δ = −378 ($^1J(^{119/117}Sn,^{77}Se)$ = 432/413 Hz). UV/VIS: λ_{max} [nm] (ε) 0345 (6790).

8: Compound **1** (2.00 g, 1.27 mmol) and selenium (0.31 g, 3.90 mmol) were refluxed in 40 mL of toluene for 15 h. The workup was analogous to that of **7**. Crystallization from *n*-pentane gave 2.1 g (91%) of colorless **8**, m.p. 243–245 °C. ^{1}H NMR: δ = 1.15 (d, ^3J(H,H) = 6 Hz, 24 H), 1.22 (d, ^3J(H,H): = 6 Hz, 48H), 2.71 (sept, 4H), 3.97 (m, 8H), 7.04 (s, $^4J(^{119}Sn,^1H)$ = 28 Hz, 8H). ^{13}C NMR: δ = 24.06, 25.20, 34.56, 37.01, 122.56, 140.16, 150.87, 154.89. ^{119}Sn NMR: δ = −253 ($^2J(^{119}Sn,^{117}Sn)$ = 318 Hz). ^{77}Se NMR: δ = 84 ($^1J(^{119/117}Sn,^{77}Se)$ = 868/831 Hz).

All new compounds gave correct C,H,S(Se) elemental analyses.

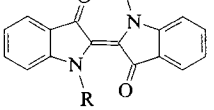
Light Absorption as well as Crystal and Molecular Structure of *N,N'*-Dimethylindigo: An Example of the Use of Synchrotron Radiation**

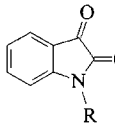
By *Gerhard Miehe,* Peter Süsse,* Vladimir Kupcik,† Ernst Egert, Martin Nieger, Gerold Kunz, Ralf Gerke, Burkhard Knieriem, Matthias Niemeyer,* and *Wolfgang Lüttke**

Dedicated to Professor Horst Prinzbach on the occasion of his 60th birthday

N,N'-Dialkylindigos (**1**) absorb at considerably longer wavelengths than the parent compound **2**[1–4] (Table 1); their solutions in organic solvents appear green to the eye, whereas those of indigo appear blue. This phenomenon was first recognized by *K. J. Braakman*,[3] who ascribed it to the inductive effect of the *N*-alkyl groups. His finding that the color band shifts to longer wavelengths as the steric bulk of the *N*-alkyl groups increases indicated, however, that the bathochromism is due less to their inductive effects than to their steric interaction with the carbonyl groups.[2, 5–8] Bathochromism due to steric hindrance was first observed in 1942 by *K. J. Brunings* and *A. H. Corvin*[9] for cyanine dyes and was interpreted theoretically in 1956 by *E. Heilbronner* and *R. Gerdil*.[10] According to their studies, such an effect is expected when the degree of double bonding in the central bond undergoing twisting is greater in the electronic ground state than in the excited state. In this case, the loss of resonance energy due to sterically induced torsion around the central bond and the resulting decrease in overlap of the π orbitals is greater in the ground state than in the excited state, assuming the torsion angles are the same; the energy of the ground state is thereby increased more than that of the excited state and the excitation energy is correspondingly decreased. An important argument favoring this model in the case of the *N,N'*-dialkylindigos **1** has been provided by *M. Klessinger* on the basis of HMO and PPP calculations:[6, 7] Indeed, the π bond order of the central bond of indigo (**2**) is substantially higher in the ground state (HMO, 0.628; PPP, 0.688) than in the first excited state (HMO, 0.453; PPP 0.494).



1 R = alkyl
2 R = H
3 R = CH_3



4 R = CH_3
5 R = H

However, experimental proof has been lacking so far; it should provide information on whether, for example, *N,N'*-

[**] Theoretical and Spectroscopic Investigations of Indigo Dyes, Part. 23. This work was supported by the Bundesministerium für Forschung und Technologie (Project: Structure Analysis with Synchrotron Radiation 05320 IAB 8). Part 22: H. Meier, W. Lüttke, *Liebigs Ann. Chem. 1981*, 1303.

Table 1. Wavelengths λ [nm] of the longest-wavelength absorption band of indigo dyes. The values measured in *n*-hexane were taken from [3], the others were measured.

	In solution					Solid
	n-Hexane	*p*-Xylene	CH_2Cl_2	$CHCl_3$	CH_3CN	KBr
indigo **2**	–	597	598.5	604	596	654
N-methylindigo	–	631.5	631	636.5	622	658
N,N'-dimethylindigo **3**	647	641	649	654.5	643	678.5
N,N'-diethylindigo	683	–	–	653	–	–
N,N'-diisopropylindigo	708	–	–	–	–	–

dimethylindigo (**3**)—like indigo (**2**)[11–15]—is planar or twisted. An X-ray structure analysis of **3** was therefore carried out;[16, 17] in addition, its structure was calculated using the π-SCF force-field program PIMM.[18, 19] Furthermore, the crystal structure of *N*-methylisatin (**4**) was determined.[20, 21] In **4**, which may be regarded as a "half-molecule" of *N,N'*-dimethylindigo (**3**), the inductive effect of the methyl groups is retained, but their steric effects are eliminated.

The first structure determination of **3**, carried out with $Mo_{K\alpha}$ radiation, yielded correct results,[17] but was inadequate owing to the low scattering ability of the small crystals, which were free of a multidomain texture. We therefore used synchrotron radiation (five-circle diffractometer in the HASYLAB[22]) to determine the structure once again. A total of 2055 unique reflections (97% of which were significant) were measured for a crystal with the dimensions $0.05 \times 0.08 \times 0.18$ mm^3 at a wavelength of $\lambda = 1.2127$ Å. The available intensity of the primary beam was about 40 times greater than that of a conventional X-ray tube. These data were easily refined and led to an *R* value of 0.032 ($R_w = 0.027$). The standard deviations of the distances of the "heavy" atoms were 0.003 Å on average, those of the C–H distances 0.015 Å (C-ring-H). The statistical variance of the individual values is on the order of magnitude of the experimental standard deviations. A reasonable determination of the anisotropic temperature factors of the hydrogen atoms was accomplished in addition to the refinement of their site parameters. Their physical relevance is immediately evident when the H atoms bonded to the aromatic ring are compared with those of the *N*-CH_3 groups. It is clearly revealed that the *N*-CH_3 groups do not rotate freely, but merely undergo a torsional vibration with a relatively large amplitude (Fig. 1). To our knowledge, this work represents the first physically meaningful determination of the hydrogen vibrational ellipsoids from X-ray diffraction data.

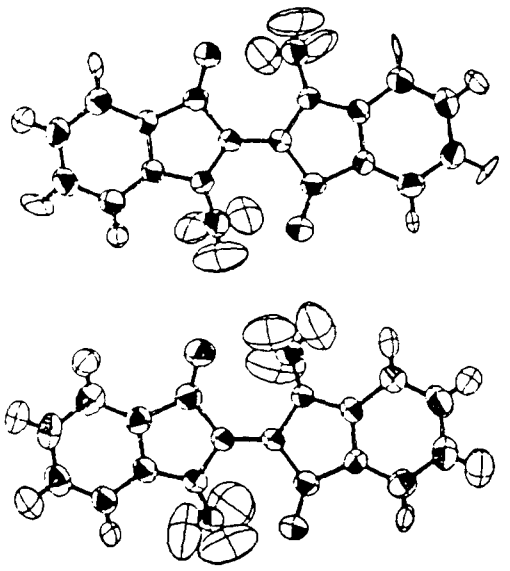

Fig. 1. The molecular shapes and thermal vibrations of **3** (top, molecule **I**; bottom, molecule **II**). The large amplitudes of the torsional vibrations of the *N*-methyl groups are clearly evident.

Although the two molecules in the asymmetric unit of the unit cell of **3** are crystallographically independent, their molecular shapes are practically identical. They have *trans* configuration; their C_2-symmetric shape is best described as that of a "bent" propeller (Fig. 2). The six carbon atoms of each benzene ring and all six atoms directly bonded to each ring are exactly coplanar within the standard deviations; only the C atoms of the central bond (C2 and C2') deviate slightly from this plane (<0.1 Å). The two planar halves of the molecule are twisted by $\beta = 26°$ with respect to each other; moreover, they are tilted in the same direction by an average of $\alpha = 9.5°$ with respect to the central C–C bond. The two C atoms of the central bond thereby adopt a slightly pyramidal bonding geometry and undergo a hybridization change from sp^2 toward sp^3. This is revealed in the fact that the length of the C=C bond of **3** (1.376 Å) considerably exceeds the value for indigo (**2**; 1.342 Å)[15] and the standard value for a C=C bond (1.337 Å) (cf. Table 2). The two *N*-

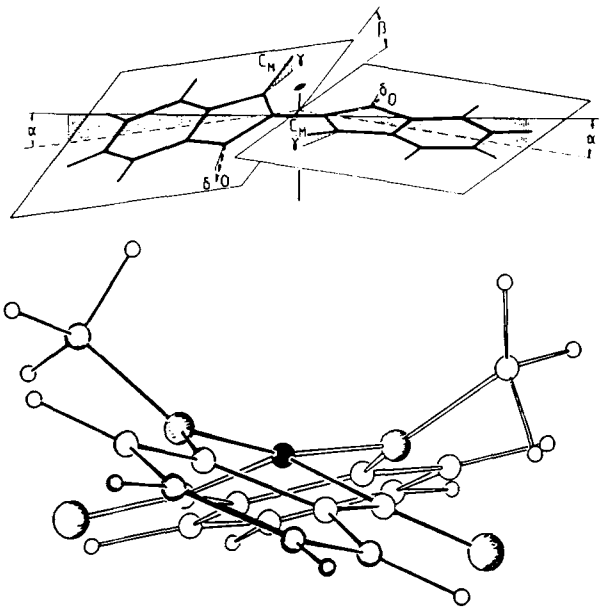

Fig. 2. Molecular shape of **3**: a) schematic; b) viewed along the C=C bond.

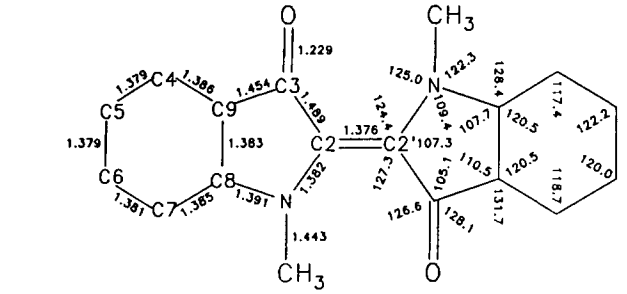
Table 2. Comparison of the average interatomic distances [Å] in **3** and **4** [a].

Bond	*N,N'*-Dimethylindigo **3**		Standard distances [23]	*N*-Methylisatin **4**	
	Crystal structure analysis	PIMM calculation [18, 19]		Crystal structure analysis	PIMM calculation [18, 19]
C–C (ring)	1.383(5)	1.401	1.395	1.381(7)	1.402
C=C (central)	1.376(2)	1.379	1.337	1.219 [b]	1.206 [b]
C–N (ring)	1.386	1.415	1.426	1.380	1.407
C–N (methyl)	1.443	1.477	1.472	1.452	1.488
C–H (ring)	0.97	1.079	1.084	-	-
C–H (methyl)	0.93	1.079	1.091	-	-

[a] The bond lengths [Å] of **3** were obtained by averaging over the four crystallographically independent "half-molecules". [b] This value corresponds to the C2–O2 bond length of **4**.

CH_3 groups are bent away from the planes of the five-membered rings; the N-CH_3 bending angles are 14 and 19.5°. Analogously, but in an opposite direction to the bending of the CH_3 groups, the two carbonyl oxygen atoms lie at an angle of $\delta = 4.5°$ on average with respect to the planes. Noticeably, the interatomic distances in **3** (Fig. 3 and Table 2)



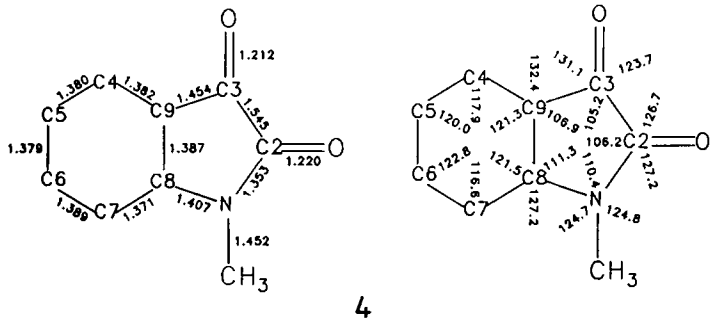


Fig. 3. Bond lengths [Å] and angles [°] of **3** (top) and **4** (bottom). The values for **3** correspond to a structure averaged from four half-molecules.

are systematically shorter than those calculated using the force-field PIMM[18,19] and than the standard distances found in tables,[23] because none of the distances have been corrected for vibrations.

N-Methylisatin (**4**; Table 2),[21] like isatin (**5**),[24] is completely planar. The C–C bonds in the benzene ring of **4** are practically just as long as those in **3**. There are differences in the five-membered rings, however, especially for C2–C3 and C2–N, as well as for N–CH_3 and the C=O bond. These differences are explained by the planar structure of **4** and probably also by the differing polarity of the C2–O bond of **4** compared to the C=C bond of **3**.

The high accuracy of the structure determination made possible by synchrotron radiation allows a detailed analysis of the effect of stacking of the molecules in the lattice on the molecular structure of **3**. The molecular shape is not significantly influenced by the intermolecular interactions in the lattice. This is also indicated by the observation that the IR spectra of the solid and of solutions of **3** in nonpolar solvents are very similar and that, on going from the solid to nonpolar solution, only a small frequency shift of 420 cm^{-1} is found for the longest-wavelength band in the visible spectrum. Thus, the twisted shape of the free molecule **3**, due to steric hindrance, is responsible for the complicated lattice structure (Fig. 4). The structure strives to achieve the greatest possible planarity of the packed layers, like that realized in the lattices of most planar indigo dyes. Although not possible for the entire *N*,*N*′-dimethylindigo molecule owing to its sterically induced nonplanarity, planar stacking is realized for its mutually twisted halves. As shown in Figure 4,

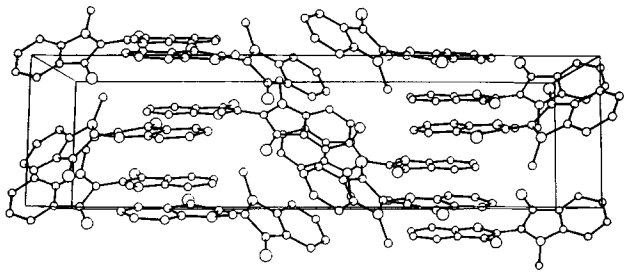

Fig. 4. Schematic representation of the crystal structure of **3**. The molecules **I** are stacked along the edges of the unit cell, the molecules **II** in between.

each molecule of **3** is involved in two stacking systems which are tilted toward each other. In contrast to biphenyl, for example, which is strongly twisted in the gas phase,[25] but is planar in the crystal,[26] the lattice energy is not sufficient in **3** to achieve a planar shape in the face of strong intramolecular steric hindrance. It may be assumed with certainty that **3** possesses the same twisted shape in solution as in the crystal.

The crystal structure of **3** is characterized by a large unit cell ($V = 2806$ Å^3; indigo (**2**), $V = 580.5$ Å^3[15]) and by different stacking of the two crystallographically independent molecules **I** and **II**. They each form separate layers; in the case of molecules **I**—arranged along the edges of the unit cells—this feature is expressed in a somewhat stronger twisting and a smaller aplanarity of the N-CH_3 groups as well as in a stronger vibrational motion compared to **II**.

Thus, *N*,*N*′-dimethylindigo (**3**) is deformed in a very complex way; therefore, the bathochromism of **3** and of its alkyl homologues[3] in comparison to indigo (**2**) is in fact a consequence of the steric interaction of the C=O groups with the N-CH_3 groups, in the sense proposed by *E. Heilbronner* and *R. Gerdil*.[10] This conclusion is confirmed by PPP CI calculations,[2] which we undertook in order to determine separately the effect of torsion around the central C=C bond and of pyramidalization at the N and CO groups on the excitation energy ΔE (S_0-S_1) and on the oscillator strength of the longest-wavelength band of **1**. As shown by the data in Table 3, each of these molecular deformations causes roughly the same bathochromism and the effects are additive.

Table 3. Effect of molecular deformation on the light absorption of **1** according to PPP calculations.

Molecular shape	Excitation energy ΔE (S_0-S_1) [nm]	[cm^{-1}]	Oscillator strength	lg ε
planar	529.5	18886	0.701	4.35
central torsion 26°	541.4	18470	0.723	4.36
N and CO pyramidalization	540.1	18515	0.619	4.29
central torsion 26° and pyramidalization	550.1	18178	0.644	4.31

According to the theory of deformation of C=C bonds,[28–33] their torsion is necessarily associated with a pyramidalization of the two C atoms, which leads to a local increase in the electron density and to a decrease in the C=C π bond order. The C=C pyramidalization found in the structure analysis of **3** ($\alpha = 9.5°$) and the analogous deformation of the N-CH_3 groups ($\gamma = 14$ and 19.5°) explain the higher reactivity of *N*,*N*′-dimethylindigo (**3**) relative to planar indigo (**2**):

(1) On irradiation with visible light, **3**—but not indigo (**2**)—is transformed into its *cis* form;[5, 34–36] the latter, in turn, transforms back into the *trans* isomer in the dark. In comparison to planar photoisomerizable indigoids, such as thioindigo,[34, 35] both processes are appreciably facilitated in **3** by the sterically caused torsion of the molecule. Since, in the photoisomerization of **3**, in contrast to that of other indigo dyes, no short-lived triplet intermediate has been observed, the *trans-cis* rearrangement presumably occurs via a singlet mechanism in the case of **3**.[37, 38]

(2) The high electron density at the central C atoms of **3** makes it readily oxidizable in solution.[39] Apparently, this oxidation occurs via a [2 + 2] cycloaddition of singlet oxygen to form a dioxetane, since we have found that *N*-methylisatin (**4**) is ultimately formed by cleavage of the C=C bond of **3**.

(3) Because of the pyramidalization of the N atoms, *N,N'*-dimethylindigo (**3**) is more basic than planar indigo (**2**). This explains why **3**, unlike **2**, reacts with mineral acids to form soluble salts.[5, 33]

(4) The twisted structure of **3**, together with its inability to form hydrogen bridges, explains why **3** possesses a much lower melting point (182 °C) and a lower density (1.31 $g\,cm^{-3}$) than indigo (**2**: 392 °C and 1.518 $g\,cm^{-3}$). Furthermore, it is responsible for the fact that **3**, in contrast to the planar indigo dyes, is soluble even in nonpolar solvents and that **3**, in contrast to planar thioindigo, has no affinity for cotton fibers.

d-Electron Density in Formal d^0 Systems from Multiplet Splitting in the Photoelectron Spectrum of Permanganates**

By *Michael Schmalz, Robert Schöllhorn,* and *Robert Schlögl**

An important aspect of current ideas on the bonding in high-temperature superconductors of the oxocuprate type is electron transfer from the 2p band of the oxygen ions to the copper d band. The resulting holes in the anion band lead to a mixed-valence state. This can be formulated according to the ionic model as shown in Equation (a).[1, 2]

$$Cu^{2+/3+}/O^{2-} \rightleftharpoons Cu^{2+}/O^{2-/1-} \qquad \text{(a)}$$

In order to assess how real the differences in charge density are in Equation (a), it is necessary to quantify the difference between formal oxidation state and real charge density. The magnitude of this difference allows an assessment of the relevance of the ionic model, which is used throughout structural chemistry, to a discussion of bonding.

A proven method for the spectroscopic analysis of charge density distribution is photoelectron spectroscopy (PES). It has been applied, for example, to transition-metal chalcogenides of the type $CuCr_2X_4$, which were shown to have

holes in the p band.[3] This charge transfer was found by analysis of the Se 3d spectra. An analogous procedure is not possible for oxidic solids, since the apparently unavoidable presence of OH^- ions makes it very difficult to distinguish between the O 1s binding energy of formal oxide ions (O^{2-}) and that of less shielded oxygen species (O^-), which are possibly also present [Eq. (a)].[2, 4, 5] Nonetheless, permanganates may be used as suitable model substances for an investigation of the difference between formal oxidation state and real charge density in oxides, since the color of these salts cannot be explained in terms of an ionic model with the formal oxidation states Mn^{7+} (d^0 system) and O^{2-} (s^2p^6). Moreover, the MnO_4^- compounds ($AgMnO_4$, $KMnO_4$) are solids that, owing to their molecular-ion lattice, exhibit only small band-structure contributions to the total electron structure, so that the charge distribution can be studied locally.

PES is a surface-sensitive method (information depth ca. 1000 pm); for the application discussed here, therefore, the surface of the sample must be an exact representation of the bulk. This condition can be fulfilled by cleaving the permanganate single crystals under ultrahigh vacuum. Owing to its molecular-ion character, moreover, this system tolerates only small oxygen disorder, in contrast to binary or polynary copper oxides, so that the uncertainty in the valence of the transition metal is much reduced. Furthermore, numerous quantum-mechanical calculations have already been carried out for the MnO_4^- ion, which has long had the same importance in theoretical inorganic chemistry as benzene has had in theoretical organic chemistry.[6]

PES allows the charge density distribution to be determined on the basis of the chemical shifts. However, the system discussed here poses difficulties, since, on the one hand, electrostatic charging—due to the insulator properties of the compounds—and, on the other hand, different lattice energies—due to the differing crystal structures of the compounds required as reference systems—perturb the chemical shifts.[7]

Therefore, the analysis of the d-electron population was performed on the basis of a quantum-mechanical effect seldom used in PES, namely, multiplet splitting. Multiplet splitting, which is caused by the exchange interaction between an unpaired core electron arising through photoionization and the total spin of the d electrons of the valence shell, leads to two final states. The very observation of multiplet splitting, therefore, shows the presence of d electrons in the valence shell.[8] Multiplet splitting is unambiguously observable for photoemission from s states, since intense additional structures appear in the spectra of p and d shells, resulting primarily from a very large number of possible final states. However, a disadvantage is the low intensity of the s bands. In practice, the interpretation of all photoemission structures is further hindered by additional characteristic energy losses.[7]

The samples were first characterized by X-ray diffraction[9] and their composition was established by atomic absorption spectrometry (AAS). The lattice constants of the compounds $AgMnO_4$, $KMnO_4$, and MnF_2 were found to be in good agreement with the reported values.[10] Older publications reported that the Mn 3s spectrum of $KMnO_4$ was not measurable.[11, 12] This may have been due to features of the instruments used, which resulted in a low intensity, or, alternatively, to sample surfaces that did not consist of MnO_4^- ions.

That the substances we investigated contained authentic MnO_4^- was revealed by the composition of the surfaces measured using theoretically determined effective cross-sections[13] (Table 1). The somewhat larger surface values for the cations in the MnO_4^- compounds are probably due to small contamination with KOH, as indicated by the results of the AAS analysis and the form of the O 1s peak in the photoelectron spectrum.[14] The slightly too large content of oxygen is due to the incorporation of OH^- groups into the crystal; these groups are also revealed by a shoulder at about 531.5 eV in the O 1s PE spectra. Under our experimental conditions (surfaces cleaved in situ, ultrahigh vacuum), the Mn 3s spectra of the permanganates exhibited a splitting that was smaller than that of the other manganese compounds; this finding is in agreement with the highest formal oxidation state Mn^{7+}. The Mn 3s spectrum of $KMnO_4$, as an example of the permanganates, is compared with that of MnF_2 in Figure 1. The contribution of the splitting, ΔE_A, is given in Table 1 for all compounds investigated.

Table 1. Binding energies E_B and mulitplet splitting ΔE_A (determined by PE spectroscopy) as well as surface and volume composition of the manganese compounds investigated.

Compound	E_B Mn $2p_{3/2}$ [eV]	ΔE_A [eV] Mn 3s	Composition Surface	Volume
$KMnO_4$	643.1	4.18	$K_{1.23}MnO_{4.24}$	$K_{0.99}MnO_{3.76}$
$AgMnO_4$	642.3	4.2	$Ag_{1.28}MnO_{4.1}$	–
MnO_2 (pyrolusite)	642.9	4.69	$MnO_{2.99}$	$MnO_{2.1}$ $MnO_{1.997}$
MnO_2 (manganite)	642.9	–	$MnO_{4.35}$	$MnO_{2.38}$
MnF_2	643.7	6.5	$MnF_{2.19}$	–

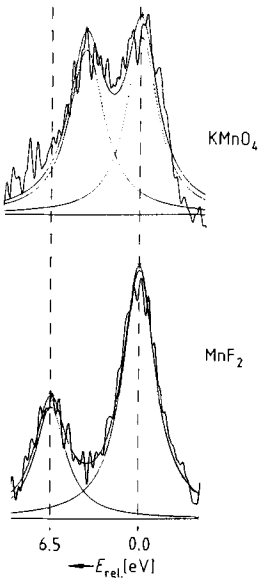

Fig. 1. Mn 3s PE spectra of $KMnO_4$ and MnF_2. The origin of the binding-energy scale in both cases was taken to be the maximum of the lower-energy peak [8, 15].

Further evidence for the presence of MnO_4^- is provided by a comparison with the Mn 2p spectra. These spectra display the same line profile for the two compounds ($AgMnO_4$, $KMnO_4$). The binding energies of the Mn 2p electrons are higher relative to the oxygen 1s electrons than in the reference compounds; the relatively small difference between these energies and that in the formally only tetravalent manganese ion in MnO_2 shows, however, that the permanganate ion cannot be identified by its chemical shift alone. The exact

position of a photoemission line is not only influenced by the electron density at the atom under consideration in its ground state, but also by a number of intra- and interatomic effects (see above). The difference in the values for the two permanganates results from the differing polarizability of the counterion (K^+ is harder than Ag^+) and confirms the effect of the spectroscopic ground state (extraatomic electrostatic shielding[7]) on the binding energies; an actual difference in the Mn charge density is ruled out by the identical geometries of the MnO_4 tetrahedra.[16–18]

The multiplet splittings for $AgMnO_4$ and $KMnO_4$ (4.2 and 4.18 eV, respectively) can now be converted into the corresponding d-electron populations by using theoretical data adjusted for the binary transition-metal compounds.[19] For $\Delta E_A = 4.2$ eV, 3.5 d electrons were calculated for MnO_4^-. This value is in general agreement with the calculated electron densities, which predict an electron deficit in the Mn 3d orbitals of 0.1–1.5 charges relative to the free atom.[20] The charge on manganese, which is small compared to the formal oxidation state, indicates that the real charge on oxygen is not -2, but rather much smaller, so that the binding energy usually given for O^{2-} in transition-metal oxides (-530.5 eV) in reality always includes a considerable covalent interaction. An attempt[21] to identify occupied Mn 3d levels in $KMnO_4$ directly through valence-band photoemission gave results that were qualitatively in agreement with the data presented here. Since valence-band spectroscopy is not state-selective, however, the data from Ref. [21] provide only evidence and not proof.

A value of -0.5 resulted for the charge on the oxygen atoms in the permanganate ion. Presumably, however, there is also an interaction between the Mn 4s/4p orbitals and the O 2p orbital.[20] The spectroscopically determined d-electron population should only be regarded as a lower limit. This uncertainty results from the fact that PES, as a typical high-energy spectroscopy, does not measure the pure electronic ground state of a system.

The results obtained here for the molecular species MnO_4^- cast doubt on an analysis of bonding that assumes formal oxidation states, at least in oxidic solids. Thus, the high-temperature superconductors that show metal-like conduction at room temperature, should exhibit considerable orbital interaction between the "cations" and "anions" owing to the formation of bands (overlap between O 2p and Cu 3d orbitals). Clearly, therefore, Equation (a) does not reflect the actual bonding, since neither ionic formula in Equation (a) is correct. Owing to covalent interactions, oxygen always has an appreciably smaller net charge than would have been expected according to the ionic formula. The differentiation of oxygen ions with differing charge (O^{2-} and O^{-}), attempted on the basis of PE O 1s data,[4] should be viewed very critically. The nonequivalence of the oxygen atoms might be due to differing geometric surroundings and *not* to different oxidation states.

Thus, the *valence problems* in inorganic solids are actually a problem of describing chemical interactions, which do not appear in the context of the multicenter orbital interaction long assumed in the theory of molecules. The description of solids in terms of ions with integral charges, which is very common in structural chemistry, is only a very crude model for the analysis of chemical bonding in extended periodic solids.

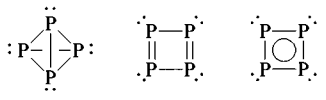
The *cyclo*-P_4 Ligand as 12-Electron Donor**

By *Manfred Scheer,** *Eckhard Herrmann,** *Joachim Sieler,* and *Matthias Oehme*

A P_4 unit can be present in complexes as the *tetrahedro*-P_4 ligand **A** as in **1**[1] and **2**[2] and as planar *cyclo*-P_4 ligands **B** (rectangular) and **C** (square) as nearly realized in **3**[3] and **4**,[4] respectively. Complexes in which the four lone pairs of a *cyclo*-P_4 ligand are each bonded to a metal atom were previously unknown.[5]



A **B** **C**

$[Ni(np_3)(\eta^1\text{-}P_4)]$ **1**
$[Rh(Ph_3P)_2Cl(\eta^2\text{-}P_4)]$ **2**
$[\{Co(\eta^5\text{-}C_5Me_4Et)\}_2(\eta^4\text{-}P_4)]$ **3**
$[Nb(\eta^5\text{-}C_5Me_5)(CO)_2(\eta^4\text{-}P_4)]$ **4**

Reaction of white phosphorus with $[M(CO)_5(thf)]$, M = Cr or W [Eq. (a)], has now afforded complexes in which a square-planar P_4 unit serves as a 12-electron donor.

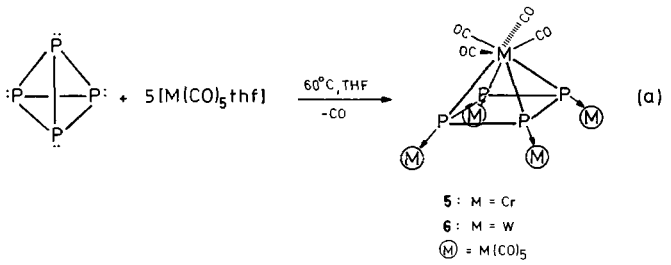
[+] X-ray structure analysis

[**] This work was supported by the Fonds der Chemischen Industrie.



The position of the ^{31}P NMR signal recorded for a solution of white phosphorus in THF ($\delta = -527.5$) hardly shifts at all ($\delta = -528.4$[6]) on addition of [(M(CO)$_5$(thf)], M = Cr or W, at room temperature; that is, no reaction is evident. On warming the solution to 60 °C, the multiplets of an AM_2X spin system appear in the ^{31}P NMR spectrum and complexes **5** and **6** can be isolated from solution. Apparently, the transformation of white phosphorus to the square-planar P_4 ligand of type **C** occurs only at higher temperature and is accompanied by decarbonylation of an [M(CO)$_5$] unit to an [M(CO)$_4$] unit.

Complex **5** forms brown crystals and complex **6** forms red, light-sensitive crystals, which are readily soluble in CH_2Cl_2, THF, acetone, and pyridine, moderately soluble in diethyl ether and toluene, and sparingly soluble in *n*-pentane. They are stable for short periods on exposure to air.

Under the conditions of EI mass spectrometry (70 eV, 100 °C), **5** and **6** cannot be ionized without decomposition. In addition to a weak-intensity peak (5%) for $P_4^{\oplus}$ (*m/z* 124), primarily peaks for the fragment ions $[M(CO)_n]^{\oplus}$ (n = 6 ··· 1) are found. In the ^{31}P NMR spectra of **5** and **6** in CD_2Cl_2 in the temperature range of 198–301 K, only one signal is observed in each case; for **6**, this signal displays a complex ^{183}W satellite pattern.[7] When **5** or **6** is dissolved in THF, on the other hand, the above-mentioned multiplet of an AM_2X spin system appears in both cases owing to an as yet unexplained interaction with the solvent.[8] In the temperature range of 215–301 K, the ^{13}C NMR spectrum of each of the two compounds in CD_2Cl_2 reveals two signals, a sharp singlet for the *cis* CO groups and, at somewhat lower field, a very broad signal for the other CO groups. In the region of CO stretching modes, the IR spectra of **5** and **6** in the solid state[7] show the band pattern expected for local C_{4v} symmetry of the [M(CO)$_5$] complex fragments.[9]

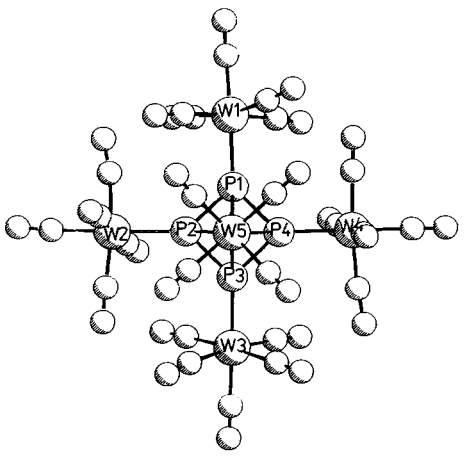


Fig. 1. Molecular structure of **6**. The atoms are drawn as spheres with arbitrary radii. Selected distances [Å] and angles [°]: P1-P2 2.148(9), P1-P4 2.155(9), P2-P3 2.161(9), P3-P4 2.147(9), P1-W1 2.451(7), P2-W2 2.445(7), P3-W3 2.457(6), P4-W4 2.428(7), P1-W5 2.620(7), P2-W5 2.592(6), P3-W5 2.602(6), P4-W5 2.601(7); P1-P2-P3 90.3(3), P2-P3-P4 89.6(3), P3-P4-P1 90.5(3), P4-P1-P2 89.7(3), W5-P1-W1 133.9(2), W5-P2-W2 135.6(2), W5-P3-W3 137.5(2), W5-P4-W4 134.5(2).

The crystal structure analysis of **6**[10] (Fig. 1) shows that a complex with higher pseudosymmetry is formed. The central unit is a square-planar P_4 group (deviations of the phosphorus atoms from the best plane: 0.006(7) Å), which formally arises from the P_4 tetrahedron by homolytic cleavage of two P–P bonds. The four valence electrons (VE) thereby made available augment the 14 VE of a [W(CO)$_4$] unit to give 18 VE, corresponding to the noble-gas rule. The tungsten atom of the [W(CO)$_4$] unit lies above the center of the P_4 ring, so that a square WP_4 pyramid is formed (distance W-P_4 (center) = 2.111(1) Å). The four CO groups are in eclipsing positions with respect to the four phosphorus atoms. The lone pair of each phosphorus atom is involved in further bonding to a [W(CO)$_5$] unit. Thus, the central *cyclo*-P_4 ligand of the entire complex provides 12 VE, the maximum number expected for a structure of type **C**.

The P–P bond lengths (average 2.153(9) Å) are shorter than that of a P–P single bond (2.21(2) Å[12]) and correspond roughly to the P–P distance calculated for the energetically most favorable "antiaromatic" structure **C** of tetraphosphacyclobutadiene (2.143 Å[13]).

Similar distances were also found for **4** (average 2.16 Å[4]) and for the pseudotetrahedral [W_2(O*i*Pr)$_6$(py)P_2], which contains a μ-P_2 ligand (2.154(4) Å[14]). The slight rhomboidal distortion of the P_4 ring in **4** might be due to the different substituents on the metal in the 14-VE complex fragment [Nb(η^5-C_5Me_5)(CO)$_2$]. In **6**, which contains the highly symmetrical [W(CO)$_4$] cap, all P–P distances are identical within the limits of error.

The plane of the four terminal tungsten atoms lies 0.408(1) Å below the P_4 square. The nearly identical $P–W_{terminal}$ bond lengths (average 2.445(7) Å) are comparable to those in [{W(CO)$_5$}(μ_4-P){Co_3(CO)$_9$}] (2.427 Å[15]), in which a lone pair of a "naked" phosphorus atom stabilizes a [W(CO)$_5$] complex fragment. As expected, the P–W bond lengths to the capping tungsten atom are somewhat longer (average 2.604(7) Å).[16]

Experimental Procedure

A solution of [M(CO)$_6$] (5.6 mmol), M = Cr or W, in 250 mL of THF was irradiated at room temperature with UV light (medium-pressure Hg lamp) until 5.6 mmol of CO had evolved. The resulting solution was concentrated under vacuum to 50 mL and then treated with P_4 (124 mg, 1 mmol), dissolved in 15 mL of THF. The solution was stirred for 30 min at room temperature, then warmed to 60 °C and immediately evaporated to dryness at this temperature under vacuum. The residue was suspended in 20 mL of *n*-pentane, filtered off, and then extracted several times with hot *n*-pentane. (In the case of M = W, 150 mg of **6** (8%) crystallized from the extracts.) The washed residue was dissolved in 10 mL of CH_2Cl_2. The resulting solution was concentrated under vacuum to about 5 mL, treated with 1 mL of a mixture of Et_2O and *n*-pentane (1:1), and allowed to stand at −40 °C. The crystals thereby formed were recrystallized several times from CH_2Cl_2/Et_2O/*n*-pentane (4:1:1, ca. −40 °C) to give, for M = Cr, 0.3 g (28%) of **5** (dec. 150 °C) and, for M = W, 0.7 g (40%) of **6** (dec. 175 °C).

Synthesis and Structure of the Pentaisopropylcyclopentadienyl Radical**

By *Helmut Sitzmann** and *Roland Boese*

Carbon radicals constitute an important and extensive area of organic chemistry. However, surprisingly little is known about cyclopentadienyl radicals.[1] Except for the pentaaryl derivatives,[2a–d] the C_5R_5 radicals are very unstable and those with R = halogen,[2e] CH_3,[2f] H, D,[1,2g] and COOMe[1] have only been characterized by ESR,[2b,d,e,f] electron-nucleus double resonance (ENDOR),[2c] UV,[2b,d] and laser-induced fluorescence spectroscopy (LIF)[2g] in solution,[2c,d,f] in the gas phase,[2g] or in a matrix.[2e]

Pentaisopropylcyclopentadienylsodium[3] and $FeCl_2$ react in THF at −75 °C (16 h) and at − 35 °C (12 h) to form the pentaisopropylcyclopentadienyl radical **1**. The yellow-green, extremely air-sensitive crystals of **1** sublime at about 75 °C/10^{-3} mbar, are stable to at least 130 °C, and dissolve in, for example, pentane, toluene, diethyl ether, and THF. The ^1H NMR spectrum[4] of a solution of **1** saturated at 60 °C shows two broad signals for the methyl and methine protons in an intensity ratio of 6:1. When the solution is warmed to 100 °C, the methyl signal shifts from $\delta = 22.0$ to $\delta = 19.4$, its half-width decreasing from 1700 to 1400 Hz, and the methine signal shifts from $\delta = 13.5$ to $\delta = 14.5$ Hz, its half-width increasing from 850 to over 1100 Hz. On cooling the solution to room temperature, **1** crystallizes unchanged from solution.

In the ESR spectrum (Bruker ESP 300) of a toluene solution of **1**, a broad singlet is observed at room temperature. At 190 K, it is split by hyperfine coupling to a multiplet with 20 observed lines. The coupling constants of 0.16 G (methine H) and 0.32 G (methyl H) were determined by spectral simulation. The g value of 2.0025 does not differ from that of the electron ($g = 2.0027$) within the limits of error. The hyperfine coupling constants of the methine protons of **1** are small compared with those of the methyl protons of the C_5Me_5 radical (6.4 G), presumably because, at 190 K, the methine proton lies in the plane of the five-membered ring and, therefore, the angle θ between the π-electron system of the ring C atoms and the methine C–H bond is 90°. Since, apart from an additive increment, this coupling is proportional to $\cos^2\theta$,[5] its small contribution is in accordance with expectation.

The EI mass spectrum of **1** displays, in addition to the molecular ion peak (m/z 275.3), which is observed in neither the mass spectrum of 1,2,3,4,5-pentaisopropylcyclopentadiene nor in that of tetraisopropylcyclopentadienone (**2**), oxygen-containing fragments,[6] including the molecular ion peak of **2**. Spectroscopic data[17] and the crystal structure of **2**[18] were obtained.

Radical **1** is the first cyclopentadienyl radical to be characterized by X-ray structure analysis.[7] As already known from dynamic NMR investigations on $[(C_5iPr_5)Mo(CO)_3(CH_3)]$[8] and $[(C_5iPr_5)CoCp]$[9] and from the crystal structure of hexaisopropylbenzene,[10] the isopropyl groups are arranged around the five- and six-membered rings in a paddlewheel-like fashion. In the crystal, half of the lattice sites are occupied by radicals with an opposite arrangement of the isopropyl groups, as confirmed by structure determinations on three different crystals, in part at

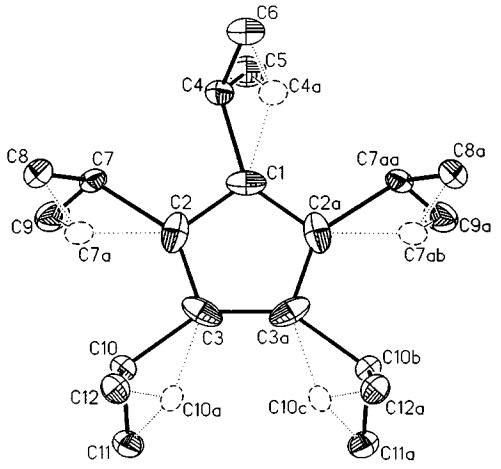

Fig. 1. Molecular structure of **1**. For important bond lengths and angles, see text. Two sets of methine C atoms (C7, C4a, C7ab, C10c, C10, and C7a, C4, C7aa, C10b, C10a) appear owing to the disorder of radicals with opposite orientation of the isopropyl groups; see Fig. 2.

higher temperatures. Superstructure reflections were not observed. The crystallographic mirror plane through C1, C5, and C6 perpendicular to the five-membered ring (Fig. 1) is obtained by averaging over this disorder (cf. Ref. [10]). The anisotropic displacement parameters (ADPs), especially of the ring C atoms, result from the overlap of oppositely oriented rings (Fig. 2). A comparable disorder in the crystal has been discussed in detail for hexaisopropylbenzene.[10]

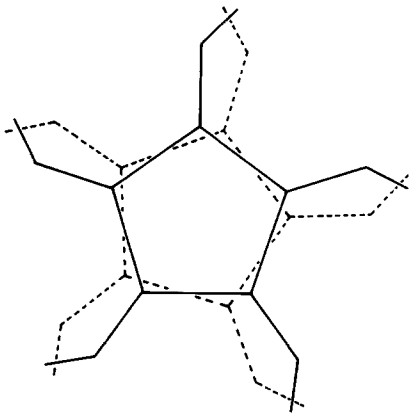

Fig. 2. Overlapping of the two possible orientations of **1** in the crystal.

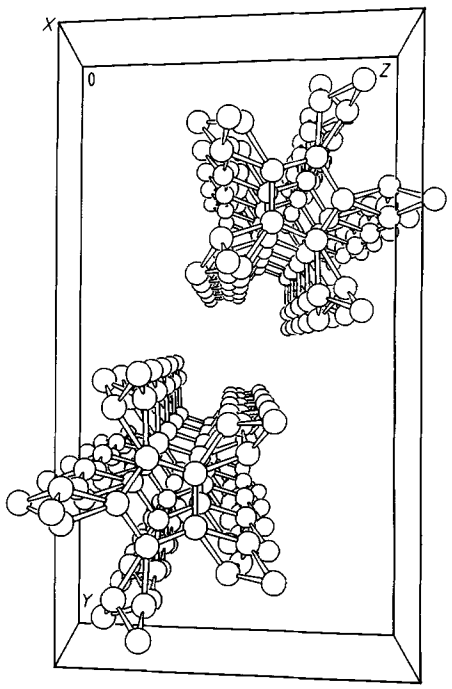

Fig. 3. Stacking of **1** in the crystal. See text for explanation.

Assuming that the differently oriented radicals differ little in their geometry, the C–C bond lengths in the ring are not affected by the disorder and are somewhat larger (C1-C2 1.412(2) Å, C2-C3 1.401(1) Å) than the C–C distance in the cyclopentadienyl anion (calculated value, 1.393 Å;[11] average value in $NaC_5Me_5 \cdot$ TMEDA, 1.377 Å[12]) and are in good agreement with the values of coordinated C_5H_5 ligands (average value in ferrocene, 1.406 Å[13]). The five-membered ring is planar, as shown by the internal ring angles at C1, C2, and C3 (107.5(2)°, 108.1(2)°, and 108.1(1)°, respectively) and the sum of the angles (529.9°). According to the Jahn–Teller theorem, stabilization of the cyclopentadienyl radical is expected to occur through distortion of the D_{5h} geometry; ab initio calculations predict a stabilization of 7–8 kcal mol^{-1}.[14] ESR spectroscopic investigations of the pentafluorocyclopentadienyl radical in a hexafluorobenzene single-crystal matrix indicate that a permanent Jahn–Teller distortion is present only below 8 K.[2e] For neither the unsubstituted nor the deuterated cyclopentadienyl radical did LIF down to 0.6 K reveal evidence of a permanent distortion.[2g] The slight distortions from the ideal geometry of a five-membered ring cannot be interpreted as a Jahn–Teller distortion in the case of **1**. A possible distortion at lower temperatures, however, cannot be ruled out for **1**. Along the crystallographic *x* axis, **1** forms stacks of eclipsing, equally spaced, planar five-membered rings, whereby the ring planes adopt an angle of 23° with respect to the stack axis (Fig. 3) (compare the stacking of $Si_5^{6\ominus}$ rings in the silicides $Li_{12}Si_7$[15a] and Li_8MgSi_6[15b]) and the rings are 5.82 Å apart owing to the bulky isopropyl substituents. This interplanar distance is apparently too large for a stable coordination of two pentaisopropylcyclopentadienyl ligands to an iron center. Possibly, other sterically encumbered cyclopentadiene ligands will also fail to form ferrocenes, but instead afford cyclopentadienyl radicals, if their dimerization or disproportionation is hindered by steric or electronic effects. In the absence of a central atom, the pentaisopropylcyclopentadienyl radical also forms the polymeric sandwich structure of a metal-free polydecker in the crystal. On the other hand, the use of lead as central atom recently gave the first decaisopropylmetallocene.[16]

Experimental Procedure

A solution of pentaisopropylcyclopentadienylsodium (1.49 g, 5.0 mmol) in 60 mL of THF was cooled to −75 °C and anhydrous iron(II) chloride (0.318 g, 2.5 mmol) was added. The reaction mixture was stirred for 16 h at the same temperature, allowed to warm to −50 °C over 3–4 h, and, finally, stirred for 3 h at this temperature and for 12 h at −30 °C, during which time the initially gray-white precipitate gradually turned dark. The black-brown suspension was concentrated at 0 °C and suspended in 80 mL of petroleum ether. The brownish solution obtained by centrifugation was concentrated in a 100-mL round-bottom flask and **1** was sublimed into a surmounting glass tube at 10^{-3} mbar and about 75 °C. The impurities caused by traces of air and moisture were more volatile and collected in the upper part of the tube. Yield 500 mg (1.8 mmol, 36%) of yellow-green crystals.

[6] EI-MS (30 eV): *m/z* 334.3 ($[M + OC_3H_7]^{\oplus}$, 6%); 318.4 ($[M + C_3H_7]^{\oplus}$, 12); 291.3 ($[M + O]^{\oplus}$, 31); 276.3 ($[M + H]^{\oplus}$, 59); 275.3 ($M^{\oplus}$, 35); 249.2 ($C_5iPr_4OH^{\oplus}$, 60); 248.2 ($C_5iPr_4O^{\oplus}$, 100); 233.1 ($C_5iPr_4H^{\oplus}$, 61); 191.0 ($C_5iPr_3H_2^{\oplus}$, 39); 148.9 ($C_5iPr_2H_3^{\oplus}$, 85); 106.8 ($C_5iPrH_4^{\oplus}$, 26). Striking here, in contrast to previously recorded EI mass spectra of isopropyl-substituted cyclopentadienes and their derivatives, is the absence of a C_3H_7 fragment. Possibly, a cation of mass 318.4 is formed from **1** and $C_3H_7^{\oplus}$, the latter arising by fragmentation. Exposure of **1** to O_2 results in formation of tetraisopropylcyclopentadienone (**2**) [17, 18] as stable end product. The fate of the fifth isopropyl group was not investigated; it is presumably lost from the initially formed oxidation product "$C_5iPr_5O_2$" as isopropoxy radical. Evidence for this is provided by the peak at *m/z* 334.4, which might

have arisen by combination of this product with **1**. A 2:1 product of **1** and O_2 might be bis(pentaisopropylcyclopentadienyl) peroxide, whose asymmetric cleavage product would be expected to give rise to the signal at m/z at 291.3.

[7] A single crystal with dimensions of 0.41 × 0.30 × 0.28 mm³, obtained by vacuum sublimation in a sealed ampoule, was used for structure determination. A total of 1263 unique reflections were collected at 110 K on a Nicolet R3m/V X-ray four-circle diffractometer with $Mo_{K\alpha}$ radiation and graphite monochromator in the angle range $3 \leq 2\theta \leq 45°$ according to the method of *Wyckoff*; 1040 with $F_0 \leq 4\sigma(F)$ were observed reflections. On the basis of the diffractometer angles of 26 reflections, the cell was determined to be monoclinic in the space group $P2_1/m$, $a = 6.337(2)$, $b = 16.225(5)$, $c = 9.257(3)$ Å, $\beta = 101.94(2)°$, $V = 931.2(5)$ Å³, $Z = 2$. The structure was solved using the program SHELXTL-PLUS; all atoms except for hydrogen atoms were refined anisotropically and the hydrogen atoms were refined isotropically as rigid groups (C-H = 0.96 Å, C-C-H and H-C-H 109.5°); 118 parameters; $R = 0.044$, $R_w = 0.054$. Further details of the crystal structure determination are available on request from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, W-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-320 289, the names of the authors and the journal citation.

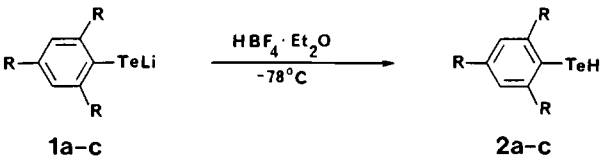
Synthesis of Sterically Hindered Tellurophenols and the Structure of $[Cd(\mu\text{-}TeC_6H_2Me_3)_2]_\infty$ **

By *Manfred Bochmann,* Andrew P. Coleman, Kevin J. Webb, Michael B. Hursthouse,* and *Muhammed Mazid*

We have recently shown that sterically hindered thiolato and selenolato complexes of cadmium show unusually low coordination numbers and possess sufficient volatility to be useful as one-component precursors for the deposition of II/VI semiconductor films from the vapor phase.[1] We now report the synthesis and isolation of related tellurols and the first structurally characterized cadmium tellurolato complex, $[Cd(\mu\text{-}TeC_6H_2Me_3\text{-}2,4,6)_2]_\infty$.

Protonation of a slurry of ArTeLi (**1**) in petroleum ether by $HBF_4 \cdot Et_2O$ at −78 °C leads to the formation of the corresponding tellurols (**2**) in almost quantitative yield (Scheme 1). Removal of the solvent at low temperature allows the isolation of the compounds as colorless crystalline low-melting solids, which are thermally unstable and light-sensitive. Whereas the high solubility of **2b** precludes crystallization from petroleum ether solutions even at −100 °C, **2a,c** may be recrystallized from petroleum ether at −70 °C. Contrary to expectation, there is no increase in thermal stability with increasing steric hindrance of the compounds; in fact, **2a** is noticeably more stable than **2c**. The instability of aryl tellurols has previously precluded their isolation;[2] for example, PhTeH was only identified in solution as a hydrolysis product of $PhTeSiMe_3$.[3]



Scheme 1. **a**, R=Me; **b**, R=*i*Pr; **c**, R=*t*Bu.

The ^{125}Te NMR data for **2** are given in Table 1; the data for the anions **1**[4] have been included for comparison. The

Table 1. ^{125}Te NMR data of [2,4,6-$R_3C_6H_2$TeM][a].

R	M=Li	$\Delta\nu_{1/2}$ [Hz]	M=H	J(Te, H) [Hz]
Me	−383.7	140	−91.41	63
*i*Pr	−478.5	38	−134.77	48.6
*t*Bu	9.2	11	153.77	51.9

[a] M = Li measured in THF, 28 °C; M = H in $CDCl_3$, −20 °C, using a 2 M solution of Ph_2Te_2 in $CDCl_3$ as external standard ($\delta = 434.24$), referenced against neat Me_2Te ($\delta = 0$).

^1J(Te,H) coupling constants are comparable to those of PhTeH,[3] H_2Te, and H_3MTeH (M = Si, Ge)[5] deduced from proton spectra, whereas for $[(C_5Me_5)Re(CO)_2H(TeH)]$ significantly higher coupling constants were found.[6]

The addition of $[Cd\{N(SiMe_3)_2\}_2]$[7] to solutions of **2a** leads to the instantaneous precipitation of $[Cd(TeC_6H_2Me_3\text{-}2,4,6)_2]$ (**3a**) as a fine-crystalline solid [Eq. (a)]. An identical

$$2\,\mathbf{2a} + [Cd\{N(SiMe_3)_2\}_2] \longrightarrow \underset{\mathbf{3a}}{[Cd(TeC_6H_2Me_3\text{-}2,4,6)_2]_\infty} + 2\,HN(SiMe_3)_2 \quad \text{(a)}$$

product is obtained from $CdCl_2$ and $C_6H_2Me_3TeSnnBu_3$.[8] Compound **3a** is almost insoluble in nonpolar solvents but is more soluble in DMF, DMSO, or pyridine than its sulfur and selenium analogues[9] and is obtained from DMF as yellow cubic crystals. It shows a very simple ^{1}H NMR spectrum in $[^2H]_5$-pyridine and presumably exists as a four-coordinate monomer, $[(py)_2Cd(TeAr)_2]$. Attempts to isolate this adduct failed, however, whereas the analogous thiolato com-

[**] This work was supported by the Science and Engineering Research Council (UK) and the Royal Signals and Radar Establishment.

plex $[(py)_2Cd(SAr)_2]$ is easily obtained.[9] Compound **3a** decomposes in refluxing mesitylene to give polycrystalline CdTe.

In spite of the importance of CdTe-based solid-state materials, the chemistry of related molecular telluride complexes is poorly developed. Surprisingly few examples of cadmium tellurolates are known,[10] and to our knowledge none have been structurally characterized. The structure of **3a** was therefore determined.[11]

Complex **3a** exists in the solid state as a one-dimensional coordination polymer, with almost symmetrically bridging mesityltellurolato ligands and tetrahedrally coordinated cadmium (Fig. 1, left). The average Cd–Te distance of

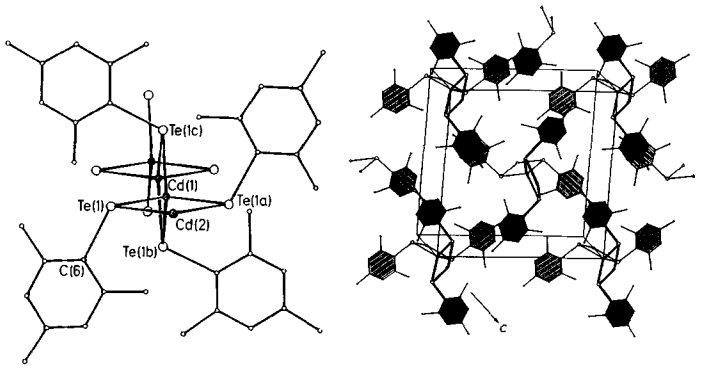

Fig. 1. Structure of $[Cd(TeCH_2Me_3)_2]_\infty$ (**3a**). Left: Part of an individual chain, showing the atomic numbering scheme. All but four of the mesityl substituents have been omitted for clarity. Right: Crystal-packing diagram, illustrating the separation of the one-dimensional polymeric units as a consequence of the spatial requirements of the mesityl substituents. Selected bond lengths [Å] and angles [°]: Cd(1)-Te(1) 2.838(8), Cd(2)-Te(1) 2.835(9), C(6)-Te(1) 2.164(12). Cd(1)-Te(1)-Cd(2) 84.0(1), Te(1)-Cd(1)-Te(1a) 95.9(1), Te(1)-Cd(1)-Te(1b) 116.7(1), Te(1)-Cd(2)-Te(1a) 96.0(1), C(6)-Te(1)-Cd(1) 107.0(10).

2.837 Å is very close to the distance of 2.80 Å of cubic (zinc blende type) CdTe. The relatively open structure is formed as a result of the spatially demanding mesityl substituents, which separate the individual $[Cd(\mu\text{-}Te)_2]_\infty$ chains (Fig. 1, right). As has been demonstrated recently, the structures of cadmium aryl thiolates, $Cd(SAr)_2$, depend on the steric requirements of the aryl groups and can range from a three-dimensional arrangement of adamantanoid cages (Ar = Ph[14]) in a macrocyclic network if an *ortho* substituent is present (Ar = $2\text{-}MeC_6H_4$[15]) to the complete disruption of the polymeric lattice, with formation of molecular dimers in the case of extreme steric hindrance.[1, 9] Compound **3a** occupies an intermediate position in this sequence.[16]

Experimental Procedure

2a: All experiments were carried out under argon with anhydrous deoxygenated solvents. To a stirred solution of dimesitylditelluride[17] (0.543 g, 1.10 mmol) in 10 mL of THF at −78 °C was added via syringe a solution of 1 M $LiBHEt_3$ in THF (2.4 mL, 2.4 mmol). The color turned from deep-red to pale yellow within a minute. After stirring the mixture for 15 min the solvent was removed in vacuo at room temperature. The residue was suspended in 40 mL of petroleum ether (b.p. 40–60 °C) and cooled to −78 °C. $HBF_4 \cdot Et_2O$ (0.80 g, 4.97 mmol) was injected via syringe and the mixture was allowed to slowly warm to −20 °C. It was stirred at this temperature until the lithium tellurolate had dissolved. After filtration the solution was concentrated in vacuo at −20 °C and cooled to −78 °C to obtain the product as a colorless solid which began to turn pink above −30 °C and decomposed above 0 °C with gas evolution and precipitation of elemental tellurium. The crude yield was essentially quantitative. ^1H NMR (90 MHz, $CDCl_3$, 0 °C): $\delta = -2.68$ (s, Te–H), 2.16 (s, 3H, *p*-Me), 2.26 (s, 6H, *o*-Me), 6.80 (s, 2H). ^{13}C NMR ($CDCl_3$, −40 °C): $\delta = 20.6$ (*p*-Me), 28.8 (*o*-Me), 126.7 (Te-*C*), 127.7 (*m*-C), 136.5 (*p*-C), 141.6 (*o*-C). If the addition of $HBF_4 \cdot Et_2O$ was carried out in THF as solvent, extensive decomposition took place even at −78 °C.

2b: $[(2,4,6\text{-}i\text{Pr}_3C_6H_2Te)_2]$: To $[2,4,6\text{-}i\text{Pr}_3C_6H_2MgBr]$, prepared from $[2,4,6\text{-}i\text{Pr}_3C_6H_2Br]$ (20 g, 70.6 mmol) in 100 mL of THF (100% yield after 2-h reflux), was added finely powdered tellurium (9.0 g, 70 mmol) at −50 °C with rapid stirring. The mixture was allowed to warm slowly to room temperature and stirred until the tellurium had reacted completely. The pale-green solution was oxidized by treatment with O_2, poured onto 2 M HCl (200 mL), and extracted with petroleum ether (3 × 200 mL). After evaporation of the solvent the red-purple product was recrystallized from ethanol, m.p. 91–93 °C (18.5 g, 80%).The tellurol **2b** was obtained from $[(2,4,6\text{-}i\text{Pr}_3C_6H_2Te)_2]$ as described for **2a**. Its high solubility prevented recrystallization. The compound turns brown slowly at −30 °C and rapidly at 5 °C. ^1H NMR ($CDCl_3$, −20 °C): $\delta = -2.95$ (s, Te–H), 1.60 (d, 18H, *o*- and *p*-$CHMe_2$), 2.80 (septet, 1H, *p*-$CHMe_2$), 3.28 (septet, 2H, *o*-$CHMe_2$), 6.95 (s, 2H). ^{13}C NMR ($CDCl_3$, −40 °C): $\delta = 23.8$ (*o*-$CHMe_2$), 24.1 (*p*-$CHMe_2$), 34.0 (p-$CHMe_2$), 39.5 (*o*-$CHMe_2$), 113.2 (Te–*C*), 121.3 (*m*-C), 148.8 (p-C), 152.6 (*o*-C).

2c: Obtained from $[(2,4,6\text{-}t\text{Bu}_3C_6H_2Te)_2]$[18] as described for **2a** as a crystalline solid. The compound begins to turn pale-pink at −40 °C and decomposes on warming to room temperature. ^1H NMR ($CDCl_3$, −20 °C): $\delta = -1.25$ (s, 1H, Te-H), 1.24 (s, 9H, *p*-*t*Bu), 1.58 (s, 18H, *o*-*t*Bu), 7.40 (s, 2H). ^{13}C NMR ($CDCl_3$, −40 °C): $\delta = 31.5$ (p-CMe_3), 32.6 (*o*-CMe_3), 34.8 (*p*-CMe_3), 39.0 (*o*-CMe_3), 119.6 (Te-*C*), 122.7 (*m*-C), 149.1 (*p*-C), 154.4 (*o*-C).

3a: To a solution of **2a** (0.545 g, 2.20 mmol) in 20 mL of petroleum ether (b.p. 40–60 °C) at −20 °C was added via syringe a solution of $[Cd\{N(SiMe_3)_2\}_2]$ (0.47 g, 1.08 mmol) in 40 mL of petroleum ether. After stirring for 20 min the residue was allowed to warm to room temperature, filtered off, washed with 20 mL of petroleum ether and recrystallized from DMF to give yellow crystals (0.372 g, 0.54 mmol, 50%). Correct elemental analysis. ^1H NMR (C_5D_5N): $\delta = 2.13$ (s, 3H, *p*-Me), 2.30 (s, 6H, *o*-Me), 6.72 (s, 2H).

Thermal and Light-Induced Spin Crossover to a Metastable Low-Spin State in $[Fe(mtz)_6](CF_3SO_3)_2$ **

By *Philipp Gütlich** and *Peter Poganiuch*

Dedicated to Professor Hans Georg von Schnering on the occasion of his 60th birthday

Thermal spin crossover in coordination compounds of 3d transition metals has been well known for many years. The high-spin (HS) $\leftrightarrow$ low spin (LS) crossover[1] has been well investigated by a number of physical methods.[2, 3] In our investigations of the spin-crossover system $[Fe(ptz)_6](BF_4)_2$ (ptz = 1-propyltetrazole), we discovered a fascinating novel photophysical phenomenon, which we called "light-induced excited spin state trapping" (LIESST):[4, 5] Irradiation with green light ($\lambda \approx 550$ nm) into the $^1A_1 \rightarrow {}^1T_1$ absorption band at sufficiently low temperatures ($T \leq 50$ K) results in quantitative transformation of the LS state of this complex to a metastable HS state, the lifetime of which can be practically infinite. The mechanism was elucidated.[5] It is crucial that the $^3T_1$ state lie lower in energy than the $^1T_1$ state, since this allows double intersystem crossing, which leads finally to the $^5T_2$ state: $^1A_1 \rightarrow {}^1T_1 \rightarrow {}^3T_1 \rightarrow {}^5T_2$. LIESST has meanwhile been achieved for several spin-crossover systems,[6-9] even when these were embedded in polymer film.[10] It was also shown that, on irradiation with red light ($\lambda \approx 750$ nm) into the $^5T_2 \rightarrow {}^5E$ band, the metastable HS($^5T_2$) state can be pumped back to the stable LS state, again via double intersystem crossing, $^5E \rightarrow {}^3T_1 \rightarrow {}^1A_1$.[11]

Recently, we also reported that irradiation of an iron(II) complex with HS ground state, $[Fe(mtz)_6](BF_4)_2$, with red light at low temperatures causes a transition to a metastable LS state with an extremely long lifetime (weeks).[12] We referred to this process as LIESST(H $\rightarrow$ L) in order to distinguish it from the original LIESST, which now is referred to as LIESST(L $\rightarrow$ H). The metastable LS state can also be pumped back to the stable HS state in the case of LIESST(H $\rightarrow$ L) by irradiation with green light.[12] The mechanism of the formation and the conditions required for a long lifetime of the metastable LS($^1A_1$) state are given in Figure 1: Red light excites the $^5T_{2g}$ state to the ^5E_g state,

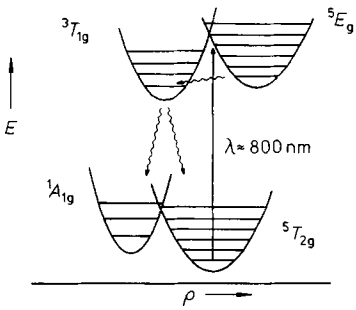

Fig. 1. The mechanism of the LIESST(H $\rightarrow$ L) process. $\rho = A_1$ vibrational coordinate.

which then undergoes intersystem crossing to the $^3T_{1g}$ state owing to favorable spin-orbit coupling. Within nanoseconds this intermediate state once again undergoes intersystem crossing to the metastable $^1A_{1g}$ state. The $^3T_{1g}$ state could also relax back to the $^5T_{2g}$ ground state with equal probability. However, continuous irradiation of the $^5T_2 \rightarrow {}^5E$ transition (the lamp is turned on for a time that is several orders of magnitude longer than the lifetimes of the excited states involved) pumps the system completely into the LS($^1A_1$) state. Decisive for very long lifetimes of the metastable $^1A_1$ state is the highest possible barrier between the $^1A_1$ and $^5T_2$ states, which can be achieved for the smallest possible difference in energy between the lowest vibrational levels and the largest possible difference in the metal–ligand distances in the $^5T_2$ and $^1A_1$ states.

Here we discuss the complex compound $[Fe(mtz)_6](CF_3SO_3)_2$ (**1**, mtz = 1-methyl-1*H*-tetrazole), which exhibits a second example of LIESST(H $\rightarrow$ L). Compound **1** shows a complex magnetic behavior, governed by a thermal spin crossover with hysteresis ($T_c\downarrow = 158$ K, $T_c\uparrow = 174$ K) and a phase transition that is independent of the spin crossover. Variable-temperature ^{57}Fe Mössbauer spectroscopic measurements confirmed the results of the magnetic measurements and, in addition, provided information on the two, apparently different iron(II) environments in this system (Fig. 2). From 295 to about 190 K, the Mössbauer spectra show only one asymmetric (texture!) quadrupole doublet, which has parameters typical for iron(II)-HS. Below 190 K, a transition (with hysteresis of only about 8 K width) takes place to another iron(II)-HS (HS1 $\rightarrow$ HS2) and is complete at about 175 K. At still lower temperatures, the above-mentioned thermal spin crossover occurs at this lattice site and, at about 140 K, is complete with an HS fraction of 65% (Fig. 3). On heating, hysteresis is observed in the conversion curve $\gamma_{HS}(T)$ of the doublet assigned to HS2; this hysteresis has the same width (16 K) and occurs in the same temperature range as for the susceptibility measurements. It is presumably due to a crystallographic phase transition that accompanies the thermal spin crossover. For LIESST investigations, we recorded a Mössbauer spectrum of **1** at 20 K (Fig. 4, top). The two outer resonance signals belong to the HS2($^5T_2$) state and the inner signal belongs to the LS($^1A_1$) state. After irradiation of **1** with green light ($\lambda \approx 350-$

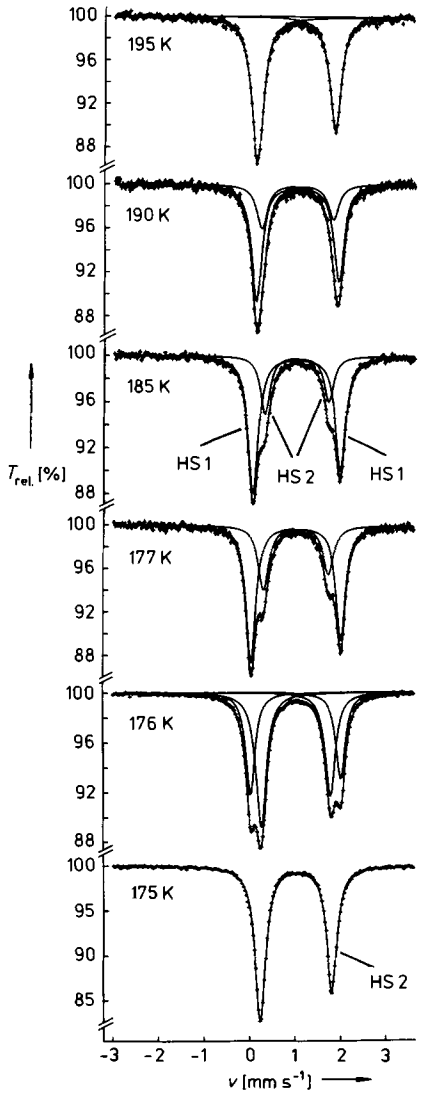

Fig. 2. ^{57}Fe Mössbauer spectra of **1** in the range $T = 195-175$ K, in which a change in the lattice and an accompanying HS1 → HS2 transition occurs. T_{rel} = relative transmission, ν = rate.

650 nm, xenon lamp and filter) at 20 K, the Mössbauer spectrum was unchanged; that is, LIESST(L → H) does not take place under these conditions. The reason is that the lifetime of the metastable HS state is less than one minute and thus too short to be detected in the Mössbauer experiment.

In a further experiment, again at 20 K, we irradiated the sample with red light ($\lambda \leq 700$ nm). The subsequently recorded Mössbauer spectrum (Fig. 1, middle) clearly shows that the intensity of the HS2 doublet has decreased and that of the singlet has increased. Unquestionably, a light-induced transition from the stable $^5T_2$ state to a metastable $^1A_1$ state has taken place, corresponding to the mechanism depicted in Figure 1. The fact that, in the experiment described here, the fraction of the HS2 state has decreased from 65% (fraction of the resonance area) to only 27% is merely due to the broadband irradiation. Wavelength ranges of $\lambda \geq 700$ nm cause the transition $^5T_2 \rightarrow {}^5E$, which requires an energy of 12200 cm^{-1},[5, 11, 12] but, at the same time, excite the very weak and broad $^1A_1 \rightarrow {}^3T_1$ band at about 10300 cm^{-1}; LIESST(L → H) can also occur via this path, namely, $^1A_1 \rightarrow {}^3T_1 \rightarrow {}^5T_2$, as recently shown by *A. Hauser* in our group.[13]

The lifetime of the metastable LS state generated by LIESST(H → L) is on the order of days at $T = 20$ K. At

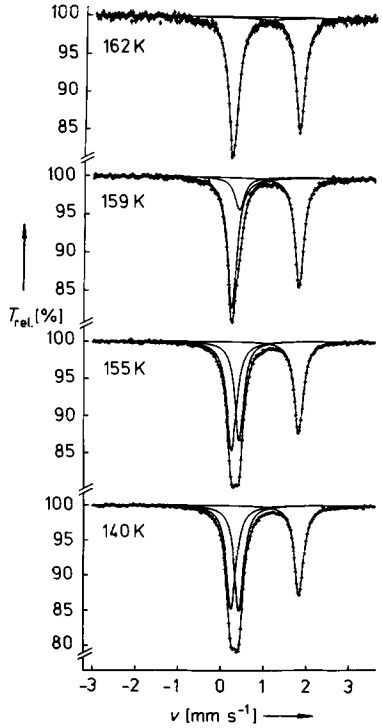

Fig. 3. ^{57}Fe Mössbauer spectra of **1** in the temperature range where the thermal spin crossover $^5T_2$(HS) ↔ $^1A_1$(LS) occurs, with a remaining HS fraction of about 65% at 140 K.

$T \approx 40$ K, noticeable decay to the stable HS2 state occurs (increase from 27% to 45% in the fraction of the HS2 doublet in the Mössbauer spectrum over 24 h). A Mössbauer spectrum recorded after warming the sample to 60 K (Fig. 4, bottom) is again nearly identical with that recorded before irradiation at 20 K. The radiationless back-relaxation to the ground state proceeds via a nonadiabatic multiphoton process.[14, 15]

Athough both complexes, **1** and $[Fe(mtz)_6](BF_4)_2$, for which a light-induced spin crossover from the stable HS($^5T_2$) state to a long-lived metastable LS($^1A_1$) state has been

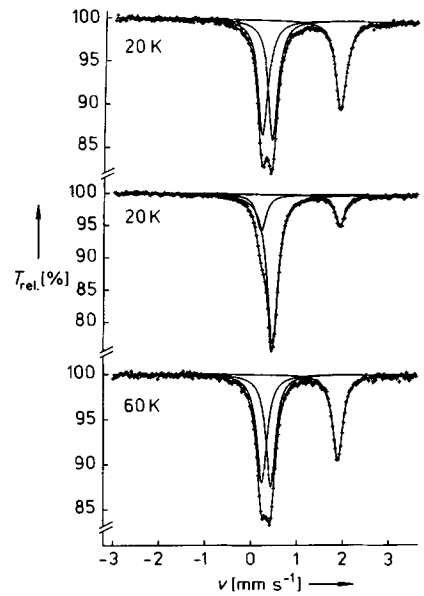

Fig. 4. ^{57}Fe Mössbauer spectra at 20 K before irradiation (top) and after irradiation with red light (middle), as well as after subsequent warming to 60 K (bottom). LIESST(H → L) is clearly revealed by the decrease in the intensity of the HS2 doublet (outer signals) and the increase in the intensity of the LS singlet.

achieved, differ only in the anion, their thermal spin-crossover behavior differs considerably; on the other hand, the LIESST(L → H) behavior is similar in the two cases.

Experimental Procedure

The ligand mtz was prepared as described in the literature [16]. In order to synthesize **1**, iron powder was first dissolved in aqueous 2 M trifluoromethanesulfonic acid (Aldrich). The excess iron powder was then filtered off and the solution was gently concentrated under nitrogen until $[Fe(H_2O)_6](CF_3SO_3)_2$ began to crystallize. The product was collected by filtration and washed with a small amount of cold water and ether. Complex **1** was obtained from a concentrated aqueous solution of $[Fe(H_2O)_6](CF_3SO_3)_2$ and mtz in a molar ratio of 1:6 under nitrogen; the solution was further concentrated by applying a stream of oxygen-free nitrogen until **1** began to crystallize. After filtration and washing, **1** was recrystallized from nitromethane. The values of the elemental analyses are in good agreement with the theoretical values.

The magnetic susceptibility χ was measured with a Foner magnetometer in the range $20 \leq T \leq 270$ K (He-flow cryostat) in a magnetic field of 1 T. The diamagnetic correction for **1** was determined by χ measurement at room temperature on an analogously prepared zinc complex ($\chi = -648 \times 10^{-6}$ cm^{3}mol^{-1}). The value of the magnetic moment was calculated from the equation $\mu_{eff} = 2.828\,(\chi_m T)^{1/2}$ (χ_m = corrected molar susceptibility).

^{57}Fe Mössbauer spectra were recorded with a conventional spectrometer. The ^{57}Co/Rh source was kept at room temperature, while the absorber (enclosed in a Plexiglass container, 3 cm^2 area, with ca. 7 mg cm^{-2} Fe) was mounted in a flow cryostat (CF506, Oxford Instruments). The cryostat was equipped with windows of transparent Mylar film. The temperature at the absorber was measured with a carbon/glass resistor mounted directly on the sample holder. The Mössbauer signals were fitted to Lorentzian curves.

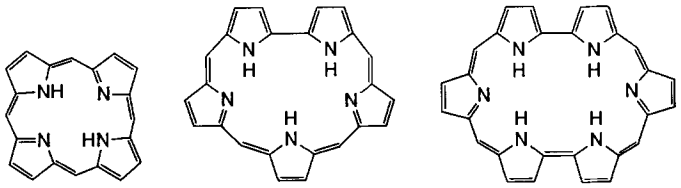
Rubyrin: A New Hexapyrrolic Expanded Porphyrin**

By *Jonathan L. Sessler,* Takashi Morishima,* and *Vincent Lynch*

Although, a number of "expanded porphyrins", large pyrrole-containing macrocyclic analogues of the porphyrins (e.g. porphine, **1**), are now known,[1-9] only a few aromatic examples have been reported which contain more than four pyrrolic subunits.[1-3] Unfortunately, for the most part the chemistry of these latter systems has been communicated in only the briefest fashion and structural information is available only for derivatives of sapphyrin (e.g. **2**)[1c-1e] in the all-pyrrole series.[3] Thus, the preparation and study of new polypyrrolic systems remains of interest. Such studies could provide important information on the fundamental and interrelated questions of ring size, aromaticity, and effective macrocycle stability, as well as providing an important entry into the development of improved photosensitizers for photodynamic applications[10] or new chelating receptors for the complexation of anions[1c,1e] and cations.[1,3,7,8] In this communication, we report the synthesis and structural characterization of an alkyl-substituted derivative of the diprotonated form of a new class of hexapyrrolic expanded porphyrins, **3**. To the best of our knowledge, this latter compound, to which we have assigned the trivial name "rubyrin" (from the Latin *rubeus*),[11] based on the intense bright red color of the diprotonated derivatives, represents the parent form of the largest structurally characterized expanded porphyrin system prepared to date.



1 **2** **3**

The synthesis of the diprotonated form of 4,8,13,18,23,27-hexaethyl-3,9,14,17,22,28-hexamethylrubyrin (**4**) contains two key steps. The first involves the acid-catalyzed condensation between the bis-α-free bipyrrole **5**[1c] and the acetoxy-activated pyrrole **6**.[12] This reaction, which was carried out in analogy to earlier syntheses of symmetric tripyrranes,[9] gave the protected tetrapyrrole derivative **7** in roughly 66% yield. Standard nearly quantitative debenzylation then gave the diacid **8**. This, in turn, was used without delay in the next step, an acid-catalyzed [4] + [2] MacDonald-type[13] oxidative condensation with the readily available[1c] diformyl bipyrrole, **9**. This second critical step of condensation and accompanying air oxidation taken together provided, following workup and chromatographic purification, the diprotonated rubyrin derivative (**4a**) in roughly 20% yield.[14] Washing either this purified ditosylate salt or the crude reaction mixture with aqueous 10% hydrochloric acid then produced the more crystalline dihydrochloride derivative, **4b** in yields of 63% (based on **4a**) and 40% (based on **8**), respectively.

Formally, rubyrin (**3**) and its derivatives may be considered as 26π-electron annulenes. Thus, the diprotonated salts **4a** and **4b** were expected to be aromatic. The spectroscopic data is consistent with this formulation. For instance, low-field *meso*-like methine signals and high-field internal NH resonances were observed in the ^{1}H NMR spectra as would be expected for a large aromatic expanded porphyrin system. In the specific case of **4b** in $CDCl_3$ these signals were observed at $\delta = 11.58$ and 11.60 (in a 1:1 ratio), and at -4.97 and -5.30 (in a 2:1 ratio), respectively, values which compare closely to those observed for the dihydrochloride salt of 3,8,12,13,17,22-hexaethyl-2,7,18,23-tetramethylsapphyrin

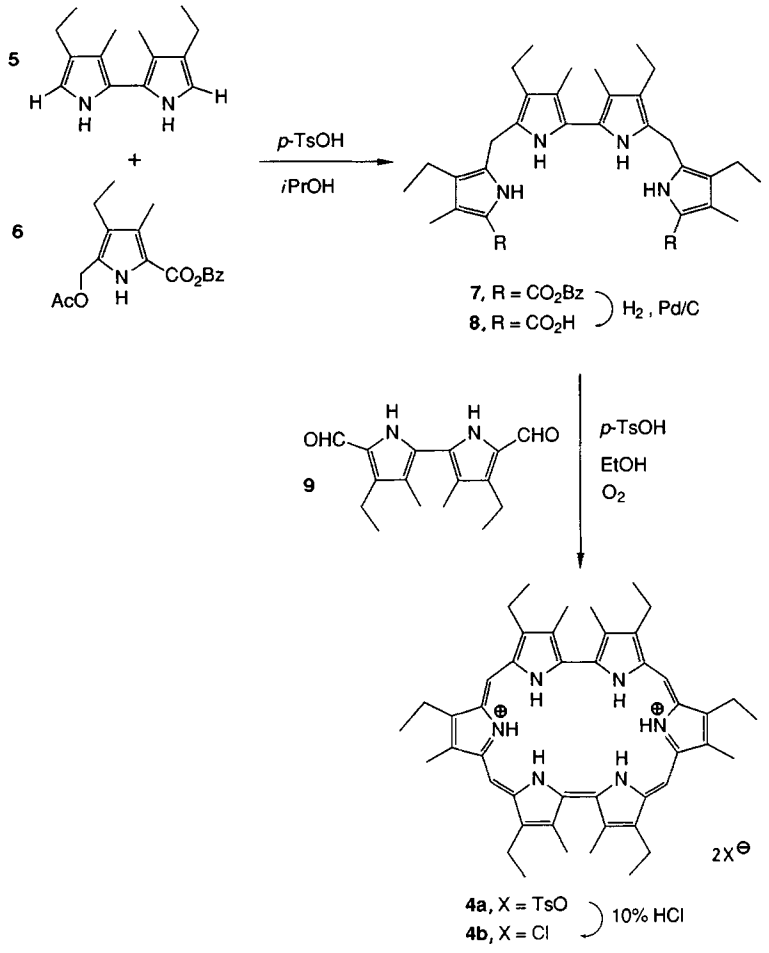
([H_2-Sap]$^{2\oplus}$) measured under the same experimental conditions.[1c] In addition, both **4a** and **4b** display Soret-like and Q-type transitions in their UV-VIS spectra, which, as would be expected for a large aromatic expanded porphyrin, are considerably red-shifted as compared to those of smaller porphyrin-like systems. In fact, relative to [H_2-Sap]$^{2\oplus}$ and [H_2-OEP]$^{2\oplus}$ (the diprotonated derivative of 2,3,7,8,12,13,17,18-octaethylporphyrin) measured under similar experimental conditions, the Soret band of **4b** is shifted by ca. 50 and 100 nm, respectively (cf. Fig. 1),[15] and the lowest energy Q-type band by about 180 and 270 nm, respectively.



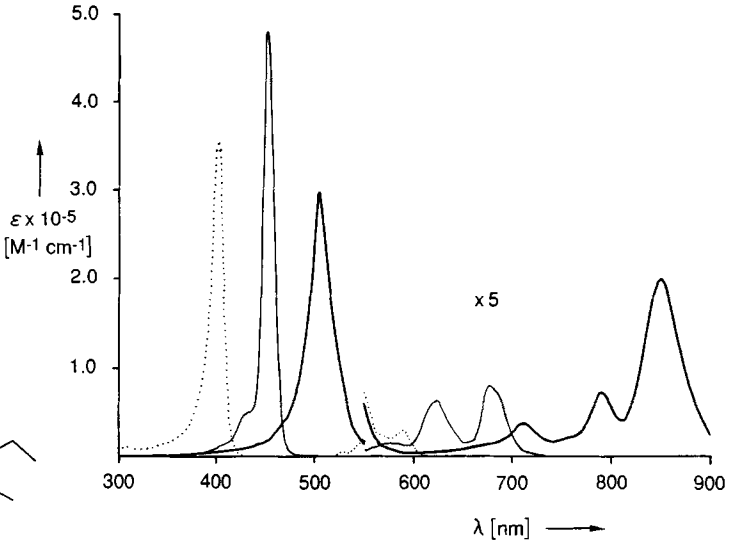


Fig. 1. The UV-VIS absorption spectra of **4b** (——) and the diprotonated derivatives of 2,3,7,8,12,13,17,18-octaethylporphyrin (recorded in the presence of excess trifluoroacetic acid (·····) and 3,8,12,13,17,22-hexaethyl-2,7,18,23-tetramethylsapphyrin (recorded as the dihydrochloride salt) [15] (——) in dilute CH_2Cl_2.

Further evidence for the aromatic nature of rubyrin was obtained from the X-ray diffraction structure analysis of **4b**.[17] As illustrated in Figure 2, this revealed a nearly planar conformation for the core macrocycle that is only slightly waffled by virtue of interactions with the hydrogen-bound chloride counter anions (the maximum deviation (for C2) of the C and N macrocycle atoms from the mean plane is 0.509(4) Å). In fact, this lack of distortion is reminiscent of that seen in the X-ray structure of [H_2-OEP]$^{2\oplus}$[18a] and several recently reported diprotonated bisvinylogous expanded porphyrins,[5d, 5e] suggesting a significant through-cycle π-electron conjugation in **4b**. Consistent with this conclusion is the finding that the average C–C and C–N bond distances within the formal 26π-electron periphery (1.394 Å and 1.375 Å, respectively) are close in value to those observed in the corresponding diprotonated OEP structure (1.390 Å and 1.375 Å, respectively).[18a] Interestingly, however, the interpyrrole angles at the bridging methines (137.0 and 137.6°) are considerably greater than those found in protonated porphyrins (ca. 127°).[18] Thus, the expanded porphyrin **4b** displays a more open inner core than is expected for a directly appended "three-quarter porphyrines" linked by two sets of interpyrrole bonds. Nonetheless, it is clear that from a structural point of view, compound **4b** displays all properties expected of an aromatic system.

In spite of the evident aromatic nature of **4b**, efforts to obtain the free-base form (corresponding to **3**), or metal complexes derived from it, have so far proved unsuccessful.[19] However, as for the diprotonated form of sapphyrin[1c, 1e] and possibly other cationic expanded porphyrins,[5, 6] the diprotonated rubyrin system acts as an effective anion receptor. For instance, preliminary spectroscopic studies indicate that diprotonated rubyrin can bind both fluoride and phosphate anions in a strong and nonlabile manner.[20] These results lead us to suggest that protonated rubyrins could prove useful in the recognition and

Table 1. Characterization data for new compounds.

4a: decomp. above 220°C; ^{1}H NMR (300 MHz, $CDCl_3$): δ = −4.14 (s, 2H, NH), −3.68 (s, 4H, NH), 1.50 (s, 6H; PhCH_3), 1.90 (d, J_{HH} = 7 Hz, 4H, phenyl H), 2.30 (m, 18H, CH_2CH_3), 3.90 (s, 12H, CH_3), 4.10 (m, 8H, CH_2CH_3), 4.30 (s, 6H, CH_3), 4.70 (q, 4H, CH_2CH_3), 4.90 (d, J_{HH} = 7 Hz, 4H, phenyl H), 11.18 (m, 4H, *meso-H*); HRMS (FAB): *m/z* 694.4707 ($M^{\oplus}$ − 2TsO$^{\ominus}$), calcd for $C_{46}H_{58}N_6$ 694.4723 (±0.0016).

4b: decomp. above 230°C; ^{1}H NMR (300 MHz, $CDCl_3$): δ = −5.30 (s, 2H, NH), −4.97 (s, 4H, NH), 2.09 (m, 12H, CH_2CH_3), 2.34 (t, J_{HH} = 7 Hz, 6H, CH_2CH_3), 4.06 (s, 12H, CH_3), 4.40 (s, 6H, CH_3), 4.43 (m, 8H, CH_2CH_3), 4.82 (q, J_{HH} = 7 Hz, 4H, CH_2CH_3), 11.58 (s, 2H, *meso-H*) 11.60 (s, 2H, *meso-H*); ^{13}C NMR (75.5 MHz, $CDCl_3$): δ = 12.98, 15.73, 17.50, 17.99, 21.05, 21.29, 92.74, 92.88, 126.47, 127.30, 129.03, 129.65, 130.73, 136.38, 139.32, 143.31; UV/VIS (CH_2Cl_2): λ_{max} [nm] (ε) = 505 (302 000), 711 (11 000), 791 (15 500), 850 (38 000); HRMS (FAB): *m/z* 694.4660 ($M^{\oplus}-Cl_2$), calcd for $C_{46}H_{58}N_6$ 694.4723 (±0.0063).

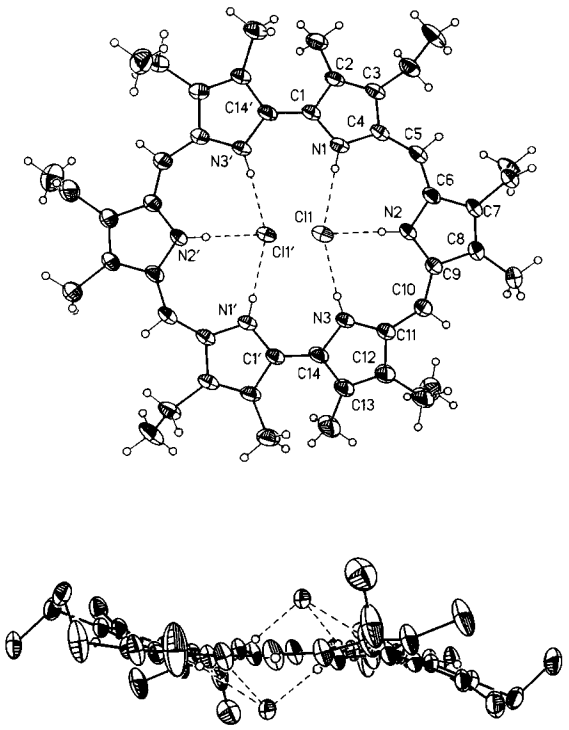

Fig. 2. Molecular structure of **4b** in the crystal showing partial atom labeling scheme and the H-bonding interactions of the chloride counterions with the macrocycle (dashed lines). Top: View perpendicular to the plane through the nitrogen atoms. Below: Side view showing the nearly planar conformation of the core macrocycle. The macrocycle has an inversion center. Atoms labeled with a′ are related by $-x,1-y,1-z$. Thermal ellipsoids are scaled to the 30% probability level. H atoms represented as spheres of arbitrary size, disordered atoms and the chloroform molecules not shown. Selected bond distances [Å] and angles [°]: N1–C1, 1.373(5); N1–C4, 1.394(6); C1–C2, 1.437(7); C2–C3, 1.362(5); C3–C4, 1.429(6); C4–C5, 1.381(5); C5–C6, 1.379(6); C6–C7, 1.421(5); C7–C8, 1.377(9); C8–C9, 1.449(8); N2–C6, 1.383(7); N2–C9, 1.367(5); N1–N2, 3.483(5); N1–N3, 5.559(5); N1–N1′, 6.352(7); N1–N2′, 5.836(5); N1–N3′, 3.078(5); N2–N2′, 7.213(7); N3–N3′, 6.354(7); N1–C11, 3.265(4); N2–C11, 3.158(4); N1–C4–C5, 130.1(4); C3–C4–C5, 123.4(4); C4–C5–C6, 137.6(5); C5–C6–C7, 122.9(5); C5–C6–N2, 129.5(4).

through-membrane transport of biologically active substrates, including for example nucleotide analogues.[21]

Experimental Procedure

7: Compounds **5** (3.72 g, 17.2 mmol), **6** (10.9 g, 34.5 mmol), and dry isopropyl alcohol (140 mL) were combined and heated at 80 °C to effect complete dissolution. *p*-Toluenesulfonic acid monohydrate (30 mg) was then added and the resulting green solution heated at reflux for 10 hours under nitrogen. The resulting suspension was then cooled and kept at 0 °C for one hour. Filtration, washing with cold ethanol, and drying in vacuo afforded **7** as a fine, off-white powder (8.24 g, 66%), which could be further purified by recrystallization from CH_2Cl_2/MeOH.

8: The dibenzyl ester **7** (0.24 g, 0.33 mmol) was dissolved in dry THF (100 mL) and subjected to hydrogenation over 10% palladium-charcoal (40 mg) at 1 atm H_2. The catalyst was then separated by filtration, the solvent reduced in volume on a rotary evaporator, and the product precipitated by trituration with hexanes. The pale blue precipitate was collected by filtration, dried in vacuo (yield 0.16 g (90%) of **8**), and used directly in the synthesis of **4a**.

4a and **4b:** Compounds **9** (136 mg, 0.5 mmol) and **8** (273 mg, 0.5 mmol) were dissolved with warming in 1.0 L of dry ethanol. The mixture was then allowed to cool to room temperature and 2.0 g of *p*-toluenesulfonic acid monohydrate added all at once. Oxygen was then bubbled through the stirred mixture for 18 h. The ethanol was then removed on a rotary evaporator and the dark purple residue taken up in $CHCl_3$ and purified by column chromatography (Merck type 60 (230–400 mesh) Silica gels; first $CHCl_3$ and then $CHCl_3$/MeOH (98/2) as eluents). Collection of the dark red fraction and removal of the solvent gave 105 mg (20%) of **4a** which could be purified further by recrystallizing from $CHCl_3$/hexane. Dissolving compound **4a** in dichloromethane and washing with a 10% aqueous solution of HCl for 2 h at room temperature then afforded, after workup, product **4b** in ca. 63% yield. This same material could also be obtained in roughly 40% net yield by treating the crude condensation product (from **8** and **9**) with a 10% aqueous solution of HCl prior to workup and chromatography. Single crystals of **4b** were obtained by vapor diffusion recrystallization from $CHCl_3$/pentane.

[14] Interestingly, in additon to **4a**, several other macrocyclic products, including 3,7,12,18,22-pentaethyl-2,8,13,17,23-pentamethylsapphyrin and a partially reduced, rubyrin-like system, 4,8,13,18,23,27-hexaethyl-3,9,14,17,22,28-hexamethyl-29,30,31,32,33,34-hexaazaheptacyclo-[24.2.1.$1^{2,5}$.$1^{7,10}$.$1^{12,15}$.$1^{16,19}$.$1^{21,24}$]tetratriaconta-1,3,5,7,9,11,13,15,17,19,21,23,25,27-tetradecaene, were also isolated in low yields in the course of this critical [4] + [2] condensation. In light of its bright violet color, this latter material is assigned the trivial name of iodyrin. ^{1}H NMR (300 MHz, $CDCl_3$): $\delta = 0.98$ (m, 9H; CH_2CH_3), 1.09 (m, 9H; CH_2CH_3), 2.06 (m, 18H; CH_3), 2.37 (m, 6H; CH_2CH_3), 2.57 (m, 6H; CH_2CH_3), 6.78 (m, 4H; „*meso*"-H), 11.85 (s, 1H; NH), 12.32 (s, 1H; NH), 12.51 (s, 1H; NH), 12.60 (s, 1H; NH), 12.62 (s, 1H; NH), 12.74 (s, 1H; NH); MS (FAB): *m/z* 696 ($M^{\oplus}$ + 1, 4%), 695 ($M^{\oplus}$, 5), 307 (22), 154 (100); UV/VIS (CH_2Cl_2): $\lambda_{max} = 538$ nm.

[15] Here, the sapphyrin dihydrochloride salt was used so as to allow a direct comparison to the rubyrin system **4b**. Adding excess TFA, however, served to increase the intensity of the sapphyrin Soret band (by ca. 15%), but not that of **4b**, suggesting that either conversion to the diprotonated form may not be complete in the former case or that the spectrum of $[H_2\text{-Sap}]^{2\oplus}$ is highly anion-dependent. On the basis of independent evidence [1e, 16] we currently favor the latter explanation.

[17] **4b**: $[C_{46}H_{56}N_6H_2]\ Cl_2 \cdot 2\ CHCl_3$, triclinic, space group P1 (No. 2), $Z = 1$, $a = 10.196(8)$, $b = 11.141(8)$, $c = 13.476(9)$ Å, $\alpha = 67.18(5)$, $\beta = 72.97(6)$, $\gamma = 68.56(6)°$, $V = 1293(2)$ Å^3, $\varrho_{calc} = 1.29\ g\,cm^{-3}$ (173 K) $F(000) = 526$. Data collected at 173 K on a Nicolet R3 diffractometer, graphite monochromator, $Mo_{K\alpha}$ radiation ($\lambda = 0.7107$ Å), ω scan, $2\theta = 50°$, 4573 unique reflections, 2871 with $F_o^2 > 3\sigma(F_o^2)$. The structure was solved by direct methods and refined by full-matrix least-squares (SHELXTL-Plus, Nicolet XRD, Madison, WI, USA) with anisotropic thermal parameters for the non-hydrogen atoms. Hydrogen atoms on C18, C19, C19A, C20, C21, C22, C22A, and C23 were idealized (C-H 0.96 Å), while all others were taken from a ΔF map. All were refined isotropically. Inversion center at 0,1/2,1/2 resulting in the occupational disorder of the ethyl and methyl groups of the pyrrole ring containing N2. The $Cl^{\ominus}$ ions are H-bonded to the pyrrolic hydrogens and to the $CHCl_3$ solvate molecules. $R = 0.0529$, $R_w = 0.0678$, goodness of fit = 2.284 for 361 parameters. The minimum and maximum peaks in the final ΔF map were -0.30 and $0.38\ e^-$ Å^{-3}, respectively. Further details of the crystal structure are available on request from the Director of the Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, GB-Cambridge CB21 1EW (UK), on quoting the full journal citation.

[19] Subsequent to the submission of this manuscript, an analogue of **4b**, derived from **8** and 5,5′-diformyl-4,4′-dipropyl-2,2′-bipyrrole, was prepared in our laboratory. This system (λ_{max} (CH_2Cl_2) = 501, 692, 771, 817 nm), which presumably allows for more rotational freedom about one of the bipyrrolic bonds (and hence a flatter macrocyclic array), was found to be stable in its free-base form. Interestingly, this new free-base material is also ruby red in CH_2Cl_2 solution (λ_{max} (CH_2Cl_2) = 513, 711, 789, 844 nm).

[20] We thank Dr. *A. K. Burrell* of this department for his help in carrying out these experiments

The Synthesis and Structure of the Yellow and Green Forms of $[Nb(O)Cl_3(PMe_3)_3]$ and the Orange and Green Forms of $[Nb(S)Cl_3(PMe_3)_3]$; Examples of Perfectly Matched Bond-Stretch Isomers?**

By *Alan Bashall, Vernon C. Gibson,* Terence P. Kee, Mary McPartlin,* Oliver B. Robinson*, and *Alan Shaw*

We report the syntheses of two pairs of seven-coordinate niobium isomers, yellow and green $[Nb(O)Cl_3(PMe_3)_3]$ (**1**) and orange and green $[Nb(S)Cl_3(PMe_3)_3]$ (**2**). These pairs of compounds appear to be perfectly matched bond-stretch isomers; there has been no previous report of this type of isomerism for a thiometal complex. The full X-ray structure analysis of the two pairs of isomers and the persistence of the thio isomers in solution (by IR spectroscopy) provide the best evidence so far for the reality of the phenomenon of bond-stretch isomerism. All four complexes are isostructural and isomorphous and have distorted mono-capped octahedral coordination geometries, with the significant differences between the isomeric pairs lying mainly in the bond lengths to the metal and the observed Nb=O and Nb=S stretches.

The first experimental evidence of the phenomenon of bond-stretch isomerism came from a series of green and blue octahedral oxomolybdenum complexes synthesized twenty years ago and thought originally to be geometric isomers.[1] X-ray structure analyses of the only suitable crystals that could be obtained, those of blue $[Mo(O)Cl_2(PMe_2Ph)_3]$ and green $[Mo(O)Cl_2(PEt_2Ph)_3]$, showed identical *cis-mer* coordinations with the only differences in the overall structures being the relative orientations of the phosphane organo groups and unexpected discrepancies in the Mo=O bonds, which were very much shorter in the more stable blue compound (1.676(7) Å)[2] than in the less stable green compound (1.803(11) Å).[3] It was deduced that the blue ($\tilde{\nu}$(Mo=O) 954 cm^{-1}) and green ($\tilde{\nu}$(Mo=O) 943 cm^{-1}) forms of the complex $[Mo(O)Cl_2(PMe_2Ph)_3]$ were the first examples of a new type of isomerism, named *distortion* isomerism at that time.[4]

Unambiguous examples of this class of isomerism have proved extremely elusive despite widespread interest,[5] and until now there has only been one case of full characterization of a perfectly matched, isostructural and isomorphous pair. They are the blue and green isomers of the cationic complex $[LW(O)Cl_2]^+$ (L = *N,N′,N″*-trimethyl-1,4,7-triazacyclononane), in which, despite relatively high errors in the parameters due to disorder of the PF_6^- counterion, significant W=O bond-length differences (1.719(18) and 1.893(20) Å, respectively) were established.[6] This has prompted a recent theoretical treatment of this phenomenon in transition-metal complexes and its reclassification as bond-stretch isomerism,[7] a term originally proposed for hypothetical organic species with double energy minima on simple bond stretching.[8]

In the present work we find that a mixture of the two isomers of compounds **1** and **2** are generated from reactions of trimethylphosphane with either base-free $[Nb(E)Cl_3]_n$ or the acetonitrile adducts $[Nb(E)Cl_3(CH_3CN)_2]$ (E = O, S) (Scheme 1). The proportions of the isomers arising in the

dures. For example, a batch of crystals consisting solely of **1a** may be obtained either by concentration and cooling (to ca. $-50°$ C) of the CH_2Cl_2 reaction solution generated from $[\{Nb(O)Cl_3\}_n]$ or by removal of the CH_2Cl_2 solvent followed by extraction of the dried residue with toluene and cooling to $-20°$ C overnight. Complex **1b** may be obtained by a similar low-temperature toluene crystallization of the mixture arising from $[Nb(O)Cl_3(CH_3CN)_2]$ or, alternatively, by allowing a solution of **1a** in toluene to stand at $-20°$ C for several days. Analogous procedures are employed to isolate single-component batches of **2a** and **2b**; **2a** is obtained by low-temperature toluene crystallization of the crude mixture arising from $[Nb(S)Cl_3(CH_3CN)_2]$ and **2b** from the mixture generated from $[\{Nb(S)Cl_3\}_n]$.

The first isomer to be isolated was yellow $[Nb(O)Cl_3(PMe_3)_2]$ (**1a**) and a Nb=O distance of 1.781(6) Å and mean Nb–Cl distance of 2.518(3) Å were established.[9] Later, the green form **1b** was obtained and, although the IR spectra of the individual isomers have a strikingly similar appearance (Fig. 1), they are readily distinguished by the

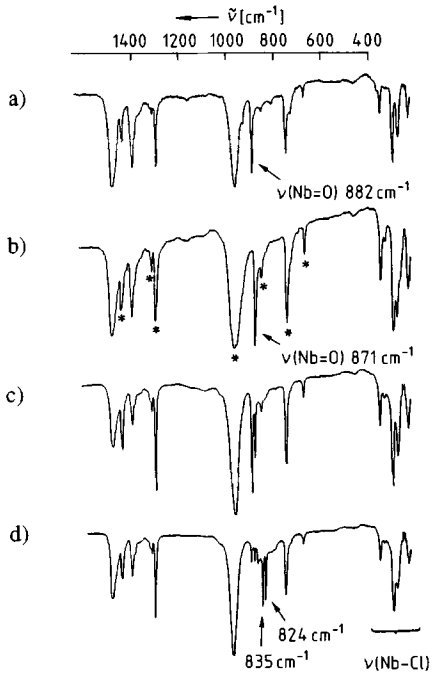

Fig. 1. Comparison of the IR spectra (Nujol mull, CsI $\tilde{\nu}$[cm^{-1}]) of the bond-stretch isomers of $[Nb(O)Cl_3(PMe_3)_2]$: a) pure **1a**; b) pure **1b**; c) a mixture of **1a** and **1b**; d) a mixture of ^{18}O-labeled **1a** and **1b**. The asterisk denotes bands attributed to Nb-PMe_3 stretching and bending modes.

observation of $\tilde{\nu}$(Nb=O) for **1a** at 882 cm^{-1} ($\tilde{\nu}$(Nb=^{18}O): found 835 cm^{-1}; calcd 833 cm^{-1}) compared to that for **1b** at 871 cm^{-1} ($\tilde{\nu}$(Nb=^{18}O): found 824 cm^{-1}; calcd 821 cm^{-1}). Although **1b** was initially thought to be a geometric isomer of **1a**, X-ray structure analysis[10] of **1b** has shown that the two structures are virtually identical in all respects except for the bond lengths to the metal (Fig. 2) and, although there are slight changes in O–Nb–Cl angles, the mean values are not significantly different in the two isomers. In the green isomer **1b** the Nb=O bond (1.929(6) Å)[11] is 0.148 Å (ca. 25σ) longer than that observed earlier[9] in the yellow isomer **1a**, and this lengthening is accompanied by a relatively small but significant contraction in the Nb–Cl distances (mean 0.023 Å, ca. 10σ). The solid-state evidence of the nature of

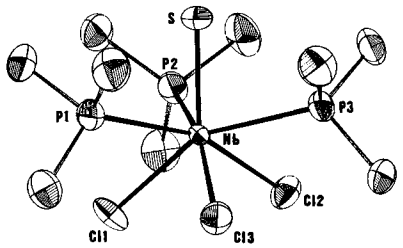

Fig. 2. The monocapped octahedral coordination geometry observed for **1** and **2** illustrated using a perspective view of **2b** with thermal ellipsoids plotted at the 50% probability level. Selected bond lengths [Å] and angles [°] with, in each case, the first parameter referring to the **a** isomer and that for the **b** isomer in square brackets (those for **1a** are from [9]): $[Nb(O)Cl_3(PMe_3)_2]$ (**1a**) [**1b**]: Nb-O 1.781(6) [1.929(6)], Nb-Cl(1) 2.516(3) [2.486(2)], Nb-Cl(2) 2.533(3) [2.508(2)], Nb-Cl(3) 2.505(3) [2.491(2)], Nb-P(1) 2.642(3) [2.645(2)], Nb-P(2) 2.633(3) [2.638(2)], Nb-P(3) 2.645(3) [2.643(2)]; O-Nb-Cl 121.2–127.8(2) [119.7–128.6(3)], O-Nb-P 73.3–76.9(2) [75.0–77.2(2)] · $[Nb(S)Cl_3(PMe_3)_2]$: (**2a**) [**2b**]: Nb-S 2.196(2) [2.296(2)], Nb-Cl(1) 2.487(2) [2.475(1)], Nb-Cl(2) 2.518(2) [2.501(1)], Nb-Cl(3) 2.490(2) [2.483(1)], Nb-P(1), 2.640(2) [2.647(1)], Nb-P(2) 2.640(2) [2.654(1)], Nb-P(3) 2.635(2) [2.647(1)]; S-Nb-Cl 123.4–128.9(1) [121.8–131.2(1)], S-Nb-P 77.4–77.6(1)–[75.8–76.9(1)].

the isomers appears unambiguous, but some caution in its interpretation is required due to a slight disorder in the crystals of **1b**;[12] fortunately, this problem does not occur for the thio analogues.

From reactions with thioniobium starting materials (Scheme 1) pure crystals of the orange (**2a**) and green (**2b**) forms of $[Nb(S)Cl_3(PMe_3)_2]$ were obtained and readily distinguished not only by their color but also by a marked difference in their IR spectra, $\tilde{\nu}$(Nb=S) occurring at 455 cm^{-1} for **2a** compared to 489 cm^{-1} for **2b** (Fig. 3a, b).

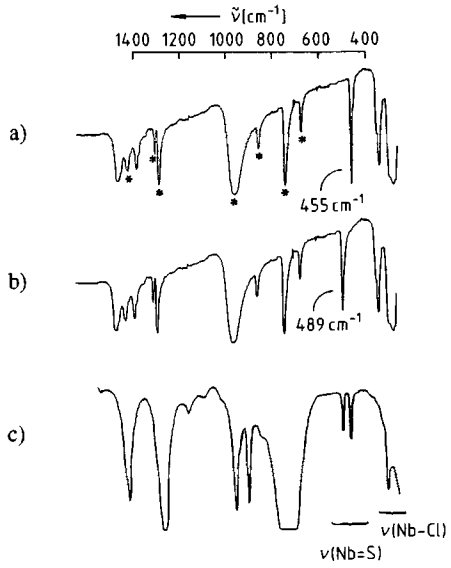

Fig. 3. Comparison of the solid-state and solution IR spectra, $\tilde{\nu}$[cm^{-1}], of the bond-stretch isomers of $[Nb(S)Cl_3(PMe_3)_2]$: a) pure **2a** (Nujol mull, CsI); b) pure **2b** (Nujol mull, CsI); c) **2a**/**2b** mixture (CH_2Cl_2 solution). The asterisk denotes bands attributed to Nb-PMe_3 stretching and bending modes.

Shifts identical to these solid-state values are obtained for **2a** and **2b** in CH_2Cl_2 solution (Fig. 3c). The X-ray structure analyses[10] of **2a** and **2b** reveal a very similar coordination geometry (Fig. 2) to that of their oxygen analogues and show that the main difference in the two isomers is in the respective Nb=S distances of 2.196(2) and 2.296(1) Å, respectively.[13]

The Nb=S length in the green isomer **2b** is thus 0.100 Å (ca. 70σ) longer than in the isomorphous orange form **2a** and there is also a slight but significant contraction in the Nb–Cl bond lengths (mean 0.012 Å, ca. 8σ) in **2b**. The large observed change in $\tilde{\nu}$(Nb=S) is in the opposite direction from that expected from the relative bond lengths of **2a** and **2b**; the origin of this anomaly is not clear.

The bromo analogues of **1** and **2** may be obtained by essentially analogous procedures, but so far only the **b** isomers have been isolated in a pure form. Interestingly, the bands due to Nb–E stretches in the IR spectra of the bromo isomers are coincident with their chloro analogues, indicating that the halide ligand apparently exerts little or no influence on $\tilde{\nu}$(Nb=E).

Our results for seven-coordinate sytems appear to provide further evidence for bond-stretch isomerism; the clear identification of the characteristic Nb=S stretches of isomers **2a** and **2b** both in Nujol mull and in CH_2Cl_2 solution seems to rule out any explanation of the phenomenon as a solid-state artifact.

[4] A recent reexamination of oxomolybdenum complexes [K. Yoon, G. Parkin, A. L. Rheingold, *J. Am. Chem. Soc. 113* (1991) 1437] shows that a continuum of apparent Mo=O bond lengthening in the solid state may be achieved when pure blue [Mo(O)$Cl_2(PMe_2Ph)_3$] is contaminated with the yellow trichloride [$MoCl_3(PMe_2Ph)_3$]. Such results for crystals with unresolved disorder of oxo and chloro ligands at equivalent sites could provide an explanation of the reported bond lengthening and the observed blue/green color differences, but the observation of different Mo=O stretches for blue and green [Mo(O)$Cl_2(PMe_2Ph)_3$] [1] is less readily explained as a result of low-level contamination with the trichloride.

Crystals were mounted in Lindemann tubes under inert atmosphere and absorption-corrected diffractometer data with $I/\sigma(I) \geq 3.0$ were used in all determinations. Further details on the crystal structure determination are available from the Director of the Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW (England), on quoting the full literature citation.
[11] It was not possible to be certain from the X-ray results alone that the O atom was not from a hydroxo ligand, but this possibility has been ruled out; there is no evidence for a hydroxyl group from IR and ^{1}H NMR spectroscopy and vibrating sample magnetometry shows **1b** to be diamagnetic; [Nb(OH)$Cl_3(PMe_3)_3$] would be a d^1 complex and therefore paramagnetic.
[12] In the initial refinement an extremely long Nb=O bond of 2.087(5) Å was observed and the oxygen-atom anisotropic thermal ellipsoid showed marked elongation in the Nb–O direction. Furthermore, there was residual electron density (ca. 1.5 e) in this direction at a distance of 0.51 Å beyond the oxygen atom. This has been interpreted as due to a small component of a second virtually isostructural molecule, with an axial chlorine atom, disordered in the crystal. Satisfactory refinement was obtained with 80% occupancy of axial positions by an oxygen atom and 20% by a chlorine atom. This gave a Nb–Cl(4) bond length of 2.33(2) Å, a value close to that observed [F. A. Cotton, M. P. Diebold, W. J. Roth, *Polyhedron 4* (1985) 1103] for the axial Nb–Cl bond of 2.409(4) Å in the green tetrachloride [$NbCl_4(PMe_3)_3$], which has crystals isomorphous with those of **1b**. It seems probable that the disorder is due to the presence of a small amount of this virtually isostructural compound in the crystal (possibly originating in the slight decomposition that occurs during the formation of **1b** from **1a**); the possibility that the 20% component is a *geometric* isomer of the oxo compound (i.e., that the 80% component is in fact residual **1a** with the apparent bond lengthening being an artifact of the disorder) was also considered, but this was ruled out by the absence of a second $\tilde{\nu}$(Nb=O) stretch corresponding to **1a** in the IR spectrum of **1b**.
[13] As Cl and S have similar numbers of electrons, the possibility that **2b** is a geometric isomer, with an "equatorial" Nb=S disordered over the three chlorine sites was also considered. However, this model may be ruled out because it would require occupancy of the axial site by a chloro ligand and consequently a very much longer bond of ca. 2.4 Å would have been observed; the thermal ellipsoid of this atom shows no evidence of any disorder that might produce apparent bond *shortening*. Furthermore, a mixture of **2a** plus a geometric isomer accounting for the bond parameters in **2b** is not consistent with the IR spectra (see Fig. 3), which show that both **2a** and **2b** are single-component species. The thermal ellipsoids of the sulfur atom in **2b** (see Fig. 2) show no elongation in the Nb–S direction and there is no evidence of any disorder of the type seen in the solid-state structure of **1b**.

trans-[Mo(η^2-*O,C*-PhNCO)(η^2-*C,N*-PhNCO)(*syn*-Me_8[16]aneS$_4$)]; Novel Discrimination of the C=O and C=N Bonds of PhNCO at Stereochemically Different Axial Sites**

By *Toshikatsu Yoshida,* Tomohiro Adachi, Kenji Kawazu, Akira Yamamoto,* and *Nobuyoshi Sasaki*

Recently we have shown that the [Mo(*syn*-Me_8[16]aneS$_4$)] moiety in the complexes *trans*-[ML_2(syn-Me_8[16]aneS$_4$)] (L=N_2, PhNC) exerts different electronic perturbation upon the two axial η^1-coordinated π-acid ligands.[1] This has been proved theoretically to arise from the stereoelectronic effect due to the pyramidal distortion of the MoS_4 frame in the [Mo(*syn*-Me_8[16]aneS$_4$)] moiety. For example, *trans*-[Mo(PhNC)$_2$(*syn*-Me_8[16]aneS$_4$)] contains both a severely bent and an essentially linear isocyanide ligand.[1c] In addition, the two axial sites of the [Mo(*syn*-Me_8[16]aneS$_4$)] moiety are in stereochemically different environments; the site surrounded by the macrocyclic carbon atoms is congested while the opposite site is uncongested.[2] Therefore, the [Mo(*syn*-Me_8[16]aneS$_4$)] moiety is expected to discriminate two π-acidic ligands possessing different electronic and steric properties at the axial sites. Indeed, this has been achieved by the bis(phenylisocyanate) complex **1**, where the η^2-*O,C*-PhNCO ligand, which is sterically less demanding than η^2-*C,N*-PhNCO, occupies specifically the congested axial site. The novel recognition of the C=O and C=N bonds of PhNCO was proved to be steric in origin by theoretical calculations on **1** and its possible isomers such as **1′**.

1 1'

trans-[Mo(η^2-*O,C*-PhNCO)(η^2-*C,N*-PhNCO)(*syn*-Me_8[16]aneS$_4$)] **1**

trans-[Mo(η^2-*C,N*-PhNCO)$_2$(*syn*-Me_8[16]aneS$_4$)] **1'**

Treatment of *trans*-[Mo$(N_2)_2$(*syn*-Me_8[16]aneS$_4$)][1b] with a 2.5 molar amount of PhNCO in toluene at room temperature for 5 h gave **1** as thermally stable crystals (35%).[3] Observation of both C=O (1702 cm^{-1}) and C=N (1570 cm^{-1}) stretching bands in the IR spectrum indicates that one PhNCO molecule coordinates through the C=N bond, the other through the C=O bond. This is shown unequivocally by its crystal structure (Fig. 1).[4]

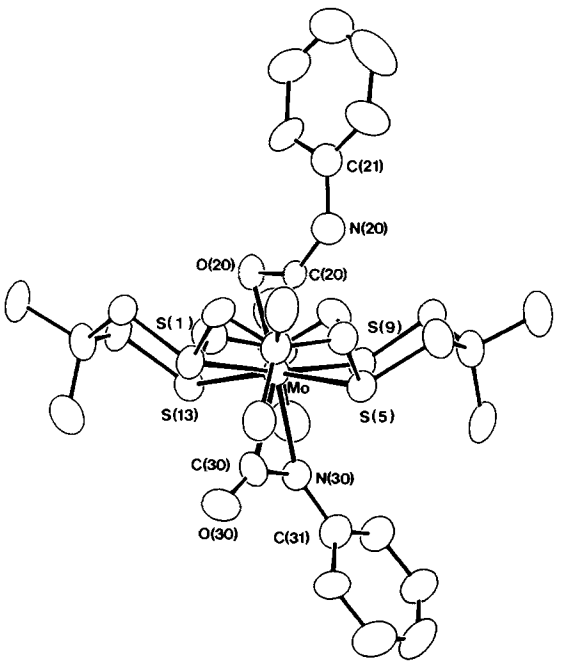

Fig. 1. Crystal structure of **1**. Selected bond lengths [Å] and angles [°]: Mo-S(1) 2.471(3), Mo-S(5) 2.472(4), Mo-S(9) 2.448(3), Mo-S(13) 2.491(4), C(20)-N(20) 1.279(11), C(30)-O(30) 1.243(14); S(1)-Mo-S(5) 89.9(1), S(5)-Mo-S(9) 90.4(1), S(9)-Mo-S(13) 91.1(1), S(1)-Mo-S(13) 90.6(1), C(30)-Mo-N(30) 34.9(4), C(20)-N(20)-C(21) 124.9(12), N(30)-C(30)-O(30) 138.8(10), C(30)-N(30)-C(31) 124.9(10).

Complex **1** crystallizes as a discrete monomer with the Mo atom in a slightly distorted octahedral environment. The η^2-C=O and η^2-C=N bonds are mutually staggered and each eclipses a *trans* S–Mo–S vector. This conformation has also been observed in *trans*-[Mo$(CH_2{=}CH_2)_2(PMe_3)_4$][5] and *trans*-[Mo$(CO_2)_2$(*i*PrNC)$(PMe_3)_3$][6] and has been confirmed theoretically to be most stable one.[7] The strong coordination of both PhNCO ligands may be deduced from the short Mo–C(20) and Mo–C(30) bond lengths (2.075(8) and 2.118(11) Å, respectively), which are evidently shorter than the Mo–C distances in *trans*-[Mo$(CH_2{=}CH_2)_2(PMe_3)_4$] (2.270(5) Å)[5] and *trans*-[Mo$(HC{\equiv}CH)_2$(*syn*-Me_8[16]aneS$_4$)] (2.166(12) Å).[8] The [Mo(η^2-*O,C*-PhNCO)] moiety is structurally similar to the [Mo(η^2-CO_2)] unit in *trans*-[Mo(η^2-$CO_2)_2$(*i*PrNC)$(PMe_3)_3$].[6] Thus, the Mo–C(20), Mo–O(20) (2.147(8) Å), and C(20)–O(20) distances (1.295(15) Å), as well as the O(20)–Mo–C(20) (35.7(4)°) and O(20)–C(20)–N(20) angles (131.8(10)°) are comparable to the corresponding values for the CO_2 complex cited above (2.105(10), 2.147(7), and 1.26(2) Å; 34.5(10) and 133.5(10)°). The Mo–C(30), Mo–N(30) (2.157(8) Å), and C(30)–N(30) distances (1.282(14) Å) of the [Mo(η^2-*C,N*-PhNCO)] moiety may be compared with the respective lengths of the η^2-iminoacyl complex [Mo(η^2-PhN=CMe)(η^5-C_5H_5)$(CO)_2$] (2.106(5), 2.143(4), and 1.233(6) Å, respectively).[9]

Although the Me_8[16]aneS$_4$ ligand adopts *syn* conformation as observed for the complexes *trans*-[ML_2(syn-Me_8[16]aneS$_4$)] (L=N_2,[1b] PhNC,[1c] CO[10]), their geometries about the Mo atom differ significantly. Thus, the MoS_4 framework of **1** deforms slightly toward tetrahedral geometry with S(1)–Mo–S(9) and S(5)–Mo–S(13) angles of 171.4(1) and 166.9(1)°, respectively. By contrast, a pyramidal distortion with *trans* S–Mo–S angles of 173.8(1)–175.7(1)° was found for the η^1-coordinated π-acid complexes, where the Mo atom deviates from the plane of the four S atoms toward the ring C atoms. Such a tetrahedral deformation may enhance the d_π–p_{π^*} interaction between the Mo atom and the C=N bond of PhNCO located at the uncongested axial site. In fact, extended Hückel MO calculations indicate that the model compound **A**, with the observed

trans-[Mo(η^2-*O,C*-HNCO)(η^2-*C,N*-HNCO){*syn*-$(SH_2)_4$}] **A**

trans S–Mo–S angles of **1**, is 13.3 kcal mol^{-1} more stable in total energy than the pyramidally distorted structure with *trans* S–Mo–S angles of 175°.[11]

Transition-metal complexes of organoisocyanates have received extensive interest as intermediates in metal-mediated transformations of isocyanates.[13a] However, only polynuclear complexes with bridging isocyanates,[13a] such as [{U(η^5-$C_5H_4Me)_3$}$_2$(μ-η^1-*O*-,η^2-*C,N*-PhNCO)][13b] and [W_2(OCCMe$_3)_6$(μ-η^2-*O,C*-, η^2-*C,N*-PhNCO)], have been characterized so far by X-ray structural study.[13c] Furthermore, the η^2-C=O coordination has only two precedents, [Mo(η^2-PhNCO)$_2$(dppe)$_2$] (dppe = 1,2-bis(diphenylphosphino)ethane)[13d] and the ditungsten complex cited above, where the bonding mode in the former complex was based only on the IR spectral data. Therefore, complex **1** represents the first example of a well-characterized mononuclear bis(organoisocyanate) complex with both η^2-C=O and η^2-C=N coordinations.

What are the origins for the novel discrimination of the C=O and C=N bonds of PhNCO at the sterochemically different axial sites in **1**? In view of the slight distortion of the MoS_4 framework toward tetrahedral geometry, electronic factors may not be crucial in determining the coordination modes at the axial sites. This is supported by extended Hückel MO calculations on four possible isomers of the model compound of **1**, **A**–**D**, where the HNCO ligand at the congested axial site of **A** and **B** is shown in the first parenthe-

trans-[Mo(η^2-*C,N*-HNCO)(η^2-*O,C*-HNCO)L_4] **B**

trans-[Mo(η^2-*O,C*-HNCO)$_2L_4$] **C**

trans-[Mo(η^2-*C,N*-HNCO)$_2L_4$] **D**

L_4 = *syn*-$(SH_2)_4$

ses. Their relative total energies are 0, 0.4, 4.4 and -3.6 kcal mol^{-1}, respectively.[11] Although the difference in energy between the (η^2-*O,C*-HNCO)(η^2-*C,N*-HNCO) and (η^2-*C,N*-HNCO)$_2$ isomers is small, the calculations are inconsistent with the observed structure.

Next, we used molecular mechanics calculations to examine the steric factor responsible for discriminating the two functionalities of PhNCO.[14] The energy-minimized structure found for **1**, which agrees well with the X-ray structure,[17] is 12.3 kcal mol^{-1} lower in total strain energy than that calculated for **1'**. The high strain energy of the latter seems to stem mainly form stereochemical repulsion between the axial hydrogen atoms of ring CH_2 groups and the η^2-*C,N*-PhNCO ligand at the congested axial site. To reduce these steric repulsions as much as possible, both of the *trans* S–Mo–S vectors should bend toward the uncongested axial site. In fact, the S(5)–Mo–S(13) angle (161.7°) in **1'** is more acute and the S(1)–Mo–S(9) angle (175.0°) more obtuse than the corresponding angles of **1** discussed above. Thus, the novel discrimination of the C=O and C=N bonds of PhNCO at the axial sites can be explained in terms of steric control rather than electronic effects.

Since the space available for an axial ligand at the congested site can be adjusted by the ring size of *syn*-crown thioethers,[2] the present result may provide a basis for further development of crown thioether complexes as hosts in molecular recognition through coordination at the metal center.

[14] Molecular mechanics calculations were carried out employing MOLBD3 *by Boyd* [15]. Stretching, bending, and torsional parameters involving the Mo atom and NCO fragments were determined by fitting the energy-minimized structure of **1** to the X-ray structure. Nonbonded parameters for the Mo atom were estimated by *Allinger*'s method [16]. The other interaction parameters were based on the values published by *Allinger* [16]. Initial coordinates for the refinement were taken from the crystal structure coordinates of **1** except for those of η^2-*C,N*-PhNCO located at the congested side in **1'**, which were derived from those of **1** by application of the S_4 symmetry operation. The total strain energies of **1** and **1'** are 61.7 and 74.0 kcal mol^{-1}, respectively. The energy-minimized structures assessed for **1** and **1'** and their selected bond lengths and angles are deposited as the supplementary material.

Unusual Mode of Addition of 1,2-Alkadienylidene Carbenes to 1,3-Dienes: 1,4 Addition to Rigid and Flexible 1,3-Dienes

By *Hikaru Sugita, Kazuhiko Mizuno,* Toshiki Mori, Kakuzo Isagawa,** and *Yoshio Otsuji**

Electrophilic carbenes, such as dihalocarbenes, add to 1,3-dienes usually in a 1,2 manner to produce cyclopropane derivatives.[1] The 1,4 addition of carbenes and carbene analogues is very rare, and it is in fact essentially limited to enforced cisoid dienes.[2–6] Earlier, we found that 1,2-alkadienylidene carbenes can be generated efficiently from 2,2-disubstituted-1,1-dibromocyclopropanes via double dehydrobromination under phase-transfer conditions and that the 1,2-alkadienylidene carbenes thus generated add to alkenes to afford alkenylidenecyclopropanes [Eq. (a)].[6–8] We now report that 1,2-alkadienylidene carbenes add to 1,3-dienes in both 1,2 and 1,4 manner. To the best of our knowledge, this is the first example in which the 1,4 addition of such carbenes becomes one of the major paths even for stereochemically flexible 1,3-dienes.

Treatment of 1,1-dibromo-2,2-diphenylcyclopropane (**1a**) with an aqueous 50% NaOH solution under phase-transfer conditions in the presence of an excess of 2-methyl-1,3-butadiene (**2b**) afforded the 1,2-adduct **3b** and the 1,4-adduct **4b** in a 78:22 ratio in 37% yield [Eq. (b)]. The 1,2-adduct **3b** was stable under the reaction conditions and no indication of isomerization of **3b** to **4b** was observed. Therefore, **4b** is probably produced directly via a 1,4 addition of 3,3-diphenylpropadienylidene to **2b**. In a similar manner, the propadienylidenes generated from **1a–c** also added to 1,3-dienes **2a–e** to afford 1,2 and 1,4 adducts in 5–87% yield

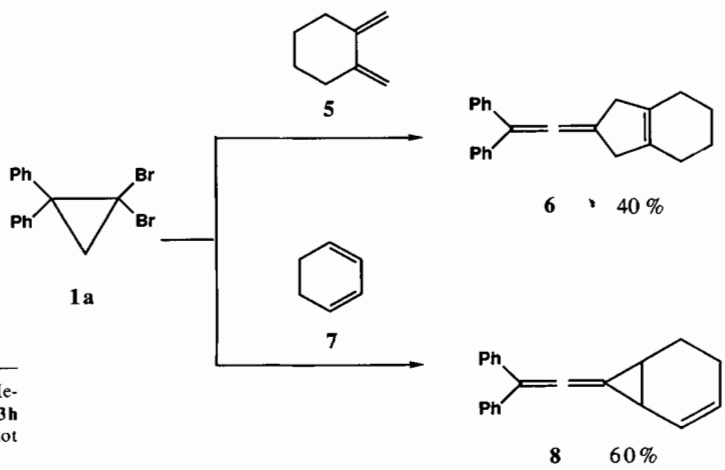
[a] Tetramethylsilane as internal standard. [b] Aliphatic and olefinic protons. [c] Chemical shifts of central carbon of 1,2-diene moiety. [d] Absorption maximum of 1,2-diene moiety. [e] Not determined.

The reaction of 3-methyl-1,2-butadienylidene (generated by 1,3 elimination from 3-chloro-3-methyl-1-butyne) with **2b** was reported by *Sasaki* et al. in 1974.[3] In that case however, only the 1,2 adduct was obtained and the regioselectivity was in sharp contrast with our results.

From **1a** and 1,2-dimethylenecyclohexane (**5**), the 1,4-adduct **6** was obtained as the sole isolable product. However, the reaction of **1a** with 1,3-cyclohexadiene (**7**) and 2,5-dimethyl-2,4-hexadiene (**2e**) gave only the 1,2-adducts **8** and **3e**, respectively. Spectroscopic data for **6** and **8** are given in Table 2.



Although we do not have unequivocal evidence, it is quite reasonable to assume that the 1,2-alkadienylidene carbenes are involved as common key intermediates in the above reactions.[6-9] They add to 1,3-dienes in both 1,2 and 1,4 manner and selectively undergo 1,4 addition to an enforced cisoid 1,3-diene such as **5**.

Experimental Procedure

3b/4b: A mixture of nBu$_4$NHSO$_4$ (2 mmol) and aqueous 50% NaOH (100 mL) was added to a benzene solution containing 1,1-dibromo-2,2-diphenylcyclopropane (**1a**, 1 mmol) and an excess of 2-methyl-1,3-butadiene (**2b**, 5 mmol). The mixture was vigorously stirred at room temperature for 24 h. Flash column chromatography on silica gel with hexane gave the 1,2-adduct **3b** and the 1,4-adduct **4b** in a 78:22 ratio in 37% yield.

Control experiment: A mixture of nBu$_4$NHSO$_4$ (0.8 mmol) and an aqueous 50% NaOH (25 mL) was added to a benzene solution containing **3b** (0.4 mmol) and the resulting mixture was vigorously stirred at room temperature for 22 h. Compound **3b** remained unchanged (270-MHz ^{1}H NMR spectrum) and was quantitatively recovered.

3b (oil): ^{1}H NMR (270 MHz, CDCl$_3$): δ = 1.69 (s, 3H), 1.79 (dd, 1H, J = 6.0, 7.0 Hz), 1.95 (dd, 1H, J = 7.0, 8.7 Hz), 2.71 (dd, 1H, J = 6.0, 8.7 Hz), 4.82 (s, 1H), 4.92 (s, 1H), 7.18–7.40 (m, 10H). ^{13}C NMR (67 MHz, CDCl$_3$): δ = 15.0, 19.2, 28.8, 83.1, 111.4, 112.2, 127.0, 126.9, 127.9, 128.3, 128.4, 128.4, 128.6, 137.7, 143.0, 189.2. IR: $\tilde{\nu}$[cm^{-1}] = 3060, 2978, 1999, (C=C=C), 1638, 1599, 1493, 1473, 1444, 1031, 888, 768, 692.

4b (oil): ^{1}H NMR (270 MHz, CDCl$_3$): δ = 1.75 (s, 3H), 3.28 (s, 2H), 3.34 (s, 2H), 5.36 (s, 1H), 7.16–7.37 (m, 10H). ^{13}C NMR (67 MHz, CDCl$_3$): δ = 16.5, 37.8, 41.5, 122.8, 126.9, 128.2, 128.4, 128.5, 128.6, 138.8, 143.0, 199.9. IR: $\tilde{\nu}$[cm^{-1}] = 3060, 3030, 2892, 1949 (C=C=C), 1659, 1601, 1493, 1454, 1444, 770, 696.

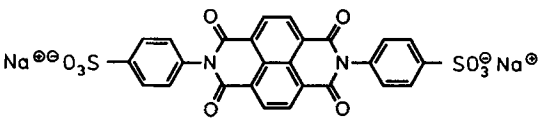
An Imide Radical Anion which Assembles into π-Stacks in Solution**

By *Jean-François Penneau* and *Larry L. Miller**

Partially oxidized or reduced π-stacks are the most common structural elements in conducting organic charge transfer salts of the broad class typified by tetracyanoquinodimethane/tetrathiafulvalene (TCNQ/TTF).[1] We have observed unusual spectral effects which lead to the conclusion that the radical anion $\mathbf{1}^{\bullet\ominus}$ assembles into similar π-stacks in solution. In particular the NIR, and ESR of $\mathbf{1}^{\bullet\ominus}$ in aqueous NaCl are extremely similar to the spectra of the conducting solid complex salt of $\mathbf{1}^{\bullet\ominus}$ and provide a spectral signature for π-stacks. Although π-dimers of radical anions are well known,[2] we know of no examples of radical ion π-stacks in solution.[3] Such entities are interesting as models for conducting solids and the solutions have potential utility as infrared dyes.[5]



1

$\mathbf{1}^{\bullet\ominus}$, formed by electrochemical reduction in DMF,[6] shows absorption in the visible spectral region, with the most intense band at λ = 473 nm (ε = 31 000), and a 13-line ESR spectrum well simulated by a_H(4H) = 1.90 G, a_N(2N) = 0.95 G. The spectra were essentially identical to those of similar naphthalene diimide radical anions[6] and a_H conformed to expectations based on a Hückel MO calculation and solution of the McConnell equation. It is concluded that the monomeric radical anion is present.

In aqueous media it was convenient to generate the radical anion by reduction of **1** with one equivalent of sodium dithionite. In the absence of oxygen the solutions were stable for weeks. In water or in 80% H_2O/20% DMF the optical spectrum of $\mathbf{1}^{\bullet\ominus}$ was quite different from the spectrum in neat DMF. There was a new NIR band at 1140 nm (ε = 3900) and the VIS band was shifted to 453 nm. This observation is consistent with the literature on radical ion dimers in aqueous media.[2] Such dimers, e.g. $(TCNQ^{\bullet\ominus})_2$, give NIR bands due to charge transfer between the π-electron systems in the stacks, and a Davidov blue shift of the VIS absorption. Since the room-temperature spectrum in water follows Beers law over the range 0.02–2 mM, we conclude that essentially all the radical anions are dimerized under these conditions. Raising the temperature to 90 °C caused the spectrum of $\mathbf{1}^{\bullet\ominus}$ in aqueous DMF to revert to that of the monomer in DMF. The ESR spectrum underwent corresponding changes. In water or aqueous DMF a weak, 25-line spectrum (a_H = 1.93, a_N = 1.08 G) was observed at room temperature. Raising the temperature of the aqueous DMF solution to 100 °C did not change the shape, but by using a nitroxyl standard it was shown that the spin concentration increased from 7% to 94% of the $\mathbf{1}^{\bullet\ominus}$ concentration. The weak signal at room temperature is consistent with literature reports which indicate that radical ion π-dimers have diamagnetic ground states.[2]

In aqueous NaCl solutions there was an unexpected evolution of the NIR absorption. As the concentration of $\mathbf{1}^{\bullet\ominus}$ or NaCl was increased the absorption moved to much longer wavelengths. This is illustrated in Figure 1 for 0.43–4.3 mM $\mathbf{1}^{\bullet\ominus}$ in 0.5 M NaCl. As a further example, the spectrum of $\mathbf{1}^{\bullet\ominus}$ (4.8 mM) in 5 M NaCl had a maximum at 1740 nm and extended far into the IR region. Such very long-wavelength absorptions are characteristic of charge transfer along the delocalized π-stacks of solid, conducting, charge transfer salts.[2, 7] The ESR spectrum underwent an unexpected change as well. In dilute solutions the weak, 25-line spectrum was observed, but in concentrated solutions the signal was asymmetric (Fig. 2).

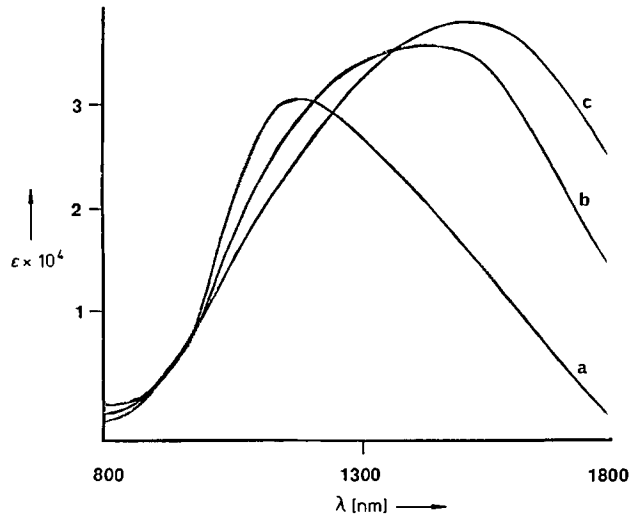

Fig. 1. NIR spectra of $1^{\cdot\ominus}$ in 0.5 M aqueous NaCl solution. Concentration of $1^{\cdot\ominus}$. a) 0.43 mM. b) 2.1 mM. c) 4.3 mM.

When a solution of $1^{\cdot\ominus}$ in water was slowly evaporated under vacuum a shiny black film resulted. The ESR spectrum of the film was anisotropic and the line shape depended on the orientation of the film in the magnetic field (Fig. 2).

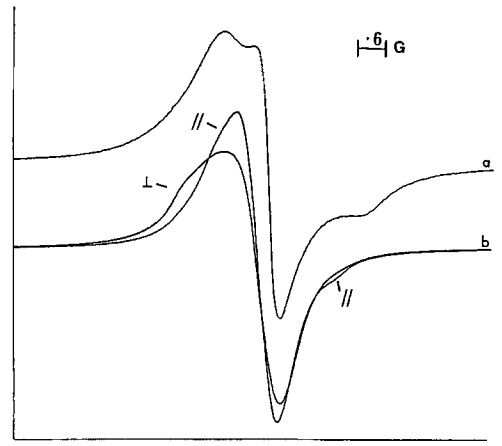

Fig. 2. ESR spectra of $1^{\cdot\ominus}$. a) 8 mM in 0.5 M aqueous NaCl at 280 K. b) Thin film, (⊥) with thin dimension perpendicular to magnetic field; (∥) with one long dimension parallel to magnetic field at 300 K. Scale bar corresponds to 0.6 Gauss.

These spectra suggest that the asymmetric solution spectrum results from unoriented, slowly tumbling aggregated radicals, that are similar to the oriented radicals immobilized in the film.[8] A KBr pellet of the film, like the NaCl solutions of $1^{\cdot\ominus}$, showed an NIR absorption extending into the IR. The 4-probe conductivity of a pure pressed pellet was 0.1 S cm^{-1}.

Thus, it has been demonstrated that $1^{\cdot\ominus}$ assembles into an aggregate in aqueous NaCl which has similar optical and magnetic resonance properties as the conducting solid. These spectral qualities are characteristic of radical anion stacks. Indeed, an X-ray crystal structure of a conducting naphthalene dianhydride salt has shown π-stacks of radical anions.[9] Whether the stacks in solution are composed of only $1^{\cdot\ominus}$ or are doped with another redox state is not known. It does seem important, however, that $1^{\cdot\ominus}$ is actually a tri-anion. This increases the water solubility and gives a propensity for ion aggregation.[4]

[3] This phenomenon is somewhat analogous to the aggregation of certain dyes [4], which form stacks and give excitonic bands. Because the dyes are closed shell molecules the bonding between molecules in the stack, the electronic structure of the stack, and the nature of the optical transition are somewhat different. There appear to be no examples of dye aggregates that absorb at such long wavelengths. There are no long-wavelength bands in aqueous NaCl solutions of neutral **1**.

Enantiomer Separation on Immobilized Chirasil-Metal and Chirasil-Dex by Gas Chromatography and Supercritical Fluid Chromatography **

By *Volker Schurig*,* *Dieter Schmalzing*, and *Michael Schleimer*

Dedicated to Professor Michael Hanack

The development of surface-bonded stationary phases by cross-linking and/or chemical binding ("immobilization") represented a breakthrough in high-resolution capillary chromatography.[1] The resulting merits are stable films, low bleeding of the stationary phase, high washout stability, and hence use in splitless and on-column sampling. To achieve universal physico-, chemo-, and enantioselective stationary phases based on chemically modified chiral polysiloxanes, e.g. Chirasil-Val,[2] Chirasil-Metal[3] and Chirasil-Dex,[4, 5] an immobilization on the glass surface is desirable.

We describe here the immobilization of *enantioselective* metal chelate and cyclodextrin phases. Chiral polysiloxanes can be immobilized thermally or radically.[6–9] The nickel(II) Chirasil-Metal **1** prepared by us according to Scheme 1 and the octanyl Chirasil-Dex **2c** obtained according to Scheme 2 can be immobilized thermally on the fused silica surface with binding rates of up to 75%.[12] The thermal immobilization does not lead to any decomposition and/or epimerization,

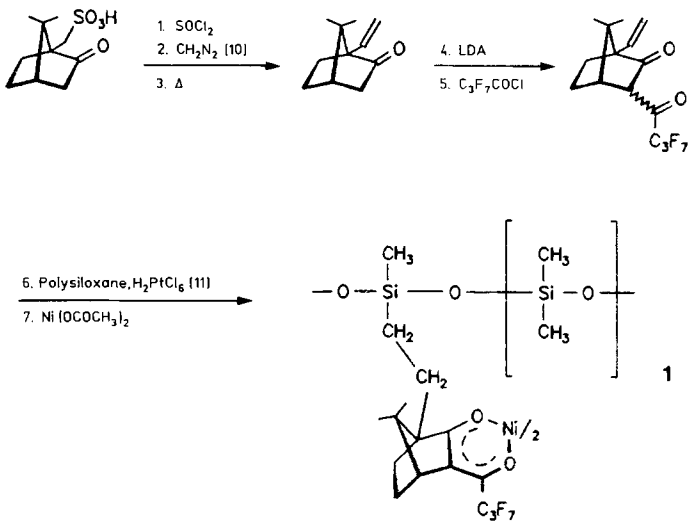
[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie und Chrompack International, Middelburg (The Netherlands) (supply of fused-silica capillary columns). We thank *G. J. Nicholson*, *U. Mühleck* and Professor *E. Bayer*, Tübingen, for valuable discussions.



Scheme 1. Synthesis of the chemically modified chiral polysiloxanes Ni^{II}/Chirasil-Metal **1** [12]. LDA = lithium diisopropylamide. The polysiloxane used in step 6 was a 10–13:90–87 mixture of methylhydro/dimethylpolysiloxane.

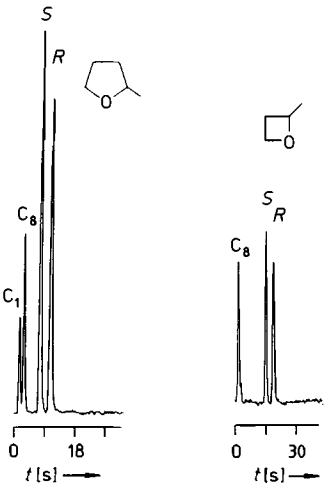


Fig. 1. Enantiomer separation by complexation GC (1.5 m × 0.05 mm (I. D.) fused silica capillary column, coated with immobilized **1** [12]). Left: 2-methyltetrahydrofuran, 115 °C, 2.0 bar N_2. Right 2-methyloxetane, 140 °C, 2.0 bar N_2.

either in the case of the metal chelates or in the case of the cyclodextrin derivatives; this is confirmed by the decrease in the separation factor α, which does not exceed 5 to 10% (depending upon the racemate checked). Typical gas-chromatographic enantiomer separations are shown in Figures 1 (immobilized **1**) and 2 (immobilized **2c**). As can be seen from Figure 1, in particular, the use of shorter columns having small internal diameters (I. D.) enables very short analysis times. The capillary column immobilized with chemically bonded Chirasil-Metal **1** exhibits a markedly higher temperature stability than the previously described physical mixtures of Chirasil-Metal phases and polysiloxanes,[13] and thus extends the scope of complexation gas chromatography considerably.

The capillary columns immobilized with chemically bound Chirasil-Dex **2c** show none of the disadvantages of

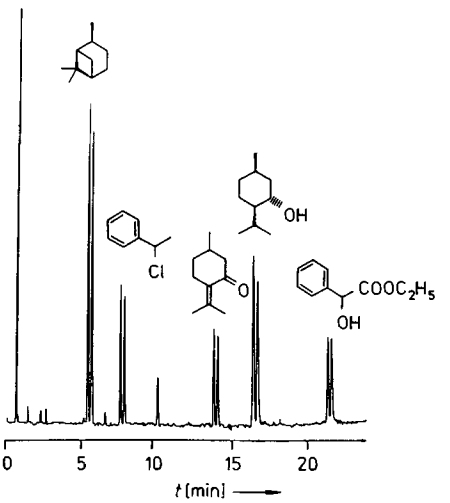

Fig. 2. Enantiomer separation of *cis*-pinane, (1-chloroethyl)benzene, pulegone, isomenthol, and ethyl mandelate by inclusion GC (10 m × 0.1 mm (I. D.) fused silica capillary column, coated with immobilized **2c** [12]). 1 min isothermally at 80 °C, then with 3 K min^{-1} up to 140 °C, 1 bar H_2.

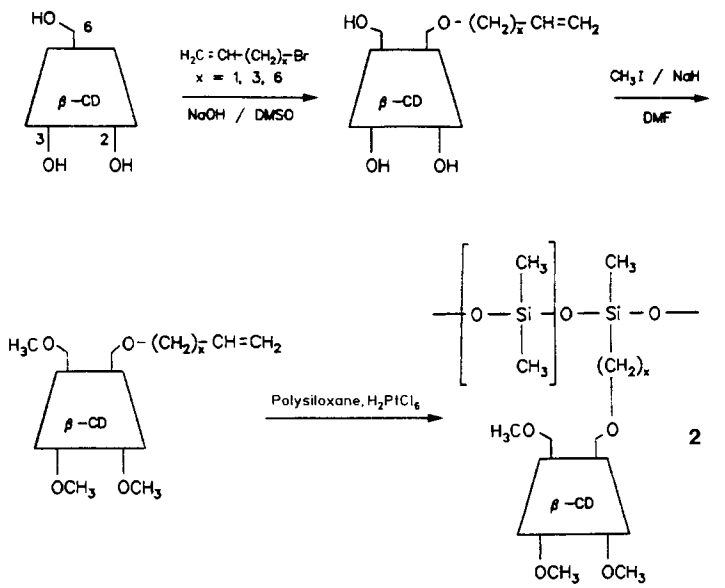

Scheme 2. Synthesis of the chemically modified chiral polysiloxanes Chirasil-Dex **2a–c** [4]. DMSO = dimethyl sulfoxide, DMF = dimethylformamide, polysiloxane = methylhydro/dimethylpolysiloxane 5/95. **2a**, $x = 3$ (Dex 1); **2b**, $x = 5$ (Dex 2); **2c**, $x = 8$ (Dex 3).

the columns coated with neat (pentylated/acylated) cyclodextrin derivatives, such as tendency to formation of droplets, sensitivity towards thermal shock, long conditioning times, low tolerance towards solvent introduction upon direct injection (splitless, on-column),[14] and limited lifetime.[15]

By quantitative immobilization of **1** in a capillary column with small internal diameter (1.5 m × 0.05 mm) it was possible for the first time to extend complexation chromatography to supercritical fluid chromatography. The enantiomers of 1-(2-naphthyl)ethanol and 1-phenylethanol could already be separated quantitatively in a 1.5-m column in less than 10 minutes at 80 °C with carbon dioxide as supercritical mobile phase (α in each case 1.4, R_s in each case 1.65; Fig. 3). Remarkably, the mobile phase carbon dioxide apparently has too low a Lewis basicity to block free coordination sites on the metal ion for enantioselective complexation of the alcohols. Together with immobilized octanyl Chirasil-Dex **2c**, which is also suitable for the separation of enantiomers in

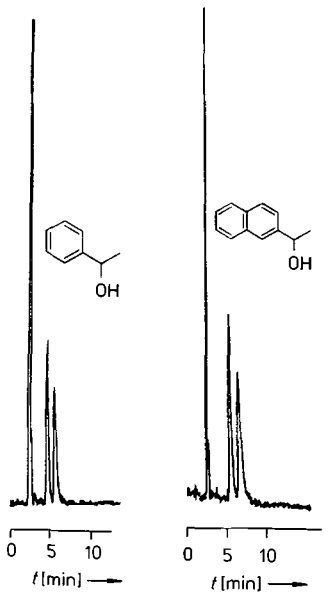

Fig. 3. Enantiomer separation by complexation SFC (1.5 m × 0.05 mm (I. D.) fused silica capillary column, coated with immobilized **1**). Left: 1-phenylethanol, 80 °C, 100 atm CO_2. Right: 1-(2-naphthyl) ethanol, 80 °C, 130 atm CO_2.

SFC,[16] two further systems, based on complementary methods are now available for the separation of enantiomers with supercritical gases. These systems combine the advantages of capillary GC (high efficiency and speed, universal detection) and high-pressure liquid chromatography (no limitation to volatile and thermally stable components). The supercritical mobile phase used, carbon dioxide, is compatible with the universal flame ionization detector and with mass spectrometric coupling. Because of the good solvating properties of the supercritical gases, SFC enantiomer separations are achieved already at low temperature. Since the separation factors α increase with decreasing temperature in the region of enthalpy-control of the enantiomer separation,[17] the lower efficiency of SFC compared to GC can thus be largely compensated.

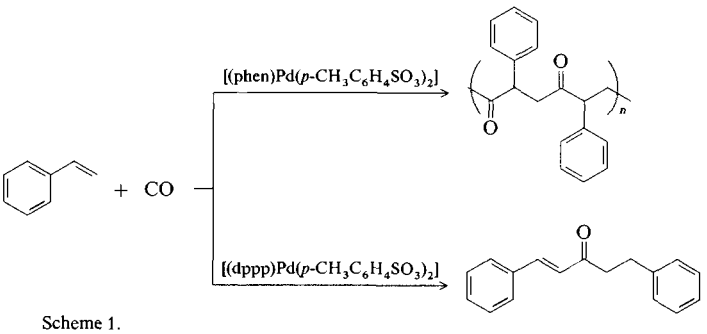
Syndiotactic Poly(1-oxo-2-phenyltrimethylene): On the Mode of the Chain Growth under Palladium Catalysis

By *Marco Barsacchi, Giambattista Consiglio,* Lorenzo Medici, Giorgio Petrucci,* and *Ulrich W. Suter*

Palladium-containing catalytic systems modified by phosphorus or nitrogen ligands and having anions that coordinate weakly or not at all display different chemoselectivity in carbonylation reactions of olefins, depending on the nature of the ligand or the anion or both. Thus, when styrene is the substrate and methanol the solvent, the catalytic system formed in situ from $Pd(CH_3COO)_2$/1,10-phenanthroline(phen)/p-$CH_3C_6H_4SO_3H$ in the absence of hydrogen and in the presence of an oxidant such as 1,4-benzoquinone catalyzes the chemo- and regioselective formation of a new interesting polymeric material, poly(1-oxo-2-phenyltrimethylene),[1] which is the strictly alternating copolymer of carbon monoxide and styrene (Scheme 1). The preformed complex



Scheme 1.

[(1,10-phen)Pd(p-$CH_3C_6H_4SO_3$)$_2$] behaves similarly.[2] By contrast, in nonprotic solvents [(dppp)Pd(p-$CH_3C_6H_4SO_3$)$_2$] (dppp = 1,3-bis(diphenylphosphino)propane) brings about selective carbonylation to *E*-1,5-diphenylpent-1-en-3-one even under high hydrogen partial pressure.[3] Steric discrimination is evident for these reactions. The formation of diastereomerically pure *E*-1,5-diphenylpent-1-en-3-one implies a complete discrimination between the two diastereotopic hydrogen atoms during β elimination from the inter-

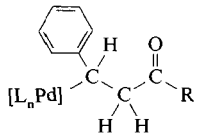
mediate complex **1**. A remarkable enantioface selection takes place instead in the formation of poly(1-oxo-2-phenyltrimethylene). In fact, previous studies have shown that this

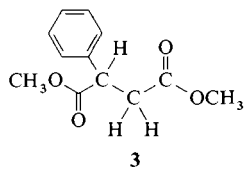


1, $R=CH_2CH_2\text{-}C_6H_5$
2, $R=[CH(C_6H_5)CH_2CO]_nR'$

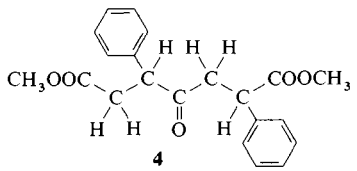
polymer is obtained with a highly stereoregular structure (ca. 80% syndiotactic triads *rr* and ca. 10% of each of the two different atactic triads *rm* and *mr*).[4]

The absence of the isotactic triad *mm* is an indication that the stereochemistry of the growing chain is chain-end-controlled.[4, 5] This type of steric control is normally considered more effective when the regioselectivity of the monomer insertion leads to intermediates that have a secondary carbon atom bound to the metal (compare **2**).[6] This mode of insertion was observed in the syndiospecific polymerization of styrene by the homogeneous $Ti(PhCH_2)_4$/methylalumoxanes catalytic system[7] or in the isospecific oligomerization of styrene using the [(η^3-methallyl)(η^4-cycloocta-1,5-diene)-nickel(II)] hexafluorophosphate/P(*cyclo*-$C_6H_{11})_3$ catalyst precursor.[8] In the case of poly(1-oxo-2-phenyltrimethylene), however, no information on how the polymeric chain grows, i.e., on the regioselectivity of the insertion of the olefinic monomer exists.[9]

We report here on the identification of the end groups in the poly(1-oxo-2-phenyltrimethylene) copolymer, from which a secondary regioselectivity for the insertion of styrene into the growing chain may be inferred. ^1H and ^{13}CNMR spectroscopy[4] gave no clear indication of possible end groups for the copolymer prepared according to *Drent*,[1] even though carbomethoxy end groups appeared probable.[1] Attempts to reduce the chain length by working in the presence of hydrogen[10] caused almost complete suppression of copolymer formation even at low hydrogen partial pressure. By increasing the amount of the oxidant (1,4-benzoquinone) the selectivity of the reaction is shifted towards the formation of low molecular weight products. Dimethyl 2-phenylbutanedioate (**3**)[11] and dimethyl 2,5-diphenyl-4-oxopimelate (**4**) (probably present as a single diastereomer) were isolated and identified by MS and ^1H



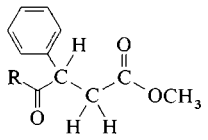
3



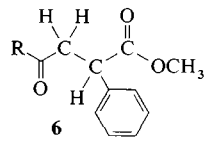
4

and ^{13}CNMR spectroscopy. Both compounds present two different carbomethoxy groups in the ^{13}CNMR spectrum (**3**: δ = 54.5, 54.0, 177.1, and 178.5; **4**: δ = 54.7, 54.1, 177.5, and 178.8 in hexafluoro-2-propanol.

A copolymerization reaction using [(1,10-phen)Pd(*p*-$CH_3C_6H_4SO_3)_2$] as the catalyst precursor allowed us to obtain a small amount of a highly stereoregular, low molecular weight copolymer ($M_n \approx 2000$) through fractional crystallization. The ^{13}CNMR spectrum also showed two different carbomethoxy groups (δ = 54.5, 54.1, 177.5 and 178.9). Similar signals at δ = 54.2 and 54.0 were recognized in the high molecular weight copolymer prepared from labeled $^{13}CH_3OH$. Studies on different copolymer samples show that quite often only one carbomethoxy group can be recognized and when two signals are present, the one at higher magnetic field has the larger intensity. These results imply that the polymer chain begins by insertion of a styrene unit into a metal–carbomethoxy bond and terminates by alcoholysis of a metal–acyl bond. The preparation of a copolymer using labeled $C_6H_5CH=^{13}CH_2$ allowed us to identify a new end group, $C_6H_5CH=^{13}CHCO$ (δ = 125.2 ppm). This end group shows that β-hydrogen elimination from an intermediate of type **2** can be responsible for chain termination, in a way similar to that observed in the synthesis of *E*-1,5-diphenylpent-1-en-3-one. At the moment we cannot specify the geometry of the double bond. We found no signals attributable to the alternative unsaturated termination $^{13}CH_2=C(C_6H_5)CO$ ($\delta \approx 118$ ppm[12]) or to the corresponding saturated end groups [$C_6H_5CH_2\text{-}^{13}CH_2$ and $^{13}CH_3CH(C_6H_5)$]. Unfortunately, due to the relatively high molecular weight, the signals corresponding to the two different carbomethoxy terminations could not be clearly identified. However, a signal at δ = 38.1 could safely be attributed to a CH_2 group in a structure of type **5**, based on DEPT experiments and the ^{13}CNMR data obtained for **4**. In all stereoregular samples of the copolymer in which only one carbomethoxy termination is observed, this signal is also always present. Since this group must correspond to the initiation of the polymeric chain, the signal at $\delta \approx 38$ identifies the regioselectivity of the first entering olefinic unit as a secondary insertion. Therefore, on the basis of the high regularity of the copolymer, the regioselectivity of the chain growth is also identified. This conclusion is also in keeping with the higher intensity (which should indicate the initiation of the chain) of the methoxy signal at higher field (54.0 as against 54.2 ppm), which can be assigned[12] to structure **5** rather than **6**.



5



6

On the basis of the secondary regioselectivity of the insertion, the presence of $C_6H_5CH=CHCO$ end groups shows that the termination of the chain is not a consequence of an inversion in the regioselectivity of insertion of the monomer. This seemed possible because of the selective synthesis of *E*-1,5-diphenylpent-1-en-3-one with [(dppp)Pd(*p*-$CH_3C_6H_4SO_3)_2$] (Scheme 1) as the catalyst precursor. The inversion of the regioselectivity was, indeed, recognized as a reason for termination for the polymerization of propylene with soluble Ziegler–Natta catalysts[13] and for the aforementioned isospecific oligomerization of styrene.[8]

To summarize, [(1,10-phen)Pd(*p*-$CH_3C_6H_4SO_3)_2$] gives rise to a carbomethoxypalladium species which catalyzes the strictly alternating copolymerization of carbon monoxide and styrene through secondary insertion of consecutive *ul* enantiofaces[14] of styrene units; chain termination is due either to a β-hydrogen elimination step or to alcoholysis of an acyl intermediate. The reasons for the high diastereoselectivity of the process, which appears to be chain-end-controlled, are not clear at the moment. It has been reported recently that complexes of the type [(Chelate ligand)Pd(COCH$_3$)(Solvent)]BF_4 coordinate styrene before under-

going olefin insertion and β-hydrogen elimination to *E*-1-phenylbut-1-en-3-one.[15] It should thus be possible to synthesize similar compounds of the type [(Chelate ligand)Pd(COR*)(Styrene)]BF_4 (R* = Chiral group related to the growing chain of the copolymer) in which enantioface discrimination can be investigated.

Oxidation of Alkanes by $[Fe(O)OH]^{\oplus}$ in the Gas Phase—the Role of Iron Oxidation State in C–H Activations**

By *Detlef Schröder* and *Helmut Schwarz**

Dedicated to Professor Horst Prinzbach on the occasion of his 60th birthday

Despite all progress our understanding of the mechanistic details of the metal-mediated functionalization of non-activated C–H bonds[1] is at best rudimentary. The role played by the iron complexes in some of these reactions has, however, been explained: high valence ionic iron oxides are present at the reaction center both in enzymatic and enzyme-free processes.[1, 2] However, the exact oxidation state of the iron as well as the exact composition of the active centers are still a matter of speculation.

On the other hand, a control of the stoichiometry and the oxidation states of the metal oxides has been realized in experiments in the gas phase; mass selected cations of metal oxides of well-defined composition are allowed to react with organic substrates. With this method it was recently possible to elucidate the details of the activation of CH_4[3] and C_2H_6[4] and the mechanisms of the dehydrogenation of alkanones[5] with naked $FeO^{\oplus}$. We report here on reactions of $[O=Fe-OH]^{\oplus}$ (formally an Fe^{IV} oxide) with selected alkanes under the conditions of Fourier Transform Ion Cyclotrotron Resonance (FTICR).[6, 7]

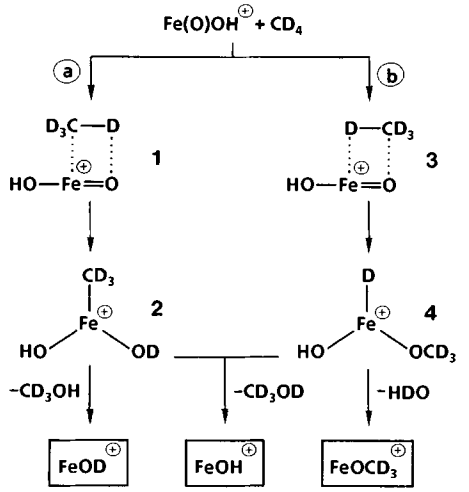
In the system $[Fe(O)OH]^{\oplus}/CH_4$ the processes described in Equation (a) take place.[14] Two findings are remarkable: 1) the rate constant k_1 of the overall reaction (ca. 10^{-10} $cm^3 s^{-1}$ per molecule) is only about half the value of that of the reaction of $FeO^{\oplus}$ with CH_4;[3] 2) the 12e-complex $[Fe(O)OH]^{\oplus}$ affords exclusively closed-shell neutral molecules (H_2O, CH_2O, and CH_3OH). On the other hand, in the case of the Fe^{III} compound $FeO^{\oplus}$, an 11e-complex, the $H^{\bullet}$ abstraction (generation of $CH_3^{\bullet}$) predominates.[3]

$$[O=Fe-OH]^{\oplus} + CH_4 \xrightarrow{k_1} \begin{cases} 25\% \rightarrow [FeOCH_3]^{\oplus} + H_2O \\ 10\% \rightarrow [HFeOH_2]^{\oplus} + CH_2O \\ 65\% \rightarrow [FeOH]^{\oplus} + CH_3OH \end{cases} \quad (a)$$

An insight into the mechanism is provided by the reaction of $[Fe(O)OH]^{\oplus}$ with CD_4 [Eq. (b)];[15] k_2 is one tenth of k_1.

$$[O=Fe-OH]^{\oplus} + CD_4 \xrightarrow{k_2} \begin{cases} 30\% \rightarrow [FeOCD_3]^{\oplus} + HDO \\ 25\% \rightarrow [FeOD]^{\oplus} + CD_3OH \\ 45\% \rightarrow [FeOH]^{\oplus} + CD_3OD \end{cases} \quad (b)$$

The abundance difference in generating $[FeOD]^{\oplus}$ or $[FeOH]^{\oplus}$ is not explainable by an isotope effect alone, since a C–D bond must be cleaved in both cases. All findings can however be described by Scheme 1: route ⓐ can, due to the symmetry of **2**, explain the formation of $[FeOH]^{\oplus}$ and $[FeOD]^{\oplus}$, but it cannot explain the specific loss of HDO. The latter presumably, arises from **4** (route ⓑ) in competition with the reductive elimination of CD_3OD. If one ignores kinetic isotope effects then it follows from the percentage ratio given in Equation (b) that ⓐ and ⓑ are almost equally probable.



Scheme 1. Mechanism of the reaction of $[Fe(O)OH]^{\oplus}$ with CD_4.

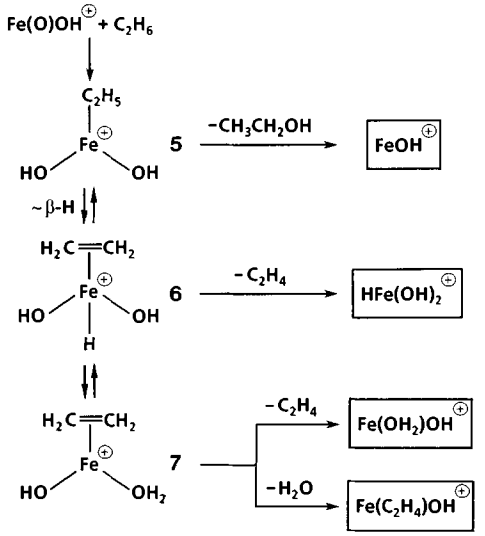
[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and the Volkswagen-Stiftung. We thank our colleagues Sir *D. H. R. Barton* (College Station), *H. Vorbrüggen* (Berlin), and *M. H. Zenk* (Munich) for literature citations.

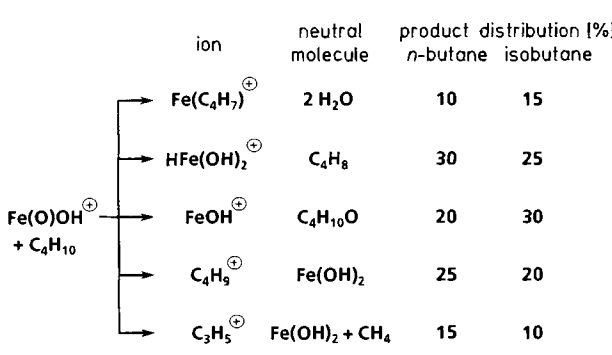
In the system $[Fe(O)OH]^{\oplus}/C_2H_6$ the generation of C_2H_4 (50%) and of $[FeOH]^{\oplus}/C_2H_6O$ (45%) predominates; formation of H_2O (5%) is a side reaction (Scheme 2). An in-



Scheme 2. Mechanism of the reaction of $[Fe(O)OH]^{\oplus}$ with C_2H_6.

sight into the course of the reaction in both processes is provided by the use of CH_3CD_3. Instead of unlabeled ethene, both $C_2H_2D_2$ and C_2HD_3 (2.3:1) are then found to be generated; we therefore conclude that the β-hydrogen transfer must be reversible.[16] Whether the generation of ethene from **6** or from **7** takes place is still unclear. Compound **7** is presumably the precursor for the dehydration. The product distribution $[FeOH]^{\oplus}/[FeOD]^{\oplus}$ (8:1) in the reaction of $[Fe(O)OH]^{\oplus}$ with CH_3CD_3 permitted the estimation of the isotope effect in the generation of **5**. If no secondary isotope effect occurs in the reductive elimination of ROD or ROH (R = ethyl), a value of $k_H/k_D \approx 3.5$ is obtained for the oxidative addition of the C–H and C–D bonds.[17]

In order to investigate the reactivity of $[Fe(O)OH]^{\oplus}$ with higher alkanes, reactions were carried out with *n*-butane and isobutane (Scheme 3). Besides the processes already ob-



Scheme 3. Reaction of $[Fe(O)OH]^{\oplus}$ with *n*-butane and isobutane.

served in the reaction with ethane, a double dehydration as well as hydride transfer to the iron oxide (generation of $C_4H_9^{\oplus}$ and $C_3H_5^{\oplus}$) is observed here for the first time.

The chemistry of $FeO^{\oplus}$[3] and of $[Fe(O)OH]^{\oplus}$ with simple alkanes is thus quite different; $FeO^{\oplus}$ is not only significantly more reactive than $[Fe(O)OH]^{\oplus}$, but also the product distribution is different, insofar as no radicals are detected in the case of the Fe^{IV} oxide. This result is possibly not without importance for an understanding of the mechanisms of enzyme-initiated oxygenations.

Grabowski, V. M. Bierbaum, *Organometallics 3* (1984) 498; b) K. K. Irikura, J. L. Beauchamp, *J. Am. Chem. Soc. 111* (1989) 75.

[7] Conditions: $Fe^{\oplus}$ ions were generated from a stainless steel target with the aid of a ND-YAG laser (Spectron system, λ = 1064 nm) by laser desorption/laser ionization [9] in the external ion-source of a Spectrospin CMS-47X mass spectrometer [8]. The metal ions were transferred to the actual ICR cell by a system of electrical potentials and lenses. After deceleration they were stored in a magnetic field of a superconducting magnet (Oxford Instruments) (maximum field strength 7.05 T). The $^{56}Fe^{\oplus}$ isotope, as also all other ions in the reactions to be described, were isolated by FERETS[10] and allowed to react with N_2O to give $FeO^{\oplus}$ [4c, 11]. Since this reaction is strongly exothermic (1.8 eV) [12], excited products are formed which are subsequently quenched by collision with the buffer gas (argon). $FeO^{\oplus}$ was isolated and allowed to react with CH_4 according to the procedure described in [3] to give $FeOH^{\oplus}$. After renewed isolation the latter was oxidized with N_2O to $[Fe(O)OH]^{\oplus}$. In order to generate a sufficient amount of $[Fe(O)OH]^{\oplus}$ for the reaction with alkanes, the sequence $Fe^{\oplus} \rightarrow FeO^{\oplus} \rightarrow FeOH^{\oplus}$ was carried out twice without isolation of the intermediates. The total cycle time (including reaction with the substrates and detection of the products) was ca. 20 s. This pulse sequence could only be realized, by using a total of four valves: pulse valve 1 for the injection of N_2O ($p \approx 10^{-5}$ mbar), pulse valve 2 for the injection of CH_4 (generation of $FeOH^{\oplus}$) with $p_{max} \approx 5 \times 10^{-6}$ mbar, leak valve 2 serves for the introduction of the alkanes, which react with $Fe(O)OH^{\oplus}$ ($p = 0.5-5 \times 10^{-9}$ mbar). Of the three conceivable connectivities for $[Fe(O)OH]^{\oplus}$ ($[O{=}Fe{-}OH]^{\oplus}$, $[O{=}Fe(O)H]^{\oplus}$, and $[FeOOH]^{\oplus}$) only $[O{=}FeOH]^{\oplus}$ is likely according to CID experiments and H/D exchange reaction with D_2O. Under CID conditions we obtained the ions $[FeOH]^{\oplus}$ (35%), $FeO^{\oplus}$ (30%) and $Fe^{\oplus}$ (35%); exchange with D_2O afforded $[OFeOD]^{\oplus}$[13].

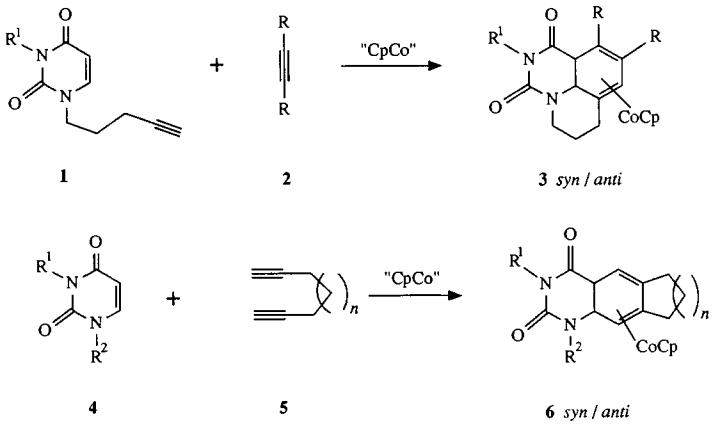
[13] For the characterization of $[M-H]^{\oplus}$ (M = transition metal) and $[M-OH]^{\oplus}$ ions see also a) T. J. Carlin, L. Sallans, C: J. Cassady, D. B. Jacobson, B. S. Freiser, *J. Am. Chem. Soc. 105* (1983) 6320; b) L. F. Halle, F. S. Klein, J. L. Beauchamp, *ibid. 106* (1984) 2543; c) C. J. Cassady, B. S. Freiser, *ibid. 106* (1984) 6176; d) D. B. Jacobson, B. S. Freiser, *ibid. 107* (1985) 72; e) C. J. Cassady, B. S. Freiser, *ibid. 108* (1986) 5690.
[14] Other processes, such as charge transfer ($[Fe(O)OH]^{\oplus} + CH_4 \rightarrow CH_4^{\oplus} + [Fe(O)OH]$) or hydride abstraction ($[Fe(OH)_2]^{\oplus} + CH_4 \rightarrow CH_3^{\oplus} + [Fe(OH)_2]$ do not take place.
[15] The loss of formaldehyde in the system $[Fe(O)OH]^{\oplus}/CD_4$ is slowed down by a considerable isotope effect. The product $[DFe(OHD)]^{\oplus}$ formed by loss of formaldehyde exchanges its deuterium atoms rapidly with the "residual water" present in the ICR cell; a quantitative description of this process is not possible.
[16] The signal corresponding to the elimination of C_2H_3D is too weak for quantitative evaluation. This holds true also for the cleavage of D_2O from the complex $[Fe(O)OH]^{\oplus}/CH_3CD_3$. H_2O and HDO are formed in the ratio 1:1.
[17] This value is based on the assumption that the pathway ⓑ for the activation of methane (Scheme 1) does not occur.



Scheme 1. The designation *syn* and *anti* indicates the position of the Co atom relative to the tertiary hydrogen atoms of the cyclohexadiene ring.

Chemo- and Stereoselective Cobalt-Mediated [2+2+2]Cycloaddition of Alkynes with Uracil Derivatives. A Novel Synthetic Entry to Modified Nucleosides**

By *Roland Boese,** *Jean Rodriguez*, and *K. Peter C. Vollhardt**

The uracil nucleus is present in a multitude of biologically important molecules, including the nucleic acids, and its selective modification has been a challenge in the quest for the development of new medicinal agents, particularly those effective for the treatment of cancer and viral infections, such as herpes and AIDS.[1] In this effort, the 5,6-double bond has played a limited role as a target for synthetic elaboration.[2] We report that $[CpCoL_2](L=CO, C_2H_4)$[3] activates this unit to undergo [2+2+2] cycloadditions to alkynes, generating novel fused 5,6-dihydropyrimidine-2,4-dione complexes, in most cases with remarkable chemo- and stereoselectivity (Scheme 1, Table 1).[4]

The starting materials **1** and **4** were prepared in high yields by adaptation or application of standard literature procedures.[5] The results summarized in Table 1 deserve several comments:

1) While systematic optimization has not been carried out, the efficiency of the cyclization is strongly affected by changes in the reaction conditions, as noted earlier in analogous cases.[6] Thus, the yields for **6a–c** are deceptively low, because of incomplete conversions of starting materials (the yields based on recovered **4a** are 96, 89, and 94%, respectively). Indeed, simply changing the solvent to boiling xylene increases the yield of isolated **6b** to 76%.

2) The reaction is remarkably chemoselective; especially noteworthy is the synthesis of **6**, in which the heterocyclic double bond is engaged in an entirely intermolecular fashion, a synthetic variant that has failed in the cases of the indole, pyrrole, and imidazole nuclei.[6]

3) As expected,[6] products **3** emerge mainly in the *anti*-configuration. Interestingly, however, the *syn*-isomers of **6a–c** are formed exclusively.

Table 1. Results of the respective cyclizations of **1** and **4** with **2** and **5** mediated by CpCo [4] [a].

Uracil derivatives **1/4**		Cocyclizing alkyne	Products (yield [%]) [b]
1a	$R^1 = C_6H_5CO$	**2a** $R = Si(CH_3)_3$	**3a** (28)[*anti:syn* = 5]
1a		**2b** $R = COOCH_3$	**3b** (61)[*anti*]
1b	$R^1 = H$	**2a**	**3c** (35)[*anti:syn* = 10]
		2b	**3d** (73)[*anti*]
4a	$R^1 = R^2 = CH_3$	**5a** ($n = 1$)	**6a** (53)[*syn*]
		5b ($n = 2$)	**6b** (57)[*syn*]
		5c ($n = 3$)	**6c** (22)[*syn*]
4b	$R^1 = CH_3$, R^2 = 	**5b**	**6d** (71) [7.5:4:1:1]
4c	$R^1 = CH_3$, R^2 = 	**5b**	**6e** (94) [45:4:1:1]
4d	$R^1 = H$, R^2 = 	**5b**	**6f** (37) [1:1:1:1]

[a] Conditions: **3**: To **1** (1 equiv.) and **2a** (co-solvent) or **2b** (5 equiv.) in THF is added $[CpCo(CO)_2]$ (1.5–1.8 equiv.) in THF at room temperature under N_2 over a period of 17–21 h (syringe pump) while irradiating the reaction mixture with a slide projector lamp (Sylvania ELH 300 W). **6a–d**: To irradiated **4a** (1 equiv.) in boiling toluene (or **4b** in xylene) is added under N_2 a mixture of **5** (2 equiv.) and $[CpCo(CO)_2]$ (2 equiv.) in toluene over a period of 18–22 h (syringe pump). **6e,f**: To irradiated **4** (1 equiv.) in boiling THF is added under argon simultaneously via two syringes **5b** (2 equiv.) and $[CpCo(CH_2CH_2)_2]$ in THF. [b] The diastereomeric ratios were determined ^{1}H-NMR spectroscopically on the crude products after flash chromatography on SiO_2 and before further chromatographic purification.

4) Most promising for future exploration are the cocyclizations of the enantiomerically pure nucleoside models **4b–d**, bearing what might be considered chiral auxiliary sugar substituents. Their potential utility is demonstrated in the *highly diastereoselective* construction of **6e**.

5) As discussed previously,[3, 6] the position of the cobalt atom relative to those of the adjacent cyclohexadiene tertiary hydrogens is readily ascertained exploiting the metal's distinctive magnetic anisotropy. In this way, the major diastereomer of **6d** and **6e** was assigned the *syn*-configuration. To corroborate these conclusions and perhaps obtain some clues with respect to the selectivity of the addition of **4c** to **5b**, an X-ray structural analysis of **6e** (major isomer) was performed (Fig. 1).[7]

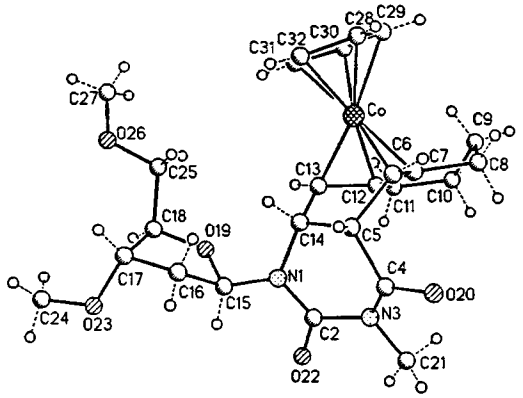

Fig. 1. Structure of **6e** (major isomer) in the crystal (SHELXTL). Selected distances [Å] and angles [°]: Co-C6 2.014(3), Co-C7 1.960(3), Co-C12 1.991(3), Co-C13 2.001(3), Co-Cp (ring centroid) 1.675, N1-C2 1.357(3), N1-C14 1.476(3), C2-N3 1.405(3), N3-C4 1.401(4), C4-C5 1.506(4), C5-C6 1.529(4), C5-C14 1.527(4), C6-C7 1.428(4), C7-C12 1.410(4), C12-C13 1.439(4), C13-C14 1.530(4), C6-C7-C12-C13 5.3, C6-C5-C14-C13 25.9, C4-C5-C14-N1 34.5.

While it is probably premature to speculate on the origin of the diastereoselectivity observed in the formation of **6e** (and the lack thereof on route to **6d** and **6f**), it is nevertheless presumed that the conformation of the sugar substituents in the starting materials is decisive.[9]

6) As noted previously,[3, 6] the [CpCo(diene)] complexes are subject to oxidative degradation, liberating hitherto unavailable heterocyclic ligands [e.g. CpCo-free **6b**, $CuCl_2$ (4 equiv.), Et_3N (12 equiv.), THF/H_2O 0 °C, 2 min, 91 %)].[4]

Extension of this methodology to other nucleic acid bases, and to the "tagging" of the nucleic acids themselves, are currently under investigation.

Arsenic Compounds in Organic Synthesis: Pentamethinium Salts from Aminoarsanes and Pyrylium Salts

By *Yves Madaule, Myriam Ramarohetra, Jean-Gérard Wolf,* Jean-Paul Declercq,* and *Antoine Dubourg*

Compared to the well known arsenic ylides, *Wittig* reagents frequently used in natural products synthesis,[1] other organoarsenic compounds are seldom used as synthetic intermediates in preparative organic chemistry. Examples

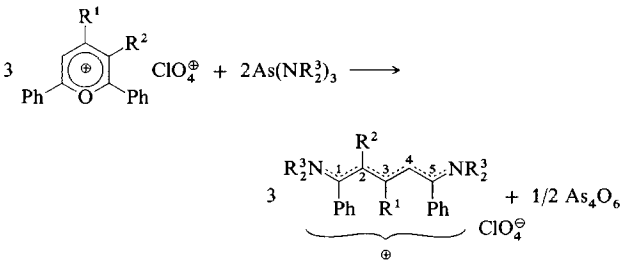
of such compounds that have been used are the very reactive *tris*(dialkylamino)arsanes[2] which react with ketones to give enamines.[3]

We describe here a novel reaction of aminoarsanes with pyrylium salts, which leads to formation of pentamethinium salts. Pyrylium salts[4] are important and versatile reagents, and methods have already been developed for the synthesis of some highly substituted derivatives.[5] In solution, oxonium and carbonium forms of the pyrylium salts are in equilibrium with each other. Our interest was thus compellingly turned to studying the electrophilic attack of aminoarsanes on this system. Due to the high reactivity of the starting compounds and the good "leaving-group" ability of As_4O_6, pure pentamethinium salts **1**–**5** are formed in high yields (≥90% in all cases in CH_3CN) in the reaction with 2,6-diarylpyrylium perchlorates (Scheme 1).



1, R^1 = Ph, R^2 = H, R^3 = Me
2, R^1 = R^2 = H, R^3 = Me
3, R^1 = Ph, R^2 = R^3 = Me
4, R^1 = Ph, R^2 = H, R^3_2 = $(CH_2)_4$
5, R^1 = Ph, R^2 = H, R^3_2 = $(CH_2)_2O(CH_2)_2$

Scheme 1. Synthesis of **1**–**5** from corresponding substituted pyrylium salts and dialkylaminoarsanes.

A closely related reaction of pyrylium salts with masked arsanes such as $As(SiMe_3)_3$ was previously attempted by *G. Märkl* et al., who hoped to obtain doubly substituted arsinines in this way. This Dilthey-like reaction (synthesis of pyridines) succeeded in the case of the synthesis of phosphinines from $P(SiMe_3)_3$ and pyrylium salts,[6] but in the case of the arsenic compounds only 3-azapyrylium salts were sufficiently electrophilic to lead to azaarsinines.[7]

All the compounds **1**–**5** were fully characterized spectroscopically (IR, UV, ^{1}H- and ^{13}C-NMR), mass spectrometrically, and by elemental analyses.

Table 1 summarizes the most important ^{13}C-NMR and UV data of **1**–**5** and of the 1,5-bis(dimethylamino)-substituted parent compound DMP ((5-dimethylamino-2,4-dienylidene)dimethylammonium perchlorate). A comparison of these data and those in the literature[9] indicates an alternate charge distribution (positive for C1, C3 and C5, negative for C2 and C4) independent of substituents effects (which could be calculated in part from the $\Delta\delta_{^{13}C}$ contributions of DMP, **1** and **2**). In fact, if we consider that the steric hindrance in our compounds increases in the order **2**, **4**, **1**, **5** and **3**, the UV spectra of these compounds indeed show a continuous bathochromic shift of λ_{max} and a continuous decrease in the extinction thus indicating a progressively weaker conjugation. This fact is confirmed by the X-ray structure analysis of **1**,[10] one of the sterically most crowded compounds (Fig. 1).

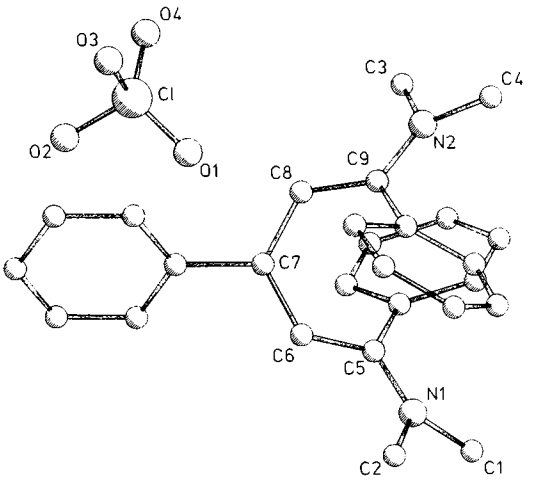


Fig. 1. Structure of **1** in the crystal. Selected bond lengths [Å] and angles [°]: N1-C1 1.488, N1-C2 1.466, N1-C5 1.305, C5-C6 1.417, C6-C7 1.385, C7-C8 1.412, C8-C9 1.422, N2-C3 1.437, N2-C4 1.470, N2-C9 1.361, C1-N1-C2 113.6, C1-N1-C5 125.7, C2-N1-C5 120.5, N1-C5-C6 120.3, C5-C6-C7 126.2, C6-C7-C8 124.2, C7-C8-C9 122.5, C8-C9-N2 119.2, C3-N2-C4 117.7, C3-N2-C9 120.4, C4-N2-C9 121.8. Deviations *D* from the mean plane (atom, *D* [Å]) N1-C5-C6-C7-C8-C9-N2 (N1, −0.14), (C5, 0.36), (C6, −0.16), (C7, 0.02), (C8, 0.16), (C9, −0.41), (N2, 0.17).

Unlike the well-known unsubstituted compound DMP,[11] compound **1** is a nonplanar, horseshoe-shaped, but still (*Z*)-conjugated system (average C–C bond length in the C_5-moiety ca. 1.41 Å). The terminal carbon atoms C5 and C9 are bent out respectively + 0.36 and − 0.41 Å from the mean N1–C5–C6–C7–C8–C9–N2 plane, which amounts to an almost symmetrical deformation. On the other hand, the ClO_4 anion rotates around Cl with two favored positions for O and O′, in each case with a structure occupation factor (SOF) equal to 77 and 23% respectively. The role of the substituents on C7 with respect to the structure of the carbon chain is presently being investigated.

We want to emphasize once again the characteristics of the reactions described here: 1) specificity: attempts to carry out

Table 1. Comparison of the most important ^{13}C-NMR (50.3 MHz, $CDCl_3$, 25°C, TMS) and UV data (CH_2Cl_2) of **1**–**5** and DMP [a].

	1	**2**	**3**	**4**	**5**	DMP [b]
^{13}C: (50.3 MHz, $CDCl_3$, 25°C, TMS)						
δC1; C5	169.29	170.16	165.75	165.16	168.77	161.62
δC2; C4	109.39	106.36	119.21, 108.80	108.52	111.52	102.77
δC3	169.03	161.66	163.75	168.81	170.71	162.52
UV: λ_{max} [nm], ε	500, 38000	442, 93300	521, 28500	498, 41000	517, 30000	416, 119500

[a] DMP is the only compound in this series for which numerous physical data are known. DMP crystallizes in two different forms, orange and yellow, which differ only in their arrangement in the lattice; in both cases the C_5-moieties and terminal amino groups are in a superimposable (*E*)-planar structure. The red form is obtained by crystallization with two molecules of H_2O. [b] ^{13}C-NMR spectrum in CD_3CN [8a], UV spectrum in EtOH [8b]. In the crystal λ_{max} = 412 nm and ε for the yellow modification 105600, for the orange modification 34600, and for the red modification 92700.

the same reaction with aminophosphanes led to addition compounds on the pyrylium moiety, analogously to the known addition of Ph_3P on pyrylium salts.[12] 2) Variation of the substitution pattern of pentamethinium salts which can be realized with both reagents: arsanes can easily introduce a large variety of amino groups; the pyrylium salt governs the substitution on the C_5-moiety. Using the method described here we were able to synthesize the first phenyl-substituted pentamethinium salts (and 1,5-disubstituted derivatives). Finally, it is important to underline the importance of developing new compounds in the pentamethinium series, which have proven useful in chemistry (dyes and intermediates in azulene synthesis[13], physics (laser, nonlinear optics in the crystal phase[14]) and biology (anthelmintics[15]).

Experimental procedure

1: A solution of 0.540 g (1.32 mmol) of 2,4,6-triphenylpyrylium perchlorate in 10 mL of acetonitrile was treated with 0.162 mL (0.88 mmol) of *tris*(dimethylamino)arsane. The mixture was stirred for two hours at room temperature. The fluorescence due to the pyrylium salt disappeared and the solution became deep red. As_4O_6 was then filtered off. After removal of the solvent, the precipitate was washed with pentane to yield a red powder (yield > 90%). Recrystallization from EtOH (100%) afforded bright red crystals, m.p. 195 °C, which were suitable for an X-ray structure analysis. **2**–**5** were obtained analogously.

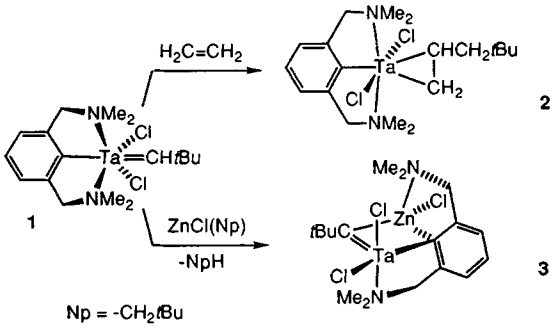
Effect of Intramolecular Coordination on Tantalum-Alkylidene-Centered Reactions: Synthesis and Structure of a Tantalum-Olefin Adduct and a Tantalum-Zinc-Alkylidene Complex**

By *Hendrikus C. L. Abbenhuis, Nantko Feiken, Henk F. Haarman, David M. Grove, Ernst Horn, Huub Kooijman, Anthony L. Spek,* and *Gerard van Koten**

Dedicated to Professor Hans-Georg von Schnering on the occasion of his 60th birthday

Recently, we started to explore the influence of intramolecular Lewis bases on tantalum-alkylidene reactivity. The potentially terdentate, monoanionic ligand $[2,6\text{-}(Me_2NCH_2)_2C_6H_3]^{\ominus}$ seemed well-suited for this research because of its demonstrated ability to stabilize high oxidation state transition metal centers [e.g. Fe^{III}[1] and Ni^{III}[2]] as well as unusual transition metal intermediates.[3] We have synthesized a tantalum-alkylidene complex $[TaCl_2\{2,6\text{-}(Me_2NCH_2)_2C_6H_3\}(CHtBu)]$ **1** that contains this spectator ligand.[4] Here we report the alkylidene-centered reactions of **1** with either an olefin (ethene) or a strong base (neopentylzinc chloride). These reactions (Scheme 1) lead to the formation of a tantalum-olefin adduct and a novel bimetallic tantalum zinc complex, respectively.



Scheme 1. Alkylidene-centered reactivity of **1**.

Treatment of the alkylidene complex **1** with an excess of ethene in pentane at 20 °C affords the neopentylethene adduct **2** which was characterized spectroscopically[5] and by X-ray structure analysis.[6] The structure determination (Fig. 1) shows **2** to be a mononuclear, distorted pentagonal bipyramidal tantalum complex. In this complex two chlorine atoms [Cl(1) and Cl(2)] occupy the axial *trans* positions. The equatorial plane contains the C(13) and C(14) atoms of the coordinated olefin together with the C(1), N(1) and N(2) atoms of the terdentate aryldiamine ligand. Both five-membered Ta–C–C–C–N chelate rings are puckered. The considerable lengthening of the olefinic bond (C(13)–C(14) = 1.436(10) Å) upon coordination to tantalum and the short distances between olefinic carbons C(13) and C(14) and tantalum (2.200(7) and 2.211(7) Å, respectively) make it more

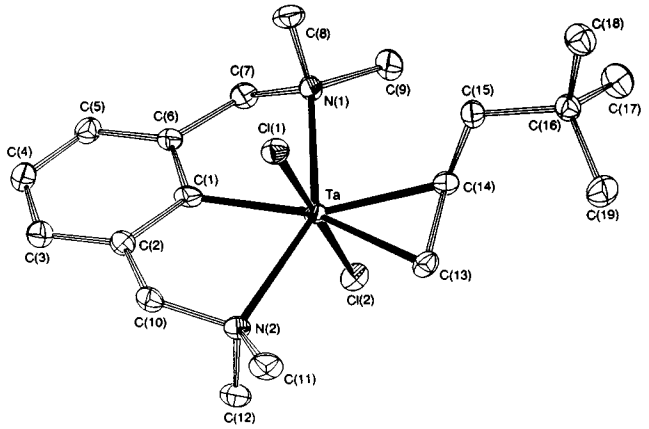

Fig. 1. Thermal motion ellipsoid plot (50% probability level) of **2** in the crystal. Selected bond lengths [Å] and bond angles [°]:Ta-Cl(1) 2.3702(18), Ta-Cl(2) 2.3608(18), Ta-C(1) 2.165(7), Ta-N(1) 2.353(6), Ta-N(2) 2.372(6), Ta-C(13) 2.200(7), Ta-C(14) 2.211(7); Cl(1)-Ta-Cl(2) 178.76(7), N(1)-Ta-N(2) 145.0(2), N(1)-Ta-C(14) 88.5(2), C(13)-Ta-C(14) 38.0(3).

acceptable to describe the structure as a tantalacyclopropane (with tantalum in oxidation state V).

The ^{1}H-NMR spectrum of **2**[5] is not temperature dependent to at least 80 °C, indicating a rigid structure of **2** also in solution. Characteristic for the terdentate coordination of the aryldiamine ligand are the four anisochronous NMe resonances at $\delta = 2.35$, 2.42, 3.27, and 3.45; olefinic multiplets shifted to high field at $\delta = 3.10$, 4.06, and 4.22 are indicative for the η^2-bonded neopentylethene function. In this function, the value of the olefinic $^1J_{^{13}C^{13}C}$ coupling is only 34 Hz (measured in an INADEQUATE $^{13}C\{^1H\}$-NMR experiment), which is more like the $^1J_{sp^3\text{-}C/sp^3\text{-}C}$ coupling in alkanes and cyclopropanes than the $^1J_{sp^2\text{-}C/sp^2\text{-}C}$ coupling in alkenes.[7] This finding again argues for the structure of **2** to be described as a tantalacyclopropane species.

Treatment of **1** with neopentylzinc chloride in Et_2O affords the bimetallic complex **3** which was characterized spectroscopically[5] and by X-ray structure analysis.[8] The structure determination (Fig. 2) shows **3** to be a tantalum-zinc-alkylidene complex that contains a bridging aryldiamine ligand that is nicely positioned to complete the coordination environment of both metal centers. The resulting coordination geometry around zinc is distorted tetrahedral, while the ligand array around tantalum is in between trigonal bipyramidal and square pyramidal (70% along the Berry pseudorotation coordinate towards the latter). The aryl ligand forms an unprecedented asymmetric bridge (via C(9)) between zinc and tantalum: the angle between the Ta–Zn vector and the least squares plane through the aryl carbon atoms is 65.2(2)° and deviates strongly from the expected 90° for a symmetrically bridging aryl unit. The structural data are such that it is possible to describe this bond as intermediate between either a two-electron three-center bond or a combination of a Ta–C σ-bond with a coordinative C → Zn bond involving electron donation from the filled p-orbital on C(9) to Zn. The latter description is equivalent to the type of bonding that would result from an electrophilic attack of a zinc cation at the *ipso*-carbon atom of the tantalum–aryl moiety.[10] The very short Ta=C alkylidene bond length (Ta–C(13) = 1.862(6) Å) together with the long Zn–C bond in the alkylidene unit (Zn–C(13) = 2.114(6)) also allow this complex to be described as a tantalum-alkylidyne species stabilized by a Lewis acid-base interaction with a zinc chloride cation. Similar arguments have been used to describe the structural characteristics of $[\{TaCl_2(\mu\text{-}C\textit{t}Bu)(MeOCH_2CH_2OMe)\}_2Zn(\mu\text{-}Cl)_2]$.[11]

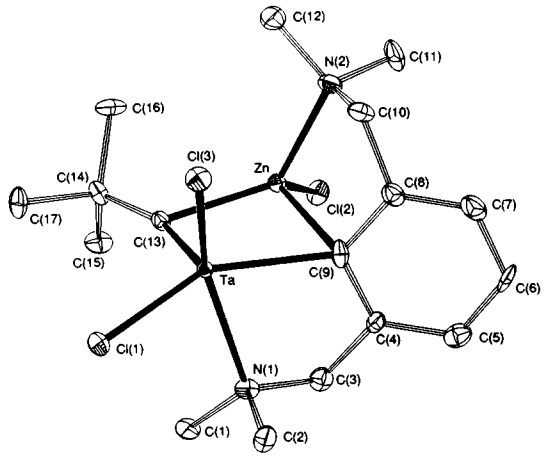

Fig. 2. Thermal motion ellipsoid plot (50% probability level) of **3** in the crystal. Selected bond lengths [Å] and bond angles [°]: Ta-Cl(1) 2.3830(15), Ta-Cl(3) 2.3628(16), Ta-C(9) 2.321(6), Ta-C(13) 1.862(6), Ta-N(1) 2.313(6), Ta-Zn 2.7286(9), Zn-Cl(2) 2.2143(16), Zn-C(9) 2.258(6), Zn-C(13) 2.114(6), Zn-N(2) 2.101(5); Cl(1)-Ta-Cl(3) 91.90(5), Cl(1)-Ta-C(13) 103.04(18), Cl(3)-Ta-C(9) 98.79(16), N(1)-Ta-C(9) 75.0(2), N(2)-Zn-Cl(2) 108.49(15), Cl(2)-Zn-C(9) 117.71(17), Cl(2)-Zn-C(13) 118.51(15).

Experimental Procedure

2: A purple suspension of 4.03 mmol of **1** [4] in pentane (100 mL) saturated with ethene at 20 °C was stirred for 24 h. The resulting green turbid solution was filtered, and the solvent removed from the filtrate in vacuo to give 3.23 mmol of emerald green **2** (80%). The complex can be crystallized from a minimum of pentane. Correct C,H,N analysis.

3: A purple suspension of 12.3 mmol of **1** [4], 7.12 mmol of $ZnCl_2$, and 6.16 mmol of $[Zn(CH_2\textit{t}Bu)_2]$ in Et_2O (100 mL) was stirred at 20 °C for five days. The solvent was removed in vacuo and the sticky residue triturated with hexane. The resulting red powder was extracted with 150 mL of warm (50 °C) benzene. The extract was concentrated in vacuo to ca. 50 mL and layered with pentane (200 mL). After storage of the extract at 20 °C for three days, large red crystals of **3** (9.70 mmol, 79%) were isolated. Correct C,H,N analysis.

Coupling of Alkynes with Carbene Ligands to Tungsten-coordinated Cyclopropenes and Their Stereoselective Isomerization to Vinylcarbene Complexes**

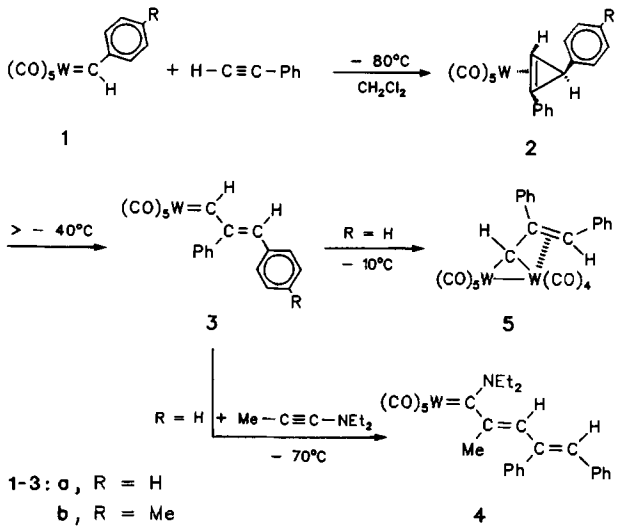
By *Helmut Fischer,* Josef Hofmann*, and *Elvira Mauz*

Dedicated to Professor Paul Binger on the occasion of his 60th birthday

Reactions of cyclopropenes with transition metals find many uses in organic synthesis.[1] For some of the transition metal-catalyzed reactions the sequence cyclopropene → cyclopropene complex → vinylcarbene complex (or metallacyclobutene) → organic product has been postulated.[2] Both cyclopropene complexes[3, 4] as well as vinylcarbene complexes[4, 5] and metallacyclobutenes[6] have been prepared from transition metal complexes and cyclopropenes. So far however, it has not been possible to verify the step cyclopropene complex → vinylcarbene complex.

Cyclopropene complexes are generally prepared by ligand substitution. Their synthesis from carbene complexes and alkynes has thus far never been reported, though the intermediary formation of a cyclopropene in the reaction of 2-butyne with a cationic benzylidenedicarbonyl(cyclopentadienyl)iron complex has been postulated on the basis of the reaction products.[7] We now report the synthesis of isolable cyclopropene complexes by addition of alkynes to carbene complexes and the demonstration of stereoselective intramolecular ring opening to give vinylcarbene complexes.

The benzylidene complex **1a**[8] reacts at −80 °C in one to two hours with an equimolar amount of phenylacetylene to give the cyclopropene complex **2a**. This is stable only below ca. −40 °C. Above −30 °C, **2a** rapidly isomerizes in solution to the vinylcarbene complex **3a**. Upon reaction of **1a** with



phenylacetylene on a preparative scale, mixtures of **2a** (major product) and **3a** are generally obtained which are difficult to separate. In contrast to **2a** however, **3a** already reacts rapidly at −70 °C with diethylpropynylamine to give **4**. The compounds **2a** and **4** can be separated chromatographically at −70 °C, hence **2a** is obtainable in pure form in this way.

The structure of the cyclopropene complex **2a** could be confirmed spectroscopically. The IR spectrum indicated a pentacarbonyl complex. The benzylidene-H NMR signal is shifted upfield by more than 14 ppm compared to that in **1a**, while the signal of the original sp-CH atom of phenylacetylene is shifted ca. 2 ppm downfield. The assignments are supported by the spectrum of [D]**2a** (obtained from **1a** and Ph–C≡C–D). The ^{13}C-NMR spectrum of **2a** shows, in addition to the signals for the CO substituents and the two phenyl groups, signals for three further carbon atoms between $\delta = 34$ and 65, of which two couple with the tungsten atom (J(W,C) = 16 and 19 Hz). Signals at low field ($\delta > 210$), characteristic for carbene complexes, are absent.

According to the NMR spectra the rearrangement of **2a** to **3a** is stereoselective; carbene complexes isomeric with **3a** could not be detected. The structure of **3a** follows unequivocally from the characteristic downfield position of the carbene-H and carbene-C NMR signals ($\delta = 16.64$ and 331.1, resp.). Above ca. −10 °C, **3a** reacts further to give **5** (major product) and two other, so far not fully characterized complexes. The formation of carbene-bridged dinuclear complexes such as **5** is typical for the thermolysis of strongly electrophilic carbene complexes in inert solvents.[8b, 10] X-ray structure analyses were carried out on the complexes **4**, **5** (Fig. 1)[9] and **6** (see below). In all compounds the two phenyl groups are *cis* oriented.

When a solution of **2a** in the presence of triphenylphosphane is warmed from −70 °C to −10 °C, the ylide complex **6** is formed. It follows, therefore, that the rearrangement **2a** → **3a** most likely proceeds intramolecularly. In the case of a dissociative process (cleavage of the cyclopropene and attack of the resulting pentacarbonyltungsten fragment at a C–C σ-bond of the cyclopropene with ring opening to give

[**] This work was supported by the Stiftung Volkswagenwerk, the Fonds der Chemischen Industrie, and the Land Baden-Württemberg (Project: Metal-Centered Substrate Transformations).

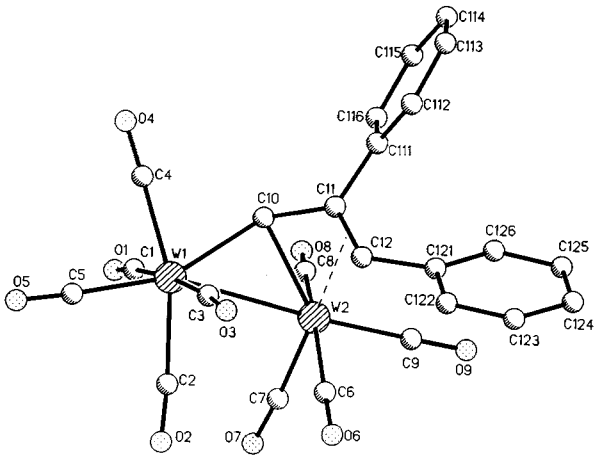

Fig. 1. Structure of **5** in the crystal (H atoms omitted). Important distances [Å], angles and torsion angles [°], standard deviations in brackets: W1–W2 3.119(1), W1–C10 2.238(8), W2–C10 2.216(8), W2–C11 2.417(9), W2–C12 2.459(8), C10–C11 1.458(10), C11–C12 1.421(10); W1–C10–W2 88.9(3), W1–W2–C10 45.9(2), W2–C10–C11 79.3(5), C10–C11–C12 116.4(7); W1–W2–C10–C11 135.6(5), W2–C10–C11–C12 −55.6(7), C10–C11–C12–C121 164.3(8).

3a) the formation of pentacarbonyl(triphenylphosphane)-tungsten would be expected. This, however, could not be detected. **6** is apparently formed by nucleophilic addition of PPh_3 to **3a**. (Phosphanes are frequently used to trap unstable carbene complexes.[11]).

Also the *p*-Me-substituted complex **1b** reacts analogously to **1a** with phenylacetylene. **2b** is slightly more stable than **2a** and rearranges somewhat more slowly to **3b**. Considerably more rapid, however, is the ring opening in the cyclopropene complex formed by addition of *p*-methylphenylacetylene to **1a**; this complex has been detected NMR spectroscopically only.

Formally, **3** is formed by insertion of the C≡C bond of the alkyne into the W=C bond of **1**. Insertion of electron-rich alkynes into metal–carbene carbon bonds have long been known[11, 12] and have been studied in detail.[13] However, the regioselectivity of these insertions and that of those described here are inverse. This shows that insertions of triple bonds into metal–carbene carbon bonds in coordinatively saturated complexes can proceed via several associative mechanisms.

Experimental

The reactions can be carried out both in CH_2Cl_2 as well as in CH_2Cl_2/pentane. The structures of all the complexes, with the exception of **3a**, were confirmed spectroscopically (IR, ^1H, ^{13}C-NMR) and by elemental analyses. **3a** was characterized only spectroscopically. X-ray structural analyses were carried out on complexes **4**–**6**.

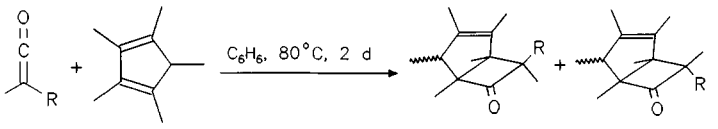
[**] Electron Transfer Catalyzed Reactions, Part 1. This work was supported by the Deutsche Forschungsgemeinschaft, the Land Baden-Württemberg, the Wissenschaftliche Gesellschaft Freiburg, and the Fonds der Chemischen Industrie (*H.v.S.*). We thank Prof. Dr. *C. Rüchardt* for continued support of our studies and *R. Burth* and *C. Wöhrle* for help with the preparative work. Thanks are also due to Prof. *Dr. H. Fritz* and Dr. *D. Hunkler* for recording the ^1H-NMR-NOE difference spectra and for help with their interpretation.

are as a rule thermodynamically more stable they are obtained only in very few special cases.[2] An explanation for this periselectivity has been given by *Woodward* and *Hoffmann*:[3] with the *antara,supra* [2 + 2] cycloaddition, a route with low activation energy is available for ketenes and dienes. Studies by *Bauld*[4] in particular have recently shown that both symmetry-allowed as well as symmetry-forbidden cycloadditions can be accelerated considerably by radical-cation catalysis. We now describe the application of this method to ketene cycloadditions so as to realize activation of electron-rich and hence thermally unreactive ketenes and to steer the selectivity in the direction of the [4 + 2] cycloadducts.

The electron-rich arylmethylketenes **1** (E_p = 0.91 V) and **2** (E_p = 1.11 V) were chosen as model compounds.[5] Both ketenes are sufficiently stable towards homodimerization



1 2 3 4a 4b 5a 5b

1, 4 : R = *p*-$MeOC_6H_4$; 2, 5 : R = *p*-MeC_6H_4

under suitable conditions and can therefore be obtained in high purity. Since the oxidation potentials of the reactants have to be matched for radical-cation catalyzed, crossed cycloadditions,[6] pentamethylcyclopentadiene **3** (E_p = 0.87 V) was chosen as diene. As electron-transfer catalyst we chose tris(*p*-tolyl)ammoniumyl hexafluoroantimonate **S1** ($E_{1/2}$ = 0.76 V).[7]

$(p\text{-}MeC_6H_4)_3N^{\bullet\oplus}\ SbF_6^{\ominus}$

S1

The slow thermal reaction (2 d, 80 °C) of **1** or **2** with **3** to give the cyclobutanones **4** (54%)[8] and **5** (37%) confirms the low reactivity of the ketenes. As in related systems, the *endo* isomers (**4a**:**4b** = 53:1; **5a**:**5b** = 27:10) are preferentially formed.

The ammoniumyl-salt induced reactions of **1** or **2** with **3** proceed orders of magnitude more rapidly, and are complete within a few minutes at 0 °C[9] (Table 1, Scheme 1). The Diels-Alder adducts **6** and **7**, respectively, are formed selectively as main products;[10] not even trace amounts of the cyclobutanones **4** and **5** can be detected. Surprisingly, additional dimers are formed in small yields as by-products

Table 1. Cycloaddition products in the ammoniumyl salt **S1** induced reaction of the ketenes **1** and **2** with the diene **3** in the molar ratio 1:1.

Ketene	Mol-% S1	*t* [min]	Products [a]
1	25	5	**6a** (31%), **6b** (11%), **8** (11%)
1	25	2	**6a** (24%), **6b** (10%), **8** (8%)
1	25	0.5	**6a** (18%), **6b** (6%), **8** (4%)
1	25 [b]	10	**6a** (21%), **6b** (8%), **8** (18%)
1	50 [c]	20	**6a** (18%), **6b** (5%), **8** (n.d.)
2	50 [d]	5	**7a** (30%), **7b** (9%), **9** (<1%)

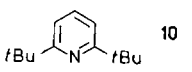
which could be identified as cycloheptadienones **8** and **9**, respectively.[11]

To establish whether radical cation or acid catalysis is involved in this reaction we investigated the influence of 2,6-di-*tert*-butyl pyridine **10** on the product formation.[12, 13] The addition of **10** to the reaction of **1** with **3** completely suppresses the formation of **8**, whereas in the case of **6** only the yield is somewhat lower. This rules out acid catalysis for the formation of **6** and **7**, whereas **8** and **9** are apparently formed via acid catalysis, as could be additionally documented by control experiments.[14]

In analogy to related reactions,[4] this cycloaddition could be explained in terms of a radical cation catalyzed chain mechanism. However, here, the chains must be very short. A problem of this reaction is apparently the high acidity[13] of the radical cations occurring as intermediates, so that in end effect acid catalyzed reactions are always taking place at the same time. Naturally these side reactions can be prevented by addition of **10**; however, added base also favors deprotonation of the radical cations and removes them from the cycloaddition.



10

The Diels-Alder adducts **6** and **7** obtained selectively in the presence of **S1** are formed with marked preference for the *endo*-isomers (**6a**:**6b** = 3:1; **7a**:**7b** = 3:1), as is also observed in other radical cation catalyzed Diels-Alder reactions.[4] Remarkably, the reaction is extremely facioselective: in each case only the *anti*-isomer could be detected NMR spectroscopically. This demonstrates once again that radical cation catalyzed reactions can proceed very selectively despite low activation energies.

Investigations by *Bauld* et al. have shown that radical cation catalyzed Diels-Alder reactions are not necessarily concerted, but often proceed stepwise.[15] Radical catalyzed cyclobutanation and 1,3-sigmatropic ring expansion take place consecutively. This raises the question of whether cyclobutanones also occur as intermediates in the formation of **6** and **7**. A detailed study by *Schwarz* et al.[16] of the reaction of the ethenone radical cation with ethylene in the gas phase clearly indicates, in contrast to results of a study by *Gross* et al.,[17] that the cyclobutanone radical cation is no minimum on the energy hypersurface along the reaction coordinate. Consequently, a concerted mechanism is plausible for the cycloaddition step leading to formation of **6** and **7**.

To answer the question concerted/stepwise the *endo*- and *exo*-vinylcyclobutanones **4a** and **4b** were allowed to react

under the conditions of the ammoniumyl salt-initiated cycloaddition. In order to avoid acid-catalyzed reactions of the vinylcyclobutanones, as have been described by *Lee-Ruff* et al.,[18] the reaction was carried out in the presence of 50 mol-% **S1** and 55 mol-% **10**. After 5 min the unchanged reactants **4** were recovered quantitatively. Hence, the cyclobutanones **4** cannot be intermediates of the ammoniumyl salt-initiated Diels-Alder reaction of **1** or **2** and **3**.

The results reported here show that Diels-Alder adducts can be obtained selectively via the ammoniumyl salt-initiated cycloaddition of ketenes and dienes. This mode of reaction ideally complements the thermal chemistry of the ketenes. Further studies are in progress concerning the reaction mechanism and the preparative scope of the reaction as well as the control of selectivity.

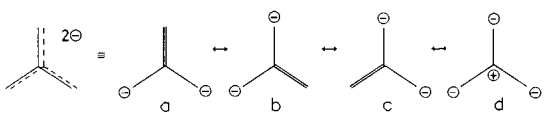
The Structure of the Trimethylenemethane Dianion and the Question of Y-Aromaticity**

By *Alberto Gobbi, Preston J. MacDougall,* and *Gernot Frenking**

The facile formation of trimethylenemethane dianion **1** from isobutene and butyllithium[1] has been explained in terms of a novel type of conjugative stabilization ("Y-aromaticity")[2] which is supposedly exhibited in the D_{3h} form **1a**[2, 3] (Fig. 1).



1a

Fig. 1. Resonance formulas for trimethylenemethane dianion **1a** (in the D_{3h} form).

Agranat and *Skancke*[3a] studied several isomers of $C_4H_6^{2\ominus}$ using ab initio methods and reported that **1a** was the most stable conformation. The stability of **1a** has also been attributed to favorable charge alternation.[4] Both explanations have been dismissed recently by *Wiberg*,[5] who studied the effect of replacing the terminal methylene groups in **1a** with oxygen.

We now report that all previous ab initio studies of **1**[2–5] have been concerned with a nonequilibrium geometry.[1,7] Dianion **1** has a nonplanar geometry with strongly pyramidal CH_2 groups. Ab initio calculations[6] show that the force-constant matrix of **1a** has three or four negative eigenvalues depending on the theoretical level![7] Thus, **1a** is a higher order saddle point on the $C_4H_6^{2\ominus}$ potential-energy surface and not "the most stable conformation".[3a] Relaxation of the symmetry constraint yields two conformations (**1b** and **1c**) which are true minima. The calculated structural data of **1a**, **1b**, and **1c** are shown in Table 1.

The methylene groups in the conformational minima **1b** and **1c** are strongly pyramidalized. The four carbon nuclei are nearly coplanar. The small deviation of the torsion angle C2-C1-C3-C4 from 180° is 2.9° in **1b** and 9.2° in **1c** (Table 1). The dihedral angle α between plane containing the CH_2

[c] Calculated total energy for **1b** is − 155.21544 Hartree at MP2/6-31 + +G(d)//HF/6-31G(d); at HF/6-31G(d) the total energy of **1b** is − 154.55975 Hartree. [d] Number of imaginary frequencies.

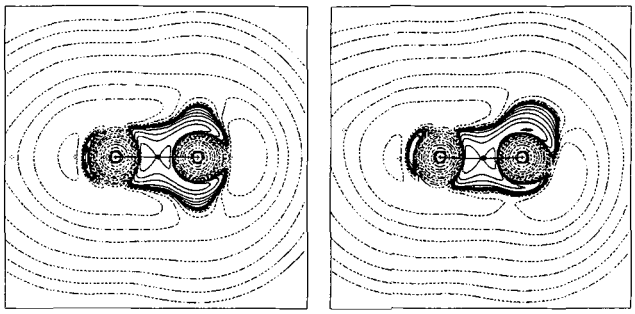

Fig. 2. Contour line diagrams of the Laplacian of the electronic charge distribution $-\nabla^2\rho(r)$ of **1a** and **1b** in the vertical (σ_v) plane. Dashed contour lines are in regions of charge depletion and solid lines in regions of charge concentration. The solid line connecting the atoms indicates the bond axis, filled circles denote bond critical points. In both plots, the central carbon C1 is on the left and C2 on the right.

groups and that defined by the terminal carbon atoms is 48.5° and 44.5° in **1b** and 42.1° in **1c**. The natural bond orbital (NBO) analysis[8] of the wave function shows the following hybridizations at carbon in the C–H bonds of **1b**: $sp^{2.93}$ (C2–H5), $sp^{2.83}$ (C3–H7), $sp^{2.84}$ (C3–H8). In **1c**, the carbon atoms are $sp^{2.46}$ hybridized in the C–H bonds. This indicates hybridization tending towards sp^3 at the terminal carbon atoms. In agreement with the change in hybridization from sp^2 towards sp^3, the C–C and C–H bonds are longer in **1b** and **1c** than in **1a**. The NBO analysis also suggests that the optimal Lewis-type structure for **1a** has nine bond orbitals (three C–C and six C–H bonds) and three lone-pair orbitals occupied by 1.75 electrons (C3, C4) and 1.77 electrons (C2). However, an occupation of 0.72 electrons is calculated for a non-Lewis type p(π) orbital at C1, which indicates strong π-electron donation from the lone-pair electrons into the formally empty p(π) orbital at C1. Thus, the "best" resonance form for **1** is *d* in Figure 1, but with pyramidal CH_2 groups.

Details of the C–C binding type and the electronic structure of **1a** and **1b** are revealed by the analysis of the one-electron density distribution $\rho(r)$ and its associated Laplacian $\nabla^2\rho(r)$.[12]

Figure 2 shows the contour lines of $\nabla^2\rho(r)$ for the C–C bonds of **1a** and **1b**.[13]

Inspection of the diagrams shown in Figure 2 clearly shows that the π-electron distribution of the C–C bond in **1a** and **1b** is shifted toward the terminal carbon atom. There is depletion ($\nabla^2\rho(r) > 0$, dashed lines) rather than charge concentration in the π-electron area at the central carbon atom. The Laplacian distribution for **1b** shows the existence of a nonbonded charge concentration, which is interpreted as a lone pair at the terminal carbon atom.[12] The shift in the charge distribution is also revealed by the location of the C–C-bond critical points r_b,[14] which are shown as dots in Figure 2.[12] In **1a**, r_b is located 0.755 Å from the central carbon atom and 0.679 Å from the terminal C. In **1b**, the corresponding values are 0.777 Å and 0.675 Å.[13] Thus, the C–C bonds in **1a** and **1b** are characterized by a strong shift of σ density towards the central carbon, with a concomitant counter-migration of the π density to the terminal carbons. This σ/π equilibrium has been observed and rationalized in allyl ions.[15]

The results of the geometry optimization indicate that **1** tries to adopt a structure in which the repulsion of electronic charge is minimized. In **1b**, two lone pairs are on one side of the plane spanned by the carbon atoms and one lone pair is one the other side.[11] In **1c**, all three lone pairs are on the same side of the plane. Consequently, **1b** is more stable than **1c** by 2.0 kcal mol^{-1} (Table 1). The minima are only 4.3 kcal mol^{-1} (**1b**) and 2.3 kcal mol^{-1} (**1c**) lower in energy than **1a**, which indicates a very low barrier for interconversion.

The trimethylenemethane dianion **1** is more stable than its isomeric forms, *cis*- and *trans*-butadiene dianions **2** and **3**, albeit much less than was previously reported.[3] Also, **2** and **3** adopt nonplanar geometries where the methylene groups are pyramidalized with the hydrogen atoms on the same (**2a**, **3a**) or on opposite (**2b**, **3b**) sides of the plane spanned by the carbon atoms (Table 2). Planar **2** is calculated with two (three in case of planar **3**) negative eigenvalues of the force-constant matrix (HF/6-31G(d)). The four conformational minima **2a**, **2b**, **3a**, and **3b** are 6.1–7.3 kcal mol^{-1} higher in energy than **1b** (Table 2). Previous studies, which considered

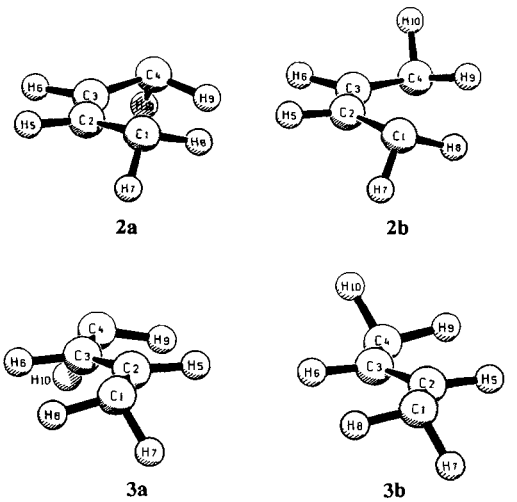

Table 2. Calculated structures for **2a**, **2b**, **3a**, **3b**. The structural data are given at HF/6-31G(d), the relative energies at MP2/6-31 + + G(d)//HF/6-31G(d). For details see Table 1.

[a] Dihedral angle between the planes H7-C1-H8 and C1-C2-C3. [b] Relative to the energy of **1b** (see Table 1).

only planar **2** and **3**, reported energy differences of 26.4 and 30.6 kcal mol^{-1} relative to **1**.[3a] The slightly higher stability of the *cis* isomers **2a** and **2b** over the *trans* forms **3a** and **3b** may be explained by the better interactions between the n$_-$ combination of the terminal lone-pair orbitals with the C–C π^* bond, which is also found for isoelectronic difluoroethylene.[9] In agreement with this interpretation, the terminal C–C bonds are shorter and the central C–C bond is longer in **2a** and **2b** than in **3a** and **3b** (Table 2). In fact, the relative energies of the most stable conformations of **1**, **2**, and **3** are even quantitatively nearly the same as found for isoelectronic 1,1-, 1,2-*cis*, and 1,2-*trans* difluoroethylene.[9b]

Why are the Y-shaped dianions **1b** and **1c** more stable than the *cis* and *trans* isomers **2a**–**3b**? The comparison of the optimized structures which are true minima on the $C_4H_6^{2\ominus}$ potential-energy surface provides a reasonable answer. The negative charge is distributed over *three* carbon atoms in **1b** and **1c**, while it is concentrated mainly on *two* carbon atoms in the *cis* and *trans* forms. Moreover, the calculation of the charge distribution using the NBO analysis[8, 10] indicates a small positive charge at the central carbon atom of **1b** and **1c** indicating attractive interactions between C1 and the terminal carbon atoms (Table 1). Internal coulombic stabilization as the cause of the higher stability of **1** has already been suggested by *Klein*,[4] although he considered only the D_{3h} form **1a**. *Wiberg*[5] dismissed the idea of charge stabilization on the ground of the small size of the positive charge at C1. However, important is not the absolute size but the *difference* in charge interactions between **1b** and the isomeric forms **2a**–**3b**. In **1b**, there are small but *attractive* coulombic interactions between all carbon atoms directly bonded to each other. In **2a**, **2b**, **3a**, and **3b**, all carbon atoms are negatively charged and the coulombic interactions are purely repulsive. Although **2** and **3** have a π bond which is missing in **1**, the additional binding energy of the π bond is lower than the sum of the stabilizations of the three lone pairs in **1**, as a result of the adjacent π vacancy. We also refer to recent theoretical studies which show that π delocalization in benzene and other ring compounds is destabilizing, and that it is the energy of the σ bonds which enforces bond equalization.[16]

The analysis of the geometries and electronic structures of the conformational energy minima **1b**–**3b** clearly shows that the higher stability of the Y-shaped structures **1b** and **1c** relative to the *cis* and *trans* isomers **2a**–**3b** is caused by *maximally distant localization of the π electrons*, not delocalization or even aromaticity. All isomers adopt nonplanar geometries with strongly pyramidalized methylene groups to further separate the lone-pair electrons; this is achieved optimally in **1b**. There is no Y-aromaticity in the trimethylenemethane dianion!

[7] The geometries and force-constant matrices of **1a**, **1b**, and **1c** have been calculated at the following levels of theory, and the number of imaginary frequencies for **1a** is given in parentheses: HF/3-21G (3), HF/6-31G(d) (3), HF/6-31 + + G(d) (4), MP2/6-31G(d) (4). Since the differences in the optimized geometries were found to be insignificant, the optimizations for isomeric forms of **2** and **3** have been carried out only at HF/6-31G(d).

[10] The calculated result that **1b** and **1c** have small positive charges at the central carbon atom has been found at all levels of theory employed here. It has also been found for **1a** using a different technique for analyzing the molecular wave function (ref. [5]).
[11] In ref. [5], the optimized structure of a dilithio derivative of isobutene is shown, which exhibits a nonplanar C_4H_6 geometry with weakly pyramidalized CH_2 groups which is very similar to **1b**. This was interpreted [5] as resulting from a tendency to maximize the coulombic attraction between the lithium cations and the anion. Our results show that isolated **1** adopts an even more strongly pyramidalized structure.

Cyclooctatetraenylene Vinylenes**

By Petra Auchter-Krummel and *Klaus Müllen**

Dedicated to Professor Heinz A. Staab on the occasion of his 65th birthday

The chemistry of stilbene, the higher oligo(*para*-phenylene vinylenes) (**1**),[1, 2] and the poly(phenylene vinylenes) (**2**)[3, 4] have been studied intensively from point of view of their synthesis, physical organic chemistry, and applications.[5] The outstanding redox and photochemical properties of the benzene homologue, cyclooctatetraene (COT),[6, 7] makes the successive replacement of the phenylene units in the linear π systems of **1** and **2** by cyclooctatetraene attractive. We

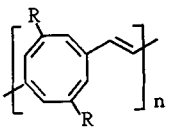
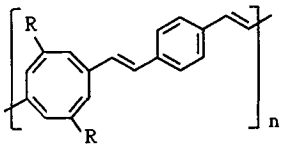
show that, starting from 1,5-difunctionalized cyclooctatetraene, derivatives of the type **3** and **4**, can be synthesized which exhibit extended π conjugation. Cyclic voltammetric and NMR spectroscopic investigations confirm the role of the title compounds as "charge storage" units and as substrates for thermally inducible charge transfer.

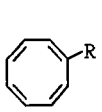


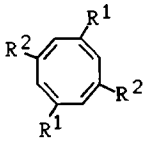
3, R = CH_3



4, R = CH_3

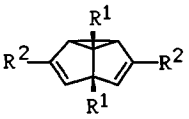
The known cyclooctatetraene carbaldehyde **5a** and its easily accessible phosphonium salt **5b** serve as building blocks for olefination by Wittig or McMurry reactions.[8] Suitable 1,5-difunctionalized cyclooctatetraenes are not known. We therefore prepared the diester **6a** by thermolysis[9] of the semibullvalene **7**[10] and then transformed **6a** into the difunctional starting compounds **6b** and **6c**. The other starting compounds, **8** and **9a**, are easily accessible. The stepwise construction of a linear π system via the dialdehyde **13b**, also requires a compound in which one functionality has been protected, such as the ketal **9b**.



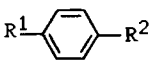


5a, R = CHO
5b, R = CH_2PPh_3Br

6a, $R^1 = CH_3$, $R^2 = COOCH_3$
6b, $R^1 = CH_3$, $R^2 = CH_2OH$
6c, $R^1 = CH_3$, $R^2 = CHO$



7, $R^1 = CH_3$, $R^2 = COOCH_3$



8, R^1 = H, $R^2 = CH_2PPh_3Br$
9a, $R^1 = R^2 = CH_2PPh_3Br$
9b, R^1 = , $R^2 = CH_2PPh_3Cl$

The following characteristics are typical for the construction of the chain:[11]
– The Wittig reaction gives better yields than McMurry coupling (**10a**[12] from **5a** and **5b** (KO*t*Bu, THF, 25°C, 65%; **10a** from 2 equiv of **5a** ($TiCl_4$), Zn/Cu, THF, 60°C) 19%).
– Chains with terminal phenyl units are distinctly more easily accessible than those with terminal cyclooctatetraene units (**13a** from **6c** and **8** 70%; **14** from **5a** and **9a** 12%).
– The "trimer" **11** and the monoaldehyde **10b** are both formed from **6c** and **5b**; **10b**, however, requires 2 equiv of **6b**.
– *E*/*Z* isomeric mixtures are formed; attempts at iodine-catalyzed formation of the all-*E* isomers (all structural formulas represent all-*E* isomers) led to decomposition, but separation of the isomers by chromatography is possible.
– The attempt to obtain a polymer from **6c** and **9a** affords the compound **4** with $n \approx 5$ as a THF-soluble fraction (30% w/w). According to the IR spectra, the higher molecular weight fractions have the same overall structure as the shorter chain products.
