On gradually raising the scan rate when the steady state of an ultramicroelectrode has already been established, one observes the transfer to the semi-infinite planar diffusion as a change from a sigmoid voltammogram to the classic cyclic voltammogram with potential-separated anodic and cathod-

ic waves. These so-called edge effects first drew electrochemists' attention to the peculiar properties of microelectrodes.[6, 13, 19, 55, 98, 99] When microelectrodes with radii between 25 and 500 μm are used, the influence of these edge effects is noticeable at upper scan rates of 5 and 0.05 Vs^{-1}, respectively. Thus, the quantitative data on the kinetics of the heterogeneous charge transfer in these time domains must take into consideration the influence of these edge effects on the peak separation and the shape of the voltammogram.[19, 100–102] On the other hand, in this time scale the iR drop and the capacitance C_d will have little effect on the voltammetric signal. Therefore, using a single microelectrode and varying the scan rate can provide very reliable data on the rate constants of the heterogeneous charge transfer, as described by Nicholson and Shain.[8, 103]

The qualitative jump that makes ultramicroelectrodes so interesting takes effect at scan rates above, say, 500 Vs^{-1}. From about this level the growing iR drop as well as the increasing influence of the RC time constant normally render data obtained with conventional electrodes impossible to interpret. For rates greater than 500 Vs^{-1}, however, conditions for planar diffusion are more or less fulfilled, even for nanodes with radii as small as 1 μm ($\sigma \leq 0.2$). Thus, as v increases, the faradaic current i_f increases proportional to $v^{\frac{1}{2}}$ and the capacitive charging current i_c proportional to v. However, due to the reduction in the radius and the corresponding lower current values, both the RC term [Eq. (19)] and the iR drop [Eq. (24)] decline, and as a result UMEs can be used in a fast-scan range up to 10^5–10^6 Vs^{-1}. "Classical" cyclic voltammetry reaches its limits at scan rates of a few megavolts per second, because the diffusion layer and the electrical double layer then assume almost the same size and can no longer be separated, as theory requires.[104]

In principle, the fast-scan technique provides much the same kind of information as conventional cyclic voltammetry,[34] with one important distinction: the time scale for measurements extends to below 1 μs (for example, at 10^6 Vs^{-1} $\tau = 25$ ns where $\tau = RT/vF$). Thus, it has become possible to measure the redox potentials of highly reactive intermediates[106–108] and rate constants for the rapid heterogeneous charge transfer,[38, 106, 109] as well as to analyze complex mechanisms including chemical steps.[64, 110, 111] Quantitative evaluations of the diffusion-controlled steps of second-order reactions are now also reality. Nor is there any difficulty in investigating and evaluating simple EC reactions.[112]

The group of McCreery were the first to obtain small time constants using ultramicroelectrodes.[113] They were able to prove through chronoamperometry and spectroelectrochemical techniques that within 150 ns concentration profiles of electroactive particles build up in the diffusion-layer region of microelectrodes. With time-dependent absorption measurements of chronoamperometrically produced radical cations of chlorpromazine (CPZ) in the presence of equimolar quantities of dopamine, they obtained values of 6.2×10^7 $M^{-1}s^{-1}$ for the rate constant of the homogeneous $CPZ^{\cdot+}$ cation reduction by dopamine at pH 6.8.

Since then, many voltammetric investigations have been carried out on electron transfer systems with coupled chemical reactions, such as addition,[106, 114] isomerization,[115] dimerization,[116] and homolytic cleavage,[112, 117] to name some examples.

In some cases, the fast-scan technique has made it possible to obtain direct evidence of the existence of reactive intermediates as well as new, unequivocal findings on reaction mechanisms. For instance, in the very rapid homolytic cleavage of halide ions from radical anions of aryl halides, it was not always clear whether the bond-breaking step occurred concurrently with the charge transfer as an inner sphere reaction,[118] or whether the cleavage took place after the formation of the radical anion, that is, in a two-step reaction. Measurements by Saveant et al.[117] of the reduction of 9-bromoanthracene confirm that at scan rates above 100 000 Vs^{-1} the formation of the radial anion is reversible. This proves the intermediacy of a highly reactive anion; the rate constant for the subsequent cleavage of the bromide ion is $k_f = 5.9 \times 10^6$ s^{-1}.

For a long time it was disputed whether the cation in the dimerization of radical cations of aromatic amines and heterocyclic compounds first coupled with its neutral species (RS dimerization) or immediately underwent radical cation coupling (RR coupling). Several independent studies support the assumption of RR coupling reactions in most cases.[116] The electropolymerization of heterocycles such as pyrrole and thiophene also involve dimerization steps. Again, Saveant et al. have demonstrated the existence of highly reactive cations of pyrrole and some derivatives within the voltammetric time scale[119] and determined the associated redox potentials. Pyrrole dimerization ($c = 4$ mM) becomes partially reversible at scan rates greater than 18 000 Vs^{-1}, which corresponds to an average cation lifetime of 30 μs. The oxidation of 3,3′-dimethoxy-2,2′-bithiophene[120] demonstrates the complexity of the reaction path involving coupling steps in a growing polymer chain. Fast-scan experiments show that the cations formed at the electrode with a rate constant of 10^{+5} initially couple to form a tetramer, which, in turn, after the loss of two protons, also transforms into a dication (Fig. 15). At scan rates greater than or equal to 5000 Vs^{-1} ($c = 1$ mM) the reaction at the electrode is chemically reversible. Further measurements at high concentrations and slow scan rates confirm that the dications comproportionate in solution with unchanged starting monomer, thereby autocatalytically initiating a new coupling step.

The fast-scan technique has proved particularly successful in investigating the kinetics of fast heterogeneous charge transfer reactions.[106, 109, 121–127] Even C_{60}, only recently accessible in large quantities, has already been measured.[114, 127] Provided that the iR influence is reduced to a negligible minimum, the method of Nicholson and Shain[8, 103] can be used without any complications to obtain rate constants from the separation of the peak potentials of the anodic and cathodic waves ($\Delta E_p = E_{pa} - E_{pc}$) (Fig. 16). To determine values between 0.01 and 0.1 ms^{-1}, scan rates must lie between 1000 and 50 000 Vs^{-1}. Independently of one another, several groups have established that anthracene, a particularly well-studied compound with a low reorganization energy during charging, has a k_s^0 value of about 0.035 ms^{-1}.[38, 109, 120, 121, 128] Similarly high values were obtained for the ferrocene/ferrocinium redox couple. It

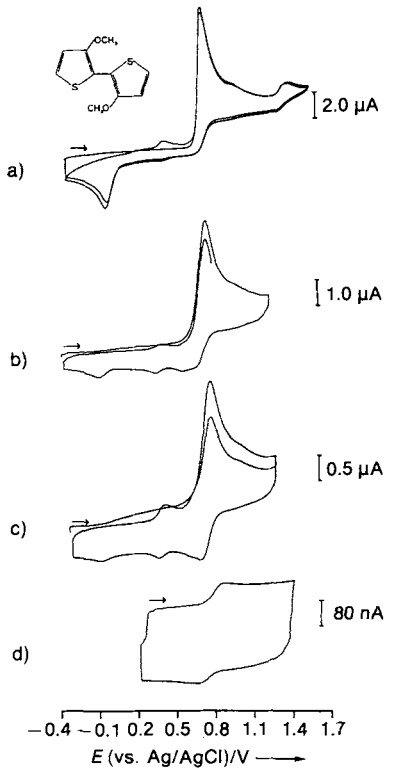

Fig. 15. Experimental cyclic voltammograms for the oxidation of 3,3'-dimethoxy-2,2'-bithiophene in acetonitrile/0.1 M [TBA]PF_6: a) $c = 2 \times 10^{-3}$ M, $v = 100\ mVs^{-1}$, $r_0 = 500\ \mu m$; in the reverse sweep the reduction of the cleaved protons is visible at 0.0 V; b) $c = 3 \times 10^{-3}$ M, $v = 20\ Vs^{-1}$, $r_0 = 100\ \mu m$; in the reverse sweep the reduction signals of the di- and monocations of the tetramer are also visible; c) $c = 3 \times 10^{-3}$ M, $v = 100\ Vs^{-1}$, $r_0 = 100\ \mu m$; d) $c = 3 \times 10^{-3}$ M, $v = 5000\ Vs^{-1}$, $r_0 = 2.5\ \mu m$.

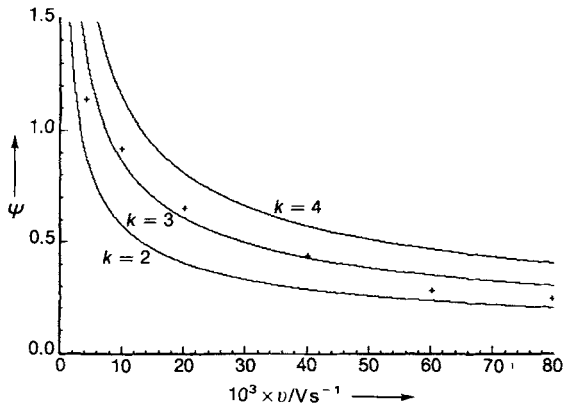

Fig. 16. Experimental and calculated data of the dimensionless ψ parameter as a function of the scan rate [34, 103]. Fast-scan experiments of the reduction of anthracene provided the experimental ψ values from ΔE_p values at different scan rates according to the equation $\psi = f(\Delta E_p)$. The calculation of the ψ values assumes that $k_s^0 = 0.02$, 0.03, or 0.04 ms^{-1}, and $D = 1 \times 10^{-9}\ m^2s^{-1}$.

is noticeable that this technique provides much higher rate constants than conventional techniques. This supports the assumption that, as in the steady-state experiments, no passivation occurs at the electrode surface.

At present, the fast scan rather than the steady state technique is preferred for studying reaction mechanisms and measuring kinetic parameters of homogeneous and heterogeneous electrochemical processes. Its crucial advantage is that all methods of evaluation used in classical cyclic voltammetry, including simulation, can be applied. Thus, all the usual mechanisms can be analyzed, and scan rates up to $10^5\ Vs^{-1}$ are accessible even with relatively large electrodes with radii of up to 2.5 μm (Fig. 17). This requires that, apart

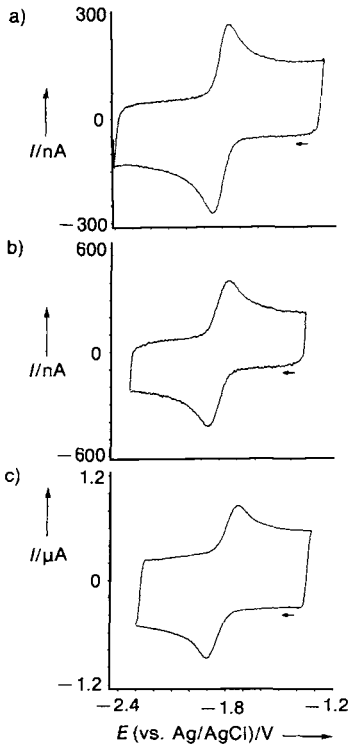

Fig. 17. Fast-scan voltammetry of the reduction of anthracene ($c = 5 \times 10^{-3}$ M) in acetonitrile/0.5 M [TBA]PF_6 at different scan rates. Gold ultramicroelectrode with $r_0 = 2.5\ \mu m$: a) $v = 20\,000\ Vs^{-1}$; b) $v = 40\,000\ Vs^{-1}$; c) $v = 120\,000\ Vs^{-1}$.

from experimental effects due to electrode size and electrolyte resistance, all instrumental influences which might distort the current–voltage curve must be kept as small as possible. Critical features are the construction of the potentiostat, including the current transducer, and the construction of the microelectrode. In respect of the potentiostat and the current transducer, it is very important that amplifiers have an extremely rapid time response and, hence, large band widths are used.[112a, 122, 125] Stray capacitances in the microelectrodes and the cables can cause heavy distortion of the current–voltage curve. For this reason, electrodes with radii of less than 5 μm have to be shielded,[129, 130] and connected to the current transducer and the potentiostat by very short leads. The appropriate *iR* compensation can produce further improvements.[121, 131]

If very high scan rates of 10^5 to greater than $10^6\ Vs^{-1}$ are used, cell resistance and the time constant will always distort the current–voltage curve. In poorly conducting electrolytes these effects are already apparent at much lower scan rates. It is then better to use simulation to evaluate the data, by inserting the capacitances and resistance values in the Butler–Volmer equation in accordance with Equation 24[60b] (Fig. 18), or by obtaining the real scan rates from the experimental voltammogram and applying them directly in the simulation.[124] Wightman et al.[132] have proposed a method that, given a suitable apparatus, will measure the

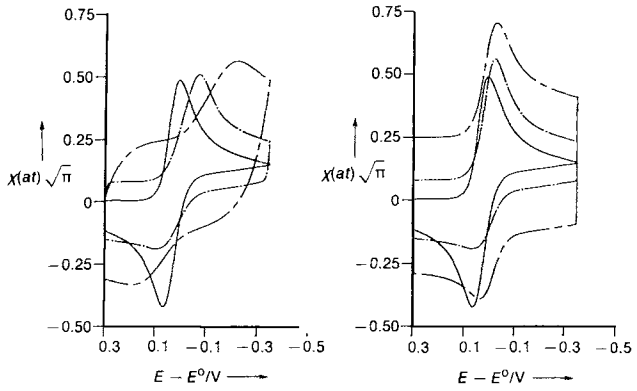

Fig. 18. Simulated cyclic voltammograms for an EC_{2rev} mechanism. Left: with uncompensated resistance $R_u = 41\ \Omega$ and double-layer capacitance $C_d = 1.56\ \mu F$. Right: after correction for the iR drop. Simulation data: $E^0 = 0.0$ V, $D = 1 \times 10^{-9}\ m^2 s^{-1}$, $K_{eq} = 10$, $k_f \times c = 0.1\ s^{-1}$, $k_s^0 = 0.04\ ms^{-1}$; scan rates: (——) $0.1\ Vs^{-1}$, (— · —) $100\ Vs^{-1}$, (— · · —) $1000\ Vs^{-1}$.

background voltammogram without the electroactive system, and then subtract this background current after adding the electroactive sample. However, this technique is only possible if the iR influence is small enough to be neglected.

3.2. Electrochemistry in Poorly Conducting Electrolytic Media

In conventional electrochemical experiments the basic electrolytic solution and the polar solvent ensure high conductivity. Hence, there are no iR problems and consequently no migration effects even at low or medium scan rates. This changes drastically when nonpolar solvents are used, or the concentration of electrolyte is very low, or measurements have to be taken in the solid state or the gas phase. In all these cases the iR drop is very large and cannot be controlled by the usual methods.

As indicated in Section 2.4, the use of UMEs reduces the iR effects, permitting interpretation of voltammetric or amperometric signals even under extremely unfavorable conditions. For example, Bond et al.[36, 133–135] measured the same diffusion-limited currents with 50 μm disk electrodes for the oxidation of ferrocene in electrolyte-free acetonitrile and in electrolytic solution. Moreover, the shape of the steady-state current–voltage curve obtained with electrodes with diameters of less than 1 μm resembles the ideal case of reversible charge transfer very closely. Other authors report similar findings.[136–139] The experimental results agree with Oldham's theoretical predictions[71] that even minute quantities of conducting "impurities" are enough for a sufficiently high conductivity in the immediate vicinity of the electrode. Voltammetric measurements of the oxidation of ferrocene in virtually electrolyte-free acetonitrile with microband electrodes[133] show that the influence of the iR drop depends not on the amplitude of the current response, but mainly on the special flux conditions in the vicinity of the electrode.[68] Despite relatively large currents, the voltammograms show only minor distortions. Some effects have still not been explained. The purpose of measuring in electrolytes with diminished or no conductivity is to obtain electrochemical data under the same conditions as used in spectroscopy or analytical chemistry. Usually, electrolytes have high ionic strengths, imparting significantly different thermodynamic and kinetic properties from those in ideal solutions without added electrolytes. This implies, for example, that in the transition from high to low ionic strengths, ion-pair equilibria, redox potentials, and rate constants of ionic reactions change. Apart from the activity of the involved reactants, the electric properties of the double layer at the electrode also change when the electrolyte concentration is reduced, which renders it difficult to draw unequivocal conclusions from the such experiments. Hence, researchers concentrate on systematically investigating the influence of the concentration of the ground electrolyte on migration and double-layer effects, comparing experimental findings with theoretical predictions, and, finally, determining the limits of electrolytic variations in nonpolar solvents.[70, 71, 134–142] The unexplained phenomena include the frequent appearance of typical cyclic voltammograms in non-electrolytic solutions, despite established steady-state conditions. Presumably the cause lies in changes in solubility after recharging the redox system.

UMEs enable the expansion of the utilizable potential range of aprotic solvents. This is confirmed by measurements in electrolyte-free acetonitrile and SO_2. It could be shown that alkanes are oxidized in acetonitrile[142] at potentials above + 3.5 V, and alkali metal ions were successfully oxidized in liquid SO_2 at potentials[143] of + 5.0 V.

Nonpolar solvents used to be taboo in electrochemical measurements. However, with ultramicroelectrodes the extremely high iR drop falls to tolerable values, and, by choosing suitable electrolytes such as tetrahexylammonium perchlorate ([THA]ClO_4) or $NaBPh_4$–crown ether complexes, amperometric or potentiodynamic experiments in solvents such as benzene, toluene, or even hexane provide interpretable results.[26, 36, 106, 144, 145] The precondition for the success of such experiments is that the electrolytes are soluble enough, and that they dissociate to some degree to provide an acceptable level of conductivity in the solution. Up to now, the chemistry of redox reactions in hydrocarbons could only be analyzed with spectroscopic methods; now, for the first time, it will be possible to use electrochemical measurements for quantitative studies. The growing interest in electrochemical investigations in aromatic hydrocarbons, alkenes, and alkanes is largely due to the fact that ionic reactions take place at quite different rates in weakly polar solutions and in polar media. Measurements that cover as wide a range of polarity as possible provide precise insights into the relationships between solvation and chemical reactivity, including the kinetics of electron transfer. For example, voltammetric studies[64] on the kinetics of the dimerization of radical anions of 9-cyanoanthracene show that the corresponding rate constants increase by almost four orders of magnitude from 1.4×10^3 to $9.0 \times 10^6\ s^{-1} M^{-1}$ between benzene ($\varepsilon = 2.27$) and the extremely polar *N*-methylformamide ($\varepsilon = 190$) (Fig. 19). Experiments of this nature show that particles with the same charge can form a covalent bond at high rates despite coulombic repulsion.

The use of nonpolar solvents also has interesting analytical applications. There is a discussion, for instance, on the use of supercritical CO_2 as a mobile phase in capillary chromatography.[146] Voltammetric measurements in this medi-

um are reproducible only after small quantities of water have been added; the use of ion-conducting membranes improves the results.[147]

Steady-state voltammetry is another challenging field for ultramicroelectrode techniques. However, to ensure that the *iR*-drop component always remains sufficiently small for the use of nanodes, conductivity values may not fall below $10^{-6}\,S\,cm^{-1}$. For this reason, inorganic[148] and organic[149] steady-state electrolytes as well as frozen electrolytic solutions[27, 150] (cryoelectrochemistry) are the most popular areas of research. Because under solid-state conditions, diffusion coefficients lie between 10^{-11} and $10^{-16}\,m^2\,s^{-1}$ ($\sigma \leq 0.3$), that is, orders of magnitude smaller than in solution, instead of steady-state curves, voltammetric measurements at UMEs often reveal a range of conditions from a transition between the steady state and planar diffusion up to classical cyclic voltammetric situation. An additional complication is the appearance, especially at very low temperatures, of voltammetric curves typical of surface processes without diffusive mass transport. Although many details are still unclear, one plausible explanation assumes that liquid microphases survive in solution well below freezing point,[150, 151] adhering to the electrode surface in thin layers.

One field of electrochemistry with spectacular promise is UME applications in the gas phase. Pons and Fleischmann have published several reports on such experiments.[28, 152, 153] It is important that a very narrow insulating field separate the working and the auxiliary electrodes, for example, in a ring–disk arrangement or two half-disks. The conductivity across the insulating gap takes place either by means of a conducting membrane or in the presence of moisture in the form of proton transport.[152a] Microelectrode detectors, affixed for this purpose at the outlet of a gas chromatograph, were able to determine the individual components of a hydrocarbon mixture as well as a heat conducting detector (Fig. 20).

3.3. Exploiting the Smallness of Microelectrodes

As already mentioned in the introduction, UMEs have a cardinal advantage because of their size, which makes it possible to conduct electrochemical measurements in minute volumes and observe discrete spatial events in microscopically small areas. Hence, it is not surprising that microelectrodes were first used for measurements in living systems. A report on electrochemical studies on the partial pressure of oxygen in tissue was published as early as 1938.[23] Baumgärtl and Lübbers' invention of the microcoaxial needle electrode, which, including the reference electrode, was only 0.3 to 0.5 μm at the tip, enabled routine measurements of oxygen gradients in cell tissue as well as at the gas/liquid interface or in pores of polymers.[154] Another important aspect of in vivo voltammetry is tracing neurotransmitters (catecholamines) or their metabolites (ascorbic acid) in the brain or in nerve cells. Building on pioneering work of Adams et al.,[155] improvements in the manufacture of microelectrodes[156–158] as well as technical progress[159, 160] have made it possible to take measurements both in living tissue and in unicellular organisms or single cells.[161] Surface-modified electrodes are becoming increasingly popular as they provide greater selectivity and sensitivity.

The patch-clamp technique,[162] for which Neher and Sakmann recently received the Nobel Prize,[163] also uses "microelectrodes". Whereas the above-mentioned microvoltammetric electrodes can cause and measure redox processes in a cell, the patch-clamp technique employs micropipettes, which measure electric currents that appear when the stimulated cell causes ions to move through channels in the cell membrane. Efforts are now being made to combine the two methods.[164]

A lot of work has been done on the electrocrystallization of metals, metal oxides, and organic salts. But quantitative

descriptions of growth processes in progress were extremely difficult because, statistically, nuclei form at several points on an electrode surface, and the measured current transients would integrate all these events. Naturally, the number of nucleation processes on the minute surface of ultramicroelectrodes is considerably smaller than on macroelectrodes. Therefore, under favorable circumstances it should be possible to detect the individual steps in the formation of a single nucleus and to analyze the kinetics of its growth process[20, 165, 166] (Fig. 21). Measurements obtained with

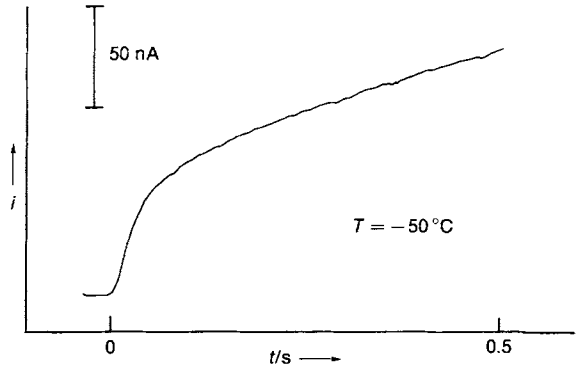

Fig. 21. Potentiostatic current–time transient for the growth of a crystal nucleus of a fluoranthene radical cation salt ($c = 2 \times 10^{-2}$ M) in acetonitrile/0.1 M [TBA]PF_6, measured at an 8 μm Pt disk electrode with a potential of +1.4 V vs. Ag/AgCl.

an ensemble of microelectrodes should provide unequivocal information on the rates of nucleus formation. The relatively large distances between the individual microelectrodes prevents the individual crystal nuclei from colliding with one another as they grow, which would unleash an undesirable dispersion of growth.[166] In recent articles, Oldham et al.[167] discuss the different mechanism of electrochemical mercury precipitation on carbon or metal microelectrodes from a thermodynamic point of view, and show that the type of precipitation process is conditioned by the surface energy at the electrode/electrolyte interface and the relative sizes of all the components involved.

The small size of UMEs is also useful for studying corrosion phenomena. They can be employed as probes to scan corrosive processes in closely defined spaces,[168] on the one hand, and serve as experimental models for local corrosive processes,[169] on the other. The small time constants are another advantage: rapid events can be recorded without complications, and interference from background currents during corrosive processes are kept to a minimum.[170]

A fascinating new development in UME techniques is based on the fact that the faradaic current, which, in the presence of an electroactive substance under diffusion-controlled conditions flows over the "tip" of the ultramicroelectrode, depends on whether the diffusion field of the microelectrode is disturbed by external influences. One consequence is that in the immediate vicinity of an insulating surface the current flowing over the UME is smaller than the undisturbed limiting current (Fig. 22). The extent of the change in current is determined exactly by the distance between the microelectrode and the nonconducting surface. Moreover, the smaller the electrode, the stronger the effect.

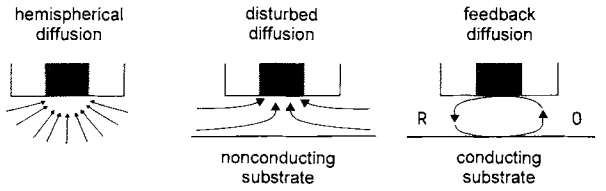

Fig. 22. Typical shapes of diffusion fields in scanning electrochemical microscopy. Left: undisturbed hemispherical diffusion field far from the substrate; diffusion-limited current i_l according to Equation (15). Center: disturbed diffusion field close to a nonconducting surface, $i < i_l$. Right: electroactive starting system regenerated (feedback effect) at a conducting substrate, $i > i_l$ [172b].

Thus, a piezoelectric scanner that moves the tip of the microelectrode parallel to the surface of a structured substrate can monitor the tip current as a function of its position. This setup generates an image of the surface topography of the sample (Fig 23). The recording technique resembles scanning

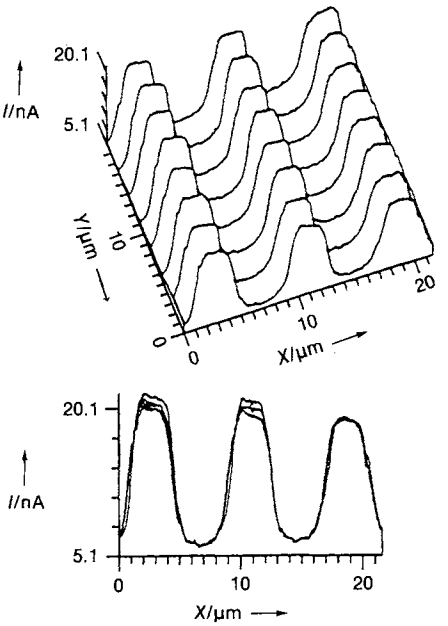

Fig. 23. SECM image of a Pt interdigitated structure on a SiO_2 substrate. Probe: Pt disk electrode embedded in a 0.3 μm poly(methyl methacrylate) layer, disk diameter ~0.5 μm, $E_s = -0.77$ V vs. SCE (saturated calomel electrode); aqueous solution with 40 mM methyl viologen and 2 M KCl. tunneling microscopy (STM)[171] as far as the movement of the electrode across the substrate surface under investigation is concerned, but the principles of measurement differ. Whereas in STM a tunnel current flows between the tip of the electrode and the substrate, the current flow in the case described here is based on redox processes that take place at the tip of the electrode or at the substrate surface (see below). Their extent is controlled by the kinetics of the charge transfer at the phase interfaces as well as by the diffusive mass transport. For this reason, this method is known as scanning electrochemical microscopy (SECM). It is a fairly recent development, largely a product of Bard's group.[29, 172] Its resolution is not as high as that of STM, but should, with further improvement, approach the 50 nm limit. In a variant of this technique, the substrate surface itself is conductive,

and thus can be given a different potential than the microelectrode. This allows, for example, a substance R produced by reduction ($O + e \rightarrow R$) at the electrode tip to be reoxidized at the substrate, a feedback which increases the diffusion current at the microelectrode (Fig. 22). This technique has advantages: the insulating shield of the electrode causes less interference than in the direct mode, and the stronger current improves depth resolution.[173] Both methods have been used to study surfaces of interdigitated arrays[174,175] (Fig. 23), polymers,[175,176] and biological samples.[177] Apart from topographical information, the SECM technique provides data on heterogeneities of the charge transfer at different points on a substrate surface.[178,179] This enables one to detect space-dependent changes in the chemical properties of surfaces, including, for instance, biocatalytic activities.[180] Furthermore, varying the perpendicular distance between the microelectrode and the substrate will provide information on diffusion profiles and kinetic parameters of homogeneous reactions.[181] This is achieved by generating different potentials at the substrate electrode and the microelectrode with a bipotentiostat, analogous to the ring–disk electrode.[182] Thus, the particles generated at the substrate can be detected with spatial and temporal resolution at the microelectrode (generator-collector mode[182]). Instead of using the microelectrode as detector, Anson[183] used the substrate electrode. This not only provides greater sensitivity to current and a better current-to-noise ratio; it also allows the two electrodes to be placed farther apart.

Interesting technical applications of SECM in the field of microsystem technologies include electroplating and etching.[184] Using the direct mode, one can generate, for example, thin metal strips in an ionic conducting polymer film, for instance Nafion containing gold, silver, or palladium ions, by polarizing the microelectrode tip to a negative potential and the substrate tip attached to the back of the polymer film to a positive potential. In the feedback mode, a mediator is oxidized or reduced at the microelectrode, which, after oxidative etching or reductive metal deposition at the substrate, is then transported back to the microelectrode, where it undergoes a new redox reaction.[185]

Reports on the SECM principle indicate an enormous range of possibilities for surface analysis, microgalvanization, and microetching. Present efforts to increase the resolution and sensitivity of the technique focus on reducing the size of the microelectrode tip[174b] and improving procedures.[186]

The aforementioned generator–collector principle can also be applied to stationary electrodes by polarizing a series of band electrodes in very close proximity (μm range) at different potentials. Reactive intermediates generated at one electrode, or which emerge in a subsequent chemical step, are detected at the collector electrode.[187] Measuring the current density (collector efficiency) as a function of the distance between the band electrodes and evaluating the findings with the aid of digital simulation provides kinetic and mechanistic information on the system under investigation. Studies of this nature have been carried out on recombination and electrochemical luminescence (ECL) of radical ion pairs, and on the catalytic oxidation of ascorbic acid and aminopyrine by $K_3[Fe(CN)_6]$.[39,188] Not only pairs of band electrodes, but also triple band electrodes[189] and interdigitated array electrodes[190] are now also being used for such work.

3.4. Ultramicroelectrodes in Chemical Analysis

Although analytical problems in the widest sense constitute an important aspect of this article, so far not much has been said about the use of UMEs in analytical chemistry, apart from electrochemical measurements of concentrations in the gas phase.

In principle, all the unconventional properties of ultramicroelectrodes can be exploited with advantage in chemical analysis. High mass transport rates and reduced capacitive effects produce both a marked improvement in the faradaic/capacitive current ratio [i_f/i_c; see Eq. (22)] and a better signal-to-noise ratio, which raises overall system sensitivity.[39,191] Digital and analog filters hold promise of further improvements.[192] The low values of the *RC* time constants lead to a fast drop in the capacitive charging current. As a result, traditional voltammetric pulse methods[32] used in chemical analysis, such as (differential) pulse voltammetry, staircase voltammetry, and square-wave voltammetry, should prove particularly suitable for UME measurements. This has been largely confirmed in experiments, some of which introduce new technical improvements.[133,138c,193–195] By using square-wave voltammetry in conjunction with a hydrodynamic modulation achieved by vibrating a microcylinder, the detection limit for ferrocene in acetonitrile could be lowered to 3×10^{-8} M.[196]

UMEs also have great potential in the stripping methods used in trace-element analysis. Because of the high mass transport coefficients, the solution does not have to be stirred during accumulation, and accumulation proceeds far faster. As the substance being analyzed was concentrated in a very small volume (the microelectrode), it is stripped completely during the anodic scan. This provides very sharp, easily interpretable peaks.[50,197–199]

If the characteristic dimensions of the microelectrodes are less than 10 μm, the high mass transport coefficients will keep the convection and hydrodynamic influences on a microelectrode's current response so small that they can be ignored. This phenomenon can be exploited to great advantage for electrochemical detection in flow systems, for example, in flow injection analysis or high performance liquid chromatography (HPLC).[200–202]

Because the *iR* drop has little influence on the current response, additional electrolytes are unnecessary, and the solution requires minimal conditioning. Furthermore, investigations can be carried out directly in samples, for example in fruit[203] (Fig. 24). Recently, band,[49] cylinder,[204] and array electrodes[133,203,205] have been used for these measurements instead of microdisk electrodes. They make it possible to measure relatively large currents in the lower μA range with the typical advantages of ultramicroelectrodes, which considerably reduces time and effort compared with other analytical techniques. The advantage of array electrodes is that they are easy and cheap to reproduce with modern lithographic techniques (see Section 4), and thus can be discarded after use.[206] Array electrodes also find in-

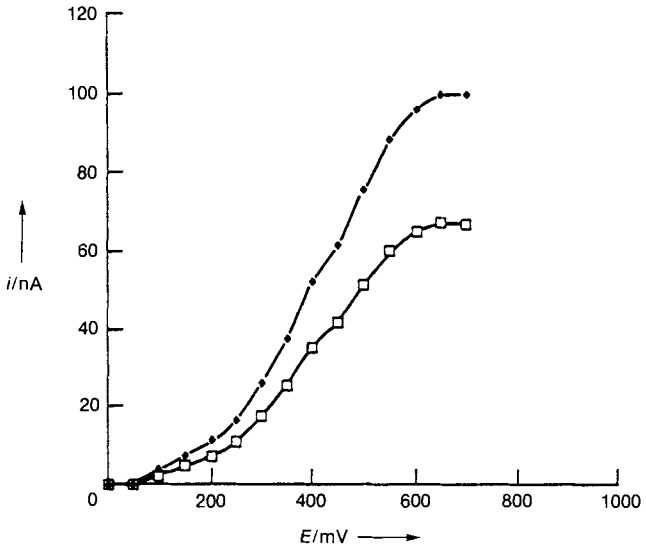

Fig. 24. Steady-state measurements of the oxidation of ascorbic acid in a Granny Smith apple with a gold microband electrode. $v = 20\ mVs^{-1}$: • at the surface, □: in the apple [203].

creasing application in the manufacture of electrochemical chemo- and biosensors, because their combination of small dimensions and relatively large sensitive area reduces response times and the signal-to-noise ratio.[207]

4. Construction of Ultramicroelectrodes

By now it should be clear that the main variables in the use of ultramicroelectrodes are geometry and size. The choice depends on the field of application. In recent years, therefore, many techniques have been developed to produce ultramicroelectrodes in varying geometries, sizes, and materials.

The most important type of electrode is still the disk electrode, which is usually made of platinum, palladium, gold, or carbon and, apart from the disk surface, fused into glass or embedded in plastic to isolate it completely from the electrolytic environment.[6b, 36–38, 63a, 90–94, 125, 132] It is essential that the electrode is reusable. This means that the electrode surface must be easy to clean; details can be found in the literature.[30a, 158] The details of techniques for manufacturing disk electrodes with diameters smaller than 0.6 μm have also been published. Because the electrode material becomes increasingly sensitive to temperature as the diameter decreases, "pullers" are used in the fusion process.[163] This step has been borrowed from the patch-clamp technique, which has long used pullers in the manufacture of extremely thin glass capillaries. They make it possible to set the exact temperatures needed to gradually soften the glass. The perfect seal obtained at the interface between glass and electrode material, a precondition for quantitative investigations with ultramicroelectrodes (Fig. 25), corroborates the quality of these fusion processes. Another problem with electrodes with diameters below 10 μm is the stray capacitances caused by additional capacitance between the electrode wire, the insulating environment, and the electrolytic solution.[129, 208, 209] It can lead to a drastic decline in the faradaic/capacitive current ratio (Figs. 26a and 27a). Recently, shielded electrodes have brought a noticeable improvement in this respect: the electrode capacitance is

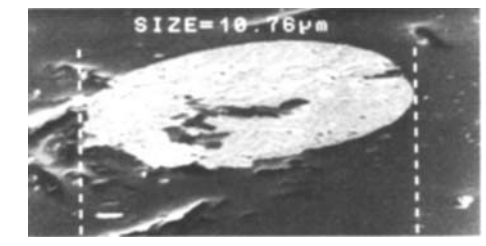

Fig. 25. Electron micrograph of a platinum disk electrode with a diameter of 10 μm embedded in soft glass.

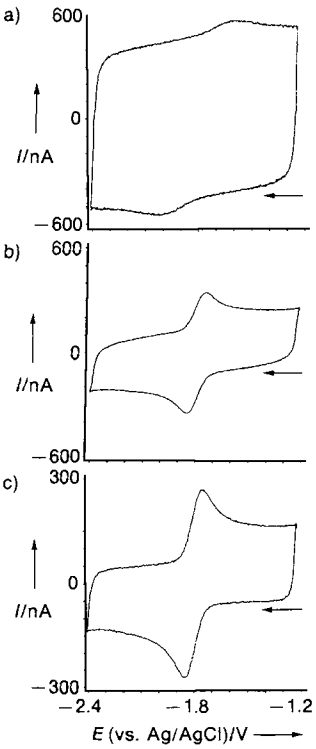

Fig. 26. Fast-scan voltammetry of the reduction of anthracene (5×10^{-3} M) in CH_3CN/0.5 M [TBA]PF_6; $v = 20000\ Vs^{-1}$; measured with a gold ultramicroelectrode with $r_0 = 2.5$ μm; a) without shield, b) shield incorporated but not activated, c) shield incorporated and activated.

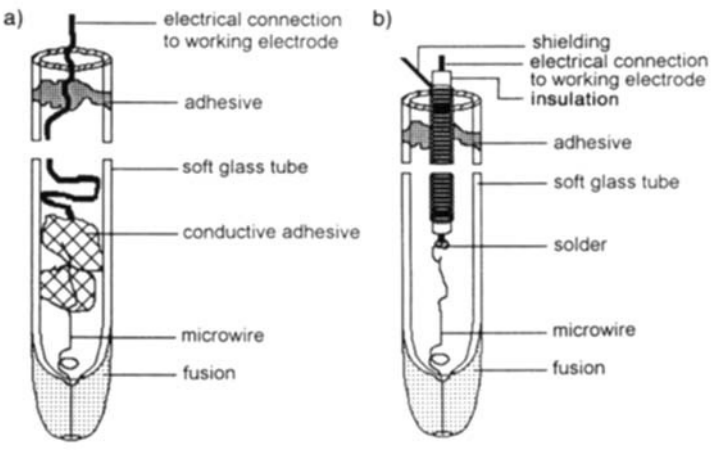

Fig. 27. Schematic setup of microdisk electrodes. a) Conventional electrode without shield. b) Electrode with electric shield.

significantly reduced by incorporating an additional, grounded metal shield or a coaxial cable in the glass fusion[129, 130b, 210] (Figs. 26b,c and 27b).

Whereas a metal wire fused into the glass is virtually indispensable in disk-electrode experiments in aprotic solutions, there is no problem in using carbon fibers as electrode material for studies in aqueous media, especially on biological objects.[30a, 211–215] The carbon fiber tips with characteristic diameters of up to 400 nm are produced by, for example, electrochemical etching or burning in a flame and isolated from the medium by electropolymerization of polyoxyphenylene.[212, 215, 216] The thin polymer layer adheres well and ensures that only the narrow tip retains its conductivity (Figs. 28 and 29). A common problem associated with carbon fiber electrodes is very slow electron transfer, which calls for appropriate activation of the tip.

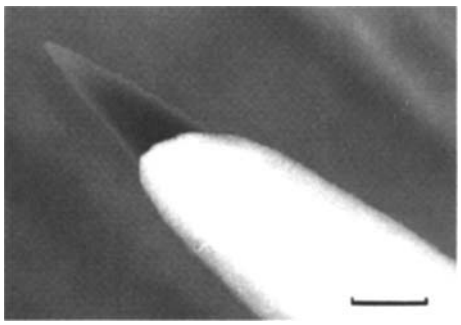

Fig. 28. Electron micrograph of a carbon-fiber tip (pitch fiber P100, Union Carbide), stuck into silicon rubber and then copper-plated. This was an experiment to test the possibility of leaving just a few μm free at the tip of the fiber on the principle of regioselective insulation. To heighten the contrast, Cu was chosen instead of insulating polyoxyphenylene [215]. The bar represents 3 μm.

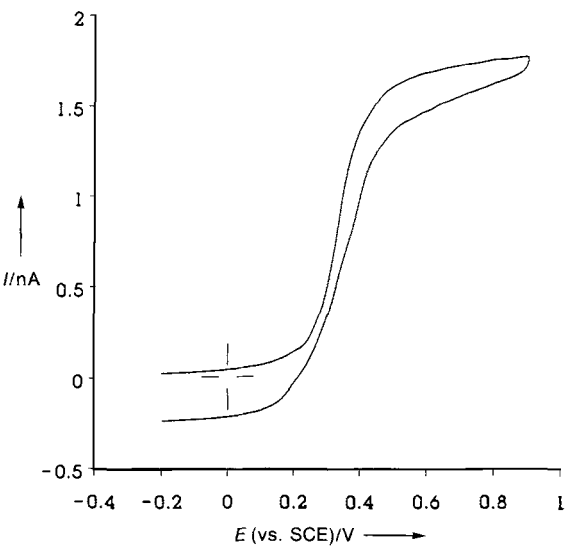

Fig. 29. Steady-state voltammogram of the oxidation of $K_4[Fe(CN)_6]$ ($c = 2$ mM) in H_2O/0.1 M KCl, $v = 1\ Vs^{-1}$, measured with a carbon-fiber tip [215].

Apart from the microdisk, microcylinder,[41, 51] microring,[43, 44] and microband electrodes[39–42] are also used. Band electrodes, employed as single-band electrodes, as double or triple band arrangements, or as arrays, have become increasingly popular in recent years. One reason is that, despite their narrowness, microband electrodes have a relatively large surface, and, therefore, give a favorable signal-to-noise ratio. Band electrodes serve as chromatographic detectors in analytical chemistry, are used to study reaction mechanisms and diffusion processes, and act as devices in microelectronics. There are different ways of manufacturing these electrodes.[217] The classical method is to fuse very thin strips of metal foil between sheets of glass or to embed them in a synthetic material with the aid of epoxy resins or films of Teflon. A far more elegant method, applicable into the lower nm range, consists of evaporation or sputtering of metals onto insulating substrates, which are then covered with a second insulating layer.[38–40, 218–220] Promising developments are microlithographic techniques, which have long been used in the electronic and semiconductor industries.[133, 187, 188, 217, 221–223] The most popular variants in electrode manufacturing are photolithographic techniques, which produce structures as narrow as 0.5 μm.[217]

5. Conclusions

Though the unconventional properties of ultramicroelectrodes were recognized only at the beginning of the 1980s, the exponential growth in literature on the subject testifies to their success. Numerous applications have stimulated the development of new methods and opened up previously inaccessible fields of research to electrochemistry. Present research goals include voltammetric measurements of the thermodynamics and analytical chemistry of poorly conducting electrolytic media from the solid state, through nonelectrolytic solutions, to the gas phase, as well as of the mechanisms and kinetics of very fast electrochemical reactions. With in vivo voltammetry, metabolic processes can be observed in cell tissue without causing any damage, and in the field of applied electrochemistry new strategies for sensor development[207] and corrosion research[224] are emerging. Moreover, with the new SECM technique an electrochemical method is available, which, for the first time, makes it possible to derive images of surface structures by measuring faradaic currents, as well as to microgalvanize and etch surfaces.

The persistent trend to smaller electrodes and simpler manufacturing techniques, assisted by efficient microsystem technologies and advances in laser research,[225] will considerably expand the scope of applications. The many aspects of an electrochemistry in a "natural" environment will surely encourage more intense interdisciplinary cooperation with other fields in chemistry, biology, and the material sciences. The priority status of the fast-scan technique and probably the SECM technique, too, should ensure that they reach a degree of perfection in the near future, which will turn them into routine methods using commercial equipment. The application of the techniques of microelectroplating will soon be used to build elements for microelectronics and micromechanics that will be able to compete with the products of photolithographic techniques. After an extraordinarily successful start, microelectrochemistry has a very promising future.

I am indebted to my excellent co-workers for their commitment and their considerable contributions in the form of ideas and experiments, which have gained for my research group its reputation in the field of ultramicroelectrodes. Their names will be found in the references. Dr. Michael Störzbach's conception of simulation models and his construction and application of UMEs were pioneering developments in this field. To him go my special thanks. I am grateful to the Deutsche Forschungsgemeinschaft, the Volkswagen Foundation, and the Fonds der Chemischen Industrie for the generous support they have given our work. Mr. Danny O'Hare, Imperial College, London, and Dr. Christian Amatore, Ecole Normale Supérieure, Paris, provided many suggestions in numerous discussions, for which I thank them both. Some aspects of the work mentioned in the text were only possible through the cooperation of other groups, in particular the Max-Planck-Institut für Systemphysiologie in Dortmund and the research group of Professor Besenhard, University of Münster. Finally, I wish to thank Dipl.-Chem. Peter Tschuncky, whose work on the fast-scan technique has set new standards for quality in microelectrodes.

Carboranes, Anti-Crowns, and Big Wheels

By *Russell N. Grimes**

Carboranes – polyhedral boranes containing carbon in the framework—have been around for over 30 years, and their intrinsic stability, versatility, structural variety, and electronic properties have been put to use in a number of diverse areas,[1] for example in the synthesis of extraordinarily heat-stable polymers, in boron neutron capture therapy (BNCT), as ligands in metallacarborane catalysts, as complexing agents for extraction of metal ions, as precursors to ceramics, conducting polymers, and nonlinear optical materials, as anticancer agents, and as carriers for radioactive metals in radioimmunodetection and radioimmunotherapy.

Although polyhedral carboranes having as few as five and as many as twelve vertices (fourteen if metal atoms are included) are known,[2] most research and applications have centered on the exceptionally stable seven- and twelve-vertex cage systems. Largely for reasons of accessibility, the twelve-vertex $C_2B_{10}H_{12}$ icosahedral carboranes have been most widely studied. The three known isomers, in which the carbon atoms occupy *ortho* (1,2), *meta* (1,7), or *para* (1,12) vertices, are white solids that rank among the most stable molecular compounds known. These clusters can be viewed as "superaromatic" systems in which 26 electrons fill the 13 bonding molecular orbitals on the polyhedral framework; moreover, the cage volume approximates that displaced by a benzene molecule rotating on one of its twofold axes. The very high intrinsic stability of the $C_2B_{10}H_{12}$ isomers, together with the acidic character of the hydrogen atoms bound to the cage carbon atoms (which allows facile introduction of functional groups at carbon), is the basis of extensive development of icosahedral carborane chemistry over three decades and its application to practical problems.[1, 2]

The remarkable versatility of carboranes presents an almost limitless range of possible roles in designed synthesis, a fact that is drawing increasing attention in organic and inorganic chemistry, materials science, engineering, and biologically related areas. A particularly elegant recent example is the design and construction of novel carborane-based macrocycles, in which both the electron-withdrawing character of the carborane cage and the close geometric relationship of icosahedral $C_2B_{10}H_{12}$ to planar C_6H_6 are exploited. In a series of papers,[3] Hawthorne et al. report the synthesis of "mercuracarborands" which incorporate three or more $C_2B_{10}H_{10}$ cages linked by an equal number of mercury atoms. The reaction of 1,2-dilithio-*ortho*-carborane $Li_2C_2B_{10}H_{10}$ with $HgCl_2$ afforded the tetramer shown in Figure 1a, which binds to a Cl^- ion, resulting in a nearly square-planar geometry for this ion (Fig. 1c), an unprecedented coordination mode for halide ions.[3a]

Since the uncomplexed THF adduct of the host macrocycle has been shown by X-ray crystallography to have S_4 symmetry with the centers of the icosahedra well outside the plane of the four mercury atoms,[3b] it has been proposed that the chloride ion functions as a template, creating the square-planar conformation. The carborane macrocycle is a Lewis acid and coordinates nucleophiles; it is therefore an "anti-crown",[4] that is, a charge-reversed analogue of the well-known family of nucleophilic hosts such as [12]crown-4 (Fig. 1b) that have figured prominently in molecular recognition studies.[5]

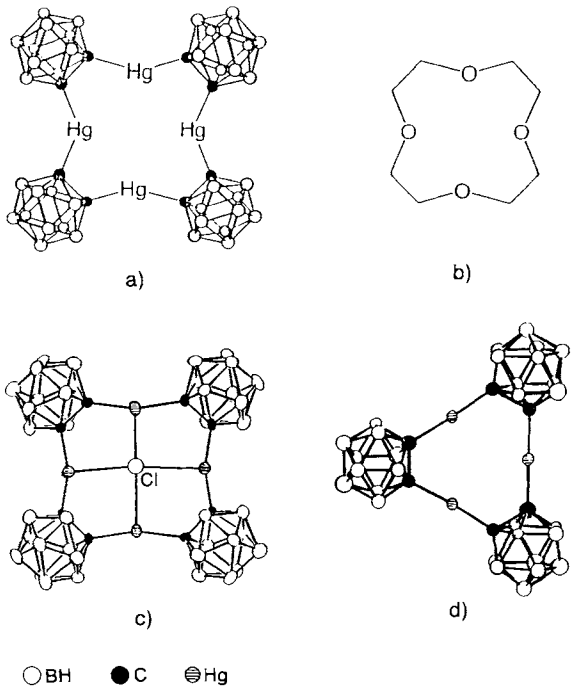

Fig. 1. a) Structure of the host tetramer $(1,2\text{-}C_2B_{10}H_{10}Hg)_4$ in its planar conformation [3a]. b) Structure of [12]crown-4. c) Structure of the tetramer with a bound chloride ion [3a]. d) Structure of the host trimer $(1,2\text{-}C_2B_{10}H_{10}Hg)_3$ (bound CH_3CN molecules not shown) [3f].

Treatment of the 1,2-dilithiocarborane with HgI_2 generated the dianionic species $[(1,2\text{-}C_2B_{10}H_{10})_4Hg_4I_2]^{2-}$ in which two iodide ions bind to the four mercury atoms;[3c] the corresponding reaction of the 1,2-dilithio-3-phenylcarborane gave a cyclic tetramer with only one I^- ion bound in the sterically encumbered cavity.[3d] Surprisingly, of the four possible stereoisomers, the only one formed was that having two phenyl rings directed "up" and two "down" with respect to the cavity. Addition of Ag^+ ions to the mercuracarborand complexes was found to remove the halide ion(s) and afford the free host molecule.[3a, c]

A related example of complexation by the mercuracarborand tetramer involves two polyhedral $B_{10}H_{10}^{2-}$ guest dianions that are bound to the four Hg atoms through three-center, two-electron B–H–Hg bonds.[3e] The reaction of dilithiocarborane with mercuric acetate[3f] yielded yet another macrocycle, this time a trimer (Fig. 1d) which coordi-

Telefax: Int. code + (804)924-3710

nates acetonitrile in a most unusual manner: the solid-state structure features two cocrystallized adducts having three and five CH_3CN-bound molecules, respectively. This anti-crown is analogous to trimeric *ortho*-phenylene mercury, but its mean Hg–Hg distance of more than 3.7 Å implies a larger central cavity than the latter compound.[3f] On treatment of $Hg_3(C_2B_{10}H_{10})_3$ with LiCl, an anionic chloride complex was formed in which the Cl^- ion is proposed to reside at the center of the Hg_3 triangle. The binding ability of these mercuracarborands toward Lewis bases implies that nitrogen-containing bases of biological relevance—adenine, guanine, and the like—may be similarly bound.[3f]

In a different synthetic tour de force that combined chemistry with art, Wade et al.[6] prepared the macrocycle shown in Figure 2. In this case the starting reagent was the dicopper

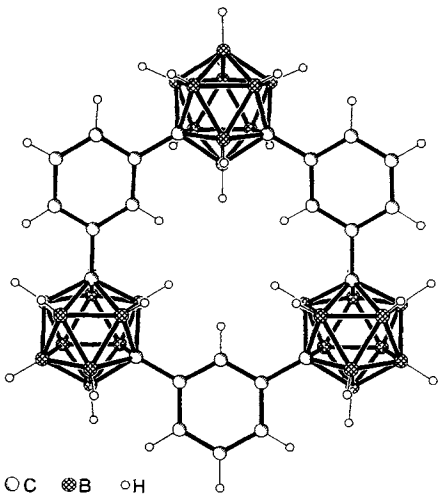

Fig. 2. Structure of $(1,7\text{-}C_2B_{10}H_{10}\text{-}1',3'\text{-}C_6H_4)_3$ [6].

meta-carborane, $1,7\text{-}Cu_2C_2B_{10}H_{10}$, which reacted with *meta*-diiodobenzene to give the desired trimeric product in low yield. As revealed by X-ray crystallography, the carborane cages are tilted away by 17° from the plane defined by their carbon atoms, while the benzene rings are tilted in the opposite direction by the same amount; consequently, the molecule has a dish-shaped structure whose central cavity is defined by three inward-directed carborane hydrogen atoms (mean separation 3.16 Å) and three phenylene hydrogen atoms that lie almost in the same plane; three other carborane hydrogen atoms are much further apart (ca. 4.47 Å). Boron atoms on the inside of the macrocycle could be removed and replaced with metals,[6] which opens truly intriguing possibilities for catalysis and other applications wherein the three metal centers act in concert.

Macrocycles incorporating the $1,2\text{-}C_2B_{10}H_{10}$ cage and linked by trimethylene or 1,3-xylyl groups have been prepared in Hawthorne's laboratory, and these include both trimers and tetramers.[7] The X-ray crystallographically determined structure of a xylyl-linked tetramer that features a remarkable 28-membered ring is shown in Figure 3.

While the geometries of the 1,2- and $1,7\text{-}C_2B_{10}$ cages are made to order for the synthesis of macrocycles through substitution at the carbon atoms, the 1,12-carborane (*para*-isomer) has carbon atoms at opposite ends of the polyhedron and is ideally suited for the assembly of rigid linear rods

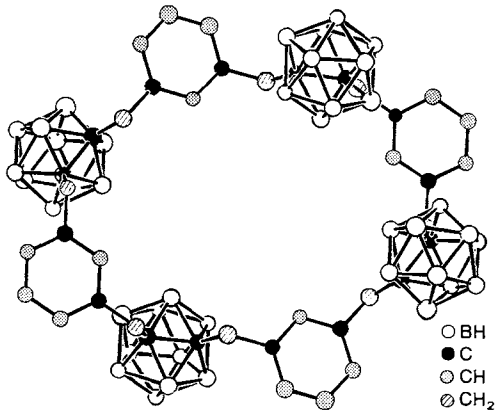

Fig. 3. Structure of $(1,2\text{-}C_2B_{10}H_{10}\text{-}1',3'\text{-}CH_2C_6H_4CH_2)_4$ [7].

through direct C–C connections, as has been demonstrated by two research groups.[8] As all these examples illustrate, the special stereochemistry of the icosahedral carboranes can be used to advantage in very innovative and creative ways. Molecular engineering employing nonicosahedral carborane or organoborane clusters is also under active investigation, as in the multidecker sandwich systems that incorporate seven-vertex MC_2B_3M' or MC_3B_2M' pentagonal bipyramidal cages.[9]

The beauty of the chemistry highlighted in this article lies in its essential simplicity, in that preorganized cyclic host molecules are generated in one or two steps from readily available reagents—an advantage not afforded by crown ethers and cryptands. These synthetic advances vividly exemplify the rapidly evolving art of "designer chemistry" in which inorganic and organometallic assemblies of specified architectures are obtained in directed reactions from available building-block molecules. It seems clear that carboranes and other boron clusters are destined to play a significant role in this field. Philosophically and historically, designed synthesis is derived from organic chemistry; but for inorganic chemists, given the entire periodic table of elements to play with, the scope of possibility seems far larger and the ultimate achievements hardly imaginable at present.

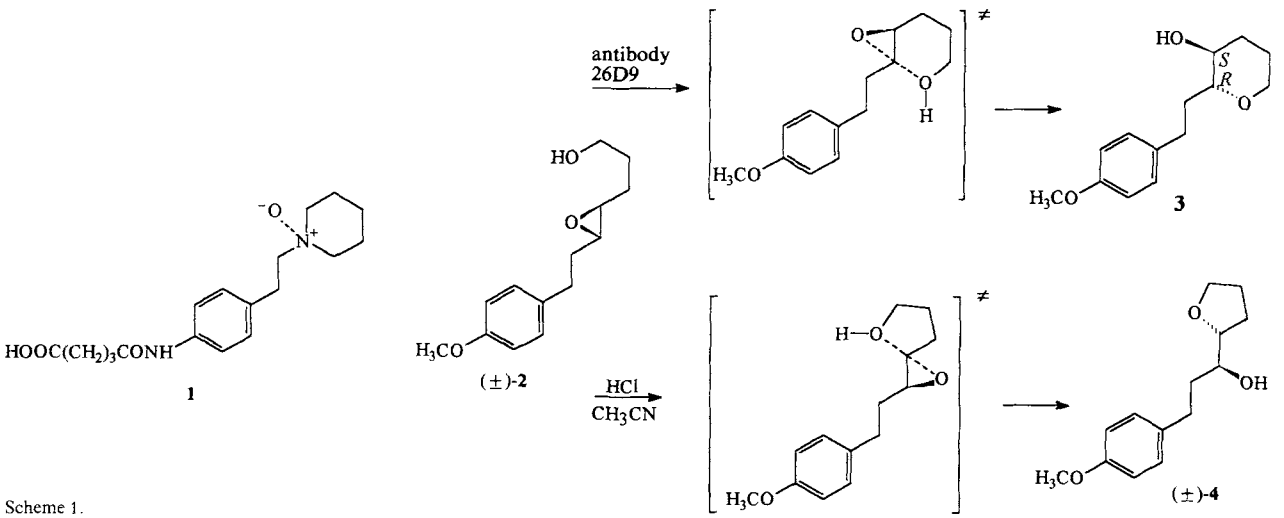
New Developments in the Chemistry of Catalytic Antibodies

By *Christian Leumann**

Since the first reports of chemical reactions catalyzed by antibodies were published in 1986,[1-2] research in this field, which borders chemistry and biology, has been rapidly established and has led to many interesting results. Within the first five years, antibodies have been elicited for the catalysis of about 40 reactions.[3] The range of transformations catalyzed by antibodies includes carbonate, ester, and amide hydrolysis reactions as well as the corresponding reverse reactions, Claisen rearrangements, light-induced cycloaddition and reversion reactions, redox processes, β-eliminations, *cis–trans* isomerizations, metal chelating reactions, and Diels–Alder reactions. The art of generating such catalysts lies in the design of the hapten which must be chemically stable while at the same time mimicking the structure and electronic properties of the transition state of the reaction in question. To produce such antibodies the immune system is challenged with the appropriate haptens conjugated to carrier proteins. The resulting antibodies bind preferentially to the transition state of the target reaction and thus accelerate the reaction. Such catalysts rival natural enzymes in terms of catalytic efficiency and substrate selectivity. The state of current knowledge has already been reviewed in a number of articles.[3-5] Current research in the field of catalytic antibodies is being carried out on a wide front, including research devoted to practical applications of this technology. In the following, several examples from the more recent literature will be used to illustrate the direction in which current research is headed.[11]



Scheme 1.

For example, the stereochemical course of an intramolecular substitution reaction can be controlled by antibodies (Scheme 1).[6] An antibody raised against hapten **1** catalyzes the intramolecular substitution reaction of the hydroxyepoxide **2** to give the tetrahydropyran derivative **3**, whereas acid catalysis in the absence of the antibody exclusively leads to the formation of the tetrahydrofuran derivative **4**. Furthermore, the antibody is substrate specific, transforming only one enantiomer of **2** into (enantiomerically pure) **3**. The structure of the hapten **1** is responsible for the observed stereochemical course of the antibody-catalyzed reaction, since this structure closely resembles the transition state on the way to the tetrahydropyran derivative **3**. This is a remarkable approach since in this case a reaction is not only accelerated but also forced in a direction that does *not* correspond to the inherent reactivity of the free substrate. Whereas the structural requirements for the transition state of an S_N2 reaction can be fulfilled in the acid-catalyzed reaction leading to **4**, the formation of **3** in the antibody-catalyzed reaction appears to be a mechanistic paradox that, however, is partly resolved by the fact that the substitution center (part of a three-membered ring) can be regarded structurally as a special case.

The antibody-catalyzed reduction of a diketone (Scheme 2) serves as a further example of regioselectivity not accessible by previous synthetic routes.[7] The antibody (37B.39.3) raised against the hapten **5**—again an *N*-oxide is used to mimic the transition state—catalyzes not only the enantioselective reduction of the *para*-nitrobenzylketones **6–8** by $NaBH_4$ to yield the corresponding alcohols **9–11** (86–96% *ee* (*S*) configuration in **9**), but also controls the reduction of the diketone **12**, such that of the three possible reaction products **13–15**, **13** is formed selectively in 95% yield (57% conversion) with 96% *ee*. While in the antibody-catalyzed reduction of **12** the keto group next to the nitrobenzyl residue reacts about 75 times faster than the keto group next to the methoxybenzyl residue, in the absence of the antibody practically no kinetic preference for one of the two reacting groups is observed. Remarkably, the antibody will tolerate a range of residues R in the ketones **6–8** but can discriminate strongly between methoxybenzyl and nitrobenzyl groups; this is a further indication of the relative insensitivity of the

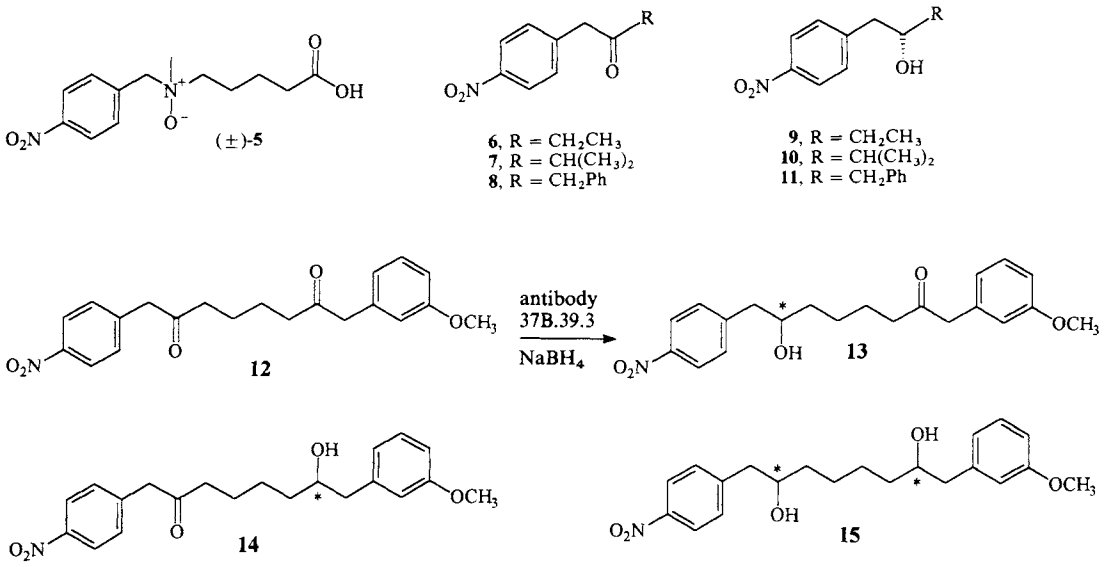
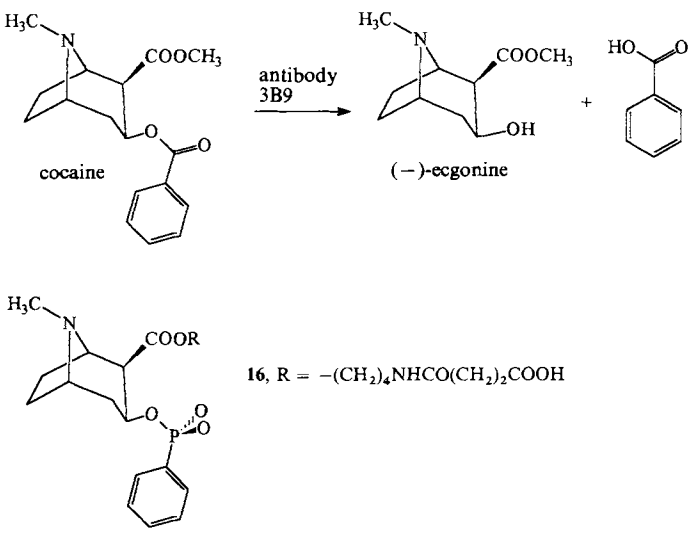


Scheme 2.

antibody to structural variations in the substrate near the conjugation site of the hapten–protein conjugate.

In the early research the main emphasis was placed on expanding the range of reactions catalyzed by antibodies and on mechanistic studies. More recent research now focuses on practical applications, in which catalytic antibodies play a central role. An example is the development of an antibody that catalyzes the hydrolysis of cocaine to (−)-ecgonine (Scheme 3).[8] This work was inspired by the wish to develop



Scheme 3.

a new cure for drug addiction. A number of factors, such as peak concentration, positive concentration gradients, and changes in the level of cocaine in the blood serum, reinforces self-administration of the drug. This led to the idea of developing a drug that could degrade cocaine in the blood before it is transported to the central nervous system. Thus, this antibody, which catalyzes the hydrolysis of cocaine to give the inactive substance ecgonine, could serve this purpose. The production of the antibodies against phosphonate **16** can already be considered as an application of an existing procedure for the development of antibodies with esterase properties. Indeed the resulting antibody exhibits a catalytic activity similar to that of the main enzyme responsible for the breakdown of cocaine in the blood, namely butyrylcholinesterase. However, to be effective an antibody would have to exhibit yet higher activity. Nevertheless, this work points the way to future applications in drug development.

Recently significant advances have also been made in the preparation of antibodies. A difficult problem here is the time-consuming and expensive immunization process in addition to the unavoidable use of test animals for the induction and production of antibodies. By using the tools and techniques of molecular biology, it is now possible to produce and screen entire antibody libraries for binding to a given hapten in vitro. A step in this direction is the "reorientation" of an anti-tetanus-toxoid antibody into an antibody that binds fluorescein.[9] This was achieved by replacing the part of the gene coding for one of the hypervariable regions of the heavy chain of the original antibody with a synthetically prepared mixture of oligodeoxynucleotides of the same length. The resulting large number of antibodies was then expressed on the surface of phages. After the selection of the phages on the basis of their ability to bind to fluorescein followed by amplification and isolation steps, the molecular nature of the individual redefined antibodies was determined. Some of the resulting antibodies exhibited a binding affinity to fluorescein comparable with those obtained by direct immunization of mice with derivatives thereof.

Whether practical applications of catalytic antibodies as drugs or diagnostic tools will find widespread use in the future not only depends on further improvements of their catalytic activities, but also on the successful elaboration of methods that avoid the immunization procedure and thus the use of test animals.[10] The first promising steps in this direction have already been taken.

[Cp*Ru(acac)] Is Not a Coordinatively Unsaturated, Stable 16-Valence-Electron Complex**

By *Michael E. Smith, Frederick J. Hollander,* and *Richard A. Andersen**

A recent publication in this journal reported that the X-ray crystal structure of [Cp*Ru(acac)] (Cp* = η^5-C_5Me_5) shows it to be a coordinatively unsaturated, sixteen-electron complex in which the angle defined by the intersection of the Me_5C_5-centroid-Ru line with the plane defined by Ru-O-O substantially deviates from 180°.[1] Kölle et al. state that [Cp*Ru(acac)] "exhibits two independent molecules in the asymmetric unit and does not show the intermolecular metal–acac interactions often observed for acac complexes (shortest intermolecular distance, Ru···C(13), >5 Å)." The authors quote preliminary extended-Hückel calculations that trace the stability of the bent geometry to a large HOMO–LUMO gap.

In recent X-ray crystallographic studies of monomeric [Cp*Co(acac)] and [Cp*Ni(acac)] we observed no deviation from linear geometry.[2] This observation led us to question the results of the X-ray crystallographic study of [Cp*Ru(acac)]. The atomic position data were retrieved from the Cambridge Structural Database.[3] A packing diagram produced by ORTEP[4] showed that the X-ray data for [Cp*Ru(acac)] had been incorrectly interpreted. Figure 1 shows the contents of the unit cell. There are indeed two independent molecules in the asymmetric unit, but they are linked through an inversion center to form dimers, and each ruthenium atom is bonded to the γ-carbon atom of the symmetry-related acetylacetonate group. The Ru1···C13 and Ru2···C28 distances are 2.418 and 2.417 Å, respectively. The geometry of the dimers is essentially identical to that reported for the isoelectronic dication in $[Cp^*_2Rh_2(acac)_2](BF_4)_2$.[5] There the Rh···C contact distance of 2.287(6) Å is 0.13 Å shorter than that found in the neutral ruthenium compound, probably due to the cationic nature of the rhodium center.

The reinterpretation of the published X-ray crystallographic data shows that the bent geometry of [Cp*Ru(acac)] is due to the interaction of the Ru atom with the γ-carbon atom of the acac group in a neighboring [Cp*Ru(acac)] molecule. The ruthenium center thus avoids coordinative unsaturation.

Reply*

In our interpretation of the solid-state structure of [Cp*Ru(acac)] we apparently made a mistake: the intermolecular distance Ru···C13 was not determined correctly. In the meantime we have obtained numerous results from derivatives of the same complex type that indicate their coordinatively unsaturated nature in solution, for example, inversion at the metal (observed by NMR spectroscopy). We will report on these findings shortly.

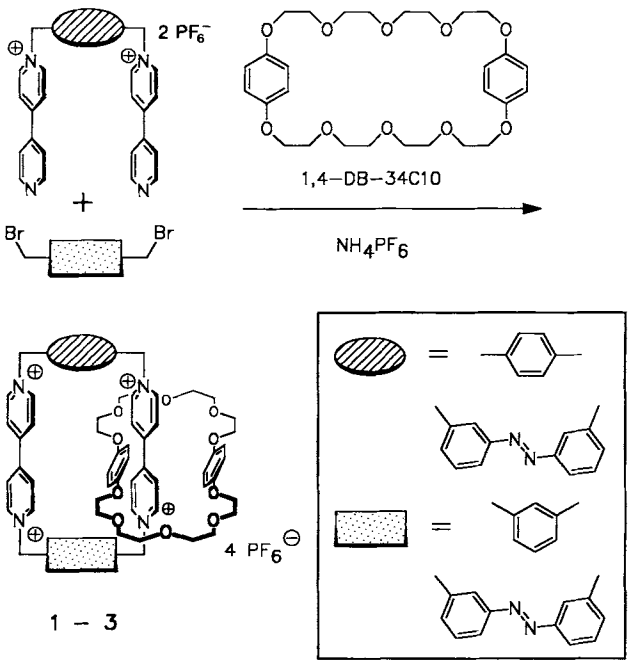
Photoswitchable Catenanes**

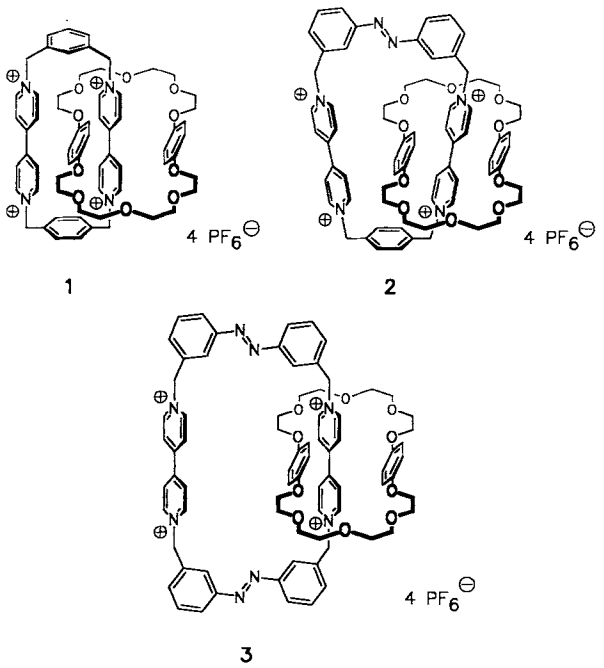
By *Fritz Vögtle,** *Walter Manfred Müller, Ute Müller, Martin Bauer,* and *Kari Rissanen*

Catenanes are not longer freaks of the laboratory since they became preparatively accessible through the use of template effects.[1-3] The strategy developed by Stoddart[4, 5] in which the formation of a donor–acceptor complex is used to preorient the building blocks participating in ring formation was applied by us to synthesize catenanes with *unsymmetrical* paraquat rings (Scheme 1).[6] This enables the use of almost any bis(bromomethyl)arene for linking the second ring. Other variations are described in the following communication by Stoddart et al.[7]

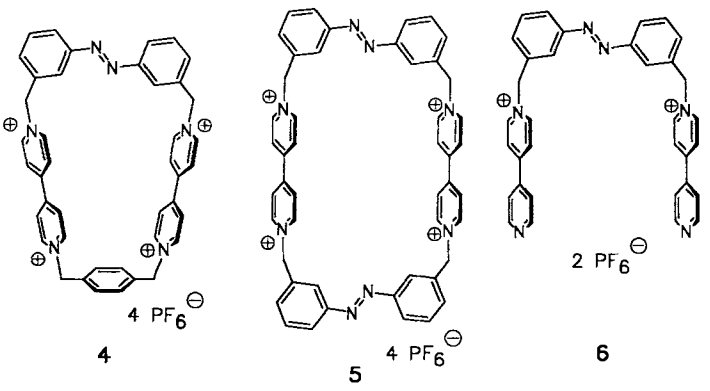
In the simplest case, two dibromides with different substitution patterns form the closely interlocked catenane **1**, which contains a *meta*-phenylene building block. More interesting examples employ photochemically or electrochemically active building blocks[8] to close the gap. We report here on the catenanes **2** and **3**, in which a photoactive switching function is integrated into one of the two large rings.



Scheme 1. Synthesis of the catenanes **1–3** containing two different spacers in each case (schematic).



The azobenzene unit in **2** and **3**, and in the new azo compounds **4–6** prepared for comparison, can be converted from the (*E*) configuration formed in their synthesis into the (*Z*) configuration by irradiation at 310 nm and revert to the (*E*) configuration on irradiation with blue light (440 nm).



Whereas photochemical switching leads to two photostationary equilibria (PSE) characterized by different (*E*)/(*Z*) populations, the starting state (that of the pure (*E*) isomer) can be attained by prolonged heating in solution (thermal reisomerization) (Scheme 2).[9]

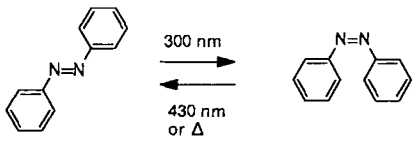
Thus, a mixture of the (*E*) and (*Z*) isomers is obtained from the catenane **2**, and a mixture of the (*E*,*E*), (*E*,*Z*), and (*Z*,*Z*) isomers from **3**. The switching can be monitored by ^{1}H NMR spectroscopy. Remarkably, in **2** not only the proton signals of the azobenzene unit itself are affected by the change in configuration at the N=N bond; it also influences the signals of the bipyridine unit of the same large ring and of the paraphenylene ring fourteen bonds away (!), as well as those of the second catenane ring, that is, of the hydroquinone component and, to some extent, the ethano groups.



Scheme 2. (*E*)/(*Z*) isomerization for the example of azobenzene.

The rate of the thermal (*Z*) → (*E*) reisomerization of the azobenzene unit depends both on the size of the macrocycle containing it and on whether the cavity is occupied, which in catenanes must be the case. The half-life of (*Z*)-**2** in acetonitrile at room temperature is about 20.5 h, while the reisomerization to (*E*,*E*)-**3** from the (*Z*,*Z*)-configurated and mixed configurated isomers proceeds with a half-life of 12 days. The "quat rings" **4** and **5** that contain no guest reisomerize more slowly than the corresponding catenanes (Table 1). The

Table 1. Rate constants k and half-lives $\tau_{1/2}$ for the reisomerization of catenanes **2** and **3**, as well as (for comparison) the corresponding empty macrocycles **4** and **5** and the open chain precursor **6** in [D_3]acetonitrile at 20 °C.

	2	**3** [a]	**4**	**5** [b]	**6**
k[s^{-1}]	9.4×10^{-6}	–	9.7×10^{-7}	5.6×10^{-7}	4.8×10^{-7}
$\tau_{1/2}$	20.5 h	12 d	8.3 d	14 d	17 d

[a] This value for $\tau_{1/2}$ refers to the backformation of (*E*,*E*)-**3** from the (*Z*) isomer mixture in the PSE. Signal overlap prevents the accurate determination of the isomerization rate of the (*Z*,*Z*) isomer. [b] These values refer to the reisomerization of (*Z*,*Z*)-**5**; for the reaction of both (*Z*) isomers to form (*E*,*E*)-**5** from the PSE the half-life is about 24 days.

crown ether apparently forces the bipyridine units that restrict it apart, particularly those in the (*Z*) configuration, thus mechanically assisting the isomerization. The comparison of catenane **2** with the macrocycle **4** clearly demonstrates this auxiliary effect: in catenane **2** the cavity is particularly crowded and consequently the mechanical forces are especially strong. The open-chain starting material **6**, in which the (*Z*) form is not favored by bridging, reisomerizes much more slowly than the catenanes or the narrow macrocycle **4**.

The results of the X-ray analysis of **1** and **2**[10, 11] suggest that the crown part of the catenanes cannot rotate freely around the bipyridine component. In **2** the enclosed hydroquinone unit does not lie in the center of the paraquat ring: the shortest distance is 3.41 Å to the inner bipyridine unit; the distance to the outer unit is 3.56 Å. The larger azobenzene spacer enables a more pronounced twisting of the outer bipyridine unit (30.8°); the torsional angle of the inner unit is only 12.1°.

In both the ^{13}C and ^{1}H NMR spectra the inner and outer part of the polyether ring of **1** give rise to different signals. The broadening of the proton signals for **2** can be observed at room temperature, but the exchange takes place too rapidly on the ^{13}C NMR time scale for a broadening to be visible in this spectrum. Finally, the bis(bipyridine) ring of **3** has been so stretched by the two azogroups that also in its ^{1}H NMR spectrum only a single averaged signal appears for the aromatic protons of the crown ether.

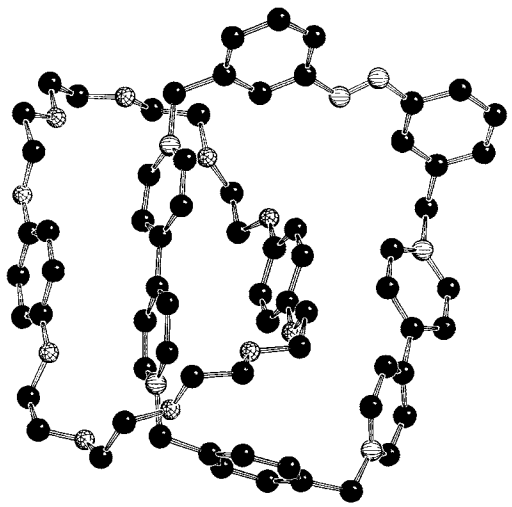


Fig. 1. X-ray crystal structure of **2**.

In the context of host/guest chemistry, the catenanes are on the one hand ideal model compounds in which the interactions between the molecule's two components are maximized. The properties observed for them—here, for example, the (*Z*) → (*E*) isomerization behavior—can, at least, be considered as a measure of the stability of a complex. On the other hand the empty monocycles **4** and **5** offer the possibility of manipulating the strength of bonding of electron-rich arene molecules by light.[12] An alternative to the incorporation of potential photoswitches will be presented in the following communication.[7]

Experimental Procedure

Preparation of the catenane **3** and the macrocycle **5**: The azo compound **6** (0.81 g, 1.0 mmol) and the crown ether 1,4-DB-34C10 (1.07 g, 2.0 mmol) were dissolved in dry acetonitrile (40 mL), treated with a solution of 3,3'-bis(bromomethyl)azobenzene (0.37 g, 1.0 mmol) in acetonitrile (40 mL), and stirred for one week at room temperature. Filtrate and precipitate were purified separately on silica gel (solvent system: methanol/5% aqueous NH_4Cl solution/nitromethane 7:2:1) by medium pressure liquid chromatography (MPLC). After anion exchange with NH_4PF_6, **3** is obtained from the filtrate in 12% yield (R_f = 0.19), and **5** from the precipitate in 4.1% yield (R_f = 0.10).

6: 3,3'-bis(bromomethyl)azobenzene (3.68 g, 10.0 mmol) and dry 4,4'-bipyridine (6.25 g, 40.0 mmol) were heated in acetonitrile (150 mL) for 12 h under reflux. The precipitate was purified on silica gel (solvent system: methanol/5% aqueous NH_4Cl solution 7:2) by MPLC (R_f = 0.34). A double exchange with NH_4PF_6 solution afforded hexafluorophosphate **6** in 53% yield.

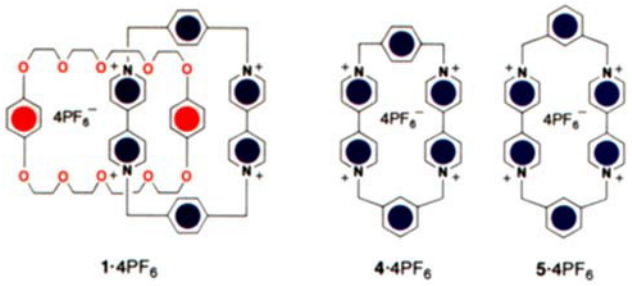
Isomeric Self-Assembling [2]Catenanes**

By *David B. Amabilino, Peter R. Ashton, Malcolm S. Tolley, J. Fraser Stoddart,** and *David J. Williams*

In 1989 we reported the efficient, template-directed[1] self-assembly[2] of the tetracationic cyclophane cyclobis(paraquat-*p*-phenylene)[3] with bis(*p*-phenylene)[34]crown-10 (BPP34C10) to form[4] the [2]catenane $\mathbf{1}\cdot 4PF_6$ in 70% yield. The noncovalent bonding—the π–π stacking interactions and [C-H···O] hydrogen bonding that combine to enhance the efficiency of the macrocyclization[5] of the tetracationic cyclophane—'lives on' both in the solution and solid-state structures of $\mathbf{1}\cdot 4PF_6$. A subsequent objective was to explore the self-assembly of molecular structures isomeric with **1** for the controlled creation of nanometer-scale, ordered supramolecular architectures.[6] To achieve this goal, we had to understand the effects of constitutional changes upon the efficiency of the self-assembly process. Here we describe the syntheses of two constitutional isomers of



$\mathbf{1}\cdot 4PF_6$, $\mathbf{2}\cdot 4PF_6$ and $\mathbf{3}\cdot 4PF_6$, in which the incorporated tetracationic cyclophanes are different, and compare the efficiency of the self-assembly process leading to the isomeric [2]catenanes with the binding properties of the free tetracationic macrocycles $\mathbf{4}\cdot 4PF_6$ and $\mathbf{5}\cdot 4PF_6$.[7] We also discuss the X-ray crystal structures of $\mathbf{2}\cdot 4PF_6$ and $\mathbf{3}\cdot 4PF_6$, and their dynamic ^{1}H NMR spectroscopic behavior in solution.

The [2]catenane $\mathbf{2}\cdot 4PF_6$ was prepared by two different routes according to Scheme 1. Although the catenations were performed under identical conditions, when **6** was added to $\mathbf{7}\cdot 2PF_6$ in dimethylformamide (DMF) in the presence of an excess of BPP34C10, $\mathbf{2}\cdot 4PF_6$ was obtained in 18% yield after counterion exchange, whereas when the self-

[**] This research was supported by the Science and Engineering Research Council in the United Kingdom, and first presented at the XIIth Royal Society of Chemistry UK Macrocycle Group Meeting at the University of Oxford (January 1993).

assembly was performed using **9** and **10**·2PF_6, the yield of the catenane isolated was 40%. Clearly, the intermediate tricationic complex **11** undergoes ring closure to give **2** much more readily than does **8**. The positive-ion FAB mass spectrum[8] of **2**·4PF_6 is similar to that[4, 5] of its isomer **1**·4PF_6, displaying peaks at *m/z* 1636 for the parent ion and at *m/z* 1491, 1346, and 1201 for loss of one, two, and three PF_6^- ions, respectively.

The catenane structure of **2** was confirmed by X-ray crystallography. The crystal structure[9, 10] of **2**·4PF_6 reveals (Fig. 1) a geometry similar to that[4, 5] of **1**·4PF_6 in the solid state. One hydroquinone ring in the crown ether component

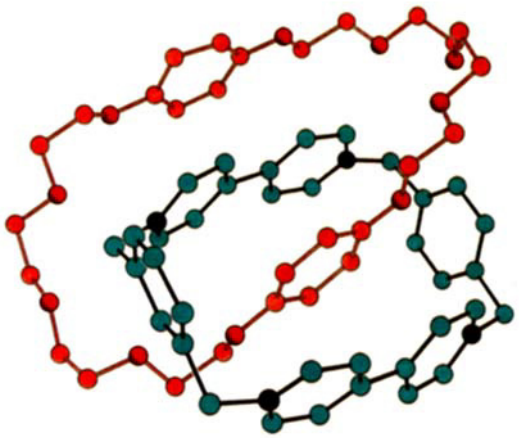

Fig. 1. The structure of **2** in the crystal; the donor and acceptor macrocycles are shaded light red and light blue, respectively. O atoms are dark red and N atoms are dark blue.

is located within the cavity of the tetracationic cyclophane such that it is sandwiched between the two π-electron deficient bipyridinum units, forming an angle of approximately 45° between its OC_6H_4O axis and the equatorial plane[11] of the cyclophane. Whereas in **1**·4PF_6 the methylene groups of the "inside" $CH_2-OC_6H_4O-CH_2$ unit are *anti* and those of the "alongside" unit are *syn*, in **2**·4PF_6 both units adopt *anti* geometries. As in **1**·4PF_6, one of the protons of the "inside" hydroquinone ring in **2**·4PF_6 is directed into the center of the *p*-xylyl spacer of the cyclophane (H···ring centroid distance, 2.75 Å; in **1**·4PF_6, 2.85 Å), whilst the hydroquinone proton directed towards the opposite end of the cyclophane makes an orthogonal approach to the carbon atom at the 2-position of the *m*-xylyl unit (H···C distance, 2.79 Å).[12] On going from **1**·4PF_6 to **2**·4PF_6, the maximum separation between the bipyridinium units is reduced[13] from 7.0 to 6.9 Å, and the distance between the xylyl spacers decreases from 10.3 to 10.0 Å. The bowing of the bipyridinium units is the same in both isomers; the angles subtended by the pairs of $N-CH_2$ bonds are approximately 26° in each case. The small diminution in the length of the tetracationic cyclophane component in **2**·4PF_6, which results in the reduced H–xylyl distance mentioned previously is supported by a low-temperature ^{1}H NMR spectroscopic study (vide infra) of **2**·4PF_6 in solution. Both **1**·4PF_6 and **2**·4PF_6 (Fig. 2) form polar stacks[14] in the solid state, comprising alternating π-electron rich and π-electron deficient aromatic moieties.

The tetracationic cyclophane component of **2**·4PF_6 was obtained as free **4**·4PF_6 from a template-directed reaction of **9** with **10**·2PF_6 in 7% yield, using a method identical to that described[5] for the preparation of cyclobis(paraquat-*p*-phenylene). When a solution of **4**·4PF_6 in CD_3COCD_3 is

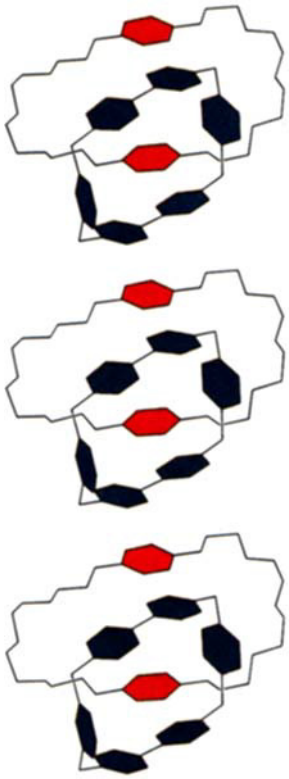

Fig. 2. Part of a polar stack of the [2]catenane **2** in the crystal illustrating the alternating sequence of π-electron-deficient and π-electron-rich aromatic moieties.

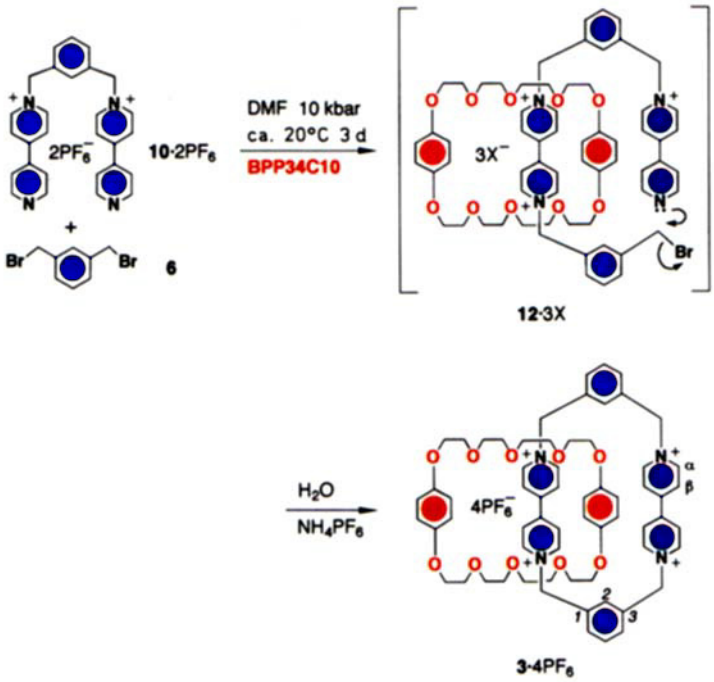
mixed with an excess of the template, 1,4-bis[(2-hydroxyethoxy)-ethoxy]benzene (BHEEB), an intensely orange-colored solution develops immediately, indicating charge transfer between the π-electron-rich and π-electron-deficient aromatic rings and therefore inclusion[15] of the template within the cavity of the cyclophane.[16] In a similar experiment, when **5**·4PF_6[7] and BHEEB are combined in CD_3COCD_3, a colorless solution results which gives rise to an ^{1}H NMR spectrum that can be superimposed upon the spectra of the components, indicating that *no* complex is



Scheme 2. Synthesis of the [2]catenene **3**·4PF_6 by self-assembly at ultrahigh pressure.

ployed[23] along with the chemical shift difference between the signals at ambient temperature ($\Delta\nu = 206$ Hz) to obtain a $\Delta G_c^{\ddagger}$ value of 16.3 kcal mol^{-1} for the site exchange.

At +25 °C, the ^{1}H NMR spectrum (CD_3CN, 90 MHz) of $\mathbf{3}\cdot 4PF_6$ is remarkably simple, since the cyclophane component exhibits averaged D_{2h} symmetry. However, the equilibration between the "inside" and "alongside" hydroquinone rings of the BPP34C10 component is slow, as evidenced by a sharp singlet at $\delta = 6.55$ for the protons on the latter ring, which broadens when the temperature is raised. The exchange method of analysis[25] of the temperature dependence of this signal gave a $\Delta G^{\ddagger}$ value of 17.6 kcal mol^{-1}. Cooling down a CD_3COCD_3 solution of $\mathbf{3}\cdot 4PF_6$ increases the complexity of its ^{1}H NMR spectrum. At −70 °C, four signals are observed for the α-CH bipyridinium protons, whilst the "inside" hydroquinone protons appear as two doublets centered on $\delta = 3.19$ and 5.63. This observation suggests that, as with $\mathbf{2}\cdot 4PF_6$, at low temperature, the degenerate structural changes of $\mathbf{3}\cdot 4PF_6$ are slow on the ^{1}H NMR timescale, and that the gross structure in solution is similar to that observed in the solid state. Coalescence of the resonances arising from the included hydroquinone ring at −1 °C indicates that the approximate barrier[23] to the rocking process[24] in $\mathbf{3}\cdot 4PF_6$ is $\Delta G_c^{\ddagger} = 11.7$ kcal mol^{-1} based on a $\Delta\nu$ value of 976 Hz.

The results presented here provide us with three important conclusions: 1) The self-assembly of isomeric [2]catenanes of the type described in this communication is extremely sensitive to constitutional changes in the tetracationic cyclophane component; the most favored[26] is cyclobis(paraquat-*p*-phenylene). 2) Changing the constitution[27] of the π-electron-deficient cyclophane influences dramatically the dynamic behavior of the isomeric [2]catenanes. 3) The solid-state structures of the [2]catenanes in and beyond their molecules is isomer dependent. It follows that it should be possible to control prescribed functions of these molecules by the most subtle of structural changes—isomerism!

Experimental Procedure

$\mathbf{2}\cdot 4PF_6$: 1,4-Bis(bromomethyl)benzene (**9**) (31 mg, 0.12 mmol), $\mathbf{10}\cdot 2PF_6$ (80 mg, 0.11 mmol), and BPP34C10 (201 mg, 0.38 mmol) were dissolved in dry DMF (5 mL), and the solution was stirred at room temperature for one week. $\mathbf{2}\cdot 4PF_6$ was isolated according to a previously described workup procedure [5] as a red solid (74 mg, 40%), m.p. > 250 °C. Single crystals suitable for X-ray crystallography were grown by vapor diffusion of iPr$_2$O into a solution of $\mathbf{2}\cdot 4PF_6$ in MeCN.

$\mathbf{3}\cdot 4PF_6$: 1,3-Bis(bromomethyl)benzene (**6**) (48 mg, 0.18 mmol), $\mathbf{10}\cdot 2PF_6$ (128 mg, 0.18 mmol), and BPP34C10 (267 mg, 0.50 mmol) were dissolved in dry DMF (5 mL) in a high-pressure reaction vessel which was pressurized to 10 kbar for 3 d at 20 °C. Following the purification procedure described above for $\mathbf{2}\cdot 4PF_6$, $\mathbf{3}\cdot 4PF_6$ was isolated as a red solid (82 mg, 28%), m.p. > 250 °C. Single crystals suitable for X-ray crystallography were grown by vapor diffusion of iPr$_2$O into a solution of $\mathbf{3}\cdot 4PF_6$ in MeCN.

$\mathbf{4}\cdot 4PF_6$: 1,4-Bis(bromomethyl)benzene (**9**) (0.42 g, 1.59 mmol), $\mathbf{10}\cdot 2PF_6$ (1.12 g, 1.59 mmol) and BHEEB (1.00 g, 3.49 mmol) were dissolved in dry DMF (30 mL), and the reaction mixture was stirred at room temperature for four weeks. $\mathbf{4}\cdot 4PF_6$ was isolated according to a previously described workup procedure [5], as a white solid (122 mg, 7%), m.p. > 250 °C, *m/z* (positive-ion FAB-MS [8]) 955 $(M - PF_6)^+$, 810 $(M - 2PF_6)^+$, 665 $(M - 3PF_6)^+$; ^{1}H NMR (300 MHz, CD_3COCD_3) $\delta = 6.18$ and 6.19 (overlapping s, 8H, NCH_2), 7.70 (t, 1H, 5-position of *m*-xylyl spacer), 7.82 (s, 4H, arom. protons of the *p*-xylyl spacer), 7.89 (s, 1H, 2-position of *m*-xylyl spacer), 7.95 (d, 2H, 4- and 6-positions of *m*-xylyl spacer), 8.40 (d, 4H, β-CH bipyridinium protons), 8.45 (d, 4H, β-CH bipyridinium protons), 9.30–9.39 (overlapping d, 8H, α-CH bipyridinium protons).

[8] The FAB mass spectra were measured on a Kratos MS80RF mass spectrometer (accelerating voltage 3 kV; resolution 1500) coupled to a DS90 data system. The atom gun was an adapted saddle field source (Ion Tech Limited) operated at 7 keV and a tube current of approximately 2 mA. Krypton was used to provide a primary beam of atoms. The samples $\mathbf{2}\cdot 4PF_6$, $\mathbf{3}\cdot 4PF_6$, and $\mathbf{4}\cdot 4PF_6$ were dissolved in 3-nitrobenzyl alcohol that had previously been coated onto a stainless steel probe tip. Spectra were recorded in the positive-ion mode at a scan speed of 30 s per decade.

[9] Crystal data for $\mathbf{2}\cdot 4PF_6\cdot 5MeCN$: monoclinic, $a = 49.47(7)$, $b = 13.945(16)$, $c = 28.88(3)$ Å, $\beta = 119.16(2)°$, $V = 17400$ Å^3, space group $C2/c$, $Z = 8$, $\rho_{calcd} = 1.40$ g cm^{-3}, $\mu(Cu_{K\alpha}) = 18$ cm^{-1}, 4543 independent observed reflections with $[|F_o| > 4\sigma(|F_o|), 2\theta \leq 110°]$ refined to a current $R = 0.139$, $R_w = 0.137$.

[10] Siemens-P3/PC diffractometer, ω scans, $Cu_{K\alpha}$ radiation (graphite monochromator). The structure was solved by direct methods and refined anisotropically. Further details of the crystal structure can be obtained from the Cambridge Crystallographic Data Centre, 12 Union Road, GB-Cambridge CB2 1EZ (UK), on quoting the full journal citation.

[11] The equatorial plane of the cyclophane is defined as the mean plane of the four methylene carbon atoms.

[12] In the solid-state structure of $\mathbf{2}\cdot 4PF_6$, there are additional weak stabilizing C–H···O interactions between, for example, the α-CH proton of the included bipyridinium unit nearest to the *m*-xylyl spacer and the central oxygen atom of the BPP34C10 component (H···O = 2.52 Å, C–H···O angle = 153°) and between the diametrically opposite central oxygen atom of the crown ether and one of the aromatic protons in the *p*-xylyl spacer (H···O = 2.57 Å, C–H···O angle = 159°).

[13] In $\mathbf{2}\cdot 4PF_6$, there is an accompanying reduction to 6.95 Å in the interplanar separation between the "inside" and "alongside" hydroquinone rings (in $\mathbf{1}\cdot 4PF_6$ this separation is 6.95 Å).

[14] Each stack contains only one of the enantiomeric forms of the [2]catenane.

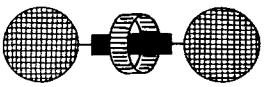
[21] ^{1}H NMR data for **2**·4PF$_6$ (400 MHz, CD_3COCD_3, 25 °C): δ = 3.40 (m, 4H, CH_2O), 3.63 (m, 6H, CH_2O and "inside" hydroquinone ring protons nearest to the π-faces of the xylyl spacers), 3.77 (m, 4H, CH_2O), 3.82 (m, 4H, CH_2O), 3.83–4.03 (m, 16H, remaining CH_2O protons), 4.42 (br. s, 2H, "inside" hydroquinone protons directed away from the cavity of the cyclophane), 6.03 (s, 4H, CH_2N), 6.10 (s, 4H, CH_2N), 6.27 (s, 4H, "alongside" hydroquinone ring protons), 7.87 (t, 1H, 5-position of *m*-xylyl spacer), 7.98 (s, 1H, 2-position of *m*-xylyl spacer), 8.05 (s, 4H, *p*-xylyl spacer arom. protons), 8.12–8.20 (overlapping d, 6H, 4- and 6-positions of *m*-xylyl spacer and β-CH bipyridinium protons), 8.25 (d, 4H, β-CH bipyridinium protons), 9.15 (d, 4H, α-CH bipyridinium protons), 9.27 (d, 4H, α-CH bipyridinium protons). ^{1}H NMR data for **3**·4PF$_6$ (400 MHz, CD_3COCD_3, 45 °C): δ = 3.42 (m, 4H, CH_2O), 3.66 (m, 4H, CH_2O), 3.80 (m, 12H, CH_2O), 3.88 (m, 4H, CH_2O), 3.98 (m, 4H, CH_2O), 4.09 (m, 4H, CH_2O), 4.41 (br. s, 4H, "inside" hydroquinone ring protons), 6.13 (s, 8H, NCH_2), 6.31 (s, 4H, "alongside" hydroquinone ring protons), 7.87 (t, 2H, 5-position of *m*-xylyl spacer), 8.04 (s, 2H, 2-position of *m*-xylyl spacer), 8.17 (d, 4H, 4- and 6-positions of *m*-xylyl spacer), 8.23 (d, 8H, β-CH bipyridinium protons), 9.13 (d, 8H, α-CH bipyridinium protons).
[22] The value of $\Delta G_c^{\neq}$ was obtained from the observed coalescence (T_c = −28 °C) of the "inside" hydroquinol resonances (δ = 3.17 and 5.53 at −60 °C, $\Delta\nu$ = 944 Hz) nearest to the *m*-xylyl spacer (see [23] for calculation).
[23] Values of k_c were obtained (I. O. Sutherland, *Annu. Rep. NMR Spectrosc.* **1971**, *4*, 71) by using the approximate expression $k_c = \pi(\Delta\nu)/\sqrt{2}$, and the Eyring equation was then used to calculate $\Delta G_c^{\neq}$ values at T_c.
[24] A process whereby the tetracationic cyclophane passes through the BPP34C10 component is also evident in the variable temperature ^{1}H NMR spectroscopic study, but estimation of the barrier to circumrotation was not possible owing to the complexity of the spectra at low temperature.
[25] The exchange method involves obtaining values of k (J. Sandström, *Dynamic NMR Spectroscopy*, Academic Press, London, **1982**, Chapter 6) from the approximate expression $k = \pi(\Delta\nu)$, where $\Delta\nu$ is the difference between the line width at a given temperature and the line width in the absence of exchange. The Eyring equation is then used to obtain values of $\Delta G^{\neq}$.
[26] Constitutional control of catenane formation can be exploited to advantage in the highly selective self-assembly of a chiral bis([2]catenane). See P. R. Ashton, A. S. Reder, N. Spencer, J. F. Stoddart, *J. Am. Chem. Soc.* **1993**, *115*, 5286.
[27] After the research described in this communication had been completed, we became aware that F. Vögtle, W. M. Müller, U. Müller, M. Bauer, and K. Rissanen (*Angew. Chem.* **1993**, *105*, 1356; *Angew. Chem. Int. Ed. Engl.* **1993**, *32*, 1295) had also prepared and obtained a crystal structure of **2**·4PF$_6$.

A Photochemically Driven Molecular Machine**

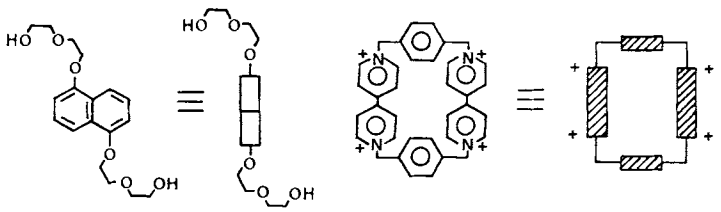
By *Roberto Ballardini,* Vincenzo Balzani,* Maria Teresa Gandolfi, Luca Prodi, Margherita Venturi, Douglas Philp, Howard G. Ricketts,* and *J. Fraser Stoddart**

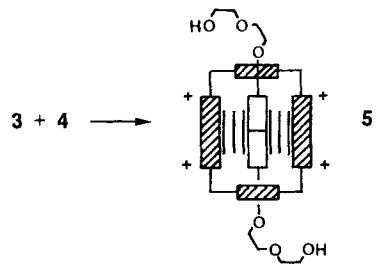
In everyday life, we make extensive use of macroscopic devices called machines, which are assemblies of components designed for specific functions. The concept of a machine can be extended to the molecular level.[1–9] Whereas the machines of the macroscopic world are designed and constructed by mechanical engineers, molecular machines, which have dimensions on the nanometer scale, are constructed by "molecular engineers", that is, chemists. Molecular machines, like macroscopic machines, need energy to operate. For several reasons, the most convenient form of energy to make molecular machines work is light. In this paper, we describe some preliminary studies aimed at the construction of simple, light-driven mechanical molecular machines that could play a role in storing and processing information at the molecular level.[10]

Amongst the numerous new types of compounds recently constructed by chemists are the rotaxanes (**1**),[11] which are composed of a macrocyclic ring threaded by a linear component resembling a dumbbell, with bulky groups at either end. When one or both of the bulky end-groups are absent, the ring can unthread. This supramolecular species is called a pseudorotaxane (**2**).[12] In the last few years a variety of rotaxanes and pseudorotaxanes have been obtained by exploiting self-assembly processes based on π-electron donor–acceptor interactions.[6–8, 11c, 13, 14]



When the molecular thread **3**, which has a 1,5-dioxynaphthalene electron-donating group, is added to a solution of the electron-accepting cyclophane **4**, it threads itself spontaneously through the center of the tetracationic cyclophane producing the 1:1 complex or pseudorotaxane **5** as indicated by the ^{1}H NMR spectra.[14] The threading process can also





be followed by absorption and emission spectra. The interaction between the π-electron donor and the π-electron acceptor causes the formation of a charge-transfer band in the visible region (λ_{max} = 520 nm, $\varepsilon_{max} \approx 700\ M^{-1}cm^{-1}$) and the disappearance of the intense luminescence of **3** (λ_{max} = 345 mm, τ = 7.5 ns).[15] The threading process takes place in a variety of solvents,[14] reaching an equilibrium more or less displaced towards the formation of the pseudorotaxane **5**. The solvent chosen for the present investigation was water, wherein, starting with a 6.0×10^{-5} M solution of **3** and **4** (as

[**] This work was supported by the Consiglio Nazionale delle Ricerche (Progetto Finalizzato Chimica Fine II) and the Italian Ministero dell'Università e della Ricerca Scientifica e Tecnologica, and by SERC and Glaxo Group Research in the UK. We thank Anna Godi for some preliminary experiments.

its tetrachloride), 80% of the species formed at room temperature is the pseudorotaxane.[16]

Since the superstructure of the pseudorotaxane is based on the donor–acceptor interaction between its two components, reduction of the electron acceptor or oxidation of the electron donor is expected[7] to destabilize the supramolecular array and cause unthreading.[17] We have now devised a simple photochemical method to govern the unthreading process in this system.

It is well known[19] that the first excited state of 9-anthracenecarboxylic acid (hereafter abbreviated as **P**) is a long-lived (250 μs) and powerful reductant ($E_{red}(P^+/{}^*P) = -0.88$ V, vs. SCE). Therefore, one might expect that irradiation of a deoxygenated solution containing **P** (5.0×10^{-6} M) and **5** (4.8×10^{-5} M) should cause the reduction of the electron acceptor component **4** of the pseudorotaxane ($E_{red} = -0.32$ V) and, as a consequence, promote the unthreading process (Fig. 1). However, the departure of the

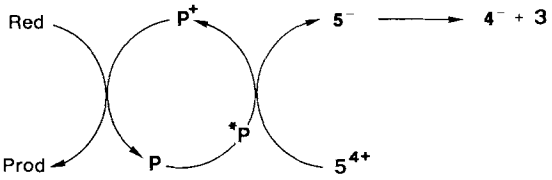

Fig. 1. Schematic representation of the light-induced unthreading process. The photosensitizer **P** is 9-anthracenecarboxylic acid and the "sacrificial" reductant Red is triethanolamine. For more details, see text. Prod = product of the oxidation of triethanolamine.

thread from the ring is slow because the process requires extensive nuclear motions. Therefore, it cannot compete with the fast back electron-transfer from the reduced **5** to the oxidized species P^+.[19] However, when a "sacrificial" reductant (like triethanolamine, 0.01 M) is also present in the solution, the oxidized species P^+, produced by the excited-state electron-transfer reaction, can be rapidly scavenged (Fig. 1). The result is that the back electron-transfer reaction is prevented and the pseudorotaxane remains reduced, as evident from the appearance of the characteristic bands of reduced paraquat-type units in the absorption spectrum of the solution (Fig. 2). Under such conditions, the charge-transfer interaction between the thread and the ring is permanently reduced, and the unthreading process takes place,

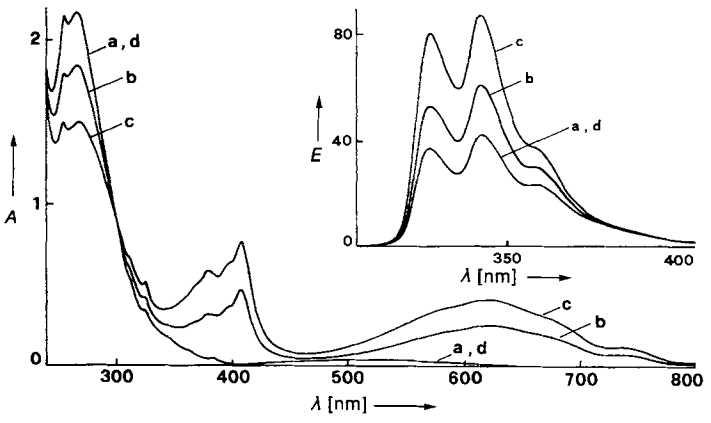

Fig. 2. Changes in the absorption (A) and luminescence spectrum (E [a.u.], of the pseudorotaxane **5** on irradiation. Curve a: starting solution; curves b and c: solutions irradiated for 4 and 15 min, respectively; curve d: solution c after oxidation with O_2.

as proven by the appearance of the fluorescence of free **3** (Fig. 2, inset).[20] Under the experimental conditions[15] 35% of the pseudorotaxane species was unthreaded after 25 minutes of irradiation. The unthreading reaction can also be performed by using $[Ru(bpy)_3]^{2+}$ (bpy = 2,2′-bipyridine) as a photosensitizer, but the reaction is not as efficient, mainly because of shorter excited-state lifetime of the complex.[21]

If oxygen is allowed to enter the irradiated solution, the reduced cyclophane is promptly reoxidized and **3** again threads through it, as shown by the decrease in the intensity of the fluorescence band and the reappearance of the initial absorption spectrum (Fig. 2). In principle, the rethreading process could also be photoinduced if a suitable "sacrificial" oxidant was added to the solution.

The strategy described above could be extended to more interesting systems in which the photosensitizer is incorporated as a stopper in the molecular structure of a rotaxane. A particularly appealing system based on the molecular shuttles[6, 8, 13] already described is shown in Fig. 3. In such

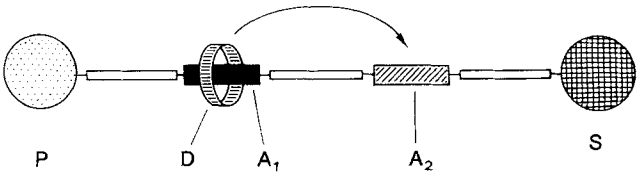

Fig. 3. Proposed structure for a light-driven molecular shuttle.

a system, an electron donor ring **D** is threaded by a dumbbell component composed of two electron acceptor "stations" $\mathbf{A}_1$ and $\mathbf{A}_2$, a bulky photosensitizer **P**, an inert stopper **S**, and suitable connectors. If $\mathbf{A}_1$ is a better electron acceptor than $\mathbf{A}_2$, the ring will reside on it preferentially. Light excitation of the photosensitizer **P** in the presence of a "sacrificial" electron donor could then be used to reduce $\mathbf{A}_1$, which would cause the displacement of the ring to $\mathbf{A}_2$. This movement would amount to the use of light to operate a molecular abacus.

[14] a) P. R. Ashton, R. Ballardini, V. Balzani, M. Blower, M. Ciano, M. T. Gandolfi, L. Prodi, C. H. McLean, D. Philp, N. Spencer, J. F. Stoddart, M. S. Tolley, *New J. Chem.*, in press; b) P. L. Anelli, P. R. Ashton, N. Spencer, A. M. Z. Slawin, J. F. Stoddart, D. J. Williams, *Angew. Chem.* **1991**, *103*, 1052; *Angew. Chem. Int. Ed. Engl.* **1991**, *30*, 1306.

[15] The experiments were carried out at room temperature in deaerated, aqueous 0.1 M MeCOONa solution. Absorption and luminescence spectra were recorded with Perkin-Elmer λ6 and LS50 instruments. Luminescence lifetimes were measured with an Edinburgh 199 single-photon counting instrument. Light excitation was performed with a Hanau Q 400 medium-pressure Hg lamp, equipped with a 365 nm filter. The incident light intensity on the 3 mL reaction cell was 2×10^{-6} N$h\nu$ min^{-1}. The fraction of the incident light absorbed by the photosensitizer was 13%.

[16] The amount of pseudorotaxane present under the conditions used for the photochemical experiments was determined from the quenching of the intensity of the luminescence of **3** and the intensity of the charge-transfer absorption band. The ^{1}H NMR spectrum (300 MHz) of the complex composed of **3** and **4** (0.013 M of each) in D_2O at room temperature shows significant changes in the chemical shifts of the aromatic protons of **3**. The largest change ($\Delta\delta = -4.52$) is for the H4 and H8 protons on the naphthalene ring. This large $\Delta\delta$ value, along with the strong charge-transfer interaction between the two components, is compelling evidence for the formation of complex **5**, whose structure in aqueous solution is best described as pseudorotaxane-like: a) P. Ashton, D. Philp, N. Spencer, J. F. Stoddart, *J. Chem. Soc. Chem. Commun.* **1991**, 1677; b) P. R. Ashton, C. L. Brown, E. J. T. Chrystal, T. T. Goodnow, A. E. Kaifer, K. P. Parry, A. M. Z. Slawin, N. Spencer, J. F. Stoddart, D. J. Williams, *Angew. Chem.* **1991**, *103*, 1055; *Angew. Chem. Int. Ed. Engl.* **1991**, *30*, 1039; c) P. R. Ashton, D. Philp, N. Spencer, J. F. Stoddart, unpublished results.

[17] In principle, the donor–acceptor interaction can be destroyed by direct excitation of the supramolecular species in its charge-transfer band. However, the back electron-transfer reaction is, as expected [4], much faster than the unthreading process [18]. Such a "direct-excitation approach", therefore, does not seem to be very promising.

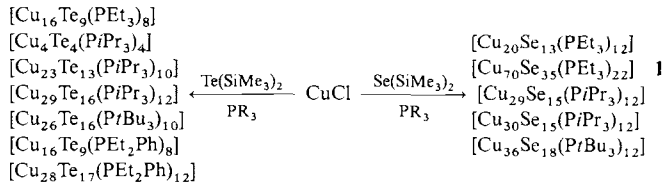
A New Copper Selenide Cluster with PPh_3 Ligands: $[Cu_{146}Se_{73}(PPh_3)_{30}]$**

By *Harald Krautscheid, Dieter Fenske,* Gerhard Baum,* and *Marcus Semmelmann*

Dedicated to Professor Hans Bock on the occasion of his 65th birthday

Complexes of transition metal halides with cyclopentadienyl, carbonyl, and above all tertiary phosphane ligands react with silylated elements of the fifth and sixth main groups to give trimethylsilyl halide and metal-rich cluster compounds.[1] In these reactions, the structure of the clusters formed is influenced by the steric demand of the phosphane ligand. For example, copper–chalcogenide clusters of differing sizes are obtained from the reaction of CuCl with PEt_3, $PiPr_3$, $PtBu_3$, or PEt_2Ph, and $E(SiMe_3)_2$ (E = Se, Te) (Scheme 1).[2]

In analogous reactions of $[CuCl(PPh_3)]_4$, $[Cu_2Cl_2(PPh_3)_3]$, or $[CuCl(PPh_3)_3]$ with $Se(SiMe_3)_2$, we found that in organic solvents either dark brown powders or black crystals were formed, which were unsuitable for X-ray crystal structure analysis.[2] However, we have now succeeded in obtaining suitable single crystals from the reaction of CuCl with PPh_3 and $Se(SiMe_3)_2$ in THF.[3] In this reaction, the reaction rate decreases with an increasing ratio of PPh_3 to CuCl. Whereas attempts at recrystallization have so far not been successful, the reaction rate and therewith also the rate of crystallization was slowed by the high phosphane concentration, so that the crystal quality improved. According to the results of the crystal stucture analysis, the product has the composition $[Cu_{146}Se_{73}(PPh_3)_{30}]$ (**2**).



Scheme 1.

$$146\ CuCl + 73\ Se(SiMe_3)_2 + 30\ PPh_3 \xrightarrow{THF} [Cu_{146}Se_{73}(PPh_3)_{30}] + 146\ Me_3SiCl$$

2

No structural information could be derived from NMR spectroscopic investigations of **2** in solution because of the low solubility of the cluster and the rapid exchange of the phosphane ligands. Only bands of weak intensity for the coordinated PPh_3 ligands are found in the IR spectrum of **2**.

Based on the systematic absences the solution and the refinement of the structure was carried out in the space groups $P\bar{3}1c$ and $P6_3/mmc$.[4] Whereas the $Cu_{146}Se_{73}$ cluster core and the P atoms of the PPh_3 ligands comply with the space group symmetry of $P6_3/mmc$, only some of the C atoms could be located and these were disordered. In contrast, the difference Fourier syntheses in $P\bar{3}1c$ yielded all the C atoms; for which a phenyl group of one PPh_3 ligand is disordered. This disorder and the large thermal ellipsoids of Cu 17, Cu 18, and Cu 25 indicate that the trigonal or hexagonal symmetry, respectively, is possibly not real. It could be a consequence of triple twinning during the growth of the crystal, and in reality a lower symmetry may exist.[5]

Compound **2** crystallizes with two formula units per unit cell and has a threefold and three twofold axes. Compound **2** (Fig. 1, top) is constructed according to the same structural principle as $[Cu_{70}Se_{35}(PEt_3)_{22}]$ **1**. As Figure 1 (bottom left) shows, the PPh_3 ligands, which are bound to 30 peripheral copper atoms (Cu 1, Cu 6, Cu 11, Cu 12, Cu 23; Cu–P 218.4–224.4 pm, mean 222.2 pm), shield the $Cu_{146}Se_{73}$ cluster core almost perfectly. In **1** and **2**, the Se atoms are organized into three planar layers with 10, 15, and 10 atoms in **1**, and 21, 31, and 21 atoms in **2** (ABA stacking). The maximum deviations from the ideal planes in **2** are 5.4 pm for the middle layer and 15.5 pm for the outer layers. As shown in Figure 1, bottom right, these layers are constructed according to the principle of a two-dimensional closest packing and have an interlayer distance of 362 pm. Only Se 1 does not follow this order. The Se–Se distances within these layers range from 371.5 to 467.7 pm (mean 412 pm), and between the layers from 418.1 to 453.4 pm (mean 436 pm).

In β-Cu_2Se, a layer structure of the Se atoms is also found, which, however, in contrast to **1** and **2** form a cubic closest packing. Here, the nonbonding Se–Se distance is 414.4 pm, and the distance between the Se layers is 338.3 pm.[6]

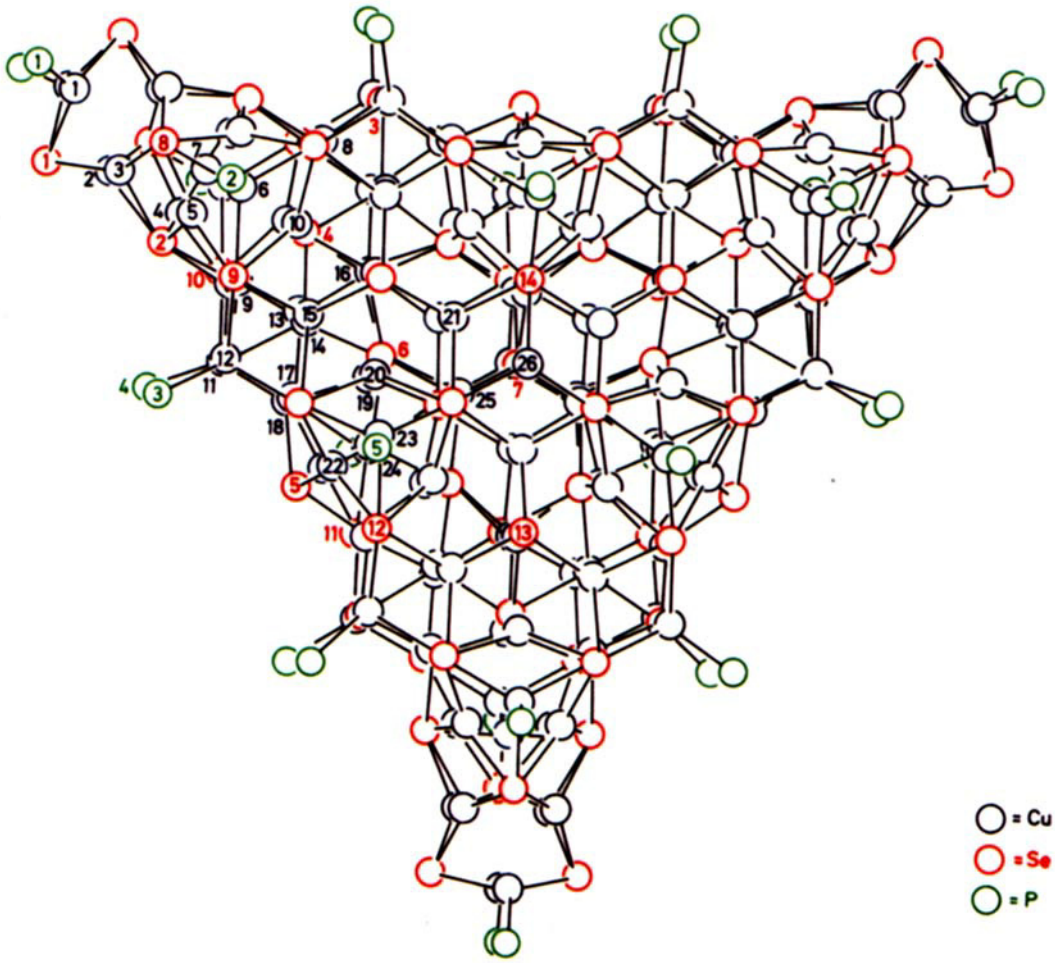
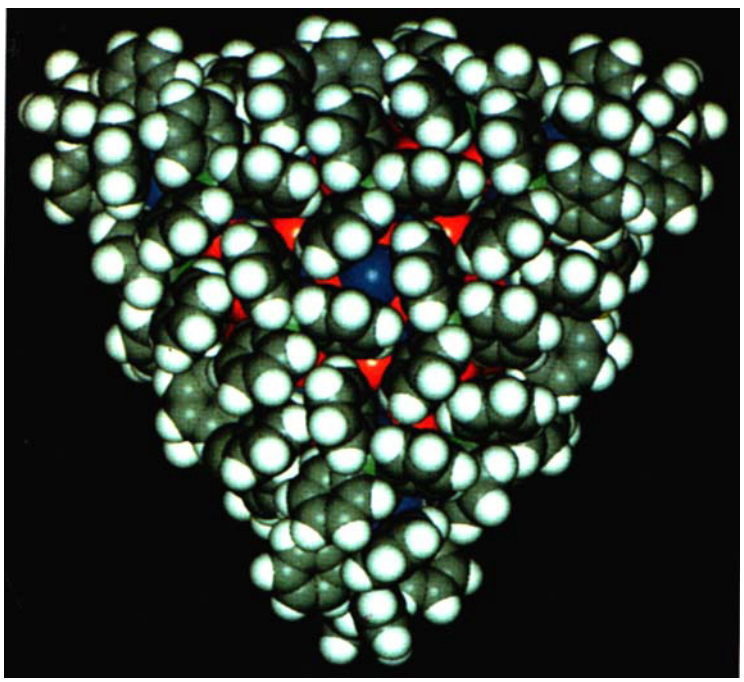
[**] This work was supported by the Deutsche Forschungsgemeinschaft (SFB 195) and the Fonds der Chemischen Industrie.

The holes generated by the Se packing are filled with Cu atoms (blue), as shown in Figure 2. Of the 146 Cu atoms 120 are found between the Se layers, 12 Cu atoms (Cu 7, Cu 14, and Cu 24) in the middle Se layer, and 14 Cu atoms (Cu 6, Cu 23, and Cu 26) outside the Se layers. If all the Cu–Se distances in the cluster less than 282 pm are considered as bonds, 12 μ_4-(Se 1, Se 13; Cu–Se 236.1–248.2 pm), 6 μ_5-(Se 8; Cu–Se 237.7–268.3 pm), 25 μ_6- (Se 7, Se 9–Se 12; Cu–Se 237.3–267.8 pm), 21 μ_7-(Se 2, Se 3, Se 5, Se 14; Cu–Se 233.8–277.4 pm), and 9 μ_8-Se bridges (Se 4, Se 6; Cu–Se





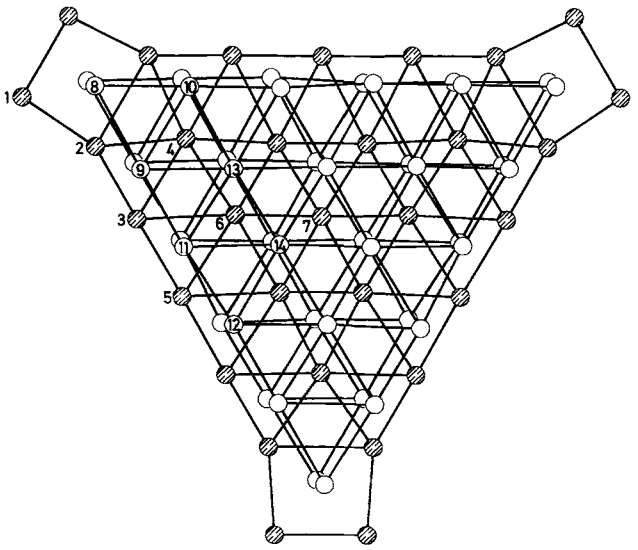


Fig. 1. Top: Crystal structure of **2** (without phenyl groups; Cu: blue, Se: red, P: green) viewed approximately down the threefold axis. For a better overview only one set of symmetrically independent atoms was labeled with atom numbers in the corresponding color. Cu–Cu bonds are not shown, but Cu–Se distances up to 282 pm are drawn. Bottom left: space-filling model of **2** in the same orientation (with phenyl groups); bottom right: stacking of the Se layers in **2**.

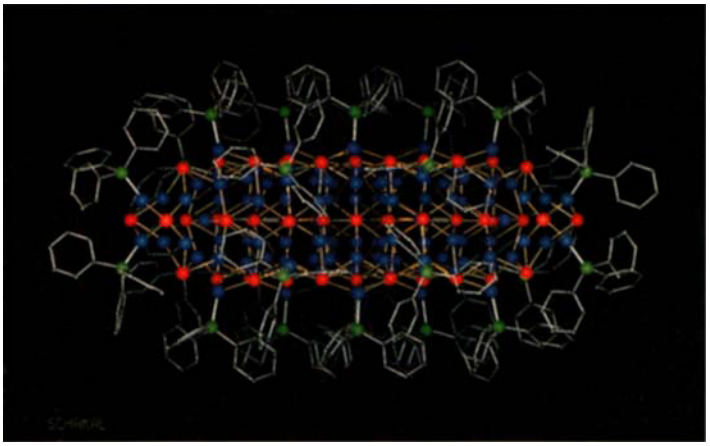

Fig. 2. Structure of **2** viewed along the Se layers (Cu: blue, Se: red, P: green). Cu–Se distances up to 282 pm are drawn.

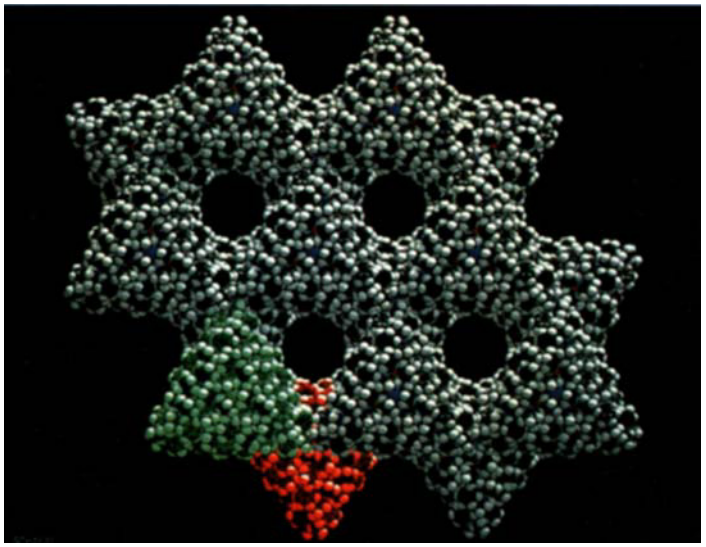

238.7–281.1 pm) are found. The mean Cu–Se distance is 251.2 pm.

The Cu atoms predominantly fill sites with threefold Se coordination. Only Cu14 and Cu24 lie in the middle of nearly equilateral Se_3 triangles, whereas the other Cu atoms are found outside the Se planes. Eighteen Cu atoms (Cu9, Cu16, Cu25) are bound nearly tetrahedrally to four Se atoms, and 24 Cu atoms (Cu6, Cu11, Cu12, Cu23) are coordinated to three Se atoms and one phosphane ligand, also in an almost tetrahedral manner. Cu1 is coordinated by one PPh_3 and two Se atoms. Cu7, which is bound to only two Se ligands, has the lowest coordination number.

In cubic β-Cu_2Se, half of the Cu atoms fill tetrahedral holes, the other half are distributed on octahedral sites and those sites which lie between the middle of the Se_3 faces and the unoccupied tetrahedral holes. For example, the Cu atoms in $Cs_2Cu_5Se_4$ are found mainly in tetrahedral holes, they are, however, shifted toward the middle of a tetrahedral face, so that here also the tendency for the coordination number 3 is apparent.[6]

The Cu–Se distances in β-Cu_2Se for the Cu atoms in octahedral holes are 293.0 pm, for Cu atoms in tetrahedral holes 253.7 pm, and for Cu atoms in a distorted trigonal environment 243.2 pm. Thus, it is clear that **2** does not exactly represent a section from the β-Cu_2Se structure; however, the coordination and separations between the Se layers show similarities.

Compound **2** forms molecules with approximately trigonal prismatic shape with an edge length of about 40 Å and a thickness of about 20 Å. The copper selenide cluster core has a maximum width of 26.7 Å and a thickness of 8.7 Å. The shortest distance between two cluster cores is found between the Se1 atoms of two molecules of one layer (Fig. 3), and is only 11.2 Å. Since Cu_2Se behaves like a semimetal, the question arises of whether the cluster unit surrounded by the insulating PPh_3 envelope already possesses physical properties similar to those of Cu_2Se. According to initial impedance spectroscopic investigations on single crystals of **2**, the electric conductivity is frequency and temperature dependent.[7] Comparable measurements on powder samples of **1** give an electric conductivity of $10^{-2}\,\Omega^{-1}\,cm^{-1}$, whereas $[Cu_{36}Se_{18}(PtBu_3)_{12}]$ is an insulator.[8] The direct current conductivity of crystalline **2** at room temperature is $\sigma' = 1.5 \times 10^{-2}\,\Omega^{-1}\,cm^{-1}$;[7] it is, however, significantly less than the value found for Cu_2Se.

As a result of the packing, channellike cavities with a diameter of about 16 Å form in the crystal along the c axis (Fig. 3). In organic solvents, the channels are probably filled with solvent molecules, which, however, can be removed under mild conditions, without destroying the crystal lattice. In the crystal structure analysis of **2**, 42 THF molecules per formula unit were located in the immediate vicinity of the PPh_3 ligands.

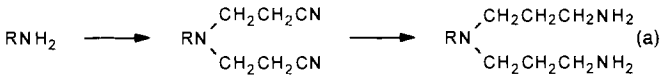
Polynitrile- and Polyamine-Functional Poly(trimethylene imine) Dendrimers**

By *Christof Wörner* and *Rolf Mülhaupt**

Dedicated to Professor K. Takemoto

Symmetrical cascade polymers, often referred to as dendrimers or starburst polymers, can be prepared by divergent or convergent synthetic methods.[1] In the divergent synthesis the generation are prepared by sequential construction of stepwise branched polymers starting from a polyfunctional core and multiplying the functionalities in each branching step.[2-9] The ideal starburst-type growth is restricted to a certain limiting generation,[10,11] and when the density of the functional groups reaches a limit, steric hindrance accounts for incomplete branching reaction and consequently increased content of structural defects. Furthermore, for the divergent syntheses large excesses of the reagents must be used. In contrast, in the convergent synthetic strategy large dendritic precursors are prepared which are subsequently coupled.[12,13] Our research is aimed at the development of high yield divergent syntheses which do not require large excess of reagents and purification.

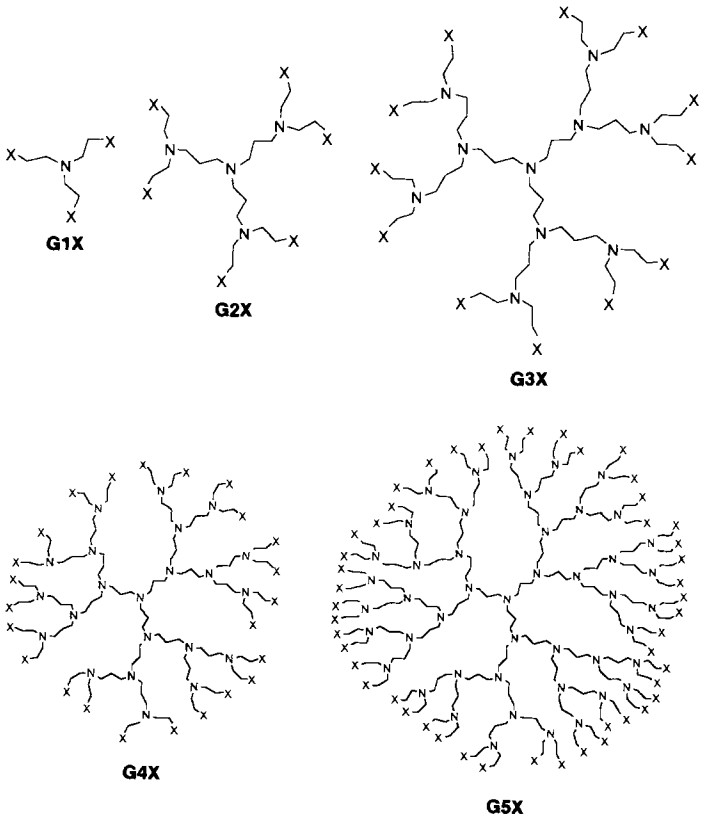
Vögtle et al.[2] had first proposed a conceptual approach involving a branching reaction sequence through cyanoethylation of amines with acrylonitrile followed by chemical reduction to double the amine end group functionality and stepwise branching the dendritic polyamines, thus forming poly(trimethylene imines). As a consequence of rather low



yields obtained in the reduction step, this reaction sequence was restricted to low molecular weight polyamine-functional oligo(trimethylene imines). The nitriles are quantitatively hydrogenated in the presence of Raney-nickel at room temperature and 8 bar hydrogen pressure, when small amounts of sodium hydroxide is added to the ethanol solvent.[14] Under such reaction conditions, the only partially ethanol-soluble polynitrile-functional poly(trimethylene imine) is suspended and hydrogenated to form ethanol-soluble polyamine-functional poly(trimethylene imines). This hydrogenation slurry process eliminates side reactions between amines and nitriles. Also it was found that in the presence of methanol the cyanoethylation occurs without formation of monosubstituted side products. In acetic acid[2] colored reaction products are formed that contain small quantities of monocyanoethylated amines, which lead to the structural defects in the dendrimers.

Since acrylonitrile, methanol, and cyanoethylated methanol are readily removed under vacuum, this synthetic route does not require special purification processes.

Starting from ammonia as initiator core, it was possible to build five generations of polynitrile- (X = CN) and polyamine-functional ($X = CH_2NH_2$, Scheme 1) cascade



Scheme 1. Starburst poly(trimethylene imine) generations G*n*X ($n = 1-5$) with X = N for nitrile (CN) and X = A for amino (CH_2NH_2) end groups.

molecules by repeating the cyanoethylation/catalytic hydrogenation reaction sequence (Table 1). Although according to growth statistics, the fifth generation is not considered to be the theoretical limitation for ideal growth, G5N could not be completely hydrogenated. Most likely, the steric hindrance of 48 nitrile groups located at the surface is sufficient to reduce the catalytic activity of the Raney-nickel. In fact, the reaction time required for quantitative hydrogenation increases substantially with increasing number of generations: G1N is hydrogenated in seven hours, G4N in four days.

Table 1. Polynitrile- and polyamine-functional poly(trimethylene imines). G*n*X represents the generations from $n = 1-5$ with X = N for nitrile- and X = A for amine end groups.

[**] This work was supported by the Deutsche Forschungsgemeinschaft. During preparation of this manuscript the authors became aware of similar results from E. M. M. de Brabander-van den Berg, E. W. Meijer, *Angew. Chem.* **1993**, *105*, 1370-1372; *Angew. Chem. Int. Ed. Engl.* **1993**, *32*, 1308-1311

tecture. The structures proposed for the individual generations in Scheme 1 have been confirmed with elemental analysis, end group titration, ^{1}H NMR, ^{13}C NMR, and IR spectroscopy, mass spectrometry, vapor pressure osmometry (VPO) and gel permeation chromatography (GPC). In addition to the molecular weights, the content of primary NH_2 end groups, and secondary NRH structural defects were determined. By potentiometric end group titration, it was possible to distinguish between primary and tertiary amine content only in the first generation G1A.[15] The ^{1}H NMR spectra of polynitrile-functional G4N (Fig. 1) and in polyamine-functional G4A (Fig. 2) show no secondary NHR structural defects, since the signals of the methylene group adjacent to the secondary amino group at $\delta = 2{,}7$ (between a and c in Fig. 1) and $\delta = 2{,}5$ (between b and d in Fig. 2) are observed in the expected region. According to the

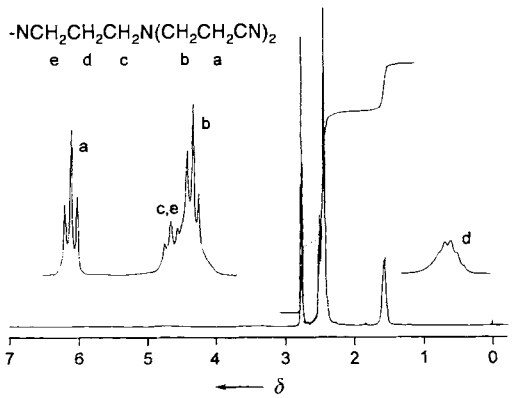

Fig. 1. ^{1}H NMR spectrum (400 MHz, CD_2Cl_2) of G4N.

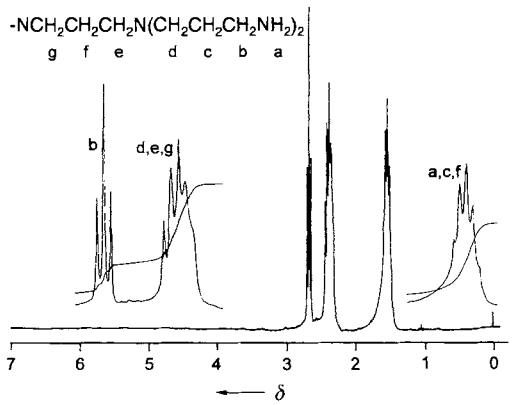

Fig. 2. ^{1}H NMR spectrum (250 MHz, $CDCl_3$) of G4A.

signal intensity ratio, highly symmetrical cascade polymers are formed. Also the signals of the CH_2 groups bound to the end groups have been assigned (triplet a in Fig. 1 at $\delta = 2{,}83$ triplet b in Fig. 2 at 2.67). The ^{13}C NMR spectra of the generations 1–4 confirm the high purities of the dendrimers. In the cyanoethylation of G4N small quantities of monocyanoethylated secondary NHR end groups are observed since steric hindrance increases drastically in the fifth reaction sequence. The ^{13}C NMR spectrum of the generation G5N (Fig. 3) reveals the signals of the methylene groups adjacent to the secondary amine (signals n and l at $\delta = 47.9$ and 45.5 respectively) and to the tertiary amine (signals d and c at $\delta = 51.6$ and 49.8 respectively). In a rough estimate based upon the signal intensities, the proportion of dendrimers with structural defects is less than 2 mol%. This means that on the surface of G5N, on average only 47 of the 48 possible nitrile groups per mol of dendrimer is achieved. This NMR study confirms that the cyanoethylation/hydrogenation reaction sequence provides excellent control of the molecular structure of these highly symmetrical cascade molecules.

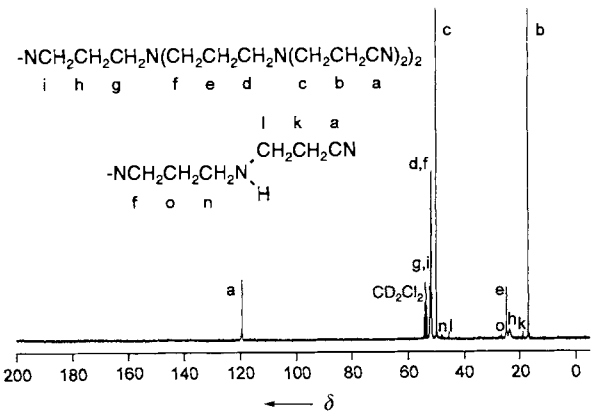

Fig. 3. ^{13}C NMR spectrum (100 MHz, CD_2Cl_2) of G5N. Spectrum confirms structural defects in the cascade molecule through monosubstitution (secondary amino end groups).

For the determination of the molecular weights, end group titration confirms the expected values for G1A and mass spectrometry for the generations G1(N, A) and G2(N, A). As apparent from Table 1, vapor pressure osmometry gives good agreement with the theoretical molecular weights over the entire range. Since in each generation size and hydrodynamic volume of the cascade molecules change substantially, gel permeation chromatography (GPC) has proven to be the best method for the characterization of the polyamine- and polynitrile-functional poly(trimethylene imines). In order to overcome adsorption problems of the highly surface-functional cascade molecules, which cause a broadening of the GPC chromatographs, electrolytes must be added to the eluent used in GPC chromatography. The characterization of the dendrimers was achieved by using an aqueous 0.05 M K_2HPO_4 buffer solution and a methanol/water (70:30) solvent mixture at pH = 11 and 60 °C. In Figure 4 the GPC chromatographs of the polyamine- and polynitrile-functional generations are shown.

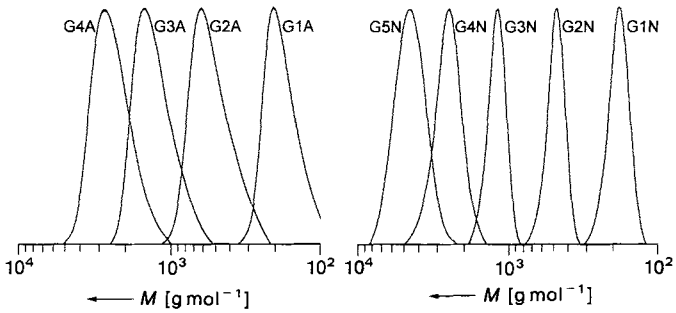

Fig. 4. Molecular weight distributions of the polyamine- and polynitrile-functional dendrimers (determined with GPC).

Using the values from vapor pressure osmometry for calibration, the polydispersities and number as well as weight average molecular weights have been determined. All generations exhibit monodisperse molecular weight distributions with polydispersities $\bar{M}_w/\bar{M}_n$ increasing with increasing number of the generation from 1.02 to 1.08. On the basis of the

GPC analyses, coupling reactions can be excluded. Interestingly, the solution behavior of poly(ethylene oxide), a typical random-coil polymer, is quite different from that of the two types of highly functional poly(trimethylene imine) cascade molecules prepared by us. As apparent from Figure 5, the polyamine-functional cascade molecules require higher elution volumes, which increase with increasing number of generations. In agreement with earlier observations,[1, 16] it ap-

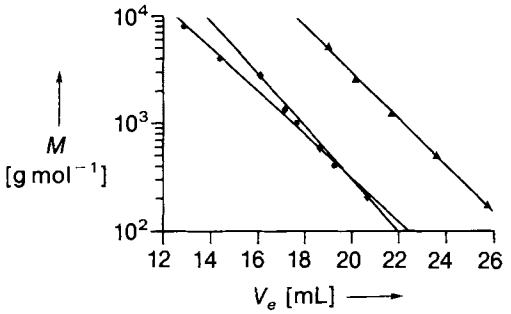

Fig. 5. Correlation of molecular weight M and elution volume V_e in GPC analyses of poly(ethylene oxide) (●), polynitrile- (▲) and polyamine-functional poly(trimethylene imines) (◆).

pears likely that cascade molecules when compared with conventional random-coil polymers exhibit higher densities, which increase with increasing molecular weight. The very high elution volumes found for the polynitrile-functional cascade molecules may result from adsorption phenomena, which do not interfer with the GPC analysis of the molecular weight distributions. In all three polymers there exists a linear correlation between molecular weight, determined by vapor pressure osmometry, and elution volume.

In conclusion, the divergent synthesis involving cyanoethylation and catalytic hydrogenation efficiently doubles the amino groups. With this reaction sequence poly(trimethylene imine) cascade molecules can be prepared in high yields and purity without requiring extensive purifications and excess reagent.

Experimental Procedure

Typical syntheses for the higher generations G4N, G4A, and G5N; the yields are summarized in Table 1.

G4N: To a cold solution of G3A (2.56 g, 2.10 mmol) in methanol (20 mL) were added acrylonitrile (20.0 mL, 305 mmol) (distilled over CaH_2 and stabilized with 0.05 wt% hydroquinonemonomethyl ether) within 90 minutes at 5–10 °C. After stirring 1 h at 10 °C and 4 days at 60 °C, the quantitative bis(cyanoethylation) was obtained. For separation of the stabilizer, the reaction mixture was passed through a neutral Al_2O_3 column and eluted with methanol/ethyl acetate (7:3), and the methanol content was increased slowly to 100%. The solvent was evaporated in vacuo to obtain 5.02 g (96%) of the highly viscous G4N. Correct elemental analysis for $C_{135}H_{222}N_{46}$ (2489.55 g mol^{-1}); ^{1}H NMR (400 MHz, CD_2Cl_2): δ = 1.62 (q, J = 7 Hz, 42 H; $CH_2CH_2CH_2$), 2.56 (m, 132 H; CH_2N), 2.83 (t, J = 7 Hz, 48 H; CH_2CN); ^{13}C NMR (100 MHz, CD_2Cl_2): δ = 17.3 (CH_2CN), 23.9, 25.1 ($CH_2CH_2CH_2$), 49.9 (CH_2CH_2CN), 51.7, 51.9, 52.2, 52.4 (CH_2N), 119.5 (CN); IR (neat): $\tilde{\nu}$[cm^{-1}] = 2920, 2800, 2220, 1450, 1410, 1350, 1250, 1160, 1120, 1050.

G4A: The hydrogenation was carried out in a 2 L stainless steel autoclave (Büchi AG, Uster/Switzerland). To 100 mL of a 1.4 M solution of NaOH in EtOH/H_2O (95:5), G4N (4.20 g, 1.69 mmol) was added. Under nitrogen the mixture was treated with Raney-nickel (2.5 g) (slurry in water, Aldrich), and the mixture was hydrogenated at 1000 rpm at 8 bar H_2 pressure for 4 days at 25 °C. The catalyst was filtered and washed with EtOH/H_2O (95/5). After diluting the filtrate with H_2O (100 mL), EtOH was evaporated and the residue extracted several times with CH_2Cl_2. Thereby, the NaOH concentration in the aqueous phase was increased in every extraction step. The organic layers were dried with Na_2SO_4 and the solvent evaporated in vacuo to give 3.01 g (69%) G4A. Correct elemental analysis for $C_{135}H_{318}N_{46}$ (2586.31 g mol^{-1}); ^{1}H NMR (250 MHz, $CDCl_3$): δ = 1.54 (m, 138 H; $CH_2CH_2CH_2$, NH_2), 2.36 (m, 84 H; CH_2N), 2.42 (t, J = 7 Hz, 48 H; $CH_2CH_2CH_2NH_2$), 2.67 (t, J = 7 Hz, 48 H; CH_2NH_2); ^{13}C NMR (100 MHz, $CDCl_3$): δ = 24.6 ($NCH_2CH_2CH_2N$), 30.9 ($CH_2CH_2NH_2$), 40.7 (CH_2NH_2), 51.9, 52.3, 52.4, 52.6 (CH_2N); IR (neat): $\tilde{\nu}$[cm^{-1}] = 3300, 3260, 2910, 2780, 1570, 1450, 1360, 1170, 1070, 960–770.

G5N: The procedure was equivalent to that reported for the synthesis of G4N. From G4A (600 mg, 0.232 mmol) was obtained 1.11 g (93%) of the highly viscous substance G5N. Correct elemental analysis for $C_{279}H_{462}N_{94}$ (5133.35 g mol^{-1}): ^{1}H NMR (400 MHz, CD_2Cl_2): δ = 1.62 (m, 90 H; $CH_2CH_2CH_2$), 2.52 (m, 276 H; CH_2N), 2.82 (t, J = 7 Hz, 96 H; CH_2CN); ^{13}C NMR (100 MHz, CD_2Cl_2): δ = 17.2 (CH_2CN), 23.8, 25.1 ($CH_2CH_2CH_2$), 49.8 (CH_2CH_2CN), 51.6, 51.8, 52.1, 52.3 (CH_2N), 119.5 (CN); IR (neat): $\tilde{\nu}$[cm^{-1}] = 2920, 2790, 2220, 1450, 1410, 1350, 1230, 1160, 1120, 1060.

The ^{1}H NMR and ^{13}C NMR spectra were measured with a Bruker AC 400 spectrometer with tetramethylsilane as internal standard; CD_2Cl_2 was used for the nitrile-functional and $CDCl_3$ for the amine-functional generations. End group titration was performed in a solution of H_2O/Et_2O (1:1) with 0.1 N HCl with a Mettler DC 25 titrator. Vapor pressure osmometry was carried out with a Perkin-Elmer Molecular Weight Apparatus Type 115 at 30 °C with $CHCl_3$ as solvent. The GPC analysis was performed on a Shimadzu LC-4A at 60 °C with a 0.05 M K_2HPO_4 buffer MeOH/H_2O (70:30) at pH = 11 (HEMA 40 and HEMA 100 column (MZ Analysentechnik), flow rate 0.5 mL min^{-1}, UV detector 228 nm, RI detector, calibrated with the values obtained from vapour pressure osmometry).

Poly(propylene imine) Dendrimers: Large-Scale Synthesis by Hetereogeneously Catalyzed Hydrogenations**

By *Ellen M. M. de Brabander-van den Berg** and *E. W. Meijer*

Dendritic macromolecules are hyperbranched polymers that emanate from a central core, have a defined number of generations and functional end groups, and are synthesized in a stepwise way by a repetitive reaction sequence.[1] The syntheses described so far are either convergent, this is discrete

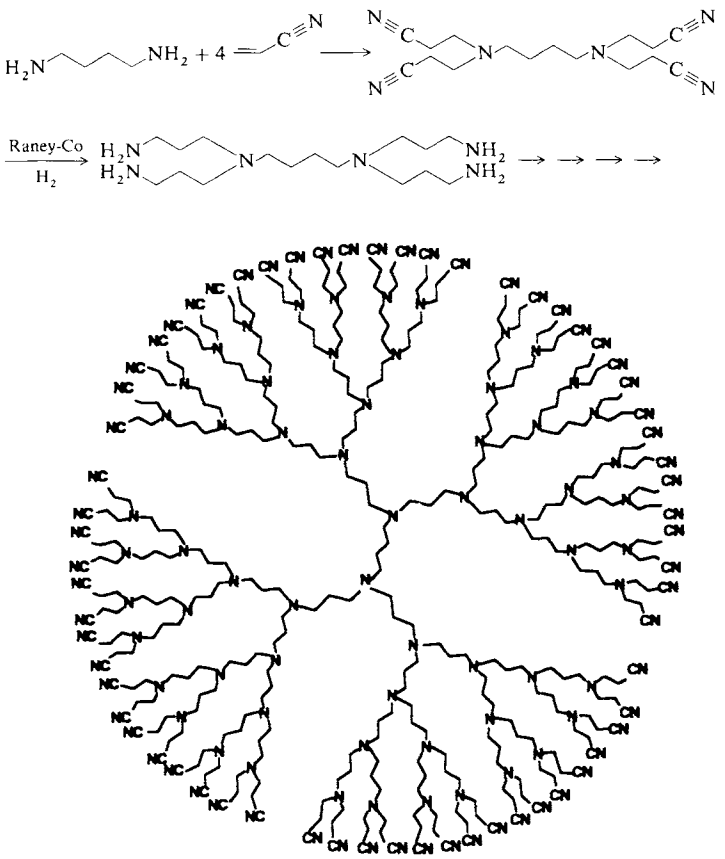
organic compounds are synthesized, or divergent, that is the construction of dendrimers can be regarded as a step polymerization with polydispersities of almost 1.[2-4] Detailed studies show that only a limited number of reaction schemes can be used for the synthesis of these dendrimers;[1,5-7] all known methods to date do not deliver pure dendrimers in large quantities, which is due to the use of sophisticated building blocks and/or (large excesses of) expensive reagents and/or complicated purifications.[6] In this paper we present a very convenient reaction sequence for the large-scale production of pure poly(propylene imine) dendrimers.

The reaction sequence presented here (Scheme 1) is based on the first approaches to dendrimeric structures by Vögtle et al. in which the low yields in the reduction hampered the synthesis of higher generations.[8] Our sequence is a repeti-



Scheme 1. Synthetic scheme for poly(propylene imine) dendrimers with diaminobutane as core.

tion of a double Michael addition of acrylonitrile to primary amines, followed by the heterogeneously catalyzed hydrogenation of the nitriles, resulting in a doubling of the number of primary amines. In this sequence 1,4-diaminobutane has been used as the dendrimer core; but a variety of molecules with primary or secondary amine groups can also be used. We have optimized conditions for both reaction steps in the sequence so that this occurs almost quantitatively and with optimal selectivity.[9]

All Michael reactions were performed similarly; 2.5–4 equivalents of acrylonitrile per primary amine are used at a concentration of 0.1 M in water; the first equivalent of acrylonitrile is added at room temperature and the second equivalent at 80 °C. The reaction time for complete conversion increases with every generation: 1 h for generation 0.5 (DAB-*dendr*-$(CN)_4$), 3 h for generation 4.5 (DAB-*dendr*-$(CN)_{64}$).[10] The excess of acrylonitrile is distilled off as a water azeotrope, leaving a clear two-phase system, from which the pure dendrimers with nitrile end groups can be isolated by pouring off the water layer. If necessary the water-soluble side products for example $HOCH_2CH_2CN$ (the Michael addition adduct of H_2O to acrylonitrile) or incompletely cyanoethylated products can be separated by washing the residue with water.

The hydrogenations of the cyanoethylated structures with H_2 (30–70 bar) and Raney/Cobalt as catalyst are also performed preferably in water. The reaction time required for complete hydrogenation increases at higher generations, but even at the higher generations this heterogeneous hydrogenation is quantitative and selective. Dendrimers with NH_2 end groups are isolated by evaporating the water from the filtered reaction mixture. The process window for a quantitative hydrogenation is small and side reactions easily occur. Three major side reactions which lead to dendrimers with structural defects have been observed, and the corresponding side products have been characterized: a) the occurrence of the retro-Michael addition during the hydrogenation, yielding secondary amines,[11] b) incomplete cyanoethylation in the Michael addition, resulting in dendrimers missing one ethyl cyanide side chain, and c) the formation of cyclic diamines and NH_3 by intramolecular addition of amines to the intermediate imines during the hydrogenation reactions. Under the optimized conditions these side products are not detectable and poly(propylene imine) dendrimers can be synthesized up to generation 4.5 with 64 terminal nitrile groups, a molecular weight of 6912 g mol^{-1} and in quantities of several grams up to several kilograms. Apart from the first generation (0.5) which is a white crystalline solid, all other generations are colourless oils, which are readily soluble: the DAB-*dendr*-$(NH_2)_x$ in H_2O and methanol, the DAB-*dendr*-$(CN)_x$ in common organic solvents.

All products were characterized by ^1H, ^{13}C NMR and IR spectroscopy, mass spectrometry, HPLC, gel permeation chromatography (GPC), differential scanning calorimetry (DSC), thermogravimetric analysis (TGA), and intrinsic viscosity. All data are consistent with the proposed dendrimer structures. NMR spectroscopy appears to be a very suitable technique to detect and assign structural failures in the outermost dendrimer generation. In the ^1H NMR spectra of the dendrimers with CN end groups the shape and intensity of the most downfield triplet of the NCH_2CH_2CN group at $\delta = 2.85$ is characteristic for defects in the outer generation, whilst the growth of the dendrimers is clearly indicated by the ratio of the integrals of the signal at $\delta = 1.40$ ($NCH_2CH_2CH_2CH_2N$ protons of the dendrimer core) to the integral of the signal at $\delta = 1.58$ ($NCH_2CH_2CH_2N$ branch protons). Incompletely cyanoethylated dendrimers are most readily concluded from additional signals in the ^{13}C NMR spectra at $\delta = 45.1$ ($NHCH_2CH_2CN$) and 18.7 ($NHCH_2CH_2CN$) as well as the products of retro-Michael additions of dendrimers with NH_2 end groups with signals at $\delta = 47.7$, 46.7, 39.1, 32.0, and 25.6.

Dendrimers with CN end groups can be separated and analyzed with HPLC. In Figure 1 a typical chromatogram of DAB-*dendr*-$(CN)_8$ from a kg-scale run is shown. From mass spectrometric experiments it has been concluded that the small peak corresponds with the fully cyanoethylated product of DAB-*dendr*-$(NH_2)_3$. If equal absorption coefficients are assumed for both compounds, the average selectivity per conversion in the first three steps is 99.8%.

Figure 2 shows a typical gel permeation chromatogram of various dendrimers with NH_2 end groups taken from a large-scale synthesis. The absence of detectable impurities is evi-

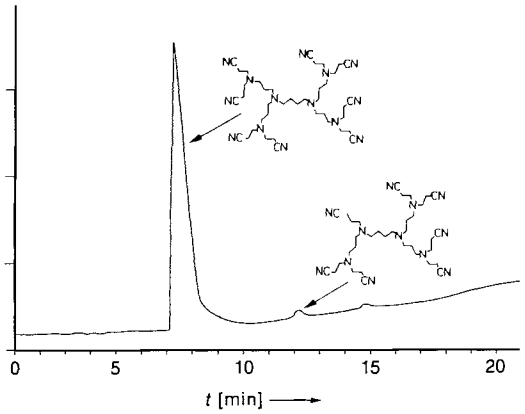


Fig. 1. Typical HPLC chromatograph of DAB-*dendr*-$(CN)_8$.

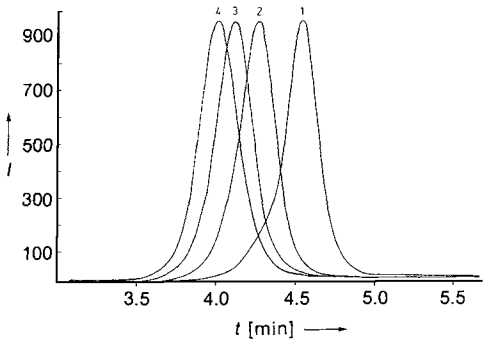

Fig. 2. Typical GPC trace of DAB-*dendr*-$(NH_2)_4$ (1), DAB-*dendr*-$(NH_2)_8$ (2), DAB-*dendr*-$(NH_2)_{16}$ (3), and DAB-*dendr*-$(NH_2)_{32}$ (4).

dent from the chromatograms. Furthermore, the characteristic relation between the molecular weight M_n and the intrinsic viscosity η is presented in Figure 3. As reported for two other classes of dendrimers, the intrinsic viscosity of the poly(propylene imine) dendrimers with CN end groups decreases with increasing molecular weight at a certain generation;[11, 12] in this case after the fourth generation.

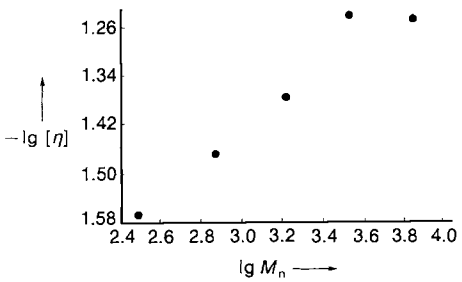

Fig. 3. Plot of $-\lg\eta$ vs. $\lg M_n$ of the various poly(propylene imine) dendrimers with CN end groups.

Thermal analysis of the dendrimers synthesized shows a number of interesting features. The glass transition temperature Tg has been recorded with DSC (Fig. 4); in both series of dendrimers with NH_2 and CN end groups the Tg's observed are low and an increase in Tg is observed by increasing molecular weight. In all cases the CN dendrimers possess the highest Tg, which is expected on basis of the dipole–dipole interaction of the CN groups. The thermal stability of the dendrimers with NH_2 end groups is unexpectably high and again increases with increasing molecular weight as determined by TGA (For DAB-*dendr*-$(NH_2)_4$, DAB-*dendr*-$(NH_2)_8$, DAB-*dendr*-$(NH_2)_{16}$, DAB-*dendr*-$(NH_2)_{32}$, TGA_{max} are 330, 378, 424, and 470 °C, respectively. For the DAB-*dendr*-$(NH_2)_8$ less than 1.0% weight loss is observed at $T = 310$ °C and scan speed 20 °C min^{-1}.) Dendrimers with CN end groups are less stable, although also in this case the stability increases at higher generations. With TGA-MS, a thermally induced retro-Michael addition is observed for DAB-*dendr*-$(CN)_{64}$, followed by a degradation similar to DAB-*dendr*-$(NH_2)_{32}$. A molecular interpretation of the latter is not possible with the data available.

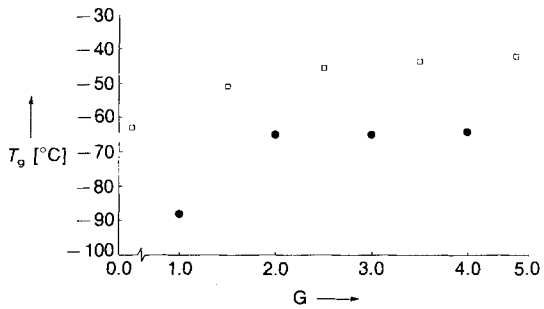

Fig. 4. Plot of the glass transition temperatures (T_g) of the poly(propylene imine) dendrimers with nitrile (□) and amino groups (●). G = generation.

As a consequence of the extensive purifications and low yields in the first approaches,[8] it was assumed until recently that this acrylonitrile–hydrogenation sequence is not suitable for dendrimer synthesis. However, by the correct choice of reagents and reaction conditions we have shown that this reaction sequence is very efficient. The main advantages of our synthetic procedures are 1) the simple reaction and isolation procedures which can readily be scaled up; 2) the use of one solvent for all reaction steps, so that the intermediates must not be isolated; 3) the use of readily available reagents which do not have to be protected; 4) the high yields and selectivities obtained; 5) a simple purification method which can easily be applied to large-scale quantities; 6) the versitility of the reaction sequence which allows for the introduction of a variety of end and core groups.

The dendrimers with NH_2 end groups offer remarkable thermal and good hydrolytic stability, and have a low T_g. The drop in intrinsic viscosity after the fourth generation indicates that a spherical shape with a sterically hindered shell is formed at the fifth generation. The low T_g indicates that the dendrimers possess a large degree of conformational freedom, despite their hyperbranching and well-defined chemical and geometrical structure. Research into the synthesis of higher generations and the functionalization of the dendrimers is in progress.

Experimental Procedure

DAB-*dendr*-$(CN)_4$: Acrylonitrile (8.35 mol, 443 g) was added to a solution of diaminobutane (1.67 mol, 147 g) in 1.176 kg water. The exothermic reaction caused the temperature to rise to 38 °C. After this exothermic effect the reaction mixture was heated at 80 °C for 1 h to complete the addition. Then the excess of acrylonitrile was removed as a water azeotrope by vacuum distillation (16 mbar, bottom temperature 40 °C). Phase separation of the reaction mixture afforded 499 g (99%) HPLC-pure DAB-*dendr*-$(CN)_4$, which was recrystallized from methanol.

^{13}C NMR (50 MHz, $CDCl_3$): $\delta = 119$ (CN), 53.1 ($NCH_2CH_2CH_2CH_2N$), 49.4 (NCH_2CH_2-CN, 24.9 ($NCH_2CH_2CH_2CH_2N$), 16.9 (CH_2CN); ^1H NMR (200 MHz, $CDCl_3$): $\delta = 2.85$ (t, 8H, NCH_2CH_2CN), 2.55 (m, 4H, $NCH_2CH_2CH_2CH_2N$), 2.48 (t, 8H, CH_2CN), 1.55 (m, 4H, $NCH_2CH_2CH_2CH_2N$); IR (KBr): $\tilde{\nu} = 2245\ cm^{-1}$ (CN).

DAB-*dendr*-$(NH_2)_4$: To a hydrogenation vessel, filled with Raney Cobalt catalyst (Cr promoted, Grace 2724, pretreated with hydroxide, 900 g) and water (22.5 L) was added DAB-*dendr*-$(CN)_4$ (450 g) dissolved in methanol. Subsequently the mixture was hydrogenated at 40 atm hydrogen pressure at 70 °C for 1 h. The cooled reaction mixture was then filtered and the solvents were evaporated at reduced pressure. The residue contained 450 g (95%) NMR spectroscopically pure DAB-*dendr*-$(NH_2)_4$ as a colorless oil.

^{13}C NMR (50 MHz, D_2O): $\delta = 53.4$ ($NCH_2CH_2CH_2CH_2N$), 51.1 ($NCH_2CH_2CH_2NH_2$), 39.5 (CH_2NH_2), 28.8 ($CH_2CH_2NH_2$), 23.9 ($NCH_2CH_2CH_2CH_2N$); ^1H NMR (200 MHz, $CDCl_3$): $\delta = 2.70$ (t, 8H, CH_2NH_2), 2.44 (t, 8H, $NCH_2CH_2CH_2NH_2$), 2.40 (m, 4H, $NCH_2CH_2CH_2CH_2N$), 1.58 (quin, 8H, $CH_2CH_2NH_2$), 1.42 (m, 12H, $NCH_2CH_2CH_2CH_2N$, NH_2); IR (film): $\tilde{\nu} = 3284$, 3355 cm^{-1} (NH_2).

Intramolecular Base Stabilization of Silicenium Ions: A New Route to Siliconium Ions

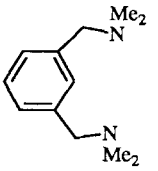
By *Claude Chuit, Robert J. P. Corriu,* Ahmad Mehdi,* and *Catherine Reyé*

The possible existence of trisubstituted silylium "silicenium" ions (R_3Si^+) has intrigued chemists for a long time.[1, 2] Nevertheless claims to have generated such species in solution[3] have been disputed,[4] and the question whether triorganylsilyl perchlorates undergo ionization in solvents has been reviewed by Eaborn[5] and Lickiss.[6] Recently silyl cations have been prepared in nonnucleophilic solvents with weakly coordinating anions.[7–8] However, the structural analysis of one of these derivatives showed a strong interaction between anion and cation.[8]

Some silyl cations that can be prepared are stabilized by the π-pentamethylcyclopentadienyl ligand,[9] intermolecular coordination,[8, 10–13] or intramolecular coordination.[14–15] However, these examples do not constitute a general route to cationic silicon species with a functional group at silicon that enables reactivity studies.

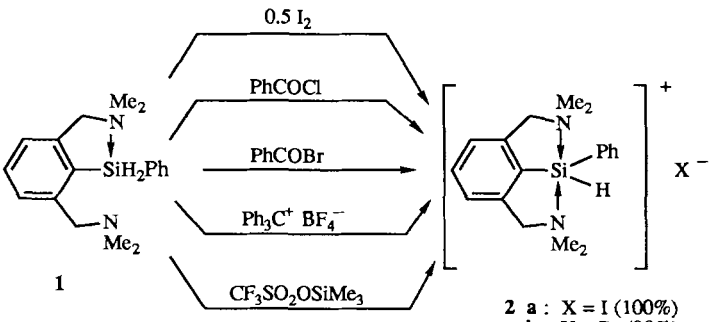
Some years ago, we showed that pentacoordinate neutral and anionic silicon species have unusual, often unexpected reactivity.[16] That led us to prepare cations containing pentacoordinate silicon centers (siliconium ions) in order to study their reactivity.

Since intramolecular coordination of the amino group stabilizes silanethione,[17] silaphosphene,[18] silanimine,[18] and transition metal silanediyl complexes very efficiently,[18, 19] we decided to extend this intramolecular stabilization to the silylium ions. We report here a novel and general route to functional and nonfunctional siliconium ions using the potentially bischelating ligand **A**.[20]



A

The reaction of the silane **1** with half an equivalent of iodine in ether at room temperature results in the formation of a precipitate and loss of half an equivalent of H_2 in a redox reaction. The precipitate was identified as the ionic species **2a** (Scheme 1).



Scheme 1.

The ^1H NMR spectrum of **2a** shows a singlet at $\delta = 5.3$, shifted to low field with respect to the resonance signal of the SiH_2 protons of **1** and assigned to the SiH proton. The signal of the methylene protons in **2a** has an AB pattern. The two NMe_2 groups are magnetically equivalent as a result of the coordination of both nitrogen atoms to the silicon center and give rise to two singlets of equal intensity. In the coupled ^1H ^{29}Si NMR spectrum of **2a**, a doublet is observed at $\delta = -29.7$ ($^1J_{Si,H} = 280$ Hz), whereas the ^{29}Si resonance of the pentacoordinate silane **1**[21] appears as a triplet at $\delta = -51.5$ ($^1J_{Si,H} = 200$ Hz). Interestingly, the ^{29}Si NMR spectrum of **2a** in the solid state shows a sharp signal with the same chemical shift ($\delta = -28.8$) as in solution, which indicates that **2a** remains ionic even in the solid state.

The IR spectrum of **2a** in $CHCl_3$ shows a Si–H stretch at $\tilde{\nu} = 2202$ cm^{-1}, substantially higher than for **1** (2111 cm^{-1}). Moreover this frequency is very close to that observed by Jutzi et al.[9] for the silyl cation $[(\pi\text{-}Me_5C_5)_2SiH]^+$.

The positive-ion FAB mass spectrum (FAB = fast atom bombardement) of **2a** shows an ion at *m/z* 297 corresponding to the mass of the siliconium ion.

The same cation can also be generated by treating **1** with one equivalent of various electrophiles such as *N*-chlorosuccinimide, PhCOX (X = Cl, Br; reduced to PhCHO[22]), $AgBF_4$, $Ph_3C^+BF_4^-$, or $CF_3SO_3SiMe_3$ (Scheme 1). Species **2b**–**2e** have all the same IR spectra, ^1H and ^{29}Si NMR spectra, and the same positive-ion FAB mass spectra as **2a**. These salts are air- and moisture-sensitive but they are stable in solution under argon, as well as in the solid state.

As a confirmation of the ionic nature of the salts **2** we carried out conductivity titrations: aliquots of reagents in CH_2Cl_2 (PhCOCl, PhCOBr, I_2, $CF_3SO_3SiMe_3$) were added to a solution of the silane **1** in CH_2Cl_2; the conductivity was measured after each addition. Figure 1 depicts a plot of conductivity as a function of the added reagent. The conductivity increases until one molar equivalent of reagent has been added, and thereafter it is constant.

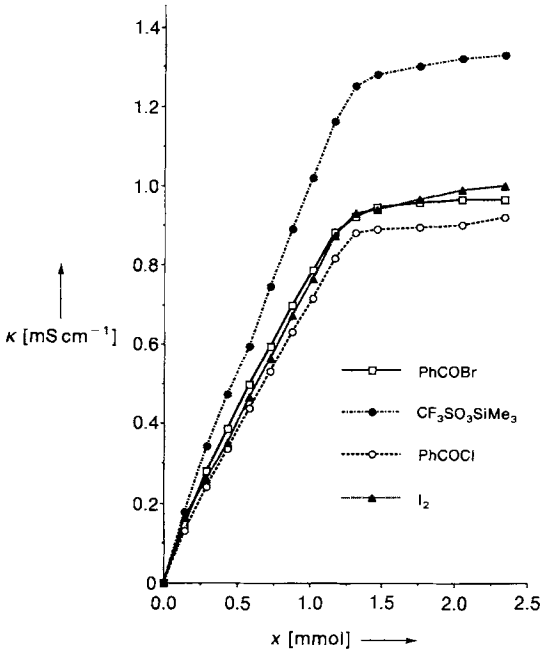

Fig. 1. The conductivity (κ) as a function of the amount of electrophilic reagent added (x) to a solution of 0.146 moles of silane **1** in CH_2Cl_2.

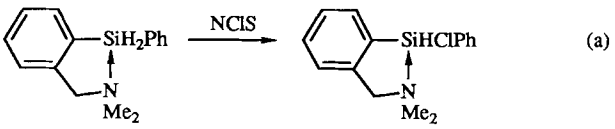
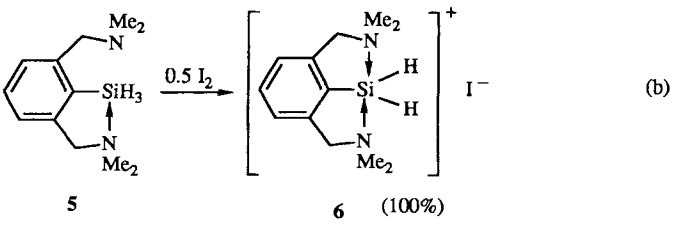
In contrast, the chlorosilane **4** resulting from the reaction of *N*-chlorosuccinimide with the silane **3** [Eq. (a), NClS = *N*-chlorosuccinimide] shows no conductance in dichloromethane, as expected for a covalent chlorosilane.[23,24]

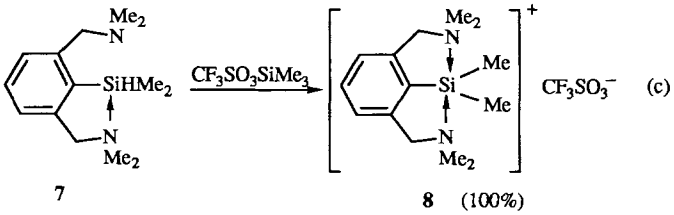


(a)

The preparation of siliconium ions by reaction of a electrophile on a silane bearing the ligand **A** and at least one hydrogen atom is quite general. As indicated in Equations (b) and (c), difunctional and nonfunctional siliconium ions have also been obtained with a good yield by this process.

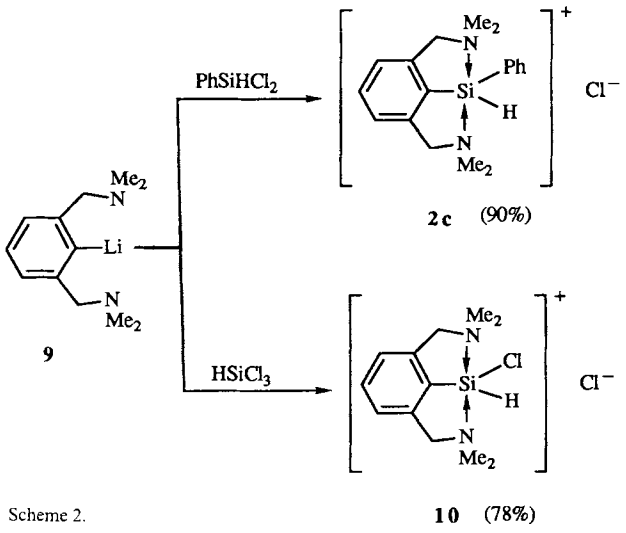


(b)



(c)

The reaction of the lithium derivative **9**[25] and dichlorophenylsilane or trichlorosilane also affords the corresponding siliconium ions (Scheme 2).



Scheme 2.

The formation of these siliconium ions should result either from the abstraction of a hydride ion (when $Ph_3C^+BF_4^-$ or $CF_3SO_3SiMe_3$ is the reagent) or from the substitution of an hydrogen atom by a halogen atom that is displaced by the nucleophilic coordination of the second NMe_2 group at silicon.

It is interesting to note that the dichlorosilane **11**, the X-ray structure of which has been determined,[19] is covalent.

11

This indicates the importance of the geometry of the ligand **A** in the formation of siliconium ions.

Experimental procedure

1: A solution of **9** [25] (22 mmol) in Et_2O (40 mL) was added slowly over 15 min at 0 °C to a solution of phenylsilane (2.4 g, 22 mmol) in Et_2O (40 mL). The mixture was stirred at room temperature for 2 h and then hydrolyzed at 0 °C with 0.4 mL of H_2O. After filtration on celite, distillation gave 5.4 g (83%) of **1** as a colorless oil. B.p. 115–117 °C/0.02 Torr; ^{1}H NMR (250 MHz, $CDCl_3$, TMS): $\delta = 2.0$ (s, 12H, CH_3), 3.51 (s, 4H, CH_2), 4.82 (s, 2H, SiH_2); ^{29}Si NMR (200 MHz, $CDCl_3$, TMS): $\delta = -51.5$ (t, ^1J(SiH), 200 Hz); IR (CCl_4): $\tilde{\nu}$[cm^{-1}] = 2111 (SiH_2). Correct elemental analyses (C,H,N,Si).

2a: A solution of iodine (0.43 g, 1.67 mmol) in ether (10 mL) was added dropwise to a solution of silane **1** (1 g, 3.35 mmol) in Et_2O (10 mL) at room temperature under argon. The resulting mixture was stirred until evolution of H_2 had ceased. It became progressively colorless as a precipitate appeared. The mixture was then filtered, and the residue washed twice with ether to give 1.4 g (100% yield) of a white microcrystalline powder. M.p. 135 °C (decomp); ^{1}H NMR (250 MHz, CD_2Cl_2, TMS): $\delta = 2.2$ (s, 6H, CH_3), 2.85 (s, 6H, CH_3), 4.0 (d, ^2J(H,H) = 16 Hz, 2H, CH_2), 4.25 (d, ^2J(H,H) = 16 Hz, 2H, CH_2), 5.3 (s, 1H, SiH); ^{13}C NMR (200 MHz, $CDCl_3$, TMS): $\delta = 63.1$ (CH_2N), 47.1, 47.6 ($N(CH_3)_2$), 123.2, 124.2, 127.3, 128.8, 131.2, 134.0, 143.0; ^{29}Si NMR (200 MHz, $CDCl_3$, TMS): $\delta = -29.7$ (d, ^1J(Si,H) = 280 Hz); IR (KBr): $\tilde{\nu}$[cm^{-1}] = 2202.

2c: A solution of **9** [25] (7.38 mmol) in Et_2O (50 mL) was added slowly to a solution of dichlorophenylsilane (1.1 mL, 7.38 mmol) in Et_2O (50 mL). The mixture was stirred at room temperature for 2 h. After filtration, the solid obtained was dissolved in CH_2Cl_2 to precipitate LiCl which was removed by filtration. After concentration, Et_2O was added to precipitate crude **2c** as a white solid (1.9 g, 90%) whose characteristics are the same as those of **2a**.

6: A solution of I_2 (0.4 g, 1.56 mmol) in Et_2O (15 mL) was added dropwise at −5 °C to a solution of silane **5** (b.p. = 45–50 °C/0.1 Torr) (0.7 g, 3.15 mmol) in Et_2O (15 mL). The mixture was stirred at room temperature for 4 h, filtered, and the solid obtained washed twice with Et_2O to give 1.1 g (100%) of crude **6**. M.p. 145 °C (decomp); ^{1}H NMR (80 MHz, $CDCl_3$, TMS): $\delta = 2.9$ (s, 12H, CH_3), 4.4 (s, 4H, CH_2), 4.9 (s, 2H, SiH_2); ^{29}Si NMR (250 MHz, $CDCl_3$, TMS): $\delta = -46.4$ (t, ^1J(Si,H) = 265 Hz); IR (KBr): $\tilde{\nu}$[cm^{-1}] = 2191 and 2209.

8: $CF_3SO_3SiMe_3$ (0.57 mL, 2.95 mmol) was added dropwise at 0 °C to a solution of 7 (b.p. = 120 °C/0.2 Torr) (0.7 g, 2.8 mmol) in Et_2O (15 mL). After stirring (30 min), the solvent was removed, and the solid obtained washed twice with Et_2O to give 1.1 g (100%) of crude **8**. M.p. = 118–121 °C; ^{1}H NMR (250 MHz, $CDCl_3$, TMS): $\delta = 0.4$ (s, 6H, $Si(CH_3)_3$), 2.4 (s, 12H, $N(CH_3)_2$), 3.8 (s, 4H, CH_2); ^{19}F NMR (80 MHz, $CDCl_3$, C_6F_6), $\delta = 85$ (s); ^{29}Si NMR (250 MHz, $CDCl_3$, TMS): $\delta = -4.1$ (s); positive-ion FAB-MS: m/z 249 (M^+, 100%).

10: A solution of **9** [25] (11.1 mmol) in Et_2O (30 mL) were added slowly to a solution of $HSiCl_3$ (1.2 g, 11.1 mmol) in Et_2O (30 mL). After 1 h at room temperature, the solvent was removed under vacuum, and CH_2Cl_2 (50 mL) was added. After filtration and evaporation of the solvent the oil obtained was solidified by addition of Et_2O. After washing twice with Et_2O, 2.5 g (78%) of crude **10** was obtained as a light yellow-green solid. M.p. 140 °C (decomp); ^{1}H NMR (250 MHz, $CDCl_3$, TMS): $\delta = 2.9$ (s, 12H, CH_3), 4.4 (s, 4H, CH_2), 5.2 (s, 1H, SiH); ^{29}Si-NMR (250 MHz, $CDCl_3$, TMS): $\delta = -40.3$ (d, ^1J(Si,H) = 334 Hz). IR (KBr): $\tilde{\nu}$[cm^{-1}] = 2204.

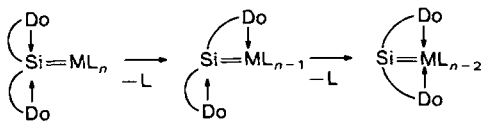
Photochemical 1,2 Shift of the Phosphane Ligands in the Silanediyl Complex $[(2\text{-}Ph_2PCH_2C_6H_4)_2Si{=}Cr(CO)_5]$**

By *Hermann Handwerker, Martin Paul, Janet Blümel,* and *Christian Zybill**

Dedicated to Professor Robert West on the occasion of his 65th birthday

The successive 1,2 shifts of two intramolecular donor groups from an atom A to an atom B in a molecule can be considered as a tandem reaction;[1] in the case discussed here A=Si and B=M=Cr.

Tandem reactions of this kind permit the abstraction of weakly bonded donor groups from silicon atoms in silanediyl complexes, by migration to the metal (Scheme 1).



Scheme 1.

Thus, the 1,2 shift of phosphane or amine donor groups opens up a thermodynamically favored route to silanediyl complexes containing a three-coordinate silicon atom.[2]

[**] We thank Professor H. Schmidbaur for generous support, as well as J. Riede for creating a crystallographic data base.

The key silanediyl complex **1** is prepared by the reaction of the corresponding dichlorosilane with $Na_2[Cr(CO)_5]$;[3] complex **1** is remarkable in many ways:

The single-crystal X-ray analysis of **1** (Fig. 1) shows a Cr–Si double bond length of 2.414(1) Å.[4] The P1–Si distance (2.380(1) Å) is longer than that of the covalent P–Si bond in H_3SiPH_2 (2.25 Å), and the P2–Si distance of 3.725(1) Å is considered as nonbonding.[5] The phosphorus atom P2 of the diphenylphosphino unit is orientated towards the silicon atom in the crystal; this configuration also corresponds to the sterically most favored arrangement of the phenyl substituents. The sum of the bond angles of the three substituents covalently bonded to the silicon atom is 352.1°.[6]

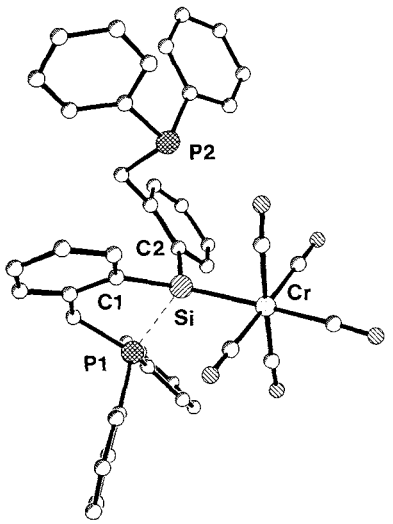

Fig. 1. Crystal structure of **1**. Selected distances [Å] and angles [°]: Cr–Si 2.414(1), P1–Si 2.380(1), P2–Si 3.725(1); C1-Si-Cr 121.8(1), C2-Si-Cr 121.0(1), C2-Si-C1 109.3(1).

A solid-state ^{31}P CP-MAS NMR spectrum (CP = cross polarization, MAS = magic angle spinning) of **1** as a powder shows two distinct signals for the two phosphane ligands at $\delta = -5.3$ and 19.6 (Fig. 2).

A dynamic "flip-flop" coordination of each phosphorus atom to the silicon is observed in solution.[7] The C_2-symmetrical transition state of this rapid exchange process can be detected by NMR spectroscopy (^{31}P NMR: $\delta = 1.78$ (s); ^{29}Si NMR: $\delta = -73.2$ (t, $^1J(^{31}P^{29}Si) = 17.5$ Hz); ^1H NMR: $\delta = 3.20, 3.47$ (ABX system, CH_2). In the ^{13}C NMR spectrum two sets of signals are found for the diphenylphosphino units. The C_6H_5 rings are diastereotopic due to the rigid tetrahedral geometry at the P atom. Therefore, in contrast to complexes with N donor groups such as **4**, the flip-flop coordination in **1** occurs without simultaneous inversion at the P atom. A related example with similar molecular dynamics is the stannanediyl complex $[(2\text{-}Ph_2PCH_2C_6H_4)_2Sn{=}W(CO)_5]$ reported by Abicht and Issleib.[3, 8] An asymmetric coordination of both phosphane or amine ligands to the silicon atom in the silanediyl complexes **1** and **4** in the ground state can be proven by the consistent results of the crystal structure analyses and variable temperature NMR studies. The two energetically degenerate ground states are interconverted via a C_2-symmetric transition state, with the retention of configuration at the silicon atom. The C_2-symmetric transition state is "seen" NMR spectroscopically in solution at 22 °C; the determination of the activation barrier for this exchange process has been described.[5a, c]

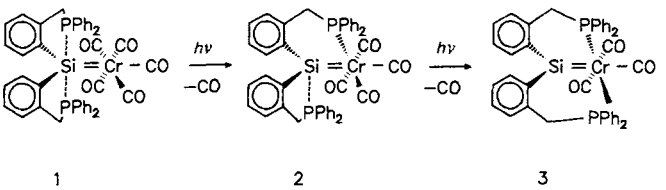
$[(2\text{-}Me_2NCH_2C_6H_4)Si{=}Cr(CO)_5]$ **4**

The photolysis of **1** results in the direct formation of **3** in a tandem reaction (Scheme 2). In the reaction of **4** with (2-dimethylaminomethyl)phenyl ligands, the intermediate **5** of one 1,2 amine shift was isolated and characterized by a single-crystal X-ray analysis.[5a] The product **6** of the tandem

$[(2\text{-}Me_2NCH_2C_6H_4)(2\text{-}Me_2\overline{NCH_2C_6H_4)Si{=}Cr(CO)_4}]$ **5**

$[(2\text{-}Me_2NCH_2C_6H_4)(2\text{-}Me_2\overline{NCH_2\text{-}C_6H_4)Si{=}Cr(CO)_3}]$ **6**

reaction **4** → **5** → **6** is thermally labile, but can be detected by trapping reactions with MeOH or HCl.[9a]



Scheme 2.

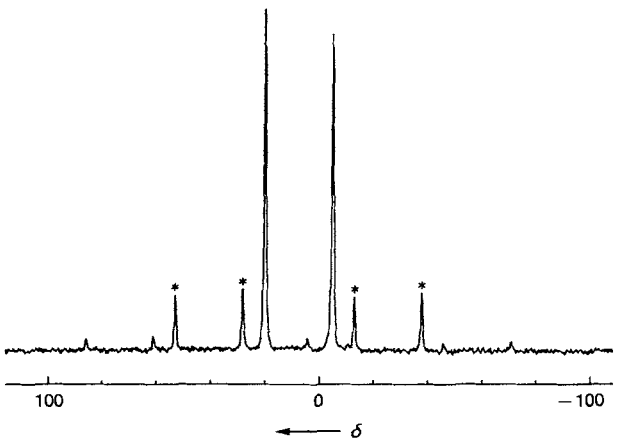


Fig. 2. Solid-state ^{31}P CP-MAS NMR (121.5 MHz) spectrum of **1**, spin frequency 4 kHz, ext. standard $\delta[(NH_4)H_2PO_4] = 0$, contact pulse = 1 ms, 90° pulse = 4 μs. Asterisks denote spinning bands.

The rearrangement **1** → **2** → **3** (Scheme 2) proceeds more quickly by an order of magnitude, however, **2** can be observed by IR spectroscopy (2021, 1901, 1875 cm^{-1}). Finally, the (phosphino)silanediylchromium complex **3** is obtained as an extremely air-sensitive, deep red powder, and is spectroscopically fully characterized. (^{29}Si NMR: $\delta = 159.7$, see also Experimental Procedure).[10] According to this the two phosphane ligands in **3** are arranged in a *trans* and the CO ligands in a meridional configuration. The silicon atom in **3** is three-coordinate. Photochemical 1,2 shifts of the donor ligands from silicon to the metal thus allow general access to complexes with low-coordinate silicon.

Experimental Procedure

1: A solution of bis(2-diphenylphosphinomethyl)phenyldichlorosilane (3.57 g, 5.5 mol) in THF (50 mL) was added slowly to a solution of $Na_2[Cr(CO)_5]$ (1.37

g, 5.8 mmol) in THF (150 mL) at −40 °C. The mixture was stirred for a further 5 h at room temperature after which the precipitated NaCl was filtered off. Compound **1** was isolated as a pale yellow powder in 34% yield. The compound was recrystallized from THF/pentane.

^{1}H NMR (400 MHz, CD_2Cl_2, 25 °C, TMS): δ = 3.20 (dd), 3.47 (d, ABX system, ^2J(HH) = 14.0, ^2J(H^{31}P) = 8.5 Hz, 4H, CH_2), 6.75 (t, ^3J(HH) = 7.3, 2H), 6.86 (d, ^3J(HH) = 7.3, 2H), 6.97 (t, ^3J(HH) = 7.9, 2H), 7.20–7.28 (br, 12H), 7.30–7.38 (br, 6H), 7.43 (t, ^3J(HH) = 7.0, 2H), 7.64 (d, ^3J(HH) = 7.9, 2H, C_6H_5P); ^{13}C NMR (CD_2Cl_2, 25 °C): δ = 33.9 (tdd, ^1J(H^{13}C) = 126, ^1J(H^{13}C) = 9.2, ^1J(H^{13}C) = 3.9, P-CH_2), 128.9 (dd, ^1J(H^{13}C) = 160, ^3J(H^{31}P^{13}C) = 8.7), 130.4 (dd, ^1J(H^{13}C) = 160, ^2J(H^{13}C) = 8.3, *m*-C_6H_5), 130.5 (d, ^1J(H^{13}C) = 155), 130.8 (d, ^1J(H^{13}C) = 156, *p*-C_6H_5), 133.3 (dd, ^1J(H^{13}C) = 161, ^2J(H^{31}P^{13}C) = 13.5, 133.6 (dd, ^1J(H^{13}C) = 161, ^2J(H^{31}P^{13}C) = 14.3, *o*-C_6H_5), 126.5 (d, ^1J(H^{13}C) = 158), 129.3 (d, ^1J(H^{13}C) = 160, *i*-C_6H_5), 130.8 (d, ^1J(H^{13}C) = 160), 131.8 (dm, ^1J(H^{13}C) = 156), 138.3 (dm, ^1J(H^{13}C) = 157, 139.4 (dm, ^1J(H^{13}C) = 159), 140.9 (m), 141.2 (m), 222.3 (s, CO_{ax}), 226.1 (t, ^3J(H^{31}P^{13}C) = 1.8, CO_{eq}); ^{31}P{^{1}H} NMR (CD_2Cl_2): 1.78 (s); ^{29}Si NMR (CD_2Cl_2, 25 °C, TMS): 73.2 (t, ^1J(H^{29}Si) = 17.5. IR (CH_2Cl_2), $\tilde{\nu}$[cm^{-1}] = 2038 (s), 1981 (w), 1912 (ss, br). Correct elemental analysis (C, H, P). M.p. 156 °C.

3: **1** (0.26 g, 0.3 mmol) was suspended in methylcyclohexane (100 mL) in a quartz Schlenk tube at −30 °C and photolyzed at 254 nm (Hg low-pressure lamp) for 30 h. The color of the suspension changed from pale yellow to dark red. After removal of the solvent, **3** was obtained (171 mg) as a red powder in 80% yield.

^{1}H NMR (400 MHz, CD_2CL_2, 25 °C, TMS): δ = 2.3 (s, 2H, CH_2), 7.6–7.1 (m, 14H, C_6H_5); ^{13}C{^{1}H} NMR (C_7D_8, 25 °C, TMS): δ = 36.2 (d, ^1J(H^{31}P^{13}C) = 8.7, CH_2), 129.3 (d, ^3J(H^{31}P^{13}C) = 8.5), 132.5 (s), 134.1 (d, ^2J(H^{31}P^{13}C) = 12.1), 142.1 (d, ^1J(H^{31}P^{13}C) = 5.1, C_6H_5), 220.1 (t, ^2J(H^{31}P^{13}C) = 5.2, CO), 227.1 (t, ^2J(H^{31}P^{13}C) = 9.2, CO); ^{31}P NMR (CD_2Cl_2 49.2 (s); ^{29}Si NMR (CD_2Cl_2: 159.7 (t, ^2J(H^{31}P^{29}Si) = 12 Hz). IR (methylcyclohexane): $\tilde{\nu}$[cm^{-1}] = 2038 (s), 1988 (s) (νCO). MS (70 eV): *m/z* 714 (M^+ for $C_{41}H_{32}CrO_3P_2Si$ with correct isotope distribution, 5%), 686 (M^+ − CO, 1.5%), 658 (M^+ − 2 CO, 0.9%), 630 (M^+ − 3 CO, 0.8%). M.p. 148 °C. Correct elemental analysis (C, H, P).

Metal-Initiated Coupling of C_2 Units to Enynes and Butatrienes: Two Different Routes for the Dimerization of 1-Alkynes**

By *Martin Schäfer, Norbert Mahr, Justin Wolf,* and *Helmut Werner**

Dedicated to Professor Reinhard W. Hoffmann on the occasion of his 60th birthday

It has recently been shown that the dimerization of 1-alkynes to enynes with electron-rich transition-metal compounds as catalysts can occur either by alkynyl–vinyl or alkynyl–vinylidene coupling.[1] The enyne is liberated, sometimes stereoselectively, from the enynyl metal complexes formed as intermediates, on treatment with an additional molecule of the 1-alkyne RC≡CH. Furthermore, Wakatsuki et al. observed[2] that the dimerization of *t*BuC≡CH with $[RuH_2(CO)(PPh_3)_3]$ as catalyst does not lead to the enyne *t*BuC≡CCH=CH*t*Bu but, surprisingly, to the isomeric butatriene (*Z*)-*t*BuCH=C=C=CH*t*Bu. The authors postulated that in this case an enynyl complex is also formed as intermediate which is in equilibrium with the σ-butatrienyl metal species that affords the butatriene. Using alkynyl(vinylidene)rhodium compounds as starting materials, we have now succeeded in preparing not only enyne but also enynyl metal complexes which react with acids HX to give, predominantly either enynes or butatrienes, depending on the strength of HX.

The key to success is the η^3-benzylrhodium(I) compound **2**. It is formed in the same way as the derivative **3**[3] on treatment of **1** with the appropriate Grignard reagent; the yield in both cases is about 80%. In solution, **2** and **3** show fluxional behavior. At low temperatures, a suprafacial rearrangement takes place,[4, 5] which is shown by the equivalence of the benzylic protons and of the ring protons in *ortho* and *meta* position; at higher temperatures a σ-to-π conversion[6] occurs in addition to the suprafacial rearrangement, which is confirmed by the equivalence of the phosphane ligands. During this process, the coordinatively unsaturated intermediate $[Rh(\eta^1\text{-}CH_2C_6H_4R)(PiPr_3)_2]$ is generated. Its formation explains why compound **2**, in contrast to the related allyl complex $[Rh(\eta^3\text{-}C_3H_5)(PiPr_3)_2]$,[7] smoothly reacts with PhC≡CH and *t*BuC≡CH to give **4** and **5**, respectively. The addition of NEt_3 to the reaction mixture facilitates the formation of the alkynyl(vinylidene) species. If the reaction of **2** is carried out with phenylacetylene in pentane at −40 °C, the alkyne(alkynyl)rhodium(I) intermediate **6** can be isolat-

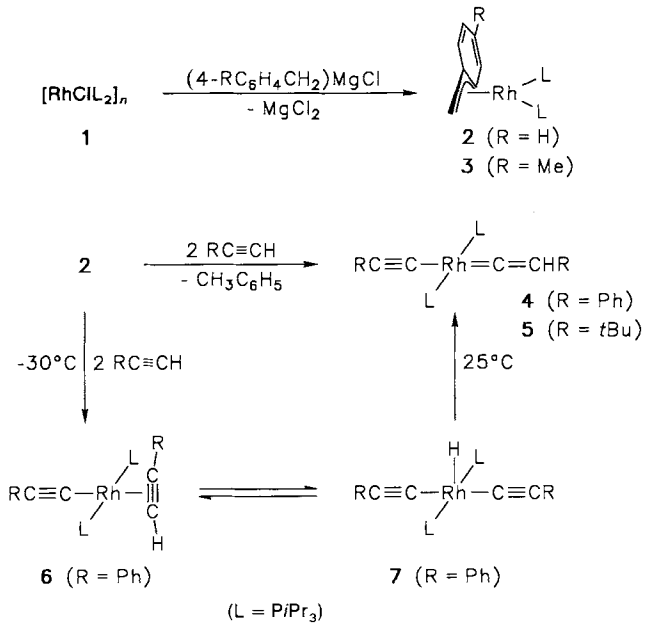
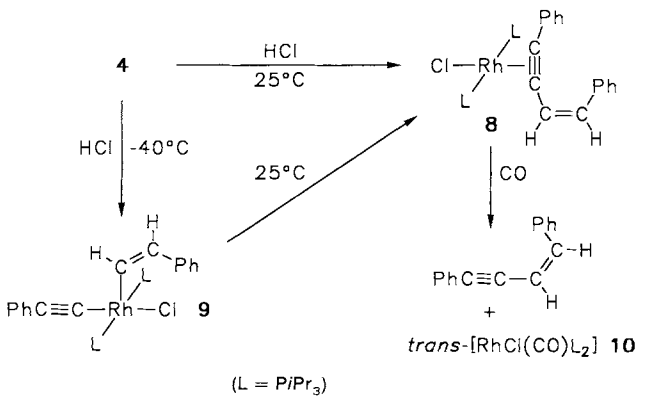
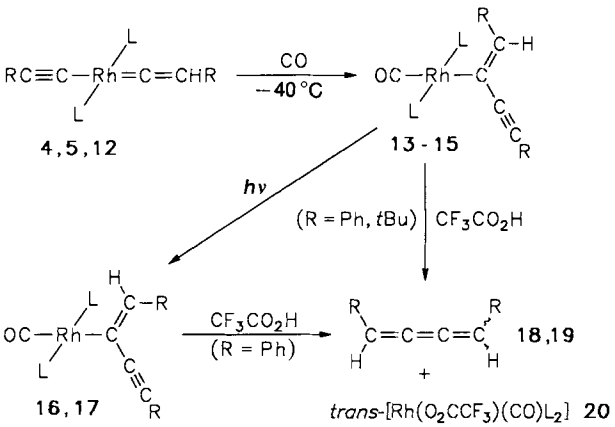
ed. In solution, there is an equilibrium between **6** and **7**, the ratio of which is 60:40 at −40 °C in [D_8]toluene. Compound **7** rearranges quantitatively in benzene at room temperature in 3 hours to yield **4**. The alkynyl(vinylidene) complexes **4** and **5**, isolated as blue-green crystalline solids, slowly decompose in solution; they thus behave differently to the remarkably stable chloro(vinylidene) compounds *trans*-[RhCl(=C=CHR)($PiPr_3$)$_2$] (R = Ph,[8] *t*Bu[9]), which cannot be used for the preparation of **4** and **5**.



Surprisingly, the reaction of **4** with a solution of HCl in benzene at room temperature does not cause the elimination of phenylacetylene but gives the enyne complex **8** in about 50% yield. If **4** is treated in ether at −40 °C with gaseous HCl, instead of **8** the alkynyl(vinyl) compound **9** is formed quantitatively. Presumably, in the initial step an oxidative addition of HCl to the metal center takes place, followed by the migration of the hydride ligand to the α-carbon atom of the vinylidene unit.[10] The reaction of **4** with HCl to give **9** is both regio- and stereoselective. The exclusive formation of the (*Z*) isomer is probably due to the kinetically preferred transfer of the hydride from the side opposite to the phenyl group. The rearrangement of **9** to **8** occurs quantitatively in benzene at room temperature and is equally selective; only the compound containing the enyne in the (*Z*) configuration is formed. On treatment of **8** with CO (C_6H_6, 25 °C), a ligand exchange occurs spontaneously to give (*Z*)-PhC≡CCH=CHPh and the carbonyl complex **10**.[11]



Coupling of the C_2 units of **4** (and also of **5**) occurs in a different way if the sequence of the addition of HX and CO is reversed. Both **4** and **5** react with CO in pentane at −40 °C to give exclusively the (*Z*) isomers of the enynyl metal complexes **13** and **14** in about 80% yield (Scheme 1). We assume



Scheme 1. **4**, **13**, **16**, **18**: R = Ph; **5**, **14**, **17**, **19**: R = *t*Bu; **12**, **15**: R = CO_2Me. L = $PiPr_3$.

that initially CO adds to the rhodium atom, thus generating a five-coordinate intermediate, which after migration of the alkynyl ligand to the α-carbon of the vinylidene unit transforms into the isolated product. The importance of steric factors probably explains why the attack of the alkynyl residue occurs only at that side of the molecule which is opposite to the group R (Ph or *t*Bu). Photolysis of a solution of **13** or **14** in benzene leads to an isomerization, which affords the thermodynamically preferred (*E*) isomers **16** and **17**. The stepwise conversion of **4** to **13** and finally to **16** (or **5** to **14** and finally **17**) is noteworthy insofar as Wakatsuki et al.[2] reported the exclusive formation of the (*E*) isomer of the enynyl ruthenium complex [RuCl(η^1-(*E*)-C(=CH*t*Bu)-C≡C*t*Bu)(CO)(PPh_3)$_2$] in the reaction of [$RuCl_2$-(=C=CH*t*Bu)(PPh_3)$_2$] with LiC≡C*t*Bu and CO.

The stereochemistry of the primary products formed in the reaction with CO by coupling of the C_2 units is confirmed by

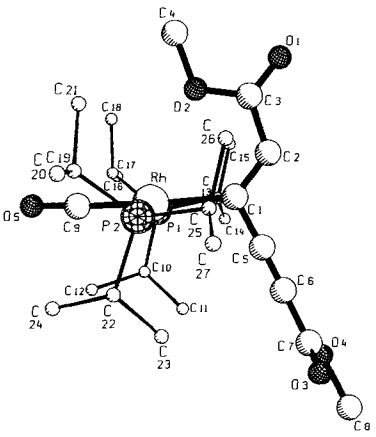


Fig. 1. Crystal structure of **15**. Selected bond distances [Å] and angles [°]: Rh-C1 2.099(4), Rh-C9 1.833(4), Rh-P1 2.347(1), Rh-P2 2.345(1), C1-C2 1.352(5), C2-C3 1.459(5), C1-C5 1.421(5), C5-C6 1.198(5), C6-C7 1.430(6), C9-O5 1.147(5); C1-Rh-C9 177.5(1), P1-Rh-P2 168.18(3), Rh-C9-O5 177.7(3), Rh-C1-C2 130.3(3), Rh-C1-C5 113.9(3), C1-C2-C3 126.8(4), C2-C1-C5 115.8(3), C1-C5-C6 177.4(5), C5-C6-C7 175.9(5).

the X-ray crystal structure analysis of **15**. In contrast to **4** and **5**, compound **12**, which is needed as a precursor to prepare **15**, cannot be obtained directly from **2** and $HC{\equiv}CCO_2Me$ but is accessible on treatment of $[Rh(\eta^2\text{-}O_2CCH_3)(PiPr_3)_2]$ (**11**)[7] with two equivalents of the alkyne in presence of Na_2CO_3. The conversion of **12** to **15** occurs under similar conditions (pentane, $-40\,^{\circ}C$) as described for **13** and **14**. The square-planar coordination of the metal center and the *trans* arrangement of the phosphane ligands in **15** is shown in Figure 1. The enynyl unit is perpendicular to the plane of the molecule; the dihedral angle between the planes [C2, C1, C5] and [P1, Rh, P2] is $91.13 \pm 0.48^{\circ}$. The bond lengths Rh–C5 (2.973(4) Å), Rh–C6 (> 3.5 Å), together with the bond angle C5-C6-C7 (175.9(5)°) and the distance Rh–O2 (3.028(3) Å), speak against an additional interaction between the C≡C bond or the cisoid ester group with the metal atom.

The cleavage of the enynyl–rhodium bond in **13**, **14**, and **16** by CF_3CO_2H in acetone or benzene gives, besides small amounts of the corresponding enyne, the butatrienes **18** and **19** in 90–95% yield. The carboxylato complex **20** is also formed (Scheme 1). Whereas compound **13** is inert toward acetic acid, the reaction of **14** with CH_3CO_2H leads to a 40:60 mixture of (*E*)-*t*BuC≡CCH=CH*t*Bu and **19**, and that of **16** gives (*Z*)-PhC≡CCH=CHPh. Both the product distribution and the isomer ratio of the (*E*/*Z*)-butatrienes (see Table 1) indicate that, with a strong proton donor such as CF_3CO_2H, the attack of the acid does not occur at the Lewis basic metal center but directly at the triple bond of the enynyl ligand. We assume that a cationic butatriene rhodium complex is formed as an intermediate,[18] from which the cumulene is displaced by the carboxylate anion. The molecular structure of **15** reveals that the proton probably attacks the C≡C bond from the side opposite to the metal, which would explain why the (*Z*)-enynyl complexes **13** and **14** predominantly afford the (*Z*) isomer, and the (*E*)-enynyl rhodium compound **16** the (*E*) isomer of the substituted butatriene.

Table 1. Product distribution and (*E*/*Z*)-isomer ratio after elimination of the C_4 unit from **13**, **14**, and **16** with HX [13].

Complex	HX/*T* [°C], *t*	Solvent	Butatriene Yield [%] (*E*/*Z*)	Enyne Yield [%] (*E*/*Z*)
13	CF_3CO_2H/40, 30 min	C_6H_6	90 (20/80)	10 (100/0)
13	CF_3CO_2H/25, 30 min	$(CH_3)_2CO$	95 (45/55)	5 (0/100)
14	CH_3CO_2H/40, 2 h	C_6H_6	40 (80/20)	60 (100/0)
14	CF_3CO_2H/25, 2 h	$(CH_3)_2CO$	> 95 (30/70)	< 5 (100/0)
16	CH_3CO_2H/25, 10 min	C_6H_6	0	100 (0/100)
16	CF_3CO_2H/25, 10 min	$(CH_3)_2CO$	95 (90/10)	5 (0/100)

In conclusion, the results described in this paper prove that the rhodium-mediated coupling of two alkyne molecules can lead to the formation of either enynes or butatrienes, provided that the reaction proceeds via an alkynyl(vinylidene) complex as a common intermediate. By changing the sequence of the reaction steps it is possible to convert this intermediate into an enyne or enynyl rhodium compound from which the dimers are liberated (spectroscopic data of the complexes are listed in Table 2). We are now investigating whether, besides the alkynyl–vinylidene coupling described here, analogous metal-initiated alkynyl–allenylidene and vinyl–vinylidene couplings can be achieved, and whether two reaction pathways are feasible also in these cases.

Table 2. Selected spectroscopic data of **8** and **13**–**17** (omitting ^1H and ^{13}C NMR data for the phosphane ligands and phenyl groups).

The First Trigonal-Bipyramidal Cluster with an Interstitial C_2 Unit: $[Rb\{Pr_5(C_2)\}Cl_{10}]$**

By *Gerd Meyer** and *Stefan Uhrlandt*

The structures of the metal-rich rare earth halides are built predominantly of octahedral M_6 or tetrahedral M_4 clusters, stabilized, almost without exception, by interstitial atoms Z (that is, also by M–Z bonds). Examples are $[(Zr_6Be)Cl_{12}]$,[1] $[(Gd_2N)Cl_3]$,[2] and $[Na_2(Pr_4O_2)Cl_9]$.[3] These compounds are formed at high temperature by symproportionation ($MX_3 + M$, X = halogen) in the presence of the element Z, sometimes with addition of alkali metal chlorides as a flux. An alternative route is the metallothermic reduction of trihalides with alkali metals A ($MX_3 + A + Z$),[4] which leads to ternary halides like $[\{Er_{10}(C_2)_2\}Br_{18}]$,[5] and also, more often, to quaternary halides such as $[Cs\{Er_{10}(C_2)_2\}I_{18}]$[6] or $[Cs_2\{Pr_6(C_2)\}I_{12}]$.[7] Surprisingly, with **1** we have now obtained an isolated trigonal-bipyramidal cluster stabilized by a C_2 unit as the first such example in the chemistry of the metal-rich rare earth halides.

$[Rb\{Pr_5(C_2)\}Cl_{10}]$ **1**

In the crystal structure of **1**,[8] each of the nine edges of the trigonal bipyramid of five Pr atoms and an interstitial C_2 unit is bridged by a chlorine atom. According to the nomenclature of Schäfer and Schnering,[9] these chlorine atoms must be labeled Cl^i atoms. In addition to the nine Cl^i atoms, twelve chlorine atoms (Cl^a) complete the coordination sphere. Of these twelve, two sets of three are located at the apexes of the bipyramid, and three sets of two around the Pr atoms of the pyramidal base (Fig. 1). The complete unit is thus described as $[\{Pr_5(C_2)Cl^i_9\}Cl^a_{12}]$.

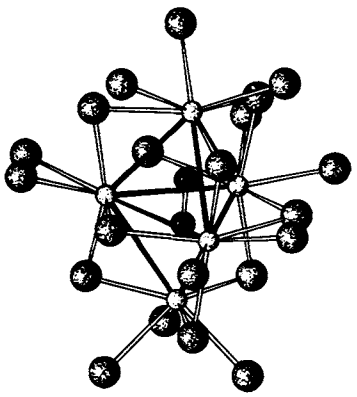

Fig. 1. The $[\{Pr_5(C_2)\}Cl_{21}]$ unit in the solid-state structure of **1**. All of the 21 Cl atoms are shared by adjacent bipyramids to yield the empirical formula $[\{Pr_5(C_2)\}Cl_{10}]$. Every edge of the trigonal Pr_5 bipyramid is bridged by one Cl^i atom. In addition, three terminal Cl^a atoms are coordinated to each of the apexes and two such atoms to each of the three Pr atoms forming the base. Solid circles are C atoms, lightly shaded circles Pr atoms, and darkly shaded circles Cl atoms.

An arrangement of 21 chlorine atoms around a trigonal bipyramid seems to be sterically demanding at first, especially since octahedral M_6 clusters like those in $[Cs_2\{Pr_6(C_2)\}I_{12}]$ are surrounded by not more than 18 halogen atoms. Yet a comparison of the $[\{M_5(C_2)\}X_{21}]$ unit in **1** with the (even smaller) tetrahedral $[\{M_4O\}X_{18}]$ unit in $[(Eu_4O)Cl_6]$[10] reveals that an arrangement of 21 chlorine atoms around an M_5 cluster is indeed possible.

In contrast to the established connections of octahedral and bioctahedral clusters, in **1** all chlorine atoms participate in the intercluster connections. We even find chlorine atoms which connect three clusters through unprecedented Cl^{a-a-a} bridges (Fig. 2). One trigonal bipyramid is connected to twelve others, of which six are in the same plane and three each above and below the central bipyramid. Connection along [001] to the out-of-plane bipyramids above and below is effected by Cl^{i-a} bridges in such a way that a chlorine atom belongs to the inner coordination sphere of one cluster and to the outer sphere of the next cluster and vice versa. Accordingly, connectivity along [001] must be described as $[\{Pr_5(C_2)Cl^{i-a}_{6/2}\}Cl^{a-i}_{6/2}]$. In-plane connectivity between the six bipyramids around a central bipyramid is achieved by Cl^{i-a} bridges of the three edge-bridging chlorine atoms positioned around the base, and three Cl^{a-i} bridges as well as three Cl^{a-a-a} bridges of the six terminal chlorine atoms. This leads to $[\{Pr_5(C_2)Cl^{i-a}_{3/2}\}Cl^{a-i}_{3/2}Cl^{a-a-a}_{3/3}]$ as a description for this plane. Figure 2 shows the connectivity within the hexagonal plane. Combination of these two motifs leads to $[\{Pr_5(C_2)Cl^{i-a}_{9/2}\}Cl^{a-i}_{9/2}Cl^{a-a-a}_{3/3}]$ as a full description of **1**. Along [001] the cluster layers are stacked with the ABAB

[**] This work was supported by the Deutsche Foschungsgemeinschaft and the Fonds der Chemischen Industrie.

sequence as in a hexagonal closest packing. Eight rubidium atoms are located on the edges of the unit cell. Of these eight, four each are in the same plane as the apexes of the bipyramid; they thus form a layer together with the Pr atoms. The coordination around Rb is a distorted tricapped trigonal prism of [6 + 3] chlorine atoms [$\bar{d}$(Rb-Cl) = 337.2 pm].

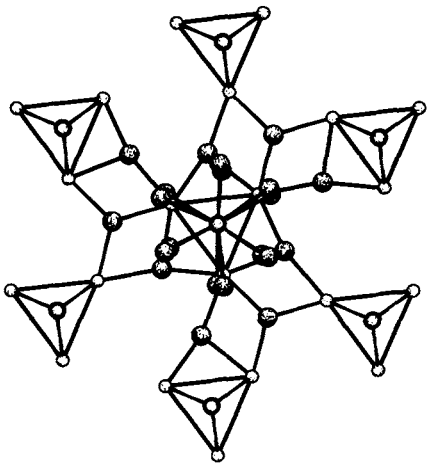

Fig. 2. Connection of a central bipyramid in **1** with six others in the hexagonal plane. Three pyramids are connected to the central one through Cl^{i-a} bridges and three through Cl^{a-a-a} bridges.

The trigonal bipyramids of five Pr atoms and an interstitial C_2 unit are not elongated as is observed when C_2 units are incorporated into M_6 octahedra, but rather contracted: the Pr–Pr distances are 404.4 pm in the base and 382.4 pm from the base to the apex. The distance from the carbon atoms of the C_2 units to the apexes is 228.5 pm. Within the carbon pair the C–C distance of 148.8 pm is somewhat longer than C–C distances observed inside octahedral clusters (143–148 pm).[11, 12] In fact, MO calculations show that the cluster electrons are localized in carbon levels, so that formally a C_2^{6-} unit results. For $[\{Gd_{10}(C_2)_2\}Cl_{18}]$,[13] similar calculations give an analogous result.

Compound **1** is to date the only known example in the chemistry of solid state clusters of transition metals (including the lanthanides and the actinides) featuring a trigonal-bipyramidal M_5 unit with an incorporated C_2 unit. All other known and isolated Pr clusters, namely, $[Cs_2\{Pr_6(C_2)\}I_{12}]$ and $[Cs_4\{Pr_6(C_2)\}I_{13}]$,[14] contain octahedral M_6 units. Main group elements do form trigonal bipyramidal clusters such as Sn_5^{2-} or Bi_5^{3+}, which must be counted among the Zintl-type polyions.[15] In transition metal chemistry $[\{(C_4H_9)N\}Mo_5Cl_{13}]$[16] has been reported as well as $(NH_4)_6[Ta_5(NH)_4Cl_{17}]$,[17] which was described only recently. These two compounds contain M_5 clusters in the form of tetragonal pyramids; in the Ta cluster, four NH^{2-} ions bridge the Ta atoms of the pyramidal base. The successful synthesis of **1** now adds the trigonal bipyramid, stabilized by M–Z bonds, as a third polyhedron to the tetrahedrons and octahedrons in the chemistry of metal-rich rare earth halides.

Experimental Procedure

1 was obtained by treating 32 mg Rb with 555 mg $PrCl_3$, 211 mg Pr, and 18 mg C. The starting materials were weighed inside an argon-filled glove box into a niobium container, which in turn was jacketed in a quartz glass ampoule and sealed under vacuum. The mixture was melted at 950 °C (4 h) and subsequently kept in the furnace at 800 °C for 50 days. Carmine red crystals of **1** were obtained in an approximately 95% yield. The remaining 5% consisted of some unchanged $PrCl_3$ and yellow needles, which were identified as $[Pr_2NCl_3]$ [18]. **1** reacts violently with water (gas is evolved) and is sensitive to air.

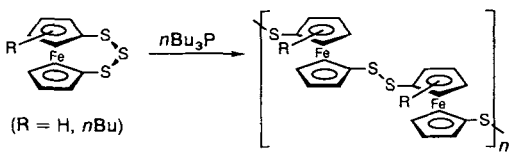
Giant Organometallic Networks Derived from Ferrocenepolysulfides**

By *Collin P. Galloway* and *Thomas B. Rauchfuss**

We recently reported a new type of organometallic polymer based on disulfido-linked metallocenes, prepared according to Equation (1).[1]



(1)

We now describe routes to related three-dimensional networks; this has involved the preparation of stereochemically novel crosslinking agents and their conversion to very high molecular weight organometallic aggregates. Conceptually related to this work are two other network materials, poly-

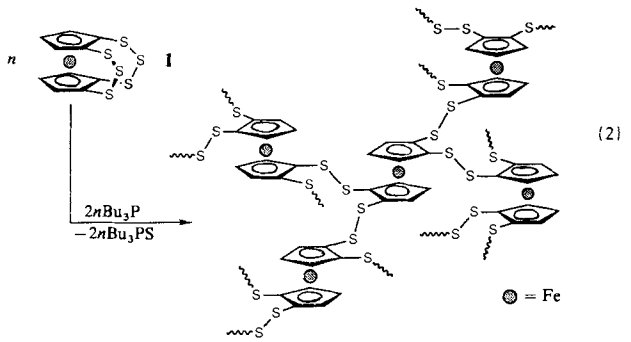
silynes, prepared by dehalogenation of trichlorosilanes,[2] and (bipyridine)ruthenium arborols.[3]

Crosslinking groups for polymeric metallocenes with disulfido bridges could in principle be prepared from the higher order ferrocenepolysulfides $[Fe(C_5H_{5-x})_2(S_3)_x]$ $(x > 1)$.[4] The hexasulfide $(x = 2)$ is available by tetralithiation of 1,1'-ferrocenedithiol followed by sulfurization with S_8; a process also described by Long et al.[5] This methodology involves deprotonation of the thiol groups followed by *ortho* metalation on each of the rings, as observed in the metalation of thiophenols.[6] An extractive workup of the reaction mixture gives **1** in about 20% yield. The spectro-

$[Fe(C_5H_3)_2(S_3)_2]$ **1**

scopic properties for **1** agree with the published values. Additionally, solutions of **1** in CH_2Cl_2 reversibly oxidize at 1.02 V (vs. Ag/AgCl). Under the same conditions the $E_{1/2}$ values for $[Fe(C_5H_5)_2]$ and $[Fe(C_5H_4)_2S_3]$ are 540 and 857 mV, respectively.[7]

Solutions of **1** react readily with the desulfurization agent nBu$_3$P [Eq. (2)] to deposit a bright orange solid with an Fe:S ratio of about 1:4. Evaluation of the molecular weight distri-



(2)

bution of this material was precluded by its complete insolubility in organic solvents. Cross polarization magic angle spinning (CP/MAS) ^{13}C NMR spectroscopy showed two signals, one at $\delta = 80$ for the CH centers and another at $\delta = 91$ for the CS centers. These chemical shifts are similar to those for the related one-dimensional polymer $[Fe(C_5H_4S)_2]_n$.[1]

In order to prepare soluble ferrocene networks we first synthesized alkyl-substituted analogues of **1**. This was accomplished in a completely regiospecific manner starting from $[Fe(t\text{BuC}_5H_3SH)(C_5H_4SH)]$.[8] Ring lithiation of this species is cleanly directed adjacent to the thiolates and away from the *tert*-butyl group to give, after sulfurization, **2**.

$[Fe(t\text{BuC}_5H_2)(C_5H_3)(S_3)_2]$ **2**

^{1}H NMR measurements (Fig. 1) confirm that this synthesis is regioselective: one observes a single CH_3 resonance signal as well as a singlet and an A_2B coupling pattern for the protons of the trisubstituted and disubstituted cyclopentadienyl rings, respectively, consistent with the conformer of C_s symmetry.[4] In the course of this analysis we discovered that **2** undergoes conformational isomerism in solution. The intensity of the signals assigned to the conformer of C_s symmetry diminish over a period of several minutes; concurrent with this is the appearance of a second CH_3 resonance signal and a new pattern for the ring protons (ABC spin system for the disubstituted ring). These new signals are assigned to the conformer of C_1 symmetry. Separate experiments confirmed that this same dynamic process applies to **1**, provided that the NMR solutions are very freshly prepared. These results reconcile the observation[5] that two isomers of **1** are present in solution, while only one conformer is seen in the crystal lattice.[9] Recrystallization of equilibrated samples of **1** and **2** affords only single conformers, although flash evaporation gives a mixture of the two. The rate constants k_1 and k_{-1} for the isomerization (19 °C) of **1** in C_6D_6 are 6.5×10^{-4} and $7.0 \times 10^{-4}\ s^{-1}$, with $K_{eq} = 0.93$. The rate constant for the inversion of individual S_3 bridges in the C_{2v} isomer is $0.5k_1$ since there are two equivalent trisulfides.[10]

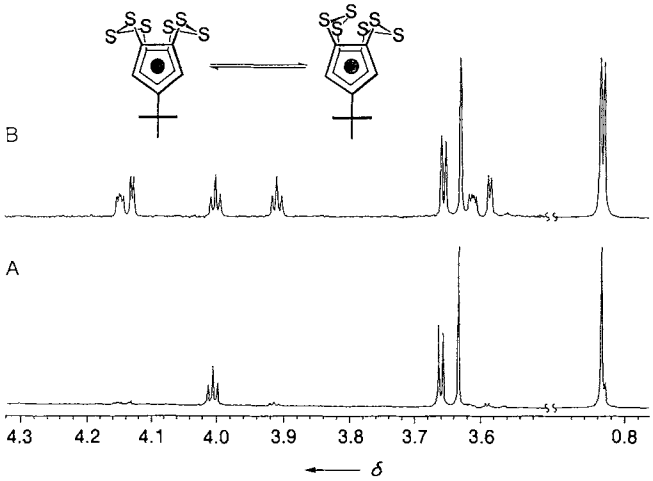


Fig. 1. ^{1}H NMR spectrum of **2** (400 MHz, C_6D_6). Spectrum A was recorded within 5 min of dissolution of the compound, spectrum B was recorded 24 h later and represents the equilibrated sample.

Desulfurization of **2** gave orange polymeric species whose molecular weight distributions proved sensitive to the reaction conditions. Treatment of **2** with two equivalents nBu$_3$P gave primarily materials with MW < 50000. This effect is attributed to the degradation of the network of S–S bonds by the phosphane. Particularly exciting results were obtained when **2** was desulfurized with only 1.5 equivalents nBu$_3$P. The clean conversion of the phosphane to SPBu$_3$ was confirmed by ^{31}P NMR spectroscopy. As indicated by gel permeation chromatographic (GPC) analysis, the initial product has a wide molecular weight distribution to $> 10^6$ Da (Fig. 2). The lighter fractions may correspond to linear polymers with relatively few crosslinks, as seen in the polymerization of the trisulfide $[Fe(t\text{BuC}_5H_3)(C_5H_4)(S_3)]$.[8] Over a period of several minutes, network formation leads to very high molecular weight species.[11] The two trisulfido groups in the monomers clearly participate in the formation of these large organometallic networks, since polymerization of $[Fe(t\text{BuC}_5H_3)(C_5H_4)(S_3)]$ affords mainly a polymer of low molecular weight $M_n < 6000$.[7]

The yellow network polymer $[Fe(t\text{BuC}_5H_2)(C_5H_3)(S_{3-x})_2]_n$ $(x = 0,1)$ was purified by preparative-scale GPC on crosslinked polystyrene; this allowed easy removal of the low molecular weight fractions. Based on analysis of the GPC traces, the purified polymer has $M_n \approx 8.5 \times 10^5$ and $M_w \approx 3.0 \times 10^6$. The observed molecular weights are exceptional for organometallic polymers and can be attributed to the networking capability of the two trisulfido groups in **2**.[12]

To summarize, a three-dimensional network of S–S linkages has been employed in the formation of particularly high molecular weight organometallic superstructures. These findings, together with the widespread occurrence of S–S

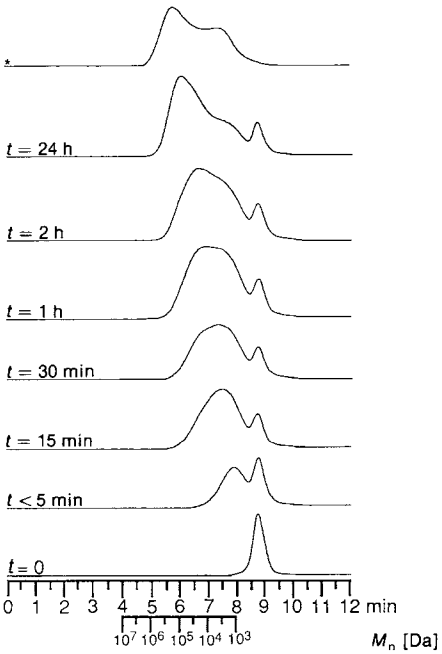

Fig. 2. GPC traces for the reaction mixture of **2** and 1.5 equivalents nBu$_3$P in THF. The top trace (*) is the reaction mixture after purification on Biobeads SX-1 (1 wt% divinylbenzene crosslinked polystyrene). The data for the average molecular weights, M_n, correspond to polystyrene standards which cover the range between 10^3 and 3×10^7 Da.

crosslinks in proteins and minerals, suggest that this structural motif could be more widely applied in synthetic polymers.

Experimental Procedure

All reactions were conducted under a dinitrogen atmosphere.

Polymerization of **1**: A solution of **1** (0.080 g, 0.02 mmol) in dry THF (20 mL) was treated with nBu$_3$P (106 μL, 0.04 mmol). A bright orange precipitate appeared immediately. After 4 h, the solid was collected and washed with THF. Yield: 65 mg (100%). Correct elemental analysis (C, H, Fe, S) for $[Fe(C_5H_3S_2)_2]_n$. IR (KBr): $\tilde{\nu}$ = 3085 (m), 2951 (m), 2921 (m), 2858 (m), 825 (s), 515 (s), 430 (s) cm^{-1}. ^{13}C CP/MAS NMR (75.5 MHz): δ = 80 (CH), 91 (CS).

Synthesis of **2**: [Fe(tBuC$_5$H$_3$SH)(C$_5$H$_4$SH)] was prepared from the trisulfide by LiAlH$_4$ reduction followed by acidification according to the literature method [13]. A solution of [Fe(tBuC$_5$H$_3$SH)(C$_5$H$_4$SH)] (2.62 g, 8.55 mmol) in hexane (50 mL) was added to a stirred solution of 1.6 M nBuLi (21.9 mL, 35 mmol) and TMEDA (5.29 mL). After 16 h at 60 °C, excess elemental sulfur (3.6 g, 112 mmol) was added and the slurry heated under reflux for 6 h. The reaction mixture was filtered and the residue was extracted with hexane (1.5 L). The hexane fractions were washed with 10% NaOH (100 mL) and dried over Na$_2$SO$_4$. Fractional crystallization from THF gave 0.500 g of **2** (12%). ^{1}H NMR (400 MHz, C$_6$D$_6$): C_s conformer δ = 0.84 (s, 9H), 3.69 (s, 2H), 3.71 (d, 2H), 4.06 (t, 1H); C_1 conformer δ = 0.83 (s, 9H), 3.64 (d, 1H), 3.67 (dd, 1H), 3.97 (t, 1H), 4.18 (d, 1H), 4.21 (dd, 1H); ^{13}C NMR (75.5 MHz, C$_6$D$_6$): both conformers (18 of 20 possible signals observed): δ = 108.7, 106.4, 101.6, 99.8, 90.3, 89.4, 80.6, 77.6, 76.1, 73.8, 72.5, 70.5, 69.3, 67.3, 31.2, 31.1. Correct elemental analysis (C, H, Fe, S) for [Fe(tBuC$_5$H$_2$)(C$_5$H$_3$)(S$_3$)$_2$]. EI-MS: (m/z): 430 (M^+). $E_{1/2}$ = 975 mV.

Polymerization of **2**: A solution of **2** (0.025 g, 0.058 mmol) in purified THF (5 mL) was treated with nBu$_3$P (21.6 μL, 0.087 mmol). An immediate color change from yellow to red occurred and the progress of the polymerization was monitored by GPC on a TSK-Gel polystyrene column (Tosoh Corp.) (λ_{det} = 300 nm, 1.5 mL min^{-1} of THF), calibrated with 13 polystyrene standards over the range 10^3 to 3×10^7 Da.

Molecular Recognition within a Rigid Host: Structural Changes Induced in μ-Carboxylato Dimetal(II) Complexes by Replacing Steric Repulsions with Hydrogen Bonds**

By *Karl S. Hagen,** *Rene Lachicotte, Alex Kitaygorodskiy,* and *Abdelaziz Elbouadili*

Dedicated to Professor Richard H. Holm on the occasion of his 60th birthday

The diverse reactivity of dioxygen with the diiron(II) nonheme proteins,[1] hemerythrin (Hr, reversible binding), ribonucleotide reductase (R2, generation of tyrosine radical),[2] and methane monooxygenase (MMO, hydroxylation of CH_4 to CH_3OH), is presumably due to the identity of the coordinated ligands and varied stereochemistry induced by the tertiary protein structure, which is an α barrel constructed from a four-helix bundle for Hr and R2. The two Fe^{II} centers in Hr are bridged by two RCO_2^- and a OH^- group and terminally ligated by five histidine residues, whereas those in R2 are bridged by only two RCO_2^- groups and terminally ligated by two histidine residues and two additional RCO_2^- groups. The ligand sphere of the reactive center in MMO is less well characterized, but the iron centers are thought to be in an oxygen-rich environment. The structure of apo-R2[2d] reveals a group of four carboxylato ligands,

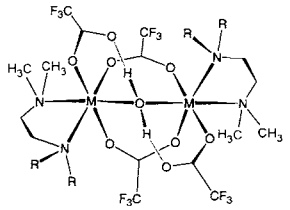
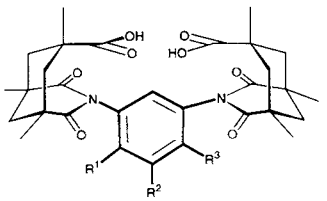
[**] This research was supported in part by the University Research Committee of Emory University and the National Institutes of Health (GM 46506).

two of which have O···O separations of 290 pm, and two histidine residues. Our initial structural models of the reduced proteins have the general formula $[M_2(OH_2)(O_2CR)_4(tmen)_2]$ **1** (M = Fe^{II}, R = CH_3, Ph,[3] CF_3 (=1-Fe), CMe_3; M = Co^{II}, R = CF_3 (= **1**-Co); tmen = *N,N,N′,N′*-tetramethyl-1,2-diaminoethane) and involve two Fe^{II} centers that interact with four carboxylato ligands. As these complexes



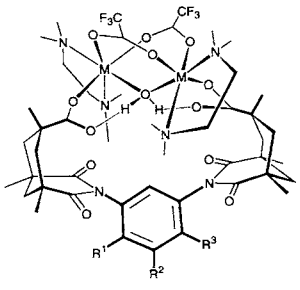
1-Fe R = CH_3; M = Fe^{II}
1-Co R = CH_3; M = Co^{II}
4 R = H; M = Co^{II}

lack the asymmetry of the protein, we have sought ligands that provide multiple, stereochemically constrained functional groups that more closely mimic the constraints of the protein sites. The series of rigid molecules having molecular clefts such as **2a**, developed by Rebek and coworkers,[5] appear to have a favorable structural configuration to serve as hosts for model complexes of metalloproteins, and in particular non-heme proteins in which the diiron(II) centers are coordinated by carboxylato ligands. In order to provide a system with potentially greater flexibility than the previously reported ligand (**2a**), alter the symmetry, and introduce ^{19}F labels for NMR spectroscopic studies, we have prepared the new dicarboxylic acids **2b** and **2c**. Ligand-exchange reac-

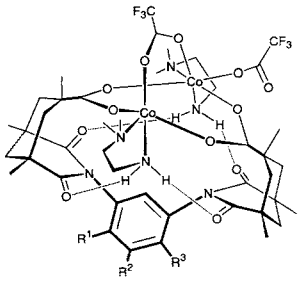


2a $R^1 = R^3 = CH_3$; $R^2 = H$
2b $R^1 = CH_3$; $R^2 = R^3 = H$
2c $R^2 = CF_3$; $R^1 = R^3 = H$

tions have been carried out between **2a**–**c** and **1**-Fe/**1**-Co to form aqua-bridged dinuclear complexes of type **3**; the analogous reaction with the dmen (*N,N*-dimethyl-1,2-diaminoethane) dicobalt complex **4** afforded a complex of type **5**.



3-Co M = Co^{II}
3-Fe M = Fe^{II}



5

The optimal method for monitoring ligand-exchange reactions is not UV-VIS but rather ^{19}F NMR spectroscopy, since the paramagnetism of Co^{II} and Fe^{II} ions affords large isotropic shifts of the resonance of the bound trifluoroacetato ligands and dicarboxylic acid **2c** (Fig. 1). The Co^{II} complexes were chosen because of the higher resolution of their spectra relative to those of Fe^{II} complexes, which results from larger dipolar contributions to the isotropic shifts of the former due to the larger magnetic anisotropy of high-spin Co^{II} relative to high-spin Fe^{II} ions.[6]

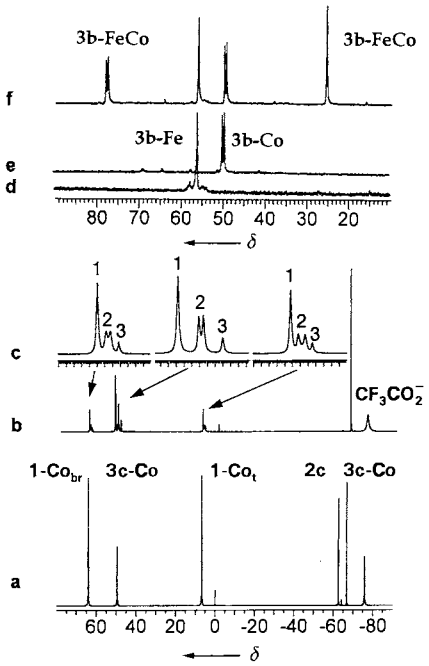


Fig. 1. 470 MHz ^{19}F NMR spectra (for abbreviations see ref. [4], values given are δ values) of a) **1**-Co (F_b 64, F_t 7.5; standard $CFCl_3$ in $CDCl_3$, 24 °C) with excess **2c** (−62.8) affords **3c**-Co (F_b 49.5, −66.8); free $CF_3CO_2^-$ (−76.0) ($1\text{-}Co_{br}$, and $1\text{-}Co_t$ mark the signals corresponding to the bridging and terminal trifluoroacetato ligands in 1-Co); b) isotopomeric mixture with excess **1**-Co; c) expanded spectrum of isotopomeric mixture: (1) D_2O as bridging ligand (1-Co F_{bD} 65.5, F_{tD} 8.1, **3c**-Co 52.4), (2) DOH as bridging ligand (1-Co $F_{b'HD}$ 64.9, $F_{b''HD}$ 64.7, $F_{t'HD}$ 7.6, $F_{t''HD}$ 7.2, **3c**-Co 51.1, 50.8), and (3) H_2O as bridging ligand (**1**-Co F_{bH} 64.1, F_{tH} 6.7, **3c**-Co 49.5); d) **3b** Fe (56); e) **3b**-Co (49.9, 49.4); f) **3b**-FeCo ($F_{b'}$ 78.0, 77.6, $F_{b''}$ 25.5).

Four experiments prove that a quantitative ligand-exchange reaction occurs and that the product has the same stereochemistry as the starting complexes **1**-Fe and **1**-Co. 1) When **1**-Fe (or **1**-Co) is treated with dicarboxylic acid **2c**, no reaction occurs until base is added, whereupon the ^{19}F NMR signals arising from the two $CF_3CO_2^-$ groups of **1**-Fe (or **1**-Co) are lost and replaced by signals of equal intensity corresponding to the diamagnetic, free $CF_3CO_2^-$ ion and paramagnetic, coordinated $CF_3CO_2^-$ ion in **3c**-Fe (or **3c**-Co, Fig. 1a). When a 1:1 mol ratio of **1**-Co and **2c** is employed with an excess of base, the ^{19}F NMR signal for the diamagnetic dicarboxylic acid **2c** at $\delta = -62.6$ is lost, and a new signal corresponding to **3c**-Co is observed at $\delta = -66.8$, indicating that the reaction is quantitative. 2) The presence of two $CF_3CO_2^-$ groups in the product is demonstrated in the reaction of **2b** and **1**-Co affording **3b**-Co, where the lack of any symmetry (C_1 point group) is reflected in two closely spaced, isotropically shifted $CF_3CO_2^-$ resonances (Fig. 1e) which are not resolved in **3b**-Fe (Fig. 1d). 3) The dinuclear nature of the complex is demonstrated by mixing solutions of **3b**-Fe with **3b**-Co which, within time of mixing, affords

the mixed-metal complex, **3b**-FeCo through facile metal exchange.[7] The spectrum of this reaction mixture (Fig. 1f) shows a statistical distribution of the resonances of **3b**-Fe and **3b**-Co as well as two new signals of **3b**-FeCo. 4) The presence of a bridging aqua ligand can be verified by using a mixture of H/D isotopomers.[8] Four ^{19}F NMR resonances of the three isotopomers (H_2O, D_2O (one signal each for C_2 point group) and HOD (two signals for each $CF_3CO_2^-$ ligand in C_1 point group)) are observed in the spectra of **1**-Co and **3c**-Co (Fig. 1b, c).

The ^{19}F NMR chemical shifts of **3**-Co and **3**-Fe suggest that it is the terminal rather than the bridging carboxylato ligands of **1**-Co and **1**-Fe that are replaced by the dicarboxylic acid. This is confirmed by crystal structures of **3a**-Co (Fig. 2) and **3a**-Fe.[9] The $[Co_2(H_2O)(O_2CCF_3)_2(tmen)_2]^{2+}$ fragment of **1**-Co has docked with the molecular cleft of **2a** through coordinate bonds between the dicarboxylic acid and the Co centers and two hydrogen bonds to the bridging aqua ligand. The positions of the C and H atoms in **1**-Co[9, 10]

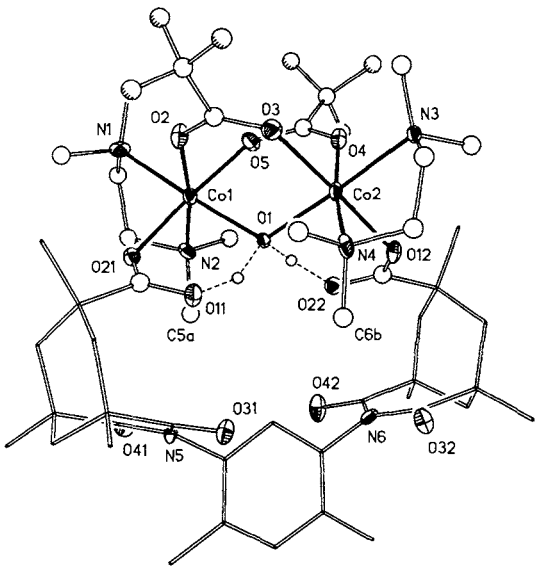

Fig. 2. Crystal structure of **3a**-Co showing 30% probability thermal ellipsoids for Co, N, and O atoms, and open and shaded circles of arbitrary size for C and F, respectively. The host (**2a**) is shown as a stick figure apart from its heteroatoms. Selected interatomic distances [pm] and angles [°] for **3a**-Co: Co1 ··· Co2 370.1; O atoms in hydrogen bonds: O1 ··· O11 249.3, O1 ··· O22 253.4; steric interactions: C5a ··· O41 331, C5a ··· O42 382, C6b ··· O31 341, C6b ··· O32 341; bonds: Co1-O1 211.5(5), Co2-O1 211.7(4), Co1-O2 210.6(5), Co1-O5 210.7(6), Co2-O3 210.0(6), Co2-O4 211.4(6), Co1-O21 208.7(5), Co2-O12 206.2(5), Co1-N1 217.7(7), Co1-N2 219.8(7), Co2-N3 217.7(6), Co2-N4 220.8(7); Co1-O1-Co2 122.0(2).

differ only slightly from those of the corresponding atoms of **3a**-Co. The distance between the convergent carboxylate groups of the dicarboxylic acid has increased considerably upon binding the complex, as compared to that between the carboxylate pair in **2b**, which have a strong hydrogen bond.[11] The carboxylate carbon atoms are 581 pm apart in **3a**-Co compared to 385 pm in **2b**. The O ··· O contacts in **3a**-Co are shorter than in **1**-Co (by 11 and 5 pm) indicating that the hydrogen bonds between the dicarboxylic acid and the bridging aqua ligand are stronger than between the aqua ligand and unrestrained terminal carboxylato ligands in **1**-Co.

The dicarboxylic acid ligand and the dimetal unit are both U-shaped with hydrophobic exteriors and hydrophilic interiors. The two units fit together tightly, and only steric interactions between the methyl groups on the amines and the diimide oxygens of **2a** prevent the closer interaction in which the carboxylate groups of the dicarboxylic acid would become bridging. In the reaction of **4** (a complex analogous to **1**-Co in which the offending methyl groups have been removed) with **2a**, these repulsive steric interactions are replaced by attractive hydrogen bonds, and **5a** forms (Fig. 3).

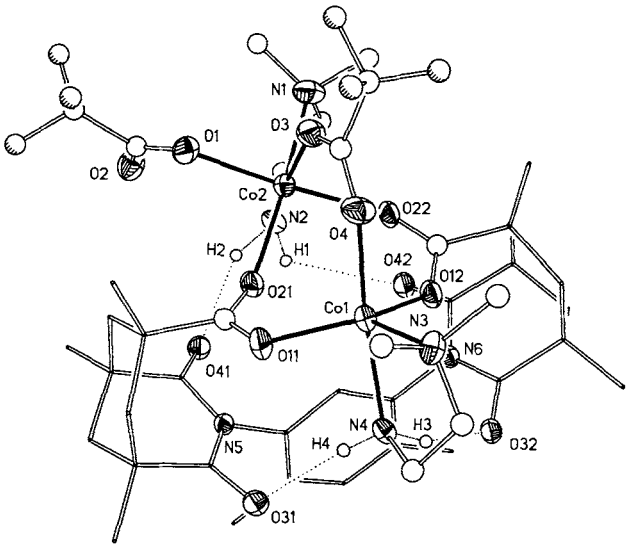

Fig. 3. Crystal structure of one of the two independent dimers of **5a** showing 30% probability thermal ellipsoids for Co, N, and O atoms, and open and shaded circles of arbitrary size for C and F, respectively. The host (**2a**) is shown as a stick figure apart from its heteroatoms. Selected interatomic distances [pm] for **5**: Co1 ··· Co2 389.5; N atoms in hydrogen bonds: N2 ··· O41 307, N2 ··· O42 332, N4 ··· O31 304, N4 ··· O32 311; bonds: Co1-O4 208.2(6), Co1-O11 198.5(6), Co1-O12 195.3(6), Co2-O1 201.7(6), Co2-O3 208.0(6), Co2-O21 214.9(6), Co2-O22 215.6(5), Co1-N3 212.3(7), Co1-N4 218.2(6), Co2-N1 225.4(8), Co2-N2 209.6(6).

The better fit and new hydrogen bonds have pulled the metal ions a further 140 pm into the cleft, and the carboxylate groups of the dicarboxylic acid now bridge the two metal centers. The bridging aqua ligand is lost and replaced by one bridging trifluoroacetato ligand affording a tris(μ-carboxylato) complex.[12] One of the metal centers is terminally coordinated only by dmen and therefore adopts trigonal-bipyramidal five-coordinate geometry. The other metal center is six coordinate with one dmen and one terminal trifluoroacetato ligand. The ^{19}F NMR spectrum of **5** shows two broad resonances at $\delta = 42$ and -4 consistent with the solid-state structure (bridging and terminal trifluoroacetato ligands).

By taking advantage of molecular recognition (weak noncovalent interactions between guest and host in the second coordination sphere of the metal ions) we have been able to alter the geometry of the metal complexes. In doing so we have formed an asymmetric complex with two different types of carboxylato ligands and a six-coordinate as well as a five-coordinate metal center, which is less coordinatively saturated. The asymmetry is relevant to di-iron(II) centers in proteins, which require open coordination sites for reaction with dioxygen. This ligand system allows for diverse terminal ligands with which to tune the stereochemistry and the reactivity of analogous diiron(II) model complexes.

Experimental Procedure

The preparations of dicarboxylic acids **2b** and **2c** were analogous to that of **2a** [5a, 13]. Compounds **3a**-Co, **3a**-Fe, and **3c**-Co were isolated in high yield by cooling acetonitrile solutions of one equivalent each of **1**-Co or **1**-Fe and **2a** or **2c**, respectively, in the presence of an excess of Et_3N under a dry, dinitrogen atmosphere. Compounds **4** and **5** were prepared analogously to **1**-Co and **3a**-Co, respectively, by using dmen instead of tmen.

A Novel 1,6-Methano[10]annulene Derivative with Bisnorcaradiene Structure—Syntheses with Transition Metal Complexes**

By *Richard Neidlein** and *Ulrich Kux*

Dedicated to Professor Werner Schroth on the occasion of his 65th birthday

Almost 30 years ago, E. Vogel and H. D. Roth[1] prepared 1,6-methano[10]annulene **1**, a 10π electron Hückel arene, some derivatives of which have a bisnorcaradiene structure (**2**). Ab initio calculations[2] have shown that **1** is lower in energy than its valence tautomer **2** by only approximately 4.5 kcal mol^{-1},[2a] a value virtually identical to the difference in energy between cycloheptatriene and norcaradiene.[3] The equilibrium shown above can be shifted in the direction of the valence tautomer **2** in several ways:

1 **2**

1) Substitution of the methylene bridge carbon atom C-11 with electron-withdrawing substituents as in, for example, 1,6-methano[10]annulene-11,11-dicarbonitrile.[4]
2) Complexation with organometallic complex fragments, for example with cyclopentadienylcobalt.[5]
3) Bridging the 2- and 10-positions with an etheno or ethano bridge as in 2,10-etheno-1,6-methano[10]annulene.[6]

In order to explore the little-studied reactivity of 1,6-methano[10]annulene derivatives with organometallic reagents, we treated 2,10-bis(phenylethynyl)-1,6-methano-[10]annulene **3**[7] and the corresponding 1,8-bis(phenylethynyl)naphthalene **4**[8] with 2,6-dimethylphenyl isocyanide (**5**) in the presence of transition metal complexes. The reaction of **3** produced **7**, which confirms that a *peri*-2,10-ethano bridge shifts the equilibrium between **1** and **2** towards **2**.

The reaction of **3** with π-cyclopentadienylbis(triphenylphosphine)cobalt[9] in benzene at room temperature produced a brownish-red compound, which is presumably

[**] We thank Dr. W. Kramer for obtaining the NMR spectra.

cobaltocycle **6**, and was not further characterized. After addition of isocyanide **5**, the reaction mixture was heated to reflux. The reaction mixture was cooled and *n*-hexane was added to precipitate a dark solid. Recrystallization from CH_2Cl_2 gave shiny black crystals of **7** in 66% yield over both steps.

The NMR spectra show that **7** is present exclusively as the bisnorcaradiene valence tautomer (Table 1). In the ^1H NMR spectrum the signals of H-1 to H-6 are shifted to higher field relative to those of **1**; selective decoupling experiments allowed the exact assignments of these protons. Additionally,

Table 1. Selected physical data for **7** and **10** (RT = room temperature).

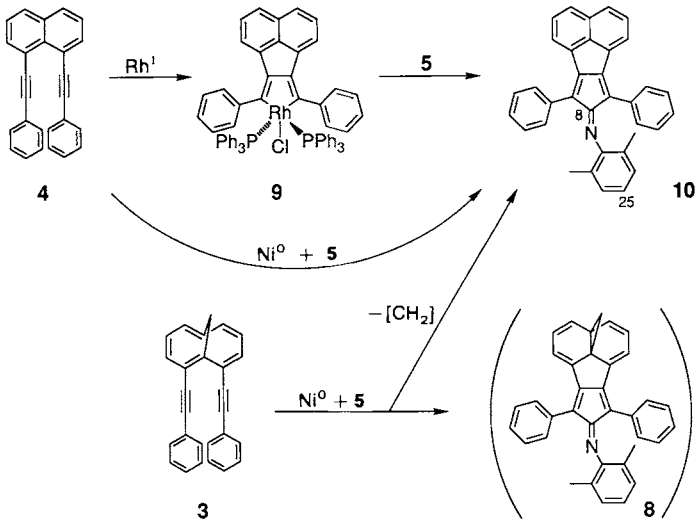
7: M.p. 175–176 °C (CH_2Cl_2); ^1H NMR (250.13 MHz, $CDCl_3$, RT): $\delta = 1.22$ (s, 2H; H-16), 1.62 (s, 3H; CH_3), 2.52 (s, 3H; CH_3), 4.86 (s, 5H; H-37), 6.03 (m, 2H), 6.26 (m, 1H), 6.37 (m, 3H), 6.48 (m, 2H), 6.75 (m, 1H), 7.16 (br. s, 6H; Ph), 7.70–8.08 (br. s, 4H; Ph); ^{13}C NMR (62.89 MHz, $CDCl_3$, RT): $\delta = 18.8$ (q; CH_3), 19.2 (q; CH_3), 22.0 (t, $^1J_{C,H} = 166.0$ Hz; C-16), 45.5 (s; C-14 or C-15), 56.4 (s; C-14 or C-15), 83.0 (d; C-37), 88.6 (s), 114.5 (d), 120.5 (d), 121.1 (d), 126.4 (s), 126.7 (d), 126.74 (d), 126.9 (d), 127.1 (d), 127.3 (s), 127.9 (d), 129.9 (d), 135.3 (s), 138.0 (s), 146.5 (s), 148.9 (s), 173.2 (s; C-8); IR (KBr): $\tilde{\nu} = 1568\ cm^{-1}$ (C=N).

10: M.p. 227–228 °C; ^1H NMR (250.13 MHz, $CDCl_3$, −60 °C): $\delta = 2.15$ (s, 6H; CH_3), 6.66 (m, 3H; H-24/25/26), 7.12 (m, 5H), 7.46 (m, 2H), 7.59 (m, 4H), 7.79 (m, 2H), 8.00 (m, 3H); ^{13}C NMR (62.89 MHz, $CDCl_3$, −60 °C): $\delta = 19.1$ (q; CH_3), 119.7 (d), 120.0 (d), 121.8 (s), 123.3 (d), 124.8 (s), 126.5 (d), 126.6 (d), 126.8 (d), 127.0 (d), 127.6 (d), 127.9 (d), 128.1 (d), 128.4 (d), 129.9 (d), 131.2 (s), 131.4 (s), 132.8 (s), 132.9 (s), 144.0 (s), 147.7 (s), 147.8 (s), 153.1 (s), 171.2 (s; C-8); IR (KBr): $\tilde{\nu} = 1629\ cm^{-1}$ (C=N).

it was determined which of the three 1,3-diene systems is complexed to the cyclopentadienylcobalt unit. The fact that eight protons of the 1,6-methano[10]annulene segment of **7** give rise to only four signals suggests the complexation of the iminocyclopentadiene unit. According to ^1H-^1H nuclear Overhauser effect (NOE) experiments, the cyclopentadienylcobalt unit and the protons of the 1,6-methano[10]annulene bridge are on the same side of **7**. Final proof for the bisnorcaradiene structure of **7** was obtained from the ^{13}C NMR spectrum: the bridgehead carbon atoms C-14 and C-15 give rise to singlets at $\delta = 45.5$ and 56.4, respectively, the methylene bridge atom C-11 shows a triplet at $\delta = 22$ (multiplicities were determined in a gated decoupling experiment). The ^{13}C-^1H coupling constant of 166 Hz is within the range characteristic for cyclopropyl carbon atoms (160–170 Hz).

Not only is **7** one of the few known complexes of 1,6-methano[10]annulene,[5] it is also the first 1,6-methano[10]annulene derivative in which a transition metal complex achieves a regioselective C–C connection between "parallel"[10] triple bonds at the *peri*-2,10-positions. Compounds such as **7** bridge the gap to the fullerenes C_{60} and C_{70}, which upon cyclopropanation produce compounds with 1,6-methano[10]annulene subunits and *peri*-2,10-annulations just as in **7**.

Surprisingly, the reaction of **3** with isocyanide **5** in the presence of an equivalent of bis(1,5-cyclooctadienyl)nickel at 120 °C in toluene gave the expected reaction product **8** in only low yield; the nearly exclusive product was iminocyclopentadiene **10**, which had previously been prepared by two independent routes.[7, 12] The formation of **8** could be proved by mass spectroscopy from the presence of the molecular ion and the virtual identity of the mass spectra of **8** and **10**. Insufficient material was at hand to allow a rigorous characterization.



The transformation of **3** into **10** is very unusual, as 1,6-methano[10]annulene derivatives, with the exception of 11,11-dihalo derivatives,[13] undergo upon heating a carbene decomposition through the energetically favored "Berson–Willcott rearrangement", in which one of the bridge or cyclopropyl C–C bonds is broken. In this case the gain of the naphthalene resonance energy is apparently sufficient to allow for the loss of the methylene group. Energy-optimized molecular models of **8** and **10** might offer an explanation (Fig. 1). Not surprisingly, the naphthalene framework in **10**

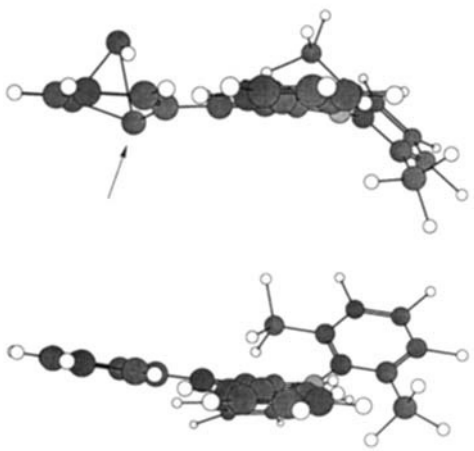


Fig. 1. Energy-minimized molecular models of **8** (above) and **10** (below) obtained using the program Chem3D, version 2.0, Cambridge Scientific Computing.

is planar, but in **8** the bridgehead carbon atom of the 1,6-methano[10]annulene leaning towards the annulated ring is clearly displaced from the plane of the molecule (arrow). This seems to suggest a distortion of the molecule which might facilitate the cleavage of the methylene bridge. The role of the nickel complex in the reaction is not yet known.

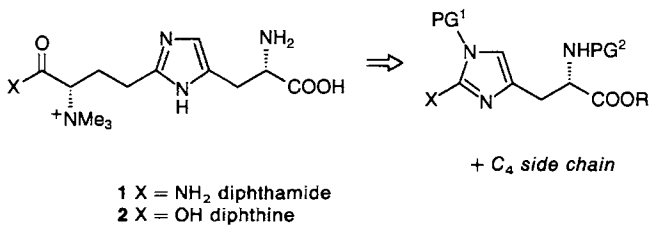
Selective Pd^0-Mediated C–C Bond Constructions on the Imidazole Ring of L-Histidine: A Practical Approach to the Synthesis of Diphthamide and Related Histidine Analogues**

By *David A. Evans** and *Thorsten Bach*

Dedicated to Professor Reinhard W. Hoffmann on the occasion of his 60th birthday

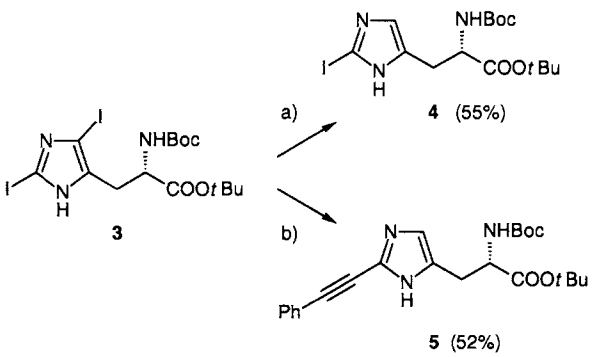
The unique amino acid diphthamide **1**, the target of diphtheria toxin-catalyzed ADP-ribosylation in elongation factor 2 (EF-2) has raised much scientific interest, in particular concerning its role in protein biosynthesis.[1] In our efforts to devise a practical synthesis of diphthamide,[2] we were attracted to the prospect of utilizing L-histidine as one of the principal building blocks for this amino acid (Scheme 1). In particular, the idea of introducing the methionine-derived, C_4 side chain late, and possibly fully functionalized, in the synthesis led us to consider mild Pd-catalyzed coupling reactions[3] for the decisive C–C bond formation. The weakness in this synthetic strategy was associated with the fact that there are few suitable literature procedures available for the regioselective functionalization of histidine at the C2 position of the imidazole nucleus. Of the various reactions reported,[4] only the reactions with diazonium salts proceed with high selectivity at C2.[5] On the other hand, histidine can be converted selectively into 4-iodo[6] or 2,4-diiodo derivatives[7] depending upon the iodine/substrate ratio. Accordingly, with the potential availability of diiodohistidine derivatives such as **3**,[8] we entertained the prospect of carrying out C2 selective Pd^0-catalyzed reactions with substituted alkynes and other organometallic reagents. In spite of the discouraging literature precedent,[9] we thought that selective cross coupling might be achieved at the more sterically accessible, electronically deficient C2 position of the imidazole nucleus.



1 X = NH_2 diphthamide
2 X = OH diphthine

Scheme 1. PG^1, PG^2 = protecting group.

Surprisingly, phenylacetylene, in the presence of Pd^0, functioned as a reducing agent to afford, by a selective H–I exchange (ca. 3/1) at the C4 atom, the monoiodide **4**, which was readily obtained in isomerically pure form by flash chromatography (Scheme 2). In addition to **4**, 1,4-diphenylbutadiyne was isolated as the major by-product of the reaction. If the same reaction is carried out in the presence of phosphane ligands, the Heck coupling[10] product **5** is obtained in 52% yield in high enantiomeric purity [>95% *ee* as determined by NMR analysis of the derivatives with (+)- and (−)-α-methoxy-α-(trifluoromethyl)phenylacetyl chloride]. This pivotal reaction thus solves the dual problem of the dehalogenation at the C4 atom and the bond construction at the C2 atom in a single operation. Although a concise mechanism cannot be established at the present time, it seems likely that the proximity of a comparably acidic NH-proton facilitates an intramolecular proton transfer to a Pd–C intermediate, initially formed by oxidative addition. Indeed, simple 5-alkyl-substituted diiodoimidazoles underwent sluggish, poorly selective dehalogenations under identical conditions.



Scheme 2. Deiodination and coupling reactions of compound **3**. Reagents and conditions: a) 3 equiv PhCCH, 0.05 equiv $[Pd(dba)_2]$ (dba = dibenzylidenacetone), 0.07 equiv CuI in NEt_3; 65 °C; 5 h. b) 3 equiv PhCCH, 0.1 equiv $[PdCl_2(PPh_3)_2]$, 0.05 equiv CuI in NEt_3; 65 °C; 12 h.

The extension of the C2 coupling process with representative alkynes was then investigated. *N*-Protection of **4** (Boc_2O, NEt_3 in CH_2Cl_2; 97%) yielded the monoiodohistidine derivative **6** which proved to be a versatile substrate for Pd-catalyzed coupling reactions (Table 1).

With **6** in hand we turned our attention towards reactions that might lead to the incorporation of functionalized car-

Table 1. Pd-catalyzed coupling of alkynes with **6**.

Alkyne	Catalyst	Equiv	Yield [%]	Product
Bu—≡—H	$[PdCl_2(PPh_3)_2]$/CuI	0.05/0.1	91	**7a**
Ph—≡—H	$[PdCl_2(PPh_3)_2]$/CuI	0.05/0.1	98	**7b**
*t*Bu—≡—H	$[PdCl_2(PPh_3)_2]$/CuI	0.05/0.1	96	**7c**
Me_3Si—≡—H	$[PdCl_2(PPh_3)_2]$/CuI	0.05/0.1	83	**7d**
HO—≡—H	$[PdCl_2(PPh_3)_2]$/CuI	0.05/0.1	94	**7e**
Ph—≡—$SnBu_3$	$[PdCl_2(PPh_3)_2]$	0.1	97 [a]	**7b**

[a] Conditions: THF, reflux, 4 h.

bon chains at C2. In this regard, the reaction of alkylzinc compounds with iodoarenes has been shown to tolerate a high degree of functionalization.[11] We therefore sought to employ a homoserine-based 4-iodobutanoic acid ester as a C_4 precursor. These esters were quantitatively metalated by using an activated Zn/Cu couple.[12] Addition of the resulting alkylzinc iodide in *N,N*-dimethylacetamide (DMA) to a solution of **6** in DMA under the influence of Pd catalysis afforded the desired products in excellent yields (Table 2).

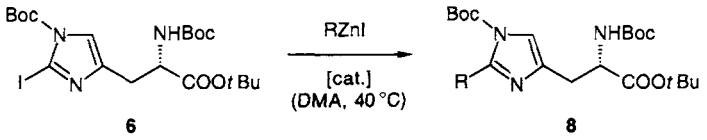

Table 2. Pd-catalyzed coupling of functionalized alkylzinc iodides with **6**.

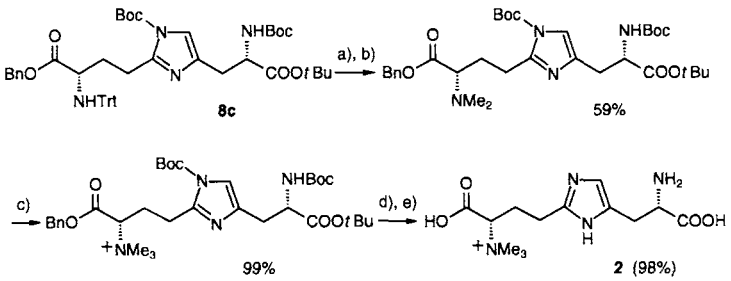
RZnI	Equiv	Catalyst	Equiv	Yield [%]	Product
EtO(C=O)—ZnI	2	$[PdCl_2(PPh_3)_2]$	0.1	84	**8a**
BnO(C=O)—ZnI, NHBoc	4	$[PdCl_2(PPh_3)_2]$	0.1	65	**8b**
BnO(C=O)—ZnI, NHTrt	3	$[PdCl_2(PPh_3)_2]$	0.1	79	**8c**

The required amino acid esters were prepared stepwise from L-homoserine by standard methods.[13] The coupling reaction proceeded smoothly without detectable epimerization, which was demonstrated by comparison of **8c** with its diastereomer, obtained from *rac*-homoserine. The practicability of this route was finally illustrated in the completion of a total synthesis of diphthine **2**, the most important degradation product of diphthamide[14] (Scheme 3). The trityl group (Trt) in **8c** was selectively cleaved by titration with 0.1 N HCl in 90% aqueous trifluoroethanol (TFE) without loss of the Boc-protecting groups.[15] Subsequent reductive elimination, quaternization, and deprotection led to (*S,S*)-diphthine **2**. Other analogues and diphthamide itself should be equally well accessible by combining this coupling sequence with previously described methods.[2]



Scheme 3. Completion of the total synthesis of (*S,S*)-diphthine **2**. Reagents and conditions: a) 0.1 N HCl in TFE (aq, 90%), pH > 4; room temperature (RT). b) CH_2O, NaOAc in $HOAc/H_2O$/MeOH; $NaCNBH_3$; RT. c) 25 equiv MeI in MeOH; RT; 2 d. d) H_2 (500 psi), Pd/C (100% w/w) in $HOAc/H_2O$/MeOH (1/1/3); RT; 14 h. e) 2 N HCl (aq); RT; 14 h.

In conclusion, the preceding study establishes the first reliable methodology for the selective carbofunctionalization of the imidazole moiety at the C2 atom in L-histidine. An extension of the Pd-catalyzed transformations to related, simpler imidazole derivatives appears possible.

$(1,7\text{-}C_2B_{10}H_{10}\text{-}1',3'\text{-}C_6H_4)_3$, a Cyclic Trimer from *meta*-Carboranediyl and *meta*-Phenylene Units: A New Category of Macrocycle**

By *William Clegg, Wendy R. Gill, J. A. Hugh MacBride,* and *Kenneth Wade**

Icosahedral carboranes $R'R''C_2B_{10}H_{10}$ with suitably functionalized aryl groups R on one or both of their carbon atoms are of considerable potential value in various respects; in boron neutron capture therapy (BNCT),[1] in polymers for high-temperature applications,[2] as precursors for boron carbide-type ceramics,[3] and in connection with their nonlinear optical (NLO) properties.[4] Here, we describe a new type of arylcarborane, the cyclic trimer **1**, that not only extends dramatically the range of systems available for applications of the above types, but also provides the first example of a new category of cyclophane[5] capable of conversion into multifunctional ligands related to calix-arenes,[6] macrocycles, and spherands.[7]

Compound **1** was first isolated in 5% yield from the reaction between $1,7\text{-}Cu_2C_2B_{10}H_{10}$, the dicopper(I) derivative of *meta*-carborane, and *meta*-diiodobenzene in 1,2-dimethoxyethane (DME) in the presence of pyridine [Eq. (a)] (a reaction type we have developed for arylation of *ortho*- and *meta*-carboranes[8]).

$$3\ 1,7\text{-}Cu_2C_2B_{10}H_{10} + 3\ 1,3\text{-}C_6H_4I_2 \longrightarrow 6\,CuI + \underset{\mathbf{1}}{(1,7\text{-}C_2B_{10}H_{10}\text{-}1',3'\text{-}C_6H_4)_3} \quad (a)$$

Compound **1** crystallized as well-formed prisms from benzene. Its cyclic trimeric molecular structure (Fig. 1), which has near threefold symmetry, and in which the skeletal B–B, B–C, and C–C bond lengths and angles are normal for icosahedral carboranes and benzene rings, was established by an X-ray crystallographic study.[9] Although the ^1H, ^{13}C, and ^{11}B NMR spectra of **1** in solution (see below) are consistent with the D_{3h} symmetry expected if all three benzene rings were coplanar (and the carborane icosahedra were bisected by that plane), in the crystal the molecules adopt a dished conformation in which the icosahedra are tilted back by an average of 17° from the plane defined by their carbon atoms. The benzene rings tilt forward by an average of 17° from the same plane. These distortions bring the hydrogen atoms connected to boron atoms of type B3 (the most inward-pointing boron atoms) much closer together (mean interatomic H–H distance 3.16 Å) than those attached to atoms B2 (the other set of inward-pointing boron atoms: mean interatomic H–H distance 4.47 Å). The hydrogen atoms on the inward pointing ring carbon atoms C2′ define a nearly equilateral triangle of mean edge length 3.70 Å. The center of the molecule is thus surrounded by a truncated trigonal pyramid of B-attached hydrogen atoms, the basal triangle of which has edge length 4.47 Å, while the upper triangle has an edge length of 3.16 Å. The C-attached hydrogen atoms occupy sites close to the plane of the upper triangle of B-attached hydrogen atoms. The hydrogen atom positions thus differ markedly from the tricapped trigonal prismatic array that would obtain in the D_{3h} structure that is indicated by solution NMR studies.

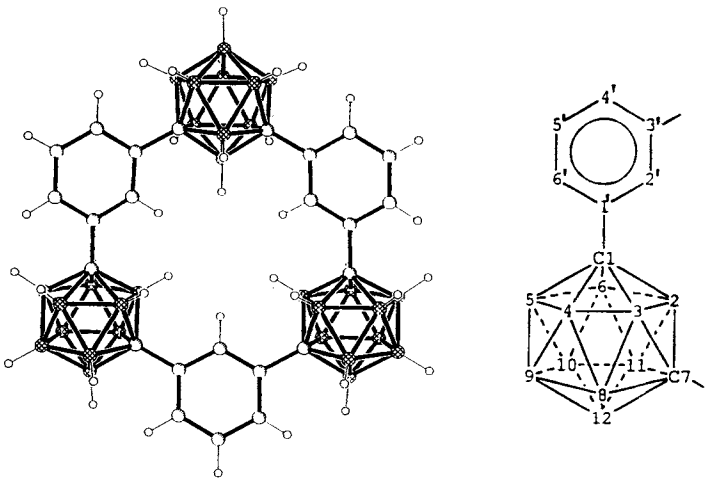

Fig. 1. Left: Molecular structure of crystalline **1**. Selected mean bond lengths [Å]: C1-C1′ and C7-C3′ 1.510, C-C (phenylene) 1.388, C1/7-B2/3 1.709, C-B (carborane) 1.730, B-B 1.774, B-H 1.10, C-H 1.00. Right: Numbering scheme for **1**.

The ^1H NMR spectrum of **1** in $CDCl_3$ solution shows the resonance signal attributable to the inward-pointing C-attached protons (H2′) at remarkably low field ($\delta = 8.14$) compared with normal values ($\delta = 7.21$ for H5′, $\delta = 7.34$ for H4′,6′) for the external protons on these benzene rings. The downfield shift of the internal protons is evidently associated with the macrocyclic structure, since the corresponding protons of the model fragment **2** (prepared from $1,7\text{-}Cu_2C_2B_{10}H_{10}$ and $1,3\text{-}C_6H_4I_2$ in 2:1 molar proportion) resonate at $\delta = 7.48$. In the ^{13}C NMR spectra, three of the four types of phenylene carbon atoms in **1** and **2** resonate at similar fields, but C2′ resonates at higher field for **1** ($\delta = 125.0$) than **2** ($\delta = 127.7$). Preliminary $^1H\{^{11}B\}$NMR spectroscopic studies on **1** and **2** show an unusually low field signal for **1** compared with **2** that appears attributable to the three pairs of internal protons (H2 and H3), since it is coupled to the highest field ^{11}B resonance signal, usually (B2 and B3).[10] Comparison of the ^{11}B NMR spectra of **1** with those of **2** and other diaryl-*meta*-carboranes[10] shows an upfield shift of the lowest field resonance signal, probably that of the boron atoms (B5 and B12) antipodal to the carbon atoms. The UV spectra of **1** and **2** are similar, revealing no cyclic conjugative effect.

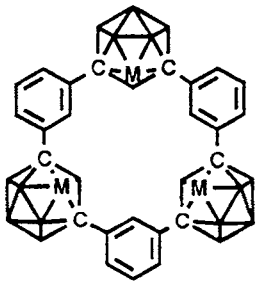
on which to build di- and trinuclear arrays of metal atoms in the icosahedral sites originally occupied by B2-H2 or B3-H3 units in **1**, for example, structure **3**. Suitably derivatized, **1** could be incorporated in polymers or used for BNCT. Heterocyclic variations on **1**, such as result from reactions between 1,7-$Cu_2C_2B_{10}H_{10}$ and 2,6-dibromopyridine,[12] add a further dimension to the ligand potential of cluster compounds of this type.



3

Experimental Procedure

1: *meta*-carborane (1,7-$C_2B_{10}H_{12}$: 2.89 g, 20 mmol) in DME (80 cm^3) was treated successively with *n*BuLi (42 mmol in 26 cm^3 hexane), Cu^ICl (4.65 g, 47 mmol), pyridine (12 cm^3), and 1,3-diiodobenzene (6.64 g, 20 mmol), and heated under reflux for 86 h. The product was precipitated by pouring the solution into dilute HCl (4 M, 300 cm^3), washed, dried, dissolved in toluene, and chromatographed on silica. The first fraction eluted by cyclohexane and recrystallized from benzene was identified as **1**, m.p. 375–378 °C. Correct C,H analysis. MS: *m/z* 625–661 (M^+, correct isotope pattern for $C_{24}H_{42}B_{30}$). IR (KBr): $\tilde{\nu}_{max}$ [cm^{-1}] = 3080w, 3040w (ArCH), 2642vs, 2596vs (BH), 1609s, 1588s, 1491s (arene skeleton), 1432s, 1327m, 1185m, 1108s, 1098s, 1018m, 1004m, 912m, 884m, 844s, 812s, 778m, 738s (carborane skeleton), 688s (*m*-C_6H_4), 610m, 442m. ^{13}C NMR ($CDCl_3$, 125.8 MHz): δ = 76.3 (carborane C); 125.0 (C2'), 128.9 (C4',6'), 129.2 (C5'), 135.2 (C3'); ^1H NMR ($CDCl_3$, 250 MHz): δ = 1.8–4.2 (m, 10H, BH), 7.21 (t, J = 7.6 Hz, 1H, H5'); 7.34 (dd, J = 7.6, 1.8 Hz, 2H, H4',6'), 8.14 (t, J = 1.8 Hz, 1H, H3'); ^1H {^{11}B} NMR ($CDCl_3$, 250 MHz): δ = 2.37 (s, 2H), 2.54 (s, 4H, H4,6,8,11) 2.87 (s, 2H), 3.59 (s, 2H), 7.21 (m, 1H, H5'); 7.34 (m, 2H, H4',6'), 8.14 (s, 1H, H3'); ^{11}B NMR ($CDCl_3$, 160.5 MHz): δ = 7.0 (br s), −9.6, −10.3 (br d), −13.7 (br s). UV/VIS (THF): λ_{max} [nm] (lg ε) = 261 (3.93), 267 (4.04); 273.5 (3.99).

2: **2** was prepared similarly, but using a 2:1 molar ratio of *meta*-carborane: diiodobenzene. The crude product was extracted with boiling butanol and recrystallized from ethanol. M.p. 240–244 °C. Correct C,H, analysis. MS: *m/z* 344–366 (M^+, correct isotope pattern for $C_{10}H_{26}B_{20}$). IR (KBr): $\tilde{\nu}_{max}$ [cm^{-1}] = 3065 (carborane CH); 2600 (BH), 1608, 1592s, 1488 (arene skeleton), 1090, 1008, 996, 909, 832, 812, 684 (*m*-C_6H_4), 728 (carborane skeleton). ^{13}C NMR ($CDCl_3$, 125.8 MHz): δ = 55.1 (C7); 77.5 (C1); 127.7 (C2'); 128.0 (C4',6'); 128.4 (C5'); 135.2 (C1',3'); ^1H NMR ($CDCl_3$, 250 MHz): δ = 3.07 (carborane CH); 7.14 (t, J = 7.9 Hz, 1H, H5'); 7.35 (d, J = 7.9 Hz, 2H, H4',6'); 7.48 (s, 1H, H2') ^1H {^{11}B} NMR ($CDCl_3$): δ = 2.18, 2.25, 2.44, 2.59 (BH) and carborane CH and aryl CH signals as before. ^{11}B NMR ($CDCl_3$, 160.5 MHz, relative intensities in parentheses): δ = −4.15 (1), −8.63 (1), −10.49 (4), −13.41 (2), −15.27 (2). UV/VIS (THF): λ_{max} [nm] (lg ε) = 274 (3.27).

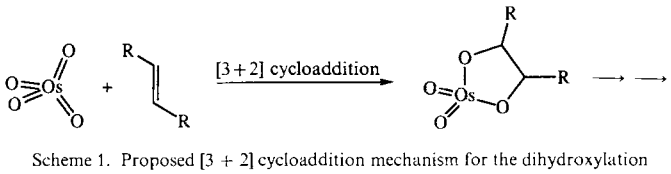
Temperature Effects in Asymmetric Dihydroxylation: Evidence for a Stepwise Mechanism**

By *Thomas Göbel* and *K. Barry Sharpless**

More than fifty years have passed since Rudolf Criegee's pioneering work on the oxidation of olefins with osmium tetroxide. It is extraordinary that he already envisioned all the essential features of the reaction in these early papers.[1] The concerted mechanism implied by Criegee (Scheme 1) is still the accepted "textbook mechanism" for the reaction of OsO_4 or MnO_4^- with olefins. The remarkable ligand-accel-



Scheme 1. Proposed [3 + 2] cycloaddition mechanism for the dihydroxylation of alkenes [1]. The heterocycle dimerizes or adds an additional ligand.

eration phenomenon in the osmylation, also discovered by Criegee, enabled us to develop an asymmetric version of this process.[2] These asymmetric *cis* dihydroxylations of olefins have been the subject of intensive research in recent years.[3] Nevertheless, the reaction mechanism is still not understood, a fact which severely hampers the development of a useful model for predicting the transfer of chirality during these reactions. Two mechanisms have been postulated, a concerted [3 + 2],[4] and a stepwise [2 + 2] process.[5] In this latter mechanism, the olefin first coordinates to the osmium center and this intermediate undergoes a fast and reversible rearrangement to the oxaosmetane intermediates **1**. Bond migration then leads to the five-membered cyclic complex **3** (Scheme 2). The coordination of an amine ligand leads to the osmium(VIII) complex **2** which is more likely than **1** to undergo rearrangement to the glycolate **3**, thus explaining the ligand-acceleration effect.[6]

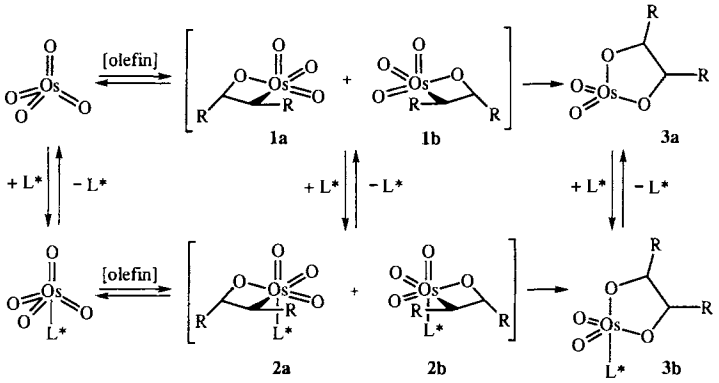
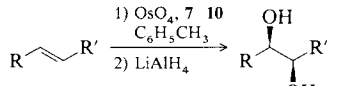


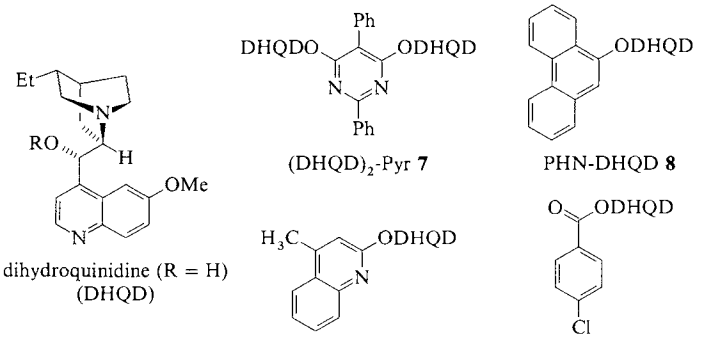
Scheme 2. Proposed [2 + 2] mechanism for the dihydroxylation of alkenes [5]. L* symbolizes the chiral alkaloid ligands.

In this communication we report the influence of reaction temperature on the enantioselectivity of the asymmetric dihydroxylation. The results show that the reaction proceeds via at least two different pairs of diastereomeric transition states, and are therefore inconsistent with a concerted mechanism.

The dihydroxylation of olefins **4**–**6** were performed by using stoichiometric amounts of OsO_4 in presence of an excess[7] of hydroquinidine derivatives **7**–**10** as chiral ligands in toluene,[8] and the temperature was varied over a range of about 100 °C. The enantiomeric excesses of the products were determined by GLC or HPLC analysis of either the diols or the corresponding α-methoxy-α-trifluoromethylphenylacetic acid esters (MTPA esters).



4: R = R′ = C_4H_9
5: R = C_6H_5; R′ = H
6: R = C_8H_{17}; R′ = H



Scheme 3.

The temperature dependence of the *ee* values was analyzed according to the modified Eyring formalism:[9] $\ln P = -(\Delta\Delta H^{\ddagger}/RT) + (\Delta\Delta S^{\ddagger}/R)$ where $P = k(\text{major diol})/k'(\text{minor diol})$ and k and k' are the overall rate constants. The results are summarized in Figures 1 and 2.

Each olefin/catalyst combination[10] shows two linear regions in the Eyring plot with a characteristic inversion point. The temperature at the inversion point is the so-called "inversion temperature" of each system. Inversion points have already been observed in a wide range of stereoselective catalytic systems, including the transition metal-catalyzed asymmetric hydrogenations,[11] and can be explained by a

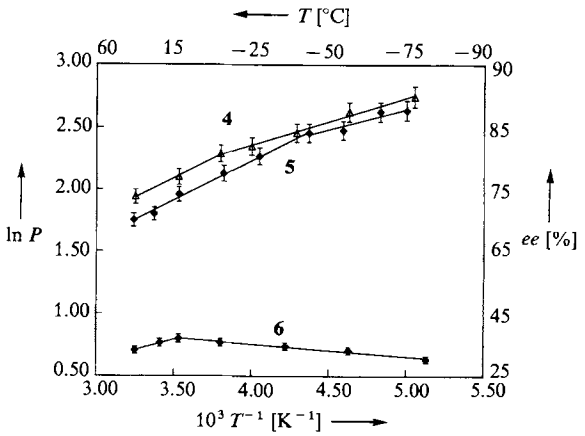


Fig. 1. Eyring plots for the enantiomeric excesses of the dihydroxylation of olefins **4**–**6** with **9** as ligand. The error bars represent confidence levels of ±95% and were determined by standard statistical analysis.

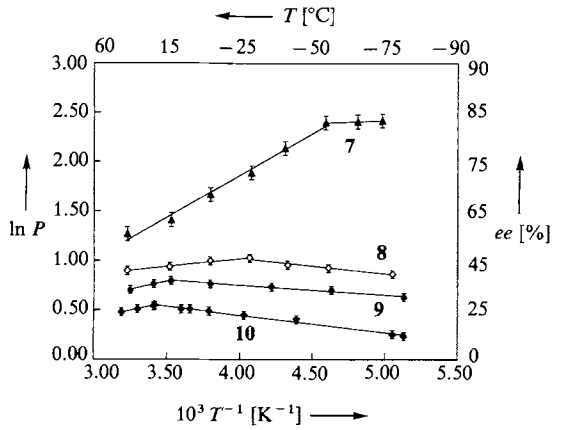

Fig. 2. Eyring plots for the enantiomeric excesses of the dihydroxylation of 1-decene (**6**) with the chiral alkaloid ligands **7**–**10**. The error bars represent confidence levels of ±95% and were determined by standard statistical analysis.

reaction pathway with at least two enantioselective steps that are weighted differentially according to temperature. Our results are therefore consistent with a stepwise process like the [2 + 2] mechanism[12] (Scheme 2) with one selectivity level being the reversible formation of the two diastereomeric oxaosmetanes **2** and the second level the rearrangement to the glycolate **3**. Depending on temperature, either the one or the other reaction is rate and therefore selectivity determining. The two lines observed in the Eyring plot reflect the different $\Delta\Delta H^{\ddagger}$ and $\Delta\Delta S^{\ddagger}$ values for the two steps. On the other hand, a concerted mechanism like the [3 + 2] cycloaddition should show no inversion point because the stereoselectivity would only depend on the difference of the free energy of activation for the two diastereomeric transition states.[13]

Experimental Procedure

In a typical experiment **9** [14] (23 mg, 0.1 mmol) was dissolved in toluene (1.75 mL) and OsO_4 (0.25 mL of a 0.2 M solution in toluene, 0.05 mmol) was added. The reaction mixture was cooled to the desired temperature (T: ±0.5 °C) and 1-decene (**6**) (28.0 mg, 0.2 mmol) was added. After the color had changed from orange to dark green the reaction was quenched with $LiAlH_4$ (1 mL of a 1.0 M solution in THF). After the mixture had been stirred at room temperature for 30 min, ethyl acetate (10 mL) was added, followed, after an additional 10 min, by 1 N HCl (5 mL). The mixture was first passed through Celite, and then the organic layer was separated and dried over $MgSO_4$. Chro-

matography over a short silica gel column yielded 1,2-decanediol which was then converted to the MTPA diester. The *ee* value was determined by HPLC (Pirkle 1 A, 0.5% *i*PrOH in hexane, 1.5 mL min^{-1}).

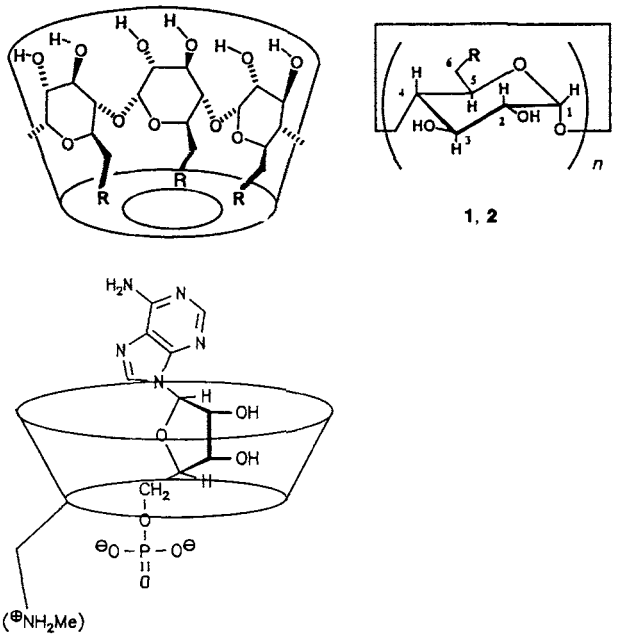
Aminocyclodextrins as Selective Hosts with Several Binding Sites for Nucleotides**

By *Alexey V. Eliseev* and *Hans-Jörg Schneider**

The selective recognition of nucleotides by synthetic host compounds[1–5] is of great importance for the understanding of biological processes as well as for future uses of supramolecular chemistry in analytical chemistry and biological or medicinal fields. The known host–guest complexes are based primarily on ionic bonding between the phosphate units of the nucleotides and positive charges on the host compounds. The host compounds may be modified by the introduction of additional functional groups which can result in some degree of selectivity with regard to the nucleobases, based on the formation of hydrogen bonds with nucleobases in lipophilic solvents.[1–6] Here we report on systems that exhibit additional selectivity by discrimination between 3′- and 5′-phosphate groups, as well as for the first time between the presence or absence of hydroxyl groups in the 2′ position of the riboses (2′-oxy and 2′-deoxy sugar phosphates).

In contrast to the unsubstituted parent compounds,[7] cyclodextrins (CD) with amino groups at the 6 position can form ionic bonds with nucleotides in which the strength of bonding can be regulated by the number of ammonio substituents (Scheme 1). The energies of complexation for such



Scheme 1. Top: Schematic representation of the aminodeoxy-β-cyclodextrins ($n = 7$) **1** (= CD-N7 with seven residues R = $^+NH_2Me$) and **2** (= CD-N2 with two R residues at position 6 of the glucose units A and D). Bottom: Postulated structure of the complex.

aminocyclodextrins[8] in water, found for example, for the binding of catecholates, in principle, agree with the general increment of about 5 kJ mol^{-1} per salt bridge found by analysis of over 60 ion pairs.[9] The binding constants K[10] (mostly determined potentiometrically) that we have measured with ATP^{4-} can reach more than 10^6 M^{-1}; they decrease as expected with decreasing number of charges on the nucleotide or on the cyclodextrin (Scheme 2). While the heptakis(6-methylamino-6-deoxy)-β-cyclodextrin CD-N7 **1** discriminates more strongly between ATP and AMP than the only doubly charged β-cyclodextrin CD-N2 **2** (with two methylamino groups at the 6 position of the glucose units A and D), the opposite is true for the discrimination with respect to the isomeric 3′- and 5′-phosphates.

Furthermore, the diamino derivative CD-N2 **2** can also recognize the presence or absence of 2′-hydroxyl groups, and this not only in nucleotides, but also in sugar phosphates for which, despite their large hydrophilicity, binding constants of still over 10^4 M^{-1} were observed (Scheme 3). The affinities increase as expected with CD-N7 **1**, however, here again at the expense of selectivity.

Finally, supramolecular complex formation proved useful in the discrimination of nucleobases (Scheme 4); as is the case with most of the host compounds investigated to date[1–7] adenine derivatives are preferred. In total, there-

fore, the systems investigated exhibit four selection possibilities which, moreover, can work in parallel and which can function in water, the biologically dominant matrix.

The inclusion geometries postulated in Schemes 1 and 4 are in agreement with molecular mechanics simulations as well as, in some cases, with preliminary NOE measurements and NMR shifts due to complex formation.[11] For instance, in the case of complexes with **1** saturation of the CD protons (H-3) located inside the CD cavity leads, for example with AMP, to Overhauser effects on the ribose protons of up to 6%. In contrast, all other intermolecular effects are less than 0.3%. In addition, only the protons (H-3 and H-5) on the inside of the CD show upfield shifts of up to $\Delta\delta = -0.16$ (calculated for 100% complexation), while all other protons have values of less than $\Delta\delta = 0.01$. To the best of our knowledge these results demonstrate for the first time the inclusion of sugars *inside* the lipophilic CD cavity.[12]

Porphyrin-Like [22]Annulenoquinones**

By *Gottfried Märkl** and *Ulrich Striebl*

Dedicated to Professor Heinrich Nöth on the occasion of his 65th birthday

The porphyrin homologues [22]porphyrin(2.2.2.2),[1] [26]porphyrin(3.3.3.3),[2] and [34]porphyrin(5.5.5.5)[3] are as fascinating as macrocyclic "super"-heteroarenes as the dicationic porphyrinoids,[4] derived from furan, thiophene, and selenophene. The simplest porphyrin analogue, porphycene **1** ([18]porphyrin(2.0.2.0), X = −NH−, =N−) was first described in 1986 by Vogel et al.[5] The next highest porphyrin analogue, the [20]porphyrin(1.2.1.2) **2** (X = −NH−, $=\overset{\oplus}{N}-$) and the corresponding porphyrinoids **2** (X = −O−, $=\overset{\oplus}{O}-$, −S−, $=\overset{\oplus}{S}-$) as well as the corresponding dihydro derivatives **3**, which can be regarded as bridged [22]annulenes, are not yet known. The next highest analogue to **2**, the

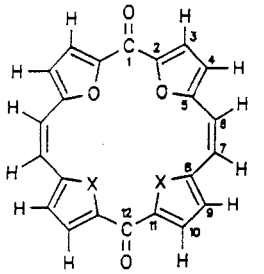
3

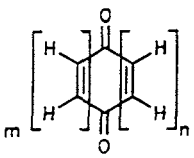
X = NR, O, S

[22]porphyrin(1.3.1.3), was first prepared in 1990 as the octaethyl derivative by Franck et al.[6] We report here on the diketones **4**, which can be regarded as [22]annulenoquinones, derived from the tetraoxa- and dioxadithia-bridged annulenes **3**, X = O, S.

Hitherto, of the annulenoquinones of general structure **5** only a few, very special compounds are known as quinoid systems: for example, the cyclooctadecatetraenetetrayne-1,6-dione **5a** ($m = 6$, $n = 2$, four triple bonds) and the cyclooctadecatetraenetetrayne-1,10-dione **5b** ($m = n = 4$, four triple bonds) of Sondheimer et al.[7, 8], together with the di-*tert*-butylbisdehydro[14]annulenedione **5c** ($m = n = 3$, two triple bonds) and the di-*tert*-butylbisdehydro[18]annulenedione **5d** ($m = n = 4$, two triple bonds) of Nakagawa et al.[9] Fuhrhop et al.[10] have proposed the description "paraporphoquinone" for an α,γ-dioxoporphomethene, although this nomenclature does not prove the quinoid character of this system.



4a, X = O
4b, X = S



5

The [22]annulenoquinone **4** was obtained by double Wittig cyclization of the dialdehyde **6** with the bis-ylide from **7** in accordance with the Ruggli–Ziegler dilution principle. Preparation of the ketodialdehydes **6a,b**[11b] was achieved according to the method of Cresp et al.[11a] by metalation of the 1,3-dioxolanes from 5-bromofuran-2-carbaldehyde[12] or 5-bromothiophene-2-carbaldehyde[13], respectively, and subsequent reaction with *N*,*N*-diethyl-ethylcarbamate. The bisphosphonium salt **7** was accessible, as described,[11a] from the 5,5′-bis(chloromethyl) derivative of 2,2′-difurylketone.[14] The Wittig reaction of the bis-ylide obtained from **7** was carried out in such a fashion that a freshly prepared solution of lithium methanolate in methanol was added dropwise at 90 °C (reaction time 3 d) to a dilute solution of **6** and **7** in anhydrous dimethylformamide (DMF). In this manner it is probable that only the mono-ylide of **7** is formed initially, which then reacts with the dialdehyde **6**, present in excess, to give the open-chain olefin. The reaction mixture was worked up by hydrolysis, followed by extraction with ether. After removal of the solvent and treatment with a little CH_2Cl_2, the [22]annulene-1,12-dione **4a**[15] precipitated out as a red, fine crystalline powder. To isolate the unsymmetrical [22]annulene-1,12-dione **4b**,[15] which crystallizes as yellow needles, repeated chromatography on silica gel 60 with diethyl ether/petroleum ether (1:1) was necessary.

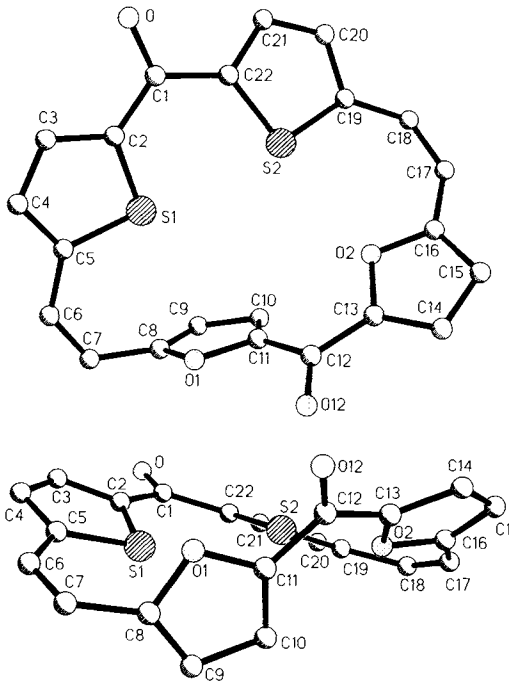

Fig. 1. Structure of **4b** in the crystal. Above: plane view, Below: side view. Selected bond lengths [Å] and angles [°] (standard deviations in parentheses): O-C1 1.227(6), C12-O12 1.217(6), C18-C19 1.464(9), C18-C17 1.318(11), C17-C16 1.411(8), C6-C5 1.456(8), C6-C7 1.312(8), C7-C8 1.467(7), C20-C19 1.383(9), C20-C21 1.357(10), C21-C22 1.387(8); C16-C17-C18 133.2(6), C17-C18-C19 134.5(5), C2-C1-C22 123.6(4), C11-C12-C13 118.0(4), C19-S2-C22 93.4(3), C13-O2-C16 107.0(3), O2-C16-C17 119.9(5); interplanar angle between two thiophene rings is 24.1°, between two furan rings is 134.7°, between furan ring (O1) and thiophene ring (S1) is 73.8°; distance S1 from plane of furan ring (O1) 3.05 Å; torsion angles: C16-C12-C18-C19 4.6°; C5-C6-C7-C8 5.8°; C10-C11-C12-C13 31.5°.

correspond to those in *p*-benzoquinone (C=O: 1.218 Å; C(=O)–CH: 1.467 Å; C=C: 1.312 Å).

The annulenodiones **4a** and **4b** dissolve in $CHCl_3$ and in concentrated H_2SO_4 to give yellow and green solutions, respectively. The UV/VIS spectra of the $CHCl_3$ solutions (Fig. 2, Table 1) are comparable with those of 1,4-benzoquinones:[17] $\lambda = 240-300$ ($\pi \rightarrow \pi^*$), 420–460 nm ($n \rightarrow \pi^*$). The spectra of **4b** show a marked bathochromic shift and simultaneously a dramatic increase in the molar extinction coefficients on changing the solvent from $CHCl_3$ to concentrated H_2SO_4. Protonation of **4** is expected to give the dicat-

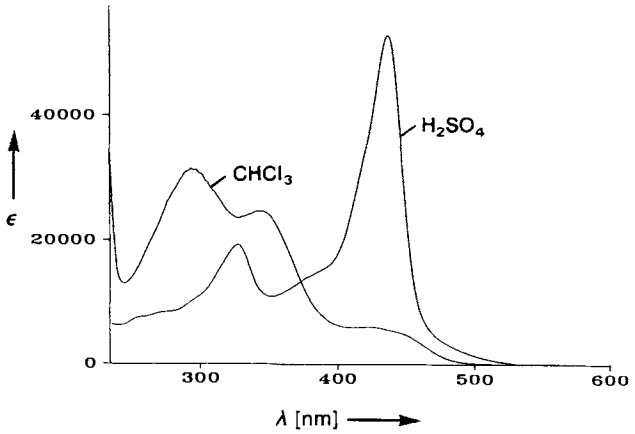

Fig. 2. UV/VIS spectra of **4b** in $CHCl_3$ and in concentrated H_2SO_4.

ions **8**, which can be described both as annulenoid and as a porphyrinoid antiaromatic 20π-electron system.

The ^1H NMR spectra of **4a**, **b** (Table 1) indicate a dynamic structure in solution in which conformational exchange results in a symmetric, planar molecular structure on the NMR timescale. In contrast to the expectation that the ring protons in the diprotonated species **8a**, **b**, as an antiaromatic, paratropic 20π system, experience a high-field shift in the ^1H NMR spectrum compared with those of **4**, quite significant low-field shifts can be observed to some extent (for **4b**

4b (CF_3COOD/CF_3COOH, red solution)						
δ, $^3J(H,H)$	8.04(d), 4.2	7.32(d)	7.15(AB), 12.0	6.65(AB)	6.84(d), 4.2	7.72(d)

in H_2SO_4: $\Delta\delta = 0.98-1.16$). A plausible interpretation of this finding could be that the low-field shifts resulting from the double positive charge carry more weight than that of the possible high-field shift caused by the paratropic system. Accordingly, the low-field shifts observed by Ogawa et al.[18] in the ^{1}H NMR spectrum on the protonation of a [15]annulenone with CF_3COOH could not be correlated unequivocally with the formation of an aromatic, diatropic [14]annulene.

Electrochemical investigations of **4a, b** in CH_3CN and in DMF show two discrete, reversible one-electron transitions, first to give the radical anions (semiquinones) **9** and then to give the dianions **10** (Fig. 3). The reduction potentials E_1 and

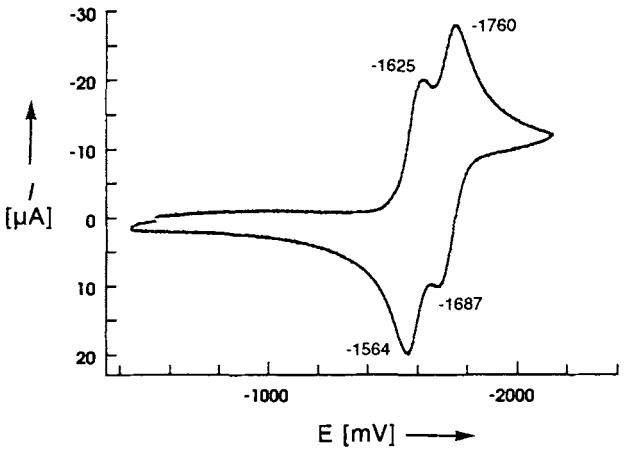

Fig. 3. Cyclic voltammogram for **4b** (acetonitrile, electrolyte tetrabutylammonium hexafluorophosphate; working electrode: Pt; reference electrode: Ag/AgCl; 250 mVs^{-1}, potentials given versus ferrocene as reference, calibrant: ferrocene versus Ag/AgCl: **4a**, 518 mV; **4b** 546 mV).

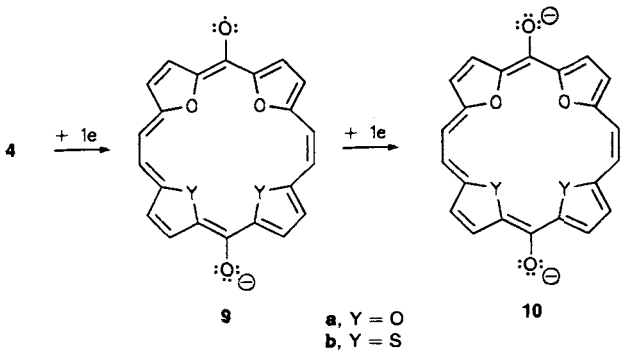
E_2 of **4a, b**, together with those of *p*-benzoquinone, 1,4-naphthoquinone, and of **5a** and **5c**, are given in Table 2. In agreement with the considerations of Breslow et al.[8] the $(E_1 + E_2)$ values reflect the energy change from the dione to the dianion and thereby further to the aromatically stabilized "hydroquinones". The required flattening of **4** in the transi-



tion from the dione to the semiquinone **9** and to the aromatic "hydroquinone" dianions **10** is probably also partly responsible for the relatively high $(E_1 + E_2)$ values of **4a** and **4b**.

Table 2. Electrochemical reduction potentials.

Posttranslational Backbone Modifications in the Ribosomal Biosynthesis of the Glycine-Rich Antibiotic Microcin B17**

By *Anja Bayer, Stefan Freund, Graeme Nicholson,* and *Günther Jung**

Dedicated to Professor Murray Goodman on the occasion of his 65th birthday

The antibiotic microcin B17 (McB17) belongs to a group of polypeptides called microcins,[1] which were discovered by Asensio et al. in 1976.[2] In contrast to the commonly known peptide antibiotics synthesized by multienzyme complexes, microcins are produced by ribosomal synthesis and posttranslational modification of precursor proteins by nonsporulating microorganisms such as Enterobacteriae. McB17 inhibits DNA replication with an impressive bactericidal activity against gram-negative bacteria: only one molecule is sufficient to kill a bacterial cell.[1] The mode of action resembles that of quinolines and a variety of antitumor drugs currently used in chemotherapy. McB17 binds to a DNA-bound gyrase, and induces thereby double-strand cleavage, because the normal gyrase activity (DNA untwisting and rejoining of the cleaved DNA) is suppressed.[3]

In previous attempts,[4] the nature of the posttranslational modifications present in McB17 could not be determined. Here, we elucidate the structure of McB17 by using various analytical techniques, including multidimensional NMR spectroscopy of ^{15}N-labeled McB17.

McB17 is produced by several strains of *Escherichia coli*.[5] The genetic determinants for the McB17 production are located in a cluster on the plasmid. The gene mcbA codes for the inactive 69 amino acid precursor molecule of McB17[6] (Fig. 1). McB17 exhibits rather unusual features: Of the 43 amino acid residues in the DNA-derived sequence of McB17, 26 are glycine residues. The mature polypeptide is very thermostable and resistant to extreme pH conditions; its poor solubility in aqueous buffers and most organic solvents is also remarkable. These properties severely hampered the isolation, purification, and enzymatic cleavage, for example by lysostaphin.

The structure of the highly purified McB17[7] was elucidated by UV-spectroscopy, mass-spectrometry, amino acid analysis, protein sequencing, GC-MS, and in particular multidimensional NMR.

The molecular mass of McB17 was determined by on-line HPLC–electrospray mass spectrometry.[8] Due to its low solubility McB17 had to be dissolved in 50% aqueous formic acid. From the triply and doubly positively charged quasi-molecular ions, a molecular mass of 3092 Da was determined. This experimental mass differs from the one calculated on the basis of the DNA sequence (Fig. 1) by 160 Da. The 48 amu higher mass of the ^{15}N-labeled McB17 proved the complete uptake of ^{15}N from a medium containing $(^{15}NH_4)_2SO_4$ as sole nitrogen source.

McB17 was hydrolyzed in the gas phase at 160 °C in 6 N HCl in a fully automated amino acid analyzer, and after derivatization with phenyl thioisocyanate and separation as phenyl thiocarbamoyl derivatives on a microbore PP-HPLC, all amino acids predicted from the DNA-sequence were found except for the following: Although four Cys and six Ser residues are predicted, none of the Cys and only two Ser residues were detected. The number of Gly residues varied from 13 to 21 out of 26. These results point clearly to a modification of four Ser, four Cys, and some of the Gly residues. The reduction of McB17 with $NaBH_4$ should yield free thiol groups in the case of disulfide bridges, but the reaction of Ellman's reagent was negative.

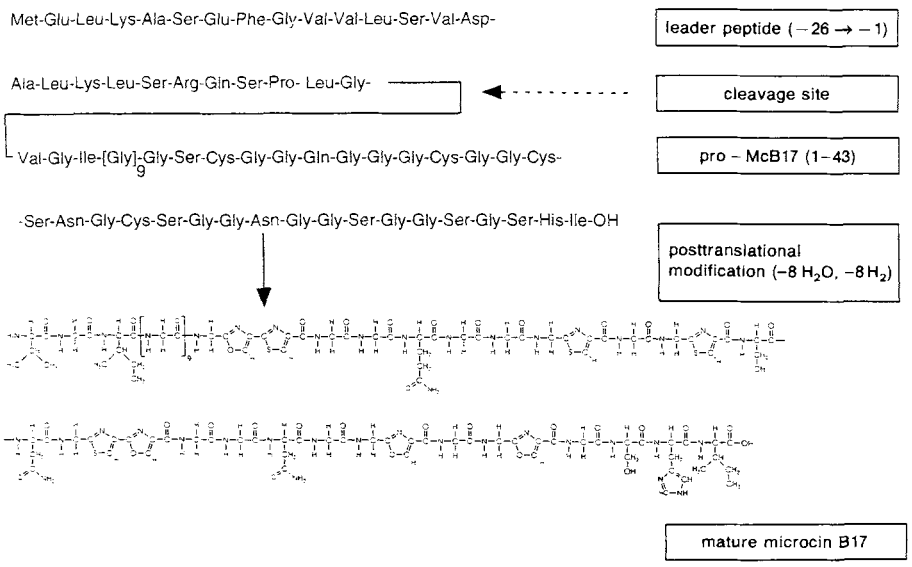

Fig. 1. Primary sequence of the precursor protein of Microcin B17 and its posttranslational modification to the mature McB17 containing 2-aminomethylthiazol-4-carboxylic acid (Atc), 2-aminomethyloxazol-4-carboxylic acid (Aoc), 2-(2-aminomethylthiazolyl)oxazol-4-carboxylic acid (Atoc) and 2-(2-aminomethyloxazolyl)thiazol-4-carboxylic acid (Aotc) as heteroaromatic residues.

Chiral-phase GC-MS investigations[9] with a derivatized total hydrolyzate of McB17 detected all amino acids expected from the results of the amino acid analysis as *N*-trifluoroacetylamino acid *n*-propyl esters by their molecular mass and rentention time. Again cysteine was not detected and only two of the six Ser residues were found. One additional compound was eluted with a very long retention time. It was identified as 2-aminomethylthiazole-4-carboxylic acid (Atc) by its characteristic MS fragmentation pattern. A possible

Hantke for the microcinogenic strain. We acknowledge Dr. M. Spraul, Bruker Karlsruhe for providing the 750 MHz NOESY spectrum of McB17.

mechanism for such a ring formation must involve attack of the thiol group of cysteine on the peptide carbonyl of the preceding N-terminal Gly residue with elimination of water and H_2 (Fig. 1).

The UV spectrum of McB17 indicated two absorption maxima at 210 nm and 270–280 nm, although the DNA-derived amino acid sequence of McB17 contains no aromatic amino acid residues. The UV absorptions were indicative of the presence of further heteroaromatic ring systems in addition to the Atc residues ($\lambda_{max} = 225$ nm).

The sequencing of McB17 with automated Edman degradation stopped after the first 12 N-terminal amino acid residues: VGIGGGGGGGGG (Fig. 1). Thus we concluded that the next amino acid residues Gly^{13} and Ser^{14} are modified in the mature peptide antibiotic.

The standard approach to define the primary sequence of peptides by 2D-NMR experiments is to use scalar-coupled experiments such as double quantum-filtered correlation spectroscopy (DQF-COSY) and total correlation spectroscopy (TOCSY) for the assignment of spin systems of residues and to connect them to adjacent residues by nuclear Overhauser effects (NOEs).[10] However, judging from the DNA-derived precursor sequence (Fig. 1), such an approach has to fail in the case of microcin B17 because up to 26 out of the 43 residues of microcin B17 are glycine units and therefore lack characteristic side-chain signals.

Furthermore, several heteroaromatic components such as Atc were expected from a deuterium exchange experiment where seven or eight singlet signals remained in the aromatic region after exchange of all labile amide signals. The preparation of uniformly ^{15}N-labeled McB17 and the extensive use of inverse-detected heteronuclear experiments with ^{13}C at natural abundance and ^{15}N labeling (100%) allowed us to record a set of two-dimensional NMR spectra that enabled us to unravel the peculiarities of McB17.

The amino acid and GC-MS analysis of the ^{15}N-labeled derivative showed that modifications in the primary structure of the precursor peptide should be found for at least five glycine, all four cysteine, and four out of the six serine residues. Obviously the three Gly-Cys sites in McB17 are modified to thiazole derivatives as shown by GC-MS; however, the analogue 2-aminomethyloxazole-4-carboxylic acid (Aoc) that would result from a similarly modified Gly-Ser could not be found in the acid hydrolyzates. As a working hypothesis, we explained the mass difference of -160 Da between pro-McB17 and McB17 as a modification of eight sites ($-H_2O$, $-H_2$) to thiazole and oxazole rings as shown in Figure 1. In the following, we summarize our 2D NMR data that enabled us to define and to localize these modification sites.

A homonuclear TOCSY experiment yielded the spin systems of all amino acid residues already found in the amino acid analysis; however, one of the two suggested unmodified Ser spin systems could be assigned only in the $^{15}N-^1H$ TOCSY spectrum (Fig. 2). Most of the signals of the Gly residues were located completely overlapped within the region of $\delta = 3.8-4.0$ in the ^1H spectra. This situation did not change in a $^{13}C-^1H$ HSQC (HSQC = heteronuclear single quantum coherence) experiment, which allowed the assignment of all carbon atoms of the standard residues mentioned above. In these two experiments several additional peaks became apparent, which had to be attributed to modified residues. A NOESY spectrum yielded sequential NOEs within the terminal positions 1–4, and 40–43 and for residues adjacent to the two Asn and one Gln residue. The NOE assignments proved that one of the unmodified serine residues was in position 41. The lack of sequential NOEs from Gly^{40} to residue 39 indicated a modification site at the position of Ser^{39}. The absence of long-range contacts in this NOESY experiment (750 MHz) points to an extended structure for McB17 and renders cross linking highly unlikely. The assignment of the N-terminus was hampered by the $(Gly)_9$ segment (Fig. 1), most of the proton and carbon signals of which overlap.

The $^{13}C-^1H$ HSQC experiment revealed eight signals with characteristic heteroaromatic carbon chemical shifts. Thus it was expected, that these CH fragments are part of modification sites that have to involve not only the four Cys but also Ser residues. In a $^{13}C-^1H$ HMQC experiment optimized for long-range couplings, four of these heteroaromatic singlet signals exhibited long-range contacts to signals in the range of $\delta = 140$, four others to signals in the region of $\delta = 160$. These signals can be attributed to C4 (at $\delta = 140$) and C2 (at $\delta = 160$) in oxazole or thiazole ring systems. Signals for the expected aminomethyl backbone fragments were found as three isolated doublets as well as three overlapping signals in the 1D experiment, with characteristic ^{13}C chemical shifts of $\delta = 40$ and $\delta = 44$. Long-range $^{13}C-^1H$ contacts to signals at $\delta = 160$ proved the connection of these aminomethyl fragments to C2 carbon atoms of adjacent heterocyclic backbone fragments. The precursor sequence (Fig. 1) shows that the modification of adjacent Ser and Cys residues should not only lead to isolated monocyclic units but also to linked cyclic systems. If all the possible modification sites are count-

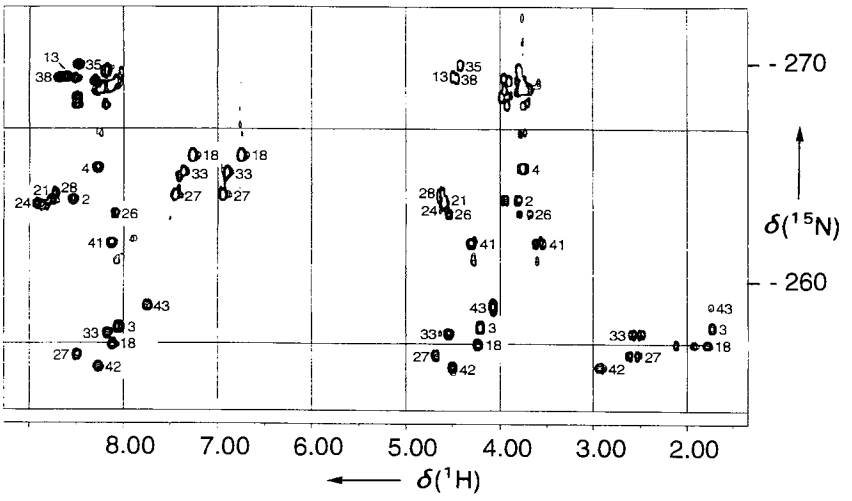

Fig. 2. $^{15}N-^1H$ HSQC–TOCSY spectrum of McB17 in [D_6]DMSO. The numbering of the residues in the mature McB17 is according to the unmodified residues in the prepeptide (Fig. 1). Gly residues are not assigned because of signal overlap. The region shown contains the signals of NH, CH_α and $CH_{\beta,\gamma}$ protons connected to the amide ^{15}N of the same spin system. The NH_2 signals of Asn and Gln appear in the spectrum at $\delta = 7.5-6.5$. The internal [D_5]DMSO (^1H, $\delta = 2.50$) signal as well as external $MeNO_2$ (^{15}N, $\delta = 0$) were used as references.

ed, six aminomethyl fragments from glycine would be expected. This is in agreement with the six partly overlapping NH–CH_2 fragments found. Thus we proved so far, that not only Gly–Cys but also Gly–Ser must be modified to aminomethyl heterocyclic backbone residues.

A direct detection of the ^{15}N signals in these heterocyclic ring systems is hampered by the low sensitivity of this nucleus. If thiazole and oxazole residues are indeed present, an inverse-detected ^{15}N–^{1}H long-range HMBC spectrum (HMBC = heteronuclear multiple bond coherence) should be able to connect the thiazole/oxazole ^{15}N through $^{3}J_{N,H}$ coupling with the C5 proton and with the methylene protons of the aminomethyl fragment in the case of isolated monocyclic residues or the aminomethylated fragment of linked cyclic systems, respectively. Figure 3 shows two regions of the long-range HMBC spectrum with signals at chemical shift positions of $\delta = -80$ and $\delta = -120$. The ^{15}N chemical shifts of these signals are characteristic for oxazoles and thiazoles.[11, 12] In both regions, four signals indicating long-range coupling between C5–H and ^{15}N were found. This finding proves that four Ser and four Cys residues are modified to oxazoles and thiazoles. In both regions, three ^{15}N signals exhibit additional long-range contacts to aminomethyl protons, which confirmed the modification of six Gly residues to aminomethyl fragments. The remaining ^{15}N signals which are not connected to aminomethyl fragments have to be part of linked ring systems, Atoc and Aotc, stemming from modified Gly-Cys-Ser and Gly-Ser-Cys segments. Thus the Aotc modification in position 13–15 can be unambiguously assigned, whereas there are two possibilities for the Atoc site. Sequential NOEs from Asn^{27} to Ser^{26} in a ^{15}N HMQC–NOESY spectrum unambiguously proved the location of Atoc at positions 28 to 30. As a further confirmation, the total synthesis of McB17 is in progress.

In summary, McB17 contains eight backbone modification sites involving three Gly-Cys, three Gly-Ser, one Gly-Ser-Cys, and one Gly-Cys-Ser segment of the precursor protein. Apart from the completely overlapping $(Gly)_9$ segment, all the standard residues as well as the modification sites could be assigned on the basis of the primary sequence of the prepeptide. A complete sequential assignment is hampered by the lack of NOEs as well as long-range contacts between the modification sites and the residues following them. The independent proof for the directly connected heteroaromatic, five-membered ring structures (Fig. 1) could only be a specific ^{13}C-labeling of Gly and/or Ser residues, which is underway.

Until now, the lantibiotics had been the only known class of ribosomally synthesized polypeptides with posttranslational modifications to unusual *side chains* such as α,β-didehydroamino acids and several cyclic sulfides.[13, 14] Here, however, for the first time posttranslational *backbone* modifications of a protein include the formation of heteroaromatic five-membered rings.

Experimental Procedure

Isolation of Microcin B17: The McB17 overproducing strain was cultivated under optimized conditions. The antibiotic remains associated to the cell envelope and is not secreted into the culture medium; we therefore harvested the bacterial cells by centrifugation. For the extraction of McB17 the cell suspension was heated in buffer containing acetic acid and EDTA (pH 4.0) at 100 °C for 10 min. After centrifugation the McB17-containing supernatant was evaporated to dryness, and the residue was dissolved in formic acid (50%). After gel chromatography to accumulate McB17 and to separate it from the low molecular mass components in the cell extract, reversed-phase HPLC on RP18 of the pooled, antibiotically active fractions yielded the antibiotic McB17 with a purity of 95%. ^{15}N-labeled McB17 was obtained from a cell culture containing $(^{15}NH_4)_2SO_4$ as the only nitrogen source in the medium.

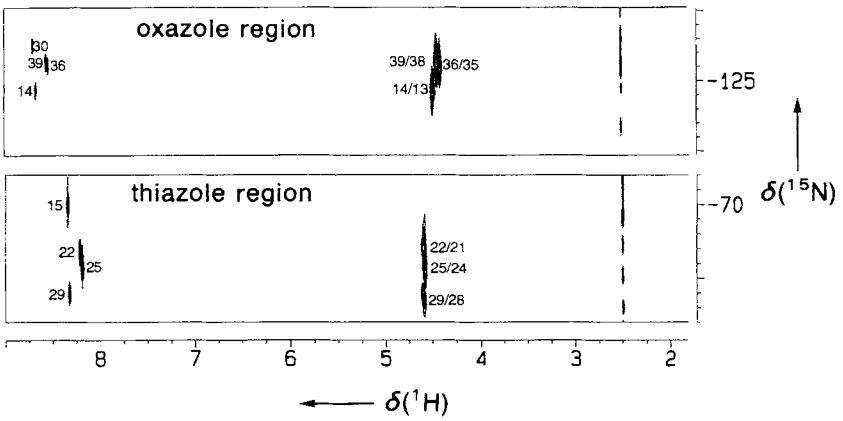

Fig. 3. ^{15}N–^{1}H HMBC spectrum of McB17 in [D_6]DMSO. The regions shown contain long-range contacts between ^{15}N (F1) and the C5 protons (F2) of the heterocyclic modification sites as well as between ^{15}N and the aminomethyl fragments. The internal [D_6]DMSO (^{1}H, $\delta = 2.50$) signal as well as external $MeNO_2$ (^{15}N, $\delta = 0$) were used as references.

NMR: 2D NMR experiments were carried out at 400 and 750 MHz on Bruker AMX spectrometers equipped with "inverse" triple resonance probes and X32 computers. All 2D experiments were recorded in the pure-phase absorption mode by using the time-proportional phase-incrementation method. NOESY experiments with mixing times of 250 ms and clean-TOCSY spectra with a MLEV17 mixing sequence of 50 ms between 2.5 ms trim pulses were recorded at 305 K. ^{13}C–^{1}H HSQC spectra and an HMQC spectrum optimized for long-range couplings ($J = 7$ Hz) were acquired with a sample at natural abundance. ^{15}N–^{1}H HSQC, HSQC-TOCSY, HMQC-NOESY, and HMQC spectra were recorded with a uniformly ^{15}N-labeled sample. Typically, 512–700 increments of 2K data points were collected with a digital resolution of 4–5 Hz in the acquisition (F2) dimension, which was set to 4800 Hz (400 MHz) and 10500 Hz (750 MHz). The ^{13}C–^{1}H HSQC and HMQC spectra were recorded with a sweep width of $\delta = 180$ in the F1 dimension. For the ^{15}N–^{1}H HSQC, HSQC-TOCSY, and HMQC-NOESY spectra, a sweep width of $\delta = 25$ was sufficient in the F1 dimension. The ^{15}N–^{1}H HMBC spectrum was recorded with a F1 sweep width of $\delta = 360$. Data processing consisted of filling up a 2K × 2K data matrix with zeros, apodization with a squared sine bell weighting function, and in the case of the NOESY experiment, linear prediction of up to 700 points in the F1 dimension.

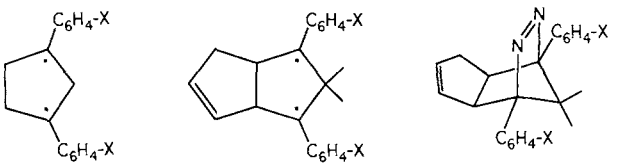
Substituent Effects on the Zero-Field Splitting Parameters of Localized Triplet 1,3-Cyclopentanediyl Biradicals**

By *Waldemar Adam,* Lothar Fröhlich, Werner M. Nau, Hans-Gert Korth,* and *Reiner Sustmann**

EPR spectra of many localized triplet biradicals[1] are readily obtained in solvent matrix at 4–77 K.[2] These spectra afford the zero-field splitting parameters which may provide valuable information on the electronic structure of the biradicals.[3] In particular, the D parameter is an effective probe for the average distance r between the unpaired spins.[4] According to the dipole approximation,[5] D varies as $1/r^3$; consequently, for r of the order of 3.5 Å and with an experimental accuracy of 0.5 mT, a change by 0.01 Å in the r value should be accessible. Unfortunately, little is presently known about substituent effects on the D parameter in localized triplet biradicals[6] except that phenyl and vinyl substitution at the radical termini decrease D in conformity with π delocalization.[7]

To fill this gap, it was desirable to study electronic substituent effects on the D parameter, namely the influence of *para* substitution in bisbenzylic triplet 1,3-cyclopentanediyl biradicals like **1**. Of particular interest was to assess whether spin delocalization by *para* substituents would show up in the D parameter and whether the observed substituent effects would coincide with observations made for the spin delocalization in substituted monobenzylic radicals. As model system, we chose a series of *para*-substituted biradicals **2**, which are readily obtained by irradiation (400–320 nm) of the corresponding azo compounds **3**. Such triplet biradicals should be sufficiently persistent in a matrix at 77 K.[8] The azo precursors **3** were, in turn, obtained by cycloaddition of cyclopentadiene and substituted 4,4-dimethyl-3,5-diphenylisopyrazoles according to a multistep synthesis published for the parent compound.[9]



2a: X = *p*-H
2b: X = *p*-Me
2c: X = *p*-MeO
2d: X = *p*-F
2e: X = *p*-Cl
2f: X = *p*-Br
2g: X = *p*-NO_2

3

As our EPR results reveal (Table 1), symmetric *para*-phenyl substitution decreases the zero-field splitting parameter D in the order F > MeO > H ≈ Me > Br > Cl ≫ NO_2. For ease of argumentation we have defined a ΔD parameter, which gives the relative D with respect to the parent compound **2a** (Table 1); thus, negative ΔD values correspond to a larger D for the substituted derivatives. The structural similarity and the common *para* substitution suggest that steric interactions with the matrix are not responsible for the observed trends in the D parameter and even a small ΔD should be significant for assessing variations of the electronic structure through substituent effects in the biradical.

Table 1. Zero-field splitting parameters [a] of substituted biradicals **2** and radical substituent constants [b].

Compd.	X	$\lvert D/hc\rvert$ [cm^{-1}]	$10^2\,\Delta D$ [c] [cm^{-1}]	$\sigma^{\bullet}$	$\sigma^{\bullet}_{\alpha}$
2a	H	0.0504	0.00	0.00	0.000

2g	NO_2	0.0414	0.90	0.27	–

[a] In MTHF matrix at 77 K; $\lvert E/hc\rvert < 0.001\ cm^{-1}$; accuracy for $\lvert D/hc\rvert \geq 0.0002\ cm^{-1}$. [b] Values for $\sigma^{\bullet}$ and $\sigma^{\bullet}_{\alpha}$ taken from ref. [11]. [c] ΔD values are relative to **2a**. [d] The correction for the contribution of spin-orbit coupling from ref. [6] gives $D^{*} = 0.0493\ cm^{-1}$ and $10^2\,\Delta D^{*} = 0.11\ cm^{-1}$ (see text).

Spin-orbit coupling contributions to the zero-field splitting of localized biradicals are generally assumed to be negligibly small[4, 6, 10] as long as heavy atoms like bromine are absent. Hence, the D parameter should reflect the average separation (r) of the spins and the ΔD parameter its variation with substituents. The negative ΔD values for *para*-fluorine and *para*-methoxy substituents indicate an increase of spin density towards the radical sites in the biradicals **2**. The *para*-methyl group leaves the D value essentially unchanged within the experimental accuracy, whereas bromine, chlorine, and nitro substituents (**2e–g**) give rise to positive ΔD values, which suggest delocalization of spin density away from the benzylic radical termini.

Since Dougherty has proposed that the spin densities in the radical sites of a biradical are similar to those in isolated monoradicals and that there are no special delocalizing effects,[4] we have compared our ΔD values for the biradicals **2** with known data for the α spin densities of benzylic monoradicals. Five σ scales have been suggested to estimate the α spin densities or, inherently related, the chemical reactivities of substituted benzylic radicals.[11] Negative σ values indicate a larger α spin density or a higher reactivity of the benzylic position in radical reactions. Fisher's $\sigma^{\bullet}$ and Arnold's $\sigma^{\bullet}_{\alpha}$ parameters are given in Table 1 for comparison.

They are derived from bromination rates of substituted *meta* tolylcarbonitriles and from EPR hyperfine splitting constants of *meta*- and *para*-substituted benzyl radicals.[11]

Evidently the $\sigma^{\bullet}$ values are in better agreement with the measured ΔD values. For **2a** and **2b** ΔD and $\sigma^{\bullet}$ are quite similar, whereas for **2c** and **2d** both parameters suggest an enhanced α spin density (relative to **2a**). The latter result is at variance with Arnold's $\sigma_{\alpha}^{\bullet}$ scale which indicates a decrease in spin density for the *para*-methoxy substituent.[11] The exceptional behavior of the *para*-methoxybenzyl radical is not only suggested by the $\sigma^{\bullet}$ values, but also implied by earlier theoretical arguments[12] and further substantiated by recent reaction rates of oxygenation.[13] The larger D value for **2f** versus **2e** is attributed to a small, but significant spin-orbit coupling effect of the bromine substituents.[14] It was shown for the related series of substituted biradicals **1**[6] that two *para*-bromine atoms give rise to an increase of D by $0.0006\ cm^{-1}$. With this spin-orbit correction, a smaller D value for **2f** results ($D^* = 0.0493\ cm^{-1}$, $10^2\ \Delta D^* = 0.11\ cm^{-1}$), in accordance with Fisher's $\sigma^{\bullet}$ scale.

The better correlation of the ΔD parameters with Fisher's kinetic $\sigma^{\bullet}$ values rather than with Arnold's $\sigma_{\alpha}^{\bullet}$ values is surprising if one recalls the fact that the D and $\sigma_{\alpha}^{\bullet}$ values are obtained from EPR spectra. However, it is noteworthy that the D parameter reflects the spin densities at all positions of the spin-bearing benzylic moiety ("average spin separation"), whereas the $\sigma_{\alpha}^{\bullet}$ parameter is regarded as a measure for the spin density in the α position only. One may argue that the D parameter is a better measure for the overall electronic nature of the benzyl radical, which is a crucial feature for chemical reactivity.

The effect of *para*-nitro substitution in **2g** is substantial. Indeed, the ΔD value for *para* nitrophenyl is larger than the relative variation of D on going from phenyl to vinyl.[7] The corresponding calculated r values[5] are 3.71 ± 0.04 Å for **2a**–**2f** and 3.97 Å for **2g**.[14] These data indicate a significant change in the chemical environment for the unpaired electrons. The propensity of the nitro group (compare $\sigma^{\bullet}$) to accept electrons cannot alone account for the drastic decrease in the D parameter. In addition, the center of gravity of the spin is more displaced in the direction of the *para*-nitro substituent, since the oxygen atoms of the nitro group can accommodate spin density as well. For the other substituents, spin density is only transferred to the atom directly attached to the phenyl ring.

Whereas the examination of additional substituents and the reproduction of experimental findings by more refined[14] MO calculations remain synthetic and theoretical challenges, the set of available data already indicates novel effects, which deserve more detailed attention.[6] Even though we cannot offer an explanation for the variations of the D parameter with substituents at this point, it appears useful that the D parameters of biradicals provide the opportunity to assess electronic effects on the reactivity of simple radicals. Since such effects are typically small and quite difficult to study,[15–17] the D parameters of the substituted triplet biradicals **2** may indeed be an appealing alternative to the kinetic measurements.[11]

Dicyanopolyynes: Formation of New Rod-Shaped Molecules in a Carbon Plasma**

By *Thomas Grösser* and *Andreas Hirsch**

Fullerenes can be obtained in preparative amounts by the vaporization of graphite in a helium atmosphere.[1] The replacement of carbon atoms by heteroatoms in the spherical structure of these fascinating molecules presents a great synthetic challenge. Calculations carried out by us to determine the heat of formation of azafullerenes[2] revealed cyanogen $(CN)_2$ to be a very promising molecule for the insertion of nitrogen atoms into the fullerene framework due to its thermodynamic properties and reactivity in a plasma.[3] This gave us reason to investigate experimentally the interaction of carbon vapor with $(CN)_2$. To this end, we vaporized graphite under Krätschmer–Huffman conditions in the presence of $(CN)_2$. Under the chosen conditions, a homologous series of dicyanopolyynes was obtained as the main product.

The reaction was carried out in a simple fullerene reactor[4] modified specifically for the present purpose (Fig. 1). The lemon-yellow colored toluene extract of the reaction products consisted of several components but did not include any of the usual fullerenes (HPLC). The major portion contained five components, which were eluted together as the first fraction on a silica gel column (toluene/hexane, 80:20). The following products have been synthesized for the

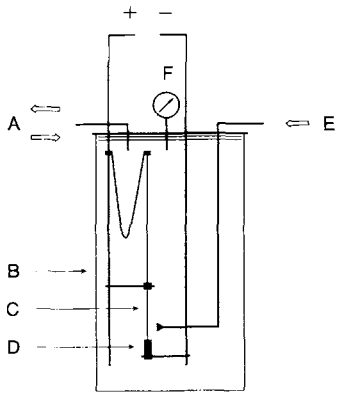

Fig. 1. Schematic diagram of the reactor used for the vaporization of graphite in the presence of $(CN)_2$ or Cl_2. Helium supply and connection to vacuum system (A), pyrex bell jar (B), graphite rod (3 mm) (C), graphite block (10 mm) (D), gas inlet tube for $(CN)_2$ or Cl_2 (E), manometer (F).

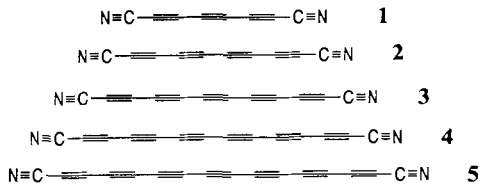
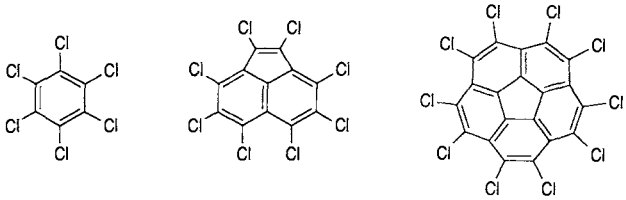
first time: $D_{\infty h}$-symmetrical dicyanopolyynes C_8N_2 **1**, $C_{10}N_2$ **2**, $C_{12}N_2$ **3**, $C_{14}N_2$ **4**, and $C_{16}N_2$ **5**.[5] The subsequent fractions have not yet been identified. The polyyne fraction consisted of up to approximately 55% **1** and 35% **2**; the higher homologues **3**–**5** formed less than 10% of the total (HPLC).



Compound **1** was obtained with a purity of 98.8% (GC) by sublimation from the remaining dicyanopolyynes, allowing complete characterization.[6] The compound forms colorless crystals, which are very soluble in toluene and chloroform but only sparingly in hexane. In the solid state, compound **1** decomposes gradually at room temperature and turns black. However, in the absence of light and moisture, dilute solutions of **1** may be stored at −18 °C without change. Compound **1** is very electrophilic; its cyclic voltammogram shows an irreversible reduction at −0.56 V (vs. Ag/AgCl) accompanied by the deposition of a black conducting film on the electrode.

Investigations by mass spectrometry have shown that the formation of the polyynes $H\text{-}(C{\equiv}C)_n\text{-}H$ occurs to a considerable extent during laser vaporization of graphite in the presence of H_2,[7] and that small amounts of dicyanopolyynes form in the presence of N_2.[7a] This is explained[7a] by the addition of H or N atoms to the ends of C_n chain species, which are considered as early intermediate products in the formation of fullerenes.[8] In addition to polyynes, monocyclic compounds and polycyclic aromatic hydrocarbons have also been detected as capture products.[7] Similar products as well as fullerenes have also been found in acetylene–oxygen flames.[9] The preferential formation of chain or cyclic products depends largely on the reaction conditions such as partial pressure of H_2,[7a] where the capture reaction takes place, and the C:O ratio.[9] The temperatures prevailing in the hot reaction zone during graphite vaporization by the Krätschmer–Huffman process are sufficiently high (6000 °C) for the formation of radicals such as CN or NCN from cyanogen to be expected.[10] If the dicyanopolyynes isolated here are to be viewed as terminal capture products arising from intermediate chains formed from carbon atoms,[11] then two alternative mechanisms of formation must be considered. One possibility is that the dicyanopolyynes could originate from subsequent reactions of other, initially formed intermediates. On the other hand, it is known that low concentrations of dicyanopolyynes up to C_8N_2 are formed in cyanogen–oxygen flames.[10] It is unlikely that the dicyanopolyynes isolated here are formed exclusively from the reactant cyanogen for the following reasons: 1) The observed intensity ratio of the mass lines corresponding to the compounds C_2N_2, C_4N_2, C_6N_2, and C_8N_2 produced in cyanogen–oxygen flames is 1000:100:9.5:0.5.[10] Our total yield of dicyanopolyynes **1**–**5**[12] is at least 50% relative to the cyanogen used and thus lies at least three orders of magnitude higher. 2) The formation of fullerenes is drastically reduced even at low cyanogen concentrations and is completely suppressed with gas mixtures having compositions below a set $(CN)_2$:He ratio of 4:6. 3) No further increase in the yield of **1**–**5** was observed when the $(CN)_2$ partial pressure was increased or when the reaction was conducted under flow conditions. The maximum yield amounts to 5% of the vaporized graphite and corresponds approximately to that obtained for fullerenes (8%) when a pure He atmosphere was used.

In order to show beyond doubt that reaction products can be formed from the C plasma and other gases, the same experiments were carried out with Cl_2. The toluene extract of the products still contained a small amount of fullerenes (<5%), but the main components that could be isolated by preparative HPLC and completely characterized were hexachlorobenzene (**6**) (60%) and perchloroacenaphthylene (**7**) (9%).[13] In addition, further perchlorinated compounds were present (in total 17%), which absorbed at longer wavelengths in the UV/VIS spectrum (up to 480 nm), and whose masses[14] matched those of perchlorinated polycondensed arenes such as decachlorocoroannulene (**8**). The carbon



6 **7** **8**

frameworks of these compounds are sections of the C_{60} structure, in which the occurence of five-membered rings necessary for the formation of fullerene is particularly noteworthy. In the cyanogen experiments no cyclic compounds were formed, whereas in the chlorine capture reaction no rod-shaped reaction products could be detected. This indicates that the interactions with the C plasma are different.

The extension of the Krätschmer–Huffman process to incorporate the use of suitable foreign gases allows access to new and interesting classes of compounds. The dicyanopolyynes synthesized here for the first time are rod-shaped molecules with the highest possible number of π electrons. Linear polyynes can be produced by traditional methods but only in multistep syntheses[15] and are considered interesting precursors of carbyne and other hypothetical carbon modifications.[16] Analogous polyynes such as HC_nN ($n = 1, 3, 5, 7$)

have been detected by Kroto et al. as molecules in interstellar space.[17] The formation of cyclic perchlorinated compounds such as **6**–**8** provides new and valuable clues to the formation of fullerenes. The isolation and characterization of capture products within the C plasma, such as the hitherto unknown **8** and components seen preferentially at low $(CN)_2$ concentrations, are the subject of further investigations.

Experimental Procedure

The fullerene reactor used was modified for the admission of $(CN)_2$ or Cl_2 by the addition of a gas inlet tube with a flat nozzle (Fig. 1). After it was synthesized [18], cyanogen was condensed in an autoclave, the outlet of which (needle valve) was connected to the gas inlet tube of the reactor. The following operating conditions were used: a voltage of 30 V DC, a current of 40 A, and a reactor pressure of 140 mbar He. After ignition of the electric arc, $(CN)_2$ or Cl_2 was fed into the reactor. The supply was quantitatively regulated so that the pressure in the reaction vessel remained constant. The cool surfaces of the reactor interior became coated with a yellow film in addition to soot. After completion of the reaction, the crude product was extracted with toluene. In each case the yield corresponded to 6–7% of the vaporized graphite.

[12] The exact determination of the yield is difficult, since the dicyanopolyynes are transformed into a black voluminous soot within a split-second by the effect of pressure or upon heating. The yields given should be interpreted as a lower limit. It has also been shown that polyynes decompose into primary soot even in the solid state.

Continuous Catalytic Synthesis of *N*-Acetyllactosamine**

By *Guido F. Herrmann, Udo Kragl,* and *Christian Wandrey**

Oligosaccharides are attracting much interest in immunological and pharmacological research because of their significance as fundamental structures of glycoproteins and glycolipids.[1] As well as the chemical syntheses of O-glycosides, syntheses employing enzymes have been established for a decade.[2] Access to large quantities of target compounds by means of both methods has been very limited.[3] The use of enzymes, in homogeneous solution, for reactions in an enzyme membrane reactor has proved to be a valuable tool in organic synthesis.[4] The enzyme-catalyzed synthesis of *N*-acetylneuraminic acid in an enzyme membrane reactor showed that large quantities of this compound could be produced in this way.[5]

We report here the enzyme-catalyzed continuous synthesis of *N*-acetyllactosamine (**3**, LacNAc) in an enzyme membrane reactor. Like *N*-acetylneuraminic acid, **3** is a structural component of many biologically active oligosaccharides.[1] Alongside the chemical syntheses of **3**[6] and as a part of higher oligosaccharides,[7] several authors used a galactosyltransferase (E.C. 2.4.1.38)[8] for the synthesis of **3**. The hitherto limited availability of this enzyme, its high price,[9] and its instability hampered its use. An alternative biocatalyst is a β-galactosidase (E.C. 3.2.1.23),[10] in particular the use of the β-galactosidase from *Bacillus circulans* resulted in high regioisomeric purity of the synthesized **3**.[10a]

Figure 1 shows the reaction scheme of the continuous synthesis described here. Starting with lactose **1**, transgalactosylation results in the transfer of the galactose moiety of **1** to *N*-acetylglucosamine **2** to afford **3** (Fig. 1a).

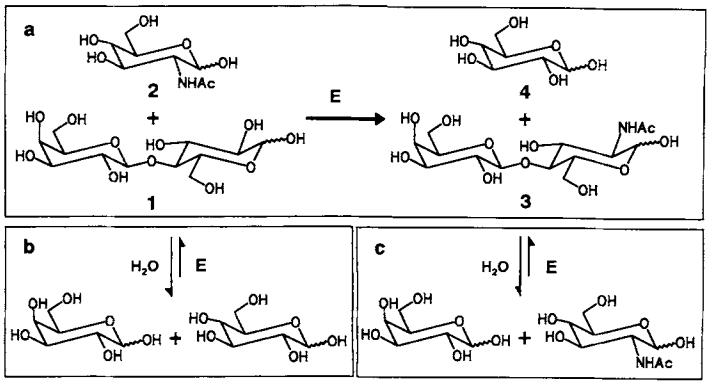

Fig. 1. Enzyme-catalyzed synthesis of *N*-acetyllactosamine **3**; the enzyme E is β-galactosidase a) Transgalactosylation, b) hydrolysis of **1** (side reaction), c) hydrolysis of the product (secondary hydrolysis).

The galactosyl donor **1** is hydrolyzed to galactose and glucose in a side reaction (Fig. 1 b). The desired product **3** is also a substrate for the β-galactosidase and is hydrolyzed

[**] We would like to thank the company Daiwa Kasei K. K., Osaka (Japan) for supplying β-galactosidase.

again in a subsequent reaction by the enzyme (secondary hydrolysis, Fig. 1c).

Experiments to investigate the stability of the enzyme showed that the β-galactosidase is a very stable enzyme,[11] and because of its low price and availability, it is a useful enzyme for synthesis.[12] The ratio of transgalactosylation to hydrolysis of **1**, that is, the selectivity[13] of the enzymatic reaction, could be optimized for the continuous process by changing the concentration ratio of **1** and **2**.

By selecting a suitable residence time τ for the reaction mixture in the reactor, the secondary hydrolysis of compound **3** could be minimized. Figure 2 shows the concentration-time curve for this continuous enzyme-catalyzed synthesis of **3** in an enzyme membrane reactor over 100 hours.

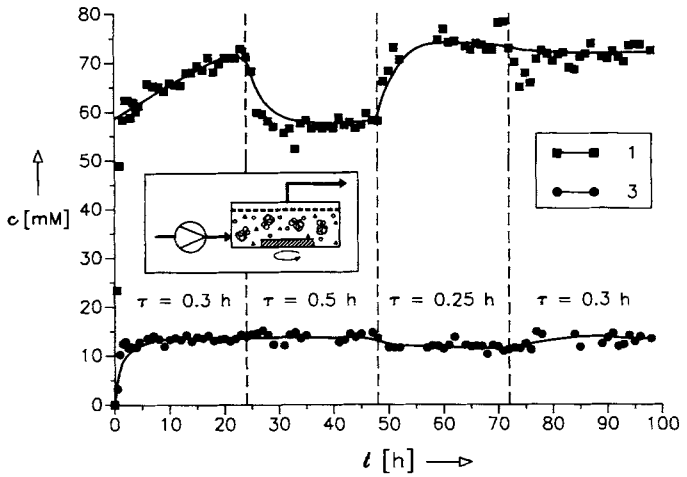

Fig. 2. Concentration-time curve for the continuous synthesis of *N*-acetyllactosamine **3** in an enzyme membrane reactor; starting concentrations: 120 mM lactose **1**, 300 mM *N*-acetylglucosamine **2**, 100 mM KH_2PO_4, 2 mM $MgCl_2 \cdot 6H_2O$, 5 mM dithiothreitol; pH 6.8; 25 °C; 3 mg mL^{-1} β-galactosidase; residence time: $\tau = 0.25$ h to $\tau = 0.5$ h.

During the course of the reaction there was no noticeable deactivation of the enzyme. The residence time was varied between $\tau = 0.25$ h and $\tau = 0.5$ h. With increasing residence time the concentration and therefore also the yield of **3** increased slightly.[14] The conversion of **1** increased from 0.37 to 0.51. The selectivity decreased with increasing conversion from 0.26 ($\tau = 0.25$ h) to 0.22 ($\tau = 0.5$ h). The space-time yield was 442 g L^{-1} d^{-1} at a residence time of $\tau = 0.25$ h and decreased to 261 g L^{-1} d^{-1} at a residence time of $\tau = 0.5$ h. After 100 h, 11.3 g of **3** was produced. The space-time yield was increased by a factor of 130 relative to the synthesis of **3** by using galactosyltransferase by Wong et al.[8a] Since reactions in a membrane reactor can be scaled up linearly,[4, 15] this method opens up an economic and a simple way of producing large amounts of **3**.[16] The process described here is the first continuous synthesis of a disaccharide that employs homogeneous catalysis. As a result of the broad spectrum of substrates for β-galactosidase from *B. ciruculans*,[17] the synthesis of derivatives of **3** with this advantageous technique is also possible.

Experimental Procedure

The enzyme membrane reactor (volume 10 mL; Bioengineering, Wald, Switzerland) fitted with an ultrafiltration membrane (YM-3, Amicon, Witten) preceded by a sterile filter (0.2 μm, Sartorius, Göttingen) was sterilized in an autoclave for 0.3 h at 120 °C (the experimental procedure corresponds to that described in [4] and [5]). Subsequently, bovine serum albumin (10 mg) and β-galactosidase (30 mg, 150 units) from *Bacillus circulans* (Daiwa Kasei K. K., Osaka, Japan) were fed into the reactor using buffer solution (100 mM KH_2PO_4, 2 mM $MgCl_2 \cdot 6H_2O$, 5 mM dithiothreitol, pH 6.8). A sterile solution (2.6 L) of the substrates (120 mM lactose **1**, 300 mM *N*-acetylglucosamine **2** in buffer solution) was then pumped through the reactor with residence times between $\tau = 0.25$ h and 0.5 h. Samples were taken regularly from the reactor outlet and analyzed by chromatography (HPLC: column ET 250/8/4 Nucleosil 5 NH_2 (Macherey-Nagel, Düren), 250 mm × 4 mm; eluent 75/25 (v/v) acetonitrile/water; flow-rate 1 mL min^{-1}; RI detection; capacity factors k': *N*-acetylglucosamine 0.84, galactose 1.26, **3** 2.09, lactose 3.09). To isolate the product **3**, the solution (containing 11.3 g of **3**) was concentrated to 0.68 L. The product was characterized by chromatography of a small portion of the solution (0.02 L) on 2/1 (w/w) activated charcoal (Darco, 20-40 mesh)/celite AFA (38 cm × 3.5 cm, eluent: H_2O with 0%-10% (v/v) ethanol, 0.5 bar). The fractions of **3** were collected and lyophilized. Yield 0.19 g. Analysis by gas chromatography (column: OV1 (Machery-Nagel, Düren); 25 m × 0.25 mm; He; temperature 275 °C, silylation according to [18] showed 4.7% *N*-acetylallolactosamine (Galβ(1,6)GlcNAc) as a by-product. Capacity factors k': **3** 5.00/5.35, allo-**3** 3.65/4.24. Correct elemental analysis.

$[\alpha]_{20.5\,°C}^{D} = 25.38$ ($c = 0.1$ in H_2O). The ^{1}H NMR spectrum (500 MHz, D_2O, internal standard [D$_4$]DSS (DSS = 3-trimethylsilyl-1-propanesulfonic acid), $\delta = 2.04$ (3 H, s, NHAc, GlcNAc), 4.47 (1 H, d, $J_{1,2} = 7.5$ Hz, HI, Gal), 5.2 (1 H, s, H1, GlcNAc)) and the 50 MHz ^{13}C NMR spectrum for **3** are consistent with published values [8a, 10d].

Carbenes in Constrained Systems I: 1,3 C–H Insertion Reaction of Adamantylidene within the β-Cyclodextrin Cavity**

By *Udo H. Brinker,* Rüdiger Buchkremer, Margaret Kolodziejczyk, René Kupfer, Murray Rosenberg, Mark D. Poliks, Mario Orlando*, and *Michael L. Gross*

Dedicated to Professor Emanuel Vogel on the occasion of his 65th birthday

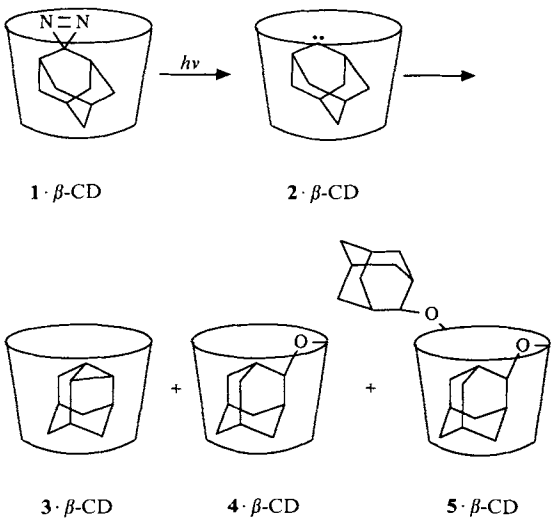
The chemistry of reactive intermediates (guests) within the confined spaces of another species (host) presents interesting opportunities for the discovery of new reactions.[1] The reactive behavior of carbenes in constrained systems is expected to be very different from that of free carbenes in solution or in the gas phase. The "tight fit" between the structures of hosts and the guest carbenes should alter both inter- and intramolecular reactions. Furthermore, suitable cavity sizes will restrict the mobility of the entrapped carbenes, which are then anticipated to react more selectively.

Carbene chemistry in different media has been studied extensively over the past decades.[2] Nearly nothing, however, is known about carbenes generated in constrained systems. Although α- and β-cyclodextrin (CD) have been the only molecules employed as hosts,[3] the intermediacy of carbenes or the corresponding carbenoids has not been firmly established.[3]

The relatively stable[4] diazirine **1** derived from adamantane[5] was chosen as the guest-carbene precursor and β-CD as the molecular reaction vessel (see Scheme 1). Compound **1** was prepared according to the literature,[6] purified by column chromatography (silica gel) under the exclusion of light, and shown to be pure by ^{1}H NMR spectroscopy. The β-CD complex of **1** (**1** · β-CD) was synthesized (ratio of host: guest ca. 3:1) and characterized. To avoid the replacement of entrapped guest molecules in the β-CD cavity by solvent molecules, solid-state NMR spectroscopy was used for the characterization. Cross polarization/magic angle spinning (CP/MAS) ^{13}C NMR spectra provide convincing evidence that an inclusion complex was formed.[7] This is further supported by powder X-ray diffraction spectra of **1**, β-CD, **1** · β-CD, and a physical mixture of **1** and β-CD. Under the conditions of fast atom bombardment (FAB) mass spectrometry, however, the loosely bound complex does not survive, and only the $(M - H)^-$ peak of β-CD is observed.[8]

In addition, molecular modeling was used to gain information about the fit and possible position of **1** within the CD cavity.[9] According to calculations carried out by using the SYBYL force field with default parameters, **1** is nearly completely submerged into the β-CD cavity with the diazirine function at the wider rim of the truncated cone.

Photolysis (Hanovia 400 W) of the solid inclusion complex of **1** · β-CD (Scheme 1) yielded the intramolecular carbene insertion product, 2,4-didehydroadamantane, as **3** · β-CD, and 2-adamantanone azine · β-CD[10] in a ratio of about 35:65.[11] Both products were identified by comparison of the NMR spectra with those of β-CD complexes of 2-adamantanone azine and 2,4-didehydroadamantane, synthesized by independent routes. When a physical mixture of β-CD and **1** was photolyzed, only about 1% of 2,4-didehydroadamantane **3** was formed! Furthermore, photolysis of **1** in the solid state leads to no detectable **3**.



1 · β-CD **2** · β-CD **3** · β-CD **4** · β-CD **5** · β-CD

Scheme 1. All guest molecules might be positioned differently within and outside the β-CD cavity. Insertion reactions of the carbene might have taken place into the secondary or primary hydroxyl groups at the wider and narrower rims, respectively, of the β-CD molecules.

Our results contrast strongly with the product distribution of the photolysis of **1** in hydrocarbon solvents, in which the carbene insertion product is not[12] (or only in traces) formed (0.2% in heptane[13]). In the photolysis in solution the formation of azine (76–85%) and adamantanone clearly dominates.[12]

Why is **3** · β-CD, the 1,3 C-H insertion product of **2** · β-CD, formed in yields as high as approximately 30% in the solid state, whereas yields of 0.2% or less are obtained by the photolysis in solution? β-CD complexation has dramatically altered the reactivity of adamantylidene; the intramolecular 1,3 C-H insertion reaction is now more likely by a factor of 150.

In the clean CP/MAS ^{13}C NMR spectrum of the product mixture, all signals of 2,4-didehydroadamantane and most of those of the azine can be assigned directly. No clear indication of the formation of products resulting from insertion of adamantylidene into the O–H bonds of β-CD, however, could be found. According to FAB and tandem mass spectrometry, however, adamantylidene inserts into one of the 21 O–H bonds of β-CD[14] to make a covalently bound host-guest complex with an $(M - H)^-$ ion of m/z 1267. Proof was obtained by treating a sample with D_2O to exchange the number of active hydrogen atoms left,[14] and by collisionally activating the m/z 1267 ion; no loss of 2,4-didehydroadamantane could be detected. A low abundance ion of m/z 1401.5 was also observed in the FAB mass spectra; it is probably due to a β-CD with *two* $C_{10}H_{14}$ moieties attached. This is confirmed by the fact that only 19 hydrogen atoms

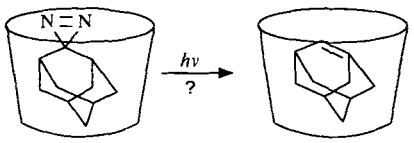
[**] Carbene Rearrangements, Part 41. We thank the American Maize-Products Company, Hammond, Indiana, for providing the cyclodextrins used in this study. Part 40: L. Xu, G. Lin, F. Tao, U. H. Brinker, *Acta Chem. Scand.*, **1992**, *46*, 650.

can be exchanged with D_2O. Thus, two insertions of two adamantylidenes into two different O–H bonds of β-CD have taken place. The absolute amount of OH insertion products **4** · β-CD and **5** · β-CD detected by FAB mass spectrometry (Scheme 1) is not yet known. Since these compounds could not be found by CP/MAS ^{13}C NMR spectroscopy, they must have been formed each in less than 5% yield.

Adamantylidene is believed to be a ground-state singlet carbene, and the generation of the triplet state fails even in the presence of photosensitizers.[15] The question of whether adamantylidene entrapped in β-CD is also a singlet cannot be answered at this time. Laser flash photolysis studies may solve this problem, as well as answer questions concerned with the detailed differences in the reactive behavior of a "free" adamantanylidene and a (partially) entrapped one.



1 · β-CD **6** · β-CD

If the carbene **2** · β-CD cannot easily encounter another reaction partner, it could rearrange to the highly strained adamantene **6**, which is known to dimerize[16] immediately, although it has been shown to exist in a matrix at low temperature.[17] This reaction, however, does not appear to take place if adamantylidene **2** is entrapped in β-CD.[18]

In conclusion, our results strongly suggest that we have established the first intra- and intermolecular carbene insertions within any constrained molecular reaction vessel.

Experimental Procedure

1 · β-CD: A solution of **1** (0.49 g, 3 mmol) in diethyl ether (12 mL) was added to a solution of β-CD hydrate (3.4 g, 3 mmol) in water (150 mL). After the mixture had been stirred for one day, the precipitate was filtered off, washed several times with water and ether, and then dried in the desiccator. Yield: 2.9 g (2.4 mmol, 81%).

[7] In **1** · β-CD the signals at $\delta = 27$–28 and 37 appear as doublets; when resolution enhancements were applied they became two distinct signals. For a physical mixture, these signals remained singlets. Cross polarization dynamics, as measured by the contact time and the proton rotating-frame relaxation time $T_{1\rho}(H)$, differed between **1** · β-CD and the physical mixture, indicating a single proton-spin reservoir for the complex and two distinct proton-spin reservoirs which are separated in space for the physical mixture (see J. R. Garbow, B. J. Gaede, *J. Agric. Food Chem.* **1992**, *40*, 156).
[8] FAB mass spectra were obtained by bombarding the samples in a glycerol or triethanolamine matrix with approximately 33 keV beam of Cs^+ ions, and the desorbed ions were analyzed with the first stage of a VG analytical ZAB-T four-sector mass spectrometer. Exact mass measurements were within <3.8 ppm of theoretical values. Collisional activation of the *m/z* 1267.4 ion and mass analysis of products with the second stage produces evidence for rupture of the CD ring but not for loss of $C_{10}H_{14}$. The mass spectrometer was briefly described by M. L. Gross *Methods Enzymol.* **1990**, *193*, 131.
[9] The calculations were performed with the SYBYL 6.0 version from Tripos Associates, Inc., on an 4D/35 IRIS workstation from Silicon Graphics.Inc. The "dock molecules" program was used to obtain the total energy of the complex with consideration of different possible conformations of **1** within β-CD.
[10] For the azine formation at least three mechanisms have to be discussed, two of them require the intermediacy of a carbene (see ref. [5b] *vol. I*, p. 111).
[11] In addition, variable amounts of adamantanone were formed.

[14] This sample which contained "empty" and "filled" β-CD molecules (ratio: ca. 2:1, determined by NMR spectroscopy) was treated with D_2O in order to exchange the number of active hydrogen atoms. The $(M - H)^-$ ion of β-CD shifts from *m/z* 1133.4 to 1153.4, indicating that all 21 active hydrogen atoms of β-CD had been replaced with deuterium atoms, and that an $(M - D)^-$ ion had been desorbed. The exchange was not complete; there were still some isomers with 20, 19, 18, and 17 deuterium atoms, but it was the most exchange that could be accomplished. For **4** · β-CD, 20 active hydrogen atoms could be exchanged as indicated by a shift from *m/z* 1267.4 for $(M - H)^-$ to *m/z* 1286.5 for $(M - D)^-$. One active hydrogen atom was lost owing to carbene insertion into an O–H bond.

[18] This could also mean that adamantene **6** is not formed from the carbene **2** but from the diazirine **1** or the rearranged linear diazo precursor (see J. E. Jackson, M. S. Platz in *Advances in Carbene Chemistry, vol. 1* (Ed.: U. H. Brinker), JAI, Greenwich, CT, in press.

Conjugated, Liquid Crystalline Polymers**

By *Luping Yu,** *Zhenan Bao*, and *Rubing Cai*

Liquid crystalline (LC) polymers are of great interest in fundamental science and the development of advanced materials.[1] Three main types of LC polymers have been extensively studied: 1) side-chain LC polymers, 2) main-chain LC polymers with flexible spacers, and 3) rigid main-chain LC polymers. The study of type 3 LC polymers stemmed from the discovery that poly(*p*-phenyleneterephthalamide) forms an LC solution from which high-modulus fibers may be spun.[2, 3] These polymers are particularly important because of their exceptional strength and high-temperature properties induced by the LC ordering. However, since these materials are not very soluble, fabrication is extremely difficult. To overcome these problems, in recent years there has been considerable efforts to prepare LC polymers with a rigid

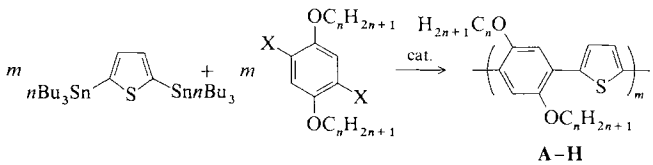
main chain and flexible side chains, for example, polyamides and polyesters with alkyl side chains.[4]

In the past decades, conjugated polymers have attracted much attention due to their electrical properties, for example conductivity, and optical properties;[5-7] however, structural studies of these materials have been limited.[8] Their potential as liquid crystalline materials has not yet been explored largely because traditional conjugated polymers are intractable and infusible.[5-7] Nevertheless, conjugated polymers obviously have a stiff chain which could act as the mesogenic unit and lead to properties known for type 3 LC polymers. In these compounds electrical, optical, and liquid crystalline properties are interrelated. For example, the conductivity and the third-order nonlinear optical (NLO) susceptibility strongly depend upon the orientation of conjugated polymer chains.[6] After a conjugated polymer is aligned by mechanical stretching, the conductivity parallel to the stretching directions is much greater than in the perpendicular direction, and the anisotropy of physical properties is enhanced.

These considerations have led to the synthesis of soluble and fusible conjugated polymers.[6] Recently, we found that the Stille reaction is very versatile for the synthesis of conjugated polymers.[9] We prepared poly(1,4-phenylene-2,5-thiophene) with different alkyl side chains utilizing this reaction (Scheme 1). Our latest studies show that these polymers form



A–H

Scheme 1. Synthesis of poly(1,4-phenylene-2,5-thiophene) **A**–**H**. **A**: $n = 4$, **B**: $n = 5$, **C**: $n = 6$, **D**: $n = 7$, **E**: $n = 8$, **F**: $n = 9$, **G**: $n = 12$, **H**: $n = 16$. [Pd(P-Ph$_3$)$_2$Cl$_2$] was used as catalyst when X = I, [Pd(PPh$_3$)$_4$]/LiCl when X = CF$_3$SO$_3$.

nematic phases when they are heated above their melting points, proving that conjugated polymers may also be liquid crystals. This paper reports our results on the LC properties of polymers **A**–**H**; the syntheses and physical properties are described in detail elsewhere.[9, 10] The spectroscopic studies (NMR, FT-IR, UV/VIS) and elemental analyses support the structures we proposed.

Thermogravimetric analyses (TGA) show that all of these polymers remain stable up to 400 °C under nitrogen. Thermograms obtained from differential scanning calorimetry (DSC; DuPont 90 calorimeter) were recorded at heating rates of 10 °C min^{-1} under a nitrogen flow. Polymers **A**, **B**, and **C** show glass transition temperatures (second-order transition) at 100, 90, and 75 °C, respectively. All of these thermograms display at least two transitions as the temperature is increased from 50 to 300 °C (Fig. 1), corresponding to the melting of the side chains (T_{m1}) and the backbones (T_{m2}). Two more transitions above the sharp melting transition for polymer **A** can also be noted. The higher temperature transition corresponds to the transition (T_c) from the liquid crystalline to the isotropic phase and was confirmed by the optical microscopy. The other transition cannot be assigned, although the difference between the phases in these two temperature regions is apparent in the X-ray diffractogram (Fig. 2). Similar behavior observed in aromatic polyesters[11]

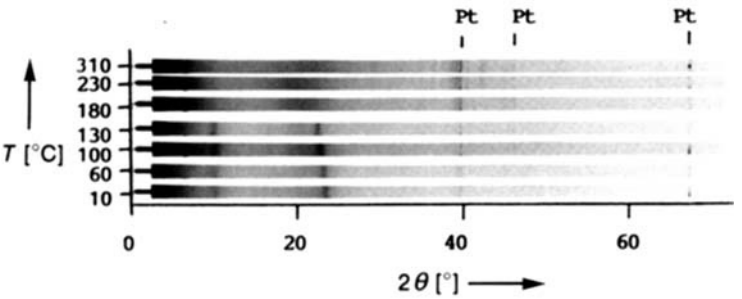


Fig. 2. Results of a temperature-dependent X-ray diffraction experiment with synchronized radiation. Each experiment lasted 8 h. The Pt line was used for calibration, the X-ray source was Ni-filtered $Cu_{K\alpha}$ radiation.

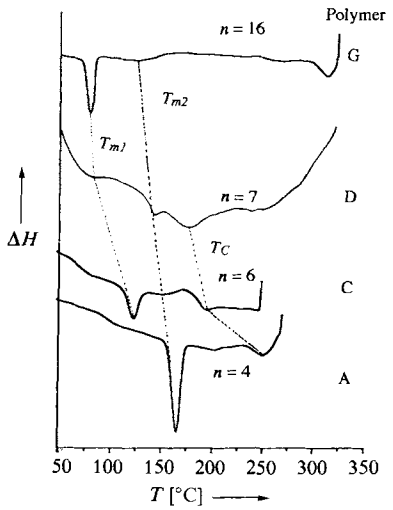

Fig. 1. DSC thermograms of polymers **A**, **C**, **D**, and **G**; heating rate 10 °C min^{-1}, nitrogen atmosphere. The polymers were annealed before the DSC scan: polymer **A**, 145 °C for 12 h; polymer **C**, 100 °C for 12 h; polymer **D**, 115 °C for 16 h; polymer **G**, 65 °C for 12 h.

has been ascribed to the smectic-to-nematic phase transition. However, polymer **A** did not show any typical smectic patterns under the optical microscope.

Since we could not detect the nematic-to-isotropic phase transition of other polymers having alkyl side chains with more than eight carbon atoms by DSC measurements, polarizing microscopy was performed (Nikon HFX-IIA microscope equipped with a Linkam (TMS-90) hot stage). All of the polymers exhibit a birefringent fluid melt above their melting temperatures and a characteristic shear opalescence, indicating a nematic phase. Figure 3 shows the textures of the mesophases of polymers **A** and **E**. Typical schlieren textures can be seen, further demonstrating the presence of a nematic phase. Both DSC studies and observations from polarizing optical microscopy indicate that the melting and the clearing transition temperatures are affected by the lengths of the side chains. In Figure 4 the transition temperatures of polymers **A**–**H** are plotted against the number of carbon atoms n in the alkyl side chain. As n increases, the melting (T_m) and clearing temperatures (T_c) of the polymers decrease steadily. Depending upon the length of the side chain, the liquid crystal range is between 56 and 20 °C.

The X-ray diffraction studies indicate that the polymers precipitated as crystalline materials. The X-ray diffraction results for polymer **A** with a synchronized diffractometer are shown in Figure 2. Two strong diffraction maxima at 2θ values of 10 and 23.5° can be noted. As temperature was increased, the spacings at 8.51 and 3.79 Å increased due to

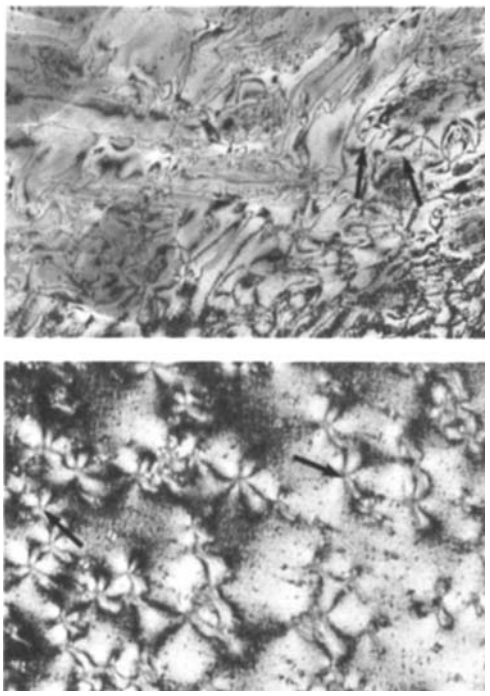

Fig. 3. The textures of the mesophases of polymers **A** (top) and **E** (bottom) under crossed polarizers at 220 °C and 159 °C, respectively, (× 100). The arrows indicate the recognizable singularities $S = \pm 1/2$.

thermal expansion. As the temperature increased above the melting temperature, these two diffraction peaks became very diffuse (barely visible), which is typical for a nematic phase.

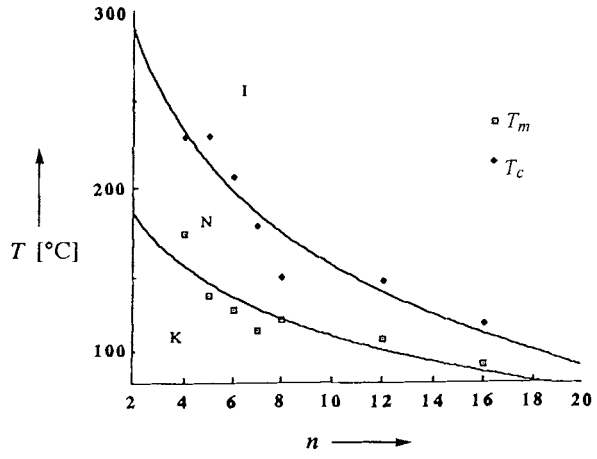

Fig. 4. Transition temperatures of polymers with different alkyl side chains.

From these results, we can see that polymers **A**–**H** have promising LC properties. Ballauff has pointed out that the side chains behave more or less like bound solvent molecules, rendering the polymer soluble and fusible.[12] This model of bound solvent molecules accounts for the change in the transition temperature as a function of the length of the side chain.

We have shown clear evidence of a nematic LC phase for the new conjugated polymers **A**–**H**, which were prepared by the Stille coupling reaction. Certain properties of the polymers such as transition temperatures, solubility, and fusibility of polymers can be controlled by the length of the side chains. We also can easily change the structure of the conjugated main chain. For example, the 2,5-linkage of thiophene results in a main chain with a bent structure, and the chain packing should thus be different from that of polymers with linear structures such as 2,5-phenylene and 1,4-naphthalene. (Although polyphenylene has been synthesized before, to our knowledge no liquid crystal property study was reported.) Our findings should serve as a basis for further investigations of LC behavior in conjugated polymers.

Structure and Electrochemical Behavior of the Paramagnetic Anion $[Ir_{14}(CO)_{27}]^-$, Possessing a Trigonal Bipyramidal Arrangement of Metal Atoms**

By *Roberto Della Pergola, Luigi Garlaschelli,* Mario Manassero, Norberto Masciocchi,** and *Piero Zanello**

The number of well-defined and structurally characterized, high-nuclearity clusters is increasing, but slowly. Knowledge in this field is somehow hampered by experimental difficulties: most compounds are obtained in very small amounts with reactions of low reproducibility, and the characterization is simply restricted to the crystal structure. In other cases in which a large number of physico-chemical measurements are available, high nuclearity clusters have been shown to possess unusual properties which deserve more detailed investigation.[1]

Within the latter group, $[Ir_{12}(CO)_{26}]^{2-}$[2] and $[Ir_{12}(CO)_{24}]^{2-}$[3] were obtained by oxidation of $[Ir_6(CO)_{15}]^{2-}$ with $[Cu(NCCH_3)_4]^+$, through the intermediacy of the

$[Ir_6(CO)_{15}\{CuNCCH_3\}]^-$ adduct;[4] the dodecanuclear clusters represented the maximum nuclearity achieved for iridium, until we were able to synthesize the new monoanion $[Ir_{14}(CO)_{27}]^-$ ($\mathbf{1}^-$) by oxidation of $[Ir_6(CO)_{15}]^{2-}$ with ferrocenium ions. This type of reaction was previously exploited for the synthesis of substituted hexanuclear iridium clusters.[5] In the absence of any coordinating ligands, the major product is the red isomer of $[Ir_6(CO)_{16}]$,[6] but other clusters are also produced. Of these, $[Ir_{14}(CO)_{27}]^-$ can be recovered as $[N(PPh_3)_2]^+$ salt. Single crystal X-ray diffraction analysis[7] showed that $[Ir_{14}(CO)_{27}]^-$ possesses an approximate D_{3h} symmetry and contains a metal core polyhedron of ν_2-trigonal bipyramidal shape,[8] showing an ABCBA stacking sequence of metal atoms down the pseudo-threefold axis (Fig. 1). This arrangement of 14 metal atoms has never been observed before, although it can be recognized as a part of the framework of $[Os_{17}(CO)_{36}]^{2-}$;[9] other truncated ν_2-trigonal bipyramids are also known, for example, $[Ir_{12}(CO)_{24}]^{2-}$[3] and $[H_xNi_{12}(CO)_{21}]^{x-4}$ ($x = 0, 1, 2$).[10]

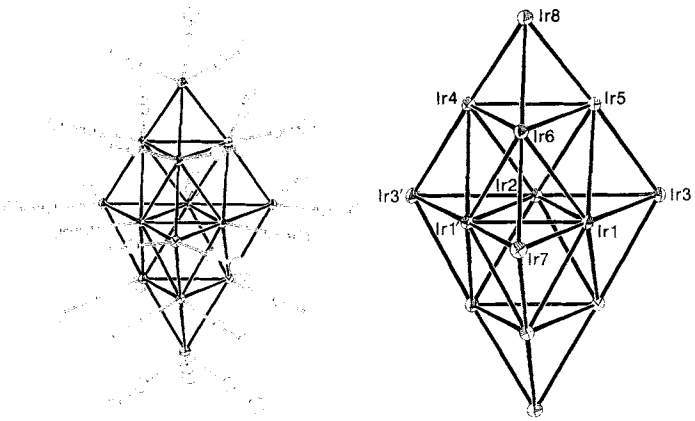

Fig. 1. Left: ORTEP drawing of the $[Ir_{14}(CO)_{27}]^-$ ion. Thermal ellipsoids are drawn at the 30% probability level. Right: Schematic drawing of the Ir_{14} metal core. Primed atoms are generated by rotation about the (crystallographic) twofold axis passing through the Ir(2) and Ir(7) atoms. Ir–Ir distances [Å]: 1–1′ 2.643(2), 1–2 2.646(2), 1–3 2.692(1), 1–4′ 2.760(1), 1–5 2.750(1), 1–6 2.767(1), 1–7 2.700(2), 2–3 2.702(1), 2–4 2.740(1), 2–5 2.770(1), 3–4′ 2.735(1), 3–5 2.724(1), 4–5 2.763(1), 4–6 2.767(1), 4–8 2.674(1), 5–6 2.758(1), 5–8 2.676(1), 6–7 2.742(1), 6–8 2.681(1).

The metal framework of $[Ir_{14}(CO)_{27}]^-$ is only slightly distorted: the 33 Ir–Ir distances (average value 2.720 Å, range 2.643–2.770 Å) can be grouped into four homogeneous subsets: 1) only the equatorial [Ir1, Ir2, Ir3 and Ir7] atoms (average 2.680 Å), 2) only the upper layer [Ir4, Ir5, Ir6] atoms, (average 2.763 Å), 3) the apical Ir8 atom (average 2.677 Å), and 4) interlayer connections (average 2.751 Å).

All the carbonyl ligands in $\mathbf{1}^-$ are terminally bound, three on each apical, two on each equatorial vertex, and one on each Ir atom in the center of the edges of the equatorial plane: this disposition matches the requirement of densest coverage of metallic surface, as observed in the ν_2-tetrahedral osmium clusters $[Os_{10}C(CO)_{24}]^{2-}$[11] and in $[Os_{17}(CO)_{36}]^{2-}$. Average distances and angles for the carbonyl ligands are 1.83 Å (range 1.73–1.92 Å) for Ir–C and 1.17 Å (range 1.10–1.22 Å) for C–O; Ir-C-O angles range from 173(3) to 180°.

Cluster $\mathbf{1}^-$ possesses 181 cluster valence electrons (CVE), corresponding to 91 occupied molecular orbitals. This number conforms to the $6N + 7$ rule suggested by Ciani and Sironi[12] and is in fairly good agreement with predictions of Teo et al.,[8] but can not be rationalized in terms of the Polyhedral Skeletal Approach,[13] probably because it is rather awkward to describe the regular ν_2 polyhedron as being derived by condensation of two octahedra, three trigonal bipyramids, and two tetrahedra. The agreement of the number of electrons with attributable to the bipyramidal core of $[Os_{17}(CO)_{36}]^{2-}$ is even lower (176 CVEs).

The odd number of electrons, which was confirmed by ESR measurements, suggests that electrons could be added or removed. As a matter of fact, Figure 2 shows that, in dichloromethane solution, the monoanion undergoes an oxidation as well as a reduction process. Both redox changes

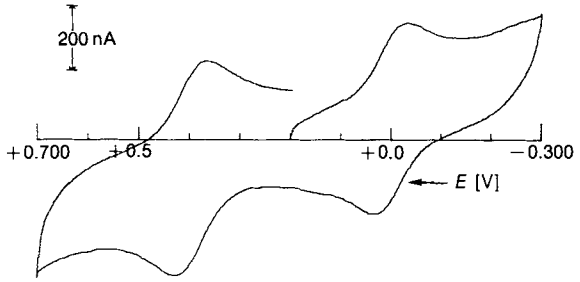

Fig. 2. Cyclic voltammetric response exhibited by a solution of $[N(PPh_3)_2][Ir_{14}(CO)_{27}]$ (1×10^{-4} mol dm^{-3}) and $[NBu_4][ClO_4]$ (0.2 mol dm^{-3}) in CH_2Cl_2. Platinum working electrode. Scan rate 0.05 Vs^{-1}. Ag/AgCl reference electrode.

look like chemically and electrochemically reversible one-electron transfers ($E^{o\prime}_{1/1^-} = +0.39$ V; $\Delta E_p(0.05\,\mathrm{Vs}^{-1}) = 65$ mV; $E^{o\prime}_{1/1^{2-}} = 0.00$ V; $\Delta E_p(0.05\,\mathrm{Vs}^{-1}) = 64$ mV). The slight increase of the peak-to-peak separation of each process from 60 mV at 0.02 Vs^{-1} to 90 mV at 1.00 Vs^{-1} in the high-resistive dichlorometane solution clearly supports the electrochemical reversibility of the redox changes. This implies that the original cluster framework does not undergo significant structural reorganizations upon the actual electron addition or removal.[14]

Experimental Procedure

$[N(PPh_3)_2]_2[Ir_6(CO)_{15}]$ (0.19 g, 0.07 mmol) was dissolved in THF (20 mL) and cooled to 0 °C under a light stream of nitrogen. Solid $[(C_5H_5)_2Fe]PF_6$ (0.05 g, 0.15 mmol) was added, and the reaction mixture stirred for two hours. The brownish-black solution was evaporated to dryness in vacuum, ferrocene was extracted with hexane (2 × 15 mL), and the residue was dissolved in CH_2Cl_2 and filtered. The filtrate was layered with cyclohexane and, after slow diffusion, produced a large number of white colorless needles of $[(N(PPh_3)_2]PF_6$ together with a few black crystals. This residue was washed with 2-propanol, toluene, and CH_3CN, leaving only black crystals of the highly insoluble product. Approximate yield: 10 mg; $\tilde{\nu}_{CO}$ (CH_2Cl_2 solution): 2082s, 2068w, 2042vs, 2014m, 1994w cm^{-1}; g (polycrystalline sample at 120 K): 2.37.

In this preliminary report, the electrochemical behavior of $[N(PPh_3)_2]$ **1** was studied only by cyclic voltammetry, because a very small amount of it (2.3 mg) remained after characterization. The number of electrons involved in the electron transfer processes was roughly evaluated by comparison with the response of an equimolar amount of $[NEt_4][Fe_5N(CO)_{14}]$[15]. The electrochemical apparatus was a BAS 100A Electrochemical Analyzer connected to a MF-1065 microcell equipped with an Ag/AgCl reference electrode and a button and a spiral platinum electrode as working and auxiliary electrodes, respectively. Under these experimental conditions, the one electron oxidation of ferrocene occurs at $E^{o\prime} = +0.47$ V vs. Ag/AgCl.

[7] Crystal data for $[N(PPh_3)_2][Ir_{14}(CO)_{27}]$: $C_{63}H_{30}Ir_{14}NO_{27}P_2$, monoclinic, $C2/c$, $a = 16.541(4)$, $b = 34.599(6)$, $c = 14.640(12)$ Å, $\beta = 91.62(4)°$, $M = 3985.6\ g\,mol^{-1}$, $V = 8375(10)$ Å^3, $Z = 4$, $\varrho_{calcd} = 3.161\ g\,cm^{-3}$; $F(000) = 6956$, $Mo_{K\alpha}$ radiation, $\lambda = 0.71069$ Å, $\mu(Mo_{K\alpha}) = 221\ cm^{-1}$. Of a total of 7359 reflections (corrected for absorption and crystal decay), 3945 were observed [$I > 3\sigma(I)$] in the $6 < 2\theta < 50$ range. $R = 0.037$, $Rw = 0.036$. The structure was solved by a combination of direct methods and difference Fourier techniques and refined by full-matrix least-squares methods. All iridium and phosphorous atoms were refined anisotropically, while the carbonyl ligands were isotropically refined at a later stage. Two half-occupancy cations have also been refined (their phenyl rings, treated as rigid bodies, occupy the same cavities between the large anions). Crystal packing drawings clearly demonstrate that their van der Waals surfaces closely match those of their centrosymmetric (disordered) images. Refinements of the structure in the non-centrosymmetric $C2$ or Cc groups did not lead to an ordered model. Further details of the crystal structure investigation are available on request from the Director of the Cambridge Crystallographic Data Centre, 12 Union Road, GB-Cambridge CB2 1EZ (UK), on quoting the full journal citation.

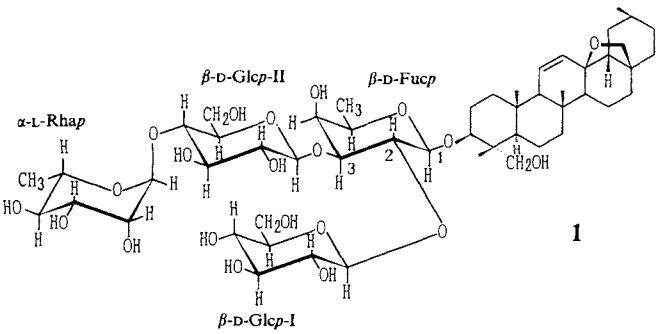
Sequential Analysis of Oligosaccharide Structures in a Few Minutes**

By *Harald Schröder* and *Ernst Haslinger**

Polysaccharides and compounds containing oligosaccharide partial structures are widespread in nature and are often highly biologically active. In order to determine the structure, not only must the monosaccharide residues be known but also their anomeric configuration, their sequence, and the positions of the glycoside linkages. NMR spectroscopy is proving to be the best method of determining both of the latter structural characteristics.[1–3] In past years, the application of 3D NMR techniques to structural investigations of oligosaccharides has gained in importance.[4–6] All the desired structural parameters, for instance, can be obtained by a 3D TOCSY-ROESY experiment.[7] However, the low digital resolution, low sensitivity, and hence the high time requirement are the greatest obstacles for routine application of 3D NMR techniques.

If the first pulse in a 3D TOCSY-ROESY experiment is replaced by a selective Gaussian pulse,[8] which only excites a particular proton, then the signals are obtained in the form of a 2D spectrum. We have carried out selective TOCSY-ROESY experiments on verbascosaponin (**1**). The spectra obtained are shown in Figures 1 and 2. Each spectrum makes it possible to determine the sugar residues adjacent to a given monosaccharide and the glycoside linkage positions. The critical advantage of this measuring technique is its high sensitivity and hence the exceptional gain in time.



The principle can be briefly explained: A nonoverlapping proton resonance signal of a monosaccharide unit (usually the anomeric H atom) is selectively excited by a Gaussian pulse. The magnetization thus generated is transferred to other protons in the same sugar residue by a subsequent TOCSY step. After this preparation, the ROESY experiment is carried out, and the magnetization is transferred through space by dipolar coupling to any proton in the neighboring sugar building blocks that is connected at the

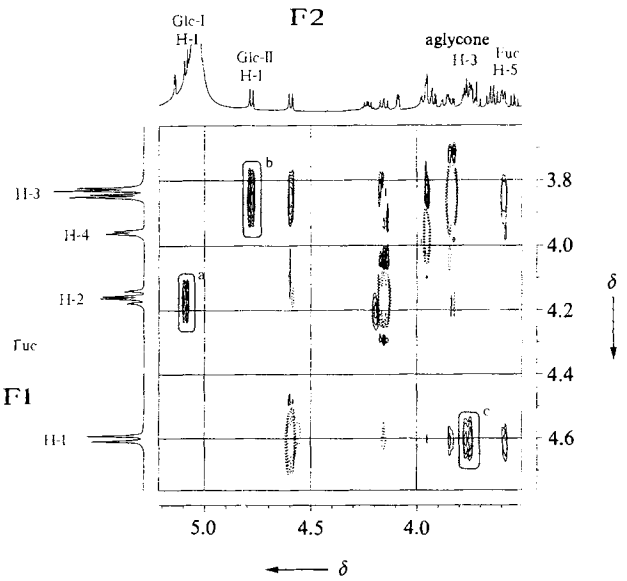


Fig. 1. 2D TOCSY-ROESY spectrum, selective excitation of the H1 atom of the fucose unit. The anomeric proton of the fucose building block is selectively excited and the magnetization transferred to the H2, H3, and H4 protons of this building block. After this preparation, the ROESY experiment is carried out. The fucose peaks in F1 give rise to diagonal peaks to the same proton (shown negative, dotted), weak COSY-like peaks (appearing antiphase), and ROESY cross-peaks (positive, solid line) within the sugar building block and to protons at the glycoside linkages of the neighboring sugar units which can be seen in the spectrum. Three interglycosidal peaks (circled, a: Fuc-H2/Glc-I-H1, b: Fuc-H3/Glc-II-H1, c: Fuc-H1/aglycone-H3) verify the partial sequence Glc-II-(1 → 3)-[Glc-I-(1 → 2)-]Fuc-(1 → 3)-aglycone. Furthermore, ROE correlations can be seen within the fucose unit: H1/H3, H1/H5, and H3/H5. A selective TOCSY of the fucose unit is shown in the F1 dimension, and a ^{1}H NMR spectrum of **1** is shown in the F2 dimension as a reference spectrum. 512 W data points, 40 experiments, TOCSY mixing time 70 ms, experiment time 4 min.

glycoside linkage position. This leads to interglycosidic correlation between protons at the glycoside linkage.

We illustrate the application of selective 3D TOCSY-ROESY measurements using verbascosaponin (**1**) as the example. Two experiments were sufficient for the complete sequencing of **1**. Figure 1 shows the spectrum obtained when the anomeric proton of the fucose unit is selectively excited. There are three interglycosidic correlation signals, a, b, and c. Signal a verifies the linkage between the C1 atom of the glucose-I unit and the C2 atom of the fucose building block. The glucose-II unit is connected at position C3 of fucose (signal b); fucose is thus the starting point for branching of the sugar chain. Magnetization transfer from the anomeric H atom to H3 of the aglycone at the site of the third glycosidic linkage accounts for signal c. The information still to be determined concerning the structure of the sugar chain can be obtained from Figure 2. Here the anomeric proton of the glucose-II unit was selectively excited and the magnetization distributed among all other protons of this sugar. Correlation signal a verifies that the rhamnose building block is connected at position 4 of the glucose-II unit. Signal b again correlates H3 proton of fucose to the anomeric proton of the glucose-II unit.

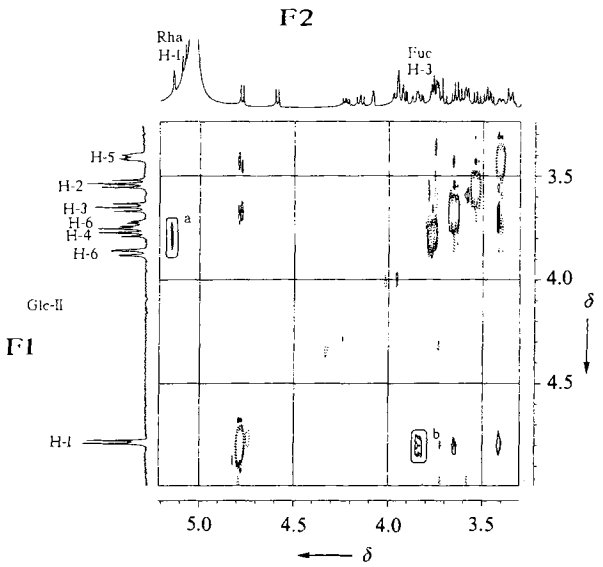

Fig. 2. 2D TOCSY-ROESY spectrum, selective excitation of the H1 atom of the glucose-II unit. The anomeric proton of the glucose-II unit is selectively excited, the magnetization transferred to all other protons in the glucose building block and the ROESY experiment then carried out. Two interglycosidal ROE cross-peaks (circled a: Glc-II-4/Rha-1, b: Glc-II-1/Fuc-3) verify the partial sequence Rha-(1 → 4)-Fuc. Therefore, the sequence and the positions of the glycoside linkages of **1** are completely determined by this experiment and that in Figure 1. The following intraglycosidal ROE peaks of the glucose-II unit can be seen: H1/H3, H1/H5, and H3/H5. A selective TOCSY of the glucose-II unit is shown in the F1 dimension, and the ^{1}H NMR spectrum of **1** in the F2 dimension serves as a reference spectrum. 512 W data points, 40 experiments, TOCSY mixing time 70 ms, experiment time 4 min.

The application of a TOCSY-ROESY pulse sequence instead of a TOCSY-NOESY experiment[9] is necessary for medium-sized molecules such as verbascosaponin since nuclear Overhauser effects (NOE) are small or nonexistent.[10] A requirement for sequencing the sugar chain is the previous assignment of the proton signals, for example by a COSY spectrum. The selective TOCSY-ROESY experiment makes unambiguous sequencing possible even with severely overlapping signals. Of course, if signals due to the selectively excited sugar unit are superimposed on one another, even this method can fail. The measurement technique described exclusively combines the advantages of selective excitation (frequency selectivity, low time and computer memory requirement) with those of 3D spectroscopy (dispersion in an additional frequency dimension and hence generation of partial spectra). We succeeded in a complete sequence analysis of **1** within 10 minutes by measuring the two spectra in Figures 1 and 2. Structural determination of oligosaccharides is simplified considerably by this method.

Experimental Procedure

The NMR spectra were recorded on a Bruker AMX-500 spectrometer (^{1}H NMR frequency: 500.13 MHz) and processed with an Aspect X32 computer using the UXNMR program. Sample tubes 5 mm in diameter, solvent: 0.2 mL [D_4]methanol/[D_5]pyridine (3:2), sample concentration: 3×10^{-5} mol, temperature: 310 K. The CD_3OD peak was used as an internal reference (^{1}H NMR: $\delta = 3.3$).

Pulse sequence for the selective 3D TOCSY-ROESY experiment: 90° soft pulse – d1 – [MLEV-17] – t_1 – [spin-lock] FID (t_2); 90° soft pulse length P1: 70 ms (64 dB, truncation level 1%), TOCSY mixing time: 70 ms (60 MLEV-17 cycles, each with two trim pulses lasting 2.5 ms, ROESY spin-lock CW pulse: 250 ms, d1 = 1/J – P1/2, ^3J(H1, H2) = 7.8 Hz (fucose and glucose), acquisition time + relaxation delay: 300 ms, 8 scans, 512 W data points, 40 increments (t_1), measurement time 4 min. A Gaussian pulse is very selective and offers advantages over Dante and semi-Gaussian pulses. A selective excitation pulse of 70 ms was chosen to achieve the required selectivity. The subsequent TOCSY transfer requires in-phase magnetization. As the delay required for this (d1 = 1/J – P1/2 = 95 ms) results in a loss in sensitivity due to relaxation, the delay chosen was as short as possible (5 μs). The loss in sensitivity due to the antiphase magnetization component was accepted. This offers the additional advantage that d1 does not have to be adjusted for different coupling constants.

$Ba_9N[N_3][TaN_4]_2$: A Nitridotantalate(v) with Nitride and Azide Ions**

By *Peter Höhn, Rüdiger Kniep,** and *Joachim Maier**

A simple method of preparing nitrodometalates is by reaction of binary or ternary metal melts (Li-EA-TE systems; where EA is a group 2 element, and TE an element of groups 4–11 of the periodic system) with elemental nitrogen.[1, 2] The compounds prepared by this method contain

nitrogen reduced to nitride, which participates in the "covalent" arrangement of complex anions (as in $Li_4[FeN_2]$[3] and $Sr_2Li[Fe_2N_3]$[4]) or is found as "isolated" nitride species surrounded by cations of an electropositive metal (as in Ca_3AuN[5]). In the course of our investigations in nitridotantalates,[2] we have now succeeded in preparing $Ba_9N[N_3][TaN_4]_2$, a compound containing the complex anions $[Ta^VN_4]^{7-}$, "isolated" nitride ions, and simultaneously also azide ions N_3^-, from the elements. The only way to prepare this metastable phase was by quenching the high-temperature system in direct contact with excess tantalum. This, together with the results of the crystal structure analysis, provide evidence that elemental nitrogen is reduced to the nitride stage via the azide under the given conditions.

$Ba_9N[N_3][TaN_4]_2$ was prepared by heating barium (Ventron, 99.5%; peeled under argon) and tantalum (Ventron, 99.9%; powder) in 10:1 molar ratio in a tantalum crucible (Plansee, 99.95%) under a stream of nitrogen (Messer Griesheim, 99.999%, 5 L h^{-1}) at a rate of 100 K h^{-1} to 1223 K, maintaining this temperature for 12 h, and finally quenching to room temperature. The reaction tube (quartz glass) containing the tantalum crucible was disconnected from the nitrogen supply, sealed, withdrawn from the oven (1223 K), and dipped into a water bath at room temperature. After temperature equilibrium was attained, black shining orthorhombic prisms of $Ba_9N[N_3][TaN_4]_2$, which appear red and translucent in thin layers, grew on the upper rim of the tantalum crucible. The reaction product at the bottom of the crucible consisted primarily of $Ba_2[TaN_3]$.[6]

In the crystal structure of $Ba_9N[N_3][TaN_4]_2$ the anionic part (Fig. 1) consists of isolated $[Ta^VN_4]^{7-}$ tetrahedra (forming a double layer parallel to (001)), "isolated" nitride ions (roughly at the boundaries of the double-layers), and azide ions (between the double layers). The bond lengths and bond

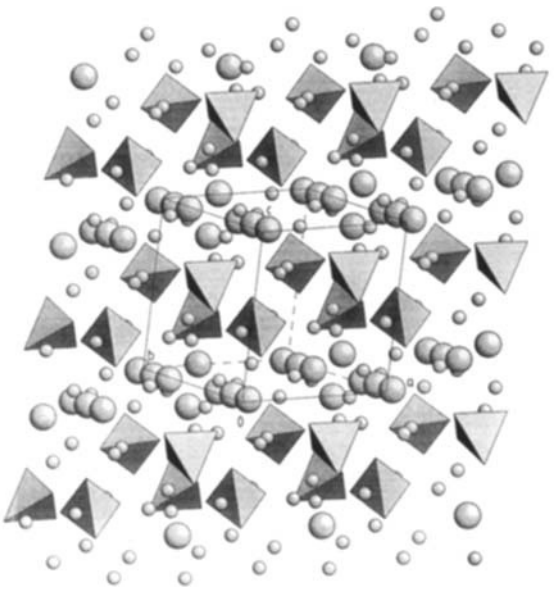

Fig. 1. Section of the crystal structure of $Ba_9N[N_3][TaN_4]_2$. Tetrahedra: $[TaN_4]^{7-}$, large spheres: nitrogen (N_3^- or N^{3-}), small spheres: Ba^{2+}.

angles within the isolated TaN_4 tetrahedra (194(2)–199(2) pm and 104.49(1)–114.30(1)°, respectively) are of the same order of magnitude as those in $Li_7[TaN_4]$[8] (195.5(2) and 196.7(3) pm, 109.0(1) and 110.0(1)°, respectively). The azide group is only slightly bent ($N_{terminal}$-$N_{bridging}$-$N_{terminal}$: 176.21(2)°; compare also the angle at the central N atom of the azide group in iodine azide, as described recently:[9] 171(7) and 174(6)°). The lengths of the $N_{terminal}-N_{bridging}$ bonds are 121(2) and 126(2) pm; the crystal structure of the binary azide $Ba[N_3]_2$[10] also contains unsymmetrical azide ions (two independent ions with bond lengths of 119.6/114.3 pm and 118.2/120.3 pm). The azide ions in the crystal structure of $Ba_9N[N_3][TaN_4]_2$[7] are surrounded by eight barium ions; the $Ba-N_{(azide)}$ distances (283 to 320 pm) lie in the range of the sum of the effective ionic radii (282 to 308 pm),[11] so that this ternary compound can be regarded as an ionic azide.[12] The N–N bonds in the ternary azide (mean value: 124(2) pm) are rather long compared with those in $Ba[N_3]_2$[10] (mean value: 118.1 pm) and in the alkali metal compounds $M[N_3]$ (M = K, Rb, Cs; mean value: 117(1) pm);[13] this corresponds with the high coordination number (CN) of the azide ions (CN = 8, in contrast to CN = 4–5 in $Ba[N_3]_2$) and the higher charge on the surrounding cations compared with the alkali metal compounds, which also contain eight-coordinate azide ions. Figure 2 illustrates the coordination of azide ions by barium ions.

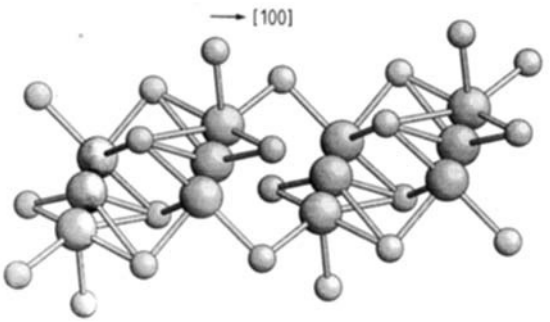

Fig. 2. Coordination of the azide ions (large spheres) by barium ions (small spheres) in $Ba_9N[N_3][TaN_4]_2$ and linkages forming ribbons along the [100] direction.

The specific arrangement of the cations and anions leads to ribbons along the [100] direction. The terminal N atoms of the azide groups are surrounded by five (291(2)–320(2) pm) or four (283(2)–312(2) pm) barium ions, whereas the central N atom has only three neighboring Ba ions (294(2)–306(2) pm). This result is in complete agreement with MO calculations for azide ions,[12, 14] according to which the central N atom has a formal charge of +0.6, while the terminal N atoms have a formal charge of −0.8, which implies that the latter should have a stronger interaction with the neighboring cations.

The isolated nitride ions are surrounded by barium ions (distorted octahedral coordination; 264(2)–295(1) pm); the mean distance of 280(2) pm is similar to that found recently for the octahedral coordination of N^{3-} by Ba^{2+} ions (273.4 pm) in the subnitride Ba_3NaN.[15]

The formation of an azide at a reaction temperature of 1223 K is rather unlikely and has never been observed before. It can thus be assumed that $Ba_9N[N_3][TaN_4]_2$ is formed only at lower temperatures during the rapid temperature equilibration between 1223 K and room temperature. The preparation is certainly reproducible, although the yield is limited to only a few small crystals. Thus it has not yet been possible to extend these studies (for example, by vibrational spectroscopy measurements).

Bi[1,3-bis(dicyanomethylene)indan-2-ylidene]—An Ethylene Derivative with Extremely Pronounced Twisting of the C=C Bond**

By *Albert Beck, Rudolf Gompper,* Kurt Polborn,* and *H.-U. Wagner*

Dedicated to Professor Heinrich Nöth on the occasion of his 65th birthday

The activation energies of the (*Z*)/(*E*) isomerization of ethylene derivatives, which is usually quite large (for example, $E_a = 64.9\ kcal\,mol^{-1}$ for ethylene[1]), can be reduced by a stabilization of the transition state or by a destabilization of the ground state occasioned by mutual steric hinderance of bulky substituents (see ref.[2]) or by ring strain (Bredt, cf. ref.[3]). The steric congestion at the C=C bond can be relieved by *syn* or *anti* pyramidalization of the olefinic C atoms or a twisting about the bond axis between them. The energy content of the molecule increases with decreasing overlap of the p_z orbitals (see Table 1), and the HOMO–LUMO gap diminishes (see ref.[4] for the $\pi-\pi^*$ absorption energy as a function of strain).

A twisting of 90° in ethylene derivatives of the type $A_2C{=}CA_2$ (A = acceptor) or $Do_2C{=}CDo_2$ (Do = donor) leads to diradicals that are expected to have a singlet ground state.[5, 6] These twisted systems represent the transition state

of the *cis*/*trans* isomerization of alkenes. A similar twisting of ethylenes of the type $A_2C{=}CDo_2$ affords 1,2-dipoles (cf. ref.[7]). Twisted olefinic structures play an important role in photochemistry, because the reversion of the excited state to the ground state might occur from the 90° twisted state.[8]

The molecular structures of some sterically hindered ethylene derivatives in the solid state are known: The C atoms of the central double bond of the thermochromic bianthron,[9] bixanthylidene,[10] and heptafulvalene[11] are *anti* pyramidalized. Five-membered ring systems like perhalogenated fulvalenes[12] and 9,9′-bifluorenylidene[13] are twisted about the central double bond.

Tetra-*tert*-butylethylene, for which a torsional angle of 44° has been determined by force field calculations,[14] would be the most strongly strained acyclic olefin. Till now, however, it could not be synthesized.[15] Hitherto, the largest twist angles found in sterically hindered tetrakis(trialkylsilyl)-substituted alkenes were 48.7[16] and 49.6°.[17]

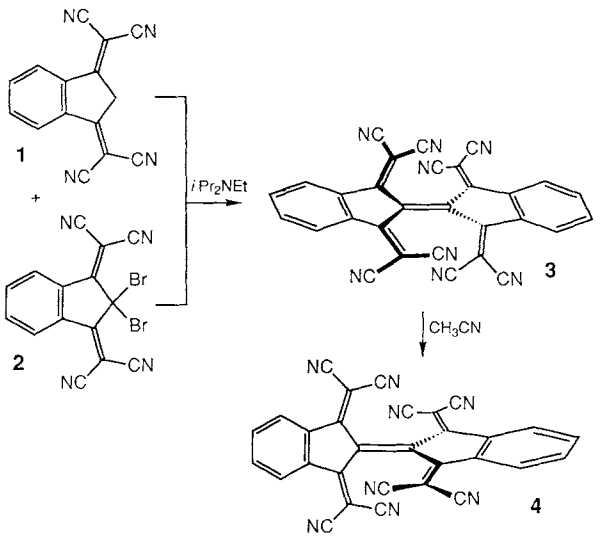
The data in Table 1 show that the twisting of a (symmetrically substituted) C=C bond causes a bathochromic shift of the longest wavelength absorption maximum (see also refs.[4,18]). However, only scant data can be found in the literature on such an effect. *N*,*N*′-Dialkylindigo derivatives with increasingly bulky alkyl groups, for instance, absorb at substantially longer wavelengths than the parent compound.[19] Moreover, quantum mechanical calculations on fulvalene predict that the bathochromism caused by twisting is accompanied by a decrease in the band intensity.[20]

The availability of semiconductor lasers with emission wavelengths between 780 and 840 nm has created a need for dyes that absorb in the near infrared (NIR). The synthesis of twisted ethylene derivatives could make a contribution to this topical research field.[21] A prerequisite is the presence of subchromophores that absorb at long wavelengths; twisting could then shift the absorption into the NIR. Such compounds have the additional advantage that information on the bonding can be obtained not only from the crystal structure analysis, but also from electronic spectra on the structure in solution.

We chose 1,3-bis(dicyanomethylene)indane (**1**)[22] as starting material, because it is sterically demanding and affords deeply colored merocyanines with donor-substituted benzaldehydes or *p*-nitrosodialkylanilines.[23] Their structures are, however, unknown. Indane **1** reacts with the dibromo derivative **2** in the presence of Hünig base (the blue color of the anion of **1** appears temporarily) to form the sparingly soluble, yellow "dimer" **3**, which is extremely susceptible to nucleophiles. The maximum of the longest wavelength absorption band of **3** at 405 nm suggests that the C atoms at the

double bond are planar or weakly pyramidalized. The relevant band in the structure-related bi(indanedionylidene) lies at 348 nm.[24]

A suspension of **3** in dry acetonitrile at room temperature converts slowly into the shiny black compound **4**; this process is complete after about six months. A qualitative electronic spectrum of the dark red mother liquor of the sparingly soluble, readily decomposable product was recorded. The longest wavelength absorption maximum (λ = 510 nm) has undergone a bathochromic shift of 105 nm relative to that of **3**.



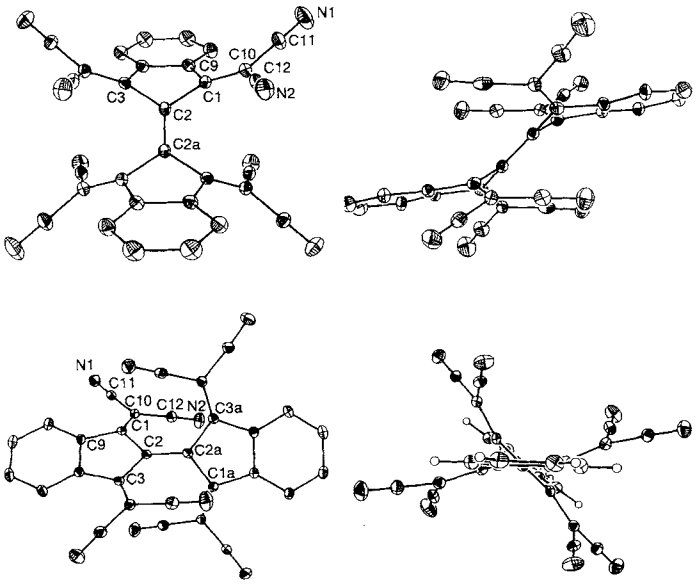


Fig. 1. Crystal structures of **3** (top) and **4** (bottom) (ORTEP). Left: View onto the central double bond. Right: side view (**3**) and view along the central double bond (**4**). Selected bond lengths [pm] and pyramidalization angles [°] for **3**: C1-C2 148.7(2), C1-C9 147.2(2), C1-C10 134.9(3), C2-C2a 134.1(3), C10-C11 143.9(3), C10-C12 143.6(3), C11-N1 113.4(3), C12-N2 113.9(3); C2-C2a: C1-C2-C3 8.0, C1-C10: C2-C1-C9 9.5, C1-C10: C11-C10-C12 5.8. **4**: Selected bond lengths [pm] and pyramidalization angles [°]: C1-C2 146.8(2), C1-C9 146.7(3), C1-C10 136.2(3), C2-C2a 140.2(3), C10-C11 143.7(3), C10-C12 143.8(3), C11-N1 113.6(3), C12-N2113.9(3); C1-C2-C2a-C3a 49.9, C3-C2-C2a-C1a 49.9; C1-C10: C2-C1-C9 9.7, C1-C10: C11-C10-C12 3.7.

The isomers **3** and **4** have different physical properties and are not interconvertible by heating the solid. Crystal structure analyses[26] show that **3** is a planar, only weakly pyramidalized ethylene derivative (Fig. 1, top), whereas **4** is a severely twisted system (Fig. 1, bottom).

The C atoms of the central double bond of **3** are weakly *anti* pyramidalized; the pyramidalization angle (definition in ref.[25]) of C2 and C2a is 8°. The C=C bond length of 134.1(3) pm is within experimental error in accord with the standard value of 133.0(9) pm.[27] The steric hinderance between the Y-shaped dicyanomethylene groups leads to a butterflylike arrangement of these groups. Each pair forms an angle of 47.2 or 47.8° with the C=C bonding plane, which is accompanied by an unusual folding of the five-membered ring of 32.0°, counteracting a strong pyramidalization of the atoms C1 and C3 of the dicyanomethylene groups. The dicyanomethylene groups are *syn* pyramidalized and twisted by 4.4 and 3.7° (definition in ref.[28]). The pyramidalization angles of the endocyclic C atoms C1 and C3 are 9.5 and 9.1°, respectively, whereas those of the exocyclic C atoms C10 and C13 are 5.8 and 6.9°, respectively. The C=C bond length in the dicyanomethylene groups (134.8 and 134.9 pm) agree with literature values.[29]

In **4** the central C=C bond is severely twisted (twist angle of 49.9°). The result is a pronounced lengthening of this double bond to 140.2 pm (134.1 in **3**). This value corresponds to 50% double-bond character. The C=C bond in the tetrasilylethylenes synthesized by Sakurai et al. are slightly shorter (136.9 pm (48.7°)[16], 137.0 pm (49.6°)[17]) and twisted to the same extent.

The remaining bond lengths of **3** are very similar to the corresponding bond lengths of **4**. The torsion in **4** causes the planarization of the indane framework to be lost. To relieve the steric congestion at the central double bond in **4**, too, the dicyanomethylene groups are *syn* pyramidalized (C1 9.7°, C3 13.9°, C10 3.7°, C13 5.1°) and slightly twisted (7.8°).

Indane **4** is probably the most twisted, symmetrically substituted ethylene derivative that has been synthesized to date. Though Sakurai et al.[16] reported a twisting of 50.2°, the twist angle is defined[28] as the average of both twist angles (50.2, 47.1°) and is thus actually 48.7° for the *anti*-pyramidalized alkene studied by them. Ballester et al.[30] give a twist angle of 67° for perchlorobifluorenylidene; the crystal structure analysis has, however, not yet been published. The structural data in a further paper on this work[31a] is very inaccurate, and this twist angle cannot be considered confirmed.

The synthesis of **3** and **4** affords for the first time an alkene[31b] in two conformations that differ by a partial rotation about the C=C bond, which allows a quantative description of the bonding changes during torsion in the crystal and in solution.

The electronic spectra of **3** and **4** calculated with an MNDO-CI program[32] from the X-ray structural data placed the longest wavelength $\pi-\pi^*$ transitions at 353 nm (oscillator strength f = 0.368) for **3** and 566 nm (f = 0.087) for **4**. The calculated excitation energies agree satisfactorily with the experimental λ_{max} values of **3** (405 nm) and **4** (510 nm).

The finding that the twisting about the central double bond in **4** relative to the almost planar structure **3** leads to a bathochromic shift of the longest wavelength absorption maximum of approximately 105 nm is the first direct experimental evidence for the thermo- and photochromism of some ethylene derivatives.[33] Torsion has already been postulated as cause of the color change on heating or irradiation; this was hitherto supported only indirectly by quantum mechanical calculations and NMR experiments.[34]

Experimental Procedure

3: Compounds **1** (0.48 g, 2 mmol) and **2** (0.88 g, 2 mmol) were suspended in dry dichloromethane (15 mL). After addition of ethyldiisopropylamine (0.70 mL, 4 mmol), the light yellow suspension immediately turned deep blue; after 15 min yellow microcrystals began to precipitate. The mixture was stirred for three days at room temperature before the crystals were filtered off by suction, washed with dichloromethane till the washings were colorless, and finally washed again with hot glacial acetic acid and with ether. Yield: 0.17 g (85%). Correct elemental analysis. Yellow prisms, m.p. > 350 °C (from CH_3CN); IR (Nujol): $\tilde{\nu}$ = 2253 (m, C≡N), 2235 (s, C≡N), 2230 (m, C≡N), 1603 (s, C=C), 1575 (s, C=C) cm^{-1}; UV/VIS(CH_2Cl_2): λ_{max} (lg ε) = 278 (42700), 293 (43100), 405 nm (8900); MS (325 °C): *m/z* = 480 (100, M^+), 4541(15, M^+−CN),453 (11%, M^+−HCN). A cubic crystal, suitable for crystal structure analysis, was obtained by recrystallization from dry acetone at 4 °C.

4: A suspension of the recrystallized compound **3** in dry acetonitrile was allowed to stand for about six months under nitrogen at room temperature. The solution slowly became very dark red, and black crystals grew at the expense of the yellow ones. Correct elemental analysis. Shiny black crystals, m.p. 280–282 °C (decomp.); IR (Nujol): $\tilde{\nu}$ = 2228(s, C≡N), 2220(m, C≡N), 2211(m, C≡N), 1584(m, C=C), 1556(s, C=C), 1510(s, C=C), 1502(s, C=C); UV/VIS(CH_3CN): λ_{max} (lg ε) = 242, 293(sh), 329, 510 nm; MS (155 °C): *m/z* = 482 (100, M^+ + 2H), 480(34, M^+), 454(13%, M^+−CN), 418(40), 390(10%).

Rapid Construction of Large-size Phenylacetylene Dendrimers up to 12.5 Nanometers in Molecular Diameter**

By *Zhifu Xu* and *Jeffrey S. Moore**

The preparation and characterization of dendrimers or cascade molecules[1] are currently of widespread interest. With dendritic macromolecules, high molecular weight and a high level of structural control are possible with tremendous synthetic efficiency, because the methods of preparation rely on repetitive, nonlinear growth schemes.[2] To date, the nonlinear mathematical relationship that forms the basis of dendrimer growth has been simple geometric progression. The corresponding molecular structures quickly fill space in three dimensions, resulting in compact, globular shapes. In fact, the increase in volume per generation, based on added the properties of these macromolecules.

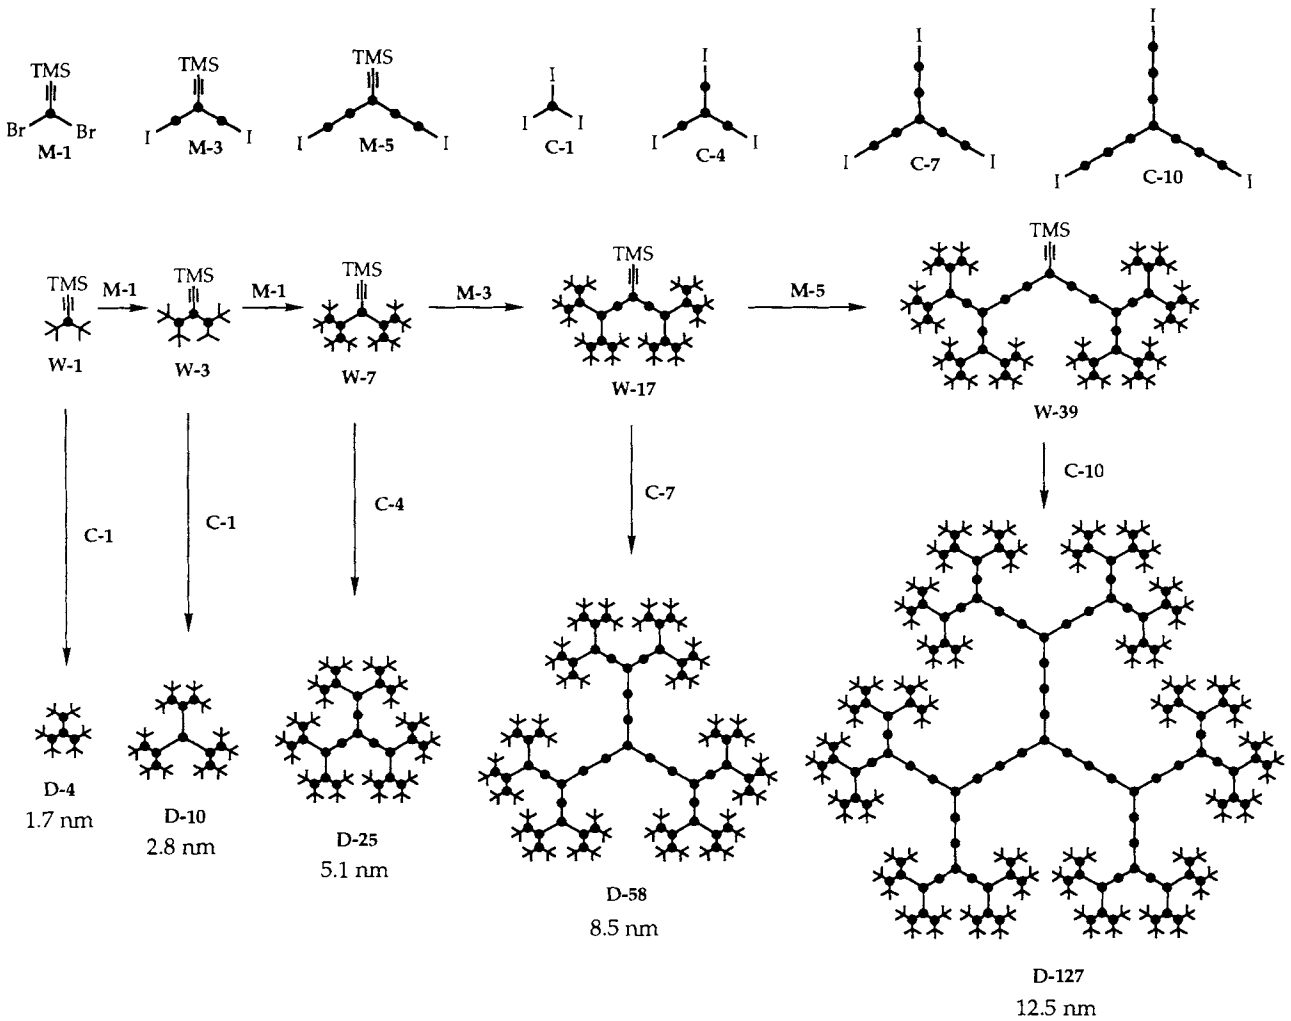
molar mass, changes at a rate that is faster than the space available given the monomer's geometric constraints.[3] We envisioned that other patterns of nonlinear repetitive growth, when translated into synthetic chemistry, would lead to molecules with molecular architectures completely different than the highly compact globular shapes of traditional dendrimers. Here we describe one strategy that leads to greatly expanded structures, enabling large-size macromolecules to be realized after only a few repetitive cycles.[4] The idea for this new strategy was proposed two years ago,[5] but poor solubility in the original dendrimers prevented growth beyond a monodendron with 17 monomer units. The solubility of phenylacetylene dendrimers is greatly enhanced by using di-*tert*-butylphenyl peripheral groups,[6] and here we use this finding to demonstrate the full utility of this new convergent synthetic method.

The new strategy combines a linear increase in monomer size per generation with the conventional convergent[1] dendrimer growth method.[7] Scheme 1 illustrates this method for dendrimers constructed from phenylacetylene monomers. In this scheme, benzene rings are represented by filled circles (•) and C≡C linkages between rings by solid lines. The angle defined by the benzene ring connectivity (*meta* or *para*) is represented in the scheme as 120° or 180° at each vertex, respectively. The advantage of constructing dendrimers from rigid building blocks such as phenylacetylene units is that the resulting macromolecules have overall dimensions that are almost invariant of conformation; thus, the interpretation of molecular size data does not depend strongly on experimental conditions nor does it require assumptions about the macromolecule's conformational state. The concept of macromolecules that are "dimension-persistent" or "shape-persistent" is important for developing molecular scaffoldings that control functional group placement on the size scale of 1–10 nm.

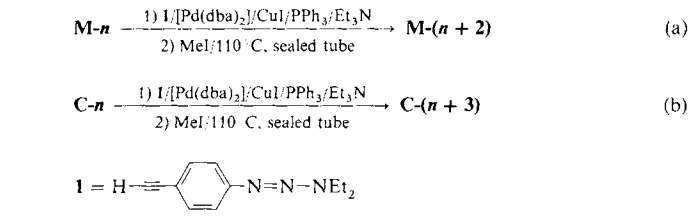
As shown in Scheme 1, the method requires a series of monomers (**M-1**, **M-3**, **M-5**) as well as cores (**C-1**, **C-4**, **C-7**, **C-10**) that gradually increase in size. For both monomers and cores, enlargement is accomplished by catenation of *para*-linked phenylacetylene structural units. Cores **C-1**, **C-4**, **C-7**, **C-10** span radii of 2.8, 9.7, 16.6, and 23.4 Å, respectively, as determined by molecular models. Core **C-10** is only sparsely soluble in organic solvents, but it has proven to be adequately soluble for subsequent transformations. These enlarged units are easily synthesized by using the repetitive protection/deprotection chemistry that we have described for linear phenylacetylene oligomers [Eqs. (a) and (b), dba = dibenzylideneacetone].[8]

For example, **M-3** is prepared by coupling **M-1** with two equivalents of *para*-protected phenylacetylene **1** followed by transformation of the triazene to the iodo functionality. Similarly, **C-4** is synthesized by coupling **C-1** and three equiva-



Scheme 1. Method for the preparation of phenylacetylene dendrimers that combines a linear increase in monomer/core size per generation with the convergent dendrimer growth process. Structural elements: ⅄: 1,3,5-connected benzene ring, —•—: 1,4-connected phenylene unit, ⋋⋌: 1,3-di-*tert*-butylphenyl unit, —: C≡C unit. TMS = trimethylsilyl.

 © *VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1993* *0570-0833/93/0909-1355 $ 10.00+.25/0*



lents of **1**, and subsequently converted to the iodide. These enlarged monomers are integrated with the convergent method of dendrimer growth as shown in Scheme 1 to prepare a series of monodendrons (**W-3**, **W-7**, **W-17**, and **W-39**) containing 3 to 39 monomeric units. This is accomplished by repetitive trimethylsilyl deprotection and then palladium-catalyzed coupling with the appropriate size monomer. All of these monodendrons have been fully characterized by ^{1}H and ^{13}C NMR spectroscopy, elemental analysis, size-exclusion chromatography (SEC), and thin-layer chromatography (TLC). ^{1}H NMR spectra acquired under carefully chosen conditions (temperature, solvent) give adequate chemical shift dispersion for **W-39** for complete assignment of all the resonance signals. Finally, the new tridendrons are obtained by coupling the deprotected monodendrons with the indicated core. The process ultimately leads to the 127-mer tridendron, **D-127**, whose overall diameter as measured from molecular models spans 125 Å. This size would be nearly impossible to achieve simply by following the traditional convergent route alone.

Structure and purity (>95%) for **D-4**, **D-10**, **D-25** has been confirmed by the characterization methods described previously. Characterization of the higher members of the series has been more challenging. By using two-dimensional H,H-COSY and *J*-resolved experiments, the signals in the ^{1}H NMR spectrum of **D-58** have been completely assigned. For spectra recorded in [D_6]benzene resonances from protons on all the *para*-linked phenyl rings are fully resolved from the resonances from protons on the 1,3,5-connected aromatic rings. The former are located further upfield and exhibit the characteristic AA'BB' pattern. The two-dimensional *J*-resolved ^{1}H NMR spectrum of the aromatic region of **D-58** shows four AB_2 (nearly AX_2) spin systems at low field corresponding to four triplet–doublet pairs and a singlet corresponding to the A_3 spin system of the core. The two-dimensional H,H-COSY-45 ^{1}H NMR spectrum also confirms the expected *J*-coupling correlations, and integration is consistent with the expected composition within ±5%. In the case of **D-127**, complete characterization has been even more difficult. Elemental analysis data of the isolated product is consistent with the chemical structure of **D-127** ($C_{1398}H_{1278}$: calcd: C, 92.87; H, 7.13; found: C, 92.84; H, 7.19). SEC data are consistent with its high purity (M_n = 31 000 and M_w/M_n = 1.04 relative to polystyrene). While NMR spectral data are consistent with the expected structure, complete assignment for this molecule has not been possible. The triconnected rings in the inner two tiers as well as all of the *para*-connected rings are strongly second order and severely overlapped. Attempts at increasing dispersion through variation of temperature, solvent, and the addition of silver-lanthanide shift reagents[9] have not proven successful. Moreover, dendrimer **D-127** shows a very strong tendency to tail on both normal and reverse phases, thus deteriorating the resolution of analytical chromatography. Because of these problems, we have not been able to unambiguously prove the structure or purity of **D-127**.

Molecular models and SEC data show that all the tridendrons made by the present method have greatly expanded molecular dimensions compared with the dendrimers prepared from the standard convergent method. Hydrodynamic radii of **D-58** and **D-127** relative to polystyrene were measured by SEC to be 40 and 59 Å, respectively.[10] Thus, the advantage of Scheme 1 for dendrimer preparations is that large sizes are achieved after only a few cycles through the repetitive process. To illustrate how rapidly the size of the molecule increases by this new method, the *third* generation tridendron **D-58** containing 58 aromatic units elutes with a polystyrene equivalent hydrodynamic radius that is almost 1.5 times larger than that of the *fourth* generation compact tridendron prepared[6] by the traditional convergent growth scheme (containing 94 aromatic units). The polystyrene equivalent hydrodynamic radius of the 94-mer was determined to be 29 Å. The rapid growth in size observed for these dendrimers is efficiently expressed because of the stiff nature of the phenylacetylene monomeric unit.

It is evident that by coupling the nonlinear character of dendrimer syntheses to a linear increase in monomer size as a function of generation, growth in terms of size is dramatically accelerated. This method also results in significant changes in molecular architecture, leading to much more expanded structures. We believe that there are other nonlinear repetitive growth schemes, each perhaps leading to unique and interesting macromolecular architectures. These structural variations may have important consequences on the properties of these macromolecules.

Experimental Procedure

General procedure for tridendron (**D-4**, **D-10**, **D-25**, **D-58**, **D-127**) synthesis: A single-neck flask with a side arm was charged with **W-*x*** (3.3 equiv), **C-*y*** (1.0 equiv), [Pd(dba)$_2$] (0.02 equiv), triphenylphosphane (0.1 equiv), copper(I) iodide (0.02 equiv), and dry triethylamine. The concentrations of the reaction varied from 0.3 to 0.01 M depending on the molecular weight of the reactants. The flask was then evacuated and back-filled with nitrogen three times, capped, and stirred at 40 °C. The disappearance of terminal acetylene was checked by TLC. After completion, the reaction mixture was diluted with dichloromethane, washed with water (3 ×) and saturated aqueous sodium chloride, dried over anhydrous sodium sulfate, and filtered. Following concentration, the product was purified by careful flash chromatography, eluting with a mixture of petroleum ether and dichloromethane.

D-4: Yield 77%, m.p. 229–231 °C. ^{1}H NMR (360 MHz, [D_6]benzene, 295 K): δ = 7.81 (s, 3H), 7.663 (d, ^4J(H,H) = 1.8 Hz, 6H), 7.518 (t, ^4J(H,H) = 1.8 Hz, 3H), 1.25 (s, 54H); ^{13}C NMR (360 MHz, $CDCl_3$): δ = 150.94, 133.87, 125.97, 124.26, 123.06, 121.91, 91.61, 86.80, 34.83, 31.35. Correct C,H analysis ($C_{54}H_{66}$).

D-10: Yield 73%. ^{1}H NMR (360 MHz, [D_6]benzene, 295K): δ = 7.845 (t, ^4J(H,H) = 1.4 Hz, 3H), 7.812 (d, ^4J(H,H) = 1.4 Hz, 6H), 7.698 (d, ^4J(H,H) = 1.8 Hz, 12H), 7.665 (s, 3H), 7.53 (t, ^4J(H,H) = 1.8 Hz, 6H), 1.25 (s, 108H); ^{13}C NMR (360 MHz, $CDCl_3$): δ = 151.00, 134.52, 134.47, 133.98, 126.02, 124.45, 123.90, 123.42, 123.17, 121.81, 91.88, 89.38, 88.59, 86.62, 34.85, 31.35. Correct C,H analysis ($C_{126}H_{138}$).

D-25: Yield 87%. ^{1}H NMR (360 MHz, [D_6]benzene, 295K): δ = 7.85 (t, ^4J(H,H) = 1.5 Hz, 6H), 7.802 (d, ^4J(H,H) = 1.5 Hz, 12H), 7.75 (s, 3H), 7.711 (d, ^4J(H,H) = 1.5 Hz, 6H), 7.702 (d, ^4J(H,H) = 1.8 Hz, 24H), 7.672 (t, ^4J(H,H) = 1.5 Hz, 3H), 7.53 (t, ^4J(H,H) = 1.8 Hz, 12H), 7.39–7.45 (m, 12H, protons on the *para*-linked phenyl rings), 1.25 (s, 216H); ^{13}C NMR (360 MHz, $CDCl_3$): δ = 150.94, 134.46, 134.35, 133.90, 131.71, 125.97, 124.44, 123.98, 123.91, 123.83, 123.40, 123.12, 123.00, 122.95, 121.81, 91.91, 90.43, 90.37, 89.81, 89.74, 89.36, 88.62, 86.62, 34.81, 31.33. Correct C,H analysis ($C_{294}H_{294}$).

D-58: Yield 88%. ^{1}H NMR (360 MHz, [D_6]benzene, 295K): δ = 7.853 (t, ^4J(H,H) = 1.6 Hz, 12H), 7.806 (d, ^4J(H,H) = 1.6 Hz, 24H), 7.75 (t, ^4J(H,H) = 1.5, 3H), 7.733 (d, ^4J(H,H) = 1.5, 6H), 7.72 (s, 3H), 7.71–7.70 (m, 60H), 7.675 (t, ^4J(H,H) = 1.5 Hz, 6H), 7.53 (t, ^4J(H,H) = 1.8 Hz, 24H), 7.37–7.45 (m, 48H, protons on the *para*-linked phenyl rings), 1.25 (s, 432H); ^{13}C NMR (360 MHz, $CDCl_3$): δ = 150.98, 134.50, 134.38, 133.93, 131.76, 131.73, 131.66, 125.99, 124.44, 123.97, 123.88, 123.39, 123.16, 121.79, 91.87, 90.35, 89.74, 89.37, 88.57, 86.60, 34.85, 31.34. Zirconium Phosphite (3,3′,5,5′-Tetramethylbiphenyl)diphosphonate, a Microporous, Layered, Inorganic–Organic Polymer**

By *Giulio Alberti,** *Umberto Costantino, Fabio Marmottini, Riccardo Vivani,* and *Piergiorgio Zappelli*

The chemistry of layered materials was greatly extended after the observation that organophosphonates with four-coordinate metal ions can be obtained in crystalline form with a layered structure similar to that of α-zirconium phosphate.[1] An appreciable number of pure and mixed metal(IV) phosphonates have already been prepared and characterized in various laboratories, and some of these may have practical applications as catalysts, hosts in intercalation compounds, and protonic conductors.[2–5] Only some years after the preparation of the first layered α-zirconium organophosphonate, metal(IV) diphosphonates $M^{IV}(O_3P\text{–}R\text{–}PO_3)$ were obtained by a similar procedure.[6] In these compounds, adjacent inorganic α-type layers are joined covalently by the organic R groups. Since materials with specific interlayer porosity can be prepared by simply changing the length of the organic R group, metal(IV) diphosphonates were termed MELS (Molecularly Engineered Layered Structures) to emphasize their practical potential.[7]

The structure of a typical "pillared" compound in which the organic group joining the α layers is an aromatic ring is shown schematically in Figure 1a. It is evident from this figure that the R groups are very crowded owing to the small distance (5.3 Å) between adjacent attachments in the α layer, and that the free space in the interlayer region is insufficient, regardless of the length of the organic R group. It was initially believed[8] that crystalline compounds would result if a number of pillars were replaced with small $O_3P\text{–}R'$ groups (R′ = H, OH, CH_3) (Fig. 1b). Unfortunately, only compounds with a low degree of crystallinity and low surface area, mainly because of intercrystalline mesoporosity, were obtained with the usual preparation methods.[9] A new synthetic strategy led to the realization of the first zirconium diphosphonate with covalently attached, interlamellar pillars with a high degree of crystallinity and interlayer porosity. To understand this approach, one should consider the O_3P groups on one side of the α layer to be arranged at alternate vertices of a hexagonal array structure separated by 5.3 Å and with a free area of 24 Å^2 around each O_3P group.[10] If the maximum van der Waals cross section of the pillar groups R is less than 24 Å^2, all the binding sites of the inorganic framework can be occupied, and a regular distribution of the pillars is expected. On the other hand, if the cross section of the pillars is greater than 24 Å^2, adjacent positions cannot be occupied by the large pillars, and pure zirconium diphosphonates cannot be obtained. The formation of mixed phosphonate phases containing large and small interlayer groups R and R′, respectively, is nevertheless possible if the sum of the cross section radii ($r_R + r_{R'}$) of two adjacent groups is ≤5.3 Å.

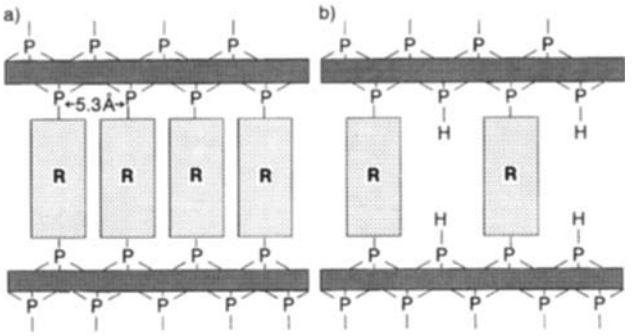

Fig. 1. a) Schematic model of a pillared zirconium phenyl diphosphonate. The size of the pillars, R = benzenediyl, is described by their van der Waals radii. b) Here some of the pillars have been substituted with small O_3PH groups.

The distribution of the large and small groups should be similar to that illustrated schematically in Figure 2. Note that the correspondenting composition is $Zr(O_3P\text{–}H)_{1.33}(O_3P\text{–}R\text{–}PO_3)_{0.33}$. Six small phosphite groups surround each large diphosphonate pillar. If the cross section of the

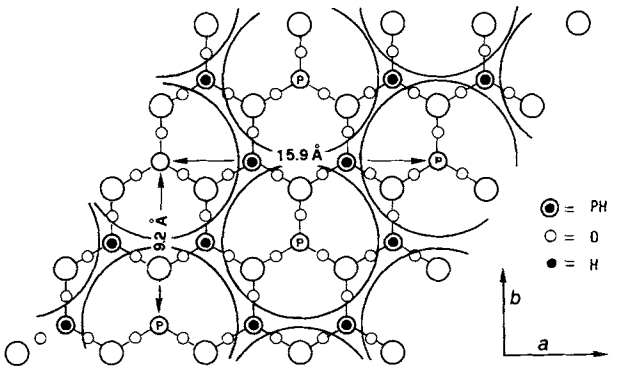

Fig. 2. Idealized arrangement of small phosphite groups and large diphosphonate pillars on one side of the α layers; the idealized structure corresponds to the composition $Zr(O_3PH)_{1.33}(O_3P\text{–}R\text{–}PO_3)_{0.33}$.

large pillars is uniform, little or no interlayer porosity is expected (Fig. 3a). However, if the cross section is not uniform, and in particular if the cross section of the pillar in the middle is smaller than at the ends, interlayer porosity results (Fig. 3b). This type of pillar could be prepared with the R

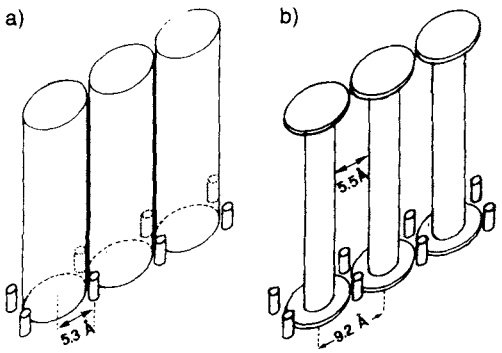

Fig. 3. a) Schematic representation of the structure described in Figure 2 (small phosphite groups and large diphosphonate groups with uniform cross section). View along the *a* axis. Note that no appreciable interlayer porosity is created. b) Here the large diphosphonate groups are broader at the ends than in the middle. Interlayer porosity is created.

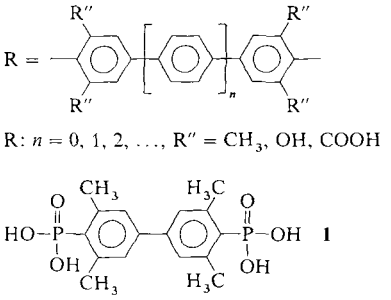
groups shown in Scheme 1. Thus we synthesized diphosphonic acid **1**, and the corresponding pillared zirconium phosphite diphosphonate **2**.



Scheme 1.

The chemical and NMR spectroscopic analyses gave a P:Zr molar ratio of 2:1 and a phosphite:diphosphonate molar ratio of 3:1, which implies that the composition of this compound is $Zr(HPO_3)_{1.2}(O_3P–R–PO_3)_{0.4}$ ($R = Me_2H_2C_6–C_6H_2Me_2$). The X-ray diffraction powder pattern of **2** is typical of a fairly crystalline, α-layered, pillared compound.[11]

The high phosphite content and the good degree of crystallinity are in agreement with the model in Figure 2; furthermore, the predicted microporosity was experimentally confirmed. The specific surface area, calculated by the BET analysis, was 375 $m^2 g^{-1}$. The micropore distribution curve obtained by the T-plot analysis, has a sharp maximum for a pore size of about 5 Å (Fig. 4). This result was also confirmed by ^{129}Xe NMR spectroscopy.[12]

A computer-generated structural model for the ideal composition $Zr(HPO_3)_{1.33}(O_3P–R–PO_3)_{0.33}$ is shown in Figure 5. In this model it was assumed that the diphosphonate groups are perpendicular to the α layers and that all the arene rings have the same orientation. Although these assumptions might be too strict, it can be noted that both the interlayer spacing (14.5 Å) and the free average intercolumnar distance

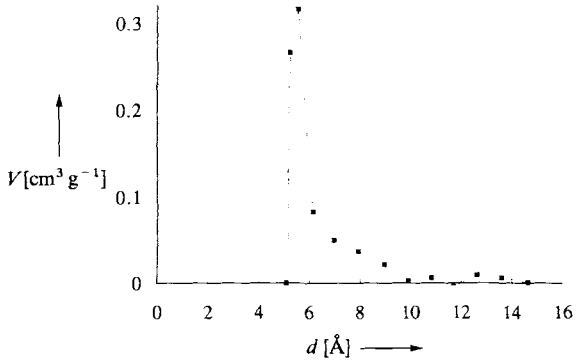


Fig. 4. Micropore-size distribution of $Zr(HPO_3)_{1.2}(O_3P–R–PO_3)_{0.4}$; R = 3,3',5,5'-tetramethylbiphenyl. *d* = pore size.

deduced from the model (5 Å) are in good agreement with the position of the first reflection in the X-ray diffraction pattern (14 Å) and with the pore size determined experimentally. The structure of this pillared compound in which the pillars have broadened bases, is reminiscent of the architecture of a Greek temple.

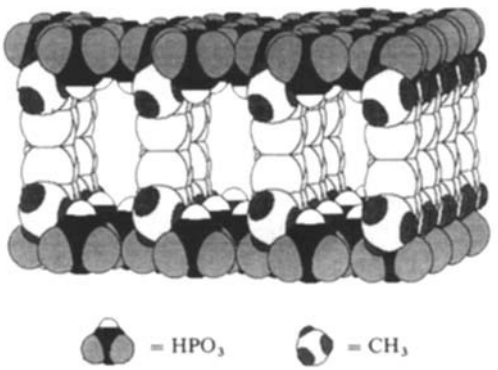

Fig. 5. Computer-generated structural model of the pillared compound with the idealized composition $Zr(HPO_3)_{1.33}(O_3P–R–PO_3)_{0.33}$; R = 3,3',5,5'-tetramethylbiphenyl. Zirconium atoms are omitted for clarity.

This type of microporous inorganic–organic polymer with tailor-made cavities of uniform size, possibly containing catalytic sites, opens the way for their application as molecular sieves and "shape-selective" catalysts.

Experimental Procedure

1: To a solution of *tert*-butyl nitrite (32 g, 312 mmol) in bromoform (75 mL) was added a solution of 3,3',5,5'-tetramethylbenzidine (25 g, 104 mmol) in bromoform (175 mL). The mixture was stirred for 2 h at 65 °C. After workup and column chromatography (silica gel, petroleum ether), the intermediate 4,4'-dibromo(3,3',5,5'-tetramethyl)biphenyl was recovered (16.5 g, 43% yield). This was then subjected to a photocatalyzed phosphonation reaction by irradiating a solution in triethyl phosphite with a high-pressure mercury vapor UV lamp. After workup and column chromatography (silica gel, ethyl acetate/petroleum ether (7:3)), the next intermediate, tetraethyl-[(3,3',5,5'-tetramethyl)biphenyl]-4,4'-bisphosphonate was collected (11.2 g, 51.7% yield). This second intermediate was hydrolyzed by heating for 4 h at 80 °C with HBr in acetic acid to afford **1** (94% yield). ^1H NMR (400 MHz, [D$_6$]DMSO, 25 °C): $\delta = 2.65$ (s, 12H, CH_3), 7.40 (4H, Ar); ^{31}P NMR (400 MHz, [D$_6$]DMSO, 25 °C): $\delta = 17.02$, relative to H_3PO_4, external.

2: Preparation according to the method of thermal decomposition of fluorozirconium complexes [13]. Diphosphonic acid **1** (1.036 g, 2.8 mmol) and H_3PO_3 (4.14 g, 50.5 mmol) were dissolved in DMSO (28 mL) and water (6 mL) in a plastic vessel, then treated with a solution of $ZrOCl_2 \cdot 8H_2O$ (0.602 g, 1.9 mmol) in conc. HF (1.6 mL) and water (4.4 mL). The closed vessel was placed in a thermostated bath at 70 °C, and the temperature was increased at the rate of 5 °C per hour. When the solution began to show a slight turbidity (at

about 80 °C), the temperature was reduced by 5 °C and then slowly increased at the rate of 2 °C per day up to 95 °C. The solid product was filtered, washed with DMSO and then acetone, dried under air, and stored under P_4O_{10}. Correct elemental analysis. ^{31}P NMR (200 MHz, DMSO/D_2O (2:1), 50 mg of **2** dissolved in 1 mL of 2 M HF, 25 °C): $\delta = 19.6$ (br. m, PCH(Ar)), 6.9 (d, $^1J(P,H) = 665.3$ Hz, PH), the shifts are relative to 85% D_3PO_4 in D_2O, external.

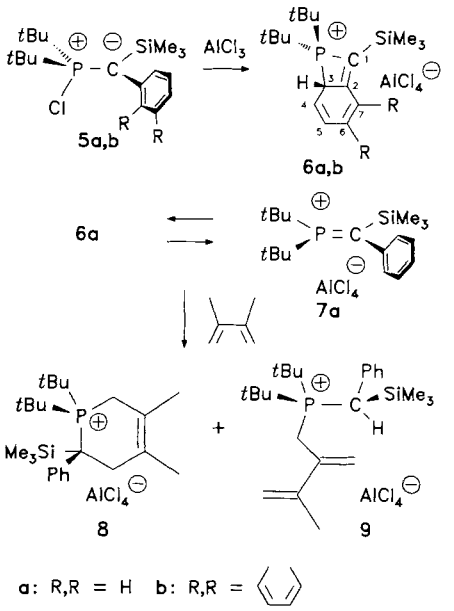
increase in charge separation between the phosphorus and carbon atoms of the double bond of about 0.2–0.3 e per silyl group, which acts as a π acceptor.[6] Replacement of the hydrogen atoms at the phosphorus center with methyl groups increases this difference still further. The polarizing effect of the silyl group can be utilized in a simple and productive synthesis of novel, four-membered phosphorus–carbon heterocycles.[7]

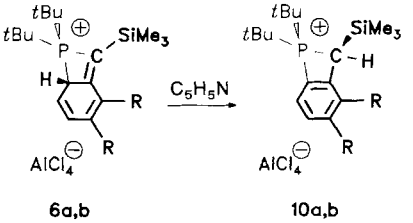
Thus, halogenated ylides **5** react almost quantitatively with $AlCl_3$ to give the previously unknown dihydrophosphetium salts **6** (Scheme 1).[8] The formation of **6** may be



Scheme 1.

explained in terms of an *intra*molecular electrocyclic ring closure of intermediate methylenephosphonium ions **7** (**7a**: aryl = phenyl, **7b**: aryl = naphthyl). A change in coordination geometry at the electrophilic phosphorus center from trigonal-planar in **7** to tetrahedral in **6** is energetically favorable, and compensates for the loss of conjugation energy of the aryl ring as well as the ring strain caused by the formation of the four-membered ring. The ring closure that leads to **6a** is reversible, and the methylenephosphonium ion **7a**, which is present at equilibrium in low concentration, reacts with 2,3-dimethylbutadiene (DMB) to give the [2 + 4] cycloadduct **8** and ene reaction product **9** [ratio **8**:**9** ca. 2:1; ^{31}P NMR: $\delta = 45.3$ (**8**), $\delta = 53.6$ (**9**); c.f. ref.[3]]. We could not, however, detect **7a** spectroscopically.

Whereas solutions of **6a** decompose within 24 h to products of indeterminate composition (not, however, **10a**), **6b** is stable, and likewise does not react with DMB. This cyclization reaction of methylenephosphonium ions described here



Benzoannulated Phosphorus–Carbon Four-Membered Rings**

By *Udo Heim, Hans Pritzkow, Ulrich Fleischer,* and *Hansjörg Grützmacher**

Dedicated to Professor Hans Bock on the occasion of his 65th birthday

The polarizing effect of silyl substituents[1] on multiply bonded systems is highly pronounced, and well defined experimentally.[2] We have previously investigated the influence of a trimethylsilyl group on the double bond of methylenephosphonium salts.[3] Population analyses for the molecules $H_2P{=}CH_2^+$ (**1**) [q(P): +0.7, q(C): −0.2], $H_2P{=}C(SiH_3)_2^+$ (**2**) [q(P): +0.7, q(C): −0.7],[4] $Me_2P{=}CH_2^+$ (**3**) [q(P): +1.0, q(C): −0.2], and $Me_2P{=}CH(SiH_3)^+$ (**4**) [q(P): +1.0, q(C): −0.5][5] show an

can be compared with the Bischler–Napieralski cyclization of iminium ions $R_2N{=}CR'^{+}_2$, in which the C terminus acts as the electrophilic center.[9] An *inter*molecular phosphorylation of arenes (toluene, anisole) with methylenephosphonium ions has not been achieved to date.

Upon addition of a tertiary amine base (preferably pyridine), both **6a** and **6b** undergo irreversible and quantitative rearrangement to the stable, isomeric phosphetanes **10a** and **10b**.[10] Whereas **6b** is unreactive towards acids (e.g. $HBF_4 \cdot OEt_2$), **6a** gives rise mainly to $tBu_2PClCHPh(SiMe_3)^+X^-$ (X = BF_4, Cl) **11**, small amounts of **10a**, and a further uncharacterized product (^{31}P NMR: $\delta = 158.3$).

The molecular structures of the heterocycles **6b** and **10b** (Fig. 1) were determined by single-crystal X-ray diffraction analyses.[11] Within the planar four-membered rings of **6b**

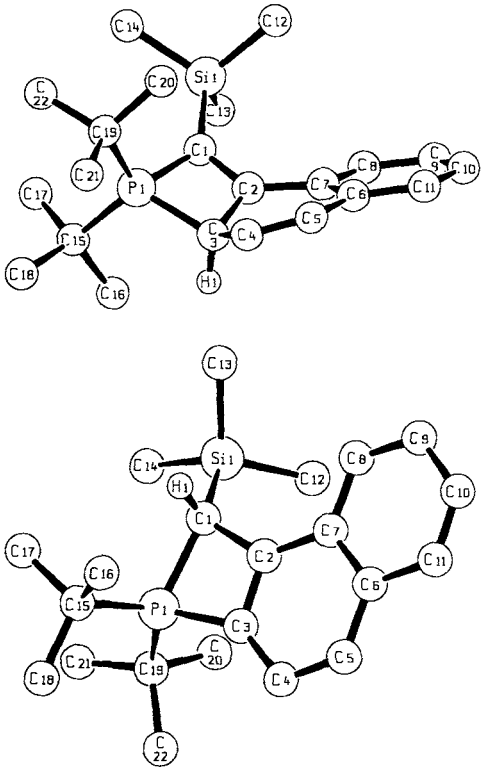

Fig. 1. Top: Crystal structure of cation **6b**: Selected distances [Å] and angles [°]: P1-C1 1.798(3), C1-C2 1.366(4), C2-C3 1.514(4), C3-P1 1.856(3), C3-C4 1.495(5), C4-C5 1.317(5), C5-C6 1.458(5), C6-C7 1.408(4), C7-C8 1.385(4), C8-C9 1.384(5), C9-C10 1.372(5), C10-C11 1.370(5), C11-C6 1.398(4), C2-C7 1.463(4); C3-P1-C1 79.1(1), P1-C1-C2 89.7(2), C1-C2-C3 107.7(2), C2-C3-P1 83.2(1), C2-C3-C4 111.7(3), C4-C3-P1 128.0(2), P1-C1-Si1 137.3(1), Si1-C1-C2 132.2(2), C1-C2-C7 132.9(2), C7-C2-C3 118.6(2). Bottom: Crystal structure of cation **10b**: Selected distances [Å] and angles [°]: P1-C1 1.859(3), C1-C2 1.549(5), C2-C3 1.360(5), C3-P1 1.781(3), C3-C4 1.420(5), C4-C5 1.350(6), C5-C6 1.409(6), C6-C7 1.438(5), C7-C8 1.402(6), C8-C9 1.360(6), C9-C10 1.401(8), C10-C11 1.328(8), C11-C6 1.421(6), C2-C7 1.424(4); C3-P1-C1 78.7(1), P1-C1-C2 83.8(2), C1-C2-C3 105.0(3), C2-C3-P1 92.5(2), C2-C3-C4 123.7(3), C4-C3-P1 143.8(3), P1-C1-Si1 129.8(2), Si1-C1-C2 123.7(2),C1-C2-C7 133.7(3), C7-C2-C3 121.2(3).

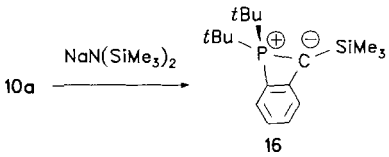
and **10b**, the bond angle at the phosphorus center is the smallest, and is almost identical for both heterocycles (79.1° **6b**, 78.7° **10b**). The P–C bonds in the four-membered ring are conistent with normal P–C(sp^3) and P–C(sp^2) distances. In the course of the de- and reprotonation, the change in coordination number of carbon atoms C1 and C3 gives rise to the predicted differences in the molecular geometry: the C1–C2 double bond in **6b** [1.366(4) Å] is lengthened to 1.549(5) Å in **10b**, corresponding to a single bond, whereas the C2–C3 distance in **6b** [1.514(4) Å] is shortened to 1.360(5) Å in **10b**. In accordance with this, a reciprocal shortening/lengthening is observed in the P1–C1 [**6b**: 1.798(3) Å; **10b**: 1.859(3) Å] and P1–C3 [**6b**: 1.856(3) Å; **10b**: 1.781(3) Å] distances. Consideration of the C–C distances in **6b** (Fig. 1 top) indicates that the bonding system in **6** is accurately represented by the valence-bond formula illustrated in Scheme 1. The C–C bond lengths in **10b** differ only slightly from those in naphthalene,[12] and only the C6–C7 distance (1.429(4) Å) is longer than that of the parent hydrocarbon (1.393 Å). Analogous with **6a** and **10a** are 3-methylene-1,4-cyclohexadiene **12** (*ortho*-isotoluene) and toluene **13**, where the latter is 24 ± 1.8 kcal mol^{-1} more stable than its isomer **12**.[13] Benzoannulation reduces the energy difference between conjugated polyenes and arenes [cf. $\Delta(\Delta H_f) = 15.8 \pm 1.8$ kcal mol^{-1}] for 1-methylene-1,4-dihydronaphthalene **14** and 1-methylnaphthalene **15**), and this explains the high stability of **6b**. Compared with **12** and **14**, compounds **6a**, **b** are remarkably resistant towards acid-catalyzed rearrangement to cyclic, conjugated electron systems. This is attributed to the π electron withdrawing effect of the Me_3Si group and to a greater degree the π electron withdrawing effect of the phosphonio group.[14] Rearrangement is thus prevented by the reduced basicity of the C1=C2 bond in the position α to the heterosubstituents in addition to the positive charge of the cation (Coulomb barrier).

With a strong base such as sodium bis(trimethylsilyl)amide, the cyclic phosphonium salt **10a** is deprotonated smoothly, to give, as expected, the neutral λ^5-phosphete **16**.[7b, 15] This ring



system has not, to our knowledge, been reported to date, and is prepared here for the first time with classical methods.[16]

Experimental Procedure

All manipulations were carried out in dry, oxygen-free solvents.

6a, b: 3 mmol of the phosphorus ylide **5a** (1.03 g) or **5b** (1.25 g) was dissolved in CH_2Cl_2 (10 mL) and added dropwise at -78 °C to a suspension of powdered $AlCl_3$ (0.53 g, 4 mmol). The reaction mixture was stirred for 10 min at -78 °C, and then filtered rapidly below -30 °C. After removal of all volatiles at 0.01 Torr, the product was obtained spectroscopically pure as a pale yellow powder, which was recrystallized from CH_2Cl_2 by layering with *n*-hexane. Yield 80–85%.

10a, b: A solution of **6a, b** in CH_2Cl_2 was treated with an equimolar quantity of pyridine. After removal of all volatiles from the clear reaction mixture at 0.01 Torr, the colorless solid residue was recrystallized as described above from a little CH_2Cl_2/*n*-hexane. Yield >90%.

16: A solution of $NaN(SiMe_3)_2$ (0.38 g) in toluene (10 mL) was added dropwise at 0 °C with a syringe to a solution of **10a** (1.0 g, 2.1 mmol) in toluene (20 mL). After stirring at 0 °C for 30 min, the bright orange reaction mixture was filtered, concentrated under reduced pressure (0.01 Torr), treated with *n*-hexane until **16** began to precipitate, and left for 24 h at -30 °C. Yield 64%. Loss of yield arose through slow decomposition of **16** in the reaction solution, which we attribute to the reaction of $NaAlCl_4$ with $HN(SiMe_3)_2$. Warming of the reaction mixture or a longer reaction time should therefore be avoided.

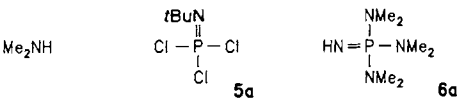
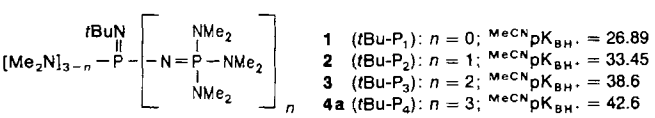
How Strong and How Hindered Can Uncharged Phosphazene Bases Be?**

By *Reinhard Schwesinger,* Christian Hasenfratz, Helmut Schlemper, Leonhard Walz, Eva-Maria Peters, Karl Peters,* and *Hans Georg von Schnering*

In 1987 we reported on the extraordinarily basic, uncharged polyaminophosphazenes **1**–**4a**[1] exhibiting $^{MeCN}pK_{BH^+}$ values[2] of up to 42.6. These compounds, readily available from **5a**,[3] **6a**,[4] and Me_2NH, are of increasing interest as bulky auxiliary bases for sensitive reactions in the basicity range of classical organometallic compounds.[5]





With the exception of proton sponges, uncharged bases are kinetically highly active even towards weak acids, and the naked anions thus generated are often extremely reactive. In reactions of such substrates with electrophiles, a low equilibrium concentration of the anion often suffices as long as the base is inert to the electrophile. Thus both an increase in basicity and steric bulk of the phosphazene bases should extend their range of applications.

An apparent approach for increasing the basicity of the phosphazene bases is homologation of their chains; the extension of the P_4 system in **4** ("*t*Bu-P_4")[5n] by one PN_3 unit proved to be the best strategy. For this synthetic concept P_2 building blocks[6] **10** must be generally accessible (Scheme 1). Coupling of the P_1 units **6a** and **7a** afford **8a**;[7] the further reactions leading to **10a** correspond to those previously employed to convert hexamethylphosphoric triamide (HMPA) into **6a**; however, the chlorination of **8** requires a somewhat higher temperature than the analogous reaction with HMPA.[9] After compound **5a** is coupled with **10a** and then with **6a** (in this order), the counterion is exchanged to provide **11a**·HBF_4. In analogy to **4a**, this salt is treated with KNH_2 in liquid NH_3 to liberate **11a**. Like all higher phosphazene bases **11a** (*t*Bu-P_5), a stable solid, is extremely hygroscopic, lipophilic, and approximately[10] 3 pK units more basic than **4a**.

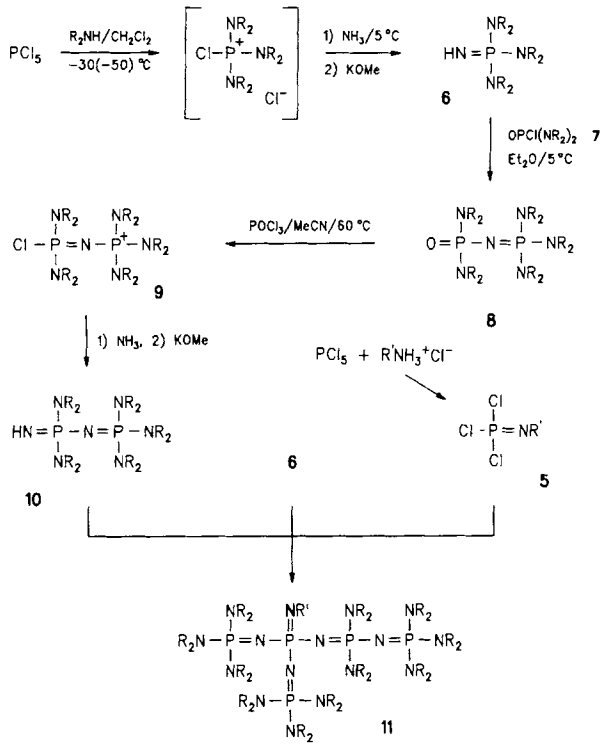
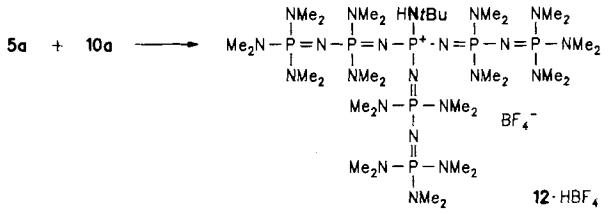
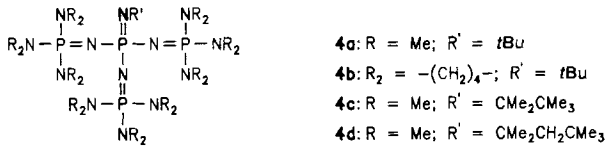


Scheme 1. **5a**: R′ = *t*Bu; **5b**: R′ = CMe_2*t*Bu; **5c**: R′ = CMe_2CH_2*t*Bu; **6a**–**10a**: R = Me; **6b**–**10b**: $R_2 = -(CH_2)_4-$; **11a**: R = Me, R′ = *t*Bu; **11b**: $R_2 = -(CH_2)_4-$, R′ = *t*Bu; **11c**: R = Me, R′ = CMe_2*t*Bu.

The easily prepared P_7 system **12** shows the limits of this homologation concept, which is surprising in a number of ways. Cation **12**·H^+ is extremely acid sensitive; traces of acetic acid in acetate solvents, for example, lead to rapid decomposition. Phosphazene **12** is not more basic than **11a**[10] and has not yet been isolated in pure form presumably on account of its oxygen sensitivity.



When all Me_2N groups of **1** are exchanged for pyrrolidine groups,[11] the basicity increases by 1.4 pK units, which is an even greater increase than when pairs of amino groups are incorporated into six-membered rings.[5a] The efficiency of this strategy with phosphazene bases was confirmed with the readily available P_4 system **4b**, the basicity of which lies between that of **4a** and that of **11a**.[10]



4a: R = Me; R′ = *t*Bu
4b: $R_2 = -(CH_2)_4-$; R′ = *t*Bu
4c: R = Me; R′ = CMe_2CMe_3
4d: R = Me; R′ = $CMe_2CH_2CMe_3$

Both strategies for increasing basicity can be effectively combined: **6b** is coupled with **7b**[12] to provide **8b**,[13] which leads to the stable base **11b**, the strongest uncharged base to date with a $^{MeCN}pK_{BH^{\oplus}}$ value of approximately 47[10] (corresponding to a $^{DMSO}pK_{BH^{\oplus}}$ value of 34–35). The thermodynamic deprotonation behavior of **11b** in THF with hydrocarbon indicators like triphenylmethane is comparable to that of lithium diethylamide; however, **11b** is kinetically much more active than the latter and less nucleophilic than lithium diisopropylamide relative to the kinetic activity.

The synthesis of the *t*Oct-P_4 base **4d**[5n] via **5b**, which is analogous to the preparation of **4a**, is a step in the direction towards even less nucleophilic bases. Amine units suitable for the synthesis of bases with even greater steric bulk were not commericially available. 1,1,2,2-Tetramethylpropylamine (*tert*-heptylamine)[14] was chosen because of its ready accessibility and, judging from molecular modeling studies, the efficient shielding effect of the alkyl group with the respect to the molecular weight.

The enormous steric bulk of the *t*Hept-P_4 base **4c**, synthesized via **5c** in high yields, is apparent from comparison of the relative rates of methylation (with MeI) of the bases in the series **4a**-**4d**-**4c** (Table 1). This high steric hindrance offers the opportunity of effectively controlling alkylations of CH acids by means of the deprotonation step; **4c** and **4d** are markedly more selective than **4a**.[5b,k]

An X-ray structure analysis of the HPF_6 salt of the *t*Hept-P_5 base **11c**, which is prepared analogously to **11a**, **b**, was conducted (Fig. 1).[16] Despite formal symmetry the cation is unsymmetric; the phosphazene chain is fairly stretched, the P-N-P angles lie between 138 and 158°, and the Me_2N

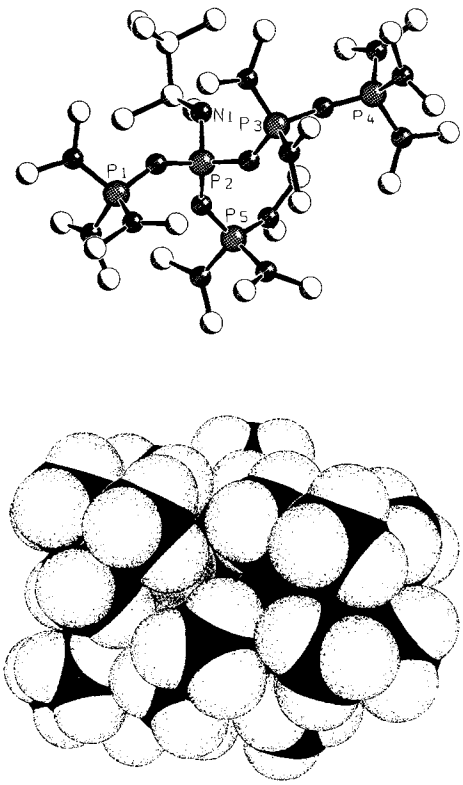


Fig. 1. Crystal structure of the cation in **11c**·HPF_6. Top: Schakal[17] representation without H atoms; bottom: space-filling model, positions of the H atoms from molecular modeling (perspective projection without the NH proton, N1 gray).

Table 1. Melting points, calculated or estimated $^{MeCN}pK_{BH^{\oplus}}$ values[10], and relative rates of methylation of **4a–d** and **11a–c**.

Compd.	M.p. [°C]	$^{MeCN}pK_{BH^{\oplus}}$ [2]	k_{Mel} (rel.)
4a [1]	208 (decomp)	42.6	1
4d	165–167 (decomp)	42.6	0.22
4c	202 (decomp)	42.6	0.001
4b	280 (decomp)	ca. 44	
11a	97	45–46	
11c	96	45–46	
11b	214 (decomp)	ca. 47	

groups are roughly trigonal planar (average sum of angles 355°). The space-filling model shows the unusually strong steric shielding of the basic N1 atom, which is almost completely hidden by the methyl groups of the side chains. Molecular modeling studies suggest that the conformations of such phosphazenium ions are determined primarily by steric interactions and that in solution several conformations of similar energy most likely exist.

We suspect that the phosphazene bases described here (for physical and spectroscopic data see Table 2) may define the limits of the base strength of stable, uncharged nitrogen bases and may approach the limits of steric bulk within this extreme range of basicities. We are currently examining whether this new class of auxiliary bases can lift the restrictions of base-catalyzed reactions and thus open completely new possibilities.

The Dynamic Jahn–Teller Effect in the Benzene Cation: Rotationally Resolved ZEKE Photoelectron Spectra of the $\nu_6(e_{2g})$ Mode**

By *Reiner Lindner, Hiroshi Sekiya,* and *Klaus Müller-Dethlefs**

Consideration of vibronic interactions is fundamental for understanding the dynamics of molecules and the mechanisms of chemical reactions such as chemical activation and catalysis.[1] One of the most important effects of vibronic interactions on degenerate electronic states of nonlinear molecules is the Jahn–Teller effect,[2] best described as the instability of a molecule with respect to distortions from its most symmetric configuration. The decline in the adiabatic potential energy surface along the Jahn–Teller active coordinate can cause a reduction of the activation energy and may thus favor the course of chemical reactions that proceed in the direction of this coordinate.[3] The classical textbook example of the Jahn–Teller effect is given by the benzene cation, the properties of which have been thoroughly examined theoretically and experimentally.[3] Until just recently, however, it was not possible to examine the benzene cation by spectroscopy with sufficient resolution for a meaningful description of its structure and symmetry. By means of rotationally resolved ZEKE spectroscopy (ZEKE = *z*ero *k*inetic *e*nergy) of the vibrational ground state $D_0\,^2E_{1g}$ of the benzene cation in the gas phase it was shown that this state is planar and has D_{6h} symmetry.[4] The high symmetry of the free ion is certainly not self-evident, since a reduction in symmetry to D_{2h} is expected as a result of the Jahn–Teller (JT) effect associated with its electronic degeneracy;[3a] this reduced symmetry was also observed by ESR in matrix studies.[5]

It is interesting to see the effect of excitation of a Jahn–Teller active vibrational mode on the structure of the ion and how vibronic interactions affect the vibrational structure of the ion's ground state. According to theory, excitation of a degenerate vibration in a degenerate electronic state should lift the degeneracy, and splitting into vibronic states of different energies is expected.[6] Because of vibronic coupling, the electronic wave function depends on the vibrational coordinate. The Jahn–Teller effect is thus one of the most significant examples of the breakdown of the Born–Oppenheimer approximation, which has as its basic tenet the separability of the motion of electrons and nuclei.

In the case of linear vibronic coupling, a good quantum number for the characterization of the vibronic wave function for a doubly degenerate electronic state is simply the sum $j = l \pm \lambda$ of the vibrational angular momentum $l = \pm v$ and half of the electronic angular momentum $\lambda = 1/2\Lambda$ ($\Lambda = \pm 1$), and not the individual angular momenta alone.[6, 7] For the benzene cation this implies that excitation of one quantum of the degenerate $\nu_6(e_{2g})$ vibrational mode (6^1) results in a splitting into two states with different vibronic angular momenta $j = \pm 1/2$ and $j = \pm 3/2$. The state with angular momentum $j = \pm 3/2$ should split further into two states with $j = +3/2$ and $j = -3/2$ due to quadratic JT coupling.[6, 7] This differing behavior of the two components with $j = \pm 1/2$ and $j = \pm 3/2$ can also be explained by group theory. The direct product of the irreducible representations of the electronic state E_{1g} and the ν_6 vibrational mode e_{2g} generates one doubly degenerate state with the symmetry species E_{1g} and two states with the symmetry species B ($\Gamma_e \otimes \Gamma_v = E_{1g} \oplus B_{1g} \oplus B_{2g}$). Higher order couplings can only split the state $\Gamma_{ev} = B_{1g} \oplus B_{2g}$ ($j = \pm 3/2$); the state $\Gamma_{ev} = E_{1g}$ ($j = \pm 1/2$) remains degenerate. An unambiguous assignment of the individual, split vibronic states and an exact determination of their energies is necessary for a precise determination of the strengths of the vibronic coupling. Rotationally resolved ZEKE spectroscopy is the method for the unequivocal assignment of the symmetry species of the vibronic states and thus the vibrational modes of the benzene cation, thereby providing very reliable values for the vibronic coupling strengths.

The rotational state of an oblate symmetric rotor is characterized by two quantum numbers. For the ground state (S_0) and the intermediate state (S_1) of the neutral benzene molecule, these are the quantum number J of the total angular momentum and the quantum number K for its projection along the molecule-fixed principal axes. For the benzene cation with the electronic spin $S = 1/2$, the rotational states are characterized (with the assumption of only a weak spin–orbit interaction) by the quantum number N^+, which describes the total angular momentum without electronic spin, and the projection quantum number K^+. In degenerate vibronic states the rotational states split by Coriolis interactions must be differentiated by an additional quantum number l.[8]

The determination of the rotational structure of the benzene cation and the assignment of the rotational transitions observed in the ZEKE spectra allow the determination of the vibronic symmetry species of the corresponding vibrational state. We employed a method that was already successfully applied to ammonia[9, 10] and to the vibrationless ground state of the benzene cation.[4] Starting with the known symmetry of the intermediate state, in which only one rovibronic state is populated, the possible final states are determined based on group theoretical considerations. The conservation of symmetry of the nuclear spin wave function and the rules for electronic symmetry selection and the coupling of angular momenta greatly restrict the possible transitions; depending on the vibronic symmetry of the final state, only a few rotational progressions can be observed.[4, 9, 10, 11]

For the benzene cation the $\nu_6(e_{2g})$ mode is the Jahn–Teller active mode with the lowest frequency.[3] Photoelectron spectra of benzene[12] indicate a splitting of the $j = 3/2$ and $j = 1/2$ components of the 6^1 band by roughly 300 cm^{-1}. Measurements with a variant of the ZEKE method, in which the ion remaining after the pulsed field ionization is detected (*m*ass *a*nalyzed *t*hreshold *i*onization, MATI[13, 14]), show vibrational structure in the region up to 800 cm^{-1} above the first ionization potential. In this vibrational structure the splitting of the two components with $j = 3/2$ and $j = 1/2$ and to some extent the separation of the components $j = +3/2$ and $j = -3/2$ can be seen.[15] However, rotational resolution, which would ensure the unambiguous assignment of the bands, was not achieved in these measurements. This is especially necessary for the $j = \pm 1/2$ band, as it lies close to high-intensity combination modes of other vibrations.

Figure 1 shows the completely rotationally resolved ZEKE spectrum in the region of the 6^1 ($j = \pm 1/2$) band of the benzene cation. The first laser is tuned to the $S_1\,6^1 \leftarrow S_0\,^rR_0(0)$ transition, and thus a single rovibronic level

($J' = 1, K' = 1, +l$) in the intermediate state is populated.[16] The second laser is scanned over the range $\nu_2 = 36598-36638\ cm^{-1}$, and the ZEKE signal is recorded versus ν_2. Figure 1 shows two vibrational bands in this region with almost the same intensity and both with resolved rotational structure. Without rotational resolution it is not possible to decide with certainty which of the two states should be assigned to the $6^1(j = \pm 1/2)E_{1g}$ band. Starting from the rotational transitions characteristic for a given vibronic symmetry, two rotational progressions with $K^+ = 1$ and $K^+ = 5$ can be assigned to the state higher in energy (right in Fig. 1).

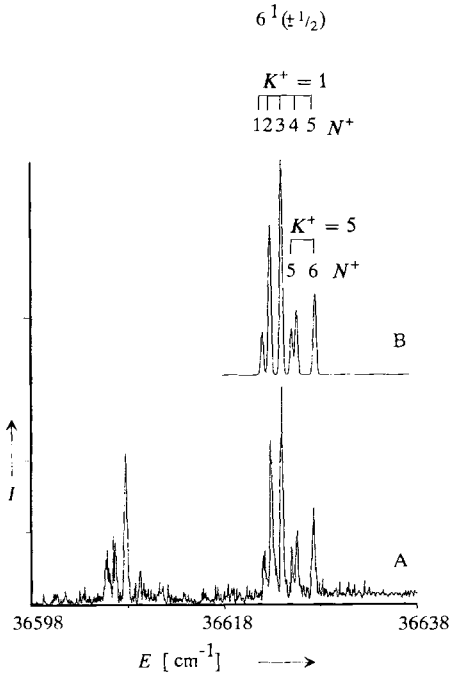

Fig. 1. Measured (A) and simulated (B) ZEKE spectra of the $6^1(j = \pm 1/2)$ band of the electronic ground state of the benzene cation via the intermediate state $S_1 6^1(J' = 1, K' = 1, +l)$. Gaussian bands with a width of 0.4 cm^{-1} (FWHM) were assumed for the simulation. The intensities are taken from the measured spectrum. *I*: ZEKE signal, *E*: energy of the ionizing laser.

The rotational structure indicates that E_{1g} is the vibronic symmetry species of this band, which can thus be unambiguously assigned to the $6^1(j = \pm 1/2)E_{1g}$ state. This assignment is supported by comparison with the spectrum of the vibrationless ground state,[4] which also has E_{1g} symmetry. The two spectra are very similar with the exception of the Coriolis splittings resulting from Coriolis coupling constants (ζ) of different sizes and signs. In contrast, the rotational structure of the lower energy state (left in Fig. 1) is not compatible with an E_{1g} symmetry species. This probably corresponds to a component of the combination mode $16^16^1(j = \pm 3/2)$.[17]

The second component of the split ν_6 band, the state with vibronic angular momentum $j = \pm 3/2$, is split due to the quadratic, dynamic Jahn–Teller effect into two states with B_{1g} and B_{2g} symmetry.[6, 7] Since both vibronic states have the same symmetry species *B* and their rotational constants should have close to the same values, very similar rotational structures are expected for the two states. Figure 2 shows the ZEKE spectrum via the same intermediate state $S_1 6^1(J' = 1, K' = 1, +l)$, in which the second laser is scanned over the range $\nu_2 = 36288-36328\ cm^{-1}$. Two clearly separated vibronic states with almost identical rotational structures can be seen, which can both be assigned to a progression with $K^+ = 3$. This leads to the vibronic symmetry species B_{1g} and B_{2g}, in agreement with the symmetry selection rules for ZEKE spectroscopy; these components must be assigned to the states $6^1(j = -3/2)$ and $6^1(j = +3/2)$. It cannot be determined yet which state has the vibronic symmetry species B_{1g} and which B_{2g}. The separations of each set of two transitions with the same quantum numbers N^+ and K^+ agree to within $\pm 0.1\ cm^{-1}$. The mean splitting between the states with $j = -3/2$ and $j = +3/2$ is 20 cm^{-1}.

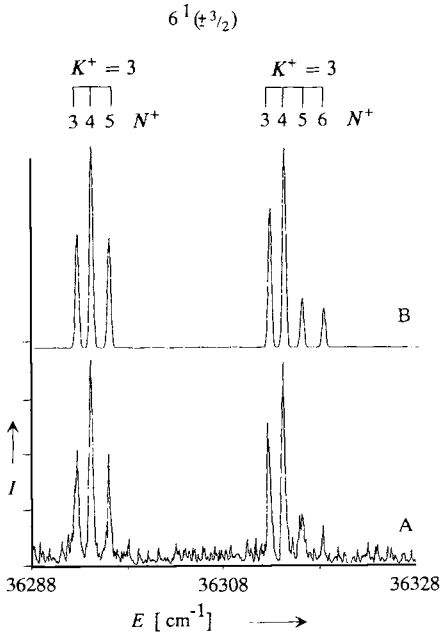

Fig. 2. Measured (A) and simulated (B) ZEKE spectra of the $6^1(j = \pm 3/2)$ band of the electronic ground state of the benzene cation via the intermediate state $S_1 6^1(J' = 1, K' = 1, +l)$. Gaussian bands with a width of 0.4 cm^{-1} (FWHM) were assumed for the simulation. The intensities are taken from the measured spectrum. *I*: ZEKE signal, *E*: energy of the ionizing laser.

With twelve rovibronic levels of the (neutral) $S_1 6^1$ state as intermediate resonance, we were able to assign 50–55 lines in the ZEKE spectrum of the individual bands. A preliminary least-squares approximation of the rotational constants based on these lines gave the values listed in Table 1. Neither the margins of error for the constants nor the standard deviation of 0.1 to 0.2 cm^{-1} are as good as expected based on the quality of the spectra and the low standard deviation (0.04 cm^{-1}) obtained for the vibrationless ground state.[4] The large difference in the rotational constant C for the two almost degenerate vibronic states of the $6^1(j = \pm 3/2)$ band, which are split due to quadratic Jahn–Teller coupling, is not plausible, and the resulting significant rotational defects of +7 and −5 amu Å^2 disagree with the planar structure of the benzene cation recently proven.[4] Apparently the simple model of the symmetric rotor, which was applied successfully for the vibrationless ground state of the cation, does not correctly describe the rotational energy of the molecule with linear and quadratic, dynamic Jahn–Teller coupling. A theory that correctly specifies the position of the rotational states in these cases must still be worked out for the benzene cation. Between the two almost degenerate components of the $6^1(j = \pm 3/2)$ state there may exist an off-diagonal Coriolis coupling such as that observed between the components of a degenerate electronic state[18] or a degenerate vibration[19] split by asymmetric isotopic substitution. Even with

the accuracy given for the rotational constants listed in Table 1, a marked expansion of the benzene ring is apparent; however, the details must still be clarified.

Table 1. Spectroscopic constants of the benzene cation for the vibrational states $6^1(j = +3/2)$, $6^1(j = -3/2)$, and $6^1(j = \pm 1/2)$ of the electronic ground state $D_0\,^2E_{1g}$.

	$6^1(j=-3/2)$	$6^1(j=+3/2)$	$6^1(j=\pm 1/2)$
Band origin [cm^{-1}]	345.4	365.4	676.4
B [cm^{-1}]	0.1867 ± 0.0008	0.1868 ± 0.0008	0.184 ± 0.002
C [cm^{-1}]	0.0895 ± 0.0004	0.0966 ± 0.0004	0.094 ± 0.001
ζ_{eff}	–	–	−0.19 ± 0.03

The differences in band origin energy between the $6^1(j = \pm 1/2)$ bands and the $6^1(j = -3/2)$ and $6^1(j = +3/2)$ bands is 331 and 311 cm^{-1}, respectively. This corresponds to roughly half of the vibrational energy of the ν_6 mode. Thus the benzene cation is a good example for intermediate coupling, in which the vibrational frequency of the Jahn–Teller active mode and the accompanying coupling strengths have almost the same values.[3b] With the precise values given here for the energies of the components of the ν_6 band affected by vibronic interaction, the results of quantum chemical ab initio calculations can be examined very closely. Comparison with values published recently shows how well these latest dynamic Jahn–Teller calculations can take into account several active modes.[20] The difference between the caluculated value for the $6^1(j = \pm 1/2)$ band of 694 cm^{-1} and the measured value of 676.4 cm^{-1} is only 3 percent.

The determination of the symmetry of a vibronic state by rotationally resolved ZEKE spectroscopy, which is demonstrated here for the ν_6 mode, would allow the elucidation of the vibrational structure of the benzene cation, which is predicted to be very irregular due to multiple-mode Jahn–Teller coupling. This would be a significant contribution to the understanding of the Jahn–Teller effect and vibronic interactions. High-resolution experimental analysis of the cation of the benzene molecule, the prototypical aromatic molecule which is frequently the subject of theoretical studies, was not possible previously.[21]

Experimental Procedure

The principles behind ZEKE spectrosopy and the exact experimental setup were described in ref. [4]. Benzene coexpanded with argon as carrier gas (p_0 = 4 bar) was ionized in a skimmed, pulsed, supersonic beam by two-photon two-color ionization (1 + 1′ REMPI). The laser system consists of a Nd:YAG laser (Continuum NY-82/20) that pumps two (frequency-doubled) dye lasers (Lumonics HD-500). The first laser populates a specific rovibronic state in the first excited electronic state $S_1\,6^1$ of the molecule. The second laser promotes the molecules to extremely long-lived Rydberg states (with very high principal quantum numbers $n > 150$) converging to rovibronic states of the cation. After a delay time of about 3 μs a pulsed electric extraction field was applied, and the resulting field-ionized electrons were detected, resolved in time[4,22,23].

Crystal Structure of [(α-Cyanoisopropylsodium · Tetramethylenediamine)$_4$]: How Coordination Expansion from Li to Na Centers can Increase the Aggregation State of an α-Nitrile "Carbanion"**

By *James Barker, Nicholas D. R. Barnett, Donald Barr, William Clegg, Robert E. Mulvey,** and *Paul A. O'Neil*

"Carbanions" generated by alkali metalation of organic nitriles possessing α-hydrogen atoms have long been important synthetic intermediates in organic chemistry. Though studies of such species abound, the first crystal structure determination appeared only in 1986.[1] This structure analysis of [(α-cyanobenzyllithium · tmeda)$_2$ · benzene] (TMEDA = *N,N,N′,N′*-tetramethylethylenediamine) **1** highlighted obstacles which have severely hindered the development of this aspect of α-nitrile carbanion chemistry, for as well as being air- and moisture-sensitive, the crystals decompose in the X-ray beam (this accounts for the unavoidably high *R* value of 0.115). The crystal structure of **1** emphasized the strong

[{Li(tmeda)CH(CN)C$_6$H$_5$}$_2$] · C$_6$H$_6$ **1**

[{Na(tmeda)CH(CN)Me$_2$}$_4$] **2**

[**] This work was supported by the Associated Octel Company Limited and by the UK Science and Engineering Research Council.

influence exerted by the metal cation (Li^+, in this example) on the molecular arrangement adopted, particularly with regard to the degree of aggregation and solvation, since it revealed that **1** was a dimer with a four-membered $(NLi)_2$ ring, in which each Li atom is bound to a bidentate tmeda ligand. MO calculations on model compounds also recognized the important structural role of the metal cation.[2] In this communication, we report the synthesis and crystal structure (refined to a final R value of 0.061) of [(α-cyanoisopropylsodium · tmeda)$_4$] **2**, a sodium complex closely related to the lithium complex **1**. Interestingly, although oligomerization is generally accepted to be more important with organolithium compounds[3] due to electrostatic considerations, here we find that the sodium complex **2** exhibits the higher (tetrameric) aggregation state.

Formally, isopropylcyanide $Me_2C(H)C{\equiv}N$ converts to α-cyanoisopropylsodium $Me_2C(Na)C{\equiv}N$ in the preparation of **2**. However, in reality, the crystal structure of **2** (Fig. 1)[4] shows that C–Na bonding does not occur, instead the Na^+ ions preferentially bind to the more electronegative N^- centers of the CN groups with concomitant formation of stable, near-linear $C{=}C{=}N$ units (mean bond angle, 178.53°; mean bond lengths, 1.360 and 1.187 Å, respectively;[5] the "anionic" C atoms are surrounded essentially trigonal planar). Furthermore, these contact ion pairs exist in a discrete tetrameric arrangement, with an $(NNa)_4$ pseudocubane core reminiscent of that in the ketimide–ketimine complex [(tBu$_2$C=NNa)$_4$·(HN=CtBu$_2$)$_2$][6] described as a stack[7] of two $(NNa)_2$ rings (one complexed and one uncomplexed). A similar description could be applied to the structure of **2** though there is no clear pattern to the N_{anion}–Na bond lengths (range, 2.424–2.489 Å) to permit identification of the stacking direction.[8]

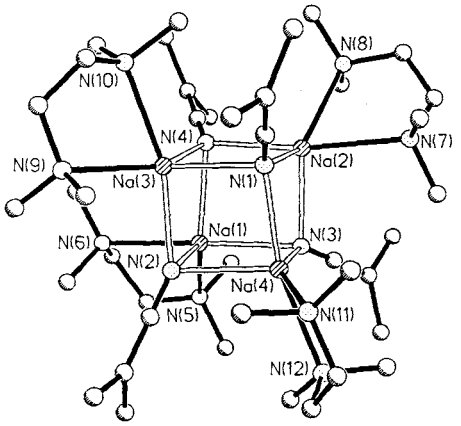

Fig. 1. Crystal structure of **2** (excluding hydrogen atoms). Principal distances [Å] and angles [°]: Na1-N2 2.424(6), Na1-N3 2.470(6), Na1-N4 2.489(6), Na1-N5 2.498(6), Na1-N6 2.567(6), Na2-N1 2.467(6), Na2-N3 2.477(6), Na2-N4 2.457(6), Na2-N7 2.528(6), Na2-N8 2.542(7), Na3-N2 2.435(6), Na3-N4 2.460(7), Na3-N1 2.474(5), Na3-N10 2.499(6), Na3-N9 2.541(6), Na4-N3 2.464(6), Na4-N1 2.467(6), Na4-N2 2.473(6), Na4-N12 2.529(6), Na4-N11 2.572(6); N2-Na1-N3 90.3(2), N2-Na1-N4 97.5(2), N3-Na1-N4 86.9(2), N2-Na1-N5 128.7(2), N3-Na1-N5 101.1(2), N4-Na1-N5 132.6(2), N2-Na1-N6 97.0(2), N3-Na1-N6 171.9(2), N4-Na1-N6 95.5(2), N5-Na1-N6 71.6(2), N1-Na2-N4 93.9(2), N3-Na2-N4 87.4(2), N1-Na2-N3 96.5(2), N4-Na2-N7 169.1(2), N1-Na2-N7 94.8(2), N3-Na2-N7 98.1(2), N4-Na2-N8 97.5(2), N1-Na2-N8 133.4(2), N3-Na2-N8 128.9(2), N7-Na2-N8 71.7(2), N2-Na3-N4 98.0(2), N2-Na3-N1 87.8(2), N1-Na3-N4 93.7(2), N2-Na3-N10 164.7(2), N4-Na3-N10 91.2(2), N1-Na3-N10 103.9(2), N2-Na3-N9 94.2(2), N4-Na3-N9 145.7(2), N1-Na3-N9 118.8(2), N10-Na3-N9 71.6(2), N1-Na4-N3 96.9(2), N2-Na4-N3 89.3(2), N1-Na4-N2 87.2(2), N3-Na4-N12 93.0(2), N1-Na4-N12 160.6(2), N2-Na4-N12 109.7(2), N3-Na4-N11 153.2(2), N1-Na4-N11 94.0(2), N2-Na4-N11 115.7(2), N12-Na4-N11 70.5(2).

Figure 1 shows one of three stacking possibilities; the other two being perpendicular to the N1-Na4-N2-Na3 and N1-Na2-N3-Na4 faces. Irrespective of the direction, this vertical association of dimeric rings raises the coordination number of their constituent Na^+ ions from two to three, making them five-coordinate in total, when the bidentate tmeda ligands are taken into account. Since Li^+ ions are significantly smaller than Na^+ ions, their coordination sphere is also appreciably smaller, that is they can bind fewer ligands. Thus, the $(NLi)_2$ ring in the related complex **1** remains discrete, and its Li^+ ions are coordinatively saturated in a fourfold environment. The scale of the steric "expansion" from Li to Na can be gauged by a comparison of mean N_{tmeda}–metal bond lengths (2.05 Å in **1**;[1] 2.534 Å in **2**; difference 0.484 Å). As a consequence of the distorted cubic morphology of **2**, the five-coordinate Na^+ ions and the four-coordinate N^- ions are greatly distorted from the respective trigonal bipyramidal and tetrahedral geometries often associated with these coordination numbers, as reflected by the bond angles (mean internal-cube angles at Na, 92.12°; at N, 87.28°: range of external-cube angles at Na, 70.5–171.9°; at N, 110.7–146.5°).

A comparison of the structures of **2** and the related sodium "carbanions" $NaC(CN)_3$ (**3**)[9] and [Na{N(nBu)$_4$}·{HC(CN)$_2$}$_2$ · THF] (**4**),[10] shows that there is a definite correlation between the N_{anion}–Na bond lengths and the coordination numbers of the Na atoms. Thus, in general the bond lengths increase sequentially (2.364–2.396 (**4**), 2.424–2.489 (**2**), 2.373–2.613 Å (**3**)) as the coordination number increases from four (in **4**) to five (in **2**) and to six (in **3**).

An IR spectrum of **2** (in Nujol) revealed a strong [ν_{as}(C=C=N)] band at 2030 cm^{-1}. Donor-free α-cyanobenzylsodium PhCH(Na)C≡N, which may have a different aggregation state, was reported to have a similar absorption band at the slightly higher value of 2080 cm^{-1}.[11]

Thus, we conclude that the structures of α-nitrile "carbanions" can differ, depending on whether they are produced by lithiation or by sodiation, since they are in reality contact ion pair aggregates, and as structure is intimately linked to reactivity this should be borne in mind when generating such intermediates for synthetic purposes.

Experimental Procedure

2: Under anaerobic and anhydrous conditions, isopropylcyanide (10 mmol) was added to a Schlenk vessel which contained a chilled, stirred hexane suspension of nBuNa (10 mmol). A yellowish precipitate formed almost immediately. Introduction of TMEDA (10 mmol) followed by mild heating redissolved the solid, and a homogeneous orange solution was formed. Refrigeration at −30 °C afforded a large crop of yellow crystalline **2**. Yield, 45%. Satisfactory C,H,Na analyses. The yellow crystals decomposed on contact with moisture or oxygen. Single crystals suitable for X-ray crystallography were sealed under argon in Lindemann capillary tubes prior to data collection.

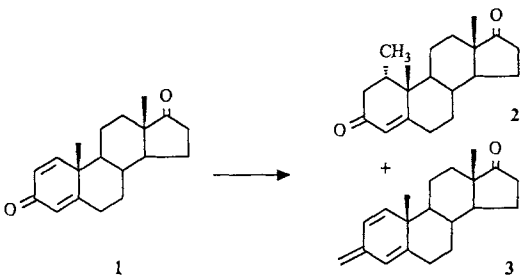
Copper-Catalyzed 1,4-Additions of Trialkylaluminum Compounds to Enones

By *Jürgen Westermann** and *Klaus Nickisch*

The 1,4-addition of organometallic compounds to enones is an important reaction in organic chemistry, which frequently provides the desired products only with low-order or high-order cuprates.[1, 2] In the reactions of enones with organomagnesium halides and organolithium compounds in the presence of catalytic amounts of copper salts according to the method of Kharasch, 1,2-addition is often a side reaction resulting from the undesired attack at the carbonyl group.

Our goal was to conduct the 1,4-addition of an alkyl group to enones and cross-conjugated dienones catalytically. Previously it was not possible to introduce aliphatic groups to, for example, the cross-conjugated system **1** to give **2**. The latter, a steroid with a methyl substituent in position 1 and an important pharmaceutical intermediate, was previously prepared from **1** only with stoichiometric amounts of Me_2CuLi[3] or under catalytic conditions only from an unconjugated dienone (Scheme 1).[3c]



Scheme 1. 1,4-Additions to steroid **1** with methylcopper and methylmagnesium compounds (reaction conditions, yield of **2** [%], yield of **3**[%]): 1.8 equiv Me_2CuLi, 0 °C, 75, 15–20; 1.1 equiv MeMgBr/10 mol% CuX, < 5, > 80; $Me_2CuLi + Me_3SiCl$, −78 to 0 °C, < 10, > 80; MeMgBr + Me_3SiCl/10 mol% CuX, < 5, > 90.

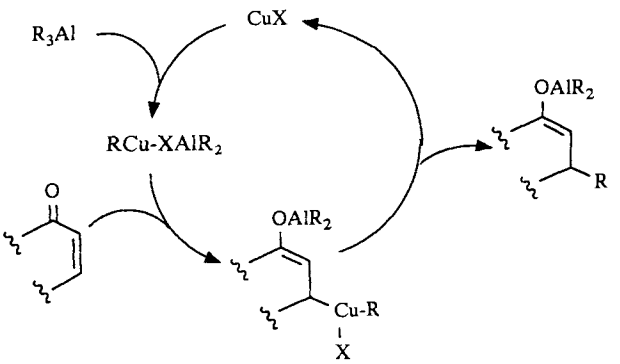
When Me_3SiCl or $BF_3 \cdot Et_2O$ was added to the reaction of **1** with equimolar amounts of low-order or high-order cuprates, or to the highly reactive organometallic compounds MeMgX or MeLi under Cu catalysis,[1, 4] then mainly the carbonyl group was attacked, leading to product **3** after hydrolysis. Thus, for achieving catalytic 1,4-addition the organometallic compounds should not react readily with carbonyl groups so that the competing 1,2-addition is suppressed. For this reason we examined trialkylaluminum compounds in more detail.

The reactions of the trialkylaluminum compounds with carbonyl groups by 1,2-addition depend on the reaction conditions,[5] but in our studies they were less reactive than expected.[6] A number of 1,4-additions of organoaluminum compounds are known: Kabalka et al. reported on a 1,4-addition of triisopropylaluminum initiated by air,[7] dialkylaluminum chlorides react with α,β-unsaturated carbonyl compounds in part without a catalyst,[8] and copper-catalyzed reactions of trialkylaluminum with acid chlorides are important routes to ketones.[9] Nickel-catalyzed 1,4-additions of Me_3Al[10a] were not selective with **1** (in our studies the yield of **2** was only 35%; see entry 18 in Table 1). Another metal-catalyzed reaction, the 1,4-addition of Me_3Al to isophorone with $[Cu(acac)_2]$ (acac = acetylacetonate), was also reported.[10b] However, Mole et al. could not reconfirm this result,[10c] and we also failed to observe this type of reaction when $[Cu(acac)_2]$ was employed as a catalyst. 1,4-Additions of the more reactive alkenyl- and alkynylaluminum compound to enones proceed smoothly,[11, 12] but until now alkyl groups from aluminum compounds could not be transferred to α,β-unsaturated ketones under Cu catalysis.

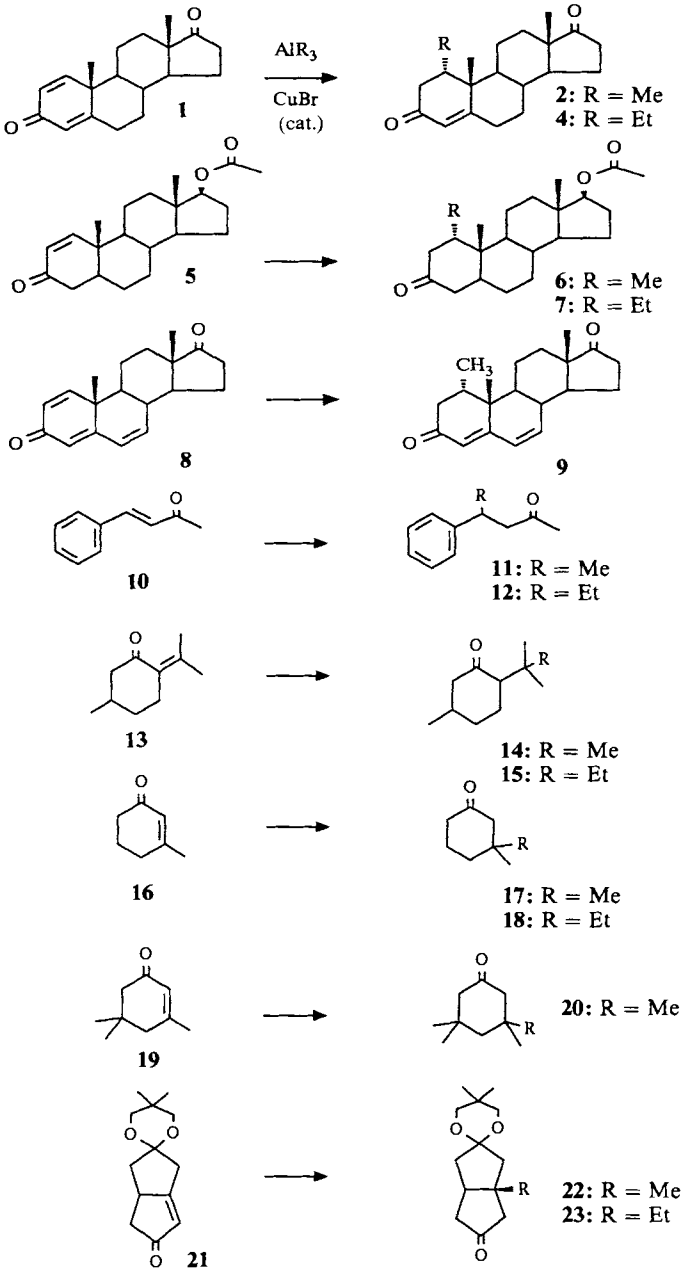
In our search for suitable catalysts we found that the 1,4-addition of Me_3Al to enones is catalyzed by CuBr. Here the transfer of the methyl group of Me_3Al to the transition metal atom and subsequently to the enone is apparently faster than the competing attack at the carbonyl group. This process could follow the path outlined in Scheme 2.



Scheme 2. CuX-catalyzed addition of R_3Al to enones. X = halogen.

Employing this method we converted dienone **1** into **2** under catalytic conditions (method A); addition of Me_3SiCl increased the reaction rate (method B). Apparently the Lewis acid promotes the reaction of trialkylaluminum with 3-keto-$\Delta^{1,4}$ steroids like **1** and suppresses competing reactions of the aluminum enolate formed as an intermediate, resulting in improved yields. In the addition of a methyl group to **1**, a high regioselectivity of >98:2 (position 1 vs. position 5) was achieved; with Me_2CuLi this selectivity was 93:7 and with $Me_3Al/[Ni(acac)_2]$ 62:38. The reaction of **1** with Et_3Al in the presence of Me_3SiCl proceeded smoothly

and furnished **4** in 87% yield. Besides steroidal enones, other cyclic and open-chain enones were tested (Scheme 3).



Scheme 3. 1,4-Additions to enones.

17β-acetoxyandrost-1-en-3-one (**5**) reacted with Me_3Al and CuBr (1 mol%) at room temperature in ethyl acetate giving **6** in 90% yield (method A). The acetoxy group was not attacked. The reactions may be conducted in either ether solvents (THF, dioxane) or ethyl acetate (for reaction conditions see Table 1).

The products obtained (Table 1) demonstrate that the copper-catalyzed 1,4-addition of alkylaluminum compounds to enones is a useful reaction, in which ethyl groups can also be transferred, in contrast to the reactions with Ni catalysis.[10] Besides CuBr, $CuBr_2$ and CuCN are suitable catalysts; CuCl, CuI,CuI·2LiCl, CuCN·2LiCl,[13] MeCu, and thienylcopper are not as effective. The amount of catalyst used in the experiments described (1–5 mol%) can be reduced further, but the reaction does not occur without catalyst.[6, 8] The high regioselectivity and good chemoselectivity of this method is notable. The catalytic aspect of this reaction and the use of ethyl acetate, a solvent with minimal environmental impact, are important in view of industrial applications.

Table 1. CuBr-catalyzed 1,4-additions of R_3Al to enones. RT = room temperature, EA = ethyl acetate.

Entry	Enone	R	Prod.	Method [a]	CuBr [mmol]	Conditions	Yield [b]

[a] Method A: 1.1 equiv R_3Al, 1 equiv enone, 1–5 mol% CuBr (no Me_3SiCl). Method B: 1.1 equiv R_3Al, 1 equiv enone, 1–5 mol% CuBr, 1.2 equiv Me_3SiCl. [b] The purity of products **2**, **4**, and **6** (determined by gas chromatography) is >99%, that of the other products >97%. The ^1H NMR data of the products are in accord with the structures shown.

Experimental Procedure

Preparation of **2** according to method B: Enone **1** (8.52 g, 30 mmol) and CuBr (86 mg, 0.6 mmol) were dissolved in THF (70 mL) under nitrogen, and a solution of 10% Me_3Al in toluene (28.4 mL, 33 mmol) was added. Me_3SiCl (3.92 g, 36 mmol) was added dropwise to the solution, which was then stirred for 2 h at 25 °C. The reaction mixture was hydrolyzed with water (3 mL) and the solid filtered off and washed. The crude product was purified by chromatography on silica gel (eluent: ethyl acetate/hexane) to give **2** (8 g, 89% yield). M.p. 154 °C; $[\alpha]_D^{20} = -205.6$ ($c = 1$ in $CHCl_3$); ^1H NMR (300 MHz, $CDCl_3$, 25 °C, TMS) $\delta = 0.95$ (s, 3H; 19-CH_3), 0.97 (d, 3H, $^2J = 7$ Hz; 1α-CH_3), 1.35 (s, 3H; 18-CH_3), 1–2.75 (m, 17H), 5.73 (s, 1H, H-4).

Preparation of **6** according to method A: Enone **5** (3.3 g, 10 mmol) and CuBr (14 mg, 0.1 mmol) were dissolved in ethyl acetate (15 mL) under nitrogen, and a solution of 10% Me_3Al in toluene (9.5 mL, 11 mmol) was added. The solution was stirred for 0.5 h at room temperature, the reaction mixture hydrolyzed with water (1 mL), and the solid filtered off and washed. The solution was concentrated to dryness to give more crude product, which then totaled 3.45 g. Recrystallization from acetone at −10 °C gave **6** (3.1 g, 90% yield). M.p. 154 °C; $[\alpha]_D^{20} = -205.6$ ($c = 1$ in $CHCl_3$); ^1H NMR (300 MHz, $CDCl_3$, 25 °C, TMS) $\delta = 0.95$ (s, 3H; 19-CH_3), 0.97 (d, 3H, $^2J = 7$ Hz; 1α-CH_3), 1.35 (s, 3H; 18-CH_3), 1–2.75 (m, 17H), 5.73 (s, 1H, H-4).

BOOKS

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the Book Editor, Dr. Gerhard Karger, Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

Book Reviews

UV-VIS Atlas of Organic Compounds. Part 1: Spectra A1/1-C9/13. Part 2: Spectra D1/1-M19. 2nd Edition. Edited by *H.-H. Perkampus*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York, 1992. Part 1: VIII, pp. 1–336, Part 2: VII, pp. 336–1525, hardcover DM 750.00.—ISBN 3-527-28510-5/1-56081-268-0

To bring out a second edition of a specialist book in unaltered form twenty years after its predecessor is a remarkably brave step, and is only possible for a standard work with an undisputed international reputation, such as the "UV-VIS Atlas". This differs from other spectral collections in having the organic compounds arranged according to typical chromophores, for which 1167 representative spectra are given, with a quality of presentation unrivalled by anything else in the available literature. In addition to the displayed spectra there are 170 tables listing extinction coefficients and positions of absorption maxima for 740 further substances, which are related to the basic chromophores with variations of structure or solvent. Short review articles on the main chromophore groups are included, and these are still relevant and topical today.

The chromophores are arranged in groups as follows: groups A1 to A15: compounds containing multiply bonded carbon atoms; B1 to B21: compounds containing C=O and C=S groups; C1 to C9: compounds containing multiply bonded nitrogen atoms; D1 to D11: monocyclic aromatics; E1 to E7: polycyclic aromatics; F1 to F4: aromatic compounds containing non-benzenoid rings; G1 to G12: mononuclear heterocyclic compounds; H1 to H22: polynuclear heterocyclic compounds; I: saturated organic compounds; J1 to J10: selected compounds of biochemical and clinical interest; K1 to K3: inorganic systems. The atlas is completed by collections of spectra of UV-VIS spectrophotometric standards (Group L) and of 19 solvents (Group M).

Thus the scientific world has access here to a wealth of comparative information on UV-VIS spectra of organic compounds, which is indispensable for a wide variety of applications in fields such as analytical chemistry (titrimetry, chromatography), laser physics (laser dyes, materials for nonlinear optics), photochemistry, clinical chemistry, molecular biology (immunoassay, photodynamic effects), and ecology (reference materials for pollution studies).

The appearance of the new edition is an appropriate occasion to emphasize the great service that was performed by the original editors. At that time the Institut für Spektrochemie und angewandte Spektroskopie in Dortmund and the Photoelectric Spectrometry Group in London together succeeded in recruiting as contributors over 200 scientists from about 80 scientific institutions and 20 industrial laboratories throughout the world. These include many names of international renown.

Obviously a reprinting of such a work without change has meant that none of the developments of the past 25 years are reflected in it. Consequently many highly interesting chromophores such as the fullerenes, the cyclophanes, the many different laser dyes, the cyclopentadienyl dyes, reference materials for fluorescence spectroscopy, many new organic solvents, and a host of others are all absent. The publishers and the institutions responsible for the scientific development program need to remedy this situation as soon as possible by issuing a supplementary volume.

The "revision" that has been carried out for the second edition deserves criticism; in fact, in the form presented here it would have been better to leave things alone. The usefulness of such an atlas stands or falls according to how well the information is organized. In this case there are only two indexes that one can use: the molecular formula index and the alphabetical index of compound names based on the Chemical Abstracts nomenclature system. However, as the latter places the substituents (which are often unimportant in relation to light absorption) at the beginning of the name, it is of no help in searching for classes of compounds with similar chromophores. The search is made even more difficult by the occasional use of trivial names instead of the systematic ones. One therefore wonders why the index of core structural units, which corresponded most closely to the layout of the atlas, has now been dropped. In the first edition one could find all the acridine derivatives, all the ethylene derivatives, all the aniline derivatives, etc. under their corresponding keyword headings. Now in contrast, for example, the 26 substituted anilines must be extracted from four different tables, and the spectra of aniline derivatives from 15 widely scattered entries in the index—a hopeless task, especially as the systematic classification means that the spectra of the substituted anilines are distributed over Groups C6, D6, D8, D9, and D10, some of which are very large!

Another fault is that the spectral data tables no longer appear immediately after the spectra of the basic chromophores. Thus, for example, considerable effort is needed to discover that Table H22/T6 on page 1396 belongs to spectrum 36 of Group H22 on page 1055. Furthermore, in the second edition the compounds listed in the tables have been deleted from the formula and alphabetical indexes, with the result that they are lost to the majority of users.

Also the decimal classification given with the spectra is useless without a corresponding index. Such an index would at least have made it possible to search for compounds according to their basic chromophores, conjugation, heteroatoms, ring sizes, substituents, etc.

The lack of additional useful indexes is even more regrettable when one considers that 31 pages of the atlas have been used for an index of *R*-values, which aims to describe by a single quantity the degree of unsaturation of a molecule and hence the position of its light absorption. If one takes this index as a guide one finds, for example, that the aliphatic compound cubane, with $R = 5.0$, has the same degree of unsaturation as tetralin or decapentaene, and is even more unsaturated than the bisdimethylamino-nonamethinium cation ($R = 4.5$, listed in the index only under *N*-(9-dimethylaminonona-2,4,6,8-tetraenylidene)dimethylammonium perchlorate!); this despite the facts that cubane absorbs at about 200 nm, tetralin at 275 nm, decapentaene above 300 nm, and the nonamethine dye at as high as 625 nm. It remains a mystery why the *R*-index, unlike the other two indexes, includes compounds listed in the tables, whereas over 700 compounds have been left out of both the spectra collection and the tables. Thus, the user who wishes to have access to the whole of this wealth of information must systematically comb through the spectra and tables of Groups A to K. The publishers would be well advised to include better indexes along with the supplementary volume suggested above.

Although some printing errors in the first edition have been corrected in the revision, the frequency of errors has, on the whole, increased significantly. Some which affect the meaning are: the omission of the words "absorption intensity" after "log ε_λ specific for the..." (p. 1), benzene ring anellation has become "annealing" (p. 3), the association of ε_{max} with the dipole moment rather than with the transition dipole moment (p. 3), "future" instead of "feature" (p. 11), "p-electrons" instead of π-electrons (pp. 12, 19), "$\varepsilon \geq 5$" instead of $\log \varepsilon \geq 5$ (p. 39), "$n \rightarrow \pi$" instead of $n \rightarrow \pi^*$ excitation (p. 40), "E1/44; E1/45" instead of E1/T3 (p. 44), and "methylene bridges" instead of methine bridges (p. 56). It is also unfortunate that in the revision six literature citations in Pestemer's review article have been wrongly numbered. Lastly, in the introduction to UV-VIS spectroscopy, the only contribution that is described as having been rewritten, one would have expected to find a more representative and up-to-date collection of literature citations. The standard work on UV-VIS spectroscopy should at least have included a reference to G. Kortüm's book "Kolorimetrie, Photometrie und Spektrometrie" (Springer, Berlin, 1992).

Despite the shortcomings mentioned above, no science library should be without the atlas. It is a valuable working resource for all laboratories concerned in any way with UV-VIS spectroscopy, and can be thoroughly recommended.

Michael Faraday and the Royal Institution: The Genius of Man and Place. By *J. M. Thomas*. Adam Hilger, Bristol, 1991. XII, 234 pp., paperback £12.50.—ISBN 0-7503-0145-7

Few subjects appealed so strongly to Victorian biographers as did Michael Faraday, the bookbinder's apprentice unschooled beyond the age of 12, who through native talent, determination, hard work, kindness, eloquence, pluck, and simple virtue became a dominant figure in British intellectual society and one of the leading physicists and chemists of all time. Within three years of his death in 1867 three biographies appeared; the first, by his colleague and successor John Tyndall, went through five editions. Childless himself, Faraday delighted in children. Introducing them, and the general public, to the wonders and promise of experimental science was a calling that he felt as strongly as that of fundamental research. So it is fitting that a series of biographies over more than a century, and the enduring presence of *The Chemical History of a Candle* and others of Faraday's timeless writings, have inspired successive generations of the young to consider devoting their lives to science.

The present biography, published during the bicentennial of Faraday's birth, aims for accessibility to "all layfolk interested in, but not well informed about, modern science and especially young people in the arts and in all branches of the sciences." Because of the author's unique perspective and authority, and his skills as a writer and analyst of human endeavors, it will also appeal to professional scientists.

Professor Thomas writes as a special admirer of Faraday. For five years he has worked in Faraday's laboratory, lectured in his theater, lived in his home, and kept vibrant the scientific and educational tradition that he labored half a century to establish. This affinity with his subject not only gives the author access to rare materials, it also sharpens his insight into the symbiosis between Faraday and the Royal Institution of Great Britain.

Five of the book's eight chapters are devoted mostly to Faraday. The longest concerns his scientific contributions; others describe his youth, his skill and productivity as a writer, and his personal character. Every reader can profit by observing the nonpareil of experimental scientists, the discoverer of benzene and of electromagnetic induction, whose scientific rigor was not a whit diminished by his ignorance of

mathematics. Extracts from Faraday's writings are particularly effective at illuminating his personality. One example comes from his letter to Tyndall after an acrimonious scientific meeting in 1855: "I found....as a general rule, it was better to be a little dull of apprehension where phrases seemed to imply pique, and quick in perception when, on the contrary they seemed to imply kindly feeling."

The remaining three chapters focus on the Royal Institution, the unique legacy that is "part university, part museum, part research centre, part classroom, part library, part club, part exhibition and broadcasting center amongst other things." Readers who have known it primarily as the address of such luminaries as Davy, Huxley, Rayleigh, and most of the outstanding X-ray crystallographers of our century will learn a great deal about the people and traditions behind this remarkable institution. Impressive extracts and lists demonstrate the scope of its famous Friday Evening Discourses and Christmas Lectures through the years and are accompanied by capsule biographies of many lecturers and members.

Faraday did much to establish the model for the clear, precise, elegant lectures that characterize the Royal Institution. The contents and writing of this book give evidence that the tradition continues healthily towards its third century.

Artificial Life II. A Proceedings Volume in the Santa Fe Institute Studies on the Sciences of Complexity. Edited by *C. G. Langton, C. Taylor, J. D. Farmer,* and *S. Rasmussen.* Addison-Wesley, Redwood City, 1992. XXI, 854 pp., hardcover $ 57.95, paperback $ 41.25.—ISBN 0-201-52570-4

This volume describes part of the proceedings of a conference that brought together individuals interested in modeling living systems. The title of the book was sufficiently provocative to attract this reviewer's attention, especially as it was apparently a sequel to an earlier book, *Artificial Life,* which was interesting to read. Unfortunately, *Artificial Life II* is a disappointment by comparison with its predecessor, and will interest only the very mathematical specialist. *Artificial Life II* contains a collection of articles discussing various attempts to model, in a largely mathematical way, certain processes and properties characteristic of living systems. As with mathematical models generally, the relationship between life and the model described in this volume is often superficial. In *Artificial Life*, the novelty of the ideas and the obvious enthusiasm created by the assembling of individuals from various backgrounds compensated for this shortcoming. Neither the novelty nor the enthusiasm has been convincingly retained in the sequel. Most of the ideas in *Artificial Life II* are extensions of those in the earlier volume, and often rather simple extensions. Most disappointing was the absence of the experimental work on modeling chemical processes found in living systems that has emerged since the first volume was prepared. Several groups of experimental scientists, including von Kiedrowski in Germany, Luisi in Zurich, and Szostak, Orgel, Rebek, and their coworkers in the United States, have constructed in the laboratory experimental systems that serve as models for several of the key behavioral patterns of living systems. Although again these models are still in a very simple form, their availability makes purely mathematical models less exciting, especially as there was little in *Artificial Life II* to suggest that the contributors were aware of this work, and little that might guide experimentalists in their efforts. It would seem that contact between the mathematical modelers and the experimental chemists would be productive on both sides, offering the experimentalists some new insights and relieving the modeler of the vapidity that comes from computations disconnected from reality. One hopes that this will be recognized when the time comes to prepare the conference that yields *Artificial Life III.*

Capillary Electrophoresis. Principles, Practice and Applications. (Journal of Chromatography Library, Vol. 52.) By *S. F. Y. Li.* Elsevier, Amsterdam, 1992. XXVI, 582 pp., hardcover HFl 395.00, $ 225.50.—ISBN 0-444-89433-0

Capillary Electrophoresis (CE) is a new instrumental method of analysis which is undergoing very rapid development. This is matched by the rate of appearance of new monographs on the subject. This book by S. F. Y. Li differs from most in being an attempt by a single author to cover the whole field. Surprisingly, the author has not previously published much in the area of CE. The declared aim of the book is to give an easily understandable survey of CE, but it turns out to be more a collection of illustrated abstracts of individual publications. There are 1089 literature citations, so taking into account the fact that some of these are repeated in different chapters, this figure is consistent with the approximately 800–900 publications on CE that have appeared up to the beginning of 1992. This indicates that the literature on the subject has been fully covered.

The eight chapters vary in quality and length. Chapter 1 ("Introduction") gives a good survey of the historical development, followed by an explanation of the theoretical principles of CE and a comparison of this new separation method with conventional methods. Chapter 2 is concerned with sample introduction techniques, which are all described in great detail but not evaluated. Little is said about the problems that can arise with individual methods. However, the discussion of the problems of overcharging and excessive concentration (sample stacking) is highly topical. Chapter 3, the longest with over 100 pages, deals with all the types of detectors that have been described in the literature. However, it is doubtful whether it was appropriate to include detailed electronic circuit diagrams here. It would certainly have been better to reduce this to a critical summary, although it might have involved more work. The ability of the author to do this is shown by the table at the end of this chapter listing the most important detector properties.

The arrangement of subject matter in the rest of the chapters seems a little arbitrary. The chapter on "Column Technology" describes the preparation of both coated and gel-packed capillaries, whereas the principles of electrophoresis in gel-packed capillaries are treated just in the final section of this chapter. The chapter on "Electrolyte Systems" discusses capillary zone electrophoresis and micellar electrochromatography, whereas the other techniques (isoelectric focussing, isotachophoresis, and methods for coupling to a mass spectrometer) are treated in the chapter on "Special Systems and Methods". The chapter on "Applications" summarizes the uses of electrophoretic separation methods in a wide variety of fields. Here the space devoted to applications involving different classes of substances (peptides and proteins: 36 pp., nucleotides: 19 pp., pharmaceuticals: 18 pp., etc.) is in keeping with the relative importance of CE

in these areas. There is a table giving a quick survey of the types of substances that have been separated, with references to the original publications. The final chapter includes a late list of publications that appeared while the book was in preparation, extending the coverage to about the end of March 1992.

To summarize, the book offers a detailed and apparently complete survey of the literature on capillary electrophoresis. The information content is greater than that in the usual *Annual Reviews of Analytical Chemistry*. On the other hand, the published work is reviewed in an uncritical way. Consequently, one finds quite contradictory results cited in short succession, and some material is repeated in the individual chapters, thus increasing the length unnecessarily. However, these criticisms should not detract from the author's achievement in having produced a book of this kind that is so up-to-date (reflecting the state of knowledge at the beginning of 1992). It should be regarded as a handbook and reference source on CE rather than a textbook. It will be extremely useful to everyone who wishes to have rapid access to the literature on the subject.

Heinz Engelhardt
Angewandte Physikalische Chemie
Universität des Saarlandes
Saarbrücken (FRG)

Electrochemistry in Colloids and Dispersions. Edited by *R. A. Mackay* and *J. Texter*. VCH Publishers, New York/VCH Verlagsgesellschaft, Weinheim, 1992. XV, 546 pp., hardcover DM 210.00.—ISBN 1-56081-573-6/3-527-89573-6

This book contains 36 contributions by 83 authors. Some of the contributions are written in the style of review articles, while others report original research. They are based on papers presented at the Symposium on Electrochemistry in Microheterogeneous Fluids, which was held in August 1991 in New York under the auspices of the Division of Colloid and Surface Chemistry of the American Chemical Society. The aim of the symposium was to review the current state of knowledge in this rapidly developing interdisciplinary field, which lies between electrochemistry and the physical chemistry of colloidal systems. Studies on biophysical systems were deliberately excluded.

The book consists of five sections as follows: 1. Electroanalytical Methods and Applications (6 articles); 2. Transport Phenomena in Micellar Systems, Suspensions of Liposomes, and Microemulsions (9 articles); 3. Polymers and Latices (5 articles); 4. Electrosyntheses and Electrocatalytic Reactions (4 articles); 5. Colloidal Metals and Semiconductors (12 articles). Readers with interests in electrochemistry and in the physical chemistry of colloidal systems will probably not find much here that is new, except for the articles in the section on colloidal metals and semiconductors which together present a good picture of current development trends in this area. For those wishing to learn about the electrochemistry of colloidal systems the introductory chapter by one of the editors (J. Texter) will be of particular interest. In about 20 pages (with 252 literature references) Texter gives a comprehensive overview of the background to the individual contributions that follow, with examples taken from important results obtained by leading workers in this field.

Although the editors acknowledge the "cheerful and professional assistance" of a number of people at the research laboratories of the Eastman Kodak Company in enabling them to submit the articles to the publishers in camera-ready form, the book is by no means cheap. What, then, makes it particularly useful? Owing to the rising costs of scientific journals and the fact that departmental libraries have had their budgets frozen for several years, they have been forced to cut out more and more titles. The disturbingly impoverished state of such libraries is readily apparent to everyone using them. As a result scientists in Germany find that access to original publications is increasingly laborious and time-consuming. Copies of articles that seem to be especially important can be obtained from central libraries, but the cost is then charged to the research group's basic operating budget, which is usually small. In view of this situation it could be worthwhile to buy this volume, provided that the interested reader can persuade the library committee to do so despite the high price.

Dietrich Woermann
Institut für Physikalische Chemie
der Universität Köln (FRG)

Proton Conductors. Solids, Membranes and Gels—Materials and Devices. (Series: Chemistry of Solid State Materials, Vol. 2, series editors: *A. R. West* and *H. Baxter*.) Edited by *P. Colomban*. Cambridge University Press, Cambridge, 1992. XXXII, 581 pp., hardcover £ 75.00.—ISBN 0-521-38317-X

The second volume of the series "Chemistry of Solid State Materials" is concerned with an aspect of the chemistry of hydrogen that is relatively unfamiliar to the chemist, namely protons in "solids with pathological symptoms". To qualify as a *solid electrolyte* a material must have disorder, which can be induced thermally or chemically. In solids the ions become mobile enough for conduction to occur only at high temperatures. Chemical modifications can be achieved in a multistage synthesis so as to introduce specific structural defects which confer the high temperature conductivity needed for applications in high performance batteries or fuel cells. In Chapter 3 of this book the special characteristics of solid ionic conductors, with the emphasis on proton conductors, are skillfully and concisely presented by the editor, P. Colomban, and A. Novak. From this it already becomes clear that, because of the complicated nature of most proton conductors, they do not yet offer the basis for a reliable technology or a large commercial market. Nevertheless, the authors report many novel and exciting results of fundamental research on hydrogen-containing materials, which are seldom adequately covered in conventional textbooks and data complications. One moves on eagerly to the chapters that treat particular groups of materials with special types of defect structures, the effects that these have on proton conduction, and especially the technology of applying them.

The chapter on "Hydrogen Bond and Protonic Species" (100 pp.) describes the fundamentals of chemical bonding and proton structure in the compounds formed by hydrogen with the strongly electronegative elements oxygen, fluorine, and nitrogen. The special position of proton conductors compared with other types of solid ionic conductors is emphasized here. This chapter also includes a contribution on hydrogen in metals, by I. Svare. The discussions of adsorption and desorption, diffusion, tunneling, and the structure of metal hydrides go beyond the area defined by the book's title: here one is not mainly concerned with the proton H^+ but with the valence states H^- and H^0. Nevertheless, the article serves a useful purpose in completing the picture of the behavior of hydrogen in its compounds, and especially the dynamics of the bonding, and at the same time defining a boundary to the subject!

Chapter 2 (225 pp.) is concerned with "Materials: Preparation, Structures and Properties". Here the reader is introduced to many different types of materials, and the temperature-dependent conducting properties of several well-known families of proton conductors such as Nafion and β″-alumina are described. In the contribution by Dickens and Chippendale we get to grips with the problems of the nonstoichiometric oxides of the transition metals W, Mo, V, Cr, and U. The analysis of the constitution of these materials has only been possible through a combination of methods, some of which are fairly unusual in chemistry: vibrational spectroscopy, magic-angle-spinning (MAS) NMR spectroscopy, and incoherent inelastic neutron scattering. To develop quantitative relationships that describe how the hydrogen in these compounds influences the constitution and properties calls for lateral thinking and an imaginative approach to analytical results, analogous to dealing with macromolecular materials in biochemistry, for example. Next some specific groups of proton conductors are discussed: perovskites, hydroxides of the alkaline earth metals, the oxyacids of phosphorus, arsenic, sulfur, selenium, and chlorine, and graphite intercalation compounds. However, it is not obvious why it was thought necessary to treat the next three groups of materials, the β- and β″-polyaluminates, the zeolites, and the Nasicon phases, in a separate sub-chapter entitled "Inorganic Ion Exchangers". The same also applies to the following sub-chapter on "Layer Hydrates"; this includes some very special groups of proton conductors (e.g., γ-$Zr(HPO_4)_2$), which are not hydrates at all but hydroxo salts or hydrogen phosphates of the tetravalent metals Ti, Zr, and Ce, and, moreover, do not necessarily have layer structures.

Chapter 3 (115 pages) is entitled "Proton Dynamics and Charge Transport", and deals with the special methods used for characterizing proton conductors. The eight articles describe the use of vibrational spectroscopy, NMR spectroscopy, various methods for measuring dielectric constants, impedance spectroscopy, and neutron scattering. Emphasis is placed on the discussion of typical results for some specific materials, thereby providing readers who intend to use these methods with the theoretical background needed to interpret spectra or other data.

Chapter 4, "Proton Diffusion Mechanisms", consists of three short articles by Slade, Colomban, Novak, and Kreuer which discuss specific proton conduction mechanisms. These discussions link up with some fundamental aspects of bonding and thermodynamics in proton conductors (e.g., the dynamics of the proton in hydrogen bonding, as treated in Chapter 1). However, it is difficult to see why the fundamental article by I. A. Ryzhkin on "Ice" was not included here instead of in Chapter 2.

In Chapter 5, "Devices", we learn something about the latest state of the art in applications to secondary energy storage and to primary energy generation using fuel cells. Also in the fields of gas sensors, electrochromic devices, field effect transistors, and super-capacitors there are articles reporting on recent developments, results with pilot systems, and prospects for new types of thin film elements.

The editor, P. Colomban, has made a good choice of topics and authors. In putting together the specialized contributions of 38 authors in five main chapters with altogether 575 pages he has, remarkably, managed to avoid over-stretching the material or losing the reader's attention by offering too heterogeneous a presentation. Chemists, physicists, and engineers will all find the book informative. The detailed introduction, comprehensive subject index, and table of symbols all afford clear and easy access to the material. References are given throughout to original papers as well as reviews, a mark of quality in a specialist book such as this with an international team of authors.

Jürgen Felsche

der Universität Konstanz (FRG)

Metallothioneins. Synthesis, Structure and Properties of Metallothioneins, Phytochelatins and Metal–Thiolate Complexes. Edited by *M. J. Stillman, C. F. Shaw III*, and *K. T. Suzuki*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York, 1992. IX, 443 pp., hardcover DM 218.00.—ISBN 3-527-28011-1/0-89573-785-X

Seven years after the publication of the two-volume work "Metalloproteins", edited by P. Harrison, the same publishing house has now brought out a volume devoted expressly to metallothioneins. The editors' aim is to present a collection of review articles by recognized experts so as to cover the rapid developments that have occurred in this field. The book consists of 16 chapters. After a succinct introduction in Chapter 1 to the metallothioneins and related polypeptides (cadystins and phytochelatins), the following topics are treated: preparation, isolation, and identification (Ch. 2), X-ray structure determination (Ch. 3), studies using circular dichroism (CD), magnetic circular dichroism (MCD), and emission spectroscopy (Chs. 4 and 5), kinetic studies of cluster formation, metal exchange reactions, and ligand substitution (Ch. 7), phytochelatins and cadystins: synthesis and biosynthesis, and studies of their role in Cd^{2+} and S^{2-} metabolism (Chs. 9–12), and model complexes: metal–thiolate complexes and NMR studies of complexes with adamantane-like structures (Chs. 13 and 14). Other topics covered include aurothioneins (Ch. 6), analysis for mercury (Ch. 8), models of Cu^{II} proteins (Ch. 15), and metallodrugs (Ch. 16).

The book gives comprehensive accounts of the present state of knowledge in each of the areas treated. The treatment of "Optical Spectroscopy of Metallothioneins" in Chapter 4 is especially interesting. So many results are presented here that one is confused at first, but the author goes on to provide the interested reader with a clear picture of the dynamics of cluster formation and the wide variety of metallothionein structures produced in this way. The picture is completed by the article on "Kinetic Reactivity of Metallothioneins" in Chapter 7. On the basis of the results on metal exchange reactions and ligand substitution the author has succeeded in reaching a better understanding of the hitherto obscure function of thioneins in an organism. Four further chapters deal with phytochelatins and cadystins. Since these peptides have only been studied for about ten years, some questions remain unanswered, for example concerning the relationship between sulfide metabolism and production of phytochelatin. Also no clear picture of the structures of these cadmium- and zinc-containing peptides has yet emerged, since there have as yet been no single crystal X-ray studies. Chapter 11 on "Metal:sulfide Quantum Crystallites in Yeast" gives a suggested structure for the metal centers in these sulfide-containing cadmium-binding proteins, based on powder X-ray diffraction patterns. The article on "Metal–Thiolate Compounds" (Ch. 13) reviews the latest findings on coordination principles in synthetic metal–thiolate and metal sulfide–thiolate complexes. Readers seeking a quick and straightforward summary of the latest developments in this area will much appreciate the clearly set out table which lists all the new complexes synthesized in the last six years. This chapter and Chapter 14 on "Adamantane-

Like Cages" together serve to bridge the gap between inorganic chemistry and biochemistry.

One of the book's weaknesses is undoubtedly that the potential of NMR spectroscopy only emerges in Chapter 14, and no mention is made of the great importance of ^{113}Cd–^{1}H NMR spectroscopy in elucidating the three-dimensional structures of metallothioneins. In recent years NMR spectroscopy has become such a powerful method in this area that even the interpretation of X-ray crystallographic data has had to rely on NMR results. The neglect of NMR spectroscopy is probably due to the fact that the book has developed out of papers presented at the symposium on "The Chemistry of Heavy Metals in Physiologically Important Roles" (Hawaii, 1989).

Altogether, this book is of interest to those involved in all aspects of metallothionein research, as it is clearly presented and contains nearly 1000 literature references which afford easy access to the original publications. It should therefore be available in every departmental library.

Inorganic Polymeric Glassses. (Series: Studies in Inorganic Chemistry, Vol. 15.) By *R. C. Popp*. Elsevier, Amsterdam, 1992. XIV, 322 pp., hardcover HFl 365.00.—ISBN 0-444-89500-0

This book contains a useful survey of experimental results on glass-forming phosphate systems, explaining clearly how these relate to applications. Special attention is devoted to the suitability of these materials for immobilizing and sealing in radioactive wastes in the nuclear energy industry.

The introductory chapter deals with the fundamentals of glass formation, the important properties that can be controlled by adjusting the process variables, and the main technological methods used in glass manufacture, including a brief survey of aspects such as sol–gel technology and fiber optics processes. However, the emphasis on phosphate glasses as inorganic polymeric glasses, thereby making a distinction between these and glasses made from other glass-forming systems, seems rather arbitrary, and can hardly be justified on structural grounds.

The main part of the book is concerned with efforts to produce glasses with the highest possible chemical stability, and with the analytical and diagnostic methods used to evaluate them. Much space is devoted to the resistance to hydrolysis and acids, and the effects of impurities (especially contamination from the crucible wall during melting) on the properties, including the recrystallization and segregation behavior, illustrated throughout by electron micrographs. However, in the course of this the author makes some statements that are unsupported by experimental evidence and do not take into account other results reported in the literature. Thus, he denies the existence of a specific mechanism for internal diffusion in glasses of this type, whereas it is known, for example, that $Na^{\oplus}$ ions have a higher mobility in $NaPO_3$ glasses than they do at comparable concentrations in silicate or borate glasses. As the book describes, glass-forming phosphate systems are used not only for encapsulating radioactive wastes but also in luminescent glasses, and the range of uses is being further extended to medical applications based on their proven biocompatibility; for example, glasses of this type or suitable glass ceramics can be used as bone cements or in dental prosthetics.

Each chapter ends with a bibliography listing important original papers and, most usefully, review articles. This is a monograph on a specialized field, in which a notable feature is the thorough survey of knowledge on the inorganic structural chemistry of condensed phosphates.

The excellent layout makes the text quick and easy to assimilate. The book will certainly be welcomed and used by specialists in the field of phosphate-containing materials. It has been produced using a computer text-processing program, and this becomes apparent especially in the diagrams, which do not always have the necessary captions. In view of this, the rather high price seems surprising.

The Battle of Calicheamicin γ_1^I

By K. C. Nicolaou*

*In memory of Franz Sondheimer***

The first total synthesis of calicheamicin γ_1^I was achieved approximately a year ago. In this article, the author presents a personal account of the events, in chronological order, that led to this success story in total synthesis.

Introduction

Chaliche, a word of Greek origin (χαλιξ≡chaliche) means "pebble made of lime stone". No one could have ever imagined that this little pebble would hide for millions of years the secrets of calicheamicin γ_1^I (**1**) (Fig. 1).[1] A microorganism attached to the pebble produces this antitumor antibiotic that has created so much excitement in scientific circles and continues to fascinate those who get to know it. Among the many groups who had the good fortune to work with this unique molecule was ours, and below we unfold the story of our battle for the total synthesis of calicheamicin γ_1^I. The drive for the conquest of this highly prized natural product generated excitement and drama rarely seen before in synthesis and, as such, it is worthwhile to record some of its details.

We begin with some rather esoteric, but fundamental, observations from the 1970s which were destined to become one of the most celebrated reactions of the 1980s and beyond. In 1972, Robert Bergman, then at the California Institute of Technology (CalTech), reported the thermal cycloaromatization of conjugated *cis*-enediynes to 1,4-benzenoid diradicals, a reaction he ingeniously designed and thoroughly studied (Fig. 2).[2] Neither he, nor anyone else could have dreamed that this fundamental process, which had also been observed by Sondheimer et al.[3] and Masamune et al.[4] and is known today as the Bergman reaction (Fig. 2), could have been used by Nature for eons in chemical warfare amongst microorganisms. For at the heart of the

mechanism of action of calicheamicin γ_1^I as a powerful antibiotic lies this very reaction (Fig. 3).

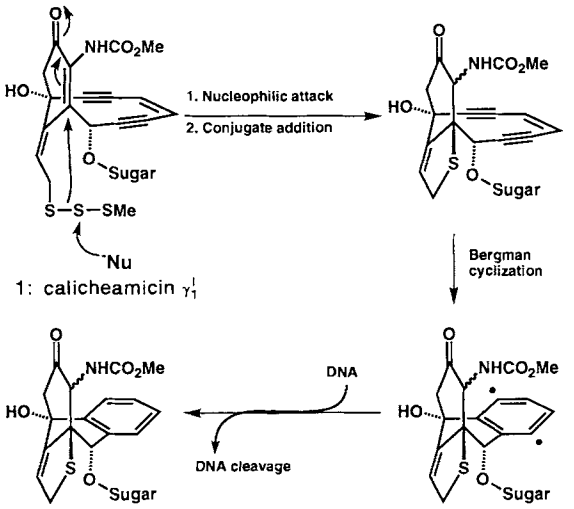

Fig. 3. Proposed mechanism of action of calicheamicin γ_1^I 1.

In July 1986, I was attending the Natural Products Gordon Conference in New Hampton, New Hampshire, where I had the good fortune of making the acquaintance of Robert Babine of Lederle Laboratories. He tantalizingly brought to my attention a new natural product that the Lederle group was working on with an "amazing structure and phenomenal biological activity" as he put it. Without revealing the structure of the molecule, Robert assured me that the structure would intrigue me, and that he would see to it that I heard about it before publication!

In September 1986, a phone call from Robert Babine brought me to Pearl River, New Jersey, the next day where the Lederle group, which included May Lee and George Ellestad, were waiting. After the obligatory signature to assure confidentiality, I was allowed to take my first glance at the structure of LL-E33288 γ_1^I –the code number for that "amazing natural product" (Fig. 4). Indeed, I was amazed!

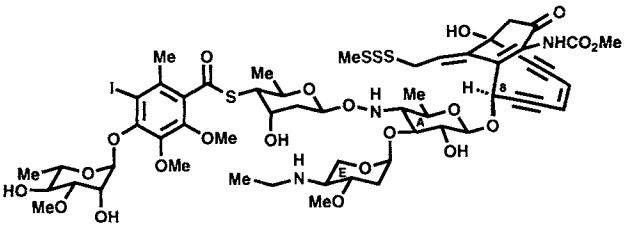

Fig. 4. September 1986: First look at the structure of LL-E33288 γ_1^I (calicheamicin γ_1^I) on a visit to Lederle Laboratories. The early structure turned out to be partly incorrect (configuration at C-8 of the aglycon and point of attachment of ring E to ring A) and was later rectified. R. Babine, M. D. Lee, G. Ellestad, personal communication.

Speechless, I proceeded to scan the structure with my eyes and mind with mixed feelings best described as alternating among disbelief, excitement, admiration, and hope! Finally, I chose to utter in disbelief, but with a secret hope of optimism, "The structure must be wrong. I cannot believe that those acetylenes could allow such a strained ring system to exist. And what about that trisulfide? Are you sure about that NH–O bond?" By the end of the day, however, the Lederle group had convinced me of the "correctness" of their structure and I drove home to Philadelphia that evening, quite excited, contemplating what this molecular structure was holding for us in terms of chemical synthesis, molecular design, biology, and medicine.

The Daring Proposal

The next morning I held a meeting in my office at the University of Pennsylvania with two of my best students, Nicos A. Petasis and Guido Zuccarello, to whom I entrusted the secret of the structure of LL-E33288 γ_1^I; together we began planning a strategy for the total synthesis and the solution of the associated chemical problems. The project was code named "Molecular Robotics" and no one was to leak the structure until we received permission from the Lederle group. By February 1987 a synthetic strategy was ready, and a proposal was submitted to the National Institutes of Health (NIH). By the summer of 1987 the structure of LL-E33288 γ_1^I, now renamed calicheamicin γ_1^I, was in the public domain (Fig. 5). At about the same time we learned from

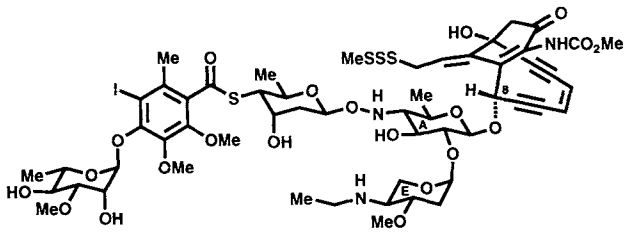

Fig. 5. February 1987: The Lederle group reports the structure of calicheamicin γ_1^I. The configuration at C-8 on the aglycon is now correct. M. D. Lee, T. S. Dunne, M. M. Siegel, C. C. Chang, G. O. Morton, D. B. Borders, *J. Am. Chem. Soc.* **1987**, *109*, 3464; M. D. Lee, T. S. Dunne, C. C. Chang, G. A. Ellestad, M. M. Siegel, G. O. Morton, W. J. McGahren, D. B. Borders, *ibid.* **1987**, *109*, 3466.

NIH that our grant had been recommended for approval with a score of 3.15 (out of 5, 1: best, 5: worst) or 87.2 percentile level (ranked worse than 87.2% of the proposals reviewed in that round!). This was obviously disappointing to us, to say the least, and remains to this day by far the worst score this group ever received from NIH! The study section at NIH was right, however: besides, the many questionable steps in our proposed synthesis (indeed, how could one not have questionable steps in a strategy towards such a diabolical and, at the time, questionable molecular structure!), we had directed our approach toward the incorrect structure! As it turned out, the structure revealed to us by the Lederle group in September 1986 had the wrong stereochemistry at C-8, and the wrong attachment site for the aminosugar (Figs. 4 and 6)!

Much to their credit, the study section enthusiastically endorsed our second attempt to secure funding from NIH in the next round. This time our strategy was directed at the correct structure, although it was, in essence, very similar to the one originally proposed. A brief consideration of our plans included in that fatal first proposal, particularly in the

context of the chemistry subsequently developed in the field, may be constructive and amusing.

In Figure 6 the retrosynthetic analysis of the target structure (incorrect) indicates how we intended to utilize the Schmidt trichloroacetimidate method for the coupling of the carbohydrate and aglycon fragments. Interestingly, this turned out to be the way we and the Danishefsky group – our major competitors (see below)—successfully carried out this step.

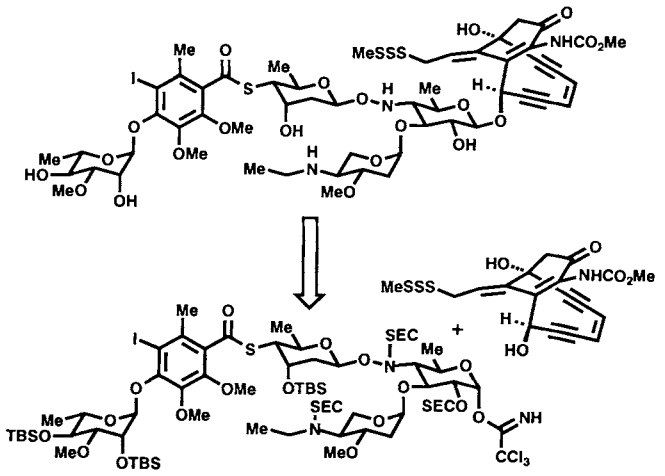

Fig. 6. Early 1987: Retrosynthetic analysis of LL-E33288 γ_1^I (incorrect isomer) according to the orginal proposal. Abbreviations and acronymns, for example for protecting groups, are not explained in this article; for details the reader should consult the orginal literature or for example the enediyne review article from Nicolaou et al. in November 1991 in *Angewandte Chemie* [1 b].

In Figure 7 a retrosynthetic analysis of the aglycon fragment is shown, depicting the original five alternative approaches to this unusual skeleton. Again, it is interesting to

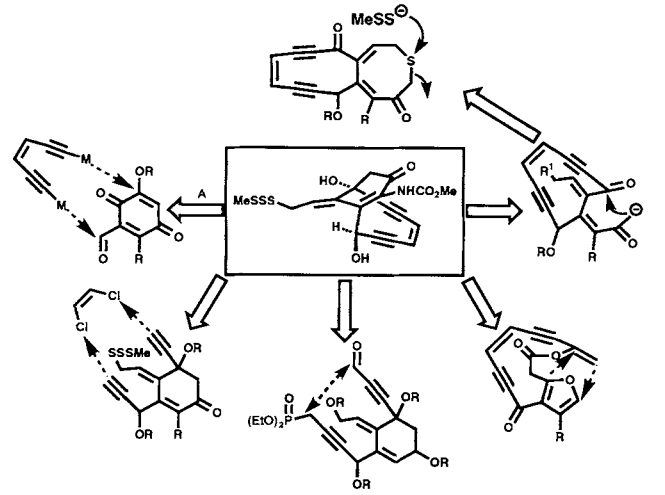

Fig. 7. Early 1987: Retrosynthesis of the aglycon of calicheamicin γ_1^I in the original proposal; a wide range of approaches was considered.

observe that one of them (approach A) contained the essence of the intramolecular acetylide–aldehyde condensation as the key step in forming the 10-membered enediyne ring, a concept that proved crucial in building calicheamicinone and related systems and was used by ourselves and by several research groups including those of Danishefsky and Kende

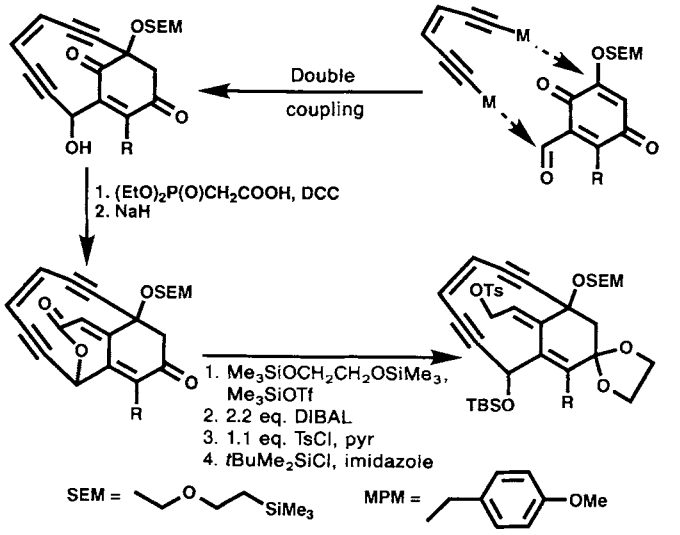

Fig. 8. Early 1987: Proposed synthesis of the aglycon of calicheamicin γ_1^I based on an acetylide–aldehyde condensation in the original proposal.

(see below). Figure 8 gives a more detailed version of this original plan and illustrates our projected elaborations towards more advanced intermediates. Some of the other strategies shown in Figure 7, however, remain curiosities to this day.

In Figure 9 our original ideas pertaining to the construction of the oligosaccharide fragment are summarized. Al-

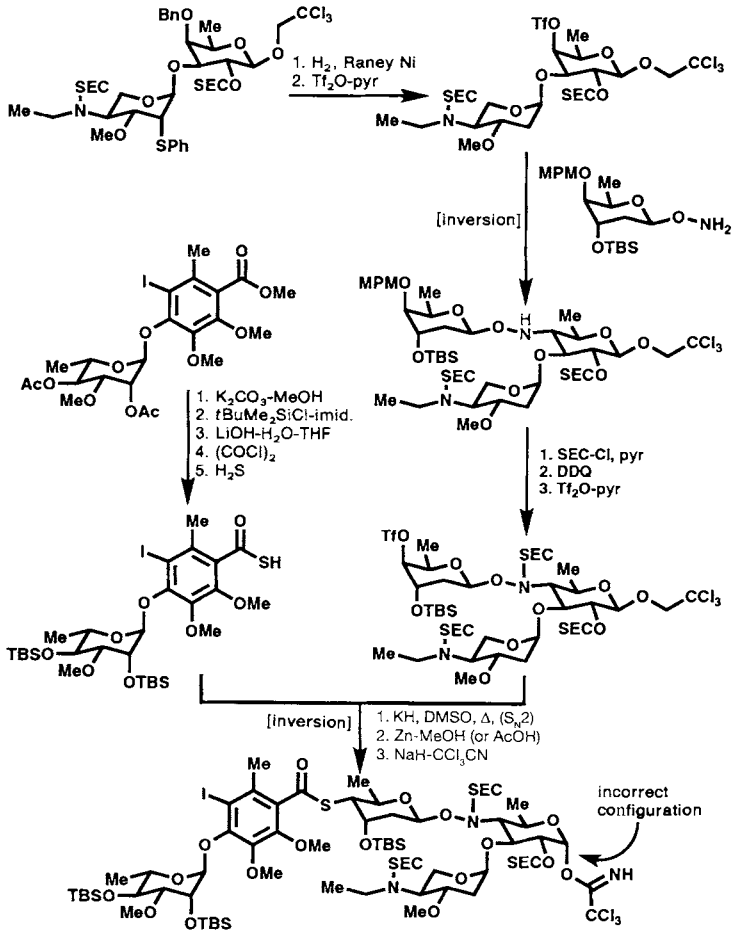

Fig. 9. Early 1987: Proposed synthesis of the oligosaccharide of calicheamicin γ_1^I in the original proposal.

though neither of the two proposed coupling reactions were used in our synthesis, the feasibility of the nucleophilic displacement of a trifluoromethanesulfonate (triflate) by a nitrogen nucleophile as a means of constructing the NH–O bond was demonstrated independently by the Kahne and Danishefsky groups in their pioneering studies on calicheamicin γ_1^I. As it turned out, we opted for an oxime forming reaction followed by reduction as a strategy for the construction of this unusual bond of calicheamicin (see below).

The Competition

The emergence of calicheamicin γ_1^I as a challenging synthetic target provided a rare opportunity for creativity in organic synthesis and molecular design. Although such endeavors should not ideally be subject to time constraints and the pressures of competition, these elements of human nature always surface, particularly when the projects are attractive and the stakes are high. Such was the case of calicheamicin γ_1^I. It is almost certain that most who entered the arena, including ourselves, had, at the outset, strong misgivings whether the total synthesis of such a complex and constrained molecule could be achieved! All of us, however, were quite convinced that interesting scientific results should emerge from such an undertaking. For the interest of the reader, and in order to extend credit to those groups who contributed so importantly to the feat of the calicheamicin total synthesis, the main landmark events along the way to this molecule are highlighted.

The first "bombshell" was dropped by Schreiber and Kiessling who submitted a paper in August 1987 to the *Journal of the American Chemical Society* (JACS) claiming the synthesis of the first calicheamicinone model system by a breathtaking intramolecular Diels–Alder reaction (Fig. 10).

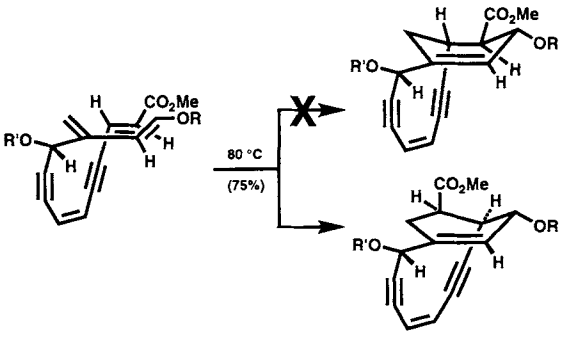

Fig. 10. August 1987: Schreiber et al. drop the first "bombshell" claiming the first synthesis of a calicheamicinone model (S. L. Schreiber, L. L. Kiessling, *J. Am. Chem. Soc.* **1988**, *110*, 631); this was later (1988) proven to be the wrong isomer and shortly thereafter (1989) was converted to the correct isomer by a clever pinacol rearrangement (see Fig. 11).

However, a little later (1988) it was determined that the major product of this reaction had the "incorrect" regiochemistry, prompting Schreiber to withdraw his claim but also to devise an ingenious solution to the isomer problem based on a clever pinacol rearrangement (1989) (Fig. 11) which had previously been reported by Tsuchihashi et al.[5]

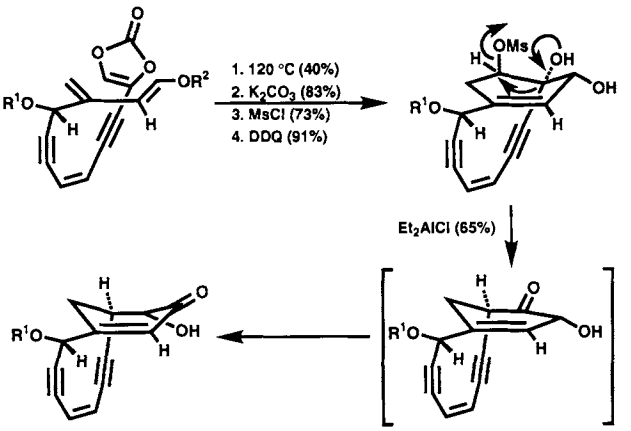

Fig. 11. May 1989: Schreiber et al. convert a Diels–Alder adduct by the pinacol rearrangement to deliver a calicheamicinone model system with the correct regiochemistry. F. J. Schoenen, J. A. Porco, Jr., S. L. Schreiber, *Tetrahedron Lett.* **1989**, *30*, 3765.

In February 1988, a paper was submitted by our group to JACS describing the synthesis and properties of the 10-membered ring parent hydrocarbon which represented the enediyne moiety of calicheamicin (Fig. 12). In May, later that year, we reported the first demonstration of DNA cleavage by a synthetic 10-membered ring enediyne system through a Bergman cyclization in the same journal. Much more work in this field was to follow from ourselves and other research groups around the world.

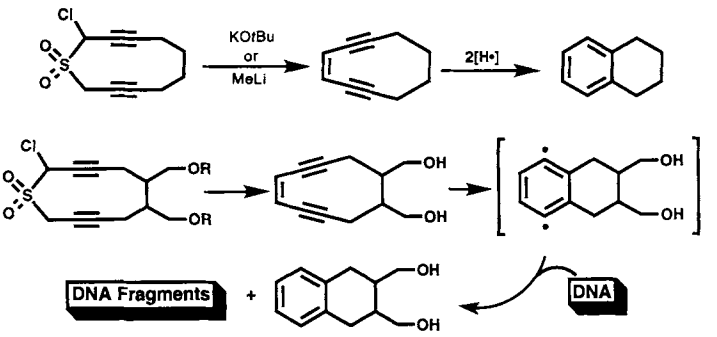

Fig. 12. February 1988: The Nicolaou group synthesizes the parent 10-membered ring enediyne unit such as in calicheamicinone (K. C. Nicolaou, G. Zuccarello, Y. Ogawa, E. J. Schweiger, T. Kumazawa, *J. Am. Chem. Soc.* **1988**, *110*, 4866) and provides the first demonstration of its ability to cleave DNA (K. C. Nicolaou, Y. Ogawa, G. Zuccarello, H. Kataoka, *ibid.* **1988**, *110*, 7247).

In March 1988, our group also reported, in a submission to *Angewandte Chemie*, the first synthesis of the aromatic ring (ring C) of calicheamicin γ_1^I and the observation of the rare phenomenon of spontaneous resolution of two enantiomeric forms of this "seemingly achiral" molecule upon crystallization (cf. Pasteur and tartaric acid) (Fig. 13).

In June 1988, Magnus and his group established the elegant cobalt route to calicheamicinone model systems (Fig. 14). This entry allowed Magnus et al. to carry out a series of mechanistic studies in the field and to penetrate further into more sophisticated models of the calicheamicinone system. The same method was also demonstrated later by Tomioka et al. [6] who reported a similar synthesis of a related enediyne system.

June 1988 was also the month in which both Danishefsky et al. and Kende et al. reported their landmark demonstrations of the intramolecular acetylide–aldehyde condensation approach to the calicheamicinone core. Danishefsky's sophisticated system was reported in JACS (Fig. 15) and Kende's work appeared in *Tetrahedron Letters* (Fig. 16). The Danishefsky group extensively utilized this entry to produce

a series of more advanced calicheamicinone systems and eventually to arrive at calicheamicinone itself (see below).

In January 1989, the Magnus group achieved the first introduction of the trisulfide moiety onto a calicheamicinone model system from a thiol by using the Harpp–Boustany method with *N*-(methyldithio)phthalimide (Fig. 17).

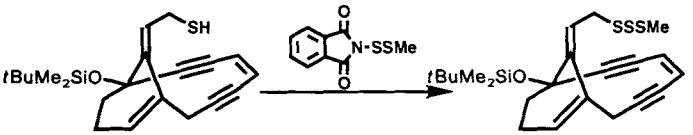

Fig. 17. January 1989: The Magnus group installs the trisulfide moiety (90% yield 1.3:1 mixture of tri- and disulfide) on a calicheamicinone model system for the first time. P. Magnus, R. T. Lewis, F. Bennett, *J. Chem. Soc. Chem. Commun.* **1989**, 916.

In December 1989, we—the Nicolaou group—reported the synthesis of an ABC model system for the carbohydrate fragment of calicheamicin γ_1^I by using a [3,3] sigmatropic rearrangement to install the sulfur group in ring B shown in Figure 18, and the oxime-based technology to construct the N–O bond (Fig. 18). This method was later adopted by the

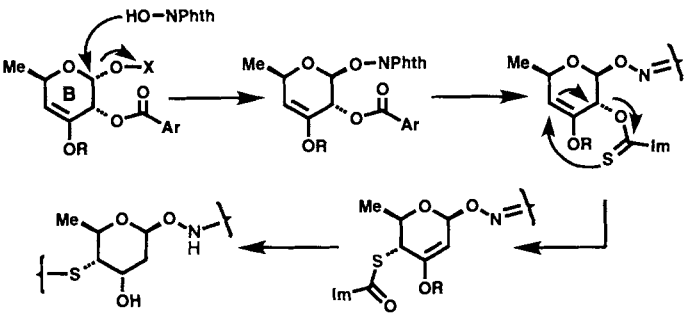

Fig. 18. December 1989: The Nicolaou group report the synthesis of an ABC model system of the oligosaccharide, in which a [3,3] sigmatropic rearrangement is used to install the sulfur group and the oxime method is used to construct the N–O bond. K. C. Nicolaou, R. D. Groneberg, *J. Am. Chem. Soc.* **1990**, *112*, 4085.

same group in the synthesis of the complete oligosaccharide segment (see below). As often is the case in total synthesis, this successful strategy was not the first we attempted. Extensive experimentation and considerable fine-tuning had to be done prior to final success. One such abortive attempt to set up the ring B functionality is shown in Figure 19 in which the [3,3] sigmatropic rearrangement was to be followed by in-

tramolecular delivery of the requisite oxygen atom. The latter operation was not to be realized, however, which forced us to redesign our strategy (see Fig. 18).

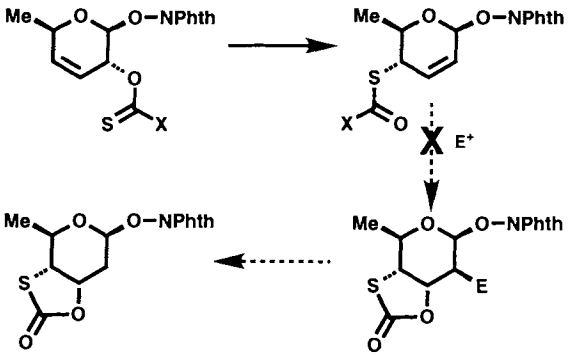

Fig. 19. A proposed electrophilically induced ring closure fails, forcing modifications of the scheme to include the requisite C-3 oxygen in the rearrangement substrate (see Fig. 18). X = NHPh, $OCH_2C_6H_4OMe$, imidazolyl.

In January 1990, the Danishefsky group moved ahead with the report of the first synthesis of racemic calicheamicinone (Fig. 20). This brilliant work was a significant breakthrough in that it provided an entry to the aglycon fragment of calicheamicin for coupling with the oligosaccharide segment which was still, however, elusive to any of the groups involved.

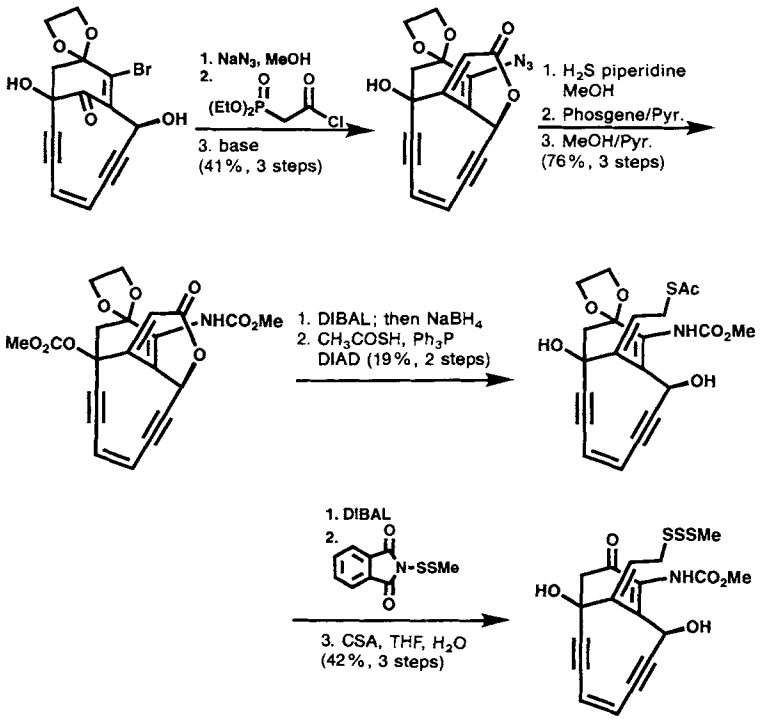

Fig. 20. January 1990: The Danishefsky group reports the first total synthesis of racemic calicheamicinone and thus moves ahead. M. Paz Cabal, R. S. Coleman, S. J. Danishefsky, *J. Am. Chem. Soc.* **1990**, *112*, 3253.

The first total synthesis of the carbohydrate fragment of calicheamicin γ_1^I was reported in July 1990 by our group (Fig. 21). Headed by Robert D. Groneberg, the group working on this fragment was able to overcome the many difficulties encountered and deliver the saccharide fragment in multigram quantities. The team, however, was still anxiously searching for a calicheamicinone route and serious concern about this problem was building in La Jolla.

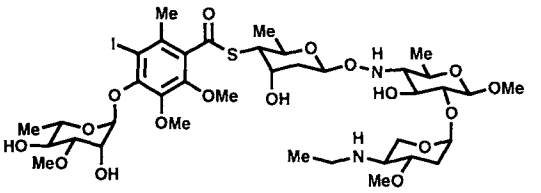

Fig. 21. July 1990: The Nicolaou group reports the first total synthesis of the pentacyclic oligosaccharide by using the sigmatropic rearrangement–oxime method. K. C. Nicolaou, R. D. Groneberg, T. Miyazaki, N. A. Stylianides, T. J. Schulze, W. Stahl *J. Am. Chem. Soc.* **1990**, *122*, 8193.

In December 1990, our group reported the first demonstration of the trichloroacetimidate-based methodology for the construction of the crucial glycoside bond which links the carbohydrate and aglycon fragments of calicheamicin. In this study we coupled the AE oligosaccharide segment with a dynemicin enediyne model system (Fig. 22). This originally

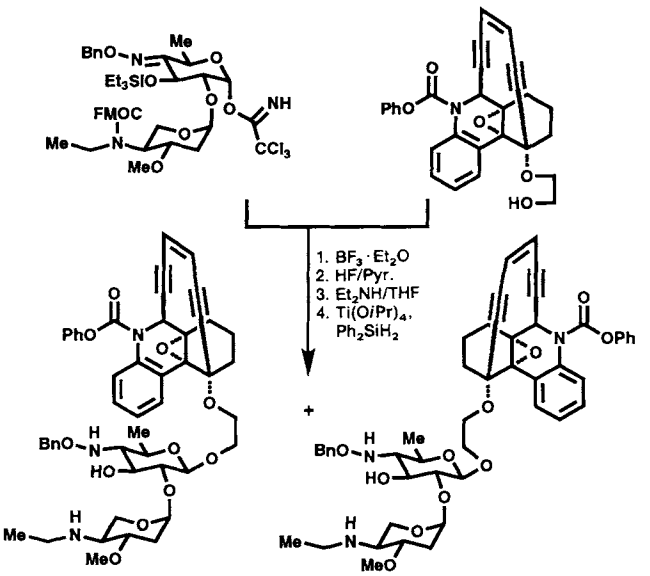

Fig. 22. December 1990: The Nicolaou camp demonstrates for the first time the viability of Schmidt's trichloroacetimidate method in the coupling of the oligosaccharide and aglycon fragments by using model systems. K. C. Nicolaou, E. P. Schreiner, W. Stahl, *Angew. Chem.* **1991**, *103*, 566; *Angew. Chem. Int. Ed. Engl.* **1991**, *30*, 585.

proposed method (see Fig. 6) was later successfully used by both ourselves and the Danishefsky groups to construct more advanced calicheamicin–dynemicin hybrid compounds and potential calicheamicin precursors (see below). Eventually, the same technology played a crucial role in the successful total synthesis of calicheamicin γ_1^I.

December 1990 was also the time of submission of the first demonstration of the triflate nucleophilic displacement approach to construct the N–O bond of calicheamicin by the Kahne group (Fig. 23). This work also included the synthesis of the oligosaccharide ABE ring system.

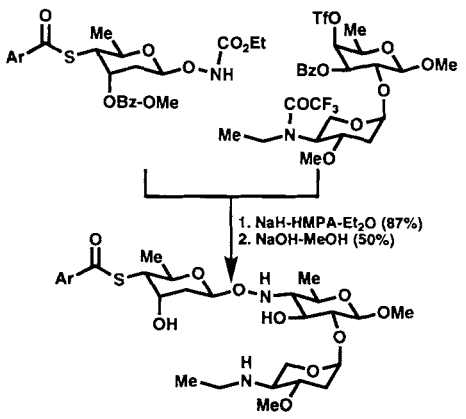

Fig. 23. December 1990: The Kahne group reports the synthesis of an ABE oligosaccharide in which the N–O bond is constructed by nucleophilic substitution of a triflate. D. Yang, S.-H. Kim, D. Kahne, *J. Am. Chem. Soc.* **1991**, *113*, 4715.

In March 1991, the Danishefsky group reported the application of the triflate displacement method for the construction of an oligosaccharide ABE model system (Fig. 24). This compound was actually one of the oligosaccharide fragments of the related esperamicin A_1.

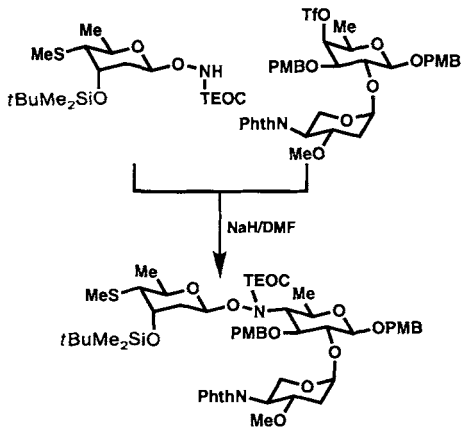

Fig. 24. March 1991: The Danishefsky group reports the synthesis of an ABE oligosaccharide model compound in which the N–O bond is also constructed by triflate displacement. R. L. Halcomb, M. D. Wittman, S. H. Olson, S. J. Danishefsky, J. Golik, H. Wong, D. Vyas, *J. Am. Chem. Soc.* **1991**, *113*, 5080.

As the autumn of 1991 was approaching our group had still not found a synthesis for calicheamicinone and there was still no sign that Danishefsky had successfully obtained the pentasaccharide fragment. We, however, had the pentasaccharide, whereas they had the aglycon. The thought of combining forces in the final drive towards calicheamicin had already crossed our minds but both Danishefsky and I politely rejected the idea. The battle was now reaching a climax as these and other groups were racing to secure the missing fragments and to establish base camps along the way.

In October 1991, our group reported the coupling of the intact pentasaccharide fragment of calicheamicin γ_1^I with dynemicin model systems by using the trichloroacetimidate technology (Fig. 25). This maneuver produced a series of calicheamicin–dynemicin hybrid compounds but also revealed, at the same time, our weakness in admitting that we still did not have the aglycon at hand! Concurrently, the Danishefsky group reported the coupling of advanced intermediates of the oligosaccharide and aglycon fragments by utilizing similar methodology (Fig. 26). It looked, for the moment, that final success in the Danishefsky camp was imminent! Despite these setbacks, we continued to surge forward, suspecting that many obstacles would still lie ahead before anyone could reach the final objective.

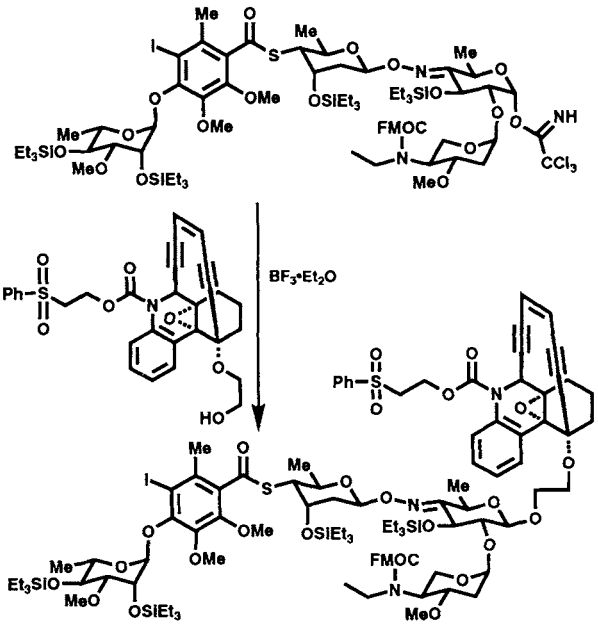

Fig. 25. October 1991: The Nicolaou group reports the total synthesis of the calicheamicin–dynemicin hybrid structure by coupling a fully functionalized pentacyclic oligosaccharide with dynemicin model compounds by using the trichloroacetimidate method. J. Danishefsky, *Angew. Chem.* **1992**, *104*, 314; *Angew. Chem. Int. Ed. Engl.* **1992**, *31*, 338.

By the end of 1991, postdoctoral fellow Adrian L. Smith and his team were rewarded with success, and in December

of that year, we submitted a paper that described the first total synthesis of enantiomerically pure calicheamicinone; the key step in this synthesis proved to be a nitrile–oxide cycloaddition (Fig. 27). As was the case in the synthesis of

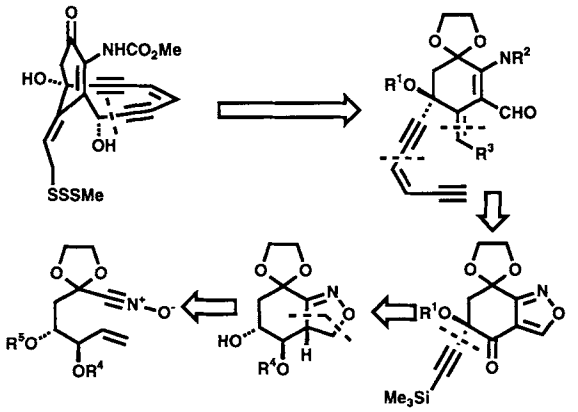

Fig. 27. December 1991: The Nicolaou group reports the first total synthesis of enantiomerically pure calicheamicinone by using the nitrile–oxide cycloaddition strategy. The long sought synthesis revives the race. A. L. Smith, C.-K. Hwang, E. Pitsinos, G. R. Scarlato, K. C. Nicolaou, *J. Am. Chem. Soc.* **1992**, *114*, 3134.

the oligosaccharide fragment, and for that matter most complex natural products, in the synthesis of the aglycon many hurdles had to be crossed. The following two paradigms exemplify the kinds of problems one often encounters in total synthesis and their role in precipitating unusual solutions. The first example involved the necessity for the protection of the amine function and the realization that most protecting groups would engage the aldehyde oxygen atom, rather than the nitrogen atom. To combat this unusual reactivity we used phthaloyl chloride, a bifunctional reagent, which reacted with both the oxygen and the nitrogen of the vinylogous amide to form a novel 9-membered ring heterocycle. This heterocycle was easily induced to rearrange to an acceptable derivative for further elaboration (Fig. 28). The next operation, the crucial ring closure to afford the 10-membered ring enediyne, was clouded with the wrong configuration at the newly generated hydroxyl center! A beauti-

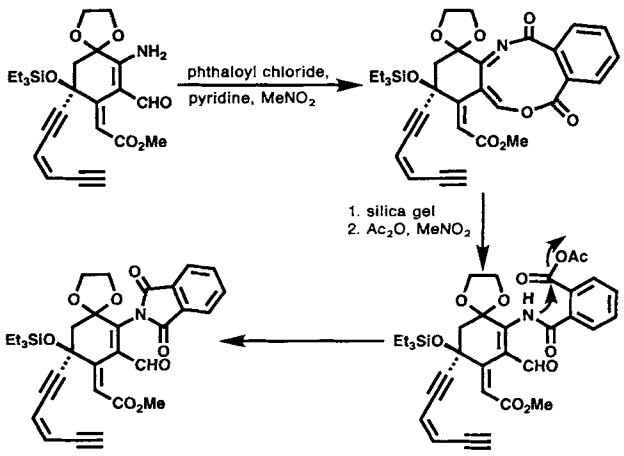

Fig. 28. The protection of the amino group of a vinylogous amide gives problems which are overcome by using a novel reaction sequence.

ful solution was, however, devised, based on the inspection of molecular models, which involved an intramolecular S_N2 type reaction with inversion of configuration (Fig. 29), thus fully correcting the course and allowing for eventual success. In the meantime, the Danishefsky camp had reported a resolution of a precursor to calicheamicinone, giving them, in principle, the capability of producing enantiomerically pure material.

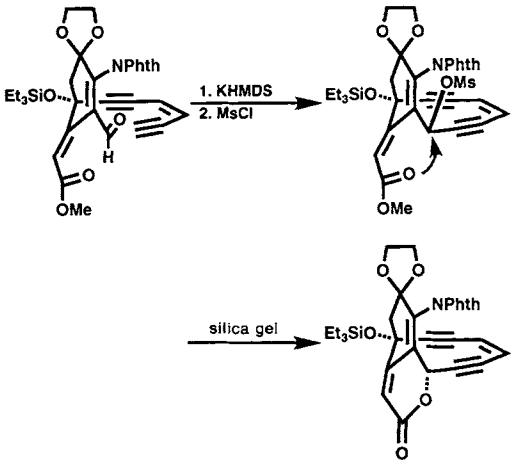

Fig. 29. The acetylide–aldehyde coupling leads to the 10-membered enediyne ring system, but with the wrong configuration! An intramolecular reaction sequence corrects the errant center and brings us back on course.

The race to the finish was now in its final lap! By this time it became evident that we were among the front-runners and that we had a good shot at completing the synthesis. As we later learned, our strong conviction that the final goal was achievable perhaps gave us the edge over a number of the other groups. However, the complexity and sensitivity of the intermediates involved, as well as the logistics of personnel continuity and of bringing starting materials to the "front" were posing enormous problems to us and persumably to the other groups involved. Even though the relationship of the participating groups was extremely cordial and friendly throughout the competition, exchange of information regarding the frontiers was scant. No group had any idea where the others were, although the fear of losing the race must have been playing on the minds of all of the members of the competing teams. We, of course, had tremendous regard and respect for the other camps and were prepared for the "worst" as we pushed for the final goal! Luck perhaps was to play the final role...

The Final Success

Finally, early in September 1992, success in our laboratories was knocking on the door. The final finish, however, was not without its scary moments! A particularly fearful moment came when, on attempting to persilylate an advanced intermediate in preparation for a pending major operation, TLC analysis indicated a heterogeneous streak, suggesting a disastrous decomposition at that step. A short time later, however, a suggestion to treat the mixture with acetic acid in dichloromethane containing silica gel resulted in the joyful

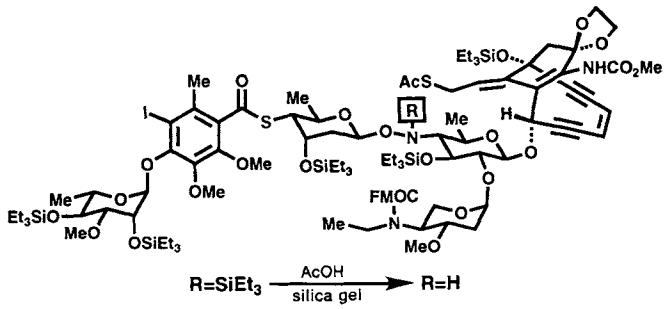

Fig. 30. A fearful moment! TLC analysis reveals a streak which soon clears up to a single spot.

observation of a clean, one-spot thin-layer chromatogram! What transpired is explained in Figure 30: Apparently, the silylation had not only taken place at all the hydroxyl groups but also at the NH–O function, giving rise to a labile intermediate which was smoothly and continuously decomposing on silica gel as the sample was moving up the plate!

The first indication that the job was complete came on Tuesday, September 16, 1992 when graduate student Conrad Hummel, the front man on the project for the last six months, obtained the first TLC picture on the final step (Fig. 31). The product matched an authentic sample! Subse-

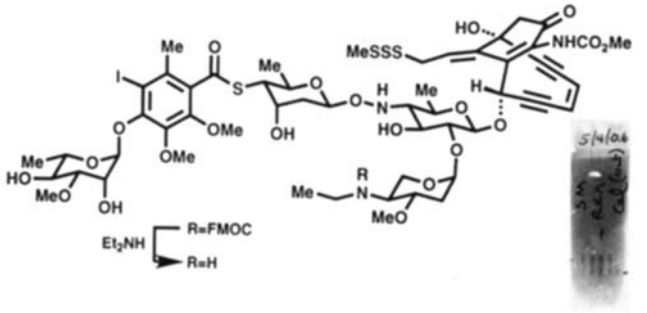

Fig. 31. September 1992: The Nicolaou group completes the first total synthesis of calicheamicin γ_1^I! The first indication of success, a TLC picture! K. C. Nicolaou, C. W. Hummel, M. Nakada, E. N. Pitsinos, A. L. Smith, K. Shibayama, H. Saimoto, *J. Am. Chem. Soc.* **1992**, *114*, 10082.

quent purification and spectroscopic measurements confirmed the identity of synthetic material with authentic calicheamicin γ_1^I! The mission was complete! Calicheamicin had been synthesized in the laboratory. Champagne was in order! (Fig. 32) On September 29, 1992, the communication announcing the total synthesis of calicheamicin γ_1^I was submitted to the JACS. In December 1992, exactly the month which we had suggested in our original NIH proposal for the completion of the synthesis, the publication appeared[7] and as well as a report in *Chemical & Engineering News*.[8] And so it was done! With this chapter closed, several new chapters opened...

Conclusion

This story was written in the hope of being interesting reading, educational, and revealing of the usually hidden side of such endeavors as the one covered here. The excite-

Fig. 32. A toast was in order. Together with the correspondence author of this review Dr. K. C. Nicolaou (seated in the center) are other members of the research group (standing from left to right: Dr. Katsuhiro Shibayama, Conrad Hummel, Dr. Masahisa Nakada, Emmanuel Pitsinos, Dr. Hiroyuki Saimoto; bottom left: Dr. Adrian Smith).

ment of my students and postdoctoral fellows who worked on this project in the period between 1987 and 1992, and the gratification I felt as their leader was too much not to share with others. Thus, this article was written in the hope that the reader will enjoy the behind the scenes emotions, setbacks, and triumphs of total synthesis.

This story could have not been written without the dedication, enthusiasm, and persistence of the talented group of students and postdoctoral fellows who participated on this project (alphabetically): K.-U. Baldenius, T. Ebata, R. D. Groneberg, C. W. Hummel, C.-K. Hwang, Y. Iwabuchi, T. Miyazaki, Y. Mizuno, M. Nakada, N. A. Petasis, E. N. Pitsinos, H. Saimoto, G. R. Scarlato, E. P. Schreiner, T. J. Schulze, K. Shibayama, A. D. Smith, W. Stahl, N. A. Stylianides, T. Suzuki, and G. Zuccarello. To these, and the rest of the members of my past and present group, I am indebted for their invaluable contributions to the research for which this group is credited. I am also indebted to Robert Babine, May Lee, George Ellestad, and Don Borders of the Lederle group for bringing my attention to this challenging molecule, calicheamicin, and for staying with me until the end! This work was carried out at the University of Pennsylvania (1987–1989), The Scripps Research Institute (1989–1992), and the University of California, San Diego (1989–1992). Financial support from the National Institutes of Health, Lederle Laboratories (USA), Merck Sharp and Dohme (USA), Schering Plough, Pfizer, and Rhone-Poulenc Rorer is gratefully acknowledged.

Organoelement Compounds with Al–Al, Ga–Ga, and In–In Bonds

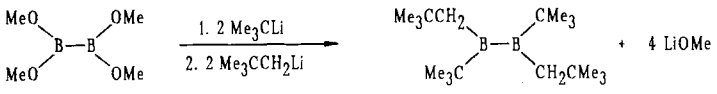
By Werner Uhl*

Dedicated to my daughter Anna Katharina

In the attempt to synthesize compounds with aluminum in a low oxidation state and an Al–Al bond, by the reduction of alkylaluminum halides with alkali metals, analogous to a Wurtz coupling, in general the deposition of elemental aluminum and the formation of the corresponding trialkylaluminum compounds is observed. Thus, tetrasubstituted dialuminum compounds $R_2Al-AlR_2$, apart from a few poorly characterized examples, were for a long time considered part of an unverified class of substances. Only with the sterically very highly shielded tetrakis[bis(trimethylsilyl)methyl]dialuminum did we achieve the synthesis of the first completely characterized organoelement compound with unlimited stability, which shows aluminum in the oxidation state + II and has an Al–Al bond. In the meantime, corresponding compounds for the elements gallium and indium have been obtained. With the simple access to tetrasubstituted dimetal compounds, a fascinating new research area has opened for preparative chemistry, in which the particular interest will naturally lie in the reactive properties of the metal–metal bond.

1. Introduction

Organoelement compounds with an element–element single bond and central atoms from the third main group were for a long time only known for the lightest element boron. The preparation of diborane(4) compounds, which are stabilized through the interaction between the empty p orbital on the boron atom and a lone pair of electrons in the α position at nitrogen, oxygen, or halogen atoms, was achieved a long time ago,[1, 2] whereas diboranes(4) substituted exclusively with alkyl groups were obtained concurrently in the research groups of Nöth[3] and Berndt[4] only in 1980. Their synthesis, transferred in the meantime to numerous compounds,[5] is achieved by the reaction of alkyllithium compounds with tetra(methoxy)diborane(4), which already contains a B–B bond (Scheme 1). They are very stable towards disproportionation because of the steric shielding by the bulky substituents.



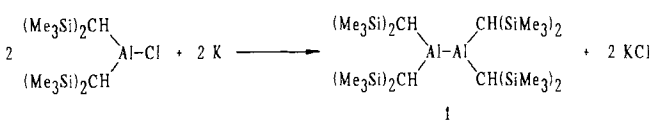
Scheme 1. Synthetic route to tetraalkylsubstituted diboranes(4) [3,4].

The corresponding compounds for aluminum and the higher homologues could at this time not be proven unambiguously. Element–element bonds, however, have been known for a long time in typical inorganic compounds, such as Ga_2Br_3,[6] In_5Br_7,[7] InS,[8] In_4Se_3,[9] and others,[10] as well as recently in the field of aluminum chemistry in Al_7Te_{10}[11] or Al_3Te_3I.[12] By treatment of the mixed-valent subhalides $Ga[GaX_4]$ (X = halogen) with Lewis bases such as dioxane, the corresponding adducts of the divalent elements can be synthesized very readily.[13, 14] Attempts to synthesize organoelement compounds, in which the metal atom has a low oxidation state, starting from such subhalides by the reaction with alkyllithium compounds, however, remained unsuccessful for a long time.[15, 16] Theoretical investigations on Al_2H_4 show that the mixed-valent form $Al^+AlH_4^-$ is preferred over that with divalent Al atoms. Moreover, the conformation is favored for the compound with an Al–Al bond, in which the substituents are arranged staggered.[17] The present review concentrates exclusively on the synthesis of stable organoelement compounds of the elements Al, Ga, and In in unusual oxidation states and with metal–metal bonds.

2. Synthesis and Physical Properties of Tetrasubstituted Dialuminum, Digallium, and Diindium Compounds

2.1. $[(Me_3Si)_2HC]_2Al-Al[CH(SiMe_3)_2]_2$

After numerous unsuccessful attempts the synthesis of a tetraalkyldialuminum compound (**1**) was achieved with the bis(trimethylsilyl)methyl substituent[18] by the reduction of the appropriate aluminum chloride with elemental potassium.[19] The compound **1** isolated in 60% yield shows a surprisingly high thermal stability and melts not before 220 °C with very little decomposition. Two reasons are chiefly responsible for this: first the high steric shielding by the bulky substituents kinetically prevents a disproportionation, and second, electronic effects caused by the $CH(SiMe_3)_2$ group, known to be a very effective electron donor.[20] The UV/VIS



1

Telefax: Int. code + (441)798-3329

spectra and the crystal structure still to be discussed indicate an electron transfer from the orbitals of the substituent into suitable atomic orbitals on the metal. Remarkably, in the ^{1}H NMR spectra of **1**, as well as in the other dimetal compounds (**10** and **11**) still to be described, a strong downfield shift of the signal for the methine protons of about $\Delta\delta = 0.7$ in comparison to the corresponding resonance signals of trialkylaluminum compounds without an Al–Al bond is observed.

The Al–Al bond in **1** (266.0(1) pm) is longer than those in the tellurides Al_7Te_{10}[11] and Al_3Te_3I[12] by 6 and 11 pm, respectively. On the basis of the unit cell shown in Figure 1, it is clear that the central Al_2C_4 unit in **1** is almost ideally planar, and the torsion angles about the metal–metal bond deviate from the values of 0° and 180° expected for a planar unit by only 8°. From a molecular model the preference of

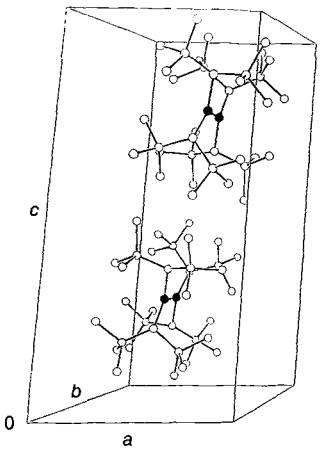

Fig. 1. Representation of a unit cell of **1**. The size of the atoms was chosen arbitrarily; aluminum atoms black; hydrogen atoms are not shown [19].

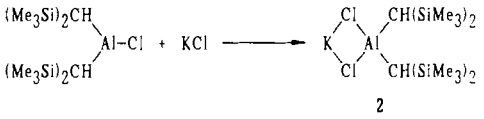
the planar Al_2C_4 conformation cannot be explained on steric grounds; however, the previously mentioned hyperconjugative interactions may be responsible for this. The C_α–Si bonds are arranged so that they adopt an optimal position for an electron transfer into the unoccupied p orbitals at the metal center and that the torsion angles between the σ and the p orbitals never become larger than the ideal value of 30°.[20] This, assumes an electronic system delocalized over the Al–Al bond.

The by-product **2** is obtained in very low and very variable yield by treatment of the precipitate formed in the synthesis of **1** with toluene. This by-product is a KCl adduct of the dialkylaluminum chloride, and forms readily and almost quantitatively in the reaction of the two components.[21] According to the results of the cryoscopic molar mass determination in benzene, **2** is monomeric and undissociated in solution, whereas in the solid state, through the formation of K_2Cl_2 heterocycles, it exists as a one-dimensional infinite coordination polymer. Remarkably, a very short contact is



2

observed between one of the C–H bonds of a methyl group and the potassium atom, which is insufficiently coordinated by four chlorine atoms.

2.2. Other Tetraalkyldialuminum Compounds

As has long been known for methyl, ethyl, or *n*-propyl compounds,[22] sterically less shielded dialkylaluminum halides react with potassium under deposition of elemental aluminum and the formation of the corresponding trialkyl compounds. We varied the substituents systematically (Scheme 2). For example, we used *sec*-butyl, (trimethylsilyl)methyl, neopentyl, and aromatic mesityl groups; however, no products were detected with aluminum in an unusual oxidation state, and the reaction course described above, corresponding to a disproportionation of intermediate tetraalkyldialuminum compounds, occurs. KCl was then added quantitatively to the aluminum chlorides so that only half of the starting material is converted under the chosen conditions at room temperature over 24 hours in hexane.

Scheme 2. Reaction of sterically less demanding dialkylaluminum chlorides. R = Me [22], Et [22], Pt [22], *sec*-butyl, H_2CCMe_3, H_2CSiMe_3, $C_6H_2Me_3$.

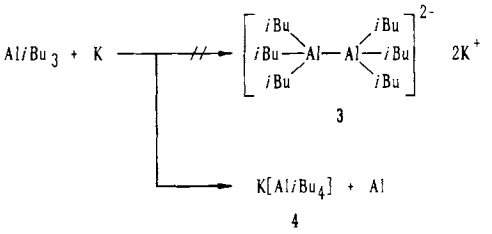
Remarkably, following the careful workup of the reaction of di(neopentyl)aluminum chloride with potassium, a dark red, highly viscous residue was obtained which cannot be recrystallized from any of the common solvents, and which

Werner Uhl was born in 1953 in Lich (Hessen, FRG), studied chemistry between 1972 and 1977 at the Universität Karlsruhe, and received his doctorate there in 1980 after two years at the Universität Marburg under the supervision of G. Becker with work on alkylidenephosphanes with P=C double bonds. Thereafter he undertook two years of industrial experience in the research and development department at the NUKEM company (Hanau, FRG), before he followed G. Becker to the Universität Stuttgart in 1983. In 1989 he completed his habilitation in inorganic chemistry and in 1992 became a professor of inorganic chemistry at the Universität Oldenburg. His main research interests are sterically highly shielded organoelement molecules with the heavier elements of the third main group.

in addition to signals of low intensity in the NMR spectra reveals mainly the presence of a single product. On the basis of a hydrolysis experiment and a molar mass determination Schram et al.[23] assumed the occurrence of a tetrameric aluminum(I) compound, similar to $Al_4Cp^*_4$ ($Cp^* = C_5Me_5$)[24] which was characterized by crystal structure analysis, and which will be discussed later.

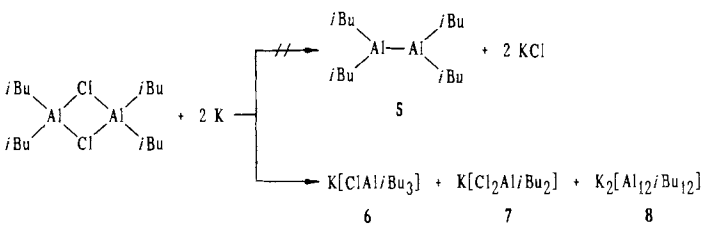
Di(*tert*-butyl)aluminum halides (Cl, Br) form with potassium in hexane a highly reactive, paramagnetic gray-green powder, which has so far not been fully characterized. If this product is dissolved in benzene or ether, spontaneous decomposition takes place and the powder turns black. From this black product, small quantities of the anion $(Me_3C)_3AlH^-$ can be isolated, and readily characterized by NMR and IR spectroscopy.[25]

For a systematic investigation of the chemical properties of compounds with an Al–Al bond, we were interested in the syntheses of further derivatives. In the literature reports are found on stable compounds, which are substituted by isobutyl groups.[26–28] We repeated these reactions; however, in no case did we obtain the described molecules. Tri(isobutyl)aluminum is supposed to yield the hexa(isobutyl)dialuminate **3** with potassium,[26] instead, in agreement with the results previously obtained for other substituents,[29] the tetra(isobutyl)aluminate **4** was formed, whose NMR spectroscopic parameters are consistent with the published values. Its crystal structure[30] shows layers of

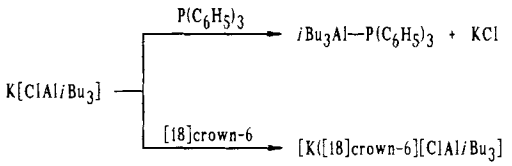


aluminate ions which are bridged by potassium ions; the alkali metal ion becomes six-coordinate, bonded to four α-C atoms and two C–H bonds of methyl groups. This coordination of C–H bonds is similar to the agostic interaction[31] and is also detected in the IR spectrum because of the unusual position of one C–H valence stretch (2600 cm^{-1}).[30]

The second dialuminum compound described in the literature is **5**, which had supposedly been prepared analogously to **1**. In the reaction of di(isobutyl)aluminum chloride with potassium, a dark brown, highly viscous liquid is formed,[27] whose spectra have unfortunately remained mainly unpublished, so that the direct comparison of the compounds obtained is impossible. The main product of the reaction cannot be recrystallized from any of the common solvents, and



decomposes on distillation with the formation of tri(isobutyl)aluminum. By a comparison of the NMR spectra obtained by us it was concluded that only an adduct from KCl and iBu_3Al (**6**) is present. Compound **6**, synthesized in a highly pure form by the stoichiometric reaction of the constituents, exhibits the same properties as those of the product obtained from the reduction with potassium and can be neither recrystallized nor distilled. With triphenylphosphane both products form $PPh_3 \cdot AliBu_3$ in over 80% yield with the displacement of the chloride ions, and with [18]crown-6, the crystalline ether adduct K([18]crown-6)[ClAliBu$_3$] is obtained almost quantitatively (Scheme 3).[25]



Scheme 3.

On treatment with toluene two compounds can be extracted from the residue of the reaction of di(isobutyl)aluminum chloride with potassium, and these compounds can be separated from each other by recrystallization: the KCl adduct **7**, as well as $K_2[Al_{12}iBu_{12}]$ **8** in low, but reproducible yield. Compound **8** forms as dark red crystals; the result of the crystal structure determination is shown in Figure 2.[32] Ac-

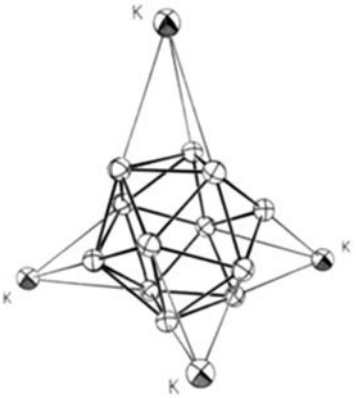


Fig. 2. Drawing of the Al_{12} icosahedron in $K_2[Al_{12}iBu_{12}]$ **8** (thermal ellipsoids drawn at 30% probability level). For clarity, only the Al and K atoms are drawn [32].

cording to this the Al_{12} dianion has an almost undistorted icosahedral framework which corresponds with the boron $B_{12}H_{12}^{2-}$ dianion both in terms of its structure and the number of electrons. The Al–Al distances in the cluster (268.5 pm) are only slightly longer than that in the tetraalkyldialuminum compound **1** with an isolated Al–Al bond (266.0 pm). The icosahedron is surrounded by a tetrahedron comprising four potassium ions, each bridging two icosahedra through contacts to six α-carbon atoms of *i*Bu groups (Fig. 3) The interaction exists, however, between the potassium ions and the C–H bonds of the *i*Bu substituents. The potassium atom is thus coordinated by six C atoms and has an almost undistorted octahedral environment. In this way a

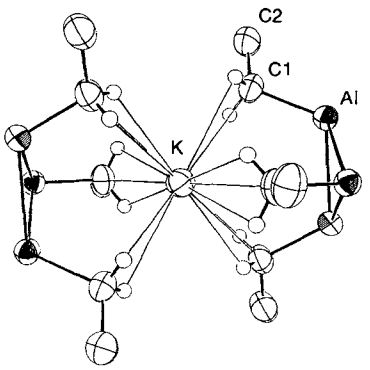

Fig. 3. Coordination of the K atoms in **8** (thermal ellipsoids drawn at 30% probability level). For clarity, the methyl groups of the *i*Bu substituents are omitted and only the α-hydrogen atoms which interact with the K atom are drawn [32].

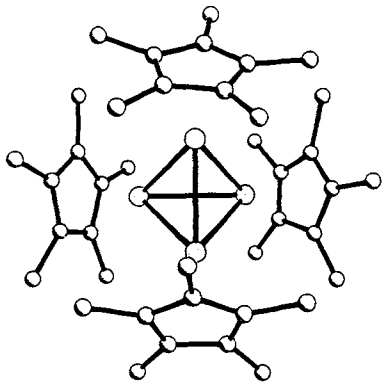

Fig. 4. Crystal structure of $Al_4Cp_4^*$ **9** (atoms with arbitrary radius; no hydrogen atoms) [24].

three-dimensional structure is obtained that is reminiscent of the structure of cuprite, as a result of the linear coordination of the K^+ ion by two icosahedra and of the tetrahedrally surrounded $[Al_{12}iBu_{12}]^{2-}$ anion. In the crystal structure of **8** very highly disordered toluene molecules are inserted into the cavities present. These solvent molecules can be removed by thorough evacuation, the crystals, however, become more unstable and disintegrate to a microcrystalline powder on the slightest touch.

Compound **8** is very unstable in solution, whereas it is very stable as a solid. Even in air, it is almost two hours before a decomposition reaction is observed. Cyclic voltammetric investigations[25] reveal a reversible one-electron oxidation, followed by a second, irreversible loss of an electron. Also in this respect the dodecaaluminate **8** is similar to the corresponding boron compounds.[33]

A further organoaluminum cluster (**9**) was obtained by Schnöckel et al.[24] by the reaction of pentamethylcyclopentadienylmagnesium with AlCl (Scheme 4). AlCl was pre-

$$2\,Al + 2\,HCl \xrightarrow{1200K} 2\,AlCl + H_2$$

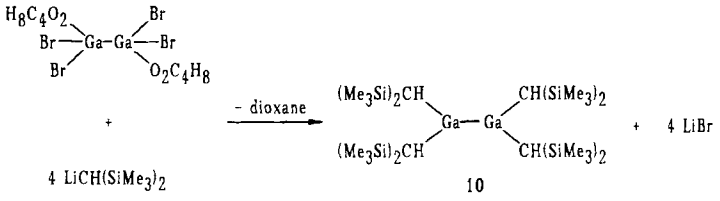
$$2\,(C_5Me_5)_2Mg + 4\,AlCl\cdot O(C_2H_5)_2 \xrightarrow{-O(C_2H_5)_2} \underset{\mathbf{9}}{Al_4(C_5Me_5)_4} + 2\,MgCl_2$$

Scheme 4.

pared in a high-temperature synthesis from elemental aluminum and HCl, and in solution has a half life[34] long enough so that reactions can be carried out. For the yellow crystals of **9** a crystal structure was determined which shows a tetrahedral Al_4 framework and an η^5-coordinated cyclopentadienyl group at each Al atom (Fig. 4). The Al–Al distance (mean 276.9 pm) is as expected significantly longer than that of the isolated Al–Al bond in **1**, and also than those in the $[Al_{12}iBu_{12}]^{2-}$ dianion (**8**).

2.3. Tetrasubstituted Digallium and Diindium Compounds

For the synthesis of the digallium compound **10** and the diindium compound **11** we did not use the reduction of the dialkyl element halides as for the preparation of **1**, since these are not accessible by simple reactions. Instead, we used halides that already contained the element–element bond. Thus, the reaction of $Ga_2Br_4\cdot 2$ dioxane[13] with four equivalents of bis(trimethylsilyl)methyllithium[18] leads to the tetraalkyldigallium **10** in over 70% yield.[35] Compound **10**



crystallizes isotypical to the corresponding aluminum compound and forms large dark yellow crystals. The Ga–Ga bond in **10** (254.1(1) pm) is, however, in comparison with the Al–Al bond in **1**, significantly shorter by 12 pm, which again shows the special role of gallium in the third main group. This exceptional role is due to the insertion of electrons into the d orbitals of the preceding 3d elements in the periodic table and the associated contraction of the atomic radius. The Raman spectrum of **10** shows a weak band at 268 cm^{-1} that is probably assigned to the vibration of the Ga–Ga bond and which only lies at slightly higher wavenumbers than the corresponding values of Ga^{II} chlorides.[36]

The UV/VIS spectra for the three compounds **10**, **1**, and $Al[CH(SiMe_3)_2]_3$[37] are given in Figure 5. In all three spectra two absorptions at the same wavelengths of 245 and 275 (shoulder) nm are observed, which we ascribe to transitions from the orbitals of the substituent, known to be a good electron donor,[20] into the empty orbitals of the metal atoms. Only in the two spectra of the dimetal compounds does an additional absorption occur at 370 nm, and is thus evidently characteristic for the metal–metal bond. For the digallium compound **10** the base of this band extends into the visible region and is thus responsible for the yellow color of **10**: the absorption band of the dialuminum compound **1** is, in contrast, narrower, which, therefore, explains the pale yellow color of **1** only recognizable in thick layers.

The preparation of the compound **11** with an In–In bond is achieved in a way similar to the synthesis of **10**. LiCH-

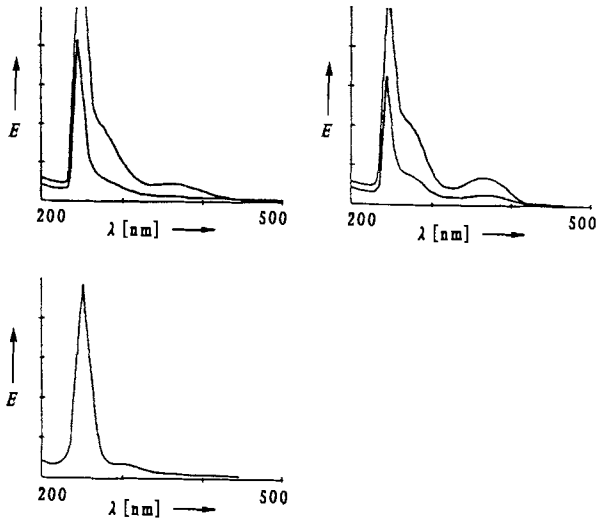


Fig. 5. UV/VIS spectra of the dimetal compounds **10** (with Ga–Ga bond; top left), **1** (with Al–Al bond; top right), and of the tris[bis(trimethylsilyl)methyl]aluminum (without a metal–metal bond, bottom) between 200 and 500 nm [35].

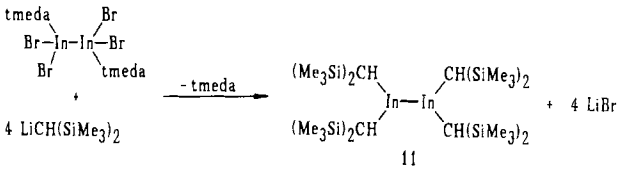
$(SiMe_3)_2$ is allowed to react with $In_2Br_4 \cdot 2\,tmeda$ (tmeda = *N,N,N',N'*-tetramethylethylenediamine), whose simple synthesis is achieved in a one-pot reaction from In metal, $InBr_3$, and TMEDA.[38] Compound **11** forms orange-red crystals and crystallizes no longer isotypically to the two homologous compounds **1** and **10**; instead, a stacking variant of the nearly planar molecules occurs which are packed to give layers.[38] The In–In bond is 282.8(1) pm long . This



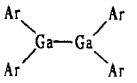
value lies—as does the Ga–Ga bond length—in the upper region of the bond lengths of typical inorganic compounds of each bivalent element. Whereas **1** and **10** are remarkably thermally stable, the indium compound **11** decomposes under metal deposition at 100 °C or with exposure to light, even at room temperature.

The UV/VIS absorption bands of In compounds are given in Table 1, and these again show the absorption characteristic for the metal–metal bond at 380 nm. In addition the dimetal compounds have very high extinction coefficients, which are 10 times higher than those in the coordinatively unsaturated trialkylindium compound without a metal–metal bond. In contrast, in the compound with a coordinatively saturated central atom only very small extinction coefficients are obtained, which are perhaps due to decomposition products of the dialkylindium dibromide which is not particularly stable in solution. Thus, the tetrasubstituted dimetal compounds, in addition to an absorption at about 370 nm, are also characterized by high extinction values in the region of the electron transfers from the substituent to the metal atom, which may occur due to an electronic system delocalized through the metal–metal bond.

Table 1. UV/VIS spectroscopic investigations of bis(trimethylsilyl)-methylindium compounds.

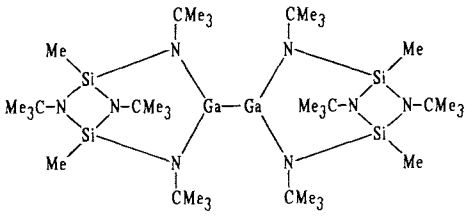
	11	$In[CH(SiMe_3)_2]_3$	$(tmeda)LiBr_2In[CH(SiMe_3)_2]_2$
λ (ε)	240 nm (24000)	240 nm (1900)	250 nm (60)
	270 nm (9500)	270 nm (1300)	270 nm (50
	380 nm (800)		

Recently in a way analogous to that for the preparation of **10**, Power et al.[39] obtained the tetraaryldigallium **12**, which unlike **10** does not have a planar central C_2GaGaC_2 unit in the solid state, but the substituents are staggered to avoid steric interactions (torsion angle about the Ga–Ga bond 43.8°). Compounds with a Ga–Ga (**13**) or an In–In bond



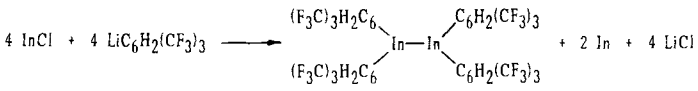
12: Ar = 2,4,6-$C_6H_2iPr_3$

and nitrogen substituents were obtained by Veith et al. from the reduction of the corresponding halides with Na/naphthalene.[40] The indium compound analogous to **13** was investigated by X-ray crystallography; this structure shows a significantly shorter In–In distance (276.8(1) pm) than that in the tetraalkyldiindium **11**. Similar to the corresponding C



13

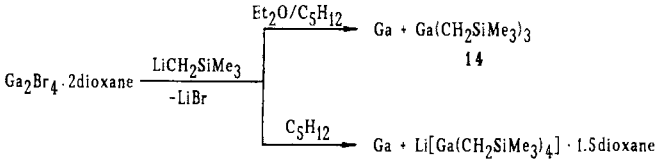
atoms in **11**, the four nitrogen atoms bound directly to the indium atoms lie almost ideally in a plane with the two metal atoms; however, an additional nitrogen atom of the substituent is coordinated to each In atom with only a slightly longer contact (15 pm), so that the coordination number at the metal atom increases to four. A compound with an In–In bond that has not been investigated by X-ray crystallography is evidently also formed on treatment of metallic indium with tetrachloro-*o*-benzoquinone in the presence of phenanthroline.[41] Recently Cowley et al. reported a tetraaryldiindium compound, which is formed from indium monochloride and 2,4,6-tris(trifluoromethyl)phenyllithium (Scheme 5). The In–In bond (274.4(2) pm) is significantly shorter than that in **11**, and the substituents are staggered; however, the coordination number at the indium atom is increased through an interaction with the fluorine atoms of

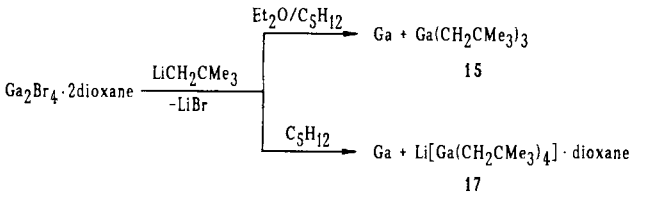


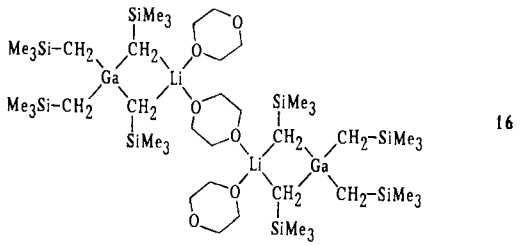
Scheme 5.

the trifluoromethyl groups.[42] Theoretical studies on the In–In interactions have also been discussed.[43]

If the attempt is made to transfer the synthesis of **10** from $Ga_2Br_4 \cdot 2$dioxane and four equivalents of an alkyllithium compound to less sterically demanding substituents such as the (trimethylsilyl)methyl or neopentyl group, disproportionation resulting in the deposition of elemental gallium is always observed. Depending on the solvent different products are obtained; in *n*-pentane/diethyl ether the formation of the corresponding trialkylgallium compounds **14** and **15** is observed, whereas in pure pentane exclusively the tetraalkyl compounds **16** and **17** are formed, which crystallize with differing dioxane content. The crystal structure was determined for **16**, and this showed a formula unit dimerized through the formation of a dioxane bridge.[44]



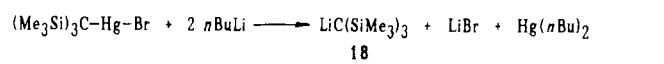




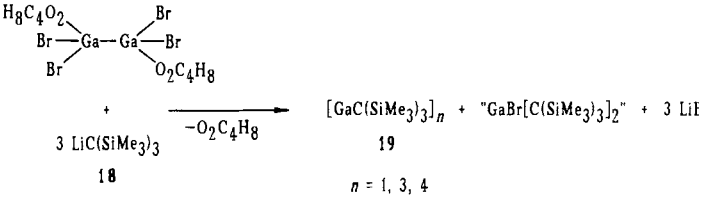
16

2.4. Reactions of Digallium and Diindium Bromides with Solvent-Free $LiC(SiMe_3)_3$

Since the reactions of $Ga_2Br_4 \cdot 2$dioxane with sterically less demanding alkyllithium compounds did not produce the desired dimetal compounds, we attempted to carry out this synthesis with the very bulky tris(trimethylsilyl)methyllithium. This lithium compound is readily accessible in the form of its THF adduct;[45] however, the reaction with the gallium(II) halide ether adduct led, with cleveage of ether, only to tris(trimethylsilyl)methane $HC(SiMe_3)_3$. The necessary solvent-free lithium compound **18** was not known; it was obtained from *n*-butyllithium and tris(trimethylsilyl)methylmercury bromide[46] by applying a method described by Bickelhaupt et al. for the synthesis of 1,3-dilithiopropanes.[47] Compound **18** is monomeric in benzene, but



dimeric in the solid state due to the formation of Li–C bridges. However, an unexpected pathway is observed in the reaction with $Ga_2Br_4 \cdot 2$dioxane: evidently for steric reasons four of the bulky substituents cannot be arranged around the Ga–Ga unit, and thus a compound is formed with at least one halogen atom bound to the gallium atom; however, this compound is not stable, and disproportionates, because one halogen atom possibly migrates through a bridging position to the second gallium atom. The disproportionation, however, does not lead to the deposition of elemental metal, as is the case for smaller substituents, but stops at an alkylgallium(I) compound **19**, which can be isolated in the form of dark red crystals.[48] Compound **19** is remarkably thermally



stable; it remains completely unaltered over several months in air. Depending on the method of characterization one of several degrees of oligomerization is determined: in the mass spectrum only the monomer with a relative intensity of 100% is detected. The cryoscopic molar mass determination in benzene in the usual concentration range (0.023 mol L^{-1}) indicates approximately a trimer, whereas with increasing dilution the dissociation increases, and at a concentration of 0.0014 mol L^{-1} finally only the monomer is present. In the solid state (Fig. 6), **19** has an almost undistorted tetrahedral Ga_4 framework, in which the Ga–Ga distance (mean 268.8 pm) is as expected very much longer (ca. 15 pm) than in the digallium compound **10** with an isolated Ga–Ga bond. An absorption band at 435 nm characteristic for the

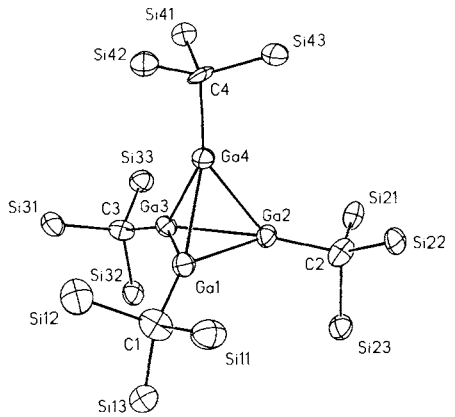


Fig. 6. Crystal structure of **19** (thermal ellipsoids drawn at 40% probability level). For a better overview, the methyl groups are not drawn [48].

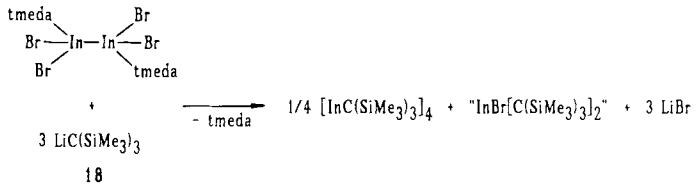
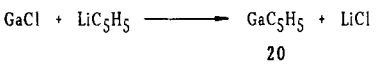
Ga_4 framework is observed in the UV/VIS spectrum, which, in comparison to those bands for compounds with an isolated metal–metal bond, shows a slight bathochromic shift, and with increasing dilution of the spectroscopically investi-

gated solution of **10**, and corresponding increasing dissociation, there is a significant loss in the intensity of this band.

In the meantime the preparation of the indium cluster analogous to **19** has been achieved by the reaction of $In_2Br_4 \cdot 2$ tmeda with **18**. This cluster is also obtained in the form of dark red crystals, and in the mass spectrum only the peak for the monomer is detected. However, the color as well as the dimensions of the unit cell are in agreement with the existence of an In_4 cluster.[49]



Similar to AlCl, GaCl can also be prepared by a high-temperature synthesis from gallium and HCl and subsequent rapid cooling to liquid nitrogen temperature.[50] In toluene and diethyl ether GaCl is thermally stable enough to allow reproducible reactions. With cyclopentadienylmagnesium or -lithium Schnöckel et al.[51] obtained colorless, crystalline cyclopentadienylgallium(I) **20**, which is extremely volatile; thus it cannot be isolated by removal of the solvent under vacuum. Compound **20** was characterized by its mass spec-



trum, in which, as for **19**, only the molecular ion of the monomer was detected, and by its ^{71}Ga NMR spectrum which showed the shift ($\delta = -714$) characteristic for Ga^I compounds. Calculations support the existence of monomeric molecules with an η^5-coordinated cyclopentadienyl group in solution, whereas in the solid, in contrast to the yellow $Al_4Cp^*_4$ **9** or the red $Ga_4[C(SiMe_3)_3]_4$ **19** (with $n = 4$), one-dimensional infinite polymers might occur similar to those in cyclopentadienylindium[52] or -thallium.[53] For InC_5Me_5 a different geometry was observed with an octahedral arrangement of the metal atoms; the very long contact distance of 395 pm precludes a strong In–In interaction.[54] With the sterically more demanding $[C_5(CH_2C_6H_5)_5]$ substituent pseudodimers are obtained, which also have a very long In–In distance (363.1 pm).[55] Similarly, no cluster structure was observed in the tris(trifluoromethyl)phenoxyindium(I) compound reported by Roesky et al.[56]

3. Chemical Properties of the Dimetal Compounds

After the successful synthesis of compounds with Al–Al, Ga–Ga, and In–In bonds, studies into the chemical properties of these compounds should now be the main focus of attention. Numerous reactions may be possible: addition of Lewis bases to the unsaturated, three-coordinate metal atoms, further reduction with the transfer of electrons into the unoccupied p orbitals, insertion reactions both into the metal–metal bond and the metal–carbon bond, substitution reactions, and in the particular case of the bis(trimethylsilyl)methyl compounds deprotonation reactions at the C–H acidic substituent by the reactions with strong bases. Most of these reactions are considered in the following.

3.1. UV Irradiation of $[(Me_3Si)_2HC]_2Al–Al[CH(SiMe_3)_2]_2$

We began our studies into the reactivity of the dialuminum compound **1** with the irradiation, in order to establish whether the Al–Al bond can be homolytically cleaved. Initially we carried out these experiments in an ESR spectrometer, to allow the detection of possible intermediate paramagnetic species. The result based on the ESR spectra is illustrated in Figure 7:[57] the top spectrum was recorded approximately three minutes after the start of the irradiation; it shows the resonance signals of two radicals, of which that of one radical stands out only a little from the background and forms a sextet of doublets, whose three inner signals are covered by the main signal. With increasing irradiation times this sextet can no longer be detected, and only the second signal of 11 equidistant lines is observed, which is scaled up in Figure 7 (bottom). This radical is very stable; it can still be detected several hours after the end of the irradiation.

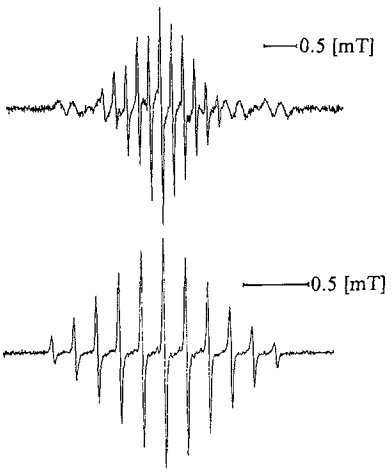


Fig. 7. The ESR spectra obtained on irradiation of a sample of **1** in *n*-pentane with UV light. The top spectrum was recorded after three minutes, the bottom spectrum after 30 minutes [57]. Sextet of doublets: $a_{Al} = 0.612$ mT; $a_H = 0.216$ mT; undecet: $a_{Al} = 0.172$ mT.

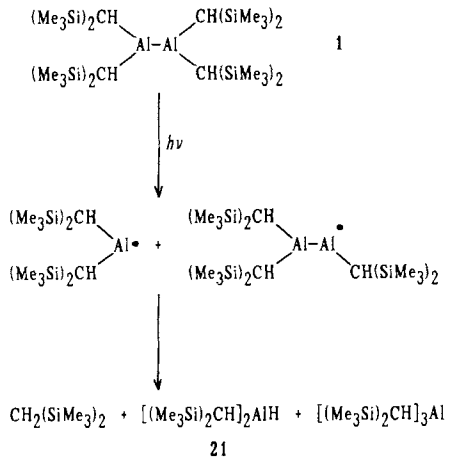
Evidently, **1** decomposes under UV irradiation by two different pathways: 1) The Al–Al bond is cleaved homolytically with the formation of two symmetrical fragments; these fragments are responsible for the sextet with low intensity ($I_{Al} = 5/2$, $a_{Al} = 0.612$ mT, Scheme 6). The further splitting to give a doublet may be due to the coupling to a hydrogen atom ($a_H = 0.216$ mT). 2) The intense signal shows 11 lines ($a_{Al} = 0.172$ mT); here the electron interacts with the two aluminum atoms, and the Al–Al bond has remained intact. The formation of this radical can be understood by the homolysis of an Al–C bond; however, the

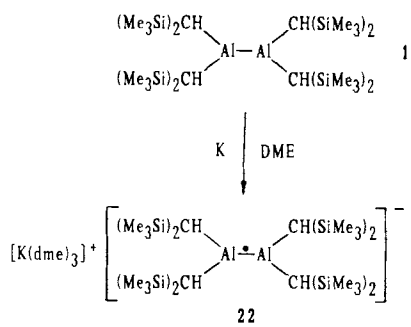


Scheme 6. Decomposition of **1** on irradiation with UV light. Reaction equation is not stoichiometric.

bis(trimethylsilyl)methyl radical formed in addition to the dialuminum radical could not be detected by ESR spectroscopy. The high stability of the aluminum radical may be due to the fact that one of the three remaining alkyl groups adopts the bridging position between the two Al atoms. In agreement with the proposed mechanism products exist which were obtained from preparative irradiation reactions in pentane: bis(trimethylsilyl)methane from the bis(trimethylsilyl)methyl radical, bis[bis(trimethylsilyl)methyl]-aluminum **21** with Al–H bond from the monoaluminum radical as well as $Al[CH(SiMe_3)_2]_3$.[37] The subsequent product of the dialuminum radical has so far not been isolated. Additional decomposition reactions do not occur, and in particular, no elemental aluminum is deposited. Compound **21** so far only accessible in this way is in equilibrium with its dimeric form in the cryoscopic molar mass determination in benzene. With increasing dilution of the sample this equilibrium shifts to the side of the monomer. Generally, dialkylaluminum hydrides exist as trimers in benzene with Al–H–Al bridges.[58]

3.2. Reactions of $[(Me_3Si)_2HC]_2Al–Al[CH(SiMe_3)_2]_2$ with Alkali Metals

The two unoccupied p orbitals of the Al–Al unit in **1** suggest that **1** can be reduced to give compounds with aluminum in the oxidation state + I. In nonpolar solvents no reaction is observed with alkali metals, whereas in DME (DME = 1,2-dimethoxyethane) with potassium or sodium,



dark blue solutions are obtained in the course of 16 hours at room temperature, from which deep blue crystals of the paramagnetic compound **22** were isolated after distillation of the solvent and recrystallization from DME/*n*-pentane. These crystals are amorphous and thus their constitution could not be elucidated by an X-ray structure determination. The existence of the radical monoanion **22** containing an Al–Al bond is, however, clearly evident from the elemental analysis with a K:Al ratio of 1:2 as well as from the ESR spectra. These spectra show 11 equidistant lines (Fig. 8), which, as a result of an insufficient averaging of anisotropic contributions, increase in width with increasing distance from the center and show additional couplings to ^{29}Si nuclei.

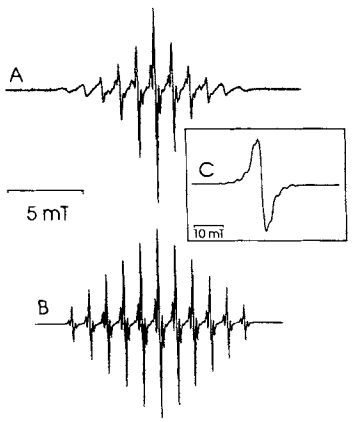


Fig. 8. A) ESR spectrum of **22**·$Li(tmeda)_2^+$ at 295 K in diethyl ether with strong anisotropic line broadening. B) Computer simulation with $a(^{27}Al)$ = 1.11 mT (2 Al atoms), $a(^{29}Si)$ = 0.435 mT (8 Si atoms). C) ESR spectrum at 110 K in glassy rigid diethyl ether [59].

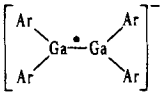
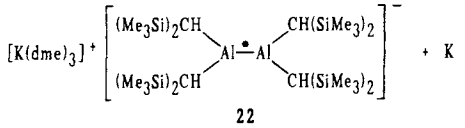
The anisotropic components of the hyperfine splitting determined from the sprectra of the radicals immobilized in the solid ether matrix, the closeness of the g value ($g = 2.0025$) to that of the free electron, and the small isotropic hyperfine splitting $a(^{27}Al) = 1.17$ mT confirm the existence of a radical with an Al–Al π bond.[59] Pörschke et al. obtained a corresponding radical anion from **1** with $[Li(tmeda)_2]^+$ as counterion in a similar way, whose crystal structure has been determined.[60] The shortening of the Al–Al distance by 13 pm in comparison to the starting material **1**, as well as the ideal planar arrangement of the central C_2AlAlC_2 unit reveal likewise the existence of a π bond in **22**. Similar compounds are known for boron,[61] and in the meantime Power et al. have also synthesized gallium analogues (Scheme 7).[39]



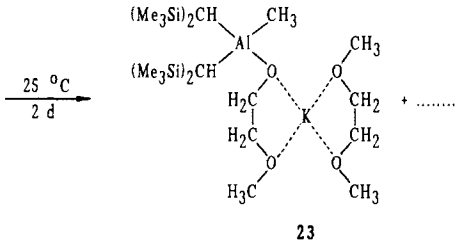
Scheme 7. Ar = 2,4,6-$C_6H_2iPr_3$.

Whereas the compound **22** purified by recrystallization can be stored even in solution at room temperature and in daylight for weeks without change, it decomposes when attempts are made to transfer a second electron by treatment with excess potassium in DME. As the NMR spectra show, three new compounds are formed, which cannot be separat-

ed from one another by recrystallization, not even after the addition of crown ether, or by distillation. As a result of its characteristic NMR spectrum, the structure of one of the products (**23**) was determined and verified by desired synthesis and a crystal structure determination; the corresponding lithium compound forms as the only product in the reaction of excess lithium with **1** in DME.[62]



22



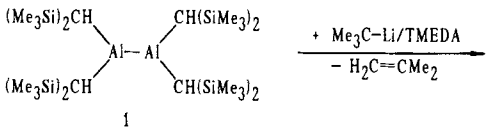
23

We propose the following pathway for the formation of **23** from **1**: initially the aluminum compound **1** is reduced with the transfer of only one electron and the formation of the radical anion **22** isolable with potassium or sodium. The desired second reduction step to an Al^I compound, however, evidently does not give a stable compound under the chosen reaction conditions in DME. Thus, the alkoxyaluminate **23** is isolated, which can be described as the product of the insertion of a molecular fragmemt with Al in the oxidation state + I into a H_3C-O bond of a DME molecule.

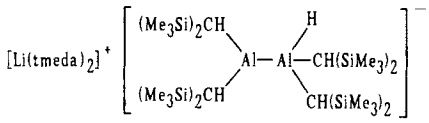
3.3. Reactions of $[(Me_3Si)_2HC]_2Al-Al[CH(SiMe_3)_2]_2$ with Alkyllithium Compounds

We set out to investigate the reactions of **1** with alkyllithium compounds for two reasons: first deprotonation reactions at the C–H acidic substituents should be possible. Thus, the previously mentioned sterically highly shielded $Al[CH(SiMe_3)_2]_3$ reacts with *tert*-butyllithium under deprotonation of a methyl group in the periphery of the molecule; the resulting carbanion is subsequently stabilized through an interaction with the coordinatively unsaturated aluminum atom, leading to the formation of a four-membered heterocycle.[37] Second, in certain cases, the reaction with alkyllithium compounds leads to the cleavage of element–element bonds with the formation of lithium–element compounds that are valuable as synthetic building blocks.[63]

With *tert*-butyllithium and **1** in the presence of the chelating ligand TMEDA none of the expected reactions is observed. Instead a β-elimination from the lithium compound occurs, and the formed hydride ion is bound to one of the aluminum atoms of the Al–Al bond (**24**), which in this reaction is retained. The length of the metal–metal bond in **24** (266.7(3) pm) remains unchanged within the range of standard deviations in comparison to the starting material **1**.[64] Remarkably, the hydride ion does not bridge the two coordinatively unsaturated metal atoms; thus, in **24** a saturated, four-coordinate Al atom is in close proximity to an unsaturated, three-coordinate Al atom.

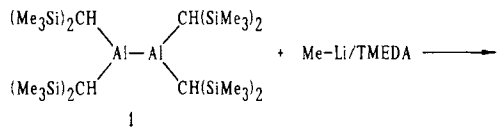


1

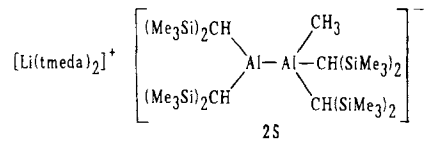


24

A similar adduct (**25**) with a methyl group bound to an aluminum atom is formed in the reaction of **1** with methyllithium.[64] Here, a significant lengthening of the Al–Al bond by 9 pm to 275.2(3) pm is observed, which is in agreement with the facile decomposition of **25** in solution with the deposition of elemental aluminum. The addition of the nucleophile in a terminal position is initially surprising, since dimers exist like $Me_2Al(\mu\text{-}H)_2AlMe_2$ (gas phase)[65] and $Me_2Al(\mu\text{-}Me)_2AlMe_2$[66] with the corresponding bridging ligands, which compensate the formal lack of electrons at the two metal atoms. With Al–Al distances of 262 and 261 pm, respectively, the structural parameters of the central molecular unit in these dimers do not deviate significantly from those observed in **24** and **25**. Apparently, also through the



1



25

hyperconjugation, which can be established at the three-coordinate metal centers on the basis of molecular conformation shown in Figure 9 and the UV/VIS spectroscopic results similar as in **1**, the Lewis acidity of the bivalent aluminum atoms is reduced to such an extent that the formation of a two-center bond to the newly added substituent is more favorable than the occupation of a bridging position with the loss of the hyperconjugative interaction to both metal atoms.

To avoid the formation of an adduct we therefore used sterically more demanding (trimethylsilyl)methyl- and neopentyllithium, which are not subject to β-elimination, with **1** and obtained a completely different reaction course. In this an electron transfer from the lithium compounds to **1** is observed with the formation of the radical anion **22** with a different cation ($Li(tmeda)_2^+$) which precipitates in the

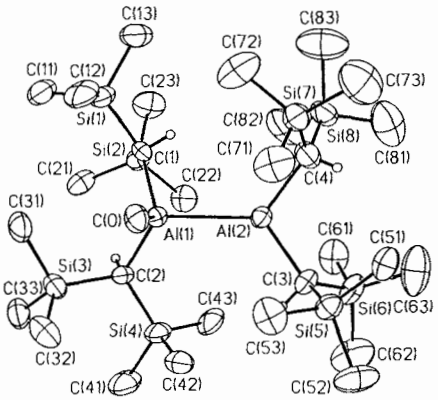


Fig. 9. Anionic part of the structure in methyldialuminate **25** (thermal ellipsoids drawn at 40% probability level). For a better overview, the hydrogen atoms of the methyl groups are not drawn, the remaining hydrogen atoms are drawn with arbitrary radius [64].

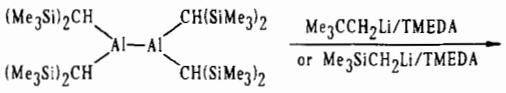
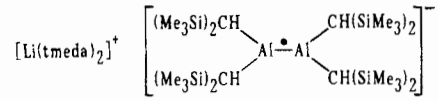
form of dark blue crystals.[59] The g value and the coupling constants in the ESR spectrum correspond to the parameters observed for **22**·K(dme)$_3^+$.

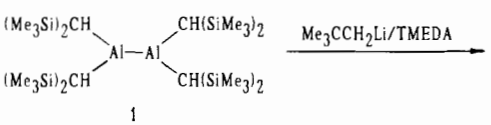


1

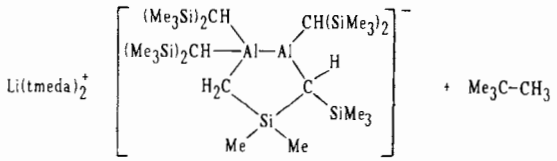


22

On careful observation it can be seen that the dark blue precipitate from the reaction of neopentyllithium with **1** contains small quantities of a yellow product, which can be extracted by treatment with nonpolar solvents. Crystals of probably two compounds can be obtained from this extract, of which, however, only one was completely characterized. As the crystal structure determination shows, the originally intended deprotonation of **1** to give **26** occurs as a side reaction. The proton is removed from a methyl group of a $SiMe_3$ group, and the resulting carbanion is stabilized by the interaction with one of the coordinatively unsaturated aluminum atoms; thus, the five-membered Al_2C_2Si heterocycle **26** is formed. The Al–Al bond is only slightly shorter (264.1(2) pm) than that in the starting material.[67]

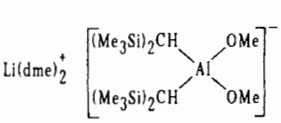


1

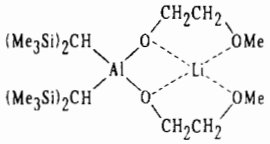


26

The reaction of **1** with lithium alcoholates does not occur as clearly as that with alkyllithium compounds. The cleavage of the Al–Al bond with the formation of the alkoxyaluminates **27** and **28** is always observed in addition to mostly inseparable product mixtures.[67]



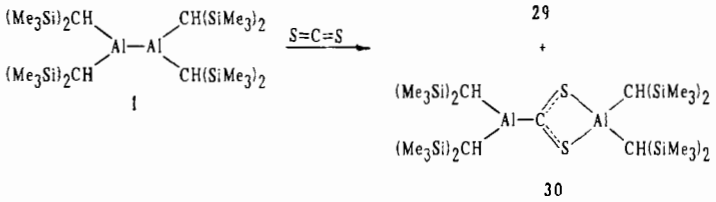
27



28

3.4. Reaction of $[(Me_3Si)_2HC]_2Al–Al[CH(SiMe_3)_2]_2$ with Carbon Disulfide

We have carried out preliminary experiments on the insertion of small molecules into compound **1** with carbon disulfide. Remarkably, irrespective of the solvent and of the reaction time, no reaction took place when stoichiometric quantities of both compounds were combined. A reaction is only observed when **1** is dissolved directly in a large excess of CS_2, and even then it takes 24 hours before the starting material **1** can no longer be detected. Thus, two compounds are formed (**29** and **30**), which can be separated from each other by repeated recrystallizations.[68] In the colorless main



1 **29** **30**

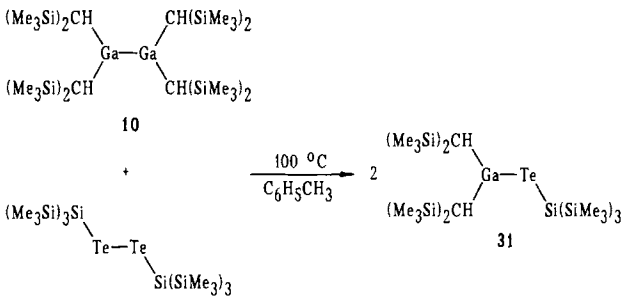
product **29**, an S atom is inserted into the Al–Al bond. This results in a molecule with a short Al–S distance and a very large Al-S-Al angle (117°). But, from the spectroscopic and crystal structure data no additional interaction can be derived between a lone pair of electrons at the sulfur atom and the empty p orbital on the aluminum atom. The large angle can be ascribed to a steric repulsion of the bulky substituents or to an electrostatic repulsion between the two positively charged Al atoms. For the same reasons we observe a corresponding increase in the angle for a compound in which the sulfur bridge is replaced by a CH_2 group.[69]

In the second product (**30**) isolated in 15% yield, a CS_2 molecule was inserted into the Al–Al bond, which binds to one of the Al atoms with the C atom and surrounds the second Al atom in a chelate-like fashion with the two S atoms. In the solid state, as in the starting material **1**, the four α-C atoms of the bis(trimethylsilyl)methyl groups lie in a plane with the two Al atoms, and the CS_2 fragment is almost perpendicular to this plane. Compound **30** can be compared with dithiocarbamates, in which the three-coordinate Al atom is replaced by a N atom. Whereas a strong interaction between the lone pair of electrons on the nitrogen atom and

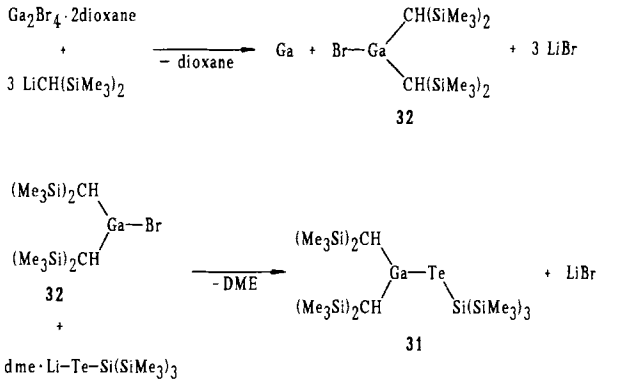
the delocalized π-electron system of the CS_2 unit is observed in such compounds, in **30** as a result of the described conformation of the molecule and of a very long Al–C distance of 205 pm, an inverse electron transfer to the metal atom can certainly be precluded. Also here a different arrangement of the substituents exists in the two halves of the molecule; whereas at the four-coordinate aluminum atom the two substituents are almost perpendicular, they adopt a parallel arrangement at the coordinatively unsaturated aluminum atom. Thus, the α-C–H bonds at the three-coordinate Al atom lie in a plane with both Al atoms, and all C–Si bonds to the two methine carbon atoms, as described several times in previous sections, are in a favorable position for the electron transfer into the unoccupied p orbital at the aluminum atom.

3.5. A Monomeric Gallium Telluride

The chemistry of the tetrasubstituted digallium and diindium compounds has been studied very little to date; the formation of a radical anion of a tetraaryldigallium compound was described in Section 3.2.[39] A remarkable reaction of the compound **10** is achieved with the sterically highly shielded bis[tris(trimethylsilyl)silyl]ditellane. In toluene at 100 °C in the course of four days complete metathesis is achieved with the formation of the gallium telluride **31**, which is monomeric both in solution and in the solid state.[70] The synthesis of



31 is also achieved by the reaction of the corresponding lithium telluride with bis[bis(trimethylsilyl)methyl]gallium bromide **32**, which is only accessible by disproportionation in the reaction of $Ga_2Br_4 \cdot 2$ dioxane with three equivalents of the alkyllithium compound.[70]



Compound **31** is the only monomeric organoelement gallium telluride reported to date which shows a range of remarkable properties. The molecular framework consisting of the atoms Ga, Te, Si1, Si2, C1, and C2 (Fig. 10) is planar; it lies on a crystallographic mirror plane. The Ga–Te distance is significantly shorter (253.5(1) pm) than the mean value of the Ga–Te distances in typical inorganic compounds and that calculated from the covalent radii of 262 pm. A hindered rotation about the Ga–Te bond with an estimated rotation barrier of 50 kJ mol^{-1} as well as an unusual chemical shift for the central methine protons is observed in the NMR spectra. The observations described may possibly be explained by an additional π interaction between the lone pair of electrons on the tellurium atom and the empty p orbital on the gallium atom.

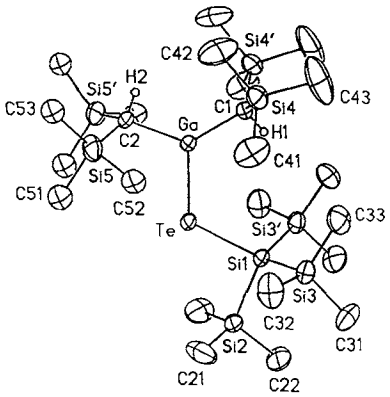


Fig. 10. Molecular structure of the gallium telluride **31** (thermal ellipsoids drawn at 40% probability level). Only the hydrogen atoms of the two CH groups were drawn with arbitrary radius; they denote the position of the $(Me_3Si)_2CH$ groups [70].

4. Outlook

The described synthesis and the preliminary studies into the reactivity of the tetrasubstituted dimetal (M–M) compounds of the heavier elements of the third main group (Al, Ga, and In) have opened the way to a fascinating and interesting new field of research in organoelement chemistry, which in the meantime has attracted many more research groups. The preparative potential of this class of compounds has by no means been completely exhausted, and the reducing properties of the metal–metal bonds in particular offer a field of activity, little studied to date. Moreover, the addition of a second Lewis base, which would lead to compounds analogous to the disilanes, or the ligand exchange with the retention of the element–element bond as well as the introduction of heteroatom substituents with coordinating oxygen or nitrogen atoms at the metal atoms is now at the forefront of current investigations.

I would like to thank the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie for the financial support of this work. My thanks also go to Prof. Dr. G. Becker and Prof. Dr. W. Kaim (Universität Stuttgart) as well as Prof. Dr. W. Hiller (München) for their generous cooperation.

Bacteria and the Biodegradation of Chemicals Achieved Naturally, by Combination, or by Construction

By Gerhard Gottschalk* and Hans-Joachim Knackmuss

The natural potential of bacteria for the biological degradation of synthetic compounds is greater than is commonly supposed and extends to many heteroarenes and even some chloroarenes. An increase in the number of substituents on the aromatic ring or a certain substitution pattern is what confers xenobiotic character to a compound. In addition, when enzymes with low substrate specificity encounter foreign compounds with random variations, products with very strong xenobiotic character often result. In this case, changing the conditions or introducing a cooperation between several different types of bacteria can be used to degrade these compounds. Finally, mineralization, the complete breakdown of organic substances into carbon dioxide and inorganic salts, of xenobiotics previously regarded as persistent can be achieved by taking advantage of natural or induced gene transfer to construct hybrid degradative pathways. After an introduction to the world of bacteria and their place in nature, we will describe their natural potential for biodegradation with reference to aliphatic and aromatic hydrocarbons. The discussion will then turn to the types of the substituents that confer xenobiotic properties to compounds and how these compounds are degraded despite their xenobiotic character.

1. The Two Faces of Bacteria

Bacteria do not generally have a very good reputation. Most people think only of the pathogens, the cause of the plague, cholera, typhus, tuberculosis, and sexually transmitted diseases. This is of course understandable, since in the Middle Ages, for example, far more people died from the plague than in wars. The worst plague epidemic of all time occurred between 1347 and 1352.[1, 2] Starting in the Black Sea area, the plague was carried by sea travelers and traders to neighboring countries and spread from Italy to central Europe and then back to the East, leaving a death count of 30–40 million. Cholera has also been one of the great banes of mankind; the last large cholera epidemic in Germany occurred in 1892 in Hamburg. Robert Koch personally led the struggle against it. Indeed, the danger from the pathogen *Vibrio cholerae* is not over yet, as the more recent news from South America indicates. New pathogens make themselves known every so often, as in the case of the causitive agent of "Legionnaires' disease" first described in 1976 which appeared during a veterans' convention in Philadelphia. As it was later shown, the veterans were infected with a new kind of bacterium spread by the air-conditioning system while they slept. Many became ill with lung inflammations and 31 died. The bacterium was named *Legionella pneumophila* following this incident.[3]

That is, however, only one aspect of bacteria; they also play a useful and vital role in recycling elements essential for life (carbon, nitrogen, and sulfur) on our planet. With the help of sunlight, green plants and phototropic bacteria convert carbon dioxide into biomass and thus provide the basis for all other organisms. Some of this biomass is respired as CO_2 by the phototropic organisms themselves and some by animals in the food chain. Large amounts of plant and animal material die and then decay, a process which to a large extent is carried out by bacteria. Organic material accumulates everywhere on the Earth—in the soil and in sediments of bodies of water and in the sewage and rubbish dumps of our civilization. In all these places microorganisms are at work mineralizing this organic material and thereby returning CO_2 to the atmosphere.[4]

A summary of the terrestrial and marine carbon cycles is shown in Figure 1. Every year roughly 200 gigatons of carbon in the form of biomass is oxidized and released into the atmosphere as CO_2; an estimated 70% of this results from the activities of fungi and bacteria.[5] Fungi mineralize wood and other cellulose-containing material; bacteria are crucial in the breakdown of organic material for three main reasons:

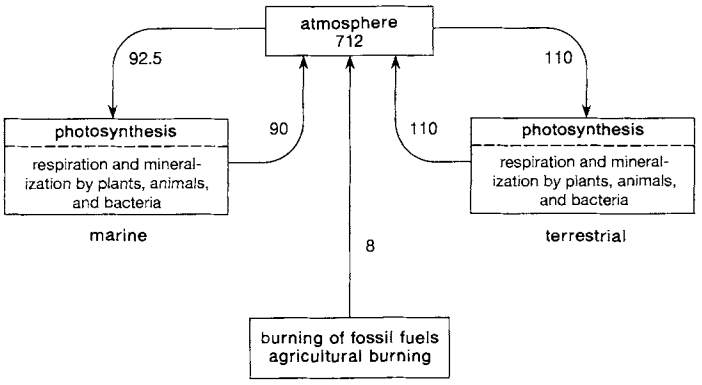

Fig. 1. The carbon cycle on the continents and in the oceans including carbon release into the atmosphere by combustion processes. Values in gigatons (10^9 t) of carbon.

1) The substrate spectrum of bacteria corresponds to the variety of naturally occurring compounds. This is apparent from the observation that no organic compounds of natural origin are accumulated on the Earth's surface or in its waters. The tremendous degradative potential of bacteria includes hydrocarbons, a large number of aromatic compounds, and even chlorine-containing compounds; thus a link to the degradation of pollutants exists already.

2) Bacteria are able to survive under a wide range of conditions. The limits for bacterial growth and survival are delineated in Table 1. Certain archaebacteria often called extremophiles are found in places where life under the prevailing conditions (temperature, pH, pressure, ionic strength) is hard to imagine.

3) Bacteria possess an enormously high metabolic activity due in part to their small size and consequent large surface-to-volume ratio. A cross section of a bacterial cell is shown schematically in Figure 2. It is evident that energy produc-

Table 1. The limits of bacterial growth.

Condition	Limits	Examples
temperature	90–110 °C	*Pyrodictium occultum* *Methanopyrus kandleri*
	15–0 °C	*Photobacterium phosphoreum*
pH	3–1.5	*Acidianus brierleyi*
	9–11	*Bacillus alcalophilus*
salinity	up to 5.2 M NaCl	*Halobacterium halobium*
O_2 concentration	0%	fermentation organisms like methanogenic bacteria and clostridia
	about 1%	microaerophilic bacteria like *Thiomicrospira denitrificans*
	20%	common bacteria found in soil and water

[a] Examples taken from refs.[6,7].

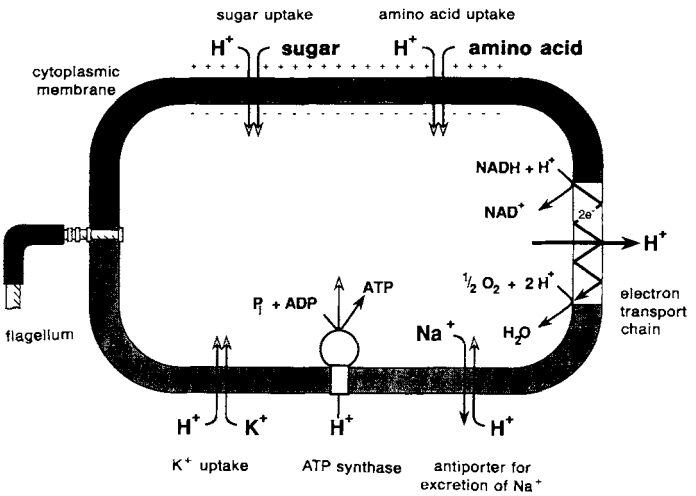

Fig. 2. Schematic diagram of a bacterial cell showing the many activities that take place in the cytoplasmic membrane. The outer cell wall and the intermediate metabolism that occurs in the cytoplasmic membrane are not shown.

Gerhard Gottschalk was born in 1935 in Schwedt/Oder and studied chemistry at the Humboldt University in Berlin from 1953 to 1959. After receiving his diploma, he moved to Göttingen in 1960, where he completed his Ph.D. dissertation in 1963 for his work with H. G. Schlegel on the biosynthesis of poly-β-hydroxybutyric acid. Following two years of postdoctoral research with H. A. Barker at the Department of Biochemistry at UC Berkeley, he completed his habilitation in microbiology at the University of Göttingen. He received a faculty appointment at the University of Münster in 1969 and took up his present position in 1970 at the University of Göttingen. He has been a guest professor at UC Davis and UC Berkeley and is a member of the Akademie der Wissenschaften zu Göttingen. In 1992 he recieved the Philip-Morris-Forschungspreis "Herausforderung Zukunft" together with A. Steinbüchel and H. G. Schlegel. His major research interests are the metabolism of anaerobic bacteria, in particular methane-producing bacteria, the enzymology and genetic organization of microbial metabolic processes, and biodegradation. He is the author of the textbook "Bacterial Metabolism".

Hans-Joachim Knackmuss, born in 1936 in Halle/Saale, studied chemistry in Heidelberg from 1957 to 1962. He obtained his diploma and Ph.D. (1963–1964) for research he conducted with Richard Kuhn at the Max-Planck-Institut in Heidelberg on natural product synthesis directed toward the structural determination of bacterial indigoidine. After one year of postdoctoral research with M. P. Starr at the Department of Bacteriology at UC Davis, he completed his habilitation at the University of the Saarland in Saarbrücken in 1970. He then switched research areas and joined the scientific staff at the Institut für Mikrobiologie der Gesellschaft für Strahlen- und Umweltforschung mbH München in Göttingen. In 1979 he was appointed professor at the Universität-Gesamthochschule Wuppertal. He took up his present position as a director of the Institut für Microbiologie at the University of Stuttgart in 1986. His main research interests are the development of microbial systems for the targeted biotransformation of synthetic compounds and for the removal of xenobiotics from the environment. His work on the physiology and enzymology of the microbial degradation of xenobiotics and the experimental evolution of new catabolic activities in microorganisms form the basis for biological waste management techniques, which are being developed in cooperation with a group at the Fraunhofer Institut für Grenzflächen and Bioverfahrenstechnik in Stuttgart.

tion and transport of material in and out of the cell occur in the cytoplasmic membrane enclosing the cell. The greater the surface area of this membrane in comparison to the volume of the cytoplasm, the more substrate and therefore the more energy in the form of ATP can be made available for the synthetic machinery in the cytoplasm. For example, the respiration rate of the nitrogen-fixing *Azotobacter vinelandii* is 2000 times greater than that of cells in liver tissue. The rate of growth and reproduction of bacterial cells is also much faster. Under optimum conditions an *Escherichia coli* cell, for example, can divide every 20 minutes, and this is not even the record. Other bacteria need only 11 minutes for one generation. The impact of such rapid cell division is shown in the following (somewhat imaginary) example.

If we ask how much bacterial mass would be produced from a single *E. coli* cell in 48 hours, assuming that cell division takes place every 20 minutes, we come up with a rather incredible answer. In this time 144 cell divisions would take place, and $N = 1 \times 2^{144} = 10^{43}$ cells would result. Since a single *E. coli* cell weighs 10^{-12} grams, 10^{43} cells would weigh 10^{25} tons (for comparison, the Earth weighs 6×10^{21} tons). Thus the weight of the bacteria produced in only two days would be 1000 times the mass of the Earth. This calculation shows that the growth of *E. coli* and other bacteria must be controlled by limiting utilizable substrates or by allowing the products of degradation to accumulate. Nevertheless, it is obvious that under the right conditions utilizable compounds are quickly broken down by bacteria.

2. Everything Depends on an Energized Cytoplasmic Membrane

A bacterium is not a passive biocatalyst, not a closed net full of enzymes that swims in an aqueous milieu allowing everything to enter and then somehow transforming these substances and releasing the products to the outside. Bacteria are in fact compartments well shielded from their surroundings. The differences in the concentrations of substances inside and outside of the cell are enormous. For example, the K^+ concentration in a bacterial cell is around 250 mM, (outside the cell the concentration of K^+ is often 20 mM or less); the Na^+ concentration is only a few mM even in bacteria in sea water, where the concentration of Na^+ is 600 mM. It is the cytoplasmic membrane, a phospholipid bilayer containing proteins,[8] that shields the cell from the outside world. This membrane does not just form a shell around the inside of the cell; the membrane is also "energized" as a result of the proton gradient across it. Consequently, the cell's interior is more alkaline than the exterior, and the inside is negatively and the outside positively charged. These combined parameters are called the protomotive force (Fig. 2).

This energized state of the cytoplasmic membrane is crucial for the survival of a bacterial cell, allowing the selective uptake and release of compounds such as neutral or charged organic compounds and inorganic ions. The gradient also makes possible the synthesis of adenosine triphosphate (ATP). Substrates are taken up by bacteria and partially oxidized through respiration, leading to the production and maintenance of the proton gradient and protomotive force just mentioned.[9] Lack of substrate leads to the death of the bacteria, as they are not able to maintain the energized state of the membrane. However, substrates themselves can be a problem: lipophilic substrates can destroy the energized state of the membrane and thus prevent ATP synthesis. Such uncoupling agents include compounds like 2,4-dinitrophenol, tetrachlorosalicylanilide, and also weak organic acids, which can pass through the phospholipid bilayer in undissociated form[10] and dissociate inside the cell, thus destroying the pH gradient between the interior and exterior (Fig. 3).

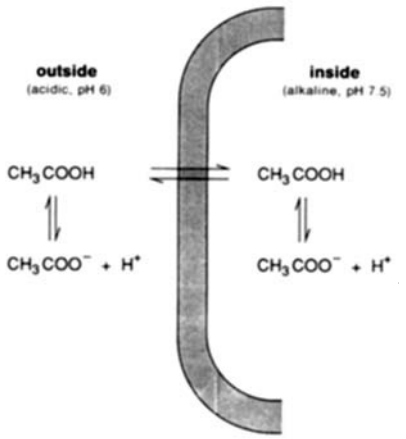

Fig. 3. The uncoupling effect of weak organic acids. The concentrations of the undissociated acid inside and outside equalize, and the difference in pH is minimized by dissociation inside.

For this reason organic acids like acetic acid or lactic acid are good food preservatives. Solvents like toluene and butanol function differently: they make "holes" in the membrane and prevent the maintenance of ion gradients. It is therefore even more remarkable that Horikoshi et al. were able to isolate strains of *Pseudomonas putida* and *P. aeruginosa* that grow on agar under a 2-mm-thick layer of toluene, *p*-xylene, cyclohexane, or *n*-heptanol.[11] Although exceptions, these strains are very interesting, and attention should be directed to understanding their fundamental tolerance mechanisms.

From the discussion so far it is clear that the lack of substrate as well as certain lipophilic substrates can cause problems for bacteria. Lipophilic compounds in particular are a potential danger, which bacteria are generally able to circumvent by metabolizing the compounds at a rate faster than the rate at which they diffuse into the neighborhood of the cell. An aqueous milieu, low concentrations of such compounds, and possible enzymatic transformations are requirements for the breakdown of many compounds, natural as well as synthetic.

3. The Degradation of Natural Compounds Is Fascinating in Itself

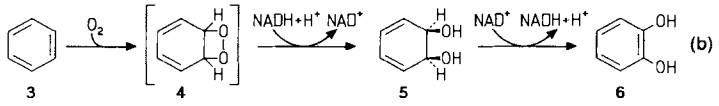
A few examples should serve to document the range of reactions used by microorganisms for the breakdown of substances. This catabolism extends beyond glycolysis and related reactions. Oxygen is generally directly involved in the breakdown of aliphatic and aromatic compounds. Aliphatic

hydrocarbons like **1** are converted into primary alcohols such as **2** by means of monooxygenase reactions [Eq.(a)].[8]

$$C_{15}H_{31}\text{-}CH_3 + O_2 + NADH + H^+ \longrightarrow C_{15}H_{31}\text{-}CH_2OH + H_2O + NAD^+ \quad (a)$$

It is characteristic of this reaction that in addition to the hydrocarbon, a coenzyme in the cell such as nicotinamide adenine dinucleotide (NADH) is also oxidized. The resulting primary alcohol can then be converted via the aldehyde into the corresponding carboxylic acid, which can then be activated by esterification with coenzyme A and then broken down further by the β-oxidation pathway.

The degradation of aromatic compounds proceeds by the following scheme: First compounds with hydroxyl groups next to each other are formed by "dioxygenase reactions". In the simplest case, the degradation of benzene, the cyclohexadienediol derivative **5** is formed, which is then dehydrogenated in a separate NAD^+-dependent reaction to give catechol (**6**) [Eq.(b)]. Dioxygenases that act on aromatic ring systems



are multicomponent systems (Fig. 4). A reductase component, a flavoprotein, accepts an electron from NADH and passes this on via ferredoxin to the oxygenase itself, which contains iron–sulfur centers (Fe-S), specifically Fe^{2+}, in its reaction center.[12] A few of these dioxygenases are listed in

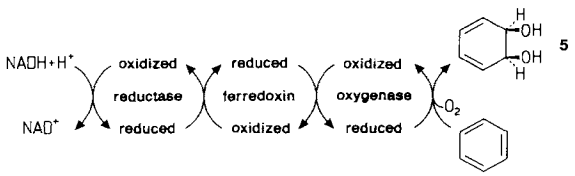


Fig. 4. Benzene dioxygenase, a three-component system.

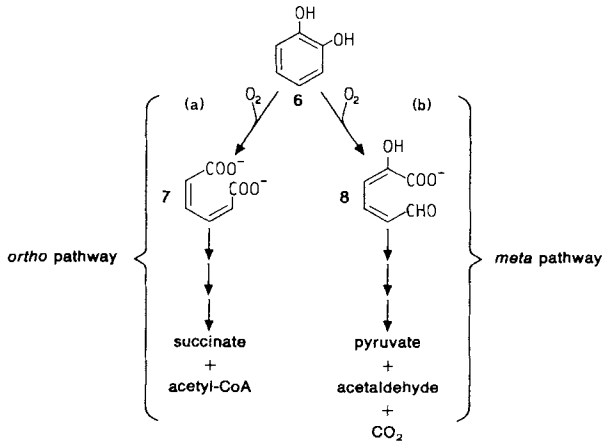
Table 2. Benzoate and *ortho*-phthalate dioxygenases are two-component systems in which electrons are transferred directly from the reductase to the oxygenase via the Fe-S centers. Catechol (**6**) and protocatechuate are cleaved with O_2 between the hydroxyl groups (*ortho* cleavage) or at a position directly next to one of the hydroxyl groups (*meta* cleavage), leading to the formation of *cis,cis*-muconic acid and hydroxymuconic acid semialdehyde, respectively, or corresponding derivatives (Scheme 1). The ability to cleave

Table 2. Multicomponent systems for the hydroxylation of arenes (dioxygenases).

Dioxygenase	Reductase			Ferredoxin	Oxygenase		
	M [a]	flavin	Fe-S center	*M*	*M*	Fe-S center	Fe^{2+}
benzene 1,2-	60	FAD	–	12	168	+	+
toluene 2,3-	46	FAD	–	15	151	+	–
naphthalene 1,2-	36	FAD	2Fe-2S	14	158	+	–
benzoate 1,2-	38	FAD	2Fe-2S	–	201	+	+
o-phthalate 1,2-	34	FMN	2Fe-2S	–	217	+	–

[a] Molecular mass in kilodalton. Data taken from refs. [12,15].



Scheme 1. Cleavage of catechol (**6**) by a 1,2-dioxygenase (a) and a 2,3-dioxygenase (b).

an aromatic ring system is amazingly widely distributed among bacteria. The genes required may lie on the bacterial chromosome (as is often the case with *ortho* cleavage), or on a plasmid (primarily for *meta* cleavage). Plasmids are small, circular, double-stranded DNA molecules, which though similar to the bacterial chromosome are much smaller (around 1% the mass of the bacterial chromosome). Plasmids often carry genes whose gene products confer resistance to specific antibiotics.

Heteroarenes, found frequently in nature in nucleic acids and some amino acids, vitamins, and alkaloids, are also biodegradable.[13] The microbial attack on unsubstituted heterocycles often begins with the introduction of a hydroxyl group next to the heteroatom. In this case the hydroxyl oxygen atom does not come from oxygen but rather from water; the enzymes responsible contain a molybdenum cofactor and in most cases flavins as well (Table 3).

Table 3. Molybdenum-containing enzymes that hydroxylate heterocycles using water.

Enzyme	Other prosthetic groups	Product
xanthine DH [a]	FAD, Fe-S	uric acid
nicotine DH	FAD, Fe-S	6-hydroxynicotine
isonicotinic acid DH	FAD	6-hydroxyisonicotinic acid
picolinic acid DH	FAD	6-hydroxypicolinic acid
quinoline DH	FAD	2-hydroxyquinolinic acid
furan-2-carboxyl-CoA DH		5-hydroxyfuran-2-carboxyl-CoA

[a] DH = dehydrogenase.

The molybdenum cofactor that occurs in bacteria is a molybdopterin guanine or cytosine dinucleotide (Fig. 5).[14]

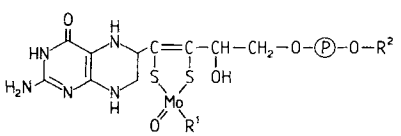


Fig. 5. Molybdenum cofactors. R^1 = O: nitrate reductase, sulfite oxidase; R^1 = S: most known molybdenum enzymes; R^1 = Se: a few molybdenum enzymes of anaerobic bacteria; R^2 = cytosine or guanosine monophosphate. Ⓟ = phosphodiester group.

How the cofactor is involved in the hydroxylation is shown in the postulated mechanism for the xanthine dehydrogenase reaction (Fig. 6).[15]

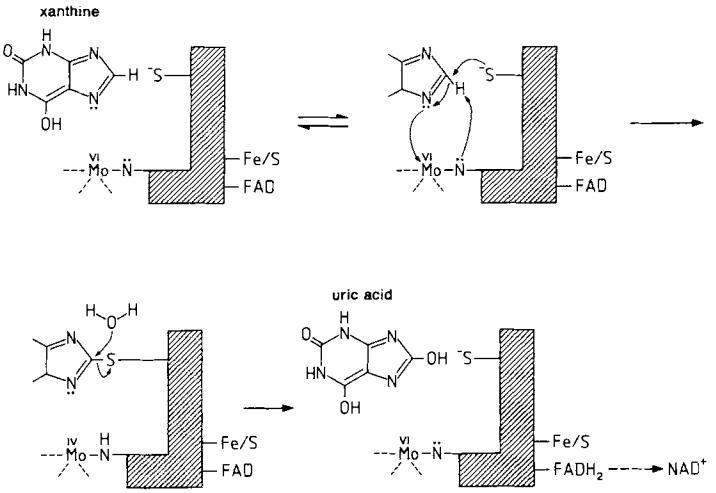

Fig. 6. A possible mechanism for the xanthine dehydrogenase reaction[15]. The shaded area represents the active center of the enzyme (S^- groups and the redox-active components).

It is reasonable that these enzymes require flavine adenine nucleotide (FAD) in addition and contain Fe-S centers. In the course of the hydroxylation Mo^{VI} is reduced to Mo^{IV}; in the reoxidation mediated by the Fe-S centers and FAD the electrons are finally transferred to NAD^+.

4. No Suitable Degradation Mechanisms Exist for a Number of Synthetic Compounds

Some of the synthetic compounds released deliberately or accidentally into the environment are xenobiotic in nature. Substituents like chlorine, bromine, and sulfonic acid and nitro groups occur relatively rarely in natural compounds; fluoro- and fluoroalkyl-substituted arenes and those with phenylazo groups are unknown. Besides the nature of the substituents, their number and position also confer xenobiotic character to synthetic compounds. For example, although methyl substituents occur widely in natural compounds, they can hinder the biodegradation of synthetic compounds. A methyl group vicinal to a substituent already present hinders the primary attack by oxygenases on aromatic structures and also hinders the degradation of aliphatic compounds by β-oxidation.

Since microorganisms have not been exposed to such xenobiotic structures during the course of evolution, corresponding degradation mechanisms have not been developed. The lack of specific enzymes for the degradation of xenobiotics in natural microbial communities is *one* of the reasons for the persistence of these compounds.

The enzymes produced by bacteria for the degradation of naturally occurring compounds do not have absolute specificity. Accordingly, xenobiotics undergo "gratuitous" changes in structure, which is referred to as cometabolism.[16] These reactions generally do not lead to the mineralization of xenobiotics, that is to say a complete breakdown into CO_2, H_2O, and inorganic nitrogen compounds etc. does not take place. Instead, complex product mixtures are produced which are subject to further biological and chemical reactions (see Section 6). The rate of such cometabolic reactions is generally slow for a number of reasons. Firstly, they do not generate any energy for the microorganism involved, and thus the active biomass does not increase. Secondly, the oxidative catabolism supporting the oxygenases actually requires energy (e.g. NADH). The only way to increase the rate of these reactions by external influences is by adding growth substances. Therefore cometabolism is referred to as unproductive, or when energy is lost and cell damage occurs it is even referred to as a counterproductive catabolism. Cometabolically active organisms therefore require a cosubstrate to provide energy and to induce the production of the cometabolically active enzymes.

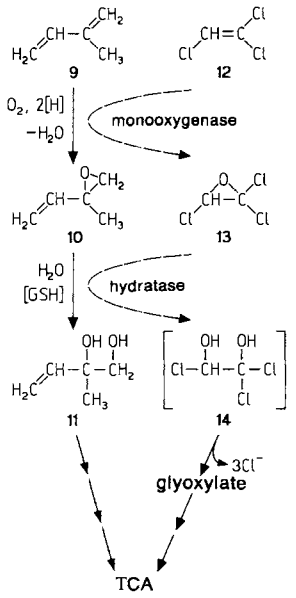
5. Process Conditions and Cosubstrates Can Be Decisive

Despite the problems mentioned, many observations confirm the role of cometabolic transformations as the key reactions for the biodegradation of xenobiotics. A good illustration is provided by nitrobenzene, which can only be broken down with great difficulty by aerobic bacteria. In contrast, the ability to mediate the gratuitous reduction of nitrobenzene to yield aniline, in other words, the cometabolic reduction by nonspecific enzymes designed for other substrates, is generally present in anaerobic populations of bacteria. The reduction to aniline occurs rapidly in the presence of electron donors like glucose or alcohols, and the resulting aniline can be easily and completely broken down in a subsequent aerobic degradation step.[16a]

The nonspecific gratuitous reduction of xenobiotics can be applied to other electrophilic compounds. The potential of such reductions in making compounds that are difficult to tackle by oxidation accessable for complete biodegradation by aerobic microorganisms has remained largely untapped. It is possible, for example, to use gratuitous reduction to cleave azo compounds yielding aromatic amines, which can then be subjected to electrophilic attack by oxygenases (see Section 7). In the case of highly chlorinated compounds like tetrachloroethene or polychlorinated biphenyls (PCBs) some of the chlorine substituents can be reductively eliminated,[17, 18] which considerably reduces the persistence of such compounds to oxidative biodegradation by bacteria.

Whereas tetrachloroethene is only slowly attacked by oxygenases, the rate of reaction increases markedly in the following series trichloroethene (**12**), dichloroethene, and vinyl chloride.[19] Here, monooxygenases whose natural function is the oxidation of naturally occurring substances like methane, alkylarenes,[20] or alkenes[21] are particularly effective. Bacterial strains that degrade isoprene have proved to be especially effective.[22] In this case, a monooxygenase transforms isoprene (**9**) to 3,4-epoxy-3-methyl-1-butene (isoprene oxide, **10**) (Scheme 2), which in turn is hydrolyzed to diol **11** by a glutathione (GSH)-dependent enzyme. In contrast to methylotrophic bacteria, isoprene-degrading bacteria can tolerate high levels of trichloroethene (**12**). The methane monooxygenases from methylotrophic bacteria are

irreversibly inactivated by the reactive epoxide **13** produced by the cooxidation of **12**.[23] In contrast, in the same reaction with isoprene-degrading bacteria three equivalents of chloride are eliminated without any loss of activity. The advantage of isoprene (**9**) over methane as cosubstrate is that the latter, which is structurally related to **12**, stimulates the growth of those bacteria able to eliminate three equivalents of chloride by means of a epoxide hydrolase, thus protecting themselves against suicide inactivation. The release of three



Scheme 2. Initial reactions of the degradation of isoprene and the cometabolism of trichloroethene (dotted arrows) by *Rhodococcus erythropolis* JE77. TCA = tricarboxylic acid cycle.

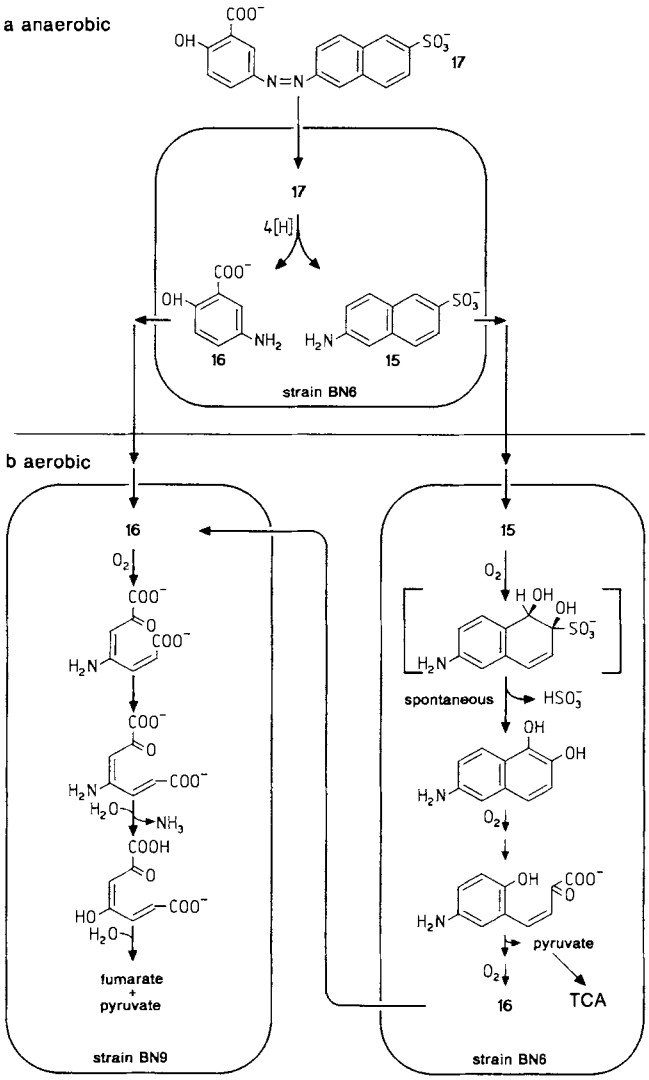
equivalents of chloride from **12** is also observed in its transformation by bacteria isolated with isopropylbenzene (cumene) as energy substrate.[20] In this case, it is apparent that a nonspecific isopropylbenzene-2,3-dioxygenase is responsible for the direct formation of **14**.

6. Bacteria Help Each Other in the Degradation of Xenobiotics

With more complex xenobiotics, structural alterations are possible by cooxidation reactions; however, complete degradation (i.e. mineralization) cannot be expected. The wide range of degradative activities of a typical mixed population of bacteria lead to products with at least as much variety. The aromatic 1,2-diols referred to in Section 3 are formed from aromatic compounds. These diols are not degraded further but undergo autoxidation and polymerization, which negatively influences the COD (chemical oxygen demand) elimination of biological wastewater treatment plants.

An improvement in the degree of biodegradation of a xenobiotic substance can be expected when the degradative activities present in a mixed microbial community complement each other, and the participation of several organisms finally leads to the mineralization of the substance concerned.

Such syntrophic interactions within mixed cultures actually occur and can lead to a complete mineralization of complex xenobiotic compounds. The aerobic degradation of 6-aminonaphthalene-2-sulfonate (**15**) illustrates this principle (Scheme 3).[24] The ability to partially degrade substituted naphthalenes to the corresponding salicylates is ubiquitous. The regioselective dioxygenation in the 1,2-position is of vital importance for the selection of baceteria that degrade naphthalene sulfonates (see also ref.[40]). This makes the



Scheme 3. Mineralization of mordant yellow (**17**) by an anaerobic–aerobic process using a syntrophic mixed culture. The reductive cleavage of **17** by cells of *Pseudomonas vesicularis* BN6 under anaerobic conditions (a) produces 6-aminonaphthalene-2-sulfonate (**15**) and 5-aminosalicylate (**16**) in a 1:1 molar ratio. These compounds are completely and productively degraded under aerobic conditions (b). After desulfonation and ring opening, strain BN6 obtains pyruvate as a utilizable metabolite. The **16** formed is excreted as a dead-end product, taken up by the accompanying *Pseudomonas* sp. BN9, and used as a growth substrate. For continuous degradation, biomass from the aerobic step must be returned to the anaerobic step.

C–S bond labile and leads to the cleavage of the sulfonic acid group generating sulfite. The reactions that follow correspond to the known degradative pathway for naphthalene and yield pyruvate, which serves as a growth substrate. On the other hand, this energy-yielding partial degradation also leads to the accumulation of toxic salicylates and their oxidation products which can damage bacteria. The complete and productive degradation of this xenobiotic is possible only when other bacteria are also present that are able to degrade

the 5-aminosalicylate (**16**) produced from **15** by using a complementary degradative pathway.

Typically, a stable continuous degradation process by this mixed culture[25] can only be achieved if the partner strains are attached to an inert support like quartz sand. The close contact of the cells attached to the support apparently facilitates the transfer of **16** from one strain of bacteria to the other. The immobilization of the bacteria completely prevents loss of substrate due to intermediates being misrouted or due to autoxidation of **16**.

Under anaerobic conditions the biomass of this mixed culture produced by the degradation of **15** is able to carry out the gratuitous reduction of sulfonated azodyes. Thus mordant yellow (**17**) is cleaved quantitatively to give **15** and **16** under anaerobic conditions (Scheme 3a), which are then completely mineralized in a final aerobic step.[26] The ability to reductively cleave the azo group is harbored only by cells of the strain BN6 when these have been grown in the presence of naphthalene sulfonates. Clearly only this organism has a transport system for sulfonates, which gratuitously also takes up **17** and thus makes the reduction possible.

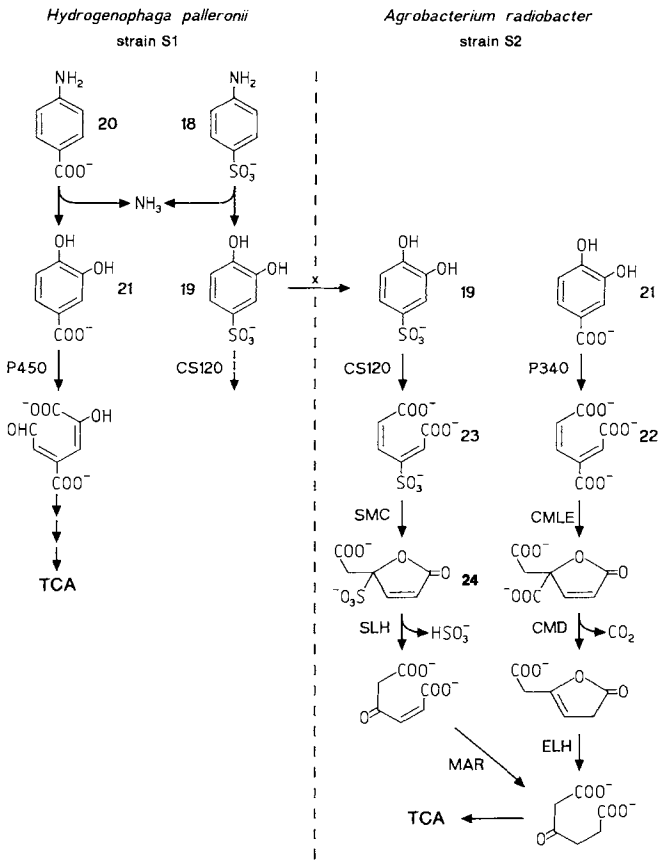
7. Amino and Nitro Groups Can Serve as a Nitrogen Source

The use of a xenobiotic as a growth substrate generally requires the complete breakdown of the carbon skeleton into intermediates of basic metabolism. At some point in the degradative pathway the substituents responsible for xenobiotic character must be eliminated, mostly in the form of anions. Complex structures thus resist complete biodegradation, as this requires too many novel reaction steps. Therefore classical enrichment cultures, in which the xenobiotic is the single growth-limiting carbon and energy source for the bacteria, can fail. The xenobiotic appears to be nonbiodegradable.

However, changing the selection conditions can lead to a completely different appraisal of the biodegradability of the compound concerned. In the presence of an easily degradable substrate such as glucose or malate and under nitrogen-limiting conditions, those bacteria able to satisfy their nitrogen requirement through the elimination of amino or nitro groups have a distinct advantage. A complete degradative pathway is not necessary in this case; a single degradative enzyme, for example, an ammonia- or nitrite-eliminating dioxygenase suffices.

Sulfanilate **18**, which resists degradation under normal carbon-limiting growth conditions, is a good example here. In contrast to the metabolism of **15** (Scheme 3), **18** is first deaminated by cultures of *Hydrogenophaga palleronii* by means of a dioxygenase to provide 3,4-dihydroxybenzenesulfonate (**19**) (Scheme 4). This reaction corresponds to the deamination of the naturally occurring substance 4-aminobenzoate (**20**) to give protocatechuate (**21**). 4-Aminobenzoate serves as both a nitrogen and a carbon source for *H. palleronii* (strain S1) by assimilation by the protocatechuate-4,5-dioxygenase (P45O) pathway. Compound **19** is, however, not cleaved by this enzyme.

In contrast, *Agrobacterium radiobacter* (strain S2) is able to cleave both **21** and its structural analogue **19** between the



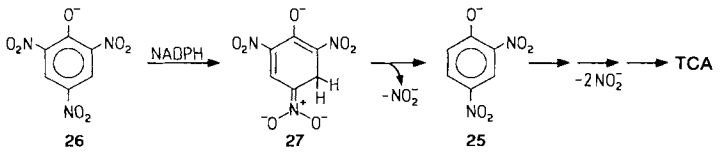
Scheme 4. Degradation of sulfanilate (**18**) by a syntrophic mixed culture: *Hydrogenphaga palleronii* (strain S1) utilizes 4-aminobenzoate (**20**) by conversion to yield protocatechuate (**21**) and deaminates **18** to give 3,4-dihydroxybenzenesulfonate (**19**). After an interspecies transfer of **19** (×), *Agrobacterium radiobacter* (strain S2) is largely responsible for the ring opening of this compound. This strain degrades **21** by the known 3-oxoadipate pathway. Compound **18** is assimilated by means of a pathway which is analogous to a large extent. However, it requires additional enzymes such as catechol-4-sulfonic acid 1,2-dioxygenase (CS12O), sulfomuconate cycloisomerase (SMC), sulfolactone hydrolase (SLH), and maleylacetate reductase (MAR). ELH = enollactone hydrolyse.

diol groups by means of a protocatechuate-3,4-dioxygenase (P34O). Subsequent mineralization of **19** and **21** takes place by a pathway analogous to the 3-oxoadipate pathway. Instead of the enzymes known from the protocatechuate pathway for ring cleavage of **21** (P34O) and cycloisomerization (CMLE) of the carboxymuconate **22**, the isoenzymes CS12O and SMC function in the transformation of the sulfur analogues substrates **19** and **23**. The elimination of sulfite from sulfolactone **24** requires the unique enzyme sulfolactone hydrolase (SLH), because the carboxymuconolactone decarboxylase (CMD) from the classical protocatechuate pathway cannot catalyze this reaction. The maleylacetate reductase (MAR) utilized in this pathway is not required in the protocatechuate pathway but is induced in the presence of **19** and is already known from degradative pathways for resorcinol and haloarenes. This enzyme allows these degradative sequences to converge with the 3-oxoadipate pathway.

When the bacterial strains S1 and S2 are cultured with **18** as the sole nitrogen, sulfur, and energy source, a stable syntrophy results.[27] Strain S2 is dependent on the initial elimination of ammonia by a regioselective dioxgenase from strain S1. In turn, strain S1 can use **18** as a nitrogen source

only because the enzyme CS12O cleaves intermediate **19** only very slowly under normal partial pressure of O_2. Exactly how *Hydrogenophaga* participates in the use of 3,4-dihydroxybenzenesulfonate as a source of carbon and energy is not yet clear.

In principle bacteria can also be isolated from nature, and under aerobic conditions they can cleave nitrite from nitroarenes and assimilate this as a nitrogen source. Under appropriate culture conditions even nitrophenols can be degraded, although they have previously been considered to be nonbiodegradable because of their high toxicity.[28] Interestingly, during selection with 2,4-dinitrophenolate (**25**) or picrate (**26**) as the sole nitrogen source, only gram-positive bacteria (mostly *Rhodococci*) grow. The strains that are isolated are found to be largely resistant to the uncoupling effect of these cell poisons.[29] Since **26** is not readily oxidized by oxygenases, the bacteria are forced to take an usual approach as shown in Scheme 5. They transfer H^- from NADPH to the aromatic ring without reducing the nitro groups.[30]



Scheme 5. *Rhodococcus erythropolis* HLPM1 utilizes picrate (**26**) and 2,4-dinitrophenol (**25**) as nitrogen source. It has been shown that the primary metabolite formed is the H^- Meisenheimer complex **27**, which is then degraded to **25** with the release of nitrite.

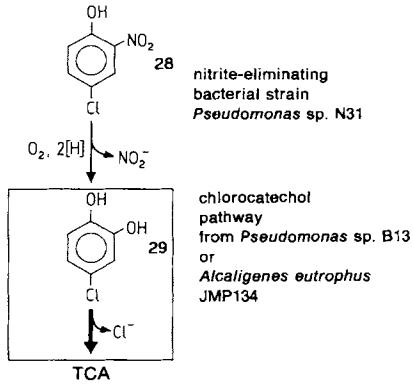
The resulting Meisenheimer complex **27** is stable and is cleaved by an additional enzyme to yield nitrite and simultaneously rearomatizes to yield **25**. The latter is completely degraded, and for each mole of **25** almost two moles of NO_2^- are released.

8. Tailor-Made Bacteria with Hybrid Degradative Pathways

Mixed cultures of microorganisms are almost always used in biological waste disposal technology. The wide variety of degradative potentials these mixed cultures display against organic substances of natural origin is much greater than that of a single species. However, complete mineralization and utilization of xenobiotics requires a complex interaction between partial activities within a mixed population, as in the degradations of **18** and **15**. This kind of syntrophic degradation is susceptible to many disturbing influences such as possible loss and misrouting of metabolites. Under real-world conditions a considerable portion of the xenobiotics is converted by cometabolic reactions into ill-defined, mostly dark-colored, high molecular weight products, which like humic substances are not suited for rapid biodegradation. This makes it clear that the interaction between microorganisms with complementary degradative abilities can be the weak link with regard to a complete degradation of xenobiotics. This is because xenobiotics or their metabolites can be misrouted into unproductive degradative pathways or be subject to abiotic reactions.

Bacterial cells that harbor complete degradative pathways and can degrade xenobiotics completely and productively should have a clear selective advantage. Under conditions of continuous cultivation in a sewage treatment system, the growth of such specialists that degrade xenobiotics productively, would automatically respond to the xenobiotics available, be self-regulating, and would suppress the level of unproductive degradation due to cometabolism.

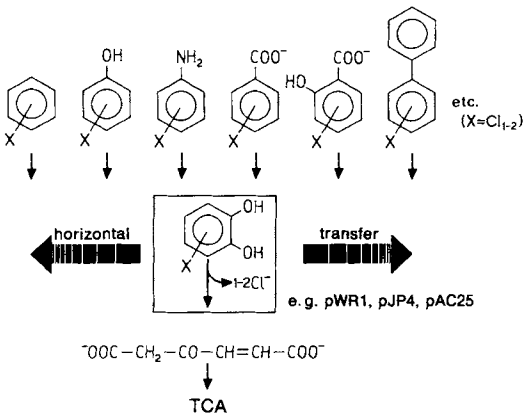
In the degradation of chloronitrophenols, bacteria with complete degradative pathways readily arise under the appropriate selection conditions. Chloronitrophenols like other nitrophenols are highly toxic to bacteria because of their uncoupling effect on the respiratory electron transport chain. If the selection conditions are chosen so that 4-chloro-2-nitrophenol (**28**) is present in low concentrations ($\leq$ 0.5 mM) as the sole source of nitrogen in the presence of an readily utilizable compound (e.g. succinate), then bacteria can be easily isolated that convert **28** to 4-chlorocatechol (**29**) and nitrite by means of an oxygenation reaction (Scheme 6). Succinate already present and the nitrite produced make the growth of the bacteria possible.



Scheme 6. Degradation of 4-chloro-2-nitrophenol (**28**) by a hybrid strain of *Pseudomonas* sp. N31 constructed in vivo.

The ability to partially degrade **28** to **29** can be easily selected for in the laboratory. However, in the real world, for example in a sewage treatment plant, this is hardly possible because nitrogen-limiting conditions necessary for its selection do not occur. In addition, the accumulating **29** is subject to autoxidation and is also toxic. In this case, bacterial strains can help that assimilate chlorocatechol and have this complementary ability (Scheme 7) on a transferable genetic element, for example on the plasmids pJP4, pWR1, or pAC25.[41] In this manner, hybrid strains with complete degradative pathways can evolve spontaneously. The bacteria produced by natural gene transfer completely degrade **28** and utilize this compound as the sole carbon, nitrogen, and energy source.[31]

As illustrated by the example of **28**, new hybrid degradative abilities for variety of other chloroarenes such as chlorobenzoates, chlorophenols, chloroanilines, chlorosalicylates, chlorobenzenes, phenoxyacetates,[41] and chlorobiphenyls[39] can be developed by natural gene transfer.[32] The basis of this evolutionary potential are natural cometabolic activities that cooxidize chloroarenes to chlorocatechols. Enzymes that degrade methylarenes are especially



Scheme 7. The principle of the evolution of hybrid degradative pathways for chloroarenes. Chloroarenes are cometabolized by arene- or methylarene-degrading bacteria to give chlorocatechols. The acquisition of the genes for chlorocatechol degradation (see Scheme 8) can lead to the formation of hybrid degradative pathways making the complete degradation of the chloroarenes possible. Donor strains for these genes are bacteria that utilize **30** or **31** and have the catabolic information on plasmids such as pWR1, pJP4, or pAC25.

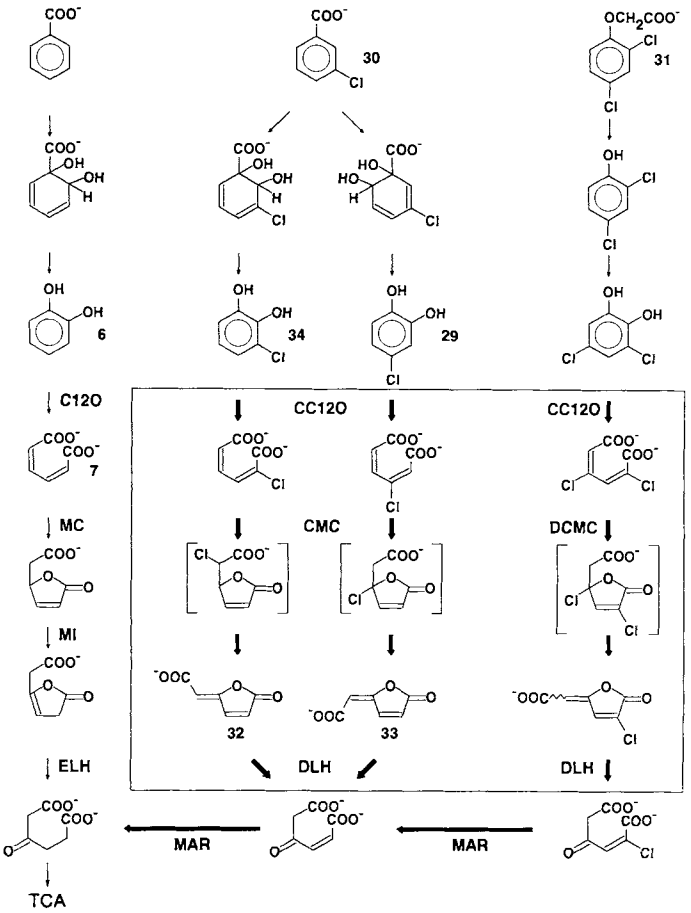
effective, since the corresponding chloro-substituted compounds are structural analogues of the natural substrates.

Bacteria with the complementary property necessary for the assimilation of chlorocatechol make up a minor part of natural populations; however, they are ubiquitous. Such specialists can be easily enriched from water and soil samples by using less toxic substrates such as 3-chlorobenzoate (**30**) and 2,4-dichlorophenoxyacetate (**31**) (Scheme 8),[33] leading to their isolation as pure cultures.

Interestingly, the catabolic sequences for **30** and **31** are analogous to the classic pathway of benzoate (3-oxadipate or *ortho* pathway, Scheme 8). Certain enzymes, for example chlorocatechol-1,2-dioxygenases (CC12O) and chloromuconate cycloisomerases (CMC and DCMC), are isoenzymes that act on the normal halogen-free substrates as well. These enzymes are only induced during growth on **30** (*Pseudomonas* sp. B13) or **31** (*Alicaligenes eutrophus*). The normal catechol-1,2-dioxygenase (C12O) and muconate cycloisomerase (MC) of the 3-oxoadipate pathway are not very effective with the chloro-substituted metabolites.

The high level of homology in the amino acid sequence of the isoenzymes indicates that they evolved from the corresponding proteins of the classical *ortho* pathway. From the frequency of the alterations in the DNA sequence which are not expressed in the amino acid sequences, it can be estimated that at least the enzymes CMC of the 3-chlorobenzoate degradative pathway and DCMC of the 2,4-dichlorophenoxyacetate degradative pathway diverged from the classical muconate cycloisomerases (MC) long before anthropogenic substrates (products of the chemical industry) could act to speed up the evolution of these proteins.[34]

The sulfolactone-hydrolyzing enzyme (SLH in Scheme 4) from the sulfocatechol pathway previously discussed has no analogue in the protocatechuate pathway with respect to its catalytic effect. The dienelactone hydrolase (DLH) of the modified *ortho* pathway (Scheme 8) is an enzyme that only attacks the dienelactones **32** and **33**, and not the corresponding lactone from the classical *ortho* pathway (benzoate route in Scheme 8).[35] The extent to which these hydrolases may be related is the subject of current investigations.

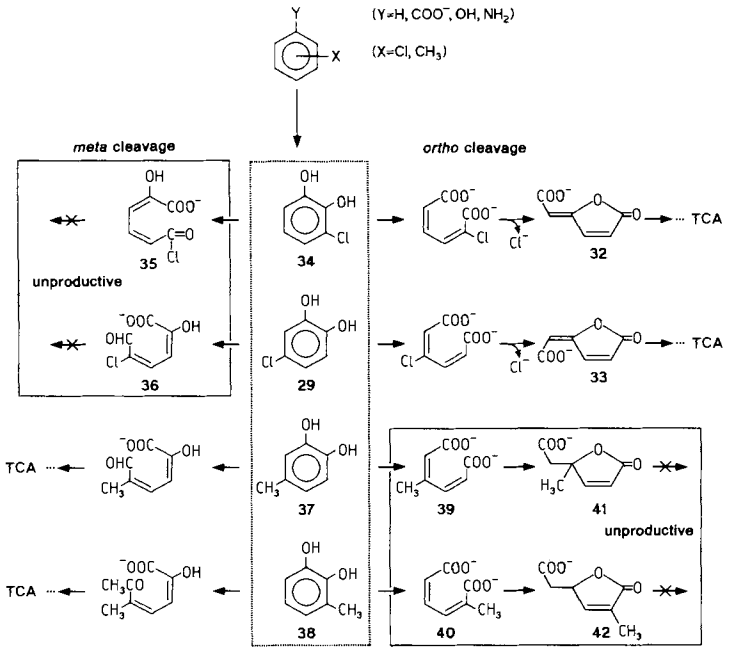


Scheme 8. Reaction sequences for the degradation of chloro- and dichloroarenes such as 3-chlorobenzoate (**30**) and 2,4-dichlorophenoxyacetate (**31**) exist in bacteria (e.g. *Pseudomonas* sp. B13 and *Alicaligenes eutrophus* JMP134). These are analogous to the known *ortho* pathway (catechol branch of the 3-oxoadipate pathway[8]). During growth on chloroarenes, specific enzymes are induced for the chlorocatechols showing high activity with the metabolites concerned. (Enzymes of the "modified *ortho* pathway" are indicated by heavy arrows).

Normally the classical[8] and the modified *ortho* pathway coexist. The genes coding for the former are usually on the chromosome, whereas the genes of the latter are plasmid encoded (shown in frames in Schemes 6, 7, and 8), and the corresponding enzymes are only induced in the presence of chlorinated compounds. In the case of substrate mixtures of arenes and chloroarenes the pathways coexist without affecting each other.

A completely different situation (and for the bacteria a fatal one) arises when chloro- and methylarenes are present at the same time.[36] The latter induce the enzymes of the *meta* pathway.[8] Because of the steric analogy, *meta*-pyrocatechase cleaves not only methyl- but chloro-substituted catechols as well (Scheme 9). Thus compound **34** is converted into acylchoride **35**, which irreversibly inactivates the ring-cleaving enzyme by acylation. The *meta* cleavage of **29** leads to the formation of stable chlorine-containing "dead-end" metabolites, primarily 5-chloro-5-formyl-2-hydroxypenta-2,4-dienoate (**36**).

It is evident that the *meta* pathway is not only unproductive for the degradation of chloroarenes but that it also loses its effectiveness for the productive degradation of methylarenes in the presence of high concentrations of chloro-



Scheme 9. Because of the relaxed specificity of the chlorocatechol-degrading enzymes (modified *ortho* pathway in Scheme 8) and the catechol-2,3-dioxygenase of the *meta* pathway[8], methyl- and chloroarenes can be misrouted into the *ortho* and *meta* pathway, respectively. This can lead to substrate incompatibilities when, for example, mixtures of chloro- and methylarenes are present and both pathways are induced at the same time.

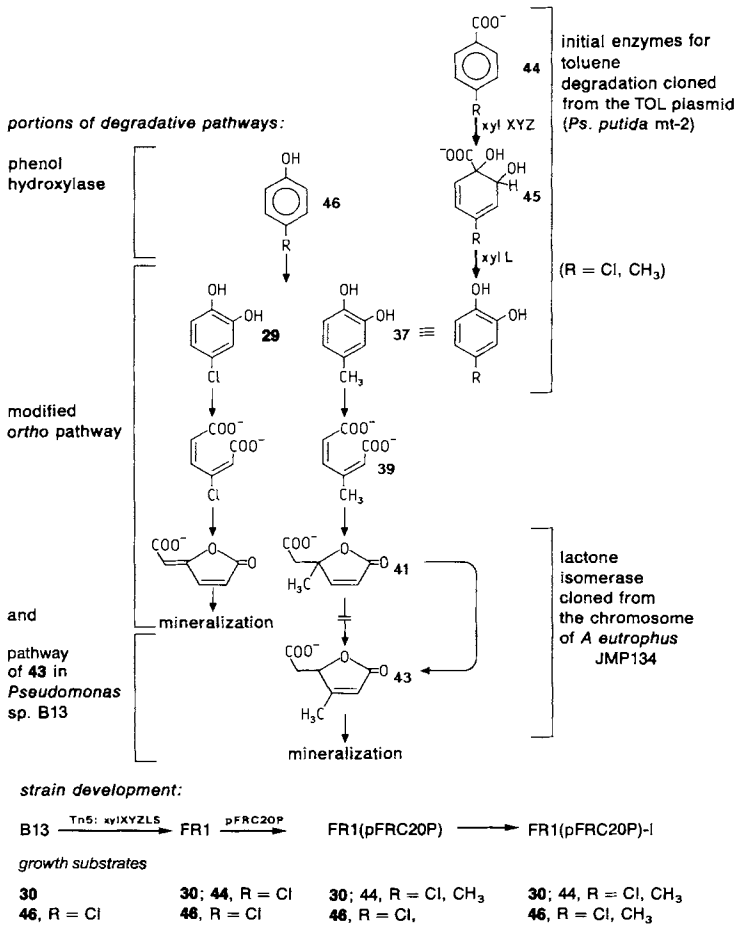
arenes due to inactivation of catechol-2,3-dioxygenase. In addition, the incompatibility of methyl- and chloroarenes is amplified, since methylcatechols **37** and **38** can easily be misrouted to the modified *ortho* pathway for the degradation of chlorocatechol. This degradation also leads to a dead end, because the corresponding methylmuconic acids **39** and **40** cannot form dienelactones. Methyllactones **41** and **42** are thus dead-end metabolites that each accumulate as only one enantiomer by means of enzymatic cycloisomerization.

The previously mentioned evolution of new degradative pathways for chloroarenes using enzymes from the degradation of methylarenes requires the inactivation of the *meta* pathway essential for the degradation of methylarenes.[8] Thus bacterial strains that have acquired the ability to degrade chloroarenes have simultaneously lost the ability to utilize methylarenes. Typically, unstable hybrid strains are formed at first, which in the presence of chloroarenes switch off the *meta* pathway by the suicide inactivation of C23O. When the culture is incubated in the presence of chloroarenes over longer periods, rapid-growing spontaneous mutations take over. In these mutants the structural gene for C23O has been inactivated by insertion, and thus the expensive regulation by suicide inactivation of C23O is circumvented.[37]

9. The Last Resort: Degradative Strains Manipulated In Vitro

Although there are microorganisms that can degrade chloroarenes or can rapidly evolve this ability by recruiting enzymes from the methylarene degradation pathway, it is clear that the simultaneous occurrence of methyl- and chloroarenes is fatal. One approach to making the complete and productive degradation of this incompatible substrate mixture possible would be a multifunctional *ortho* pathway. Not only would arenes and chloroarenes be assimilated by such a pathway, but methylarenes would also be accessible as growth substrate by *ortho* cleavage.[36]

Pseudomonas sp. B13 is almost ideal for the development of such a multifunctional *ortho* pathway (Scheme 10), because this organism degrades catechol (**6**) and the chlorocatechols **34** and **29** by *ortho* cleavage and does not have the *meta*-cleaving activity that interfers with chloroarene degradation. For the assimilation of **37** one enzyme is missing which would transform **41** into the isomeric 3-methyllactone **43**. This lactone is then, like the muconolactone of the known *ortho* pathway (Scheme 7), isomerizable to the enol-lactone and fully degradable in an analogous reaction sequence.



Scheme 10. The construction of a hybrid degradative pathway in vitro for the simultaneous degradation of chloro- and methylarenes. The strain *Pseudomonas* sp. B13 acquires the ability to degrade 4-chlorobenzoate (**44**, R = Cl) by the insertion of the genes for the initial enzymes of toluene degradation (TOL plasmid). The gene for lactone isomerase recruited in addition from the chromosome of *Alicaligenes eutrophus* makes the degradation of 4-methylbenzoate (**44**, R = CH_3) possible. The constructed strain FR1(pFRC20P) can simultaneously utilize 4-chlorobenzoate and 4-methylbenzoate, and after a spontaneous mutation (strain FR1(pFRC20P)-1)) 4-chlorophenol (**46**, R = Cl) and 4-methylphenol (**46**, R = CH_3) as well.

The gene for the required lactone isomerase is found on the chromosome of *Alcaligenes eutrophus* JMP134. After being cloned on the cosmid vector pFRC20P, the property was transferred by conjugation to the B13 strain. In order to

enable the new ability (assimilation of **37** by *ortho* cleavage) to be applied to a selective growth substrate, the genes for the enzymes of the initial degradation of toluene were transposed into the chromosome of the B13 strain by means of a hybrid transposon (Tn5: xylXYZLS). The gene products toluate-1,2-dioxygenase (xylXYZ), cyclohexadienediol-1-carboxylate dehydrogenase (xylL), and the regulatory gene (xylS) provide the B13 strain with initial enzymes of low substrate specificity and at the same the ability to utilize 4-chlorobenzoate (**44**, R = Cl). Through the conjugative recruitment of the isomerase the ability to degrade 4-methylbenzoate (**44**, R = CH_3) was also acquired. The derivative strain thus constructed FR1(pFRC20P) simultaneously degrades 4-chloro- and 4-methylbenzoate (**44**, R = Cl and CH_3, respectively) without any of the substrate mixture being misrouted or released as dead-end metabolites into the culture medium.

Mixtures of chlorophenols and cresols are more relevant than chloro- and methylbenzoates to actual environmental problems. Since strain B13 can completely degrade 4-chlorophenol (**46**, R = Cl), it should be able to acquire the ability to degrade cresol. This requires a spontaneous mutation (rate of mutation 10^{-7}–10^{-8}) that enables the bacterium (strain FR1(pFRC20P)-1) to recognize cresol (**46**, R = CH_3) as an inducer for chlorophenol hydroxylase.

The example of the simultaneous degradation of chloro- and methylarenes shows that the evolution of complex degradative pathways requires multiple genetic changes (see ref.[38]). Since these must occur successively and selection favors only the last evolutionary step, this process can occur only very slowly in nature. Clearly the recombination of activities already present in nature for partial degradation to provide new, active degradative sequences for xenobiotics requires a carefully drawn blueprint. Each evolutionary step must be linked to a corresponding selection principle. If this is the case, then genetic manipulation allows crucial reaction steps to be overcome. The evolution and degradative potential of natural bacterial populations against structurally related xenobiotics can be decisively increased by mobilizing specific genes and blocks of genes encoding nonspecific multifunctional degradative sequences.

A major advantage of experimental evolution of degradative pathways is that planned and targeted evolution may be possible. This, however, requires detailed knowledge of the biochemistry and regulation of xenobiotic degradation as well as the analysis of the genes involved.

Unfortunately, this basic knowledge is not available for the majority of xenobiotics relevant in practice. Thus the current application of biodegradation to problems in the real world is characterized by a pragmatic, scientifically not very demanding approach. To increase the degradative performance of natural microbial populations against xenobiotics, methods that satisfy the nutrient and energy requirements of the organisms involved, or the use of auxiliary substrates that increase the number of cometabolically active organisms and therefore favor natural gene transfer are still the methods of choice given the current state of knowledge.

Triplet States in Organic Chemistry**

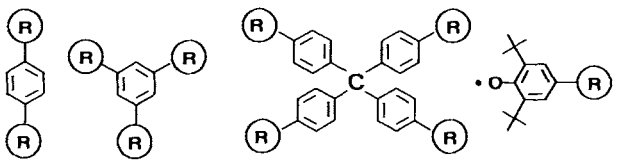
By *Harry Kurreck**

After the successful characterization of a hexacarbene in the tridecet ground state in 1992, the synthesis of a branched nonacarbene with an $S = 9$ ground state was recently published in this journal[1] and described as a new record on the way to supermagnetic polycarbenes. This nonacarbene is an unusual molecule with 18 unpaired electrons, if the spin pairing is considered as the basis of the chemical bonding. In carbene chemistry such systems, even though constructed from fewer carbene units, could be detected by EPR spectroscopy, that is those with four (quintet state), six (septet state), and ten (undecet state) unpaired electrons.[2]

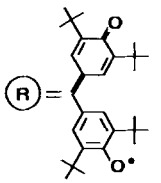
The quite optimistic announcement of J. U. Nef in 1895 can be considered as the beginning of the history of organic triplet molecules: "It will now be my next task to prepare methylene or its derivatives".[3] Later from the investigation of the electronic properties of carbenes it was postulated that singlet carbenes are added stereospecifically to the olefinic double bond, whereas triplet carbenes are added nonstereospecifically (Skell rule).[4] After the classical optical experiments on methylene by Herzberg in 1961,[5] R. A. Bernheim et al. and E. Wasserman et al., 75 years after Nef, were able to identify the parent carbene methylene by its triplet state clearly as the expected paramagnetic species by EPR spectroscopy.[6]

Triplet molecules have become increasingly more important in many areas of organic, bioorganic, and biophysical chemistry. They can be classified according to their ground and excited states into "real" triplet molecules, characterized by a strong coupling of the unpaired electrons, and diradicals, which show a weak coupling of the unpaired electrons. The latter, in particular, can be further divided into triplet molecules with completely delocalized triplet electrons which belong to a common π-electron system, and into diradicals in which the π-electron systems of the radical fragments are localized to a great extent; in the limiting case the so-called point/dipole approximation is valid. These types of triplet states show markedly different chemical and physical (magnetic) properties.

The galvinoxyls (Coppinger radicals), named after Galvin Coppinger, derivable from phenoxyl are appropriate for the description of the diradicals.[7] According to EPR investigations, if two such components are linked, for example, by a *para*-phenylene bridge, the diradical **1** is formed with a triplet ground state, in which the unpaired electrons are weakly coupled and are located in almost completely separate π-electron systems. Thus, the point/dipole model can be used and an average distance between the unpaired electrons can be determined from the zero field splitting value which is consistent with the structure derived from molecular modeling calculations. If three galvinoxyl fragments are linked together through the 1,3,5 positions of a benzene ring, the triradical **2** in the quartet state can be identified with EPR and electron nuclear double resonance (ENDOR) spectroscopy. Finally, four *para*-positioned galvinoxyl units can be linked by a tetraphenylmethane bridge; the tetraradical **3** with tetrahedral symmetry in the quintet state is formed with properties basically the same as those of the diradical and the triradical. Other known bridged radicals are, for example, the triphenylmethyl radical derivatives (Tschitschibabin and Schlenk hydrocarbons), double cyclopentadienyl radicals (Ziegler radicals), or double nitroxide radicals.



1 **2** **3** **4**



If an additional phenoxyl component is introduced into the galvinoxyl fragment, the Yang diradical **4** is obtained, which provides an interesting transition into the family of the real triplet molecules with complete delocalization of the unpaired electrons in a common π-electron system; here their coupling, however, is still classified as *weak*. Indeed, EPR and ENDOR investigations reveal a diradical with threefold symmetry in the triplet state; thus, the two unpaired electrons are delocalized over three substituted phenyl wings arranged in the form of a propeller and therefore their complete equality is retained. In this context the recent studies from the laboratory of H. Bock on the successful crystallization and X-ray structure analysis of the Yang biradical are of particular interest,[8] because these also confirm the results of the spectroscopic investigations carried out in solution and thereby the axial symmetry of the molecule with phenoxyl rings that are likewise tilted away from the plane by about 30°. Quantum mechanical calculations show that the spin density of the unpaired electrons is localized to about 50% at the outermost centers of the molecule, whereas the charges at these positions are so small that they can be neglected.

A genuine ground state triplet molecule with a triplet state more stable than the singlet state structurally related to the Yang diradical by about 110 kJ mol^{-1} is the axial symmetric trimethylenemethane **5**, whose two degenerate HOMOs, ac-

cording to Hund's rule, are each occupied with one electron of the same spin.[9]

Non-Kekulé hydrocarbons, such as triangulene **6** (Clar hydrocarbon), for which no classical Kekulé structures can be formulated, are characterized by the fact that not all the spins of the electrons of the π-electron system are paired. The triangulene with two half-filled degenerate MOs should, therefore, have a triplet ground state and be paramagnetic; however, this has not been proved to date. Recently, however, a derivative, the trianion **7** of trioxytriangulene, was prepared and identified by EPR spectroscopy as a diradical triplet molecule of threefold symmetry.[10] The diradical is remarkably stable under the exclusion of oxygen, even at room temperature.

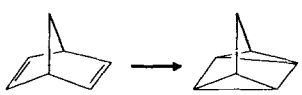
7

Triplet states have also played a role in the history of the concept of aromaticity [$(4n + 2)\pi$ electrons, Hückel's rule] with the proof of an antiaromatic molecule with $4n\pi$ electrons. Exactly 20 years ago, in a fundamental work on the chemistry and spectroscopy of the electron spin states of higher multiplicity, three research groups joined forces and proved the triplet ground state (predicted according to simple HMO concepts) for the unsubstituted cyclopentadienyl cation by EPR spectroscopy, and thus determined its "antiaromatic" character.[11] In this context the antiaromatic compound par excellence, cyclobutadiene, should not go unmentioned, for which a triplet ground state had been proposed for decades. In particular, the studies of G. Maier et al.[12] (photochemical generation and matrix isolation of cyclobutadiene at low temperatures) and of D. C. Cram et al.[13] (taming and thus stabilization of cyclobutadiene in a hemicarcerand even at room temperature) derived a singlet ground state[14] for the "Mona Lisa of organic chemistry".[13]

Hitherto only triplet ground states—resulting from the geometry of the molecule—have been considered. Triplet excited states are of significance in photochemistry both from a mechanistic and (due to their long lifetime in comparison to singlet excited states) a preparative point of view. As an example, the double photocyclization of norbornadiene (**8**) shall be discussed. Whereas on irradiation norbornadiene (**8**) reacts only slightly to give a little quadricyclane (**9**), this photoreaction proceeds in high yield by the addition of small quantities of benzophenone. Apparently, the substrate is converted into the triplet state by the sensitizer with great efficiency and with structural changes; an optimal geometry for the ring closure is employed.[15]



8 **9**

At present one cannot resist the temptation to include the fashionable molecules of the nineties, the fullerenes, in *Highlights*. The intensive investigations of these molecular footballs also include photochemically produced triplet states in solution, in liquid crystalline matrix, and in the solid state. The interpretation of the spectroscopic results, for example, the unequivocal identification of the triplet states and their differentiation from doublet states, is the subject of ongoing discussions. Apparently, however, due to Jahn–Teller distortion the triplet state is not of I_h symmetry, and the two Jahn–Teller states are rapidly interconverted.[16]

Triplet states are also of current significance in photobiology. Here, the light-induced charge separation taking place in the primary step in the reaction centers of the photosynthesis apparatus may be shown.[17] Today these electron transfer steps are considered to occur over singlet states, however, triplet states can occur if, for example, the electron flow in the transport chain is "blocked" by too intense light irradiation. Then under back-electron transfer the triplet state of the primary donors, and thus of chlorophyll or of bacteriochlorophyll, can be formed. This state can also be forced artificially by the prereduction of the quinone, which serves as the primary electron acceptor, because then the complete charge separation of the primary process is blocked. In the study of photosynthesis model compounds from porphyrin donors and quinone acceptors triplet states and triplet electron transfer processes could likewise be proven; the membrane orientation of native pigments can be modeled by the incorporation of the donor/acceptor systems in liquid crystals.[18]

Finally two more experiments taken from the world of curiosities deserve mention: 1. If dibenzyl ketone (advantageous in micellar systems) is irradiated, the corresponding radical pair with triplet character is formed by the homolytic bond cleavage of the bond between the carbonyl-C atom and the CH_2-C atom. If one ensures a long lifetime of these radical pairs in solvent cages—or in a micelle—the molecules with a carbonyl ^{13}C atom attain singlet character quicker by ^{13}C hyperfine interaction and can recombine. Thus, in the reformed starting material, a ^{13}C enrichment can be achieved with *sunlight and soap*.[19] 2. If a mixture of crystals of a donor (zinc tetraphenylporphyrin) and an acceptor (substituted quinones) is ground in a agate mortar, intense typical EPR powder spectra of a triplet ground state can be observed. The authors assume that this triplet ground state is generated by a mechanochemically induced electron transfer with the formation of the stable diradical zinc tetraphenylporphyrin radical cation/semiquinone-radical anion.[20]

Triplet states are not only of high diagnostic value for quantum mechanical or mechanistic studies, they are also of significance for applied fields of research. Excited states of the fullerenes in the solid state and crystalline triplet diradicals such as the described Yang diradical are of interest for material sciences, because of their possible ferromagnetism. In photosynthetic research, contributions to the understanding of the high efficiency of the photosynthesizing systems are to be expected, which, for example, could be of signifi-

cance in the development of regrowing raw materials or more generally for the use and in the storage of solar energy.

Fast Solid-State Chemistry: Reactions under the Influence of Microwaves

By *Rüdiger Kniep**

Method: Take copper (powder), indium (powder), and sulfur (powder)—all powders with particle size between 100 and 300 mesh—in a molar ratio of 1:1:2, prepare a homogeneous mixture, load this into a quartz glass ampule, seal this under vacuum (ca. 10^{-3} Torr), place the ampule in an everyday microwave oven and "irradiate" this with 400 W at 2450 MHz. Already after 5–10 seconds, blue flashes caused by the formation of a sulfur plasma are observed in the ampule. After the light has faded, that is after about another 40–50 seconds, the ampule is removed from the microwave oven and shaken to homogenize the contents of the ampule. This procedure is performed a total of three times. Thus, the experiment lasts a little longer than 180 seconds. *Results*: Crystalline $CuInS_2$ (chalcopyrite structure); side product: small quantities of amorphous phases. *Identification/Characterization*: X-ray powder methods, scanning electron microscopy, energy dispersive X-ray analysis, and X-ray photoelectron spectroscopy. *Features*: 1. The fast reaction; 2. the fact that the ampule did not explode at temperatures, at least localized temperatures, of greater than 1000 °C (consider the vapor pressure of the (still) unreacted sulfur!). *Source of the "recipe"*: A publication by C. C. Landry and A. R. Barron[1] who extended the technique first developed by A. G. Whittacker and D. M. P. Mingos[2] for binary chacogenides to ternary semiconductor chalcogenide materials.

So what is so "exciting": "Microwaves" in the kitchen—that is already sufficiently well known. "Microwaves" in "solvent and molecular chemistry"—that is also known (here of course also the polar components are coupling).[3] "Microwaves" for the production of diamonds (e.g. microwave plasma chemical vapor deposition)[4]—that should have already been spread around. With "microwaves" even some oxides can be heated up to a good 1000 °C.[5, 6] In contrast, bulk metals or metal layers are inclined to undergo plasma discharges with microwave irradiation and are therefore, according to popular opinion, rather unsuitable to be heated by this method.

The new realization[1, 2] consists of the fact that metal *powders* can be very efficiently coupled to microwave fields (2450 MHz), so that temperatures of 1000 °C and greater can be reached within a few seconds without the occurrence of noticeable electrical discharges. Thus, the whole process resembles the "coupling" of zirconium metal (imbedded in ZrO_2 powder) to a high-frequency induction heater, a technique ("skull melting") which is used for growing large ZrO_2 single crystals.[7]

In particular, the reaction for the formation of $CuInS_2$ from the elements under the influence of microwaves apparently proceeds as follows: the dielectrical loss of the Cu powder is—in contrast to that of indium—large enough to initiate the reaction. The exothermic formation of copper

sulfide and/or the high temperature of the copper metal cause the indium to melt (m.p. 157 °C), so that a homogeneous ternary melt is subsequently produced, from which the ternary phase crystallizes by homogeneous nucleation during the rapid quenching. Particularly interesting in this respect is the formation of spherical particles.

Besides $CuInS_2$, the crystalline phases $CuInSe_2$ and CuInSSe, which also have the chalcopyrite structure, could be synthesized through this route.[1] The products are, however, not of "semiconductor quality", which is particularly unfortunate because these materials are of interest as solar cell materials.[8] However, the method itself is so fascinatingly simple that a greater dissemination of this solid-state synthesis by microwave irradiation is not only to be wished for but rather to be expected.

The Mechanism of Fullerene Formation

By *Helmut Schwarz*

Of course there must be hundreds of mechanisms whereby a fullerene like C_{60} can form.[1]
It should be stated at the outset that almost everything in this section falls into the category of (we hope not wild) speculation. Next to nothing is known about how fullerenes actually grow and form.[2]
The data presented here unlocks the mystery of how fullerenes appear.[3]

1. The Problem

More diverse statements than the above on how fullerenes arise are hardly conceivable; though we are amazed at such contradictory quotations from renowned fullerene research scientists, we are even more astounded at the conditions under which fullerenes are formed: At plasma temperatures of over 3000 °C at which the $T\Delta S$ term should favor the existence of structurally little-organized, *highly entropic* molecules, *highly symmetric* molecules are created in carbon vapor![4] The fact that, although fullerenes are substantially destabilized relative to graphite[5] and C_{60} is distinctly less stable than C_{70} and higher fullerenes,[2, 6] C_{60} is often the major product of the graphite vaporization also precludes a thermodynamically controlled pathway. In the face of these anomalies it is not surprising that scientists wish to understand the mechanism of the formation of fullerenes, whether or not they consider the on-going fullerene activity as exaggerated or even as an expression of the lack of really important challenges.

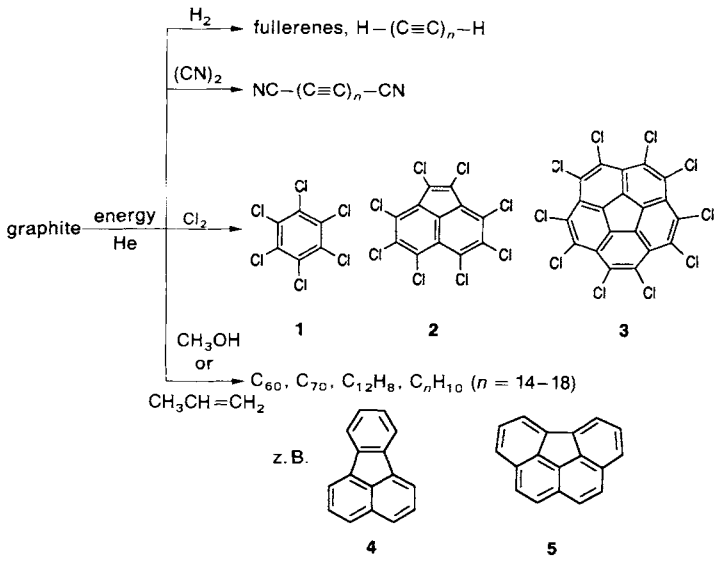
2. The Facts

- Experiments using mixtures of $^{12}C/^{13}C$-labeled graphite demonstrate that the rate of carbon isotope incorporation conforms exactly to a Poisson distribution.[7] This implies that in any phase of the growth process, carbon *atoms* must be involved in the construction of fullerenes.
- If fullerenes are generated in the presence of electrostatic fields, the *neutral* carbon cluster is isolated almost exclusively from the cathode and not from the anode.[8] Apparently *cationic* intermediates play a role in the growth process.
- The coalescence of *cationic* (and not anionic) carbon rings furnish fullerenes in ion/molecule reactions that necessarily implicate a *size-selective* growth process:[9] While a reaction of C_{30}^+ with C_{30} produces predominantly C_{60}^+, the reaction of C_{18} and C_{24} with C_{18}^+ and C_{24}^+, respectively, yields mainly—via C_{72}^+—the C_{70} fullerene. Larger fullerenes can also be explained as multiples of smaller building blocks of defined size.[10] Consequently, the sequential addition of much smaller carbon fragments C_x ($x = 2, 3$) to larger fragments in the growth process does not necessarily have particular significance.
- Optimal fullerene yields during "graphite vaporization" are obtained only under a relatively narrow set of conditions, since both the temperature of the plasma and the pressure of the buffer gas are critical. Furthermore, if reactive components are mixed with the buffer gas helium, not only is the generation of fullerenes suppressed, but compounds that might be interpreted by some authors as indications for possible intermediates in the fullerene generation are also trapped. However, one has to recognize that the growth of valence-unsaturated carbon clusters can proceed differently from that of the partially derivatized clusters. A few examples suffice as illustration: Addition of H_2 to He generates polyacetylenes.[11] If the Krätschmer–Huffman conditions are modified[4] by addition of dicyanogen $(CN)_2$ instead of fullerenes, rodlike "dicyanopolyynes" $NC-(C{\equiv}C)_x-CN$ ($x = 3-7$) are formed.[12] Apparently in an early stage of

both cases, the radicals H$^{\bullet}$ or CN$^{\bullet}$ add irreversibly to the ends of *chains* of C_n species. If graphite vaporization is performed in the presence of Cl_2, beside small amounts of fullerenes (< 5%), the perchlorinated *cyclic* compounds **1**–**3** are isolated in good yields.[12] Rodlike chloroacetylene $Cl-(C\equiv C)_x-Cl$ cannot be detected. Each carbon framework of the arenes **1**–**3** represent a section of the C_{60} structure, and the occurrence of the five-membered ring in decachloroannulene (**3**), which is essential to the C_{60} structure, is particularly noteworthy. Apart from C_{60} and C_{70}, polycyclic arenes of the composition $C_{12}H_8$, C_nH_{10} ($n = 14-18$) and C_nH_{22} ($n = 20-24$) are isolated when the graphite vaporization is performed in an atmosphere of He/propene or He/methanol.[13a] Particularly interesting is the appearance of **4** and **5**, which likewise contain the structural motive of fullerenes.[13] Do the five-membered rings in the structures



2–**5** offer support, or perhaps even confirmation, for Smalley's famous "pentagon road model", that has become widely known and that is the concept seen at present to be most consistent with the majority of the experimental data?

3. Models, Clues, and Evidence

Three criteria determine the pentagon road model: It is assumed that above a certain number of C atoms ($n \geq 30$) the energetically most favorable form of an arbitrary "graphitic sheet" is characterized by 1) only five- and six-membered rings as structural elements, 2) as many five-membered rings as possible, and 3) an avoidance of unstable pentalene units, that is, adjacent five-membered rings ("isolated pentagon rule"[16]). These surfaces have an advantage over *chainlike* C_n clusters[17] in that the average coordination numbers of the carbon atoms are higher. Furthermore, above a certain size the number of free valences on the periphery (the "dangling bonds") can be drastically reduced by the formation of closed spherical surfaces ("fullerenes"), or even completely disappear, as for the first time with C_{60}.[14b] This simple model can explain several experimental findings well: 1) The high temperature is not required only to vaporize the graphite, but is needed specifically to activate the carbon cluster thermally ("annealing") so strongly that the isomers find a pathway via the intermediate stage of graphitic sheets to optimal closed spheres that obey the Euler rule.[18] 2) The pressure of helium is likewise essential for this process, because the concentration of helium controls the diffusion of the C_n species from the hot plasma to the colder periphery. If too much buffer gas is present, the concentration of reactive C_n – and therefore the products resulting therefrom – increase so rapidly that the conditions for the annealing process are no longer optimal, and the isomerization of graphitic sheets by the pentagon road model increasingly loses its significance. How likely is the assumption of such a "self-organization" of graphite fragments?[1] It is not unfounded, since even corannulene is a higly flexible molecule already at room temperature, and thus at the higher temperatures the efficiency of annealing of larger carbon clusters will be large. But what is the experimental evidence for the intermediacy in the growth process of graphite-like molecular species with curved surfaces, which crumple to fullerenes after annealing?

The crucial experiments on this question have been performed in the past two years in the research group of M. T. Bowers.[3, 20a–c] Application of the well-established method of ion mobility (IM) in the gas phase, which in Santa Barbara[21] was developed to an "ion chromatography" led the group to fundamental insights. Despite some unexplained details, a mechanism of fullerene generation has emerged from the correlation of IM measurements with the results of ab initio and Monte Carlo calculations on the mobility of *structural types* of carbon clusters in a helium atmosphere. Initially it could be shown the C_n^+ clusters generated by laser vaporization can be attributed to different structural types depending on the cluster size n: C_5^+ and C_6^+ are linear, C_7^+ – C_{10}^+ are present both as linear species and as monocyclic cations, and C_{11}^+–C_{20}^+ exist only as monocycles. The range C_{21}^+–C_{28}^+ is characterized by planar mono- and bicyclic systems, and the first three-dimensional structure appears for C_{29}^+. Fullerenes arise for the first time at C_{30}^+ and dominate from C_{50}^+ (see Fig. 1).

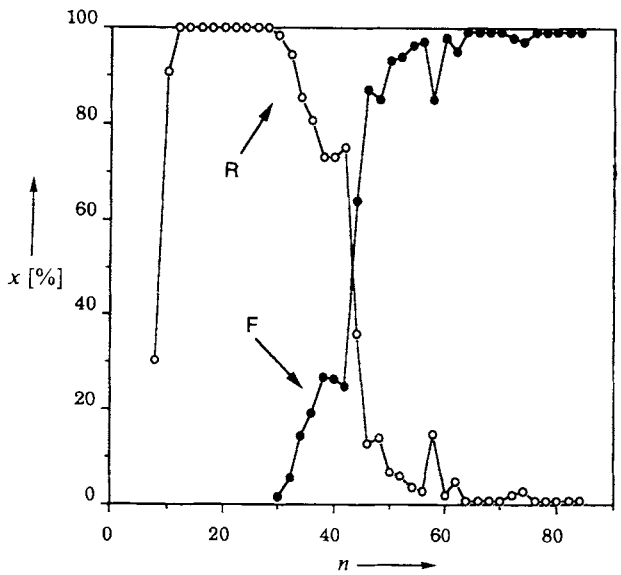


Fig. 1. The dependence of the proportion x of cationic fullerenes (F) and ring structures (R) in C_n^+ on n (according to ref. [3]).

Although for a cluster size of $n \geq 30$ several structural types coexist (see, for example, Fig. 2 for C_{30}^+ or Fig. 3a for C_{37}^+), the signals can be correlated with neither a graphitic sheet structure nor a bowl-shaped intermediate, both of which are essential for the pentagon road model. These structures cannot be detected in a cationic plasma.

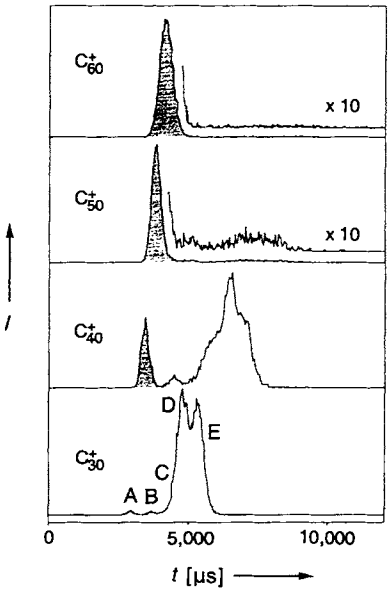

Fig. 2. Ion chromatograms for C_{30}^+, C_{40}^+, C_{50}^+, and C_{60}^+. (I is the intensity in arbitrary units.) The five isomeric families (A–E) are assigned to the following classes: A, Fullerenes (hatched region); B, three-dimensional rings; C, planar tricycles; D, planar bicycles; E, monocycles (according to ref. [20b]).

What happens when these ion mixtures are annealed by collision? The answer is contained in Figure 3 for the C_{37}^+ system. At relatively low collision energies (Fig. 3a), decomposition or isomerization is not yet observable. If the collision energy is increased (Fig. 3b), the isomer distribution for those C_{37}^+ ions that do not decompose is quite different: tri- and bicyclic species (signals C and D) disappear on annealing in favor of the monocycle (signal E). The spectra for the *decomposition products* of excited C_{37}^+ are also exceptionally instructive, because C_{36}^+ and C_{34}^+ (loss of C_1 or C_3) are undoubtedly present as fullerenes, while C_{23}^+ ("vaporization" of C_{14}^+ from C_{37}^+) again corresponds to a monocycle.

Very similar results are found for many other C_n^+ clusters with $n \geq 33$ too,[3, 20] and all experiments suggest the following scenario: deposition of energy initially causes predominantly the generation of monocyclic systems from the polycyclic C_n^+ clusters; fullerene formation does not yet occur, and no evidence for the intermediacy of graphite-like structures as discussed in the pentagon road model is found. Further excitation induces an isomerization to fullerenes. In this process the internal energy of the system increases enormously; for example, in the isomerization of a bicyclic-planar C_{36} to a C_{36}-fullerene, approximately 9 eV is released.[22] Adding the energy transferred by the collisions (5–20 eV) readily yields vibrational temperatures of about 4000 K, and the highly excited C_n^+ fullerene generated thus cools by evaporation of C_1 or C_3 (for uneven n) or C_2 (for even n). The behavior of C_{40}^+ may serve as illustration.

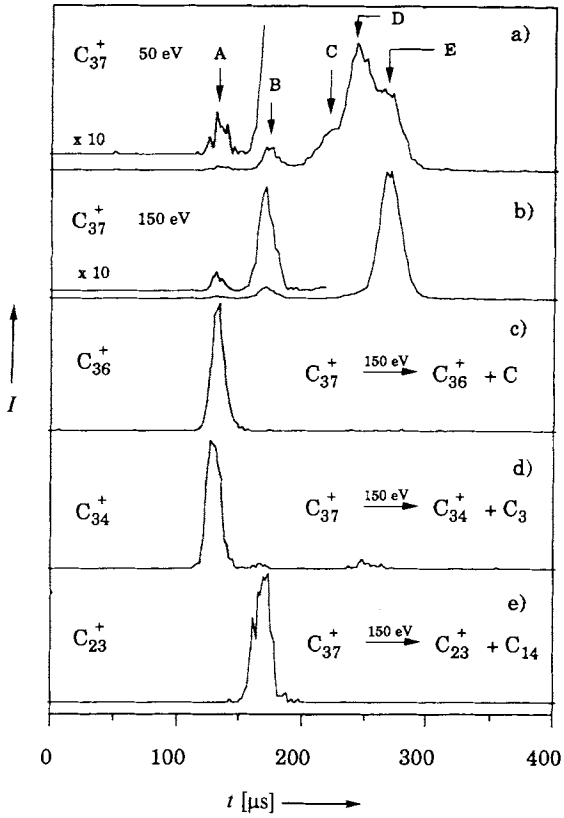

Fig. 3. Ion chromatogram for C_{37}^+ and its major decomposition products C_{36}^+, C_{34}^+, and C_{23}^+. Notation A–E as for Fig. 2. For details see text (according to ref. [20c]).

Provided that it will be possible to explain *how* the monocycles convert into fullerenes, an exciting chapter can be added to the dossier on the mechanism of fullerene formation. As spin-off of these mechanistic studies the idea arises

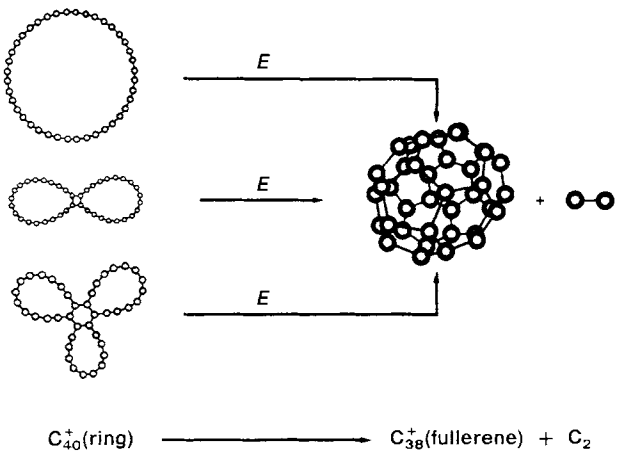

Fig. 4. Excitation of monocyclic C_{40}^+ by collision-induced heating, and generation of C_{38}^+ fullerenes.

that cyclic polyynes might be used for the tailor-made production of size-selected fullerenes:[9a, 23, 24] photochemical excitation of polymers in an inert medium may give rise to the formation of fullerenes.

The Solution of the Sherman Paradox or the Successful Search for the Huntington Gene

By *Ernst-L. Winnacker**

It was Linus Pauling, the chemist, who formulated the concept of "molecular diseases" currently playing such an important role in our understanding of a variety of genetic disorders. In the late 1940s, long before the first protein sequence was established, he showed that hemoglobins from healthy people differed from those of patients with sickle cell anemia in their electrophoretic mobilities.[1] It took seven years until Vernon Ingram managed to ascribe these differences to the exchange of a single amino acid in the β-chain of hemoglobin from glutamic acid to valine.[2]

Since that time, advances in molecular biology have permitted determination of the causes of many more molecular diseases. The mutations responsible for genetic defects can be single amino acid substitutions, that is point mutations, or deletions and insertions of longer stretches of DNA. Any given gene can be subject to different types of mutations and these may lead to varying degrees of disease symptoms. A common feature however of (almost) all known hereditary diseases is their stable inheritance once a mutation has established itself. Thus, within an afflicted family the courses of a disease will not differ significantly among parents and their children. As is so often the case, exceptions should prove the rule. Well, maybe not in this case!

Human geneticists have been aware for some time of a number of genetic diseases which do not fit in with what was mentioned above. There appear to be cases in which the severity of the disease changes from generation to generation, in most cases becoming more severe. It is almost as if an initial mutation served as a basis for more and more new genetic alterations. As no explanation for this phenomenon was available, this particular situation in which the health risk of a person depends on his or her position in a pedigree was referred to as Sherman's paradox.[3]

What exactly lies behind this paradox? Could it be a reflection of local instabilities of the genetic material? Indeed, this is the case. The nature of this new type of mutation is exemplified best by the prototype of such diseases, Huntington's chorea (often abbreviated as HD, for Huntington's Disease). Huntington's chorea, also called St. Vitus dance, was first described in 1892 by the American practioner and neurologist George Huntington who, in addition, had also already recognized the hereditary nature of the disease.[4]

This rare disease—with an incidence of 7–10 per 100000 persons—manifests itself between the ages of 35 and 50. Huntington's disease is characterized by disturbances of the neural and motor systems. The name "chorea" refers to the involuntary tremors and sudden body movements shown by afflicted individuals. Symptoms become more and more severe with time and are accompanied by a dramatic decline in mental abilities. Death inevitably follows after a few years.

It has been known for a long time that the symptoms can be ascribed to a loss of neurons in the brain; however, the biochemical causes of this phenomenon have so far remained a mystery. The classical methods of identifying genes by the isolation and characterization of a modified protein, which in cases such as sickle cell anemia can then be ascribed readily to a defective gene, could not and cannot be applied in this case. This left only the reverse procedure, fittingly known as "reverse genetics". This approach involves the direct search for the defective gene whose DNA sequence can then be used to derive the corresponding protein sequence, thus eventually allowing the biochemical properties of the protein to be investigated. Such an approach is by no means simple since the human genome contains at least 100000 genes; only one of these is the Huntington gene in question, but which one? There are two prerequisities in performing such a task. First extended families comprising as many people as possible from several generations are needed so that the hereditary course of the disease can be followed. Second characteristic markers or tags on the DNA are needed. The closer such markers are spaced along the chromosome the more accurate will be the localization of a "suspicious" DNA fragment to a specific section of the genetic material.

A large number of suitable markers are in fact available along human (and other) chromosomes in the form of DNA sequence variations known as DNA polymorphisms. These lie mostly outside of coding regions. If such markers happen to involve restriction enzyme recognition sites, this leads to DNA fragments of differing lengths that are characteristic for a particular genome and thus for an individual. These are referred to as "restriction fragment length polymorphisms" (RFLPs or RIFLIPs). Such alterations are passed on from parents to their children just like any other mutations and can be used to determine the degree of relatedness between individuals. To return to the search for the Huntington gene, if such a marker lies in close proximity to the Huntington gene it will be coinherited. Therefore it was necessary to search for a DNA fragment in Huntington pedigrees that was always present in members afflicted with the genetic disease but did not occur in disease-free individuals. To achieve this, the genome of persons from a Huntington family tree[5] is fragmented with a restriction enzyme that recognizes such polymorphic DNA cleavage sites. The resulting fragments are separated according to their sizes and hybridized with radioactively labeled human DNA fragments randomly selected from a gene library. Randomness is important because it is not known which DNA fragment will lie close to the Huntington gene. In principle it may be necessary to test thousands and thousands of DNA fragments before obtaining a fragment pattern characteristic for Huntington patients and which at the same time is not observed in healthy members of the same pedigree.

James Gusella and co-workers[6] at the Massachusetts General Hospital (MGH) in Boston were extremely lucky when they scored a hit in 1983 after having tested for eight fragments only. This particular fragment had been chosen at random, lottery-like, so to speak, from a collection of millions of cloned DNA fragments. It stemmed from chromosome 4 which established that the Huntington gene must be located on this chromosome.

Starting from this fragment, the site of the Huntington gene has been localized more and more precisely over the last ten years. By the end of 1992 it was certain that the gene was located on a 500000 base pair fragment at the end of the short arm of chromosome 4. However, even such a relatively small fragment is still large enough to accommodate 10–20 normal-sized genes. To identify their coding sequences within the plethora of noncoding sequences is no easy task. It should also be borne in mind that coding sequences are usually broken up into a large number of separate units called exons.

A variety of techniques are now available for the identification of exons. The following are of particular significance: a) the identification by sequence databank searches of evolutionarily related sequences that may have been identified previously in the genomes of other organisms; b) the detection of hypomethylated CpG islands known to be located often in promoter regions of genes; c) the identification of long open reading frames by DNA sequencing. A new technique called exon amplification was used in searching for the HD gene.[7] This involves the use of an expression vector for mammalian cells that contains a functional easily identifiable marker gene. To determine whether a piece of DNA contains an exon, it is cloned into the intron of the marker gene. If no exon is present, mRNA corresponding to the vector gene is formed after transfection of the vector into a mammalian cell; if, on the other hand, a functional exon has been inserted, the marker gene-specific mRNA formed will be extended by an amount corresponding to the length of the inserted exon. The polymerase chain reaction (PCR) is used subsequently to amplify and characterize the exon sequence.

When applied to the 500 kBp segment from the short arm of chromosome 4 this approach, among other things, identified a reading frame, designated IT15 (IT is the abbreviation for "interesting transcript"), coding for a previously unknown protein of 348 kDa.[8] This reading frame attracted the authors' attention because it had 21 copies of the triplet CAG near its 5' end which codes for the amino acid glutamine (Q) (Fig. 1). When this section of the gene was compared with the corresponding sections in other healthy persons, it was immediately apparent that there were length variations with respect to this one codon with the number of codon repetitions varying between 11 and 34. Apparently the gene was instable in this region.

Fig. 1. Part of the amino acid sequence of huntingtin and the corresponding DNA sequence. The presence of 23 glutamine residues in this sequence from a healthy individual is clearly visible. In healthy individuals the number of glutamine residues varies between 11 and 34, while it can increase to more than 80 residues in dieseased individuals.

Is it this section of the gene which perhaps is responsible for the Huntington's disease mutations? Actually it was found that patients with Huntington's disease had even longer repetitions. The largest number of repetitions found so far is 86. Furthermore, the number of repetitions appears to correlate with the age of onset of the disease; the larger the repetition number the younger the patient. Thus, not only was Sherman's paradox resolved but there was also little doubt that the gene found was the Huntington's disease gene. The corresponding protein has 3144 amino acids and was named huntingtin. It shows no homologies with other proteins, so that there is still no clue to its biochemical function.

Nevertheless, the finding is of importance in several respects. It demonstrates that reverse genetics allows individual genes to be located within large genomes without information being available about their functions. Furthermore, this work revealed the existence of a novel type of mutation not known previously, a kind of dynamic mutation characterized by increases in codon or trinucleotide repetitions. In the meantime it has been established that four other genetic diseases are based on the same kind of unstable codon repetition (see Fig. 2). Despite their differences in clinical symptoms these diseases have a number of similarities, including for example, their association with a progressive decline in motor functions and mental ability, symptoms becoming progressively more severe from generation to generation, and rising numbers of codon repetitions correlating with the onset of the age of onset of the diseases.

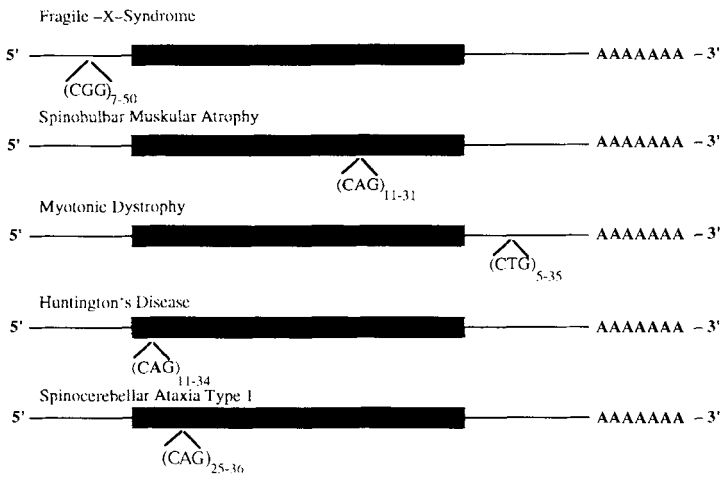

Fig. 2. Order of trinucleotide repeats in 5 different genes responsible for the occurrence of five genetic disorders which are characterized by codon instabilites (according to *Science* **1993**, *260*, 1422–1423). All five syndromes are rare hereditary diseases which are associated with neurodegenerative symptoms.

As always in cases like this progress poses more questions than it answers. For example, are there particular codons that are inherently prone to this kind of generation-dependent instability? In this context it is interesting to note that the three repetitive-prone codons observed so far, namely, CAG, CTG, and CGG (Fig. 2), have complementary bases (C and G) at positions 1 and 3. Thus, longer sections of these codons can fold back on themselves and form stable secondary structures, so-called stem–loop structures. The postulated A–A, T–T, and G–G (homo purine and homo pyrimidine) base pairs are by no means forbidden. On the contrary, they contribute significantly to the free energy of formation of such secondary structures.[9]

Why is it that trinucleotide repetitions show this instability and not di- or tetranucleotide repetitions which are also known to occur in the human genome? What effects do codon repetitions have on gene expression? Some of the codon repetitions occur outside of coding regions and therefore can "only" affect the mRNA and not the protein, as is the case in the Fragile-X-Syndrome.[10] It is easily imagined that and how such repetitions might influence the formation of mRNA secondary structures, half-life, modifications localization of the mRNA, and all the other factors which control mRNA translation. It is also possible that binding sites for mRNA binding proteins are formed in this way, which may control the efficiency of the translation process as in the case of the ferritin/transferrin receptor.[11]

The effects of codon repetitions occurring in coding regions are also easily imagined. A polyglutamine section at the N terminus of a protein must affect its folding, solubility, biological half-life, and its interactions with other proteins. However, all explanations must account for the observation that the Huntington mutation is dominant, and thus that the "defective" protein does not only cause the disease on its own but that even in the presence of the "normal" protein the mutant huntingtin must somehow have a negative effect on the normal protein as well.

These observations raise the question of the molecular causes of these instabilities. Apparently they originate in gametes which, in turn, are the product of a characteristic series of cell divisions and so-called reductive cell divisions (meiosis) of the corresponding precursor cells. During these stages of differentiation, DNA synthesis and repair processes may be accompanied by the exchange of genetic material, a process known as homologous recombination. It is conceivable that the enzymes involved in these processes may have specificities that differ from those participating in general synthetic processes. Chemistry and biochemistry are now challenged in a totally unexpected way in their endeavors to answer these and many other questions posed by these investigations.

Finally, it should be mentioned that the results discussed here also have ethical implications. Now that the gene for Huntington's disease has been identified, a diagnostic test for the disease is bound to follow. Codon repetition numbers could also be used as the basis for prognoses of life-expectancies of afflicted patients. Will it be ethically acceptable to inform an apparently healthy person that he or she will def-

initely die from Huntington's disease even if this may only happen in ten or more years's time? How can unauthorized use of such data be prevented? Such questions are not new to the field of human genetics; modern developments in molecular biology may, however, exacerbate the problem, particularly when therapeutical capabilities lag behind diagnostic means, as is so often the case. There is not sufficient space here to discuss this matter further. The identification of the gene responsible for Huntington's disease certainly is a triumph for modern genetics. The enthusiasm about this stunning achievement, however, should not prevent us from realizing that this kind of knowledge will not only benefit humanity but may also raise certain fears, worries, and social conflicts, and these will have to be properly resolved.[12]

Synthesis and Structure of Bis(tri-*tert*-butylphenyl)-iminohalogenphosphoranes X–P(=N*t*Bu$_3$C$_6$H$_2$)$_2$**

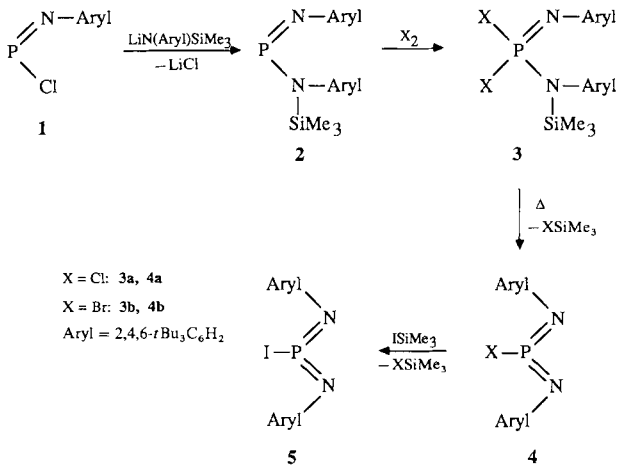
By *Alexander Ruban, Martin Nieger,* and *Edgar Niecke**

Dedicated to Professor Otto Scherer on the occasion of his 60th birthday

The discovery of a stable phosphorus(v) compound with a trigonal planar coordinated phosphorus atom[1] has led to a rapid development of the chemistry of this and structurally related phosphorus compounds.[2] The halogenphosphoranes, which could be obtained in a stable form[3] so far only from the bis(methylene)phosphorane system,[2c] are especially interesting as a result of their synthetic potential.

Attempts to obtain kinetically stabilized halogenbis(imino)phosphoranes XP[=N(alkyl)]=N(aryl) by N_2 elimination from halogen-4,5-dihydro-1*H*-tetraazaphospholes X–PN(aryl)N=NN(alkyl) have shown that the 2,4,6-tri-*tert*-butylphenyl group as aryl substituent combined with a sterically demanding alkyl substituent cannot stabilize the products sufficiently against subsequent reactions.[4] As we have now found, only the introduction of a second aryl substituent prevents a coordinative saturation of the reactive phosphorus center.

The reaction of (arylimino)chlorophosphanes[5] **1** with LiN(aryl)SiMe$_3$ gave the aryl(silyl)amino(arylimino)phosphane **2** (aryl = 2,4,6-*t*Bu$_3$C$_6$H$_2$), and subsequent addition of halogen (X = Cl, Br) led to the dihalogenphosphoranes **3a**,[6] **b**. From these the bis(arylimino)halogenphosphoranes **4a**, **b** were obtained thermally (110 °C) with the elimination of halogentrimethylsilane. Br/I exchange in **4b** with Me$_3$SiI affords the iodine derivative **5**. All the compounds can be isolated pure in the form as colorless to orange-red solids and can be characterized unambiguously on the basis of their analytical, NMR spectroscopic, and mass spectrometric data. Furthermore, the solid-state molecular structure of **5** was determined.[7]



As in all structurally investigated bis(ylene)phosphoranes,[2] the phosphorus atom is in a trigonal planar environment ($\Sigma \sphericalangle 359.9°$; Fig. 1). The carbon atoms of the *t*Bu$_3$C$_6$H$_2$ substituents linked to the imine nitrogen atoms also lie in this plane; the two phenyl rings are arranged orthogonal to the central NPN π-bond system. The *exo*/*exo* conformation of

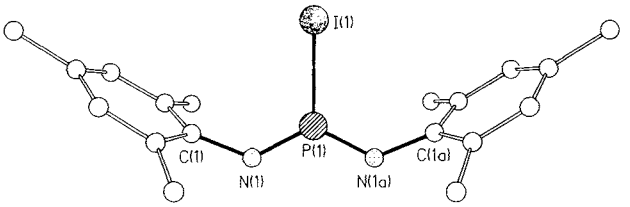


Fig. 1. Crystal structure of the bis(imino)phosphorane **5** (without peripheral methyl groups). Selected bond lengths [pm], bond angles [°], and torsion angles [°]: P(1)–I(1) 239.4(3), P(1)–N(1) 152.5(4), N(1)–C(1) 142.1(7); I(1)-P(1)-N(1) 119.0(2), N(1)-P(1)-N(1a) 121.9(2), P(1)-N(1)-C(1) 127.1(4); I(1)-P(1)-N(1)-C(1) –1.1(5), N(1a)-P(1)-N(1)-C(1) 178.9(5).

the CNPNC framework[8] in **5** is in accord with the results from an ab initio calculation of the parent chlorobis(imino)phosphane Cl–P(=NH)$_2$,[9] which also provides an explanation for the relatively small N-P-N angle (121.9(2)°). In the solid state, this conformation gives rise to a chain arrangement of the molecules (Fig. 2) due to weak I···N interactions[9] (343 pm). The P–I distance (239.4(3) pm) is significantly shorter than that in the comparable bismethylenephosphorane (253 pm in I–P[=C(SiMe$_3$)$_2$]$_2$[11]), which can be interpreted in terms of an enhancement of the positive partial charge at the phosphorus atom in **5** as compared to that in the bismethylenephosphorane system.[12] The P–N (152.5(4) pm) and N–C distances (142.1(7) pm) as well as the C-N-P (127.1(4)°) angle correspond to those of typical structural features of bis(imino)phosphoranes.[2b]

The equivalence of the resonance signals of the two *t*Bu$_3$C$_6$H$_2$ groups in the ^{1}H NMR spectra of the compounds **4** and **5** reveal their monomeric construction in solution. The sheilding of the phosphorus nucleus in the ^{31}P NMR spectrum (δ = –18.5 (**4a**), –30.2 (**4b**), –42.9 (**5**)) which is unusual for bis(imino)phosphoranes[13] is easily explained by the positive partial charge at phosphorus.[12] Further experiments will need to be carried out to determine the degree to

Experimental Procedure

2: A solution of **1** (20 mmol) in THF (50 mL) was treated with an equimolar quantity of $LiN(tBu_3C_6H_2)SiMe_3$, dissolved in THF (40 mL) at −30 °C and stirred. The mixture was then allowed to warm to 25 °C. The solvent was removed under vacuum and the residue was taken up in hexane (40 mL), and the LiCl present was removed by filtration. The filtrate was concentrated and the residue recrystallized from toluene. Yield: 82%, m.p. 168–170 °C. ^{31}P NMR (C_6H_6): $\delta = 318.1$; ^1H NMR (C_6H_6): $\delta = -0.44$ (s, 9H, $SiMe_3$), 1.27, 1.42 (s, 9H, *p*-*t*Bu), 1.59, 1.73 (s, 18H, o-tBu), 7.59, 7.64 (s, 2H, C_6H_2).

3a [**3b**]: A solution of **2** (20 mmol) in CH_2Cl_2 at −30 °C was treated with an equimolar quantity of $Cl_2[Br_2]$, dissolved in CH_2Cl_2 (30 mL). The mixture was allowed to warm to 25 °C, stirred, and the solvent was removed under vacuum. The residue was taken up in *n*-hexane (100 mL) and recrystallized at −80 °C. Yield: 58% [74%], m.p. 74 °C (decomp) [62 °C]. ^{31}P NMR (THF): $\delta = -75.2$ [−81.4]; ^1H NMR (C_6D_6): $\delta = 0.54$ [0.62] (s, 9H, $SiMe_3$), 1.27 [1.27], 1.34 [1.35] (s, 9H, *p*-*t*Bu), 1.43 [1.42], 1.66 [1.71] (s, 18H, *o*-*t*Bu), 7.43 [7.43] (d, $J(H,P) = 3.86$ Hz [4.58 Hz], C_6H_2), 7.57 [7.58] (d, $J(H,P) = 1.59$ Hz [0.9 Hz], C_6H_2).

4a [**4b**]: A solution of **2a** [**2b**] (10 mmol) in toluene (50 mL) was heated under reflux for 2 h. The volatiles were removed under vacuum at 25 °C, and the remaining solid residue was recrystallized from toluene. Yield: 66% [82%], m.p. 156–159 °C [194–196 °C]. ^1H NMR (C_6H_6): $\delta = 1.30$ [1.31] (s, 9H, *p*-*t*Bu), 1.66 [1.69], (s, 18H, *o*-*t*Bu), 7.55 [7.74] (d, $J(H,P) = 4.40$ Hz [4.36 Hz], C_6H_2); MS (70 eV): 584 (M^+, 9%) [628 (M^+, 56%)], 290 ($tBu_3C_6H_2NP^+$, 100%) [290 ($tBu_3C_6H_2NP^+$, 100%)].

5: A solution of **2a** or **2b** (10 mmol) in benzene (15 mL) was treated with a slight molar excess of $ISiMe_3$ and stirred for 1 h at 25 °C. The solvent and the halogensilane were removed under vacuum and the residue was recrystallized from a little THF. Yield: 92%, m.p. 161–164 °C. ^1H NMR (C_6D_6): $\delta = 1.32$ (s, 9H, *p*-*t*Bu), 1.78 (s, 18H, *o*-*t*Bu), 7.54 (d, $J(H,P) = 4.28$ Hz, C_6H_2); MS (70 eV): 675 (M^+, 51%), 290 ($tBu_3C_6H_2NP^+$, 100%).

The Coupled Activation of Molecular Oxygen and C–H and C–C Bonds in Gas-Phase Reactions of $[M(C_2H_4)]^+$ (M = Sc – Zn) with O_2**

By *Detlef Schröder* and *Helmut Schwarz**

Dedicated to Professor Rudolf Zahradnik

Iron compounds are essential for the transportation, activation, and storage of molecular oxygen in biological systems.[1] In addition, iron-centered proteins, like cytochromes and ferrodoxins, are of particular relevance in numerous redox-processes involving C–H and C–C bond activation.[2] With respect to biochemistry, only copper compounds mediate various oxidation processes as efficiently as iron-centered molecules do.[3]

It is a fundamental question whether the exceptional role of iron reflects an intrinsic property of this element, or whether the reactivity is due to a specific ligand environment of the reactive intermediates. Since in the gas phase intrinsic properties can be studied in the absence of additional effects caused by ligands, counterions, solvation, etc., we designed a simple gas-phase model, which, in principle, should allow

us to screen the capabilities of the first-row transition metal cations with respect to the coupled activation of molecular oxygen[4] and of C–H and C–C bonds of organic substrates. Here we report the gas-phase reactions of thermalized $[M(C_2H_4)]^+$ complexes (M = Sc–Zn) with molecular oxygen under single-collision conditions by using Fourier transform ion cyclotron resonance (FT-ICR) mass spectrometry.[5, 6]

The reactivity of the $[M(C_2H_4)]^+$ complexes towards molecular oxygen[14] can be classified as follows (Table 1): 1) The complexes of the late transition metal ions Co^+–Zn^+ do not undergo O_2 or C_2H_4 activation. The same behavior is also observed for the reaction of O_2 with $C_2H_4^{\bullet+}$, $C_2H_5^+$, $[Na(C_2H_4)]^+$, or $[Mg(C_2H_4)]^+$. 2) Ligand exchange of $[M(C_2H_4)]^+$ with molecular oxygen, leading to $[M(O_2)]^+$, is observed for the early transition metal ions ($M^+ = Sc^+$–Mn^+, indicating that for these metals the binding energies $[M(O_2)]^+$ exceed that of $[M(C_2H_4)]^+$. 3) Activation of the O–O bond and product formation at the rate of collision is observed for complexes of the metal ions Sc^+, Ti^+, V^+, and Fe^+. The manganese complex $[Mn(C_2H_4)]^+$ also reacts with O_2 to form $MnOH^+$; this slow process is not yet fully understood.[4] Since rapid activation of O_2 is observed for the complexes $[M(C_2H_4)]^+$ (M = Sc, Ti, V, Fe) only, we will confine the discussion to these systems.

Table 1. Reaction efficiency and yields of the reaction products of $[M(C_2H_4)]^+$ ions with O_2 (intensities are normalized to 100%).

M	k_R/k_{ADO} [a]	M^+	MO^+	MOH^+	MO_2^+	$OMOH^+$	$OM(C_2H_4)^+$
Sc	1.0		80	<1	15		5
Ti	1.0		55	<1	25	10	10
V [b]	1.0		40	<1	15	15	30
Cr	0.8				100		
Mn	0.01			10	90		
Fe[c]	1.0	20	10	40	<1		
Co	<0.002						
Ni	<0.002						
Cu	<0.002						
Zn	<0.002						

[a] Reaction efficiency: ratio of reaction rate constant k_R versus collision rate k_{ADO} ref. [9, 15]. [b] Propene complex of vanadium cation; see text. [c] 30% are other products; see text. Small amounts of M^+, formed after several seconds reaction times, are due to incomplete thermalization of $[Fe(C_2H_4)]^+$ or reactions with the background gases.

As far as the ethylene complexes of the early transtion metal cations Sc^+, Ti^+, and V^+ are concerned, their reactions can be ascribed to the high oxophilicities of these metal ions. This is in line with the formation of MO^+ from the corresponding "bare" metal ions and O_2.[16] Therefore, we assume that the ethylene ligand remains intact in the reaction of $[M(C_2H_4)]^+$ with O_2. This conjecture is supported by the results of consecutive ligand exchange reactions of the reaction product $[OM(C_2H_4)]^+$ with other ligands (Scheme 1). Thus, these reactions of the $[M(C_2H_4)]^+$ complexes of the early transtion metal ions Sc^+, Ti^+, and V^+ can simply be ascribed to the favorable thermochemistry of M^+-O bond formation, and the organic ligand is not involved in the activation of O_2.

$$[M(C_2H_4)]^+ \xrightarrow[-O]{+O_2} [OM(C_2H_4)]^+ \xrightarrow[-C_2H_4]{+L} [OM(L)]^+$$

Scheme 1. M = Sc, Ti, V; L = C_2D_4, H_2O, O_2.

The sole products, which unequivocally establish C–H bond activation of the olefin in the course of the reaction, are the oxohydroxide cations $OMOH^+$ (M = Ti, V). However, there is no evidence for C–C bond activation in these systems. The C–H bond activation may be rationalized by invoking first the formation of the metal dioxide cations OMO^+, followed by a hydrogen abstraction process (Scheme 2). The relatively large amount of $OVOH^+$ must certainly result from the fact that only the propene complex $[V(C_3H_6)]^+$ was accessible, for which allylic C–H bond activation is facile. In conclusion, the behavior of the olefin complexes of Sc^+, Ti^+, and V^+ towards O_2 is comparable with that of the bare metal ions. Indications of a *coupled activation* of O–O, C–H, and C–C bonds do not exist for these complexes.

$$[M(C_2H_4)]^+ + O_2 \longrightarrow [O{=}\overset{+}{M}{=}O\cdots C_2H_4] \longrightarrow OMOH^+ + C_2H_3^{\bullet}$$

Scheme 2. M = Ti, V.

If $[Fe(C_2H_4)]^+$ is reacted with oxygen extensive oxidation processes occur (Scheme 3). Not only the formation of Fe^+ confirms that in the encounter complex the C_2H_4 ligand and O_2 have reacted with each other, moreover, the generation of CH_3CO^+ as well as most of the other reaction products lend support to this interpretation. Furthermore, both C–H and C–C bond activation are observed, as evidenced by the detection of $FeOH^+$, CH_3CO^+, $Fe(O_2CH)^+$, $Fe(OCH_2)^+$, and $FeCH_2^+$ ions. Although the FT-ICR experimental setup does not allow the determination of neutral products formed in the course of the reaction, thermochemical considerations as well as the observation of $Fe(OCH_2)^+$ indicate that two formaldehyde molecules accompany the formation of bare Fe^+ in the reaction of $[Fe(C_2H_4)]^+$ with O_2. Evidently, the iron cation uniquely activates three important bonds (O–O, C–H, and C–C) at the same time.

$$[Fe(C_2H_4)]^+ + O_2 \longrightarrow \begin{cases} Fe(O_2CH)^+ + CH_3^{\bullet} & 4\% \\ Fe(OCH_2)^+ + CH_2O & 10\% \\ FeOH^+ + CH_3CO^{\bullet} & 40\% \\ FeO^+ + C_2H_4O & 10\% \\ FeCH_2^+ + CH_2O_2 & 6\% \\ Fe^+ + C_2H_4O_2 & 20\% \\ CH_3CO^+ + FeOH & 10\% \end{cases}$$

Scheme 3.

A straightforward rationalization of the extraordinary reactivity of $[Fe(C_2H_4)]^+$ towards O_2 can neither be derived from a consideration of the M–O bond strengths nor from the binding energies of the corresponding ethylene complexes alone. As indicated by the data in Table 2, Fe^+ does not

Table 2. Some relevant data for MO^+, $[M(C_2H_4)]^+$, and M^+. E_D = bond dissociation energy [a].

	Sc^+	Ti^+	V^+	Cr^+	Mn^+	Fe^+	Co^+	Ni^+	Cu^+
$E_D(M^+\text{-}O)$ [b]	159	161	131	85	57	81	64	45	82

electronic state $[M(C_2H_4)]^+$ [d]	$^1A_1^*$	$^2A_1^*$	$^5A_1^*$	$^6A_1^*$	$^7A_1$	$^4B_2$	$^3A_2$	$^2A_1$	$^1A_1$
4s occupancy [d]	0.24	0.33	0.12	0.16	1.13	0.27	0.24	0.24	0.24

[a] In kcal mol^{-1}. [b] Taken from ref. [16]. [c] Taken from ref. [17]. [d] Taken from ref. [18]. [e] A reviewer has pointed out that the E_D for Ti^+-C_2H_4 and V^+-C_2H_4 are much too high due to excited state reactions which were not taken into account when the data were analyzed. According to the reviewer, more accurate bond energies for Ti^+-C_2H_4 and V^+-C_2H_4 are 32 and 33 kcal mol^{-1}, respectively.

occupy a special position with regard to thermochemical properties, although one may speculate that in the reaction of $[Fe(C_2H_4)]^+$ with O_2 iron has just the right balance of bond energies to oxygen, hydrogen, and carbon to make a sequence of processes energetically feasible. Similarly, the 4 s occupancy is not unique for Fe^+. The only exceptional finding with respect to iron concerns the fact that the $[Fe(C_2H_4)]^+$ complex is not derived from the ground state of the corresponding bare metal ion. A phenomenological explanation for the unique behavior of the $[Fe(C_2H_4)]^+$ complex may be derived from the ease with which iron compounds are known to change their oxidation states. Similarly, one may argue that the position occupied by iron in the periodic table helps to avoid problems with the stability of filled and half-filled d shells; thus making a diverse range of intermediates accessible. Although, we do not yet have a solid theoretical model to explain the unusual reactivity of the iron complex in the activation of O_2, the present gas-phase behavior in a sense parallels the essential role of iron for oxygen activation in the condensed phase. Thus, the present findings may suggest that the unique role of iron in biochemical oxidation processes reflects an inherent property of this metal ion.

Finally, it should be mentioned that the reactivity of the iron complexes towards molecular oxygen is not limited to $[Fe(C_2H_4)]^+$. In fact, even the thermalized benzene/Fe^+ complex, generated by the ligand exchange $[Fe(C_2H_4)] + C_6H_6 \rightarrow [Fe(C_6H_6)]^+ + C_2H_4$, is oxidized efficiently by O_2 (Scheme 4).[19]

$$[Fe(C_6H_6)]^+ + O_2 \xrightarrow{k_R} \begin{cases} \xrightarrow{0.55} [Fe(C_5H_6O)]^+ + CO \\ \xrightarrow{0.45} [Fe(C_5H_4)]^+ + CO + H_2O \end{cases}$$

Scheme 4. $k_R = 6.9 \times 10^{-10}$ cm^3 molecule^{-1} s^{-1}
$k_{ADO} = 7.8 \times 10^{-10}$ cm^3 molecule^{-1} s^{-1}

We are currently exploring the iron-mediated oxidation of different organic substrates by molecular oxygen. In addition, further experimental and theoretical[20] work on the reaction of the olefin complexes is necessary to understand the reaction mechanism and the origin of the remarkable ability of iron to mediate activation of molecular oxygen for the oxidation of C–H and C–C bonds.

[6] The experiments were performed with a Spectrospin CMS 47X FT-ICR mass spectrometer described previously [7]. The metal ions were formed in the external ion source by laser desorption/ionization (LD/LI) of a pure metal target with a Nd:YAG laser (Spectron Systems, 1064 nm), transferred into the analyzer cell by a system of electric potentials and lenses, and trapped in a magnetic field of a superconducting magnet (Oxford Instruments, max. field strength 7.05 Tesla). The most abundant M^+ isotopes were isolated by using the FERETS technique [8] and thermalized by collisions with argon. Reactant gases were introduced through pulsed valves; argon and molecular oxygen were introduced through leak valves at typical pressures of $2-10 \times 10^{-8}$ mbar and $2-20 \times 10^{-9}$ mbar, respectively. For the determination of the absolute rate constants, k_R, the ionization gauge was calibrated on the basis of known reaction rate constants [9, 10]. The accuracy of the absolute rate constant measurements is $\pm 25\%$ for $k_R > 10^{-12}$ cm^3 molecule^{-1} s^{-1}. The $[M(C_2H_4)]^+$ complexes were generated from the bare metal ions by one of the following methods [5]: 1) Dehydrogenation of ethane (M = Sc, Ti), 2) demethanation of propane (M = Fe, Co), and 3) dehydrohalogenation of ethylhalides (M = Cr, Mn, Fe, Co, Ni, Cu, Zn). Unfortunately, none of these methods was suitable for the generation of sufficient amounts of $[V(C_2H_4)]^+$, which under the conditions reacted further, generating oligomers of the type $[V(C_2H_4)_x]^+$; thus, the corresponding propene complex $[V(C_3H_6)]^+$ had to be used for comparison [11]. Since some of the $[M(C_2H_4)]^+$ complexes undergo ligand exchange reactions with residual background water, present in the mass spectrometer [12], all reactions described were confirmed by use of either $[M(C_2D_4)]^+$ complexes or $^{18}O_2$. Relevant bond dissociation energies and thermochemical data were taken from ref. [13].

Chromatographic Separation of the Four Possible Structural Isomers of a Tetrasubstituted Phthalocyanine: Tetrakis(2-ethylhexyloxy)-phthalocyaninatonickel(II)

By *Michael Hanack,* Gabriele Schmid,* and *Michael Sommerauer*

Phthalocyanines, especially those in ligand-bridged, stacked arrangements $[PcM(L)]_n$ (Pc = phthalocyanine, M = Si, L = O; M = Fe, Ru, L = pyrazine, tetrazine) are of interest because of their electrical properties; they are also gaining interest in other areas such as nonlinear optics (NLO) and Langmuir–Blodgett technology.[1] A decisive disadvantage of phthalocyanines and metal phthalocyanines is their low solubility in organic solvents; however, the solubility can be increased by introducing alkyl and alkoxy substituents into

[*] Prof. Dr. M. Hanack, G. Schmid, M. Sommerauer

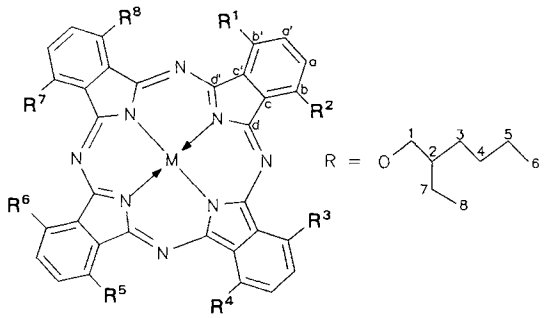
Telefax: Int. code + (7071)29-5244

the peripheral positions of the phthalocyanine framework. Because of their lower degree of order in the solid state, tetrasubstituted phthalocyanines are more soluble than the corresponding symmetrical octasubstituted compounds.[2]

In spite of many attempts, hitherto it has not been possible to separate and characterize all four possible structural isomers of a tetrasubstituted metal phthalocyanine.[3] Recently we separated two isomers of tetra(*tert*-butyl)phthalocyaninatonickel(II) [(*t*Bu)$_4$PcNi].[4] We report here for the first time the successful, complete separation of all four structural isomers of tetrakis(2-ethylhexyloxy)phthalocyaninatonickel [(EHO)$_4$PcNi] (Scheme 1) and their characterization by ^{1}H NMR spectroscopy.



Isomer	R^1	R^2	R^3	R^4	R^5	R^6	R^7	R^8
C_{4h}	H	R	H	R	H	R	H	R
C_{2v}	H	R	R	H	R	H	H	R
C_s	H	R	H	R	H	R	R	H
D_{2h}	H	R	R	H	H	R	R	H

Scheme 1. The four structural isomers of [(EHO)$_4$PcNi] with point groups. EHO = 2-ethylhexyloxy.

The separation of the isomers of [(EHO)$_4$PcNi] was achieved analytically by high-pressure liquid chromatography (HPLC); the isomers could be isolated on a preparative scale by medium-pressure liquid chromatography (MPLC). The ^{1}H NMR spectra of the MPLC fractions allow the D_{2h}, C_s, C_{2v}, and C_{4h} isomers to be characterized unambiguously (Scheme 1). Strictly speaking, the point groups are only valid for nonchiral substituents and a completely planar phthalocyanine framework, however, the above-mentioned designation of the isomers should be retained. Figure 1 shows the

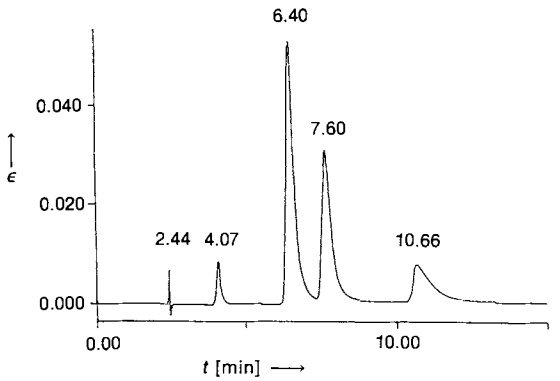


Fig. 1. HPLC chromatogram of [(EHO)$_4$PcNi]. Column: ET 250/8/4 nucleosil 5 NO_2; 5 μm; eluent: toluene/*n*-hexane (1:1); flow rate: 1 mL min^{-1}; pressure: 74.5 bar.

HPLC chromatogram of [(EHO)$_4$PcNi]. According to this, the mixture consists of 4.2% D_{2h}, 49.2% C_s, 31.3% C_{2v}, and 15.3% of the C_{4h} isomer (order of elution).

The low proportion of the D_{2h} isomer in comparison with the other three isomers is remarkable. One reason for this is the steric hindrance of the respective neighboring alkoxy groups (see Scheme 1). The individual isomers were assigned on the basis of the ^{1}H NMR signals of the H^1 alkoxy protons as well as on the basis of the aromatic protons H^a, H$^{a'}$, and H^b or H$^{b'}$ of the Pc ring system (see Scheme 1). Since nickel phthalocyanines tend to aggregate, the ^{1}H NMR spectra of [(EHO)$_4$PcNi] were recorded as very dilute solutions (0.7 mg mL^{-1}; 400 MHz). Two groups of signals are observed in the resonance region of the H^1 protons, one in the range $5.09 \leq \delta \leq 4.91$ and the other in the range $4.52 \leq \delta \leq 4.32$, that is some of the signals of the H^1 protons are shifted to low field. If the isomers D_{2h}, C_s, C_{2v}, and C_{4h} are considered as pairs of isoindolenine units, the alkoxy groups may or may not be neighbors. When alkoxy groups are neighbors,the electron density around the H^1 protons increases, explaining why the signals are shifted downfield. Accordingly, the isomer with only one group of signals, shifted downfield between $\delta = 4.99$ and 4.85 is assigned D_{2h} symmetry. The spectrum with only one group of signals between $\delta = 4.51$ and 4.41 belongs to the C_{4h} isomer. The spectra exhibiting both groups of signals, in a ratio of 1:1 are assigned to the C_s and C_{2v} isomers. The H^1 protons are magnetically nonequivalent and are located in the vicinity of the chiral centers of the ethylhexyloxy groups (C^2). Each of the four isomers exists as a mixture of diastereomers; thus, no clear multiplicity can be recognized (Table 1).

Table 1. ^{1}H NMR data of the four isomers of [(EHO)$_4$PcNi]; (400 MHz, [D$_6$]benzene $c = 0.7$ mg mL^{-1}) [a].

Isomer	D_{2h}	C_{2v}	C_s	C_{4h}
δ(H^b/H$^{b'}$)	9.46 (d, ^3J = 7.1 Hz, 4H)	9.62 (d, ^3J = 7.6 Hz, 2H) 9.24 (d, ^3J = 7.6 Hz, 2H)	9.67 (d, ^3J = 7.1 Hz, 1H) 9.45 (d, ^3J = 7.6 Hz, 2H) 9.29 (d, ^3J = 7.6 Hz, 1H)	9.49 (d, ^3J = 7.6 Hz, 4H)
δ(H^a)	7.96 (t, ^3J = 7.6 Hz, 4H)	8.17 (t, ^3J = 7.6 Hz, 2H) 7.91 (t, ^3J = 7.9 Hz, 2H)	8.16 (t, ^3J = 6.3 Hz, 1H) 8.12 (t, ^3J = 6.4 Hz, 1H) 7.98 (t, ^3J = 7.6 Hz, 1H) 7.89 (t, ^3J = 7.6 Hz, 1H)	8.13 (t, ^3J = 7.6 Hz, 4H)
δ(H^a)	7.65 (d, ^3J = 8.1 Hz; 4H)	7.75 (d, ^3J = 7.6 Hz, 2H)	7.72 (d, ^3J = 7.6 Hz, 1H) 7.68 (d, ^3J = 7.6 Hz, 1H) 7.44 (d ^3J = 7.6 Hz, 1H)	7.44 (d, ^3J = 7.6 Hz, 4H)
δ(H^1)	4.99–4.85 (m; 8H)	5.12–4.97 (m, 4H) 4.44–4.35 (m, 4H)	5.08–4.91 (m, 4H) 4.50–4.33 (m, 4H)	4.51–4.41 (m, 4H)

[a] The data of the protons H^2–H^8 were not included in the table, because an assignment, especially for the isomers with low symmetry (C_s, C_{2v}) is not possible due to the large number of signals. The signals of the H^a protons lie partly under the benzene signal.

Owing to vicinal coupling, a doublet is observed for H^a, H^b, or $H^{b'}$ (Fig. 2), in the region of the aromatic protons and a doublet of a doublet is observed for $H^{a'}$, which appears as a triplet in the spectrum. Three signals are observed for the C_{4h} and the D_{2h} isomers, (two doublets, one doublet of a doublet) for the three aromatic protons H^a, $H^{a'}$ and H^b or $H^{b'}$. It is

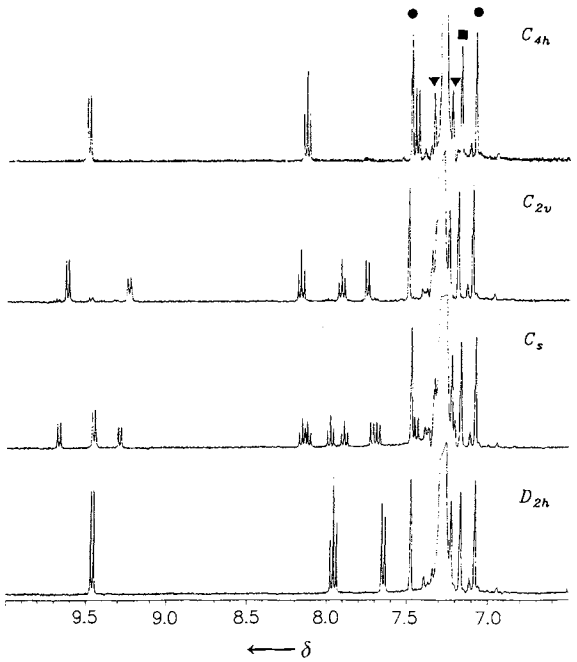

Fig. 2. ^1H NMR spectra of the four isomers (resonance range of the aromatic protons) (400 MHz, [D_6]benzene, 0.7 mg mL^{-1}). ^1J(C,H) coupling in [D_5]benzene (●), signal of [D_4]benzene (■); rotational side bands (▼).

observed that the H^a protons of the D_{2h} isomer are shifted to lower field than those of the C_{4h} isomer. In the C_s isomer, only part of the doublet is shifted. The $H^{a'}$ protons of the C_{4h} isomer are shifted downfield. The C_{2v} isomer exhibits one nonshifted group of signals and one group of signals shifted downfield, whereas the C_s isomer shows one nonshifted group of signals and two groups of signals that are shifted downfield when the triplet of the D_{2h} isomer is used as reference. One group of signals of the C_s isomer is shifted upfield in comparison with the reference. For the C_{2v} isomer, six signals (four doublets, two doublets of a doublet) are expected in the aromatic region of the spectrum. However, the spectrum exhibits two doublets for H^b or $H^{b'}$, two doublets of a doublet for $H^{a'}$, and a doublet for H^a. The second doublet expected for H^a is covered by the benzene signal. This could be proven by varying the concentration of the solution. Twelve signals are expected for the C_s isomer (eight doublets, and four doublets of a doublet). However, three doublets are observed for H^b or $H^{b'}$ whose integration corresponds to four protons. Again, by varying the concentration of the solution it could be proven that two doublets overlap. Moreover, the spectrum of the C_s isomer exhibits four doublets of a doublet for $H^{a'}$ and three doublets for H^a. The fourth doublet for H^a is likewise covered by the benzene signal.

The UV spectra of the four structural isomers of [$(EHO)_4$PcNi] do not differ significantly.[5] The IR spectra of the isomeric mixture of [$(EHO)_4$PcNi] and the isolated isomers are identical. The C_{4h} isomer is the least soluble (e.g. in benzene) and forms the last fraction on the column, whereas the D_{2h} isomer is readily soluble. One reason for the difference in solubility between the isomers might be the spatial arrangement of the substituents of the neighboring isoindolenine units.

Experimental Procedure

HPLC: Beckmann system Gold 5.1; column; Machery-Nagel; ET 250/8/4 nucleosil 5 NO_2; 5 μm; eluent: toluene/*n*-hexane (1:1); 74.5 bar; 1 mL min^{-1}.

MPLC: pump: ProMinent CfG Duramat; column: 93 × 2.54 cm packed with Merck 15–40 μm silica gel 60H.; eluent: toluene/*n*-hexane (3:2); 6 bar; 1.6 mL min^{-1}; flow detector: Büchi UV/VIS filter photometer with preparative flow cell (measuring wavelength 365 nm). For separation, [$(EHO)_4$PcNi] (50 mg), dissolved in toluene/*n*-hexane (10 mL) (3:2), was chromatographed on the MPLC column.

[$(EHO)_4$PcNi]: A solution of 1,2-dicyano-3-(2-ethylhexyloxy)benzene (racemate)[6] (2 g, 7.8 mmol) in *N*,*N*-dimethylaminoethanol (DMAE) was heated with $NiCl_2$ (260 mg) for 24 h at 140 °C. The solvent was distilled off under vacuum and the product was purified several times by column chromatography (SiO_2; toluene/*n*-hexane (7:3). A dark blue solid was obtained. Yield: 220 mg (10%). IR (KBr): ν [cm^{-1}] = 2956 (s), 2923 (s), 2869 (s), 2856 (s), 1597 (m), 1549 (w), 1528 (m), 1493 (m), 1462 (m), 1333 (m), 1271 (s), 1238 (m), 1175 (m), 1142 (m), 1128 (m), 1086 (s), 1065 (s), 947 (w), 901 (w), 808 (w), 795 (w), 758 (w), 741 (m). ^{13}C NMR (63.5 MHz, [D_6]benzene): δ = 11.48–12.05 (C^8), 14.85–14.95 (C^6), 24.22 (C^7), 24.80 (C^5), 29.53–30.54 (C^4), 31.01–31.48 (C^3), 39.85–40.88 (C^2), 71.77/76.29 (C^1), 111.23–111.59 (C^a), 113.81–117.04 (C^b/C^b), 123.62–127.20 (C^d/$C^{d'}$), 129.41–130.06 ($C^{a'}$), 139.45–141.75 (C^c), 145.29–146.32 ($C^{c'}$), 155.48–157.43 (C^b/$C^{b'}$).

Sterically Controlled, Metal-Induced Synthesis of a 1-Thia-2,4-diphosphole**

By *Ekkehard Lindner,* Cornelius Haase, Hermann A. Mayer, Martin Kemmler, Riad Fawzi,* and *Manfred Steimann*

Dedicated to Professor Jochen Ellermann on the occasion of his 60th birthday

Cyclooligomerizations of phosphaalkynes in the protective coordination sphere of transition metal complexes have been thoroughly investigated.[1] A diphosphabicyclobutane bound to [Cp_2Zr] was used by Regitz et al. for the directed synthesis of cyclic phosphorus compounds[2] and of tetraphosphacubane.[3] In contrast, the thermal cyclotetramerization of *t*BuC≡P proceeds with minimal selectively and affords the cubane only in low yield.[4] The same research group isolated derivatives of triphospha-Dewar benzene in an $AlCl_3$-medi-

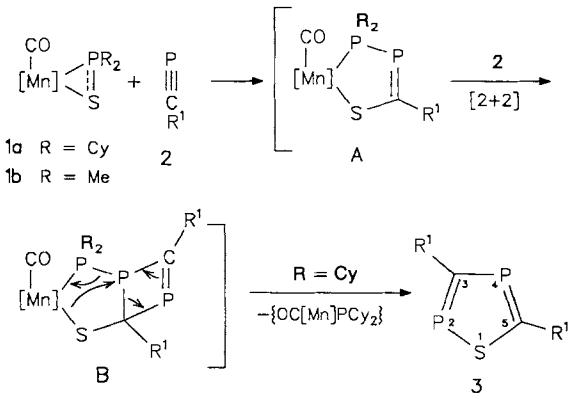
[**] Preparation and Properties of and Reactions with Metal-Containing Heterocycles, Part 84. This work was supported by the Volkswagen-Stiftung and the Fonds der Chemischen Industrie. The BASF AG and Schering AG are thanked for supplying starting materials, Priv.-Doz. Dr. J. Hahn, Universität Köln, for recording selective ^{31}P decoupled $^{13}C\{^1H\}$ NMR spectra. Part 83: [6d].

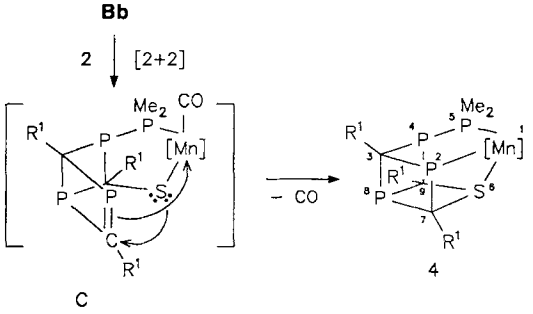
ated spirocyclotrimerization of *t*BuC≡P.[5] The metal-induced, regioselective cyclocotrimerization of the alkyne-like anions $R_2P{=}S^-$ with electron-poor acetylenes leads to thiophenes, phosphole complexes, and furans, which are otherwise difficult to obtain.[6] We have now achieved the direct and desired preparation of the 1-thia-2,4-diphosphole **3** in high yields (Scheme 1), by the reaction of the (η^2-thiophosphinito)manganese complex **1a** with *tert*-butylphosphaacetylene (**2**).



Scheme 1. [Mn] = $Mn(CO)_3$, R^1 = *t*Bu.

Recently we reported that as a result of the effect of **2** on the sterically highly strained nickel complexes [(η^5-C_5H_5)Ni-(η^2-$R_2P{\cdots}S$)] (R = *m*-xylyl, mesityl) of the type **1**, the P···S bond is cleaved with the formation of stable, nickel compounds analogous to **A**. These have been characterized by X-ray crystallography.[7] The thiadiphosphole **3** is thus formed only in traces. If the steric demand of the organometallic group in **1** is reduced by the use of a $Mn(CO)_4$ unit together with cyclohexyl groups at the phosphorus atom (⇒**Aa**), it can be assumed that this is followed by a [2 + 2] cycloaddition to give **Ba**. The latter decomposes with the elimination of the thermodynamically stable heterocycle **3**[8] (Table 1), which is obtained as a colorless liquid. The remaining metal complex fragment reacts with more **1a** to give [($OC)_3$($HPCy_2$)Mn(η^2-$PCy_2{\cdots}S$)] (Table 1) and a sparingly soluble, $Mn(CO)_x$-containing solid (IR spectrum), which could not be characterized.

Further reduction of the steric demand by the exchange of the cyclohexyl groups for methyl groups in **1** (⇒**Ab**) leads to a [2 + 2] cycloaddition of **Bb** to **2**, which via **C** affords the thermodynamically stable, orange pentacycle **4** as the final product (Table 1, Scheme 2).



Scheme 2. [Mn] = $Mn(CO)_3$, R^1 = *t*Bu.

Table 1. Selected spectroscopic data of **3**, [($OC)_3$($HPCy_2$)Mn(η^2-$PCy_2{\cdots}S$)], **4**, and **5** [a].

[a] ^1H (250.13 MHz, internal standard: $CHCl_3$ relative to TMS), $^{13}C\{^1H\}$ (62.90 MHz, internal standard: $CDCl_3$ relative to TMS or [D_6]DMSO for **3**), $^{31}P\{^1H\}$ NMR spectra (32.44 MHz, 1% H_3PO_4/[D_6]acetone) in THF for **3**, in *n*-hexane for [($OC)_3$($HPCy_2$)Mn(η^2-$PCy_2{\cdots}S$)], in $CDCl_3$ for **4**, and in $CHCl_3$ for **5**. [b] For atom numbering see Scheme 2.

The $^{31}P\{^1H\}$ NMR spectrum of **4** in $CDCl_3$ shows four groups of signals, in which all four phosphorus atoms are coupling with each other. Since the X-ray structure analysis of **4** showed three possibilities for the positions of the three-coordinate P and S atoms, a ^{31}P solid-state NMR spectrum was also recorded. Likewise four signals were obtained, whose chemical shifts are in agreement with those in the $^{31}P\{^1H\}$ NMR solution spectrum. Two signals in the ^{31}P CP/MAS NMR spectrum are very broad and display a high anisotropy of the chemical shift. These effects can only be explained by the existence of a Mn–P quadrupolar interaction[9] (^{55}Mn nucleus: I = 5/2, 100%). Thus, *two* Mn–P bonds are present in **4**.

In agreement with the NMR data, the sulfur atom cannot occupy the positions P3 and P4 (large $^1J_{P,P}$ coupling between P2 and P4) in the crystal of **4** (Fig. 1).[10] The molecule has crystallographic *m* symmetry; since its constitution does not allow such symmetry, this means that in the crystal, disorder exists with respect to this mirror plane, and thus it is not possible to distinguish between P1 and S1. The pentacycle shows half of the tetraphosphacubane framework,[3, 4]

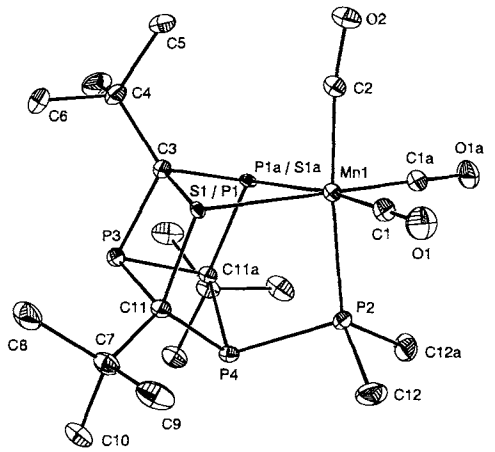

Fig. 1. Crystal structure of **4**. Selected distances [Å] and angles [°]: Mn1-P2 2.255(1), P2-P4 2.189(1), P4-C11 1.859(2), P3-C11 1.894(2), P3-C3 1.878(2), P3-P4 2.655(1); Mn1-P2-P4 105.8(1), P2-P4-C11 108.1(1), P4-C11-P3 90.0(1), C11-P3-C3 85.2(1). The atom numbering is different from that in Scheme 2.

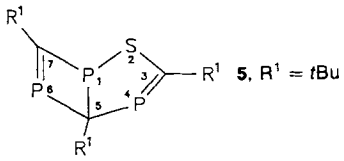
in which one P atom is replaced by an S atom, and one edge consists of a $Mn(CO)_3-PMe_2-P$ unit. The structural parameters of the cubane section are similar to those of the parent compound.[3,4] The phosphorus atom P4 is shifted from the ideal cubic position because of the PMe_2 bridge (the interplanar angle between C11-P3-C11a and C11-P4-C11a is 147.7°). The P2–P4 distance is somewhat shorter than that of a single bond.

If reactions, in which the steric demand of the R group is between methyl and cyclohexyl, for example R = Ph, are carried out starting from **1**, in addition to **3** and the corresponding pentacycle **4** with Ph instead of Me, the metal-free, intense yellow bicyclic compound **5** is obtained (Table 1).



5, $R^1 = t$Bu

The described reaction can also be transferred to other phosphaalkynes such as adamantyl- and methylcyclohexylphosphaacetylenes (δ^{31}P of **3**, R^1 = adamantyl (in dimethoxyethane): 245.04 and 256.24, $^2J_{P,P} = 48.7$ Hz; of **3**, R = MeC_6H_{10} (in C_6D_6): 255.26 and 265.16, $^2J_{P,P} = 49.7$ Hz).

Experimental Procedure

3: A solution of **1a** (535 mg, 1.35 mmol) and **2** (340 mg, 3.40 mmol) was heated to 66 °C for 5 h in THF (50 mL). After the removal of the solvent at 50 mbar the residue was taken up in petroleum ether 60/90 (20 mL) and purified on a short silica gel column. The main product was separated by MPLC with petroleum ether 60/90 on a silica gel column. First fraction: **3** (122 mg, 78% yield based on 0.675 mmol **1a**), correct elemental analysis, m.p. 10 °C; third fraction: $[(OC)_3(HPCy_2)Mn(\eta^2\text{-}PCy_2\text{-}S)]$ (310 mg, 81% based on 0.675 mmol **1a**; H stems from traces of moisture), yellow powder, correct elemental analysis, m.p. 123 °C.

4: **1b** (470 mg, 0.90 mmol, exists as dimer [6c]) and **2** (640 mg, 6.40 mmol) in THF (50 mL) were mixed together and heated under reflux for 22 h. The workup was carried out as for **3** but with petroleum ether/ethyl acetate 3/1 as eluent. Third fraction: **4** (420 mg, 44%), orange single crystals from *n*-hexane, correct elemental analysis, m.p. 210 °C.

5: **1**, R = Ph, (263 mg, 0.34 mmol) was heated with **2** (200 mg, 2.00 mmol) in THF (40 mL) to 50 °C for 44 h. After the removal of the solvent under vacuum, the residue was taken up in petroleum ether/ethyl acetate (10/1) (20 mL), filtered (P4), and separated on a silica gel column with the same eluent. First fraction: **5** (12.4 mg, 11%) yellow solid.

For the assignment of the ^{31}P and ^{13}C NMR signals, **3**, **4**, and **5** were synthesized with ^{13}C-labeled **2**.

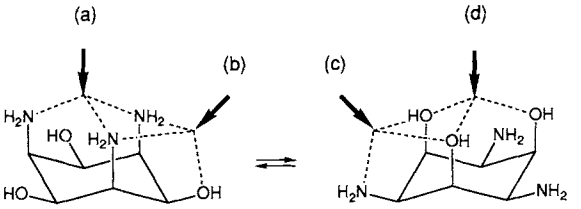
Hydrolysis to a Complex with a Central, Octahedral (μ_6-O)In$_6$ Unit**

By *Kaspar Hegetschweiler,* Michele Ghisletta, Thomas F. Fässler, and Reinhard Nesper*

In a number of studies over the last two years we have been able to show that the ligand 1,3,5-triamino-1,3,5-trideoxy-*cis*-inositol (taci) is remarkably versatile in complexing metal ions.[1–4] In aqueous solution monovalent to tetravalent cations of the groups 1–15 are readily complexed. Two different chair conformations (Scheme 1) enable the binding of a metal ion to three nitrogen atoms (a), two nitrogen atoms and one oxygen atom (b), two oxygen atoms and one nitrogen atom (c) as well as three oxygen atoms (d). In the $[M(taci)_2]^{3+}$ complexes (M = Al, Ga, Tl), coordination proceeds by binding the cations at the triaxial sites (a) or (d). The oxophilic Al^{3+} is coordinated exclusively by oxygen donors, whereas Tl^{3+} shows an N_6 coordination sphere. Ga^{3+} lies in between Al^{3+} and Tl^{3+} and consequently is bound to three nitrogen atoms of one ligand and to three oxygen atoms of the other.[3] In contrast, Pb^{2+} and Bi^{3+} prefer the asymmetric coordination mode (c).[4]



Scheme 1. Possible coordination modes of the ligand taci.

The stability constants determined in aqueous solution show that the Al, Ga, and Tl complexes are not stable with respect to the formation of solid hydroxides or oxides.[3] Indeed, the tendency to hydrolyze was confirmed by spectro-

[**] 1,3,5-Triamino-1,3,5-trideoxy-*cis*-inositol, a new, ligand with a remarkable versatility for metal ions, part 6. This work was supported by the ETH Zürich. Part 5: K. Hegetschweiler, R. D. Hancock, M. Ghisletta, T. Kradolfer, V. Gramlich, H. W. Schmalle, *Inorg. Chem.*, in press.

scopic and potentiometric measurements. These measurements clearly show that the rate of hydrolysis increases dramatically in the sequence $Al^{III} < Ga^{III} < Tl^{III}$. Starting from the corresponding In^{III} complex we could isolate a hydrolysis product of the composition $[OIn_6(taci-3H)_4](NO_3)_4 \cdot 8H_2O$ from aqueous solution. Spectroscopic methods[5, 6] as well as an X-ray structural analysis[7] were used for its characterization.

Discrete $[OIn_6(taci-3H)_4]^{4+}$ ions, whose structure is shown in Figure 1, are found in the crystal. A single oxide ion in the center of the complex is surrounded by six In^{III} ions.[8]

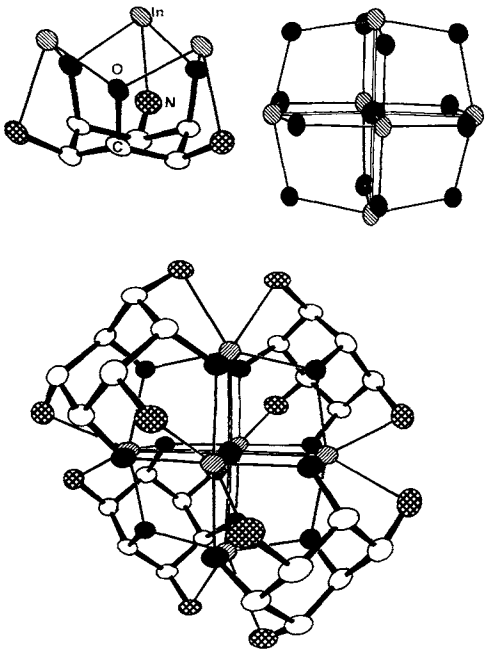

Fig. 1. Structure of $[OIn_6(taci-3H)_4]^{4+}$. $[In_3(taci-3H)]$ fragment (top left), In_6O_{13} core (top right), and perspective overall view (bottom). The vibrational ellipsoids correspond to the 50% probability level. Bond lengths [pm]: In-O_{oxo} 241.7(5)-264.3(6), In-O_{taci} 213.0(5)-220.8(5), In-N 232.3(6)-236.0(5), C-O 141.7(6)-143.7(7), C-N 145.5(8)-147.5(6), C-C 151.2(6)-154.3(8). Selected angles [°]: O-In-O (intraligand) 85.1(2)-87.0(1), O-In-O (interligand, *cis*) 89.2(1)-90.7(2), O-In-O (interligand, *trans*) 154.5(2)-161.5(5), O-In-O_{oxo} 76.7(2)-81.0(1), O-In-N (intraligand) 71.5(2)-75.4(2), O-In-N (interligand) 122.3(2)-129.0(1), N-In-O_{oxo} 141.4(2)-144.1(1), N-In-N 73.0(2)-76.4(3), In-O_{oxo}-In (*cis*) 88.6(1)-90.4(1), In-O_{oxo}-In (*trans*) 177.2(2)-180.0, C-O-In 113.4(3)-115.6(4), C-N-In 97.3(3)-98.8(4).

This OIn_6 unit is in turn encapsulated by four triply deprotonated taci molecules. All six donor atoms of each ligand molecule interact with the In^{III} ions with the hydroxyl groups deprotonated. In contrast to the terminally coordinating amino groups, these deprotonated hydroxyl groups bridge two In^{III} ions. Each ligand molecule binds three In^{III} ions, and every In^{III} ion is simultaneously coordinated by two ligand molecules, so that all six In^{III} ions obtain the coordination number 7. The In-O_{oxo} bonds are unusually long. However, the other In-O and In-N bond lengths agree well with those values found in other complexes with a sevenfold coordinated In^{III}.[9] The twelve coordinating alkoxo groups, together with the six In^{III} ions and the central oxide ion, form an In_6O_{13} core with approximate O_h symmetry.

The crystallographic symmetry of the entire complex is C_2. However, NMR spectroscopic measurements reveal that the complex has tetrahedral T_d symmetry in solution: the observation of only two signals in the ^1H NMR and ^{13}C NMR spectra, respectively, demonstrate the equivalence of the four ligands as well as that of the three O and the three N substituted CH groups within a ligand. Four C_3 axes thus pass through the central oxygen atom and the center of the cyclohexane rings, whilst the three S_4 axes correspond to the space diagonals in the OIn_6 octahedron. It is noteworthy that $[OIn_6(taci)_4\text{-}xH]$ units are also preserved in the mass spectrometer. Signals due to single monopositive ions, which are generated by multiple deprotonation and by association of NO_3^-, are observed.[6]

The reaction of taci with Tl^{III} in the ratio of 2:1 in methanol gave the mononuclear complex ion $[Tl(taci)_2]^{3+}$.[3] The analogous reaction with In^{III} gives a crude product which contains the mononuclear ion $[In(taci)_2]^{3+}$ as main component according to mass spectrometry and NMR spectroscopy. $[OIn_6(taci-3H)_4]^{4+}$ is formed subsequently in aqueous solution and can be regarded as a first intermediate in the hydrolytic polymerization of a mononuclear precursor complex. However, in the thermodynamically stable In_2O_3, the final product of this polymerization, the oxygen atoms are four- and not six-coordinate.[19]

Polynuclear metal complexes with a central OM_6 unit are well known.[11-13] In the isopoly anions of V^V, Nb^V, Ta^V, Mo^{VI}, and W^{VI}, this unit is obtained by the linking of MO_6 octahedra over common edges, resulting in the formation of the characteristic M_6O_{13} core.[12] Related structures have recently also been found for complexes of V^{IV}, Mn^{II}/Mn^{III}, and Fe^{III}. However, in these complexes, the peripheral oxo ligands are replaced by alkoxo groups.[13] To date, the M_6O_{13} core described here has only been known for transition metals. $[OIn_6(taci-3H)_4]^{4+}$ is the first main group element complex of this type. Moreover, it differs from the previously known complexes by adopting the coordination number 7 at the metal.

The formation of complexes with a M_6O_{13} core can be understood as a spontaneous self association of a mononuclear precursor complex. It is noteworthy that this core is observed in $[OIn_6(taci-3H)_4]^{4+}$, $[OFe_6(OCH_3)_{18}]^{2-}$, and $[Mo_6O_{19}]^{2-}$, that is metal ions with distinctly different chemical properties. We therefore assume that the M_6O_{13} unit, due to its particularly favorable geometry, is a common structural element in oligonuclear hydrolysis products of metal complexes with a relatively small number of metal centers.

Experimental Procedure

A solution of indium(III) nitrate (0.42 g, 1.4 mmol) in methanol (20 mL) was added dropwise with stirring to a solution of taci (0.51 g, 2.88 mmol) in methanol (20 mL). A white solid precipitated immediately. The suspension was stirred for an additional hour at room temperature and the solid was then filtered off. This residue was dissolved in water (10 mL), filtered through Celite and the colorless filtrate was layered with ethanol. After a few days colorless crystals were formed which were suitable for single-crystal X-ray analysis.

[8] We exclude the possibility of OH^- instead of O^{2-} being in the center for the following reasons: 1) The resulting divergence of the charge balance $O^{2-} + 6In^{3+} + 4(taci-3H)^{3-} + 4NO_3^-$ would require compensation by either a lower oxidation state for one In atom, by an additional deprotonation of a ligand, or by the occupation of a noncoordinated H_2O position by OH^-. However, the NMR spectroscopic evidence of four symmetry-equivalent ligands, the In–O and In–N distances, and the observation that the aqueous complex solution showed almost no alkaline reaction are all not in agreement with such compensations. 2) A disordered hydroxide ion in the center of the approximately octahedral complex should result in an increased temperature factor. This also is not observed.

$[AltBu]_6^-$: EPR Spectroscopic Evidence and Ab Initio Calculations**

By *Carsten Dohmeier, Mario Mocker, Hansgeorg Schnöckel,* Albert Lötz, Uwe Schneider,* and *Reinhart Ahlrichs**

Dedicated to Professor Hans Bock on the occasion of his 65th birthday

Perhalogenated *closo*-borates $[BX]_n^{2-}$ (X = Cl, Br, I) with $n = 8$–12[1–3] have been known for some time.[4] Recently, the first analogous aluminum compound, $[AlBu]_{12}^{2-}$,[5] was characterized. We report here on the second anionic aluminum cluster, the radical anion $[AltBu]_6^-$ $\mathbf{1}^{\bullet-}$.[6] After tetrahedral $[(AlCp^*)_4]$[9, 10] and icosahedral $[AlBu]_{12}^{2-}$,[5] $\mathbf{1}^{\bullet-}$ is the first aluminum cluster derived from octahedral symmetry.

The reaction of a solution of AlCl in toluene and diethyl ether[11] with *t*BuLi gave a dark red solution from which LiCl slowly precipitated.[11] A homogeneous reaction pathway is revealed by NMR spectroscopy.[12] The analysis of the product shows it to be a monovalent aluminum compound.[13] If the solution is reduced with Na/K alloy, hardly any differences in the NMR spectra can be detected. Only the proton spectrum indicates the presence of a paramagnetic species by showing a very broad resonance ($\delta = 1.4$). This was confirmed by the EPR spectrum (Fig. 1). The 31 lines

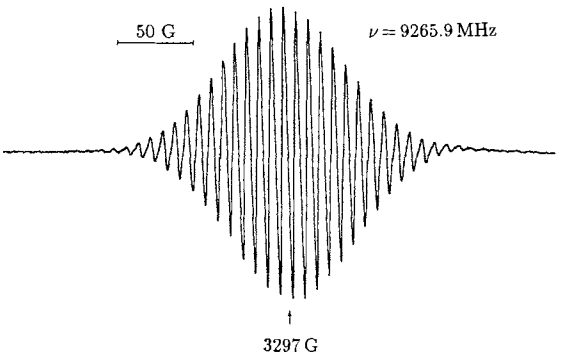

Fig. 1. EPR spectrum of $[AltBu]_6^-$ in C_6D_6 ($a(^{27}Al) = 8.2$ G, $g = 2.008$).

clearly point to a compound with six equivalent aluminum atoms (^{27}Al: 100%, $I = 5/2$). The analogous alkylation of AlBr[14] instead of AlCl, gives, without reduction, a product with the same NMR and EPR spectra.[15] The compound, evidenced by EPR, thus cannot be a species containing halogen. Since neither isomerization nor elimination of the *t*Bu substituents are observed, the conclusion is that the radical anion $[AltBu]_6^-$ ($\mathbf{1}^{\bullet-}$) must be present. The isolation of $[(AltBu)_6]$ (**1**) and $M_A^+\mathbf{1}^{\bullet-}$ [Eq. (a)] has so far not been successful.[16]

$$6AlCl \xrightarrow[-LiCl]{tBuLi} \text{“}[(AltBu)_6]\text{”} \xrightarrow{Na/K} M_A^+[AltBu]_6^- \qquad (a)$$

In order to elucidate the structure and electron distribution of $\mathbf{1}^{\bullet-}$, a quantum chemical geometry optimization[17] was carried out at the SCF level. In addition, Al*t*Bu and **1** were also studied with these methods.

Wade's rules predict a perfectly regular octahedron for Al_6 cages only for the dianion. For neutral compounds or monoanions, however, an octahedral cage leads to the occupation of the t_{2g} HOMO with four or five electrons, respectively, and thus to a Jahn-Teller distortion, which was verified in the SCF approximation. All calculations were carried out in D_{3d} symmetry (Fig. 2), since this is the highest possible symmetry consistent with *t*Bu groups as ligands, leads to six equivalent Al atoms, and, moreover, allows a continuous transition between octahedron and ring.[18] Then, from the t_{2g} HOMO

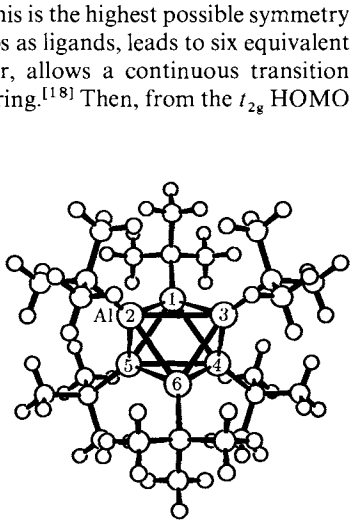

Fig. 2. Ball-and-stick model of the structure of $[AltBu]_6^-$ (D_{3d} symmetry) as calculated with ab initio methods.

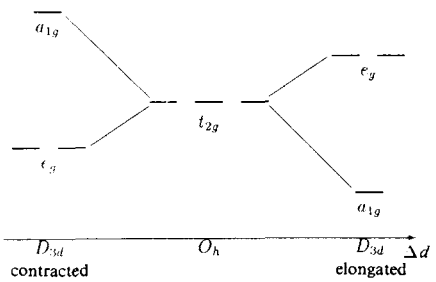

Scheme 1. Correlation diagram of the HOMOs of octahedral Al_6 compounds with distortion towards D_{3d}. Δd = change of distance.

in the octahedron, an a_{1g} and an e_g orbital result. Their energy level sequence depends on whether elongation or contraction occurred along the threefold axis (Scheme 1). We investigated all states that are obtained by assigning a total of four or five elctrons to these a_{1g} and e_g orbitals (Tables 1 and 2 for **3** and **1**, respectively).[19] The analysis of the SCF-MOs shows that these orbitals are restricted to the Al_6 cage, that is the *t*Bu ligands contribute only very little.[20]

Table 1. The configurations of [(Al*t*Bu)$_6$] in D_{3d} symmetry. Numbering of atoms as in Figure 2, energies relative to $^3A_{1g}$ ($a_{1g}^2e_g^2$, $E_{SCF} = -2389.35068$ a.u.).

State	$^1A_{1g}$ ($a_{1g}^0e_g^4$)	^3E_g ($a_{1g}^1e_g^3$)	$^3A_{2g}$ ($a_{1g}^2e_g^2$)
ΔE_{SCF} [kJ mol^{-1}]	+12	+12	0
ΔE_{Hex} [kJ mol^{-1}]	−536	−536	−548
d(Al1–Al2) [pm]	289.1	275.2	262.7
d(Al1–Al4) [pm]	258.2	267.2	281.1
d(Al–C) [pm]	201.1	201.0	201.3

Table 2. The configurations of the [Al*t*Bu]$_6^-$ anion in D_{3d} symmetry. Numbering of atoms as in Figure 2, energies and electron affinities relative to $^3A_{1g}$ ($a_{1g}^2e_g^2$, $E_{SCF} = -2389.35068$ a.u.).

State	$^2A_{1g}$ ($a_{1g}^1e_g^4$)	^2E_g ($a_{1g}^2e_g^3$)
ΔE_{SCF}/[kJ mol^{-1}] (eV)	−143 (−1.48)	−128 (−1.33)
ε(HOMO)[eV]	−2.59	−2.52
d(Al1–Al2) [pm]	275.2	263.9
d(Al1–Al4) [pm]	261.7	272.7
d(Al–C) [pm]	203.4	203.5

For the neutral system and the anion, several configurations are separated from one another by only a few kJ mol^{-1}; however, they differ considerably with respect to the structure of the Al_6 cage. The most important result is the remarkable stability of the hexamer compared to that of six monomers [Eq. (b)].[21]

$$\Delta E_{Hex} = 6\,E(\text{Al}t\text{Bu}) - E([(\text{Al}t\text{Bu})_6]) \approx 540\ \text{kJ mol}^{-1} \qquad \text{(b)}$$

The vertical electron affinity of the neutral cluster can be estimated, on the one hand, from the energy difference between the neutral species and the anion (with the same geometry as the neutral species) and on the other, from the HOMO energy of the anion, by using Koopmans' theorem.[22]

$E_A = 1.41$ eV ($a_{1g}^0e_g^4 \rightarrow a_{1g}^1e_g^4$) and $E_A = 1.24$ eV ($a_{1g}^2e_g^2 \rightarrow a_{1g}^2e_g^3$)

Even though the calculated Al–Al distances vary between 258 and 289 pm (Tables 1 and 2), the average Al–Al distances are 271 ± 3 pm for all treated cases, and fall in the range typical for AlX tetramers.[10]

$E_A = 2.14$ eV ($a_{1g}^0e_g^4 \rightarrow a_{1g}^1e_g^4$) and $E_A = 2.33$ eV ($a_{1g}^2e_g^2 \rightarrow a_{1g}^2e_g^3$)

The D_{3d} symmetry of an $[AlR]_6^-$ anion also appears plausible in view of the bonding in $[n\text{Bu}_4\text{N}][BI]_6$.[7, 8] The two (crystallographically different) anions (C_i symmetry) of the latter exhibit significantly longer B–B bonds (175–191 pm) within the B1,B2,B3 and B4,B5,B6 triangles (numbering as in Fig. 2) than those between these triangles (175–191 pm). Thus, the distorted D_{3d} structure of the $[BI]_6^-$ unit – in line with the results of the quantum chemical calculations for $\mathbf{1}^{\bullet-}$ – offers additional support for the reasoning that Al_6 clusters with D_{3d} symmetry are responsible for the hyperfine structure of the EPR spectrum.

Experimental Procedure

All operations were carried out under nitrogen. NMR spectra (C_6D_6, 25 °C): JEOL-GSX-270 spectrometer (^{1}H, ^{13}C, ^{27}Al; reference: TMS or (external) $[Al(H_2O)_6]^{3+}$), Bruker-AC-200 (^{7}Li; reference (external): LiCl/D_2O). The EPR spectra were recorded with a Varian-E-Line (E101) spectrometer.

1: A solution of *t*BuLi (2.24 mmol) in pentane (6 mL) was added dropwise at −78 °C to a solution of AlCl (2 mmol) in toluene/diethyl ether (3:1) (6.6 mL). After 18 h the mixture was warmed to room temperature and after another 24 h the dark red solution was filtered and analyzed by NMR spectroscopy. Another solution prepared analogously was treated with Na/K alloy (1:3) (90 mg) and stirred at +4 °C for 24 h. This solution, now even darker than before, was also filtered. The solvent was removed under vacuum from a sample of this solution, and the residue was taken up in C_6D_6 and used for the EPR spectroscopic analysis. The yield of **1** after a reduction time of 24 h was estimated by EPR spectroscopy to be approximately 5% (relative to 2,2,6,6-tetramethyl-piperidine-1-oxyl as a concentration standard in C_6D_6).

[13] The filtered solution was protolyzed with semidilute HCl, and the amount of H_2 evolved ($Al^+ + 2\,H^+ \rightarrow Al^{3+} + H_2$) correlated with the total aluminum content. The average oxidation state for Al is 1 ± 0.3.
[14] M. Mocker, H. Schnöckel, unpublished results.
[15] Possibly in this case subvalent Al–Br species act as reducing agents.
[16] From the NMR spectra,[12] a very symmetrical structure is derived for the primary product formed from the reaction of AlCl and *t*BuLi. We consider

the formation of the hexamer **1** according to Equation (a) is plausible, since the resulting high Al–Al binding energy in the alkylated aluminum clusters (see also [10]) obtained in the quantum chemical calculations has the result that the oligomers $[(AlrBu)_n]$ with $n < 6$ are energetically disfavored in comparison with the hexamer, whereas, the cleavage of larger clusters is very unlikely under the given experimental conditions. Moreover, there are no indications in the EPR and NMR spectra of radical anions or dianions, which would be expected had reduction of other oligomers occurred.

[17] The computations were performed with the program system TURBOMOLE (R. Ahlrichs, M. Bär, M. Häser, H. Horn, C. Kölmel, *Chem. Phys. Lett.* **1989**, *162*, 165) on an IBM RISC 6000 workstation. The open-shell molecules were treated with the RHF-SCF formalism (C. C. J. Roothan, *Rev. Mod. Phys.* **1960**, *32*, 179). Basis sets: Al: (10s7p)/[4s3p] + d(η = 0.30); C (quaternary): (7s4p)/[3s2p] + d(η = 0.80), C (primary): (6s3p)/[2s1p]; H: (3s)/[1s]. The first two basis sets were fully energy optimized on the atom, and the last two basis sets on neopentane (A. Schäfer, H. Horn, R. Ahlrichs, *J. Chem. Phys.* **1992**, *97*, 2571).

[18] For the model compound $[(AlMe)_6]$, the structure obtained was verified as a local minimum by SCF force field calculations.

[19] It should be noted that for the relatively high-lying ^3E_g $(a_{1g}^1e_g^3)$ and $^2E_g(a_{1g}^2e_g^3)$ energy states the Jahn-Teller theorem predicts a further lowering of the symmetry, which leads to nonequivalent Al atoms.

[20] Mulliken population analysis shows the electrons in the high-lying a_{1g} and e_g orbitals to be 99% localized within the Al_6 cage.

[21] The inclusion of the correlation energy with single point MP2 calculations (2nd order perturbation) increases the stabilization energy for the model compound $[(AlMe)_6]$ by 320 kJ mol^{-1} from 540 kJ mol^{-1} to 860 kJ mol^{-1}. This corresponds with the AlX tetramers, where MP2 calculations result in a stabilization energy of 50 kJ mol^{-1}.

[22] Koopmanns' theorem systematically overestimates the electron affinity because it neglects orbital relaxation.

The Structures of Tris(8-dimethylamino-1-naphthyl)phosphane and Tris[2-(dimethylaminomethyl)phenyl]phosphane: Crystallographic Evidence of Seven-Coordinate Phosphorus

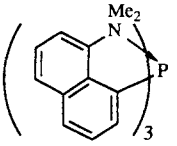
By *Claude Chuit, Robert J. P. Corriu,* Pascal Monforte, Catherine Reyé, Jean-Paul Declercq*, and *Antoine Dubourg*

Dedicated to Professor Hans Bock on the occasion of his 65th birthday

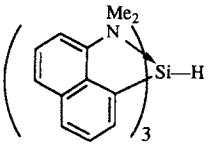
Following our work on the chemistry of hypercoordinate silicon compounds,[1] we are at present investigating the ability of phosphorus to expand its coordination number by intramolecular coordination. Surprisingly, with the exception of phosphoranes in which the formation of intramolecular coordination has been shown,[2–6] few studies[4, 7] have been reported in this field. While phosphanes with one N-donor group appropriately placed for intramolecular chelation[8–13] have been prepared, the possible formation of such an interaction has been suggested only rarely.[14]

We report here the preparation, structural characterization, and some observations on the reactivity of phosphanes in which increase in coordination number at the phosphorus atom is achieved by three intramolecular N–P dative bonds.

The phosphane **1** was prepared by reaction of an excess of 8-dimethylamino-1-naphthyllithium[15] with PBr_3 in 67% yield. It was identified on the basis of its mass spectrometric and NMR spectroscopic data. The ^{1}H NMR solution spectrum shows the equivalence of the three NMe_2 groups whose resonances appear as two singlets of equal intensity, which correspond to two sets of diastereotopic methyl groups resulting from the coordination of the nitrogen atoms to the phosphorus atom. Interestingly, **1** shows no change in its ^{1}H NMR spectrum at high temperature (90 °C, 250 MHz).



1



2

Confirmation of the intramolecular coordination of the three NMe_2 groups at the phosphorus atom was provided by a single-crystal X-ray structural analysis.[16] In the crystal, the molecules of **1** have a helicoidal shape (Fig. 1) with a pseudo threefold rotation axis in contrast with the lack of symmetry of the triphenylphosphane molecule.[17] The pyramidal configuration about the phosphorus atom is retained with C-P-C angles of 106.6(3), 107.2(3), and 107.8(3)° [average value 107.2(3)°], whereas for triphenylphosphane the average C-P-C angle is 103.44°. The nitrogen–phosphorus distances (2.805, 2.844, and 2.853 Å) are significantly shorter than the sum of the N and P van der Waals radii (3.4 Å),[18] but much more longer than a covalent N–P bond (1.77 Å), so that these bonds can be considered as weak coordinative bonds. Nitrogen coordination is observed *trans* to a C–P bond with an average C-P-N angle of 171.6°, and the naphthyl groups remain approximately planar as indicated by some selected torsion angles (Fig. 1).

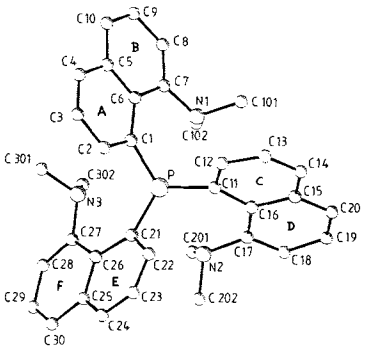


Fig. 1. Crystal structure of **1**. Selected angles [°]: C(1)-P···N(1) 75.4(3), C(1)-P···N(3) 80.2(3), C(11)-P···N(1) 78.9(3), C(21)-P···N(2) 79.5(3), C(21)-P···N(3) 74.2(3). Angle between normals to planes: A-ring–B-ring = 3 ; C-ring–D-ring = 6 ; E-ring–F-ring = 6°.

It is worth noting that the geometry of the silane **2**,[19] revealed by X-ray analysis, is the same as that of **1**, the hydrogen atom at silicon occupying the position of the phosphorus lone pair. The angles are very similar, the C-Si-C angles ranging from 104.8(4) to 107.6(4)° [average value 105.7(4)°] with Si–N distances from 2.876 to 2.928 Å.

Since intramolecular coordination by the NMe_2 groups is facilitated in **1** by the rigid geometry of the 8-dimethylamino-1-naphthyl group, we thought it might be interesting to prepare a further example of possible tris-chelated phosphane by using a coordinating ligand with a more flexible geometry, such as the [2-(dimethylaminomethyl)phenyl] ligand.[20] Phosphane **3** was prepared by the reaction of an excess of 2-(dimethylaminomethyl)phenyllithium[21] with PBr_3 in 65% yield. Its ^{1}H NMR spectrum exhibits the resonance signal of the three NMe_2 groups as a sharp singlet at room

4a: M = Ge
b: M = Si

temperature and the ^{31}P (NMR) chemical shift appears at $\delta = -34$ upfield from that of triphenylphosphane ($\delta = -6$),[22] suggesting an increase in phosphorus atom coordination number. That was confirmed by the X-ray crystal structure determination of **3**[23] which indicates the same helicoidal shape observed for **1** (Fig. 2). The other main

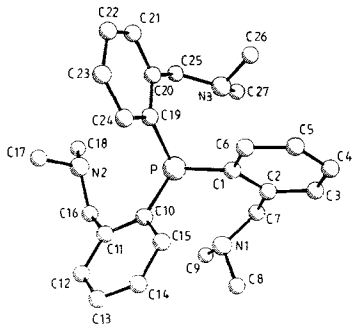

Fig. 2. Crystal structure of **3**. Selected angles [°]: C(1)-P···N(1) 72.9(3), C(1)-P···N(3) 76,4.(3), C(10)-P···N(1) 78.6(2), C(19)-P···N(2) 76.1(2), C(19)-P···N(3) 72.5(3).

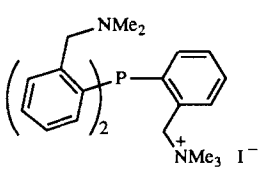
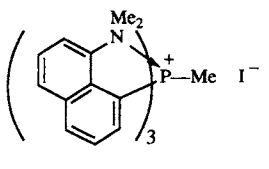
features of this structure are the following: 1) The average C-P-C angle is 100.7(5)° compared with 107.2(3)° for **1** and 103.44° for triphenylphosphane; thus the basic pyramidal geometry is also retained. 2) The NMe_2 groups are directed towards the phosphorus center, *trans* to a C–P bond with N···P-C angles varying from 171.2(3) to 173.1(3)° (average value 172.1(9)°). The N···P separations (2.999 Å, 3.010 Å, 3.071 Å) are slightly longer than for **1**, but here too remain below the sum of the N and P van der Waals radii (3.4 Å), thus suggesting a weak interaction. Interestingly, the geometry of this phosphane is also similar to those of the germane **4a**[24] and the silane **4b**.[24]

It is important to emphasize that phosphanes **1** and **3** adopt the same geometry when there is no steric constraint in phosphane **3** to force the NMe_2 donor groups to interact with the phosphorus center. The flexibility of the 2-(dimethylaminomethyl)phenyl ligand compared with the rigidity of the 8-dimethylamino-1-naphthyl group explains why a) the N···P distances in **3** (2.999–3.071 Å) are slightly longer than those in **1** (2.805–2.853 Å), and b) the ^1H NMR spectrum of **3** exhibits the resonance of the NMe_2 groups as a sharp singlet, while the resonance of three NMe_2 groups in **1** appears as two singlets even at high temperature (90 °C, 250 MHz). This indicates that **1** remains coordinated in solution, while an equilibrium exists between the opened and closed forms of **3** in solution. This interpretation is corroborated by the difference of reactivity between **1** and **3** toward MeI. Phosphane **3** reacts rapidly with MeI to give the ammonium salt **5**, while **1** reacts very slowly to give the phosphonium salt **6**.



5



6

Thus, the P atom in compounds **1** and **3** is formally seven-coordinate with three carbon atoms, three nitrogen atoms, and its lone pair, which together form a tricapped tetrahedron. Another example of a complex with a seven-coordinate phosphorus atom results from the insertion of CS_2 in the P–N bonds of an aminophosphane.[25] The single-crystal X-ray structural analysis of this complex, the empirical molecular formula of which is $(Me_2N)_3P \cdot 3CS_2$, has shown that the phosphorus center is surrounded by six sulfur atoms, which together with the phosphorus atom lone pair form a distorted capped trigonal antiprism.

Experimental Procedure

All experiments were performed under a nitrogen atmosphere in Schlenk tubes and with predried solvents.

1: PBr_3 (2.6 g, 9.6 mmol) was added dropwise at −80 °C to a stirred suspension of yellow (8-dimethylamino-1-naphthyl)lithium [15] (6.4 g, 36 mmol) in diethyl ether (80 mL). The reaction mixture was allowed to warm to room temperature and was refluxed for 2 h. Subsequently, 10% NaOH solution (100 mL) was slowly added to the cooled yellow suspension. The yellow solid was filtered off, washed with water, acetone and diethyl ether, and dried in vacuum to give 1.55 g of crude product. After two recrystallizations from benzene, 1.15 g (67%) of pure **1** was obtained as a yellow powder: M.p. 300–303 °C; ^1H NMR (300 MHz; $CDCl_3$): $\delta = 1.4$ (s, 3H), 2.8 (s, 3H), 7.7 (m, 6H); ^{31}P NMR (250 MHz, CD_2Cl_2): $\delta = 6.07$, positive-ion FAB MS [(*m*-nitrobenzylalcohol) matrix (NOBA)]: *m/z* 542 $[M + H]^+$. Correct C,H,N analysis for $C_{36}H_{36}N_3P$.

Crystals of **1** suitable for an X-ray diffraction study could not be obtained in this way. Instead when the crude product was recovered by filtration without hydrolysis, yellow crystals of **1**, suitable for X-ray analysis were obtained after two recrystallizations in ethanol. Under these conditions, **1** crystallized with one molecule of HBr and one molecule of EtOH. M.p. 50–55 C (decomp). Correct C,H,N, analysis for $C_{38}H_{43}BrN_3OP$.

3: PBr_3 (3.7 g, 13.7 mmol) was added dropwise at −80 °C to a stirred suspension of 2-(dimethylaminomethyl)phenyllithium [21] (7.29 g, 52 mmol) in Et_2O (200 mL). The temperature was maintained at −80 °C during the addition. The reaction mixture was then allowed to warm very slowly to room temperature, and refluxed for 2 h. 10% NaOH solution (150 mL) was added to the yellow suspension. The colorless precipitate obtained was filtered off, washed with water/acetone and dried in vacuum. The powder was recrystallized from Et_2O/EtOH (1/1) to give 3.94 g (65%) of white crystals of **3**: M.p. 117–120 °C; ^1H NMR (250 MHz, CD_2Cl_2): $\delta = 2.05$ (s, 6H), 3.55 (s, 2H), 7.15 (m, 4H); ^{31}P NMR (250 MHz, CD_2Cl_2): $\delta = -34$; positive-ion FAB MS (NOBA matrix) *m/z*: 434 $(M + H)^+$; correct C,H,N analysis for $C_{27}H_{36}N_3P$.

5: A mixture of **3** (0.52 g, 1.2 mmol), methyl iodide (0.07 mL, 1.2 mmol) and toluene (20 mL) were heated in a sealed tube at 100 °C for 3 h. Then the white precipitate formed was filtered off, washed with toluene and anhydrous ether. After two recrystallizations from EtOH/benzene, 0.427 g of a white powder identified as **5** was obtained (62%): M.p. 210–213 °C. ^1H NMR (250 MHz, CD_2Cl_2): $\delta = 2.1$ (s, 12H), 3.2 (s, 9H), 3.3 (s, 4H), 5.1 (s, 2H), 6.4–8.0 (m, 12H); ^{31}P NMR (250 MHz, D_2O): $\delta = -7.85$; positive-ion FAB MS (NOBA matrix) *m/z*: 448 $(M - I)^+$; correct C,H,N analysis for $C_{28}H_{39}IN_3P$.

6: A mixture of **1** (1 g, 1.84 mmol) and MeI, (0.95 mL, 15 mmol) in toluene (5 mL) was heated in a sealed tube at 100 °C. After 10 days, the precipitate formed was filtered off and recrystallized twice from EtOH/benzene (1/3) to give 0.402 g (32%) of a pale yellow powder which was identified as **6**: M.p. 350 °C (decomp); ^1H NMR (80 MHz, $CDCl_3$): $\delta = 0.8$ (s, 9H), 2.0 (s, 9H), 2.4 (d, $^2J(P,H) = 20$ Hz, 3H), 7.0–8.6 (m, 18H); ^{31}P NMR (250 MHz, CD_2Cl_2): $\delta = 12.26$; positive-ion FAB MS (NOBA matrix): *m/z* 556 $(M - I)^+$. Correct C,H,N analysis for $C_{37}H_{39}IN_3P$.

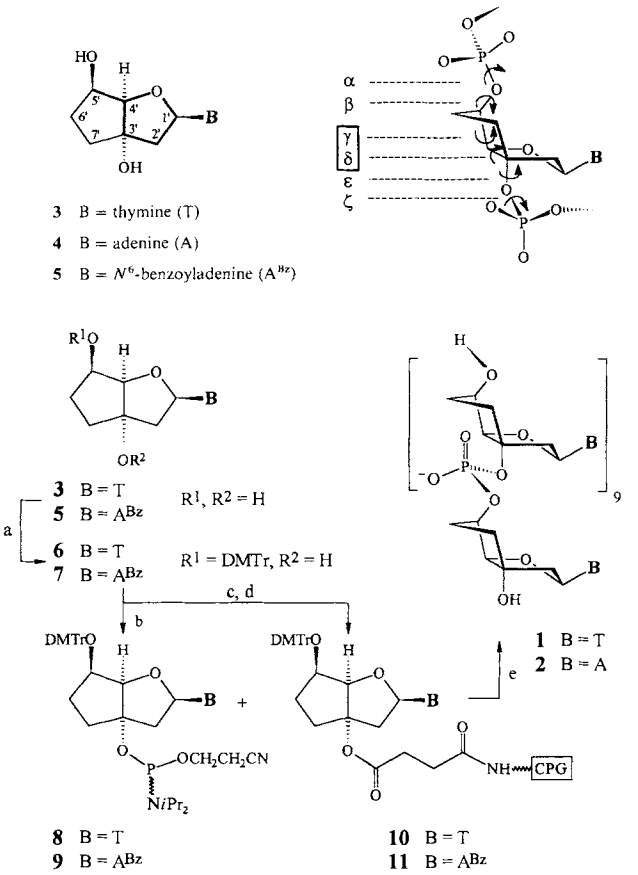
Synthesis and Pairing Properties of Deca-nucleotides from (3′*S*,5′*R*)-2′-Deoxy-3′,5′-ethano-β-D-ribofuranosyladenine and -thymine**

By *Markus Tarköy* and *Christian Leumann**

Sequence-specific complexation of RNA single strands and DNA duplexes by oligonucleotides provides a way of selective inhibition of protein biosynthesis.[1] Specificity in the recognition process relies on the fundaments of the Watson–Crick base pairing rules[2] and the corresponding rules for triplex formation,[3] and depends on the base sequence and the length of the oligonucleotide. With the goal of a possible therapeutic application, an extensive search for oligonucleotide analogues that exhibit stronger binding to complementary DNA and RNA and show higher enzymatic resistance towards nucleases as well as higher membrane permeability has evolved over the last decade.[4]

Recently we introduced a new type of nucleosides ("bicyclonucleosides") that differs from the natural deoxyribonucleosides by an additional ethylene bridge between the C3′ and C5′ centers (Scheme 1).[5] These bicyclonucleosides show



Scheme 1. Synthesis of deca-(3′*S*,5′*R*)-2′-deoxy-3′,5′-ethano-β-D-ribonucleotides **1** and **2** of the nucleobases adenine and thymine, respectively. a) $DMTr^+CF_3SO_3^-$, pyridine, 3h, room temperature (RT), 88%, **6**, (85%, **7**); b) $[(NCCH_2CH_2O)(iPr_2N)PCl]$, iPr_2EtN, THF, RT, 1 h, 63%, **8**, (76%, **9**); c) succinic anhydride, pyridine, 4-(dimethylamino)pyridine (DMAP), RT, 70 h, then *p*-nitrophenol, THF, *N*,*N*′-dicyclohexylcarbodiimide, RT, 2 h, 73%, B = T (63%, B = A^{Bz}); d) LCAA-CPG (Sigma), dioxane, dimethylformamide (DMF), Et_3N, RT, 2 d, then Ac_2O, pyridine, DMAP, RT, 30 min.; e) see [9].

less conformational flexibility in the furanose framework than the natural deoxyribonucleosides and were designed to confer, as constituents of an oligonucleotide chain, a higher degree of preorganization of a single strand for hybridization. This should lead to an entropic advantage for the pairing process and, eventually, to thermodynamically more stable complexes. Furthermore, oligonucleotides consisting of bicyclonucleosides have secondary and tertiary phosphodiester groups, and can be expected to be more resistant against enzymatic degradation by phosphodiesterases than their natural counterpart. Here we report on the synthesis of the two bicyclo-DNA decamers **1** and **2** and their pairing behavior with complementary RNA and DNA.

[**] Nucleic Acid Analogues with Constraint Conformational Flexibility in the Sugar-Phosphate Backbone, Part 2. This work was supported by a grant from ETH and from the Stipendienfonds der Basler Chemischen Industrie. Part 1: [5].

For automated oligonucleotide synthesis, according to standard phosphoramidite chemistry,[6] the bicyclic nucleoside derivatives **3** and **5**[5] were initially converted to the corresponding trityl derivatives **6** and **7** with 4,4'-dimethoxytriphenylmethyl (DMTr) trifluoromethanesulfonate.[7] The reactions of **6** and **7** with chloro-(β-cyanoethoxy)diisopropylaminophosphane in THF led to the phosphoramidite building blocks **8** and **9**, respectively. The supports derivatized with nucleoside (long-chain alkylamine controlled pore glass, LCAA-CPG), **10** and **11**, were obtained in analogy to standard methods in oligonucleotide chemistry[8] from the nitrophenylsuccinates of **6** and **7**, respectively; thus, loading capacities of 22–39 μmol g^{-1} (trityl assay) were achieved. The synthesis of the deca(bicyclodeoxynucleotides) **1** and **2** was performed on a DNA synthesizer with a modified synthesis protocol[9] and proceeded with coupling yields of >98% per step (trityl assay). After removal of the protecting groups and detachment from the solid support according to standard procedures (conc. NH_3, 55 °C, 10–16 h), the crude oligomers were purified by HPLC and analyzed by mass spectrometry[10] as well as by enzymatic degradation (snake venom phosphodiesterase/alkaline phosphatase), followed by identification of the mononucleosides **3** and **4**, respectively, with reversed-phase HPLC (coinjection with authentic material).

T_m values from UV melting curves of complexes of **1** and **2** with the natural DNA and RNA complements and with each other at comparable oligonucleotide concentrations are summarized in Table 1. At neutral pH values, the duplex

Table 1. T_m values [°C] (hyperchromicity [%]) from melting curves (260 nm) in 10 mM Tris·HCl (Tris = 2-amino-2-hydroxymethyl-1,3-propanediol) pH 7.0, 0.15 M NaCl (base pair concentration = 44 μM ± 10%).

d($T)_{10}$	25 (35)	23 (27)	27 (45)	24 (40)
poly(U)	45 (50) [a]	32 (42) [a]	45 [b]	57 [b]

[a] base pair concentration = 26 μM. [b] adapted from the work of M. Riley et al. [11].

2·poly(U) is considerably more stable than the natural hybrid d(A_{10})·poly(U) (ΔT_m = 13 K, Fig. 1),[11] whereas the duplex **1**·poly(A) is slightly less stable than its natural equivalent d(T_{10})·poly(A) (ΔT_m = − 4 K). With DNA as the complex partner, duplex stability decreases in the order **2**·d(T_{10}) ≈ d(A_{10})·d(T_{10}) > **1**·d(A_{10}). Of all possible pairings in the series of decamers, the fully bicyclic duplex **1**·**2** is the most

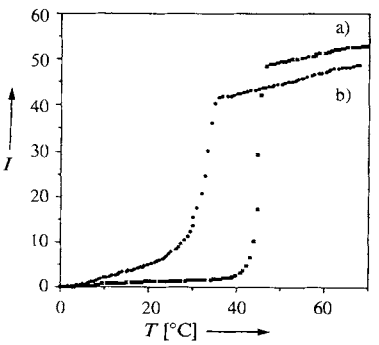

Fig. 1. UV melting curves (260 nm) of a) **2**·poly(U) and b) d(A_{10})·poly(U) in 10 mM Tris·HCl pH 7.0, 0.15 M NaCl. (base-pair concentration 26 μM). I = % hyperchromicity at 260 nm.

stable. The bicyclothymidine oligomer **1** shows preferential binding to poly(A) over poly(dA) (ΔT_m = 13 K) which is not observed in the case of its natural analogue d(T_{10}) (ΔT_m = − 3 K). In the hybrid systems **2**/d(T_{10}) and **1**/**2**, we have determined the pairing stoichiometry by recording UV mixing curves according to the method of Job.[12] It was found that (T-A-T)-type but not (A-A-T)-type triplexes were formed in both systems at the appropriate stoichiometric strand ratio under conditions (0.15 M NaCl) in which only duplex formation is found in the natural d(A_{10})/d(T_{10}) system[13] (Fig. 2, mixing curve of **1**/**2** is not shown). Oligo(bicyclodeoxy)nucleotides of adenine and thymine thus show a higher propensity for triplex formation relative to the natural sequences.

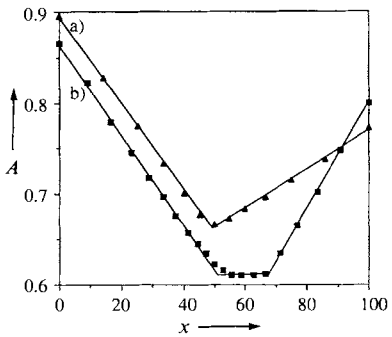

Fig. 2. UV mixing curves (260 nm, 8 °C) of a): d(A_{10})/d(T_{10}) (total strand concentration c_T = 8.4 μM) and b) **2**/d(T_{10}) (c_T = 8.3 μM) in 10 mM Tris·HCl pH 7.0, 0.15 M NaCl. A = absorption at 260 nm, x = concentration of T in mol%.

To answer the question whether the entropy change upon pairing is influenced by the structural modifications in the sugar part of the oligo(bicyclonucleotide), we determined pairing enthalpies (ΔH) and entropies (ΔS) in the series of decamers from the UV melting curves (Fig. 3) by a curve-fitting procedure as well as from a plot of T_m^{-1} against the logarithm of oligonucleotide concentration according to the method of Marky and Breslauer[14] (Table 2). From the data

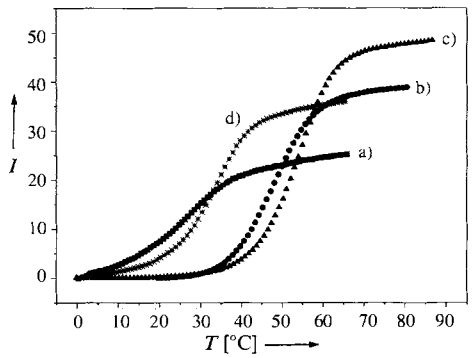

Fig. 3. UV melting curves of the duplexes a) **1**·d(A_{10}) (c_T = 8.3 μM), b) **2**·d(T_{10}) (11.9 μM), c) **1**·**2** (11.9 μM), and d) d(A_{10})·d(A_{10}) (12.2 μM) in 10 mM NaH_2PO_4, 1 M NaCl, pH 7.0.

of either method it emerges that in both hybrid duplexes **2**·d(T_{10}) and **1**·d(A_{10}), as well as in the completely bicyclic duplex **1**·**2**, the pairing entropy term (ΔS) is (numerically) reduced relative to the natural duplex d(A_{10})·d(T_{10}).[15] The pairing enthalpy term is generally affected in a way that destabilizes duplex formation. The deviation of the data for **2**·d(T_{10}) (Table 2), obtained by the two different methods,

may be an indication that the "two-state model", on which the elucidation of the thermodynamic data is based, is most likely an oversimplification in this case. It seems reasonable that the reduction of the enthalpy term in the hybrid duplexes is due to a partly "incorrect" pairing geometry or to strain within the bicyclic strand. The reduction of the entropy term can be attributed to the reduced degree of rotational freedom in the sugar-phosphate backbone of the DNA analogues, although other contributions, especially from differences in duplex and single strand solvation, may also play an important role.

Table 2. Thermodynamic data of duplex formation from UV melting curves (curve-fitting and plots of T_m^{-1} against ln[c] [14]) in 10 mM NaH_2PO_4, pH 7.0, 1 M NaCl. Estimated errors $\leq \pm 5\%$.

	curve fitting		T_m^{-1} vs. ln[c]

[a] Average of six measurements at six different concentrations in the range of $c_T = 1-30$ μM.

A further aspect in the design of nucleic acid analogues is concerned with their stability against enzyme-catalyzed degradation. From oligo(bicyclodeoxynucleotides), containing exclusively secondary and tertiary phosphodiester linkages between nucleosides, one would expect an enhanced stability against phosphodiesterases. This was investigated by subjecting the decamer **1** to hydrolysis catalyzed by snake venom phosphodiesterase (SVP), nuclease S1, and fetal calf serum phosphodiesterase (CSP), and determining its stability relative to that of natural d(T_{10}).[16] While **1** showed an enhanced resistance against SVP (a 3′-exonuclease) by a factor of 3, its relative stability increased to factors of 100 and 1.4×10^3 in the cases of nuclease S1 (endo- and exonuclease) and CSP (5′-exonuclease), respectively.

The concept of reducing the pairing entropy upon bimolecular duplexation by reducing the torsional flexibility of the sugar phosphate backbone, as derived from observations of the pairing properties of oligo-2′,3′-dideoxy-β-D-glucopyranonucleotides (homo-DNA) by Eschenmoser et al.,[17] can successfully be applied to structures that were designed to bind to complementary natural DNA and, therefore, opens novel routes in the design of antisense analogues.

[7] $DMTr^+CF_3SO_3^-$ was obtained in crystalline form by reaction of the corresponding chloride with CF_3SO_3Ag in THF (82%). Correct elemental analysis (C, H, F, S) for $C_{22}H_{19}O_5F_3S$.
[8] M. J. Gait, *Oligonucleotide Synthesis - a Practical Approach*, IRL Press, Oxford, **1984**.
[9] Oligonucleotide synthesis was performed on a Pharmacia Gene Assembler Plus DNA synthesizer in scales of 0.6–1.3 mmol. The only parameters changed relative to the synthesis of natural DNA oligomers were the detritylation time (extended to 60 s) and the coupling time (extended to 6 min). The last step in every synthesis was the removal of the 5′-terminal trityl group (trityl off mode).
[10] Crude **1** and **2** were purified by anion exchange HPLC (column: Nucleogen 60 DEAE Macherey-Nagel; elution with a linear KCl gradient in 20 mM KH_2PO_4, pH 6.0 in H_2O:CH_3CN 4:1). Quality of the isolated material was checked by reversed-phase HPLC (column: Aquapore Rp 300, Brownlee; elution with a linear gradient of CH_3CN in 0.1 M aqeous Et_3NHOAc, pH 7.0). Mass spectrometric analysis of **1** and **2** (NH_4^+ form) was performed by matrix-assisted laser desorption time of flight mass spectroscopy (*m/z* 3240.8 (**1**), 3330.8 (**2**)).
[11] Whereas **2**·poly(U) forms a duplex at a ratio of bases of 1:1, d(A_{10})·poly(U) disproportionates to the (U-dA-U)-triplex and unpaired d$(A)_{10}$ under the buffer conditions used for recording the UV melting curves. This is in accordance with previous findings on the pairing behavior of poly(dA) with poly(U) (M. Riley, B. Maling, M. J. Chamberlin, *J. Mol. Biol.*, **1966**, *20*, 359-389).

Multiring Catenanes with a Macrobicyclic Core**

By *Christiane Dietrich-Buchecker,* Bruno Frommberger, Ingo Lüer, Jean-Pierre Sauvage,** and *Fritz Vögtle**

Catenanes consist of two or more interlocking rings.[1, 2] Two templated strategies based either on interactions with transition metals[3] or on π-stacking interactions[4] have been developed and used to make catenanes with increasingly more complex structures and topologies. Furthermore, recently a hydrogen bond template synthesis was introduced.[5] Up to now, all the catenanes synthesized contain *mono*cycles, although it is easy to imagine that by applying construction

[**] This work was supported by the Bundesministerium für Forschung und Technologie (BMFT-03 291 209). We thank the Mass Spectrometry Laboratory (Strasbourg) for analysis, and J.-P. Kintziger and P. Maltese for recording the NMR spectra and fruitful discussions.

principles derived from the template routes mentioned above, catenanes containing polycyclic components may be obtained.[6] In other words, the molecular graphs of all the previously synthesized catenanes only contain two-order vertices.[7] The introduction of higher order vertices represents an interesting extension, in which the simplest case would be to use a *bi*cyclic skeleton as the interlocking component for which the two bridgehead atoms are three-order vertices. Indeed, the successful application of this strategy (Fig. 1) is reported herein.

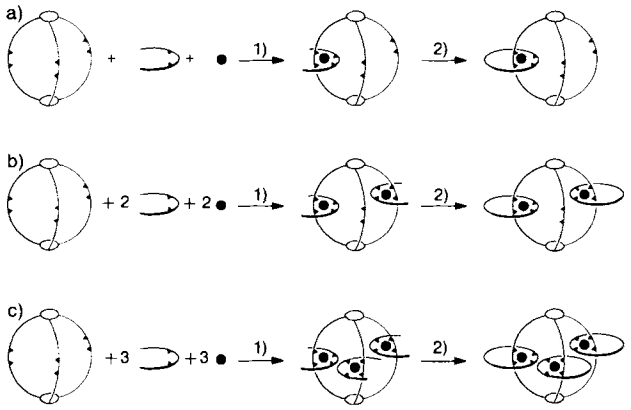

Fig. 1. The reaction pathway to catenanes starting from a bicyclic compound with three coordinating arms (the small black triangles symbolize the 1,10-phenanthroline nitrogen atoms). The metal centers (black circles) control the assembly and orientation of the components. The number of metal ions used per bicyclic molecule, in principle, determines the number of monocycles interlocked to the central organic unit. 1) Complexation, 2) cyclization.

A series of macrobicyclic endoreceptors containing three convergent 2,9-diphenyl-1,10-phenanthroline (dpp) units, which can complex three Cu^{I} ions and three open-chain dpp units, has recently been described.[8] The same assembling principle has now been applied to synthesize the precursors for catenanes (step 1 of Fig. 1). The structures of the compounds used and the reactions performed are represented in Figure 2.

The macrobicycle **1** was prepared as previously described.[8] It was allowed to react in CH_3CN/dimethylformamide (DMF) with three equivalents of $[Cu(CH_3CN)_4]BF_4$ and subsequently with three equivalents of **2** to yield $\mathbf{3}^{3+}$ almost quantitatively. The ^1H NMR spectrum of $\mathbf{3}^{3+}$ clearly shows that the three components **2** are sterically congested inside the cage cavity (strong upfield shift of the signals for the $H'_{5,6}$ protons which suggests that the three phenanthroline units of **2** overlap). The cyclization of the open-chain components **2** in $\mathbf{3}^{3+}$ in presence of Cs_2CO_3 and **4** leading to $\mathbf{5}^{+}$, $\mathbf{6}^{2+}$, and $\mathbf{7}^{3+}$ was carried out according to a method derived from the one used for making catenates[9] (see Experimental Procedure). After repeated careful chromatographic separation, $\mathbf{5}^{+}$, $\mathbf{6}^{2+}$, and $\mathbf{7}^{3+}$ were obtained in 8%, 4%, and 0.5% yield, respectively. Substantial amounts of insoluble materials were also formed. The structure and the topology of these three catenates were confirmed by FAB and electrospray mass spectrometry (see Experimental Procedure). The ^1H NMR spectra afforded valuable information regarding the structure of the catenane framework and, in particular, the level of crowding within the cavity of the macrobicyclic component. Some data are collected in Table 1.

Interesting conclusions with regard to the structure can be drawn from the chemical shift values (Table 1). Three types of dpp groups have to be considered:

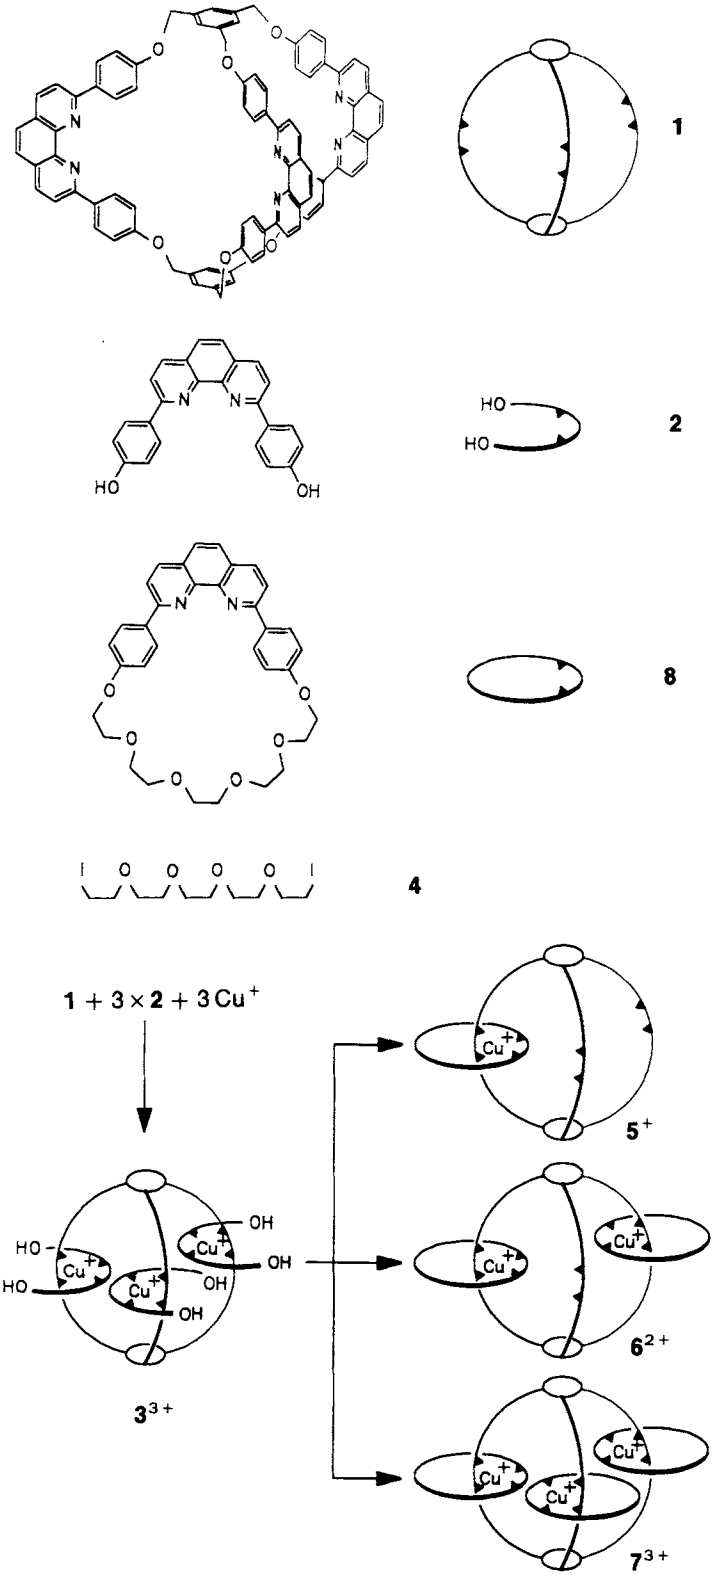

Fig. 2. Starting materials and synthesis of the catenanes $\mathbf{5}^{+}$, $\mathbf{6}^{2+}$, and $\mathbf{7}^{3+}$ as well as the precursor $\mathbf{3}^{3+}$.

1) *The complexed arms,* which belong to the bicyclic central unit and coordinate to Cu^{I} ions. Each cycle of the macrobicycle (**1**) consists of a 42-membered ring, and is thus much larger than **8**, the other components of the interlocking systems (30-membered ring; see Fig. 2). It is expected that the smaller the rings, the tighter and more entwined the catenane units. This is reflected by the H_o signal, which ap-

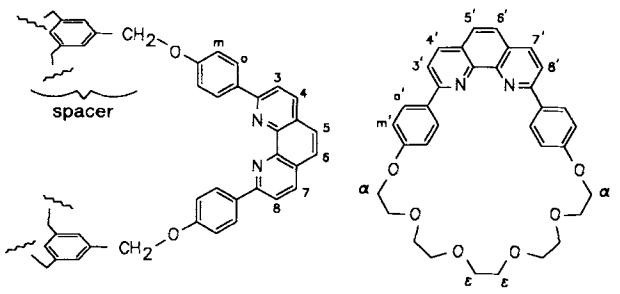

Table 1. Chemical shifts for the complexes 5^+, 6^{2+}, and 7^{3+} as well as $[Cu(8)_2]^+$ and **8** at 25 °C in $CHDCl_2$ ($\delta H = 5.320$) at 400 MHz [a].

			$[Cu(8)_2]^+$						**8**										
	8.66	8.28	7.87	7.37	6.02	3.62 [d]	8.44	8.30	8.10	7.79	7.23	4.37 [d]							

[a] The ^1H NMR spectra contain all the characteristic patterns of the dpp subunits present in the cage **1** as well as in the interlocked macrocycles **8**: a singlet for H_5 and H_6, an AB pattern for H_3 or H_8 and H_4 or H_7 ($J \approx 8.5$ Hz) and a AA'XX' system ($J \approx 8.7$ Hz) for H_o and H_m. [b] In complex 6^{2+}, the dpp subunits of the two interlocked macrocycles **8** present an AB pattern for their H'_5 and H'_6 protons, whereas their H'_o protons appear as two distinct doublets. [c] In $[Cu(8)_2]^+$ the signal for H_ε also occurs at $\delta = 3.82$. [d] Signal for H_ε.

pears at higher field for the simple catenate $[Cu(8)_2]^+$ than for the interlocking systems 5^+, 6^{2+} and 7^{3+}. In addition, by filling-up the cavity with more and more dpp units, the steric strain within each complex subunit increases, leading to less stacking interactions between the phenyl and phenanthroline rings, with the same consequences as the reduction in the ring size. Overall, the less and less entwined situation of the Cu^I complexes from $[Cu(8)_2]^+$ to 7^{3+} leads to significant increase of the δ values for H_o, H_m and OCH_2. Indeed, the latter protons feel less and less the shielding effect of the phenanthroline units of the macrocycle **8**. It is worth noting that, as expected, the signals of the protons outside the cage ($H_{4,7}$, $H_{5,6}$, and $H_{3,8}$ of the complexed arms) are almost completely insensitive to the filling-in of the cavity.

2) *The internal phenanthroline units*, which belong to the 30-membered rings. The ring current effect of the two capping phenylene units onto the "rear" of the phenanthroline groups is very significant. The $H'_{4,7}$ and $H'_{5,6}$ signals undergo an upfield shift when switching from $[Cu(8)_2]^{2+}$ to 5^+ ($\Delta\delta \approx -0.3$). In order to explain the large shielding of the $H'_{5,6}$ protons in 7^{3+} (upfield shift by $\Delta\delta = -0.64$ in comparison to $H_{5,6}$ in $[Cu(8)_2]^+$), two factors can be invoked: a) the ring current effect of the two phenylene units and b) the pronounced overlap of the three internal phenanthroline units, especially in the $H'_{5,6}$ region. To a lesser extent, the same is true for the $H'_{4,7}$ protons ($\Delta\delta = -0.29$ between $[Cu(8)_2]^+$ and 7^{3+}). CPK (space-filling) models show that the three phenanthroline rings inside the cavity must stack in order to accomodate the size of the bicyclic component. By contrast, all the other signals of the aromatic protons are slightly shifted downfield on going from $5^+ \rightarrow 6^{2+} \rightarrow 7^{3+}$.

3) *The free arms*, which are completely unperturbed by the complexation of their neighboring arms. It is striking that the signals of the outside $CH_{2\varepsilon}$ protons are also totally insensitive to modification occurring inside the cage ($\delta = 3.82 \pm 0.01$ for $CH_{2\varepsilon}$ of the four Cu^I complexes).

The new types of structures 5^+, 6^{2+}, and 7^{3+} should allow the study of steric and electronic interactions between transition metal complex subunits nested inside the cavities of large bicyclic cage compounds.

Experimental Procedure

3^{3+}: $[Cu(CH_3CN)_4]BF_4$ (318 mg, 1.01 mmol) in degassed CH_3CN (50 mL) was added to **1** (424 mg, 0.32 mmol) in degassed DMF (50 mL) with stirring under argon and at room temperature (RT). The solution turned dark yellow. It was stirred for a further 30 min, after which the diphenol **2** (368 mg, 1.01 mmol), dissolved in degassed DMF (40 mL), was added slowly over 30 min. The solution turned dark red. After it was stirred for about 15 h at RT, the solvents were evaporated to dryness. The black-red complex 3^{3+} was obtained quantitatively as a glassy solid (921 mg, 0.32 mmol). Compound 3^{3+} was utilized without further purification. Electrospray mass spectra confirmed the composition of precatenate 3^{3+}: m/z = 2778.7, 1346.5, and 868.8 correspond to $[3(BF_4)_2]^+$, $[3(BF_4)]^{2+}$, and 3^{3+}, respectively. ^1H NMR (CD_3CN): δ = 8.55 (d, 6H, H_4 or H_7); 8.07 (s, 6H, H_5 and H_6); 8.04 (d, 6H, H'_4, H'_7); 7.92 (d, 6H, H'_3 or H'_8); 7.73 (d, 6H, H_3 or H_8); 7.57 < m < 7.43 (24H, H_o, $H'_{5,6}$, H_{spacer}); 7.40 (d, 12H, H'_o); 6.30 (d, 12H, H_m); 5.90 (d, 12H, H'_m); 4.96 (s, 12H, H_{OCH_2}).

Macrocyclization leading to 5^+, 6^{2+}, and 7^{3+}: A degassed suspension of Cs_2CO_3 (1.6 g, 5 mmol) in DMF (150 mL) was added by the double-ended needle transfer technique (addition made by small successive batches over a 24 h period) to a solution of **3** $(BF_4)_3$ (921 mg, 0.32 mmol) and **4**, the diiodo-derivative of pentaethyleneglycol (485 mg, 1.06 mmol) in DMF (350 mL) kept under argon at 60–65 °C. The reaction was monitored by TLC which showed that **4** was consumed faster than 3^{3+}. Additional **4** (470 mg, 1.03 mmol) in DMF (50 mL) was added over a period of 4 h. After this second addition of **4**, stirring and heating was continued for 24 h at about 60 °C after which classical workup was carried out [9]. The crude reaction mixture was purified by numerous successive column chromatographic separations (silica gel, eluent: CH_2Cl_2/MeOH 100:1 to 100:5 v/v). Besides significant amounts of insoluble material and recovered cage **1**, we isolated 52.2 mg of 5^+ (8% yield, eluent: CH_2Cl_2/MeOH 100:1), 35.3 mg of 6^{2+} (4% yield, eluent: CH_2Cl_2/MeOH 100:1.5) and 5.5 mg of 7^{3+} (0.5% yield, CH_2Cl_2/MeOH 100:2–4).

5^+: Dark brown-red solid. ^1H NMR (CD_2Cl_2): (see Table 1). ES-MS: m/z = 1951.3, 976.8, and 651.2, corresponding to 5^+, 5^+H^+, and 5^+2H^+, respectively. UV/VIS (CH_2Cl_2), λ_{max} (nm, [ε]): 442 [2668]; 422 [2683]; 321 [96229]; 284 [159557]; 239 [120286].

6^{2+}: Dark purple solid. ^1H NMR (CD_2Cl_2): (see Table 1). ES-MS: m/z = 1290.7, 861.3, corresponding to 6^{2+} and $6^{2+}H^+$. UV/VIS (CH_2Cl_2), λ_{max} (nm, [ε]): 438 [5055]; 323 [97502]; 287 [151287]; 248 [151287].

7^{3+}. Dark purple solid. ^{1}H NMR (CD_2Cl_2): (see Table 1). ES-MS: m/z = 1070.5 corresponding to 7^{3+}. UV/VIS (CH_2Cl_2), λ_{max} (nm, [ε]): 444 [5870]; 325 [94 147]; 284 [126 626]; 247 [141 444].

Oxoferryl π-Cation Radical of β-Pyrrole Octachlorinated *meso*-Tetramesitylporphyrin: Electronic and Structural Properties**

By *Philippe Ochsenbein, Dominique Mandon, Jean Fischer, Raymond Weiss,* Rachel Austin, Karupiah Jayaraj, Avram Gold,* James Terner,* Eckhard Bill, Markus Müther,* and *Alfred X. Trautwein**

Iron tetraarylporphyrins with halogenated pyrrole units and protected methine positions, for example **1** or **2** (Scheme 1), are very efficient catalysts for the hydroxylation of poorly reactive alkanes.[1] The chemo- and regioselectivities of the oxidations differ considerably from those observed with "planar peripherally unsubstituted" porphyrin catalysts such as **3**, suggesting a change in the structure of the high-valent iron–oxo intermediates.[2]

8	$Fe^{IV}O$	Br

Scheme 1. Structures of the porphyrins discussed in the text.

Indeed, recent structural determinations of β-pyrrole octabrominated tetraarylporphyrins and their nickel(II) derivatives have established that halogen substitution at the β positions induces severe saddle-shaped distortions of the porphyrin core.[3, 4] In this report we show that 1) the cores of the five-coordinate iron(III) derivatives of the β-pyrrole octahalogenated porphyrins **1** and **2** also adopt a saddle shape and 2) that a high-valent iron porphyrin species, with EPR spectral properties similar to those reported for the oxoferryl π-cation radicals of "planar protected" tetraarylporphyrins such as $\mathbf{4}^{\bullet+}$, can be generated in dichloromethane by reaction at −80 °C of **1** with *m*-chloroperoxybenzoic acid (*m*-CPBA).[5, 6]

Complexes **1** · H_2O and **2** · H_2O crystallize,[7, 8, 10–12] like the metal-free porphyrins **5** and **6**,[3, 9] in space group $P\bar{4}2_1c$ with two molecules per unit cell. The macrocycles lie on a crystallographic fourfold inversion axis; therefore, the Fe-Cl groups are orientationally disordered along this axis; the effective symmetry of each molecule is C_2. The high-spin iron ion is bound to the four pyrrole nitrogen atoms of the ring and to a chloride ion (Fig. 1). In both compounds, the

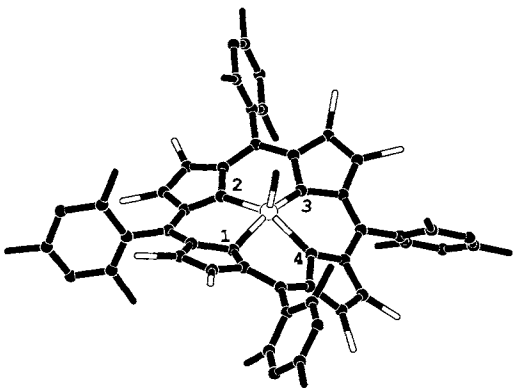

Fig. 1. Structure of **1** and **2** in the crystal (stick plot, hydrogen atoms are omitted and the orientational disorder of the Fe-Cl group is not shown.) Selected bond lengths in **1** · H_2O: Fe-Cl = 2.21(1), Fe-N_p1 = Fe-N_p3 = 2.04(1), Fe-N_p2 = Fe-N_p4 = 2.09(1) Å; selected bond lengths in **2** · H_2O: Fe-Cl = 2.30(2), Fe-N_p1 = Fe-N_p3 = 2.03(1), Fe-N_p2 = Fe-N_p4 = 2.09(1) Å.

coordination polyhedron of the iron center is a pyramid in which one set of opposing Fe–N_p bond lengths is longer than the other set (see legend to Fig. 1). In **1** and **2**, the iron atoms lie 0.55(1) Å above the 4 N_p and 24-atom core mean-planes of the porphyrins. Both molecules are severely nonplanar; however, the saddle is somewhat less pronounced in

the iron complexes **1** and **2** than in the metal-free porphyrins **5** and **6**. Indeed, the average displacements of 0.87 and 0.90 Å of the β-C atoms from the mean-planes of the porphyrins in **1** and **2**, respectively, are slightly smaller than those of 0.90 and 0.95 Å, respectively, in the metal-free porphyrins **5** and **6**. A small ruffling is also present, with the *meso*-carbon atoms in **1** and **2**, respectively, deviating by 0.34 and 0.33 Å from the mean porphyrin planes. The dihedral angles between adjacent and opposite pyrrole rings indicate that the twist of the pyrrole rings around their central axes is slightly greater in **1** than in **5** and slightly smaller in **2** than in **6**; for opposite rings these dihedral angles average to 49.0 and 48.4° in **1** and **5**, respectively, and 49.3 and 49.8° in **2** and **6**, respectively. For adjacent rings these values are 34.1 and 33.7°, respectively for **1** and **5**, and 34.3 and 34.7°, respectively for **2** and **6**.

The chloroiron(III) octahalogenated or porphyrins were oxidized in toluene/[D_4]methanol (6:1) dichloromethane/[D_4]methanol (6:1) at -80 °C by addition of an approximately fourfold molar excess of *m*-CPBA in [D_4]methanol to an approximately 10^{-3} molar solution of iron(III) porphyrin. Techniques for obtaining UV/VIS, ^{1}H NMR, EPR, resonance Raman (rR), and Mössbauer spectra have been described elsewhere.[5, 6] In toluene, only the EPR-inactive oxoferryl complexes **7** and **8** were obtained and characterized by UV/VIS, ^{1}H NMR, rR, and Mössbauer spectroscopy.[9] In dichloromethane, **2** also led to EPR-inactive **8**; however, **1** yielded EPR-active oxoferryl porphyrin π-cation radical $\mathbf{7}^{\bullet+}$, with spectral properties similar to those of the oxoferryl porphyrin π-cation radical of the "planar" tetramesitylporphyrin **4**.[5, 6]

Indeed, the X-band EPR spectrum of $\mathbf{7}^{\bullet+}$, (Fig. 2) shows resonances at effective g values of 4.2, 3.7, and 1.99 which are typical of a quartet species $S_t = 3/2$. The fact that the average of g_x^{eff} and g_y^{eff} is less than 4 indicates that the spectrum originates from a low-spin iron(IV) center ($S = 1$) ferromagnetically coupled to a porphyrin π-cation radical ($S' = 1/2$).[13] A quantitative measure of spin coupling could be derived by inspection of the temperature dependence of the EPR signal intensities and by simulating the EPR spectrum, for example at 10 K (Fig. 2).[6] This temperature dependence is appropriately described by a three-state model of the three Kramers doublets, the energy separations of which are consistent with the spin-Hamiltonian parameters derived by simulating the EPR spectrum measured at 10 K (Fig. 2): $D_{Fe} = 18\ cm^{-1}$, $E_{Fe}/D_{Fe} = 0.063$ (zero-field parameters of Fe^{IV}), $g_{Fe} = 2.14$, 2.17, 1.995 and $J^0 = 25\ cm^{-1}$ (J^0 = isotropic exchange interaction between iron and radical spin in $-J^0(S \cdot S')$. Since it has not yet been possible to generate $\mathbf{7}^{\bullet+}$ in a form suitable for Mössbauer spectroscopy, these parameters had to be derived from EPR studies alone.

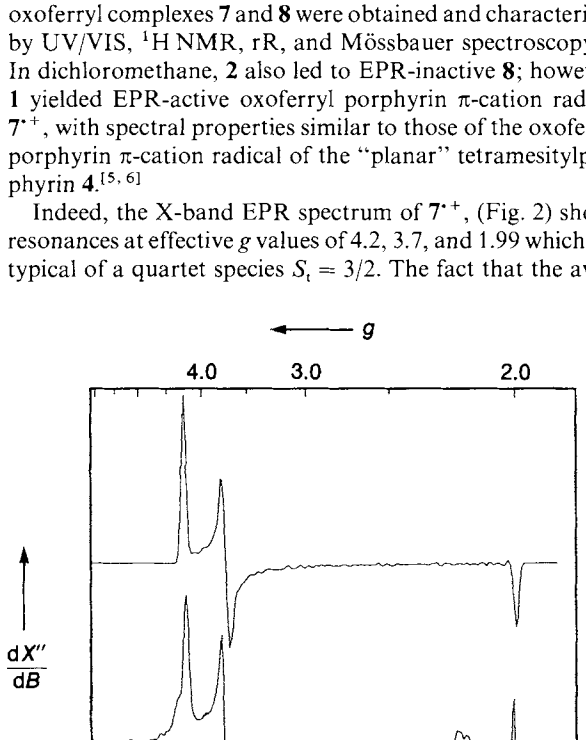

Fig. 2. Lower part: Experimental EPR spectrum of $\mathbf{7}^{\bullet+}$ at 10 K, microwave frequency 9.4316 GHz, power 20 μW, modulation amplitude 100 KHz; upper part: Simulated EPR spectrum based on the analysis of the spin-Hamiltonian operators [6] with parameters as given in the text, using a g-strain model for the line shapes, which is based on a Gaussian distribution $\sigma(E_{Fe}/D_{Fe}) = 0.08$ of the rhombicity E_{Fe}/D_{Fe} of Fe^{IV}.

However, all other spectral data of $\mathbf{7}^{\bullet+}$ are also consistent with an oxoferryl porphyrin π-cation radical: UV/VIS (CH_2Cl_2, -80 °C): λ_{max} [nm] (ε [$cm^2\,mmol^{-1}$]) = 391 (13.6; Soret), 725 (1.64); ^{1}H NMR (500 MHz, -65 °C, CD_2Cl_2/CD_3OD, TMS): $\delta = 13.5$ (12H, *p*-CH_3), 21.8 (12H, *o*-CH_3) 24.0 (12H, *o'*-CH_3) (the phenyl *meta*-proton resonances were not identified because of broadening). In the rR spectrum of **1** (CH_2Cl_2, -65 °C), porphyrin marker band assignments in the high-frequency region (wavelength of the laser 4067 Å) (based on polarization studies at 5145, 4545, 4131, 4067, and 3564 Å) are: $\nu_4 = 1345\ cm^{-1}$; $\nu_3 = 1461\ cm^{-1}$; $\nu_{11} = 1481\ cm^{-1}$, and overlapping bands $\nu_2 = 1528$ and $\nu_{10} = 1539\ cm^{-1}$. On *m*-CPBA oxidation of **1** to $\mathbf{7}^{\bullet+}$, the band intensities are markedly reduced, as expected for ring oxidation; ν_4 could not be definitively assigned but ν_2 was observed at 1538 cm^{-1}. This upfield shift of ν_2 suggests differences between the structural parameters of $\mathbf{7}^{\bullet+}$ and the oxoferryl π-cation radical of tetramesitylporphyrin ($\mathbf{4}^{\bullet+}$). In conclusion, the electronic properties of $\mathbf{7}^{\bullet+}$ are similar to those of $\mathbf{4}^{\bullet+}$, in which the oxoferryl and the π-cation radical spins are also ferromagnetically coupled;[5, 6] that is, the saddle distortion of the porphyrin does not influence the coupling of the oxoferryl center to its radical.

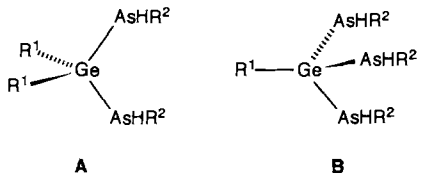
The Dimeric Tris(lithioarsino)germane *t*BuGe[As(Si*i*Pr$_3$)Li]$_3$: A Self-Assembled, Solvent-Free Lithium–Main Group Element Aggregate with a $Ge_2As_6Li_6$ Rhombododecahedral Framework**

By *Laszlo Zsolnai, Gottfried Huttner,* and *Matthias Driess**

In memoriam Joachim Rudolph

P- and/or Si-rich silylphosphanes, that is compounds with Si–P bonds, reveal a considerable structural diversity and reactivity.[1] Whether and in how far the heavy homologues of the acyclic and cyclic silylphosphanes (silaphosphanes), that is germylarsanes (Ge–As), stannylstibanes (Sn–Sb), and plumbylbismutanes (Pb–Bi), have a similarly diverse molecular chemistry, are challenging questions of current main group element chemistry that cannot be answered at present. To date very little is known about even the simple acyclic germylarsanes of the type $R_3Ge-AsH_{2-n}R_n$ (R = H, alkyl; $n = 0-2$).[2] In the course of our investigations on germylarsanes we have also studied the synthesis of primary and secondary di- and triarsinoorganogermanes of the type **A** and **B** (Scheme 1), respectively, which may be considered as synthetic building blocks for the construction of cyclic germa- and heterogermaarsanes.



Scheme 1. R^1 = alkyl, aryl; R^2 = H, triorganosilyl.

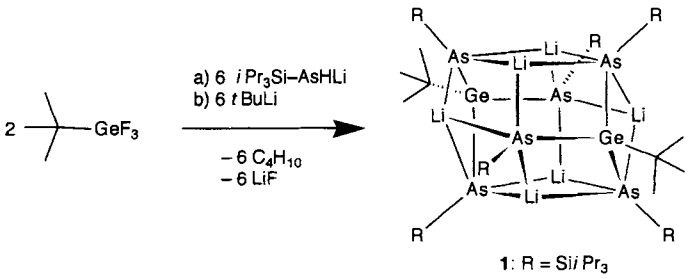
[+] X-ray structure analysis.

[**] This work was supported by the Deutsche Forschungsgemeinschaft (SFB 247) and the Fonds der Chemischen Industrie.

We recently prepared the first compounds of type **A** by the reaction of diorganodifluorogermanes with bulky substituents with lithio(triorganosilyl)arsanes.[3] It appeared to us that the next logical step was to examine whether derivatives of type **B** could be obtained from organotrifluorogermanes and three molar equivalents of lithio(triorganosilyl)arsanes. We report here on the reaction of *tert*-butyltrifluorogermane with lithio(triisopropylsilyl)arsane, in which surprisingly the dimeric, solvent-free tris[lithio(triisopropylsilyl)arsino]*tert*-butylgermane (**1**) is formed.

*t*BuGeF$_3$ reacts with LiAsH(Si*i*Pr$_3$) already at -80 °C in Et$_2$O in the molar ratio 1:6; a clear, orange solution forms, from which **1** can be isolated in the form of yellow-orange crystals in 19% yield. Apparently, in this reaction not only the complete substitution of the F atoms at the Ge atom by arsino groups, but also the subsequent lithiation of the three As atoms in the intermediately formed *t*BuGe[As(Si*i*Pr$_3$)H]$_3$ occurs very readily. In total three equivalents of lithioarsane were required for the nucleophilic substitution and three more for the lithiation. To ensure an efficient use of the lithioarsane, however, *tert*-butyllithium can also be employed as an auxiliary base; as a result of which the yield of **1** increases to 24%.



Compound **1** is the first lithioarsinoorganogermane derivative. Its molecular structure was determined by X-ray crystallography (Fig. 1).[4] Compound **1** has a $Ge_2As_6Li_6$ molecular framework with a center of symmetry; this novel

lithium–main group element aggregate has the topology of a distorted rhombododecahedron. The Ge atoms are each bound to three As atoms in the molecular framework and are thus almost ideally tetrahedrally surrounded. The Ge–As distances (average 2.444(2) Å) differ very little from one another and are similar to the values found in the Zintl phase Ba_4GeAs_4[5] and in 1,3-diarsa-4-sila-2-germacyclobutanes.[3] The Ge–Li distances of 3.18–3.19 Å are considerably longer than the sum of the van-der-Waals radii (ca. 2.02 Å) and are thus not significant for the interpretation of the bonding in the aggregate. Each As atom is bound to three Li atoms, one Ge atom, and one exocyclic $SiiPr_3$ group; thus, it is five coordinated. The coordination geometry at the arsenic atom, however, does not correspond to an ideal tetragonal pyramid: the silyl group is pushed out of its ideal position as a result of the steric hindrance caused by the neighboring *tert*-butyl group at the germanium atom (Fig. 1). The Li–As distances (2.54(2)–2.62(1) Å) also differ considerably in length, probably likewise for steric reasons. In the only lithiosilylarsanes structurally characterized to date, [LiAs(SiMe$_3$)$_2$·dme] (dimeric in the crystal)[6a] and Is$_2$SiF–As(Si*i*Pr$_3$)Li(thf)$_2$ (Is = 2,4,6-*i*Pr$_3$C$_6$H$_2$) (monomeric in the crystal),[6b] the Li–As distances are 2.59(2) and 2.46(3) Å, respectively. The coordination of the lithium centers in **1** unprecedented for a lithium silylpnictogenide is particularly noteworthy. Through the self-assembly of two tris[lithio(triisopropylsilyl)arsino]*tert*-butylgermane molecules the Li centers can be stabilized electronically without additional coordination of solvent molecules (**1** is prepared in Et_2O!). However, the surprising stability of the aggregate apparently might also result from the shielding by the sterically demanding silyl and *tert*-butyl groups. The bonding of the lithium atoms can be generally described as follows: the contributions to the electronic saturation are mainly ascribed to lithium–arsenic multicenter bonds in the sense of a cluster and less importantly also to Li–H–C interactions; the latter are formed between lithium and several hydrogen atoms of the methyl groups of the $SiiPr_3$ groups close by, which is supported by the relatively short Li–H distances (2.34(7)–2.6(1) Å) observed. The positional parameters of the methyl H atoms, considered for Li–H–C interactions (at C 9, C 13, C 16, C 22, C 27, and C 30) because of their short Li–H distances, were localized in the difference Fourier synthesis and refined. The observed positions of the relevant ligand atoms to the lithium centers can be interpreted in such a way that an almost tetragonal pyramidal coordination geometry is assigned to each Li atom; each Li atom forms strong interactions with three As and two H atoms of different methyl groups. Considerably shorter Li–H distances were observed in solvent-free organolithium compounds (e.g. 2.04(2) Å in (nBuLi)$_6$),[7a] whereas in solvent-free, hexameric lithium bis(trimethylsilyl)phosphide[7b] similar values to those in **1** were found.

The relatively high stability of the "inner complexed" $Ge_2As_6Li_6$ aggregate also becomes clear in view of the solubility of **1**, depending on the donor properties of the solvent. Thus, **1** is almost insoluble in aliphatic and aromatic solvents as well as in diethyl ether, whereas it is readily soluble in highly coordinating solvent mixtures such as THF/TMEDA (tetramethylethylenediamine) and THF/PMDETA (pentamethyldiethylenetriamine). Here a complete degradation of the aggregate into two discrete tris(triisopropylsilylarsanide)*tert*-butylgermane anions and six solvent-coordinated lithium cations (chelate complexation of the lithium atoms) probably occurs. The exact molecular structures of the thus obtained complexes are not known to date. Further investigations shall determine the structures of these complexes and the reactivity of **1**, as well as establish whether the phosphorus analogue can also be synthesized.

Experimental Procedure

A solution of *t*Bu–GeF$_3$ (878 mg, 4.69 mmol) in Et_2O (20 mL) was treated at −80 °C with LiHAs–Si*i*Pr$_3$ (14.08 mmol) [dissolved in Et_2O, prepared from H_2As–Si*i*Pr$_3$ (3.296 g, 14.08 mmol) and *t*BuLi (901 mg, 14.08 mmol, 1.5 M solution in pentane) at −80 °C in Et_2O (10 mL)]. The solution was allowed to warm to about −20 °C over the course of 2 hours, then recooled to −80 °C and a solution of *t*BuLi (901 mg, 14.08 mmol) in pentane was added. After the removal of the solvent under vacuum (10^{-2} Torr), an orange, viscous oil remained, which was taken up in hexane (10 mL). Compound **1** crystallized out after about 2 weeks. Yield: 96 mg (0.59 mmol, 24%), yellow-orange crystals; correct C, H analysis.

Relative Significance of Electrostatic- and Hydrophobic-Induced pK_a Shifts in a Model Protein: The Aspartic Acid Residue

By *Dan W. Urry*, Shao Q. Peng, Timothy M. Parker, D. Channe Gowda,* and *Roland D. Harris*

A common theme in biology is protein function that is dependent upon an amino acid residue with an unusual pK_a. In thioredoxin the amino acid residue is Asp 26 with a pK_a of 7.5,[1, 2] in chicken egg white lysozyme Glu 35 with a pK_a of 6.1,[3] in phosphofructokinase Asp 27 with pK_a values in two different functional states of 6.6 and above 9.6,[4] and in bacterial photoreaction centers Glu 212 with a pK_a of about

[**] This work was supported in part by contracts (DAAL03-92-C-0005 (to R. D. H.) from the Department of the Army, Army Research Office, and N00014-89-J-1970 (to D. W. U.) from the Department of the Navy, Office of Naval Research.

9.[5] Most commonly these shifts are explained as arising from electrostatic interactions,[6, 7] but increasingly the role of hydrophobic effects is being appreciated.[3, 8] In this communication both electrostatic- and hydrophobic-induced pK_a shifts are observed and can be compared in a family of aspartic acid containing polypentapeptides. It is argued that the most effective means of achieving a pK_a shift in water arises not from the predominance of the coulombic interactions of electrostatics, but from a competition of hydrophobic (apolar) and charged (polar) species for hydration in which the respective hydration shells cannot be shared. This results in an apolar–polar repulsive free energy of hydration that can be calculated from the magnitude of the pK_a shift in the hydrophobic domain.

Figure 1 depicts a plot of f_D, the mole fraction of pentamers containing aspartic acid (D) for the set of protein-based polymers poly[f_V(IPGVG),f_D(IPGDG)], versus pK_a, where $f_V + f_D = 1$ and where I = Ile, P = Pro, G = Gly and V = Val. As seen in Figure 1, the minimal value, found at $f_D = 0.5$ in water and at $f_D = 1.0$ in saline, is essentially 3.9, which is the normal pK_a for the carboxyl moiety of the aspartic acid residue.[9]

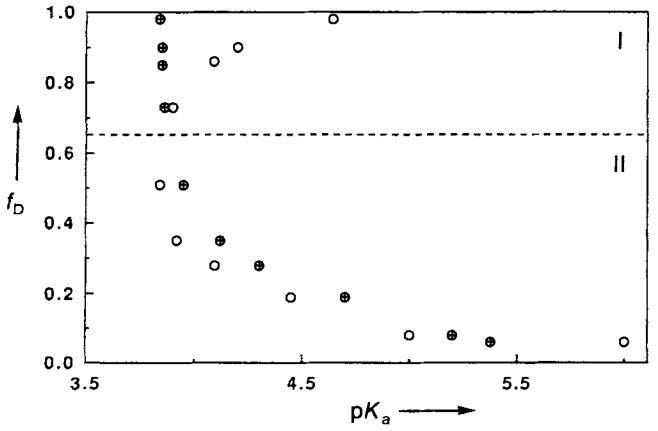

Fig. 1. The pK_a values determined by classical acid–base titrations for poly[f_V(IPGVG),f_D(IPGDG)], in which values of f_D range from 1.00 to 0.06 in water with a resistance of greater than 11 MΩ (i.e., Type 1 water) and in 0.15 M NaCl (⊕) at 37 °C (see text for further details). I: Region dominated by electrostatic interactions. II: Region dominated by hydrophobic interactions.

In water, the curve is parabolic with respect to the f_D axis; at $f_D = 1.0$ the pK_a is 4.6, and it systematically decreases to a minimum near 3.9 for $f_D = 0.5$; for values of $f_D < 0.5$ the pK_a values again increase systematically until the value of 6.0 is reached at $f_D = 0.06$. Since the positive pK_a shift decreases as the density of Asp residues (that is, negative charges) decreases to one in ten residues ($f_D = 0.5$), and as the positive shift in this region is entirely removed by the addition of 0.15 M NaCl, which can screen charge–charge interactions, the domain defined by $f_D > 0.5$ is clearly the electrostatic, or charge–charge repulsion, domain. For $f_D < 0.5$, the increase in pK_a becomes greater as the number of chargeable aspartic acid residues diminishes. Accordingly, this larger shift cannot be due to charge–charge repulsion; instead, it is proportional to the increase in hydrophobicity due to the replacement of polar aspartic acid residues with hydrophobic Val residues.

The increasing hydrophobicity as f_D decreases may be quantified using an experimental hydrophobicity scale based on the value of T_t (the temperature of the inverse temperature transition, at which hydrophobic folding, assembly, and phase transition occur on raising the temperature). The experimental value of T_t, having been determined in the polypentapeptide sequence for all of the amino acid residues,[10, 11] is seen to decrease as the hydrophobicity of the amino acid residue increases, such that a calulated mean value of T_t, i.e., $\langle T_t \rangle$, for a given polypeptide sequence, becomes a quantitative measure of hydrophobicity. In Table 1, $\langle T_t \rangle$ is seen to decrease as f_D decreases.

On the basis of this hydrophobicity scale, the domain identified by $f_D < 0.5$ is reasonably defined as the hydrophobic, or apolar–polar repulsion, domain. In 0.15 M NaCl, the charge–charge repulsion effect is entirely suppressed, and the hydrophobic-induced pK_a shift begins to appear as f_D decreases below 0.7.

Of course, the magnitude of the positive shift in pK_a due to charge–charge repulsion can be increased by increasing charge density to more than one COO^- moiety per fifteen backbone atoms of the polypentapeptide. In poly(methacrylic acid), $-(CH_3)C(COOH)CH_2-_n$, there is one COO^- moiety per two backbone atoms, a greater density than is possible for polypeptides. Here the pK_a in water is 7.3,[12] several pH units higher than that of the carboxylic acid moiety in the monomer.

In deciding the relative importance of electrostatic- and hydrophobic-induced pK_a shifts, the question becomes how large can the hydrophobic-induced shifts be in polypeptides and proteins. By using the broader family of poly(pentapeptides), poly[f_V(VPGVG),$f_{\alpha\beta}$(αPGβG)] ($f_V + f_{\alpha\beta} = 1$, where α may be one of a few hydrophobic residues, such as Val, Ile, or Phe, and β can be any of the naturally occurring amino acid residues or chemical modifications), a series of polytricosapeptides have been prepared in which a single Asp

residue occurs with five hydrophobic phenylalanine (Phe) residues per 30-mer. When the five Phe residues were placed as far from the Asp residue as possible without changing the filamentous β-spiral molecular structure of the polypentapeptides with three pentamers per turn of helix,[13, 14] the pK_a was shifted to 6.7 from the usual value of 3.9.[9] When the five Phe residues were placed as close to the Asp residue as possible but still consistent with the retention of the molecular structure, a remarkable pK_a of 10.0 was found (D. W. Urry, D. C. Gowda, S. Peng, T. M. Parker, N. Jing, R. D. Harris, unpublished results). This is a pK_a shift of 6, twice as great as that found for the excessively charge-dense poly(methacrylic acid). Thus it would appear that the capacity to shift pK_a values is greater when the apolar–polar repulsion mechanism is employed.

Our understanding of electrostatic-induced pK_a shifts comes from Coulombs law, in which the increase in energy (i.e., repulsive energy) between a pair of like charged species, q_1 and q_2, is the product of the charges q_1q_2, divided by the distance, r, and the effective dielectric constant, ε, between the two charges: $E = q_1q_2/\varepsilon r$. Polymers have been explicitly treated by Harris and Rice[15] and by Katchalsky et al.,[16] and Honig et al. have extensively considered proteins.[7, 17] There is as yet no formal expression for the apolar–polar repulsive free energy of hydration, but, as the name intends to convey, it involves the interference that each apolar (hydrophobic) and polar (e.g., charged) moiety experiences due to the presence of the other in a structurally constrained, and thereby, hydration-limiting polymer such as a protein or polypeptide. In short, when the distance between apolar and polar moieties is sufficiently short, the intervening water molecules cannot simultaneously provide the full free energy of hydration for both the apolar and polar species.

When, in the hydrophobic domain where apolar hydration dominates, the carboxyl species, for example, cannot achieve the hydration required of the carboxylate moiety, a higher hydroxyl ion concentration is required before the COOH proton can be removed to form COO^-.[10] In this case the change in chemical potential, $\Delta\mu$, of proton, as Gibbs free energy per mole, is given by $\Delta\mu = -2.3\,RT\Delta pK_a$, where $R = 1.987\ \mathrm{cal\,K^{-1}\,mol^{-1}}$ and T is in degrees Kelvin. Under these circumstances, $\Delta\mu$ becomes a direct measure of the repulsive apolar–polar free energy of hydration. On the other hand, when the charged species does form, its pull for hydration is sufficient to destructure the water of hydrophobic hydration, the driving force for hydrophobic folding and assembly is lost, and disassociation and unfolding occur.

In fact, as the number of ionized species increases, the temperature T_t, at which the hydrophobic folding and assembly transition occurs, increases.[10, 11] When the value of T_t becomes greater than the working temperature of the polypeptide or protein, disassembly and unfolding sets in. Also, as seen by differential scanning calorimetry, the endothermic heat of the transition, which is interpreted as the heat required to destructure the more structured hydrophobic hydration to form less ordered bulk water, decreases as the degree of ionization increases, consistent with the charged species destructuring of the hydrophobic hydration.[18] A more extensive discussion of these hydrophobic effects is available in references[10, 19].

Experimental Procedures

The family of polypentapeptides, poly[f_V(IPGVG),f_D(IPGDG)] with $f_D = 1.0$–0.06 for a total of ten polypentapeptides were characterized by using classical acid–base titrations to determine the pK_a values. The specific syntheses, which will be described elsewhere, were carried out analogously to those in [20] for Glu-containing peptides but with care to avoid the α/β exchange of the Asp residue, and were verified by means of amino acid analyses and ^{13}C NMR spectroscopy, which also provided accurate values for f_D (see Table 1). The acid–base titrations for the $COOH/COO^-$ couple, carried out at 37 °C as previously described [20] under argon, allowed 45 min per data point, thus requiring approximately 24 h per titration for concentrations of Asp-containing pentamers ranging from 22 to 29 mM. In general, the samples remained in a viscoelastic state until the degree of ionization was sufficient for dissolution.

High-Pressure Synthesis of LiSi: Three-Dimensional Network of Three-Bonded Si^- Ions**

By *Jürgen Evers,** *Gilbert Oehlinger,* and *Gerhard Sextl*

Lithium germanide LiGe[1] crystallizes under normal pressure (NP) with MgGa[2] structure and belongs to the Zintl phases.[3] According to current textbooks,[4] several binary Li–Si compounds such as $Li_{21}Si_5$,[5] $Li_{13}Si_4$,[6] $Li_{14}Si_6$,[7] and $Li_{12}Si_7$[8] have been characterized, however, "LiSi is not known".[4]

Our investigations also confirmed the results of previous experimenters: simple fusion of equimolar amounts of Li and Si at NP always results in a phase mixture, but never in LiSi. LiSi should be stabilized with respect to a mixture

consisting of 1/12 $Li_{12}Si_7$ and 5/12 Si, however, if, under sufficiently high pressure, it could be considerably more densely packed than the mixture. For this reason, a high-pressure (HP) synthesis was attempted in boron nitride and molybdenum crucibles by using the Belt apparatus according to Equation (a). Typical reaction conditions were p = 4 GPa, T = 600 °C, t = 5 min: after this time the reaction

$$Li_{12}Si_7 + 5\,Si \rightleftharpoons 12\,LiSi \qquad (a)$$

mixture was quenched to room temperature and the pressure relieved. It proved favorable to use an excess of Li (10 atom%) in the starting mixture. Due to the high sensitivity of the reactions towards both air and moisture, all preparative work with open crucibles was performed in a glove box.

The Guinier diffractogram ($Cu_{K\alpha 1}$ radiation) of the reaction product was indexed by the Dicvol method[9] and found to have a tetragonal unit cell and very good reliability indices (F_{20} = 36, M_{20} = 40).[10] The sequence of the reflections and the course of the intensities indicate that the structures of LiSi and NP-LiGe[1] are isotypic (MgGa structure[2]) (Rietveld method[11]). A single-crystal X-ray analysis[12, 13] confirmed the results of the powder experiment.

According to the Zintl–Klemm concept,[3] silicon in Li^+Si^-, like a phosphorus atom in elemental phosphorus, possesses five valence electrons and has, correspondingly, three nearest Si neighbors (241.7(6) (2×) and 250.2(6) pm). The Si-Si-Si bond angles are 107.2(2), 110.7(2), and 117.9(2)°. The Si–Si bond length of 250.2 pm in LiSi is one of the longest yet observed in binary metal silicides. Longer Si–Si distances have only been found in organometallic compounds with bulky *tert*-butyl groups, such as in hexa(*tert*-butyl)disilane (Si–Si = 269.7 pm).[14, 15] Typical Si–Si bond lengths in $Li_{14}Si_6$ and $Li_{12}Si_7$ lie in the range 233–239 pm.[7, 8]

Lithium silicide forms a three-dimensional network in which each Si^- ion is connected with three further Si^- ions (Fig. 1). A three-dimensional arrangement of Si^- ions is also

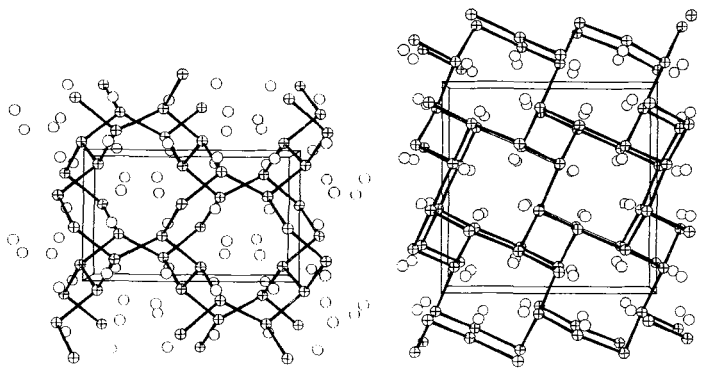

Fig. 1. Lithium silicide, LiSi (MgGa structure): three-dimensional network of three-bonded Si^- ions. Right: view along [001]; left: view along [100]. ○ = Li, ⊗ = Si.

found in $SrSi_2$[16, 17] and in α-$ThSi_2$.[18, 19] As in LiSi, the cavities in these three-dimensional networks are also filled by cations. A stabilization of this type in structures formed by elemental phosphorus requires that these disproportionate to form cations and anions. For this reason, the structures formed by elemental phosphorus that have been observed until now, all consist of isolated tetrahedra and layers of three-bonded P atoms which pack together without the formation of larger cavities. The structure of β-manganese,[20, 21] on the other hand, may be considered as a three-dimensional network of $Mn^{\delta-}$ atoms, whose cavities are filled by $Mn^{\delta+}$ atoms. In the space group $P4_332$ (a = 631.5(2) pm), the three-bonded $Mn^{\delta-}$ atoms (bond length 236.4(2) pm),[21] like the Si^- ions in NP-$SrSi_2$ (a = 653.5(3) pm, bond length 239.2(1) pm),[17, 22] occupy the 8c site with very similar site parameters.

In LiSi, the three-dimensional network contains fourfold screw axes of silicon atoms aligned along the a axis; neighboring screw axes are of opposite chirality. The two shorter Si–Si distances (241.7 pm) and the smaller Si-Si-Si bond angles (107.2, 110.7°) are found between atoms of one particular fourfold axis. Cross-linking of the fourfold screw axes with one another leads to formation of the longer Si–Si bond (250.2 pm) and the larger Si-Si-Si bond angle (117.9°). The puckered Si_8 rings formed in this manner are centered on z = 1/8, 3/8, 5/8, and 7/8. The Li^+ cations are arranged as tetrahedra and are located in the cavities formed by the Si_8 rings. The tetrahedron centers are displaced by $c/2$ with respect to the Si_8 rings. Each Li^+ ion has six Li^+ neighbors within a distance of 305 pm; three of these are in the same tetrahedron, two in the next nearest and one in the next nearest but one. The long Li–Li distances effectively rule out a discussion of tetrahedral Li_4 clusters with bonding Li–Li interactions.

Each Li^+ cation has eight Si neighbors within a distance of 326 pm (and vice versa). Five of these come from the nearest fourfold Si screw axis, two from the next nearest and one from the next nearest but one. This implies a formal 8:8 coordination in the three-dimensional network structure of LiSi. 1:1 silicides of the heavier alkali metals (Na–Cs) have lower coordination numbers. In these alkali metal silicides the three-bonded Si^- ions form isolated tetrahedra, as also found for P atoms in white phosphorus. NaSi with the NaSi structure[23] formally has a 6:6 coordination, as have NP-KSi, NP-RbSi, and NP-CsSi with the KGe structure.[24] In contrast, HP-KSi, HP-RbSi, and HP-CsSi[25] with the NaPb structure[26] achieve 7:7 coordination. NaSi could possibly be converted into another modification under HP, but a new phase has not yet been proven on quenching from pressures of up to 4 GPa.

$$5\,Li + 7\,LiSi \rightleftharpoons Li_{12}Si_7 \qquad (b)$$

$$12\,LiSi \rightleftharpoons Li_{12}Si_7 + 5\,Si \qquad (c)$$

Although it is synthesized under high-pressure conditions, LiSi is, somewhat surprisingly, not a metastable HP phase under normal conditions. This is confirmed first by coulometric titrations and second by thermal analysis. Reaction (b) (NP, 400 °C, LiCl/KCl melt) can be reversed by reversing the polarity, resulting in a negative free energy of formation.[27] The thermogram (NP, Ta crucible, Ar atmosphere) shows an endothermic signal between 470–490 °C ($\Delta H = +0.9 \pm 0.2$ kJ mol^{-1}) which may be attributed to reaction (c). A strongly endothermic signal is observed at 590 ± 10 °C, which corresponds to the melting point of the eutectic in the Li–Si phase diagram.[28] In attempting to prepare LiSi by cooling a LiSi melt, it has to be taken into consideration that NP-LiSi is thermodynamically unstable above 470 °C under NP. Thus, LiSi can only be prepared under NP at temperatures below 470 °C. The formation of LiSi from the phase mixture is extremely slow under these conditions due to kinetic hindrance. In ignorance of this, earlier experiments at NP failed due to a lack of patience. At HP (4 GPa, 600 °C, 5 min), the synthesis is achieved in a shorter time, since LiSi is about 6% more densely packed than the mixture, and thus a rise in pressure leads to its

formation in accordance with Le Chatelier's principle ($-p$, ΔV).

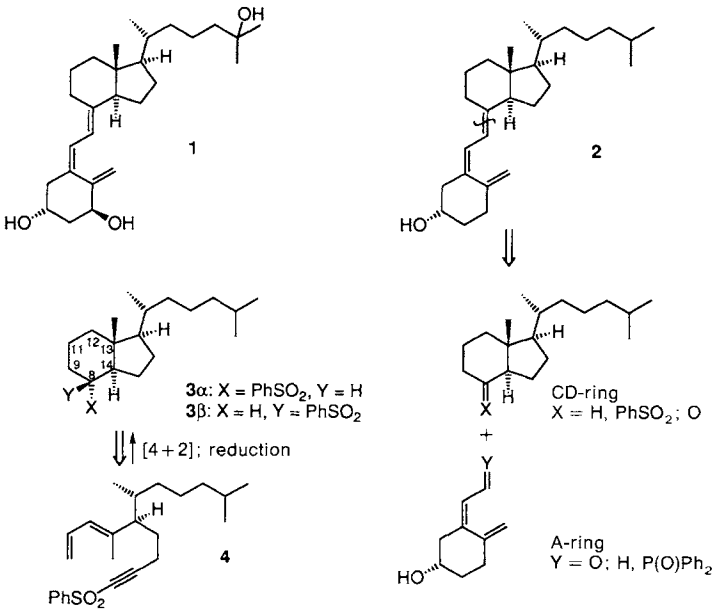
Vitamin D_3 Synthetic Studies: Enantiospecific Synthesis of the CD Ring Fragment**

By *Martin C. Clasby, Donald Craig,** and *Andrew Marsh*

The discovery that 1α,25-dihydroxy vitamin D_3 (**1**), the hormonally active form of vitamin D_3 (**2**),[1] induces cellular differentiation and suppresses cell proliferation[2] has aroused renewed interest in this classical synthetic target.[3] Many of the published synthetic approaches to this class of compounds involve coupling of CD-ring and A-ring fragments by olefination procedures such as the Julia[4] and Wadsworth–Emmons[5] reactions. This strategy is particularly attractive for the synthesis of semisynthetic analogs of **1** and **2** as drug candidates;[6] combination of modified A- and CD-ring fragments prepared by chemical elaboration of degradatively derived materials allows access to a wide range of unnatural vitamin D_3 mimics.



In this context, there has recently been an upsurge in research aimed at developing both new methods for A-ring assembly and improved procedures for coupling these intermediates with CD-ring units.[7] We have embarked on a program seeking on synthesize analogs of vitamin D_3 in which the CD-ring fragment is assembled by total synthesis. Such an approach is uniquely able to deliver analogs of the natural system incorporating extremely subtle structural changes, including isotopically labeled materials, which may serve as probes of the origins of biological activity.

We selected the known[4b] bicyclic sulfones **3** as the synthetic target. We envisaged that **3** would be accessible by stereoselective dihydrogenation of the product of the intramolecular Diels–Alder (IMDA) reaction[8] of dienynylsulfone **4**.[9, 10] This approach contrasts with existing IMDA-based strategies,[11] in that the C8–C9 and C13–C14 bonds rather than the C11–C12 and C13–C14 bonds are formed in the cyclization reaction. The stereocenters in IMDA substrate **4** would be installed by using a combination of the chiral pool[12] and the well-established asymmetric enolate alkylation methodology developed by Evans et al.[13]

Our synthesis of **3** started from (+)-(*R*)-citronellic acid, which was prepared on about a 1 mol scale in 61% yield from (+)-(*R*)-pulegone according to a published procedure.[14] Catalytic hydrogenation gave (+)-(*R*)-dihydrocitronellic acid, which was converted into the corresponding acid chloride **5** by thionyl chloride. Treatment of the anion of oxazolidone **6**[15] with **5** gave the crystalline[16] *N*-acyloxazolidone **7** in good yield (Scheme 1). Allylation of the sodium enolate[17] of **7** at low temperature proceeded efficiently with ≥20:1 diastereoselectivity to give alkene **8** as an oil after chromatographic separation of the diastereomers. Removal of the chiral auxiliary was attempted by several liter-

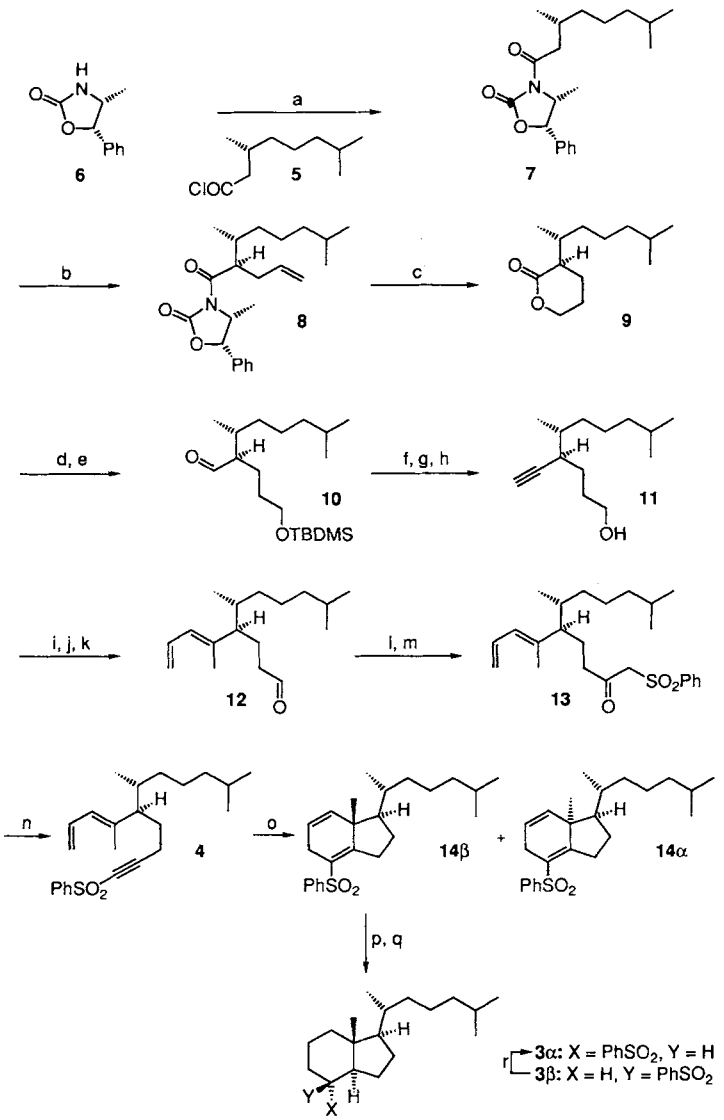
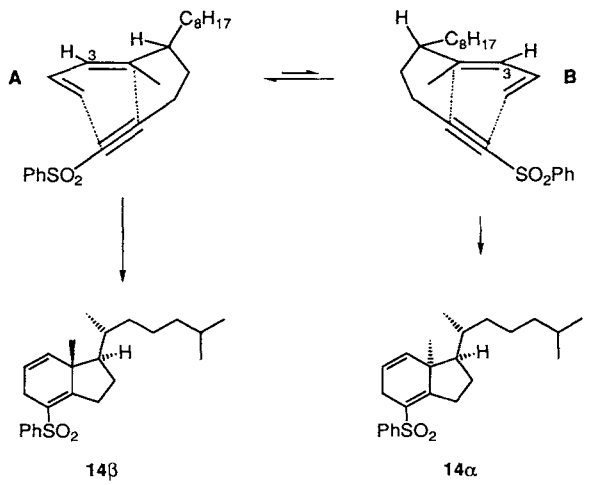
ature procedures.[18] Exposure of **8** to trimethylaluminum–*O*,*N*-dimethylhydroxylamine[19] resulted in incomplete cleavage of the oxazolidone moiety. Compound **8** was poorly reactive towards lithium benzyloxide,[20] and sodium benzyloxide caused extensive (approximately 20%) epimerization at the α-stereocenter. Finally hydroboration of **8** with oxidative workup gave the expected primary alcohol, which was treated crude with *catalytic* potassium *tert*-butoxide[21] to give δ-lactone **9** in good overall yield for the two steps from **8**. Reduction of **9** mediated by diisobutylaluminum hydride to form the corresponding lactol, followed by chemoselective silylation[22] of the open-chain tautomer, gave the protected δ-hydroxyaldehyde **10**. Incorporation of the alkyne unit in readiness for diene assembly was accomplished by sequential *Z*-selective iodomethylenation,[23] potassium *tert*-butoxide induced E2 elimination, and desilylation with tetrabutylammonium fluoride to give alkynol **11**.[24] In order to ensure *E*-specificity during the formation of the 1,3-diene unit, we subjected **11** to the *syn*-specific, zirconocene dichloride mediated carbometalation procedure developed by Negishi,[25] trapping the intermediate vinylalane with iodine. Palladium(0)-mediated coupling of the resulting *E*-iodoalkene with vinylmagnesium bromide[26] and oxidation of the product alcohol with dimethylsulfoxide activated with oxalyl chloride[27] gave dienal **12** in high yield (from **11**).[28] The final phase of the synthesis of IMDA substrate **4** involved the introduction of the dienophile group, alkynylsulfone. This was effected with our recently published procedure.[29] Thus, addition of **12** to lithio(phenylsulfonyl)methane gave a mixture of diastereomeric β-hydroxysulfones, which were oxidized with pyridinium dichromate to the β-ketosulfone **13**. Treatment of **13** with triflic anhydride in the presence of Hünig's base gave dienyne **4** in excellent yield.



Scheme 1. a) *n*BuLi, THF, −78 °C, **+5**, −78 °C → room temperature (RT) (71%). b) $NaN(SiMe_3)_2$ (NaHMDS), THF, −78 °C; $CH_2=CHCH_2Br$, −78 °C → −50 °C, 5 h; −50 °C, 12 h (87%). c) 1: 9-Borabicyclo[3.3.1]nonane, THF, RT; NaOH, 30% w/v H_2O_2, 0 °C; 2: KO*t*Bu (0.02 equiv.), *t*BuOH (20 equiv.), THF, 0 °C (72%). d) iBu_2AlH, PhMe, −78 °C (87%). e) $TBDMSOSO_2CF_3$, Et_3N, CH_2Cl_2 (79%). f) $[Ph_3PCH_2I]I$, NaHMDS, THF, −78 °C (82%). g) KO*t*Bu (2 equiv.), THF, −78 °C (97%). h) nBu_4NF (2 equiv.), THF, RT (98%). i) Me_3Al, $[(C_5H_5)_2ZrCl_2$, $ClCH_2CH_2Cl$; I_2, THF (88%). j) $CH_2=CHMgBr$ (3 equiv.), $(Ph_3P)_4Pd$ (0.05 equiv.), PhMe–THF, RT (90%). k) $(COCl)_2$, dimethylsulfoxide, Et_3N, CH_2Cl_2, −60 °C → RT (79%). l) $PhSO_2Me$, *n*BuLi, THF, −78 °C, **+11** (90%). m) $(pyH^+)_2Cr_2O_7$, 4 Å molecular sieves, CH_2Cl_2, RT (71%). n) $(CF_3SO_2)_2O$ (1 equiv.), $EtNiPr_2$ (3 equiv.), CH_2Cl_2, 0 °C (93%). o) PhMe, 115 °C, 9 h (99%). p) H_2, 10% Pd/C, EtOAc (99%). q) $LiAlH_4$ (1 equiv.), THF, reflux, 20 min (**3α**: 76%; **3β**: 8%). r) KO*t*Bu (4 equiv.), *t*BuOH (40 equiv.), THF, RT, 1 h (99%).

The selectivity, albeit modest, of the cyclization of **4** to give **14** may be rationalized by considering the competing transition-state conformations (Scheme 2). In conformation **A**, $A_{1,3}$ strain between the diene H3 and H5 is less than that between H3 and the α-branched side chain in conformation **B**.



Scheme 2. **14β** is the major product.

In summary, we have accomplished the enantiospecific synthesis of the key building block **3** of vitamin D_3 in 18 steps from commercially available oxazolidone **6** and (+)-(*R*)-dihydrocitronellyl chloride. The highly convergent nature of the synthetic sequence makes it especially attractive for the synthesis of structural analogs of the natural systems that are inaccessible with semisynthetic or degradative procedures. We are currently exploring new methods for the construction of the A-ring unit, and are actively investigating novel coupling strategies. The results of these studies will be reported in due course.

Carbonyl–Metal Complexes of Diphosphadiboretane (mesB–P*t*Bu)$_2$ and of Triphosphatriborinanes (mesB–P*t*Bu)$_3$**

By *Bernhard Kaufmann, Heinrich Nöth*, Robert T. Paine, Kurt Polborn*, and *Martina Thomann*

Dedicated to Professor Hans Bock on the occasion of his 65th birthday

2,4-Bis(dialkylamino)-1,3-diorgano-1,3,2,4-diphosphadiboretanes **1** react with $[Cr(CO)_6]$ or $[Cr(CO)_5(thf)]$ to yield the mononuclear metal carbonyl complexes **2** or the binuclear complexes **3**, respectively.[1] If bulky amino groups such as the 2,2,6,6-tetramethylpiperidino group (R_2N = tmp) are bound to the B atoms, cycloreversion occurs, and allene-analogous complexes are formed, for example **4**, which contain a B–P double bond.[2] The stability of **4**, like that of the borylideneammonium ions $[R_2N{=}BX]^+$ (X = NR_2, OR, R),[3] is afforded by the BN π-bond. We, therefore expected that compounds of the types **2** or **3** would form, when tetraorgano-1,3,2,4-diphosphadiboretanes (RB-PR′)$_2$ react with metal carbonyls.

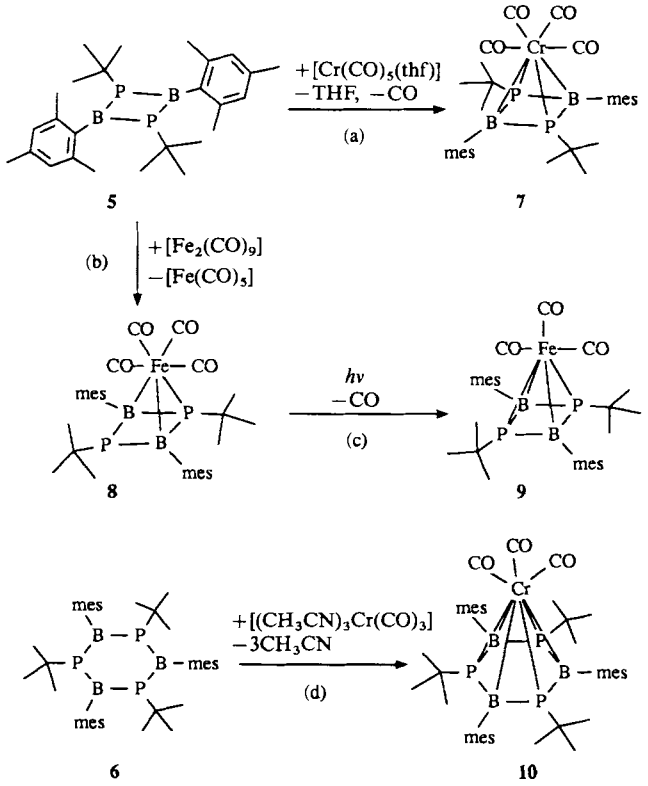
complex when irradiated with UV light, releases one CO ligand to afford **9** [Eq. (c)]. Ligand **5** thus differs from the compounds **1** by its pronounced ability to form clusters with metal carbonyl fragments. Compound **10** is obtained [Eq. (d)] as golden yellow fine needles analogously to Equation (a) from 1,3,5,2,4,6-triphosphatriborinane (**6**). The B



nuclei in **5** are shielded distinctly better ($\delta^{11}B = 86.2$) than those in the thexyl (tex) compound (texB–Pmes)$_2$, ($\delta^{11}B = 95.1$),[5] but they show almost the same chemical shift as those of the mesityl derivative (mesB–Pmes)$_2$ ($\delta^{11}B = 86.3$).[4] The ^{11}B NMR signals of complexes **7** and **9** are considerably shifted upfield ($\Delta\delta^{11}B = 56.5, 78.9$) in comparison to those of **5**. The improved shielding effected by a central Fe atom in a complex (e.g., in **9**) exceeds that of a central Cr atom (**7**) by $\Delta\delta > 20$, because the HOMO of the Fe(CO)$_3$ group allows for a stronger interaction between the metal d-electrons and the orbitals of the B atoms than the HOMO of the Cr(CO)$_4$ group.

The ^{31}P NMR signal of **5** is substantially shifted toward high field ($\Delta\delta^{31}P = 50.4, 64.5$) relative to that of (texB–Pmes)$_2$ ($\delta^{31}P = 80$)[5] and (mesB–Pmes)$_2$ ($\delta^{31}P = 65$).[4] The ^{31}P nuclei in the complexes **7** and **9** are much more strongly shielded, though. The ^{31}P NMR spectrum of **8** shows two downfield-shifted signals ($\Delta\delta^{31}P = -4.0, -38.4$), whereas the B atoms in **8** are shielded better than those in **5** by $\Delta\delta = 56$. Thus the bonding conditions in **7**, **8**, and **9** are mutually comparable. These data support the notion that the Fe(CO)$_4$ group in **8** is η^3-bound to a B_2P ring entity, whereas the diphosphadiboretane ligand in **7** and **9** is η^4-coordinated. This assignment is corroborated by the ^{13}C NMR spectra as well, which, in addition, display a single signal for the C atoms of the carbonyl groups. Consequently the carbonyl groups exhibit fluxional behavior at ambient temperature. The bonding parameters and conformations of **5**,[6] **7** (Fig. 1) and **9** (Fig. 2) were determined by X-ray structure analysis.

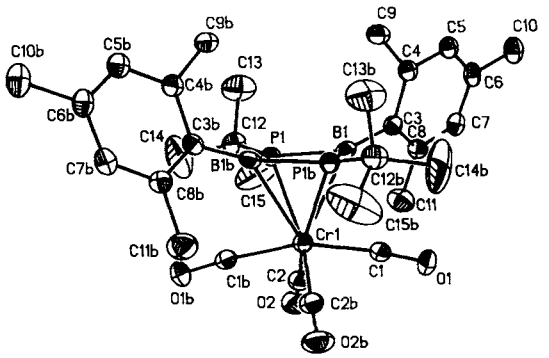


Fig. 1. Molecular structure of one of the two independent molecules **7** (ORTEP). H atoms are not shown, for clarity. Selected bond lengths [Å] and bond angles [°]: P1-B1 1.864(6), P1-B1b 1.911(7), Cr-P1 2.400(3), Cr-B1 2.542(7), Cr-C1 1.877(6), Cr-C2 1.853(7), B1-C3 1.573(9), P1-C12 1.858(7); B1-P1-B1b 93.8(3), P1-B1-P1b 85.8(3), B1-P1-C12 130.0(3), B1b-P1-C12 133.8(3), P1-B1-C3 133.6(4), C3-B1-P1b 137.0(4), P1-Cr-P1b 64.8(1), B1-Cr-B1b 65.6(3), P1-Cr-B1 44.2(1), P1-Cr-C1 113.3(2), P1-Cr-C2 99.7(2), B1-Cr-C1 71.2(2), B1-Cr-C2 109.7(3), C1-Cr-C2 85.8(3).

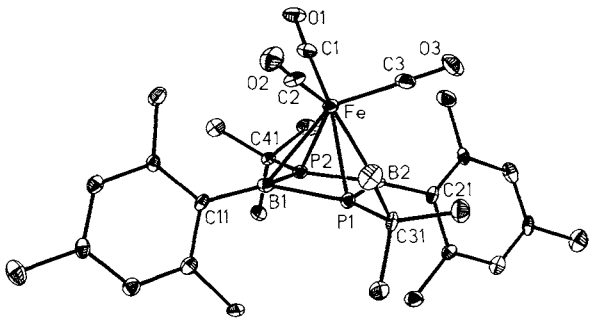

Fig. 2. Molecular structure of **9** (ORTEP). H atoms are not shown, for clarity. Selected bond lengths [Å] and bond angles [°]: P1-B1 1.94(1), P1-B2 1.910(8), P2-B1 1.888(8), P2-B2 1.872(10), Fe-P1 2.289(3), Fe-P2 2.294(2), Fe-B1 2.339(9), Fe-B2 2.325(9), Fe-C1 1.763(8), Fe-C2 1.771(9), Fe-C3 1.785(10), P1-C31 1.862(7), P2-C41 1.841(7), B1-C11 1.541(13), B2-C21 1.566(12); P1-B1-P2 83.5(4), B1-P2-B2 97.3(4), P2-B2-P1 84.7(4), B2-P1-B1 94.3(4), P1-Fe-P2 67.6(1), B1-Fe-B2 74.5(3), B1-Fe-P1 49.5(2), P2-Fe-B1 48.1(2), P1-Fe-B2 48.9(2), P2-Fe-B2 47.8(2), B1-P1-C31 136.2(4), B2-P1-C31 129.2(4), B1-P2-C41 130.1(4), B2-P2-C41 132.5(4), P1-B1-C11 136.0(5), P2-B1-C11 135.9(6), P1-B2-C21 134.1(6), P2-B2-C21 136.9(5).

The B–P bonds of the planar B_2P_2 four-membered ring in **5** [1.901(5) Å, 1.892(4) Å] are to be perceived as equally long.[7] They are, however, significantly shorter than those in most diphosphadiboretanes of the type **1** (1.94–1.97 Å).[8] On clustering to form **7** and **9**, the B_2P_2 four-membered ring of **5** is slightly deformed toward a diamond shape, which gives rise to a differentiation in the lengths of the B–P bonds [1.911(7) and 1.864(6) Å in **7**; 1.94(1), 1,910(8), 1.87(1), 1.888(8) Å in **9**]. The B atoms in **5** have a strictly planar configuration, as opposed to the B atoms in **7** (sum Σ of the bond angles at the B atoms in the B_2P_2 four-membered ring: 355.7°) and **9** (Σ = 357.5°). The formation of the clusters **7** and **9**, though, causes the P atoms in these compounds to become surrounded by the atoms B and C in an almost planar geometry (Σ = 357.5° in **7** and 359.8° in **9**), in contrast to the pyramidalized P atoms in **5** (Σ = 329.3°). There is another important difference between **5** on one hand and **7** and **9** on the other: The B_2P_2 four-membered rings in the clusters are folded: the angles between the P-B-P planes and an idealized planar structure are 10.4° in **7** and 3.9° in **9**. The B–C and P–C bonds are not significantly affected.

The P–Cr bond in **7** is distinctly longer (2.400(3) Å) than the P–Fe distances in **9** [2.289(3), 2.294(2) Å]. The boron–

metal distances are only slightly larger [2.542(7) Å in **7** and 2.339(9), 2.325(9) Å in **9**]. Although the covalent radius of a B atom ($r \approx 0.85$ Å) is smaller than that of a P atom ($r \approx 1.1$ Å), the boron–metal distances fall in the range of those in metallaboranes and metallacarboranes.[9] The B–Fe bonds in **9** are shorter than the B–Cr bonds in **7**, which is consistent with the smaller atomic radius of Fe.

While the change in the configuration of **5** on cluster formation (**7**, **9**) has been proven unambiguously, the discussion about the structure of **10** must be based on NMR data alone. The upfield shifts of $\Delta\delta \approx 40$, observed for both the ^{11}B and the ^{31}P signals, correspond to the differences between **5** and **7**. This fact justifies the proposition of an essentially planar CPB_2 configuration and of a structure analogous to **7**.[10] It also indicates some strong interaction between the Cr and the B atoms, beyond the metal-phosphorus coordination. Whether ligand **6** contains a planar six-membered ring, as $(mesB-PC_6H_{11})_3$ does,[11] remains unknown at present.

According to the Rudolph–Williams–Wade rules,[12] **8** may be considered as an *arachno* cluster, and the complexes **7**, **9** and **10** as *nido* clusters. Diazadiboretane(carbonyl)metal complexes $[(CO)_nM(RN-BR')_2]$, for example, are counted among the *nido* clusters, too.[13] Rehybridization at the N atoms does not necessarily occur when the complex is formed from the BN heterocycle and the complex fragment, because the N atoms in the free ligand are surrounded by their bonding partners in a planar geometry anyway. Attempts to convert the above *nido* clusters into *closo* clusters $[(RB-PR)_n\{M(CO)_n\}_2]$ by reactions with carbonyl complex fragments have remained unsuccessful so far.

Experimental

7: $[Cr(CO)_6]$ (1.21 g, 5.50 mmol) in 70 mL THF was converted into $[Cr(CO)_5(thf)]$ by irradiation (Hg vapor lamp, Hanovia S200W). The solution was slowly pipetted to a stirred solution of **5** (0.57 g, 1.31 mmol) in 20 mL hexane. After stirring for about 15 h, the volatiles were removed in vacuo. The residue was treated with 30 mL hexane, insolubles were fritted off, and the product crystallized at −30 °C. Yield: 0.34 g, 0.57 mmol, 52%; small yellow rods, m.p. 174 °C (decomp.; discoloration to brown above 125 °C). ^{1}H NMR (400 MHz, C_6D_6): $\delta = 1.04$ (pseudo t, N [16] = 19.0 Hz, 18 H, *t*Bu), 2.11 (s, 6 H, *p*-CH_3), 2.60 (s, 12 H, *o*-CH_3), 6.79 (s, 4 H, *m*-H); ^{13}C NMR (50 MHz, C_6D_6): $\delta = 21.0$ (s, *p*-CH_3), 25.4 (s, *o*-CH_3), 30.4 (d, $^2J(P,C) = 27.0$ Hz, $C(CH_3)_3$), 37.2 (d, $^1J(P,H) = 25.0$ Hz, $C(CH_3)_3$), 128.9 (s, *m*-C), 138.0 (s, *o*-C), 140.6 (s, *p*-C), 229.2 (t, $^2J(P,C) = 7.0$ Hz, CO); ^{31}P NMR (81 MHz, C_6D_6): $\delta = -39.8$; ^{11}B NMR (64 MHz, C_6D_6): $\delta = 29.7$, ($h_{\frac{1}{2}} = 525$ Hz); MS (70 eV): *m/z* 544 ($M^+ - 2CO$, 5%), 516 ($M^+ - 3CO$, 7%) 488 ($M^+ - 4CO$, 14%), 438 (51%), 436 ($M^+ - Cr(CO)_4$, 39%), 432 ($M^+ - 4CO$ − *iso*-butene, 34%), 379 ($M^+ - Cr(CO)_4 - t$Bu, 69%), 249 ($M^+ - Cr(CO)_4 - t$Bu − mesB, 100%); IR (Hostaflon): $\tilde{\nu}$(C≡O)[cm^{-1}] = 2000.4, 1991.3, 1918.0, 1899.4.

8: A solution of $[Fe_2(CO)_9]$ (0.38 g, 1.04 mmol) in benzene (25 mL) was slowly added dropwise to a stirred solution of **5** (0.45 g, 1.04 mmol) in hexane (20 mL), at ambient temperature. After 3 days all volatiles were removed from the dark brown solution in vacuo (oil pump). The residue was extracted with 25 mL pentane. Insolubles were removed by filtration. At −30 °C **8** crystallized in dark red platelets, which gradually decayed in daylight to yellow **9** ($\delta^{31}P = -53.7$). Yield: 0.45 g (0.74 mmol, 75%); m.p. 244 °C (decomp. > 233 °C); ^{1}H NMR (400 MHz, C_6D_6): $\delta = 0.94$ (d, $^3J(P,H) = 18.1$ Hz, 9 H, *t*Bu), 1.12 (d, $^3J(P,H) = 16.9$ Hz, 9 H, *t*Bu'), 2.14 ($N = 6.2$ Hz, 6 H, *p*-CH_3), 2.68 ($N = 14.2$ Hz, 12 H, *o*-CH_3), 6.83 ($N = 25.9$ Hz, 4 H, *m*-H); ^{13}C NMR (50 MHz, C_6D_6): $\delta = 21.0$ (s, *p*-CH_3), 25.2 (m, $N = 77.2$ Hz, *o*-CH_3), 28.5 (s, $C(CH_3)_3$), 29.6 (s, $C(CH_3)_3$), 34.4 ($N = 38$ Hz, $C(CH_3)_3$), 129.2 (s, *m*-C), 129.3 (s, *m*-C'), 139.2 (s, *o*-C), 139.6 (s, *o*-C'), 141.4 (s, *p*-C); 215.6 (s, CO); ^{31}P NMR (81 MHz, C_6D_6): $\delta = 14.6$ ($h_{\frac{1}{2}} = 180$ Hz), 49.0 ($h_{\frac{1}{2}} = 160$ Hz); ^{11}B NMR (64 MHz, C_6D_6): $\delta = 8.5$, $h_{\frac{1}{2}} = 520$ Hz; IR (Hostaflon): $\tilde{\nu}$(C≡O)[cm^{-1}] = 2022.5, 1969.7, 1957.7.

9: A solution of **7** (0.19 g, 0.31 mmol) in 5 mL toluene is irradiated (Hg vapor lamp, Hanovia S200W) in a quartz cuvette for 8 h. Addition of 5 mL of pentane effects crystallization of **9** as light yellow platelets. at −30 °C. Yield: 0.11 g (0.18 mmol, 58%); m.p. > 250 °C (decomp.); ^{1}H NMR (200 MHz, C_6D_6): $\delta = 0.98$ (pseudo-t, $N = 19.5$ Hz, 18 H, *t*Bu), 2.16 (s, 6 H, *p*-CH_3), 2.65 (s, 12 H, *o*-CH_3), 6.70 (s, 4 H, *m*-H); ^{13}C NMR (50 MHz, C_6D_6) $\delta = 21.1$ (s, *p*-CH_3), 25.9 (s, *o*-CH_3), 30.8 (s, $C(CH_3)_3$), 35.7 (pseudo-t, $N = 18.1$ Hz, $C(CH_3)_3$), 129.3 (s, *m*-C), 137.4 (s, *o*-C), 142.0 (s, *p*-C), 218.4 (s, CO); ^{31}P NMR (81 MHz, C_6D_6): $\delta = -53.9$, $h_{\frac{1}{2}} = 150$ Hz; ^{11}B NMR (64 MHz, C_6D_6): $\delta = 7.3$, $h(1/2) = 340$ Hz; IR (Hostaflon): $\tilde{\nu}$(C≡O[cm^{-1}] = 2002.9, 1946.1, 1933.9.

10: $[(CH_3CN)_3Cr(CO)_3]$ (0.35 g, 1.4 mmol) was added to a stirred solution of **6** (0.45 g, 0.69 mmol) in dioxan (150 mL). Twice a day 50 mL of dioxan was distilled off at 1 torr, and the same volume of dioxan was replenished. After 8 days the red solution was filtered, and the dioxan distilled off at 1 torr. At −30 °C the residue deposits **10** as golden yellow, very fine needles, from toluene/hexane. Yield: 0.37 g (0.47 mmol, 69%); m.p. > 250 °C (decomp.); ^{1}H NMR (400 MHz, C_6D_6): $\delta = 1.08$ (m, $N = 17$ Hz, 27 H, *t*Bu), 2.12 (s, 9 H, *p*-CH_3), 2.56 (s, 9 H, *o*-CH_3), 2.94 (s, 9 H, *o*-CH_3), 6.74 (s, 3 H, *m*-H), 6.80 (s, 3 H, *m*-H'); ^{13}C NMR (50 MHz, C_6D_6): $\delta = 21.1$ (s, *p*-CH_3), 25.5 (s, *o*-CH_3), 27.0 (s, *o*-C'H_3), 31.5 (s, $C(CH_3)_3$), 40.9 (s, $C(CH_3)_3$), 129.3 (s, *m*-C), 129.5 (s, *m*-C'), 137.7 (s, *o*-C), 142.2 (s, *p*-C), 243.9 (s, CO); ^{31}P NMR (81 MHz, C_6D_6): $\delta = 20.3$, $h_{\frac{1}{2}} = 150$ Hz; ^{11}B NMR (64 MHz, C_6D_6): $\delta = 20.9$, $h_{\frac{1}{2}} = 480$ Hz. MS (70 eV): *m/z* 790 (M^+, 11%), 706 ($M^+ - 3CO$, 100%), 649 ($M^+ - 3CO - t$Bu, 15%), 597 ($M^+ - Cr(CO)_3$, 34%), 592 ($M^+ - 3CO - 2t$Bu, 27%), 535 ($M^+ - 3Cr(CO)_3$ − mes, 13%); IR(CH_2Cl_2): $\tilde{\nu}$(C≡O)[cm^{-1}] = 1930.7, 1863.0.

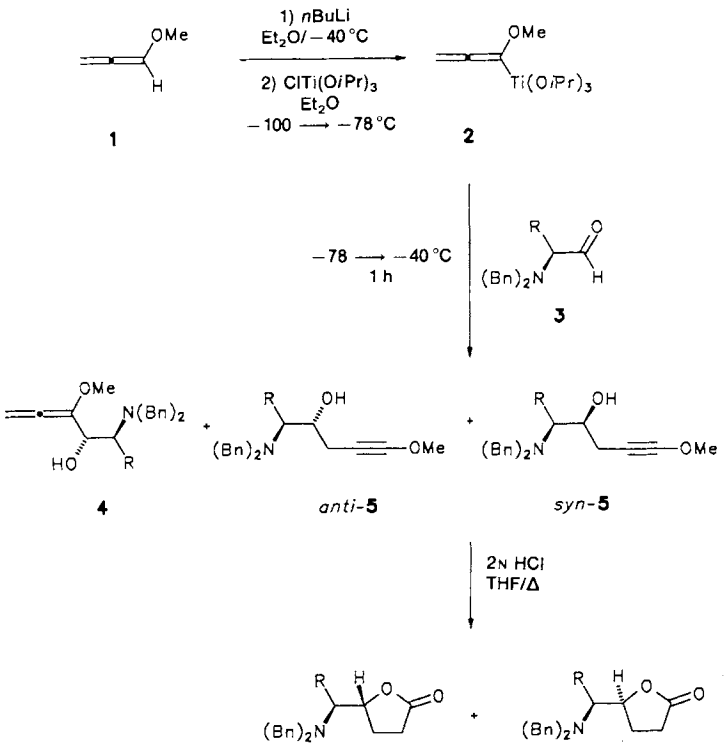
Titanated Methoxyallene as Novel Homoaldol Equivalent for Diastereoselective Additions to Chiral Amino Aldehydes**

By *Stephan Hormuth, Hans-Ulrich Reissig,** and *Dieter Dorsch**

Dedicated to Professor R. W. Hoffmann on the occasion of his 60th birthday

Methoxyallene **1** is a structural unit which has found many applications in organic synthesis.[1] Thus the lithium derivative of methoxyallene can be used as synthetic equivalent of the α-acrolein anion[2] and has recently also been applied in diastereoselective reactions with α-amino aldehydes.[3] We have now investigated whether it is also possible to achieve γ-additions to produce methoxyalkyne derivatives by changing the metal. Several other research groups have already reported on such reactions for other metalated allene derivatives. Especially with allenyltitanium compounds it was hoped that in analogy to allyltitanium compounds a very high γ-selectivity could be expected; no results were available for hetero substituted allenyl titanium compounds.[5] Such addition to α-amino aldehydes would open a new, possibly diastereoselective, path to precursors of homostatine derivatives,[6] which are of major significance as the components of some inhibitors of aspartyl proteases such as renin,[7] a blood pressure regulatory enzyme, and HIV-1 protease, an enzyme which is involved in the production of infectious HIV particles.[8] We report here on the diastereoselective additions of titanated methoxyallene **2** to α-*N*,*N*-dibenzyl amino aldehydes **3**, which result in methoxyalkyne derivatives **5**. Some subsequent reactions of **5** are also described.



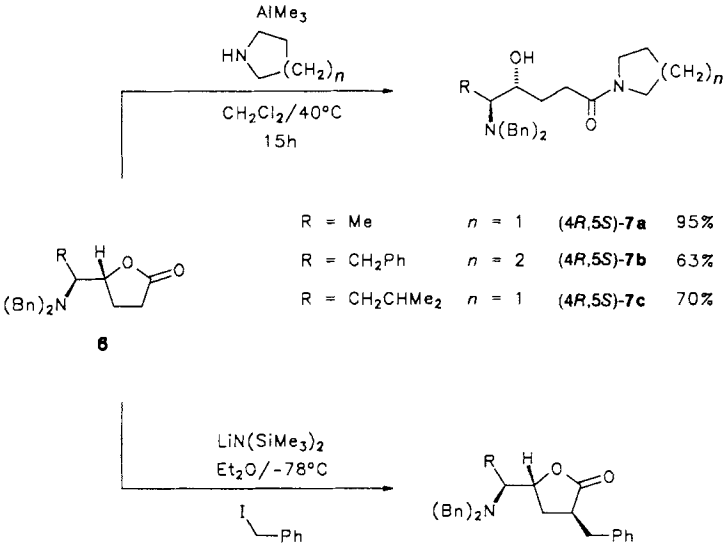
R = Me	*anti*-**6a**	94	: 6	*syn*-**6a**	53%
R = CH_2Ph	*anti*-**6b**	90	: 10	*syn*-**6b**	46%
R = CH_2CHMe_2	*anti*-**6c**	82	: 18	*syn*-**6c**	46%

Scheme 1.

Methoxyallene **1** was lithiated with *n*-butyl lithium.[2] The lithium compound was transmetalated into the titanium compound **2** by reaction at −50 °C with a molar equivalent of chlorotriisopropoxytitanium.[9, 10] Intermediate **2** was then treated with *N*,*N*-dibenzylalaninal **3a** (Scheme 1).[11] To achieve a satisfactory yield and a high γ-selectivity, the transmetalation reaction with chlorotriisopropoxytitanium needs to be carried out within 14 h at temperatures between −100 °C and −78 °C. Under these conditions the proportion of α-addition product **4a** (mainly *anti*-diastereomer) to both γ-addition products *anti*-**5a** and *syn*-**5a** was 9:91 (determined by the comparison of methoxy signals in the ^{1}H NMR spectrum).[12] The *anti* configuration of the main product was determined beyond doubt by the X-ray structural analysis of the derived compound *anti*-**6a**.[13] Similar to additions of lithiated methoxyallene to α-*N*,*N*-dibenzylamino aldehydes,[3] the stereochemical course of the reaction can be explained by the Felkin–Anh model *without* having to postulate the formation of a chelate.

As reactive carboxylic acid derivates, methoxalkynes such as **5** have great synthetic potential. For example, according to Arens et al.,[14] they can easily be hydrolyzed in acidic media to produce lactones, in this case compound **6**. It is convenient to carry out the addition and the hydrolysis as "one pot" reactions. By this procedure N-protected homostatine lactones **6** are produced in 50% yields from N-protected α-amino aldehydes in one step (Scheme 1).[15]

According to Weinreb et al.,[16] the lactones **6**, when treated with secondary amines such as pyrrolidine and piperidine



R = Me	*n* = 1	(4*R*,5*S*)-**7a**	95%

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

in the presence of trimethylaluminum, open up to the homostatine derivatives **7**. By means of chromatography hydroxycarboxylic acid amides (*4R,5S*)-**7** can be isolated in diastereomerically pure form. The yields vary between 70 to 90% (Scheme 2).

The deprotonation of the lactones **6** and subsequent alkylation with benzyl iodide[17] proceeds with high stereoselectivity to form *trans*-substituted benzyllactones **8** (Scheme 2). Their *trans* configuration has been determined by the 500 MHz 2D ROESY NMR spectrum of **8a**. These lactones are intermediates in the synthesis of stereoisomers of HIV protease inhibitors.

In addition to the reactions of titanated methoxyallene described here, a number of other applications of these homoaldol equivalents in reactions with achiral and chiral aldehydes seem possible. Also, the methoxyalkynes formed as primary products are activated carboxylic acid derivatives that can also react directly with electrophiles[14] to effect other functionalization.

Experimental Procedure:

Preparation of lactones **6** described with compound **6a** as typical example: A 1.6 M *n*-butyl lithium solution in hexane (12.0 mmol in 7.5 mL) is added to a solution of methoxyallene **1** (980 mg, 6.00 mmol) in dry ether (12 mL) at −40 °C. The reaction mixture is stirred for an additional 5 min and then cooled down to −78 °C. Then freshly distilled chlorotriisopropoxytitanium (3.12 g, 12.0 mmol) dissolved in dry ether (24 mL) is added over 1 h at −78 °C. The mixture is stirred for 14 h at −78 °C, after which the aldehyde **3a** (1.67 g, 6.00 mmol) dissolved in dry ether (12 mL) is added. The reaction mixture is allowed to warm from −78 °C to −40 °C in 1 h. Then 40 mL of a 1:1 mixture of THF and 2 N HCl is added. After hydrolysis the mixture is heated at reflux for 3 h. Thereupon it is cooled to room temperature, neutralized with a saturated $NaHCO_3$ solution, saturated with NaCl, and extracted five times with 25 mL portions of ether. The combined organic layers are dried over Na_2SO_4, and the solvents removed under vacuum. The residue is purified by chromatography on silica gel (30 cm column, petroleum ether/ethyl acetate 5:1). A light yellow oil is recovered (1.08 g, 53%), which is a mixture of the lactones *anti*-**6a** and *syn*-**6a** in the ratio of 94:6. By recrystallization from methanol, the pure diastereomer *anti*-**6a** (825 mg, 44%) is obtained as a colorless solid: m.p. 83–84 °C, $[\alpha]_D^{20} = +29.0$ ($c = 1.0$ in $CHCl_3$).

Formation of Monomeric Terminal Chalcogenides by Template-Induced Disilylchalcogenide Elimination; the Crystal Structures of [ETa{$(Me_3SiNCH_2CH_2)_3N$}] (E = Se, Te)**

By *Victor Christou* and *John Arnold**

Compounds containing terminal M = E bonds are relatively common for the lighter Group 16 elements, oxygen and sulfur, and show a wide variety of interesting and unusual reactivities.[1, 2] Only recently, however, have their heavier analogues, terminal selenides and tellurides, been described.[3, 4] Because of the current interest in the chemistry of metal–chalcogenides as thin-film semiconductors,[5] and since terminal metal–chalcogenide species are implicated as intermediates in the decomposition pathway of monomeric precursors to bulk materials,[6, 7] we sought to expand the range of known terminal tellurides and selenides in an effort to probe their reactivity. Here, we report the synthesis of rare, monomeric, terminal metal–chalcogenide species and the first structural comparison of terminal M = Se and M = Te interactions in closely related compounds.

A suitable ligand to support these terminal chalcogenide species seemed to be the substituted amine $[(Me_3Si)HNCH_2CH_2]_3N$ (H_3[TMStren])[8] that has been used to prepare a wide range of complexes.[8, 9] We hoped that this ligand would engender high solubility, prevent oligomerization, and promote the elimination reaction shown in Equation 1.[6, 10]

$$[L_nM(ER)_2] \rightarrow [L_nM{=}E] + ER_2 \qquad (1)$$

Treatment of $TaCl_5$ with Li_3[TMStren][11] in Et_2O led to the formation of [$TaCl_2$(TMStren)] (**1**) in yields of 40 to 60%. Subsequent reaction of **1** with two equivalents of $(thf)_2LiESi(SiMe_3)_3$ (E = Se,[12] Te[13]) at −78 °C afforded the terminal chalcogenides **2** and **3** and one equivalent of the disilylchalcogenide $E[Si(SiMe_3)_3]_2$ upon warming to room temperature. These reactions appear to be quantitative, as judged by ^1H NMR spectroscopy; colorless **2** and orange **3** were isolated as analytically pure crystals, typically in yields ranging from 55 to 80% and were characterized by a wide range of experimental techniques including Raman, ^{125}Te and ^{77}Se NMR spectroscopy and X-ray crystallography.

1, E = Cl_2
2, E = Se
3, E = Te

As with **1**, both the ^1H and ^{13}C NMR spectra of **2** and **3** (Table 1) show resonances that confirm the threefold symmetry of the Ta(TMStren) fragment. Compound **2** also exhibits a single resonance in its $^{77}Se\{^1H\}$ NMR spectrum ($\delta = 1518$) attributable to the terminal selenide group and close to the value reported for the terminal selenide resonance for $[PPh_4]_2[W_2Se_6]$, ($\delta = 1559$).[14] Likewise, **3** exhibits a single resonance in its $^{125}Te\{^1H\}$ NMR spectrum at $\delta = 1681$, which is assigned as the terminal telluride resonance. This value is shifted by nearly $\Delta\delta = 1000$ downfield of the resonances we reported for the terminal tellurides in the species $[M(Te)\{TeSi(SiMe_3)_3\}_2dmpe_2]$ (M = Zr, Hf; dmpe = bis(dimethylphosphino)ethane);[6] however, it lies close to the value reported by Parkin et al. for $[W(Te)_2(PMe_3)_4]$.[15] The extremely similar IR spectra of **2** and **3** support the isostructural assignment. The Raman spectrum of **2**, recorded between 100–600 cm^{-1}, shows only one peak, at 507 cm^{-1}, which we assign to the symmetrical Ta–Se stretch. A similar peak at 460 cm^{-1} was observed in the Raman spectrum of **3** and was therefore ascribed to the Ta–Te stretch. The difference in wavenumbers between these two resonances is in rough agreement with that expected on the basis of reduced mass calculations ($\Delta\nu \approx 70$ cm^{-1}) and is in line with values reported by Gibson and Siemeling from their studies of [Cp*Nb(NAr)(PMe_3)E] (Ar = 2,6-$iPr_2C_6H_3$, E = S, Se, Te).[16]

The X-ray structures of the selenide and telluride complexes[17] show both to have the central tantalum atom coordinated in a roughly trigonal bipyramidal fashion (Fig. 1). For the selenide compound there is a strict threefold axis along the Se-Ta-N vector, whilst in the telluride complex this symmetry is destroyed by the disposition of the methylene bridges in the backbone of the TMStren ligand, although overall threefold symmetry is retained. In common with other complexes chelated by related tripodal ligands,[18] the metal atoms in both **2** and **3** are displaced out of the equatorial plane, away from the basal atom of the ligand. This displacement is larger for the telluride complex (0.529 Å) than for the selenide (0.476 Å) and is presumably related to the shorter Ta–N (basal) bond in the latter (2.349 Å in **2**; 2.487 Å in **3**). We ascribe this feature to the difference in electronegativity between the two chalcogens, with the more electronegative selenium in **2** inducing a stronger N → Ta bond than does the tellerium in **3**. Steric interactions between the chalcogenide and the Me_3Si fragments on the ligand do not appear to play an important role in these two complexes, as all Ta-N-Si angles are within the normal ranges expected for an sp^2-hybridized amide nitrogen. Equatorial Ta–N bond lengths for both molecules fall within 3 σ of each other and lie in the range 2.011–1.982 Å, typical for tantalum–amide bonds.[19] Similarly all E-Ta-N bond angles fall within a narrow range (106.3–103.7°) and are close to those seen for other crystallographically characterized tren derivatives.[8, 9] The Ta–Te bond length of 2.568 Å is noticeably shorter than either of the previously reported values for terminal metal telluride species (Zr–Te, 2.650 Å und W–Te, 2.596 Å); however, this merely reflects the difference in ionic radii between the metals and is not significant. Compared to the analogous bond in **3**, the Ta–Se bond length (2.330 Å) is close to that expected, based on the 0.20 Å difference in radius between selenium and tellurium; however, it is longer than those reported in other examples of terminal selenide complexes (V–Se, 2.196 Å;[20] Mo–Se, 2.270 Å;[21] W–Se, 2.247, 2.254 Å[22]).

Table 1. Spectroscopic data for the compounds **1**–**3** [a, b].

1: M.p. 157–158 °C (decomp); ^1H NMR (400 MHz): $\delta = 3.84$ (t, $^3J(H,H) = 5$ Hz, 2H, CH_2), 2.49 (t, $^3J(H,H) = 5$ Hz, 2H, CH_2), 0.41 (s, 9H, $SiMe_3$); $^{13}C\{^1H\}$ NMR (100 MHz): $\delta = 65.82$, 55.73, 2.16; IR (Nujol/cm^{-1}): $\tilde{\nu} = 1292$ m, 1253 sh, 1244 s, 1141 m, 1129 m, 1087 s, 1077 m, 1033 s, 1001 w, 959 s, 928 s, 904 s, 838 vs, br, 785 s, br, 750 sh, 745 s, 682 m, 631 w, 604 m, 575 w; MS (70 eV): *m/z* (%): 612(15) [M^+], 597(15) [$M^+ - Me$], 575(25) [$M^+ - Cl$], 496(100) [$M^+ - Me_3SiNCH_2CH_2$].

2: M.p. 185–186 °C; ^1H NMR (400 MHz): $\delta = 3.43$ (t, $^3J(H,H) = 5$ Hz, 2H, CH_2), 1.87 (t, $^3J(H,H) = 5$ Hz, 2H, CH_2), 0.62 (s, 9H, $SiMe_3$); $^{13}C\{^1H\}$ NMR (100 MHz): $\delta = 55.27$, 51.52, 4.23; $^{77}Se\{^1H\}$ NMR (57 MHz): $\delta = 1518$(s); IR: $\tilde{\nu} = 1287$ m, 1268 m, 1253 m, 1241 s, 1143 w, 1073 s, 1027 w, 949 s, 930 s, 910 s, 845 vs, br, 789 s, br, 762 sh, 729 w, 679 w, 633 w, 589 m, 446 m, 356 m; MS: *m/z* (%): 620(20) [M^+], 605(100) [$M^+ - Me$].

3: M.p. 226–227 °C; ^1H NMR (400 MHz): $\delta = 3.39$ (t, $^3J(H,H) = 5$ Hz, 2H, CH_2), 1.70 (t, $^3J(H,H) = 5$ Hz, 2H, CH_2), 0.60 (s, 9H, $SiMe_3$); $^{13}C\{^1H\}$ NMR (100 MHz): $\delta = 58.39$, 50.40, 3.89; $^{125}Te[^1H]$ NMR (95 MHz): $\delta = 1681$(s); IR: $\tilde{\nu} = 1269$ m, 1244 m, 1146 w, 1056 s, 1018 w, 936 s, 922 sh, 905 w, 843 vs, br, 785 s, br, 777 sh, 755 w, 741 w, 725 w, 689 w, 676 w, 572 w, 353 w; MS: *m/z* (%): 670(60) [M^+], 655(70) [$M^+ - Me$], 611(100) [$M^+ - SiMe_2$], 541(50) [$M^+ - Te$].

[a] Al NMR spectra were recorded in C_6D_6 at 25 °C. [b] All compounds gave satisfactory C,H, and N analyses.

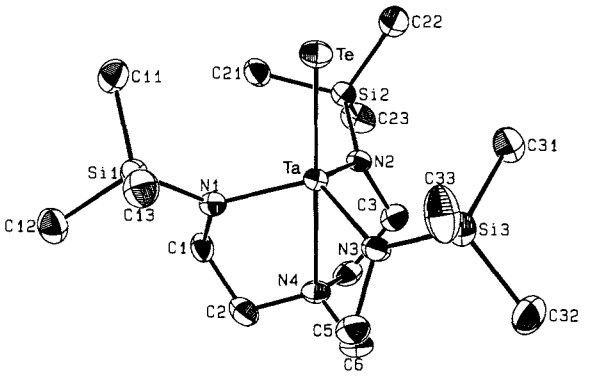

Fig. 1. Crystal structure of $[TaTe\{(Me_3SiNCH_2CH_2)_3N\}]$ (**3**) with thermal ellipsoids drawn at the 50% probability level (ORTEP). Hydrogen atoms have been omitted for clarity. The crystal structure of **2** appears identical and is not shown. Selected bond lengths [Å] and angles [°] for **3**: Ta-Te 2.568(1), Ta-N(1) 2.000(5), Ta-N(2) 1.986(5), Ta-N(3) 1.982(5), Ta-N(4) 2.487(5); Te-Ta-N(4) 178.2(1), [Te-Ta-N(1,2,3)] (averaged) 105.4(1), [Ta-N(1,2,3)-Si] (averaged) 126.5(3), [N(1,2,3)-Ta-N(4)] (averaged) 74.6(2), N(1)-Ta-N(2) 111.4(2), N(1)-Ta-N(3) 116.5(2), N(2)-Ta-N(3) 111.7(2). Selected bond lengths [Å] and angles [°] for **2**: Ta-Se 2.330(1), Ta-N(1) 2.011(4), Ta-N(2) 2.349(2): Se-Ta-N(1) 103.7(1), Se-Ta-N(2) 180.0(0), Ta-N(1)-Si 124.9(2), N(1)-Ta-N(2) 76.3(1), N(1)-Ta-N(1) 114.6(1).

Experimental Procedure

1: A mixture of $TaCl_5$ (3.70 g, 10.3 mmol) and $Li_3TMStren$ (4.00 g, 10.8 mmol) were cooled to −78 °C, and diethyl ether (150 mL), also at −78 °C, was added rapidly with vigorous stirring. The heterogeneous mixture was warmed slowly

to room temperature, the solvent removed in vacuo, and the dark brown residue extracted into Et_2O (60 mL). This ether solution was filtered and concentrated to roughly half of the original volume, at which point the product began to precipitate as yellow crystals. The solution was slowly cooled to $-40\,^{\circ}C$ over a period of 12 h to afford the product as bright orange crystals (3.24 g, 51%).

2: 50 mL of hexanes at $-78\,^{\circ}C$ was added to a mixture of **1** (1.00 g, 1.63 mmol) and $(THF)_2LiSeSi(SiMe_3)_3$ (1.56 g, 3.28 mmol), also at $-78\,^{\circ}C$. The resultant orange solution was allowed to warm to room temperature. After stirring for a further 2 h, the volatiles were removed under reduced pressure to give an orange residue, which was extracted into Et_2O, filtered, concentrated, and cooled to $-40\,^{\circ}C$. The product precipitated as colorless plates, which were recrystallized from Et_2O. The yield of analytically pure materials was 0.67 g (66%).

3: A mixture of **1** (1.00 g, 1.63 mmol) and $(thf)_2LiTeSi(SiMe_3)_3$ (1.73 g, 3.30 mmol) were dissolved in hexanes (20 mL) at $-78\,^{\circ}C$. Immediately upon addition of the hexanes, the solution became dark red. Then, over 1 h while the solution was warming to room temperature, it gradually lightened in color to yellow brown accompanied by precipitation of a colorless solid. When room temperature had been reached, the mixture was stirred for a further 2 h, upon which the volatiles were removed under reduced pressure to give a dark brown solid, which was extracted into hexanes, filtered, concentrated, and cooled to $-40\,^{\circ}C$ to give the product as red crystals. Multiple recrystallizations were necessary to remove traces of dark brown impurities (0.60 g, 55%).

[11] Li_3TMStren was prepared by the following modification to the procedure reported in ref. [9a]: After preparation according to the reported procedure, the lithium salt was recrystallized from hot toluene, thereby removing occluded hexanes and improving crystallinity. This modification leads to improved purity and better yields of $[TaCl_2(TMStren)]$.

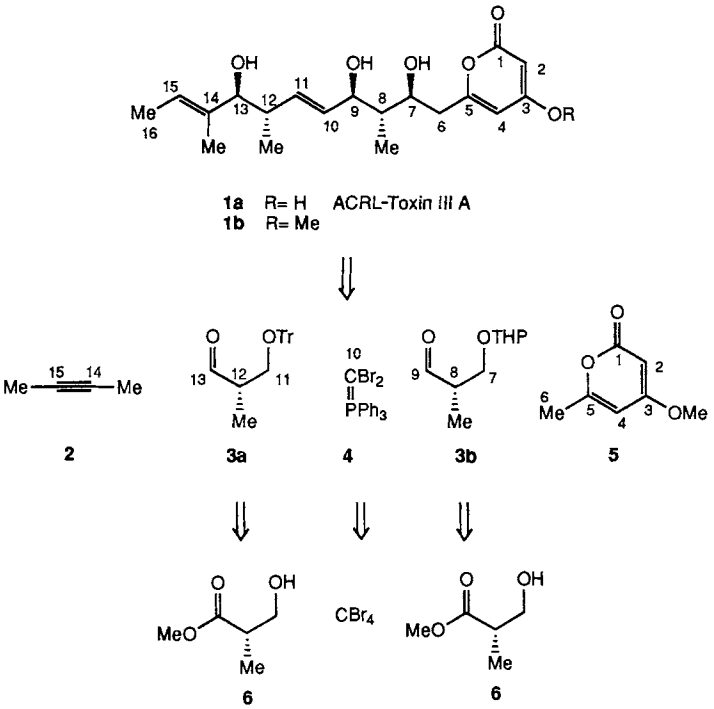
Linear Total Synthesis of (−)-ACRL Toxin III B**

By *Johann Mulzer,* Susanne Dupré, Jürgen Buschmann,* and *Peter Luger*

ACRL toxin III A (**1a**)[1] is one of a group of toxins present in the fungus *Alternaria citri* which causes crop-threatening necroses on the leaves and fruits of certain types of citrus (brown spot disease). Compound **1a** was isolated, together with other components of the toxin complex, in small quantities and in what was clearly an impure form. It also proved to be unstable; adequate characterization was only possible for the 3-methyl ether **1b** (ACRL toxin III B). Despite some recent confusion in the literature on this matter,[2] there is no ambiguity in the structure and configuration of **1a, b**. Next to nothing is known about the mechanism of action and further physiological properties of the toxins. Whereas the main active component of the toxin complex, ACRL toxin I [(5*R*)-4,5-dihydro-**1b**], has been synthesized in a multistep sequence from D-glucose,[3] compounds **1a, b** have not hitherto been prepared.

The methyl ether **1b** is an attractive synthetic target. Biogenetically, this compound is a polyketide; a distinguishing feature is the alternating, partly dehydrated, acetate (C1/2, C3/4, C5/6, C9/10, C15/16) and propionate (C7/8, C11/12, C13/14) units. These are present in saturated and unsaturated form as well as in the form of an α-pyrone ring. The hydroxymethyl units at C7/8/9 and C12/13 are *anti*-configurated and thus pose a synthetic problem which is still difficult to solve by classical aldol addition methodology.[4]



Scheme 1. Retrosynthetic analysis of compounds **1a, b**. Tr = trityl, THP = tetrahydropyranyl.

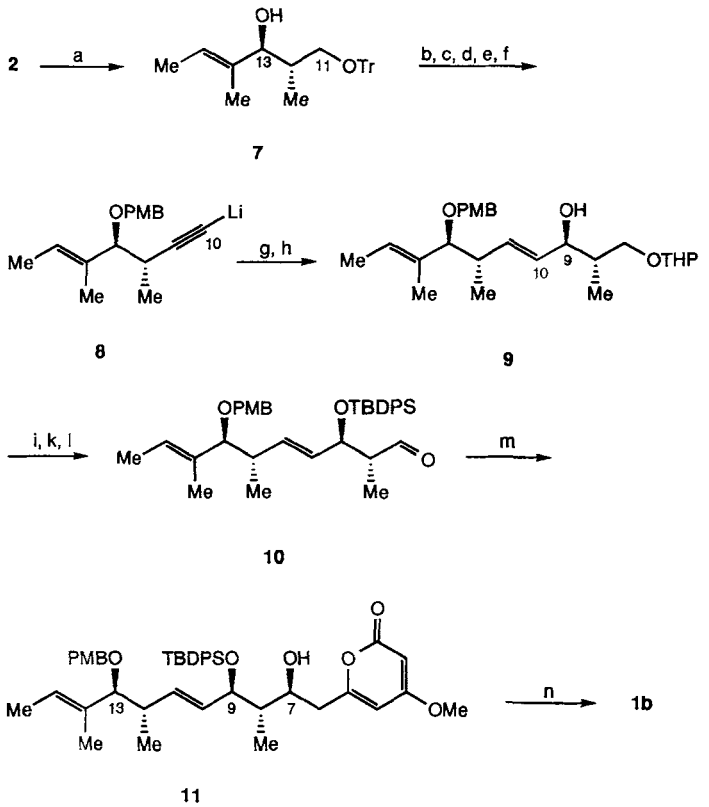
[**] This work was supported by the Deutsche Forschungsgemeinschaft.

Our retrosynthetic analysis (Scheme 1) is aimed at a synthesis of **1b** which proceeds linearly from C16 to C1. Of the required building blocks, **2** and **5** are commercially available. Compounds **3a, b** were prepared on a multigram scale in three steps from the ester **6** (total yield 90–95%),[5] which is the central chiral building block in the synthesis. Compound **4** was formed in situ from CBr_4 and PPh_3.

All C–C connections were achieved by addition of carbanions, generated in various ways, to aldehydes (Scheme 2).



Scheme 2. Overview of the synthesis. a) *i*BuMgCl, $[Cp_2TiCl_2]$ (2 mol %), THF, **3a** 78%; b) NaH, DMF, PMBCl (*p*-methoxybenzyl chloride), 95%; c) $ZnBr_2$, CH_2Cl_2, 71%; d) $(COCl)_2$, DMSO, iPr_2NEt, CH_2Cl_2, −60 °C, 96%; e) CBr_4, PPh_3, Zn, CH_2Cl_2, 89%; f) 2 equiv *n*BuLi, 91%; g) **3b**, 57%; h) $LiAlH_4$, THF, 50 °C, quantitative; i) TBDPSCl (*tert*-butyldiphenylsilyl chloride), imidazole, CH_2Cl_2, 84%; k) EtOH, *p*-toluenesulfonic acid, 45 °C, 84%; l) $(COCl)_2$, DMSO, iPr_2NEt, CH_2Cl_2, −60 °C, 87%; m) KHMDS (K-hexamethyldisilazide), −100 °C, 55%; n) DDQ (2,3-dichloro-5,6-dicyano-1,4-benzoquinone) CH_2Cl_2, then TBAF (tetrabutylammonium fluoride), AcOH, THF, 65%.

The vinyl anion, formed in an (*E*)-selective (> 99%) hydromagnesation of **2**,[6] adds to **3a** to give the allyl alcohol **7** (a 1:1 mixture of the 13-epimers). After separation by HPLC, protection of the 13- and detritylation of the 11-hydroxyl group, alcohol **7** is subjected to a Corey–Fuchs sequence[7] to give the acetylide **8**. This is added in situ[8] to the aldehyde **3b**, and the resulting propargyl alcohol (1:1.8 mixture of the (9*S*)- and (9*R*)-epimers) is reduced to the allyl alcohol **9**. After separation of the diastereoisomers by HPLC, the (9*R*)-diastereomer is transformed into aldehyde **10**, which is then coupled with anion **5**. The regioselectivity of this addition depends critically on the reaction temperature and the cation. Only under the conditions described can formation of the 4-adduct be suppressed in favor of the desired 6-adduct.[9]

After removal of the protecting groups from positions 9 and 13, **1b** is isolated as a 96:4 mixture with its 7-epimer. After chromatographic purification, **1b** is obtained in pure crystalline form. The crystal structure analysis shows that the saturated ketide fragments C4/5 and C8–11 (positions refer to numbering in Fig. 1) are almost coplanar; the hydroxyl groups protruding on one side of the plane and the methyl groups on the other. The "upper face" is thus hydrophilic and the "lower face" hydrophobic in character. As a result of numerous 1,3-interactions (e.g. C2/4, C3/5, C6/8), the six-membered ring and the olefinic units (C6/7 and C2/3) are tilted out of the plane in the same direction and form a dihedral angle of 50–60° with the plane. The *syn*-coplanar arrangement of the hydroxyl groups at C8 and C10, which would normally be disfavored, is stabilized by an intramolecular hydrogen bond.[10]

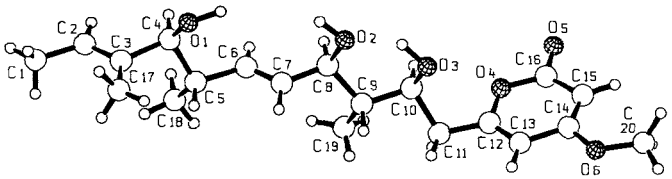


Fig. 1. Crystal structure of **1b** [16].

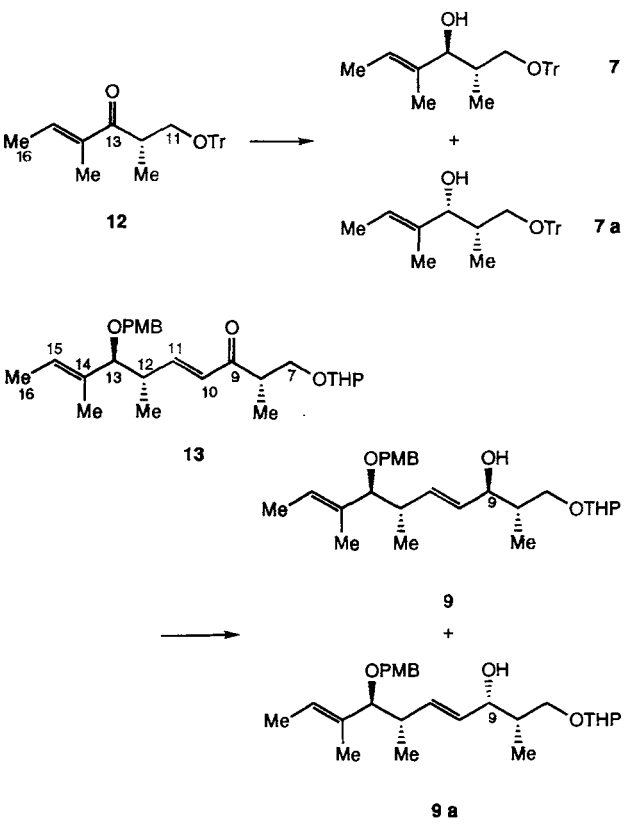
The synthesis comprises 16 steps—including the two straightforward HPLC separation steps—from **6** and provides the target molecule **1b** in 1.3% overall yield. The formation of the alcohols **7** and **9** is not selective; this can be rectified by employing an oxidation–reduction sequence. Ketones **12** and **13**, which are available in good yields (80 and 95% respectively) from the Swern oxidation of **7** and **9**, respectively, are reduced with very variable selectivity. In the



case of **12**, the highest (Felkin–Ahn) selectivity (**7**:**7a** = 96:4, overall yield 83%) is obtained with $LiBEt_3H$ (superhydride). Selective reduction of **13** to **9** (**9**:**9a** = 85:15, overall yield 84%) can only be achieved with the help of double asymmetric induction by using the reducing agent (*R*)-oxazaborolidine developed by Corey et al.[11, 12] In contrast, reduction with (*S*)-oxazaborolidine gives a 4:96 ratio of **9**:**9a** (overall yield 89%). Hydroboration does not take place at either the conjugated or the isolated double bonds during the above reaction. On reducing the 7-OTr protected ketone **13** with L-selectride, a *de* of 91% (overall yield 88%) is achieved to give 7-OTr-**9**. Thus, with a slightly modified procedure,[13] it is possible to manage with a commercially available reducing agent.

Thus two options exist for the synthesis of compound **1b**. If we accept the lack of selectivity in the two aldehyde additions and perform the two resulting HPLC separation steps, an overall yield of 1.3% over 16 steps is obtained, which corresponds to 2.3 steps per stereogenic unit (five chiral centers and two double bonds). If, on the other hand, we choose the route via the ketones **12** and **13**, 20 steps are required (overall yield 2%). This corresponds to 2.8 steps per stereogenic unit, but the selectivity of each step is now > 90%! This sequence can again be reduced to 16 steps if the corresponding Weinreb amides[14] are employed instead of the aldehydes **3**. Ketones **12** and **13** are then generated directly in the C–C bond-formation step.

Since the chiral starting material **6** is available in both (*R*)- and (*S*)-forms, the two enantiomers of **1b** are also equally accessible—an indispensable requirement for pharmacological testing. Remarkably, the purity of the synthetic product is higher than that of the isolated natural product, since compound **1b** is described as an oil in the literature.[1] The ^1H and ^{13}C NMR spectra are consistent (superimposable) with those of our synthetic material.[15] The originally assigned absolute and relative configurations of the natural product[1] have thus been confirmed.

$Ba_{44}Cu_{48}(CO_3)_6O_{87.9}$: The Structure of "$BaCuO_2$" from Simultaneous X-ray and Neutron Powder Diffraction**

By *Miguel A. G. Aranda** and *J. Paul Attfield*

"$BaCuO_2$" is often formed as an unwanted impurity in the synthesis of high-temperature cuprate superconductors. Previous attempts to determine the structure of this disordered material have been only partially successful, so we have taken advantage of the different relative X-ray and neutron scattering factors of Ba, Cu, and O and developed the structural model from powder X-ray and neutron diffraction profiles simultaneously. This has enabled us to identify a previously unsuspected carbonate ion within the disordered region of the structure and to show that the true stoichiometry of "$BaCuO_2$" is $Ba_{44}Cu_{48}(CO_3)_6O_{81+x}$ ($x = 6.9(3)$ for our sample). The mechanism of nonstoichiometry is similar to that in $YBa_2Cu_3O_{6+y}$. Our determination of this structure (volume of unit cell 6135 Å^3) demonstrates the power of simultaneous X-ray and neutron refinements.

Early studies showed that "$BaCuO_2$" is semiconducting and has a body-centred cubic structure with lattice parameter $a \approx 18.3$ Å,[1, 2] and a small range of nonstoichiometry up to $x = 0.12$ in "$BaCuO_{2+x}$."[3] The structure was originally solved by single-crystal X-ray diffraction,[4] and had subsequently been reexamined by using these data,[5] X-ray data from a new crystal,[6] and powder neutron diffraction profiles for two samples with differing oxygen contents.[7] All of these studies demonstrate that the structure contains two unusual clusters, $Cu_{18}O_{24}$ cages and Cu_6O_{12} rings, built from edge-sharing CuO_4 square planes, which are surrounded by the Ba atoms. However, no satisfactory models for the disordered region between these entities were found, and so the exact composition and structure remained uncertain. As the relative magnitudes of the Ba, Cu, and O scattering factors for X-rays ($f(0) = 56$, 29, and 8 electrons per atom) and neutrons ($b = 5.25$, 7.72, and 5.81 fm) are very different, they may be used together to identify the atoms present in the disordered regions of the "$BaCuO_2$" structure. We have

collected powder X-ray and neutron diffraction data (Fig. 1) from the same polycrystalline sample to determine the crystal structure and composition of this material (see Experimental Procedure).

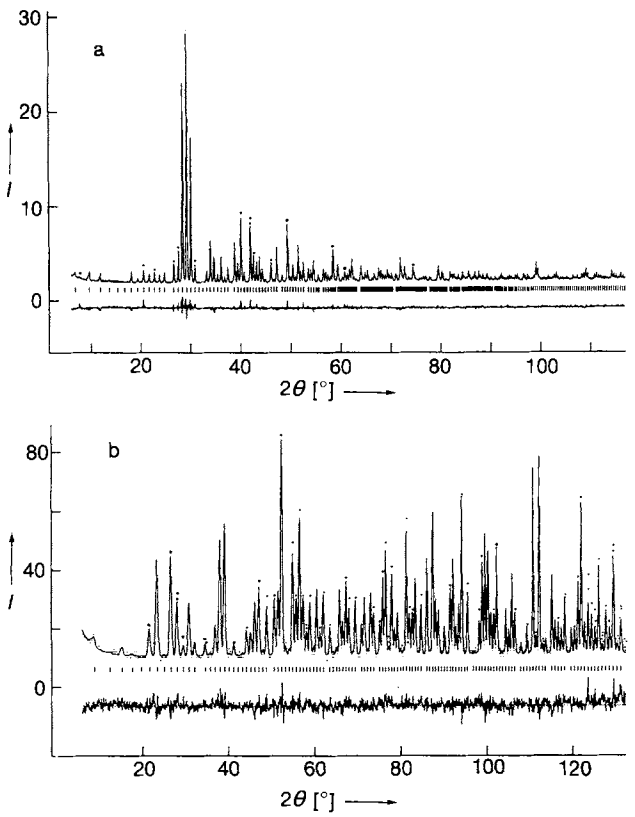

Fig. 1. Observed powder diffraction plots (points), calculated (full line), and difference profiles for $Ba_{44}Cu_{48}(CO_3)_6O_{87.9}$. a) X-ray diffraction ($\lambda = 1.54$ Å); b) neutron diffraction, ($\lambda = 1.98$ Å); positions of reflections marked. I = intensity (counts, for a) the values are multiplied by 10^3).

A view of the local geometries in the disordered part of the $Ba_{44}Cu_{48}(CO_3)_6O_{81+x}$ structure is shown in Figure 2. Each C atom is surrounded by eight O sites due to the statistical disorder of four CO_3^{2-} orientations. The carbonate group lies between two Cu_6O_{12} rings and forms a long Cu–O contact with one of them. The $Cu_{18}O_{24}$ clusters are linked by O5-Cu4-O7-Cu4-O5 bridges (see also Tables 1 and 2) in one of four possible orientations around [100], which refine to

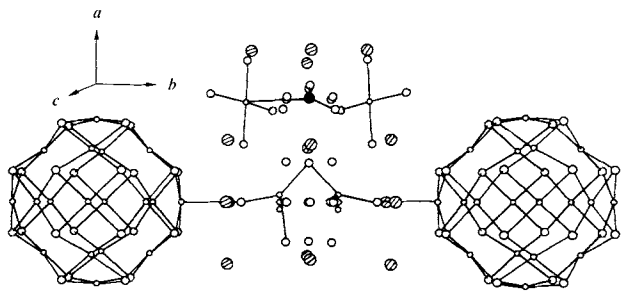

Fig. 2. The disordered region of $Ba_{44}Cu_{48}(CO_3)_6O_{87.9}$ (Cu small open circles; O medium open circles; C filled circle, Ba large hatched circles). All possible Cu and O sites are drawn with bonds showing one particular configuration for the bridge between two $Cu_{18}O_{24}$ clusters, and the carbonate group lying between two CuO_4 groups from different Cu_6O_{12} rings.

($x = 0$), the Cu4 sites contain Cu^+ in a typical two-coordinate environment and the other Cu sites have an average formal charge of +1.90. This is comparable to the charge distribution in $YBa_2Cu_3O_6$. The occupation of two O6 sites around one Cu4 site in each bridge ($x = 6$) gives a distorted square planar coordination (right hand side of the bridge in Fig. 2) with short Cu–O bonds, consistent with oxidation to Cu^{3+}. The mean oxidation state for the Cu atoms in the clusters is now +2.12, showing that they act as charge reservoirs during the oxidation of the Cu4 sites, as is found in $YBa_2Cu_3O_{6+y}$. Filling a third O6 site giving $x = 9$ is sterically possible and results in an unusual trigonal environment around Cu (left hand side of bridge in Fig. 2). Our refined value of $x = 6.9(3)$ does not represent a significant filling of this site.

As $Ba_{44}Cu_{48}(CO_3)_6O_{81+x}$ is stoichiometric in carbonate, and all previous structure determinations found an atom at the C site, we conclude that carbonate ions are required to stabilize this structure. Evidence that the analogous nickel compound, cubic "$BaNiO_2$," contains carbonate ions has very recently been reported,[9] although the proposed composition, $Ba_{42}Ni_{36}(CO_3)_6O_{72}$, is slightly different. The compound "$BaCuO_{2.5}$,"[1] which decomposes into cubic "$BaCuO_{2+x}$" above 800 °C,[10, 11] is probably an oxocarbonate as well. The formation of $Ba_{44}Cu_{48}(CO_3)_6O_{81+x}$

as an equilibrium phase at 850 °C in air highlights the ability of Ba and related elements to form very stable oxocarbonates. This has recently led to the development of superconducting phases such as $(Ba_{0.55}Sr_{0.45})Cu_{1.1}(CO_3)_{0.1}O_{2.2}$ (T_c = 40 K)[12] and $Tl_{0.5}Pb_{0.5}Sr_4Cu_2(CO_3)O_7$, a 70 K superconductor containing layers of carbonate groups.[13] Rigorously excluding carbon should prevent the formation of "$BaCuO_2$" during the synthesis of superconducting cuprates and may also enable new, superconducting, infinite-layer type materials $(Ba,Sr)_{1-y}CuO_2$ to be prepared with small or zero strontium contents.[14]

Our determination of the complex disorder within this large unit cell (6135 Å^3) demonstrates the power of simultaneous refinements. The combined information from powder X-ray and neutron patterns of moderate quality has proved more effective than previous individual single-crystal X-ray data sets.

Experimental Procedure

"$BaCuO_2$" was synthesized by heating an intimate, equimolar (Ba:Cu = 1:1) mixture of $BaCO_3$ (Aldrich, 99.98 %) and CuO (Aldrich, 99.99 + %) at 850 °C in air for 24 h. The sample was reground and reheated at the same temperature for a further 24 h.

Structure determination: X-ray powder diffraction data were recorded for $2\theta = 6-117°$ on a Siemens D501 diffractometer by using monochromated $Cu_{K\alpha}$ radiation, counting for 20 s per 0.03° step. Neutron powder diffraction data were collected on instrument D1A at the Laboratoire Leon Brillouin, Saclay, France, by using a wavelength of 1.9841(2) Å for $2\theta = 5-132.5°$ in 0.05° steps. Rietveld analysis [15] with the GSAS package [16] enabled the structural model to be fitted to either or both data sets. No impurity phases were observed.

Starting coordinates were those reported for "$BaCuO_{2.07}$" from powder neutron refinement [7], but this model gave a poor fit to our neutron data. Examination of the structure revealed an anomalous atom at (1/4,0,1/2), which has been reported in all previous studies as either an O atom [4, 5, 7] or a partially occupied Cu site [6]. We refined the scattering factor of this atom by using the X-ray and neutron data separately, giving $f(0) \approx 9$ electrons per atom and $b \approx 7$ fm, respectively. These values clearly rule out partial occupation by Ba or Cu, although they are consistent with O. However, the long distances (> 3.2 Å) from this site to the nearest cations make oxygen occupation chemically unrealistic. We therefore considered possible cationic impurity atoms: an obvious candidate was carbon in view of the scattering factors ($f(0) = 6$ electrons per atom, $b = 6.65$ fm) and the ability of barium to form thermally stable carbonates.

Carbon refined to full occupancy at (1/4,0,1/2) in both the X-ray and neutron refinements, and a neutron difference Fourier map revealed two partially occupied oxygen positions (O8 and O9) approximately 1.3 Å from this site. These positions define four possible orientations of a CO_3^{2-} group, pivotally disordered around the C atom. Including the carbonate group improved the profile fits and further simultaneous X-ray and neutron refinements enabled us to resolve other disordered features more clearly than in previous determinations. Disorder in the Cu2 position, which has been modeled by refining this atom off (0,x,x), reflects a slight disorder in the orientation of the near-spherical $Cu_{18}O_{24}$ cages around the symmetry axes. The final model (space group $Im3m$, $a = 18.3069(2)$ Å, $Z = 2$) shown in Table 1 has composition $Ba_{44}Cu_{48}(CO_3)_6O_{81+x}$ ($x = 6.9(3)$) and gives good fits (Fig. 1) to both X-ray ($R_{WP} = 0.040$, $R_F = 0.066$, R factors are defined in refs. [15] and [16]) and neutron ($R_{WP} = 0.081$, $R_F = 0.057$) profiles. This model gives satisfactory bond lengths and angles for all atoms (Table 2) and bond valence calculations [17] give total valence of 4.1 for C and values between 1.8 and 2.3 for all the Ba, Cu, and O sites, except Cu2 and O6 where low valences of 1.6 indicate further slight disorder. Further details of the crystal structure investigation may be obtained from Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, D-76344 Eggenstein-Leopoldshafen (FRG) on quoting the depository number CSD-57708, the names of the authors and the journal citation.

IR Spectroscopy: The presence of carbonate groups was corroborated by the IR spectrum (Perkin-Elmer 1710 FT spectrometer, CsI disk) of "$BaCuO_2$" which showed typical carbonate absorptions at 1410 and 865 cm^{-1}; those for $BaCO_3$ are at 1440 and 875 cm^{-1}.

Synthesis and Reactivity of Hexafluoro-1,2-diisocyanocyclobutanechromium Complexes**

By *Dieter Lentz,* Frank Nowak, Dagmar Preugschat,* and *Markus Wasgindt*

Di- and triisocyanides have recently acquired considerable significance, owing to their interesting coordination chemistry,[1] in particular their ability to function as polydentate ligands. Fluorinated cycloalkyl isocyanides and fluorinated diisocyanides are hitherto unknown. The chemistry of perfluorinated isocyanides, inaccessible through conventional isocyanide syntheses,[2] was until recently restricted to trifluoromethyl isocyanide[3] and pentafluorophenyl isocyanide.[4] The more thoroughly investigated trifluoromethyl isocyanide is particularly noteworthy due to its unusual ligand properties[5] and reactivity.[6] As shown by Fehlhammer et al., pentacarbonyl(cyano)chromate undergoes radical-type alkylation,[7] giving rise to pentacarbonylchromium complexes of functionalized isocyanides. We recently succeeded in synthesizing the first fluorinated alkenyl isocyanide $F_2C{=}CF{-}NC$ **1** by the formation of the corresponding $[Cr(CO)_5]$ complex, followed by flash vacuum pyrolysis.[8] We now report the synthesis and preliminary reactions of the thus far unique complex-stabilized, fluorinated diisocyanide.

If pentacarbonyl(trifluorovinyl isocyanide)chromium **2** is heated to 70 °C under atmospheric pressure, cleavage of the isocyanide ligand does not take place; instead a [2 + 2] cycloaddition reaction occurs. [2 + 2] Cycloaddition reactions are thermally forbidden according to the Woodward–Hoffmann rules,[9] and do not normally occur. Fluorinated alkenes, on the other hand, display a strong tendency to undergo [2 + 2] cycloadditions,[10] from which four possible isomeric

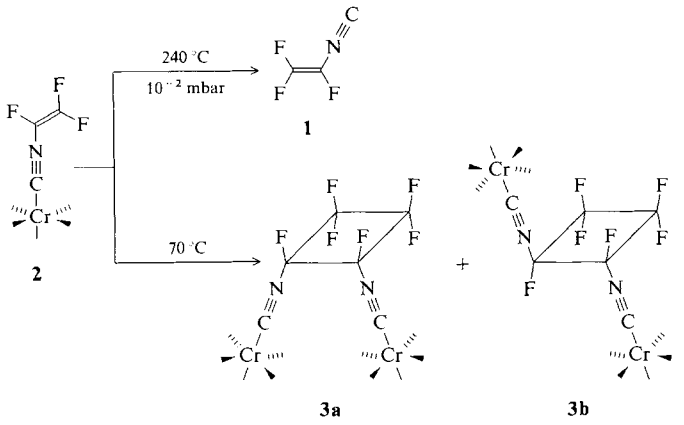
[**] This work was supported by the Fonds der Chemischen Industrie, the Deutsche Forschungsgemeinschaft, and the Graduiertenkolleg "Synthese und Strukturuntersuchung niedermolekularer Verbindungen" of the Freie Universität and Technische Universität, Berlin. We thank Hoechst AG for a gift of 1,2-dichloro-1,1,2-trifluoroethane.

products may, in principle, arise. Head-to-head dimers of *cis* and *trans* geometry are usually observed, whose formation is explained by a stepwise diradical mechanism.[11]



Upon dimerization of **2**, a 1:1 isomeric mixture of *cis*- and *trans*-hexafluorodiisocyanocyclobutanechromium complexes (**3a** and **3b**, respectively) is formed. The structures of both compounds were established spectroscopically; in addition an X-ray crystal structure analysis was performed for the *cis* isomer **3a**.[12] The cyclobutane ring in **3a** is distinctly puckered, as is the case for unsubstituted cyclobutane[13] and octafluorocyclobutane[14] (Fig. 1). The angles between the

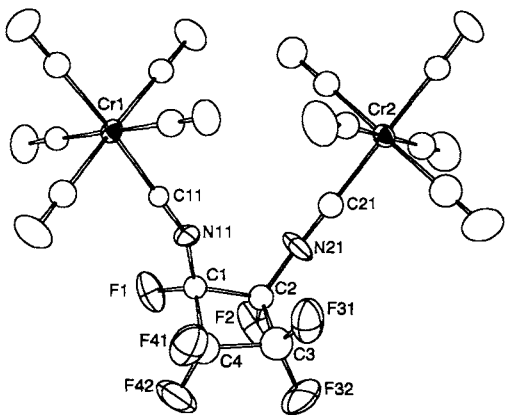


Fig. 1. Molecular structure (ORTEP [17]) of **3a**, (ellipsoids drawn at 30% probability). Selected bond lengths [pm] and angles [°]: Cr-CO 188.1(7)–191.4(6), C-O 113.0(7)–114.7(7), C11-N11 117.4(7), C21-N21 117.5(7), C1-N11 140.7(7), C2-N21 137.7(7), C-F 128.3(8)–138.0(7), C1-C2 155.8(8), C2-C3 149(1), C3-C4 155.1(9), C1-C4 153.7(9); N11-C1-C2 113.4(5), N11-C1-C4 110.3(5), N21-C2-C1 118.5(5), N21-C2-C3 119.4(7), C11-N11-C1 155.7(5), C21-N21-C2 163.8(7), C2-C1-C4 89.5(5), C1-C2-C3 88.9(5), C2-C3-C4 91.3(6), C1-C4-C3 87.5(5), C-C-F 107.9(6)–116.9(7), F-C-F 109.2(7)–112.9(6), N-C-F 111.5(6)–112.3(6).

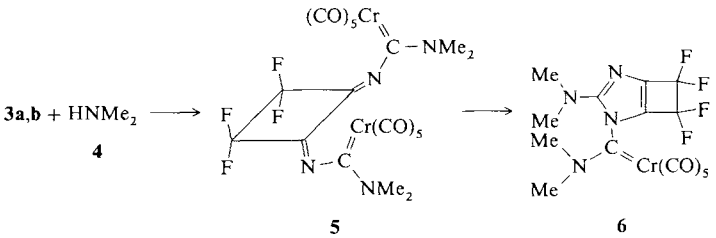
planes C1-C2-C3/C1-C3-C4 and C1-C2-C4/C2-C3-C4 are 21.3 and 21.1°, respectively. The N-C-C bond angles at the cyclobutane ring [110.3(5)–119.4(7)°] and the bending of the isocyanide function at the nitrogen atom [C1-N11-C11 155.7(5), C2-N21-C21 163.8(7)°], allow the two bulky $(CO)_5Cr(CN)$ substituents to adopt a *cis* orientation. The two chromium atoms exhibit approximately octahedral coordination geometry, and the Cr–C distances to the carbonyl ligands [188.1(7)–191.4(6) pm] are very similar, showing, above all, no significant differences compared to those to the isocyanide carbon atoms [Cr1–C11 190.3(6), Cr2–C21 190.0(6) pm].

The isomers **3a** and **3b** do not differ appreciably in their solubility, hence separation by fractional crystallization was not possible. Attempts to separate the isomers by chromatography were likewise unsuccessful. The complexes **3**, however, crystallize in different forms; thus, the fine needles of **3a** could be separated from the intergrown mass of platelets of the *trans* isomer **3b**.

The ^{19}F NMR spectra of both isomers show the signal patterns of AA'BB'CC' spin system, which could not be analyzed completely because of the very small vicinal coupling constants. Of note are the geminal $^2J_{F,F}$ coupling constants (218 Hz), which are typical for fluorinated cyclobutane rings.[15] Analysis of the vibrational spectra was unsuccessful due to the strong coupling of the CN vibration with the CO vibrations. The location of the intense carbonyl bands in the IR spectra highlights the strong π-acceptor properties of these fluorinated isocyanide ligands.

Starting from **3**, nucleophilic attack at the isocyanide-carbon atom[16] ought to permit the synthesis of biscarbene complexes. Indeed, an isomeric mixture of **3** reacts readily with dimethylamine **4**, even at −78 °C. This gives rise to a deep blue solution, whose ^{19}F NMR spectrum at −100 °C (an ABCD spectrum with large $^2J_{F,F}$ coupling constants and unresolved $^3J_{F,F}$ couplings) indicates the presence of biscarbene complex **5**. Above −20 °C, the solution becomes yellow, and the ^{19}F NMR spectrum shows the appearance of signals due to the carbene complex **6**, generated through cleavage of $[Cr(CO)_5]$ fragment and the subsequent cyclization to give the imidazole ring system. Despite the instability,



of the biscarbene complex **5**, we succeeded in obtaining single crystals, allowing us to clarify its structure by X-ray crystallography[12] (Fig. 2). The most important structural element is the tetrafluorocyclobutane ring with the iminonitrogen atoms N1 and N3 in the 1,2 positions, bonded to the carbene carbon atoms C16 and C26, respectively. The carbon atom C16 points towards, and C26 away from the neighboring fluorine atoms and the $[Cr(CO)_5]$ fragments are arranged above and below the plane of the four-membered ring, respectively. The orientation of atoms N1, C1, C4, N3, and C26 appears decisive for the reactivity, allowing nucleophilic attack at C26 by the nitrogen atom N1, which leads to carbene complex **6**, upon cleavage of a $[Cr(CO)_5]$ fragment. Compound **6** can be isolated as the final product of this reaction, and has been fully characterized on the basis of spectroscopic data and a crystal structure analysis.[12]

If this reaction can be generalized and the removal of the organometallic protecting group can be achieved successfully, this would be a convenient synthesis for imidazole deria-

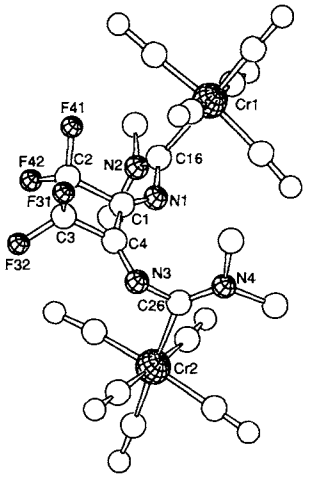


Fig. 2. Molecular structure (SCHAKAL [18])) of **5**. Selected bond lengths [pm], bond angles [°], and dihedral angles [°]: Cr1-C16 209(3), Cr2-C26 213(3), Cr-CO 181–193(3), C-O 109–120(4), C16-N1 134(3), C16-N2 132(3), C26-N3 134(3), C26-N4 128(3), C1-N1 123(3), C4-N3 128(3), C1-C2 160(4), C2-C3 154(4), C3-C4 150(4), C1-C4 146(4), C-F 131-135(3); Cr1-C16-N1 110(2), Cr1-C16-N2 135(2), N1-C16-N2 113(2), Cr2-C26-N3 108(2), Cr2-C26-N4 135(3), N3-C26-N4 117(3), C16-N1-C1 127(2), C26-N3-C4 123(2), C2-C1-N1 135(2), C4-C1-N1 137(3), C2-C1-C4 88(2), C1-C4-N3 136(3), C3-C4-N3 129(3), C1-C4-C3 94(2), F-C-F 105(2), C1-N1-C16-Cr1 96(3), C4-N3-C26-Cr2 −99(3).

tives with annelated, fluoro-substituted, four-membered rings.

Experimental Procedure

3: **2** (1.26 g, 4.2 mmol) was heated to 70 °C for 7 h. After cooling to room temperature, recrystallization from *n*-hexane gave pale yellow crystals as a mixture of **3a** and **3b**. Yield 1.02 g (81 %). **3a**: colorless crystals, m.p. 111 °C, ^{19}F NMR (376.442 MHz, $CDCl_3$, C_6F_6/$CFCl_3$) δ = 20.6/−139.4 (s, 2 F), 32.8/−127.2 (d, ^2J(F,F) = 218 Hz, 2 F), 39.7/−120.3 (d, ^2J(F,F) = 218 Hz, 2 F); MS (80 eV): *m/z* 598 [M^+], 458 [$M^+ - 5CO$], 318 [$M^+ - 10CO$], 299 [$(CO)_5Cr(CNCFCF_2)^+$] and additional smaller fragments; IR (CH_2Cl_2): $\tilde{\nu}$ = 2027(w), 1994(vs), 1975(vs), 1902(w) cm^{-1}.

3b: Light yellow crystals, m.p. 95 °C; ^{19}F NMR (376.442 MHz, $CDCl_3$, C_6F_6/$CFCl_3$) δ = 21.6/−138.4 (s, 2 F), 35.5/−124.5 (d, ^2J(F,F) = 218 Hz, 2 F), 36.7/−123.3 (d, ^2J(F,F) = 218 Hz, 2 F); MS (80 eV): *m/z* 598 [M^+], 458 [$M^+ - 5CO$], 318 [$M^+ - 10$ CO], 299 [$(CO)_5Cr(CNCFCF_2)^+$] and further smaller fragments; IR (CH_2Cl_2): $\tilde{\nu}$ = 2027(w), 2010(w), 1986(s), 1953(w), 1918(m) cm^{-1}.

5: A THF (25 mL) solution of **3** (100 mg, 0.17 mmol) in a Schlenk flask was cooled to −196 °C. Dimethylamine **4** (0.85 mmol) was condensed into the flask by using a vacuum line. Upon warming to −78 °C, the yellow solution turned deep red and then dark blue. The mixture was stirred for 1 h at −78 °C, after which the bulk of the THF was removed under high vacuum at −78 °C. The solution was layered with *n*-pentane and left to crystallize at −40 °C. After several days, **5** crystallized as deep blue plates, which decomposed slowly at room temperature. Yield: 62 mg (56 %). ^{19}F NMR (84.25 MHz, THF, $CFCl_3$, −100 °C): δ = −113.3, −129.4, ^2J(F,F) = 239 Hz, −118.3, −122.3, ^2J(F,F) = 234 Hz; ^{19}F NMR (84.25 MHz, THF, $CFCl_3$, −40 °C): −116.4, −125.9, ^2J(F,F) = 239 Hz.

6: **4** was passed into a rapidly stirred solution of **3** (97 mg, 0.16 mmol) in diethyl ether (20 mL), until the solution turned deep blue. Within 30 min, the dark blue solution turned green and then yellow. Cooling to −30 °C gave **6** (63 mg, 89 %), which was purified further by recrystallization from diethyl ether to give yellow air-stable crystals (49 mg, 70 %); decomp >110 °C. ^{19}F NMR (84.25 MHz, $CDCl_3$, $CFCl_3$) δ = −96.6, −101.2; ^{1}H NMR (89.55 MHz, $CDCl_3$) δ = 2.98 (s, 6 H), 3.29 (s, 3 H), 3.95 (s, 3 H); MS (80 eV) *m/z* 456 [M^+], 428 [$M^+ - CO$], 400 [$M^+ - 2CO$], 372 [$M^+ - 3CO$], 344 [$M^+ - 4CO$], 316 [$M^+ - 5CO$], 301 [$M^+ - 5CO\text{-}CH_3$]; IR (CH_2Cl_2): $\tilde{\nu}$ = 2061(m), 1983(sh), 1942(vs) cm^{-1}.

A Light-Induced Molecular Shuttle Based on a [2]Rotaxane-Derived Triad**

By *Andrew C. Benniston* and *Anthony Harriman**

Illumination of an intimate (or tight) charge-transfer complex, as formed by close association of an electron donor with a complementary electron acceptor, results in instantaneous formation of an intimate radical ion pair (RIP).[1] Charge recombination,[2] to reform the ground state, competes with dissociation of the RIP into separated radical ions[3] and with solvent penetration to form a solvent-separated (or loose) RIP.[4] If illumination is provided by a short laser pulse, the rates of charge recombination and dissociation of the RIP can be determined and correlated with thermodynamic,[5] electrostatic,[6] or structural[7] properties of the system. Indeed, recent work[8] has established that the rate of charge recombination correlates remarkably well with the energy of the optical charge-transfer transition for a series of cyclophane-derived RIPs having well-defined molecular architecture. This study revealed, however, that the strong electronic coupling between the partners within the RIP, which is an inherent feature of such compact systems, favored rapid charge recombination. In attempting to prolong the lifetime of the redox intermediates, we have synthesized a [2]rotaxane-derived system in which the terminal stoppers are redox active and which facilitates spatial separation of the primary redox charges.[9] The resultant molecular triad mimics those prepared earlier containing a central porphyrin with appended donor and acceptor functions.[10, 11]

The ferrocenyl-stoppered [2]rotaxane **3** was synthesized by the route depicted in Scheme 1, which follows the procedure pioneered by Stoddart et al.[12] Ferrocenyl carboxylic chloride,[13] prepared from ferrocene-1-carboxylic acid and oxalyl chloride, was added to a solution of 1,4-bis[2-{2-(2-hydroxyethoxy)ethoxy}ethoxy]benzene[12] and triethylamine to form **1**. Compound **1** and 1,1′-[1,4-phenylenebis(methylene)]-bis-4,4′-bipyridinium bis(hexafluorophosphate) (**2**)[12] yielded **3** in 10% yield a a brownish-red solid, according to the template method introduced by Stoddart et al.[14] The compound was purified by gravitational chromatography followed by anion exchange.

X-ray crystallography and ^{1}H NMR spectroscopy established that for **3**, and for closely-related cyclophanes[12, 15] and [2]rotaxanes,[12, 16] the dialkoxybenzene subunit is held inside the cavity of the cyclophane. Indeed, for the corresponding [2]rotaxane possessing triisopropylsilyl groups in place of ferrocene there is sufficient interaction between the π systems of the dialkoxybenzene donor and the cyclophane-derived acceptor to cause appearance of a pronounced charge-transfer absorption band centered at 467 nm ($\varepsilon = 350\ M^{-1}cm^{-1}$) and a weak emission band centered at 548 nm in acetonitrile solution. These spectral measurements can be used to calculate[17] the reaction exergonicity for charge recombination ($\Delta G^0 = -2.46$ eV), the total reorganization energy accompanying charge recombination ($\lambda = 0.19$ eV), and the electronic matrix coupling element

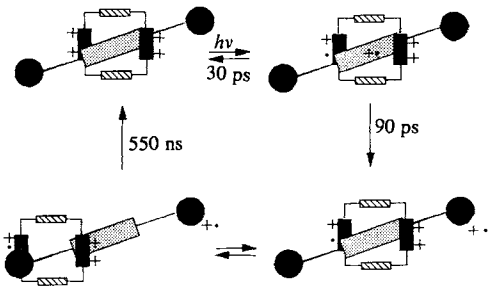
($V = 1215\ cm^{-1}$).[18] For **3**, the charge-transfer absorption band partially overlaps a weak transition associated with the ferrocene subunit, which renders calculation of the above parameters a difficult task. Consequently, we assume that the ferrocene subunits do not affect the charge-transfer characteristics of the complex; X-ray crystallography and ^1H NMR spectra provided firm evidence in support of the dialkoxybenzene subunit residing within the central cavity of the cyclophane. From CPK molecular models, the maximum edge-to-edge separation between the dialkoxybenzene and ferrocene subunits was estimated to be approximately 10 Å for a fully extended conformation. Preliminary X-ray crystal structure data, however, indicated π-stacking between the ferrocene subunits and the cyclophane implying that, in the solid state, a folded conformation is preferred.

Cyclic voltammetry studies made with **3** in deaerated acetonitrile solution containing tetra *N*-butylammonium perchlorate (0.2 M) gave one-electon redox potentials of −0.53 V vs the saturated calomel electrode (SCE) for reduction of the cyclophane and 0.46 and 1.14 V vs SCE, respectively, for oxidation of the ferrocene and dialkoxybenzene subunits. We might expect, therefore, that the dialkoxybenzene π-radical cation formed by excitation of the charge-transfer complex could oxidize one of the appended ferrocene subunits, since there is a high thermodynamic driving force for this reaction ($\Delta G^0 = -0.68$ eV).

Excitation of **3** in acetonitrile solution with a 500 fs laser pulse at 437 nm resulted in the immediate appearance of a species possessing a transient differential absorption spectrum very similar to that formed[8] by addition of a single electron to the cylophane (Fig. 1a). Therefore, this species is believed to be the RIP as formed by electron transfer from the included dialkoxybenzene to the cyclophane within the confines of a charge-transfer complex. The same absorption spectral features appear following laser excitation of the [2]rotaxane having the terminal ferrocene subunits replaced with triisopropylsilyl groups. However, whereas the transient absorption signal observed for this latter system decayed completely to the prepulse baseline with a lifetime of about 9 ps, that observed for **3** decayed with a lifetime of about 22 ps to leave a residual signal (Fig. 1a). The transient absorption spectrum of the longer lived species, as recorded following excitation at 532 nm with a 30 ps laser pulse (Fig. 1b), was very similar, if not identical, to that observed immediately after excitation of **3**, and the species decayed slowly by first-order kinetics with a lifetime of 550 ns (Fig. 1b). Excitation of the rotaxane without the cyclophane (i.e., compound **1**) under conditions identical to those described above did not give rise to any detectable transient species.

The laser flash photolysis records can be explained in terms of Scheme 2. Excitation of **3** at a wavelength corresponding to absorption into the charge-transfer transition generates the corresponding RIP. Deactivation of the RIP occurs predominantly by rapid charge recombination ($\Delta G^0 \approx -2.46$ eV), for which the rate constant is $3.4 \times 10^{10}\ s^{-1}$. This process competes with oxidation of one of the appended ferrocene subunits by the dialkoxybenzene π-radical cation ($\Delta G^0 \approx -0.68$ eV), which occurs with a rate constant of $1.1 \times 10^{10}\ s^{-1}$. The ground state system is recovered by slow electron transfer from the π-radical cation of the cyclophane to the adjacent ferrocenium cation ($\Delta G^0 \approx -1.0$ eV), for which the rate constant is $1.8 \times 10^{6}\ s^{-1}$. In this way, some 25% of the primary redox charge is preserved for 500 ns or so.



Scheme 2. Proposed scheme for the photoprocesses occurring upon excitation of the [2]rotaxane **3** into the charge-transfer absorption band.

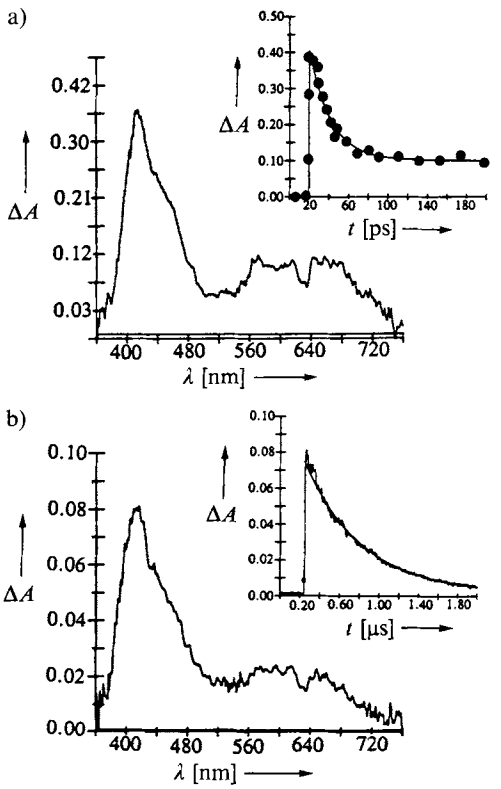


Fig. 1. Transient differential absorption spectra recorded a) 5 ps and b) 200 ps after laser excitation of the [2]rotaxane **3** in acetonitrile solution. The insert to each spectrum shows the decay profile recorded at 410 nm together with its computed best fit.

The close proximity of the threaded components ensures rapid and quantitative formation of the RIP upon illumination, and the large amount of energy that must be dissipated by this species contributes towards its relatively long lifetime. This lifetime is sufficient to permit secondary electron transfer to an appended ferrocene subunit, which separates the redox charges spatially. It should be noted that whereas there is strong electronic coupling between the reactants in the RIP, the dialkoxybenzene π-radical cation and the terminal ferrocene subunits are expected to be coupled only weakly. Thus, direct charge recombination may be under adiabatic contol,[19] whilst oxidation of the ferrocene subunit should be under nonadiabatic control.[20] Annihilation of the remote redox charges is relatively slow and is reduced by a factor of approximately 20000 with respect to the primary charge recombination process. The slowness of this reaction may permit migration of the cyclophane along the thread in

order to minimize electrostatic repulsion between the positively charged reactants. In fact, if the cyclophane is centered over the dialkoxybenzene subunit in the RIP it would require only about 10 ns for it to migrate coherently to the nonoxidized ferrocene subunit.[21] In this respect, **3** operates as a light-induced molecular shuttle, since absorption of light induces migration of the cyclophane along the thread before reverse electron transfer restores the original conformation.

Experimental Procedure

1: To a vigorously stirred solution of 1,4-bis[2-{2-(2-hydroxyethoxy)ethoxy}-ethoxy]benzene [12] (1.2 g, 3.2 mmol) in dried CH_2Cl_2 (50 mL) containing triethylamine (1 g, 9.9 mmol) was added dropwise a solution of ferrocenyl carboxylic chloride [13] (2 g, 8.0 mmol) in dried CH_2Cl_2 (25 mL). The mixture was stirred for a further 48 h before addition of water (20 mL). The organic layer was separated, washed with water, dried, and evaporated to dryness under reduced pressure to give a red oil. The oil was purified by chromatography on silica (60–200 mesh) with CH_2Cl_2 as eluent to remove unchanged starting materials and subsequently with CH_2Cl_2/CH_3OH (95/5) to elute compound **1**. Removal of the solvent gave **1** as a yellow solid. Yield: 1.6 g (62%). ^1H NMR (250 MHz, $CDCl_3$, 25 °C): $\delta = 3.71-3.85$ (m, 16H), 4.04–4.08 (t, 4H, $J = 5$ Hz); 4.20 (s, 10 H), 4.37–4.41 (m, 8 H), 4.81–4.83 (m, 4H); 6.82 (s, 4H). ^{13}C NMR (63 MHz, $CDCl_3$, 25 °C): $\delta = 63.23$, 68.00, 69.44, 69.79, 69.87, 70.17, 70.64, 70.79, 70.88, 71.30, 115.52, 153.03, 170.90. FAB-MS (nitrobenzyl alcohol matrix): 798 $[M]^+$; 585 $[M - FcCO]^+$. UV/VIS (CH_3CN): λ_{max} [nm] (ε [$M^{-1}cm^{-1}$]) = 442 (500).

3: A mixture of **2** [12] (180 mg, 0.25 mmol), 1,4-bis(bromomethyl)benzene (66 mg, 0.25 mmol), **1** (600 mg, 0.75 mmol), and $AgPF_6$ (158 mg, 0.63 mmol) in dried CH_3CN (50 mL) was stirred for 7 days at room temperature. Subsequently, the solution was filtered and evaporated to dryness under reduced pressure. The residue was washed with CH_2Cl_2 (15 mL) and centrifuged. After removal of the supernatant liquid, the residue was washed again with CH_2Cl_2 (2×15 mL) and centrifuged. The solid was dissolved in a mixture of CH_3NO_2 (15 mL) and CH_2Cl_2 (10 mL) and centrifuged once more. The liquid phase was separated, and the solid residue was extracted with a mixture of CH_3NO_2 (10 mL) and CH_2Cl_2 (10 mL). The liquid phases were combined, and the solvent removed under vacuum without heating to give a brown oil. Chromatography on silica with CH_3OH/aq. NH_4Cl (2 M)/CH_3NO_2 (7/2/1) as eluent yielded the required fraction ($R_F = 0.37$), from which the solvent was removed by freeze-drying to give a brown solid. This material was dissolved in water (20 mL), and the required product was precpitated by addition of aqueous NH_4PF_6. Yield: 31 mg (6%). ^1H NMR (250 MHz, $[D_6]$-dimethylsulfoxide, 25 °C): $\delta = 3.32-3.66$ (m, 20H); 3.89–3.93 (m, 8H), 4.21 (s, 10H), 4.39 (t, 2H, $J = 5$ Hz), 4.48 (t, 2H, $J = 5$ Hz), 4.61 (t, 2H, $J = 5$ Hz), 4.72 (t, 2H, $J = 5$ Hz), 5.75 (s, 8H), 7.88 (s, 8H), 8.21–8.24 (d, 8H, $J = 6.5$ Hz), 9.23–9.26 (d, 8H, $J = 6.5$ Hz). FAB-MS (nitrobenzyl alcohol matrix): 1898 $[M]^+$; 1753 $[M - PF_6]^+$; 1608 $[M - 2PF_6]$. UV/VIS (CH_3CN): λ_{max} [nm] (ε[$M^{-1}cm^{-1}$]) = 452 (700).

[21] Calculated according to $d = (2Dt)^{1/2}$ where d is the one-dimensional translation distance (10 Å), D is the diffusion coefficient of the cyclophane ($\approx 5 \times 10^{-7}$ $cm^2 s^{-1}$), and t is the time required for the migration.

DNA Supercoiling Imaged in Three Dimensions by Scanning Force Microscopy**

By *Bruno Samorì,* Carmelo Nigro, Valerio Armentano, Salvatore Cimieri, Giampaolo Zuccheri,* and *Carla Quagliariello*

Scanning force microscopy (SFM) is being employed ever more extensively in organic[1] and biological chemistry.[2, 3] With SFM molecules can be imaged both in water[4] and organic solvents.[2, 5, 6] Though this technique is still being developed, there is no question about the profound impact it will have on the study of molecular structure and behavior.

In essentially all organisms the DNA double strand is coiled in a right-handed fashion termed negative supercoiling.[7] Supercoiled and relaxed circular DNA molecules are now routinely imaged by SFM.[2, 4, 6] Up until now this kind of imaging provided, like electron microscopy (EM),[7] only a planar projection of the molecular shape of supercoiled circular DNA.[2, 4, 5] However, these SFM images also contain surface height information for the DNA molecules examined, although the vertical resolution attained is not high enough to allow the complete three-dimensional path of the chains to be observed directly. The image in Figure 1 shows, however, that this can indeed be achieved.

The number of turns (two) of the DNA molecule chain about the superhelical axis and the right-handedness of the winding are well distinguished. We can thus fully and directly characterize the supercoiling of this molecule because we "see" it. This high resolution has so far been obtained only for molecules with two or three turns.[8] In the other cases stratigraphic analysis can be applied[6] to obtain the third-dimension data contained in SFM images of more tightly supercoiled molecules, and the chirality of the supercoiling can be identified for most well-detected loops.

This display of the complete three-dimensional path of the axis of the DNA double strand opens up several important prospects:

1. Experiments can now be designed so that one can directly monitor the local modulations of supercoiling, which facilitate and drive many important biological processes such as DNA transcription[9, 10] and polymorphism.[11] Supercoiling stabilizes H-triple helices and cruciform and left-

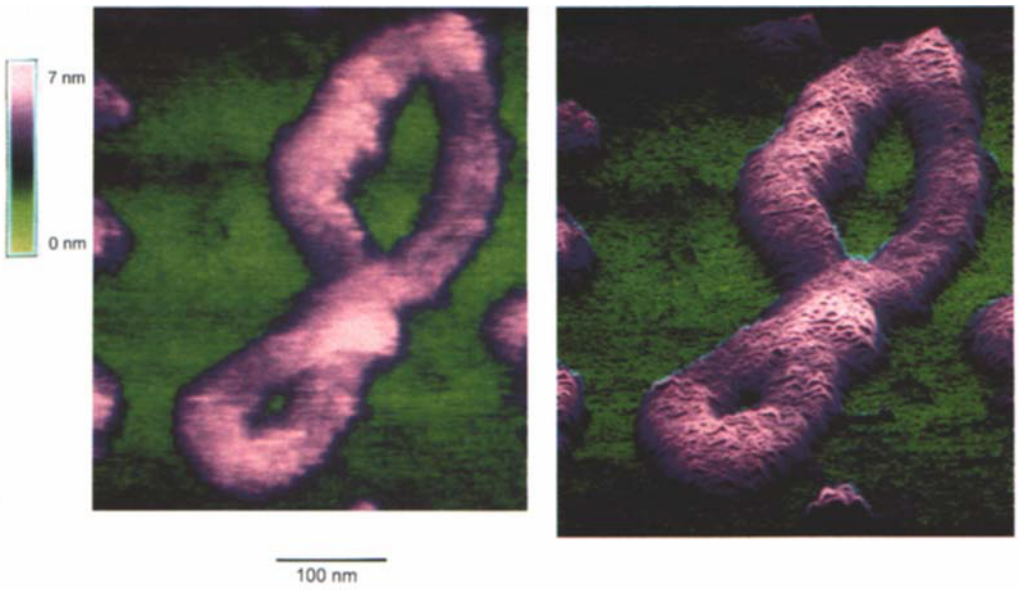

Fig. 1. SFM image of a supercoiled pBR322 DNA molecule. The three-dimensional shape of a circular DNA molecule is clearly displayed by the unfiltered image (left) in which the height information is coded by shades of purple (the lighter, the higher). In the line plot (right), which is obtained by plotting each scan line on an x,y,z scale, the path of the DNA double strand is even more distinct. The two turns of the DNA chains about the superhelical axis and the right-handedness of the supercoiling can be directly recognized by inspection.

handed Z-DNA structures.[11] The conversion from negative to positive supercoiling is reported as characterizing highly transcribed genes.[10] The modulations of supercoiling depend upon local sequences, the position of promoters, and the vectorial tracking of macromolecular complexes along the DNA.[9–12]

2. The writhing number (W_r) of coiled molecules,[7, 13] the most complete and accurate parameter for describing supercoiling and the overall hydrodynamic shape of DNA molecules, can now be determined experimentally. The most widely used descriptor of supercoiling has thus far been the "linking deficit" ($\Delta L_k = L_k - L_{k0}$), which reduces the three-dimensional intertwining of DNA strands to a single number that can be measured by two-dimensional gel electrophoresis. The linking number L_k is the sum of the signed indexes associated with the crossing between either DNA strand and the DNA axis.[3] These nodes can arise in either of two ways: from the winding of the strands about the axis of the double helix, which is related to the twisting number (T_w), or from the crossings of the helix axis itself, which are described by the writhing number (W_r). L_{k0} is the reference linking number of the relaxed circular DNA molecule.

There are at least two reasons to regard the linking deficit as a poor descriptor of supercoiling. It is a topological property defined independently of DNA geometry, whereas supercoiling is a geometric concept. Then, too, it is formally possible to have a nonzero linking deficit ΔL_k for a perfectly planar DNA molecule.[13]

By contrast, W_r is a truly geometric property of the DNA axis. It is directly proportional to the number of times the DNA winds round the supercoiling axis and equal to zero for relaxed DNA. The use of W_r in place of ΔL_k as a descriptor of supercoiling has been very limited heretofore, as W_r could not be experimentally determined. The W_r of an ideal model of the supercoiled helical winding was indirectly computed from EM-derived DNA geometric parameters.[14] Resolution like that of the image in Figure 1 allows the direct determination of the W_r of the imaged molecules as the Gauss integral of the complete three-dimensional path of the chain.[13] In simple cases like that in Figure 1 it is also possible to estimate W_r directly from the image. For this molecule deposited on mica the contribution from planar looped pieces is zero. Because of the tight interwinding of the chain in the central part of the molecule, the number of negative[7] crossings is two for almost all projections. W_r of the molecule in Figure 1 is therefore very close to -2.

3. The partition of ΔL_k between the changes in the supercoiling state (W_r) and the change in the twist of the DNA strand (T_w) can now be experimentally determined too. In fact, the measurement of W_r in plasmid samples of defined ΔL_k yields ΔT_w.

4. SFM makes it possible to study the spatial architecture, intertwining, and coiling of polymers other than DNA.

In conclusion, images like those in Figure 1 demonstrate that it is now possible to monitor local modulations in the supercoiling of single DNA molecules directly and to fully characterize their topology.

Experimental Procedure

10 μL of a solution of pBR322 plasmid DNA (10 μg mL^{-1}) in TE buffer (10 mM Tris, 1 mM EDTA, pH 8.0) was deposited on the surface of freshly cleaved mica. After 2 min the excess solution was blotted off with filter paper. The sample was immediately rinsed with 15 μL of water and then dried for 5 min under a flow of nitrogen. The sample was imaged with the NANOSCOPE III AFM (Digital Instruments) under 1-propanol with silicon nitride tips ("nanoprobes", Digital Instruments). PBR322 plasmid DNA was obtained from transformed DH5 *E. coli* cells. Large-scale plasmid purification was performed using a method employing thermal lysis, followed by two cycles of density-gradient centrifugation with ethidium bromide/CsCl to equilibrium [15]. The sample showed three bands in its agarose gel electrophoresis pattern: the fastest has been attributed to supercoiled forms, the second to nicked and relaxed, and the slowest to high molecular weight DNA.

[8] The three-dimensional resolution of the complete path of very tightly intertwined chains appeared to be hardly achievable with the commercial tips we used in this investigation. This is likely to be due both to the decrease of the superhelix radius with the increase of the supercoiling [14] and the tip's shape and profile. In fact, in SFM images the horizontal

resolution depends on the end radius of curvature of the tip (M. J. Allen, N. V. Hud, M. Balooch, R. J. Tench, W. J. Siekhaus, R. Balhorn, *Ultramicroscopy* **1992**, *42–44*, 1095; J. Vesenka, M. Guthold, C. L. Tang, D. Keller, E. Delaine, C. Bustamante, *ibid.* **1992**, *42–44*, 1243), whereas the vertical resolution, in other words, how well steep features are visualized, is determined by the opening angle of the tip (D. Keller, D. Deputy, A. Alduino, K. Luo, *Ultramicroscopy* **1992**, *42–44*, 1481). A chain crossing profile can thus be resolved in three dimensions only if its opening angle is greater than that of the tip. The unusually large width and double-traced path of the DNA chain in Figure 1 suggest that this image was traced by a probe with two very sharp and close tips at its end. Under these conditions unusually high vertical resolutions are frequently obtained also imaging straight pieces of DNA.

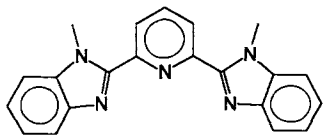
Structure of a One-Dimensional Infinite Double-Helical Copper(I) Complex**

By *Riccardo F. Carina, Gérald Bernardinelli,* and *Alan F. Williams**

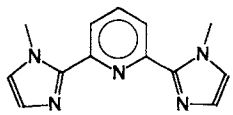
Dedicated to Professor Erwin Parthé on the occasion of his 65th birthday

Supramolecular chemistry, the chemistry of complicated structures formed by the controlled association of simple molecular units, is currently an area of considerable interest.[1] In supramolecular coordination chemistry the structure is assembled by the coordination of suitably structured ligands about a metal ion, and the assembly may be controlled by the disposition of binding sites within the ligand structure, and by the stereochemical preferences of the metal ion.[2] The synthesis of helical complexes has recently attracted particular attention: double-helical complexes containing up to five Cu^I ions have been reported by Lehn et al.[3] by using oligobipyridyl ligands; Constable has prepared helical complexes with a variety of metal ions by using polypyridyl ligands,[4] while we have previously reported triple-helical complexes of six-coordinate Co^{II}[5] and nine-coordinate Eu^{III}.[6] A general feature of these complexes is that the length of the helix is determined by the number of binding sites of the ligand; thus, a ligand with three bipyridyl binding sites can bind up to three cations, and will form a helical, trinuclear complex. If it is desired to extend the helix, it will be necessary to design a new ligand with additional binding sites. An alternative strategy is to form an extended helix, in the ideal case a one-dimensional infinite helical complex, in two steps: an initial formation of a helical subunit, which is followed by an association to give an extended helical structure. We report here the realization of this strategy to give a one-dimensional infinite double-helical copper(I) complex.

Some years ago we reported the synthesis and structure of the simple double-helical complex $[Cu_2(\mathbf{1})_2]^{2+}$ (**3**).[7] A feature of **3**, which is also found in many other helical complexes, is the intramolecular stacking between the aromatic planes of the heterocyclic ligands. In order to study the importance of this stacking we have prepared the ligand 2,6-bis(1-methyl-imidazol-2-yl)pyridine (**2**), in which molecular models suggested that the intramolecular stacking interactions would be greatly reduced.



1



2

The X-ray crystal structure of $[Cu_2(\mathbf{2})_2](ClO_4)_2$ (**4**) shows that the basic $[Cu_2L_2]^{2+}$ unit found in **3**[7] is also observed with ligand **2**. The ligands bind in a bis-monodentate coordination mode, and form the strands of the helix that twist around the helical axis on which the copper ions lie. Each Cu^I center is essentially linearly coordinated by two imidazole units, and is slightly bent towards the second Cu^I center of the $[Cu_2L_2]^{2+}$ unit; the interaction with the two bridging pyridines is weak. The asymmetric unit is composed of two independent half molecules, and a crystallographic twofold symmetry axis passes through the Cu ions so that the two ligand strands are symmetry related. Relevant bond lengths and angles of **4** are given in Table 1, and Figures 1 to 3 show different views of the complex cations. The $Cu-N_{imidazole}$ distances in **4** are slightly shorter than the $Cu-N_{benzimidazole}$ distances in **3**; the $Cu-N_{pyridine}$ distances, however, are significantly longer in **4** than in **3**, although the Cu–Cu distances (2.821(5), 2.828(5) Å) are 0.03 Å shorter. The dihedral angles between the pyridine and the imidazole groups, which describe the twisting of the ligand, are in **4** slightly smaller than the average value for **3**, but more significantly, they show much less variation than for **3** where the variation was from 18 to 44°. As expected, the intramolecular stacking of the

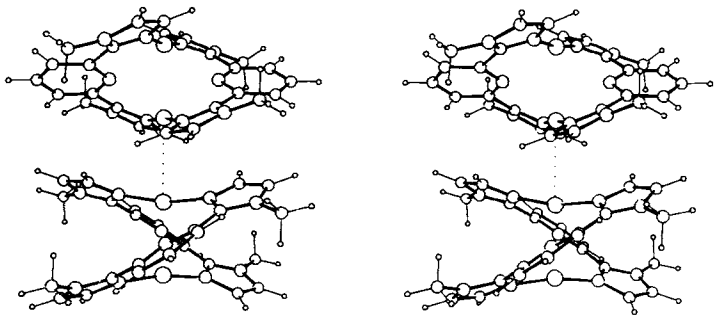


Fig. 1. ORTEP [13] stereoview of two $[Cu_2(\mathbf{2})_2]^{2+}$ units. The crystallographic twofold axis passes through all four copper ions, and the two molecules of complex are crystallographically nonequivalent.

[a] py = pyridine, imid = imidazole. Columns 1 to 4 refer to the sites of the four crystallographically inequivalent copper ions. The values for **3** are averages. The torsion angle between the imidazole rings and the pyridine ring is the angle between the least-squares planes defined by the atoms of the cycle.

benzimidazoles, which was observed in **3**, is absent in **4**. In general the complex **4** is much closer than **3** to D_2 symmetry.

The major difference between **3** and **4** lies in the crystal packing; **4** contains two crystallographically distinct $[Cu_2(\mathbf{2})_2]^{2+}$ complexes which are stacked on top of each other along the twofold symmetry axis. The two distinct complexes

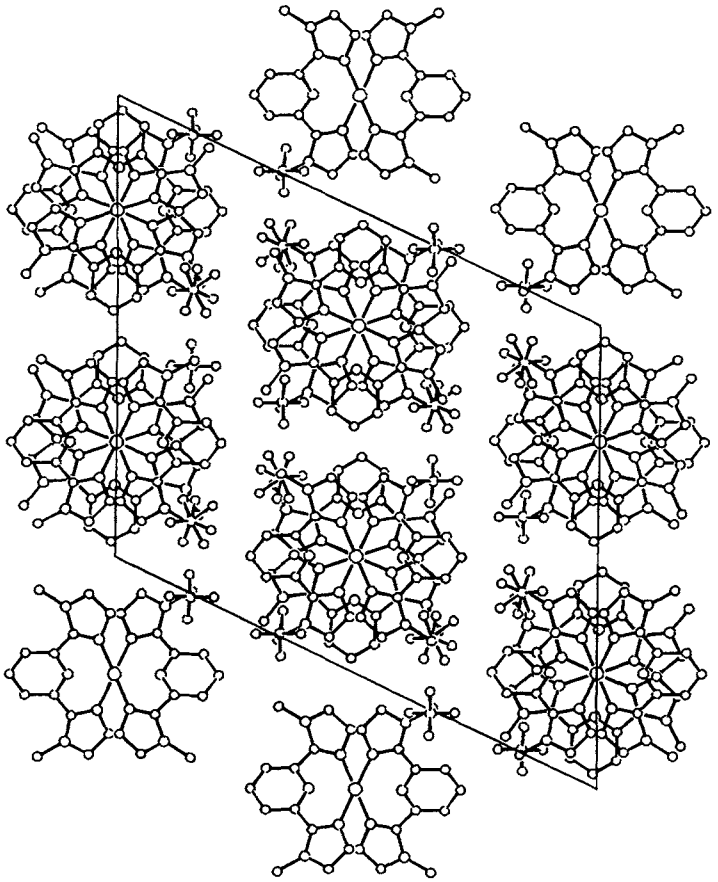

Fig. 2. ORTEP [13] view of the packing along the *b* axis. Adjacent columns are of opposite helicity.

do not differ significantly in their structure, but the second is rotated by approximately 90° about the twofold axis with respect to the first. This allows a strong stacking interaction between the imidazole planes of superposed complexes with interplanar angles of 10.7(8) and 6.8(8)° and average interplanar distances of 3.48 and 3.45 Å, respectively. The intermolecular Cu–Cu distances are 3.291(5) and 3.425(5) Å. The rotation by 90° about the Cu–Cu axis of successive complexes allows the double-helical $[Cu_2(\mathbf{2})_2]^{2+}$ units to mesh together perfectly so that the structure appears as an infinite double helix (Fig. 3). In this each strand is a series of molecules of the ligand **2**, and the strands are held together by a combination of coordination and stacking interactions.

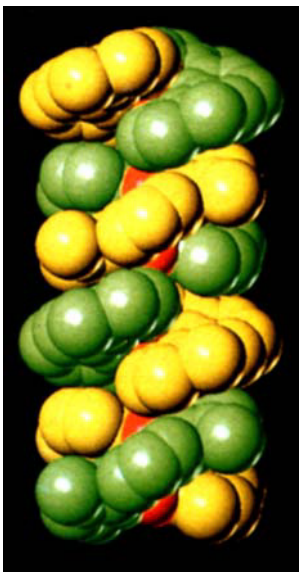

Fig. 3. MOLCAD [14] view of four $[Cu_2(\mathbf{2})_2]^{2+}$ units stacked along the *b* axis. The eight copper ions are red, and the ligands yellow and green.

The loss of the intramolecular stacking present in **3** has been compensated by the intermolecular stacking between units in **4**. The selectivity of the interaction is nicely illustrated by the complete separation of complexes with different helicity: in this racemic compound complexes of positive and negative helicity are formed in equal amounts; upon crystallization, however, the complexes stack together in parallel columns of constant but different helicity. The final structure may therefore be considered as resulting from the stereoselective assembly (by stacking interactions) of double-helical subunits formed by the coordination of **2** to copper(I) to give infinite double-helical columns. These columns are arranged in an almost ideal heaxagonal packing of rods along [010] as described by O'Keefe and Andersson,[8] although the rods show alternating chirality.

On dissolution of **4** in nonpolar solvents, the one-dimensional infinite chains dissociate; the NMR data, however, show that the double-helical $[Cu_2(\mathbf{2})_2]^{2+}$ units are maintained.[15]

Experimental Procedure

2,6-bis(2-imidazol-2-yl)pyridine was prepared by barium manganate oxidation [9] of 2,6-bis(2-imidazolin-2-yl)pyridine obtained by condensation of pyridine-2,6-dicarboxylic acid with ethylenediamine [10]. 2,6-bis(2-imidazol-2-yl)pyridine was methylated to give ligand **2** as described previously [7]. Complex **4** was obtained by reaction of ligand **2** with $[Cu(CH_3CN)_4]^+$ as for complex **3** [7].

Crystals of **4** suitable for X-ray difffraction were obtained by vapour diffusion (under nitrogen) of THF into a concentrated solution of **4** in acetonitrile:DMF (9:1). An orange-red crystal (0.12 × 0.17 × 0.31 mm) was mounted on a quartz fiber. $M_r = 804.6$, monoclinic, $I2/a$, $a = 22.369(4)$, $b = 12.365(2)$, $c = 25.421(4)$ Å, $\beta = 115.74(1)°$ based on 23 reflections ($16° < 2\theta < 28°$), $V = 6334(2)$ Å^3, $Z = 8$. Intensity data were collected at room temperature on a Philips PW1100 diffractometer with $Mo_{K\alpha}$ radiation ($\lambda = 0.71069$ Å), $6° < 2\theta < 44°$. 3858 unique reflections measured. The structure was solved by direct methods [11], other calculations were made with XTAL 3.2 [12]. The perchlorate ions lie in general positions and are disordered. Full-matrix refinement with anisotropic thermal displacement parameters for all non-hydrogen atoms (apart from two disordered oxygen atoms) and hydrogen atoms in calculated

positions gave a final R factor $R = R_w = 0.072$ for 1935 observed reflections ($|F_o| > 4\sigma(F_o)$) and 453 variables. Further details of the crystal structure are available on request from the Director of the Cambridge Crystallographic Data Centre, 12 Union Road, GB-Cambridge CB2 1EZ (UK), on quoting the full journal citation.

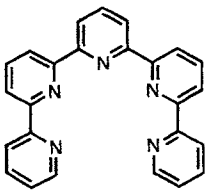
The First Structurally Characterized Heterodinuclear Double-Helicate Complex**

By *Edwin C. Constable,* Andrew J. Edwards, Paul R. Raithby*, and *Juliet V. Walker*

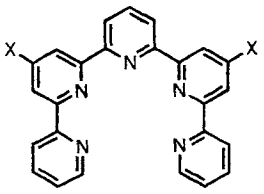
Metal-directed self-assembly of topologically novel supramolecular arrays has attracted considerable attention in recent years.[1] We and others have shown that oligopyridines provide versatile metal-binding domains for the assembly of helicate and double-helicate complexes.[2] We have developed a strategy involving the matching together of the donor characteristics of a ligand array to the coordination requirements of metal centers. Helicates are the result of the partitioning of the donor set of an oligopyridine into two metal-binding domains; for a 2,2′:6′,2″:6″,2‴:6‴,2⁗-quinquepyridine (**1**, qpy) this involves a rotation about an interannular C–C bond to separate the ligand into a tridentate 2,2′:6′,2″-terpyridyl and a didentate 2,2′-bipyridyl part. A double-helical array of two qpy ligands presents a total of ten nitrogen donor atoms, which are usually arranged to create a six-coordinate [tpy + tpy] and a four-coordinate [bpy + bpy] metal-bonding cavity, although two five-coordinate [bpy + tpy] cavities are also possible.[2]

In the solid state, $[Co_2(\mathbf{1})_2(OAc)](PF_6)_3$ is double-helical, but upon dissolution in a donor solvent, a mononuclear seven-coordinate species $[Co(\mathbf{1})(solv.)_2]^{2+}$ (solv. = MeCN, MeOH, or H_2O) is formed.[3] We argued that this was the result of a destabilization of the cobalt in the [bpy + bpy] site, and showed that treatment of the solution species with Ag^+ ions resulted in the formation of the heterodinuclear double-helicate $[CoAg(\mathbf{1})_2]^{3+}$ in which we assumed the cobalt to be in a [tpy + tpy] and the silver in the [bpy + bpy] site. We now describe a high yield systematic synthesis of these complexes and the structural characterization of $[CoAg(\mathbf{1})_2](ClO_4)_3$.

The reaction of the two mononuclear cations $[Co(\mathbf{1})(MeOH)_2]^{2+}$ and $[Ag(\mathbf{1})]^+$[4] in a 1:1 ratio gave $[CoAg(\mathbf{1})_2]^{3+}$ in near-quantitative yield. The reactions with the substituted qpy ligands, **2**–**5** proceeded in a precisely similar manner to give the substituted analogues. In all cases,



1



2, X = MeS
3, X = Ph
4, X = 4-ClC_5H_4
5, X = 4-ClC_6H_4

the complexes were readily purified by chromatography to yield pale yellow microcrystalline materials. Attempts to prepare specifically the heterodinuclear heteroleptic double-helicates, such as $[CoAg(\mathbf{1})(\mathbf{3})]^{3+}$, by the reaction of either $[Co(\mathbf{1})(MeOH)_2]^{2+}$ and $[Ag(\mathbf{3})]^+$ or $[Co(\mathbf{3})(MeOH)_2]^{2+}$ and $[Ag(\mathbf{1})]^+$ were unsuccessful, and gave inseparable statistical mixtures of $[CoAg(\mathbf{1})_2]^{3+}$, $[CoAg(\mathbf{3})_2]^{3+}$, and $[CoAg(\mathbf{1})(\mathbf{3})]^{3+}$ as shown by FAB mass spectrometry and also by ^1H NMR spectroscopy. The ^1H NMR spectrum indicated that these heterodinuclear complexes were the only species observable on the NMR time-scale; the mononuclear silver complexes were not observed. We attempted to obtain X-ray quality crystals of $[CoAg(\mathbf{1})_2]^{3+}$ with a variety of substituted ligands, a range of counterions, and from a variety of solvents but in all cases we obtained either powders, or small crystals which immediately lost solvent upon removal from the crystallization solvent.

We finally obtained small crystals of $[CoAg(\mathbf{1})_2](ClO_4)_3 \cdot 2\,H_2O$ (**6**) from acetone/H_2O and mounted these in perfluoropolyether oil RS3000 and determined the structure of 153 K.[5] The lattice consists of dimeric $\{CoAg(\mathbf{1})_2\}_2^{6+}$ units and hydrogen bonded, but disordered, water molecules and perchlorate anions. The structure of one of the two crystallographically independent $[CoAg(\mathbf{1})_2]$ units in the dimeric cation is shown in Figure 1. The structural determination confirms our predictions that the heterodinuclear double-helical cation has been formed, and that the cobalt is in a [tpy + tpy] and the silver in a [bpy + bpy] environment. The

Co···Ag distances within the two independent units are 4.167 and 4.224 Å, respectively, and these are comparable to, but slightly shorter than, the Co···Co distance (4.461 Å) in $[Co_2(\mathbf{1})_2(OAc)](PF_6)_3$.[3] The Co–N and Ag–N bond lengths and angles in **6** are not unusual, although the coordination geometry about the silver differs substantially from that observed in the double-helical cation $[Ag_2(qtpy)_2]^{2+}$ (qtpy = 2,2′:6′,2″:6″,2‴-quaterpyridine).[6] A detailed comparison of the four-coordinate metal coordination spheres in the complexes $[Cu_2(\mathbf{1})_2(OAc)](PF_6)_3$, $[Ag_2(qtpy)_2](BF_4)_2$, and **6** is not particularly informative.

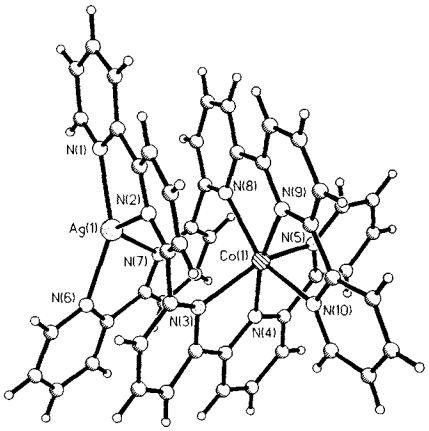

Fig. 1. Structure of one of the two $[CoAg(\mathbf{1})_2]^{3+}$ units present in **6**, showing the numbering scheme adopted. Selected bond lengths [Å] and angles [°] within the coordination sphere include: Ag(1)-N(1) 2.294(7), Ag(1)-N(2) 2.350(6), Ag(1)-N(6) 2.311(6),Ag(1)-N(7) 2.329(6), Co(1)-N(3) 2.239(6), Co(1)-N(4) 2.050(6), Co(1)-N(5) 2.161(6), Co(1)-N(8) 2.228(6), Co(1)-N(9) 2.058(6), Co(1)-N(10) 2.194(6); N(1)-Ag(1)-N(2) 71.4(2), N(6)-Ag(1)-N(7) 71.2(2), N(8)-Co(1)-N(9) 75.4(2), N(9)-Co(1)-N(10) 76.4(2), N(3)-Co(1)-N(4) 76.1(2), N(4)-Co(1)-N(5) 76.5(2). Angles and lengths within the other crystallographically independent dinuclear unit of **6** are similar.

The summation of the individual variations in interannular twisting along the oligopyridine chains results in significant but not readily explained changes in the coordination sphere. The cation exhibits the usual stacking interactions between approximately coplanar rings of the two different qpy ligands with rings 2 and 9 (numbered by the nitrogen atom they contain) with a centroid-to-centroid distance of 3.480 Å. The partitioning of the qpy ligands into bpy and tpy portions is achieved by interannular twistings of approximately 60° between rings 2 and 3 and rings 7 and 8, very similar to those observed in $[Co_2(\mathbf{1})_2(OAc)](PF_6)_3$.[3] The individual bpy and tpy domains are approximately, but not precisely, planar.

The most interesting feature of this structure is the assembly of the dimeric unit by the head-to-head interaction of two $[CoAg(\mathbf{1})_2]^{3+}$ units (Fig. 2) with a nonbonded Ag(1)···Ag(1′) contact of 3.822 Å. The long Ag···Ag contact cannot account for the formation of the head-to-head dimer. No such interactions are present between $[Ag_2(qtpy)_2]^{2+}$ units in the solid state.[6] The shortest contacts between the two double-helical $[CoAg(\mathbf{1})_2]^{3+}$ cations are those of approximately coplanar pyridine rings. Specifically, rings 6 and 6′ are stacked with a centroid-to-centroid distance of 3.663 Å whilst the corresponding rings 1 and 1′ are at 3.606 Å. These stacking interactions are undoubtedly responsible for the formation of the dimer, and unambiguously establish the importance of such interactions in determining the solid-state structures and conformations of helicates. The entire dimeric assembly is seen to exhibit a series of stacking interactions along its entire length (Fig. 2 bottom).

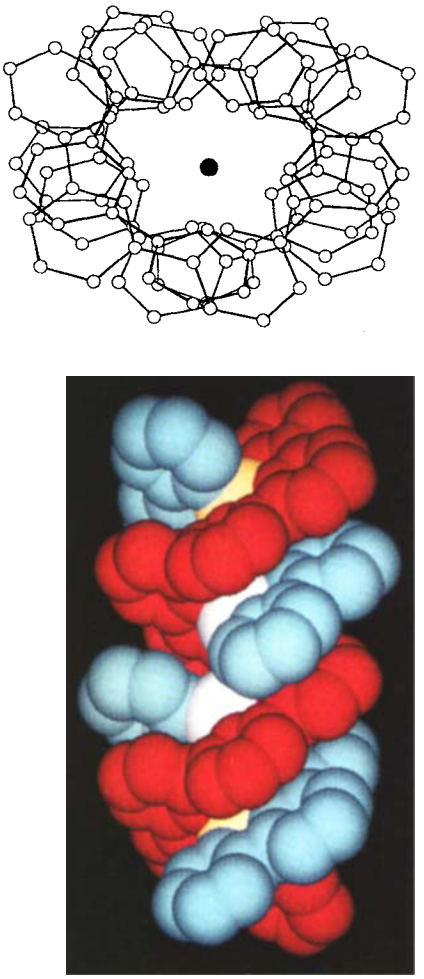

Fig. 2. The tetranuclear assembly of two $[CoAg(\mathbf{1})_2]^{3+}$ cations. Top: The view along the cobalt-cobalt vector. The metal–N bonds and hydrogen atoms have been omitted for clarity. Bottom: A space-filling representation of **6** showing the numerous stacking interactions which are present. The cobalt ions are yellow, the silver ions white, and the two ligand strands are colored red and blue. The stacking is between the red strand of one ligand and the blue strand of the other.

Experimental Procedure

The ligands **1**–**5** were prepared by the literature methods [7].

$[CoAg(\mathbf{1})_2](PF_6)_3$ and $[CoAg(\mathbf{1})_2](ClO_4)_3 \cdot 2\,H_2O$ **6**: Cobalt(II)-acetate (1 mmol, 25 mg) and **1** (1 mmol, 38 mg) were warmed in methanol (20 cm^3) and treated with ultrasound until dissolution was complete. A suspension of silver(I) acetate (1 mmol, 17 mg) and **1** (1 mmol, 38 mg) was treated similarly again to complete dissolution. The solution of the silver complex was then added dropwise with swirling to the solution of cobalt complex. The complexes were readily purified by chromatography (silica, 8:1 MeCN/saturated aqueous KNO_3 or $NaClO_4$) to yield pale yellow solutions, from which yellow microcrystalline materials were precipitated by the addition of methanolic ammonium hexafluorophosphate or sodium perchlorate. The hexafluorophosphate salt was recrystallized from acetonitrile by ether diffusion to yield yellow/orange crystals. The perchlorate salt could be recrystallized from a mixture of acetonitrile, acetone, and water by slow evaporation again to yield yellow/orange crystals. Yields were ≈65% in each case. FAB mass sepctrum, *m/z*: 1230, $[CoAg(\mathbf{1})_2](PF_6)_2$; 1085, $[CoAg(\mathbf{1})_2](PF_6)$ (based on ^{107}Ag).

A similar reaction with the ligand **5** gave the analogous complex $[CoAg(\mathbf{5})_2](PF_6)_3$ in 60% yield. FAB mass spectrum, *m/z*: 1525; $[CoAg(\mathbf{5})_2](PF_6)$; 1380, $[CoAg(\mathbf{5})_2]$ (based on ^{107}Ag, ^{35}Cl).

Rotation about the C–Se Bond as the Rate-Determining Step in the Racemization of α-Selenium-Substituted Alkyllithium Compounds**

By *Thomas Ruhland, Ruprecht Dress,* and *Reinhard W. Hoffmann**

Structural aspects of organolithium compounds have been investigated both experimentally[1] and theoretically[2] in recent years. The extent of aggregation can be determined,[3] and it is known which solvents favor contact ion pairs and which favor solvent-separated ion pairs.[4] In addition, there are reliable data on the configurational stability of organolithium compounds.[5] However, what is not yet fully elucidated is the mechanism of racemization.[6–8] In α-heterosubstituted alkyllithium compounds **1** (e.g., where X = S, Se, PR, SiR_2), the negative charge is stabilized by, amongst other effects, n → σ* delocalization (negative hyperconjugation) into the X–R bond.[9] In **1** this results in an antiperiplanar arrangement of X–R and C–Li bonds.[10] For lithium compounds of this type, a three-step racemization is postulated (Scheme 1). Step (1) is the dissociation of lithium from carbon (only the anionic parts of the contact ion pairs **2** and **3** are shown), step (2) is inversion at the pyramidal carbanion C atom, and step (3) is the rotation about the $C_{carbanion}$–heteroatom bond.

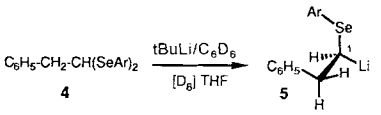
[**] This work was funded by the Graduierten-Kolleg Metallorganische Chemie at the University of Marburg, the Deutsche Forschungsgemeinschaft (SFB 260), and the Fonds der Chemischen Industrie.

For the development of configurationally more stable organolithium compounds it is important to identify the rate-determining step for racemization in order to control it. The following results clearly show that in certain systems the rotational step (3) could be rate-determining,[11] and that sterically demanding residues at the heteroatom increase the threshold for racemization.

We studied the rate of enantiomerization of racemic arylselenoalkyllithium compounds **5** in [D$_8$]THF/[D$_6$]benzene (6:1) with ^{1}H NMR spectroscopy. The lithium compounds **5** were prepared from the selenoacetal **4** and *tert*-butyllithium at −78 °C. After irradiation of the H1 signal, the



diastereotopic benzylic protons showed an AB pattern in the ^{1}H NMR spectrum, which for **5a**–**5c** coalesced on warming (see Table 1). By applying line-shape analysis (233–313 K),[12] the barrier to racemization for **5a** was calculated to be $\Delta G^{\ddagger}_{275} = 12.4$ kcal mol^{-1} ($\Delta H^{\ddagger} = 11.9 \pm 0.3$ kcal mol^{-1}, $\Delta S^{\ddagger} = -2.5 \pm 1.3$ cal K^{-1} mol^{-1}). We

Table 1. Topomerization of the diastereotopic benzylic protons in **5**.

5	Ar =	Δν [Hz]/T [K]	T_c [K]	$\Delta G^{\ddagger}$ [kcal mol^{-1}]
a		248/233	273	12.4 [a]
b		269/223	278	12.7 [b]
c		230/223	268	12.3 [b]
d		56/213	> 273	> 14.3 [b]
e		35/223	> 293	> 14.5 [b]

[a] Determined by line-shape analysis (QUABEX [12]). [b] Estimated from the coalescence temperature T_c.

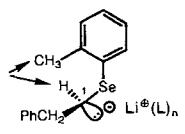
deduce that **5** exists as a contact ion pair,[13] because the ^{13}C NMR spectrum of the doubly labeled 1-^{13}C, ^{6}Li-**5a** shows $^{6}Li/^{13}C$ coupling. The $^{6}Li/^{6}Li$ exchange, the rate of which is concentration-dependent, can be followed in this doubly labeled system (see ref. [7]). This process is not coupled to racemization, the rate of which does not change on altering the concentration by up to a factor of 3. The racemization of **5a** is therefore first order, in contrast to that of secondary alkyllithium compounds.[8] The extent of aggregation of a 0.15 M solution of **5a** in THF was cryoscopically determined to be 1.04 ± 0.07 at $-108\,^{\circ}C$.

The barriers to rotation scarcely altered on changing the solvent to $[D_{10}]Et_2O$ ($\Delta G^{\ddagger}_{278} = 12.7\ kcal\,mol^{-1}$, $\Delta H^{\ddagger} = 10.9 \pm 0.4\ kcal\,mol^{-1}$, $\Delta S^{\ddagger} = -6.3 \pm 1.5\ cal\,K^{-1}\,mol^{-1}$) or on addition of 1.1 equivalents of pentamethyldiethylenetriamine ($\Delta G^{\ddagger}_{275} = 12.4\ kcal\,mol^{-1}$).

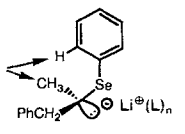
At this stage it was not possible to conclude from the data whether step (1), the dissociation of lithium from carbon, an ion-pair reorganization step, was rate-determining. The magnitude of the activation barriers of processes of this type are known,[14] but more negative values ($-15\ cal\,K^{-1}\,mol^{-1}$) were reported for the entropy of activation.

Could step (2), the inversion at carbon, be rate-determining? Ab initio calculations[15] for pyramidal sulfur-substituted carbanions gave inversion barriers of approximately $3\ kcal\,mol^{-1}$. This value is well below the barrier to racemization determined for **5**. Carbanion inversion could show an α-deuterium isotope effect; for example the analogous nitrogen inversion in $(CH_3)_2ND$ has an isotope effect k_H/k_D of 24,[16] which indicates a tunnel effect. We therefore studied the isotope effect of the racemization of **5a** but found no effect, within experimental error, with 1-deuterio-**5a** ($0.87 < k_H/k_D < 1.3$). This also suggests that inversion is not the rate-determining step of racemization of **5a**.

Therefore attention is focused on the rotational step (3). This should be affected by steric hindrance. Accordingly the aryl group (Ar) bonded to selenium was varied. The results in Table 1 show that the barrier to rotation is not affected by *one* methyl group in an *ortho* or para position in the aryl moiety, but that *two ortho* methyl groups raise the rotational barrier by more than $2\ kcal\,mol^{-1}$. This may be understood if the rate-determining step, based on Scheme 1, is the rotation about the C1–Se bond (cf. **6**). In the case of **5d** and **5e** a methyl group in the *ortho* position *must* come into contact with H1.[17]

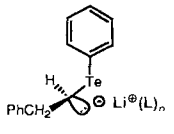


6



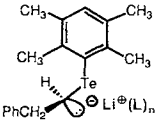
7

$\Delta G^{\ddagger}_{253} > 12.9\ kcal\,mol^{-1}$



8

$\Delta G^{\ddagger}_{248} = 11.6\ kcal\,mol^{-1}$



9

$\Delta G^{\ddagger}_{285} = 14.1\ kcal\,mol^{-1}$

The same steric hindrance should occur when the positions of CH_3 and H marked with arrows in **6** are interchanged. Therefore we studied the system **7**, in which no coalescence of the signals due to the diastereotopic benzylic protons within the stability range ($T < -20\,^{\circ}C$) was observed.

These results strongly suggest that, at least in **5d**, **5e**, and **7**, the rate-determining step for racemization is rotation about the C1–Se bond.[18] We can only speculate that the same may be true for compounds **5a**–**5c**. The exact fate of the lithium cation after leaving the carbon atom is still unclear. It could be coordinated to the heteroatom during the change in configuration of the carbanion system or form a solvent-separated ion pair.

The extent of the substituent-induced hindrance to rotation on the enantiomerization of **1** should also be dependent on the length of the C–X bond. This is evident on going to the analogous tellurium compounds **8** and **9**, in which the topomerization barriers calculated from the coalescence temperatures are 11.6 and 14.1 $kcal\,mol^{-1}$. If these rotational barriers crucial for the racemization are raised by $2.5\ kcal\,mol^{-1}$ or more by *ortho* substitution in an aryltellurium compound, the substituent effects in arylselenium compounds should be more pronounced. Accordingly we expect a substantial increase in the configurational stability of mesitylthio- or durylthio-substituted alkyllithium compounds.

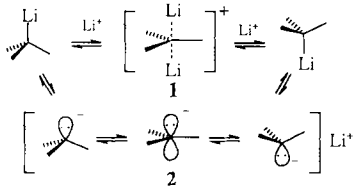
This study of other α-heterosubstituted alkyllithium compounds likewise suggests that rotation about the carbanion-heteroatom bond could be rate-limiting in racemization. We thank Prof. H. J. Reich for advance information.

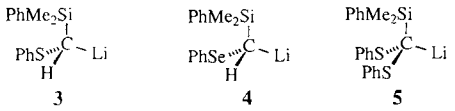
Effects of Ion Pair Separation on Inversion and Rotation of Sulfur-, Selenium-, and Silicon-Stabilized Organolithium Reagents**

By *Hans J. Reich** and *Robert R. Dykstra*

Most vinyl,[1] cyclopropyl,[2] and α-alkoxy[3] lithium reagents are configurationally stable. Other types racemize too rapidly for trapping experiments[4a, 5] or require very low temperatures to avoid rapid equilibration.[4a, 6] Advances in the utility of chiral organolithium reagents depend on detailed structural information[7] and mechanistic understanding of their racemization. One limiting mechanism for organolithium reagent epimerization is a bimolecular associative process through intermediate **1**.[4b] An alternative ion pair dissociation process via **2** has been frequently proposed since polar solvents usually accelerate racemization,[1a, 2a, 6a] but this has not been directly testable since the ion pair status of most organolithium reagents is not known. Our hexamethylphosphoric triamide (HMPA) titration technique[4c, d, 8] addresses this problem by allowing the unequivocal identification of contact and separated ion pairs. The correlation between ion pair structure and inversion barriers for several organolithium reagents can now be established.



We selected compounds **3**[9] and **4** for detailed study. These and related compounds are valuable reagents[10] that are easily prepared and stable in polar solvents. The presence



of several NMR-active nuclei (^{1}H, ^{13}C, ^{7}Li, ^{29}Si, and ^{77}Se) facilitates careful NMR investigations. Figure 1 shows the results of an HMPA titration of **3**. The ^{7}Li, ^{31}P, and ^{13}C data, as well as other spectra not shown, indicate that in THF **3** is a contact ion pair ($^1J_{Li\text{-}C}$ = 18.5 Hz) with a pyramidal carbanion center ($^1J_{C\text{-}H}$ = 132 Hz,[7, 11] $^1J_{C\text{-}Si}$ = 75 Hz).[9] The dimethyl(phenyl)silyl group served as a probe and indicated the configurational equilibration of **3**; below −100 °C **3** is chiral on the NMR timescale. The adduct **3** · 1 HMPA is also a pyramidal ($^1J_{C\text{-}H}$ = 136 Hz, $^1J_{C\text{-}Si}$ = 85 Hz), chiral contact ion pair ($^1J_{C\text{-}Li}$ = 14.4 Hz). After the addition of three equivalents of HMPA, **3** is a fully solvent-separated ion pair, as shown by the characteristic $R^-//Lih_3^+$ quartet and

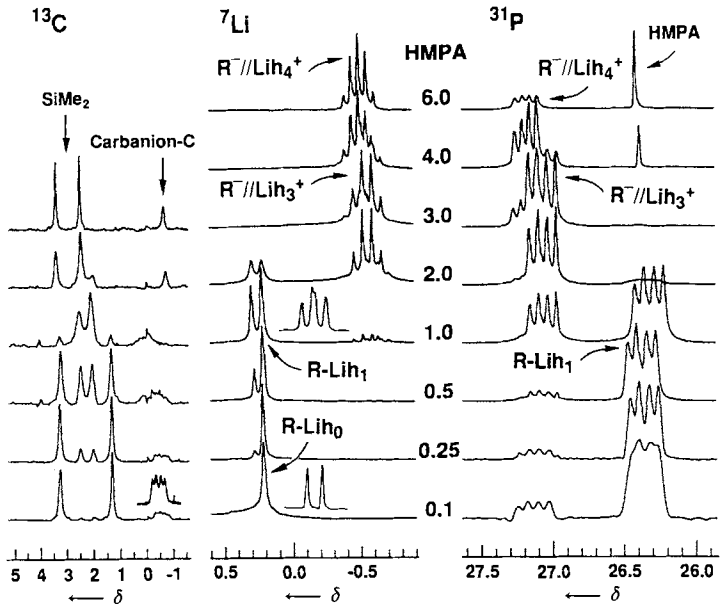


Fig. 1. ^{13}C, ^{7}Li, and ^{31}P NMR spectra of an HMPA titration of **3** in a 3:2 mixture of THF/ether at −121 °C. The insets show spectra from a ^{13}C-enriched sample (h = HMPA, // = solvent-separated ion pair).

$R^-//Lih_4^+$ quintet in the ^{7}Li NMR spectra and absence of coupling between lithium and carbon. Formation of separated ion pairs did not result in the loss of diastereotopicity of the $SiMe_2$ group even though increases in $^1J_{C\text{-}H}$ from 136 to 148 Hz and $^1J_{C\text{-}Si}$ from 85 to 106 Hz[4e] indicate significant planarization at the carbanion center.

Variable-temperature ^{13}C NMR spectra of **3** in THF, THF/1HMPA, and THF/3HMPA are shown in Figure 2. In THF, coalescence is observed at −100 °C and in THF/1HMPA at −112 °C. The slight lowering of the barrier on

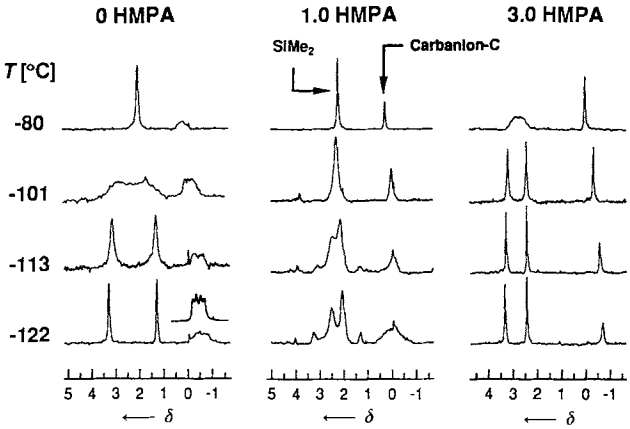

Fig. 2. Variable-temperature ^{13}C NMR spectra of **3** in a 3:2 mixture of THF/ether after addition of 0, 1, and 3 equiv of HMPA.

coordination to HMPA ($\Delta G^{\neq}$ = 8.0 to 7.8 kcal mol^{-1} for **3**, 8.2 to 7.8 kcal mol^{-1} for **4**) would seem to indicate that inversion of the pyramidal structure is accelerated by the strong donor ligand HMPA which loosens C–Li coordination. One might, therefore, expect an even lower barrier for the separated ion pair. The separated ion pair, however, racemizes more slowly (approximately 1/20 as fast at −101 °C)

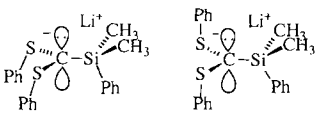
with a coalescence temperature above $-80\,^{\circ}C$ ($\Delta G^{\ddagger}$ = 9.1 kcal mol^{-1} for **3**, 9.5 kcal mol^{-1} for **4**). The separation of the ion pair (formation of **2**) cannot be the rate-determining step for the racemizaton of **3** and **4**. These data cannot easily be explained by an inversion process but fit well for rotation. Similar conclusions have been reached by R. W. Hoffmann et al. in a study of arylseleno- and aryltelluro-substituted alkyllithium reagents.[12] Barriers to rotation in carbanions have origins in stabilizing n-σ^* interactions when the carbanion lone pair is aligned with the S–Ph or Si–R bonds, and destabilizing repulsions between lone pairs when the carbanion is not aligned.[13] Such interactions should be stronger in a free carbanion than in a contact ion pair. When the carbanion C atom rotates away from the favored orientation, the charge density on the C atom must increase. This extra charge is more effectively stabilized by lithium in a contact rather than in a separated ion pair.

The racemization of **3** in THF is independent of concentration (0.04 to 0.64 M). In addition, the presence of 1 mol equiv of the separated ion pair lithium fluorenide[4d] had no effect on the racemization rate, so the reaction does not involve intermediate **1**. Since lithium fluorenide did lower the coalescence temperature for loss of Li-C coupling from -92 to $-112\,^{\circ}C$, Li–Li exchange may be intermolecular.

The complex behavior of **3** and **4** prompted us to examine a system in which there is no ambiguity between inversion and rotation. The organolithium reagent **5** is achiral in the absence of rotational barriers even if inversion is slow. We studied this compound, as well as the related PhS(PhSe)CLiSiMe$_2$Ph (**6**). Both are largely separated ion pairs in THF as well as in THF/HMPA, and both show diastereotopic SiMe$_2$ groups up to at least $-20\,^{\circ}C$. For **5** in a 1:3 mixture of THF/ether the SiMe$_2$ signals coalescence at $-12\,^{\circ}C$ ($\Delta G^{\ddagger}$ = 13.3 kcal mol^{-1}), whereas for **6** in a 3:2 mixture of THF/ether coalescence is reached at $7\,^{\circ}C$ ($\Delta G^{\ddagger}$ = 14.3 kcal mol^{-1}). The measured barrier probably corresponds to rotation about the C–S bond, which converts the chiral conformation of **5** to the achiral.



5

These findings provide a basis for understanding one odd facet of the behavior of **3**: the racemization barrier of the separated ion pair *increased* as more HMPA was added (T_c = $-98\,^{\circ}C$ at 2 equiv of HMPA, $-79\,^{\circ}C$ at 3 equiv, and $-75\,^{\circ}C$ at 6 equiv). This suggests that the racemization of the separated ion pair R$^-$//Lih$_3^+$ might actually proceed via the contact ion pair. If the rotation barrier for the separated ion pair **3** is as high as those measured for **5** and **6**, then a mechanism involving recoordination of lithium to carbon (accompanied by loss of one or more coordinated HMPA molecules) explains the rate-retarding effect of high HMPA concentrations. Clearly, the racemization is mechanistically complex. A coupled inversion–rotation process fits our data: the inversion is more significant for the contact ion pair in THF, and rotation dominates for the (probably planar) solvent-separated ion pair in THF/HMPA. We envision a mechanism in which lithium coordination to S or Se allows the lithium to move from one face of the carbanion to the other without separation of the ion pair. Coupled rotation–inversion processes have been extensively studied for sulfenamides, which are isoelectronic with phenythiocarbanions.[14]

Substantial rotation barriers have been reported for lithiated sulfones,[6d, 15] in which lithium coordinates to oxygen, but not for lithiated sulfides, selenides, or silanes.[12] However, the strong preference of Li for the equatorial position in dithianes[16] is equivalent to high rotation barriers in acyclic systems. The observation of a diastereotopic CH$_2$ group in the tetramethylethylenediamine (TMEDA) adduct of Ph$_2$PCH$_2$Li ($\Delta G^{\ddagger}$ = 7 kcal mol^{-1}),[17] interpreted as indicating a barrier to inversion, implies that there is a significant rotation barrier associated with C–P bonds as well. The relatively high epimerization barriers of α-lithio selenides,[4a, 6a] sulfides,[4a, 5] amines,[6b] and ethers[3] take on a new perspective with this information.

The Search for an Isolable Silyl Cation Must Continue**

By *Paul von Ragué Schleyer,* Peter Buzek, Thomas Müller, Yitzhak Apeloig,** and *Hans-Ullrich Siehl**

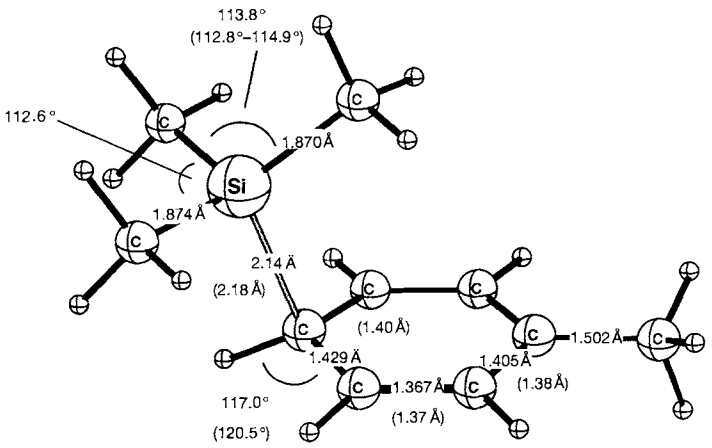
In a well-publicized new development in the over forty-year search for an isolable R_3Si^+ cation,[1, 2] Lambert, Zhang, Stern, and Huffman[1] reported the "crystal structure of a silyl cation [as the salt **1**] with no coordination to anion and distant coordination to solvent". This claim was based on the use of the very non-nucleophilic $[(C_6F_5)_4B]^-$ anion. However, their crystal structure also included the solvent, toluene, along with the $(C_2H_5)_3Si^+$ moiety. The au-

$Et_3Si[B(C_6F_5)_4]$ **1**

thors argued that the silyl cation and the toluene molecule were not involved in a possible σ complex, since the toluene moiety had a nearly planar geometry and the $Si-C_{(ring)}$ distance (2.18 Å) was relatively long. But two features argued against this interpretation. The SiR_3 moiety was not planar; the average C-Si-C angle was 114°, and the ^{29}Si NMR chemical shift ($\delta = 81.8$, measured in toluene)[1b] deviated considerably from the $\delta = 355$ computed by the IGLO method for planar Me_3Si^+.[3] The authors attributed this discrepancy to pyramidalization of the R_3Si group, which they suggested might result in a more shielded Si chemical shift. They concluded, "This structure, albeit nonplanar, is best termed a stable silyl cation because it entirely lacks coordination to the anion, the distance to the weakly coordinating toluene is unprecedented for bonding, and the toluene lacks any of the geometric characteristics of the σ complex."[4]

We dispute this interpretation and now present decisive evidence that the species observed by the authors is an $[R_3Si-toluene]^+$ σ complex—arenium ion—in which the positive charge is substantially delocalized to the aromatic ring.

Our evidence is based on ab initio calculations[5] of the $[Me_3Si-toluene]^+$ (**2**) and the $[Me_3Si-benzene]^+$ and $[H_3Si-benzene]^+$ (**3**) complexes, which are close models for the $[Et_3Si-toluene]^+$ complex in **1** · toluene. Optimization at the HF/3-21G, HF/3-21G(*), and HF/6-31G* levels were carried out, and, for $[H_3Si-benzene]^+$ (**3**) also at the MP2(fc)/6-31G* level (i.e. with inclusion of electron correlation).[*] All calculations resulted in theoretical geometries which not only are very similar among themselves, but also closely resemble the main features found in the crystal structure of **1** · toluene. Hence, it suffices to show the HF/6-31G* geometry of **2** as well as the MP2(fc)/6-31G* geometry of **3** in Figure 1. The $Si-C_{(ring)}$ separations, the 114° average



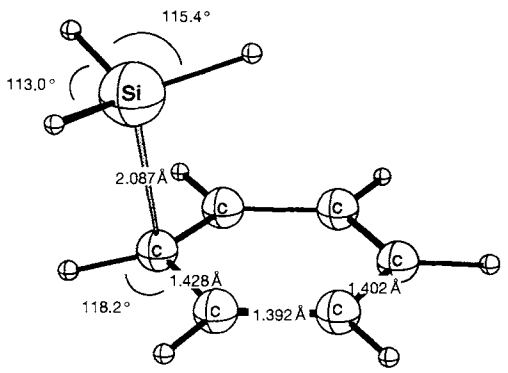


Fig. 1. The geometries of the $[Me_3Si-toluene]^+$ complex (**2**) ($E = -677.31182$ Hartree) and the $[H_3Si-benzene]^+$ complex (**3**) (MP2(fc)6-31G*, $E = -521.94073$ Hartree) determined by ab initio methods. The values for **2** in parentheses show the data from the X-ray structure analysis of **1** · toluene for comparison [1a]. Note the close correspondence of the structure **2** with the calculated structure **3** at the higher theoretical level.

bond angle at silicon in the silyl groups, and the near planarity of the six-membered rings, correspond precisely with those reported for **1** · toluene.[1a] Carbocations are stabilized strongly by vicinal silyl groups.[6, 7] Hence, the *ipso* positions of silyl-substituted arenes have enhanced proton affinities.[8, 9] Cationic Si–C hyperconjugation is also responsible for the $Si-C_{(ring)}$ bond lengths[6] (ca. 2.1 Å) in **2**, **3**, and **1** · toluene. The $C-C^+$ bonds involved in the X-C-C^+ moieties (X = R_3Si) are shortened: compare the $C_{ipso}-C_{ortho}$ separations in **2** (1.429 Å) and **3** (1.426 Å) with that in the ben-

[**] Presented at the Third World Congress, World Association of Theoretical Organic Chemists (WATOC), Toyohashi, Japan, July 27, 1993, and the Tenth International Symposium on Organosilicon Chemistry, Poznan, Poland, August 15–20, 1993. This work was supported by the Deutsche Forschungsgemeinschaft, the Volkswagen-Stiftung, the Fonds der Chemischen Industrie, the Convex Computer Corporation, the Minerva Foundation, the Wolf Fund for the Promotion of the Sciences and the Arts, administered by the Israel Academy of Sciences and Humanities, and by the Alexander Goldberg Memorial Fund (Technion). We also thank Prof. G. A. Olah warmly for a preprint of his related paper which reports the same conclusions.

[*] MP2 = Møller–Plesset perturbation theory second order; fc = frozen core, that is the nonvalence electrons are not correlated.

zenium ion (1.464 Å).[10] Strong bond length alternation in the benzene ring (quinonoid distortions) is not to be expected when strongly hyperconjugating groups are present at the *ipso* position. In $C_8H_9^+$ (**4**), a phenonium ion, in which the positive charge is stabilized by strong hyperconjugative interaction with the strained three-membered ring bonds, the MP2(fc)/6-31G* six-ring C–C distances (1.401 ± 0.018 Å) are all nearly the same.[10]

High-pressure mass spectrometric measurements of silyl cation–arene complexes[8, 9] have established that the binding energies of the Me_3Si cation to benzene, toluene, and other arenes (Table 1) are nearly as large as those for the binding of water (30.1 kcal mol^{-1}) and weaker oxygen bases (e.g. CH_3OH 39.2 kcal mol^{-1}).[11] Direct aromatic substitution and other reactions have established "that σ complex intermediates are formed".[8, 9b] Our computed binding energies, relative to the separated R_3Si^+ and arene species, also summarized in Table 1, agree quite well with the measured values. Although these data pertain to the gas phase, association energies can be expected to be nearly as large in the nonpolar media employed by Lambert et al.[1] in their experiments.

Table 1. Experimental and computed association energies [kcal mol^{-1}] of silyl and *tert*-butyl cations with arenes

Arenium ion	Method	Association energy [a]
$C_6H_6SiH_3^+$	HF/3-21G(*)//3-21G(*)	− 51.1
	HF/6-31G*//6-31G*	− 47.1 [b]

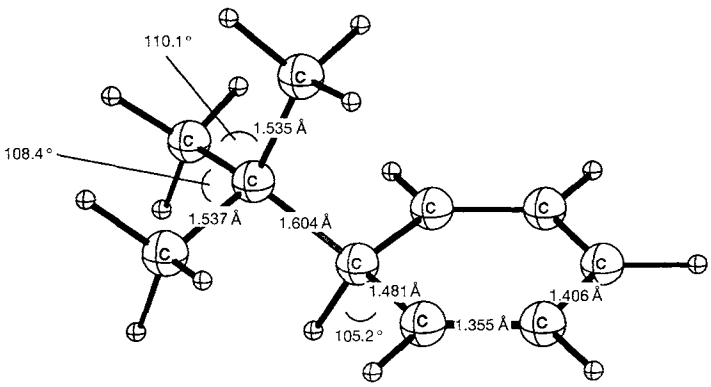
$CD_3C_6D_5CMe_3^+$	exp.	− (28.6 ± 0.8) [e, f]

[a] Zero point energy (ZPE) corrections (computed at HF and scaled by 0.89) are included. [b] The basis set superposition error is 1.97 kcal mol^{-1}, computed by the counterpoise method [5], for $C_6H_6SiH_3^+$ at HF/6-31G*//HF/6-31G*, and 4.72 kcal mol^{-1} at MP2/6-31G* with the same geometry. The other computed association energies may be too high by similar amounts. [c] Ref. [8a]. [d] Ref. [11]. [e] These experimental values refer to lower energy, rearrangement isomers, for example, **8** instead of **7**; see ref. [8b, 9d] and the text. [f] Ref. [8b].

According to natural population analysis[12] of the HF/6-31G* wave functions, the Si–C Wiberg bond index in **3** is 0.44, about half the size of the bond indexes found for the polar covalent Si–C bonds in neutral models, methylsilane (0.82) and phenylsilane (0.77). The positive charge on the six-membered rings is appreciable, +0.29 in **2** and +0.27 in the less strongly bound [Me_3Si–benzene]$^+$ complex. In **3** the complimentary charge on the smaller SiH_3 group is only +0.62. This is only about 36% larger than those in neutral compounds. The charge of the SiH_3 group is +0.49 in the quinoid model (**5**), +0.45 in phenylsilane, and +0.43 in methylsilane.

IGLO chemical shift computations[3d] afford even more dramatic evidence for the consequences of complexation. As has been reported for CH_3^+,[3b] pyramidalization of silyl cations results in even greater deshielding rather than the opposite effect as required by the interpretation by Lambert et al. Thus, an IGLO computation (basis II//HF/6-31G*) on the distorted Me_3Si^+ ion, by using the C-Si-C average bond angle of 114° (cf. X-ray structure from Lambert et al.), results in a ^{29}Si chemical shift of $\delta = 368$, very far from the reported experimental value for $[Et_3SiC_6H_6]^+$ ($\delta = 83.6$ in benzene[1b]). In sharp contrast, an IGLO calculation on the [Me_3Si–benzene]$^+$ complex (dz basis (C,H), basis II (Si)//HF/6-31G*) gives a chemical shift of $\delta(^{29}Si) = 80.9$, in good agreement with the experimental value for $[Et_3SiC_6H_6]^+$.[1b] The same IGLO basis gives a chemical shift of $\delta(^{29}Si) = 60$ for the [Me_3Si–toluene]$^+$ σ-complex (**2**) (HF/6-31G* geometry). These computed ^{29}Si chemical shifts are in line with the trends reported by Lambert and Zhang,[1b] as the association energies to toluene are larger than those to benzene (Table 1).

While carbocations are stabilized more strongly by α- than by β-alkyl groups, just the opposite is true for silyl substituents (see Scheme 1) where β is more effective hyperconjugatively than α attachment.[6, 7, 13, 14] Consequently, *ipso* protonation of silylarenes, that is **7** (R = SiH_3), is preferred thermodynamically, and the resulting arenium ions, like **2** and **3**, do not undergo 1,2-H shifts readily.[8, 9] The bonding and structures of the arenium ions resulting initially from the association of, for example benzene, with Me_3Si^+ (which resembles **2**, Fig. 1) and with Me_3C^+ ($C_6H_6CMe_3^+$ (**6**) Fig. 2) differ considerably. While **6** also has an elongated



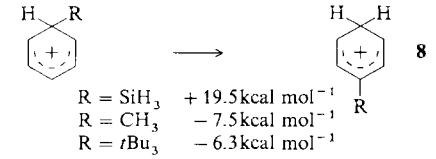
6

Fig. 2. The geometry of the [Me_3C–benzene]$^+$ complex (**6**) (HF/6-31G*, $E = -387.15397$ Hartree) determined by ab initio methods.

bond ($rC-C = 1.604$ Å at HF/6-31G*) between the substituent and the *ipso* carbon, the *tert*-butyl group has nearly tetrahedral C-C-C bond angles and the ring bond lengths show more pronounced alternation. Due to their greater degree of hyperconjugative involvement, silyl groups are bound less covalently than their alkyl counterparts. Hyperconjugation in **2** (and in **3**) results in the Si–$C_{(ipso)}$ bond lengthening and is responsible for the small distortion of the arene geometry as well as the widening of the R-Si-R angles in the R_3Si groups from 109.5° to about 114°.

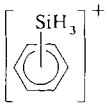
The energy of the initial association of Me_3C^+ with benzene is much less than that with Me_3Si^+ (cf. the computed data in Table 1), and the same will be true of other arenes. While the carbocation and silyl cation association energies deduced from high-pressure mass spectrometry[10] appear to be comparable (see Table 1), these data refer to different overall reactions. Unlike **2**, the *ipso* species (e.g., **6**) formed

initially from Me_3C^+ and arenes, rearranges during the measurements to isomers (e.g., the *para* species **8** (R = *t*Bu)) in which the alkyl group stabilizes the cyclohexadienyl carbocation more effectively.[8, 9] We compute an exothermic **7** → **8** (R = *t*Bu) isomerization energy of 6.3 kcal mol^{-1} (Scheme 1). When the *tert*-butyl group is replaced by a methyl group, the corresponding *ipso* → *para* isomerization energy **7** → **8** (R = Me) is nearly the same (−7.5 kcal mol^{-1}). In contrast our computations show the *ipso* silyl compound **3** to be 19.5 kcal mol^{-1} more stable than its *para* isomer **8** (R = SiH_3) (Scheme 1). The benzene–SiH_3^+ π com-



Scheme 1. Relative energies of $C_6H_6R^+$ isomers (MP2(fc)/6-31G*//HF/6-31G* + ZPE for R = *t*Bu and MP2(fc)/6-31G*//MP2(fc)/6-31G* + ZPE for R = SiH_3 and R = CH_3).

plex (**9**) with C_{3v} symmetry which was proposed as a possibility in the early literature,[8a] is even higher in energy, 28.2 kcal mol^{-1} vs **3** at MP2(fc)/6-31G*//MP2(fc)/6-31G*, and, having a degenerate pair of imaginary frequencies, is not a minimum.



9

We conclude that the $[Et_3Si$–toluene$]^+$ X-ray structure reported by Lambert et al. is that of an arenium ion—a bound σ complex—as are the models we have calculated (see Fig. 1 and Table 1). Benzene and toluene are not weak bases towards silyl cations. These silylarenium ions are similar to the heteroatom-bound complexes described by Reed et al.[4] and the β-silyl-substituted cyclohexadienyl cations of McClelland et al.[15] generated by flash photolysis. Free silyl cations were not detected. Even a modest degree of pyramidalization at silicon is prima facie evidence for complexation, as silyl cations are inherently planar.[13] The search for these elusive species must continue.

Non-Twisted Tetrakis(organosilyl)ethene**

By *Masahiro Murakami, Michinori Suginome, Kenzo Fujimoto,* and *Yoshihiko Ito**

The change in the positions of the electronic transitions of organic chromophores caused by structural deviation and/or heteroatom-substitution has been a subject of continuing interest. Mono- or bis(organosilyl) ketones are some of the most extensively studied compounds owing to the marked bathochromic shift of the n → π* transition.[1] Tetrakis(organosilyl)ethenes **1**, synthesized by Sakurai et al., possess unusual properties.[2, 3] The compounds exhibit weak ab-

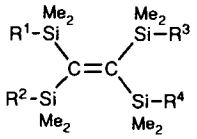
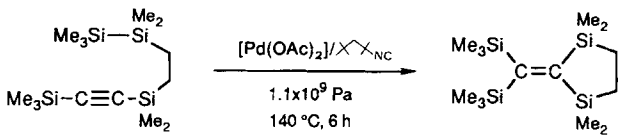
[**] We thank Prof. E. Nakamura and Dr. S. Yamago (Tokyo Institute of Technology) for carrying out experiments under high pressure. We also thank Dr. C. Katayama and Mr. H. Inoue (MAC Science) for collecting the diffraction data at low temperature.

sorptions at 341–434 nm together with strong $\pi \rightarrow \pi^*$ transitions in their UV spectra, and all but **1a** twist along the C–C double bond to yield a dihedral angle of between 30° and 53° in order to relieve a steric repulsion between the organosilyl groups. We now report an intramolecular bissilylation reaction under pressure leading to the efficient synthesis of a new cyclic tetrakis(organosilyl)ethene, which exhibits an analogous absorption behavior despite the non-twisted structure.



1a: $R^1 = R^2 = R^3 = R^4 = H$
1b: $R^1 = R^2 = R^3 = R^4 = Me$
1c: $R^1 = R^2 = Me$, $R^3 = R^4 = t\text{Bu}$
1d: $R^1 = R^3 = Me$, $R^2 = R^4 = t\text{Bu}$
1e: $R^1 = Me$, $R^2 = R^3 = R^4 = t\text{Bu}$

We reported recently that a catalyst of $[Pd(OAc)_2]$/*tert*-alkyl isocyanide effectively promotes the bissilylation of C–C triple bonds and that the intramolecular version renders it possible to bissilylate otherwise unreactive internal alkynes.[4] This method was next applied to 1,2-bis(organosilyl)alkyne **2** in which one organosilyl substituent is tethered to a disilanyl group (Scheme 1). Although sluggish under



2 **3**

Scheme 1. Synthesis of **3** by an intramolecular bissilylation under high pressure.

atmospheric pressure, the bissilylation reaction did take place on heating **2** under high pressure (1.1×10^9 Pa) at 135–140 °C in the presence of $[Pd(OAc)_2]$/*tert*-alkyl isocyanide to afford a new tetrakis(organosilyl)ethene **3**, in which one of the olefinic carbon atoms is part of a heterocycle, in 66% yield.[5] Recrystallization of **3** from ethanol provided colorless crystals. When dissolved, however, **3** was slightly yellow at room temperature. Notably, in hexane the cyclic **3** exhibits UV absorptions at 228 nm ($\varepsilon = 16800$) and 361 nm ($\varepsilon = 160$), very close to those of the acyclic tetrakis(trimethylsilyl)ethene **1b** [224 nm ($\varepsilon = 17900$), 370 nm ($\varepsilon = 710$)].[2]

Next, the single crystal was subjected to X-ray crystallographic study (Fig. 1).[6] In marked contrast to the acyclic tetrakis(organosilyl)ethenes **1b–e**, neither twisting nor pyramidalization of the sp^2 carbons was observed. The four silicon atoms of **3** lie almost in a plane. The angle between the planes Si1-C11-Si2 and Si3-C12-Si4 is 3.9°. Although small, the twisting increases the intramolecular repulsive interactions; for example, the distance between C5 and C16 is only 329 pm, about 18% less than the sum of the van der Waals radii of two methyl groups (400 pm, Fig. 1c). Noteworthy is that the angle Si3-C12-Si4 is exceedingly narrow (102.72(7)°) to bring Si3 and Si4 as close as 299 pm, due to the constraints imposed by the 5-membered ring. It is conceivable that this narrow angle leads to the tolerable nonbonded distances between the peripheral methyl groups on the non-twisted C=C backbone.[7] The C=C and Si–C_{sp^2} bonds (137 and 191–192 pm, respectively) are longer than standard ones and these lengths agree well with those of the acyclic tetrakis(organosilyl)ethenes **1**.

The origin of the weak absorptions that were observed in the region of 341–434 nm with all tetrakis(organosilyl)-

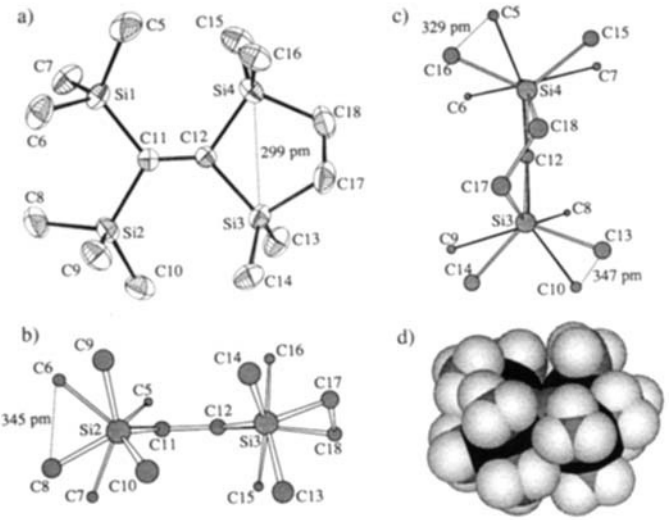


Fig. 1. Single crystal X-ray structure of **3**. Hydrogens are omitted for clarity in (a)–(c). (a) Top view (40% probability ellipsoids); b) front view; c) side view; d) space-filling model. Selected distances [pm] and angle [°]: Si1–Si2 316.65(7), Si1–Si4 364.92(7), Si2–Si3 362.80(7), C6–C9 365.0(4), C7–C8 350.7(4); Si1–C11–Si2 111.79(8).

ethenes **1** and **3** is of much interest.[8] One important deduction from a comparison of the UV spectra and crystal structures of **1** and **3** is that the weak UV absorption of tetrakis(organosilyl)ethenes is not necessarily a result of structural twisting but of the substitution with silicon. For comparison, UV spectra of tris(trimethylsilyl)ethene (**4**)[9] and 1,2-bis(trimethylsilyl)ethene (**5**) were measured; **4** absorbs at 293 nm ($\varepsilon = 690$), whereas **5** exhibits a small peak around 220 nm on the shoulder of the strong $\pi \rightarrow \pi^*$ transition [215 nm ($\varepsilon = 14000$)]. These results reveal that more silicon

4 **5**

substituents at an olefinic skeleton shift the absorption to longer wavelength. Although more precise theoretical treatment is awaited, the present experimental studies indicate that the fourfold substitution with silyl groups primarily causes the bathochromic shift of the weak absorption of tetrakis(organosilyl)ethenes.[10]

Experimental Procedure

2: To (trimethylsilyl)ethyne (3.2 g, 33 mmol) in THF (20 mL) at room temperature was slowly added MeMgBr (22 mmol) in ether. After evolution of methane ceased, 1,1,4,4,5,5-hexamethyl-1,4,5-trisilahexyl chloride (2.7 g, 11 mmol), prepared by the platinum-catalyzed hydrosilylation reaction of vinylpentamethyldisilane with chlorodimethylsilane, was added. The mixture was stirred for 2 h at room temperature, then diluted with a saturated aqueous solution of NH_4Cl, extracted with ether, and distilled to afford **2** (3.2 g, 92%). B.p. 142–143 °C/20 Torr; ^{1}H NMR ($CDCl_3$): $\delta = 0.02$ (s, 6H), 0.06 (s, 9H), 0.14 (s, 6H), 0.17 (s, 9H), 0.47–0.61 (m, 4H); ^{13}C NMR ($CDCl_3$): $\delta = -4.9$, -2.6, -2.1, -0.3, 6.5, 9.0, 113.3, 114.4.

3: A mixture of **2** (420 mg, 1.33 mmol), $[Pd(OAc)_2]$ (13 mg, 56 μmol), and 1,1,3,3-tetramethylbutyl isocyanide (114 mg, 0.84 mmol) in toluene (2.9 mL) was heated under pressure of 1.1×10^9 Pa at 135–140 °C for 6 h. The cooled reaction mixture was eluted through a short column of silica gel with hexane, and the subsequent preparative TLC (hexane) afforded **3** (278 mg, 66%). M.p. 114–115 °C; ^{1}H NMR ($CDCl_3$): $\delta = 0.23$ (s, 30H), 0.73 (s, 4H); ^{13}C NMR ($CDCl_3$): $\delta = 1.5$, 4.0, 11.6, 188.3, 188.7; MS: *m/z* 314 (M^+).

A Nickel–Anthracene Complex Having η^3 and η^4 Coordination in One Crystal

By *Roland Boese,* Amnon Stanger,* Peter Stellberg,* and *Anat Shazar*

Only a few compounds are known that contain structural isomers within one crystal, and to the best of our knowledge, these compounds all contain ionic species. These systems are of special interest because the two isomers must be almost isoenergetical; therefore, there is a high probability of seeing interconvergence between the two forms in the solid state.

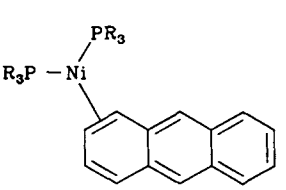
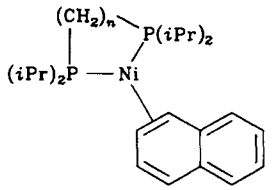
Nickel complexes are natural candidates for the study of such phenomena, since nickel(0) has the ability to form 16e and 18e complexes, depending on the ligand.[1] For example, $[Ni(CO)_4]$ is far more stable than $[Ni(CO)_3]$, whereas $[Ni(C_2H_4)_3]$ is more stable than $[Ni(C_2H_4)_4]$. Quantification of the bonding in Ni complexes is of prime importance for understanding catalysis in which Ni compounds play an important role.[2] Ni^0–arene complexes are particularly suitable for the investigation of the dependence of the coordination number on the type of ligands. Although all the complexes of this type which have been structurally determined (**1** and **2a**) are η^2 bound,[3] the energy difference between these 16e complexes and the corresponding η^4, 18e complexes is expected to be rather small.[4]

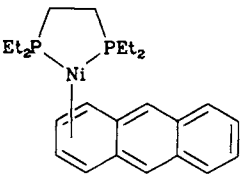


1a, R = Cy
1b, R = Bu
1c, R = Et



2a, $n = 2$
2b, $n = 3$

In addition, a comparison of **1a**–**1c** led to a prediction regarding the type of phosphane ligands that should be used to stabilize the η^4 18e coordination in Ni–anthracene complexes.[3b] For these reasons we prepared **3**, and we report here the results of the single-crystal X-ray investigation.



3

Compound **3** was prepared from $[Mg(C_{14}H_{10})(thf)_3]$, anthracene ($C_{14}H_{10}$), and [(depe)$NiCl_2$] (depe = 1,2-bis(diethylphosphino)ethane), in analogy to the synthesis of **1b** and **1c**.[4a, 5] Single crystals suitable for X-ray study were obtained with a slow cooling crystallization technique.[6] These crystals break when cooled below about 150 K, indicating a possible solid-state phase transition; thus, the X-ray study had to be carried out at relatively high temperature.[7] There are two independent isomeric molecules in the asymmetric unit. One is the expected[3b] η^4-complex **3a** and the other is the unique η^3-complex **3b** (Fig. 1).

In **3a** (Fig. 1 top) the Ni is bound to C1 to C4 with usual bond lengths (e.g., 2.014(8)–2.303(6) Å). The P-Ni-P angle is 91.6(1)°, significantly smaller than the corresponding angle in **1b** and **1c** (108.9 and 106.4°, respectively), but similar to that of other diphosphinoethane derivatives.[3c] The most striking difference between **1** and **3a** is, however, the interplanar angle ϕ of the plane between the atoms C1–C4 and that of the naphthalene residue. Thus, in the η^2 complexes the anthracene ligands deviate only slightly from planarity (ϕ is 6.3, 8.1, and 12.4° for **1a**, **1b** and **1c**, respectively), whereas ϕ is 26.2(3)° for **3a**. This is in accordance with the prediction[3b] based on the structures of **1** and an η^4-tantalum–anthracene complex.[8] The η^3-complex **3b** (Fig. 1 bot-

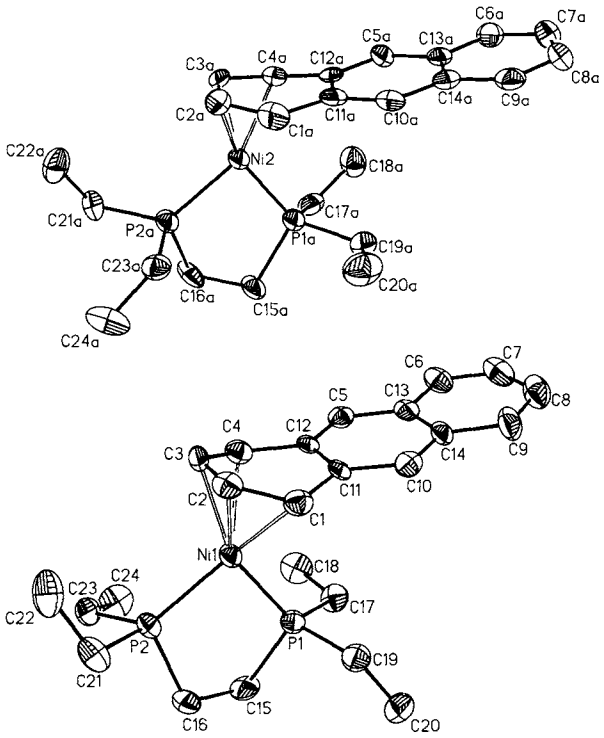


Fig. 1. The molecular structures of **3a** (top) and **3b** (bottom) (drawn at 50% probability levels of the ellipsoids) hydrogen atoms are omitted. Selected bond lengths [Å] and angles [°] (standard deviations in parentheses): **3a**: C1-C2 1.404(11), C2-C3 1.434(9), C3-C4 1.388(9); P1-C15-C16-P2 38.8(7); **3b**: C1a-C2a 1.363(11), C2a-C3a 1.411(9), C3a-C4a 1.423(10); P1a-C15a-C16a-P2a −44.8(7).

tom) has an intermediate value of $\phi = 17.3(4)°$. The comparison between the three complexes is illustrated in Figure 2 top. Table 1 gives the most relevant data for **1a–1c**, **2a**, **3a**, and **3b**; note that there is, at least qualitatively, a connection between ϕ and the P-Ni-P angle.

Table 1. The most important structural parameters of the $(PR_3)_2Ni$–arene complexes **1a–1c** and **2a** in comparison to those of the title molecules **3a** and **3b**.

	1a [a]	**1b**	**1c**	**2a** [a]	**3a**	**3b**
Ni-C1 [Å]	2.060	2.007(3)	2.013(7)	2.002	2.176(8)	2.824(8)
Ni-C2 [Å]	1.993	1.963(3)	1.961(7)	1.987	2.014(8)	2.343(8)
Ni-C3 [Å]	2.769	2.714(3)	2.698(7)	2.761	2.069(7)	1.963(9)
Ni-C4 [Å]	3.448	3.335(3)	3.337(7)	3.378	2.303(6)	2.057(8)
P-Ni-P [°]	118.3	108.9(1)	106.4(1)	92.2	91.6(1)	90.3(1)
ϕ [°]	6.3	8.1(2)	12.4(6)	5.0	26.2(3)	17.3(4)
(P,Ni,P)/ (Ni,C1,C2) [°] [b]	22.0	12.0(3)	12.3(3)	2.0	80.5(1)	42.7(1)

[a] The data taken from the literature have no standard deviations. [b] Ni1,X1, X2; Ni2,X3,X4 for **3a** and **3b**, in which X1, X2, X3, and X4 are dummy atoms in the center of the bonds C1/C2 (X1), C3/C4 (X2), C2a/C3a (X3) and C3a/C4a (X4) for the calculation of the geometry of the coordination spheres around the Ni atoms. These angles are expected to be 0° for ideal square-planar and 90° for ideal tetrahedral coordination.

Another interesting feature of the η^3 complex is the coordination sphere around the Ni atom. The ideal geometries for Ni^0 complexes with 16e and 18e are square planar and tetrahedral, respectively. The geometries of **1** and **3a** confirm this (see Table 1). The Ni atom in the η^3-complex **3b** shows an intermediate geometry (Table 1 last column, Fig. 2 bottom).

These results concerning the structure suggest that **3b** closely models an intermediate of the dynamic process

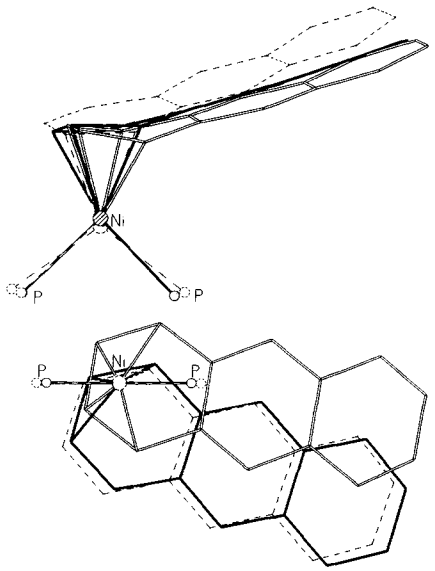

Fig. 2. Overlap pictures of **1b** (dashed lines), **3a** (open bars), and **3b** (solid bars) in a side view (top) and a top view (bottom). The overlapping features are the two Ni–P bonds. Alkyl groups and hydrogen atoms are omitted for clarity.

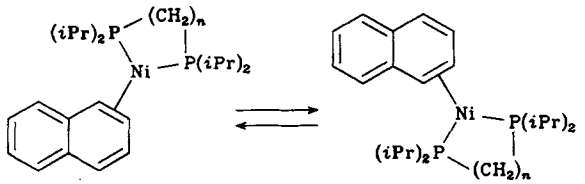
($\eta^2 \rightleftarrows \eta^3 \rightleftarrows \eta^4 \rightleftarrows \eta^3 \rightleftarrows \eta^2$) which was observed for **2**. To the best of our knowledge, this is the first time that all possible intermediates for such a dynamic process have been isolated and characterized in the solid state. All other structural parameters of **3b** are consistent with the η^3 coordination; for example, the C1–C2 distance for **3a** is 1.404(11) Å and 1.363(11) Å for **3b**, and the Ni2–C1a distance in **3b** (2.824(8) Å) is clearly a nonbonding distance.

Formally, the Ni center in **3b** contains 17e, thus **3b** should be a diradical which shows paramagnetic behavior.[9] We are currently investigating this point as well as the connection between ϕ, the size of the phosphane ligands, and the P-Ni-P angle. As mentioned Ni–arene complexes undergo dynamic processes.[4] In solution one observes the migration of the $(R_3P)_2Ni$ moiety between the two terminal rings of the arene.[4] This rearrangement can be intra-[4b] or intermolecular.[10] The bridged-naphthalene complexes **2** have been investigated in the solid state, and they undergo the rearrangement described in Scheme 1.[4c]



Scheme 1.

Compounds **1b** and **1c** undergo the same type of rearrangement in solution.[11] The NMR spectra of the solution of **3** show that this complex is diamagnetic. Thus, in solution **3** is only an 18e, η^4 complex. Some preliminary variable temperature NMR studies suggest that the solution behavior of **3** is rather different from that of **1**. The main difference is that **3** undergoes an intermolecular (possibly also intramolecular) process with an amazingly low activation energy. Thus, saturation transfer to a free ligand and to the uncomplexed ring can be observed already at −101 °C.[12]

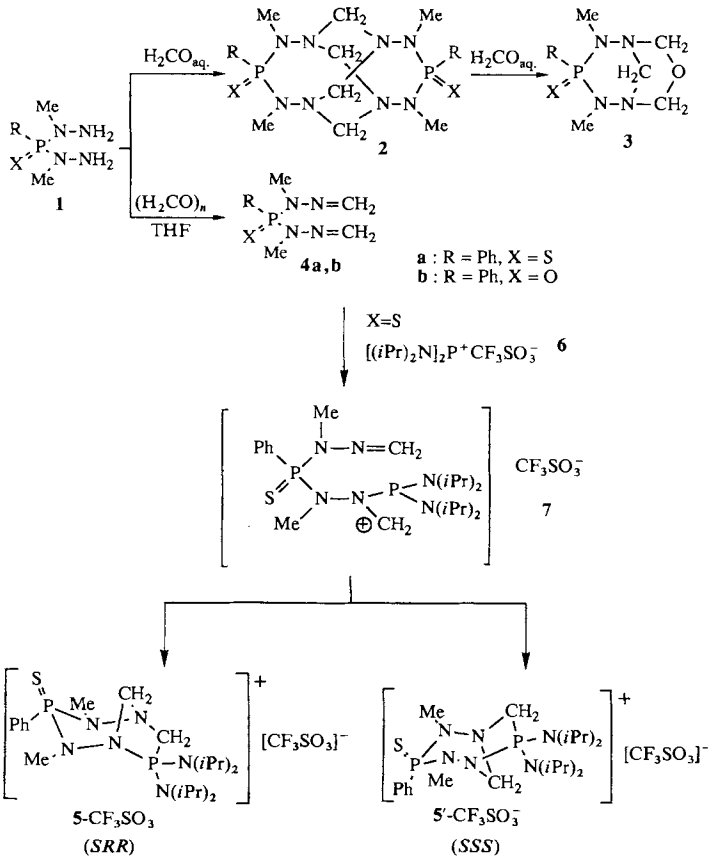
Synthesis, Structure, and Reactivity of Stable PN Heterocycles with Two and Six Methyleneamine Units: $[H_2C{=}N{-}N(Me)]_2P(S)(Ph)$ and $[H_2C{=}N{-}N(Me)]_6P_3N_3$

By *Christophe Galliot, Anne-Marie Caminade, Françoise Dahan,* and *Jean Pierre Majoral**

N-Methyleneamine type compounds $H_2C{=}N{-}R$ (R = CR'_3, NR'_2, OR', etc.) are useful reagents in organic synthesis; however, most of these compounds are unstable and dimerize,[1] trimerize,[2] or polymerize spontaneously. Consequently, only X-ray structures of some related salts or complexes have been described.[3] We report here the first single-crystal X-ray analysis of a neutral, uncomplexed compound of this type, the bis(*N*-methylenehydrazone) **4a**, as well as those of the rather unexpected cationic heterocycles **5** and **5'**, which arise from the stereoselective reaction of **4a** with $[(iPr_2N)_2P]^+[CF_3SO_3]^-$. Remarkably, this reaction can be extended to the synthesis of the cyclotriphosphazene **11** possessing six perfectly stable $H_2C{=}N$ moieties!

Various strategies have been designed to generate compounds with $H_2C{=}N$ units,[4] the most straightforward of which uses formaldehyde.[5] The reaction of aqueous formaldehyde with phosphono dihydrazide **1** leads initially to the dimer **2**, then to the bicycle **3**.[1c, 6] Completely different products are isolated when paraformaldehyde $(CH_2O)_n$ in THF and a molecular sieve are used instead of aqueous formaldehyde; thus, the bis(*N*-methylenehydrazone) derivatives **4a**, **b** are isolated in near quantitative yield (Scheme 1).



Scheme 1.

Compounds **4a**, **b** are stable at room temperature for several days in air and for several months under dry argon. Their structures were first deduced from ^{1}H NMR spectra, which exhibited an AB pattern in the range expected for the $H_2C{=}N$ group[5b, 7] (**4a**[8]: δ_{H_A} = 6.37, δ_{H_B} = 6.48, $^2J_{H_A,H_B}$ = 9.3 Hz; **4b**[8]: δ_{H_A} = 6.25, δ_{H_B} = 6.41, $^2J_{H_A,H_B}$ = 10.8 Hz), and mass spectra. These surprising results prompted us to undertake an X-ray structure determination of **4a**.[9]

The molecular structure of **4a** is consistent with NMR spectroscopic and mass spectrometric data (Fig. 1). The most interesting feature of the structure is the two slightly different $H_2C{=}N$ subunits. The bond lengths are similar to those of C-substituted imines and hydrazones:[10] (N(2)–C(7) 1.265(7) and N(4)–C(9) 1.276(7) Å), and no interaction exists between the two C=N bonds ($d_{N2\cdots N4}$ = 4.090 and $d_{C7\cdots C9}$ = 3.732 Å). The bond lengths and angles in the phosphono dihydrazide part are similar to the values previously reported for N_4P_2 macrocycles.[10]

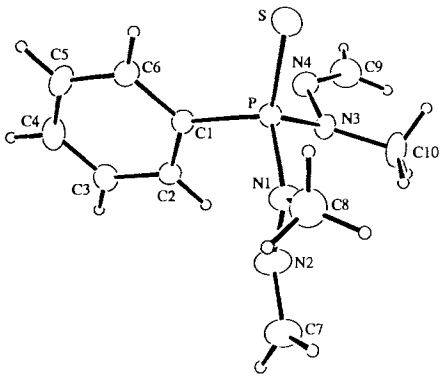

Fig. 1. Molecular structure of **4a**. Selected bond lengths [Å] and angles [°]: N2-C7 1.265(7), N4-C9 1.276(7), P-N1 1.679(4), P-N3 1.682(4), N1-N2 1.385(6), N3-N4 1.376(5); N1-P-N3 102.0(2), P-N1-N2 113.2(3), P-N3-N4 110.7(3), N1-N2-C7 118.8(4), N3-N4-C9 118.8(4).

Compounds **4a**, **b** should be interesting reagents in heterocyclic chemistry and should react differently to the corresponding C-substituted derivatives. Indeed **4a**, **b** react quantitatively (Scheme 1) with bis(diisopropylamino)phosphanylium trifluoromethanesulfonate,[11] while species like $PhP(S)(NMe-N=CHPh)_2$ do not react at all. The ^{31}P NMR spectra of the crude reaction mixture in CH_2Cl_2 reveal the presence of two singlets ($\delta = 64.4$ and 77.5) and two doublets ($\delta = 69.2$ and 81.0, $J_{P,P} = 8.5$ Hz) in a 70:30 ratio. Two compounds (**5** and **5′** as $CF_3SO_3^-$ salts) can be isolated following repeated extraction and washing with Et_2O and THF, and subsequent crystallization from toluene: the two doublets are assigned to **5** and the two singlets to **5′**. The ^{31}P NMR data of both compounds indicated the presence of a phosphonium type phosphorus (**5**: $\delta = 81.0$; **5′**: $\delta = 77.5$) in addition to the thiophosphono dihydrazide type phosphorus (**5**: $\delta = 69.2$; **5′**: $\delta = 64.4$). The ^1H and ^{13}C NMR spectra of **5** and **5′** showed no signals for sp^2 CH_2 groups, only those for sp^3 CH_2 groups.[8] Surprisingly, mass spectra (FAB^+) revealed that both compounds had the same molecular weight, corresponding to the addition of one phosphanylium ion to one bis(*N*-methylenehydrazone). Since several structures are conceivable for **5** and **5′**, two single-crystal X-ray structure determinations were carried out.

The structures of **5** and **5′** are illustrated in Figures 2 and 3, respectively. Both compounds are heterobicycles, constructed from a six- and a five-membered ring with a common $N-CH_2-N$ unit. The five-membered rings are formed by the unsymmetric addition of the phosphanylium ion on two $H_2C=N$ bonds. The six-membered rings, built from the phosphono dihydrazide part, adopt a boat type conformation, in contrast to the six-membered ring in **3** which has a chair type conformation.[6] Furthermore, the sum of angles around the nitrogen atoms of the $N-CH_2$ unit (**5**: $\Sigma N2 = 325.3$, $\Sigma N3 = 319.5$; **5′**: $\Sigma N2 = 319.6$, $\Sigma N3 = 327.9°$) shows that they are highly pyramidalized. Compounds **5** and **5′** differ mainly with regard to the position of the phosphonium group and the position of the phenyl group relative to the six-membered ring: *"cis"* in the minor compound **5**, and *"trans"* in the major compound **5′**. This gives rise to a difference in the dihedral angles between the planes P1-N4-N3 and P2-N3-N4 (109.6(1)° for **5** and 93.8(1)° for **5′**), which in turn may account for the difference observed for the $^3J_{P,P}$ coupling constant: 8.5 Hz for **5** and $\triangleq 0$ Hz for **5′**. It should be noted that no thermal equilibration between **5** and **5′** was detected by variable-temperature NMR experiments.

Selected bond lengths [Å] and angles [°]: N2-C7 1.467(3), N3-C7 1.487(3), N2-C8 1.478(3), P1-N1 1.662(2), P1-N4 1.699(2), P2-N3 1.715(2), P2-N5 1.627(2), P2-N6 1.620(2); N1-P1-N4 99.25(8), C8-P2-N3 94.46(8), C1-P1-N4 111.11(8), N3-P2-N5 117.87(9), P2-N3-N4 114.4(1).

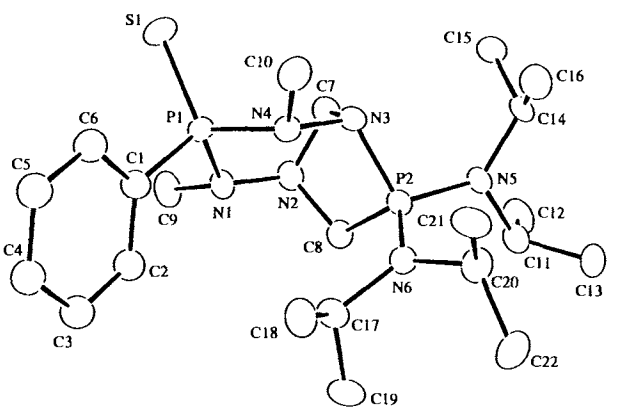

Fig. 2. Molecular structure of the cation **5**. Selected bond lengths [Å] and angles [°]: N2-C7 1.457(3), N3-C7 1.486(3), N2-C8 1.480(3), P1-N1 1.684(2), P1-N4 1.701(2), P2-N3 1.719(2), P2-N5 1.619(2), P2-N6 1.613(2); N1-P1-N4 98.61(8), C8-P2-N3 94.05(9); C1-P1-N4 105.74(9), N3-P2-N5 104.46(8), P2-N3-N4 107.7(1).

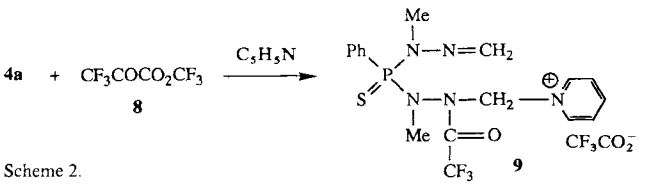
The formation of **5** and **5′** may involve two steps. The first one, initiated by the Lewis acidity of **6** led to the transient carbocation **7**, which is intramolecularly trapped to give **5** and **5′** (Scheme 1). This mechanism implies that **4a** reacts as an imine[13] and not as hydrazone in which conjugation of the C=N bond with the adjacent nitrogen atom makes the azomethine carbon atom negatively charged.

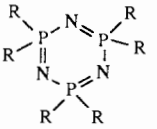
Hydrazones $R_2N-N=CHR'$ (R = Me, R′ = Et, Ph) generally react with trifluoroacetic anhydride (**8**) in the presence of base (pyridine, 2,6-lutidine) by an electrophilic substitution reaction at the azomethine carbon atom to give compounds of the type $R_2N-N=C(R')COCF_3$.[14] The addition of **8** to **4a** in the presence of pyridine, however, afforded the pyridinium salt **9** in 80% yield (Scheme 2).[15] The formation



Scheme 2.

of **9** was particularly interesting since it corroborated the proposed mechanism for the generation of the transient cation **7** (Scheme 1). The synthesis of **9** involved the electrophilic attack of CF_3CO^+ at one of the imino nitrogen atoms and trapping of the resulting carbocation with pyridine (Scheme 2).[16]

Preparation of stable compounds which contain methyleneamine units is not limited to **4a, b**. Thus, treatment of hexahydrazinocyclotriphosphazene **10** with a large excess of paraformaldehyde $(CH_2O)_n$ in the presence of molecular sieves affords quantitatively compound **11** possessing six $H_2C{=}N$ units. The structure of **11** was proposed on the basis of mass spectrometric (m/z 477) and NMR spectroscopic data,[17] and confirmed by a single-crystal X-ray diffraction study.[18]



10: R = N(Me)-NH_2
11: R = N(Me)-N=CH_2

The surprising stability of **4a, b** and **11** in comparison with other $H_2C{=}N$ compounds cannot be explained satisfactorily at present. Ab initio calculations, as well as more detailed experimental studies on the synthetic potential of these new powerful reagents are underway.

Experimental Procedure

4a: A mixture of **1** (0.280 g, 1.22 mmol) and paraformaldehyde (0.260 g, 8.66 mmol) in THF (30 mL) was stirred for 10 hours in the presence of molecular sieves (4 Å). Filtration of the solution, followed by evaporation to dryness gave **4a** as a white powder, which was recrystallized in acetone or toluene.

5 and **5′**: A solution of **6** (0.483 g, 1.27 mmol) in CH_2Cl_2 (10 mL) was added by canula at −80 °C to a solution of **4a** (0.323 g, 1.27 mmol) in CH_2Cl_2 (10 mL). The mixture was stirred overnight, then the solvent was evaporated to give a residue which was washed with CH_2Cl_2/pentane (1:3) to give an oil. Treatment of this oil with Et_2O (10 mL) then THF (10 mL) gave a white powder (**5′**-CF_3SO_3) and a solution which was evaporated to give an oil. After several treatments of this oil with Et_2O then THF as above, **5** was obtained as a white powder.

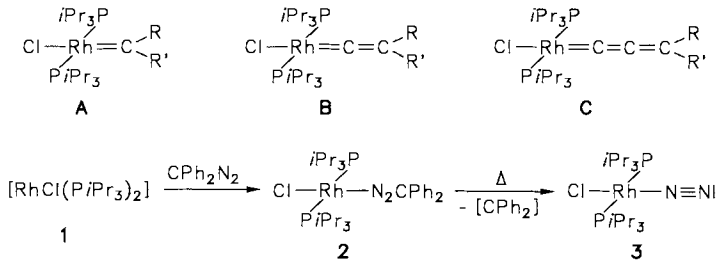
Carbenerhodium Complexes with Diaryl- and Aryl(alkyl)carbenes as Ligands: The Missing Link in the Series of the Double Bond Systems *trans*-[RhCl{=C(=C)$_n$RR'}(L)$_2$] Where $n = 0$, 1, and 2**

By *Peter Schwab, Norbert Mahr, Justin Wolf,* and *Helmut Werner**

Dedicated to Professor Ernst Otto Fischer on the occasion of his 75th birthday

There are but a few comparative studies concerning the reactivity of homologous trialkylphosphane and trialkylstibane transition metal complexes to date.[1] We observed a remarkable difference in the behavior of rhodium(I) compounds containing P*i*Pr$_3$ and Sb*i*Pr$_3$ as ligands, when we tried to prepare carbene complexes **A** as relatives to the known vinylidene and allenylidene complexes of type **B**[2] and **C**.[3] The missing link in the series of Rh–C double bond systems **A**–**B**–**C** is not accessible from **1** (the starting material for the synthesis of **B** and **C**), because on warming the diazoalkane complex **2** (Scheme 1), obtained from **1** and CPh_2N_2, does not eliminate N_2 but CPh_2 to give the dinitrogenrhodium compound **3**.[4] The original goal can be achieved, however, if a rhodium complex possessing two Sb*i*Pr$_3$ ligands is prepared first, and after the carbene–metal bond has been generated a subsequent ligand exchange is carried out. Crucial is the longer M–Sb distance (compared with M–P) and the weaker M–SbR$_3$ bond (compared with M–PR$_3$[1]) in the stibane rhodium compounds that open reaction pathways which for kinetic reasons are hindered in the case of the corresponding phosphane metal complexes.



Scheme 1.

Treatment of compound **4**[5] with CPh_2N_2 in pentane at room temperature leads to a rapid displacement of ethene by the diphenylcarbene ligand. The olive-green crystals of **5** (Scheme 2), which were isolated in 96% yield, can be stored under argon at $-20\,^{\circ}C$ but decompose in solution in a few hours. The X-ray crystal structure analysis of **5** (Fig. 1)[6] reveals that the rhodium has a somewhat distorted square-planar coordination sphere. The angle Sb1-Rh-Sb2 (155.48(2)°) deviates significantly from the ideal value of 180°, which is probably due to the repulsive forces between the isopropyl and phenyl groups. The Rh–Cl bond is surprisingly short (it is, to the best of our knowledge, the shortest Rh–C(carbene) distance ever found[7]) and thus indicative of a strong Rh–C back-bonding.

Scheme 2.

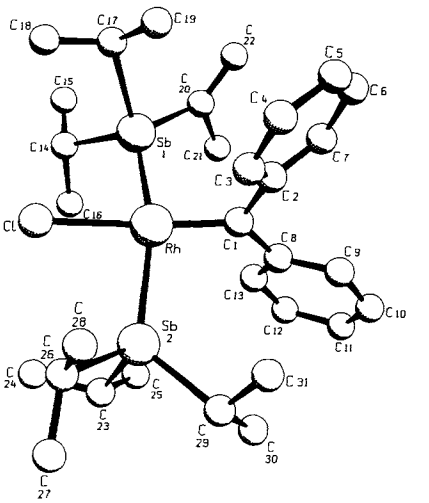

Fig. 1. Crystal structure of **5**. Selected bond distances [Å] and angles [°]: Rh–Sb1 2.5843(5), Rh–Sb2 2.5633(5), Rh–Cl 2.452(1), Rh–C1 1.863(4), C1–C2 1.489(6), C1-C8 1.497(6); Sb1-Rh-Sb2 155.48(2), Cl-Rh-C1 171.0(1), Sb1-Rh-Cl 84.15(3), Sb1-Rh-C1 96.8(1), Sb2-Rh-Cl 84.75(3), Sb2-Rh-C1 97.6(1), Rh-C1-C2 115.7(3), Rh-C1-C8 127.6(3), C2-C1-C8 116.6(4).

With di-*p*-tolyldiazomethane, phenyl-*o*-tolyldiazomethane, and even with phenyl(trifluoromethyl)diazomethane, carbene complexes **6**–**8**, structurally related to **5**, are obtained in nearly quantitative yield. In general, the rate of reaction increases considerably in the order **6** < **7** < **5** < **8**, that is, faster for alkyl(aryl) derivatives. The composition of **6**–**8** is confirmed both by elemental analysis and spectroscopic data (Table 1). Compound **4** also reacts spontaneously with benzoyldiazomethane and PhC(O)CPhN$_2$ (azibenzil) in ether at $-78\,^{\circ}C$, but in these cases a diazoalkanerhodium complex is formed instead of a carbenerhodium species.

Scheme 3 illustrates that the square-planar carbenerhodium compounds have great potential as starting materials for the synthesis of other organorhodium derivatives. Both **5** and **7** react with NaC_5H_5 in THF to give the half-sandwich type complexes (**9** and **10**), which are isolated in 70–80% yield. The fact that in contrast to **5**–**8** they are not 18-electron compounds is reflected in the high field shift of the signal of the carbene C atom, which for **9** is observed at $\delta = 260.97$ (cf. **5**: $\delta = 316.16$).

The reactions of **9** with CO and *t*BuNC lead, in pentane at room temperature, almost quantitatively to the displacement of the stibane ligand and to the formation of the corresponding carbonyl and isocyanide complexes. Half-sandwich complexes **11** and **12** are red crystalline solids which are stable under inert atmosphere (Ar). We note that carbene(carbonyl)rhodium compounds of half-sandwich type were originally prepared by Erker et al.[9] upon treatment of

Scheme 3.

$[(C_5H_5)Rh(CO)_2]$ with a reactive metallocene derivative such as $[(C_5H_5)_2Zr(\eta^4\text{-}C_4H_6)]$. No carbene(isocyanide) complex similar to **12**, however, is known.

The reactions of compound **5** with CO and $PiPr_3$ take a completely different course. Whereas by passing CO through a solution of **5** in pentane the carbonylrhodium complex **13**[5] and diphenylketene (identified by the IR and ^{13}C NMR spectra) are formed, on treatment of **5** with $PiPr_3$ a substitution of the stibane by the phosphane takes place. The yield of **14**, a yellow-green crystalline solid, is 98%! A complex of type **A**, which was the main target of this work, thus can be prepared from $[\{RhCl(C_2H_4)_2\}_2]$ not on a direct but an indirect route (via **4** and **5**), and such a complex is remarkably stable.

Compounds **5**–**8**, **9**–**12**, and **14** are the first carbenerhodium(I) complexes carrying a carbene ligand that is not stabilized by linkage to a hetero atom (O or N).[10] It should be emphasized that not only the primary reaction products **5**–**8** but also the subsequently formed compounds **9**–**12** and **14** are isolated in excellent (sometimes quantitative) yields. Furthermore, in the reactions of **5** the attack of the nucleophile (with the exception of CO) is preferentially directed to the metal and not to the carbene carbon atom as in Fischer-type carbene complexes.[10a, 11] Although diphenyldiazomethane and its derivatives were already used in 1974 by Herrmann et al. for the synthesis of carbenemetal compounds,[12] more recently this source of carbenes has hardly been employed for the formation of $M=CR_2$ bonds.[10] The crucial point is that in most of these reactions diazoalkane metal complexes are formed that do not lose N_2 to give the corresponding metal carbenes at ambient temperatures.

Experimental Procedure

5: A solution of **4** (87 mg, 0.13 mmol) in pentane (10 mL) was treated at −78 °C with a solution of CPh_2N_2 (51 mg, 0.26 mmol) in pentane (2 mL). After warming to room temperature, the solution was stirred for 30 min, and then the solvent was removed. The residue was washed twice with small amounts of methanol and dissolved in hexane (2 mL). The product mixture was separated by chromatography on Al_2O_3 (neutral, activity grade V, 3 cm column) with hexane, the dark green fraction was evaporated to dryness, and the residue was recrystallized from pentane (−78 °C) to give olive-green crystals. Yield 101 mg (96%); m.p. 61 °C (decomp). Compounds **6**, **7**, and **8** were prepared in a similar way. For **6** and **7**, the reaction time at room temperature is 90 and 60 min, respectively; for **8** the reaction is performed (without warming) at −78 °C, and column chromatography is unnecessary. **6**: yield 94%; m.p. 55 °C (decomp.). **7**: yield 93%; m.p. 28 °C (decomp.). **8**: yield 91%; m.p. 43 °C (decomp.).

9: A solution of **5** (83 mg, 0.10 mmol) in THF (10 mL) was treated at room temperature with NaC_5H_5 (44 mg, 0.50 mmol). The solution was stirred for 30 min, the solvent then removed, the oily residue extracted with pentane (10 mL), and the extract concentrated to about 0.5 mL. The concentrate was chromatographed on Al_2O_3 (see **5**) with hexane, and the dark fraction was evaporated to dryness in vacuum. The residue was washed twice with methanol (−30 °C) and recrystallized from pentane (−78 °C) to give deep blue crystals. Yield 57 mg (78%); m.p. 30 °C (decomp.). Compound **10** (blue violet oil) was prepared analogously; yield 73%.

11: CO was passed through a solution of **9** (70 mg, 0.12 mmol) in pentane (10 mL) for 30 s at room temperature. After the solution had been stirred for 1 h, the solvent was removed, and the residue worked up as described for **9**: red crystals; yield 38 mg (87%); m.p. 49 °C (decomp.). Compound **12** was prepared in an analogous way. Pure material (red crystals) was obtained without column chromatography; yield 89%; m.p. 88 °C (decomp.).

13: CO was passed through a solution of **5** (81 mg, 0.10 mmol) in pentane (10 mL) for 30 s at room temperature. After the solution had been stirred for 1 h, it was concentrated to about 1 mL, and the concentrate chromatographed on Al_2O_3 (neutral, activity grade III, 6 cm column). With hexane a yellow fraction was eluted, which, after removal of the solvent, gave a solid that was characterized by IR and ^1H and ^{13}C NMR spectroscopic data as **13** [5]. With hexane/benzene a red substance was eluted, which was identified by IR and ^{13}C NMR data as $Ph_2C=C=O$.

14: A solution of **9** (81 mg, 0.10 mmol) in pentane (10 mL) was treated with $PiPr_3$ (41 µL, 0.20 mmol) and stirred for 30 min at room temperature. After removal of the solvent, the oily residue was washed twice (at 0 °C) with small amounts of methanol, then dissolved in hexane (2 mL), and the solution was worked up as described for **5**: yellow-green crystals; yield 61 mg (98%); m.p. 81 °C (decomp.).

Synthesis and Structure of Surprisingly Stable Tetrakis(trifluoromethyl)cuprate(III) Salts**

By *Dieter Naumann,* Thomas Roy, Karl-Friedrich Tebbe,* and *Wolfgang Crump*

Previously only a few copper(III) compounds could be characterized unequivocally.[1] The single known copper(III) compound containing a perfluoroalkyl group is $[Cu(CF_3)_2SC(S)NEt_2]$;[2] the oxidation of bis(trifluoromethyl)cuprate(I) was reported to yield $[Cu(CF_3)_4]^-$, but no further details were given.[2]

We report here on the synthesis, isolation, and structure of $[Cu(CF_3)_4]^-$ salts. These compounds were prepared by oxidation of a mixture of Cu^I-CF_3 compounds in dimethylformamide (DMF)[3] with a stoichiometric amount of XeF_2, iodine, bromine, chlorine, or ICl; when an excess of the oxidant was used, the product decomposed giving CF_3X (X = F, Cl, Br, I). The reaction mixture was then treated with a salt with a bulky cation ([Bu_4N]Br, [Ph_4P]Cl, or [PNP]Cl(PNP=Ph_3PNPPh_3)), the solvent removed by distillation, and the residue taken up in CH_2Cl_2. After chromatography and concentration of the eluate, the product was dried under vacuum to provide the salts $[cat]^+[Cu(CF_3)_4]^-$ (cat = Bu_4N, Ph_4P, PNP) as colorless crystalline solids; these were not sensitive to light, air, and moisture. The higher homologues Cu^I-C_2F_5 and Cu^I-*i*-C_3F_7 were not oxidized under these conditions. The surprisingly stable $[Cu(CF_3)_4]^-$ compounds decompose upon melting at temperatures above 140 °C,[4] roughly 50 °C higher than for the homologous Ag^{III} compound $[Ag\{Ag(CF_3)_4\}]$.[5] In contrast to the Cu^I-CF_3 compounds these cuprates(III) are soluble in almost all organic solvents without decomposition.

Examination of the Cu^{III} salts by differential thermoanalysis/thermogravimetry (DTA/TG) indicates that the mass loss at the melting point corresponds roughly to the cleavage of four CF_2 groups, as was also the case for the Ag^{III} compound.[6] The vibrational spectra are in accord with the D_{4h} symmetry expected for compounds with d^8 configuration.[7] Because of the quadrupole moment of the ^{63}Cu and ^{65}Cu isotopes, the NMR spectra do not give any definite structural information.[8] The crystal structure determination confirms the approximately square-planar arrangement of the four C atoms around the Cu atom in the complex anion[9] (Fig. 1). The neighboring CF_3 groups are staggered,

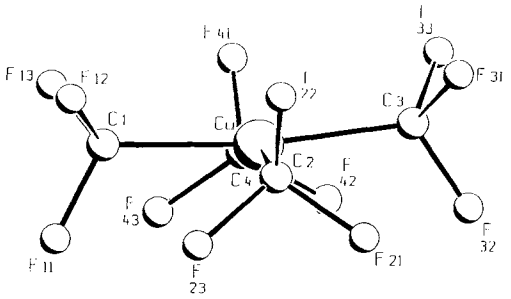

Fig. 1. Crystal structure of the $[Cu(CF_3)_4]^-$ anion in [PNP][$Cu(CF_3)_4$]. Bond lengths [pm] and angles [°]: Cu-C1 194.9(15), Cu-C2 198.3(13), Cu-C3 195.4(16), Cu-C4 198.0(17), C1-F11 130(2), C1-F12 140(2), C1-F13 136(2), C2-F21 136(1), C2-F22 131(2), C2-F23 136(2), C3-F31 136(2), C3-F32 131(2), C3-F33 139(2), C4-F41 133(2), C4-F42 136(2), C4-F43 133(2); C3-Cu-C4 91.3(7), C2-Cu-C4 165.0(7), C2-Cu-C3 90.2(6), C1-Cu-C4 89.1(7), C1-Cu-C3 172.2(6), C1-Cu-C2 91.4(6).

the *trans* groups eclipsed, and the C atoms are displaced from the ideal plane by approximately 20 pm. The two sets of six F atoms form a planar hexagon above and below the CuC_4 plane. The Cu atom is thereby shielded from nucleophilic attack. This "shielding" may explain the high chemical and thermal stability.

Experimental Procedure

All operations were conducted under nitrogen. The $[Cd(CF_3)_2]$ complexes employed in the synthesis of the Cu^I-CF_3 compounds were prepared according to ref.[10]. All other chemicals are commercially available.

cat[$Cu(CF_3)_4$]: The preparation of [Ph_4P][$Cu(CF_3)_4$] with iodine as oxidant serves as an example. The solution of Cu^I-CF_3 compounds[3] at −40 °C was treated with iodine (155 mg, 0.6 mmol) in DMF, stirred for 2 h, and slowly allowed to warm to room temperature. [Ph_4P]Cl (3.747 g, 10 mmol) in DMF was added. The solvent was removed by distillation at room temperature. The soluble residue was taken up in CH_2Cl_2 and purified by column chromatography (silica gel, eluent CH_2Cl_2/acetone (5/1)). The solvent was distilled off, and [Ph_4P][$Cu(CF_3)_4$] was obtained as a colorless, light-, air-, and moisture-insensitive crystalline solid, which does not sublime up to 80 °C/10^{-2} Torr. Total yield: 51.3% (based on $Cd(CF_3)_2 \cdot D$).

[**] This research was supported by the Fonds der Chemischen Industrie and the Ministerium für Wissenschaft und Forschung des Landes Nordrhein-Westfalen (Arbeitsgemeinschaft Fluorchemie).

The salts [PNP][Cu(CF$_3$)$_4$] and [(nBu)$_4$N][Cu(CF$_3$)$_4$] were synthesized analogously; Br_2, Cl_2, ICl, and XeF_2 are also suitable oxidants.

Molecular masses determined in CH_3CN (calcd) for cat = PNP: 426.7 (878.2); cat = Ph_4P: 356.3 (679.0); cat = Bu_4N: 298.6 (582.0); thus in CH_3CN the salts are completely dissociated. Correct elemental analyses.

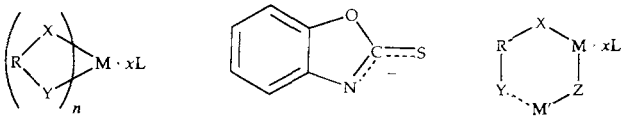
Synthesis and Structure of a Sixteen-Membered (AlNCO)$_4$ Ring**

By *Craig M. Bird, Catherine Breheny, Matthew G. Davidson, Andrew J. Edwards, S. Clare Llewellyn, Paul R. Raithby*, and *Ronald Snaith**

We described recently the syntheses and structures of alkali and alkaline earth metal chelate complexes **A** containing ligands of type (Y-R-X)$^-$.[1, 2] In these, R is a heterocyclic framework, X and Y are two electronegative centers, and L is a neutral ligand, for example, hexamethylphosphoric triamide (HMPA). Most attention has focused on complexes with ligand **B**, the anion of 2-mercaptobenzoxazole (OxSH; X, Y = N, S). Solutions of these complexes will dissolve salts M′Z of other metals such as $PtCl_2$[2a] and $HgCl_2$.[2b] When the metal center M in complex **A** is complexed by Z, one center of its chelating ligand, for example Y, is displaced and then coordinates to the inserted metal M′ to give a cocomplex of the general type **C**. We have been interested in an Al-Ti cocomplex of this type with regard to Ziegler–Natta catalysis.[3] Here we describe the synthesis of a precursor Al complex containing the [C$_6$H$_4$OC(=O)N]$^-$ anion (OxO$^-$; X,Y = N,O). This ligand is similar to **B**, but S is replaced by O, since O coordinates better to hard cations like Ti^{3+} and Ti^{4+}.



A; n = 1, 2 B C

Reaction of Me_3Al with OxOH (1:1 mol ratio) in toluene afforded a pale yellow solution, refrigeration of which gave crystals of **1** (see Experimental Procedure). Two possible

[{(OxO)AlMe$_2$}$_4$] **1**

solid-state structures were envisaged for **1**: 1) a monomer with a four-membered ring in which the OxO$^-$ ligand chelates the Me_2Al unit through its N and *exo*-O centers, or 2) a dimer in which these centers act "intermolecularly" and span two Al centers, affording an eight-membered (Al-O-C-N-Al-O-C-N) ring. A search of the Cambridge Crystallographic Data Base revealed that the second structure type is the norm for (Y-R-X)Al compounds, for example in [(PhNCPhOAlMe$_2$)$_2$] (NCO system),[4a] in the mercaptopyridine complex [NC$_5$H$_4$SAlMe$_2$SC$_5$H$_4$NAlMe$_2$] (NCS system),[4b] and in [(Me$_2$AlNMeCMeNMe)$_2$] (NCN system).[4c] No structures with larger than eight-membered rings (e.g., a trinuclear Al complex with a twelve-membered ring) are known. Indeed, in Al complexes with (Y-R-R′-X)$^-$ ligands, dimerization to give a ten-membered ring is resisted; instead monomers with five-membered rings are found, for example, [Me_2Al(CONMe)$_2$AlMe$_2$] (NCCO system)[5a] and [Me_2Al{C(NMe$_2$)$_2$}$_2$AlMe$_2$] (NCCN system).[5b] In contrast to these earlier results, an X-ray diffraction study on **1**[6] has revealed a *tetramer* with a 16-membered (AlNCO)$_4$ ring.

[**] This work was supported by the Science and Engineering Research Council (all authors), the Associated Octel Co. Ltd. (M. G. D., R. S.), St. John's College, Cambridge (M. G. D.), and the Cambridge Crystallographic Data Centre (A. J. E.).

Figure 1 shows the whole tetrameric solid-state structure of **1**, and Figure 2a highlights the central core (including the uncoordinated O atoms of the heterocycle. The key feature in the structure is the alternation of OxO^- ligands and their $[N{-}C{-}O]^-$ coordinating units around the sixteen-membered ring. The resulting sequence is (Al(1)-NCO-Al(2)-OCN-Al(3)-OCN-Al(4)-NCO)], in which Al(1) and Al(3) are coordinated by N and O, Al(2) by O and O, and Al(4) by N and N. The effect of this alternation is to organize and space out the ring components of the OxO^- ligands, thus allowing the formation of such a large ring. As shown in Figure 2b (and as indicated in Fig. 1), these ring components are aligned in two nearly parallel pairs: the ring system containing N1 with that containing N3, and the ring system containing N2 with that containing N4. That this effect is steric (rather than electronic) in origin is emphasized by the fact that the distances between these aligned rings are long, >4.2 Å; this rules out graphite-like π interactions. The distances between the heterocyclic rings of neighboring tetramers are 3.6 Å or greater. Within the tetramer, distances to Al are as expected: Al–O 1.820–1.840 Å (average 1.832 Å), Al–N 1.948–1.955 (1.951 Å), Al–C 1.945–1.963 (1.953 Å). The relevant distances with the OxO^- anions are N–C 1.318–1.333 (average 1.327 Å), C–*exo*-O 1.260–1.268 (1.265 Å), and C–(ring)O 1.345–1.359 (1.351 Å). Thus the coordinating section of the anion, N-C-(*exo*)O, is best represented as $[N{-}C{-}O]^-$.

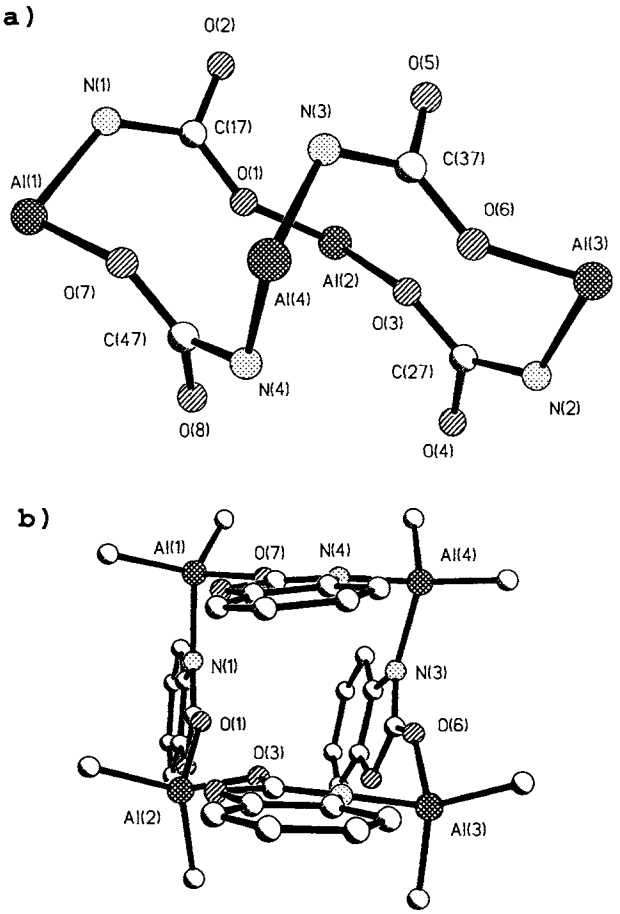

Fig. 2. a) The central 16-membered ring of **1**. b) A view of the molecular structure of **1** highlighting the two sets of aligned parallel heterocycles and the central cavity.

These findings are intriguing on two counts. Firstly, they form an interesting contrast to the widespread use of bulky ligands to *restrict* association; in **1** a *flat* bifunctional ligand allows formation of a ring of unprecedented size. Secondly, **1** could be regarded as a metallacoronand in its own right: each N is only three coordinate, and both O centers of each anion are merely two coordinate. Given this coordinative unsaturation, and the fact that the molecular structure of **1** has a cavity (Fig. 2b), we are exploring the use of **1** to coordinate other compounds including $TiCl_4$ and $[Cp_2TiCl_2]$.

Experimental Procedure

1: Me_3Al (2.5 mL of a 2.0 M solution in toluene) was added to a solution of OxOH (0.676 g, 5 mmol) in 15 mL of dry toluene at −78 °C. On warming to room temperature, a vigorous effervescence occurred, leaving a clear, pale-yellow solution. Refigeration of the solution at −5 °C afforded colorless crystals of **1** (first batch yield 0.537 g, 56%) m.p. 127–129 °C. Correct elemental analyses. ^1H NMR (250 MHz, C_6D_6, 25 °C): δ = 7.50–6.50 (series of m, 4H; OxO^-), 0.10 – 0.50 (series of s, 6H; $AlMe_2$)].

The First Example of an Increase in the Enantioselectivity of a Chemical Reaction in the Presence of a Chiral Lewis Acid under High Pressure**

By *Lutz F. Tietze,* Christian Ott, Kerstin Gerke,* and *Michael Buback**

The development of methods for asymmetric synthesis is an important and widely investigated area of organic chemistry. Of particular interest is the use of chiral catalysts and mediators. In the last few years numerous chiral Lewis acids have been developed[1] which allow intermolecular reactions to be carried out with high enantioselectivity. More recently it has been shown that highly enantioselective intramolecular reactions are also possible.[2] The dependence of enantioselectivity on pressure has not been studied previously. Also the effect of pressure on reactions mediated by achiral Lewis acids has only been studied for a few cases.[3] For the first time we have recently shown for a hetero-Diels–Alder reaction that the diastereoselectivity can be increased significantly by applying high pressure ($\Delta\Delta V^{\neq} \approx 7\ cm^3\ mol^{-1}$).[4, 5] In this report we describe the first example of a reaction with increased enantioselectivity under high pressure.

The intramolecular hetero-Diels–Alder reaction of the benzylidene compound **1** proceeds by a *meta*-addition to give the two enantiomeric bridged cycloadducts **2** and **3** (Scheme 1).[6, 7] In the presence of the chiral titanium Lewis acid **4** (first described by K. Narasaka et al.[8] and available from natural tartaric acid) at 1 bar pressure, **2** was formed preferentially with 4.5% *ee*.[9]

[**] Inter- and Intramolecular Hetero-Diels–Alder Reactions, Part 43. This work was supported by the Deutsche Forschungsgemeinschaft within the Graduiertenkolleg "Kinetics and Selectivity of Chemical Transformations in Condensed Fluid Phase" and the Fonds der Chemischen Industrie. – Part 42: L. F. Tietze, P. Saling, *Chirality* **1993**, in press.

The pressure dependence of the enantioselectivity of this cycloaddition was studied by treating solutions of **1** and the chiral Lewis acid **4** (1.1 equiv) in dichloromethane, prepared under an inert atmosphere and with the exclusion of water, with powdered molecular sieves (4 Å) at −78 °C in a teflon cell. After the teflon cell was sealed, it was placed in an autoclave, where cyclization was performed at room temperature (296 K) under pressures between 1 and 5000 bar. The enantioselectivity was determined by analytical chiral reverse-phase HPLC on a sample following aqueous workup, removal of solvent under vacuum, and separation from the diol on silica. A silica-supported cellulose derivative was used as the chiral phase.[10]

This investigation shows that formation of the (−) enantiomer **2**[9] is favored at high pressure. Thus, the enantioselectivity of the cycloaddition can be increased from 4.5% *ee* at 1 bar to 20.4% *ee* at 5 kbar. In addition the chemical yield is improved (Table 1). From the plot of enantioselectivity (ln[**2**/**3**]) versus applied pressure (**P**), it can be seen that the difference in the activation volumes for the two diastereomeric transition states, $\Delta\Delta V^{\neq}$, is $-(1.7 \pm 0.2)\ cm^3\ mol^{-1}$ (Fig. 1). This value is significant; for intermolecular diasteroselective cycloadditions, however, $\Delta\Delta V^{\neq}$ values of up to $\approx 7\ cm^3\ mol^{-1}$ have been reported.[5, 11]

Table 1. Pressure dependence of the ratio of enantiomers (**2**/**3**) at 296 K in dichloromethane.

p [bar]	*t* [h]	ln (**2**/**3**) [a]	*ee* [%]	$[\alpha]_D^{20}$ [b]	Yield [%]
1	31	0.089	4.5	−13.0	50
1000	26	0.131	6.6	−22.5	85
2000	26	0.203	10.1	−26.0	81
2800	24	0.216	10.7	−33.5	89
3600	24	0.341	16.9	−54.5	95
5000	7	0.414	20.4	−61.7	89

[a] Determined by HPLC: CHIRACEL OD-R, 10 μm, 0.46 × 25 cm, Daicel Chemical Industries, Ltd.; acetonitrile/water (40:60), flow rate: 0.7 mL min^{-1}, t_r (**3**) = 21 min, t_r (**2**) = 26 min. [b] Optical rotation (c = 1 in chloroform).

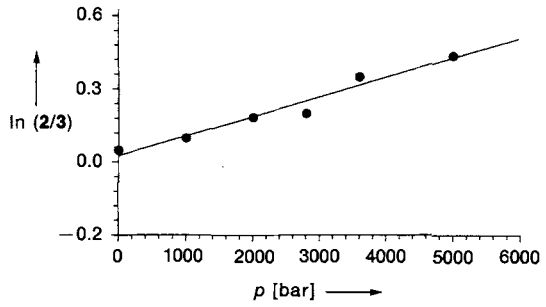

Fig. 1. Pressure dependence of the enantioselectivity of the hetero-Diels–Alder reaction of **1** in the presence of **4** at 296 K in dichloromethane. $\Delta\Delta V^{\neq} = -1.7 \pm 0.2\ cm^3\ mol^{-1}$.

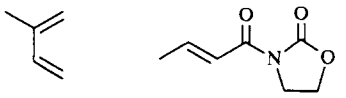
Interpretation of these results is not simple, particularly because the effect of pressure on the structure of Lewis acids has not yet been examined. Dynamic effects[12] on the activation volume should be negligible, since the competing processes leading to the two enantiomers take place in the same reaction medium. The observed effect should be considered with respect to the static contribution to the activation volume, which mainly affects the equilibrium properties of the transition structures surrounded by solvent molecules. Here

it must be assumed that heterodiene **1** and Lewis acid **4** form at least two diastereomeric transition structures in which the ratio of **1** to **4** is unknown. The pressure dependence of the enantioselectivity implies that the transition structure that leads to **2** has a smaller (more negative) activation volume and thus is more compact. Therefore the preferential formation of **2** at normal pressure is enhanced at increased pressure. However, this advantageous result for the enantioselective transformation of **1** cannot be generalized. Preliminary investigations[13] on the intermolecular cycloaddition of **5** and **6** in the presence of chiral Lewis acid **4** showed a decrease in enantioselectivity when pressure was increased.



5 **6**

This is what we expected, because it can be assumed that the diene attacks the complex of the dienophile and the chiral Lewis acid from the less hindered side; the corresponding transition structure should therefore have a larger volume than that leading to the other enantiomer, and will thus be disfavored at high pressure.

The observed increase in the enantioselectivity of the intramolecular reaction of **1** at higher pressure may be due to the formation of complexes with different stoichiometry. This point will be clarified by further investigations with other substrates, and by varying the Lewis acid concentration. In particular, chiral and achiral Lewis acid/substrate complexes will be studied at high pressure by NMR spectroscopy.

The Behavior of Cp^*MoBr/Br_2 Redox Systems: The Unusual Structure of $[(Cp^*_2Mo_2Br_4)_2(Cp^*MoBr_4)_3]$, a Compound Containing Mo^{III}, Mo^{IV}, and Mo^V**

By *Jahanvi U. Desai, John C. Gordon, Heinz-Bernhard Kraatz, Beth E. Owens-Waltermire, Rinaldo Poli,** and *Arnold L. Rheingold*

There is considerable interest in the use of cyclopentadienyl transition metal complexes having one or more halo ligands as convenient starting materials for the synthesis of a large variety of organometallic compounds.[1] Although complexes of the group 6 metals molybdenum and tungsten are well known for the III and V oxidation state, Mo^{IV} and W^{IV} complexes have received little attention. Only recently, we were able to obtain $[CpMoCl_3]$ ($Cp = \eta^5$-C_5H_5), an insoluble powder and presumably an oligomer[2] In order to obtain complexes that lend themselves to structural characterization, we have moved to the more soluble Cp* complexes ($Cp^* = \eta^5$-C_5Me_5). We report here on the synthesis and highly unusual crystal structure of **1**.

$[\{[Cp^*Mo(\mu\text{-}Br)_4MoCp^*]^+[Cp^*MoBr_4]^-\}_2][Cp^*MoBr_4]$ **1**

This compound is novel in that it is 1) the first known tetrabromo-bridged d^2-d^3 dimer, 2) the first d^2 $[Cp^*MX_4]^-$ complex to be structurally characterized, and 3) the first neutral Mo^V tetrabromide to be structurally characterized. In addition, molybdenum is found in three different oxidation states in the same crystal. This is possible because of the particular redox properties of the Cp^*MoBr/Br_2 system which we will describe here. Complex **2** has been prepared from **3**[3] and sodium amalgam in toluene as a diamagnetic

$[Cp^*Mo(\mu\text{-}Br)_4MoCp^*]$ **2** $[Cp^*MoBr_4]$ **3**

crystalline complex, which is isostructural to the neutral (d^3-d^3) complex [Cp'Mo(μ-Br)$_4$MoCp'] (Cp' = η^5-1-(2,5-dimethoxyphenyl)-2,3,4,5-tetraphenylcyclopentadienyl)[4] and to [(*i*Pr)CpMo(μ-Cl)$_4$MoCp(*i*Pr)].[5] The unit cell of **2**[6] contains two independent molecules, one located at an inversion center and the second one in a general position. The two crystallographically independent molecules are chemically equivalent and can be described as two four-legged piano stool structures sharing a common square face defined by the four bridging bromo ligands (Fig. 1). Complex **2** undergoes two reversible one-electron oxidations at $E = -0.30$ V and $+0.73$ V (vs. ferrocene).

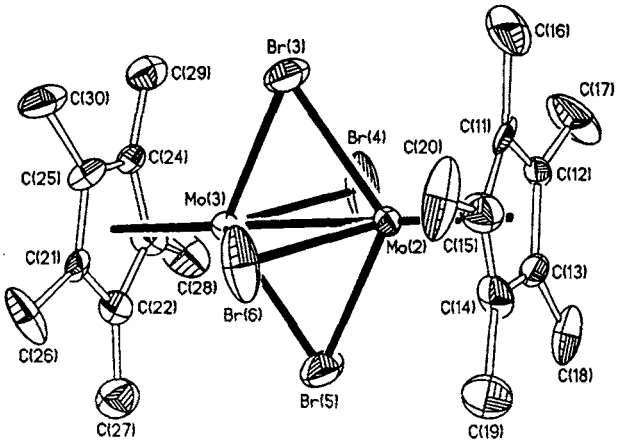

Fig. 1. Crystal structure of **2** (ORTEP plot shows the molecule in a general position). The geometry is identical to that of the molecule located at an inversion center in **2** and also to that in cation 2^+. Selected bond lengths [Å] and angles [°] (averaged over all chemically equivalent groups of atoms): **2**: Mo-Mo 2.643(2), Mo-Br 2.613(9); Mo-Br-Mo 60.8(3). 2^+: Mo-Mo 2.643(5) Mo-Br 2.64(3); Mo-Br-Mo 60.0(8).

In an attempt to prepare **4** by bromination of **2** with Br_2 (mol ratio 1:1) in benzene, we obtained a brick-red precipitate (**5**), which analyzes as Cp*MoBr$_{3.3}$ and shows a single

[{Cp*MoBr$_3$}$_2$] **4** [{Cp$^*_2$Mo$_2$Br$_4$}]$^+$[Br, Br$_3$]$^-$ **5**

broad resonance at $\delta = 4.3$ in its ^{1}H NMR spectrum in $CDCl_3$. This resonance is identical to that of the product obtained upon treatment of **2** with one equivalent of $AgBF_4$. Thus **5** is interpreted as being a salt of [Cp*Mo(μ-Br)$_4$MoCp*]$^+$ (2^+), and its anion is presumably a 1:4 mixture of Br^- and Br_3^-. According to our electrochemical investigations and the literature,[7] Br_2 does not have sufficient oxidizing power to produce the dication 2^{2+} (see Fig. 2).

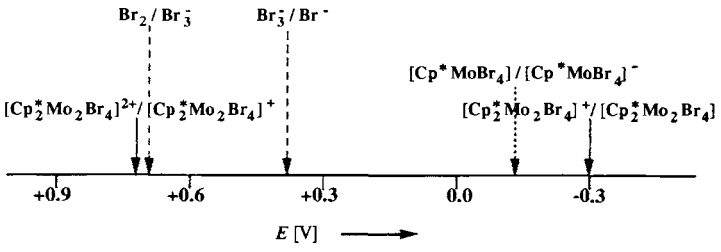

Fig. 2. Electrochemical behavior of the [Cp$^*_2$Mo$_2$Br$_4$]$^{n+}$, [Cp*MoBr$_4$]$^{n-}$, and $Br_2/Br_3^-/Br^-$ systems.

Recrystallization of **5** from CH_2Cl_2/*n*-heptane yielded the title compound **1** as a dark red, crystalline material, which is paramagnetic and displays two broad peaks at $\delta = 4.2$ and -19.5 in its ^{1}H NMR spectrum. The resonance at $\delta = -19.5$ is assigned to the anion [Cp*MoBr$_4$]$^-$ (3^-) (vide infra). The cyclic voltammogram of **1** shows, in addition to the two reversible one-electron oxidations characteristic of **2**, a reversible wave at $E = -0.14$ V (vs. ferrocene), which is due to the [Cp*MoBr$_4$]^0/[Cp*MoBr$_4$]$^-$ couple as shown by an independent study of **3** (Fig. 2). A comparison of the oxidation potentials in Figure 2 indicates that **1** consists of the mixed-valence cation [Cp*Mo(μ-Br)$_4$MoCp*]$^+$ and a 2:1 mixture of the anion [Cp*MoBr$_4$]$^-$ and the corresponding Mo^V neutral analogue. This rules out the alternative formulation of **1** as a 1:1 mixture of monocation and dication for the dinuclear complex accompanied by three negatively charged mononuclear complexes.

Compound **1** crystallizes in the monoclinic space group $P2_1/m$ with two formula units per unit cell.[8] The dinuclear monocation 2^+ is located in a general position, and its structure is practically identical to that of the neutral precursor **2** (Fig. 1). According to theoretical considerations,[9] the HOMO of **2** should be nonbonding. This explains the little change in the Mo–Mo separation upon oxidation (d(Mo–Mo): **2** = 2.645(2) Å; 2^+ = 2.691(4) Å). This is the first direct comparison of metal–metal distances in a pair of [{CpMX$_2$}$_2$]$^{n+}$ complexes and experimentally confirms the theoretical predictions by Green et al.[9] The two Mo^{IV} anions 3^- and the neutral Mo^V complex **3** are located on mirror planes. These all have the familiar four-legged piano stool structure (Fig. 3). The bond angles are not significantly

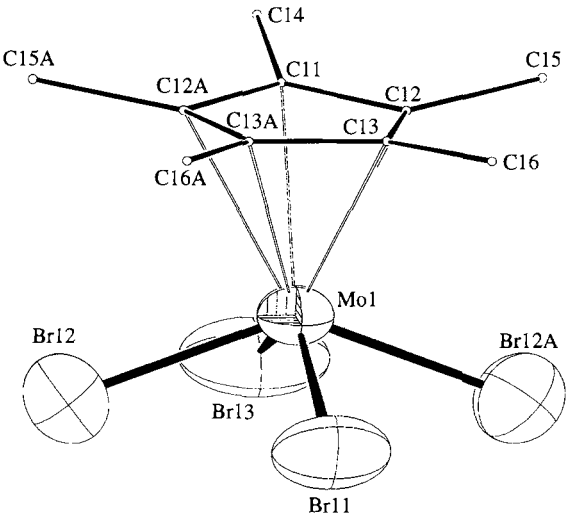

Fig. 3. Crystal structure of **3** (ORTEP). The two crystallographically independent anions 3^- have identical structural parameters. Selected bond lengths [Å] and angles [°] (averaged over all chemically equivalent groups of atoms): 3^-: Mo-Br 2.62(4), Br-Mo-Br (*cis*) 81.8(4), Br-Mo-Br (*trans*), 136(3). **3**: Mo-Br 2.48(3), Br-Mo-Br (*cis*) 82.8(4), Br-Mo-Br (*trans*) 138(2).

different in the three mononuclear complexes; however, the Mo–Br distances at atom Mo1 are significantly shorter (average 2.48(4) Å) than those at atoms Mo4 and Mo5 (Mo4: range 2.595(6)–2.616(9) Å; Mo5: range 2.591(6)–2.721(8) Å). This reflects the stronger π acidity of the neutral d^1 complex [Cp*MoBr$_4$] and allows us to identify Mo1 as the central atom in as **3**. An ORTEP representation of the unit

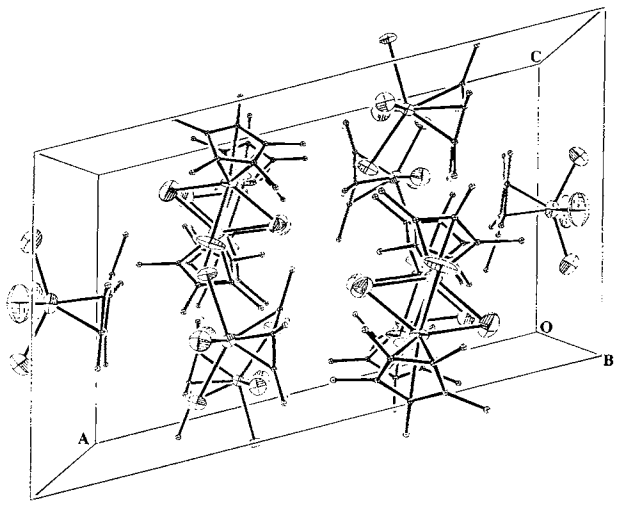

Fig. 4. Unit cell of **1** (ORTEP).

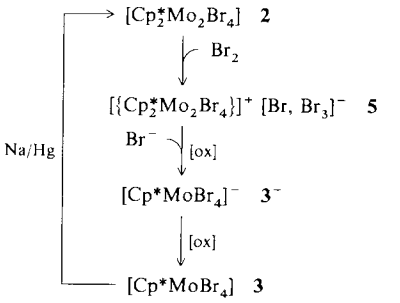
cell of **1** giving the relative orientations of all three constituents to each other is shown in Figure 4.

The formation of **1** from **2** and Br_2 can be understood in terms of their redox behaviors (see Fig. 2). Initially, Br_2 oxides **2** to give the benzene-insoluble salt **5**, which contains the cation $\mathbf{2}^+$ and a mixture of Br^- and Br_3^- as discussed above. During the crystallization from CH_2Cl_2, Br^- can add to $\mathbf{2}^+$ to give the neutral adduct **2**-Br. Oxidation with Br_3^- and subsequent reaction with Br^- via the possible intermediate $[Cp^*MoBr_3]_2$ will give the paramagnetic anion $\mathbf{3}^-$ (Scheme 1).



Scheme 1. [ox] = oxidation.

Any residual Br_3^-, according to the electrochemical study (Fig. 2), would be capable of oxidizing $\mathbf{3}^-$ to give neutral **3**. Thus, considering the composition of compound **5**, a mixture of **2**, $\mathbf{3}^-$ and **3** in a mol ratio of 1:1:2.1 should be produced in solution. But a mixture of the three components in a mol ratio of 2:2:1 is found in the crystal, presumably because a compound with this particular combination is the least soluble material in the solvent combination used for crystallization. Treatment of compound **5** with excess Br^- eventually leads to a product with a single broad ^{1}H NMR resonance at $\delta = -19.5$, which is attributed to $\mathbf{3}^-$ in agreement with the reactions depicted in Scheme 1. Figure 2 indicates that the two neutral complexes **3** and **2** are not stable with respect to electron transfer. In fact, mixing a stoichiometric amount of **3** and **2** produces a solution that exhibits the ^{1}H NMR resonances of the cation $\mathbf{2}^+$ and the Mo^{IV} anion $\mathbf{3}^-$.

Currently, efforts are under way to isolate $[\{Cp^*MoBr_3\}_2]$ (**4**), which requires reaction conditions under which free bromide ion cannot exist.

Experimental Procedure

3: $[Cp^*MoBr_4]$ was prepared by a procedure similar to that described for $[Cp'MoBr_4]$ [3]: $[\{Cp^*Mo(CO)_3\}_2]$ (1.03 g, 1.62 mmol) was dissolved in CH_2Cl_2 (20 mL), and the red-orange solution was transferred by cannula to a slurry of yellow PBr_5 (2.80 g, 6.52 mmol) in CH_2Cl_2 (20 mL). Vigorous gas evolution indicated an immediate reaction. The reaction mixture was then refluxed approximatly 12 h. The solution was reduced in volume to approximately 30 mL. The almost black precipitate was collected by filtration, washed with cold CH_2Cl_2 (3 × 5 mL) and dried under vaccum to yield 1.56 g (87%) of **3**. Correct elemental analysis (C, H, Br).

2: Compound **3** (3.427 g, 6.22 mmol) was placed in a Schlenk tube containing freshly prepared sodium amalgam (311 mg of Na, 13.5 mmol in 31 g Hg). Toluene (40 mL) was added, and the dark suspension was allowed to stir at room temperature (21 °C) for about 12 h, during which the solution developed a tan brown color. The reaction mixture was filtered and the precipitate washed with toluene until the washings were colorless (4 × 20 mL). The combined filtrates were reduced in volume and cooled to −20 °C to yield 2.18 g (90%) of **2**. ^{1}H NMR (200 MHz, $CDCl_3$, 25 °C): $\delta = 1.93$(s). Cyclic voltammogram (CH_2Cl_2/0.1 M nBu_4NPF_6, E[V] vs. Cp_2Fe/Cp_2Fe^+): −0.30 ($[\{Cp^*MoBr_2\}_2]$/$[\{Cp^*MoBr_2\}_2]^+$), +0.73 ($[\{Cp^*MoBr_2\}_2]^+/[\{Cp^*MoBr_2\}_2]^{2+}$). Correct elemental analysis (C, H).

1: Compound **2** (538 mg, 0.69 mmol) was dissolved in benzene (10 mL). A solution of Br_2 (35 μL, 0.69 mmol) in benzene (5 mL) was added, causing the immediate formation of a red precipitate. The product was collected by filtration, washed with *n*-heptane, and dried under vacuum (381 mg). ^{1}H NMR (200 MHz, $CDCl_3$, 25 °C): $\delta = 4.3$ (br, $w_{1/2} = 120$ Hz). Recrystallization of this product from CH_2Cl_2/*n*-heptane yielded **1** as dark red plates. ^{1}H NMR (200 MHz, $CDCl_3$, 25 °C): $\delta = 4.2$ ($w_{1/2} = 120$ Hz), −19.5 ($w_{1/2} = 137$ Hz). One of these crystals was used in the crystallographic investigation.

Reaction between **3** and **2**: To a solid mixture of **2** (17 mg; 0.022 mmol) and **3** (23 mg; 0.042 mmol) in a Schlenk tube, was added $CDCl_3$ (1 mL). The resulting orange-brown solution was transferred to an NMR tube (5 mm o.d.). ^{1}H NMR (200 MHz, $CDCl_3$, 25 °C): $\delta = 4.13$ ($w_{1/2} = 85$ Hz), −19.53 ($w_{1/2} = 137$ Hz).

The reflections were measured on an Enraf-Nonius CAD4 diffractometer with $Mo_{K\alpha}$ radiation ($\lambda = 0.71073$ Å) by using the ω-2θ scan method. The structure of **1** was solved using the TEXSAN program package. The positions of all non-hydrogen atoms were determined from difference Fourier maps. The Mo and Br atoms were refined anisotropically; the C atoms were refined isotropically. All Cp* ligands were restrained to ideal pentagons with C–C(ring) = 1.42(1) Å and C–C(Me) = 1.56 Å and the interstitial heptane molecule restrained to C–C = 1.54(2) Å (SHELX76). Some of the Cp* methyl carbon atoms refined with very a high thermal parameter, indicating fast rotation of the rings about the metal–ring axis and/or partial disorder of the rings. Further details of the crystal structure can be obtained upon request from the Director of the Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, GB-Cambridge CB21EZ (UK), on quoting the full journal citation.

Coherence Selection by Gradients without Signal Attenuation: Application to the Three-Dimensional HNCO Experiment**

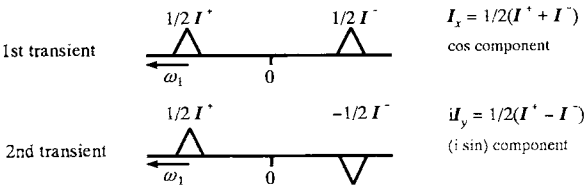
By *Jürgen Schleucher, Michael Sattler,* and *Christian Griesinger**

Pulsed field gradients, that is, short, defined inhomogeneities of the static magnetic field B_0, have recently been introduced into high-resolution NMR.[1] In multidimensional NMR experiments they offer a reduction of artifacts and can substitute phase-cycles. Spectra can therefore be recorded more quickly, provided that the experiment duration is determined by the need to suppress undesired transfer pathways rather than by S/N requirements. By the application of a gradient pulse during the evolution time of the magnetization of the heteronucleus and before acquisition of proton signals, a heteronuclear gradient echo[2] can be generated.[3] This results in excellent suppression of signals from all protons that are not bound to the heteronucleus (e.g., solvent resonances). Thus, proton signals underlying the water resonance can be observed in proton-detected ^{13}C correlations at natural abundance for millimolar concentrations.

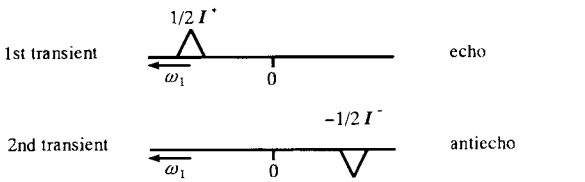
If applied in standard pulse sequences, the excellent suppression of the water signal provided by the use of heteronuclear gradient echoes is associated with a loss in signal-to-noise ratio (S/N), as shall be explained in the following. In amplitude-modulating NMR experiments, to which all multidimensional standard pulse sequences belong, two coherence transfer pathways contribute intensity $\frac{1}{2}$ to the signal recorded.[4] These are called echo pathway ($p(t_1) = 1 \rightarrow p(t_2) = -1$) and antiecho pathway ($p(t_1) = -1 \rightarrow p(t_2) = -1$) ($p$: coherence order) (Fig. 1a). Echo and antiecho are recorded simultaneously, however, with different relative signs in two transients. Pure phases are obtained according to the method introduced by States, Haberkorn, and Ruben.[5] The signal intensity acquired in these transients is $4 \times \frac{1}{2} = 2$. Because of addition of the two free induction decays (FIDs) and of folding at $\omega_1 = 0$, the noise increases by $\sqrt{4}$. Therefore, the S/N obtained is $2/2 = 1$.

In the course of a pulse sequence, pulsed field gradients select coherence orders p according to the condition $\sum_i p_i \gamma_i G_i = 0$ (i is an index for the ith gradient pulse applied in the course of the sequence, γ_i and p_i are the gyromagnetic ratio and the coherence order of the nucleus (nuclei) affected by the gradient pulse i, and G_i is the strength of the ith gradient). If a gradient pulse is applied in an evolution time of an amplitude-modulating pulse sequence, and the magnetization to be observed is refocused by a gradient applied before the detection period, only one of the two possible coherence transfer pathways is retained. Depending on the relative sign of the gradients, either the echo or the antiecho is selected (Fig. 1b). Thus, the application of gradients for coherence selection in amplitude-modulating pulse sequences results in the recording of phase-modulated signals. The accumulated signal intensity is $2 \times \frac{1}{2} = 1$, and the noise increases to $\sqrt{2}$ as a result of summation of the transients. The S/N obtained is $1/\sqrt{2}$, that is, a factor of $\sqrt{2}$ poorer than the original amplitude-modulating pulse sequence without gradients. If gradients are applied during fixed delays (where two coherence orders of opposite sign contribute to the signal equally), such as in the mixing time of a relayed-COSY or DQF-COSY, S/N is a factor of 2 smaller than for the same sequence without gradients, since the signals sketched in Figure 1a are selected in such sequences, but their intensity is again reduced by half.

a) States–Haberkorn–Ruben method yields pure phases and sign discrimination for amplitude-modulating experiments.



b) Gradient-selected echo and antiecho spectrum from an amplitude-modulating experiment yields pure phases with reduced intensity.



c) Gradient-selected echo and antiecho spectrum from a phase-modulating experiment yields pure phases with enhanced intensity.

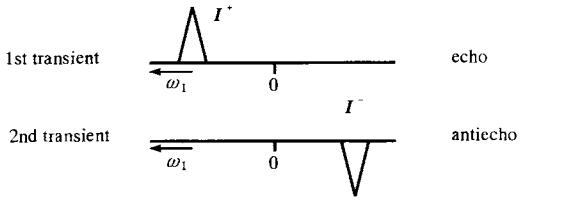


Fig. 1. Schematic drawing of the signals resulting from different NMR experiments for the evolution time: a) quadrature detection according to States, Haberkorn and Ruben in an amplitude-modulating pulse sequence; b) signals selected by the application of gradients in the evolution time and before acquisition of an amplitude-modulating sequence; c) signals obtained in a phase-modulating sequence.

The substantial drawback of reduced sensitivity, which is inherent to the application of gradients in the evolution time and before signal acquisition of amplitude-modulating NMR experiments, is overcome in phase-modulating experiments, since only one coherence order contributes to the signal in such sequences. This coherence order can be selected without attenuation, that is, with intensity 1, by the application of gradients during the evolution time (Fig. 1c). In the two transients recorded for each t_1-increment of such an experiment, the intensity $2 \times 1 = 2$ is accumulated. As the noise is $\sqrt{2}$, the optimal S/N of $\sqrt{2}$ is obtained. Whilst all conventional correlation experiments yield amplitude-modulated time signals, the advantage in sensitivity of phase-modulation in conjunction with the use of gradients for coherence selection can be exploited in the so-called "sensitivity-enhanced" HSQC experiments:[6] In the case of X–H spin systems (X: heteronucleus), these experiments yield a phase-

modulated, two-dimensional data set even in the absence of gradients. From this data set, consisting of FIDs formed by echo and antiecho selection, an amplitude-modulated data set in States–Haberkorn–Ruben format can be reconstituted.[6] No additional methods for sign discrimination in ω_1, such as time-proportional phase incrementation (TPPI)[7] or States–Haberkorn–Ruben,[5] need to be applied.

One example of a HSQC experiment using gradients for coherence selection without loss in sensitivity has recently been published.[8] Here we demonstrate the application of this general principle to heteronuclear multidimensional NMR experiments. The HNCO experiment[9] is used to obtain sequential connectivities of the backbone atoms in proteins uniformly labeled with ^{15}N and ^{13}C. In this experiment coherence is transferred through ^1J couplings from the amide proton to the amide nitrogen atom and further to the carbonyl carbon resonance of the preceding amino acid. After evolution of the carbonyl chemical shift (t_1) coherence is transferred back to the amide nitrogen atoms ("constant time" evolution time t_2), and to the amide protons for detection. The pulse sequences of a conventional CT-HNCO ("constant time"-HNCO), a gradient CT-HNCO, and a sensitivity-enhanced gradient CT-HNCO experiment are shown in Figure 2. In the two gradient experiments, coherence selection is achieved by the application of a gradient pulse during t_2 and before acquisition (t_3).

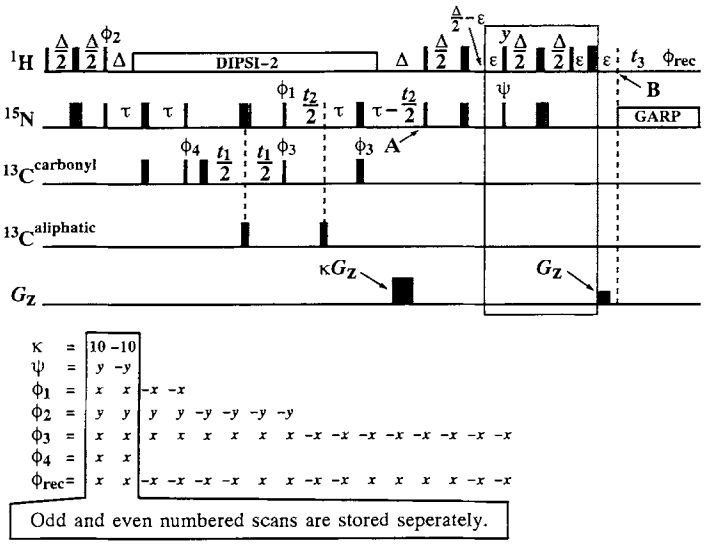

Fig. 2. Pulse sequence of the "sensitivity-enhanced" gradient CT-HNCO experiment. Narrow bars represent 90° pulses and wide bars 180° pulses. Unless stated otherwise, all pulses are applied along x. Simultaneous acquisition of complex data points is used during t_3. The nitrogen magnetization evolution must occur immediately prior to the N → H transfer for the application of sensitivity enhancement. The sign of the gradient acting on nitrogen atoms as well as the phase ψ are inverted from one scan to the other and the resulting FIDs stored separately. The echo and antiecho signals obtained in this way are converted into an amplitude-modulated data set by the following procedure: For all values of t_1 and t_2 the echo and antiecho FIDs are added (resulting in FID1) or subtracted and shifted by 90° (resulting in FID2). FID1 and FID2 have States–Haberkorn–Ruben format and can be processed by standard software. The state of the spin system at times A and B is discussed in the text. Spectra were recorded on an AMX600 spectrometer equipped with a triple resonance probe with a self-shielded gradient coil. ^{13}C pulses were delivered by a BSV-10 amplifier feeding a supplementary BLKX 300 W linear amplifier. ^{13}CO pulses were applied at 176 ppm as selective G4 or G3 pulses [11] (duration 400 μs and 250 μs, respectively). Selective inversion of the aliphatic carbon resonances was achieved with a phase-modulated G3 pulse (duration 250 μs, modulation frequency 20000 Hz). Bloch–Siegert effects of zeroth and first order occurring during t_1 and evolution of the ^{13}CO chemical shift for $t_1 = 0$ were compensated, respectively, by correcting ϕ_4 and by introduction of a delay before the ^{13}CO 180° pulse before t_1. The delays are: $\varepsilon = 2.2$ ms, $\Delta = 5.0$ ms, $\tau = 14.7$ ms. Eight scans were used to record $40(t_1) \times 36(t_2) \times 768(t_3)$ complex points. Corresponding acquisition times were 9.75 ms (t_1), 9.5 ms (t_2), and 192 ms (t_3). Total measurement time was 20 h. Omission of the pulses and delays inside the frame results in the pulse sequence of a gradient CT-HNCO experiment; omitting the gradient pulses as well and including presaturation instead leads to a conventional HNCO experiment [9c]. G_z is a pulsed field gradient along the static magnetic field B_0 of length 2 ms.

We use product operators to describe the back transfer from ^{15}N to ^1H. Operators acting on nitrogen are designated N; those acting on proton spins are designated H. We use H^-, N^-, N^+ for transverse operators and H_z for the longitudinal operator. The "double INEPT" back transfer converts heteronuclear single quantum coherence $2N^-H_z$ or $2N^+H_z$ at the end of t_2 completely into detectable proton coherence H^-. In the first transient of each t_2-increment, the echo $2N^-H_z$ (time A in Fig. 2) → H^- (time B in Fig. 2) is selected by the combination of a gradient pulse of amplitude 10 (in general $|\gamma_H/\gamma_X|$) during the evolution time of nitrogen atoms and a gradient of amplitude 1 acting on protons before acquisition. Note the reverse definition in terms of operators of echo and antiecho due to the negative γ_N/γ_H. The antiecho signal $2N^+H_z$ (time A) → H^- (time B) is detected in the second transient of each t_2-increment by the combination of gradient of strength −10 during the evolution time of nitrogen atoms and a gradient of strength 1 acting on protons before acquisition. Since selection of either $2N^+H_z$ or $2N^-H_z$ is achieved in sensitivity-enhanced sequences by an inversion of the phase ψ of the last 90° (^{15}N) pulse, the inversion of this phase and the change of the relative sign of the gradients have to occur simultaneously if gradients are to be implemented for coherence selection into such sequences. For the conventional detection of H^-, the transfer amplitudes (t_2, t_3) of the two FIDs (which are stored separately) are given in Scheme 1.

First transient (echo): $\exp(-i\Omega_N t_2)\exp(i\Omega_H t_3)$
Second transient (antiecho): $\exp(i\Omega_N t_2)\exp(i\Omega_H t_3)$

Scheme 1. Definition of transfer amplitudes.

By addition and subtraction of the two phase-modulated signals, and subsequent phase correction by 90° of the FID obtained by subtraction, two amplitude-modulated signals are obtained (Scheme 2).

FID 1 (Addition): $\cos(\Omega_N t_2)\exp(i\Omega_H t_3)$
FID 2 (Subtraction and phase-correction by 90° in t_3): $\sin(\Omega_N t_2)\exp(i\Omega_H t_3)$

Scheme 2. The two amplitude-modulated signals obtained from the phase-modulated signals.

Complex Fourier transformation of these signals results in a spectrum with pure phases in ω_2 and ω_3. In Figure 3, traces taken from the first ω_2, ω_3 spectrum ($t_1 = 0$) are shown for a) a conventional (amplitude-modulating) CT-HNCO experiment using gradients for coherence selection in t_2 (Fig. 2, neglecting the part of the pulse sequence inside the frame), b) a conventional CT-HNCO experiment[9c] (cf. legend to Fig. 2), and c) a phase-modulating CT-HNCO experiment using gradients for coherence selection in t_2 (Fig. 2).

Experiments of equal duration were recorded on a complex of uniformyl $^{13}C/^{15}N$ labeled Calmodulin und C20W, a Calmodulin recognition sequence of the plasma membrane calcium pump.[10] We choose experiment (a) as a reference for S/N with a value of $1/\sqrt{2}$ (in accordance with Fig. 1 b). Averaging eleven traces, we calculated a relative S/N of 0.78 for experiment (b) (corresponding to Fig. 1 a) and a relative

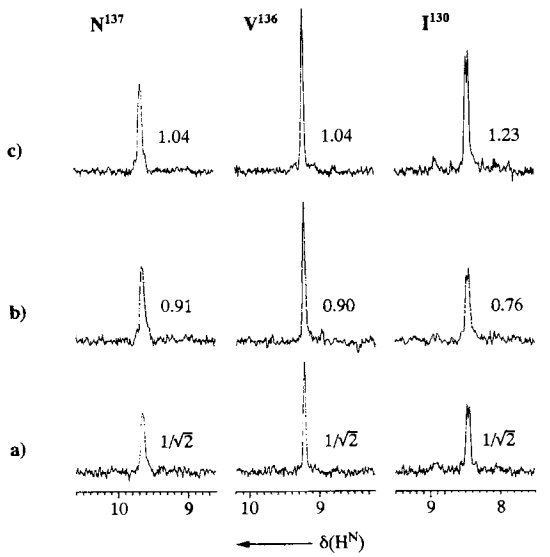

Fig. 3. Traces taken from the first ω_2, ω_3 spectra ($t_1 = 0$). For a)–c) see text. The numbers next to the traces indicate the S/N relative to experiment (a). The measurement time was the same for all experiments.

S/N of 1.11 for experiment (c) (corresponding to Fig. 1c). The enhancement for experiment (b) relative to (a) of 1.11 is smaller than the expected value of $\sqrt{2}$. The theoretical factor is not observed because of a loss of magnetization in experiment (b) due to saturation transfer from the water to the amide protons. In contrast, no presaturation is needed in experiments (a) and (c). The increase of 1.55 in S/N over experiment (a) in experiment (c) does not correspond to the theoretical gain in sensitivity either, since sequence (c) is longer and signal is therefore lost due to relaxation. Nevertheless, (c) is clearly the most sensitive sequence. Compared to the second best sequence b), a reduction of the measuring time of 50% is possible for the same signal-to-noise ratio.

We have introduced B_0-gradients into a phase-modulating three-dimensional triple-resonance NMR sequence and have demonstrated the sensitivity of this method using the sensitivity-enhanced gradient CT-HNCO experiment on a protein/peptide complex as example. Phase-modulating, heteronuclear backtransfer can be implemented in any 3D NMR sequence that detects the H^N resonances. This principle offers optimum sensitivity and at the same time uses gradients most efficiently to suppress artifacts.

Amination of Methane and Ethane by Mercury Photosensitization in the Presence of Ammonia**

By *Demetrius Michos, Caroline A. Sassano, Paul Krajnik,* and *Robert H. Crabtree**

Methods for the direct functionalization of saturated hydrocarbons are actively sought in connection with the problem of natural gas utilization.[1] Methane and ethane have strong C–H bonds (CH_4, 105 kcal mol^{-1}; C_2H_6, 101 kcal mol^{-1}) and are thus particularly difficult to functionalize. Overoxidation is a severe problem, because the initial oxidation products are usually more reactive than the alkanes themselves. We have looked at several alkane functionalization reactions based on mercury photosensitization. Here, the initial products are prevented from reacting further by condensation, as their vapor pressures are lower than those of the reactants.[2] The abstraction of a hydrogen atom from methane or ethane by the excited mercury atom Hg* ($^3P_1$, $d^{10}s^1p^1$, 112 kcal mol^{-1}) is not efficient because of their poor interaction. Recent studies by Soep et al.[3a] show that the Hg($^3P_1$)-NH_3 exciplex [Hg-NH_3]* has a heat of formation of 17 kcal mol^{-1}. In this exciplex NH_3 is bound to the Hg* atom like a ligand in a transition metal complex, except that the presence of three electrons, two from NH_3 and the Hg* s electron, leads to an Hg*–N bond order of 0.5. This strong interaction allows efficient energy transfer from the mercury atom to ammonia resulting in homolytic cleavage of the N–H bond to produce H$^\bullet$ and $NH_2^\bullet$ radicals.[3b] Since the H_2N–H bond strength is 107 kcal mol^{-1}, we thought that the $NH_2^\bullet$ radical should be capable of abstracting an H atom from CH_4 and C_2H_6. We therefore exposed alkane/NH_3 mixtures (mol ratio: 1:1) containing a trace of Hg vapor to UV light ($\lambda = 254$ nm). An oligomeric high-boiling liquid containing C, H, and N resulted, which is still under investigation.

It was clear that activation was taking place, but the initial products, which are more reactive than the starting alkane and still volatile, were reacting further. To avoid this, we devised a simple reactor (Fig. 1) in which the gas mixture is cycled by a peristaltic pump through a photolysis chamber and then into a cold trap (−20 °C) to remove the initial photoproducts. We find that this leads to efficient amination

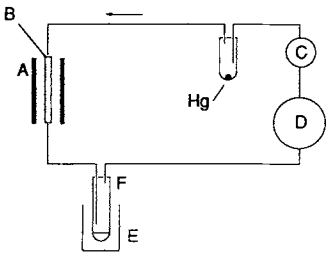

Fig. 1. Schematic representation of the apparatus used for the Hg photosensitization of CH_4 and C_2H_6. A = Hg lamps, B = photolysis chamber, C = peristaltic pump, D = gas reservoir, E = cooling bath, F = trap (see Experimental Procedure for details).

of these alkanes to give the corresponding imines. The products were hydrolyzed to give the corresponding aldehydes, converted into water-insoluble 2,4-dinitrophenylhydrazones, and identified.[4, 5] No amines were detected in the products.[6] These data are consistent with the formulation of the products as RHC=NH (R = H, Me). The proposed sequence of reactions is shown in Equations (a)–(e) for methane.

$$Hg^* + NH_3 \longrightarrow H^{\cdot} + NH_2^{\cdot} + Hg \quad (a)$$

$$CH_4 + NH_2^{\cdot} \longrightarrow CH_3^{\cdot} + NH_3 \quad (b)$$

$$CH_3^{\cdot} + NH_2^{\cdot} \longrightarrow CH_3NH_2 \quad (c)$$

$$CH_3NH_2 + Q^{\cdot} \longrightarrow {}^{\cdot}CH_2NH_2 + QH \quad (d)$$

$${}^{\cdot}CH_2NH_2 + Q^{\cdot} \longrightarrow H_2C{=}NH + QH \quad (e)$$

$MeNH_2$ is not expected as a final product because it is converted to $H_2C{=}NH$ [Eq. (d) and (e)] by Hg photosensitization;[7] $EtNH_2$ should behave similarly. The overall reaction can be expressed by Equation (f). When the gas flow rate is decreased, we see formation of higher molecular weight products, for example, MeHC=NH from CH_4/NH_3. This probably arises according to Equation (g). Hydrogen atoms are known to add to imines at the nitrogen atom.[8]

$$RCH_3 + NH_3 \xrightarrow{h\nu} RHC{=}NH + 2H_2 \quad (f)$$

$$H_2C{=}NH \xrightarrow{H^{\cdot}} {}^{\cdot}CH_2NH_2 \xrightarrow{Me^{\cdot}} MeCH_2NH_2 \longrightarrow MeHC{=}NH \quad (g)$$

Hg photosensitization reactions in the presence of NH_3 are dominated by Hg^*/NH_3 exciplex formation leading to the formation of the $NH_2^{\cdot}$ radical, a powerful $H^{\cdot}$ abstractor capable of functionalizing CH_4 and C_2H_6. These experiments show that functionalization and oligomerization of methane is possible if the initially formed products are prevented from reacting further.

Experimental Procedure

The apparatus (Fig. 1) consisted of a Rayonet photoreactor with 16 8-W low-pressure Hg lamps (254 nm). The surface of the cylindrical quartz photolysis vessel exposed to light had an area of 210 cm^2. The cooling bath was maintained at −20 °C and the peristaltic pump (Rainin, Rabbit-plus) at a circulation rate of 2.4 $mL\,s^{-1}$. The gas reservoir had a volume of 5.5 L. The gas mixture was saturated with Hg vapor by passing it over Hg before it entered the photolysis chamber. The pressure of the closed circulating system was periodically checked and adjusted to 1 atm by introducing an alkane/NH_3 mixture (1:1).

Analysis: Amines were detected with $NaBPh_4$ at pH = 2–3. The precipitated NH_4BPh_4 does not interfere with the ^1H NMR spectroscopic analysis (in C_5D_5N) of the precipitate, which did not show signals for alkyl groups. The 2,4-dinitrophenylhydrazones were prepared by acidifing the reaction product to pH = 3–4 and adding a 2 N HCl solution of 2,4-dinitrophenylhydrazine. The yellow precipitate was stirred for approximately 15 h, filtered, and washed (2 × 5 mL) with water. In a typical run (120 h, 2.4 $mL\,s^{-1}$ flow rate) 0.7 g of the corresponding pure hydrazone was isolated. A quantum yield of 0.04 was observed relative to Et_3SiH ($\Phi = 0.8$) [2a].

A New Type of Paratungstate**

By *Hans Hartl,* Rosemarie Palm,* and *Joachim Fuchs*

Whether hexatungstate anions exist in acidified tungstate solutions has been disputed for the last 65 years;[1] up to now a salt containing such an anion, $[HW_6O_{21}]^{5-}$ or $[H_3W_6O_{22}]^{5-}$, has not been isolated.

By following the increasing acidification of an alkali metal tungstate solution through physical measurements (such as potentiometry, conductometry),[2] a distinct jump in the course of the curve is observed after the addition of about 1.15 H^+/WO_4^{2-} ($7H^+/6WO_4^{2-}$ or $8H^+/7WO_4^{2-}$), which is labeled the paratungstate step. Molar mass determinations conducted by various methods[2] indicate that hexameric anions could be present in the paratungstate solutions; however, in all of these techniques, which are performed at equilibrium, only an average molar mass or particle count can be

[*] Prof. Dr. H. Hartl, R. Palm, Prof. Dr. J. Fuchs

[**] This work was supported by the Fonds der Chemischen Industrie.

determined. The crystallization of salts from such solutions is extremely difficult, because transformation reactions are continuously taking place. From aged solutions in which the transitions are complete or the equilibrium state has been reached, the isolation of crystals is easy. These crystals contain the dodecameric anion $[H_2W_{12}O_{42}]^{10-}$, whose structure has been known for some time.[3]

Until now, crystalline solids could be obtained from freshly acidified solutions only (paratungstate A solutions) by the precipitation with acetone and the application of appropriate organic cations. However, as shown by the X-ray crystal structure determinations of piperidinium tungstate $(C_5H_{10}NH_2)_6[W_7O_{24}]$[4] and sodium tungstate $Na_6[W_7O_{24}]\cdot 14H_2O$,[5] the heptatungstate is isolated, not the hexatungstate. The results of Raman spectroscopic studies[4] as well as ^{17}O and ^{183}W NMR measurements[6] indicate that $[W_7O_{24}]^{6-}$ is the dominating species in paratungstate A solutions. Based on the chemical reaction behavior of the solution with aging (e.g. reaction with H_2O_2[7]) and pure mechanistic considerations, it must be

$Na_5[H_3W_6O_{22}]\cdot 18\,H_2O$ **1**

assumed, as already discussed earlier,[4] that besides $[W_7O_{24}]^{6-}$ and $[H_2W_{12}O_{42}]^{10-}$ additional intermediates are formed. The anion of the sodium salt **1** may represent such an intermediate product. This compound was obtained through the reaction of $Na_2WO_4\cdot 2H_2O$ and $WO_3\cdot H_2O$ in a hydrolysis autoclave as well as at room temperature from weakly alkaline solutions. Decisive for the formation of **1** is a high tungstate concentration and the addition of only 1/8 the stoichiometric amount of $WO_3\cdot H_2O$ necessary for the theoretical equation of formation (a) (see Experimental Procedure). From the IR and Raman spectra, it is immediately

$$5\,Na_2WO_4 + 7\,WO_3 + 3\,H_2O \longrightarrow 2\,Na_5[H_3W_6O_{22}] \qquad (a)$$

recognizable that the complex generated is an unprecedented polytungstate compound. The IR spectrum of **1**, in particular, clearly differs from that of the heptatungstate (Fig. 1), although, as found in the X-ray crystal structure analysis, the anion $[H_3W_6O_{22}]^{5-}$ is a structural fragment of the heptatungstate anion (Fig. 2).

The occurrence of this particular structural unit in **1** is very interesting, because it contains two WO_6 octahedra with free octahedra faces (i.e. with three terminal oxygen atoms in *fac* configuration). Previously, it was assumed that polymetallates containing MO_6 octahedra with more than two neighboring terminal oxygen atoms ("free octahedra edges") were not stable.[9, 10] After the molybdate ions $[Mo_8O_{26}(OH)_2]^{6-}$[11] and $[Mo_{36}O_{112}(H_2O)_{16}]^{8-}$,[12] **1** represents a further example of a polymetallate structure in which the MO_6 octahedra have "free octahedra faces", however, always in "protonated" form because here the protons of the anion are coordinated to the oxygen atoms of the free octahedra faces. Only *one* significantly lengthened distance between tungsten and a terminal oxygen atom occurs (187 pm versus an average value of 176 pm); however the results of valence sum calculations[13] with respect to the Na^+ coordination by the terminal oxygen atoms suggest that a second proton is bound to the oxygen atom of the other free octahedra face. The probable positions are marked with arrows in Figure 2. The valence sums for the terminal oxygen atoms amount to 1.12 and 1.49 as compared with the expected value of 2. The position of the third proton remains in question. The sodium ions are surrounded in an octahedral environment by water molecules and oxygen atoms of the anion.

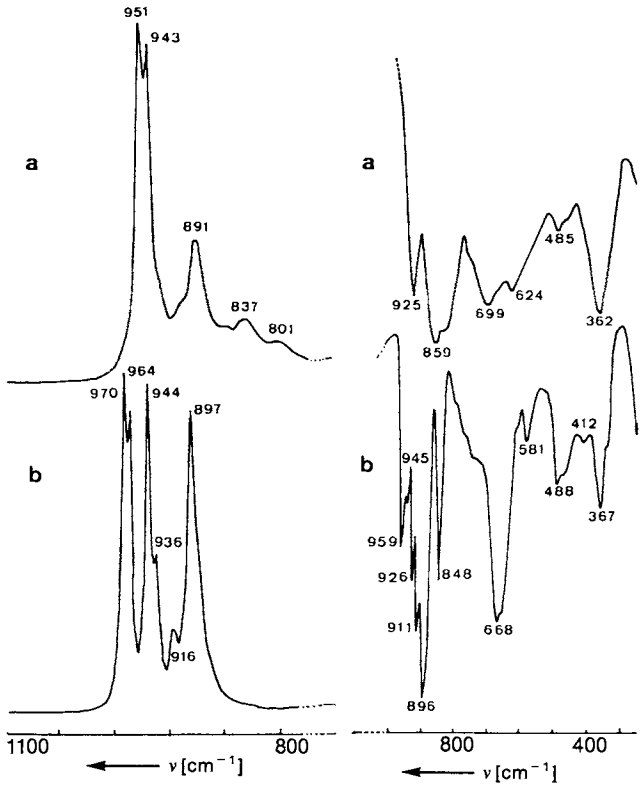

Fig. 1. IR and Raman spectra of $Na_5[H_3W_6O_{22}]\cdot 18H_2O$ **1** (a) and $Na_6[W_7O_{24}]\cdot 21H_2O$ (b) in the region for the W–O vibrational bands. Left: Raman, right: IR spectrum.

Through the construction of $Na(H_2O)_6$, $Na(H_2O)_5O$, $Na(H_2O)_4O_2$, and $Na(H_2O)_3O_3$ octahedra, the polytungstate anions of **1** are interconnected within the crystal lattice. Four of the water molecules do not have any contact to Na^+ ions, however, they do apparently interact, as evidenced by short distances, through strong hydrogen bonding with other water molecules or oxygen atoms.

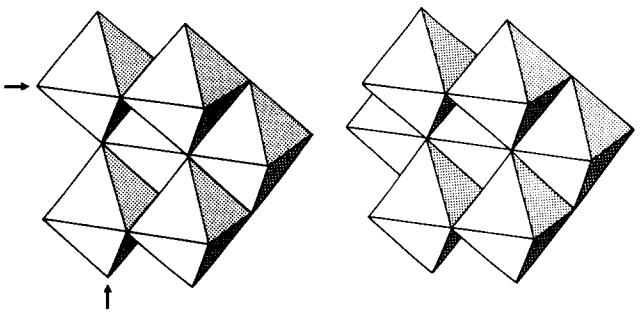

Fig. 2. Polyhedral representation of the structures of $[H_3W_6O_{22}]^{5-}$ (left) and $[W_7O_{24}]^{6-}$ (right). W–O bond lengths [pm] of **1**: W–O (terminal) 171–187, average value 176; W–μ_2O 177–227, average value 198; W–μ_3O 190–227, average value 212; W–μ_4O 214–228, average value 219; standard deviation ±3 pm.

The question of whether the anion of **1** is a precursor in the formation of $[W_7O_{24}]^{6-}$ or a hydrolysis product of the latter, still remains to be answered. Most likely both are true and in aqueous solution an equilibrium exists between the two species, which, however, as already implied, is shifted towards the side of the heptatungstate. Tytko and Glemser have compiled 18 possible geometric forms, derived from WO_6 octahedra, for hexatungstate ions and have developed probability

criteria for their existence.[14] In addition they have discussed conceivable formation mechanisms for hexatungstates and the heptatungstate ion.[15]

Experimental Procedure

$Na_2WO_4 \cdot 2H_2O$ (45 g) was stirred with $WO_3 \cdot H_2O$ (5 g) in water (50 mL) at 20 °C under argon in a closed Cautex vessel. After about 30 min, the WO_3 was completely dissolved; shortly thereafter a colorless precipitate formed, which was then filtered off. Acetone was carefully added to the filtrate until turbidity was first noted. After about 15 min the hexatungstate crystallized. The use of glass vessels should be strictly avoided because otherwise tungsten silicates are easily formed. Compound **1** cannot be recrystallized from water, but rather only from the alkaline mother liquor, in which, however, it is not indefinitely stable. On standing for some time, it was converted into a compound with the composition $Na_2W_2O_7 \cdot 4H_2O$.

The compound was originally isolated in a hydrolysis autoclave (pressure hydrolysis system II, Berghof). $WO_3 \cdot H_2O$ (0.7 g) was added to $Na_2WO_4 \cdot 2H_2O$ (1 M, 10 mL) in a PTFE insert (50 mL) and diluted with H_2O (ca. 12 mL). The mixture was heated at 150–180 °C for 24–48 h. The product mixture was subsequently worked up as described above. The yield in both cases was very low.

β-Na_3Hg: A Solid with a Quasi-Fluid Sodium Substructure between 36 and 60 °C

By *Hans-Jörg Deiseroth** and *Matthias Rochnia*

Na_3Hg is the outermost compound on the sodium-rich side of the binary sodium–mercury phase diagram. It is dimorphic, with an α form below 36 °C (modified Na_3As type, single-crystal structure investigation at room temperature[11]) and a β form between 36 and 60 °C (modified Li_3Bi type, powder data[1, 2]). We here report on temperature-dependent single-crystal studies of β-Na_3Hg. These studies not only clarify the hitherto puzzling deviation of the compound's true structure from the ideal Li_3Bi type. In combination with heat capacity measurements they also yield the surprising result that the sodium sublattice must be regarded as a "quasi fluid" in the temperature range between 36 and 60 °C, that is, across the full stability range of the solid β phase. β-Na_3Hg forms from α-Na_3Hg in a reversible (first-order) phase transition ($\Delta H_u = +0.3(1)$ kJ mol^{-1} based on a composition of $Na_{0.75}Hg_{0.25}$), accompanied by about 10% decrease in molar volume (α-Na_3Hg: 75.6 cm^3 mol^{-1} at 34 °C, β-Na_3Hg: 68.1 cm^3 mol^{-1} at 42 °C) and is the thermodynamically stable modification up to the melting point. On the mercury-rich side of the phase diagram, the β form is in equilibrium with solid Na_8Hg_3 (= $Na_{2.67}Hg$);[3] on the sodium-rich side it is in equilibrium with the melt. The conditions under which single crystals of β-Na_3Hg can be obtained have been described.[4] Here we note that with due care while lowering the temperature, crystals once formed can be kept in a metastable state down to a temperature of 16 °C below the phase transition temperature $T_u = 36$ °C (hysteresis). Only at even lower temperatures do we find changes in the X-ray patterns indicating retransformation.

The crystallographic data[5] show β-Na_3Hg to be a variant of the Li_3Bi type structure. The mercury atoms form a capacious cubic close-packed structure (slightly distorted towards rhombohedral symmetry) in which sodium atoms fill the octahedral and tetrahedral voids ($d_{Hg-Hg} \approx 5.5$ Å). The rhombohedral distortion of the cubic unit cell of the Li_3Bi type can also be unequivocally derived from Guinier diffractograms and increases the c/a ratio to 2.483 (42 °C, ideal value $c/a = 2.449$). Though this description apparently implies an ionic character for the compound, β-Na_3Hg is a solid with a silver metallic luster and metallic conductivity, as evidenced by preliminary conductivity measurements on pressed powders. Considering the geometrical conditions, we find that actually only the tetrahedral voids should be ideally suited to accommodate the sodium atoms Na2 ($d_{Na-Hg} = 3.3$ Å). From the incorporation of sodium atoms Na1 into the center of the octahedral voids, however, unacceptably long interatomic Na–Hg distances of 3.9 Å ensue. This observation is, in fact, essential for understanding the anomalies of the sodium substructure, as discussed in the following.

The temperature-dependent single-crystal studies clearly show the sodium atoms, especially those in the octahedral interstices, to undergo an increasingly statistical distribution with increasing temperature (Fig. 1b–1d).

At + 20 °C, substantial electron density can be detected inside the octahedral interstice. There it decreases strongly with increasing temperature and delocalizes ("smears") into the periphery. Attempts to simulate it by partially occupied split positions (Na1a–Na1d in ref. [5]) during the refinement cycles remain unsatisfactory. Concurrently, the electron density corresponding to the sodium atoms in the tetrahedral interstices also becomes delocalized, but to a much lesser degree. This is expressed in increased Debye–Waller temperature coefficients. The X-ray data, along with the split positions, only hint at possible diffusion paths through the lattice or at preferred locations of the sodium atoms. One can see, however, that the maxima of the electron density concentrate primarily in the periphery of the octahedral voids with distinct components towards the centers of the adjacent tetrahedral voids and vice versa. This effect is enhanced by increasing the temperature.

These structural features correlate directly with the specific heat capacity (c_p) curve in the stability range of the β-Na_3Hg phase (Fig. 2), which indicates melting of a sublattice below the melting point proper of the compound.

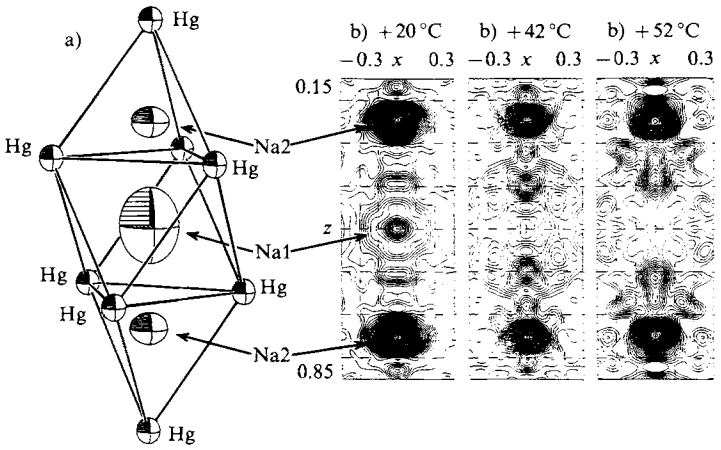

Fig. 1. a) ORTEP plot of a characteristic motif from the rhombohedral crystal structure of β-Na_3Hg. An octahedral interstice, occupied by a sodium atom Na1, and two adjacent face-sharing tetrahedral interstices along [001], occupied by sodium atoms Na2, are shown. b–d) Fourier sections $\rho(x\,0\,z)$ through a motif analogous to a), but without the mercury atoms, for different temperatures. Electronic density contours in steps of 2 e Å^{-3}. Note the obvious delocalization in the area of the octahedral interstice increases with temperature.

From the foregoing discussion, the mobility of the sodium atoms in a structure analogous to a Li_3Bi type seems inconceiveable at first, because in such a structure all octahedral and tetrahedral interstices are fully occupied. Therefore vacancies should only be available in small concentrations, depending on the thermal vacancy equilibrium. In this respect, one of our earlier observations is noteworthy.[1] Well-grown β-Na_3Hg crystals can only be obtained from samples slightly but significantly substoichiometric in sodium with composition $Na_{8.5}Hg_3$ (= $Na_{2.85}Hg$), rather than with the ideal composition of Na_9Hg_3. A corresponding sodium deficiency, and consequently a proportion of approximately 5% unoccupied sodium positions, must thus be assumed in the solid-state structure. This gives a plausible explanation of the mobility of the sodium atoms and makes the formula chosen as Na_3Hg for the title compound but a limiting, sodium-rich composition resulting from the associated structure type.

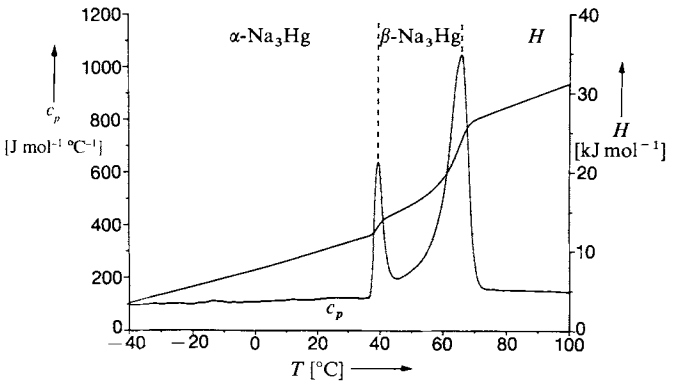

Fig. 2. Specific heat capacity c_p as a function of temperature T for β-Na_3Hg (H: total enthalpy, heating rate = 7 °C min^{-1}, sample mass 19.2 mg). The c_p curve does not return to its initial base line after the α/β phase transition.

For obvious reasons, in the present case the exact composition of the investigated crystals (with respect to sodium) cannot be determined from the X-ray occupation factors. For the 6c site (Na2, tetrahedral void), full occupation is found within experimental error, provided that the mercury positions are also fully occupied. The occupation factor for the 3b site (Na1, octahedral void), as well as the partial occupation factors for the split positions (Na1a–Na1d) introduced to simulate the delocalized electron density, however, converge during refinement at physically meaningless values, due to strong correlations.

[4] Sample preparation: from preliminary experiments with samples of different net composition we found that single-crystals of β-Na_3Hg (silver metallic luster, tetrahedral habit, $\varnothing \approx 0.25$ mm, air sensitive) suitable for X-ray analysis can be obtained as follows: samples with a net composition of $Na_{2.85}Hg$ are annealed at $T = 50$ °C for 30 days and then quenched in a mixture of dry-ice/methanol. The regulus is crushed under an inert atmosphere in an agate mortar, and the crystals picked under the microscope are wedged into X-ray capillaries. From samples with a composition of Na_xHg ($x < 2.85$), Na_8Hg_3 precipitates besides β-Na_3Hg. Samples richer in sodium produce β-Na_3Hg crystals surrounded by melt.
[5] Crystal data for β-Na_3Hg: space group $R\bar{3}m$ (no.166), $Z = 3$, $a = 5.404(1)$, $c = 13.420(4)$ Å, $\mu = 340.7$ cm^{-1}, (rhombohedral cell: $a = 5.454(1)$ Å, $\alpha = 59.4°$), CAD4 diffractometer, $T = 42$ °C, $Mo_{K\alpha}$ radiation, $2\theta_{max} = 80°$, crystal size: $0.21 \times 0.18 \times 0.25$ mm^{-3}, 287 unique reflections observed, of which 154 with $I > 2.5\sigma(I)$. $R_{aniso} = 0.055$ (reflections with $I > 2.5\sigma(I)$, $R' = 0.089$ (all reflections); empirical absorption correction: Ψ-scan; maximum/minimum residual electron density: ± 1.5 e Å^{-3}. Atomic positions (with respect to the hexagonal setting in $R\bar{3}m$): Na1(3b): 0, 0, 0.5, ideal central position in the octahedral void. Split positions (see text): Na1a(6c): 0, 0, 0.401; Na1b(18h): 0.032, −0.032, 0.071; Na1c(18h): 0.425, 0.575, 0.145; Na1d(18h): 0.103, −0.103, 0.059; Na2(6c): 0, 0, 0.245, ideal central position in the tetrahedral void would be $z = 1/4$ instead of 0.245; Hg(3a): 0, 0, 0. The program system NRCVAX [6] was used for all structure calculations. Tetranuclear Silver(I) Clusters Linked by Bridging Succinate Anions in a Three-Dimensional Network: Crystal Structure of Succinatodisilver(I)

By *Adonis Michaelides,* Vangelis Kiritsis, Stavroula Skoulika,* and *Andre Aubry*

In the design of new solids, weak intermolecular interactions are usually taken into account in order to engineer the desired crystal structure.[1–2] The use of metal cations to link organic molecules is an alternative method for the design of new structures. Some authors have indeed obtained two-dimensional solids,[3–4] as well as porous solids,[5–7] by combining the strongly directional coordination bonds around the metal with an appropriate multifunctional ligand (coordination polymers). In our program of crystal engineering, we plan to study the formation of coordination polymers of silver(I) with various polycarboxylato ligands. Silver (I) principally exhibits linear, trigonal, and tetrahedral coor-

dination,[8] and frequently forms polynuclear complexes (molecular or polymeric) with carboxylic acids.[9] To get initial information about the possible structural patterns in systems with complex polycarboxylato ligands, we studied complexes of silver(I) with α,ω-dicarboxylic acids. Herein we report the highly unusual crystal structure of succinatodisilver(I) **1**.[10]

Single crystals of $[Ag_2\{OOC\text{-}(CH_2)_2\text{-}COO\}]_\infty$ suitable for X-ray crystallography are formed at room temperature by slow diffusion of a solution of Ag^+ ions into a silica gel medium containing succinate anions.[11-13]

X-ray analysis[14] shows that the structure of **1** consists of planar tetranuclear silver clusters (Fig. 1) strictly parallel to the *ac* plane and bridged by succinate anions (Fig. 2). In the direction perpendicular to the *ac* plane (*b* axis), the clusters form helicoidal sequences around quasi 4_1 axes (exact 2_1).[15] All ligands lie on crystallographic inversion centers. The oligomer, represented by the Ag_4 cluster with its four succinate anions, exhibits pseudo-S_4 symmetry and is linked through its four ligands to four neighboring clusters. If we consider only the centers of the clusters that are bridged by the ligands, then we obtain an infinite structure formed by three interpenetrating, distorted diamandoid frameworks (Fig. 3).[16] Between these frameworks there are no bonds. The shortest intercluster Ag–Ag distance is 3.67 Å, too long for any metal–metal interaction (3.40 Å is the van der Waals contact distance). As far as we know, this is the first example of a three-dimensional coordination polymer containing metal clusters and might constitute a link between purely inorganic solids on the one hand, and extended cation aggregates and molecular clusters on the other.

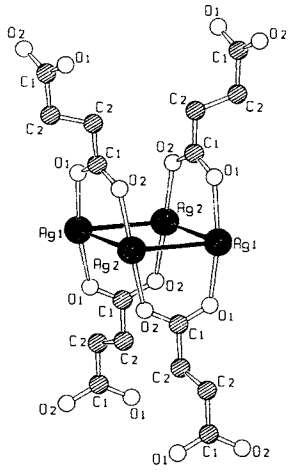

Fig. 1. SCHAKAL[21] view of the cluster and surrounding ligands. Selected distances [Å] and angles [°] are: Ag1–O1 2.211(4), Ag2–O2 2.174(4), Ag1-Ag2 2.938(1), Ag2-Ag2 3.104(1); O1-Ag1-O1 169.1(1), O2-Ag2-O2 177.6(1), Ag2-Ag1-Ag2 63.8(1), Ag1-Ag2-Ag1 116.2(1).

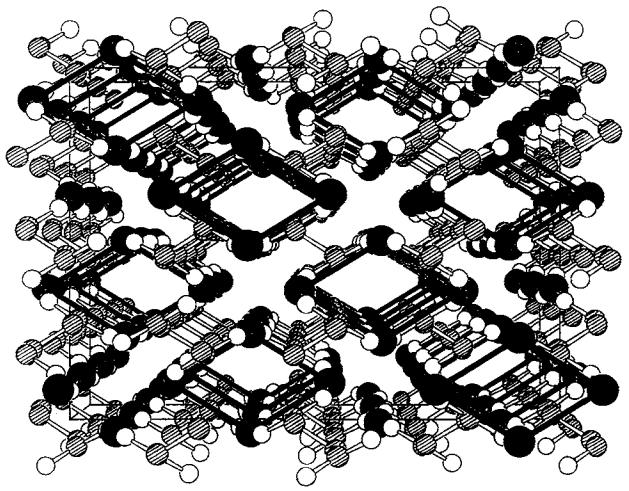

Fig. 2. SCHAKAL perspective view of the polymer **1** down the *b* axis.

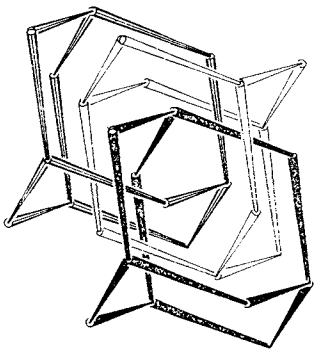

Fig. 3. SCHAKAL view of the three interpenetrating distorted diamandoid networks. The intersections represent the centers of the Ag_4 clusters while the interconnecting rods symbolize the succinate anions.

Each cluster is a Ag_4 rhombus with sides of 2.938(1) Å, interior angles of 63.8(1)° and 116.2(1)° and shortest diagonal of 3.104(1) Å (Fig. 1). These distances are within the range of weak bonding interactions.[17] The center of the rhombus is located on a *222* site, and half of these sites in the unit cell are "occupied" by clusters. The silver cations are held together by bridging carboxylato ligands that are approximately perpendicular to the Ag_4 plane; adjacent carboxylato ligands are on opposite sides of the plane. This is the first example of such unusual arrangement of carboxylato ligands around a Ag_4 cluster.[18] The coordination of silver is quasi linear ($\sphericalangle = O_1\text{-}Ag_1\text{-}O_1 = 169.1(1)°$ and $O_2\text{-}Ag_2\text{-}O_2 = 177.6(1)°$) and the Ag–O distances ($Ag_1\text{–}O_1 = 2.211(4)$ Å and $Ag_2\text{–}O_2 = 2.174(4)$ Å)[4] are similar to previously reported values.[19]

It would be interesting to see if other polyfunctional ligands can lead to similar structures. We wonder, for instance, if it is possible to reduce the intercluster distances, thus forming organometallic compounds with extended cation aggregates as in purely inorganic solids. Work in this direction is in progress.[20]

Experimental procedure

A sodium silicate solution ($\varrho = 1.1$) was slowly added to an aqueous solution of succinic acid (10 mL, 0.1 M) until the pH reached 5.6. The resulting gelling solution was poured into a test tube and was allowed to stand for about 24 h. Then, an aqueous solution of $AgNO_3$ (10 mL, 0.1 M) was carefully added at the top of the gel. Pale yellow prismatic crystals elongated along the *c* axis formed within 2 days.

BOOKS

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the Book Editor, Dr. Gerhard Karger, Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

Book Reviews

Human Protein Data. 1st Instalment. Edited by *A. Haeberli*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York, 1992. XLV, 424 pp., looseleaf collection DM 275.00, subscription price DM 225.00.—ISBN 3-527-28211-4/1-56081-110-2

To begin compiling a collection of data on human proteins probably strikes most of us as an unending task, comparable with the rapidly growing data banks of protein sequences. It is, therefore, all the more pleasing that three years ago A. Haeberli had the courage to make a start on this, and especially that he had the good sense to delegate much of the work, in which so far 167 authors have covered 147 proteins. Anyone who sees gaps in this and feels a duty to contribute is likely to be enthusiastically recruited by the editor to join in. Thus one can envisage that the necessary continuation and updating of this looseleaf collection, which the publishers plan to extend by about 70 more proteins per year, will proceed successfully. The 147 proteins in this first instalment are mainly plasma proteins, together with a number of protein hormones and protein factors. The descriptions are concise, comprehensible to the general user and not too specialized, and contain quite enough information for a first source. Relevant literature references enable one to go into more detail.

The same clear layout is used for each protein, listing synonyms, abbreviations, classification, e.g. according to EC number or from serum electrophoresis, short description, structural features, molecular mass, sedimentation constant, isoelectric point, extinction coefficient, enzymic activity, coenzymes/cofactors, substrates, inhibitors, biological function, physiological and pathological role, breakdown behavior, genetics and mutants, biological half-life, concentration and isolation procedures, sequence, and disulfide or SH groups. In many cases the structure is illustrated at the end by a clear schematic diagram, or by three-dimensional diagrams and ribbon models where these are known. The above list is, of course, very comprehensive, and it is not surprising that in many cases not every item of information has yet been included. However, this does not indicate that the searching has been inadequate but rather that an effort has been made to present the very latest knowledge. In view of the brevity of the ID codes of proteins as given in sequence data banks, it would not have been a bad idea to include cross-references to, for example, PIR, SWISSPROT, or the protein structure data bank.

The question arises: why a growing file for our bookshelves rather than a data bank for interrogating through the VDU screen? Ten years from now the answer to this question is likely to be different. At present the proportion of biochemists and medical scientists who can gain access to a central external data bank through a computer terminal near their desk, or who wish to learn how to do so, is probably less than 10%. However, for the VDU enthusiasts among them a diskette is included in the package.

In 1990 the Gesellschaft für Biotechnologische Forschung (GBF) in Braunschweig issued an "Enzyme Handbook" consisting of five A5-size files, listing enzymes according to their EC numbers. Although the GBF files and the "Human Protein Data" collection reviewed here appear to have similar aims, they are somewhat different in style. Neither makes the other redundant: to begin with, the "Enzyme Handbook" sets out to cover all the known sources for each enzyme. It is desirable that the different approaches should be maintained, so that the two works will complement rather than duplicate each other.

The "Human Protein Data" collection will become increasingly important as the human genome project gets under way. It is only by combining information on the many possible human DNA sequences with a data bank on gene products that advances in practically useful knowledge can be achieved.

Organic Peroxides. Edited by *W. Ando*. Wiley, Chichester, 1992. XVI, 845 pp., hardcover £ 140.00.—ISBN 0-471-93438-0

Qinghaosu is a naturally occuring tetracyclic peroxide with high anti-malarial activity, and is extracted from *Artemisia annua*, a plant that is widely distributed in China. An unusual structure might be expected to be associated with unusual properties, and this is confirmed for many peroxides. This class of compounds has been much studied by chemists since the end of the nineteenth century. In recent decades research activity has further intensified, because peroxides are in many cases ideal reagents for the synthesis of oxyfunctionalized compounds, they play an essential role in the metabolization of chemicals by organisms, and reactive peroxides often undergo thermal or photochemical breakdown through unusual pathways. These different aspects of the subject are drawn together in this excellent book.

The editor, W. Ando, has succeeded in recruiting expert authors for all the chapters, and thereby presenting an overview of this important area of chemistry which is thoroughly up-to-date (including many literature citations from the last five years). Synthetic routes to the above mentioned compound qinghaosu alone are described in five chapters. However, the overall layout of the book is unimaginative. Thus, the first ten chapters deal with different compound classes, and only in the last five chapters is the subject matter arranged according to oxidation pathways. Consequently, although finding an answer to a question of detail should be relatively quick and straightforward, there has evidently been no attempt to unite the topics in a way that could also introduce non-specialists to the field.

In the first hundred pages Yamaguchi and co-authors give an excellent overview of theoretical aspects of organic peroxides. Modern views concerning the Sharpless epoxidation are discussed, as also are the studies by Bernardi on the addition of singlet oxygen to ethylene and by Robb on the breakdown of 1,2-dioxetanes (1990, 1991). The chapters on alkyl hydroperoxides (Ch. 2, Porter), dialkyl peroxides (Ch. 3, Matsugo and Saito), diacyl peroxides (Ch. 7, Fujimori), sulfur and phosphorus peroxides (Ch. 8, Kim), and peroxyacids and peroxyesters (Ch. 9, Sawaki) are well worth reading and of appropriate length, and give particular attention to the uses of these compounds in synthesis. In cases where chapter subjects have not been clearly defined beforehand, overlapping always results. Thus, under the heading of dialkyl hydroperoxides we find that many endoperoxides and their reactions are treated, then these appear again in the chapter with this title (Ch. 6, Clennan and Foote). Of special interest here are the important studies by Jefford on the synthesis of 1,2,4-trioxanes and by Hayes on copper(II)- and iron(III)-catalyzed cyclizations of alkyl hydroperoxides (both of which are also relevant to the synthesis of qinghaosu and its analogues). Dioxiranes and dioxetanes are treated very briefly in Chapters 4 and 5 (Adam et al.). Here one is relieved to find that the authors have avoided giving an encyclopedic list of all the available data on reactions of dioxiranes and properties of dioxetanes, which would be enough to fill another book. Dioxirane chemistry is undergoing a near-explosive phase of development, as is apparent from the bibliography, in which half the papers cited are for the period 1989–1992. In contrast, dioxetane chemistry is relatively quiet, although some interesting transformations of these highly reactive peroxides have recently been discovered. Polyoxides, a class of compounds that chemists tend to group under "exotica", are described by Plesničar in Chapter 10. The author gives a nice explanation of how these compounds have gradually emerged from being regarded as merely unstable intermediates or models for theoretical studies, and are now even used in synthesis. One of special interest is triethylsilylhydrotrioxide (Corey, Posner), which can be used as a source of singlet oxygen, or for the direct (per)oxyfunctionalization of carbon–carbon double bonds or thioethers.

Chapters 11–14 are concerned with four methods for the synthesis of peroxides. Modena et al. report on the current state of metal-catalyzed oxidation reactions. However, there is no mention of biochemical processes, and only a very inadequate treatment of applications of the Sharpless and Kagan methods to enantioselective oxidations, *cis*-hydroxylations, and the oxidation of thioethers. The photosensitized oxygenation of heteroatoms (Ch. 12, Akasaka and Ando), the ozonolysis method (Ch. 13, McCullogh and Nojima), and reactions using superoxides (Ch. 14, Nagano et al.) yield peroxides with a great variety of structures, and these methods are therefore treated very thoroughly. But here, if not earlier in the book, one notes with annoyance that there is no chapter on the synthesis of peroxides by reactions using singlet oxygen. Whereas a separate chapter is devoted to heteroatom photooxidation reactions (which are the editor's specialty), photooxidations of alkenes, alkynes, dienes, etc. are only mentioned under the corresponding compound classes, inevitably resulting in incomplete coverage. There are, of course, alternative publications such as the (now rather outdated) book by Murray (1979), or the CRC collection by Frimer (1985), but this remains a shortcoming in the present work. Lastly, with the aim of making a link with biology, a brief discussion of peroxides in biological systems has been added (Ch. 15, Niki).

Overall this is a very useful collection of articles on the current state of peroxide chemistry, and despite a few gaps in the coverage it deserves to reach a wide readership. Additional points in its favor are the high standard of production and the consistent quality of the figures.

Writing Reaction Mechanisms in Organic Chemistry. By *A. Miller*. Academic Press, New York, 1992. X, 488 pp., hardcover (spiral binding) $ 34.95.—ISBN 0-12-496711-6

The title accurately describes what this book is about: writing equations that represent the "correct" (i.e. most plausible) reaction mechanisms. It is intended mainly for students beginning their first course in organic chemistry; some parts of the chapters on free radicals and pericyclic reactions will also be of interest to more advanced students.

It cannot be used as a substitute for a conventional textbook, but it includes many explanations and useful hints that make it much more than just a collection of exercises. The author summarizes in a lucid and understandable form the important principles of organic chemistry that must be observed in writing reaction mechanisms. In doing so she deals in detail with possible misunderstandings and logical errors, and discusses examples of unclear mechanistic equations picked out from the literature.

The book consists of seven chapters, each containing many exercise problems in which one is given the structures of the starting materials and products and the reaction conditions and has to derive a probable reaction mechanism. The solutions to these problems are discussed in considerable detail, sometimes in the main text and sometimes at the end of the chapter.

In the first chapter the author discusses some fundamental principles such as Lewis structures, formal charges, hybridization, charge distributions, and aromaticity. Terms such as resonance, equilibrium, tautomerism, basicity, acidity, nucleophilicity, and electrophilicity are clearly defined and discussed with the help of examples. A comprehensive table of pK_a values is included, and much use is made of these data in solving the problems in this chapter, and also in setting those of the following chapters. However, throughout the book the reader is hindered by the lack of definitions and examples to distinguish between kinetic and thermodynamic control of product formation.

The second chapter explains some further basic concepts related to chemical reactions, and discusses the stoichiometry of atoms and charges, and the use of curved arrows to indicate a redistribution of electrons (e.g., in nucleophilic attack). A method is also suggested whereby, on comparing the structures of the starting material and the product, one can most easily identify the bonds that are broken and those that are newly formed.

The next chapter is concerned with nucleophilic substitutions and additions, and with base-induced eliminations and rearrangements. These are again illustrated by a wealth of well chosen example problems. However, Exercise 3–18 raises doubts: here a Favorskii rearrangement is explained in terms of a bicyclobutanone intermediate (alternative: semibenzilic acid rearrangement).

Chapter 4 continues by discussing reactions that proceed via intermediates with electron-deficient carbon atoms or related species. These include rearrangements of carbenium ions, electrophilic additions, acid-catalyzed reactions of carbonyl compounds, electrophilic aromatic substitutions, and reactions of carbenes, nitrenes, and nitrenium ions. Here and in the following chapter the word regiospecificity is often used when what is meant is regioselectivity. Also it seems doubtful whether simple *primary* carbenium ions are formed from the reaction of alcohols with common acids (p. 213).

Chapter 5 deals with reactions that proceed via free radical intermediates. The main emphasis is on radical chain processes, but fragmentations and rearrangements of radicals are also touched on, as also are the $S_{RN}1$ reaction and the Birch reduction.

Chapter 6 is concerned with pericyclic reactions. First the author discusses the shapes of molecular orbitals from a qualitative standpoint, before going on to the question of allowed and forbidden reaction pathways and its solution, either in terms of the sum of the $[4q + 2]_s$ and $[4r]_a$ components or by considerations of frontier orbitals. In this connection electrocyclic and sigmatropic reactions, cycloadditions, and the ene reaction are all treated in detail. The many clearly understandable example problems are treated without reference to the concepts of retention and inversion in sigmatropic shifts that are usually employed; in the case of 1,3-dipolar cycloadditions the author avoids introducing the 1,3-dipolar resonance form. The statement on page 392 that thermal $[{}_\pi 2_s + {}_\pi 2_a]$-cycloadditions cannot be concerted reactions on geometrical grounds conflicts with textbook reactions of ketenes. One might also question the assumption of a concerted [1,5] hydrogen shift in the problem on the *trans* isomer of 2,4-pentadienylbenzene (Exercise 6–15a).

The last chapter contains an assortment of slightly more difficult exercises. In a few cases here (as also in the preceding chapter) the stereochemistry of the starting material and/or the product is ignored, perhaps to simplify the problem.

The book has been produced in a spiral binding which turns out to be surprisingly durable. It is written in an easily understandable style, and should present no difficulties even for students whose first language is not English. The reaction mechanisms are shown by formula diagrams that are clear, though somewhat too large, with the result that a single example can extend over several pages. The reaction equations seldom indicate yields, an omission that is not entirely made up for by the many literature citations. Printing errors are few, but unfortunately these usually occur in the formula diagrams where they can lead to some confusion: for example, students will have a hard time with Exercise 7–4 as the structural formula given for the product is wrong.

Despite a few minor shortcomings the book can be recommended for students as an accompaniment to a standard textbook. By reading it they will learn about many factors to be considered in assessing the plausibility of reaction mechanisms, and will be encouraged to search systematically for a likely reaction path, even for rather more complex reactions. For teachers too the book not only provides a collection of problems for seminars and examinations, but also identifies some misunderstandings and difficulties that students often encounter in the treatment of reaction mechanisms.

Structures of Organo Alkali Metal Complexes and Related Compounds

By Erwin Weiss*

Dedicated to Professor Ernst Otto Fischer on the occasion of his 75th birthday

The investigation of the reactivity and structure of organometallic compounds of alkali metals has experienced a blustering development in the last decades. This class includes compounds that are especially important for our understanding of chemical bonding and also quite simple, for example methyl alkali metal complexes, whose structures have been unequivocally determined. Organometallic compounds of alkali metals (and also magnesium) generally exist as ion aggregates whose properties can be significantly modified through solvation by, for example, ether or amines. Important advances in the synthesis of new compounds, especially those of the heavier alkali metals, have been based on these results. It was long believed that the alkali metals had little tendency to undergo coordination and that their coordination chemistry would offer few surprises. This picture has now changed completely. Results from crystal structure investigations have revealed a variety of often surprising structure types (rings, heterocubanes, chains, layers, etc.) not only with the organometallic compounds but also with the amides, imides, alkoxides, phenoxides, enolates, and even halides. A comparison reveals interesting similarities between compounds that appear to be so different and leads to a general classification of the structure types possible with C, N, O, and halo ligands.

1. Introduction

Organo alkali metal complexes were first reported in 1914, 14 years after the discovery of the Grignard compounds, in the pioneering work of Wilhelm Schlenk.[1] His name also remains associated with the development of inert gas techniques for the handling of reactive compounds. A comprehensive monograph published in 1937[2] showed that only few advances had been achieved in the study of organo alkali metal compounds up to the 1930s. A revival in organolithium chemistry occurred soon afterwards, however, which was particularly promoted through the work of Karl Ziegler, Georg Wittig, and Henry Gilman. The application of lithium compounds in preparative chemistry was the main area of interest, and this class of reagents soon achieved an importance similar to that of the Grignard compounds.

Structure investigations were first performed in the 1960s and have since then yielded many new and unexpected results on the structures and coordination modes of alkali metal and magnesium compounds involving not only carbanions but also amides, alkoxides, and other anions. Since these reagents are typically used in solution, the nature of their solvent adducts is an obvious area of interest. Structure information enables a better understanding of the reaction mechanisms and is therefore useful in synthetic chemistry. The important structure types will be presented and compared in this contribution. Because of the tremendous volume of published results and space limitations, the list of references is unfortunately rather incomplete. For this reason the reader is referred to further review articles and monographs[3–9] as well as to annual reports.[10]

Crystal structure analysis (X-ray diffraction and, more recently, neutron and synchrotron X-ray diffraction) is unquestionably the most important method of investigation. As such, these results will be emphasized in this report. Some of the knowledge gained from crystal studies may also allow conclusions to be drawn about the structures in solution; however, direct methods for the investigation of structures in solution are also available (NMR and IR spectroscopy, and measurements of colligative properties).

2. Simple, Unsolvated Organo Alkali Metal Compounds

2.1. Methyllithium: Structure and Bonding

The investigation of the structure of methyl alkali metal compounds began in 1964 with methyllithium.[11a] Since single crystals were not available, X-ray powder methods had to be applied. Shortly before this and independently, the structure of ethyllithium had been reported by H. Dietrich[12] as the first organo alkali metal compound (single-crystal methods). Both compounds form tetrameric aggregates having a Li_4C_4 heterocubane framework. The tetramers in $(LiCH_3)_4$ have ideal T_d symmetry and form a body-centered cubic lattice (Fig. 1). A structure refinement[11b] also provided the approximate positions of the H atoms and thus evidence for pyramidal methyl groups (C_{3v} symmetry). In this structure the C atom of each methyl group has three short contacts to three of the Li atoms of its tetramer as well as a further contact only about 5–10 pm longer to a neighboring tetramer located on a space diagonal of the body-centered cubic unit cell (coordination number of 7 for C!).

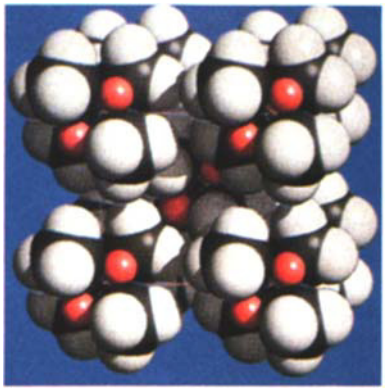

Fig. 1. Space-filling model of the body-centered cubic unit cell of $(LiCH_3)_4$[11,18]. The Li radii were chosen to be 75 pm, in accord with approximately 85% ionic character (normal ionic radius of 65 pm).

Each tetramer interacts with its eight neighbors. The very low volatility and the nonmelting character of methyllithium are direct consequences of this three-dimensional network. The strength of these interactions is drastically reduced for ethyllithium and falls off almost entirely for organolithium compounds having larger organic residues. The compounds become increasingly more volatile and have lower melting points or are even liquid as with $(LinBu)_6$. It is misleading to try to deduce covalent bonding from these properties as was often done earlier. The physical properties result from the overall structures that form from approximately spherical aggregates, which are lipophilic on the outside but can be strongly polar on the inside.

A few remarks on bonding relationships are in order at this point. These are of general interest for the organolithium compounds, and particularly for methyllithium, and have been the topic of numerous and sometimes controversial discussions. Since organolithium compounds contain only light atoms, they are well suited for theoretical studies, especially ab initio calculations. Many authors, but above all P. von R. Schleyer et al.,[4,13] have carried out these types of calculations. In the first publication on $(LiCH_3)_4$[11a] we interpreted the bonding in the tetramer based on a qualitative MO model. These ideas have been refined many times by other authors, and $(LiCH_3)_4$ has even been mentioned in textbooks as an illustration of LiC_3 two electron–four center bonds.

Initially, the covalent contribution to the Li–C bond was considerably overestimated based on the observation of ^7Li-^{13}C couplings in the NMR spectra.[14] Streitwieser et al.,[15] however, had already shown in the late 1970s that the tetrameric structure of methyllithium can also be explained with a purely electrostatic point charge model. This model was extended and generalized by describing the atoms as hard spheres (Hard Sphere Electrostatic Model).[16] Although the ionic contribution to the M–C bond is not easily determined for M = Li, recent calculations[4,13,17] estimate it to be about 80–88% and to be even greater with the heavier alkali metals. According to the current viewpoint, therefore, the alkali metal–carbon bond should be considered predominantly ionic, and the results of numerous structure investigations presented in the following discussions fully support this. The aggregates often observed are, in fact, ion aggregates having only a small covalent bonding contri-

Erwin Weiss, born in 1926 in Arzberg/Oberfranken, studied chemistry at the Technische Hochschule in Munich and received his Ph.D. in 1956 for his work with Walter Hieber on the structure of metal carbonyls and arene complexes. After conducting postdoctoral research (Massachusetts Institute of Technology, Cambridge, USA, 1956), he worked in research laboratories in Europe (European Research Institute, Brussels, 1957–1961, Cyanamide European Research Institute, Geneva, 1961–1965) and was than was appointed to the faculty of the University of Hamburg, where he remained until 1991. His research interests focus on the synthesis and structure of organometallic compounds with main group and subgroup metals. This review was written in part during a research sabbatical in Paris which was associated with the French Alexander-von-Humboldt-Preis 1992.

bution. This approach can also be reflected in the nomenclature where, for example, the methyl alkali metal compounds would be denoted as alkali metal methanides.[21, 25] In this report, however, the more conventional "-yl" nomenclature will be used.

We have recently further refined the structure of methyllithium from neutron diffraction data and have thereby also found that no phase transition occurs down to 1.5 K.[18] Since the incoherent scattering of ^1H nuclei causes a high level of background noise in the diffraction diagram, powder samples of the deuterated compound $(LiCD_3)_4$ were examined. These investigations furnished the first precise structure data for a trigonal-pyramidal methyl carbanion (we will return to this in Section 2.4). These studies also confirmed a staggered orientation of the methyl carbanion relative to the three neighboring Li atoms of the tetramer.

2.2. Methylpotassium, Methylrubidium, and Methylcesium

Since the structures of the methyl compounds of the heavier alkali metals are simpler, their descriptions will be treated before that of methylsodium. Methylpotassium was first described by Schlenk and Holtz[1c] as a black coating on potassium metal obtained upon its reaction with dimethylmercury. These samples were not suitable for X-ray investigations because of substantial amalgam impurities. Our synthesis of nearly colorless and pure methylpotassium from a metal-exchange reaction between methyllithium and potassium *tert*-butoxide allowed its structure to be determined.[19] The first preparation and investigation of the highly reactive compounds methylrubidium and methylcesium was possible in an analogous way.[20]

All three compounds display the NiAs structure type and contain CH_3^- ions with trigonal-prismatic coordination to six K ions. Although the diffraction data, which was once again obtained from powder samples, could not furnish the exact H atom positions, IR spectroscopic investigations suggested pyramidal CH_3^- ions.[19] Later, a more precise neutron diffraction analysis was carried out on the deuterated compound KCD_3 (powder samples, measurements at 290 and 1.4 K).[21]

A significant result from this structure refinement was the experimental verification of pyramidal methyl anions. Their orientations alternate within the lattice whereby, rather than the hexagonal cell previously measured, a larger orthorhombic cell results. The relation between the two unit cells is illustrated in Figure 2. Each methyl group is surrounded by six K ions in a distorted trigonal prism. This distortion is a consequence of the CH_3^- structure and also causes smaller deviations of the K ions from their ideal positions in the NiAs structure. The three K ions surrounding the lone pair of electrons on CH_3^- have shorter K–C distances (295 and 302 pm) than those of the three K atoms associated with the H atoms (330 and 344 pm). A space-filling model of the unit cell of methylpotassium is shown in Figure 3. Methylrubidium and methylcesium crystallize in the same orthorhombic structure type, as a recent reexamination[22] of the earlier powder data[20] proved.

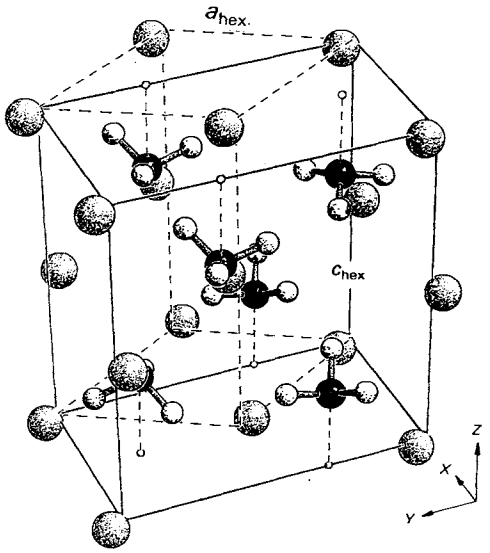

Fig. 2. Crystal structure of KCH_3 (ball-and-stick model) illustrating the relationship between the orthorhombic (*Pmcn*) and hexagonal unit cells ($b_{orthorh} \approx \sqrt{3}\,a_{hex}$)[21].

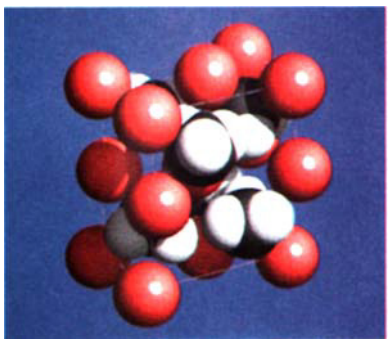

Fig. 3. Space-filling model of the unit cell of KCH_3 (K radius chosen to be 145 pm)[21].

2.3. Methylsodium

2.3.1. Methyllithium-Containing Methylsodium $(NaCH_3)_4 \cdot [(LiCH_3)_4]_x$, $x \leq 0.333$

In earlier work[23] we described the synthesis and structure of methylsodium containing variable amounts of methyllithium. Finely crystalline samples were obtained from $LiCH_3$ and sodium *tert*-butoxide by a metal-exchange reaction [Eq.(a)], and various amounts of $LiCH_3$ (mol ratios of $NaCH_3$:$LiCH_3$ from ca. 3:1 to 36:1) could be incorporated depending on the composition of the solvent.

$$LiCH_3 + NaO\,tBu \xrightarrow{\text{ether/(hexane)}} NaCH_3(LiCH_3)_x + LiO\,tBu \qquad (a)$$

In these experiments, $NaO\,tBu$ was added to a solution of $LiCH_3$. The structure of the product (Fig. 4), as determined from the powder data, is a giant cubic cell in which 24 tetrameric $(NaCH_3)_4$ aggregates build a zeolite-like host lattice. Although it is similar to the methyllithium lattice, the arrangment of the $(NaCH_3)_4$ units is more complicated. Large cavities result which firmly and selectively incorporate $(LiCH_3)_4$ units up to a structurally specified $NaCH_3$:$LiCH_3$

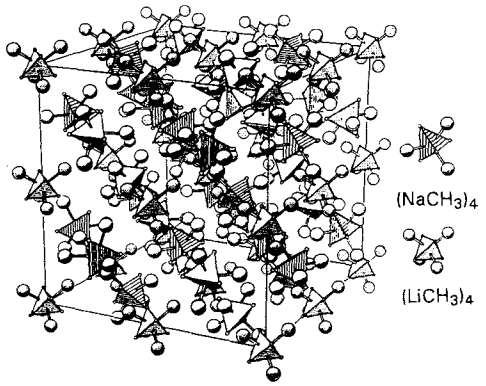

Fig. 4. The host–guest compound $(NaCH_3)_4 \cdot [(LiCH_3)_4]_x$ ($x \leq 0.333$)[23]. The host lattice (cubic cell, $a = 2020$ pm with 24 $(NaCH_3)_4$ units) contains large cavities that can incorporate a maximum of 8 $(LiCH_3)_4$ aggregates.

ratio of 3:1. To our knowledge this is the first example of an organometallic supramolecular compound. Previously obtained methyl/ethyl- and ethyl/*tert*-butyllithium compounds[24] most probably are similar types of clathrates with complicated structures.

2.3.2. *Methylsodium: Synthesis and Structure*

Only later[25] did we realize that pure methylsodium has a different, more compact structure. It is obtained when the reaction following Equation (a) is performed in the opposite sequence; that is, the $LiCH_3$ solution must be added to the NaO*t*Bu solution. Thus, the tetrameric methyllithium aggregates present in the ether solution[26] envelop the $(NaCH_3)_4$ tetramers that form upon addition of NaO*t*Bu, and thereby a special clathrate lattice is constructed. The formation of the $NaCH_3/LiCH_3$ inclusion compound is therefore template directed.

Methylsodium crystallizes as a new and complicated structure type (orthorhombic, $I222$, $Z = 16$). The structure solution was in no way trivial, for it was only possible by a combination of the complimentary methods of neutron diffraction and X-ray synchrotron diffraction on $NaCD_3$ powder samples.[27] In this new approach the Na and C positions were determined from the synchrotron data, and the D positions were subsequently obtained from the neutron diffraction data. Measurements performed at 1.5 and 293 K indicated that no phase transformation took place. Representations of the structure are shown in Figures 5 and 6 (and as stereoplots in ref.[25]).

In this structure, half of the ions form $(NaCH_3)_4$ tetramers that have slightly distorted T_d symmetry but are very similar to those in methyllithium. The remaining eight Na and eight methyl ions connect the tetramers through Na–C contacts. Depending on the orientation of the methyl ion relative to the cation, both short and long M–C distances (253 to 291 pm) are observed here, too. The distances are short within the tetramers and longer to the immediately adjoining ions ("backsides" of the methyl groups). The ions located between the tetramers also show this type of coordination: each CH_3^- ion is surrounded by three Na ions at shorter distances and one Na at a longer distance in a distorted tetrahedron. The structure of methylsodium is thus related to that of methyllithium, and its lower symmetry is a result

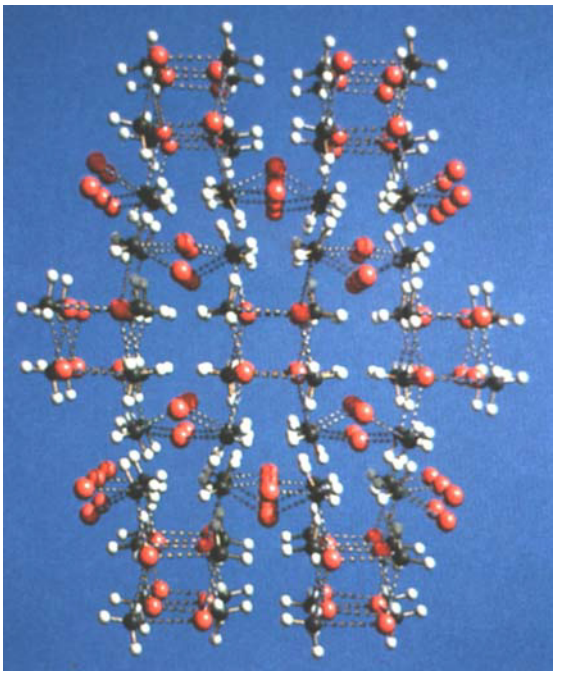

Fig. 5. Ball-and-stick model of the methylsodium lattice (Na red, C gray); adjoining unit cells of methylsodium[25]. A row of two tetrameric aggregates is found at each edge and in the middle of the picture. Dashed lines denote Na–C contacts less than 270 pm. Thus the methyl groups located between the tetramers also appear to be coordinated to three Na ions.

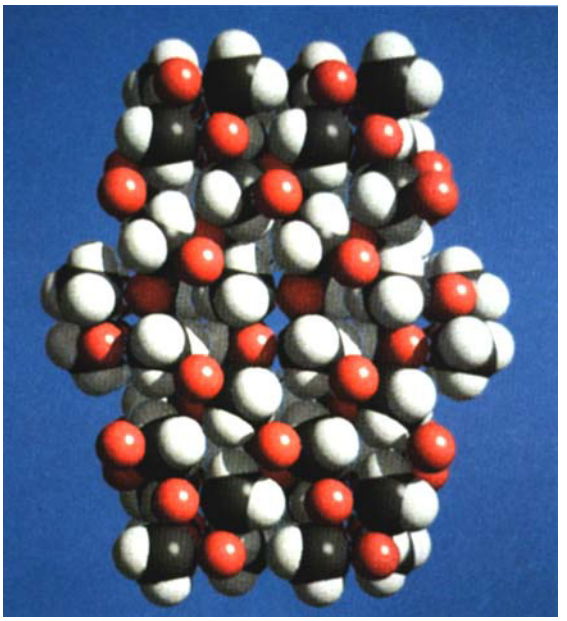

Fig. 6. Space-filling model of the crystal structure of methylsodium (orientation as in Fig. 5). The Na radii have been chosen to be 110 pm in accord with approximately 90% ionic character (standard ionic radius 97 pm).

of the different cation radii. All of the methyl ions are trigonal pyramidal with C–H bond lengths of 109 pm and H-C-H bond angles of 106° (at 1.5 K).

These results filled the gap in our knowledge on the structures of the methyl alkali metal compounds. Methylsodium takes on a median position between methyllithium and the methyl compounds of the heavier alkali metals, because its structure contains both tetrameric aggregates as well as single ions. An optimal packing in the ionic lattice is achieved through its special structure.

2.4. A Comparison of the Structures of CH_3^-, SiH_3^-, and GeH_3^-

The exact structure determinations performed with neutron diffraction that were discussed in the previous sections provide good data for the CH_3^- ion in crystalline solids.[28] It is always pyramidal (average H-C-H bond angle 107°) and isostructural with NH_3 (H-N-H bond angle 107.6°, Table 1), but the inversional bending modes known for ammonia are not possible for the CH_3^- ion in a rigid crystal lattice.

Table 1. Comparison of CH_3^-, SiH_3^-, and GeH_3^- with each other and with their analogues from the fifth main group.

$EH_3^{(-)}$	Distance E-H [pm]	Angle H-E-H [°]	Determined for
CH_3^-	107.2	108.2	$LiCD_3$ (1.5 K [18])
	109.4 (ave.)	106.2 (ave.)	$NaCD_3$ (1.5 K [25])
	109.6 (ave.)	105.1 (ave.)	KCD_3 (1.5 K [21])
NH_3	106	107.6	(2 K [33])
SiH_3^-	-	94(4)	$KSiH_3$ (NMR [30])
	143	95	$KSiH_3$ [32]
PH_3	141	93.5	
GeH_3^-	-	93(4)	$KGeH_3$ (NMR [30])
AsH_3	152	91.8	

We had previously examined a number of alkali metal silanides and germanides: $KSiH_3$, $RbSiH_3$, $CsSiH_3$,[29] $KGeH_3$, $RbGeH_3$, and $CsGeH_3$.[30, 31] We found that with the exception of $CsGeH_3$ all the compounds crystallize at room temperature in the NaCl structure type. The H-E-H bond angles for the silanide and germanide ions were determined by solid-state NMR spectroscopy and are listed for comparison in Table 1.

For the understanding of the structure of KCH_3 (distorted NiAs type), a comparison with the room-temperature modification of $KSiH_3$ (NaCl type)[29] is especially informative. The trigonal-prismatic coordination of the methyl carbanions to six alkali metal ions is a consequence of the trigonal CH_3^- structure. In contrast, the SiH_3^- ion is more spherical on account of the larger radius of Si. Thus, steric factors are less important than electrostatic factors in the alkali metal silanides (and germanides), and octahedral coordination (NaCl structure type) results, at least in the high-temperature modifications.[32]

2.5. Ethyllithium, Ethylsodium, Alkali Metal Alkynides and Acetylides, and Dilithiomethane

As already mentioned, ethyllithium forms tetramers that are similar to those of methyllithium but of lower symmetry. Very different, however, is the layered structure found for ethylsodium (Fig. 7).[34] This structure is a consequence of the larger radius of the cation and clearly indicates ionic interactions. An ABC arrangement of three sequentially staggered but identical double layers lies perpendicular to the long c axis of the crystal. The Na ions are located within the double layers, and the ethyl ions are oriented perpendicular to the layers with their methyl groups pointing outward (Na–C 263 and 268 pm).

The alkali metal ethynides $MC{\equiv}CH$ (M = Na, K, Rb)[35] and propynides $MC{\equiv}CCH_3$ (M = Na, K)[35a] (Fig. 8), as

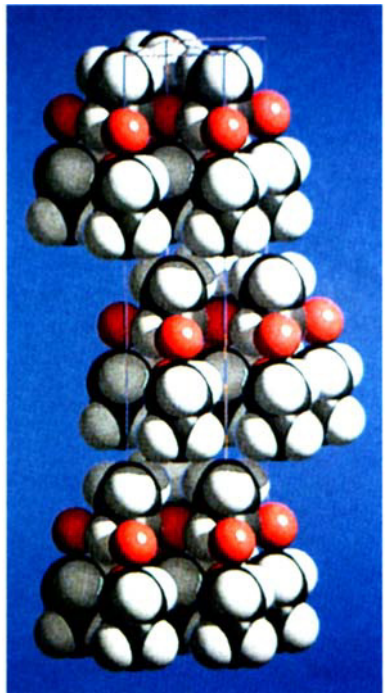

Fig. 7. The layered structure of ethylsodium (rhombohedral space group $R\bar{3}m$; Na radii chosen to be 110 pm).

well as the methoxides and ethoxides (discussed in Section 8), have related structures. As a result of their layered structures, they are neither volatile nor soluble in nonpolar solvents, and so, once again, structure investigations could only be performed on microcrystalline powder samples. The alkali metal acetylides $MC{\equiv}CM$ (M = Li, Na, K) have also been investigated (Fig. 8).[36] A distorted antifluorite structure is shown by Na_2C_2,[36b] and the K analogue is isostructural.[36c]

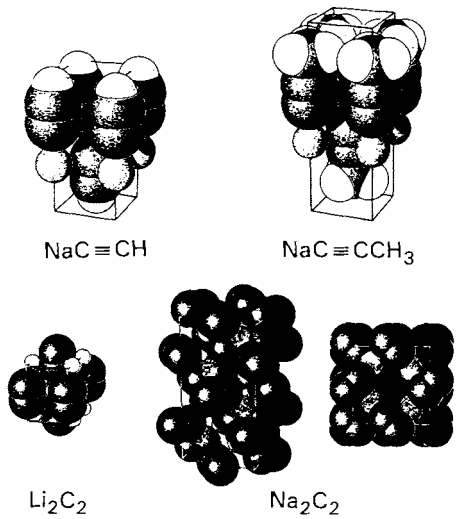

Fig. 8. Space-filling model of the layered structures of several alkynides; the structure type and the metal ions that lead to isotypic structures are given in parentheses. $NaC{\equiv}CH$ (tetragonal; K, Rb, Cs), $NaC{\equiv}CCH_3$ (tetragonal; K), Li_2C_2 (tetragonal)[36a], Na_2C_2 (tetragonal[36b]; K[36c]).

Polylithiated hydrocarbons were first structurally investigated in the early 1980s.[37] The theoretical proposition[38] that the *cis* planar structure of gas-phase dilithiomethane Li_2CH_2 is more stable than the tetrahedral structure has

drawn great attention. Unfortunately, the only experimental information available to date is for the solid phase. Following earlier, still incomplete powder X-ray diffraction investigations,[39] the structure was finally completely determined by neutron diffraction.[40] Here, bent CH_2 anions are coordinated in a complicated way to six Li ions in a strongly distorted antifluorite structure.

3. The Significance of Solvation: Base Adducts of Organolithium Compounds

3.1. Solvation

Solvation has great impact on the physical and chemical properties of organolithium compounds.[8, 9] Organolithium compounds are generally employed as ether solutions, and Grignard reagents only exist as ether adducts since dismutation to MgR_2 and MgX_2 occurs otherwise.[41] Solvation increases solubility and can also cause a drastic increase in reactivity.[42] Thus, base adducts have found important applications in synthetic chemistry. The metalation of benzene by *n*BuLi, for example, is only possible with the addition of tmeda or *tert*-butoxide ("LICKOR superbase").[42]

Solvation often lowers the degree of aggregation; nevertheless, organolithium compounds remain mostly associated even in polar solvents, as the examples in Table 2 show. Here, molar mass determinations[43] and especially NMR investigations[44] have provided important results. Since solid-state investigations are the primary source of detailed structural information, we will report exclusively on these results. Crystalline ether adducts are only slightly thermally stable and thus easily degraded. Therefore, more stable adducts with amines and especially those with the respective bidentate and tridentate chelating ligands tmeda ($Me_2NCH_2CH_2NMe_2$) and pmdta ($Me_2NCH_2CH_2N(Me)CH_2CH_2NMe_2$) are usually examined. Non-N-methylated amines such as ethylenediamine are easily metalated and therefore seldom used as donor ligands. Even ethers, in particular thf, can be attacked and cleaved,[45] which can lead to problems with the more reactive organometallic compounds of the heavier alkali metals.

Often, but not always, the structure of an amine adduct can be used to infer that of the corresponding ether adduct. Many structure investigations have revealed the specific influence of not only the carbanion but also the donor ligand on the total structure. Examples of aggregated organolithium compounds both in solution and in the solid state are listed in Table 2. Also included are some unsolvated tetramers and hexamers like $[Li(1\text{-norbornyl})]_4$[46] and $[Li(cyclohexyl)]_6$[48] (Fig. 9).

Table 2. Degree of aggregation for some organolithium compounds in solution and in the crystals[a].

Compound	Degree of association	Solvent or ref.
a) *In solution* [9, 10]		
LiMe	tetramer	Et_2O, THF
LiEt	tetramer	Et_2O, THF
LiEt	hexamer	hydrocarbon
Li*n*Bu	hexamer	hydrocarbon
Li*n*Bu	tetramer/dimer	THF
Li*t*Bu	tetramer	hydrocarbon
Li*t*Bu	dimer/monomer	Et_2O, THF
LiPh	dimer	Et_2O, THF
$LiCH_2Ph$	> monomer	Et_2O, THF
LiC_3H_5	> monomer	Et_2O, THF
b) *In crystals*		
$(LiMe)_4$	tetramer	[11, 18]
$(LiEt)_4$	tetramer	[12]
$[Li(1\text{-norbornyl})]_4$	tetramer	[46]
$(Li\,t\text{Bu})_4$	tetramer	[47]
$(Li\,n\text{Bu})_6$	hexamer, cluster	[47]
$[Li(cyclohexyl)]_n$	hexamer, cluster	[48]
$[Li(tetramethylcyclopropylmethyl)]_6$	hexamer, cluster	[49]
$[Li\{2,6\text{-}(NMe_2)_2C_6H_3\}]_3$	trimer, ring	[50]
$[Li(CH_2SiMe_3)]_6$	hexamer, ring	[51]
$[LiC(SiMe_3)_3]_2$	dimer	[52]
c) *Base adducts*

$[Li[12]crown\text{-}4)_2][CHPh_2]$ $[Li[12]crown\text{-}4)_2][CPh_3]$	ion pair	[73]

[a] Abbreviations: tmeda = tetramethylethylenediamine, tmpda = tetramethyl-1,3-propylenediamine, tmhda = tetramethyl-1,6-hexylenediamine, pmdta = pentamethyldiethylenetriamine, dabco = 1,4-diazabicyclo[2.2.2]octane.

3.2. Base Adducts of Organolithium Compounds

3.2.1. Methyllithium and Its Derivatives

The $LiCH_3$ tetramer is relatively stable and cannot be cleaved by either ethers or amines. In its tmeda adduct $[(LiCH_3)_4(tmeda)_2]_n$,[53] the tmeda molecules do not act as chelating ligands but rather as bridges between the tetramers and effect the formation of a three-dimensional network. Recent investigations have shown that the tetramer $(Li\,t\text{Bu})_4$ is transformed into the dimer $[Li\,t\text{Bu}(Et_2O)]_2$ upon solvation with ether.[47]

A monomer, $[Li\{CH(SiMe_3)_2\}(pmdta)]$,[54] is formed under the large steric requirements of, on the one hand, the highly substituted methyl carbanion $CH(SiMe_3)_2^-$ and, on the other hand, the tridentate base pmdta. Still greater shielding can lead to solvent-separated ion pairs as observed

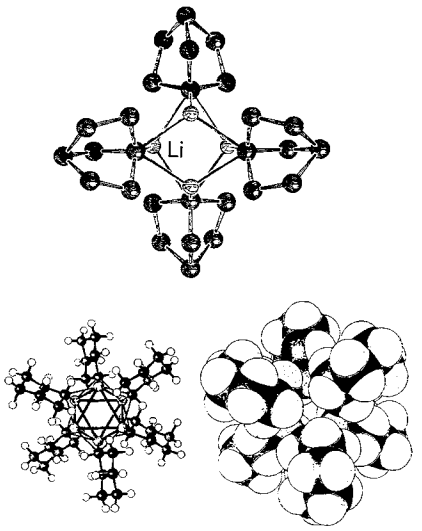

Fig. 9. Structures of $[Li(1\text{-norbornyl})]_4$ (top) and $[Li(cyclohexyl)]_6$ (bottom, ball-and-stick and space-filling models).

in the ate complex $[Li(thf)_3][Li\{C(SiMe_3)_3\}_2]$.[55] Crown ethers likewise lead to ion pairs such as $[Li([12]crown\text{-}4)_2]^+$ with the counterions $[CHPh_2]^-$ and $[CPh_3]^-$.[73] "Internal solvation" occurs when an appropriately functionalized carbanion is employed, as in $[\overline{LiCH_2CH_2CH_2OMe}]_4$[56] and $[\overline{LiCH_2CH_2CH_2NMe_2}]_4$.[57]

3.2.2. Phenyllithium

This compound is a prime example illustrating the influence that the donor ligand has on the structure: with Et_2O or Me_2S the respective heterocubane-type tetramers $[LiPh(Et_2O)]_4$[58a] and $[LiPh(Me_2S)]_4$[58b] are generated, with tmeda the dimer $[LiPh(tmeda)]_2$ having somewhat unsymmetric phenyl bridges,[59] and with the tridentate pmdta ligand the monomer [LiPh(pmdta)][60] (Fig. 10). Since the Li ion is always four coordinate, it is understandable that the degree of aggregation decreases as the hapticity of the ligands increases. Recent solid-state ^{13}C NMR investigations have also verified this.[74]

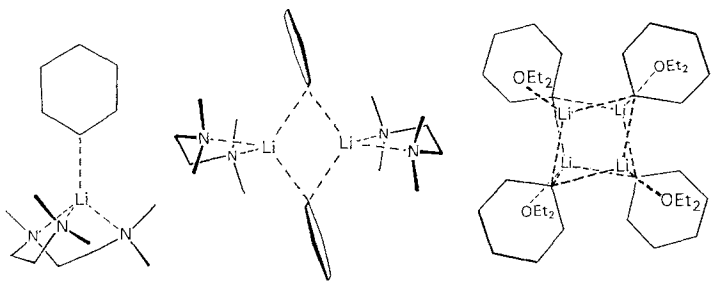

Fig. 10. The influence of the solvent on the aggregation of phenyllithium. From left to right: [LiPh(pmdta)][60], $[LiPh(tmeda)]_2$[59], and $[LiPh(Et_2O)]_4$[58]. The π electron system of the benzene rings is not indicated.

3.2.3. Alkynyllithium Compounds

Ethynyllithium is only stable as a base adduct. Our investigations[62] have shown that with ethylenediamine (en), ethynyllithium forms the polymeric compound $[LiC{\equiv}CH(en)]_n$, whose crystal structure reveals double strands connected in a ladder-like fashion by ethylenediamine bridges.

Phenylethynyllithium is solvated by the longer chained diamines tmpda ($Me_2N(CH_2)_3NMe_2$) and tmhda ($Me_2N(CH_2)_6NMe_2$). With the former, the dimer $[LiC{\equiv}CPh(tmpda)]_2$ having nearly symmetric alkynyl bridges results,[63] and with the latter, tetramers are formed that are linked by pairs of bridging tmhda ligands to make a double helix, $[(LiC{\equiv}CPh)_4(tmhda)_2]_n$.[64]

Depending on the conditions for crystallization, the thf adducts of *tert*-butylethynyllithium will form as either tetramers, $[(LiC{\equiv}CtBu)_4(thf)_4]$, or dodecamers, $[(LiC{\equiv}CtBu)_{12}(thf)_4]$ (Fig. 11).[65] These especially interesting examples illustrate an often observed structural principle: the stacking of dimers. Thus, the stacking of two dimers produces a cubane structure and that of six dimers a dodecamer. Other degrees of aggregation are also conceivable, and examples are found among the alkali metal amides (Section 7.2).

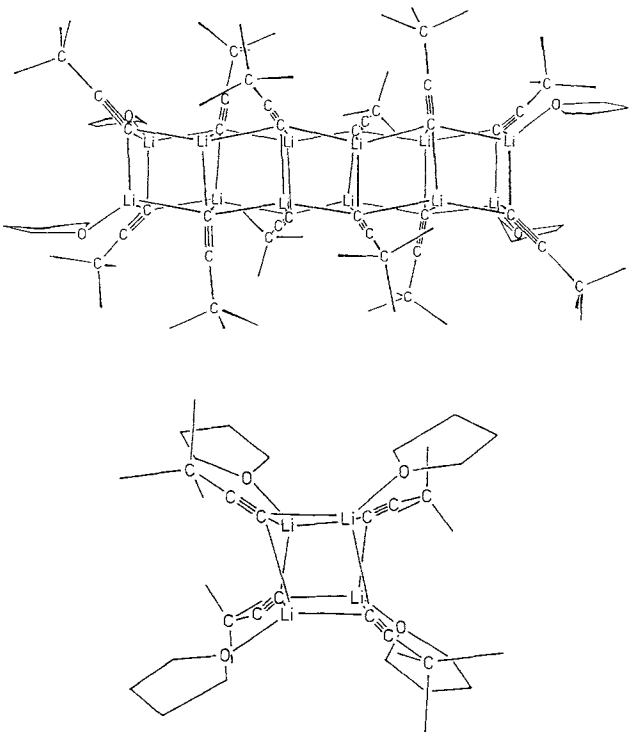

Fig. 11. Structures of $[(LiC{\equiv}CtBu)_4(thf)_4]$ (bottom) and $[(LiC{\equiv}CtBu)_{12}(thf)_4]$ (top) can be described as stacks of cyclic dimers.

3.2.4. Allyllithium

The allyl ion is particularly interesting since it is one of the simplest π electron systems. The first crystal structure investigation on a tmeda adduct revealed a chain structure $[Li(allyl)(tmeda)]_n$, in which solvated Li ions act as bridges between the terminal CH_2 groups of the allyl ions as $(\cdots Li(allyl)Li(allyl)\cdots)$.[66] A Li ion coordinated to the allyl π electron system was first found in the pmdta adduct $[Li(\eta^2\text{-}allyl)(pmdta)]$[67] which appears as a monomer as expected because of the greater hapticity of the tripod ligand. In agree-

ment with the results from model calculations,[3] the carbanion is no longer planar as a result of its (predominantly ionic) interaction with the cation. The unexpected η^2-coordination is a consequence of the very strong shielding of the Li ion by the pmdta ligand, which occupies three coordination sites on the Li. These factors are to a large extent not applicable in the compound $[Li(\eta^3\text{-}1,3\text{-diphenylallyl})(Et_2O)]_n$[68a], and the expected η^3-coordination is observed (polymer chains).

3.2.5. Benzyl- and Triphenylmethyllithium

The early X-ray structure analyses of $[Li(\eta^2\text{-benzyl})\text{-}(N(CH_2CH_2)_3N)_2]_n$ (polymer chains)[69] and $[Li(benzyl)(Et_2O)]_n$ (polymer chains)[70a] are representative of the structures of the numerous benzyllithium compounds. The benzyl ligands are planar in these chain structures, and the Li atoms lie in approximately symmetrical positions above and below the benzylic carbon atoms. The monomers [Li(benzyl)(tmeda)(thf)][70b] and $[Li\{CH(SiMe_3)Ph\}(tmeda)]$[70c] are rare examples showing benzyl C atoms with pyramidal coordination.

The monomeric triphenylmethyl compounds $[Li(CPh_3)\text{-}(tmeda)]$[71] and $[Li(CPh_3)(Et_2O)_2]$[72] contain central C atoms with planar coordination. Additional alkali metal compounds having this carbanion will be discussed in the next section.

4. Base Adducts of Organometallic Compounds of the Heavier Alkali Metals

4.1. Synthesis of Organosodium and Organopotassium Compounds

The organometallic compounds of the heavier alkali metals are more reactive and less soluble than their lithium analogues, which makes their syntheses particularly problematic. The strongly polar solvent (ether) required in these reactions is readily attacked by the reactive organometallic compounds, and even with cooling this process can be slowed but not halted. For a long time only a few representatives were known; only those derived from strong C–H acids like cyclopentadiene or alkynes were significant.

Based on the fundamental work of L. Lochmann et al.,[42a, b] we began in 1968 to use metal-exchange reactions between organolithium compounds and soluble alkali metal alkoxides (sodium and potassium *tert*-butoxide, see Section 8) to successfully prepare various compounds of the heavier alkali metals; important examples of these compounds were discussed in Sections 2.2 and 2.3). We also described the synthesis of unsolvated phenylsodium and phenylpotassium,[75] whose structure determinations are still pending.

In an alternative preparative route to these compounds, *n*-butyllithium and sodium *tert*-butoxide are used to prepare *n*-butylsodium, whose C–H acidity is strong enough to serve in the metalation of hydrocarbons. Aromatic hydrocarbons as well as amines and other compounds can be used in these reactions. Solvated organosodium compounds can be prepared in the presence of donor ligands, as was first shown with $[Na(CPh_3)(tmeda)]$.[76] In a valuable variation of this metalation reaction, [Na*n*Bu(tmeda)], an adduct soluble in hydrocarbon solvents and readily synthesized from *n*BuLi and NaO*t*Bu, is employed.[77, 78] The analogous potassium compound, [K*n*Bu(tmeda)], is likewise soluble and also an effective metalating agent.[79]

4.2. Structures of Solvated Organometallic Compounds of the Higher Alkali Metals

4.2.1. Phenylsodium and Biphenylylsodium

In contrast to the monomeric lithium compound [LiPh-(pmdta)],[60] the adduct formed from phenylsodium and pmdta, $[NaPh(pmdta)]_2$, is a dimer in the solid state (Fig. 12).[80] The difference is a consequence of the different

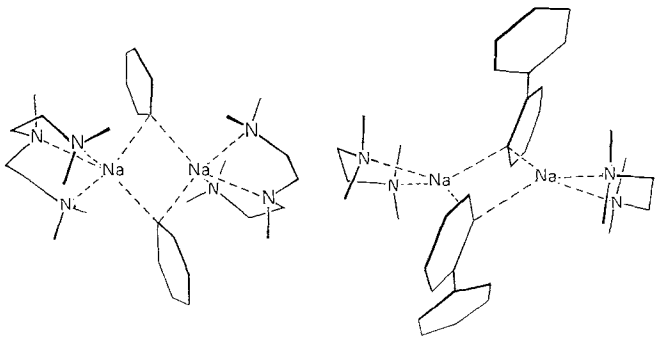

Fig. 12. Dimeric amine adducts of phenylsodium (left) and biphenylylsodium (right).

cation radii: the larger Na ion has a coordination number of 5 and thus the dimer structure is possible. A similar structure is also exhibited by the Na derivative of biphenyl having bidentate tmeda ligands, $[Na(C_6H_4Ph)(tmeda)]_2$ (Fig. 12).[81] Here, the two benzene rings of the bridging biphenylyl ligands are no longer coplanar, a result also observed in the corresponding lithium compound $[Li(C_6H_4Ph)(tmeda)]_2$.[82]

4.2.2. Benzyl, Diphenylmethyl, and Triphenylmethyl Compounds

In the following, examples containing the phenyl-substituted methyl anions benzyl, diphenylmethyl, and triphenylmethyl anion will be presented. Depending on the steric requirements of both the carbanion and the donor ligand, a number of different structure types result.

Benzyl anion: Both the benzyl and the *o*-xylyl carbanion form cyclic tetramers with the tmeda-solvated Na ion in the respective complexes $[Na(benzyl)(tmeda)]_4$[83] and $[Na(o\text{-}xylyl)(tmeda)]_4$[84] (Fig. 13 left). In contrast, with the tridentate pmdta ligand, a polymeric structure results, $[Na(\eta^1\text{-benzyl})(pmdta)]_n$,[84] in which only the *ipso* carbon atoms of the planar benzyl anions are coordinated to the Na ions and form the zigzag chains (Fig. 13 right). Similar polymer chains are also formed in the lithium compound $[Li(\eta^2\text{-benzyl})(OEt_2)]_n$[70a] (see Section 3.2.5) and in the recently re-

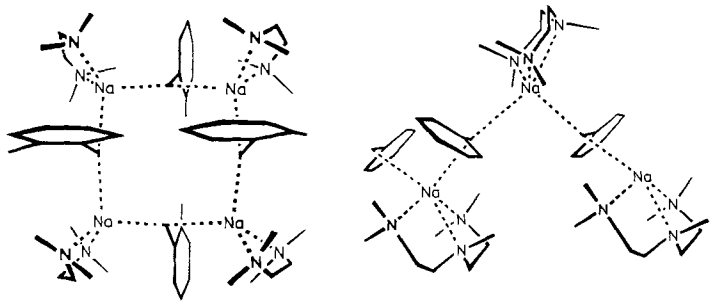

Fig. 13. Aggregation of [Na(*o*-xylyl)(tmeda)]$_4$ (left) and [Na(benzyl)(pmdta)]$_n$ (right).

ported potassium compound [K(η-benzyl)(pmdta)]$_n$,[85a] although the hapticity is different.

Diphenylmethyl anion: The diphenylmethyl ion is also planar in its sodium compounds. Its adduct with the tridentate base pmdta, [Na(CHPh$_2$)(pmdta)], is, as expected, monomeric. With tmeda, however, it forms a cyclic tetramer, [Na(CHPh$_2$)(tmeda)]$_4$[84] (Fig. 14); isotypic compounds [M(CHPh$_2$)(pmdta)]$_n$ (M = K, Rb, Cs)[85b] are polymers.

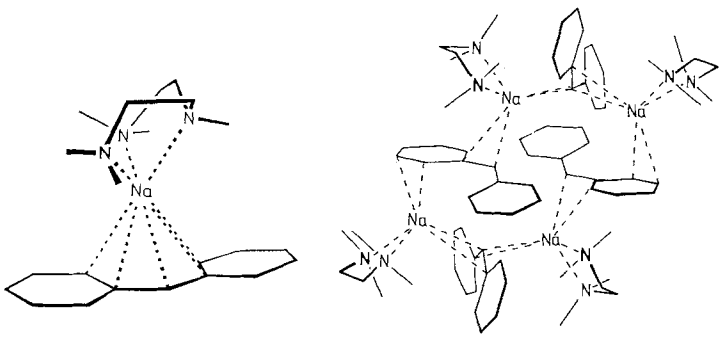

Fig. 14. The influence of the solvent on the aggregation of diphenylmethylsodium. [Na(CHPh$_2$)(pmdta) (left), [Na(CHPh$_2$)(tmeda)]$_4$ (right). The asymmetric unit of [Na(CHPh$_2$)(pmdta)] contains two very similar molecules.

Triphenylmethyl anion: The aliphatic H atom in triphenylmethane is easily replaced by a metal atom. It was already noticed in the first examples, [Li(CPh$_3$)(tmeda)][71] and [Na(CPh$_3$)(tmeda)]$_n$,[76] that the propeller-shaped carbanion contains a central planar sp^2 carbon atom. The cation takes up an asymmetrical position relative to this carbon atom in order to accommodate a maximum number of M–C contacts. Additional weak intermolecular contacts are present in the sodium compound leading to polymer chains with zigzag structures (Fig. 15 top). Since these early reports, triphenylmethyl compounds of all the alkali metals have been examined. In these, the position of the cation relative to the CPh_3^- anion can vary greatly such that it is shifted towards the peripheral phenyl groups as the cation radius increases. We have recently investigated three potassium compounds with various bases (including ethers)[86] and found that [K(CPh$_3$)(pmdta)] is monomeric, [K(CPh$_3$)(thf)]$_n$ a two-dimensional network, and [K(CPh$_3$)(diglyme)]$_n$ a polymer chain (Fig. 15 middle and bottom). The large counterions K, Rb, and Cs allow not only greater hapticity but are also particularly well suited for η^6-coordination to the phenyl groups, as recently observed in the polymeric chain compounds [Rb(CPh$_3$)(pmdta)]$_n$ and [Cs(CPh$_3$)(pmdta)]$_n$ as well as the monomeric compound [K(CPh$_3$)(pmdta)(thf)].[87]

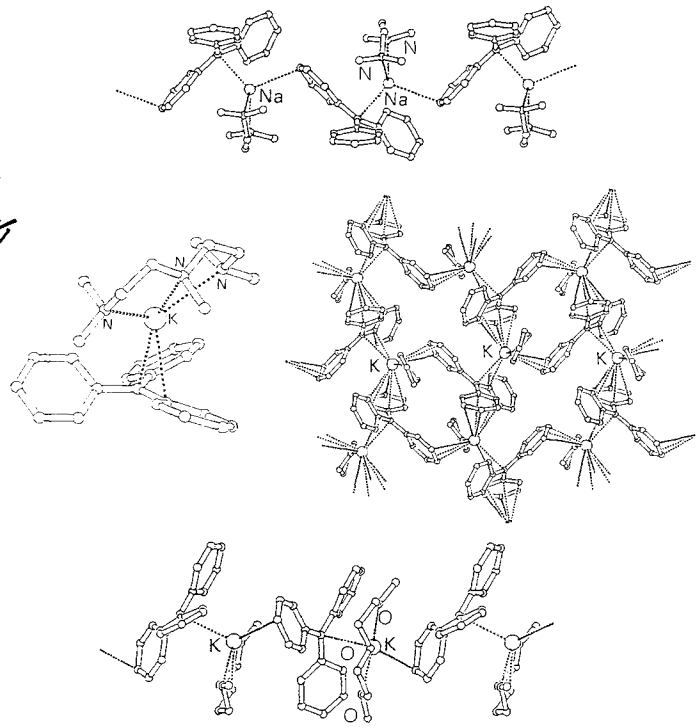

Fig. 15. Structures of some adducts of triphenylmethylsodium and -potassium. [Na(CPh$_3$)(tmeda)]$_n$ (top) [76], [K(CPh$_3$)(pmdta)] (middle left) [86], [K(CPh$_3$)(thf)]$_n$ (middle right)[86], [K(CPh$_3$)(diglyme)]$_n$ (bottom)[86].

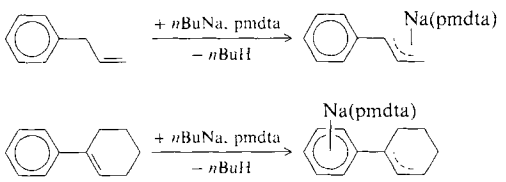
All the compounds described in this section have been shown to be either ion pairs or complicated aggregates of carbanions and solvated counterions. The structure is determined by a combination of electrostatic interactions and steric effects (structure of the carbanion and donor ligand, cation radius). The following examples also emphasize this principle.

The metal–C distances can vary tremendously even within one compound. In such cases, the number of M–C contacts, in other words the coordination number of the cation, often cannot be definitively established. The coordination number of sodium is always greater than 4, that of potassium, rubidium, and cesium often around 8. The minimum distance for a proposed Na–C contact is roughly 265 pm; in the figures distances up to 300 pm are typically indicated with dashed lines. In general, the larger the cation radius, the greater the number of M–C contacts.

4.2.3. Allyl Compounds

The metalation of allylbenzene by butylsodium in the presence of pmdta yields the monomeric compound [Na(1-phenylallyl)(pmdta)][88] with the expected η^3-coordination (Scheme 1; compare to [Li(η^2-allyl)(pmdta)][67]). The analogous metalation of 1-phenylcyclohexene also produces a carbanion having an allyl system[88] (Scheme 1). Surprisingly, here the solvated Na ion is not coordinated to the allyl part of the carbanion but instead is centered η^6 over the phenyl group. This arrangement is analogous to that in a Na-benzene complex in which the Na ion is sandwiched between the amine and the carbanion. What is the explaination for this unusual coordination? The Na ion is so strongly shielded by its solvation shell that the allyl system of the



Scheme 1. Synthesis of phenylallyl compounds with η^3-allyl and η^6-phenyl coordination [88].

cyclohexenyl ion can no longer approach it (hindrance by the CH_2 groups of the carbanion). In addition, the negative charge on the carbanion is also distributed over the phenyl part by conjugation. Thus, in consideration of both steric and electrostatic interactions, the energetically most favorable position for the solvated cation is centered above the phenyl group.

Additional examples in which the alkali metal has η^6-coordination at the center of phenyl ligand are known, for example, [Na(tetraphenylallyl)(Et_2O)][89] (distorted dibenzene sodium sandwich complex) and the triple contact ions in [Na_2(tetraphenylethene)(Et_2O)$_2$][90] and [Na_2(1,1,4,4-tetraphenylbutane-1,4-diyl)(Et_2O)$_2$].[91]

The compound [Na(1-phenylethyl)(tmeda)]$_n$, obtained by the sodium metalation of ethylbenzene, is also worth mentioning in this context.[84] Here, the carbanions lie in a bridged zigzag chain and are coordinated through their CH_3CH groups as well as through the phenyl rings (η^2- and η^3-coordination).

4.2.4. Cyclopentadienyl, Indenyl, and Fluorenyl Compounds

Solvated Cyclopentadienyl Alkali Metal Compounds: The structures of these compounds have been repeatedly described and summarized.[92] A number of important examples with lithium and sodium have been known for quite some time now and include [Li(η^5-$C_5H_4SiMe_3$)(tmeda)][93] (monomer), [Li(η^5-C_5H_4Me)(tmeda)][94] (monomer), and [Na(η^5-Cp)(tmeda)]$_n$[95] (zigzag chain) (Fig. 16 left). In contrast, almost no crystal structures of the higher homologues have been described till now. Recent examples are the potassium compounds [K{η^5-C_5(CH_2Ph)$_5$}(thf)$_3$][96] ("piano-stool geometry") and [K(η^5-Cp)(OEt_2)]$_n$[97] (polymer chain) (Fig. 16 right). In the latter, the polymer chain is only slightly angled as a result of the larger radius of potassium, and the structure thus corresponds well to a "multidecker structure". The first structurally characterized cyclopentadienyl alkali metal compound that is not solvated is [K(η^5-$C_5H_4SiMe_3$)]$_n$ (chains with weak interactions between the strands).[98]

Solvated Indenyl Alkali Metal Compounds: Examples of structurally characterized indenyl compounds include [Li(η^5-indenyl)(tmeda)][99] (monomer) and [Na(indenyl)-(tmeda)]$_n$[100] (polymer chains with η^1/η^2 coordination). In the structures shown in Figure 17 it is not surprising that [Na(η^5-indenyl)(pmdta)] forms as a monomer. Also, because of the larger radius of the potassium cation, the compounds [K(η^5-indenyl)(tmeda)]$_n$ and [K(η^5-indenyl)(pmdta)]$_n$ form slightly angulated polymer chains (multidecker).[101] A detailed discussion of the factors that are structure determining in the indenyl complexes is given in ref.[100] and in the work cited therein.

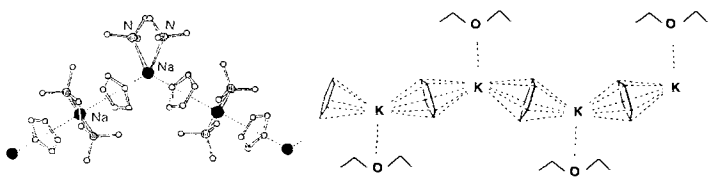


Fig. 16. Solvated cyclopentadienyl alkali metal compounds. [Na(η^5-Cp)-(tmeda)]$_n$ (left), [K(η^5-Cp)(OEt_2)]$_n$ (right).

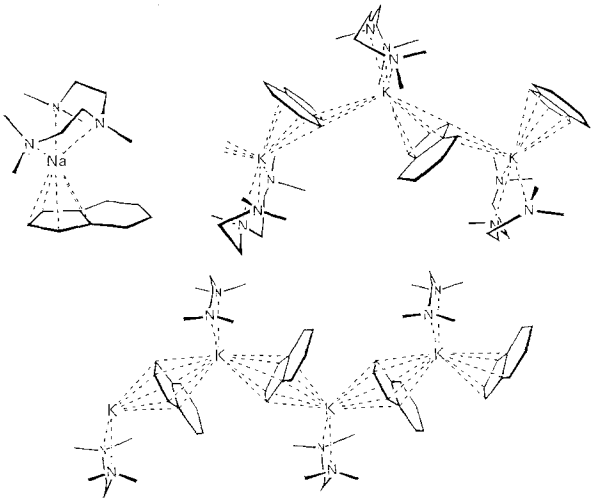

Fig. 17. Solvated indenyl alkali metal compounds[101]. [Na(η^5-indenyl)-(pmdta)] (top left). [K(η^5-indenyl)(pmdta)]$_n$ (top right). [K(η^5-indenyl)(tmeda)]$_n$ (bottom).

Solvated Fluorenyl Alkali Metal Compounds: Three different structures are found for fluorenylsodium and result from a simple variation in the donor ligands:[102] [Na(fluorenyl)L], with L = pmdta, tmeda, and tmpda. The compound is monomeric with the sterically demanding tridentate pmdta ligand, forms polymer chains with the smaller tmeda, and exists as rings constructed from four monomer units with tmpda, despite the fact that the chain lengths of tmeda and tmpda differ by only one C atom. These examples are an impressive illustration of the significance of steric effects. Monomers, polymers, and cyclic tetramers comprise the most important structure types for solvated organosodium compounds. In contrast to these, [K(fluorenyl)(pmdta)]$_2$ (Fig. 18) is a cyclic dimer, no doubt as a result of the larger radius of the cation.[101] In the complicated structure of [K(fluorenyl)(tmeda)]$_2$,[103] the tmeda can no longer coordinate the large potassium ion in a chelating fashion, and so it bridges between two cations. Chains with "square waves" are formed in [Rb(η^5-fluorenyl)(pmdta)]$_n$.[104]

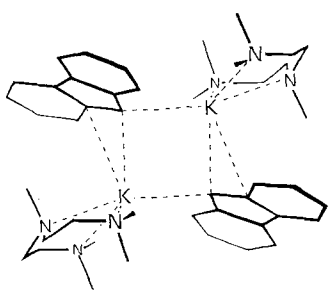

Fig. 18. Structure of [K(fluorenyl)(pmdta)]$_2$ [101].

4.2.5. The Influence of the Metal Ions on the Structure of the Carbanions

It has been repeatedly shown both experimentally and theoretically[3, 4] that the structures, reactivities, and energies of organometallic compounds are strongly influenced by the metal cations. Some carbanions, for example $C_2H_5^-$, are only stable in the presence of a counterion.[4] Numerous examples (see for example refs.[67,69,100]) illustrate the influence the cation has on the structure of the carbanion. It is noticeable that the phenyl groups bound to metal centers have regular distortions of the six-membered rings. The C2-C1-C6 angle is always less than 120° (down to ca. 112°), and the angles at C2 and C6 atoms are widened to ca. 124°. Of the many examples known, we mention here only [LiPh(pmdta)], [NaPh(pmdta)]$_2$, and [MgPh$_2$(tmeda)]. A qualitative correlation exists between the endocyclic angles and the electronegativity of the metal.[61]

5. Organomagnesium Compounds

In this section, as in the preceding, our own investigations will be highlighted. The reader is referred to the literature citations given in ref.[5] for additional examples, and to the discussion of organomagnesates in Section 6.4.

5.1. Diorganomagnesium Compounds

Four unsolvated diorganomagnesium compounds are especially important: $MgMe_2$, $MgEt_2$, $MgPh_2$, and $MgCp_2$ (Figs. 19–21). Bis(η^5-cyclopentadienyl)magnesium (magnesocene) was the first structurally characterized organomagnesium compound; its sandwich structure was first determined in 1955[105a] and later refined[105b]. Dimethylmagnesium and diethylmagnesium are obtained as fine crystalline powders by drying their thermally labile ether adducts. Their polymeric structures, $[MgMe_2]_n$[106] and $[MgEt_2]_n$,[107] were discovered by us quite some time ago. Recent investigations have shown that diphenylmagnesium is also polymeric.[108] As expected, these compounds are not volatile and only sparingly soluble in hydrocarbon solvents. Ether and other polar solvents break the polymer chains by formation of solvated monomers.

The magnesium ions in the polymer chain are each surrounded by a tetrahedron of four carbanions which form pairs of μ_2 bridges between the Mg ions similar to that found in dimethylberyllium.[109] Unsolvated monomers are obtained with more bulky carbanions as in

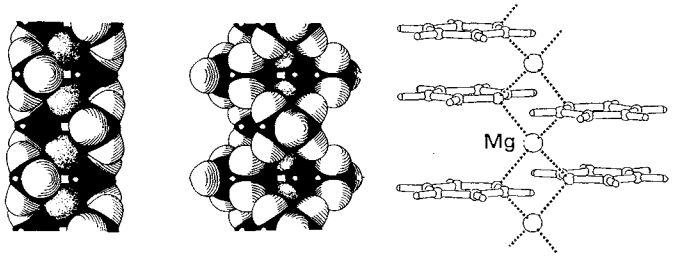

Fig. 19. Polymer chains of dimethylmagnesium (left), diethylmagnesium (middle), and diphenylmagnesium (right).

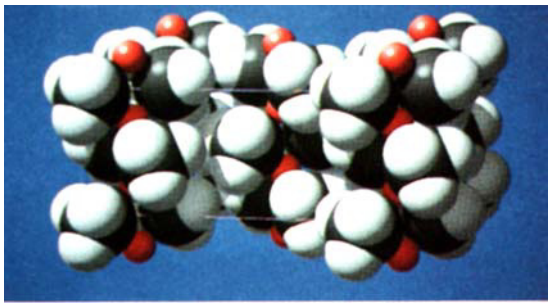

Fig. 20. Space-filling model of $[MgMe_2]_n$ (body-centered orthorhombic unit cell; Mg radius chosen to be 70 pm).

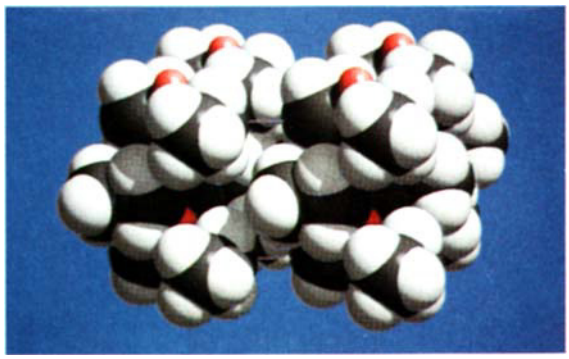

Fig. 21. Space-filling model of $[MgEt_2]_n$ (tetragonal unit cell; high-temperature modification; Mg radii chosen to be 70 pm).

$[Mg\{C(SiMe_3)_3\}_2]$.[110] in which the magnesium ion has linear coordination.

As with the methyl alkali metal compounds, there was some uncertainty as to the H positions in $[Mg(CH_3)_2]_n$ and $[Mg(C_2H_5)_2]_n$. Therefore, we recently carried out new structure determinations from neutron diffraction data on the deuterated compounds $[Mg(CD_3)_2]_n$ and $[Mg(C_2D_5)_2]_n$ at 293 and 1.5 K.[111] These structures verified the earlier results but also showed a statistical or dynamic disorder in the alkyl groups (rotation of the methyl groups). A phase transition only occurs with $[MgEt_2]_n$ (tetragonal $\rightleftharpoons$ monoclinic at ca. 260 K). As a result of the bent ethyl groups, the chains are chiral helices (right- and left-handed screw sense) in a statistical distribution, whereby a higher pseudosymmetry is attained.[107]

5.2. Solvated Diorganomagnesium Compounds

As already mentioned, because the ether adducts of the organomagnesium compounds are thermally labile, the more stable adducts of the chelating amines were examined in preference. Since improvements in instrumentation have made low-temperature measurements experimentally more accessible, the number of ether adducts investigated has increased. The structural characterization of the species involved in the Schlenk equilibrium of the Grignard compounds is especially challenging. The halo-bridged dimers belong to this group of compounds but will not be discussed here. Even though base adducts of the amines can also serve as models for the ether adducts, they are interesting in their own right. Similar to the alkali metal compounds, the reac-

tivity of the magnesium compounds can be increased through solvation, whereby the character of the carbanion is strengthened. The complexes formed from the addition of tmeda to Grignard compounds have proved to be cocatalysts in the anionic polymerization of olefins, and some yield syndiotactic polymers.[112]

Only monomeric adducts are listed in Table 3. They contain magnesium atoms with various coordination modes as illustrated in Figure 22 by selected examples. Tetrahedrally coordinated magnesium can be found in the compounds with tmeda: $[MgMe_2(tmeda)]$,[113] $[MgEt_2(tmeda)]$,[114] and $[MgPh_2(tmeda)]$.[115] The coordination number 5 (distorted trigonal bipyramid) is also possible as shown by recent examples with pmdta—$[MgMe_2(pmdta)]$,[114] $[MgEt_2(pmdta)]$[114]—and a few Grignard compounds. The "slender" alkynyl carbanions allow for even octahedral coordination in $[Mg(C{\equiv}CPh)_2(tmeda)_2]$[118] and $[Mg(C{\equiv}CtBu)_2(tmeda)_2]$.[119]

Table 3. Solvated monomeric organomagnesium compounds.

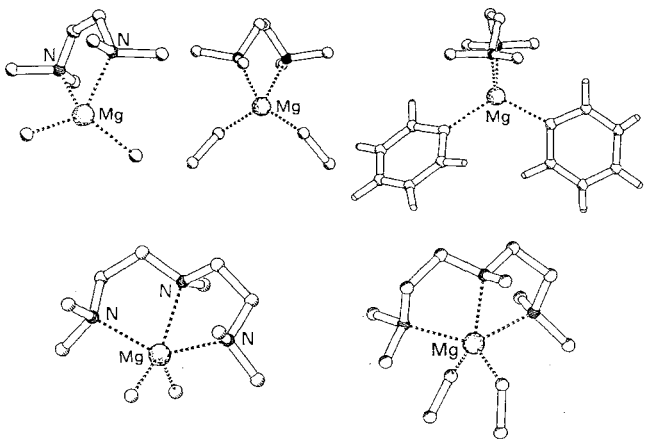

Fig. 22. Structures of $[MgMe_2(tmeda)]$ (top left), $[MgEt_2(tmeda)]$ (top middle), and $[MgPh_2(tmeda)]$, all of which have tetrahedral coordination at Mg; structures of $[MgMe_2(pmdta)]$ (bottom left) and $[MgEt_2(pmdta)]$, which both have distorted trigonal-bipyramidal coordination at Mg.

5.3. Unsymmetric Diorganomagnesium Compounds

The base adducts that are soluble in hydrocarbon solvents, for example $[MgR_2(tmeda)]$ (R = Me, Et), are suitable starting materials for the preparation of unsymmetric diorganomagnesium compounds, a class of compounds that has been hardly investigated till now. By their reaction with C–H acidic hydrocarbons R'H (alkynes, cyclopentadiene, indene, fluorene) in a 1:1 ratio, we have recently[125] synthesized the adducts $[MgMe(\eta^3\text{-Cp})(tmeda)]$, $[MgMe(\eta^3\text{-indenyl})(tmeda)]$, $[MgMe(\eta^1\text{-fluorenyl})(tmeda)]$, and $[Mg_2Et(C{\equiv}CPh)_3)(tmeda)]_2$. It is remarkable that none of the π carbanions exhibit η^5-coordination. On account of steric hindrance of the methyl groups, at most η^3-coordination can be achieved, and with the fluorenyl carbanion only η^1-coordination is attained.

6. Organometalates: Compounds with Two Different Metals

These compounds are among the organometallic compounds longest known and include, for example, $NaEt{\cdot}ZnEt_2$.[126] They are often obtained by simply mixing together stoichiometric amounts of the components and were initially considered as double compounds. The true nature of these compounds was recognized only later when G. Wittig termed them *ate complexes*.[127] In many cases their true nature could only be completely elucidated by X-ray structure analysis. We investigated compounds that contain in addition to an alkali metal the following elements in the organometalate: lithium, copper (as Cu^I), beryllium, magnesium, zinc, cadmium, boron, aluminum, gallium, indium, and thallium (Table 4; further examples in refs.[3,4] and the work cited therein). In these compounds the coordination numbers 2 (Cu, linear), 3 (Zn, trigonal planar), 4 (tetrahedral), and 5 (Mg, trigonal bipyramidal) have been observed. Sometimes the organometalate ion is di- or even trinuclear; these special cases will be discussed in more detail.

Although sometimes the partitioning of these compounds into a complex organometalate ion and a counterion is only formally possible, it is very useful as an ordering principle as well as for the nomenclature. In most cases the relation of the organic substituents to the central atom is clearly discernible from the structures. The charge localization on the carbanion is always greatest for the cation with the highest charge ($M^{3+} > M^{2+} > M^+$) and, for cations with the same charge, the one with the smaller radius ($Li^+ > Na^+$). This is then the coordination center. As far as it is sterically possible, the carbanions orient their most strongly negative polarized centers toward the coordination centers and form as many and as short contacts as possible. In this way carbanions can also become bridging ligands (e.g. μ_2-Me, μ_2-Ph), whereby both symmetric and unsymmetric bridges are possible as the examples in Figure 23 show. Solvation of the counterion is often observed, especially with the small lithium ion. Solvent-separated ion pairs are ultimately formed with sterically demanding donor ligands.

6.1. Lithates

In 1958 Wittig et al. described a sodium diphenyllithate ("diphenyllithium sodium")[156] whose structure could not

be characterized. Under similar reaction conditions, but with tmeda, we were able to isolate the compound $[LiNa_3Ph_4(tmeda)_3]$.[128] It contains a tetrahedral tetraphenyllithate ion surrounded by three solvated sodium ions—$[Na(tmeda)]_3[LiPh_4]$ (Fig. 24). Also of note is $[Li(thf)_4][Li\{C(SiMe_3)_3\}_2]$, only the second example of an organolithate known to date. It is a solvent-separated ion pair in which a diorganolithate having a central atom with linear coordination is the anion.[129]

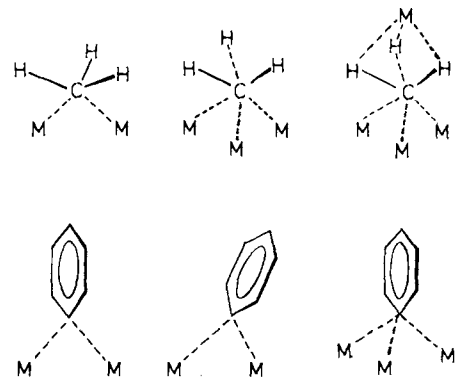

Fig. 23. Coordination modes for bridging methyl and phenyl groups.

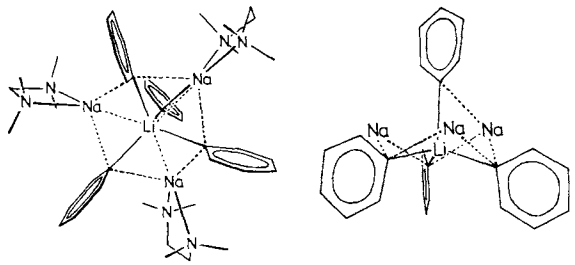

Fig. 24. $[Na(tmeda)]_3[LiPh_4]$, a tetraphenyllithate with three solvated counterions; amine ligands are not shown in the picture on the right.

6.6. Cuprates

Many examples of lithium organocuprates are known.[157] They are important in organic synthesis and in many cases even superior to the traditional Grignard and organolithium reagents. These very labile compounds are generally introduced as ether solutions and usually decompose upon attempted isolation. For this reason the first example of a simple ether-solvated lithium cuprate confirmed by X-ray crystallography is of particular significance. This dimer, $[\{Li(Et_2O)\}(CuPh_2)]_2$ (Fig. 25), is formed from two linear diphenylcuprate units held together by solvated Li ions.[130]

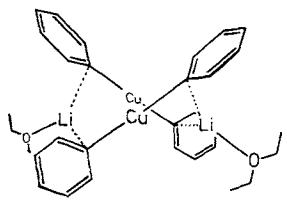

Fig. 25. $[\{Li(OEt_2)\}(CuPh_2)]_2$, a dimeric lithium diphenylcuprate.

The compound $[Li_6(Et_2O)_3Cu_4(C{\equiv}CPh)_{10}]$ is an example of the even rarer, higher order organocuprates ("HO cuprates").[132] It contains a $[Cu(C{\equiv}CPh)_4]^{3-}$ tetrahedral anion "crowned" by a cyclic $[Li_3Cu_3(C{\equiv}CPh)_6]$ unit. The Li_3Cu_3 atoms of this unit form a slightly bent six-membered ring and are bridged by the C_α atoms of the six phenylethynyl ligands. The three remaining Li atoms are solvated by Et_2O and lie below the base of the anion.

6.3. Beryllates

Organoberyllates are not very well investigated. The compound $Li_2[BeMe_4]$,[133] prepared without solvent, contains the tetrahedral tetramethylberyllate ion (see Fig. 28). In contrast, simple planar threefold coordination occurs with the voluminous *t*-butyl anion in $Li[Be(tBu)_3]$.[134]

6.4. Magnesates

Organomagnesates exist in many interesting structure types and with various coordinations (3, 4, 5) at the magnesium centers (see Table 4). The compounds $[Li(tmeda)]_2[MgMe_4]$[136] and $[Na(pmdta)]_2[MgPh_4]$[137] have tetrahedral coordination (Fig. 26 top), and the organic groups form unsymmetric μ_2 bridges between magnesium and the solvated alkali metal atom.

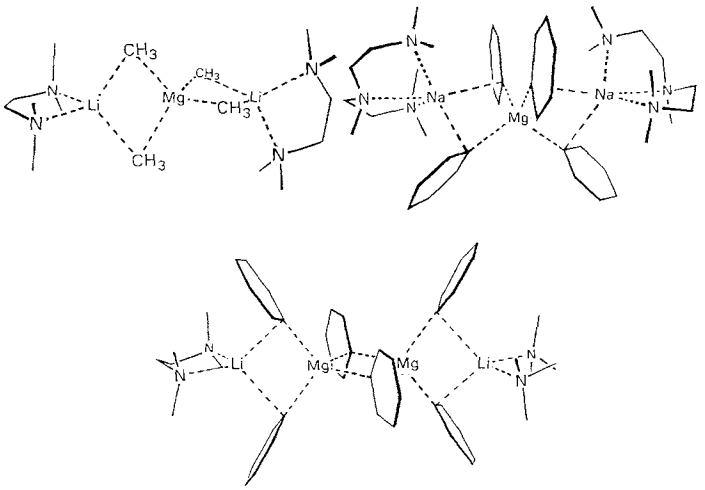

Fig. 26. Top: Tetraorganomagnesates with methyl and phenyl bridges: $[Li(tmeda)]_2[MgMe_4]$ and $[Na(pmdta)]_2[MgPh_4]$. Bottom: $[Li(tmeda)]_2[Mg_2Ph_6]$, an example of a hexaorganodimagnesate. The pairs of phenyl groups form either symmetrical or unsymmetrical bridges.

The two magnesium atoms in the dinuclear hexaorganodimagnesates $[Li(tmeda)]_2[Mg_2Ph_6]$[138] (Fig. 26 bottom) and $[Mg(neopentyl)([2,1,1]cryptand)]_2[Mg_2Et_6]$[135] have distorted tetrahedral coordination. The (formally) $[Ph_2Mg(\mu\text{-}Ph)_2MgPh_2]^{2-}$ ion is, incidentally, isoelectronic and isostructural with the neutral compound Al_2Ph_6[158] and contains symmetric phenyl bridges between Mg and Mg but unsymmetric bridges between Mg and Li (Fig. 26 bottom).

We recently found the first octaorganotrimagnesate with the compound $[Mg_2Me_3(tacn)_2]_2[Mg_3Me_8]$,[139] which is obtained from the reaction of $MgMe_2$ with the cyclic triamine tacn. Unprecedented here is also the occurrence of an organomagnesium cation with a "triple-decker structure" in which three μ_2-Me groups bridge the solvated magnesium ions—$[LMg(\mu_2\text{-}Me)_3MgL]^+$.

A few organomagnesates exist as dimers in which the pentacoordinate magnesium center is bound to three organic substituents and one bidentate diamine ligand: $Li_2[Mg(C{\equiv}CPh)_3(tmeda)]_2$,[140] $Na_2[Mg(C{\equiv}CtBu)_3(tmeda)]_2$,[137] and $Na_2[Mg(C{\equiv}CtBu)_3(pmdta)]_2$.[137] The alkali metal ions connect the two units of the dimer through contacts to the alkyne groups as shown in Figure 27.

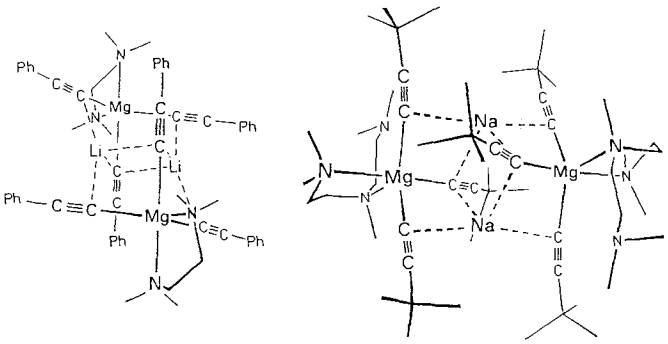

Fig. 27. Organomagnesates with pentacoordinated magnesium: $Li_2[Mg(C{\equiv}CPh)_3(tmeda)]_2$ and $Na_2[Mg(C{\equiv}CtBu)_3(pmdta)]_2$.

Finally, solvent-separated ions are found in the benzylmagnesate $[Li(tmeda)_2][(tmeda)Li(\mu_2\text{-benzyl})_2Mg(benzyl)_2]_2$.[140] The anion has a complicated structure in which two of the four benzyl groups of a strongly distorted tetrahedral $Mg(benzyl)_4$ unit are bridged at their CH_2 groups by a lithium atom.

6.5. Zincates and Cadmates

The zincates $Li_2[ZnMe_4]$[141] and $K_2[Zn(C{\equiv}CH)_4]$,[142] and the cadmate $K_2[Cd(C{\equiv}CH)_4]$[142] all contain tetrahedral anions. The simple substitution of potassium for lithium in the methyl zincate causes a change to the rarely encountered trigonal-planar coordination as found in the triorganozincate $K[ZnMe_3]$ (Fig. 28).[143]

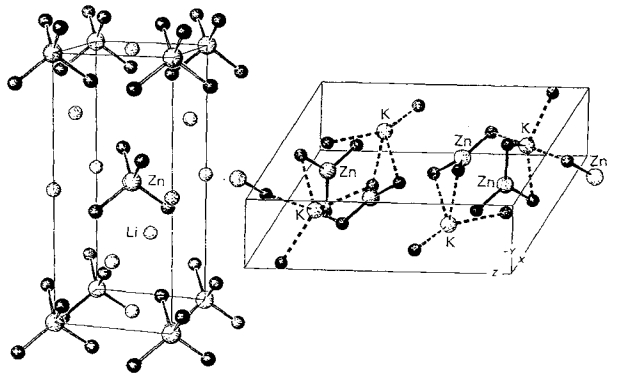

Fig. 28. Methylzincates with tetrahedral and trigonal-planar coordination at the zinc atom. Left: $Li_2[ZnMe_4]$ (isotypic to $Li_2[BeMe_4]$[133]). Right: $K[ZnMe_3]$ (monoclinic unit cell).

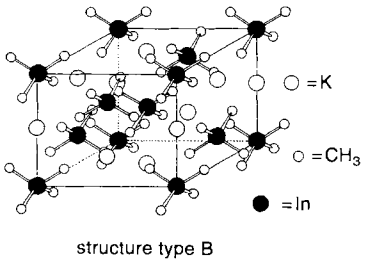
6.6. Borates, Aluminates, Gallates, Indates, and Thallates

All the compounds presented here are tetraorganometalates with the exception of the hydridometalate $K[AlHMe_3]$.[151] Apart from $[Li(BMe_4)]_4$ (ring structure),[144] they all contain quite distinct MR_4^- units and display a number of crystallographically different structure types. Orthorhombic (type A), tetragonal (types B and D), and cubic (type C) lattices have been observed for the methyl compounds (Figs. 29 and 30). The isotypic representatives of each type



structure type B

7. Alkali Metal Amides

Together with the organometallic compounds, the alkali metal amides have established themselves as the most important metalating and deprotonating agents. For this reason a great interest in their structures has developed.

7.1. Simple Alkali Metal Amides

The structures of the simple alkali and alkaline earth metal amides $M(NH_2)_n$ ($n = 1, 2$) have been known for a long time from the investigations of R. Juza, H. Jacobs, and others.[159] The H atoms were located by either X-ray ($LiNH_2$[159b]) or neutron diffraction ($NaND_2$[159e]). Because of the difference in the anion shapes, no structural relationships exist between the methyl compounds MCH_3 and the amides MNH_2. In an X-ray refinement of the structure of sodium amide we were also able to locate the H atoms in good agreement with the neutron diffraction results (Fig. 31).[97] The structure can be understood as a three-dimensional network of dimeric $(NaNH_2)_2$ units.

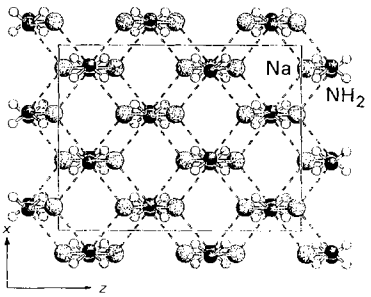

Fig. 31. Structure of $NaNH_2$. Projection is along (010) in the centrosymmetric setting of *Fddd*[97,159e].

More recently a number of solvated alkali metal amides derived from organic amines have been investigated; these will be discussed in Section 7.2. In contrast, the study of the nonsolvated compounds is only in its initial phases. Here, potassium diethylamide is one of the first examples and contains $(KNEt_2)_2$ units which build rings in a complicated arrangement.[97] An interesting "ladder structure" has been found in $[Na(2,3,4,5\text{-tetramethylpyrrolyl})]_n$ (azacyclopentadienyl ligand),[160] in which the characteristic features of amide bridges are combined with those of the π coordination of the cyclopentadienyl ligands.

7.2. Base Adducts of Alkali Metal Amides and Imides

The structural chemistry of the solvated lithium amides and imides having organic substituents on N has made great progress. Numerous original papers and some excellent reviews[6, 161, 162] attest to the multitude of structure types known for these compounds, including stacked rings and ladder structures. In the following, the amides of the heavier alkali metals, which have been less well investigated, will be highlighted. In general, alkali metal amide adducts are very often observed as dimers with four-membered M_2N_2 rings; however, other structure types are also known (Table 5). New, as yet unpublished examples of dimeric amides are shown in Figure 32. Structural investigations on their base adducts are also of interest here since the reactivity of amides can be increased by such additives.[163]

Alkali metal amides are generally obtained by the direct reaction of amines with the metals. Often, hydrides and organo alkali metal compounds such as the soluble adduct [Na*n*Bu(tmeda)] are more suitable for metalation reactions, since the synthesis can then take place in a homogeneous medium. Many of the amides listed in Table 5 have been prepared in this way. As a result of the high reactivity of butylsodium, however, cleavage of tmeda under formation of $NaNMe_2$ cannot be ruled out.[167] This product crystallizes in situ in the form of oligomeric aggregates. The interesting stacked structures of $[Na_{10}(NMe_2)_{10}(tmeda)_4]$ and $[Na_{12}(NMe_2)_{12}(tmeda)_4]$ were thus obtained in this way (Fig. 33).[167] These are decameric and dodecameric aggre-

$[NaN=CtBu_2]_4[HN=CtBu_2]_2$	cubane	[166]	$[Cs(carbazolyl)(pmdta)]_2$	dimer	[170]

[a] $[K_2(NPh_2)(tmeda)_3]_n$ forms chains of $[K(NPh_2)(tmeda)]_2$ units bridged by tmeda.

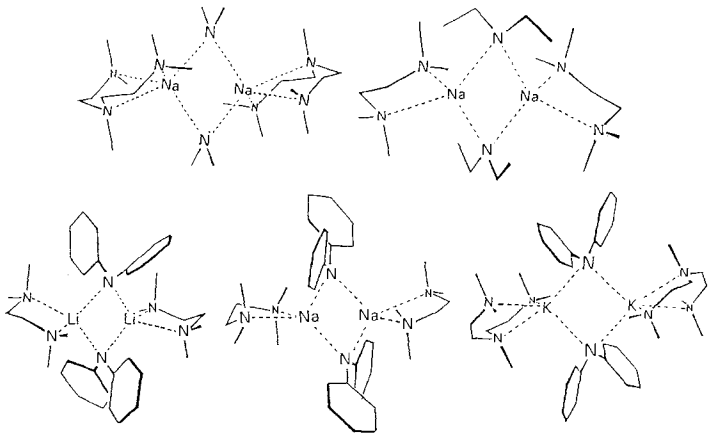

Fig. 32. Structures of dimeric base adducts of alkali metal amides. Top: $[NaNMe_2(pmdta)]_2$, $[NaNEt_2(tmeda)]_2$; bottom: $[LiNPh_2(tmeda)]_2$, $[NaNPh_2(tmeda)]_2$, and $[KNPh_2(pmdta)]_2$ [97].

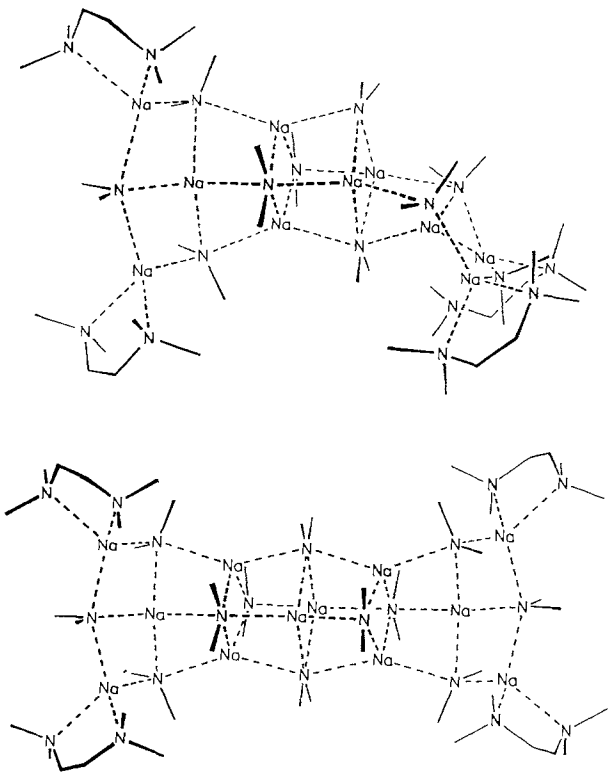

Fig. 33. The stacked structures of the amine adducts of sodium dimethylamides: $[Na_{10}(NMe_2)_{10}(tmeda)_4]$ (top) and $[Na_{12}(NMe_2)_{12}(tmeda)_4]$ (bottom).

gates, which can be considered to be constructed from ring-shaped dimers and bounded by terminal donor molecules. Thus, analogies to the organolithium compound $[(LiC\equiv CtBu)_{12}(thf)_4]$[65] discussed in Section 3.2.3 can be drawn. The occurrence of $[Na_{12}(NMe_2)_{10}(p\text{-xylyl})_2(pmdta)_4]$ indicates that carbanions can also be fitted into the amide stack.[167]

Related examples can be found under the amides listed in Table 5 which are formed from the heterocycles pyridine, carbazole, and indole. These amides also form bridges in the dimers and can exhibit both σ and π interactions. The amide bridges are unsymmetric in $[Na(indolyl)(tmeda)]_2$ and symmetric in $[Na(indolyl)(pmeda)]_2$ and thus reflect the difference in the spatial requirements of the solvate bases.[168]

8. Alkoxides, Aryloxides, Enolates, and Acetylenediolates

Investigations on the structures of alkali metal alkoxides also began relatively late, as the appearance of a monograph first in 1978 indicates.[171] A review on phenoxides is given in ref.[172]. Considering the importance of these compounds, not many structures are known even today. Table 6 contains a few simple but important examples of some unsolvated compounds.

8.1. Layered Structures: Methoxides, Ethoxides, Propoxides

The standard synthesis of alkali metal alkoxides from a metal and an alcohol leads to solvent adducts which are

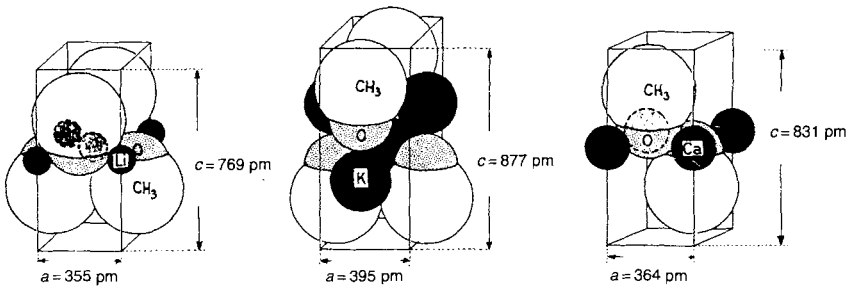

Fig. 34. The layered structures of (from left to right) LiOMe, KOMe (tetragonal), and $Ca(OMe)_2$ (hexagonal).

often crystallizable; the solvent-free compounds usually provide finely crystalline powder upon drying. Their X-ray investigations are thus more difficult, and the determination of the hydrogen atom positions is rarely possible. Disorder arising from rotomers is likely; solid-state ^1H NMR investigations[179b] have shown that the alkyl groups rotate in crystalline samples.

All of the simple alkoxides investigated so far, MOMe (M = Li–Cs),[173–176] and MO*i*Pr (M = K–Cs),[177] have layered structures (Fig. 34). The methoxides of calcium, strontium, and barium[182] as well as the thiolates MSMe (M = Li–K)[183] are also to be included here. The alkyl groups are always found on the outside of the layers, and the cations are distributed within the layer over one (Li, Na, Ca, Sr, Ba) or two (K, Rb, Cs) sites depending on the radius of the ion. The compounds are nonvolatile and insoluble in apolar solvents as a consequence of their layered structures.

8.2. Spherical and Cyclic Aggregates: *tert*-Butoxides, Enolates

Layered structures are no longer possible with large bulky alkyl groups (the lower boundary seems to lie by *t*-butyl), and so spherical or cyclic aggregates are formed in these cases. The compounds initially investigated, $(MO\,t\mathrm{Bu})_4$ (M = K, Rb, Cs; Fig. 35),[179] as well as the trimethylsilanolates $(MOSiMe_3)_4$ (M = K, Rb, Cs)[180] and the recently described imide $(CsNHSiMe_3)_4$,[187] are all tetrameric and form cubane structures in crystalline samples. The corners of the distorted cube are occupied by metal atoms alternating with O or N atoms.

The compounds are soluble and volatile as a result of their spherical structures, whereby the outer surfaces have predominantly hydrocarbon character. Molar mass determinations in aprotic solvents[188] indicate similar degrees of aggregation as found in the crystal. According to mass spectrometric investigations, tetramers—$(KO\,t\mathrm{Bu})_4$,[179b] $(MOSiMe_3)_4$ (M = K, Rb, Cs)[179b]—and hexamers—$(LiOCMe_3)_6$[189] and $(MOSiMe_3)_6$ (M = Li, Na)[189]—also exist in the gas phase.

The application of these alcoholates in the synthesis of organometallic compounds (see Sections 2.2, 2.3, and 4.1) as well as their versatility as synthetic building blocks and catalysts for organic reactions is ultimately based upon their structure-dependent solubility.[190a] Soluble alkoxides are also valuable precursors for the preparation of metal oxides under mild reaction conditions (sol–gel and MOCVD methods). The discovery of high-temperature superconductors has recently sparked a lively interest in mixed oxide systems and other ceramic materials and has thus contributed to a renaissance in the chemistry of the alkoxides.[190b,c]

The structure of sodium *tert*-butoxide (Fig. 36) is especially noteworthy. Within its unit cell, hexameric $(NaO\,t\mathrm{Bu})_6$

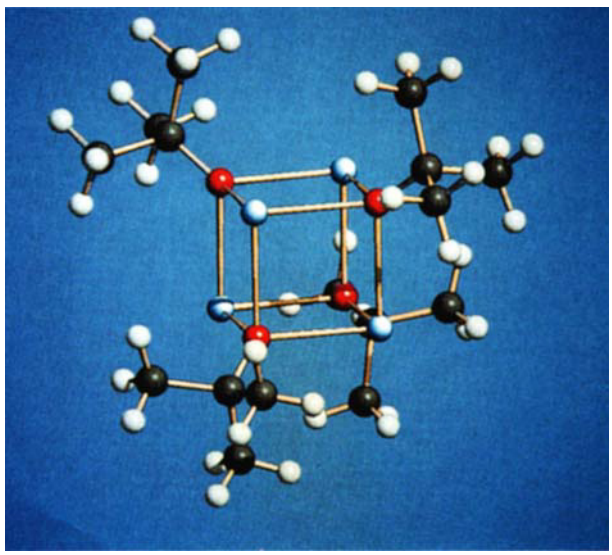

Fig. 35. The cubane structure of $(KO\,t\mathrm{Bu})_4$; isotypic structures include $(MO\,t\mathrm{Bu})_4$ (M = Rb, Cs) and $(MOSiMe_3)_4$ (M = K, Rb, Cs).

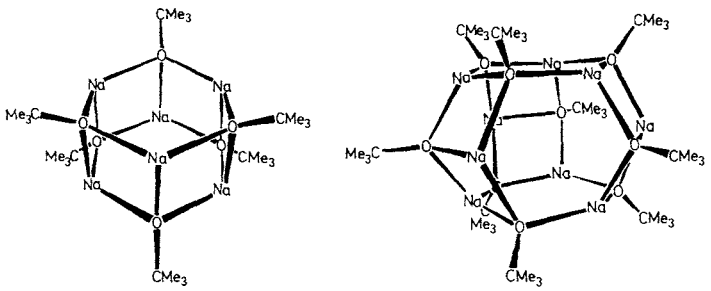

Fig. 36. The structures of $(NaO\,t\mathrm{Bu})_6$ (left) and $(NaO\,t\mathrm{Bu})_9$ (right). The central six-membered ring in the nonamer is expanded to the extent that only three Na–O contacts are possible here.

and nonameric $(NaO\,t\mathrm{Bu})_9$ aggregates (1:1 ratio) lie in very close proximity to one another, a rarity even from a crystallographic viewpoint.[178] Just as a cubane structure can result from the stacking of two ring-shaped dimers, so can the trigonal-prismatic structure of $(NaO\,t\mathrm{Bu})_6$ be regarded as a stacking of two ring-shaped trimers. Although inadequate crystal quality has prohibited a definitive investigation on

lithium *tert*-butoxide, hexamers are probably also present in its crystals.

Copper(I) can hardly be compared to the alkali metals. In its complexes the metal center strives for linear coordination, as the structures of the diorganocuprates show. Thus, copper *tert*-butoxide forms the four-membered ring structure $(CuO\,t\mathrm{Bu})_4$[181] (Fig. 37). Although the very explosive compound methylcopper has not yet been crystallographically investigated, it should have an analogous structure.

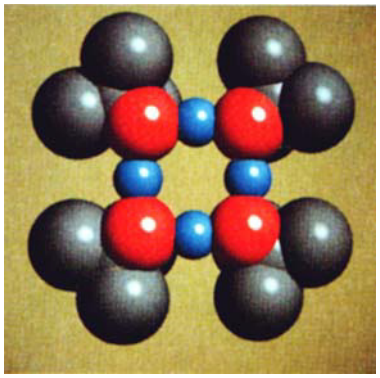

Fig. 37. The ring structure of $(CuO\,t\mathrm{Bu})_4$.

The enolates are very important members of the group of lithium compounds having O ligands. Their structures have been well investigated and included in reviews over the last decade.[191] It is sufficient to indicate here that the known structure types (dimers, tetramers, hexamers, etc.) also occur with these compounds. Most compounds have been investigated as their solvent adducts. The trimeric magnesium-acetylacetonate $Mg_3[MeC(O)CHC(O)Me]_6$ and its phosphinoyl derivative $Mg_3[(Et_2O)_2P(O)CHC(O)Me]_6$[192] are solvent-free enolates. As a consequence of the octahedral coordination preferred by the dications, these compounds contain face-sharing MO_6 polyhedra similar to those found in $[Zn_3(acac)_6]$[193] and $[Ni_3(acac)_6]$.[194]

8.3. Base Adducts of the Alkoxides and Phenoxides, Complexes from Alkoxides and Organometallic Compounds

Apart from the alkali metal enolates, there are very few structurally characterized compounds with other, even simple, alkoxides. Two examples are the dimeric phenoxides (phenolates) $[Li(p\text{-}OC_6H_4Br)(tmeda)]_2$[195] and $[Na(OPh)(pmdta)]_2$[195] which contain central M_2O_2 rings. A few compounds with more highly substituted phenoxides also have ring structures: lithium-2,6-di(*t*-butyl)phenoxide $[Li(OC_6H_3t\mathrm{Bu}_2)(Et_2O)]_2$[196] and sodium-2,4,6-tris(trifluoromethyl)phenoxide $[Na(OR)(thf)_2]_2$.[197] In $[Li\{O\text{-}2,6\text{-}(CH_2NMe_2)_2\text{-}4\text{-}MeC_6H_2\}]_3$, a cyclic trimer $(LiOR)_3$ is formed by "inner solvation" with a phenoxide having two amine substituents.[198]

Some recent investigations on soluble (oxo)alkoxides of the heavier alkali earth metals, and especially those with barium,[199] are worth mentioning with regard to the interest in superconductors noted in the previous section. The structural framework in $[Ca_6O_2(OEt_2)_8]\cdot 14Et_2O$ is made up of a stack of three Ca_2O_2 rings,[200] and $[Ca_9(OCH_2CH_2OMe)_{18}(HOCH_2CH_2OMe)_2]$[201] is the largest alkoxo complex known.

It was already mentioned in Section 3.1 that the reactivity of the organometallic compounds can often be drastically increased by the addition of amines (tmeda) or *tert*-butoxides. This very important effect is based on the formation of complexes from organometallic compounds and the base ("superbases"). The solubility of the organometallic compound usually increases parallel to this. Although crystal structure investigations on appropriate compounds are only in their initial stages at this point, the benzene-soluble tetramer $[n\mathrm{BuLi}\cdot Li\,O\,t\mathrm{Bu}]_4$[202a] and [Li(4,6-dimethyl-2-sodiomethylphenoxide)(tmeda)]$_4$,[202b] which contains a Li_4O_4 cubane framework, are the first examples. The solubilization of organosodium compounds by magnesium alkoxides[203a] is also possible and, conversely, polymeric diphenylmagnesium forms benzene-soluble complexes with alkali metal alkoxides.[203b]

8.4. Acetylenediolates

J. Liebig reported in 1834 on the formation of a black and extremely reactive "potassium carbonyl" from the reaction of CO and melted potassium in a 1:1 mol ratio.[204] The product was later formulated as $K_6C_6O_6$, since small amounts of hexahydroxybenzene (together with its oxidation products) could be obtained by careful hydrolysis (otherwise an explosive reaction occurs).

The reaction can also be performed with alkali metals dissolved in liquid ammonia. Following the introduction of CO into the blue solution of the metal, a colorless and likewise very reactive powder precipitates which, upon hydrolysis, yields small amounts of glyoxal together with other products. The "alkali metal carbonyls" prepared in this way were the subject of our systematic investigations with W. Büchner starting in 1963.[184–186] X-ray diffraction studies, among others, proved these compounds to exist as dimers. The Na, K, Rb, and Cs salts of these acetylenediolates were examined and found to be isotypic (Fig. 38). The lithium compound is

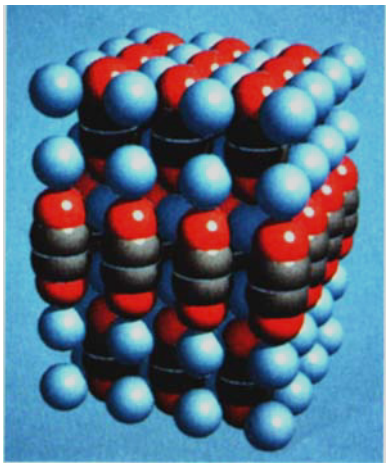

Fig. 38. Space-filling model of the crystal structure of KOC≡COK[185]. NaOC≡CONa[184], RbOC≡CORb, and CsOC≡COCs[186] are isotypic.

extremely shock sensitive and thus its structure determination has not been possible. Generally the compounds become more stable with increasing cation radius, since intermolecular reactions within the crystal are then minimized.

The following reaction steps apparently occur during the reaction of CO with alkali metals (Scheme 3). First, CO is

$$M + CO \rightarrow M^+ + CO^{\cdot -}$$
$$2\,CO^{\cdot -} \rightarrow {}^-OC{\equiv}CO^-$$

Scheme 3. Formation of acetylenediolate from the reaction of CO with an alkali metal.

reduced to the radical anion $CO^{\cdot -}$ (isoelectronic with NO), which immediately dimerizes to form the acetylenediolate (along with other compounds[205]). If the reaction is carried out in a potassium melt, then cyclotrimerization directly follows to form $K_6C_6O_6$. Such cyclization reactions are well known with the alkynes.

9. Solvated Alkali Metal Halides

Gas-phase alkali metal halide homo-complexes[206] like $(NaCl)_n$ ($n = 2-4$) have been known for a long time. Their structures usually represent sections of the crystal lattice, for example the Na_4Cl_4 heterocubane, and they can be stabilized by solvation. Appropriate bases containing N and O atoms can form adducts, a few of which are even soluble in hydrocarbon solvents. The most commonly known complexes are those formed from crown ethers, cryptands, and calixarenes and are usually solvent-separated ion pairs.[207]

In contrast, simple adducts of the alkali metal halides with amines, and particularly those with chelating amines, remain less well known, even though they display special properties[208] and despite the fact that their structure investigations were conducted as far back as the 1960s.[209] Since the small Li ion is easily solvated, most of the investigations have been performed with Li derivatives. Adducts of the heavier alkali metals, and especially their chlorides, are not very soluble in amines. Apparently their solvation enthalpies and entropies are often not sufficient to overcome the lattice energy; many adducts cannot be synthesized by simply mixing the salts with the donor ligands. They are formed more easily when the metal halides are as dry and as finely dispersed as possible. These conditions sometimes exist in the preparation of organo alkali metal compounds in the presence of halide sources. This explains the often unexpected formation of solvated alkali metal halides during the synthesis of organometallic compounds. Thus, solvated lithium complexes having both carbanions and halide ions in the same aggregate have been obtained. The compounds $[Li_4(cyclopropyl)_2Br_2(Et_2O)_4]$[210] and $[Li_4Ph_3Br(Et_2O)_3]$,[211] which crystallize as heterocubanes, are examples.

Syntheses aimed at preparing water-free solvent adducts of lithium halides of the form $[LiX \cdot x\,L]_n$ are based on the reactions of *n*BuLi with *n*BuX/L[212] or reactions of *n*BuLi (or LiH) with solid ammonium halides in the presence of bases L.[213] We have been able to prepare sodium compounds analogously by using *n*BuNa and RX/L.

Among the systematic investigations on solvent adducts of alkali metal halides carried out recently, those by R. Snaith et al. and A. H. White et al deserve particular note. We have also investigated several adducts including $[(LiCl)_8(tmeda)_7]$ (two solvated Li_4Cl_4 units connected by a tmeda bridge),[214] $[NaI(tmeda)]_4$ (heterocubane; Fig. 39),[215] $[NaI(tmeda)_2]_n$ (*catena*-μ-I[Na(tmeda)$_2$], polymer chain; Fig. 40),[216] and $[NaI(pmdta)]_2$ (dimer; Fig. 40).[217] These structures compliment those described in the literature, and in many cases the compounds were examined independently by several research groups. A surprising variety of structures is also found with these compounds; the most important types include monomers, rings (dimers, trimers), stacks (cubanes, double cubanes), and polymer chains.

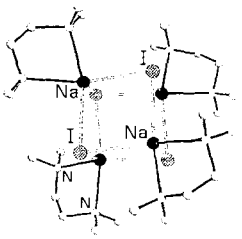

Fig. 39. The structure of $[NaI(tmeda)]_4$ (heterocubane).

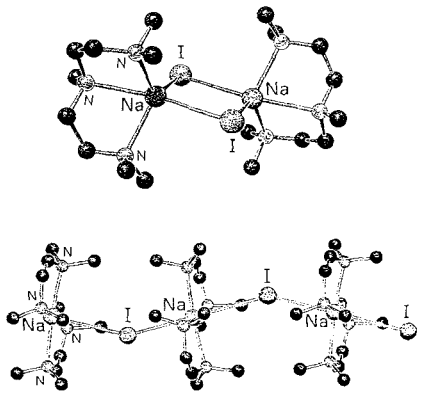

Fig. 40. The structures of $[NaI(pmdta)]_2$ (dimer) and $[NaI(tmeda)_2]_n$. A dimer structure very similar to that of $[NaI(pmdta)]_2$ is found as a component in the crystal of the mixed aggregate $[NaI(pmdta)]_2[Li(pmdta)(OH_2)I]_2$[218]. In *catena*-$\mu$-I[Na(tmeda)$_2$] the Na ions have distorted octahedral coordination.

10. Closing Remarks

The structures of organometallic compounds presented in this review display an unexpected and fascinating variety with the most diverse C, N, O, and X ligands. Many of the physical and chemical properties of these ion aggregates first became understandable through their structure determinations. For example, the solubility of many organometallic compounds is a consequence of their structure and not of "covalent bonding". The application of the structure information to the study of reaction mechanisms and to the directed control of reactions is still in its infancy.

The largest structural diversity is found with the lithium compounds. Here, almost all of the important structure

types occur: monomers, dimers (rings), trimers (rings), tetramers (heterocubanes and rings), hexamers (pseudooctahedra), decamers, dodecamers (stacked rings), and polymers (chains, double chains). The heavier alkali metal ions allow for a greater hapticity, whereby not only the formation of two- and three-dimensional ion aggregates is promoted, but also multihapto contacts to aromatic ring systems. The important structure types are presented in simplified form in Figure 41 (Lewis-basic solvent molecules are excluded).

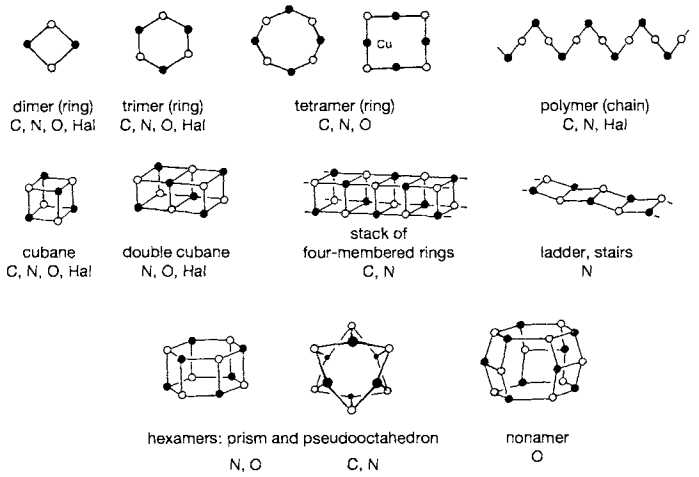

Fig. 41. Important idealized coordination types for ion aggregates of the alkali metals (●) with C, N, O, and halogen anions (○). The pseudooctahedron can also be considered a distorted hexagonal prism. The anions for which each coordination type has been found are listed for each case.

The organic compounds of the main group metals continue to be of tremendous interest. At the moment it seems that a rapid development in the compounds of the heavier alkali metals is taking place. Of the elements of the second main group, magnesium remains at the focus of interest. When will the decisive breakthrough occur for the heavier alkaline earth metals?[219] Conditional here are substantial advances in the further development of low-temperature techniques. Good progress has been made in crystal structure analysis which has enabled an increasing number of routine investigations on thermally labile substances.[220] Further surprises in this field of study may certainly be expected.

My special thanks go to the many co-workers and colleagues who have carried out or supported our work over the past nearly three decades. Since their large number prevents mentioning all their names, I can only refer to the literature citations. I would, however, like to thank especially Prof. Dr. U. Behrens and Priv.-Doz. Dr. J. Kopf for continuous and valuable help, particularly with difficult crystal structure analyses, and also Dr. J. Cockcroft for the neutron diffraction investigations. I have had the pleasure of working with many very dedicated and imaginative co-workers who have contributed substantially to the results presented here. I am grateful to the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

Water-Soluble Ligands, Metal Complexes, and Catalysts: Synergism of Homogeneous and Heterogeneous Catalysis

By Wolfgang A. Herrmann* and Christian W. Kohlpaintner*

Dedicated to Professor Ernst Otto Fischer on the occasion of his 75th birthday

Rapid developments in the field of catalysis are leading to an increased demand for tailor-made catalysts. Water-soluble complex catalysts, which are being intensively investigated at the present time, combine the advantages of homogeneous and heterogeneous catalysis: simple and complete separation of the product from the catalyst, high activity, and high selectivity. From the large number of available water-soluble ligands, the appropriate catalysts can be developed for many reactions. The industrial applications in the fields of hydrogenation and hydroformylation have already indicated the wide scope of this type of catalyst. In addition, the annual production of 300000 tons of butyraldehyde through application of water-soluble rhodium complexes at Hoechst AG in Oberhausen, Germany, has demonstrated the industrial importance of the concept of complex-catalyzed reactions in aqueous two-phase systems. The efficient operation of catalytic processes increasingly requires the loss-free recycling of the noble metal catalyst, and this can be simply and economically realized in two-phase systems. Special applications in biochemical problems open up developments in the field of water-soluble transition metal complexes that far transcend the familiar kinds of homogeneous catalysis. In the near future, the investigation and application of metal complex catalysts that are compatible with the physiological, cheap, and environmentally friendly solvent, water, is likely to become a high priority in catalysis research.

1. Introduction[**]

The chemistry of water-soluble ligands and their metal complexes is presently undergoing very rapid growth. The special advantages of water-soluble catalysts are being increasingly recognized, as is borne out alone by the number of publications and patents. Following the introduction to industry of the valuable Ruhrchemie/Rhône–Poulenc process in 1984 there was spate of publications, which is still continuing (Fig. 1). Meanwhile, about a dozen research groups applied for patents, and the number of these now even surpasses the number of publications in the open literature.

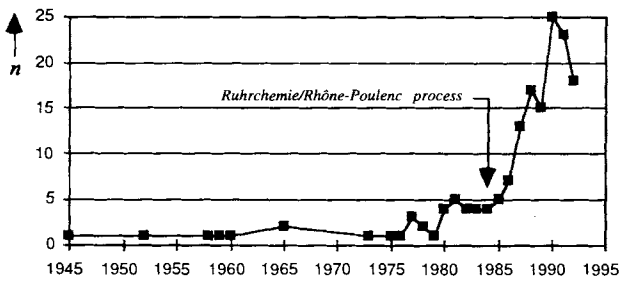

Fig. 1. Number (n) of publications annually on water-soluble complex ligands and catalysts (excluding patent applications).

What are the advantages of water-soluble catalysts? The basic problem of homogeneously catalyzed processes is the separation of the product phase from the (molecular) catalyst, which is soluble in it. The process stages necessary to achieve this usually include thermal operations such as distillation, decomposition, transformation, and rectification, which normally lead to thermal stresses on the catalyst. These can cause decomposition reactions and progressive deactivation during the lifetime of the catalyst. Furthermore, thermal separation processes seldom give quantitative recovery of the catalyst, which causes loss of productivity through loss of metal.

Product separation is simpler for two-phase systems incorporating water-soluble catalysts as shown in Figure 2. The

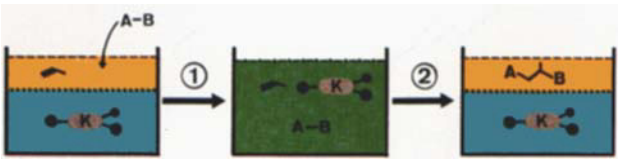

Fig. 2. General principle of two-phase catalysis in water. The metal complex catalyst (K), which is solubilized by hydrophilic ligands, converts the starting material (in this case, propene and A–B, such as CO/H_2) to the products, which can be separated from the catalyst (medium) by phase separation. Thorough mixing of the phases is necessary during the catalytic process.

hydrophilic catalyst, which is insoluble in the organic product phase, is an (organometallic) coordination complex, and as such is molecularly well defined like conventional homogeneous catalysts. It brings about the catalytic reactions (e.g., C–C coupling) in the aqueous phase or at the phase boundary, and is removed from the desired product at the end of the reaction by a simple phase separation. Thermal separation processes, which can have a detrimental ef-

[**] Often used abbreviations: tpp = triphenylphosphane; tppts = trisodium salt of 3,3',3''-phosphanetriylbenzenesulfonic acid; tppms = sodium salt of 3-diphenylphosphinobenzenesulfonic acid.

fect on the active life of the catalyst, are thereby avoided. Because of the high polarity of the water-soluble catalyst and its consequent insolubility in the organic phase, the loss rate is often below the limit of detection.

Rates achievable with two-phase systems are strongly dependent on the polarity of the reacting substrate. For example, the rhodium-catalyzed hydroformylation of propene using the water-soluble complex $[HRh(CO)(tppts)_3]$ takes place with the apparent activation energy of a homogeneous reaction, whereas with 1-hexene the rate-determining step appears to be mass transfer.[1] Therefore, although overall reaction rates are lower than in homogeneous reactions, the simplicity of the process for separating the product from the catalyst compensates for this disadvantage.

Another technique, which has been practiced for a long time without any spectacular success, is to immobilize solid complex catalysts on solid ("stationary") supports. Here, the continuous loss of the metal ("bleeding", "leaching") and low reaction rates are serious disadvantages. However, the immobilization of a catalyst in a "mobile phase", that is, an aqueous solution immiscible with the product phase, represents an almost ideal combination of homogeneous and heterogeneous reaction processes.

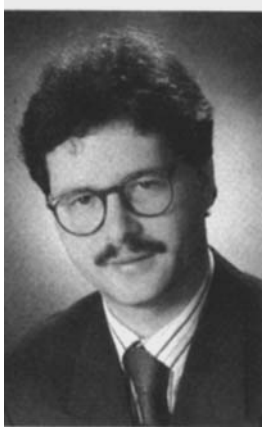
This article reviews current developments in both research and technology, and indicates the areas where this new class of catalysts has gained acceptance within only a few years to become "state of the art". The review covers the classification of water-soluble ligands and their metal complexes to catalytic uses in the laboratory and industry, and special applications in biochemistry.

2. Concept of Two-Phase Catalysis

Under the simplified assumption that all starting materials E are in solution, three variations of the two-phase process of homogeneous catalysis can be considered (Fig. 3): In the simplest case the solubilities of the components E and of the catalyst K are so different that a perfect phase separation results (Figs. 2 and 3a). A workup step for the product P follows, depending on its properties and purity, and as a rule is a distillation. The technical desirable ideal would be a catalyst K which formed its own phase in which the components E and the products P are not in the least soluble (Fig. 2 and 3a). If the product P is partly dissolved in the catalyst phase, an extraction is necessary according to Figure 3b, and is performed with the phase of E (for example, petroleum) which is completely insoluble in K (for example, water). It is also possible that a two-phase system forms from an initially uniform phase during the reaction, because the product P is insoluble in the original medium of the catalyst (Fig. 3c). A phase separation in the skimmer enables continuous return of the catalyst to the reactor. Only when the products P are partly soluble in the catalytic medium K is a solvent extraction step (related to a distillative workup) necessary for the whole contents of the reactor (Fig. 3c).

The concept of two-phase catalysis was first realized industrially in the "*S*HELL *H*igher *O*lefins *P*rocess" (SHOP) designed by W. Keim et al.[2a-c] In this procedure ethylene is polymerized at 80–120 °C and 70–140 bar in a polar phase of 1,4-butanediol that also contains the organonickel catalyst to afford oligomers (mainly linear C_{4-20}-α-olefins).

Wolfgang A. Herrmann was born in 1948 in Kelheim/Donau (Bavaria). After studying chemistry (Diplom at the Technische Universität München) under E.O. Fischer (1971), he obtained his doctorate on a theme from early organometallic stereochemistry at the Universität Regensburg with Henri Brunner (1973). From 1975–1976 he pursued his research interests in the USA at Penn State University with P.S. Skell, and in 1978 completed his habilitation with a thesis on "Organometallic Syntheses with Diazoalkanes". He was appointed Professor at the Universities of Regensburg (1979) and full professor in Frankfurt (1982). In 1985 he accepted the chair at the Technische Universität München as successor to E.O. Fischer. His area of research is synthetic and catalytic chemistry, mainly in the field of organometallic chemistry. He is author of 350 original papers and holder of 30 patents, and has received many honours including the Karl Winnacker Fellowship (1979–1983), the Leibniz Award of the Deutsche Forschungsgemeinschaft (1986), the German/French Alexander von Humboldt Award (1988), the Otto Bayer Prize (1990), and the Max-Planck-Forschungspreis (1991). He is member of the Akademie der Wissenschaften und Literatur zu Mainz (1990) and Honorary Doctor of the University of Lyon, France (1990).



Christian W. Kohlpaintner was born in 1963 in Schloßberg, near Rosenheim (Bavaria), and began his study of chemistry at the Technische Universität München in 1984. In October 1989, he joined the research group of Prof. W.A. Herrmann. He completed his Diplom in March 1990 on new water-soluble phosphane ligands and catalysts, and received the Ph.D. students' Award from Hoechst AG. He completed his Ph.D. thesis in August 1992 following work on the Ruhrchemie/Rhône–Poulenc process, the two-phase hydroformylation process which is used on industrial scale. He then joined Hoechst AG and has worked in the Central Research Department at Frankfurt since the beginning of this year. He has coauthored 6 papers and holds 7 patents.

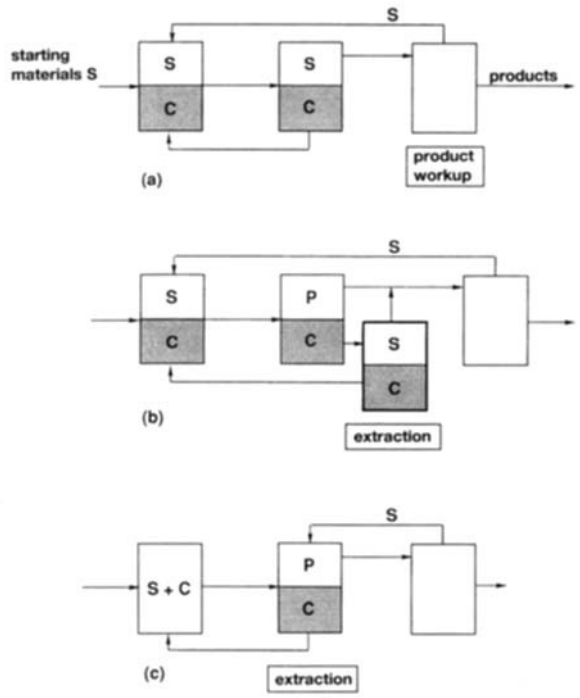


Fig. 3. Simplified flow diagram for two-phase catalysis: a) Product(s) P are completely insoluble in the medium that contains the catalyst C; b) product(s) P are soluble in the medium containing C; c) formation of the second phase occurs during catalytic process; cf. text.

The catalyst is formed from $[Ni(1,5\text{-cod})_2]$ and $(C_6H_5)_2PCH_2COOH$. The products separate as a second, transparent liquid phase above the 1,4-butanediol and can therefore be removed without difficulty. After this simple catalyst/product separation, catalyst traces are washed out of the olefin phase in the phase separator. The distillation fractions of the subsequent purification are either marketed directly or fed into the next two SHOP catalytic steps of isomerization and metathesis (cf. Fig. 4). This combination of homogeneous and heterogeneous catalytic steps now occupies a key position in olefin chemistry.

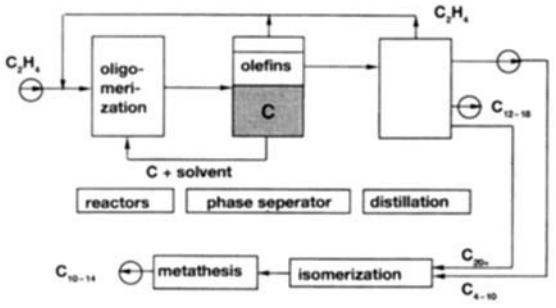

Fig. 4. Simplified flow diagram for the first catalytic stage of the *S*HELL *h*igher *o*lefins *p*rocess (SHOP). The subsequent steps of isomerization and metathesis are not given in detail.

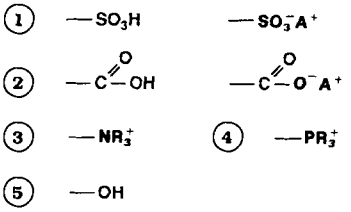
A process for the oligomerization of butadiene developed along the lines of this technology, which has been known since 1968, likewise employs 1,4-butanediol as polar phase. Thus, Keim et al.[2d, e] describe the dimerization of 1,3-butadiene to 1,3,7-octatriene with Pd/phosphane catalysts in acetonitrile with isooctane as extractant for the product. On addition of phthalic acid this reaction yields octylphthalates. Surprisingly, no further information on the use of highly polar solvents as the second phase is available in the literature, although in many cases miscibility gaps exist with saturated hydrocarbons, for example, methanol, acetonitrile, nitromethane, dimethylsulfoxide (DMSO), dimethylformamide (DMF), ethyleneglycol, and sulfolan. Nevertheless, reactions of these solvents with homogeneous catalysts are known, and therefore the influence of the second phase on the chemical and kinetic characteristics of the catalytic cycle must be taken into account. This treatise, however, aims to concentrate on water as catalytic medium.

3. Classes of Water-Soluble Phosphanes

Phosphanes can be converted into water-soluble derivatives by the introduction of polar groups, including sulfonate, carboxylate, ammonium, phosphonium, and hydroxyl groups.[3-7] A classification based on these functional groups seems expedient and is shown in Scheme 1. Other hydrophilic substituents, for example, phosphate groups, have so far been of little importance.



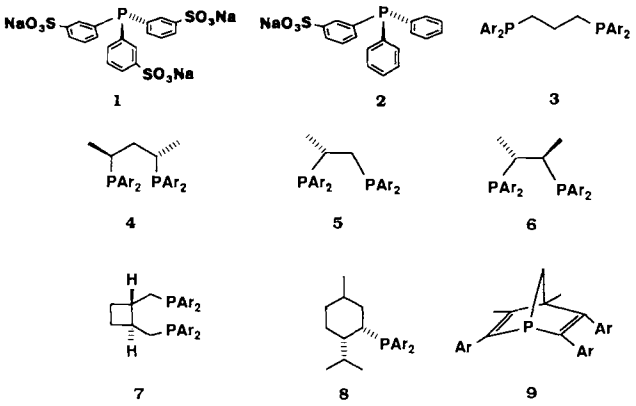
Scheme 1. Functional groups in water-soluble phosphanes (A^+ = cation).

3.1. Sulfonated Phosphanes

3.1.1. Water-Soluble Phosphanes by Direct Sulfonation

Owing to their diverse coordination chemistry, sulfonated phosphanes at present constitute the most widely used class of ligands in water-soluble metal complexes, especially in catalysis. Apart from the compound tppts (**1**), which is used in a rhodium catalyst for the production of butyraldehyde on an industrial scale, the monosulfonated derivative tppms (**2**) must be mentioned. Both these compounds (sodium salts) can be obtained by the sulfonation of triphenylphosphane with oleum and subsequent neutralization with NaOH. The technique of sulfonating water-insoluble ligand precursors can be applied to di- and polydentate, and also chiral phosphanes, for example, **3**–**9** (Scheme 2).[8-12] The sulfonate group mostly occupies the position *meta* to the phosphorus atom. Tris(*p*-fluorophenyl)phosphane can be sulfonated in the *meta* position.[13] The introduction of a sulfonate group by reaction with oleum is not limited to arylphosphanes. It can also be carried out with the tris(ω-phenylalkyl)-phosphanes $P[(CH_2)_n(C_6H_5)]_3$ ($n = 1$, 2, 3, and 6).[14] Here, the sulfonate groups, as expected, occupy the *para* and, to a lesser extent, the *ortho* positions.

The sulfoxylic derivative of 1,2-bis[di(*m*-sodium-sulfonatophenyl)phosphino]ethane (dppets) is now also available



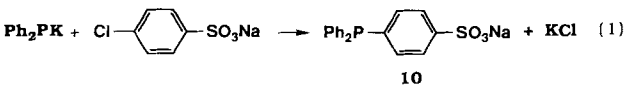
Scheme 2. Water-soluble phosphanes obtained by direct sulfonation with oleum (Ar = m-$C_6H_4SO_3Na$; for **9**, Ar = p-$C_6H_4SO_3Na$).

as a ligand for hydroformylation in the two-phase process since direct sulfonation of 1,2-bis(diphenylphosphino)-ethane(dppe) by means of oleum (20% SO_3) was successful. However, the Rh/dppets catalyst is not very active in hydroformylation.[67]

Because of the oxidizing effect of oleum, an appreciable fraction of the phosphane is converted into the phosphane oxide during the process of sulfonation, which complicates the purification of water-soluble phosphanes substantially (Section 4). Complete oxidation affords sulfonated phosphane oxides, which can be reduced by trichlorosilane after conversion to sulfonic esters.[15] The water-soluble ligands are available after hydrolysis of the ester. The use of this laborious method is meaningful only for phosphanes that are very sensitive to oxidation. It is not likely to increase in importance, however, since we discovered an efficient direct sulfonation method in which the formation of phosphane oxide is strongly inhibited.[16]

3.1.2. *Introduction of the Sulfonate Group during Synthesis of the Aryl Phosphane*

Sulfonate groups can be introduced during the course of phosphane synthesis. For example, as shown in Equation (1), the sodium salt of p-diphenylphosphinobenzenesulphonic acid (**10**) is formed from potassium diphenylphosphide and sodium p-chlorobenzenesulfonate.[17]

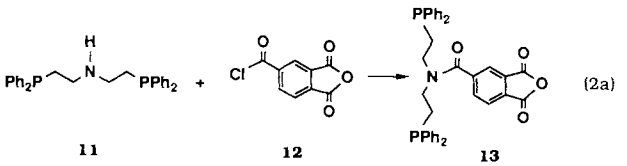


(1)

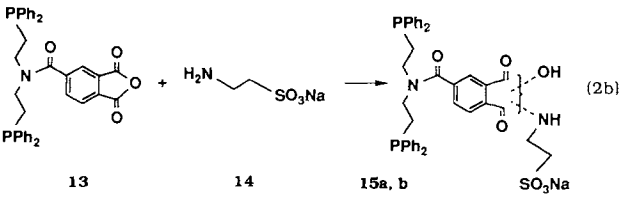
Water-soluble phosphanes of the type $R_{3-n}P$-$(p\text{-}C_6H_4SO_3K)_n$ (R = C_6H_5, 2-pyridyl, 3-pyridyl; $n = 1-3$) can be obtained by the reaction of potassium p-fluorobenzenesulfonate with PH_3 or primary or secondary phosphanes in the "superbasic" medium DMSO/KOH.[18] The unpleasant properties of PH_3 have to be mastered here, but otherwise this is a very powerful, general synthetic method. Surprisingly hydrolysis-resistant sulfonated phenylphosphites have recently been prepared.[19] The ammonium salts, in particular, are more water-stable than triphenylphosphite: whereas $P(OC_6H_5)_3$ is decomposed within 3 h, the hydrolysis of the derivative $P[p\text{-}OC_6H_4SO_3\{NH(i\text{-octyl})_3\}]_3$ is only complete after 24 h.

3.1.3. *Phosphanes with Peripheral Hydrophilic Functional Groups*

Functionalized phosphanes that carry sulfonic acid groups in one or more side chains are also known. The class of substances developed by Whitesides et al.[20] is represented by the example in Equations (2a) and (2b). The water-soluble phosphane **15** is obtained by acylation of bis(2-diphenylphosphinoethyl)amine (**11**) with the carboxylic chloride (**12**) of phthalic anhydride followed by reaction with sodium taurinate (**14**). This synthesis principle can be applied to many functionalized acid chlorides. The opening of the anhydride **13** by **14** is unspecific, so two constitutional isomers **15a** and **15b** are always obtained. The maximum attainable solubility in water is 0.3 mol L^{-1}. Further work on this class of compounds was carried out by Sinou et al.[21] The tertiary phosphane $(C_6H_5)_2PCH_2CH_2SO_3Na$ was prepared from sodium diphenylphosphide and the sodium salt of 2-bromoethylsulfonic acid.[22]

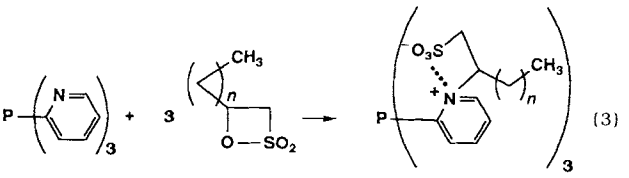


(2a)



(2b)

Another route to water-soluble phosphane ligands through ring opening of sultones was established by Oehme et al.[23,24] Fell et al. extended this concept to tris-(pyridyl)phosphanes, which can be prepared in water-soluble form by sulfoalkylation with 1,2-alkanesultones.[25] This procedure results in zwitterionic sulfobetaines with n = 0, 3, 5, 7, and 11 [Eq. (3)].

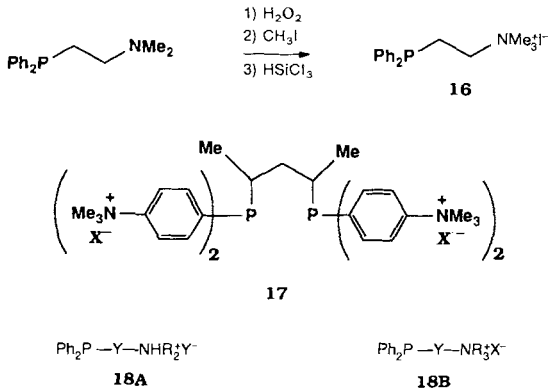


(3)

3.2. Phosphanes with Quaternized Aminoalkyl and Aminoaryl Groups

Water-soluble phosphanes can also result from the quaternization of the nitrogen atom of aminoalkyl and aminoaryl

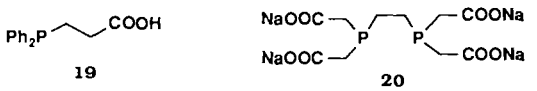
phosphanes. However, before the nitrogen atom can be alkylated, the (more reactive) phosphorus center has to be protected, either by oxidation or by coordination to a metal. Subsequent reduction or decomplexation, respectively, yields the desired phosphane ligands. The most important example of this class of substances is "amphos" (**16**), first synthesized by Baird et al.[26-28] Tóth et al.,[29] Peiffer et al.,[30] and Nagel et al.[31] were able to extend this synthesis principle to other phosphanes (Scheme 3).



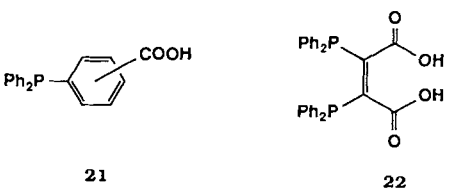
Scheme 3. Aminoalkyl- and aminoarylphosphanes (Y = $-CH_2CH_2-$, $-CH(CH_3)CH_2-$, $-CH_2CH(CH_3)CH_2-$; R = CH_3) made water-soluble by quaternization of the N atom.

3.3. Carboxylated Phosphanes

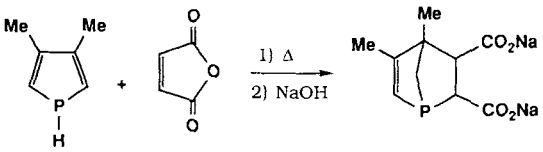
Phosphanes with carboxylic groups were some of the earliest investigated water-soluble phosphanes. The first example **19** was prepared by Mann et al.[32] in 1952 through cyanoethylation of diphenylphosphane with subsequent nitrile saponification. The development of the "carboxyalkylphosphanes" (phosphinocarboxylic acids) was carried out predominantly by the research groups of Rauhut, Issleib, and Podlahová.[33-38] The most important example is the phosphane analog of ethylenediaminetetraacetic acid (H_4edta).[39] It is obtained as an air-stable monohydrate of the tetrasodium salt (**20**). A new short review of the catalytic uses of the carboxyalkylphosphanes was published by Jegorov and Podlahová.[40]



The history of the phosphinobenzoic acids **21** goes back as far as 1945. Gilman and Brown synthesized *meta*- and *para*-diphenylphosphinobenzoic acid. Not till 1977 did Luckenbach and Lorenz[42] succeed in preparing the *ortho* isomer. Further work was done by Schumann et al.,[43] and Lindner reviewed the progress.[44] A newer report refers to a phosphorylated derivative **22** of maleic acid.[45]



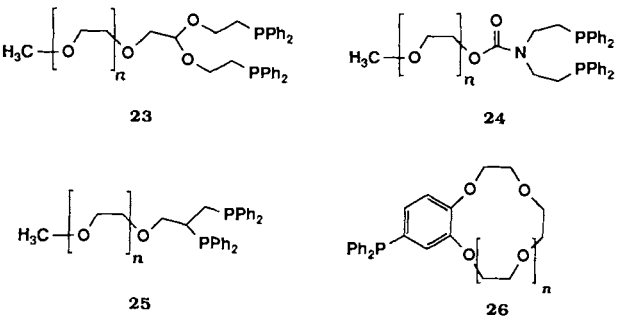
Phosphanorbornadienes with a carboxylic anhydride function can be obtained by [4 + 2] cycloaddition of 3,4-dimethylphosphol to maleic anhydride and subsequent rearrangement [Eq. (4)].[46] Alkaline hydrolysis yields the water-soluble carboxylates.



(4)

3.4. Phosphanes with Hydroxyalkyl and Polyether Substituents

By varying the length of the polyether chain of substituted phosphanes, the solubility can be deliberately adjusted. Bisphosphanes of the type **23** ($n = 5$) are insoluble in water. For $n \geq 16$ (e.g., $n = 42$), however, they are extremely soluble.[47] Other examples related to **23** are the class of compounds **24** ($n = 12$, 16, 110) and **25** ($n = 18$).[48,49] The number n gives the average "degree of polycondensation". Supplementary work was performed by Okano et al.,[50] who were the first to prepare phosphanes **26** substituted by crown ethers.[51,52]

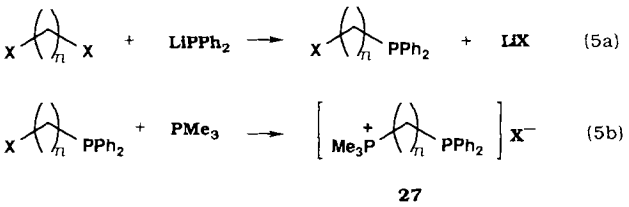


Investigations into water-soluble hydroxyalkyl-substituted phosphanes were carried out by Chatt et al. in 1973.[53] The phosphanes are significantly soluble in water only if they carry several hydroxyalkyl groups.[54] The water-soluble, commercially available trisubstituted phosphane $P(CH_2OH)_3$ is being tested in the form of metal complexes for catalytic properties in the addition of PH_3 to formaldehyde.[55] Homoleptic nickel, platinum, and palladium complexes of this phosphane were synthesized, and the elucidation of the structure of the palladium complex $[Pd\{P(CH_2OH)_3\}_4 \cdot CH_3OH]$ was carried out by single crystal X-ray structural analysis.[56]

Finally ethylene glycol derivatives react with sugar diacetonides to form monoallyl ethers that can be brominated at the double bond. Successive reaction with phenyl- and diphenylphosphanes yields hydrophilic phosphanes exhibiting a sugar function in the side chain.[57]

3.5. Phosphinoalkylphosphonium Salts

A new class of water-soluble phosphanes, named "phophos", was opened up in 1991 by Baird et al.[58] Monoquaternization of bisphosphanes yields phosphinoalkylphosphonium salts $[Ph_2P(CH_2)_nPMe_3]X$, where $n = 2$, 3, 6, or 10, and $X = NO_3^-$, Cl^-, or PF_6^-. The synthesis proceeds according to Equations (5a) and (5b). For increasing chain



(5a)

(5b)

length n, the more reactive bromine (or iodine) derivative must be used instead of the chloro compound. The halides are converted into the more stable nitrates and hexafluorophosphates by ion exchange or salt metathesis. The rhodium-catalyzed hydrogenation of 1-hexene gave the following activity series: [6]-phophos > [10]-phophos ≥ [3]-phophos > [2]-phophos, where the numbers correspond to the chain length n. The reasons for this particular series remain unclear. The X-ray structural analytical characterization of the rhodium complex [(nbd)RhCl([2]-phophos)]PF_6 (nbd = norbornadiene) and the attachment of the free ligands to cation exchangers[59] underline the rapidly growing interest in this class of compound.

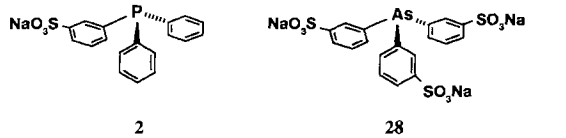
3.6. Other Ligands

As the present article concentrates on metal complexes and catalysts whose solubility in water depends on hydrophilic phosphane ligands, the following topics are not considered: phase-transfer reagents, saltlike metal catalysts such as $Pd(OAc)_2$ and Pd(edta), metal complexes of sulfonated 2,2'-bipyridine[60, 61] and alizarin,[62, 63] metal complexes of sulfonated phenanthroline derivatives,[64] water-soluble porphyrins, and cyclopentadienyl ligands.[65] A summary is given in Ref. [7].

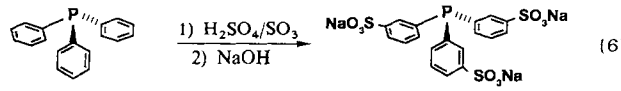
4. Purification of tppts and its Metal Complexes

Besides their catalytic uses, the characterization of the water-soluble complexes is of interest. Firstly, their bond strengths, complex geometry, and coordination properties, for example, can be compared with those of analogous water-insoluble complexes.[83] Secondly, well-defined water-soluble model complexes are essential for the understanding of the individual steps in the catalytic cycle of two-phase systems, and in kinetic studies. For instance, the Hieber base reaction could also be successfully applied to $[Co_2(CO)_6(tppts)_2]$, the water-soluble pendant of $[Co_2(CO)_6(PPh_3)_2]$, which is converted into the carbonyl metalate $Na[Co(CO)_3(tppts)]$ in aqueous NaOH at pH > 10.[67]

The first synthesis of tppts (**1**)[66] was carried out some years after Chatt's first reports on the monosulfonation of triphenylphosphane (tpp).[68] Although it was possible to obtain the triply sulfonated arsenic compound **28**, triphenylphosphane only gave the monosulfonated tppms (**2**). In 1975, E. G. Kuntz of Rhône-Poulenc Ind., Lyon, was able to prepare the sodium salt **1** of tppts according to Equation (6) by prolonging the reaction time, obtaining it in a purity adequate for industrial use on repeated precipitation from methanol/water mixtures.



2 28



(6)

1

The excellent solubility of tppts in water (about 1100 $g\,L^{-1}$)[69] and its related insolubility in almost all organic solvents prepared the way for its use in two-phase catalytic processes on an industrial scale. However, for a long time there was no access to analytically pure tppts and its metal complexes, mainly due to problems of separation. The phosphane oxides produced during sulfonation of tpp could not be completely removed for chemical reasons ($-SO_3H$ vs. $-P{=}O$), and the separation of the various sulfonated products also presented problems. Only recently has it been possible to avoid the oxidation of the phosphane during sulfonation with oleum.[16] Optimization of temperature, reaction time, and oleum concentration can also help to reduce the extent of the oxidation of easily oxidizable phosphanes.[1]

The use of "soap chromatography" for the purification of water-soluble mono- and bisphosphanes is only useful for analysis, but not for preparative work.[70, 71] Alone the poor availability of an exactly defined ligand complicates the preparation of analytically pure metal complexes. Difficulties are caused by slight oxidation of the phosphane by atmospheric oxygen in the aqueous phase. Analytically pure metal complexes of tppts could therefore not be obtained with conventional methods of purification.[72-74] The breakthrough came from a change to the use of gel permeation chromatography, adapted to the solution of this problem, with cyclodextrane as the stationary phases.[75-77] The experimental apparatus is shown in Figure 5.[78] This was used for the first convenient preparation of analytically pure metal complexes of tppts on laboratory scale. The metal complexes were obtained by direct synthesis, by ligand exchange, and through addition methods in which the water-soluble phosphane combines with a coordinatively unsaturated complex intermediate without displacing another ligand. With this purification method over 40 metal complexes of the ligand tppts were prepared analytically pure and characterized (Fig. 6).[77] Spectroscopic data for tppts and its oxide have been published.[82]

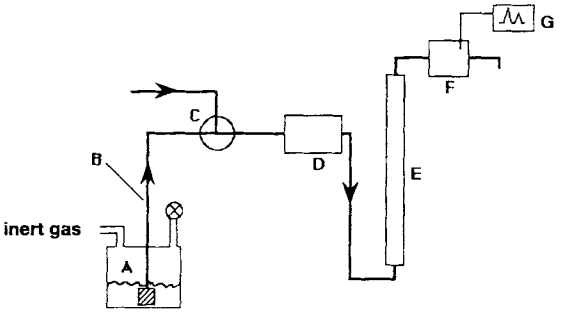


Fig. 5. Experimental equipment for gel permeation chromatography for the purification of metal complexes of tppts. The eluent water is pumped from the storage vessel A through the flexible poly(vinylidene fluoride) ("Viton", "Isoversinic") tube B, the peristaltic pump D, and the three-way valve C into the column E, which is filled with the gel. A UV/VIS detector or refractometer F fitted with a recorder G is connected to the exit of the chromatography column. As many water-soluble metal complexes and ligands absorb UV strongly, the fractions are sometimes difficult to separate with a UV detector. In these cases, a refractometer should be used, which, after compensation for water, detects very low amounts of substance. The chromatography is operated in "upside-down" mode as this gives the best separation results (no tailing). The stationary phases used are standard gels from LKB Pharmacia (Sephadex G15, G25, and G50) and Merck (Fractogel TSK HW-40F). A detailed description of the equipment and its function has been published [76, 78].

An example of the efficiency of gel permeation chromatography as a diagnostic method is the revision of the formula of the complex "[Ni(tppts)$_4$]",[69] which should be formulated as [Ni(tppts)$_3$].[77] The rhodium complexes, isolated as pure substances, were crucial in the elucidation of degradation steps occurring in the two-phase hydroformylation of propene catalyzed by Rh–tppts catalysts.[79] More recent investigations show that the purification method is not only successful for tppts, but is applicable to a wide range of water-soluble ligands and their metal complexes.[12]

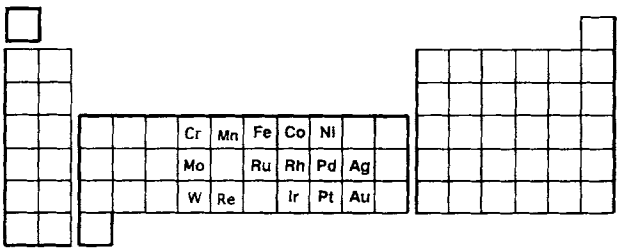

Fig. 6. Central atoms of tppts–metal complexes characterized to date.

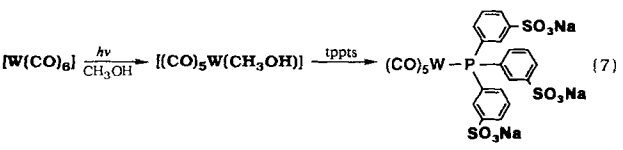
The X-ray characterization of a tppts–metal complex was recently carried out by Darensbourg et al.[80] UV irradiation of [W(CO)$_6$] in methanol, according to Equation (7), caused the labile methanol adduct of the W(CO)$_5$ intermediate to react with solid tppts to give the desired complex [W(CO)$_5$(tppts)]. After complexation of the sodium ions by kryptofix-[2.2.1], **29** crystallizes out of the solvent mixture THF/methoxyethanol/acetonitrile. Crystallization and structural characterization of tpp, sulfonated in the *para* position, is similarly performed.[18] Bartik et al. report the molecular structure of [Co$_2$(CO)$_6$(tppts)$_2$].[67]



29 (with Kryptofix [2.2.1])

The steric demand of the tppts ligand is about 20% greater than that of triphenylphosphane (tpp). The cone angle θ according to Tolman[81] is 170° for tppts (tpp: $\theta = 145°$), and is the same as that of tricyclohexylphosphane (PCy_3, Table 1). This explains the tendency of tppts to form complexes in which the transition metal has a lower coordination number.[75, 76] Thus, the compound "[HRh(tppts)$_4$]", unlike [HRh(tpp)$_4$], is unknown.[77] The linear relationship between ^{31}P NMR shifts and the cone angle in [L$_2$PdCl$_2$] complexes has been stressed.[14] For steric reasons, sulfonated bisphosphane chelate ligands, for example biphenyl derivatives, can more efficiently differentiate regio- and stereospecificity if the conformative mobility of the ligand is limited. This possibility for control of a reaction has so far hardly been recognized.

Table 1. Cone angles θ according to Tolman [81] of some phosphanes.

Phosphane ligand	θ [°]	Phosphane ligand	θ [°]

5. Hydrogenation with Water-Soluble Catalysts

5.1. Reduction of Achiral Unsaturated Substrates

The reduction of CC- and OC-unsaturated compounds was the first application of water-soluble catalysts.[84–87] Dror has stated that cosolvents are necessary for acceptable hydrogenation rates.[85] A large number of different catalysts and substrates have been studied (Table 2). The TOFs

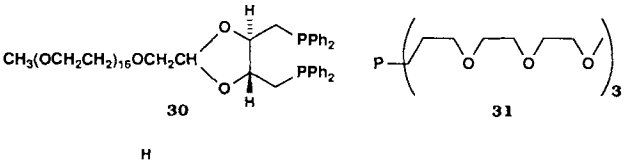
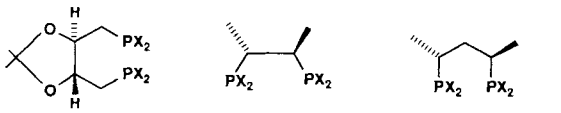
[a] $p(H_2) = 1$ bar. [b] TOF (*t*urnover *f*requency) defined as mol(product) mol(catalyst)$^{-1}$ h^{-1}. Note that TON (*t*urnover *n*umber) is defined differently: mol(product) mol(catalyst)$^{-1}$. [c] RC(O)COOH and RCH=CHCOOH. [d] See Section 5.2 for formulas. [e] Sodium formate as hydrogen source. [f] $p(H_2) = 20$–50 bar.

(*turnover frequencies*—definition in Table 2) are in general low, but can be increased by the use of cosolvents such as methanol or ethanol. The rates are limited mainly by the low solubility of the unsaturated substrate in the aqueous solution of the catalyst. However, the question where the reaction takes place—phase boundary, organic phase, or aqueous phase—has hardly been investigated and is still unclear. From the comparison of the catalysis results with $[RuHCl(tpp)_3]$ (homogeneous) and $[RuHCl(tppms)_3]$ (two phases), Wilkinson concludes that the hydrogenation of unsaturated substrates in the two-phase system proceeds considerably more slowly. The low rate of hydrogenation is due to the necessary diffusion of the hydrogen to the alkene/water interface. In this way, the isomerization, which is the substantially slower reaction, can compete with the hydrogenation. However, the hydrolytic cleavage of water-soluble ligands, for example by cleavage of the dioxolan ring in PGE-17-DIOP (**30**), does not support the low reaction rates,[47] as the reduction in reactivity applies to all water-soluble catalysts.

New work by Rhône–Poulenc Ind. with ruthenium and rhodium tppts complexes shows that hydrogenation in simple two-phase systems (aqueous/organic) is possible without cosolvents.[88, 89]



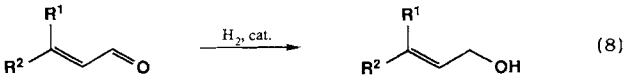
30 **31**



32 **33** **17**

$X = [p\text{-}C_6H_4(NHMe_2)]^+, [p\text{-}C_6H_4(NMe_3)]^+$

One valuable application is the selective reduction of α,β-unsaturated aldehydes to unsaturated alcohols according to Equation (8).[89]



(8)

A catalyst formed from $RuCl_3$/tppts reduces 3-methyl-2-butenal to 3-methyl-2-buten-1-ol ("prenol") with 96% selectivity ($R^1 = R^2 = CH_3$) and 84–99% conversion. Other CC-unsaturated aldehydes are also efficiently reduced (selectivity ≥ 97%). Analogous iridium complexes are less active. The selectivity of ruthenium is the reverse of that observed with the Rh–tppts system, as in this case the C–C double bond in the α-position is reduced. Under 20–40 bar (2–4 MPa) pressure of hydrogen, the selectivity is >95% at 30–80 °C (conversions are mostly around 90%).

Sodium and ammonium formates are also suitable as hydride donors for the hydrogenation of α,β-unsaturated and aromatic aldehydes with water-soluble Ru complexes.[90, 91] With $[RuCl_2(tppms)_2]$, both the catalyst and the formate are in the aqueous phase; the phase-transfer problem associated with catalysts not soluble in water and aqueous formate solutions does not arise.[92] Aromatic aldehydes can be almost quantitatively hydrogenated, with the exception of aromatic aldehydes bearing in the *ortho* position substituents that can coordinate (e.g., 2-hydroxy-1-naphthaldehyde or 2-hydroxybenzaldehyde). On the whole, hydride donors such as formates in a homogeneous phase constitute an interesting situation that deserves further investigation, even though other authors[88, 89] are of the opinion that, due to their basic properties, the carbonates formed from the formates deactivate the catalysts more strongly than hydrogen, which is not associated with by-products.

5.2. Reduction of Prochiral Substrates

The enantioselective hydrogenation of prochiral substrates has been thoroughly investigated. Here, too, the reaction rates are lower than with homogeneous systems. By using chiral water-soluble Rh-catalysts, prochiral α-acetamidoacrylic esters (**36**; $R^1 = R^4 = H$; $R^2 = NHCOCH_3$; $R^3 = H, CH_3$) and α-acetamidocinnamic esters (**34**; $R^1 = H, CH_3, Na$; $R^2 = CH_3, C_6H_5$) are reduced in up to 91% *ee* (Table 3) and prochiral imines of the type **37** in 94% *ee*.[97, 98] However, the optical yields obtainable with the majority of substrates **34**–**36** are still unsatisfactory.

Table 3. Enantioselective hydrogenation of prochiral substrates with water-soluble catalysts [a].

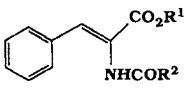
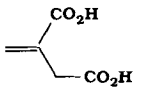
[a] $p(H_2) = 1$–30 bar. Catalysts prepared from Rh^I and Rh^{III}. [b] For definition of turnover frequency see Table 2. [c] Mono- and disulfonated derivatives. [d] **de** [%] = diastereomeric excess.

Selectivities are influenced by water content and H_2 partial pressure. If the reduction is carried out in solvent mixtures (e.g., $EtOH/H_2O$), an increase in water content reduces stereoselectivity.[49, 99] Increase in pressure can in extreme cases even reverse the selectivity.[100]

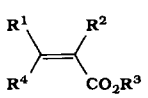
An explanation for the poor optical yields in aqueous media is provided by the reaction mechanism. According to



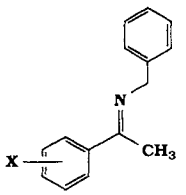
34



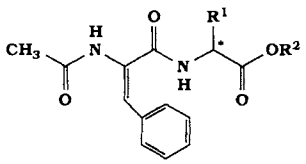
35



36

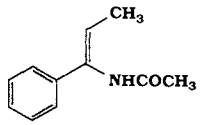


37 (X = H, OMe, Cl)



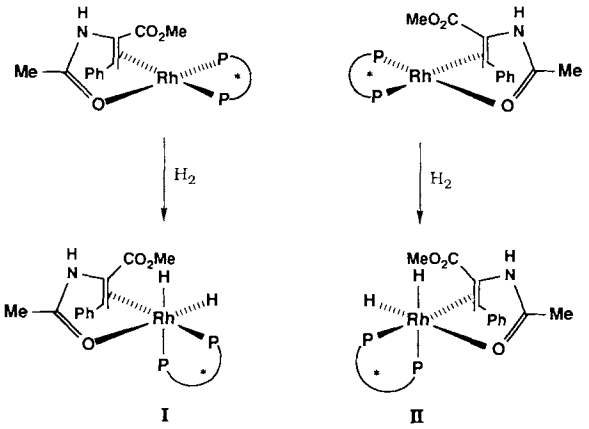
38

39 (X = Cl, $OC(O)CH_3$)



40

Scheme 4, the chiral catalyst forms diastereomeric adducts with the prochiral substrate, and these then undergo irreversible oxidative H_2 addition. According to Halpern, this step decides the enantioselection.[101] The two possible adducts react with hydrogen at rates differing by a factor of 1000. The existence of the catalyst–substrate adduct in aqueous solution has been proved.[9] The energy content of the dihydrido species **I** and **II** can be influenced by solvation. If the energy difference is very small, only a small enantiomeric excess is achievable. Amrani and Sinou have therefore postulated a small ΔE for the solvent water and a concomitant low optical yield.[49]



I II

Scheme 4. Oxidative H_2 addition (according to Halpern [101]) to diastereomeric catalyst–substrate adducts. All complex species are positively charged.

In a later study, a linear relationship between lg(% S/% R) and the "solvophobicity parameter" S_p is demonstrated.[99] It indicates the change in the free energy of formation ΔG_s for the transfer of a hydrocarbon from the gas phase into a given solvent.[102] Upper and lower limits are $S_p = 1$ (water) and $S_p = 0$ (hexadecane). A series of experiments with hydrophilic Rh complexes in solvent mixtures has shown that, with increasing S_p, the enantioselectivity lg(% S/% R) decreases linearly. The close relationship between stereoselectivity and the composition of the alcohol/water mixture used strongly suggests that the "two-phase hydrogenation" takes place in the polar phase and not at the phase boundary.

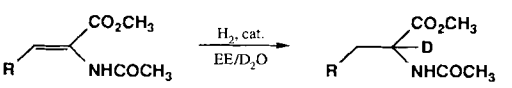
Sinou et al. and de Vries et al. have reported another parameter that influences enantioselectivity.[97, 98] In the reduction of prochiral imines **37** with Rh complexes of mono- or disulfonated (2*S*,4*S*)-bdpp [bdpp = 2,4-bis(diphenylphosphino)pentane], the optical yield is greater than 92% for monosulfonated ligands and only 2% for disulfonated ligands! Also, the reaction rate for the monosulfonated phosphane is many times greater. The catalytic activity of water-soluble phosphanes is apparently "tunable" by the degree of sulfonation. No explanation is yet available, and the influence of electronic and conformational effects must still be elucidated. Interestingly, the hydrolysis of imines to amines and ketones plays a subordinate role, so the imine reduction can proceed chemoselectively.

In the reduction of dehydropeptides **38** with water-soluble chiral Rh complexes of the chelating phosphanes **4**, **6**, and **7**, the diastereomeric excess (% *de*) is strongly dependent on the absolute configuration of the substrate.[103] With the tetrasulfonated bisphosphane [(*S*,*S*)-bdpp, **4**] a *de* value of only 10% can be achieved for a dehydropeptide of an *R*-configurated amino acid (Ac-Δ-Phe-(*R*)-Ala-OCH_3), but for the same peptide with an *S*-amino acid (Ac-Δ-Phe-(*S*)-Ala-OCH_3), the *de* value is as high as 72%. However, a higher diastereomeric excess for *S*-dehydropeptides is not a general feature, as, for the tetrasulfonated (*S*,*S*)-cbd (cbd = "cyclobutanediop", **7**), exactly the opposite result was obtained (higher *de* from *R*-dehydropeptide).

The choice of the reducing agent for the hydrogenation does not influence the stereoselectivity.[104] Formates of ammonium, potassium, and sodium give very similar results to molecular hydrogen. The cation has a small effect, although it is reported that the highest reaction rates and selectivities are observed with ammonium formate. This small salt effect is in contrast with the results of Basset et al., who have established a strong dependence of the reduction rate on the salt concentration.[96, 105] The addition of salts produces higher activities than in homogeneous systems for the reduction of propionaldehyde with water-soluble Ru complexes.

The fact that water is not only a solvent, but also has a chemical effect on reductions in two-phase systems is shown by the Rh-catalyzed hydrogenation of α-acetamidocinnamic ester in ethyl acetate/D_2O. Depending on the phosphane ligands used, 75% deuterium is incorporated in the reduced product.[111] The deuteration takes place selectively according to Equation (9) in the α position to the acetamido and ester function. Multiple deuteration does not occur.

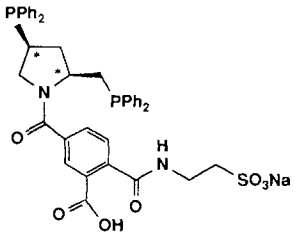
Due to their negatively charged substituents, sulfonated phosphanes can compete with the unsaturated substrate at



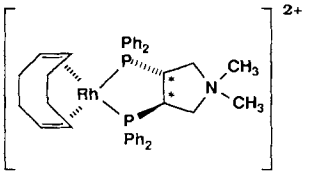
(9)

R = H, Ph
cat. = [{ Rh(cod)Cl }$_2$]/ligand; EE = $CH_3CO_2C_2H_5$

the electrophilic metal center. Various research groups have therefore synthesized cationic water-soluble Rh complexes, and have investigated their behavior in enantioselective hydrogenation. Nagel et al. reported that the cationic complex **42**[31] shows slightly improved enantioselectivity and is a factor of over 100 more reactive than a similar catalyst based on a ligand of type **41**.[21] The nucleophilic carboxylate and sulfonate groups of **41** are regarded as being responsible for the reduction in activity.[31] However, the lack of similarity in reaction conditions casts doubt on the validity of these experiments.



41



42

The substitution pattern of the P-bonded phenyl residue has little influence on the stereoselectivity. Ligands of the type **17**, **32**, and **33**, which have their hydrophilic groups *para* to the phosphorus atom, were investigated by Tóth et al.[29, 106] In the hydrogenation of dehydrocinnamic acid derivatives, the Rh-catalysts based on the cationic bisphosphanes show almost the same selectivity as those with sulfonated ligands. Chiral phosphanes sulfonated in the *para* position would unequivocally clarify the influence of the substitution pattern on the stereoselectivity, but these compounds are not yet available. The *para* isomer of tppts,[18] which has very recently been prepared and characterized by X-ray structural analysis, could serve as the starting point for the synthesis of such bisphosphanes.

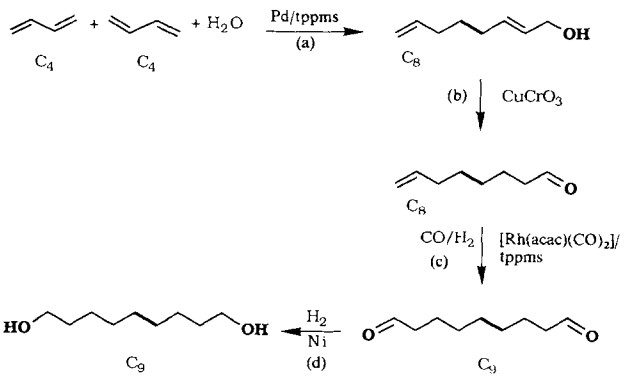
The principal advantages of water-soluble catalysts—ease of separation of the product from the catalyst and long term stability—have been demonstrated in all investigations. The aqueous solutions of used catalysts show the same activity and selectivity on reuse after they have been recovered from the product phase. The industrial outlook for continuous hydrogenation processes based on water-soluble catalysts therefore seems to be full of promise.

6. C–C Coupling with Water-Soluble Catalysts

The reported CC coupling reactions include diene hydrodimerization, alkylation of CH-acidic compounds, addition reactions to the CC double bonds (hydroamination and hydroformylation), and carbonylation of allylic systems.

6.1. Hydrodimerization

The Kuraray Company in Japan is said to operate a pilot plant for the hydrodimerization of 1,3-butadiene according to Scheme 5, in which step (a) is a two-phase system with a Pd/tppms catalyst. The primary product is then isomerized

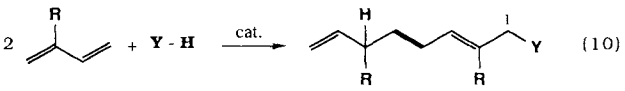


Scheme 5. The new Kuraray process for the production of 1,9-nonanediol by hydrodimerization of 1,3-butadiene.

to the C_8 aldehyde with a copper chromite heterogeneous catalyst, and the resulting product hydroformylated in a third process step (c), once again with a two-phase catalyst. The resulting ω,ω'-dialdehyde is extracted, probably with cyclohexane, and hydrogenated over molybdenum-doped Raney nickel to yield 1,9-nonanediol (step d).[1108]

6.2. Alkylation of CH-Acidic Compounds

The telomerization of dienes has been extensively investigated by Rhône-Poulenc Industries.[109] Functionalized 1,6-octadienes can be obtained from butadiene or isoprene and acidic compounds according to Equation (10). A catalyst obtained from Pd^{2+}/tppts (1/4) is very effective, while rhodium and platinum instead of palladium give poor yields. With optimized process operation, the reaction has a regioselectivity of 95/5 (Y functionality in position 1 or position 3).

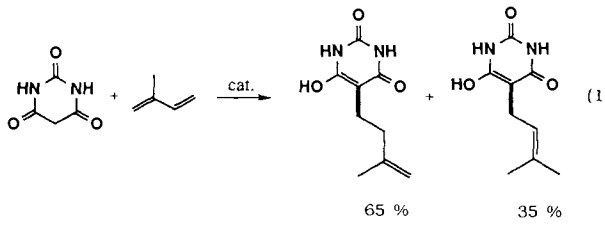


(10)

R = H, Me
Y = MeO, EtO, PhO, HO, MeCOO, Me_2N

The telomerization of dienes with N-quaternized aminophosphanes as the catalyst ligands was recently reinvestigated.[30] When $[Pd(OAc)_2]$ and **18** (fourfold excess) are used together, a water-soluble catalyst is obtained that is more active but less selective than its tppts analog (TOF = 5–26). The reaction is chemoselective; the yield of side products (e.g., 1,3,7-octatriene) is insignificant. Recycling and reuse of the catalyst are possible with only little loss of activity.

The isoprenylation of CH-acidic compounds is a similar type of reaction.[110–112] In particular, 1,3-dicarbonyl compounds can be alkylated with Rh–tppts catalysts in two-phase systems. An example is the isoprenylation of barbituric acid according to Equation (11). The two potential isomers are not always produced. When Pd catalysts are used, the terminal double bond is shifted to an inner location, as in the isomerization of Isofeprazon to Feprazon. The



(11)

activated methylene compound adds remarkably regioselectively, and the attack takes place exclusively at the monosubstituted double bond. A twofold alkylation of the 1,3-dicarbonyl compound, only possible under drastic conditions, is not observed if conditions are normal (25 °C, 48 h). The ease of recovery and reuse of the catalyst—without loss of activity—have been convincingly demonstrated.

CC couplings can also be carried out with tppms-containing Pd catalysts.[113] The compound **43** catalyzes, in yields

$[Pd(tppms)_3]\cdot 3H_2O$ **43**

which can be greater than 99%, the arylation (biphenyl synthesis), acetylation, phosphorylation, and vinylation (Heck reaction) of halogenated arenes and heteroarenes. In solution, a rapid phosphane exchange is observed which presumably takes place through the intermediacy of a PdL_4 species. However, there is no direct proof of the existence of a complex containing tetracoordinated palladium. Compound **43** can be used for diverse functionalities, including those in unprotected nucleotides and amino acids. The good results of the Heck reaction and the cross-coupling of terminal alkynes with vinyl and aryl iodides are confirmed in an independent study.[114] Although the active catalytic species was not characterized in this case, it must nevertheless be **43**.

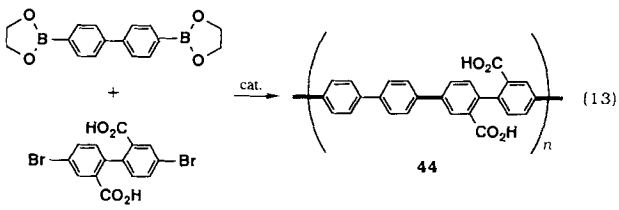
Water-soluble Pd compounds catalyze allyl substitutions according to Equation (12) in yields up to 95%. With acetates and carbonates of cinnamyl alcohol (R = C_6H_5), the *E* enantiomers are selectively formed.[114]

(12)

R = H, C_6H_5, CH_2OH; R′ = $CO_2C_2H_5$, $COCH_3$
Nu = $CH(COCH_3)_2$, $SO_2C_6H_4$-*p*-CH_3, $N(CH_2CH_2)_2O$ (morpholino)

The ring opening of 3,4-epoxy-1-butene by ethyl acetoacetate to give 2-acetyl-6-hydroxy-4-hexenoic acid proceeds in greater than 80% yield (*E*/*Z* = 85/15).[115] Allyl halides can be directly carbonylated by using water-soluble Pd catalysts.[116, 117] Under normal CO pressure and in the presence of sodium hydroxide or alkoxide, the β,γ-unsaturated acids or esters are obtained. Benzyl chloride can also be carbonylated to phenylacetic acid in this way.[118] The yields vary between 4 and 93%, depending on the substrate. With allyl halides, only *E* isomers are formed.

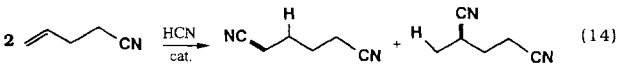
The preparation of poly(*para*-phenylene) derivatives using "Pd/tppms" is currently in progress.[119] Starting from 1,1′-biphenyl-4,4′-bis(ethylenedioxyborane) and 4,4′-dibromo-1,1′-biphenyl-2,2′-dicarbonic acid, the water-soluble polymer **44** with an average molecular weight of 50000 can be obtained according to Equation (13) (C–C coupling with elimination of the end groups $-\overline{B(OCH_2CH_2O)}$ and –Br). The polymerization process is strongly favored by the solubilities of the monomer, the growing polymer, and the catalyst. Polymerization reactions could therefore open up a new area of applications for water-soluble metal complexes that has so far been virtually ignored. Incidently, water should also be an excellent solvent for radical processes, because the OH bond enthalpy is extremely high (120 kcal mol^{-1}).[120]



(13)

6.3. Addition of Hydrogen Cyanide

The nickel-catalyzed addition of hydrogen cyanide to CC multiple bonds is reported in a patent.[121] Adipic acid and methylglutaronitrile are obtained from 3-pentenenitrile according to Equation (14). The linear product is formed preferentially (> 10/1). In 1990, it was recognized that the correct formula of the catalyst "$[Ni(tppts)_4]$" is in fact $[Ni(tppts)_3]$.[77]



(14)

6.4. Hydroformylation

The "Oxo synthesis" (hydroformylation), which was discovered by Otto Roelen (1897–1993)[122] in 1938 at the Ruhrchemie AG, is one of the most important metal-catalyzed alkene reactions.[123] World capacity for Oxo products is about 5.6 million tons per annum (excluding 2-ethylhexanol, the most important product of a subsequent reaction). The importance of water-soluble catalysts in this type of process may be deduced from the increase in capacity (Fig. 7)[123–130] and improvement in the performance parameters of the catalytic process (Table 4). After the discovery of tppts at Rhône–Poulenc Ind. in Lyon in 1975, its implementation on an industrial scale was developed by the Ruhrchemie AG (now Hoechst AG) in Oberhausen.

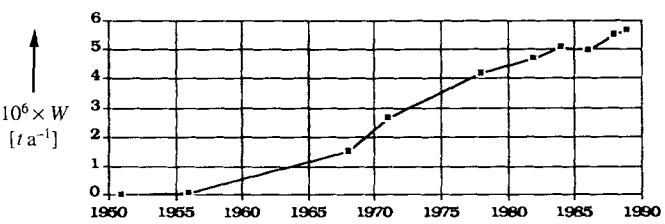


Fig. 7. Growth of worldwide Oxo capacities *W* (in million tons per annum). The sudden increase in 1968 coincides with the introduction of the Union Carbide Process (Rh catalysis). Up to that time, hydroformylation was performed with cobalt catalysts only.

Table 4. Technical parameters of the Oxo synthesis.

Catalyst parameters	Catalyst $[HCo(CO)_4]$	$[HCo(CO)_3PR_3]$ R = n-C_4H_9	$[HRh(CO)(PR_3)_3]$ R = C_6H_5	R = m-$C_6H_4SO_3Na$
p [bar]	200–350	50–100	15–20	10–100
T [°C]	110–180	160–200	85–115	50–130
n/iso ratio [a]	80/20	88/12	92/8	95/5 [b]
selectivity	medium	low	high	very high
hydrogenation activity	medium	high	low	low

[a] Depending on the position of the formyl group at the terminal or internal C of the double bond, a linear (n) or branched (iso) aldehyde arises. The desired products are linear. [b] Variants with n/iso = 99/1 are now also known.

6.4.1. Ruhrchemie/Rhône–Poulenc Process

The first patents were applied for in September 1982 for the synthesis of aldehydes,[131] the recovery of the rhodium,[132] and the production of sufficiently pure sulfonated phosphanes.[133] In particular, the elegant extraction–reextraction process[133, 134] for the tonnage production of tppts paved the way for the industrial operation of two-phase hydroformylation. The patent applications that were published afterwards describe further improvements: process optimization,[135–137] recovery of the rhodium catalyst,[138–140] reactivation of catalyst,[208] synthesis of water-soluble triarylphosphanes,[16, 133, 134] and synthesis of new ligands and metal coordination compounds for catalytic two-phase systems.[13, 141–144] These patent applications cannot be treated individually in this review, but the fact that there are so many of them bears out the extent of the research activity in this field.[204]

The Ruhrchemie/Rhône–Poulenc process went into operation in 1984. Two plants now produce 300 000 tons per annum of butyraldehyde. Depending on the quality of the propene starting material, 99 % conversion and a crude aldehyde product with an n/iso ratio (for explanation, see footnote to Table 4) of approximately 95/5 is attained. Both the hydrogenation of the alkene and the formation of condensation products by aldolization are insignificant. The loss of rhodium in the organic phase, despite the high price of this metal, is a "quantité negligeable".[145, 146] Catalysts that generate selectivities of $n/iso \geq 99/1$ have recently been discovered.

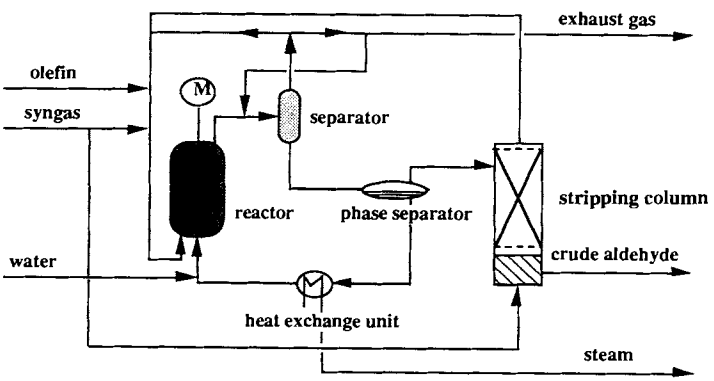

Fig. 8. Flow diagram of the Ruhrchemie/Rhône–Poulenc process for the production of n-butyraldehyde, in operation at the Ruhrchemie works of Hoechst AG (Oberhausen) [146, 151]. M = stirring device.

A flow diagram of the process is shown in Figure 8. The separation of the catalyst/product mixture is simply carried out in a phase separator, from which the aqueous catalytic solution flows back to the reactor, while the organic product continues to the stripping column. An optimized heat recovery system ensures a favorable overall energy balance for this modern process.

6.4.2. New Catalysts

The development of even better water-soluble phosphanes for two-phase hydroformylation has become a necessity in recent years. The international downward pressure on the prices of Oxo products, mainly caused by the cheap products from the "developing countries", prescribes the continuous improvement of the existing process. For the Ruhrchemie/Rhône–Poulenc process, this implies the synthesis of new, more active catalysts. To name only two examples, the sulfonated phosphanes bisbis (**45**) and norbos (**9**) enabled Rh catalysts to be produced with superior properties to those of the standard Rh–tppts system (see Fig. 9).[1, 143, 144] Jumps

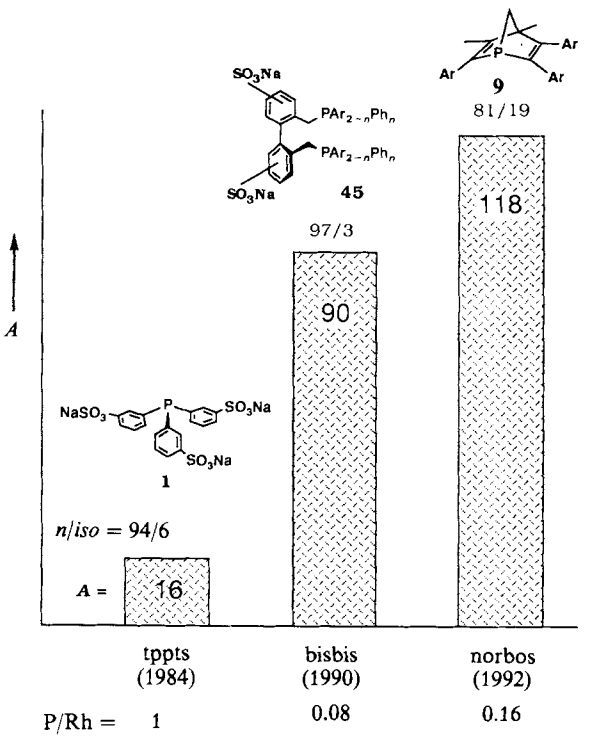

Fig. 9. Results of catalysis with water-soluble rhodium–phosphane complexes (activity A is shown on a linear scale). Activity A = n(aldehyde)n(Rh)$^{-1}$ h^{-1}, Ar = $-C_6H_4SO_3Na$, P/Rh ratios are normalized.

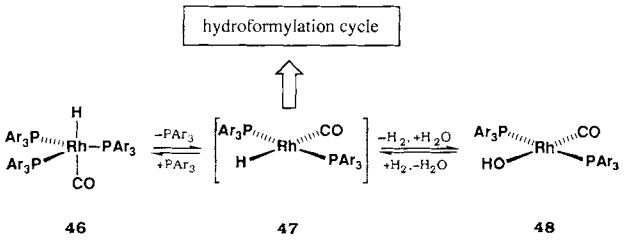
in activity from 16 to 90 (bisbis) or to 118 (norbos) indicate the currently attainable activity levels. The n/iso ratios in the propene hydroformylation reaction fall below 95/5 in the case of norbos only. The large phosphane excess normally required in the Rh/tppts system and many other standard catalysts (e.g. Rh/tpp) can be reduced by more than an order of magnitude without causing problems of long-term stability. Thus, the rhodium–norbos system is the most active water-soluble hydroformylation catalyst known so far.

Losses in selectivity are compensated for by the similar commercial values of *n*- and *iso*-butyraldehyde. Moreover, the ready accessibility of the norbos systems is attractive, because they allow a systematic variation of substituents.[12] Phosphane chelating ligands are attracting more attention for future industrial use, because the special phosphites of Union Carbide show extremely high activities and selectivities in *homogeneously catalyzed* hydroformylation.[148–150] However, these ligands are readily hydrolyzed, and therefore cannot be considered for aqueous systems, which was recently clearly shown in the case of sulfonated phosphites.[19] The previously mentioned sulfonated tris(ω-phenylalkyl)phosphanes P[$(CH_2)_n$*p*-$C_6H_4SO_3Na$]$_3$ ($n = 1-3$ and 6)[14] are more active in rhodium-catalyzed hydroformylation of 1-octene at low P/Rh ratios (2/1) than an analogous Rh–tppts system. In this case, the highest conversion was observed for $n = 6$. Interestingly, higher P/Rh ratios lead to a decrease in catalytic activity.[203]

Other than in the two-phase catalysis employing Rh/dppets,[67] there is a successful example of homogeneous catalysis in which the nonsulfonated parent ligand 1,2-bis(diphenylphosphino)ethane (dppe) is used. Substrates like 1,3-butadiene undergo hydroformylation to the C5-aldehyde with a TOF of 250.[205] The analogous Rh/tpp catalyst has hardly detectable activities under otherwise identical reaction conditions. An application in aqueous medium by sulfonation of the tpp ligand right be interesting.

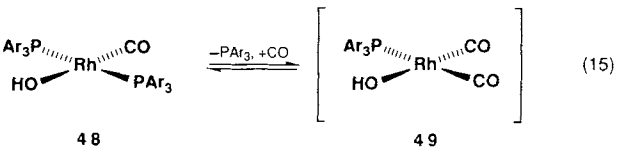
6.4.3. Catalyst Deactivation Mechanisms

Although the standard Rh^I/tppts system has extremely good long-term stability, a slight loss of activity occurs after several years' use. The catalyst deactivation mechanism has recently been clarified in detail (Scheme 6).[78, 79, 151]



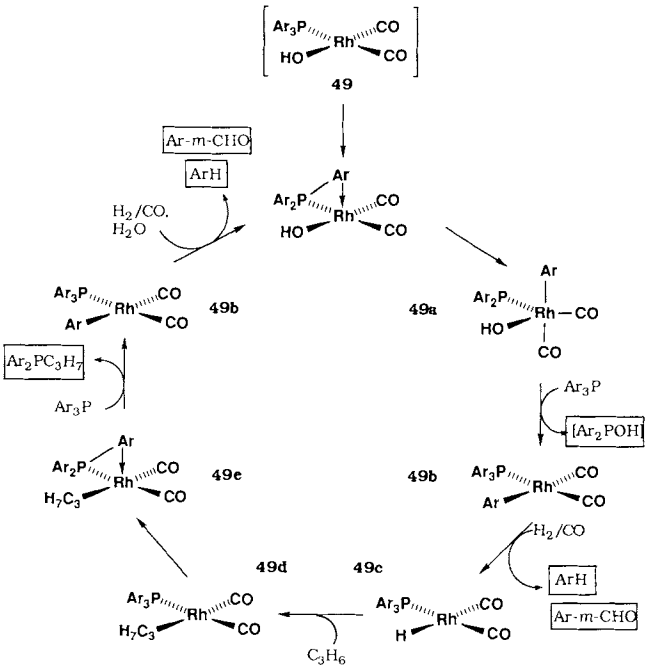
Scheme 6.

Compound **46**, which is strictly only a "precatalyst", dissociates to the active 16e species **47**. This is supported by a high-pressure NMR study by Horváth et al.,[152] which shows that **46** itself does not take up a further CO molecule from syngas, even at a pressure of 200 bar (20 MPa). The active species **47** initiates the hydroformylation cycle, which is not considered further here. The hydroxo complex **48**, which has been isolated and characterized, is formed in water under hydroformylation conditions (H_2/CO) and can be reversibly converted into **46**. The equilibrium lies almost completely on the side of **46**; accordingly, during hydroformylation there is no danger of the transformation of **46** into the catalytically inactive hydroxo complex **48**. According to Equation (15), carbon monoxide displaces a phosphane ligand from **48**. The deactivation mechanism starts with the



(15)

formation of the intermediate **49** (not isolable), as shown in Scheme 7.



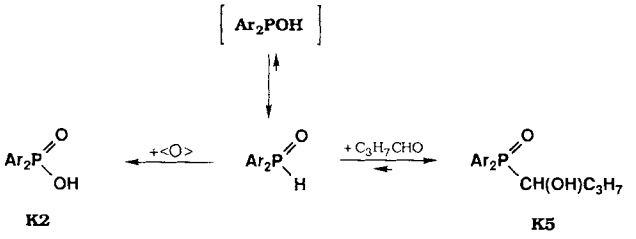
Scheme 7. Deactivation mechanism of Rh^I–tppts catalyst in the Ruhrchemie/Rhône–Poulenc process (framed products have been isolated and characterized; see text and ref. [78, 151]).

The cleavage of the P–C bond in the phosphane, which deactivates the catalyst, is caused by the oxidative addition of tppts to Rh^I with the formation of **49a**, a Rh^{III} species with a five-coordinate central atom. The cleavage of the P–C bond, combined with an aryl rearrangement, was previously recognized by Garrou et al. as the origin of the deactivation of phosphane-modified catalysts.[153] The coordination of a further molecule of tppts causes the reductive elimination of bis(*meta*-sulfophenyl)phosphinous acid as the tautomer Ar_2POH. Benzenesulfonic acid (ArH) and *meta*-formylbenzenesulfonic acid (Ar-*m*-CHO) are formed from the Rh^I intermediate compound **49b** under the given reaction conditions (and presence of syngas). Both these compounds have been detected in "exhausted" catalyst solutions.[78]

Species **49c**, which is formed by H_2 addition and product elimination, combines with propene to form the propyl complex **49d**. The later course of the reaction is determined by this intermediate stage. The insertion of CO would produce the acyl complex and finally the hydroformylation product butyraldehyde. The oxidative addition of another tppts ligand (→ **49e**), however, would mean that three products could arise from this cycle: 1) the phosphane, $Ar_2PC_3H_7$ (pdspp) by phosphido/propyl coupling; 2) benzenesulfonic acid (ArH); and 3) *meta*-formylbenzenesulfonic acid (Ar-*m*-CHO) from the intermediate compound **49b**.

The phosphane pdspp was isolated from used catalyst solutions ("contact" solutions). In an aqueous reaction medi-

um, the starting compound of the deactivation mechanism is then regenerated from **49b** under CO/H_2 pressure. The formation of *meta*-formylbenzenesulfonic acid in isolable quantities rules out the deactivation of the phosphane by *ortho*-metalation: as the formyl group is located at the position originally occupied by the phosphorus atom, the deactivation must be started off by an oxidative addition of the tppts ligand to Rh^I. Other workers confirm this observation for Rh–tpp complexes.[154–156] The subsequent fate of the reductively eliminated bis(*meta*-sulfophenyl)phosphinous acid Ar_2POH is shown in Scheme 8. For phosphinous acids,



Scheme 8. Formation of the main degradation products **K5** and **K2** from bis(*meta*-sulfophenyl)phosphinous acid (Ar = m-$C_6H_4SO_3Na$, <O> from H_2O).

$R_2P(O)H$, an equilibrium between the hydroxy species Ar_2POH and the phosphane oxide $Ar_2P(O)H$ form is postulated, and in fact $(CF_3)_2POH$ is the only hydroxy tautomer that has yet been isolated. For all weakly electron-withdrawing substituents R the phosphinous acid is present as phosphane oxide. Therefore, the reductive elimination of Ar_2POH is followed by rapid tautomerization to $Ar_2P(O)H$. This compound reacts with the butyraldehyde in solution to form **K5**, and is partially oxidized to phosphinic acid **K2**. Both products were isolated from catalyst solutions originating from the plant operation.

6.4.4. Further Concepts in Catalytic Hydroformylation

Other aspects of the use of water-soluble catalysts for hydroformylation include complexes with cationic ligands,[93, 157] binuclear rhodium–tppts complexes,[158–162] immobilization of water-soluble Rh complexes on ion exchangers,[163] polymers,[164, 165] cyclodextrins,[166] and micellar two-phase hydroformylation.[25]

Some Rh^I complexes of the cationic ligand amphos **16**, $[Ph_2PCH_2CH_2NMe_3]^+$, are efficient hydroformylation catalysts when in aqueous solution or immobilized on strongly acidic cation exchangers.[93, 157] Leaching of rhodium does not occur; nevertheless, the metal can be recovered by elution from the ion exchange resin with acids.[93] In contrast, the cobalt complex $[Co(CO)_3(amphos)]_2(PF_6)_2$ suffers from considerable metal leaching. Moreover, when it is in the liquid/liquid two-phase system or immobilized on the ion exchange resin, it is less active, and gives poor *n/iso* ratios.

Recently, immobilization of water-soluble metal complexes on solid supports has been investigated,[163–166] for example, $[HRh(CO)(tppts)_3]$ on the ion exchange resin Amberlyst A-26.[163] Unlike the SAP catalysts (Section 7), the catalyst-loaded resin can be prepared with no water content. Hence, the disadvantageous oxidation of tppts to the corresponding phosphane oxide by water and Rh^{III} should be avoidable. The tppts ligand binds to the carrier by *three* sulfonate groups; hence the greater stability of the tppts system relative to the amphos systems can be explained.

1-Tetradecene, 1-dodecene, and 1-octene are hydroformylated at 100 °C and 70 bar pressure with an *n/iso* ratio of 2.3–3.4/1. The yield of aldehyde is low (seldom greater than 50%), but the extent of isomerization is high and solvent-dependent (up to 42%). The thermal instability of the resin at temperatures above 100 °C limits its use. The surprising long-term stability of this group of catalysts is more encouraging. After multiple use of the resin-supported catalyst, productivity and selectivity hardly decrease (reduction of P/Rh ratio). Rhodium leaching has not been found. After 16 cycles (corresponding to TON = 15000!), the extent of phosphane oxidation was 80%, caused by moist and oxygen-containing substrates and solvents. The exceptionally long lifetime of this class of catalysts is promising.

Polymer-fixed Rh catalysts still have a long way to go before they become industrial materials. Drawbacks are leaching and thermal instability.[167] A poly(styrenedivinylbenzene) copolymer with hydrophilic $-CH_2P(C_6H_4SO_3H)_2$ groups was investigated in Rh^I-catalyzed propene hydroformylation.[164–165] With a metal loading of 3.4 wt% Rh and P/Rh = 8.7/1, the conversion rate is 3×10^5 mol(aldehyde) per g(Rh) per min after 4 h at 100 °C and 30 bar. The selectivity (*n/iso* = 1.2/1) is very low, but this is a promising opening for asymmetric (= enantioselective) variants of hydroformylation (see ref. [206]). Again, catalyst stability is favorable.

The use of longer chain alkenes in liquid/liquid two-phase systems is limited by the solubility of the substrate in the aqueous (catalytic) phase. Cyclodextrins, which have inner lipophilic cavities and hydrophilic surfaces, offer novel possibilities. As shown in Figure 10, α-cyclodextrin can bind one molecule of 1-hexene in its cavity, and thus transfer the alkene across the phase interface. The specific orientation of the alkene in the cyclodextrin favors the formation of the linear aldehyde.[166]

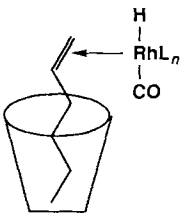


Fig. 10. Orientation and complexation of alkenes in individual cyclodextrin molecules.

The positive prognostication is not yet fulfilled with $[HRh(CO)(tppms)_3]$. By adding α-cyclodextrin, the aldehyde yield is reduced from 55% (without added dextrin) to 11%. The *n/iso* ratio, 7/3, is unaffected. The authors attribute this to hydrogen bonds between the hydroxyl groups of the α-cyclodextrin and the sulfonate groups of the tppts, which is said to hinder dissociation of a phosphane ligand and hence the coordination of the alkene. Nevertheless, modified cyclodextrins are expected to become important for the Oxo synthesis, because of their ability to cause steric orientation of substrates.[168]

Fell et al. first achieved the micellar two-phase hydroformylation of longer chain alkenes by the use of the sulfobetaine of tris(2-pyridyl)phosphane (see Eq. (3)).[125] The properties of these interfacially active compounds ($n = 0$, 3, 5, 7, 9, and 11) can be tuned. The phosphanes form complexes and promote dissolution. By suitable choice of n, they acquire surfactant properties, and, above a critical concentration, form micelles. The lipophilic alkenes can be trapped in the long alkyl groups of the micelles. The active Rh center is also inside the micelle as a result of the coordination to the phosphorus atom. For example, tetradecene can be hydroformylated, with a 79% yield of aldehyde (*n/iso* ratio $\approx 3/1$). The most suitable phosphane has a chain length n of 5. If $n > 5$, stable emulsions are formed and phase separation can become a problem. In no case is rhodium loss observed.

The binuclear rhodium complexes of the type $[Rh_2(\mu\text{-}SR)_2(CO)_2(tppts)_2]$ of Kalck et al. should also be mentioned.[158-162] They show the usual activity in the hydroformylation of 1-hexene, but unusually high selectivity (*n/iso* = 18/1). The hydroformylation can also be carried out without hydrogen, since the solvent water can function as the H_2 source through the water–gas shift reaction: $CO + H_2O \rightleftharpoons CO_2 + H_2$. 1-Hexene at pH = 4.8 can be converted into 1-heptanol with 75% yield (80 °C, $p(CO) =$ 8 bar, P/Rh = 6, 15 h, selectivity 95.8%). The use of water as a source of hydrogen makes this class of complexes especially interesting.

7. Supported Aqueous Phase Catalysts

The recent development of "*s*upported *a*queous *p*hase *c*atalysts" (SAP catalysts)[169, 170] began in 1989 with a publication in *Nature*.[171] By their work on SAP catalysts, Davis et al. opened the way to hydroformylate very hydrophobic alkenes such as oleyl alcohol, octene, or dicyclopentadiene with the water-soluble catalyst $[HRh(CO)(tppts)_3]$, using the principle sketched in Figure 11.

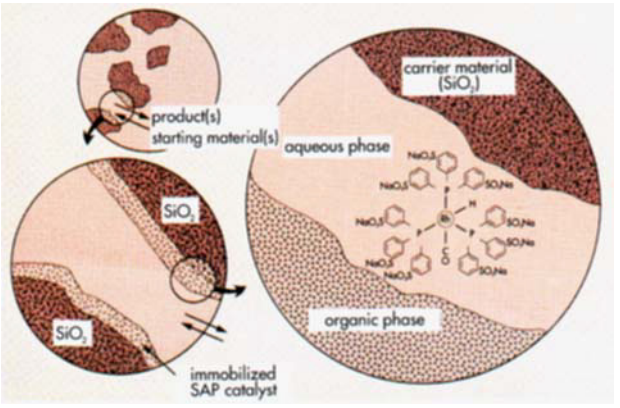

Fig. 11. Schematic diagram of a SAP catalyst according to ref. [169]. Working principle: a thin, aqueous film containing a water-soluble catalyst, for example $[HRh(CO)(tppts)_3]$, adheres to silica gel with a high surface area. These catalysts act at the liquid/liquid interface.

7.1. Preparation of SAP Catalysts

To produce SAP catalysts, a granulated, porous support material with a large inner surface is added to a stirred aqueous solution of $[HRh(CO)(tppts)_3]$ and tppts (ligand excess), and then dried under vacuum. The hydrophilic carriers consist of "*c*ontrolled-*p*ore *g*lass" (CPG) with a definite but variable large inner surface (CPG-240, CPG-350). CPG-240 has a mean pore diameter of 237 Å, a pore volume of 0.95 mL g^{-1} ($\pm 4.3\%$) and a specific surface area of 77.5 $m^2 g^{-1}$. After removal of all the solvent, a dry, yellow powder remains which still contains about 2.9 wt% water. The metal complex is homogeneously distributed on the inner and outer surface of the support. If this catalyst material is treated at 30 Torr and 30 °C with water vapor, a controlled amount of water can be added, depending on the contact time. A comprehensive account of the process is given in Ref. [172].

7.2. Hydroformylation and Hydrogenation with SAP Catalysts

The SAP catalysts were developed for the hydroformylation of liquid substrates that are completely insoluble in water, for example, oleyl alcohol.[172] In the Ruhrchemie/Rhône–Poulenc process, longer chain alkenes can only be hydroformylated in the presence of solubilizers, for example, tetraalkylammonium salts containing four long-chain alkyl groups.[151] Oleyl alcohol is converted into the C_{19} aldehyde at 100 °C, 51 bar, and a CO/H_2 ratio of 1/1, in 96.6% yield without any rhodium loss at all. Moreover, after filtering off the stationary phase, the liquid phase does not contain rhodium, either as a complex species or as a colloid. The water content of the support is important. For example, the hydroformylation of 1-octene is characterized by a reduction in activity for a water content of more than 8 wt%. Also, the *n/iso* ratio and the system stability are reduced with increasing water content. It is thought that the resulting greater mobility of $[HRh(CO)(tppts)_3]$ promotes decomposition reactions.

The site of the reaction is well established. On supports with physically different structures, the activity depends on the specific surface; that is, the reaction takes place at the phase boundary. Thus, the results are in agreement with those of solid $[HRh(CO)(tppts)_3] \cdot n H_2O$. In its isolated state, the solid contains up to 16 wt% water—it is in a sense a "primitive SAP catalyst". In the hydroformylation of 1-octene in cyclohexane, the results almost match values with SAP catalysts: 98.7% conversion, *n/iso* = 2.1–2.9. As the Rh complex is insoluble in the organic reactants, the reaction must take place at the solid/liquid interface. This conclusion is supported by comparative investigations of two-phase systems and SAP catalysts.[173] For classical liquid/liquid systems, the rate of hydroformylation decreases in the series 1-hexene > 1-octene > 1-decene; with the SAP catalytic method, these alkenes react at virtually the same rate. Typically for surface effects, the solubility of the alkene in the aqueous phase is no longer the rate-determining factor. The low *n/iso* ratio of 2.8 in the three cases is due to coordinatively unsaturated complexes such as $[HRh(CO)_2(tppts)]$, which are known for their poor regioselectivities.[152]

When the complex $[Co_2(CO)_6(tppts)_2]$[77] is immobilized on CPG-340 and used for the hydroformylation of 1-hexene, there is only negligible leaching of cobalt into the product

phase.[174] However, in a typical two-phase reaction, the metal loss is not inconsiderable. At 190 °C, 55 bar ($CO/H_2 = 1/1$) the degree of conversion reaches 68% ($n/iso \geq 2$) after 8 h, depending on the water content. Other publications describe improved methods of producing SAP catalysts, and the extension of hydroformylation to other unsaturated compounds.[175]

In variations of the SAP catalytic method, platinum/tin tppts complexes can be obtained.[176] The most active water-insoluble, homogeneous hydroformylation catalyst based on platinum is the compound $[PtCl(tpp)_2SnCl_3]$. Tin(II) chloride increases both the reaction rate and the *n/iso* ratio. However, due to the sensitivity of the platinum–tin bond to hydrolysis, a tppts-modified system cannot be used in water. As the amount of water on the SAP catalyst (as little as 3%) is required only for the solubilization of the sulfonate groups of the tppts, the hydrolysis of the metal–metal bond should be able to be kinetically limited. Therefore, CPG-350 was impregnated with $[PtCl_2(tppts)_2]$, and treated with a solution of $SnCl_2$ in CH_2Cl_2. The vacuum-dried SAP catalyst contains 1.4 wt% water (TGA data). The high selectivity (*n/iso* = ca. 12/1) compared with the tin-free system $[PtCl_2(tppts)_2]$ (*n/iso* = 3/1) indicates a stable Pt... Cl... Sn interaction. The reaction rates are low, and decrease further as the water content increases to 7.4 wt% because the active species decomposes. Hydrogenation and isomerization are strikingly dominant. In the SAP catalytic method after 120 h, $[PtCl(tppts)_2SnCl_3]$ at 100 °C, 70 bar (H_2/CO), and a P/Rh ratio of 2/1 converts 1-hexene into only 26% heptanal and 12.7% hexane, but 21.2% 2-hexene and 7.6% 3-hexene are also formed. However, as no metal loss is observed, this method of immobilization seems to have some industrial future if further optimization of the parameters can be achieved.

With SAP catalysts based on Ru–tppts complexes, the selective reduction of α,β-unsaturated aldehydes to allyl alcohols can be performed. Thus, at 100 bar pressure of H_2(!), 3-methyl-2-butenal and *all-trans*-retinal are reduced with almost quantitative yield and high selectivity (up to 89%). The reduction in activity on recycling the catalyst material is due to successive adsorption of the reactants. Metal loss only dominates when polar solvents such as methanol are used. For the first time such a decrease in activity following catalyst recycling has been clearly documented; as a result, the industrial use of SAP catalysts for this particular reaction is viewed with skepticism.[177] It remains to be seen whether the concept of SAP catalysts meets the high expectations for it.[171]

7.3. Wacker Oxidation

The Wacker process for long-chain alkenes also requires solubilizing agents. To compare performance with SAP catalysts, $PdCl_2$ and $CuCl_2$ (1/1) were immobilized on CPG-240 (15 wt% H_2O).[178] In 3 h, this catalyst converted 1-heptene at 100 °C, $p(O_2) = 4$ bar, and an alkene/Pd ratio of 210/1 into 2-heptanone (oxidation), 2-heptene, and 3-heptene (isomerization). In the conventional Wacker process, isomerization is insignificant. In the SAP catalytic process, the oxidation of Pd^0 to Pd^{2+} is probably very slow, so isomerizations at the stage of the Pd–alkene complex become more significant. The reduction in isomerization with increasing O_2 partial pressure is consistent with this conclusion and with a more rapid Cu^+ oxidation. In spite of the unfavorable product distribution, SAP catalytic technology has the advantage that use of corrosive solutions of Cu^{2+} is avoided. The latter problem affects all conventional Wacker processes.

To sum up, immobilized water-soluble complex catalysts extend the concept of two-phase reactions to a new technical dimension.[179]

8. Special Uses of Water-Soluble Ligands

In addition to their main use in catalysis, water-soluble ligands have a number of special uses.

8.1. Membrane Modification by Selective Hydrogenation

The hydrogenation of unsaturated fatty acids is an important process, because these compounds form part of the membrane structures of a wide range of lipid classes.[180–186] Water-soluble catalysts are very much more suitable than their lipophilic derivatives, as no solvent vector such as THF or DMSO is needed for the transport of the metal complex into the membrane. Furthermore, water-soluble catalysts are easier to remove from the still intact membrane at the end of the reaction, and even the polarity of the catalyst can be controlled by suitable choice of ligand. The location of the reaction can be selected by exploiting the variable extent of penetration into the membrane.

The initial research in this field was carried out by Madden et al. during 1978–1980.[180, 181] The hydrogenation activity of the catalyst $[RhCl(tppms)_3]$ on phosphatidylcholine from soya lecithin was determined for the vesicles produced by ultrasound or mechanical perturbation. The water-soluble metal complex has amphiphilic character due to its sulfonated phosphane ligands and unsubstituted phenyl groups. This bipolarity facilitates the transition between the polar aqueous phase and the lipophilic hydrocarbon phase. Approximately 85% of the catalyst is either on or in the membrane—like moths in the fold of a curtain. The membrane structure is not destroyed even if 20 mol% catalyst (based on phospholipid) is present. All the double bonds can usually be hydrogenated, even including those deep inside the membrane layer. The catalyst therefore diffuses through the membrane in a few hours. At the end of the reaction, approximately 70% of the metal complex can be recovered from the membrane by means of ion exchangers.

Further investigations of the hydrogenation of dioleylphosphatidylcholine liposomes were published, in which the hydrogenation activity of the complexes $[RhCl(tppms)_3]$ and $[RhCl(dpup)_3]$ were compared,[182] [dpup = disodium diphenylphosphinoundecylphosphate, $(C_6H_5)_2P(CH_2)_{11}P(=O)(ONa)_2$]. At 37 °C, 1.2 bar H_2, and pH = 6.9, a *cis/trans* isomerization (oleic acid to elaidic acid) takes place before the hydrogenation. The *cis* isomer is not hydrogenated, but the *trans* isomer is. The rate of hydro-

genation is independent of the catalyst concentration. The kinetics are indicated by the equilibrium in (16). If

$$[\mathrm{Cat}]_{\mathrm{micelles}} \rightleftharpoons [\mathrm{Cat}]_{\mathrm{monomer}} \rightleftharpoons [\mathrm{Cat}]_{\mathrm{membrane}} \quad (16)$$

the critical micelle concentration is exceeded, the water-soluble catalyst is present as a large reservoir in the form of micelles. The micelles are in equilibrium with the monomeric form of the catalyst, whose concentration remains constant irrespective of the initial amount used. The monomeric Rh complex diffuses to the membrane and catalyzes hydrogenation there. As the monomer concentration does not change, the rate of hydrogenation is constant. Equilibrium (16) raises the question of the self-association of water-soluble metal complexes for the first time, a subject which is also of interest in connection with colloids (see Section 9).

The phospholipids located on the outside of the membrane can be hydrogenated with $[RhCl(tppms)_3]$,[183] and the cholesteryl acids and triacylglycerides located further inside the membrane are also reduced, but with decreased activity. The hydrogenation of the "inner" compounds that can nevertheless be observed is explained by the intermingling of the CC unsaturated alkyl chains with the phospholipids bonded to the surface (Fig. 12). The sulfonate groups of the water-soluble catalyst are oriented at the hydrated surface of the lipoprotein, while the active rhodium center penetrates the alkyl chain layer of the phospholipid.

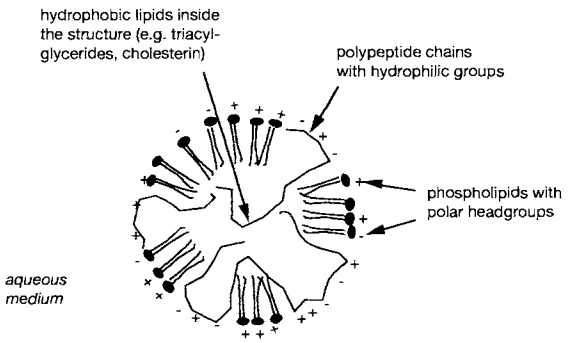

Fig. 12. Schematic diagram of a plasma lipoprotein (from ref. [184]).

Vigh et al.[185] have compared Ru and Rh catalysts for the hydrogenation of membranes. Under normal conditions, the complex $[RuCl_2(tppms)_2]$ is more active than the normally used catalyst $[RhCl(tppms)_3]$, which becomes superior to the Ru analog above 30 °C (Fig. 13).

The hydrogenation of protoplast membranes is also possible.[186] The fluidity properties of biomembranes are mainly determined by the number and position of the *cis* double bonds in the unsaturated fatty acids. Many physiological and biochemical processes are fundamentally linked to the viscosity of the cell membrane. The homogeneously catalyzed hydrogenation of the *cis* double bonds of fatty acids within an intact membrane by means of a water-soluble catalyst can therefore contribute to a deeper understanding of the modification of membrane fluidity. The complex $[RuCl_2(tppms)_2]$[87] has been used for this purpose. The catalyst is very selective at 30 °C and 7 bar H_2 for the conversion of linoleic acid (C18, three double bonds) into less unsaturated C18 acids (two to zero double bonds). If the extent of hydrogenation exceeds 30%, a serious loss of living protoplasts takes place. Destruction of intact protoplasts can be avoided by shorter contact times. From kinetic considerations, cell-like defense reactions can work against the continuing hydrogenation according to the principle of "homeoviscous adaptation".

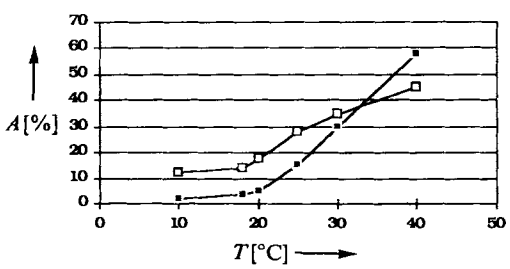

Fig. 13. Comparison of hydrogenation activities A (in % hydrogenation) of $[Ru^{II}Cl_2(tppms)_2]$ (□) and $[Rh^{I}Cl(tppms)_3]$ (■).

8.2. Light and Membrane Fluidity

Natural liposomes with a single or double layer can be hydrogenated by using the catalyst system $[RuCl_2(bpy)_3]$/$[RhCl(tppms)_3]$ (bpy = 2,2'-bipyridine)[187] with ascorbate as a light-induced hydride donor.[188] The combination of ruthenium and rhodium enables the nascent hydrogen to be produced in an ascorbate buffer. The light-collecting species is the complex $[RuCl_2(bpy)_3]$, and hydrogen transfer is performed by $[RhCl(tppms)_3]$/ascorbate.

The system is effective for the hydrogenation of ethene and ethyne and for the hydroformylation of ethene.[187] The in situ generated hydrogen enables hydrogenation even at 0.1 bar partial pressure (TON = 40 for ethene, quantum yield = 1.8). The pressureless(!) hydroformylation gives a TON of 3.5 with a quantum yield of 0.1% The mechanism of the quantum uptake by the Ru^{II} complex (Ru^{II}/Ru^{I} reduction) and the formation of the active species $[HRu(CO)(tppms)_3]$ is formulated in Equations (17–19). Despite these interesting results, the catalyst system is still somewhat unstable.

$$[Ru(bpy)_3]^{2+} + HA^- + e^- \xrightarrow{h\nu} [Ru(bpy)_3]^+ + A^{2-} + H^+ \quad (17)$$

$$2[Ru(bpy)_3]^+ + [RhCl(tppms)_3] \xrightarrow{2H^+} 2[Ru(bpy)_3]^{2+} + [H_2RhCl(tppms)_3] \quad (18)$$

$$2[Ru(bpy)_3]^+ + [RhCl(tppms)_3] \xrightarrow[-Cl^-]{H^- CO} 2[Ru(bpy)_3]^{2+} + [HRh(CO)(tppms)_3] + 2e^- \quad (19)$$

8.3. Regeneration of $NAD(P)^+$ with Water-Soluble Catalysts

$NAD(P)^+$ cofactors have important applications in biotechnological processes, for example, the conversion and storage of solar energy. According to the initial research into the regeneration of $NAD(P)^+$ cofactors,[189] $NAD(P)^+$ can be reduced in the presence of the water-soluble rhodium(III)

complex with tris(2,2'-bipyridyl-5-sulfonic acid) both electrochemically and photochemically with $[Ru(bpy)_3]^{2+}$ as a photosensitizer in aqueous alcoholic solution. However, reaction of the NAD(P)H and alcohol dehydrogenase with cyclohexanone yielded cyclohexanol in only small amounts. Only 46 catalytic cycles were performed in 33 days (based on the Rh complex). Higher conversions were achieved with $[RhCl(tppms)_3]$.[190] $NAD(P)^+$ cofactors are thermally and photochemically reduced. Formate and ascorbate were used as hydrogen sources. Kinetic investigations show that the rate-determining step is cleavage of the C–H bond and subsequent formation of a hydridorhodium species. The reaction follows Michaelis–Menten kinetics with an apparent activation energy of 20 kcal mol^{-1}. If the reduction is followed by an enzymatic reaction, such as reduction of acetaldehyde to ethanol by horse liver alcohol dehydrogenase, biologically active NAD(P)H can be produced, but the activities are inferior to reactions with conventionally regenerated NAD(P)H. Higher activities cannot be obtained, because the free ligand tppms produced by photodissociation acts as an inhibitor towards the metal complex. Reaction rates and regioselectivities of the reduction of $NAD(P)^+$ are low in comparison to enzymatic systems. A further problem is the inhibition of secondary enzymatic reactions by tppms.

9. Water-Soluble Catalysts—Colloids?

In spite of their catalytic potential, colloidal transition metals have so far attracted little attention. The preparation of stable water-soluble colloidal metals is comparatively simple, and their stability has recently been improved with the aid of sulfonated phosphane ligands such as tppms. Schmid et al. have carried out truly remarkable work on the preparation of water-soluble gold colloids (formula $[Au_x(tppms)_y]$, where $x/y = 20/1$, relative molecular weight about 40×10^6, particle diameter about 18 nm). The material has metallic properties, and can be repeatedly dissolved in and reprecipitated from water.[191, 192] Bönnemann et al. have shown that colloidal particles of various metals can be prepared from solution as a solid substance by stabilization with alkylammonium ions, can be stored in a stable condition, and subseqently redissolved. These operations leave the catalytic properties almost unchanged.[193, 194]

If the complex $[RhCl(tppts)_3]$ is prepared by the reaction of $RhCl_3 \cdot 3H_2O$ with tppts in an ethanol/water mixture, the ligand tppts is quickly and completely oxidized during the hydrogenation of an alkene (detected by ^{31}P NMR). This shows that rhodium colloids stabilized by phosphane oxide are the active species, as the rhodium remains in solution. Several publications on this theme have appeared recently, but they do not adequately explain the role of rhodium colloids in two-phase catalysis.[195–200]

Sinou et al. used the example of alkene hydrogenation to investigate the question of the homogeneous or heterogeneous nature of the active catalyst species in two-phase systems.[107] Catalysis experiments with chiral, water-soluble phosphanes and their oxides clearly showed that Rh^I forms enantioselective homogeneous catalysts with water-soluble phosphanes. On the other hand, systems containing Rh^I and phosphane oxide show the same hydrogenation activity but no optical induction, from which the existence of a colloidal "heterogeneous catalyst" is deduced. The same is true if a Rh^{III} starting complex is present. The reduction to Rh^I (preformation) is associated with the oxidation of the phosphane. The catalyst formed shows hydrogenation activity but is not enantioselective. All these findings support the view that rhodium colloids, which are stabilized by phosphane oxides and are active hydrogenation catalysts, are present in aqueous systems.

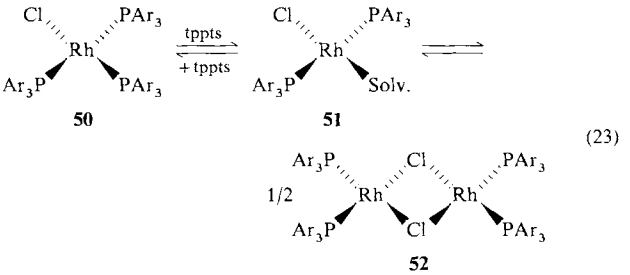
The redox chemistry of the simple system $RhCl_3 \cdot 3H_2O$/tppts in water was thoroughly investigated by Patin et al.[201] The formation of an Rh^{III}–hydroxo complex according to Equation (20) followed by coordination of a molecule of tppts according to Equation (21) leads to the reduction of Rh^{III} to Rh^I. Labeling experiments with $H_2{}^{18}O$ identified water as the source of oxygen in the concomitant phosphane oxidation. In the presence of acids or chloride-containing salts, the formation of the chloro(hydroxo) complex in Equation (20) can be suppressed. Accordingly, the addition

$$RhCl_3 + H_2{}^*O \rightleftharpoons [RhCl_2(^*OH)] + HCl \quad (20)$$

$$[Rh^{III}Cl_2(^*OH)] + P(m\text{-}C_6H_4SO_3Na)_3 \xrightarrow{-HCl} \underset{\mathbf{1}}{} \{Rh^ICl\} + {}^*O{=}P(m\text{-}C_6H_4SO_3Na)_3 \quad (21)$$

$$\{Rh^ICl\} + 3P(m\text{-}C_6H_4SO_3Na)_3 \longrightarrow \underset{\mathbf{50}}{[Rh^ICl\{P(m\text{-}C_6H_4SO_3Na)_3\}_3]} \quad (22)$$

of 0.5 M $HClO_4$ or 2 M NaCl solution reduced the extent of phosphane oxidation from 70% (without addition) to 12% or 5%.[199] The solvent-stabilized Rh^I chloride is coordinated by free unoxidized tppts, and forms the water-soluble complex **50** analogous to the Wilkinson compound [Eq. (22)]. It eliminates a molecule of tppts to form the solvated complex **51,** which dimerizes to the stable compound **52** (P = phosphane) [Equation (23)]. This study emphasizes that the situation for even simple catalyst systems in water is much more complex than for normal homogeneous catalytic systems in organic media. The findings further support the idea of catalytically active colloids. Their role is still poorly understood, but their potential is obvious.[193, 194]



(23)

10. Perspectives

Following the technological breakthrough of the Ruhrchemie/Rhône–Poulenc process (1984), water-soluble catalysts based on coordination complexes and organo-

metallic compounds have promoted the long overdue bridging of the chasm between homogeneous and heterogeneous catalysis. The concept of stationary supports ("immobilized" homogeneous catalysts), which has to date not had any convincing success, has been overtaken by that of "mobile carriers", in which water, the catalyst medium, brings additional process advantages. Common ground first appeared in 1989 with the development of supported aqueous phase catalysts (SAP catalysts). The sometimes excellent compatibility of complex catalysts with water (up to 130 °C process temperature) was not expected even by experts in catalysis, who need to get accustomed to the idea. To ensure success, the ligands selected must have very high solubility in water. Experience suggests that 1 $kg\,L^{-1}$ is a practical guideline. However, this criterion is not met by all the ligand classes usually used in homogeneous catalysis, so synthetic chemistry is again required. Rh-catalyzed hydroformylation, the most extensively investigated process, provides convincing evidence of the advantages of the two-phase aqueous reaction system. All the phosphane ligands tested so far are more active and selective in their water-soluble (sulfonated) forms than in the homogeneously catalyzed process, often by a very large margin. Water is excellent as a reaction and catalyst medium on grounds of solubility (for example, differential solubility of starting compound and product(s)) or the thermodynamics of a desired reaction.[207] These advantages combine ideally with the techniques of separation and recycling of the noble metal, which are continuously being perfected. This young interdisciplinary field of modern catalyst research and technology belongs to the future in research at universities and in industry.[169] Even organometallic complex catalysts such as the much investigated methyltrioxorhenium(VII) ($[CH_3ReO_3]$) are soluble and stable in water.[202]

This article results from a joint research project of Hoechst AG (Werk Ruhrchemie) and the Technische Universität München. Since 1986 this project has followed the new developments in two-phase hydroformylation and its potential. As is typical for this field, the authors came into contact with the subject through practical industrial experience and must thank their colleagues in Oberhausen for numerous consultations over several years of collaboration, especially Drs. Bahrmann, Frohning, Heymanns, Konkol, Kottmann, Lappe, Peters, Reichelt, and Weber. We also acknowledge fruitful cooperation with former Doctoral students Jürgen Kulpe (Hoechst AG), Jürgen Kellner (Deutsche Shell AG), and Herbert Riepl (Klinge-Stiftung Holding GmbH) in the Munich institute as well as the present PhD students Rainer Manetsberger, Guido Albanese, and Rochus Schmid. Special thanks are due to Professor Boy Cornils and Professor Klaus Kühlein (both Hoechst AG) for their hospitality to W.A.H. and for numerous scientific discussions.

Hydrophobic Effects. Opinions and Facts

By Wilfried Blokzijl* and Jan B. F. N. Engberts*

The term hydrophobic interactions denotes the tendency of relatively apolar molecules to stick together in aqueous solution. These interactions are of importance in many chemical disciplines, including the chemistry of in vivo processes. Enzyme–substrate interactions, the assembly of lipids in biomembranes, surfactant aggregation, and kinetic solvent effects in water-rich solutions are all predominantly governed by hydrophobic interactions. Despite extensive research efforts, the hydration of apolar molecules and the noncovalent interactions between these molecules in water are still poorly understood. In fact, the question as to what the driving force for hydrophobic intractions is shifts the study into a quest for a detailed understanding of the remarkable properties of liquid water. This review highlights some of the novel insights that have been obtained in the past decade. The emphasis is on both hydrophobic hydration and hydrophobic interactions since both phenomena are intimately connected. Several traditional views have been found to be deeply unsatisfactory, and courageous attempts have been made to conceptualize the driving force behind pairwise and bulk hydrophobic interactions. The review presents an admittedly personal selection of the recent experimental and theoretical developments, and when necessary, reference is made to relevant studies of earlier date.

1. Introduction

1.1. General Remarks and Outline of the Review

At moderate temperatures and pressures, apolar compounds are poorly soluble in water. Traditionally, the reluctance of apolar compounds to dissolve in water has been attributed to the hydrophobicity of these compounds, in other words, their fear of water. In fact, the term hydrophobicity is misleading. The London dispersion interactions between water and apolar compounds are favorable and quite substantial.[1] It is more appropriate to point out that the apolar compound must intrude into a liquid that is characterized by an extended network of hydrogen bonds and an extremely high cohesive energy density. Each water molecule is strongly inclined not to sacrifice any of its hydrogen bonds, leading inevitably to significant reorientation of water molecules at the surface of the nonpolar solute molecule. Water is unique among solvents, because it has not only an exceptionally small molecular volume, but also the capacity to form a molecular network with tetrahedral coordination and an extremely low isothermic compressibility. This provides water with an almost unrivaled propensity to wrap itself around an apolar solute particle and simultaneously maintain most or all hydrogen bonds. But in spite of this unique structural solution, water must be considered a notoriously poor solvent for apolar compounds.

Unabated, chemists have sought a molecular interpretation of the hydrophobicity of apolar compounds. The first explanations were based on the capricious thermodynamic parameters of the hydration of these compounds in water at room temperature. The thermodynamic parameters of the solvation of gaseous methane in various organic solvents and water at 25 °C are given in Table 1. At room temperature, the dissolution of apolar gases in water is strongly promoted by enthalpy and characterized by an anomalously large change in heat capacity (for gaseous methane, the change in heat capacity (at 25 °C) amounts to 209 kJ mol^{-1} K^{-1}[2]). In contrast, the change in heat capacity upon solvation of gaseous methane in organic solvents is generally small. The poor solubility is completely governed by an extremely large loss of entropy. The partial molar volume of an apolar gas dissolved in water is generally similar to the molar volume of the gas at the boiling point, which is remarkable since the partial molar volume of solutes in organic solvents is significantly higher. Some of these striking thermodynamic properties were first identified by Butler and Reid.[3] In 1945 Frank and Evans[4] gave a molecular interpretation for these observations which would later become the archetype for further studies on hydrophobic effects. The model, generally known as the iceberg model, explained the unusually large entropy loss upon dissolution of apolar gases in terms of the structuring of water molecules in the near vicinity of the apolar solute. The emphasis on the enhanced local structure led to overinterpretation of the original idea in later studies, and frequently the hydration

Table 1. Thermodynamic parameters of solvation for gaseous methane in various organic solvents and water at 25 °C (taken from ref. [31]) [a].

Solvent	$\Delta G^{\ominus}$ [kJ mol^{-1}]	$\Delta H^{\ominus}$ [kJ mol^{-1}]	$-T\Delta S^{\ominus}$ [kJ mol^{-1}]

shell of apolar solute particles has been pictured as a rather rigid clathrate-like structure.[5] The idea of a special kind of hydration, referred to as hydrophobic hydration, became generally accepted.

It was proposed that the tendency of water molecules to avoid entropically unfavorable interactions with apolar solutes constitutes a driving force for the aggregation of apolar solutes. The notion that the interactions between apolar species in aqueous solution are primarily entropy driven gave chemists a genuine feeling of discomfort. In 1959 Kauzmann[6] introduced the concept of hydrophobic interactions, the alleged solvent-induced attractive forces between apolar molecules or moieties in aqueous solution. He suggested that the attractive interactions between apolar molecules or moieties in aqueous solution are promoted by the solvent as a result of destructive overlap of structured hydrophobic hydration shells, involving the release of structured hydration water into the bulk. Later, the idea of a hydrophobic bond received much attention, particularly in the field of protein chemistry.

Hydrophobic effects play a pivotal role in many chemical phenomena in aqueous solution. The stability of biological membranes as well as of the tertiary structure of proteins in aqueous solution depends critically on interactions between apolar moieties. Molecular recognition also relies strongly on noncovalent interactions, for which hydrophobic regions in host and guest molecules are often crucial. Apart from their importance in biological processes, hydrophobic effects are also important for various solution phenomena such as surfactant aggregation, mineral flotation, coagulation, complexation, and detergency. In addition, hydrophobic effects play a decisive role in the formation of gas clathrates and in surface phenomena such as wetting, aggregation processes at air–water interfaces, and forces between apolar surfaces. In view of the wide interest in hydrophobic effects it is essential to have a clear understanding of the molecular nature behind these phenomena.

Although the qualitative concept of the increased structuring of water in hydrophobic hydration shells has provided a popular explanation for the unusual thermodynamic properties of aqueous solutions of apolar compounds, serious doubts have been voiced occasionally concerning the existence of hydrophobic effects. Frequent suggestions have been made to reassess the traditional ideas about hydrophobic effects and to adjust the somewhat dogmatic picture of hydrophobic hydration. More recently, rapid maturation of computational methods such as molecular dynamics and Monte Carlo calculations, the introduction of elaborated integral theories and refined versions of scaled particle theory for a description of liquids and solutions, the development of sophisticated microcalorimetry to measure highly accurate thermodynamic solvation data not only at room temperature but also at elevated temperatures, and the application of protein engineering to study the role of hydrophobic amino acid residues in protein folding and stability have yielded increasing evidence against the traditional interpretation of hydrophobic effects. In spite of growing doubts about the validity of the original models, the classic interpretation of hydrophobic effects still prevails in the recent literature. The fact that arguments against traditional ideas have been largely ignored must, at least in part, be attributed to notorious ambiguities in the nomenclature pertaining to the hydrophobic effect; this has lent recent discussions a strongly semantic flavor.

At this stage, we feel that there is a need to stand back a little and review recent experimental as well as theoretical studies of hydrophobic effects in different areas of chemistry. Because of the yearly surge of papers on hydrophobic effects, our survey can by no means be exhaustive. Our major goal is to signal remarkable results and to identify important shortcomings in current views on hydrophobic effects. Our review is therefore deliberately biased and aims at a critical reappraisal of hydrophobic effects in which the validity of the whole concept of hydrophobic hydration and hydrophobic interactions will be questioned. To avoid unnecessary ambiguities, definitions will be given for hydrophobic hydration and hydrophobic interactions in Section 1.2. Unfortunately, these definitions are as yet not unanimously accepted.

Jan B. F. N. Engberts was born in 1939 in Leiden, the Netherlands. He studied synthetic and physical organic chemistry at the University of Groningen under supervision of Prof. J. Strating and Dr. B. Zwanenburg. After graduating with a Ph.D. degree in 1967, he was a postdoctoral fellow with Prof. T. J. de Boer at the University of Amsterdam (1968–1969). He returned to Groningen in 1969 as Associate Professor and was appointed Professor of General Chemistry in 1978. Since 1992 he has held a chair in Physical Organic Chemistry at the same university. The research in his group is centered around the theme "organic chemistry in water" and includes projects in molecular recognition, surfactant aggregation, synthesis and properties of polymers and polysoaps, and vesicle fusion.

Wilfried Blokzijl received his degree in chemistry at the University of Groningen in 1987 for his research with Prof. G. Challa on the catalytic behavior of flavine-modified polyelectrolyte complexes. The same year he started as a Ph.D. student in the group of Prof. J. B. F. N. Engberts and collaborated also with Prof. M. J. Blandamer of the University of Leicester. In 1991 he completed his doctoral thesis entitled "Organic Reactivity in Mixed Aqueous Solvents", which described a quantitative link between kinetics and thermodynamics. He is currently examining the catalysis of organic reactions in homogeneous aqueous media. He will take a position at the Research Laboratories of Unilever in Vlaardingen in 1994.

This survey focuses mainly on developments reported during the past decade. Where necessary, reference is made to relevant studies of earlier date. Many experimental studies of hydrophobic effects applying nuclear magnetic resonance, ultrasound, diffraction methods, and calorimetry were reported in the sixties and seventies. For detailed accounts of this work, we refer to the series of books, *Water. A Comprehensive Treatise*, edited by Franks.[7] A short historical excursion into the field of hydrophobic effects presented by Franks[8] in 1982 showed that these experimental studies were often consistent with the molecular interpretation of hydrophobic effects as given by the traditional iceberg model. More theoretical approaches to understanding hydrophobic effects have been described in textbooks by Tanford,[9] Ben-Naim,[10] and Luck.[11] Following the classic review of Kauzmann,[6] the sixties and seventies witnessed a number of attempts to quantify the concept of hydrophobic interactions. Some important contributions, briefly reviewed in Section 1.3, set the stage for ensuing theoretical studies of hydrophobic effects.

This review has two parts comprising, respectively, experimental and theoretical studies of hydrophobic effects. The criteria for defining the separation of these sections are somewhat arbitrary, and activities can show considerable overlap. Following tradition, Part A is inaugurated by a survey of results of recent calorimetric studies as well as reinterpretations of previous data for the solvation of apolar gases and liquids in water over a broad temperature range (Section 2.1). In subsequent sections the importance of hydrophobic effects for the stability of tertiary protein structures (Section 2.2), molecular recognition (Section 2.3), aggregation of amphiphiles (Section 2.4), and surface forces (Section 2.5) will be discussed. This will be followed by a selection of recent results obtained by spectroscopic techniques (Section 2.6). Finally, Part A concludes with a section in which applications of water as a medium for organic reactions are discussed (Section 2.7).

Part B starts off with a brief introduction of theoretical descriptions of hydrophobic effects that have been presented over the years (Section 3.1). Subsequently, efforts are described for the development of rather simple molecular models to account for the thermodynamic properties of aqueous solutions of nonelectrolytes (Section 3.2). In Section 3.3 more sophisticated theories are summarized that are mainly based on virial expansions of thermodynamic excess properties of aqueous solutions to quantify interactions between apolar solutes in aqueous media. Section 3.4 contains a concise summary of applications of scaled particle theories to the problem of hydrophobic effects. Part B concludes with an extensive survey of results of computational studies of both hydrophobic hydration and hydrophobic interactions (Section 3.5).

A final summary and outlook is presented in the epilogue (Section 4) which signals inconsistencies between results of experimental and theoretical studies of hydrophobic effects and also identifies aspects that are currently unanimously accepted. On the basis of these considerations, we present a molecular interpretation of the solvation of apolar compounds in water as well as their aggregation in aqueous solution which is conceptually different from traditional ideas.

1.2. Hydrophobic Effects; The Terminology

Many of the existing definitions of hydrophobic effects reflect the lack of clarity with respect to the exact meaning of the terms that have been introduced to describe the unusual thermodynamic behavior of apolar solutes in aqueous solution (see, for example, the discussion in *Science* two to three years ago)[12-15]). Although the concept of hydrophobicity is widely used, its exact meaning is somewhat vague. We prefer to define hydrophobicity on the basis of the thermodynamics of the transfer of apolar compounds, either from their liquid state or from a solution in an apolar solvent, to water. This process involves the disruption of interactions between the apolar molecule and its apolar environment, refilling of the vacancy in the apolar medium, the creation of a cavity in water, the initiation of water–solute interactions, and the concomittant reordering of the water molecules in the near vicinity of the solute. Thus, hydrophobicity yields information about the limited solubility of apolar compounds in water and can be quantified on the basis of solubility measurements or partitioning studies.

The definition of hydrophobic hydration is even more troublesome, and several interpretations can be encountered in the literature. Hydrophobic hydration refers to the way a nonpolar solute affects the local structure of water in its immediate environment. A convenient definition of hydrophobic hydration considers the process of cavity formation in liquid water, the insertion of an apolar solute particle, the onset of solute–solvent interactions, and the concomittant reordering of the water molecules in close proximity to the solute. Unfortunately, this process is difficult to study by experimental means.

The occurrence of hydrophobic interactions is perhaps the most dramatic revelation of the limited solubility of apolar compounds in water. It is essential to make a clear distinction between pairwise and bulk hydrophobic interactions.[16] Scheme 1 shows a thermodynamic cycle taken from a paper by Wood and Thompson,[16] which illustrates the relation between these distinct phenomena. In this cycle, R stands for

$$\begin{array}{ccc} n\mathrm{R}(\mathrm{g},c^{\ominus}) & \xrightarrow{\Delta G_n(\mathrm{g},c^{\ominus})} & \mathrm{R}_n(\mathrm{g},c^{\ominus}) \\ n\Delta G_1^{\mathrm{s}} \downarrow & & \downarrow \Delta G_n^{\mathrm{s}} \\ n\mathrm{R}(\mathrm{aq},c^{\ominus}) & \xrightarrow[\Delta G_n(\mathrm{aq},c^{\ominus})]{} & \mathrm{R}_n(\mathrm{aq},c^{\ominus}) \end{array}$$

Scheme 1. Thermodynamic cycle for the transfer of n molecules R (nR) as well as of a cluster of n molecules R (R_n) from the gas phase into an aqueous solution, illustrating the difference between bulk and pairwise hydrophobic interactions (taken from ref. [16]). s denotes the solvation steps.

a hydrophobic compound, $c^{\ominus}$ is a standard or reference concentration (vide infra), g denotes the gas phase, and aq the aqueous phase. For $n = 2$, $\Delta G_2(\mathrm{aq},c^{\ominus})$ is the Gibbs energy involved in the interaction of a pair of molecules R in aqueous solution and provides a measure of the pairwise hydrophobic interaction. The solvent-induced part can be computed by comparing $\Delta G_2(\mathrm{aq},c^{\ominus})$ with $\Delta G_2(\mathrm{g},c^{\ominus})$.[17] Bulk hydrophobic interactions are characterized by large values of n. Interestingly, when $n \to \infty$, ΔG_n^{s} approaches zero. In this case $-(1/n)\Delta G_n(\mathrm{aq},c^{\ominus})$ is the Gibbs energy for the

transfer of an apolar compound from an aqueous solution to its liquid state. ΔG_1^s is the Gibbs energy for the solvation of a gaseous compound R in water. This process is sometimes incorrectly considered equivalent to hydrophobic hydration.

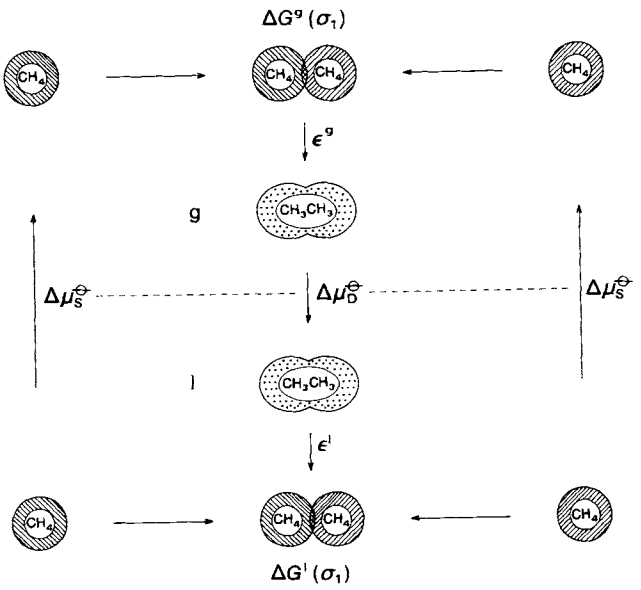
The magnitudes of the thermodynamic parameters of the various processes depend critically on the choice of standard states *c*.[18, 19] The most commonly used standard state assumes gaseous compounds at 1 atm that are dissolved in water at a mole fraction of one. The advantage of this particular choice is that the statistical part of the chemical potential (which is mainly entropic in origin) does not differ when solvents with different molecular weights and densities are considered. Other standard states such as 1 mol dm^{-3} and 1 mol kg^{-1} suffer from this disadvantage. When standard states are explicitly known, data can be easily interconverted.[18] As shown convincingly by Abraham,[18] the interpretation of transfer parameters or solvation data is often seriously hampered by application of erroneous reference states. In particular, the pure liquid is an often used but very hazardous reference state. Ben-Naim[20] enunciated the advantages of an alternative standard state based on the transfer of an apolar gas to a fixed position in water. In a subsequent step, the solute is released into the solvent, gains kinetic energy, and becomes indistinguishable from the other molecules in the solution. The so-called pseudochemical potential can be computed from known thermodynamic parameters of solvation but cannot be determined directly. The popularity of this particular standard state can be attributed to the fact that the solute molecule can always be distinguished from solvent molecules. This offers interesting possibilities for studying the solvation of organic compounds in mixed aqueous solvents.

1.3. Classic Models for Hydrophobic Effects

As mentioned in the introduction, Frank and Evans[4] were the first to speculate about the molecular origin of the thermodynamic behavior of aqueous solutions of nonelectrolytes. In their classic paper largely devoted to aqueous solutions of electrolytes, they stated that "when a rare gas atom or a nonpolar molecule dissolves in water at room temperature it modifies the water structure in the direction of greater crystallinity—the water, so to speak, builds a microscopic iceberg around it". The promotion of crystalline-like regions was rationalized by arguing that these structures contain more free space in which apolar solute particles could be accommodated. This model, based on well-known mixture models for liquid water, achieved great fame as the "iceberg model" and found a more sophisticated quantitative counterpart in a model developed by Némethy and Scheraga,[21, 22] in which the flickering cluster model for liquid water[*] proposed by Frank and Wen[23] was used. An important aspect of this model is the assumed cooperativity in the formation of hydrogen bonds in liquid water. This cooperativity was attributed to the fact that the formation of a hydrogen bond by a water molecule is greatly facilitated when a second hydrogen bond is already present. As a consequence, hydrogen bonds are made and broken as a collective rather than an isolated event. Thus, short-lived regions of either strongly hydrogen-bonded or isolated water molecules occur, described as flickering clusters. Insertion of an apolar solute particle causes a change in the energy levels of water molecules at the surface of the solute. A fully hydrogen-bonded water molecule will be stabilized by additional van der Waals interactions with the solute, and hence the number of these water molecules will increase in the vicinity of apolar solutes. In the original model of Frank and Wen,[23] the nonpolar solute is assumed to act as an effective wall unable to transmit disruptive forces that tend to destruct the icelike clusters.

One of the first critical evaluations of iceberglike models was reported by Miller and Hildebrand,[24] who developed a model for the loss of entropy upon solution of apolar gases without assuming the formation of more rigid structures. Instead, they suggested that hydrogen bonds are destroyed when water molecules are brought into contact with air or apolar surfaces, causing the low solubility of apolar compounds in water. An interesting alternative was offered by Howarth,[25] who reported an interpretation of the entropy of hydration of apolar compounds in terms of restricted motion of the hydrophobic parts of the solute molecules.

Classic models for hydrophobic interactions originate from the molecular interpretation given by Kauzmann.[6] Pioneering work in this area was done by Ben-Naim[10, 26] and Friedman et al.[27–29]. In an elegant approach by Ben-Naim[10, 26] the process of the hydrophobic association of two methane molecules in water is considered. The indirect part of the work associated with this process (δG^{HI} or $\delta G(R)$), the part that reflects the properties of water, is evaluated by computing the difference between the thermodynamic parameters of the hydration of gaseous methane and ethane as illustrated in Scheme 2 (see also Section 3.3.1). Here, $\Delta\mu_S^{\ominus}$ and $\Delta\mu_D^{\ominus}$ are the standard chemical potentials for the solvation of gaseous methane S and ethane D, respec-



Scheme 2. Cyclic process in which two methane molecules in aqueous solution as well as in the gas phase are brought from infinite separation to a close separation σ_1 and subsequently replaced by an ethane molecule (taken from ref. [10]).

[*] In the flickering cluster approach small regions in liquid water with a given structure are assumed to undergo sudden cooperative transitions into other structures.

tively. ε^g and ε^l account for the differences between an associated pair of CH_4 molecules and a covalent bond between CH_3 moieties. The assumption is made that ε^g and ε^l are similar in magnitude. The Gibbs energy involved in the solvent-induced part of the process of hydrophobic interaction can now be expressed as $\Delta G^{HI} = \Delta\mu_D^{\ominus} - 2\,\Delta\mu_S^{\ominus}$.

Having a method to estimate the solvent-induced part of hydrophobic interactions, one can study the influence of temperature or the presence of organic cosolvents on the magnitude of hydrophobic interactions. The model developed by Friedman et al.[27-29] quantifies the thermodynamic parameters involved in the overlap of hydrophobic hydration shells upon association of apolar solute molecules and is treated in some detail in Section 3.3.3.

2. Part A. Experimental Studies

2.1. Hydrophobic Effects across a Broad Temperature Range; A Thermodynamic Approach

Traditionally, hydrophobic effects have been studied by measuring thermodynamic parameters for the solvation of gaseous or liquid organic compounds in water or, alternatively, by relating them to partition coefficients of solutes between aqueous and nonpolar phases (see, for example, Abraham et al.[30, 31] and Zaslavsky and Masimov[32]). An excellent review on previous studies of solvation of apolar gases in water is given by Wilhelm et al.[33] Since then, techniques for the measurement of solubility data on the basis of vapor–liquid equilibria have been improved significantly.[34] Furthermore, in the past decade microcalorimetry has reached a high level of sophistication. Recently, Pollack devoted an interesting discussion to the general question of why gases dissolve in liquids.[35]

The general aim of this section is twofold. First, emphasis is placed on a method to correlate thermodynamic data of solvation at 25 °C with solute parameters. This method provides a refreshing view of hydrophobic hydration and yields an interesting comparison between the thermodynamic parameters of the solution of apolar compounds in water and in organic solvents. The second part of this section describes an analysis of thermodynamic hydration parameters as a function of temperature and shows that the emphasis on the entropy-controlled nature of the solubility of apolar compounds in water cannot be maintained. Highly accurate enthalpies and heat capacities of solvation for apolar gases and liquids in water now available over a broad temperature range have seriously challenged the traditional view of hydrophobic effects.

It is notoriously difficult to correlate thermodynamic parameters of solvation with some property of the solute.[33] Correlations with the surface area[36] and molecular volume of the solute often gave satisfactory results but also revealed some remarkable discrepancies. These were explicitly noted by Cramer[37] but became more obvious in a excellent analysis of solvation data of a large series of organic compounds, presented by Abraham.[18, 31] Both approaches focused on a comparison of thermodynamic solvation data for a series of apolar gases. In Figure 1 the Gibbs energies, enthalpies, and entropies (expressed as $T\Delta S$) of solvation for a series of

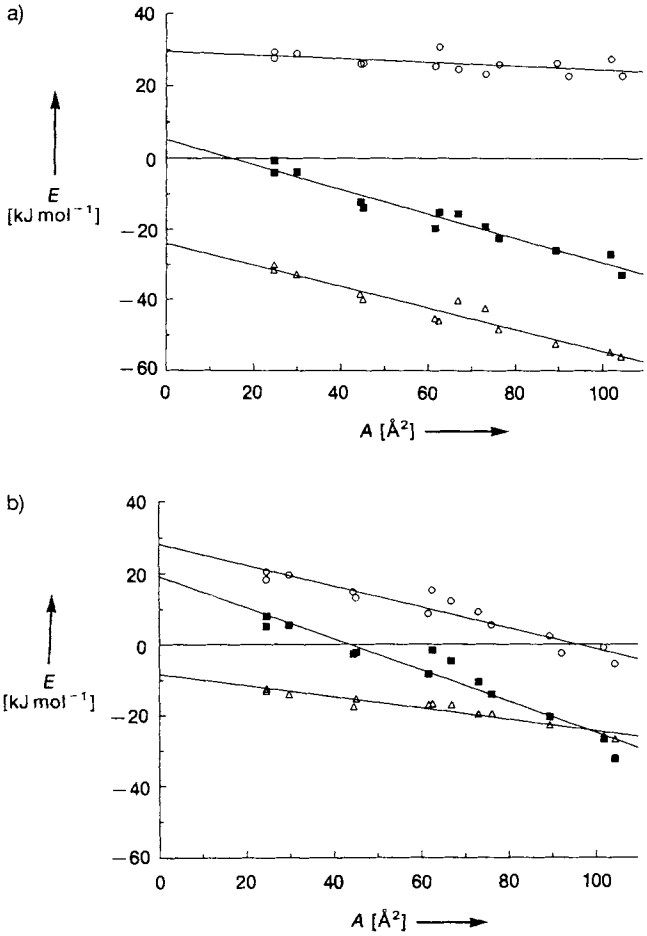


Fig. 1. $\Delta G^{\ominus}$ (○), $\Delta H^{\ominus}$ (■), and $T\Delta S^{\ominus}$ (△) of solvation for the apolar gases hydrogen (24.57 Å²), helium (24.65 Å²), neon (29.80 Å²), argon (44.41 Å²), methane (45.04 Å²), ethane (61.55 Å²), tetrafluoromethane (62.44 Å²), krypton (66.75 Å²), xenon (72.98 Å²), propane (76.08 Å²), *n*-butane (89.33 Å²), cyclopentane (92.04 Å²), *n*-pentane (101.64 Å²), cyclohexane (104.19 Å²). a) in water, b) in *n*-hexane (1 atm, 1 mol%, 298 K) as a function of the surface area *A* of the solute (in parentheses). Thermodynamic parameters are taken from ref. [31].

apolar gases in water and in *n*-hexane are plotted as a function of the surface area of the solute. Although the correlations are generally poor, the trends are obvious. Abraham developed a set of generally applicable solute parameters which are closely correlated with the surface area but have been optimized in order to correlate with thermodynamic solvation data in various organic solvents. These parameters have little physical meaning, and for the present purpose we prefer to use the surface area.

Strikingly, at 25 °C the Gibbs energy of solvation for apolar gases in water is only moderately dependent on the nature of the solute as compared to other solvents. Moreover, the dependence on the nature of the solute is quite remarkable. Helium is, for example, slightly less soluble than the larger (and more polarizable) xenon. In contrast, methane is slightly *better* soluble in water than in *n*-pentane. In organic solvents, the solubility increases rapidly with increasing size (or polarizability) of the solute. As suggested by Tanford[9] and Abraham,[18, 31] it is interesting to compare the methylene increment for the dissolution of gaseous hydrocarbons in water and in organic solvents. Table 2 lists the methylene group contributions to the Gibbs energy, enthalpy, and entropy (expressed as $T\Delta S$) of solvation for gaseous C_2–C_8

Table 2. Methylene group contributions to the Gibbs energy, enthalpy, and entropy of solvation for gaseous *n*-alkanes (C_2-C_8) in various solvents at 298.15 K (taken from ref. [31].

hydrocarbons in various solvents at 25 °C. The Gibbs energy increment per methylene moiety in water deviates significantly. The enhanced solubility of larger hydrocarbons in organic solvents is governed by the growing importance of the enthalpy, which is only partly counteracted by the decrease in entropy. In water, the enthalpy of solvation also increases with increasing apolar surface area, but the increase is less pronounced. In contrast, the entropy loss increases more strongly with increasing alkane size. Hence, hydrophobicity becomes more pronounced as the size of the apolar solute increases, and the slight dependence of the Gibbs energy of solvation on surface area is the most eye-catching revelation of hydrophobic hydration. This phenomenon is, however, a result of subtle differences between contributions of methylene groups to the entropy and enthalpy of solvation. The exceptionally large and positive Gibbs energy of solvation of hydrocarbons in water at 298 K finds expression in the *absolute* values of the enthalpy and entropy of solvation. Figure 1 suggests that even for a solute molecule of negligible size, the entropy of solvation in water still remains highly unfavorable.

From the methylene increments listed in Table 2 the thermodynamic parameters can be calculated for the transfer of a methylene group from an organic solvent to water. For example, the transfer of a methylene group from *n*-hexane to water is an unfavorable process (the Gibbs energy increment is +3.85 kJ mol^{-1}), and it is characterized by a loss of entropy (increment is −1.09 kJ mol^{-1}) as well as by a positive enthalpy (increment is +2.76 kJ mol^{-1}). Transfer of a methylene group from the gas phase to water is, however, *promoted* by enthalpy. This indicates that a considerable part of the unfavorable Gibbs energy involved in the transfer of an apolar methylene moiety from an organic solvent to water must be attributed to the disruption of dispersion interactions between the apolar solute and the organic solvent.

The Gibbs energies for the transfer of apolar solutes from nonpolar solvents to water have been correlated with accessible surface areas. These correlations showed that the Gibbs energy per unit surface area involved in the transfer of apolar compounds from a hydrocarbon-like solvent to water amounts to 70 to 130 J mol^{-1} Å^{-2}. The exact magnitude depends strongly on the reference solvent, the computational method used to determine the surface area, and the fitting procedure.[9, 38–43] A macroscopic measure for the hydrophobic Gibbs energy per unit surface area can be derived from liquid hydrocarbon–water surface tensions, which are about 310 J mol^{-1} Å^{-2}.[44] The discrepancy between the macroscopic and microscopic Gibbs energy relations on surfaces cannot be explained simply on the basis of differences in the curvature of the surface (see also Greco[45]). In 1991 Sharp et al.[46] reappraised the surface area dependence of the solubilities of hydrocarbons in water and showed that "hydrophobicity scales" significantly underestimate the magnitude of the hydrophobic effect. However, even in the revised estimate of the Gibbs energy per unit surface area, a considerable gap remains between macroscopic and microscopic surface tensions.[46]

During the past decade the temperature dependence of the thermodynamic parameters of solvation for many apolar gases and liquids has been determined with high accuracy. The standard molar Gibbs energy, enthalpy, and entropy ($T\Delta S$) of solvation for gaseous and liquid neopentane are represented in Figures 2a and 2b, respectively. For comparison, the temperature dependence of the thermodynamic parameters for the transfer of gaseous neopentane to its liquid state is shown in Figure 2c. The pseudo-chemical potential is used as a standard state (see Section 1.2). Using microcalorimetry, Naghibi et al. measured the heats of solution of methane,[2] ethane,[47] *n*-propane,[47] and *n*-butane[48] and showed that the enthalpy of solvation becomes less favorable with increasing temperature. This reflects the large and positive heat capacity of solvation observed near room temperature.

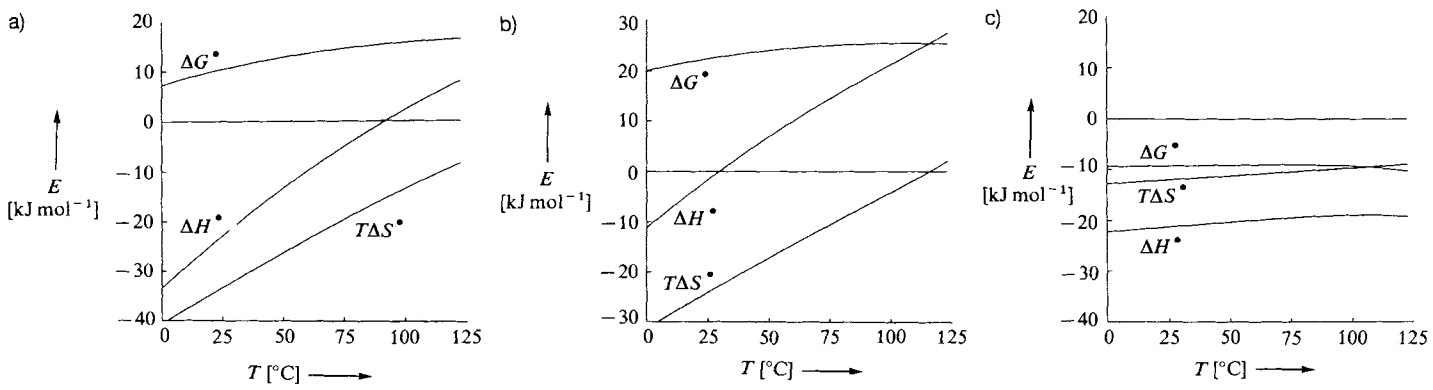

Fig. 2. Temperature dependence of ΔG°, ΔH°, and $T\Delta S^{\circ}$ of the solvation for a) gaseous neopentane and b) liquid neopentane in water, and c) gaseous neopentane in its pure liquid (taken from ref. [230]).

Solubility measurements have shown that the entropy of solvation becomes less unfavorable with increasing temperature. At elevated temperatures the solubility of apolar compounds in water is, however, still exceptionally low, since it is then governed by the unfavorable enthalpy of solvation. The Gibbs energy of solvation is only slightly dependent on temperature. The heat capacity of solvation for gaseous hydrocarbons was shown to decrease significantly with increasing temperature.[49] Unfortunately, microcalorimetric techniques did not allow accurate measurements of heats of solvation of apolar gases above 55 °C. The results, however, suggest that the heat capacity of solvation decreases continuously and eventually reaches zero at elevated temperatures. This is expected, because the hydrogen bond structure of water at these high temperatures is suggested to be completely destroyed.[36] Makhatadze and Privalov[50] determined the specific heat capacity of solvation for liquid toluene and benzene between 0 and 150 °C. Although these data confirm the decrease of the heat capacity of solvation, even at 150 °C a considerable heat capacity change was observed.

Accurate measurements of the temperature dependence of the solubility of apolar gases and liquids in water analyzed with the van't Hoff equation also yield a temperature dependence of the thermodynamic parameters of solvation. Using this approach, Shinoda[51] and Rettich et al.[52–54] found that the heat capacity of solvation decreases noticably above 80 °C and drops to zero near 160 °C. These data are in contrast with solubility data of Crovetto et al.,[55] who did observe a considerable decrease in the heat capacity of solvation for inert gases and methane between 25 and 325 °C, but even at 325 °C the heat capacity change remained quite substantial. Unfortunately, solubility measurements at high temperatures are generally subjected to large experimental errors. In later studies Biggerstaff et al.[56] used a flow calorimeter to measure directly the molar heat capacity of aqueous argon from 33 to 305 °C and found only a small decrease of the molar heat capacity when the temperature was raised to about 160 °C. Above this temperature, the heat capacity again *increases*. Near the critical point of water (about 250 °C), the heat capacity even increases extremely rapidly and goes to positive infinity.

The temperature dependences of the thermodynamic parameters of solvation for a large variety of apolar liquids in water show remarkable similarities. First, the enthalpy of solvation for apolar liquids is zero near room temperature, irrespective of the nature of the species (see Fig. 2b). Near 110 °C, the entropy of solvation for apolar liquids becomes zero. Apparently, both temperatures are universal, and are now generally referred to as T_H and T_S, respectively. The temperature dependence of the thermodynamic parameters of solvation for apolar liquids strongly resembles that for apolar gases (Fig. 2a, b). Also for the dissolution of a large series of apolar gases, temperatures can be found where $\Delta H^{\ominus}$ and $T\Delta S^{\ominus}$ reach common values but differ from zero. The occurrence of isoenthalpic and isoentropic temperatures for the thermodynamics of solvation for apolar compounds in water was rationalized by Lee.[57] His explanation is based on the assumption that the changes in enthalpy and entropy are linear functions of some property of the solute [Eq. (1)].

$$\Delta X^{\ominus} = a_X \sigma + b_X \tag{1}$$

Here $\Delta X^{\ominus}$ is the thermodynamic quantity involved, σ the property of the solute (usually the surface area), a_X a species-independent linear function of temperature, and b_X the value of $\Delta X^{\ominus}$ when a_X is zero. The molar thermodynamic quantities of solvation for apolar liquids and gases can now be expressed as functions of temperature in terms of the heat capacity change, assuming that the latter is independent of temperature,[57] according to Equations (2)–(4), where T_H^* and T_S^* are the isoenthalpic and isoentropic temperatures.

$$\Delta G^{\ominus} = \Delta G^* + \Delta C_p(T - T_H^*) - T\Delta C_p \ln(T/T_S^*) \tag{2}$$

$$\Delta H^{\ominus} = \Delta H^* + \Delta C_p(T - T_H^*) \tag{3}$$

$$\Delta S^{\ominus} = \Delta S^* + \Delta C_p(\ln T/T_S^*) \tag{4}$$

ΔH^* and ΔS^* are the values of the enthalpy and entropy of solvation at T_H^* and T_S^*, respectively. The solubility function [Eq. (5)] shows that the solubility of apolar compounds in

$$\Delta G^{\ominus}/T = \Delta G^*/T + \Delta C_p(1 - T_H^*/T) - \Delta C_p \ln(T/T_S^*) \tag{5}$$

water reaches a minimum at T_H^*. Lee[230] argued that T_H^* and T_S^* are the temperatures at which the enthalpy and the entropy of solvation, respectively, are independent of the selected property of the solute. The heat capacity change fully accounts for the temperature dependence of enthalpy and entropy of solvation,[58] and ΔH^* and ΔS^* are independent of temperature. According to Equations (3) and (4), a plot of $\Delta H^{\ominus}$ and $\Delta S^{\ominus}$ versus ΔC_p for a series of apolar gases or liquids at a selected temperature T should be linear. This has been experimentally confirmed by Sturtevant,[59] Murphy et al.,[60] and Baldwin.[61] From these plots the values of T_H^* and T_S^* have been derived.

Interestingly (vide supra), ΔS^* and ΔH^* are zero for the solvation of apolar *liquids* in water. Hence T_S^* and T_H^* equal T_S and T_H (about 110 and 25 °C, respectively), and Equation (6) applies at each temperature T.[59] Equation 6 does

$$\ln(T_S/T) = \Delta C_p/\Delta S^{\ominus} \tag{6}$$

not hold for the dissolution of apolar *gases* in water since ΔS^* and ΔH^* are *not* zero. T_S^* and T_H^* are about 124 and 94 °C, respectively.[62, 63] Apparently, the entropy of solvation is not completely proportional to the surface area, and even a mathematical point solute gives rise to an entropy of solvation of about $-80\ \mathrm{J\,K^{-1}\,mol^{-1}}$.[60] $T\Delta S^*$ is similar to the difference in translational Gibbs energy between the gas and the liquid phase. A similar phenomenon was observed in Figure 1. Although Biggerstaff et al.[56] showed that the heat capacity of an aqueous solution of argon does not depend dramatically on the temperature, T_S^* is a hypothetical temperature. Nevertheless, the variation in T_S^* for the solvation of apolar gases and liquids with temperature is surprisingly small. In contrast, the standard deviation of T_H^* is quite substantial. The existence of a unique value of T_H^* seems to be reserved only for larger liquid hydrocarbons.

The strong temperature dependence of the enthalpy and entropy of solvation for apolar gases and liquids in water

throws a different light on the analysis of thermodynamic solvation parameters measured at or near room temperature. The analysis of thermodynamic parameters of solvation for linear alkanes by means of increments (Table 2) is substantially dependent on temperature. For example, the entropy of solvation for gaseous alkanes decreases strongly with increasing temperature and eventually becomes identical for all alkanes near T_S^*. This means that the incremental methylene contribution to the entropy of solvation at T_S^* is zero. With respect to the enthalpy of solvation, the methylene contribution is zero at T_H^*. The incremental contributions to entropy and enthalpy of solvation can adopt virtually a broad range of values dependent on the temperature. In contrast, the Gibbs energy increment is hardly sensitive to temperature changes.

2.2. The Role of Hydrophobic Interactions in Protein Conformation and Stability

The stability of native protein structures and the folding of an extended protein chain have been subjects of extensive research for more than fifty years.[64, 65] Today, it is almost generally accepted that hydrophobic interactions constitute an important factor in the stability of the folded structure of water-soluble proteins.[65] The spatial distribution of α-amino acid residues in the native protein shows that, on average, α-amino acids with apolar character are found in a dense hydrophobic core in which the exposure to water is minimized.[66–68] Recently, Rose et al.[68] showed that the average spatial requirement of the α-amino acids that make up this apolar core is related to the residue hydrophobicity. Of course, Kauzmann[6] introduced the whole concept of hydrophobic interactions in connection with the interactions between apolar side chains of α-amino acid residues and their proposed importance for the stability of biopolymers. A controversy remains whether the stability of the native structure of proteins is caused by van der Waals interactions between apolar side chains or whether water actively induces the formation of an apolar core.[13, 14, 69] Obviously, this discussion strongly relates to our current understanding of the molecular basis of hydrophobic interactions. Since native structures of proteins unfold upon cooling as well as upon heating,[70] a study of both the cold and hot denaturation of native protein conformations might give valuable information about hydrophobic interactions. It must be recognized that these interactions are primarily *bulk* hydrophobic interactions.

Another topical debate centers on the question as to what extent the alleged hydrophobic interactions determine the structure of native proteins. On one hand, Dill et al.[71, 72] reported a successful theoretical analysis accounting for the temperature dependence of stability and folding of large globular proteins based on the assumption that hydrophobic interactions are the driving force for the folding of globular proteins. According to Dill,[64] hydrophobic interactions between apolar α-amino acid residues allow the extended protein chain to fold itself in only a limited number of ways. The ultimate and unique conformation is subsequently determined by more specific polar interactions. On the other hand, the theoretical analysis of solvent effects on protein folding in terms of solvation energies of individual parts of the total protein reported by Ben-Naim[73, 74] has been taken as evidence that the importance of hydrophobic interactions has generally been overestimated. The suggestion was made that correlations between hydrophilic functional groups are even more important than those between hydrophobic side chains. In particular hydrogen bonds, also at the surface of the protein, were proposed to be of paramount importance for the stability of native protein conformations.

The native structure of proteins is generally only about 50 kJ mol^{-1} more stable than the denatured state. The formation of a compact, folded protein is strongly opposed by entropic forces. A variety of intramolecular forces between α-amino acid residues in the folded state are known that contribute to the overall stability of the native protein structure. Due to the marginal stability of the folded conformation, each of these individual contributions can be decisive. Intramolecular interactions are well established, and most authors agree that these include electrostatic interactions, torsional or other "local" interactions, polar interactions (hydrogen bonds), van der Waals interactions, *and* hydrophobic interactions.[64, 75] The long-range electrostatic interactions include the classical repulsions between charged residues as well as specific electrostatic interactions due to bridging of oppositely charged α-amino acids.[76] Ion pairing is especially important at the surface of proteins.[77] Torsional and local interactions originate from preferential conformations of sequences of three or four α-amino acids, arising from short- and long-range interactions among these neighboring residues. Karplus and Holley[78] were quite successful in accounting for the architecture of proteins on the basis of these local interactions.

Hydrogen bonding is also very important in determining the structure of proteins, but if it is to be the driving force for the folding of proteins, hydrogen bonding of the unfolded protein with water must be less favorable than hydrogen bond interactions between α-amino acids in the native state of the protein. Jorgensen[79] showed on the basis of computer simulation studies that amides tend to stack in aqueous solution, but that stable amide–amide hydrogen bonds are not very likely. Dimerization of organic compounds in water has only been observed when multiple hydrogen bonds are involved. Hydrogen bonding between α-amino acids buried in the apolar core of the native protein can, nevertheless, provide additional stability for the structure.[80] Finally, interactions between permanent or induced dipoles, generally qualified as van der Waals forces, are of great importance for the stability of native protein structures.[81] This has commonly been traced back to the fact that water constitutes the natural environment for most soluble proteins. Dispersion forces between the side chains of apolar α-amino acids in the native conformation of the protein replace interactions with water in the extended conformation. As argued above, it is very difficult to make a proper distinction between van der Waals interactions and hydrophobic interactions, and the active role of the solvent is still far from clear.

α-Amino acid sequences determine the native structure of a protein. It is known that these sequences are not unique, and many different sequences can code for proteins with essentially the same native conformation. Creation of cavities in the hydrophobic core of the protein by shortening the

side chains of certain α-amino acids, the introduction of α-amino acid residues with unsatisfied hydrogen bonding, and the formation of sterically crowded regions by incorporation of bulky α-amino acids are generally not favorable for the stability of the protein, but the way in which a protein can accommodate mutations commands respect.[82]

A few years ago Sauer et al.[82, 83] elegantly showed that the sequence of α-amino acids, which plays an essential role in the formation of the core of the protein, can be replaced by alternative α-amino acids on two conditions: first, these residues must maintain the overall hydrophobicity, and second, the new packing arrangement must satisfy steric requirements. Site-directed mutagenesis combined with sophisticated calorimetric stability measurements have shown that substitution of individual α-amino acids buried in the hydrophobic interior of the protein does lead to changes in stability of the native protein.[84] The creation of a cavity in the interior of the protein destabilizes the native conformation to an extent that is strongly dependent on the actual site of the mutation.[81, 85, 86] Usually, the destabilization increases with increasing cavity size.

Kellis et al.[85, 86] and Eriksson et al.[81] studied the effects of several side-chain mutations on protein stability and focused on the response of the protein structure to cavity-creating mutations, such as the replacement of leucine residues by alanine (which is equivalent to decreasing the hydrophobicity by removing one methylene group). Eriksson et al.[81] showed on the basis of crystal structures of six mutants of T4 lysozyme that the packing of the core did not completely fill the created cavity, although side chains protruded into the cavity to some extent. Apparently, the protein interior consists of rigid parts alternating with more flexible regions. The presence of water molecules in the remaining cavities could not be determined. It is, however, extremely difficult to detect isolated water pools or water molecules. Generally, a considerable part of the volume of protein crystals is occupied by water molecules. Water molecules are found inside the protein at positions where they can form hydrogen bonds with the α-amino acids buried in the apolar interior. They may also be located in cavities and crevices created by insufficient packing. These interactions have been an important topic of research.[87] The role of these isolated water molecules for the stability of the folded protein structure can be substantial.[88]

In the last few years Monte Carlo and molecular dynamics simulations have been used to compute changes in the Gibbs energy for protein folding when a particular α-amino acid residue is replaced by another less hydrophobic moiety (e.g. leucine → alanine) by using Gibbs energy perturbation methods (see Section 3.5).[85, 89, 90] Prevost et al.[90] showed that solvation of the unfolded, unsolvated wild-type protein is hardly affected by the mutation, but that folding of the dissolved chain becomes more favorable when the more apolar residue is incorporated. This phenomenon can be reconciled with the fact that the Gibbs energy of solvation for apolar gases in water is only slightly dependent on the magnitude of the apolar surface area (see Section 2.1). This emphasizes that the interactions between apolar moieties in the core of the native protein are essentially bulk hydrophobic interactions. The conclusion given by Prevost et al.[90] that the observed decrease in stability of the mutant structure cannot be attributed to a hydration phenomenon is not correct. The decreased stability resulting from the leucine–alanine mutation is usually attributed to the loss of van der Waals interactions in the core of the protein.[81, 85, 86, 91] A remarkable result of recent simulation studies is that intrinsic side-chain terms contribute significantly to the reduced stability of mutated proteins.[90]

The packing of hydrophobic α-amino acids in a hydrophobic core leads to a highly compact conformation. Thermodynamic parameters of folding for an inactive protein chain show remarkable similarities with thermodynamic parameters of the solvation for apolar liquids in water.[12, 36, 61, 92–94] Moreover, the ratio of the entropy and heat capacity change of denaturation is constant [see Eq. (6)].[59] The heat capacity for the denaturation of proteins is linearly related to the fraction of hydrophobic residues[92] but is only slightly dependent on the temperature.[36, 70, 94] Therefore, the interior of the protein has been frequently treated as an apolar liquid or an oil drop.[95] The process of "hiding" apolar α-amino acids from water in the hydrophobic core has been modeled by determining the relative solubilities of these α-amino acids in water and in various apolar solvents.[9, 96–98]

An intriguing observation was made by Privalov,[92] who found that for the unfolding of a number of globular proteins the changes in enthalpy and entropy per amino acid residue reach a common value at 110 °C. Baldwin[61] noticed that this temperature agrees very well with the temperature at which the entropy of dissolution for apolar liquids in water becomes zero (T_S, see Section 2.1). An analogy was drawn between the thermodynamics of folding for inactive proteins in water and of the transfer of hydrocarbons from an aqueous solution to their liquid state. It was suggested[61] to estimate the hydrophobic contribution to protein stability from the characteristic temperatures T_S and T_H (the hydrocarbon model).

By using Equations (2)–(4), the Gibbs energy of protein folding can be expressed [Eq. (7)]. This relation suggests that

$$\Delta G^{\ominus}_{\text{folding}} = \Delta G^{\ominus}_{\text{nh}} + \Delta G^{\ominus}_{\text{h}} = \Delta H^{\ominus}_{\text{nh}} + T\Delta S^{\ominus}_{\text{nh}} + \Delta C_{p,\text{h}}\,(T - T_H) + \Delta C_{p,\text{h}}\,T \ln (T_S/T) \tag{7}$$

the nonhydrophobic (nh) contributions to the thermodynamics of protein folding are independent of the temperature.[61] A favorable nonhydrophobic enthalpy term is counteracted by a serious loss of entropy. At high temperatures the nonhydrophobic entropy term is large enough to cause denaturation of the protein. The analysis shows that hydrophobic interactions lead, at all temperatures, to a stabilization of the native structure of the protein. Near room temperature the stabilization is governed by a gain in entropy. Above 60 °C, however, the enthalpy becomes dominant and even prevails over the nonhydrophobic enthalpy contribution. The similarity with the solvation of apolar liquids in water is obvious.

However, much evidence indicates that it is misleading to view the interior of a protein as an apolar liquid. The packing densities of the hydrophobic core approach those of crystalline α-amino acids.[99] In addition, the interior of proteins contains several types of polar α-amino acid residues,[68] and exchange of certain core residues by more hydrophobic

counterparts does not always lead to higher protein stability.[100] In 1991 Sandberg and Terwilliger[101] showed that some polar residues reside in the core of the protein without actually interacting with each other. Apparently, the local polarity and the site-dependent packing energy are important factors for the stability of the native protein.[102]

Application of the hydrocarbon or oil-drop model to describe thermodynamic properties for the folding of proteins is also controversial for other reasons.[61] An important point of concern is that T_S^* and T_H^* are set equal to T_S and T_H, whereas Privalov et al.[12, 36] found that the entropy *and* enthalpy for the unfolding of native protein structures reach common values at T_S^*. Replacing T_S and T_H in Equation (7) by a single temperature T_S^* (or T_H^*) leads to the remarkable conclusion that hydrophobic effects *destabilize* the native protein conformation. The remaining nonhydrophobic terms show striking similarities with the thermodynamic solvation data for solid cyclic dipeptides,[12] suggesting that the structure of the interior of the folded protein is related to a solid structure.

The conclusion that hydrophobic effects destabilize the structure of proteins drawn by Privalov et al.[12, 36] contradicts a flood of experimental evidence obtained since the classical paper of Kauzmann[6] and recently sparked interesting discussions about the meaning of hydrophobicity.[13–15] Lee[57] rightfully remarked that these discussions did not provide much insight into the fundamental problem that T_S^* equals T_H^*. He argued that the assumed relation between the solvation of apolar liquids in water and the denaturation of globular proteins is based on the questionable assumption that only nonpolar groups are transferred from water to the interior of the proteins. He suggested invoking polar interaction terms as well, which would shift T_H^* without altering T_S^*. The term $\Delta G_h^{\ominus}$ introduced by Murphy et al.,[12] in which T_S equals T_H [see Eq. (7)], measures not only hydrophobic contributions but also the difference between the average contributions of polar and nonpolar interactions.

The analysis reported by Lee[57] reinforced the view of Privalov[75, 92] that cold denaturation is reflected by the fact that the favorable nonpolar, or hydrophobic terms become too small at low temperature. The temperature dependence of the Gibbs energy of hydrophobic interactions is very modest, which emphasizes the fact that native structures of proteins are only marginally stable. The cooperative effects of bulk hydrophobic interactions and polar interactions between α-amino acid residues in the interior of the protein are sufficient only over a very small temperature range to overcome the loss of configurational entropy. Indeed, the occurrence of cold and hot denaturation is indicative of opposing hydration contributions arising from the solvation of polar and nonpolar α-amino acid residues of the unfolded protein.[70]

2.3. The Role of Hydrophobicity in Molecular Recognition and Host–Guest Complexation

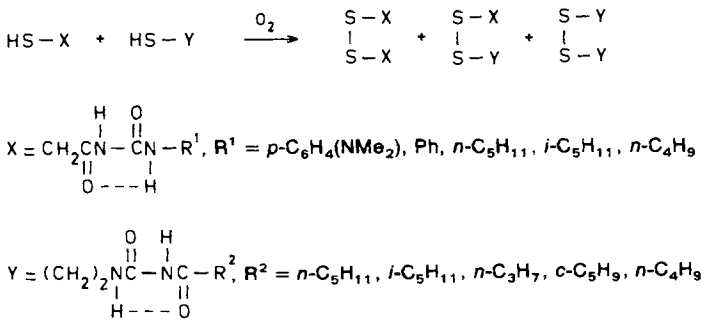
The specific binding of reactants in the active site of enzymes constitutes an important research topic. In these molecular recognition processes hydrophobic interactions are expected to play a major role. Originally molecular recognition was a term reserved for biochemistry and biomimetic chemistry.[103, 104] The current popularity of supramolecular chemistry has caused a shift to a more general interpretation of the term.[105, 106] Noncovalent interactions, which lie at the heart of molecular recognition, have become a fashionable topic of research.[107]

A convenient approach to studying basic aspects of noncovalent interactions is provided by synthetic host–guest chemistry. The formation of strong host–guest complexes is particularly feasible in aqueous solutions. Generally, this has been attributed to hydrophobic effects, although electrostatic interactions are also important.[107] Host–guest complexes are often stabilized by π–π or stacking interactions[108] and hydrogen bonding.[107] Stacking interactions play a dominant role in aggregation of dye molecules and hydrotropic compounds.[109, 110] In addition, a combination of stacking interactions and hydrogen bonding governs the strong binding of nucleotides to receptor sites.[111]

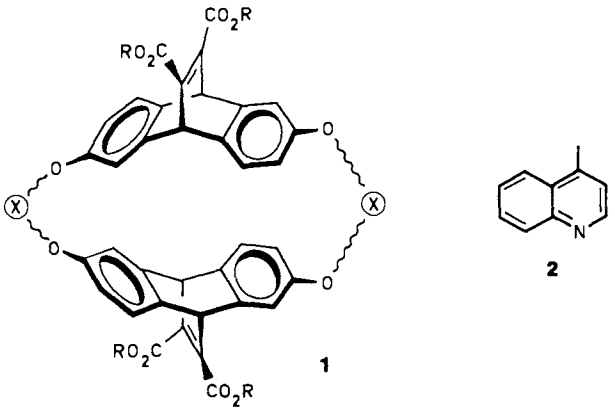
The role of hydrophobic interactions in host–guest chemistry and molecular recognition is still ambiguous. The arguments show remarkable similarities with those that characterize discussions in the field of protein stability and mainly center on the question whether van der Waals interactions or hydrophobic interactions govern host–guest complexation. In addition, one should recognize that host–guest complexation can involve either bulk or pairwise hydrophobic interactions. To illustrate this point we note that complexation of an apolar guest molecule in an apolar cavity of a macrocyclic host is usually accompanied by complete desolvation of the guest molecule, whereas pairwise stacking of, for example, nucleotides or dye molecules involves only local dehydration. In this section, we would like to signal a few remarkable results obtained in the field of synthetic host–guest chemistry. In the light of the feverish activities in this field, we restrict ourselves to a few examples that illustrate the current debate. For extensive surveys of synthetic host–guest chemistry in aqueous solutions we refer to reviews by Schneider[107] and Diederich.[112]

Complexation of neutral molecules with cyclic host molecules, and molecular complexation in general, involves a variety of different binding interactions, and it is difficult to separate the hydrophobic component even if one has agreed upon the exact definition of the term. In their studies of solvent and salt effects on binding constants, Schneider et al.[113] found evidence that hydrophobic interactions play a major role in the binding of apolar substrates to macrocyclic host compounds. An interesting contribution was reported by Endo et al.,[114] who studied the oxidation of associated thiols having an amide-like binding site and an alkyl recognition site (Scheme 3). A small but significant selectivity was observed in the formation of symmetrical and unsymmetrical products, which was attributed to recognition of hydrophobic moieties. Unfortunately, many of these reactions were carried out with a considerable amount of organic cosolvents and not in a dilute aqueous solution.

Thermodynamic parameters of complexation processes are sometimes difficult to interpret because of conformational changes of the host molecule upon complexation.[115] Particularly solvation of the cavity prior to complexation causes ambiguities in interpretations of thermodynamic



Scheme 3. Schematic representation of the oxidative coupling of thiols HSX and HSY to yield the symmetrical and unsymmetrical disulfides. The recognition sites X and Y are given as well (see ref. [114]).



Scheme 4. Electron-rich synthetic receptor molecule **1** and electron-deficient guest molecule **2**.

parameters at the molecular level. In spite of these pitfalls, measurement of the temperature dependence of binding constants provides valuable new insights into the molecular origin of recognition processes. Frequently, a large and positive entropy change upon complexation has been found (see, for example, Stauffer et al.[116]), which is an indication for the occurrence of hydrophobic interactions. The binding efficiency of host molecules has also been successfully enhanced by increasing the hydrophobic character of the binding site.[112] The existence of a large and negative heat capacity change upon association of apolar molecules in water is generally considered to be a decisive criterion for the occurrence of hydrophobic interactions. Indeed, Harrison and Eftink[117] and Stauffer et al.[116] found a negative heat capacity change for some host–guest complexation processes.

In textbooks[118] hydrophobic contributions to molecular recognition are attributed to positive entropy changes due to the release of structured water molecules in the hydration shells of apolar moieties. More recently, some experimental results have cast serious doubt on the active role of water molecules. Diederich et al.[115] found that complexation of benzene in a cyclophane host molecule is *enthalpy* driven at room temperature. The process is even accompanied by a slightly *negative* entropy change. Enthalpically controlled complexation was also found by Harata et al.[119] These observations caused some discomfort, which tempted Diederich et al.[115] to introduce the paradoxical term "enthalpic hydrophobic effect". The molecular origin of the complexation process was attributed to London dispersion interactions between host and guest and the binding state of water molecules in the interior of the host before binding.[120]

Stauffer et al.[116] showed that the enthalpy for the binding of **2** in host **1** (Scheme 4) is extremely sensitive to temperature. These heat capacity effects are more pronounced when guest molecules of increased hydrophobicity are involved. The heat capacity effects for host–guest complexation in organic solvents such as chloroform are also considerable, though less pronounced than in water.[116] In Figure 3 the changes in Gibbs energy, enthalpy, and entropy ($T\Delta S$) are plotted as a function of temperature for the binding of compound **2** in host **1** in water. Near room temperature the complexation is governed by a favorable entropy, whereas at elevated temperatures the enthalpic contribution prevails. The striking resemblance to the data plotted in Figure 2b suggests a relation to the solvation of apolar liquids in water.[120] The gain in entropy occasionally observed for complexation of apolar guest molecules in an apolar cavity of a macrocyclic host near room temperature[116] cannot be considered the sole driving force for hydrophobic contributions to host–guest interactions and certainly cannot apply to those cases for which the enthalpy governs host–guest complexation even near room temperature.[115]

2.4. Association of Amphiphiles

Aggregation of amphiphilic compounds in aqueous solution leads to complex supramolecular structures. Largely depending on the molecular architecture of the amphiphile, a wealth of three-dimensional structures can be formed, ranging from spherical and rodlike micelles to bilayer or multilayer structures, inverted hexagonal phases, and other sometimes very intriguing spatial arrangements. Introduction of chiral centers in the polar headgroup area can lead to beautiful structures (see, for example, Fuhrhop et al.[121, 122]). For a survey of the relation between surfactant structure and aggregation behavior we refer to a paper by Nusselder et al.;[123] for other reviews see Kunitake et al.[124] and Menger et al.[125]

It is almost generally accepted that an aqueous environment is a prerequisite for the three-dimensional assembly of amphiphilic molecules. However, examples have been found

for surfactant aggregation in other solvents such as hydrazine,[126] formamide,[127] ethylene glycol,[128] and ethylammonium nitrate.[129] Interestingly, partially fluorinated alkanes behave as amphiphilic compounds in apolar solvents in which they aggregate readily.[130, 131] Traditionally, however, hydrophobic interactions are considered to be the major driving force for amphiphile aggregation.[9] Results of studies on the micelle formation of cetyltrimethylammonium bromide (CTAB) and trimethyltetradecylammonium bromide in various solvents and at elevated temperatures urged a reappraisal of this traditional view.

As shown in Table 3, the Gibbs energies for the micelle formation of CTAB at room temperature in water and in hydrazine are not very different.[132] In contrast, the enthalpy and entropy for micelle formation differ dramatically.

Table 3. Gibbs energy, enthalpy, and entropy of micelle formation for CTAB in water and in hydrazine at different temperatures (taken from ref. [132].

Solvent	T [°C]	ΔG [kJ mol^{-1}]	ΔH [kJ mol^{-1}]	$-T\Delta S$ [kJ mol^{-1}]
water	25	−43.8	−12.6	−31.2
	95	−48.0	−51.9	3.9
	166	−44.4 [a]	−65.3	22.1
hydrazine	35	−29.7	−46.0	16.8

[a] A value of −43.2 is obtained by calculation; the values for ΔH and $T\Delta S$ may also be incorrect.

In water, micelle formation is driven by a favorable entropic contribution. As evident in Figure 4 and Table 3, the enthalpy and entropy of micelle formation of CTAB[133] and other surfactant molecules[134] are strongly dependent on temperature. At elevated temperatures the formation of micelles is governed by a favorable enthalpy and even counteracted by a loss of entropy. In fact, the thermodynamic parameters for micelle formation in water at these temperatures become similar to those found for micelle formation in hydrazine near room temperature. The aggregation number decreases with increasing temperature, and at 170 °C the aggregation number is similar to that found in polar organic solvents at room temperature.[135] Apparently, the exceptional position of water among hydrogen-bonding solvents is less evident at higher temperatures. It is furthermore remarkable that the Gibbs energy for the formation of micelles is only moderately affected by temperature, in other words, the enthalpy and entropy changes (as $T\Delta S$) are almost fully compensating. Lumry et al.[136] as well as Evans and Wightman[133] have provided a firm basis for discussions about compensation behavior of thermodynamic parameters of solvation and micelle formation in aqueous solvents (see Section 3.2).

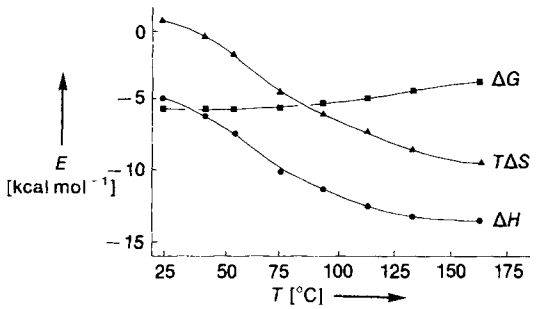

Fig. 4. Thermodynamics of micelle formation of trimethyltetradecylammonium bromide as a function of temperature, as determined by the equilibrium model (taken from ref. [133]).

The temperature dependence of the thermodynamics of micelle formation in water is remarkably similar to that of the solvation of apolar compounds in water and of the complexation of synthetic host and guest molecules (cf. Figs. 2a, b, 3, 4). This strongly suggests that these processes have a common molecular origin described by the term hydrophobic interactions. The molecular interpretation of this term in relation to aggregation of amphiphilic molecules is still a matter of debate. In 1989 Evans and Miller[135] emphasized the importance of van der Waals interactions for the aggregation of amphiphilic compounds. This, again, stresses the current dilemma centering on the distinction between dispersion interactions and hydrophobic interactions. A possible answer has been provided by Ben-Naim,[20] who clearly distinguishes the solvent-induced contribution to solute–solute interactions from the van der Waals forces. A serious disadvantage of this approach is that it is very difficult to estimate the magnitude of the solvent-induced contribution.

2.5. Surface Forces and Hydration of Flat Surfaces

In the past decade, much attention has been paid to the forces between aggregates of amphiphilic compounds in aqueous solution (for recent surveys, see Israelachvili and Wennerström[137, 138]). These so-called surface forces play an important role in biological processes as well as in a number of industrial applications such as mineral flotation, colloid stability, wetting of surfaces, and coating. In order to understand the molecular origin of surface forces between, for example, bilayer structures, forces between apolar surfaces were also considered. These forces exhibit a quite remarkable dependence on the distance between the macroscopic bodies.[139] In particular, forces between apolar surfaces show extremely long-range attractions unknown for polar surfaces.[140–145] In contrast with previous experimental results obtained by Israelachvili and Pashley[140] and Pashley et al.,[141] who found an exponential decay of attractive forces between apolar surfaces when the separation was increased from 0 to 15 nm, it has recently been shown that attractive forces between charge-free surfaces are measurable even at separations of 70–90 nm.[143–146] This means that the attractive forces are transmitted over distances corresponding to more than 300 interfacial water molecules! Claesson and Christenson[143] showed that the force between fluorocarbon surfaces in water increases exponentially until they are separated by a distance of about 10 nm. Beyond 10 nm the attractive force is even more amplified. A typical example is shown in Figure 5.

Today, much is known about the predominantly repulsive interactions between amphiphilic and polar surfaces.[137, 138, 147, 148] Despite the increasing interest in the

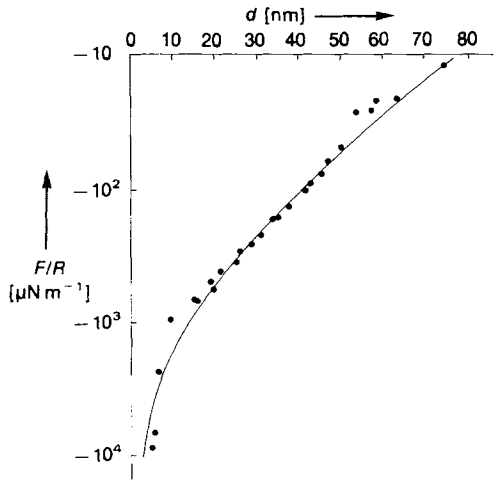

Fig. 5. Attractive surface force F/R plotted versus the separation d of fluorocarbon-covered mica surfaces (taken from ref. [167]).

anomalous forces between nonpolar surfaces in water, the origin of these forces is a matter of continuing discussions. Clearly, hydrophobicity of the surface areas is essential for the observed long-range forces. Long-range attractions have not been found between uncharged *and* nonhydrophobic surfaces such as carbohydrates[149, 150] nor between surfaces coated with a mixture of hydrophobic and hydrophilic compounds.[150] Claesson et al.[142] showed that the measured force is significantly stronger than would be expected on the basis of simple van der Waals forces. Moreover, van der Waals forces are only effective at surface separations of at most 10 nm. Some attempts have been reported to explain these amazing hydrophobic attractive forces. A possibility that has been considered is the formation of vapor cavities between the surfaces at distances less than a few hundred nanometers. The presence of such cavities has been established repeatedly.[146, 151, 152] On account of these cavities the force between the apolar surfaces is not an equilibrium force. Claesson et al.[152] showed, however, that these cavities can never give rise to the observed attractive forces. An alternative explanation is based on the possible role of electrostatic forces, but the fallacy of this view was demonstrated by Christenson et al.[145]

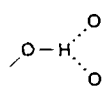
Several approaches focus on the properties of water present between the apolar surfaces. The hydrophobic forces are thought to arise from the alleged metastable character of water between the surface. The structure of water molecules near a large flat apolar surface has been a topic of extensive computer simulation studies. These studies[153–166] show clearly that water molecules adjacent to a hydrophobic surface are not capable of forming the optimal number of hydrogen bonds, although near the hydrophobic surface they clearly tend to form a clathrate-like structure.[157, 161] This structural response does not penetrate far into the medium, and the order in the fluid persists only over a few molecular diameters.[157, 159]

In 1989 Eriksson et al.[167] presented a phenomenological theory for the long-range attractive forces. The model was based on the variational mean-field theory developed by Marčelja et al.[168] to account for the interactions between small hydrophobic solute molecules. Eriksson et al.[167] suggested a structural mechanism based on a layer-to-layer propagation of the force due to ordering of the water molecules at the surface. Unfortunately, the question of how the force can be passed through so many water molecules remains unanswered. In the same year Attard[169] attributed the long-range attractions to van der Waals forces. Since these forces can normally not account for the observed magnitude and distance dependence of the attractive forces, he invoked an anomalous electrostatic response of the fluid between the surfaces. The large electrostatic response was assigned to the structural changes of liquid water at the surface. The molecular origin of this effect has, however, not been identified yet. In summary, although some efforts have been made to understand the inexplicably long-range action of the hydrophobic attractive forces between apolar surfaces in water, these attempts only rephrase the intriguing question of how water can mediate these forces across such a great distance.

2.6. Spectroscopy, Ultrasound, Light Scattering, and Diffraction Studies: Selected Results from the Last Few Years

The application of spectroscopic techniques to study hydrophobic effects peaked more than a decade ago. Because of the limitations of these techniques, these studies focused mainly on average changes in the organization of water molecules induced by apolar solute particles or, alternatively, on the preferential solvation or bulk hydrophobic interactions occurring at higher concentrations of the apolar solutes. Readers interested in applications of NMR spectroscopy are referred to publications of Zeidler[170] and Hertz and Leiter.[171] Results in the field of IR spectroscopy have been reviewed in detail by Walrafen[172] and Luck.[173] For more recent applications of IR spectroscopy we refer to the work of Symons et al.[174–176] and recent work of Engberts et al.[177] Most of the ultrasound studies of aqueous solutions also date from the sixties and seventies and have been reviewed thoroughly by Blandamer.[178] ESR spectroscopy has not been applied frequently, but it has been used almost exclusively to probe the environment of the solutes by inducing a spectroscopic response of the solute itself.[179] Most of these spectroscopic studies gave results that were consistent with the traditional picture of hydrophobic hydration. The question whether the structure of water is enhanced by the formation of more hydrogen bonds, stronger hydrogen bonds, or a reduction of free OH bonds has not been unambiguously answered.

In 1989 Raman scattering studies[180] confirmed the presence of bifurcated hydrogen bonds (Scheme 5), the existence



Scheme 5. Schematic representation of a bifurcated hydrogen bond.

of which had been proposed several times. Water molecules with five neighbors cause defects in the tetrahedral hydrogen bond network of liquid water and lower the energy barriers

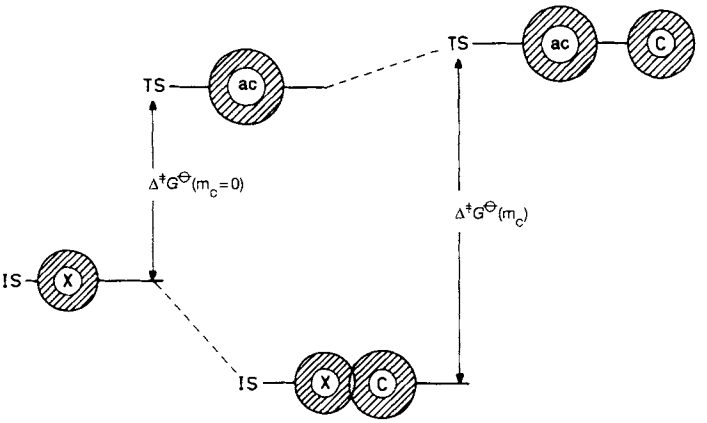
between different arrangements of the network.[181] The "extra" water molecule acts as a catalyst by making fast restructuring possible without disrupting hydrogen bonds. Recently, Sciortino et al.[182] tentatively suggested a link with hydrophobic hydration. The inert hydrophobic solute prevents water molecules in the hydrophobic hydration shell from being approached by a fifth neighbor, thus slowing down the molecular motion of the water molecules involved. The decreased mobility of water molecules in the hydrophobic hydration shell is therefore attributed to an *increased* local density of water. The opposite, increased mobility in water of decreased density, was observed by Pottel et al. a few years ago.[183]

The most direct information about the structure of hydrophobic hydration shells can be obtained from diffraction studies, since these experiments yield the total pair correlation function $G(R)$, which is the averaged sum of a large number of partial distribution functions $g_{ij}(R)$ representing the average distribution of atom type j relative to atom type i in solution (see also Section 3.3.1).[184] Unfortunately, it is extremely difficult to obtain accurate information concerning solute–water and solute–solute interactions in hydration shells present in highly dilute aqueous solutions, since the total $G(R)$ function is dominated by the water–water terms.[185] Isotopic labeling of components of the aqueous solutions provides a possible solution of this problem.[185] In 1990 Turner et al.[186] reported a neutron diffraction study of the hydration of tetramethylammonium chloride (TMACl) in aqueous solution (0.5–2 mol kg^{-1}) with isotopic substitution of nitrogen, chlorine, and hydrogen. The results indicate that the TMA ion is surrounded by water molecules that tend to orient their OH bonds tangentially to the surface of the solute. In this respect, the results confirm the general picture of a somewhat distorted, clathrate-like solvation cage. The water correlations, however, suggest that the relative orientation of water molecules in the hydration shell is not significantly different from that in bulk water. Moreover, no evidence was found for aggregation of the TMA ions, and the structure of the hydration shell appeared to be independent on the concentration of TMACl. Results of more diffraction studies of aqueous solutions of isotopically labeled solutes are eagerly awaited.

2.7. Organic Reactions in Water

Although living organisms depend in a unique way on water as a solvent and reagent for biochemical transformations, synthetic organic chemists do no particularly like water as a solvent for chemical reactions. This "hydrophobic" attitude stems from the fact that water is a bad solvent for many organic compounds and is, in addition, highly reactive towards many organic reagents. Nevertheless, the past decade has witnessed a remarkable reappraisal of water as a solvent for organic reactions. The pioneering work of Breslow et al.,[187] who reported intriguing solvent effects of water on notoriously solvent-insensitive Diels–Alder reactions constituted a major source of inspiration.

Our interest in organic reactivity in water and mixed aqueous solvents goes back some time and was mainly excited by the unpredictable effects of the solvent on the thermodynamic parameters of activation in the water-rich region of mixed aqueous solvents.[188, 189] Solvent effects in highly aqueous media directly reflect the interactions between solute particles, in other words, the interactions between the reactant(s) and the cosolvent, and between the activated complex and the cosolvent. In dilute solutions the rate effects are mainly caused by pairwise interactions, and the results indicate that these interactions are governed by the apolar character of the reacting species and the cosolvent (from a thermodynamic point of view, it is more appropriate to speak of a cosolute). In Scheme 6 a general example is given; the rate-decreasing effect of an apolar cosolvent C on a reaction involves a loss of apolar character during the activation process, schematically represented by the transformation of reactant X into activated complex ac.



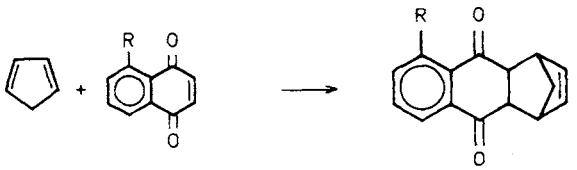
Scheme 6. Schematic representation of the effect of cosolvent molecule C on a reaction involving reactant X and activated complex ac in aqueous solution. IS = initial state, TS = transition state, $\Delta^{\ddagger}G^{\ominus}$ = standard Gibbs energy of activation.

Towards the end of the eighties Blokzijl et al.[190–194] reported a quantitative approach to explain solvent effects in dilute aqueous solvents in terms of pairwise interactions of cosolvents with reactant(s) and activated complex, respectively. By using the additivity principle developed by Savage and Wood (Section 3.3.2), contributions of functional groups in cosolvent molecules to the overall solvent effects could be determined. This approach does full justice to the complexity of intermolecular interactions in aqueous solutions. The additivity of functional group interactions was critically analyzed, and it was shown that the hydration shells of functional groups in close proximity are not independent of each other.[191] Hydrophobic methylene moieties were shown to generally retard organic reactions involving a decrease of apolar character during the activation process, whereas hydrophilic groups such as hydroxyl functionalities counteract this effect.[193] In the solvent systems examined, preferential solvation or solute aggregation does not occur. The solvent effects are therefore a consequence of hydrophobic encounters between apolar moieties in solution. These encounters are akin to molecular recognition processes but do not lead to aggregation or complexation.

Interactions between apolar groups in water are accompanied by the destructive overlap of hydrophobic hydration shells. Curiously, even apparently hydrophilic cosolutes like

carbohydrates and polyols induce a significant reduction of the rate constant of reactions involving apolar reactants and a more polar activated complex.[193, 195, 196] The hydration of polyols and carbohydrates is predominantly governed by hydrogen bonding. The rate-retarding effects suggest that apolar groups are always "noticed" by reacting species, even in the absence of hydrophobic hydration shells, whereas hydrophilic groups can be camouflaged and become almost indistinguishable from the OH groups of water.[195] Tentatively, we have made the suggestion[195, 196] that nature uses this feature in molecular recognition processes that involve polysaccharides at the surface of living cells.[197]

Diels–Alder reactions are dramatically accelerated *in* water.[198–203] The reaction of cyclopentadiene and 5-methoxynaphthoquinone (Scheme 7) has been studied in detail. The rate constants in *n*-hexane and in water are



Scheme 7. Intermolecular Diels–Alder reaction of cyclopentadiene with 5-methoxy-1,4-naphthoquinone. R = OCH_3.

7.73×10^{-4} and 5.26 $dm^3 mol^{-1} s^{-1}$, respectively. An interesting aspect of a bimolecular Diels–Alder reaction of apolar reactants in water is that the formation of the activated complex necessarily models the pairwise hydrophobic interaction between the apolar reactants. According to Breslow,[198] the hydrophobic packing of diene and dienophile is the most likely explanation for the observed rate effects. This idea is mainly based on a series of kinetic experiments in solutions of "salting-in" or "salting-out" materials.[198] The enhancement or disruption of the water structure is used as a criterion for the respective promotion or inhibition of hydrophobic packing. The finding that Diels–Alder reactions are also accelerated in the presence of β-cyclodextrin by complexation of the reactants in the hydrophobic interior, appears to support this view.[198, 201] In addition, rate constants for Diels–Alder reactions in mixed aqueous solvents were successfully related to solvent parameters such as the solvophobicity parameter S_P,[201] the polarity parameter $E_T(30)$,[202, 204] and the cohesive energy density.[199, 200] These correlations strongly suggest a relation with the hydrophobicity of diene and dienophile. Schneider et al.,[201] however, did not find a correlation between the hydrophobicity of the dienophile and the observed rate effect.

These explanations for the remarkable effect of water on the rate of Diels–Alder reactions in water are doubtful and leave some important questions unanswered. On the basis of a combined quantitative and qualitative study of solvent effects in a series of Diels–Alder reactions in dilute aqueous solvents, Blokzijl et al.[205, 206] found that the rate effect arises primarily from changes in the Gibbs energy of the initial state. The activated complex appeared to be only moderately sensitive towards solvent effects. The formation of a complex between diene and dienophile could not be detected.

A study of solvent effects on a series of intramolecular Diels–Alder reactions confirmed also that hydrophobic packing of diene and dienophile in the aqueous medium cannot be held responsible for the exceptional rate effects. Therefore, the high rate constant was attributed to the fact that the hydrophobicity of diene and dienophile is considerably relieved during the activation process, a process which has been termed "enforced hydrophobic interaction".[205, 206] The term "enforced" has been introduced to stress the fact that under the employed reaction conditions diene and dienophile do not aggregate spontaneously in water. The reactive encounter is subjected to serious geometrical constraints and in water is *less unfavorable* in terms of Gibbs energy than in organic solvents. Apparently, the activated complex is a highly adaptable species that can adjust itself to the aqueous environment. Hydrogen bonding to the polarized carbonyl bond of the dienophile appears to contribute significantly to the interaction between water and the activated complex (see also Desimoni et al.[207]). A computer simulation study of Diels–Alder reactions in aqueous solution reported by Jorgensen et al.[208] suggests a similar explanation.

Other organic reactions are also accelerated when conducted in aqueous solvents.[209–214] In most cases, a reduction of the hydrophobic surface of the reactants during formation of the activated complex can largely account for the observed rate effect, although polarization effects are important as well. It is remarkable that the low solubility of the reactants enhances their reactivity, whereas complexation or aggregation only renders them less reactive. A few examples have been given, mainly photochemical processes, for which aggregation of reactants in water is favorable for the rate and product distribution.[215]

Up to this point we have discussed primarily organic reactions in dilute aqueous solvents. But mixed aqueous solvents are particularly popular reaction media in physical organic chemistry. When high proportions of an organic cosolvent are used, the preferential solvation of the reagents due to bulk hydrophobic interactions becomes a dominant factor for the observed solvent effects. The onset of bulk hydrophobic interactions is a consequence of the occurrence of highly dynamic, cosolvent-rich domains. The absolute solvent effect is then a measure of the extent of pseudo-phase separation. Recently, we have shown that these solvent effects can be analyzed quantitatively by using an inverse Kirkwood–Buff treatment[216] (see also Section 3.3.1).

3. Part B. Theoretical Studies

3.1. An Overview of the Theoretical Approaches to Explain Hydrophobic Effects

Theoretical studies of hydrophobic effects can be divided into four major categories. Most straightforward are those studies in which a model is developed that accounts for the observed thermodynamic parameters of solvation of apolar compounds in water on the basis of thermodynamic considerations; these include the liquid hydrocarbon model, multiple-step models for solvation, compensation models, and mixture models. Most of these models aim at a better under-

standing of hydrophobic hydration, and approaches along these lines will be reviewed in Section 3.2. Many of the theoretical approaches to describe hydrophobic effects center on virial expansions of thermodynamic properties of aqueous solutions containing apolar solute particles. As will be shown in some detail in Section 3.3.1, virial coefficients can be related to interactions between solute particles in aqueous media. Hence, these studies mainly deal with hydrophobic interactions either pairwise or bulk. Theoretical studies have either aimed at an empirical documentation of virial coefficients for aqueous solutions of organic solutes (Section 3.3.2), or, alternatively, have been devoted to a (semi)-quantitative description of these virial coefficients on the basis of intermolecular forces (Section 3.3.3). As will be discussed in Section 3.3.1, virial coefficients can also be interpreted in terms of the distribution of solute particles over the entire solution. Computation of these distribution functions can therefore yield both interaction potentials and virial coefficients. The accuracy of the applied methods can be tested by comparing the results with experimentally obtained virial coefficients. During the past fifteen years highly sophisticated integral theories have been developed for the solute–solute and solute–solvent distribution functions. These interaction site models (ISM) are equally suited for studying both hydrophobic hydration and hydrophobic interactions. Some approaches that have received particular attention will be described in Section 3.3.4.

A very elegant but often criticized approach to the study of hydrophobic effects uses the scaled particle theory (SPT).[*] Although the SPT is inherently a rather rigorous simplification of reality, applications of SPT yield surprisingly accurate results, and researchers in the field constantly draw attention to this remarkable fact. Some intriguing results of improved versions of SPT in the past few years are summarized in Section 3.4. The rapid maturation of theories concerning molecular liquids and solutions during the past fifteen years has made computer simulations one of the most valuable tools in the study of hydrophobic effects. Monte Carlo (MC) and molecular dynamics (MD) calculations have provided chemists with detailed information on hydrophobic effects on a molecular level that has been largely unaccessible by experimental methods. The molecular picture that has emerged from computational studies has reinforced some aspects of the traditional ideas about hydrophobic hydration, but has caused growing doubts about the validity of the whole concept of hydrophobic interactions. A detailed discussion will be given in Section 3.5.

3.2. Thermodynamic Properties of Aqueous Solutions of Apolar Compounds; Some Models

Since the introduction of the concepts of hydrophobic hydration and hydrophobic interactions, theories have been developed to account for the remarkable thermodynamic properties of aqueous solutions of apolar compounds. As will be shown in this section, thermodynamic parameters are a notoriously unspecific starting point for developing structural models. Many models can account for the thermodynamics of the solvation of apolar compounds in water, and most have a strongly qualitative character. Although each model emphasizes different aspects of hydrophobic hydration and hydrophobic interaction, most models can be categorized as mixture models. In these, water is considered to be a mixture of two or more species characterized by some differentiating property such as the number, strength, or length of hydrogen bonds. Introduction of apolar solute particles is thought to shift the equilibrium between the species. The classic models of Frank and Evans,[4] Frank and Wen,[23] Neméthy and Scheraga,[21, 22] Kauzmann,[6] and Ben-Naim[10, 26] are in fact mixture models (Section 1.2).

The geometric relaxation model developed by Lumry et al.,[217] a more recent example of a mixture model, is a hybrid of the classic model of Frank and Evans[4] and the flickering cluster model of Frank and Wen.[23] It is based on the water model of Sceats and Rice[218] and considers the water structure as composed of pairwise-bonded water molecules with continuously distributed energies, bond angles, and bond lengths. Two limiting structures are defined on the basis of bond length. One is characterized by short bonds, low entropy and enthalpy, and a large free volume available for solute particles; the other is characterized by long bonds, a large librational freedom of individual water molecules, and little free space for solute particles. Lumry et al.[217] expected small clusters of water molecules to undergo spontaneous "cluster contractions and expansions", thereby fluctuating between the limiting structures. An apolar solute particle was thought to promote the structure with short bonds by occupying the free volume and thus shifting the equilibrium.

The thermodynamic aspects of mixture models can be illustrated by a recent mixture model developed by Muller.[219] This model clearly finds its precursor in the classic model of Neméthy and Scheraga[21, 22] and is based on the assumption that every hydrogen atom in an aqueous solution can either participate in a hydrogen bond or is not involved in hydrogen bonding at all. An additional distinction is made between hydrogen atoms of bulk solvent molecules and hydrogen atoms that are perturbed by the presence of an apolar solute particle. The formation and disruption of hydrogen bonds is considered an equilibrium process, on the basis of which the enthalpy and heat capacity can be defined. A crucial aspect of the model is that it is not necessary to make any statements about the extent of structuring in the hydration shell (hs) in relation to the bulk (b) other than that $\Delta H^{\ominus}_{hs} \neq \Delta H^{\ominus}_{b}$ and $\Delta S^{\ominus}_{hs} \neq \Delta S^{\ominus}_{b}$. In this way the heat capacity of the bulk and the hydration shell can be analyzed separately. When n^h is the number of hydrogen atoms in the hydrophobic hydration shell, the heat capacity increment is given by Equation (8), in which $C^h_{p,b}$ and $C^h_{p,hs}$ are the heat

$$\Delta C^{\ominus}_{p} = n^{h}(C^{h}_{p,hs} - C^{h}_{p,b}) \qquad (8)$$

capacity contributions per mole of hydrogen atoms in the bulk and the hydration shell, respectively. The heat capacities can be quantified on the basis of the enthalpy of the equilibrium between broken and intact hydrogen bonds.

The heat capacity contribution of hydrogen atoms in the hydration shell was shown to be described by Equation (9),

[*] In the scaled particle theory all particles are assumed to be spherical with diameters defined such that thermodynamic quantities of solutions and pure liquids are reproduced.

$$C^{h}_{p,hs} = (\Delta H^{\ominus}_{hs})^2 K_{hs}/RT^2(1 + K_{hs})^2 \quad (9)$$

in which K_{hs} is the equilibrium constant. If $K_b = K_{hs}$, a positive heat capacity change can only occur when $\Delta H^{\ominus}_{hs} > \Delta H^{\ominus}_{b}$. Alternatively, if $\Delta H^{\ominus}_{hs} = \Delta H^{\ominus}_{b}$, then K_{hs} must be larger than K_b. Hence, the heat capacity effect can either be caused by increasing the strength of the hydrogen bonds or by increasing the number of broken bonds. A cooperative effect observed if $\Delta S^{\ominus}_{hs} > \Delta S^{\ominus}_{b}$ can lead to a very large heat capacity effect. A realistic choice of the parameters in Equation (9) yields a satisfactory description of the temperature dependence of the thermodynamic parameters for the solvation of apolar compounds in water. This mixture model clearly shows that statements about structure of the hydration shell with respect to bulk water are irrelevant without a proper definition of structure. Muller[219] stressed the fact that even at elevated temperatures, structural reorganization in hydrophobic hydration shells is still substantial and that the heat capacity change does not become zero; this was proven experimentally as well (see Section 2.1).

A similar but more general two-state model has been used by Gill et al. and Wadsö et al.[58, 63, 220–222] According to this model of a noncooperative hydration shell, each water molecule exists in two thermodynamic states separated by an enthalpy difference ΔH. These different states are caused by the fact that a water molecule in the solvation shell is affected by the presence of a solute boundary and cannot participate in the maximum number of hydrogen bonds. Each water molecule is assumed to behave independently of its neighbors, and cooperative effects are not taken into account. The heat capacity for the solvation process is now given by Equation (10), in which N is the number of water molecules in the solvation shell, τ the reciprocal temperature $(1/T)$, and τ_m the

$$\Delta C^{\ominus}_{p} = N\frac{(\Delta H)^2}{RT^2}\frac{\exp[-(\Delta H/R)(\tau - \tau_m)]}{[1 + \exp[-(\Delta H/R)(\tau - \tau_m)]^2} \quad (10)$$

reciprocal temperature at which the concentrations of water molecules in the two states are equal. Shinoda[51] estimated that this mean temperature is 370 K. Equation (10) is rather similar to Equation (9).

Unfortunately, thermodynamic analyses based on mixture models do not aid the molecular interpretation of hydrophobic effects, as long as water is considered as a mixture of two or more species with different characteristics. Although two-state models are somewhat simplistic, they usually do provide an adequate quantitative description of the temperature dependence of the thermodynamics of solvation of apolar compounds in water. The molecular interpretation of these mixture models remains a matter of assumptions.

Closely related to two-state or mixture models are models that we will describe as compensation models. Lumry et al.[217, 223] showed that the Gibbs energy for the transfer of argon from cyclohexane to water, hydrazine, and ethylene glycol are remarkably similar (Table 4). The low solubility of argon in the hydrogen-bonded solvents glycol and hydrazine is due to the unfavorable enthalpy change. The transfer of argon from glycol or hydrazine to water is accompanied by significant changes in enthalpy and entropy which, however, show almost complete compensation.

This observation led to the suggestion that the thermodynamics for the solvation of apolar compounds in water result

Table 4. Thermodynamic parameters for the transfer of one mole of argon from solvent I to solvent II at 298 K (taken from refs. [217, 218]).

Solvent I	Solvent II	$\Delta G^{\ominus}$ [kJ mol^{-1}]	$\Delta H^{\ominus}$ [kJ mol^{-1}]	$-T\Delta S^{\ominus}$ [kJ mol^{-1}]
cyclohexane	water	10.4	−11.2	21.6
cyclohexane	hydrazine	11.9	9.5	2.4
cyclohexane	ethylene glycol	10.3	0	10.3
ethylene glycol	water	0	−11.3	11.4
hydrazine	water	−1.5	−20.7	19.2

from two contributions. First, the low solubility of apolar compounds in water, hydrazine, and glycol is caused by the extensive hydrogen-bonded structure of the liquid;[224, 225] this contribution to the Gibbs energy of solvation is defined as the "motive" part. The second contribution is attributed to the characteristic fluctuation behavior of liquid water that distinguishes water from hydrogen-bonded organic solvents. Obviously, this aspect originates from classic mixture models (vide supra). The fluctuation of the hydrogen bond network leads to the remarkable heat capacity effects and compensation of enthalpy and entropy. This contribution is thus identified as the "compensative" part. According to Lumry,[217] the fluctuation behavior can be explained on the basis of a simple two-state, geometric relaxation model, and he attributed the low solubility of apolar compounds in water to the distortion of the hydrogen bond network. A detailed theoretical description of compensation laws was given by Grunwald[226, 227] in the mid-eighties.

In 1985 Lee[228] reported an interesting analysis of the compensation model of Lumry based on a dissection of the Gibbs energy of solvation into a contribution arising from the creation of a cavity in the solvent (G_c) and a contribution accounting for the attractive forces between the solute and the solvent (G_i). Both the cavity formation term and the interaction term were used to express the enthalpy and the entropy of the solvation process [Eqs. (11) and (12)]. The

$$\Delta h = G_i - \sigma^2_{v,H} \quad (11)$$

$$T\Delta s = -G_c - \sigma^2_{v,H} \quad (12)$$

factor $\sigma^2_{v,H}$ is a compensation term affecting both the entropy and enthalpy of solvation.[*] A statistical mechanical approach to the fluctuation behavior of liquid water has been offered by Oguni and Angell,[229] Lumry et al.,[217] and Lee.[228, 230] The compensation terms are related to the mean square fluctuations in H and S, $\langle\sigma^2_H\rangle$ and $\langle\sigma^2_S\rangle$, and can be expressed in terms of temperature and heat capacity. An important parameter determining the magnitude of the compensation term is the isothermal expansion coefficient α. The compensation term originates from the loss of solvent–solvent interactions and counteracts the favorable G_i term. For organic solvents, $\sigma^2_{v,H}$ and G_i are similar and Δh is small. The isothermal expansion coefficient α of water is extremely small, which implies that the enthalpy of water is not affected when the volume of water changes; in other words, water can accommodate large volume fluctuations without a significant enthalpy loss. Hence the compensation term for water is small, and Δh is similar to G_i, which is large and favorable.

[*] In this review the symbol σ is used in several contexts, in analogy to the literature usage.

The cavity formation term G_c results from the restricted motion of the solvent molecules in the presence of the solute particles and is governed by entropy. A large number of configurations available to the molecules in the pure solvent are unavailable in solution since they produce solvent–solute hard-core overlap. The compensation term reflects the increase in volume that leads to a loss of solvent–solvent interactions and an increase in entropy. In water the hydrogen bond network is hardly affected by the apolar solute, and the compensation term is small. According to Lee[228] it is misleading to say that apolar solute particles enhance the structure of liquid water. The low solubility of apolar compounds in water is thus mainly due to the unfavorable cavity term, which arises from the extremely small molecular volume of a water molecule (Section 3.4).[228, 230]

In the hydrocarbon model proposed by Baldwin[61] and Privalov et al.,[36, 60, 231] the thermodynamic parameters for the solvation of apolar compounds in water are also a result of two contributions—from the disruption of dispersion interactions between the hydrocarbon molecules in the liquid state and from the solvation of the hydrocarbon molecule in water. The model is based on the temperature dependence of the thermodynamic parameters of solvation for liquid hydrocarbons in water and was inspired by the role of hydrophobic effects in the folding and stability of proteins.

The crucial assumption in the hydrocarbon model is that at T_S^* (Section 2.1) water has lost its capacity to form a hydrophobic hydration shell. By applying Equation (3) the enthalpy of solvation of an apolar liquid at T_S^* can be expressed as Equation (13).[*] Combining Equations (2) and (13) provides Equation (14), in which the Gibbs energy of

$$\Delta H^{\ominus}(T_S^*) = \Delta C_p(T_S^* - T_H^*) \tag{13}$$

$$\Delta G^{\ominus} = \Delta H^{\ominus}(T_S^*) - [\Delta C_p(T_S^* - T) + T\Delta C_p \ln(T/T_S^*)] \tag{14}$$

solvation of liquid hydrocarbons is expressed as a function of T_S^*. $\Delta H^{\ominus}(T_S^*)$, the enthalpy of solvation at T_S^*, and the term in brackets are labeled as nonhydration and hydration terms, respectively. The hydration term is negative at all temperatures and counteracts the positive nonhydration term (Figs. 2a, b). In order to interpret Equation (14) in terms of a molecular model, Privalov et al.[14] introduced a somewhat artificial description of the solvation of a liquid hydrocarbon in water as a two-step process. At T_S^* the apolar liquid is first transformed into a compressed gas that has the same entropy and heat capacity properties as the liquid state but the enthalpy properties of the gas state. The second step involves the transfer of the compressed gas into water and is defined as the hydration step. The introduction of this fudged two-step process was tempting, because the nonhydration term $\Delta H^*(T_S^*)$ so beautifully equals the enthalpy of evaporation of the apolar liquid. This approach leads to the at first sight paradoxical conclusion that hydrophobic hydration increases the solubility of apolar liquids in water. The favorable Gibbs energy of hydration is small because of the compensating contributions from entropy and enthalpy. The low solubility of apolar liquids in water is fully accounted for by the nonhydration term. Hydrophobic interactions (bulk hydrophobic interactions) are most pronounced at T_S^*.

The practical value of the two-step model is questionable. It is not clear whether the contribution identified as the hydration term completely accounts for the process of hydrophobic hydration. An inherent contradiction in the approach is that the hydrocarbon model is based on the assumption that the heat capacity change is independent of temperature, whereas the two-step interpretation strongly relies on the absence of heat capacity effects at T_S^*. But the change in heat capacity of solvation at T_S^* is still considerable. In addition, at temperatures above T_S^* the entropy of solvation becomes positive, which would imply "reversed" hydrophobic hydration.

Equation (15) is a modified version of Equation (14) in which T_H^* is used instead of T_S^*. The compensative or hydration part in brackets is small and positive. The temperature-independent part describes the low solubility of apolar liquids and is comparable to the enthalpy term in Equation (14). This approach requires a different two-step model which is more difficult to interpret[36] and finds a detailed molecular expression in the scaled particle theory.[228]

$$\Delta G^{\ominus} = [\Delta C_p(T - T_H^*) - T\Delta C_p \ln(T_H^*/T)] - T_H^* \Delta S^{\ominus}(T_H^*) \tag{15}$$

Recently, Ruckenstein[232] proposed a mechanistic picture of hydrophobic hydration with a two-step model that distinguishes the process of cavity formation and the subsequent reorganization of the water molecules into "icebergs" based on earlier ideas of Shinoda.[51] The features of this model closely resemble those of the compensation models of Lumry et al.[217] and Lee.[228] Alternative two-step models for the solvation of apolar compounds in water have been proposed by Hvidt[233] and Ben-Naim.[10] From a thermodynamic point of view, two-step descriptions of solvation processes can be very convenient, but the definition of the separate steps remains an arbitrary exercise. In general, introduction of artificial intermediate states provides a deceptive sensation of clarity with respect to the molecular nature of hydrophobic effects.

3.3. Potentials of Mean Force, Virial Coefficients, Distribution Functions; Probing Hydrophobic Effects

3.3.1. Introduction

Another class of theoretical approaches to describe hydrophobic effects centers on theoretical models of molecular liquids and solutions based on statistical thermodynamics. In this section some basic terminology will be introduced to provide the context for the discussion of results in the following sections. Hydrophobic hydration is most conveniently described based on the distribution of water or, alternatively, oxygen and hydrogen atoms around a solute particle. The corresponding radial distribution function $g_{AO}(r)$ is defined as the average number of oxygen nuclei in a thin spherical shell of width Δr and radius r, which is centered on solute A [Formula (16)]. In this formula, ϱ_W is the average number of

$$4\pi r^2 \varrho_W g_{AO}(r)\Delta r \tag{16}$$

[*] In the literature T_S^* and T_H^* have been replaced by T_S and T_H, respectively, when the solvation of apolar liquids in water is considered. To avoid unnecessary confusion, we prefer to use T_S^* and T_H^* without exception.

water molecules per unit volume. The excess chemical potential of the solute particle can be computed by an integration of $g_{AO}(r)$ over a well-specified radius (at large r the integral diverges).[234] The aim is now to determine the radial dependence of the distribution function, an exercise which obviously requires detailed knowledge of the structure of liquid water. Comparison of the distribution functions of hydrogen and oxygen atoms gives insight into the orientation of the water molecules with respect to the surface of the solute particle.

When two or more apolar solute particles are present in water, the question arises as to the forces between these particles as a function of their relative distance. The chance of finding a second solute particle at a distance r from the center of the first directly measures the magnitude of the interactions between the solute particles. The potential of mean force between two solute particles A, ΔG,[*] is defined as the work required to bring two molecules of A, which were originally at infinite separation, to a separation R (which is on the order of the diameter of A). Following statistical thermodynamics, ΔG can be expressed[10, 17] by Equation (17), where $U(R)$ is the direct pair interaction between

$$\Delta G(R) = U(R) + \delta G(R) \tag{17}$$

the solute particles in the absence of solvent and $\delta G(R)$ the contribution of the solvent. The force acting between the particles is given by the first derivative of ΔG with respect to distance. Occasionally, $\delta G(R)$ is taken as a measure for hydrophobic interactions.[10, 23] Although this definition is formally more appropriate than the definition given in Section 1.2, a major disadvantage is that $\delta G(R)$ is difficult to determine experimentally.

Solvent-induced interactions result from changes in the solvation of solute particles when they approach each other. Even solute particles considered as hard spheres dissolved in a featureless solvent composed of hard spheres are subjected to solvent-induced interactions. This phenomenon is well established and is a consequence of partial shielding of solute surfaces when the particles are in close proximity.[26] When solute and solvent do not consist of hard spheres but have soft potentials, shielding leads to repulsive forces. These repulsive forces are, however, counteracted by attractive contributions caused by solvent molecules that simultaneously interact with two solute particles.

The potential of mean force acting on two solute particles is related to the distribution of the solute particles in the aqueous solution by Equation (18), where $g_{AA}(R)$ is the pair

$$g_{AA}(R) = \exp[-\Delta G(R)/k_B T] = \exp[-U(R)/k_B T] + \exp[-\delta G(R)/k_B T] \tag{18}$$

distribution function giving the chance of finding a second particle A at a distance R from the center of reference particle A [Eq. (16)]. The art of theoretical approaches to explain of hydrophobic interactions is to give a description for the behavior of either $\Delta G(R)$ or $g_{AA}(R)$.

Qualitatively, the pair distribution of spherical solute particles dissolved in a solvent containing only spherical solvent molecules can be rationalized on the basis of a number of preferred solute–solute arrangements. As shown in Figure 6, the contact arrangement and the solvent-separated arrangement give rise to well-defined maxima in the pair distribution function. More elaborate treatments also yield preferred arrangements at greater solute–solute distances.

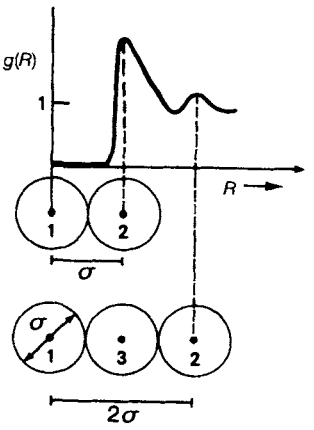


Fig. 6. Pair distribution function $g(R)$ for spherical solute particles 1 and 2 in solvent 3. Solute and solvent are shown as spherical particles with the same diameter σ. The first and second maximum in the pair distribution function correspond to the preferred arrangements (taken from ref. [17]).

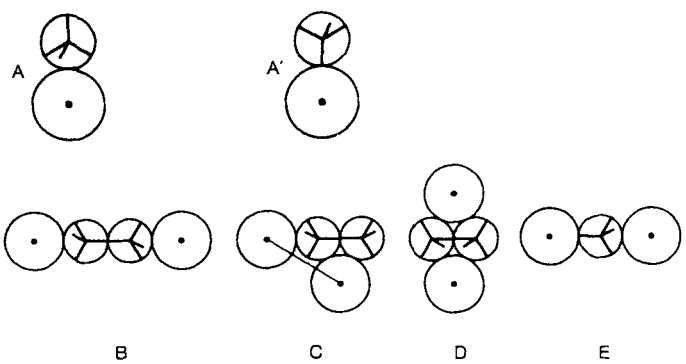
Any solute–solute distribution function therefore exhibits oscillatory behavior as a function of the solute–solute distance. Unfortunately, a water molecule can hardly be taken as a spherical particle with a homogeneous charge distribution. An elegant and illustrative semiquantitative solution to this dilemma has been provided by Ben-Naim.[17] According to his approach, water is viewed as a Lennard–Jones sphere equipped with four additional binding sites, two hydrogen bond donor sites and two hydrogen bond acceptor sites. The binding energy B_W of each water molecule may be divided into a Lennard–Jones contribution and a hydrogen bond contribution [Eq. (19)].

$$B_W = B_{LJ} + B_{HB} = B_{LJ} + \sum_{l=1}^{4} B_l^{HB} \tag{19}$$

As shown in Scheme 8[17] each water molecule will be inclined to maintain hydrogen bond interactions. Thus, a water molecule near an apolar solute particle is far more likely to adopt orientation A rather than A'. Some preferred solvent-separated arrangements of two solute particles in an aqueous medium are shown by B–E. The shortest solute–



Scheme 8. Schematic representations of various arrangements of water molecules with respect to one or two apolar solute molecules (taken from ref. [17]).

[*] From this point on ΔG is used to denote the potential of mean force.

solute distance, about 6 Å, is found in arrangement C. This arrangement seems more probable than E, which has no hydrogen bonds. However, this preference has not been unambiguously confirmed by computational studies (Section 3.5). Although these qualitative and semiquantitative considerations are instructive, it remains a challenge to develop more sophisticated and quantitative molecular theories to account for the thermodynamic behavior of aqueous solutions of nonelectrolytes in terms of intermolecular potentials and distribution functions.

A convenient way of thinking about the distribution of solute particles in a solution is provided by the solution theory of McMillan and Mayer.[236] According to this theory, solutes in a solution are distributed in the same way as in a hypothetical gaseous state. The concentration of this gas equals that of the solution, and the interaction potentials in the hypothetical gas are related to the solute–solute potentials of mean force in a solution of infinite dilution. The chemical potential of the hypothetical gas is given by Equation (20), where w_2 and w_N are the pairwise and higher-

$$W(r_{1,\ldots,r_N}) = \sum w_2(r_{i,j}) + \sum w_3(r_{i,j,k}) + \ldots \quad (20)$$

order potentials of mean force acting between the solute molecules. The potentials of mean force can be calculated from the distribution at infinite dilution and used to compute the distribution of the solutes at finite concentration.

Traditionally, computer simulations only consider two-body interactions and are therefore perfectly suited for a study of pairwise hydrophobic interactions. It is, however, questionable whether the pair potential w_2 is sufficient to account for bulk hydrophobic interactions occurring in aqueous solutions of finite concentration. The theory of McMillan and Mayer[236] offers a relation between experimentally accessible thermodynamic parameters of solution and intermolecular potentials by the expression of the osmotic pressure Π in terms of a virial density expansion [Eq. (21)]. Here B_2^* is the second osmotic coefficient and directly related to the potential of mean force according to Equation (22).[236] The pointed brackets indicate that orientational averaging has been performed.

$$\Pi/kT = \rho + B_2^*\rho^2 + B_3^*\rho^3 + \ldots \quad (21)$$

$$B_2^* = 2\pi\int\langle 1 - \exp[-\Delta G(R)/kT]\rangle r^2 dr \quad (22)$$

In thermodynamic studies of aqueous solutions, thermodynamic excess functions are more widespread than osmotic pressures. The Gibbs excess function, for example, can be expressed in a molality expansion [Eq. (23)]. Here g_{AA} and

$$G^E = g_{AA}[m_A^2/m_0^2] + g_{AAA}[m_A^3/m_0^3] + \ldots \quad (23)$$

g_{AAA} are the parameters for the interaction of two and three particles, respectively; they are also known as the Lewis–Randall coefficients and should not be mixed up with $g_{AA}(R)$. Friedman[237, 238] derived a formal link between g_{AA} and the second osmotic virial coefficient B_2^* [Eq. (24)]. Here

$$g_{AA} = (RT/V_w^\ominus)(NB_2^* - V_A^\ominus + 1/2\kappa RT) \quad (24)$$

$V_w^\ominus$ is the volume of 1 kg of pure water, $V_A^\ominus$ the partial molar volume of the solute at infinite dilution, κ the isothermal compressibility, and N Avogadro's number. The second osmotic coefficient and the Lewis–Randall coefficient of aqueous solutions of nonelectrolytes are therefore a direct measure of the magnitude of pairwise hydrophobic interactions, since they reflect the number of encounters between both molecules beyond that expected statistically.

The existence of substantial triplet and higher-order terms reflects the occurrence of bulk interactions. Although it is theoretically feasible to calculate these higher-order terms from excess functions at elevated concentrations, this is not commonly done. To account for solute–solute (or solvent–solvent) interactions in more concentrated solutions or even in binary solvents, application of the theories of Kirkwood and Buff[239] is more convenient and provides insight into the molecular organization of these solutions. The crucial parameter in this theory is the Kirkwood–Buff integral G_{AA} [Eq. (25)], which is a measure of the mutual affinity of mol-

$$G_{AA} = \int_0^\infty (g_{AA}(r) - 1)4\pi r^2 dr \quad (25)$$

ecules A and yields, when multiplied with the number density of A, the excess or deficiency of particles A in the proximity of a solute particle A. The integral decays to unity beyond a certain distance R. In practice, the integral can be cut off at a distance of a few molecular diameters; the volume element is then defined as the correlation volume.[240] The integral can be related, along with other thermodynamic quantities, to the excess chemical potential of the aqueous solution (vide supra).[240] In fact, the Kirkwood–Buff integral collects all virial coefficients in the density expansion of the McMillan–Mayer theory [Eq. (21)] in one single integral function and becomes equal to the second osmotic coefficient in the limit $m_A \rightarrow 0$ [Eq. (23)]. For a recent treatment of the Kirkwood–Buff theory, see Matteoli et al.[241]

Theoretical approaches to account for structural and thermodynamic properties of aqueous solutions require knowledge of the distribution functions $g(R)$ and intermolecular potential functions. Here the previously discussed approaches run into serious difficulties.[242] First of all, various relations have been proposed to express the distribution of molecules in solution in terms of potentials of mean force acting between these molecules. In solutions in which the concentration of the solute approaches zero, the pair correlation function for the solute particles can be effectively described by Equation (18). As the density is large, which is always the case for solvent molecules, the situation is far more complicated. A number of so-called integral equations have been proposed which express the distribution of the components present in the solution in terms of potential functions. In the theoretical treatments of hydrophobic effects, the Ornstein–Zernicke equation and the Percus–Yevick equation are frequently encountered.[242] These integral equations can be solved only by numerical methods. By using computers and simple pair potential functions, such as hard-sphere potentials or Lennard–Jones potentials, solutions can be obtained[242] (see also Section 3.3.4).

3.3.2. *Virial Coefficients and Distribution Functions; (Semi)empirical Approaches*

In Figure 7 the second osmotic coefficients (at 25 °C) for homotactic interactions in aqueous solutions of noble gases and methane are plotted as a function of Henry's law constant K_H. The polarizability of the solute affects the sign and

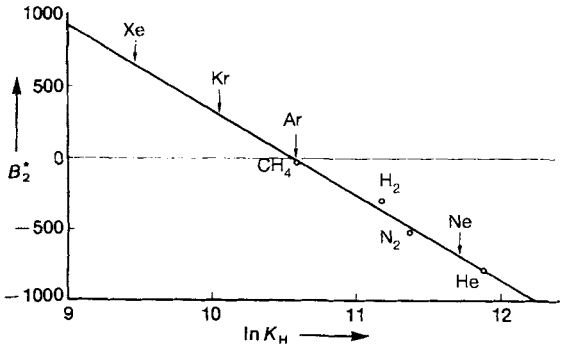


Fig. 7. Correlation between the logarithm of Henry's law constant and the osmotic virial coefficient (in Å^3) for small nonpolar solutes in water at 25 °C (taken from ref. [246]).

the magnitude of the virial coefficient. Apparently, krypton atoms repel each other in an aqueous environment, whereas methane molecules attract each other, though only slightly. On the basis of a limited number of accurate osmotic coefficients, Clark et al.[243] suggested that the association of alcohols in water is less than in the gas phase. This was also established for aqueous solutions of pure hydrocarbons such as cyclohexane and benzene[244, 245] and for noble gases such as krypton.[246] In Table 5 the second virial coefficients (at 25 °C) are given for some organic compouds in aqueous solution and in the gas phase. Remarkably, the Lewis–Randall coefficients differ quite substantially from the second osmotic coefficients and sometimes even have opposite signs; this can be reconciled by Equation (24). The results summarized in Table 5 emphasize that apolar molecules in a dilute aqueous solution show less tendency to associate than in the gas phase. Water apparently shields apolar solutes from each other and does not seem to promote their association.[16, 247] A few years ago Archer[248] studied the effect of temperature on the second virial coefficients of aqueous alcohols and showed that the "screening" effect of water weakens with increasing temperature.

Table 5. Experimental values of the second virial coefficients g_{AB} and B_{AB}^* at 25 °C (taken from ref. [16].

Second virial coefficients in the Lewis–Randall representation of thermodynamic excess functions for solvation of nonelectrolytes in water have been frequently treated by empirical models. Solute–solute interactions reflect the interactions between the functional groups that form the solute molecules and are able to interact with their surroundings. In 1976 Savage and Wood introduced a model that has received much attention during the past decade, in which the enthalpies[249] and later also Gibbs energies[273] of interaction, represented by the second Lewis–Randall coefficients h_{AB} and g_{AB}, are expressed in terms of a summation of pairwise functional group interactions [Eq. (26)]. Here $G_{i\leftrightarrow j}$ repre-

$$g_{AB} = \sum_{i,j} n_i^A n_j^B G_{i\leftrightarrow j} \tag{26}$$

sents the interaction between n_i^A groups i in solute A and n_j^B groups j in solute B in the Lewis–Randall representation. Similar equations can be set up for enthalpy and entropy. The Savage–Wood additivity of groups is based on three major assumptions: 1) Each group i of solute A interacts with each group j of solute B, 2) each of these interactions makes a characteristic contribution to the parameter for the interaction between A and B, and 3) each group interaction is independent of other groups and their relative position in the solute. A slightly different group additivity approach has been proposed by Bloemendal and Somsen.[250]

The group additivity approach can be criticized for being too simplistic.[251–253] The importance of neighboring group effects and stereochemistry have been recognized but purposefully neglected. In addition, some doubtful assumptions have been made in dissecting solute molecules into separate groups (see, for example, Tasker et al.[254] and Spitzer et al.[255]). Group additivity approaches are therefore considered to be first approximations. Theoretically, the potential of mean force acting between the solutes must be small in comparison to the thermal energy kT, since only in this case is linearization of the exponential term $\exp[W_{AB}/kT] - 1$ according to Equation (27) a valid approxima-

$$\exp[W_{AB}/kT] - 1 = \exp[(W_1/kT + W_2/kT)] \cong W_1/kT + W_2/kT \tag{27}$$

tion.[256] This exponential term expresses the solute–solute interactions as shown in Equation (18).

In spite of these shortcomings, the additivity approach has been applied to calculate pairwise interaction parameters (both Gibbs energies as well as enthalpies) for many organic compounds and functional groups (see for recent examples, Suri et al.,[257] Bloemendal et al.[258] Check et al.,[259] Borghesani et al.,[260] and Barone et al.[261, 262] and references cited therein). A selection of Gibbs energies and enthalpies of pairwise functional group interactions in aqueous solution at 25 °C is given in Table 6. In a pragmatic sense, the breakdown of the additivity rules may be used to signal atypical effects.

In studies of both heterotactic[263] and homotactic interactions[264] between a large variety of organic compounds in

aqueous solution researchers concluded that hydrophobic solutes are characterized by $g_{AB} < 0$ and $Ts_{AB} > h_{AB} > 0$. The classification of compounds as hydrophobic or hydrophilic is somewhat ambiguous, and some compounds such as carbohydrates[264] clearly show both hydrophobic and hydrophilic behavior. Because of the lack of solubility, interactions between unsubstituted hydrocarbons or noble gases can unfortunately not be studied. Hence, the approach does not provide insight into the molecular origin of pairwise hydrophobic interactions but yields a straightforward inventory of single group contributions to interactions of solutes more complex than noble gases and alkanes.

The relation between pairwise and bulk hydrophobic interactions is notoriously vague and difficult to describe in a theoretical model. To account for bulk hydrophobic interactions, Kirkwood–Buff integral functions have been frequently used.[265, 266] A typical example representing the distribution of 2-propanol and water in their binary mixture as a function of composition is shown in Figure 8. Apparently

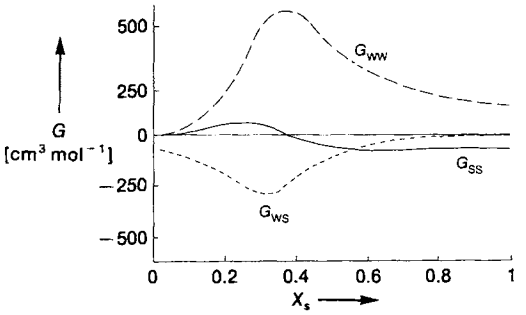

Fig. 8. Kirkwood–Buff integral functions G for mixtures of water (W) and 2-propanol (S) as a function of the mole fraction X of the organic cosolvent at 25 °C (taken from ref. [265]).

the preference of the organic component for alike molecules becomes greater with increasing concentration, and G_{SS} reaches a maximum in the water-rich region. At this concentration, the thermodynamic behavior of the mixture deviates strongly from that of an ideal mixture. A relevant question in this respect is whether the pairwise interactions predominantly present in dilute solution are additive or cooperative in more concentrated solutions. As shown above, water reduces the attractive forces between pairs of some apolar gases, but evidence suggests that it enhances the interactions between many solute particles. The molecular origin of this phenomenon is still unclear.

3.3.3. Virial Coefficients; The Models

During the past twenty years a number of approaches have been developed to calculate second osmotic coefficients on the basis of (semi)quantitative potential models for interactions between apolar solute particles in aqueous solution. A classic approach was reported by Kozak et al.,[267] who used lattice theories and the McMillan–Mayer theory to account for trends in second osmotic coefficients. Their main conclusions were that solute–solvent interactions decrease the magnitude of attractive forces between apolar solute particles and that the magnitude of the osmotic coefficient strongly depends on the size of the solute.

Friedman et al.[27–29] developed a model for solute–solute interactions on the basis of a repulsion term for hard spheres (hard-core repulsion term) and a term for the overlap of hydration spheres (cosphere overlap term) which became very popular in qualitative explanations of hydrophobic effects. The cosphere overlap term, often referred to as the Gurney contribution (in honor of Gurney[268] who first suggested the importance of overlapping hydration spheres for ion–ion interactions in aqueous solution), is estimated from the overlap volume of two solvation spheres. Following the classic ideas of Kauzmann,[6] the overlap of hydration shells leads to the release of structured water molecules into the bulk.

The basis of the model is schematically shown in Scheme 9. Water molecules in the hydrophobic hydration

Scheme 9. Schematic representation of the pairwise hydrophobic interaction between two apolar solute particles S, involving overlap of hydrophobic hydration shells and the concomittant release of structured hydration water to the bulk, according to the Gurney overlap model.

shells have a less favorable Gibbs energy than bulk water molecules; this is expressed in the Gurney coefficient. As the solute particles approach each other, the unfavorable situation of water molecules in overlapping hydration shells is gradually lost, and an attractive force increases as a function of the decreasing distance between the solute particles. The magnitude of the Gurney coefficient can be estimated from experimental data. However, it is questionable whether the Gurney overlap term measures only hydrophobic interactions, since the Gurney overlap term is a repository for all forces that are not hard-core repulsions.[269] The model has, however, been quite successful in accounting for experimental osmotic coefficients.[270, 271]

Various attempts[269, 272] to improve the cosphere overlap model have been reported. Clark et al.[269] suggested to exclude attractive solute–solute dispersion interactions from the Gurney overlap terms. The solvent-induced contribution to the solute–solute interactions was computed by compar-

ing the interactions in solution with those in the gas phase. Interestingly, the model also suggested that the attraction between apolar compounds in the gas phase and in the absence of solvent molecules appears to be stronger than in aqueous solution (vide supra).[269]

Calculation of second osmotic coefficients for interactions between hydrocarbons is hampered by the low solubility of these compounds in water and the concomittant lack of experimental data. Wood et al.[16, 273, 274] applied several additivity approaches to calculate second osmotic coefficients for interactions between medium-sized hydrocarbons such as cyclohexane. More recently Kang et al.[275–277] developed a sophisticated hydration shell concept for a quantitative description of thermodynamic parameters for the solvation of a large series of organic compounds in water. An improvement of the cosphere overlap approach was reported by Marčelja et al.[278] based on the Pople model for water. Their approach predicted a smooth exponential decay of the attraction between two apolar solutes with increasing separation.

In the late seventies and early eighties, however, it became increasingly clear that the potential of mean force between apolar solute particles is characterized by an oscillatory dependence on the separation between the particles. Using this knowledge, Wood et al.[247] developed an interaction site model (ISM) similar to that used by Clark et al.[269] However, Wood et al. employed a number of simple square-well potential functions to fit experimental osmotic coefficients. These square-well potential functions were chosen to represent both the contact arrangement and the solvent-separated arrangement, the latter by introduction of a barrier to avoid association of the solutes. In addition, nonpairwise additive contributions were introduced. The results reinforced the notion that water decreases the attractive forces that are present between (solute) particles in the gas phase under conditions of equal concentrations. Unfortunately, these models merely rephrase the question regarding the molecular origin of hydrophobic interactions.

3.3.4 Interaction Site Models; Integral Theories

One of the major problems in theoretical studies of hydrophobic effects is the description of liquid water. In water, strong attractive interactions between molecules compete with short-range repulsive forces, which is quite unusual for organic solvents. In spite of these difficulties, computer simulations of hydrophobic effects have been quite successful. To circumvent the inherent problem of having to develop a theoretical water–water potential, semiempirical approaches have been advanced that employ experimental data for liquid water. The ST2 model developed by Stillinger and Rahman[279–281] is a typical example of this approach (Section 3.5). Almost simultaneous to the appearance of the first computer simulation studies of hydrophobic effects in the literature, Pratt and Chandler[234, 282] developed an alternative microscopic theory, now known as the Pratt and Chandler theory (PC). This approach is more ambitious than the scaled particle theory and is essentially a statistical mechanical treatment using an interaction site model represented by a sum of pairwise, additive, spherically symmetric potentials acting between specified sites located on each molecule. A similar approach had already been considered useful in accounting for properties of nonassociated organic solvents. In these fluids the molecules interact predominantly through hard-core repulsions. The integral equation formulation for these solvents is generally known as the repulsive interaction site model (RISM)[283]. For a description of liquid water Pratt and Chandler[282] used the experimentally determined, orientationally averaged, pair correlation function for the oxygen–oxygen distribution. Subsequently, an Ornstein–Zernike-type integral equation (Section 3.3.1) was used to obtain the solute–solvent and solute–solute distribution functions after insertion of a solute molecule in the pure liquid.

Figure 9a shows the radial distribution of water molecules around a methane-like particle and reveals that the water molecules occupy a distinct position in the hydration shell of methane.[282, 284] As shown in Figure 9b, the PC theory predicts an oscillatory dependence of the solute–solute pair correlation function $g_{AA}(R)$ on the separation of the solute particles.[285] Simultaneously, computer simulation studies yielded similar results (see Section 3.5). The occurrence of

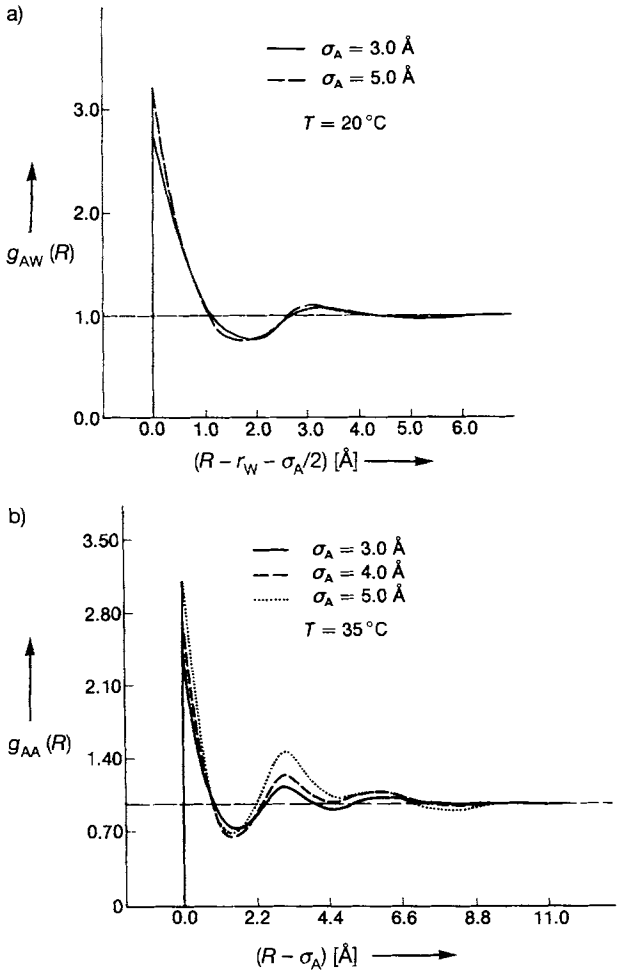

Fig. 9. Radial distribution functions $g_{AW}(R)$ (a, infinite dilution) and $g_{AA}(R)$ (b) for hard-sphere solute particles A dissolved in water W at 1 atm and 20 °C (a) and 35 °C (b). σ_A is the diameter of the solute and r_W the radius of water. g_{AA} was calculated based on the theory of Pratt and Chandler (taken from ref. [282]).

preferred arrangements of solute particles was anticipated on the basis of packing phenomena (see Section 3.3.1). Surprisingly, however, the populations of the contact and the solvent-separated arrangement appeared to be similar. The solute–solute pair correlation function was shown to be significantly altered by introducing attractive forces between the solute particles.

Unfortunately, as a result of the application of an orientationally averaged pair correlation function for water, information about the orientation of water molecules surrounding apolar solutes is lost. Tani[286] recognized this inherent weakness of the PC theory and generalized the PC model by introducing orientational aspects of water–water interactions. Application of the improved PC theory reinforced the traditional idea of clathrate-like solvation of apolar solutes in water. Tani found[286] that quantitative features of the calculated radial distribution function critically depend on the applied pair correlation function for liquid water and applied both experimental and theoretical potential models for liquid water. Generally, theoretical models for liquid water tend to exaggerate pair correlations between apolar solutes and water molecules.

Pratt and Chandler[284] and Tani[286] studied the hydration of solutes with more than one interaction site (nonspherical solutes) and found that the hydration characteristics of each site are qualitatively the same as that for an isolated interaction site. The solute–solute distribution function obtained by Tani[287] is qualitatively similar to that obtained by Pratt and Chandler.[234, 282] Remarkably, water–solute attractive forces hardly affect the quantitative features of the solute–solute distribution function. In contrast to its predecessor, the improved interaction site model[287] completely excludes the occurrence of contact interactions between apolar solutes. The size dependence of hydrophobic interactions is suggested to be small, but with increasing solute size the proportion of contact arrangements appears to be even less, which is in contrast with results obtained by other theoretical approaches (see, for example, Thompson et al.[247]).

Another extension of the PC theory was provided by Rossky et al.,[288, 289] who introduced a nonuniform charge distribution by employing an interaction site model (ISM) with charged interaction sites for dipolar and quadrupolar fluids. The extended repulsive interaction site model (XRISM) equation was used to determine the potential of mean force acting between rigid, polyatomic solutes in polar molecular solvents such as water.[290] To describe the interactions between water molecules, Rossky et al. used a theoretical model for water developed by Jorgensen et al.[291] (Section 3.5). Interestingly, Rossky et al.[290] confirmed that in both a solvent consisting of diatomic molecules and in water the potential of mean force between apolar solute particles is characterized by an oscillatory dependence on their separation. The XRISM was also used to determine internal motions of polyatomic molecules in aqueous solution.[292] More recently, Tanaka et al.[293] made a comparison between Monte Carlo simulations of aqueous solutions of apolar compounds and the results obtained by the XRISM. They confirmed the intuitively wrong result suggested by interaction site models that the solvent-separated arrangement is favored with increasing solute size.

3.4. Scaled Particle Theory (SPT); The Formation of Cavities in Liquid Water

An interesting attempt to explain thermodynamic data of solvation for apolar compounds in liquid water is the scaled particle theory (SPT). Thanks to the pioneering work of Pierotti, application of SPT to the study of hydrophobic effects should probably be considered one of the first theoretical approaches to hydrophobic effects.[294–296] In this model the dissolution of a particle is separated into two steps. The first step is the creation of a cavity in the solvent (see also Section 3.5.2) which has the appropriate size to accommodate the solute particle. The second step is the onset of interactions between the solute and the solvent. The Gibbs energies of these two processes are generally referred to as G_c and G_i respectively. The structural implications of solute–solvent interactions for the solvent in close proximity to the solute cannot be treated by the SPT. The theory uses statistical arguments based on pair distribution functions of solvent molecules in the pure liquid and yields expressions for the work that is involved in introducing a spherical particle into a solvent of spherical particles. An essential feature of the SPT is that the creation of a volume element in a liquid to accommodate a solute particle requires exclusion of solvent particles, a process that involves a certain amount of work. This can be expressed in a Boltzmann equation [Eq. (28)].[296]

$$p_o(r,\varrho) = \exp\{-W(r,\varrho)/kT\} \tag{28}$$

Here ϱ is the number of solute particles per unit volume (N/V), $W(r,\varrho)$ the work required to create a cavity of radius r, and $p_o(r,\varrho)$ the probability that such a cavity arises from statistical fluctuations in the solvent network. The second osmotic coefficient B_2^* is directly related to $p_o(r,\varrho)$. The aim of the SPT is now to determine $p_o(r,\varrho)$ as accurately as possible on the basis of statistical mechanical and geometrical arguments. Essential is that the solvent is considered to be a spherical particle with a radius σ. The general approach followed is to start off with a cavity radius of zero after which the cavity size is gradually expanded.

An important parameter for the calculation of the work involved in formation of a spherical cavity of radius R is the probability of finding a center of a spherical solvent molecule in this spherical volume element. This probability is defined in a distribution function describing the conditional distribution of solvent particles in the solution. The theory provides an expression for this conditional probability function $G(r,\varrho)$ in which experimental properties of the solvent such as the density and isothermal compressibility appear. Thus, structural information for the solvent, absent in basic forms of the SPT, is introduced and provides the theory with a semiempirical character. Nonetheless, the application of SPT to liquid water has been vigorously critized.

In a classic paper, Stillinger[297] developed methods to incorporate the strongly directional character of water–water interactions and made the SPT suitable for applications to aqueous solutions by incorporating some rudimentary aspects of the hydrogen bond structure of liquid water. This approach led to the development of the famous ST2 model

for liquid water (see Section 3.5). A pragmatic application of SPT yields very good results in calculating thermodynamic parameters for the solvation of apolar gases in water.[294, 296] In 1988 Langlet et al.[298] reported a modified SPT with excellent results for nonaqueous solvents.

During the past decades, application of the SPT to the study of the solvation behavior of apolar gases in liquid water has led to the remarkable suggestion that the low solubility of apolar gases in water is mainly due to the small molecular volume of the water molecule. In other words, because of this feature, the frequency of observing a cavity of sufficient volume to accommodate an single-atom solute or larger particle in water is much lower than in organic solvents. Lucas[299, 300] was one of the first to make this suggestion after a careful study of the role of the molecular size and the isobaric expansion coefficient α for the thermodynamics of solvation. Later Lee[228] developed a model for the solvation of apolar gases in water on the basis of cavity formation and the compensative behavior of enthalpy and entropy terms (Section 3.2) and stressed the fact that the contribution of G_i is similar for all solvents. The low solubility of apolar compounds in water is reflected almost exclusively by the G_c term, which deviates strongly from that for organic solvents. According to the SPT as well as to the theory of Pratt and Chandler (Section 3.3.4), G_c is directly correlated with the number of solvent molecules that hit the surface of the cavity during its growth. Obviously, this number is related to the size and the density of the solvent. The small molecular size of water enhances the unfavorable character of G_c, whereas the low packing density of liquid water, which is a consequence of the open hydrogen-bonded structure of liquid water, counteracts this effect. The packing density of hydrazine, whose molecular volume is somewhat larger than that of water, is considerably higher. Indeed, the solubility of apolar compounds in hydrazine is just as bad as in water and in some cases even worse. As noted by Lee,[228] the low density caused by the hydrogen bond network in liquid water promotes the dissolution of apolar gases.

Recently, Lee[230] used the experimental thermodynamic data of solvation for hydrocarbons in water and their pure liquid state in combination with solute–solvent interactions obtained from computer simulation studies to compute the enthalpy change upon solvent reorganization. In addition, the cavity term H_c was determined for the solvation of hydrocarbons in their liquid phase. These data were compared with parameters obtained from the SPT. It was shown that the thermodynamic parameters for solvent reorganization and cavity formation, in particular the enthalpy and the entropy, are strongly dependent on temperature. The SPT appeared to reproduce the temperature dependence of the Gibbs energy of cavity formation very accurately. The temperature dependence of the enthalpy and entropy of cavity formation was not reproduced as satisfactorily.

In Figure 10 the *differences* between the Gibbs energy for cavity formation G_c, the energies of the solute–water interactions E_a, and the enthalpic solvent reorganization enthalpies H_r are plotted versus temperature for the solvation of neopentane in water and in its neat phase. In addition the total Gibbs energy change ΔG^* (* indicates that the standard state advocated by Ben-Naim is used (see Section 1.2)), enthalpy change ΔH^*, and entropy change $T\Delta S^*$ for the transfer

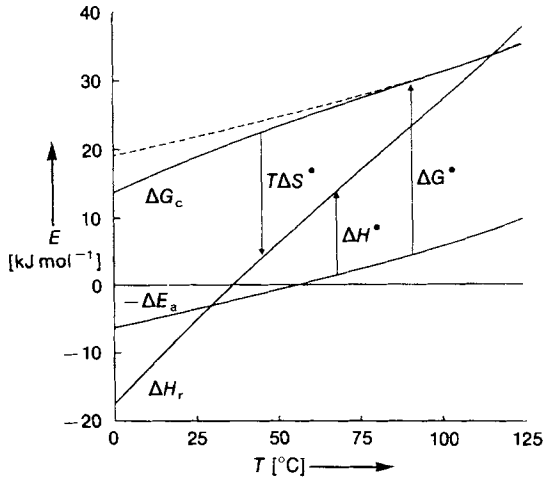

Fig. 10. Temperature dependence of changes in the Gibbs energy of cavity formation ΔG_c, the solute–solvent interaction energy ΔE_a, and the solvent reorganization enthalpy ΔH_r for the solvation of neopentane in water as opposed to in its neat phase. Thermodynamic parameters based on the Ben-Naim standard state are indicated as well (taken from ref. [230]).

of liquid neopentane to water are indicated. Figure 10 is very revealing and shows that ΔG^* is rather insensitive towards temperature, because the temperature dependence of changes in solute–solvent interactions and the changes in the cavity term are similar. By contrast, the change in the enthalpy of solvent reorganization is dramatically dependent on the temperature and causes a separation of ΔG^* into entropy and enthalpy terms that are equally temperature dependent. These terms compensate each other almost completely (see also Section 3.2). ΔH_r for the transfer of gaseous neopentane to water increases rapidly with temperature, whereas ΔH_r for the transfer of gaseous neopentane to its neat phase decreases with temperature (for solvation of apolar compounds in water, the assumption is made that $\Delta H_r = \Delta H_c$). Even near room temperature, the enthalpy of solvent reorganization is positive for both solvation processes. This observation seriously conflicts with the idea of increased solvent structure due to enhanced hydrogen bonding around the inert solute particles. In addition, solute–solvent interaction energies are remarkably similar and attractive. Thus, the low solubility of apolar compounds in water is fully governed by the Gibbs energy of cavity formation G_c, which is accurately reproduced by the SPT. According to Lee,[230] hydrophobicity must therefore be attributed to an excluded volume effect and the compensation of enthalpy and entropy to changes in the volume of the solvent.

The SPT has been criticized on various grounds, in particular for its results in applications to hydrogen-bonded solvents.[301] In fact, in addition to the SPT and the hybrid approach followed by Lee (vide supra), two other approaches are available for calculating the thermodynamic parameters of cavity formation in liquids. A semiempirical method going back to publications of Sinanoglu[302, 303] considers the formation of a cavity in a liquid in terms of the work against counteracting surface forces. The theoretical approach is based on the concept of microsurface tension in the solvent (see Section 2.1). A few years later Reisse et al.[304, 305] drew an analogy between the process of creating a molecule-sized cavity and the evaporation of the liquid.

Unfortunately, the Sinanoglu–Reisse approach is less suited for hydrogen-bonded solvents. More recently, Moura-Ramos et al.[306] showed that changes in the molecular order during the evaporation process hamper the Sinanoglu–Reisse analysis. Thus they proposed to describe the process of cavity formation in analogy to the evaporation of a disordered liquid by using the corresponding state principle.[306, 307] Entropies and enthalpies for cavity formation in various solvents, unfortunately not including water, were calculated. In contrast to the data reported by Lee[228, 230] and Sinanoglu,[303] negative entropies were found for the creation of cavities in organic solvents near room temperature.

During the past decade, computer simulations have become increasingly popular for the calculation of thermodynamic parameters for the formation of solute-sized cavities in water (see Section 3.5). Since it has been generally questioned whether the solubility of apolar compounds in water can be interpreted in terms of a packing phenomenon for spherical solvent molecules, and since even incorporation of some structural aspects of real water did not enhance the confidence in the results of SPT, the main goal of these computer simulation studies was to test the results of the SPT. The traditional idea that water is a liquid with a remarkably open structure argued against the conclusions from SPT. Computational approaches were reported by Postma et al.,[308], Jorgensen et al.,[309] Tanaka,[293] and recently by Guillot et al.[310] Particularly interesting was the approach reported by Guillot et al.[310] in which a comparison was made between the work of creating a cavity in water, described by a realistic water model, and in a liquid composed of hard spheres. The calculations show unequivocally that the Gibbs energy for the creation of cavities in liquid water is not primarily determined by the specific structure of water but by factors such as packing density, size of the solvent molecule, and the equation of state.

Recently Pohorille and Pratt[311] used molecular dynamics (MD) and Monte Carlo (MC) simulations to calculate the thermodynamics of formation of a cavity in various organic liquids and water in order to study the impact of the structure of hydrogen-bonded liquids. They found that water has a larger fractional free volume which is, however, more disperse than that of organic solvents. They also found that the work required for cavity formation predicted by the SPT is about 20% below the value obtained with the TIP4P model (see Section 3.5) for liquid water. As shown by Guillot et al.,[310] a solvent composed of hard spheres of similar size to water molecules has a significantly better capacity to accommodate apolar solute particles in its free volume. Unfortunately, the sizes of the cavities considered were still rather small. In a more detailed study of the so-called transient cavities in molecular liquids, the statistics for cavity formation in water, *n*-hexane, and *n*-dodecane were compared in relation to the density of the solvent at the surface of the spherical solutes, referred to as the contact density $\varrho_S G(\lambda)$.[312] The contact density at the surface of a hard sphere is significantly greater in water than in the organic solvents; in other words, water squeezes the solute out of solution more strongly.[312] This force reaches a maximum for cavities roughly 2.4 Å in diameter. According to Lee,[228, 230] this conclusion is essentially a different way of saying that the low solubility of apolar compounds in water is mainly an excluded-volume effect.

3.5. Computer Simulation Studies of Aqueous Solutions; An Introduction

During the past fifteen years, computer simulation studies have provided a rich source of detailed information on the molecular organization of aqueous solutions. Structural aspects of hydrophobic hydration and hydrophobic interactions became apparent that were not easily accessible by alternative methods. Results of computer simulation studies have confirmed the traditional ideas on hydrophobic effects to some extent, but have also raised a number of important questions. A typical simulation considers a limited number of water molecules (usually 100–500) at equilibrium in a box confined by periodic boundaries. One or more of these water molecules are replaced by a solute particle. The subsequent structural and thermodynamic changes are monitored by sophisticated sampling methods. The new equilibrium properties of the solution are calculated either by averaging over a large number of selected configurations (MC), or by solving the Newtonian equations of motion and taking a time average (MD). The choice of intermolecular potential functions describing the interactions between the components of the system is therefore of paramount importance.

For liquids like water with strong, attractive intermolecular interactions, the development of potential functions describing the interactions between the molecules in the liquid has been notoriously difficult. Computer simulation studies of hydrophobic effects have employed a number of well-known potential models for liquid water. Most of these potential models are (semi)empirical.[313] Charge distributions and Lennard–Jones parameters have been optimized in order to reproduce experimental properties of water with high accuracy. Stillinger and Rahman[279–281] developed a pair potential for rigid water molecules on the basis of scaled particle theory. This ST2 model became very popular and was used frequently with or without adjustments for the system investigated. Other popular mean field models are the simple point charge model (SPC) developed by Berendsen et al.[314] and the transferrable intermolecular potential functions (TIPS, TIPS2, and TIP4P) developed by Jorgensen et al.[291] A popular analytical potential model based on ab initio calculations has been advanced by Matsuoka, Clementi, and Yoshimine (MCY model).[315]

In most computer simulation studies, the total potential energy of an aqueous solution is assumed to be the sum of individual *two-body* interactions. Polarizabilities and the corresponding induced dipoles, nuclear polarization, and intramolecular flexibility are not normally included in simulations of liquid water. This is regrettable, since polarizability effects involving cooperativity of a large number of water molecules might be significant in the molecular origin of hydrophobic effects. Recently, some important progress has been made by incorporating electric polarizabilities, intramolecular degrees of freedom, and many-body effects in empirical[316, 317] as well as in nonempirical[318–321] potential models for liquid water. Unfortunately, this knowledge has not yet been employed in computer simulation studies of

hydrophobic effects. Since water–water interactions are so exceptionally strong, solute–water interactions are not a major factor for the structure of water molecules in the near vicinity of apolar solutes and are usually described by simplified interaction laws. Occasionally, quantum mechanical potentials are used to model these interactions, though ab initio calculations are not necessarily an improvement in this respect.[322]

The decisive thermodynamic quantity in chemical processes is the free energy change (either Gibbs energy or Helmholtz energy). Unfortunately, calculations of these quantities for the solvation of apolar compounds in water are still extremely difficult, and the results are subject to large errors.[79, 323–328] Alternatively, the free energy difference between two systems, for example, two aqueous solutions containing different solute particles, can be calculated by stepwise perturbations of one system by which it is slowly converted into the other. For example, aqueous solutions of propane and ethane can be compared by stepwise elimination of a methylene group. Although this might seem like a bizarre kind of alchemy to an organic chemist, it is a very convenient procedure and a valid thermodynamic path between these two states. Free energy perturbation methods are a relatively new, important improvement in the calculation of relative free energies of processes in solution on the basis of computer simulations.[79, 329]

3.5.1. Description of Hydrophobic Hydration from Computer Simulations

In hydrophobic hydration the position, orientation, mobility, and potential energy of water molecules in close proximity to single apolar solute particles all play a role. In qualitative studies of hydrophobic hydration, these parameters have been associated with the structure of water in the solvation shell. In order to determine to what extent water molecules are affected by the presence of an apolar solute particle, it is convenient to make a clear distinction between water molecules in the solvation shell and in bulk water. One useful method is the "partitioning of the configuration space". According to this method, water molecules whose oxygen nucleus is found within a certain radius R from the center of the solute particle are considered part of the hydration shell.[330, 331] The exact value of radius R is rather arbitrary and obviously depends on the diameter of the solute particle. Usually, only the first hydration shell is taken into account by including merely the first peak of the solute–solvent radial distribution function. In an alternative approach, distribution functions for the aqueous solution are simply compared to those for pure liquid water.[332] One drawback of this method is the fact that the number of water molecules that are affected by the apolar solute particles is relatively small in comparison to the total number of water molecules.

In 1974 Dashevsky and Sarkisov[333] were the first to report a MC computer simulation of a solution of methane in 64 water molecules at constant volume and temperature. The computational methods applied in this simulation study were severely criticized and the results considered unreliable.[334, 335] Three years later Owicki and Scheraga[330] performed a more sophisticated MC simulation of an aqueous solution of methane at fixed temperature and pressure. The first extensive MD simulation of an aqueous solution of two Lennard–Jones particles was published by Geiger et al.[335] almost two years later. Almost simultaneously Rossky and Karplus[331] carried out a detailed MD study of a dilute aqueous solution of an alanine dipeptide with both polar and nonpolar regions. These investigations might be considered the precursors of many computer simulation studies of the hydration of organic compounds in water.

With the aim of studying hydrophobic hydration and hydrophobic interactions simultaneously, most simulations deal with the behavior of water molecules in the presence of more than one solute particle. The solvation of prototypes of apolar solutes such as methane[163, 310, 324, 326, 330, 332, 336, 337] and noble gases[325, 334, 335, 338–343] has been studied extensively. Since *n*-butane is a popular model for studies of solvation effects on conformational equilibria, studies of the solvation of *n*-butane have been conducted frequently.[344–347] In addition to computer simulations of the solvation of other alkanes,[309, 348, 349] fundamental studies of the hydration of formaldehyde,[350] methanol,[349, 351–353] ethanol,[309, 349, 354] 2-methyl-2-propanol,[355] and a series of α-amino acids and nucleotides[356] have also been reported. Occasionally solute–water interactions have been described by potential functions based on ab initio calculations.[330, 332, 351, 352] In other cases, solute–water interactions were represented by relatively simple Lennard–Jones potentials[293] or even by merely short-range repulsive forces.[357] Recently Cramer and Truhlar[358] reported self-consistent field calculations to compute absolute free energies for the solvation of apolar organic and small inorganic molecules in water.

Although different potential functions, simulation times, and computational methods have been used, the results are qualitatively remarkably similar. Pair distribution functions representing the distribution of hydrogen and oxygen nuclei with respect to argon atoms in aqueous solution as reported by Guillot et al.[310] are shown in Figure 11. The fact that

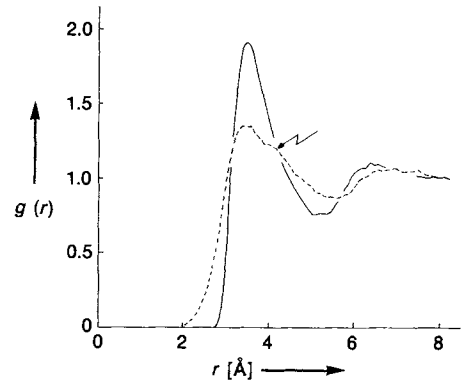

Fig. 11. Argon–oxygen and argon–hydrogen pair distribution functions $g_{AO}(r)$ (solid line) and $g_{AH}(r)$ (dashed line), respectively, for a dilute aqueous solution of argon (taken from ref. [310]). For further explanation see text.

$g_{AH}(r)$ and $g_{AO}(r)$ almost coincide indicates that water molecules adjacent to the solute particle are orientated such that their O–H bonds are tangential to the surface of the solute. This conclusion has been almost unanimously confirmed by

other computer simulation studies (see, for example refs. [310, 330, 332, 335, 338, 357]). Water molecules clearly avoid pointing their O–H bonds directly toward the nonpolar solute. The second maximum in the distribution functions shows that most water molecules in the second hydration shell point their oxygen atom toward the solute and their hydrogen atoms toward the bulk and, on average, orient themselves tangentially on the first hydration layer. An interesting feature revealed by some computer simulation studies[310, 335, 339] is the weak shoulder in the peak of the hydrogen–solute pair distribution function (see arrow in Fig. 11). The increased probability of finding hydrogen atoms of water molecules participating in the second hydration shell at a shorter distance from the solute particle gives reason to infer that some water molecules point their O–H bonds in the direction of the first hydration layer and appear to couple the two hydration shells.

The number of water molecules involved in the solvation of an apolar solute particle depends strongly on the definition of the size of the hydration shell. On the basis of "partitioning of configuration space", several computer simulation studies report hydration numbers.[330, 359] They tend to be large and vary from 20 for methane to 34 for *n*-pentane. Jorgensen et al.[359] reported an excellent correlation between the number of water molecules in the first hydration layer of a series of linear and branched alkanes and the entropy of solvation. Curiously, a Lennard–Jones solute with a diameter corresponding to the hard-sphere diameter of a water molecule is surrounded by significantly more water molecules than a water molecule itself.[357] Some evidence indicates that the coordination number of water molecules in the solvation shell is preferentially four, but differences to the coordination numbers in pure water are small.[332, 337, 348]

Although differences between binding energies of water molecules in the bulk and in the hydration shell are small, discernible shifts have been observed towards stronger binding among water molecules in the hydration shell. Most simulation studies reveal that the total binding energy distribution of water molecules generally becomes narrower after insertion of the apolar solutes and shifts towards lower energy (see, for example, refs. [330, 332, 338, 341]). In contrast, Jorgensen[346] reported a slightly lower binding energy for water molecules in the solvation shell of *n*-butane.

Okazaki et al.[348] found that the number of hydrogen bonds increases significantly when an alkane is dissolved in water, but they did not observe a relation between the size of the apolar solute particle and the observed shift in the hydrogen bonding distribution function. Geiger et al.[335] and Pangali et al.[338] observed only a modest increase in the number of hydrogen bonds in aqueous solutions of apolar compounds. Introduction of an apolar solute particle into liquid water is apparently accompanied by a small increase in the number of stronger, less distorted hydrogen bonds.[335, 341, 348]

Significant effects of an apolar solute particle on the hydrogen bonding properties of water molecules should be revealed in the librational motion of the water molecules, which can be obtained from an analysis of the dynamic pathway of these water molecules (see, for example, refs. [331, 335, 336, 342, 351, 355]). Dynamic parameters are difficult to interpret when a water molecule spends only a fraction of the total run time in the hydration shell of an apolar solute particle. The translational motion can be monitored within a very short period of time, during which relatively few water molecules exchange between the hydration shell and the bulk. Unfortunately, rotational motion of molecules in a strongly hydrogen-bonded fluid such as water is considerably slower than translational motion. The average angular reorientation of a water molecule while it is in the solvation shell is quite small, and a comparison of rotational motions of water molecules in bulk water and in a hydrophobic hydration shell is hazardous. Rossky and Karplus[331] were the first to conclude that water molecules near apolar moieties have longer translational and rotational relaxation times than bulk water molecules. A study of the shell occupancy of the hydration shell of a hard-sphere solute as a function of time showed that the exit rate of water molecules from the solvation shell is some 20% less than that from the solvation shell of bulk water.

The restricted motion of water molecules in the hydration shell was later corroborated by Zichi and Rossky,[342] who showed that the translational mobility of water molecules adjacent to Lennard–Jones particles is reduced by about 30%. The reduced translational and rotational motion was shown to be reflected in an increase of the average lifetime of hydrogen bonds. It has been suggested that structural changes in the solvation shell are more concerted than in the bulk. In contrast, Postma et al.[308] did not observe a significant reduction of the translational motion of water molecules near a hydrophobic solute. On the basis of computer simulations it has been found that molecules in the hydration shell oscillate at somewhat higher frequencies than molecules in the bulk.[360] This implies that the restoring forces following a slight perturbation of a single water molecule in the hydration shell are larger than those for a perturbed molecule in bulk water. An analysis in terms of hindered rotations and hindered translations presented by Zichi and Rossky[342] and Rossky and Karplus[331] indeed suggests a strong correlation of the movement of water molecules in close proximity to an apolar surface. However, it must be recognized that a considerable reduction in the translational motion in the hydration shell can be explained by the fact that the solute particle acts as a fixed wall.

Recently Wallqvist[163] presented evidence that the number of hydrogen bonds at the interface between an apolar phase and liquid water is significantly reduced and that the average attractive energy between the water molecules at a water–hydrocarbon interface is also reduced considerably. This observation should be considered in light of the hydration of large apolar molecules or surfaces without sufficient curvature for all hydrogen bonds of the adjacent water molecules to be maintained. Furthermore, Wallqvist showed that interactions between water and methane molecules at the interface between bulk water and a hydrocarbon phase are enhanced by the orientation of water molecules at the interface.

Computer simulations of aqueous solutions of organic compounds containing both apolar and polar goups show without exception that water molecules in close proximity to the apolar moieties exhibit characteristics similar to those of the surrounding perfectly apolar solute particles.[309, 349–355]

As indicated by Jorgensen et al.,[309, 353] the introduction of a polar hydroxyl group strongly facilitates the solvation process by increasing the solute–water interactions. This is reflected by the bimodal energy distribution function for water–alcohol interactions. Hydrogen bonding leads to a low-energy interaction band, while London dispersion interactions involving many water molecules contribute to a large interaction band with close zero energy. As might be expected, structural analysis of the solvation shell of amphiphilic molecules indicates that solvation of apolar moieties and polar functional groups is mutually obstructive.

The results obtained from computer simulations of the hydration of apolar particles in water present a coherent picture of clathrate-like hydration, and the presence of pentagonal structures has been observed.[310, 332, 361, 362] The slightly reduced mobility of the water molecules and the moderate shift to the formation of stronger hydrogen bonds reinforce the traditional idea that water molecules in the solvation shell of an apolar solute particle behave like bulk water at lower temperature. The existence of "frozen patches" can be safely excluded, since the clathrate-like solvation shell appears to be extremely labile and permits solvent exchange on a picosecond timescale.

Most computer simulation studies of hydrophobic hydration were performed to trace differences between water molecules in hydrophobic hydration shells and in the bulk near room temperature. Interestingly, Jorgensen et al.[346, 359] emphasized that the remarkable property of water molecules in the hydrophobic hydration shell is that they are almost indistinguishable from water molecules not participating in hydrophobic hydration shells. Furthermore, Jorgensen et al.[309, 359] showed that the large and favorable enthalpy of solvation of apolar gases in water near room temperature can be fully attributed to solute–water interactions. The qualitative features of the solvation shell surrounding an apolar solute particle are, however, hardly affected by removing the attractive part of the solute potential.[308, 332] Recently, Rashin et al.[363, 364] drew similar conclusions from continuum-based calculations of hydration enthalpies and entropies of a series of inert gases. Thus, the crucial question remains to what extent the thermodynamic parameters of hydration for apolar compounds in water are affected by the moderate changes in the hydrogen-bonding properties of water molecules in the hydration shell.

3.5.2. Simulations of Pairwise and Bulk Hydrophobic Interactions

Computer simulation studies of hydrophobic interactions aim at calculating the pair distribution function or, alternatively, the potential of mean force between two or more apolar solute particles in an aqueous environment. In 1974 Dashevsky and Sarkisov[333] used a MC procedure to compute the potential of mean force acting between two methane molecules in 64 water molecules and found a monotonic decay of $w_{CH_4-CH_4}(r)$ to zero as a function of the distance between the particles. The computational methods were ill-defined, and the results generally considered unreliable.

In 1979 Geiger et al.[335] reported the first MD simulation study of a system comprising two Lennard–Jones solute particles in 214 ST2 water molecules. Surprisingly, the Lennard–Jones solutes, initially placed in contact and dissolved in water, were almost immediately forced slightly apart in order to be hydrated in separate solvent "cages" that shared one layer of water molecules tangential to the surfaces of both solute particles.[335]

Swaminathan and Beveridge[365] carried out a MC simulation on a solution of two methane molecules in a similar number of water molecules but applied ab initio methods to describe the interactions between the components in solution. Their computer simulation confirmed the existence of a contact- *and* a solvent-separated hydrophobic bond.[365] Since then a series of computational studies have appeared with the aim of studying hydrophobic interactions between a variety of solute particles, for example, relatively simple Lennard–Jones solutes,[293, 334, 335, 338, 341, 342, 357, 362] noble gases,[246] and methane[163, 328, 336, 361, 365, 366] as well as more complex systems such as methanol,[351] 2-methyl-2-propanol,[355] and quinuclidine.[367] The interactions of these solute particles have been simulated by using relatively simple Lennard–Jones potentials. Incidentally, more sophisticated potentials have been applied based on ab initio calculations.[351, 355, 365] Water–water interactions have usually been modeled by empirical models such as the ST2 model,[246, 334, 335, 338, 341, 342, 362] the SPC model,[163, 366, 367] and the TIP4P model;[328, 336] the nonempirical MCY model[351, 355, 357, 361, 365] has been used as well. The run time of the simulations varied from only 7 ps (Geiger et al.[335]) to 450 ps (Andersen and Watanabe[246]).

Regardless of the computational methods and the applied potential functions, computer simulation studies generally yield potentials of mean force between apolar solute particles that oscillate as a function of the distance between the particles. Thus these results reinforce the ideas that emerged from integral theories (Section 3.3.4). A representative example, shown in Figure 12, is taken from the work of Wata-

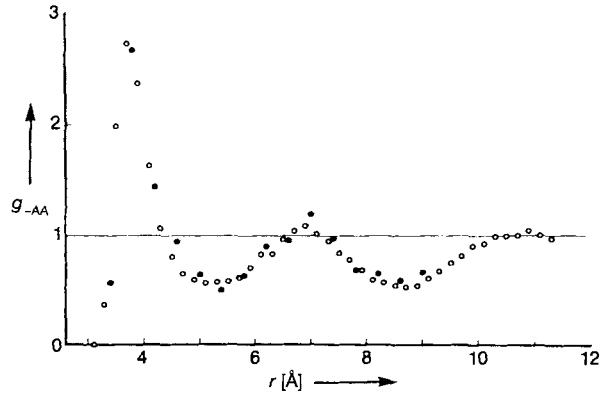

Fig. 12. Solute–solute pair distribution function $g_{AA}(r)$ for a solution of 6 solute particles (krypton-like Lennard–Jones particles; $\sigma = 3.44$ Å) in 394 water molecules (○) and for a solution of 5 solute particles in 195 water molecules (●) (taken from ref. [246]).

nabe and Andersen,[246] who carried out an extensive MD simulation of hydrophobic interactions between krypton atoms in an aqueous solution of finite concentration. The position of the first maximum corresponds to the expected contact pair, and the second maximum to an arrangement in

which the solute particles are separated by one water molecule. Even a third maximum can be distinguished, suggesting an arrangement in which the particles are separated by two layers of water molecules. The exact distance between the solute particles in the solvent-separated arrangements depends on the choice of potential models. Computer simulations by Ravishanker et al.[361] indicate that arrangement C (Scheme 8) is preferred, whereas other simulations[334] as well as the theory of Pratt and Chandler (see Section 3.3.4) suggest a preference for arrangement E.

The equilibrium solvation structure for the solvent-separated arrangement has been studied in more detail by Zichi and Rossky;[362] they placed two Lennard–Jones particles at a solvent-separated distance (arrangement E) and studied the orientation and dynamic properties of the water molecules in close proximity to the solute particles. The MD simulation revealed a variety of clathrate-like structures surrounding the two apolar particles.

Conflicting results have been reported with respect to the height of the barrier between the solvent-separated and contact pair.[342] Generally, the solvent-separated arrangement is found at higher free energy; however, this arrangement has the greater population because of the greater volume of its potential well. The relative and absolute values of the minima depend strongly on the solvent–solute interaction potential. When the interactions between solute and water decrease, the preference for the formation of hydrophobic contact pairs increases. Pangali et al.[338, 334] presented evidence that the contact and solvent-separated arrangements are equally populated, whereas Ravishanker et al.[361] and Andersen and Watanabe[246] noted a strong preference for the solvent-separated arrangement.

In order to determine the importance of attractive solute–solute interactions, Rapaport and Scheraga[357] simulated an aqueous solution of four essentially hard-sphere solutes. Solute–solute interactions were reduced to simple short-range repulsive forces by removing the long attractive tail of the full Lennard–Jones potential. The solute particles were initially not brought in contact distance. Although the solutes were shown to be highly mobile, no evidence was found for their association during a 70 ps simulation. The results of the MD simulation performed by Andersen and Watanabe[246] were similar. These authors even observed that krypton atoms tended to avoid each other in an aqueous solution of finite concentration. A compact cluster of five krypton atoms appeared to have a lifetime of about 180 ps, but this was not the dominant equilibrium arrangement. Hence, a prerequisite for reliable results are extended-time simulations.[246]

Jorgensen et al.[328] obtained the potential of mean force between two methane molecules in water by using statistical perturbation theory. The free energy for the binding of two methane molecules in water was estimated as -1.8 (± 1.4) kJ mol^{-1}, of which -1.2 kJ mol^{-1} arises from simple Lennard–Jones attractions between the solute particles. Recently, Smith et al.[366] applied traditional thermodynamic integration methods to compute the free energy and the entropy of the association of two methane molecules in water on the basis of an extensive MD simulation. They showed that the solvent-induced forces between methane molecules in water are small but attractive at short separations as a result of a favorable entropy change.[366] In contrast to Ravishanker et al.,[361] who performed a preliminary MC study of the effect of temperature on the pair distribution of methane in an aqueous solution, the results of Smith et al.[366] confirmed the experimental observation that attractive interactions between apolar solutes at short distance increase and the potential well for the contact arrangement well becomes deeper as the temperature increases.

Computational studies of pairwise hydrophobic interactions have often been frustrated by the fact that spontaneous association of two apolar solute particles has never been observed on the simulation timescale. Wallqvist and Berne[158] have shown that the stability of the solvent-separated arrangement even holds for the interaction of one apolar solute with a large flat apolar surface. A plausible explanation for this might be that the barrier between the contact arrangement and the solvent-separated arrangement is too high and the solute particles are trapped inside a solvent cage. During the simulation time, escape from this cage can be an extremely rare event. Furthermore, the formation of a contact pair from randomly distributed particles can be an unfavorable process in terms of Gibbs energy, despite substantial attractive forces between the solute particles. The existence of solvent-separated solute pairs appearing as local minima on a potential energy map is, strictly speaking, unrelated to the hydrophobic interactions. The occurrence of distinct arrangements of the solute particles is the result of a well-established packing phenomenon and occurs even in the most simple solvent systems (see Section 3.3.1). The additional arrangement of water molecules separating the solute molecules is a consequence of the directional character of the hydrogen bonds connecting the water molecules.

The fact that two apolar solute particles in dilute aqueous solution do not spontaneously aggregate on the simulation timescale has also seriously obstructed studies of bulk hydrophobic interactions. Recently Laaksonen and Stilbs[336] studied the distribution and the dynamics of methane molecules in aqueous solutions with increasing concentrations of methane. At higher concentrations more methane molecules were able to overcome the barrier between the solvent-separated and the contact arrangement and occasionally stuck together. Eventually, the solvent-separated arrangement disappeared completely.

A similar computational study was reported by Wallqvist,[163] who studied the behavior of a system comprising 18 Lennard–Jones solutes, representing methane, dispersed in 107 water molecules. Obviously, the concentration is extremely high, and spontaneous aggregation of the solute particles is inevitable. Indeed, phase separation was observed which resulted in hydrocarbon-rich domains dispersed in water. This result led Wallqvist to emphasize the necessity of invoking higher-body interactions for a successful simulation of a spontaneous aggregation of many apolar solutes.

Computer simulations of intramolecular hydrophobic interactions have generally been carried out by simulating the effect of water on the conformation of simple apolar molecules.[368] *n*-Butane is the simplest alkane for which the effect of the solvent on the conformation in solution is not a trivial problem and might be considered the prototype for conformational studies in water. Several computer simulation studies showed that the population of the more compact *gauche*

conformer increases when *n*-butane is transferred from the gas phase to an aqueous solution.[344-347] Although the applied computational methods are different, most authors find a shift of 10–35% at the expense of the extended *trans* conformer. Recently Tobias and Brooks[345] reported that the *gauche* conformer is also favored in CCl_4. In water, however, the effect is significantly larger. A thermodynamic analysis showed that the *gauche* conformer is energetically destabilized but strongly favored by entropy.

Some computer simulation studies focused on interactions between solute particles having both polar and apolar regions. MD simulations of a 3 mol% solution of 2-methyl-2-propanol and a 5 mol% solution of methanol in water using the MCY potential model for water and an ab initio description of solute–solvent interactions showed that these alcohols tend to associate in water; this is consistent with experimental findings.[351, 355] Unfortunately, it was not explicitly reported whether solvent-separated or contact pairs were formed. Hydrogen bonds between the alcohol molecules were not detected. Maliniak et al.[367] reported aggregation of quinuclidine in a 6 mol% solution using MD simulation methods. In a more dilute solution (2 mol%), the solutes did not show any tendency to form aggregates. Recently, MD methods have even been successfully applied to simulate aggregation of surfactant molecules.[369]

4. Epilogue

Traditionally, chemists have attributed a pivotal role to the structure of water in the vicinity of apolar solutes or apolar moieties in aqueous solutions as expressed in the concept of hydrophobic hydration and hydrophobic interaction. Inextricably wrapped up with the concept of hydrophobic hydration is the notion of stronger (or more) hydrogen bonds in hydrophobic hydration shells. In particular, the idea of a clathrate-like hydration layer led to the exaggerated picture of iceberg formation at the surface of apolar solute particles in water. Recent computational studies have yielded little evidence for a significant increase of either the number or the strength of hydrogen bonds in aqueous solutions of apolar compounds when compared to pure water.

The large and favorable enthalpy of solvation of apolar compounds in water, presented in classic papers as a convincing piece of evidence for enhanced hydrogen bonding in hydrophobic hydration shells, can be conveniently explained on the basis of interactions between water and the apolar solute without assuming additional interactions among water molecules. Various studies, however, have confirmed that O–H bonds of water molecules adjacent to an apolar solute are predominantly oriented tangentially to the apolar surface. Current evidence strongly indicates that water does not undergo a structural enhancement in the presence of apolar solute particles but *maintains* its original structure by accommodating the apolar solute in its original hydrogen bond network. The unique property of water is that it can dissolve an apolar solute of limited size without sacrificing a significant number of hydrogen bonds.

London dispersion interactions between water and the apolar solute create an additional source for enthalpy, resulting in a large and negative enthalpy for the solvation of apolar gases in water. The orientation of the water molecules in the first hydration layers might even give rise to a bulk polarization phenomenon induced by "proton hopping". Thus, it might be speculated that solute–water interactions are enhanced by the orientation of the water molecules in the immediate surroundings of the solute particle. Computational chemistry would be the most appropriate tool to validate or disprove this idea.

The tendency of water molecules not to sacrifice any (or only a small number) of their hydrogen bonds and to interact favorably with apolar solute particles does not mean that water is a good solvent for apolar compounds. At lower temperatures the loss of entropy hampers solvation. The interpretation in terms of "structure-making" properties of apolar solutes or related terminology is in our opinion not very elucidative and may be even wrong. As shown elegantly by applications of scaled particle theory, a large part of the negative entropy of solvation can be attributed to the small molecular volume of the water molecules; in other words, many water molecules are involved in dissolving a single solute particle. In fact, the hydrogen bond structure of water, which provides the solvent with an exceptionally low density, is even favorable for dissolving inert solutes. However, it must be noted that scaled particle theories do incorporate some structural information for the solvent such as the isothermal compressibility. As argued by Lee,[228, 230] reduction of rotational freedom and possibly compression of water molecules in the first hydration layers will contribute to the loss of entropy as well. Nonetheless, one crucial point emerges: the orientation of the water molecules in the hydration shell of apolar solute particles, generally referred to as hydrophobic hydration, *aids* the dissolution of apolar compounds in water and is not the cause for their low solubility.

At higher temperatures water gradually loses its capacity to maintain hydrogen bonds upon intrusion of apolar solute particles. This leads to less favorable solute–water interactions, expressed in a gradual reduction of the enthalpy of solvation, which even becomes positive at elevated temperatures. Since hydrogen bonds break, the entropy increases as well. At high temperatures the increase in entropy is very significant and counteracts the reduction of entropy that stems from the small molecular volume of the water molecules. Apparently, the Gibbs energy accompanying the disruption and formation of hydrogen bonds in the hydration shell of apolar solute particles is small. The entropy and enthalpy characterizing the changes due to variation in temperature are almost fully compensative. This does not necessarily imply that this compensation behavior is a result of an intrinsic property of the water structure, as is often assumed in "compensation models". Changes in the orientation and binding properties of water molecules in the hydration shell due to changes in temperature can also affect solute–water interactions. It is notoriously difficult to separate the thermodynamics of water–water interactions in hydrophobic hydrations shells from those of solute–water interactions. Although the capacity of water to dissolve apolar solutes decreases as the temperature is raised, the influence of temperature is remarkably small. This fact supports the notion that structural changes in liquid water are not the main cause for the low solubility of apolar compounds in water.

A more effective way of preventing water molecules from maintaining their hydrogen bonds upon intrusion of foreign solute particles is to increase the concentration of the solute. The hydrophobic hydration shell is apparently quite extensive. At a certain concentration of solute particles, the number of water molecules is not sufficient to form a complete hydrophobic hydration shell, which leads to interference and mutual obstruction of hydration shells and the inevitable sacrifice of hydrogen bonds. An alternative but related way of destroying hydrogen bonds is to increase the size of the apolar solute particle. In the limiting situation of a hydrophobic wall, water molecules are not able to salvage all hydrogen bond interactions, even when their O–H bonds are tangentially aligned towards the hydrophobic surface. Finally, introduction of polar functionalities leads to mutual obstruction of hydration shells. A hydroxyl group will contribute strongly to the solubility of a predominantly apolar solute particle and will considerably reduce the necessity and possibility for the formation of (local) hydrophobic hydration shells. This phenomenon governs the hydration of polyols and carbohydrates. Strikingly, the apolar methylene functionalities remain available for interactions with other apolar moieties in solution; this might be crucial for molecular recognition phenomena at the surface of living cells, in which polysaccharides play a prominent role.

Hydrophobic interactions, both pairwise and bulk, have traditionally been treated as a natural consequence of hydrophobic hydration. It was, however, alarming that computer simulations of dilute aqueous solutions of apolar solute particles do not reveal any tendency of the apolar solutes to form long-lived pairwise or higher-order aggregates on a typical simulation timescale. The concept of partial destruction of hydrophobic hydration shells involving the release of structured hydration water to the bulk, which plays a dominant role in the traditional interpretation of hydrophobic effects, has lost much of its attraction as a molecular model of hydrophobic interactions. Following the argument that hydrophobic hydration aids the dissolution of apolar compounds in water, it cannot also be considered as a cause for the association of apolar solutes in aqueous solution. In contrast, hydrophobic interactions are *counteracted* by the formation of a hydrophobic hydration shell. Apolar solute particles are "screened" in dilute aqueous solution as compared to the gas phase.

Pairwise and bulk interactions between apolar moieties do lead to partial desolvation of the apolar surface and to a concomittant reduction of the number of water molecules involved in the solvation of the solute particles. Inherently, this leads to a gain of entropy. In dilute solutions the gain in entropy is insufficient to overcome the unfavorable enthalpic effect and the loss of entropy due to the association of solute molecules and, consequently, the formation of long-lived pairs of apolar solute particles is an infrequent event. The molecular origin of the slightly unfavorable enthalpy involved in bulk hydrophobic interactions near room temperature can be explained in terms of a loss of solute–water interactions which are not completely counteracted by a gain in solute–solute interactions, while water–water interactions remain effectively unchanged. Recent computational studies of hydrophobic interactions gave rise to arguments about the preference of solvent-separated over contact solute pairs. In our opinion, this is not a very relevant question. As shown in several studies, the existence of well-defined geometrical configurations of pairs of solutes in solution is an inherent property of all solvent systems and not restricted solely to water. More interesting is the question as to the actual distance between the solute particles in the solvent-separated configuration. As shown in Section 3.3.1, the directionality of hydrogen bonds might have a significant effect on this distance.

Following the arguments given above, destruction of hydrophobic hydration shells *increases* the frequency of hydrophobic contacts. This can be accomplished by either increasing the temperature or, more effectively, by increasing the concentration of apolar compounds. Increasing temperature is not very effective in increasing hydrophobic interactions, as has been clearly demonstrated by studies of host–guest complexation and micelle formation at elevated temperatures. However, when the number of solute particles in solution prevents the formation of complete hydrophobic hydration shells, hydrogen bonds are sacrificed and an increasing number of O–H bonds will point towards the apolar surface; this is an energetically unfavorable event. As a result, the tendency to form aggregates of two or more apolar particles increases rapidly. This behavior has been repeatedly confirmed by computational studies. When the apolar solute particles can form a well-defined aggregate by means of directional bonding, for example, a micelle or an aggregate with a more complex morphology, the concentration at which aggregation takes place can be very critical. Additional factors such as surface forces, headgroup effects, and aggregate size play a decisive role, and it is too simplistic to consider only hydrophobic effects. Even aggregation of less complex organic compounds such as monohydric alcohols into small, short-lived clusters is very difficult to describe theoretically. It is still a considerable challenge to relate pairwise interactions between solutes in dilute aqueous solutions to the occurrence of bulk interactions in more concentrated solutions.

In conclusion, we believe that hydrophobic interactions are not so much a result of a structural property of the hydrophobic hydration shell of apolar compounds but rather reflect the limited capacity of liquid water to accommodate the apolar solute and maintain its original network of hydrogen bonds. It is surprising that apolar compounds dissolve in water at all; this must be attributed to the formation of a hydrophobic hydration shell.

Answers to pertinent questions regarding hydrophobic effects must be expected from either sophisticated neutron diffraction studies or from accurate computer simulatons. Incorporation of polarization effects is highly desirable if one wishes to test the proposition that solute–water interactions are enhanced by cooperative polarization effects in the hydrophobic hydration shell. Polarization effects must also be considered in investigations of the molecular origin of the exceptionally long-range interactions between large apolar surfaces.[370] Furthermore, it would be most instructive to perform an extensive comparative computational study on solutions of apolar compounds in water and in a solvent of similar size but without hydrogen bonds, for example liquid methane. In general, comparative studies of the solvation behavior of apolar compounds in various organic solvents

and water are scarce. In particular, the structural response of solvation shells to changes of temperature and concentration has been rather neglected by computational studies. Advances in this area are eagerly awaited.[371]

Carbon(IV) Nitride C_3N_4—A New Material Harder Than Diamond?

By *Wolfgang Schnick**

The prediction of the existence and the structure of previously unknown solid-state compounds seems to be particularly difficult, because numerous complex, interacting factors must be taken into account. A simplification to a certain extent is possible with predominantly covalent polymeric solid-state compounds in which coordination numbers and geometries are unambiguously stipulated for the constituent elements.

Desired properties of new materials are, above all, extreme hardness, good thermal conduction, and high thermal stability. These properties are particularly likely in compounds with highly cross-linked structures with mainly covalent chemical bonds that are very stable. The material property, hardness, can be described by the bulk modulus B, which, on atomic scale, is influenced fundamentally by the strength and compressibility of the chemical bonds.[1] Thus logically, the highest bulk moduli have been found for covalent materials: diamond not only has the highest value (4.43 Mbar), but also is the solid with the greatest hardness.[1]

A simple empirical relationship for the estimation of the bulk modulus B of solids with the zinc blende structure was presented recently by Liu and Cohen [Eq. (a)].[1] This predicts a dependence of the magnitude of this property on the ionicity λ and the interatomic distance d. In accord with recent experiments[2] this empirical relation yields a bulk modulus for cubic boron nitride that is lower than that of diamond. Furthermore, on the basis of the expression (a), Liu and Cohen predict for a similarly constructed, covalent C–N solid an extremely high mechanical hardness.[1]

$$B = (19.71 - 2.2\,\lambda)/d^{3.5} \qquad \text{(a)}$$

Of particular significance for the development of novel inorganic materials with interesting properties is the nitride class of substances containing nitrogen as electronegative bonding partner in the oxidation state −III. As a result of its lower electronegativity, nitrogen forms bonds with stronger covalent character as compared to oxygen. Moreover, nitrogen offers more extensive structural possibilities, since it forms not only one or two, but also three or four covalent bonds to neighboring atoms.[3] In combination with light main group elements from the p block (e.g., boron, aluminum, silicon, phosphorus), highly cross-linked and predominantly covalent, polymeric solid-state compounds arise.

At present in the group of known binary nitrides of main group elements in which the group number of each corresponds to the maximum oxidation state, a carbon(IV) nitride C_3N_4 is absent. According to the double bond rule, which favors the formation of multiple bonds over the construction of polymeric structures for elements of the second row, C_3N_4 could be assumed to have a molecular structure in the form of tricyanoazane $N(CN)_3$. However, also conceivable in principle and structurally feasible is a polymeric structure analogous to one of the modifications of binary Si_3N_4 with a three-dimensional network structure of CN_4 tetrahedra, sharing corners in all directions. The carbon atoms would be bound covalently to four adjacent carbon atoms like the silicon atoms of Si_3N_4, while the nitrogen atoms would be coordinated to three tetrahedral centers (C instead of Si) in an almost trigonal-planar arrangement (Fig. 1). Although

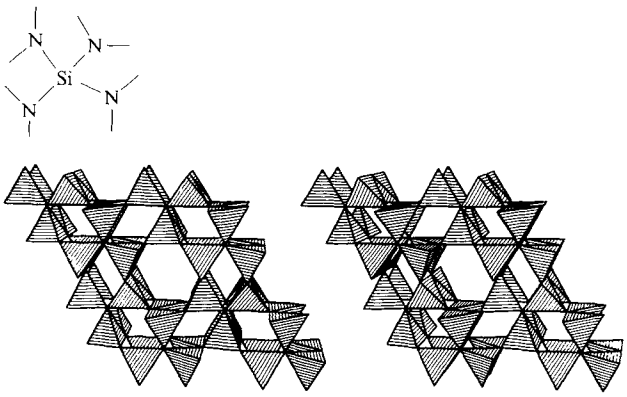

Fig. 1. Bonding and coordination of silicon and nitrogen in β-Si_3N_4 (top) and the stereoscopic representation of the crystal structure of β-Si_3N_4 viewed along [001] (bottom). The SiN_4 tetrahedra are shown as closed polyhedra. An analogous structure is postulated for β-C_3N_4 [4, 8].

no suggestion of the existence of a binary carbon nitride C_3N_4 has yet been found, the cyanamides (e.g. Na_2CN_2) are compounds that can be interpreted as ternary carbon(IV) nitrides. In accord with the double bond rule, however, carbon as an element of the second row has been shown to have a lower coordination number (CN = 2), so these compounds contain isolated, linear anions CN_2^{2-}, isosteric with CO_2.

But is there perhaps also a polymeric C_3N_4 with a structure analogous to Si_3N_4? And what material properties might be anticipated for such a compound?

The supposition formulated by Liu and Cohen that solids will have a particularly high bulk modulus when they display short bond lengths and low ionicities, that is, when the compound has a high proportion of covalent bonding, was the starting point for exact theoretical investigations into the potential stability and mechanical properties of binary carbon nitride C_3N_4. First-principles pseudopotential calculations of the structural and electronic properties (lattice constants, bulk modulus, and electronic band structure) of β-Si_3N_4 and its isotype, hypothetical β-C_3N_4, were in good agreement with experimental data obtained from silicon nitride. Two significant statements about C_3N_4 can be made: The bulk modulus of this compound should be comparable with that of diamond. Moreover, β-C_3N_4 should be able to be synthesized, at least as a metastable form under normal conditions, because of its moderately large cohesive energy.

As regards thermodynamic stability, β-C_3N_4 therefore fits into the series of other superhard materials, that, like diamond or cubic boron nitride, are also only metastable under normal conditions.

Efforts of various groups to synthesize a binary carbon nitride with a β-C_3N_4 structure initially yielded no indication that a polymeric solid containing carbon atoms tetrahedrally surrounded by nitrogen atoms exists.[5-7] These experiments employed, in particular, plasma deposition from CH_4/N_2 mixtures and pyrolytic decomposition of organic C–N–H compounds. Also shock wave compression in pyrolysis products of melamine–formaldehyde resins did not bring the desired success. Considerably more promising were the recently published studies of Niu, Lu, and Lieber,[8] in which synthetic methods are presented that generate both highly energetic carbon species as well as atomic and reactive nitrogen. The product was obtained by trapping of the resultant C–N products by low-temperature thin-film growth. The generation of the highly energetic carbon species takes place through the ablation of a very pure graphite target with a Nd:YAG laser. Atomic nitrogen with high kinetic energy (>1 eV) was generated by radio frequency discharge in a high-flow stream of $He-N_2$.

C–N films containing different nitrogen content were obtained with this process. Quantitative analysis of the reaction products with Rutherford back-scattering spectroscopy (RBS) revealed nitrogen contents in the studied samples of maximally 45%. This value lies distinctly below the theoretical value of 57% for β-C_3N_4. Moreover, it has been shown that a C–N solid with a nitrogen content worth mentioning can be constructed only when atomic nitrogen is introduced during the sputtering process. X-ray photoelectron spectroscopy (XPS) of the samples gave clear evidence for nonpolarized, covalent bonds between carbon and nitrogen. Transmission electron microscopic investigations (TEM) showed at first a pure crystallinity in the sputtered C–N films; however, small crystallites with grain sizes of less than 10 nm were detected. The diffraction pattern obtained under the electron microscope was readily observed to be consistent with the assumption of a structure analogous to β-Si_3N_4 having the lattice constants determined theoretically for β-C_3N_4. The remarkable material properties of β-C_3N_4 predicted by theoretical studies were able to be confirmed, at least qualitatively: the material showed a high thermal and mechanical stability.

Certainly one cannot yet speak of the synthesis of a defined, crystalline carbon nitride of composition C_3N_4 amongst the C–N layers of Niu, Lu, and Lieber. Nevertheless, the but short history of these compounds is remarkable: Whereas, for instance, in Gmelin's Handbook of Inorganic Chemistry a compound of the composition C_3N_4 is not even mentioned, simple empirical studies lead to the assumption that such a C–N solid should have particularly attractive material properties (exceptional hardness). This qualitative statement is confirmed by ab initio calculations. Simultaneously, an adequate stability is claimed that makes synthesis of C_3N_4 feasible, at least in metastable state. After some unsuccessful preparative attempts a process was finally developed to circumvent the former thermodynamic problems in the formation of C_3N_4 through the generation of highly reactive carbon species and atomic nitrogen. The solid, which is formed in a potentially metastable state is stabilized kinetically by growth at low temperatures.

Apparently the difficult prediction of the existence and structure of a previously unknown solid-state compound and its experimental verification has indeed been achieved. The results are certainly stimulating both for materials research and for solid-state chemistry. It will inspire a whole series of further preparative efforts and investigations. After all, not only is the preparative route to a new binary nitride of one of the most important main group elements attractive, but also the synthesis and applications of a new material with potentially particularly desirable properties. As with other binary nonmetal nitrides, the question of an extensive chemistry in the form of ternary and higher compounds also arises (cf. [9]).

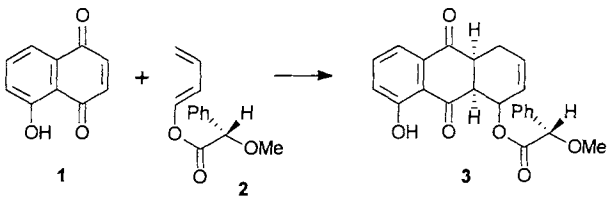
Chiral 2-Amino-1,3-butadienes: New Reagents for Asymmetric Cycloadditions

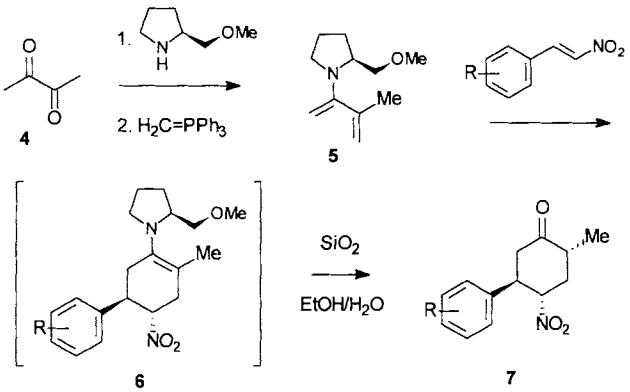
By *Karsten Krohn**

Since its discovery over sixty years ago[1] the Diels–Alder reaction has lost none of its attraction.[2] It enables, in a one-step inter- or intramolecular reaction, the rapid preparation of cyclic compounds having a six-membered ring. During the course of the [4 + 2] cycloaddition four new stereocenters can be introduced directly, and their stereocontrol is a topic of major interest in modern synthetic chemistry. In addition, in intermolecular reactions, the relative positions of the reaction partners (regiochemistry) must be taken into account. If a concerted reaction is assumed, both a *cis* addition (suprafacial mode) and a preferred *endo* orientation (Alder Rules) can be expected. But how can the *absolute* configuration of the desired product be controlled? There are three basic possibilities: the use of a chirally modified diene, a chirally modified dienophile, or a chiral catalyst. Although the first successes resulted from the attractive, but difficult, catalytic route,[3, 4b] the majority of the investigators are concerned with the stoichiometric approach using chiral dienophiles (mostly derivatives of acrylic esters.)[4–7] Chiral dienes have been used less frequently, although Trost et al. in 1980 had achieved an attention-riveting result with the (1*S*)-butadiene derivative **2**.[8] This diene reacted regioselectively with juglone (**1**) to yield a single adduct **3** with 97% *ee*! The well-known π-stacking model was developed from this example, although it does not appear to be applicable to all reactions.[9]



Unfortunately the result obtained by Trost et al. remained unique for more than a decade, at least in terms of enantioselectivity. The slow development in the area of chiral dienes may be ascribed to the difficulty of preparing these compounds.[4b] Recently, in quick succession and independently of one another, the research groups of Enders[10] and Barluenga[11] reported on the cycloaddition of chiral 2-aminobutadienes and described elegant solutions to the stereochemical problems (regio-, diastereo-, and enantioselectivity). The prospects of 2-aminobutadienes in this reaction were not promising, since the results of MINDO3 calculations had indicated that they would not undergo (concerted) Diels–Alder reactions.[12] Nevertheless, Valentin et al. in 1977[13] and Gompper et al. in 1979[14] obtained evidence for the cycloaddition of electron-rich methoxy- and amino-substituted dienes. Since then, the research groups of Barluenga[15–17] in Spain and Valentin[13, 18] in Italy have been able to carry out other cycloadditions with activated olefins, aldehydes, and imines. These investigations show, however, a distinct difference from reactions with the highly successful siloxydienes related to the Danishevsky diene.[19, 20] The enamine character of 2-aminodienes (or dienamines) is clearly demonstrated by non-Lewis acid catalyzed reactions, and open-chain adducts are frequently isolated alongside the cyclic adducts.[16] Nevertheless, in many cases the stereochemistry of the products indicates a concerted reaction. According to Enders et al. the stereochemistry of the final products can be explained equally plausibly by means of a concerted cycloaddition or a sequential series of ionic addition steps, and the authors leave the question of the actual mechanism open.[10a]

The chiral 2-aminobutadiene **5** was prepared in good yield from diacetyl **4** and (*S*)-2-(methoxymethyl)pyrrolidine (SMP), obtained from proline, by means of enamine formation and a Wittig reaction. The cycloaddition of **5** with five different nitrostyrenes (R = H, 4-F, 4-OMe, 4-Me, 3,4-OCH_2O) proceeded at room temperature without catalysis and yielded labile cycloadducts **6** (enamine substructure), which decomposed on silica gel to form the corresponding ketones **7**.[10a] Careful analysis of the spectra of the products



shows that the saponification of the intermediate enamines **6** ("ketonization") does not proceed in a completely uniform manner; epimers are formed at the position α to the carbonyl group. For the reaction in diethyl ether, enantioselectivities from 96 to > 99% *ee* were obtained for the main products—record values for cycloadditions not catalyzed by Lewis acids. In addition, the reaction is completely regioselective, which, in view of the strongly polarized reaction components, 2-aminobutadiene and nitrostyrene, is compatible with both the frontier orbital model for a concerted reaction and the stepwise ionic course (1,2- and 1,4-addition). The two reaction modes can be described by transition states **A** and **B**.

Barluenga et al.[11] have investigated slightly modified 2-SMP-butadienes **8** with a hydroxy- or alkoxymethyl group attached to C-4 (R = H, alkyl). The dienes can be synthesized by the addition of SMP to commercially avail-

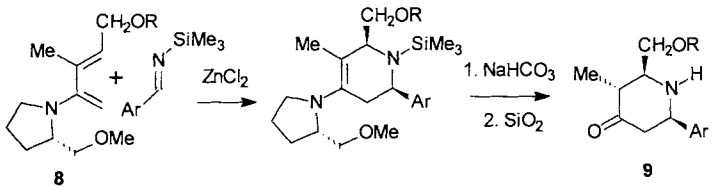
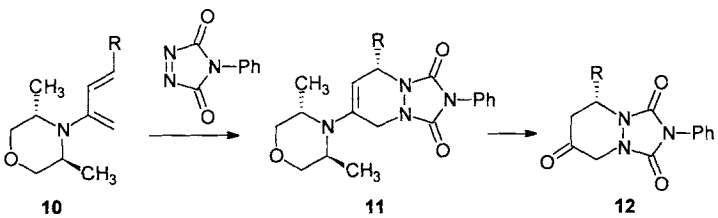
A B

able enynes. Independently of Enders et al., they also used nitrostyrenes as dienophiles in reactions with the chiral 2-aminobutadienes **8**. These workers obtained slightly lower *ee* values (82 and 90%) with the reactions in methanol, a result which the German authors had already observed with this solvent. For an unbiased observer these otherwise analogous results confirm the reproducibility of the reaction. The Spanish authors demonstrate, in addition, two highly interesting reactions which considerably extend the area of application of the new chiral 2-aminodienes. One of these is the hetero-Diels–Alder reaction with *N*-silylimines, whose products can be hydrolyzed to provide substituted piperidones **9** with a high degree of enantioselectivity (85 and 95% *ee*). Such piperidones are required for the synthesis of alkaloids and pharmaceuticals.



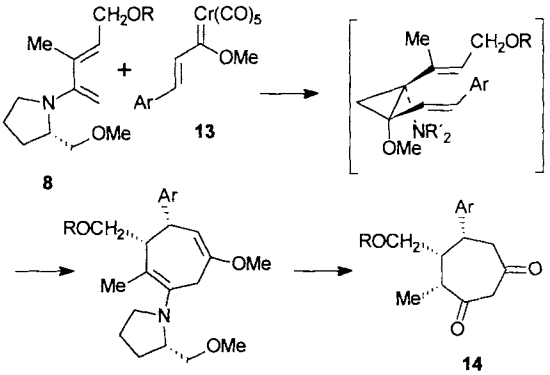
8 **9**

Recently Enders et al.[10b] treated azadienophiles such as phenyltriazoledione with (*S,S*)-2-(3,5-dimethylmorpholino)butadiene **10** (R = *n*Pr, *i*Pr, cyclohexyl, cyclopentyl, *t*Bu, Ph–C≡C) to form heterocyclic enamines which, after acid-catalyzed removal of the chiral C_2-symmetrical amine, yielded the hexahydropyridazines **12** (six examples) with an *ee* of 90–91%. The successful use of another chiral amine, [(*S,S*)-3,5-dimethylmorpholine], gives further indication of the efficiency of chiral induction by means of coupling at the C-2 position of the diene.



10 **11** **12**

Another example from the Spanish authors[11] is especially interesting, as the cycloaddition leads to the formation of a compound with a seven-membered ring. The literature shows that in recent years a tremendous amount of effort has been expended in trying to prepare carbocyclic five-membered rings by a route as simple and elegant as the Diels–Alder reaction for the synthesis of six membered-rings.[4c] Is a counterpart for seven-membered rings now in sight? The aminodienes **8** were allowed to react with α,β-unsaturated Fischer carbene complexes.[21] The reaction consists of two well-known concerted reactions which occur sequentially: cyclopropanation and a Cope rearrangement of the intermediate divinylcyclopropane. The principle was first demonstrated by Wulff et al.[22] with the reaction of the Danishefsky diene (1-methoxy-3-trimethylsiloxy-1,3-butadiene) and unsaturated carbene(carbonyl)chromium complexes. The Cope-type rearrangement occurs so rapidly with *cis*-oriented vinyl groups on the cyclopropane that the intermediate usually cannot be isolated. Barluenga et al. were recently able to show that the analogous reaction with 2-aminobutadienes **8** in place of the siloxybutadiene leads to the formation of seven-membered rings.[23] The decisive advantage lies, however, in the additional possibility of using a chirally modified diene component.[11] The reaction of **8** with the carbene complex **13** gave satisfactory yields (52–82% for the multistep sequence) with total regio- and diastereoselectivity and excellent enantiomeric excesses of 81 and 86% *ee*.



8 **13** **14**

What are the advantages of the new chiral 2-aminobutadienes? Firstly, as the well-established SMP is a commercially available chiral reagent, the chances are good that it will find broad application. Secondly, there are established methods for the coupling of SMP with other starting materials to form 2-aminobutadienes.[10c, 17] Finally, as is shown by the examples, especially the nitroolefins,[10, 13, 18] good control of the regiochemistry is possible because of the strong electron donor in the 2-position. The increased electron density of the diene increases the reactivity (for cycloadditions with "normal" electron requirements), and the reaction can be extended to compounds with, for example C=N bonds. In addition, the reaction with α,β-unsaturated Fischer carbenes opens the door to the single-pot, stereoselective synthesis of carbocyclic seven-membered rings. Especially important is the fact that the chiral component can be removed under very mild conditions and can, in principle, be recovered. Decisive, however, is the excellent enantioselectivity of the reaction which, as has been shown by Enders et al.,[10a] can be further improved by the choice of the reaction conditions.

Arene–Arene Interactions: Electrostatic or Charge Transfer?

By *Christopher A. Hunter**

Noncovalent interactions between aromatic molecules play a major role in determining the structures and properties of molecular assemblies in biology, chemistry, and materials science. However, they are not well understood. When molecular scientists obtain an unexpected result in a system which contains π systems, they tend to invoke the mythical powers of the "π–π interaction", "π-stacking", "charge transfer" (CT), "π-acid/π-base" or "electron donor acceptor (EDA) interaction". The range of terms used reflects a confusion about the precise nature of these interactions.[**] Recent experimental work shows that the concept of CT or EDA interactions is highly misleading and that π-π interactions are dominated by electrostatics.[1, 2]

Several different factors contribute to the magnitude of any noncovalent interaction between two molecules.[3]

1. The van der Waals energy; that is the sum of the dispersion energy and the repulsion energy.

2. The electrostatic interaction due to different static charge distributions in molecules.

3. The induction energy which is the interaction between the static charge distribution of one molecule and the proximity-induced change in the charge distribution of the other. It is not yet clear whether this contribution is experimentally significant.

4. CT which is a stabilization due mixing of the ground state (A B) of a molecule with an excited charge-separated state ($A^+ B^-$).

5. Desolvation of the interacting molecular surfaces.

If we are to understand the role of π-π interactions in controlling the behavior of biomolecules, and if we are to use these interactions to design synthetic receptors for small molecules, drugs for biological receptors, homogeneous catalysts or self-assembling polymolecular aggregates, then it is vital that we know the relative significance of the contributions listed above. For example, suppose we wanted to design a molecular assembly in which two π systems were held together in a face-to-face stacked orientation (this might be a self-organizing molecular material). If CT is the major factor governing the π-π interaction, then we should make one π-electron system a good electron donor and the other a good electron acceptor. On the other hand, if electrostatics dominate, then we should use two π systems with a very low π-electron density to minimize unfavorable interactions between the two closely approaching π-electron clouds (Fig. 1).[4] Perhaps tetracyanoquinodimethane (TCNQ) would be good!

Diederich et al. have carried out extensive investigations of π-π interactions in host–guest complexes between cyclophanes and aromatic compounds.[5, 6] This work has established the role played by the solvent. The association constants are up to 10^6 times larger in polar solvents like water than in nonpolar solvents like Me_2S. The strength of the interaction varies uniformly with solvent polarity and correlates well with the empirical $E_T(30)$ parameter.[5] Diederich et al. have also investigated the effect of polarizing

[**] The term used in this article is π-π interaction. This is intended as a shorthand for noncovalent interactions between π systems. It does not imply anything about the nature of the interaction.

substituents. The π-π interactions are most favorable for guest compounds with electron withdrawing (acceptor) substituents, and as the host π systems have electron donating (donor) substituents, this was taken as evidence in favor of the EDA model.[6] However, the results can also be rationalized by using an electrostatic model.[4]

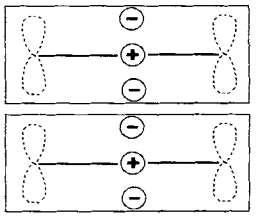

Fig. 1. A schematic representation of the charge distribution for two π systems stacked in a face-to-face orientation. There are repulsive electrostatic interactions associated with the out-of-plane π-electron density (the closest approaching charges are the negative π-electron charges). The interaction will be sensitive to substituents which change the π-electron density [4].

Flexible molecular clefts studied by Hamilton et al. provide evidence that electrostatic effects play a major role in determining the orientation of π-π interactions.[7] Hunter and Sanders have shown that the geometry of π-stacking interactions between porphyrins can be explained on the basis of electrostatic interactions involving the out-of-plane π-electron density.[4] They have used these results to develop a general model for π-π interactions based on electrostatics. A recent report by Zhang and Moore also suggests that electrostatic interactions involving the out-of-plane π-electron density may be more important than CT or EDA effects.[8]

Despite extensive literature on π-π interactions, there has not been a systematic experimental study of a simple aromatic system that has unambiguously established the relative importance of all of the contributions previously mentioned. One problem with carrying out such a study is that noncovalent interactions between small aromatic molecules are relatively weak and are highly sensitive to orientation. In order to carry out a systematic investigation, the two interacting partners must be forced together in a fixed orientation so that a change in the strength of the interaction will not lead to a change in geometry.

Cozzi, Siegel et al. have come up with a very simple and elegant way of doing this (Fig. 2).[1, 2] Naphthalene is used as

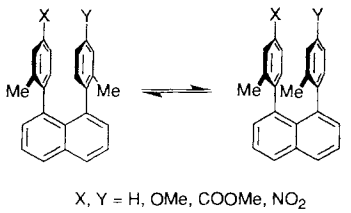

Fig. 2. Cozzi, Siegel et al. have used the energy barrier to this restricted rotation process to investigate substituent effects on π-π interactions between the two aromatic rings which are held in a face-to-face orientation [1, 2].

a covalent scaffold to hold two interacting aromatic rings in a face-to-face stacked geometry. The relative strengths of different π-π interactions are then estimated by measuring the energy barrier to the conformational exchange process shown in Figure 2. The methyl groups act as markers so that the restricted rotation can be monitored by NMR spectroscopy. The observed barrier to rotation depends markedly on the nature of the X and Y groups which polarize the π systems. The authors claim that these differences are a direct measure of the relative magnitudes of the π-π interaction energies between the aromatic rings in the ground state stacked orientation.

There are two important assumptions. The naphthalene bridge forces the interacting π systems very close together, so that the spacing of the carbon atoms connected to the *peri*-positions of the naphthalene framework is 2.8 Å, well within their van der Waals contact distance (3.4 Å). The distance dependence of electrostatic interactions between π systems varies between r^{-1} and r^{-5}, whereas orbital interactions vary as e^{-r}.[9] Thus the enforced proximity should exaggerate any CT effects over electrostatics. The second assumption is that the π-π interactions in the transition state do not depend strongly on X and Y. This would be true if orbital interactions such as CT were important but does not necessarily hold if electrostatics dominate. These limitations restrict the generality of the approach but still allow a clear experimental test of whether electrostatics or CT determines the properties of noncovalent interactions between stacked π systems.

The results suggest that it is the electrostatic interactions associated with the out-of-plane π-electron density which are the dominant factor controlling the magnitudes of the π-π interactions. The most favorable interaction is found when X and Y are both strongly electron-withdrawing: the π-electron density on the aromatic rings is lowest for these systems and therefore the π-electron repulsion is correspondingly small (Fig. 1). The least favorable interaction is found when X and Y are both strongly electron-donating: the π-electron density on the aromatic rings is highest for these systems and therefore the π-electron repulsion is correspondingly large. When X is electron donating and Y is electron withdrawing, the interaction energy lies in between these two extremes. If CT or EDA effects were significant, these systems should show the most favorable interactions. This is clearly not the case. Indeed, when the results are plotted against Hammett σ values, a straight line correlation is obtained. In other words, the only significant factor affecting the π-π interactions is the electrostatics which depend on the molecular charge distributions and π-electron density on the aromatic rings. Charge transfer effects are negligible.

Recent studies by Schwabacher et al.[10] on noncovalent interactions between charges and aromatic molecules show that electrostatic effects dominate in these systems as well. The edges of aromatic rings interact more favorably with negatively charged groups than with positively charged groups.

These experiments represent an important development in our understanding of weak intermolecular forces. They show that simple electrostatic models which allow for out-of-plane π-electron density are sufficient to explain the properties of noncovalent interactions between aromatic molecules. This provides us with a theoretical framework for modeling and interpreting these phenomena and a set of guidelines for use in molecular design. There are implications in several areas. Interactions between aromatic molecules play a role in

protein structure,[11] they determine the sequence-dependent structure of DNA,[9] and they control many molecular recognition and self-assembly processes in solution and in the solid state.[12]

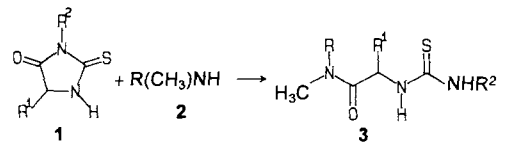
Gas/Solid Reactions of Aliphatic Amines with Thiohydantoins: Atomic Force Microscopy and New Mechanisms**

By *Gerd Kaupp** and *Jens Schmeyers*

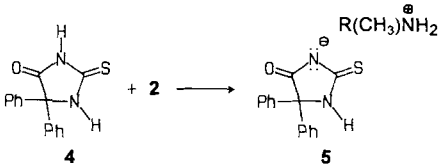
Gas/solid reactions involving simple aliphatic amines and ammonia are not only of interest in synthetic chemistry but could also help to reduce the undesirable introduction of ammonium compounds into woodland, which causes excessive fertilizing and thus contributes predominantly to the new type of forest damage.[1] We report here on the first reactions of thiohydantoins with gaseous amines and on atomic force microscopy (AFM) measurements from which new mechanisms for solid-phase rebuilding can be identified and explanations on the molecular level can be deduced.

Crystalline thiohydantoins **1** with at least one H substituent at position 5 react quantitatively with gaseous methylamine **2a** or dimethylamine **2b** with cleavage of the 3–4 bond to yield crystalline compounds **3** (Scheme 1).



1 + $R(CH_3)NH$ (**2**) → **3**

3a: $R^1=R^2=R=H$
b: $R^1=R^2=H$, $R=CH_3$
c: $R^1=R=H$, $R^2=Ph$
d: $R^1=H$, $R^2=Ph$, $R=CH_3$
e: $R^1=CH_2Ph$, $R^2=R=H$
f: $R^1=CH_2Ph$, $R^2=H$, $R=CH_3$



4 + **2** → **5**

Scheme 1. **1a**, $R^1=R^2=H$; **1b**, $R^1=H$, $R^2=Ph$; **1c**, $R^1=CH_2Ph$, $R^2=H$; **2a**, **5a**, $R=H$; **2b**, **5b**, $R=CH_3$.

[**] This work was supported by the Fonds der Chemischen Industrie. We would like to thank Prof. Dr. N. Karl and Dr. M. Möbus, Universität Stuttgart, as well as Dipl.-Chem. W. Saak for the determination of the Miller indices of the crystal surfaces, and BASF AG, Ludwigshafen, for supplying gaseous amines.

There are no indications for competing processes involving cleavage of the "thiourea" bonds 1–2 and 2–3. This remarkable selectivity even in the case of **1b** is substantiated by the spectra (in particular ^{13}C NMR and MS) of the uniform derivatives **3**. This is all the more surprising, as 5,5-diphenylthiohydantoin **4** does not undergo ring opening in gas/solid reactions with **2**, but instead forms quantitatively the salts **5**. Since the five-membered ring of these salts does not open even in solution (CH_3OH, [D$_6$]DMSO), it appears that the fact that **4** is more acidic than **1** is the determining factor for the reactivity (according to semiempirical PM3 calculations the deprotonation of **1a** is 1.7 kcal mol^{-1} less favorable than that of **4**). Calculations show that the significantly higher dipole moment of the anion in **5** (14.4 D) compared to the anion of **1a** (deprotonation at N3, $\mu = 6.5$ D) could lead to an additional gain in lattice energy in the salts **5**.

Neither **1** nor **4** reacts with the less nucleophilic and less basic ammonia. Up to now, ammonia can only be caused to undergo the gas/solid reaction with crystalline acids or hydrolysis-sensitive anhydrides.[2] The compounds **3**[3] are the easiest to obtain, whereas the salts **5** can *only* be prepared by the gas/solid reaction. Compound **4** has such a low acidity that **5** can be completely decomposed at room temperature in the course of one day by pumping off **2** which is released under high vacuum. Likewise, **4** can be recovered quantitatively from **5a**,**b** after dissolution in methanol or acetone and evaporation under vacuum.

The products **3** and **5** are obtained in a crystalline form without passing through a liquid phase: Powder diagrams immediately show new X-ray reflections. The true density of the crystals (DENARMAT, krypton sensor) decreases markedly with the formation of **3**, although the mass increases. This means that the volume of the crystals substantially increases during the phase rebuilding (true densities: **1a** 1.595, **3a** 1.416, **3b** 1.335, **1b** 1.376, **3c** 1.161, **3d** 1.045, **1c** 1.112, **3e** 1.053, **3f** 1.024 g cm^{-3}). The same applies to the specific surface areas: When **1a** reacts quantitatively with **2a** to yield **3a** or with **2b** to yield **3b**, the specific surface area increases by a factor of 28 from 0.0426 to 1.1914 or by a factor of 9 from 0.0426 to 0.3864 m^2 g^{-1} (2-parameter BET-analysis, DENARMAT, krypton sensor). The mechanisms of the phase rebuildings in the submicroscopic region can be determined[4, 5] by AFM, and can possibly be interpreted at a molecular level if the crystal structure of the starting material is available.[6]

Figure 1 shows remarkable differences in the reaction of methylamine **2a** on the natural face (110) and on the cleavage face (10$\bar{2}$) of **1a**, the cleavage face being inclined at 66.07° to (110). The high ridges and valleys[4] formed on (110) (also seen for **2b**) display a clear if not uniform orientation (Fig. 1b) in contrast to the "volcanos"[4] formed on (10$\bar{2}$) (Fig. 1d). The flanks of the ridges (Fig. 1b) are tilted at 26 and 41° to the mean horizontal (planefit).[7]

Particularly noteworthy is the behavior of the 9-nm-high step in Figure 1c during reaction: Despite the small height (27 molecular layers with an interlayer separation of 3.34 Å) it behaves as a crystallographic face in its own right. High ridges and valleys are formed here (inclined, of course), but without any "volcanos" as on (10$\bar{2}$). Fine details of this sort are only discernable by AFM, and allow previously unimaginable insights on the basis of the known crystal structure[8] of **1a**.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1993 0570-0833/93/1111-1587 $ 10.00+.25/0

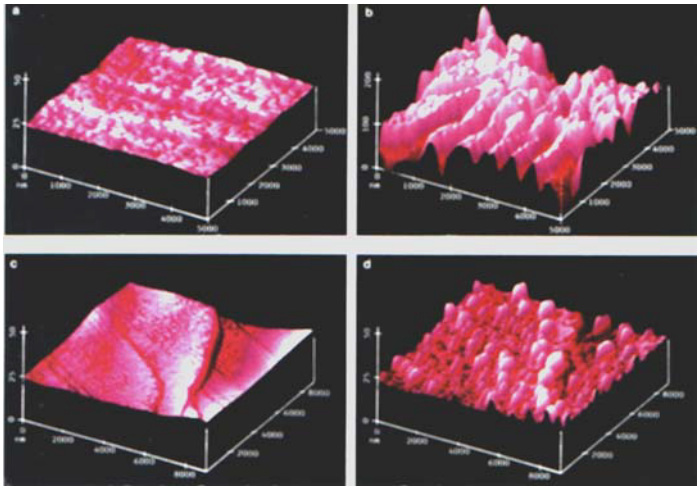

Fig. 1. AFM surfaces of **1a**. a) (110) fresh, b) (110) after a second treatment with gaseous **2a**, c) (10$\bar{2}$) before reaction, d) (10$\bar{2}$) after a second treatment with gaseous **2a**.

Figure 2 shows the layers of molecules of **1a** ($P2_1/c$) on the (110) and (10$\bar{2}$) faces. A steep layer (66°) of molecules on (110) and an almost parallel layer on (10$\bar{2}$) can be recognized. There is formation of hydrogen-bonded dimers (3-NH/4′-CO + 3′NH/4-CO). Clearly, the volume increase upon reaction on (110) causes growth in height along the cleavage face inclined at 66.07° (there are no H bonds between the layers). The finer structures on the high ridges are formed in the early stages of the reaction (not shown), but without lateral orientation. On the (10$\bar{2}$) face, the molecules of **1a** lie flat. From this position the volcano-type mounds rise continually upwards (they are approximately half as high in the early stage of the reaction (not illustrated)). Since the molecules which lie flat penetrate at a steep angle through the surface at the step in Figure 1c, it is understandable that behavior similar to that on (110) is observed, even though there are only 27 layers of molecules present.

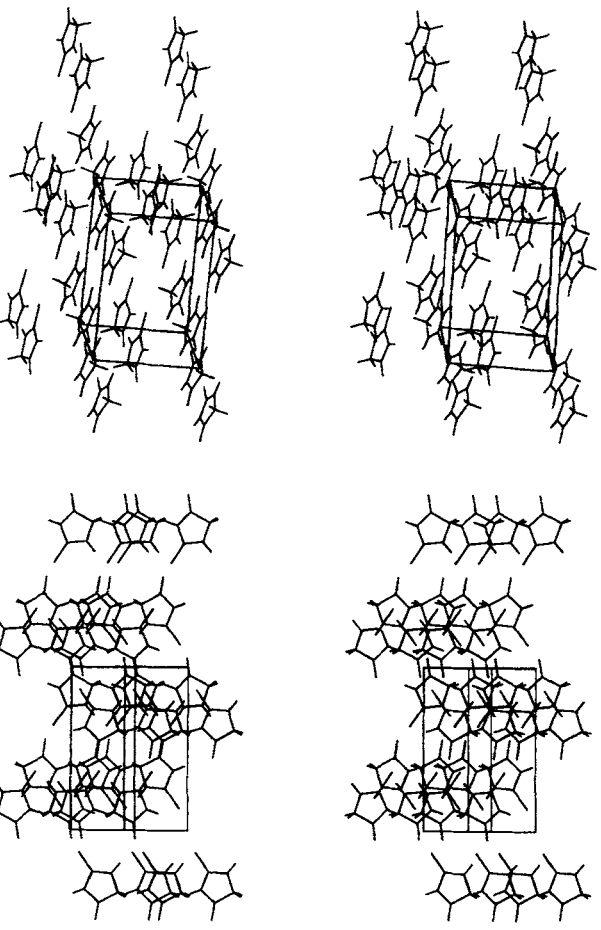

Fig. 2. Stereorepresentation of the molecular layer of **1a**. Top: view of (110); bottom: view of (10$\bar{2}$).

In the reaction with **2a**, the morphologically dominant face (10$\bar{3}$) of **1b** (platelike crystals, $P2_1/c$[9]) behaves completely differently to that of **1a**. Here, a hitherto unobserved[4, 5] *island mechanism* occurs in the phase rebuilding. The smooth surface with sharp-edged steps (Fig. 3a) does not react uniformly, but rather by the formation of widely spaced islands comprising a circular trench enclosing hills, which may surpass the 16 nm step (20 molecular layers high). The islands grow concentrically outward from smaller circular walls initially without any inner elevations, until they touch one another and merge together. Figure 3b shows several stages in the development process side by side. The reaction of **1b** with **2a** is consequently hindered. Information about this hindered reaction can actually be deduced from the crystal structure of **1b**.

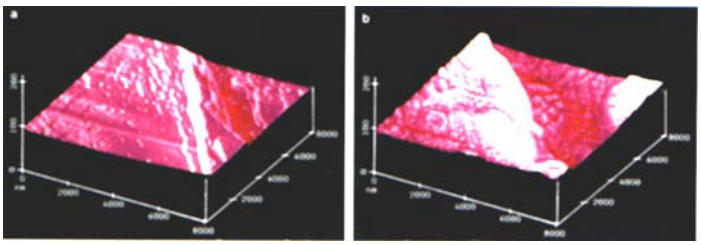

Fig. 3. AFM surfaces of **1b**. a) (10$\bar{3}$) fresh, b) (10$\bar{3}$) after a second treatment with gaseous **2a**.

Figure 4 shows a stereorepresentation of the (10$\bar{3}$) surface of **1b**.[10] The reacting amide bond never points forward, but is effectively shielded from the upward pointing methylene groups and the neighboring phenyl groups. Thus, the approach of the gas **2a** is sterically hindered, since the OC–N bond which is broken on addition of the amine lies underneath. Clearly, the chemical phase rebuilding occurring dur-

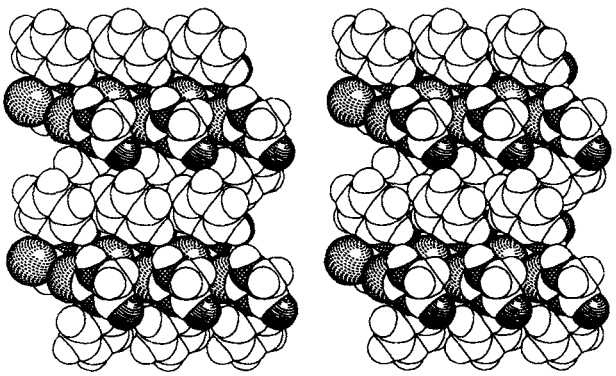

Fig. 4. Stereorepresentation of the molecular layers of **1b** on (10$\bar{3}$) using a space-filling representation to estimate the steric hindrance during the attack of a gaseous reagent on the amide bond (O: circles, N: grids, S: hatched circles).

ing the volume expansion after nucleation does not progress zonally as previously described for different reactions,[4] but rather concentrically, as long as a gas supply is available. On the inside of the wall, where the surface structure is broken up, the amine **2a** obviously has an easier route to reaction. The effects of the crystal structure on the chemical reactivity are clearly discernible. The product must rise up above the original level, as is shown in Figure 3b.

Compound **1c** behaves differently again on reaction with **2a** (morphologically dominant plane, small plates). Well-developed "volcanos"[4] of considerable height with a surrounding groove (Figs. **5a, b**) form out of the very smooth surface. A lack of crystal data means that a molecular interpretation is not possible here, however, it has been demonstrated once more just how important phase-reorganization processes[4] are in gas/solid reactions.

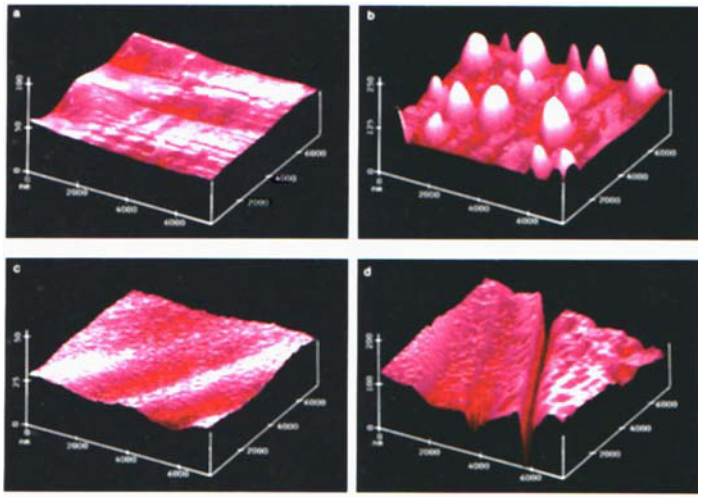

Fig. 5. Top: AFM surfaces of **1c**. a) fresh, b) after a short reaction period with gaseous **2a**. Bottom: AFM surfaces of **4**. c) fresh, d) after a second treatment with gaseous **2a**.

When studied by using AFM, the reaction of **4** with **2a** exhibits a dual mechanism. Initially craters up to 6 nm deep form on the slightly puckered, faintly undulated surface (Fig. 5c). After repeated treatment with **2a** these become only marginally deeper (7 nm), but the surface develops in addition to that deep, parallel trenches (inclination of the flanks: 22 and 32°). Figure 5d shows an already very deep channel as well as further trench formation on both sides. The ditches do not progress along the original undulations, but at an angle of approximately 55° to them. This leads once again to profound material rearrangements.

The reactions presented here indicate how free amines can be absorbed out of the gas phase without the use of solvents, through the formation of the compounds **3**, which are interesting synthetic building blocks. AFM measurements of chemical transformations have only just recently been possible.[4, 5] They provide unparalleled resolution and create the basis for the understanding of the gas/solid reactivity. A seventh mechanism for the requisite solid–phase rebuilding involving island formation has been identified and interpreted in molecular terms (for the first six mechanisms see [4, 5]).

Experimental Procedure

Thiohydantoin (2 mmol) was treated at room temperature in an evacuated 500 mL flask through a vacuum line with gaseous **2** (1 bar). After the mixture had been left to stand for about 12 hours the excess gas was pumped off. The weight increase in each case corresponded to the uptake of 1 mol equivalent of the gas **2**.

Highly Branched Liquid Crystalline Polymers with Chiral Terminal Groups

By *Stephan Bauer, Hartmut Fischer*, and *Helmut Ringsdorf**

In recent years an innovative field of polymer chemistry has been the synthesis of dendrimers[1, 2] and highly branched polymers.[3, 4] These macromolecules are distinguished by their three-dimensional fractal structure. Their synthesis requires monomers with an AB$_m$ functionalization. Dendrimers can be constructed in successive synthetic steps, resulting in the formation of defined, unimolecular compounds. In an alternative and easier approach hyperbranched polymers are synthesized from AB$_m$ molecules in a one-pot reaction.[3]

Thermotropic liquid crystalline (LC) polymers constructed following this principle were first described by Percec et al.[4] The approach described here is based on the consideration that branched, liquid crystalline polymers contain numerous terminal groups, which can be functionalized in a

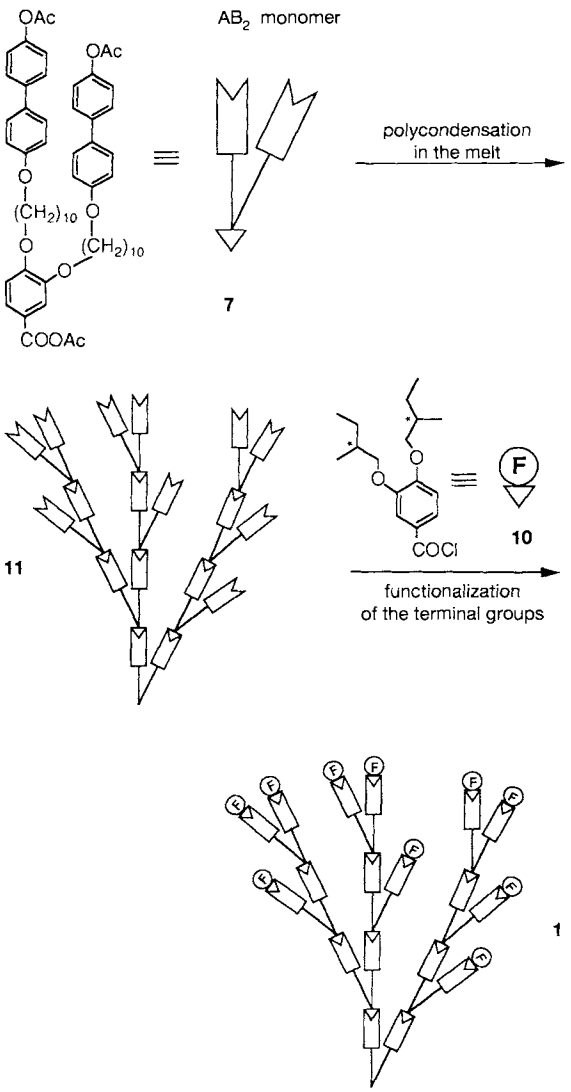
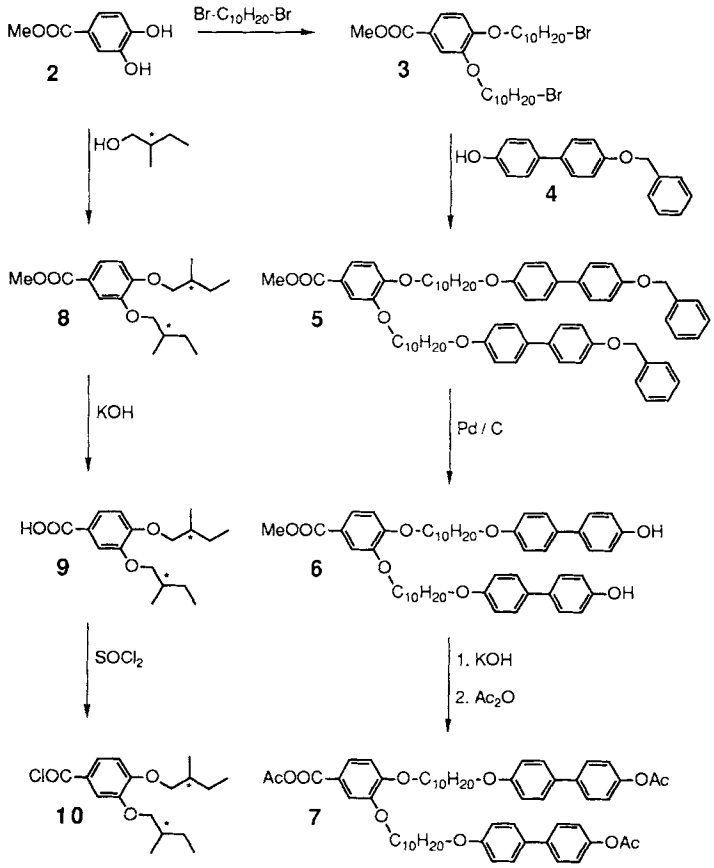
second reaction step (Scheme 1). We have selected a chiral functional group in order to induce a cholesteric mesophase in the highly branched polymer.



Scheme 1. Synthetic approach to polymer **1**.

The AB_2 monomer **7** chosen as the starting material consists of a mixed anhydride component and two mesogenic biphenylacetate units. The synthesis of monomer **7** and the chiral benzoyl chloride **10** is outlined in Scheme 2. Methyl 3,4-dihydroxybenzoate (**2**) was treated with excess 1,10-dibromodecane under Claisen conditions to provide ether **3**. The remaining bromine terminal groups reacted with 4-hydroxy-4′-benzyloxybiphenyl (**4**)[5] under analogous conditions yielding **5**. After cleavage of the benzyl protecting groups, ester **6** was saponified and converted into monomer **7** with acetic anhydride. In the synthesis of the chiral benzoyl chloride **10**, compound **2** was treated with 2-(*S*)-methylbutanol following the Mitsunobu method[6] to give ether **8**. Subsequent saponification and reaction with thionyl chloride provided **10**. Biphenyl benzoate mesogens linked by a spacer were then synthesized by polycondensation of the AB_2 monomer **7** in the melt (see Scheme 1). In the second reaction step, the resulting highly branched polymer **11**, with a degree of polymerization n, was then functionalized at its $(n+1)$ biphenyl acetate terminal groups by a further condensation reaction with the chiral benzoyl chloride **10**.



Scheme 2. Synthesis of the key components **7** and **10**.

The hyperbranched polymer thus obtained is distinguished by its good solubility, for example in chloroform, toluene, and tetrahydrofuran, and has a medium degree of polymerization ($P_n = 6$) as determined by gel permeation chromatography (GPC). The ^{1}H NMR spectrum (Fig. 1) shows the almost complete disappearance of the resonance signal of the acetate groups at $\delta = 2.3$. This proves that the coupling of the chiral carboxylic acid chloride to polymer **11** was achieved with a yield of over 95%. Polarimetric investigations verify the chirality of polymer **1**, which has an optical rotation of $[\alpha]_D^{20} = +6.8$ in dichloromethane.

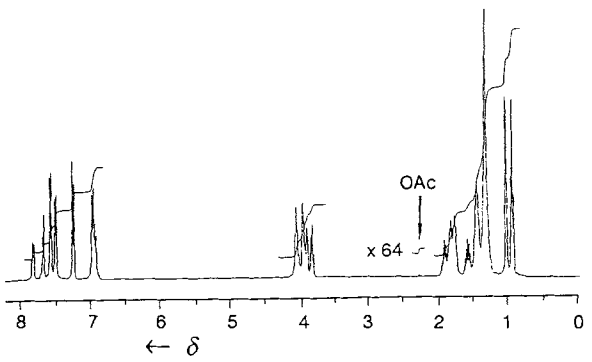


Fig. 1. ^{1}H NMR spectrum of polymer **1** ($CDCl_3$, 400 MHz). The signal indicated with OAc and an arrow is assigned to the acetate groups.

The thermal behavior of polymer **1** was characterized by polarization microscopy, differential scanning calorimetry (DSC), and X-ray scattering analysis. The DSC thermograph shows a glass transition step at 60 °C and two phase transitions at approximately 95 °C and at 151 °C in the second heating curve (Fig. 2). In the cooling curve, a phase

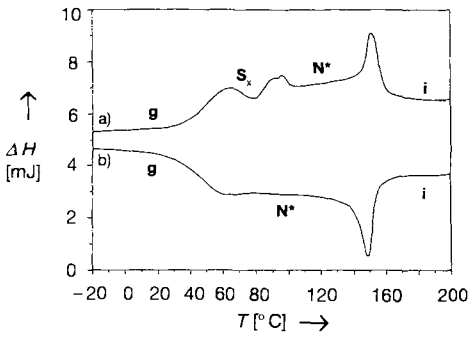

Fig. 2. DSC curve of polymer **1** (heating rate 10 K min^{-1}): a) heating curve, b) cooling curve (g = glassy, Sx = crystalline or smectic, N* = cholesteric, i = isotropic).

transition is observed only at 148 °C. Investigations of this mesophase with polarization microscopy show a typical uniform Grandjean texture,[7] which is characteristic for cholesteric phases (N*). The X-ray diffraction pattern of a fiber extruded from the polymer melt reveals a scattering diagram typical of nematic and cholesteric systems (Fig. 3).

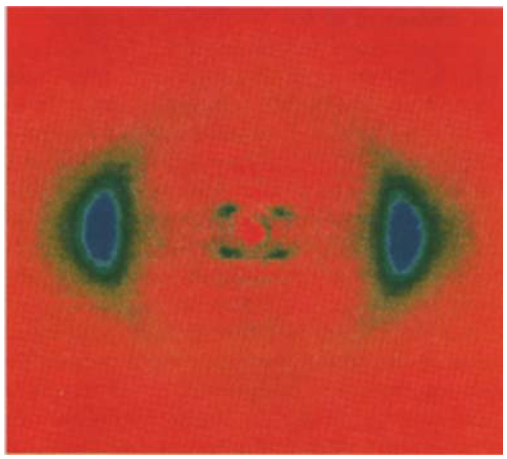

Fig. 3. X-ray diffraction pattern of polymer **1** in the cholesteric mesophase.

In the wide-angle X-ray scattering patterns a diffuse halo of high intensity is visible, which corresponds to an average distance between the mesogens of 4.4 Å. The low-intensity small-angle reflections indicates a layer structure of the cholesteric phase with a layer spacing of 28 Å. Furthermore, the small azimuthal elongation of the halo verifies that a very good unidirectional orientation was achieved during the drawing of the strand. The orientation factor $S = 0.88$ calculated from the X-ray patterns is comparable to that of main chain – side group polymers.[8] The structure of the low-temperature phase, which occurs in the heating curve between 60 and 95 °C, has not yet been elucidated. Ongoing investigations are being carried out to determine whether this is a crystalline or a smectic phase.

The introduction of functional groups in the last reaction step of the synthesis of highly branched liquid crystalline polymers opens up a large palette of possible structural variations in LC systems. Examples are the introduction of polar terminal groups for the syntheses micellar and lyotropic systems with treelike structures, and the application of these highly branched LC polymers with variable surfaces for the production of polymer blends.

Experimental Procedure

Synthesis of **7**: A mixture of **2** (10 mmol), 1,10-dibromodecane, K_2CO_3 (20 g), and KI was refluxed in anhydrous methyl propyl ketone (4 Å molecular sieves) for 24 h. After the excess dibromodecane was removed by distillation, the residue was recrystallized from acetone (yield: 92%, m.p. 30 °C). The conversion of **3** (8 mmol) into its ether derivative by treatment with **4** [5] (20 mmol) under the above conditions gave, after recrystallization in chloroform, **5** (yield: 85%, m.p. 155 °C). Compound **5** (6 mmol) was hydrogenated using Pd/C (300 mg) in methanol as catalyst, and purified by flash chromatography eluting with $CHCl_3$/MeOH 10:1 (yield: 55%, m.p. 149 °C). Ester **6** (3 mmol) was refluxed in 20 mL of EtOH/H_2O and KOH (10 mmol) for 1 h, the free acid was precipitated with 2 N HCl, dried, and refluxed in 20 mL of acetic anhydride for 20 min. The cooled reaction mixture was suction-filtered and the white precipitate recrystallized from acetone (yield: 87%, m.p. 157 °C).

7: ^{1}H NMR (200 MHz, $CDCl_3$): δ = 7.65 (d, 1H, $H_{Ph}6$), 7.48 (m, 9H, $H_{Ph}2$, $H_{biph}2$, 6, 2′, 6′), 7.10, 6.93 (2d, 8H, $H_{biph}3$, 5, 3′, 5′), 6.86 (d, 1H, $H_{Ph}5$), 3.99 (m, 8H, OCH_2), 2.34 (s, 3H, CO-O-CO-CH_3), 2.30 (s, 6H, -O-CO-CH_3), 1.78 (m, 8H, O-CH_2-CH_2), 1.5-1.2 (m, 24H, CH_2); ^{13}C NMR: (50 MHz, $CDCl_3$): δ = 169.6, 162.1, 158.7, 154.6, 149.5, 148.7, 138.6, 132.6, 128.0, 127.6, 125.0, 121.7, 120.3, 114.7, 114.6, 111.7, 69.2, 69.0, 68.0, 29.5, 29.4, 29.3, 29.0, 28.9, 26.0, 25.9, 22.3, 21.1; FD-MS: *m/z* (%) 929.2 (100), [M^+].

Synthesis of **10**: Diethyl azodicarboxylate (25 mmol) was added dropwise to a solution of **2** (10 mmol), triphenylphosphine (25 mmol), and 2-(*S*)-methylbutanol in 200 mL of anhydrous tetrahydrofuran at 0 °C and stirred at room temperature for ca. 15 h. After filtration, the solvent was distilled off and the residue purified by flash chromatography eluting with petroleum ether/acetic acid 10:1 (yield 25%, colorless oily product). Compound **8** was saponified under the previously described conditions (yield: 95%, m.p. 108 °C). The resulting acid **9** (1.5 mmol) was stirred with thionyl chloride (3 mmol), catalytic amounts of DMF, and 20 mL of benzene for ca. 15 h, freeze-dried, and used immediately in the subsequent reaction.

9: ^{1}H NMR (200 MHz, $CDCl_3$): δ = 7.70(d, 1H, $H_{Ph}6$), 7.56 (s, 1H, $H_{Ph}2$), 6.87 (d, 1H, $H_{Ph}5$), 3.85 (m, 4H, OCH_2), 1.91 (m, 2H, O-CH_2-CH), 1.58, 1.25 (2m, 4H, CH_2-CH_3), 0.99 (d, 3H, CH_3), 0.90 (t, 6H, CH_2-CH_3); FD-MS: *m/z* (%) 293.6 (100), [M^+]; $[\alpha]_D^{20}$ = +14.1 (c = 1 in CH_2Cl_2).

Synthesis of **1**: Monomer **7** (1 mmol) and *p*-toluenesulfonic acid (0.05 mmol) were stirred under vacuum at 240 °C for 8 h. The chiral benzoyl chloride **10** (1.2 mmol) and *p*-toluenesulfonic acid (0.05 mmol) were added to the cooled reaction mixture, which was then heated to 200 °C in an atmosphere of argon for 1 h. The pressure was then slowly reduced to 10^{-6} mbar. The resulting polymer was dissolved in chloroform and precipitated in methanol (yield: 89%).

1: ^{1}H NMR (200 MHz, $CDCl_3$): δ = 7.80 (d, $H_{Ph}6$), 7.64 (s, $H_{Ph}2$), 7.55, 7.48 (2d, $H_{biph}2$, 6, 2′, 6′), 7.21, 6.93 (2d, $H_{biph}3$, 5, 3′, 5′), 6.88 (d, 1H, $H_{Ph}5$), 4.1-3.8 (m, OCH_2), 2.0-1.7 (m, O-CH_2-CH_2, O-CH_2-CH), 1.7-1.2 (m, CH_2), 0.99 (d, CH_3), 0.90 (t, CH_2-CH_3); ^{13}C NMR (100 MHz, $CDCl_3$): δ = 165.1, 158.8, 154.2, 153.9, 150.1, 149.2, 148.7, 138.5, 132.8, 128.1, 127.6, 124.4, 124.3, 122.0, 121.7, 121.6, 115.6, 114.8, 114.7, 112.0, 103.8, 74.1, 73.8, 69.4, 69.1, 68.1, 34.9, 34.8, 29.5, 29.4, 29.3, 29.2, 29.1, 26.2, 26.1, 26.0, 25.9, 16.6, 16.5, 11.3; $[\alpha]_D^{20}$ = +6.8 (c = 1 in CH_2Cl_2); GPC ($CHCl_3$, polystyrene standard): M_w: 20000, M_n: 6500 g mol^{-1}.

Refinement of a Model for the Nitrogenase Mo–Fe Cluster Using Single-Crystal Mo and Fe EXAFS**

By *Jie Chen, Jason Christiansen, Nino Campobasso, Jeffrey T. Bolin, Roland C. Tittsworth, Brian J. Hales, John J. Rehr*, and *Stephen P. Cramer**

The enzyme nitrogenase catalyzes the reduction of dinitrogen to ammonia.[1] Substrate conversion is thought to occur at the M clusters, which are two $MoFe_7S_9$ clusters embedded in the α subunits of the $\alpha_2\beta_2$ MoFe protein (M_r = 220000).[2] Each M cluster presumably receives electrons from a companion P cluster, an Fe_8S_8 structure located at the interface between the α and β subunit. Accurate dimensions for these clusters are important for synthetic modeling, for theoretical studies, and for the observation of possible structural changes during the catalytic cycle. The structures for MoFe proteins Cp1 and Av1 from *C. pasteurianum*[3] and *A. vinelandii*[4] respectively, are being determined by X-ray diffraction with increasing accuracy, and models for the structures of the M cluster and P cluster have been presented. However, given the limited resolution of the diffraction data (2.2 Å), it is likely that the root mean square error in the atomic positions of these models is on the order of 0.2–0.3 Å, and errors in the interatomic distances are somewhat larger. Since changes of metal–metal distances of even 0.1 Å are chemically significant, more accurate cluster dimensions are important. Now that the construction of the cluster frameworks has been established by the X-ray diffraction experiments, greatly improved metric information can be obtained from solution and especially single-crystal EXAFS spectra.

We report here the first single-crystal Fe and Mo EXAFS spectra of nitrogenase at low temperature. A new Mo–Fe component at approximately 5 Å was observed along with seven other distances between metal atoms and neighboring atoms. These data were combined with that from previous solution Fe EXAFS[5] and a new solution Mo EXAFS to refine the current model for the M cluster. The model is compared with a current electron density map for the protein from *C. pasteurianum* having a 2.3 Å resolution.[3] Although the spectroscopic results are qualitatively in complete agreement with the Kim and Rees model for the M cluster, some average distances differ by roughly 0.2 Å. The EXAFS results also suggest less variation in individual Fe–Fe and Mo–Fe distances than seen in the Kim and Rees model; in other words, the Mo–Fe cluster is more symmetrical.

Fourier transforms of the Mo and Fe K edge EXAFS for a solution of Av1, a single crystal of Cp1, and the capped-prismane model complex $(Et_4N)_3[Fe_6S_6Cl_6\{Mo(CO)_3\}_2]$[6] are shown in Figure 1. The transform of the model complex shows the expected first-shell Mo–C, Mo–S, and Mo–Fe distances (2.0, 2.6, and 2.9 Å, respectively) as well as a long-range Mo–Fe interaction at 4.28 Å. Buried under the shorter Mo–Fe component is a multiple-scattering contribution from a Mo-C-O interaction. Fitting the EXAFS yields distances within 0.05 Å of the values obtained by X-ray crystallography[6] (Table 1).

The Fourier transform of the Mo EXAFS spectrum of Av1 in solution exhibits two main peaks, which fit (Fig. 1) as Mo–S and Mo–Fe interactions at 2.37 and 2.70 Å, along with an unresolved Mo–O,N component at 2.20 Å (Table 1). The Mo–S and Mo–Fe distances, like those from previous EXAFS studies,[7–9] are clearly shorter than the corresponding distances in both the capped-prismane model and the respective average distances of 2.46 and 2.92 Å in the Kim and Rees model of the M cluster. As shown in Figure 1, the Mo EXAFS spectrum generated from the distances obtained by X-ray diffraction has different frequencies and beats (because of different distances) and damps out more rapidly (because of the greater spread in the distances between Mo and neighboring atoms). In the 3–5 Å region of the Fourier transform, a number of smaller peaks are observed, which may arise from interactions of C atoms of homocitrate and histidine ligand with Mo, as well as Fourier transform truncation ripple. We do not interpret these features at this time. There is also a modest peak at approximately 5 Å, where a second Mo–Fe interaction is expected. However, the feature is quite weak, and numerous other interactions might occur at such a distance.

We have used single-crystal EXAFS to enhance this signal at 5 Å and confirm the Mo–Fe assignment. The strength of specific metal–neighbor EXAFS components varies by $\cos^2\theta$, where θ is the angle between the photon polarization vector **E** and the metal–metal vector.[9] Although there are four M centers in the unit cell, their long axes tend to lie near the bc^* plane, as shown in Figure 1. Furthermore, the longer Mo–Fe vectors form an angle of only about 15° ($\cos^2 15° = 0.93$) with the approximately threefold symmetry axes.[3] Thus, by orienting a crystal with the **E** vector parallel to the

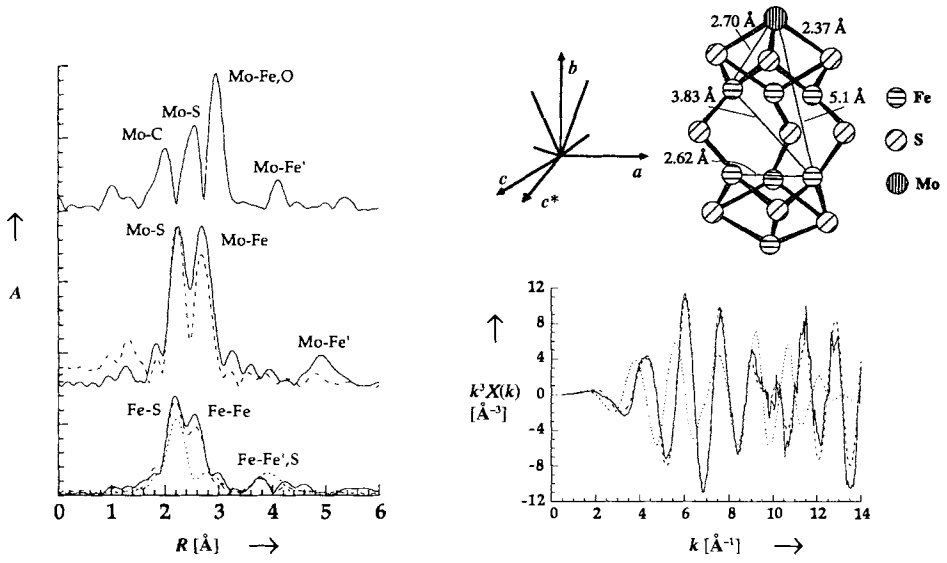

Fig. 1. Left: phase-corrected Fourier transforms (top) of the k^3 Mo EXAFS spectrum for $(Et_4N)_3[Fe_6S_6Cl_6\{Mo(CO)_3\}_2]$; Fourier transforms of the Mo (middle) and Fe EXAFS spectra (bottom) for the MoFe proteins Av1 (solution, - - -) and Cp1 (crystal, ——). Right: top: approximate orientation of the threefold symmetry axes in the M clusters of the unit cell of the MoFe protein and an assignment of EXAFS distances in the M cluster; bottom: experimental (-) and fitted (- - -) EXAFS spectra of the Mo K edge for the MoFe protein in solution. The Mo EXAFS spectrum (right bottom: dotted line) and Fourier transform of the Fe EXAFS spectrum (left bottom: dotted line) generated from crystallographic models having 2.2 Å resolution are also shown for comparison. A = amplitude.

b axis in the bc^* plane, the amplitude of the interaction at approximately 5 Å should be enhanced. In fact, a nearly twofold increase is observed (Table 1 and Fig. 1). Fourier-filtering and fitting this peak yields a good fit for several Mo–Fe interactions at 5.1 Å, close to the value of 5.2 Å obtained by X-ray crystallography. The Mo–Fe interaction at 2.7 Å also gets stronger in this orientation, while the intensity of the Mo–S signal is isotropic, consistent with three Mo–S bonds at nearly right angles to each other in each M center.

Solution EXAFS spectra of the Fe K edge reveal Fe–Fe components at 2.63 and 3.75 Å. These values change little with orientation in the single-crystal spectra, and similar Fe–Fe distances were found for the isolated FeMo cofactor.[10] The crystallographic model can be divided into two groups of Fe–Fe distances averaging 2.87 and 3.73 Å (averaging over both P and M clusters). However, the 2.87 Å group has a root mean square deviation (σ) of 0.22 Å, which does not include thermal disorder. Using the average crystallographic coordination number, the EXAFS simulation finds $\sigma = 0.09$ Å, including thermal disorder. As shown in Figure 1, larger disorder in the group with the short Fe–Fe distances would result in drastically damped Fe–Fe EXAFS. We conclude that most of the short Fe–Fe distances lie within 0.1 Å of the average distance of 2.62 Å. This is significantly shorter than the range 2.69–2.85 Å seen in Fe–S clusters with four coordinate Fe.[6, 11]

In the model obtained from X-ray diffraction, the long Fe–Fe distances average to 3.73 Å with a σ of 0.44 Å. Most of the diagonal interactions among the Fe atoms of the M cluster lie near 3.85 Å (see Fig. 1), and this is no doubt the group that the EXAFS fits find with an average distance of 3.72 Å. Although there are numerous other long Fe–Fe vectors in the range 3.0–4.4 Å, the EXAFS analysis cannot deal with a large number of minor components.

Altogether, the single-crystal Mo and Fe EXAFS studies provide eight predictions for metal–neighbor distances. Combining all the values from EXAFS and using the geometry of the M cluster proposed by Kim and Rees allows a refined model to be constructed, as shown in Figure 1. We have compared our refined model with an unbiased electron density map of Cp1 (resolution 2.3 Å) from an ongoing X-ray diffraction study.[3] The comparison was done by refining our model as a rigid body against the Cp1 diffraction data using the program TNT.[12] This process gives a very good fit to the diffraction data, as shown by Figure 2, and electron density values at the atomic positions. The mean interpolated electron density values (on an arbitrary scale) in the electron density map of Cp1 for the seven Fe and nine S atoms in the refined EXAFS model are 1886 ($\sigma = 182$) and 969 (141). For comparison, the values for the current crystallographic model for Cp1 which has been refined to $R = 0.17$ against data with 2.3 Å resolution, are 1903 (191) and 928

Table 1. Comparison of interatomic distances found by X-ray diffraction and EXAFS for nitrogenase MoFe protein and the model complex $(Et_4N)_3[Fe_6S_6Cl_6\{Mo(CO)_3\}_2]$.
